negative. At the same time the bands in the C···C and C···O region (1500–1600 cm^{-1}) move to lower energy. This trend is also followed on going from $TiCl_2(acac)_2$ to the compound $TiCl_3(acac)$, with the exception that the higher frequency band (tentatively assigned to C···C) does not move significantly. Formation of halide bridges between the two titanium atoms would be expected to have such an effect proposed since the bridging chlorines will become more electronegative with respect to the $Ti(acac)_2$ fragment. Shifts to higher energy are also observed for the band assigned to π(C—H) of the acetylacetone. The band at 675 cm^{-1}, assigned to ring deformation and metal–oxygen stretch moves to higher energy and splits into a doublet. However, the general appearance of the spectra are otherwise very similar except for the ν(Ti—Cl) region, where the band at 378 cm^{-1} is no longer seen in the trichloro derivative. This is not unexpected since ν(Ti—Cl) for bridging halides has been found (9, 10) below 300 cm^{-1}. A new band, broad with almost a doublet appearance, centered at 405 cm^{-1} appears and can be assigned to the stretching modes of the terminal Ti—Cl bonds. Terminal ν(Ti—Cl) modes have been reported between 380 and 420 cm^{-1} in several cases (9–11). Also, the infrared (i.r.) spectra for $TiCl_4(L)$, where L is the keto form of a β-diketone, have been reported (12) unassigned. These spectra all have fairly strong bands in the region 370 to 430 cm^{-1}, which are probably associated with the titanium–chlorine bonds. From the i.r. spectra, the existence of a lattice of ions, such as $Ti(acac)_2^{2+}$ and $TiCl_6^{2-}$, can probably be ruled out (15).

Hydrolysis of the solid in the atmosphere yielded HCl, $TiCl_2(acac)_2$ which was isolated by extraction with benzene, and an unidentified residue containing titanium and chlorine. Treatment with ethanol yields a red oil (2) previously held to be $TiCl_2(OEt)(acac)EtOH$. This is almost certainly a mixture of two known compounds, $TiCl_2(acac)_2$ and $TiCl_2(OEt)_2(EtOH)_2$, since on pumping *in vacuo* for several days ethanol is lost and a yellow solid formed. This recrystallizes from benzene petroleum-ether to give two crops of crystals, the first being orange-red $TiCl_2(acac)_2$ and the second white needles of $TiCl_2(OEt)_2$, both compounds being readily identifiable by analysis and spectroscopy.

Recent studies (13) on titanium(IV) halide complexes of the 3-methyl-2,4-pentanedionate anion have suggested the existence of monomeric five coordinate structures for $X_3Ti(C_6H_9O_2)$, where X is chloride or bromide. However, the spectral data and solubilities reported are all consistent with an interpretation based on Fig. 1, in which the dimer structure dissociates to the two monomer species of 4 and 6 coordination number, respectively. The greater solubility of the bromide derivative would reflect a greater degree of dissociation due to weaker halide bridging between titanium atoms. A five coordinate structure has been proposed (14) for $[TiOCl(acac)]_2$, the preparation of which may suggest a feasible route to the five coordinate trialkoxy derivatives.

Thermochemistry of Silver Bromate[1]

L. M. GEDANSKY[2] AND L. G. HEPLER
Department of Chemistry, The University of Lethbridge, Lethbridge, Alberta

Received June 10, 1970

Calorimetric measurements of the heat of solution of $AgBrO_3$(c) in NH_3(aq) have been combined with earlier data on heats of solution of $AgNO_3$(c) in water and in NH_3(aq) to yield $\Delta H^0 = 11.78 \pm 0.11$ kcal mol^{-1} for $AgBrO_3$(c) = Ag^+(aq) + BrO_3^-(aq). Combination of this value with $\Delta G^0 = 5.83$ kcal mol^{-1} from the solubility product gives $\Delta S^0 = 19.96$ cal deg^{-1} mol^{-1} for the standard entropy of solution of $AgBrO_3$(c) at 298 °K.

Canadian Journal of Chemistry, 49, 523 (1971)

Introduction

Sillen and Martell (1) have cited four investigations of the solubility of $AgBrO_3$(c) in H_2O(liq) at 25 °C. Results of these investigations lead to K_{sp} values and thence to ΔG^0 values ranging from 5.79 to 5.84 kcal mol^{-1} for the reaction represented by

[1] $AgBrO_3(c) = Ag^+(aq) + BrO_3^-(aq)$

Weighting the work of Ramette and Dratz (2) most heavily, we adopt ${\Delta G_1}^0 = 5.83$ kcal mol^{-1}. Ramette and Dratz (2) have also calculated ${\Delta H_1}^0 = 11.7 \pm 0.3$ kcal mol^{-1} via the van't Hoff equation applied to their K_{sp} values at 14.7, 25.0, and 35.0 °C. They also measured the solubilities of $AgBrO_3$(c) in D_2O(liq) at these same temperatures and carried out similar calculations.

Because of interest in comparison of H_2O and D_2O as solvents (3) and the possibility of large errors in ΔH^0 and ΔS^0 values derived via the van't Hoff equation (4), we undertook calorimetric measurements leading to an independent value of ${\Delta H_1}^0$.

Experimental

The calorimetric apparatus has been described (5). All reported ΔH values refer to 25.00 ± 0.15 °C and are in terms of the defined calorie (1 cal = 4.1840 J).

Two samples of $AgBrO_3$(c) were prepared according to the method described by Ramette and Dratz (2). Iodometric analyses corresponded to each sample being 99.7 ± 0.2% $AgBrO_3$. Aqueous ammonia solution was prepared from Baker and Adamson reagent ammonium hydroxide and standardized against aqueous HCl.

Results

Heats of solution of $AgBrO_3$(c) in 0.16 M NH_3(aq) are given in Table 1 as ΔH_2 values corresponding to the reaction represented by

[2] $AgBrO_3(c) + 2\,NH_3(M = 0.16) \rightarrow Ag(NH_3)_2^+(M) + BrO_3^-(M)$

We take $\Delta H_2 = -1.72$ kcal mol^{-1} of $AgBrO_3$(c) for $M = 0.02$ for our calculations that follow.

Earlier calorimetric measurements (6) of heats of solution of $AgNO_3$(c) in 0.16 M NH_3(aq) and in water have led to $\Delta H_3 = -8.06$ kcal mol^{-1} and $\Delta H_4 = 5.46$ kcal mol^{-1} for reactions (both with $M = 0.02$) represented by

[3] $AgNO_3(c) + 2\,NH_3(M = 0.16) \rightarrow Ag(NH_3)_2^+(M) + NO_3^-(M)$

and

[4] $AgNO_3(c) \rightarrow Ag^+(M) + NO_3^-(M)$

We combine results cited above to obtain $\Delta H_1 = \Delta H_2 - \Delta H_3 + \Delta H_4 = 11.80$ kcal mol^{-1} for $M = 0.02$. Taking ϕ_L (the relative apparent molal enthalpy) for $AgBrO_3$($M = 0.02$) to be the same as tabulated (7) for $AgNO_3$ at the same concentration, we obtain ${\Delta H_1}^0 = 11.78$ kcal mol^{-1}. Total uncertainty due to sample composition, calorimetric errors in all the reactions, and estimated ϕ_L is about ±0.11 kcal mol^{-1}. There is excellent agreement between our calorimetric

[1]Calorimetric data reported in Table 1 were obtained at Carnegie Institute of Technology with the aid of a grant from the National Science Foundation.

[2]Present address: Scott Paper Co., Philadelphia, Pennsylvania.

$\Delta H_1^0 = 11.78 \pm 0.11$ kcal mol^{-1} and $\Delta H_1^0 = 11.7 \pm 0.3$ kcal mol^{-1} from Ramette and Dratz (2).

We have combined our ΔH_1^0 with the ΔG_1^0 cited above to obtain $\Delta S_1^0 = 19.96$ cal deg^{-1} mol^{-1}, compared to $\Delta S_1^0 = 19.7$ cal deg^{-1} mol^{-1} from Ramette and Dratz (2).

Combination of our ΔH^0 and ΔS^0 values with thermodynamic properties (8) of $Ag^+(aq)$ and $BrO_3^-(aq)$ leads to $\Delta H_f^0 = -6.55$ kcal mol^{-1} and $S_{298}^0 = 36.4$ cal deg^{-1} mol^{-1} for $AgBrO_3(c)$. These values are in excellent agreement with those cited recently by the National Bureau of Standards (8), apparently obtained on the basis of the results reported by Ramette and Dratz (2).

We are grateful to Dr. Gary Bertrand, now at the University of Missouri, Rolla, for his advice and help.

Alkaloids of *Lycopodium alopecuroides*. Part 4.[1] The Structure of Lycopecurine

William A. Ayer and Norio Masaki[2]
Department of Chemistry, University of Alberta, Edmonton, Alberta

Received August 31, 1970

Lycopecurine, an alkaloid of *Lycopodium alopecuroides* has been shown by an X-ray crystallographic study of the hydrobromide to possess structure **2**.

Canadian Journal of Chemistry 49, 524 (1971)

In Part 2 of this series (1), we described the isolation of a small quantity of a compound $C_{16}H_{25}ON$, m.p. 239–241°, which appears not to have been described previously and for which we suggested the name *lycopecurine*. We have succeeded in isolating this compound only once (2), and then in small quantity, and thus have been forced to rely almost exclusively on physical methods in the determination of the structure of this alkaloid. This paper summarizes the results of this investigation.

The molecular formula $C_{16}H_{25}ON$ for lycopecurine was established by high resolution mass spectrometry (h.r.m.s.). The mass spectrum, shown in Fig. 1, is characterized by an intense M^+-15 peak, a feature which is not predominant in the mass spectra of the common Lycopodium alkaloids (3).

The n.m.r. spectrum of lycopecurine, determined on a small amount of material, was not particularly revealing, but did show the presence of a secondary *C*-methyl group and the absence of olefinic protons.

The oxygen atom in lycopecurine is present as a secondary hydroxyl group as indicated by the i.r. spectrum (Fig. 2) and by the fact that oxidation with Jones' reagent furnished a ketone, *dehydrolycopecurine*, which absorbed at 1695

cm^{-1} in the i.r. The i.r. spectrum also showed no olefinic absorption, and it thus appeared that the alkaloid was pentacyclic. This view was strengthened by the fact that the i.r. spectrum showed an unusual absorption band at 1505 cm^{-1} (see Fig. 2). During our work on the pentacyclic alkaloid alopecurine (**1**, R = COC_6H_5) (1) we had noticed an absorption band in the 1490–1510 cm^{-1} region of the spectra of this alkaloid and its derivatives, *e.g.*, debenzoylalopecurine (**1**, R = H), shown in Fig. 2. It has previously been shown that high frequency methylene vibrations are frequently associated with tightly-bridged systems (4, 5), and since the tetracyclic *Lycopodium* alkaloids do not show this absorption band, this suggested that lycopecurine might have the alopecurine skeleton. Since the known lycopodium alkaloids are invariably oxygenated (or unsaturated) at C-5, structure **2** (without regard to stereochemistry at C-5) seemed worthy of consideration. However, attempts at a direct correlation of lycopecurine with alopecurine were precluded by a lack of material and we turned to X-ray methods for confirmation of the structure.

Lycopecurine hydrobromide crystallizes in two orthorhombic forms, the α-form from methanol–acetone and the β-form from methanol – ethyl acetate. The crystal data for these two modifica-

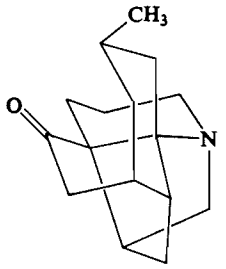
tions are shown in Table 1. The complete solution,[3] including absolute configuration, was obtained on the α-form and is shown in Fig. 3. Lycopecurine is thus represented by structure **2**. It is of interest to note that ring C is in the chair conformation. In alopecurine and debenzoylalopecurine ring C adopts the twist conformation (1). As summarized in Scheme 1, it appears that the non-bonded interaction between an oxygen substituent at C-2 and the hydrogen shown at C-9 is sufficient to tip the energy balance in favor of the twist conformation.



3

[3]Complete details of the X-ray analysis will be published separately.

[4]The general experimental details are the same as those given in Part 2 of this series (1).

Recently, dehydrolycopecurine (**3**) has been isolated from *L. inundatum* and has been correlated with lycopecurine (6).

Experimental[4]

Lycopecurine

Lycopecurine, m.p. 239–241°, was isolated as previously described (1). Mass spectrum: see Fig. 1. The i.r. spectrum: see Fig. 2.

Lycopecurine Hydrobromide

A solution of lycopecurine (8 mg) in acetone was acidified with two drops of concentrated hydrobromic acid. The crystalline material obtained on standing was recrystallized from methanol–acetone to give lycopecurine hydrobromide (α-form), m.p. 308–312° (dec). Crystallization from methanol – ethyl acetate provided the β-form, m.p. 305–307° (dec). The properties of the

two forms are described in Table 1. Because of the limited amount of material available, combustion analyses were not performed. The i.r. spectrum (β-form): ν_{max}(Nujol) 3370 (OH), 2550–2750 ($^+$NH), 1505 cm^{-1}.

Dehydrolycopecurine

Lycopecurine (5 mg) was dissolved in acetone (2 ml) and Jones' reagent (2 drops) was added. Methanol (2 drops) was added after 5 min and the resulting solution evaporated to dryness. The residue was dissolved in chloroform and washed with dilute sodium bicarbonate. Evaporation of the chloroform left a low melting solid which was purified by sublimation, m.p. 55–56°. The i.r. spectrum: ν_{max}($CHCl_3$) 1695, 1500 cm^{-1}.

Mol. Wt. Calcd. for $C_{16}H_{23}NO$: 245.1780. Found (h.r.m.s.): 245.1785.

We wish to thank Drs. S. Valverde-Lopez and B. Altenkirk for their contributions to the early phases of this work, and the National Research Council of Canada for financial support.

Structure of the Amino Sugar Component in Baker's Yeast Mannan[1]

P. A. J. Gorin

Prairie Regional Laboratory, National Research Council of Canada, Saskatoon, Saskatchewan

Received September 1, 1970

Baker's yeast mannan was methylated and the fully methylated polysaccharide hydrolyzed. The product contained a trace of 2-deoxy-3,6-di-*O*-methyl-2-methylamino-glucose which was characterized chromatographically. It likely arose from one or more 4-*O*-substituted 2-acetamido-2-deoxy-D-glucopyranose units (or the 5-*O*-substituted furanosyl isomer). One possibility is that it arose from a 4-*O*-substituted 2-acetamido-(1-L-β-aspartamido)-1,2-dideoxy-β-D-glucopyranose unit which is probably the bridge in one of the carbohydrate–peptide links in the glycoprotein of the cell wall.

Canadian Journal of Chemistry, 49, 527 (1971)

Ethylenediamine extraction of baker's yeast cell walls gives rise to two glycoproteins which are distinguishable on ultracentrifugation, but on prolonged extraction only the component with the lower sedimentation coefficient is formed (1). Sentandreu and Northcote have examined the glycoprotein in detail and shown that it contains two types of peptide–carbohydrate linkages. One linkage is probably represented by 2-acetamido-(1-L-β-aspartamido)-1,2-dideoxy-β-D-glucopyranose which connects a high molecular weight mannan moiety to a peptide (2). The other is mannose, or oligosaccharides consisting of mannose units, connected by glycosidic linkages to the hydroxyl groups of serine and threonine (3).

The glucosamine unit or units are *N*-acetylated and some, at least, are resistant to oxidation by periodate (2). From these data 3-*O*- and/or 4-*O*-substituted 2-acetamido-2-deoxy-D-glucopyranose units were considered to be the most likely (2) although 5-*O*-substitution of furanose units or the presence of more than one *O*-substituent per sugar unit is also possible. The present study describes a methylation–fragmentation study on yeast mannan derived from the glycoproteins and identification of a partially methylated glucosamine fragment.

The mannan was more amenable to methylation than the glycoprotein which is insoluble in *N*,*N*-dimethylformamide. The mannan was obtained by extraction of yeast cells with hot aqueous alkali and purified via the insoluble copper complex formed with Fehling solution (4). It contains, in addition to mannose, small amounts of amino acids, phosphate, and glucos-

two forms are described in Table 1. Because of the limited amount of material available, combustion analyses were not performed. The i.r. spectrum (β-form): ν_{max}(Nujol) 3370 (OH), 2550–2750 ($^+$NH), 1505 cm^{-1}.

Dehydrolycopecurine

Lycopecurine (5 mg) was dissolved in acetone (2 ml) and Jones' reagent (2 drops) was added. Methanol (2 drops) was added after 5 min and the resulting solution evaporated to dryness. The residue was dissolved in chloroform and washed with dilute sodium bicarbonate. Evaporation of the chloroform left a low melting solid which was purified by sublimation, m.p. 55–56°. The i.r. spectrum: ν_{max}($CHCl_3$) 1695, 1500 cm^{-1}.

Mol. Wt. Calcd. for $C_{16}H_{23}NO$: 245.1780. Found (h.r.m.s.): 245.1785.

We wish to thank Drs. S. Valverde-Lopez and B. Altenkirk for their contributions to the early phases of this work, and the National Research Council of Canada for financial support.

1 2 3

amine (2). An estimate of 1 mol of the latter per molecular weight of 73 000 was made, but this may be low if hydrolytic decomposition of glucosamine took place. Korn and Northcote (1) quote 59 000 as the molecular weight of baker's yeast mannan.

The mannan was partially *O*-methylated by the Haworth procedure (5) and methylation completed by the method of Kuhn *et al.* (6). During the latter procedure the nitrogen proton of the *N*-acetyl group (**1**) was replaced by a methyl group **2** (7, 8). Methanolysis of the methylated mannan by refluxing methanolic hydrogen chloride followed by hydrolysis with hydrochloric acid gave a mixture of sugars. These corresponded on a paper chromatogram to di-*O*-, tri-*O*-, and tetra-*O*-methyl mannoses and a faint ninhydrin-positive 2-deoxy-di-*O*-methyl-2-methylaminoglucose with R_{Rh} 1.00 (Table 1). The latter was concentrated by cellulose column chromatography. The resulting fraction, when examined on the Spinco amino acid analyzer, gave a peak with a retention time (r.t.) corresponding to the 3,6-di-*O*-methyl **3**, but not the 4,6-di-*O*-methyl derivative (9) (Table 1, Fig. 1). The peak was typically broader than that arising from an amino acid. The presence of the 3,6-di-*O*-isomer was confirmed by g.l.c. of its trimethylsilyl (t.m.s.) derivative (9), since a peak with typical r.t. (Table 1, Fig. 2) was obtained. A peak corresponding to the 4,6-di-*O*-isomer was absent. The structure of the *N*-methyl sugar is consistent with the presence of a 4-*O*-substituted 2-acetamido-2-deoxy-D-glucopyranosyl unit or units although the possibility of a 5-*O*-substituted furanosyl counterpart is not eliminated. The amino sugar could be part of a 2-acetamido-(1-L-β-aspartamido)-1,2-dideoxy-β-D-glucopyranosyl moiety.

Although 2-deoxy-3,6-di-*O*-methyl-2-methylamino-glucose could arise from chitin, the presence of such a contaminant is unlikely with the extraction procedure used. Furthermore, when the mannan was treated with a chitinase from *Streptomyces griseus*, no *N*-acetyl-D-glucosamine could be detected on paper chromatograms using the Elson–Morgan spray reagent.

The above results can be related to the methylation–fragmentation data obtained from the 2-acetamido-2-deoxy-D-gluco-D-mannans of *Pichia bovis* and *Saccharomyces phaseolosporus* (7). The hydrolysis products each contained 2-deoxy-3,4,6-tri-*O*-methyl-2-methylamino-glucose arising from amino sugar non-reducing end-units and small amounts of the 3,6-di-*O*-methyl isomer. This fragment could well also arise from *N*-acetyl glucosamine unit(s) associated with polysaccharide–protein linkages.

Experimental

Methylation–Fragmentation Study on Baker's Yeast Mannan

Mannan (1.0 g) was extracted from Fleischmann's baker's yeast with hot aqueous alkali and purified via the insoluble copper complex formed with Fehling solution (4). A sample (1.0 g) was partially methylated with aqueous sodium hydroxide – dimethyl sulfate (5) and methylation was completed by the Kuhn procedure (6). The product did not show hydroxyl absorption at 3400–3650 cm^{-1} in the i.r. A portion (0.20 g) of the total product (0.95 g) was refluxed in 3% methanolic hydrogen chloride (20 ml) for 18 h, which was evaporated and hydrolysis completed with 3 *M* HCl (20 ml) at 100° for 3 h. Following evaporation the product was examined on a paper chromatogram (solvent: butyl alcohol – ethanol–water (40:11:19 v/v/v)) and with the *p*-anisidine hydrochloride spray spots were obtained with color reactions and R_f's corresponding to di-*O*-, tri-*O*-, and tetra-*O*-methylmannose. With the ninhydrin spray a faint blue spot was obtained running at the speed of rhamnose. This corresponded to a 2-deoxy-di-*O*-methyl-2-methylamino-glucose and was concentrated by chromatography of the mixture on a cellulose column (eluant: benzene–ethanol 5:1 v/v). A portion (10 mg) of the concentrate (29 mg) was examined on a Model 120C Spinco amino acid analyzer with the UR-30 type resin and a 250 min running time ((10) see Spinco Procedures Manual 120C-PM-1); a peak was obtained corresponding in r.t. to 2-deoxy-3,6-di-*O*-methyl-2-methylamino-glucose ((9) Table 1, Fig. 1). A portion (2 mg) of the concentrate was trimethylsilylated and examined by g.l.c. (9). The resulting chromatogram, depicted in Fig. 2, contained a peak with an r.t. (Table 1) corresponding to the 3,6-di-*O*-methyl derivative.

Treatment of Mannan with Chitinase from Streptomyces griseus

Samples of mannan (50 mg) were dissolved in 0.2 *M* phosphate buffers (2 ml) of p*H* 4, 5, 6, 7, and 8. Chitinase (10 mg), isolated from *Streptomyces griseus* and supplied by Calbiochem, was added to each solution. After 18 h, excess ethanol (10 ml) was added to precipitate the polysaccharides, and the supernatants were decanted. These were evaporated to residues which were deionized by aqueous slurries of mixed Amberlite IR120 (H^+ form) and Dowex 1-X8 (bicarbonate form). The filtered solutions were evaporated and examined on a paper chromatogram (solvent: as above, spray: the Elson–Morgan reagent as used by Partridge and Westall (11)). Mauve spots corresponding to *N*-acetyl-D-glucosamine were not detected. Identical attempted enzymolyses were carried out in the presence of *N*-acetyl-D-glucosamine (0.2 mg) which would be approximately the amount of amino sugar formed (2) if it were combined completely in the form of chitin. In these runs, strong mauve spots of typical R_f were detected on a paper chromatogram.

Benzo[*b*]phosphole[1] and Derivatives

T. H. CHAN AND L. T. L. WONG[2]
Department of Chemistry, McGill University, Montreal, Quebec

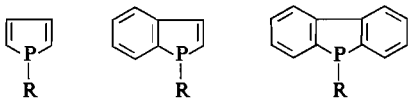
Received October 8, 1970

A potentially general synthesis of 1-heteroindene has been developed and applied to the preparation of 1-phenylbenzo[*b*]phosphole, a novel heterocyclic system.

Une synthèse qui peut s'avérer générale pour la synthèse d'hétéro-1 indène a été développée et appliquée à la préparation du phényl-1 benzo[*b*]phosphole, un nouveau système hétérocyclique.

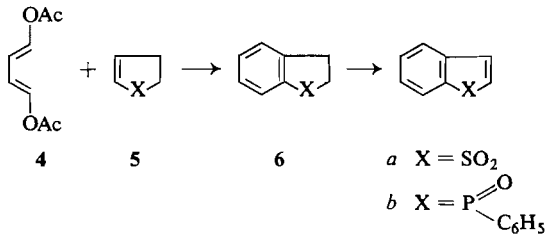
Canadian Journal of Chemistry, **49**, 530 (1971)

Since the first isolation of 9-phenyl-9-phosphafluorene (**3**, R = C_6H_5) in 1953 (1), the chemistry of phosphole (**1**) derivatives has been extensively investigated (2, 3). Recent achievements are the synthesis of 1-methylphosphole (4) and 1-phenylphosphole (5). However, other than a brief report on the preparation of a highly substituted benzo[*b*]phosphole derivative (6), there is lacking a description on the chemistry of benzo[*b*]phosphole (**2**). This is somewhat surprising in view of the fact that the aromatic character involving delocalization of phosphorus electron pair has been a subject of much current interest (7). In this communication, we wish to report on a potentially general synthesis of 1-heteroindene; its application to the preparation of a simple benzo[*b*]phosphole derivative and the chemistry of the benzo[*b*]phosphole system.



1 **2** **3**

A general synthesis of 1-heteroindene is developed according to Scheme 1. Thus, 2,3-dihydrothiophene-1,1-dioxide (**5***a*) reacted with *trans-trans*-1,4-diacetoxybutadiene (**4**) at 150° for 7 days to give 2,3-dihydrobenzothiophene-1,1-dioxide (**6***a*). The construction of benzene ring is based on the method developed by Hill and Carlson (8). Free radical bromination of **6***a* with *N*-bromosuccinimide (NBS) followed by dehydrobromination with triethylamine gave benzothiophene-1,1-dioxide, identical with authentic compound.



4 **5** **6** *a* X = SO_2 *b* X = $P(=O)C_6H_5$

SCHEME 1

1-Phenyl-2-phospholene 1-oxide (**5***b*), obtained from the reaction of butadiene with phenyldichlorophosphine (9) and basic hydrolysis (10), reacted with **4** at 150° for 10 days to give 50% yield (based on reacted **5***b*) of 1-phenyl-2,3-dihydrobenzo[*b*]phosphole 1-oxide (**6**),[3] m.p. 97–101°. The p.m.r. spectrum ($CDCl_3$) of **6***b* was in accord with structure [2H multiplet at 2.5, 2H multiplet at 3.3, and 9H multiplet at 7.5 p.p.m.]. Benzoyl peroxide-initiated NBS bromination of **6***b* in refluxing benzene for 3 h followed by triethylamine dehydrobromination gave 1-phenylbenzo[*b*]phosphole 1-oxide as the sole product, isolable by sublimation as a colorless hygroscopic solid, m.p. 84–88°.[3] Its p.m.r. spectrum showed only aromatic and vinylic hydrogens. It was reduced to 1-phenylbenzo[*b*]phosphole (**2**, R =

[1]Phosphindole is the trivial name for this compound according to Ring Index.

[2]Holder of an NRCC Studentship 1968–1970.

[3]All new compounds have satisfactory elemental analysis and spectroscopic data consistent with structures.

phenyl) by trichlorosilane (11) in refluxing benzene. Compound **2** could be purified by sublimation and had m.p. 66–68°.[3] The mass spectrum showed a strong molecular ion (exact mass; found: 210.0591; calcd: 210.0598).

The u.v. spectrum of **2** (R = phenyl) in ethanol showed λ_{max} (log ε) at 233 (4.39), 260 (4.05), 306 (3.56), 316 nm (3.56), a pattern common to most benzo-heteroaromatics, and resembled closely that of 1-phenylindole[4] [217(4.41), 258(4.26), 291(3.91), 297 nm (3.89)]. The phenyl and vinylic protons were well separated in the 220 MHz n.m.r. spectrum of **2**.[5] The vinylic protons could be considered as part of the AMX (X = phosphorus) system with the following spectral parameters: J_{AM} = 7.2, J_{AX} = 16, J_{MX} = 38 Hz; δ_M = 6.80 and δ_A = 7.49. The coupling constants are in close agreement with those deduced for 1-methylphosphole (4). The chemical shifts of the vinylic protons are in the region generally considered as aromatic. Compound **2** (R = phenyl) quaternized with benzyl bromide to the corresponding phosphonium salt. Compound **2** could also be oxidized readily by air to the oxide. In these respects, the chemistry of **2** (R = phenyl) differs somewhat from that of **1** (R = methyl or phenyl). The oxides of **1** dimerized spontaneously and have eluded isolation thus far.

Kinetics of the Mercury-Photosensitized Decomposition of Propane. Part I. The Overall Mechanism

M. M. PAPIC[1] AND K. J. LAIDLER

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received April 22, 1970

The mercury-photosensitized decomposition of propane was investigated from 250 to 350 °C, and at pressures from 5 to 700 Torr. The following products were identified and their initial rates of formation measured: H_2, CH_4, C_2H_4, C_2H_6, $(CH_3)_2CHCH(CH_3)_2$, $(CH_3)_2CHCH_2CH_2CH_3$, and n-C_6H_{14}. The results lead to conclusions about the mechanism. The pressure dependence of the rates were determined and interpreted in terms of a simplified steady-state treatment based on the mechanism.

Canadian Journal of Chemistry, 49, 535 (1971)

Introduction

Recent investigations in this laboratory have been concerned with the mercury-photosensitized decompositions of ethane (1) and dimethyl ether (2–5), the object being to obtain more reliable kinetic parameters for the decompositions of the various radicals produced. In particular, an effort has been made to study the decompositions of these radicals over a range of pressure as well as temperature, in order to obtain the limiting behavior at high and low pressures. The present investigation is concerned with the mercury-photosensitized decomposition of propane, the object being to establish the mechanism and to study the decompositions of the *n*-propyl and *i*-propyl radicals in their high and low pressure regions. The work relates to a study by Lin and Laidler (6) of the decomposition of propane sensitized by azomethane. One matter of particular concern in the present investigation was the establishment of a reliable value for the activation energy for the decomposition of the *n*-propyl radical into $CH_3 + C_2H_4$, seven previous studies (6–12) having given values ranging from 20 to 35 kcal mol^{-1}.

There have been many previous investigations of the mercury-photosensitized decomposition of propane (7, 12–22). This earlier work, together with that on related systems (*cf.* Cvetanovic (23)) has established the main features of the mechanism. Initially the $Hg(^1S_0)$ is excited into $Hg^*(^3P_1)$ which has an excitation energy of 112.2 kcal mol^{-1}

$$Hg + h\nu \rightarrow Hg^*$$

This is followed by

$$Hg^* + C_3H_8 \rightarrow Hg + C_3H_7 + H$$

the radicals produced being either n-C_3H_7 or i-C_3H_7. Below 300 °C the main subsequent reactions are

$$H + C_3H_8 \rightarrow H_2 + C_3H_7 \ (n \text{ or } i)$$

$$2n\text{-}C_3H_7 \rightarrow n\text{-}C_6H_{14}$$

$$2i\text{-}C_3H_7 \rightarrow \text{2,3-dimethylbutane}$$

$$n\text{-}C_3H_7 + i\text{-}C_3H_7 \rightarrow \text{2-methylpentane}$$

$$2n\text{-}C_3H_7 \rightarrow C_3H_8 + C_3H_6$$

$$2i\text{-}C_3H_7 \rightarrow C_3H_8 + C_3H_6$$

$$n\text{-}C_3H_7 + i\text{-}C_3H_7 \rightarrow C_3H_8 + C_3H_6$$

Bywater and Steacie (7) and Back and Takamuku (12) suggested that above 300 °C, methane and additional hydrogen are produced by the following reactions

$$C_3H_7 \ (n \text{ or } i) \rightarrow H + C_3H_6$$

$$C_3H_7 \ (n \text{ or } i) \rightarrow CH_3 + C_2H_4$$

followed by abstractions by H and CH_3. In the present work measurements have been made of

[1]Present address: Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia.

the initial rates of formation of more products than have been studied in previous investigations. All of the expected products have, in fact, been determined with the exception of propylene and the C_4 hydrocarbons, which presented special difficulties.

The present paper deals with the over-all mechanism; the following paper (Part II) analyzes the results for the decompositions and other reactions of the *n*-propyl and *i*-propyl radicals.

Experimental

Apparatus

The reaction was studied in a conventional static system. The reaction vessel was a quartz cylinder about 10 cm in length and about 5 cm in diameter, with plane windows at each end; its volume was 166 cm^3. It was wrapped in asbestos and placed inside a cylindrical iron collar 23 cm in length, 6 cm in diameter, with walls 0.5 cm thick to ensure even heating. The iron collar was well insulated and heated electrically, the heating being regulated by a Thermo Electronic Co. signalling controller potentiometer connected with the control relay. The controller was activated by means of a chromel–alumel thermocouple, and the temperature could be maintained constant within a degree. The temperature of the reaction vessel was measured at three positions by means of chromel–alumel thermocouples.

The concentration of mercury in the reaction zone was controlled by the temperature of a spiral trap in the lead to the reaction vessel. The temperature of the trap was kept constant at −33 °C by means of 1,3-dibromopropane slush.

A low-pressure mercury resonance lamp of low light intensity, operated at 9.0 mA, was supported at about 30 cm from the incident face of the reaction vessel. Between the lamp and the reaction vessel was placed a Corning glass ultraviolet (u.v.) color filter C.S. No 9-54, which was non-transparent for the light of wavelength shorter than 2000 Å; in this way the mercury 1849 Å line was eliminated.

Gas Chromatography

The reaction products were analyzed by a gas chromatograph assembled from commercially available units. As a detection unit the Gow-Mac Co. Model A-9283 thermal conductivity cell for gas chromatography was used, supplied by power from Trygon Electronics power supply Model HR 40-750. The output used was 12 V d.c., and the current through the filament in the detector was 250 mA. In order to obtain high sensitivity the signal from the detector was pre-amplified by means of a Leeds and Northrup stabilized d.c. microvolt amplifier, Model 9835-A. The amplified signal was put through a 10 mV Leeds and Northrup Co. Speedomax recorder, Model S. Edwards Vacuum Ltd. vacuum and pressure controllers, Model V. P. C. -1, were inserted in both the reference flow and the sample flow of the chromatograph, in order to eliminate the fluctuations of pressure between the helium source and the detector.

Materials

The propane used was obtained from Phillips Petroleum Company with stated research-grade purity of 99.99 mol%. It was subjected to several trap-to-trap distillations at −160°; gas-chromatographic analysis of such a sample showed no impurities. The purified propane was stored in a black-painted storage bulb and was degassed from time to time.

The hydrogen, methane, ethylene, ethane, 2,3-dimethylbutane, and 2-methylpentane used for calibrations of the chromatograph were obtained from the Phillips Petroleum Company; *n*-hexane was obtained from the Matheson Company. 2,3-Dimethylbutane, 2-methylpentane, and *n*-hexane were subjected to thorough degassing at −130 °C to eliminate air.

Procedure and Analysis

Before each experiment the system was evacuated to 10^{-5} Torr. Propane was allowed to pass over mercury at room temperature and then through the spiral trap at −33 °C, after which it was admitted to the reaction vessel. The mercury lamp was switched on about 30 min before use; the reaction was started by the removal of a shutter and was stopped by switching off the lamp. The residual propane and the reaction products were first condensed in a trap immersed in liquid nitrogen, and then separated into fractions by pumping them through a series of traps by a mercury diffusion pump and a Toepler pump; the fractions were: (*1*) non-condensables; (*2*) condensable at −210 and −196 °C (solid nitrogen and liquid nitrogen, respectively), and (*3*) condensable at −130 °C (*n*-pentane slush).

The non-condensable products, which comprised hydrogen and methane, were collected in a sample tube by a Toepler pump. They were analyzed on a 6.0 m long column filled with 80–100 mesh Porapak Q (Waters Assoc. Inc.) operating at 0 °C with a helium flow of 50 cc min^{-1}. On this column hydrogen could be separated from air; this is important since small quantities of air could cause big errors in the analysis. The traps at −210 and −190 °C retained ethylene and ethane (and C_3 and C_4 hydrocarbons which were not analyzed). Ethylene and ethane were analyzed on a 3.5 m long column filled with 80–100 mesh Porapak Q operating at 35 °C with a helium flow of 100 cc min^{-1}; the characteristics of this column have been described elsewhere (24). The traps at −130 °C (two in tandem) retained 2,3-dimethylbutane, 2-methylpentane, and *n*-hexane (and some of the C_4 hydrocarbons). 2,3-Dimethylbutane and 2-methylpentane were analyzed on a 7.0 m long column filled with 4% α-chloronaphthalene (Fisher Scientific Co.) on chromosorb P a.w. (Johns–Manville Co.), 45–60 mesh operating at 0 °C, with helium flow of 120 cc min^{-1}. The retention time of *n*-hexane on this column was too long (42 min) and the amounts of *n*-hexane were considerably smaller than those of the other two C_6 isomers. For this reason separate runs were made and *n*-hexane was analyzed on a 2.0 m long column filled with 20% di-2-ethylhexylsebacate (Chromatographic Specialities Ltd.) on Chromosorb P a.w., 45–60 mesh operating at 25 °C with helium flow of 150 cc min^{-1}. 2,3-Dimethylbutane could not be separated from 2-methylpentane on this column.

Peak-height measurements provided good calibration

For personal use only.

curves for all products except for C_6 hydrocarbons, for which it was necessary to make area measurements.

All columns were made from copper tubing with an inner diameter of 4 mm, and helium was used as carrier gas.

In the experiments where the effect of CO_2 as a foreign gas was studied, CO_2 was first trapped together with ethylene and ethane at -210 and -196 °C and then removed from the product mixture by adsorbing it on ascarite.

Reaction Conditions

The work was done at five different temperatures, 252.0, 276.0, 301.0, 325.0, and 350.0 °C, and the propane pressure varied from 5 to 700 Torr; above 350 °C there is considerable thermal decomposition of propane. Mercury vapor in the reaction zone was at its equilibrium vapor pressure at -32 °C, which is about 3.5×10^{-6} Torr. The low concentration of mercury in the reaction zone was necessary in order to approach a homogeneous absorption of light throughout the reaction vessel. With the reaction vessel used the mercury saturator at -32 °C should give rise to a fairly homogeneous reaction, as shown by Loucks and Laidler (1); effects of inhomogeneous absorption will be very much less than in earlier work by Bywater and Steacie (7) and by Back and Takamuku (12) in which the mercury saturator was kept at room temperature and at 0 °C, respectively.

The low-pressure mercury resonance lamp of low light intensity was used so that the concentration of radicals produced was not too high. Under these conditions the reaction could be investigated at very low conversions of about 10^{-1}–10^{-2}%. This ensures that true initial rates are measured, the addition of hydrogen atoms and radicals to olefins produced being negligible.

Results and Interpretations

The reaction products analyzed were H_2, CH_4, C_2H_4, C_2H_6, 2,3-dimethylbutane (2,3-DMB), 2-methylpentane (2-MP), and *n*-hexane. The C_4-hydrocarbons could not be separated from propane by distillation, and the huge propane peak made gas-chromatographic analysis impossible. For all of the products the plots of yield against time were linear, so that reliable initial rates could be calculated from the slopes; as an example, Fig. 1 shows the yield of hydrogen as a function of time. All rates quoted in the present and following paper are initial rates. The initial rates of formation of the various products are shown plotted against propane pressure, at five different temperatures, in Figs. 2–8.

The rates of formation of all of the products are seen to be proportional to propane pressure at low pressures, and to become independent of propane pressure at higher pressures. The limiting propane pressure for H_2, 2,3-DMB, 2-MP, and n-C_6H_4 is about 150–160 Torr, and is hardly

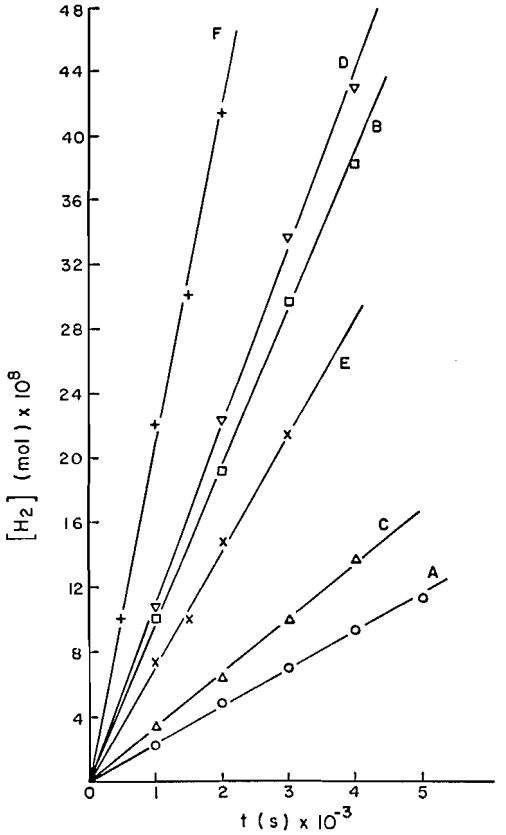

FIG. 1. Typical curves for hydrogen yield as a function of time under various conditions: *A*, 252 °C and 10 Torr; *B*, 252 °C and 382 Torr; *C*, 301 °C and 11 Torr; *D*, 301 °C and 394 Torr; E, 350 °C and 8 Torr; *F*, 350 °C and 386 Torr.

dependent on temperature. For CH_4, C_2H_4, and C_2H_6, on the other hand, the limiting pressure increases significantly with increasing temperature. This behavior can be explained as follows. At low propane pressures the rate of quenching of Hg* increases with increasing concentration of the C_3H_8 molecules. At a certain C_3H_8 pressure complete quenching of Hg* is achieved, and further increase in the C_3H_8 concentration does not affect the rates of formation of H and C_3H_7. At higher temperatures the C_3H_7 radicals also undergo decomposition into $H + C_3H_6$ and $CH_3 + C_2H_4$. The H atoms produced react with C_3H_8 much faster ($k = 6.3 \times 10^{13} \exp(-8.0/RT)$ cc mol^{-1} s^{-1}) than do the CH_3 radicals ($k = 8.1 \times 10^{11} \exp(-10.3/RT)$ cc $mol^{-1}s^{-1}$) (25). Consequently, the rate of H_2 production becomes pressure-independent at lower C_3H_8

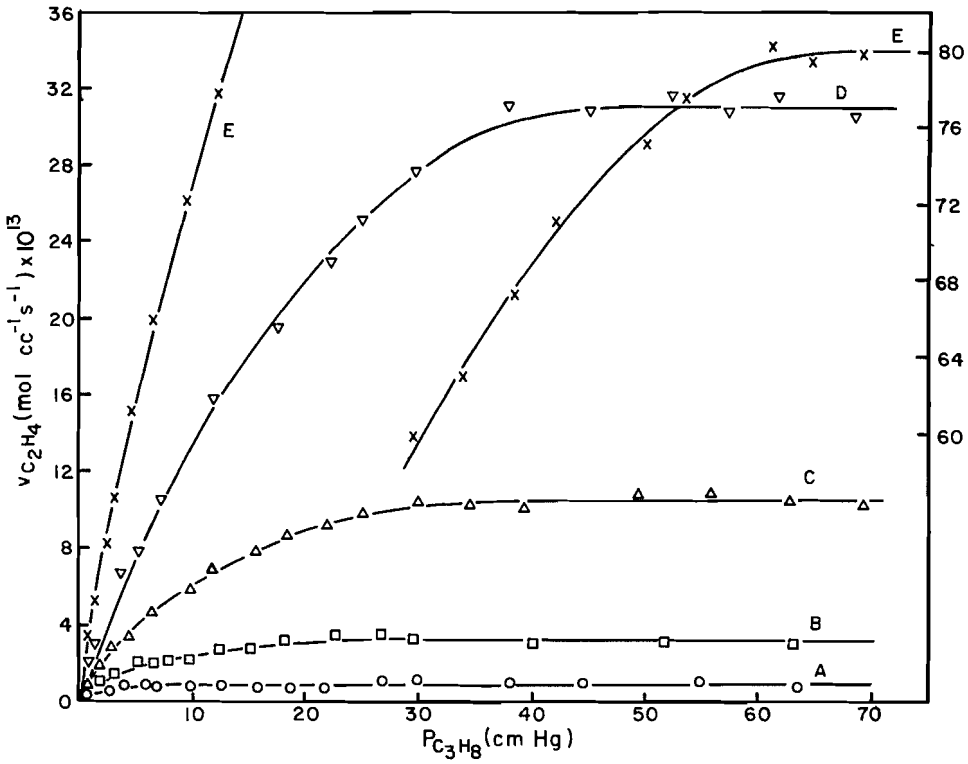

FIG. 4. Plots of initial rates of ethylene production against propane pressure; temperatures as in Fig. 2.

pressures, and the rate of CH_4 production at higher pressures. This matter is later discussed in more detail.

At the lower temperatures (252 and 276 °C) there is little decomposition of the C_3H_7 radical, so that the rate of H_2 production is independent of temperature and is greater than the rate of production of any other product. In the high-temperature region (including 301, 325, and 350 °C) C_3H_7 radicals do decompose to a considerable extent; the rate of H_2 production then becomes temperature-dependent, and the rate of CH_4 production becomes considerably greater than that of H_2 production.

Hydrogen Production

The yield–time curves for hydrogen shown in Fig. 1 indicate that the rates measured are truly initial rates. Reactions such as the scavenging of H atoms by C_3H_6 are therefore not playing an important role as far as the present results are concerned.

Double logarithmic plots of v_{H_2} against propane pressure are shown in Fig. 9. The orders are unity at the lower pressures and zero at the higher ones. Curve *A* in Fig. 10 shows a plot of the logarithm of the rate of hydrogen production against the reciprocal of the absolute temperature; in the low-temperature region the rate is independent of temperature, the H_2 then resulting only from the H atoms produced in the initial step. By subtraction of the low-temperature rate of H_2 production from the total rate one obtains the rate of H_2 production by the chain mechanism; the resulting plot is shown as curve *B* in Fig. 10. From this plot an activation energy of 38.7 ± 0.5 kcal mol^{-1} was obtained for the chain-hydrogen production of 300 Torr. The same procedure was applied at other propane pressures, and the resulting activation energies are shown plotted against propane pressure in Fig. 11.

Methane Production

The order plots for CH_4 production, at the five temperatures, led to orders of about 0.8 at lower propane pressures and of zero at higher pressures. Activation energies for methane production were

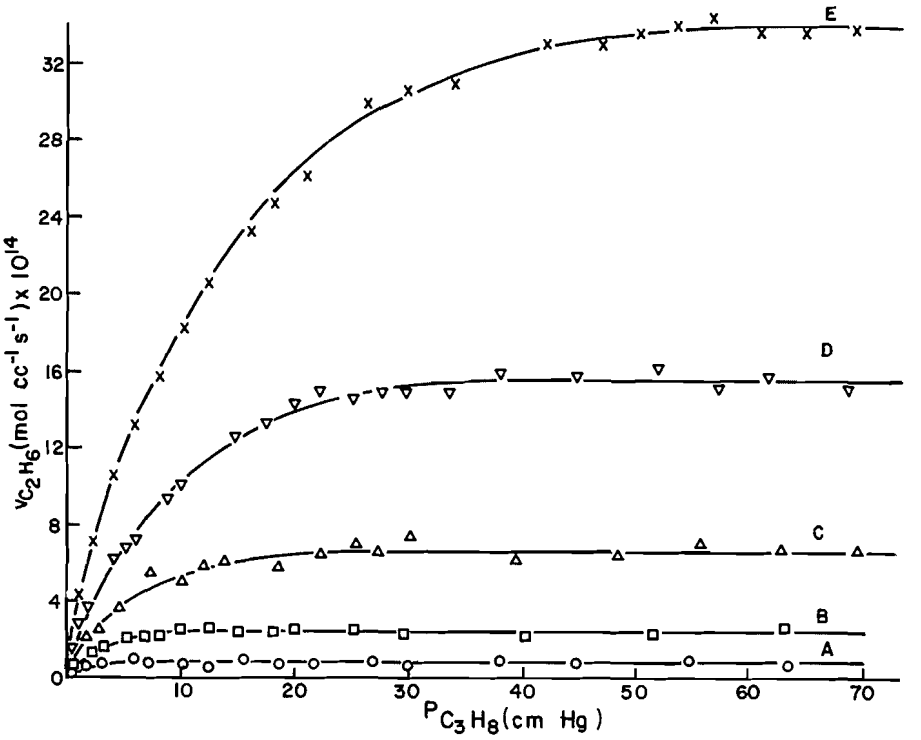

FIG. 5. Plots of initial rates of ethane production against propane pressure; temperatures as in Fig. 2.

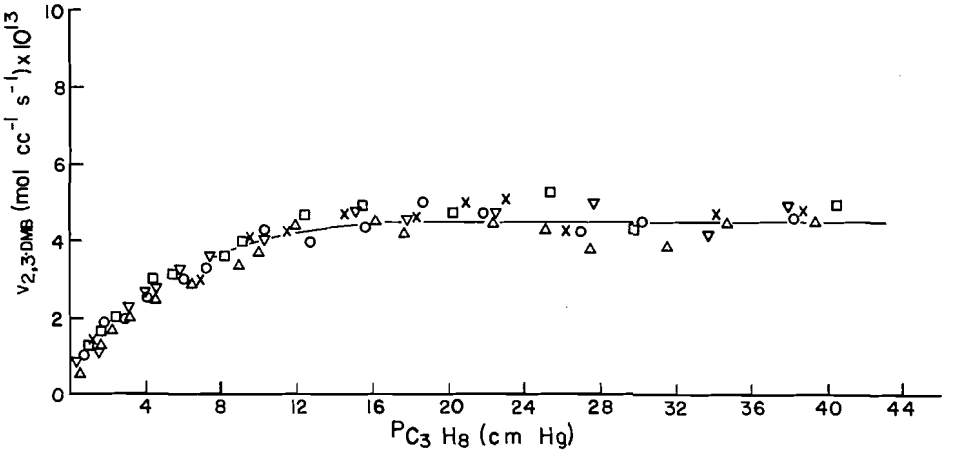

FIG. 6. Plots of initial rates of formation of 2,3-dimethylbutane against propane pressure; ○, 252.0 °C; □, 276.0 °C; △, 301.0 °C; ▽, 325.0 °C; ×, 350.0 °C.

obtained at a number of propane pressures, and are shown plotted against pressure in Fig. 12. The activation energy is seen to increase from an extrapolated value of 15 kcal mol^{-1} at zero propane pressure to a limiting value of 29.5 kcal mol^{-1} at high pressures of propane.

Formation of Other Products

The same procedure as for methane was applied to the rates of formation of ethylene, ethane, 2,3-dimethylbutane, 2-methylpentane, and *n*-hexane. Figures 13 to 16 show the variations of activation energy with propane pressure for these products

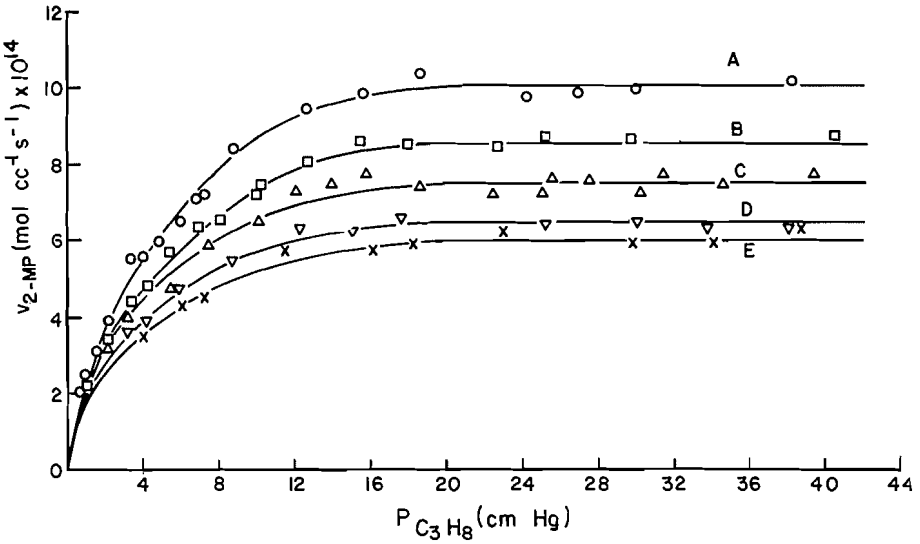

FIG. 7. Plots of initial rates of formation of 2-methylpentane against propane pressure; temperatures as in Fig. 2.

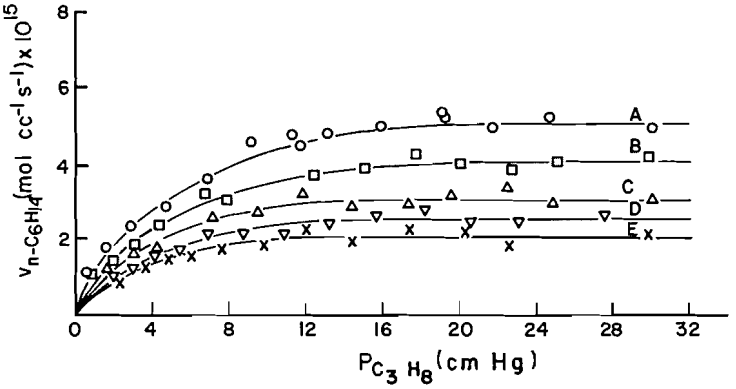

FIG. 8. Plots of the initial rates of formation of *n*-hexane against propane pressure; temperatures as in Fig. 2.

measured except 2,3-dimethylbutane, for which the activation energies were zero. Table 1 gives the low- and high-pressure orders of reaction, and the extrapolated low-pressure and limiting high-pressure activation energies.

Inert-Gas Effect

The overall dependence of the rates of product formation on the propane pressure, shown in Figs. 2 to 8, is attributed to the complete quenching of the excited mercury atoms at the higher pressures. If this is the case, introduction of some other gas of comparable quenching cross section would cause a decrease in the rates of product formation, and complete quenching would occur at lower propane pressures. A few experiments were carried out to test these conclusions.

The effects of carbon dioxide and helium on the rates of product formation were examined at 301 °C and at a propane pressure of 15 Torr. The results with carbon dioxide are shown in Fig. 17; helium showed very similar behavior. There is seen to be marked effect of inert gases, the rates falling to $\leqslant 20\%$ of their values in the absence of added gas. This behavior is atrributed to quenching of excited mercury by the CO_2 or He; the former has a quenching cross-section of about 3 Å, to be compared with 2 Å for propane (26).

Discussion

The subsequent discussion will be based on the following reaction scheme

[1] $Hg + h\nu \rightarrow Hg^*$

[2p] $Hg^* + C_3H_8 \rightarrow Hg + H + P$

[2s] $Hg^* + C_3H_8 \rightarrow Hg + H + S$

[3p] $H + C_3H_8 \rightarrow H_2 + P$

[3s] $H + C_3H_8 \rightarrow H_2 + S$

[4] $2P \rightarrow n\text{-}C_6H_{14}$

[5] $2S \rightarrow$ 2,3-DMB

[6] $P + S \rightarrow$ 2-MP

[7] $2P \rightarrow C_3H_8 + C_3H_6$

[8] $2S \rightarrow C_3H_8 + C_3H_6$

[9] $P + S \rightarrow C_3H_8 + C_3H_6$

[10p] $CH_3 + C_3H_8 \rightarrow CH_4 + P$

[10s] $CH_3 + C_3H_8 \rightarrow CH_4 + S$

[11*a*] $P \rightarrow H + C_3H_6$

[11*b*] $P \rightarrow CH_3 + C_2H_4$

[12*a*] $S \rightarrow H + C_3H_6$

[12*b*] $S \rightarrow CH_3 + C_2H_4$

In this scheme P represents the *n*-propyl radical, and S the *i*-propyl radical.

In addition to the above reactions the following processes may also play some part; they are un-

important at higher propane pressures and become relatively more important at lower pressures

[13] $H + C_3H_6 \rightarrow C_3H_7^* \rightarrow (H_2 + C_3H_5)$

[14] $H + C_3H_7 \rightarrow CH_3 + C_2H_5$

[15] $H + C_3H_7 \rightarrow C_3H_8$

[16] $C_2H_5 + C_3H_8 \rightarrow C_2H_6 + C_3H_7$

[17] $CH_3 + C_3H_7 \rightarrow C_4H_{10}$

[18] $2CH_3 \rightarrow C_2H_6$

It may be noted that there is considerable doubt as to the importance of reaction 12*b*, which is included for completeness; the present results have no bearing on the occurrence of this reaction.

Besides the products studied, and propane itself, the above scheme is seen to lead to propylene and butane. These products could not be determined because of the interference of the propane, although butane was detected. The present results are entirely consistent with this scheme of reactions, and with the conclusion that the decomposition of the propyl radicals is important only at the higher temperatures studied.

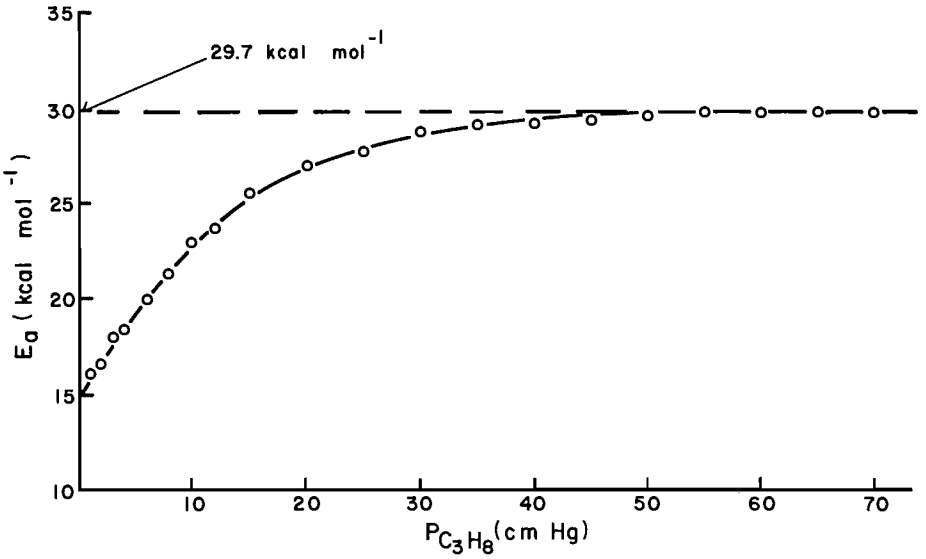

FIG. 13. Plot of the energy of activation for ethylene production against the pressure of propane.

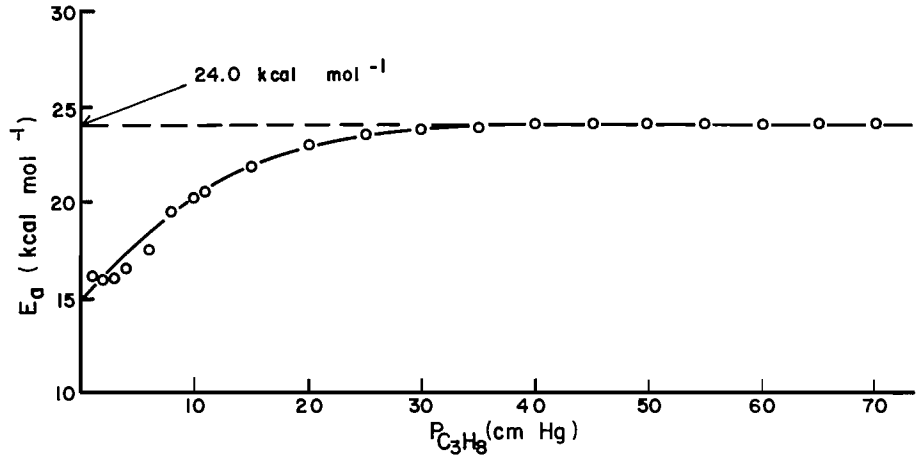

FIG. 14. Plot of the energy of activation for ethane production against the pressure of propane.

Arrhenius parameters for the various reactions, taken from various sources including the present results, are summarized in Table 2. On the basis of these values, and of the initial rates measured in the present investigation, it is possible to calculate the concentrations of free radicals. The results are shown in Table 3 for pressures of 10 and 700 Torr and at the five temperatures.

It is to be noted that the total concentration of free radicals in the system, $[R]_{total}$, is essentially independent of temperature. This is consistent with the fact that the total radical concentration depends only on the rate with which the excited mercury is quenched by propane, a process that is temperature-independent. Once complete quenching is achieved, *i.e.* at the higher propane pressures, the total radical concentration is also independent of propane pressure.

With increasing concentration of propane the concentrations of the n-C_3H_7 and i-C_3H_7 radicals are seen from Table 3 to increase slightly, whereas the concentrations of C_2H_5, CH_3, and H atoms decrease fairly strongly.

Simplified Steady-State Treatment; Kinetics of Product Formation

mechanism, the steady-state analysis is complicated and does not lead to rate equations which are sufficiently simple to permit a useful analysis of the experimental results. As an alternative, the following simplified treatment is useful in leading to an understanding of the behavior.

For the rate of hydrogen production the steady-state equations lead to

$$[19] \qquad v_{H_2} = \frac{F_1}{1 + \dfrac{F_2}{k_3[C_3H_8]}}$$

where F_1 and F_2 are given by

$$[20] \qquad F_1 = \phi I_a + k_{11a}[P] + k_{12a}[S]$$

$$[21] \qquad F_2 = k_{14}[C_3H_7] + k_{15}[C_3H_7] + k_{13}[C_3H_6]$$

Reference to Table 3 shows that F_1 and F_2 vary only weakly with $[C_3H_8]$; at low pressures of C_3H_8 the rate should thus be proportional to $[C_3H_8]$, and independent of it at higher pressures. This is the behavior observed. The result is easy to understand at the lower temperatures, where the hydrogen arises only from the initial split of C_3H_8 by the Hg*; at the lower pressures the rate of quenching is proportional to $[C_3H_8]$, but at higher pressures there is complete chemical quenching by C_3H_8. At higher temperatures the situation is complicated by the chain reactions, involving reactions 11*a*, 12*a*, 3p, and 3s, but again there is a levelling-off due to complete quenching by C_3H_8.

According to the mechanism the rates of formation of CH_4 and C_2H_4 should be approximately equal, their main sources being reactions 11*b* and 12*b*, of which the latter is unimportant. The rates are in fact close to one another (Figs. 3 and 4). At lower propane pressures (< 40 Torr) v_{CH_4} is slightly higher, whereas at higher pressures $v_{C_2H_4}$ predominates. This may be due to the fact that at lower pressures reaction 14 is relatively more important, and gives rise to additional CH_4. At lower pressures, but not at the higher ones, it may more than compensate for the loss of CH_3 through reactions 17 and 18.

The steady-state treatment leads to

$$[22] \qquad v_{CH_4} = \frac{F_3}{1 + \dfrac{F_4}{k_{10}[C_3H_8]}}$$

where

$$[23] \qquad F_3 = k_{14}[H][C_3H_7] + k_{11b}[P] + k_{12b}[S]$$

$$[24] \qquad F_4 = k_{17}[C_3H_7]$$

Again (*cf.* Table 3) F_3 and F_4 vary only weakly with $[C_3H_8]$, so that the order is expected to vary from ~ 1 at low pressures to zero at high pressures; Table 1 shows that this is the case. The fact that the methane production becomes pressure independent at higher pressures than does the hydrogen production (compare Figs. 2 and 3) may be due to the fact that $k_3 \gg k_{10}$. The variation of the activation energy for methane production with the pressure is due to the pressure-dependence of the first-order rate coefficient for the decomposition of a propyl radical into CH_3 and C_2H_4; this is considered in detail in the following paper. Similar remarks apply to the rates of ethylene production.

The steady-state equations for the formation of ethane and the three hexanes are complicated, and are not helpful in explaining the orders at lower pressures; they do explain the zero-order dependence at higher pressures, however.

Chain Lengths

Chain length for this system, involving several radicals and chain processes, may be defined in

several ways. One definition is the number of H atoms released by the decomposition of propyl radicals divided by the number of propyl radicals formed; its order of magnitude is v_{H_2} (chain)/$v_{C_6H_{14}}$. This rough procedure leads to a magnitude of about unity at the lowest temperature. Alternatively, chain length may be defined as the number of ethylene molecules produced for each *n*-propyl radical formed, *i.e.* approximately $v_{C_2H_4}/(v_{n\text{-}C_6H_{14}} + v_{2\text{-MP}})$. This procedure leads to an order of magnitude of unity at 250 °C, increasing to 10^2 at 350 °C.

Kinetics of the Mercury-Photosensitized Decomposition of Propane. Part II. Reactions of the Propyl Radicals

M. M. PAPIC[1] AND K. J. LAIDLER
Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received April 22, 1970

The results of the previous paper are analyzed to yield information about the reactions of the *n*-propyl and *i*-propyl radicals. The various combination and disproportionation reactions are considered. The rate of decomposition of the *n*-propyl radical was determined as a function of temperature and pressure, and limiting high-pressure and low-pressure kinetic parameters were obtained. The high-pressure activation energy is 32.6 kcal mol^{-1}, and this leads to a value of 24.3 kcal mol^{-1} for the dissociation energy of the C—C bond in the *n*-propyl radical, to 22.2 kcal mol^{-1} for its heat of formation, and to 99.1 kcal mol^{-1} for the primary C—H dissociation energy in propane. Entropy changes are also calculated from the results.

For the decomposition of the *i*-propyl radical $E_\infty = 38.7$ kcal mol^{-1}, and this leads to 37.7 kcal mol^{-1} for the C—H bond dissocation energy in this radical and to 19.3 kcal mol^{-1} for its heat of formation. The secondary C—H dissociation energy in propane is calculated to be 96.2 kcal mol^{-1}. Corresponding entropy changes are calculated.

Canadian Journal of Chemistry, 49, 549 (1971)

Introduction

In the present paper the results of Part 1 are analyzed as far as the reactions of the *n*-propyl and *i*-propyl radicals are concerned. Particular attention is given to the unimolecular decompositions of these radicals at their high- and low-pressure limits, and to their thermochemistry.

Calculations, Results, and Discussion

Combination and Cross-combination of Propyl Radicals

According to either simple collision theory or activated-complex theory, the rate ratio

$$v_{2\text{-MP}}/(v_{2,3\text{-DMB}} \times v_{n\text{-}C_6H_{14}})^{1/2}$$

should have a statistical factor of 2. The effects of different masses and moments of inertia in the rate expressions will be fairly unimportant, and one might therefore expect that the above ratio of rates will also be 2. That this is so is confirmed by the results shown in Table 1. The mean value and standard deviation of our ratio of rate constants is

$$k_6/(k_4k_5)^{1/2} = 2.0 \pm 0.1$$

The same ratio is to be expected for the sum of the rate constants for combination and disproportionation

$$[1] \quad (k_6 + k_9)/(k_4 + k_7)^{1/2}(k_5 + k_8)^{1/2} = 2$$

From these two equations

$$[2] \quad \frac{k_9}{k_6} = \left(1 + \frac{k_7}{k_4}\right)^{1/2}\left(1 + \frac{k_8}{k_5}\right)^{1/2} - 1$$

The ratios $k_7/k_4 = 0.16$ and $k_8/k_5 = 0.63$ are reliably known (1), but k_9/k_6 is more difficult to measure; Terry and Futrell (2) have given a value of 0.41 ± 0.02. Insertion of the k_7/k_4 and k_8/k_5 ratios into eq. 2 leads to

$$k_9/k_6 = 0.38 \pm 0.04$$

which agrees very well with the value of Terry and Futrell (2).

Concentrations of Propyl Radicals

The *i*-propyl radical is more stable than the *n*-propyl radical, its energy being about 3.5 kcal/mol lower; if equilibrium were established in the reaction the concentration of *n*-C_3H_7 would be only a few percent of that of *i*-C_3H_7. From the mechanism (Part 1) it is to be seen that if $k_4 = k_5$,

$$[3] \quad \frac{[S]}{[P]} = \left(\frac{v_{2,3\text{-DMB}}}{v_{n\text{-}C_6H_{14}}}\right)^{1/2}$$

The ratios calculated from these rates range from 9.5 at 252 °C to 15.0 at 350 °C, so that there is much more *n*-C_3H_7 than the corresponding value at equilibrium. Figure 1 shows a plot of log [S]/[P] against $1/T$, from which it is deduced that

$$[4] \quad [S]/[P] = 1.7 \times 10^2 \exp(-3.1/RT)$$

Not only is the [S]/[P] ratio smaller than the cor-

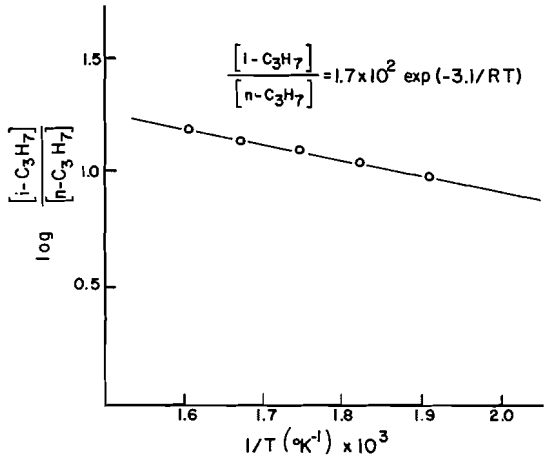

FIG. 1. Plot of the logarithms of the ratios of concentrations of *i*-propyl and *n*-propyl radicals against $1/T$; propane pressure = 300 Torr.

responding one at equilibrium, but the temperature dependence is in the opposite direction.

The result expressed in eq. 4 is qualitatively the same as that obtained by Lin and Laidler (4), but there is a considerable numerical difference, their result being

$$[5] \quad [S]/[P] = 5 \times 10^6 \exp(-17.0/RT)$$

Decomposition of n-Propyl Radicals

The decomposition of *n*-propyl radicals to ethylene and CH_3 is about 10^3 faster than the decomposition of *i*-C_3H_7 into the same products (5), and the rate of decomposition of *n*-C_3H_7 to C_3H_6 and H is lower than the rate of their decomposition to C_2H_4 and CH_3 by a factor of $\sim 10^3$. The ethylene can therefore be assumed to result entirely from reaction 11*b*, and the loss of *n*-C_3H_7 radicals by reaction 11*a* can be neglected in the present discussion. Therefore, from the reaction scheme

$$[6] \quad \frac{k_{11b}}{k_4^{1/2}} = \frac{v_{C_2H_4}}{(v_{n\text{-}C_6H_{14}})^{1/2}}$$

With k_4 taken as $10^{13.4}$ cc mol^{-1} s^{-1}(6), k_{11b} can therefore be evaluated from the rates of C_2H_4 and *n*-C_6H_{14} formation. The results are shown plotted in Fig. 2 at the five different temperatures. Figure 3 shows an Arrhenius plot for the limiting high-pressure rate constants; the line corresponds to the equation

$$k_{11b}^{\infty} = 2.5 \times 10^{14} \exp(-32.6 \pm 0.5/RT) \text{ s}^{-1}$$

The activation energy obtained from the rate of formation of ethylene at high propane pressures (*cf.* Fig. 13 of Part 1) was 29.7 kcal mol^{-1}, the difference being due to the temperature dependence of [P]. From the k_{11b}^{∞} value and the ethylene rates it can be deduced that

$$[7] \quad [P] \propto \exp(2.9/RT)$$

and in view of eq. 4

$$[8] \quad [S] \propto \exp(-0.2/RT)$$

This agrees with the result (Table 3 of Part 1) that [P] decreases with increasing temperature and [S] remains practically constant.

Values of k_{11b}^0, the limiting low-pressure rate constant, were obtained from plots of $1/k_{11b}$ against $1/[C_3H_8]$. The Arrhenius plot is shown in Fig. 4 and leads to

$$k_{11b}^0 = 2.5 \times 10^7 \exp(-17.0 \pm 0.5/RT) \text{ cc mol}^{-1} \text{ s}^{-1}$$

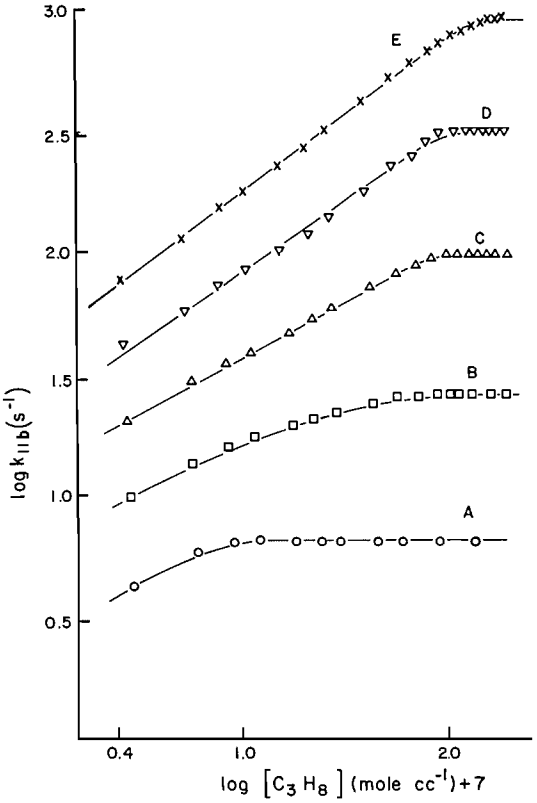

FIG. 2. Double logarithmic plots of the rate constant k_{11b} for the process n-$C_3H_7 \rightarrow CH_3 + C_2H_4$ against the propane concentration; A = 252.0 °C; B = 276.0 °C; C = 301.0 °C; D = 325.0 °C; E = 350.0 °C.

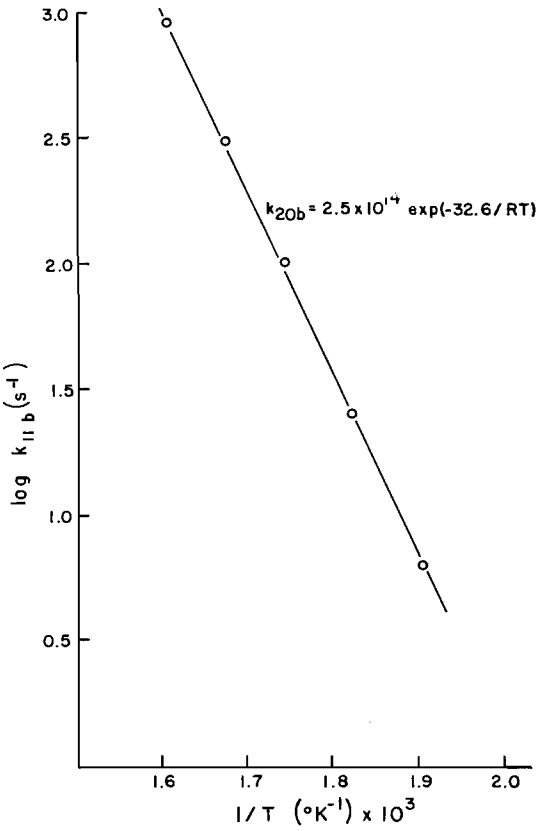

FIG. 3. Arrhenius plot of k_{11b}, at a pressure (700 Torr) at which the limiting rate has been attained.

The abnormally low value obtained for the frequency factor of this reaction might possibly be due to the formation of hot C_3H_7* radicals by the reaction H + C_3H_6.

On the basis of the Hinshelwood–Kassel–Rice–Ramsberger theories of unimolecular reactions

$$[9] \qquad E^{\infty} - E^{0} = (s - 1)\,RT$$

where s is the number of effective degrees of freedom for the decomposition. This equation leads to s = 15; the total number of vibrational degrees of freedom is 24, so that, as is common, s is roughly half the total number.

The various values which have been reported for the rate constant of this decomposition are summarized in Table 2; the activation energies quoted are seen to range from 20 to 35 kcal mol^{-1}. Our value is in reasonable agreement with those obtained by Kerr and Calvert (8), Calvert and Sleppy (9), Jackson and McNesby (10), and Lin and Laidler (4). The lower values obtained (7, 11, 12) are almost certainly due to the fact that the reaction was somewhat in its pressure-dependent region.

Thermochemistry

The activation energy E_{11b}^{∞} = 32.6 kcal mol^{-1} is related to the enthalpy change ΔH_{11b} by

$$[10] \qquad \Delta H_{11b} = E_{11b}^{\infty} - E_{-11b} + RT$$

$$[11] \qquad = \Delta H_{11b}^{0} + \int_0^T \Delta C_p \, dT$$

where ΔH_{11b}^{0} is the enthalpy change at 0 °K, equal to the dissociation energy D^0(n-CH_3—CH_2-CH_2—) at 0 °K. The enthalpy of n-C_3H_7 was assumed to be the same as that of C_3H_8 and with the use of the enthalpies of C_2H_4, C_3H_8, and CH_3 (13, 14) the value of the integral in eq. 11, with T = 600 °K, is 1.3 kcal mol^{-1}. With E_{-11b} = 8.6 kcal mol^{-1} (15) we obtain

TABLE 2. Kinetic parameters for the decomposition of n-C_3H_7 into $CH_3 + C_2H_4$

Method of investigation	log k (s^{-1})	Reference
Photolysis of n-C_3H_7CHO	11.7–25.2/2.3 RT	Kerr and Trotman-Dickenson (7)
Photolysis of n-$C_3H_7N_2C_3H_7$	15.4–34.5/2.3 RT	Kerr and Calvert (8)
Photolysis of $CH_3N_2CH_3$ in the presence of n-C_3H_7CHO	15.3–34.9/2.3 RT	Calvert and Sleppy (9)
Thermochemical estimate	13.9–31/2.3 RT	Jackson and McNesby (10)
$CH_3N_2CH_3$-sensitized decomposition of C_3H_8	13.5–31.4/2.3 RT	Lin and Laidler (4)
Hg-photosensitized decomposition of C_3H_8	9.2–20/2.3 RT	Bywater and Steacie (11)
Hg-photosensitized decomposition of C_3H_8	9.6–22/2.3 RT	Back and Takamuku (12)
Hg-photosensitized decomposition of C_3H_8	14.4–32.6/2.3 RT	This work; limiting high-pressure results
Hg-photosensitized decomposition of C_3H_8	7.4–17.0/2.3 RT	This work; limiting low-pressure results

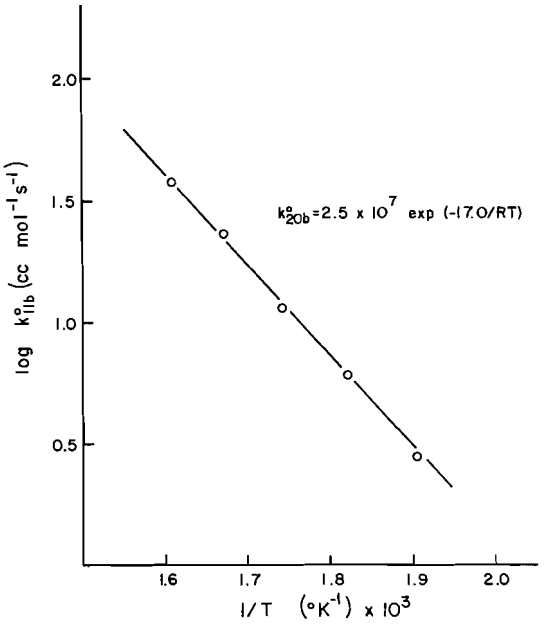

FIG. 4. Arrhenius plot of $k_{11b}{}^{0}$ obtained by extrapolation to the low-pressure limit.

$D^0(n\text{-}CH_3\text{—}CH_2CH_2\text{—}) =$ 23.9 kcal mol^{-1} at 0 °K

and

$D(n\text{-}CH_3\text{—}CH_2CH_2\text{—}) =$ 24.3 kcal mol^{-1} at 25 °C.

The latter value agrees satisfactorily with 23.0 kcal mol^{-1} listed by Lin and Laidler (4) and 25.5 obtained by Benson (3).

With the use of the following heats of formation: CH_3, 34.0 kcal mol^{-1} (3, 17); C_2H_4, 12.5 kcal mol^{-1} (16), the value for the n-propyl radical is found to be

$$\Delta H_f\,(n\text{-}C_3H_7) = 22.2 \text{ kcal mol}^{-1} \text{ at } 25\ ^\circ\text{C}$$

This is to be compared with the value of 20.9 listed by Calvert and Pitts (16) and with that of 21 ± 2 listed by Kerr (17).

The primary C—H bond dissociation energy in propane can be calculated from the following heats of formation: C_3H_8, −24.8 kcal mol^{-1}; H, 52.1 kcal mol^{-1} (16); n-C_3H_7, 22.2 kcal mol^{-1} (present work). The result is

$D\,(CH_3CH_2CH_2\text{—H}) =$ 99.1 kcal mol^{-1} at 25 °C

Kerr (17) listed a value of 98 ± 2 kcal mol^{-1}.

The entropy change for the reaction 11b can be calculated from the frequency factors in forward and reverse directions; the values used are $A_{11b} = 10^{14.4}$ s^{-1} (present work) and $A_{-11b} = 10^{12.1}$ cc mol^{-1} s^{-1} (15). The result is

$$\Delta S_{11b} = 10.6 \text{ cal deg}^{-1} \text{ mol}^{-1}$$

the standard state being 1 mol/cc. This value agrees satisfactorily with 12.0 cal deg^{-1} mol^{-1} calculated from entropies for C_2H_4, CH_3, and n-C_3H_7 listed by Calvert and Pitts (16). The entropy of activation for reaction 11b is calculated to be 4.1 cal deg^{-1} mol^{-1} at 600 °C, and estimated as 5.4 cal deg^{-1} mol^{-1} at 25 °C. These values indicate a fairly loose structure for the activated complex.

Decomposition of i-Propyl Radicals

There is some uncertainty about the relative rates of the processes

[12a] $\quad i\text{-}C_3H_7 \rightarrow C_3H_6 + H$

and

[12b] $\quad i\text{-}C_3H_7 \rightarrow C_2H_4 + CH_3$

If i-C_3H_7 does give rise to C_2H_4 it is not certain whether the process occurs directly or via isomerization into n-C_3H_7. There is no direct evidence

TABLE 3. Kinetic parameters for the decomposition of i-C_3H_7 into H + C_3H_6

Method of investigation	log k (s^{-1})	Reference
Photolysis of i-C_3H_7CHO	13.8–36.9/2.3 RT	Kerr and Trotman-Dickenson (21)
Photolysis of $(i$-$C_3H_6D)_2CO$	13.1–35/2.3 RT	Heller and Gordon (22)
Thermochemical estimate	15.0–42/2.3 RT	Leathard and Purnell (23)
Hg-photosensitized decomposition of C_3H_8	14.6–38/2.3 RT	Bywater and Steacie (11)
Hg-photosensitized decomposition of C_3H_8	14.0–37/2.3 RT	Back and Takamuku (12)
Hg-photosensitized decomposition of C_3H_8	14.3–38.7/2.3 RT	This work; limiting high-pressure results

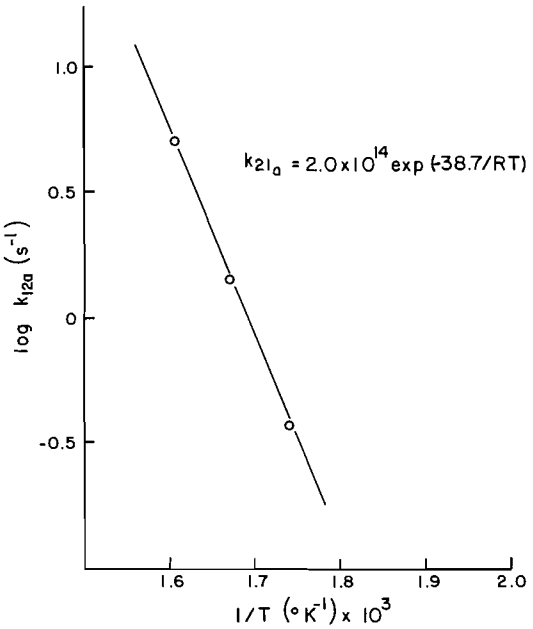

FIG. 5. Arrhenius plot of k_{12a}; the pressure is 300 Torr, and there was no pressure dependence over the entire pressure range.

for such isomerization; Billinge and Gowenlock (18) pyrolyzed separately di-n-propylmercury and di-i-propylmercury, but in neither case found evidence for isomerization.

Jackson and McNesby (19) found the ratio k_{12b}/k_{12a} to be about 0.04 at 500 °C, with little temperature dependence. They concluded that if the isomerization of i-C_3H_7 to n-C_3H_7 is simultaneous with, or occurs just before, decomposition, the ratio k_{12b}/k_{12a} is approximately 0.07. Falconer, Rabinovitch, and Cvetanovic (20) suggested that this value is an upper limit.

On the other hand, Kerr and Trotman-Dickenson (21) and Heller and Gordon (22), who studied the photolysis of i-C_3H_7CHO and $(i$-$C_3H_6D)_2CO$, respectively, have presented evidence that in the temperature range from 250 to 350 °C the ratio k_{12b}/k_{12a} is approximately unity. The percentage conversions in these experiments is not stated; it is possible that C_2H_4 is produced not directly but from the scavenging of H atoms by C_3H_6 with the formation of n-C_3H_7 which breaks down into CH_3 + C_2H_4.

From the point of view of hydrogen production, the eventual loss of i-propyl radicals via reaction 12b tends to be compensated for by the occurrence of reaction 11a. The present discussion will be based on the assumption that all chain hydrogen comes from the decomposition of i-C_3H_7, and that i-C_3H_7 radicals decompose entirely via reaction 12a. If this assumption proves to be incorrect, the derived kinetic parameters would correspond to some average value for n-C_3H_7 and i-C_3H_7. The kinetic parameters for the decomposition of n-C_3H_7 and i-C_3H_7 into C_3H_6 are close to one another (*cf.* Table 2 of Part 1) so that the error involved in the assumption will not be great.

The rate of hydrogen production by reaction 12a (chain hydrogen) is obtained by subtracting the low-temperature rate of H_2 production, v_3, from the total rate of H_2 production. The rate of 2,3-DMB production is

$$[13] \qquad v_{2,3\text{-DMB}} = k_5[S]^2$$

whence

$$[14] \qquad k_{12a} = k_5^{1/2} v_{H_2(\text{chain})}/(v_{2,3\text{-DMB}})^{1/2}$$

The value of k_5 was taken to be $10^{13.4}$ cc mol^{-1} s^{-1} and to be temperature-independent (6). The rate constants observed showed no fall off down to the lowest pressures, so that they must be limiting high-pressure values. An Arrhenius plot of the results obtained in this way is shown in Fig. 5. The resulting rate equation is

$$k_{12a}^{\infty} = 2.0 \times 10^{14} \exp(-38.7)RT)\, s^{-1}$$

A comparison with other values is shown in Table 3. The agreement is satisfactory except with the activation energy of Leathard and Purnell

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(23), which was based on thermochemical estimates and may not be too reliable.

Thermochemistry

From the value of $E_{12a}^{\infty} = 38.7$ kcal mol^{-1} various energy values can be derived. Thus, by analogy with eq. 11

$$[15]\quad D^0(i\text{-}CH_3CHCH_2\text{—}H) = E_{12a} - E_{-12a} + RT - \int_0^T \Delta C_p \, dT$$

From the enthalpies the value of the integral at 600 °K is 1.5 kcal mol^{-1}. With $E_{-12a} = 2.0$ kcal mol^{-1} (24) we obtain

$$D^0(i\text{-}CH_3CHCH_2\text{—}H) = 36.4 \text{ kcal mol}^{-1} \text{ at } 0\,^{\circ}\text{K}$$

and

$$D\,(i\text{-}CH_3CHCH_2\text{—}H) = 37.7 \text{ kcal mol}^{-1} \text{ at } 25\,^{\circ}\text{C}$$

A value of 39 kcal mol^{-1} is listed by Kerr (17).

Use of the value of 37.7 together with $\Delta H_f(H) = 52.1$ kcal mol^{-1} and $\Delta H_f(C_3H_6) = 4.9$ kcal mol^{-1} (16) leads to

$$\Delta H_f(i\text{-}C_3H_7) = 19.3 \text{ kcal/mol}$$

Benson (3) listed a value of 17.6 kcal mol^{-1}.

The secondary C—H bond dissociation energy in C_3H_8 can be obtained using the above values together with $\Delta H_f(C_3H_8) = -24.8$ kcal mol^{-1} (16); the result is

$$D\,[(CH_3)_2CH\text{—}H] = 96.2 \text{ kcal mol}^{-1}$$

Kerr (17) listed the value of 94.5 kcal mol^{-1}.

The present results lead to the following entropies of activation for the decomposition of i-C_3H_7 into $C_3H_6 + H$

$$\Delta S_{12a}^{\ddagger} = 3.7 \text{ cal deg}^{-1} \text{ mol}^{-1} \text{ at } 600\,^{\circ}\text{K}$$

$$\Delta S_{12a}^{\ddagger} = 5.0 \text{ cal deg}^{-1} \text{ mol}^{-1} \text{ at } 25\,^{\circ}\text{C}$$

These values suggest a loose structure for the activated complex.

With Yang's (24) value of 10^{13} cc mol^{-1} s^{-1} for A_{-12a}, it is found that the overall entropy change is

$$\Delta S_{12a} = 6.0 \text{ cal deg}^{-1} \text{ mol}^{-1}$$

the standard state being 1 mol cc^{-1}. This value agrees satisfactorily with that of 5.2 cal deg^{-1} mol^{-1} calculated from listed entropies (16) for C_3H_6, H, and i-C_3H_7 at 25 °C.

Thanks are due to Drs. M. H. Back, R. A. Back, and J. L. Holmes for helpful suggestions.

The Crystal and Molecular Structure of Bis-(2,4-pentanedionato)-4-aminopyridinecopper(II)

G. W. BUSHNELL
Department of Chemistry, University of Victoria, Victoria, British Columbia
Received June 29, 1970

The crystal structure of bis-(2,4-pentanedionato)4-aminopyridinecopper(II) has been refined to an R value of 0.070 from photometric Weissenberg film measurements. The cell is monoclinic with $a = 836 \pm 3$ pm, $b = 1475 \pm 3$ pm, $c = 1435 \pm 3$ pm, $\beta = 112.14 \pm 0.20°$. The space group is $P2_1/c$ (No. 14) with four molecules per cell. The density is 1.44 ± 0.01 g cm^{-3} (measured), 1.442 ± 0.013 g cm^{-3} (calculated). The geometry about each copper atom is approximately that of a tetragonal pyramid, with the copper atom 22 pm above the basal plane. The apex of the pyramid is occupied by an oxygen atom, the heterocyclic nitrogen is in the basal plane, and the 4-amino group is uncoordinated and hydrogen bonded to oxygen in a neighboring molecule.

Introduction

A survey of known five coordinate copper(II) complexes (1) shows that the geometry about the central metal atom is usually based on that of a tetragonal pyramid. Trigonal bipyramidal structures are known but they are fewer in number, and sometimes the reason for their occurrence can be rationalized in terms of rigid ligand geometry (2), or adverse steric effects in the tetragonal pyramidal model (3).

A large fraction of the known five coordinate complexes contain two bidentate ligands and one unidentate. In this case, a central metal atom with tetragonal pyramidal geometry affords the possibility of two kinds of structure, Type 1 with the unidentate ligand at the apical position, and Type 2 with the unidentate ligand in the basal plane. There is no way of predicting which structure will arise in any particular reaction, but Type 1 has been found more often than Type 2.

The structure of bis-(2,4-pentanedionato)-copper(II) contains a square planar copper atom (4). Graddon (5) measured the formation constants of a number of pyridine adducts of bis-(2,4-pentanedionato)copper(II), which he claimed were five coordinate. Traill (6) pointed out that one side of a diketone ligand might become detached in the presence of pyridine or chloroform. Reference was made to the early work of Burgess and Lowry (7) on the catalytic action of pyridines on the mutarotation of bis-(benzoylcamphor)beryllium(II) in chloroform or carbon tetrachloride. Graddon and Watton (8) replied to the query and gave evidence for a five coordinate structure, rather than a four coordinate one. The pyridine was assumed to be in the apical position of a tetragonal pyramid. Walker and Li (9) investigated the equilibrium constant for the formation of bis-(2,4-pentanedionato)4-methylpyridinecopper(II) in solution.

Duckworth *et al.* (10) reported the crystal structure of bis-(*o*-hydroxyacetophenonato)4-methylpyridinecopper(II). The molecule contains a tetragonal pyramidal five coordinate copper atom with nitrogen at the apex and the two chelates at the base (Type 1). Ooi and Fernando (11) crystallized bis-(2,4-pentanedionato)quinolinecopper(II) from a solution of bis-(2,4-pentanedionato)copper(II) in quinoline. They report a molecular structure of Type 1. The diketone ligands are bent downwards away from the apex of the pyramid. The plane of the quinoline molecule lies between the two diketone ligands.

The crystal structure of bis-(2,4-pentanedionato)4-aminopyridinecopper(II) was undertaken when spectral results suggested five coordination, and the crystals were found to be markedly different and of better quality than those which could be obtained from the corresponding pyridine and 4-methylpyridine compounds. The electron donating amino group in the 4-position was expected to increase the stability of the pyridine coordination without adverse steric effects. The amino group also made prediction of the structure very uncertain; known structures of copper complexes showed such variety (1) that they were of little help for this purpose.

Experimental

The 4-aminopyridine used was recrystallized from acetone. Bis-(2,4-pentanedionato)copper(II) was prepared by the method of Jones (12), and allowed to react with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

an equimolar quantity of 4-aminopyridine in chloroform under reflux for 5 min. The reaction mixture was filtered and allowed to crystallize by evaporation. Bis-(2,4-pentanedionato)4-aminopyridinecopper(II) appears as well formed green crystals.

Anal. Calcd. for $C_{15}H_{20}CuN_2O_4$: C, 50.63; H, 5.66; Cu, 17.85. Found: C, 50.77; H, 5.74; Cu, 18.0.

Crystallographic Measurements

The crystal habit and dimensions of the specimen used for the main data set are shown in Fig. 1. The acute angle shown was calculated from the cell dimensions to be 49.6°, microscopic observation gave 49.2, 49.4, and 49.9°. The crystal data are listed in Table 1. Systematic absences gave an unequivocal space group determination. Cell dimensions were measured from Weissenberg films, calibrated using pure copper wire. The density was measured by flotation in a trichloroethene/acetone solution.

Intensity measurements were obtained using CuKα radiation and the multiple film technique. Integrated equi-inclination Weissenberg photographs were taken of all accessible layers on the *a*-axis, and of the zero layer on the *b*-axis. The films were measured using a Hilger Model 1 photometer and processed using the expression $\ln I_0/I$. Of the 2319 reflections scanned, 1573 were found above background using this technique. No absorption corrections were made (μt(max) = 0.82, μt(min) = 0.14). Lorentz and polarization factors were applied and the

h,0,*l* data were used to put the 0,*k*,*l* to 5,*k*,*l* data onto a common scale.

Structure Determination

Atomic scattering factor curves were obtained from the International Tables for X-Ray Crystallography (13). All atoms were assumed to be uncharged. A correction of -2.1 *e* was made for the real part of the anomalous dispersion of copper. Computations were done on an I.B.M. 360/44 computer using the programs of Ahmed *et al.* (14). The copper atom was located by using a three dimensional Patterson synthesis. A Fourier synthesis using phases calculated from the copper atom alone gave the complete structure. Structure factors were calculated for all reflections but only the observed reflections were used in the minimization of $\Sigma w(|F_o| - |F_c|)^2$ by the block diagonal least squares method. (3 × 3) and (6 × 6) blocks were used for each atom, and a 2 × 2 block was used for the scale and an overall thermal parameter. The weighting scheme was $\sqrt{w} = |F_o|/P_1$ if $|F_o| \leqslant P_1$ and $\sqrt{w} = P_1/|F_o|$ if $|F_o| > P_1$ with $P_1 = 30.0$. This scheme gives low weight to the very weak as well as to the very strong reflections, and was appropriate to the measurement technique used as shown by analysis of $w(|F_o| - |F_c|)^2$ for systematic variations. A partial shift of 0.8 was used in the refinement. The final *R*-values decreased in the sequence 0.076, 0.070, 0.070. When the refinement was terminated, no temperature factor shift was greater than one standard deviation, the atomic position parameter shifts were all less than 0.65 of a standard deviation, and generally much smaller than this. No systematic trends were to be found in the shifts.

The estimated standard deviations of the parameters were calculated according to the formula

$$\sigma(P_i) = [(a^{-1})_{ii}(\Sigma w\Delta^2)/(m - n)]^{\frac{1}{2}}$$

where $(a^{-1})_{ii}$ is a diagonal element in the inverse matrix, *m* is the number of reflections included in the least squares refinement, *n* is the number of variable parameters in the structure, and *w* is the relative weight. The final difference map showed a slight negative peak at the Cu atom position (−2.7% of the Fourier peak height). There was no indication of misplacement of any atom. The hydrogen atom peaks were visible at approximately twice the background variations. The methyl hydrogens were most poorly defined. The structure factor table is in the Depository for Unpublished Data.[1]

Results

The fractional atomic coordinates of bis-(2,4-pentanedionato)4-aminopyridinecopper(II) are given in Table 2. The molecular structure is shown in Fig. 2 and the complete unit cell in Fig. 3. The origin of the cell is at the lower left front, with *y* vertical, *z* left to right, and *x* approximately into the page. Atoms marked N1 in Fig. 3 belong to neighboring cells, and the thin

*Bond length × 10 is in pm, standard deviation in parentheses.

lines denote the three shortest intermolecular distances. It is evident that the copper atom is five coordinate and that there is no atom near the sixth coordination position. Table 3 gives the intramolecular bond lengths. Comparable measurements from the literature are given in Table 4. In the basal plane the copper to ligand bond lengths are normal. The apical Cu—O(3) length at 216.5 pm is greater than the basal Cu—O distances but, limited by the span of the chelate, it is shorter than any of its kind shown in Table 4.

The bond lengths within each 2,4-pentanedionato ligand agree well with the average values given by Lingafelter (22). In Table 4 $(C—C)_i$ and $(C—C)_x$ are bond lengths internal and external to the chelate ring, respectively. In Table 5, the O—O distance in each ligand is compared with the values cited by Lingafelter. The O(3)—O(4) distance is larger than usual; together with the short Cu—O(3) bond this may indicate an ener-

*Bond length × 10 is in pm.

The coordinative bond lengths were measured in the following compounds given in the same order as the tabulated data.

bis-(N-phenylsalicylaldiminato)pyridinecopper(II),
anhydrous cupric formate,
N-salicylideneglycinatoaquocopper(II),
bis-(8-hydroxyquinolinato)copper(II) dimer (β form),
bis-(dimethylglyoximato)copper(II) dimer,
NN'-ethylenebis-(acetylacetoneiminato)aquocopper(II),
pyridoxylidene(±)-valinecopper(II),
bis-(*o*-hydroxyacetophenonato)4-methylpyridinecopper(II).

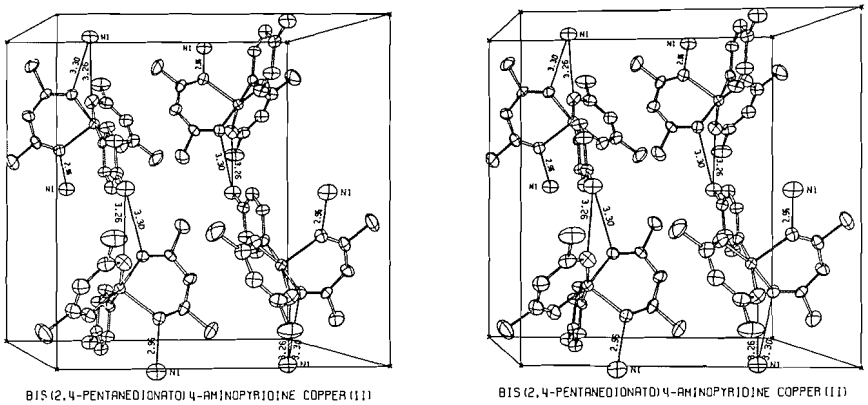

FIG. 3. Complete unit cell showing intermolecular contacts. (Atoms marked N1 belong to neighboring cells.)

getically unfavorable factor which had to be overcome in the formation of a Type 2 copper complex rather than a Type 1. The 1,1,1,5,5,5-hexafluoro-2,4-pentanedionato ligands in the six coordinate complex, $Cu(hfacac)_2$ bipyridine have been shown to have Cu—O distances of 196.7 and 229.6 pm (23). In this case the O—Cu—O angle is acute, the span of the chelate is normal, and accompanied by an alternation of bond lengths suggestive of the enol form of the ligand. There is no indication of a similar effect in the unfluorinated ligands of our five coordinate complex.

Table 6 gives the distribution into various ranges of intermolecular distances between 290 and 400 pm. Those below 360 pm have been specified and their lengths given owing to their probable role as structure determining factors. The three shortest distances are marked in Fig. 3 by thin lines. The shortest of them all (N(1)—O(3), 296 pm) may be attributed to a N—H---O hydrogen bond, for which a typical N—O distance is 290 pm (24). The difference map has a peak attributable to hydrogen at approximately the correct position. The N(1)—O(2) and N(1)—O(4) lengths are more difficult to interpret, being at the upper limit of those expected for a bifurcated hydrogen bond but still considerably shorter than average. If the atom N(1) were pressed wedge-like

between atoms O(2) and O(4), the O(2)—O(4) distance would be larger than normal. In fact this distance is remarkably short at 264 pm and subtends an angle of only 85.2° at the copper atom. Furthermore the angle Cu—N(2)—C(11), 118.1°, is less than Cu—N(2)—C(15), 124.5°, supporting the view that N(1) is weakly hydrogen bonded to O(2) and O(4). The difference map has a reasonably well shaped peak attributable to hydrogen lying in the N(1), O(2), O(4) triangle. The short C(14)—O(3) and C(12)—O(4) distances may be attributed to the proximity of C(12) and C(14) to N(1), and the pyridine ring position. The closest contact definitely not affected by hydrogen bonding is between two C(10) methyl groups. It is clearly visible across the center of Fig. 3, and may control the plane of the pyridine ring.

The bond angles are given in Table 7. The angles subtended by the copper atom deviate markedly from the 90, 180° values of a pure tetragonal pyramid but are best described in terms of this geometry. O(1) and O(2) are bent downwards away from the apex by 10.6 and 10.3°. This is similar to the effect observed by Ooi and Fernando (11). O(4) and N(2) are bent away from the apex by 2.4 and 2.7°, thus the symmetry of coordinated atoms about a plane defined by Cu, C(3), and O(3) is remarkably good.

The angles of the pentanedionato groups agree well with the following average values (22): $(O—C—C)_i = 125.3$, $(O—C—C)_x = 115.7$. Angles of the type $(C—C—C)_i$ are known (22) to be dependent on the (O—O) span; this is confirmed by the results.

The least squares planes for the three ligand molecules and the basal plane of the tetragonal pyramid (excluding Cu) are given in Table 8. The orthogonal axis system used has x along a, y in the (a,b) plane, and z along c^*. The quantity minimized was $R = \sum_i W_i P_i^2$, where the weight W_i for atom i is given by $3/(\sigma^2(x_i) + \sigma^2(y_i) + \sigma^2(z_i))$ and P_i is the perpendicular distance of atom i from the plane. The quantity $\chi^2 = \sum_i (P_i^2/\sigma^2(P_i))$ is calculated as an index of the planarity of the group.

We conclude that the 4-aminopyridine ligand and the basal group O(1), O(2), O(4), and N(2) are planar, the copper atom lying 0.22 Å above the basal plane. Deviations from planarity of the 2,4-pentanedionato groups are shown in Fig. 4.

The thermal vibration parameters are given in Table 9 and pictorially displayed in Figs. 2 and 3, of which the viewing lines are mutually perpendicular. Figure 2 shows the lower left hand molecule of Fig. 3 as seen from above. The terminal carbon atoms of the diketone ligands have large amplitudes of vibration. Atoms C(12) to C(15), and N(1) which constitute the far end of the 4-aminopyridine ligand, appear to be moving in a concerted fashion. This is consistent with the ring structure having a certain rigidity and the amine group being hydrogen bonded to a neighboring molecule. Relative motion of adjacent molecules might be expected to cause the 4-aminopyridine to wag.

Conclusion

The structure of bis-(2,4-pentanedionato)4-aminopyridinecopper(II) has been shown to be

approximately tetragonal pyramidal and of Type 2 (see Introduction). The axial bond is longer than the basal bonds and in order to span from the apex to the base of the pyramid, one of the diketone chelates is strained open more than usual. Nevertheless, the axial bond is shorter than analogous bonds in many other tetragonal pyramidal copper complexes in which the compressive effect of chelation is absent. It is reasonable to suppose that energy has been expended in attaining this molecular structure and regained in the formation of a more stable crystal structure. Intermolecular hydrogen bonding is suggested as an important stabilizing factor. The difference between this structure and the Type 1 structure of bis-(2,4-pentanedionato)quinolinecopper(II) can also be rationalized in terms of the base strengths of the

*Anisotropic values have been multiplied by 10^4. $T = \exp[-(h^2\beta_{11} + k^2\beta_{22} + l^2\beta_{33} + kl\beta_{23} + hl\beta_{13} + hk\beta_{12})]$. Estimated standard deviations in parentheses.

two heterocyclic molecules, provided that the diketone groups are assigned a non-dominant role, as is observed experimentally. We assume a C_{4v} ligand field for the d^9 Cu ion. The strongly basic 4-aminopyridine molecule ($pK_a = 9.114$) donates electrons toward the half filled $d_{x^2-y^2}$ orbital. The more weakly basic quinoline molecule ($pK_a = 4.81$) is better able to tolerate the electron density of the Cu atom at the apical position.

Operating funds were obtained from the National Research Council of Canada and the Committee for Research, Leave, and Travel of the University of Victoria. A major equipment grant and computing facilities were provided by the University of Victoria. Mr. R. D. Menhenett and Dr. A. Tweedale have generously given computing assistance. The author gratefully acknowledges all these contributions.

Investigations of Paramagnetic Centers Produced by Tritium β-Particle Irradiation. I. The Cd(I) Cation in Single Crystals of Calcium Tetraacetato Cadmium (II) Hexahydrate

R. S. EACHUS AND F. G. HERRING
Chemistry Department, University of British Columbia, Vancouver 8, British Columbia

Received July 8, 1970

The Cd(I) center has been produced by both tritium β-particle irradiation and by γ-irradiation. The tritium was introduced as water of crystallization in calcium tetraacetato cadmium(II) hexahydrate in the form of THO. It is found that both forms of irradiation lead to the same center. The orientation of the hyperfine components of the Cd(I) center throws some light on the possible mechanism of its formation.

Canadian Journal of Chemistry, 49, 562 (1971)

Introduction

The primary interaction of high energy radiation with a solid is the ejection of electrons from the constituent molecules of the solid. When these high energy electrons become thermalized they can either recombine with the parent molecule to produce an excited state (which will often undergo homolytic fission to produce a radical fragment) or an electron may become trapped at an impurity center or at another molecule to produce an electron excess center. This last trapping may require either an intramolecular or an intermolecular configuration change (1).

The usual sources of high energy radiation are X-rays and γ-rays. However, an alternative procedure for producing electrons in a lattice, which may be subsequently trapped, is the β-particle decay of the tritium atom. Previous studies using this form of internal radiation are limited. One of the first studies appears to have been carried out by Spinks *et al.* (2) who used electron spin resonance (e.s.r.) to monitor the decay of tritium oxide in frozen water. Subsequently Lassmann (3) studied the self-radiolysis of tritium-labelled amino and dicarboxylic acids. This study showed that, in these systems, stable free radicals are formed by the conversion of primary unstable free radicals; the unstable precursors being detected at 77 °K. Lloyd, Magnotta, and Wood (4) studied the free radical reaction initiated by the radioactive decay in solid naphthalene-1-*t*. Very recently Hase and Kevan (5) undertook an e.s.r. study of the trapped species produced by tritium β-particles in alkaline and acid ices at 77 °K. They found that the yield of trapped species was always larger in γ-irradiated systems than in the corresponding β-irradiated systems.

In order to study the production of free radicals in the solid state the tritium is most conveniently incorporated into the lattice as water of crystallization as THO. The following decay is expected

$$HTO \rightarrow HHeO^+ + \beta^-$$

$$HHeO^+ \rightarrow HO^+ + He$$

The electron produced will cause some 200 ionizations or excitations in about 10^4 Å due to the high linear energy transfer of the β-particle radiation. The secondary electrons so produced will become thermalized and consequently can be trapped at, for example, a heavy metal ion whose inelastic scattering cross section is expected to be high due to the large number of electrons present on the ion (6).

This first study reports the formation of the Cd(I) center produced by β-particle decay in calcium tetraacetato cadmium(II) hexahydrate. These results are compared with the effects of γ-irradiation, previously described in a preliminary report (7).

Experimental

(i) Sample Preparation

All solid reagents used were AnalaR grade and tritium oxide, having a specific activity of 0.5 Ci g^{-1}, was obtained from the New England Nuclear Corporation. Calcium tetraacetato cadmium(II) hexahydrate was prepared according to the method described by Holden and Singer (8). Single crystals for irradiation by tritium β-particles were grown by slow cooling from a saturated solution in tritiated water. Samples for γ-irradiation were grown by slow evaporation from aqueous solution. Large, colorless crystals were readily obtained by both methods, the majority of which had the characteristic form

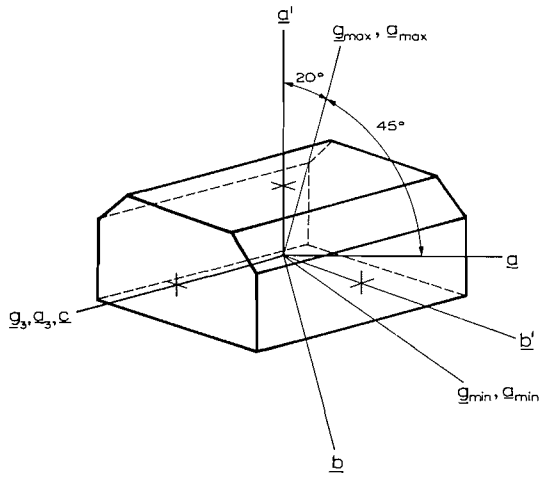

FIG. 1. Crystal morphology and axis systems. (g_{max}, a_{max}, g_{min}, a_{min} are the maximum and minimum values of the Cd(I) g- and hyperfine tensors in the a' b' plane.)

depicted in Fig. 1. Suitable "tritiated" crystals were mounted upon a quartz rod and maintained at 77 °K for approximately 14 days prior to the measurement of electron paramagnetic resonance (e.p.r.) spectra. γ-Irradiations were accomplished using a ^{60}Co γ-source whose effective dose rate was approximately 0.3 Mrads per hour. The crystal was mounted on a "spectrosil"-grade quartz sample holder and immersed in liquid nitrogen in a Dewar vessel designed to fit close to the radiation source. An approximate total dose of 1.2 Mrads was necessary to obtain e.p.r. spectra of sufficient intensity.

(ii) Electron Paramagnetic Resonance Measurements

Electron paramagnetic resonance measurements were made at 77 °K on a conventional X-band spectrometer, operating at approximately 9.3 GHz, incorporating a Varian variable-temperature accessory. This spectrometer and the method of field calibration have been described in detail elsewhere (9). With this assembly the sample temperature could be controlled within ±5° of 77 °K. A metal pointer attached to the exposed end of the quartz sample holder, coupled with a fixed protractor of large radius, enabled accurate orientations of the crystals to be made. Crystal alignments, with respect to the direction of the applied magnetic field, were accurate to within ±2.5°.

Results

(i) Single-Crystal Studies of $CaCd(CH_3COO)_4.6H_2O$ Grown from Water Containing Tritium Oxide

For e.p.r. measurements of a "tritiated" crystal of $CaCd(CH_3COO)_4.6H_2O$ rotations were performed about the well defined elongated c-axis and about orthogonal directions projecting from two well developed faces. The latter directions are labelled a' and b' in Fig. 1.

A typical e.s.r. spectrum was dominated by signals from two paramagnetic species. The less stable radical, which we tentatively identify as the methyl radical, was characterized by an isotropic 1:3:3:1 quartet.

A first derivative spectrum of the second center, measured with the applied magnetic field ($\boldsymbol{H}_0$) in the ac plane at $\theta = 40°$ (where θ is the angle between $\boldsymbol{H}_0$ and the c-axis), is shown in Fig. 2. For all orientations of the crystal resonant fields were disposed over approximately 5000 G. The multiplet spectrum is composed, essentially, of a five line hyperfine pattern with a superimposed doublet site splitting. Also, as is clear from Fig. 2, the free spin features and the resonances at highest field are accompanied by weaker pairs of satellite lines separated by approximately 10.6 G at $\mathbf{g} = 2$ and 17.0 G around $\boldsymbol{H}_0 = 4250$ G. The intensity of these weaker resonances increased, with respect to the associated hyperfine feature, as the incident microwave power was increased. Such behavior is characteristic of features arising from the sympathetic nuclear spin-inversion of neighboring protons (10, 11). Similar interactions were observed in the e.p.r. spectrum of Cu(II) ions doped substitutionally for Cd(II) in this lattice (12). The separation, $\Delta\boldsymbol{H}$ between the satellite lines and the corresponding central resonance has been shown to vary with the applied magnetic field strength. At approximately $\boldsymbol{H}_0 = 1000$ G, $\Delta\boldsymbol{H}$ would be less than 3 G and consequently the satellite features, which necessarily accompany the low field features in Fig. 2, would be hidden within, and contribute to, their excessive linewidths.

This complex spectrum has been interpreted in terms of the paramagnetic Cd(I) cation which has a $^2S_{1/2}$ ground state configuration and is isoelectronic with atomic silver. There are two magnetic isotopes of cadmium in natural abundance (^{111}Cd:I = 1/2, $\mu_n = -0.5912$ N.M.; 12.86% and ^{113}Cd:I = 1/2, $\mu_n = -0.6195$ N.M.; 12.34%). We assign the strong central resonances to the even isotopes of the Cd(I) ion and consider that the weaker features at low and high fields arise from the less abundant magnetic ^{111}Cd and ^{113}Cd isotopes.

A structural analysis of calcium tetraacetato cadmium(II) hexahydrate has recently been completed by Langs and Hare (13) at room temperature. Figure 3 shows the Cd(II) environment

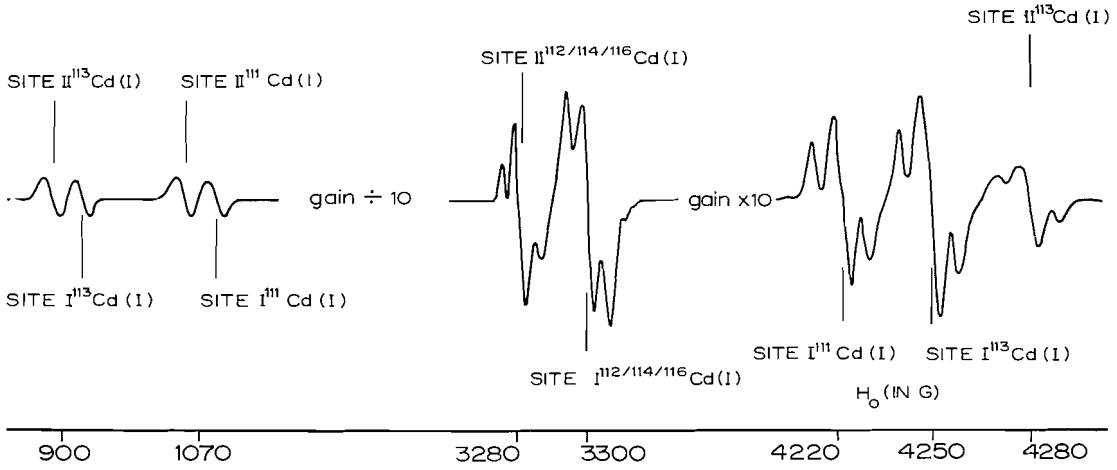

FIG. 2. Electron paramagnetic resonance spectrum of the Cd(I) center in the $a'c$ plane at $\theta = 40°$.

in the undamaged crystal. This crystal belongs to the tetragonal system with four molecules per unit cell at ambient temperature. When the crystal is cooled to 77 °K, however, it undergoes a distinct tetragonal–orthorhombic transition and four sites are now no longer equivalent at all orientations of the magnetic field (14).

When $\boldsymbol{H}_0$ was parallel to the crystal c-axis the multiplet spectrum coalesced completely into a five line pattern. This was not the case when $\boldsymbol{H}_0$ was parallel to a' or b'. We conclude from rotation studies in the plane perpendicular to c that the crystallographic a- and b-axis make angles of 65° to a' and b'. The orientation of the four Cd(I) sites relative to the a, b, and c crystallographic axes shown in Fig. 4. The principal axes of the **g**- and hyperfine tensors are seen to be spatially coincident. The angle θ is small, less than 5°. Consequently, since the hyperfine tensor is almost isotropic and linewidths approaching 5.0 G are common, rotation in the $a'c$- and $b'c$-plane revealed only two magnetically non-equivalent sites, instead of the four expected.

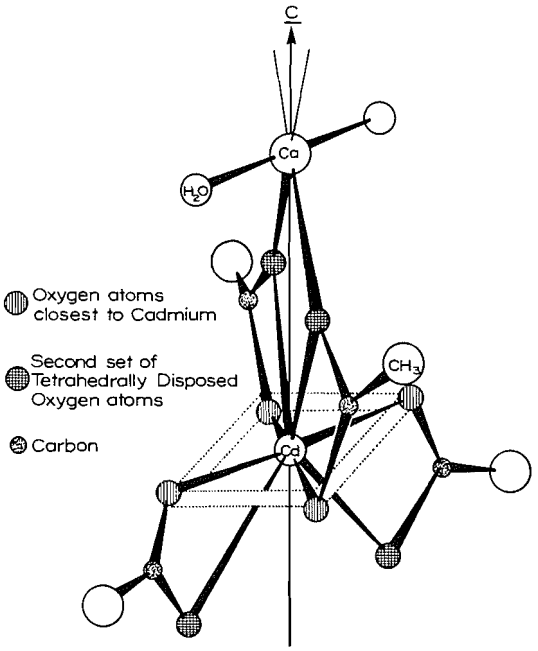

FIG. 3. The molecular structure of the undamaged system.

The angular variation in the $a'c$-plane of the hyperfine features arising from the two distinguishable Cd(I) sites is given in Fig. 5. The solid lines and dotted lines are the computer fit of the experimental data to the spin Hamiltonian.

$$\mathcal{H} = \boldsymbol{H}.\mathbf{g}.\boldsymbol{S} + \boldsymbol{S}.\mathbf{A}.\boldsymbol{I}. - \mathbf{g}_N\beta_N\boldsymbol{H}.\boldsymbol{I}$$

Computations were accomplished using a program written by J. A. Hebden based on the general method of Byfleet *et al.* (15) and the values collated in Table 1 yielded the best fit. The direction arbitrarily labelled x in the Table is parallel to the crystallographic c-axis whilst y and z make angles of 20° to a and b, respectively. It was also found that the Cd(I) centers are divided into two symmetry-related pairs whose principal z and y directions are interchanged. This result, together with the form of the hyperfine tensor, sheds some light on a possible mechanism for the formation of the Cd(I) center.

(ii) Single Crystal Investigations of Samples Exposed to γ-Rays

A typical e.p.r. spectrum revealed the existence of several distinguishable paramagnetic centers. By analogy to the results of Rogers and Kispert (16) for the effect of γ-rays on polycrystalline $Ca(CH_3CO_2)_2.H_2O$ we can offer tentative identifications for the centers arising from radiation damage of the acetate ligands. A strong isotropic quartet centered upon $\mathbf{g} = 2$ almost certainly arises from the methyl radical; a well-characterized product in inorganic acetates possessing a large number of molecules as water of crystallization. A second, weaker asymmetric spectrum underlying the quartet remains unidentified, although the electron-excess $CH_3CO_2^{2-}$ cannot be ruled out. Both centers were temperature sensitive and decayed rapidly when the host crystal was annealed at 120 °K. Their decomposition resulted in the formation of the stable $CH_2CO_2^-$; the product of radiation damage at ambient temperature.

Features from a third paramagnetic species, having a **g**-value lower than that of the free-electron, dominated the spectrum of a crystal which was irradiated at 77 °K, warmed to 120 °K for 5 min, and recooled to 77 °K for the measurement of spectra. All subsequent investigations of this latter center were carried out upon irradiated crystals which had undergone this annealing process prior to study.

The magnetic parameters of this relatively stable species were identical to those of the Cd(I) cation formed by β-electron capture in the "tritiated" crystal. Furthermore, careful orientation studies revealed that the principal axis system of the Cd(I) center produced by γ-irradiation was coincident with that produced by tritium β-irradiation.

Discussion

The Cd(I) center has been observed previously (17–19); Table 1 contains the results of these

*Separate components corresponding to the ^{111}Cd and ^{113}Cd isotopes were not resolved.

observations. The large isotropic hyperfine coupling for Cd is ascribed to the large Fermi contact term of the 5s orbital in which the odd electron is thought to reside. The center observed in an argon lattice has the largest isotropic hyperfine component, the present center having the smallest.

The magnitude of the Fermi contact term depends mainly upon the spin density in the 5s orbital and to a smaller extent the polarization of inner s orbitals on the Cd(I) cation. The spin density in the 5s orbital can be reduced in two ways; firstly if the cation interacts with the lattice substantially the spin density may be distributed to neighboring atoms. Secondly the symmetry of the site in which the cation finds itself may allow the admixture of a cadmium 5p orbital into the odd electron orbital which again will decrease the probability of the odd electron being in the 5s orbital. In addition to these two main effects the polarization contribution to the Fermi contact term will also be reduced by increased covalent participation of the 5s orbital (20).

Thus the Cd(I) center produced in ethanol at 77 °K has a reduced isotropic hyperfine coupling, relative to Cd(I) produced in argon (17), due to solvation by the lattice (18) which causes a decrease in the spin density in the cadmium 5s orbital. In the present case it is expected that the original Cd(II) is covalently bound to the acetate ligands and that the Cd(I) center produced by radiation damage will be similarly bound. Further the center considered here also possesses an anisotropy (-68, $+34$, $+34$ for ^{111}Cd) in its hyperfine tensor which is larger than previously observed. This suggests that the ground state for this ion contains some 5p orbital admixture. Thus the substantially reduced Fermi contact term of the center produced in calcium tetraacetato cadmium(II) hexahydrate can be understood.

With regard to the anisotropy of the Cd(I) hyperfine coupling tensor it will be noticed that the largest component of the anisotropy does not lie parallel to the crystallographic *c*-axis. This indicates that some intramolecular rearrangement has taken place. Some evidence as to the nature of this rearrangement is found in the fact that the radiation induced Cd(I) centers are divided into two symmetry-related pairs whose principal *z* and *y* directions are interchanged.

These observations can be understood if we make the reasonable assumption that the primary process involved in both the γ- and β-irradiation of the acetate is the formation of the electron-excess $CH_3CO_2^{2-}$. The mechanism of radiation-damage in a variety of inorganic acetates has been discussed by Rogers and Kispert (16). At 77 °K, the principal product in hydrated salts was found to be CH_3, a highly reactive intermediate which was rapidly anihilated by a process involving hydrogen abstraction from the lattice. The paramagnetic $CH_2CO_2^-$ was the stabilized product from this reaction. The methyl radical itself was almost certainly formed as a result of the decomposition of the unstable $CH_3CO_2^{2-}$. If the reduction of Cd(II) in calcium tetraacetato cadmium(II) hexahydrate occurred through the reaction of this ion with the decomposition products of the primary center, $CH_3CO_2^{2-}$, the resultant Cd(I) molecular complexes would have the structures displayed in Fig. 6. We would then expect, as we indeed find, two pairs of equivalently oriented complexes in the unit cell related by a plane of reflection. If the remaining nearest oxygen atoms retain their essentially planar configuration, the molecule will have

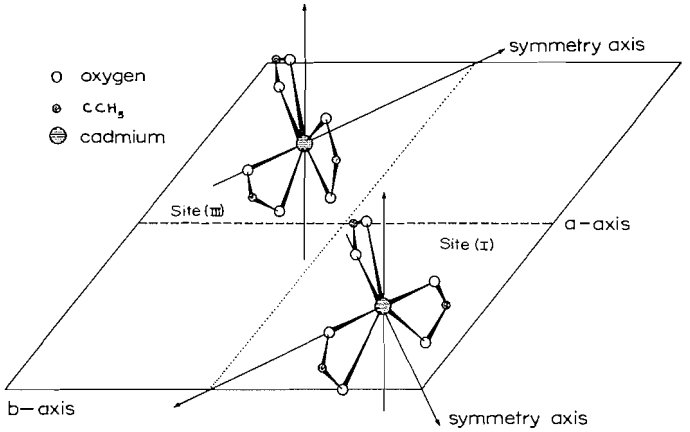

FIG. 6. Disposition of the symmetry axes for two radicals in the unit cell relative to *a* and *b*.

effectively C_{2v} symmetry, the unique axis lying in the plane perpendicular to *c*. This point group allows the $5p_z$ orbital to mix with the 5s orbital and this will lead to the observed anisotropy of the hyperfine tensor.

The authors wish to thank Professor McDowell for his interest in this work. The National Research Council of Canada is thanked for its financial support.

A New Approach to 3′-Amino-3′-deoxynucleosides. Synthesis of 9-(3-Amino-3-deoxy-α-L-ribofuranosyl)adenine[1]

HANS H. BAER AND MONIKA BAYER[2]

Department of Chemistry, University of Ottawa, Ottawa 2, Canada

Received August 28, 1970

Methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranoside (**1**) was acetolyzed to give 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranose (**2**). Compound **2** (or alternatively, 6-deoxy-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose **4**) was converted into 2,3,4-tri-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranosyl bromide (**3**) which was condensed with chloromercuri 6-benzamidopurine. De-*O*-acetylation of the condensation product **5** afforded 6-benzamido-9-(6-deoxy-6-nitro-β-D-glucopyranosyl)purine (**6**) which could be hydrogenated to the corresponding 6′-amino nucleoside **7**. Periodate oxidation of **6** followed by internal Henry cyclization and borohydride reduction gave 6-benzamido-9-(3-deoxy-3-nitro-α-L-ribofuranosyl)purine (**10**) which upon catalytic hydrogenation and subsequent de-*N*-benzoylation produced the title compound, **12**. The sensitivity of certain nitro intermediates towards alkali is commented upon.

Canadian Journal of Chemistry, 49, 568 (1971)

Amino nucleosides command great interest especially because of the biological activity of such natural products as puromycin, 3′-amino-3′-deoxyadenosine, and gougerotin (1–3), and because of the potential usefulness of synthetic analogs in biochemical and medicinal research. Among other methods for the synthesis of 3′-amino-3′-deoxy-hexopyranosyl nucleosides, the cyclization of sugar dialdehydes with nitromethane (4) has been applied (5, 6) with much success, and the related principle of adding nitromethane to oxo sugars (7–9) has been used in the synthesis of nucleosides that contain branched-chain amino sugars (9, 10). In our laboratory was recently accomplished (11) a novel furanoside synthesis which involves the conversion of methyl 6-deoxy-6-nitro-α-D-glucopyranoside into methyl 3-deoxy-3-nitro-β-L-ribo- and -arabinofuranosides and the corresponding amino sugars, and we now report an application of this reaction to a nucleoside. The work opens a new avenue into the hitherto comparatively little-investigated class of ribonucleosides having the L-configuration (12).

As key starting compound, a nucleoside bearing a nitro group at the terminal carbon of the sugar moiety was required. We attempted to prepare 5′-deoxy-5′-nitro-inosine and -uridine from the corresponding 2′,3′-*O*-isopropylidene-6-iodo derivatives (or 6-tosylates) by displacement with sodium nitrite, using a wide variety of solvents and reaction conditions. However, the desired nitro compounds could not be obtained. We therefore resorted to a nucleoside synthesis departing from a nitro sugar and a purine base. It was decided to prepare in this fashion 6-benzamido-9-(6-deoxy-6-nitro-β-D-glucopyranosyl)-purine (**6**) which would then serve as an intermediate for the synthesis of 9-(3-amino-3-deoxy-α-L-ribofuranosyl)purine (**12**) whose β-D isomer (3′-amino-3′-deoxyadenosine) has been reported to possess antitumor activity (13).

Acetolysis of known (11, 14) methyl 2,3,4-tri-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranoside (**1**) afforded 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranose (**2**) in 92% yield. The tetraacetate was then converted into 2,3,4-tri-*O*-acetyl-6-deoxy-6-nitro-α-D-glucopyranosyl bromide (**3**). Although one of the standard procedures for such a bromination, namely the use of hydrogen bromide in glacial acetic acid, was successfully applied (15) to the 3-nitro isomer of **2**, it did not prove satisfactory in this instance.[3] However, the modification of Scheurer and Smith (16) readily gave the desired bromide in 77% yield. Alternatively, the known (17) 6-deoxy-1,2-*O*-isopropylidene-6-nitro-α-D-glucofuranose (**4**) was deacetonated with 80% acetic acid and then brominated by the same method (16), giving **3** in about 50% yield. Analytical, spectral, and optical rotation data of **2** and **3** were in accord with the structures. Employing the general method of Davoll and Lowy (18) we then pro-

[1]Part XVIII in a series on the reactions of nitro sugars. For Part XVII see ref. 15.

[2]Postdoctoral Fellow 1968–1970. Present address: Syntex Institute of Molecular Biology, Palo Alto, California 94309.

[3]Only unchanged **2** could be isolated even after prolonged reaction times.

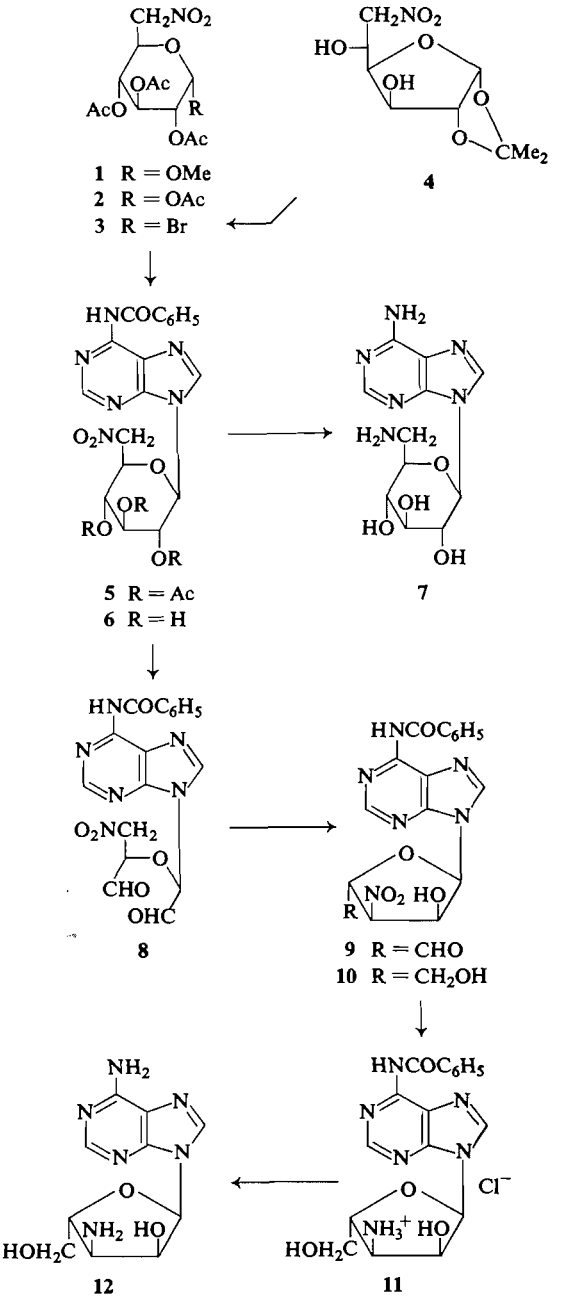
For personal use only.

ceeded to couple **3** with chloromercuri 6-benzamidopurine (19) in refluxing toluene. A 36% yield of crystalline 6-benzamido-9-(2,3,4-tri-*O*-acetyl-6-deoxy-6-nitro-β-D-glucopyranosyl)-purine (**5**) was obtained. The β-D configuration was indicated by its levorotation ($[\alpha]_D$ −26° in $CHCl_3$), and definitely established by a large splitting observed in the n.m.r. signal assignable to H-1′ (doublet at τ 3.92, $J_{1',2}$ = 8.7 Hz, in $CDCl_3$). The t.l.c. of the mother liquor revealed the presence of unreacted **3**, 6-benzamidopurine, an unidentified sugar derivative,[4] and a second nucleoside. The latter possibly was the α-anomer of **5**; however, it could not be isolated.[5]

Next, removal of the acetyl blocking groups in **5** was necessary. Since the nucleosidic bond in this nitro derivative is extremely prone to cleavage in alkaline media as will be outlined further below, we first tried methanolytic deacetylation catalyzed by *p*-toluenesulfonic acid, which had served satisfactorily (11) in the de-*O*-acetylation of **1**. Unfortunately, in the present case, debenzoylation and salt formation at N-6 predominated, and deacetylation was extremely slow, remaining incomplete even after a reaction time of 2 weeks. However, the acetyl groups were selectively removed by cautious treatment of **5** with sodium methoxide in chloroform at −19°, which produced 6-benzamido-9-(6-deoxy-6-nitro-β-D-glucopyranosyl)purine (**6**) in yields of 72–90%. In order to buttress the structure of the product at this stage, a sample was converted by catalytic hydrogenation and subsequent debenzoylation into the known (21) 6′-amino-6′-deoxy-β-D-glucopyranosyladenine (**7**). The potential usefulness of nitro sugar bromides in conjunction with the chloromercuri procedure for the synthesis of amino nucleosides was thereby demonstrated.

Periodate oxidation of the nitro nucleoside **6** was carried out in aqueous suspension and, although proceeding sluggishly, it afforded the dialdehyde **8** in good yield. Without characterization other than by t.l.c., **8** was then cyclized in methanolic solution by the addition of sodium methoxide at −19°, and the 5′-aldo derivative **9** that arose was immediately reduced with sodium borohydride, at low temperature, to give crystalline 6-benzamido-9-(3-deoxy-3-nitro-α-L-ribofuranosyl)purine (**10**) in a yield of 50% (based on **8**). Catalytic hydrogenation in the presence of 1 equiv of hydrochloric acid converted **10** into the corresponding 3′-amino ribonucleoside hydrochloride (**11**) which, although crystalline



[4]Compare the formation of an unsaturated sugar in a similar nucleoside synthesis (19).

[5]Attempted separation of the mother liquor components by column or preparative t.l.c. resulted in extensive decomposition. Equally discouraging were pilot experiments to synthesize the α-anomer by the boron trichloride method recently described by Furukawa *et al.* (20).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and chromatographically homogeneous, was difficult to handle due to considerable hygroscopicity and was, therefore, not analyzed. Treatment of **11** with picric acid removed the *N*-benzoyl group and gave a crystalline dipicrate from which the title compound **12** was liberated, by anion exchange, in a yield of 37% based on **10**. The L-*ribo* configuration was proved by hydrochloric acid hydrolysis producing the known 3-amino-3-deoxy-L-ribose hydrochloride (22, 23). The anomeric center must possess the same absolute configuration as that of the precursor **6** and consequently receives the α designation. In agreement herewith, physical constants found for **12** are different from those expected[6] for the β-L anomer. The reaction sequence **6** → **8** → **9** → **10** is therefore seen to have taken a stereochemical course that was predictable on the basis of our previous work (11). That is to say, an α-L-ribofuranosyl derivative was generated from a β-D-glucopyranosyl derivative, in full harmony with the analogous, earlier synthesis of a β-L-ribofuranoside.[7]

The mother liquor of the nitro ribonucleoside **10** contained a small proportion of a compound that moved slightly faster in t.l.c. and was presumed to be an isomeric nucleoside. Complete separation from remnant **10** could not be effected, but a sample enriched in this by-product was hydrogenated and hydrolyzed with hydrochloric acid for inspection by paper chromatography. The major, ninhydrin-positive spot had the same mobility as an authentic sample of 3-amino-3-deoxy-L-arabinose hydrochloride (25), and a minor spot corresponded to the L-*ribo* isomer. Assignment of the α-L-arabinofuranosyl structure to the by-product must remain tentative but would be in line with previous results (11).

The nitro nucleosides **5**, **6**, and **10**, as well as the intermediates **8** and **9**, possess an acetal linkage activated by a nitro group in β-position, and such linkages are known to be prone to eliminative cleavage by alkali (4). For example, the primary nitro compound **5** suffered complete loss of the aglycon in a 1:1 mixture of acetone and 0.1 *M* sodium bicarbonate within 5 min at room temperature, and **6** was cleaved to about 50% after 35 min. The secondary nitro compound **10** was stable under these conditions but was cleaved to about 50% by *N* alcoholic potassium hydroxide within 50 min at room temperature. It was largely cleaved by 0.1 *N* aqueous sodium hydroxide within a few minutes at 98°. Further examples are given in the Experimental. It is obvious that, with compounds of this type, synthetic work in which alkaline reagents are indispensable must be conducted under most carefully controlled conditions.

[6]Compare the data published for the β-D enantiomer (24*a*, *b*). The α-D antipode of **12** has been encountered (24*a*), but no physical constants were given.

[7]These configurational inversions result from the interchange of positions, relative to each other in the sugar chain, that is incurred by C-4 and -6 of the pyranose structure when these carbon atoms become C-5 and -3, respectively, in the furanose structure. No chemical epimerization takes place at the configurationally determinant carbon atom, at least not as far as the products isolated under the reaction conditions are concerned (11).

Experimental

General Techniques

Melting points were determined in capillaries in an electric aluminum block apparatus equipped with a calibrated thermometer. Optical rotations were measured at about 25° in a Perkin–Elmer 141 automatic polarimeter. The i.r. spectra were obtained from Nujol mulls on Beckman IR-8 or IR-20 instruments, and significant bands only are reported as ν_{max} values. The u.v. data reported were obtained with a Jasco ORD/UV-5 spectrophotometer, whereas a Perkin–Elmer 202 instrument was used for routine monitoring. The n.m.r. spectra (100 MHz) were recorded on a Varian HA-100 spectrometer. The t.l.c. was performed on silica gel HT-254 according to Stahl, with the following solvent systems (v/v): *a*, chloroform–ether (2:1); *b*, chloroform–methanol (9:1); *c*, chloroform–methanol (4:1); *d*, 2-propanol – water (7:3); *e*, ethyl acetate – methanol (9:1). The t.l.c. plates were viewed under u.v. light and (or) sprayed with ceric sulfate – sulfuric acid and heated. For paper chromatography, the following systems were used: *f*, 1-propanol – water (8.5:1.5); *g*, ethyl acetate – pyridine – water – acetic acid (5:5:3:1); *h*, 1-butanol – ethanol – water (10:5:7). The spots were indicated by ammoniacal silver nitrate or ninhydrin.

1,2,3,4-Tetra-O-acetyl-6-deoxy-6-nitro-α-D-glucopyranose (2)

The nitro glucoside triacetate **1** (11) (26 g) was dissolved in a mixture of acetic acid (260 ml) and acetic anhydride (260 ml), and the solution was cooled to 0°. Concentrated sulfuric acid (26 ml) was added dropwise and with stirring which was maintained for 2 h at 0° and 5 days at room temperature, during which time some of the product crystallized. The reaction mixture was poured into ice–water (2.5 l) and the solid was collected and washed successively with water, ethanol, and ether. The dried product (23.5 g, 92%) consisted of white needles, m.p. 241°, which gave a single spot on t.l.c. (system *a*) and could be used without further purification. Samples were recrystallized from ethanol–chloroform, acetone, acetic acid, or dioxane: m.p. to 245°; $[\alpha]_D$ +99.3° (*c*, 0.5 in dimethylformamide); ν_{max} 1740 (acetyl C=O), 1545 (NO_2), 1230 with shoulder at 1260 cm^{-1} (acetyl C—O); n.m.r. data ($CDCl_3$), τ 3.70 (doublet, H-1, with $J_{1,2}$ = 4

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Hz), 7.79 (singlet, axial acetyl), 7.93, 7.97, 7.98 (singlets, 3 equatorial acetyls); in DMSO-d_6, τ 3.89 (doublet, H-1, with $J_{1,2}$ = 4 Hz), 7.82 (singlet, axial acetyl), 8.00–8.02 (singlets, 3 equatorial acetyls).

Anal. Calcd. for $C_{14}H_{19}NO_{11}$ (377.3): C, 44.56; H, 5.08; N, 3.71. Found: C, 44.72; H, 5.20; H, 3.84.

2,3,4-Tri-O-acetyl-6-deoxy-6-nitro-α-D-glucopyranosyl Bromide (3)

(a) From 2

Bromine (48 ml) was added dropwise to a chilled suspension of red phosphorus (24 g) in glacial acetic acid (240 ml). When all the bromine had reacted, the mixture was filtered through glass wool and the filtrate was stored at 0° if it was not to be used immediately. The tetraacetate **2** (22 g) was introduced, and the mixture was stirred for 2 h at 60–70° (bath temperature) and then kept at room temperature overnight. The crystalline product **3** (16 g) was collected on a fritted funnel and washed thoroughly with ether. Additional **3** (2 g) was obtained from the mother liquor by aeration with nitrogen under diminished pressure; total yield, 77%. The product, which is only sparingly soluble in most common solvents except dimethylformamide (DMF) and dimethyl sulfoxide (DMSO), was recrystallized by dissolution in a large volume of boiling acetone and concentration of the solution at reduced pressure. It forms white needles that decompose at 212–215° and show $[\alpha]_D$ +148° (*c*, 1.6 in DMF). The mobility in t.l.c. (system *a*) is slightly greater that that of **2**. The i.r. data, ν_{max} 1740 (C=O), 1555 (NO_2), and 1220 with shoulder at 1250 cm^{-1} (C—O); n.m.r. data ($CDCl_3$), τ 3.48 (doublet, H-1, with $J_{1,2}$ = 4 Hz), 7.90, 7.92, 7.97 (singlets, 3 equatorial acetyls); in DMSO-d_6 the corresponding signals were at τ 3.17, 7.96, 7.99, and 8.01.

Anal. Calcd. for $C_{12}H_{16}NO_9Br$ (398.2): C, 36.19; H, 4.05; Br, 20.07. Found: C, 36.19; H, 3.96; Br, 19.97.

(b) From 4

The monoisopropylidene derivative **4** (14.3 g) (17) was hydrolyzed in 80% acetic acid (300 ml) for 6 h at 100–105°, with the progress of deacetonation being monitored by t.l.c. (system *d*). Evaporation followed by one co-evaporation with toluene gave a syrup which was treated with the brominating reagent (300 ml) as described in section (*a*). The product (11.5 g, 50%) was identical with **3** in every respect.

6-Benzamido-9-(2,3,4-tri-O-acetyl-6-deoxy-6-nitro-β-D-glucopyranosyl)purine (5)

A suspension of chloromercuri 6-benzamidopurine (6 g) (19) and Celite (8.5 g) in toluene (500 ml) was dried azeotropically by distilling off about 150 ml of the solvent. The bromide **3** (5 g) in dry toluene (100 ml) was added at about 70° and the bath temperature was then raised slowly to 130–135°. Reflux and vigorous stirring were maintained for 3 h. The reaction mixture was then filtered and the filtrate evaporated to dryness. The residue as well as the filter cake were extracted by stirring each with 150 ml of chloroform for 30 min. The filtered and combined extracts were washed successively with 30% aqueous potassium iodide solution (2 × 50 ml), and water (3 × 50 ml), dried over magnesium sulfate, and evaporated to give a partly oily residue (*ca.* 6 g). The material crystallized from 99% ethanol (60 ml) upon scratching of the flask. Recrystallization from ethanol furnished **5** (2.5 g, 36%) as colorless needles, m.p. 203° (dec.); $[\alpha]_D$ −26° (*c*, 1.4 in chloroform); homogeneous in t.l.c. (system *b*); ν_{max} 3650 (NH), 1755 (acetyl C=O), 1700 (*N*-benzoyl C=O), 1615, 1585 (purine C=N and C=C), 1555 (NO_2), 1255–1215 cm^{-1} (C—O); λ_{max} 277 nm (ε 20 900) and λ_{min} 242 nm (in methanol). The n.m.r. data ($CDCl_3$), τ 1.17, 1.78 (singlets, H-2 and -8), 1.94 and 2.40 (2- and 3-proton multiplets of benzoyl), 3.92 (doublet, H-1′, with $J_{1',2'}$ = 8.7 Hz), 4.24, 4.43, 4.74 (three triplets with spacings of 9–10 Hz assigned to H-2′, -3′, and -4′, but not necessarily in that order), 5.4 region (overlapping signals of H-5′, -6*a*′, -6*e*′), 7.89, 7.96, 8.24 (singlets, 3 acetyls). The high value τ 8.24 is noteworthy; it presumably represents the C-2′ acetoxy group which is strongly shielded by the purine ring.

Anal. Calcd. for $C_{24}H_{24}N_6O_{10}$ (556.5): C, 51.80; H, 4.35; N, 15.10. Found: C, 51.62; H, 4.46; N, 14.95.

In the above condensation, deviations from the 3-h reaction time on either side, or use of xylene as the solvent, were found to decrease the yield. Even though substantial quantities of unreacted **3** remained after 3 h, employment of a large excess of the purine component was of little effect, and yields generally ranged from 15–30%. Equimolar proportions of **3** and the chloromercuri derivative in DMF solution reacted at room temperature (4 days), but the isolation of **5** was difficult (yield, <20%).

Column chromatography of the mother liquor of **5** on silica gel or acid-washed alumina (Brockmann, activity grade 1) with chloroform and chloroform containing 5–10% of methanol resulted in extensive decomposition of the nucleoside components to give yellow substances that could not be eluted.

6-Benzamido-9-(6-deoxy-6-nitro-β-D-glucopyranosyl)-purine (6)

High-purity anhydrous solvents stored over molecular sieves were used, and moisture was excluded during the reaction. To a magnetically stirred solution of the acetate **5** (3.6 g) in chloroform (18 ml), which was kept at −19°, was added dropwise from a syringe a solution of sodium (360 mg) in methanol (18 ml). Stirring at −19° was continued for 1 h after which time the mixture was stirred for 5–10 min with added water (18 ml) and then acidified to p*H* 4–5 with methanolic hydrochloric acid under continued cooling. Removal of most of the organic solvents *in vacuo* (bath temperature 35°) caused sudden crystallization of white needles from the concentrated, largely aqueous solution. The product was collected at once, washed with water, and air-dried. Recrystallization from methanol gave **6** (2.0 g, 72%) showing a single spot in t.l.c. (system *c*) and decomposing at 194° (with gradual darkening above 175°). Yields up to 90% were obtained in smaller-scale runs. The compound exhibited $[\alpha]_D$ +4° (*c*, 1.2 in DMF), λ_{max} 278 nm (ε 21 800) and λ_{min} 242 nm (in methanol), ν_{max} 3600–3100 (broad, NH, OH), 1690 (*N*-benzoyl C=O), 1610, 1585 (C=C, C=N), 1550 cm^{-1} (NO_2).

Anal. Calcd. for $C_{18}H_{18}N_6O_7$ (430.4): C, 50.24; H, 4.22; N, 19.53. Found: C, 50.04; H, 4.12; N, 19.24.

9-(6-Amino-6-deoxy-β-D-glucopyranosyl)adenine (7)

A solution of the nitro nucleoside **6** (100 mg) in 95%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

ethanol (15 ml) was hydrogenated using 10% palladium-on-charcoal (200 mg) at ordinary temperature and pressure (3 days). Paper chromatography (system *h*) then revealed a single ninhydrin-positive spot, R_f about 0.6. The filtered solution was concentrated to a small volume (*ca.* 1 ml), a solution of picric acid (140 mg) in ethanol (3 ml) and water (1 ml) was added, and the mixture was refluxed on a steam bath for 1 h. The crystalline picrate that separated on cooling was recrystallized once from water; decomposition point 217° (with sintering at 160–170°); lit. (21), dec. 215° with sintering from 168°. It was dissolved in a sufficiently large amount of water, and the solution was stirred with Dowex 1-X2 (carbonate form) until it was colorless. The ion exchange resin was filtered off and washed well with water. Evaporation of the combined filtrate and washing water gave a residue which by trituration with ethanol yielded **7** as a white powder that showed a single spot ($R_{adenine}$ 0.36) in paper chromatography (system *h*), decomposed at 210°, and exhibited λ_{max} 259 nm (in water), in agreement with the reported data (21).

*6-Benzamido-9-(3-deoxy-3-nitro-α-L-ribofuranosyl)-purine (**10**)*

A suspension of finely powdered nitro nucleoside **6** (1.5 g) in a solution of sodium metaperiodate (3 g) in water (60 ml) was stirred in the dark for 3 days. The t.l.c. of the reaction mixture (system *c*) indicated the conversion, in heterogeneous phase, of **6** into fast-moving dialdehyde **8** which was the only major reaction product that exhibited u.v. absorption. The product was collected by filtration, washed thoroughly with water, dried in a vacuum desiccator over P_2O_5, and stored below 0°. The yield was 1.0 g (72%).

A solution of **8** (500 mg) in absolute methanol (25 ml) was cooled to −19° in an ice–salt bath, and a chilled, 0.1 *N* sodium methoxide solution (15 ml) was added dropwise with magnetic stirring. The mixture was kept at −19° for 1 h after which time almost complete conversion of **8** into a slightly slower-migrating product **9** was indicated by t.l.c. (system *b*). With continued cooling, sodium borohydride (200 mg) suspended in chilled ethanol (10 ml) was added immediately, and the mixture was then allowed to stand at −15° for 24 h. Although the 5′-aldo nucleoside **9** and its reduction product **10** had identical R_f values in several t.l.c. and paper chromatographic systems tested, the course of the reduction could be conveniently monitored on short paper strips (ascending technique in system *f*), unreacted **9** being detectable by spraying with Tollens reagent. The reaction mixture was then acidified with acetic acid – methanol (1:1) and evaporated to dryness. Three portions of methanol were successively evaporated from the oily residue which was then triturated twice with small amounts of cold water to remove sodium acetate. The remaining, water-insoluble gum was dissolved in ethanol or methanol from which colorless crystals of **10** were deposited overnight at −15°. Recrystallization from methanol yielded **10** (250 mg, 50% based on **8**); m.p. 172°; $[\alpha]_D$ −61° (*c*, 1 in DMF); λ_{max} 277 nm (ε 20 300) and λ_{min} 245 nm (in methanol); ν_{max} 3600–3100 (broad, NH, OH), 1690 (*N*-benzoyl C=O), 1610, 1580 (C=N, C=C), and 1550 cm^{-1} (NO_2).

Anal. Calcd. for $C_{17}H_{16}N_6O_6$ (400.4): C, 51.00; H, 4.03; N, 20.99. Found: C, 50.90; H, 4.03; N, 20.98.

The mother liquor from which **10** had crystallized was shown by t.l.c. (system *e*) to contain, besides a large amount of additional **10**, a minor component of slightly greater mobility. Preparative t.l.c. (system *e*) provided a material in which this by-product was enriched but which contained some **10** (see Discussion).

*6-Benzamido-9-(3-amino-3-deoxy-α-L-ribofuranosyl)-purine Hydrochloride (**11**)*

Platinum dioxide catalyst (150 mg) was prehydrogenated in 36 ml of 0.01 *N* hydrochloric acid. The solid nitro nucleoside **10** (150 mg) was added, and it went slowly into solution as its hydrogenation proceeded. About 3 h of vigorous shaking under hydrogen at ordinary temperature and pressure was needed. The filtered solution was then concentrated to a volume of about 5 ml. A small sample was withdrawn and evaporated to dryness with several additions of absolute ethanol. Trituration of the residue with ethyl acetate gave hygroscopic needles of the hydrochloride **11** which decomposed above 160° and showed a single spot in paper chromatography (system *g*, ninhydrin spray).

*9-(3-Amino-3-deoxy-α-L-ribofuranosyl)adenine (**12**)*

The major part of the concentrated aqueous solution from the hydrogenation just described (estimated to contain about 130 mg of **11**) was mixed with a solution of picric acid (74 mg) in ethanol (2 ml). The mixture was refluxed on a steam bath for 1 h, and for another 30 min following the addition of a second, identical portion of alcoholic picric acid. The debenzoylation could be monitored by paper chromatography (system *g*). On cooling of the reaction mixture, the picrate of **12** (m.p. 185°) crystallized in part but was redissolved by dilution with ethanol. The solution was stirred with 20 ml of Dowex 1-X2 (OH^-), 50–100 mesh, and then applied to a column (2 × 15 cm) of the same ion exchange resin. The column was eluted with water, 15-ml fractions being collected and checked for u.v. absorption at 257 nm which appeared in fractions 17–65. These fractions were pooled and evaporated to dryness, with several portions of ethanol finally being evaporated from the residue which was then dried in a high vacuum. Compound **12** was thus obtained as a white powder (32 mg, 37% based on **10**), m.p. 162° with sintering from 150°, $[\alpha]_D$ +18° (*c*, 0.4 in water), λ_{max} 257 nm (ε 13 600) and λ_{min} 225 nm (in 0.1 *N* HCl). It appeared homogeneous in paper chromatography (system *g*) and t.l.c. (system *d*).

Anal. Calcd. for $C_{10}H_{14}N_6O_3$ (266.3): C, 45.11; H, 5.30; N, 31.57. Found: C, 44.88; H, 5.17; N, 31.32.

A sample of **12** (5.00 mg) was hydrolyzed in 3 *N* hydrochloric acid (1.00 ml) for 2 h at 98°. The hydrolysate had a rotation of α_D +0.067° (1 dm tube, 25 °C), corresponding to a specific rotation of $[\alpha]_D$ +19° calculated for the aminodeoxypentose hydrochloride produced. Reported for 3-amino-3-deoxy-L-ribose hydrochloride: +18.9° (11), +23° (23). The hydrolysate was evaporated with several additions of water, and paper chromatography (system *g*) of the residue indicated complete cleavage of **12** into adenine and a single amino sugar whose spot was indistinguishable from that of an authentic sample of 3-amino-3-deoxy-L-ribose hydrochloride.

Alkaline Degradations

The behavior of the nitro compounds **5**, **6**, **8**, **9**, and **10** in alkaline media was examined by t.l.c. Samples taken at intervals were acidified with dilute acetic acid before application. The chromatograms were viewed under u.v. light and spot intensities were estimated visually, with 6-benzamidopurine and adenine used as controls. The aglycons were readily distinguished from the nucleosides not only by the mobilities but also by spraying the plates with ceric sulfate – sulfuric acid followed by heating, dark spots being produced from carbohydrate-containing substances only.

(*a*) To compound **5** (2 mg) in acetone (0.4 ml) was added aqueous, 0.1 *M* sodium bicarbonate buffer (0.4 ml, p*H* 8.4). After 5 min at room temperature, 6-benzamidopurine was the only spot visible in the u.v., indicating complete cleavage of the nucleoside (system *b*).

(*b*) A similar experiment with compound **6** revealed 50% cleavage in 35 min (system *c*).

(*c*) A solution of the dialdehyde **8** (100 mg) in methanol (5 ml) was adjusted to p*H* 7.5 with alcoholic potassium hydroxide, at room temperature, and 50% cleavage was observed after 30 min (system *e*).

(*d*) To an ice-cooled solution of **8** (100 mg) in methanol (5 ml) was added 3 ml (1.2 equiv) of a 0.1 *N* sodium methoxide solution. After 1 h at 0°, about 30% of the aglycon was liberated (system *e*).

(*e*) When the sodium borohydride reduction of intermediate **9** (for the preparation of **10** as described above) was carried out at room temperature rather than at −19 to −15°, the *N*-glycosidic bond was cleaved to the extent of 30–50% depending on the amount of $NaBH_4$ employed (system *e*).

(*f*) A few milligrams of compound **10** were tested in 1 ml of each of the following media: *i*, 0.1 *M* sodium bicarbonate – acetone (1:1) at 25°; *ii*, 0.01 *N* sodium hydroxide – acetone (1:1) at 25°; *iii*, *N* potassium hydroxide, ethanolic, at 25°; *iv*, 0.1 *N* sodium hydroxide, aqueous, at 98°. Compound **10** appeared to be stable overnight in *i* and *ii*, but was 50% cleaved within 50 min in *iii* and still more extensively within 3 min in *iv* (system *e*).

Attempted Displacements with Nitrite

5′-Deoxy-5′-iodo-2′,3′-*O*-isopropylideneinosine (26) was treated with sodium nitrite (1–3 equiv) according to the general procedure of Kornblum (27). Solvents tried were DMF, DMSO, mixtures of the same, and hexamethylphosphoric triamide. Reaction times and temperatures ranged from 2–4 days and 5 to 25° respectively. Trials were made with and without addition of phloroglucinol or urea. The t.l.c. (system *b*) revealed the formation of several reaction products, but the desired 5′-nitro derivative could not be isolated.

Support of this work by the Life Insurance Medical Research Fund, Rosemont, Pennsylvania, and in part by the National Research Council of Canada is gratefully acknowledged.

Received August 11, 1969[3]

Reaction of 1,5-dicarbomethoxy-2,4-dimethyl-3-oxaquadricyclane with water gave a mixture of *cis,cis, cis*- and *cis,cis,trans*-1,2-diacetyl-3,4-dicarbomethoxycyclobutanes. The latter on treatment with acid epimerized to the corresponding *trans,trans,trans*-isomer, whereas the former yielded the *trans,trans,cis*-epimer together with 3,10-dimethyl-3,10-epoxy-5,8-dioxo-4,9-dioxatricyclo[5.3.0.$0^{2,6}$]decane which contains a new bridged ring system. The structure and stereochemistry of each compound was derived from symmetry considerations as reflected in its p.m.r. spectrum, and was facilitated by selective deuteration experiments. Vicinal and long-range spin–spin interactions between the cyclobutane ring hydrogens were deduced from pertinent p.m.r. sub-spectra using the NMRIT–NMREN computer program.

Canadian Journal of Chemistry, **49**, 574 (1971)

Classical methods of synthesis of cyclobutanes (1) have been largely superseded in recent years by the introduction of generally applicable photocycloaddition procedures (2), such as the photosensitized dimerization of olefins (3) or enones (4) or the photoaddition of enones to olefins (5). In this communication we show that in suitable cases (see section on generality) a cyclobutane ring may be formed by hydrolyzing a 3-oxaquadricyclane derivative of type **2**. This approach to the synthesis of substituted cyclobutanes is of more limited scope than the more general photochemical methods discussed above.

The Diels–Alder adduct **1** may be converted photochemically in very high yield to the known 3-oxaquadricyclane **2** (6). The latter reacts readily with water in acetone, methanol, or tetrahydrofuran, to give a mixture of isomers **3** and **4** (approximate ratio 1:2) in *ca.* 90% yield. Since **3** and **4** were recovered unchanged when heated in these aqueous solvents it follows that the reaction product from **2** was not an equilibrium mixture, and that the two isomeric products must have been formed by competitive reactions. Both **3** and **4** are isomerized if treated with sulfuric acid in CH_2Cl_2 at room temperature, **3** being converted to **6** (and **9**) and **4** to **7**.

Compounds **3**, **4**, **6**, and **7** each had a molecular formula of $C_{12}H_{16}O_6$ (mass spectra), and their p.m.r. spectra (Table 1) contained resonances indicating the presence of four cyclobutane ring hydrogens (7) as well as two acetyl and two carbomethoxy groups. Positive iodoform tests for acetyl, carbonyl absorptions in the i.r. for ester (1737–1743 cm^{-1}) and ketone (1710–1719 cm^{-1}) functions, as well as characteristic losses of 15 (CH_3), 31 (CH_3O), 42 ($CH_2{=}C{=}O$), and 43 (CH_3CO) mass units from the parent ions in the mass spectra further confirmed the presence of the two types of functional groups. From these data it could be deduced that these compounds contained a cyclobutane ring substituted with two acetyl and two carbomethoxy groups.

If D_2O was substituted for H_2O in the original reaction, **2** was converted to a mixture of **3**-d_2 and **4**-d_2. The molecular formula, $C_{12}H_{14}D_2O_6$, for each pure compound was confirmed by mass spectral analysis, and their i.r. spectra only differed from those of the corresponding undeuterated compounds in the regions associated with C—H or C—D vibrations. The only difference in the p.m.r. spectra (Table 1) of **3** and **3**-d_2 was the replacement of an AA'BB' multiplet for the cyclobutane ring hydrogens in the former by a singlet for two chemically equivalent ring hydrogens, $J = 9.3$ Hz (derived from the ^{13}C—H satellites), in the latter. Similarly, only the ABMX multiplet for the ring hydrogens in **4** was replaced by an AM quartet, $J = 9.0$ Hz, in **4**-d_2. Spin-decoupling experiments further established that each of the two ring hydrogens in **3**-d_2 and **4**-d_2 was coupled ($J \approx 0.3$ Hz) to the methyl hydrogens of an acetyl group; in **3**-d_2 the acetyl groups were chemically equivalent whereas in **4**-d_2 they

*The spectra of 3, 4, 6 and their deuterated analogues were recorded in benzene-d_6 at a concentration of 10 mg/0.35 ml. The spectra of 7 and its analogues were recorded in acetone-d_6, also at 10 mg/0.35 ml. The spectra of 9 and 9-d_2 were measured in trifluoroacetic acid using 25 mg/0.35 ml.

†The chemical shifts reported in this column refer to the centroid of the AA′BB′ (3, 7, 9), AM (4-d_2), H-2 (6), or H-4 ( ) multiplet. In the case of the ABC (6-d_1) or ABB′ (7-d_1) systems the range of the multiplet is given.

‡For computer purposes the chemical shift of the lowest-field proton (or protons when chemically equivalent) was empirically given a value of 0.0 Hz and all others were measured relative to it.

§Values for $J_{1,2}$ were obtained either directly from the AM or AX spectra of 4-d_2 and 6-d_2, or from the ^{13}C—H satellite spectra in the case of 3-d_2, 7-d_2, and 9-d_2.

‖In 3-d_2 long-range coupling (J < 0.3 Hz) was observed between H-1 and -2 and the acetyl methyl protons. Similar coupling was observed in 4-d_2 between H-1 ($J \simeq 0.1$ Hz) and the protons of one acetyl methyl (8.25 τ) and between H-2 ($J \simeq 0.3$ Hz) and those of the second acetyl methyl group (7.99 τ).

¶br. s = broad singlet.

**The acetyl methyl protons underwent deuterium exchange in the presence of D_2SO_4 (conditions of preparation).

were not. The above evidence requires that the two ring hydrogens in **3**-d_2 and **4**-d_2 be vicinal and that each of them is geminal to an acetyl group. Since no epimerization had occurred at the carbons bearing these hydrogens and acetyl groups during the conversion from **2** it follows that the acetyl groups (and therefore hydrogens) must have a *cis*-relationship. Each of the two deuterium atoms in **3**-d_2 and **4**-d_2, or the corresponding hydrogens in **3** and **4**, must therefore be geminal to a carbomethoxy group since there is no acceptable mechanism by which they could both be present on the same carbon atom. In any case **3**, in addition to the structural features discussed above, must possess at least C_2 symmetry (AA′BB′ system for the ring hydrogens and two chemically equivalent acetyl and carbomethoxy groups) clearly invalidating such a possibility, and analyses of the 4-spin systems in **3** and **4** (Table 1) established the presence of four vicinal but no geminal spin–spin coupling constants. Consequently, **3** and **4**, and therefore **6** and **7**, must be isomeric 1,2-diacetyl-3,4-dicarbomethoxycyclobutanes.

Structure of 4

The six possible stereoisomeric 1,2-diacetyl-3,4-dicarbomethoxycyclobutanes are depicted in Scheme 1. Of these only **3**, **4**, and **5** have the acetyl substituents in a *cis*-relationship; *a necessary requirement in the two reaction products* (**3** and **4**) *formed from* **2** (see above). Because of rapid interconversion between two equivalent conformations both **3** and **5** would behave as if they possessed at least C_2 symmetry and the ring hydrogens would be expected to give an AA′BB′ (or AA′XX′) multiplet in their p.m.r. spectra. Structure **4**, on the other hand, has no element of symmetry and all of the ring hydrogens would therefore be expected to be chemically nonequivalent. Since **4** contained an ABMX multiplet for the ring hydrogens in its p.m.r. spectrum as well as signals for pairs of chemically nonequivalent acetyl and carbomethoxy groups (Table 1), it follows that this compound must possess structure **4** with the substituents in a *cis,cis,trans*-orientation. Furthermore, the other reaction product must possess structure **3** or **5**.

Structures of 3 and 9

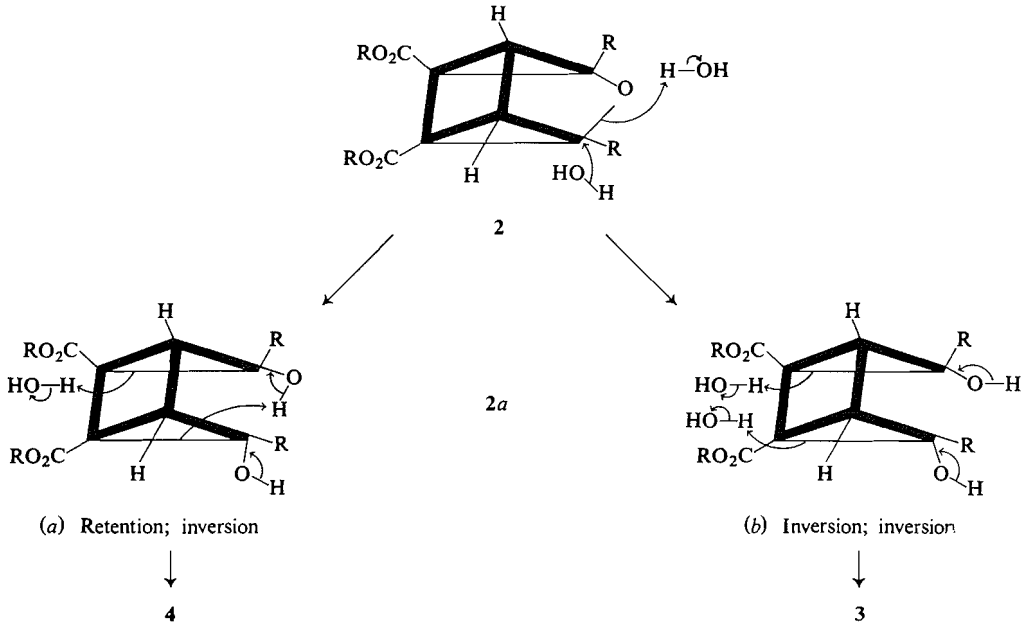
Both H_2SO_4 and D_2SO_4 converted **3** to **9**, or **3**-d_2 to **9**-d_2 (Scheme 1). The other products of reaction, **6** and **6**-d_1, or **6**-d_2 and **6**-d_3, are not pertinent to the discussion at this stage. From the above observations it was clear that **9** was formed from **3** *without epimerization* having occurred at any center in the latter.

Compound **9** had a molecular formula of $C_{10}H_{10}O_5$ (mass spectrum), and its i.r. spectrum contained no carbonyl absorptions for the two types of functional groups present in **3** but instead *contained a single band at 1790 cm^{-1} characteristic of a γ-lactone grouping*. Its p.m.r. spectrum (Table 1), moreover, contained no resonances for carbomethoxy methyl groups but did have a singlet for two chemically equivalent methyl groups whose chemical shift was consistent with their being attached to carbon atoms bearing two oxygen substituents. The molecular formula of **9** and the chemical shifts of the four remaining hydrogens required that the latter be attached to a cyclobutane ring. These hydrogens in addition appeared as a characteristic AA′BB′ multiplet in the p.m.r. spectrum establishing that **9** possessed at least C_2 symmetry. The molecular formula of **9**-d_2 as well as its i.r. and p.m.r. spectra only differed in a predictable fashion from those of **9** although from the latter it was possible to assign the hydrogens β to the lactone carbonyl group. The collective evidence is thus only compatible with **9** being 3,10-dimethyl-3,10-epoxy-5,8-dioxo-4,9-dioxatricyclo[5.3.0.0^{2,6}]decane, *i.e.* structure **9** in Scheme 1.

In **9** the substituents are *cis* to one another and it is formed from **3** without epimerization. Consequently, the latter must possess structure **3** of Scheme 1, in which the substituents have a *cis,cis,cis*-orientation, and not the alternative structure **5**, which has the substituents in a *cis,trans,cis*-relationship.

Structure of 6

Conversion of **3** to **6**, and **3**-d_2 to **6**-d_2, with H_2SO_4 and of **3** to **6**-d_1, and **3**-d_2 to **6**-d_3, with D_2SO_4 (Scheme 1; Table 1) established that the transformations were accompanied by epimerization only at C-1 or -2 of **3** or **3**-d_2. Consequently, the acetyl substituents in **6** must be *trans* since they were *cis* in **3**. Moreover, the product formed by epimerization at C-1 (equatorial acetyl) of **3** is simply the enantiomer of that produced by a corresponding change at C-2 (axial acetyl). In other words epimerization at either center in **3** leads to the same product (**6**) in which the substituents are in a *trans,trans,cis*-relationship. The



SCHEME 2

four ring hydrogens in **6** should therefore be chemically non-equivalent and it was observed experimentally that they appeared as an ABCX system (Table 1) in the p.m.r. spectrum of this compound. Furthermore, epimerization could only have occurred at the carbon atom in **3** bearing the axial acetyl substituent, otherwise it would be difficult to explain why further deuterium exchange did not occur in **6**-d_1 and **6**-d_3 which both contain two equatorial acetyl substituents. It should be borne in mind that **3** can exist in two equivalent conformations and that the substituents which are equatorial in one conformation are axial in the other. This of course results in **6** being produced as a racemic mixture. Previous work has shown that the cyclobutane ring is puckered and that substituents do in fact occupy positions analogous to the axial and equatorial positions of cyclohexane (8) and will prefer an equatorial orientation where possible.

Structure of 7

As in the above case the formation of **7** from **4**, and **7**-d_2 from **4**-d_2, with H_2SO_4, as well as of **7**-d_1 from **4**, and **7**-d_3 from **4**-d_2 with D_2SO_4 (Scheme 1; Table 1) established that epimerization had occurred at C-1 or -2 of **4**, or **4**-d_2, and that the acetyl groups in **7** must be *trans* to one another. Structure **5** (Scheme 1) is therefore eliminated as a possibility since in this compound the acetyl groups are *cis*. Furthermore, if **8** was produced from **4** we would anticipate further deuterium incorporation at the carbon atoms bearing acetyl substituents since one of the two possible conformations in which **8** could exist would have both acetyl groups in an axial orientation. The above evidence therefore requires that epimerization occur at C-2 of **4** to produce **7** in which the substituents are in a *trans,trans*, *trans*-relationship. The m.p. and i.r. spectrum of the latter were also identical to those reported for *trans,trans,trans*-1,2-diacetyl-3,4-dicarbomethoxycyclobutane (9) thereby confirming our structural assignment. As **7** contains a C_2 axis of symmetry its p.m.r. spectrum showed resonances for pairs of chemically equivalent acetyl and carbomethoxy methyl groups as well as an AA'BB' multiplet for the ring hydrogens as expected.

Mechanism of Formation of 3 and 4

Any mechanism must explain (*i*) the formation of isomers possessing two *cis* acetyl groups, (*ii*) the incorporation of two D atoms at the ester-bearing carbon atoms when D_2O is used, and (*iii*) the absence of the *cis,trans,cis*-isomer **5**. We believe that fission of the oxygen bridge prob-

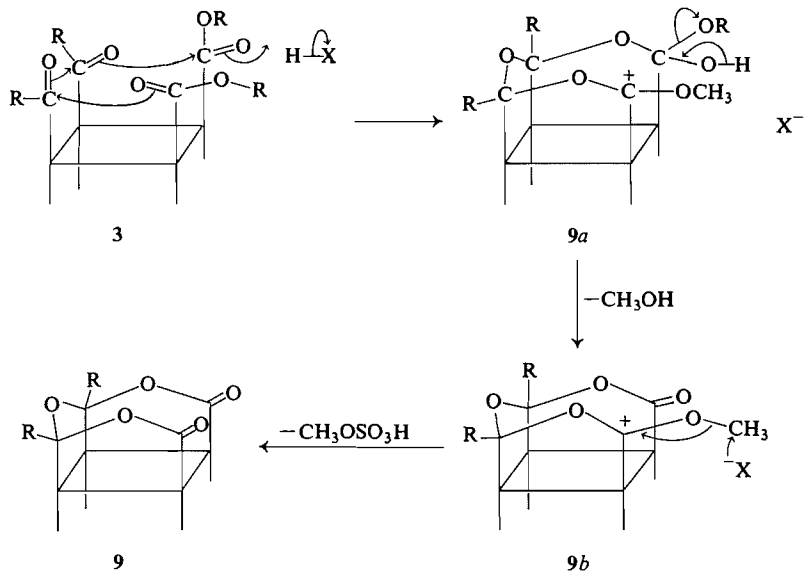

SCHEME 3

ably proceeds as shown in Scheme 2, to give the diol **2***a*. This can then react with water in two ways: either in the intramolecular pathway (*a*), with retention and inversion of configuration at C-3 and -4, to give **4**, or as in (*b*), with double inversion at these carbon atoms to give the all-*cis* isomer **3**. Isomer **4** is the major product, suggesting that (*a*) is favored. Formation of the *cis,trans,cis*-compound would necessitate retention of configuration at both ester-bearing centers, and such a transformation is not possible from **2***a*.

Mechanism of Formation of 9 from 3

Initial protonation at one of the ester carbonyl oxygen atoms in **3** would induce participation of the three remaining carbonyl groups as depicted in Scheme 3 to produce carbonium ion **9***a*. Loss of methanol from the latter followed by nucleophilic attack of $^-OSO_3H$ at the methoxyl methyl of carbonium ion **9***b* would then result in the production of **9**. Both carbonium ions would be stabilized by electron delocalization from adjacent oxygen atoms.

Proton Magnetic Resonance Analyses (see Table 1)

Chemical Shift Assignments

The chemical shifts of H-1 and -2 in **3** (behaves as if it possessed C_2 symmetry), **7** (C_2 symmetry), and **9** (C_s symmetry) could be assigned because they gave singlet resonances in the spectra of **3**-d_2, **7**-d_2, and **9**-d_2. These hydrogens occurred at higher field than H-3 and -4 in **3** and **9** whereas the reverse was true for **7**.

In **6** H-2 and the carbomethoxy group attached to C-4 are in a 1,3-diaxial relationship so it could be anticipated that the former would experience a paramagnetic shift due to magnetic anisotropy associated with the ester carbonyl group (10). The X part of the ABCX spectrum for the four ring hydrogens of **6** appeared at lowest field and was therefore provisionally assigned to H2. This could be confirmed since H-1 appeared as a broadened singlet in the spectrum of **6**-d_3 and this resonance had the same chemical shift as the high field A component of the AX spectrum for H-1 and -2 in **6**-d_2. Furthermore, the low field X part of the ABCX spectrum for the ring hydrogens of **6** was missing from the spectrum of **6**-d_1; the three ring hydrogens of the latter gave an ABC spectrum broadened by coupling with deuterium. Since only H-2 was replaced by deuterium in **6**-d_1 it follows once again that the low field X part of the ABCX spectrum for the ring hydrogens of **6** must have been due to this hydrogen. From these experiments it could also be deduced that H-1 resonated at higher field (lower frequency) than H-3 and -4. Double

For personal use only.

irradiation experiments also established unambiguously that H-2 was vicinally coupled to the two ring hydrogens appearing at highest field thus enabling H-3, and therefore H-4, to be assigned.

The four ring hydrogens of **4** gave an ABMX spectrum, the X component occurring at lowest, and the M component at highest, field. The AB multiplet was always partially hidden beneath the signals for the two carbomethoxy methyl groups irrespective of the solvent used. Since H-4 was in a 1,3-diaxial relationship to the acetyl substituent at C-2, the low field X component of the above system was assigned to this hydrogen for the same reason as the low field X component of the ABCX spectrum of **6** was assigned to H-2. Decoupling experiments also established that H-4 was *vicinally coupled* to the hydrogen occurring at highest field (M component of ABMX spectrum). The latter was also present as the M doublet of an AM quartet for H-1 and -2 in the spectrum of **4**-d_2. This evidence, therefore, established that H-1 was at highest field, and since H-2 and -3 constitute the AB part of the ABMX system, the chemical shift of H-2 required that it occur at lower field than H-3.

Assignments of Spin–Spin Coupling Constants

Values for $J_{1,2}$ were measured directly from the spectra of **4**-d_2 and **6**-d_2, or from the ^{13}C—H satellite spectra of **3**-d_2, **7**-d_2, and **9**-d_2. The other spin–spin coupling constants for **3**, **7**, and **9** were first obtained from preliminary analyses of their AA′BB′ sub-spectra (11), and later the final values were determined with the NMRIT–NMREN programs of Swalen and Reilly (12).[4] Data obtained from **3** and **7**, or from other similarly substituted cyclobutanes reported in the literature (13–15), were then used as trial parameters in the computer analysis (12) of the sub-spectra of **4** (ABMX) and **6** (ABCX) taking due account of substituent effects and the steric relationships of relevant hydrogens. Only the non-iterative part of the NMRIT program was used in the case of **4** because the signals for H-2 and -3 were partially hidden by those for the carbomethoxy methyl groups. In this case chemical shift and spin–spin coupling values were adjusted by trial and error until the experimental and calculated sub-spectra for H-1 and -4, and for H-2 and -3 where visible, were in close agreement. In all cases experimental and calculated spectra agreed within the limits of experimental error. A similar analysis of other cyclobutanes has been reported recently (13). The spectra of **6**-d_1 and **7**-d_1 were not analyzed because many of the hydrogen resonances were excessively broadened due to hydrogen–deuterium coupling.

[4]Both the 60 and 100 MHz spectra of **3**, **7**, and **9** were analyzed, good agreement being obtained in all cases.

Conclusions from Proton Magnetic Resonance Data

(*1*) In **3**, **4**, **6**, and **7** vicinal hydrogens with a *trans* diaxial orientation have slightly larger spin–spin coupling constants than those in a *cis*-relationship, although in other cyclobutanes the reverse has been observed (14). (None of the above compounds have vicinal hydrogens which are diequatorial.)

(*2*) The sign and magnitude of the spin–spin coupling constants between hydrogens in a 1,3-relationship in **3**, **4**, **6**, and **7** depend on whether they are in a diequatorial ($J_{e,e}$), diaxial ($J_{a,a}$), or axial–equatorial ($J_{a,e}$) orientation. From the data obtained for **4**, **6**, and **7** it would appear that both $J_{a,a}$ and $J_{a,e}$ are negative with the latter being of slightly greater magnitude. Although $J_{e,e}$ could not be obtained directly it was known that $J_{1,3} = J_{2,4} = 1/2(J_{a,a} + J_{e,e}) = 0.7$ Hz in **3** and an average value of $J_{a,a} = -0.3$ Hz could be obtained from the data for **4**, **6**, and **7**. Substitution then gave a value for $J_{e,e} = 1.7$ Hz indicating that $J_{e,e}$ was probably of greater magnitude and opposite sign to $J_{a,a}$ and $J_{a,e}$.

(*3*) Vicinal *cis* spin–spin coupling constants in the more rigid molecule **9** are considerably lower than the corresponding value in **3**, but the 1,3-spin–spin interactions are somewhat greater.

Generality

Further experiments have established that hydrolysis of **2** (R = H, CH_3) yields one stereoisomeric form of 1-formyl-2-acetyl-3,4-dicarbomethoxycyclobutane. It is, therefore, possible that such conversions may be general for 3-oxaquadricyclanes bearing one or more alkyl substituents at the bridgehead, and that the conversions in some cases may take place with a high degree of stereospecificity. On the other hand, compounds of type **2** with aryl substituents at the bridgehead are not converted to cyclobutane derivatives but undergo spontaneous thermal rearrangement to oxepines in the presence of water. The results of these investigations will be published at a later date.

Experimental

The p.m.r. spectra were obtained on Varian HA-100 and Varian A-60A spectrometers with tetramethylsilane as internal standard. The spectra were analyzed with the aid of the NMRIT and NMREN programs (12) using the IBM 360 at Dalhousie University Computer Centre Halifax, Nova Scotia. The i.r. spectra were recorded on a Perkin–Elmer model 521 spectrometer, and mass spectra using a Consolidated Electrodynamics Corporation 21-110B mass spectrometer, with electrical detection being used for mass measurements. The deuterium oxide and deuteriosulfuric acid used were of minimum isotopic purity 99.7 and 98% D respectively.

The adduct **1** was prepared by thermal Diels–Alder reaction of 2,5-dimethylfuran and dimethylacetylenedicarboxylate (6).

Preparation of the Oxaquadricyclane 2 (cf. (6))

A solution of the adduct **1** (4.0 g) in anhydrous ether (450 ml) was irradiated for 12 h at room temperature in a Rayonet Photochemical reactor with light of wavelength 3100 Å, the reaction mixture being water-cooled by means of an internal jacket immersed in the solution. Evaporation of the solvent gave the oxaquadricyclane **2** as a yellow oil; p.m.r. analysis indicated essentially quantitative conversion. This material was used without further purification. It should be noted that **2** can cause a temporary but painful irritation of the eyes and skin.

Preparation of 3 and 4

A solution of **2** (10.0 g) in 50% aqueous acetone (100 ml) was refluxed for 6 h. It was then diluted with water (60 ml) and thoroughly extracted with chloroform. Evaporation of solvent from the dried (Na_2SO_4) extract gave a viscous red–brown oil (10.6 g), which on cooling slowly solidified. Trituration with cold ether gave a colorless solid (4.72 g, 44%).[5] Fractional crystallization from ether gave (*i*) isomer **3** as colorless needles (1.52 g, 14%); m.p. 130–132°; parent molecular ion (for $C_{12}H_{16}O_6$) at *m/e* 256 with prominent ions at *m/e* 241, 225, 214, and 213; ν_{max} (CCl_4): 1719, 1743 cm^{-1}; **3** can be recrystallized from ether or benzene; and (*ii*) colorless prisms and needles; m.p. 76–83°; shown by p.m.r. to be *ca.* 90% **4**, contaminated by **3**. Pure **4** (2.85 g, 26.5%) could be obtained by crystallization from water as colorless prisms, m.p. 83–84°; parent molecular ion (for $C_{12}H_{16}O_6$) at *m/e* 256 with prominent ions at *m/e* 241, 225, 214, and 213; ν_{max} (CCl_4): 1710, 1738 cm^{-1}.

Conversion of **2** to **3** and **4** also proceeded in refluxing 50% aqueous tetrahydrofuran, although more slowly (*ca.* 60% conversion in 6 h). The reaction was promoted (complete in 2 h) by a few drops of acetic acid, but the product obtained was somewhat less tractable.

Solutions of **3** and **4** in 50% aqueous acetone were each refluxed for 2 h. On dilution with water and extraction with chloroform quantitative recoveries of the starting compounds were made.

Preparation of 3-d_2 and 4-d_2

The conversion of **2** to **3**-d_2 and **4**-d_2 was accomplished as above, but using a 50% mixture of tetrahydrofuran and deuterium oxide and refluxing for 16 h. The yields of **3**-d_2 and **4**-d_2 were similar to those of **3** and **4**. The molecular formula $C_{12}H_{14}D_2O_6$ was confirmed by mass spectrometry [peaks at *m/e* 258, 243, 227, 216, and 215].

Conversion of 3 to 9

A stirred solution of **3** (300 mg) in CH_2Cl_2 (15 ml) was treated with an excess of concentrated sulfuric acid (900 mg). Stirring was continued at room temperature for 1 h, during which a reddish oil precipitated. The mixture was washed twice with water, dried, and evaporated to give a solid residue. Trituration of the latter with cold ethyl acetate gave **9** as a colorless solid (142 mg, 58%) m.p. 229–230°. The ethyl acetate - soluble portion afforded a gummy solid, shown by p.m.r. to be mainly **6** (see below).

The expected parent molecular ion for **9** (for $C_{10}H_{10}O_5$) at *m/e* 210 was absent. However mass measurements of ions at *m/e* 195 (measured 195.0297, $C_9H_7O_5$ requires 195.02935) and 166 (measured 166.0625, $C_9H_{10}O_3$ requires 166.0630) indicated losses of 15 (CH_3) and 44 (CO_2) mass units; ν_{max} (KBr): 1790 cm^{-1}. Compound **9** was only sparingly soluble in common organic solvents.

Conversion of **3** to **9** was promoted by D_2SO_4 and the conversion of **3**-d_2 to **9**-d_2 could also be carried out under similar conditions using either H_2SO_4 or D_2SO_4.

The ratio of **9** to **6** obtained by acid treatment of **3** increases with the concentration of acid present.

Conversion of 3 to 6

A stirred solution of **3** (100 mg) in CH_2Cl_2 (6 ml) was cooled to 0° and treated with concentrated sulfuric acid (90 mg) in CH_2Cl_2 (4 ml). After stirring at room temperature for 1 h the reaction mixture was washed with water, dried, and evaporated to give a colorless crystalline solid (97 mg). Analysis of the latter by p.m.r. indicated 70–75% **6**, with 20–25% **9**, and 5–10% unreacted **3**. The crude product was triturated with ethyl acetate to remove **9** (see above) and the ethyl acetate – soluble residue crystallized from a small amount of ether or water to give **6** as colorless prisms, m.p. 65–67°, parent molecular ion (for $C_{12}H_{16}O_6$) at *m/e* 256, with prominent ions at *m/e* 241, 225, 214, and 213; ν_{max} (CCl_4): 1710, 1743 cm^{-1}.

Conversion of **3**-d_2 to **6**-d_2 was carried out under identical conditions.

The conversions of **3** to **6**-d_1 and of **3**-d_2 to **6**-d_3 were brought about under similar conditions using D_2SO_4 in place of H_2SO_4. In each case D_2O was substituted for H_2O in the work-up. However, exchange of D with the acetyl methyl protons causes dilution and it is therefore necessary to employ an excess of D_2SO_4 to ensure complete exchange at the site of epimerization. Under such conditions (high acid concentration) the yields of **6**-d_1 and **6**-d_3 are limited by production of **9** and **9**-d_2 respectively.

Conversion of 4 to 7

A stirred solution of **4** (100 mg) in CH_2Cl_2 (6 ml) was cooled to 0° and treated with concentrated sulfuric acid

[5]A p.m.r. analysis of the crude product indicated a very high (*ca.* 90%) conversion to **3** and **4**. However attempted separations by column chromatography on silicic acid or neutral alumina or by preparative g.l.p.c. using 20% carbowax on chromosorb W at 200°, led to epimerization of the products. A better method for recovery of **3** and **4** is now being sought.

(90 mg) in CH_2Cl_2 (4 ml). Stirring was continued at room temperature for 1 h. After washing with H_2O, drying and evaporation gave a crystalline solid. This was crystallized from ether to give **7** as colorless needles (90 mg), m.p. 82–83° [lit. (10) 82°], parent molecular ion (for $C_{12}H_{16}O_6$) at *m/e* 256, with prominent ions at *m/e* 241, 225, 224, 214, and 213; ν_{max} (CCl_4): 1712, 1737 cm^{-1}.

Conversion of **4**-d_2 to **7**-d_2 was carried out under identical conditions.

The conversions of **4** to **7**-d_1 and of **4**-d_2 to **7**-d_3 were brought about in the presence of a 6 mole excess of D_2SO_4, to ensure complete exchange at the site of epimerization.

We thank J. van Ingen for measurement of some p.m.r. data and D. J. Embree and Dr. W. D. Jamieson for measurement of and assistance with the interpretation of the mass spectra.

Some Factors Affecting the Synthesis of Hindered Diphenyl Ethers[1]

W. D. CHANDLER, J. J. BERGMAN, AND G. H. HAAS
Department of Chemistry, University of Saskatchewan, Regina, Saskatchewan

Received July 16, 1970

A study is presented which shows how, in the Hems synthesis of two tri-ortho-substituted diphenyl ethers, the nature of the *leaving group* of the substrate is important in determining yield. The yield increases in the order: OTosyl (p-$OSO_2C_6H_4CH_3$) < Cl < F. As well, a synthetic method, involving reaction of an activated substrate with a sodium phenoxide in dimethyl sulfoxide, has been investigated in a similar way and a number of highly-hindered diphenyl ethers, which cannot be synthesized by the Hems synthesis, have been prepared.

Canadian Journal of Chemistry, 49, 583 (1971)

Introduction

In undertaking a conformational study of diphenyl ethers it was found necessary to synthesize a number of these compounds having one ring substituted at positions-2 and -4. Recently, Neville and Moir (1) have discussed the synthesis of some highly hindered diphenyl ethers by a modification of the Hems synthesis in which *N*-(4-carbomethoxy-2,6-dinitrophenyl)pyridinium chloride (**1***a*) was heated with various phenols in pyridine. Their modification allowed easier purification, and, in some cases, larger yields than had been the case previously (2–5).

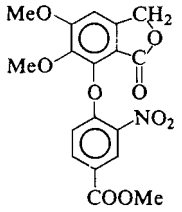
a $R_1 = R_3 = NO_2$; R_2 = COOMe; X = Py^+Cl^-
b $R_1 = NO_2$; R_2 = COOMe; R_3 = H; X = $Py^+OTosyl^-$
c R_1 = COOMe; $R_2 = NO_2$; R_3 = H; X = $Py^+OTosyl^-$
d $R_1 = NO_2$; R_2 = COOMe; R_3 = H; X = OTosyl
e R_1 = COOMe; $R_2 = NO_2$; R_3 = H; X = OTosyl

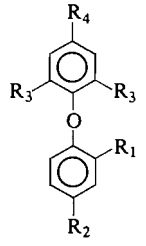


2

[1]Some of the material for this paper is taken from the Honors Thesis of G. H. Haas, University of Saskatchewan, Regina, Saskatchewan, April, 1969.

The use of *N*-(4-carbomethoxy-2-nitrophenyl)-pyridinium tosylate (**1***b*) has been reported with 7-hydroxymetameconine in the Hems synthesis of **2** (4–6) but no reaction occurred when the phenol was methyl salicylate (5).

Although we have succeeded in preparing 2-(4′-carbomethoxy-2′-nitrophenoxy)-1,3,5-trichlorobenzene (**3***a*) by reacting 2,4,6-trichlorophenol with **1***b* in pyridine using a method essentially that of Neville and Moir, the isomeric ether, **3***b*, could not be made in the same way since the corresponding *N*-phenylpyridinium tosylate (**1***c*) could not be synthesized by the usual method (4).



3

a $R_1 = NO_2$; R_2 = COOMe; $R_3 = R_4$ = Cl
b R_1 = COOMe; $R_2 = NO_2$; $R_3 = R_4$ = Cl
c $R_1 = NO_2$; R_2 = COOMe; $R_3 = R_4$ = Me
d $R_1 = R_2 = NO_2$; $R_3 = R_4$ = Me
e $R_1 = R_2 = NO_2$; $R_3 = R_4$ = *t*-Bu
f $R_1 = R_2 = NO_2$; R_3 = *i*-Pr; R_4 = H

In their original paper on the Hems synthesis, Borrows *et al.* (2) pointed out that, although the pyridinium salt was essential for the reaction, they had not found it necessary to isolate it from the reaction mixture prior to adding the phenol. In all of their reactions, Neville and Moir formed and reacted **1***a in situ*. On this basis, it seemed reasonable to expect that diphenyl ethers **3***a* and *b* would be formed directly from the action of 2,4,6-trichlorophenol on the appropriate tosylate

TABLE 1. Comparison of yields of diphenyl ethers prepared using 2,4,6-trichlorophenol with various substrates in the Hems synthesis and the method of Wright and Jorgenson

Substrate	Hems synthesis		Wright and Jorgenson method

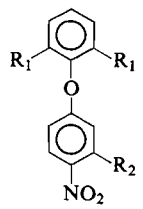
esters (**1***d* and *e*) in pyridine without the necessity of isolating and purifying the salts, **1***b* and *c*.

As expected, when **1***d* was used with the *in situ* technique, **3***a* was formed in about 50% yield, nearly the same yield as for the reaction of **1***b* with the phenol under the same experimental conditions. However, 2,4,6-trichlorophenol and **1***e* would not react to give **3***b* even after 48 h in pyridine at 90°. Compound **3***b* was, however, synthesized in up to 20% yield when methyl 2-chloro-5-nitrobenzoate was used as the substrate in the Hems synthesis.

Since so little is known about the role of the leaving group in the Hems synthesis and since the practice has been to use tosylate esters in difficult syntheses and chloro compounds in easier ones (1, 4–6), it was decided that an investigation of the relation between leaving group and the yield of the two diphenyl ethers (**3***a* and *b*) would be undertaken. For this purpose, seven substrates were reacted with 2,4,6-trichlorophenol and pyridine at 90°. The yields of the ethers formed are given in Table 1.

Using a different approach to the synthesis of hindered diphenyl ethers, Wright and Jorgenson (7) showed that good yields of some ethers of type **4** could be obtained by reacting a phenol, sodium hydroxide and an activated chloro compound together in dimethyl sulfoxide. The reaction of a phenol with an activated halide and base or of a phenoxide with an activated halide to form a diphenyl ether is not novel as there are numerous examples in the literature (3, 8–11). However, the use of dimethyl sulfoxide as a solvent and the ease of product isolation are new and worthy of investigation.



4

R_1 = Me, *i*-Pr, *sec*-Bu, *t*-Bu; R_2 = H, Me

By means of a procedure similar to that of Wright and Jorgenson, the effect of the leaving group on the yields of the two diphenyl ethers, **3***a* and *b*, was studied. The results are compared with the yields from the Hems synthesis in Table 1.

In addition, because Wright and Jorgenson were able to prepare alkyl-substituted diphenyl ethers, **4**, in good yield, we used their method to investigate some of the steric factors associated with the synthesis and we have prepared some additional hindered ethers (**3***c*, *d*, *e*, and *f*) for conformational studies. The yields, melting points, and elemental analyses are given in Table 2.

*Yields are the maximum obtained after optimum reaction time.
†See Table 1.
‡The crude reaction mixture was first distilled and the fraction, b.p. 205°/5 mm Hg, was collected and recrystallized.

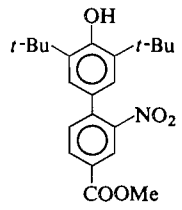
Results and Discussion

Using the Hems synthesis, the yields of **3***a* are, for the most part, better than those of **3***b* where substrates having the same leaving group are compared. This observation is to be expected since a nitro group ortho to the leaving group should be better able to delocalize the negative charge formed during a nucleophilic substitution than would a para-nitro.

Where sufficient data are available, the yield of diphenyl ether appears to reach a maximum with time and then decrease; Constantin and L'Ecuyer (12) observed similar behavior in some Hems syntheses they studied. Undoubtedly, pyridine scission of the ether in competition with ether formation lowers the yield. With the two fluoro compounds the reaction is so fast that the formation of diphenyl ether must be essentially complete in less than 48 h while such cannot be the case with other substrates. It is clear that halogen-containing substrates are preferable to tosylate esters in the Hems synthesis. A fluoro compound would react faster but in some cases the more easily prepared chloro analogue would give satisfactory yields.

With one exception, the method of Wright and Jorgenson gives yields as good as or better than the Hems synthesis. For the more activated substrates, the yields by the two methods are very similar, and there does not appear to be any problem of by-product formation. The observation of poor yields with the tosylate esters agrees with the results of Borrows *et al.* (2) who noted that the lithium salt of phenol gave only a *trans*-tosylated product when treated with a tosylate ester but the expected diphenyl ether did form when the *N*-phenylpyridinium tosylate was used.

The synthetic advantage of the method of Wright and Jorgenson becomes obvious from the fact that 2,4,6-trimethylphenol and methyl 4-chloro-3-nitrobenzoate did not react to form **3***c* in a Hems synthesis after 24 h at 90°. Under the same conditions a 50% yield of **3***c* was obtained by the method of Wright and Jorgenson.



5

With methyl 4-chloro-3-nitrobenzoate, 2,6-di-*t*-butylphenol gave only the phenolbiphenyl, **5**, in complete agreement with previous results using *p*-chloronitrobenzene as substrate (7). Under the same conditions 2,4,6-tri-*t*-butylphenol and methyl 4-chloro-3-nitrobenzoate formed no diphenyl ether after 48 h. With the more activated substrate, 2,4-dinitrochlorobenzene, 12% of **3***e* was obtained after 48 h at 90°. Refluxing the reaction mixture in dimethyl sulfoxide for 76 h increased the yield to 17% but reaction for 7 days at 95–100° did not increase it further. By comparison, **3***d* was isolated in 70% yield when 2,4,6-trimethylphenol and 2,4-dinitrochlorobenzene were heated together at 90° for only 4.5 h and **3***f* was obtained in greater than 13% yield when 2,6-diisopropylphenol and 2,4-dinitrochlorobenzene were reacted together for 20 h at 85°.

When the yields noted in Table 2 are compared to those obtained by Wright and Jorgenson for some of the ethers in series **4** (R_2 = H, R_1 = Me (82%); R_2 = H, R_1 = *i*-Pr (75%); R_2 = H, R_1 = *sec*-Bu (70%)) it becomes clear that large alkyl groups ortho to the phenol oxygen severely hinder attack on the substrate. This is especially true in the case of a large substituent such as NO_2 in a position ortho to the leaving group of the

For personal use only.

substrate. The steric crowding around the oxygen in 2,6-di-*t*-butylphenol is so large that the nucleophilic center becomes the carbon para to the oxygen rather than the oxygen itself. Diphenyl ethers with two *t*-butyl ortho to the oxygen can be prepared if a sufficiently activated substrate is used and if the para position of the phenol is blocked. It is interesting to note that Neville and Moir (1) were unable to prepare such an ether in their series using the Hems synthesis.

It appears that the method of Wright and Jorgenson is preferable to the older Hems synthesis for preparing tri-ortho-substituted diphenyl ethers. Work is continuing with attempts to prepare even more-highly hindered diphenyl ethers.

Experimental

All melting points were obtained on a Kofler, hot stage apparatus and are reported uncorrected. The structures of all the reported compounds were consistent with their n.m.r. and i.r. spectra.

Except as noted, all reagents (phenols and substrates) were purchased from chemical suppliers and were used without further purification.

The following compounds were prepared by methods described previously: 4-carbomethoxy-2-nitrophenyl *p*-toluenesulfonate (**1***d*) (6), m.p. 96–97°; *N*-(4-carbomethoxy-2-nitrophenyl)pyridinium *p*-toluenesulfonate (**1***b*) (4), m.p. 223–225°; methyl 4-fluoro-3-nitrobenzoate (13), m.p. 53–55°.

2-Carbomethoxy-4-nitrophenyl p-Toluenesulfonate (1e)

Salicylic acid (reagent) was nitrated according to the method of Epstein and Meyer (14) to obtain 5-nitrosalicylic acid, m.p. 233–235° (45%). The acid was methylated in methanol, dichloroethane, and sulfuric acid using the procedure of Clinton and Laskowski (15) and the ester was recrystallized twice from ethanol (95%) as long, yellow–white needles, m.p. 116–118° (lit. m.p. 116–117° (16)).

Methyl 5-nitrosalicylate (15 g), *p*-toluenesulfonyl chloride (15 g, technical), and pyridine (25 ml, reagent) were shaken in a stoppered flask for 1 h. The sludge that formed was poured into a mixture of ice-water (500 g) and concentrated HCl (26 ml, 12 *N*) and the solid was crushed to yield a nearly white product. This was collected and recrystallized from ethanol (95%) as large needles, m.p. 74–76°, yield, 23.5 g (88%). The analytical sample was obtained after two further recrystallizations from absolute ethanol, m.p. 75–76°.

Anal. Calcd. for $C_{15}H_{13}NSO_7$: C, 51.28; H, 3.73; N, 3.99. Found: C, 51.31; H, 3.63; N, 3.89.

Methyl 4-Chloro-3-nitrobenzoate and Methyl 2-Chloro-5-nitrobenzoate

The corresponding acids (Eastman white label) were methylated by the method of Clinton and Laskowski (15). The crude esters were recrystallized as needles from methanol, m.p. 82–83° and 69–70° respectively (lit. m.p. 83 and 73° respectively (17)).

Methyl 2-Fluoro-5-nitrobenzoate

Methyl 2-chloro-5-nitrobenzoate was heated with KF in dimethyl formamide at 155° for 4 h as described by Finger and Kruse (13) in their preparation of methyl 4-fluoro-3-nitrobenzoate. The impure product was distilled and the material boiling at 130–135°/5 mm Hg was collected (62%). Light, yellow needles were obtained after recrystallization from methanol, m.p. 44–45°.

Anal. Calcd. for $C_8H_6FNO_4$: C, 48.25; H, 3.04; N, 7.04. Found: C, 48.11; H, 3.18; N, 7.00.

Generalized Hems Synthesis

The results listed in Table 1 were obtained by the following procedure:

The appropriate substrate (0.02 mol) and 2,4,6-trichlorophenol (6.0 g, 0.03 mol, Eastman white label) were dissolved[2] in chloroform (20 ml, stock) and pyridine (45 ml, reagent). The solution was heated with magnetic stirring for the designated time at a temperature of 90 ± 1°.

At the end of the reaction time, the dark mixture[3] was poured into a beaker containing ice-water (400 g), concentrated HCl (75 ml, 12 *N*), and chloroform (40 ml, stock). The reaction flask was rinsed with chloroform (20 ml) and water (10 ml) which were also added to the beaker. After the two-phase mixture had been stirred vigorously for 5 min, the chloroform layer was drawn off and diluted with absolute ethanol (100 ml). If a solid formed at the water–chloroform interphase, it was removed by filtration prior to extracting the chloroform layer.

The volume of the chloroform–ethanol solution was reduced by boiling with stirring until the vapor temperature reached 74°. Any solid that formed when the solution was chilled in ice was collected, washed with cold absolute ethanol, and recrystallized from ethanol. The yield of once-recrystallized product is that reported in Table 1.

Generalized Method of Wright and Jorgenson

The results listed in Table 1 were obtained by the following procedure:

2,4,6-Trichlorophenol (5.0 g, 0.025 mol, Eastman white label) and NaOH (0.82 g, 0.02 mol, reagent) were heated with stirring in dimethyl sulfoxide (30 ml, reagent) at 90° until the base dissolved and a dark blue solution resulted. To this solution was added the substrate (0.02 mol) and heating was carried out for the designated time at 90 ± 1°.

At the end of the reaction time, the mixture[4] was poured into a beaker containing ice-water (300 g), concentrated HCl (25 ml, 12*N*), and chloroform (60 ml, stock). The flask was rinsed with water (10 ml) and chloroform (10 ml) which were also added to the beaker. The procedure of isolating and purifying the diphenyl ether product was the same as for the generalized Hems syn-

[2]The *N*-phenylpyridinium tosylate (**1***b*) did not dissolve.

[3]A solid formed from the solution when **1***d* and methyl 2-chloro-5-nitrobenzoate were substrates. This solid did not entirely disappear. The *N*-phenylpyridinium tosylate (**1***b*) did not entirely disappear either.

[4]If Cl or F were the leaving group a precipitate of NaCl or NaF formed.

thesis. The yield of once-recrystallized product is reported in Table 1.

For synthesis of the new ethers (*3c*, *d*, *e*, and *f*) the procedure was exactly that outlined above except the nature of the phenol was changed and, in some cases, temperatures other than 90° were used. The reactants were always in the ratio: NaOH (0.02 mol), phenol (0.025 mol), substrate (0.02 mol), and dimethyl sulfoxide (30 ml). Yields and elemental analyses of these ethers are given in Table 2 along with melting points.

2,6-Di-t-butyl-4-(4'-carbomethoxy-2'-nitrophenyl)phenol (5)

2,6-Di-*t*-butylphenol (Aldrich, m.p. 36°) and methyl 4-chloro-3-nitrobenzoate were reacted together for 41 h by the method of Wright and Jorgenson at 80–85° to give an orange solid, m.p. 144–147° (88%). A recrystallization from ethanol (absolute) gave a mixture of two types of needles: brown needles melting sharply at 247° and yellow-green needles melting at 152–153°. A separation of the two was achieved by washing the solid with methanol. The methanol was evaporated and the product recrystallized from ethanol (absolute) five times to give greenish cubes, m.p. 154–155°. The n.m.r. and i.r. spectra showed the presence of a hydroxyl group in the molecule.

Anal. Calcd. for $C_{22}H_{27}NO_5$: C, 68.55; H, 7.06; N, 3.64. Found: C, 68.27; H, 7.04; N, 3.89.

The brown needles have not been identified.

Studies of Carbohydrate Derivatives by Nuclear Magnetic Double Resonance. Part VI. The Identification of ^{13}C Chemical Shifts of Methyl Resonances via the ^{1}H–$\{^{13}C\}$ INDOR Technique

R. BURTON, L. D. HALL, AND P. R. STEINER[1]

Department of Chemistry, The University of British Columbia, Vancouver 8, British Columbia

Received August 26, 1970

The ^{13}C chemical shifts of acetate- and methoxyl-methyl substituents of several pyranose carbohydrate derivatives have been measured by the ^{1}H–$\{^{13}C\}$ INDOR technique. The chemical shifts ($\delta^{13}C$) of anomeric methoxyl-methyl resonances fall into two groups: for α-anomers (axial substituent), $\delta^{13}C$ = 55.12–56.63 p.p.m.; for β-anomers (equatorial substituent), $\delta^{13}C$ = 56.63–58.69 p.p.m. *O*-Acetyl-methyl shifts fall between 20.54–20.72 p.p.m. and *N*-acetyl-methyl shifts were detected between 22.98–23.08 p.p.m.

Canadian Journal of Chemistry, 49, 588 (1971)

Introduction

Recent improvements in n.m.r. instrumentation have made possible the direct measurement of the "natural-abundance" ^{13}C n.m.r. spectra of complex organic derivatives such as carbohydrates (1) on a routine basis. However, in certain instances it is convenient, indeed advantageous, to obtain ^{13}C n.m.r. spectra via indirect methods and in the present discussion we describe measurements based on the ^{1}H–$\{^{13}C\}$ INDOR technique.[2] Although a number of other workers (3) have previously discussed such experiments the present paper describes the first measurements in the carbohydrate area. For a general discussion of the INDOR technique the reader is referred to three review articles (4); a simplified discussion was given in the previous paper of this series (5).

As part of another project (1*a*) we had previously measured *directly* the natural-abundance ^{13}C resonances of several pyranose derivatives and had shown that the chemical shifts of anomeric methoxyl resonances have a stereospecific dependence. This dependence has now been investigated further.

Experimental

The compounds used were synthesized by standard literature methods:

Methyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (**1**), m.p. 102° (lit. (6), 101°); methyl 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**2**), m.p. 105° (lit. (6), 104°); methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (**3**), m.p. 88–89°; methyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside (**4**), m.p. 116–117°; 1,2,3,4,6-penta-*O*-acetyl-β-D-galactopyranose (**5**), m.p. 142–143° (lit. (7), 142°); methyl-α-D-glucopyranoside[3] (**6**), m.p. 160–161°; methyl-β-D-glucopyranoside[4] (**7**), m.p. 102–104°; methyl-α-D-xylopyranoside[5] (**8**), m.p. 93°; methyl-β-D-xylopyranoside[4] (**9**), m.p. 154–156°; 2-acetamido-2-deoxy-D-glucopyranose[4] (**10**), m.p. 215° (dec.); 2-acetamido-2-deoxy-D-mannopyranose[4] (**11**), m.p. 127–130°.

The n.m.r. spectra of derivatives **1–5** were measured using *ca.* 35% (w/v) solutions in chloroform-*d*, contained in a 5 mm o.d. sample tube; tetramethylsilane was used as the internal reference for the field–frequency lock.

The n.m.r. measurements on compounds **6–11** were made with samples prepared as follows: the derivative was lyophilized several times with deuterium oxide and then a solution (*ca.* 40% w/v) was made with deuterium oxide. The sample was contained in a 5 mm o.d. tube. Tetramethylsilane, contained in a capillary tube, was used as the lock signal for the spectrometer.

All n.m.r. measurements were made with an extensively modified Varian Associates HA-100 spectrometer, using components originally (8) purchased for heteronuclear spin-decoupling experiments. A block diagram of the accessories used is given in Fig. 1.

In order to obtain the required frequency–frequency lock, several standard frequencies {34, 34, and 32 MHz} were taken from a Hewlett Packard synthesizer driver (model 5110 B) and added together using Hewlett Packard double balanced mixers (model 10514 A). The resultant 100 MHz signal was then amplified to 6.5 V (r.m.s.). The oscillator tube (V-103) was removed from a 100 MHz V-4311 radiofrequency unit and the 6.5 V, 100 MHz signal was injected via a B.N.C. connector at J 108.

The ^{13}C frequency was obtained from a Hewlett Packard frequency synthesizer (model 5105 B). The output frequency was digitally programmed using a Barry Research[6] linear sweep control (model LSC-7B).

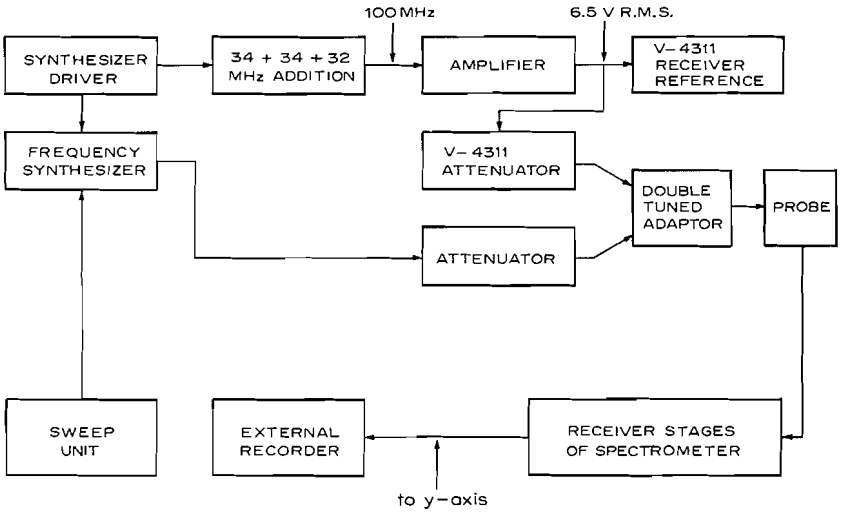

FIG. 1. Block diagram of the components used for ^1H–$\{^{13}C\}$ INDOR measurements.

The power output of the frequency synthesizer was suitably attenuated with a Telonic Industry[7] attenuator (model TG-9050).

The transmitter coil of a Varian V-4311 probe was double-tuned to 100 and 25.1 MHz following previously reported methods (8).

For convenience, the INDOR spectra were recorded on either a Varian Associates Strip Chart Recorder (model G-14) or a Hewlett Packard, Moseley Recorder (model 7005B). The *y*-axis drive was obtained from the EXTERNAL-RECORDER output of the V-4391 unit. The *x*-axis of the charts was calibrated directly using the time-base, event-marker output of the Barry Programmer. Repeated measurements made over a period of time showed that the reproducibility of the chemical shifts obtained directly from 1000 Hz sweep-width charts is better than ± 2 Hz (± 0.08 p.p.m. for ^{13}C shifts) which was adjudged to be adequate for most organo-chemical applications. Higher precision could be obtained by measuring, in turn, the resonance frequency of each transition using much narrower sweep-widths, or by direct calibration methods. The sole limitation in the accuracy of shifts obtained by either of these latter methods is then governed by the line-widths of the INDOR responses themselves.

The general procedure followed during these INDOR measurements was as follows. The frequency–frequency lock was set-up as described above and the field–frequency lock established in the usual fashion via a tetramethylsilane reference, with the instrument in the frequency-swept mode. The normal ^1H n.m.r. spectrum of the compound was measured under conventional conditions and then the "gain" settings increased to measure the ^{13}C-satellites of the appropriate resonance. The sweep-oscillator of the Varian recorder was set to the precise resonance frequency (± 0.1 Hz) of the satellite which was to be monitored and then the receiver output of the spectrometer was connected to the *y*-axis of the recorder. With the full power output of the synthesizer connected to the probe, the synthesizer was swept over the 10 000 Hz range at a rate of 100 Hz/s. The broad resonance initially detected in this way was subsequently measured on a narrower sweep-width (1000 Hz) and with a somewhat slower sweep rate (2 Hz/s).

Although the experimentally determined shifts may be quoted in "absolute" frequency units it is more convenient to compare them with the ^{13}C shift of tetramethylsilane. Several groups of workers have given formulae whereby the experimental frequency data may be converted to a basis where the ^{13}C shift is given in p.p.m. from that of tetramethylsilane and at a magnetic field such that the protons of tetramethylsilane resonate at precisely 100 MHz. We have followed the procedure of White and Olah (3*f*) which is based on the relationship formulated by Paul and Grant (3*g*), *i.e.* eq. 1.

$$[1] \qquad \delta^{13}C = \frac{\Gamma_i - \Gamma_{TMS}}{\Gamma_{TMS}} \times 10^6 + \delta_H$$

where $$\Gamma_i = \frac{\text{frequency at which a particular proton is measured}}{\text{frequency of the corresponding } ^{13}C \text{ resonance}}$$

and δ_H = proton chemical shift (in p.p.m.) of the lock proton from tetramethylsilane

TABLE 1. Resonance frequencies for the ^1H and ^{13}C resonances of tetramethylsilane (TMS)

Solution	^1H-Frequency (ν_0 MHz)	^{13}C-Frequency (f_0 MHz)	$\Gamma = \nu_0/f_0$
Neat TMS	100.002505	25.145632	3.9769334
TMS:acetone (7:3)	100.002505	25.145628	3.9769341
TMS:chloroform (1:1)	100.002505	25.145639	3.9769323

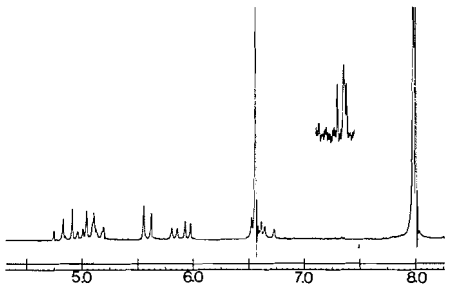

FIG. 2. The ^1H n.m.r. spectrum (100 MHz) of methyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside (**4**) in $CDCl_3$ solution. The ^{13}C satellites of the methoxyl-methyl and acetate-methyl substituents, measured at higher gain, are shown as an insert.

We were concerned that our evaluation of Γ_{TMS} differed from the value (3.9769331) quoted both by White and Olah (3*f*) and by Paul and Grant (3*g*). Repeated evaluation of this parameter gave the value listed in Table 1. The difference between these values is noteworthy. The value for neat tetramethylsilane was used for the conversion of the data obtained for aqueous solutions and the value for chloroform solution was used for the data from chloroform solutions.

The values for $\delta^{13}C$ given in Tables 2 and 3 were also calculated using the formula given in reference 4*b*. Identical values were obtained.

Results and Discussion

The normal ^1H n.m.r. spectrum of methyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside (**4**) is shown in Fig. 2. The high-field ^{13}C satellite of the methoxyl-methyl resonance, recorded at increased gain, is shown as an insert. The ^{13}C spectrum of the methoxyl-carbon, measured using the methods given in the Experimental section, is given in Fig. 3A. It will be noted that all of the peaks are negative-going; this indicates that the "spin-tickling" mechanism involving both population and energy level changes is the main process responsible for their occurrence (4). The ^{13}C spectrum of the methoxyl-carbon of methyl 2,3,4-tri-*O*-acetyl-α-D-xylopyranoside (**3**) is shown in Fig. 3B. It is obvious that this shift is significantly different from that of **4**.

The ^1H and ^{13}C parameters of the anomeric methoxyl resonances of derivatives **1**–**4** and **6**–**9** are summarized in Table 2. Although there is a systematic difference between the ^1H chemical shifts of the α- and β-anomeric pairs of derivatives, this is so small that it could not be used with confidence as the basis for a configurational assignment. The ^{13}C chemical shift difference is also systematic, with that of the β-anomer coming to *higher* frequency (*lower* field) in every instance. Furthermore, the shift difference is now sufficiently large for it to be used with confidence for structural assignments. Interestingly, the shift difference appears to be slightly larger for the methyl glycosides than it is for the methyl glycoside peracetates.

The ^{13}C–^1H couplings for the methoxyl-methyl substituents are also listed in Table 1. The values lie between 143 and 148 Hz and do not appear to have any diagnostic significance.

In contrast to the above findings, where ^{13}C shifts of methoxyl resonances appear to be more useful than ^1H shifts for structural assignments, it is evident that the converse is true for the acetate substituents. The data obtained for several acetylated pyranose derivatives are summarized in Table 3. The ^{13}C shifts of the acetate-methyl groups all fall within a rather narrow range, with no immediately obvious dependencies, beyond the trivial fact that they fall *ca.* 1 KHz (40 p.p.m.) to low frequency of those of methoxyl-methyl groups.

Had the acetate-methyl shifts had any diagnostic value, we had originally planned to exploit one of the advantages which INDOR spectroscopy has over the direct-measurement method. Horton and Lauterbach (9) had previously identified the ^1H resonances of the individual acetate-methyl resonances of several pyranose

peracetates via a study of a series of specifically trideuteroacetylated derivatives. Their study thus provided the assignment of the individual ^{13}C satellites of the acetate-methyl resonances which in turn, would have enabled the ^{13}C shifts of the acetate-methyl resonances to be assigned. To make a similar assignment of these ^{13}C resonances by the direct-measurement technique would have required us to repeat the original syntheses of the specifically trideuteroacetylated

compounds. Although this intention was frustrated in this instance, it remains that the assignment of ^{13}C resonances via the known assignment of a proton spectrum is a most useful technique.

We took this opportunity to measure the methyl ^{13}C shifts of two acetamido derivatives. These data are also reported in Table 3; again, these shifts appear to have no diagnostic value, even though they are *ca.* 50 Hz (2 p.p.m.) removed from the *O*-acetyl-methyl shifts.

In summary, the ^{13}C shifts of the methyl groups of *O*-methyl, *O*-acetyl, and *N*-acetyl substituents of carbohydrate derivatives can be readily measured by the INDOR method and the shifts of the methoxyl-methyl substituents have a pronounced stereospecific dependence which has some diagnostic potential. The INDOR method appears to have several important advantages over the direct measurement approach for obtaining the *natural-abundance*, ^{13}C spectra of methyl substituents. For example, spectra can be obtained on a rapid, *single-scan*, basis using moderate concentrations and 5 mm o.d. n.m.r. tubes. However, it is quite obvious that these advantages do not apply as directly to the measurement of the ^{13}C shifts of other substituents such as the ring-carbons of pyranose sugars. For such resonances, it is probably best

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

to use direct-measurement methods which are, mercifully, becoming less time consuming (1) than they were.

We have used the apparatus outlined in this paper to measure on a routine-basis the resonances of a number of other nuclear species, including ^{2}H, ^{19}F, ^{29}Si, ^{31}P, ^{117}Sn, ^{119}Sn, ^{199}Hg, and ^{207}Pb; we shall report on these studies elsewhere.

We thank the National Research Council of Canada for their generous financial support, especially for the equipment grant (E 1338) for the frequency synthesizer which forms the basis of our INDOR spectrometer. The digital programmer was purchased with funds from the President's Research Fund of the University of British Columbia. It is a pleasure to thank Professor C. A. McDowell for his continued interest.

Effect of an External Heavy Atom on the Photochemistry of Monofluorobenzene Vapor. II

M. E. MacBeath and I. Unger

Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received August 25, 1970

The effect of added Xe on the singlet and triplet yields of monofluorobenzene vapor excited at 2670, 2520, and 2470 Å has been reinvestigated. The fluorescent yields, and hence the singlet yields, were monitored directly while triplet yields were determined by both the sensitized emission of biacetyl technique and the isomerization of olefins technique. The data obtained confirm that Xe enhances intersystem crossing in monofluorobenzene (1). However, contrary to results previously published from this laboratory (1), Xe does not quench the triplet state of biacetyl.

Canadian Journal of Chemistry, 49, 594 (1971)

Introduction

It has been established that Xe enhances singlet–triplet transitions in all phases (2–5). The effect appears to be most marked in liquid phase and it was recently reported (6) that for benzene solutions irradiated at 254 nm, a [Xe] of 0.2 *M* completely converts all the benzene singlets to the triplet state. A communication (1) from this laboratory indicated that Xe promoted intersystem crossover in monofluorobenzene (FB) vapor excited at 2470, 2520, and 2670 Å. It was also suggested, in the previous report (1), that Xe could quench the phosphorescent emission of biacetyl (BiA) by the reaction

$$^3\text{BiA} + \text{Xe} \rightarrow \text{BiA} + \text{Xe}$$

Further work (7) on the photochemistry of BiA excited at various wavelengths and with a number of added inert gases including Xe showed that the above reaction did not occur. Consequently it was decided to reexamine the effect of Xe on FB and to monitor the triplet yield of FB by both the sensitized emission of BiA technique (8), as was the case previously (1), and by the isomerization of olefins technique (9).

Experimental

Materials

The monofluorobenzene used was obtained from the Aldrich Chemical Company and used without further purification after a vapor phase chromatographic (v.p.c.) check showed it to be 99.98% pure. The biacetyl, from the same company, was stored in a dark bulb and purified by bulb-to-bulb distillation in vacuo. The xenon was "Research Grade" from Matheson Company and was used without purification since the only impurity quoted was 10 p.p.m. of krypton. Similarly, Philips research grade *cis*-butene-2 having less than 0.1% impurity was used without further purification. The CO_2 was obtained from "Dry Ice" by bulb-to-bulb sublimation *in vacuo*, only the middle portion being retained for use. All materials were thoroughly out-gassed prior to use.

A modified Aminco-Bowman spectrophotofluorometer was used for all emission and absorption measurements. Experimental details concerning the light source, slit widths, band pass, method of obtaining absorption and emission measurements, and correction factors have been given previously (10) except that an R136 potted photomultiplier tube (Aminco: No. C156-62140) was used for viewing emission.

The vacuum system was exactly the same as that described in ref. 1.

For the isomerization experiments two quartz cylindrical cells were used, 10 cm long by 5 cm in diameter. The light source employed was a compact arc Hg–Xe 1000 W lamp from Hanovia (No. 1-5080-000). It was operated at 27 A and 26 V d.c., and cooled by air flow to 110–130 °C during operation. The beam from this lamp was focused on a 6.0 mm entrance slit of the first of two 0.25 m Ebert Monochromators operating as a double monochromator (Model 82-410 obtained from Jarrell-Ash Company). The exit slit from the second monochromator was 2 mm. This arrangement gave the following spectral distributions

Setting (Å)	Range (Å)	Maximum intensity (Å)	Half band width (Å)
2470	2390–2490	2445	52
2520	2495–2530	2523	10
2660	2600–2685	2657	28

The emerging light beam was made to strike a torroidal mirror placed at a 45° angle off axis and 3 cm from the exit slit of the second monochromator. This mirror, 7.5 cm in diameter, had a tangential radius of 41.19 cm and a sagittal radius of 20.60 cm. The reflected beam impinged on a diagonal beam splitting plate, 7 cm away. This plate of fused quartz and achromatic from 2000 Å to the visible was made by the Continental Optical Corporation (Farmington, New York). It was 3 in. in diameter, parellel to 2 in. with its two surfaces flat to 1/20 wave and had transmission approximately equal to reflection. The split beam then passed through the cells

(labelled A and B) containing the samples to be photolyzed. Cell B always contained 10 Torr FB and 100 Torr *cis*-butene-2 while cell A in control experiments contained exactly the same mixture. In those photolyses when the effect of Xe was being studied, both cells contained the same mixture as in control experiments except that a given pressure of Xe was put into cell A. A Hg- and grease-free high vacuum system equipped with Hoke metal valves was used for filling the cells and in obtaining samples from them.

Samples from the cells after photolysis were analyzed by v.p.c. on a Model 500 Linear Programmed Temperature Gas Chromatograph made by the F and M Scientific Corporation. A 25 ft column containing 15% dinonylphthalate on Chromosorb P was used at 35 °C with helium carrier gas and a flow rate of 45 cc/min. The retention time for *trans*-butene-2 was 13 min 40 s; for *cis*-butene-2, 14 min 10 s.

Results and Discussion

All emission yields reported in this paper are on a relative basis, they may be converted to absolute values by referring to absolute fluorescent yields given previously (11).

Addition of Xe to FB excited at 2470, 2520, and 2670 Å produces a decrease in the fluorescent emission yield and plots of $1/\Phi_f$ *vs.* Xe are linear, see Fig. 1. The above is also true when Xe is added to mixtures of FB and BiA, see Fig. 2. The fluorescent data substantiate those reported previously (1) and thus will not be discussed extensively here. However, it should be noted that other added gases (CO_2, $CHCl_3$) do not quench the fluorescent yield (10).

Addition of Xe to mixtures of FB and BiA produces an increase in the sensitized emission yield at all exciting wavelengths studied, see Fig. 3. While this behavior is completely contrary to that noted previously (1) for the Xe, FB, BiA system, it is consistent with the known photochemical behavior of BiA excited below 4000 Å (12).[1] Furthermore this sort of effect should be expected since the triplet of FB is estimated to lie at 80 kcal (13). Consequently energy transfer from FB triplets to BiA will result in BiA triplets whose energy would be more nearly equivalent to those formed from the direct excitation of BiA at about 3600 rather than 4358 Å. Such BiA triplets are vibrationally hot and will dissociate, without emitting, unless a vibrational quencher

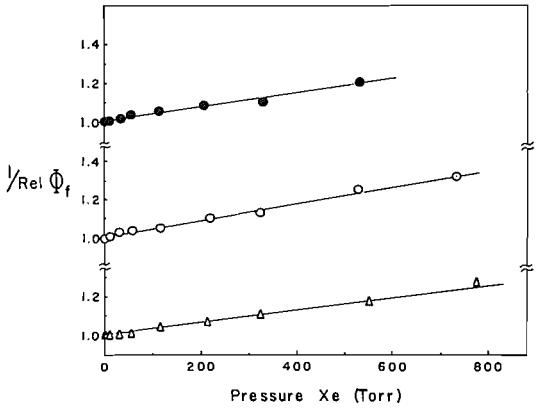

FIG. 1. The effect of Xe on the relative fluorescent yield of FB excited at 2470 Å, △; 2520 Å, ○; 2670 Å, ●. FB pressure constant at 10 Torr.

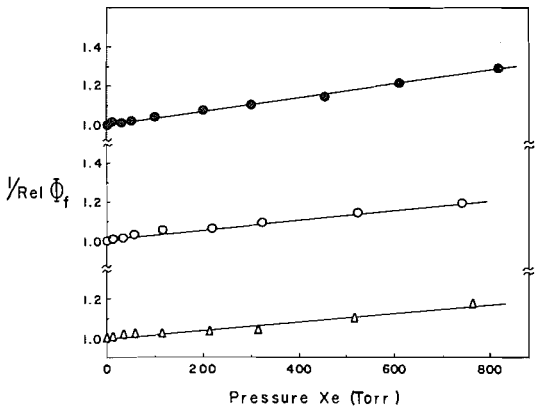

FIG. 2. The effect of Xe on the relative fluorescent yield of mixtures of FB and BiA, excited at 2470 Å, △; 2520 Å, ○; 2670 Å, ●. FB pressure = 10 Torr, BiA pressure = 5 Torr.

is present. We suggest therefore that in the system FB–BiA, the addition of Xe serves both to enhance intersystem crossover from the FB singlet to the triplet and to quench vibrationally hot triplet BiA molecules, thus causing an increase in the sensitized emission yield of BiA. Consequently the sensitized emission of BiA technique cannot be used to establish whether or not Xe enhances intersystem crossover in this system.

That the presence of Xe increases the triplet yield of FB, at all exciting wavelengths studied, is corroberated by the olefin isomerization experiments; the results are summarized in Table 1. The increase in triplet yield given in Table 1 should be fairly accurate in spite of the possibility

[1]A recent study done in this laboratory (7) indicates that when a sample of BiA vapor (at a pressure of 9 Torr) is irradiated at 3650 Å and Xe is added, the phosphorescent yield of BiA increases steadily, leveling off at around 400 Torr of Xe when the increase amounts to a little over 100% of the original quantum yield.

2670	300	0	0.569±0.029	15.0

*FB pressure = 10 Torr, *c*-B-2 pressure = 100 Torr, in both cells. Cell B was used as a control containing no added CO_2 or Xe. Photolysis time = 9 h.
†Average value of 4 runs interspersed between runs with either CO_2 or Xe added in cell A.
‡The increase in the triplet yield was calculated, using recent values for the ratio of the rates of *cis–trans* isomerization (16, 17), i.e. (the difference in the amount of isomerization with and without added gas) × 1.98.

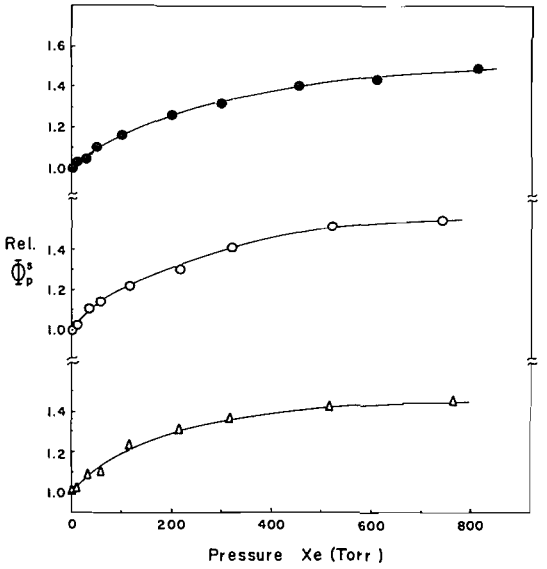

FIG. 3. The effect of Xe on the relative phosphorescent yield of BiA sensitized by FB excited at 2470 Å, △; 2520 Å, ○; 2670 Å, ●. FB pressure = 10 Torr, BiA pressure = 5 Torr.

of photo-adduct formation between FB and *cis*-butene-2 (*c*-B-2) since such reactions only occur in very small yield (14) and since the experimental set up was such that two identical cells containing identical mixtures of FB and *c*-B-2 were irradiated simultaneously by a beam of light originating from a single source, being split just prior to entering the cells. The only difference was that Xe was added to one of the cells. Finally, in order to be certain that the increase in triplet FB formation in the presence of Xe was not due to some sort of pressure effect, several experiments were carried out with added CO_2 in place of Xe. Addition of CO_2 does not markedly increase the triplet FB yield, except at 2470 Å. At 2470 Å, CO_2 prevents the dissociation of vibrationally hot singlet FB molecules, see Table 1.[2]

A kinetic scheme capable of explaining our experimental observations is given below

[1*a*] $FB + h\nu \rightarrow {}^1FB^I$

[1] ${}^1FB^I \rightarrow FB + h\nu_f$

[2] ${}^1FB^I \rightarrow {}^3FB^I$

[3] ${}^1FB^I + Xe \rightarrow {}^3FB^I + Xe$

[4] ${}^1FB^I + FB \rightarrow 2\ FB$

[5] ${}^3FB^I \rightarrow FB$

[2]The fluorescent yield of FB excited in the 2500 Å region has been given as 0.13 to 0.17 (10) depending on wavelength and the triplet yield in this region varies from 0.39 to 0.48 (10). Our fluorescence data indicate that the net decrease in the singlet yield at λ_{ex} 2470 Å and 500 Torr of Xe is 2%, at λ_{ex} 2520 Å and 500 Torr of Xe it is 3.5%, while at λ_{ex} 2670 Å and 300 Torr of Xe it is 2%. The isomerization studies show that the net increases in triplet yield at the same wavelengths and pressures are respectively ~ 3.2, 7.4, and 7.4%.

[6] $^1FB^I + BiA \rightarrow {}^1BiA^{II} + FB$

[7] $^3FB^I + BiA \rightarrow {}^3BiA_v^I + FB$

[8] $^1BiA^{II} \rightarrow$ Dissoc

[9] $^3BiA_v^I + M \rightarrow {}^3BiA_0^I + M$

[10] $^3BiA_0^I \rightarrow BiA + h\nu_p$

[11] $^3BiA_0^I \rightarrow BiA$

[12] $^3BiA_v^I \rightarrow$ Dissoc

In the above scheme arabic numerals denote spin multiplicity, roman numerals indicate 1st and 2nd excited states, the subscript 0 represents a molecule in its lowest vibrational level, the subscript v a molecule in a hot vibrational level, and M denotes any species capable of removing vibrational energy, or, in our case, the total pressure of FB, BiA, and Xe. This kinetic scheme differs only from the one suggested previously (1) in that it allows for the formation, dissociation, and vibrational deactivation of hot triplet BiA molecules. The scheme predicts (1) that plots of $1/\Phi_f$ *vs.* Xe pressure should be linear which is confirmed experimentally, see Figs. 1 and 2.

Application of the steady state treatment to this scheme gives for the phosphorescent emission yield of BiA

$$[13] \quad \Phi_p = \left(\frac{k_{10}k_9[M]}{k_{10} + k_{11}}\right)\left(\frac{k_7[BiA]}{k_4[M] + k_{12}}\right)\left(\frac{k_2 + k_3[Xe]}{k_5 + k_7[BiA]}\right) \times \left(\frac{1}{k_1 + k_2 + k_3[Xe] + k_4[FB] + k_6[BiA]}\right)$$

Our experimental observations indicate that k_3 is small, also it has been shown that k_2 is large (15); one may therefore neglect $k_3[Xe]$ with respect to k_2 and bearing in mind that in all the experiments the FB and BiA pressures were constant eq. 13 reduces to

$$[14] \quad 1/\Phi_p = K_1 + K_2/[M]$$

where K_1 and K_2 are collections of constants. Equation 14 predicts that a plot of $1/\Phi_p$ *vs.* 1/[M] should be linear. This prediction is confirmed experimentally at low pressures of Xe; at high pressures of Xe the assumption made above is not justified and the plots rapidly begin to deviate from linearity, see Fig. 4.

The only explanation that we can offer for the previous observation that Xe quenched the phosphorescent emission of BiA (1) is that trace quantities of O_2 must have been present in the previous study.

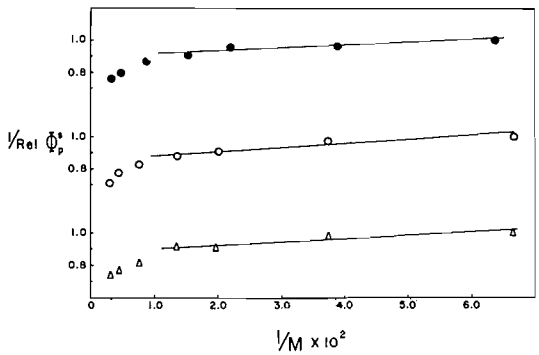

FIG. 4. Plots of $1/\Phi_p$ *vs.* 1/[M] excited at 2470 Å, △; 2520 Å, ○; 2670 Å, ●. FB pressure = 10 Torr, BiA pressure = 5 Torr, M = total pressure of FB + BiA = Xe.

Chalkogenides of the Transition Elements. VIII. An X-Ray and Neutron Diffraction Study of the Spinel $CoNi_2S_4$[1]

CHUNG-HSI HUANG[2] AND OSVALD KNOP
Department of Chemistry, Dalhousie University, Halifax, Nova Scotia

Received August 26, 1970

The crystal structure of the spinel $CoNi_2S_4$ was refined from X-ray and neutron powder-diffractometer data. The lattice parameter at room temperature and the positional parameter of the sulfur atom were determined as 9.424(1) Å and 0.2591(3). The neutron intensities show clearly that $CoNi_2S_4$ is an inverse spinel, $Ni[CoNi]S_4$.

Canadian Journal of Chemistry, 49, 598 (1971)

In a previous investigation by X-ray and neutron diffraction (1) it was established that the spinel $NiCo_2S_4$ is normal or essentially normal, $Ni[Co_2]S_4$. The analogous spinel $CoNi_2S_4$ was prepared by Bouchard *et al.* (2), who reported its lattice parameter but did not refine its structure or determine the distribution of the Co and Ni atoms. This has now been done by X-ray and neutron powder diffraction.

Experimental

The sample (120 g) for neutron diffraction was prepared by direct synthesis from the elements *in vacuo* (sample I). Freshly reduced high-grade cobalt and nickel powders (Sherritt-Gordon Grade S) and sublimed sulfur were slowly reacted by raising the furnace temperature gradually to 500°. The product was ground to pass 100 mesh, thoroughly mixed by repeated screening, resealed under vacuum and kept at 550° for 3 days. The procedure was then repeated and the powder annealed successively at 600° for 2 days, 550° for 5 days, and 500° for 6 days; ground again and kept at 500° for one month; and finally at 500° for 20 days. In each annealing step the sample was cooled from 500° to room temperature at an average rate of 50°/day and the condition of the product was examined by powder diffraction.

For comparison, a 15 g sample was prepared in a similar manner from spectrographic-grade elements (sample II). After the final annealing both samples were homogeneous and their lattice parameters were practically the same (Table 1). Both were slightly larger than the a_0 reported in ref. 2.

Density of sample I was determined by weighing in air and in CCl_4 (for details of method *cf.* ref. 15). The mean of 4 determinations at 22.5(5)° was 4.756(8) g/cm³. This is 1.6(3)% lower than the density calculated from a_0 and $N = 6.0226 \times 10^{23}$, 4.829(3) g/cm³, which indicates that the intrinsic vacancy concentration could not have been unusually high.

Integrated X-ray diffraction intensities from sample I were obtained with a Philips powder diffractometer fitted with a focussing monochromator after the rotating specimen. This arrangement gave very low background counts. Copper K radiation ($\lambda_{\alpha_1} = 1.54056$ Å, $\lambda_{\alpha_2} = 1.54440$ Å) was used throughout. For details of specimen preparation (smear mounts), counting, etc., refs. 1 and 16 may be consulted.

The neutron-diffraction experiments were performed at the NRX reactor of Atomic Energy of Canada Limited at Chalk River, Ontario. The neutron beam was monochromatized by Bragg reflection from the (111) plane of

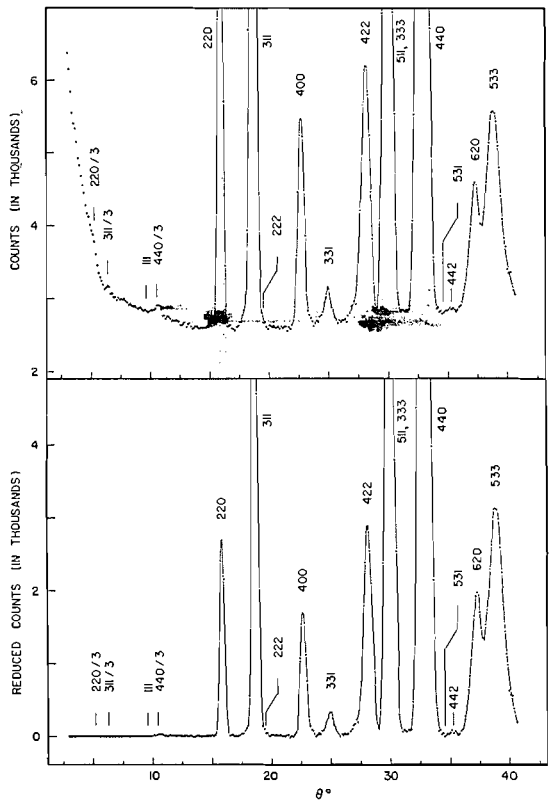

FIG. 1. Raw (*top*) and reduced (pF^2; *bottom*) neutron diffraction patterns of $CoNi_2S_4$ at room temperature. Monochromator, Ge(111); $\lambda = 1.801$ Å; average counting time per point, 8 min.

a squeezed Ge crystal ($\lambda = 1.801$ Å, $2\theta_M = 32.0°$). This choice of wavelength and a single-crystal quartz filter 5 in. thick practically eliminated the third-order contamination of the incident beam. The raw diffraction pattern was reduced to a pF^2 pattern (Fig. 1) and the peaks were fitted (and resolved, where necessary) by Gaussian analysis.

The origin of the unit cell of the spinel structure (space group *Fd3m*) was taken at the center of symmetry. Cromer and Waber's X-ray scattering factors (17) and dispersion corrections (both parts; ref. 18) for Co and Ni, and neutron scattering amplitudes listed in ref. 19, were used in full-matrix least-squares refinements (*cf.* ref. 1 for other details). Weighting scheme W3 was normally employed in refinements from $|F_o|$, while in refinements from intensities the weights were defined as $w(hkl) = \varepsilon^{-1}(hkl)$ (*cf.* ref. 20).

Results and Discussion

Refinement from X-Ray Data

The 40 integrated powder intensities that were measured correspond to the 53 reflections possible in *Fd3m* up to and including 10.6.0 + 866. The refinements from intensities thus included all the information obtainable from a powder specimen of $CoNi_2S_4$ within this volume of the Cu K_α sphere of reflection. These refinements and *F*-refinements from the 28 single reflections in the measured set gave practically identical values of x(S), regardless of whether individual isotropic temperature factors or an overall temperature factor were employed (Table 2). There was no significant difference, at the 50 or 25% levels (21), between results which were obtained using neutral scattering factors, ionic scattering factors, and different cation distributions. However, it was found that *I*-refinements gave best results when the weighting scheme $\varepsilon^{-1}(hkl)$ was employed, while the *F*-refinements responded best to the weighting scheme W3.

The value of 0.2591(3) is considered to be the best estimate, from the present investigation, of

x(S) in $CoNi_2S_4$. The agreement of $|F_o|$ and F_c is shown in Table 3.

Refinement from Neutron-diffraction Data

The raw pattern was of a better quality than a similar pattern obtained previously for $NiCo_2S_4$ with an Al(111) monochromator (1). Twelve of the 14 peaks extracted from the reduced pattern corresponded to single reflections and were used in F-refinements (Table 4). In spite of uncertainties in the baseline correction the three-parameter refinement based on a completely inverse distribution, Ni[CoNi]S_4, gave very reasonable values of R and e.s.d.(w) (*cf.* the corresponding figures for $NiCo_2S_4$ in ref. 1). As might be expected, the scale factor was strongly correlated with the temperature factor (0.516), but the other two correlations were weak. The x(S) value was quite close to those obtained in the X-ray refinements.

*The intensities have been normalized to $I_c(311) = 100$. These monochromatized integrated intensities are converted to conventional integrated intensities I' by multiplication by the ratio of the polarization factors, $(1 + \cos^2 2\theta)/(1 + 0.66 \cos^2 2\theta)$.

†Inverse model. The pF_c^2 values are based on the F-refinement using individual isotropic temperature factors (see text). The reduced intensities have been normalized to $pF_c^2(440) = 100$.

The results of the refinements for random and normal distributions were very poor (Table 4). Compared with the inverse model they could be rejected at the 0.5% significance level. The drastic increase in R from the inverse to the random model shows unmistakeably that the inverse ordering is complete or very nearly so: R or e.s.d.(w) plotted against the ordering parameter s give straight lines.[3] A separate K,s,B-refinement based on x(S) = 0.2591 resulted in a value of s that corresponds clearly to an inverse arrangement, 0.00(2) (Table 4).

The observed and calculated pF^2 values for the inverse model are compared in Table 3, and a comparison of the reduced intensities is shown for all three models in Fig. 2. The trend, with increasing θ, toward low F_c values was removed by using individual temperature factors instead of B(overall), but $B(8a)$ tended to assume negative indefinite values, and the B's were strongly correlated among themselves and with the scale factor; an exception was $B(16d) - B$(S). Since the positional parameter refined to 0.2592(2), further attempts to improve on the pF^2 agreement were abandoned.

Interatomic Distances

These are compared in Table 1 with similar distances in a number of related sulfospinels. Since in Co_3S_4, $NiCo_2S_4$, and $CoNi_2S_4$ the numerical values of x(S) are very similar, the M—S distances are determined essentially by the lattice parameter a_0. The differences in a_0 being real (*i.e.*, well outside the standard deviations), the differences between the corresponding Co—S and Ni—S distances, though slight, should also be real. On the other hand, $\delta(M^{IV}—S) \simeq 17\,\delta x + 0.22\,\delta a_0$ and $\delta(M^{VI}—S) \simeq -9\,\delta x + 0.24\,\delta a_0$. For typical values of $\delta x = 3\sigma(x) = 0.001$ and $\delta a_0 = 2\sigma a_0 = 0.002$ Å one has $\delta(M^{IV}—S) = (0.017 + 0.0005)$ Å and $\delta(M^{VI}—S) = (-0.009 + 0.0005)$ Å. Hence the distances are much more sensitive to variations in x(S) than to variations in a_0. This must be taken into

[3] *Cf.* ref. 1 for definition of s.

TABLE 4. Results of full-matrix refinements of $CoNi_2S_4$ from neutron data

Nature of refinement	No. of cycles	x(S)	B(overall) (Å^2)	s	R (%)	R_w (%)	e.s.d.(w)

K,s,B							
s (initial) $= \frac{1}{3}$	22	—	1.12(20)	0.000(21)	4.62	3.83	0.14

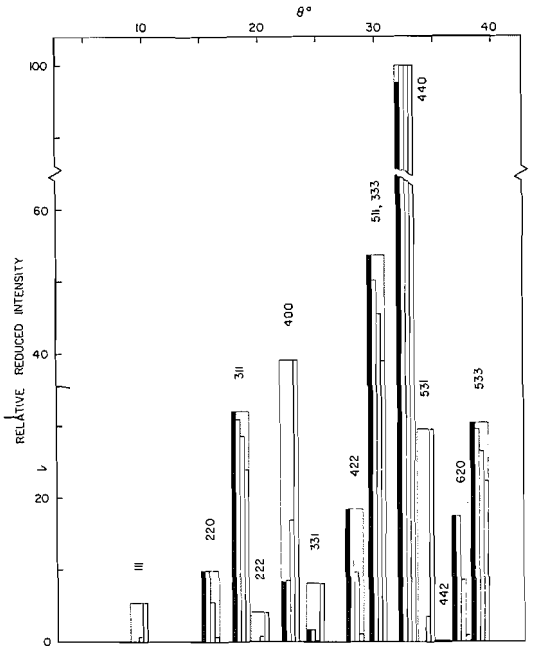

FIG. 2. Comparison of the reduced (pF^2) neutron diffraction pattern of $CoNi_2S_4$ with the pF^2 patterns calculated for the three assumed model structures. The individual peak heights in each composite column correspond, from left to right, to the observed pattern, to the completely inverse, to the random, and to the completely normal distributions, respectively. The relative reduced intensities have been normalized to pF_c^2(440).

account when considering the apparent constancy of x(S) in the three sulfides in the light of the respective $3\sigma(x)$ estimates. For example, while the independent estimates of Co^{VI}—S in Co_3S_4 and $NiCo_2S_4$ are very similar and appear to support the optimistic view of the accuracy of determination of this interatomic distance, the independent estimates of the Ni^{IV}—S distances in $NiCo_2S_4$ and $CoNi_2S_4$ differ by 0.016 Å, which in magnitude is almost three times the difference between Co^{IV}—S in Co_3S_4 and Ni^{IV}—S in $CoNi_2S_4$. All these differences are however within their respective error estimates.

The uncertainties in x(S) and the smallness of the differences in the lattice parameters and M—S distances render interpretations of the oxidation and spin states in the four $(Co,Ni)_3S_4$ spinels from dimensional arguments largely speculative. The Co^{VI}—S distance in Co_3S_4 and $Ni[Co_2]S_4$, 2.27 Å, is significantly smaller than similar distances in CoS_2 (*C*2) and Co_9S_8, 2.32 and 2.39 Å respectively (1). If cobalt is present in CoS_2 as Co_{LS}^{2+} (*cf.* ref. 1), then Co^{VI} in Co_3S_4 would appear to be at least partly Co^{3+} and probably Co_{LS}^{3+} (*cf.* ref. 7), so that Co_3S_4 could be formulated as $Co_{HS}^{2+}[Co_{LS}^{3+}\ Co_{LS}^{3+}]S_4$.[4] The analogous formulation of $Ni[Co_2]S_4$ as $Ni_{HS}^{2+}[Co_{LS}^{3+}\ Co_{LS}^{3+}]S_4$ would seem to account for the increase of 0.037(4) Å in a_0 from $Ni[Co_2]S_4$ to $Ni[CoNi]S_4 = Ni_{HS}^{2+}[Co_{LS}^{3+}\ Ni_{LS}^{3+}]S_4$, and for the further increase of 0.056(6) Å from $Ni[CoNi]S_4$ to $Ni_3S_4 = Ni_{HS}^{2+}[Ni_{LS}^{3+}Ni_{LS}^{3+}]S_4$, even though the observed increase in M^{VI}—S from $Ni[Co_2]S_4$ to $Ni[CoNi]S_4$ is very small, if any, 0.006(14) Å. However, substitution of the tetrahedrally-coordinated Co^{IV} atom in Co_3S_4 by Ni causes the lattice parameter to decrease by 0.019(4) Å (Table 1). This decrease implies a reduction instead of the expected increase in M^{IV}—S and consequently in a_0, unless there is compensation by a simultaneous decrease in x(S); the increase would be small for $Co_{HS}^{3+} \rightarrow Ni_{HS}^{3+}$. If compensation were present, the Co^{VI}—S distance would become greater, which is inconsistent with the assumption of Co^{VI} being in the Co_{LS}^{3+} state in both compounds.

The difficulty with this and alternative explanations based solely on size criteria is that they do not take account of the effect of possible differences in the degree of electron delocalization on the metal atoms in the four sulfospinels, nor of the possible existence of mixed oxidation states.

[4]It is appreciated that the formulae used here are not completely appropriate descriptions of these sulfides, which show metallic conduction (2).

Furthermore, a change in a_0 amounting to 0.01 Å will produce a variation of 0.005 Å in an M—S distance, but the same variation results in M^{IV}—S by changing x(S) by only 0.0003, and in M^{VI} by changing x(S) by only about 0.0006. To explain with confidence the reasons for an observed difference in the lattice parameters of any two of the four spinels the x(S) values would have to be known to within at least ± 0.0001 or better, an accuracy which cannot be achieved by powder diffractometry. This constitutes a strong plea for redetermination of the structures of these sulfospinels from accurate low-temperature single-crystal intensities, paying proper attention to the dependability of available scattering factors for Co and Ni.

We wish to express our gratitude to the staff of the Neutron Physics Branch, Atomic Energy of Canada Limited, for making available the neutron diffraction facilities and for assistance with the experiments. Award of an INCO graduate fellowship to one of the authors is gratefully acknowledged.

Oxochloride Complexes of Rhenium[1]

A. GUEST[2] AND C. J. L. LOCK[3]

Department of Chemistry and Institute for Materials Research, McMaster University, Hamilton, Ontario

Received September 4, 1970

Attempts to prepare rhenium hexachloride by the method described by Colton (2) have been unsuccessful. The products of the reaction were always impure rhenium oxotetrachloride and rhenium pentachloride. A compound of rhenium(VI), $ReOCl_4OPCl_3$, is shown to have a structure analogous to that of rhenium(V) ions $[ReOX_4.L]^-$ in which the ligands are in a pseudooctahedral arrangement with L *trans* to the oxo-group (3). Reactions of $ReOCl_4$ and $ReOCl_4$-$OPCl_3$ with pyridine and 2,2′-dipyridyl are described, and a scheme is proposed for the reactions of the products. Two stable complexes of perrhenyl chloride with the above amines have been obtained.

Introduction

The highest chlorides of molybdenum and tungsten are $MoCl_6$ (4) and WCl_6 (5). The highest chlorides of ruthenium and osmium are $RuCl_3$ (5) and $OsCl_4$ (5). Thus, there is a decrease in the highest formal oxidation state which is stabilized by chlorine in going from the group VIA metals to the group VIII metals. The preparation of $TcCl_6$ (6) as the highest chloride of technetium was surprising therefore, particularly because both $MoCl_6$ and $ReCl_6$ were unknown at the time, the highest chloride of rhenium being the pentachloride (5).

Subsequently, the preparation of rhenium hexachloride was reported (2) by Colton. Colton noted that previous workers who prepared their own rhenium metal had observed "green vapors" in chlorination reactions (7), but these reports ceased when the metal became available commercially. Commercial metal gave only rhenium pentachloride on chlorination. Colton repeated the work of the early workers and was able to get small amounts of "green vapors". A much improved yield could be obtained if ammonium perrhenate was absorbed on porous pot, the salt reduced to rhenium metal with hydrogen and the resulting finely divided metal chlorinated. The product was "dark dichroic crystals which melt a few degrees above room temperature to give a black liquid and green vapors", and was claimed to be rhenium hexachloride (2). The observed magnetic moment of 2.07 B.M. was high for a d^1 system (9), particularly as ReF_6 has a reported effective magnetic moment of 0.25 B.M. at room temperature (10). The low moment of ReF_6 has been attributed to large spin–orbit coupling effects resulting from the postulated O_h symmetry of the molecule. Brown and Colton (9) postulate that this high symmetry was not present in $ReCl_6$, and thus a low magnetic moment was not observed. We were interested in studying the magnetic properties of $ReCl_6$ further but we have tried without success to prepare $ReCl_6$. Studies of $ReOCl_4$ suggest that "$ReCl_6$" might be impure $ReOCl_4$. Certain of the results of our studies on $ReOCl_4$ have been anticipated in another paper (11). As a continuation of our studies of this system we have investigated reactions of $ReOCl_4$ and also ReO_3Cl.

Experiments

Most analyses for carbon, hydrogen, chlorine, and phosphorus were performed by Galbraith Laboratories, Inc., Knoxville, Tennessee. Some carbon, hydrogen, nitrogen, and chlorine analyses were performed by A. B. Gygli, Toronto, Ontario and some phosphorus analyses were performed by A. Bernhardt, West Germany. Rhenium and chloride analyses and rhenium:chlorine ratios were determined by neutron activation using a method described by us previously (12).

Infrared spectra were recorded on Perkin–Elmer 337, 521, and 301 instruments. Solid samples were ground into a mull with dry Nujol and mounted between potassium bromide or polyethylene plates. The Nujol was dried by refluxing over phosphorus pentoxide and then vacuum distilled. Solution samples were prepared using carbon tetrachloride or titanium tetrachloride as solvents. The solutions were contained in standard solution cells with potassium bromide windows, or were injected into sealed polyethylene sacks using a syringe. Gas samples were contained in the special cell described by us previously (13) or in a glass cell with polyethylene windows fused directly to the glass under pressure. Magnetic susceptibilities were determined for solid samples from −180 to 25 °C using an apparatus described previously (1).

Purification of Reagents and Solvents

Carbon Tetrachloride

Carbon tetrachloride was dried by distillation from phosphorus pentoxide, and stored in a dry-box[4] over freshly regenerated molecular sieve (type 4A).

Chlorine

Commercial chlorine (supplied by Matheson, Whitby, Ontario) was dried by passing through concentrated sulfuric acid and phosphorus pentoxide traps, then condensed in a trap cooled in liquid nitrogen. The solid chlorine was evacuated at 10^{-4} mm Hg. The chlorine was allowed to warm up, melt, and start to boil and was then refrozen in liquid nitrogen and again evacuated to 10^{-4} mm Hg. This process was repeated until no increase in pressure was observed when the trap containing solid chlorine was opened to the vacuum line. A steady stream of chlorine was obtained from the trap by allowing the liquid to boil off at −31.5 °C. This temperature was maintained by standing the chlorine container in a slush of "*m*"-toluidine.

Hydrogen

Commercial grade hydrogen (supplied by Canadian Liquid Air) was dried by passing through concentrated sulfuric acid and phosphorus pentoxide traps.

Nitrogen

Purified grade nitrogen (supplied by Canadian Liquid Air) was deoxygenated by hot activated copper in an apparatus described elsewhere (14), and then dried by passing through concentrated sulfuric acid and phosphorus pentoxide traps.

Oxygen

Commercial grade oxygen (supplied by Canadian Liquid Air) was dried by liquefication of the gas in a liquid nitrogen cooled trap in a similar manner to that described for chlorine. The oxygen was then allowed to evaporate slowly by controlled cooling with liquid nitrogen.

Pyridine

Reagent grade pyridine was dried by distillation from barium oxide as recommended by Leis and Currans (15).

Thionyl Chloride

Thionyl chloride was purified by the method of Friedman *et al.* (16) by distillation from triphenyl phosphite.

All other reagents and solvents used were of the normal reagent grade.

Preparation and Purification of Rhenium Compounds used as Starting Materials

Metallic Rhenium

Rhenium metal was obtained commercially in powdered form and purified by reduction with hydrogen where indicated in the text. In all other cases, the powder was vacuum dried at 120 °C for 24 h before use. Suppliers of rhenium were Johnson, Matthey and Mallory (Toronto, Ontario), The University of Tennessee, and Chase Brass and Copper Company, Rhenium Division, Solon, Ohio.

[4]Vacuum Atmospheres Corporation Dryboxes Models DRILAB HE-43 and HE-43-2.

Rhenium Heptoxide

Some rhenium heptoxide was purchased from the University of Tennessee and some from Koch-Light Laboratories, Colnbrook, Bucks., England, but most was prepared by burning rhenium in oxygen, in an apparatus of the type described by McLaren *et al.* (17).

Rhenium Trioxide

Rhenium trioxide was prepared by reduction of rhenium heptoxide by two different methods. (*i*) Rhenium heptoxide was reduced with dioxan as described by Nechamkin and Hiskey (18). This method was found to be messy and high yields of trioxide were difficult to obtain. (*ii*) A method (19) for producing ReO_3 by reducing Re_2O_7 with CO was modified and the reaction carried out at high pressure. Re_2O_7 was finely ground in a dry-box and transported to the autoclave in a stoppered bottle. The Re_2O_7 was placed in a glass liner and the autoclave sealed and flushed with carbon monoxide as rapidly as possible to minimize hydrolysis of the Re_2O_7 by atmospheric moisture. After reduction at 200 °C and 500 p.s.i.g. carbon monoxide pressure for 24 h, the product was washed with water to remove unreacted starting material and dried at 110 °C. Ninety percent yields of very pure rhenium trioxide were recorded.

Perrhenyl Chloride

Perrhenyl chloride was prepared according to the method of Wolf *et al.* (20) by direct chlorination of rhenium trioxide at 180 °C. The pale yellow product was isolated in break seals and purified by trap-to-trap distillation to give a colorless liquid product. Yields of pure compound were about 70%.

Rhenium Oxotetrachloride

(*a*) Rhenium oxotetrachloride was prepared by the method of Bagnall *et al.* (21) from rhenium heptoxide and thionyl chloride. The product of this reaction was invariably contaminated by sulfur dioxide, which proved very difficult to remove by vacuum distillation. The presence of sulfur dioxide was readily detected by its gas-phase ultraviolet spectrum (22). (*b*) Direct chlorination of rhenium metal gave low yields of rhenium oxotetrachloride if powdered rhenium was used, but gave high yields of rhenium oxotetrachloride if rhenium metal suspended on porous brick was used. The oxotetrachloride was separated from pentachloride which was also produced by pumping at reduced pressure, but separation from other volatile products was tedious. Thirty or forty trap-to-trap distillations were sometimes required to remove all impurities (see Discussion).

Rhenium Pentachloride

Some rhenium pentachloride was purchased from Alpha Inorganics, Beverley, Mass. and Shattuck Chemical Company, but was generally prepared either by a modification of the method of Hurd and Brimm (23) using distillation through U-tubes as the method of purification, or by the method of Knox *et al.* (24). The material obtained was usually in the form of small crystals. The best method of purifying the material was to seal rhenium pentachloride in a Carius tube with chlorine and distil it along the tube by applying a temperature gradient. Large plate-like crystals were obtained. Rhenium pentachloride so obtained is a black crystalline material which melts at 261 °C.

Anal. Calcd. for Cl_5Re: Cl, 48.8; Re, 51.2. Found: Cl, 49.7; Re, 51.6. Re:Cl ratio (average of twelve different samples) 1: 4.98 ± .02.

Rhenium pentachloride was refluxed with liquid chlorine for several hours in an evacuated system. In certain experiments the bulb was irradiated with ultraviolet light during the period of reflux. Rhenium pentachloride was obtained essentially unchanged; there was no sign of a higher chloride. This was confirmed by analysis and by a mixed melting point (261 °C) with a genuine sample.

New Rhenium Compounds and New Methods of Obtaining Known Rhenium Compounds

Rhenium Oxotetrachloride

Rhenium pentachloride and dry oxygen were sealed in a Carius tube which was fitted with a break-seal. The tube was heated to 180 °C in a furnace for a few hours. The break-seal was then attached to a vacuum line, which was evacuated and heated for at least 24 h before the seal was broken and the product distilled. This was the most convenient preparative method. Only two or three vacuum distillations were necessary to produce very pure oxotetrachloride in about 70% yield. The average Re:Cl ratio found for 18 independent neutron activation analyses on $ReOCl_4$ was 1:3.92 (±0.02).

Anal. Calcd. for Cl_4ORe: Cl, 41.4; Re, 54.1. Found[5]: Cl, 41.3, 41.1; Re, 54.1, 54.4.

Oxotrichlorobispyridinerhenium(V), [$ReOCl_3py_2$]

(*a*) Rhenium oxotetrachloride was sealed under vacuum in a tube fitted with a break-seal, and the tube above the break-seal filled with pyridine. The seal was broken with a glass rod, causing the pyridine to be sucked onto the $ReOCl_4$. The tube was shaken vigorously to dissolve the $ReOCl_4$ and form a red solution. Heat was evolved during dissolution. After 1/2 h a green precipitate was formed and continued to be formed until the red solution faded to a pale yellow. The green compound, which could also be obtained by a similar reaction using $ReOCl_4.OPCl_3$, was shown to be identical with the isomer of $ReOCl_3py_2$ described previously (25).

Anal. Found: C, 25.6; H, 2.3; Cl, 22.6; N, 5.9. Neutron activation analysis gave Cl, 22.9; Re, 40.0 (stoichiometry Re:Cl; 1:2.97(0.03)).

This was confirmed by converting our sample of $ReOCl_3.py_2$ to blue $ReOCl_2.OEtpy_2$ which had identical properties to an authentic sample (27).

Found: C, 30.2; H, 3.0; Cl, 14.7; N, 5.6. The residual yellow solution gave $[Re(py)_4O_2Cl]$ (26) on evaporation.

Oxotrichloro(2,2-Dipyridyl)Rhenium(V)

[$ReOCl_3$dipy] (28) was prepared by the reaction of α,α′-dipyridyl and rhenium oxotetrachloride.

Found: C, 25.3; H, 1.8; Cl, 22.4; N, 5.60. Neutron activation analysis gave Cl, 22.7; Re, 40.6.

μ-Oxobis[Oxodichloro(2,2-Dipyridyl)Rhenium(V)], [(dipy)$ReOCl_2$—O—Cl_2ORe (dipy)]

[$ReOCl_3$dipy] was refluxed with boiling absolute ethanol. Very slowly the solution changed to a pale orange color and a green compound was precipitated. The green compound was filtered, washed with ice-cold absolute ethanol and vacuum dried.

Anal. Calcd. for $C_{20}H_{16}Cl_4N_4O_3Re$: C, 27.5; H, 1.8; Cl, 16.3; N, 6.4. Found: C, 27.8; H, 2.1; Cl, 16.2; N, 6.3.

Yield of green, air-stable crystalline material, melting point > 300 °C was 60%.

Trioxochlorobispyridinerhenium(VII), [ReO_3Clpy_2]

Pyridine and perrhenyl chloride were dissolved separately in carefully dried carbon tetrachloride and the solutions mixed. A white precipitate was formed immediately. The precipitate was filtered, washed with carbon tetrachloride, and pumped on a vacuum-line at room temperature to remove volatile impurities. The compound was then sublimed at 100 °C in vacuum. The yield of pure, air-unstable very pale yellow compound, melting point 155 °C (decomp.) was approximately 40%.

Anal. Calcd. for $C_{10}H_{10}ClN_2O_3Re$: C, 28.1; H, 2.3; Cl, 8.3; N, 6.5; Re, 43.6. Found: C, 28.0; H, 2.9; Cl, 8.4; N, 6.3. Neutron activation analyses gave Cl, 7.9; Re, 43.4.

Trioxochloro-2,2′-Dipyridylrhenium(VII), [ReO_3Cldipy]

2,2′-Dipyridyl and perrhenyl chloride were dissolved separately in carefully dried carbon tetrachloride and the solutions mixed. The heavy white precipitate which formed immediately was filtered, washed with carbon tetrachloride, and pumped at room temperature for 24 h to remove volatile impurities. The yield of white, involatile, air-stable, compound melting point 280 °C (decomp.), was estimated at 60–70%.

Anal. Calcd. for $C_{10}H_8ClN_2O_3Re$: C, 28.2; H, 1.9; Cl, 8.3; N, 6.6; Re, 43.8. Found: C, 26.7; H, 1.7; Cl, 8.4; N, 6.1. Neutron activation analysis gave Cl, 8.0; Re, 43.1.

Oxotetrachloro(Oxotrichlorophosphorus(V)) Rhenium(VI), [$ReOCl_4(OPCl_3)$]

(*a*) A Pyrex tube was constructed with a constriction in the middle giving two sections A and B. A break-seal was fitted to A and an inlet tube to B. In a dry-box, powdered phosphorus pentachloride was weighed into section A and rhenium heptoxide into section B (mole ratio $5PCl_5$: $1Re_2O_7$). The tube was removed from the dry-box and the inlet tube sealed before the reactants were allowed to mix. The tube was then shaken until the solids reacted with evolution of heat to form a red-brown semi-liquid mass. The tube was attached to a vacuum line and after pumping and heating the line for at least 24 h, the seal was broken and the reaction products fractionated. Phosphoryl chloride and unreacted phosphorus pentachloride were volatile at room temperature. The $ReOCl_4.OPCl_3$ sublimed more slowly at room temperature and was freed from phosphorus chlorides after three or four trap-to-trap sublimations. The yield of $ReOCl_4.OPCl_3$ was about 50%.

(*b*) $ReOCl_4.OPCl_3$ was prepared in a manner analogous to (*a*) using ReO_3 instead of Re_2O_7 as starting material.

(*c*) $ReOCl_4$ and $POCl_3$ were sealed in glass apparatus fitted with a break-seal and allowed to mix. A red solution was formed and heat was evolved. The apparatus was attached to a vacuum-line, and after baking the glassware dry the seal was broken and excess $POCl_3$ pumped off at ice temperature. The $ReOCl_4.OPCl_3$ was purified by sublimation and isolated in break-seals.

[5]Analysis by conventional wet method; the sample was hydrolyzed with hydrogen peroxide. Chloride was determined gravimetrically as silver chloride, and perrhenate gravimetrically as tetraphenylarsonium perrhenate.

Yields of approximately 70% were recorded. $ReOCl_4$-$.OPCl_3$ forms long acicular crystals with a melting-point of 90.5 °C.

Anal. Calcd. for Cl_7O_2PRe: Cl, 49.9; P, 6.2; Re, 37.5. Found: Cl, 53.5; P, 5.8 (Galbraith), 6.2 (Bernhardt). Neutron activation analyses gave (mean of 12 analyses) Cl, 52.5; Re, 38.7 (Re:Cl = 1:7.08 ± 0.12).

Results and Discussion

Rhenium Hexachloride and Rhenium Oxotetrachloride

It was mentioned above that the reported thermal stability and high magnetic moment of rhenium hexachloride (9) were unexpected. Attempts were made to prepare rhenium hexachloride by Colton's method (2). The major product resembled the compound described by Colton, and a little rhenium pentachloride was also produced. In many early experiments the first test applied to the product was the measurement of the infrared spectrum of a carbon tetrachloride solution of the compound prepared in a dry-box. Invariably, absorption peaks were observed in the range 900–1050 cm^{-1}. This region of the spectrum is too high in energy for any metal–chloride vibrational frequency (29), but is the normal region for heavy metal–oxygen stretching frequencies (30). Therefore the absorptions appeared to be the result of oxygen contamination of the product.

In an effort to eliminate any contamination, increasingly rigorous conditions were applied to keep moisture and oxygen out of the reactants, solvents, and products. Vacuum systems used contained no greased taps, joints or seals and all handling was done using break-seals. A special high temperature vacuum infrared cell was designed (13) to enable the product to be examined in the gas phase and a neutron activation analysis method (12) was developed to enable accurate analyses to be performed without risk of contamination of the product.

Early analysis results by classical wet methods (31, 32) were not precise but indicated that the ratio of rhenium to chlorine atoms was about 1:4. After development of the neutron activation analysis technique, many analyses were performed. It was found possible to prepare a product having a chlorine-to-rhenium atom ratio of approximately six, but careful separation showed that more than one component was present (see later). Samples which were purified by many trap-to-trap sublimations (30 or 40 in some cases) formed large black crystals (appearing dichroic in smaller samples, being dark green by reflected light and dark red by transmitted light). The crystals had a very sharp melting point at 32 °C and had a chlorine–rhenium atom ratio of 4. On hydrolysis with ammonium hydroxide solution the compound gave a Re^{VIII}:Re^{IV} ratio of 2:1 which is typical of rhenium(VI) (33, 34).

Gaseous infrared spectra of the vapor of the compound in the special gas cell filled on a vacuum line, with no possibility of oxygen entering the system, showed a large peak with two distinct shoulders centered at 1040 cm^{-1}. The lower branch was 1033 cm^{-1} and the higher at 1047 cm^{-1} and we assign these to the P, Q, and R branches of an Re=O stretch of the compound. The absorption occurred at slightly lower energies in solution: 1033 cm^{-1} in CCl_4 and 1029 cm^{-1} in $TiCl_4$. From the above evidence, it was apparent that the chlorination product was rhenium oxotetrachloride. Subsequent investigations showed that it was possible to obtain classical wet analyses for rhenium and chlorine, and these analyses confirmed the formulation of the chlorination product as $ReOCl_4$. Another strong peak was observed in the gas-phase infrared spectrum at 368 cm^{-1}. A similar strong peak was observed at 372 cm^{-1} for carbon tetrachloride and titanium tetrachloride solutions. The peak is probably ν_{Re-Cl} for $ReOCl_4$ but some attack of the polythene windows occurred, so that we cannot be certain that this peak was not caused by an impurity.

Further support for this formulation is afforded by a study of the magnetic susceptibility of the compound. The susceptibilities of samples of $ReOCl_4$ prepared by direct chlorination and by the reaction of pentachloride with oxygen are recorded in Table 1, together with the results obtained by Klemm and Schuth (35).

The effective magnetic moments from the measurements of Klemm and Schuth and this work are not in agreement. This is understandable when one considers the method of filling the sample tube. Because of the low melting point of the compound, both others (9) and ourselves have found it impossible to grind solid $ReOCl_4$ and pack a tube in the normal manner. The method used by us was to seal the quartz sample tube through a graded seal onto Pyrex apparatus, which contained the $ReOCl_4$ under a break-seal. The apparatus was evacuated and heated to re-

move surface moisture. The seal was then broken, and the compound melted, and poured into the tube as a liquid. Thaw–melt techniques were employed in an attempt to obtain a continuous 10 cm length of rod of solid compound, but as the solid has a smaller specific volume than the liquid some empty space was apparent in all cases.

If the disagreement in the results is caused only by packing, one would expect that the magnetic susceptibility (uncorrected for diamagnetism) of a given sample will have a constant ratio to that of another sample throughout the whole temperature range and give the same Curie–Weiss constant. Such is the case for our results and those of Klemm and Schuth. The Curie–Weiss constants are identical within experimental error and the ratio of the uncorrected magnetic susceptibilities is 1.20 ± 0.01. It is interesting to note that the values given by Brown and Colton (9) for $ReCl_6$ when compared to our values for $ReOCl_4$ also fulfil this condition. The ratio of magnetic susceptibilities is 1.52 ± 0.01 which is somewhat larger than the above ratio, but this can be reduced to 1.31 if Brown and Colton's gram susceptibilities are multiplied by the molecular weight for $ReOCl_4$ rather than $ReCl_6$. A more recent study of the magnetic properties of $ReCl_6$ prepared by another method (36) gives quite different results. The Curie–Weiss constant of 75° is much larger and a constant ratio is not obtained; the values ($ReCl_6/ReOCl_4$) vary from 1.07 at 294° to 1.21 at 105°.

It seemed strange that the major product of chlorination of rhenium should be altered so much, just by using metal with a higher specific surface area. The first conclusion drawn was that a higher chloride was formed which attacked the glass or ceramic to abstract oxygen. A small amount of volatile yellow material, from which it was difficult to separate the $ReOCl_4$, had often been observed during trap-to-trap sublimations, and it now seemed possible that this was a higher chloride. By many careful sublimations a few milligrams of this compound were isolated. Activation analysis gave a rhenium:chlorine ratio of 1:50 and the γ-ray spectrum of ^{24}Na was observed. An emission spectrographic analysis[6] of the compound showed that it contained several percent of Si and Al, about 1% of Na and Ti, and traces of Sn, Mg, Pb, Fe, Be, V, Cu, Ni, Co, and Cr. Obviously, the yellow "compound" was "ceramic chloride", and the oxygen in the major chlorination product was the result of attack on the porous brick.

Further experiments established that attack of the ceramic was essential to the production of $ReOCl_4$. Experiments using glass wool yielded mostly $ReCl_5$. It was also established that attack of the ceramic was not caused by chlorine, rhenium pentachloride, or rhenium trichloride.

The most reasonable explanation of this attack was offered by Chatt (37). He suggested that rather than a higher chloride being formed which then attacked the ceramic, the rhenium metal was acting as a reducing agent, and that the reduced

ceramic and oxidized rhenium were then chlorinated.

We have been unable to make rhenium hexachloride by the method of Colton (2), obtaining, instead, rhenium oxotetrachloride. We feel that the material described by Colton as "rhenium hexachloride" may be impure rhenium oxotetrachloride rather than $ReCl_6$. We cannot be certain of this since the data given for "rhenium hexachloride" are of minimal value in identifying the material. Properties such as melting point, color, and magnetic properties are very like those of $ReOCl_4$, but no data useful for identification purposes, such as vibrational spectra or X-ray diffraction data, are given. The reported thermal stability of "rhenium hexachloride" is not that which would be expected on the basis of the chemistry of neighboring elements. Rhenium hexachloride should be decomposed quite easily to a lower chloride and chlorine. However, the reported thermal stability is consistent with that for rhenium oxotetrachloride.

Rhenium Pentachloride

The melting point of rhenium pentachloride is quoted in the standard texts as 220 °C (33, 34), but it should be noted that the melting point of rhenium pentachloride prepared throughout this work was much higher (261 °C), very close to the value of 260 °C quoted by Lebedev (38). Nevertheless, the magnetic results we obtained (given in Table 1) are in close agreement with those of previous workers (9, 35, 39).

$ReOCl_4.OPCl_3$

Attempts were made to prepare rhenium halides and oxohalides by using phosphorus halides as chlorinating agents, but the reaction of both ReO_3 and Re_2O_7 with PCl_5 yielded the volatile molecular complex oxotetrachloro(phosphoryl chloride)rhenium(VI). This compound was subsequently synthesized from $POCl_3$ and $ReOCl_4$. Cotton and Lippard (3) have shown that rhenium(V) ions of the type $[ReOX_4.L]^-$(X = Br, Cl, L = H_2O, CH_3CN) have a pseudo-C_{4v} structure with the oxo-group *trans* to the ligand, which is very weakly bonded to rhenium. We consider that $ReOCl_4.OPCl_3$ has a similar structure.

The infrared spectral data presented in Table 2 show that $POCl_3$ is bonded in the normal manner (40) through the oxygen atom. The P—O stretching frequency is lowered by $\sim$ 40 cm^{-1}, as the bond is weakened by donation of electron density from the oxygen atom to the rhenium atom and the phosphorus–chlorine stretching frequency is increased slightly. The infrared data show clearly that the compound, $ReOCl_4.OPCl_3$ exists in the solid state and in titanium tetrachloride solution, but in the gas phase it is completely dissociated into $ReOCl_4$ and $POCl_3$. In carbon tetrachloride an equilibrium is evident between $ReOCl_4$, $POCl_3$, and $ReOCl_4.OPCl_3$. This suggests that the Re—O bond between $ReOCl_4$ and $OPCl_3$ is relatively weak.

The magnetic susceptibility data for $ReOCl_4$-$.OPCl_3$ (Table 1) obey the Curie–Weiss Law with $\theta = 23\ ^\circ K$ and $\mu_{eff} = 1.71$ B.M. These results are similar to those for $ReOCl_4$ so the addition of $OPCl_3$ to $ReOCl_4$ has not significantly affected the magnetic properties. Spin–orbit coupling effects are again absent and the local symmetry cannot be higher than C_{4v}.

Rhenium(V) Amine Complexes

We attempted to prepare a series of $ReOCl_4.L$ compounds by ligand replacement reactions with $ReOCl_4.OPCl_3$. Ligands such as triphenyl phosphine and alkyl or aryl phosphites gave black tars on direct reaction with $ReOCl_4.OPCl_3$, and no

products were isolated. Pyridine and 2,2′-dipyridyl, which are more resistant to oxidation than the ligands mentioned above, underwent clean reactions forming easily isolated, stoichiometric compounds. None of the products was of the expected type, however; in all cases reduction had taken place to yield compounds of Re(V). The amine complexes isolated appeared to be the same isomeric forms as had been prepared in other reactions (25–27, 41). The preparation and reactions of the amines are summarized in Fig. 1 which is based on our results and those of Johnson *et al.* (27). One feature, worthy of note, is the significant difference in the reactivity of the bispyridine- and 2,2′-dipyridyl-rheniumoxotrichloride complexes with ethanol. $ReOCl_3dipy$ gives the oxo-bridged dimer molecule which does not react further whereas $ReOCl_3py_2$ gives the ethoxo-complex; in addition the oxo-bridged dimer containing pyridine is readily cleaved by ethanol. It is difficult to rationalize this marked difference in reactivity unless the two oxo bridged compounds have completely different structures, but our attempts to show structural differences by vibrational spectroscopy were unsuccessful.

Rhenium(VII) Amine Complexes

Re(VII) is a common, stable, formal oxidation state of rhenium found in the perrhenate ion and perrhenyl halides. Reports of coordination compounds are restricted to $Cs_2ReO_3Cl_3$ (42), $(ReO_3Cl)_2SO_2Cl_2$ (21), $ReO_3Cl[(CH_3)_2SO]_2$, and $ReO_3Cl[(CH_3)_2N.CO.H]_2$ (43), but all were obtained from Re_2O_7 or perrhenate ion. It appeared possible that direct interaction of ReO_3Cl and a ligand might also yield complexes. Since this work was started Ringel (49) has obtained amide complexes in this manner.

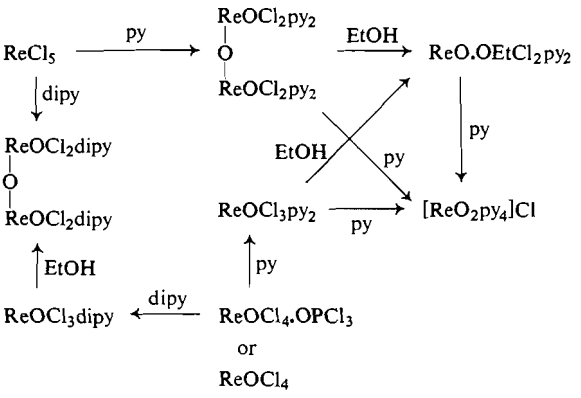

FIG. 1. Reactions of rhenium(V) amines.

Trioxochlorobispyridinerhenium(VII) (ReO_3Clpy_2) and trioxochloro-2,2′-dipyridylrhenium(VII) were obtained from the direct reaction of perrhenyl chloride and the corresponding ligand in carbon tetrachloride solution. The compounds were almost white and decomposed slowly in air, the pyridine complex being less stable. $ReO_3Cl.dipy$ was involatile at 100 °C, but the pyridine complex sublimed at this temperature. A small amount of residue was shown, by analysis and infrared spectroscopy to be pyridinium perrhenate. The compounds are interesting in that the central rhenium atom must have a co-ordination number of six. Rhenium(VII) normally has a coordination number of four, but it has been shown that in solid Re_2O_7 mixed six and four coordination is observed (44).

The infrared spectra of ReO_3Clpy_2 and $ReO_3Cldipy$ both showed the absorptions normally associated with the coordinated ligands (45, 46), and in addition showed several absorptions in the range 800–1000 cm^{-1} which may be assigned to rhenium–oxygen vibrations (26, 30). $ReOCl_3py_2$ showed absorptions at 858, medium, 901 and 914, very strong, 939, strong, and 946, shoulder, and $ReOCl_3dipy$ showed absorptions at 888 and 913, strong, 918, very strong, and 943, strong, all data having units of cm^{-1}. From the complexity of the spectra it appears the molecule is highly asymmetric. The spectra are very similar in appearance, suggesting the two compounds have similar structures. It is not possible to decide unambiguously whether the three oxygen atoms have the 1,2,3 or 1,2,6 arrangement, but Griffith's arguments (47) concerning the expected spectra for such arrangements suggest that the 1,2,6 arrangement is more probable.

We thank the National Research Council of Canada for financial support of this work and the award of a Graduate Scholarship to one of us (A.G.).

Received August 10, 1970

Thermal pressure and energy–volume coefficients are reported for several DMSO–water mixtures over the temperature range 13–55 °C. The energy–volume coefficient at 25 °C is found to pass through a maximum at 0.3–0.4 mole fraction DMSO and this observation is rationalized in terms of maximization of intercomponent interactions. The relationship between the energy–volume coefficient and the cohesive energy density of the binary liquid system is examined. The temperature dependence of the thermal pressure coefficient is discussed in terms of the effect of temperature on the susceptibility of the entropy of DMSO–water mixtures to isothermal expansion.

Canadian Journal of Chemistry, 49, 611 (1971)

Introduction

Dimethylsulfoxide (DMSO) – water mixtures have been used extensively as solvent media for kinetic studies (1–4) including recent work reported by the authors concerning the effect of pressure on the solvolysis of benzyl chloride in several aqueous DMSO solvent systems (1). It was found in this study, and many others of the same type (5), that variation in solvent composition greatly influences the various psuedo-thermodynamic parameters of activation through differential effects on the properties of the initial and transition states. Since these properties are determined, at least in part, by the structural and molecular interaction properties of the solvent, it is necessary to possess detailed information on solvent structure and the extent of intercomponent interaction if the kinetic behavior is to be fully understood.

It is generally accepted that deviation of liquid mixtures from ideality is a consequence of intercomponent interaction. Many studies, both thermodynamic and non-thermodynamic, have been performed in an effort to characterize the type and extent of these interactions in a great variety of liquid mixtures. Surprisingly, however, few studies appear to have been made on the energy–volume coefficient of binary liquid mixtures. Since both the energy–volume coefficient and the cohesive energy density are closely related to the extent and strength of intermolecular interaction, it seems that these two parameters would be of particular value in investigating the structural properties and intercomponent interactions in liquid mixtures.

In this paper we report the energy–volume coefficients and cohesive energy densities of various DMSO–water mixtures. These data further illustrate the importance of intermolecular association in determining the properties of this system.

Experimental

Materials

DMSO was dried over freshly cut calcium hydride and distilled at reduced pressure (~ 0.1 mm Hg). The middle 70% cut was collected and stored in a tightly stoppered flask until use. The purity of the distilled liquid was determined by melting point (found, 19 °C; lit. (6), 18.55 °C) and refractive index (found, $n_D^{20} = 1.3590$; lit. (6), $n_D^{19.4} = 1.35886$).

Aqueous mixtures were prepared by weight from doubly distilled water and were degassed using the conventional freeze–pump–thaw technique.

Apparatus and Method

The apparatus used to determine the thermal pressure coefficient $\gamma_V = (\partial P/\partial T)_V$ of the liquid mixtures was similar in design to that employed by several other investigators (7, 8). The sample cell was constructed from Pyrex glass and had a volume of about 23 ml. The condition of constant volume was determined by a metal probe, mercury contact which activated a milliammeter in an external circuit. The metal probe was constructed from tungsten for rigidity and was tipped with a platinum spike for a cleaner contact with mercury. The sample cell was enclosed in a 316 stainless steel pressure vessel equipped with a heat exchanger constructed from a coil of 0.25 in. i.d. copper tubing. Pressure (0–20 atm) was generated by a Blackhawk Model P228 hand pump using transformer oil as the pressurizing medium. The pressure was measured with an Ashcroft–Bourdon tube gauge (0–20 atm). The gauge was checked periodically against a dead weight tester and was found to be accurate to ±0.03 atm. The apparatus was connected to the pressure line, and placed in an oil thermostat bath which was controlled to better than ±0.02 °C. The pressure was adjusted until the platinum–mercury contact was made. The temperature was then changed and the pressure readjusted to again make contact. Temperature changes

[1]Present address: Materials Science Branch, Atomic Energy of Canada Ltd., Pinawa, Manitoba.

were measured with a 6° Beckman thermometer which was calibrated to ±0.005 °C against a platinum resistance thermometer.

It is important to examine at this stage the effect of the heat of compression of the oil and sample liquid on the *P–T* data obtained as described above. When liquids are compressed adiabatically (*i.e.* rapidly), the temperature increases according to eq. 1.

$$[1] \qquad \left(\frac{\partial T}{\partial P}\right)_s = \frac{T\alpha V}{C_p}$$

where α is the coefficient of thermal expansion, V the volume, and C_p the heat capacity of the liquid. Over a small pressure range (*e.g.* 20 atm) the temperature change may be expressed as

$$[2] \qquad \Delta T = (T\alpha V/C_p).\Delta P$$

Equation 2 predicts a temperature increase on rapid compression at room temperature of ~ 0.04 and ~ 0.4 °C for water and a number of organic liquids (including oil), respectively. It is clear, therefore, that rapid compression of the system introduces serious errors into temperature measurement since the temperature intervals used in the measurement of γ_V varied between 0.8 and 2.5 °C. In order to alleviate this problem a thermistor was placed inside the pressure vessel to monitor the temperature of the contents. It was found that before a *P–T* reading could be taken the pressure had to be maintained to within ±0.5 atm of the contact pressure for 1 h so that the heat of compression could be fully dissipated to maintain isothermal conditions between the vessel contents and the thermostatting oil.

Results

Typical plots of applied pressure (P) *vs.* temperature (T) over the range of temperature employed in each determination (0.8 to 2.5 °C) showed that the data are adequately represented by the linear expression

$$[3] \qquad P = mT + C$$

where the gradient m is equal to the observed *thermal–pressure coefficient*, γ_{obs}. Each γ_{obs} value requires correction for the finite expansion and compression of glass. This correction is normally made (9) using eq. 4.

$$[4] \qquad \gamma_V = \gamma_{obs}\left(1 - \frac{\beta_g}{\beta_l}\right) + \frac{\alpha_g}{\beta_l}$$

where α_g and β_g are the coefficients of thermal expansion and compressibility of Pyrex glass and β_l is the coefficient of compressibility of the liquid under investigation. Insufficient data are available in the literature on the compressibility of aqueous DMSO as a function of composition and temperature to allow the correction to be made using eq. 4 directly. Instead, the necessary correction can be applied using the following equality derived from thermodynamics.

$$[5] \qquad \beta_l = \alpha_l/\gamma_V$$

Substitution of eq. 5 into eq. 4 results in the following expression for γ_V

$$[6] \qquad \gamma_V = \gamma_{obs} \cdot \left(\frac{\alpha_l}{\gamma_{obs}\beta_g + \alpha_l - \alpha_g}\right)$$

Numerical values for α_g and β_g were taken as 9.9×10^{-6} deg^{-1} (8) and 3.06×10^{-6} atm^{-1} (8) and were assumed to be independent of temperature over the range of temperature employed in this study. Coefficients of expansion of the mixtures were calculated using eq. 7 where ρ_T is the density of the liquid at temperature T.

$$[7] \qquad \alpha_l = -(\partial \ln \rho_T/\partial T)$$

Plots of ρ_T *vs.* T using data reported in the literature (10) revealed that for all the liquid systems studied except pure water, α_l could be considered temperature independent without significantly altering the magnitude of the correction to γ_{obs}. In the case of pure water, α_l was calculated for each temperature from density data tabulated in the literature (11).

The *energy–volume coefficient*, $(\partial U/\partial V)_T$, of a system can be related to the thermal pressure coefficient, $(\partial P/\partial T)_V$ or γ_V by eq. 8 which is often termed the "thermodynamic equation of state."

$$[8] \qquad \left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V - P$$

For most systems (including aqueous DMSO) $T\gamma_V$ is very much greater than the external pressure, P, and eq. 8 can be approximated to

$$[9] \qquad \left(\frac{\partial U}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V, \qquad P = 1 \text{ atm}$$

Thermal pressure and energy–volume coefficients calculated using eqs. 6 and 9, respectively, for various DMSO–water mixtures at several temperatures are listed in Table 1. In view of the probable errors in temperature (< 0.02 °C) and pressure (< 0.05 atm), both quantities are considered accurate to better than ±2%. Thermal pressure coefficients listed in parentheses were calculated from data given in the literature. In general the agreement between both sets of data is very satisfactory.

Numerical values for γ_V, $(\partial U/\partial V)_T$, and the temperature dependence of γ_V were calculated graphically at 25 °C and are listed in Table 2. The $d\gamma_V/dT$ values are considered accurate to ± 0.015 atm deg^{-2}. It is interesting to note that the value obtained in this work for pure DMSO is significantly less negative than that reported by Lau, Malcolm, and Fenby (8). However, the value measured in this work was found reproducible to within the error limits claimed.

In 1945 Frank (12) proposed that for small changes in volume the energy of the liquid, U, can be written as

$$[10] \qquad U = U_g - A/V^n$$

where U_g represents the energy of the perfect gas state. Differentiation of U with respect to volume at constant temperature results in eq. 11 for the energy–volume coefficient of the system.

$$[11] \qquad \left(\frac{\partial U}{\partial V}\right)_T = n\left(\frac{U_g - U}{V}\right)$$

This relationship is commonly expressed as eq. 12.

$$[12] \qquad \left(\frac{\partial U}{\partial V}\right)_T = n\left(\frac{\Delta U_V}{V}\right)$$

where ΔU_V is the energy of vaporization to the perfect gas state. The quantity $\Delta U_V/V$ is referred to as the *cohesive energy density* of the liquid.

The energy of vaporization of a real liquid mixture to the perfect gas state can be calculated using eq. 13, which was derived from simple thermodynamics.

$$[13] \qquad \Delta U_V = x_1\Delta H_{V,1} + x_2\Delta H_{V,2} - \Delta H_M - RT$$

The quantities $\Delta H_{V,1}$ and $\Delta H_{V,2}$ are enthalpies of vaporization to the perfect gas state for com-

ponents 1 and 2, respectively, and ΔH_M is the heat of mixing per mole of mixture. At 25 °C the enthalpies of vaporization of water and DMSO to the perfect gas states are 10.52 (13) and 12.60 kcal mol^{-1} (8, 13), respectively. Energies of vaporization for various DMSO–water mixtures were calculated using these data and heats of mixing taken from the literature (14). Division of each ΔU_V value calculated as described above by the molar volume of the mixture (14) results in the cohesive energy density. The cohesive energy densities are listed in Table 2 together with energy–volume coefficients interpolated at 25 °C from data listed in Table 1. Numerical values for n are also listed and were calculated using eq. 12.

Discussion

Energy–Volume Coefficients

The variation of the energy–volume coefficient, $(\partial U/\partial V)_T$, with solvent composition for the DMSO–water binary liquid system is illustrated in Fig. 1. The most significant feature of this plot is the rapid increase in $(\partial U/\partial V)_T$ on addition of DMSO to water culminating in a maximum in this parameter at 0.3–0.4 mole fraction cosolvent. Many other properties of this system, including the excess thermodynamic functions of mixing (14, 15) and various non-thermodynamic properties such as viscosity (10), exhibit extrema in this region of solvent composition. Various workers (10, 16) have attributed these extrema to maximization of DMSO–water interactions resulting in the formation of transient polymeric species of the type, $(DMSO.2H_2O)_n$, in the liquid mixture. This same hypothesis can be used to account for the maximum in the variation of $(\partial U/\partial V)_T$ with solvent composition.

Gibson and Loeffler (17, 18) and others (19) postulate that where classical mechanics are applicable, the total energy of a fluid may be regarded as the sum of three terms; (*a*) the mean kinetic energy of the molecules at their equilibrium positions including the energy associated with rotation or internal degrees of freedom, $U(T)$; (*b*) the potential energy due to attractive intermolecular forces, U_A; and (*c*) due to repulsive forces U_R.

$$[14] \qquad U = U(T) + U_A + U_R$$

Since $U(T)$ is dependent only on temperature then differentiation of the total energy, U, with respect to volume at constant temperature yields

$$[15] \qquad \left(\frac{\partial U}{\partial V}\right)_T = \left(\frac{\partial U_A}{\partial V}\right)_T + \left(\frac{\partial U_R}{\partial V}\right)_T$$

The variation of the experimentally measured energy–volume coefficient can now be discussed in terms of separate components for intermolecular attraction and repulsion. Before doing so, however, it is necessary to examine the properties of the two terms on the right hand side of eq. 15.

U_A and U_R are known to vary with intermolecular distance, and therefore volume, as illustrated in Fig. 2, $(\partial U_A/\partial V)_T$ and $(\partial U_R/\partial V)_T$ are clearly positive and negative, respectively; and since

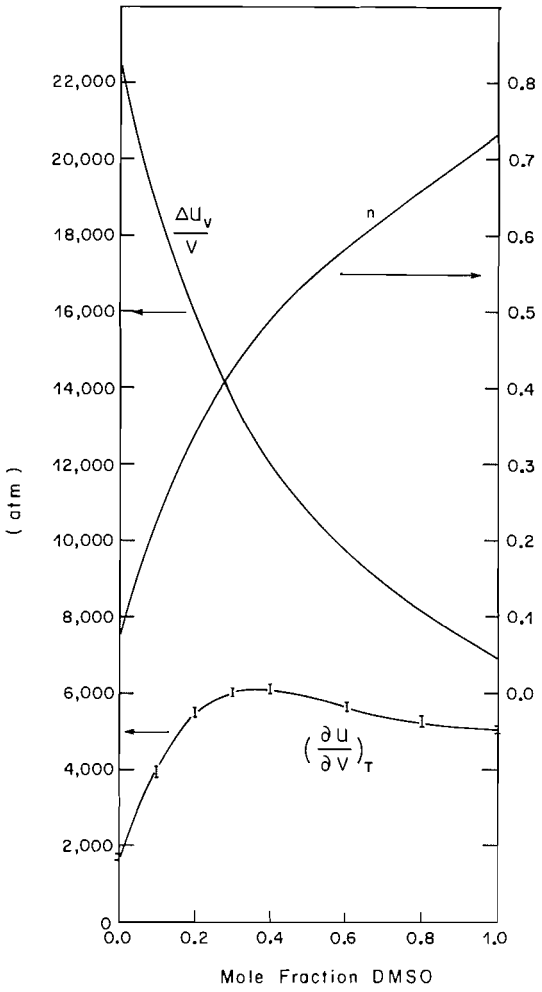

FIG. 1. Energy–volume coefficients and cohesive energy density parameters for DMSO–water mixtures at 25 °C.

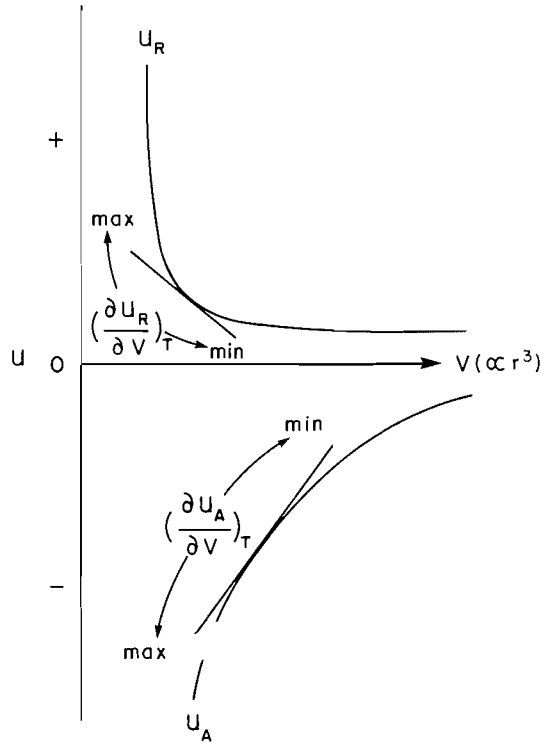

FIG. 2. Schematic representation of intermolecular interaction potential energy curves.

the sum of these terms, $(\partial U/\partial V)_T$, is observed to be positive the attractive term must always be numerically larger than the repulsive term. However, the excess volume of mixing of DMSO–water mixtures (14) passes through a minimum at 0.3 to 0.4 mole fraction DMSO and it is reasonable to expect that the average molecular separation passes through a minimum in the same region of solvent composition. Inspection of Fig. 2 shows that if the average intermolecular distance passes through a minimum $(\partial U_A/\partial V)_T$ and $(\partial U_R/\partial_V)_T$, the tangents to the curves in Fig. 2 will pass through positive and negative maxima, respectively. Since the observed $(\partial U/\partial V)_T$ passes through a positive maximum we conclude that the energy–volume coefficient behavior of the mixture results from the dominance of the attractive term $(\partial U_A/\partial V)_T$. Hence the observed maximum in the energy–volume coefficient at 0.3 to 0.4 mole fraction DMSO is consistent with the previously suggested (10, 16) maximization of attractive intercomponent (*i.e.* DMSO–water) interactions in this region of solvent composition. The low energy–volume coefficient observed for pure water probably reflects a large negative contribution from $(\partial U_R/\partial V)_T$ due to repulsive forces which attempt to arrange the molecules in the energetically favored open three-dimensional structure characteristic of ice.

The foregoing arguments permit the prediction that, for a system with a positive maximum in the excess volume of mixing, $(\partial U/\partial V)_T$ will exhibit either a minimum or at least negative deviations from ideal behavior, *i.e.* the reverse situation to that observed and rationalized above for the DMSO–water case. Very few systems have been examined in sufficient detail to permit a test of this prediction. Dunlap and Scott (20), however, have reported that the energy–volume coefficient for the perfluoro-*n*-hexane/*n*-hexane system shows negative deviations from ideality. Since this system exhibits a positive maximum in the excess volume of mixing the energy–volume coefficient behavior is in keeping with our prediction.

Cohesive Energy Densities

The dependence of $(\partial U/\partial V)_T$ on solvent composition can also be examined by considering the relationship between the energy–volume coefficient and the cohesive energy density $(\Delta U_V/V)$ of the system. This has been examined at length (21, 22) for one-component systems, but no equivalent analyses appear to have been performed for aqueous–organic binary mixtures. Such an analysis for the system under investigation in this work is shown in Fig. 1. Both the cohesive energy density and n vary monotonically with solvent composition although their product, $(\partial U/\partial V)_T$, does not. The initial rapid increase of $(\partial U/\partial V)_T$ with solvent composition is seen to be a consequence of a rapid increase in n which outweighs the simultaneous decrease in the cohesive energy density. On the other hand, at DMSO mole fractions greater than 0.4, $(\partial U/\partial V)_T$ decreases and this behavior is seen to result from the continued decrease of $(\Delta U_V/V)$ with solvent composition and a less pronounced increase in n.

While few conceptual difficulties exist in the interpretation of cohesive energy densities, the significance of n is less clear. Hildebrand (21) and Allen, Gee, and Wilson (22) report that for non-polar liquids, n is approximately equal to unity, and this provides a useful rule for esti-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mating energy–volume coefficients from cohesive energy densities for these liquids. However, the extensive compilation of n values reported by Allen, Gee, and Wilson (22) reveal that for strongly associated liquids, n is much less than unity and especially so for hydrogen bonded liquids. Thus, the monotonic increase in n from 0.075 for pure water to 0.733 for pure DMSO may reflect a general decrease in the overall hydrogen bonding in the system with increasing DMSO content. Despite the unidirectional trend of n from pure water to pure DMSO, it is worth remarking that there is a distinct change in the form of the dependence of n on solvent composition at or near the mole fraction commonly associated (10, 16) with the DMSO–water complex.

Entropy–Volume–Temperature Relationships

An important relationship, eq. 16, exists between the thermal pressure coefficient and the volume derivative of the entropy of a system at equilibrium.

$$[16] \qquad \gamma_V = (\partial S/\partial V)_T$$

The data reported in Table 2 reveals that γ_V passes through a maximum at 0.3–0.4 mole fraction DMSO. Equation 16 demands that at this composition the entropy (structure) of the system is most susceptible to isothermal expansion. Since expansion of the system should result in destruction of intermolecular interactions, these data indicate that the interactions present in a mixture of composition 0.3 to 0.4 mole fraction DMSO are more easily disrupted by isothermal expansion of the system than those present in either pure water or pure DMSO. It is reasonable to assume that the relatively specific intermolecular interactions that would be present in any transient complex of the form, $(DMSO.2H_2O)_n$, might be expected to show such susceptibility to isothermal expansion of the system.

The temperature dependence of γ_V as a function of solvent composition is illustrated in Fig. 3. This plot clearly shows that the sign of $(\partial\gamma_V/\partial T)$ changes from positive to negative on passing through 0.2 mole fraction DMSO. This observation is rationalized as follows. Ordered configurations in water are not favored at smaller volumes, *i.e.* entropy increases as volume decreases and hence for these configurations, $(\partial S/\partial V)_T$ is negative. With increasing temperature, this order is destroyed and the contribution to the total $(\partial S/\partial V)_T$ becomes less negative. Thus for pure water, $(\partial\gamma_V/\partial T) = \partial(\partial S/\partial V)_T/\partial T$ is positive as observed. Conversely, for a "normal" associated liquid such as DMSO, the ordered configurations are energetically favored at smaller V resulting in a positive $(\partial S/\partial V)_T$. With increasing temperature $(\partial S/\partial V)_T$ becomes less positive due to thermal agitation, resulting in the observed negative value for $(\partial\gamma_V/\partial T)$. It should also be noted that at DMSO mole fractions greater than 0.5, $(\partial\gamma_V/\partial T)$ is virtually independent of solvent composition. This observation is in keeping with the suggestion of Lindberg and Kenttämma (16) that between 0.5 mole fraction DMSO and pure DMSO the structure of this system varies little with composition.

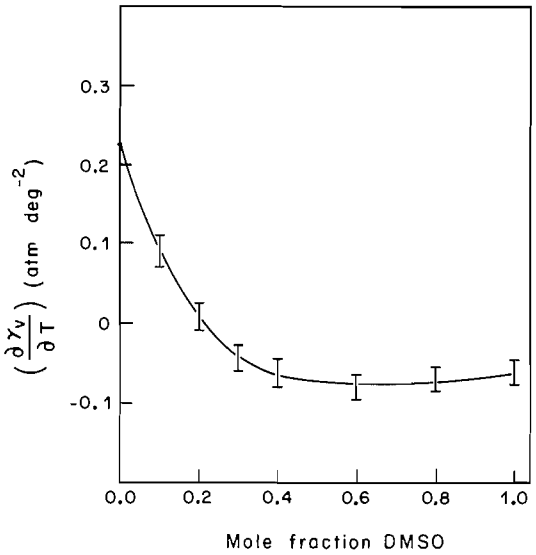

FIG. 3. Plot of the temperature dependence of the thermal pressure coefficient *vs.* solvent composition for DMSO–water mixtures at 25 °C.

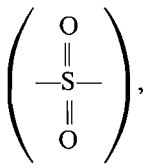
Received September 9, 1970

The preparations of $[CpFe(CO)_2]_2Sn[OS(O)Ph]_2$, $CpFe(CO)_2SnPh[OS(O)Ph]_2$, $CpFe(CO)_2SnPh[OS(O)Ph]OH$, and $Ph_2Sn[OS(O)Ph]_2$ by sulfur dioxide insertion into the C—Sn bond and also by reaction of the sodium phenyl sulfinate with the corresponding chloro-compounds are reported. The infrared (i.r.) spectra and some reactions of these compounds are also discussed.

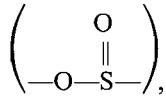
Canadian Journal of Chemistry, **49**, 618 (1971)

Introduction

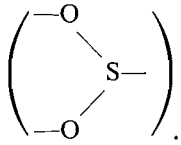
Insertion reactions between sulfur dioxide and organometallic compounds have received much attention during the last few years (*e.g.*, refs. 1–6 and references therein). A wide variety of reactions and of types of insertion product has now been claimed. Thus, for a compound containing Fe—Sn—C bonds, insertion of sulfur dioxide between either the Fe—Sn and/or the Sn—C bonds might be expected. The product could also be an *S*-sulfinate



O-sulfinate



or a polymeric O-bonded sulfinate



The first insertion of sulfur dioxide into a C—Sn bond was briefly reported earlier by two of us (7). We now discuss this reaction and others in more detail.

[1]Presented in brief at the C.I.C.–A.C.S. Joint Conference, Toronto, 24–29 May, 1970. Abstract No. 30.

Discussion

Bis(dicarbonyl-π-cyclopentadienyliron)diphenyltin(IV) reacts with sulfur dioxide, either in benzene solution or in liquid sulfur dioxide, giving $[CpFe(CO)_2]_2Sn[OS(O)Ph]_2$ in good yield (70 and 60%, respectively). The infrared spectrum shows no bands in the 1200–1300 and 1030–1150 cm^{-1} regions expected for the ν_{asym} S=O and ν_{sym} S=O of compounds containing the  group (8, 9). Instead, a pattern is observed at 800–900 cm^{-1} (Fig. 1) which is assigned to $\nu_{S=O}$ and ν_{S-O} of an *O*-sulfinate and also the δ_{CH} of the cyclopentadienyl group. The same compound is also obtained using sodium phenylsulfinate

$$[CpFe(CO)_2]_2SnCl_2 + 2NaSO_2Ph \rightarrow [CpFe(CO)_2]_2Sn[OS(O)Ph]_2\ (60\%) + 2NaCl$$

This shows that the product is an *O*-sulfinate rather than an *S*-sulfinate or a sulfone. Ultimate proof of this structure has been obtained by X-ray analysis (10).

On heating at 180° for 48 h, $[CpFe(CO)_2]_2Sn[OS(O)Ph]_2$ decomposes to give diphenyldisulfide and a black non-volatile solid. Although organic sulfones and diphenyl-*O*-sulfinato-mercury evolve sulfur dioxide on thermal decomposition, no sulfur dioxide was detected in this case (11, 12), *cf.*

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

$$Hg(SO_2Ph)_2 \xrightarrow{\Delta} HgPh_2 + SO_2$$

$$R{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}R^1 \xrightarrow{\Delta} R{-}R^1 + SO_2$$

(R = alkyl, R^1 = alkyl or aryl)

Reaction with hydrogen chloride likewise evolved no sulfur dioxide. The products were $[CpFe(CO)_2]_2SnCl_2$ and diphenylthiolsulfonate (13, 14), *cf.*

$$Mn(CO)_5SO_2Me \xrightarrow{Cl_2} Mn(CO)_5Cl + SO_2$$

$$[CpFe(CO)_2]SnPh_3 \xrightarrow{HCl} [CpFe(CO)_2]SnCl_3$$

The diphenylthiosulfonate probably arises via decomposition of phenylsulfinic acid under acidic conditions (15) although no sulfonic acid was detected.

$$[CpFe(Co)]_2Sn[OS(O)Ph]_2 \xrightarrow{HCl} [CpFe(CO)_2]_2SnCl_2\ (79\%) + 2PhSO_2H$$

$$3\ PhSO_2H \xrightarrow{H^+} PhSO_2SPh\ (80\%) + PhSO_3H + H_2O$$

Treatment of (dicarbonyl-π-cyclopentadienyliron)triphenyltin(IV) with sulfur dioxide was expected to yield the analogous $[CpFe(CO)_2]Sn[OS(O)Ph]_3$. However, the initial yellow product was found to be $[CpFe(CO)_2]SnPh[OS(O)Ph]_2$ which decomposed on treatment with boiling ethanol to give orange crystals of $CpFe(CO)_2SnPh[OS(O)Ph]OH$.

$$CpFe(CO)_2SnPh_3 \xrightarrow{SO_2} CpFe(CO)_2Sn(Ph)(OS(O)Ph)(OS(O)Ph)$$

$$\xrightarrow{EtOH} CpFe(CO)_2Sn(Ph)(OS(O)Ph)(OH)\ (32\%)$$

Fong and Kitching (3) have very recently shown that the insertion of sulfur dioxide into a carbon–tin bond is very likely an electrophilic substitution. A consequence of this in the present system is that insertion of sulfur dioxide is more difficult into the second Sn—Ph bond than into the first, and no insertion occurs into the third Sn—Ph bond. A similar product is obtained in the reaction between $(CO)_5MnSnPh_3$ and sulfur dioxide (16). Confirmation of the identity of the two iron compounds was provided by the synthesis using sodium phenylsulfinate

$$CpFe(CO)_2SnPhCl_2 + NaSO_2Ph \rightarrow CpFe(CO)_2SnPh[OS(O)Ph]_2\ (18\%) + CpFe(CO)_2SnPh[OS(O)Ph]OH\ (18\%)$$

The nuclear magnetic resonance (n.m.r.) and infrared (i.r.) spectra are consistent with these formulations. The $\nu_{S=O}$ and ν_{S-O} occur in the same region as for $[CpFe(CO)_2]_2Sn[OS(O)Ph]_2$ where the *O*-sulfinate structure is confirmed by X-ray analysis (Fig. 1).

Thermal decomposition of $CpFe(CO)_2SnPh[OS(O)Ph]OH$ at 190° yields diphenyldisulfide; no sulfur dioxide was evolved. Treatment with hydrogen chloride yields $[CpFe(CO)_2]SnCl_3$ and diphenylthiolsulfinate, again no sulfur dioxide was evolved.

The only product which was isolated when $[CpFe(CO)_2]_2SnMe_2$ was treated with sulfur dioxide was $CpFe(CO)_2SO_2Me$ (8). This may be a decomposition product of $[CpFe(CO)_2]_2Sn[OS(O)Me]_2$ although the reaction between $CpFe(CO)_2SnMe_3$ and sulfur dioxide is said to yield a product containing $Fe{-}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}{-}Sn$ (4). The lack of reactivity of $[CpFe(CO)_2]_2SnCl_2$ towards sulfur dioxide at 50° for 5 days clearly reflects the stability of this compound. No insertion of sulfur dioxide between the Fe—Sn bond or substitution of sulfur dioxide for carbonyl groups was detected. The starting material was completely recovered in 97% yield.

Although diphenyltin dichloride and tetraphenyltin are recovered unchanged after 24 h at 20° in liquid sulfur dioxide (the latter probably owing to its insolubility), triphenyltin chloride readily reacts under identical conditions yielding diphenyltin dichloride and a white insoluble compound, diphenylbis(phenyl *O*-sulfinato)tin(IV).

$$2Ph_3SnCl \xrightarrow{SO_2} Ph_2SnCl_2\ (80\%) + Ph_2Sn[OS(O)Ph]_2\ (84\%)$$

The same product was also obtained from the reaction between diphenyltin dichloride and sodium phenylsulfinate

$$Ph_2SnCl_2 + 2PhSO_2Na \rightarrow Ph_2Sn[OS(O)Ph]_2\ (99\%) + 2NaCl$$

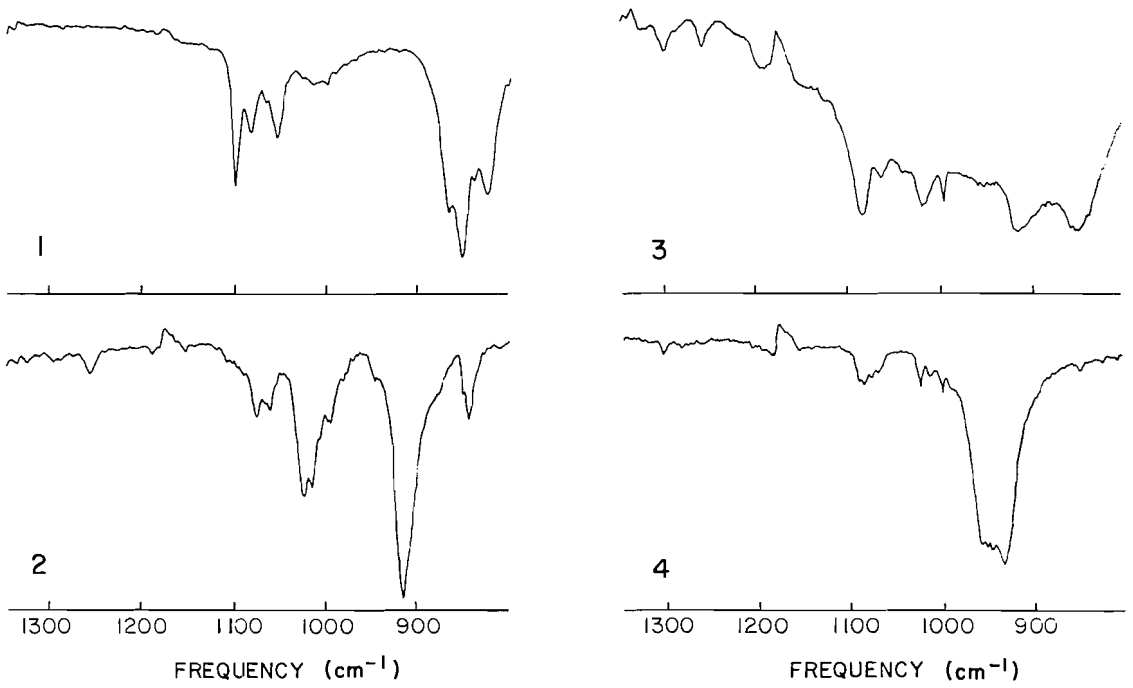


FIG. 1. Infrared spectra in the region 1350 to 800 cm^{-1}; (1), $[CpFe(CO)_2]_2Sn[OS(O)Ph]_2$; (2), $CpFe(CO)_2SnPh[OS(O)Ph]OH$; (3), $CpFe(CO)_2SnPh[OS(O)Ph]_2$; (4) $Ph_2Sn[OS(O)Ph]_2$.

Other workers have very recently reported similar results (5). The infrared spectrum of $Ph_2Sn[OS(O)Ph]_2$ showed ν_{SO} at 850 cm^{-1} which is consistent with the *O*-sulfinate linkage, probably in a hexacoordinate *O*-sulfinate-bridged polymer (*5b*) (Fig. 1).

It is possible that sulfur dioxide inserts into one Sn—Ph bond of triphenyltin chloride and that anion exchange then occurs between two such mono-substitution products

$$Ph_3SnCl + SO_2 \rightarrow Ph_2Sn\begin{matrix}OS(O)Ph\\Cl\end{matrix}$$

$$2Ph_2Sn\begin{matrix}OS(O)Ph\\Cl\end{matrix} \rightleftharpoons Ph_2Sn[OS(O)Ph]_2 + Ph_2SnCl_2$$

Further electrophilic substitution in either product is then probably unfavorable. An analogous reaction with sulfur trioxide has also been reported (17).

$$Me_3SnCl + SO_3 \rightarrow Me_2Sn(OSO_2Me)_2 + Me_2SnCl_2$$

Thermal decomposition of $Ph_2Sn[OS(O)Ph]_2$ at 225° yields diphenylsulfone; no sulfur dioxide is evolved. When $Ph_2Sn[OS(O)Ph]_2$ is treated with hydrogen chloride in methylene dichloride suspension, an oil is obtained which yields $Ph_2Sn[OS(O)Ph]_2$ on treatment with water. Presumably a hydrochloride is formed. Reaction with concentrated hydrochloric acid under reflux gives some diphenylthiolsulfonate and a hygroscopic oil, probably tin(IV) chloride.

Experimental

The starting materials were either purchased (Alfa Inorganics Ltd.) or prepared as reported in the literature. Anhydrous grade sulfur dioxide (*ex.* Matheson) was dried by passing through concentrated sulfuric acid and over phosphorus pentoxide/calcium chloride. All experiments were carried out under an atmosphere of nitrogen. Compounds containing iron and tin tended to be unstable in air especially when in solution. Infrared spectra were obtained as KBr discs using a Perkin–Elmer Model 457 spectrometer. Nuclear magnetic resonance spectra were recorded using a Varian A60 instrument operating at 60 Hz and for mass spectrometry a Perkin–Elmer Hitachi RMU6E spectrometer was employed. Element analyses were carried out by the A. Bernhardt Microanalytical Laboratory, West Germany, or the Schwarzkopf Microanalytical Laboratory, New York, except for the iron analyses which were performed in this laboratory using a Unicam S.P. 90 Atomic Absorption instrument.

Reaction of Sulfur Dioxide with Bis(dicarbonyl-π-cyclopentadienyliron)diphenyltin(IV)

(*a*) Sulfur dioxide (*ca.* 15 ml) was condensed into a 100 ml Pyrex ampoule containing bis(dicarbonyl-π-cyclopentadienyliron)diphenyltin(IV) (18) (2.02 g, 3.22 mmol). The ampoule was sealed *in vacuo* and left for 24 h at 22°. The volatile products were removed under reduced pressure leaving a reddish tar which yielded bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) (1.47 g, 1.95 mmol, 60%) as yellow crystals on crystallization from ethanol.

(*b*) In a similar reaction sulfur dioxide was passed through a solution of bis(dicarbonyl-π-cyclopentadienyliron)diphenyltin(IV) (3.3 g, 5.3 mmol) in benzene (400 ml) during 48 h. The solvent was removed under reduced pressure leaving a yellow oil which crystallized from ether/petroleum ether (b.p. 60–80°). Recrystallization from methylene chloride/petroleum ether (b.p. 30–40°) yielded yellow crystals of bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) (2.8 g, 3.7 mmol, 70%) m.p. 153–155°.

Anal. Calcd. for $C_{26}H_{20}O_8S_2Fe_2Sn$: C, 41.4; H, 2.7; S, 8.5; $Fe_2O_3SnO_2$, 41.1. Found: C, 41.7; H, 2.8; S, 8.2; residue 40.4.

Intensity 1:1.

(*c*) Bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) was also prepared when dichlorobis-(dicarbonyl-π-cyclopentadienyliron)tin(IV) (3.0 g, 5.5 mmol) and sodium phenylsulfinate dihydrate (1.86 g, 9.3 mmol) were heated under reflux (65°) in methanol (300 ml) during 22 h. The solvent was removed under reduced pressure leaving a yellow solid which recrystallized from methylene chloride/petroleum ether (b.p. 40–60°) to give bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) (3.29 g, 4.4 mmol, 79% [based on $[CpFe(CO)_2]_2SnCl_2$]) m.p. 153–155°.

Anal. Calcd. for $C_{26}H_{20}O_8S_2Fe_2Sn$: C, 41.4; H, 2.7; S, 8.5; $Fe_2O_3.SnO_2$, 41.1. Found: C, 41.4; H, 3.0; S, 8.2; residue 41.0.

Reactions of Bis(dicarbonyl-π-cyclopentadienyliron)-bis(phenyl-O-sulfinato)tin(IV)

(a) Effect of Heat

Bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) (0.29 g, 0.38 mmol) was placed in a sublimation apparatus fitted with a water-cooled finger and open to the atmosphere (fume hood) via a trap at −78° (solid CO_2/MeOH) and a calcium chloride tube. The sample was kept at 180° for 48 h. A white solid collected on the cold finger and was identified by i.r. (9) and mass spectrometry as diphenyldisulfide (0.026 g, 0.12 mmol, 31%) m.p. 58–60° (lit. (9) m.p. 61°). The non-volatile residue was a black solid (0.23 g) which contained no carbonyl groups (i.r.) and was not identified. No sulfur dioxide was detected (19).

(b) Effect of Hydrogen Chloride

Hydrogen chloride was passed through a stirred solution of bis(dicarbonyl-π-cyclopentadienyliron)bis(phenyl-*O*-sulfinato)tin(IV) (0.37 g, 0.49 mmol) in benzene (40 ml) during 1 h. The exit gases from the reaction vessel were passed through a trap cooled to −78°. No sulfur dioxide was detected in the trap after the reaction. The solvent was removed under reduced pressure leaving a reddish tar. Treatment with petroleum ether (b.p. 30–60°) afforded a white solid identified by its i.r. (9) and mass spectra as diphenylthiosulfonate (0.10 g, 0.40 mmol, 80%). The residual red tar which was insoluble in the petroleum ether was crystallized from ethanol to yield (i.r. and mass spectral analysis) dichlorobis(dicarbonyl-π-cyclopentadienyliron)tin(IV) (0.21 g, 0.39 mmol, 79%) m.p. 166–168% (lit. (20) m.p. 166–168°).

Reaction of Sulphur Dioxide with (Dicarbonyl-π-cyclopentadienyliron)triphenyltin(IV)

(Dicarbonyl-π-cyclopentadienyliron)triphenyltin(IV) (15) (10.24 g, 19.4 mmol) was stirred under reflux (−10°) in sulfur dioxide (*ca.* 30 ml) for 10 h. The sulfur dioxide was removed in a stream of nitrogen leaving a sticky yellow residue which slowly solidified *in vacuo*. The solid was treated with petroleum ether (b.p. 60–80°) in a Soxhlet apparatus which extracted a pale yellow solid, (dicarbonyl-π-cyclopentadienyliron)triphenyltin(IV) (1.50 g, 2.85 mmol, 15% recovery). The residue, insoluble in petroleum ether, was a yellow solid which was identified by i.r. spectroscopy (see later) as $CpFe(CO)_2SnPh[OS(O)Ph]_2$. However, recrystallization from boiling ethanol gave yellow needles of $CpFe(CO)_2SnPh[OS(O)Ph]OH$ (3.30 g, 6.22 mmol, 32%), m.p. 149–151°.

Anal. Calcd. for $C_{19}H_{16}SSnFeO_5$: C, 42.97; H, 3.04; S, 6.04; Fe, 10.52; $Fe_2O_3.SnO_2$, 43.41. Found: C, 42.98; H, 2.97; S, 5.82; Fe, 10.7; residue, 42.71.

λ_{max}(KBr) 3400–2800 bw, 3112 w, 3079 vw, 3056 vw, 2018 vs, 1995 w, 1970 vs, 1928 w, 1576 vw, 1479 w, 1473 vw, 1442 w, 1436 vw, 1429 m, 1414 w, 1358 vw, 1301 vw, 1261 vw, 1194 vw, 1157 vw, 1114 vw, 1080 vw, 1065 vw, 1027 m, 1020 m, 1000 w, 997 w, 920 vs, 847 w, 771 m, 732 m, 703 sh, 697 m, 691 sh, 626 m, 590 s, 578 s, 496 m, 451 m, 389 vw, 375 vw, 359 vw, 303 vw, 265 w, cm^{-1}. $^1H_{n.m.r.}$ $\delta_{(CDCl_3)}$ 5.53 (singlet, C_5H_5), 2.5 (multiplet, C_6H_5) τ. Intensity 1:2. Molecular weight (benzene) 1050 ± 2% (calcd. 531).

An identical sample was obtained from the reaction between dichloro(dicarbonyl-π-cyclopentadienyliron)-phenyltin(IV) and sodium phenylsulfinate:

Dichloro(dicarbonyl-π-cyclopentadienyliron)phenyltin-(IV) (0.986 g, 2.22 mmol) and sodium phenylsulfinate (2.43 g, 14.8 mmol) were stirred under reflux in absolute ethanol (50 ml) for 24 h. The solvent was removed under reduced pressure and the residue treated with methylene chloride and filtered through celite. The filtrate was evaporated to yield a reddish oil which on crystallization from absolute ethanol yielded yellow crystals of $CpFe(CO)_2SnPh[OS(O)Ph]OH$ (0.214 g, 0.403 mmol, 18% yield).

Anal. Calcd. for $C_{19}H_{16}SSnFeO_5$: C, 42.97; H, 3.04; S, 6.04; $Fe_2O_3.SnO_2$ 43.41. Found: C, 42.93; H, 2.94; S, 6.09; residue 43.25.

Evaporation of the ethanol filtrate yielded a reddish oil which gave $CpFe(CO)_2SnPh[OS(O)Ph]_2$ as a yellow powdery solid on washing with ether (0.265 g, 0.404 mmol, 18% yield).

Reactions of (Dicarbonyl-π-cyclopentadienyliron)-phenyl(phenyl-O-sulfinato)tin(IV)hydroxide

(a) Effect of Heat

$[C_5H_5Fe(CO)_2]SnPh[OS(O)Ph]OH$ (0.304 g, 0.572 mmol) was placed in a sublimation apparatus fitted with a water cooled finger and open to the atmosphere (fume hood) *via* a trap cooled to −78° and a calcium chloride tube. The sample was kept at 190° for 72 h. The apparatus was then evacuated and maintained at 190° for a further 6 h. No sulfur dioxide was detected. A white solid collected on the cold finger and was shown to be diphenyldisulfide (0.010 g, 0.046 mmol). The black tar-like residue contained no carbonyl groups (i.r.) and was not identified.

(b) Effect of Hydrogen Chloride

Hydrogen chloride was passed through a stirred solution of $[C_5H_5Fe(CO)_2]SnPh[OS(O)Ph]OH$ (0.597 g, 1.090 mmol) in benzene (40 ml) in 1 h. The exit gases from the reaction were passed through a trap cooled to −78°. No sulfur dioxide was detected. The solvent was removed under reduced pressure leaving a sticky yellow solid. Treatment with petroleum ether (b.p. 40–60°) and diethyl ether extracted a white solid identified by i.r. and mass spectroscopic analysis as diphenylthiosulfonate (0.116 g, 0.463 mmol). The yellow solid which was insoluble in the petroleum ether and diethyl ether was shown to be (i.r., mass spectroscopy) trichloro(dicarbonyl-π-cyclopentadienyliron)tin(IV) (14) (0.275 g, 0.684 mmol, 63%) m.p. 159–160° (from ethanol) (lit. (14) 150° decomp.).

Reaction of Sulfur Dioxide with Bis(dicarbonyl-π-cyclopentadienyliron)dimethyltin(IV)

Sulfur dioxide was passed through a stirred solution of bis(dicarbonyl-π-cyclopentadienyliron)dimethyltin(IV) (1.19 g 2.37 mmol) in diethylether (40 ml) in 3 h. The solvent was removed under reduced pressure leaving a dark red oily solid which proved difficult to crystallize. The oil was heated with methylene chloride (10 ml) and petroleum ether (b.p. 100–120°) (60 ml). The supernatant yellow solution was decanted and on cooling to 0° yielded pale yellow needles of dicarbonyl-π-cyclopentadienyl methyl-*S*-sulfinatoiron (8) (0.05 g, 0.20 mmol, 8%) m.p. 143–145° (lit. (8) 135°) identified by n.m.r., i.r. and mass spectrometry.

Reaction of Sulfur Dioxide with Dichlorobis(dicarbonyl-π-cyclopentadienyliron)tin(IV)

Sulfur dioxide (*ca.* 10 ml) was condensed into a 100 ml Pyrex ampoule containing dichlorobis(dicarbonyl-π-cyclopentadienyliron)tin(IV) (1.44 g 2.65 mmol). The ampoule was sealed *in vacuo* and left for 24 h at 22°. The reddish crystalline solid dissolved to give an orange red solution. The sulfur dioxide was removed under reduced pressure leaving a yellow solid, dichlorobis(dicarbonyl-π-cyclopentadienyliron)tin(IV) (1.37 g, 2.52 mmol, 95% recovery).

A similar experiment carried out at 50° for 5 days afforded only the dichlorobis(dicarbonyl-π-cyclopentadienyliron)tin(IV) (97% recovery).

Reaction of Sulfur Dioxide with Diphenyltin Dichloride

No reaction was observed between diphenyltin dichloride (5.79 g, 16.8 mmol) and sulfur dioxide (*ca.* 15 ml) after 24 h at 23°. On removal of the sulfur dioxide, a white solid was obtained, diphenyltin dichloride (5.56 g, 16.2 mmol, 96% recovery).

Reaction of Sulfur Dioxide with Triphenyltin Chloride

Sulfur dioxide (*ca.* 20 ml) was condensed into a 100 ml Pyrex ampoule containing triphenyltin chloride (2.27 g, 5.89 mmol). The ampoule was sealed *in vacuo* and left at 22° for 20 h. As the ampoule warmed up to 0° the colorless crystalline triphenyltin chloride dissolved to form a colorless solution. At 20° a white milky precipitate was formed and after 20 h at 22° the mixture was a stiff suspension. The sulfur dioxide was removed under reduced pressure and the white residue placed in a Soxhlet apparatus. Extraction with diethyl ether during 24 h afforded a colorless oily liquid which crystallized from petroleum ether (b.p. 30–60°) as a white crystalline solid identified by m.p. (41–42°) (lit (21) m.p. 40–41.5°), i.r., and mass spectroscopy as diphenyltin dichloride (0.81 g, 2.36 mmol, 80%). The white powdery residue which was insoluble in ether was $Ph_2Sn[OS(O)Ph]_2$ (1.38 g, 2.49 mmol, 84%) m.p. 218–219°.

Anal. Calcd. for $C_{24}H_{20}O_4S_2Sn$: C, 51.90; H, 3.64; S, 11.54; SnO_2, 27.14. Found: C, 52.00; H, 3.74; S, 11.46; residue, 26.89.

λ_{max}(KBr), 3082 vw, 3065 w, 1485 vw, 1475 w, 1442 w, 1429 m, 1083 w, 1079 w, 1060 sh, 1024 w, 1013 vw, 1001 w, 959 vs, 946 vs, 934 vs, 756 w, 741 sh, 737 m, 700 m, 691 m, 600 m, 590 m, 474 m, 459 m, 414 vw, 348 vw, 329 vw, 298 w cm^{-1}. $^1H_{n.m.r.}$ $\delta_{(dimethylsulfoxide)}$ 2.53 (broad singlet) τ.

An identical sample of diphenyldi[phenyl-*O*-sulfinato]-tin(IV) was obtained from the reaction of diphenyltin dichloride with sodium phenylsulfinate.

Diphenyltin dichloride (2.09 g, 6.09 mmol) in 95% ethanol (20 ml) was added to a stirred solution of sodium phenylsulfinate (3.15 g, 19.2 mmol) in 95% ethanol (50 ml). A copious white precipitate was immediately formed. The mixture was stirred under reflux for 1 h before the white product was filtered, washed with water, and dried over phosphorous pentoxide *in vacuo* to yield diphenyldi[phenyl-*O*-sulfinato]tin(IV) (3.34 g, 6.01 mmol, 98% yield) m.p. 218–220°.

Found; C, 51.96; H, 3.77; S, 11.46; Residue, 26.84%. $C_{24}H_{20}O_4S_2Sn$ requires; C, 51.90; H, 3.64; S, 11.54; SnO_2, 27.14%.

Reactions of Diphenyldi[phenyl-O-sulfinato]tin(IV)

(i) Effect of Heat

$Ph_2Sn[OS(O)Ph]_2$ (0.95 g, 1.71 mmol) was placed in a water-cooled sublimation apparatus open to the atmosphere (fume hood) via a cold trap (−78°) and a calcium chloride tube. A white solid sublimed during 18 h at 225° which was identified as diphenylsulfone (0.32 g,

1.47 mmol). The sublimation residue was a brownish solid (0.52 g). No sulfur dioxide was detected.

(ii) Effect of Hydrogen Chloride

Hydrogen chloride was passed through a stirred suspension of $Ph_2Sn[OS(O)Ph]_2$ (0.67 g, 1.21 mmol) in methylene chloride (40 ml) in 30 min. The exit gases from the reaction vessel were passed through a cold trap (−78°). After 10 min, the white suspension dissolved forming a colorless solution. The solvent was removed under reduced pressure yielding a colorless oil. On addition of water a white solid was formed. It was filtered, washed with water and diethylether to yield $Ph_2Sn[OS(O)Ph]_2$ (0.43 g, 0.77 mmol, 64% recovery), identical to the starting material (i.r.), m.p. 216–218°. No sulfur dioxide was detected.

(iii) Effect of Hydrochloric Acid

$Ph_2Sn[OS(O)Ph]_2$ (0.48 g, 0.86 mmol) and concentrated hydrochloric acid (40 ml) were heated under reflux during 20 h. A white oily solid was formed within 10 min, and became a white suspension in another 10 min. After 20 h a colorless solution was obtained containing a colorless oil ($d > 1$). Water (40 ml) was added and the mixture extracted with methylene chloride (3 × 40 ml) to yield a colorless oil (0.19 g), which was mostly diphenylthiolsulfonate containing probably some diphenyltin dichloride (i.r.). A foul odor was also detected. The aqueous solution was evaporated, yielding a white oily solid which, after 24 h *in vacuo* over phosphorus pentoxide and sodium hydroxide pellets, became an oily liquid. The liquid produced white fumes on contact with air with the formation of a white solid (0.13 g), probably $SnCl_4.nH_2O$.

Reaction of Sulfur Dioxide with Tetraphenyltin

No reaction was observed between tetraphenyltin (0.94 g, 2.20 mmol) and sulfur dioxide (*ca.* 15 ml) after 24 h at 22°. The tetraphenyltin appeared to be completely insoluble in the sulfur dioxide and was recovered after removal of the sulfur dioxide under reduced pressure (0.92 g, 2.15 mmol, 98% recovery).

Optical Activity of Symmetric Compounds in Chiral Media. I. Induced Circular Dichroism of Unbound Substrates

L. D. HAYWARD AND R. N. TOTTY
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received August 5, 1970

In the presence of chiral environment compounds, C, optical rotation is induced in symmetric substrates, S, and may be detected as circular dichroism in the electronic spectra of the solutions. Thus the n–π^* transitions of symmetric and racemic carbonyl compounds, and of symmetric nitro and azo compounds, become optically active when these S are dissolved in chiral hydrocarbons, ketones, or carbinols, or in solutions of these C in achiral solvents. The rotational strengths of the induced circular dichroism bands of S are solvent, temperature, and concentration dependent. Only limited correlation of the sign and magnitude of the induced bands with the stereochemistry of C and S is evident on the data so far accumulated. Halogenated achiral solvents enhance the intensity, and, in some cases reverse the sign of the induced bands.

A new mechanism of asymmetric induction is proposed in which specific bonding of C with S is not prerequisite.

Canadian Journal of Chemistry, **49**, 624 (1971)

Introduction

The induced circular dichroism (i.c.d.) of the n–π^* transition of symmetric aromatic ketones (symmetric substrates, S) in chiral solvents (chiral environment compounds, C) was first observed by Bosnich (1). In a preliminary communication (2) we reported i.c.d. of symmetric and racemic aliphatic carbonyl compounds in the presence of chiral tetrahydrofuranols. Subsequent reports confirmed these results and indicated that circular dichroism may be induced in the lowest energy isotropic transitions of nitroalkanes (3) and thiones (4). Bolard, assuming that induction occurred *via* a hydrogen-bonded 1:1 ketone–alcohol complex, calculated the induced rotational strength (R_s) of acetone in the presence of (−)-menthol from the probable geometry of the complex but was unable to predict the sign of the i.c.d. band (5, 6). A similar 1:1 hydrogen-bonded complex was proposed by Noack on the basis of the concentration dependence of R_s of the n–π^* transition of cyclohexanone in (−)-menthol (3). However, Axelrod, Barth, and Bunnenberg have shown that hydrogen-bonding is not prerequisite to i.c.d. as circular dichroism is induced in the n–π^* transition of p,p′-dimethoxythiobenzophenone by a chiral ether or a chiral ketone (4).

We report here our investigations of the i.c.d. of symmetric and racemic carbonyl compounds, and of symmetric nitro and azo compounds in 2- and 3-component liquid systems. The plan of the work was to map on the largest practical scale the interactions of C of known configuration with S having accessible chromophores in ranges of solvent, temperature, and concentration in order to reveal the mechanism of induction of optical activity.

Experimental

Although the optical activity of a chiral compound is fully described by the signs and magnitudes of the rotational strengths, R, of each of its optically active electronic transitions, it is customary to report only the maximum differential molar absorption coefficient, $\Delta\varepsilon$, or the related quantity $[\theta] = 3300\,\Delta\varepsilon$ (deg mol^{-1} cm^2) of the experimentally accessible bands. Molar absorption coefficients are defined as molecular properties of solutes although it is well recognized that there are no truly "inert" solvents. Continuing these conventions $[\theta]_{max}$ values are quoted herein for the accessible i.c.d. bands of S in C + S systems as if they referred to S alone.

Circular dichroism spectra were measured on a JASCO ORD/UV/CD-5 spectrophotometer with a sensitivity of 1×10^{-4} with reference to a baseline of the chiral solution run at the same temperature. Racemic solvents gave no detectable circular dichroism (c.d.) signals. Measurements were repeated at intervals of up to 18 months using freshly prepared solutions of varying concentration. Low temperature measurements were made using 0.1 cm cells cooled in a quartz Dewar (J. F. Scanlon Co.) with the boil-off from liquid nitrogen (7); by controlling the flow rate a temperature stability of $\pm 2°$ was achieved. At the temperature of measurement solutions were either in the liquid state or formed stable glasses and the spectra were uncorrected for changes in density. All compounds, after purification, had infrared (i.r.), nuclear magnetic resonance (n.m.r.), and ultraviolet (u.v.) spectra and specific rotations in agreement with literature data.

†1.37 M in acetonitrile.

4,8-dihydroxy-*cis*-2,6-dioxabicyclo[3.3.0]octane, **1**), in acetonitrile solution as C, symmetric and racemic carbonyl compounds (S) show a single positive or negative circular dichroic absorption band at or near the wavelength maximum characteristic of their lowest energy isotropic transition (Table 1). The i.c.d. band approximates the shape of the n–π^* absorption band and R_s of the ketones shows only slight dependence on their geometry, although Noack found that strongly sterically hindered ketones, such as hexamethylacetone, exhibit only very weak i.c.d. (3). Our failure to observe i.c.d. in several aromatic carbonyl compounds, including some that are relatively sterically unhindered, and in diketones, does not indicate that the induction of optical activity in these systems is not possible, but rather that it is too weak to be detected under our experimental conditions. Indeed, benzil and 9-fluorenone give rise to relatively strong i.c.d. bands in other C (1, 4).

Whilst the i.c.d. band of benzophenone in the presence of **1** is negative, the i.c.d. bands of the aliphatic ketones are all positive. To determine whether this behavior is general, the i.c.d. of benzophenone (S1) and 3-methylcyclohexanone (S2) were compared in the presence of a series of C of known absolute configuration (**1** to **14**, Table 2). It is at once apparent that the sign of the i.c.d. is a property of the C/S system and does not reflect the geometry of either C or S. There is no correlation between the sign of the $[\alpha]_D$ of C (or of the c.d. bands which determine $[\alpha]_D$) with the sign of the i.c.d. band of a particular S, nor between the signs of the i.c.d. bands of C/S1 and C/S2.

Although it may be taken as axiomatic that the enantiomers of C should give rise to i.c.d. bands of opposite sign with a particular S, this was verified with the enantiomers of 2-octanol, pantolactone, and diethyl tartrate; the observed bands are opposite in sign and equal in magnitude within experimental error.

The temperature dependence of the i.c.d. bands of aliphatic ketones has been reported (3, 6). We confirm these observations and note that the i.c.d. of benzophenone is also temperature dependent, $[\theta]_{max}$ in solvent **8** increasing from −130 at 25° to −330 at −40°. A similar increase is observed in solvent **11**.

A solution of benzophenone in (−)-*cis*-pinane (**13**) exhibits no detectable circular dichroism at 25° but at 10° a distinct negative i.c.d. band appears which increases in R_s when the temperature is further lowered to −45°. This observation confirms that hydrogen bonding is not essential for the induction of optical activity in achiral ketones, as has already been demonstrated for the thione chromophore (4).

Both benzophenone and 3-methylcyclohexanone show i.c.d. bands in solutions of **1** in a large molar excess of methanol (14:1) (Table **3**). In such 3-component systems competition between C and the achiral solvent for hydrogen-bonding sites would be expected, and the fact that the observed R_s are similar to those in non-hydroxylic "inert" solvents (Table 3) also indicates that hydrogen bonding between C and S is not prerequisite for i.c.d. Significantly in this context the use of 1,1,1-trifluoro-2-propanol as achiral solvent leads to an increase in R_s of the carbonyl i.c.d. band in comparison to a meth-

anolic solution; perfluoroalcohols are usually considered capable of forming stronger hydrogen bonds to carbonyl compounds than are the hydrocarbon analogues (8, 9). The absence of i.c.d. in trifluoroacetic acid is probably due to rapid chemical change in the system.

We find no correlation between the molar ellipticities of the i.c.d. bands of benzophenone and 3-methylcyclohexanone and the polarity of the "inert" solvent, as measured by dielectric constant or E_T values (10) with (+)-D-isosorbide as C. Solvents of low dielectric constant such as 1,4-dioxan or tetrahydrofuran lead to i.c.d. bands of the same strength as solvents of high dielectric constant, such as methanol or sulfolane, although formamide, with an exceptionally high dielectric constant, gives rise to no detectable i.c.d. No shifts in wavelength of the i.c.d. band maxima or multiple i.c.d. bands are occasioned by the use of any "inert" solvent.

The molar ellipticity of the i.c.d. band of S in the systems benzophenone/(+)-D-isosorbide (**1**)/methanol and 3-methylcyclohexanone/(+)-D-isosorbide (**1**)/methanol is directly proportional

to the molarity of C, at constant molarity of S. No saturation effect appears even at the highest concentration of C (Fig. 1). This difference from the nonlinear relationship of i.c.d. and [C] at constant [S] found by Noack (3) for the menthol/cyclohexanone/cyclohexane system may be due to the conformational rigidity of the C used here.

The inductive properties of (−)-diethyl tartrate (**5**) appear to be atypical of chiral environment compounds in general. The i.c.d. of benzophenone in this solvent shows distinct fine structure and is bathochromically shifted by *ca.* 30 nm from the maximum of the isotropic spectrum, and that of 3-methylcyclohexanone is similarly shifted by *ca.* 10 nm. Whilst such considerable shifts are usually deemed to be indicative of the presence of multiple circular dichroic absorption bands, attributed to asymmetric solvation (11) when observed for chiral ketones in achiral solvents (12), we propose that the formation of charge-transfer complexes between C and S in this solvent be considered (13, 14).

Alone of the C compounds so far examined,

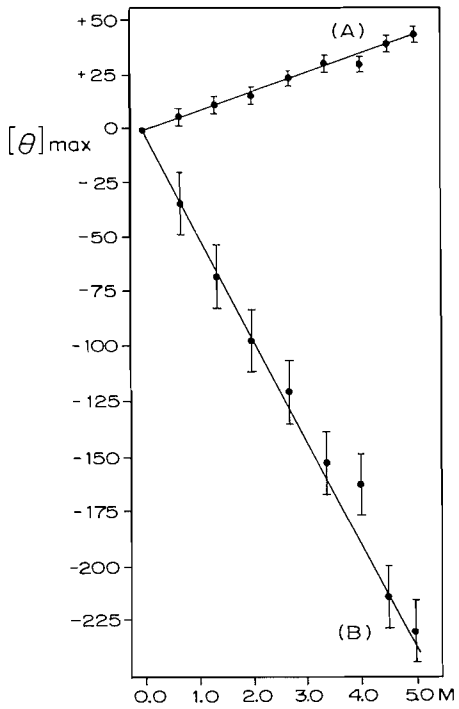

FIG. 1. Induced circular dichroism of S as a function of [C] in methanol at constant [S] and 25°. C = (+)-D-isosorbide, S = 3-methylcyclohexanone 0.45 *M* (*A*), S = benzophenone 0.10 *M* (*B*).

(−)-diethyl tartrate (**5**) gives rise to i.c.d. bands which show distinct fine structure or are shifted in wavelength from the isotropic absorption (4). The structurally related solvents **6** and **7** give rise to strong single i.c.d. bands, and 2-adamantanone (which shows two oppositely signed i.c.d. bands in solvent **5** (4)) shows a single positive i.c.d. band in the presence of (+)-D-isosorbide (**1**).

Since the stable conformation of benzophenone is itself chiral (15), in a chiral environment the equilibrium between the two enantiomers might be disturbed, leading to a higher population of one of them. Although i.c.d. of the rigid bicyclic ketones camphor and 2-adamantanone shows that any mechanism involving adoption of preferred chiral configurations is not of general applicability, there remains the possibility that induction of circular dichroism in benzophenone and in similar labile structures proceeds by this means.

Nitro Compounds

The lowest energy isotropic absorption band of nitroalkanes is at approximately 275 nm, at almost the same position as that of the carbonyl chromophore, and is similarly attributed to a n–π^* transition (16). For chiral nitro compounds the transition is optically active and its sign may be predicted by application of a sector rule (17). In the presence of C, symmetric nitroalkanes (S) show a single positive or negative i.c.d. band at, or near, 275 nm (Table 4). Primary, secondary, tertiary, and halogenated nitroalkanes give i.c.d. bands of the same sign and magnitude in the same C.

The i.c.d. band of these S is positive with (+)-diethyl-L-tartrate (**5**) as C, and does not change sign upon dilution with methanol, whereas when 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) is used as diluant the i.c.d. band becomes negative and is shifted to shorter wavelengths by *ca.* 8 nm (Fig. 2). A similar shift has been reported for the isotropic n–π^* absorption of nitroalkanes in perfluoroalcohols (18). Although fluorinated solvents have large effects (9, 19) and fluorine substituents are "antioctant" (20, 21) in the c.d. of chiral carbonyl compounds, fluorine substitution in nitromethane does not affect either the sign or frequency of the i.c.d. band although the rotational strength is somewhat decreased (Table 4). A reversal of sign of an i.c.d. band upon addition of a halogenated solvent has been

reported for the system diethyl tartrate/cyclohexanone (4).

In order to determine if the reversal of the sign of the i.c.d. band of the system RNO_2/**5** upon addition of HFP is due to a specific interaction between HFP and either C or S which may disturb the conformational or solvational equilibrium of C or S, we have examined the c.d. and optical rotatory dispersion (o.r.d.) spectra of **5** and the c.d. spectrum of a chiral primary nitrocompound (methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-3-*C*-nitromethyl-α-D-*ribo*hexopyranoside, **15**) in both HFP and methanol. In both solvents **5** exhibits a single negative c.d. band, at 218 nm in methanol ($[\theta] = -1850$) and at 213 nm in HFP ($[\theta] = -1900$). The slight blue shift of the c.d. band is consistent with data for other hydroxyesters in perfluoroalcohols (22). The o.r.d. spectrum of **5** is consistent with the c.d. spectrum and previously reported o.r.d. data (23). The c.d. spectrum of **15** shows a single negative band at 282 nm in methanol ($[\theta] = -3900$) and at 274 nm in HFP ($[\theta] = -4600$). There is thus no factor evident from the chiroptical spectra of **5** or **15** to which the sign reversal of the i.c.d. band of the system RNO_2/**5** upon addition of HFP may be attributed, and we conclude that the action of HFP is upon the system C/S rather than on either C or S alone. That the strong hydrogen-bonding properties of HFP (9) are not *per se* the cause of the sign reversal is indicated by the strong positive i.c.d. of the system CH_3NO_2/**5** in aqueous solution (2.4 *M* **5**, $[\theta]_{max} = +25$).

It is generally agreed that the nitro group can act as a proton acceptor for hydrogen bonding from alcohols (18, 24, 25). As the efficiency of HFP for hydrogen-bonding to proton acceptors is greater than that of methanol (9), the appearance of i.c.d. in the system RNO_2/(+)-D-iso-

sorbide (Table 4) in HFP, but not in methanol solution, is evidence against hydrogen-bonding of C and S as the cause of induced optical activity in nitroalkanes (*cf.* ref. 3).

We have attempted to observe i.c.d. of nitromethane in (−)-*cis*-pinane (**13**), however, experimental conditions are not favorable due to low solubility and at both 25 and −15° no i.c.d. is apparent in a 0.18 *M* nitromethane solution.

The 330 nm band in the isotropic spectrum of nitrobenzene is usually attributed to a n–π^* transition by analogy with nitroalkanes (16). This transition should therefore exhibit i.c.d. in a suitable C, and, although the band is partly obscured by higher energy transitions, we have observed i.c.d. in that part of the band experimentally accessible in both nitrobenzene ($[\theta]$ = *ca.* 80 at 330 nm, C = **5**, 2.4 *M* in methanol) and in *o*-nitrotoluene. The sign of the band is not reversed when methanol is replaced by HFP as solvent.

Azo Compounds

The diazenes ("azo" compounds (11)) were selected as S because they have conveniently isolated isotropic absorption bands, which have been assigned to the n_+–π^* transition (26, 27) and afford the possibility of observing i.c.d. in both alkyl (at ~340 nm) and aryl (at ~450 nm) substituted compounds with different degrees of conformational rigidity, and because of interest in the i.c.d. of this class of organic dyes in biopolymer–dye complexes (28, 29).

The R_s of the symmetric azobenzenes **17** and **18** at −48° in the chiral saturated hydrocarbon solvent, **13**, were comparable in magnitude with the rotational strengths of chiral diazenes at 25° in isooctane solution (11, 26, 30) (Table 5). These stereoisomeric diazenes differed in response to a given C in both sign and magnitude of R_s. The i.c.d. band of the conformationally rigid alicyclic diazene, 2,3-diazabicyclo[2.2.1]-hept-2-ene, (**16**) in the diol solvents (**8** and **9**) was non-Gaussian, its shape closely resembling that of its isotropic absorption band in ethanol solution (31), and the temperature coefficient of R_s for **16** in the hydrocarbon solvent (**13**) was zero within experimental error, whereas for the other C + diazene systems examined (Table 5, Fig. 3) it was significantly negative. It should be noted that Severn and Kosower (11) were unable to detect i.c.d. in 1-ethyl-2-methyldiazene in the presence of β-lactoglobulin.

For the three component systems C/S1/S2 (*e.g.* C = **1**, 2.4 *M* in methanol, S1 = 3-methylcyclohexanone, S2 = **16**) an i.c.d. band appeared for each S, and the spectrum was equivalent to superimposed spectra of the C/S1 and C/S2 systems. For three component systems C1/C2/S (*e.g.* C1 = (+)-**5**, C2 = (−)-**19**, S = **17**) where the R_s for C1/S and C2/S were of opposite sign and approximately equal magnitude, the net R_s was essentially zero, as it was also for the case where C1 and C2 were enantiomers.

As for the carbonyl and nitro compounds there was no apparent correlation in sign and magnitude between i.c.d. of S and $[\alpha]_D$ of C; the i.c.d. band of the diazenes was not significantly shifted in frequency or changed in shape when compared to the isotropic n–π^* absorption band.

Discussion

(*1*) Considering the signal enhancement that may be obtained by cooling, by the use of fluorinated achiral solvents, and by increasing [C]/[S] and dichrometer sensitivity, there is little doubt that all stable C/S solutions of the type described here will show i.c.d. under appropriate conditions; we conclude that the induction of optical rotation in n–π^* transitions by chiral media is completely general.

(*2*) Limited patterns of correlation of n–π^* i.c.d. with the structure of C and S are evident in Tables 1, 3, and 4; however, the data base is still too small (*e.g.* Table 5), and solvent effects insufficiently understood (*cf.* Table 4) to permit accurate prediction of sign or magnitude outside these patterns.

(*3*) We arrive at the conclusion that induction of optical activity does not require specific bonding between C and S by the following arguments: (*a*) The structural integrity of C and S is maintained in the C/S solutions as shown by their spectra. (*b*) Although hydrogen-bonding occurs between proton–donor C and X = Y chromophores in S, it is neither necessary nor sufficient for the appearance of i.c.d. (*c*) With the possible exception of the atypical system diethyl tartrate/S, the observed i.c.d. bands do not show the bathochromic shift, enhanced intensity, and band broadening characteristic of electronic absorption of charge-transfer complexes (13, 14). (*d*) If the equilibrium C + S $\rightleftarrows$ CS occurs in C/S systems the position of equilibrium should be revealed by methods used for organic charge-transfer complexes (13); however, application of the Foster–Hammick–Wardley equation (13) to the data in Fig. 1 gives equilibrium constants close to zero for both C/S systems. (*e*) It is difficult to envisage specific bonding of the saturated hydrocarbon *cis*-pinane (**13**) with benzophenone or with the diazenes **16**–**18**. (*f*) In 3-component systems C1/C2/S and C/S1/S2 each C/S pair appears to behave independently of the other.

(*4*) In the absence of specific bonding the origin of i.c.d. must lie in perturbation of the S chromophore by the dissymmetric field (33) of the chiral medium. The fact that the magnetic circular dichroism bands of acetone and 2-adamantanone are of opposite sign (32) and their i.c.d. bands have the same sign suggests that it is the electric rather than the magnetic field that is involved.

(*5*) This mechanism implies that in enzymic reactions (28) and chiroptical studies of biopolymer structure (29, 34) "binding" of small molecules at specific sites in the chiral macromolecules may not be prerequisite to induction of optical activity.

Competitive Reactions in the Thermal Decomposition of Cellulose

DONALD F. ARSENEAU
Department of Chemistry, Xavier College, St. Francis Xavier University, Sydney, Nova Scotia
Received September 11, 1970

Further evidence is presented to show that when cellulose is heated it undergoes two competitive reactions. The actual sequence of these is clarified, being different from that previously postulated. The natures of these reactions are studied, activation energies are determined, and their possible mechanisms are suggested. The thermogram for levoglucosan decomposition is given and briefly discussed.

Introduction

The combustion of cellulose has been studied quite frequently during recent years (1–7), and several reviews have appeared (8, 9). Much of the evidence strongly suggested that when the cellulose is heated, the following sequence of reactions occurs (1):

(*1*) Dehydration of the cellulose by an endothermic process to produce what Kilzer and Broido call a "dehydrocellulose". This reaction can be detected by differential thermal analysis techniques in the range 200–280 °C.

(*2*) At 280°, a depolymerization reaction competes for the residual cellulose by an endothermic process, and the product escapes as a tar. Work (10) has shown that levoglucosan (1,6-anhydro-β-D-glucopyranose) is an essential intermediate in this step.

(*3*) A decomposition of the "dehydrocellulose" formed in the first step via one or several exothermic reactions into a number of gaseous products and residual char.

More recently, MacKay using i.r. spectroscopy, g.l.c., and differential thermal analysis (2), gained further evidence that supported the fundamental ideas of sequential and competitive reactions. His review however (9) pointed out some interesting discrepancies that required clarification. This present work was undertaken to seek these clarifications.

Experimental

Most of the work was done on Whatman No. 1 filter paper having an ash content of about 0.1%. For differential scanning calorimetry (d.s.c.) small discs having an area of 0.33 cm^2 and a weight of about 3 mg were prepared using a simple paper punch, and dried in an oven at 110° for 1 h before use. The source of "ash-free" cellulose was Whatman No. 41 filter paper having an ash content of less than 0.01%. The cellulose powder was standard grade ashless Whatman Cellulose Powder. All were products of W. and R. Balston Limited of England.

Levoglucosan was prepared by heating 200 g of commercial corn starch in a 1-l pyrex round bottom flask which was connected directly to a condenser and a receiver. The receiver was placed in an ice bath, and was evacuated using a water aspirator. The reaction flask was rapidly heated with the flame from two Fischer burners. Vapors distilled at 250 to 300°. These were condensed, and the viscous brownish-black syrup was evaporated to dryness until there was no trace of moisture remaining. Dry acetone (50 ml) was added and the mixture warmed on a steam bath to the b.p. of acetone. The distillate dissolved and after seeding, was allowed to crystallize in a refrigerator for several days. The product was recrystallized from dry methanol, and showed a m.p. of 179° (16, 27).

Reduction Using Sodium Borohydride

The removal of carbonyl from heated cellulose was attempted using sodium borohydride and a modification of the method reported by Wolfrom and Wood (11). Preheated cellulose (40 mg) was added to 10 ml of water in which 8.0 mg of sodium borohydride had been dissolved. The p*H* was adjusted to 3–4 using *N* sulfuric acid. A nitrogen atmosphere was put over the solution, and the flask stoppered. It was periodically agitated. After 1 week, the solid was filtered off, washed with distilled water, and permitted to stand for 2 more days in a methanolic hydrogen chloride solution. The solid was once more filtered, washed with distilled water, and dried in a vacuum desiccator.

The i.r. spectra were obtained using the potassium bromide disc technique (12) and a Perkin–Elmer 237B Grating Infrared Spectrophotometer.

Thermograms

Thermograms were obtained using a Perkin–Elmer DSC-1 Differential Scanning Calorimeter with Effluent Analyser. In this instrument the sample is heated at a preselected rate in a controlled atmosphere. As the sample undergoes an endothermic transition, the extra power required to maintain the selected heating rate in the sample is plotted against its linearly increasing temperature. Should the sample undergo an exothermic change it is the amount of power withheld that is plotted. Thus the final graph records the energy of the transition and the temperature ranges in which these transitions occur.

During a run the sample chamber is continuously swept by a nitrogen flow. This nitrogen is passed through

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

a detector system which records the passage of any effluent from the sample decompositions.

The sample for this work, whether cellulose or levoglucosan, was placed in an aluminum pan and an aluminum cover was crimped on. To ensure rapid exit of volatile decomposition products, ten random holes were made in the cover using a pin. The nitrogen used had a maximum oxygen content of 20 p.p.m. To ensure removal of atmospheric oxygen the heating chamber was swept with nitrogen for at least 15 min prior to each run.

The signal from the DSC-1 was used to plot the thermogram on a Leeds and Northrup Speedomax W, with a 20 mV span and a 1 s response. Simultaneously the signal was led into a Cahn Time Derivative Computer which produces an output voltage proportional to the rate of change of the input voltage. This output became the input for a Brown Electronik, 1 mV span recorder, thereby giving the derivative of the original curve (Fig. 1*b*).

Thermogravimetry

For thermogravimetric analysis, a rectangular sample of filter paper weighing about 180 mg and measuring 4¼ in. by ¾ in. was coiled into a loose spiral and tucked into the porcelain crucible suspended from the balance spring in the pyrolysis chamber of American Instrument Company's ThermoGrav. Nitrogen (50 cc/min) was used to continuously sweep the reaction vessel. Heating began at room temperature and was programmed upwards at 1.5 °/min. The outputs from the instrument were recorded using a Plotomatic 690 X-Y recorder (Data Equipment Company) with the temperature being recorded along the abscissa (16 °/in.) and weight loss along the ordinate (25 mg/in.).

Results and Discussion

In Fig. 1, curve *a* is the thermogram for the decomposition of a thin (0.46 mm) layer of Whatman No. 1 filter paper at a heating rate of 10 °/min in a flowing nitrogen atmosphere. A very mild endotherm is discernible beginning at about 180°, followed by a mild exotherm at 220°. These phenomena are so gentle that they are easily lost in the baseline. Repeated experiments utilizing varying heating rates, sample sizes, and recorder chart speeds show that they are real. This portion of the curve presumably indicates the formation of the "anhydrocellulose" suggested by Kilzer and Broido (1). This rising exotherm gives way to a more rapid endotherm at a temperature of about 280°. It is apparent that this endotherm consists of a composite of at least two reactions. At 350° there is a gentle break in the curve, this being especially noticeable in the derivative curve *b* of Fig. 1. The endotherm recovers, peaks at about 370°, and then quickly returns to the baseline. Contrary to the results of other workers (13, 14) there is no exotherm evident beyond 350°. Apparently the two reactions contributing to this endotherm are, first, the depolymerization of the residual cellulose (1, 2), followed by the volatilization of most of the product, levoglucosan.

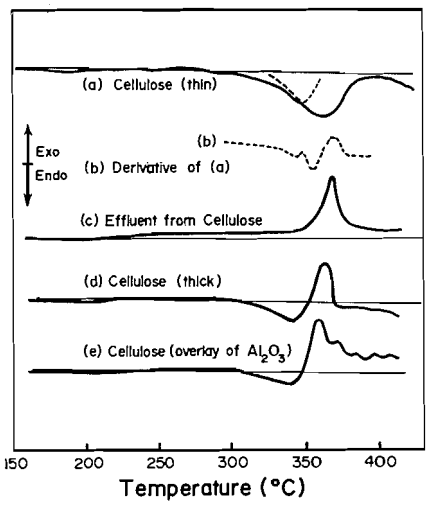

FIG. 1. The d.s.c. curves for cellulose in nitrogen and the gas effluent curve for the decomposition.

It has been demonstrated that the manner in which cellulose decomposes is modified by the presence of even low quantities of ash (1). Therefore similar runs were made using ashless (0.01%) filter paper and cellulose powder. No significant differences were found from the above.

To test this two-step possibility, conditions were modified to reduce the probability of loss of the volatile levoglucosan. Figure 1*d* shows the thermogram of Whatman No. 1 filter paper but this time using sufficient discs to give a sample thickness of 0.9 mm. Figure 1*e* is the thermogram of a thin layer of the same kind of paper over which 25 mg of dried alumina had been placed. These two runs were also made in a flowing nitrogen atmosphere at a heating rate of 10 °/min. They differ from Fig. 1*a* in the region above 350°. Whereas the thin layer of cellulose permits the easy loss of levoglucosan, both the alumina and the overlay of cellulose trap the levoglucosan, thereby eliminating the latter portion of the endotherm observed in Fig. 1*a*. Indeed, the hot surfaces of these overlays cause a thermal decomposition of the levoglucosan giving the exotherm so evident in *d* and *e* of Fig. 1, and reported by other workers (13,14). One must conclude that the exotherm appearing

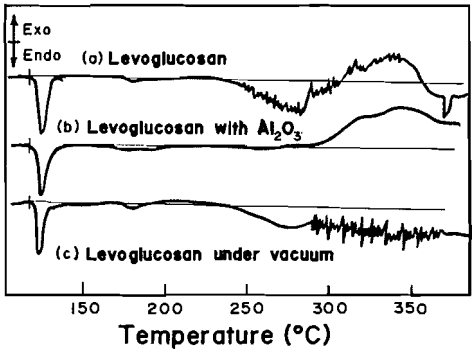

FIG. 2. The d.s.c. curves for levoglucosan (1,6-anhydro-β-D-glucopyranose) under various conditions.

in the thermograms of cellulose is not the result of the decomposition of the "anhydrocellulose" as suggested by Kilzer and Broido (1), but rather is the breakdown of the product of the depolymerization reaction, presumed to be levoglucosan.

Thermograms of Levoglucosan

The thermal decomposition of prepared levoglucosan was studied under conditions parallelling those used above. Figure 2*a* is the thermogram of a 5 mg sample that was heated at the rate of 10 °/min in a nitrogen atmosphere. The endotherm beginning at 117° apparently indicates a transition in the solid phase because no melting occurs at this point. The endotherm beginning at 175° represents the melting of the crystal, while the broad one commencing at 240° signals the onset of boiling. The jagged tracings seen in this region are often indicative of boiling or evaporation. Before all of the levoglucosan can escape, an exothermic reaction takes over, the product being a porous char. The rapid upturn occurs at 286°, and the exotherm continues upward until it peaks at 340°. This is the same temperature range in which the exotherm for thick cellulose and for cellulose overlaid with alumina occurs. When levoglucosan is overlaid with alumina, it is noted (Fig. 2*b*) that evidence of evaporation is clouded, while the thermal decomposition peaks persist. When levoglucosan was heated under reduced pressure (Fig. 2*c*), ready evaporation of the levoglucosan occurred, but no exotherm appeared.

Evidence gained from the thermograms of levoglucosan support the conclusion made earlier that the exotherm appearing in the thermograms of thick or overlaid cellulose marks the breakdown of the depolymerization product rather than of the "anhydrocellulose". A revision of the sequence of reactions proposed by Kilzer and Broido (1) must therefore be made. While steps *1* and *2* are left essentially unchanged, step *3* departs from that proposed by Kilzer and Broido.

(*1*) The dehydration of cellulose beginning at temperatures as low as 210°, resulting in the formation of "anhydrocellulose". The gas evolution curve shown in Fig. 1*c* suggests that reaction begins at this low temperature. This "anhydrocellulose" is quite reactive and soon undergoes further reactions that result in the formation of CO, CO_2, and H_2O, and most of the residual char.

(*2*) The depolymerization of non-reacted cellulose yielding the levoglucosan tar. This reaction becomes significant at about 270°, and builds up quite rapidly, becoming dominant over the one initiated earlier, but which is still going on.

(*3*) The final reaction observed by d.s.c. will vary depending upon the conditions of the experiment. It may be endothermic or exothermic, or indeed, neither. The levoglucosan formed in step *2* may volatilize giving an endotherm or it may be trapped by the overlay of cellulose and decomposed exothermally. Probably both of these are occurring simultaneously but to varying degrees depending upon heating rate, sample thickness, pressure, and so on. The amount of char left from the levoglucosan decomposition would therefore vary.

There is much in literature to support the above proposals:

(*a*) Kilzer and Broido (1) report that cellulose first held at 250° for a day forms about three times the amount of char at 400° as does a sample heated directly to 400°. Such preheats allow the early char-producing reaction to proceed to a greater extent. The sample directly heated to 400° rushes through the char-producing reaction, and on into levoglucosan-formation, some of which volatilizes before decomposition.

(*b*) Berkowitz (5) heated cellulose to about 200° for 20 min and then did a differential thermal analysis of the sample. The early exotherm observed in our work (at 220°) was greatly enhanced. When a similar sample was heated to

For personal use only.

250° for 1–2 h, and then scanned, the endotherm beginning at 280° disappeared entirely. Very likely, the preheat to 200° for 20 min formed more-than-usual quantities of "anhydrocellulose" which enhanced the exotherm at 220° when it was analyzed. The same phenomenon occurred at 250° but to such an extent that the heat evolved exceeded the heat absorbed by the depolymerization reaction of step 2. Thus the endotherm is replaced by an exotherm. Work done in our laboratory duplicating Berkowitz's finding supports this conclusion.

(*c*) MacKay (2) reproduces thermograms of cellulose preheated in a nitrogen atmosphere to a temperature of 350° for 5, 10, 15, and 30 min. Although neither sample size nor density of packing were rigidly controlled, the traces suggest in some cases the lack of an exotherm in the region above 360° (his curves 2 and 3), as well as showing an exotherm prior to the major depolymerization endotherm (his curves 2, 3, and 4).

(*d*) MacKay (2) used i.r. spectrophotometry and found the absorption bands at 1700 and 1625 cm^{-1} were two of the few features remaining in the spectrum of the residue from cellulose heated at 325° for 1 h. Our work has shown that these bands appear after heating for only a few hours at 260°. This ready formation along with their persistence in the residue which contains only about 10% of the weight of the material in the original sample, strongly suggests that it is the product of the earliest reaction that contributes to the major portion of the char.

(*e*) Domansky and Rendos (15) report an exotherm at 230°, and a strong endotherm at 315–320°, but no exotherm above these. Their experimental set-up allowed the depolymerized product to escape.

(*f*) Morita and Rice (13) found no exotherm at 230° but an endotherm at 340° and a strong exotherm beginning at 400° and peaking at 655°. (Differences in positions of peaks can be attributed to furnace designs and heating rates.) In this work the sample was intimately mixed with alumina which probably adsorbed the depolymerized product and held it for further reactions.

(*g*) Browne and Tang (14), using samples weighing about 5 g obtained an exotherm peaking at about 450° as might be expected since chances of the volatile product being trapped are very great. Their results (their Fig. 5) also give a hint of the existence of the exotherm preceding depolymerization.

(*h*) Reported yields (3, 16) of levoglucosan are increased by the rapid heating of cellulose under vacuum to the temperature required for volatilization. Rapid heating quickly moves the sample through the regions of competitive reaction and into the range where depolymerization occurs rapidly. Vacuum draws the product out of the reaction zone quickly thereby minimizing further degradation.

(*i*) In their fine work, Chatterjee and Conrad (7) found that when their data were plotted, they obtained good straight lines in all cases, thereby supporting the theory which they had proposed. But they point out that the lines do not pass exactly through the origin as expected. They go on to say "This deviation could be due to some unavoidable decomposition before the desired temperature was reached, leading to small errors in the determination of the arbitrary origin". Their proposed decomposition could well be the exotherm observed in this work.

(*j*) Golova *et al.* (17) report that during the decomposition of the first 5–10% (which are the approximate limits of our earlier exotherm), the cellulose macromolecule yielded no levoglucosan.

(*k*) Glassner and Pierce (18) used gas chromatographic techniques to analyze the products from the controlled application of heat to paper and levoglucosan. Their results revealed that at 242° and above, the degradation products were essentially the same for the two substances. Data obtained at 190 and 215° did not correlate well. The explanation may be that cellulose degrades in this lower temperature range by a mechanism not involving levoglucosan as an intermediate, but by a route through the "anhydrocellulose".

The Nature of the "Anhydrocellulose"

The nature of the "anhydrocellulose" and of the reaction producing it were investigated. Figure 3 shows the i.r. spectra over the range 2000–650 cm^{-1} of cellulose and of cellulose heated at 260° for 5 h in a nitrogen atmosphere. Although several changes are noted, the one of particular interest here is the appearance of a strong absorption band at 1700 cm^{-1} and the intensifying of the band at 1625 cm^{-1} relative to other absorptions. These two bands have been attributed by Higgins *et al.* (19) and by

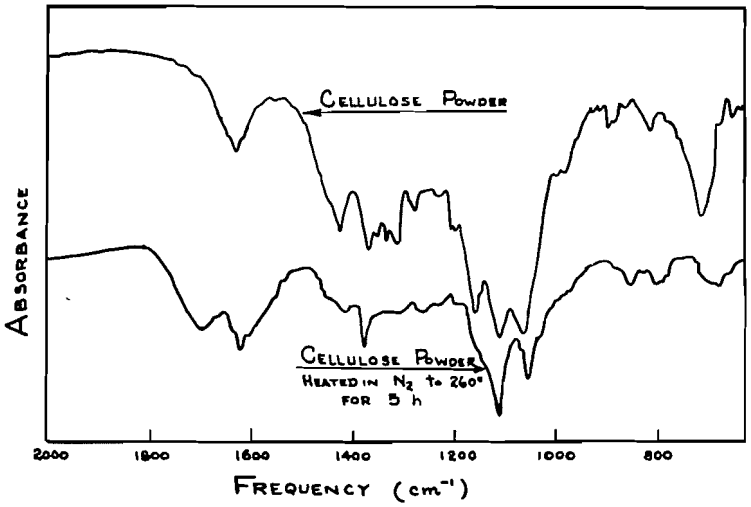

FIG. 3. The i.r. spectra for cellulose and cellulose heated in N_2 to 200° for 5 h.

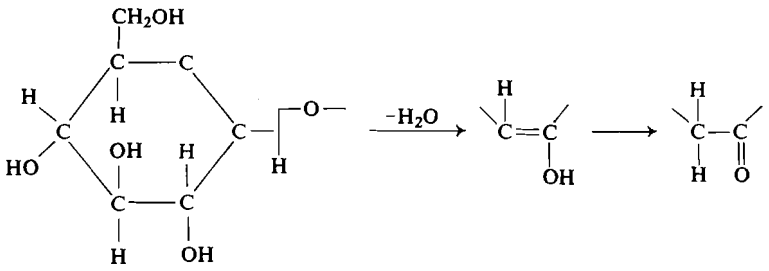
[1]



Tang and Bacon (20) to C=O and C=C. Attempts were made to reduce the C=O using sodium borohydride. The absorption at 1625 cm^{-1} was decreased slightly, but that at 1700 cm^{-1} did not change. This test might not have been too meaningful however because of difficulty in penetration of the preheated cellulose by the reducing reagents. Thus the unstable acidic sodium borohydride solution could have decomposed before reaching the interior reaction sites.

A possible explanation for the appearance of the absorption bands at 1625 and 1700 cm^{-1} is the dehydration and rearrangement shown in eq. 1. Theander (21) points out that the formation of oxo-groups, either aldehyde groups at C-6, or keto-groups at C-2 and -3, is of importance not only under controlled conditions known to produce reducing types of oxidized cellulose (chromate oxidation) but also under conditions considered specific for the introduction of carboxyl groups at C-6 (*e.g.* NO_2-oxidation). Further, he says, most of the very reactive keto-groups undergo further changes, these keto-groups probably being the starting points for the formation of dicarboxylate groups (carbonyl groups at C-2 and -3) which make the cellulose chain susceptible to depolymerization. Browne (8) says that such ketones may be produced before hydrolysis or pyrolytic scission begins. Hurd (22) points out that such ketones commonly decompose thermally to ketenes, compounds of the structure $\diagdown C{=}C{=}O$. Note that these contain both the C=C and C=O linkages suggested in the i.r. spectrum of heated cellulose (Fig. 3). Ketenes have been reported by Browne (8) among the pyrolysis products of cellulose but they are very reactive and can be expected to react further, possibly to the residual char.

Usually dehydration of alcohols proceeds by a carbonium ion mechanism. A polar or ionic environment would stabilize this carbonium ion

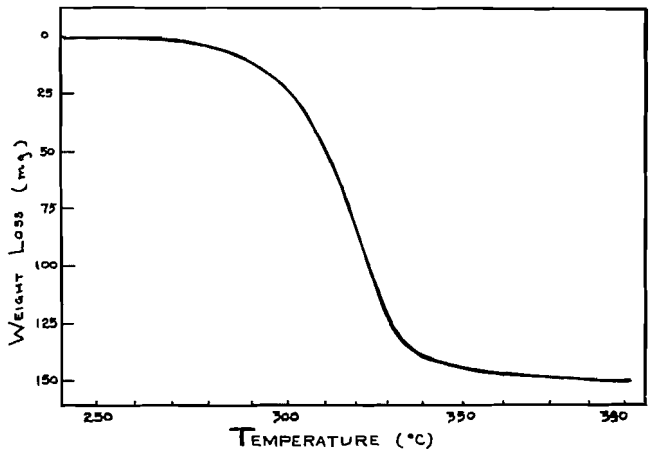

FIG. 4. Weight loss *vs.* temperature curve for cellulose heated in nitrogen at a rate of 1.5°/min.

intermediate and would favor this route to decomposition. Many workers (14, 23, 24) have reported that the presence of inorganic salts in cellulose influences its flammability by modifying the ability of the cellulose to produce the volatile tar (levoglucosan). It may be that the presence of salts favors the formation of "anhydrocellulose" and its subsequent decomposition, thereby diminishing the amount of levoglucosan that can be formed. Further, carbonium ions readily rearrange to produce more stable carbonium ions. This would account for the wide array of products obtained from the thermal decomposition of cellulose (25).

Determination of Activation Energies

Once aware of the temperature ranges wherein each of the two competing reactions is dominant, and of some of the variables (*e.g.* sample thickness) which might introduce errors into the determinations of true weight losses, the activation energies of the two reactions were found as outlined in the Experimental. The coiled paper permitted rapid escape of levoglucosan, and a heating rate of 1.5 °/min assured a slow passage through the earlier reaction thereby providing adequate data for meaningful calculations.

The data were treated according to the method outlined by Ingraham and Marier (26). Whereas their method yielded a linear relationship between weight loss and reciprocal temperature, all other methods attempted gave lines of continuously changing slopes. The method of Ingraham and Marier allows for changing surface area of the paper as decomposition progresses, by plotting $\log aw/T$ against $1/T$, where a is the weight loss per unit area, w is the heating rate, and T is the absolute temperature. A preliminary run had to be carried out to determine the paper's area loss with rising temperature. The activation energies of the reactions are calculated from the slopes, and equal $2.303 \times R \times$ Slope, where R is the gas constant. The weight loss *vs.* temperature curve is shown in Fig. 4 while the Arrhenius' graph for the determination of activation energies is shown in Fig. 5.

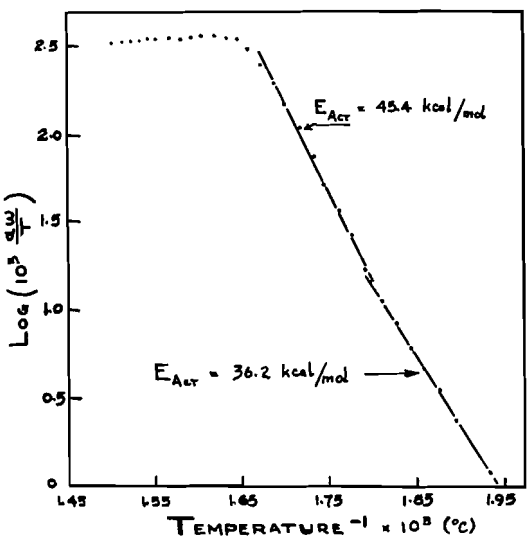

FIG. 5. Modified Arrhenius' graph for the determination of activation energy of the thermal decomposition of cellulose.

It is seen that two distinct straight lines result. The first runs from 250°, the point of first detectable weight loss, up to 280°, when only 5% of the toal weight loss has taken place. The second line runs from 285–320°, by which time about 60% of the total weight loss has occurred. The reaction at the lower temperature has an activation energy of 36.2 kcal/mol, while for the depolymerization reaction it is 45.4 kcal/mol. Murphy (4) who used the rate at which gas was evolved from heated cellulose to determine reaction rates, obtained results that suggested two reactions were present, and reported activation energies of 34.0 and 39.4 kcal/mol for these two. He proposed however that the former one was due to an impure substance in the cellulose, or perhaps end groups of the cellulose chains. The work of Chatterjee and Conrad (7) considered weight changes that occurred only after a temperature of 275° had been reached, thereby missing most of the reaction resulting in the formation of "anhydrocellulose".

The author wishes to gratefully acknowledge equipment grants from the National Research Council of Canada and the Defence Research Board, and financial assistance for technical help from the Council for Research of St. Francis Xavier University. He also wishes to thank Vincent Morrison for his help in the i.r. studies and Allan McIntyre for his work in thermogravimetry.

Proton Magnetic Resonance Study of the Conformational Equilibria in Some Substituted *N*-Acetylpyrrolidines

C. M. WONG, J. BUCCINI, R. SCHWENK, AND J. TE RAA
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received January 28, 1970[1]

In the p.m.r. spectra of eight *N*-acetyl-2-(*p*-methoxybenzyl)-pyrrolidines, the acetamido methyl group gives rise to two peaks in the range 7.7–8.5 τ. Compounds **9** and **10** also exhibit two peaks for the acetoxy methyl group in the same range. When the samples were heated, the pairs of peaks coalesced to give singlets. These results are interpreted as evidence for the existence of conformational equilibria.

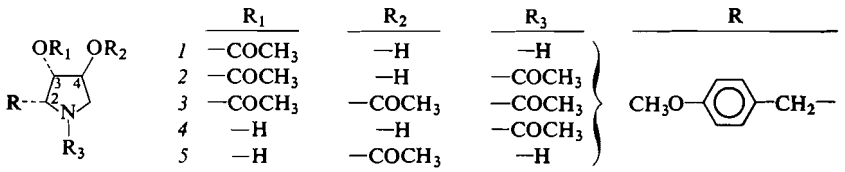
Canadian Journal of Chemistry, **49**, 639 (1971)

Introduction

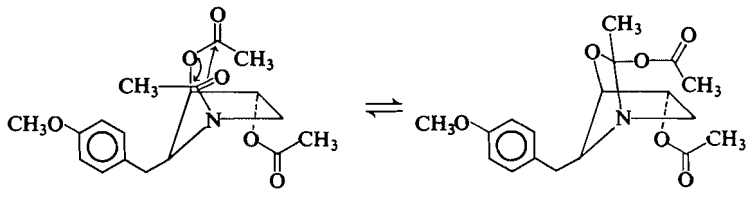
Recently, a communication (1) appeared which dealt, in part, with the n.m.r. spectra of *N*-acetylanisomycin (**2**) and diacetylanisomycin (**3**). The n.m.r. spectra of these compounds merited attention because the acetamido methyl group exhibited two different singlets in the range 8.0–8.5 τ. As an explanation for this phenomenon, Butler proposed that there existed in solution an equilibrium between **3** and **12** involving a four-centered mechanism as shown in eq. 1.

The main support for this proposal came from the following experimental evidence. In separate runs, labelled anisomycin (**1**, $R_1 = —^{14}COCH_3$) and labelled isoanisomycin (**5**, $R_2 = —^{14}COCH_3$) were refluxed with acetic anhydride and pyridine to give diacetylanisomycin (**3**), which gave the diol-amide **4** on alkaline hydrolysis. Liquid scintillation counting showed that the sample of **4** derived from anisomycin contained 27–30% of the label originally present in **1** while the sample of **4** derived from isoanisomycin contained only 7% of the original label. This transfer of the labelled acetyl group from oxygen to nitrogen was interpreted as evidence for the existence of an intermediate such as **11** or **12**. From the quantitative results, Butler concluded that **12** is more stable than **11**. It was also observed that when diacetylanisomycin (**3**) was subjected to t.l.c., two bands were observed which gave identical i.r. and n.m.r. spectra. When these two fractions were again subjected to t.l.c., each gave two bands.

During our recent synthetic study (2) of anisomycin (**1**), we observed that all the intermediates containing an *N*-acetylpyrrolidine ring showed two absorptions in the n.m.r. spectrum corresponding to the acetamido group. In two of the compounds, **9** and **10**, the acetoxy methyl also appeared as two singlets. Further n.m.r. studies of these compounds have led us to believe that the



[1]



[1]Revision received August 17, 1970.

[2] 
two absorptions of both the acetamido and the acetoxy methyl groups are due to restricted rotation about the C—N bond of —N—CO—CH_3 (3) and hydrogen bond formation between the hydroxy and the acetamido groups of **9** and **10**.

Experimental

The preparations of *N*-acetylanisomycin (**2**), diacetylanisomycin (**3**) and *N*-acetyldeacetylanisomycin (**4**) have been reported (5). Compounds **6–10** were reported in our synthesis o anisomycin (2). The n.m.r. samples were prepared with either $CDCl_3$ or DMSO-d_6, with TMS added as internal reference. The samples were degassed and sealed in thick-walled glass tubes. The spectra were recorded on a Varian A-56/60 A NMR Spectrometer which is equipped with a variable temperature apparatus.

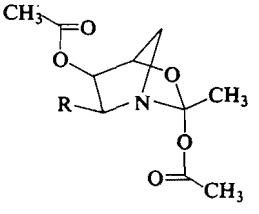
9 **10**



11

Results and Discussion

The acetamido methyl groups of compounds **2–4** and **6–10** appear as two singlets in their n.m.r. spectra at about 40 °C (Table 1). The acetoxy methyl group of **10** appears as two singlets at 39 °C while the acetoxy methyl group of **9** appears as a singlet at 39 °C, but at 20 °C, two peaks are observed. The magnitude of the separation between the pairs of peaks generally increased with cooling of the sample and decreased with heating until a coalescence temperature was reached. Such temperature behavior is typical of rate processes in which two conformers, appearing non-equivalent in the n.m.r. spectrum, are forced into a rapid rate of interconversion, thus becoming equivalent in the n.m.r. spectrum. We therefore postulate that the two acetamido methyl peaks arise from the type of equilibrium shown in eq. 2. The acetamido methyl group experiences a different environment due to the difference of anisotropic effect of the *p*-methoxybenzyl group in the two conformers. Using the Eyring equation and Nakagawa's method, we have estimated the free energy barrier to rotation to be about 17–21 kcal/mol.[2] These values agree with the values obtained for some 2,4,6-trialkylacetanilides (8, 9) where similar chemical shift differences were observed and a similar type of hindered rotation is implied.

A conformational equilibrium would explain the change in the magnitude of the chemical shift differences in the n.m.r. spectrum. If, as suggested

[2]Due to the unequal population of the two conformers, the estimated values of the free energy barrier to rotation (ΔF) obtained from coalescence temperatures, are not very accurate (7). Estimations obtained by Nakagawa's method (6) also would not be accurate because the formation of hydrogen bonded intermediates, eq. 4, makes the precise measurement of free energy barrier (ΔF) very difficult. Changes in internal shift of the exchanging proton sites arising from solvent effects were measured in the region of very slow exchange and extrapolated to temperatures where the exchange is relatively rapid. Unless such corrections are made, substantial errors in ΔF occur (10).

[3] 
1

by Butler, the two peaks were due to an equilibrium between **3** and **11** or **12**, changing the temperature would shift the equilibrium and hence alter the peak intensities, but a coalescence of lines is not likely. The proposal of conformational equilibrium is further supported by the fact that n.m.r. spectra of compounds **4**, **6** (Fig. 1), **7**, and **8** all show two singlets for the acetamide methyl groups but these compounds cannot enter into the equilibrium suggested by Butler.

Based on a study of the ring proton absorptions in the n.m.r. spectra of anisomycin (**1**) and isoanisomycin (**5**), Butler concluded that **1** existed in the conformation shown in eq. 3 and that **5** existed in a similar but somewhat less stable conformation. In such a conformation, the transfer of a labelled acetyl group from oxygen to nitrogen could take place as shown in eq. 3. The fact that **1** transferred four times more label than **5** would indicate that Butler's conclusions

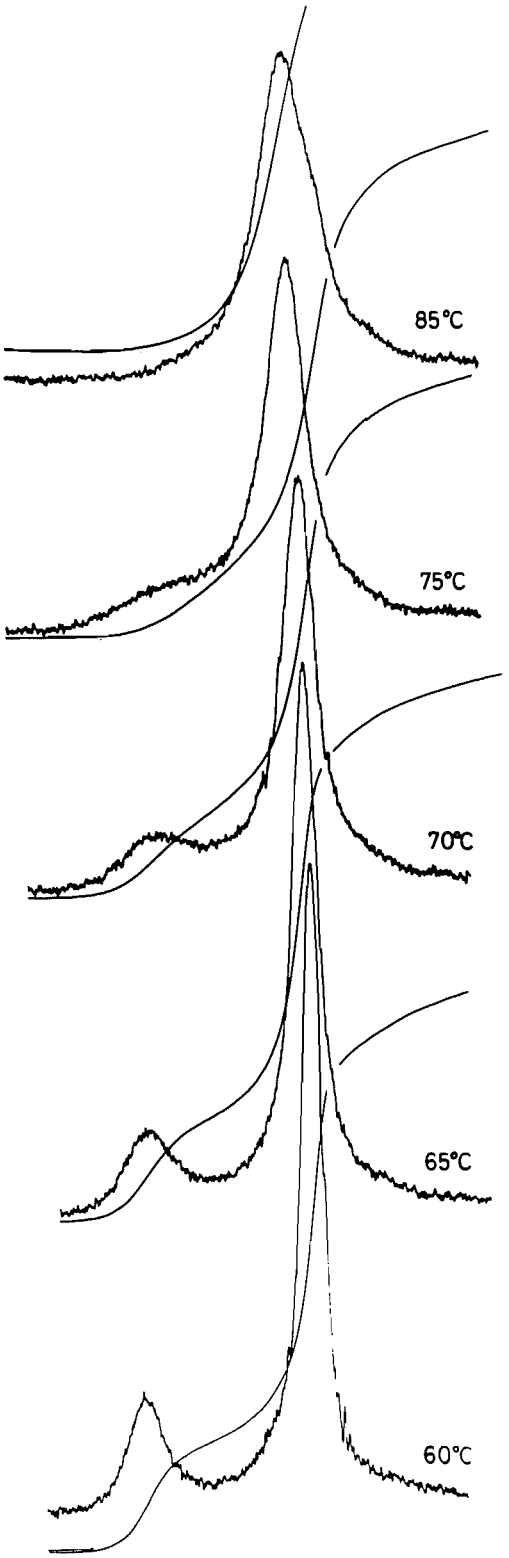

FIG. 1. Coalescence of the acetamido methyl group of **6**.

as to the conformations of the pyrrolidine ring are correct.

The t.l.c. separation of diacetylanisomycin (**3**) into two fractions which showed identical i.r. and n.m.r. spectra does not necessarily indicate the presence of an equilibrium between **3** and **12**; rather it could mean the separation of the two conformers as has been reported in the case of some 2,4,6-trialkylacetanilides (8).

In the case of simple formate and acetate esters, the presence of *s-cis* and *s-trans* rotamers has been detected by i.r. and ^{13}C n.m.r. studies (4). However, this is not the reason for the splitting of acetoxy groups of **9** and **10**, because such a conformational difference amounts to an energy difference of about 3 kcal/mol. Non-equivalence in anisotropy due to the difference in the relative positions of the acetamido group in the two conformers could be the reason. However, low temperature n.m.r. studies of **9** and **10** reveal an unusual phenomenon which can explain the splitting of the acetoxy methyl group more satisfactorily.

The interconversion of conformers **9***a* and *c* involves a transition state **9***b*, [4], which loses the partial double bond character of an amide. This transition state usually is unstable and thus cannot be detected by spectroscopic methods. However, due to the formation of a strong intramolecular hydrogen bond as shown in **9***b*, this otherwise unstable transition state becomes a stable conformer, [4]. Evidence came from the downfield shift of the hydroxy proton and simultaneously the collapse of the two peaks of the acetamide methyl group (Fig. 2). The broadening and resharpening of the hydroxy proton signal as the temperature lowered further substantiate the formation of **9***b*.

The formation of **9***b* at low temperature would bring the i.r. absorption of the acetamide group from 1650 cm^{-1} to that of a normal ketone. However, the i.r. spectrum at -70 °C showed the reverse effect. The acetamide group sharpened and moved down to 1640 cm^{-1}. Hydrogen bond formation is known to lower the carbonyl group absorption by 50 cm^{-1} (11) and the result here agrees with the formation of **9***b*. In the dilute solution i.r. spectrum the hydroxy stretching of **9** at room temperature shows quite a strong hydrogen bonding character at 3300 cm^{-1} while

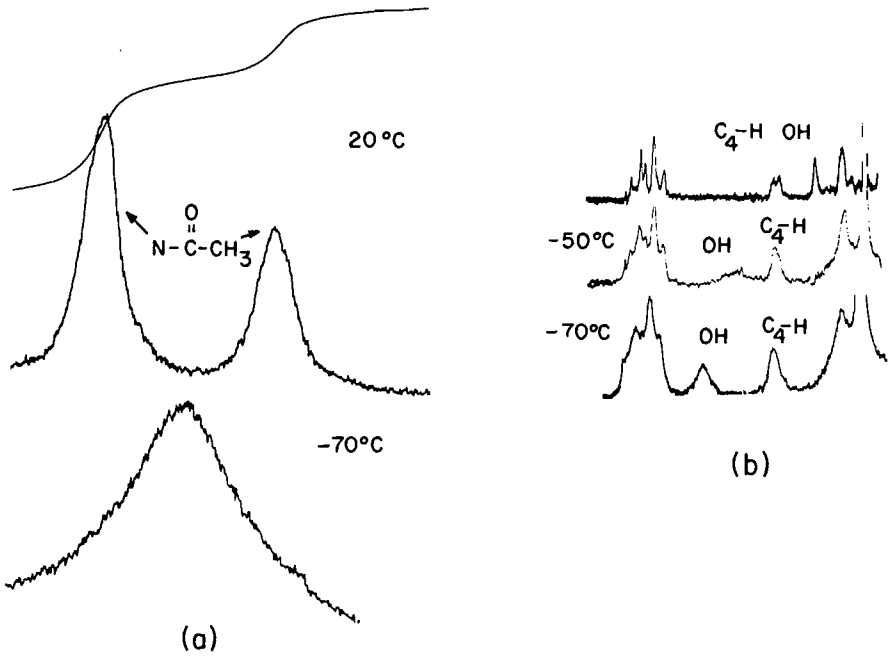

FIG. 2. (*a*) The two singlets of the acetamido methyl group of **9** at 20 °C and its coalescence at −70 °C. (*b*) Broadening and resharpening of the hydroxy proton of **9** at −50 and −70 °C.

the *N*-benzyl anisomycin shows only a sharp absorption at 3550 cm^{-1}.

The technique of n.m.r. has been used very extensively to study hindered rotation. However, the transition state has not been detected. The formation of conformer **9***b* would show the existence of the transition during a hindered rotation, although **9***b* in this case is more a conformer than a true transition state.

More work will be done on similar systems with emphasis on the accurate measurement of free energy barrier to rotation.

We thank Professor T. Schaefer of the Department of Chemistry, University of Manitoba, Winnipeg. Manitoba, for his very helpful discussions. We would also like to thank the National Research Council of Canada for financial support.

Preparation and Properties of some Non-Metallic Derivatives of Pentafluorothiophenol

M. E. PEACH AND H. G. SPINNEY
Department of Chemistry, Acadia University, Wolfville, Nova Scotia

Received June 12, 1970

Various non-metallic derivatives of pentafluorothiophenol, containing sulfur bonded to boron, carbon, silicon, germanium, phosphorus, arsenic, antimony, sulfur, and chlorine, have been prepared, mainly from the reaction of $Pb(SC_6F_5)_2$ with a non-metallic halide, and characterized. The ^{19}F n.m.r. spectra have been examined. The coordinating power of sulfur attached to a C_6F_5 group is minimal.

Divers dérivés non-métalliques du pentafluorothiophénol contenant du soufre lié au bore, au carbone, au silicium, au germanium, au phosphore, à l'arsenic, à l'antimoine, au soufre, et au chlore ont été préparés, principalement par réaction de $Pb(SC_6F_5)_2$ avec des halogénures non-métalliques et caractérisés. Les spectres r.m.n. de ^{19}F ont été examinés. Le pouvoir de coordination du soufre attaché à un groupe C_6F_5 est minimal.

Canadian Journal of Chemistry, **49**, 644 (1971)

The metallic derivatives of pentafluorothiophenol, $M(SC_6F_5)_x$ (1) and complex ions of the types $M(SC_6F_5)_x^{n-}$, where M is a metal, have been investigated (2, 3). Few non-metallic derivatives have been reported; this paper describes the preparation of some pentafluorophenylthio derivatives of B, C, Si, Ge, P, As, Sb, S, and Cl. The aims of this study were to examine the effects, if any, of the relatively electronegative C_6F_5 group, on the ease of preparation of these derivatives and its effect on the coordinating ability of the sulfur. The electronegativity of the C_6F_5 group depends on its interaction with the rest of the molecule, and has been estimated to be between that of chlorine and bromine to less than that of iodine in various organotin compounds (4). The C_6F_5 group could be classified as a pseudohalide group.

Non-metallic derivatives of thiols may be prepared by two general methods, starting with the non-metallic halide (5).

(*a*) The reaction of a thiol with the non-metallic halide in a suitable solvent; when the product is susceptible to attack by the hydrogen halide generated, a hydrogen halide acceptor, such as triethylamine is added. Similar products may be obtained from the reaction of a sulfenyl chloride with some non-metallic hydrides.

(*b*) The reaction of a thiol salt, such as a lead salt, with the non-metallic halide.

The compounds $C_6F_5SMR_3$, where MR_3 = $SiMe_3$, $SiPh_3$, $GeMe_3$, and $GePh_3$ (6), have been prepared using method *a*. Pentafluorothiophenol slowly polymerizes in air in the presence of a base (1), including triethylamine which was used as a hydrogen chloride acceptor in method *a*. Exclusion of air, either by working in a nitrogen atmosphere or using vacuum line techniques has enabled simple salts of pentafluorothiophenol with bases such as diethylamine, which would cause polymerization in air, to be prepared. Method *b*, which was used with the majority of compounds described in this paper, can be used in air without polymerization occurring.

The compounds $(C_6F_5S)_xY$, where Y = B, Me, CPh_3, CH_2, CH_2CH_2, MeCO, PhCO, C_6F_5CO, Me_3Si, Ph_3Ge, Ph_2Ge, Ge, P, PO, Ph_2P, As, PhAs, Sb, MeHg, and PhHg, were prepared from the corresponding chloride or iodide and bis(pentafluoro-phenylthio) lead, $Pb(SC_6F_5)_2$, subsequently referred to as the lead salt, in an inert solvent such as carbon tetrachloride or benzene. The products containing B—S, Si—S, and P—S bonds were somewhat hydrolytically sensitive.

No reaction was observed with $Me_{4-x}SiCl_x$, x = 2, 3, or 4, and the lead salt although this is a standard method for preparation of this type of mercapto silicon derivative (7). Trimethyl(pentafluorophenylthio) silane was also prepared from pentafluorothiophenol and hexamethyldisilazane in benzene, eq. 1. A similar reaction occurs with

[1] $(Me_3Si)_2NH + 2C_6F_5SH \rightarrow 2Me_3SiSC_6F_5 + NH_3\uparrow$

allylthiol(8). Phosphorus and arsenic trichlorides react with bis(trifluoromethylthio) mercury to give the compounds $(CF_3S)_xMCl_{3-x}$, x = 1, 2, or 3, depending on the stoichiometry of the reactants (9). No mixed pentafluorophenylthio chloro derivatives of phosphorus or arsenic,

*See ref. 18.

$(C_6F_5S)_xMCl_{3-x}$, $x = 1$ or 2, were obtained in the present work even if a considerable excess of the trichloride was present, the products being always the fully substituted derivative, $(C_6F_5S)_3M$, and the unreacted trichloride.

Bis(pentafluorophenyl) disulfide is readily obtained by oxidation of pentafluorothiophenol (1) and reacts with ammonia breaking the S—S bond according to eq. 2. Initial cleavage of the

[2] $2(C_6F_5S)_2 + 3NH_3 \rightarrow (C_6F_5S)_2NH + 2NH_4SC_6F_5$

S—S bond would form C_6F_5SH and $C_6F_5SNH_2$. The thiol forms the ammonium salt with excess ammonia, and the sulfenamide decomposes to the sulfenimide on purification by sublimation (10). A similar reaction of ammonia and $C_6F_5SSCF_3$ is observed, but the thiol formed, CF_3SH, reacts with the excess ammonia forming ammonium fluoride and thiocyanate (10). Attempted preparations of $(C_6F_5)_2S_x$, $x = 3$ or 4, from the lead salt and sulfur dichloride or sulfur monochloride, gave products whose mass spectra indicated that they were primarily mixtures of the disulfide and sulfur, although some of the desired product was present, but this may have been formed by recombination in the source. It was not possible to prepare $C_6F_5S—SO_x$ bonds. Thionyl and sulfuryl chlorides reacted with the lead salt yielding the disulfide, sulfur dioxide, and sulfur (thionyl chloride only) and benzene- and *p*-toluenesulfonyl chlorides did not react with the lead salt. The same types of reaction were observed with bis(trifluoromethylthio) mercury and thionyl and sulfuryl chlorides (11).

Attempts were made to prepare compounds containing S—Se—S and S—Te—S bridges. The compound $C_6F_5SSeC_6F_5$ has been prepared by heating bis(pentafluorophenyl) disulfide and bis(pentafluorophenyl) diselenide (12). Compounds of the type $(RS)_2M$, M = Se, Te, are known, but are relatively unstable (13), decomposing to the disulfide and selenium or tellurium; analogous results were obtained in the present work when R = C_6F_5. The reactions of R_2MCl_2 (R = Me, M = Se, Te: R = Ph, M = Se) with the lead salt yielded R_2M and the disulfide, the reaction probably proceeding through the formation of $R_2M(SC_6F_5)_2$ as an intermediate.

Sulfur compounds should theoretically be able to act as donors or acceptors. Sulfur acts as a donor in complexes such as $Me_2S.BCl_3$ (14), but examples where sulfur is an acceptor are rarer and usually occur with S(IV), as in liquid sulfur dioxide solution (15). The presence of the relatively electronegative C_6F_5 group attached to the sulfur would be expected to weaken its donor properties and enhance its acceptor properties, although the ^{19}F n.m.r. indicates π electron donation from the C_6F_5 ring to the sulfur. Sulfur complexes with the class B metals undoubtedly involve metal to ligand as well as ligand to metal bonding; the π electron donation from the C_6F_5 ring to the sulfur would impede the metal to ligand bonding, and complexes with the class B metals if formed, would not be expected to be particularly stable. Bis(pentafluorophenyl) sulfide formed no adducts with various donors or acceptors, such as the boron trihalides, various amines, metal ions, etc. The disulfide did not form complexes with Pd^{2+} or Ag^+ ions. The coordinating properties of both these potential ligands can be classified as minimal. The coordinating ability of the metal derivative, $Hg(SC_6F_5)_2$ has been studied; it formed an adduct with PPh_3, and an unstable adduct with $Ph_2P(SC_6F_5)$ but no adduct with triethylamine or ammonia.

The ^{19}F n.m.r. spectra of some of the products have been examined and the results are shown in Table 1. Similar spectra have been obtained for various other C_6F_5S derivatives (1). Using the derivations of Hogben *et al.* (16), it can be seen that the coupling constant $J_{2,4}$ varies regularly

with the chemical shift δ_4 in a particular solvent. The values of $J_{2,4}$ suggest π electron withdrawal from the C_6F_5 nucleus due to the vacant d orbitals on the sulfur, and the magnitude of the withdrawal increases $CH_2CH_2SC_6F_5 < C_6F_5 < CPh_3 < SCN < SCl$. The i.r. spectra are analogous to those expected for compounds containing the C_6F_5S group and the requisite functional group (17).

Experimental

Most reagents were available commercially. Microanalyses were performed by Mikroanalytisches Laboratorium Beller, Göttingen, Western Germany. The i.r. spectra were recorded on a Perkin–Elmer 457 spectrophotometer as mulls with Nujol or hexachlorobutadiene or as liquid films. The n.m.r. spectra were recorded on a Varian A60 instrument. The new, and some known, compounds prepared are shown in Table 2, together with some physical properties and analytical data. All experiments were performed using 1–2 mmol of reagents.

On refluxing a benzene solution of pentafluorothiophenol and triethylamine in air for 18 h a yellow precipitate formed; further precipitation occurred on standing at room temperature. Analysis showed it to be somewhat impure perfluoropoly(phenylene sulfide), and the reaction is similar to that of other nitrogenous bases with the thiol (1).

Methods A and B

The lead and silver salts of pentafluorothiophenol (used in methods A and B respectively) were prepared by literature methods (1). The requisite amount of a nonmetallic chloride or iodide was added to a suspension of the lead or silver salt in a suitable solvent and the mixture was stirred at room temperature (A or B) or refluxed (A′ lead salt only). The extent of the reaction was estimated qualitatively by the disappearance of the yellow lead salt and the appearance of white plumbous chloride, and quantitatively by weighing the plumbous halide formed; all reactions proceeded in greater than 80% yield. Products were purified by standard techniques, recrystallizations being from EtOH or CCl_4.

Known products were obtained with the following reagents (products shown after reagents): MeI - C_6F_5SMe (19); PCl_5 - $(C_6F_5S)_3P$ and $(C_6F_5S)_2$ (19); $SOCl_2$ - $(C_6F_5S)_2$, SO_2, and S; SO_2Cl_2 - $(C_6F_5S)_2$ and SO_2; Se_2Cl_2 - $(C_6F_5S)_2$ and Se; Me_2SeCl_2 (preparation (20)) - $MeSe_2$ and $(C_6F_5S)_2$; Ph_2SeCl_2 - Ph_2Se and $(C_6F_5S)_2$; $SeOCl_2$ - $(C_6F_5S)_2$, SeO_2, and Se; $TeCl_2$ - $(C_6F_5S)_2$ and Te; Me_2TeCl_2 (preparation (20)) - Me_2Te and $(C_6F_5S)_2$; Br_2 - $(C_6F_5S)_2$. The products were identified by standard techniques, including melting points, boiling points, i.r. spectra, and molecular weights (mass spectroscopically).

The lead salt did not react appreciably (less than 10%) with $SiCl_4$, $MeSiCl_3$, Me_2SiCl_2 (anhydrous CCl_4 as solvent) $PhSO_2Cl$ (CCl_4), or *p*-$TolSO_2Cl$ (toluene); the latter two did not react with the silver salt.

Method C

Stoichiometric amounts of C_6F_5SH were allowed to react in an N_2 atmosphere with the appropriate amine by shaking at room temperature in CCl_4. The product precipitated in high yield from solution. In method C′ C_6F_5SH was refluxed with $(Me_3Si)_2NH$ in C_6H_6.

Method D

Stoichiometric amounts of C_6F_5SH and NH_3 or Cl_2 were allowed to react in a sealed tube. Method D′ used the lead salt in place of C_6F_5SH. Quantitative yields were obtained.

Method E

Equimolar amounts of $Hg(SC_6F_5)_2$ (1) and PPh_3 or $Ph_2PSC_6F_5$ were refluxed in C_6H_6 and the product precipitated. No reactions were observed between $(C_6F_5)_2S$ (preparation (21)) and BCl_3 (sealed tube), BBr_3 (CCl_4), $BI_3(C_6H_6)$, NH_3 (sealed tube), $MeI(Et_2O)$, $Hg(SC_6F_5)_2(C_6H_6)$, $Et_3N(C_6H_6)$, $Hg^{2+}(H_2O,C_6H_6)$, Pd^{2+} $(2NHCl,C_6H_6)$, $Ag^+(H_2O,C_6H_6)$; $(C_6F_5S)_2$ and Pd^{2+} $(2NHCl, C_6H_6)$, $Ag^+(H_2O,C_6H_6)$; $(C_6F_5SCH_2)_2$ and $Hg^{2+}(H_2O,C_6H_6)$, $Pd^{2+}(2MHCl,C_6H_6)$; $Hg(SC_6F_5)_2$ and $Et_3N(C_6H_6)$, NH_3 (sealed tube); $PhHgSC_6F_5$ and $PPh_3(C_6H_6)$. The reactants were recovered unchanged after refluxing or allowing the sealed tube reactions to stand at room temperature for up to 5 days.

$(C_6F_5S)_2$ and NH_3

After allowing 10.0 mmol of $(C_6F_5S)_2$ and 30.0 mmol of NH_3 to stand at room temperature in a sealed tube for 6 days, 10.4 mmol of NH_3 were recovered on opening the tube. The increase in weight of the solid product recovered corresponded to 18.4 mmol of NH_3 having reacted. On vacuum sublimation of the solid product $(C_6F_5S)_2NH$, m.p. 80–82° (lit. 80–82° (10)) sublimed, which is formed by decomposition of $C_6F_5SNH_2$ on vacuum sublimation (10), leaving $C_6F_5SH.NH_3$, identified by its i.r. spectrum. The stoichiometry of the reaction is,

$$2(C_6F_5S)_2 + 4NH_3 \rightarrow 2C_6F_5SNH_2 + 2C_6F_5SH.NH_3$$
$$\downarrow \text{ Vacuum sublimation}$$
$$(C_6F_5S)_2NH + NH_3$$

Mechanism of Oxidative Decarboxylation of α-Hydroxy Acids by Bromine Water. Part I. Oxidation in Neutral and Alkaline Medium[1]

JUDITH M. PINK[2] AND ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 2, 1970

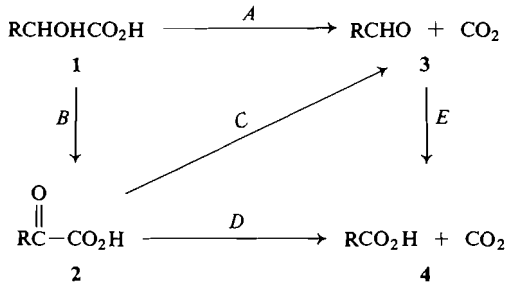
A kinetic study of the oxidative decarboxylation of α-hydroxy acids by bromine water shows that above p*H* 6 Br_2 is a much more significant oxidant for these compounds than is HOBr, and that OBr^- is virtually inert. The rate law $-d[oxidant]/dt = k[oxidant][substrate]$ is observed and the oxidation pattern differs from that of alcohols in that the α-hydrogen is not involved in the reaction.

All the compounds studied (benzilic, mandelic, and 2-hydroxy-2-methylpropanoic acids) exhibit bell-shaped p*H*–rate profiles with maxima at about p*H* 8. A mechanism is proposed involving the attack of Br_2 (or HOBr) at the carboxylate site concurrently with base-catalyzed loss of the hydroxylic proton. A steady state treatment based on this mechanism yields calculated rates in good agreement with the observed values. Furthermore, the same parameters predict the rates observed at lower p*H* in the presence of added excess bromide. The Br_2 oxidation rate is greater than the HOBr rate by a factor of 60 for benzilic acid, 37 for 2-hydroxy-2-methylpropanoic acid, and 10 for mandelic acid.

Canadian Journal of Chemistry, 49, 649 (1971)

Introduction

α-Hydroxy acids possessing an α-hydrogen **1** may undergo oxidative decarboxylation by a number of routes (1) (Scheme 1). Reaction *B* is exemplified by the conversion of lactic acid



SCHEME 1

(**1**, R = CH_3) to pyruvic acid under the influence of lactic dehydrogenase. Other enzymic processes (*C*, *D*, *E*) can convert pyruvic acid to acetate (**4**, R = CH_3), either directly or via the aldehyde, **3**.

Many chemical oxidants, on the other hand, convert **1** to **4** by paths *A* and *E* in which the keto acid **2** is not an intermediate and the reaction can often be stopped at the aldehyde **3** stage. Reactions which appear to follow path *A* include the Hunsdiecker reaction (2), anodic oxidation (3), and oxidation by many, but by no means all, transition metal oxidants (4–10). For example, manganese(VII) oxidations follow *A* in acid solution but *B* in basic solution (10), and chromium(VI) is believed to react by path *B* (5, 9).

The present work is a study of the oxidative decarboxylation of three α-hydroxy acids, benzilic, mandelic, and 2-hydroxy-2-methylpropanoic acids, by bromine water in neutral and alkaline solution. The accompanying paper deals with the somewhat different situation that exists under acidic conditions (11).

A mechanistic study of α-hydroxy acid oxidation by bromine water is all the more interesting because of the different behavior of this oxidizing agent towards alcohols on the one hand and towards many carboxylic acids on the other. There is now considerable evidence (12–19) that alcohol oxidation occurs through a rate determining abstraction of a hydride ion from an α-position by Br_2 and that this step is assisted by the removal of the hydroxylic hydrogen as a proton. This interpretation is in agreement with the kinetic isotope effects (12–14), substituent effects (17, 18), and the presence of general base catalysis (17, 19), though it fails to explain the observations of Barker *et al.* (20) concerning the oxidation of cycloalkanols. The oxidation of formate is analogous to the alcoholic oxidation pattern (21) but that of oxalic acid is entirely different. In the latter case HOBr is a much more efficient oxidant than Br_2 and reaction takes place with oxalic acid or mono-oxalate but not with the dioxalate (19).

Experimental

Analar grade inorganic reagents were used throughout. The highest grade organic reagents available were several times recrystallized or freshly distilled prior to use. Water was doubly distilled and cooled under a stream of nitrogen. All glassware was meticulously cleaned with chromic acid or with a 5% solution of hydrogen fluoride and rinsed several times with distilled water. The u.v. spectra were recorded on a Bausch and Lomb 502 or on a Cary Model 14 Spectrophotometer. The pH was determined by a Beckman Model G pH meter and, for most of the kinetic runs, by a Radiometer TTT1 Titrator. The computations were carried out with the aid of IBM 1620 and 1130 computers.

Product Analysis

The hydroxy acids gave nearly quantitative yields of the corresponding ketones or aldehydes. Yields were estimated on the basis of absorption in the u.v.; the identity of the ketones was also established by preparing their 2,4-dinitrophenylhydrazone derivatives.

Kinetics

The pH of the reaction medium was monitored by continuous titration with a Radiometer Model TTT1 Titrator. The reactions were carried out in a 150 ml darkened glass vessel having four necks with ground glass joints. Through the necks were fitted (*a*) a glass electrode; (*b*) a fritted glass salt bridge connecting the reaction vessel with a calomel electrode; (*c*) a syringe filled with 0.5 M KOH, its tip ending in a fine glass capillary under the surface of the reaction mixture; (*d*) a glass stopper. The vessel, containing a teflon coated magnetic stirring bar and a known volume (about 100 ml) of freshly prepared bromine water (10^{-4}–10^{-3} M), was equilibrated in a constant temperature bath at 25°. The pH of the stirred reaction mixture was brought to the desired value by adding acid from a pipette or base from the syringe. Three 5 ml aliquots were removed for analysis at 3–5 min intervals for determining the initial oxidant concentration. The substrate solution was made up to have a pH similar to that intended in the run in order to minimize pH changes caused by its addition to the reaction mixture. The reaction was started by adding a stoichiometrically equivalent amount of substrate (2–5 ml) by blowing from a specially calibrated pipette. Aliquots were withdrawn at appropriate time intervals, using a fast delivery pipette, and were quenched in acidified potassium iodide solution and titrated. The pH was controlled by the instrument to within 0.10 pH units and the volume of base added during the reaction never amounted to more than 0.4 ml. Most reactions were complete within 5 min, corrections for bromine loss due to evaporation were made for slower reactions. In calculations the concentration of all compounds were corrected according to the total volume of the reaction mixture after adding the substrate.

Results and Discussion

The oxidation of benzilic, mandelic, and 2-hydroxy-2-methylpropanoic acids by bromine water above pH 5.5 was found to follow second order kinetics; first order with respect to each

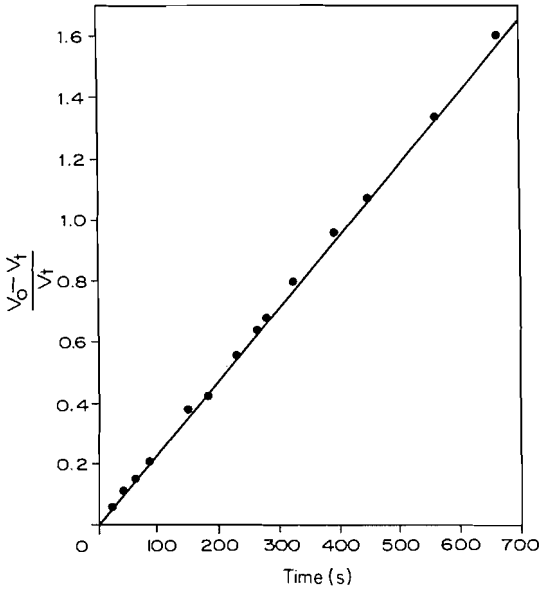

FIG. 1. A typical second-order rate plot for the oxidation of mandelic acid by bromine water, pH = 8.5, T = 25 °C. The initial concentration, C_0, of substrate and oxidant was 2.84×10^{-3} M; $k_2 = (V_0 - V_t)/V_t \cdot 1/tC_0 = 0.829$ 1 mol^{-1} s^{-1}; V = thiosulfate titre.

reagent (Fig. 1). The stoichiometry of the oxidation by molecular bromine shows that acid is released during the reaction (eq. 1). Furthermore,

[1] $$RR'COHCO_2^- + Br_2 \rightarrow RR'C{=}O + CO_2 + 2Br^- + H^+$$

both the composition of bromine water and the nature of the substrate are pH dependent and it was therefore necessary to maintain a constant pH during individual runs.

The reaction was found to be subject to general base catalysis, but not in a simple manner; *e.g.* the oxidation rate of benzilic acid was greatly enhanced by certain buffers (phosphate at pH 6 for example) but the Brønsted relation was not obeyed. Thus, in order to simplify the kinetics a constant pH was maintained by means of a pH-stat. In the absence of buffers the pH–rate profile of each substrate is bell-shaped and the rate maximum occurs at about pH 8 (see Figs. 2–4). This superficially corresponds to the HOBr content of these solutions[3] and suggests

[3]At a given bromide concentration the HOBr content is a function of the pH and can be calculated from the following equations:

$K_h = [Br^-][HOBr][H^+]/[Br_2] = 9.6 \times 10^{-9}$ (ref. 22)

and

$K_{HOBr} = [H^+][OBr^-] = 2.1 \times 10^{-9}$ (ref. 23)

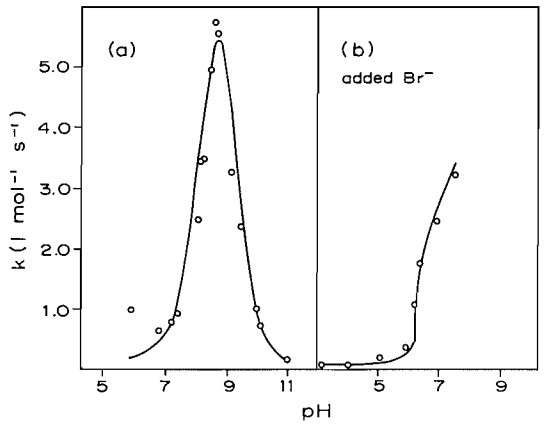

FIG. 2. The pH dependence of the rate of benzilic acid oxidation by bromine water in (*a*) the absence and (*b*) the presence of added bromide ion (0.0338 – 0.153 M). The curves in both cases were drawn using values calculated from eqs. 6 and 7 and the values $\kappa_{H_2O} = 4.5 \times 10^{-2}$, $\kappa_{OH} = 9 \times 10^3$, $\kappa_{HOBr} = 2 \times 10^5$, and $\kappa_{Br} = 1.2 \times 10^7$. The open circles represent experimental points.

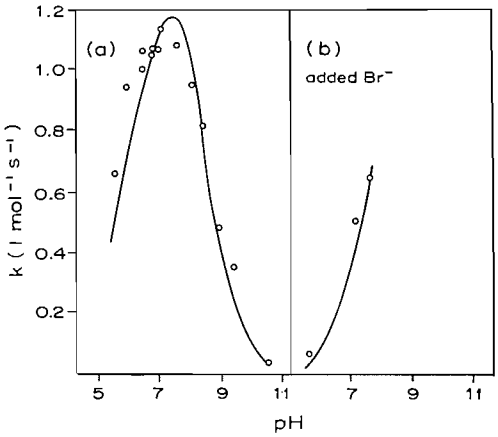

FIG. 3. The pH dependence of the rate of mandelic acid oxidation by bromine water in (*a*) the absence and (*b*) the presence of added bromide ion (0.0540 – 0.0763 M). The curves in both cases were drawn using values calculated from eqs. 6 and 7 and the values $\kappa_{H_2O} = 5 \times 10^{-5}$, $\kappa_{OH} = 6 \times 10^4$, $\kappa_{HOBr} = 8 \times 10^4$, $\kappa_{Br} = 8 \times 10^5$. The open circles represent experimental points.

that OBr^- is inert. However, when the HOBr concentration in reaction mixtures having a pH above 5 was reduced by adding bromide, the rate was found to increase. This shows Br_2 to be a better oxidant than HOBr under these conditions. (In more acidic solutions the reactivity order is reversed; see accompanying paper.) Above pH 5 all the substrates studied are completely dissociated and a likely possibility would

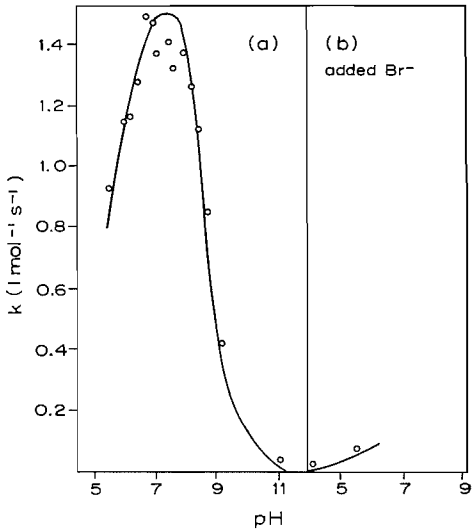

FIG. 4. The pH dependence of the rate of 2-hydroxy-2-methylpropanoic acid oxidation by bromine water in (*a*) the absence and (*b*) the presence of added bromide ion (0.054 – 0.055 M). The curves in both cases were drawn using values calculated from eqs. 6 and 7 and the values $\kappa_{H_2O} = 8 \times 10^{-4}$, $\kappa_{OH} = 3 \times 10^4$ $\kappa_{HOBr} = 5 \times 10^4$, $\kappa_{Br} = 1.87 \times 10^6$. The open circles represent experimental points.

be a base-catalyzed bromine–carboxylate reaction. The eventual rate decrease as the pH is increased beyond 8.6 is expected on the basis of the pH dependence of the composition of bromine water. Above this pH the concentration of Br_2 is negligible and the oxidant is all in the form of HOBr and OBr^-.

A possible mechanism is shown in eq. 2, where S^- is the dissociated form of the α-hydroxy acid

$$[2] \qquad S^- + Br_2 \overset{K_{Br}}{\rightleftharpoons} SBr + Br^- \qquad SBr + :B \longrightarrow \text{products}$$

and :B represents a base. (In the unbuffered systems the two strongest bases are OH^- and OBr^-.)

An attempt was made to measure K_{Br} for a closely related compound, α-methoxyphenylacetic acid, which is only slowly degraded by bromine water. Calculations based on the pH-drop, observed when solutions of this acid and of bromine water, both initially at the same pH, were mixed, showed that in this reaction the upper limit of the equilibrium constant, K_{Br}, is 0.1. By assuming an equilibrium constant of the same order of magnitude for the hydroxy acid – bromine water reaction, and estimating the catalytic rate coefficients for hypobromite and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

hydroxide by comparing rate constants observed at constant pH and constant hypobromite concentration, respectively, it can be shown that if Br_2 were the only oxidant the rate maximum for benzilic acid would appear at a pH no higher than 7.5 instead of at the observed value of 8.6. This indicates the presence of an HOBr reaction path. Scheme 2 should then be considered.

$$S^- + HOBr \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SBr + OH^-$$

$$S^- + Br_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} SBr + Br^-$$

$$SBr + H_2O \xrightarrow{k_3} S^- + HOBr + H^+$$

$$SBr + OH^- \xrightarrow{k_P} \text{products}$$

$$SBr + OBr^- \xrightarrow{k_P'} \text{products}$$

SCHEME 2

In this case the SBr concentration is assumed to be low, so that a steady state approximation is applicable. The observed rate is given by eq. 3,

$$[3] \quad \text{rate} = k_P[SBr][OH^-] + k_P'[SBr][OBr^-]$$

where the second term can be neglected to a first approximation. Accordingly, the steady state concentration of SBr is eq. 4.

$$[4] \quad [SBr] = \frac{k_1[S^-][HOBr] + k_2[S^-][Br_2]}{k_{-1}[OH^-] + k_{-2}[Br^-] + k_3 + k_P[OH^-]}$$

Since good second order kinetics was observed above pH 6 when stoichiometrically equivalent amounts of substrate (S^-) and oxidant (Ox) were used, eq. 5 results.

$$[5] \quad \text{rate} = k_{obs}[S^-][Ox] = k_{obs}[S^-]^2 = k_P[SBr][OH^-]$$

The substitution of eq. 4 into 5 gives eq. 6.

$$[6] \quad k_{obs}k_{-2}[S^-][Br^-] + k_{obs}k_3[S^-] + k_{obs}(k_P + k_{-1})[S][OH^-] - k_Pk_1[HOBr][OH^-] - k_Pk_2[Br_2][OH^-] = 0$$

Equation 6 can be used, in principle, to calculate the composite rate constants if the variables

$$[7] \quad \kappa_{H_2O} = k_3/k_{-2} \qquad \kappa_{OH} = (k_{-1} + k_P)/k_{-2}$$
$$\kappa_{HOBr} = k_Pk_1/k_{-2} \qquad \kappa_{Br} = k_Pk_2/k_{-2}$$

k_{obs}, $[S^-]$, $[Br^-]$, [HOBr], $[Br_2]$, and $[OH^-]$ are known for four runs. However, the pH of the runs could be maintained only within $\pm.10$ pH units which is not sufficient precision to obtain accurate values for the partition of the oxidant between Br_2, HOBr, and OBr^-. Equation 6 is ill-conditioned and thus it is not possible to solve for the rate constants from experimental values. Therefore, values were chosen for the composite rate constants defined in eq. 7 and eq. 6 was solved for k_{obs} instead. The self-consistently calculated values of k_{obs} at different pH's showed fair agreement with the observed rate constants, as can be seen in Figs. 2–4.

If Scheme 2 is indeed valid then it must be applicable to all conditions when the $[Br_2]$/[HOBr] ratio is constant throughout the reaction. This is not the case for oxidation by bromine water below pH 6, for the bromide accumulating during the course of the reaction changes the oxidant composition considerably. If, however, the reaction is carried out in the presence of a fairly large excess of Br^-, the effect of Br^- formed will be negligible. Thus, the composite rate constants (κ), used in the calculations at high pH should also predict the observed rate constants for runs carried out at lower pH in the presence of excess Br^-. Figures 2*b*, 3*b*, and 4*b* show that this indeed is the case. This result is significant, for the concentration terms of these two sets of runs differ from each other by several powers of ten. Further refinement of the self-consistent calculations could bring the calculated rate constants even closer to the observed values but in the opinion of the authors the present numerical data are sufficient to support the proposed mechanism.

The apparently autocatalytic kinetics of mandelic acid oxidation at pH 6–7 in the presence of added bromide is explained by further reaction of the primary oxidation product, benzaldehyde. Rate studies carried out on pure benzaldehyde showed its rate of oxidation to be about a third of that of mandelic acid under these conditions. Our results also support earlier observations (24) that Br_2 is a much more important oxidant for benzaldehyde than HOBr and that the reaction is subject to general base catalysis (25).

The relative importance of the HOBr and Br_2 oxidation paths for the various α-hydroxy acids can be assessed by comparing the ratios of $\kappa_{HOBr}/\kappa_{OH}$ with those of κ_{Br}/κ_{OH}, listed in Table 1. The ratio of the HOBr/Br_2 routes is of the same

TABLE 1. Comparison of HOBr and Br_2 oxidation rates of α-hydroxy acids in alkaline medium*

α-Hydroxy acid	$\kappa_{HOBr}/\kappa_{OH} = \alpha k_1$	$\kappa_{Br_2}/\kappa_{OH} = \alpha k_2$	Br_2 rate/HOBr rate

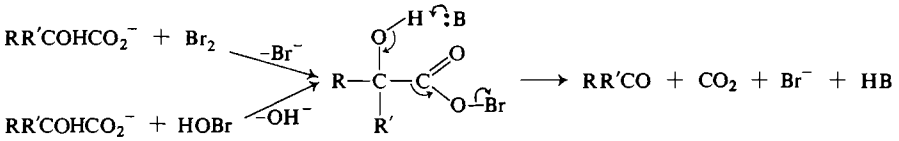
Mandelic	1.33	13.3	10

*$\alpha = \frac{k_P}{k_P + k_{-1}}$



SCHEME 3

order of magnitude as was found for formate oxidation by Binoun and Perlmutter-Hayman (26). It is not surprising that the highly polarizable Br_2 is more reactive towards carboxylate than is HOBr, though it is puzzling why oxalate should be an exception. We have confirmed previous reports (19) that HOBr is much the more significant oxidant for oxalate throughout the p*H* range.

The results presented show that the presence of an α-hydrogen is not a requirement for oxidative decarboxylation indicating that path *A* (Scheme 1), rather than paths *B* and *C* convert mandelic acid to benzaldehyde. Isotopic studies reported in the accompanying paper (8) support this conclusion.

The most reasonable mechanism that is in agreement with the kinetic analysis is formation of an acyl-hypobromite type intermediate which can readily decompose if the hydroxylic proton is removed by base (Scheme 3). Thus the observed rate is determined by the Br_2 and HOBr concentrations (which decrease with increasing p*H*) and by the concentration of base.

It is interesting to note that the rate maximum for the oxidative decarboxylation of α-hydroxy acids by bromine water occurs under near-neutral conditions, unlike those prevailing in most other *in vitro* oxidations.

The financial support of the National Research Council of Canada is gratefully acknowledged. Some of the experimental work was done by J.M.P. in Mr. R. P. Bell's laboratory at the University of Oxford, Oxford, England, and we express our thanks for this and for his interest.

Mechanism of Oxidative Decarboxylation of α-Hydroxy Acids by Bromine Water. Part II. Oxidation in Acidic Medium. A Comparison with the HOBr – Oxalic Acid Reaction[1]

JUDITH M. PINK[2] AND ROSS STEWART
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

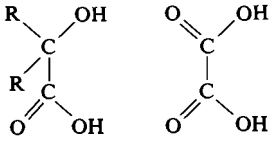
Received September 2, 1970

The oxidative pattern of α-hydroxy acids by acidic bromine water is shown to be similar to the oxalic acid – bromine water reaction. In both cases HOBr is the oxidant and the undissociated form of the organic acid is required for reaction to occur. The rate law $-d[HOBr]/dt = k[HOBr][\text{hydroxy acid}]$ is observed for oxidations carried out in the presence of Ag^+ ion in the p*H* range 2–5. Below that p*H* bromination occurs. Bell-shaped p*H*–rate profiles are obtained for the oxidations of benzilic, mandelic, and 2-hydroxy-2-methylpropanoic acids. The calculated rates, based on a steady state treatment of a reaction path involving a hypobromite intermediate ($R_2COBrCO_2H$) are in agreement with the observed values and with the observation that the rates of oxidation of mandelic acid in D_2O and H_2O are the same.

Canadian Journal of Chemistry, 49, 654 (1971)

Introduction

In Part I it was shown that α-hydroxy acids undergo ready oxidative decarboxylation by the action of bromine water under neutral conditions (1). The reaction appears to take place via the carboxylate anion with Br_2 being a much more effective oxidant than HOBr. The reverse is true for the oxidation of oxalic acid by bromine water; in this case HOBr is the oxidant and only the mono-oxalate and the undissociated acid appear to react (2). Oxalic acid seems to be exceptional in this regard since all other compounds studied to date are preferentially oxidized by Br_2 (3). α-Hydroxy acids (**1**) are structurally related to oxalic acid (**2**), and it was hoped that their behavior might shed some light on this enigma.



1 **2**

Experimental

Reagents

Most of the reagents and apparatus used were described in Part I. D_2SO_4 was prepared using Ingold's method (4). α-D-Mandelic acid was obtained by exchanging sodium mandelate in 99.87% D_2O in a sealed tube at 150° for 3 weeks. The α-hydrogen exchange was shown to be quantitative by n.m.r. spectroscopy.

The methods published for the preparation of α-methoxydiphenylacetic acid (5) failed to give satisfactory yields. The following synthetic method was therefore developed. A mixture of 12 g of benzilic acid and 15 ml of phosphorus tribromide was allowed to react for 12 h at 100° in a flask fitted with a condenser and drying tube containing silica gel. After standing overnight the solution was cooled in ice, the precipitate formed was filtered off, washed with ligroin, then added to anhydrous ice-cold methanol. The product thus obtained was hydrolyzed in alcoholic potassium hydroxide on a steam bath, then this solution was evaporated to dryness and the residue extracted with boiling water. The cooled acidified aqueous solution was extracted with ether. The amorphous acidic material obtained after evaporating the ether was dissolved in a 5% solution of sodium bicarbonate and this solution was then carefully acidified until it became cloudy. Upon standing, colorless needles separated. After two recrystallizations from benzene–ligroin, the compound had a m.p. of 109.5–110.0 (lit. 110.0–110.6 (6)).

Product Analysis

Reaction mixtures containing excess bromine and silver nitrate relative to the substrate, but otherwise similar to those employed in kinetic runs, were allowed to react. Then excess aqueous ammonia was added in order to dissolve the silver bromide and to react with the unused hypobromous acid. The mixture was then extracted with ether. The u.v. spectra were taken of the aqueous fraction and of an alcoholic solution of the solid obtained from the ether extract. Nearly quantitative yields of the appropriate ketones or aldehyde were obtained above p*H* 2.5.

Kinetics

The procedure described in Part I was followed. The iodometric determination of the oxidant in the presence of added silver ion involves a grey to yellow color change at the end point; it requires some experience to distinguish this transition reproducibly.

Oxidation of triphenylacetic acid: Triphenylacetic acid (0.10 g) was dissolved in 10 ml glacial acetic acid and added to a 3×10^{-3} *M* bromine solution (100 ml) containing excess silver nitrate (1×10^{-2} *M*). This mixture was allowed to stand at room temperature for 1 month in the dark. Occasionally 5 ml aliquots were withdrawn for analysis. After 1 month the oxidizing power of the reaction mixture decreased to 41% relative to the control solution containing all the components except triphenylacetic acid. The reaction was terminated by quenching the oxidant with an equivalent amount of sodium bisulfite; then the silver was precipitated by adding potassium bromide. The mixture was centrifuged, the solid residue extracted with benzene, and the liquid analyzed by t.l.c. The spots developing in the chromatogram corresponded to those of a mixture of triphenylacetic acid and triphenylcarbinol, chromatogrammed concurrently. No triphenylcarbinol was formed when triphenylacetic acid was allowed to react with bromine water in the presence of added silver bromide.

The IBM 1620 and 1130 computers were used in carrying out the computations.

pK_a Determination of Mandelic Acid in 90% D_2O

A standard potentiometric technique (7) was employed, using Radiometer SBR2c/SUB1/TTA3 titration equipment in conjunction with a type PHA 630T Scale Expander. The pK_a of mandelic acid in water was determined to be 3.385 ± .007 (lit. 3.388, (8)) at 25°. The pK_a in 90% D_2O was found to be 3.472 ± .006 using activity corrections based on the equation given by Glasoe and Long (9).

Results and Discussion

The kinetics of α-hydroxy acid oxidation by bromine water below p*H* 5 is complex. When stoichiometrically equivalent amounts of oxidant and substrate are used autoretardation occurs. This is due to the accumulation of bromide, which inhibits the reaction greatly; Br^- forms Br_3^- with Br_2 (10), but the depletion of oxidant by tribromide formation can only account for a part of the observed rate decrease.

When the formation of bromide is suppressed by the addition of excess silver ion the reaction occurs at a much higher rate and obeys a second order rate law, first order with respect to oxidant and with respect to substrate (Fig. 1). At least 2 mol of Ag^+ are necessary per mol of bromine to obtain good second order kinetics, but increasing the $[Ag^+]$ beyond that point does not alter the rate (see Fig. 1). Hence the effect of silver ion on the rate can be attributed to its shifting the bromine hydrolysis equilibrium in favor of HOBr (eq. 1) rather than to its participation in the rate-controlling step.

[1] $Br_2 + H_2O + Ag^+ \rightarrow HOBr + H^+ + AgBr(s)$

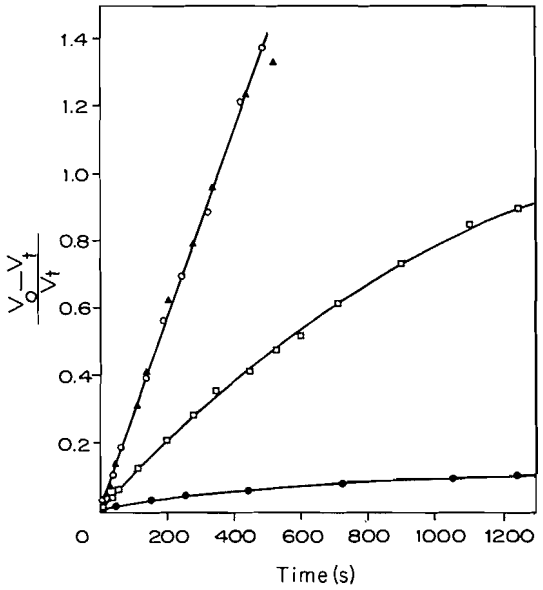

FIG. 1. The effect of silver ion concentration on the rate of oxidation of benzilic acid by bromine water at p*H* 1.77; $[Ag^+]_0/[\text{oxidant}]$ = 0.0 (●), 1.0 (□), 2.0 (▲), 13 (○); *V* = thiosulfate titre.

In strongly acidic media and in the presence of silver ion bromine water brominates aromatic α-hydroxy acids. The logarithm of the rate of benzilic acid bromination in this system shows a linear dependence on the H_0 function. Such a relation has also been observed previously for halogenation by positive agents (11). The rate of bromination becomes negligible above p*H* 1.5; hence the study of the oxidative decarboxylation process in the presence of silver ion was restricted to the p*H* range 2–5. Above p*H* 5 bromine water was found to be unstable in the presence of silver ion.

The oxidative decarboxylation of α-hydroxy acids by hypobromous acid is accompanied by the liberation of acid, eq. 2.

[2] $RR'COHCO_2H + HOBr \rightarrow RR'C{=}O + CO_2 + Br^- + H_2O + H^+$

Two methods of maintaining a constant p*H* during the reaction were employed. The first method, the use of buffers, increased the reaction rates appreciably relative to the values observed when the p*H* was kept constant by the second method, that of continuous titration. However, no simple relation could be established between buffer concentration and rate data. Changing the ionic strength had no effect on the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rate. The rate increase due to increasing buffer concentration may be due either to base catalysis, or to the formation of species like acetyl hypobromite (12) or bromine–phosphate complexes (13). For this reason the discussion below is restricted to treatment of data obtained in unbuffered, p*H*-statted systems.

The p*H*–rate profiles for oxidations carried out in the presence of silver ion are bell-shaped for all the hydroxy acids studied in the p*H* region 2–5 (see Figs. 2–4). The only significant oxidant in these solutions is HOBr. The rate increase with increasing p*H* as the pK_a of the substrate is approached would suggest that the rate controlling step involves the carboxylate anion but does not explain the rate decrease on the high p*H* side of the bell-shaped curve. Scheme 1, in which HOBr reacts with the undissociated acid to form a hypobromite intermediate, HZ, satisfies

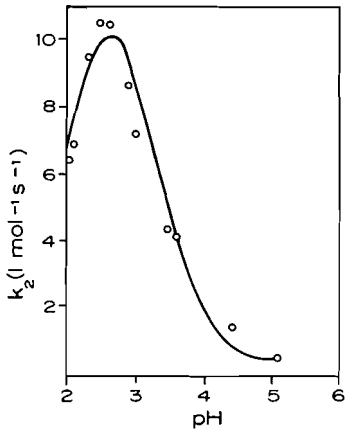

FIG. 2. The p*H*-dependence of the rate of oxidation of benzilic acid by bromine water in the presence of silver ion. Solid line is calculated using eq. 10, pH_{max} = 2.60, pK_s = 3.05.

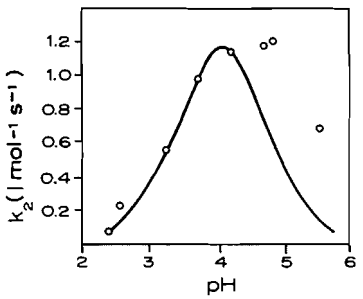

FIG. 3. The p*H*-dependence of the rate of oxidation of 2-hydroxy-2-methylpropanoic acid by bromine water in the presence of silver ion. Solid line is calculated using eq. 10, pH_{max} = 4.05, pK_s = 3.97.

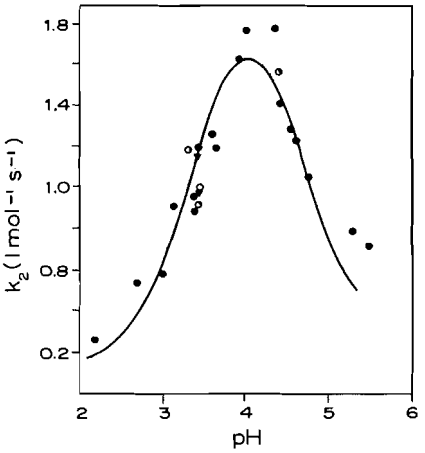

FIG. 4. The p*H*-dependence of the rate of oxidation of mandelic acid by bromine water in the presence of silver ion. Solid line is calculated using eq. 10, pH_{max} = 4.04, pK_s = 3.39. Legend: mandelic acid in H_2O (●), mandelic-α-*d* acid (○), mandelic acid in D_2O (p*H* corrected) (▼).

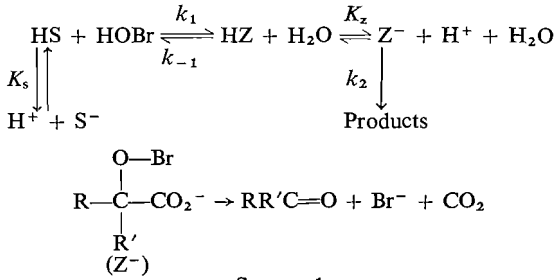
both requirements. This intermediate can decompose into oxidation products when it loses a proton. Scheme 1 requires that the hypobromite be formed at the hydroxyl site, not at the carboxyl site as in the oxidation at higher p*H* (1), because



SCHEME 1

the intermediate HZ must be sufficiently acidic to ionize in acid solution. Furthermore, reaction of the neutral α-hydroxy acid with hypobromous acid should occur more readily at the hydroxyl than at the carboxyl group. The terms in Scheme 1 are defined as:

$$\mathrm{HS} = \mathrm{RR'COHCO_2H}$$

$$K_s = [\mathrm{H^+}][\mathrm{S^-}]/[\mathrm{HS}]$$

$$\mathrm{HZ} = \mathrm{RR'COBrCO_2H}$$

$$\left\{ \begin{array}{l} \mathrm{Z^-} = \mathrm{RR'COBrCO_2^-} \\ K_z = [\mathrm{H^+}][\mathrm{Z^-}]/[\mathrm{HZ}] \end{array} \right. \quad [3]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

furthermore,

$$[4] \quad \begin{cases} [S_t] = [HS] + [S^-] \\ [Z_t] = [HZ] + [Z^-] \end{cases}$$

The rate of formation of the hypobromite intermediate $[Z_t]$ is eq. 5.

$$[5] \quad d[Z_t]/dt = k_1[HS][HOBr] - k_{-1}[HZ] - k_2[Z^-]$$

Assuming a steady state concentration of $[Z_t]$ and substituting the appropriate mole fractions according to [3] and [4] we get eq. 6.

$$[6] \quad [Z_t] = \frac{k_1 \dfrac{[HOBr][S_t][H^+]}{K_s + [H^+]}}{k_{-1}\dfrac{[H^+]}{K_z + [H^+]} + k_2 \dfrac{K_z}{K_z + [H^+]}}$$

The observed rate depends on the Z^- concentration (eq. 7) where k is the experimental second

$$[7] \quad \text{rate} = k[HOBr][S_t] = k_2[Z^-] = k_2 \frac{K_z[Z_t]}{K_z + [H^+]}$$

order rate constant. Combining eqs. 6 and 7 we get eq. 8. According to eq. 8 k vanishes as

$$[8] \quad k = \frac{k_1 k_2 \dfrac{[H^+]}{K_s + [H^+]} \dfrac{K_z}{K_z + [H^+]}}{\dfrac{k_{-1}[H^+] + k_2 K_z}{K_z + [H^+]}}$$

$[H^+] \to 0$ and as $[H^+] \to \infty$ and has a maximum at

$$[9] \quad [H^+]_{max} = \left(\frac{K_s K_z}{k_{-1}}\right)^{1/2}$$

A combination of eqs. 8 and 9 gives eq. 10. Thus

$$[10] \quad k = k_1 \frac{[H^+][H^+]^2_{max}}{(K_s + [H^+])(K_s[H^+] + [H^+]^2_{max})}$$

it is seen that the dissociation constant, K_s, of the hydroxy acid and the experimental pH value at the observed rate maximum uniquely determine k in terms of k_1. If we designate the coefficient of k_1 in eq. 10 as k_{calc} ($k = k_1 k_{calc}$), k_{calc} can be readily computed for any value of $[H^+]$. The comparison of k_{calc} with the experimentally observed rate constant gives $k_1 = k/k_{calc}$. The constancy of k_1 is indicative of the validity of Scheme 1.

In some cases better agreement between calculated and observed rates could be achieved throughout the pH range if a pH maximum slightly different from the observed value was assumed. If the observed rates are not solely due to the process described, but there is contribution from other processes (*e.g.* bromination at low pH, reaction with the carboxylate at high pH) then, even if the contribution from these is small, the true rate maximum may be masked.

The results of some computations are shown graphically in Figs. 2–4. The calculated rate constants show a reasonable agreement with the experimentally obtained values. Of course, the nature of the intermediate cannot be determined on the basis of kinetics alone. The above treatment is compatible not only with a low steady state concentration of a hypobromite intermediate, formed at the hydroxyl site, but also with a concerted reaction between undissociated carboxylic acid, hypobromous acid, and base. The data of Fig. 4 also show that the oxidation rate in water and in 90% D_2O are almost the same when rates are compared at pH values corresponding to the same degree of ionization of mandelic acid. This is in accordance with Scheme 1 if the steady state concentration of the intermediate Z^- is unaffected by isotopic substitution. A concerted reaction between neutral mandelic acid, HOBr, and base seems somewhat less likely since it is difficult to conceive of a concerted mechanism that does not involve O—H cleavage and a cancellation of isotope effects would be required. However, the solvent isotope experiments are not definitive; they were conducted at a single pH and the effect of D_2O on the various equilibria is hard to assess.

At this point it may be of interest to recall the parallel behavior of oxalic acid. In that case too, HOBr is the most important oxidant and while the mono-oxalate is the most reactive species, the dioxalate is inert. An unionized carboxyl group is thus required for the oxidation in both cases. The importance of the $—CO_2H$ group is further illustrated by the observation that neither methyl benzilate nor the carboxylate anion of α-methoxydiphenylacetic acid are oxidized by bromine water but the undissociated form of α-methoxydiphenylacetic acid reacts slowly. The presence of a reaction path for oxidative decarboxylation other than that shown in Scheme 1 is revealed by the slow but definite oxidation of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

triphenylacetic acid by HOBr (again, no oxidation takes place with Br_2) and by the rapid degradation of α-amino acids by HOBr. Amino acids behave rather differently to hydroxy acids in basic solution; glycine is rapidly degraded by hypobromite ion whereas glycolic acid is inert.

In the case of mandelic acid it might be expected that the compound would be oxidized both as an alcohol and as a hydroxy acid. A comparison of rates for α-H and α-D mandelic acids (Fig. 4) shows that α-deuteriation has no effect on the rate. Thus the hydroxy acid route is energetically much more favorable and the α-proton is not involved in the reaction at all.

Comparison of Oxidation in Acidic and Basic Solution

The oxidative decarboxylation of α-hydroxy acids by bromine water exhibits bell-shaped curves both in acid solution (Figs. 2, 3, and 4) and in neutral or basic solution (1). If the two curves were combined a camel-like pH–rate profile would appear, with peaks at pH 2.8 and 8.6 for benzilic acid. However, the conditions for the two reactions are different; the acid reaction was conducted in the presence of silver ion to allow a satisfactory kinetic analysis to be made.

Combining the two reaction paths, one can derive a rate law describing the complex kinetics observed in acidic bromine water, in the absence of Ag^+.

Neglecting the less important contributions, we have eq. 11. Because of the accumulation of

$$[11] \quad \text{rate} = k_{HOBr}[HOBr][HS] + k_{Br_2}[Br_2][S^-][OH^-]$$

bromide during the course of the reaction, the $HOBr/Br_2$ ratio changes with time in accordance with the equilibria

$$K = [Br_2][Br^-]/[Br_3^-] = 0.0594 \text{ (ref. 10)}$$

$$K_h = [H^+][HOBr][Br^-]/[Br_2] = 9.6 \times 10^{-9} \text{ (ref. 14)}$$

When stoichiometrically equivalent oxidant and substrate are used,

$$[\text{total oxidant}] = [\text{total substrate}] = S$$

Assuming that the initial bromide concentration, due to hydrolysis of Br_2, is negligible, the bromide concentration at any time is expressed as

$$[Br^-] = 2(S_0 - S)$$

Thus eq. 11 yields eq. 12. where K_s and K_w are the dissociation constants of the substrate and

$$[12] \quad -\frac{dS}{dt} = \frac{S^2}{KK_h + 2[H^+](S_0 - S)[2(S_0 - S) + K]} \times \left\{k_{HOBr}KK_h + k_{Br_2}\frac{2K_sKK_w(S_0 - S)}{[H^+] + K_s}\right\}$$

water respectively. The integrated form of eq. 12 is not suitable for the separation of unknowns, but using the graphically determined value of $-dS/dt$ and assuming that the rate constants observed in the presence of Ag^+ are identical to k_{HOBr} at the given pH, one can determine k_{Br_2}. The value of k_{Br_2} was found to be acceptably constant for benzilic acid (see Tables 1 and 2). For the other substrates the approximation $k_{HOBr} \approx k_{Ag}$ is less valid because the oxidation of the carboxylate by HOBr is not negligible relative to Br_2 oxidation. However, since at high pH only the relative rates could be established,

TABLE 1. The kinetics of the oxidation of benzilic acid by bromine water in the presence of accumulating bromide.* A typical run

Time (s)	$k_{Br_2} \times 10^{-10}$
50	1.24
100	1.45
200	1.04
300	1.19

500	0.98
600	0.84
800	1.00
1000	1.05

*[Benzilic acid] = [oxidant] = 7.40 × 10^{-4} M; pH maintained by a pH-stat at 3.35; k_{Br_2} was calculated on the basis of eq. 12.

TABLE 2. Calculated rate constants for the oxidation of benzilic acid by bromine water in the presence of accumulating bromide*

pH	$k_{Br_2} \times 10^{-10}$
2.60	0.98±0.01
3.35	1.07±0.14
3.60	1.10±0.12
3.90	1.17±0.11

*[Benzilic acid] = [oxidant] = 7.40 × 10^{-4} M; pH maintained by a pH-stat; k_{Br_2} was calculated on the basis of eq. 12.

it is not possible to correct k_{Ag} numerically for contributions from carboxylate oxidation.

In summary, the principal oxidant in neutral or basic solution is molecular bromine and the substrate is the carboxylate anion of the α-hydroxy acid. In acid solution containing silver ion the oxidant is hypobromous acid and the substrate appears to be the neutral α-hydroxy acid.

Charge Localization in the Mass Spectra of Substituted Phenylbutyrophenones

D. A. LIGHTNER AND FRANK S. STEINBERG
Department of Chemistry,[1] *University of California, Los Angeles, California 90024*

Received August 18, 1970

A study of the McLafferty rearrangement of substituted phenylbutyrophenones relative to butyrophenones and 1-(4-butyrophenyl)-2-ethanes shows a peculiar non-linear relationship with the type of substituent and the distance of the substituent from the reaction site.

Canadian Journal of Chemistry, 49, 660 (1971)

Introduction

The role of electron-donating and -withdrawing substituents in localizing charge in unimolecular ion reactions observed in mass spectra has been investigated in substituted butyrophenones (1), valerophenones (2), nitro- and butyryldiphenyl ethers (3), and methyl butyrates (4). Among the conclusions reached for the McLafferty rearrangements of substituted butyrophenones are that the reaction is (*i*) enhanced by an increased positive charge at the reaction site (the ratio $[M\text{-}C_2H_4]/[M]$ is greater for an electron-withdrawing substituent than for an electron-donating substituent) (1*a*), and (*ii*) much slower when the substituent has been removed and "isolated" from the reaction site (1*b*, 2). The influence of a *remote but conjugated* substituent in the McLafferty rearrangement has been discussed only briefly in connection with the fragmentation of nitrodiphenylethers (3). In this note we discuss new information on remote substituent effects.

Experimental

All mass spectra were determined on an AEI MS-9 mass spectrometer at varied ionizing voltages using a 100 μA electron beam. The i.r. spectra were taken on a Perkin–Elmer Model 137 spectrophotometer and n.m.r. spectra were determined on a Varian Model A-60 instrument. All melting points (capillary) are uncorrected. Satisfactory micro analyses were performed on all compounds in this work.

In a typical experiment, the substituted (except amino and hydroxy) phenylbutyrophenones were obtained by acylation of the substituted biphenyl with butanoyl chloride and a molar excess of anhydrous aluminum chloride in gently refluxing carbon disulfide. The aminophenylbutyrophenones were prepared by stannous chloride reduction (5) of corresponding nitro compounds, and the hydroxy isomer via diazotization of the corresponding amino isomer. Most substituted butyrophenones may be obtained as indicated (6) or synthesized by modification (R. Nicoletti, this laboratory) of established procedures (7, 8).

Results and Discussion

In our work we have investigated the behavior of substituted phenylbutyrophenones (**1** and **2**) and have noted several new effects (see Table 1) which were not observed for the [M-28] fragmentation of substituted butyrophenones (**3**) (1*a*) or 1-(4-butyrophenyl)-2-phenylethanes (**4**) (1*b*). (*1*) Whereas electron-donating substituents have a very similar influence on the [M-28] rearrangement in **1**, **2**, and **3**, electron-withdrawing substituents do not, and (*2*) the influence of an electron-withdrawing substituent in enhancing the [M-28] fragmentation is an order of magnitude greater in **3** than in **1** and **2** but is smaller (by a factor of 2) in **1** ($Y = NO_2$) compared to **4** ($Y = NO_2$),[2] wherein the substituent is not only remote from but incapable of conjugation with the reaction site. The behavior mentioned under (2) may be contrasted with that of electron-donating substituents in **1**, **2**, and **3** in which the closeness of the [M-28] values suggests that fragmentation behavior here is relatively *insensitive* to the substituent's distance from the reaction center. Considering the very large difference shown by **1**, **2**, and **3** for electron-withdrawing groups, the behavior noted for

[1]Contribution no. 2566.

[2]At 75 eV, [M-28] in **4** ($Y = NO_2$) is 94 for M = 100%. See ref. 1*b*.

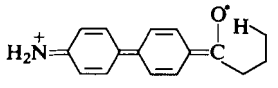
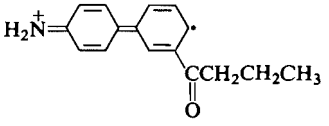
electron-donating groups is rather surprising. Also, judging from the usual behavior of an electron-donating substituent far removed from the reaction site, *e.g.*, **4** (Y = NH_2),[3] the [M-28] intensities of **1** and **2** are expected to be considerably smaller than those of **3**.

The peculiar non-linear effects in **1**, **2**, **3**, and **4** noted by varying distance from the reaction site and changing from electron-withdrawing to electron-donating substituents suggest that the qualitative arguments of charge localization (1–4) do not sufficiently explain certain types of fragmentation behavior. Conjugation of the substituent Y of **1** with the carbonyl group (presumed transfer site) by resonance appears to have no special influence on the [M-28] intensities which are very similar for the meta- and para-nitro or amino isomers.[4] Thus, canonical resonance structures such as **5** and **7** apparently contribute no more to the total picture than either **6** or **8**, although the rationalization (1) for the butyrophenone (**3**) behavior was interpreted using the concept of radical site *and* positive charge localization on the carbonyl oxygen.

Probably a more satisfying explanation of the data of Table 1 is lodged in the quasi-equilibrium treatment (4) and a knowledge of how given substituents perturb the energy profile for excited states leading to product. Even though a clear linear parallel is observed between the effect of a substituent on the [M-28] fragmentation of phenylbutyrophenones and the ionization poten-



5



6

[3]At 75 eV, [M-28] in **4** (Y = NH_2) is < 1 for M = 100%. See ref. 1*b*.
[4]This behavior holds for the nitrobutyrophenones **3** (Y = NO_2) as well and suggests that biphenyl twisting is not responsible for the observed effects.

X-Ray and Infrared Studies of Lead Apatites

Vijay Mohan Bhatnagar[1]

Chemistry Department, University of New Brunswick, Fredericton, New Brunswick

Received July 27, 1970

The cell constants and infrared spectra of lead apatites have been investigated. The lowering of the molecular symmetry T_d of the phosphate ion, and the nature and extent of changes in vibration frequencies of lead apatites with the ionic substitution of PO_4^{3-} by AsO_4^{3-} and VO_4^{3-} are discussed.

Canadian Journal of Chemistry, 49, 662 (1971)

We are investigating the infrared spectra of apatites in the light of detailed knowledge of atomic positions provided by X-ray studies. A previous study (1) was on the investigation of synthetic apatites and the present work is a report on the study of mineralogical apatites. The mineral specimens of this investigation were obtained from the United States National Museum. A description of them has been reported (2). The unit cell dimensions of these samples calculated from the X-ray powder diffraction patterns are given in Table 1. There seems to be no variation of X-ray data for phosphatian-mimetite of this work with the replacement of arsenic by phosphorus. In fact, the unit cell dimensions should have different values with the changing composition. Our observation is confirmed by the interesting work of Adler (3) who could not determine in his X-ray spectrogram the presence of phosphate in his phosphatian-mimetite sample.

Table 1. Unit cell dimensions of lead apatites

Apatite	*a*-Axis (Å)	*c*-Axis (Å)	*c*/*a*

Although pyromorphite, mimetite, and vanadinite are isomorphous, their infrared spectra

[1]This work was carried out at Fisk University, Nashville, Tennessee, U.S.A., and Faculté des Sciences de Toulouse, Toulouse, France.

show certain basic differences. The free phosphate ion, PO_4^{3-}, belongs to the point group T_d. The normal modes of the tetrahedral phosphate ion are (4): ν_1, symmetric P—O stretching; ν_2, OPO bending; ν_3, P—O stretching, and ν_4, OPO bending. The observed frequencies are: ν_1, 980; ν_2, 363; ν_3, 1082; and ν_4, 515. In the undistorted state, only the absorptions corresponding to ν_3 and ν_4 vibrations are observed. The two remaining fundamentals ν_1 and ν_2 become infrared active when the configuration of the PO_4^{3-} ion is reduced to some lower symmetry. The degenerate modes are split by distortion of the phosphate groups through lack of symmetry in the lattice sites. The frequencies thus vary somewhat for different crystal structures.

The frequencies observed for PO_4^{3-}, AsO_4^{3-}, and VO_4^{3-} ions in pyromorphite, $Pb_{10}(PO_4)_6Cl_2$; phosphatian-mimetite, $Pb_{10}[(As,P)O_4]_6Cl_2$; and vanadinite, $Pb_{10}(VO_4)_6Cl_2$ in our present work are shown in Table 2.

The absorption frequencies of PO_4^{3-} in phosphatian-mimetite are given in Table 3. They are compared with those reported by Adler (5) in his phosphatian-mimetite specimens from Zacatecas, Mexico and Cumberland, England. Our data agree very well with the experimental results of Adler (5). As the number of allowable bands for each fundamental mode depends on the symmetry of the individual ion, a slight variation in frequencies is observed in pyromorphites. The symmetry of the three ions in lead apatites is expected to be C_s (2, 3, 5, 6). If this is the case, it appears that not all of the modes are being resolved completely. It is also possible that there is coincidence of ν_1 and ν_3 in some of these apatites. It is difficult to resolve

TABLE 2. Absorption frequencies of PO_4^{3-}, AsO_4^{3-}, and VO_4^{3-}

Ion	ν_1	ν_2	ν_3	ν_4

AsO_4^{3-}	—	—	785, 805, 816	385, 415
VO_4^{3-}	—	—	740, 805	322, 380, 419

TABLE 3. Absorption frequencies of PO_4^{3-} in phosphatian-mimetite

Reference	ν_1	ν_2	ν_3	ν_4
This work	920	325	955, 985, 1000	538, 550, 565
Adler (5)	917	—	951, 982, 1000	537, 548, 564

TABLE 4. The number of infrared active vibrations for molecular point groups C_s and C_{3v}

Point group	ν_1	ν_2	ν_3	ν_4
C_s	1	2	3	3
C_{3v}	1	1	2	2

ν_1 for mimetite and vanadinite, although the vibration is allowed by structural considerations. According to Siebert (7), the Raman lines for ν_1 and ν_3 in AsO_4^{3-} show coincidence at 813 cm^{-1}; this may account for absence of ν_1 in the infrared spectrum of mimetite.

Considering the site group data for apatite (the P atom is on a C_s site) and the bond length data for the phosphate group in apatite by Posner *et al.* (8), C_s molecular symmetry appears reasonable for all apatites. However, the infrared data for pyromorphite conform to the vibrational requirements of C_{3v} symmetry for the PO_4^{3-} ion. The number of infrared active vibrations for molecular point groups C_s and C_{3v} are (3) given in Table 4.

Thus the one band of ν_3 and one band of ν_4 in the pyromorphite spectrum are not resolved. However, ν_3 and ν_4 of phosphate ion in phosphatian-mimetite show resolution of three ν_3 and ν_4 bands at 955, 985, and 1000 cm^{-1}, and at 538, 550, and 565 cm^{-1}, respectively. This supports the position that the PO_4^{3-} group in phosphatian-mimetite, which is isostructural with the apatite, has C_s symmetry rather than C_{3v} symmetry. It is still impossible, however, to identify the third bands in ν_3 and ν_4 for PO_4^{3-} in pyromorphite.

The apatite work was supported by research grants DE-02105 from the U.S. Department of Health, Education, and Welfare and Office National de l'Azote, France.

A Facile Formation of Dibenzo[*a*,*d*]cycloheptenylium Ion by Decarbonylation. Color Reactions of the Cyheptamide Metabolites

K. SESTANJ

Department of Biochemistry, Ayerst Research Laboratories, Montreal, Quebec

Received August 17, 1970

Treatment with concentrated sulfuric acid of different 10-hydroxylated metabolites of the anticonvulsant cyheptamide results in intensely colored products. These have been identified as dibenzo-[*a*,*d*]cycloheptenylium ions.

Canadian Journal of Chemistry, 49, 664 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Studies (1) of the metabolic fate of the anticonvulsant cyheptamide (AY-8682) (**1**) have indicated that in laboratory animals and man the compound is mainly hydroxylated, preferably on the benzylic carbon, C-10. Of particular interest is the property of 10-hydroxylated metabolites of cyheptamide upon acid hydrolysis to undergo deamination followed by transannular lactone formation, to yield **2** (1). The fact that several of the compounds produced, *e.g.* **2**, **3**, **4**, on treatment with concentrated or 30 *N* H_2SO_4 give intense color reactions was used as the basis for a procedure for the quantitative determination of 10-hydroxylated metabolites of cyheptamide (2). The purpose of the present communication is to describe the chemical nature of this reaction, the products of which have been identified as tropylium ions.

Tropylium ions are remarkably stable organic cations. They are energetically favored even in the case of a two-fold fusion with benzene rings, **6**, where the coplanarity and electronic delocalization tend to be largely distorted (3–5). It has been known that 5*H*-dibenzo[*a*,*d*]cyclohepten-5-ol (**5**) gives an intense orange–red coloration in concentrated sulfuric acid, due to the formation of dibenzo[*a*,*d*]cycloheptenylium ion (**6**) (3). We have found that solutions of the lactone **2** and the acid **3** in concentrated sulfuric acid are spectroscopically undistinguishable from an equimolar solution of the alcohol **5** in sulfuric acid. On dilution with water an identical mixture of the alcohol **5** and the ether **7** is obtained from each of the three solutions.

The formation of dibenzo[*a*,*d*]cycloheptenylium ion **6** from **2** and **3** is initiated by dehydration followed by decarbonylation; the stability of the ion **6** which acts as driving force could also account for the cleanness of the reaction. Another example of tropylium ion formation by decarbonylation is the conversion of cyclohepta-2,4,6-triene carbonylchloride with silver perchlorate reported by Dewar and Ganellin (6). Pertinent examples of carbonium ion formation by decarbonylation are tritylium ion generation from triphenylacetic acid (7) and of cyclopropenium ion from cyclopropene carboxylic acid (8).

The 5-hydroxy lactone **4** in concentrated or 30 *N* sulfuric acid solution produces a deeper red color than compounds **2**, **3**, and **5**. The tropylium ion **8** is formed by opening of the transannular lactone bridge and loss of the benzylic hydroxyl by protonation. This reaction is analogous to the formation of the ion **6** from alcohol **5**. Conjugation of the carboxylic group and the tropylium ion causes a shift to longer wavelengths. The 5-hydroxy acid **9** (9) has been isolated on dilution with water and was characterized by i.r., u.v., and n.m.r. spectra as well as by lead tetraacetate oxidation to the dibenzotropone **10**.

Experimental

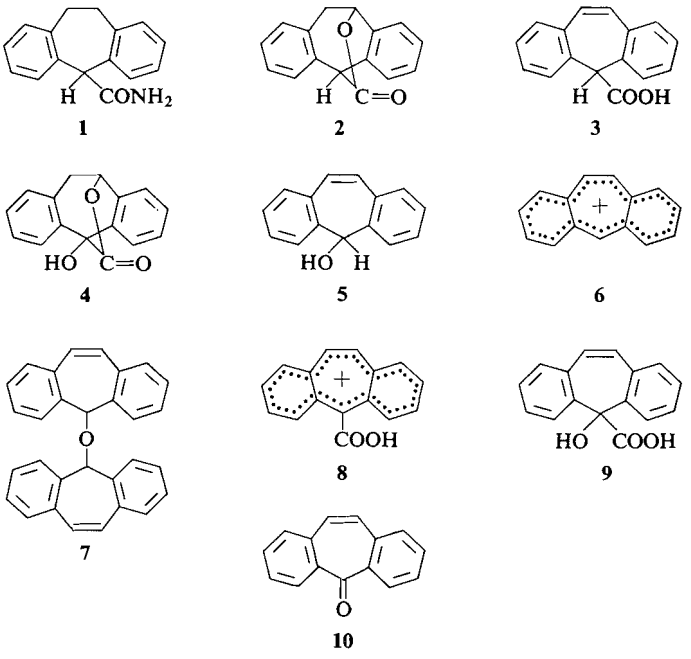
The u.v. and visible spectra were recorded on a Unicam SP-800 UV Spectrophotometer, i.r. spectra on a Perkin–Elmer 225, and n.m.r. spectra on a Varian A-60A instrument with tetramethylsilane as internal standard. Melting points were not corrected.

Reaction of Compounds 2, 3, and 5 with Concentrated Sulfuric Acid

The compounds **2** (11), **3** (10), and **5** (5–10 mg each) were dissolved in 10 ml of concentrated H_2SO_4 and heated for 2–3 min in a boiling water bath. After cooling to room temperature, the absorption spectra were measured. Identical absorption maxima and molecular extinction coefficients were obtained with all of the three compounds: λ_{max} (ε) 528 (2860); 500 (3170); 392 (7720); 376 (9035); 305 mμ, (115 840).

Reaction of the 5-Hydroxylactone 4 with Concentrated Sulfuric Acid

A solution of the lactone (11) in concentrated or



30 *N* H_2SO_4 had the following absorption maxima: λ_{max} (ε) 564 (2700); 528 (3010); 412 (7790); 392 (7060); 314 (103 820); 270 (8720); 242 mμ (15 780).

Formation of 5-Hydroxy Acid ***9*** *from 5-Hydroxylactone* ***4***

The 5-hydroxylactone **4** (233 mg, 0.025 mmol) was dissolved in 23 ml of 30 *N* H_2SO_4, the red solution stirred for 15 min at 50° and poured on ice; the mixture was extracted with ether, the extract dried over magnesium sulfate, and evaporated under reduced pressure. The residue crystallized from ether and carbon tetrachloride to give 138 mg (60%) of **9**, m.p. 166–168°. Purity was verified by t.l.c. in ethyl acetate/benzene (1:4) and spraying with concentrated H_2SO_4. The u.v. spectrum: λ_{max} (ε) 283 mμ (11 170); i.r. spectrum (Nujol): ν_{OH} 3550, ν_{COOH} 3000 (broad); $\nu_{C=O}$ 1730 and 1750 cm^{-1} (split); n.m.r. spectrum: multiplet between δ 8.0 and 7.0.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.42; H, 4.99.

*Formation of Dibenzo[a,d]cyclohepten-5-one (****10****) from 5-Hydroxy Acid* ***9***

To 25.2 mg of the acid **9** (0.1 mmol) dissolved in 5 ml of benzene a solution of 56 mg of lead tetraacetate in 1 ml of benzene and one drop of acetic acid was added and stirred for 15 min at room temperature. Ten milliliters of hexane were added, the mixture filtered, and the filtrate washed repeatedly with an aqueous solution of $NaHCO_3$ and water, dried over magnesium sulfate, and evaporated under reduced pressure. The residue crystallized from hexane to give 14.8 mg of a product shown to be identical with an authentic sample of dibenzotropone **10** (commercial product, Aldrich Chem. Co.).

The author acknowledges with gratitude the skillful assistance of Mrs. Diane Watts, B.Sc. and wishes to thank Dr. D. Dvornik for his interest in this work, and Drs. M. A. Davis and T. A. Dobson for the authentic samples of the compounds used in the study.

The Effects of Substituents on the Abstraction of Halogens by Fluoroalkyl Radicals

LEONARD O. MOORE

Research and Development Department, Chemicals and Plastics, Union Carbide Corporation, South Charleston, West Virginia 25303

Received September 1, 1970

The relative reactivities of halogens to abstraction by fluoroalkyl radicals at 125° have been found to be 58.0 for $-CF_2-I$, 4.9 for $-CF_2-Br$, 1.8 for $-CCl_2-Cl$, and 1.0 for $-CClF-Cl$. The nature of halogens on adjacent carbons does not appear to affect the reactivity significantly.

The recent report by Tarrant and Tandon (1) on the reactions of chlorofluoroalkanes with unsaturated hydrocarbons prompts publication of some similar results involving tetrafluoroethylene. It was known that the abstraction of chlorine from compounds such as trichlorofluoromethane was difficult since the reaction of this compound with ethylene gave only very high molecular weight telomers (2). Tarrant and Tandon (1) have also noted that their attempts to utilize trichlorofluoromethane in radical addition reactions to olefins were unsuccessful.

There are, however, other reports in the patent literature of chain transfer using chlorofluoroalkanes to give telomeric products; for example, 1,1,1-trichloro-2,3,3,3-tetrafluoropropane with tetrafluoroethylene (3) and chlorotrifluoromethane (4), 1,1,2-trichloro-1,2,2-trifluoroethane (5, 6), and 1,2-dichloro-1,2,3,3,4,4-hexafluorocyclobutane (6) with chlorotrifluoroethylene. It was felt that telomer reactions could be used to obtain information on reactivity of halogen[1] in molecules variously substituted with chlorine and fluorine, which would shed additional light on the relative importance of resonance and polar effects in radical abstraction reactions.

Reactivities of several halofluoroalkanes were determined by treating them with tetrafluoroethylene catalyzed by benzoyl peroxide. The values for the reactivities were based on chain transfer constants, calculated using the method of Walling (7) based on the average chain length of the telomers. These values were then divided by the number of equivalent atoms to arrive at a relative reactivity for the individual atoms. The concentration of tetrafluoroethylene was estimated by calculating the amount in the vapor state ($P_{total} = P_{telogen} + P_{C_2F_4}$ and $PV = nRT$) and subtracting this from the total charged for an initial concentration and from the amount unreacted for a final concentration. The average concentration was used in calculating the chain transfer constant. It is assumed that the chain transfer constants are nearly independent of chain length, primarily since the radicals formed initially as well as the growing chain radicals are perhalogenated and the variation of chain transfer constant with chain length due to differing inductive effect noted by Lewis and Mayo (8) would not be expected. The results are presented in Table 1.

The possibility that the phenyl radicals from the benzoyl peroxide added to tetrafluoroethylene to initiate telomerization was considered, but analysis indicated little incorporation of phenyl groups into the telomeric product.

The ease of abstraction of the different halogens is in the same sequence as previous results (9) I > Br > Cl, but relative values can now be given, $-CF_2-I$, 58; $-CF_2-Br$, 4.9; $-CCl_2-Cl$, 1.8; and $-CClF-Cl$, 1.0.

The results reported here further allow the effects of substituted chlorine and fluorine to be evaluated. Chlorine is abstracted by fluoroalkyl radicals from a trichloromethyl group approximately twice as readily as from a dichlorofluoromethyl group. However, there is no difference in the reactivity of chlorine to radical abstraction with varying ratios of chlorine to fluorine on adjacent carbons.

In perhalocarbons, the influences of adjacent halogens on reactions are based mainly on two effects, the inductive effect and resonance interactions. Substituents on the same carbon as an atom being abstracted will exhibit both effects. The present study indicates that the transition state during the reaction, the radical being formed, or both, are stabilized more by chlorine

[1]Since this discussion considers the reactions of chlorine, bromine, and iodine in fluorine-containing compounds, the term *halogen* as used here excludes fluorine.

TABLE 1. Telomerization of chlorofluoroalkanes with tetrafluoroethylene (1 h at 125°)

Run No.	Telogen		Pressure (p.s.i.g.)	C_2F_4 recovered (g)	Telomer		Chain transfer constant	Constant per reactive atom
	Structure	Moles			(g)	$\bar{n}$		
1	CF_3CF_2I	0.325	275	5	17	5.72	0.213	0.213
2	$CBrF_2CBrF_2$	0.308	225	9	14	15.71	0.036	0.018
3	CCl_2FCCl_3	0.363	225	15	3	11.22	0.021	0.007
4	$CClF_2CCl_3$	0.392	205	12	9	20.90	0.018	0.006
5	CF_3CCl_3	0.427	250	17	6	19.52	0.020	0.007
6	CCl_2FCCl_2F	0.392	275	14	7	30.77	0.015	0.004
7	$CClF_2CCl_2F$	0.427	185	17	5	57.63	0.008	0.004
8	$CCl_2FCF_2CCl_2F$	0.315	225	9	8	23.39	0.013	0.003

on the same carbon atom than by fluorine (10) as seen by comparing experiments 3–5 with experiments 6–8. This result agrees with the apparent greater stability of the $—CCl_2\cdot$ radical over the $—CF_2\cdot$ radical in olefin cyclodimerization reactions (11) and the differences of bond energies in CCl_3—Cl, 68 kcal/mol, and CF_3—Cl, 83 kcal/mol (12).

Variation of the amount of chlorine relative to fluorine on an adjacent carbon will change only the inductive effect. The unchanged reactivity in experiments 3–5 and experiments 6–8 indicate that in perchlorofluorocarbons the differences of the inductive effects of chlorine and fluorine do *not* affect the ease of chlorine abstraction.

It is well to keep in mind that these values are applicable only to the present system. Other results might be observed if the attacking radicals were alkyl or aryl radicals, or if the molecule attacked were not a perhalofluorocarbon. For example, chlorine and fluorine influence the reactivity of hydrogen to abstraction by chlorine atoms in an entirely different way (13).

Experimental Section

Materials

The tetrafluoroethylene used for these reactions was purchased from Peninsular ChemResearch, Gainsville, Florida. It was found to be 99.9% pure with 1% *alpha*-pinene added as an inhibitor. The vaporization of tetrafluoroethylene from the cylinder effectively separated it from the inhibitor so no further purification was used. The saturated halofluorocarbons used were commercial grades which were carefully redistilled or were samples prepared in the laboratory. All were over 99.9% pure by gas chromatography.

General Procedure

To a 300 cc Parr Magnedash autoclave made of 316 stainless steel was charged 80 g of halofluoalkane and 1.6 g of benzoyl peroxide. The autoclave was cooled to −70° in a Dry Ice – acetone bath, evacuated, and 20 g (0.20 mol) of tetrafluoroethylene was added. The autoclave was heated to 125° and stirred at 300 oscillations per min for 1 h. Unreacted tetrafluoroethylene was bled from the reactor and the mixture of halofluorocarbon and telomer was poured out. The telomer was isolated as a residue from distillation of the halofluorocarbon. Analyses for chlorine, fluorine, and carbon were used to determine the molecular weight or chain length, $\bar{n}$, of the telomer and indicate whether there was incorporation of phenyl groups in the telomer. Table 1 shows the results obtained for the experiments.

Synthesis of 1-Substituted Derivatives of Anhydro(3-chloroacetyl-2-hydroxyimidazo[1,2-*a*]pyridinium Hydroxide)

WAYNE K. ANDERSON[1] AND ALAN E. FRIEDMAN

Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, New York 14214

Received September 14, 1970

The reaction of chloroacetic anhydride and chloroacetic acid with *N*-substituted 2-aminopyridine derivatives **3** produced 1-substituted derivatives of anhydro(3-chloroacetyl-2-hydroxyimidazo[1,2-*a*]-pyridinium hydroxide) (**4**). The isomeric anhydro(1-benzyl-2-chloroacetyl-3-hydroxyimidazo[1,2-*a*]-pyridinium hydroxide) (**10***a*) was prepared by a reported procedure and the spectral data of the two isomeric series of compounds were compared. The significant differences in the n.m.r. spectra of the two series were attributable to the deshielding influence of the exocyclic acyl moiety.

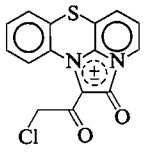
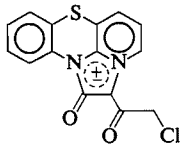
During an investigation of the reaction of 1-azaphenothiazine with chloroacetic anhydride and chloroacetic acid it was found that acylation of the secondary amine did not proceed as expected. 10-Chloroacetyl-1-azaphenothiazine was not obtained and the mesoionic compounds, **1** and **2**, have been proposed as possible structures for the compound produced from this reaction.[2]

The present investigation was undertaken as a model study to explore further the utility of this reaction in the synthesis of ring-fused mesoionic systems and to examine the structure of the compounds prepared.



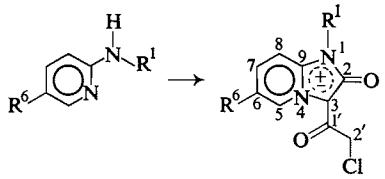
1



2

Reaction of chloroacetic anhydride (100 mmol) and chloroacetic acid (100 mmol) with 2-benzylaminopyridine (**3***a*; 50 mmol) for 1 h in refluxing dioxane gave anhydro(1-benzyl-3-chloroacetyl-2-hydroxyimidazo[1,2-*a*]pyridinium hydroxide) (1)[3] (**4***a*) in good yield. Similarly, reaction of **3***b*, *c*, *d*, and *e* with chloroacetic anhydride and chloroacetic acid yielded mesoionic compounds **4***b*, *c*, *d*, and *e* respectively. Melting points and microanalytical data for the compounds prepared are given in Table 1.

Scheme 1 outlines a possible mechanism for the formation of **4**. The first step involves chloroacetylation of **3** to give **5**. Acylation of the exocyclic nitrogen, in preference to the nuclear nitrogen, appears most probable based on the report by Jones and Katritzky (2*a*) that acylation of 2-amino- and 2-(methylamino)pyridine (with acetic anhydride–acetic acid) occurred exclusively on the exocyclic nitrogen.[4]



3 4

a $R^1 = -CH_2C_6H_5$; $R^6 = H$
b $R^1 = -C_6H_5$; $R^6 = H$
c $R^1 = -SO_2C_6H_5$; $R^6 = H$
d $R^1 = -CH_3$; $R^6 = H$
e $R^1 = -CH_3$; $R^6 = NO_2$

The situation for 2-benzenesulfonamidopyridine is less clear. It is known that 2-methanesulfonamido- and 2-benzenesulfonamido-pyridine exist in a tautomeric equilibria in which the imino forms predominate (2*b*). Thus acylation of **3***c* could have presumably occurred at the nuclear nitrogen, in which case compound **10***c* ($R^1 = SO_2C_6H_5$; R = Cl) would have been produced. The low field position of the C-5 proton in the n.m.r. spectra (see Table 2) is consistent with structure 4*c* and it was concluded that acylation

[1]To whom all inquiries should be addressed.
[2]J. W. Steele *et al.* (8).
[3]Katritzky's nomenclature has been adopted in this paper.
[4]Several attempts were made to isolate the intermediate chloroacetate **5**. In each instance only cyclized, acylated mesoionic compounds **4** were isolated. Moreover, no intermediate was formed in sufficient concentration to be detected by t.l.c.

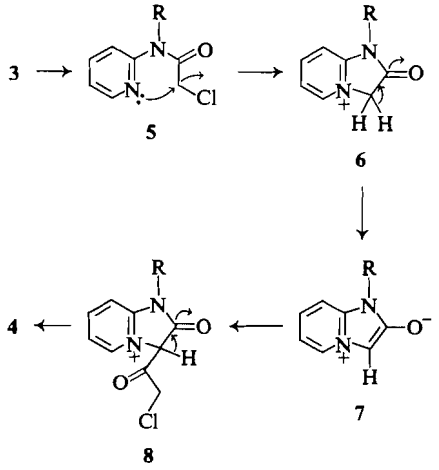
‡‡Recrystallized from benzene–hexane; mixture m.p. with **4***a* showed significant depression.

of the exocyclic nitrogen was preferred in this reaction.

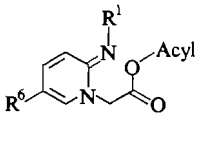
Intramolecular cyclization (3) of **5** with concomitant proton abstraction from **6** would afford the mesoionic intermediate **7**. Acylation (*4a–j*) of **7** with subsequent proton abstraction would give **4**.



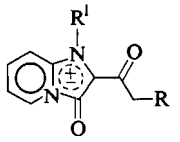
SCHEME 1

An alternative explanation for the formation of **4** involving initial nucleophilic attack by the nuclear atom to form an imino intermediate **9**, was considered unlikely since chloroacetonitrile, chloroacetic acid, and α-bromopropionic acid failed to react with **3***a* in refluxing dioxane.

If the initial acylation of **3** occurred at the nuclear nitrogen, rather than the exocyclic nitrogen, the resultant product would be **10**. Although



9



10

this seemed unlikely, the isomeric compound, **10***a*, was synthesized by an unambiguous route in order to effect a spectral comparison with **4***a*. Benzylation of *N*-2-pyridylaminoacetonitrile (prepared by treatment of 2-aminopyridine with formalin, sodium bisulfite, and sodium cyanide) followed by acid hydrolysis of the nitrile afforded *N*-benzyl-*N*-2-pyridylglycine, which was isolated as the sodium salt (*4i*, 5). Cyclization of sodium *N*-benzyl-*N*-2-pyridylglycine with chloroacetic anhydride and chloroacetic acid in refluxing dioxane gave anhydro(1-benzyl-2-chloroacetyl-3-hydroxyimidazo[1,2-*a*]pyridinium hydroxide (**10***a*: R^1 = —CH_2Ph; R = Cl). Cyclization with acetic anhydride afforded the known **10***b* (R^1 = —CH_2Ph; R = H) (*4i*).

The most significant differences between the n.m.r. spectra of the two isomeric series of compounds were the chemical shifts for the C-5 protons and the benzylic methylene protons of R^1 (see Table 2). The exocyclic acyl moiety strongly deshielded the C-5 aromatic proton in **4***a–e* while in the isomeric series (**10***a* and *b*) the benzylic methylene protons were shifted downfield by *ca.* τ 0.8.[5]

[5]*Cf.* the benzylic methylene protons of *N*-benzyl-2-aminopyridine acetamide which appeared as a 2-proton singlet at τ 4.87.

¶The u.v. solvent was 95% ethanol.

The first reported example of this mesoionic 4-oxoimidazole system was the dye "Besthorn's red" (6). The only other fused ring system of this type has been prepared by Ohta and Sato (7). The monocyclic mesoionic ring system has been synthesized by Lawson and Mills (4*i*) and more recently by Roche and Stansloski (4*j*). The advantage of the method reported in this communication lies in the relatively simple synthesis for these ring systems. Furthermore, the reaction may have potential application in the synthesis of other mesoionic ring systems (*e.g.* thiaza and oxaza systems).

This investigation was supported by a training grant (5-T1-GM-555-08) from the Division of Medical Sciences, U.S. Public Health Services, Bethesda, Maryland. We thank Dr. R. A. Coburn for many helpful discussions and comments.

Measurement of Depolarization Ratios in the Raman Spectra of Powdered Crystalline Solids

D. W. JOHNSON AND D. SUTTON
Department of Chemistry, Simon Fraser University, Burnaby 2, British Columbia

Received July 23, 1970

The change in apparent depolarization ratio as a function of the refractive index of the surrounding liquid medium has been measured for the Raman active vibrational modes of powdered crystalline barium nitrate and sodium sulfate. This method provides an accurate measurement of the refractive index and depolarization ratios for barium nitrate, but fails to do so for sodium sulfate due to birefringent effects. The general applications of this technique for determining depolarization ratios of powdered crystalline solids are discussed.

Canadian Journal of Chemistry, **49**, 671 (1971)

Introduction

The recent advances in instrumentation brought about by the introduction of continuous-wave laser excitation have made the recording of excellent Raman spectra from powdered crystalline samples almost a routine matter. Nowhere has this advantage been recognized more than in the study of solid inorganic compounds, for which the alternative and more usual technique of making measurements on solutions is frequently hindered by lack of an appropriate solvent or because of problems associated with complexing or dissociation. Where measurements on solutions are practicable, the additional information from depolarization measurements considerably aids assignment by enabling bands which arise from totally symmetric modes to be distinguished. Similar information may be obtained from the study of oriented single crystals. However, experience shows that the Raman emission from powdered crystalline solids is almost invariably depolarized as a result of the multiple reflections and refractions which both the polarized incident radiation and the Raman emitted light suffer at crystal surfaces within the sample. Two authors (1, 2) have recently de-

scribed instances in which the measurement of depolarization ratios on powdered solids was made possible by immersing the solid in a liquid of similar refractive index. In the present study, we have applied a similar technique to a quantitative study of the variation of ρ with refractive index of the liquid phase to determine its suitability for obtaining accurate values of the refractive index of the solid and depolarization ratios for the Raman modes. In addition, we have been concerned with the adaptation of this method to the regular 180° coaxial sample arrangement of the Cary Model 81 Raman spectrometer.

Experimental

Spectra

Finely ground anhydrous samples of barium nitrate or sodium sulfate were contained in a 3 mm diameter borosilicate glass tube with smoothly rounded end to a depth of 2–3 mm. Sufficient liquid of known refractive index was added to yield a thick paste. Spectra were obtained for 180° coaxial viewing using the Cary Model 81 Raman spectrophotometer with 60 mW Spectra-Physics Model 125 He/Ne laser excitation. In some preliminary runs, the light scattered at 90° was analyzed, but these were abandoned in favor of the much higher Raman intensity collected in the 180° viewing mode. Polarization measurements were made by rotating the plane of polarization of the incident radiation relative to the fixed analyzer. The values obtained were in all cases corrected by reference to a depolarization ratio calibration curve obtained using a similar depth of liquid carbon tetrachloride in the same sample cell. The liquid was held in place by means of a tightly fitting glass piston. Methylene diiodide and diethyl ether were mixed in various proportions to provide a range of refractive index values measured using a standard Abbé refractometer.

Results

(a) Barium Nitrate

Crystalline barium nitrate exhibits a Raman spectrum which consists of the following three Raman active nitrate bands: 733 cm^{-1} (e'), 1048 cm^{-1} (a_1'), and 1367 cm^{-1} (e'). The totally symmetric mode (a_1') is expected to yield a polarized band with a depolarization ratio (ρ) close to zero, whilst the e' mode should be depolarized with $\rho = 0.75$ when plane polarized incident radiation is used. Spectra recorded using the powdered sample alone showed negligible difference in the intensities of the bands with respect to the orientation of the plane of polarization of the incident radiation. However, when the sample was immersed in either diethyl ether (refractive index $\eta = 1.349$), methylene diiodide ($\eta = 1.756$) or mixtures of the two liquids yielding intermediate η values, a close direct correlation of ρ with $(\eta_{solid} - \eta_{liquid})$ was observed. The results for the 733 and 1047 cm^{-1} bands are summarized in Table 1. The 1367 cm^{-1} band is close to a polarized solvent band in methylene diiodide (1353 cm^{-1}) so that the results are less reliable but follow a similar trend.

TABLE 1. Variation of apparent depolarization ratio (ρ) for $Ba(NO_3)_2$, with refractive index (η) of liquid phase

	ρ	
η	733 (cm^{-1})	1047 (cm^{-1})
1.349	0.84	0.835
1.486	0.82	0.343
1.499	0.79	0.305
1.505	0.82	0.235
1.519	0.82	0.208
1.540	0.81	0.180
1.548	0.78	0.087
1.561	0.78	0.045
1.572	0.75	0.023
1.583	0.76	0.025
1.605	0.77	0.073
1.639	—	0.230
1.647	0.77	0.285
1.675	0.79	0.325
1.707	0.82	0.360
1.756	0.84	0.390

The polarized 1047 cm^{-1} band showed the largest effect, as illustrated in Fig. 1, the apparent value of ρ dropping rapidly to a minimum of $\rho = 0.023$ at the true unique refractive index of the cubic solid, $\eta = 1.572$. The utility of the method for the qualitative identification of polarized bands is seen from the fact that the band appears significantly polarized ($\rho < 0.4$), even when $(\eta_{solid} - \eta_{liquid})$ is as large as 0.15. Again, the method provides the refractive index of a solid which exhibits strongly polarized Raman bands. The plot of ρ *vs.* η for the depolarized 733 cm^{-1} band (Fig. 2) is much more erratic and less symmetrical. Nevertheless, the same general trend is observed and the curve minimizes again at $\eta = 1.572$, at the expected value of $\rho = 0.75$. A similar plot for the 1367 cm^{-1} band gave a value of $\rho = 0.70$, the error being due to overlap with a polarized solvent band.

(b) Sodium Sulfate

The free sulfate ion has T_d symmetry and four Raman active frequencies: 451 cm^{-1}(e), 613

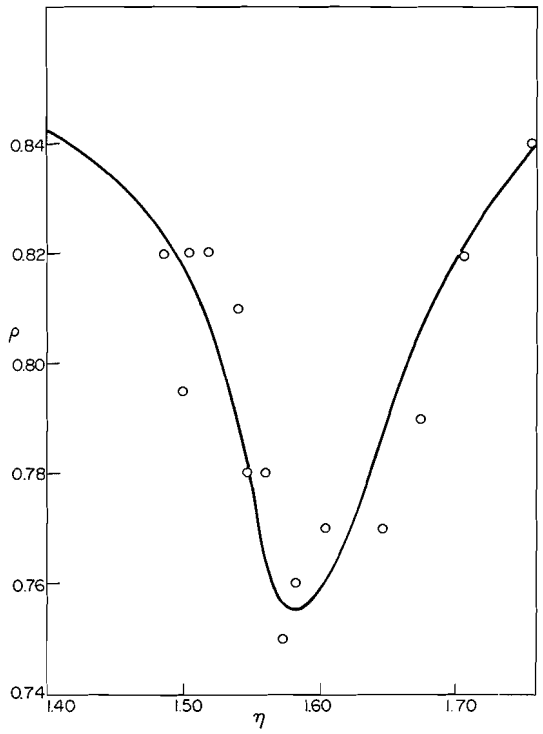

FIG. 2. Variation of apparent depolarization ratio (ρ) for the 733 cm^{-1} band of $Ba(NO_3)_2$ with refractive index η of the liquid.

$cm^{-1}(t_2)$, 981 $cm^{-1}(a_1)$, and 1104 $cm^{-1}(t_2)$. In orthorhombic anhydrous sodium sulfate the symmetry is lowered sufficiently to split all the modes into their non-degenerate components, so that the Raman spectrum of Na_2SO_4 consists of nine bands in the sulfate ion region. It was hoped that the symmetric components of the split modes could be identified in a similar manner as was used for $Ba(NO_3)_2$. The totally symmetric mode (a_1) is expected to be totally polarized with ρ close to zero, so we studied the variation of the apparent ρ value for this band as a function of the refractive index of the liquid to determine the most favorable η at which to examine the other bands (Table 2). The plot of ρ *vs.* η for this band, which occurred at 993 cm^{-1} in our sample (Fig. 3), displayed an effect which was quite different from that displayed by any of the nitrate bands in $Ba(NO_3)_2$. Rather than reaching a distinct minimum at any of the three refractive indices of Na_2SO_4 (1.464, 1.474, 1.485), only two minima were observed. Furthermore, the depolarization ratios at the minima

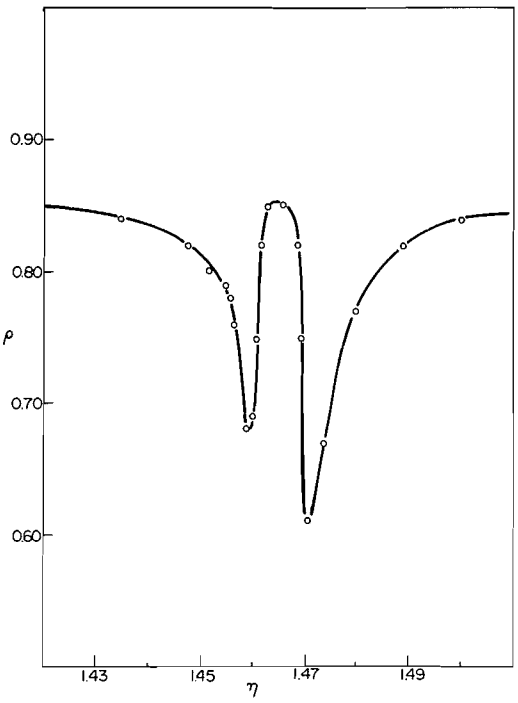

FIG. 3. Variation of apparent depolarization ratio (ρ) for the 993 cm^{-1} band of Na_2SO_4 with refractive index η of the liquid.

are not representative of a totally polarized band and an extremely sharp increase in ρ between the minima is observed. The band at no time appears to be strongly polarized, and it is evident that this is a result of birefringent effects in the anisotropic solid. A single crystal of anhydrous sodium sulfate in the form of a pyramidal plate (height 0.5 mm, base 2.2 mm × 2.2 mm) was viewed in the 180° mode with incident and scattered radiation propagated normal to the base. With the plane of polarization of the incident radiation parallel to the crystallographic axes, the 993 cm^{-1} band gave $\rho = 0.05$; the apparent ρ value increased steadily as the crystal was rotated about the incident beam to a maximum value of $\rho = 0.97$ corresponding to complete depolarization when the plane of polarization was 45° to the crystallographic axes. This is exactly the result expected as a result of birefringence splitting of the incident radiation into two components polarized at right angles (3, 4).

Discussion

The results described above indicate that there are severe limitations to this immersion technique as a method of obtaining accurate depolarization ratios for a powdered anisotropic solid. For the method to be effective, the sample should be isotropic (*cf.* $Ba(NO_3)_2$) with a single refractive index. In powdered anisotropic solids, birefringent effects will always operate to increase the apparent ρ value, and high values may be obtained even for totally symmetric modes, making it virtually impossible to distinguish reliably between polarized and depolarized Raman bands. For this reason we were not able to apply the powder method further to the study of site splitting in sodium sulfate. Problems may also arise with respect to the immersion liquid. Pairs of liquids which are miscible and yield mixtures which cover a sufficiently wide range of refractive index are difficult to find; if the solid is reactive this difficulty is increased. Thus we have found it a great problem to obtain suitable mixtures for the study of powdered nitrato-complexes. The most satisfactory liquid in our work has been methylene diiodide – diethyl ether, which is inert towards ionic nitrates and the majority of monodentate nitrato complexes; however it is unsuitable for use with many bidentate nitrato complexes (5) because of reaction.

The authors gratefully acknowledge support of this work by the National Research Council of Canada through operating grants, and Dr. E. J. Wells for discussion.

Photolysis of 2,4,6-Tri-*t*-butylnitrobenzene

L. R. C. BARCLAY AND I. T. MCMASTER
Department of Chemistry, Mount Allison University, Sackville, New Brunswick

Received October 21, 1970

Photolysis of 2,4,6-tri-*t*-butylnitrobenzene gave 5,7-di-*t*-butyl-3,3-dimethyloxindole. The latter was synthesized by an unambiguous route from 3,3-dimethyloxindole. The mechanism of this intramolecular photocyclization is discussed.

La photolyse du tri-*t*-butyl-2,4,6 nitrobenzène conduit au di-*t*-butyl-5,7 diméthyl-3,3 oxindole. Ce dernier composé a aussi été synthétisé par une méthode non ambiguë à partir du diméthyl-3,3 oxindole. Le mécanisme de cette photocyclisation intermoléculaire est discuté.

Canadian Journal of Chemistry, 49, 676 (1971)

Intramolecular cyclizations involving an aromatic nitro group in the ground or excited states ortho to a reactive function are well known (1); those involving an aromatic nitro group in an excited state ortho to a relatively unreactive group have not been reported. We now wish to report an example of a cyclization into an ortho-*t*-butyl group, which exhibits some unusual features.

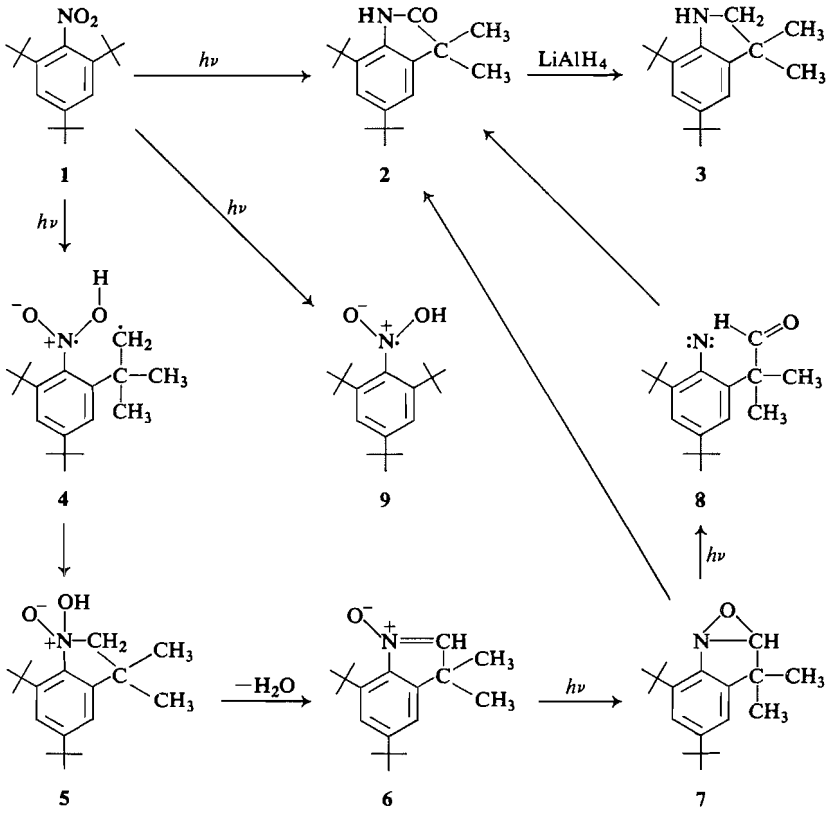
Photolysis of 2,4,6-tri-*t*-butylnitrobenzene (**1**) in cyclohexane at ambient temperatures after 114 h gave, in addition to starting material (38% recovery) and unidentifiable tars, a new compound 5,7-di-*t*-butyl-3,3-dimethyloxindole (**2**) (20%), m.p. 237–238° ν_{max} (KBr) 3220, 1700 cm^{-1}, n.m.r. (CCl_4 with tetramethylsilane as internal standard) 8.68, 8.62, 8.56 (singlets, 24H), 2.98 (doublet, 1H), 2.82 (doublet, 1H), and −0.55 τ (singlet, 1H, exchanges with D_2O).[1–3] Photolysis of **1** in benzene after 67 h increased the yield of **2** to 36%; starting material was completely consumed in this reaction. That the carbon skeleton had not rearranged in the transformation of **1** into **2** was shown by an unambiguous synthesis of **2** in 65% yield from 3,3-di-methyloxindole (2) and *t*-butylchloride using aluminum chloride as catalyst. Lithium aluminum hydride reduced **2** to the amine **3** (64%), m.p. 105° ν_{max} (KBr) 3440 cm^{-1}, n.m.r. (CCl_4) 8.62, 8.55 (singlets, 24H), 6.62 (singlet, 2H), 6.27 (singlet, 1H), 3.03 (doublet, 1H), and 2.89 τ (doublet, 1H).[2]

Of the various possible mechanisms that may be considered for the conversion of **1** into **2**, the one outlined receives support from current literature. Electronically excited aromatic nitro compounds are reported to abstract hydrogen atoms from solvent molecules to produce a low stationary-state concentration of aromatic monohydronitro radicals (3). Due to the proximity of an ortho-*t*-butyl group to the nitro function in **1**, monohydronitro radicals may alternatively be formed during photolysis by hydrogen abstraction from an ortho-*t*-butyl group with the formation of an intermediate biradical **4**, which might be expected to spontaneously cyclize to **5** before the side-chain alkyl radical had time to rearrange (4). Elimination of water from **5** would yield the *N*-oxide **6**, which under photolytic conditions may be expected to rearrange to the oxaziridine **7** (5). This in turn might be expected to undergo photofragmentation to give the nitrene **8** (6). The latter species are well known to intramolecularily insert readily into carbon-hydrogen bonds which are sp^2 hybridized (7). Nitrenes are least reactive towards primary carbon-hydrogen bonds which are sp^3 hybridized (8). Alternatively, it is possible that **7** may rearrange directly to **2** (5). The decrease in yield of **2** from **1** in changing solvent from benzene to cyclohexane is expected since hydrogen abstraction from the secondary carbon of cyclohexane by the electronically-excited nitro group (**1** → **9**)

[1]An accurate mass determination by high resolution mass spectroscopy established the molecular formula to be $C_{18}H_{27}NO$.

[2]New compounds reported gave microanalyses in agreement with their formulae.

[3]Photolyses were performed using a quartz vessel in a Rayonet Photochemical Reactor and a 2537 Å u.v. light source.



would compete with hydrogen abstraction from a primary carbon of adjacent *t*-butyl groups (**1** → **4**).[4]

There is no close analogy in the literature to this reaction, which apparently involves three photolytic steps and two intramolecular cyclization steps by electrophilic nitrogen, without rearrangement of any portion of the carbon skeleton. In this regard, a comparison may be made with the intramolecular alkylation of an ortho-*t*-butyl group observed recently in this laboratory (9).

This reaction is under further study to substantiate the proposed mechanism and to explore its synthetic significance.

[4]Hydrogen abstraction from an ortho methyl to a photochemical excited nitro group has been reported (Morrison and Migdalof, ref. 10.). We are not aware of such hydrogen abstraction from an *o*-*t*-butyl group.

This research was supported by a grant from the National Research Council of Canada. The mass spectroscopic analysis was performed by Dr. W. D. Jamieson of the National Research Council, Halifax, Nova Scotia.

The photochemical loss of cyanide from $Mo(CN)_8^{4-}$ is shown to be sensitized by common organic triplet donors naphthalene, phenanthrene, anthraquinone, and benzophenone, but not by biacetyl. This suggests that the reactive state may be $^3B_1$, not the lower lying $^3A_2$. The quantum yields for sensitized photolysis (near 0.25) are larger than for the direct reaction (near 0.15). This is unlike the behavior of $Co(CN)_6^{3-}$ where the similarity of the two yields leads to the conclusion that higher excited states are efficiently converted to "the lowest triplet".

Naphthalene irradiated at 286 nm leads to a quantum yield of 0.4 which is, perhaps, associated with a new process involving sensitized production of a solvated electron.

Thermal solvolysis rates in several media are also reported. The medium dependence of solvolysis is small.

Il est démontré que la perte photochimique de cyanure par $Mo(CN)_8^{4-}$ est sensibilisée par les donneurs organiques de triplets tels que naphtalène, phénanthrène, anthraquinone et benzophénone mais pas par le diacétyle. Ceci suggère que l'état intermédiaire peut être $^3B_1$, mais pas l'état inférieur $^3A_2$. Les rendements quantiques de la photolyse sensibilisée (près de 0.25) sont plus grands que pour la réaction directe (près de 0.15). Ceci est contraire au comportement de $CO(CN)_6^{3-}$ où la similarité des deux rendements a conduit à la conclusion que les états excités les plus élevés sont efficacement amenés au niveau du "plus bas triplet".

Le naphtalène irradié à 286 nm conduit à un rendement quantique de 0.4 qui est peut être associé avec un nouveau processus impliquant la production sensibilisée d'un électron solvaté.

Les taux de solvolyse thermique dans plusieurs milieux sont aussi rapportés. La dépendance de la solvolyse sur le milieu est faible.

Canadian Journal of Chemistry, 49, 679 (1971)

Introduction

Sensitized photolysis has proved its value in attempts to understand organic photochemical pathways and has recently been applied to analysis of mechanisms of photo substitution reactions of complexes of Cr(III) (1), Co(III) (2), and Pt(II) (3). Photochemical substitution of $Mo(CN)_8^{4-}$ in basic aqueous buffers has been described (4), and it has been suggested that the wavelength independence of quantum yield in the ligand field bands implies a pathway involving efficient conversion of singlet excited states to the lowest triplet which then undergoes either relaxation to the $Mo(CN)_8^{4-}$ ground state or relaxation to an intermediate on the substitution pathway, with the ratio of efficiencies of these two processes determining the magnitude of the quantum yield. Such a pathway is entirely analogous to the mechanism proposed for reaction of $Co(CN)_6^{3-}$ and implies that sensitized quantum yields produced by energy transfer from efficient organic triplet donors should equal the direct yield.

Several well characterized organic triplet donors are discussed in this study. Their properties (5, 6) are collected in Table 1. E_T denotes the triplet energy (from emission spectroscopy). The variations of E_T are significant in comparison to the energy levels of the acceptor complex $Mo(CN)_8^{4-}$. Our spectrum of $Mo(CN)_8^{4-}$ complex is consistent with that described by Perumareddi *et al.* (7) and we follow their assignments which are based on an approximate D_{2d} symmetry for the ion. Figure 1 shows the energy

level scheme with orbital configurations indicated. Table 2 lists the experimental absorption bands with band maxima quoted in both wavelength and energy (kcal) units.

Experimental

Preparation of Potassium Octacyanomolybdate(IV)

The complex was prepared using the method of Furman and Miller (8). The golden yellow crystals that were formed were dried at 110 °C and stored in the dark. The purity of the complex was checked by comparison with the spectrum in the literature (7). Periodic recrystallizations from ethanol–water mixtures were found to be necessary during the course of the investigation. The pure product was analyzed for total molybdenum by titration with standard permanganate.

308	260	$^1E_1 \leftarrow {}^1A_1$	93.0

Anal. Calcd. for $K_4Mo(CN)_8.2H_2O$: Mo, 19.35. Found: Mo, 19.6.

The infrared spectrum of the complex showed C≡N stretching frequencies at 2160, 2130, and 2090 cm^{-1}, and the presence of water of crystallization. The salt is extremely soluble in water and concentrated aqueous solutions turn green on exposure to light.

Cyanide Analysis

The *microquantities* of cyanide produced in the photolysis were determined by the method of Epstein (9). The method is based on the conversion of cyanide to cyanogen chloride with an aqueous solution of chloramine-T and the reaction of this cyanogen chloride with a mixture of pyridine containing 0.1% bis-pyrolazone and 1-phenyl-3-methyl-5-pyrolazone. The blue dye that develops is stable for several hours in the p*H* range 7–9, and measurements of optical density at 630 nm may be performed after 30 min. The calibration of the method was performed by making a stock solution from analytical grade KCN and taking aliquots in the 0.2–1.2 μg interval. The stock solution was analyzed by potentiometric titration, with standard 0.002 *M* $AgNO_3$, using a silver electrode. The analysis was found to be quantitatively unaffected by the presence of the sensitizers used, although color development required a longer period of time.

Actinometry

Irradiation equipment consisted of a 1000 W xenon–mercury source (Oriel Optics) and the beam collimated by lenses of 7.5 and 5 cm focal length passed through Jarrell-Ash monochromator (model 82-410) and then to 5 cm cell thermostatted at 25 ± 0.1 °C (13). The light source was calibrated using Ferrioxalate (10, 11) for wavelengths below 380 nm and reineckate system (12) for longer wavelengths. The quantum yields obtained were in good agreement with the values reported for these systems assuring that the band pass was comparable to interference filter system of ref. 12.

Sensitizers

Naphthalene, phenanthrene, and benzophenone were sensitizer grade chemicals as supplied by the J. T. Baker Chemical Co. These were recrystallized from ethanol and their purity was determined spectroscopically. Biacetyl was Fisher reagent grade which was distilled at 88 °C before use and stored in darkness, as degradation was observed on exposure to light. The anthraquinone was British Drug Houses reagent.

The spectra of all the sensitizers were recorded on a Cary-14 model recording spectrophotometer; the compounds being dissolved in the solvents which were used

in the photolysis. Spectral parameters were compared to those found in the literature (5).

Photolysis Solutions

Solutions of the octacyanomolybdate complex were prepared by dissolving the total amount of salt required in a minimum volume of water and adding this to the remainder of the solvent mixture, for the case of mixed solvents. For solutions containing the organic sensitizers the complex was dissolved in a minimum volume of the solvent mixture and the sensitizer dissolved, with heating, in the remainder. The sensitizer solution was then added slowly, with vigorous stirring, to the dissolved molybdenum cyanide complex. All operations were carried out in the presence of red "photographic" light to eliminate any predecomposition of the complex before photolysis.

Deaeration of solutions was accomplished by passing a vigorous stream of nitrogen through the solvent mixture for periods of 3 to 12 h. The solutions were then prepared as before, all operations including transfer to the reaction cell were carried out in a nitrogen atmosphere in red light.

Complex concentrations were chosen so that a minimum of 99% of the incident light was absorbed by the reacting solution. Concentration ratios in the sensitized reactions were chosen so as to have 95–98% of the light absorbed by the sensitizer, and the sensitized quantum yields were calculated on the basis of the number of moles of cyanide released and the quanta of light absorbed by the sensitizer.

Kinetics

The thermal reactions were slow enough to allow conventional manual analytical techniques to be used. Runs were carried out in darkened flasks with transfer being carried out in the presence of red "photographic" light. Aliquot portions of the reaction solution were diluted by a factor of 12.5 and the cyanide analyzed by the spectrophotometric method previously described. The analysis was calibrated for each of the mixed solvents used.

Results

In common with earlier workers (4), we lack satisfactorily detailed information on the Mo-containing product. It seems likely that it is initially $Mo(CN)_7OH^{4-}$ in aqueous basic buffers. What is clear is that the reaction is a substitution process which we study by initial *cyanide release* at quite low conversion. The quantum yields are for cyanide release in every case and the thermal rate constants are pseudo first order rate constants for cyanide release in the media in question. Table 3 contains thermal rate constants for CN^- formation in aqueous carbonate buffers, dimethylsulfoxide (DMSO) – water mixtures, and CH_3CN – water mixtures (also buffered to a glass electrode reading of "pH" = 10), the most interesting point is the low solvent sensitivity.

TABLE 3. Thermal solvolysis rate constants for $Mo(CN)_8^{4-}$ at 0.05 M, pH 10 (carbonate buffer)

Solvent	T(°C)	k(s^{-1})*	E_a (kcal/mol)
H_2O (pH=10.0)	22.0	8.5×10^{-8}	
H_2O (pH=10.0)	50.1	1.17×10^{-7}	13
DMSO/H_2O			
70/30 (V/V)	22.0	4.7×10^{-8}	
40/60 (V/V)	22.0	7.3×10^{-8}	
CH_3CN/H_2O			
70/30 (V/V)	22.0	4.0×10^{-8}	
40/60 (V/V)	22.0	7.0×10^{-8}	

*The rate constant describes the initial rate of CN^- release.

TABLE 4. Direct CN^- release quantum yields from irradiation of 0.05 M solutions of $Mo(CN)_8^{4-}$ in buffers of boric acid, KOH, and KCl

Solvent	Wavelength (nm)	Φ (24.8 °C)	Φ (37.3 °C)
pH 8.00 buffer	368	0.149	
pH 10.00 buffer	368	0.158	0.141
pH 12.00 buffer	368	0.155	
pH 10.00 buffer	431	0.155	
pH 10.00 buffer	308	0.152	
H_2O/C_2H_5OH			
50/50 (V/V)	368	0.135	0.115
70/30 (V/V)	368	0.141*	
H_2O/DMSO			
50/50 (V/V)	368	0.161	0.144
H_2O/CH_3CN			
50/50 (V/V)	368	0.141	0.123

*This result is the "control" for all the sensitization experiments reported in Table 5.

Table 4 collects quantum yields for direct photolysis of the complex in various media. The values which are comparable to earlier work (4) (aqueous buffers) are slightly higher and possibly within experimental error. But, the small increases reported may be real since our analytical system allowed study at much lower net cyanide release and product absorption may have been better avoided. These quantum yields are seen to be wavelength independent from 368 to 431 nm, relatively solvent insensitive, and apparently decreasing with increasing temperature.

Table 5 reports results of sensitization experiments. The solvent system was C_2H_5OH/H_2O in the ratio 70/30 (V/V) buffered to a pH meter reading of 10.0 (borate buffer). Only biacetyl was ineffective as a sensitizer. At basic pH biacetyl phosphorescence is quenched significantly, casting doubt on the significance of the biacetyl ineffectiveness.

TABLE 5. Quantum yields for sensitized photolysis of $Mo(CN)_8^{4-}$ at 24.8 °C in C_2H_5OH/H_2O mixtures (70/30, *V*/*V*), at p*H* 10 (boric acid, KCl, KOH)

Sensitizer*	Irradiation Wavelength (nm)	Sensitizer Conc. (*M*)	Complex Conc. (*M*)	Φ
Naphthalene	311	0.10	0.002	0.26
	286	0.10	0.002	0.42
Benzophenone	360	0.05	0.001	0.31
Phenanthrene	376	0.05	0.001	0.28
Anthraquinone	400	0.05	0.001	0.33
Biacetyl	410	0.05	0.001	Nil

*Solutions deaerated except naphthalene and phenanthrene.

In neutral solutions, phosphorescence of biacetyl was not quenched. However, 0.001 *M* $Mo(CN)_8^{4-}$ quenched the phosphorescence of 0.05 *M* biacetyl by 40% suggesting triplet energy transfer to the $^3A_2$ state of $Mo(CN)_8^{4-}$. In these neutral solutions, the direct yields for photolysis of $Mo(CN)_8^{4-}$ and 368 nm was $\phi = 0.151$. But, in the neutral solution, the biacetyl sensitized yield remained zero. These results support the idea that energy transfer from biacetyl can occur but that such energy transfer is *not* fruitful for solvolysis of $Mo(CN)_8^{4-}$

Discussion

The effectiveness of four well-known organic triplet donors in sensitizing the photosolvolysis of $Mo(CN)_8^{4-}$ implicates a low lying triplet in the reaction. The energy level diagram in Fig. 1 suggests the $^3B_1$ and $^3A_2$ as the most likely candidates. In conjunction with the triplet energies cited in Tables 1 and 2, the "unique" failure of biacetyl suggests that the $^3B_1$ might be the reactive state. This suggestion would require that radiationless deactivations from $^3B_1$ to the lower $^3A_2$ is not efficient in competition with reaction of the $^3B_1$ state. This could arise if the $^3B_1$ state were substantially structurally distorted which seems plausible but cannot be established in the absence of $Mo(CN)_8^{4-}$ phosphorescence data. (This suggestion deserves further research.)

We can make another point with more assurance. The quantum yields of the sensitized reactions are significantly larger than for direct reactions. This circumstance contrasts to that for $Co(CN)_6^{3-}$ (2). It implies that the direct reaction cannot proceed by highly efficient conversion of singlet excited states to the reactive triplet followed by a quantum yield determining competition between deactivation and reaction of that triplet. The wavelength independence of the direct quantum yield must be consistent with an intersystem crossing yield of significantly less than unity.

Flash photolysis studies on $Mo(CN)_8^{4-}$ in the ultraviolet (14) have suggested a high energy electron ejection mechanism. The high sensitized yield for naphthalene irradiated at 286 nm suggests that the electron ejection process may also be subject to sensitization.

Finally, it is interesting that the thermal and photochemical reactions both show low medium sensitivity. This suggests that there may be a resemblance between the photoreactive excited state and the transition state for thermal solvolysis.

Activities and Ionic Distributions in Cobalt Silicate Melts[1]

I. B. SMITH AND C. R. MASSON
Atlantic Regional Laboratory, National Research Council of Canada, Halifax, Nova Scotia

Received October 13, 1970

Activities of CoO in $CoO–SiO_2$ melts were measured at 1450–1500 °C by equilibrating the melts, held in Pt–Rh containers, with atmospheres of known oxygen potential. Activities were calculated by the relationship

$$CoO_{(melt)} \rightleftarrows Co_{(in\ container)} + \tfrac{1}{2}O_2 \qquad K = a_{Co}p_{O_2}^{\frac{1}{2}}/a_{CoO}$$

where a_{Co}, the activity of cobalt in the container, was determined in separate experiments.

The results were compared with theoretical activity–composition curves based on the application of polymer theory to silicate melts. The results were in good agreement with theoretical curves calculated on the assumption of linear chains. In contrast, for all other binary silicate melts so far investigated the results are best represented in terms of theory in which all chain configurations are allowed. Ionic distributions and number average and weight average molecular weights were calculated as functions of the silica content from the experimental data. The calculated proportions of monomeric ion, SiO_4^{4-}, dimer $Si_2O_7^{6-}$, and trimer $Si_3O_{10}^{8-}$ were in reasonable agreement with experimental values based on trimethylsilylation and gas-chromatographic separation of the ionic constituents in quenched melts.

On a mesuré l'activité de CoO dans des mélanges fondus $CoO–SiO_2$ en équilibre avec des atmosphères d'oxygène de potentiel connu, dans des récipients de Pt-Rh, à 1450–1500 °C. Les activités ont été calculées à l'aide de la relation

$$CoO_{(mélange\ fondu)} \rightleftarrows Co_{(recipient)} + \tfrac{1}{2}O_2 \qquad K = a_{Co}p_{O_2}^{\frac{1}{2}}/a_{CoO}$$

où a_{Co}, l'activité du cobalt dans le récipient, a été déterminée à partir de mesures séparées.

Les résultats sont comparés aux courbes théoriques activité–composition établies en appliquant la théorie des polymères aux silicates fondus. Ils sont en bon accord avec les courbes théoriques établies en supposant que l'on a affaire à des chaînes linéaires. Par contre, les résultats obtenus pour tous les autres silicates binaires étudiés jusqu'à présent se montrent en meilleur accord avec les courbes théoriques établies en supposant toutes les configurations possibles pour les chaînes. La distribution des ions ainsi que les masses moléculaires moyennes en nombre et en poids ont été calculées en fonction de la teneur en silice. Les proportions calculées des monomères ioniques SiO_4^{4-}, dimères $Si_2O_7^{6-}$ et trimères $Si_3O_{10}^{8-}$ présentent un accord raisonnable avec les valeurs expérimentales obtenues de la triméthylsilylation et de la séparation par chromatographie en phase gazeuse des constituants ioniques dans les silicates trempés.

Canadian Journal of Chemistry, 49, 683 (1971)

Introduction

Recent work in this laboratory has been concerned with theoretical interpretations of the structure of simple binary silicate melts, regarding them as equilibrium distributions of polyanionic silicate units (1–4). Experimental activity–composition data upon which to test the theory are relatively scarce, being largely confined to systems of greatest practical or industrial importance, *e.g.* the systems 'FeO'–SiO_2 (5, 6) and PbO–SiO_2 (7–9). Comparison between theory and experiment has often had to be made indirectly by interpolation from ternary systems ($CaO–SiO_2$, (10)) or from phase diagrams ($CoO–SiO_2$, (11)). To obtain more direct evidence for comparison, a study of activity–composition relationships has been made on the system $CoO–SiO_2$ and forms the subject of the present paper. In addition to the further insight to be gained into the ionic structure of silicate melts from such a study, the work forms a logical extension to studies already carried out on $MnO–SiO_2$ (12) and 'FeO'–SiO_2 (5, 6), systems which also involve oxides of transition or group VIII metals with incompletely filled d-orbitals.

The technique used was to equilibrate $CoO–SiO_2$ melts of varying composition in 80% Pt – 20% Rh containers under known partial pressures of oxygen in the temperature range 1450–1500 °C. The equilibrium of interest is

$$[1] \qquad CoO_{melt} \rightleftarrows Co_{Pt-Rh} + \tfrac{1}{2}O_2$$

This equilibrium has already been studied with pure CoO (13), so that the cobalt oxide activities can be calculated from these results.

[1]NRCC No. 11 705.

Experimental

Materials

Cobalt Oxide

Pure CoO was prepared as described previously (13).

Silica

Mallinckrodt silicic acid (100 mesh powder) was fired at about 1000 °C and stored in a vacuum dessicator.

Batch slags were prepared by melting CoO–SiO_2 mixtures of the appropriate compositions in air in a Pt crucible. The melts were quenched between brass plates and crushed in a percussion mortar. This procedure was repeated several times to ensure a homogenous slag.

Containers

The 80% Pt – 20% Rh containers and strips were the same as described previously. The containers held about 1 g of silicate.

Gas Mixtures

A variety of methods was employed to obtain the required partial pressures of oxygen. These can be summarized as

(1) Ar–CO_2–H_2

(*a*) The three gases were purified, metered and mixed as described before.

(*b*) Premixed Ar–CO_2–H_2 gas mixtures were prepared in the laboratory. The mixtures were analyzed at room temperature by mass spectrometry and also at the temperature of interest by means of a lime-stabilized zirconia solid electolyte cell installed directly in the equilibrium furnace.

(2) CO_2

For several experiments CO_2 only was used to generate the required p_{O_2} value. Exact partial pressures of oxygen were determined using the solid electrolyte cell.

Apparatus

The apparatus used has been described previously (13).

Procedure

The Pt–Rh cups containing the coiled strips and charge of slag were supported on cradles of Pt–Rh wire mounted in turn on preshaped alumina trays. Four cups were used in each experiment.

To vary conditions as much as possible in any one experiment the slag compositions and initial cobalt content of the crucibles and strips were varied. Slag compositions were chosen to cover as wide a range as possible within the liquid region of the phase diagram. The initial cobalt content of the crucibles and strips varied from zero to values in excess of that required for equilibrium. Thus, by starting an experiment with slags of one composition and four cups and strips of widely differing cobalt content, equilibrium could be approached from both sides. Conversely, the same type of effect could be obtained by using four cups and strips of one cobalt content and slags of varying composition. This method also served as a useful check on the time required to establish equilibrium between the melt and the container and strip.

The furnace was brought to the required temperature and flushed with dried, purified argon. The slag samples were pushed slowly into the hot zone in the stream of argon, the furnace was closed and the carbon dioxide and hydrogen admitted. When premixed Ar–CO_2–H_2 gas mixtures or pure CO_2 were used the procedure was similar, except that the argon flow was turned off after the samples had been introduced.

Gas analyses were performed immediately before and after an experiment. Samples of the gas mixtures were collected at the inlet and exit of the furnace for analysis by mass spectrometry and a direct estimation of the partial pressure of oxygen at the temperature of interest was made using the lime-stabilized zirconia solid electrolyte cell.

At the end of an experiment the mixed gas flow, or CO_2, was turned off and argon reintroduced to the furnace. The samples were then quickly pulled into the water-cooled end of the equilibration tube in the stream of argon and quenched with a blast of helium.

The coiled strips were separated from the quenched melt and thoroughly cleaned as described previously.

Analysis

Each silicate sample was dissolved in concentrated HCl and the resulting solution evaporated to dryness. The material was then boiled in 50% HCl, filtered, and washed several times. The precipitated silica was determined by a conventional gravimetric method, being volatilized with HF. Occasionally, as a check, the filtrate was anlayzed spectrophotometrically to determine the CoO. The Co–Pt–Rh strips were analyzed using the technique described earlier.

Results

The results are presented in Table 1. Activities of CoO were calculated, relative to pure solid oxide as standard state, in a manner analogous to that described by Abraham *et al.* (12). Thus

$$[2] \qquad a_{CoO} = (p_{O_2}/p_{O_2}{}^0)^{1/2}$$

where p_{O_2} is the partial pressure of oxygen above the melt during equilibration and $p_{O_2}{}^0$ is the partial pressure of oxygen which would be in equilibrium with pure CoO and a Co–Pt–Rh alloy containing the same amount of cobalt as found in the slag experiment. In the range of temperatures and partial pressures used in the present work, solid CoO is virtually stoichiometric, so that the activity of solid CoO may be set at unity. Values of $p_{O_2}{}^0$ were derived from the data on the equilibrium between solid CoO and 80% Pt – 20% Rh (13). Figure 1 shows the activities, relative to the pure solid oxide, plotted as functions of composition.

Discussion

Activities of CoO were calculated with reference to pure liquid CoO as standard state by assuming a value of 9100 cal mol^{-1} for the heat of fusion of CoO (2). These values are plotted against the mole fraction of silica in Figs. 2 and 3. Included for comparison are activities cal-

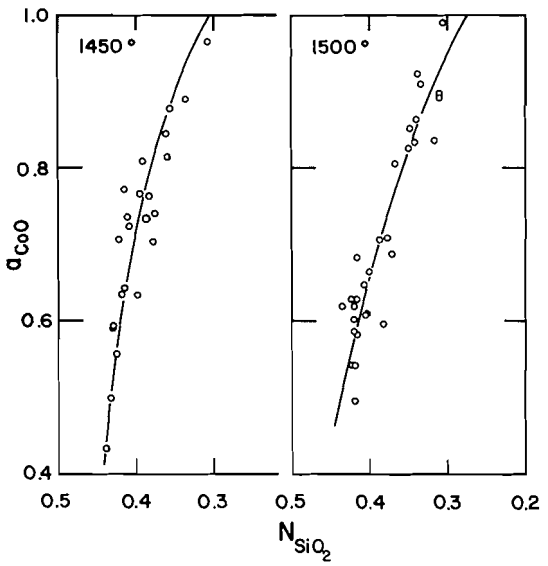

FIG. 1. Experimental activities of CoO, with respect to the solid oxide as standard state, plotted against mole fraction of silica for the two temperatures studied.

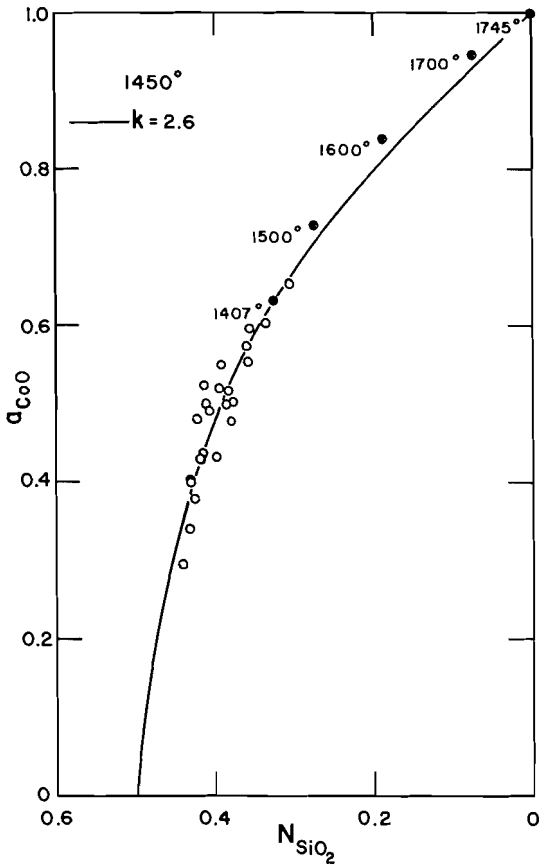

FIG. 2. Calculated activities of CoO, with respect to liquid oxide as standard state, plotted against mole fraction of silica at 1450 °C. The filled circles are points calculated from the phase diagram (11). The line is theoretical, corresponding to $k = 2.6$, calculated on the basis of a bifunctional condensation polymerization.

culated from the phase diagram of Masse and Muan (11). Experimental activities decrease steadily with increasing silica content of the melt. The line is a theoretical curve, the significance of which has been discussed previously (1, 2). The most striking result is the close fit between the experimental data and the theoretical treatment for linear chains. For all other binary silicate systems so far studied, the results are in better agreement with a theory (3, 4) in which all chain configurations are allowed, as might be expected for a condensation polymerization involving the tetrafunctional monomeric unit SiO_4^{4-}. The experimental evidence so far accumulated for the system $CoO–SiO_2$ indicates that the reactive unit SiO_4^{4-} is rendered pseudobifunctional in this system. Ionic distributions can therefore be calculated in a manner analogous to that used in ref. 1, or by reference to the more general polymer theory for the case of a multifunctional condensation (4, 14) by setting $f = 2$. In either case identical results are obtained, as ref. 1 deals with a particular case of the more general theory.

In the application of polymer theory to silicate melts, a particular ionic distribution for the anions present (O^{2-}, SiO_4^{4-}, $Si_2O_7^{6-}$, $Si_3O_{10}^{8-}$, etc.) can be calculated and activity–composition curves drawn on the basis that the distribution can be characterized by a constant k_{11}. This represents the equilibrium ratio for the reaction

$$[3] \quad SiO_4^{4-} + Si_nO_{3n+1}^{2(n+1)-} \rightleftarrows Si_{n+1}O_{3n+4}^{2(n+2)-} + O^{2-}$$

where $n = 1$. In the case where $f = 2$, all k_{1n} values for polycondensation reactions of this type become identical, and are referred to in the figures and text of this paper merely as k. As a consequence of the mathematics, values of activity become zero at $N_{SiO_2} = 0.5$, the limit of applicability of the theory. In practice, however, activities will remain finite beyond this region, due to the onset of intramolecular condensation. The observation that activities close to $N_{SiO_2} = 0.5$ were low lends further support to the linear chain model and indicates the virtual absence of

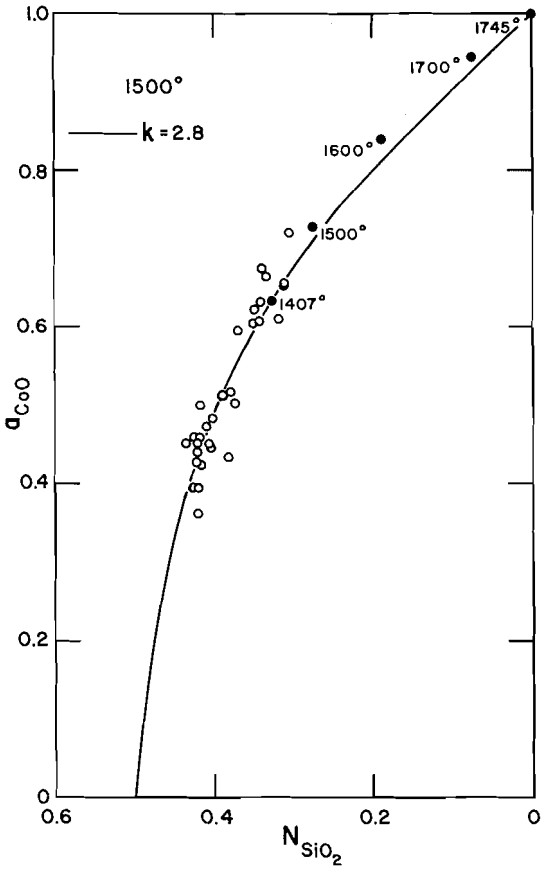

FIG. 3. As Fig. 2 but for 1450 °C read 1500 °C and for $k = 2.6$ read $k = 2.8$.

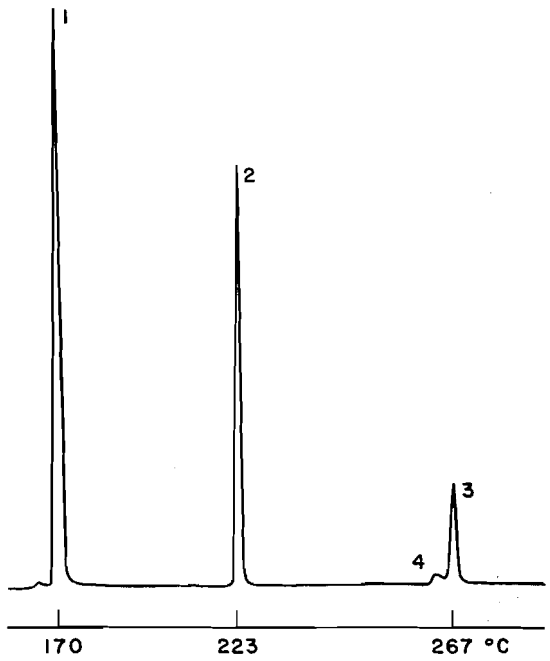

FIG. 4. Gas–liquid phase chromatographic trace of a cobalt silicate slag of overall composition $CoO/SiO_2 = 1.38$ (close to $Co_4Si_3O_{10}$), showing peaks due to monomer (*1*), dimer (*2*), trimeric chain (*3*), and tetrameric ring (*4*).

cross-linked or extensively branched structures. Activity–composition values beyond the metasilicate region (*i.e.* for $N_{SiO_2} > 0.5$) cannot be obtained at the present temperatures since the liquid region for $CoO–SiO_2$ does not extend into this range. Temperatures in excess of 1700 °C are required for studies at these compositions.

Further indirect evidence for lack of branching in the system $CoO–SiO_2$ comes from the observation that it proved impossible to quench any of the slags studied to glasses; there was always some crystalline material present. A highly branched slag would presumably be fairly viscous and be readily quenched to a glass. In spite of the failure to achieve a homogeneous glass, a sample of quenched cobalt silicate was analyzed by a gas–liquid partition chromatography technique (15, 16). The result is shown in Fig. 4. The quenched slag had a CoO/SiO_2 ratio of 1.38, *i.e.* representation by conventional formula would place it close to $Co_4Si_3O_{10}$ in composition. Although the gas–liquid phase chromatographic analysis is qualitative, it is evident that there is a distribution of silicate ions, with monomer the most abundant species, and including a small fraction of tetrameric ring species, $Si_4O_{12}^{8-}$.

Ion fractions of SiO_4^{4-}, $Si_2O_7^{6-}$, $Si_3O_{10}^{8-}$, etc., (based on all anions, including O^{2-}) were calculated as described previously (1, 2). Figure 5 shows ion fractions of monomer, dimer, trimer, tetramer, and decamer plotted against mole fraction of silica for the two temperatures. Since the theory cannot be applied to intramolecular condensations, ion fractions appear to approach zero at $N_{SiO_2} = 0.5$, although around and beyond this region rings and cross-linked structures will occur, resulting in finite ion fractions at these compositions. Figure 6 is a plot of ion fractions against chain size for the case when $N_{SiO_2} = 1/3$, the orthosilicate composition. This plot shows clearly that although the orthosilicate ion, SiO_4^{4-}, is the predominant species, there are also substantial amounts of

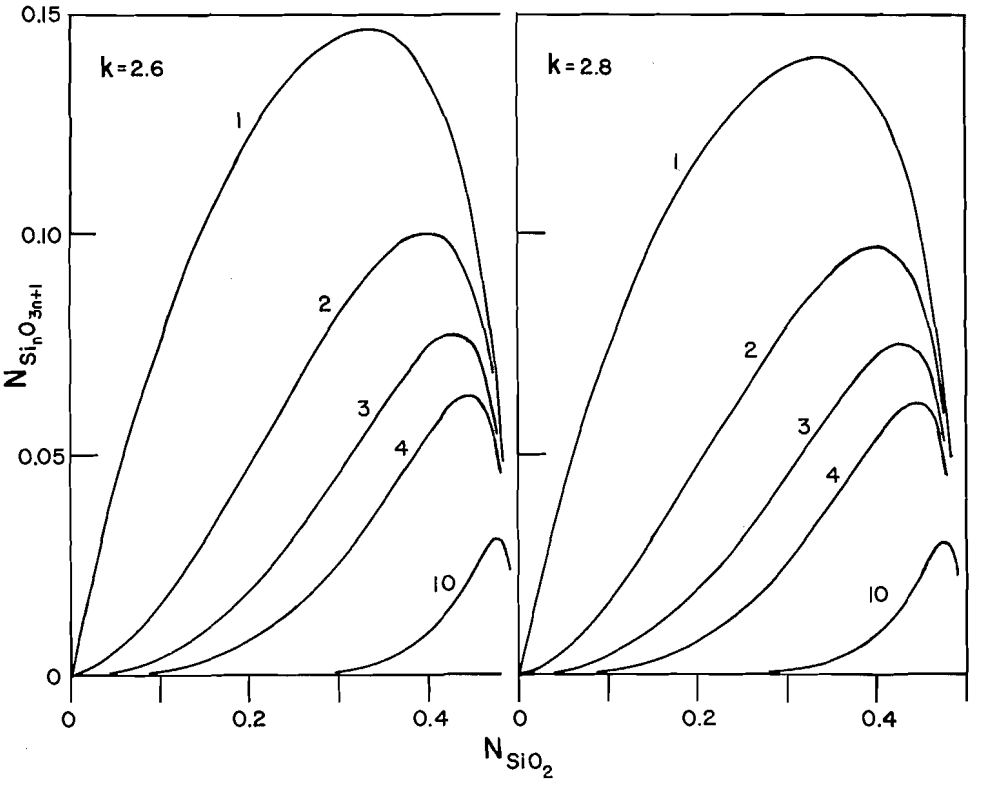

FIG. 5. Calculated ion fractions of SiO_4^{4-}, $Si_2O_7^{6-}$, $Si_3O_{10}^{8-}$, $Si_4O_{13}^{10-}$, and $Si_{10}O_{31}^{22-}$ plotted against mole fraction of silica for the two values of k corresponding to temperatures of 1450 and 1500 °C.

dimer, trimer, etc. In theory, monomeric ion is the most abundant species at all compositions. The broken curve for $k = 2.8$ crosses the value for $k = 2.6$ around $n = 4$ indicating that the distribution of anions becomes very slightly broader and larger anions become relatively more important as temperature increases. This effect also holds as the slag composition becomes more acid. These effects are displayed more clearly in Fig. 7 which shows the percentage by weight of the various silicate species (these calculations exclude O^{2-}) for the two compo-

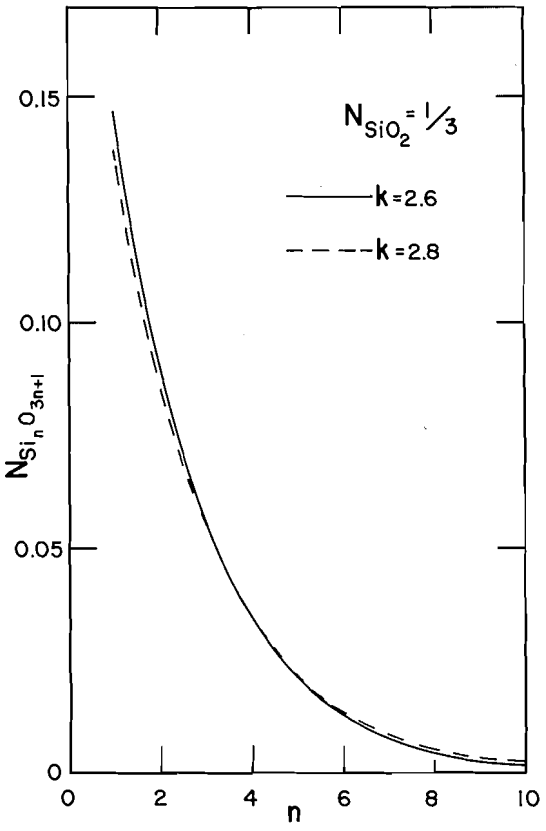

FIG. 6. Calculated ion fractions of silicate anions for the two values of k, when the overall composition is the orthosilicate, $N_{SiO_2} = 1/3$.

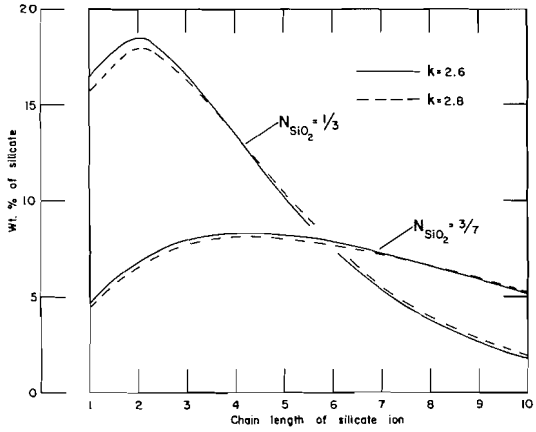

FIG. 7. Calculated weight % of silicate constituents plotted against chain length for both values of k, when the overall compositions are Co_2SiO_4($N_{SiO_2} = 1/3$) and $Co_4Si_3O_{10}$($N_{SiO_2} = 3/7$).

sitions Co_2SiO_4($N_{SiO_2} = 1/3$) and $Co_4Si_3O_{10}$ ($N_{SiO_2} = 3/7$). For purposes of comparison, calculated values of weight % of the silicate constituents for the orthosilicate composition are shown in Table 2 for three binary silicate systems, $CaO–SiO_2$, $SnO–SiO_2$, and $CoO–SiO_2$ (at 1450 °C). Values of k_{11} for $CaO–SiO_2$ and $SnO–SiO_2$ are taken from ref. 4 and weight % values calculated for x-mers from 1 to 10 on the basis of tetrafunctional condensation. Values for $CoO–SiO_2$ are calculated on the basis of bifunctional condensation, as outlined in this paper. The system $CaO–SiO_2$, with a low value of k_{11}, is highly depolymerized, and weight % values become negligible beyond trimer. The distribution of ions is very narrow, monomer being by far the dominant species. In contrast, for the system $SnO–SiO_2$, with a high value of k_{11}, the silicate is highly polymerized, even at the orthosilicate composition and the distribution is much broader. Although monomer is still the most abundant species weight % values are quite appreciable even up to the decamer. For the system $CoO–SiO_2$ the maximum weight % of silicates occurs around the dimer. This is a reflection of the fact that for linear chains, where

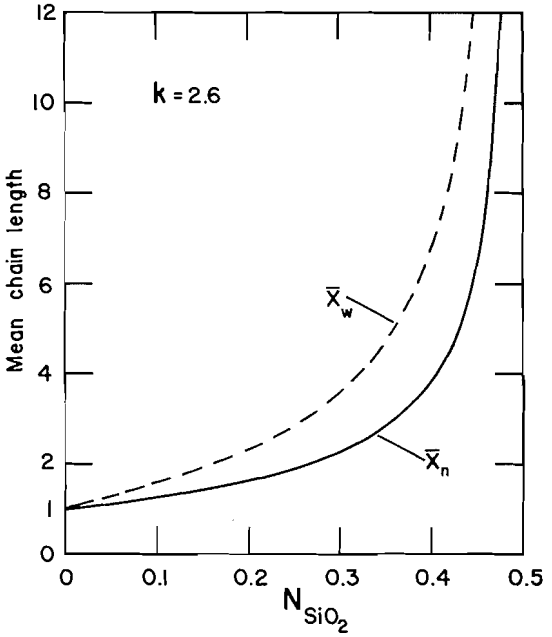

FIG. 8. Calculated number average ($\bar{x}_n$) and weight average ($\bar{x}_w$) chain lengths of silicate anions plotted against mole fraction of silica for the system $CoO–SiO_2$ at 1450 °C.

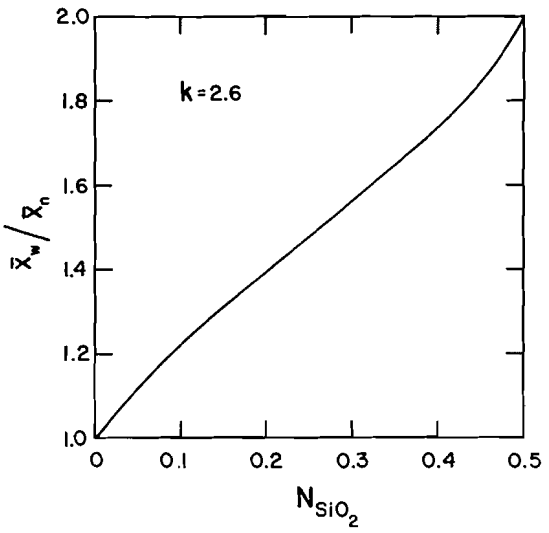

FIG. 9. Calculated ratio of $\bar{x}_w$ to $\bar{x}_n$ plotted against mole fraction of silica for $k = 2.6$.

only one configuration is possible for any x-mer, values of $N_{SiO_4}{}^{4-}$ are slightly lower at all compositions and values for the other species slightly higher, compared to those for systems where all configurations are allowed.

Number average chain lengths ($\bar{x}_n$) and weight average chain lengths ($\bar{x}_w$) of the silicate ions are shown in Fig. 8 as functions of the mole fraction of silica for one temperature, 1450 °C. At the orthosilicate composition the number average chain length is about three, *i.e.* the "average" silicate species corresponds closely to the formula $Co_4Si_3O_{10}$. The balance of the melt may be regarded as CoO, which accounts for the finite activity of CoO at this composition. Finally Fig. 9 shows a plot of $\bar{x}_w/\bar{x}_n$ against N_{SiO_2} up to the maximum applicable value of $N_{SiO_2} = 0.5$. At the maximum extent of reaction, neglecting intramolecular condensation, the ratio of $\bar{x}_w$ to $\bar{x}_n$ remains finite and equal to two, as for all linear condensation polymerizations.

We thank Mr. G. W. Caines for the chemical analyses, Mr. T. J. Uher for performing the mass spectrometric analysis of the gas mixtures and Dr. J. Götz for the chromatographic analysis of the quenched slag.

Aqueous Nonelectrolyte Solutions. Part VIII. Deuterium and Hydrogen Sulfides Solubilities in Deuterium Oxide and Water[1]

E. C. W. Clarke and D. N. Glew
Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received September 30, 1970

A new apparatus is described in which the solubility of deuterium sulfide in deuterium oxide and of hydrogen sulfide in water have been determined with 0.1% accuracy between 0 and 50 °C. Solubility equations are derived and the solubility standard thermodynamic function changes, together with their standard errors, are tabluated. Equal solubilities would occur at −1 °C. The solubility of hydrogen sulfide in water is greater than for deuterium sulfide in deuterium oxide, the solubility difference increases to a maximum at 40 °C and thence decreases at higher temperatures.

Un nouvel appareil permettant la mesure de la solubilité du sulfure de deutérium dans l'oxyde de deutérium et celle du sulfure d'hydrogène dans l'eau entre 0 et 50 °C avec une précision de 0.1% est décrit. Les équations de solubilité sont dérivées et les changements des fonctions thermodynamiques standards de solubilité de même que leurs erreurs standards sont présentés sous forme de tableau. Les solubilités seraient égales à −1 °C. La solubitilé du sulfure d'hydrogène dans l'eau est plus grande que celle du sulfure de deutérium dans l'oxyde de deutérium, la différence de solubilité passe par un maximum à 40 °C et décroit par la suite aux températures plus élevées.

Canadian Journal of Chemistry, 49, 691 (1971)

Introduction

In the evaluation of thermodynamic functions for the formation of deuterium sulfide deuterate (1), we required values for the solubility of deuterium sulfide in deuterium oxide. It seemed that this solubility might be obtained by the application of isotope effect correction factors to the well-known solubility of hydrogen sulfide in water (2). A literature search was made to find the magnitude, direction, and temperature coefficient for these isotope effects.

Carbon dioxide at 25 °C is equally soluble in water and deuterium oxide (3). The methyl halides are more soluble in water at 30 °C, except for methyl fluoride which is more soluble in deuterium oxide (4). At higher temperatures all methyl halides showed an increasing preference for dissolution in deuterium oxide. The hydrocarbons *n*-heptane, cyclohexane, and toluene are more soluble in water than in deuterium oxide at 60 to 90 °C and also show an increasing preference for dissolution in deuterium oxide at higher temperatures (5). Argon, however, is more soluble in deuterium oxide than in water at 25 °C and shows a decreasing preference for dissolution in deuterium oxide at higher temperatures (6). Evidently no reliable estimate of aqueous solution isotope effects can be made at present.

To measure the small solubility differences between deuterium sulfide in deuterium oxide and hydrogen sulfide in water we have designed and constructed a new solubility apparatus capable of 0.1% accuracy in the 0–50 °C temperature range.

Experimental

Materials

Water was laboratory distilled. Deuterium oxide contained 0.25 weight% protium oxide as supplied by Atomic Energy of Canada, Limited. Hydrogen and deuterium sulfides were prepared as previously described (7).

A diagram of the solubility apparatus is shown in Fig. 1. All tubing, fittings, and diaphragm valves were made of type-316 stainless steel which was found to resist corrosion. Only vessels B, C, D, and E were made of Pyrex glass and these were fused to capillary tubing and attached to the apparatus via 1/4 in. Swagelok fittings using Teflon front and nylon back ferrules.

Apparatus Calibration

In preliminary experiments the volume of the precision variable piston, A (stainless steel volumetric micrometer, Volumetrics Incorporated), was calibrated by weighing water, using the density compilation of Dorsey (8). At 25 °C over its 200 cm^3 range the standard error on a single volume determination was 0.013 cm^3.

The 130-cm^3 solubility cell B, containing magnetic stirring bar, and the 55-cm^3 vessels C, D, and E were immersed in a thermostat bath controlled to ±0.0015 °C. The bath temperature adjacent to the solubility cell was measured with a precision of 0.001 °C by a platinum resistance thermometer in conjunction with a Mueller bridge, amplifier, and galvanometer. Pressure was measured with an accuracy of 0.02% by a 0–16 p.s.i. range Texas Instruments Incorporated fused quartz precision Bourdon

[1]Contribution No. 187.

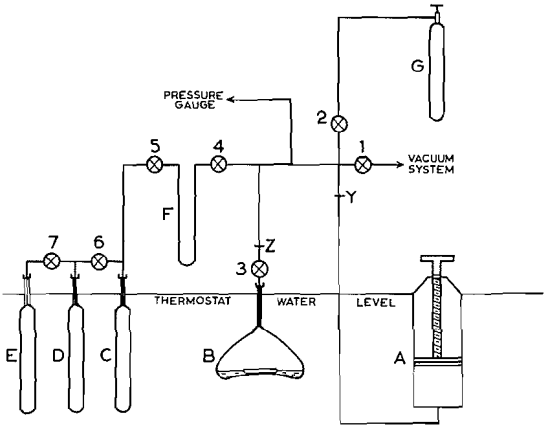

FIG. 1. Solubility apparatus.

gauge. The gauge was calibrated against a wide-bore mercury manometer, for which the column height difference was determined by cathetometer comparison against a meter standard. The apparatus not immersed in the thermostat bath was at room temperature (26 °C) for solubilities below 27 °C, or was heated by infrared lamps to about 60 °C for solubilities above 27 °C.

The volumes of B, C, D, and E at each experimental temperature were determined by isopiestic displacement of nitrogen from A. The variable piston A, set to maximum volume, was attached via capillary tubing to the apparatus at Y. The system was evacuated with valves *1*, *4*, *5*, *6*, and *7* open, and all others closed. After closing valves *7*, *6*, and *5* dry nitrogen was admitted through *1* until the pressure reached about atmospheric when *1* was closed and the pressure measured. Valve *5* was opened and A adjusted to restore the pressure to its original value. The volume difference of A was equal to the volume equivalent of C and its connections at thermostat temperature. Valve *6* was opened and A adjusted to restore the same pressure: this volume change of A gave the volume equivalent of D and its connections at thermostat temperature. Valve *7* was opened and the procedure repeated for the volume equivalent of E. At each experimental temperature the C, D, and E volumes were determined three times with a standard error of less than 0.010 cm^3. The volume equivalent of the solubility cell B below valve *3* was similarly determined with the same accuracy. The variable volume was then detached and the system plugged at Y. The volume between valves *1*, *2*, *3*, and *5*, including F and the pressure gauge, was calibrated with a standard error of 0.02 cm^3 by three separate nitrogen expansions into C.

The temperature scales are related by 0 °C ≡ 273.15 K, and the gas constant R is taken as 1.98717 thermochemical cal/mol deg (9). The International Practical Temperature Scale of 1948 defines the Celsius temperature.

Solubility Measurement

The evacuated solubility cell B with *3* closed was detached from the apparatus at Swagelok fitting Z and weighed. Approximately 23 cm^3 of water or deuterium oxide were sucked into B. The liquid was degassed at ambient temperature by evacuation for 10 min with vigorous stirring leaving about 21 cm^3 in B, which was reweighed and reattached at Z. Cylinder G containing hydrogen or deuterium sulfide was immersed in liquid nitrogen and the apparatus evacuated to 0.005 Torr with all valves open except *3*. After closing *1* the liquid nitrogen was removed from G and the vapor pressure rose to a predetermined value at which *2* and the cylinder valve were closed. The equilibrium pressure and temperature were measured The quantity of gas taken was such that the pressure ranged from ~ 720 Torr at 0 °C to ~ 530 Torr at 50 °C. The glass-covered stirring bar in B was activated by an air-driven magnetic stirrer (not shown). Valve *3* was opened and after about 20 min stirring the equilibrium pressure and temperature were measured, after which *4* was closed. U-tube F was immersed in liquid nitrogen for 10 min, *7* was closed and F was then heated to ambient temperature. Valve *4* was reopened and after about 20 min stirring the equilibrium pressure and temperature were measured. Valve *4* was closed, F immersed in liquid nitrogen for 10 min, *6* closed, F heated to ambient, *4* opened, and after 20 min stirring the equilibrium pressure and temperature were measured. Finally, *4* was closed, F cooled in liquid nitrogen for 10 min, *5* closed, F heated to ambient, *4* opened, and after 20 min stirring the equilibrium pressure and temperature were measured. In each experiment the known weight of water and volume of hydrogen sulfide were brought to pressure equilibrium four times, making successive transfers of dry hydrogen sulfide from E + D + C + F to D + C + F to C + F to F in such a manner to limit the water vapor to B below *3*.

Results and Discussion

Solubility is expressed as the Henry Law constant $H = f_2/a_2$ in which f_2 is the solute vapor fugacity in atm and a_2 its equilibrium solution activity. The activity is defined by $a_2 = x_2 \exp (P - 1)\bar{v}_2/RT$ in which x_2 is the mole fraction of unionized solute in solution, $\bar{v}_2$ its partial molar volume, and P the total pressure. The fugacities and volumetric properties of all components are evaluated from the Redlich–Kwong (10) equation of state

$$[1] \qquad (P + a/T^{1/2}V(V + b))(V - b) = RT$$

At our experimental pressures of 350–750 Torr these properties are relatively insensitive to the values taken for the covolume b. For hydrogen and deuterium sulfides b_{22} was taken as 35.91, and for water and deuterium oxide b_{11} was 18.02 cm^3/mol. The hydrogen sulfide a_{22} was 9.613×10^7 $(cm^2/mol)^2$ atm $(°K)^{1/2}$, derived from the least squares fit of the P–V–T data of Wright and Maass (11). The deuterium sulfide a_{22} was 9.592×10^7 obtained taking the same ratio to the hydrogen sulfide value as in our earlier

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

work (7). The water-vapor a_{11} was 54.39×10^7 $(cm^2/mol)^2$ atm $(°K)^{1/2}$, derived from a least-squares fit of P–V–T data supplied by Liley (12); the same a_{11} value was taken for deuterium oxide.

Values of the Redlich–Kwong constants for the binary vapor mixtures, hydrogen sulfide – water and deuterium sulfide – deuterium oxide were calculated from the pure-component values using the relations (13),

$$[2] \quad a_{12} = 0.875\,(a_{11}a_{22})^{1/2}$$

$$[3] \quad b_{12} = (b_{11}b_{22})^{1/2}$$

$$[4] \quad a_m = a_{11}y_1^2 + 2a_{12}y_1y_2 + a_{22}y_2^2$$

$$[5] \quad b_m = b_{11}y_1^2 + 2b_{12}y_1y_2 + b_{22}y_2^2$$

in which y_1 and y_2 are the component mole fractions and a_m and b_m are the constants for the vapor mixture. The factor of 0.875 in [2] was assessed for systems containing hydrogen sufide from the work of Spear, Robinson, and Chao (13). The component fugacities and molar volumes were evaluated by standard methods (10) from [1] using the mixing laws [2]–[5].

For the fugacity f_1 in a binary mixture we obtain

$$[6] \quad \ln f_1 = \ln\left(\frac{RTy_1}{(V-b_m)}\right) + \frac{b_{11} + (2b_{12} - b_{11} - b_{22})y_2^2}{(V-b_m)} - \frac{2(a_{11}y_1 + a_{12}y_2)}{b_mRT^{3/2}}\ln\left(\frac{V+b_m}{V}\right) + \frac{a_m(b_{11} + [2b_{12} - b_{11} - b_{22}]y_2^2)}{b_m^2RT^{3/2}}\left\{\ln\left(\frac{V+b_m}{V}\right) - \frac{b_m}{V+b_m}\right\}$$

with a similar expression for the second component.

Figure 2 illustrates the equilibria attained in cell B during solubility measurement. An iterative computer program was written which took the solubility total pressure P with the water vapor pressure to yield initial values for the water and hydrogen sulfide vapor mixture mole fractions y_1 and y_2, and fugacities f_1 and f_2. Taking this f_2 with a preselected value of H we obtained the unionized hydrogen sulfide solution

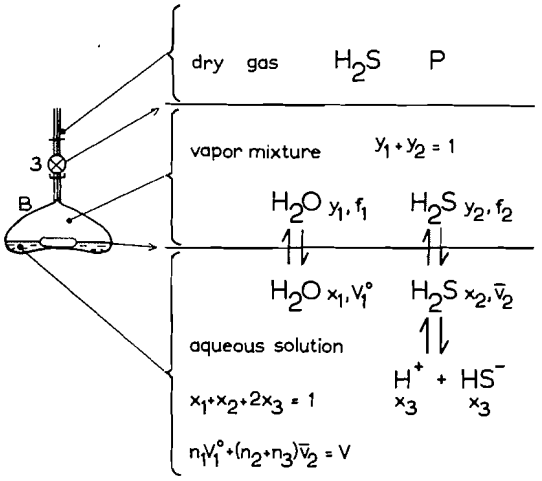

FIG. 2. Equilibria established in solubility cell.

mole fraction x_2, which was used to calculate the mole fraction of hydrosulfide ions x_3 (14), and thence obtained the water mole fraction x_1 from the relation $x_1 + x_2 + 2x_3 = 1$. Using x_1 with the pure water activity a new value was obtained for the water vapor fugacity f_1. The value of y_1 was iterated to obtain coincidence of the values of f_1 from the vapor and solution phases. In this manner we obtained values for the vapor and liquid phase compositions at total pressure P, consistent with the preselected value of H. The number of moles of hydrogen sulfide, dissolved in the water, contained in the mixed vapor phase in B, and in the dry state beyond *3* in F and etc., was compared with the known initial number of moles of hydrogen sulfide. The square of this difference of moles of hydrogen sulfide was minimized to zero by iteration of H. In this manner we obtained the unique value of H consistent with all experimental quantities for the solubility measurement at P. Similarly the three other solubility pressures each gave a value for H. To obtain the best H for the whole experiment the iteration was performed minimizing the sum of squares of the mole differences for the four solubility pressures.

The ionization of hydrogen sulfide in water was determined from the equation

$$[7] \quad \log_{10} K_{H_2S} = 55.06 - 3760/T - 20\log_{10} T$$

given by Ellis and Milestone (14) with K_{H_2S} in molarity units and T in degrees absolute. From the difference of ionization constants for the deuterium and protium acids (16) and assuming a constant ratio between H_2S and D_2S, we obtain the equation

$$[8]\quad \log_{10} K_{D_2S} = 54.50 - 3760/T - 20 \log_{10} T$$

for the ionization of deuterium sulfide in deuterium oxide. The effect of the second ionizations for hydrogen and deuterium sulfides is negligible.

The volume of the aqueous solution was taken as $n_1 V_1^0 + 34(n_2 + n_3)$, in which V_1^0 is the pure water molar volume in cm^3, 34 cm^3 is the partial molar volume, $\bar{v}_2$, assumed to be temperature-invariant for hydrogen sulfide in water (15), and n_1, n_2, and n_3 are the number of moles of water, unionized hydrogen sulfide, and hydrosulfide ion in solution. The value of n_1 is smaller than the total number of moles of water by the amount present as vapor in B. The partial molar volume of deuterium sulfide in deuterium oxide was taken as 34 cm^3, the same as for hydrogen sulfide.

Vapor pressures and volumetric properties of water were taken from Dorsey (8), those for deuterium oxide from the critical review by Whalley (17).

In Table 1 are presented the individual temperature and pressure measurements, the derived fugacities, phase compositions, and Henry's Law constants for the solubility of hydrogen sulfide in water. The individual solubility measurements for deuterium sulfide in deuterium oxide are presented in Table 2.

New solubility measurements for hydrogen sulfide in water between 0 and 50 °C are presented in Table 3, together with calculated values from the best (18) representative equation

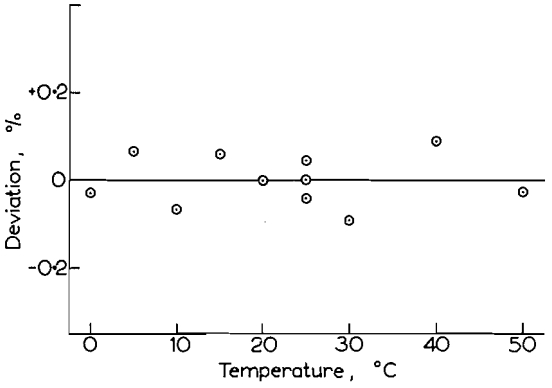

FIG. 3. Deviations from eq. 9 of Henry's law constants for hydrogen sulfide solubility in water.

unthermostatted parts of the apparatus, while that at 25.017 °C was made without heating. The experiment at 25.016 °C was made using 41 g water, double the usual amount. The correctness of our solubility method is demonstrated by the very good agreement of these experiments with each other and with eq. 9.

The hydrogen sulfide solubility work of Wright and Maass (2) provides insufficient data to calculate H_{H_2S} so that in Table 4 we compare our measurements with their x_2/p_2 values. Good agreement is found. The measurements of Selleck, Carmichael, and Sage (19) at 37.8 °C are unreliable and give H_{H_2S} values varying between 640 and 780 atm compared with our value of 709.5 ± 0.3 from eq. 9.

Unique solubility measurements for deuterium sulfide in deuterium oxide between 5 and 50 °C are presented in Table 5, together with calculated values from the best (18) representative equation

$$[10] \quad \log_{10} H_{D_2S}\,(\text{atm}) = 137.39155 - 5463.378/T - 49.56328 \log_{10} T + 0.0211857T$$

The percentage differences of the measurements from eq. 10, plotted in Fig. 4, lead to a standard error of 0.12% on a single solubility determination. We do not know why this error

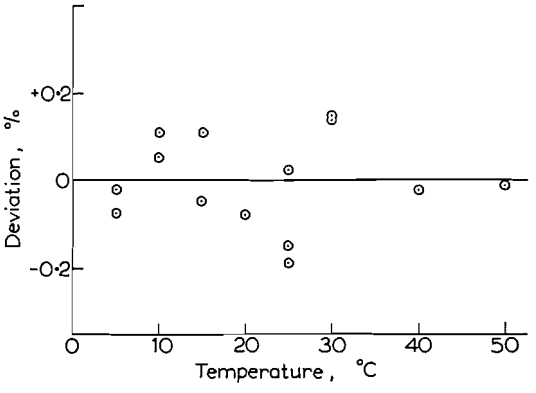

FIG. 4. Deviations from eq. 10 of Henry's law constants for deuterium sulfide solubility in deuterium oxide.

is nearly twice that for the hydrogen sulfide measurements and conclude that the standard error for our solubility method is about 0.10%.

The H_{D_2S}/H_{H_2S} ratio is plotted against temperature in Fig. 5. Extrapolated solubilities are equal at about − 1 °C, above which hydrogen sulfide is more soluble in water than deuterium sulfide in deuterium oxide. A maximum ratio of 1.028_5 is attained near 40 °C.

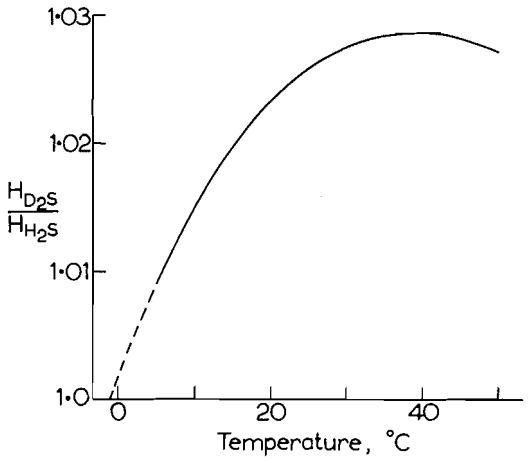

FIG. 5. Temperature effect on the Henry's law constant ratio H_{D_2S}/H_{H_2S}.

Standard Thermodynamic Functions for Solute Evolution

The solute evolution equilibrium constant H (atm) at total pressure P and T absolute is defined by the relation

$$[11] \quad \ln H = \Delta G^0/(-RT) = \ln f_2 - \ln x_2 - (P - 1)\bar{v}_2/RT$$

in which ΔG^0 is the standard free energy change for the transfer of 1 mol of solute from solution at unit mole fraction and 1 atm pressure to give vapor at 1 atm fugacity. The standard thermodynamic function changes, the enthalpy ΔH^0, entropy ΔS^0, heat capacity ΔC_p^0, and its temperature derivative $d\Delta C_p^0/dT$, together with their errors, are evaluated by treating the ln H values from eq. 11 according to the method of Clarke and Glew (18). Tables 6 and 7 present values for the standard thermodynamic function changes, together with their standard errors σ, between 0 and 50 °C for hydrogen sulfide evolution from water and for deuterium sulfide from deuterium oxide. Proper representation of our solubility measurements required use of the $d\Delta C_p^0/dT$ term, its value arising from chance alone with 16% probability for hydrogen sulfide in water, and with 28% probability for deuterium sulfide in deuterium oxide.

The values of $d\Delta C_p^0/dT$ agree in sign and magnitude with those found for the methane–water system (20) and with predictions from the Eley model. This model predicts that the value of ΔC_p^0 at 25 °C should be about 20% larger in deuterium oxide than in water and our experimental value is larger by 16 ± 2%. At 5 °C the enthalpy change for deuterium sulfide evolution from deuterium oxide is 4.1% larger than for hydrogen sulfide evolution from water, at 40 °C the enthalpies are equal, and at higher temperatures the deuterium sulfide evolution has the smaller value. Literature solubilities for the

The Reaction of Carbon Disulfide with Aziridine Complexes of Nickel(II)

B. JACK MCCORMICK, ROY I. KAPLAN, AND BENJAMIN P. STORMER
Department of Chemistry, West Virginia University, Morgantown, W.Va. 26506

Received August 31, 1970

Carbon disulfide has been shown to undergo insertion reactions with $[Ni(aziridine)_{4,6}]^{2+}$ and $[Ni(2\text{-methylaziridine})_4]^{2+}$. The diamagnetic products are formulated as planar dithiocarbamate complexes in which the heterocyclic ring remains intact. The complexes have properties which are atypical of all dithiocarbamate complexes heretofore reported, and infrared and optical spectral measurements suggest that the insertion products may be the first examples of N,S-bonded dithiocarbamate ligands. In methanol the products slowly rearrange to give S,S-bonded complexes in which the aziridine rings have been opened.

Introduction

Most primary and secondary amines react smoothly with carbon disulfide to produce dithiocarbamic acids (1). In contrast the three-membered, heterocyclic amine aziridine (ethyleneimine) undergoes ring opening when treated with carbon disulfide to form 2-thiazolidinethione (2).

[1] 
A similar reaction occurs with 2-methylaziridine (3, 4), although it has been reported in the patent literature that dithiocarbamate salts can be obtained from 2-methylaziridine, carbon disulfide, and base (5, 6). Since dithiocarbamate complexes

[2] 
can be prepared directly from many amine complexes by carbon disulfide insertion reactions (7–10), it was of interest to investigate the reaction of carbon disulfide with aziridines coordinated to a metal ion. We report here the results of these investigations and some tentative conclusions concerning the structure of the unusual compounds formed.

Experimental

Materials

Aziridine (az) and 2-methylaziridine (meaz) were obtained from the Dow Chemical Corporation and from Matheson, Coleman and Bell, respectively. Both compounds were distilled before use. Reagent grade nickel(II) salts and carbon disulfide were used without further purification. The aziridine compounds, $Ni(az)_4SO_4$, $Ni(az)_6(NO_3)_2$, and $Ni(az)_4Cl_2$ were prepared according to Jackson and Edwards (11).

Preparation of $Ni(meaz)_4Cl_2$

To 1.0 g (0.0042 mol) of $NiCl_2 \cdot 6H_2O$ in 5 ml of ethanol was added slowly 0.92 g (0.018 mol) of 2-methylaziridine to give a blue solution of $Ni(meaz)_4Cl_2$. Cooling the solution to 0° with periodic scratching of the sides of the container resulted in the crystallization of a light blue powder which was dried and then recrystallized from absolute ethanol. The recrystallized product was dried in vacuum over P_4O_{10} for 24 h. The complex was soluble in water, methanol, and ethanol, slightly soluble in dimethyl sulfoxide and dimethyl formamide, and insoluble in acetone, ether, and methylene chloride.

Anal. Calcd. for $[Ni(C_3H_7N)_4]Cl_2$: C, 40.3; H, 7.88; N, 15.7. Found: C, 40.1; H, 7.65; N, 15.7.

Reaction of Aziridine and 2-Methylaziridine Complexes with Carbon Disulfide

The three aziridine complexes studied in this work, $Ni(az)_4SO_4$, $Ni(az)_6(NO_3)_2$, and $Ni(az)_4Cl_2$, all react with carbon disulfide to provide the same product; hence, only one such reaction will be described in detail.

A 3.3 g (0.010 mol) sample of $Ni(az)_4SO_4$ was dissolved in 50 ml of methanol to which was added 7.6 g (0.10 mol) of carbon disulfide in 10 ml of methanol. The solution rapidly went through a series of color changes from blue, through several shades of green, to brown. After about 1 min a red crystalline precipitate began to form, and after 5 min the red compound was collected on a filter, washed with 100 ml of cold methanol, and air dried for 20 min at room temperature.

Anal. Calcd. for $Ni(S_2NC_3H_4)_2$: C, 24.4; H, 2.73; N, 9.49; S, 43.5. Found: C, 24.0; H, 2.76; N, 9.30; S, 43.7.

A solution of 0.354 g (0.001 mol) of $Ni(meaz)_4Cl_2$ in 6 ml of methanol was treated with 0.315 g (0.004 mol) of carbon disulfide. Again a series of color changes was observed, the color being deep red after 5 min. This red solution was cooled in ice and the sides of the container were scratched with a glass rod, whereupon a reddish-brown, microcrystalline product formed. The analytical sample was recrystallized quickly from methanol and dried in vacuum over P_4O_{10} for 2 h.

Anal. Calcd. for $Ni(S_2NC_4H_6)_2$: C, 29.7; H, 3.74; N, 8.67; mol. wt., 323. Found: C, 28.9; H, 3.75; N, 8.62; mol. wt., 336.

Properties of Insertion Products

The compound prepared from $Ni(az)_{4,6}^{2+}$ is thermally unstable and at room temperature decomposes completely within a few hours; however, it can be stored at $-10°$ for several weeks without significant decomposition. On several occasions the compound decomposed somewhat violently upon grinding with a mortar and pestle. The complex is slightly soluble in numerous polar organic solvents, but it decomposes so rapidly as to preclude most types of solution study, *e.g.*, molecular weight determinations. Addition of the complex to pyridine at room temperature resulted in the formation of an emerald green solution, from which was deposited a brown powder after 1–2 min. The complex prepared from $Ni(meaz)_4^{2+}$ has properties very similar to those derived from $Ni(az)_{4,6}^{2+}$. In general, however, the former derivative is somewhat more stable and more soluble than the latter.

At $-15°$ dilute solutions of the compounds in methylene chloride containing pyridine (in excess) exhibit an absorption band at 8.83 kK. This band is absent in methylene chloride alone. It can be concluded that the compounds become six-coordinate and pseudo-octahedral in the presence of pyridine. Infrared studies indicate that neither compound contains N—H bonds, since bands assignable as NH stretching or deformation modes were not found.

Decomposition Reactions

In methanol, a suspension of the red aziridine derivative decomposes slowly to give a diamagnetic green material which is very slightly soluble in dimethyl sulfoxide.

Anal. Calcd. for $Ni(S_2NC_3H_5)_2$: C, 24.3; H, 3.39; N, 9.43. Found: C, 24.3; H, 3.49; N, 9.42.

A methanol solution of the 2-methylaziridine derivative behaves similarly.

Anal. Calcd. for $Ni(S_2NC_4H_7)_2$: C, 29.6; H, 4.34; N, 8.62. Found: C, 29.3; H, 4.04; N, 8.36.

Infrared spectroscopic studies clearly show the presence of NH bonds in these products; NH stretching and deformation bands were found at 3150–3200 and 1610–1620 cm^{-1}, respectively. Bands found at 1495 and 1520 cm^{-1} in the aziridine and 2-methylaziridine derivatives, respectively, are reasonably assigned as C···N stretching vibrations. This band is quite characteristic of the previously reported dithiocarbamate complexes that involve chelation through the two sulfur donors (1, 10). Electronic spectral studies also indicate that both of the decomposition products are the usual type of dithiocarbamate complex. The diffuse reflectance spectra of the samples were quite similar to that of bis(*N*,*N*-dimethyldithiocarbamato)nickel(II).

In the presence of solvents such as chloroform or carbon tetrachloride, or in the dry state, both of the red complexes decompose to black insoluble materials that have not been characterized. When the solids decompose in the dry state, there is no perceptible weight change.

Measurements

All measurements were made on freshly prepared samples, unless otherwise indicated.

Electronic spectra were measured with a Cary Model 14 spectrophotometer. Diffuse reflectance spectra were measured in conjunction with a Cary Model 1411 reflectance attachment. The reflectance standard was $MgCO_3$. The reflectance spectra of the red products were measured for samples which were held at *ca.* 0°. Solution spectra were measured as quickly as possible in order to minimize effects due to decomposition. Infrared spectra were measured with Beckman Models IR-8 and IR-12 spectrometers by using Nujol and perfluorokerosene mulls as well as KBr discs. Very concentrated samples were required to observe the carbon–hydrogen stretching frequencies in the red reaction products. Infrared and electronic spectra are shown in Figs. 1 and 2, respectively.

Magnetic susceptibility measurements were made with a Gouy balance of standard design. Both of the insertion products are diamagnetic.

The molecular weight determination was carried out with a vapor pressure osmometer using benzene as the solvent.

Elemental analyses were done by Galbraith Laboratories. In some cases the samples were packed in Dry Ice for shipment and were analyzed within a few hours of preparation.

Results and Discussion

When treated with carbon disulfide, solutions of $Ni(az)_{4,6}^{2+}$ and $Ni(meaz)_4^{2+}$ form the red complexes $Ni(S_2NC_3H_4)_2$ (**1**) and $Ni(S_2NC_4H_6)_2$ (**2**), respectively. Initially it was thought that the aziridine rings would be opened in the reactions to provide coordinated 2-thiazolidinethione groups. However, infrared studies indicate that the reaction products are not 2-thiazolidinethione complexes, since the infrared spectra of authentic samples of bis(2-thiazolidinethionato)nickel(II) (12, 13) are quite different from those of compounds **1** and **2**. Indeed, the infrared spectral studies indicate that the heterocyclic rings

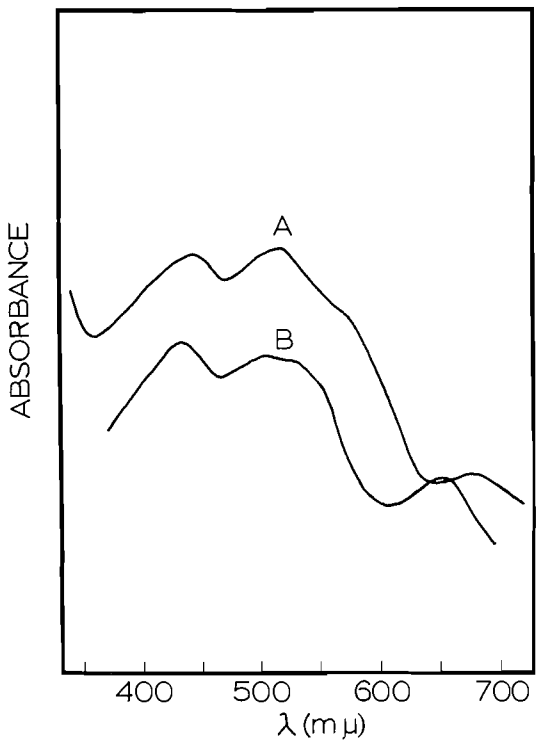

FIG. 2. Diffuse reflectance spectrum of $Ni(S_2NC_3H_4)_2$, *A*; and *B*, $Ni(S_2NC_4H_6)_2$.

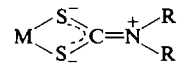
remain intact in both insertion products. It has been established that C—H stretching frequencies are abnormally high in strained three membered ring systems (14). In aziridine and 2-methylaziridine C—H stretching frequencies have been assigned from 3079 to 2940 cm^{-1} (15, 16). In $Ni(az)_4SO_4$ and $Ni(meaz)_4Cl_2$ we have observed C—H stretching frequencies in the 2900–3015 cm^{-1} region. In compounds **1** and **2** corresponding weak bands are located at 2992 and 2970 cm^{-1}, respectively. Should the rings have been opened by carbon disulfide, the C—H stretching frequencies would be expected at lower energies. Since there are no N—H bonds in products **1** and **2**, as there are in the parent compounds and in 2-thiazolidinethione complexes, it is concluded that $Ni(az)_{4,6}^{2+}$ and $Ni(meaz)_4^{2+}$ undergo carbon disulfide insertion reactions [3] to provide dithiocarbamates as has been reported previously for other nickel(II)–amine complexes (10).

[3] 
A particularly intriguing feature of compounds **1** and **2** is their red color (most nickel(II) dithiocarbamates have been described as green). Further, the infrared spectra (Fig. 1) of the insertion products suggest that they are not "normal" dithiocarbamate complexes. It is well known that canonical forms of type **A** play an important role in the description of the electronic structure of the usual type of S,S-bonded dithiocarbamate complexes (17, 18). The $(S_2)C—N$ bond order is



A

greater than one, and, consequently, a characteristic C⋯N stretching frequency is found as a generally broad and intense band near 1500 cm^{-1} in *N,N*-dialkyldithiocarbamate complexes (17). In product **1** there is no band near 1500 cm^{-1}, but there is a very strong broad band at 1383 cm^{-1} (Fig. 1) which is assigned as the $(S_2)C—N$ stretching frequency. The sharp weak bands at 1429 and 1450 cm^{-1} are reasonably assigned to CH_2 deformation modes (14). The infrared spectrum of product **2** is complicated in the 1300–1500 cm^{-1} region by CH_3 and CH_2 deformation modes, as well as by CH bending modes, but there is a strong band located at 1381 cm^{-1} that can be assigned as the $(S_2)C—N$ stretching frequency. Thus, the $(S_2)C—N$ bond order in the insertion products is significantly reduced from that normally observed in *N,N*-dialkyldithiocarbamate complexes. Such a significant reduction in the $(S_2)C—N$ bond order might arise in one of two ways. If the dithiocarbamate ligand should be N,S-bonded, the lone pair on the nitrogen atom would not be available for π-donation to the carbon atom. Consequently the $(S_2)C—N$ bond order would be reduced from that normally observed. If the ligands are S,S-bonded with a low contribution from canonical forms of type **A**, a low $(S_2)C—N$ bond order might also be expected. In this case the complexes would resemble those of xanthate ligands for which it is known that structures of type **B** are not of great significance (19).

In dithiocarbamate complexes that are coordinated through two sulfur atoms there nor-

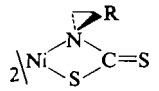
For personal use only.

mally are observed three bands in the 1130–1290 cm^{-1} region which are associated with the NCS_2 group (20). This band structure is absent in compounds **1** and **2**, again suggesting that these compounds are not "normal" dithiocarbamates. It is particularly significant to point out, however, that in both compounds a band is found at 1045 cm^{-1}, which is in the region where C=S stretching frequencies are usually located (21). In a closely related complex, $Ni(CS_3)_2^{2-}$, the C=S stretch has been assigned at 1010 cm^{-1} (22). The presence of the 1045 cm^{-1} band in both complexes is strongly indicative of the presence of an uncoordinated C=S group and suggests that the complexes have structure **3** rather than **4**.



3

4

Sharp bands at 378 and 384 cm^{-1} in compounds **1** and **2**, respectively, can be assigned with confidence as nickel–sulfur stretching frequencies (19, 23). Compounds having structure **3** should also exhibit a nickel–nitrogen stretching frequency. Bands of moderate intensity are located in the 450–600 cm^{-1} region that can be assigned to the Ni—N stretch. However, because of the uncertainty usually associated with the assignment of metal–nitrogen frequencies (23), we are reluctant to attach any structural significance to the bands in this region.

Electronic spectral data are recorded in Fig. 2. The spectra are similar to those that have been observed previously for planar complexes such as xanthates and dithiocarbamates (24). These spectra do not provide a clear indication as to whether the complexes have structure **3** or structure **4**.

In the absence of X-ray crystallographic studies we cannot unequivocally make a choice between structures **3** and **4**. However, we believe that the data favor structure **3**, which is unique in dithiocarbamate complex chemistry. Such structures were alluded to as a "delicate problem" in 1931 by Cambi and Cagnasso (25), although all crystal structure determinations to date on dithiocarbamate complexes have revealed that coordination is through sulfur alone. There seems to be no fundamental reason for not observing simultaneous coordination through nitrogen and sulfur atoms, although N,S-bonded complexes are expected to be unstable owing to the loss in resonance stabilization energy involving canonical forms of type **A**. On the other hand, the Walsh model (26) of the bonding in aziridine, which has recently received additional experimental confirmation (27), suggests that dithiocarbamates derived from aziridines would not be expected to involve in a significant way canonical forms of type **A** because the lone-pair electrons on the nitrogen atom would be directed *away* from the carbon atom of the CS_2 moiety by 120°. In fact the expected orientation of the lone-pair renders it available for coordination, as judged from molecular models. We conclude that N,S-coordination is entirely possible because of the unique nature of the bonding in the three membered rings.

Decomposition Reactions

Suspensions of insertion products **1** and **2** in methanol slowly decompose to give green S,S-bonded dithiocarbamate complexes in which the heterocyclic rings have been opened, as judged by infrared and electronic spectral studies. These complexes appear to be polymeric and although we do not know the details of the structures, it seems plausible that the rings may open to give an unstable vinyl derivative (28) followed by polymerization, *viz.*

The Gas Phase Raman Spectrum and Molecular Structure of Dichlorodibromotellurium(IV) $TeCl_2Br_2$. Novel Penta- and Hexa-co-ordinate Mixed Halide Anions of Tellurium(IV). Synthesis and infrared and Raman Spectra of $[Et_4N]TeCl_2Br_3$ and $[Et_4N]_2TeCl_2Br_4$

G. A. Ozin and A. Vander Voet
Department of Chemistry and Erindale College, University of Toronto, Toronto 181, Ontario

Received August 10, 1970

The Raman spectrum of gaseous $TeCl_2Br_2$ at 310 °C is reported for the first time. The gas phase data is consistent with the presence of a monomolecular species having C_1 symmetry. A synthetic route for the preparation of penta- and hexa-co-ordinate mixed halide anions of tellurium(IV), under anhydrous conditions, is described for the first time. The infrared and Raman spectra for solid $[Et_4N]TeCl_2Br_3$ and $[Et_4N]_2TeCl_2Br_4$ are reported. A stereochemistry based on a square pyramid, is favored for $[Et_4N]TeCl_2Br_3$. In the case of $[Et_4N]_2TeCl_2Br_4$ the vibrational data strongly suggests the presence of a *cis*-octahedral anion, having C_{2v} symmetry.

Le spectre Raman de $TeCl_2Br_2$ à l'état gazeux à 310 °C est décrit ici pour la première fois. Les résultats obtenus en phase gazeuse s'expliquent par la présence d'une espèce monomoléculaire de symétrie C_1. Pour la première fois, on décrit une méthode synthétique en milieu anhydre pour la préparation des anions penta- et hexacoordonnés d'halogénures mixtes de tellure(IV). Les spectres Raman et infrarouges des solides $[Et_4N]TeCl_2Br_3$ et $[Et_4N]_2TeCl_2Br_4$ sont aussi décrits. Pour $[Et_4N]TeCl_2Br_3$, la stéréochimie favorisée est une pyramide carrée. Dans le cas de $[Et_4N]_2TeCl_2Br_4$ les spectres suggèrent fortement la présence d'un anion cis-octaédrique ayant une symétrie C_{2v}.

Canadian Journal of Chemistry, 49, 704 (1971)

Dichlorodibromotellurium(IV)

Dichlorodibromotellurium(IV) $TeCl_2Br_2$ was first prepared and characterized by Aynsley (1) in 1953. Until 1968 the literature was devoid of structural information concerning this interesting mixed halide (2). $TeCl_2Br_2$ represents the only known example of a Group VI mixed tetrahalide which is sufficiently stable in the vapor phase to allow a structural investigation by gas phase laser Raman spectroscopy. By analogy with gaseous $TeCl_4$ (3–6), the species present in the vapor of $TeCl_2Br_2$ would also be expected to be molecular although suitable electron diffraction data is not available. As far as the authors can be certain, the only spectral data available for $TeCl_2Br_2$ is an infrared study of the solid and of a benzene and dimethylformamide solution (2).

The possible gas phase dissociations

$$[1] \qquad TeCl_2Br_2 \rightleftharpoons TeCl_2 + Br_2$$

$$[2] \qquad TeCl_2Br_2 \rightleftharpoons TeBr_2 + Cl_2$$

$$[3] \qquad 2TeCl_2 \rightleftharpoons Te_2 + 2Cl_2$$

$$[4] \qquad 2TeBr_2 \rightleftharpoons Te_2 + 2Br_2$$

at temperatures near and above the boiling point of $TeCl_2Br_2$ (415 °C) were found to be negligible at the temperature of our gas phase Raman experiment (310 °C). This was confirmed by the non-observation of the extremely intense and depolarized resonance fluorescence spectra of diatomic bromine, diatomic tellurium, and triatomic tellurium dibromide (7, 8) which would be expected to be observed using 4880 Å laser excitation, even for vapor pressures of Br_2, Te_2, or $TeBr_2$ of the order of less than 1 mm of Hg. Our Raman data for $TeCl_2Br_2$ (Tables 1 and 4 and Fig. 1) parallel that for $TeCl_4$ and show that the structure in the solid state differs from that in the vapor phase and in solution in C_6H_6 and MeCN in which a molecular form is probable. Let us consider the Raman data for $TeCl_2Br_2$ in the gaseous

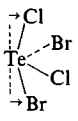
1 (C_{2v}) **2** (C_{2v}) **3** (C_1)

All of the observed Raman lines for $TeCl_2Br_2$ in the gaseous and solution phases were definitely polarized. Also, *four polarized* Raman active *stretching* modes were observed, the frequencies of which correspond very closely with those to be expected for equatorial and axial Te—Cl stretching modes (370 and 285 cm^{-1}), and equatorial and axial Te—Br stretching modes (242 and 198 cm^{-1}), respectively.

In the analysis of the gas phase data one should also consider the possibility that the axial bonds may be somewhat distorted from the 180° configuration as shown below.



4 (C_1)

A distortion of structure **3** of the kind shown in **4**,

which is tending towards a *distorted* square pyramidal configuration about tellurium, would tend to reduce the lone pair-bonding pair interactions (9). Note that a similar distortion of structure **1** and **2** retain the symmetry C_{2v}. To summarize we can say that the Raman data for molecular $TeCl_2Br_2$ is consistent with either of the low symmery (C_1) structures **3** or **4** and not structure **2** which would have been predicted (10).

Penta- and Hexa-Co-ordinate Mixed Halide Ions of Tellurium(IV)

Five co-ordinate anionic species of Se(IV) and Te(IV) are rare and very little definitive structural data are available. X-Ray crystallographic data (11, 12) shows that $KTeF_5$ contains the discrete TeF_5^- anions and βMe_2TeI_2 exists as $[Me_3Te^+][MeTeI_4^-]$ where both anions can be considered to be based on an octahedral stereochemistry with an apical, non-bonding electron pair. The presence of $SeBr_5^-$ together with the $SeBr_6^{2-}$ anion has been inferred from the Raman spectra of SeO_2–HBr solutions (13). Infrared data is available (14) for solid $(Et_4N)TeCl_5$ and ultraviolet (u.v.) spectral data (15) provide evidence for the existence of $TeCl_5^-$ in methyl cyanide solution, in equilibrium with $TeCl_4$ and $TeCl_6^{2-}$. Square pyramidal, penta-co-ordinate Te(IV) has also been postulated (16) for the trimethylamine complex $Me_3N.TeF_4$ which is supposed to exist in the ionized form $(TeF_32NMe_3^+)(TeF_5^-)$.

It is important to note that infrared, Raman, Mossbauer, nuclear quadrupole resonance, and X-ray crystallographic data (17) all support a regular octahedral stereochemistry for TeX_6^{2-} (X = Cl, Br, or I) despite the presence of a 14 electron valency shell for Te(IV) in the complexes. The absence of hexa-co-ordinate fluoride anionic complexes of Te(IV) is also noteworthy.

The purpose of this paper is to (*a*) report a general synthetic route to five and six co-ordinate mixed halide anions of Te(IV) and (*b*) to investigate by means of infrared and Raman spectroscopy the structures of the various species and whether any trends in their stereochemistry and bonding are apparent.

Previous work on mixed halide anionic systems of tellurium(IV) is limited to an early report (18) on an aqueous type preparation of $(pyH)_2TeCl_4Br_2$ and $(pyH)_2TeCl_2Br_2I_2$. Spectral or structural data has not been reported for either of the above species and the synthetic route is itself restricted.

We discovered that two general approaches for the preparations of five and six co-ordinate mixed halide anions of Te(IV) were feasible. The first consisted of mixing (*in vacuo*) benzene – methylene dichloride solutions of Et_4NX (X = halide) with the appropriate tellurium tetrahalide in exact 1:1 and 1:2 molar ratios. The complexes immediately precipitated from solution. In the case of the 1:1 product, it was necessary to shake the mixture for at least 1 h to effect quantitative conversion to the desired 1:1 complex. The second approach consisted of directly triturating the tellurium tetrahalide with Et_4NX or CsX in exact 1:1 or 1:2 molar proportions. The second technique was less satisfactory for the 1:1 complexes from the point of view of successfully effecting a quantitative conversion to the pure 1:1 mixed halide salt. The analyses of the complexes precipitated from solution by the first method and the corresponding infrared and Raman spectra of the solids were satisfactory and characteristic of penta- and hexa-co-ordinate species (Tables 2 and 3).

Let us now formalize the evidence in favor of the formation of penta- and hexa-co-ordinate *mixed* complex anions of Te(IV)

$$[5]\quad TeCl_2Br_2 + Br^- \xrightarrow{C_6H_6/CH_2Cl_2} TeCl_2Br_3^-$$

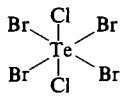
$$[6]\quad TeCl_2Br_2 + 2Br^- \xrightarrow{C_6H_6/CH_2Cl_2} TeCl_2Br_4^{2-}$$

$$[7]\quad TeBr_4 + 2Cl^- \xrightarrow{C_6H_6/CH_2Cl_2} TeCl_2Br_4^{2-}$$

Different infrared and Raman spectra were obtained for the products of reactions 5 (Table 2) and 6 (Table 3) which were both different to the spectra of the starting material $TeCl_2Br_2$ (Table 4). The alternative synthetic route to $TeCl_2Br_4^{2-}$ (reaction 7) yielded a complex with identical spectra to the product of reaction 6. The spectra were not superpositions of the $TeCl_6^{2-}$ and $TeBr_6^{2-}$ species (13, 17). The products of reactions 5, 6, and 7 analyzed satisfactorily for the 1:1 and 1:2 complexes, respectively.

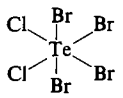
Thus we feel that the evidence is overwhelmingly in favor of the penta- and hexa-co-ordinate mixed halide anions $TeCl_2Br_3^-$ and $TeCl_2Br_4^{2-}$, respectively.

The possible stereochemistries for $TeCl_2Br_4^{2-}$ are shown below together with the respective vibrational representations.



D_{4h}

$\nu_{TeCl}\ a_{1g} + a_{2u}$
$\nu_{TeBr}\ a_{1g} + b_{1g} + e_u$



C_{2v}

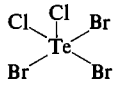
$\nu_{TeCl}\ a_1 + b_2$
$\nu_{TeBr}\ 2a_1 + b_1 + b_2$

$$\Gamma_{vib}^{trans} = 2a_{1g}(R) + b_{1g}(R) + b_{2g}(R) + e_g(R) + 2a_{2u}(i.r.) + b_{2u}(i.r.) + 3e_u(i.r.)$$

$$\Gamma_{vib}^{cis} = 6a_1(i.r./R) + 2a_2(R) + 3b_1(i.r./R) + 4b_2(i.r./R)$$

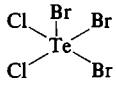
The infrared and Raman spectra for $(Et_4N)_2TeCl_2Br_4$ are extremely informative (Table 3) and show a total of *six* tellurium–halogen stretching modes, all of which are Raman active. This is very strong evidence in favor of a *cis*-octahedral stereochemistry[1] for $TeCl_2Br_4^{2-}$ as the corresponding *trans*-octahedral species should display a total of five tellurium–halogen stretching modes of which only *three* are Raman active.

The vibrational spectrum of the $TeCl_2Br_3^-$ species is clearly not that to be expected for a D_{3h} trigonal bipyramidal species but rather like $TeCl_5^-$ and TeF_5^-, that is, based on a square pyramidal five co-ordinate stereochemistry. For a species $TeCl_2Br_3^{3-}$ with D_{3h} symmetry (*cf.* $CuCl_2Br_3^{3-}$) the metal–halogen stretching modes to be expected are $2a'$ (R) + a_2'' (i.r.) + e' (i.r./R). Consider now the three possible configurations shown below, which are based on a square pyramidal stereochemistry.



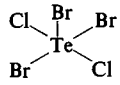
5 (C_s)

$\nu_{TeCl}\ 2a'$
$\nu_{TeBr}\ 2a' + a''$



6 (C_{2v})

$a' + a''$
$2a' + a''$



7 (C_s)

$a_1 + b_1$
$2a_1 + b_2$

Thus on the basis of the metal–halogen stretching modes we can immediately eliminate the D_{3h} structure on the basis of infrared and Raman activities.

For the three configurations **5**, **6**, and **7** all tellurium–halogen stretching modes are infrared and Raman active. Without additional data it is virtually impossible to distinguish these three configurations.

[1] $TiX_4Y_2^{2-}$ and $SnX_4Y_2^{2-}$ (X = Cl, Br, or I; Y = Cl; Br, or I) are reported to be *cis*-octahedral (18).

Experimental

$TeCl_2Br_2$ (m.p. 292 °C) and $TeBr_4$ were prepared by standard techniques (1) and were purified before use by sublimation in vacuo. The tetraethylammonium and cesium halides were dried by heating to 100° under vacuum. All solvents were dried by refluxing with CaH_2 followed by vacuum distillation. Preparations of the 1:1 and 1:2 complexes were carried out in either an all-glass vacuum system or in a glove box.

Analyses

The method employed consisted of the quantitative hydrolysis of the complex in acetic acid (0.1 *N*) or nitric acid. The resulting solutions were titrated potentiometrically against a standard solution of silver nitrate.

Anal. Calcd. for $[Et_4N]TeCl_2Br_3$: Cl, 12.5; Br, 42.2. Found: Cl, 11.2; Br, 40.8.

Anal. Calcd. for $[Et_4N]_2TeCl_2Br_4$: Cl, 9.1; Br, 41.0. Found: Cl, 9.2; Br, 39.5.

Spectra

Infrared spectra were recorded as Nujol mulls using a Beckmann IR-11. Raman spectra of powdered solids were recorded using a Carson argon ion or krypton ion laser coupled to a Spex Raman Spectrometer. Gas phase Raman spectra were recorded for $TeCl_2Br_2$ at 310 °C and a pressure of approximately 1 atm.

We wish to thank Dr. R. J. O'Brien for helpful discussion and the National Research Council of Canada for generous financial support.

Osmotic and Activity Coefficients of Some Simple Borate Solutions at the Freezing Point

R. F. PLATFORD
Canada Center for Inland Waters, Burlington, Ontario
Received September 25, 1970

Activity coefficients for aqueous sodium and potassium tetraborate, sodium metaborate, sodium and potassium fluoroborate, and orthoboric acid were derived from their freezing points. The measurements confirmed in general the behavior of these salts at 25° except that the tetraborates showed different low concentration behavior from that predicted from isopiestic data. Because of this difference, the 25° activity coefficients reported earlier for sodium and potassium tetraborates have been revised. The new values for 0.15 *m* solutions of the tetraborates are 0.345 at 25° and 0.303 at the freezing point.

Canadian Journal of Chemistry, 49, 709 (1971)

Introduction

The osmotic properties of some borates of geochemical interest have been determined at 25° by means of the isopiestic vapor pressure method (1). In order to obtain more detailed information on the low concentration behavior of these borates, a series of freezing point measurements was made for concentrations 0.6 *m* and below. The mineral avogadrite (KBF_4) which was not soluble enough to be studied by the isopiestic method was investigated also.

Experimental

Potassium fluoroborate was precipitated by mixing aqueous sodium fluoroborate and aqueous potassium chloride and was recrystallized three times from water. The other chemicals were those used in the previous study (1). All solutions were made up by weight. It is worth noting the large solubility difference at 25° between KBF_4 (0.03 *m*) and $NaBF_4$ (9.8 *m*) and the solubility difference in the opposite sense between $K_2B_4O_7$ (0.65 *m*) and $Na_2B_4O_7$ (0.16 *m*).

All the freezing points were measured with an Advanced Instruments 3R osmometer. This comparative thermometer is used in the following way. A 2.5 ml sample of solution of known concentration is supercooled by 3° (a preliminary measurement may be needed if the freezing point is not known to better than about 0.02°). The sample is then thermally isolated and a 1-s period of violent stirring causes a small fixed fraction of solvent to be frozen out. This fraction is 3° times the ratio of the heat capacity of the solution to the heat of fusion of ice. The temperature of the solution in equilibrium with the ice is then measured with a thermistor. Good reproducibility depends on freezing out the same fraction of solvent each time (the fraction chosen is not critical as long as it is reproducible from one measurement to the next). Calibration with solutions of known freezing points is essential because the osmometer measures the freezing point of a solution about 4% more concentrated than the starting solution, and calibration very nearly compensates for this error. Compensation would be exact if all the solutions had the same heat capacity.

In this work, the osmometer was calibrated with solutions of both NaCl and KCl using the freezing points of Scatchard and Prentiss (2). The results were consistent with each other and reproducible to within 0.002° times the molality up to 0.6 *m*, the maximum concentration studied, and the calibration did not change over the six month period during which the measurements were made.

Results and Discussion

The results are reported in Table 1 as $1 - \phi$ values at rounded concentrations,[1] where ϕ, the osmotic coefficient at the freezing point ($-\theta$) is given by $(1/\nu m\lambda)(\theta + 4.9 \times 10^{-4}\theta^2)$ using a value for λ of 1.860 (3). At the concentrations referred to here the values of $1 - \phi$ differ by less than 0.001 from the *j* values which are often used in freezing point measurements. The imprecision in ϕ was not greater than 0.001 and the inaccuracy probably was not greater than 0.002. There was no detectable difference in behavior either between sodium and potassium tetraborate (see Fig. 1) or between sodium and potassium fluoroborate in the regions of common solubilities, and for this reason, the results for each pair of salts are combined in Table 1.

The fluoroborates hydrolyzed in solution (4) and the two sets of data in Table 1 refer firstly to solutions less than a few hours old and secondly to solutions which had been stored in polypropylene bottles until the freezing point depressions had reached constant values, thus

*Also applies to KBF_4.

indicating probable equilibrium between the fluoroborates and their hydrolysis products. The times for the initial freezing points to go halfway to their equilibrium values are given in Table 2 as an aid to those who wish to store such solutions.

One obvious way to use the freezing points is to apply them to correct low concentration isopiestic measurements, even though this may require some assumptions to be made regarding temperature coefficients of the osmotic data. The evaluation of activity coefficients from osmotic coefficients is complicated by the evaluation of an integral of the form $n\int(1 - \phi)/\sqrt[n]{m} \cdot d\sqrt[n]{m}$ and this quantity must usually be estimated graphically (3). The limit for $2(1 - \phi)/\sqrt{m}$ at $m = 0$ for 1–1 electrolytes is given by the Debye–Hückel theory (5); it is 0.77 ± 0.01 from 0–25° and this facilitates the extrapolation. The limit for non-electrolytes or mixtures cannot be calculated from theory although it is known to be finite (5) for non-electrolytes.

The tetraborates are equivalent to equimolal mixtures of boric acid and metaborate and their low concentration integral limit is not known. The uncertainty that can arise in evaluating the integral term is illustrated by Fig. 1, which combines 25° isopiestic data (1) with freezing point data. The limit given by the freezing points is near zero, whereas the isopiestic limit is very large. The difference may be due to different behavior at the two temperatures, but it seems unlikely that the limits could be so different. If it is assumed that the osmotic coefficients for concentrations of tetraborates below 0.04 m are more accurately represented by the freezing point data than the extrapolated isopiestic data of ref. 1, the values originally reported will be changed as shown in Table 3. The only osmotic coefficient change is that at 0.01 m which changes from 0.89 to 0.93. At concentrations above 0.04 m there are real differences between the freezing point results and the isopiestic results and these give rise to the results shown in Table 3.

TABLE 4. Mean activity coefficients of borates at the freezing point and at 25°

	0.1 m		0.5 m	
Borate	Freezing point	25°	Freezing point	25°
H_3BO_3	0.99	0.97	0.97	0.94
$NaBO_2$	0.77	0.80	0.55	0.61
$NaBF_4$	0.77	0.82	0.50	0.65

The freezing point data for boric acid indicated a limit for $2(1 - \phi)/\sqrt{m}$ of 0.032 compared with a limit of 0.066 at 25° (1) These gave values for γ at the two temperatures listed in Table 4.

Both the freezing point and the isopiestic measurements led to the same value for the limit for $NaBO_2$ of 0.50 ± 0.05 as opposed to the theoretical value of 0.77. The limit for $NaBF_4$ also was less than expected with a value of about 0.55 for freshly prepared solutions and a negative value for aged solutions. This difference and the difference at high concentrations was consistent with the hydrolysis constant reported (4) which indicates that the BF_4^- ion was hydrolyzed to less than 0.2% at above 1 m, and about 2% at 0.1 m. The activity coefficients calculated using limits of 0.50 for $NaBO_2$ and 0.55 for $NaBF_4$ are shown in Table 4. If the theoretical limits had been used instead, such as would apply for comparisons with e.m.f. measurements, the $\gamma_\pm$ values would have been 0.02–0.03 lower at both 0.1 and 0.5 m. The values for the fluoroborates in Table 4 refer to freshly prepared solutions. It should be realized that the osmotic coefficients reported here are sensitive to the total number of particles in solution including dissociation products, whereas e.m.f. measurements would respond to specific ions and for this reason, the two types of measurements may not be entirely consistent for metaborates and fluoroborates.

Dielectric Relaxation of the Butyl Alcohols in *p*-Xylene Solution

JOHN CROSSLEY
Chemistry Department, Lakehead University, Thunder Bay, Ontario
Received September 24, 1970

Dielectric constants and losses of the four butyl alcohols have been measured at concentrations of 0.02–0.12 mol fraction in *p*-xylene solution over the frequency range 1–35 GHz at 25 °C. The data for the most dilute solutions can be represented by a symmetrical distribution of relaxation times. For the more concentrated solutions the Cole–Cole plots indicate a separation into two absorption regions and the data can be analyzed in terms of two relaxation times both of which lengthen with increased alcohol concentration. The contribution from the long relaxation time and the apparent dipole moment for each butanol, is independent of alcohol concentration and decreases in the order *n*-butanol > iso-butanol > *sec*-butanol > *t*-butanol. The results are discussed in terms of previous dielectric relaxation studies of pure liquid aliphatic alcohols and their solutions in non-polar solvents.

Canadian Journal of Chemistry, 49, 712 (1971)

The dielectric absorption of pure liquid aliphatic alcohols, which has been extensively investigated over a wide range of frequency and temperature (1–4), is characterized by three discrete relaxation processes. A model capable of satisfactorily explaining the experimental results is as yet unavailable and even further experimental data are desirable if one is to be obtained. Dielectric constant and loss measurements of monohydric aliphatic alcohols in non-polar solvents at microwave frequencies offer an excellent means of examining the high frequency relaxation processes (5, 6) which are obscured in the pure liquids by the dominant Debye-like low frequency process whose contribution diminishes on dilution with a non-polar solvent (7). In addition, this type of study provides valuable information on inter- and intramolecular relaxations for simple aliphatic molecules (8, 9) which, if carefully selected, may provide suitable models for the more complex polymer systems.

In dilute benzene and *n*-heptane solutions, the dielectric absorption of primary aliphatic alcohols is characterized by two dielectric relaxation times which have been attributed to —OH group and whole molecule reorientations (5, 6). However, the dielectric absorption of the same alcohols in *p*-dioxane solution shows a symmetrical distribution of relaxation times with a short mean relaxation time (6). In this study *p*-xylene has been used as solvent since it is non-polar and a stronger base than *n*-heptane and benzene but weaker than *p*-dioxane. The four butyl alcohols were selected as solutes because of the variation in the steric environment of the hydroxyl group amongst these molecules, and *n*-butanol had been measured previously in *n*-heptane, benzene, and *p*-dioxane at 25 °C.

Experimental

The apparatus and procedure for determining the dielectric constant and loss at the frequencies employed in this study have been described previously (10, 11).

Materials

The butyl alcohols were all dried over calcium hydride and fractionally distilled using a spinning band column; *p*-xylene was dried over and distilled from sodium.

Experimental Results

Typical Cole–Cole plots obtained for the butyl alcohols in *p*-xylene solution at 25 °C are shown in Fig. 1. For the most dilute solutions it is possible to draw smooth semicircular arcs, with only slightly depressed centers, through the experimental points plotted in the complex plane. For this reason these data were analyzed using a computer programmed to solve the Cole–Cole equations (12) for the most probable or mean relaxation time, τ_0, the Cole–Cole distribution parameter, α, and the high frequency dielectric constant ε_∞. The Cole–Cole plots for the other solutions were either asymmetric or had significant distribution parameters (>0.1) and these data were analyzed, using an IBM 360 computer, for two relaxation times, τ_1 and τ_2, and their relative contributions, C_1 and C_2, using eqs. 1 and 2.

$$[1]\quad \varepsilon' - i\varepsilon'' = \varepsilon_0 + (\varepsilon_0 - \varepsilon_\infty) \times \left[\frac{C_1}{1 + i\omega\tau_1} + \frac{C_2}{1 + i\omega\tau_2}\right]$$

$$[2]\quad C_1 + C_2 = 1$$

The errors involved in the measured ε' and ε'' values and the accuracy of the relaxation data obtained as described here have been assessed previously (13).

Apparent dipole moments, μ, were calculated from eq. 3, in which kT is the thermal energy and

$$[3] \qquad \mu^2 = \frac{9kT}{4\pi N} \cdot \frac{(\varepsilon_0 - \varepsilon_\infty)(2\varepsilon_0 + \varepsilon_\infty)}{\varepsilon_0(\varepsilon_\infty + 2)^2}$$

N is the number of solute molecules per ml of solution.

The experimentally determined dielectric constant and dielectric loss data which have been corrected for the small absorption of *p*-xylene are given in Table 1. The values for τ_0, α, τ_1, τ_2, C_1, and ε_∞ obtained from the analytical procedures outlined above, the static dielectric constants measured at 2 MHz, and the apparent dipole moments calculated using eq. 1 are listed in Table 2.

Discussion

The Cole–Cole plots for all the butanols at 0.02 mol fraction in *p*-xylene solution are symmetrical with small distribution parameters, and their mean relaxation times are very similar. A separation of the data into two dispersion regions becomes increasingly evident with increased alcohol concentration, especially for *n*- and iso-butanol. The analyses, Table 2, indi-

cate that the separations are due more to increased τ_1/τ_2 ratios than increased C_1/C_2 ratios. The most significant difference between the results for the butanols is in the C_1 values which decrease *n*-butanol > iso-butanol > *sec*-butanol > *t*-butanol.

The results for *n*-butanol in *p*-xylene solution, Table 2, may be compared with previous relaxation data for this alcohol (5, 6), at similar concentrations in benzene, *p*-dioxane, and *n*-heptane solution also at 25 °C and as the pure liquid at 20 °C, in Table 3. Methanol and *n*-decanol show similar behavior to *n*-butanol in benzene solution (6); *n*-hexanol, *n*-heptanol, *n*-decanol, and six isomers of octanol show a similar behavior to *n*-butanol in *n*-heptane solution (5) at similar concentrations. The Cole–Cole plots for the benzene and *n*-heptane solutions separate into two dispersion regions; the low frequency process (τ_1) lengthens and the high frequency process (τ_2) remains almost constant with increased molecular size. For methanol, *n*-butanol, and *n*-decanol in *p*-dioxane solution the dielectric constant and loss data may be fitted to symmetrical depressed center Cole–Cole plots with short mean relaxation times which lengthen with increased molecular size (6).

The apparent dipole moment for *n*-butanol shows a significant solvent dependence and increases *n*-heptane < *p*-xylene < benzene < *p*-dioxane. For all the alcohols at concentrations less than 0.12 mol fraction in benzene, *n*-heptane, and *p*-xylene the apparent dipole moments are less than their vapor phase and pure liquid values, ~ 1.7 and ~ 2.8 D respectively, which

*The τ_1 and τ_2 values listed here are the τ_2 and τ_3 values respectively reported by Garg and Smyth (1). Pure liquid alcohols have an additional low frequency relaxation process (for *n*-butanol $\tau \sim 670 \times 10^{-12}$s at 25 °C) which dominates the absorption.

suggests the presence of weakly polar multimers in these solutions. In the pure liquid state at low temperatures several isomers of octanol have dipole moments very close to zero and association into non-polar closed dimers has been suggested as a reasonable explanation (14). The large dipole moments for pure liquid straight chain alcohols probably result from association into larger multimers, either linear chains (14) or cyclic tetramers (15) and pentamers (16).

The short relaxation time τ_2 for alcohols in benzene (6) has been interpreted in terms of —OH group rotation since it shows only a small increase with increased molecular size and is of a similar magnitude to the —OH group relaxation times found for phenols (17, 18). The τ_2 values for the butanols in *p*-xylene solution given in Table 2 are all longer than those for *n*-butanol in benzene and *n*-heptane solution at similar concentrations, Table 3. Magee

and Walker (19) observed that the —OH group relaxation time in cholesterol lengthened considerably with increased solvent basicity. Thus the fact that the τ_2 values in Table 2 are longer than obtained previously may be partially explained by increased solute–solvent interactions since *p*-xylene is a stronger electron donor than benzene and *n*-heptane (the even stronger electron donor solvent *p*-dioxane leads to a symmetrical arc plot with a short mean relaxation time). By analogy the considerable concentration dependence shown by τ_2 in *p*-xylene solution could be reasonably explained by solute–solute interactions. However, τ_2 is seemingly independent of concentration in *n*-heptane and benzene solution where solute–solute interactions should be stronger.

Electric polarization measurements over a wide range of temperatures (20) indicate that the degree of association amongst the butanols decreases *n*-butanol $\simeq$ iso-butanol > *sec*-butanol > *t*-butanol. The C_1 values for these alcohols in *p*-xylene solution also decrease in this order. In addition the C_2 values for both straight and branched chain alcohols appear to decrease with increased alcohol concentration in *n*-heptane solution. It would seem then that increased solute–solute interactions lead to a decrease in the contribution to the total absorption from —OH group rotation because of a decrease in the number of relaxing hydroxyl groups due to association. This effect is probably partly responsible for the corresponding decreases shown by the apparent dipole moments. However, the C_2 values for each butanol in *p*-xylene solution and for methanol, *n*-butanol, and *n*-decanol in benzene solution are, within the limit of error, almost independent of concentration and in *p*-xylene solution both τ_1 and τ_2 lengthen indicating increased association. In analyzing dielectric data by computer methods based on the Budó equations (13) a bias towards a fixed C_2 could possibly result in a varying τ_2 and vice versa. The experimental results for the alcohols in benzene and *n*-heptane solutions obtained by the Princeton workers (5, 6) were re-analyzed with the program used in this study to analyze the *p*-xylene solution data, and very probably quite different initial estimates of τ_1, τ_2, and C_2. The analyses were almost identical with those reported by the Princeton workers.

The τ_1 values for *n*-butanol, Table 2, compare well with those obtained in *n*-heptane and benzene solution, Table 3, and like τ_2, lengthen with increased alcohol concentration. The values for all the butanols in *p*-xylene solution are significantly longer than the molecular relaxation times for chloroethanes, which are of a similar size as the butanols, also in *p*-xylene solution (21). However, the alcohols are much stronger electron acceptors and τ_1, which increases with increased molecular size (5, 6), is probably due to a molecular rotation mechanism. The lengthening of τ_1 with increased alcohol concentration in *n*-heptane and *p*-xylene solution is probably due to increased solute–solute interactions. Although the experimental data for the *p*-xylene solutions reveal no evidence of the third lowest frequency process which is evident at slightly higher concentrations (5) and dominate the absorption of the pure liquids (1), the onset of highly polar multimer formation cannot be discounted and may be partially responsible for the lengthening of τ_1.

In benzene solution increased alcohol concentration, over a limited range, has virtually no effect on the relaxation data; increasing alcohol concentration in *n*-heptane solution has almost no effect on the τ_2 values but τ_1 lengthens and C_1 increases; increasing alcohol concentration in *p*-xylene solution gives rise to constant C_1 values and lengthening τ_1 and τ_2 values. These results, especially the solvent effect on τ_2 and C_1, are not readily explained and further work is in progress on a number of alcohols in a variety of non-polar solvents.

Synthesis and Properties of 5-Hydroxymethyl-2′-deoxyuridine and its α-Anomer[1]

V. S. GUPTA[2] AND G. L. BUBBAR

Department of Physiology, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan

Received September 4, 1970

The synthesis and properties of 5-hydroxymethyldeoxyuridine (**6**) and its α-anomer **7** are described. Treatment of 5-hydroxymethyluracil (**2**) with trimethylchlorosilane in the presence of triethylamine gave 2,4,5-tris(trimethylsilyl)-5-oxymethyluracil (**3**) in excellent yield (92%) which, upon condensation with 3,5-di-(*O*-*p*-toluoyl)-2-deoxy-D-ribofuranosyl chloride in acetonitrile at room temperature, furnished an anomeric mixture of substituted nucleosides β-anomer (**4**) and α-anomer (**5**) in high yield 90% (by a fusion method (12) yield of blocked nucleosides was 70%). Compound **4** was the major product formed by both methods and was recovered as a crystalline solid in high yield. However, condensation of **3** with chlorosugar in benezene with mercuric chloride as a catalyst at room temperature gave a mixture of protected nucleosides; the amount of **5** formed was appreciably higher (34%) and was isolated as a microcrystalline solid from mother liquors in low yield (without the catalyst nucleosides were formed in low yield 30%). Removal of the blocking groups by alcoholysis gave **6** and **7** in high yields. The structure was confirmed by n.m.r. studies, u.v. and i.r. absorption spectra, elemental analysis, and by conversion of **4** to β-thymidine (**8**).

5-Hydroxymethyl-2′-deoxyuridylate replaces thymidylate of the DNA of a virulent group of *Bacillus subtilis* bacteriophages (1–4). Its biosynthesis from deoxyuridylate and 5,10-methylene tetrahydrofolate is catalyzed by the enzyme, hydroxymethylase (5, 6), which is analogous to the hydroxymethylation of deoxycytidylate of *Escherichia coli* T-even bacteriophages (7). The enzymic transformation of thymidine to 5-hydroxymethyldeoxyuridine (**6**), has been demonstrated in *Neurospora*, and 5-substituted pyrimidines may be intermediates in the transformation of thymine to RNA pyrimidines (8).

The synthesis of **6** from deoxyuridine under acidic conditions[3] was reported by Cline *et al.* (9), and the base-catalyzed hydroxymethylation[4] of deoxyuridine has been described by Baker *et al.* (10). Recently the chemical synthesis of **6** using a mercury procedure[5] has been reported (11); in this method the removal of the benzyl group by catalytic hydrogenation is a critical step for the synthesis of **6**. Although a quantitative yield of **4** from **9** has been reported (11), we were able to recover **4** in a yield of only 45–55% even after repeated experiments under similar conditions. Since none of these methods (9–11) was particularly suitable for the synthesis of **6** on a preparative scale (see also footnotes (3–5), we have therefore devised its synthesis by the following methods: (*a*) a fusion method developed by Nishimura and Schimizu (12); (*b*) a modified condensation method using mercuric chloride – benzene (13); and (*c*) by the interaction of silyl–pyrimidine with halogenose in organic solvents at room temperature,[6] all of which have several distinct advantages over the mercury procedure (11). They obviate the need for the synthesis of 5-benzyloxymethyluracil and debenzylation by catalytic hydrogenation. The desired natural β-anomer predominated in the reaction mixture in methods *a* and *c*.

5-Hydroxymethyluracil (**2**) on treatment with trimethylchlorosilane in the presence of triethylamine furnished tris(trimethylsilyl)-5-methoxyuracil (**3**) as an oil (92%). Condensation of **3** with 3,5-di-(*O*-*p*-toluoyl)-2-deoxy-D-ribofuranosyl chloride at 185–195° under anaerobic conditions (12) gave an anomeric mixture[7] of the

[1]This work was supported by the Medical Research Council of Canada (Grant MA-3136).

[2]To whom correspondence should be sent.

[3]From a mixture of products, **6** was isolated by ion exchange chromatography in poor yield (19%). Using the described conditions, Baker *et al.* (10) reported an even lower yield (< 10%).

[4]Although **6** was the main product under basic conditions, it could not be induced to crystallize and was difficult to isolate in the pure state.

[5]Mercury salt of 5-benzyloxymethyluracil was coupled with 3,5-di-(*O*-*p*-toluoyl)-D-ribofuranosylchloride, and from the reaction mixture, the blocked nucleoside 1-(2-deoxy-3,5-di-(*O*-*p*-toluoyl)-β-D-ribofuranosyl-5-benzyloxymethyluracil (**9**) was isolated in a yield of 57%. The removal of the benzyl group by catalytic hydrogenation yielded **4** which, upon deacylation gave **6**.

[6]Using this method we have also prepared 5-fluorodeoxyuridine, 5-iododeoxyuridine, and several other pyrimidine deoxyribonucleosides in excellent yields (14).

[7]Since the *trans* rule (15) is not obeyed during synthesis of the deoxyribonucleosides, both anomers are formed during the condensation reaction.

substituted nucleoside **4** and its corresponding α-anomer, **5**, in a ratio of *ca.* 8.5:1.5. After removal of the silyl groups by refluxing in aqueous acetone (60%), compound **4** was isolated from the reaction mixture as a crystalline solid in 44% yield. Chromatography of the filtrate on a silica gel column gave an additional 14% yield of **4**.

The β-configuration was assigned to **4** on the basis of a triplet for the anomeric proton at δ 6.33 with a coupling constant ($J_{1',2'} = J_{1',2''} = 6.95$ Hz). Catalytic hydrogenation of **4** with palladium oxide followed by alcoholysis resulted in almost complete conversion to β-thymidine (**8**) (16). This established the site of attachment of the deoxyribose and also its configuration. After deblocking with hot sodium methoxide in methanol, **6** was recovered as a microcrystalline solid in 80% yield. The structure and configuration of compound **6** and its corresponding α-anomer **7** was unequivocally established from the n.m.r. spectrum. In compound **6** the signal of the anomeric hydrogen (H-1′) appeared as a triplet at δ 6.18 and exhibited a coupling constant ($J_{1',2'} = J_{1',2''} = 7.0$ Hz). From mother liquors, 1-(2-deoxy-3,5-di-(*O*-*p*-toluoyl)-α-D-ribofuranosyl)-5-hydroxymethyluracil (**5**), was recovered in small yield (10%).[8] In compound **5**, the signal of the anomeric proton (H-1′) appeared as a quartet at δ 6.28. Deblocking by alcoholysis gave 1-(2-deoxy-α-D-ribofuranosyl)-5-hydroxymethyluracil (**7**) as a micro-crystalline solid in 62% yield. The α-configuration was assigned to **7** on the basis of a quartet at δ 6.12 for the anomeric proton and a coupling constant ($J_{1\ 2''} = 3.2$ and $J_{1',2'} = 7.8$ Hz). The signals of all other protons in compounds **6** and **7** appeared at the expected positions and the observed integration ratios were equal to the calculated values. The reactions are summarized in Scheme 1.

With the hope of improving further the yield of the deoxyribonucleosides and avoiding the formation of α-anomers, the synthesis of **6** was attempted under mild experimental conditions. Initially, the reactions were carried out using a recently published procedure (13).[9] The reaction mixture, consisting of **3**, halogenose, and the Lewis acid ($HgCl_2$) in benzene, was stirred at room temperature for 30 h. The total yield of the blocked nucleosides, **4** and **5**, as indicated by chromatography (t.l.c.) was higher (85–90%), but contrary to our expectations the amount of α-anomer formed was also appreciably increased (34%).

In order to obviate the formation of α-anomer, the synthesis of **6** in solvents (without catalyst) was studied. The reactions were carried out in benzene (nonpolar); and two polar solvents, dioxane and acetonitrile. The chlorosugar was allowed to react with **3** in the appropriate solvent for 30 h at room temperature. In benzene and dioxane, only relatively small amounts of the nucleosides were formed (yields 28 and 62% respectively) but in acetonitrile the blocked nucleosides were formed in excellent yields (90–95%). The yield of the β-anomer under these conditions was 80–85%. These results suggest that acetonitrile has a catalytic effect in the condensation reaction and its use provides a simple alternative procedure for the synthesis of **6** and other pyrimidine deoxyribonucleosides in high yields.

Experimental

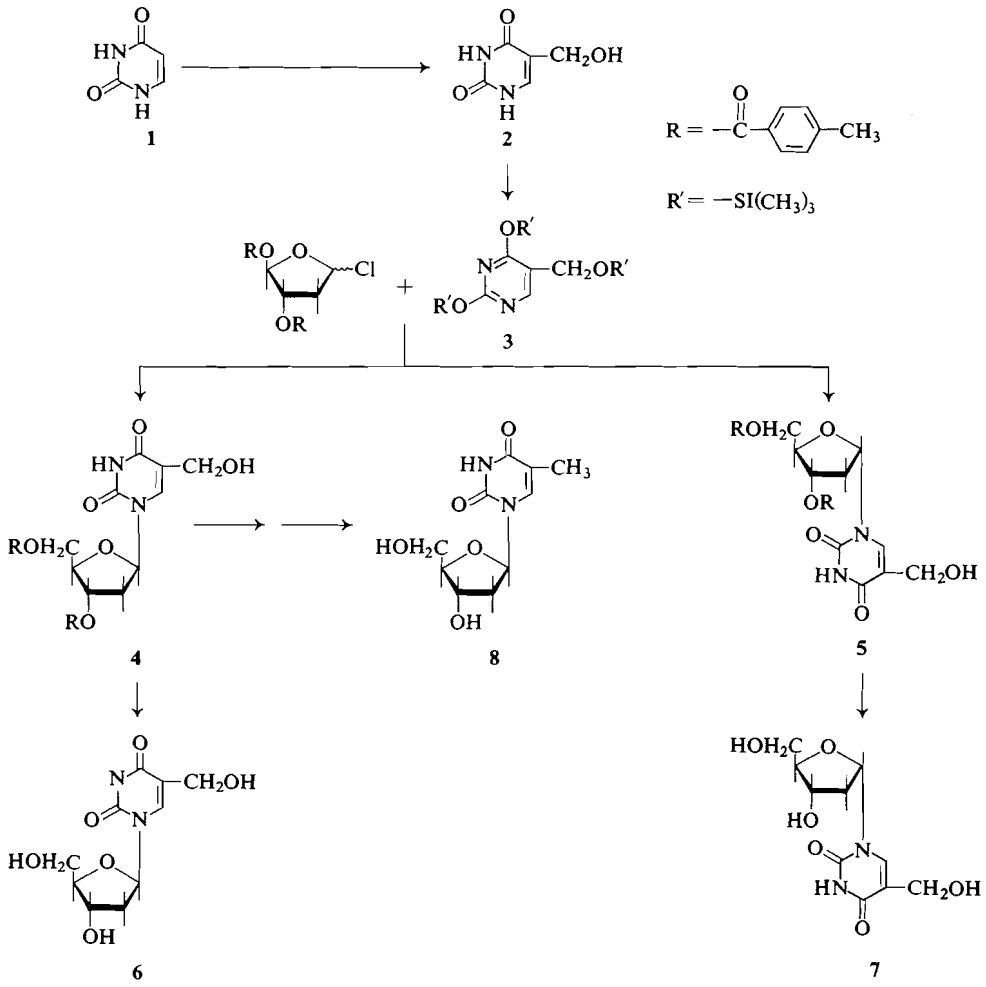
Melting points were observed with a Gallenkamp apparatus and are uncorrected. Specific rotations were measured (1 dm tube) with a Perkin–Elmer model 141 automatic digital read out polarimeter. The n.m.r. spectra were recorded on a Varian Associate A-100 spectrometer using tetramethylsilane (TMS) as a standard (unless otherwise indicated). All compounds were dissolved in dimethylsulfoxide (DMSO-d_6). The i.r. spectra were recorded with a Perkin–Elmer Model 421 spectrophotometer. The Unicam spectrophotometer, Model SP800 was used to measure the complete u.v. absorption spectra. Microanalyses were performed by the microanalytical laboratories of the Prairie Regional Research Laboratory, Saskatoon, Saskatchewan. The t.l.c. was carried out on silica gel (HF_{254}) at room temperature. Ascending paper chromatography was carried out on Whatman No. 1 paper at room temperature using the following solvents (by volume): (*A*) *n*-butanol – glacial acetic acid – water (4:1:5), upper phase and (*B*) *i*-propanol–NH_4OH–water (7:1:2). The spots were detected by visual examination under u.v. illumination. The R_f values are ±0.05. Evaporations under diminished pressure were performed on rotary evaporators at 35°.

5-Hydroxymethyluracil (2)

The base-catalyzed hydroxymethylation of uracil was carried out by the method of Cline *et al.* (9) and the product was twice crystallized from aqueous ethanol to give **2** as a microcrystalline powder; n.m.r. spectrum was at δ 11.02 (1H,s,3-NH), 10.67 (1H,s,1-NH), 7.23 (1H,s, H-6), 4.81 (1H,t,J = 6.0 Hz, proton of the hydroxyl group 5-CH_2OH), 4.12 (2H,d,5-CH_2—) p.p.m. The

[8]The high specificity for β-configuration of the silyl condensation method has been observed previously (17 18).

[9]Besides mercury halides (see also 19–21), the use of several other catalysts in the synthesis of pyrimidine nucleosides has been discussed (20, 22–25).



SCHEME 1

product showed a homogenous spot by t.l.c. on silica gel (R_f 0.53) using $CHCl_3$–MeOH (8:2) as the developer. The u.v. absorption spectrum and m.p. were the same as reported (9).

2,4,5-Tris(trimethylsilyl)-5-oxymethyluracil (3)

Trimethylchlorosilane (17.36 g, 160 mmol) was added to a stirring suspension of **2** (5.62 g, 40 mmol) in 100 ml of anhydrous benzene. After 5 min triethylamine (16.16 g, 160 mmol) was added dropwise over a period of 30 min, and the reaction mixture was stirred at room temperature for 20 h. Precipitated triethylamine hydrochloride was filtered and the residue was washed with benzene (3 × 20 ml). The filtrate and washings were combined and the solvent was removed *in vacuo* at 30° to yield a viscous, oily liquid of crude product. The oil was distilled at 124°/0.1 mm to yield **3** (13.20 g 92%); i.r. (26) ν_{max} (liquid film) cm^{-1} 1030 (Si—O—C), 830 and 1246 Si-$(CH_3)_3$, no absorption at 3500 (free OH).

The n.m.r. (solvent CCl_4; formic acid external to locate trimethylsilyl groups) at δ 2.59 (9H,s,2 or 4-Si$(CH_3)_3$), 2.55 (9H,s,2 or 4-Si$(CH_3)_3$), 2.34 (9H,s,5-*O*-Si$(CH_3)_3$), 6.69 (2H,s,5-CH_2—) p.p.m. to locate the 6 position proton of the pyrimidine ring (TMS lock) at δ 7.97 (1H,s,6-H) and 4.34 (2H,s,5-CH_2—) p.p.m. integration ratio 1:2:27.

1-[2-Deoxy-3,5-di-(O-p-toluoyl)-β-D-ribofuranosyl]-5-hydroxymethyluracil (4)

(a) Fusion Method (12)

A mixture of **3** (5.37 g, 15 mmol) and 3,5-di-(*O*-*p*-toluoyl)-2-deoxy-D-ribofuranosyl chloride (27) 5.83 g, 15 mmol) was placed in a preheated (to 170°) oil bath under anhydrous conditions. As soon as the halogenose melted, the mixture was flushed with nitrogen, the temperature of the bath was raised to 185–195°, and the reaction mixture was kept at this temperature for an additional 30 min under a continuous stream of nitrogen. The gummy residue was triturated with 75 ml of aqueous acetone (60%), and the resulting mixture was refluxed for 30 min and filtered hot through a bed of celite–charcoal under reduced pressure. The celite–charcoal mixture was washed with hot EtOH (3 × 25 ml) and examined by chromatography (t.l.c. $CHCl_3$–MeOH, 95:5). In addition to the blocked nucleosides (R_f 0.55) there were two

For personal use only.

additional quenching spots (R_f 0.05, minor unreacted **2** and R_f 0.98, sugar by-products). The solvent was evaporated to dryness and the residue was shaken with chloroform (2 × 15 ml). The insoluble material was collected by filtration, the solvent was removed *in vacuo*, the residue was dissolved in hot EtOH (30 ml) and after standing overnight at room temperature, the crystals (2.83 g) were filtered. Recrystallization from MeOH gave white glistening needles of the β-anomer (1.87 g m.p. 167–168°). The combined mother liquors were concentrated to dryness and the residue (3.25 g) was dissolved in benzene (15 ml) and applied to a column (2 × 25 cm) of silica gel packed in benzene. Elution was begun with benzene (2 l) and followed with benzene containing increasing amounts of ether (10, 20, 30, and 40%, 200 ml of each). Fractions (25 ml) were collected and monitored by t.l.c. using $CHCl_3$–MeOH (9:1) as the developer. Only sugar by-products and other contaminants were eluted until fractions 27 and 28, in which a small amount of nucleosides (< 5%) along with sugar components appeared (as shown by t.l.c.). All these fractions were discarded. The mixture of nucleosides was finally desorbed from the column with ether (1200 ml) and the solvent was evaporated to dryness. The residue (2.135 g) containing both anomers of blocked nucleoside was dissolved in hot MeOH and on standing at room temperature gave an additional 0.53 g of **4**. The total yield of **4** was 2.403 g, 57.6%.

(b) Benzene – Mercuric Chloride (13)

The mixture of **3** (716 mg, 2 mmol), halogenose (855.1 mg, 2.1 mmol), and $HgCl_2$ (108.6 mg, 0.4 mmol) in anhydrous benzene (10 ml) was stirred at room temperature for 30 h. Two ml of water was added and after stirring for 30 min at room temperature the solvent was removed under reduced pressure. The gummy residue was taken up in $CHCl_3$ (15 ml) and the resulting mixture was refluxed for 30 min. The aqueous layer was separated and extracted with $CHCl_3$ (2 × 10 ml). The combined organic extract was washed with NaI (10 ml of 10% aqueous solution), water (3 × 20 ml), dried, and evaporated to yield an anomeric mixture of nucleosides as a white fluffy powder (975 mg). Crystallization from MeOH followed in EtOH gave **4** as a crystalline solid (410 mg, 41.5%). Mother liquors on standing gave an additional quantity (112 mg, 11.33%). Total yield of **4** was 52.83%.

(c) Using Acetonitrile

To a stirred suspension of chlorosugar (4.274 g, 11 mmol) in anhydrous acetonitrile (15 ml) was added **3** (3.58 g, 10 mmol). The reaction mixture was slightly warmed and then stored at room temperature for 30 h. Water (5 ml) was added, stirred for 30 min, solvent was removed, and the residue was extracted with $CHCl_3$ (3 × 20 ml). The chloroform layer was washed with water, dried, the solvent was removed *in vacuo*; the residue was dissolved in hot MeOH (30 ml) and after keeping overnight at room temperature the crystals (3.80 g, 67.9%) were collected by filtration; m.p. 167–168° (lit. (11), 167–169°); $[\alpha]_D^{25}$ −60.5° (*c*, 0.08 in $CHCl_3$); u.v. (EtOH 95%) λ_{max} 242.0 (ε 36.6 × 10^3 M^{-1} cm^{-1}) and broad sh. at 265–270 mμ; n.m.r. at δ 11.45 (1H,s,3-NH), 7.62 (1H,s,H-6), 4.93 (1H,t,J = 5.5 Hz, proton of the hydroxyl group of 5-CH_2OH), 4.12 (2H, d, 5-CH_2— with ring), 6.33 (1H,t,$J_{1',2'} = J_{1',2''}$ = 6.95 Hz H-1′ (lit. (11), 6.34, t, J = 6.7 Hz), 5.59 (1H,m,H-3′, 4.57 (2H,s,5′-CH_2—) 4.49–4.52 (1H,m,H-4′ overlapped by the hydroxy group of 5′-CH_2OH), 2.46–2.68 (2H,m, solvent and H-2′, -2′′), 7.87 and 7.95 (4H, d, 2 sets, two phenyl rings H-3 and -5), 7.29 and 7.37 (4H, d, 2 sets, two phenyl rings H-2 and -6), 2.40 p.p.m. (6H,s,two *p*-methyl groups of benzene rings).

Anal. calcd. for $C_{26}H_{26}N_2O_8$ (mol. wt. 494.5): C, 63.15; H, 5.30; N, 5.66. Found: C, 62.95; H, 5.35; N, 5.62.

From mother liquors an additional quantity (0.39 g, 7.89%) of **4** was recovered as a crystalline solid. Examination of the mother liquor by t.l.c. showed that it contained mostly α-anomer **5** along with a small amount of **4** (*ca.* 5%). This compound was homogeneous by t.l.c. on silica gel (R_f 0.56) using $CHCl_3$–MeOH (95:5) as the developer.

1-[2-Deoxy-3,5-di-(O-p-toluoyl)-α-D-ribofuranosyl]-5-hydroxymethyluracil (5)

(a) Fusion Method (12)

Mother liquors left after the removal of the β-anomer (**4**) were combined, concentrated (*ca.* 15 ml), and on standing at 4° after several days slowly gave a microcrystalline solid (555 mg, m.p. 148–151°). On recrystallization from MeOH–ether **5** was obtained as fine needles (255 mg). Examination of the mother liquors by t.l.c. showed a single spot corresponding to the nucleosides; but additional quantity of either nucleoside anomer was not obtained by crystallization. After deblocking, the corresponding free anomers **6** and **7** could be separated by preparative t.l.c. (*vide infra*).

(b) Benzene – Mercuric Chloride (13)

The solvent was evaporated from the mother liquors and the residue (480 mg) was dissolved in boiling ether (20 ml). On cooling the crystals (320 mg) separated and were collected by filtration. Crystallization from MeOH gave **5** as fine needles (187 mg, 18.92%). Mother liquors on keeping at room temperature gave an additional amount (34 mg) of the material. Total yield of **5** (221 mg, 22.36%); m.p. 154–155° (lit. (11), 151–152°); $[\alpha]_D^{25}$ −13.9° (*c*, 1.0 in $CHCl_3$); u.v. (EtOH 95%) λ_{max} 241.5 (ε 34.4 × 10^3 M^{-1} cm^{-1}) and broad sh. 265–270 mμ; n.m.r. at δ 11.38 (1H,s,3-NH), 7.76 (1H,s, H-6), 5.04 (1H,s,proton of the hydroxyl group of 5-CH_2OH overlapped with H-4′), 4.17 (2H,d,5-CH_2— with ring) 6.28 (1H, q, $J_{1'} = J_{2'} = 6.0$ Hz, $= J_{1'} = J_{2''} = 1.7$ Hz, H-1′), 4.93 (1H,t, H-4′ overlapped with the hydroxy group of 5-CH_2OH), 4.46 (2H,d,5′-CH_2—), 2.82–3.14 p.p.m. (2H,m, solvent and H-2′ and -2′′ and all other bands for protons given under **4**).

Anal. Calcd. for $C_{26}H_{26}N_2O_8$ (mol. wt. 494.5): C, 63.15; H, 5.30; N, 5.66. Found: C, 63.20; H 5.25; N, 5.57.

The compound showed a single quenching spot by t.l.c. on silica gel (R_f 0.56, $CHCl_3$–MeOH, 95:5).

1-(2-Deoxy-β-D-ribofuranosyl)-5-hydroxymethyluracil (6)

Compound **4** (300 mg) was dissolved in 4.0 ml of NaOH (2 *N*) containing EtOH (8.0 ml) and the solution was left overnight at room temperature or, alternatively, refluxed with MeONa (150 mg) in absolute MeOH (5 ml) for 30 min. Dowex 50 (H^+; X_8; 200–400 mesh) was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the solution (p*H* 4–5) was stirred for 30 min. The resin was removed by filtration and was repeatedly washed with water (2 × 4 ml). The acidic filtrate and washings were combined, the solvent was evaporated, and the syrup was triturated with water (30 ml). Precipitated toluic acid was filtered and the mother liquors were freed of residual toluic acid by extraction with ether (2 × 30 ml). The aqueous phase was concentrated and finally co-evaporated with absolute ethanol to remove the last traces of water. The residue was crystallized from absolute EtOH–EtOAc (95 mg, 61%); m.p. 182° (lit. (9) 176–179°, and (11) 180–182°); $[\alpha]_D^{25}$ +19.5° (*c*, 1.25 in water); u.v. at p*H* 1 λ_{max} 264 (ε 10.55 × 10^3 M^{-1} cm^{-1}), 208 mμ (ε 11.15 × 10^3 M^{-1} cm^{-1}) and λ_{min} 232 mμ (ε 2.73 × 10^3 M^{-1} cm^{-1}); n.m.r. at δ 11.29 (1H,s,3-NH), 7.73 (1H,s, H-6), 4.85 (1H,t, proton of the hydroxyl group of 5-CH_2OH overlapped with the proton of the hydroxyl group of 5′-CH_2OH), 4.12 (2H,d,5-CH_2 with ring), 6.18 [1H,t,$J_{1',2'} = J_{1',2''}$ = 7 Hz, H-1′, lit. (11) 6.20 (1H,t,$J_{1',2'} = J_{1',2''}$ = 6.6 Hz), 4.24 (1H,t, H-3′), 5.23 (1H,d,proton of the hydroxyl group of 3′-CHOH), 3.80 (1H,q, H-4′), 3.55 (2H,t,5′-CH_2—), 4.92 (1H,t,proton of the hydroxyl group of 5′-CH_2OH overlapped with the proton of the hydroxyl group of 5-CH_2OH), 2.10 p.p.m. (2H,q,*J* = 6 Hz, H-2′ and -2″).

Anal. Calcd. for $C_{10}H_{14}N_2O_6$ (mol. wt. 258.2): C, 46.50; H, 5.46; N, 10.85. Found: C, 46.24; H, 5.26; N, 10.55.

The compound moved as a homogeneous spot on paper (R_f 0.34, 0.48) in solvents *A* and *B* and on silica gel (R_f 0.28, $CHCl_3$–MeOH 8:2). Mother liquors gave an additional (30 mg) of product with a slightly lower m.p. (176–178°) but it was chromatographically homogeneous (R_f 0.31).

1-(2-Deoxy-α-D-ribofuranosyl)5-hydroxymethyluracil (7)

(a) Hydrolysis of 5

Compound **5** (300 mg) was added to 5 ml of absolute MeOH containing MeONa (150 mg), and refluxed for 30 min, deionized, and worked-up as described for **6** (above). The residue was twice crystallized from EtOAc–cyclohexane and **7** (85 mg) was recovered as a microcrystalline solid.

(b) By Preparative Thin-layer Chromatography of Mother Liquors (Fusion Method)

After removal of **4** and **5**, the mother liquors were combined, the solvent was removed *in vacuo*, and the residue (0.95 g) was hydrolyzed by refluxing with sodium methoxide (500 mg in 15 ml of anhydrous MeOH) and treated as above for **6**. The concentrated solution (*ca.* 6 ml) was spread on silica gel plates (8, 20 × 20 cm, 0.65 mm) and developed with $CHCl_3$–MeOH (80:20). The respective zones were marked under u.v. and nucleoside bands were separately extracted with hot MeOH. The solvent was removed and the residue (395 mg) was crystallized from ethylacetate–cyclohexane to yield **7** as a microcrystalline solid (137 mg, 62%); m.p. 171° (lit. (11) 169–170°; $[\alpha]_D^{25}$ + 5.8° (*c*, 1.35 in water); u.v. at p*H* 1, λ_{max} 264.5 (ε 10.4 × 10^3 M^{-1} cm^{-1}), 207 mμ (ε 11.05 × 10^3 M^{-1} cm^{-1}) and λ_{min} 231 mμ (ε 2.68 × 10^3 M^{-1} cm^{-1}); n.m.r. at δ 7.90 (1H,s, H-6), 6.12 (1H,q,$J_{1',2''}$ = 3 Hz, and $J_{1',2'}$ = 7.5 Hz H-1′), 2.44–2.78 (1H,m, partially buried under the solvent, H-2′), 1.82 and 1.96 (1H, two triplets, H-2″), 4.17–4.26 (2H,m, H-3′ and H-4′) p.p.m. and all other proton peaks as given under **6**.

Anal. calcd. for $C_{10}H_{14}N_2O_6$ (mol. wt. 258.2): C, 46.50; H, 5.46; N, 10.85. Found: C, 46.75; H, 5.46; N, 10.45.

The product was homogeneous on paper (R_f 0.51, 0.75 in solvents *A* and *B*) and t.l.c. (R_f 0.44, $CHCl_3$–MeOH, 8:2). Mother liquors showed a single quenching spot (R_f 0.5) but the nucleoside did not crystallize.

1-(2-Deoxy-β-D-ribofuranosyl)5-methyluracil (β-Thymidine) (8)

Compound **4** (200 mg) was added to glacial acetic acid (15 ml) containing palladium oxide (300 mg) and hydrogenated for 4 h at 2 lb pressure in Parr's apparatus. The catalyst was filtered, solvent removed *in vacuo*, and the residue was crystallized from EtOH to yield 1-[2-deoxy-3,5-di-(*O*-*p*-toluoyl)-β-D-ribofuranosyl]5-methyluracil, (130 mg, m.p. 198–199°, R_f 0.85, $CHCl_3$–MeOH, 95:5). Toluoyl groups were removed using sodium methoxide, and β-thymidine (7) was isolated from the reaction mixture in quantitative yield. Specific rotation, u.v. absorption and n.m.r. spectra were identical with the authentic sample.

The authors wish to thank Drs. J. C. MacDonald (P.R.L., Saskatoon) for allowing use of the polarimeter, and F. M. Loew (Veterinary College) for helpful suggestions in the preparation of this manuscript; Mr. T. Mazurek for measuring the n.m.r. spectra and Mr. B. Haid for recording the i.r. spectra and microanalyses.

γ-Radiolysis of Cysteine-Cysteamine Disulfide in Aqueous Solution[1]

J. W. PURDIE[2]
Division of Biology, National Research Council of Canada, Ottawa, Canada

Received September 21, 1970

γ-Radiolysis of a mixed disulfide, cysteine-cysteamine disulfide, in unbuffered aqueous solution (0.3 m*M*) was investigated in the presence and absence of oxygen. The principal products were the thiols (cysteine and cysteamine), the corresponding sulfinic and sulfonic acids, the symmetrical disulfides (cystine and cystamine) and ammonia. Cystine and cystamine were formed in very high yields in deaerated solution; (G(CySSCy) ~ 15) but addition of oxygen reduced the yield sharply and it was inversely proportional to the oxygen concentration except at very low oxygen levels. In aerated solution G(CySSCy) = 0.8. These observations were attributed to a chain reaction which was suppressed by oxygen:

$$RS\cdot + R'SSR \rightleftarrows RSSR + R'S\cdot$$

$$RS\cdot + O_2 \rightarrow RSOO\cdot$$

In the case of proteins, it was concluded that although chain reactions between RS· radicals and protein disulfide bonds were possible, they should be inhibited by oxygen.

On a exposé un disulfide asymétrique, cysteine-cysteamine disulfide, dans une solution aqueuse (0.3 m*M*), aux rayonnements gamma avec et sans la présence de l'oxygène. Les produits principaux étaient les thiols (cysteine et cysteamine), les acides sulfiniques et sulfoniques, les disulfides symétriques (cystine et cystamine) et l'ammoniaque. Les rendements de cystine étaient grands dans les solutions déaérées (G(CySSCy) ~ 15) mais ils ont diminué rapidement lorsqu'on a ajouté de l'oxygène et ils étaient en proportion inverse de la concentration de l'oxygène. Dans les solutions aérées G(CySSCy) = 0.8. Pour expliquer ces résultats on propose une réaction chaîneuse qui est supprimée par l'oxygène:

$$RS\cdot + R'SSR \rightleftarrows RSSR + R'S\cdot$$

$$RS\cdot + O_2 \rightarrow RSOO\cdot$$

Tant qu'aux protéines, on a conclu que des réactions entre les radicaux RS· et les disulfides du protéine sont possible mais ils doivent être inhibités par l'oxygène.

Canadian Journal of Chemistry, 49, 725 (1971)

In previous communications (1–3) we have reported results from the γ-radiolysis of cystine, penicillamine disulfide, and cysteine-penicillamine mixed disulfide. The study has now been extended to cysteine-cysteamine disulfide. This series of disulfides provides a direct comparison of cysteine in combination with a protective thiol (cysteamine) and a non-protective thiol (penicillamine). The radiation chemistry of these compounds is important to studies of the mechanism of radiation protection and the effects of ionizing radiation on protein disulfide bonds. Recent work in this field has been concentrated mainly on the radiation chemistry of cysteine and related thiols; Armstrong and co-workers (4), Packer and Winchester (5), Adams *et al.* (6), and Henglein and co-workers (7).

The abbreviation CySSCya is used to represent *L*-cysteine-cysteamine disulfide hydrochloride which was used in this study, *i.e.* (1,6-diamino-3,4-dithiahexane-1-carboxylic acid hydrochloride).

$$COO^-CH(NH_3^+)CH_2SSCH_2CH_2NH_3^+Cl^-$$

Experimental

Materials

Reference amino acids were obtained from Mann Research Laboratories or Calbiochem. Cystine and cystamine for irradiation were purchased from Mann Research Laboratories (M.A. grade) and were used without further purification. A sample of the cystamine hydrochloride was converted to the sulfate salt by passing a solution through a column of Dowex 1-X8 anion exchange resin in the sulfate form. The cystamine sulfate was crystallized from aqueous ethanol.

L-*Cysteine-cysteamine Disulfide Hydrochloride*

The material used for irradiation was prepared from cysteamine hydrochloride and cystine-*S*-monoxide (8). The monoxide was prepared by the method of Savige *et al.* (9) as described previously (3). Cystine-*S*-monoxide (3.2 g) in water (10 ml) was mixed with cysteamine hydrochloride (2.5 g) in water (10 ml) and shaken for 30 min. Sufficient ethanol was added to precipitate the product (about 100 ml) which was filtered off and dried.

For personal use only.

The material obtained (3.3 g) was dissolved in 0.1 *N* hydrochloric acid (15 ml) then the solution was filtered, adjusted to p*H* 5 with pyridine and again filtered. The product crystallized out at 5 °C after addition of ethanol (10 ml). A further fraction was obtained after addition of more ethanol to the filtrate. Total yield 2.5 g (50%), m.p. 181–182 °C.

Anal. Calcd. for $C_5H_{13}N_2O_2S_2Cl$: C, 25.81; H, 5.65; N, 12.04; S, 27.52; Cl. 15.26. Found: C, 25.74; H, 5.73; N, 11.92; S, 27.27; Cl, 15.10.

Examination with the amino acid analyzer showed only slight traces of cystine and cysteine sulfinic acid. The n.m.r. spectrum of the mixed disulfide in trifluoroacetic acid had peaks centered at $\tau = 2.28$ (NH_3^+ of Cy—), 2.90 (NH_3^+ of Cya—), 5.20 (CH), 6.42 ($2 \times CH_2$). and 6.74 (CH_2).

Irradiations and Analysis

Solutions of CySSCya for irradiation were unbuffered, 0.3 m*M* except where otherwise stated, and were prepared using triply distilled water with the usual precautions (1). The aerated solution had a p*H* close to 5. Preliminary irradiations were performed with a ^{60}Co source in a well as before but the work was completed using a "Gammacell" 220 (Atomic Energy Canada Ltd.) which provided approximately the same dose rate; 600 rad per min (ferrous sulfate dosimetry).

Most of the products were measured using a Technicon amino acid analyzer with columns of "Chromobeads" cation exchange resin and Dowex 1-X8 anion exchange resin (10). However, cystamine was too basic to be eluted successfully from the cation exchange resin and it could not be separated from the mixed disulfide on Dowex 1 resin since buffers of p*H* greater than 6 would have converted the mixed disulfide to a mixture of cystine and cystamine. Consequently, the yield of cystamine was determined by electrophoresis on strips of cellulose polyacetate "Sepraphore" III (Gelman Ltd.) (11). The disulfides separated well in 20 min at 200 V using a sodium acetate – acetic acid buffer at p*H* 5. The strips were developed with ninhydrin and the yields were estimated using a densitometer (Photovolt Ltd.) or a microdensitometer (Joyce Recording Microdensitometer, Model 12B Mark III).

Results

The products of the radiolysis of cysteine-cysteamine disulfide in aqueous solution consisted of those products which have been obtained by radiolysis of cystine (1, 12) and cystamine (13) together with the symmetrical disulfides cystine and cystamine. In aerated solution the yields were linear with dose up to at least 10 krad and the *G* values (molecules formed per 100 eV) of the products were determined from several experiments following exposure to 10 krad or less. In deaerated solution the yields of products were linear with dose in the same range with the exception of the symmetrical disulfides, CySSCy and CyaSSCya. The yields of the latter compounds were very high and *G* values were determined from the initial slopes of dose-yield plots.

Solutions of cystamine hydrochloride, 0.3 m*M*, were irradiated for comparison with the unsymmetrical disulfide under similar conditions. The sulfate of cystamine was also irradiated and it was found to give the same results as the hydrochloride. The p*H* of the unbuffered aerated solutions was close to 5. In solutions of low p*H* the chloride ion reacts with an ·OH radical to give a chlorine atom which can cause deamination (14) but this problem did not arise in the present work. Additional results were obtained by irradiating a mixture of cystine and cystamine hydrochloride and measuring the yield of products resulting, including the unsymmetrical disulfide. The solution contained equimolar amounts of cystine and cystamine and had a total disulfide concentration of 0.3 m*M*. The yields of the thiols were determined by adding sodium iodoacetate to the irradiated solution to produce the *S*-carboxymethyl derivatives and then analyzing with the amino acid analyzer. Table 1 contains the results of these experiments: *G* values are given for the major products from the mixed disulfide, from the mixture of cystine and cystamine, and from cystine and cystamine irradiated separately.

The yields of the products from CySSCya were reproducible to within ±5% with the exception of the thiols (±10%) and the disulfides in deaerated solution (±30%). The yields of disulfides in deaerated solution were very sensitive to traces of oxygen. The loss of unsymmetrical disulfide, *G*(—CySSCya), was 2.8 in aerated solution and hence the recovery of nitrogen in the products after 10 krad was about 90%. The recovery of nitrogen in deaerated solution, measured after exposure to 10 krad, was approximately 80%.

In contrast with cysteine-penicillamine disulfide (3), very little trisulfide was obtained from cysteine-cysteamine disulfide by radiolysis. No trisulfide of cystamine (*i.e.* CyaSSSCya) was observed and only trace amounts of ethylamine and ethanolamine were found. The latter compounds could be by-products resulting from splitting of the C—S bond of the cystamine half of the mixed disulfide. In the case of penicillamine disulfides significant yields of penicillamine trisulfide, valine, and hydroxyvaline were obtained.

TABLE 1. Radiolysis of CySSCya in 0.3 m*M* solution. The *G* values for principal products and comparison with CySSCy and CyaSSCya

Product	Aerated solutions			Deaerated solutions

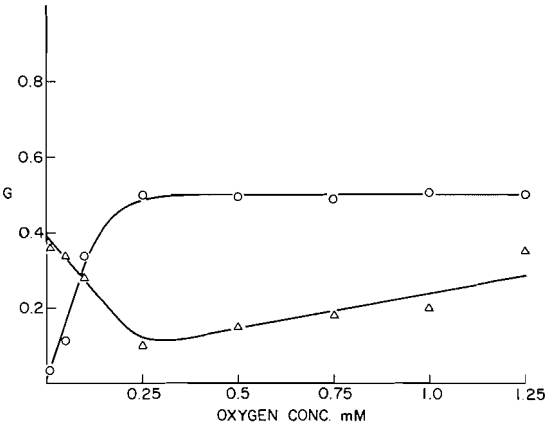

FIG. 2. Effect of oxygen concentration on $G(CySO_3H)$, ○, and $G(CySO_2H)$, △.

In view of the large difference in the yields of symmetrical disulfides between aerated and deaerated solutions, the effect of oxygen on the yield of cystine was investigated in more detail. Solutions were degassed in the usual way (four cycles of freezing, pumping, and thawing) and a measured amount of oxygen was added before sealing and irradiating the samples. The *G* values were determined for each oxygen concentration studied from the slope of the initial dose–yield plot. The results are illustrated in Fig. 1 which shows the variation of *G*(CySSCy) with oxygen concentrations. The reciprocal, 1/*G*(CySSCy), was approximately linear with oxygen concentration. The effect of oxygen on two other products was also interesting and Fig. 2 illustrates the changes in $G(CySO_3H)$ and $G(CySO_2H)$. The effect of changing the concentration of the solute on *G*(CySSCy) was investigated: two oxygen levels were chosen for this, aerated ($[O_2]$ = 0.25 m*M*) and oxygenated ($[O_2]$ = 1.2 m*M*), and the results are shown in Fig. 3. The yield of cystine was followed in these experiments as it could be measured more accurately than that of cystamine. Similarly, it was easier to measure the sulfinic and sulfonic acids of cysteine since they separated easily from all other products using the Dowex 1 column.

The effect of nitrous oxide on the yield of cystine was measured by degassing 25 ml samples then adding nitrous oxide. The concentration of

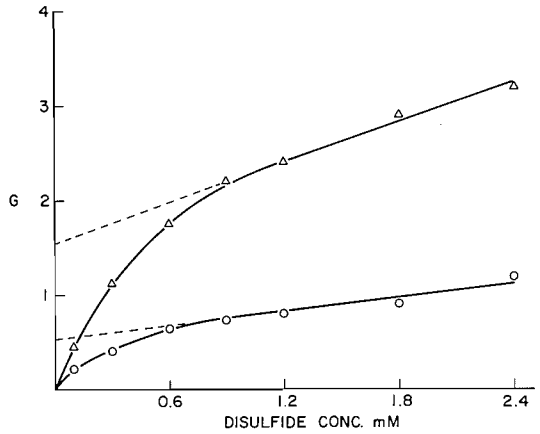

FIG 3. Effect of disulfide concentration on *G*-(CySSCy): △, aerated solution; ○, oxygenated solution.

nitrous oxide used was 20 m*M*. Found: *G*(CySSCy) = 8.0. A similar yield was obtained using a solution saturated with N_2O at atmospheric pressure.

Discussion

Radiolysis of cysteine-cysteamine disulfide was similar to radiolysis of cysteine-penicillamine disulfide in that the same products were obtained irrespective of whether the cysteine and cysteamine were combined in symmetrical or unsymmetrical disulfides. Also, as shown in Table 1, the mixed disulfide, the mixture of both symmetrical disulfides, and the pure symmetrical disulfides gave the same products and in the same relative yields. Hence it is concluded that the cysteine and cysteamine sulfur atoms react with the free radicals from water at approximately equal rates. Some variations in the yields were found between the mixed disulfide and the symmetrical disulfides, but these could have resulted from the secondary reactions rather than from the primary radical attack.

It has been reported that when a mixture of cystine and cystamine is irradiated in aqueous solution only the cystamine is attacked (15). This statement was not substantiated. Products from both cystine and cystamine were invariably produced when a mixture in aqueous solution was irradiated.

The principal reactions of solvated electrons (6, 7) and hydroxyl radicals (16) with disulfides appear to be as in reactions 1–3. From recent

[1] $\mathrm{RSSR + \cdot OH \rightarrow RSOH + RS\cdot}$

[2] $\mathrm{RSSR + e_{aq}^- \rightarrow (RSSR)^-}$

[3] $\mathrm{(RSSR)^- \rightarrow RS\cdot + RS^-}$

measurements of the yields of free radicals from water at low doses Bielski and Allen (17) obtained values of $G_{OH} = 2.74$ and $G_{red} = 3.3$. If all primary free radicals reacted to produce RS· radicals which combined to give symmetrical disulfides, *i.e.* eq. 4, the maximum possible yield

[4] $\mathrm{2\,RS\cdot \rightarrow RSSR}$

of both symmetrical disulfides from this reaction would be *G*(RSSR) = 3.0. Only a limited amount could be formed from reactions not involving RS· radicals. Thus the high yields of symmetrical disulfides from the mixed disulfide in deaerated solutions indicate that a chain reaction must be involved. The initial *G* values of cystine and cystamine were close to 15 which is too high to be attributed to any non-chain mechanism. The simplest explanation is that RS· radicals react with the solute causing extensive rearrangement of the disulfide bonds before they are eliminated by recombination, *e.g.* eqs. 5*a* and *b*. This chain

[5*a*] $\mathrm{RS\cdot + R'SSR \rightleftarrows RSSR + R'S\cdot}$

[5*b*] $\mathrm{R'S\cdot + R'SSR \rightleftarrows R'SSR' + RS\cdot}$

reaction was surprising in view of the low yields of symmetrical disulfides obtained from cysteine-penicillamine disulfide (CySSPen). In the latter case the yield of cystine was always higher than that of penicillamine disulfide. This may have been due to CyS· radicals reacting with mixed disulfide but it appears that PenS· radicals did not participate in a chain reaction.

As illustrated in Fig. 1, the presence of oxygen in solution during radiolysis reduced the yield of cystine very significantly. A small part of this may be due to competition between oxygen and the disulfide for the solvated electron: $k_{RSSR+e^-} = 1.3 \times 10^{10}\ M^{-1}\ s^{-1}$ for cystine; $k_{O_2+e^-} = 1.8 \times 10^{10}\ M^{-1}\ s^{-1}$ (18). However, oxygen must also be suppressing the chain reaction (see below),

[6] $\mathrm{RS\cdot + O_2 \rightarrow RSOO\cdot}$

probably by reacting with RS· radicals. This reaction has also been postulated to explain the radiolysis of cysteine in the presence of oxygen (5). Packer (19) estimated the rate of this reaction during pulse radiolysis studies and found it was fast: $k_{CyS\cdot + O_2} = 8 \times 10^9\ M^{-1}\ s^{-1}$. When the oxygen concentration was the same as the

For personal use only.

disulfide concentration (0.3 mM) the yield of cystine was reduced approximately by an order of magnitude. Hence it appears that reaction 6 is much faster than reaction 5 and k_6/k_5 is probably about 10. The exact ratio could not be derived due to uncertain factors such as the fate of the RSOO· radical and the ultimate yield of cystine in oxygen-free solution.

The experiments with N_2O-saturated solutions were performed to distinguish between reactions of RS· radicals and the $(RSSR)^-$ anion-radical. Under these conditions most of the solvated electrons would be scavenged by the N_2O to yield mainly ·OH radicals: $k_{e^- + N_2O} = 5.6 \times 10^9\ M^{-1}\,s^{-1}$ (18). Hence $(RSSR)^-$ would not be produced directly by reaction 2. A chain reaction still occurred although the yield of cystine was lower than in degassed solution. It was concluded that the main chain reaction was reaction 5 rather than the alternative reaction 7.

[7] $\quad RSSR' + (RSSR')^- \rightleftarrows RSSR + (R'SSR')^-$

Reaction 7 could also be inhibited by oxygen; *i.e.* reaction 8. The solvated electron would be

[8] $\quad (RSSR')^- + O_2 \rightarrow RSSR' + O_2^-$

scavenged in solutions saturated with nitrous oxide or oxygen, preventing formation of $(RSSR)^-$. Hence, since the chain reaction occurred in the presence of nitrous oxide but not in oxygenated solution, reaction 6 must be the main chain-suppressing reaction.

The chain reaction was demonstrated by plotting G(CySSCy) *vs.* solute concentration for aerated solution, Fig. 3. The graph became linear at solute concentrations above 1 mM with an upward slope due to the effect of increasing RSSR′ concentration in reaction 5. Extrapolation back to zero solute concentration gave a value of 1.5 for G(CySSCy) in the absence of a chain reaction when all primary free radicals are scavenged. This value is still surprisingly high and suggests that the RSOO· radicals may have reacted to yield disulfide, *e.g.* reaction 9. In

[9] $\quad RSOO\cdot + RS\cdot \rightarrow RSSR + O_2$

oxygen-saturated solution the chain reaction was almost completely suppressed and the value of G(CySSCy) at zero chain reaction was reduced to 0.5. However another product, cystine-S,S-dioxide, was obtained in significant yield; $G(CyS(O_2)SCy) \sim 1$. This product probably comes from the RSOO· radical, reaction 10.

[10] $\quad RSOO\cdot + RSOO\cdot \rightarrow RS(O_2)SR + O_2$

This is analogous to reactions which have been observed in photochemistry.

The RSOO· radical is probably the precursor of sulfonic acid which is a major product from radiolysis of cystine or cystamine, in solutions containing oxygen. The relationship between $CySO_3H$, $CySO_2H$, and oxygen concentration is illustrated in Fig. 2. Only $CySO_2H$ was produced in deaerated solution. When oxygen was present $CySO_3H$ was formed and the yield increased with increasing oxygen concentration up to a value of $G(CySO_3H) = 0.5$ at oxygen levels above 0.25 mM. The value for $G(CySO_2H)$ reached a minimum at the same oxygen concentration indicating that $CySO_2H$ has a precursor in common with $CySO_3H$. Reactions 11–13 are consistent with these observations and with the dose-rate effect observed previously in the radiolysis of cystine (1).

[11] $\quad RSOO\cdot + RSOH \rightarrow RSO_3H + RS\cdot$[3]

[12] $\quad 2RSOH \rightarrow RSO_2H + RSH$

[13] $\quad RSOH + H_2O_2 \rightarrow RSO_2H + H_2O$

The sulfinic acid formed at the higher oxygen concentrations may come indirectly from the RSOO· radical, *e.g.* reaction 10 followed by [14].

[14] $\quad RS(O_2)SR + RSH \rightarrow RSO_2H + RSSR$

It is difficult to relate the present findings to the radioprotective ability of the respective thiols. The chain reaction between RS· radicals and disulfides is undesirable in a biological system as it could result in damage to sulfur-containing proteins. However, the observation that the chain reaction is suppressed by oxygen may explain the fact that radioprotective compounds are more effective in the presence of oxygen. There appears to be little difference between the reactivities of the different sulfur atoms of the disulfides towards the free radicals from water and this agrees with the rate constants for these reactions (16, 18). The reduced reactivity of the penicillamine radicals, as indicated from the low yield of penicillamine disulfide from a mixed

[3]Alternatively, RSOO· may react with an initial ·OH-disulfide complex (3)

$$RSOO\cdot + RS(OH)SR' \rightarrow RSO_3H + RSSR$$

disulfide, and the higher yield of products resulting from C—S bond splitting in penicillamine disulfides, suggest that penicillamine may be less efficient than cysteine or cysteamine in a hydrogen transfer process of radiation repair.

The tertiary structure of many proteins is maintained by disulfide bridges and hence destruction or rearrangement of these bridges by ionizing radiation would be harmful (20). The present results indicate that extensive rearrangement of disulfide bridges is unlikely to occur in an aerated environment although reactions could occur between favorably positioned groups. This may be the case with papain where a large part of the activity lost by irradiation can be regenerated by treatment with cysteine (21, 22). Chain reactions have been reported for the destruction of thioctic acid (α-lipoic acid) during photolysis (23) and radiolysis (24) and hence it was postulated that the main effect of ionizing radiation is rearrangement of protein disulfide bonds (24). However, in the case of thioctic acid the chain reaction was not affected by oxygen so it differs significantly from the disulfides of amino acids and does not provide a satisfactory model of protein disulfide bonds.

I wish to thank Dr. R. A. Back of the Division of Chemistry, National Research Council of Canada, for many valuable discussions. Thanks are also extended to Mrs. D. E. Hanafi for excellent technical assistance throughout this investigation.

Nuclear Magnetic Resonance Studies of Molecular Motion in a Number of Stearates and Oleates

J. A. RIPMEESTER[1,2] AND B. A. DUNELL

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 1, 1970

The broad line p.m.r. spectra of the alkali metal oleates have been observed from 77 °K up to or beyond the crystalline to waxy phase transition. Lower phase transition temperatures are observed in the oleates than in the stearates. This fact is attributed to larger entropies of transition in the oleates than in the stearates. The n.m.r. second moments indicate that in the stearates the packing of chains is probably not closer than in the oleates and consequently that the barriers to chain reorientation are not significantly higher in the stearates than in the oleates. Sodium oleate and stearate both appear to behave irregularly in the series of alkali metal soaps. Spin-lattice relaxation times have been measured by adiabatic rapid passage methods for both alkali metal oleates and stearates. Values of T_1 and of the activation energy barrier for the reorientation of end methyl groups are compared with values obtained by other workers. No significant difference is seen between relaxation processes in stearates and oleates, at least in the lower temperature range. Soaps which seem to have some amorphous character have a second relaxation mechanism, in addition to end methyl group rotation, which is evidently important in the region of about 150–250 °K.

Canadian Journal of Chemistry, 49, 731 (1971)

Introduction

Interpretation of the nature of molecular motion in the various phases of the alkali metal salts of long chain fatty acids from a study of their p.m.r. absorption has been the subject of a number of papers that have appeared during the past ten years or so. Recently van Putte has investigated spin-lattice relaxation times of sodium and lithium salts of fatty acids of varying chain length (1, 2) and Lawson and Flautt have used line widths, shapes, and second moments to study various soaps (3–5). Earlier work from this laboratory has also been concerned with the use of line width and second moment to describe the behavior of fatty acids and their soaps (6–8).

It is the purpose of this paper to report the results of n.m.r. line width and second moment studies on the alkali metal oleates and also the results of spin-lattice relaxation studies by the adiabatic rapid passage technique on these oleates and the alkali metal stearates.

Experimental

Oleic acid was obtained from the Hormel Foundation, Austin, Minnesota. It was quoted to be better than 99% pure and was used without further treatment to prepare the alkali metal oleates. A hot aqueous ethanol solution of reagent grade metal hydroxide was used to neutralize a hot ethanol solution of the acid. On cooling, the solution generally deposited white flaky crystals, which were filtered, washed with cold ethanol and then acetone, and air dried. The soaps were dried at about 100 °C under vacuum for a day, powdered and packed into sample tubes, heated again under vacuum at 110 °C for another day and finally sealed off under vacuum. The stearates were prepared directly from Eastman Kodak white label grade stearic acid, but were then all recrystallized once from ethanol before being dried and treated as the oleates. We may note that not all the soaps precipitated as flaky white crystals. Sodium stearate normally came down as a gel, and to some extent the sodium oleate also. On drying, however, these soaps resembled the other fatty acid salts. Caesium oleate was a sticky white solid, and rather difficult to handle. These materials did not improve physically on reprecipitation from solvent.

The steady-state or continuous wave n.m.r. spectra were run at 16 or 30 MHz. The spectrometer and the techniques and precautions which were used have all been described elsewhere (9). The adiabatic rapid passage experiments were done at 8 MHz using the methods reported by Janzen *et al.* (10).

In all experiments an equilibration time of at least 1 h was allowed at each different temperature, and at least two spectra were obtained for each line width and second moment reported. Values of T_1 were generally obtained from the slopes of lines plotted from "π–$\pi/2$" sequences of rapid passages (10).

Results and Discussion

(1) Line Width and Second Moment

Line widths and second moments for the oleates are displayed as functions of temperature in Figs. 1–5, together with the spin lattice relaxation times derived from the adiabatic rapid passage experiments. Inspection of these curves allows

[1]Present address: Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois 61801, U.S.A.

[2]National Research Council of Canada Scholarship holder 1967–1970.

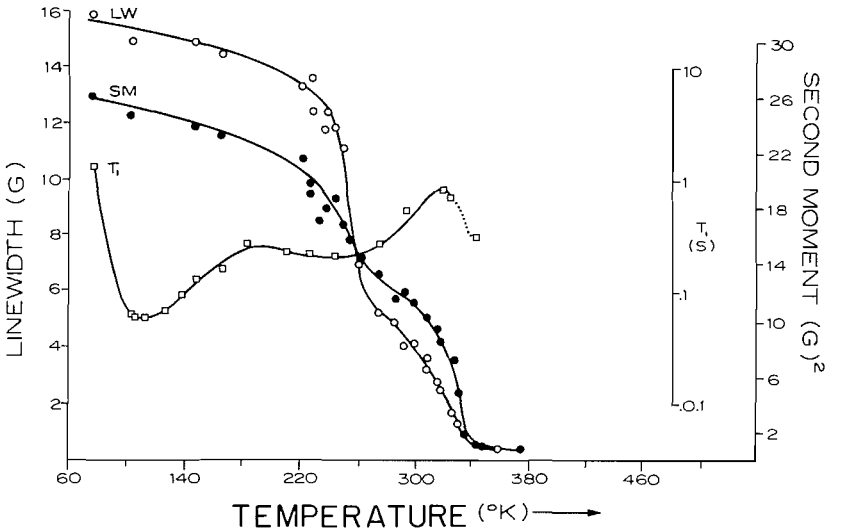

FIG. 2. Line width, second moment, and spin-lattice relaxation time plotted as functions of temperature for sodium oleate.

one to distinguish two transitions in all but caesium oleate (for which there is one observable transition) within the temperature range of the measurements. The higher temperature transition is the more abrupt one, leading at the high temperature side to second moments of about 1 G^2 and line widths which are determined by depth of modulation. In terms of n.m.r., the nature of this transition is very similar to the crystalline to waxy phase transitions of the alkali metal stearates (6, 11–13). The lower temperature transition, which is apparently absent in caesium oleate and not especially well defined in rubidium and sodium oleates, is a more gradual one in terms of the n.m.r. results. Second moments on the low temperature side of the transition are in the range of about 16–20 G^2, which is very similar to the values on the low temperature side of the crystal–crystal phase transitions of the alkali metal stearates, and on the high temperature side they have decreased to about 12 G^2. The lower temperature transitions in the stearates are quite

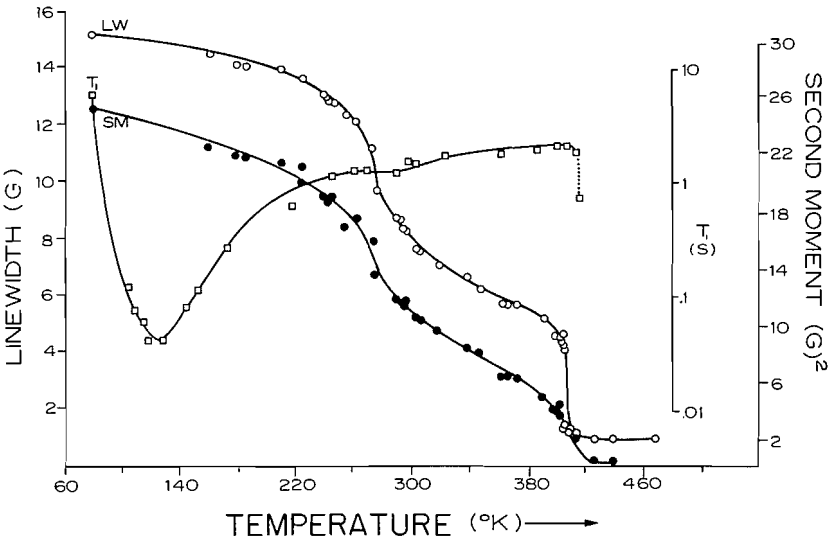

FIG. 3. Line width, second moment, and spin-lattice relaxation time plotted as functions of temperature for potassium oleate.

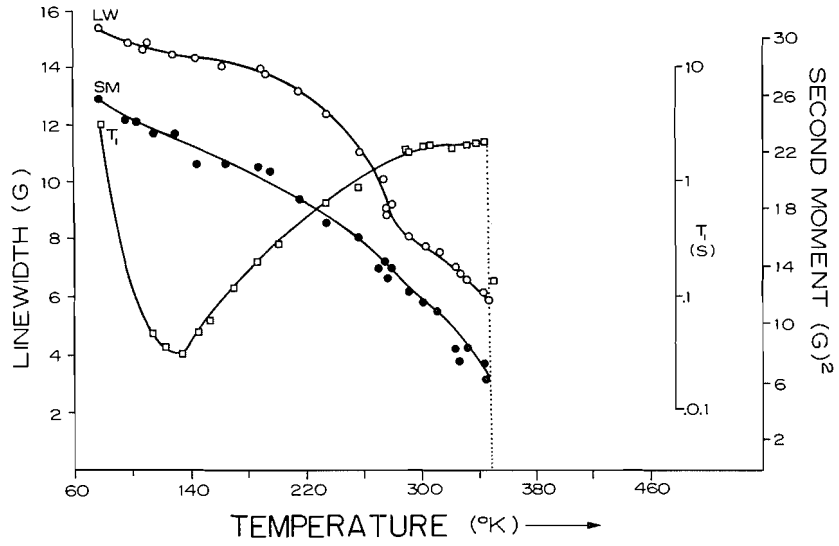

FIG. 4. Line width, second moment, and spin-lattice relaxation time plotted as functions of temperature for rubidium oleate.

abrupt, and correspond to a change in crystal structure (6, 11–13). Although the gradualness of this transition in the oleates makes one doubt that the transition involves a phase change, the motional changes in the hydrocarbon chain seem to be very similar to those of the hydrocarbon chains of the stearates in their low temperature crystal phase change. Further evidence that this low temperature transition in the oleates is not a crystal–crystal phase transition is the fact that we observed no peaks in the differential scanning calorimeter thermograms in the vicinity of this n.m.r. transition temperature for the oleates. Table 1 gives a summary of the transition temperatures of the oleates and stearates. One can see that the behavior of the sodium soaps is irregular in the alkali metal soap series. Apart from the sodium salts, there is a progressive

*Numbers in parentheses are literature references.

decrease in the temperature of the crystal–waxy transition as the cation size increases from lithium to caesium. The low temperature transitions are more irregular and less sensitive to cation size. For each alkali metal oleate the transition temperatures are lower than the corresponding stearate transition temperatures.

At liquid nitrogen temperature, the experimental second moments of the oleates range from 25–26 G^2, which is effectively the same as the corresponding range of 25–28 G^2 for the stearates. The rigid lattice intramolecular contribution to the second moment of the oleate chain may reasonably be taken as 18.5 G^2 (8), and that of the stearate chain as the same value (12). One concludes that at liquid nitrogen temperature the intermolecular contribution to the second moment is about the same for the stearate and oleate soaps. Since both second moment and van der Waals interactions depend on the inverse sixth power of internuclear distances, we may assume (14) that interactions between chains are very similar at liquid nitrogen temperature in all the oleates and stearates studied. With the exception of caesium oleate, whose second moment decreases much more rapidly than that of the other oleates, the oleate second moments do not differ greatly one from another until one is somewhat above the low temperature transition. Between liquid nitrogen temperature and higher temperatures where the second moment is in the vicinity of 16–20 G^2, the second moments of all the alkali metal oleates decrease a little more rapidly with increasing temperature than do

For personal use only.

those of the stearates. One could attribute this decrease in second moment from 25 or 26 G^2 at 77 °K to torsional oscillation of the chains. The oscillation is probably of somewhat greater amplitude in the oleate chain than in the stearate chain up to the low temperature side of the low temperature transition. Reorientation of the end methyl groups already takes place at sufficiently high frequency at liquid nitrogen temperature to provide the significant spin-lattice relaxation mechanism for the protons. This will be considered in the next section. Above the low temperature transition the second moment of the oleates is in the range of 11–14 G^2, corresponding to an increase in the amplitude of torsional oscillation of the hydrocarbon chains. The extent of this motion is not so great, or at least not greater than, the extent of motion in the stearates above their low temperature transitions. For the stearates, the second moments above the crystal–crystal transitions lie in the range of 4–12 G^2. One should presumably attribute, therefore, the lower value of the temperature of transition in the oleates to larger entropy effects due to chain disordering because of the influence of the double bond in the oleates more than to less dense packing of chains in the oleates than in the stearates at low temperature. If density of chain packing and energy barriers to oscillation are only slightly smaller in oleates than stearates, one can understand that the second moments of the oleates above the low temperature transition should be generally larger than those of the stearates above their higher temperatures of crystal–crystal transition.

Above the crystal–waxy phase transition (the higher temperature transition) the observed second moments of 0.5–2 G^2 indicate reorientation of the hydrocarbon chains about several axes for both oleates and stearates. Such motion requires space for the chains and one may understand the progressively lower transition temperature for increasing size of cation (except for the irregular sodium soaps) in terms of the lower energy required to separate larger diameter ions than smaller ones. Once again it is suggested that the oleates have a much lower crystal–waxy transition temperature than stearates because of an entropy effect; that is, because of greater disorder in the oleate chains than in the stearate chains on the high temperature side of the transition. It seems reasonable to associate the greater disorder of the oleate chains with the presence of the double bond with its cis configuration.

It is worth mentioning that for sodium stearate (15) and caesium oleate, and to a lesser extent for sodium oleate, a narrow component, whose linewidth was much less than 1 G, appeared in the spectra well below the first transition temperature. The intensity of this narrow component is dependent on the history and method of preparation of the sample. The existence of a narrow component in n.m.r. spectra of some polymers has been attributed to the presence of amorphous regions in the polymer (16). It is suggested that amorphous regions are present to a significant extent in sodium stearate and oleate and caesium oleate. This is consistent with the peculiar character of these soaps as they were precipitated from solution (see Experimental).

(2) Spin–Lattice Relaxation Time

The spin-lattice relaxation times of the alkali metal oleates, as determined by adiabatic rapid passage methods at 8 MHz, are displayed as a function of temperature in Figs. 1–5. They are also plotted as functions of reciprocal temperature for oleates in Fig. 6 and stearates in Fig. 7. The uncertainties in T_1 are greatest at liquid nitrogen temperature, where the adiabatic rapid passage signal is comparatively weak for these substances, and at temperatures near the T_1 minimum, where T_1 becomes rather too short for completely satisfactory measurement by this technique. We estimate the uncertainty in these two regions to be ± 15 to 20%. Elsewhere we estimate the T_1 values to be reliable to within ± 5 to 10%. Except for sodium and caesium oleate and sodium stearate, whose irregular behavior has already been mentioned, the plots of $\log T_1$ *vs.* T^{-1} are, up to about 250 °K, the V-shaped curves typical of a single relaxation process. The often used expression, developed by Bloembergen *et al.* (17), Kubo and Tomita (18) and others, and applied by, among others, Anderson and Slichter in their study of long chain hydrocarbons (19), relating spin–lattice relaxation time with the correlation time τ_c for reorientation of pairs of spins is eq. 1, where K is a constant that

$$[1] \quad \frac{1}{T_1} = K\left(\frac{\gamma^4\hbar^2}{\omega_0}\right)I(I+1)\sum_j r_{ij}^{-6} \times \left[\frac{\omega_0\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\omega_0\tau_c}{1+4\omega_0^2\tau_c^2}\right]$$

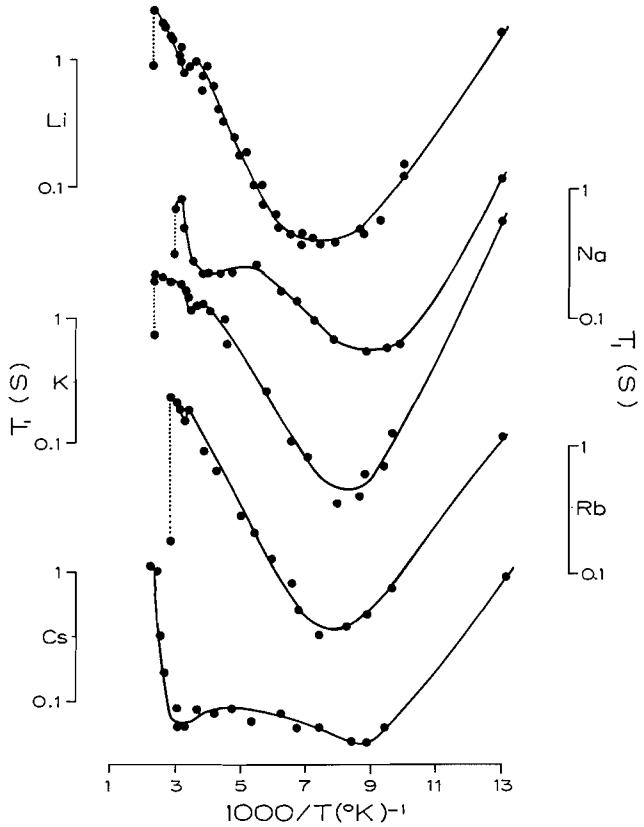

FIG. 6. Spin-lattice relaxation time on a logarithmic scale as a function of reciprocal temperature for the alkali metal oleates.

depends on the reorientation process, ω_0 is the Larmor frequency, and r_{ij} is the separation between spins in the pairs. There is a minimum in T_1 at $\omega_0\tau_c = 0.62$. If there exists a single τ_c which has a simple Arrhenius dependence on activation energy and temperature, $\tau_c = \tau_c^0 \exp(E_a/RT)$, it is easily seen that at low temperature, where $\omega_0\tau_c \gg 1$, $\ln T_1 = \text{constant} + E_a/RT$, and at high temperature, where $\omega_0\tau_c \ll 1$, $\ln T_1 = \text{constant} - E_a/RT$. One may note that Hubbard and his co-workers (20, 21) have predicted a more complex relaxation behavior for an isolated three spin system reorienting about a C_3 axis and have experimental evidence substantiating their analysis in the case of a methyl group which has been isolated by isotopic dilution. In the systems we are discussing here, however, the methyl groups are not isolated, and in the temperature range where we believe that methyl group reorientation provides the dominant relaxation mechanism, the decay of magnetization in the Z direction does not depart observably from the simple exponential decay predicted by eq. 1. The values of T_1 at the minimum in the curve, the temperature of the minimum, and the apparent activation energies determined from the slopes of the straight line portions of the curves on either side of the minimum are listed in Table 2.

The principal minimum in the T_1 curves, which lies between 110 and 132 °K may be attributed to relaxation through reorientation of the end methyl groups. Similar minima have been observed for *n*-alkanes (19), polymers (22–24), and other compounds containing methyl groups (25), and in previous studies on soaps (1). The studies on the *n*-alkanes (19) showed that the methyl group rotation provided a sink for the relaxation of the methylene protons by means of a spin diffusion process and that the minimum value of T_1 is directly proportional to the ratio of the total number of protons to the number of protons in reorienting methyl groups. According to Anderson and Slichter's results for *n*-alkanes, a ratio of total protons to methyl protons of 11.7,

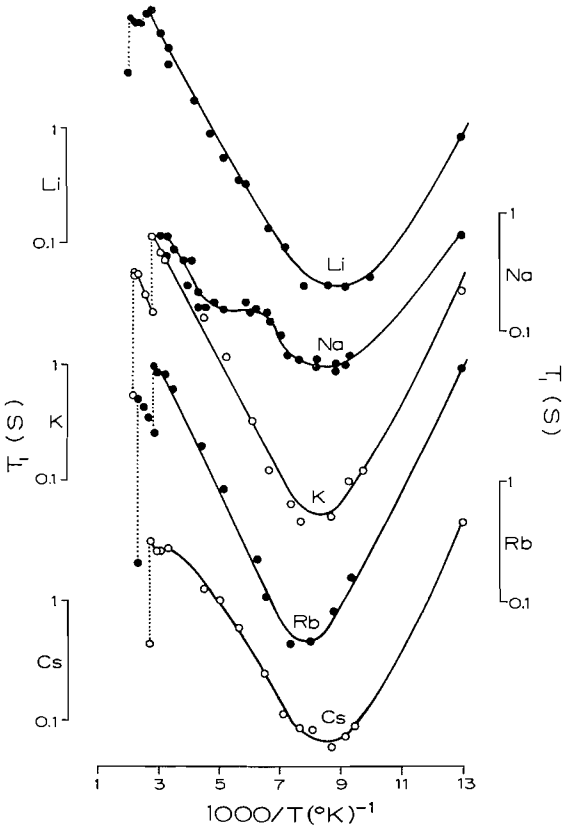

FIG. 7. Spin-lattice relaxation time on a logarithmic scale as a function of reciprocal temperature for the alkali metal stearates.

which is the appropriate value for stearate chains, corresponds to a T_1 minimum of 257 ms at 50 MHz. Equation 1 indicates that T_1 minimum is directly proportional to the Larmor frequency. Assuming that the activation energy for methyl group reorientation is the same in stearates and *n*-alkanes, one should then expect a T_1 minimum of 41 ms for the stearates observed at 8 MHz if they relax by spin diffusion to reorienting methyl groups which have a single relaxation time. As indicated in Table 2, our observed values of T_1 minimum range from 42–59 ms for the stearates and from 33–56 ms for the oleates, in reasonable agreement with predictions based on the work of Anderson and Slichter. Van Putte found a T_1 minimum, uncorrected for H-1 inhomogeneity, of 380 ms for sodium stearate at 60 MHz. Correction for H-1 inhomogeneity (1) gives a T_1 minimum of 475 ms. This value would reduce to 63 ms at 8 MHz, which corresponds reasonably well with our value of 58 ms at 8 MHz. The fact that we observe the T_1 minimum at a lower temperature than Anderson and Slichter (19) or van Putte (1) is consistent with the lower frequency at which our measurements were made. From eq. 1 and the Arrhenius expression for τ_c we can obtain eq. 2, a simple relation between the temperatures T and T' of T_1 minima measured at Larmor frequencies ν and ν'. If we may again assume that

$$[2] \qquad \log(\nu/\nu') = E_a(T - T')/2.3\,RTT'$$

the activation energy for methyl group reorientation is the same in stearates and *n*-alkanes, we can compare Anderson and Slichter's value of $T = 148$ °K for measurements on *n*-alkanes at 50 MHz with our average value of $T = 121$ °K for stearate soaps at 8 MHz and calculate $E_a = 2.4$ kcal/mol. Dispensing with the supposition that energy barriers to methyl group reorientation are the same in the different substances, one may compare van Putte's value of $T = 161$ °K for sodium stearate at 60 MHz with our value of

$T = 118$ °K for sodium stearate at 8 MHz and obtain $E_a = 1.8$ kcal/mol. These values are consistent with the values of the activation energy of the relaxation process obtained from the slopes of the straight line portions of the T_1 curve to either side of the minimum and listed in Table 2. It is estimated that the activation energies in Table 2 are reliable to within about ± 0.2 kcal/mol. The average of the values listed in Table 2 is 2.0 kcal/mol for the activation energy of the relaxation process. This may be compared with a value of 2.6 ± 0.2 kcal/mol found (19, 25) for reorientation of methyl groups in paraffins, and 2.1 kcal/mol, the average obtained by van Putte (1) for sodium soaps containing an even number of carbon atoms. Van Putte's average value for the even-numbered lithium soaps is 2.65 kcal/mol. The activation energies obtained from our results appear to be rather low. It seems unlikely that we should attribute this to the presence in the samples of residual molecular oxygen, which would be particularly effective in lowering the relaxation time at low temperatures and thereby would lead to a low activation energy on the low temperature side of the T_1 minimum. However, even though samples were pumped off at elevated temperature for a considerable length of time (see Experimental), one should not rule out this as a possible explanation. It is also possible, since only modest precautions were taken to ensure purity of sample, that residual impurities have broadened and raised the T_1 minimum sufficiently to give slightly low slopes on either side of the minimum. Although it is somewhat surprising that the activation energy obtained from the low temperature side of the T_1 minimum is smaller than that from the high temperature side, such a situation has been reported previously for polymers containing methyl groups attached to the main polymer chain (26). One might expect the apparent activation energy on the high temperature side to be lower because of possible contributions to the relaxation mechanism from motions other than methyl group reorientation lowering T_1 on the high temperature side of the T_1 minimum. One might attribute our observation to the presence of residual oxygen, as discussed above, or to an inadequate number of points between 77 °K and the T_1 minimum or to the somewhat larger uncertainty in the value of T_1 at 77 °K than in its value at temperatures appreciably above the T_1 minimum. None of these explanations seems to us at the moment to be totally convincing.

The average value of T_1 minimum found for oleates (42 ms) is lower than that for stearates (51 ms), but considering the range of deviation of individual values from the mean, they are very similar. It would seem reasonably clear, therefore, that the presence of the double bond in the middle of the oleate chain does not offer a bottleneck or rate limiting step in the spin diffusion process which is believed to serve as the main pathway for relaxation of the methylene hydrogens in the lower temperature range.

In the oleates the low temperature transition is accompanied by at most a small dip, or shallow minimum, in the T_1 *vs.* temperature curve; the higher temperature transition, however, involves a very rapid decrease, if not a discontinuity in T_1. It should be mentioned that for all the oleates, the higher temperature transition was preceded by the appearance, in the steady state spectra, of a narrower component which grew gradually at the expense of the broad component until only the narrow line remained at the transition point. This narrow component is much dependent on sample purity and thermal history. It may affect the observed T_1 to some extent since the narrow component must have a smaller T_1 than the broad component (there being a marked decrease in T_1 just at the transition temperature). This would explain the slight drop-off in T_1 observed somewhat below the higher temperature transition and the moderation of the decrease in T_1 at the transition.

Sodium and caesium oleates and sodium stearate are notable for showing low values of T_1 with either a plateau or a minimum in T_1 between about 160 °K (lower for caesium oleate) and the phase transition temperatures. In this temperature region, T_1 minima have been observed in polyethylene (22, 23) and other polymers (23, 27). Bergmann and Nawotky (22) found the value of this T_1 minimum to be proportional to the percent crystallinity of the sample and therefore the minimum has been associated with relaxation through chain motion in amorphous regions of the solid. Spin diffusion to relaxation sinks in the amorphous regions may operate in this case also, and lead to a dominant relaxation mechanism and single relaxation time. The irregular behavior of the two sodium soaps and of caesium oleate has already been mentioned.

These results for the spin–lattice relaxation time add support to the suggestion that these soaps have been obtained in a more amorphous state than the other soaps.

In lithium, potassium, and rubidium stearate there is an abrupt drop in T_1 at, or somewhat above, the crystal–crystal phase transition. In the lithium case, the drop is less abrupt than in the other cases. The question has been raised as to whether this drop in T_1 is related to the genotypical transition reported by Thiessen and Ehrlich (28). The genotypical transition in stearates should be at 343 °K. This corresponds to the drop in T_1 for potassium stearate at approximately 343 °K, but seems scarcely related to the drop in T_1 at approximately 385 °K for lithium stearate or 355 °K for rubidium stearate. For these three soaps there is better correlation of the T_1 drop with the crystal–crystal transition temperature than with the "genotypical transition". Values of T_1 for sodium stearate were not obtained above 360 °K because no part of the magnetization decays could be fitted by a single exponential. Between 150 and 360 °K, the magnetization decay was somewhat complex, but T_1 values could be found, and the shorter T_1 values are plotted. In the caesium case only a very small perturbation in T_1 occurs near the crystal–crystal transition. An abrupt drop in T_1 occurs at the crystal–waxy transition.

Electrochemical Bifunctionalization of Olefins in the Presence of Halide Ions[1]

N. L. WEINBERG[2] AND A. KENTARO HOFFMAN
American Cyanamid Company, Central Research Division, Stamford, Connecticut 06904

Received August 25, 1970

An electrochemical procedure has been developed for halofunctionalization of olefins, which allows for introduction of both nitrogen and oxygen containing substituents. The method obviates the need for silver salts or chemical oxidants, presently employed in analogous chemical routes. Thus 1-phenyl-2-butene on electrolysis in acetonitrile solution containing Et_4NI, Et_4NBr, or Et_4NCl was converted to the corresponding haloamide derivative. In a related study, which extends the scope of electrochemical functionalization by nitrogen to negatively substituted olefins, dimorpholinization of *trans*-dibenzoylethylene was carried out by anodic oxidation of an acetonitrile solution of the olefin in presence of morpholine and Et_4NI.

Canadian Journal of Chemistry, **49**, 740 (1971)

Electrochemical oxidation has been previously employed for halofunctionalization of olefins. Indeed epoxidation of lower alkenes with electrochemically generated HOCl has become a commercially viable route to olefin oxides (1). Other examples in the literature describe the formation of the halohydrin ethers of cinnamic acid (2) and *trans*-stilbene (3) on electrolysis of these olefins in methanol containing chloride or bromide electrolytes. We were interested in extending the scope of electrochemical halofunctionalization to include introduction of other nucleophiles especially those containing nitrogen.

The use of halogens, especially iodine, and silver salts for functionalization of olefins is well-known (4–9). In general the method involves the reaction of a cyclic halonium ion intermediate (**1**) with a suitable nucleophile to give a halofunctionalized (**2**) or bifunctionalized derivative (**3**) (eqs. 1 and 2) of the olefin. Precipitation of insoluble silver halide serves to drive the reaction to completion. For X = I and R = OAc eqs. 1 and 2 represent the well-known Prévost reaction (4, 5) and **3** (R = OAc) the observed product. Hassner and co-workers (6–9) are largely responsible for developing the corresponding reactions allowing introduction of nitrogen substituents to give synthetically useful haloadducts (**2**; X = I, Cl, or Br, and R = NO_2, N_3, NCO, and $\overset{+}{N}{\equiv}CCH_3$).

[1] $\text{C=C} + X_2 \rightleftharpoons$

X = I, Br, Cl

R = OH, O–alkyl, OAc, NO_2, N_3, NCO, $\overset{\oplus}{N}{\equiv}CCH_3$, X

Halonium ion **1** can be partitioned between starting material and **2**. Since **1** may be regarded as an ion pair, electrochemical oxidative removal of halide ion from **1** suggested itself as a means of driving [1] and [2] to the right.

Results

A series of reactions have been carried out which demonstrate that not only oxygen but nitrogen functionalization of olefins may be carried out electrochemically. An electrolysis cell divided into compartments for anode, cathode and reference electrode was employed to minimize possible side reactions of the product with the cathode. Table 1 lists results of controlled potential electrolyses of cyclohexene and 1-phenyl-2-butene in 0.5 *M* $LiClO_4$ in acetonitrile with a variety of halogen sources. It is emphasized that no attempt was made to maximize yields by seeking the optimum reaction conditions. High anodic potentials were avoided since organic halides are known to undergo electrooxidation (10). It is noteworthy that soluble salts

‖Estimated value.

of I^-, Br^-, and Cl^- can be used as a convenient source of halogen in these reactions and the need for handling reactive halogens is thereby conveniently avoided.

Haloamides are produced in acetonitrile solution, with solvent acting as the nucleophilic reagent. It is interesting that the product isolated on electrolysis of 1-phenyl-2-butene with Et_4NBr was not the bromoamide **4** but the acetoxy amine hydrobromide **6**. Strong evidence (i.r.) for the presence of **4** in the crude electrolysis product suggests that **6** arises as a result of an intramolecular nucleophilic displacement reaction to give an oxazoline intermediate **5** which is hydrolyzed to **6** (eq. 3). This type of displacement reaction has been studied previously (11).

In a related study, which extendes the scope of electrochemical functionalization by nitrogen to negatively substituted olefins, dimorpholinization of *trans*-dibenzoylethylene (**7**) was carried out. Electro-oxidation of **7** in acetonitrile in presence of Et_4NI and excess morpholine at +0.35 V *vs.* Ag, Ag^+ (0.01 *M*) gave the dimorpholino product (**9**) in 37% yield, and the previously unobserved iodomorpholino adduct **8** in 27% yield (12). An attempt to apply the morpholinization reaction to 1-phenyl-2-butene failed and almost all of the olefin was recovered

7 9 8

unchanged, in agreement with the unsuccessful analogous chemical reaction reported in the literature (12). The mechanism of this reaction probably involves addition of *N*-iodomorpholine to the olefin in a Michael-type reaction (eq. 4). This electrochemical procedure should prove applicable to other negatively substituted olefins as well as to primary amines.

Table 2 lists examples of oxygen functionalization reactions of olefins. Cyclopentene and cyclohexene undergo an electrochemical Prévost-type reaction in which the intermediate iodoacetate is isolated as the major product. The diacetate may be obtained as the major constituent by carrying out the electrolysis at elevated temperatures[3] for extended reaction times, thus facilitating the comparatively slow displacement of iodide. The electrolysis of 1-phenyl-2-butene in methanol containing Et_4NBr affords the expected products of reaction including a relatively sizable quantity of the glycol dimethyl ether. The latter observations agree with similar results previously reported (2, 3).

[3]Details of studies at elevated temperatures will be reported elsewhere.

Discussion

Electrochemical oxidation of iodine or of halide salts (I^-, Br^-, Cl^-) in the presence of an olefin and nucleophile has been found to be a promising method for halofunctionalization of olefins. Moreover, both oxygen and nitrogen functionalized products may be obtained under certain conditions, and negatively substituted olefins may be functionalized as well.

While bromide and chloride electrolytes are conveniently employed in the electrochemical method, vicinal dihalides are formed in appreciable amount. Iodide ion and I_2 do not possess this disadvantage because of the appreciable steric interaction present in vicinal diiodides. A number of additional properties of I^- and I_2 contribute to the unique success of electrochemical iodofunctionalization of olefins. Thus it is well recognized that I^-, besides being a very powerful nucleophile is a very effective leaving group (13). In addition, the low oxidation potentials of I^- and I_3^- compared to that of most olefins and nucleophiles allow for a conveniently wide range in which to control the electrolysis potential. While controlled potential methods have been employed in most of the examples in this report, constant current techniques should be applicable where iodide ion is used, providing it is present in excess. In this case discharge of iodide ion would keep the electrolysis potential at a low anodic value.

The anodic half-wave potential of I_2 ($E_{1/2} \approx$ 1.9 V *vs.* Ag, Ag^+ (0.01 *M*)(10)is comparable to that of olefins. Yet an acetonitrile solution of cyclohexene ($E_{1/2}$ = 2.05 V *vs.* Ag, Ag^+ (0.01 *M*) (14) containing I_2 is oxidized at +0.3 V *vs.* Ag, Ag^+ (0.01 *M*). Polarization curves for 0.5 *M* $LiClO_4$ in acetonitrile with added iodine and with added cyclohexene are shown in Fig. 1. To understand the large cathodic shift in the latter curve, a blank run was carried out using the same reaction conditions but with no current flowing. The product, *trans*-1-iodo-2-acetamidocyclohexane (**10**) was isolated in 70% yield. An explanation is that I_2 can compete effectively for I^- in the iodonium ion, forming I_3^-. In addition, traces of water could react with the resultant nitrilium ion giving the product **10** (eqs. 5 and 6) in an irreversible reaction. The large oxidation current observed at 0.3 V appears, therefore, to result from electro-oxidation of I_3^-, eventually converting all I_3^- in solution to organically bound iodoamide **10**.

Experimental[4]

Acetonitrile was purified as previously described (10). Sodium and lithium perchlorate were G. F. Smith Anhydrous Grade, dried over P_2O_5 *in vacuo*. Other chemicals used were reagent grade. A three compartment electrolysis cell divided for anode, cathode, and reference electrodes,

[4]Melting points are corrected. Microanalyses were performed by Mrs. P. Stehman and associates. The i.r. spectra were obtained with a Perkin–Elmer Infracord spectrometer. The n.m.r. spectra were carried out by Dr. J. Lancaster and Mrs. M. Neglia with a Varian Model A-60 instrument. The v.p.c. analyses on SE-30 and preparative separations using QF-1 on Gas Chrome CLA (60-80 mesh) were performed by Dr. R. Landowne and associates.

[6] $$I^- + I_2 \rightleftharpoons I_3^-$$

and separated by fine glass frits was employed throughout. The anode was smooth platinum (10 cm^2) and the cathode either platinum or a mercury pool. All reactions were carried out with magnetic stirring of the anode solution and under an atmosphere of dry nitrogen at 20° unless otherwise stated. The electronic equipment has been described (15).

Iodoamidation of Cyclohexene

(a) Electrochemical Preparation

A solution consisting of 3.2 g iodine, and 10 ml of cyclohexene in 100 ml of 0.5 *M* $NaClO_4$ in acetonitrile containing 3% water was electrolyzed at a smooth platinum anode (10 cm^2) at +0.32 V *vs.* Ag, Ag^+ (0.01 *M*). After 2106 C had been passed, during which the current dropped from 245 to 7 mA, the solution in the anode compartment was concentrated *in vacuo* at 35°, 10 mm. The residue was taken up in chloroform, washed with water, dilute aqueous sodium bisulfite solution, and the organic layer dried over anhydrous $MgSO_4$. On filtration and evaporation 6.6 g of solid m.p. 90–100 was obtained. This was identified as *trans*-1-iodo-2-acetamidocyclohexane by comparison of its i.r. spectrum with that of an authentic sample (6). After three recrystallizations from diethyl ether – acetone, the solid had m.p. 118–120.5°.

(b) Chemical Preparation

The above reaction was repeated using the same reaction conditions but without passage of current. After 16 h the solution was worked-up as above to give 2.0 g of crude *trans*-1-iodo-2-acetamidocyclohexane (i.r. mineral oil): 3250 (w), 1665 (w), 1640 (s), 1560 (s) cm^{-1}).

Electrochemical Iodoamidation of 1-Phenyl-2-butene

Using the above procedure, a solution of 1.3 g (0.010 mol) 1-phenyl-2-butene and 2.6 g (0.010 mol) Et_4NI in 0.5 *M* $LiClO_4$ in acetonitrile was electrolyzed at 0.5 V *vs.* Ag, Ag^+ (0.01 *M*). After 1800 C had been passed, work-up gave 1.9 g, m.p. 182–184°, of 1-phenyl-2-iodo-3-acetamidobutane on crystallization from acetone. The i.r. and n.m.r. analyses (the n.m.r. spectrum was similar to that described for the chloroamidation product) were in agreement with the structural designation, including one acetone of crystallization (i.r. (mineral oil): 3250 (w), 1745 (s), 1675 (s), 1520 (w) cm^{-1}).

Anal. Calcd. for $C_{12}H_{16}NIO \cdot C_3H_6O$: C, 48.00; H, 5.87; N, 3.70; I, 33.87. Found: C, 48.23; H, 6.00; N, 3.61; I, 33.82.

Electrochemical Bromoamidation of 1-Phenyl-2-butene

In a similar manner 0.01 mol of 1-phenyl-2-butene, and Et_4NBr in 0.5 *M* $LiClO_4$ in acetonitrile, electrolyzed at 1.3 V *vs.* Ag, Ag^+ (0.01 *M*) gave 2.26 g of a crude oily product. This material exhibited strong absorption bands at 3350 (w), 1645 (s) and 1560 (m) cm^{-1} in the i.r. (mineral oil). On standing a solid was slowly deposited. Crystallization of this from diethyl ether – acetone gave 0.35 g of 1-phenyl-2-acetoxy-3-aminobutane hydrobromide, m.p. 184–186.5° (i.r. (mineral oil): 1725 (s), 1560 (m) cm^{-1}). The n.m.r. spectrum in $CDCl_3$ exhibited a broad band at 1.6 (NH_2), aromatic at 2.6, a multiplet at 4.8 (O—C—H), a broad absorption at 6.5 (N—C—H), a double doublet at 6.9 ($ArCH_2$), a single peak at 7.8 ($OCOCH_3$), and a doublet at 8.4 τ (C—CH_3). The proton ratios were 2:5:1:1:2:3:3 respectively. Spin decoupling experiments demonstrated that the 8.4 doublet was coupled to the 6.5 proton and the 6.9 double doublet was coupled to the 4.8 proton.

Anal. Calcd. for $C_{12}H_{18}NBrO_2$: C, 49.85; H, 6.27; N, 4.67; Br, 27.70. Found: C, 50.00; H, 6.26; N, 4.86; Br, 27.70.

On distillation, the mother liquors provided 0.19 g of 1-phenyl-2,3-dibromobutane (b.p. 90°, 0.15 mm). This oil was identical (i.r.) to a sample of the olefin dibromide prepared by conventional methods.

Anal. Calcd. for $C_{10}H_{12}Br_2$: C, 41.27; H, 4.15; Br, 54.58. Found: C, 41.06; H, 4.12; Br, 54.54.

Electrochemical Chloroamidation of 1-Phenyl-2-butene

In the above manner, a solution of 0.02 mol of Et_4NCl and 0.01 mol of olefin in 100 ml of 0.5 *M* $LiClO_4$ in acetonitrile was electrolyzed at +1.2 to 1.3 V *vs.* Ag, Ag^+ (0.01 *M*) until 2000 C had been passed. Work-up gave 0.35 g of colorless solid identified by i.r. and n.m.r. analyses as 1-phenyl-2-chloro-3-acetamidobutane, m.p. 122–124°; (i.r. (mineral oil): 3350 (m), 1650 (s), 1545 (m) cm^{-1}). The proton integral in the n.m.r. spectrum was in agreement with the designated structure with ratios 5:1:2:2:3:3 for aromatics at 2.8, NH at 4.2, two C—H's at about 5.7, CH_2 at 7.0, CH_3CO at 8.0, and CH_3—CH at 8.8 τ respectively.

Anal. Calcd. for $C_{12}H_{16}NOCl$: C, 63.85; H, 7.08; N, 6.19; Cl, 15.71. Found: C, 63.88; H, 7.16; N, 6.24; Cl, 15.83.

The mother liquor provided a small amount of an oil whose i.r. spectrum suggested that it was 1-phenyl-2,3-dichlorobutane along with some 1-phenyl-2-butene. No attempt was made to separate this mixture.

Dimorpholinization of trans-1,2-Dibenzoylethylene

A solution of 2.4 g of *trans*-1,2-dibenzoylethylene,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1.3 g of Et_4NI, and 4 ml of morpholine in 100 ml of 0.5 *M* $LiClO_4$ in acetonitrile was electrolyzed at +0.35 V *vs.* Ag, Ag^+ at a smooth platinum anode (10 cm^2). After 1990 C, the solid which had precipitated during the course of the reaction was filtered off and crystallized from methanol to give 1.6 g, m.p. 180–183°, of 1,2-dibenzoyl-1,2-dimorpholinoethane. The i.r. spectrum of this solid was identical to a sample prepared according to the literature (12). A mixed m.p. was not depressed.

Anal. Calcd. for $C_{24}H_{28}O_4N_2$: C, 70.56; H, 6.91; N, 6.86. Found: C, 70.77; H, 6.89; N, 6.82.

From the mother liquor 1.2 g of a second product was isolated, m.p. 125–130° (dec.). Crystallization from ethanol–benzene gave 0.9 g, m.p. 132–134° (dec.), of pale yellow crystals, identified as the iodomorpholino adduct **8**.

Anal. Calcd. for $C_{20}H_{20}NO_3I$: C, 53.46; H, 4.49; N, 3.12; I, 28.25. Found: C, 53.89, 54.03; H, 4.54, 4.52; N, 3.16; I, 27.83.

The i.r. spectrum in mineral oil had characteristic bands at 1645 (s), 1580 (m), and 1560 (w) cm^{-1}. The n.m.r. spectrum in $CDCl_3$ exhibited a ratio of aromatic to all other protons of 10.0 to 10.4 respectively.

Electrochemical Iodoacetoxylation of Cyclopentene

Electro-oxidation of a solution consisting of 30 ml of cyclopentene and 3 g of iodine in 3 *M* KOAc in glacial acetic acid (containing 5% of acetic anhydride) was carried out at 50° (reflux temperature) under a $CaCl_2$ tube. A silver wire dipping into 3 *M* KOAc in glacial acetic acid containing AgOAc (saturated) served as the reference electrode.[5] A controlled potential electrolysis was conducted at +0.4 V *vs.* Ag, AgOAc until 2260 C had been passed. Removal of solvent and electrolyte gave 5.1 g of liquid product. The v.p.c. analysis showed the presence and yields of acetates listed in Table 2. The i.r. spectra of the three components separated by preparative v.p.c. techniques were identical to those of authentic samples.

Electrochemical Iodoacetoxylation of Cyclohexene

In a similar manner as that described in the preceding section, electrolysis at 80° of cyclohexene (10 ml) and 3 g iodine in 100 ml of 3.0 *M* KOAc – glacial acetic acid at +0.4 V *vs.* Ag, AgOAc gave 3.7 g of product after 2072 C had been passed. The products and yields are listed in Table 2.

[5]The Ag, AgOAc (saturated) reference electrode was +0.44 V *vs.* SCE at 20°.

Electrochemical Bromomethoxylation of 1-Phenyl-2-butene

A mixture of 4.2 g (0.020 mol) of Et_4NBr and 2.64 g (0.020 mol) of 1-phenyl-2-butene was electrochemically oxidized in 100 ml of 0.5 *M* $NaClO_4$ in methanol at +0.9 V *vs.* SCE. After 2650 C was passed the solution was concentrated *in vacuo*, the residue taken up in water, extracted with diethyl ether, and the ether extract dried over anhydrous $MgSO_4$. Filtration and evaporation of solvent gave 4.55 g of crude product. The v.p.c. analysis on a QF-1 column showed the presence of four compounds. Two were identified by retention times with authentic samples as 1-phenyl-2-butene (0.72 g) and 1-phenyl-2,3-dibromobutane (1.4 g). The other two, 1-phenyl-2,3-dimethoxybutane (0.74 g) and 1-phenyl-2-bromo-3-methoxybutane (1.7 g) were separated by preparative v.p.c. methods; i.r. and mass spectrometry were consistent with the designated structures.

Derivatives of 1-Phenylphthalan, 2-Methyl-1-phenylisoindoline, and 5*H*-Dibenzo[*a*,*d*]cycloheptene Oxides; Synthesis and Conformational Aspects

ROBERT R. FRASER AND ROGER N. RENAUD[1]
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received August 10, 1970

For the purpose of correlation of chemical shifts and geminal coupling constants with stereochemistry a number of compounds of fixed geometry have been synthesized. These include seven 6-substituted 1-phenylphthalans, five 6-substituted 2-methyl-1-phenylisoindolines, and six 2-substituted 5*H*-dibenzo-[*a*,*d*]cycloheptene oxides. The geometrical properties of the three ring systems are discussed and arguments in favor of a quasi-equatorial epoxide substituent in the latter series are supported by n.O.e. measurements.

Canadian Journal of Chemistry, 49, 746 (1971)

In an accompanying paper (1) we have investigated substituent effects on the geminal coupling constant between protons on a methylene carbon adjacent to a benzene ring. The chemical shifts of these protons have also been described (2). Three series of compounds were synthesized in which the substituent para to the benzylic methylene group was varied. In each series the substituent effects on the geminal coupling constant and on the shifts were determined and discussed in relation to the stereochemistry at the benzene—CH_2 bond. This paper describes the synthesis and conformational properties of each series of compounds; the 6-*X*-1-phenylphthalans, **1**, the 6-*X*-2-methyl-1-phenylisoindolines, **2**, and the 2-*X*-5*H*-dibenzo-[*a*,*d*]cycloheptene oxides, **3**.

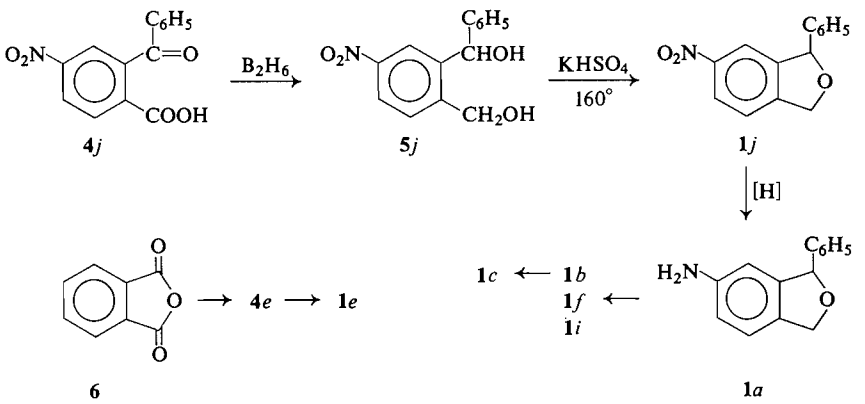
[1]Present address: Division of Chemistry, National Research Council of Canada, Ottawa, Canada.

Synthesis of Substituted 1-Phenylphthalans

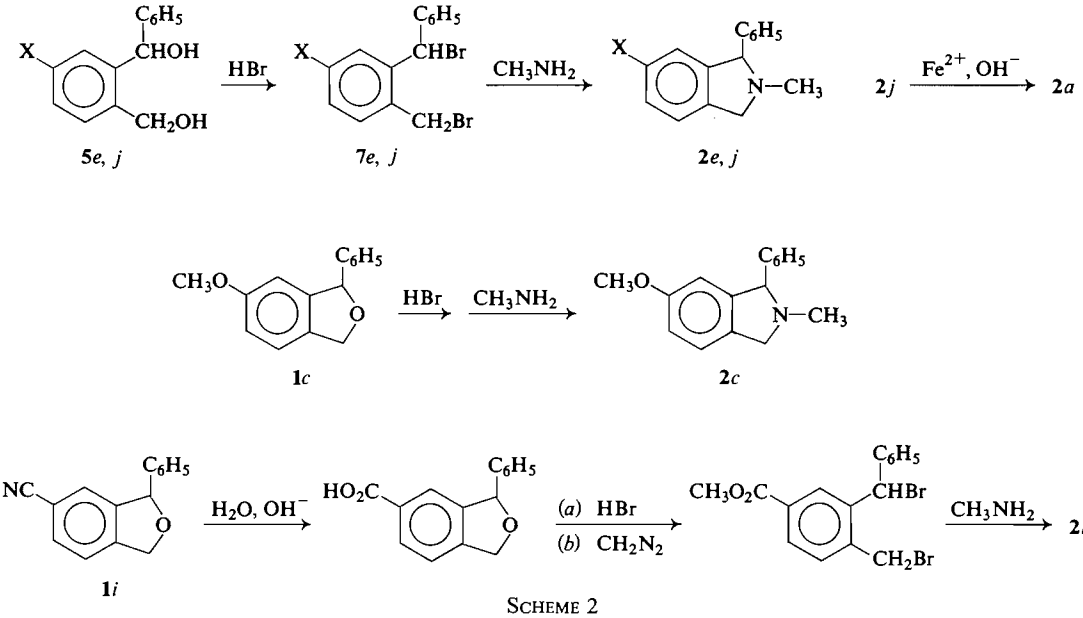
One method of synthesis of the parent compound 1-phenylphthalan (**1***e*) has been described by Vaulx *et al.* (3). Unfortunately, their method is unsuitable to the preparation of derivatives in the 6-position. A second method (4), involving cyclization of the appropriate diol, readily gave **1***e* and proved adaptable to the preparation of the series of 6-substituted 1-phenyl phthalans as shown in Scheme 1. 4-Nitro-2-benzoylbenzoic acid (**4***j*) prepared by Kliegl's method (5), was converted in two steps to 6-nitro-1-phenylphthalan (**1***j*). The yield in the cyclization was increased from 60 to 87% by use of potassium bisulfate rather than phosphoric acid (4). Reduction of **1***j* gave the amino derivative, **1***a*, which was easily converted to the hydroxyl, chloro, and cyano compounds, **1***b*, *f*, and *i* via the diazonium salt. Methylation of the hydroxyl function gave **1***c*.

Synthesis of Substituted 2-Methyl-1-phenylisoindolines

The parent compound, **2***e*, was originally prepared by Wittig *et al.* (6). We chose to use a more recently described route (7) which could utilize the available diols, **5***e* and *j*. Conversion of the diols to their corresponding dibromides, **7***e* and *j*, and subsequent treatment with methylamine gave **2***e* and *j* in good yields. Reduction of the nitro group in **2***j* with ferrous sulfate gave **2***a*. For the synthesis of the other members of this series we used the remaining available phthalans, **1***c* and *i*. Conversion of **1***c* to the isoindoline **2***c* was accomplished in good yield by treatment with HBr, followed by methylamine. The cyano derivative,



SCHEME 1



SCHEME 2

1*i*, was used to prepare the ester derivative, **2*h***. All these transformations are summarized in Scheme 2.

As can be seen in the Experimental, considerable difficulty was encountered in obtaining acceptable combustion analyses for derivatives in this series. All of these compounds became light green on exposure to air. Due to limited supplies of their precursors, the compounds were prepared, purified, and then immediately dissolved in deuterochloroform for recording of their n.m.r. spectra. The second crop of crystals from the preparation was recrystallized several times to produce an analytical sample. The nitro, amino, and methoxy derivatives gave combustion analyses close to the theoretical values but outside of the acceptable limits. Nevertheless the n.m.r. spectral properties of all members of this series strongly support the structural assignments and showed no identifiable impurities.

Synthesis of Substituted 10,11-Dihydro-10,11-epoxy-5H-dibenzo[a,d]cycloheptenes

For the preparation of the series of epoxides, **3**, we required the immediate precursors, the 5*H*-dibenzo[*a*,*d*]cycloheptenes, **9**. The parent mem-

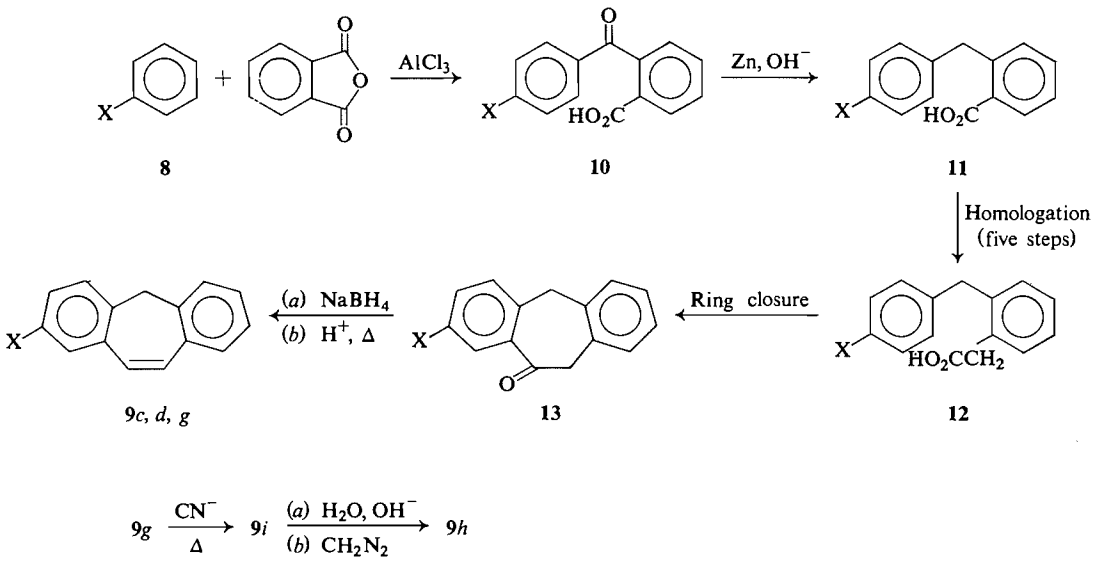
For personal use only.



SCHEME 3

ber **9e** was prepared by methods described in the literature (8, 9). Several syntheses of related dibenzo[*a*,*d*]cycloheptane derivatives have been disclosed (10–13) from which we chose the approach of S. A. Rhone-Poulenc (13) as most suitable for obtaining derivatives at position 2. This patent describes the synthesis of several 11-keto derivatives, **13**, which we could easily convert to the desired olefins. This sequence of reactions is outlined in Scheme 3. Although lengthy, the route presented no difficulties in the preparation of **9***c*, *d*, and *g*. Since the first step in this route works only with electron-donating substituents, the bromo derivative **9***g* was used as the precursor of the remaining compounds in the series. For this purpose the bromine in **9***g* was displaced by cyanide in DMF, a solvent shown to be advantageous by Friedman and Shechter (14). This reaction gave **9***i* in good yield but in *N*-methylpyrrolidone (15) an improved yield of 79% was achieved. The cyano group was then hydrolyzed and esterified with diazomethane to give **9***h*.

Epoxidation of all members of series **9** by meta-chloroperbenzoic acid proceeded in yields of 50 to 60% to give series **3**.

Conformations of 1-Phenylphthalan and 2-Methyl-1-phenylisoindoline

To the extent that Dreiding models represent the geometrical features of a molecule, it can be said that 1-phenylphthalan has a planar five-membered ring. Although the molecule is quite rigid certain allowed torsional vibrations may be present. Also, the phenyl substituent gives asymmetry to the molecule, which may result in at least a slightly puckered preferred conformation. The best estimate of the amount of puckering can be made from crystallographic data (16) available for a related compound, 3-*p*-bromophenylphthalide (**14**). This compound, though not an ideal model, provides some basis of assessment. A detailed X-ray analysis revealed the five-membered ring to have its oxygen atom within 0.03 Å of the completely planar conformation. The molecule was found to possess a distortion of the C_3—phenyl bond in a direction bending away from both the adjacent oxygen and carbon atoms but exhibited little distortion elsewhere. It would seem reasonable that the structural features common to the phthalans and phthalides (a strained five-membered ring attached to a rigid *o*-disubstituted benzene) would confer similar

For personal use only.

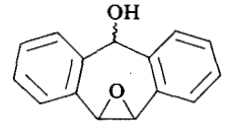
conformational properties to each. We would then expect the projected angle ϕ[2] in the 1-phenylphthalans, and in the 2-methyl-1-phenylisoindolines also, to be within 5° of zero, the value for a completely planar molecule.

Conformation of 3e

Although information regarding the exact geometry of the seven-membered ring in the epoxide **3e** is not available, an X-ray analysis of the related compound dibenzo[*b*,*f*]tropone has been reported (17). In this molecule the tropone ring is in a boat conformation and the two benzene rings are inclined by an angle of 40° from a planar arrangement. In a Dreiding model this angle is about 50°, the difference being due to molecular distortions in the crystal form but not in the liquid state and also to the fact that the Dreiding model is, in general, too rigid. With this in mind, one can examine a Dreiding model of **3e** and estimate the various bond angles of the molecule. The angle of particular interest to us is the projected angle ϕ at the benzene–methylene bond. In the model of **3e** this angle is 73°. Distortion which would decrease the angle between the benzene rings would also decrease the angle ϕ, but not by as many degrees. The above estimate of 73° should be accurate to within 5°.

Two other aspects of the conformation of **3e**, the barrier to inversion and the preferred conformation of the epoxide ring, merit consideration. Barriers to inversion have been measured on several compounds closely related to **3e**. The dibenzo[*a*,*d*]cycloheptene **9e** has been found to have a barrier of 9.2 kcal/mol (18, 19) while the 5,5-dimethoxy derivative is reported to have a barrier to inversion of 15 kcal/mol (20). It is likely that the barrier in **3e** is similar to that of **9e**, in which case the molecule should be inverting rapidly at room temperature on the n.m.r. time scale. An examination of the temperature dependence of the n.m.r. spectrum of **3e** over the temperature range of −90 to +140 °C failed to detect any significant spectral changes. Either the molecule has a very low or a very high barrier to inversion, or else it possesses one dominant conformation.

For a hydroxyl derivative of **3e**, 10,11-dihydro-



15

10,11-epoxy-5-hydroxy-5*H*-dibenzo[*a*,*d*]cycloheptene (**15**), a dominant conformation in which both the epoxide ring and the hydroxyl group occupy the quasi-axial positions (*cis* configuration) has been proposed by Bauld and Rim (21). The authors made this assignment to account for the presence of a bonded OH absorption in its i.r. spectrum (ν = 3440 cm^{-1}). Furthermore an H—C—O—H coupling of 12 Hz led them to propose a *trans* or *anti* orientation (22) for the OH proton relative to the proton at C-5.

From an examination of Dreiding models of **15** and **3e** it would appear that the above assignment is in error and that the epoxide ring is quasi-equatorial in both compounds. In a model of *cis*-**15** occupying the proposed conformation, the distance between the epoxide and hydroxyl oxygens is estimated as 1.5 Å and the distance between the O—H proton and the epoxide oxygen is less than 1 Å. In a model of **3e** the distance between a quasi-axial epoxide oxygen and the quasi-axial proton at C-5 is 1.8 Å. Since all these distances are much less than the sums of the Van der Waals' radii of the two atoms, the repulsive interactions would make these conformations much less stable than the ones with a quasi-equatorial epoxide ring in which no significant steric interactions are present. In all likelihood the 5-hydroxy derivative, **15**, has a *trans* configuration for the two substituents with the epoxide in the quasi-equatorial position. The unusual spectral properties (i.r. and n.m.r.) might be accounted for by hydrogen-bond formation between the quasi-axial O—H and the C_{10}—C_{11} bond of the epoxide ring. Such bonding to a three-membered ring has precedence in cyclopropane–OH interactions (23, 24) although these were not so strong ($\Delta\nu$ = 40 cm^{-1}). Perhaps the C_{10}—C_{11} bond is a better donor due to its large amount of strain and the fact that in **15** C-10 and -11 are benzylic.

We sought additional evidence for the quasi-equatorial orientation of the epoxide ring from a study of the n.O.e.'s in a degassed sample of **3c** in deuterochloroform. Figure 1 gives the spectrum, as well as a drawing of the boat form of **3c**, show-

[2]The angle ϕ is taken as zero when an imaginary line joining the benzylic methylene protons is parallel to the adjacent π orbitals of the benzene ring (1).

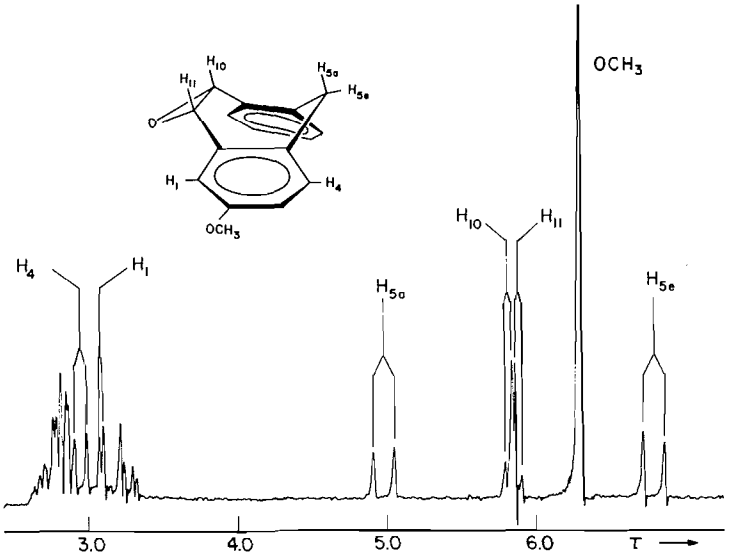


FIG. 1. The 100 MHz spectrum of compound 3*c* in deuterochloroform, with the assignment of protons as indicated in the formula.

ing the numbering of the protons. The results of our n.O.e. experiments are listed in Table 1.

Interpretation of n.O.e.'s must be made with caution as many mechanisms of relaxation may contribute to the observed effects. Discussions of these problems in interpretation have been made in many papers, a few of which (25–27) are particularly helpful. The data in Table 1 provide some information on the preferred conformation for 3*c*. Observation of a 5% increase in intensity of the signal for the quasi-axial proton at C-5 on irradiation of H-11 is consistent with a quasi-equatorial epoxide ring (H_{11}–H_5 distance = 3.1 Å) but not with a quasi-axial ring (H_{11}–H_5 distance = 3.9 Å). The inverse experiment gives a similar result in that an n.O.e. of 3% for H-11 on irradiation of H-5 (quasi-axial) was seen. Assignments for the H-5 protons are made on the basis of the last two n.O.e.'s in Table 1. The small magnitude for all of the n.O.e.'s in Table 1 is expected since each proton investigated has either a geminal or a vicinal neighbor proton which also contributes to its relaxation. Nevertheless, since values of 3 and 5% are in the range of the experimental error in measurement (±3%), they can only be interpreted as mild support for a quasi-equatorial epoxide ring in 3*c*. A quasi-equatorial cyclopropane ring has been proposed in a similar case (35).

Experimental

All melting points are corrected. Unless specified, the drying agent used for solutions was magnesium sulfate. All i.r. spectra were recorded on a Perkin–Elmer Infracord spectrometer. Only the characteristic bands are reported (cm^{-1}). The n.m.r. spectra were measured in deuterochloroform and the chemical shifts are reported on the τ scale. The instrument used was a Varian HA-100 spectrometer. The technique used for determining the n.O.e.'s is the same as that described previously (27).

1-Phenylphthalan (1e)

o-Benzoylbenzoic acid was prepared from phthalic anhydride and converted to 1-phenylphthalan by the procedure of Pernot and Willemart (4). The crude oily product obtained was purified by bulb-to-bulb distillation and the fraction distilling at 155° (0.25 mm) collected.

The overall yield was 54%. The i.r. and n.m.r. spectra of this product were identical to those reported by Vaulx *et al.* (3).

(5-Nitro-2-hydroxymethylphenyl)phenyl Carbinol (5j)

Reduction of 3.2 g of 4-nitro-2-benzoylbenzoic acid (5) with diborane, generated as described by Schmitt and co-workers (28) gave an oil in 96% yield (3.3 g) which slowly crystallized to a light brown solid, m.p. 92–93°; i.r. (film): 3490 (OH), 1530, 1355 (NO_2); n.m.r. (DMSO): 1.80 (1H doublet, proton at C-6), 2.02 (1H quartet, proton at C-4), 2.54 (1H doublet, proton at C-3), 2.86 (5H singlet, aromatic), 3.82 (1H doublet, hydroxyl proton of CHOH), 4.04 (1H doublet, methine), 4.52 (1H triplet, hydroxyl proton of CH_2OH), 5.44 (2H octet, methylene).

Anal. Calcd. for $C_{14}H_{13}NO_4$: C, 64.86; H, 5.02; N, 5.21. Found: C, 64.68; H, 5.25; N, 5.24.

6-Nitro-1-phenylphthalan (1j)

To a solution of **5***j* (6.8 g) in ether (150 ml) was added 100 g of freshly powdered fused potassium bisulfate. The ether was distilled off and the residue heated at 160° for 1 h. The cooled residue was extracted with ether and the dark solution was passed through a column containing magnesium sulfate and aluminum oxide. Concentration of the eluent gave a solid, m.p. 55.5–56.5°, in a yield of 87% (5.8 g); i.r. (KBr): 1522 and 1350 (NO_2), 1048 (C—O—C); n.m.r.: 1.82 (1H quartet, proton at C-5), 2.14 (1H doublet, proton at C-7), 2.66 (6H multiplet, aromatic), 3.81 (1H multiplet, methine), 4.70 (2H octet, methylene).

Anal. Calcd. for $C_{14}H_{11}NO_3$: C, 69.70; H, 4.57; N, 5.81. Found: C, 69.67; H, 4.74; N, 5.65.

6-Amino-1-phenylphthalan (1a)

6-Nitro-1-phenylphthalan (2.7 g) dissolved in 25 ml methanol was reduced at room temperature in the presence of 0.2 g of 10% palladium-on-charcoal catalyst under hydrogen at a pressure of 4 atm. The theoretical volume of hydrogen was absorbed in 5 h. Removal of the catalyst by filtration followed by evaporation of the methanol gave a dark brown oil. This crude material was treated with excess of dilute hydrochloric acid and filtered. The filtrate on treatment with dilute sodium hydroxide solution gave 2.2 g (93%) of a light brown amorphous solid, m.p. 84–85°, which was recrystallized from water. Long colorless needles, m.p. 85.5–86°, were obtained; i.r. (KBr): 3475 and 3385 (NH_2), 1032 (C—O—C); n.m.r.: 2.73 (5H singlet, aromatic), 2.98 (1H at C-4), 3.44 (1H quartet at C-5), 3.72 (1H doublet at C-7), 3.96 (1H broad singlet, methine), 4.83 (2H octet, methylene), 7.05 (2H broad singlet, NH_2).

Anal. Calcd. for $C_{14}H_{13}NO$: C, 79.62; H, 6.16; N, 6.64. Found: C, 79.75; H, 6.35; N, 6.80.

6-Chloro-1-phenylphthalan (1f)

Conversion of the aminophthalan, **1***a*, by diazotization and reaction under standard conditions (29) gave a 35% yield of a yellow oil, **1***f*; i.r. (film): 1040 (C—O—C); n.m.r.: 2.69 (7H multiplet, aromatic), 3.00 (1H broad singlet at C-7), 3.88 (1H broad singlet, methine), 4.77 (2H octet, methylene).

Anal. Calcd. for $C_{14}H_{11}ClO$: C, 72.88; H, 4.77; Cl, 15.41. Found: C, 73.21; H, 5.01; Cl, 15.02.

6-Cyano-1-phenylphthalan (1i)

Diazotization of **1***a*, followed by reaction with cyanide (29) gave a 46% yield of a semi-solid, which, after sublimation and recrystallization from ethanol, melted at 104.5–105.5°; i.r. ($CHCl_3$): 2260 (C≡N); 1040 (C—O—C); n.m.r.: 2.70 (8H multiplet, aromatic), 3.86 (1H broad singlet, methine), 4.71 (2H octet, methylene).

Anal. Calcd. for $C_{15}H_{11}NO$: C, 81.49; H, 5.21; N, 6.33. Found: C, 81.56; H, 5.13; N, 6.04.

6-Hydroxy-1-phenylphthalan (1b)

Diazotization of **1***a* and decomposition in boiling water (29) gave, after work-up, an oily solid which was purified by sublimation and recrystallization from water to give 0.27 g (34.5%) of long colorless needles melting at 133–134°; i.r. ($CHCl_3$): 3225 (OH), 1020 (C—O—C); n.m.r.: 2.72 (5H multiplet, aromatic), 2.92 (1H doublet at C-4), 3.30 (1H quartet at C-5), 3.58 (1H doublet at C-7), 3.92 (1H broad singlet, methine), 4.82 (2H octet, methylene).

6-Methoxy-1-phenylphthalan (1c)

To a stirred solution of 6-hydroxy-1-phenylphthalan (0.13 g) in 5 ml of aqueous sodium hydroxide (10%) was added dropwise dimethyl sulfate (0.4 ml). Stirring was continued for 5 h. The product was extracted into ether and the slightly orange solid obtained after removal of the dried solvent was purified by sublimation to give 0.11 g (79%) of a colorless solid melting at 78.5–79.5°; i.r. (KBr): 1040 (C—O—C); n.m.r.: 2.70 (5H singlet, aromatic), 2.84 (1H doublet at C-4), 3.18 (1H quartet at C-5), 3.48 (1H doublet at C-7), 3.90 (1H broad singlet, methine), 4.79 (2H octet, methylene).

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.60; H, 6.19. Found: C, 79.50; H, 6.39.

2-Methyl-1-phenylisoindoline (2e)

To 2 g of (2-hydroxymethylphenyl)phenyl carbinol dissolved in 2 ml of chloroform was added 50 ml of 48% hydrobromic acid. The mixture was kept at 70° for 6 h. During this time hydrogen bromide was passed into the reaction mixture. The reaction product was extracted with chloroform, dried, and concentrated *in vacuo* to give a red oil which was dissolved in 15 ml of benzene and added to a stirred saturated solution of methylamine in 25 ml of benzene. The mixture was kept at 40° for 3 h while methylamine was passed through the reaction mixture. The supernatant benzene solution was decanted and concentrated. The residue was dissolved in ether and extracted with dilute hydrochloric acid. The free base was then precipitated from the acid solution with NaOH solution, re-extracted into ether, and the ether solution dried and concentrated to dryness. The solid residue after crystallization from ethanol amounted to 1.4 g (71%) of a white solid, m.p. 59–59.5°, lit. m.p. 58.5–59° (6); n.m.r.: 2.64–2.84 (8H multiplet), 3.24 (1H doublet at C-7), 5.48 (1H quintet at C-1), 5.62 (1H quartet at C-3), 6.25 (1H quartet at C-3), 7.56 (3H singlet, *N*-methyl).

6-Nitro-2-methyl-1-phenylisoindoline (2j)

By use of the above procedure, 0.4 g of (5-nitro-2-hydroxymethylphenyl)phenyl carbinol (**5***j*) was converted to 0.26 g of 6-nitro-2-methyl-1-phenylisoindoline in 66% yield. The product was a yellow solid, m.p. 84.0–85°; i.r.

For personal use only.

($CHCl_3$) 1348 and 1528 (NO_2); n.m.r.: 1.90 (1H doublet, aromatic), 2.41 (1H singlet, aromatic), 2.60 (6H singlet, aromatic), 5.43 (1H multiplet, methine), 5.56 (1H quartet, methylene), 6.20 (1H quartet, methylene), 7.55 (3H singlet, methyl).

Anal. Calcd. for $C_{15}H_{14}N_2O_2$: C, 70.03; H, 5.47; N, 11.02. Found: C, 70.42; H, 5.98; N, 10.87.

*6-Amino-2-methyl-1-phenylisoindoline (**2a**)*

Reduction of the nitro group of **2***j* with ferrous sulfate and ammonium hydroxide (30) followed by work-up and purification as described for **2***e* gave an 85% yield of light green solid, m.p. 87.5–89°. This material rapidly darkened on exposure to air. The i.r. ($CHCl_3$) 3400 and 3480 (NH_2); n.m.r.: 2.61 (6H broad singlet, aromatic), 3.02 (1H doublet, aromatic), 3.51 (1H doublet, aromatic), 5.57 (1H multiplet, methine), 5.73 (1H quartet, methylene), 6.36 (1H quartet, methylene), 7.57 (3H singlet, methyl).

Anal. Calcd. for $C_{15}H_{16}N_2$: C, 80.36; H, 7.14; N, 12.50. Found: C, 79.48; H, 7.53; N, 12.32.

*6-Methoxy-2-methyl-1-phenylisoindoline (**2c**)*

This compound was prepared from **1***c* using the procedure reported above for the preparation of **2***j* except that the reactions were done at room temperature. A 78% yield of a light green solid, m.p. 54.5–56.5°, was obtained; n.m.r. 2.61–3.02 (7H, aromatic), 3.35 (1H doublet, aromatic), 5.49 (1H multiplet, methine), 5.68 (1H quartet, methylene), 6.40 (1H quartet, methylene), 6.37 (3H methoxyl), 7.58 (3H singlet, N-methyl).

Anal. Calcd. for $C_{16}H_{17}NO$: C, 80.2; H, 7.1; N, 5.9. Found: C, 78.2; H, 6.6; N, 6.1.

*6-Carbomethoxy-2-methyl-1-phenylisoindoline (**2h**)*

A mixture of 6-cyano-1 phenylphthalan (82 mg) and 10 ml of 10% aqueous NaOH was heated at 100° for 5 h. Then the reaction mixture was cooled on ice and acidified with hydrochloric acid. The solid that separated was collected by filtration and treated with hydrobromic acid as described in the preparation of **2***e* above. The resulting dibromoacid was then esterified with diazomethane. The solution was concentrated *in vacuo* and the resulting oil in benzene was treated with methylamine at room temperature for 3 h. The light green solid obtained after evaporation of the solvent was purified by sublimation at reduced pressure (0.02 mm) to give a colorless solid (50 mg; 51%), m.p. 79–80.5°; i.r. ($CHCl_3$), 1728 (CO); n.m.r.: 2.10 (1H doublet, aromatic at C-5), 2.58–2.78 (7H, aromatic), 5.45 (1H multiplet, methine proton), 5.59 (1H quartet at C-3), 6.22 (1H quartet at C-3), 6.21 (3H singlet, methoxyl), 7.57 (3H singlet, *N*-methyl).

*5H-Dibenzo[a,d]cycloheptene (**9e**)*

This compound was prepared from commercially available 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-one, by bromination and dehydrobromination (8) followed by reduction of the carbonyl group (9). Physical constants and spectral properties agreed with those previously reported (9).

*Reactions Leading to 2-Bromo-5H-dibenzo[a,d]cycloheptene (**9g**)*

Since the reactions of Scheme 3 up to and including the synthesis of **13***g* are documented in the literature, only a general description of the methods employed is given below. A Friedel–Crafts reaction of phthalic anhydride with bromobenzene gave 2-(4-bromobenzoyl)benzoic acid (31). This was reduced, via the phthalide (32), to 2(4-bromobenzyl)benzoic acid (32). Reduction to the alcohol with diborane (28), treatment with HBr, displacement by cyanide, and hydrolysis of the nitrile gave 2-(4-bromobenzyl)phenylacetic acid (11). Cyclization with polyphosphoric acid according to the industrial method (12) gave only trace amounts of the ketone, **13***g*. Different cyclization conditions were then sought.

A mixture of compound **12***g* (2 g) and thionyl chloride (6 ml) was heated under reflux for 3 h. Then the excess thionyl chloride was removed *in vacuo*. The oily residue was dissolved in carbon disulfide (25 ml) and added dropwise during 2 h to a stirred suspension of aluminum chloride (5 g) in carbon disulfide (100 ml) at room temperature. After 1 h of additional stirring, the mixture was poured onto ice containing hydrochloric acid. The organic layer was washed with 5% sodium bicarbonate, with water, and then dried. The brown solid obtained after evaporation of the solvent was sublimed as a light yellow solid (1.7 g; 90%) melting at 101–102°, (lit. m.p. 106°, (12)), i.r. ($CHCl_3$): 1675 (C=O); n.m.r.: 1.76 (1H doublet, aromatic proton at C-1), 2.70 (6H multiplet, aromatic), 5.79 and 5.82 (total of 4H, two singlets, $2CH_2$).

Anal. Calcd. for $C_{15}H_{11}BrO$: C, 62.72; H, 3.83; Br, 27.88. Found: C, 62.72; H, 3.93. Br, 27.99.

2-Bromo-10,11-dihydro-5H-dibenzo[a,d]cyclohepten-11-ol

To a solution of compound **13***g* (1 g) in absolute ethanol (25 ml) was added during a period of 10 min a solution of sodium borohydride (1.3 g) in absolute ethanol (20 ml). The mixture was stirred at room temperature for 20 h and then enough water was added to decompose the complex. The solvent was removed *in vacuo*. Water (5 ml) was added to the residue which was then extracted with ether. Drying and concentration of the solution gave 1 g (99%) of a colorless solid melting at 99–103°, lit. m.p. 106° (12). The crude alcohol was not purified further and was used as such in the next step.

*2-Bromo-5H-dibenzo[a,d]cycloheptene (**9g**)*

A mixture of the above alcohol (1 g) and *p*-toluenesulfonic acid (0.05 g) in toluene (40 ml) was heated to boiling and the azeotropic mixture was slowly collected for 3 h. Then the toluene solution was washed with a solution of sodium bicarbonate and dried. The solvent was evaporated to dryness and the residue recrystallized from ethanol to give 0.84 g (70%) of colorless plates melting at 117–118°; n.m.r.: 2.70 (7H multiplet, aromatic), 3.00 (2H quartet, CH=CH), 6.33 (2H singlet, CH_2).

Anal. Calcd. for $C_{15}H_{11}Br$: C, 66.42; H, 4.06; Br, 29.52. Found: C, 66.24; H, 4.01; Br, 29.35.

*2-Cyano-5H-dibenzo[a,d]cycloheptene (**9i**)*

A stirred mixture of **9***g* (0.6 g), freshly prepared cuprous cyanide (0.36 g) and *N*-methylpyrrolidone (23 ml) was refluxed for 3 h. To the resulting brown mixture was added a hot solution of 1.8 g of ferric chloride in 3.5 ml of 1.7 *N* hydrochloric acid. After heating the mixture at 60° for 20 min to decompose the complex, dilute hydrochloric acid was added and the organic material was extracted

TABLE 2. Analytical data for epoxides, 3

into four 25 ml portions of toluene. The extracts were washed with sodium hydroxide (10%), water, then dried and concentrated. The light brown solid residue obtained was purified by sublimation to give 0.38 g (79%) of light yellow crystals melting at 102.5–103.5°; i.r. ($CHCl_3$): 2250 (C≡N); n.m.r.: 2.60 (7H multiplet, aromatic), 2.92 (2H quartet, CH=CH), 6.25 (2H singlet, CH_2).

Anal. Calcd. for $C_{16}H_{11}N$; C, 88.48; H, 5.07; N, 6.45. Found: C, 88.40; H, 4.99; N, 6.27.

2-Carbomethoxy-5H-dibenzo[a,d]cycloheptene (9h)

To a solution of compound **9***i* (0.2 g) in ethylene glycol monoethyl ether (3 ml) was added a solution of potassium hydroxide (0.7 g) in water (0.5 ml). The resulting mixture was heated to 140° for 7 h with stirring. Then the solvent was removed, the residue dissolved in water, and the solution acidified with dilute sulfuric acid. The product was collected by filtration and dried in air. The yield was 0.2 g (92%) (m.p. 227–228°).

Into a solution of 0.1 g of this acid in ether was distilled an ethereal solution of diazomethane until the yellow color persisted. After evaporation of the solvent *in vacuo*, the residue was purified by sublimation to give 0.09 g (85%) of colorless crystals melting at 110–110.5°; i.r. ($CHCl_3$): 1700 (C=O); n.m.r.: 2.01 (1H singlet at C-1), 2.71 (6H multiplet, aromatic), 2.92 (2H singlet, CH=CH), 6.12 (3H singlet, CH_3), 6.23 (2H singlet, CH_2).

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.60; H, 5.60. Found: C, 81.70; H, 5.56.

2-Methoxy-5H-dibenzo[a,d]cycloheptene (9c)

Most of the reactions used for the preparation of **9***g* were used to obtain the methoxy derivative, **9***c*. Differences were that **10***c* was reduced to **11***c* with zinc in alkali (33) and the carboxyl group **11***c* was reduced to the primary alcohol with lithium aluminum hydride. The overall yield of **9***c* for the ten steps was 23%. The final product was a colorless solid, m.p. 131–132°, i.r. ($CHCl_3$): 2850, 1260 (CH_3O); n.m.r.: 2.76 (5H multiplet, aromatic), 3.00 (2H singlet, CH=CH), 3.16 (2H multiplet, aromatic protons at C-1 and C-3), 6.25 (3H singlet, CH_3), 6.33 (2H singlet, CH_2).

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.49; H, 6.31. Found: C, 86.64; H, 6.17.

2-Methyl-5H-dibenzo[a,d]cycloheptene (9d)

Compound **9***d* was prepared via the sequence of reactions used for the preparation of the 2-methoxy derivative starting with toluene instead of anisole. The yield was essentially the same at each step. Colorless plates melting at 137–138° were obtained from ethanol; n.m.r.: 2.80 (7H multiplet, aromatic), 3.00 (2H singlet, CH=CH), 6.31 (2H singlet, CH_2), 7.71 (3H singlet, CH_3).

Anal. Calcd. for $C_{16}H_{14}$: C, 93.20; H, 6.80. Found: C, 93.32; H, 6.97.

10,11-Dihydro-10,11-epoxy-5H-dibenzo[a,d]cycloheptene (3e)

5H-Dibenzo[*a*,*d*]cycloheptene (**9***e*) (1 g) was added to a solution of *m*-chloroperbenzoic acid (1.2 g) in chloroform (10 ml) and the mixture was stirred at room temperature for 20 h. The *m*-chlorobenzoic acid formed was removed by shaking with a 5% solution of sodium bicarbonate. The organic layer was dried, then evaporated to dryness *in vacuo*. The crude residue was recrystallized from ethanol to give 0.59 g (54%) of colorless plates melting at 144–145° (lit. m.p. 144–146°) (34); n.m.r.: 2.80 (8H multiplet, aromatic), 4.83 (1H doublet, axial proton of CH_2), 5.77 (2H singlet, epoxide protons), 6.69 (1H doublet, equatorial proton of CH_2).

Anal. Calcd. for $C_{15}H_{12}O$: C, 86.54; H, 5.77. Found: C, 86.42; H, 5.95.

2-Substituted 10,11-Dihydro-10,11-epoxy-5H-dibenzo-[a,d]cycloheptenes (3)

Five new 2-substituted 10,11-dihydro-10,11-epoxy-5H-dibenzo[*a*,*d*]cycloheptenes were obtained in yields of 50 to 60% from their olefinic derivatives as described for **3***e*. A list of the melting points and elemental analyses are given in Table 2. The n.m.r. spectra of all compounds were similar to that of **3***e* and completely consistent with structure.

The Effect of Substituents on Geminal Proton–Proton Coupling Constants; a Conformational Dependence. II

ROBERT R. FRASER AND ROGER N. RENAUD[1]
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received August 10, 1970

The effect of para-substituents on the geminal coupling constants in benzylic methylene groups has been studied as a function of the conformation at the benzene—CH_2 bond. The slopes of Hammett plots of J_{gem} *vs.* σ are large (-1.6 to -1.9) when the geometry permits a hyperconjugative interaction between the benzene ring and the methylene group but negligible ($+0.2$) when this interaction is geometrically restricted. The effect of a change in electronegativity of the group attached to the methylene carbon has also been investigated. The change in the slope, ρ, from -1.7 to -1.6 on protonation of the nitrogen attached to the methylene group in a series of isoindolines shows this effect to be extremely small. Solvent effects on ρ are also very small. The potential of this J–σ relation for conformational analysis of benzyl groups is discussed in comparison with existing methods.

Canadian Journal of Chemistry, **49**, 755 (1971)

The influence of an aromatic ring on the magnitude of a geminal coupling constant between the methylene protons at an adjacent carbon has been the subject of theoretical treatments (1, 2) and extensive experimental measurements (3). Both valence bond (v.b.) (1) and molecular orbital (m.o.) (2) methods have predicted the ring to provide a negative increment to the geminal coupling constant, the magnitude of which will be conformationally dependent. This increment results from a hyperconjugative interaction and will be maximal when the H–H axis of the methylene group is aligned parallel to the adjacent π orbitals of the aromatic ring. For this conformation the projected angle ϕ is 0° (see Fig. 1). A 90° rotation about the Ar—CH_2 bond produces a conformation which was predicted to have a minimal interaction between the aromatic ring and the geminal methylene group. Direct evidence pertinent to these theoretical predictions was provided by the independent observations of two groups of workers (4, 5). Both reported that the geminal coupling constants in the benzylic methylene groups of a series of para-substituted 2-benzyloxytetrahydropyrans showed a linear correlation with the Hammett sigma values of the para-substituents. In a second series a strikingly different effect was noted (4) in that invariant geminal coupling constants were found for a series of para-substituted benzyl phenyl sulfoxides. This led to the proposal (4) that the slope ρ, in the J_{gem} *vs.* σ plot, was conformationally dependent and should be proportional to $\cos^2\phi$.

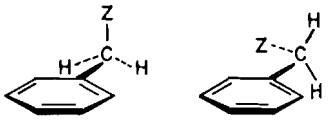

FIG. 1. The conformations in which maximal ($\phi = 0°$) and minimal ($\phi = 90°$) hyperconjugative enhancement of geminal coupling constants occur.

In order to continue an investigation of the angular dependence of ρ, we have undertaken the synthesis of three new series of para-substituted benzyl derivatives in which the benzylic methylene group is constrained in a definite orientation with respect to the adjacent benzene ring. The synthesis and conformational properties of the compounds studied herein will be described in an accompanying paper (6). In this article we wish to present the results of a determination of the coupling constants in each series of compounds which show that the sensitivity parameter ρ indeed appears to depend primarily on ϕ and only slightly on the electronegativity of the substituent attached to the benzylic methylene group.

[1]Present address: Division of Chemistry, National Research Council, Ottawa, Canada.

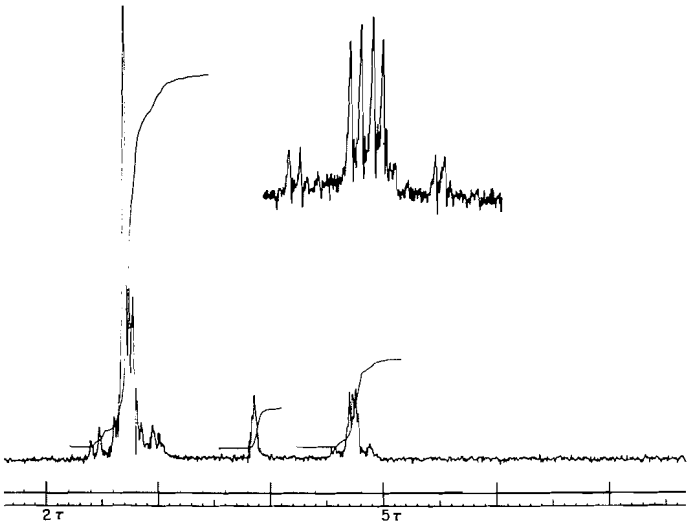

FIG. 2. The 100 MHz spectrum of 6-cyano-1-phenylphthalan (**1**, X = CN) (0.1 *M* in $CDCl_3$). The inset shows the absorption of the C-3 methylene protons during simultaneous irradiation at τ 2.7 (sweep-width 250 Hz).

Results

The systems chosen for study are the 1-phenylphthalans, **1**, the 2-methyl-1-phenylisoindolines, **2**, their conjugate acids, **3**, and the dibenzo[*a*,*d*]-cycloheptene-10,11-oxides, **4**. The n.m.r. spectra of series **1** and **2** were measured in deuterochloroform. For series **3** solutions of **2** in trifluoroacetic acid were studied. Series **4** was studied in two solvents, deuterochloroform and acetone-d_6. In series **1** and **2** the absorptions due to the methylene and methine protons in the five-membered ring comprised an ABX system because of the presence of appreciable cross-ring coupling. These long-range interactions have been noted previously in both systems (7–9). Other smaller long-range couplings between the aromatic and benzylic protons produce substantial line-broadening. These effects were adequately removed by double irradiation of the aromatic proton ortho to the methylene group. Figure 2 presents a typical spectrum of **1** (X = CN) in which the complete spectrum is shown, and, in the inset, the ABX portion appears on an expanded scale having been measured during double irradiation of the ortho aromatic proton at τ 2.7. In series **1** all ABX absorption patterns were analyzed using the LAOCN3 program of Castellano and Bothner-By (10). It was found that the differences between the spacings and the exact values for the long-range couplings were negligible (<0.1 Hz) and of course the geminal couplings[2] are directly obtainable from the experimental spectrum (11). For this reason first-order analysis was used for series **2** and **3**. In series **3** (**2** in trifluoroacetic acid) the spectra were remarkable in that the long-range cross-ring coupling constants were greatly reduced from those observed in **2**.[3] They were always less than 1.2 Hz and could not be accurately determined since several long-range couplings to the ring protons were also present, not all of which could be removed by multiple irradiation and, in addition, the spectrum consisted of absorptions due to two diastereomeric conjugate acids. In each diastereomer strong vicinal H—C—N—H coupling was present. The values for the geminal couplings were obtained by first-order analysis of the absorption due to the major diastereomer which always comprised 80% of the mixture. As a result of the above complications the parameters for series **3** are less accurate (±0.2 Hz). In series **4** the methylene group appears essentially as an AX pattern, the chemical shift difference between the diastereotopic methylene protons being 1.8 p.p.m. The large nonequivalence in shifts has precedence in observations on similarly

[2]The observation of a negative geminal coupling constant in 2,3-diphenylpropionic acid (31) supports the assumption that all geminal couplings reported herein are negative in sign.

[3]Similar effects due to increasing the effective electronegativity of the nitrogen atom have been reported by Gerig (8).

constrained diarylmethane derivatives (12, 13). The geminal coupling constants obtained by analysis of all four series of compounds are presented in Table 1.

Discussion of Results

In order to determine directly a geminal H–H coupling constant in any molecule, the molecule must itself be chiral (on the n.m.r. time scale) or else possess a pseudoasymmetric center. In view of the considerable difficulties inherent in the synthesis of any such series it was felt at the outset that it would be wiser to survey several limited series to determine whether or not a geometrical dependence of ρ is encountered, rather than to concentrate efforts on synthesis of a large number of compounds in any one series. Should the initial survey prove encouraging, more complete studies might prove advantageous later. We chose five as the minimum number of compounds necessary for a series with the requirement that they cover at least a range of one unit of Hammett σ values.

The results from Table 1 have been analyzed by the least squares method and the results of these analyses are presented in Table 2. In series **1–3** it can be seen that a good linear relation is present, the correlation coefficient being 0.976 or greater. A plot of J_{gem} *vs.* sigma[4] for the data in series **1** is presented in Fig. 3. The data for series **4** in deuterochloroform is presented in Fig. 4. Even though the correlation coefficient for this series is much lower (0.619) the deviations (in Hz) of individual points from the best straight line are smaller than in **1–3** so this series shows at least as good a correlation of J_{gem} with σ. Others have commented previously about the significance of correlation coefficients, pointing out the fact that they decrease as ρ decreases (14).

The magnitudes of ρ are −1.9, −1.7, −1.6, and +0.2 for series **1** through **4** respectively. The slight decrease in the ρ value in series **2** is of the

[4]It has been suggested to us that a more rigorous treatment would require plotting $\Delta J/J$ *vs.* σ in order to plot one dimensionless quantity against another (ΔJ represents the difference between geminal couplings in the para-substituted and unsubstituted benzyl groups). However, the value for J depends on several factors besides the hyperconjugative effect (2) and for this reason its inclusion would weaken the correlation.

order of accuracy of the correlations, and does not necessarily reflect a deviation from planarity in the isoindoline ring. If we assume that the projected angle ϕ in series **1–3** is zero,[5] then any variation in ρ for these series must be due to changes in internal bond angles or bond hybridizations resulting from a change in the electronegativity of the atom attached to the methylene group. The very slight difference in ρ's for series **2** relative to **3**, for which one of the largest possible changes in electronegativity has been made, indicates the electronegativity effect to be small. A point of concern in making this conclusion is what the effect of changing solvent might be. It has been widely recognized that solvent effects on J_{gem} are normally less than 0.2 Hz (15) and tend to make J_{gem} more negative as the dielectric constant of solvent is increased. The values in Tables 1 and 2 show that the changes in J_{gem} in series **4** using acetone solvent are small and that the solvent effect on ρ is negligible. One noteworthy point in comparing the data for series **4** in both solvents is that, in contrast to the findings of Smith and Cox (15), J_{gem} becomes more positive as the medium dielectric is increased.

The change in the value of J_{gem} for an individual member of series **2** relative to series **3** is of interest, the value becoming more negative by 1.2 ± 0.3 Hz on protonation. This change can be attributed to the dominant effect of removing the "lone pair" on the adjacent nitrogen atom (16) which overrides the effect of increasing the substituent electronegativity (2).

In contrast to the substantial negative slopes in series **1**, **2**, and **3**, series **4** shows a small positive slope of 0.2. The value of ϕ for the compounds in series **4** can be estimated from Dreiding models to be 72°. Thus the change in ρ is in qualitative agreement with a $\cos^2\phi$ relation. The experimental values can be compared with the existing theoretical predictions. Figure 5 shows the angular dependence of the increment to J_{gem} produced by a hyperconjugative interaction as calculated by (*a*) the $\cos^2\phi$ relation of Pople and Bothner-By (2), (*b*) a $\cos\phi \cdot \cos\phi'$ relation in which the angles describe the contributions from individual C—H bond m.o.'s, (*c*) the v.b. calculations of Barfield and Grant (1). It should be remembered that our ρ values

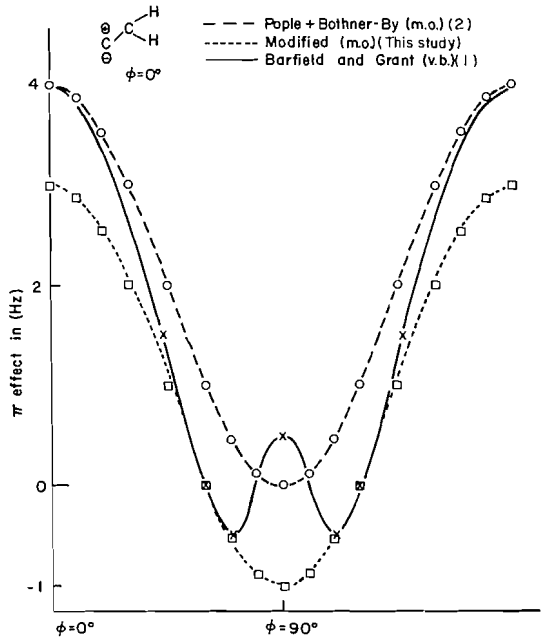

FIG. 5. A plot of the theoretical predictions for hyperconjugative enhancement of geminal coupling constants.

represent only a perturbation of the total hyperconjugative effect whose maximum magnitude has been estimated to be 4 Hz per π interaction (1, 3). The ρ values for series **1–4** are in good agreement with either relation (*b*) or (*c*). Data for a series in which $\phi = 90°$ will be of particular interest as it could distinguish between these alternatives.

In summary, the findings for series **1–4** provide support for the theoretical and experimental evidence that ρ is a conformationally dependent parameter. In spite of the limited scope of our investigations we feel the results are sufficiently promising to warrant further study, particularly in view of the scarcity of information regarding rotation about a benzene to carbon bond. Indeed, most examples of compounds in which conformational assignments to benzyl rotamers have been made, involved strong hindrance to rotation about the benzene—CH_2 bond. This allowed n.m.r. observation of individual rotamers. The compounds studied in this manner include 2,6-disubstituted benzyl halides (17), 2,6-dichlorobenzal chloride (18), 2,4,6-trimethylcumene (19), di-*t*-butylanisylcarbinol (20), and 1,2,3,4-tetramethyl-5,6-dineopentylbenzene (21). In addition,

[5]Justification for this assumption is presented in ref. 6.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

conformational assignments have been made to ortho-substituted benzotrifluorides (22) and related fluorotoluenes (23) on the basis of the temperature dependence of F–F coupling constants. In compounds lacking hindrance the barrier to rotation is very much lower, that in toluene having been reported to be 14 cal/mol (24). In freely rotating systems ρ offers the potential ability to determine the time-average of all existing conformations and in this way will provide an indication of the dominant conformer. For instance, our present results support the original claims (4) that the tetrahydropyranyl ethers possess a dominant conformation having $\phi = 0°$ while the sulfoxides have $\phi = 90°$ as their dominant conformation. Closely related to this are Chow's recent observations on para-substituted benzyl 2-methylpiperidines (25). Chow observed a correlation between J_{gem} and σ in this series which had a slope of -1.4 in carbon tetrachloride and 0.0 in 1 *N* deuterium chloride solution. He proposed a dominant conformation of $\phi = 0°$ in the former solvent, and either a change to $\phi = 90°$ or a medium effect being responsible for the decrease in ρ. Our results eliminate the medium effect as an explanation.

One other study of substituent effects on J_{gem} has been reported since our initial paper (4). Ripka and Applequist (26) determined the geminal coupling constants in a series of para-substituted toluenes by measuring the H–D coupling constants. From their data we estimate ρ to be -0.6. From our data the value for ρ in a freely rotating methyl group can be estimated as $\frac{1}{2}\cos^2\phi_{max}$ or 0.95. This discrepancy for the toluenes is not beyond the limits of accuracy of the method since their precision in J_{gem} is reduced sixfold by measuring J_{H-D} and only those toluenes bearing an electron-withdrawing para-substituent were examined.

An additional feature in the spectra obtained from series **1** and **2** is the presence of appreciable long-range couplings between protons on C-1 and -3. These couplings, listed in Table 3, show a slight increase with increasing substituent electronegativity. In series **1** the low field absorption is assigned to the proton at C-3 and *cis* to the phenyl group at position 1, for reasons put forward previously by Roberts and co-workers (27). This means $|J_{trans}| > |J_{cis}|$ in series **1**. In series **2**, it is the high field absorption which shows the larger long-range splitting. It is not possible to make an assignment of chemical shifts to the protons at C-3 in this series since the effects of the *N*-methyl group and the lone pair on nitrogen will be conformationally dependent (28) and not readily estimated. To make an assignment on the basis of $|J_{trans}| > |J_{cis}|$ in analogy with series **1** would be unwise since the long-range couplings are likely a composite of two effects (29).

Experimental

All spectra were recorded with a Varian HA 100 n.m.r. spectrometer using 0.3, 0.2, and 0.1 *M* solutions of each compound in series **1**. As no detectable difference in coupling constants was seen, 0.2 *M* solutions were used for series **2**, **3**, **4**. Spin-decoupling experiments were performed in the frequency-sweep mode. The spectral line positions were always determined from the average of at least ten measurements. Exact analyses of the ABX spectra in the 1-phenylphthalan series were performed using the LAOCN3 program (10) on an IBM 360 Model 65 computer. All slopes from the plotting of geminal coupling constants against Hammett substituent constants were obtained by a least squares analysis of the data using a program prepared by Dr. Gurudata. A paper describing the synthesis of all compounds studied herein appears in this issue (6). The chemical shifts and their substituent dependence will be described shortly (30).

The authors thank the National Research Council of Canada for financial support of this work. Discussions with Professor Bothner-By are greatly appreciated.

Nitrato and Acetylacetonato Complexes of Copper(I)

W. A. ANDERSON, A. J. CARTY,[1] G. J. PALENIK, AND G. SCHREIBER
Department of Chemistry, University of Waterloo, Waterloo, Ontario

Received July 28, 1970

Copper(I) nitrate complexes of the types L_2CuNO_3, L_3CuNO_3, and L_4CuNO_3 (L = tertiary phosphine) have been synthesized by reduction of copper(II) nitrate with tertiary phosphines. Infrared spectra and single crystal X-ray measurements indicate the presence of bidentate nitrate in L_2CuNO_3, monodentate nitrate in L_3CuNO_3, and ionic nitrate in L_4CuNO_3. The single crystal X-ray structure of nitratobis(tricyclohexylphosphine)copper(I) is reported. $CuO_3N(PC_{18}H_{33})_2$ crystallizes in the monoclinic space group $C2/c$ with $a = 18.18(1)$ Å, $b = 9.240(6)$ Å, $c = 22.41(2)$ Å, and $\beta = 96.57(5)°$. The structure was solved by the heavy atom method and refined with isotropic thermal parameters to an R of 0.14. The copper atom is tetrahedrally coordinated by two phosphorus atoms and two oxygen atoms of a bidentate nitrate group. The P—Cu—P angle (140(1)°) and Cu—P bond lengths (2.29(1) Å) are the largest reported for tetrahedral copper complexes.

A facile synthetic route to acetylacetonatobis(phosphine)copper(I) complexes is also described.

La réduction du nitrate de cuivre (II) avec des phosphines tertiaires (L) a permis de synthétiser des complexes du cuivre(I) de formules L_2CuNO_3, L_3CuNO_3 et L_4CuNO_3. La spectroscopie infrarouge et l'étude de monocristaux par rayons X indiquent que le groupe nitrate est bicoordiné dans L_2CuNO_3, monocoordiné dans L_3CuNO_3 et ionique dans L_4CuNO_3. On a déterminé au moyen de la diffraction des rayons X par monocristaux la structure du nitratobis(tricyclohexylphosphine)cuivre(I). $CuO_3N(PC_{18}H_{33})_2$ cristallise dans le système monoclinique, groupe spatial $C2/c$: $a = 18.18$ (1) Å, $b = 9.240$ (6) Å, $c = 22.41$ (2) Å et $\beta = 96.57$ (5)°. On a appliqué la méthode de l'atome lourd et, utilisant des facteurs thermiques isotropes, on a obtenu après affinement un facteur R égale à 0.14. Deux atomes de phosphore et les deux atomes d'oxygène d'un groupe nitrate bicoordiné assurent à l'atome de cuivre une coordination tétraédrique. L'angle P—Cu—P (140(1)°) et la longueur de liaison Cu—P (2.29 (1) Å) sont les plus grandes qu'on ait rapportés pour des composés tétraédriques du cuivre.

On présente également une méthode commode pour la synthèse des complexes acétylacétonatobis-(phosphine)cuivre(I).

Canadian Journal of Chemistry, 49, 761 (1971)

Introduction

The synthesis and stereochemistry of copper(I) complexes of tertiary phosphines are of current interest (1–11) because of the wide variety of structural types that have been found. X-Ray structural studies have revealed tetrahedral (1–5), pseudo-tetrahedral (6), a tetrahedral–trigonal dimer (7), dimeric (3), tetrameric (3), and polymeric (8) molecules including compounds with halogen (5, 7) and azide (4) bridges. Although several of the above complexes can be synthesized by the reduction of the appropriate copper(II) salt with the tertiary phosphine, the scope of this preparative method has not been explored. We have now extended the reaction of copper(II) nitrate with triphenylphosphine (13) to include a variety of other tertiary phosphines. Several new types of phosphine–copper(I) nitrate complexes have been prepared and the crystal structure of nitratobis(tricyclohexylphosphine)-copper(I) has been determined. An extension of the reaction to copper(II) acetylacetonates has provided a more convenient route to substituted acetylacetonatobis (tertiaryphosphine) copper(I) complexes than that previously reported (11, 12).

Experimental

The copper(II) nitrate trihydrate and acetylacetone were British Drug Houses reagent grade and the substituted acetylacetones were obtained from Columbia Organic Chemicals, Columbia, South Carolina. The tertiary phosphines were supplied by Orgmet Inc., Hampstead, New Hampshire in sealed ampoules and were subsequently handled *in vacuo* or in a Vacuum Atmospheres Corporation Dri-Lab filled with a 10% hydrogen–nitrogen mixture. All solvents were spectral grade and were thoroughly degassed before use.

Microanalyses were performed by A. B. Gygli, Toronto, Ontario and/or Chemalytics Inc., Tempe, Arizona. Molecular weights were measured by an osmometric method using benzene or chloroform as solvents (14). Infrared spectra were taken on Beckman IR-9 and IR-12 spectrometers and the frequencies are accurate to ± 2 cm^{-1}.

Preparations

Nitratobis(tri-m-tolylphosphine)copper(I)

Cupric nitrate trihydrate (0.5 g) in hot ethanol (30 ml) was added carefully to tri-*m*-tolylphosphine (*m*-tol$_3$P) (2 g) in hot ethanol (60 ml). The color of the copper(II) solution was discharged immediately and colorless crystals precipitated. Colorless needles were obtained after recrystallization from chloroform–ethanol, m.p. 166–167°.

Anal. Calcd. for [(*m*-tol)$_3$P]$_2$CuNO$_3$: C, 68.70; H, 5.77; N, 1.92. Found: C, 68.06; H, 6.04; N, 1.88.

Nitrato[bis(diphenylphosphino)methane]copper(I)

[(DPPM)CuNO$_3$] (DPPM = bis(diphenylphosphino) methane) was prepared in a similar manner and gave colorless crystals, m.p. 228° decomp.

Anal. Calcd. for [(DPPM)CuNO$_3$]: C, 58.88; H, 4.35; N, 2.74. Found: C, 59.03; H, 4.69; N, 2.73.

Nitratobis(tricyclohexylphosphine)copper(I)

(Cy$_3$P)$_2$CuNO$_3$ (Cy$_3$P = tricyclohexylphosphine) was prepared in a similar manner to give colorless crystals; m.p. 225–227°.

Anal. Calcd. for (Cy$_3$P)$_2$CuNO$_3$: C, 62.98; H, 9.69; N, 2.04. Found: C, 62.85; H, 9.56; N, 1.96.

Nitratotris(ethyldiphenylphosphine)copper(I)

Ethyldiphenylphosphine (EtPh$_2$P) (1 ml) in warm ethanol was treated with cupric nitrate in ethanol until the blue color was no longer discharged and a pale green color persisted. The total volume of ethanol was approximately 30 ml. Addition of cyclohexane (10 ml) and chilling gave colorless crystals which were recrystallized from ethanol–cyclohexane; m.p. 128–129°.

Anal. Calcd. for (EtPh$_2$P)$_3$CuNO$_3$ (mol. wt., 768): C, 65.66; H, 6.24; N, 1.82. Found (mol. wt., 758, benzene): C, 65.44; H, 6.27; N, 1.69.

Nitratotris(dimethylphenylphosphine)copper(I)

The product was prepared by the same method used for (EtPh$_2$P)$_3$CuNO$_3$. Recrystallization from ethanol–diethylether gave colorless prisms; m.p. 84–85°.

Anal. Calcd. for (Me$_2$PhP)$_3$CuNO$_3$ (mol. wt., 540): C, 53.4; H, 6.16; N, 2.59. Found (mol. wt., 527, chloroform); C, 52.28; H, 6.24; N, 2.55.

Nitratotris(methyldiphenylphosphine)copper(I)

A solution of methyldiphenylphosphonium nitrate in hot methanol was added to Cu(NO$_3$)$_2$.3H$_2$O (0.7 g) in methanol (30 ml) until the blue color was discharged. Refrigeration at 0° for 30 h gave colorless crystals which were recrystallized from methanol; m.p. 158–160°.

Anal. Calcd. for (MePh$_2$P)$_3$CuNO$_3$: C, 64.49; H, 5.38; N, 1.93. Found: C, 65.17; H, 5.55; N, 1.88.

The same product was obtained from the direct reaction of MePh$_2$P with cupric nitrate in ethanol.

Reaction of 1,2-Bis(diphenylphosphino)ethane (DPPE) with Cu(NO$_3$)$_2$.3H$_2$O

Reduction of copper(II) nitrate by DPPE in hot ethanol followed by addition of *n*-hexane yielded colorless crystals; m.p. 131–135° decomp. These crystals were occasionally contaminated with a light green product which could be removed manually, with the aid of a microscope.

Anal. Calcd. for (DPPE)$_3$(CuNO$_3$)$_2$: C, 64.77; H, 5.02; N, 1.94. Found: C, 64.34; H, 5.11; N, 2.41.

This complex is very unstable in halogenated solvents, yielding dark green solutions and evolving nitrogen dioxide.

A second product was isolated from solutions of (DPPE)$_3$(CuNO$_3$)$_2$ by bubbling oxygen through a refluxing ethanolic solution for 3 h. Large crystals of (DPPE)$_2$CuNO$_3$ were obtained on slow evaporation; m.p. 213–215°.

Anal. Calcd. for (DPPE)$_2$CuNO$_3$: C, 67.6; H, 5.24; N, 1.52. Found: C, 66.82; H, 5.69; N, 1.49.

Tetrakis(diphenylphosphinopropyne)copper(I) Nitrate

Cupric nitrate in hot ethanol was added to diphenylphosphinopropyne (DPPP) (1 g) in hot ethanol (10 ml) until a pale yellow color persisted. The solution began turning red after several minutes and addition of diethyl ether yielded the crude product contaminated with red oil. Recrystallization from ethanol–pentane–ether (1:1:20) mixtures gave colorless crystals; m.p. 176–178°.

Anal. Calcd. for [Cu(DPPP)$_4$]NO$_3$: C, 70.4; H, 5.11; N, 1.37. Found: C, 70.59; H, 5.08; N, 1.26.

Oxidation of 1,2-Bis(diphenylphosphino)ethane Complexes of Copper(I) in Halogenated Solvents

Dinitrato[1,2-Bis(diphenylphosphinyl)ethane]-copper(II)

(DPPE)$_3$(CuNO$_3$)$_2$ (0.3 g) was dissolved in dichloromethane (7 ml) with evolution of brown fumes and production of a green solution. High boiling petroleum ether (6 ml) was added and the solution cooled for several weeks to yield bright green crystals; m.p. 225–226°.

Anal. Calcd. for (DPDO)$_2$Cu(NO$_3$)$_2$ (DPDO = 1,2-bis(diphenylphosphinyl)ethane): C, 58.6; H, 4.61. Found: C, 58.88; H, 4.61.

Dichlorobis[1,2-bis(diphenylphosphinyl)ethane]-copper(II)

The complex [CuCl(DPPE)]$_3$ (6) was dissolved in hot chloroform and allowed to stand in air for several days. The solution became green and deposited yellow-green crystals; m.p. 278–280°.

Anal. Calcd. for [CuCl$_2$(DPDO)]: C, 55.30; H, 4.29; Cl, 12.54. Found: C, 55.52; H, 4.55; Cl, 12.69.

Hexafluoroacetylacetonatobis(triphenylphosphine)-copper(I), Trifluoroacetylacetonatobis(triphenylphosphine)copper(I), and Thienyltrifluoroacetylacetonatobis(triphenylphosphine)copper(I)

The bis chelates Cu(hfac)$_2$, Cu(tfac)$_2$, and Cu(ttfac)$_2$, where hfac is hexafluoroacetylacetone, tfac is trifluoroacetylacetone, and ttfac is thienyltrifluoroacetylacetone, were prepared by published procedures (15–17). The chelates were purified by recrystallization from benzene (Cu(hfac)$_2$ and Cu(tfac)$_2$) or by soxhlet extraction with chloroform (Cu(ttfac)$_2$).

The copper(I) complexes were prepared by adding a stoichiometric quantity of triphenylphosphine in warm ethanol to 0.001 mol of copper(II) chelate in the same solvent. The color of the copper(II) solution gradually changed to the lighter color of the phosphine adduct. The complexes were recrystallized from ethanol.

(Ph$_3$P)$_2$Cu(hfac); yellow needles, m.p. 154°.

Anal. Calcd.: C, 61.93; H, 3.93. Found: C, 61.93; H, 3.88.

(Ph$_3$P)$_2$Cu(tfac); yellow-orange crystals, m.p. 121°.

Anal. Calcd.: C, 66.42; H, 4.13. Found: C, 66.32; H, 4.10.

TABLE 1. Infrared spectra (1500–1700 cm^{-1}) for acetylacetonate complexes

Complex	Frequency (cm^{-1})
$(Ph_3P)_2Cu(hfac)$	1649s, 1590vw, 1576vw, 1546w, 1518sh, 1505s
$(Ph_3P)_2Cu(tfac)$	1630s, 1589vw, 1542vw
$(Ph_3P)_2Cu(ttfac)$	1614s, 1588sh, 1528s, 1509m

$(Ph_3P)_2Cu(ttfac)$; orange-yellow needles, m.p. 123°. Mol. wt. calcd. (4 molecules per unit cell): 809.3. Found (X-ray): 807.3. The molecular structures of all three substituted acetylacetonato complexes have been determined by X-ray methods (18).

Attempts to reduce bis(acetylacetonato)copper(II) with triphenylphosphine under a variety of experimental conditions were unsuccessful. Addition of trimethyl and triethyl phosphines to copper(II) nitrate resulted in reduction to copper(I) as evidenced by complete removal of the blue color of copper(II). However, attempts to obtain crystalline complexes from these solutions yielded only sticky, colorless oils which could not be induced to crystallize. Infrared spectra of these oils revealed the presence of only ionic nitrate bands in addition to phosphine absorptions.

Results and Discussion

Acetylacetonate Complexes

Reduction of copper(II) acetylacetonates with triphenylphosphine in ethanolic solution yields complexes of formulae $(Ph_3P)_2Cu(B)$ (B = anion of hexafluoroacetylacetone, trifluoroacetylacetone, and thienyltrifluoroacetylacetone). Previous investigators have used either the metathetical reaction of $(Ph_3P)_2CuCl$ with thallium(I) acetylacetonate (11) or the reaction of $(Ph_3P)_2CuBH_4$ with acetylacetone (12) to obtain copper(I) acetylacetonato complexes. The method described herein is considerably more convenient than either of the above syntheses.

The failure of triphenylphosphine to reduce copper(II) acetylacetonate is rather surprising. However, the substituted acetylacetonate ligands are poorer donors than the acetylacetone anion and hence form weaker complexes with copper(II). Moreover, the ability of a tertiary phosphine to reduce copper(II) salts in solution will clearly be related not only to the R_3P/R_3PO oxidation–reduction potential but also to the stability to reduction of the original copper(II) salt.

The infrared spectra of the acetylacetonates between 1700–1500 cm^{-1} are shown in Table 1. Agreement is reasonable with frequencies previously reported (11) for the hexafluoro- and trifluoro derivatives. Strong absorptions in this region of the spectrum are due to coupled ν(C=O) and ν(C=C) modes. If the frequency of the highest absorption band is taken as a rough estimate of the strength of the donor–acceptor interaction between the anion and copper, the results suggest that the strongest C=O bonds (and weakest Cu—O interaction) occur in the hexafluoro complex. This is borne out by the X-ray data for $(Ph_3P)_2Cu(hfac)$ (18) where the C—O and Cu—O average bond lengths are 1.240 and 2.120 Å, respectively compared with $(Ph_3P)_2Cu(ttfac)$ (C—O, 1.247 Å; Cu—O, 2.102 Å) and $(Ph_3P)_2Cu(tfac)$ (C—O, 1.247 Å; Cu—O, 2.086 Å). Comparison of frequencies and bond lengths for $(Ph_3P)_2Cu(ttfac)$ and $(Ph_3P)_2Cu(tfac)$ shows no such correlation, however, thus pointing out the dangers of an oversimplified approach to the interpretation of frequency shifts.

Nitrate Complexes

Complexes of the formulae $L_2Cu(NO_3)$ (L = (*m*-tol)$_3$P, Cy_3P, ½DPPM), $L_3Cu(NO_3)$ (L = $EtPh_2P$, $MePh_2P$, Me_2PhP), $L_4Cu(NO_3)$ (L = ½DPPE, DPPP), $L_3(CuNO_3)_2$ (L = DPPE) have been synthesized by reaction of copper(II) nitrate trihydrate with tertiary phosphines in ethanolic solution. Since the simple copper(I) nitrate is unknown, this method provides the most facile route to nitrato complexes of copper(I). Although the majority of copper(I) halide – tertiary phosphine complexes have been prepared from copper(I) halides by prolonged reaction with phosphines (12), a recent paper (19) has also demonstrated that simple reduction of copper(II) halides is an alternative method of synthesis.

Compounds of the type $L_2Cu(NO_3)$ are analogous to $(Ph_3P)_2CuNO_3$ prepared earlier by Cotton and Goodgame (13). The crystal structure of $(Ph_3P)_2CuNO_3$ has recently been reported (2). The copper atom is approximately tetrahedrally coordinated by two phosphine molecules and a bidentate nitrate group. The infrared spectra of the new compounds $[(m\text{-tol})_3P]_2CuNO_3$, $(Cy_3P)_2CuNO_3$, and $(DPPM)CuNO_3$ are virtually identical with that of $(Ph_3P)_2CuNO_3$ in the regions of

nitrate absorption (Table 2). This argues strongly in favor of similar bidentate behavior for nitrate in these compounds. In the case of (DPPM)-$CuNO_3$, a formulation involving bidentate nitrate and tetrahedral copper(I) presupposes either a chelating or bridging diphosphine molecule. We have now confirmed the bidentate coordination of nitrate ion in $(Cy_3P)_2CuNO_3$ by a single crystal X-ray diffraction study. Crystal data are

$C_{36}H_{66}P_2CuNO_3$ mol. wt. = 686.42

Monoclinic crystals, space group $C2/c$ (from intensity statistics), $a = 18.18(1)$ Å, $b = 9.240(6)$ Å, $c = 22.41(2)$ Å, $\beta = 96.57(5)$, $U = 3740.2$ Å^3, $D_m = 1.206$ g/cm^3, $D_c = 1.218$ g/cm^3, and $Z = 4$.

The positions of the copper and phosphorus atoms were determined by examining the sharpened three dimensional Patterson function. Successive Fourier syntheses were used to locate the remaining light atoms. The structure was refined by isotropic least-squares methods to an R of 0.14.[2]

[2]Due to instrumental problems this is the limit of refinement justified by the quality of our data.

The main features of interest are the copper–phosphorus bond distance of 2.29(1) Å, the P—Cu—P angle of 140(1)° and the bidentate nitrate group. The P—Cu—P angle is one of the largest observed to date for a presumably tetrahedral copper(I)–phosphine complex. Furthermore the Cu—P bond length is the longest found in a series of similar complexes (18). Since the tricyclohexylphosphine is very bulky, apparently steric factors have a strong influence on the dimensions of copper(I)–phosphine complexes. A detailed analysis of factors affecting bond angles and bond lengths in copper(I) complexes will be presented elsewhere.

The nitrate group is bonded symmetrically in bidentate fashion to the copper atom with the terminal N—O bond lying on a twofold axis of symmetry and a Cu—O distance of 2.34(2) Å. In view of the obvious similarity to the structure of $(Ph_3P)_2CuNO_3$ (2), further discussion is unwarranted.[3]

The trisphosphine complexes of the type L_3CuNO_3 have nitrate spectra which differ considerably from the spectra of the bis complexes containing bidentate nitrate (Table 2). In particular, the two highest frequency nitrate bands which arise from removal of the degeneracy of the ν_3 NO_3^- mode on coordination are separated by < 125 cm^{-1} whereas for the bis species, ν_1 and ν_4 of the bidentate nitrate differ in frequency by > 150 cm^{-1}. ν_6 for $(EtPh_2P)_3CuNO_3$ and $(Me_2PhP)_3CuNO_3$ is also at higher frequency than in L_2CuNO_3. These results suggest either monodentate or very weakly bonded bidentate nitrate in these complexes. While it is not possible from vibrational spectroscopy, without Raman polarization data, to establish positively the monodentate or bidentate coordination of nitrate, the known preference of copper(I) for tetrahedral coordination and the low polarizing power of a copper(I) ion attached to three phosphine molecules leads us to favor a unidentate formulation in the complexes L_3CuNO_3. Molecular weight measurements on $(Me_2PhP)_3CuNO_3$ and $(EtPh_2P)_3CuNO_3$ reveal that the compounds are monomeric and undissociated in solution. Single crystal X-ray measurements in this laboratory

[3]Photocopies of tables of atomic positional parameters and related data may be obtained free of charge, upon request, from the Depository of Unpublished Data, National Research Council Library, National Research Council of Canada, Ottawa, Canada.

For personal use only.

have now confirmed the monodentate behavior of nitrate in $(MePh_2P)_3CuNO_3$. These complexes thus belong to a relatively small group of molecules in which the unidentate nature of coordinated nitrate has been definitely established by X-ray methods (21).[4]

The complex $(DPPE)_3(CuNO_3)_2$ has the same molecular formula as $(DPPA)_3(CuNO_3)_2$ (DPPA = bis(diphenylphosphino)acetylene) which has been shown to be a binuclear diphosphine bridged complex containing pseudo tetrahedral copper atoms (10). Since 1,2-bis(diphenylphosphino)-ethane can also behave as a bridging ligand (10), a similar structure seems likely for $(DPPE)_3$-$(CuNO_3)_2$.

The third class of compounds prepared are exemplified by $[(DPPE)_2Cu]NO_3$ and $[(DPPP)_4$-$Cu]NO_3$. Both compounds contain ionic nitrate only and in the latter, $\nu(C{\equiv}C)$ of the ligand appears at 2205 cm^{-1}, 5 cm^{-1} higher than in the free ligand, thus confirming the absence of coordination via the triple bond. Both complexes are clearly analogous to $[Cu(PPh_3)_4]ClO_4$ and $[Cu(PPh_3)_4]BrO_3$ prepared earlier by Cotton and Goodgame (13). These are nevertheless the first ionic copper(I) nitrate complexes prepared by direct reaction of a copper(II) salt with a tertiary phosphine and demonstrate that nitrate groups can be displaced from copper provided a suitable phosphorus donor is chosen.

Finally the compounds $(DPDO)CuCl_2$ and $(DPDO)_2Cu(NO_3)_2$, derived from $[(DPPE)$-$CuCl]_3$ and $(DPPE)_3(CuNO_3)_2$, respectively, by atmospheric oxidation in the presence of a halogenated solvent, are worth mentioning. All of the nitrate complexes described in this paper (with the possible exception of $(DPPM)(CuNO_3)$ which is rather insoluble in halogenated solvents) give blue-green solutions on standing for several days in $CHCl_3$ or CH_2Cl_2. Phosphine oxide complexes of copper(II) can be readily crystallized from these solutions on slow evaporation. However, we have only characterized the complexes of $Ph_2P(O)CH_2CH_2P(O)Ph_2$ since we were interested in the coordinating properties of this ligand and in the possibility of chelation involving a seven-membered ring. Both complexes show several strong bands in the infrared between 1050–1200 cm^{-1} due to P=O stretching. $(DPDO)CuCl_2$: 1195vs, 1171vs, 1160vs, 1140vs, 1125vs, 1085. $(DPDO)_2Cu(NO_3)_2$: 1140vs, 1122vs, 1086s. DPDO: 1182sh, 1170vs, 1120vs, 1100m, 1085m, 1070m. The spectra of the free ligand and complexes are so complex in the ν(P=O) region that little information, if any, can be gleaned concerning the magnitude of the shift in the P=O stretching frequency on complexing.

X-Ray studies on $(DPDO)CuCl_2$ have revealed a polymeric structure with a distorted tetrahedral configuration around copper and bridging $Ph_2P(O)CH_2CH_2P(O)Ph_2$ moieties (22). Nitrate absorptions for $(DPDO)_2Cu(NO_3)_2$ confirm the presence of coordinated nitrate in this compound (1496vs, 1290vs, 1015m, 802w). A polymeric structure based on octahedral copper(II) and monodentate nitrate groups therefore seems most likely for this species. Both of the above complexes are highly crystalline even though polymeric in the solid state. Although other workers (23) have usually formulated diphosphine dioxide complexes as monomeric species having chelating ligands, polymeric formulations now seem more reasonable.

The series of copper(I) nitrate complexes described would seem to indicate that the stoichiometry of a complex crystallizing from solution is not a simple function of the basicity of the ligand involved. The evidence suggests that replacement of electron withdrawing aryl groups on phosphorus by electron donating alkyl groups favors an increase in the number of molecules of phosphine coordinated.

Compare, for example, the pK_a values for Ph_3P (2.73), Ph_2EtP (4.49), and Me_2PhP (6.49) with the stoichiometry of the complexes formed. However, Cy_3P, a ligand of high basicity (pK_a = 9.70) but large size, gives only $(Cy_3P)_2CuNO_3$ and the electron withdrawing nature of the $-C{\equiv}CCH_3$ group does not prevent formation of $[(DPPP)_4Cu]NO_3$. Apparently, as in other systems (14), prediction of stoichiometry based on ligand properties alone can be misleading.

We acknowledge the support of the National Research Council of Canada.

[4]A recent paper (24) has suggested that X-ray crystallographic evidence for monodentate nitrate coordination is non-existent. This assumption is erroneous.

Peptide Conformations. I. Nuclear Magnetic Resonance Study of the Carbamate Reaction of Amino Acids and Peptides[1]

R. U. LEMIEUX AND M. A. BARTON[2]
University of Alberta, Department of Chemistry, Edmonton, Alberta

Received August 12, 1970

Nuclear magnetic resonance spectroscopy has been applied to the study of carbamate formation in solutions of amino acids and peptides in a carbonate–bicarbonate system. The possible conformations of these carbamates are discussed in terms of the n.m.r. data obtained. The n.m.r. parameters are reported for the diastereomers L-alanyl-L or D-phenylalanine and L-phenylalanyl-L or D-alanine and for the dipeptide glycyl-L-phenylalanine and their carbamates. The results are interpreted in terms of preferred rotamers about the C_α—C_β bond of the phenylalanine residue and a β-type conformation of the peptide chain, wherein the two α-protons lie in the plane of the amide bond. All observations are in agreement with a shorter end to end distance in L,D- compared with L,L-dipeptides.

Canadian Journal of Chemistry, 49, 767 (1971)

Introduction

Amines, amino acids and peptides enter into equilibrium with their carbamate derivatives ($RHNCO_2Na$) in weakly alkaline aqueous carbonate.

$$2NaHCO_3 \rightleftarrows Na_2CO_3 + H_2CO_3$$

$$H_2CO_3 \rightleftarrows CO_2 + H_2O$$

$$Na_2CO_3 + H_2O \rightleftarrows NaHCO_3 + NaOH$$

$$RHNH + CO_2 + NaOH \rightleftarrows RHNCO_2Na + H_2O$$

Mild alkalinity is required to maintain free amine and an adequate concentration of carbon dioxide. Caplow (1) has proposed a detailed reaction scheme. The reaction has also been studied by other workers (2–9). Carbamate formation occurs at the terminal amino groups of hemoglobin in the blood stream and thus is important for the physiological transport of carbon dioxide. A carbamate derivative, *N*-carboxybiotin, is also formed as an intermediate in some enzyme catalyzed carbon dioxide transfer reactions (10–12).

The studies of carbamate formation have generally depended on the physical separation of the reaction products. In the present work we report the observation of carbamate formation by p.m.r. spectroscopy. This method provides an experimentally simple means of distinguishing the reaction products in the intact equilibrium mixture. We have made use of the carbamate reaction in an investigation of dipeptide conformations.

[1]Presented in part at the Annual Meeting of the Canadian Federation of Biological Societies, Montreal, Quebec, June 12th, 1970.

Experimental

The amino acids were recrystallized to high purity. The dipeptides were prepared by coupling of the benzyloxycarbonyl amino acid and amino acid methyl ester using dicyclohexylcarbodiimide according to conventional procedures (13). Saponification and hydrogenation yielded the free dipeptides having the following physical constants: glycyl-L-phenylalanine, $[\alpha]_D^{25}$ +40.0°, *c* 2, water (lit. value (14), $[\alpha]_D^{25}$ +41.5°, *c* 2, water); L-phenylalanyl-L-alanine, $[\alpha]_D^{20}$ +12.7°, *c* 2, water (lit. value (15), $[\alpha]_D^{20}$ +12.8°, *c* 2, water); L-phenylalanyl-D-alanine, Anal. Calcd. for $C_{12}H_{16}N_2O_3$: C, 61.00; H, 6.83; N, 11.86. Found: C, 61.04; H, 6.94; N, 11.81, $[\alpha]_D^{25}$ +119°, *c* 2, water; L-alanyl-L-phenylalanine, Found: C, 60.93; H, 6.53; N, 11.77, $[\alpha]_D^{25}$ +38.8°, *c* 2, water; L-alanyl-D-phenylalanine, Found: C, 60.92; H, 6.62; N, 11.93; $[\alpha]_D^{25}$ −16.4°, *c* 2, water.

Molar solutions of the sodium salts in deuterium oxide were prepared by adding equivalent amounts to NaOD in deuterium oxide (1.7 *M*) followed by dilution. In order to observe carbamate formation at various p*H*'s in the range 8–12, the p*H* of an aliquot of the *M* solution was adjusted, using DCl (6.4 *M*) in deuterium oxide, to that required. This solution was then mixed with a molar solution of sodium carbonate in deuterium oxide whose p*H* had been adjusted to that required in the same way. In all experiments 1 mol of the amino compound was present per mol of added carbonate and the solution was 0.5 *M* in the amino compound used. The p*H*'s recorded in Fig. 2 were determined at the temperature of the n.m.r. probe immediately before obtaining the spectrum. The solutions were kept a further 24 h and the spectra were redetermined to ensure that equilibrium conditions had been achieved. The peaks assigned to the carbamate derivative were not observed in control experiments wherein sodium carbonate had not been added.

The n.m.r. spectra were obtained using a Varian A56/60 spectrometer, operating at 40 °C with tetramethylsilane as external reference. The increased sensitivity of the Varian HA-100 spectrometer, operating at 33 °C, was required for the dipeptides. The chemical shifts and coupling constants were determined using pyrazine as internal standard. In order to avoid the possible effect of pyrazine on the equilibrium for the carbamate reaction, the equilibrium data at 100 MHz were obtained

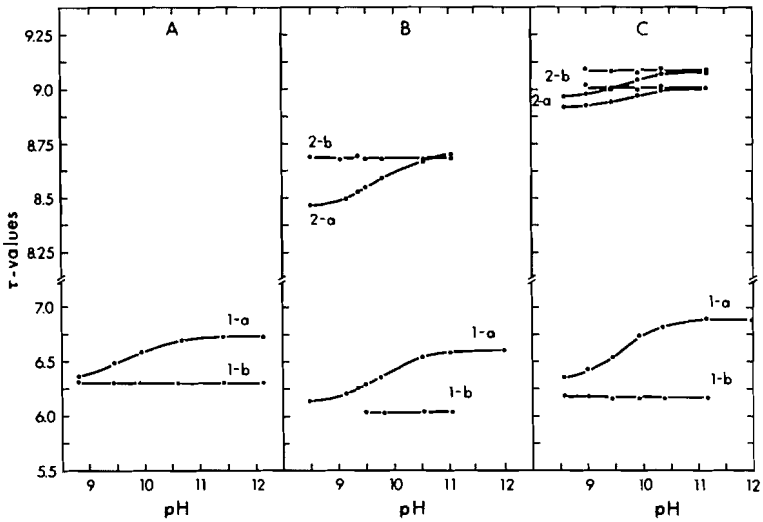

FIG. 1. Chemical shift as a function of p*H* in equilibrium mixtures of amino acid and carbamate, obtained from 0.5 *M* solution of amino acid in 0.5 *M* sodium carbonate – bicarbonate buffer in D_2O (A, glycine; B, alanine; C, valine): 1, α-protons; 2, methyl protons; a, amino acid; b, carbamate.

using hexamethyldisilane as external reference. The chemical shifts reported herein are all relative to tetramethylsilane as external reference at 60 MHz in the A56/60 spectrometer. These were calculated on the basis of the chemical shifts of pyrazine and 3-(trimethyl)-1-propane sulfonic acid sodium salt in both spectrometers relative to the external references mentioned above. In the p*H* range 2–12 the chemical shifts (τ) of the reference compounds were as follows: external tetramethylsilane, 10.00; external hexamethyldisilane, 10.11; 3-(trimethyl)-1-propane sulfonic acid sodium salt, 10.28; pyrazine, 1.55. A plot of chemical shift against p*H* showed the pyrazine resonance to move downfield in the range p*H* 0–2. At p*H* 0.5 the chemical shift of pyrazine was τ 1.14.

The three coupling constants characteristic of the ABX system of the phenylalanine residue in dipeptides were obtained from spectra recorded at a sweep width of 250 Hz. The geminal coupling constant of the glycyl residue in glycyl-L-phenylalanine was determined at the same sweep width.

Results and Discussion

We have studied the extent of carbamate formation in deuterium oxide solutions of the amino acids glycine, alanine, valine, α-amino-isobutyric acid, lysine and histidine over the p*H* range 7–12, in a carbonate–bicarbonate system. In this p*H* range, equilibria are established between the zwitterionic and anionic forms of the amino acid, and between the amino acid anion and carbamate derivative. The rapid exchange between zwitterion and anion leads to a time-averaged spectrum for these species. However, the rate of exchange between the carbamate derivative and the amino acid is sufficiently slow to give separate peaks for the carbamate and thus the extent of carbamate formation can be determined by integration. The carbamate peaks are readily identifiable since their positions are independent of p*H* under their conditions of formation. The time-averaged peaks of the zwitterion and anion move upfield with increase in p*H*, due to dissociation of the ammonium group. The assignment of the p*H*-independent spectrum to carbamate was confirmed by the use of ^{13}C-enriched (58%) carbon dioxide, since the α-proton of the amino acid in the presumed carbamate produced a signal which displayed the expected coupling with the ^{13}C-atom. The results obtained with ^{13}C-labelled carbamates, including the measurement of $^{13}C—N—C—H$ coupling constants, will be discussed in a subsequent paper.

The chemical shifts of the α-hydrogens of glycine, alanine and valine in the p*H* range 9–12 are plotted in Fig. 1. The decreased shielding observed as the α-amino group is liberated, is well known (16). In contrast, it is seen that the chemical shifts for these hydrogens in the carbamate derivative are p*H* independent.

Figure 2 reports the effect of p*H* on the equilibrium of the carbamate forming reaction for the three amino acids, glycine, valine, and

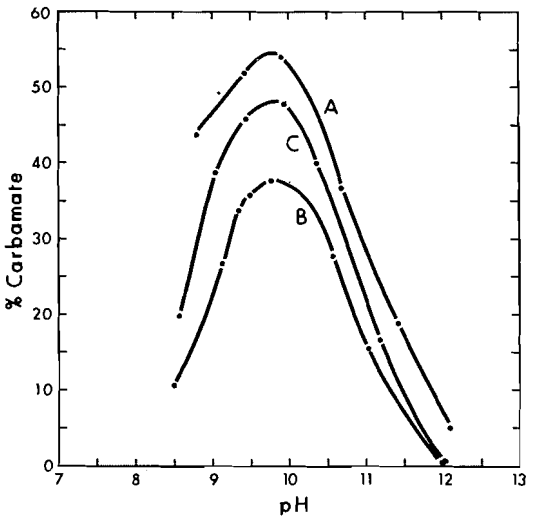

FIG. 2. Variation of percentage carbamate with change in p*H* in equilibrium mixtures obtained from 0.5 *M* solutions of amino acid in 0.5 *M* sodium carbonate – bicarbonate buffer in D_2O: (A, glycine; B, alanine; C, valine).

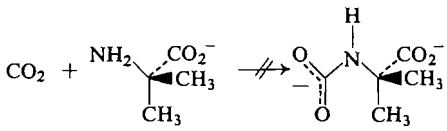
alanine. It is seen that the optimum p*H* is about p*H* 9.8 in all cases. The pK_a's of the amine group for these amino acids are 9.60, 9.62, and 9.69, respectively, in good agreement with the optimum p*H* for extent of carbamate formation. Increasing alkalinity is expected to depress the concentration of carbonic acid, which is considered to be the precursor in the rate controlling stage for carbamate formation. Strong support for this contention was found by Giustina *et al.* (17), who showed that the addition of carbonic anhydrase, an enzyme known to catalyze the dehydration of carbonic acid to carbon dioxide, caused carbamate formation to occur at an increased rate. Thus increased alkalinity not only depresses the extent of carbamate formation but also the rate of carbamate formation. In keeping with these known characteristics of carbamate formation, integrations of the signals obtained in the n.m.r. spectra of solutions of sodium glycinate with equimolar amounts of sodium carbonate after various reaction times showed the reaction to reach equilibrium in less than 1 h at p*H*'s below 9.8 but that increasingly longer reaction times were required at higher p*H*'s up to about 6 h at p*H* 11.6.

Carbamate formation was not observed at the imidazole group (pK_a 5.97) of histidine. However in the p*H* range 8.7–10.7, carbamate formation was clearly indicated at the α-amino group (Fig. 3). In the case of lysine, carbamate formation at the α-position clearly occurred in the p*H* range 9.4 to 10. At higher p*H*'s, carbamate formation was evident at both amino groups. The pK_a's of the amino groups of lysine are 8.90 and 10.28. In summary, n.m.r. spectroscopy can serve as a convenient tool to monitor carbamate formation in deuterium oxide solutions.

It was found that α-aminoisobutyric acid (**1**) did not form a detectable amount of carbamate under conditions where valine gave about 50% yield. Carbamate formation should have been detected by the presence of a p*H* independent peak due to the carbamate methyl group. In practice only the p*H* dependent signal of the methyl group of the free amino acid was obtained.



I

We consider this result to be important since it indicates that the general conformation of a carbamate contains the α-proton in non-bonded interaction with an oxygen atom of the carbamate group. In α-aminoisobutyric acid a methyl group is substituted for the α-hydrogen, a strongly unfavorable interaction is therefore introduced, and the carbamate is destabilized.

This conclusion appears supported by the strong deshielding observed for the α-hydrogen on carbamate formation. That is, strong electrostatic deshielding of the α-hydrogen can be expected should the carbamate exist largely in the conformation **2***a*. Although resonance stabilization of the negative charge of the carbamate group cannot be expected to involve the nitrogen atom, it seems likely that the grouping is planar in order to achieve coplanarity of a C—O and the N—H bond. Regardless of whether the nitrogen is trigonal or tetrahedral, clearly conformations which bring an oxygen in *syn*-axial-like relationship with the α-hydrogen seem energetically most favorable in view of the undoubtedly planar $-CO_2^-$ group. It is of interest to note in this regard the analogy between the deshielding effects observed for carbamates and amides depending on whether there are only one or two α-hydrogens. In the case of amides, as seen in

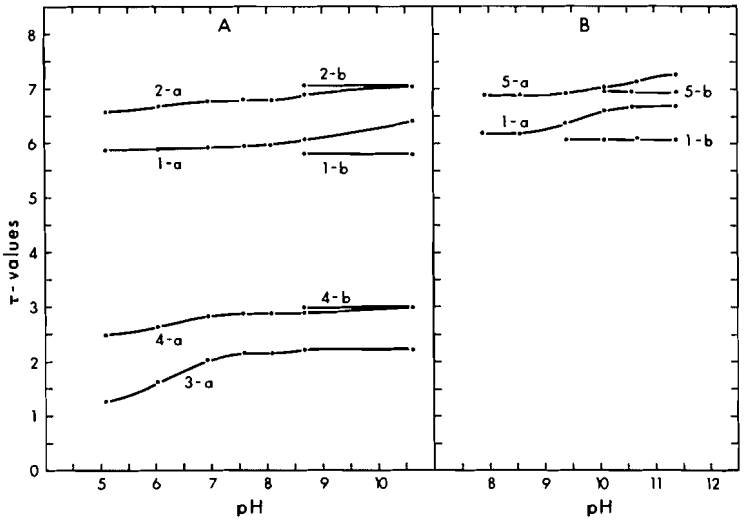


FIG. 3. Chemical shift as a function of p*H* in equilibrium mixtures of amino acid and carbamate, obtained from 0.5 *M* solution of amino acid in 0.5 *M* sodium carbonate – bicarbonate buffer in D_2O (A, histidine; B, lysine): 1, α-protons; 2, β-protons; 3, H-2 protons (imidazole); 4, H-4 protons (imidazole); 5, ε-protons; *a*, amino acid; *b*, carbamate.

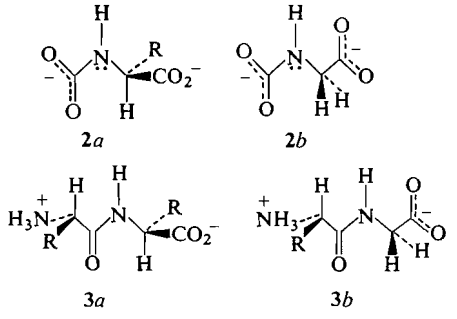
Table 1, the chemical shifts for the *N*-acyl derivatives of glycine as compared to glycine are substantially less (about 0.4 τ-values) than when the amino acid has only one α-hydrogen. This difference can be ascribed to the carbonyl oxygen bisecting the H—C—H angle in the case of the *N*-acyl glycines (**3***b*) but in much closer non-bonded interaction with methine α-hydrogens, **3***a* (18). As seen from Table 1, the carbamates for glycine show differences in chemical shift that are about 0.2 τ-values less than those of the other amino acids which have only one α-hydrogen. For these reasons, it can be expected that the carbamates of glycine exist mainly in the conformation depicted in **2***b* rather than conformations corresponding to **2***a* with R = H.

It can be seen that the arrangement about the N—C_α bond in our proposed carbamate conformation, **2***a*, is identical to that in the β-type structure of a dipeptide, **3***a*. The β-structure, with both α-protons in the plane of the amide link has recently been proposed by Lande (19) as accounting for many of the observed properties of dipeptides and the analogy with the carbamates is a further indication of the importance of this conformation.



2*a* **2***b*

3*a* **3***b*

In the course of this study we obtained the n.m.r. parameters for two pairs of diastereomeric peptides L-phenylalanyl-L or D-alanine and L-alanyl-L or D-phenylalanine, and also for the dipeptide glycyl-L-phenylalanine. The peak positions obtained for each of these peptides, in acid, basic and neutral solution, are given in Tables 2–4. In general the —CH_2—CH— system of the phenylalanine residue gave a well resolved 12-line pattern of the ABX type and the three coupling constants could be obtained on this basis. In the case of L-phenylalanyl-D-alanine anion, the spectrum collapsed to a six-line pattern and only the average of the vicinal coupling constants was obtained. The coupling constants J_{AX} (*vic*), J_{BX} (*vic*), and J_{AB} (*gem*) and the chemical shifts of the A and B protons are included in Tables 2–4. The high field resonance is assigned to the B proton.

From Tables 2 and 3 it can be seen that the CH_3 resonance is always shifted upfield in the L,D-peptides compared to the corresponding L,L-isomers. This effect has been noted in many

pairs of dipeptide diastereoisomers containing an aromatic function (20–22). It is known from the work of Kenner and co-workers (23–25) that peptides containing some D-amino acids show a shorter end-to-end distance than do all L-peptides. In the case of dipeptides these results find a ready explanation if the conformation of both L,L- and L,D-peptides is assumed to be of the β-type, ***4a*** and *b* (19).

In this conformation the charged groups exist

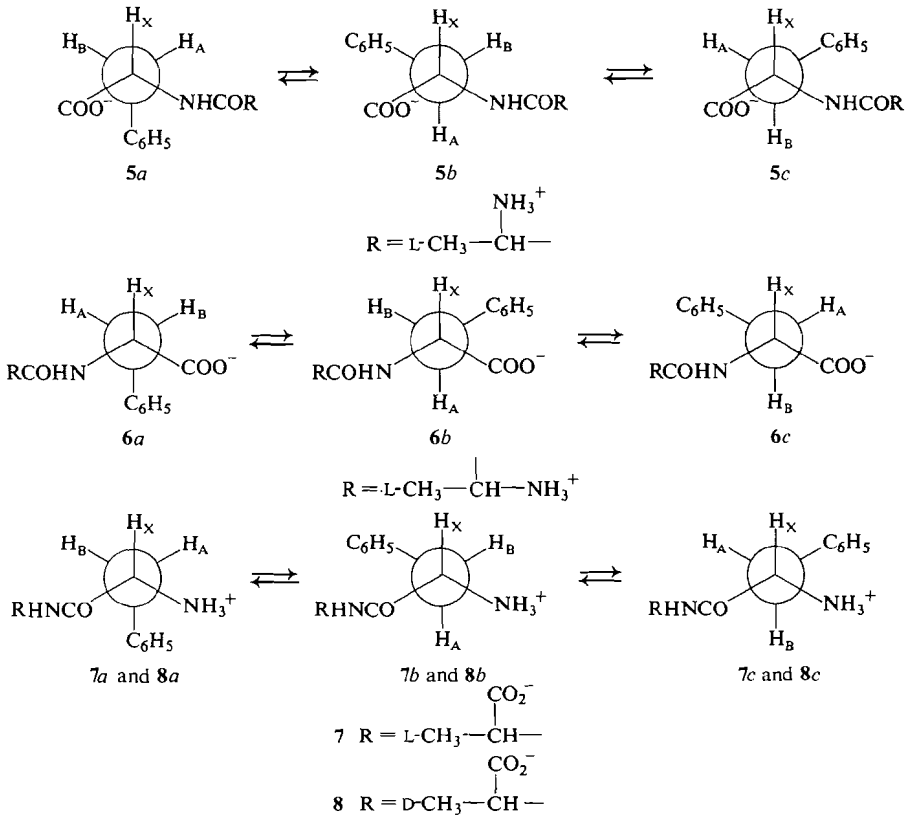
on opposite sides of the amide bond in the L,L-diastereomer, as also do the two side chains R_1 and R_2. In the L,D-form the charged groups both exist on the same side of the amide bond and R_1 and R_2 are both on the opposite side. Thus shielding of R_1 by R_2 is possible in the L,D-peptide but not in the L,L-case.

The rotational isomerism about the C_α—C_β bond of amino acids and peptides has been studied by several workers by the n.m.r. method (26–33). These studies have generally been based on the assumption of constant values for the vicinal couplings between hydrogen atoms in *gauche* (J_g) and *trans* (J_t) positions to each other. The validity of this approach is open to some doubt since it is known, for example (34), that the size of a *gauche* coupling can be significantly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



affected by substituents in a *trans* coplanar arrangement with either of the coupled protons. Also, there is no basis for assuming that torsional angles for *gauche* hydrogens are 60°; indeed, for open-chain compounds these angles, in the absence of evidence to the contrary, must be assumed in the range 45–75° and the coupling constant, therefore, in the range of *about* 1 to 5 Hz (35). This uncertainty obviously severely limits the utility of n.m.r. in establishing the relative population of rotamers for acyclic structures such as dipeptides since the dependence of coupling constant on torsional angle is very high in the range 45 to 75° (35). However, it is possible to make some deductions simply on the basis that J_t is very much larger than J_g.

A comparison of the coupling constants (Table 2) for diastereomeric L-alanyl derivatives of L-phenylalanine (**5**) and D-phenylalanine (**6**) shows that the change in configuration has little effect on the coupling constants for the $—CH_X—CH_AH_B—$ grouping of the phenylalanine residues. Also, the same situation is evident for the L-phenylalanyl derivatives, **7** and **8**, of L-alanine and D-alanine, respectively. However, it is seen that time averaged coupling constants labelled J_{AX} are substantially smaller for **5** and **6** than for **7** and **8** and those assigned J_{BX} are substantially larger for both **5** and **6** than for **7** and **8**. Obviously, therefore, compounds **5** and **6** are much richer in a conformer that has the B and X hydrogens in antiplanar relationship. A consideration of the staggered conformations for the $—CH—CH_2—$ groups of these compounds clearly requires conformations **5***a*, **6***a*, **7***a*, and **8***a* to be of little importance and this is substantiated for compounds **5** and **6** in view of the large values for J_{BX} (9.3 $\pm$ 0.5 Hz at p*H*'s 0.5, 6, and 13). Also, for all compounds, values for $(J_{AX} + J_{BX})/2$ are close (about 7 Hz) to the expected values (about 8 Hz) (31) for conformations involving H_X antiplanar to either H_A or H_B. The shift in conformational equilibria on passing from either compounds **5** and **6** to either of the positional isomers **7** and **8** must arise from the change of the vicinal carboxyl group in **5** and **6** to amino group in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

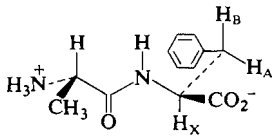
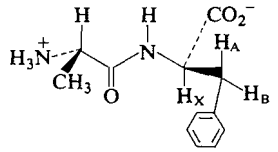
7 and 8. One must expect a stronger non-bonded interaction between the large phenyl group and the large carboxyl group when in *gauche* relationship as seen in the conformers 5*b* and 6*b* than between the phenyl group and the *gauche* group in conformers 7*b* and 8*b*. Indeed, it is to be expected on well established conformational theory that 5*c* and 6*c* should be favored over 5*b* and 6*b*, respectively, whereas a smaller energy difference should exist both between 7*b* and *c* and between 8*b* and *c*; precisely as demanded by the n.m.r. data. Thus, there can be no doubt that conformers 5*c* and 6*c* are the largely favored conformers for compounds 5 and 6. There can be no such certainty as to which is the preferred conformer for compounds 7 and 8. However, it is likely that the amino rather than the amide grouping would tend to be *gauche* to the phenyl group. That is, conformations 7*c* and 8*c* seem preferred on steric grounds but, as will be seen below, solvation and dipole–dipole interactions also appear important in establishing these conformational preferences.

Assuming a basically β-form for the peptide linkage, projection formulae 9 and 10 for the conformers 5*c* and 6*c*, respectively, are implied. Of course, the ionic state will depend on the p*H*; the carboxylate group being protonated at p*H* 3, the zwitterionic stage largely prevailing at p*H* 6, and the unprotonated amine existing at p*H* 13.



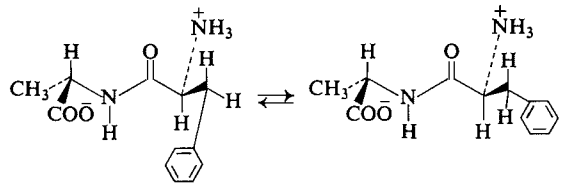
9 (5*c*)



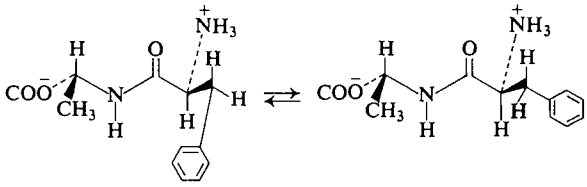
10 (6*c*)

Examination of molecular models for 6*c* suggests the methyl group should project toward the plane of the phenyl group at a distance of about 4.5 Å and perpendicular to the plane of the ring at about the edge of ring. The relationship derived by Johnson and Bovey (36) would predict for this situation (*z*-value = 3.2 and *p*-value = 1) a shielding from this origin of the methyl group in 6*c* of 0.46 p.p.m. For compound 5 in conformation 5*c* the methyl group and the phenyl group are separated by about 6 Å and the *p*-value is estimated to be about 3. On this basis, and by extrapolation of the Johnson–Bovey table, the phenyl group should shield the methyl group by about 0.06 p.p.m. Thus, assuming all other shielding effects on the methyl groups to be equal for the compounds in conformations 5*c* and 6*c*, it would be expected that the methyl group in 6*c* would produce its signal about 0.4 p.p.m. to higher field than that in 5*c*. However, other conformations are expected to be present all of which should experience smaller such shielding effects. Therefore, the observed difference in chemical shift should be less than that expected on the basis of conformations 5*c* and 6*c* only and probably about 0.3 p.p.m. Indeed, the observed difference (0.25 and 0.31) at p*H*'s 0.5 and 6, respectively (see Table 3), are of this order of magnitude and confirm well the assignments (based on vicinal coupling constants and conformational analysis) of conformations close to 5*c* and 6*c* as the predominant conformations for the dipeptides 5 and 6, respectively. It is noteworthy with regard to the relatively small difference, 0.12 p.p.m., observed at p*H* 13 that J_{BX} also is substantially smaller at this p*H* for compound 6 than at the lower p*H*'s (see Table 2). It is expected that conformation 6*c* will best accommodate the electrostatic attraction between the NH_3^+ and COO^- groups and thereby serve as a stabilizing influence for this conformation. Indeed, the methyl group is most strongly shielded for compound 6 relative to that for compound 5 at p*H* 6. As will be seen below, the fact that the hydrophobic phenyl group extends into close contact with the peptide portion of the molecule may be a further important stabilizing factor for conformations 5*c* and 6*c*.

In accord with the foregoing discussion of the conformational equilibria for compounds 7 and 8 and assuming the β-form for the peptide linkage, these compounds can be represented by the projection formulae 11*a* and *b* (in the case of 7) and 12*a* and *b* (in the case of 8). In view of the prevalence of 12*a*, it would be expected that the methyl group signal would be to somewhat higher field for compound 8 than for compound 7. Indeed, as has been already noted (Table 3), this



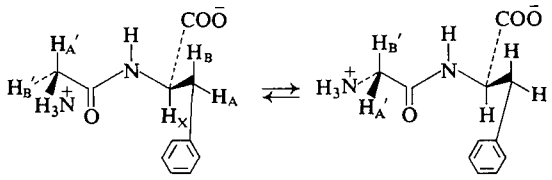
11*a* (7*b*) **11***b* (7*c*)



12*a* (8*b*) **12***b* (8*c*)

was found to be the case with the chemical shift difference being the greatest for the zwitterionic form. In fact, the large difference of 0.26 p.p.m. observed at p*H* 6 (Table 3) appears to favor conformation **12***a* substantially over **12***b*. If so, this situation likely results at least in part from a tendency for the hydrophobic phenyl group to minimize solvation by water (in other words, to maximize the water structure of the system).

The n.m.r. data for glycyl-L-phenylalanine reported in Table 4 confirm the stabilizing effect of the zwitterionic state for the dipeptide in the β-form. That is, the largest chemical shift for the methylenic hydrogens of the glycyl residue would be expected for conformation **13***b* which is also the conformer having most favorable spatial disposition of the NH_3^+ and COO^- groups. In fact we find a chemical shift difference of 0.15 in the zwitterion, 0.08 in the cation, and 0 in the anion.



13*a* **13***b*

The coupling constants J_{AX} and J_{BX} for the ABX grouping of **13** (Table 4) have magnitudes similar to those observed for the alanylphenylalanines **5** and **6**, and **13** is assigned the conformation for the phenylalanine residue as shown in **13***a* and *b* for the same reasons as discussed earlier for **5** and **6**.

Carbamate formation in solutions of the four isomeric dipeptides was studied by n.m.r. in the p*H* range 7–11. In all cases the carbamate could be distinguished by the p*H*-independent resonances of the *N* terminal α-proton and of the alanyl methyl group. The remaining protons of the carbamate gave peaks superimposed on those of the free peptide. The peptides showed yields of carbamate comparable with those obtained for glycine (Table 5). However, carbamate formation occurred in solutions of lower p*H* in the case of the peptides, in keeping with the generally lower pK_a values of dipeptides compared with amino acids. The yields of carbamate obtained for the four dipeptides were identical within experimental error.

TABLE 5. Percent yields of carbamate

	Alanylphenyl-alanine		Phenylalanyl-alanine	
p*H*	L,L-	L,D-	L,L-	L,D-
10.4	40	38	35	34
8.6	50	50	55	50
7.3	0	0	0	0

It was noticed that for alanine, the chemical shift of the methyl group was nearly the same for the anion as for the carbamate (see Fig. 1B). For this reason, it was expected that the chemical shift of the methyl group for the alanyl residue would be unaffected on converting the L,L-dipeptide anion of **5** to carbamate. The same situation should apply for the L,L-dipeptide **7** in view of the distance between the methyl group and the carbamate group with the compound in the β-conformation. As seen in Table 6, this was the case within 0.02 p.p.m. However, for the corresponding L,D-isomers, carbamate formation introduces a negatively charged group on the same side of the β-structure as the negatively charged carboxylate group. As a consequence, a conformational change away from the β-conformation could result and, if so, this would likely be reflected by a substantial chemical shift

TABLE 6. Downfield shift of CH_3 hydrogens in dipeptide carbamate relative to dipeptide anion

	Δ Anion–carbamate (τ units)
L-Phenylalanyl-L-alanine	0.02
L-Phenylalanyl-D-alanine	0.08
L-Alanyl-L-phenylalanine	0.02
L-Alanyl-D-phenylalanine	0.09

difference between the methyl group of the L,D-dipeptides as anions and as carbamates. As seen in Table 6, a small but definite such change did occur inferring an increased distance between the phenyl group and the methyl group in the carbamate derivatives of compounds **6** and **8** as compared to the distances in the anionic forms.

In conclusion, all the data accumulated in the course of this research are in accord with a shorter end-to-end distance in L,D- compared with L,L-peptides. This evidence is compatible with a β-structure for dipeptides.

Thanks are expressed to D. Gifford for the determination of the 100 MHz n.m.r. spectra. The financial support of the National Research Council of Canada is gratefully acknowledged.

The Anomeric Effect: The Conformational Equilibria of Tetrahydro-1,3-oxazines and 1-Methyl-1,3-diazane

H. BOOTH[1] AND R. U. LEMIEUX
Department of Chemistry, University of Alberta, Edmonton, Alberta

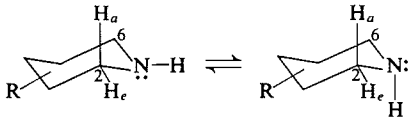
Received August 14, 1970

By measurement of CH–NH coupling constants at low temperatures, the N—H axial conformation was shown to be the dominant, or sole, conformation for tetrahydro-1,3-oxazine, tetrahydro-2-methyl-1,3-oxazine, and 1-methyl-1,3-diazane. These results provide further experimental evidence for the generalized anomeric effect. Nuclear Overhauser experiments established the partial axial character of the *N*-methyl substituent in tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine.

The n.m.r. spectral data for a number of tetrahydro-1,3-oxazines and derived salts are tabulated and discussed.

Canadian Journal of Chemistry, 49, 777 (1971)

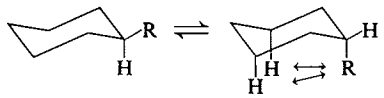
The position of conformational equilibria (*e.g.* **1** ⇄ **2**) in saturated six-membered nitrogen-containing heterocycles is a problem which has provoked considerable effort, discussion, and controversy (1–15). The microwave spectrum of piperidine has been interpreted in terms of a mixture containing 60% N—H equatorial and 40% N—H axial conformations (12). Lines characteristic of the N—H equatorial conformation were recorded in the microwave spectrum of morpholine, but since the undetected lines for the N—H axial conformation were *expected* to be weak, no assessment of the position of equilibrium was possible (13).



1 **2**

The position of equilibria (*e.g.* **3** ⇄ **4**) in cyclohexane compounds, corresponding to **1** ⇄ **2**, is thought to depend largely on the repulsive 1,3-interactions illustrated, and these in turn are a function of the size and polarizability of the group R, the bond length C—R and the nature of the solvent. In the case of a heterocycle (**1** ⇄ **2**) there is the further complication caused by the presence of unshared electron pair(s) on the heteroatom.

Allinger *et al.* (10) have maintained that the concept of size for a lone-pair has been an unfortunate one. Nevertheless, equilibria such as



3 **4**

1 ⇄ **2** are undoubtedly influenced by 1,3-interactions involving lone-pair orbitals, and evaluation of such effects is, therefore, a study of some importance. Recent work on *N*-substituted aziridines has suggested that interactions between lone-pair orbitals on directly bonded atoms are also important in determining conformational equilibria (16).

However, according to the recent proposals regarding the stereochemical requirements of adjacent electron pairs and polar bonds (17), interactions between lone-pair orbitals are unimportant. Instead, the interactions of *bonded* electron pairs of polar bonds with each other are considered of importance. A non-directional behavior of lone electron pairs was concluded on the basis of *ab initio* quantum mechanical calculations.

The problem of assessing the position of conformational equilibria such as **1** ⇄ **2** has been approached by the use of n.m.r. techniques, but with some exceptions (18–20), these have all utilized chemical shift data for the protons on C-2 and -6, adjacent to the nitrogen atom. Comparisons of chemical shifts (τ_{2a}, τ_{2e}) (21), or chemical shift differences ($\tau_{2a} - \tau_{2e}$) (3), in the parent amines **1** ⇄ **2** with those in their *N*-methyl derivatives **5** ⇄ **6**, are not expected to yield reliable information on the position of equilibrium **1** ⇄ **2**, for the following reasons: (*a*) lack of standards, of known conformation about the nitrogen atom; (*b*) uncertainty as to the position

[1]University of Alberta Visiting Professor, 1968–1969. Present address: Department of Chemistry, University of Nottingham, England.

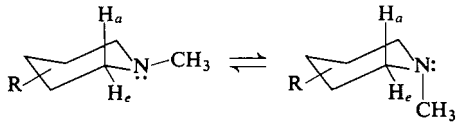
For personal use only.

of conformational equilibrium **5** ⇄ **6** in the *N*-methyl derivatives themselves (6, 22, 23); (*c*) the problem, hitherto unsolved, of separating those effects on τ_a and τ_e due to the anisotropy of the *N*-alkyl substituent, from those effects on τ_a and τ_e due to the anisotropy of the nitrogen lone pair (4, 24).

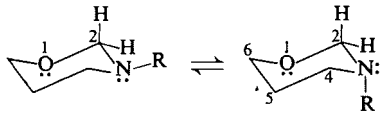
Hutchins *et al.* (21) have recently made the statement: "It is known that the signal of an axial hydrogen on carbon next to an amino nitrogen undergoes an appreciable upfield shift when the nitrogen bears an axial electron pair and equatorial methyl group, as compared to the case when the electron pair is equatorial and the methyl group is axial or absent." Unfortunately, there is no convincing evidence in the literature to support the statement. It is *only* possible to state that the conversion of a cyclic amine **1** ⇄ **2** (position of equilibrium in dispute) into its *N*-methyl derivative **5** ⇄ **6** (position of equilibrium in dispute) causes a shielding of the axial



5 **6**

proton H_a which is usually much greater than the shielding of the equatorial proton H_e (*N.B.* tetrahydro-1,3-oxazine is an exception, *vide infra*).

The cyclic compounds studied in this investigation are derivatives of tetrahydro-1,3-oxazine **7** ⇄ **8**, a molecule which exhibits an effect not present, for example, in simple piperidines **1** ⇄ **2**.



7 R = H **8** R = H
9 R = Me **10** R = Me

This is the generalized anomeric effect (25-27), a phenomenon first associated with the unexpectedly higher stability of glycosyl halides in that conformation bearing the halogen axial (28). Edward pointed out that the placing of the halogen axial avoided an interaction between the polar C—halogen bond and the axial orbital of the ring oxygen. Later Kabayama and Patterson (29) discussed the effect in terms of a destabilization of the equatorial conformation by repulsion between lone-pair orbitals on halogen and ring oxygen. This aspect of the "anomeric effect" was fully discussed by Lemieux (30) in 1964. Hutchins *et al.* (21) have recently introduced the term "rabbit-ear" effect to describe the generalized anomeric effect, *i.e.*, that aspect of the anomeric effect involving the disfavoring of conformations in which unshared electron pairs are *syn*-axial on non-adjacent atoms. Lemieux and Chü (25) showed that the anomeric effect was enhanced by the introduction of more electronegative groups at the 5-position of 1,2,3,4-tetra-*O*-acetyl-D-glucopyranoses. It was therefore suggested that the origin of the anomeric effect may reside at least in part from the relative orientations of the polar C—O bonds about the acetal linkage (30). Edward *et al.* (31) found confirmatory evidence in studies involving 3-alkoxy-4-oxa-5α-cholestanes. Indeed, as mentioned above, recent theoretical studies by Wolfe and co-workers (17) seem to favor this origin for the anomeric effect over that involving repulsions between *syn*-axial lone-pair orbitals. Thus, the presence of a *syn*-axial disposition of lone-pair orbitals may serve more for the identification of the anomeric effect than for its understanding.

Taking the bulk of evidence available at present, neither the *N*–H equatorial nor the *N*–H axial conformation is strongly preferred for piperidine and morpholine. However, the situation is different for tetrahydro-1,3-oxazine **7** ⇄ **8**, where **8** is expected to predominate, since here the polar *N*–H bond is more favorably disposed electrostatically to the O—C_2 bond. This situation is formally analogous to the conformational preference for fluoromethanol anticipated by calculation (17). It was hoped that additional information on these matters would be provided by an investigation of the positions of equilibria **7** ⇄ **8** and **9** ⇄ **10**.

Tetrahydro-1,3-oxazine **7** ⇄ **8** was readily prepared from 3-aminopropan-1-ol and formaldehyde, both by the method of Eden (32), involving azeotropic removal of water from the mixture in benzene, and by the method of Lehn *et al.* (33), in which the two components react smoothly in the presence of water. In principle, the most direct method of establishing the position of equilibrium **7** ⇄ **8** involves measurement of the proton–proton CH–NH coupling constant, on the reasonable assumptions that such coupling

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

constants will occur in the range 0 to 14 Hz (*cf.* the corresponding proton–proton CH–OH coupling constants (34)), and that such coupling constants show a dependence on torsional angle similar to that shown by the corresponding CH–CH coupling constants.

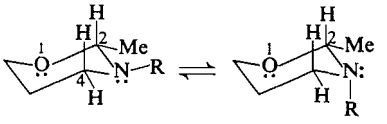
Hitherto, to our knowledge, observations of proton–proton CH–NH coupling constants in *amines* have not been made (see, especially, footnote on p. 3766 of ref. 3), owing to rapid proton exchange between amine and amine, and/or amine and solvent, and/or amine and water. Proton–proton CH–NH coupling constants are readily observed in protonated amines dissolved in strongly acidic solvents and in amides.

The n.m.r. spectrum of tetrahydro-1,3-oxazine **7** ⇄ **8** showed no evidence for CH–NH coupling at room temperature, even when the solvent was dimethyl sulfoxide. The spectrum in $CDCl_3$ showed features which are expected for a molecule which is undergoing rapid ring inversion, in addition, presumably, to rapid nitrogen inversion (**7** ⇄ **8**). Thus, we observed a singlet at τ 5.60 (protons at 2), a fairly broad singlet at 7.90 (N—H), a triplet at 6.97 (protons at 4), a triplet at 6.09 (protons at 6), and a quintet at 8.40 (protons at 5). The spectrum in $CFCl_3$ at +10° was similar. However, interesting changes were observed when the spectrum in $CFCl_3$ was recorded at reduced temperatures. At −10°, exchange of proton on nitrogen was already sufficiently slow for the 2-protons signal to appear as a *doublet*, separation about 7 Hz. At −30°, the 2-protons signal was a doublet, J = 8.5 Hz, due to CH–NH coupling; for the same reason the 4-protons signal now consisted of *two* triplets (separation of triplets ~8 Hz). The correctness of the explanation was evident from the observation that, at the same temperature, (−30°), the signal for the 6-protons remained a well resolved triplet; clearly, ring inversion was still relatively rapid at −30° and the process which had been slowed was that of proton exchange between nitrogen and other electronegative atoms (the possibility exists that nitrogen inversion had also been slowed at −30°, but this possibility could not be revealed by the n.m.r. methods owing to the bias of the equilibrium **7** ⇄ **8**).

At −50°, with the slowing of ring inversion, all signals were very broad, except, interestingly, the N—H resonance, which was a clearly defined quintet, separations ~8.5 Hz.

At −80°, ring inversion was slow, and a well resolved spectrum was obtained, from which the chemical shifts and coupling constants listed in Tables 1 and 2 were deduced. The signals for H_{2a} and H_{6e} overlapped, but assignments were proved by double irradiation. The protons at position 2 gave an octet (AB part of ABX), analysis of which yielded the following parameters: J_{AB} = 10.1, J_{AX} = 2.9, J_{BX} = 13.1 Hz; H_A at τ 5.62, H_B at 5.93, H_X at 7.5. That the small splittings in the A quartet were due to coupling with the N—H proton was confirmed by decoupling; irradiation at the N—H frequency caused these splittings to disappear. The values of the coupling constants J_{AX} and J_{BX} suggest strongly that conformation **8**, with N—H axial, makes the major or sole contribution to the conformational equilibrium **7** ⇄ **8**.

Tetrahydro-2-methyl-1,3-oxazine (**11** ⇄ **12**) was next studied. The ring inversion process is not important in this instance, since that ring conformation having the methyl equatorial is expected to predominate to the extent of about 95% (see later for evidence from spectra that the 2-methyl group is indeed equatorial). The spectrum of **11** ⇄ **12** at 40° in $CDCl_3$ permitted a



11 R = H **12** R = H
13 R = Me **14** R = Me

first-order interpretation (see Tables 1 and 2). At this temperature, the spectrum gave no evidence for CH–NH coupling, presumably due to rapid exchange of protons on nitrogen. However, at 0° this exchange was already relatively slow, since the signals for H_{2a}, H_{4e}, and H_{4a} were broadened, whilst the remaining signals maintained their sharpness.

At −50°, with very slow exchange, a well resolved spectrum was obtained (see Tables 1 and 2 for full details). In particular, the signal for H_{2a} consisted of *two* 1,3,3,1-quartets, with coupling constants of 12.6 Hz ($J_{2a,NH}$) and 5.8 Hz (J_{2a,CH_3}). It was concluded that the conformation with axial N—H made the major or sole contribution to the equilibrium **11** ⇄ **12**.

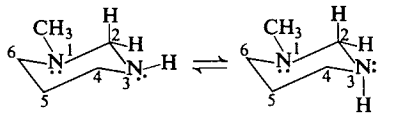
1-Methyl-1,3-diazane (**15** ⇄ **16**), readily prepared from *N*-methyl-1,3-diaminopropane and formaldehyde, is a molecule which, at room temperature, is expected to undergo rapid ring inversion in addition to rapid nitrogen inversion about both nitrogen atoms. However, it was of interest to discover whether spectra recorded at low temperatures would reveal the preferential orientation of the N—H bond.



15 **16**

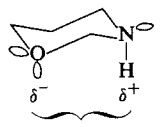
The following data were observed in the spectrum of **15** ⇄ **16** measured at room temperature in $CDCl_3$; a singlet at τ 6.70 (protons at 2), a multiplet at 7.22 (protons at 4), a multiplet at 7.46 (protons at 6), a multiplet at 8.50 (protons at 5), and a singlet at 7.85 (*N*-CH_3). The N–H resonance at τ 8.05 was relatively sharp. With $CFCl_3$ as solvent, and at reduced temperatures, broadening of signals commenced at about −5°, and at −70° ring inversion was slow. The protons at position-2 gave a doublet (H_{2e}), each component showing broadening due to a further coupling, and a quartet (H_{2a}) (AM portion of AMX system). Analysis gave the following parameters: $J_{2a,2e} = 11.3$, $J_{2a,NH} = 13.0$, $J_{2e,NH} \leqslant 3$ Hz; H_{2e} at τ 6.58, H_{2a} at 7.50. The *N*-H signal was not seen clearly. However, irradiation of H_{2e} caused the quartet for H_{2a} to collapse to a doublet, $J \sim 13$ Hz, thus confirming the assignments.

It is clear from the coupling constants obtained that the preferred conformation of 1-methyl-1,3-diazane (**15** ⇄ **16**) is conformation **16**, with the N—H bond in the axial orientation.

Attempts to extend the technique to the determination of the preferred orientation of the N—H bond in piperidine and morpholine were not successful. Thus, no evidence was obtained for CH–NH coupling from the spectrum of piperidine, recorded at temperatures down to −100° ($CFCl_3$), and from the spectrum of morpholine, recorded at temperatures down to −115° (CF_2Cl_2).

It is remarkable that a technique which enabled the $J_{2a,NH}$ coupling to be measured for **7** ⇄ **8** at −80°, failed to reveal this information for either piperidine (−100°) or morpholine (−115°). Only −50° was required for **11** ⇄ **12**. Likely, the relatively slow proton exchange for compounds **7**, **11**, and **15** is due to the presence of highly electronegative geminal heteroatom which reduces the basicity of the NH group and thereby inhibits proton exchange as is found for amides. According to Wolfe and co-workers (17) "Electron pair – electron pair, electron pair – polar bond or polar bond – polar bond interactions cause a significant increase in rotation–inversion barriers of atoms bearing these substituents." It is interesting to note in this regard that ring inversion was slow at −50° for compound **7** and that signal broadening commenced at about −5° for 1-methyl-1,3-diazane.

It is concluded that the equilibria **7** ⇄ **8**, **11** ⇄ **12**, and **15** ⇄ **16** are predominantly toward the conformation with N—H in axial orientation at the temperature where the CH–NH coupling could be observed. However, no information on the temperature effects on these equilibria was obtained. In view of the nature of the anomeric effect, it seems likely that these conformations also prevail at room temperature. It is possible that presumably quite polar N—H bonds in these compounds have established a substantial bond, akin to a hydrogen bond, through electrostatic attraction with the *syn*-axial lone-pair electrons as depicted below. Such an *added* driving force for maintaining the N—H axial

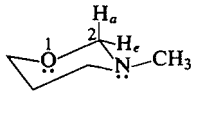


Attractive

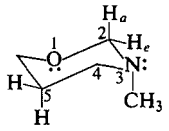
orientation seems needed, should, as expected from the magnitudes of the CH–NH coupling constants, the compounds exist virtually entirely in the one conformation. Further information on these matters promises to be of importance in relation to solvation effects on the anomeric equilibria of sugars and on the orientation of axial aglycons of glycopyranosides (35).

It was considered of interest to examine further the conformational properties of tetrahydro-3-methyl-1,3-oxazine (**9** ⇄ **10**) in order to gain further insight into the generalized anomeric effect.

Riddell and Lehn (19), using chemical shift differences $\tau_{2e} - \tau_{2a}$, and the geminal coupling constant $J_{2e,2a}$, in comparison with those of conformationally rigid standards, deduced that the percentage of conformation **10** (axial N—CH_3)



9



10

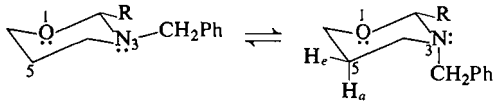
was 60 ± 10 (shifts) or 45 ± 10 (coupling constants). Allingham *et al.* (20) measured geminal coupling constants for ring protons in a series of 5-methyl-5-nitrotetrahydro-1,3-oxazines substituted on nitrogen by alkyl groups. The figures were interpreted in terms of a preference for *N*-alkyl *axial* when the alkyl substituent was methyl, ethyl, or propyl, and a preference for *N*-alkyl *equatorial* when the substituent was isopropyl, cyclohexyl, or *t*-butyl.

The determination of the position of equilibrium **9** ⇄ **10** by the application of nuclear Overhauser effects (n.O.e.) appeared promising. This effect, which has found increasing application to stereochemical problems during the past few years (36–53), involves saturation of the signal due to a nucleus H_A, whilst a second nucleus H_K is observed, usually by integration. If H_K lies close to H_A, then an enhancement of up to 30% (theoretical maximum 50%) may be observed in the intensity of the signal for H_K. Enhancements are not usually observed if H_A and H_K are separated by more than 3 Å, but become measurable at distances 2.5 to 3 Å. Distances of only 1.8 to 2.5 Å may lead to enhancements of up to 30%.

The experimental conditions necessary for the success of a nuclear Overhauser experiment have been clearly described (36, 48, 52). We carried out our experiments without degassing the sample, having obtained satisfactory enhancements (15%) on a control sample of dimethylformamide which had not been degassed. All experiments mentioned in the literature have employed instrumental integration to measure signal intensities. We obtained inconsistent results by this method. We attributed this to the fact that we were generally integrating signals covering 25 to 40 Hz, and phase alteration during the frequency sweep caused poor reproducibility of the integral. This difficulty was overcome by measurement of signal areas using a planimeter (see Experimental).

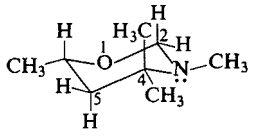
In the case of tetrahydro-3-methyl-1,3-oxazine (**9** ⇄ **10**), studied at temperatures low enough to cause a slowing of ring-inversion, the proximity of the axial N—CH_3 and H_{5a} in **10** should allow observation of a n.O.e. Since no effect will occur in conformation **9**, where the N—CH_3 bond is equatorial, the *magnitude* of n.O.e. experiments can be carried to the proportion of **10** in the mixture, *provided* an assessment can be made, from a model compound with the characteristics of **10**, of the expected n.O.e. for the isolated conformation **10**. As far as we are aware, n.O.e. effects have not been applied to rapidly interconverting mixtures of conformers such as **9** ⇄ **10**, presumably due to the difficulty of placing measurements on a quantitative basis.

Unfortunately, a n.O.e. study of **9** ⇄ **10** at −90° was frustrated by the closeness in shift of *N*-CH_3 and H_{5a} signals (see Table 1). An attempt to study the enhancement of the H_{5a} signal, on irradiation of the benzylic proton signal in the spectrum of 3-benzyltetrahydro-2-methyl-1,3-oxazine **19** ⇄ **20** also failed, because the benzylic proton resonance was an AB quartet ($J \sim 14$ Hz) needing a high power of irradiation to cause saturation.

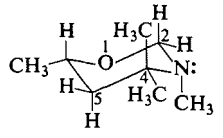


17 R = H **18** R = H
19 R = Me **20** R = Me

Finally, tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine **21** ⇄ **22** was selected, as possessing features of advantage for an n.O.e. study. Thus the *N*-CH_3 signal (τ 7.80, benzene) and the H_{5a} signal (τ 8.58) are now well shifted, as a result of replacement of two adjacent equatorial hydrogens by methyl groups (54). Moreover, in both



21



22

conformations **21** ⇄ **22**, the axial methyl group at position-4 is in a 1,3-diaxial relationship to the axial hydrogen at position-2. Therefore, the magnitude of a nuclear Overhauser enhancement for H_{2a} on irradiation of the axial CH_3 at position-4 is a convenient standard on which to base any quantitative treatment of the enhancement observed for H_{5a} on irradiation of the *N*-CH_3.

Indeed, measurements on Dreiding models gave the distance between H_{2a} and the closest hydrogen of the axial CH_3 at position-4 as almost the same as that between H_{5a} and the closest hydrogen of the *N*-CH_3 (1.95 to 2.00 Å, staggered conformations assumed). Therefore, it might be expected that the enhancement observed for H_{2a} (on saturation of the signal for axial CH_3 at position-4) would be the same as that observed for H_{5a} (on saturation of the *N*-CH_3 signal) in **22**, if the compound possessed this conformation only. However, even this is unlikely since nuclear Overhauser enhancements are proportional to the sixth power of the separation between the nuclei involved (55) and therefore highly sensitive to small differences in molecular dimensions. Furthermore, since relaxation of H_{5a} (for example) may occur by protons other than those of the N—Me group, it is clear that a quantitative treatment is not feasible.

The results obtained from nuclear Overhauser experiments on **21** ⇄ **22** are listed in Table 3. In view of the limitations mentioned above, the only conclusion possible is the qualitative one that the contribution made by conformation **22** in which the *N*-CH_3 group is in axial orientation is appreciable and may dominate. These results are equivalent to those of Riddell and Lehn (19) in that the evidence does not necessarily require a large preponderance of the conformer **10** which has the *N*-CH_3 group in axial orientation. Nevertheless, the indication is clear that the anomeric effect, as expected and whatever its origins, may well have an influence on these conformational equilibria.

In trifluoroacetic acid as solvent, the salts of *N*-alkyl tetrahydro-1,3-oxazines **27**, **28**, **30**, and **33** exist in the conformation which has the *N*-H in axial orientation as expected in view of the conformational preference of tetrahydro-1,3-oxazine. The reverse anomeric effect (56) is expected to strongly influence the conformational preferences of these salts, especially the quaternary salts **31**, **32**, and **34**.

TABLE 3. The n.O.e. results on **21** ⇄ **22**

Signal saturated	Signal observed	Increase in area (%)
CH_3 (4-axial)	H_{2e}	2.0
CH_3 (4-axial)	H_{2a}	8.8
N-CH_3	H_{5a}	6.0

The recorded values of the vicinal axial–axial coupling $J_{2a,\overset{+}{N}H}$ ($J_{2a,3a}$ of Table 5) lie in the range 7.5 to 9.6 Hz, in agreement with reported figures (19); these values are considerably less than the values of $J_{2a,\overset{+}{N}H}$ ($J_{2a,3a}$ of Table 2) in the free bases.

The spectrum of **30** in CF_3CO_2H was clearly that of a single conformation, and the value of 7.5 Hz for $J_{2a,\overset{+}{N}H}$ shows that this conformation possesses both methyl substituents in equatorial orientation. However, the spectrum in $CDCl_3$ indicated the presence of two species which are geometrical isomers, differing, most probably, only in the orientation of the $\overset{+}{N}—CH_3$ substituent. For one isomer, the 2-proton appeared as two 1,3,3,1-quartets, separated by 7.8 Hz ($J_{2a,\overset{+}{N}H}$); for the second isomer, the 2-proton appeared as two 1,3,3,1-quartets, separated by only 1.2 Hz ($J_{2a,\overset{+}{N}H}$). When spectra in $CDCl_3$ were recorded at different concentrations, there was not only a marked variation in chemical shifts, but also in the relative proportions of the two isomers. Similar observations have been made by Japanese workers (57) in the case of *cis*-1,2,6-trimethylpiperidine hydrochloride dissolved in organic solvents.

Finally, the fact that the geminal coupling constant $J_{5e,5a}$ is numerically larger than $J_{2e,2a}$, $J_{4e,4a}$, or $J_{6e,6a}$ is in agreement with theory (58) and with some previous observations (59).

The preparation of tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine involved some points of interest. The reaction of mesityl oxide and methylamine was carried out by the published method (60), and was found to give mostly 4-methyl-4-methylaminopentan-2-one (**23**), contaminated with the derived *N*-methylimine **24**. Reduction

33 $R_1 = CH_3$; $R_2 = H$
34 $R_1 = R_2 = CH_3$

tetrahydro-1,3-oxazines and salts have previously been contributed by Gurne *et al.* (61), by Riddell *et al.* (19, 33), and by Allingham *et al.* (20). In general, our figures are in broad agreement with previous data.

Most spectra were obtained at both 60 and 100 MHz; the 100 MHz spectra were first order, or nearly first order, and chemical shifts were obtained directly, except for the ABX patterns mentioned below. Coupling constants were generally obtained by direct measurement and are, therefore, accurate to about ± 0.2 Hz. The following, obtained by ABX analyses, are accurate to ± 0.1 Hz:

$J_{2e,2a}$ $J_{2e,2a}$ $J_{2a,3a}$ in **7** ⇄ **8**

$J_{2e,2a}$ $J_{2e,3a}$ $J_{2a,3a}$ in **33**

$J_{5e,5a}$ $J_{5e,6a}$ $J_{5a,6a}$ in **34**

For all compounds examined, H_{5a} occurs at *lower* field than H_{5e}. A similar situation holds for the 5-position of 1,3-dioxans (62) and the 3-position of morpholines (63) and has been associated particularly with the presence of an oxygen atom in a 1,3-relationship to the carbon atom holding the protons (63, 64).

The proof that the 2-methyl substituent has the equatorial orientation in **11** ⇄ **12** and **13** ⇄ **14** rests on the observation that the chemical shifts of the 6-axial proton in **11** ⇄ **12** (entry 11, Table 1) and **13** ⇄ **14** (entry 13) are almost identical with the shifts of H_{6a} in **7** ⇄ **8** (entry 3) and **9** ⇄ **10** (entry 8). An axial methyl group would have caused a noticeable deshielding of the H_{6a} signal (54). A similar argument establishes the equatorial orientation of the 2-methyl group in tetrahydro-2,3-dimethyl-1,3-oxazine methiodide (**32**). Thus, the mean (τ 5.84) of the chemical shifts of H_{6e} and H_{6a} in **32** is almost identical to the chemical shift (τ 5.82) of the 6-protons in the spectrum of the rapidly inverting tetrahydro-3-methyl-1,3-oxazine methiodide (**31**).

The assignment of signals to H_{2a} and H_{2e} in **7** ⇄ **8**, **27**, **28**, and **33** is trustworthy, requiring only the usual assumption that $J_{a,a} > J_{e,a}$. On the other hand, it is likely, but not certain, that a correct assignment of signals to H_{2e} and H_{2a} in tetrahydro-3-methyl-1,3-oxazine **9** ⇄ **10** (entry 8) has been made (*cf.* ref. 19). In the tetramethyl compound **21** ⇄ **22**, the H_{2e} and H_{2a} protons give an AB quartet in the spectrum. The low field half of the quartet is due to H_{2a}, rather than H_{2e}, a result of one of the n.O.e. experiments described earlier. Interestingly, the lines of the high field doublet, due to H_{2e}, were significantly broader than those due to H_{2a}. That this was due to 5-bond coupling with the protons of one or both methyl groups at position-4 was demonstrated by double irradiation. It was not possible to irradiate separately the equatorial and axial 4-methyl signals, but stereochemical considerations (*cf.* ref. 59) suggest that the protons of the equatorial methyl group are responsible for this long-range coupling.

In the spectrum of **34**, it was possible to assign the *N*-methyl signals by decoupling experiments, with the usual assumption that a planar zig-zag arrangement of atoms produces an appreciable 4-bond coupling. Thus, irradiation of the low-field *N*-methyl signal (τ 6.95) caused the lines of the doublet at τ 4.97, due to *one* of the protons

at position-2, to be sharpened, the lines of the doublet at τ 5.27, due to the other proton at position-2 being affected only slightly. On the other hand, irradiation of the *N*-methyl signal at τ 7.17 produced no effect on the doublet at τ 4.97 and only a slight sharpening of the doublet at τ 5.27. It was concluded that the signal at τ 6.95 was due to the axial *N*-methyl group, and that the doublet at τ 4.97 (*J* 9.3 Hz) was due to the axial proton H_{2a}. However, a similar decoupling experiment, designed to confirm the assignment of *N*-methyl signals in the spectrum of **32**, was unsuccessful.

Experimental

Melting points were determined in capillary tubes. The n.m.r. spectra were recorded on Varian A60, A56/60, HA-100, and HA-100-15 spectrometers. Variable temperature n.m.r. measurements were recorded on Varian A56/60 and HA-100-15 spectrometers.

Tetrahydro-1,3-oxazine

Tetrahydro-1,3-oxazine, prepared by literature methods (32, 33), had b.p. 120–121° at 700 mm. The derived picrate, prepared in benzene and crystallized from methanol, had m.p. 138–139°.

Anal. Calcd. for $C_{10}H_{12}N_4O_8$: C, 37.98; H, 3.83; N, 17.72. Found: C, 37.8; H, 3.8; N, 17.4.

The hydrobromide, prepared in dry ether and crystallized from dry acetone, was extremely hygroscopic.

3-Ethyltetrahydro-1,3-oxazine

Tetrahydro-1,3-oxazine (9.5 g) was dissolved in benzene (20 ml) containing pellets of sodium hydroxide (4.5 g). Ethyl iodide (17 g) was added to the mixture, and the whole was warmed on the steam bath for 2 h. The benzene layer was decanted from solid material and dried (KOH). Distillation gave benzene and crude 3-ethyltetrahydro-1,3-oxazine (1.5 g, 12%), b.p. (bath temperature) 115–116° at 695 mm. The picrate, prepared in benzene and crystallized from methanol, had m.p. 190–192° but a satisfactory analysis could not be obtained.

Anal. Calcd. for $C_{12}H_{16}N_4O_8$: C, 41.86; H, 4.68; N, 16.28. Found: C, 43.13, 43.48; H, 5.11, 5.23; N, 15.31.

The hydrobromide, prepared in dry benzene and recrystallized from dry acetone, was hygroscopic. The n.m.r. spectra of free base and hydrochloride were satisfactory.

Tetrahydro-2-methyl-1,3-oxazine

(*i*) A solution of 3-aminopropan-1-ol (50 g) in benzene (100 ml) was distilled in a Dean–Starck apparatus until no more water was evolved. The mixture was cooled in iced water and acetaldehyde (32 g) was added, with stirring, during 50 min. The mixture was finally heated for 12 h, water (12 ml) being collected. Distillation of the residue gave benzene and crude tetrahydro-2-methyl-1,3-oxazine, b.p. 100–105° at 690 mm (15 g, 22%).

(*ii*) To a solution of 3-aminopropan-1-ol (7.5 g) in water (5 ml) was added, during 20 min, an ice cold mixture of acetaldehyde (6.5 ml) and water (5 ml). The solution was allowed to remain at room temperature for 60 min, and was then saturated with pellets of potassium hydroxide. The upper organic layer was removed, dried (KOH), and distilled, giving tetrahydro-2-methyl-1,3-oxazine, b.p. 100–105° at 700 mm (5.4 g, 53%).

Tetrahydro-2-methyl-1,3-oxazine hydrochloride, prepared in benzene and crystallized from acetone–methanol, had m.p. 133–135°.

Anal. Calcd. for $C_5H_{12}NOCl$: C, 44.0; H, 8.8; N, 10.2. Found: C, 43.7; H, 9.0; N, 10.1.

Tetrahydro-2,3-dimethyl-1,3-oxazine

To a mixture of 3-methylaminopropan-1-ol(33) (3.5 g) and water (5 ml) was added a solution of acetaldehyde (2.5 ml) in water (5 ml) during 20 min with cooling in ice. The mixture was allowed to remain at room temperature for 60 min, and then saturated with pellets of potassium hydroxide, when the product separated as an upper layer. The layer was removed, dried (KOH), and distilled, giving tetrahydro-2,3-dimethyl-1,3-oxazine as a colorless liquid, b.p. 97° at 700 mm (3.3 g, 73%).

The methiodide was produced rapidly from methyl iodide and a solution of the base in dry acetone at 30°. Recrystallization of the solid from acetone–methanol gave tetrahydro-2,3-dimethyl-1,3-oxazine methiodide, m.p. 223.5–224° (dec.).

Anal. Calcd. for $C_7H_{16}NIO$: C, 32.7; H, 6.3; N, 5.5. Found: C, 32.3; H, 6.2; N, 5.8.

3-Benzyltetrahydro-1,3-oxazine

To 3-benzylaminopropan-1-ol (4.12 g) in water (15 ml) was added, during 15 min, aqueous formaldehyde (2.5 ml, 37%). A white oil was precipitated. The mixture was allowed to remain at room temperature for 15 min and then extracted several times with ether. The combined ethereal extracts were dried (KOH) and distilled, giving 3-benzyltetrahydro-1,3-oxazine as a colorless liquid, b.p. 128° at 35 mm (4.0 g, 90%).

Anal. Calcd. for $C_{11}H_{15}NO$: C, 74.5; H, 8.5; N, 7.9. Found: C, 74.2; H, 8.5; N, 8.1.

3-Benzyltetrahydro-2-methyl-1,3-oxazine

The method was similar to that in the preceding experiment.

From 3-benzylaminopropan-1-ol (4.1 g) and acetaldehyde (1.5 g) was obtained 3-benzyltetrahydro-2-methyl-1,3-oxazine as a colorless liquid, b.p. 126° at 37 mm (4.0 g, 85%).

Anal. Calcd. for $C_{12}H_{17}NO$: C, 75.4; H, 9.0. Found: C, 74.9; H, 9.0.

4-Methyl-4-methylaminopentan-2-one (60)

Using the published method, freshly distilled mesityl oxide (19.6 g) was reacted with aqueous methylamine (25 ml, 33%). After the reaction, the mixture (mixture *A*) was allowed to remain at room temperature for 30 min, and then treated with anhydrous potassium carbonate (18 g). Extraction with ether, and distillation of the dried ($MgSO_4$) extracts gave 4-methyl-4-methylaminopentan-2-one, contaminated with 4-methyl-4-methylaminopentan-2-one *N*-methylimine, b.p. 59–61° at 20 mm (17.4 g).

Treatment of the crude ketone with picric acid in methanol, followed by crystallization of the product from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

methanol, gave 4-methyl-4-methylaminopentanone-2-picrate, m.p. 150–153°.

Anal. Calcd. for $C_{13}H_{18}N_4O_8$: C, 43.6; H, 5.03; N, 15.64. Found: C, 43.5; H, 5.4; N, 15.6.

4-Methyl-4-methylaminopentanol-2 hydrochloride

(*i*) To mixture *A*, obtained as described in the preceding experiment, was added, with stirring, a solution of sodium borohydride (12 g) in water (50 ml). The temperature of the mixture rose initially to 50°, but was later maintained at 30° by external cooling. Finally, the solution was stirred at room temperature for 3 h, cooled in ice, and treated slowly with hydrochloric acid (80 ml, 18%). After 16 h, the solution was extracted with ether (2 × 100 ml), the ether extracts being discarded. The aqueous portion was evaporated under reduced pressure to a small volume, and then saturated with potassium hydroxide. The upper layer was extracted into ether, the ether extracts dried (KOH) and distilled, giving 4-methyl-4-methylaminopentan-2-ol, contaminated with 4-methyl-2,4-di(methylamino)pentane, b.p. 73–74° at 20 mm (18 g). This mixture (11.0 g) was dissolved in dry ether (200 ml) and treated with dry hydrogen chloride, with external cooling. The precipitated oil was separated by decantation and triturated with dry acetone containing 2% methanol. A solid (solid *B*, see below) was removed by filtration and evaporation of the filtrate to dryness gave 4-methyl-4-methylaminopentan-2-ol hydrochloride as a thick uncrystallizable oil (6.0 g). The n.m.r. spectrum proved the absence of the diamine.

(*ii*) To mixture *A* (see above) was added, with ice cooling, glacial acetic acid (40 ml). The solution was hydrogenated over platinum oxide (2.4 g) until the uptake of hydrogen ceased (72 h). The mixture was filtered, treated with hydrochloric acid (20 ml, 25%) and evaporated to dryness under reduced pressure. The mixture of hydrochlorides thus obtained was separated as described in section (*i*).

4-Methyl-2,4-di(methylamino)pentane Dihydrochloride

Solid *B*, from the previous experiment, was washed with dry acetone and crystallized from acetone–methanol, giving 4-methyl-2,4-di(methylamino)pentane dihydrochloride, m.p. 195–198° (1.08 g).

Anal. Calcd. for $C_8H_{22}N_2Cl_2$: C, 44.2; H, 10.2; N, 12.9. Found: C, 44.4; H, 10.3; N, 12.8.

Tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine

4-Methyl-4-methylaminopentanol-2 hydrochloride (6.0 g) was dissolved in water (5 ml) and the solution was treated first with 40% potassium hydroxide (5 ml) and then with solid potassium hydroxide. The upper organic layer was separated and dissolved in water (5 ml). To the solution was added aqueous formaldehyde (3.5 ml, 37%) during 10 min. The mixture was allowed to remain at room temperature for 45 min and then saturated with potassium hydroxide. The organic phase was separated, dried (KOH), and distilled, giving tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine (3.0 g), b.p. 105–110° at 704 mm. The derived hydrochloride crystallized from acetone, had m.p. 144–147°. The methiodide, prepared in acetone and crystallized from acetone – 2% methanol, had m.p. 252–253° (dec.).

Anal. Calcd. for $C_9H_{20}NI$: C, 37.9; H, 7.1; N, 4.9. Found: C, 37.8; H, 6.9; N, 5.1.

1,3,4,4,6-Pentamethyl-1,3-diazane Dihydrochloride

The mixture (6.5 g) of 4-methyl-4-methylaminopentan-2-ol and 4-methyl-2,4-di(methylamino)pentane, prepared as described above, was dissolved in water (5 ml) and to the solution, cooled in ice, was added aqueous formaldehyde (4.1 ml, 37%) during 20 min. The mixture was allowed to remain at room temperature for 60 min and then saturated with potassium hydroxide. The upper layer was separated, dried (KOH), and distilled, giving (*a*) a fraction, b.p. 100–121° at 700 mm (1.0 g), consisting of methanol and tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine and (*b*) a fraction, b.p. 122–130°, consisting of tetrahydro-3,4,4,6-tetramethyl-1,3-oxazine and 1,3,4,4,6-pentamethyl-1,3-diazine. Fraction (*b*), dissolved in ether and treated with dry hydrogen chloride, gave a sticky precipitate which was separated from ether by decantation and crystallized from acetone–methanol. 1,3,4,4,6-Pentamethyl-1,3-diazane dihydrochloride (0.75 g) had m.p. 183–184° (dec.).

Anal. Calcd. for $C_9H_{22}N_2Cl_2$: C, 47.2; H, 9.7; N, 12.2. Found: C, 47.5; H, 9.8; N, 11.9.

1-Methyl-1,3-diazane

Using the method of Riddell (65), *N*-methyl-1,3-propanediamine (4.4 g) and formaldehyde (5.1 ml, 40% aqueous solution) yielded 1-methyl-1,3-diazane (4.0 g, 80%), b.p. (bath temperature) 150° at 705 mm. The derived dipicrate, crystallized from methanol, had m.p. 210–214°.

Anal. Calcd. for $C_{17}H_{18}N_8O_{14}$: C, 36.6; H, 3.3; N, 20.1. Found: C, 36.3; H, 3.6; N, 20.1.

Nuclear Overhauser Experiments

Nuclear Overhauser experiments were performed using a Varian HA-100-15 spectrometer. Samples were not specially prepared and were not degassed. The power of irradiation causing saturation was varied within the range 50 to 200 mV, but in all cases the optimum power level was at about 100 mV. Instrumental integration of the signals affected did not give reproducible results. Therefore, relatively large samples (20–40 mg) were employed, affected signals were amplified and expanded to a sweep width of 100 Hz, and areas were obtained by using a planimeter. A number of scans were made to check the reproducibility, both of "blank" spectra (irradiation in a signal-free region) and of spectra recorded with nuclear Overhauser enhancements. Area measurement figures were reproduced to better than 2%.

The authors are grateful to Glen Bigam, David Gifford, and Peter Bohlmann for helpful discussion, and considerable technical assistance during experiments involving n.m.r. measurements.

Applications of Proton Magnetic Resonance to Rotational Isomerism in Halotoluene Derivatives. V. α,α,α′,α′,2,3,5,6-Octachloro-*p*-xylene, Semiempirical Barrier Calculations

B. H. BARBER[1] AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received August 25, 1970

In toluene-d_8 solution the p.m.r. spectrum of α,α,α′,α′,2,3,5,6-octachloro-*p*-xylene at temperatures below −25 °C consists of two sharp peaks corresponding to the two conformations in which the methine protons lie *cis* and *trans* to each other in the plane of the aromatic ring. The barrier to rotation of the dichloromethyl groups is derived from a line-shape analysis of the rate-dependent spectra using the computer program ABXFIT. The activation parameters are $E_A = 13.6 \pm 0.4$ kcal/mol, $\log A = 11.3 \pm 0.3$, $\Delta H‡ = 13.1 \pm 0.4$ kcal/mol, $\Delta S‡ = -7.3 \pm 1.3$ e.u., $\Delta G‡ = 15.4$ kcal/mol at 286 °K. The quoted errors are standard errors from least squares fits. These parameters are compared to the extensive data known for α,α,2,4,6-pentachlorotoluene. A series of barrier calculations, based on modified Buckingham and on van der Waals potential energy functions, are discussed with reference to various halotoluenes.

Canadian Journal of Chemistry, 49, 789 (1971)

Introduction

In previous studies (1–3) of the barrier to rotation about the sp^2–sp^3 carbon–carbon bond in α,α,2,4,6-pentachlorotoluene (PCT) and α,α-dichloro-2,4,6-tribromotoluene (DCTBT), various spectral types and line-shape analyses were used to establish the probably small and negative entropies of activation for the rotation as well as the conformations of the unactivated molecules. In this study, a similar investigation is carried out for α,α,α′,α′,2,3,5,6 - octachloro - *p* - xylene (POCX) and is briefly described. In addition, a moderately successful barrier calculation is carried out for PCT and similar molecules using the modified Buckingham and van der Waals potential energy functions (4–6).

Experimental

The POCX was prepared by chlorination of 2,3,5,6-tetrachloro-*p*-xylene and was also obtained from Aldrich Chemical Company. A 3 mol % solution of POCX in toluene-d_8 was degassed by the freeze–pump–thaw technique and tetramethylsilane (TMS) served as an internal reference and lock signal.

The p.m.r. measurements were made on an HA-100D spectrometer in the frequency sweep mode. Frequency calibrations were obtained by a period averaging technique. Variable temperature work involved the V4341/V6057 accessory and temperature calibrations were based on thermocouple measurements in a dummy toluene sample. All spectra were recorded at a sweep rate of 0.02 Hz/s.

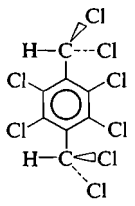
[1]Holder of an NRCC Scholarship, 1969–1970.

Results and Discussion

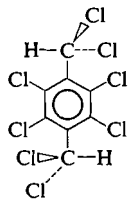
(*1*) *Determination of Rate Constants*

(a) General Remarks

In the low temperature region the spectrum consists of two sharp peaks, of *equal* intensity within experimental error, which are attributed to **1** and **2**. The C—H bonds lie in the plane of the



1



2

ring in **1** and **2** as expected on the basis of the behavior of PCT (1, 2) and on the basis of potential barrier calculations described below. At higher temperatures the peaks broaden and eventually collapse to a single sharp peak. The equal populations of **1** and **2** are somewhat surprising because **1** is expected to have a finite dipole moment[2] and therefore a higher stability

[2]A 3 mol % solution of POCX in the polar solvent CH_2ClBr (dielectric constant = 8.5) also displayed two peaks of equal intensity with an internal shift at −15 °C of 3.6 Hz. Solubility problems at lower temperatures did not allow a determination of the intrinsic temperature dependence of the shift. The small shift of 3.6 Hz made an accurate determination of other than $\Delta G‡$ very difficult (small temperature range).

For personal use only.

in a solvent of dielectric constant greater than unity. On the other hand, it is likely that **1** is less stable than **2** because of steric strain arising from the dichloromethyl group orientation in **1**. It may be that the two opposing causes fortuitously cancel in POCX.

(b) Solvent Effects on the Internal Chemical Shift

The well-known solvent shifts induced by aromatic solvents vary with temperature (7) and, as described for PCT (1), must be accounted for before a proper line-shape fit can be made. Below −4 °C the exchange rate is slow enough to cause little shifting of the two peaks. An assumed linear decrease of the internal shift as the temperature increases between −39 and −4 °C gave the least squares eq. 1 ($r = 0.9863$). Rate-independent

$$[1]\quad \text{internal shift (Hz)} = 0.0438 \pm 0.002T(°C) + 7.118 \pm 0.075$$

shifts were calculated at higher temperatures using eq. 1 in a manner similar to that described for PCT (1). The internal shift in absence of exchange varies from 8.84 Hz at −39.3 °C to 4.21 Hz at 66.5 °C.

(c) Line-shape Fitting Procedure

Line-shapes were fitted as before (1) to theoretical spectra generated by the computer program ABXFIT (1), based on a proper density-matrix treatment of the exchange process. The effective T_2 values were determined from the width at half-height of a weak impurity peak arising from α,α,α′,α′,α′,2,3,5,6 - nonachloro - *p* - xylene. This width could be kept constant at 0.185 ± 0.02 Hz over the temperature range and yields T_2 = 1.72 s.

The rate constants k ranged from 185 s^{-1} at 52.3 °C to 0.0535 s^{-1} at −35 °C, a change of more than a factor of 10^3.

(2) Derivation of Activation Parameters

Plots of log k *vs.* $1/T$ ($r = 0.9964$) gave the activation energy and the frequency factor. A plot of log k/T *vs.* $1/T$ (8) is shown in Fig. 1 (r = 0.9961) from which the enthalpy of activation, $\Delta H‡$, and the entropy of activation, $\Delta S‡$, were derived. The parameters are $E_A = 13.6 \pm 0.4$ kcal/mol, log $A = 11.3 \pm 0.3$, $\Delta H‡ = 13.1 \pm 0.4$ kcal/mol, $\Delta S‡ = -7.3 \pm 1.3$ e.u., $\Delta G‡ = 15.4 \pm 0.1$ kcal/mol at 286 °K. The errors are

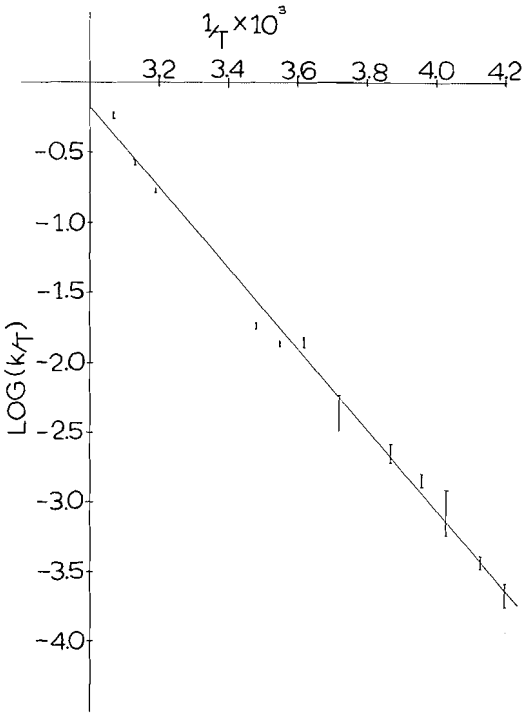

FIG. 1. A plot of log (k/T) *vs.* $1/T$ for the internal rotation in α,α,α′,α′,2,3,5,6-octachloro-*p*-xylene. The error bars reflect the estimated error in the rate constant derived from the line-shape analysis at various temperatures. The least squares line is drawn.

standard errors from the least squares fits. In CH_2ClBr we found $\Delta G‡ = 15.2 \pm 0.1$ kcal/mol at 286 °K. The values for PCT in methylcyclohexane, toluene-d_8, and carbon disulfide solutions (2) are $E_A = 14.2 \pm 0.3$ kcal/mol, log $A = 11.9_5 \pm 0.2$, $\Delta H‡ = 13.7 \pm 0.3$ kcal/mol, $\Delta S‡ = -4.4 \pm 1.0$ e.u., and $\Delta G‡$ 15.1 ± 0.1 kcal/mol at 286 °K.

(3) Discussion of Activation Parameters

Within experimental error the activation parameters are nearly equal for PCT and POCX. Yet the barrier calculations below indicate that if normal bond angles are maintained throughout the rotation of the dichloromethyl group in PCT, the barrier should be considerably greater than the experimental values. Consequently a certain degree of bond bending probably occurs in order to relieve the repulsive interactions and thereby lowers the barrier. In PCT the ring substituents in the ortho positions are relatively free to relieve

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the strain but in POCX a further source of steric hindrance is met in the adjacent chlorine ring substituents.

Conformational calculations show that 2,3,5,6-tetrahalosubstitution of the benzene nucleus introduces considerable distortion of the bond angles in the plane of the ring (9). The calculated equilibrium conformation of 2,3,5,6-tetrachlorobenzene has an adjacent chlorine–chlorine internuclear distance of 3.18 Å whereas the equilibrium van der Waals distance for chlorine–chlorine is 3.60 Å (10). Steric interactions of this nature very likely raise the ground state of the tetrachloro structure relative to the 2,6-dichloro structure.

It would appear, therefore, that the ground state energy of POCX is raised by more than its transition state energy, leading to an equal or slightly lower energy barrier than in PCT. It is tempting to suggest that the transition state in POCX will be more crowded than in PCT, thus rationalizing a tendency towards a somewhat more negative $\Delta S\ddagger$ in POCX. The transition state in both molecules has eclipsed Cl–Cl interactions (see below).

In summary, the rate of rotation of the dichloromethyl group is not significantly different at any given temperature in POCX and PCT. Any "buttressing" effect of the ring chlorine atoms apparently does not dramatically alter the nature of the internal rotation.

(4) Semiempirical Barrier Calculations

(a) The Potential Functions

Molecular orbital methods are not at present suitable for the calculations of barriers to internal rotation in molecules containing halogens (11). Therefore, following Jonas *et al.* (6) and, on the assumption that the largest part of the rotational barrier arises from the pair-wise, nonbonded steric and electrostatic interactions between the dichloromethyl group and the ortho ring substituents (4), two separate potential energy functions were used. In eqs. 2 (modified Buckingham potential) and 3 (van der Waals function) each summation is over the jth pair of atoms and r_j is the internuclear distance.

$$[2] \quad V(\theta) = \sum_j A_j \exp(-B_j r_j) - C_j/r_j^6 + D_j/r_j$$

$$[3] \quad V(\theta) = \sum_j A_j \exp(-r_j/P_j)$$

Equation 2 was applied in the form developed by Scott and Scheraga (4). The parameters A, B, and C are the normal ones for the six-exponential potential (12–14). The constant D enters as the dipole moment contribution (15). Equation 3 was employed as described by Howlett (5) and the interaction constants A_j and P_j, including Br–Cl, F–Cl, and Br–F interactions as estimated by the geometric mean method (4, 15) are tabulated in ref. 16.

(b) Computational Method

The computation of the barrier involved the determination of six internuclear distances, *i.e.*, the distance of each ring substituent to each of the three methyl group substituents for each degree of the rotation, and applying these distances to the designated function. The bond lengths were taken from data available for analogous compounds (17).

Two programs were written in Fortran IV for use on an IBM 360/65 computer. One program, POTL1, was designed to handle asymmetric ring substitution and the other, POTL2, handles symmetric substitution. For example, for the compound, α,α,2,6-tetrachlorotoluene, the input parameters include the C—Cl bond length of the ring, the C—Cl bond length of the methyl group substituent, and the methyl C—H bond length in Å. Depending upon the choice of potential function, one requires the appropriate interaction constants for the Cl–Cl and Cl–H interactions. The value of the potential energy in kcal/mol is output for each degree of rotation about the sp^2–sp^3 carbon–carbon bond and can be had as data on the line printer and/or as a Calcomp plot. Both programs in their present form require that two of the methyl substituents be the same, although three different substituents on the methyl rotor could be accommodated by a modest modification.

In realization of the probable importance of bond bending in the rotation process, a rather naive approach (necessary to retain simplicity in the computing) consisted of repetition of the calculation after changing from normal bond angles[3] of all bonds to a geometry where all bonds

[3]Normal bond angles in this context refer to 109° 28′ at the sp^3 carbon, and 120° at sp^2 carbon, atoms.

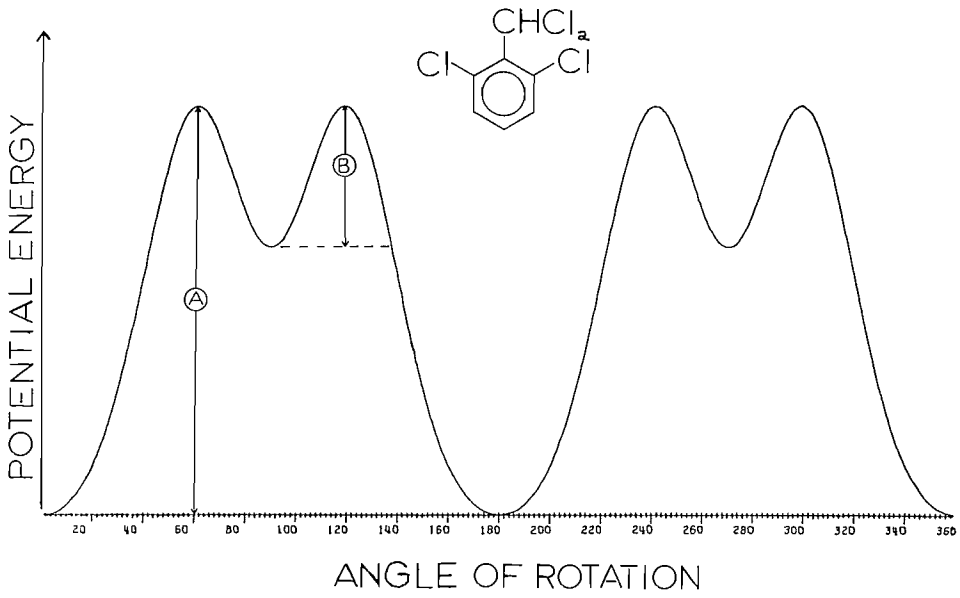

FIG. 2. The shape of the potential energy barrier to rotation as given by both the modified Buckingham and the van der Waals functions for α,α,2,6-tetrachlorotoluene. The values of the barriers *A* and *B* are collected in Table 1. The 0° angle of rotation has the C—H bond of the sidechain in the plane of the aromatic ring.

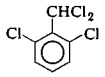
4	3.689	0.896	9.542	2.220
5	2.987	0.713	7.576	1.764

*The compound has structure shown below with the following bond lengths: ring C—Cl, 1.71 Å; methyl C—Cl, 1.78 Å; methyl C—H, 1.11 Å.



Comment on the barrier shape: the barrier shape appears in Fig. 2 and is unchanged for 5° of bending. Both potential energy functions indicate the same barrier shape.

†Note that bend = 0 refers to the normal bond angle case, bend = 1 to all five bonds involved in the rotational interactions bent back by 1°, etc.

‡All barrier values are in kcal mol^{-1}.

§All barrier values are recorded to three decimal places with the realization that the accuracy of the constants does not necessarily warrant this number of significant figures in the final barrier value.

were bent back by a specified number of degrees. Thus, the methyl substituent bonds were bent towards the sp^2–sp^3 bond axis while the ring substituent bonds were bent away from the rotational site but in the plane of the ring.

This treatment of bond bending is in no way rigorous. A more realistic mechanism is more likely that of bond-wagging at points of greatest strain in the rotation and the energy of bond bending, although relatively small, should be

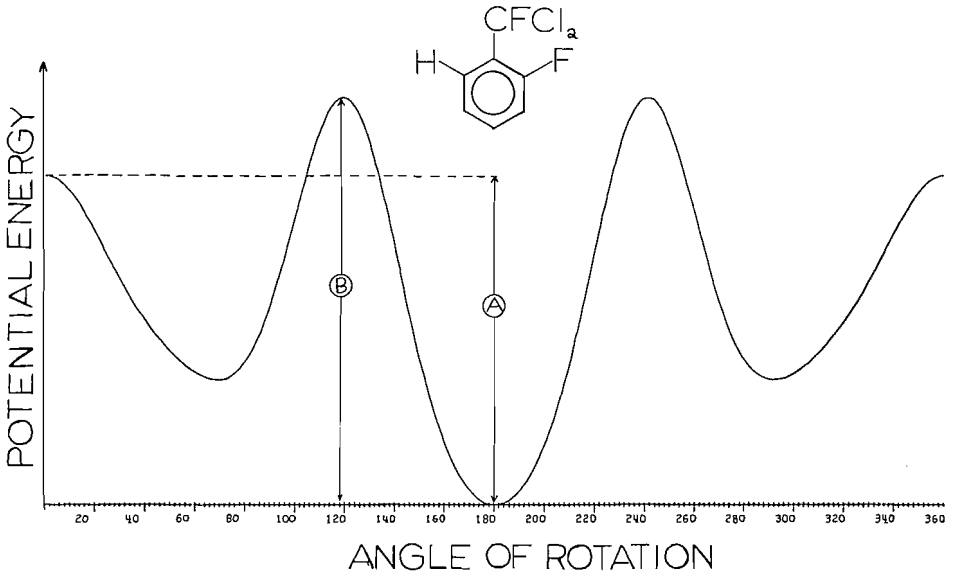

FIG. 3. The shape of the potential barrier to internal rotation as given by the modified Buckingham potential for α,α-dichloro-α,2-difluorotoluene. Barrier values at points *A* and *B* are given in Table 2. At 0° of rotation the C—F bond of the sidechain eclipses the C—F bond in the ring.

included at these points. Such a treatment would be comparable to one on a dynamic framework but would also require large amounts of computer time.

(c) An Example: PCT Barriers and Conformers

As an example of the computations, Fig. 2 reproduces the shape of the rotational potential energy barrier for the dichloromethyl group of α,α,2,6-tetrachlorotoluene. The zero angle of rotation has the C—H bond of the group in the plane of the ring. In this case both potential functions yield the same barrier shape. The magnitude of the barrier is different for the two functions and a set of values for different degrees of bond-bending is given in Table 1. The shape of the barrier does not change as the bond angles are bent back.

The two potential functions yield the same results whether or not a chlorine is substituted in position 4 so that the computation is also valid for PCT (and roughly also for POCX). The

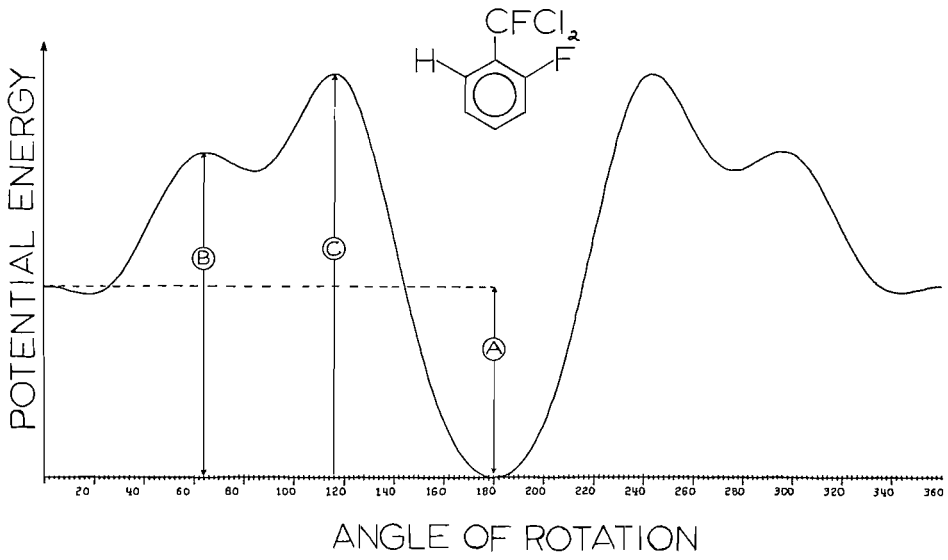

FIG. 4. As in Fig. 3 but for the van der Waals function. Barriers *A*, *B*, *C* are tabulated in Table 2.

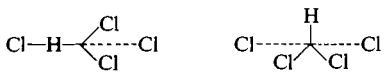
experimental barrier of near 14 kcal/mol is reproduced by the van der Waals function for a bond-bend of just over 1° while the Buckingham function would "demand" a bend of just over 2°.

The qualitative result (1) that **3** is the ground state of the molecule and that **4** is not appreciably populated at any of the temperatures up to 400 °K, is well reproduced by the computation.



3 **4**

Experimentally (3) the barrier in α,α-dibromo-2,6-dichlorotoluene is about 1.5 kcal/mol higher than in PCT. For the bond-bend which reproduces the barrier in PCT, the van der Waals function predicts a barrier about 5 kcal/mol higher in the bromo compound while the Buckingham potential overestimates it by 10 kcal/mol. Of course, the amount of bond bending during the rotation could well be larger in the bromo compound than in PCT.

(d) The Usefulness of the Functions

Computations for a variety of halosubstitution patterns indicate that fluorine or hydrogen substituents lead to barriers which are too small to allow the detection of individual conformers by n.m.r. For example, in Table 2 results for some of the calculations on α,α-dichloro-α,2-difluorotoluene are given. The barriers correspond to those drawn in Figs. 3 and 4. Both potential energy functions predict the most stable conformation as one in which the C—F bond of the sidechain eclipses the ortho C—H bond of the ring for normal bond angles (0° bend) and that this conformation is the only one appreciably populated near room temperature. Again, both functions agree in predicting the highest energy for an eclipse of the ring C—F bond by the C—Cl bond in the sidechain. On the other hand, the functions predict different potential shapes in the region of a 20–100° twist of the sidechain C—F bond from its eclipsed position over the C—F bond in the ring.

By using the stereospecificity of the H–H and H–F coupling constants from the sidechain to the ring, it is probable that at least some of these predictions can be verified experimentally. Such experiments are in progress.

The extensive help of Mr. Bruce Goodwin with the computing problems is gratefully acknowledged. This work was supported by the National Research Council of Canada. We thank Dr. C. M. Wong and Mr. K. Chum for the synthesis of POCX.

Synthesis of Paratose (3,6-Dideoxy-D-*ribo*-hexose) and Tyvelose (3,6-Dideoxy-D-*arabino*-hexose)[1]

E. H. WILLIAMS, W. A. SZAREK, AND J. K. N. JONES
Department of Chemistry, Queen's University, Kingston, Ontario

Received August 14, 1970

Convenient syntheses of the biologically important 3,6-dideoxyhexoses paratose (**12**) and tyvelose (**8**) from the readily available chlorodeoxy sugar methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**) are described.

Canadian Journal of Chemistry, 49, 796 (1971)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Introduction

Paratose (3,6-dideoxy-D-*ribo*-hexose) and tyvelose (3,6-dideoxy-D-*arabino*-hexose) have been isolated from lipopolysaccharides elaborated by Gram–negative bacteria (1–3). They, along with abequose (3,6-dideoxy-D-*xylo*-hexose) and colitose (3,6-dideoxy-L-*xylo*-hexose), were first recognized among the *Salmonella* and *E. coli* strains. When present, these 3,6-dideoxyhexoses occur at the nonreducing ends of chains and constitute immunodominant groups of their respective antigenic determinants (1–5). Syntheses of paratose (6, 7) and tyvelose (7–11) have been reported previously. In continuation of our studies on the synthesis and reactions of chlorodeoxy sugars (12–14), we now report convenient syntheses of both paratose (**12**) and tyvelose (**8**) from the same intermediate, methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**). This work demonstrates further the utility of the readily available chlorodeoxy sugars in the synthesis of biologically significant sugars.

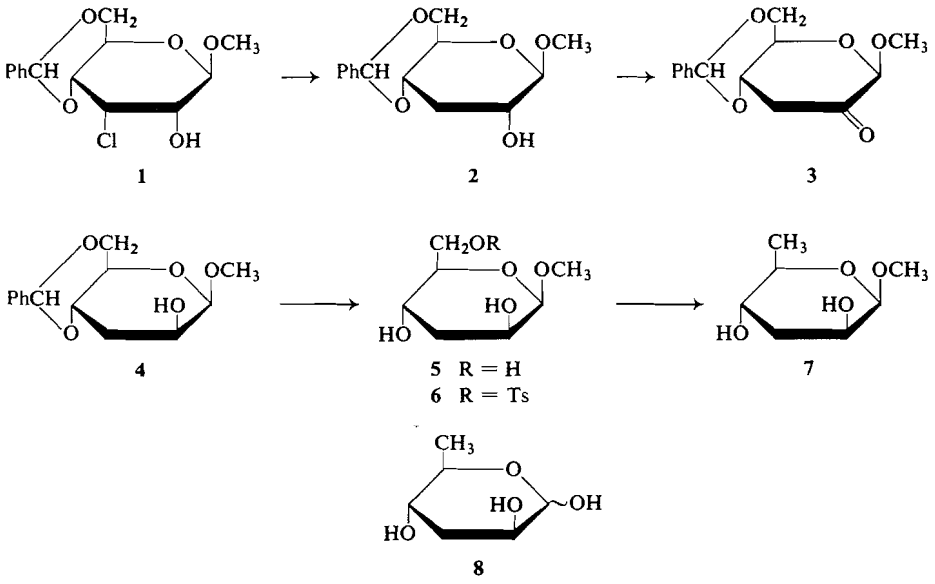
Results and Discussion

Crystalline methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**) was prepared by reaction of methyl 4,6-*O*-benzylidene-β-D-glucopyranoside with sulfuryl chloride, and dechlorosulfation of the product using sodium iodide, as described previously (14, 15). Hydrogenation of compound **1**, in the presence of potassium hydroxide, over a W-4 Raney nickel catalyst (12), afforded methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*ribo*-hexopyranoside (**2**) (16–18) (Scheme 1). Oxidation of the 3-deoxy sugar derivative **2** with ruthenium tetroxide, according to the improved procedure of Lawton *et al.* (19), gave methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*erythro*-hexopyranosid-2-ulose (**3**) (16). Treatment of the 2-ketone **3** with sodium borohydride in methanol at reflux temperature yielded compound **2** and methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*arabino*-hexopyranoside (**4**) (10), which were separated by column chromatography on silica gel. The remaining steps in the route for the synthesis of tyvelose were the same as those employed by Stirm *et al.* (10). Thus, acid-catalyzed de-*O*-benzylidenation of **4** gave methyl 3-deoxy-β-D-*arabino*-hexopyranoside (**5**), which yielded the 6-*O*-*p*-tolylsulfonyl derivative **6**. Desulfonyloxylation of **6** with lithium aluminum hydride in tetrahydrofuran afforded methyl 3,6-dideoxy-β-D-*arabino*-hexopyranoside (methyl β-D tyveloside) (**7**), which was converted into the crystalline free sugar **8** by acid-catalyzed hydrolysis.

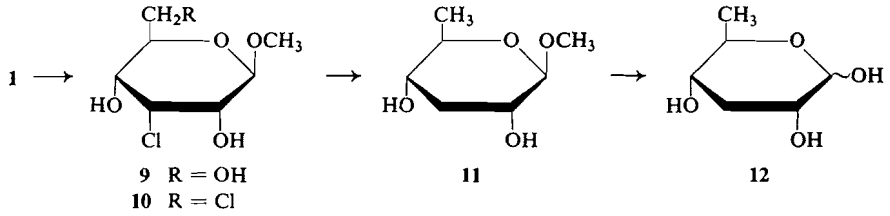
The first route in the present work for the synthesis of paratose, with methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**) as an intermediate, involved a further reaction with sulfuryl chloride (Scheme 2). Acid-catalyzed de-*O*-benzylidenation of compound **1** gave the previously reported (15) methyl 3-chloro-3-deoxy-β-D-allopyranoside (**9**) as a syrup. Treatment of **9** with sulfuryl chloride yielded a syrup, which, on dechlorosulfation, gave crystalline methyl 3,6-dichloro-3,6-dideoxy-β-D-allopyranoside(**10**) (20). The lack of substitution by chloride ion of the intermediate chlorosulfonyloxy group at C-4 is attributed to the presence of the vicinal axial substituent at C-3; also, a chlorosulfonyloxy group at C-2 is deactivated to nucleophilic substitution by chloride ion (14, 15, 20, 21). Hydrogenation of **10**, in the presence of potassium hydroxide, over a W-4 Raney nickel catalyst (12), gave crystalline methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside (**11**).

The glycoside **11** was prepared also by an alternative procedure (Scheme 3). Treatment of methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*ribo*-hex-

[1]Part IV in the series Synthesis and Reactions of Chlorodeoxy Sugars.



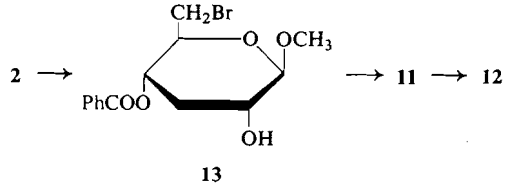
SCHEME 1



SCHEME 2

opyranoside (**2**) with *N*-bromosuccinimide (22) in boiling carbon tetrachloride, in the presence of barium carbonate, gave a high yield of methyl 4-*O*-benzoyl-6-bromo-3,6-dideoxy-β-D-*ribo*-hexopyranoside (**13**). When compound **13** was heated with lithium aluminum hydride in tetrahydrofuran at reflux temperature, debromination and debenzoylation occurred to give **11**. Acid-catalyzed hydrolysis of **11** afforded paratose (**12**).

A synthesis of abequose (3,6-dideoxy-D-*xylo*-hexose) was attempted also from methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**). It has been shown previously (14, 23) that heating the chlorodeoxy sugar (**1**) in *N*,*N*-dimethylformamide at reflux temperature with sodium benzoate gives a high yield of an unsaturated derivative, methyl 4,6-*O*-benzylidene-β-D-*erythro*-hex-3-enopyranoside. An effort was made to convert this unsaturated compound into methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*xylo*-hexopyranoside, which would be a convenient precursor to abequose. Thus, when a solution of the unsaturated compound in ethanol containing palladium-on-carbon was subjected to a hydrogen pressure of 40 p.s.i.g., even after 3 days, only a 50% conversion to compound **2** was achieved; there was no evidence for the presence of the desired compound.



SCHEME 3

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 141 automatic polarimeter at 23 ± 2°. The n.m.r. spectra were determined at 60 MHz in chloroform-*d* and using tetramethylsilane as internal standard. The t.l.c. was per-

formed with Silica Gel G as the adsorbent. The developed plates were air dried, sprayed with 5% ethanolic sulfuric acid, and heated at about 150°. The term "petroleum ether" refers to the fraction of b.p. 60–80°.

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (1)

This compound was prepared from methyl 4,6-*O*-benzylidene-β-D-glucopyranoside (15 g) as described previously (14, 15). The crystalline product was recrystallized from ether – petroleum ether to give colorless prisms (14.9 g, 93%) with the same physical constants as reported by Lawton *et al.* (14) for compound **1**.

Methyl 4,6-O-Benzylidene-3-deoxy-β-D-ribo-hexopyranoside (2)

A solution of compound **1** (5 g) in ethanol (300 ml) containing potassium hydroxide (2.5 g) and W-4 Raney nickel catalyst (12) (1 g) was shaken in an atmosphere of hydrogen for 2 h. A solid product was isolated in the usual manner; recrystallization from chloroform – petroleum ether gave compound **2** (3.85 g, 87%), m.p. 174°, $[\alpha]_D$ −61° (*c*, 1.0 in chloroform); lit., m.p. 174–175° (16), 165° (17), 168–169° (18), $[\alpha]_D^{18}$ 59.5° (*c*, 4.1 in chloroform) (17), $[\alpha]_D$ −60.5° (*c*, 1.05 in chloroform) (18).

Methyl 4,6-O-Benzylidene-3-deoxy-β-D-erythro-hexopyranosid-2-ulose (3)

This compound was prepared by oxidation of methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*ribo*-hexopyranoside (**2**) (1 g) with a mixture of ruthenium dioxide and potassium metaperiodate in chloroform, in the presence of potassium carbonate, by the procedure described by Lawton *et al.* (19). The crystalline product was recrystallized from ethyl acetate – petroleum ether to give colorless needles (0.7 g, 70%), whose physical constants were the same as those obtained previously (16) for compound **3**, namely, m.p. 153–155°, $[\alpha]_D$ −30° (*c*, 0.5 in chloroform).

Reduction of Methyl 4,6-O-Benzylidene-3-deoxy-β-D-erythro-hexopyranosid-2-ulose (3) with Sodium Borohydride

To a solution of the 2-ketone **3** (650 mg) in methanol at reflux temperature was added dropwise a solution of sodium borohydride in methanol. The t.l.c. (1:4 ethyl acetate – chloroform) revealed after 3 h the presence of an approximately 1:1 mixture of methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*ribo*-hexopyranoside (**2**) (R_F 0.7) and another component (R_F 0.55). The mixture of these two components was isolated in the usual manner, and chromatographed on silica gel, with 1:4 ethyl acetate – chloroform as eluent, to yield compound **2** and a second crystalline product. Recrystallization of the latter from chloroform – petroleum ether gave methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*arabino*-hexopyranoside (**4**) (230 mg, 35%), m.p. 171–172°, $[\alpha]_D$ −66.3° (*c*, 1.0 in chloroform); n.m.r. data: τ 2.38–2.78 (5-proton multiplet, aromatic H's), 4.41 (1-proton singlet, benzylidene-methine H), 5.57 (1-proton doublet, $J_{1,2}$ 2Hz, H-1), 6.46 (3-proton singlet, OMe), 7.34–7.85 (2-proton multiplet, 2H-3's).

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.2; H, 6.8. Found: C, 63.1; H, 6.7.

Stirm *et al.* (10) report m.p. 172–174° and $[\alpha]_{5461}^{25}$ −75 ± 2° (*c*, 0.7 in chloroform) for compound **4**.

Methyl 3-Deoxy-β-D-arabino-hexopyranoside (5)

A solution of methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*arabino*-hexopyranoside (**4**) (200 mg) in acetone (6 ml) and 0.1 *N* hydrochloric acid (4 ml) was heated at reflux temperature for 1 h. The acetone was removed by distillation, and the aqueous solution was neutralized with Duolite A-4 (OH^-) ion-exchange resin and concentrated to yield a chromatographically homogeneous (t.l.c., 6:1 chloroform–methanol) syrup (100 mg, 91%), $[\alpha]_D$ −67.6° (*c*, 0.9 in methanol); n.m.r. data: τ 5.43 (1-proton doublet, $J_{1,2}$ 2 Hz, H-1), 6.46 (3-proton singlet, OMe), 7.49–8.35 (2-proton multiplet, 2H-3's).

Methyl 3-Deoxy-6-O-p-tolylsulfonyl-β-D-arabino-hexopyranoside (6)

Methyl 3-deoxy-β-D-*arabino*-hexopyranoside (**5**) (170 mg) was treated with *p*-toluenesulfonyl chloride (260 mg) in dry pyridine (5 ml) at 0°. The solution was kept at room temperature for 24 h, and then poured into water; the mixture was extracted several times with chloroform. Concentration of the combined extracts, after they had been washed with 2 *N* sulfuric acid and then water, yielded a syrup, which was chromatographed on silica gel, with 19:1 ethyl acetate – methanol as eluent. Compound **6** was obtained as a syrup (155 mg, 71%), $[\alpha]_{5461}$ −41° (*c*, 1.0 in chloroform); n.m.r. data: τ 2.04–2.74 (4 protons, aromatic H's), 5.59 (1-proton doublet, $J_{1,2}$ 2 Hz, H-1), 6.5 (3-proton singlet, OMe), 7.5 (3-proton singlet, aromatic Me). Stirm *et al.* (10) report $[\alpha]_{5461}^{25}$ −43 ± 2° (*c*, 1.3 in chloroform) for compound **6**.

Methyl 3,6-Dideoxy-β-D-arabino-hexopyranoside (7)

The 6-*O*-*p*-tolylsulfonyl derivative **6** (150 mg) was heated under reflux with lithium aluminum hydride in tetrahydrofuran for 1 h. Fractionation of the product on silica gel, with 9:1 ethyl acetate – methanol as eluent, gave the glycoside **7** as a homogeneous syrup (65 mg, 89%), $[\alpha]_{5461}$ −72° (*c*, 1.1 in methanol); R_F 0.4 (19:1 ethyl acetate – methanol); n.m.r. data: τ 5.62 (1-proton doublet, $J_{1,2}$ 2 Hz, H-1), 6.49 (3-proton singlet, OMe), 8.52 (3-proton doublet, *J* 6 Hz, C-5 Me). Stirm *et al.* (10) report $[\alpha]_{5461}^{25}$ −72 ± 2° (*c*, 0.9 in methanol) for compound **7**.

3,6-Dideoxy-D-arabino-hexose (Tyvelose) (8)

A solution of methyl 3,6-dideoxy-β-D-*arabino*-hexopyranoside (7) (57 mg) in 0.2 *N* sulfuric acid (5 ml) was heated at 90° for 3 h. The cooled solution was neutralized with Duolite A-4 (OH^-) ion-exchange resin and concentrated to a syrup (48 mg, 92%). Distillation of this material at 100–125° (bath)/0.01 Torr gave a homogeneous syrup, with R_F 0.33 (19:1 ethyl acetate – methanol), which crystallized spontaneously. Recrystallization from acetonitrile gave tyvelose (**8**), m.p. 95–99°, $[\alpha]_D$ +22° (*c*, 0.7 in water). These physical constants are in agreement with those reported previously (1, 7) for tyvelose.

Methyl 3-Chloro-3-deoxy-β-D-allopyranoside (9)

A solution of methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (**1**) (2.45 g) in acetone (40 ml) and 0.2 *N* hydrochloric acid (13 ml) was heated at reflux temperature for 4h. The acetone was removed by distillation, and the aqueous solution was neutralized with Duolite A-4(OH^-) ion-exchange resin and concentrated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

to yield a chromatographically homogeneous (t.l.c.) syrup (15) (1.56 g), R_F 0.5 (6:2:1 1-butanol–ethanol–water); $[\alpha]_D$ −49° (*c*, 1.0 in water).

*Methyl 3,6-Dichloro-3,6-dideoxy-β-D-allopyranoside (**10**)*

This compound was prepared from methyl 3-chloro-3-deoxy-β-D-allopyranoside (**9**) (1.39 g) by reaction with sulfuryl chloride and subsequent dechlorosulfation, as described by Cottrell *et al.* (20). The crystalline product was recrystallized from chloroform – petroleum ether to give **10** (0.5 g, 33%), m.p. 162–163°, $[\alpha]_D$ −43° (*c*, 0.6 in chloroform). Cottrell *et al.* (20) report m.p. 154–156° and $[\alpha]_D$ −45° (*c*, 1.0 in chloroform) for **10**.

*Methyl 3,6-Dideoxy-β-D-ribo-hexopyranoside (**11**)*

A solution of compound **10** (148 mg) in ethanol (50 ml) containing potassium hydroxide (70 mg) and W-4 Raney nickel catalyst (12) (40 mg) was shaken in an atmosphere of hydrogen for 2 days. A solid product was isolated in the usual manner; recrystallization from ethyl acetate – petroleum ether gave compound **11** (89 mg, 86%), m.p. 63–65°, $[\alpha]_D$ −60° (*c*, 1.5 in methanol); n.m.r. data: τ 5.89 (1-proton doublet, $J_{1,2}$ 8 Hz, H-1), 6.49 (3-proton singlet, OMe), 8.7 (3-proton doublet, *J* 6 Hz, C-5 Me). The molecular formula of the crystalline compound was confirmed as $C_7H_{14}O_4$ by mass spectrometry: M^+ 162.0862 (Calcd. for $C_7H_{14}O_4$: 162.0892).

*Methyl 4-O-Benzoyl-6-bromo-3,6-dideoxy-β-D-ribo-hexopyranoside (**13**)*

A solution of methyl 4,6-*O*-benzylidene-3-deoxy-β-D-*ribo*-hexopyranoside (**2**) (250 mg) and *N*-bromosuccinimide (190 mg) in carbon tetrachloride (15 ml) containing barium carbonate (91 mg) was heated at reflux temperature with vigorous stirring for 3 h. The reaction mixture was filtered, and the filtrate concentrated to a syrup, which was chromatographed on silica gel, with 1:2 ethyl acetate – chloroform as eluent. Compound **13** was obtained as a homogeneous (t.l.c.) syrup (489 mg, 84%), R_F 0.52 (1:2 ethyl acetate – chloroform); n.m.r. data: τ 1.86–2.74 (multiplets, 5 protons, aromatic H's), 4.71–5.24 (1-proton multiplet, H-4), 5.7 (1-proton doublet, $J_{1,2}$ 8 Hz, H-1), 6.4 (3-proton singlet, OMe).

Anal. Calcd. for $C_{14}H_{17}O_5Br$: C, 48.6; H, 4.9; Br, 23.2. Found: C, 48.3; H, 5.3; Br, 23.1.

A mixture of compound **13** (450 mg) and lithium aluminum hydride (250 mg) in tetrahydrofuran (10 ml) was heated at reflux temperature for 3 h. The product was isolated in the usual manner, and chromatographed on silica gel, with 19:1 ethyl acetate – methanol as eluent, to give a homogeneous (t.l.c.) syrup which crystallized spontaneously. Recrystallization from ether – petroleum ether gave pale yellow prisms (137 mg, 65%) with the same physical constants as obtained above for methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside (**11**).

*3,6-Dideoxy-D-ribo-hexose (Paratose) (**12**)*

A solution of methyl 3,6-dideoxy-β-D-*ribo*-hexopyranoside (**11**) (86 mg) in 1 *N* sulfuric acid (10 ml) was heated at 90° for 5 h. The cooled solution was neutralized with Duolite A-4 (OH^-) ion-exchange resin and concentrated to yield paratose (**12**) as a homogeneous (t.l.c.) syrup (61 mg, 78%), R_F 0.21 (6:1 chloroform – methanol); $[\alpha]_D$ +7° (*c*, 1.1 in water), in agreement with values reported previously (1, 7) for paratose.

Effect of Substituents on the Chemical Shift of Benzylic Protons. III

ROBERT R. FRASER AND ROGER N. RENAUD[1]
Department of Chemistry, University of Ottawa, Ottawa, Canada

Received September 21, 1970

The effects of para substituents on the chemical shifts of the diastereotopic benzylic protons in three series of chiral molecules have been determined from a study of the 100 MHz spectra of these molecules in deuterochloroform. The results show that the slope, ρ, obtained from a plot of τ *vs.* Hammett σ constant, is influenced by a number of factors and that the conformational disposition of the benzylic proton with respect to the aromatic ring is not a dominant factor.

Canadian Journal of Chemistry, 49, 800 (1971)

The effect of substituents on the chemical shift of benzylic protons is a subject of current controversy. Concurrent with the appearance of our complete paper (1) on this topic a comprehensive review and assessment of the same subject was published by Yokoyama *et al.* (2). These authors showed that several literature discrepancies regarding the substituent chemical shifts (s.c.s.) for the benzylic protons of benzyl chlorides and fluorides were caused by association effects (solute–solute interactions) of considerable magnitude. From an examination of their own data in conjunction with that already in the literature, Miller and co-workers expressed the opinion that at present "correlations of the Hammett type are of little value" mainly because there is an urgent need for isolating and identifying the factors which affect them. In a very recent paper, Bentley and Dewar report s.c.s. for several series of the type $ArCH_2Z$, in which Ar represents a variety of alternant aromatic nuclei including naphthyl, anthryl, and phenanthryl and Z = OH, Cl, Br, I, H, and OTs. They conclude that ring-current anisotropy rather than hyperconjugation is responsible for the s.c.s. resulting from changes in Ar. Both papers, then, are in conflict with the proposal (1) that the slope ρ of an s.c.s. *vs.* σ plot for the CH_2 protons in a series of the type $X—C_6H_4—CH_2Z$ is strongly conformationally dependent, possibly as a result of a hyperconjugative interaction between the benzene ring and the methylene protons.

Data herein will describe further investigations in this field and, in particular, a test of the proposal that ρ is a conformationally dependent parameter. Three new series of *p*-substituted benzyl derivatives have been studied and the chemical shifts of the benzylic protons measured as a function of the para substituent. The compounds examined include seven 6-X-1-phenylphthalans, **1**, five 6-X-2-methyl-1-phenylisoindolines, **2**, and five 2-X-5[*H*]dibenzo[*a*,*d*]cycloheptene oxides, **3**. In all three series, the disposition of the benzylic protons with respect to the adjacent benzene rings is fixed in a known geometry. A companion paper (4) on the synthesis and conformational properties of these three series provides an assessment of geometry for the molecules in each series. The assignment of absorption due to the diastereotopic protons in series **1** was made (5) in analogy with previous chemical shift arguments for similar 1-phenylphthalans (6), in series **3** on the basis of n.O.e. experiments (4). In series **2** unambiguous assignment was not possible.

Results and Discussion

The data for the three series of compounds are presented in Table 1. In Fig. 1, a plot of the chemical shifts for each of the diastereotopic protons at C-3 in series **1** is shown. A least squares analysis of plots of chemical shifts *vs.* σ values leads to reasonable correlations in all three series, the results of which are presented in Table 2.[2] It can be seen that the diastereotopic protons in series **1** and **2** exhibit similar ρ values. Unequal ρ values are found for the two diastereotopic protons in the series **3** in which these protons differ significantly in their orientation with respect to the adjacent π orbitals of the benzene ring. The magnitudes of all ρ's differ from those expected if the chemical shifts of the benzylic protons were being altered solely by a hyperconjugative effect. For example in series **3**, a $\cos^2\phi$ relation would predict the ρ's for H_A (quasi-axial) and H_B (quasi-equatorial) ($\phi = 40$ and 80°) to be -0.23 and -0.02 respectively (assuming $\rho_{max} = -0.42$ or twice the value for the freely rotating methyl group of toluene). Nevertheless the larger value for the slope of H_A *vs.* H_B in **3** ($CDCl_3$ solvent) is in qualitative agreement with the conformational effect.

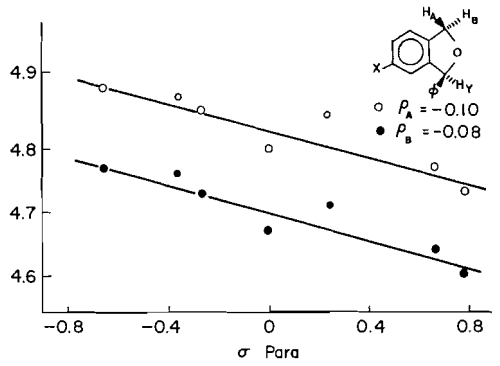

FIG. 1. A plot of the chemical shifts (τ values) of the diastereotopic protons at position 3 *vs.* the Hammett σ constant of the substituent at position 6 in a series of 6-X-1-phenylphthalans, **1**.

The effect of solvent on s.c.s. can be seen to be

[2]It has been suggested (2, 3) that a minimum of ten members of any series be required to provide a reliable assessment of any τ *vs.* σ correlation. While such a requirement is desirable, it was felt at the outset of the investigation, that its practical disadvantages could be offset by the advantages of studying a wider range of series containing fewer members. It seems highly unlikely that the conclusions reached in this paper would be altered by increasing the number of compounds studied in each series.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

particularly influential from the data for series **3** in acetone. In this solvent the quasi-axial proton at C-5 shows a ρ similar to that for the $CDCl_3$ measurements, but the ρ for the quasi-equatorial proton at C-5 increases from -0.12 to -0.25.[3] It would appear then that the concern of Miller and co-workers regarding the influence of solvent on s.c.s. is forcefully justified. The dominance of solvent in completely reversing the relative magnitudes of ρ values for the fixed protons in **3** weakens our proposal that conformational effects determine the size of ρ. It remains possible that deuterochloroform, as solvent, does not exert a significant influence on ρ.

The cause of the pronounced effect of solvent can only be speculated upon. It has been shown previously (1) that, for the series **4**, variations in ρ with changing solvent failed to show any correlation with the dielectric constant of the medium, indicating the possibility of specific solute–solvent interactions or "complex formation". One way to account for the data in series **3** would be to invoke a substituent effect on the stability of the solute–solvent complex.[4] In this complex both aromatic rings may interact with the electron-deficient carbon of the acetone carbonyl group in such a way that the anisotropy of the carbonyl (9, 10) exerts a deshielding effect on the quasi-equatorial proton at C-5 while the quasi-axial proton may be situated in an insensitive region of the deshielding cone (10). Whether or not the above explanation is valid in its detail, it is obvious that a substituent effect on complex formation, or its orientation, will influence the s.c.s. and thus decrease the importance of conformational effects on ρ.

In view of the mounting evidence that solvent, association, conformation, ring-current, and substituent anisotropy all influence s.c.s. it would appear that Miller's rather pessimistic viewpoint (2) on the understanding of their causes is justified.

Experimental

All spectra were run on a Varian HA-100 spectrometer. The data reported herein were obtained by exact analysis of the AB patterns or by using the iterative computer program of Castellano and Bothner-By for the ABX patterns. Dilution effects were found to be negligible from a study of the spectra at concentrations of 0.3, 0.2, and 0.1 *M* solutions in deuterochloroform. The shifts are reported for 0.1 *M* solutions in series **1** and **3** and 0.2 *M* solutions in series **2**. All line positions were obtained from the average of five measured spectra. The least squares analyses were performed by computer calculation. The sigma constants employed in the calculation are taken from the compilation of McDaniel and Brown (11). The syntheses of the compounds and the other n.m.r. spectral parameters obtained by analyses are described in separate papers (4, 5).

The authors thank the National Research Council of Canada for generous financial support.

[3]The slight possibility that the assignments for H_A and H_B might be reversed in acetone was eliminated by examining the spectra for the methoxy derivative of **3** in mixtures of $CDCl_3$–acetone, wherein intermediate values of τ H_A and H_B showed that no reversal occurred.

[4]Formation of such "complexes" between aromatic solvents and ketone solutes are well-known (7). The exact nature of the "complex" is the subject of considerable controversy (8).

Reaction of Hydrogen Atoms with Carbon Suboxide

NICK DEMCHUK[1] AND H. D. GESSER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received April 11, 1969[2]

The gas phase reaction of hydrogen atoms with carbon suboxide was studied over the temperature range of −96 to 235 °C and was found to proceed via a chain reaction. The products found were CH_4, CO, CH_2CO, C_2H_6, $(CHO)_2$, and polymer. A mechanism is proposed and the chain reaction is explained by the intermediate formation of ketene and the formyl radical.

Canadian Journal of Chemistry, 49, 803 (1971)

Within the past decade a great deal of interest has been shown in the relatively unfamiliar compound C_3O_2 chiefly because of the formation of the suboxide or its polymer as a product in the radiolysis of CO and CO_2 (1–4) and in the photolysis of CO (5). The suboxide polymer is also formed during the pyrolysis, photolysis, and radiolysis of C_3O_2 (6–8). Comprehensive studies (9–11) on the photochemical decomposition of carbon suboxide have shown that the primary process is wavelength dependant and can be described by the sequence of reactions shown in eq. 1, where S refers to the singlet state, T the triplet state, and the asterisk indicates an energetic species. The CCO intermediate was found to be very reactive and its reaction has been studied in the presence of added gases such as C_2H_4, O_2 and NO (12–17).

[1] $$C_3O_2 + h\nu \rightarrow C_3O_2^* \begin{cases} \xrightarrow{(a)} CO + CCO(S) & 2000\,\text{Å} < \lambda < 2500\,\text{Å} \\ \xrightarrow{(b)} CO + CCO(T) & \lambda > 2900\,\text{Å} \end{cases}$$

Carbon suboxide has been recently photolyzed in the presence of H_2 (18) and the products found and analyzed were CO, CH_4, C_2H_6, and C_3H_8. Ketene was not found. Reaction 2 was proposed to account for the products.

[2] $$CCO(S) + H_2 \rightarrow CH_2(S) + CO$$

Carbon suboxide has been reacted with oxygen atoms (18–20) as well as N-atoms (20) but as yet no report has been published on its reaction with hydrogen atoms. We have previously reported on the reactions of H-atoms with ketene (21) and in view of the similarity between C_3O_2 and ketene it was desirable to examine this reaction.

Experimental

The apparatus was similar to that used previously (21) except for a few changes. (*1*) A D.C. condensed discharge system was connected across a Wood–Bonhoeffer tube (with aluminum electrodes) with the hope of obtaining a more constant hydrogen atom supply. However, spark gap difficulties were encountered. (*2*) The reaction vessel was altered to prevent back diffusion of reactants into the discharge zone and to prevent a direct light path from the discharge to the reaction region (22).

The hydrogen was purified by passage through a copper furnace at 450 °C and then through two silica gel traps maintained at 77 °K. The molecular hydrogen flow rate was about 2.7×10^3 μmol/min with 1.05 ± 0.01 Torr as the reaction pressure. The reaction vessel was not poisoned and the H atom concentration as determined from the HCl formed from reaction with C_2H_5Cl at 65 °C (23) was 45 μmol/min or about 1.7%.

The C_3O_2 was prepared by the dehydration of malonic acid (Matheson, Coleman and Bell), with P_2O_5 according to Stock and Stoltzenberg (24) and was fractionated by bulb-to-bulb distillation *in vacuo*. The final product contained less than 3 mol% of CO_2 and suitable corrections were made for this.

The non-condensable products, CO and CH_4, were trapped in a silica gel trap (25) pumped into the gas burette and quantitatively determined by gas chromatography.

Results and Discussion

The products identified and analyzed were CO, CH_4, C_2H_6, and ketene. Glyoxal was detected in experiments at 77 and −78 °C but no attempt was made to estimate it quantitatively. In all experiments a small amount of a dark residue was formed in the reaction vessel. This may have been carbon or polymer, or both, and probably accounts for the lack in material balance. This residue was not removed after each run. At

5.0	139 adsorbed	27	13	trace	nil	nil	trace glyoxal

*A blank indicates that the product was not analyzed for. "Trace" indicates that the amount of product was less than 2 μmol/min.
†The "carbon balance" was determined by taking the ratio of the total carbon in the gaseous products to three times the C_3O_2 reacted.

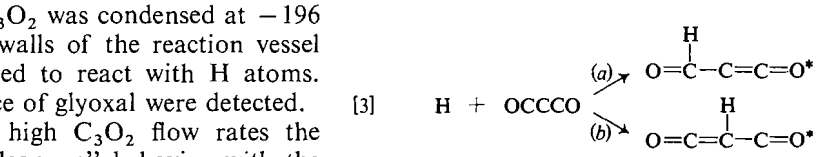
235 °C large amounts of a dark brown polymer were formed within the reaction zone near the C_3O_2 inlet. Because of the predominant polymer formation at this temperature it is believed that a thermopolymerization of C_3O_2 took place in the presence of hydrogen, catalyzed by hydrogen atoms. These high temperature results will be discussed separately.

The results are tabulated in Table 1. In one experiment some C_3O_2 was condensed at −196 °C onto the inner walls of the reaction vessel where it was allowed to react with H atoms. Only CO and a trace of glyoxal were detected.

At −96 °C and high C_3O_2 flow rates the reaction follows "clean up" behavior with the yield of CO and the C_3O_2 consumed approaching the H-atom flow rate. At low flow rates of C_3O_2 the yield of CO is almost twice that of the H-atom and the C_3O_2 consumed almost equals the H-atom flow rate. The CH_4 similarly shows a maximum in yield as a function of the C_3O_2 flow rate.

Though similar trends are obtained at −78 and 77 °C, the yield of products far exceeds the H-atom flow rate and a chain reaction must be effective.

The primary reaction most consistent with the results would seem to be the addition of a hydrogen atom to the double bond (eq. 3). Displacement reactions must be rejected because of the endothermic nature of such reactions



where reaction 3*a* is believed to be more likely in view of the presence of glyoxal as a product.

At low flow rates of C_3O_2 where H-atoms are in excess, reactions 4 and 5 occur, where OCC

Conformation in Solution of 1,1,2,3,4,4-Hexachlorobutane

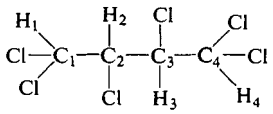
J. B. ROWBOTHAM,[1] H. M. HUTTON,[2] AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received September 16, 1970

Commercially available (Aldrich) 1,1,2,3,4,4-hexachlorobutane is as the meso isomer. On the basis of the values of the three distinct proton–proton coupling constants it is concluded that, with respect to the C—H bonds, the conformation is *gauche* about the C_1—C_2 bond and *trans* about the C_2—C_3 bond.

Canadian Journal of Chemistry, 49, 806 (1971)

In carbon disulfide (CS_2) and in dimethylsulfoxide (DMSO) solution the p.m.r. of **1** is an $[AX]_2$ spectrum. Analysis by LAOCN3 (1) yields $J_{1,2} = J_{3,4} = 1.80$ (1.86), $J_{2,3} = 10.14$ (10.08),



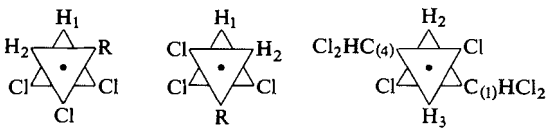
1

$J_{1,3} = J_{2,4} = -0.22$ (−0.16), and $J_{1,4} < 0.05$ Hz; the values in DMSO solution are given in brackets. The error in the coupling constants is very likely less than 0.05 Hz.

In ethane derivatives the vicinal *trans* proton–proton coupling, J_t, is much larger than the vicinal *gauche* coupling J_g (2). For example, in meso 2,3-dibromobutane $J_t = 10.3$ Hz while $J_g = 2.9 \pm 0.4$ Hz (3). In 2,3-dibromosuccinic acid $J_t = 10.7$ Hz (4), while $J_g < 2$ Hz in both sets of rotational isomers of 1-chloro-1,2-dibromo-2-iodoethane (2). Solvent effect studies (3) suggest $J_t = 6.3$ and $J_g = 2.0 \pm 0.6$ Hz in 1,1,2-trichloroethane.

Now, space-filling models indicate clearly that the meso form of **1** has minimum steric hindrance between groups when the C—H_2 and C—H_3 bonds are *trans* and that the destabilizing "parallel 1-3 interactions" between C—Cl bonds on C-1 and -3 (5) need not occur when the C—H_1 and C—H_2 bonds are *gauche*. On the other hand, the *dl*-isomer has the greatest steric freedom when C—H_1 and C—H_2 are *trans* while C—H_2 and C—H_3 are approximately *gauche*. The magnitudes of the coupling constants above, where $J_{1,2} \approx J_g$ and $J_{2,3} \approx J_t$, are therefore consistent with the meso form of **1**.

The preferred conformations of **1** about C_1—C_2 and C_2—C_3 are then as in **2** (or **2***a*) and **3**, respectively. Conformation **2** is preferred over **2***a* because $J_{1,3} = -0.2$ Hz. Thus, $J_g^{H,CH_3} \approx -0.3$ and $J_t^{H,CH_3} \approx 0.5$ Hz in propane derivatives (3, 6).



2 **2***a* **3**

R = $C_{(3)}H_{(3)}C_{(4)}H_{(4)}Cl_3$

Hence **2** is indicated as more stable than **2***a* if it is assumed that the two chlorine substituents on

Conformation in Solution of 1,1,2,3,4,4-Hexachlorobutane

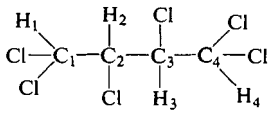
J. B. ROWBOTHAM,[1] H. M. HUTTON,[2] AND T. SCHAEFER
Chemistry Department, University of Manitoba, Winnipeg, Manitoba

Received September 16, 1970

Commercially available (Aldrich) 1,1,2,3,4,4-hexachlorobutane is as the meso isomer. On the basis of the values of the three distinct proton–proton coupling constants it is concluded that, with respect to the C—H bonds, the conformation is *gauche* about the C_1—C_2 bond and *trans* about the C_2—C_3 bond.

Canadian Journal of Chemistry, 49, 806 (1971)

In carbon disulfide (CS_2) and in dimethylsulfoxide (DMSO) solution the p.m.r. of **1** is an $[AX]_2$ spectrum. Analysis by LAOCN3 (1) yields $J_{1,2} = J_{3,4} = 1.80$ (1.86), $J_{2,3} = 10.14$ (10.08),



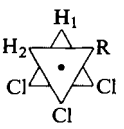
1

$J_{1,3} = J_{2,4} = -0.22$ (−0.16), and $J_{1,4} < 0.05$ Hz; the values in DMSO solution are given in brackets. The error in the coupling constants is very likely less than 0.05 Hz.

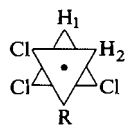
In ethane derivatives the vicinal *trans* proton–proton coupling, J_t, is much larger than the vicinal *gauche* coupling J_g (2). For example, in meso 2,3-dibromobutane $J_t = 10.3$ Hz while $J_g = 2.9 \pm 0.4$ Hz (3). In 2,3-dibromosuccinic acid $J_t = 10.7$ Hz (4), while $J_g < 2$ Hz in both sets of rotational isomers of 1-chloro-1,2-dibromo-2-iodoethane (2). Solvent effect studies (3) suggest $J_t = 6.3$ and $J_g = 2.0 \pm 0.6$ Hz in 1,1,2-trichloroethane.

Now, space-filling models indicate clearly that the meso form of **1** has minimum steric hindrance between groups when the C—H_2 and C—H_3 bonds are *trans* and that the destabilizing "parallel 1-3 interactions" between C—Cl bonds on C-1 and -3 (5) need not occur when the C—H_1 and C—H_2 bonds are *gauche*. On the other hand, the *dl*-isomer has the greatest steric freedom when C—H_1 and C—H_2 are *trans* while C—H_2 and C—H_3 are approximately *gauche*. The magnitudes of the coupling constants above, where $J_{1,2} \approx J_g$ and $J_{2,3} \approx J_t$, are therefore consistent with the meso form of **1**.

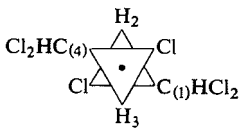
The preferred conformations of **1** about C_1—C_2 and C_2—C_3 are then as in **2** (or **2***a*) and **3**, respectively. Conformation **2** is preferred over **2***a* because $J_{1,3} = -0.2$ Hz. Thus, $J_g^{H,CH_3} \approx -0.3$ and $J_t^{H,CH_3} \approx 0.5$ Hz in propane derivatives (3, 6).



2



2*a*



3

R = $C_{(3)}H_{(3)}C_{(4)}H_{(4)}Cl_3$

Hence **2** is indicated as more stable than **2***a* if it is assumed that the two chlorine substituents on

[1]Postdoctoral fellow, 1970–1971.
[2]University of Winnipeg, Winnipeg, Manitoba.

C-1 do not substantially affect $J_{1,3}$. The value of -0.2 Hz is, in fact, in agreement with the relationship (3, 7) ${}^4J = \cos^2\psi_1 + \cos^2\psi_2 - 0.7$ Hz where ψ_1 and ψ_2 are the dihedral (60°) angles of the fragments $H_1—C_1—C_2—C_3$ and $H_3—C_3—C_2—C_1$, respectively.

Of course, steric repulsions in the hexachlorobutane have probably altered the C—C—H angles somewhat and the dihedral angle of the fragment $H_2—C_2—C_3—H_3$ of **3** is almost certainly less than 180° while the dihedral angles of the *gauche* form **2***a* are probably also somewhat less than 60°. Furthermore, the electronegativities of bromine and chlorine are somewhat different so that a direct comparison of J_t in hexachlorobutane and meso-2,3-dibromobutane is difficult. Finally, the alternating electronegativity effect (8), as well as the steric dependence of the influence of the substituent electronegativity (9), introduces further complexities.[3] The alternating effect implies that the 1,1 and 4,4 chlorine atoms will compensate for the higher electronegativity of chlorine at positions 2 and 3. In spite of these second order effects it is felt that the conclusions above are valid.

Conformation **2** avoids the 1:3 interactions between C—Cl bonds and has a zero dipole moment. The invariance of the coupling constants to the dielectric constant of the solvent (2.6 for CS_2 and 48 for DMSO) suggests that **2** and **3** are by far the most stable of the possible conformations (3) and perhaps that their stability is determined mainly by intramolecular steric interactions as opposed to intermolecular dipole or quadrupole interactions with the dielectric medium.

[3]See ref. 10 for a full discussion of stereochemical and substituent effects on ${}^4J$.

Experimental

The proton resonance spectra of 1,1,2,3,4,4-hexachlorobutane as dilute (less than 10 mol %) degassed solutions in CS_2 and DMSO were taken on a DA60I spectrometer in the frequency sweep mode. The spectra were calibrated by period-averaging techniques. The r.m.s. error in the LAOCN3 analyses was 0.011 and the probable errors in the coupling parameters were 0.01 Hz or less.

method led to the formation of cyanide. We have tried two methods: Juza and Hillenbrand's, but at room temperature, and reaction of methylamine with potassium hydride either at room temperature or at −20 °C. Both methods yielded products that could be handled, but the first was very slow. The method using hydride took 4–6 h at room temperature, or 24–36 h at −20 °C. This method only is described in detail in the Experimental.

An i.r. spectrum of potassium methylamide (CsI disc) was obtained. The bands observed are listed in Table 1 as well as those bands and assignments reported for gaseous methylamine by Barceló Matutano and Bellanato (7). It will be noted that most of the bands we observed can be related to methylamine bands by suitable shifts. The unassigned band at 2165 cm^{-1} is due to cyanide.

Caution

(*1*) The method described involves evolution of hydrogen (a mole for each mol of potassium hydride). The quantities used must not be so large that dangerous pressures are generated in the sealed tubes.

(*2*) Potassium methylamide is very hygroscopic and pyrophoric, and may explode on contact with air. It reacts very vigorously with water and alcohols. It must be stored in vials sealed *in vacuo* or under argon, and opened with proper precautions.

Experimental

Potassium hydride (50% in oil, Alfa) was washed several times with sodium-dried cyclohexane to free it from oil and fines. Small-scale preparations (~2 mmol) were carried out in break-seal ampoules of about 20 ml capacity. About 0.1 g of the cleaned potassium hydride was transferred to the ampoule along with some cyclohexane. (This operation was performed in a dry-box in argon.) The ampoule was attached to a vacuum line and the cyclohexane was removed by distillation. Methylamine (Matheson), about 5 ml, was distilled from the cylinder onto lithium metal, allowed to stand at Dry-Ice temperature for 8–10 h, then degassed and subjected to several bulb-to-bulb fractional distillations, before being distilled onto the potassium hydride in the ampoule. This was then sealed. After 4–6 h at room temperature the reaction was complete, and a clear yellow solution was obtained. This solution was transferred into another vessel through the break-seal and a sintered filter, on the vacuum line. The excess of methylamine was removed under vacuum, and white crystals of potassium methylamide remained. These were subjected to further evacuation, and then sealed *in vacuo*.

Somewhat larger scale (~20 mmol) preparations were carried out in a ground joint flask, which was fitted for attachment to the vacuum line, and which contained a syphon tube with a sintered-glass filter permitting transfer of the yellow amide solution to another flask, to separate the product from the potassium hydroxide that was always formed in small amount. Procedure was as before, except that the reaction was carried out at −20 to −15 °C rather than at room temperature. Since at this temperature the reaction took 24–36 h to complete, a cryostat was used to maintain the temperature.

For personal use only.

The product was analyzed acidimetrically. The sealed tube containing potassium methylamide was opened in the dry box, and samples weighed into separate vials. An entire sample was then added quickly to excess standard hydrochloric acid and the excess acid titrated with standard base, with methyl orange as indicator. Equivalent weight required (for $KCH_3NH + 2HCl = KCl + CH_3NH_3Cl$) 34.50; found, 35.50, 35.30, 35.10; average, 35.30. This discrepancy, if KCN is the sole impurity, corresponds to an assay of 95.2% $KNHCH_3$.

Significance of Heterogeneous Catalysis of Certain Oxidation Reactions by Oxides in Relation to their Heats of Formation

ASHOK K. VIJH[1] AND P. LENFANT[2]
Hydro-Quebec Institute of Research, Varennes, Quebec

Received May 6, 1970

The significance of previous correlations observed by Morooka *et al.* between heats of formation per oxygen atom, ΔH_0, for oxides and their catalytic activity towards oxidation of some hydrocarbons has been discussed. It has been pointed out that ΔH_0 values do not represent metal–oxygen bond energies, as assumed by Morooka and co-workers, but instead signify band gap values for the oxides. The catalytic activity of these oxides must therefore be interpreted in terms of their electronic conductivity and not in relation to the stength of metal–oxygen bond involved.

La signification des corrélations antérieures, observées par Morooka *et coll.*, entre la chaleur de formation des oxydes par atome d'oxygène, ΔH_0, et leur activité catalytique dans l'oxydation de certains hydrocarbures a été discutée. Il a été montré que les valeurs de ΔH_0 ne représentent pas les énergies de liaison métal-oxygène, comme supposé par Morooka *et coll.*, mais signifient plutôt des valeurs de bande d'énergie interdite des oxydes. L'activité catalytique de ces oxydes doit donc être interprétée en termes de leur conductivité électronique et non pas en relation avec la force des liaisons métal–oxygène impliquées.

Canadian Journal of Chemistry, **49**, 809 (1971)

It has been shown in the literature that certain regularities exist in the catalytic behavior of some metal oxides towards oxidation of propylene (1), ethylene (2), propane (2), acetylene (2), and isobutene (2). Specifically, it was observed that with increasing (exothermic) heat of formation (standard state) per oxygen atom, ΔH_0, of an oxide, the rate of oxidation of a given hydrocarbon decreases. These experimental observations were interpreted by *assuming* that ΔH_0 signifies the strength of a metal–oxygen (MO) bond in an oxide; and, that since heterogeneous oxidation catalysis by oxides involves surface reactions in which loosening or breaking of MO bonds probably occurs, relation between ΔH_0 and the catalytic activity of the oxide must follow.

The purpose of the present note is to point out that: (*1*) the ΔH_0 values do *not* represent the strength of the MO bond; therefore the previous interpretations (1, 2) merit modifications; (*2*) in fact, there exists no correlation between MO bond energy of an oxide and its catalytic activity towards oxidation of hydrocarbons; (*3*) re-

lationship between ΔH_0 and the catalytic activity arises because ΔH_0 is the band gap and hence related to the electronic conductivity of the oxide.

Some Definitions and Related Matters

It may be shown by means of a Born–Haber cycle (3) that heat of formation per mol of a substance in its standard state, *e.g.*, of solid NiO, is given by

$$[1] \quad \Delta H_m = I_m + \Delta H_S + \tfrac{1}{2}\Delta H_D + A_X - U$$

where ΔH_m is the heat of formation (standard state) of NiO per *mol*; I_m is the sum of first and second ionization potentials of Ni; ΔH_S is the heat of sublimation of Ni metal to give Ni atoms; ΔH_D is the heat of dissociation of O_2 molecule to give O atoms; U is the lattice energy of NiO; A_X is the electron affinity of O atom to form O^{2-} ion.

All quantities refer to the heat absorbed by the system for the indicated process.

All the above quantities are per mol, which in the case of NiO is the same as per oxygen atom. However, in the case of, say, Ta_2O_5, ΔH_0, the heat of formation *per oxygen atom* (*i.e.* the quantity used in refs. 1 and 2) is 1/5 the heat of formation per *mol*. Here, we define another quantity, namely, heat of formation per equivalent, ΔH_e, which will be the heat of formation per mol of Ta_2O_5 divided by the number of valence electrons transferred (*viz.* 10) in the formation of 1 mol of Ta_2O_5. The foregoing definitions for a typical case, *e.g.*, Ta_2O_5 may be summarized by the equation

$$[2] \quad -(\Delta H_m)_{Ta_2O_5} = -(1/5)(\Delta H_0)_{Ta_2O_5} = -(1/10)(\Delta H_e)_{Ta_2O_5}$$

The negative signs in eq. 2 signify exothermicity. Neither ΔH_m, nor ΔH_0, nor ΔH_e, however, represents *bond* energy. The bond energy, after suitable corrections for some minor factors which may arise in certain cases (4), *e.g.*, NiO is essentially given by

$$[3] \quad b = (-\Delta H_m + \Delta H_S + \tfrac{1}{2}\Delta H_D)/2$$

where b is the MO bond energy; ΔH_m, ΔH_S, ΔH_D are defined as above, and 2 is the number of valence electrons transferred in the formation of the nickel oxide from the constituent elements in the standard state.

The b value thus obtained is the enthalpy change (see eq. 10) in the process MO(S) $\rightarrow$ O(g) + M(g). The $-\Delta H_0$ of Morooka *et al.* (1) is the enthalpy change (see eq. 11) in the process MO(S) $\rightarrow \frac{1}{2}O_2$ (g) + M (S). Further amplification of the significance of this matter is given in a subsequent section here.

The basic misconception in the interpretations of Morooka *et al.* has been to equate b of eq. 3 here with the ΔH_0 of eq. 2; the two quantities are, of course, quite different. The observation of Morooka *et al.* that ΔH_0 is related to the catalytic activity of the oxide is still correct; however, their assumption that ΔH_0 represents bond energy of the oxide is incorrect. An excellent discussion of these matters has been given by Howald (4).

What then is the significance of ΔH_0? It follows from eq. 2 that for any oxide

$$[4] \quad -(\Delta H_0) = -2(\Delta H_e)$$

It has been shown previously (5) that

$$[5] \quad E_g \simeq -2(\Delta H_e)$$

where E_g is the band gap of a material, oxide in the present context. Combination of eqs. 4 and 5 would give

$$[6] \quad E_g = -(\Delta H_0)$$

i.e., ΔH_0 does not represent the bond energy but it denotes the *band gap* of the oxide.

Relation to Catalysis of Hydrocarbon Oxidation

Results of Morooka *et al.* (1, 2) in which with decreasing (exothermic) ΔH_0 values of oxides, rate of hydrocarbon oxidation increases may now be interpreted in a somewhat different way. Since ΔH_0 is *not* the bond energy but a band gap value, the rate of hydrocarbon oxidation may be concluded to increase with increasing oxide conductivity, *i.e.*, with decreasing value of $-\Delta H_0$.

The fact that $-\Delta H_0$ ($= -2\Delta H_e$), is indeed related to the conductivity values of the oxides may also be seen in Fig. 1. For semiconducting materials, the intrinsic electronic conductivity, σ (6), is given by

$$[7] \quad \sigma = \sigma_0 \exp(-E_g/kT)$$

where k is the Boltzmann's constant, and, T, the absolute temperature; σ_0 is the limiting electronic conductivity when E_g approaches zero.

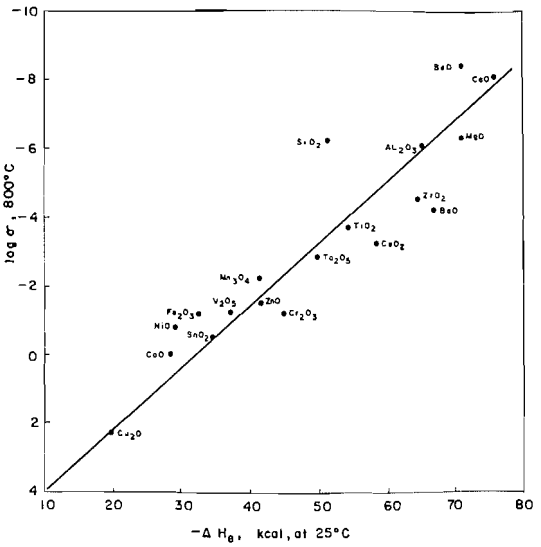

FIG. 1. Relationship between logarithm of "intrinsic" electronic conductivity and heats of formation per equivalent for several oxides. Data for this figure have been obtained from refs. 7 and 9.

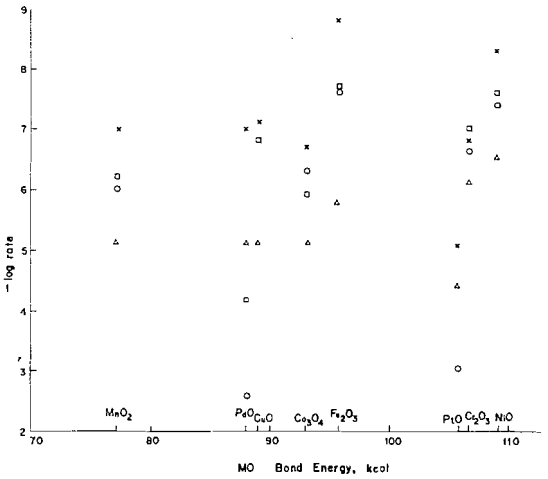

FIG. 2. A plot of heats of atomization per equivalent (*i.e.* approximate value of average bond energies as calculated from thermochemical data in ref. 8) for various oxide catalysts *vs.* their catalytic activity at 300 °C for the oxidation of isobutene (○), acetylene (△), ethylene (□), and propane (×). Reaction rate for acetylene oxidation refers to 220 °C. Rate data have been obtained from ref. 2. Thermochemical data for calculation of bond energies of CeO_2 and ThO_2 are not available. It may be noted that no correlation exists between catalytic activity and bond energies for the several oxides shown in this figure. The bond energies plotted here are, of course, the *b* values as obtained from eq. 3 of the paper.

Combination of eqs. 7 and 5 gives

$$[8] \qquad \sigma = \sigma_0 \exp - (\Delta H_e/kT)$$

or

$$[9] \qquad \log \sigma = \log \sigma_0 - \Delta H_e/2.303\, kT$$

Equation 9 predicts a linear relation between $\log \sigma$ and $1/T$ for a *given* oxide, with a slope equal to $\Delta H_e/2.303\ k$. If, however, $\log \sigma_0$ values for several oxides fall within a narrow range, an approximate correlation between $\log \sigma$ and $-\Delta H_e$ values for various oxides will be expected with the value of slope *roughly* equal to $1/2.303\, kT$, at a constant T.

This is what is indeed observed in practice and is depicted in Fig. 1. It is clear that Fig. 1 only arises, because, fortuitously, values of $\log \sigma_0$ for various oxides have a roughly constant value. In any case, the empirical significance of Fig. 1, namely, higher $-\Delta H_e$ $(= -\frac{1}{2}\Delta H_0)$ values for oxides are associated with lower electronic conductivity, is quite clear.

The fact that the catalytic activity for hydrocarbon oxidation is not related to the bond energy (as calculated, of course, by eq. 3 above) of the oxides, as implied in the foregoing analysis, is directly supported by Fig. 2. Here the bond energy values, *b*, for various oxides are taken from Sanderson (8) and plotted against the rate of catalytic oxidation of various oxides reported by Morooka *et al.* (2). No correlation is indeed observed.

The higher catalytic activity of the oxides associated with higher electronic conductivity, as concluded here, would seem to emphasize that the rate-determining step in these catalytic oxidations is probably limited by the availability of charge carriers in the oxides, namely, electrons and holes. This is not entirely unexpected since oxidation reactions must involve either injection of electrons into the oxide or consumption of holes extracted from the oxide at some stage during the overall oxidation reaction.

Even though there is no relationship between the catalytic activity of the oxides and their bond energies as usually defined (4), *i.e.*, as the enthalpy change in the reaction (*viz.* eq. 3 above)

$$[10] \qquad \mathrm{MO\ (S)} \rightarrow \mathrm{M\ (g)} + \mathrm{O\ (g)}$$

one could always write the rupture of metal oxide bond as represented by

$$[11] \qquad \mathrm{MO\ (S)} \rightarrow \mathrm{M(S)} + \mathrm{O\ (g)}$$

The enthalpy change in reaction 11, which is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

not the bond energy of the oxide according to the accepted definition of the term (4), may then be denoted by $(\Delta H)_{11}$ and would be given by

[12] $$(\Delta H)_{11} = -\Delta H_m + \tfrac{1}{2}\Delta H_D$$

For a series of oxides, $\frac{1}{2}\Delta H_D$ is, of course, constant so that

[13] $$(\Delta H)_{11} = -\Delta H_m + \text{constant}$$

In other words, $(\Delta H)_{11}$ would be linearly related to $-\Delta H_m$; hence, any relationship between $-\Delta H_m$ (or $-\Delta H_0$) and catalytic activity, as indeed is observed by Morooka *et al.*, would signify that the catalytic activity is related to the enthalpy change in reaction 11, probably because of the involvement of a bond-breaking reaction of the type

[14] MO (S) + HyC (g) → M(S) + gaseous products

In this sense, therefore, one may speak of the relationship of catalytic activity to the enthalpy change in a bond-breaking reaction of types [11] and [14]. Even though this interpretation may be extended to the data of Morooka *et al.*, the alternative interpretation in terms of relationship to band gaps and hence electron–hole concentration, as suggested here, is not entirely excluded. Furthermore, even if the foregoing interpretation of the data of Morooka *et al.* in terms of bond rupture is accepted as valid, the catalytic activity is related to the enthalpy of reaction 11 and not to the bond energy (4), the latter being given by eq. 3.

Conclusions

For the particular data reported by Morooka *et al.* (1, 2) on the catalytic oxidation of several hydrocarbons by various oxides, it has been shown that Morooka's correlations between ΔH_0 and catalytic activity do not signify the dependence of latter on the bond energy; instead, they arise because ΔH_0 is equal to the band gap of the oxide and is thence related to its conductivity and therefore to its catalytic activity.

Electron Spin Resonance Spectra of Radicals Produced in the Thermal Reaction of Benzophenone with Triphenylsilane

A. R. McIntosh[1] and J. K. S. Wan
Department of Chemistry, Queen's University, Kingston, Ontario

Received September 21, 1970

Thermal reaction of benzophenone with triphenylsilane at 400 °K produced an electron spin resonance (e.s.r.) spectrum which is interpreted due to the triphenylsiloxydiphenylmethyl radical, $Ph_2\dot{C}OSiPh_3$.

La réaction thermique de la benzophénone avec le triphénylsilane à 400 °K produit un spectre r.p.e. qui peut être interprété comme étant du au radical triphénylsiloxydiphenylméthyle, $Ph_2\dot{C}OSiPh_3$.

Canadian Journal of Chemistry, 49, 812 (1971)

Introduction

The question of d-orbital participation in π-bonding in simple organic radicals has recently been of great interest. Direct e.s.r. evidence has been reported for d–p π-bonding in a series of Group IV*B* substituted methyl radicals (1). A number of silyl radicals have also been reported (2). We have recently attempted to generate triphenylsilyl radicals in liquid solution by various methods for e.s.r. study, since such radicals

[1]National Research Council of Canada Postgraduate Scholar, 1968–1971.

not the bond energy of the oxide according to the accepted definition of the term (4), may then be denoted by $(\Delta H)_{11}$ and would be given by

[12] $$(\Delta H)_{11} = -\Delta H_m + \tfrac{1}{2}\Delta H_D$$

For a series of oxides, $\frac{1}{2}\Delta H_D$ is, of course, constant so that

[13] $$(\Delta H)_{11} = -\Delta H_m + \text{constant}$$

In other words, $(\Delta H)_{11}$ would be linearly related to $-\Delta H_m$; hence, any relationship between $-\Delta H_m$ (or $-\Delta H_0$) and catalytic activity, as indeed is observed by Morooka *et al.*, would signify that the catalytic activity is related to the enthalpy change in reaction 11, probably because of the involvement of a bond-breaking reaction of the type

[14] MO (S) + HyC (g) → M(S) + gaseous products

In this sense, therefore, one may speak of the relationship of catalytic activity to the enthalpy change in a bond-breaking reaction of types [11] and [14]. Even though this interpretation may be extended to the data of Morooka *et al.*, the alternative interpretation in terms of relationship to band gaps and hence electron–hole concentration, as suggested here, is not entirely excluded. The question of d-orbital participation in π-bonding in simple organic radicals has recently been of great interest. Direct e.s.r. evidence has been reported for d–p π-bonding in a series of Group IV*B* substituted methyl radicals (1). A number of silyl radicals have also been reported (2). We have recently attempted to generate triphenylsilyl radicals in liquid solution by various methods for e.s.r. study, since such radicals

should prove to be interesting for the study of d-orbital effect in π conjugation.

We have studied by e.s.r. the thermal reactions of *t*-butylperoxide and benzoylperoxide with triphenylsilane in solution at high temperature, the photolyses of *t*-butylperoxyperbenzoate with triphenylsilane in CF_3CCl_3 at low temperature, the photochemical reactions of benzophenone with triphenylsilane at a range of low temperatures. Unfortunately all our attempts to date to produce resolvable e.s.r. spectra from triphenylsilyl radicals in solution have failed. Other efforts to produce triphenylsilyl radical by γ-irradiation of polycrystalline triphenylsilane have resulted only in unresolvable broad line spectra. We have just learned that Geoffroy and Lucken (3) have analyzed the e.s.r. spectra of X-irradiated single crystal of triphenylsilane at room temperature and assigned the main radical species to triphenylsilyl radical, formed both as isolated and pair-wise trapped radicals. However, their value of the ^{29}Si coupling constant obtained from the analysis is much smaller than those reported for various silyl radicals in the fluid state (2). The authors (3) pointed out that although the crystal structure of triphenylsilane is not known, the trapped radical is presumably non-planar and thus the small value of the ^{29}Si coupling constant is not in accord with the simple valence theory. Furthermore, no proton hyperfine structures were observed.

In the present note, the study of the thermal reaction of benzophenone with triphenylsilane in the fluid state was undertaken as a possible means to generate the triphenylsilyl radical for e.s.r. observation, since benzophenone is known (4) to abstract an H atom from triphenylsilane at high temperatures. However, it was disappointing that the primary intermediate triphenylsilyl radical was not detected and instead an e.s.r. spectrum believed to be due to secondary triphenylsiloxydiphenylmethyl radical, $Ph_2\dot{C}OSiPh_3$ was observed. The results would cast some light on the mechanism of the thermal reaction.

Experimental

Benzophenone (Aldrich) and benzophenone-d_{10} (Merck Sharp and Dohme) were repeatedly recrystallized from ethanol–water until completely free from paramagnetic contaminants. Triphenylsilane (Alfa) was used without further purification, after it was established that samples using zone-refined triphenylsilane gave identical e.s.r. results.

Samples of mixtures of benzophenone and triphenylsilane (1:1 and 2:1 molar ratio) form supercooled liquid solutions at room temperature. They were placed in suprasil tubes sealed off after being degassed and evacuated to 10^{-5} Torr. The sample tube was then introduced into the microwave cavity equipped with a variable temperature controller which heated the sample up to 400 °K. In a few separate experiments samples were dissolved in *p*-dichlorobenzene (0.2 *M*) and they gave less resolved e.s.r. spectra under identical conditions.

Electron spin resonance spectra were recorded with a Varian 4500 X-band spectrometer with 100 kc modulation. The magnetic field was calibrated with a Varian F-8A fluxmeter by monitoring its transmitter frequency with a Hewlett–Packard 5245M frequency counter. The microwave frequency was measured using the same counter and a 5256A frequency converter.

Results and Discussion

A typical e.s.r. spectrum recorded when samples of benzophenone and triphenylsilane solution were heated within the microwave cavity to temperatures between 370–420 °K, is given in Fig. 1*a*. Below 370 °K no appreciable spectrum was dectected and above 420 °K the observed spectrum decayed rapidly. An optimum steady-state concentration of radicals was achieved at about 400 °K. During the recording of e.s.r. spectra, the originally colorless solution became slightly pink. The *g*-value of the e.s.r. spectrum was found to be 2.00305 $\pm$ 0.0001.

Previous reports of the thermal (4) and photochemical (5) reactions of benzophenone with triphenylsilane have suggested that the reactions proceed via free radical intermediates. Thus, Gilman and Wittenberg (4) obtained a 62% yield of $Ph_2HCOSiPh_3$ after heating an equimolar mixture of benzophenone and triphenylsilane at 510 °K for 3 h. Becker (5) found a major product of $Ph_3SiOCPh_2CPh_2OH$ in the photolysis of a benzene solution of benzophenone and the silane. Upon heating the product to 95 °C at 10 mm pressure, $Ph_3SiOCPh_2CPh_2OH$ was found to decompose into benzophenone and $Ph_2HCOSiPh_3$. Their results appear to be consistent with the following common mechanism

[1] $Ph_2CO + Ph_3SiH \xrightarrow{h\nu \text{ or heat}} Ph_2\dot{C}OH + Ph_3\dot{S}i$

[2] $Ph_3\dot{S}i + Ph_2CO \rightarrow Ph_2\dot{C}OSiPh_3$

[3] $Ph_2\dot{C}OH + Ph_2\dot{C}OSiPh_3 \rightarrow Ph_3SiOCPh_2CPh_2OH$

[4] $Ph_3SiOCPh_2CPh_2OH \xrightarrow{\text{heat}} Ph_2CO + Ph_2HCOSiPh_3$

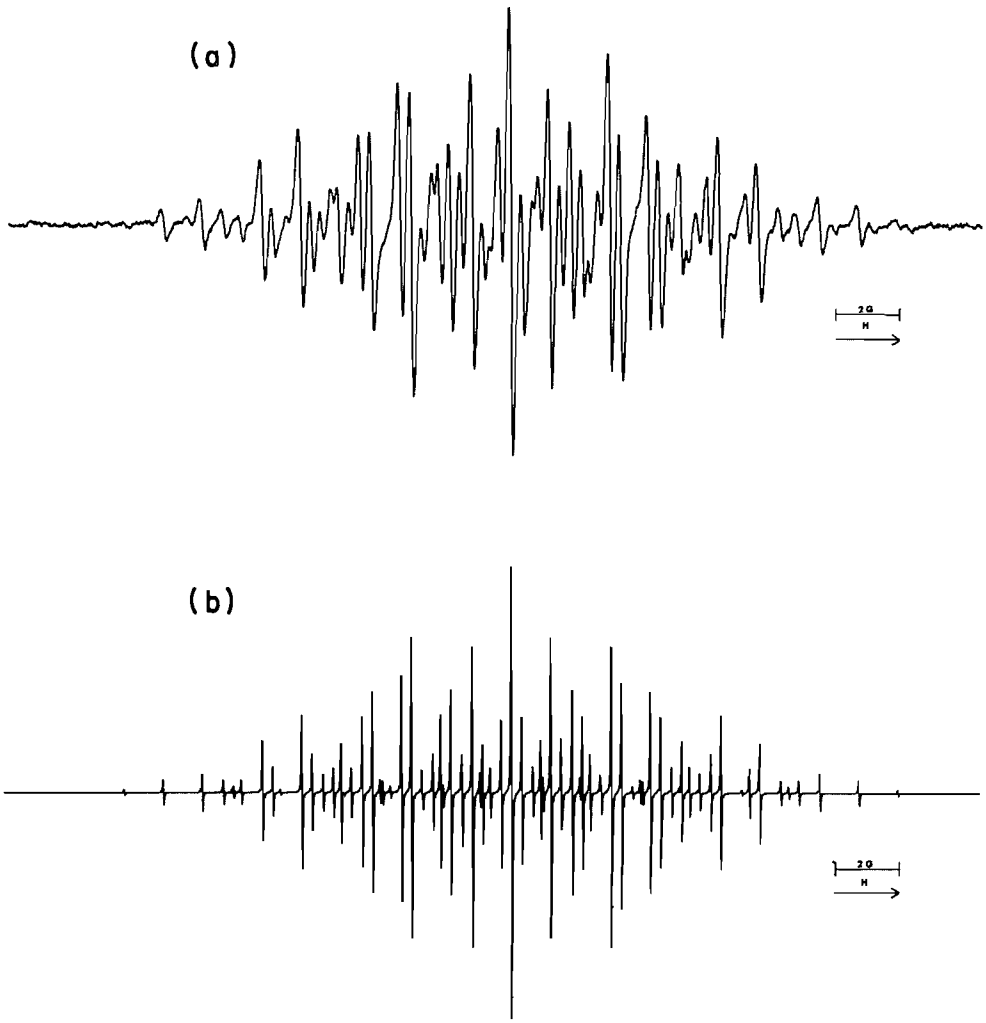

FIG. 1. The e.s.r. spectra at 400 °K of the thermal reaction of benzophenone with triphenylsilane: (*a*) experimental spectrum, (*b*) computer simulated spectrum.

Cage recombination of the primary radicals is considered to be less important at high temperatures. Moreover, Brook (6) has shown that the recombined product Ph_3SiCPh_2OH would be readily converted to $Ph_2HCOSiPh_3$. However, it should be emphasized that the exact nature of the thermal initiation leading to reaction 1 is not known and the overall reaction may proceed via a chain-mechanism as suggested by one of the referees

[2] $$Ph_3\dot{S}i + Ph_2CO \rightarrow Ph_2\dot{C}OSiPh_3$$

[5] $$Ph_2\dot{C}OSiPh_3 + Ph_3SiH \rightarrow Ph_3SiOCHPh_2 + Ph_3\dot{S}i$$

In an attempt to identify the radical responsible for the observed e.s.r. spectrum, all three radicals $Ph_3\dot{S}i$, $Ph_2\dot{C}OH$, and $Ph_2\dot{C}OSiPh_3$ were therefore considered. The possibility of the radical being $Ph_3\dot{S}i$ was eliminated, since the e.s.r. spectrum drastically changed its structure when benzophenone-d_{10} was used (Fig. 2*a*). The second possibility of a $Ph_2\dot{C}OH$ radical was also ruled out by comparing the observed spectrum with those of $Ph_2\dot{C}OH$ reported in the literature (7). Thus it is thought that the species responsible for the spectrum is the triphenylsiloxydiphenylmethyl radical, $Ph_2\dot{C}OSiPh_3$. Computer analysis of the experimental spectrum based on this radical yields the spectral param-

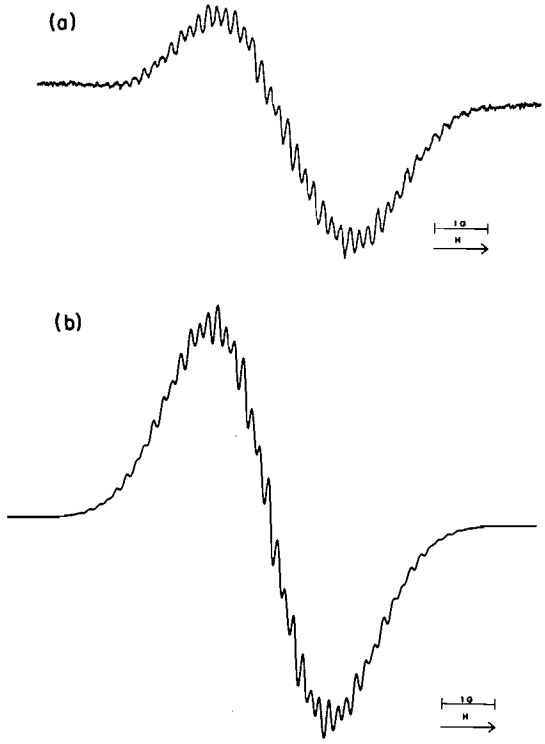

FIG. 2. The e.s.r. spectra at 400 °K of the thermal reaction of benzophenone-d_{10} with triphenylsilane: (*a*) experimental spectrum, (*b*) computer-predicted spectrum.

eters given in Table 1. The proton coupling constant assignments are supported by comparing the $(C_6D_5)_2\dot{C}OSiPh_3$ spectrum (Fig. 2*a*) with the theoretically predicted one (Fig. 2*b*). Using the familiar McConnell relationship, the proton hyperfine splitting can account for more than 90% of the unpaired spin. Thus, hyperfine splitting due to ^{29}Si would be very difficult to resolve, since the natural abundance of ^{29}Si having a nuclear spin of $\frac{1}{2}$ is only 4.7%.

Several authors (8, 9) have reported evidence for the relative ease of rotation of the phenyl rings in the ketyl radical $Ph_2\dot{C}OH$. Theoretical considerations also led to the conclusion (10) that in the ketyl radical the phenyl rings are not locked into a planar configuration for a time as long as a microsecond. In the present experiment, the spectra of $Ph_2\dot{C}OSiPh_3$ were obtained at 400 °K and it is conceivable that the phenyl rings of the radical are freely rotating and that the observed proton splittings are indeed time-averaged values.

While the observation of $Ph_2\dot{C}OSiPh_3$ radical during the thermal reaction appears to be consistent with the above mechanism, the failure of detecting the primary triphenylsilyl radical remains to be explained. Perhaps it is due to the great affinity of the silyl radicals for the oxygen atom of the benzophenone leading to a more stable $Ph_2\dot{C}OSiPh_3$ radical.

Present effort in producing triphenylsilyl radicals in solution for e.s.r. study involves electrolysis and pulsed electrolysis experiments.

Valence Force Field Calculations for Octahedral Anions

A. M. QURESHI, A. H. HARDIN, AND F. AUBKE[1]

Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received September 23, 1970

Vibrational force constants for the octahedral anion AsF_6^-, SbF_6^-, SnF_6^{2-}, and $SnCl_6^{2-}$ in the corresponding potassium salts are calculated using a simple valence force field treatment, with the intention of obtaining better agreement with recently reassigned bending modes in these compounds and to arrive at improved values for the inactive mode $\nu_6[F_{2u}]$.

Introduction

Whereas potential constants for many neutral octahedral molecules have been calculated by various authors (1–3), little attention has been given to the octahedral hexahalo anions formed by Group IV and Group V elements. In addition to an earlier report on force constants of some hexachloro anions (4), valence force field calculations on a number of hexafluoro anions were recently reported (5).

During recent studies (6, 7) on heterocation complexes with the anions $SnCl_6^{2-}$, SnF_6^{2-}, SbF_6^-, AsF_6^- it became apparent that infrared data for both force constant calculations (3, 4) did not extend below 250 cm^{-1}, so that $\nu_4[F_{1u}]$ was either not recorded (4) at all as for $SnCl_6^{2-}$ or had been wrongly assigned (5) as for SnF_6^{2-} and SbF_6^-. This of course renders the reported force constants somewhat unreliable, in particular, where the bending force constants are concerned. As a consequence, all calculations of the inactive mode $\nu_6[F_{2u}]$, which is generally not accessible experimentally for solids where only a small number of combination bands are observed, appear to be questionable.

The obtained set of new vibrational frequencies (6, 7) was taken as a basis for a normal coordinate analysis, using a simple valence force field treatment. The potassium salts were selected because the unit cell dimensions are known for all four compounds, thus permitting us to assess site symmetry effects on the vibrational spectra, and interatomic distances are reported for all but one of the salts. The intention of the calculation is to check the correctness of the new assignment via comparison of calculated values and to gain more accurate information regarding the position of ν_6. Anion–cation interaction has been found for a number of heterocation complexes with hexafluoro anions (6, 7) to reduce the symmetry of the anion, whereby ν_6 may now become partly infrared and/or Raman active.

Experimental

The far infrared spectrum of K_2SnCl_6 was recorded on a Perkin–Elmer 301 spectrophotometer for the range of 300–150 cm^{-1}. Polyethylene windows were employed and Nujol was used as a mulling agent.

The force constants were calculated by using a Fortran IV program written by Schachtschneider (10) and adjusted for an IBM 360/67 computer. The construction and orientation of the symmetry coordinates, the potential and kinetic energy matrices, and the secular equations giving the normal frequencies have been discussed previously by Pistorius (1) and Classen (11). The harmonic potential function in terms of the internal coordinates is given by the expression

$$\begin{aligned}2V = {} & k_r[(\Delta R_1)^2 + (\Delta R_2)^2 + (\Delta R_3)^2 + (\Delta R_4)^2 + (\Delta R_5)^2 + (\Delta R_6)^2] \\ & + 2k_{rr}\,[(\Delta R_4 + \Delta R_2)(\Delta R_6 + \Delta R_3 + \Delta R_7 + \Delta R_5) + (\Delta R_3 + \Delta R_5)(\Delta R_6 + \Delta R_7)] \\ & + 2k_{rr'}\,[(\Delta R_6)(\Delta R_7) + (\Delta R_3)(\Delta R_5) + (\Delta R_4)(\Delta R_2)] \\ & + 2d^2k_\delta\,[(\Delta\theta_{63})^2 + (\Delta\theta_{64})^2 + (\Delta\theta_{65})^2 + (\Delta\theta_{62})^2 + (\Delta\theta_{34})^2 + (\Delta\theta_{37})^2 + (\Delta\theta_{32})^2 \\ & + (\Delta\theta_{47})^2 + (\Delta\theta_{45})^2 + (\Delta\theta_{75})^2 + (\Delta\theta_{72})^2 + (\Delta\theta_{52})^2] \\ & + 2d^2k_{\delta\delta}\,[(\Delta\theta_{64} + \Delta\theta_{62})(\Delta\theta_{63} + \Delta\theta_{65}) + (\Delta\theta_{34})(\Delta\theta_{63} + \Delta\theta_{64} + \Delta\theta_{37}) \\ & + (\Delta\theta_{32})(\Delta\theta_{63} + \Delta\theta_{62} + \Delta\theta_{37}) + (\Delta\theta_{47})(\Delta\theta_{34} + \Delta\theta_{37} + \Delta\theta_{75}) \\ & + (\Delta\theta_{45})(\Delta\theta_{64} + \Delta\theta_{65} + \Delta\theta_{47} + \Delta\theta_{75}) + (\Delta\theta_{72})(\Delta\theta_{37} + \Delta\theta_{32} + \Delta\theta_{75}) \\ & + (\Delta\theta_{52})(\Delta\theta_{65} + \Delta\theta_{62} + \Delta\theta_{75} + \Delta\theta_{72})]\end{aligned}$$

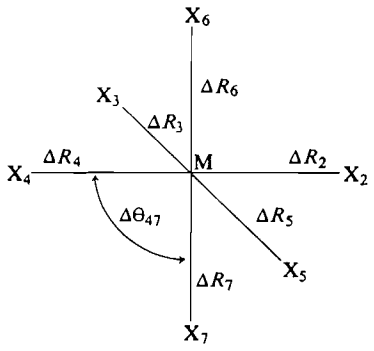
where ΔR_1, ΔR_2, etc. are the deviation from the element halogen bond lengths and $\Delta\theta$'s are the changes in the non-linear bond angles. The position of the halogen atoms is shown in the figure, which depicts the equilibrium geometry of the MX_6 species where the six halogen atoms are labelled from X_2 to X_7 and the central metal



atom M is at the origin of the coordinate system. The angles are measured in radians and consequently the bending force constants are multiplied by the square of the bond lengths (d) in order to keep the units of the stretching and bending force constants consistent (mdyn/Å). The bond lengths (d) for each ion are shown in Table 1, together with other pertinent structural information. The Sn—F bond distance for K_2SnF_6 is not reported. The average values (12) for the distorted octahedral SnF_6^{2-} ion in Na_2SnF_6 is taken instead. The site symmetry of the anion is deduced according to Halford (13).

Results

The values of the force constants in mdyn/Å are given in Table 2 together with reported values for hexafluorides SeF_6, isoelectronic to AsF_6^- and TeF_6, isoelectronic to SbF_6^- and SnF_6^{2-}. In this table, k_r is the element–halogen stretching force constant, k_{rr} is the stretching interaction constant for M–Hal bonds perpendicular to each other, and $k_{rr'}$ is the corresponding constant for bonds opposite to each other; k_δ is the bending force constant of bonds with non-linear angles and $k_{\delta\delta}$ is the bending interaction constant for bonds with adjacent angles.

Other stretching–bending interactions have been ignored in this study because of the complexity of the problem.

Discussion

The vibrational frequency for $\nu_4[F_{1u}]$ in K_2SnCl_2 is found at 172 cm^{-1} in rather poor agreement with the previously predicted (4) value of 143 cm^{-1} but consistent with recent reports (21, 22). As pointed out previously, splittings due to site symmetry effects are found only for $\nu_3[F_{1u}]$ and $\nu_4[F_{1u}]$ in K_2SnF_6 (6) and for $\nu_5[F_{2g}]$ in $KSbF_6$ (7, 14) where doublets are found, suggesting a splitting into A_{2u} and E_u as well as A_{1g} and E_g modes. Assignment of the observed bands is made strictly on the basis of intensity differences and average frequencies are calculated according to Lehmann's rule (15).

As was expected, good agreement with previously reported stretching force constants exists (4, 5). The conclusions reached by those authors are identical with our point of view. The decrease in k_r from SeF_6 to AsF_6 and from TeF_6 over SbF_6^- to SnF_6^{2-} is expected but it should be pointed out that the most recent reference values

§Average deviation, 0.05%.
¶Average deviation, 0.15%.

(20) for SeF_6 and TeF_6 are obtained *via* a modified Urey–Bradley force field calculation.

The bending force constants show marked departure from the previous values and as a consequence the calculated values for the inactive mode $\nu_6[F_{2u}]$ are found considerably lower than reported. In particular, for the hexafluoro anions, differences of about 100 cm^{-1} are found. Doubt in the correctness of the previously (5) calculated values for ν_6 is centered around the value for SbF_6^-, which is reported to be higher than experimental values for ν_4 and ν_5 in departure from the observed trends. The ν_6 values reported in this paper compare favorably with experimental values for SeF_6 and TeF_6. Furthermore, good agreement with the observed frequencies is found: the average deviation does not exceed more than $\frac{1}{4}\%$ as shown in Table 3.

The Decomposition of Benzoyl Hypochlorite in the Presence of Metal Ions[1]

N. J. BUNCE[2] AND L. O. URBAN

Department of Chemistry, University of Guelph, Guelph, Ontario

Received August 5, 1970

The decomposition of benzoyl hypochlorite, the intermediate in the Hunsdiecker reaction between chlorine and silver benzoate, is accelerated by light and by azobisisobutyronitrile (AIBN), but not by transition metal ions. The molar yield of the chlorobenzene produced in the decomposition increases as the temperature of the reaction mixture is raised, but is independent of whether or not the reaction is promoted by light or AIBN. It is suggested that this variation in the yield is a result of the readier decarboxylation at higher temperatures of the benzoyloxy radicals which are believed to be intermediates in the decomposition process. No such pronounced effect of temperature on the yield of halides from aliphatic silver carboxylates has been observed, presumably because aliphatic acyloxy radicals decarboxylate readily even at low temperatures.

La décomposition de l'hypochlorite de benzoyle, l'intermédiaire dans la réaction de Hunsdiecker entre le chlore et le benzoate d'argent est accélérée par la lumière et l'azo bis isobutyronitrile mais non par les ions des métaux de transition. Le rendement molaire de chlorobenzène produit lors de la décomposition augmente proportionnellement avec la température du mélange réactionnel mais est indépendant des catalyseurs comme la lumière ou l'AIBN. Il est suggéré que ces variations dans le rendement sont le résultat d'une décomposition plus facile à haute température des radicaux benzoyloxy qui seraient les intermédiaires dans le processus de décomposition. Un effet aussi prononcé de la température sur les rendements de dérivés halogénés aliphatiques provenant des carboxylates d'argent correspondants n'a pas été observé probablement parce que les radicaux acyloxy aliphatiques se décarboxylent facilement même à basse température.

Canadian Journal of Chemistry, 49, 821 (1971)

The reaction between chloride ion and benzoyl peroxide has recently been investigated by several groups of workers (1–3). The first formed intermediate was found to display chemistry similar to that of the intermediate in the reaction between the halogens and silver carboxylates. The reactions compared included the decomposition to chlorobenzene and CO_2, addition to olefins, electrophilic chlorination of arenes, and free radical halogenation of alkanes. The reaction between halogens and silver carboxylates is the basis of the Hunsdiecker halodecarboxylation reaction (4, 5), which has been supposed to involve an acyl hypohalite as an intermediate. It was proposed therefore that the reaction of chloride ion with benzoyl peroxide also gives rise to such an intermediate, in this case benzoyl hypochlorite.

[1] $Cl^- + PhCO.OO.COPh \rightarrow PhCO_2Cl + PhCO_2^-$

[2] $Cl_2 + PhCO_2Ag \rightarrow PhCO_2Cl + AgCl$

In the Hunsdiecker reaction it is thought that the intermediate acyl hypohalite suffers homolytic fission (reaction 3) and that this initiates a free radical chain pathway for alkyl (or aryl) halide formation (reactions 4 and 5).

[3] $RCO_2X \rightarrow RCO_2^{\cdot} + X^{\cdot}$

[4] $RCO_2^{\cdot} \rightarrow R^{\cdot} + CO_2$

[5] $R^{\cdot} + RCO_2X \rightarrow RX + RCO_2^{\cdot}$

This homolytic fission of the O—X bond of the acyl hypohalite might be presumed to be a very facile process, for the Hunsdiecker reaction may often (5) be carried out successfully at temperatures below 0°. By contrast, however, the pre-

sumed benzoyl hypochlorite of the previous work did not seem to suffer homolysis with great ease. For example (1, 2), at neither 60° nor 100° did it cause the polymerization of added styrene (addition is preferred), nor in the absence of excess benzoyl peroxide as a free radical initiator did it either cause free radical chlorination of an added alkane or decompose cleanly to chlorobenzene.

A possible cause of this apparently different behavior might be that the Hunsdiecker reaction is carried out with silver carboxylates, whereas no transition metal ions were present in the reaction mixtures of chloride ion with benzoyl peroxide. Since transition metal ions are well known to catalyze the homolytic decomposition of organic peroxides (6, 7), peresters (8), *N*-chloroamines (9), and alkyl hypochlorites (10), it is possible that a similar catalytic decomposition of the acyl hypohalite to free radicals could account for the apparent ease of reaction of Hunsdiecker reaction mixtures and the lack of reactivity of the chloride ion/benzoyl peroxide reagent. Such reasoning is consistent with the observation that the Hunsdiecker decarboxylation reaction proceeds more readily with heavy metal salts than with the salts of the alkali or alkaline earth metals.

This study was therefore initiated to discover whether silver (or copper) salts are effective catalysts for the decomposition of benzoyl hypochlorite, with a view to enlarging our knowledge of the Hunsdiecker reaction mechanism. During the work we had occasion to examine the effect of temperature on the reaction, and these results are also included.

Results and Discussion

The required metal-free solutions of benzoyl hypochlorite were prepared by filtration of silver benzoate – chlorine mixtures in carbon tetrachloride as solvent (11).[3,4] Aliquots of these solutions were allowed to decompose at different temperatures under identical conditions except for the presence or absence of various initiators or reagents; after 1 h the solutions were analyzed for the extent of benzoyl hypochlorite decomposition and for chlorobenzene formation (Tables 1–4).[5]

From an examination of these Tables, the following points may be noted. First, light (at all temperatures) and AIBN (at 60°) accelerated the decomposition of the acyl hypochlorite, as would be expected since the reaction is known to be a free radical chain process (4, 5).

Second, neither cuprous ions nor silver ions cause any increase in the rate of decomposition, indicating that neither is a catalyst for the reaction. This is in contrast to the previously mentioned findings for peroxides, chloroamines, etc., but is consistent with the observation by Kochi *et al.* (3) that in the reaction of benzoyl hypochlorite (from benzoyl peroxide/lithium chloride) with toluene, the free radical chlorination of the side chain is not catalyzed but rather is suppressed by the addition of cupric ions to the reaction mixture. In a related system Jennings and Ziebarth (12) have found that the decomposition to 1-bromobutane of the intermediate in the reaction between bromine monoxide and valeric acid (presumed to be valeryl hypobromite) is not

[3]Other metal benzoates could not successfully be substituted for the silver salt, neither could acetonitrile be used as solvent instead of carbon tetrachloride. In acetonitrile there forms a red silver-containing substance whose chemistry is under investigation.

[4]The benzoyl peroxide – chloride ion route to benzoyl hypochlorite is inapplicable because reaction 1 is so slow that the hypochlorite decomposes at a rate comparable with its rate of production (2, 3).

[5]Tables 1 and 2 record the average of duplicate experiments; at 60° (Table 3) identical results were not obtained and both values are quoted.

catalyzed by mercuric salts. Furthermore, in the reaction of silver carboxylates with iodine (reaction 6), the Simonini complex (4, 13) of constitution (**1**) may often be isolated, whereas it might be anticipated that if silver ions were active catalysts for acyl hypohalite decomposition, the silver ions in the complex would cause its ready destruction.

[6] $2RCO_2Ag + I_2 \rightarrow AgI + RCO_2I.RCO_2Ag$

(1)

A third point to note from Tables 1–3 is the effect of temperature on the decomposition. Apart from the rate of reaction increasing at higher temperatures, the yield of chlorobenzene (per mol of hypochlorite destroyed) is markedly greater at higher temperatures (Table 4) and is virtually independent of whether photoinitiation is employed. Since photoinitiation must increase the rate of reaction 3, we conclude that the temperature dependence of the yield is *not* caused by there being some other reaction competing with free radical decomposition. If that had been so, photoinitiation would have increased the yield by promoting reaction 3, the initiation step of the free radical chain reaction.

The temperature dependence of the yield of chlorobenzene is consistent with step 4 or step 5 having a large activation energy. This is unlikely for step 5 because of its analogy with one of the steps in free radical chlorinations by alkyl hypochlorites, which proceed readily even at −80° (14, 15). An appreciable activation energy for step 4 is consistent with the well-known stability of benzoate radicals towards decarboxylation, in particular, their ability to survive long enough to be intercepted by a variety of other reagents (16–20) to give products retaining the benzoate moiety intact. Of interest in the present connection are occasional observations of variations with temperature of the ratio of carboxyl-retaining to decarboxylated products (17, 21). Correspondingly in our studies, the decomposition of benzoyl hypochlorite in carbon tetrachloride at 0° gave benzoic acid as a major product, even when moisture was excluded from the system. It is not clear from where the hydroxyl hydrogen in the acid arises. Small quantities of chlorinated benzoic acid were also formed, presumably by electrophilic chlorination, since the *meta* isomer was produced in the largest amount (*cf.* the production of *m*-bromobenzoic acid from bromine and silver benzoate (5, 22)).

An alternative fate of a benzoyloxy radical is free radical substitution of a suitable aromatic substrate to give the aryl benzoate (23). Because of this reaction, benzene has been noted to be a poor solvent for carrying out Hunsdiecker reactions (4, 24). In our studies we found that the decomposition of silver-free solutions of benzoyl hypochlorite in benzene gave virtually no phenyl benzoate, and that even at 0°, electrophilic chlorination of the solvent occurred almost exclusively. Benzoyl hypobromite was found to be a much less active halogenating agent, and on decomposition in benzene at 3° afforded a moderate yield of phenyl benzoate, though little

of this product was formed at reflux. It was noted that silver salts have a slight catalytic effect as halogen carriers for both benzoyl hypochlorite and elemental chlorine, and that benzoyl hypochlorite is the more reactive halogenating agent (Table 5). Acetyl hypohalites are likewise more reactive electrophilic reagents than the elemental halogens (25–27).

The dependence of the yield of aryl halide on the temperature of decomposition is not peculiar to benzoyl hypochlorite. Benzoyl hypobromite and substituted benzoyl hypobromites behave similarly. The polar solvent acetonitrile gave results similar to those obtained in the non-polar carbon tetrachloride (Table 6).

In Table 6 we have also collected literature values for the yields of aliphatic halides from Hunsdiecker reactions that have been conducted at different temperatures, for comparison with our own data. Aliphatic substrates do not exhibit the same marked depression of the yield on lowering the temperature; indeed halides derived from *secondary* alkyl groups R are produced in better yield at lower temperatures. On the limited data at hand we propose the following explanation. Aryl halides form with difficulty at low temperatures because of the less facile decarboxylation of the resonance-stabilized aroyloxy radicals; by contrast alkanoy oxy radicals decarboxylate readily even at low temperatures (28). There is thus less tendency for alkanoyloxy radicals to be diverted to other products before decarboxylation occurs. Readier formation of halide in aliphatic compared with aromatic systems has also been observed in diacyl peroxide/chloride ion systems (3, 29), again indicating the importance of the nature of the R group in decarboxylations. In the valeryl peroxide reaction (29), a faster reaction in the presence of copper salts was attributed to copper catalyzed decomposition of the peroxide rather than of an intermediate valeryl hypochlorite.

The increased yield of secondary halides at low temperatures probably results from less of the product being destroyed after formation: tertiary halides cannot be synthesized by the Hunsdiecker method (4, 5) because the silver salts present in solution destroy them as they are formed by assisted ionization (eq. 7).[6]

[7] $$RX + Ag^+ \rightarrow AgX + R^+ \rightarrow \text{products}$$

Silver salts attack secondary halides less rapidly, and this reaction may be suppressed by low temperature operation, so that a better yield of halide is obtained.

To conclude, these experiments show that neither silver nor cuprous ions are catalysts for the decomposition of benzoyl hypochlorite. The only reservation we have to this conclusion is that while we were unable to detect any silver salts in the carbon tetrachloride solutions used in our experiments, there remains the possibility that a small but undetected quantity was present and that this was sufficient to catalyze the decomposition even when no further quantity was added. To try to resolve this problem, we are currently trying to prepare acyl hypohalites by routes not involving metallic precursors. Concerning the effect of temperature on the yield of aryl halides from the Hunsdiecker reaction, we suggest that this is simply a reflection of the readier decomposition of benzoate radicals at elevated temperatures.

[6]In the case where R = cyclobutyl, products derived by rearrangement of R^+ are observed.

Experimental

Solvents were reagent grade materials, dried with activated molecular sieve. Silver benzoate was supplied by Eastman Organic Chemicals or alternatively by British Drug Houses Ltd. Substituted silver benzoates were prepared by the method of Dauben and Tilles (32). Lithium benzoate (m.p. > 360°) was prepared by the action of lithium hydroxide on benzoic acid. Cupric benzoate was prepared by reacting cupric sulfate solution with aqueous sodium benzoate; the product was recrystallized from acetonitrile. Lead benzoate (m.p. 90–95°) was prepared from lead acetate and hot aqueous benzoic acid; mercuric benzoate (dec. > 156°) from mercuric nitrate/nitric acid solution and hot aqueous benzoic acid. All the metal benzoates were dried at 70° (120° for the alkali metal salts) for several days before use.

Solutions of chlorine or of benzoyl hypochlorite were estimated iodometrically. The color of iodine was used as its own indicator.

Vapor phase chromatography (v.p.c.) analyses were carried out on a Varian Aerograph Model 90-P3 instrument using helium as the carrier gas. Where quantitative determinations were to be made a weighed quantity of a standard substance was added to the reaction mixture, and the product in question quantitated by measuring the area of the product relative to the area of the standard. All such analyses were carried out in triplicate, and the reported values are the average. In the present study, chlorocyclohexane or bromobenzene were used as standards for chlorobenzene, and chlorobenzene or chlorocyclohexane as standards for bromobenzene. The response of the gas chromatograph was shown to be approximately equal towards these three compounds.

Attempts to Prepare Benzoyl Hypochlorite

(i) Reaction of Chlorine with Silver Benzoate and Addition of the Product to Cyclohexene

A 0.37 *M* solution of chlorine in carbon tetrachloride (18 ml) cooled to 0° was allowed to react in the dark with dry silver benzoate (3.0 g, 13.1 mmol) for 5 min and then filtered. To the filtrate was added cyclohexene (5 ml), after which the solution was washed twice with 0.1 *M* sodium bicarbonate (50 ml), with water (50 ml), and dried over calcium chloride. The solvent was removed,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

and the residue was redissolved in carbon tetrachloride and examined by nuclear magnetic resonance (n.m.r.) (τ 1.8–3.0, 5H; τ 4.8–5.3, 1H; τ 5.7–6.3, 1H; τ 7.0–9.1, 8H; all multiplets). The n.m.r. was identical to that previously reported for 2-chlorocyclohexyl benzoate (1) and the compound was essentially free of 1,2-dichlorocyclohexane, which would change the spectrum by increasing the relative intensities of the resonances at τ 5.7–6.3 and τ 7.0–9.1.

(ii) Reaction of the Halogens with Other Metal Benzoates

Chlorine (occasionally bromine) was allowed to interact with various metal benzoates in different solvents (carbon tetrachloride, acetonitrile, *N,N*-dimethylformamide (*cf.* ref. 2), and water (*cf.* ref. 33), at temperatures in the range 0–100°. There was no evident reaction when the lithium, sodium, cupric, or lead salts were used. Both the mercuric and silver salts reacted with the halogens, but only the latter was used because the reactions with the mercuric salt were very slow and, furthermore, did not subsequently yield any aryl halide (possibly because the mercuric salt is hydrated).

Decomposition of Benzoyl Hypochlorite at Different Temperatures

A solution (approximately 0.3 *M*) of chlorine in carbon tetrachloride was cooled to 0° and allowed to react at 0° with silver benzoate (5.0 g), so that the latter was in at least two fold excess. After 5 min the solution was filtered, and 2 ml portions of the solution were placed in Pyrex ampoules, some of which already contained added reagents. (At this point two 2 ml portions were allowed to react with acidified potassium iodide solution and shown by v.p.c. *not* to have decomposed to chlorobenzene in the procedure.) The ampoules were cooled to 77 °K and evacuated to a pressure of 1 mm, after which they were sealed and placed in a constant temperature bath. Those samples to be irradiated were placed a few inches from two 100 W tungsten lamps; the other samples were protected from the light by means of aluminum foil. After 1 h the reaction ampoules were cooled to 77 °K, opened, their contents poured into acidified potassium iodide solution, and the liberated iodine was estimated volumetrically. The carbon tetrachloride solution from each such analysis was recovered; to a 1 ml portion was added bromobenzene as a standard and the chlorobenzene produced was estimated by v.p.c. The results of this study are given in Tables 1–4.

Decomposition of Benzoyl Hypochlorite at 0°

To silver benzoate (2.5 g) was added 15 ml of a 0.33 *M* solution of chlorine in carbon tetrachloride. After 5 min the reaction mixture was filtered and the filtrate was stored at 3° in a corked ampoule for 16 days, at which time the "positive chlorine" content of the sample was 0.06 *M*. Vapor phase chromatographic analysis of the carbon tetrachloride phase gave an estimated yield of chlorobenzene at 0.116 *M* (34%). A 5 ml portion of the solution was extracted with aqueous sodium bicarbonate; the aqueous phase was acidified and after extraction into ether, drying and evaporation of the solvent, yielded 107 mg of a white solid, m.p. 105–109°. The solid was esterified with methanol/sulfuric acid and analyzed by v.p.c. (10% diisodecyl phthalate on acid-washed 60/80 Chromosorb W). The esters of benzoic acid and of *o*-, *m*-, and *p*-chlorobenzoic acids were present in the ratio of 80:1.2:6.1:1.0.

Reaction of Halogens with Silver Benzoate at 80 and 0°

(i) Bromine at 80°

The following procedure is typical: To duplicate samples of dry silver benzoate (5.8 g, 25 mmol) and dry acetonitrile (40 ml) in 100 ml flasks equipped with reflux condensers and calcium chloride drying tubes was added in small portions a mixture of bromine (4.0 g, 25 mmol) and acetonitrile (total volume 10 ml). After 9.5 (9.5) ml of this mixture had been added, the solution assumed the red color of molecular bromine, and this color was not discharged by refluxing for a further 0.5 h. Heating now continued for 3 h more, after which weighed quantities of chlorobenzene were added to two aliquots of each solution. The bromobenzene produced was estimated by v.p.c. (Carbowax 20 *M*, 130°) and a sample of bromobenzene was isolated and its identity checked by infrared (i.r.) (this was not done in subsequent experiments).

(ii) Bromine at 0°

To a solution of bromine in the appropriate solvent cooled to 0° was added an equimolar quantity of silver benzoate. The reaction mixture was stirred at 0° with a magnetic stirrer for 4 h, then analyzed by v.p.c. as described above.

(iii) Chlorine at 0°

A solution of chlorine in the appropriate solvent was cooled to 0° and estimated iodometrically. Sufficient of this solution to contain 12.5 mmol of chlorine was added to silver benzoate (12.5 mmol) and the mixture was stirred at 0° for 4 h, then analyzed by v.p.c. as described previously.

(iv) Chlorine at 80°

Silver benzoate (12.5 mmol) and the appropriate solvent (40 ml) were placed in a two-necked flask equipped with reflux condenser and the mixture was brought to reflux. Through the second neck of the flask was introduced a slow stream of chlorine gas, which was maintained for 0.5 h. The mixture was refluxed for 1 h more, then analyzed by v.p.c. as described above.

Reaction of Bromine with Substituted Silver Benzoates

The following procedure is typical. To duplicate reaction mixtures of silver *p*-nitrobenzoate (2.7 g, 10 mmol) and carbon tetrachloride (40 ml) at reflux was added bromine (1.6 g, 10 mmol) and the solution was refluxed for 2 h. After the reaction bromine (0.050, 0.052 *M*) was estimated by iodometric titration of aliquots of the solution. To other aliquots was added bromobenzene as a v.p.c. standard (SE30, 200°), when the *p*-bromonitrobenzene produced was estimated at 0.20, 0.18 *M*. The solutions remaining were combined and filtered, yielding 52 ml of filtrates. Evaporation of the solvent followed by chromatography of the residue on silica gel (50 g) eluted *p*-bromonitrobenzene (1.6 g, 61%) as pale yellow needles, m.p. 126–126½°, undepressed by admixture with authentic material made from *p*-nitroaniline by the Sandmeyer reaction.

The experiment at 3° was also carried out in duplicate as follows. To the mixture of carbon tetrachloride and

the silver salt cooled to 0° was added bromine, after which the mixture was allowed to stand in a refrigerator (3 ± 2°) for 140 h. Analysis of the solutions was as described above but there was too little product to be isolated.

Hydrogen Abstraction from Methyl Formate by Methyl Radicals[1]

T. R. Donovan,[2] W. Dorko, and A. G. Harrison
Department of Chemistry, University of Toronto, Toronto 181, Ontario

Received March 13, 1970

The reactions of CH_3 radicals with methyl formate and CD_3 radicals with methyl formate and methyl formate-*d* have been studied. The CH_3 and CD_3 radicals were produced by the photolysis of acetone and acetone-*d*. The Arrhenius parameters (log *A*, *A* in l mol^{-1} s^{-1}; *E*, in kcal mol^{-1}) for hydrogen abstraction are as follows

$$CH_3 + HCO_2CH_3 \rightarrow CH_4 + C_2O_2H_3: \log A, 8.7_0; E, 10.3;$$

$$CD_3 + HCO_2CH_3 \rightarrow CD_3H + C_2O_2H_3: \log A, 8.6_4; E, 10.1;$$

$$CD_3 + DCO_2CH_3 \rightarrow CD_4 + CO_2CH_3: \log A, 8.4_8; E, 11.7;$$

$$CD_3 + DCO_2CH_3 \rightarrow CD_3H + DCO_2CH_2: \log A, 8.0_9; E, 10.8;$$

$$CD_3 + HCO_2CH_3 \rightarrow CD_3H + CO_2CH_3: \log A, 8.5_5; E, 10.0.$$

Les réactions du radical $CH_3\cdot$ avec le formiate de méthyle et du radical $CD_3\cdot$ avec le formiate de méthyle et $DCOOCH_3$ ont été étudiées. Les radicaux $CH_3\cdot$ et $CD_3\cdot$ ont été obtenus par photolyse de l'acétone et de l'acétone-d_6 respectivement. Les paramètres d'Arrhénius (log *A*, *A* en l mol^{-1} s^{-1}; *E*, in kcal mol^{-1}) pour l'abstraction d'hydrogène sont les suivants

$$CH_3 + HCO_2CH_3 \rightarrow CH_4 + C_2O_2H_3: \log A, 8.7_0; E, 10.3;$$

$$CD_3 + HCO_2CH_3 \rightarrow CD_3H + C_2O_2H_3: \log A, 8.6_4; E, 10.1;$$

$$CD_3 + DCO_2CH_3 \rightarrow CD_4 + CO_2CH_3: \log A, 8.4_8; E, 11.7;$$

$$CD_3 + DCO_2CH_3 \rightarrow CD_3H + DCO_2CH_2: \log A, 8.0_9; E, 10.8;$$

$$CD_3 + HCO_2CH_3 \rightarrow CD_3H + CO_2CH_3: \log A, 8.5_5; E. 10.0.$$

Canadian Journal of Chemistry, 49, 828 (1971)

Introduction

Arthur and Gray (1) recently have reported the results of a study of the hydrogen-abstraction reactions of methyl radicals attacking methyl formate. Using isotopically labelled formate ($DCOOCH_3$) they measured the Arrhenius parameters for abstraction of both the methyl and formyl hydrogens and showed that at 182 °C, approximately 15% of the hydrogen is abstracted from the methyl position. This result is in contrast with those of Thynne (2) who concluded that abstraction occurred only from the formyl position for several alkyl formates, including methyl formate.

Prior to the publication by Arthur and Gray (1), we had undertaken a study of the reaction of methyl radicals with $DCOOCH_3$ to determine the position of abstraction. It has been suggested (3) that abstraction of hydrogen from the alkyl group in formates could be followed by CO_2 elimination to yield an alkyl radical. This reaction sequence in $DCOOCH_3$ would give a CH_2D radical which, by subsequent reaction with the methyl radical source, acetone, would yield CH_3D. Such a reaction sequence if it occurred would make the determination of the rate of abstraction of D from $DCOOCH_3$ ambiguous. To eliminate such ambiguity we have studied the reactions of CD_3 with $DCOOCH_3$. For comparison with previous work we have also studied the reaction of CH_3 radicals with unlabelled methyl formate. The results obtained support, on the whole, the conclusions reached by Arthur and Gray (1) although we differ in some of the details and it therefore appeared worthwhile to present our results at this time.

Experimental

Methyl radicals were produced by photolysis of acetone and methyl-d_3 radicals by photolysis of acetone-d_6, in both cases the total decomposition being limited to

[1]This work constitutes part of the M.Sc. thesis of W. Dorko (University of Toronto, 1967) and T. R. Donovan (University of Toronto, 1969).

2–3%. The apparatus and experimental techniques were essentially identical with those used in a previous study (4) with the exception that the product analysis was carried out using an AEI MS-10 mass spectrometer.

The acetone was Fisher Spectroanalyzed Grade, dried and distilled *in vacuo* before use. Eastman Spectro Grade methyl formate was distilled *in vacuo* before use and showed no detectable impurities in its mass spectrum. Acetone-d_6 and methyl formate-d were obtained from Merck, Sharp and Dohme, Montreal.

Mass spectrometric analyses at low electron energy showed that the acetone-d_6 contained 2.3_6 mol% acetone-d_5, while the methyl formate-d contained 1.0% unlabelled formate.

Results[3]

Photolysis of Acetone

Above 373 °K the production of methane and ethane in the photolysis of acetone can be described by the mechanism

[1] $(CH_3)_2CO + h\nu \rightarrow 2\,CH_3 + CO$

[2] $2\,CH_3 \rightarrow C_2H_6$

[3] $CH_3 + (CH_3)_2CO \rightarrow CH_4 + CH_2COCH_3$

leading to the expression

$$R_{CH_4}/R_{C_2D_6}^{1/2}[Ac] = k_3/k_2^{1/2}$$

In the present work acetone was photolyzed in the temperature range 400 to 513 °K. Least squares analysis of the results for $k_3/k_2^{1/2}$ led to the expression

$$\log k_3/k_2^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.26\ (\pm 0.15) - 2.07_1\ (\pm\ 0.067)\ 10^3/T$$

In combination with $k_2 = 2.2 \times 10^{10}$ l mol^{-1} s^{-1} and $E_2 = 0$ (5), this result leads to $E_3 = 9.4_8 \pm 0.3$ kcal/mol and log A_3 (l mol^{-1} s^{-1}) = $8.4_3 \pm 0.15$, in good agreement with the previous values of E and log A, respectively, of 9.3 and 8.3_5 (4), 9.43 and 8.42 (6), 9.63 and 8.53 (1), and 9.53 and 8.2 (7).

Photolysis of Acetone-d_6

The main products can be accounted for by the following mechanism, similar to that for the unlabelled acetone

[1′] $(CD_3)_2CO + h\nu \rightarrow 2CD_3 + CO$

[1″] $CD_3COCD_2H + h\nu \rightarrow CD_3 + CD_2H + CO$

[2′] $2CD_3 \rightarrow C_2D_6$

[3′] $CD_3 + (CD_3)_2CO \rightarrow CD_4 + CD_2COCD_3$

[3″] $CD_2H + (CD_3)_2CO \rightarrow CD_3H + CD_2COCD_3$

[5] $CD_3 + HCD_2COCD_3 \rightarrow CD_3H + CD_2COCD_3$

Reactions 1″, 3″, and 5 must be included because of the presence of 2.3_6 mol% acetone-d_5. Letting $[CD_2H]/[CD_3] = K_1$ and $[\text{Ac-}d_6]/[\text{Ac-}d_5] = K_2$, we may derive expressions 6 and 7 from the above mechanism

[6] $$\frac{R_{CD_4}}{R_{C_2D_6}^{1/2}[\text{Ac-}d_6]} = \frac{k_3'}{k_2'^{1/2}}$$

[7] $$\frac{R_{CD_3H}}{R_{C_2D_6}^{1/2}[\text{Ac-}d_5]} = \frac{k_5 + k_3''K_1K_2}{k_2'^{1/2}}$$

Experimental results were obtained over the temperature range 385 to 499 °K. Analysis of the experimental results by eq. 6 led by least squares treatment to the expression

$$\log k_3'/k_2'^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.77\ (\pm\ 0.086) - 2.605\ (\pm\ 0.038)\ 10^3/T$$

Assuming $k_2' = k_2$ and $E_2' = 0$, we obtain log A_3' (l mol^{-1} s^{-1}) = 8.94 (± 0.09) and $E_3' = 11.9 \pm 0.2$ kcal mol^{-1}. These results are in reasonable agreement with earlier determinations of log A_3' and E_3', respectively, of 8.6_2 and 11.5_4 (8), 8.7 and 11.4 (9), 9.1 and 11.5 (10), and 8.7 and 11.5 (11).

The rate of formation of CD_3H is required primarily to correct the results in the photolysis of mixtures for the CD_3H arising from the acetone alone. Since the same sample was used for all experiments, K_1 and K_2 should remain essentially constant and we have evaluated only the expression

$$(k_5 + k_3''K_1K_2)/k_2'^{1/2}$$

as a function of temperature by treating the experimental results of eq. 7. Least squares treatment of the results led to the expression

$$\log (k_5 + k_3''K_1K_2/k_2'^{1/2}) = 3.25\ (\pm\ 0.15) - 2.28_5\ (\pm\ 0.066)\ 10^3/T$$

This expression was then used in the following to correct for CD_3H formation from the labelled acetone itself when mixtures with the labelled acetone were photolyzed.

Photolysis of Acetone – Methyl Formate Mixtures

When acetone is photolyzed in the presence of

[3] Photo copies of the complete tables of data upon which the present conclusions are based may be obtained free of charge, upon request, from the Depository of Unpublished Data, National Science Library, National Research Council of Canada, Ottawa, Canada.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methyl formate, reaction 8 must be added to reaction 3 as a source of CH_4.

[8] $CH_3 + HCO_2CH_3 \rightarrow CH_4 + C_2O_2H_3$

The following equation may be derived

$$[9] \quad \left[\frac{R_{CH_4}}{R_{C_2H_6}^{1/2}[Ac]} - \frac{k_3}{k_2^{1/2}}\right]\frac{[Ac]}{[Form]} = \frac{k_8}{k_2^{1/2}}$$

Results obtained in the photolysis of acetone–formate mixtures ([Ac]/[Form] = 1.17 to 1.69) over the temperature range 405 to 519 °K are shown in Fig. 1 as an Arrhenius plot of log $(k_8/k_2^{1/2})$ *vs.* $10^3/T$. Least squares analysis yields the expression

$$\log k_8/k_2^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.53\ (\pm 0.10) - 2.25_3\ (\pm 0.044)\ 10^3/T$$

leading to $\log A_8\ (l\ mol^{-1}\ s^{-1}) = 8.70 \pm 0.10$ and $E_8 = 10.3 \pm 0.20$ kcal mol^{-1}.

Photolysis of Acetone-d_6 – Methyl Formate Mixtures

In the photolysis of these mixtures reaction 10 must be considered in addition to reactions 3'' and 5 as a source of CD_3H.

[10] $CD_3 + HCO_2CH_3 \rightarrow CD_3H + C_2O_2H_3$

The ratio $k_{10}/k_2'^{1/2}$ may be evaluated from the relation

$$[11] \quad \left[\frac{R_{CD_3H}}{R_{C_2D_6}^{1/2}[Ac\text{-}d_5]} - \frac{k_5 + k_3''K_1K_2}{k_2'^{1/2}}\right] \times \frac{[Ac\text{-}d_5]}{[Form]} = \frac{k_{10}}{k_2'^{1/2}}$$

Results obtained over the temperature range 408 to 494 °K are shown as an Arrhenius plot in Fig. 1 and lead, on least squares analysis, to the relation

$$\log k_{10}/k_2'^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.47\ (\pm 0.14) - 2.207\ (\pm 0.064)\ 10^3/T$$

yielding $\log A_{10} = 8.64 \pm 0.14$ and $E_{10} = 10.1 \pm 0.3$ kcal/mol.

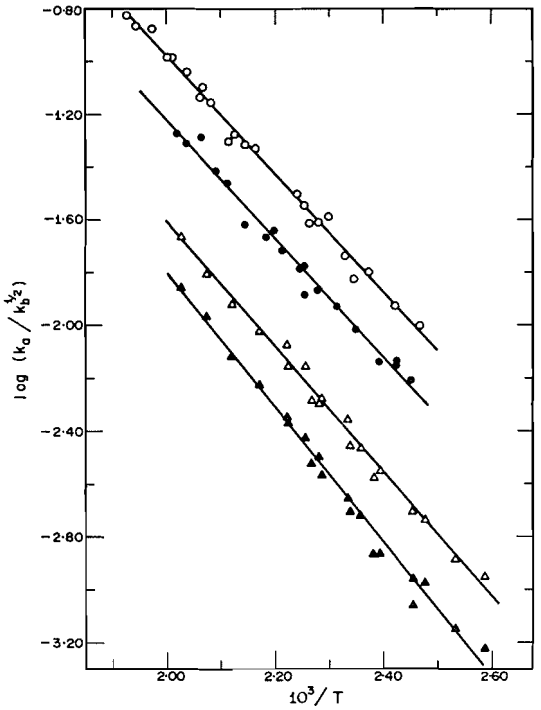

FIG. 1. Arrhenius plots for methyl radical reactions ○, log $(k_8/k_2^{1/2})$ *vs.* $10^3/T$; ●, log $(k_{10}/k_2'^{1/2})$ *vs.* $10^3/T$, curve displaced downwards by 0.3 units; △, log $(k_{14}/k_2'^{1/2})$ *vs.* $10^3/T$, curve displaced upwards by 0.2 units; ▲, log $(k_{12}/k_2'^{1/2})$ *vs.* $10^3/T$.

Photolysis of Acetone-d_6 – Methyl Formate-d Mixtures

In the photolysis of these mixtures CD_4 is formed by reaction 12 in addition to reaction 3'

[12] $CD_3 + DCD_2CH_3 \rightarrow CD_4 + CO_2CH_3$

The reaction scheme leads to the expression

$$[13] \quad \left[\frac{R_{CD_4}}{R_{C_2D_6}^{1/2}[Ac\text{-}d_6]} - \frac{k_3'}{k_2'^{1/2}}\right] \times \frac{[Ac\text{-}d_6]}{[Form\text{-}d]} = \frac{k_{12}}{k_2'^{1/2}}$$

Acetone-d_6 — methyl formate-d_1 mixtures were photolyzed over the temperature range 387 to 493 °K with the values of $k_{12}/k_2'^{1/2}$ being evaluated from eq. 13. The results are plotted as a function of temperature in Fig. 1 and treatment of the data by the method of least squares leads to the result

$$\log k_{12}/k_2'^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.31\ (\pm 0.16) - 2.55_4\ (\pm 0.070)\ 10^3/T$$

from which one obtains $\log A_{12} = 8.48 \pm 0.16$ and $E_{12} = 11.7 \pm 0.3$ kcal mol^{-1}.

In the photolysis of these mixtures CD_3H may be formed by the following reactions, where reaction 10 is included to allow for the 1.0% HCO_2CH_3 impurity in the labelled formate.

[3''] $CD_2H + (CD_3)_2CO \rightarrow CD_3H + CD_2COCD_3$

*Units of A and k l mol^{-1} s^{-1}.

[5] $CD_3 + CD_2HCOCD_3 \rightarrow CD_3H + CD_2COCD_3$

[10] $CD_3 + HCO_2CH_3 \rightarrow CD_3H + C_2O_2H_3$

[12′] $CD_2H + DCO_2CH_3 \rightarrow CD_3H + CO_2CH_3$

[14] $CD_3 + DCO_2CH_3 \rightarrow CD_3H + DCO_2CH_2$

Letting $[HCO_2CH_3]/[DCO_2CH_3] = K_3$ we obtain the following expression for the rate of formation of CD_3H

$$[15]\quad R_{CD_3H} = (k_5 + k_{3''}K_1K_2)[CD_3][\text{Ac-}d_5] + (k_{14} + k_{10}K_3 + k_{12'}K_1)[CD_3][\text{Form-}d]$$

where K_1 and K_2 are as defined in the section of photolysis of acetone-d_6 alone. From eq. 15 we may derive

$$[16]\quad \left[\frac{R_{CD_3H}}{R_{C_2D_6}^{1/2}[\text{Ac-}d_5]} - \frac{k_5 + K_1K_2k_{3''}}{k_{2'}^{1/2}}\right] \times \frac{[\text{Ac-}d_5]}{[\text{Form-}d]} - \frac{k_{10}K_3}{k_{2'}^{1/2}} - \frac{k_{12'}K_1}{k_{2'}^{1/2}} = \frac{k_{14}}{k_{2'}^{1/2}}$$

The expression within the brackets on the left hand side of eq. 16 may be evaluated from the experimental results for photolysis of the mixture and the results from photolysis of acetone-d_6 alone. The expression $k_{10}K_3/k_{2'}^{1/2}$ corrects for the CD_3H formed by reaction 10 and may be evaluated from the results for $k_{10}/k_{2'}^{1/2}$ obtained above taking $K_3 = 0.010$. The expression $k_{12'}K_1/k_{2'}^{1/2}$ corrects for the CD_3H formed by reaction 12′. Assuming $k_{12'} = k_{12}$, this correction can be estimated from the measured value of $k_{12}/k_{2'}^{1/2}$ taking $K_1 = 0.012$. These two corrections amounted to approximately 8% of the first term. The values of $k_{14}/k_{2'}^{1/2}$ obtained after these corrections are shown in the form of an Arrhenius plot in Fig. 1 and lead on least squares analysis to the expression

$$\log k_{14}/k_{2'}^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 2.92\ (\pm 0.11) - 2.36_6\ (\pm 0.044)\ 10^3/T$$

From this expression one derives log A_{14} (l mol^{-1} s^{-1}) = 8.09 ± 0.11 and E_{14} = 10.8 ± 0.2 kcal mol^{-1}.

Neglecting secondary isotope effects, as is customary, the rate coefficient for the reaction

[17] $CD_3 + HCO_2CH_3 \rightarrow CD_3H + CO_2CH_3$

may be obtained from the relation

$$[18]\quad \frac{k_{17}}{k_{2'}^{1/2}} = \frac{k_{10}}{k_{2'}^{1/2}} - \frac{k_{14}}{k_{2'}^{1/2}}$$

Using the relevant experimental data we obtain

$$\log k_{17}/k_{2'}^{1/2}\ (l^{1/2}\ mol^{-1/2}\ s^{-1/2}) = 3.38\ (\pm 0.24) - 2.19_2\ (\pm 0.107)\ 10^3/T$$

leading to log A_{17} (l mol^{-1} s^{-1}) = 8.5_5 ± 0.24 and E_{16} = 10.0 ± 0.5 kcal mol^{-1}.

Discussion

Table 1 summarizes the data available concerning hydrogen abstraction from methyl formate by methyl radicals. Although the rate constants at 182 °C for the overall hydrogen abstraction from the unlabelled formate are in reasonable agreement, our activation energies both for CH_3 and CD_3 are considerably higher

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

than obtained by Arthur and Gray (1) and by Thynne (2*a*), although they are in agreement, within experimental error, with the results of Kutschke (12). There are no readily apparent reasons for this spread in Arrhenius parameters.

The present results for abstraction of D from DCO_2CH_3 are in excellent agreement with the results of Arthur and Gray (1); however, the results for abstraction of the methyl hydrogen, while agreeing in the rate constant at 182 °C disagree significantly in the activation energy and A factor. Arthur and Gray point out that the accuracy of their Arrhenius parameters for abstraction from the methyl position is limited, presumably because the amount of CH_4 produced by this reaction is small compared to the CH_4 produced by abstraction from the radical source, acetone. In our experiments the product resulting from abstraction from the methyl group is CD_3H and, at a maximum, only 3% of the total CD_3H arises from reaction involving the acetone-d_5 isotopic impurity. Thus for experimental reasons we would suggest that the present results are to be preferred.

Some support for our data comes from the following observations. The activation energy for abstraction from the methyl group of methyl formate, $E = 10.8 \pm 0.2$ kcal/mol, is in reasonable agreement with the activation energy, $E = 10.0 \pm 0.2$ kcal/mol, for hydrogen abstraction from dimethyl ether. Our Arrhenius parameters when compared to Arthur and Gray's results for abstraction of a methyl hydrogen from methyl formate by CF_3 radicals leads to $E_{CD_3} - E_{CF_3} = 2.0$ kcal/mol and a ratio of A factors of $A_{CF_3}/A_{CD_3} = 1.2_3$ while Arthur and Gray's data lead to $E_{CH_3} - E_{CF_3} = 0.14$ kcal/mol and $A_{CF_3}/A_{CH_3} \approx 10$. As Arthur and Gray point out, abstraction by CF_3 is usually faster than abstraction by CH_3 and this rate difference usually arises from a lower activation energy rather than a higher frequency factor. Our results thus appear more in line with previous experience assuming their kinetic data for the CF_3 reaction is correct.

The difference between the present work and that of Arthur and Gray for attack on the methyl position of methyl formate is counterbalanced by the difference in the parameters for the total hydrogen abstraction reaction, with the result that we obtain essentially the same Arrhenius parameters for abstraction of hydrogen from the formyl position of the unlabelled formate. Our experimental results for k_{14} and k_{17} lead to the conclusion that at 182 °C, approximately 10% of the total hydrogen is abstracted from the methyl position, in agreement with the conclusion of Arthur and Gray.

The authors are indebted to the National Research Council of Canada for financial support and to Dr. A. Herod for helpful discussions.

Influence of p*H* on the Kinetics of Hydration of Tricalcium Silicate

K. G. McCURDY AND B. P. ERNO
Department of Chemistry, University of Lethbridge, Lethbridge, Alberta

Received September 1, 1970

An investigation has been made of the influence of p*H* on the kinetics of hydration of tricalcium silicate in a large excess of water. The rate constants increase with increasing hydrogen ion activity $(a_{H^+})_{aq}$ in the liquid phase when the $(a_{H^+})_{aq}$ is low; however, as the $(a_{H^+})_{aq}$ is increased further the rate constants become independent of the $(a_{H^+})_{aq}$. The results have been interpreted by proposing that the rate constants are proportional to the hydrogen ion activity adsorbed, $(a_{H^+})_{ads.}$, on the solid surface. The Langmuir adsorption isotherm was used to correlate the hydrogen ion activity on the surface to the hydrogen ion activity in the liquid phase.

Several particle sizes of tricalcium silicate were investigated and a surface area effect is indicated.

Introduction

Tricalcium silicate, Ca_3SiO_5, contains calcium (Ca^{2+}), oxide (O^{2-}), and silicate (SiO_4^{4-}) ions (1). When tricalcium silicate is dissolved in basic aqueous solutions, the reaction products are calcium hydroxide and calcium silicate hydrates of various compositions (2). When a large excess of water, 1000:1 weight liquid to weight solid ratio, is used the dissolution reaction is complete and may be represented as in eq. 1 with no precipitation of calcium silicate hydrate

[1] $3Ca^{2+}(c) + O^{2-}(c) + SiO_4^{4-}(c) + nH_2O(l) \rightarrow$

$$3Ca^{2+}(aq) + 6OH^-(aq) + SiO_2(aq)$$

The silicate species is denoted by $SiO_2(aq)$, realizing that it is distributed among the species H_4SiO_4, $H_3SiO_4^-$, and $H_2SiO_4^{2-}$ as a function of the p*K*'s of silicic acid and the p*H* of the medium. The reaction generates hydroxide ions and the p*H* increases as the reaction proceeds. In a previous publication (3) from this laboratory, a p*H* stat technique was described for following the progress of the reaction. The following mechanism was proposed for the overall chemical reaction in reaction 1

[2] $3CaO.SiO_2(s) + nH_2O(l) \xrightarrow{k_1} 1.5Ca^{2+}(aq) + 3OH^-(aq) + 1.5CaO.SiO_2(s)$

[3] $1.5CaO.SiO_2(s) + nH_2O(l) \xrightarrow{k_2} 1.5Ca^{2+}(aq) + 3OH^-(aq) + SiO_2(aq)$

[4] $1.5CaO.SiO_2(s) + SiO_2(aq) \overset{K_3}{\rightleftharpoons} 1.5CaO.SiO_2.SiO_2(s)$

[5] $1.5CaO.SiO_2.SiO_2(s) + nH_2O(l) \xrightarrow{k_4} 1.5Ca^{2+}(aq) + 3OH^-(aq) + 2SiO_2(aq)$

This mechanism successfully accounted for the amount of hydroxide produced at various times (3).

No other investigations using the constant p*H* technique of hydration of tricalcium silicate have been reported. Recent reviews (4, 5) report experiments that have been conducted in systems which rapidly reach lime saturation and therefore do proceed at a constant p*H* corresponding to lime saturation. Since calcium silicate hydrates are precipitated during this reaction, these results are not directly comparable with the present results.

Lerch and Bogue (6) hydrated tricalcium silicate in a medium in which the supernatant, containing the soluble products of the hydration, was intermittently replaced by water. This technique is only remotely comparable to the present continuously controlled p*H* method. They reported that the rate of production of $Ca(OH)_2$ was faster when the supernatant was replaced intermittently than when the supernatant was not replaced.

The heterogenous reaction kinetics of the dissolution of hydrated metal silicates by aqueous acid solutions have been studied by several investigators (7–9). It has been suggested that the rate of dissolution of a crystalline powder by excess acid (or alkali) should depend on the surface area of the solid and on the mean ionic activity of the liquid phase (10, 11).

In the present study, tricalcium silicate was hydrated in a large excess of water at several

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

different but constant pH's in order to determine the pH dependence of the various steps in the mechanism described by reactions 2 to 5.

Experimental

Materials

The tricalcium silicate studied was synthesized from Baker analyzed low alkali calcium carbonate and Baker analyzed reagent silica with a 3:1 molar ratio, lime to silica, in platinum crucibles in a high temperature furnace. The mixture was put into the cold furnace and the temperature slowly raised to 950 °C and then rapidly raised to 1510 °C. The sample was removed from the furnace, ground to pass a 200 mesh sieve and reignited at 1510 °C until tests for free lime (12) were less than 0.5%. Chemical analysis of the product indicated 73.2% lime and 26.3% silica, and 0.4% free lime. Calculations of the composition of the product from the above data indicated 96.0% tricalcium silicate and 3.1% dicalcium silicate.

The particle size ranges used in the present study were obtained by sieving the tricalcium silicate for 30 min with a stack of Endicott N.B.S. sieves. Sieve openings for U.S.B.S. sieve numbers 400, 325, 270, 230, 100, and 50 are 0.037, 0.044, 0.053, 0.062, 0.149, and 0.297 mm, respectively. Samples *A*, *B*, *C*, *D*, and *E* were obtained with the following characteristics

Sample	Passed through N.B.S. sieve number	Did not pass through N.B.S. sieve number
A	400	—
B	325	400
C	270	325
D	230	270
E	50	100

All solutions were prepared using doubly distilled water.

Lime solutions were prepared by igniting low alkali Baker analyzed calcium carbonate to lime and dissolving in water. Calcium ion was determined by EDTA titration (13).

All reactions were initiated in 0.2 mM calcium hydroxide solution. The various experimental pH's were obtained by adjusting the calcium hydroxide with concentrated solutions of HCl or NaOH.

Equipment and Procedure

The experimental apparatus and the kinetic analysis procedure have been previously described (3). All reactions were again treated as first order with respect to the weight of solid.

All experiments involved 10 mg of tricalcium silicate in 10 ml of solution at 25 °C.

Results

Experimental conditions of the series and results of the kinetic analysis are given in Table 1. All series are results of at least duplicate investigations.

Series 41 to 61 were with Sample *A* of tricalcium silicate. Series 62 to 64 were with Sample *B* of tricalcium silicate. Series 65 to 69 were with Sample *D* of tricalcium silicate. Series 70 to 74 were with Sample *E* of tricalcium silicate. Series 75 to 84 were with Sample *C* of tricalcium silicate.

Discussion

Influence of pH on the Rate Constants k_1, k_2, and k_4

The results reported in Table 1 indicate that the first order rate constants k_1, k_2, and k_4 are affected by varying the pH of the reaction medium. The rate constants increase with increasing hydrogen ion activity in liquid phase, $(a_{H^+})_{aq}$, up to a certain hydrogen ion activity and then remain constant with further increases in the activity of the hydrogen ion in the liquid phase. A typical graph is given in Fig. 1, a_{H^+} is plotted as pH to compress the scale.

It has been suggested (10, 11) that dissolution reaction rates should depend on the surface area of the solid and on the mean ionic activity of the liquid phase.

The rate constants in this investigation are for a reaction that is first order with respect to the weight of solid. A first order mechanism suggests a two dimensional attack with adsorption on the solid surface.

The fraction of the total surface covered at any time by hydrogen ions is (14)

$$\theta = \alpha\mu/(\alpha\mu + \nu)$$

where α is the fraction of molecules striking the surface which adhere, μ is the number striking 1 cm^2 per unit of time, and ν is a constant for adsorption of hydrogen ions on the surface. The rate constants reported in Table 1, k_n, (n = 1, 2, or 4) are proportional to the fraction of the total surface covered by hydrogen ions, therefore since μ is proportional to $(a_{H^+})_{aq}$

$$[6] \qquad k_n = k_n^1 \frac{\alpha[a_{H^+}]_{aq}}{\alpha[a_{H^+}]_{aq} + \nu}$$

where $k_n = k_n^1$ when θ = 1 and is the pH independent rate constant for the dissolution of solid in excess water. Rearranging eq. 6 gives

$$[7] \qquad \frac{(a_{H^+})_{aq}}{k_n} = \frac{(a_{H^+})_{aq}}{k_n^1} + \frac{\nu}{\alpha k_n^1}$$

Plots of $(a_{H^+})_{aq}/k_n$ *vs.* $(a_{H^+})_{aq}$ should be linear with a slope of $1/k_n^1$ and intercept $\nu/\alpha k_n^1$.

Figure 2 gives a typical plot for sample *A*. The reciprocal of the slope is k_n^1. The results, in terms of k_n^1, of the plots for the samples investigated are given in Table 2.

The results of Table 2 suggest a surface area dependence of the rate constants k_n^1. The values of k_n^1 for sample *B* may have a considerable

error. They were determined from only three p*H* investigations, and the apparently larger values for k_n^1 for *A* and *B* compared to *C* and *D* may be due to the values for *B* being too high. The effect of surface on the kinetics of the various steps in the proposed mechanism is under further investigation in this laboratory with a larger number of samples with various particle sizes.

Influence of pH on K_3

The influence of p*H* on the value of K_3 is small over the p*H* range investigated. If the equilibrium represented by reaction 4 depended on a particular species of silica, H_4SiO_4, $H_3SiO_4^-$, or $H_2SiO_4^{2-}$, the equilibrium constant should show a considerable variation over the range of p*H*'s investigated. The amounts of each silicic acid species present can be calculated from a knowledge of the p*H* and the ionization constants of silicic acid $pK_1 = 9.77$ and $pK_2 = 11.8$ (15, 16). Over the p*H* range of investigation the relative amounts of each species changes many fold. This is not reflected in the change of K_3 with p*H*, thus the association of $1.5CaO.SiO_2$ with silica is independent of the species of silica involved.

H_2O, HDO, and CH_3OH Infrared Spectra and Correlation with Solvent Basicity and Hydrogen Bonding[1]

D. N. GLEW AND N. S. RATH[2]

Exploratory Research Laboratory, Dow Chemical of Canada, Limited, Sarnia, Ontario

Received August 4, 1970

A study has been made of the infrared O—H bands for CH_3OH, DOH, and H_2O in solution and of their correlation with hydrogen bonding and solvent basicity. Infrared bands for the three fundamentals and the first bending overtone of H_2O and for the O—H stretching fundamentals of DOH and CH_3OH have been measured between 30 and -40 °C in a solvent range extending from weakly interacting fluorocarbons to strongly hydrogen-bonding organic amines. The O—H stretching bands for the weakly acidic solutes CH_3OH, DOH, and H_2O are mostly Lorentzian in shape and move to lower frequencies with higher extinctions in the more basic solvents. Many correlations are found between the stretching frequencies and band areas, and between the frequencies and solvent basicity. Monofunctional CH_3OH is found to be a stronger acid and forms stronger hydrogen-bonds with a given base than do the doubly bonded DOH and HOH which show equal dibasic acid strengths.

The wide, overlapped, fundamental stretching bands for H_2O strongly hydrogen-bonded to the tertiary amines and for ice have been partially resolved and unequivocally assigned, showing that there is no cross-over of the ν_3 and ν_1 bands despite the strong hydrogen-bonding.

At higher temperatures in solvents containing both hydrophobic and strongly basic groups water was found with the lower C_s type symmetry, in which unbonded O—H groups gave sharp bands in the 3680–3650 cm^{-1} region in addition to the wide hydrogen-bonded bands at lower frequencies.

Une étude infrarouge des bandes O—H des molécules CH_3OH, DOH et H_2O en solution et de leur corrélation avec la liaison hydrogène et la basicité du solvant a été effectuée. Les bandes infrarouges des trois fondamentales et de la première harmonique de déformation de H_2O ainsi que les fondamentales de valence de DOH et CH_3OH ont été mesurées entre 30 et -40 °C dans une série de solvants connus pour leurs interactions faibles: fluorocarbures et également connus pour leurs interactions spécifiques par liaison hydrogène comme les amines aromatiques. Les bandes de valence OH des solutés faiblement acides CH_3OH, DOH et H_2O sont de forme quasi-Lorentzienne et se déplacent vers les basses fréquences avec des extinctions supérieures dans les solvants davantage basiques. Plusieurs corrélations sont trouvées entre les fréquences de valence et les surfaces de bande et entre les fréquences et la basicité du solvant. La molécule monofonctionnelle CH_3OH est un acide plus fort et forme des liaisons hydrogènes plus fortes avec une base donnée que les molécules doublement liées DOH et HOH qui montrent des forces acides égales aux différents protons.

Les bandes fondamentales de valence, larges et recouvertes, de H_2O fortement lié par la liaison hydrogène aux amines tertiaires et pour la glace ont été partiellement résolues et attribuées sans ambiguité, montrant qu'il n'existe aucun croisement des bandes ν_3 et ν_1 en dépit de la liaison hydrogène forte.

Aux températures supérieures dans les solvants contenant des groupes hydrophobes et fortement basiques l'eau possède la symétrie inférieure de type C_s suivant laquelle des groupes O—H non-liés procurent des bandes fines dans la région 3680–3650 cm^{-1} en plus des bandes larges causées par les liaisons hydrogènes aux fréquences inférieures.

Canadian Journal of Chemistry, 49, 837 (1971)

Introduction

The bent, triatomic H_2O molecule exhibits three, nondegenerate, fundamental vibrations (1), of which two are high frequency, O—H valence-stretching modes absorbing in the 3756–3200 cm^{-1} region, while the remaining vibration is a lower frequency angular-deformation or bending mode absorbing at 1595–1670 cm^{-1}. When both protons of H_2O are subject to nearly equivalent force fields, both unbonded or both H-bonded (hydrogen-bonded) equally, so that the H_2O molecule retains its normal C_{2v} type symmetry (1, 2), the two O—H stretching modes are coupled and split to yield an upper-frequency, antisymmetric-stretch, molecular vibration, ν_3, and a lower-frequency, symmetric-stretch, molecular vibration, ν_1, which is isosymmetric with the low-frequency bending vibration ν_2. However, when the H_2O molecule in its force field has the lower C_s type symmetry, as for the asymmetrically bonded HOH molecule in which one proton forms an H-bond but the second proton does not, or for the mass-asymmetric DOH species, the two stretching modes remain uncoupled and behave as independent group vibrations.

Early infrared studies of dissolved H_2O (3)

showed displacements to lower frequencies of the stretching bands with increased H-bonding to the solvent. Later studies have been made on higher-dispersion instruments. Greinacher, Lüttke, and Mecke (4) measured the H_2O fundamentals and overtones in a solvent range extending from weakly interacting CCl_4 in which the ν_3 and ν_1 bands at 3705 and 3614 cm^{-1} (5, 6) were narrow and well-resolved, to the strongly H-bonding pyridine in which the bands were both wide and unresolved with a peak at 3412 cm^{-1}. Saumagne and Josien (7) measured the stretching fundamentals for H_2O, HDO, and D_2O in the same solvent range: in inert CCl_4 similar narrow O—H and O—D stretching bands were shown, whereas in pyridine wide bands at lower frequency attested strong H-bonding. Those authors demonstrated the decoupling of the two stretching modes for H_2O in CCl_4–pyridine mixtures, where the unbonded stretching mode, O—H u, gave a narrow band at 3678 cm^{-1} and the H-bonded mode, O—H b, gave a wide band at 3400 cm^{-1}: the similarly uncoupled O—H b mode for DOH H-bonded to pyridine gave a wide band with peak at 3415 cm^{-1}. More recently Mohr, Wilk, and Barrow (8) measured the H_2O stretching bands in CCl_4 solutions containing a series of organic bases and in solutions containing the halide ions as bases. The spectra again showed the decoupled bands for singly H-bonded H_2O molecules with C_s type symmetry, and the coupled molecular bands for doubly H-bonded H_2O molecules with C_{2v} type symmetry.

In our recent measurements of both the thermodynamic properties and the proton magnetic resonance chemical shifts of the water solvent (9–11), it was shown that the addition to water of small quantities of the solutes, ethylene oxide, propylene oxide, 1,4-dioxane, acetone, tetrahydrofuran, and *t*-butyl alcohol (2-methyl-2-propanol) gave solutions exhibiting both water stabilization and enhanced H-bonding. Since this group of solutes was known from other studies (9, 11–14) to form only relatively weak H-bonds with water protons, the water stabilization probably arose from stronger H-bonding between the oriented water molecules adjacent to the solute. To confirm the relative strengths of water H-bonding to these hydrophilic solutes in the absence of cooperative water structural effects, we have used the same organic liquids as solvents for measurement of the dilute H_2O infrared spectra.

It was our purpose to resolve and to assign the wide H-bonded stretching bands of H_2O in strongly interacting solvents such as pyridine to provide a better basis for the band assignments in the liquid water and ice spectra. We further wanted to establish an experimental infrared scale for H_2O proton H-bonding acceptance by a range of the more common hydrophilic groups.

To provide additional cross checks on our water band assignments we have measured the O—H stretching bands for dilute DOH and CH_3OH in many of the same solvents. The present study thus may be regarded as defining three infrared scales for the "basicity" (15) of various organic solvents using the H-bonded infrared shifts from the gas phase for the three weakly acidic proton donors HOH, DOH, and CH_3OH. In this sense our measurements are complementary to earlier studies using the deuteron donors DOD and CH_3OD (16).

Experimental

All composition percentages are given on a mole basis unless denoted otherwise.

Materials

Laboratory distilled water, 99.75 wt.% deuterium oxide from Atomic Energy of Canada, Limited, and 99.998% ethylene oxide from Dow Chemical of Canada, Limited were used without further purification.

Other solvents were the best grades available from the listed suppliers and all were purified immediately before use. Eastman Organic Chemicals supplied spectro-grade 1,2-dichloroethane and nitromethane; white label grade 2,4,6-collidine, 3-ethyl-3-pentanol, 2,6-lutidine, pentachloroethane, and 4-picoline; and practical grade hexachloro-1,3-butadiene and 2-picoline. Fisher Scientific Company supplied certified A.C.S. grade chloroform, dimethyl sulfoxide, 1,4-dioxane, methanol, 2-propanol, and pyridine; certified grade acetone, *t*-butanol (2-methyl-2-propanol), and tetrahydrofuran; and reagent grade *t*-amyl alcohol (2-methyl-2-butanol) and 1,1,2,2-tetrachloroethane. Pierce Chemical Company supplied 1,2-dibromotetrafluoroethane, hexafluorobenzene, perfluoro-*n*-heptyl iodide, perfluoro-*n*-propyl iodide, and perfluoromethylcyclohexane. City Chemical Company supplied triethylamine, Canadian Industrial Alcohols and Chemicals Limited supplied U.S.P. absolute ethyl alcohol, and Merck, Sharp and Dohme of Canada, Limited supplied the methyl alcohol-*d* of 99 at.% isotopic purity. CCl_4 (carbon tetrachloride), methylene chloride, tetrachloroethylene, and 1,1,1-trichloroethane of better than 99.8% purity were supplied by Dow Chemical of Canada, Limited.

Method

The water-immiscible solvents, shown above nitromethane in Tables 1, 2, and 4, were washed with water to remove acidic impurities, separated and dried by passing

through a 15-cm column containing Woelm neutral activated alumina. In these solvents spectra were measured at 30 °C, first for the dry solvent and then for the dilute solution of water, in a Research and Industrial Instruments Company (R.I.I.C.) P-E.I. variable-path cell with Irtran-2 windows set at 0.1–0.5 cm path length, compensated in the reference beam by a similar cell containing dry solvent. The water content in hexafluorobenzene, CCl_4, and in 1,2-dichloroethane solutions was determined by Karl Fischer titration.

The water-soluble solvents, including and below nitromethane in Tables 1, 2, and 4, were both dried and purified by passing twice (or more times if required) through fresh 15-cm columns of Woelm neutral activated alumina. Tetrahydrofuran was distilled under nitrogen from a still-pot containing lithium aluminum hydride and then was passed through a fresh activated alumina column. All water solutions (0.05–0.4 mol/l) in these solvents were prepared by weight. Infrared spectra, first for the dry solvent and then for the solution of water, were measured at set temperatures in a R.I.I.C. VLT-2 variable-temperature cell with Irtran-2 windows at 0.0105 cm path length, compensated in the reference beam by a R.I.I.C. AT-04 attenuator. Sample cell temperatures between −45 and 30 °C were kept constant to ±1 °C by manual addition of Dry Ice to acetone in the central reservoir, and were measured by a copper–constantan thermojunction cemented to the front Irtran-2 window just out of the infrared beam path.

The DOH spectra in water-soluble solvents were obtained in the same way as the H_2O spectra, replacing each 2 mol H_2O by 1 mol H_2O + 5 mol D_2O. For example, the H_2O extinction in pyridine was determined from the transmittance ratio for a dry pyridine blank divided by that for a pyridine solution containing 0.250 mol H_2O/l. The DOH spectrum in the O—H stretch region similarly was determined from the transmittance ratio for a pyridine blank containing 0.625 mol D_2O/l divided by that for a pyridine solution containing 0.125 mol H_2O/l and 0.625 mol D_2O/l.

The molar extinction coefficient ε_{H_2O} for water was evaluated from the solution absorbance A using the equation

$$A = \log T_b/T_s = d\,[\varepsilon_{H_2O}C_{H_2O} - \varepsilon_s(V_{H_2O}/V_s)C_{H_2O}]$$

in which T_b/T_s is the transmittance ratio of the blank relative to the solution containing C_{H_2O} mol H_2O/l and d is the cell path length in cm. ε_s is the known molar extinction coefficient for the solvent and V_{H_2O} and V_s are the molar volumes for the water and solvent, respectively. The molar extinction coefficient ε_{DOH} for DOH was evaluated similarly from the deuterium oxide – water solution absorbance using

$$A = d\,[\varepsilon_{DOH}C_{DOH} + \varepsilon_{H_2O}C_{H_2O} - \tfrac{1}{2}\varepsilon_{D_2O}C_{DOH} - \varepsilon_s(V_{H_2O}/V_s)(C_{H_2O} + \tfrac{1}{2}C_{DOH})]$$

in which ε_{H_2O}, ε_{D_2O}, and ε_s are known and the concen-

trations C_{H_2O}, C_{DOH}, and C_{D_2O} were obtained from the equation

$$(C_{DOH})^2 = 4\,C_{H_2O}C_{D_2O}$$

using the initial weights of H_2O and D_2O. At frequencies above 3200 cm^{-1} the term containing ε_{D_2O} was always negligible, while the term containing ε_s was small and decreased rapidly with increasing frequency.

All methanol solutions (0.05–0.2 mol/l) were prepared by weight and their spectra measured in the R.I.I.C. VLT-2 cell as for the water solutions.

The spectra for solid CH_3OH in methyl alcohol-*d* at −150 °C and for solid DOH in deuterium oxide at −10 °C were measured in the VLT-2 cell cooled respectively with liquid nitrogen and cold acetone in the central chamber. The ice spectra at −50 °C were obtained from condensed films on the windows of the VLT-2 cell cooled using Dry Ice – acetone.

Infrared spectra were all measured on a Perkin–Elmer 221G double-beam spectrophotometer in the grating region 4000–1450 cm^{-1}, using the water vapor and polystyrene bands for wavenumber calibration (17). In a typical run the sample-cell initially containing pure solvent was arranged to give transmittances above 90% and the spectrum was scanned very slowly giving the pure solvent baseline. The spectrum for the dilute solution of water was measured and typically was arranged to give a minimum transmittance between 40 and 70%. Wavenumber calibration bands were superposed and finally the 0% transmittance line was traced with the sample shutter closed. All spectra were scanned at the lowest speed of about 10 cm^{-1}/m, using maximum amplification short of oscillation with no suppression. During the 3-h period required to complete a run covering the 3800–3100 cm^{-1} region, the instrument drift was normally less than 1% at 90% transmittance, as shown by replicate experiments and by the usually exact superposition of the solution spectra on the pure solvent baseline outside the regions of the water extinction. For the sharp stretching bands above 3600 cm^{-1} and for the bending bands near 1600 cm^{-1} the uncertainty of the band peak positions was ±3 cm^{-1}, while for the wide H-bonded stretching bands between 3500 and 3200 cm^{-1} the uncertainty was increased to ±10 cm^{-1}.

All correlation lines shown in the figures and regression coefficients in all equations have been evaluated by the method of least squares. All errors quoted are standard errors.

Results and Discussion

Fundamental O—H Stretching Bands of Methanol

Table 1 presents new measurements between 3800 and 3100 cm^{-1} for the fundamental O—H

stretching band of monomeric methanol in a solvent range from weakly interacting perfluoromethylcyclohexane at 30 °C to strongly H-bonding triethylamine at −44 °C. Following the vapor phase value (18), the solvents are listed in order of decreasing band frequency, ν_{MeOH} (cm^{-1}), which order generally corresponds with both increasing band width at half-extinction, w (cm^{-1}), and increasing peak extinction coefficient, ε (l mol^{-1} cm^{-1}, decadic logarithms).

Good agreement is found between our bands at 3643 cm^{-1} in CCl_4 and tetrachloroethylene and earlier values between 3642 and 3644 cm^{-1} (20–24), between our highest frequency band at 3676 cm^{-1} in perfluoro-methylcyclohexane and 3675 cm^{-1} in the similarly inert perfluoro-octane (22), and between our wide band at 3247 cm^{-1} in triethylamine and the earlier value of 3243 cm^{-1} (21).

The observed band shapes were similar to those illustrated elsewhere (21, 22, 24), but, because our measurements were made at methanol concentrations of up to 0.20 mol/l, the spectra showed weak dimer bands, so that the monomer extinctions recorded in Table 1 are slightly low. For a few monomer bands the extinction coefficient dependence on frequency was fitted numerically by skewed Lorentz–Gauss product functions (25), using a least-squares technique similar to Pitha and Jones' method V (26). Our monomer band contours showed an approximate fraction 0.7 Lorentzian to 0.3 Gaussian character. The bands were slightly skewed with larger extinctions on the low-frequency side of the peaks, due only in part to the weak dimer bands (24).

Results in Table 1 show that at lower temperatures the peaks move to lower frequencies and most bands become sharper, with higher extinctions and smaller half-widths. In tetrahydrofuran and the tertiary amines the band areas change little with temperature, so that at low temperatures the increased extinctions are almost exactly compensated by the decreased band-widths.

For the methanol monomer bands, which are of similar shape, the integrated band area is proportional to the $\varepsilon \cdot w$ product. Figure 1 presents the correlation of $\varepsilon \cdot w$ with frequency ν_{MeOH} represented numerically by the one-constant equation

$$[1] \qquad \varepsilon \cdot w = 91.0\,(3687 - \nu_{MeOH})$$

The regression coefficient 91.0 has a standard error of 2.5. The band area enhancement at lower frequencies is characteristic of more strongly H-bonded stretching modes (3), and here the O—H stretching band area is increased by a factor of 15 on changing from the chlorinated hydrocarbon solvents to pyridine and its homologs.

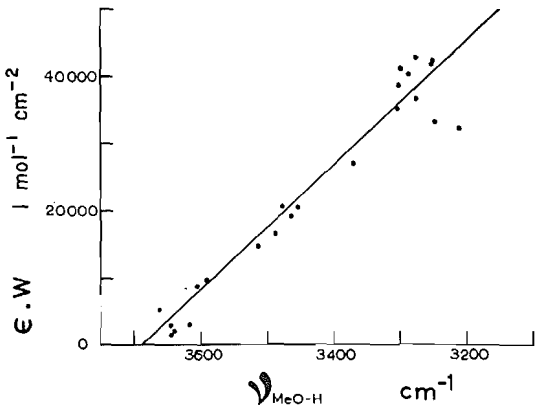

FIG. 1. Correlation of band area with frequency for the O—H stretch vibration of CH_3OH in various basic solvents at 30 °C.

In all solvents below nitromethane a search was made for extra bands in the 3687–3560 cm^{-1} region, in addition to those in Table 1, which might arise from non-bonded O—H stretching modes. None was observed. It is therefore certain that in these dilute solutions all methanol O—H groups form H-bonds and that the concentration of non-bonded methanol is below our limit of detection.

Measurements at 30 °C for methanol in solutions with more extensive H-bonding, for example dilute methanol in methyl alcohol-*d* and concentrated methanol in inert solvents, showed absorption in the three distinct O—H stretching band regions 3680–3600, 3560–3450, and 3360–3344 cm^{-1}. Similar bands in these regions have been reported previously for benzyl alcohol by Fox and Martin (27) and for 1-dodecanol and *t*-butyl alcohol by Smith and Creitz (28). Following the Bellamy and Pace proof (24) of the open-chain dimers for methanol, which is consistent with the measurements of Fox and Martin, we assign the three groups of bands to the H-bonded methanol species as follows.

(*i*) The sharp monomer band at 3643 cm^{-1} is pre-eminent for 0.5% methanol in CCl_4. For 55% methanol diluted with 45% CCl_4 we found the sharp band moved to 3635 cm^{-1}, occurring as a narrow, weak band superposed on the high fre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

quency edge of intense lower frequency bands. For liquid methanol in the absence of CCl_4 we could detect no sharp band near to 3635 cm^{-1}. Since the sharp band at 3643–3635 cm^{-1} occurs only in methanol solutions containing CCl_4, this band must arise from the direct, weakly H-bonding interaction of the O—H group with the covalent chlorine atoms of the "inert" CCl_4. The monomer band at 3643 cm^{-1} is thus assigned to the methanol species *A*, O—H---Cl, with un-
|
CH_3
bonded oxygen and the hydroxyl proton interacting with CCl_4. The band at 3635 cm^{-1} for 55% methanol is then assigned to the methanol species *B*, ---O—H---Cl, in which the oxygen is H-
|
CH_3
bonded by other methanol and the hydroxyl proton interacts with CCl_4. Our band at 3635 cm^{-1} is in very good agreement with similar bands at 3637 and 3633 cm^{-1} reported (24) for the methanol dimer and the methanol–phenol adduct respectively in CCl_4, which bands again are assigned to the methanol species *B*. Species *B* is one half of the methanol dimer and also occurs at the end of the open polymer chains with the hydroxyl group adjacent to the CCl_4.

(*ii*) A wide, weak shoulder centered around 3450–3480 cm^{-1} for 2% methanol in methyl alcohol-*d* causes the main band at 3344 cm^{-1} to appear asymmetric. This weak shoulder is assigned to the methanol species *C*, O—H---O, on
|
CH_3
which oxygen is unbonded and the hydroxyl proton is H-bonded to oxygen of adjacent methanol. The same band is calculated (vide infra) to occur at 3446 cm^{-1} using the methanol pK_a of -2.2 (15) in the correlation [31] for methanol H-bonded to aprotic solvents with no bonding to the methanol oxygen. Similar bands were reported at 3488 cm^{-1} for the benzyl alcohol dimer (27), at 3484 and 3490 cm^{-1}, respectively, for the 1-dodecanol and *t*-butyl alcohol dimers (28), and within the range 3565–3482 cm^{-1} depending on solvent for the methanol dimer (22). Species *C* is the other half of the methanol dimer and occurs as the second type of polymer chain-terminating group.

(*iii*) The main, intense and wide band at 3344 cm^{-1} found for 2% methanol in methyl alcohol-*d* is assigned to the methanol species *D*, ---O—H---O, in which both the oxygen and hy-
|
CH_3
droxyl proton are involved in H-bonds with methanol neighbors. Similar intense wide bands were reported at 3348 and 3323 cm^{-1}, respectively, for polymeric benzyl alcohol in CCl_4 and in the pure liquid (27), and at 3322 and 3356 cm^{-1} for polymeric 1-dodecanol and *t*-butyl alcohol in CCl_4 (28). The methanol species *D*, predominant in the liquid and in concentrated solutions at room and lower temperatures, is the species forming the unbranched polymer chains, which may be cyclic or open-ended terminated by species *B* and *C*. The methanol polymer chains are presumably zigzag with approximately tetrahedral angles along their O—H---O—H---O—H length,
| | |
R R R
being the dynamic liquid phase analogs of the stronger infinite zigzag chains (29) in the solid, which exhibits the 3222 cm^{-1} band for 1% methanol in methyl alcohol-*d* at -150 °C. The same band has been reported (18) at 3225 cm^{-1} and -180 °C.

The almost constant O—H frequency for the polymer chain H-bonds of methanol and of the substituted methanols, benzyl alcohol, 1-dodecanol, and *t*-butyl alcohol, attests the maximum strength of these intra-chain H-bonds, which is evidently insensitive to the very different steric and inductive effects of the various substituent groups.

The greater stability of the methanol species *D* relative to species *C* is best interpreted by the specific dipolar association model suggested by Bellamy, Morgan, and Pace (30). On this model the 241 cm^{-1} frequency shift from the gas phase to the singly bonded species *C* is enhanced further to 343 cm^{-1} for the doubly bonded species *D*. This 102 cm^{-1} shift between methanol species *C* and *D* is entirely comparable with the 71 cm^{-1} shift to lower frequency of the methanol dimer band in CCl_4 on addition of H-bonding chloroform (30). Since the weakest methanol H-bonds occur at the chain ends, whereas the strongest are intra-chain H-bonds, there will be a tendency in the liquid and in concentrated solutions to form rings and long chains with few unbonded ends and fewer of the less stable trimers and dimers. This is why the high frequency bands of the rela-

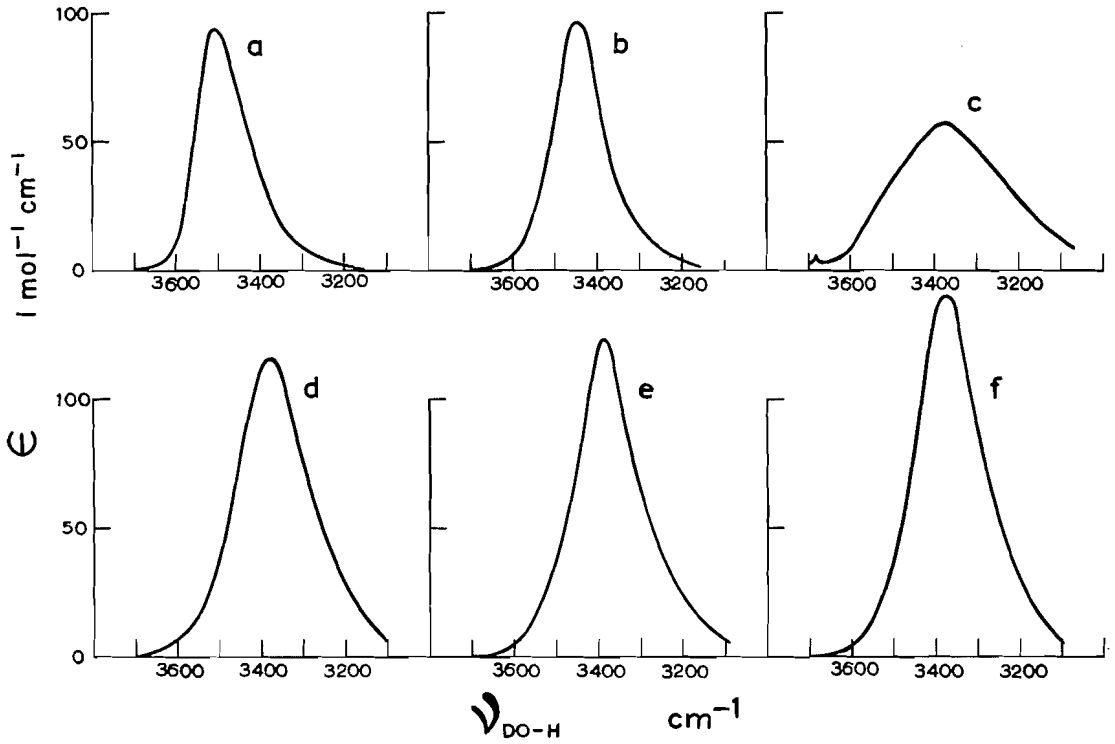

FIG. 2. The O—H stretch bands for DOH, (*a*) in tetrahydrofuran at 0 °C, (*b*) in dimethyl sulfoxide at 30 °C, (*c*) in triethylamine at 30 °C, (*d*) in pyridine at −20 °C, (*e*) in 2,4,6-collidine at −20 °C, and (*f*) in 2-picoline at −44 °C.

tively unstable dimers, readily found at high dilutions, are not found in liquid methanol at room and lower temperatures.

Fundamental O—H Stretching Bands of Hydrogen Deuterium Oxide

New measurements are presented in Table 2 for the fundamental O—H stretching bands of monomeric DOH in solvents of widely differing basicities. The D_2O/H_2O mole ratio used for the DOH solute is listed in the third column. Extinction coefficients for DOH have been corrected for the presence of equilibrium water. Figure 2 illustrates the characteristic Lorentzian shapes of the DO—H stretching bands in H-bonding solvents.

Below the vapor phase band origin at 3707 cm^{-1} (31), solvents are listed in order of decreasing frequency for the most intense band, ν_{DO-H} b, which is also the order of increasing H-bonding to the solvent and correlates with both band width at half-extinction and peak extinction coefficient.

The narrow bands at 3662 cm^{-1} in CCl_4 and tetrachloroethylene are 3 cm^{-1} above the earliest value (5), agree well with more recent values 3660 and 3662 cm^{-1} (7, 34) and show that the value of 3670 cm^{-1} (32) is too high. At 30 °C in pyridine the wide H-bonded band, denoted DO—H b, at 3405 cm^{-1} is just within experimental error of the earlier determination at 3415 cm^{-1} (7); its position agrees better with the similar wide H-bonded band at 3400 cm^{-1} (7) for singly bonded HOH with C_s type symmetry in the mixed CCl_4–pyridine solvent. Our band parameters for DOH in liquid deuterium oxide at 30 °C and for the sharp Lorentzian band in deuterium oxide ice at −10 °C are in general agreement with earlier measurements (32, 33).

New weak and narrow bands have been found in the 3680–3650 cm^{-1} region at 30 °C in solvents more basic than tetrahydrofuran, in addition to the main H-bonded bands reported under DO—H b. The new bands are assigned to low concentrations of weakly bonded or unbonded O—H u stretching vibrations and are listed in Table 2

For personal use only.

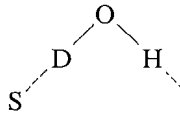
under DO—H u, where the u for unbonded refers to the O—H groups not being bonded to the most basic group of the solvent molecule. The O—H u groups are probably adjacent to the hydrophobic alkyl-group protons in dimethyl sulfoxide and triethylamine, and near and weakly bonded to the aromatic ring of the substituted pyridines. In liquid deuterium oxide the DO—H u band is difficult to locate in the infrared (32, 33, 36), so we have included the better resolved Raman band at 3628 cm^{-1} (37).

At lower temperatures the weak DO—H u bands disappear below the limit of detection, indicating that substantially all DOH molecules then form two H-bonds (strictly one H-bond and one D-bond) to the basic groups of the solvent giving the bent, double-bonded, b D—O—H b, di-solvent complexes,



, already suggested for dissolved water (7, 8, 38).

The DO—H b bands, which are invariably uncoupled from the O—D stretching mode, at lower temperatures move to lower frequencies and become more Lorentzian in shape with smaller half-widths and higher peak extinctions, indicating fewer and more specific configurations for the di-solvent complexes. The DO—H b bands in all organic solvents at lower temperatures and in deuterium oxide ice exhibit predominantly Lorentzian band shapes despite the strong H-bonding, whereas only in liquid deuterium oxide is the band shape more nearly Gaussian. These results are in complete accord with recent measurements (39) on the similar HO—D b stretching band which exhibited a narrow Lorentzian contour in ice at −8 °C and which was replaced on melting by a much wider Gaussian contour in liquid water at 4 °C.

The intensification of the DO—H b band area with stronger H-bonding to the solvent is illustrated in Fig. 3, and represented by the one-constant equation

$$[2] \qquad \varepsilon \cdot w = 66.3\,(3707 - \nu_{DOH})$$

The regression coefficient 66.3 has a standard error of 1.7. The band area is smaller by a factor of 18 in the inert solvents hexafluorobenzene and CCl_4 than in the strongly H-bonding pyridines and triethylamine.

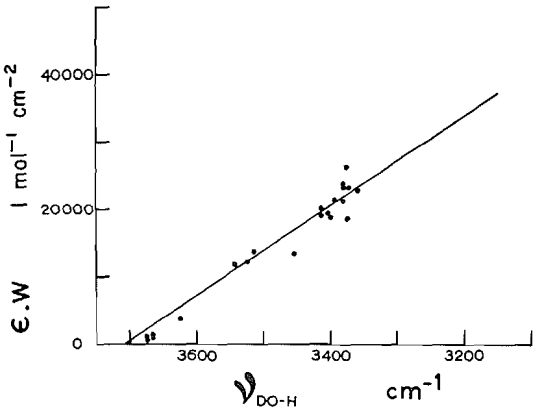


FIG. 3. Correlation of band area with frequency for the O—H stretch vibration of DOH in various basic solvents at 30 °C.

The uncoupled DO—H b stretching band in liquid deuterium oxide, despite its more Gaussian shape, falls properly within the correlation of [2] and does not exhibit any special intensification due to the extensive bonding to both the HDO lone pairs and the O—D group by the deuterium oxide solvent. Since it is clear from the earlier (39) and the present work that strongly H-bonded DOH normally gives Lorentzian-shaped fundamental-stretch band contours, we ascribe the more Gaussian contour in liquid deuterium oxide to a Gaussian distribution of Lorentzian DOH oscillators arising from the thermally induced multiplicity of radial and orientational configurations of the bonded nearest neighbors. Suggestions similar to this have been made elsewhere (32, 33, 40, 54). Thus for the hydroxyl stretching vibration of DOH the main perturbation leading to Gaussian band shape derives from the motions of the oxygen nearest-neighbor bonded directly to the O—H group. Additional smaller inductive and dynamic perturbations arise indirectly from the effect of the nearest neighbors bonded to the lone pairs and to the O—D group.

Fundamental O—H Stretching Bands for Water with C_s Type Symmetry

In this section we consider bands for the decoupled O—H stretching modes of HOH molecules with C_s type symmetry arising from unequal H-bonding of the two protons with the solvent. In Table 3 we report new bands from C_s-symmetric water molecules, denoted u H—O—H b, in which the O—H u stretching mode is weakly bonded or unbonded while the O—H b is strongly

H-bonded to a basic group of the solvent. In the first row the vapor phase band origins for the decoupled vibrations are shown at 3707 cm^{-1}, the mean of ν_3 and ν_1 (31), notably the same as for the uncoupled O—H stretching vibration of DOH. The mixed solvents are listed with their component volume percentages and are followed by the single-component solvents ordered for comparison with Table 4. Approximate values for the extinctions are included in Table 3 to show trends, these values being obtained from the total water concentration without allowance for the fraction of C_{2v}-symmetric species.

In mixed solvents containing CCl_4 with 1,4-dioxane and pyridine our results are in agreement with earlier measurements and assignments (7, 8) which we follow here. Replacement of nonpolar CCl_4 by dipolar 1,2-dichloroethane in admixture with pyridine enhances the extinction and shifts the sharp O—H u band from 3674 to 3657 cm^{-1}, but leaves the wide O—H b band H-bonded to the nitrogen of pyridine unaffected. The decoupled HO—H b band assignment is confirmed by the similarity of its 3400 cm^{-1} frequency and 265 cm^{-1} half-width in CCl_4–pyridine to 3405 and 232 cm^{-1} for the uncoupled DO—H b in pyridine.

The wide HO—H b bands are not reported in the single-component solvents since they are overlapped by the strong ν_3 and ν_1 water bands

in dimethyl sulfoxide and in the tertiary amines, and by the strong H-bonded bands in the alcohols.

Sharp HO—H u bands with 25–30 cm^{-1} half-widths are found over the 3684–3655 cm^{-1} frequency range. In the saturated aliphatics and in the mixed solvents with CCl_4 the sharp bands occur near 3680 cm^{-1}, characteristic of decoupled modes with O—H u groups adjacent to and interacting with non-bonding alkyl groups or weakly bonding chlorine. In the pyridines, alone and with 1,2-dichloroethane, the frequency is decreased to about 3657 cm^{-1} through the stronger interaction of the O—H u groups with the pyridines' aromatic rings and the dipolar $—CH_2Cl$ groups. In the more intense dipolar fields of liquid water between 20 and 35 °C, in which an 80 cm^{-1} KBM shift was expected (40), the well-known, weak Raman (41–44) and weak infrared (45) bands at about 3625 cm^{-1} undoubtedly arise from the decoupled, unbonded O—H u stretching mode of C_s-symmetric water molecules, for which the second protons and presumably the lone pairs remain H-bonded. This assignment properly corresponds with that for the weak Raman band at 3628 cm^{-1} for dilute DOH in liquid deuterium oxide (37), which band derives from the uncoupled, unbonded O—H u stretching mode of invariably C_s-symmetric DOH molecules, for which the deuterons and presumably the lone pairs remain D-bonded. These assignments are strongly supported by the reduction of the 3625 cm^{-1} band extinction at lower temperatures where liquid water H-bonding is stronger and more complete, and by the total absence of any similar unbonded band for completely H-bonded ice.

In the alcohol solvents at 30 °C the HO—H u extinctions increase roughly with the number of alkyl group protons per solvent molecule, which suggests that the O—H u groups are mostly adjacent to the non-bonding alkyl groups. In triethylamine, which is structurally similar to 3-ethyl-3-pentanol, the HO—H u band frequency, half-width, extinction, and shape are all similar to those found in the alcohol. At the other end of the alcohol series, the low extinction for O—H u in water (45) is consistent with water as the first alcoholic solvent having only covalent hydrogen as the nonbonding alkyl group.

When the temperature is reduced the O—H u bands (*i*) invariably decrease in extinction, indicating reduced fractions of singly unbonded b H—O—H u species, as shown in Fig. 4(*a*, *b*, *d*) for isopropyl and tertiary-amyl alcohols, (*ii*) further decrease in extinction to give shoulders, as found in the substituted pyridines at 0 °C reported in Table 3, and (*iii*) finally disappear below the detection limits, as found for pyridine and 2,4,6-collidine at −20 °C and for 2-picoline at −45 °C and shown in Fig. 5(*c*, *d*, *e*). Under these low temperature conditions essentially all the C_s-symmetric, singly unbonded b H—O—H u molecules are converted to C_{2v}-symmetric, doubly bonded b H—O—H b species forming two H-bonds to the most basic groups of the solvent molecules (7, 8, 38).

When the water solute percentage is increased in the single-component solvents the O—H u extinction falls continuously whereas the H-bonded extinction at lower frequencies increases, as shown for iso-propyl and *t*-butyl alcohols, pyridine and triethylamine in Fig. 4(*a*, *b*, *c*, *e*, *f*). This behavior indicates an invariably decreasing fraction of singly unbonded b H—O—H u species relative to the doubly bonded b H—O—H b species at higher water concentrations.

The helium–neon gas laser excited Raman spectra of 10, 20, 40, and 60% water in *t*-butyl alcohol at 30 °C, determined for us by Dr. J. C. Evans, exhibited the same sharp band at 3680 cm^{-1} which evidences a decreasing fraction of unbonded O—H u groups with increasing water concentration. In a solution containing 80% water the sharp band was not detected.

Infrared Bands for Water with C_{2v} Type Symmetry

The main infrared bands for monomeric water in a range of basic solvents are presented in Table 4. In the first row of the table are shown the water vapor band origins assigned (31, 46) to the fundamental antisymmetric stretch ν_3 at 3756 cm^{-1} and symmetric stretch ν_1 at 3657 cm^{-1}, the first bending overtone $2\nu_2$ at 3152 cm^{-1} and its fundamental ν_2 at 1595 cm^{-1}. The solvents are listed in order of decreasing frequency for the ν_3 and ν_1 bands, which order generally corresponds with increasing water H-bonding to the solvent, as in Tables 1 and 2.

Our measurements are in good general agreement with earlier determinations (3–8) and show sharp, well-resolved ν_3 and ν_1 bands with low extinctions in the inert solvents. In CCl_4 our ν_3 and ν_1 bands are 3 and 2 cm^{-1}, respectively,

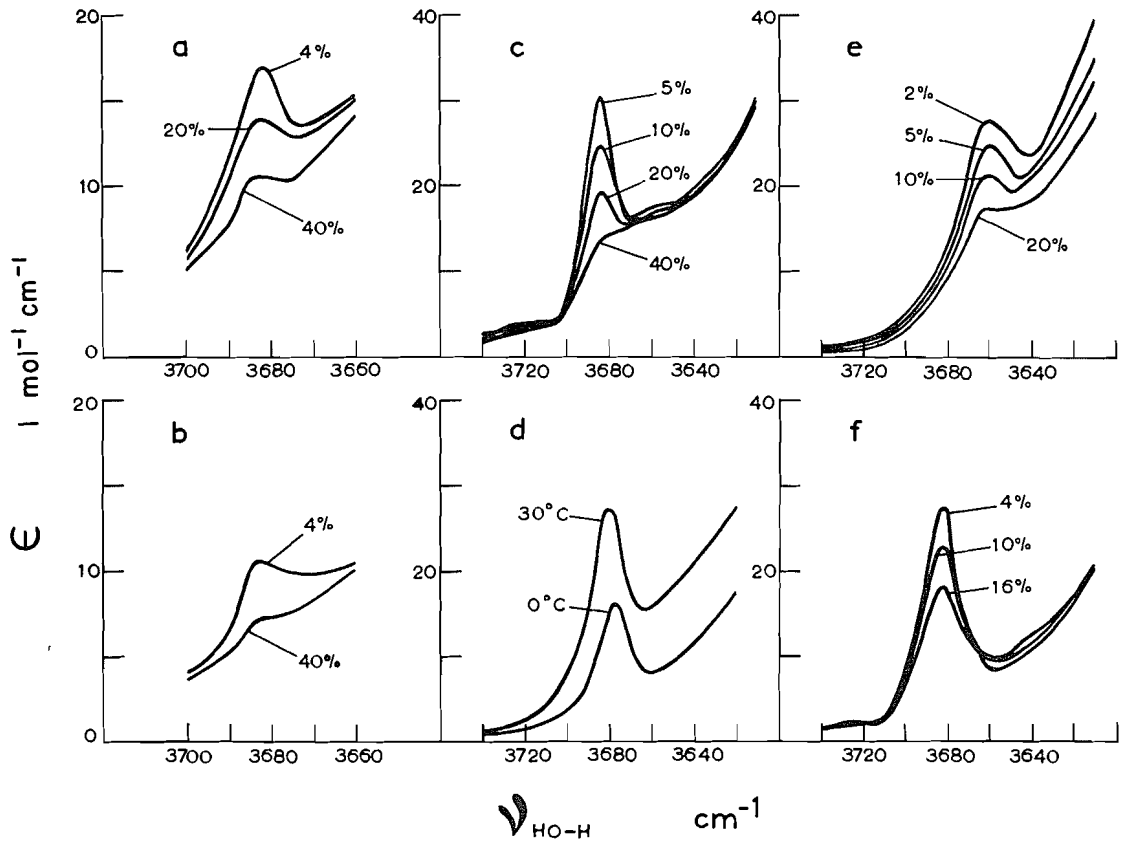

FIG. 4. Fundamental stretch bands for unbonded, decoupled O—H groups of H_2O, (*a*) in iso-propyl alcohol at 30 °C, (*b*) in iso-propyl alcohol at 0 °C, (*c*) in tertiary-butyl alcohol at 30 °C, (*d*) for 5% H_2O in tertiary-amyl alcohol at 0 and 30 °C, (*e*) in pyridine at 30 °C, and (*f*) in triethylamine at 30 °C. H_2O mol% are indicated.

higher in frequency than the earliest measurements (5), agree well with the values 3705 and 3614 cm^{-1} (4, 6) and 3706 and 3614 cm^{-1} (8), and indicate that of the values 3708 and 3613 cm^{-1} (7) that for ν_3 is too high. Our extinction coefficient ε_3 of 34 ($l\ mol^{-1}\ cm^{-1}$) in CCl_4 agrees with the earlier value of 37 determined (6, 47) on instruments of different design.

Results for the solvent series, inert fluorocarbons, nonpolar chlorocarbons, dipolar chlorohydrocarbons, and weakly H-bonding nitromethane, show well-separated ν_3 and ν_1 bands, illustrated elsewhere (4, 6, 7), for which we report the increasing extinctions ε_3 and ε_1 and the increasing half-widths w_3 and w_1. However, with slightly stronger H-bonding to ethylene oxide and tetrahydrofuran, the further increased half-widths lead to overlapped ν_3 and ν_1 contours, shown in Fig. 5*a* for ethylene oxide and elsewhere (4, 7) for dioxane and diethyl ether (8). For the more strongly H-bonding dimethyl sulfoxide, tertiary amines, and ice we show in Fig. 5(*b–f*) the progressively more strongly overlapped contours of the three water bands, ν_3, ν_1, and $2\nu_2$, resolved for the first time (4, 6–8, 14). The ice extinctions are in arbitrary units since the film thickness was unknown. For these strongly overlapped contours, in Table 4 we report (*i*) ν_3 and ν_1 for the frequencies of the observed peaks or shoulders, although these are displaced towards each other from their true positions, (*ii*) ε_3 and ε_1 for the extinctions observed at ν_3 and ν_1, recognizing that these values contain significant contributions from both bands, and (*iii*) w_{13} for the width of the overall band contour at half-extinction.

The ν_3 and ν_1 band frequencies for 54 water

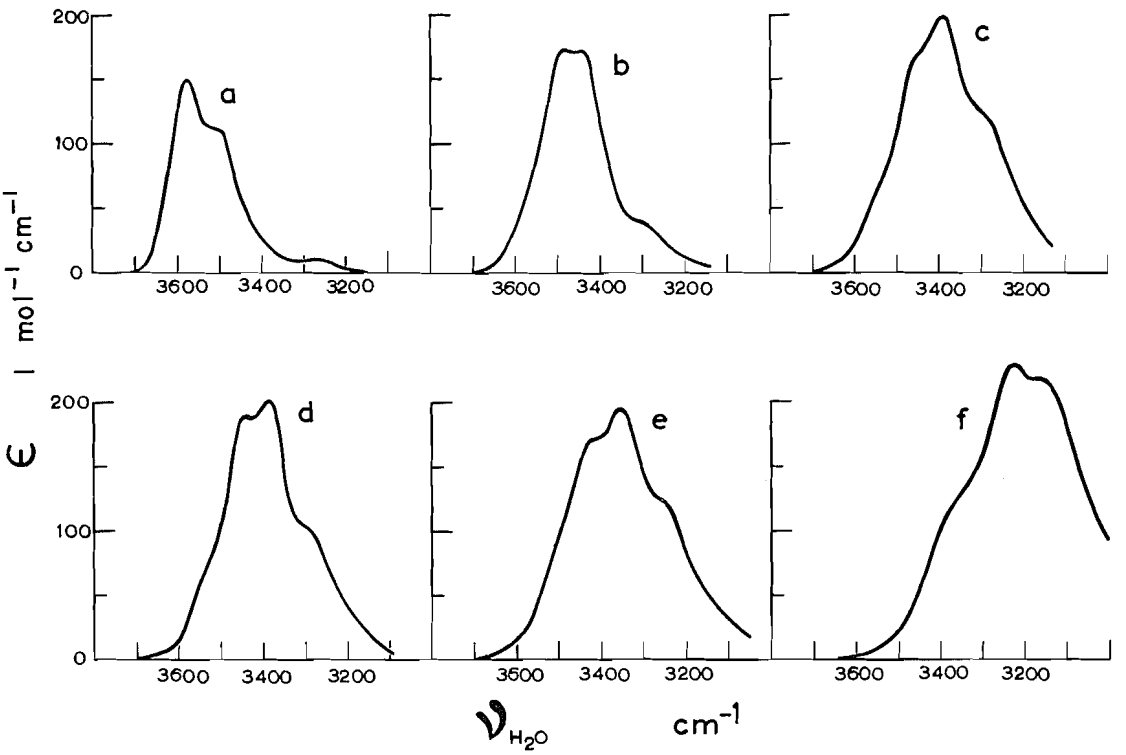

FIG. 5. Antisymmetric and symmetric stretch and bending overtone bands for H_2O, (*a*) in ethylene oxide at 0 °C, (*b*) in dimethyl sulfoxide at 30 °C, (*c*) in pyridine at −20 °C, (*d*) in 2,4,6-collidine at −20 °C, (*e*) in triethylamine at −44 °C, and (*f*) for ice at −50 °C.

solutions in the 24 solvents of Table 4 are seen to be linearly correlated in Fig. 6, and are properly represented by the one-constant equation

$$[3] \qquad 3657 - \nu_1 = 0.8285(3756 - \nu_3)$$

giving an assessed standard error of 6.7 cm^{-1} on a single determination of ν_1. The regression coefficient 0.8285 has a standard error of 0.0044. This eq. 3 for dissolved water is in good agreement with the earlier eq. 11 given by Schiffer and Hornig (54) for undistorted water molecules in crystalline hydrates and organic solvents.

In solvents down to and including dimethyl sulfoxide in Table 4 the highest extinction of the overlapped band contour, ε_{13}, invariably obtains near ν_3, whereas in the more strongly H-bonding amines and ice the maxima occur near the narrower ν_1 band, as shown in Fig. 5. The monotonous and approximately linear correlation of $\varepsilon_1/\varepsilon_3$ with ν_3, shown in Fig. 7, is represented by the empirical equation

$$[4] \qquad \varepsilon_1/\varepsilon_3 = 0.276 + 0.00263(3756 - \nu_3)$$

which gives a standard error of 0.055 on a single $\varepsilon_1/\varepsilon_3$ determination.

The correlation of the sum $\varepsilon_3 \cdot w_3 + \varepsilon_1 \cdot w_1$ for resolved bands or of $\varepsilon_{13} \cdot w_{13}$ for overlapped bands with ν_3 is shown in Fig. 8 together with the representative one-constant equation

$$[5] \qquad \varepsilon_{13} \cdot w_{13} = 131.3(3756 - \nu_3)$$

The regression coefficient 131.3 has a standard error of 2.6. As expected, the band area increases with stronger H-bonding (3, 4) and the regression coefficient for H_2O in [5] is almost exactly double that in [2] for DOH containing half as many O—H stretching modes per molecule.

The systematics and continuity of our data in [3], [4], and [5], from the gas phase and for all solvents examined, positively establish our assignments of the wide, overlapped bands in the strongly basic solvents to the ν_3 and ν_1 modes of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

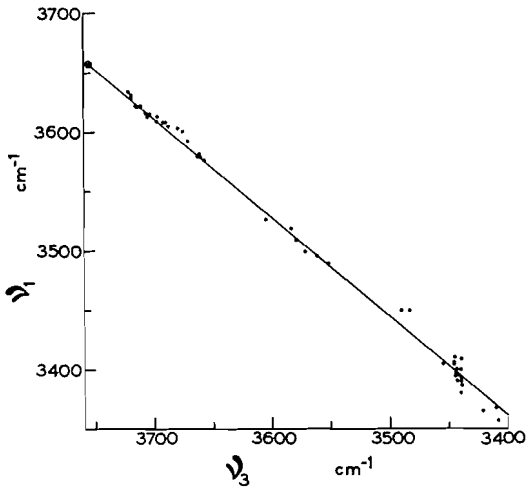

FIG. 6. Correlation of the symmetric ν_1 and antisymmetric ν_3 stretch frequencies for H_2O in various basic solvents.

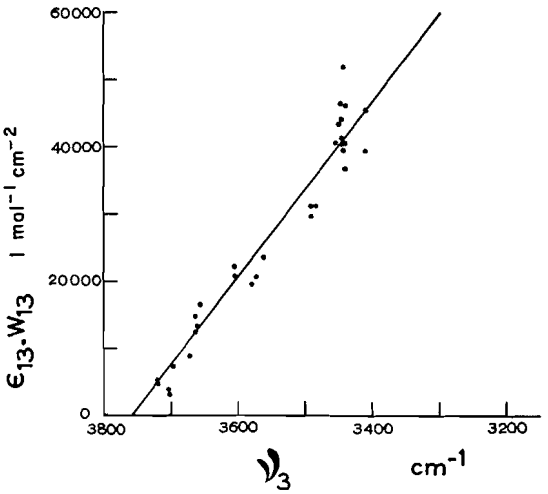

FIG. 8. Correlation of band area with antisymmetric stretch frequency ν_3 for H_2O in various basic solvents at 30 °C.

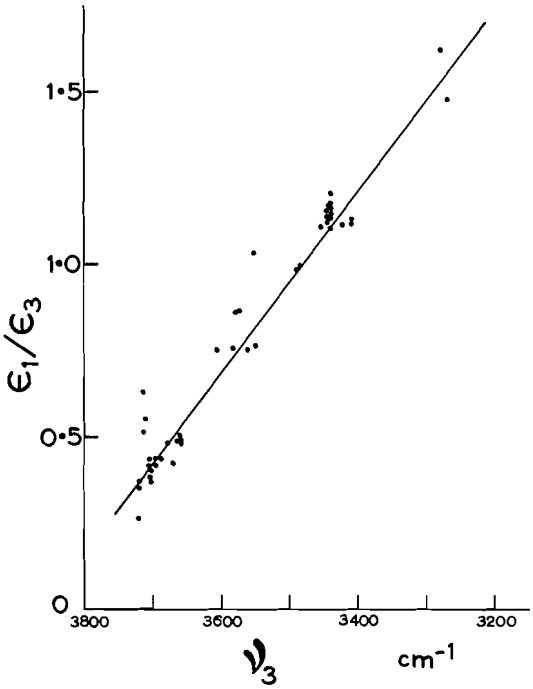

FIG. 7. Correlation of the extinction ratio $\varepsilon_1/\varepsilon_3$ with antisymmetric stretch frequency ν_3 for H_2O in various basic solvents.

doubly H-bonded H_2O molecules with nearly C_{2v} type symmetry. Our water stretching bands in ethylene oxide, dimethyl sulfoxide, and the amines, similar to those for DOH, all exhibit predominantly Lorentzian shapes, showing again that strong H-bond formation does not of itself lead to Gaussian band shapes.

Results for the bending fundamental ν_2 band in Table 4 show that stronger water H-bonding leads to (*i*) the well-known shift (3, 4) of the ν_2 band to higher frequencies, (*ii*) an increase of w_2, (*iii*) a decrease of ε_2, and (*iv*) a decrease of the $\varepsilon_2 \cdot w_2$ product.

In solvents below nitromethane we report the frequency of the first bending overtone $2\nu_2$, which occurs as a weak band (extinction $\varepsilon \sim 3.5$ l mol^{-1} cm^{-1}) in ethylene oxide at 0 °C, and which increases in intensity due to Fermi resonance (1, 43, 48) with the isosymmetric ν_1 to yield a moderate shoulder (extinction $\varepsilon \sim 50$ l mol^{-1} cm^{-1}) in pyridine at −20 °C. The progressive enhancement of the $2\nu_2$ band extinctions is shown in Fig. 5.

Assignment of the ice bands using eqs. 3 and 4 favors the wider ν_3 at the higher frequency and the sharper ν_1 at 3220 cm^{-1} in Fermi resonance with an enhanced $2\nu_2$ at 3150 cm^{-1}.

Comparison of O—H Stretching Bands for CH_3OH, DOH, and H_2O

(a) Correlation of Frequencies

In Table 5 are presented the 12 equations for the best linear regressions between the O—H stretching frequencies of the weak acids CH_3OH, DOH, and H_2O in our range of basic solvents.

*Regression $Y = B1 \cdot X + B2 \cdot X^2$.

The equations are written for evaluation of the best Y at specified X, where $B1$ is the regression coefficient Y on X. Also shown are $\sigma(Y)$ the assessment from the regression of the standard error on a single determination of Y with X assumed to be error-free, $\sigma(B1)$ the standard error on $B1$ expressed as a percentage, and ϕ the number of degrees of freedom (in this case the number of data pairs minus one) used to evaluate $\sigma(Y)$. The final column shows the correlation coefficient between the X and Y variates.

All correlation coefficients are seen to be 0.9940 or larger evidencing high degrees of correlation between the stretching frequency shifts for CH_3OH, DOH, and H_2O in the same solvents. Excellent correlations are shown between the frequencies ν_3, ν_1, and ν_{DOH} for H_2O and DOH, represented by eqs. 3, 6 to 10 for which the $\sigma(Y)$ values of 6–10 cm^{-1} are of the correct magnitude for the known experimental error. Regressions [9] and [10] prove that within experimental error the frequency shift for the ν_3 molecular vibration of H_2O in a particular solvent is identical with the ν_{DOH} for the O—H group vibration of DOH. Fifer and Schiffer (55) have given a theoretical explanation for the smaller shifts to lower frequency of ν_1.

Uniformly poorer correlations are found between the methanol frequency shifts and those for H_2O and DOH as represented by eqs. 11 to 16 for which the $\sigma(Y)$ assessments of 13–22 cm^{-1} are larger than experimental error by a factor of about two. Thus to adequately represent the experimental relationships between the frequencies of methanol and of the water, we use the quadratic function $Y = B1 \cdot X + B2 \cdot X^2$, for which Table 6 presents the Y and X variates together with values for the regression coefficients $B1$ and $B2$. The values of $\sigma(Y)$, the error assessment from the quadratic equation based on error-free X measurements, are now of the correct magnitude for the known experimental error.

The assessments for $\sigma(Y)$ from eqs. 3, 6 to 10 and eqs. 17 to 22 only provide proper estimates for the true standard error on Y when the X variate measurements are error-free. But since X and Y are infrared band frequency measurements and are both subject to comparable errors of measurement, the $\sigma(Y)$ assessments presented in Tables 5 and 6 are too large and must be divided by the

TABLE 7. Correlation of O—H stretch band areas for CH_3OH, DOH, and H_2O

Equation	Y = $B1$	X	$\sigma(Y)$	$\sigma(B1)$ (%)	ϕ	Correlation coefficient
[23]	$(\varepsilon.w)_{H_2O}$ = 2.0361	$(\varepsilon.w)_{DOH}$	3000*	2.01	17	0.9932
[24]	$(\varepsilon.w)_{DOH}$ = 0.4878	$(\varepsilon.w)_{H_2O}$	1500			
[25]	$(\varepsilon.w)_{MeOH}$ = 1.7562	$(\varepsilon.w)_{DOH}$	4400	3.45	17	0.9802
[26]	$(\varepsilon.w)_{DOH}$ = 0.5581	$(\varepsilon.w)_{MeOH}$	2500			
[27]	$(\varepsilon.w)_{MeOH}$ = 0.8543	$(\varepsilon.w)_{H_2O}$	5100	3.88	21	0.9693
[28]	$(\varepsilon.w)_{H_2O}$ = 1.1347	$(\varepsilon.w)_{MeOH}$	5800			
[29]	w_{13} = 1.2347	w_{DOH}	4.5*	0.52	9	0.9998
[30]	w_{DOH} = 0.8097	w_{13}	3.6			

*Units for $\varepsilon.w$, l mol^{-1} cm^{-2} for w, cm^{-1}.

term, $(1 + B1^2)^{\frac{1}{2}}$, which then gives an estimate of the standard error on a single Y measurement when X and Y are equally in error. The standard error on a single frequency determination then becomes 6.0 cm^{-1} for methanol, 5.7 for hydrogen deuterium oxide, 6.1 for the antisymmetric, and 5.1 for the symmetric stretching bands of water.

The average frequency shifts for singly H-bonded methanol in eqs. 11 and 13 are seen to be 26–28% larger than those for the doubly bonded water and hydrogen deuterium oxide; in the more basic amine solvents the methanol shifts are some 50% larger. Since more acidic phenol forms stronger H-bonds and exhibits even larger frequency shifts than methanol in these same solvents (3, 15, 49), our frequency shifts indicate that (*i*) with a given base, singly bonded methanol forms stronger H-bonds than doubly bonded water and hydrogen deuterium oxide, and (*ii*) monobasic methanol is more acidic than the dibasic water and hydrogen deuterium oxide, which are about equally acidic.

(b) Correlation of Areas

The six best linear equations relating the band area products $\varepsilon \cdot w$ for the hydroxyl stretching bands of CH_3OH, DOH, and H_2O are presented in Table 7. The best correlation is shown between the water bands of DOH and H_2O, with correspondingly poorer correlations for each of these with the methanol bands. The slopes in eqs. 23 and 24 are within experimental error equal to the theoretical values 2.00 and 0.50, respectively, confirming identical transition dipole derivatives (1, 2) and equally strong H-bonding for the group stretching vibration of DOH and for the molecular stretching vibrations of H_2O. The singly H-bonded methanol in eq. 25 shows a 76% greater band area and 33% larger transition dipole moment derivative than doubly bonded DOH. Thus again the singly bonded methanol is indicated to form significantly stronger H-bonds than the doubly bonded hydrogen deuterium oxide and water, which form essentially equivalent H-bonds.

The complete absence of non-bonded, sharp O—H u bands for methanol in dimethyl sulfoxide, the pyridines and in triethylamine, together with the occurrence of such sharp bands for both the DOH and HOH solutes, is consistent and supports the view that in these aprotic, basic solvents the singly H-bonded methanol forms stronger H-bonds with the solvent than do the doubly H-bonded hydrogen deuterium oxide and water. Similarly, weaker H-bonding by water is indicated in protonic liquid methanol at 0 °C, in which the proton magnetic resonance chemical shift for the protons of dilute water is 0.3 p.p.m. to higher field than that for the hydroxyl proton of methanol (unpublished work).

In addition to the band area correlations we include in Table 7 the band-width relations [29] and [30], valid in dimethyl sulfoxide and in more basic solvents, between w_{13} for the overlapped water bands and w_{DOH} for hydrogen deuterium oxide.

The transition dipole moment derivatives (2), $d\mu/dr$, for the O—H stretching modes of CH_3OH, DOH, and H_2O are given in Table 8. These are derived from the band area products $\varepsilon \cdot w$ (l mol^{-1} cm^{-2}, decadic logarithms) using the relations $d\mu/dr = 2.27 \times 10^{-12} \sqrt{\varepsilon \cdot w}$ for CH_3OH and DOH, and $1.61 \times 10^{-12} \sqrt{\varepsilon \cdot w}$ for H_2O.

At the head of the table good agreement is seen for $d\mu/dr$ of water vapor (50) and water dissolved in weakly interacting solvents. It is remarkable that these band areas are equal, despite the very

different extinction ratios and rotational structures of the ν_3 and ν_1 bands in the gas and liquid solvent phases. In a given solvent DOH and H_2O show essentially equal $d\mu/dr$ values which are invariably smaller than for CH_3OH.

The solvent order in Table 8 is that of increasing $d\mu/dr$ and thus of generally increasing H-bonding between the solute O—H group and the solvent base. This order is similar to those in Tables 1, 2, and 4, except for the position of triethylamine which differs significantly. The small $d\mu/dr$ values indicate that triethylamine forms either fewer or weaker H-bonds with CH_3OH, DOH, and HOH than do the substituted pyridines, whereas the frequency shifts indicate that triethylamine H-bonds are stronger than those of the pyridines. We consider that the low $d\mu/dr$ values for CH_3OH at both 30 and −44 °C in triethylamine reflect steric repulsions due to the librations of the ethyl groups. The DOH and HOH bands in triethylamine exhibit low peak extinctions with larger half-widths and more Gaussian shape (see Fig. 2*c*) than in the pyridines, which we interpret by the wider thermal distribution of O—H---N configurations arising from the three relaxing ethyl groups of triethylamine, absent in the rigid pyridines.

Recent absolute intensity measurements (51) for the stretching bands of the H_2O, DOH, and D_2O ices at −100 °C show overlapped ν_3, ν_1, and ν_2 contours similar to those in Fig. 5*f* and yield a $d\mu/dr$ of 4.01×10^{-10} e.s.u. for the water molecule in ice. This attests stronger H-bonding of water in ice than in the liquid tertiary amines, consistent with the frequency-shift orders in Tables 2 and 4. The proper sign for $d\mu/dr$ is almost certainly positive as given in Table 8, in the same sense that the gas phase water molecule has the positive dipole moment, +1.85 D, with an excess positive charge at the protons when the O—H internuclear separation r is 0.958 Å (1). This means that the extension of r to 1.01 Å (52) by the H-bonding in ice leads to a further increase of positive charge at the protons giving an en-

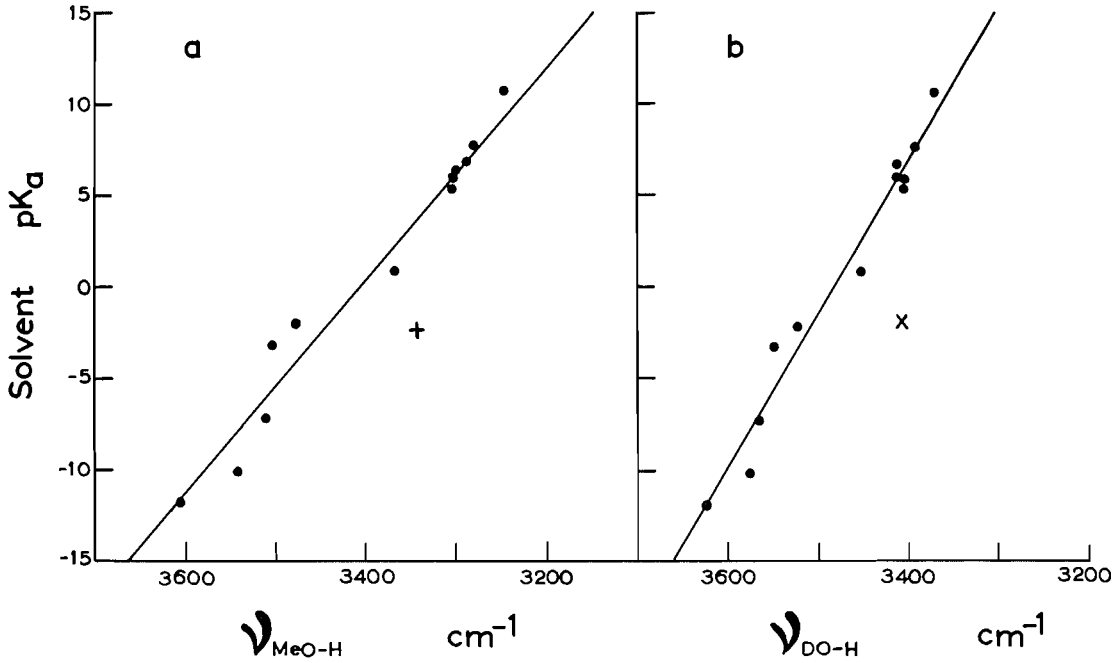

FIG. 9. Correlation of basicity pK_a values for aprotic solvents with O—H stretch frequency for two weakly acidic solutes at 30 °C. (*a*) The solute CH_3OH, showing its deviation at + in methyl alcohol-*d*. (*b*) The solute DOH, showing its deviation at × in deuterium oxide.

hanced dipole moment of about 1.99 D for the water molecule in ice, as evaluated assuming a constant $d^2\mu/dr^2$ over the range of r.

Solvent Basicity

The solvents in Tables 1, 2, and 4 are ordered according to the frequency value for the solute O—H stretch bands. These orders are very similar for each of the weakly acidic solutes, CH_3OH, DOH, and H_2O, and this common spectral order corresponds closely with the basicity order defined by the solvent pK_a values (15). Arnett has shown an impressive correlation of solvent pK_a values with the O—D stretching frequencies of dissolved methyl alcohol-*d*, while Gordy and Stanford (16) earlier showed a good correlation between the O—D stretching band wavelengths for D_2O and CH_3OD in a wide range of basic solvents.

Correlations between the solvent pK_a values (15, 53) and our O—H stretching frequencies for CH_3OH and DOH in aprotic solvents are presented in Fig. 9. Representative linear equations, including one for H_2O, are

$$[31]\quad pK_a = -16.11 + 0.0577(3687 - \nu_{MeOH})$$

$$[32]\quad pK_a = -19.10 + 0.0847(3707 - \nu_{DOH})$$

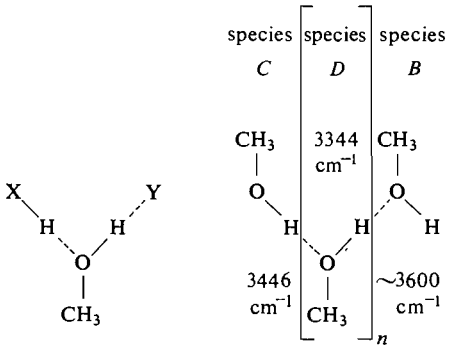
$$[33]\quad pK_a = -19.09 + 0.0821(3756 - \nu_3)$$

with standard errors on single pK_a values of 1.61, 1.62, and 1.40 for eqs. 31 to 33, respectively, and with standard errors on the regression coefficients of 0.0038, 0.0056, and 0.0047. These empirical equations are recommended and give equivalent results for interpolation of aprotic solvent pK_a values within the range −11.9 for nitromethane and +10.7 for triethylamine. They should not be used for extrapolation since the lack of linearity of the CH_3OH and DOH frequency scales leads to significantly different predicted pK_a values.

A large deviation for the D-bonded solvent methyl alcohol-*d* from the correlation line, eq. 31, for methanol in aprotic solvents is shown in Fig. 9*a*. If we calculate the oxygen basicity for methyl alcohol-*d* using the methanol frequency 3344 cm^{-1} in eq. 31 we obtain a pK_a value of 3.7 ± 0.5, which is 5.9 units higher and more strongly basic than the −2.2 reported for methanol (15). Alternately, if the −2.2 value for methanol is accepted, substitution into eq. 31 gives an O—H frequency of 3446 cm^{-1}, similar to that for methanol in tetrahydrofuran, but 102 cm^{-1}

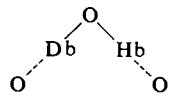
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

higher than for the main band at 3344 cm^{-1}. This deviation exceeds possible experimental error and is most readily understood in terms of a specific dipolar association model for methanol H-bonding (30), represented by

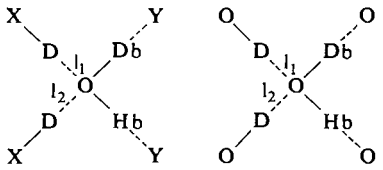


in which electronic charge displacements at the methanol oxygen atoms arise (*i*) from the H-bonding of Y by the hydroxyl proton which makes the oxygen atom more basic, and (*ii*) from the X—H bonding of the oxygen atom which makes the hydroxyl proton more acidic. This is an induction–polarization effect in which the field of the hydroxyl proton attracts the regions of high electronic charge on Y. The electrons of Y attract the proton but repel its bonding electrons so that the O—H bond length is increased and electronic charge is returned to the oxygen atom, making it more basic. In the same sense the H-bond formation by X—H attracts electronic charge onto the oxygen atom and withdraws some of this charge from the O—H bond, thereby reducing the shielding of the proton and making it more acidic. For each of these H-bonds the charge polarization at the oxygen atom is in the same direction, so that simultaneous formation of both bonds leads to their mutual stabilization and strengthening. Thus, we expect strongest H-bonds between doubly bonded methanol species *D* within the alcohol polymer chains and rings, with weaker H-bonds to the terminal species *B* and *C*, and with weakest H-bonds in the dimer between species *C* and *B*.

The D-bonded solvent deuterium oxide in Fig. 9*b* shows a similar large deviation from the correlation line, eq. 32, for DOH in aprotic solvents. Evaluation of the deuterium oxide oxygen basicity using the frequency 3407 cm^{-1} in eq. 32 gives a pK_a of 6.3 $\pm$ 0.6, which is 8.1 units more basic than the -1.8 reported for water (15). If we take the -1.8 for the oxygen basicity in deuterium oxide, substitution into eq. 32 gives 3503 cm^{-1} for the O—H frequency of the double bonded species



denoted b D—O—H b, with no bonds to the oxygen lone pairs: this frequency is 96 cm^{-1} higher than for the main band at 3407 cm^{-1}. This large discrepancy for DOH in liquid deuterium oxide is again beyond possible experimental error and is interpreted in terms of tetrahedrally induced polarization and charge redistribution on each central oxygen atom caused by the bonding of four nearest neighbors. The formation of D-bonds by X—D with the central oxygen atom



enhances the electronic charge density within the lone pair orbitals l_1 and l_2 oriented towards the D—X groups. This shift of charge on the central oxygen withdraws some charge within the O—D and O—H orbitals and reduces the electronic shielding of the deuteron and proton, making them become more acidic and form stronger D- and H-bonds. Similarly the electrons of the basic Y atoms attract the deuteron and proton but repel their orbital electrons so that the O—D and O—H bond lengths are increased while electronic charge is displaced back to the central oxygen atom, making it more basic and able to form stronger bonds. The formation of both the O—D b and O—H b donor and the l_1 and l_2 acceptor bonds leads to charge polarization of the central oxygen atom in the same sense and corresponds to increasing dipole moments for unbonded gaseous DOH, through two-bonded b D—O—H b in aprotic tetrahydrofuran, to four-bonded l_1l_2b D—O—H b in deuterium oxide liquid and ice.

In the contrary sense and opposing the four bond-stabilizing interactions (l_1 – O—D b, l_1 – O—H b, l_2 – O—D b, l_2 – O—H b) between the acceptor and donor bonds of four-bonded hydrogen deuterium oxide, the formation of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

second acceptor bond at lone pair l_2 inductively opposes and weakens the first acceptor bond at l_1, while similarly the formation of the second donor bond O—H b weakens the first donor bond O—D b. Thus, each of the four bonds to dibasic hydrogen deuterium oxide in liquid deuterium oxide is weaker than each of the two bonds to monobasic methanol within its liquid polymer chains.

Synthesis of 1*H*-Benzo[*d*,*e*-1,7]naphthyridines, a Novel Heterocyclic Ring System

L. G. HUMBER
Ayerst Research Laboratories, Montreal, Quebec

Received August 31, 1970

A simple six-step synthesis, from homoveratrylamine, of 5,6-dimethoxy-2,3,7,8,9,9*a*-hexahydro-1-(*p*-toluenesulfonyl)-1*H*-benzo[*d*,*e*-1,7]naphthyridine, the first representative of a novel heterocyclic ring system, is described. Various transformation products and derivatives of the ring-system are also recorded.

Une synthèse simple, en six étapes à partir de l'homovératrylamine de la diméthoxy-5,6 hexahydro-2,3,7,8,9,9*a* *p*-toluènesulfonyl-1 1*H*-benzo[*d*,*e*-1,7]naphthyridine, le premier représentant d'un nouveau système hétérocyclique, est décrite. Divers produits de transformation et dérivés de ce système cyclique sont aussi rapportés.

Canadian Journal of Chemistry, 49, 857 (1971)

Compounds containing the benzo[*d*,*e*-1,7]-naphthyridine ring system, *e.g.* **17**, have hitherto been undescribed. As part of a program aimed at the syntheses of novel heterocyclic systems for the study of their chemical and biological properties, a synthetic route to this ring-system has been developed and is described in this report.

The general approach selected required the use of a 1-aminomethyl-1,2,3,4-tetrahydroisoquinoline (*e.g.*, **8**–**13**, **15**, **16**) which should give rise to the desired tricyclic system on application of either the Bischler–Napieralski, the Pictet–Spengler, or the Friedel–Crafts reaction to the appropriate derivative.

Initially, the Bischler–Napieralski reaction on the 1-formamidomethyl-2-methyltetrahydroisoquinoline **11** was investigated. Compound **11** was obtained via the methylation of **3** with formic acid and formaldehyde to afford **5** which was treated with hydrazine to remove the phthalyl blocking group. The resultant 1-aminomethyl-2-methyl derivative **8** was converted to **11** with formic acetic anhydride. Ring closure of **11** was investigated using conventional Bischler–Napieralski reagents such as phosphorous oxychloride, phosphorous pentoxide, and phosphorous pentachloride (2), as well as the use of polyphosphoric acid (3), polyphosphoric ester (4), phosphorous oxychloride and tin dust (5), the mixture of phosphorous pentoxide and phosphorous oxychloride in pyridine (6), and the action of aluminum chloride on the imidochloride formed from **11** with phosphorous pentachloride in ether (7). In no instance was any of the benzonaphthyridine of type **14** observed. Either starting material **11**, its hydrolysis product **8**, or intractable tars were obtained.

The non-basic 2-(*p*-toluenesulfonyl)-1-formamidomethyl derivative **12** was next investigated in the Bischler-Napieralski reaction. Compound **12** was obtained from **3** through intermediates **6** and **9** by the sequence of tosylation, hydrazinolysis, and formylation. Using variants of the Bischler–Napieralski reaction as described above, no cyclization products could be detected. Cyclizations were also attempted without success on **13**, (obtained from **2** as shown in Scheme 1), the 5,6-dimethoxy analog of compound **12**, which does not bear a methoxyl group ortho to the intended site of ring closure, while retaining activation by methoxyl at that site. Attempted cyclization of the 2-(*p*-toluenesulfonyl)-isocyanates in both the 6,7-dimethoxy- and the 5,6-dimethoxy- series, **15** and **16** respectively, with aluminum chloride in toluene, and with *p*-toluenesulfonic acid in toluene failed to yield any tricyclic lactam.

The next variant of the general approach to be investigated was the application of the Pictet–Spengler reaction to a suitable substrate. Thus, the 1-aminomethyl-5,6-dimethoxy-2-(*p*-toluenesulfonyl) derivative **10**, obtained through intermediate **7**, was employed. When the hydrochloride salt of this compound, in water, was treated with one molar equivalent of aqueous formaldehyde for 45 min on the steam bath, then allowed to remain at room temperature for 12 h, there was obtained by filtration, a 90.5% yield of the hydrochloride of the desired benzo[*d*,*e*-1,7]-naphthyridine **17**. That ring-closure had occurred was readily confirmed by the n.m.r. spectrum of the product. The distinguishing feature of the spectrum is the aromatic region, which shows the four protons of the toluenesulfonyl group as two

doublets centered at 7.28 and 7.88 δ (J = 8 Hz), the one aromatic proton on the benzo[*d*,*e*-1,7]-naphthyridine nucleus as a singlet at 6.79 δ, and the two hydrogens at C-7 as a sharp singlet at 3.97 δ. A similar ring closure on the 6,7-dimethoxy analog **9** affords a 65% yield of the benzo[*d*,*e*-1,7]-naphthyridine **18**, reflecting a steric effect of the methoxyl group adjacent to the site of closure.

The former facile cyclization, in high yield under almost "physiologic" conditions, is striking when viewed in contrast to the various unsuccessful attempts, described above, to obtain the tricyclic ring system. Application of the Pictet–Spengler reaction using the conditions described above with the intermediate **8** which bears a basic center apart from the primary amino group that is expected to react, fails to give any cyclization product.

With the benzo[*d*,*e*-1,7]naphthyridine derivative **18** readily available by a six-step synthesis from commercially available homoveratrylamine, various transformations were studied. The *p*-toluenesulfonyl blocking group of **18** was removed in 61% yield with sodium–ammonia to give **24**, or alternatively, compound **18** was converted to the methylated derivative **19** followed by lithium–ammonia reduction to afford **25**, in which the two nitrogens are differentiated. Lithium–ammonia reduction of the acetyl derivative **20** allows the preparation of the corresponding detosylated

derivative **27**, while detosylation and simultaneous reduction of the 8-acetyl group of **20** occurs, to afford the 8-ethyl derivative **28** in 61% yield. Analogously, the treatment of the 1-tosyl-8-dimethylaminopropionyl derivative **22**, obtained through the chloropropionyl derivative **21**, afforded **29** bearing the dimethylaminopropyl group in the 8-position. Alkylation of **18** with ethyl bromoacetate yielded the ethoxycarbonyl derivative **23**, while an acylation of **25** followed by reduction with lithium aluminum hydride afforded the 1-(3,4-dimethoxy-β-phenethyl)-substituted benzo[*d*,*e*-1,7]naphthyridine **30**.

Experimental

Melting points were taken on a Thomas-Hoover apparatus. Analyses were done by Mr. W. Turnbull and staff of the Ayerst Research Laboratories. The n.m.r. spectra were recorded on a Varian A-60-A instrument. All new compounds gave i.r. and n.m.r. spectra consistent with their respective structures. Unless stated otherwise, reported yields are for materials homogeneous by t.l.c. and further identified by i.r. and/or n.m.r. spectroscopy.

N-Phthalimidoacetyl-2,3-dimethoxy-β-phenethylamine

To a vigorously stirred mixture of 2,3-dimethoxy-β-phenethylamine (1) (47.7 g, 0.263 mol), dichloromethane (200 ml), sodium carbonate (13.25 g, 0.125 mol), and water (200 ml) was added during 45 min at 5°, a solution of phthalylglycyl chloride (58.9 g, 0.263 mol) dissolved in dichloromethane (200 ml). The mixture was stirred at 22° for 1 h and the insoluble product was filtered off, dissolved in warm chloroform, washed with 3 × 150 ml of saturated sodium chloride solution, dried over sodium carbonate, and the solvent evaporated *in vacuo* to give 65.0 g of product (67%) as a solid, m.p. 196–198° from ethanol.

Anal. Calcd. for $C_{20}H_{20}N_2O_5$: C, 65.20; H, 5.47. Found: C, 64.98; H, 5.61.

N-Phthalimidoacetyl-3,4-dimethoxy-β-phenethylamine

Using the procedure described above but substituting 3,4-dimethoxy-β-phenethylamine for 2,3-dimethoxy-β-phenethylamine, the title compound is obtained in 78% yield. It has m.p. 188–189° (ethanol). This compound has been described previously (8), but no m.p. is given.

3,4-Dihydro-5,6-dimethoxy-1-phthalimidomethyl-isoquinoline (2)

N-Phthalimidoacetyl-2,3-dimethoxy-β-phenethylamine (65.0 g, 0.176 mol) was dissolved in 1 l of benzene and 500 ml of phosphorous oxychloride was added. The mixture was refluxed for 16 h, cooled, and diluted with 4 l of petroleum ether (b.p. 60–80°). The supernatant was decanted and the residual red oily phosphate salt of the title compound was dissolved in chloroform (500 ml) and shaken vigorously with 4 × 200 ml of 5% aqueous sodium carbonate solution. The chloroform solution was dried over sodium sulfate, concentrated to 150 ml, and passed through a column of alumina (650 g of activity II, neutral). Elution with chloroform gave 36.0 g of the product (58.2%) m.p. 204–206° (chloroform–methanol).

Anal. Calcd. for $C_{20}H_{18}N_2O_4$: C, 68.55; H, 5.18. Found: C, 69.02; H, 5.37.

3,4-Dihydro-6,7-dimethoxy-1-phthalimidomethyl-isoquinoline (1)

Using the procedure described above with *N*-phthalimidoacetyl-3,4-dimethoxy-β-phenethylamine affords a 71% yield of the title compound, m.p. 204–204.5° (chloroform–hexane). This compound has been described previously (8) but without a m.p.

5,6-Dimethoxy-1-phthalimidomethyl-1,2,3,4-tetrahydroisoquinoline (4)

Compound **2** (29.8 g, 0.085 mol) was dissolved in a mixture of 2 *N* hydrochloric acid (42.4 ml, 0.085 mol) and 200 ml of glacial acetic acid. Platinum oxide catalyst (1.0 g) was added and the mixture was hydrogenated at 22° and at an initial pressure of 50 p.s.i. After 2 min the reduction was complete. Filtration and dilution with ether gave a solid which was distributed between chloroform and aqueous sodium carbonate solution. The chloroform phase afforded 22.5 g (75.7%) of the product, m.p. 186–188° (benzene).

Anal. Calcd. for $C_{20}H_{20}N_2O_4$: C, 68.20; H, 5.68; N, 7.95. Found: C, 68.48; H, 5.81; N, 7.78.

The *2-(p-toluenesulfonyl)-derivative 7* was prepared in pyridine in 65% yield. Analytically pure material had m.p. 181–182° (acetonitrile).

Anal. Calcd. for $C_{27}H_{26}N_2O_6S$: C, 64.02; H, 5.17; N, 5.53; S, 6.32. Found: C, 64.24; H, 5.15; N, 5.47; S, 6.61.

6,7-Dimethoxy-1-phthalimidomethyl-1,2,3,4-tetrahydroisoquinoline (3)

Using the procedure described above with **1** affords a 65% yield of the title compound, m.p. 132–133° (acetone–hexane). This compound has been described previously as the hydrochloride (8) but no m.p. is given.

Anal. Calcd. for $C_{20}H_{20}N_2O_4$: C, 68.20; H, 5.68; N, 7.95. Found: C, 68.19; H, 5.75; N, 7.72.

6,7-Dimethoxy-2-methyl-1-phthalimidomethyl-1,2,3,4-tetrahydroisoquinoline (5)

Compound **3** (183 g, 0.519 mol) was dissolved in a mixture of 97% formic acid (183 ml), water (183 ml), and 37% aqueous formaldehyde (183 ml). The mixture was heated on the steam bath for 3 h, then poured into 4 l of water. The p*H* of the mixture was adjusted to 7 with sodium carbonate and it was extracted with benzene to afford 112 g (59%) of product, m.p. 146–148° (benzene–hexane).

Anal. Calcd. for $C_{21}H_{22}N_2O_4$: C, 68.83; H, 6.05; N, 7.65. Found: C, 68.93; H, 6.23; N, 7.66.

1-Aminomethyl-6,7-dimethoxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (8)

To a solution of **5** (89.6 g, 0.245 mol) in 1.61 of ethanol at 50° was added 1.35 l of 1 *M* hydrazine in ethanol. The mixture was heated on the steam bath for 1.5 h, concentrated to a thick paste *in vacuo*, then heated for 30 min on a steam bath with 2 l of 2 *N* hydrochloric acid. After

For personal use only.

filtration, the filtrate was made alkaline with potassium hydroxide and extracted with chloroform to afford the product, (49.6 g, 86%) b.p. 140° (0.03 mm.).

Anal. Calcd. for $C_{13}H_{20}N_2O_2$: C, 66.10; H, 8.52; N, 11.86. Found: C, 65.88; H, 8.41; N, 11.77.

The corresponding *2-(p-toluenesulfonyl)-derivative*, **6** was prepared in pyridine in 84% yield. It had m.p. 146–147° (ethanol).

Anal. Calcd. for $C_{27}H_{26}N_2O_6S$: C, 64.02; H, 5.17; N, 5.53; S, 6.32. Found: C, 63.75; H, 5.36; N, 5.56; S, 6.50.

*6,7-Dimethoxy-1-formamidomethyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (**11**)*

Compound **8** (11.5 g, 0.049 mol) was added to formic acetic anhydride prepared by heating at 60° for 2 h, a mixture of 97% formic acid (53 ml) and acetic anhydride (125 ml). The mixture was kept at 22° for 18 h, poured into iced water, and extracted with chloroform to afford the product (12.4 g, 90%) b.p. 200° (0.3 mm). An analytical sample had m.p. 109–111° (acetone).

Anal. Calcd. for $C_{14}H_{20}N_2O_3$: C, 63.61; H, 7.63; N, 10.60. Found: C, 63.81; H, 7.55; N, 10.70.

*1-Aminomethyl-6,7-dimethoxy-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**9**)*

Using the hydrazinolysis procedure described in the preparation of **8** with compound **6** affords an 84% yield of the title compound, m.p. 138–139° (benzene).

Anal. Calcd. for $C_{19}H_{24}N_2O_4S$: C, 60.62; H, 6.43; N, 7.44. Found: C, 61.03; H, 6.59; N, 7.37.

The hydrochloride salt had m.p. 225–226° (2-propanol–ether).

Anal. Calcd. for $C_{19}H_{25}ClN_2O_4S$: C, 55.28; H, 6.10; Cl, 8.59; N, 6.79. Found: C, 55.05; H, 6.17; Cl, 8.79; N, 6.66.

*1-Aminomethyl-5,6-dimethoxy-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**10**)*

Using the hydrazinolysis procedure described above with **7** affords a 98% yield of the product as an oil. The hydrochloride salt had m.p. 235–238° (methanol–ether).

Anal. Calcd. for $C_{19}H_{25}ClN_2O_4S$: C, 55.28; H, 6.10; Cl, 8.59; N, 6.79. Found: C, 55.26; H, 6.12; Cl, 8.61; N, 6.59.

*6,7-Dimethoxy-1-formamidomethyl-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**12**)*

Using the formylation procedure described above for the preparation of **11** with compound **9** affords a 62% yield of the product, m.p. 115–116° (chloroform–hexane).

Anal. Calcd. for $C_{20}H_{24}N_2O_5S$: C, 59.40; H, 5.98; N, 6.93. Found: C, 59.47; H, 6.20; N, 6.93.

*5,6-Dimethoxy-1-formamidomethyl-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**13**)*

Using the formylation procedure described above with **10** affords a 90% yield of the title compound as a gum which could not be obtained crystalline. It was homogeneous by t.l.c. and the i.r. spectrum in chloroform had bands at 1675 (CONH) and 3400 cm^{-1} (NH). Good analyses could not be obtained with this gum.

*6,7-Dimethoxy-1-isocyanatomethyl-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**15**)*

Phosgene was bubbled for 1 h into a refluxing mixture of **9** (7.53 g, 0.02 mol) in toluene (100 ml) which had been saturated with hydrogen chloride. The homogeneous solution was cooled and the solvent evaporated *in vacuo* to give an oily residue. Crystallization from benzene gave the product (6.02 g, 75%) m.p. 125–126°.

Anal. Calcd. for $C_{20}H_{22}N_2O_5S$: C, 59.69; H, 5.51; N, 6.96. Found: C, 59.88; H, 5.66; N, 6.90.

*5,6-Dimethoxy-1-isocyanatomethyl-1,2,3,4-tetrahydro-2-(p-toluenesulfonyl)-isoquinoline (**16**)*

Using the procedure described above, phosgene was reacted with **10** to afford the product in 54% yield, m.p. 116–119° (benzene–hexane).

Anal. Calcd. for $C_{20}H_{22}N_2O_5S$: C, 59.69; H, 5.51; N, 6.96. Found: C, 59.80; H, 5.74; N, 7.04.

*5,6-Dimethoxy-2,3,7,8,9,9a-hexahydro-1-(p-toluenesulfonyl)-1H-benzo[d,e-1,7]naphthyridine (**18**)*

Compound **9** (1.0 g, 0.00266 mol) was dissolved in 2 *N* hydrochloric acid (13.3 ml, 0.00266 mol) with gentle warming. Aqueous 37% formaldehyde (2.5 ml, 0.00266 mol) was added all at once and the mixture heated on the steam bath for 45 min. The solution was kept at 22° for 12 h and the resulting crystals isolated by filtration. They were washed with water then acetone and dried to give the product (730 mg, 65%), homogeneous by t.l.c. The analytical sample had m.p. 238–239° (methanol–ether) and the free base obtained from the hydrochloride had m.p. 90–92° (isopropanol); λ_{max} (EtOH) 225 (ε 22 080), 275 (ε 2680), 284 mμ (ε 2800). The n.m.r. spectrum of the hydrochloride in dimethylsulfoxide showed the lone aromatic proton of the benzonaphthyridine nucleus as a singlet at 6.42 δ.

Anal. Calcd. for $C_{20}H_{25}ClN_2O_4S$: C, 56.54; H, 5.93; Cl, 8.34. Found: C, 56.72; H, 6.10; Cl, 8.47.

*4,5-Dimethoxy-2,3,7,8,9,9a-hexahydro-1-(p-toluenesulfonyl)-1H-benzo[d,e-1,7]naphthyridine (**17**)*

Using the procedure described above with **10** a 90.5% yield of the hydrochloride salt of the title compound was obtained. It had m.p. 224–226° (acetonitrile); λ_{max} (EtOH) 231 (ε 15 450), 264 (ε 1525), 275 (ε 1746), 292 mμ (ε 1455). The n.m.r. spectrum showed characteristic bands, *viz.* two doublets centered at 7.28 (J = 8 Hz) and 7.88 δ (J = 8 Hz) (4 tosyl aromatic protons), a singlet at 6.79 (benzonaphthyridine aromatic proton), and the two hydrogens at C-7 as a sharp singlet at 3.97 δ. The free base obtained from the hydrochloride had m.p. 103–109° (benzene–hexane).

Anal. Calcd. for $C_{20}H_{25}ClN_2O_4S$: C, 56.54; H, 5.93; Cl, 8.34; N, 6.59. Found: C, 56.26; H, 5.95; Cl, 8.73; N, 6.71.

*5,6-Dimethoxy-2,3,7,8,9,9a-hexahydro-8-methyl-1-(p-toluenesulfonyl)-1H-benzo[d,e-1,7]naphthyridine (**19**)*

A mixture of **18** (5.0 g, 0.013 mol) 37% aqueous formaldehyde (5 ml), formic acid (5 ml), and water (5 ml) was heated on the steam bath for 2 h. Water (200 ml) was added, the mixture was made basic with ammonium hydroxide, and extracted with chloroform to afford the product (5.0 g, 95%) as an amorphous solid. The hydrochloride salt had m.p. 208–209° (methanol–ether).

Anal. Calcd. for $C_{21}H_{27}ClN_2O_4S$: C, 57.45; H, 6.20; Cl, 8.08; N, 6.38. Found: C, 57.16; H, 6.23; Cl, 7.99; N, 6.40.

5,6-Dimethoxy-2,3,7,8,9,9a-hexahydro-8-methyl-1H-benzo[d,e-1,7]naphthyridine (25)

A solution of **19** (1.0 g, 0.0025 mol) in 25 ml of tetrahydrofuran was added to 200 ml of anhydrous ammonia, followed by 2-propanol (1.0 ml). Lithium wire (0.043 g/cm) was added in small pieces until the resulting blue color persisted for 3 min (4.0 cm of lithium wire was required). The ammonia was evaporated and benzene (50 ml) and saturated sodium chloride solution (75 ml) were added. The benzene phase afforded the product as an oil (600 mg). It was chromatographed on neutral alumina (activity II). Elution with chloroform gave the pure product (520 mg, 76%) as an oil. It could be obtained crystalline from benzene–hexane and had m.p. 40–43°. The n.m.r. spectrum in chloroform shows a 3-proton peak at 2.5 (N—CH_3) and a one-proton peak at 6.52 δ (aromatic proton). The dihydrochloride salt had m.p. 257° (methanol–ether).

Anal. Calcd. for $C_{14}H_{22}Cl_2N_2O_2$: C, 53.33; H, 6.91. Found: C, 53.02; H, 7.14.

The *1-acetyl derivative* **26** was prepared with acetic anhydride and pyridine. It had m.p. 116–117° (ethyl acetate – hexane).

Anal. Calcd. for $C_{16}H_{22}N_2O_3$: C, 66.31; H, 7.76; N, 9.44. Found: C, 66.18; H, 7.64; N, 9.65.

5,6-Dimethoxy-2,3,7,8,9,9a-hexahydro-1H-benzo-[d,e-1,7]naphthyridine (24)

Compound **18** (1.0 g, 0.0035 mol) was dissolved in 10 ml of tetrahydrofuran and 100 ml of anhydrous ammonia. Sodium was added in small pieces until the blue color persisted for 10 min, then the ammonia was allowed to evaporate. The residue was distributed between chloroform and water. The organic phase afforded the product (500 mg, 61%), m.p. 134–135° (2-propanol – ether). The dihydrochloride salt had m.p. 295–297° (methanol).

Anal. Calcd. for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74; N, 11.96. Found: C, 66.95; H, 7.71; N, 11.91.

The *8-acetyl derivative* **20** was prepared with acetic anhydride in pyridine at 75°. It had m.p. 134–136° (benzene–hexane).

Anal. Calcd. for $C_{22}H_{26}N_2O_5S$: C, 61.11; H, 5.98; N, 6.33. Found: C, 61.38; H, 6.09; N, 6.51.

5,6-Dimethoxy-8-ethyl-2,3,7,8,9,9a-hexahydro-1H-benzo[d,e-1,7]naphthyridine (28)

Compound **20** (2.1 g, 0.005 mol) was refluxed for 16 h with 2.0 g of lithium aluminum hydride in 30 ml of tetrahydrofuran to afford, after a conventional work-up procedure, 800 mg of the product (61%). The dihydrochloride salt had m.p. 239–240° (methanol–ether).

Anal. Calcd. for $C_{15}H_{24}Cl_2N_2O_2$: C, 53.72; H, 7.22; Cl, 21.15. Found: C, 53.96; H, 7.38; Cl, 20.84.

8-Acetyl-5,6-dimethoxy-2,3,7,8,9,9a-hexahydro-1H-benzo[d,e-1,7]naphthyridine (27)

To a solution of **20** (1.0 g, 0.0025 mol) in ammonia (300 ml) was added lithium wire (0.035 g, 0.0025 mol) during 5 min. The ammonia was allowed to evaporate overnight and the residue was distributed between water and chloroform. The chloroform phase afforded the product (560 mg, 81.5%), m.p. 115–117° (ethyl acetate – hexane). The hydrochloride salt had m.p. 235–240° (ethanol–ether).

Anal. Calcd. for $C_{15}H_{21}ClN_2O_3$: Cl, 11.33; N, 8.96. Found: Cl, 11.61; N, 9.15.

8-(3′-Chloropropionyl)-5,6-dimethoxy-2,3,7,8,9,9a-hexahydro-1-(p-toluenesulfonyl-1H-benzo[d,e-1,7]-naphthyridine (21)

To a refluxing solution of **18** (10.0 g) in 120 ml of benzene was added 3-chloropropionyl chloride (3.5 ml). After refluxing for 2 h, the solvent was evaporated *in vacuo* to give a semi-solid residue. Crystallization from methanol gave the product (7.7 g, 64%), m.p. 125–127°.

Anal. Calcd. for $C_{23}H_{27}ClN_2O_5S$: C, 57.53; H, 5.84; Cl, 7.47; N, 5.56. Found: C, 57.68; H, 5.69; Cl, 7.40; N, 5.85.

5,6-Dimethoxy-8-(3′-dimethylaminopropionyl)-2,3,7,8,9,9a-hexahydro-1-(p-toluenesulfonyl)-1H-benzo[d,e-1,7]naphthyridine (22)

Compound **21** (11.4 g) and dimethylamine (15 ml) were combined in 70 ml of ethanol and heated in a pressure bottle at 95° for 16 h. The alcohol was evaporated *in vacuo* and the residue was distributed between chloroform and dilute ammonium hydroxide. The organic phase afforded the product (10.0 g, 79%), m.p. 129–131° (ethyl acetate – hexane).

Anal. Calcd. for $C_{25}H_{33}N_3O_5S$: C, 61.49; H, 6.73; N, 8.52. Found: C, 61.58; H, 6.82; N, 8.62.

The hydrochloride salt had m.p. 190–192° (2-propanol).

Anal. Calcd. for $C_{25}H_{34}ClN_3O_5S$: Cl, 6.57; N, 7.69. Found: Cl, 6.77; N, 8.02.

5,6-Dimethoxy-8-(3′-dimethylaminopropyl)-2,3,7,8,9,9a-hexahydro-1H-benzo[d,e-1,7]naphthyridine (29)

Compound **22** (6.0 g) and lithium aluminum hydride (6.0 g) were combined in tetrahydrofuran (100 ml) and refluxed for 16 h. A conventional work-up procedure afforded the product (2.4 g, 56%) as a gum. It was converted to the trihydrochloride salt which was obtained as a monohydrate. It had m.p. 247–249°.

Anal. Calcd. for $C_{18}H_{34}Cl_3N_3O_3$: C, 48.46; H, 7.67; Cl, 23.80; N, 9.40. Found: C, 48.82; H, 7.66; Cl, 23.92; N, 9.39.

5,6-Dimethoxy-8-ethoxycarbonylmethyl-2,3,7,8,9,9a-hexahydro-1-(p-toluenesulfonyl)-1H-benzo-[d,e-1,7]naphthyridine (23)

A mixture of **18** (970 mg), ethyl bromoacetate (417.5 mg), potassium carbonate (1.0 g), and benzene (40 ml) were stirred vigorously and heated at 100° for 3 h. The mixture was filtered and the benzene evaporated *in vacuo* to leave an oil. Trituration with hexane gave the product (850 mg, 72%). It had m.p. 133–134° on crystallization from an ethyl acetate – hexane mixture.

Anal. Calcd. for $C_{24}H_{30}N_2O_6S$: C, 60.75; H, 6.37; N, 5.90. Found: C, 60.91; H, 6.12; N, 6.02.

5,6-Dimethoxy-1-(3,4-dimethoxy-β-phenethyl)-2,3,7,8,9,9a-hexahydro-8-methyl-1H-benzo-[d,e-1,7]naphthyridine (30)

Compound **25** (5.86 g), ethylene dichloride (40 ml), and aqueous sodium hydroxide (23.67 ml of 1 *N*) were combined and stirred vigorously while a solution of 3,4-dimethoxyphenylacetyl chloride (5.04 g) was added. The mixture was stirred at 22° for 2 h then the organic phase was separated, washed, dried, and evaporated to

afford *5,6-dimethoxy-1-(3,4-dimethoxyphenylacetyl)-2,3,7,8,9,9a-hexahydro-8-methyl-1H-benzo[d,e-1,7]naphthyridine* as a foam (10.0 g). It was homogeneous by t.l.c. but could not be obtained crystalline. It was reduced directly by refluxing with lithium aluminum hydride (9.0 g) in tetrahydrofuran (200 ml) for 16 h. A conventional work-up procedure afforded the product (6.3 g) as a semi-solid. The dihydrochloride salt was prepared and crystallized from a methanol–ether mixture. It had a m.p. in excess of 275°.

Anal. Calcd. for $C_{24}H_{34}Cl_2N_2O_4$: C, 59.39; H, 7.06; Cl, 14.61. Found: C, 59.69; H, 6.92; Cl, 14.88.

The author wishes to acknowledge the technical assistance of Messrs. R. Otson, P. Berchtold, and R. Thomas. Thanks are also due to Mrs. J. Jachner for i.r. and u.v. spectra.

Reaction of 9-Acetyl-2,3,4,4*a*-tetrahydrocarbazoles with Ozone: a Novel Oxidative Rearrangement[1]

STEWART MCLEAN AND U. O. TROTZ
Department of Chemistry, University of Toronto, Toronto 181, Ontario

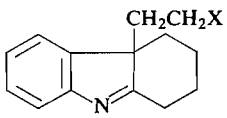
Received August 11, 1970

When 4*a*-ethyl-2,3,4,4*a*-tetrahydrocarbazole or its 4*a*-bromoethyl analog reacted with ozone, only a small amount of material that corresponded to the anticipated ozonolysis product was obtained, the principal reaction pathway leading to a 4*a*-substituted 1-acetoxytetrahydrocarbazolenine, the product of an oxidative rearrangement.

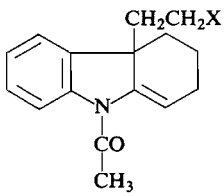
La réaction de l'éthyl-4*a* (ou bromoéthyl-4*a*) tétrahydro-2,3,4,4*a* carbazole avec l'ozone fournit seulement des faibles quantités du produit d'ozonolyse attendu; la réaction principale conduit à un produit de réarrangement oxydant, l'acétoxy-1 tétrahydrocarbazolénine substitué en position 4*a*.

Canadian Journal of Chemistry, **49**, 863 (1971)

In connection with our studies of synthetic pathways to compounds containing the indole nucleus, we converted the tetrahydrocarbazolenines, **1***a* and *b* (1), to the 4*a*-substituted 9-acetyl-2,3,4,4*a*-tetrahydrocarbazoles, **2***a* and *b*, by treatment with acetic anhydride. These crystalline products were characterized by elemental analysis and spectroscopy, critical features of the latter being the appearance of an amide carbonyl (5.99 μ) in the i.r. and the signals for one vinyl proton and an aromatic proton adjacent to the *N*-acetyl group (2) in the n.m.r. spectra; the methyl signal of the 4*a*-substituent in **2***a* appeared at τ 9.38, providing evidence that it still experienced some shielding from the π system, but that this effect was not as pronounced as in the parent tetrahydrocarbazolenine, **1***a* (1).



1



2

a X = H
b X = Br

It was our intention to convert the compounds of formula **2** to oxindoles of type **3** by ozonolysis, but in neither case was an oxindole the principal product of treatment of the tetrahydrocarbazole with ozone under a variety of conditions. When a solution of **2***a* or *b* in methanol at −78° was treated with ozonized oxygen under standard conditions followed by treatment of the reaction mixture with sodium iodide in acetic acid, t.l.c. of the product obtained showed that two components, one major and one minor, were present. In the case of **2***a*, the minor component was separated by chromatography and obtained as a white powder which melted in the range 88–92°. That this was the product, **3** (X = Y = Z = H), of ozonolysis and solvolysis of **2***a* is suggested on the following grounds: the molecular formula (from the high resolution mass spectrum) was $C_{14}H_{17}NO_2$, the i.r. spectrum included peaks at 2.90, 3.64, and 5.84 μ (broad and very strong suggesting that the two carbonyl peaks were superimposed), and the n.m.r. spectrum had signals at τ 0.70 and 0.90 (removed by D_2O) that could be associated with the CHO and NH protons, respectively. However, the spectra were not entirely characteristic of a single pure substance, and since the material resisted purification and conversion to useful derivatives, this component was not studied further. In the case of the reaction of ozone with **2***b*, there was some indication in the spectra of the crude product that the corresponding minor component was present, but it was not isolated in that series.

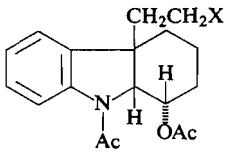
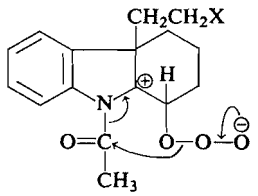
The major component in both cases was an oxidative rearrangement product to which a structure corresponding to **4** has been assigned. Compound **2***a* afforded an 80% yield of **4***a*, m.p. 75–77°, $C_{16}H_{19}NO_2$, the u.v. spectrum of which was compatible with the presence in the molecule of the proposed tetrahydrocarbazolenine chromophore, and its i.r. spectrum showed an ester carbonyl absorption at 5.72 μ in place of the amide carbonyl of **2***a*, and a peak at 6.32 μ, indicative of the presence of ArN=C in the molecule (1). The n.m.r. spectrum was particularly informative, showing the signals for the four aromatic protons in the range τ 2.4–3.0, the methyl triplet of the 4*a*-substituent at τ 9.62, a position that has been found to be characteristic of 4*a*-ethyltetrahydrocarbazolenines (1), the acetyl methyl at τ 7.86, and the C*H*OAc proton as a four-line pattern centered at τ 4.50, the appearance of which was consistent with its being the X part of an ABX system with $|J_{AX} + J_{BX}| \sim 18$ Hz. The low τ value for this proton can be attributed to the presence of the adjacent C=N moiety and its multiplicity indicates that it is axial with one axial–axial and one axial–equatorial coupling to an adjacent CH_2 group. These observations consequently lead us to conclude that the compound has the structure and stereochemistry depicted by **4***a*. Hydrolysis converted **4***a* to the corresponding alcohol, the spectroscopic characteristics of which showed the presence of an OH group in place of the OAc group in the precursor, but were otherwise very similar to those of **4***a*. Catalytic hydrogenation of **4***a* in the presence of acetic anhydride converted it to an uncrystallizable viscous oil to which structure **5***a* is assigned. The u.v. spectrum is that of an *N*-acetylhexahydrocarbazole; the i.r. spectrum shows both carbonyl peaks, the ester at 5.74 μ and the amide at 6.01 μ, and the absence of the 6.3 μ band; the n.m.r. spectrum now has the methyl triplet of the 4*a* side chain at τ 9.26, the OAc singlet is at τ 7.80, and a three-proton singlet at τ 8.52 assigned, despite its high value indicative of unusual shielding, to the NAc protons. Two one-proton signals, a multiplet at τ 4.62 assigned to the C-1 proton, and a doublet with $J = 5$ Hz at τ 5.90 assigned to the C-9*a* proton, which could be decoupled by double irradiation, provide strong support for the structural assignments in **5***a*, and the value of the coupling constant is indicative of an axial–equatorial relationship between the protons and is in accord with the stereochemistry shown in **5***a*. This evidence provides confirmation for stereostructure **4***a* assigned to the ozonization product, and suggests that the catalytic hydrogenation has followed a path leading to the *cis*-fused hexahydrocarbazole, a stereochemical outcome we have recently demonstrated for certain other 4*a*-substituted tetrahydrocarbazolenines (1, 3).

In a completely analogous manner, **2***b* reacted with ozone to afford in 85% yield a product, m.p. 148–149°, $C_{16}H_{18}NO_2Br$, to which the structure **4***b* is assigned. The spectroscopic characteristics of **4***b* corresponded closely to those of **4***a*, all differences being just those expected on the basis of the difference in chemical constitution. Although attempted hydrolysis led only to an intractable oil, catalytic hydrogenation of **4***b* in acetic anhydride smoothly converted it to **5***b*, which bore the expected spectroscopic relationship to **5***a* except that the n.m.r. signal of the C-9*a* proton was very much broader, indicative of a difference in conformational mobility of **5***a* and *b*. One further feature of the n.m.r. spectrum of **5***b* was that the signal for the CH_2Br protons appeared at τ 6.88, while for its precursor **4***b*, in which the shielding effect already noted is expected, the corresponding signal was probably buried in the envelope of absorption at higher field.



5



6

a X = H
b X = Br

The conversion of compounds **2** to **4** by ozone is an unusual reaction for which we can find no direct precedent. Although the details of the mechanism of the reaction of ozone with carbon–carbon double bonds are still a subject of some controversy and it is probable that no single mechanism is followed in all reactions (4), there is general agreement that an adduct, or molozonide, in which a carbon–carbon linkage is still intact is formed first, followed by a rearrangement to form an ozonide in which the two carbon atoms are no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

longer directly bonded to each other. It is clear in the cases described here that the major product, **4**, is formed by a reaction that diverts the process before the ozonide is reached, and this is supported by the observations that much less than an equivalent of iodine was liberated in the reductive work-up of the reaction mixture and that **4** was also obtained in exploratory runs in which the work-up employed oxidative conditions. On the other hand, the minor product, **3**, appears to result from a process which incorporates the cleavage of the carbon–carbon linkage and the formation of an ozonide. (However, since there is no evidence bearing on the timing of the solvolysis that also occurs, it is still possible that this reaction does not follow the "ordinary" ozonolysis pathway.) Although a number of possible mechanisms can be suggested to account for the formation of **4**, the most economical description of the process in terms of present theories of the ozonization reaction is given in **6**.

NOTE ADDED IN PROOF

Professor S. Fliszár, to whom we extend our thanks for his interest and courtesy, has kindly pointed out to us that **2** represents a special case of a heavily substituted (and rigid) *cis* olefin, a class of compounds that he has demonstrated (5) follows an "abnormal" ozonolysis pathway, and he feels that an "abnormal" route (related to that which leads to epoxide formation) seems plausible in this case. A referee has pointed out that the reported rearrangement of the epoxide of an enamide to an α-acycloxyketone under hydrolytic conditions (6) may be a related reaction. (It may be noted, however, that the enamide underwent a normal ozonolysis.)

Experimental

Melting points were determined on a Thomas–Kofler micro hot stage. The i.r. spectra were obtained on a Perkin–Elmer 237B spectrometer, u.v. spectra on a Perkin–Elmer 350 or Unicam SP800 spectrometer with solutions in Fisher "Certified" methanol, and n.m.r. spectra on a Varian A60, T60, or HA100 spectrometer with tetramethylsilane as the internal standard in the solvent indicated. Only certain significant i.r. data are reported; n.m.r. chemical shifts are reported, followed in parentheses by an indication of the multiplicity and number of protons associated with each signal or group of signals. Mass spectrometric molecular weights were determined on an AEI MS-902 mass spectrometer.

9-Acetyl-4a-ethyl-2,3,4,4a-tetrahydrocarbazole (2a)

A solution of 4*a*-ethyltetrahydrocarbazolenine (**1***a*) (1) (2.90 g; 14.5 mmol) in 10 ml acetic anhydride under a nitrogen atmosphere was stirred at 100° for 2.5 h and then at room temperature for 14 h. The acetic anhydride was removed under reduced pressure and the residue was stirred with water and extracted with methylene chloride. The extract afforded an oil (2.97 g; 12.3 mmol), which was obtained as white crystals, m.p. 68–69°, on recrystallization from hexane.

Anal. Calcd. for $C_{16}H_{19}NO$: C, 79.63; H, 7.94; N, 5.80. Found: C, 79.61; H, 7.97; N, 6.11.

The i.r (CCl_4) 5.99, 6.21 μ; u.v. max (strong absorption < 220 mμ) 257 (ε 7600), 276 (infl.), 284 mμ (infl.); n.m.r. (τ, CCl_4, 60 MHz) 2.02 (d, J = 7 Hz, with further splitting, 1), 2.7–3.2 (m, 3), 4.65 (three peaks, splitting 3 Hz, 1), 7.70 (s, 3), 7.7–8.8 (complex, 8), 9.38 (t, J = 7.5 Hz, 3).

9-Acetyl-4a-(2'-bromoethyl)-2,3,4,4a-tetrahydrocarbazole (2b)

In a manner corresponding to that used for the preparation of **2***a*, **1***b* (630 mg; 2.3 mmol) was converted to **2***b* (712 mg; 2.2 mmol). The product, after recrystallization from a hexane–acetone mixture, was obtained as white crystals, m.p. 119–120°.

Anal. Calcd. for $C_{16}H_{18}NOBr$: C, 60.02; H, 5.66; N, 4.37; Br, 24.96. Found: C, 60.25; H, 5.66; N, 4.60; Br, 24.94.

The i.r. (CCl_4) 5.99, 6.23 μ; u.v. max (strong absorption < 220 mμ), 261 (ε 6500), 275 (infl.), 283 mμ (infl.); n.m.r. (τ, CCl_4, 60 MHz) 1.98 (d, J = 7.5 Hz with further splitting, 1), 2.7–3.2 (m, 3), 4.52 (three peaks, splitting 4 Hz, 1), 6.8–7.3 (m, 2), 7.68 (s, 3), 7.7–9.0 (complex, 8).

Ozonization of 2a

Ozonized oxygen (3–5% ozone) was passed through a solution of **2***a* (0.80 g; 3.3 mmol) in 75 ml methanol at −78° until the solution turned blue. After excess ozone had been removed by a stream of nitrogen, the reaction mixture was poured into a solution of sodium iodide (20 g) in 12.5 ml acetic acid and 38 ml methanol, shaken thoroughly, and allowed to reach room temperature. The iodine liberated was discharged by titration with sodium thiosulfate (the amount corresponded to 1.2 mmol), and the solution was diluted with a large volume of water and thoroughly extracted with methylene chloride. The extract afforded a yellow oil (1.05 g) which, after its behavior on t.l.c. had been checked, was chromatographed on a column of neutral alumina. The major fraction (**4***a*), eluted with 1:1 chloroform–ether, was obtained as crystals (665 mg; 2.6 mmol) which, after recrystallization from ether–hexane, had m.p. 75–77°.

Anal. Calcd. for $C_{16}H_{19}NO_2$: C, 74.68; H, 7.44; N, 5.44. Found: C, 74.89; H, 7.61; N, 5.51.

The i.r. (CCl_4) 5.72, 6.32 μ; u.v. max (strong absorption < 220 mμ), 225 (infl.), 258 mμ (ε 7700); n.m.r. (τ, $CDCl_3$, 100 MHz) 2.4–3.0 (complex, 4), 4.50 (four lines, X part of ABX with $|J_{AX} + J_{BX}| \sim 18$ Hz, 1), 7.5–9.2 (complex, 8), 7.86 (s, 3), 9.62 (t, J = 7.5 Hz, 3).

The minor fraction, a pale yellow oil (127 mg; 0.55 mmol) eluted by 4:1 chloroform–methanol, precipitated from hexane–chloroform as a white powder which melted in the range 88–92°, but could not be recrystallized; most of the data reported here are therefore only approximate. The mol. wt. determined from mass spectrum, 231.1265;

calcd. for $C_{14}H_{17}NO_2$, 231.1259; i.r. ($CHCl_3$) 2.90, 3.64, 5.84 (vs), 6.16 μ; u.v. max (strong absorption < 220 mμ), 250 (ε 8200), 278 mμ (ε 1800); n.m.r. (τ, CCl_4, 60 MHz) 0.70 (narrow m, 1), 0.90 (broad, removed by D_2O, 1), 2.8–3.2 (m, 4), 7.4–9.0 (complex, 8), 9.40 (t, J = 7 Hz, 3).

Ozonization of 2b

A methanolic solution of **2b** (1.5 g; 4.7 mmol) was ozonized in the manner just described. The crude product was a solid which showed t.l.c. evidence for the presence of a major component and a very small amount of a second component. Recrystallization from ether–hexane yielded the principal product (**4b**) (1.35 g; 4.0 mmol) as white needles, m.p. 148–149°.

Anal. Calcd. for $C_{16}H_{18}NO_2Br$: C, 57.16; H, 5.35; N, 4.17; Br, 23.79. Found: C, 56.92; H, 5.45; N, 4.15; Br, 23.91.

The i.r. (CCl_4) 5.72, 6.30 μ; u.v. max (strong absorption < 220 mμ), 225 (infl.), 258 mμ (ε 5400); n.m.r. (τ, $CDCl_3$, 100 MHz) 2.3–2.9 (complex, 4), 4.34 (four lines, X part of ABX with $|J_{AX} + J_{BX}| \sim 18$ Hz, 1), 7.0–9.0 (complex, 10), 7.80 (s, 3).

1-Hydroxy-4a-ethyltetrahydrocarbazolenine

A solution of **4a** (42 mg; 0.16 mmol) in 6 ml methanol containing 1 ml 2 *N* aqueous sodium hydroxide was stirred under nitrogen for 10 h. The reaction afforded a colorless oil (33 mg; 0.15 mmol) from which crystals, m.p. 84–88°, that were very sensitive to air or light were obtained. The mol. wt. determined from mass spectrum, 215.1306; calcd. for $C_{14}H_{17}NO$, 215.1310; i.r. ($CHCl_3$) 2.82, 6.30 μ; u.v. max (strong absorption < 220 mμ), 225 (infl.), 253 mμ (ε 7400); n.m.r. (τ, CCl_4, 60 MHz) 2.2–2.8 (complex, 4), 5.32 (four lines, X part of ABX with $|J_{AX} + J_{BX}| \sim 18$ Hz, 1), 5.71 (broad, removed by D_2O, 1), 7.2–9.1 (complex, 8), 9.63 (t, J = 8 Hz, 3).

1-Acetoxy-4a-ethyl-9-acetyl-1,2,3,4,4a,9a-hexahydrocarbazole (5a)

A solution of **4a** (24.5 mg; 0.095 mmol) in 1 ml acetic anhydride was hydrogenated at room temperature and atmospheric pressure in the presence of pre-reduced platinum oxide. After 10 h the reaction was complete and the solution afforded a colorless oil (27 mg; 0.09 mmol). The mol. wt. determined from mass spectrum, 301.1686; calcd. for $C_{18}H_{23}NO_3$, 301.1678; i.r. (CCl_4) 5.74, 6.01 μ; u.v. max (strong absorption < 220 mμ), 254 (ε 11 900), 278 (ε 3300), 286 mμ (ε 2900); n.m.r. (τ, CCl_4, 60 MHz) 2.3 (broad, 1), 2.8–3.2 (m, 3), 4.62 (m, 1), 5.90 (d, J = 5 Hz, 1) (τ 4.62 and 5.90 signals decoupled by double irradiation), 7.80 (s, 3), 7.8–8.8 (complex, 8), 8.52 (s, 3), 9.26 (t, J = 7 Hz, 3).

1-Acetoxy-4a-(2'-bromoethyl)-1,2,3,4,4a,9a-hexahydrocarbazole (5b)

A solution of **4b** (82 mg; 0.24 mmol) in acetic anhydride was hydrogenated in the manner just described. The product was isolated as a colorless oil (87 mg; 0.23 mmol). The mol. wt. determined from mass spectrum, 379.0765; calcd. for $C_{18}H_{22}NO_3Br$, 379.0784; i.r. (CCl_4) 5.74, 6.00 μ; u.v. max (strong absorption < 220 mμ), 254 (ε 12 700), 280 (ε 3000), 287 mμ (ε 2900); n.m.r. (τ, $CDCl_3$, 100 MHz) 2.2 (broad, 1), 2.6–3.0 (m, 3), 4.46 (m, 1), 5.6–6.3 (broad, 1), 6.88 (three lines, 8.5 Hz spacing, with further fine splitting, 2) 7.67 (s, 3), 7.7–8.8 (complex, 8), 8.48 (s, 3).

We thank the National Research Council of Canada for financial support of this research, and the Canadian Commonwealth Scholarship and Fellowship Committee for a Fellowship awarded to U.O.T.

Reaction of *trans*-Chlorocarbonylbis(triphenylphosphine) Iridium(I) and its Analogues with Oxidizing Metal Salts

D. N. CASH AND R. O. HARRIS[1]

Scarborough College Chemical Laboratories, Department of Chemistry, University of Toronto, 1265 Military Trail, West Hill, Ontario

Received September 2, 1970

The effect of several oxidizing metal salts on the square planar iridium(I) complexes *trans*-$[Ir^{I}(CO)(PPh_3)_2X]$ (where $X^- = Cl^-$, Br^-, I^-, N_3^-, NCO^-, NCS^-, and NO_2^-) has been investigated. With nitrate salts of Ce(IV), Fe(III), and Cu(II), several of the reactions gave products characterized by analysis and i.r. spectroscopy as $[Ir^{III}(CO)(PPh_3)_2X(NO_3)_2]$. With $CuCl_2 \cdot 2H_2O$ and $CuBr_2$ several of the same starting materials gave products, $[Ir^{III}(CO)(PPh_3)_2XY_2]$ (where $X^- = NCO^-$, NCS^-, NO_2^- and $Y^- = Cl^-$; and $X^- = NCO^-$, NCS^-, Br^-, NO_2^- and $Y^- = Br^-$). These have been similarly characterized. An iridium(III) complex, $[Ir^{III}(PPh_3)_2(NO_3)_2H]$ has also been characterized.

L'effet de plusieurs sels métalliques oxydants sur les complexes plan carré $[Ir^{I}(CO)(PPh_3)_2X]$ *trans* (ou $X^- = Cl^-$, Br^-, I^-, N_3^-, NCO^-, NCS^-, et NO_2^-) a été étudié. Avec les nitrates de Ce(IV), Fe(III), et Cu(II), plusieurs de ces réactions ont conduit à des produits caractérisés par analyse et spectroscopie i.r. comme étant $[Ir^{III}(CO)(PPh_3)_2X(NO_3)_2]$. Avec le $CuCl_2 \cdot 2H_2O$ et $CuBr_2$ plusieurs des mêmes composés de départ ont fourni $[Ir^{III}(CO)(PPh_3)_2XY_2]$ (où $X^- = NCO^-$, NCS^-, NO_2^- et $Y^- = Cl^-$; et $X^- = NCO^-$, NCS^-, Br^-, NO_2^- et $Y^- = Br^-$). Ces derniers ont été caractérisés de la même manière. Un complexe d'iridium(III), $[Ir^{III}(PPh_3)_2(NO_3)_2H]$ a aussi été caractérisé.

Canadian Journal of Chemistry, 49, 867 (1971)

Introduction

Reactions of *trans*-chlorobis(triphenylphosphine) carbonyliridium(I) and its analogues have been discussed in some detail (*1*, *2a*). The reactions described here are very much like the oxidative addition reaction (eq. 1) which is characteristic of iridium(I) d^8-square planar compounds. However, in this case (eq. 2), oxidation is carried out by an oxidizing metal cation, with the ligand which is to enter the co-ordination sphere of the iridium already present in its ionic form.

Oxidative addition:

[1] $$[Ir^{I}(CO)P_2X] + Y_2 \rightarrow [Ir^{III}(CO)P_2XY_2]$$

Reaction under discussion:

[2] $$[Ir^{I}(CO)P_2X] + 2M^{n+}(Y)_n \rightarrow [Ir^{III}(CO)P_2XY_2] + 2M^{(n-1)+}(Y)_{n-1}$$

($P = PPh_3$ in all complexes)

In some cases, as when chlorine is the oxidizing agent, use of reaction 1 can lead to the decomposition or replacement of other ligands in the complex (*2b*); use of method 2 can avoid such complications. Also, as will be described, use of the latter method can introduce unusual ligands such as nitrate into the co-ordination sphere (eq. 3).

[3] $$[Ir^{I}(CO)P_2X] \xrightarrow[\text{acetone}]{M(NO_3)_n} [Ir^{III}(CO)P_2X(NO_3)_2]$$

These dinitrato species are not stable indefinitely in solution and, under some conditions, the decomposition products can be characterized. When the complex $[Ir^{III}(CO)P_2(NCO)(NO_3)_2]$ is left standing, in the open air and light, in a solution mixture of chloroform and ethanol, reaction 4 occurs.

[4] $$[Ir^{III}(CO)P_2(NCO)(NO_3)_2] \xrightarrow[\text{Several days}]{CHCl_3/EtOH} [Ir^{III}P_2(NO_3)_2H]$$

Results and Discussion

Infrared Spectroscopy

The compounds reported have been characterized mainly by analysis and i.r. spectroscopy. The latter can be discussed, for the purposes required here, in four sections.

(i) Co-ordinated Nitrato Ligand

The vibrational absorptions characteristic of a co-ordinated nitrate ion are understood on the basis of a lowering of the D_{3h} symmetry of the free ion to C_{2v} (or lower) symmetry when co-ordination through one or more of the oxygen

[1]Author to whom communications should be directed.

TABLE 1. Reaction of $[Ir(CO)(PPh_3)_2X]$ with metal nitrate salts, in acetone at room temperature*

Compound X^- in $[Ir(CO)(PPh_3)_2X]$	Nitrate salt		
	$(NH_4)_2Ce^{IV}(NO_3)_6$	$Fe^{III}(NO_3)_3 \cdot 9H_2O$	$Cu^{II}(NO_3)_2 \cdot 3H_2O$
Cl^-	CO lost	CO retained	CO retained
Br^-	CO lost	CO retained	CO retained
I^-	CO lost	CO retained	CO retained
NCO^-	CO, NCO^- retained	CO, NCO^- retained	CO, NCO^- retained
N_3^-	CO, N_3^- retained	CO, N_3^- retained	CO, N_3^- retained
NCS^-	CO, NCS^- retained	CO, NCS^- retained	CO, NCS^- retained
NO_2^-	No product obtained	Some CO retained, NO_2^- lost	Some CO retained, NO_2^- lost

*Notes:
(*i*) Absorptions due to triphenylphosphine indicated that this ligand was retained in each reaction (6).
(*ii*) In each case that it was observed, the position of ν_{CO}, the carbonyl stretching mode, indicated that oxidation to Ir(III) had occurred.
(*iii*) In each case, modes due to coordinated nitrato ligand were observed (3).

atoms occurs (3). Absorption in the regions ~1500, ~1250, ~950, and ~800 cm^{-1} indicates a co-ordinated rather than an ionic nitrate group. However, it is impossible, without reference compounds, to deduce the mode of co-ordination from the band positions (4). Moreover, since the observed spectra are all those of solid state mulls, correlation coupling effects may be observed (5). For this reason, no deductions about *cis* or *trans* stereochemistry for the nitrato ligands can be made. This restriction also applies to the dichloro and dibromo complexes described below.

(ii) Carbonyl Ligand

Co-ordinated carbon monoxide exhibits well known i.r. absorptions, in both the C—O stretching region, and the M—C—O bending and M—C stretching region. The C—O stretch is often taken as being characteristic of the oxidation state of the iridium in a given compound ranging from ~1950 cm^{-1} in iridium(I) to ~2080 cm^{-1} in iridium(III) complexes.

(iii) Triphenylphosphine Ligand

The vibrational spectrum of this ligand, both free and complexed, has been assigned (6), and can be separated from the absorptions due to other ligands in these complexes.

(iv) Other Ligands

The ligands isocyanate (NCO^-) (7), azide (N_3^-) (8), thiocyanate (NCS^-) (9), and nitrite (NO_2^-) (10) all exhibit characteristic frequencies in the i.r., depending on whether, and in what manner, they are co-ordinated to a metal. In each case, an asymmetric and symmetric stretching mode, and a bending mode may be observed, along with a metal-ligand mode. In the case of halide as ligand, only the latter metal-halide mode is expected.

Reactions with Nitrate Salts

The products obtained when $[Ir^I(CO)P_2X]$ (where $X^- = Cl^-$, Br^-, I^-, NCO^-, N_3^-, NCS^-, and NO_2^-) was reacted with the nitrate salts of several oxidizing metal cations are described in Table 1. In each case, the solid complex was added to a solution or slurry of excess salt in acetone at room temperature. The product was obtained by adding several volumes of water, filtering off, and drying with ethanol and ether, and then examined by running a Nujol mull i.r. spectrum of the solid. The position of the carbonyl absorption was taken (if present) as an indication of the oxidation state of the metal. Similarly the modes due to triphenylphosphine, nitrato, and other ligands could also be observed.

Some features of the results deserve comment. None of the products recovered when X^- was NO_2^- contained any nitro modes in the i.r. spectrum; in the case of Ce(IV) ion oxidation, no product could be recovered because of the formation of an emulsion. In Ce(IV) oxidation, when $X^- = Cl^-$, Br^-, or I^-, carbon monoxide was clearly absent from the products. This was true even when these reactions were repeated at acetone/carbon dioxide bath temperatures. In the case of $X^- = I^-$, although an apparently satisfactory product was obtained by reaction with Fe(III) or Cu(II) nitrates, in fact it proved impossible to reprecipitate an analytically acceptable sample of the desired $[Ir(CO)(PPh_3)_2I(NO_3)_2]$ from these reactions. Whether some loss of carbon monoxide or some other side

reaction occurs during the oxidation, or the desired product is unstable in solution, is not known.

The products, $[Ir^{(III)}(CO)P_2X(NO_3)_2]$ (where $X^- = Cl^-$, Br^-, NCO^-, N_3^-, NCS^-) are all sparingly soluble in solvents such as benzene, chloroform, or dichloromethane, and insoluble in ethanol, ether, or pentane. They can be reprecipitated from suitable solvent combinations, with the solids so formed giving the analytical results shown in Table 2. The solid state Nujol mull i.r. spectra are described in Table 3. None of these compounds is sufficiently soluble in chloroform ($<0.005\ M$) to give a reliable molecular weight.

From Table 3 it will be seen that all these compounds exhibit the i.r. absorptions characteristic of co-ordinated nitrato-ligand. In these compounds bands are seen at ~1520 (strong to very strong), ~1280 (strong to very strong), ~970 (medium), and ~780 cm^{-1} (weak). The relative intensities of these bands to each other are essentially the same in all the compounds, but the splitting patterns do vary; the weak but sharp absorption at ~780 cm^{-1} is unsplit in each.

A compound of formula $[Ir^{III}(CO)P_2Cl(NO_3)_2]$ has been reported (11) as the product of reacting $[Ir^{I}(CO)P_2Cl]$ with nitric acid in tetrahydrofuran. This material, however, has a reported i.r. spectrum which is not the same as that reported here. This difference is not due to the fact that the compound reported here is a chloroform solvate, since a recrystallization from benzene solution with ether gave a non-solvated product in extremely low yield, which gave satisfactory analysis, and showed virtually identical i.r. absorptions as the solvated product, including the sharp mode at ~780 cm^{-1}.

Reactions with Cu(II) Halides

To demonstrate the general use of this reaction, the dichloro and dibromo adducts of several iridium(I) species were prepared (eq. 5).

$$[5]\qquad [Ir^{I}(CO)P_2X] \xrightarrow[\text{acetone}]{CuY_2} [Ir^{III}(CO)P_2XY_2]$$

$$X^- = NCO^-, NCS^-, NO_2^-;\ Y^- = Cl^-, Br^-$$

In addition, since it has been reported that the addition of bromine to $[Ir^{I}(CO)P_2Br]$ does not proceed simply in chloroform (12), an addition was carried out using $CuBr_2$ in acetone (eq. 6)

$$[6]\qquad [Ir^{I}(CO)P_2Br] \xrightarrow[\text{acetone}]{CuBr_2} [Ir^{III}(CO)P_2Br_3]$$

The products of all these reactions are described in Tables 2 and 3.

The carbonyl stretching frequency of the complex $[Ir^{III}(CO)(PPh_3)_2Br_3]$ observed here (2076 cm^{-1}, very strong, sharp) is in agreement with that previously reported (12), but in this case no absorptions due to impurities or by-products are observed.

Hydridodinitratobis(triphenylphosphine)-iridium(III)

This compound, of formula $[Ir^{III}(PPh_3)_2(NO_3)_2H]$, was first prepared accidentally. A sample of the compound $[Ir^{III}(CO)(PPh_3)_2$-

$(NCO)(NO_3)_2$] had been prepared by precipitation from dichloromethane with ether and the solid was found to contain a molecule of solvent (dichloromethane) in the crystal. In order to carry out a proposed molecular weight in chloroform, a reprecipitation from chloroform with ethanol was attempted. The solution stood at room temperature for several days, during which time it became progressively more yellow in color, and pale yellow crystals began to deposit. This solid was found to have quite different properties from the starting material, which is white. The analytical details and i.r. spectrum are given in Tables 2 and 3. The compound is diamagnetic (Gouy Method), and a molecular weight (M) determination in chloroform ($\sim$0.01 M) gave $M = 840 \pm 20$.

The analytical results suggest an empirical formula $[Ir(PPh_3)_2(NO_3)_2]$ ($M = 840$), and this is confirmed by the molecular weight results. However, since the material is diamagnetic, and exhibits a weak but definite i.r. absorption at $\sim$2270 cm^{-1}, the formula $[Ir^{III}(PPh_3)_2(NO_3)_2H]$ has been assigned. The position of the Ir—H stretching mode is in agreement with the previously reported complexes of formulae $[Ir^{III}(PPh_3)_2Br_2H]$ (13) and $[Ir^{III}(PPh_3)_2Cl_2H]$ (14) which are at 2250 and 2242 cm^{-1} respectively. Unfortunately, the solubility of this compound ($\sim$0.02 M in $CDCl_3$) is insufficient to allow the observation of a high-field metal hydride resonance in the n.m.r. (attempted on a Varian T60).

The absence of any carbonyl or isocyanate modes in the i.r., where they would normally be very intense, is indicative that both these ligands have been lost during the reaction. The nature of the reaction route is unclear, though it has been shown that the same procedure without ethanol (or methanol) present gives other, less easily characterized products.

*Indicates that observed splittings may be due to the presence of more than one isomer and/or solid state effects. Notes:
(*i*) v, very; w, weak; m, medium; s, strong; br, broad; sp, sharp; sh, shoulder.
(*ii*) All spectra were recorded as Nujol mulls of the solids, employing polyethylene, KBr, or KRS-5 plates, or some combination to obtain the range 200–2500 cm^{-1}.
[a]Absorptions due to ligand triphenylphosphine are present in each compound, and are omitted from this table (6).
[b]Carbonyl stretching modes, νCO.
[c]Carbonyl bending modes, δMCO (17).
[d]Iridium–chlorine stretching modes, νIr–Cl.
[e]Unassigned modes.
[f]Asymmetric isocyanate stretching modes, ν_3NCO.
[g]Symmetric isocyanate stretching modes, ν_1NCO.
[h]Asymmetric thiocyanate stretching modes, ν_3NCS.
[i]Symmetric thiocyanate stretching modes, ν_1NCS; the observed absorptions are characteristic of N-bonded thiocyanate (9).
[j]The absorption is an overlapping of νCO and the asymmetric stretching mode, ν_3N_3, of the azido ligand (8).
[k]The absorption is an overlapping of νCO and the asymmetric stretching mode, ν_3NCS, of the thiocyanate.
[l]These are modes due to N-bonded nitrite ligand (10).
[m]Iridium–hydride stretching modes, νIr–H.

The pattern of the nitrato modes, and the splitting of the mode at 770 cm^{-1} suggest that there may be more than one type of nitrate co-ordination with one mono- and one bidentate nitrate group. However, based only on a solid mull spectrum, this is speculation. It will be noted that this compound is much less reactive than $[Ir^{III}(PPh_3)_2Cl_2H]$ (14), and this might be rationalized if the molecule was indeed six co-ordinate, since the co-ordinately saturated iridium would then be much less reactive. In fact, $[Ir^{III}(PPh_3)_2(NO_3)_2H]$ is not reactive to $CHCl_3$, EtOH, CCl_4, or PPh_3; it does interact with CO, to give an as yet uncharacterized product.

Experimental

All reagents and solvents were reagent or solvent grade used as supplied. The i.r. spectra were recorded on a Beckman I.R. 12 spectrophotometer. The molecular weight measurement was made with a Hewlett-Packard Mechrolab 302 osmometer, in chloroform solution. Analyses were by A. Gygli of Toronto, and Huffman Laboratories of Colorado.

trans-[Ir^I(CO)(PPh$_3$)$_2$Cl]

This material was prepared by a standard method (15) from a variety of chloroiridium complexes. The material was then used without recrystallization.

trans-[Ir^I(CO)(PPh$_3$)$_2$Br]

This was prepared by a standard route (15), from $K_2[Ir^{IV}Br_6]$.

trans-[Ir^I(CO)(PPh$_3$)$_2$X] (X$^-$ = NCO$^-$, N$_3^-$, NCS$^-$)

These were all prepared from *trans*-$[Ir^I(CO)(PPh_3)_2Cl]$ through exchange of the chloride ligand with the ligand X^-. The $[Ir^I(CO)(PPh_3)_2Cl]$ and a 100-fold excess of the sodium or potassium salt of the ligand X^- were refluxed in acetone (10 ml per 0.1 g of Ir(I) complex). After 15 min, the solution was cooled by diluting with several volumes of water. A yellow solid product rapidly separated, was filtered off, washed well with water, ethanol, and ether, and dried under vacuum, yield: up to 100%. The products have i.r. spectra in agreement with those from previously reported preparations.[2]

[2]For X = NCO and NCS see ref. 16*a*; for X = NCS, N_3, and I see ref. 16*b*.

trans-[Ir^{I}(CO)(PPh$_3$)$_2$I]

This was prepared exactly as above, from [Ir^{I}(CO)(PPh$_3$)$_2$Cl] and KI, but the procedure was carried out under nitrogen until the product had separated out. The solid is air stable, and has i.r. absorption in agreement with those from previous preparations.[2]

trans-[Ir(CO)(PPh$_3$)$_2$NO$_2$]

This was prepared by the reaction of [Ir^{I}(CO)(PPh$_3$)$_2$Cl] (0.3 g) and KNO_2 (5 g) in acetone (600 ml). The acetone was degassed by boiling under nitrogen prior to adding the solid reagents. The solids were then added and the solution was refluxed under nitrogen for 1 h, when water (1200 ml) was added to precipitate the product. The water had previously been degassed by boiling under nitrogen. The yellow solid is stable in air, but is extremely oxygen sensitive in solution. The bright yellow product was washed with water, ethanol and ether, and dried under vacuum, yield ~95%.

The analytical and i.r. spectral details for the compound are given in Tables 2 and 3. The absorptions at 1375, 1338, and 815 cm^{-1} indicate an *N*-bonded nitrite (nitro) group (10).

[Ir^{III}(CO)(PPh$_3$)$_2$Cl(NO$_3$)$_2$] · 1½(CHCl$_3$)

The [Ir^{I}(CO)(PPh$_3$)$_2$Cl] (0.25 g) was added with excess solid $Cu(NO_3)_2 \cdot 3H_2O$ (0.5 g) to acetone (20 ml) at room temperature, and the resulting green slurry was stirred for 5 min, during which time it became blue. The solvent was removed under vacuum. The product was extracted with three portions of chloroform (8 ml each), and the resulting solution filtered several times. This pale yellow solution was then slowly diluted with several volumes of *n*-pentane, giving fine white fibrous crystals over several days, which were filtered off and dried under vacuum, yield 0.20 g.

[Ir^{III}(CO)(PPh$_3$)$_2$Br(NO$_3$)$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$Br] (0.21 g) was added with excess $Cu(NO_3)_2 \cdot 3H_2O$ (0.5 g) to acetone (20 ml) at room temperature and the initially green slurry stirred for several minutes, during which time it became blue. This slurry was then diluted to 115 ml with water, and after some minutes the resulting yellow solid was filtered from the pale blue solution, and washed with water, ethanol, and ether. The solid was then dissolved in chloroform, and the resulting solution (bright yellow, 10 ml) filtered. This solution was diluted to 200 ml with ether, and after several hours the resulting pale yellow powder was filtered off, washed with ether, and dried under vacuum, yield 0.069 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCO)(NO$_3$)$_2$] · (CH$_2$Cl$_2$)

The [Ir^{I}(CO)(PPh$_3$)$_2$NCO] (0.30 g) was added to a stirring solution of $(NH_4)_2Ce^{IV}(NO_3)_6$ (0.8 g) in acetone (20 ml) at room temperature. The solid rapidly dissolved in the orange solution, and addition of water (80 ml) gave a white product. The solid was filtered off, washed with water, ethanol, and ether, and dried. The crude product was reprecipitated by dissolving in a minimum of dichloromethane, in which it is sparingly soluble, filtering, and adding several volumes of ether. The solid rapidly separated as white needles, which were filtered off and washed with ether, and dried in vacuum, yield ~0.15 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCS)(NO$_3$)$_2$]

This is prepared exactly as the isocyanate complex above, but crystallizes as a white solid with no CH_2Cl_2 in the crystal, yield ~40%.

[Ir^{III}(CO)(PPh$_3$)$_2$N$_3$(NO$_3$)$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$N$_3$] (0.39 g) was stirred with $Fe^{III}(NO_3)_3 \cdot 9H_2O$ (0.5 g) in acetone (20 ml) at room temperature for several minutes. Then the slurry was diluted to 100 ml with water. A brownish solid was filtered off and washed with water, ethanol, and ether. The crude solid was reprecipitated after dissolving in a minimum of dichloromethane, filtering, and adding several volumes of ether. The product, a silky, pale brown solid, separated rapidly and was collected and washed with ether, and dried in vacuum, yield 0.22 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCO)Cl$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$NCO] (0.11 g) was added as a solid to $CuCl_2 \cdot 2H_2O$ (0.3 g) stirring in acetone (15 ml) at room temperature. After some 10 min, the slurry was diluted to 40 ml with water. The resulting white solid was filtered from the blue solution and washed with water, ethanol, and ether. This crude product was reprecipitated from chloroform (10 ml) after filtration of the solution and addition of methanol (30 ml). The product, a yellow powder, separated over several hours at −5 °C, yield 0.050 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCO)Br$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$NCO] (0.11 g) was reacted with $CuBr_2$ (0.3 g) exactly as in the preceding preparation. The crude product was reprecipitated from chloroform (10 ml) by filtration of the bright yellow solution, followed by addition of methanol (35 ml). The bright yellow solid separated rapidly, yield 0.080 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCS)Cl$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$NCS] (0.15 g) was reacted with $CuCl_2 \cdot 2H_2O$ (0.4 g) as above. The crude product was reprecipitated from chloroform (8 ml) by filtration of the pale yellow–green solution, followed by addition of methanol (35 ml). The product pale yellow solid separated over several hours at −5 °C, yield 0.11 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NCS)Br$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$NCS] (0.11 g) was reacted with $CuBr_2$ (0.3 g) as above. The crude product was reprecipitated from chloroform (10 ml) by filtration of the bright yellow solution and addition of methanol (35 ml). The product, a bright yellow solid, separated rapidly, yield 0.10 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NO$_2$)Cl$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$(NO$_2$)] (0.128 g) was reacted with $CuCl_2 \cdot 2H_2O$ (0.3 g) as above. The product was reprecipitated from dichloromethane solution (20 ml, brownish yellow) with methanol (80 ml). The product, a pale yellow solid, separated rapidly, yield 0.070 g.

[Ir^{III}(CO)(PPh$_3$)$_2$(NO$_2$)Br$_2$]

The [Ir^{I}(CO)(PPh$_3$)$_2$(NO$_2$)] (0.156 g) was reacted with $CuBr_2$ (0.3 g) exactly as above. The product was repre-

cipitated from chloroform (35 ml, bright yellow solution) with methanol (85 ml). The product, a bright yellow solid, separated within minutes, yield 0.065 g.

[$Ir^{III}(CO)(PPh_3)_2Br_3$]

The [$Ir^{I}(CO)(PPh_3)_2Br$] (0.13 g) was reacted with $CuBr_2$ (0.3 g) as above. The crude product is very sparingly soluble in chloroform (100 ml), from which it was reprecipitated after filtration by the addition of ether (300 ml). The product, a bright yellow solid, was collected after several hours at −5 °C, yield 0.052 g.

[$Ir^{III}(PPh_3)_2(NO_3)_2H$]

The [$Ir^{III}(CO)(PPh_3)_2NCO(NO_3)_2$] · ($CH_2Cl_2$) (0.3 g, prepared as above) was dissolved in chloroform (20 ml) and the pale yellow solution was filtered. Ethanol (25 ml) was added, and the resulting solution left at room temperature in a stoppered flask, in air and light. After 2 days, the solution became more brightly yellow and yellow crystals were deposited. When no further solid was formed, the solution was diluted with ethanol, to 150 ml total volume. After another day, the product yellow solid, mostly powder, was filtered off, yield 0.125 g.

Thermal and Photochemical Ring Expansion of Some Phosphole Derivatives

A. N. HUGHES AND CHIT SRIVANAVIT
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

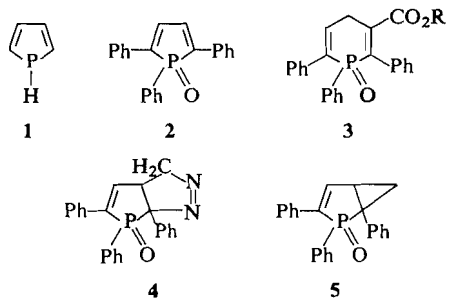
Received August 28, 1970

Pyrolysis and photolysis of 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide and the 1:1 adduct of diazomethane with 1,2,5-triphenylphosphole oxide lead to the formation of compounds of formula $C_{46}H_{36}O_2P_2$ and $C_{46}H_{34}O_2P_2$, respectively. These compounds are shown to be derivatives of the 4,4′-diphosphabi(cyclohexa-1,5-dienyl) and 4,4′-diphosphabi(cyclohexa-2,5-dienylidene) systems, respectively, and possible mechanisms for the formation of these systems are briefly discussed.

La pyrolyse et la photolyse du triphényl-3,4,5 phospha-4 bicyclo[3.1.0]hexène-2 oxyde-4 et du produit d'addition 1:1 du diazométhane avec l'oxyde du triphényl-1,2,5 phosphole conduisent respectivement à la formation de composés de formule $C_{46}H_{36}O_2P_2$ et $C_{46}H_{34}O_2P_2$. Il est démontré que ces composés sont respectivement des dérivés des systèmes du diphospha-4,4′ bis(cyclohexadienyl-2,5) et du diphospha-4,4′ bis(cyclohexadienylydène-2,5). Les mécanismes possibles pour la formation de ces systèmes sont discutés brièvement.

Canadian Journal of Chemistry, 49, 874 (1971)

Unsaturated six-membered ring phosphorus heterocycles, particularly the phosphorins, have received considerable attention recently, and several synthetic routes to these systems have been developed (1). It is well known that pyrrole derivatives will undergo ring expansion reactions to give pyridine derivatives, sometimes in good yield. For example, pyrrole on treatment with methylene chloride and methyl lithium gives pyridine in 32% yield (2). In principle then, phosphole (**1**) derivatives should also undergo ring expansion reactions although not necessarily by the same mechanistic path as for pyrrole derivatives. Indeed, certain 9-phosphafluorene (dibenzophosphole) derivatives have already been shown to undergo ring expansion on treatment with methyl propiolate in the presence of water (3) or with methylene iodide followed by alkaline hydrolysis (4). There is, however, only one report of the ring expansion of a simple phosphole derivative (5). In this reaction, treatment of 1,2,5-triphenylphosphole oxide (**2**) with methyl diazoacetate in boiling dioxan leads to the formation of the phosphacyclohexa-2,5-diene derivative **3** (R = Me). The same workers showed that reaction of the phosphole oxide **2** with diazomethane followed by treatment of the intermediate pyrazolino derivative **4** with copper in boiling diglyme leads to the formation of 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (**5**) which could possibly be a convenient starting material for ring expansion reactions of the phosphole system. Moreover, it was observed (5) that this compound resolidifies above its m.p. to give a dark red compound which was not further investigated. The following is therefore an account of the thermal and photochemical ring expansion reactions of **4** and **5**.

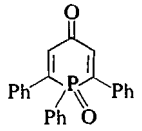


1 **2** **3** **4** **5**

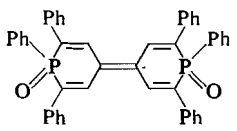
The cyclopropano derivative **5** was carefully pyrolyzed in a Woods metal bath at 238° until gas evolution ceased and the material turned dark brown and resolidified. The crude product was recrystallized from a chloroform/ethanol mixture and a good yield of a deep orange compound, m.p. 386–387°, was obtained. Pyrolysis of **5** under vacuum gives a slightly higher yield of the same compound. The high m.p. and very low solubility of the pyrolysis product indicate a higher molecular weight than the starting material. Elemental analyses are consistent with a formula of $C_{46}H_{38}O_2P_2$, $C_{46}H_{36}O_2P_2$, or $C_{46}H_{34}O_2P_2$, *i.e.* a dimer of the starting material, a dimer minus H_2, or a dimer minus $2H_2$, although trimeric structures cannot be entirely ruled out. Because of the highly involatile nature of the product, its mol. wt. could not be determined by mass spectrometry. However, pyrolysis of **5** under high vacuum ($< 4 \times 10^{-7}$ Torr) followed by mass spectrometric analysis of the gas evolved showed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

that hydrogen is given off in substantial amounts during the reaction and that water is not a significant product. This suggests that thermal dimerization of **5** occurs with elimination of hydrogen and, therefore, the molecular formula $C_{46}H_{38}O_2P_2$ can be tentatively ruled out.

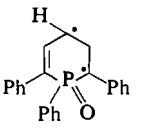


6

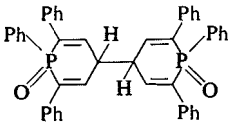


7

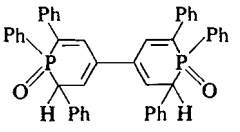
A compound of molecular formula $C_{46}H_{34}O_2P_2$ having two unsaturated phosphorus-containing six-membered rings has previously been prepared (6) by treatment of 1,2,6-triphenyl-1-phosphacyclohexa-2,5-diene-4-one-1-oxide (**6**) with triethylphosphite to give 3,3′,4,4′,5,5′-hexaphenyl-4,4′-diphosphabi(cyclohexa-2,5-dienylidene)-4,4′-dioxide (**7**). This compound melts at 425–428° and shows λ_{max} at 324.5 and 437 mμ. It is therefore not identical with the pyrolysis product of **5** which shows in ethanol λ_{max} (log ε) at 315 (483) and 408 mμ (4.87). Furthermore, the i.r. spectrum (Nujol) of the pyrolysis product shows a typical P=O stretching band at 1180 cm^{-1} and the n.m.r. spectrum (in trifluoroacetic acid) shows a ratio of 17 aromatic and olefinic protons (complex multiplet at τ 2.01–3.13) to one tertiary proton (very broad unresolved hump at τ 6.11). The n.m.r. evidence then is consistent with the formula $C_{46}H_{36}O_2P_2$.



8

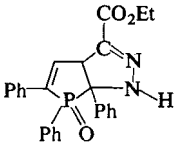


9

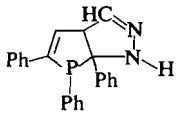


10

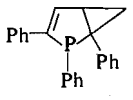
A number of modes of reaction are open to the cyclopropane **5** on pyrolysis. For example, the vinylcyclopropane → cyclopentene type of rearrangement (7) could possibly occur although this seems unlikely in this case since the products would contain little conjugation. A more likely mode of reaction is one in which one of the three bonds of the cyclopropane ring (probably the bond forming the ring junction) is cleaved to give a diradical such as **8** which dimerizes and eliminates molecular hydrogen to give **9** or **10**. However, since mechanistic studies were not undertaken, a dipolar mechanism cannot be ruled out. Clearly structure **9** may be discarded because there would be insufficient conjugation to account for the u.v. spectrum although this structure is consistent with the n.m.r. spectrum. Moreover, the related structure **3** is colorless (5). Cleavage of the other bonds of the cyclopropane ring followed by dimerization and elimination of hydrogen would again give products containing too little conjugation to account for the u.v. spectrum. Thus, it seems that structure **10** is the most likely structure for the pyrolysis product since it fits all the evidence available at this point.



11



12



13

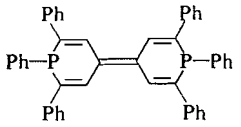
The same compound is obtained in good yield (60%) by pyrolysis of **4** under vacuum at 238° although pyrolysis of the related compound **11** yields only the phosphacyclohexadiene **3** (R = Et) in excellent yield (75%). Reduction of **4** and **5** with trichlorosilane in dry benzene (8) gives the corresponding tertiary phosphines **12** and **13** respectively in good yield (60 and 73% respectively) but pyrolysis of these phosphines only gives general decomposition and no ring expanded products could be isolated. It should also be noted that in the reduction of **4** to **12**, a prototropic shift occurs to give the 2-pyrazoline structure rather than the 1-pyrazoline structure which is present in **4**. Evidence for this comes from the fact that in the i.r. spectrum of **12** there is a strong N—H stretching absorption at 3280 cm^{-1} which is not present in the i.r. spectrum of **4**. The prototropic shift is not unexpected since the reduction of **4** is carried out under acidic conditions and it is known (9) that 1-pyrazolines isomerize under these conditions to give the corresponding 2-pyrazolines.

Irradiation of the cyclopropane **5** in dry, peroxide-free tetrahydrofuran under dry, oxygen-free nitrogen with a medium pressure mercury

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

lamp (100 W) through pyrex for 8 days gives a 44% yield of a deep orange compound (m.p. 439–440°) similar, but not identical, to the pyrolysis product. Irradiation of the pyrazoline **4** under similar conditions gives a 14% yield of the same compound.

Elemental analyses of the photolysis product are in excellent agreement with the formula $C_{46}H_{34}O_2P_2$. The u.v. spectrum shows λ_{max}(log ε) at 325 (4.53) and 438 mμ (4.91) which confirms extensive conjugation in the molecule. The i.r. spectrum shows a typical P=O stretching vibration at 1169 cm^{-1} and the n.m.r. spectrum (in trifluoroacetic acid) shows only aromatic and olefinic protons as a complex multiplet at τ 2.22–2.96. The m.p. of the photolysis product is very similar to that of Märkl's compound **7** (6) and the n.m.r. spectrum is in good agreement with this structure. The u.v. spectrum is virtually identical with that of compound **7** (although Märkl does not quote values for the extinction coefficients) and it therefore appears that the photolysis product has structure **7**.



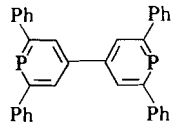
14

Confirmation of this structure is provided by the fact that it may be reduced to the corresponding phosphine **14** by treatment first with phosphorus pentachloride to give an unisolated deep red *P,P,P',P'*-tetrachloro compound which is reduced smoothly to **14** with lithium aluminum hydride as briefly outlined by Märkl (6). The sample of **14** isolated is identical (m.p. and u.v. spectrum) with that described by Märkl (6) and the molecular weight was confirmed as 648 by mass spectrometry.

The mechanism of formation of the photolysis product **7** is again uncertain although it is probable that an intermediate such as **8** is involved. However, both further pyrolysis at 380° under vacuum of the initial pyrolysis product **10** and irradiation of the same compound in dry, peroxide-free tetrahydrofuran under nitrogen for several days leave the material unchanged and it therefore seems likely that **10** is not an intermediate in the formation of **7**. Since the irradiation of **5** occurs over a very long period of time, ring enlargement to a phosphacyclohexadiene of type **3** (without the CO_2R group) followed by photo-oxidation by trace amounts of oxygen to give **6** which condenses with unoxidized material to give **7** cannot be excluded. However, both pyrolysis and irradiation of the phosphacyclohexadiene **3** (R = Et) under conditions very similar to those used for **5** for extended periods result in virtually complete recovery of the starting material and the intermediacy of **6** and its phosphacyclohexadiene precursor in the photolysis of **5** therefore seems unlikely.

Irradiation of **12** and **13** under similar conditions gives only some general decomposition and recovery of some starting material.

Turning again to the pyrolysis product tentatively assumed to be **10**, treatment of this compound with a large excess of phosphorus pentachloride followed by reduction of the intermediate deep-red *P,P,P',P'*-tetrachloro compound with lithium aluminum hydride gives the 4,4'-diphosphabi(cyclohexa-2,5-dienylidene) system **14** identical in all respects with an authentic sample. This, then, confirms the basic skeleton of the pyrolysis product. Final confirmation of the ring structure of the compound assigned structure **10** comes from the fact that on treatment with ethereal lithium aluminum hydride alone, it is transformed into the photolysis product **7** in good yield. A similar reaction occurs between the pyrolysis product and sodium hydride in benzene. The mechanisms of these last two reactions are obscure but, in view of all the foregoing evidence, the structures of the pyrolysis and photolysis products of **4** and **5** are established as **10** and **7** respectively.



15

Compounds of type **14** (with the P—Ph grouping replaced by the P—CH_2Ph grouping) have recently been found (10) to be converted into the previously unknown biphosphorinyl system **15** on heating and it is possible that pyrolysis or irradiation of compounds such as **12** or **13**, in which the P—Ph grouping is similarly replaced by the P—CH_2Ph grouping, could lead directly to the biphosphorinyl system.

Attempts to prepare other compounds of type

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

5 by addition of dichlorocarbene or dibromocarbene to **2** were unsuccessful.

Experimental

The i.r. spectra were recorded in Nujol mulls using a Beckman IR12 spectrophotometer while u.v. spectra were obtained on dilute ethanol or chloroform solutions using a Unicam SP800 spectrophotometer. The n.m.r. measurements were made with a Varian Associates model A60-A spectrometer using deuteriochloroform or trifluoroacetic acid solutions with tetramethylsilane as internal reference. Mass spectra were determined using an Hitachi–Perkin–Elmer model RMU-7 double focussing mass spectrometer fitted with a direct heated inlet system. Melting points are uncorrected and were recorded using a Mel-Temp high-temperature m.p. apparatus.

Ether was dried by distillation from sodium or lithium aluminum hydride while tetrahydrofuran and benzene were dried by distillation from calcium hydride.

1,2,5 - Triphenylphosphole, 1,2,5 - triphenylphosphole oxide (**2**), the phosphacyclohexadiene **3** (R = Et), 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (**5**), and the pyrazolines **4** and **11** were prepared by the method of Campbell (5).

*Reduction of **4** and **5** with Trichlorosilane*

A solution of the pyrazoline **4** (4.0 g, 10.82 mmol) in dry benzene (200 ml) was treated with a large excess of trichlorosilane (15 g, 110.5 mmol) and the mixture was heated under reflux in a slow stream of dry nitrogen for 48 h. With ice-bath cooling and vigorous stirring, the reaction mixture was then treated slowly with water (100 ml) until evolution of hydrogen chloride ceased. The mixture was filtered and the benzene layer was separated and washed with water (3 × 50 ml) as was the residue in the funnel. All of the washings were added to the acidic aqueous layer. The aqueous solution was neutralized with dilute aqueous sodium hydroxide, saturated with sodium chloride, and extracted with chloroform (3 × 50 ml). The chloroform extracts were combined, dried over anhydrous sodium sulfate, and evaporated to dryness under reduced pressure. The crude solid was recrystallized from hot ethanol to give long colorless needles (2.3 g, 60%) of the pyrazoline **12**, m.p. 211–212° (dec.).

Anal. Calcd. for $C_{23}H_{19}N_2P$: C, 77.95; H, 5.36; N, 7.91; P, 8.77. Found: C, 77.67; H, 5.46; N, 8.04; P, 8.54.

The i.r. spectrum shows ν_{max} at 3280, 1596, 1490, 1443, 1431, 1329, 1300, 1201, 1119, 1084, 1065, 1040, 1024, 1019, 998, 946, 910, 899, 880, 850, 814, 758, 740, and 690 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max} at 224 and 250 mμ and the n.m.r. spectrum ($CDCl_3$) shows 16 aromatic and olefinic protons at τ 2.32–3.06, one amino proton at 3.39, and two methine protons at 4.47. The mass spectrum shows a strong molecular ion peak at *m/e* 354.

3,4,5-Triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (**5**) (5.0 g, 14.62 mmol) was reduced in a similar manner with trichlorosilane (20 g, 147.7 mmol) to give the bicyclic phosphine **13** (3.5 g, 73%) as colorless needles, m.p. 134–135° (dec.).

Anal. Calcd. for $C_{23}H_{19}P$: C, 84.63; H, 5.84; P, 9.53. Found: C, 84.71; H, 5.94; P, 9.38.

The i.r. spectrum shows ν_{max} at 1601, 1580, 1495, 1445, 1432, 1304, 1269, 1095, 1088, 1072, 1022, 1000, 935, 911, 902, 871, 851, 828, 760, 751, 698, and 688 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max} (log ε) at 214.5 (4.50) and 267 mμ (4.24). The n.m.r. spectrum ($CDCl_3$) shows a ratio of 16 aromatic and olefinic protons (complex multiplet at τ 2.43–3.12) to one methine proton (multiplet centered at τ 7.32) to two methylene protons (multiplet centered at τ 8.82). The mass spectrum shows a very strong molecular ion peak at *m/e* 326.

Pyrolysis of 3,4,5-Triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (5)

A pure sample of the cyclopropane **5** (1 g, 2.92 mmol) was carefully pyrolyzed in a Woods metal bath at 238° until gas evolution ceased and the material turned dark brown and resolidified. The crude product was washed with ether followed by ethanol and the reddish-yellow solid left was recrystallized from a hot chloroform/ethanol mixture to give orange crystals (0.47 g, 47%) of 3,3′,4,4′,5,5′-hexaphenyl-4-4′-diphosphabi(cyclohexa-1,5-dienyl)-4,4′-dioxide (**10**), m.p. 386–387° (dec.).

Anal. Calcd. for $C_{46}H_{36}O_2P_2$: C, 80.91; H, 5.28; P, 9.08. Found: C, 80.46; H, 5.33; P, 9.34.

The i.r. spectrum shows ν_{max} at 3062, 2862, 1606, 1500, 1465, 1442, 1352, 1180, 1117, 1079, 1041, 900, 770, 754, 703, 670 cm^{-1}. The u.v. spectrum in chloroform shows λ_{max} (log ε) at 315 (4.83) and 408 mμ (4.87) and the n.m.r. spectrum in trifluoroacetic acid shows a ratio of 17 aromatic and olefinic protons (complex multiplet at τ 2.01–3.13) to one tertiary proton (very broad unresolved hump centered at τ 6.11).

The experiment was repeated on the same quantity of material at the same temperature in an evacuated (< 4 × 10^{-7} Torr) small cylindrical tube fitted with a high vacuum tap to which was attached a 10/30 ℧ glass cone such that the reaction tube could be connected directly to the liquid inlet of the mass spectrometer. A yield of 51% of **10** was obtained and mass spectral analysis of the gas evolved showed a ten-fold increase in the intensity of the H_2 peak over the background but no significant increase in the water peak.

*Pyrolysis of the Pyrazoline **4***

The pyrazoline (1 g, 2.7 mmol) was carefully pyrolyzed under vacuum (*ca.* 1 Torr) in a Woods metal bath at 238° until gas evolution ceased and the dark brown material resolidified. The crude product was worked-up as before to give orange crystals of the pyrolysis product **10** (0.55 g, 60%).

*Pyrolysis of the Pyrazoline Ester **11***

The pyrazoline ester (2.0 g, 4.53 mmol) in an evacuated (*ca.* 1 Torr) tube was pyrolyzed at 220–225° in a Woods metal bath for 20 min. The crude product was washed with a little ether and the off-white solid left was recrystallized from a benzene/light petroleum (60°–80°) mixture to give colorless needles (1.4 g, 75%) of ethyl 1,2,6-triphenyl-1-phosphacyclohexa-2,5-diene-3-carboxylate-1-oxide (**3**, R = Et), m.p. 217–218°, identical in all respects (m.p., i.r., n.m.r., mass spectrum) with a sample prepared by Campbell's method (5).

Photolysis of 3,4,5-Triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (5)

A solution of the cyclopropane **5** (3 g, 8.76 mmol) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dry, peroxide-free tetrahydrofuran (1000 ml) was irradiated under dry, oxygen-free nitrogen with a medium pressure mercury lamp (100 Watt) through pyrex for 8 days. After evaporation of the mixture to dryness, the crude solid was digested with ethanol to remove starting material and the residue was recrystallized from a hot chloroform/ethanol mixture to give orange crystals (1.3 g, 44%) of 3,3′,4,4′,5,5′-hexaphenyl-4,4′-diphosphabi(cyclohexa-2,5-dienylidene)-4,4′-dioxide (**7**), m.p. 436–438° (lit. (6) m.p. 425–428°).

Anal. Calcd. for $C_{46}H_{34}O_2P_2$: C, 80.90; H, 4.98; P, 9.06. Found: C, 80.64; H, 4.90; P, 9.45.

The i.r. spectrum shows ν_{max} at 1604, 1490, 1463, 1443, 1336, 1245, 1169, 1106, 1075, 1066, 1031, 937, 887, 771, 750, 698 cm^{-1}. The u.v. spectrum in chloroform shows λ_{max} (log ε) at 325 (4.53) and 438 mμ (4.91) and the n.m.r. spectrum in trifluoroacetic acid shows only aromatic and olefinic protons as a complex multiplet at τ 2.22–2.86.

Irradiation of the pyrazoline **4** (8 g, 21.65 mmol) under very similar conditions gave the same product (1.0 g, 14%).

*Reduction of the Photolysis (**7**) and Pyrolysis (**10**) Products with Phosphorus Pentachloride and Lithium Aluminum Hydride*

The photolysis product **7** (0.1 g, 0.15 mmol) was fused with a large excess of phosphorus pentachloride (3 g, 14.51 mmol) at 120–130° until the mixture turned deep red (1 h). The excess of phosphorus pentachloride was removed by sublimation at 100° under vacuum. With Dry Ice/acetone cooling, the resulting deep red powder was treated dropwise with saturated ethereal lithium aluminum hydride under dry nitrogen until gas evolution ceased and the mixture was allowed to warm slowly to room temperature. The excess of hydride was decomposed with water-saturated ether, water (100 ml) was then added, and the ether removed under vacuum. The resulting aqueous suspension was extracted with chloroform (3 × 10 ml) and the chloroform extracts were combined and dried over anhydrous sodium sulfate. The chloroform solution was then evaporated to dryness and the crude solid was washed with ethanol and recrystallized from a hot chloroform/ethanol mixture to give red crystals (0.07 g, 74%) of 3,3′,4,4′,5,5′-hexaphenyl-4,4′-diphosphabi(cyclohexa-2,5-dienylidene) (**14**), m.p. 338–340° (lit. (6) m.p. 335–337°).

Anal. Calcd. for $C_{46}H_{34}P_2$: C, 85.18; H, 5.24; P, 9.57. Found: C, 84.37; H, 5.32; P, 9.50.

Good analyses are difficult to obtain since the compound crystallizes with up to 4% occluded chloroform which is very difficult to remove. Pumping the compound at 180–200° under high vacuum leads to slow loss of the chloroform but, even under vacuum, oxygen scavenging also takes place and slow oxidation of **14** occurs.

The i.r. spectrum shows ν_{max} at 3075, 1618, 1500, 1446, 1438, 1369, 1350, 1250, 1100, 1041, 941, 922, 889, 861, 776, 767, 749, 718, 700, and 694 cm^{-1}, *i.e.* the P=O bond present in the spectrum of **7** at 1169 cm^{-1} has vanished. The u.v. spectrum in chloroform shows λ_{max} (log ε) at 339 (3.88) and 468 mμ (4.64) (lit.(6) λ_{max} 337 and 467 mμ). The n.m.r. spectrum in trifluoroacetic acid shows only aromatic and olefinic protons as a complex multiplet at τ 2.18–2.87. The mass spectrum shows a molecular weight of 648.

Reduction of the pyrolysis product **10** (0.5 g, 0.73 mmol) with phosphorus pentachloride (15 g, 72.55 mmol) and lithium aluminum hydride under very similar conditions also gave **14** (0.4 g, 84%).

As stated by Märkl (6) the phosphine **14** is air stable but with traces of acid it oxidizes back to **7** very rapidly.

*Treatment of the Pyrolysis Product **10** with Lithium Aluminum Hydride*

With cooling (Dry Ice/acetone) and vigorous stirring, a suspension of the pyrolysis product **10** (0.6 g, 0.88 mmol) in dry ether (60 ml) was treated dropwise with a solution of lithium aluminum hydride (0.34 g, 8.82 mmol) in dry ether under dry nitrogen. The temperature of the reaction mixture was allowed to rise to room temperature and the mixture was maintained at this temperature for a further 15 min. Destruction of the excess hydride was carried out with water saturated ether. Water (60 ml) was added and the mixture was evaporated until ether-free. The resulting aqueous suspension was extracted with chloroform (3 × 60 ml). The chloroform extracts were combined, dried over anhydrous sodium sulfate, and evaporated to dryness. The crude solid was washed with ethanol and recrystallized from a hot chloroform/ethanol mixture to give orange crystals (0.55 g, 92%) of 3,3′,4,4′,5,5′-hexaphenyl-4,4′-diphosphabi(cyclohexa-2,5-dienylidene)-4,4′-dioxide (the photolysis product **7**) identical in all respects with an authentic sample.

The same reaction occurs with sodium hydride.

Alkaline Hydrolysis of 1-Iodomethyl-1,2,5-triphenylphospholium Iodide, a New Route to the 4-Phosphabicyclo[3.1.0]hex-2-ene System

A. N. Hughes and Chit Srivanavit
Department of Chemistry, Lakehead University, Thunder Bay, Ontario

Received September 25, 1970

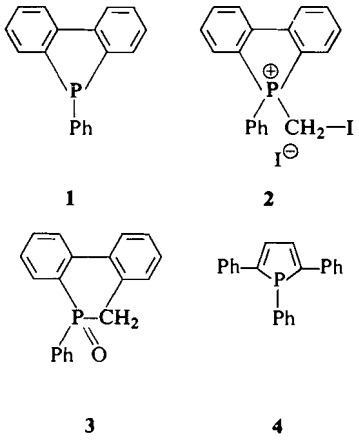
Alkaline hydrolysis of 1-iodomethyl-1,2,5-triphenylphospholium iodide gives 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide in very high yield. Three possible mechanisms are discussed and isolation of a key intermediate allows one of these mechanisms to be discarded. Alkaline hydrolysis of 1-allyl-1,2,5-triphenylphospholium bromide in methanol gives 1,2,5-triphenylphosphole and small quantities of a compound $C_{26}H_{27}O_2P$ which is an adduct of the original phospholium ion, hydroxide ion, and methanol.

L'hydrolyse alcaline de l'iodure de l'iodométhyl-1 triphényl-1,2,5 phospholium donne le triphényl-3,4,5 phospha-4 bicyclo[3.1.0]hexène-2 oxyde-4 avec un excellent rendement. Trois mécanismes possibles sont discutés; un de ceux-ci peut toutefois être rejeté en se basant sur le fait qu'un intermédiaire important a pu être isolé. L'hydrolyse alcaline du bromure d'allyl-1 triphényl-1,2,5 phospholium dans le méthanol donne le triphényl-1,2,5 phosphole et de petites quantités d'un composé en $C_{26}H_{27}O_2P$ qui est un produit d'addition de l'ion phospholium original avec l'ion hydroxyle et le méthanol.

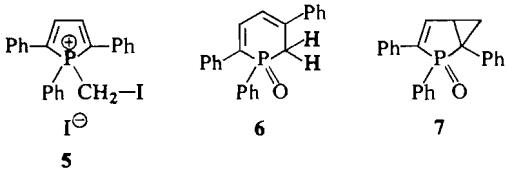
Canadian Journal of Chemistry, 49, 879 (1971)

Ring expansion reactions of the phosphole system have been comparatively little explored as possible routes to six-membered unsaturated phosphorus heterocycles (1–4). One approach, due to Millar (3), involves the reaction of 9-phenyl-9-phosphafluorene (the dibenzophosphole **1**) with methylene iodide to give the salt **2** which on treatment with hydroxide ion gives **3** (in very good yield) by cleavage of the phosphole ring in the manner observed by Bergesen (5) followed by attack of the resulting carbanion (which migrates from the apical position of a trigonal bipyramidal intermediate (3)) upon the methylene group and displacement of iodide ion. This type of 1,2-migration has been shown to be fairly general in the hydrolysis of suitably substituted phosphonium compounds and similar ring expansions occur in the phosphetan system (6).

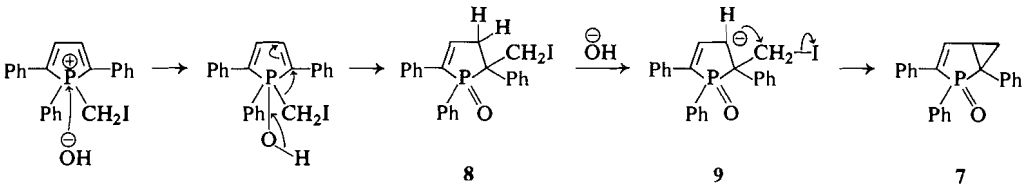
Simple phospholes are now relatively easily available (7) and the above reaction applied to simple phospholes could prove to be a convenient route to phosphorins, particularly those with unsymmetrical substitution patterns. In order to explore this possibility, 1,2,5-triphenylphosphole (**4**) was treated with methylene iodide in a pressure bottle for $4\frac{1}{2}$ days to give an excellent yield of the corresponding phospholium iodide **5**. Alkaline hydrolysis of **5** was expected to give the phosphacyclohexa-2,4-diene **6** since the five-membered ring should occupy an apical–equatorial arrangement in the expected trigonal bipyramidal intermediate (6) but, rather surprisingly, a 74% yield of 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (**7**) (identical with an authentic sample (1)) was obtained when **5** was treated with aqueous methanolic sodium hydroxide for 24 h under reflux followed by acidification of the reaction mixture. This bicyclic compound has recently been shown (4) to be of value in the synthesis of six-membered ring phosphorus heterocycles.



1 **2** **3** **4**

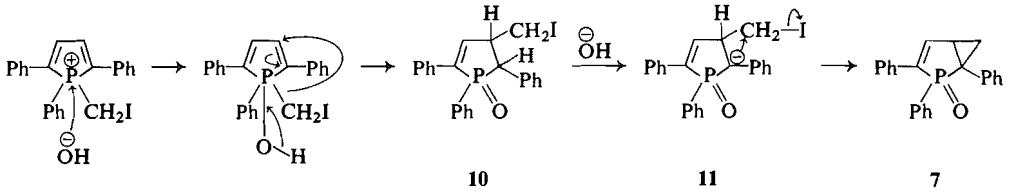


5 **6** **7**



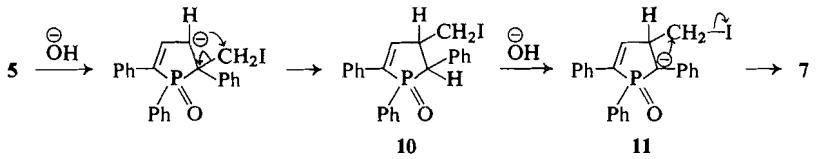
8 9 7

SCHEME 1



10 11 7

SCHEME 2



10 11

SCHEME 3

There are several possible mechanisms for the formation of **7** from **5**. At first sight perhaps the most likely of these is a 1,2-migration of the iodomethyl group followed by proton abstraction by hydroxide ion and ring closure involving expulsion of iodide ion as shown in Scheme 1. However, hydroxide ion abstraction of the allylic protons would seem unlikely. This reaction would parallel the 1,2-migrations observed (6) in other phosphonium salt hydrolyses but it would imply that, in this case, the five-membered ring does not occupy an apical–equatorial arrangement in the intermediate or that in the case of **2**, a $-CH_2I$ migration of the type outlined in Scheme 1 is inhibited by the fused nature of the ring system.

A second possible mechanism is illustrated in Scheme 2. In this case a 1,3-migration of the iodomethyl group occurs and the intermediate carbanion **11** could be to some extent stabilized by overlap with the d-orbitals of the neighboring phosphorus atom. However, this would be a most unusual type of rearrangement which would be difficult to account for except that it involves attack at the β-position of a vinylphosphonium type of system.

A third possibility[1] (Scheme 3) is that the intermediate **10** is formed by two consecutive 1,2-shifts of the iodomethyl group rather than a single 1,3-shift. The driving force for the second of these migrations would presumably come from the conversion of an allylic carbanion type of intermediate into the protonated α-phosphoryl benzylic carbanion **10**.

If any of these reaction schemes operates and if the predicted intermediate **8** or **10** has a significant lifetime it could possibly be isolated. Therefore, in an attempt to isolate the predicted intermediate, the reaction was carried out under much milder conditions at room temperature for 2 h. The product (obtained in good yield) was not **7** but analyzed well for $C_{23}H_{20}OPI$ and the mass spectrum confirmed the molecular weight as 470. The i.r. spectrum shows a typical P=O stretching vibration at 1180 cm^{-1} and the u.v. spectrum (ethanol) shows λ_{max}(log ε) at 220 (4.33) and 261 mμ (4.07), indicating considerable loss of conjugation relative to **5**. The n.m.r. spectrum shows a ratio of 16 aromatic and olefinic protons

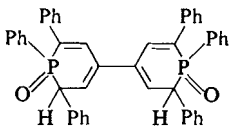
(complex multiplet at τ 2.19–3.16) to two methylene or methine protons (multiplet at τ 5.52–6.08) to two methylene protons (multiplet at τ 6.65–7.02). That the compound is not a mixture of **8** and **10** was shown by a detailed t.l.c. examination on both alumina and silica of various activities using several solvent systems.

In our opinion, this evidence fits structure **10** considerably better than it fits structure **8**. Thus, structure **8** contains two allylic methylene protons which could possibly account for the multiplet in the n.m.r. spectrum at τ 6.65–7.02, although a signal at somewhat higher field would be expected. However, this would mean that the methylene protons of the iodomethyl group would be responsible for the signal at τ 5.52–6.08 which is clearly at too low field for such protons even bearing in mind the probable deshielding effect of the P=O grouping. Indeed, even in **5**, where the deshielding effect of the neighboring phosphonium grouping (8) is at a maximum, the methylene protons appear only as low as τ 5.68.

Equally, if the n.m.r. signal assignments for **8** are reversed, the signal at τ 6.65–7.02 would agree well with that expected for the methylene protons of the iodomethyl group (*cf.* ethyl iodide (9)) but the signal at τ 5.52–6.08 is again at too low field for the allylic methylene group which is relatively remote from the P=O grouping and attached to only a mildly electron-withdrawing group. Such a signal would be unlikely to occur below τ 7 unless some additional strong deshielding effect were present. For example, even in allyl bromide, where deshielding is very strong, the allylic methylene protons still resonate at τ 6.07 (10). The additional deshielding effect could conceivably be provided by the neighboring phenyl group but, if this were the case, it seems unlikely that both of the non-equivalent protons would be deshielded to the same extent bearing in mind the probable stereochemistry of the system.

On the other hand, in structure **10**, the signal at τ 6.65–7.02 agrees well with that expected for the iodomethyl group as in ethyl iodide (9) and the signal at τ 5.52–6.08 could be generated by the two tertiary protons both of which are allylic (or benzylic) and adjacent to electron-withdrawing groups. Furthermore, the benzylic protons in **12** have been shown to resonate in the same region at τ 6.11 (4).

It is worth noting that the side-chain methylene



12

group of **10** appears as a multiplet of at least five peaks rather than a doublet in the n.m.r. spectrum. This is almost certainly because the two methylene protons are non-equivalent due to the adjacent asymmetric center since long-range coupling with the phosphorus atom would be very small. Such a case is similar to that of the diastereomeric methylene protons of 1,2-dichloropropane (11). The methine protons appear as a multiplet because of coupling with each other, the non-equivalent methylene protons and the phosphorus atom. In structure **8**, the protons in both methylene groups would be non-equivalent due to the neighboring asymmetric center so that the multiplicities of the signals are of little value in distinguishing between **8** and **10**. Also, the fact that both **8** and **10** could be mixtures of the various possible stereoisomers cannot be ignored.

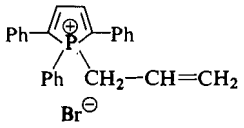
Further treatment of **10** with sodium hydroxide in aqueous methanol under reflux for 24 h gives an almost quantitative yield of the cyclopropane **7**. This supports our tentative conclusion that **10** (and not **8**) is the intermediate isolated since it is unlikely that the protons of the allylic methylene group in **8** would be sufficiently acidic to be abstracted by hydroxide ion whereas benzylic protons of the type present in **10** and **12** are known to be abstractable by strong base (4). The compound assumed to be **10** is also converted very rapidly into **7** on treatment with sodium hydride in rigorously dried (molecular sieves) dimethylformamide. This, then, strongly suggests that **10** is formed as an intermediate in the alkaline hydrolysis of **5** and that the reaction proceeds via Schemes 2 or 3. Attempts to reduce the side-chain iodomethyl group of **10** with lithium aluminum hydride gave only resinous materials.

In a final attempt to confirm the identity of **10**, deuterium exchange studies were undertaken. Thus, it was observed that a solution of the compound assigned structure **10** in perdeuteroacetone containing NaOD and D_2O showed no exchange (n.m.r. studies) at room temperature over a period of 2 days. Treatment of the same compound in rigorously dried (molecular sieves) di-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

methylsulfoxide with NaOD and D_2O resulted in the formation of **7**. The reaction was complete in little over a minute and n.m.r. measurements showed no incorporation of deuterium into the product. A solution of the compound assigned structure **10** in perdeuteroacetone containing NaOD and D_2O was heated under reflux until about 75% conversion into **7** had occurred (approximately 30 min). The n.m.r. studies of the mixture of the product and starting material showed that no deuterium exchange had occurred in the starting material (the peaks at τ 6.65–7.02 and 5.52–6.08 remained of equal area) and that no deuterium had been incorporated into **7**. These studies are inconclusive in that they do not favor either structure **10** or structure **8**. They show only that the proton abstraction steps **8** → **9** (Scheme 1) or **10** → **11** (Schemes 2 and 3) are not reversible under the conditions used and that intramolecular cyclization occurs before reprotonation can occur. However, in our opinion, all the evidence available strongly favors structure **10** in preference to structure **8** for the hydrolysis intermediate $C_{23}H_{20}OPI$.

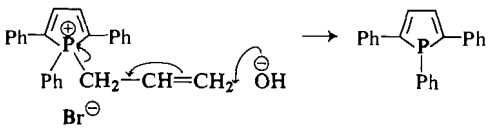
Similar experiments were carried out with 1-allyl-1,2,5-triphenylphospholium bromide (**13**) in order to see if any corresponding migration of the allyl group occurs.



13

The quaternary salt **13** is readily prepared in very high yield by heating the phosphole **4** with allyl bromide in dry benzene under reflux for several days. Treatment of the quaternary salt with aqueous methanolic sodium hydroxide at room temperature gives at least two products together with large amounts of oily material. The first of these is the phosphole **4**, *not* its oxide as would be expected from normal attack (5) of hydroxide ion at the phosphorus atom, and it therefore appears that attack occurs at the terminal carbon atom of the allyl group with displacement of the neutral phosphole **4** as shown in Scheme 4.

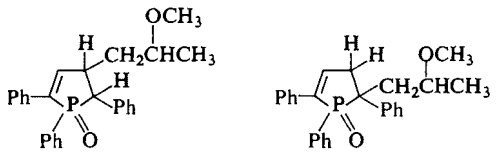
The second product, obtained in very small quantities, is a colorless material analyzing for $C_{26}H_{27}O_2P$ and which is therefore an adduct of



13 **4**

SCHEME 4

the phospholium ion **13**, hydroxide ion, and methanol. The mass spectrum confirms the molecular weight as 402 and elemental analyses show the presence of one methoxy group. The u.v. spectrum shows λ_{max}(log ε) at 219.5 (4.27) and 258 mμ (4.01) indicating that the diphenylbutadiene portion of the molecule is no longer intact and that the molecule contains little unsaturation. The i.r. spectrum shows P=O and ether-type C—O stretching vibrations at 1170 and 1105 cm^{-1} respectively. The n.m.r. spectrum shows 16 aromatic and olefinic protons as a complex multiplet at τ 2.15–3.14, three methoxy protons as a sharp singlet at 6.97, five methylene and/or methine protons as a complex multiplet at 5.81–7.99, and three methyl protons as a doublet (J = 6 Hz) at 9.0. Since the methoxy protons appear as a sharp singlet in the n.m.r. spectrum, the methoxy group is not attached to the phosphorus atom because this would give a doublet due to ^{31}P coupling (12).



14 **15**

It therefore seems likely that migration of the allyl group has occurred and that some kind of addition of methanol to the unsaturated portion of the allyl group has also occurred to give a methyl group adjacent to a tertiary proton. Since only very small quantities of the product were available, the structure determination was not completed. However, structures **14** and **15** are consistent with all the evidence (with **14** preferred by analogy with **10**) but, apart from migration of the allyl group to the 2- or 3-position of the phosphole ring, it is difficult to visualize the reaction sequence which could lead to these structures. Some further evidence for the proposed structures **14** and **15** is given by the u.v. spectrum which is almost identical with that of **10**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and by the mass spectrum which shows a very intense peak at *m/e* 329 corresponding to loss of the allylic or tertiary $-CH_2CH(OMe)CH_3$ group and another strong peak at *m/e* 328 which suggests that the oxide of the phosphole **4** is regenerated on electron impact. The peak at *m/e* 329 is also present in the spectrum of the product tentatively assigned structure **10** but is much weaker. This is presumably due to the easy loss of the iodine atom which would lead to a different major fragmentation pattern. The structure of this adduct must, however, remain in doubt pending a complete structure determination.

Experimental

The i.r. spectra were recorded in Nujol mulls using a Beckman IR12 spectrophotometer while u.v. spectra were obtained on dilute ethanol solutions using a Unicam SP800 spectrophotometer. The n.m.r. measurements were made with a Varian Associates model A60-A spectrometer using trifluoroacetic acid or deuteriochloroform solutions with tetramethylsilane as internal reference. Mass spectra were determined using an Hitachi–Perkin–Elmer model RMU-7 double focussing mass spectrometer.

1,2,5-Triphenylphosphole was prepared by the method of Campbell (1).

1-Iodomethyl-1,2,5-triphenylphospholium Iodide (5)

A well-mixed paste of 1,2,5-triphenylphosphole (10 g, 32.05 mmol) and methylene iodide (26 g, 96.95 mmol) in a pressure bottle under dry nitrogen was kept with constant stirring at 80–85° for 4½ days. When cooled, the reaction mixture turned to a dark brown solid which was broken up and washed thoroughly with acetone. The yellow residue (17 g, 91%) was found to be almost pure 1-iodomethyl-1,2,5-triphenylphospholium iodide, m.p. 174–175° (dec.).

Anal Calcd. for $C_{23}H_{19}I_2P$: C, 47.59; H, 3.28; I, 43.79; P, 5.34. Found: C, 47.74; H, 3.45; I, 43.82; P, 5.37.

Attempts to recrystallize the yellow powder from a number of solvents such as benzene, chloroform, acetone, ethanol, methanol, water, acetic acid, dimethylformamide, and mixed solvents were unsuccessful and the material was therefore used directly for further investigation.

The i.r. spectrum of **5** shows ν_{max} at 1579, 1538, 1491, 1472, 1447, 1441, 1384, 1371, 1318, 1302, 1259, 1233, 1168, 1161, 1110, 1080, 1031, 1000, 946, 923, 860, 800, 766, 750, 740, 730, 700, 690 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max}(log ε) at 225 (4.58), 275 (3.71), and 411 mμ (4.19). The n.m.r. spectrum in trifluoroacetic acid shows a ratio of 17 aromatic and olefinic protons (complex multiplet at τ 1.75–2.76) to two methylene protons (doublet centered at τ 5.68 with J_{HP} = 8 Hz).

Complete Alkaline Hydrolysis of 1-Iodomethyl-1,2,5-triphenylphospholium Iodide (5)

To a suspension of the quaternary salt **5** (8 g, 13.79 mmol) in methanol (800 ml) was added slowly a 10% aqueous solution of sodium hydroxide (55 ml, 137.6 mmol) at room temperature with vigorous stirring. After the addition was complete, the reaction mixture was heated under reflux for 24 h. The cooled solution was then treated dropwise with dilute aqueous hydrochloric acid until it was just acidic to litmus paper. Water (200 ml) was added and the mixture was evaporated under reduced pressure to remove most of the methanol. The aqueous suspension was then extracted with chloroform (3 × 100 ml). The extracts were combined, dried over anhydrous sodium sulfate, reduced to a volume of 50 ml, and chromatographed on a silica gel column using chloroform as the eluent. Evaporation of the eluate to dryness yielded a pale yellow solid which was recrystallized from hot ethanol to give very pale yellow crystals (3.5 g, 74%) of 3,4,5-triphenyl-4-phosphabicyclo[3.1.0]hex-2-ene-4-oxide (7), m.p. 234–235° (dec.), identical in all respects with an authentic sample (1).

Incomplete Alkaline Hydrolysis of 1-Iodomethyl-1,2,5-triphenylphospholium Iodide (5)

To a suspension of the quaternary salt **5** (12 g, 20.68 mmol) in methanol (1200 ml) was added slowly a 10% aqueous solution of sodium hydroxide (83 ml, 207.1 mmol) at room temperature followed by vigorous stirring for 2 h. The solution was then treated dropwise with dilute aqueous hydrochloric acid until it was just acidic to litmus paper. Water (300 ml) was added and the mixture was evaporated under reduced pressure to remove most of the methanol. The aqueous suspension was extracted with chloroform (3 × 50 ml) and the extracts were combined, dried over anhydrous sodium sulfate, and evaporated to dryness. The dark brown residue was dissolved in the minimum amount of benzene and chromatographed on a column of silica gel using successively benzene and chloroform as eluents. The benzene fraction, upon evaporation, yielded a colorless solid which was recrystallized from a hot benzene/cyclohexane mixture to give long colorless needles (5.6 g, 58%) of 4-iodomethyl-1,2,5-triphenyl-2-phospholene-1-oxide (**10**), m.p. 199–200° (dec.).

Anal. Calcd. for $C_{23}H_{20}OPI$: C, 58.71; H, 4.26; I, 27.08; P, 6.60. Found: C, 59.01; H, 4.25; I, 27.09; P, 6.60.

The i.r. spectrum shows ν_{max} at 3058, 1601, 1587, 1499, 1438, 1422, 1304, 1268, 1180, 1159, 1148, 1104, 1068, 1025, 1000, 918, 881, 824, 792, 760, 748, 719, 699, 691 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max}(log ε) at 220 (4.33) and 261 mμ (4.07). The n.m.r. spectrum in deuterated chloroform shows a ratio of 16 aromatic and olefinic protons (complex multiplet at τ 2.19–3.16) to two tertiary protons (multiplet at τ 5.52–6.08) to two methylene protons (multiplet of at least five peaks at τ 6.65–7.02). The mass spectrum shows a good molecular ion peak at *m/e* = 470.

The chloroform fraction, upon evaporation to dryness yielded pale yellow crystals of 7 (0.7 g, 10%) identical in all respects with an authentic sample.

Alkaline Hydrolysis of 4-Iodomethyl-1,2,5-triphenyl-2-phospholene-1-oxide (10)

To a solution of the 2-phospholene oxide **10** (1 g, 2.13 mmol) in methanol (100 ml), was added slowly a 10% aqueous solution of sodium hydroxide (8.5 ml, 21.28 mmol) at room temperature with vigorous stirring. After

the addition was complete, the mixture was heated under reflux for 24 h. The cooled solution was treated dropwise with dilute hydrochloric acid until it was acidic to litmus paper and the mixture was worked-up and chromatographed in chloroform solution as before. The eluate from the silica column yielded a pale yellow solid which was crystallized from hot ethanol to give very pale yellow crystals (0.65 g, 90%) of the cyclopropane **7** identical in all respects with an authentic sample.

*1-Allyl-1,2,5-triphenylphospholium Bromide (**13**)*

The phosphole **4** (15 g, 48.09 mmol) and allyl bromide (29 g, 240 mmol) in dry benzene (500 ml) were heated under reflux in a dry nitrogen atmosphere for 5 days. The yellow solid which separated was collected and recrystallized from hot water or a hot methanol/benzene mixture to give yellow crystals (19 g, 91%) of 1-allyl-1,2,5-triphenylphospholium bromide (**13**), m.p. 202–203° (dec.).

Anal. Calcd. for $C_{25}H_{22}BrP$: C, 69.26; H, 5.07; Br, 18.52; P, 7.15. Found: C, 68.97; H, 5.01; Br, 19.05; P, 7.10.

The i.r. spectrum shows ν_{max} at 3038, 1635, 1610, 1579, 1490, 1443, 1344, 1313, 1259, 1190, 1154, 1108, 1078, 1030, 998, 981, 939, 906, 878, 813, 761, 748, 726, 685 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max} (log ε) at 212 (4.52), 227 (4.58), and 410 mμ (4.12). The n.m.r. spectrum in deuterated chloroform shows a ratio of 20 aromatic and olefinic protons (complex multiplet at τ 1.26–2.96) to two methylene protons (poorly defined quartet centered at τ 5.27).

*Alkaline Hydrolysis of 1-Allyl-1,2,5-triphenylphospholium Bromide (**13**)*

A solution of the quaternary salt **13** (1.4 g, 3.24 mmol) in methanol (70 ml) was treated dropwise with a 10% aqueous solution of sodium hydroxide (6.5 ml, 16.25 mmol) at room temperature with constant stirring for 10 min. Water (50 ml) was added and the mixture was evaporated to remove most of the methanol. The aqueous suspension was extracted with chloroform (3 × 50 ml) and the chloroform extracts were combined, dried, and evaporated as before. The residue was chromatographed on a neutral alumina column using successively benzene and chloroform as eluents.

The benzene fraction, upon evaporation to dryness, yielded an oily solid which, on recrystallization from hot ethanol gave the phosphole **4** (0.12 g, 12%) identical with an authentic sample.

Evaporation of the chloroform fraction also yielded an oily solid which was sublimed under vacuum (*ca.* 1 Torr) at 165° to give a colorless compound (0.16 g, 12%), m.p. 171–172°.

Anal. Calcd. for $C_{26}H_{27}O_2P$: C, 77.71; H, 6.72; P, 7.71; OCH_3, 7.71. Found: C, 77.4; H, 6.73; P, 7.60; OCH_3, 6.83.

The i.r. spectrum shows ν_{max} at 3051, 1610, 1600, 1578, 1494, 1431, 1368, 1299, 1262, 1220, 1170, 1105, 996, 955, 920, 878, 826, 791, 774, 752, 743, 718, 688 cm^{-1}. The u.v. spectrum in absolute ethanol shows λ_{max}(log ε) at 219.5 (4.27) and 258 mμ (4.01). The n.m.r. spectrum shows 16 aromatic and olefinic protons as a complex multiplet at τ 2.15–3.14, three methoxy protons as a sharp singlet at 6.97, five methylene and methine protons as a complex multiplet at 5.81–7.99, and three methyl protons as a doublet (J = 6 Hz) at 9.0. The mass spectrum shows a strong molecular ion peak at m/e = 402.

Alkaline hydrolysis using only water as solvent gave a mixture of uncrystallizable oils together with traces of the phosphole **4** and *p*-terphenyl.

We thank the National Research Council of Canada and the Ontario Department of University Affairs for generous financial support.

Bromination of Norbornene: the Question of Bromonium Ions *vs.* 6,1-Hydride Shift

D. R. MARSHALL, P. REYNOLDS-WARNHOFF, AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ontario

AND

J. R. ROBINSON

Received October 1, 1970

The reaction of norbornene (**1**) with bromine has been re-investigated and found to give in addition to bromonortricyclene (**2**) and 2-*exo*-bromonorbornane (**20**) a complex mixture of dibromides of which five (**15–19**) have been isolated and identified. These dibromides have been found to be kinetically controlled products of ionic addition. Apparently dibromide **15** is also formed to some extent in carbon tetrachloride by a radical mechanism. The product composition from the bromine addition has been compared with that of the analogous chlorination and bromofluorination reactions. Degradation of the 2-*exo*,3-*endo*-dibromonorbornane from bromination of 5,6-^{14}C-norbornene has shown that this dibromide is formed by two ionic routes: (*a*) from a bromonium ion **14** (or its equivalent), and (*b*) from the cation **12** formed by 6,1-hydride shift. Improvements have been made in the first and final steps of the standard norbornene degradation method.

La réaction du norbornène (**1**) avec le brome a été réexaminée et s'est avérée donner, en plus du bromonortricyclène (**2**) et de l'*exo* bromo-2 norbornane (**20**), un mélange complexe de composés dibromés dont cinq (**15–19**) ont été isolés et identifiés. Il a été montré que ces composés dibromés sont des produits cinétiquement contrôlés résultant d'une addition ionique. Il semble que le dibromo **15** se forme également de façon appréciable dans le tétrachlorure de carbone par un mécanisme radicalaire. La composition des produits de la réaction d'addition du brome a été comparée aux réactions analogues de chloration et de bromofluoration. Par dégradation du dibromo *exo*-2,*endo*-3 norbornane obtenu par bromation du ^{14}C-norbornène-5,6, il a été montré que ce dibromure est formé par deux voies ioniques: (*a*) à partir d'un ion bromonium **14** (ou ses équivalents), et (*b*) à partir du cation **12** formé par une migration-1,6 d'hydrure. Des améliorations ont été apportées à la première et dernière étapes de la méthode standard de dégradation du norbornène.

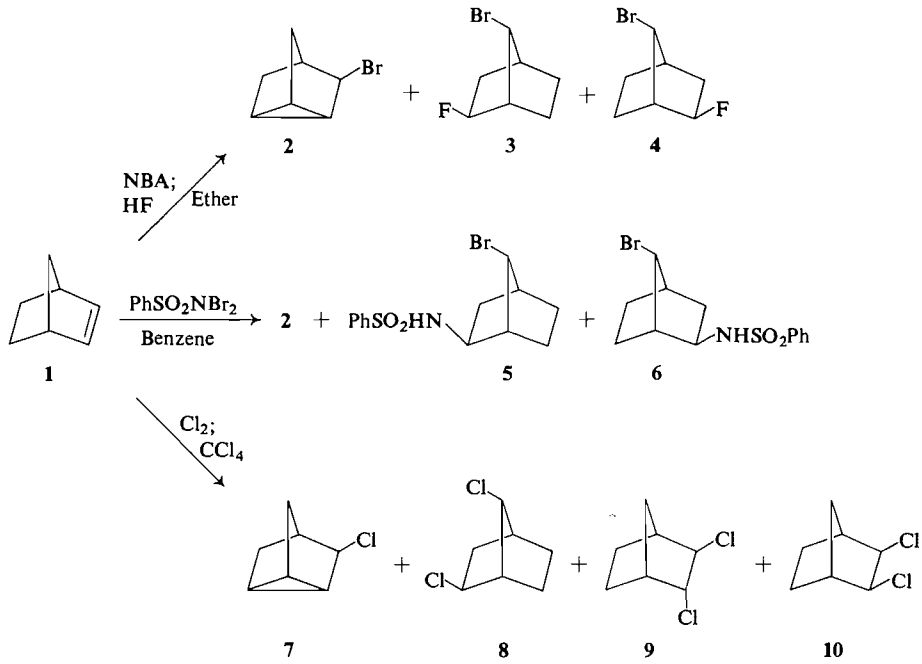
Introduction

In the course of a study of the reaction of "bromine fluoride" (*N*-bromoacetamide + hydrogen fluoride) with norbornene (**1**), it was found that the major dihalo products were 7-*syn*-bromo-2-*exo*-fluoronorbornane (**3**) and 7-*anti*-bromo-2-*exo*-fluoronorbornane (**4**), (Scheme 1) (1, 2). Since the ionic reaction of either "bromine fluoride" or bromine with norbornene would presumably lead to the same first intermediate, the 7-*anti*-isomer **4** was unexpected on the basis of the reported bromination of norbornene (3–5), from which the only dibromo products identified were 7-*syn*,2-*exo*-dibromonorbornane (**19**) and 2-*exo*,3-*endo*-dibromonorbornane (**15**). Most of the earlier investigation of this bromination reaction was done before g.l.p.c. and n.m.r. spectroscopy were available, and although some of the conclusions reached earlier (3, 4) have since been revised (5) (the bromination product was found to contain other dibromides), no further report has been published. To clarify the situation a re-investigation of the bromination reaction was undertaken. After the present work was undertaken, three other studies of halogenation of norbornene were reported which further underlined the desirability of reconciling the various reaction products. In one case (6) *N*,*N*-dibromobenzenesulfonamide was the halogenating agent, and the products **2**, **5**, and **6** were analogous to those from the "bromine fluoride" reaction, while in the other studies describing the chlorination of norbornene (7, 8), three of the four products, **7–10**, of the ionic reaction were analogous to the compounds reported from the bromination (Scheme 1).

Structural and Stereochemical Assignment of the Dibromides

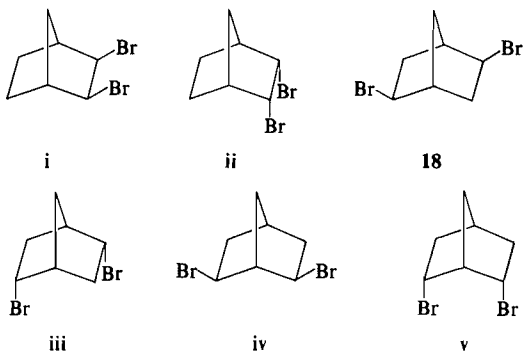
When the bromination of norbornene in carbon tetrachloride at 0° was repeated according to the directions of Kwart and Kaplan (3, 4) and



SCHEME 1

the crude product was examined by g.l.p.c.,[1] there were present eight peaks with retention times expected for dibromonorbornanes (Fig. 1). Five of these peaks corresponded to compounds present in greater than 1% yield, and they were isolated by preparative g.l.p.c.[1] From the clean n.m.r. spectra (Fig. 2) of four of the five g.l.p.c. fractions there is no reason to suspect the presence of more than one compound per peak. The five dibromonorbornanes[2] were assigned structure and stereochemistry on the basis of their n.m.r. spectra (including double irradiation spectra), dipole moments, g.l.p.c. retention times, and stability relationships.

Integration of the n.m.r. spectrum of each dibromide shows that every bromine atom is on a carbon atom bearing a hydrogen atom, thereby restricting the number of possible structures to 13 (Table 1). The three 2,3-dibromides have been synthesized previously and their stereochemistry determined unambiguously (10, 11). The *exo-cis*-2,3- and *endo-cis*-2,3-isomers were not identical with any of the five bromination products isolated. However, the first eluted (g.l.p.c.) di-



[1]When g.l.p.c. equipment with metal columns (copper or stainless steel) and a metal injection block was used, the dibromides were partially decomposed. For this reason a gas chromatograph with a glass column and injection chamber was used both for analytical and preparative g.l.p.c. For preparative work a stainless steel splitter was attached to the exit of the glass column, but little or no decomposition occurred during the short contact time in the metal splitter as tested by re-injection of the eluate.

[2]There appears to be no reason to doubt that all five compounds have the norbornane skeleton. For two of the isomers this has been proved: **19** has been reduced to norbornane by sodium and *t*-butyl alcohol, and **15** has been degraded to *cis*-1,3-cyclopentane dicarboxylic acid. Moreover, **19** is readily isomerized to the other four dibromides by hydrogen bromide, and the bicyclo[2.2.1] system would not be expected to be equilibrated with a more strained, less stable bicyclo[3.2.0], [3.1.1], or [4.1.0] system. For example, the bicyclo[3.2.0] system rearranges to the bicyclo[2.2.1] skeleton (9). The n.m.r. spectra exclude the presence of methyl groups and olefinic hydrogens.

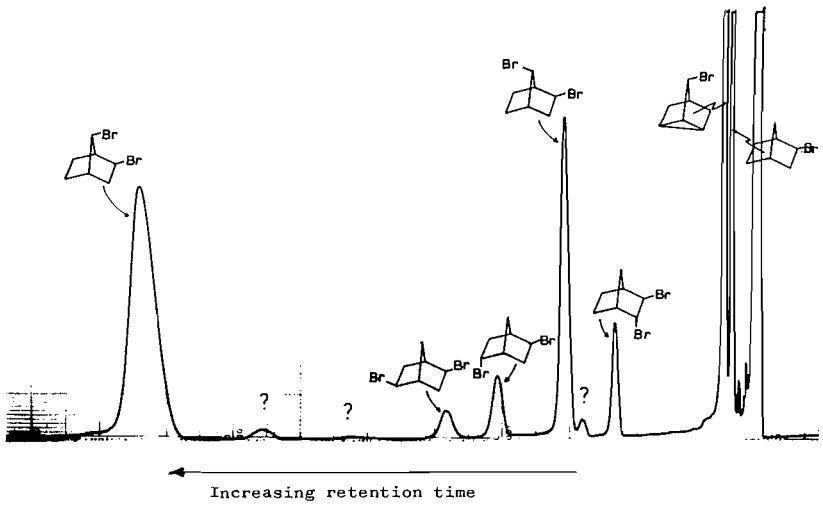

FIG. 1. The g.l.p.c. chart of the norbornene bromination product.

bromide was identical with 2-*exo*,3-*endo*-dibromonorbornane (**15**), one of the two compounds identified by Kwart and Nyce (5). The n.m.r. spectrum (Fig. 2*a*) is in agreement with that reported (10). Double irradiation of *exo* H-3 at 4.42 p.p.m. caused the three line pattern from *endo* H-2 at 3.83 p.p.m. to collapse to a doublet ($J_{endo}H_2$-*anti* H-7 ~3 Hz), and double irradiation of the bridgehead H-1 and -4 peaks at 2.46 p.p.m. caused the *exo* H-3 signal to collapse to a doublet ($J_{endo}H_2$-*exo* H-3 ~ 2.9 Hz) while the *endo* H-2 signal at 3.83 p.p.m. was undisturbed.[3,4] Therefore the two low field protons are on adjacent carbon atoms. Also in agreement with a vicinal structure is the fact that this dibromide is the most easily dehydrobrominated of the five. The final proof of structure was the degradation of this isomer to *cis*-1,3-cyclopentane dicarboxylic acid (5) (see below).

The second dibromide to be eluted (g.l.p.c.) was assigned the 7-*anti*,2-*exo* dibromo structure **16**. In its n.m.r. spectrum (Fig. 2*b*) the narrow absorption at 4.43 p.p.m. ($w_{1/2}$ ~ 4 Hz) is characteristic of a proton on C-7 bearing bromine. (2). The position and three line pattern of the peak at 3.93 p.p.m. is typical of a 2-*endo* proton on a carbon atom bearing bromine and coupled to the adjacent methylene group. The absence of additional observable splitting from long range coupling with an *anti* H-7 suggests that the C-7 bromine occupies this position. The *anti* orientation of the C-7 bromine atom is confirmed by the dipole moment of 2.4 D (calcd. (12): 2.07 D), a value much too small for the *syn*-isomer (calcd. (12): 3.92 D) which has been found to be the fifth dibromide. As expected for **16**, double irradiation of the bridgehead H-1 (2.56 p.p.m.) had no apparent effect on the *endo* H-2 peaks but caused H-7 to collapse to a doublet ($J_{H\text{-}7}$-*endo* H-6 < 1 Hz).[3]

The fourth dibromide eluted (g.l.p.c.) was crystalline, m.p. 94–95.5°, which property together with very simple i.r. and n.m.r. spectra (Fig. 2*d*) indicated the presence of a high degree of symmetry in the molecule. Both CHBr protons absorb at the same place (3.77 p.p.m.) with the same pattern and are therefore in identical environments. Of the six possible structures, **i** and **ii** have already been excluded. Of the remaining four isomers only **18** and **iv** have *endo* protons on carbon bearing bromine as required by the fact that double irradiation of both bridgehead methine hydrogens (2.55 p.p.m.) had no effect on the CHBr pattern. Moreover, double irradiation of the methylene protons (2.08 p.p.m.) caused the CHBr pattern to collapse to a singlet.[3] Structure **18** is preferred to **iv** since both bridgehead methine protons are in identical environments. The low value (0.66 D) of the observed dipole moment is also consistent with structure **18** which would have the lowest moment of any of the 13 isomers (Table 1).

The last dibromide to be eluted (g.l.p.c.) had

[3]For further details and double irradiation spectra see ref. 1.

[4]LeBel and co-workers (10, 11) have proved the stereostructure of **15** by double irradiation measurements on 2-*exo*,3-*endo*-dibromonorborn-5-ene which on hydrogenation gives **15**.

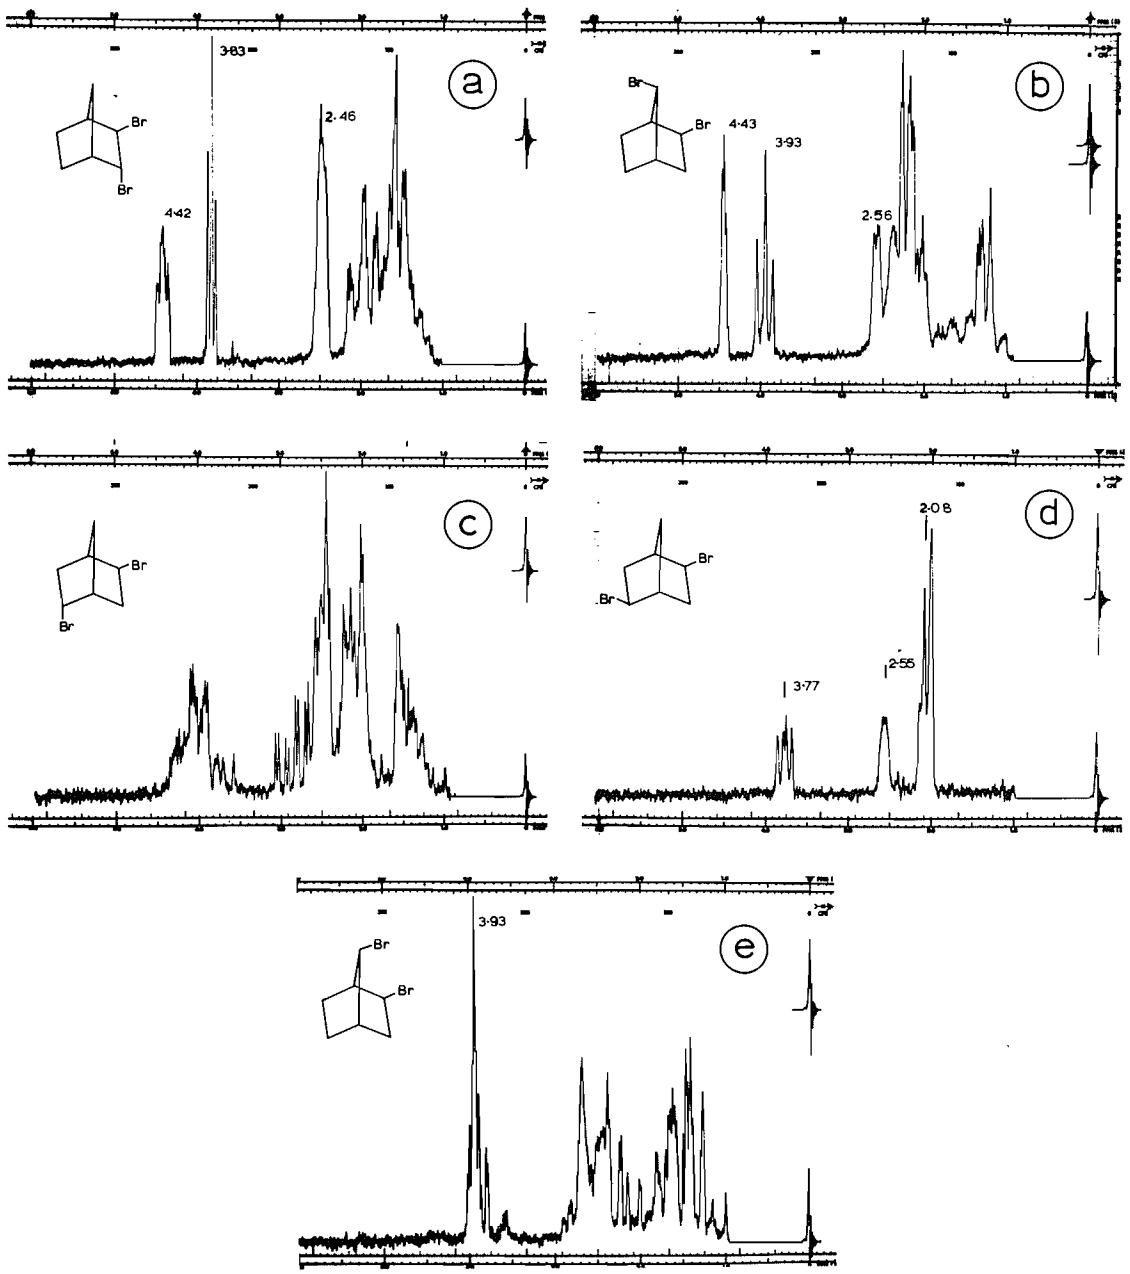

FIG. 2. The n.m.r. spectra of dibromonorbornanes in CCl_4 solution at 60 MHz.

an i.r. spectrum identical with that of the 7-*syn*-2-*exo*-dibromonorbornane isolated by Kwart and Kaplan (3, 4) and converted by them into norbornane-7-carboxylic acid. The dipole moment of this dibromo isomer (3.30 D) excludes all but five of the possible stereoisomers **19**, **i**, **ii**, **iii**, and **v** (see Table 1 for calculated dipole moments), and of these five, the four having both CHBr groups in identical environments can be excluded to leave only **19**. The two —CHBr protons of this isomer are clearly different in the n.m.r. spectrum (Fig. 2*e*) although they overlap.

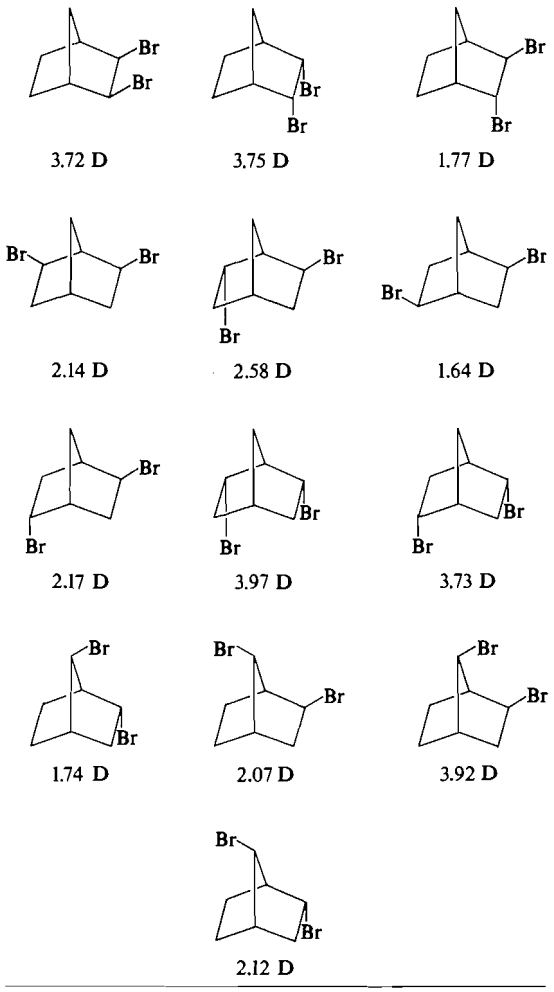
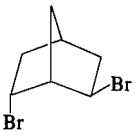
TABLE 1. Permissible dibromonorbornanes and their calculated dipole moments



The chemical shift (~3.90 p.p.m.) is that expected for an *endo* CHBr proton on which is superimposed the "broadened singlet" of C_7HBr proton (3.93 p.p.m.). Comparison with the CHBr n.m.r. region of the 7-*anti*-bromo isomer **16** (Fig. 2*b*) clearly shows that the 2-*endo*-proton of the last eluted dibromide has an additional long range coupling (*endo* H-2 – *anti* H-7) which is missing in the 7-*anti*-bromo isomer **16** which has no 7-*anti* proton.[3] Additional chemical evidence for assigning the 7-*syn*-2-*exo* stereochemistry to this isomer is its facile isomerization to a mixture of the other four dibromides upon treatment with hydrogen bromide. The instability of this isomer relative to the others is explicable in terms of repulsive non-bonded interaction between the two bromine atoms which is diminished or absent in the other four isomers found.

The third dibromide eluted has not been assigned a unique structure on spectroscopic grounds alone; however, the number of possible structures may be limited to two, and a choice made on the basis of mechanistic arguments. The n.m.r. spectrum (Fig. 2*c*) reveals that the two CHBr protons are not in the same environment, nor is either CHBr proton on C-7 since the characteristic narrow peak is not present. Therefore only **17** and **vi** remain as possibilities.



vi

Structure **vi** would arise from a more circuitous path than **17**, and moreover a path requiring a 3,2-hydride shift. There is abundant evidence that 3,2-hydride shift in norbornyl cations is much slower than 6,1- and 6,2-hydride shift and becomes appreciable only under equilibrating conditions (13). However, the bromination reaction is kinetically controlled (see below), and furthermore no other products attributable to 3,2-hydride shift were found unless the three very minor unidentified components (Fig. 1) arise in this way. For these reasons structure **17** is assigned to the third dibromide.[3]

Results and Discussion

Fortunately, it was possible to show that the products of bromination of norbornene at 0° in carbon tetrachloride are those of the kinetically controlled addition reaction. Both bromonortricyclene (**2**) and dibromide **19** can react with hydrogen bromide to give a mixture of the five dibromides, but *under the conditions of the addition* these reactions are undetectable.[5] In control experiments in the present work it was found that treatment of bromonortricyclene (**2**) or

[5]Kwart and Kaplan (3) reported that bromonortricyclene reacts with anhydrous hydrogen bromide at 0° in carbon tetrachloride. However, in their reaction, hydrogen bromide was passed through the solution for 12 h, much more drastic treatment than in the addition reaction which was worked-up after 5–20 min and in which the hydrogen bromide concentration was much lower.

dibromide **19** at 0° in methylene chloride (in which hydrogen bromide is more soluble than in carbon tetrachloride) with more than 1 mol equiv of anhydrous hydrogen bromide gave no reaction over periods longer than the time required for bromine addition to norbornene (see Experimental).[6] The other four dibromides were also shown to be inert to hydrogen bromide under the addition reaction conditions. Brominations of norbornene carried out in the presence of suspended powdered calcium carbonate gave the same proportional yields of the five dibromides as were obtained in the absence of calcium carbonate within experimental error, although the yield of 2-*exo*-bromonorbornane was drastically reduced with a corresponding increase in **2** (Table 2). In bromination reactions in which the crude product was not washed to remove hydrogen bromide, the product composition was insensitive to the time that elapsed between reaction and g.l.p.c. analysis. Therefore, the dibromide isomers found are kinetically controlled addition products and do not result from secondary reactions or isomerizations.[7]

In view of Kwart and Kaplan's earlier suggestion that a radical chain reaction might be involved in the formation of one of the dibromides, and since Poutsma's recent work (7) revealed both ionic and free radical components in the chlorination of norbornene in carbon tetrachloride solution, it was necessary to establish the nature of the processes involved in the bromination reaction. The choice of solvent is apparently critical. The bromination in methylene chloride was found to be insensitive to concentration differences and to the radical scavenger oxygen (Tables 2 and 3). If some of the dibromides had been partially or wholly formed by radical processes, a change in product ratios would have been expected, but within experimental variation none was observed. In carbon tetrachloride on the other hand, although the dibromide distribution did not change in the presence of oxygen (7), the amount of 2-*exo*,3-*endo* dibromide **15** increased with increasing concentration of norbornene or bromine while the amount of 2-*exo*,7-*syn* dibromide **19** decreased. Furthermore, when a radical, diphenylpicrylhydrazyl, was present in the bromination of high concentrations of norbornene in carbon tetrachloride, the amount of **15** was reduced by half compared to bromination in the absence of the radical, and the dibromide distribution was essentially that obtained in methylene chloride solution. This evidence points to a radical component leading mainly to **15** in the formation of dibromonorbornanes in carbon tetrachloride; if radical intermediates are formed in methylene chloride, they are apparently scavenged by the solvent before they can give rise to dibromonorbornanes.[8]

A mechanistic interpretation of the *ionically* formed products and product ratios can now be made. The origin of the five dibromonorbornane isomers is consistent with *exo*-addition of a cationic bromine species to norbornene followed by 6,1- or 6,2-hydride shift in the resulting nonclassical ion (or Wagner–Meerwein related classical cations **21**) and reaction with bromine or bromide ion. The three non-classical ions, **11**, **12**, and **13**, can give rise to three pairs of dibromides (Fig. 3) of which the only one not formed was the

[6]Actually, the maximum amount of hydrogen bromide that would have been present at 0° was much less than 0.2–0.36 of the molar amount of norbornene used since some of the hydrogen bromide produced in the formation of bromonortricyclene then reacted with norbornene to give 2-*exo*-bromonorbornane (**20**). This latter reaction was fast since the amounts of **2** and **20** were always approximately equal.

[7]The formal possibility that some or all of these kinetically controlled products might have arisen from initially formed *exo-cis*-2,3-dibromonorbornane (**i**) in a fast reaction is excluded both by LeBel's finding (10) that **i** is a major product of the radical addition of hydrogen bromide to 2-bromonorbornene, and also by our finding that **i** is unchanged by hydrogen bromide in methylene chloride at 0°.

[8]The unlikely possibility that all of the dibromides are being formed by free radical mechanisms in carbon tetrachloride can be excluded by two observations. Firstly, addition of diphenylpicrylhydrazyl changed the distribution of dibromonorbornanes contrary to what would be expected for an all radical path. Secondly, the bromination of a mixture of norbornene and toluene gave less than 0.5% of benzyl bromide. From bond dissociation energies (14) the addition of a bromine atom to a double bond is approximately thermally neutral. However, if the difference (~6 kcal/mol) in heat of hydrogenation of cyclohexene or cyclopentene and norbornene (15) is taken as a measure of the relief of strain in the latter on breaking the π-bond, then the addition of a bromine atom to norbornene should be exothermic by ~6 kcal/mol. Since the rate of benzylic hydrogen abstraction by bromine atoms from toluene is 290 times greater than from the methylene group of propane and is exothermic to the extent of ~10 kcal/mol from bond dissociation energies (14), benzyl bromide should have been formed in quantity if the bromination of norbornene were exclusively a radical process, provided that the activation energies for the two reactions being considered here paralleled the energy differences between starting materials and intermediates.

*The difference between 100% and the horizontal sum of % for a reaction is due to small amounts of other unidentified compounds, presumably dibromides because of their g.l.p.c. retention times, see Fig. 1 for example.

cis-exo-2,3-dibromonorbornane (**i**). An authentic sample of **i** was synthesized (10) and shown by mixed g.l.p.c. not to be identical with any peak from the bromination product. The absence of this isomer may be attributed to steric shielding by the bromine atom already present in cation **11**.[9]

As has been pointed out by Berson (16), one of the dibromides, the 2-*exo*,3-*endo* compound **15**, may arise by two routes: normal *trans* addition of bromine to norbornene via bromonium ion **14** as suggested by Kwart and Kaplan (3), or else by 6,1-hydride shift[10] in the initially formed cation **11** with subsequent attachment of bromide at C-2 of **12**. In the present work it has been found that both processes occur simultaneously. Evidence for two ionic paths to **15** comes from bromination in methylene chloride in the presence of a large amount of bromide anion (Table 2, entry 7). The dibromo product was almost entirely the 2-*exo*,3-*endo* isomer **15** with no detectable amount of **17** or **18** and a marked decrease in **16**. The increased formation of the 2-*exo*,3-*endo* dibromide **15** in this experiment requires a mechanism allowing capture of an intermediate cation by bromide before much hydride shift has taken place. Still, the fact that *some* 2-*exo*,7-*anti* dibromide **16** from 6,1-hydride shift cation **12** is formed in all of the brominations suggests that some of the 2-*exo*,3-*endo* dibromide must also result from bromide attack on the 6,1-hydride shift cation **12**.

To settle the point, an experiment with labelled norbornene was carried out. Bromination of 5,6-^{14}C-norbornene in carbon tetrachloride at 0° gave the previously described mixture of mono- and dibromo products. Rather than separate the small amount of labelled 2-*exo*,3-*endo* dibromide, advantage was taken of its greater reactivity toward dehydrobromination compared to the other four dibromides. After removal of the 2-*exo*-bromonorbornane and most of the bromonortricyclene by fractional distillation, the remaining mixture was treated with phenyllithium at 0° for 30 min, which conditions had been found to dehydrobrominate the 2-*exo*,3-*endo* dibromide cleanly without affecting bromonortricyclene, 2-*exo*-bromonorbornane, or the other dibromides. The crude product was distilled with added decalin to remove the lower boiling 2-bromonorbornene. Ozonization of the distillate gave *cis*-1,3-cyclopentane dicarboxylic acid which was degraded

[9] *Cf.* the corresponding methylnorbornyl cation in ref. 17.

[10] In this paper for convenience the carbon atoms of cations **11–13** and **24–26** as well as bromonortricyclene **2** have been numbered to retain the generally used terms for referring to hydride shifts in the unsubstituted norbornyl cation.

by a modification (see below) of the customary procedure (18). The degradation results are shown in Fig. 4. If **15** arose entirely from bromonium ion **14** or from the radical process in which rearrangement would not occur, the radioactive carbon would appear exclusively in the ethylenediamine, whereas if 6,1-hydride shift occurred, label would also appear in C-2 of the cyclopentanediamine and in a carboxyl group of the derived succinic acid. The carbon dioxide from degradation of the succinic acid was radioactive but the figure given is probably the least reliable of the five,[11] and the value given is a minimum figure (see Experimental). If this figure is disregarded, the amount of 2-*exo*,3-*endo* dibromide which arises from 6,1-hydride shift is 19–27%, depending on the way in which it is calculated (see Experimental) with the rest of the dibromide **15** arising from the bromonium ion **14** and from the radical pathway. Since the radical scavenger experiments indicate that at least half of the 2-*exo*,3-*endo* dibromide is formed by a radical path in carbon tetrachloride at the high concentrations used (3–5), and since about one quarter of the **15** arises by 6,1-hydride shift, the remaining quarter is all that results from bromonium ion **14** under these conditions.

various halogenations of norbornene is given in Table 4. In comparing the chlorination and bromination reactions, which have been examined in greatest detail, the greater yield of chloronortricyclene relative to bromonortricyclene is perhaps a reflection of the greater basicity of chloride ion than bromide ion in aprotic solvents. The absence of hydride shift products in the chlorination reaction is explicable on the basis of a less stabilized (chlorine being more electronegative and less efficient at bridging than bromine) (20), and hence more reactive, initial cation reacting with the more nucleophilic (in aprotic solvents) chloride ion (however, see ref. 19).

As mentioned in a previous publication (2), two probably related points of difference between the bromination and bromofluorination reactions deserve comment. These are the absence of 2-*exo*,3-*endo* isomers as major products[12] and the much larger proportion of the 6,1-hydride shift product 7-*anti*-bromo,2-*exo*-fluoronorbornane in the latter reaction. Any initially formed bromonium ion in the bromofluorination reaction would presumably have a longer lifetime to undergo hydride shift since associated fluoride–hydrogen fluoride species in ether should be poorer nucleophiles than bromide anion in aprotic medium. If so, it would not be surprising to find much less product of attack on a bromonium ion and an increase in 6,1-hydride shift products. As an approximation, the proportion of 2-*exo*-fluoro-3-*endo*-bromo isomer to be expected from the 6,1-hydride shift cation **12** can be estimated to be the same (~10% of the 7-*anti* isomer) as for the bromination, or only about 4% of the total product and could be present as one of the minor components.[12] The observed product yields are not likely to be the result of prior formation of a 2-*exo*,3-*endo* compound followed by rearrangement; loss of bromide from such a product would eventually lead to 7-fluoro derivatives which are not observed.

A comparison of the relative rates of anion capture at each pair of Wagner–Meerwein related sites in the three substituent-bearing nonclassical ions is presented in Table 5. Although the reactions were not all run under the same conditions, the variation in the product ratios can be accounted for by a combination of steric and inductive effects. The preponderance of 7-*syn* isomer from reaction of cation **24** is favored by the steric bulk of the substituent X, which would hinder formation of the more crowded 2-*exo*,3-*exo* isomer. The difference in ratio for X = methyl *vs.* bromine is expected both from the electron withdrawing effect of bromine rendering C-1 relatively more positive than C-2 (compared to the reverse situation for the methyl substituted cation) and from the smaller size of the entering acetate oxygen atom (relative to bromide) when X = methyl.

In the capture of cation **25**, there is no steric interaction of entering nucleophile and substituent. However, a preference for attack at C-6 when X = bromine is consistent with the expected inductive effect of bromine rendering C-6

[12]There were three unidentified minor (< 3% of total) products detected during g.l.p.c. examination of the bromofluorination product. One or two of these may have been 2-*exo*,3-*endo* isomers.

more electron deficient and therefore relatively more reactive than C-2. To harmonize this rationale with the result (approximately equal attack at both sites) for the same cation when X = methyl requires the introduction of some factor (torsional effect of the methyl with C-2 hydrogen being pushed up?) to explain why there is not more attack at C-2 in this case.

For cation **26**, in which not only is direct interaction of entering nucleophile and substituent X not possible, but also the inductive effect through bonds (not through space, however) would be the same for both C-1 and -6, the distinction between the two positions is almost negligible and the ratio of capture for X = bromine and methyl approaches unity.[13]

The effect of solvent on the bromination reaction was examined because of the previous reports[3,4,5] of the effect of added pyridine. In the present work it was found that the effect of pyridine and pyridine derivatives is much too complex to be accounted for by a simple solvent effect (1). However, when the solvent was changed from carbon tetrachloride to the more polar methylene chloride and acetonitrile, the relative constancy of the dibromide product composition was consistent with purely ionic bromination.

With the bromination of norbornene rationalized, a related reaction, the bromination of *exo*-trimethylene-2-norbornene (**22**), was also reexamined. In agreement with the previous report (21) we find that in carbon tetrachloride the major product (80%) is the 2-*exo*,3-*endo* dibromide **23** accompanied by minor amounts of at least seven other compounds. This same product was formed in the same 80% yield when the bromination was conducted in pyridine, but the proportions of the minor products changed (see Experimental). The minor products were not further investigated.

*For the i.r. spectra see ref. 1.

oxidation and Schmidt reactions suffers from low yields. In the present work the yields and convenience of the first and last steps have been improved. In the first step, when ozone instead of permanganate was used as the oxidizing agent in ethyl acetate at $\sim -70°$, 87–99% yields of 1,3-cyclopentane dicarboxylic acid were obtained in agreement with previous work (22). The acid was a mixture of 92% of the *cis* isomer and 8% of an impurity which was not the *trans* isomer, but which was removed by recrystallization. Ethyl acetate was used as the ozonization solvent to avoid the formation of some monomethyl ester which occurred in methanol.

The second step, the Schmidt reaction on the diacid, proceeds well as described in the literature (18), but the third step, the oxidation of the cyclopentane-1,3-diamine to succinic acid has always been troublesome. Since succinic acid is stable to aqueous Cr^6 (23), this oxidizing agent was tried, but the reaction was capricious and the isolated yields were never more than 27%. On the possibility that initially formed succinic acid (or the diamine) was being oxidized further by Cr^5 or Cr^4 (24), oxidations were tried with Cr^6 in the presence of Mn^2 as scavenger for Cr^5 and Cr^4 (25), but the yield of succinic acid was still only 26%, which is about the yield obtained from oxidation by permanganate. In control experiments it was shown that succinic acid was recovered in over 90% yield from the Cr^6–Mn^2 reagent, and therefore the cyclopentane-1,3-diamine is oxidized by Cr^6 mainly to products not degraded to succinic acid.

The final step in the degradation sequence, the Schmidt reaction on succinic acid has been reported to go in only 8% yield (26), and for this reason the alternative Curtius degradation via the azide and urethane has been employed (27). This procedure, although a big improvement, is tedious and gives only 50% of the diamine. Since in succinic acid each carboxyl group may be considered as an electronegative substituent in close proximity to the other, it seemed that the Stothers–McNamara modification (28) of the Schmidt reaction might give better results. These workers found that the use of 20% oleum in the reaction with electronegatively substituted aromatic acids gave much better yields of carbon dioxide. When this procedure was applied to succinic acid, yields of 41–83% of barium carbonate and 30–51% of the dibenzamide derivative of ethylenediamine were realized. Although the yield of diamine from the modified Schmidt reaction is no better than from the Curtius procedure, the Schmidt procedure is more economical.

Experimental

General

Experimental details are the same as in ref. 2 with the following additions. For gas chromatography a Glowall Model 400 instrument equipped with a heated exit port and a hydrogen flame detector was employed. Its all glass column and injection chamber was a 1.8 m length of coiled 3.4 mm i.d. (analytical) or else 10 mm i.d. (preparative) tubing. Helium or argon was used as the carrier gas. For preparative work a 50:1 stainless steel splitter was used in conjunction with the 10 mm column. FFAP refers to Wilkens free fatty acid phase and DEGS to diethylene glycol succinate. The response of the hydrogen flame detector to the five dibromides and **2** and **20** was determined by analysis of synthetic mixtures of known weight percent (see ref. 1 for details). No correction factor was necessary for the dibromides to convert peak areas to weight percent, but an average factor of 0.81 was required for 2-*exo*-bromonorbornane.

For integration of the g.l.p.c. charts, the amount of **2** and **20** relative to the total dibromide area was determined by the cut-and-weigh technique or by planimeter from a trace in which all peaks were on scale. Dibromide ratios were obtained from a second trace in which the height of the dibromide peaks was optimized.

Melting points were taken on a Reichert Kofler microscope hotstage unless otherwise specified. Refractive

indices were measured on a Bausch and Lomb refractometer. Microanalyses were performed in the laboratories of A. Bernhardt, Mülheim, Germany, and A. B. Gygli, Toronto.

The ^{14}C counting was carried out with a Nuclear Chicago MK1 liquid scintillation counter. The "TFC" scintillation solution (29) used for counting was prepared by diluting 5 volumes of toluene containing 0.4% PPO (2,5-diphenyloxazole) and 0.005% bis-MSB [*p*-bis(*o*-methylstyryl)-benzene] with 4 volumes of methyl cellosolve (ethylene glycol monomethyl ether); samples were weighed (see Table 10) into scintillation vials and counted in 15 ml of TFC. Barium carbonate was counted by trapping the acid-liberated $^{14}CO_2$ in a scintillation vial containing 1.0 ml of NCS (a quaternary ammonium base, 0.6 *N* in toluene, supplied by Nuclear–Chicago Corp.) and then adding 15 ml of TFC for counting. Samples were counted at balance point in a 0.5–9.9 V window, using a channels ratio method to ensure that counting efficiency did not change from sample to sample. As there was no variation in counting efficiency, counts per min data were adequate for comparison.

In view of the fatalities which have occurred in work with closely related dibromo compounds (30), all operations with the dibromonorbornanes, including g.l.p.c., were conducted in a fume cupboard.

Dibromonorbornanes

The procedure of Kwart and Kaplan (3) was used. Norbornene[14] (20 g, 0.21 mol) in 40 ml of carbon tetrachloride was cooled to −10° with an ice–salt bath. A solution of 29 g (0.18 mol) of bromine in 20 ml of carbon tetrachloride was added with stirring at a rate such that the temperature remained at or just below 0°. After 30 ml of the bromine solution had been added, the persistence of red color and lack of exothermicity indicated that the olefin had been consumed. Evaporation of solvent left 40.4 g of crude product whose g.l.p.c. (Fig. 1) at 130° on a column of 5% DEGS on 60–80 mesh Chromasorb P indicated the presence of at least seven major components and three minor ones.

Bromonortricyclene and 2-*exo*-bromonorbornane, two of the major products, were separated as the lowest boiling (b.p. 60° at 11 mm) materials by fractional distillation on a 45 cm Nester and Faust platinum spinning band column. The mixture of higher boiling dibromides (b.p. 30–75° at 0.06 mm) was separated by preparative g.l.p.c. on a column of 10% FFAP on non acid-washed 60–80 mesh Chromasorb P. Operating conditions: injector temperature 270°, column temperature 170°, exit port temperature 200°, argon carrier gas flow rate ~80 ml/min, 40–50 μl of dibromide mixture per injection. Fractions collected were re-injected and the other five major products (numbered in order of elution) were obtained in the purity indicated in Table 6. Peak 4 (2-*exo*,5-*exo*-dibromonorbornane) was obtained as a crystalline solid, m.p. 94–95.5°, after recrystallization from petroleum ether (b.p. 30–60°).

[14]Norbornene (Aldrich Chemical Co.) was purified by distillation. It gave a single g.l.p.c. peak on a column of 5% DEGS on Chromasorb P. The purity must be checked regularly because even purified norbornene gives rise to higher boiling material on long standing.

Isomerization of Dibromonorbornanes

(a) A mixture of 418 mg of 7-*syn*,2-*exo*-dibromonorbornane (**19**) and 1 ml of 47% aqueous hydrobromic acid was refluxed for 3.25 h (*cf.* refs. 3 and 4). The resulting dark-colored mixture was cooled and extracted with 10 ml of ether and analyzed by g.l.p.c. to yield the following composition: **15**, 15.2%; **16**, 34.5%; **17**, 22.8%; **18**, 21.3%; **19**, 0.5%; 3 minor products (one in the starting material), total 6.0%. On shorter reflux times (1.5–2 h) the amount of **16** was greater at the expense of **17** and **18**.

(b) Hydrogen bromide gas was passed continuously at room temperature into a solution of 67 mg of the 7-*syn*,2-*exo* isomer **19** in 3 ml of carbon tetrachloride. Samples were withdrawn at intervals and analyzed by g.l.p.c. for the ratios of **15**:**16**:**17**:**18** (see Table 7).

(c) Each of the purified dibromides was treated with 5 ml of a standardized solution of hydrogen bromide in methylene chloride[15] at 0°. After the allotted time, the reaction was quenched with 2 ml of 10% aqueous sodium bicarbonate solution. The separated and dried organic layer was analyzed by g.l.p.c. and the results are summarized in Table 8.

Reaction of Bromonortricyclene with Hydrogen Bromide

Bromonortricyclene was treated with standardized solutions of hydrogen bromide in methylene chloride.[15] After the allotted time the reaction was quenched with aqueous sodium bicarbonate solution. The separated and dried organic layer was analyzed by g.l.p.c., and the results are summarized in Table 9. The kinetically controlled product from the 58% reaction entry had the following composition: **15**, 3.3%; **16**, 29.3%; **17**, 33.1%; **18**, 18.4%; **19**, 15.9%.

Brominations under Other Conditions

(a) With Calcium Carbonate

A solution of 543 mg (5.8 mmol) of norbornene in 100 ml of methylene chloride[15] was cooled to 0° and stirred vigorously (magnetic bar) with 5.0 g of suspended powdered calcium carbonate. A solution of 1.0 g (6.25 mmol) of bromine in 5 ml of methylene chloride was added during 20 min. Then 5 ml of 10% sodium bicarbonate solution was added, followed by 25 ml of water. Suspended solid was removed by filtration, and the organic layer was filtered and dried. After removal of solvent, the crude product was analyzed by g.l.p.c. (entry 5, Table 2). In an attempt to diminish further the amount of 2-*exo*-bromonorbornane the reaction was repeated with 25.0 g

TABLE 7. Products of reaction of **19** with HBr

Compound	3 h	20 h	25 h
15	12.7	14.3	16.8
16	54.9	49.8	39.8
17	17.8	19.3	24.0
18	14.6	16.5	19.2

[15]Except where carbon tetrachloride was used to reproduce exactly the conditions of Kwart and Kaplan (3), methylene chloride was generally substituted because of its lower freezing point and because of the greater solubility of hydrogen bromide and salts in this solvent.

TABLE 8. Reaction of dibromides with HBr

Compound	Weight (mg)	mg HBr/5 ml	Time (h)	The g.l.p.c. result
15	25.0	31	17	No isomerization
16	25.0	31	17	No isomerization
17	14.0	31	17	No isomerization
18	18.0	31	17	No isomerization
19	19.6	31	5	No isomerization or at most a trace (<4%)
19	7.4	42/1 ml	14.5 (25°)	No isomerization
i	15.0	13.4/2 ml	1	No isomerization

TABLE 9. Reaction of bromonortricyclene with HBr

mg of **2**	Time (h)	Temperature (°C)	mg HBr	Volume (ml)	The g.l.p.c. result
76.4	73	0	43.5	25	No reaction
5 μl	0.33	25	6.6	1	No reaction
6.5	1.0	25	20.2	1	Slight reaction
5	14.5	25	42	1	58% reaction
7.4 of **19**	14.5	25	42	1	No isomerization

of calcium carbonate to give 1.17 g (98%) of crude products (entry 6, Table 2).

(b) Dilution

The above experiment (*a*) was repeated without calcium carbonate on two different solutions of norbornene in methylene chloride,[15] one containing 498 mg in 100 ml and the other containing 481 mg in 2 ml. The reactions were quenched with aqueous sodium bicarbonate solution, and the organic layers were separated and dried over magnesium sulfate. The g.l.p.c. analyses of the crude products are entries 1 and 2 in Table 2.

(c) With Oxygen Scavenger

Oxygen was passed through a sintered glass bubbler into a vigorously stirred (magnetic bar) solution of 518 mg of norbornene in 100 ml of methylene chloride[15] maintained at 0°. A solution of 1.0 g of bromine in 2 ml of methylene chloride was added during 20 min. The reaction was worked up as in (*b*). The g.l.p.c. analyses gave the figures in entry 4 in Table 2.

(d) With Toluene

To a stirred (magnetic bar) solution of 526 mg (5.6 mmol) of norbornene and 2.415 g (26.2 mmol) of toluene in 100 ml of methylene chloride[15] maintained at 0.5–1.5° was added during 20 min a solution of 350 mg (2.19 mmol) of bromine in 2 ml of methylene chloride. The g.l.p.c. analysis showed that the dibromide products were formed in the same ratios as in the absence of toluene and that the small peak corresponding in retention time to benzyl bromide constituted less than 0.5% of the total products. The experiment was repeated with carbon tetrachloride solutions (see Table 3).

(e) With Other Solvents

Small scale brominations were run in carbon tetrachloride and acetonitrile as well as in methylene chloride. The general procedure was to add the bromine diluted with a little of the solvent to a stirred (magnetic bar) solution of norbornene in the solvent. The reaction mixture was washed with aqueous bicarbonate and analyzed by g.l.p.c. The total area under peaks in the dibromide region was equated to 100%, and the normalized percents of compounds **15–19** were calculated on this basis. The results are summarized in Table 3. Reactions in acetonitrile and in the more concentrated carbon tetrachloride solutions gave rise to variable amounts of a g.l.p.c. peak (different for the two solvents) suspected to arise from involvement of solvent in the reaction.

(f) With Diphenylpicrylhydrazyl

To a solution of 430 mg of norbornene in 1 ml of carbon tetrachloride was added 100 mg of diphenylpicrylhydrazyl. The radical was only partially soluble. Neat bromine (20 μl) was added dropwise at 0° with vigorous stirring by a magnetic bar. The reaction mixture was analyzed by g.l.p.c. Control experiments showed that diphenylpicrylhydrazyl had no effect on the dibromides, and also that the preformed product of bromine plus the radical acting on norbornene gave the same proportion of dibromides as bromine alone acting on norbornene at a given concentration (see Table 3).

(g) At −78°

To a solution of 510 mg (5.4 mmol) of norbornene in 100 ml of methylene chloride[15] cooled to −78° by a Dry-Ice – acetone bath was added with stirring (magnetic bar) during 20 min 1.0 g (6.2 mmol) of bromine dissolved in 2 ml of methylene chloride. The reaction was quenched with 5 ml of 10% aqueous sodium bicarbonate, and the separated organic layer analyzed by g.l.p.c. (entry 3, Table 2).

(h) With Tetraethylammonium Bromide

A solution of 68.8 mg (0.73 mmol) of norbornene in 10 ml of methylene chloride[15] was saturated with tetraethylammonium bromide (1.271 g, 6.05 mmol) at 0°. Bromine (0.20 g, 1.2 mmol) was added with stirring (magnetic bar) during 3 min at −5 to −3°. The mixture was allowed to stir at 0° for 17 min more. Work-up gave 157 mg of crude product whose g.l.p.c. analysis is entry 7, in Table 2.

TABLE 10. Counting results from degradation of ^{14}C-labelled norbornene and dibromonorbornane*

Compound	Weight (mg) counted		Counts ($min^{-1} \times 10^{-3}$)		Counts (min^{-1} $mmol^{-1} \times 10^{-5}$)	
	A	B	A	B	A	B
1,3-Cyclopentane dicarboxylic acid	2.89	5.72	21.3	20.0	11.6	5.53
1,3-Cyclopentanediamine dibenzamide	3.18	3.21	11.3	5.93	10.9	5.70
Succinic acid	1.34	2.30	12.2	9.59	10.7	4.93
Barium carbonate	6.75	1.70	0.0	0.172	0.0	0.20
Ethylenediamine dibenzamide		2.38		3.91		4.39

*All samples were counted to 10^5 total counts. A, Norbornene control degradation; B, degradation of 2-*exo*,3-*endo* dibromide **15** from norbornene.

Hydrogenolysis of 7-syn,2-exo-Dibromonorbornane (19)

Tetrahydrofuran (10 ml), *t*-butyl alcohol (2.1 ml, 22 mmol), and finely chopped sodium (1.5 g, 63 mga) were heated to reflux with stirring. 7-*syn*,2-*exo*-Dibromonorbornane (**19**) (1.01 g, 4.0 mmol) was added and the resulting dark solution was refluxed for 45 h. After dilution with water and extraction with ether, the organic solution was slowly distilled until the distillation temperature reached 40° when norbornane just began to sublime. The residual 1.00 g of liquid, containing some solvent, on analysis by g.l.p.c., was shown to contain 110 mg (30%) of norbornane. A sample was isolated by preparative g.l.p.c. and shown to be identical (i.r. spectrum, g.l.p.c. retention time) with an authentic specimen.

cis-1,3-Cyclopentanedicarboxylic Acid

A solution of 5.86 g (62 mmol) of norbornene in 150 ml of ethyl acetate was cooled to $\sim -78°$ in a Dry-Ice – acetone bath, and ozone was passed in until a blue color persisted. The solution was allowed to warm to room temperature, and the solvent was evaporated at reduced pressure on a rotating evaporator. The residual viscous oil was warmed with a mixture of 50 ml of 98% formic acid and 30 ml of 30% aqueous hydrogen peroxide solution, whereupon a vigorous exothermic reaction occurred at ~60° which caused the solution to reflux. Reflux was maintained for 1 h before the solution was evaporated to leave 9.53 g (97%) of a viscous oil which slowly solidified, m.p. 87–107°. The g.l.p.c. analysis of the methyl ester gave two peaks showing this material to be 92% of *cis*-diacid and 8% of an impurity. The impurity was not the *trans*-diacid since methoxide-catalyzed epimerization of the methyl ester of pure *cis*-diacid gave two isomers of g.l.p.c. retention times: 6.0 min (*trans*-dimethyl ester) and 7.5 min (*cis*-dimethyl ester) neither of which was identical with the impurity of retention time 4.5 min. However, the impurity was removed by recrystallization from ether – petroleum ether (b.p. 30–60°). Four such recrystallizations gave colorless diacid, m.p. 118–120° (lit. (22*b*): 121.5–122.5°).

Dehydrobromination of 2-exo,3-endo-Dibromonorbornane (15)

Pure (97%) **15** (101 mg) was treated under nitrogen at ice bath temperature with 0.75 ml of a 1.5 *M* solution of phenyllithium in benzene–ether (Alfa Inorganics). Samples withdrawn for g.l.p.c. showed complete reaction after 15 min. The n.m.r. spectrum of the solution had a vinyl proton doublet at 5.81 p.p.m. different from the vinyl proton absorption of added norbornene at 5.92 p.p.m. (dd).

In separate experiments it was demonstrated that **2** and **16–20** did not react with phenyllithium under the conditions used for **15** (see ref. 1).

Degradation of Radioactive 2-exo,3-endo-Dibromonorbornane (15)

(a) 1,3-Cyclopentanedicarboxylic Acid

Norbornene-5,6-^{14}C (752 mg, 1 mCi) supplied by Mallinckrodt Nuclear, Orlando, Florida, and synthesized by the Diels–Alder addition of ethylene-1,2-^{14}C to cyclopentadiene (31) was dissolved in 100 ml of carbon tetrachloride. A 1 ml aliquot was diluted with inactive norbornene and degraded to prove that the ^{14}C was entirely at C-5 and -6. See Table 10.

An aliquot of this radioactive norbornene solution (20 ml, ~200 μCi) was diluted with inactive norbornene (20.24 g, 0.22 mol) in 20 ml of carbon tetrachloride and cooled in an ice–salt bath. A solution of 34 g (0.21 mol) of bromine in 23 ml of carbon tetrachloride was added with stirring (magnetic bar) at a rate which kept the temperature between -2 and $+2°$. After ~1.25 h when the reaction solution retained the bromine color, addition of bromine was stopped and the solvent was removed at reduced pressure and room temperature. Most of the monobromides **20** and **2** were distilled at 72° (16 mm) to leave 38.23 g of dibromides containing some **2** and **20**. The g.l.p.c. analysis calculations gave 2.64 g (6.9%) of 2-*exo*,3-*endo*-dibromide **15** in this mixture. The normalized percents of the dibromonorbornanes were **15** (9.8%), **16** (20.5%), **17** (4.1%), **18** (3.6%), and **19** (62%); the difference between these figures and those for the 430 mg/ml reaction in Table 3 may be due to differences in instantaneous bromine/norbornene ratio for the large *vs.* small scale reaction. To this mixture, which was cooled under nitrogen in an ice bath, was added 75 ml of 1.9 *M* phenyllithium solution through a rubber septum. After 30 min the solution was cautiously quenched with 10 ml of aqueous sodium hydroxide. The g.l.p.c. of the organic layer showed **15** to have been completely destroyed, but the ratios of **16**:**17**:**18**:**19** remained the same. The aqueous layer was separated and the benzene–ether solvent removed under reduced pressure at room temperature. Decalin (20 ml) was added and distillation (a Bunsen burner was used to limit frothing) was carried out until a temperature of 80° (16 mm) was reached. A further 30 ml of decalin was added and the distillation continued until approximately 30 ml of distillate (receiver cooled in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

For personal use only.

an ice bath) had been collected. The distillate was diluted with 25 ml of ethyl acetate, and the solution cooled in a Dry-Ice – acetone bath. Ozone was passed into the stirred (magnetic bar) solution for 90 min by which time the solution was pale green. After evaporation of the solvent, 25 ml of 98% formic acid and 15 ml of 30% aqueous hydrogen peroxide was added, and the mixture *gently* warmed until reaction was initiated as indicated by gas evolution. When the exothermic reaction subsided, the mixture was heated on a steam bath for 30 min. After evaporation of most of the formic acid the solution was cooled and extracted with 10% aqueous sodium hydroxide. Acidification with 20% hydrochloric acid, saturation with sodium chloride, and extraction with six 30 ml portions of ether afforded 865 mg (57%) of a pale brown oil which slowly solidified. A sample recrystallized from ethyl acetate had m.p. 121–122° (lit. (22*b*): 121.5–122.5°).

(b) 1,3-Cyclopentanediamine Hydrochloride

The 865 mg of crude active diacid was diluted with 720 mg of inactive acid by solution in ethyl acetate and evaporation. A portion (1.43 g, 9.05 mmol) of the resulting acid was dissolved in 15 ml of 100% sulfuric acid in a 50 ml flask. The flask was equipped with a gas outlet attached to a wash bottle containing dilute aqueous chromic acid, a side arm for addition of solid sodium azide, and a nitrogen inlet projecting below the surface of the solution. After the system was flushed with dry nitrogen, the chromic acid wash bottle was attached to a wash bottle containing carbon dioxide free sodium hydroxide solution. Sodium azide (2.5 g, 38.5 mmol) was added as the solution was stirred (magnetic bar) and heated to 40–45°. After the addition (~0.75 h) a slow stream of nitrogen was passed through the system for a further 30 min. The carbon dioxide absorbed in the sodium hydroxide solution was precipitated as barium carbonate by treatment with 25 ml of a solution of barium chloride and ammonium chloride (0.33 *M* in each). The yield of barium carbonate after filtration and drying at 120° for 6 h was 2.114 g (59%).

The sulfuric acid solution was carefully neutralized with ~30 ml of 50% aqueous sodium hydroxide and the resulting solution distilled to dryness into 20 ml of 15% hydrochloric acid. Water (30 ml) was added to the residue and the resulting mixture again distilled to dryness; this procedure was repeated six times. Failure to distill almost to complete dryness results in very low yields. The aqueous distillate after evaporation afforded 819 mg (53%) of 1,3-cyclopentanediamine hydrochloride as a buff powder. Yields in other experiments ranged between 40 and 92%.

The *dibenzamide* derivative used for counting was obtained by vigorously shaking a solution of 51 mg (0.29 mmol) of the diamine hydrochloride in 3 ml of 10% aqueous sodium hydroxide with 0.15 ml of benzoyl chloride. The white precipitate was filtered, and the filtrate extracted with two portions of ether. The material (87.7 mg, 97%) from the combined precipitate and ethereal extracts was recrystallized thrice from ethanol to give colorless needles, m.p. 213.5–215° (lit. (18): 213–215°).

(c) Succinic Acid

Potassium permanganate (6.21 g) was added to a solution of 770 mg (4.45 mmol) of the diamine hydrochloride prepared in (*b*) in 60 ml of water. The reaction was heated in an oil bath (130–140°) for 15 min, cooled, and acidified with 5 ml of 10% hydrochloric acid. Sulfur dioxide was passed in until the solution was clear and colorless. Continuous ether extraction for 42 h afforded 146 mg (28%) of pale yellow solid succinic acid. The g.l.p.c. of the dimethyl ester of the crude acid indicated the absence of other components. Five recrystallizations from ethyl acetate gave colorless needles, m.p. 175–185°.

(d) Ethylenediamine Dibenzamide

Several variations in reaction procedure were tried, and it was found that failure to follow exactly the procedure described below frequently resulted in very low or no yield of the dibenzamide.

The same apparatus was used as described in (*b*) for the preparation of 1,3-cyclopentanediamine. A solution of 20 mg (0.17 mmol) of recrystallized succinic acid from (*c*) in 1 ml of 20% oleum was prepared in the 50 ml flask and warmed to 40°. The apparatus was flushed with dry nitrogen before attachment of the wash bottle containing sodium hydroxide. Sodium azide (104 mg, 1.6 mmol) was added *rapidly* (~1 min addition time) to the stirred solution (magnetic bar) at 40°. After the vigorous reaction was over, the flow of nitrogen was maintained for 60 min. The carbon dioxide was precipitated as barium carbonate from 10 ml of ammonium chloride – barium chloride solution (0.33 *M* in each). The yield of barium carbonate after filtration and drying was 27.3 mg. (41%).

The sulfuric acid solution was chilled in an ice bath, diluted with 6 ml of water, and carefully basified with 3 ml of 50% aqueous sodium hydroxide. The solution was allowed to warm to room temperature and water was added to dissolve any precipitated salts. Benzoyl chloride (0.10 ml) was added and the mixture shaken vigorously until a white precipitate formed. Filtration, water washing, and solution in ethanol gave 23.0 mg (51%) of crude dibenzamide after evaporation of the ethanol. Recrystallization from ethanol–water gave 10 mg of white needles, m.p. 259–260° (capillary) (lit. (32): 249°), undepressed on admixture with an authentic specimen.

Calculation of the Amount of 2-exo,3-endo-Dibromonorbornane (15) Formed by 6,1-Hydride Shift

$$\frac{2(\text{act. cyclopent. diacid} - \text{act. succinic}) \times 100}{\text{act. cyclopent. diacid}} = 22\%$$

$$\frac{2(\text{act. diamine} - \text{act. succinic}) \times 100}{\text{act. diamine}} = 27\%$$

$$\frac{(\text{act. cyclopent. diacid} - \text{act. ethylenediamine}) \times 100}{\text{act. cyclopent. diacid}} = 21\%$$

$$\frac{(\text{act. diamine} - \text{act. ethylenediamine}) \times 100}{\text{act. diamine}} = 23\%$$

$$\frac{2(\text{act. succinic} - \text{act. ethylenediamine}) \times 100}{\text{act. cyclopent. diacid}} = 20\%$$

$$\frac{2(\text{act. succinic} - \text{act. ethylenediamine}) \times 100}{\text{act. diamine}} = 19\%$$

Chromic Acid Oxidation of 1,3-Cyclopentanediamine

(a) To show that succinic acid could be recovered in good yield from chromic acid oxidation, 121 mg of pure succinic acid was dissolved in 7.5 ml of the oxidation reagent prepared by dissolving 33.6 g of chromium trioxide in 200 ml of water and 50 ml of concentrated sulfuric acid. The control mixture was diluted with water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

and continuously extracted with ether for 46 h. The ether solution was dried over sodium sulfate and evaporated to leave 111 mg (93% recovery) of succinic acid which was found to be pure by g.l.p.c. of its methyl ester. From another control reaction refluxed for 1.5 h the recovery was 89%.

(b) 1,3-Cyclopentanediamine hydrochloride (379 mg, 2.19 mmol) was dissolved in 25 ml (33 mmol) of the chromic acid solution prepared in (*a*), and the resulting mixture was refluxed for 1.5 h. The oxidation mixture was then cooled, diluted with 120 ml of water, and extracted continuously with ether for 41 h. Evaporation of the dried ethereal solution left 70 mg (27%) of white crystalline succinic acid, m.p. 185–188°.

(c) 1,3-Cyclopentanediamine hydrochloride (250 mg, 1.45 mmol) was dissolved in 16.5 ml (22 mmol) of the chromic acid solution prepared in (*a*) to which had been added 4.0 g (23 mmol) of manganous sulfate. The reaction mixture was refluxed for 1.5 h, cooled, and the excess chromic acid destroyed with sodium sulfite. Continuous ether extraction for 40 h yielded 46 mg (26%) of crystalline succinic acid.

Bromination of exo-Trimethylenenorbornene

exo-Trimethylenenorbornene was prepared from dicyclopentadiene by the procedure of Cristol *et al.* (33). The purity of the crystalline precursor, 2-*exo*-benzoyloxy-5,6-*exo*-trimethylenenorbornane, was carefully checked by n.m.r. spectroscopy and had m.p. 71–72° (lit. (33): m.p. 71.5–72°). The liquid olefin obtained on pyrolysis had n_D^{25} 1.4940 (lit. (33): n_D^{25} 1.4943) and gave a single g.l.p.c. peak (>98%) on a column of 5% DEGS/Chromasorb P. The i.r. spectrum of a liquid film showed no discernible peaks at 6.08, 7.42, 8.06, or 8.74 μ from the *endo* isomer. The phenyltriazole derivative melted at 137–143° indicating <5% *endo*-trimethylene derivative present (33).

(a) In Carbon Tetrachloride

A solution of the olefin (4.31 g, 32 mmol) in 50 ml of carbon tetrachloride was cooled in an ice–salt bath, and a solution of 5.0 g (31 mmol) of bromine in 10 ml of carbon tetrachloride was added during 45 min with stirring (magnetic bar) at such a rate that the reaction temperature remained between −3 and 0°. The crude product (11.33 g) was analyzed by g.l.p.c. on a 5% DEGS/Chromasorb P column after removal of solvent and found to contain 80% of **23** and a total of 20% of seven other components. For spectra and further details see ref. 1.

(b) In Pyridine

To a cooled solution of the olefin (3.84 g, 28.6 mmol) in 50 ml of reagent grade pyridine (dried over potassium hydroxide) was added with stirring (magnetic bar) during 15 min a solution of 5 g (31 mmol) of bromine at a rate which kept the temperature between −5 and −1°. The solution was stirred at 0° for a further 45 min. The reaction mixture was diluted with 100 ml of ether and extracted with eight 100 ml portions of water. Evaporation of the dried solution left 4.58 g of liquid product which was analyzed by g.l.p.c. on a 5% DEGS/Chromasorb P column and found to contain 80% of **23** and a total of 20% of six other compounds which were not all identical in retention times with the products formed in carbon tetrachloride. For further details see ref. 1.

A pure (>98% by g.l.p.c.) sample of the major product, 2-*exo*,3-*endo*-dibromo-5,6-*exo*-trimethylenenorbornane, was obtained by vacuum distillation of the product from a larger scale pyridine reaction.

Control Comparison with exo,cis-2,3-Dibromonorbornane (i)

A specimen of authentic *exo,cis*-2,3-dibromide **i** was prepared by the Diels–Alder procedure of LeBel (10) and had m.p. 60.5–60.8° (lit. (10): 60.4–61.3°). The g.l.p.c. comparison (admixture) showed that the compound was not identical with any of the components of the bromination mixture. On a 5% DEGS/Chromasorb P column at 150° the following retention times (min) were observed: **15** (4.0), minor component (4.6), **16** (4.9), **17** (6.15), **18** (7.1), minor components (8.75 and 9.5), **i** (10.2), and **19** (12.0).

A sample of 15 mg of *exo,cis*-2,3-dibromide **i** was dissolved in 2 ml of a solution of hydrogen bromide in methylene chloride (6.7 mg/ml) previously cooled to 0°. The reaction mixture was allowed to stand for 1 h at 0°, and was then diluted with methylene chloride, washed with aqueous sodium bicarbonate, and dried over magnesium sulfate. Evaporation of the solvent left 13 mg of residual **i** whose g.l.p.c. trace was identical with starting material; there was no additional peak present.

The authors would like to thank Professor W. A. Ayer, Edmonton, Alberta, through whose courtesy the 100 MHz n.m.r. spectra and decoupling data were obtained, Professor R. K. Chan for help with the dipole moment measurements, Professor J. A. Berson for helpful discussions, and the National Research Council of Canada for financial support.

Reçu le 30 juillet 1970

Les relations décrivant l'effet Overhauser dans des systèmes en échange font apparaître dans le domaine où les temps de vie sont du même ordre que les temps de relaxation des augmentations relatives des signaux des protons concernés ce qui peut donner des informations sur leur environnement. Pour des températures suffisamment inférieures à la température de coalescence cette méthode permet donc de mettre en évidence des conformations préférentielles par examen du rapport des accroissements en fonction des dispositions spatiales des sites d'échange. Nous avons ainsi déterminé la conformation des formyl-2 bromo-4 thiophène et acétyl-2 dibromo-4,5 thiophène qui présentent à température ordinaire un seul rotamère de structure OS-*cis*. Dans le cas du formyl-2 bromo-4 furanne qui existe à -90 °C en équilibre entre les formes OO-*cis* et OO-*trans*, les résultats des différentes irradiations indiquent une conformation OO-*cis* pour le rotamère préférentiel. Cette méthode, dont une évaluation des limites est donnée, est, en outre, susceptible de fournir une estimation des temps de vie de chacun des sites.

The equations of the nuclear Overhauser effect (n.O.e.) in exchanging systems predict relative increases for proton signals where the life times for exchange are of the same order of magnitude as the relaxation times. This method allows one to obtain structural informations. Hence, for a temperature sufficiently below that of the coalescence, it allows one to infer a conformational preference by an examination of the relative increase in intensity with respect to spatial position of exchange sites. We have hereby determined the conformations of formyl-2 bromo-4 thiophene and acetyl-2 dibromo-4,5 thiophene. The compounds show at ambient temperature a single rotamer OS-*cis*. Formyl-2 bromo-4 furan exists at -90 °C in an equilibrium between the rotamers OO-*cis* and OO-*trans*. In this case, the results of different irradiations show OO-*cis* to be the preferred rotamer. Moreover, this method is able to give indications of the life time on different sites. We also give an evaluation of the limits of the method.

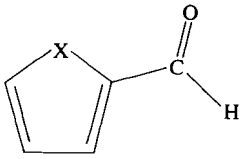
Canadian Journal of Chemistry, 49, 904 (1971)

L'effet Overhauser (n.O.e.) repose sur le phénomène de relaxation dipolaire de spins nucléaires et fournit des informations sur leurs voisinages. Depuis son observation en 1965 par Kaiser (1), Anet et Bourn (2) l'effet Overhauser a été utilisé pour résoudre un grand nombre de problèmes structuraux ou conformationnels en chimie organique (3). On peut citer parmi ceux-ci les échanges chimiques qui ont été étudiés par Forsen et Hoffman (4). L'application de l'effet Overhauser à des molécules en échange conformationnel n'a généralement été utilisé que dans les systèmes où l'échange est suffisamment lent pour que les temps de relaxation des protons concernés soient petits devant leur temps de vie sur chaque site (réf. 2 par exemple). Toutefois, dans une récente publication (23) Saunders et Bell font état, dans le cas de la *N*,*N*-diméthylformamide, des modifications de l'effet Overhauser en fonction de la température.

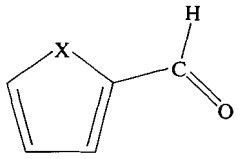
Par contre, il était admis que l'observation d'un effet Overhauser n'avait pas de signification dans le cas des échanges où les temps de vie et les temps de relaxation des protons irradiés étaient du même ordre. Dans un premier temps, nous avons étudié ce dernier système et établi les relations des rapports d'accroissement à partir des équations générales de l'effet Overhauser. Il ressort de ces relations que les transferts d'aimantation entre sites ne sont pas complets ce qui, a priori, autorise des conclusions structurales à partir d'expériences Overhauser. Dans un deuxième temps, nous avons cherché à vérifier expérimentalement ces résultats théoriques. Les systèmes hétérocycliques à cinq sommets (thiophène, furanne, pyrrole) se prêtent particulière-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ment bien à des recherches en r.m.n. du fait de la relative simplicité de leurs spectres. Nous avons donc choisi d'examiner la conformation des formyl-2 bromo-4 thiophène et furanne qui du fait de la forte conjugaison du groupement formyle peuvent exister sous deux conformations planes OX-*cis* ou OX-*trans* (X = S, O).



OX-*cis*



OX-*trans*

Le choix de la structure des rotamères par r.m.n. était basé jusque là sur deux critères: variation de l'influence du carbonyle selon le conformère au niveau du proton ortho (5); existence d'une stéréospécificité des couplages entre le proton aldéhydique et les protons du cycle (6) (disposition *trans–trans*). Les résultats déduits de ces deux critères n'étant apparemment pas toujours concordants (7) nous avons étudié dans un mémoire précédent (8) le problème controversé de la stéréospécificité des couplages dans les aldéhydes α thiophéniques et furanniques par r.m.n. et RX.

Dans le présent mémoire nous avons donc recherché une confirmation des précédentes conclusions dans une application de l'effet Overhauser à des systèmes en échange conformationnels. Ceci nous a amené à établir les relations décrivant les rapports des accroissements Overhauser dans le cas général des systèmes en échange. Le bon accord entre les résultats expérimentaux et les équations nous permet de proposer une nouvelle méthode d'analyse des systèmes en échange par irradiation sélective des sites d'échange pour des températures inférieures à la température de coalescence. Les augmentations Overhauser observées dans certains exemples permettent une estimation des temps de vie dans chacun des sites.

Calcul relatif à l'effet Overhauser dans un système soumis à un échange conformationnel

(A) Rappel des équations générales de l'effet Overhauser

Le traitement quantitatif de l'effet Overhauser peut se faire au moyen des équations de Bloch (9) modifiées par Solomon (10). Ainsi si l'on considère deux protons I et S relaxés par leur interaction mutuelle, les variations de leurs aimantations sont couplées et peuvent se décrire par le système, eqs. 1 et 2.

$$\left.\begin{aligned}[1]\quad \frac{dI_Z}{dt} &= -\alpha_I(I_Z - I_0) \\ &\quad -\beta_I(S_Z - S_0) \\ [2]\quad \frac{dS_Z}{dt} &= -\alpha_S(S_Z - S_0) \\ &\quad -\beta_S(I_Z - I_0)\end{aligned}\right\} \text{système A}$$

I_Z et S_Z sont les aimantations longitudinales instantanées et I_0 et S_0 leurs valeurs à l'équilibre. Si on impose $S_Z = 0$ par une irradiation prolongée de la résonance du proton S, on obtient pour l'aimantation I_Z une valeur d'équilibre supérieure à I_0, éq. 3.

$$[3]\qquad \frac{I_Z}{I_0} = 1 + \frac{\beta_I}{\alpha_I}$$

Dans cette présentation, nous ne tenons pas compte du couplage scalaire éventuel entre I et S. Si la seule interaction efficace pour la relaxation est l'interaction dipolaire entre I et S, on calcule $\beta_I/\alpha_I = 0.5$, et l'accroissement du signal des protons I dû à l'irradiation du signal des protons S est de 50%. En général d'autres interactions sont efficaces pour relaxer les spins I et l'on a, éqs. 4, 5

$$[4]\qquad \alpha_I = \alpha_I^0 + \alpha_I' = Kr_{IS}^{-6} + \alpha_I'$$

$$[5]\qquad \beta_I = 0.5\,\alpha_I^0$$

K est un coefficient dans lequel intervient le temps de correlation de la rotation moléculaire (10); r_{IS} est la distance entre I et S, α_I' est la vitesse de relaxation du spin I qui n'est pas due au couplage dipolaire entre I et S. L'accroissement Overhauser est alors, éq. 6

$$[6]\qquad \eta = \frac{0.5Kr_{IS}^{-6}}{Kr_{IS}^{-6} + \alpha_I'}$$

L'existence du terme α_I' explique que les valeurs expérimentales de l'accroissement η soient inférieures à 50% et permet des mesures relatives des distances r_{IS} (11).

(B) Equations relatives à l'effet Overhauser pour un système en échange

Si les spins I et S peuvent occuper plusieurs sites d'équilibre, la description de l'effet Overhauser est compliquée par l'existence d'un échange éventuel entre les différents sites. Qualitativement on peut distinguer les domaines suivants:

(*a*) Si le temps de vie d'un spin dans un site est long devant le temps de relaxation dans ce site, l'équilibre thermique est atteint séparément pour chaque site et l'on peut dire que l'échange n'a aucune influence sur les accroissements Overhauser.

(*b*) Si au contraire les temps de vie sont très courts devant les temps de relaxation (sans toutefois que les raies du spectre soient coalescées) les aimantations se transmettront d'un site à l'autre et le même accroissement Overhauser sera observé sur toutes les raies. L'effet Overhauser est alors non sélectif et ne peut plus être appliqué à l'étude des conformations correspondant à chaque site.

(*c*) Dans le domaine intermédiaire cependant, où les temps de vie sont du même ordre que les temps de relaxation, les transferts d'aimantation entre sites ne sont pas complets et des conclusions peuvent être déduites des expériences Overhauser.

Pour étudier quantitativement ce dernier cas, il faut remplacer les éqs. 1 et 2 du système A par des éqs. 7, 8, 9 et 10 qui tiennent compte de l'échange. Dans le cas où les spins I et S peuvent occuper deux sites d'indice 1 et 2, on écrit (système B)

$$\left.\begin{aligned}
[7]\quad & \frac{dI_{Z1}}{dt} = -\alpha_{I1}(I_{Z1} - I_{01}) - \beta_{I1}(S_{Z1} - S_{01}) + \frac{I_{Z2}}{\tau_2} - \frac{I_{Z1}}{\tau_1} \\
[8]\quad & \frac{dI_{Z2}}{dt} = -\alpha_{I2}(I_{Z2} - I_{02}) - \beta_{I2}(S_{Z2} - S_{02}) + \frac{I_{Z1}}{\tau_1} - \frac{I_{Z2}}{\tau_2} \\
[9]\quad & \frac{dS_{Z1}}{dt} = -\alpha_{S1}(S_{Z1} - S_{01}) - \beta_{S1}(I_{Z1} - I_{01}) + \frac{S_{Z2}}{\tau_2} - \frac{S_{Z1}}{\tau_1} \\
[10]\quad & \frac{dS_{Z2}}{dt} = -\alpha_{S2}(S_{Z2} - S_{02}) - \beta_{S2}(I_{Z2} - I_{02}) + \frac{S_{Z1}}{\tau_1} - \frac{S_{Z2}}{\tau_2}
\end{aligned}\right\} \text{ système B}$$

Entre[1] I_{01}, I_{02}, S_{01}, S_{02}, τ_1 et τ_2 existent les relations 11

$$[11]\quad \frac{\tau_1}{\tau_2} = \frac{I_{01}}{I_{02}} = \frac{S_{01}}{S_{02}} \text{ avec } I_{01} = S_{01} \text{ et } I_{02} = S_{02}$$

En tenant compte des relations 11 et en supposant l'équilibre atteint, le système d'équation B peut être écrit sous la forme d'un système linéaire homogène, éqs. 12, 13, 14 et 15.

$$\left.\begin{aligned}
[12]\quad & A_{I1}I_1 - \frac{1}{\tau_1} I_2 + \beta_{I1}S_1 + = 0 \\
[13]\quad & -\frac{1}{\tau_2} I_1 + A_{I2}I_2 + + \beta_{I2}S_2 = 0 \\
[14]\quad & \beta_{S1}I_1 + + A_{S1}S_1 - \frac{1}{\tau_1} S_2 = 0 \\
[15]\quad & + \beta_{S2}I_2 - \frac{1}{\tau_2} S_1 + A_{S2}S_2 = 0
\end{aligned}\right\} \text{ système C}$$

En posant

$$A_{Ij} = \alpha_{Ij} + \frac{1}{\tau_j} \qquad A_{Sj} = \alpha_{Sj} + \frac{1}{\tau_j}$$

$$I_j = \frac{I_{Zj} - I_{0j}}{I_{0j}} \qquad S_j = \frac{S_{Zj} - S_{0j}}{S_{0j}}$$

$$j = 1 \text{ (site 1)} \qquad j = 2 \text{ (site 2)}$$

[1] τ_1 et τ_2 sont les temps de vie dans les sites 1 et 2.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

En l'absence de toute perturbation, ce système n'admet pas d'autres solutions que la solution banale où les I_j et S_j sont nuls, c'est-à-dire où $I_{Zj} = I_{0j}$ et $S_{Zj} = S_{0j}$.

Par contre, la dégénérescence est levée quand, à une température inférieure à la température de coalescence, on procède, par irradiation prolongée, à une saturation de la résonance des protons S dans le site j ce qui se traduit par $S_{Zj} = 0$ (soit $S_j = -1$). Le système d'équations C est ramené, suivant qu'est irradié le site 1 ou le site 2, aux deux systèmes d'équations D_1 (éqs. 16, 17, 18) et D_2 (éqs. 19, 20, 21).

$$\left.\begin{aligned}
[16]\quad & A_{I1}I_1 - \frac{1}{\tau_2}I_2 = +\beta_{I1} \\
[17]\quad & -\frac{1}{\tau_2}I_1 + A_{I2}I_2 + \beta_{I2}S_2 = 0 \\
[18]\quad & \beta_{S2}I_2 + A_{S2}S_2 = -\frac{1}{\tau_2}
\end{aligned}\right\} \text{système } D_1$$

$$\left.\begin{aligned}
[19]\quad & A_{I1}I_1 - \frac{1}{\tau_2}I_2 + \beta_{I1}S_1 = 0 \\
[20]\quad & -\frac{1}{\tau_2}I_1 + A_{I2}I_2 = \beta_{I2} \\
[21]\quad & \beta_{S1}I_1 + A_{S1}S_1 = -\frac{1}{\tau_1}
\end{aligned}\right\} \text{système } D_2$$

Les résultats de la résolution des systèmes D_1 et D_2 sont donnés dans les tableaux 1 et 2. Outre les expressions générales de I_{Zj} et S_{Zj} figurent dans ces tableaux les solutions correspondant à quelques cas limites.

(C) Discussion des résultats des tableaux 1 et 2

(*a*) Cas général. Il est facile de déterminer, compte tenu de ce que les termes β sont toujours inférieurs aux termes α correspondants, que les fractions figurant dans les expressions des I_{Zj}/I_{0j} et S_{Zj}/S_{0j} sont toujours positives. Par suite, dans le cas général, la saturation de S_{Z1} (tableau 1) entraîne celle de S_{Z2} à un degré plus ou moins grand selon les valeurs de τ (4). En outre, un transfert d'aimantation se produit de I_{Z1} sur I_{Z2}, I_{Z2} subissant lui aussi un accroissement.

La saturation de S_{Z2} (tableau 2) entraîne partiellement celle de S_{Z1}. Il se produit encore un transfert d'aimantation entre I_{Z2} et I_{Z1} qui est responsable de leurs accroissements respectifs.

(*b*) Lorsque l'échange est très lent ($\tau_j \to \infty$) on retrouve évidemment les expressions classiques de l'effet Overhauser, mais appliquées à un mélange de deux isomères.

L'irradiation de S_{Z1} (tableau 1) provoque un effet Overhauser β_{I1}/α_{I1} sur I_{Z1} et laisse I_{Z2} inchangé.

L'irradiation de S_{Z2} (tableau 2) ne modifie pas I_{Z1} et produit un effet Overhauser β_{I2}/α_{I2} sur I_{Z2}. Remarquons que cet effet disparaît lorsque β_{I2} est nul.

(*c*) Par ailleurs, le cas particulier du bromo-4 formyl-2 furanne, examiné à une température légèrement inférieure à la température de coalescence, nous a amené à considérer la situation où $\beta_{I2} = \beta_{S2} = 0$ et où l'échange est suffisamment rapide ($\tau \to \tau_c$) pour que les termes $\alpha\tau$ deviennent négligeables devant 1. On constate alors (*cf.* tableaux) que la saturation de S_{Z1} comme celle de S_{Z2} entraîne des augmentations égales pour I_{Z1} et I_{Z2}.

(*d*) Un cas d'intérêt plus général est celui où $\beta_{I2} = \beta_{S2} = 0$ (dernière colonne des tableaux 1 et 2). Il correspond à une situation telle que dans le site 1, les protons I et S sont proches et sont relaxés par leur interaction mutuelle ($\beta_{I1} \neq 0$, $\beta_{S1} \neq 0$) alors que dans le site 2 ces deux protons sont suffisamment éloignés pour que leur relaxation mutuelle ne soit plus efficace ($\beta_{I2} = \beta_{S2} = 0$).

Il est à remarquer que pour $\beta_{I2} = \beta_{S2} = 0$, la relation 13 (*cf.* système d'équations C) peut se mettre sous la forme éq. 22.

$$[22]\qquad I_1 = [1 + \alpha_{I2}\tau_2]I_2$$

Cette dernière relation qui implique que I_1 est toujours supérieure à I_2, reste vérifiée lorsque l'indétermination inhérente au système C est

levée par irradiation des protons S, soit dans le site 1, soit dans le site 2.

C'est donc sur le signal des protons I dans le site 1 qui est celui où I et S sont spatialement proches, que les effets Overhauser les plus importants se manifesteront et ceci indépendamment de la population relative des sites 1 ou 2 ainsi que de la nature du site S irradié.

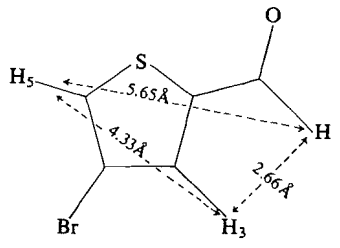
Une application de ces considérations est présentée dans le cas d'aldéhydes thiophéniques et furanniques.

Etude de la conformation du formyl-2 bromo-4 thiophène et du formyl-2 bromo-4 furanne

(A) Formyl-2 bromo-4 thiophène

L'analyse aux RX du formyl-2 bromo-4 thiophène révèle qu'il existe à l'état solide sous la conformation plane OS-*cis* (8). Les distances entre le proton aldéhydique et le proton H_3 dans les deux conformères déterminée grâce aux résultats de l'étude cristalline sont de $r(cis) = 2.66$ Å, $r(trans) = 3.98$ Å (fig. 1).

En solution dans le chloroforme deutérié ou le THF-d_8 le spectre r.m.n. de ce composé à



OS-*cis*

FIG. 1. La structure de OS-*cis* ($r_{trans} = 3.98$ Å).

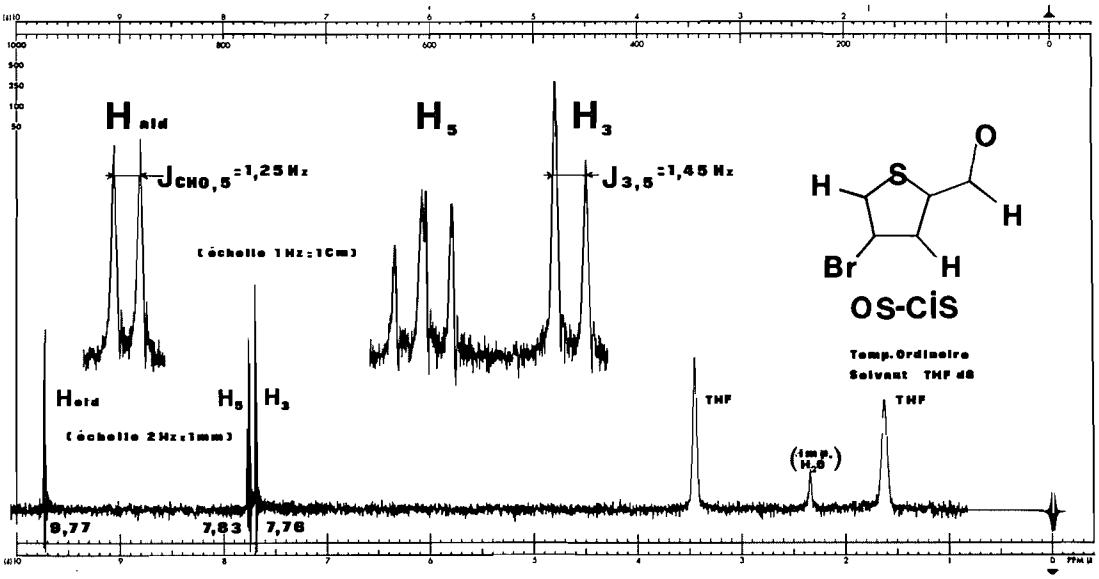

FIG. 2. Spectre r.m.n. du formyl-2 bromo-4 thiophène dans le THF-d_8 à température ordinaire.

température ordinaire présente un ensemble de signaux analysable au premier ordre (fig. 2, tableau 3).

Le signal du proton aldéhydique qui est un doublet par couplage avec le proton H_5(J_{CHO-5} = 1.25 Hz) ne subit aucune modification ni dans son intensité, ni dans sa largeur pour des températures allant de 25 à −75 °C. Dans ces conditions on peut considérer que le formyl-2 bromo-4 thiophène existe en solution sous une seule conformation au moins dans cet intervalle de température.[2] Cette hypothèse est du reste en accord avec des mesures de moment dipolaire de formylthiophènes (12). A température ordinaire et en termes de r.m.n. la conformation de ce dérivé apparaît donc comme bloquée c'est-à-dire que le temps de vie du spin du proton aldéhydique dans le rotamère préférentiel est infiniment long devant son temps de relaxation. On pourra donc étudier la structure de ce conformère par effet Overhauser en irradiant successivement le proton aldéhydique et le proton H_3 et en notant les modifications de l'intensité des signaux sur H_3 dans le premier cas et sur le proton aldéhydique dans le deuxième cas. Les augmentations (mesurées en %) du signal initial sont rassemblées dans le tableau 4.

La forte augmentation du signal de H_3 prouve

9.77	7.83	7.76	1.25	1.45	THF-d_8

*δ en p.p.m. par rapport au HMDS utilisé en référence interne.
†J en Hz.

[2]Les barrières de rotation des formyl-2 thiophène et furanne sont du même ordre (≈ 10.5 kcal/mol) (13). La température de décoalescence du furfural étant voisine de −60 °C, ceci entraînerait dans le cas d'un mélange de rotamères pour le formyl-2 bromo-4 thiophène une modification des signaux du spectre r.m.n. pour une température supérieure à −75 °C. Les effets sur la barrière de rotation produits par un atome de brome en série hétérocyclique sont considérés comme négligeables.

TABLEAU 4. Effet Overhauser observé dans le formyl-2 bromo-4 thiophène*

Proton irradié	Effet (%)			
	Hald	H_3	H_5	Solvant
Hald		35	0	$CDCl_3$
		30	0	THF-d_8
H_3	16		†	$CDCl_3$
	22		†	THF-d_8
H_5	0	†		$CDCl_3$
	0	†		THF-d_8

*Exprimé en % d'augmentation du signal initial.
†L'intégration de H_3 ne peut être effectuée lors de l'irradiation de H_5 et réciproquement du fait de la faible différence de déplacement chimique entre ces protons.

la proximité de ce proton avec le proton aldéhydique irradié. La conformation du bromo-4 formyl-2 thiophène en solution est donc OS-*cis* ce qui est en accord avec notre étude précédente (8).

Il est intéressant de remarquer que si l'irradiation du proton aldéhydique entraîne une augmentation de l'ordre de 30% du signal de H_3, l'irradiation de H_3 par contre ne produit qu'une augmentation de 16% du proton aldéhydique dans $CDCl_3$ et 22% dans le THF-d_8. Cette différence pourrait tenir à des vitesses de relaxation différentes pour le proton H_3 et le proton aldéhydique.

(B) Dibromo-4,5 acétyl-2 thiophène

Nous avons effectué une expérience similaire dans le cas du dibromo-4,5 acétyl-2 thiophène. On sait que la conformation dans le cristal de l'acétyl-2 bromo-5 thiophène est OS-*cis* (14). D'autre part, des études préliminaires ont montré qu'en r.m.n. l'absence de modification des signaux de l'acétyl-2 thiophène à basse température était en faveur d'une conformation bloquée, vraisemblablement OS-*cis*. Au cours de nos mesures nous avons observé une augmentation de 37% du signal du proton H_3 par irradiation du pic méthyle. Il se confirme donc que la conformation préférentielle du groupement acétylé α thiophénique est bien OS-*cis*.

(C) Formyl-2 bromo-4 furanne

L'étude aux RX (15) du formyl-2 bromo-4 furanne a montré que ce composé existe à l'état cristallisé dans la conformation OO-*cis*, comme son correspondant thiophénique. Les angles et distances dans les conformations OO-*cis* et OO-*trans*, calculées d'après cette étude se trouvent dans les schémas de la fig. 3.

En revanche le spectre de r.m.n. (fig. 4) du formyl-2 bromo-4 furanne enregistré à basse température (−90 °C) montre l'existence en solution des deux conformères OO-*cis* et OO-*trans*. Les déplacements chimiques du conformère majoritaire (80%) et du conformère minoritaire (20%) sont rassemblés dans le tableau 5.

En augmentant la température, l'échange s'accélère. La coalescence des signaux est observée vers −72 °C, l'échange étant très rapide à la température ordinaire. Le spectre de la fig. 4 met en évidence la présence d'un couplage $J_{CHO\text{-}5}$ de 1 Hz pour le rotamère majoritaire.

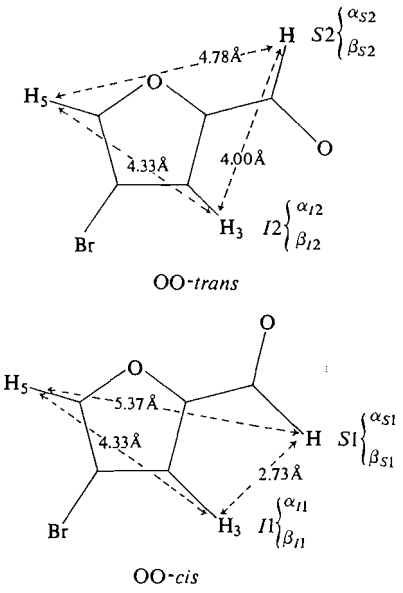

FIG. 3. La structure de OO-*trans* et OO-*cis*.

Nous avons effectué les expériences Overhauser à une température de −90 °C, inférieure à la température de décoalescence (t_C = −72 °C), en irradiant successivement chacun des signaux correspondant au proton aldéhydique et en mesurant dans chaque cas la surface des signaux de H_3 par intégration (figs. 5 et 6), les résultats expérimentaux étant regroupés dans le tableau 6.

Quel que soit le site irradié on constate une augmentation des signaux du proton H_3, l'augmentation relative la plus importante étant toujours observée dans le cas du rotamère majoritaire (30 et 13% pour, respectivement, 18 et 7%). Or, d'après la fig. 3, dans le conformère OO-*cis* (site 1), la distance entre le proton H_3 (proton *I*) et le proton aldéhydique (proton *S*) est assez faible (2.73 Å) pour qu'ils se relaxent mutuellement. Mais en revanche, dans le conformère OO-*trans*, (site 2) la distance entre *I* et *S* est assez grande (4 Å) pour que l'interaction soit pratiquement nulle.

On peut donc considérer que l'on se trouve dans le cas précédemment envisagé (tableaux 1 et 2) où $\beta_{I2} = \beta_{S2} = 0$. L'application de la relation 22 amène alors à conclure que le conformère pour lequel l'effet Overhauser est le plus marqué est le conformère OO-*cis*, et qu'il s'agit ici du conformère majoritaire.

Hald $\delta = 9.45$ (conformère majoritaire)	18%	30%	0%

*Exprimé en % d'augmentation du signal initial.

Ce résultat est en accord avec une étude (8) précédente de deux d'entre nous. Il faut toutefois noter à cet égard que cette étude avait été faite par r.m.n. à basse température et rayons X. Or, l'emploi simultané de ces techniques présente deux inconvénients

(*a*) il exige des composés cristallisés possédant de préférence un substituant lourd.

(*b*) il repose sur l'existence d'une identité entre la structure du conformère le plus stable en solution et dans le cristal. Bien que très largement vérifiée (16) cette analogie peut sans doute présenter des exceptions (17).

Remarques

(*a*) L'effet Overhauser sur des systèmes en échange permet en outre d'obtenir dans le cas particulier où $\beta_{I2} = \beta_{S2} = 0$ une valeur approchée du terme $\alpha_{I2}\tau_2$. En effet le rapport des accroissements relatifs I_1 de I_{Z1} et I_2 de I_{Z2} s'exprime très simplement en $\alpha\tau$ (éq. 22).

$$[22] \qquad \frac{I_1}{I_2} = (1 + \alpha_{I2}\tau_2)$$

Les valeurs expérimentalement déterminées sont

$$\left(\frac{I_1}{I_2}\right)_{S_{Z1}=0} \approx \frac{30}{18} = 1.7;$$

$$\left(\frac{I_1}{I_2}\right)_{S_{Z2}=0} \approx \frac{13}{7} = 1.9$$

ce qui compte tenu des incertitudes de mesure conduit à

$$1.5 < \left(\frac{I_1}{I_2}\right) = 1 + \alpha_{I2}\tau_2 < 2$$

La valeur correspondante de $\alpha_{I2}\tau_2$ est donc comprise dans le domaine

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$0.5 < \alpha_{I2}\tau_2 < 1$$

Si l'on admet un temps de relaxation de l'ordre de 50 s (18) la valeur de τ_2 est comprise dans l'intervalle

$$20\text{ s} < \tau_2 < 50\text{ s}$$

la valeur de τ_1 correspondante étant comprise dans l'intervalle

$$80\text{ s} < \tau_1 < 200\text{ s}$$

(*b*) Le précédent calcul n'est évidemment pas significatif si le terme $\alpha_{I2}\tau_2$ est négligeable devant 1. Dans ce cas (échange rapide notamment) les augmentations relatives I_1 et I_2 tendent vers une même limite (*cf.* tableaux 1 et 2).

Conclusion

L'établissement des relations décrivant les rapports des accroissements Overhauser dans les systèmes en échange fait apparaître pour des températures suffisamment inférieures à la température de coalescence, des augmentations relatives des signaux de *I* et *S* caractéristiques de leur environnement.

Dans ces conditions, l'utilisation de ces effets est applicable en particulier à l'analyse conformationnelle. Nous l'avons mis en évidence dans l'étude de la conformation des formyl-2 bromo-4 thiophène, acétyl-2 dibromo-4,5 thiophène et formyl-2 bromo-4 furanne. Les deux premiers composés possèdent à température ordinaire une conformation unique OS-*cis*. Le dérivé furannique qui existe en équilibre entre les formes OO-*cis* et OO-*trans* dans l'intervalle de température étudié, possède à $-90\,^{\circ}C$ une prépondérance du rotamère OO-*cis*.

Les valeurs des accroissements Overhauser observés permettent en outre une estimation des temps de vie de chacun des sites.

Cette méthode d'analyse structurale de systèmes en échange semble devoir s'appliquer à l'étude d'autres problèmes. Nous poursuivons actuellement l'étude de la conformation d'aldéhydes hétérocycliques substitués, à l'aide de cette technique.

Partie expérimentale

Les composés utilisés dans cette étude ont été préparés selon les méthodes décrites dans la littérature: formyl-2 bromo-4 thiophène (19), formyl-2 bromo-4 furanne (20), acétyl-2 dibromo-4,5 thiophène (21). Leur pureté a été contrôlée par chromatographie en phase gazeuse.

Les spectres ont été enregistrés en balayage de fréquence sur un appareil Varian HA 100. Le second champ de radio-fréquence nécessaire aux expériences de double irradiation est fourni par un générateur basse fréquence Hewlett–Packard modèle 200 AB.

L'intensité du champ est mesurée à l'aide de l'oscilloscope incorporé dans l'appareil. Les déplacements chimiques ainsi que les différentes fréquences sont obtenus par la lecture directe sur le fréquencemètre de l'appareil.

Les solutions soigneusement filtrées ont été dégazées sous vide à très basse température. La concentration est en moyenne de 10% dans le chloroforme ou le THF deutériés et la stabilisation interne est faite sur le signal du HMDS (hexaméthyldisiloxanne) dont le déplacement chimique par rapport au TMS est de 0.06 p.p.m. Pour la mesure des effets Overhauser nous avons procédé selon la méthode décrite par Bell et Saunders (11).

Nous tenons à exprimer nos très vifs remerciements au Dr. Scheidegger (Varian Ass. Zürich) pour l'aide qu'il nous a apportée dans les expériences Overhauser et aux rapporteurs du Can. J. Chem. pour leurs conseils et leurs suggestions.

Preparation of Substituted Anisylic Phenyl Ethers

J. M. PROKIPCAK AND T. H. BRECKLES
Department of Chemistry, University of Guelph, Guelph, Ontario

Received October 14, 1970

It is shown that anisylic phenyl carbonates thermally decompose to yield the corresponding anisylic phenyl ethers. The method involves heating the carbonates to their decomposition temperatures using hexamethylphosphoramide or toluene as a solvent. Thirteen anisylic phenyl ethers were prepared in good to excellent yields by this apparently general and simple procedure.

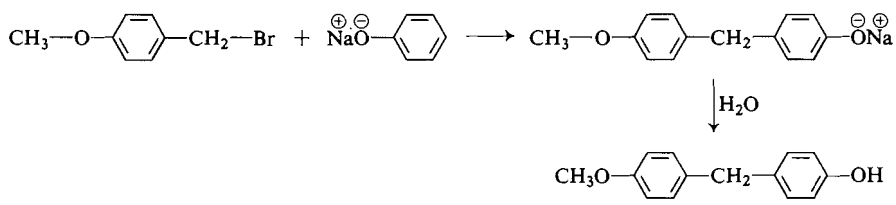
Il est démontré que les carbonates doubles de phényle et d'anisyles se décomposent thermiquement pour fournir les phénoxy anisoles correspondants. La méthode implique le chauffage des carbonates jusqu'à leur température de décomposition dans l'hexaméthylphosphoramide ou le toluène comme solvants. Treize éthers ont été préparés, avec des rendements variant de bons à excellents, par cette méthode simple et apparemment générale.

Canadian Journal of Chemistry, 49, 914 (1971)

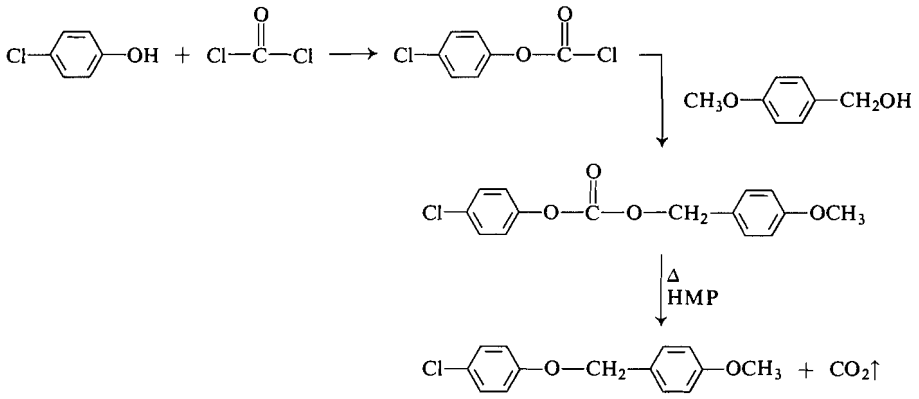
In the process of preparing some substituted benzyl phenyl carbonates for study in our laboratory, unexpected difficulty was encountered in purifying anisyl phenyl carbonate (*p*-methoxybenzyl phenyl carbonate) by distillation. Instead of obtaining the desired carbonate, a white solid was recovered which was tentatively assigned the structure of anisyl phenyl ether. Attempts to prepare the ether by conventional methods *i.e.* by reacting anisyl bromide with sodium phenoxide failed. This is in accordance with the difficulty encountered by Russell and Williamson (1) who found that using the aforementioned method, *p*-methoxy-*p'*-hydroxydiphenylmethane (**1**) was the major product formed (Scheme 1). Product **1** might be anticipated as the phenoxide ion could readily undergo electrophilic substitution by a very stable anisyl carbonium ion which could form from the anisyl bromide (2). A further survey of the literature revealed that very few anisylic phenyl ethers had been reported and thus it became of interest whether the pyrolysis reaction encountered in our laboratory could be used as a general synthetic route to the title compounds.

All the carbonates were prepared by well-documented conventional methods. Substituted phenols were treated with phosgene to give the substituted phenyl chloroformates which were then reacted with the anisylic alcohols yielding the desired carbonates. The overall reaction scheme for the preparation of anisyl *p*-chlorophenyl carbonate and its subsequent thermal breakdown is shown in Scheme 2. Table 1 of the Experimental section lists the carbonates prepared in this study.

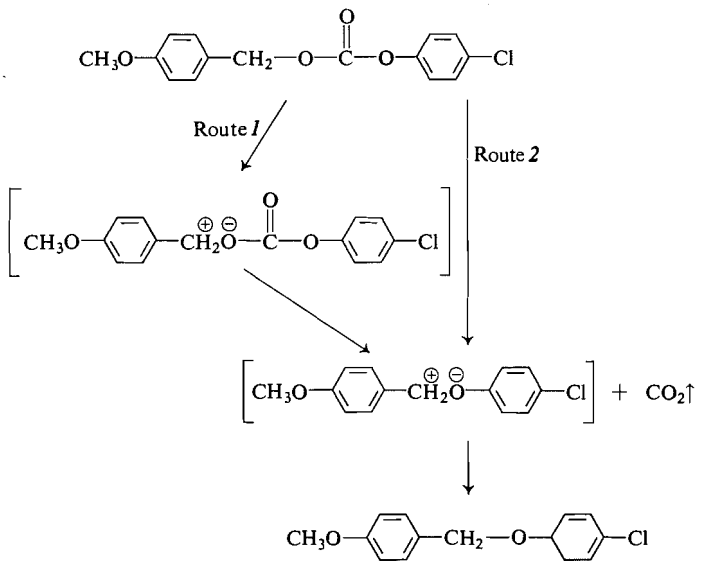
When the pyrolyses of the carbonates were first attempted without the use of solvent, the decomposition temperatures ranged from 100–170° and the crude ether yields were 30–60%. Starting phenols were identified as the major side product along with other unidentified materials (possibly multi-substituted phenols). Use of dimethylsulfoxide (DMSO) and hexamethylphosphoramide (HMP) as solvent media lowered reaction temperatures by 10–25°. However HMP had an additional advantage in that most of the carbonates which were decomposed using it as a solvent yielded ethers which crystallized after the pyrolysis was complete. In the case of *p*-methoxybenzhydryl phenyl carbonate, use of toluene as a solvent gave the most satisfactory results. In all the cases examined, the ether yields were good to excellent (see Table 2) and



SCHEME 1



SCHEME 2



SCHEME 3

the amount of work required to obtain pure anisylic phenyl ethers from the corresponding carbonates was minimal.

The thermal decomposition of these aralkyl carbonates could well follow the SNi mechanism established for the decomposition of alkyl chlorocarbonates (3) and more recently to that proposed for the decomposition of aralkyl thiocarbonates (4) (Scheme 3). The question of the timing of the different bond scissions cannot be commented on at this time *i.e.* whether the heterolysis of the aralkyl-oxygen bond and the carbonyl-phenoxy bond occurs simultaneously (route *2*) or in two successive steps (route *1*). Extensive work has been carried out on the kinetics of the decomposition along with some stereochemistry which will help elucidate the mechanism involved. This will be reported in a later paper.

Experimental

All melting points were determined on the Fisher–Johns m.p. apparatus and are uncorrected. Analyses were performed by Organic Microanalyses, 5757 Decelles Avenue, Montreal, Quebec. The n.m.r. spectra were measured on a Varian A60A instrument using tetramethylsilane as a standard and the i.r. spectra on a Beckman IR 5A.

Preparation of Anisylic Alcohols

Anisyl alcohol and 3,4-dimethoxybenzyl alcohol were available commercially and used without further purification. *p*-Methoxybenzhydrol was prepared using a normal Grignard reaction. Phenyl magnesium bromide was

reacted with *p*-anisylaldehyde to yield *p*-methoxybenzhydrol, m.p. 65–66° (lit. (5) m.p. 66–67°) in a 70% yield.

Preparation of Chloroformates

Commercial grade phenyl chloroformate was used without further purification. The substituted phenyl chloroformates were prepared by reacting the properly substituted phenol with phosgene according to the method of Zabik and Schuetz (6) who had previously prepared all the chloroformates used in this study. Yields for the chloroformates were in general 70% or greater.

Preparation of 3,4-Dimethoxybenzyl p-Methoxyphenyl Carbonate

The general method used in the preparation of the carbonates will be given. To a stirring solution of 40.0 g (0.238 mol) of 3,4-dimethoxybenzyl alcohol in 200 ml of anhydrous pyridine cooled to 0°, was added dropwise 49.0 g (0.262 mol) of *p*-methoxyphenyl chloroformate. The mixture was then stirred at room temperature for 12 h. Methylene chloride (200 ml) was added and the mixture was extracted twice with 200 ml of 5% HCl. The organic layer was then washed with 200 ml of 5% NaOH to remove any phenolic materials, washed with water, and dried over sodium sulfate. The solvent was removed *in vacuo* to give a white solid which was recrystallized from chloroform–petroleum ether (b.p. 30–60°) to give 66.3 g (88%) of pure carbonate, m.p. 70–71°. The carbonate had the following spectral data: n.m.r. ($CDCl_3$) δ (p.p.m.) 6.80–7.32 (7H multiplet, aromatic), 5.20 (2H singlet, methylene), 3.83 (6H singlet, benzyl CH_3O—), 3.77 (3H singlet, phenyl CH_3O—); i.r. (CCl_4) 1754 (C=O stretch), 1265–1200 (ester C—O stretch), and 1033 cm^{-1} (R—O—R^1 stretch).

Anal. Calcd. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70. Found: C, 64.39; H, 5.65.

The remainder of the carbonates were prepared in a similar manner and the details are shown in Table 1. The only variation in the method was in the case of the benzhydryl system where better results were obtained by reducing the amount of pyridine used by four-fifths. The spectral data for the carbonates prepared were consistent with the assigned structures.

Pyrolysis of 3,4-Dimethoxybenzyl p-Methoxyphenyl Carbonate

In a typical experiment, 5.0 g (0.016 mol) of 3,4-dimethoxybenzyl *p*-methoxyphenyl carbonate was placed in 3 ml of hexamethylphosphoramide (HMP) and the solution was heated. When CO_2 began to evolve at a steady rate (limewater trap was used), the temperature (140°) was kept constant. After 1 h an i.r. spectrum of the reaction mixture showed no starting material remained and the heating was stopped. Upon cooling, a solid formed in the reaction flask. Water (about 4 ml) was added dropwise to cause further precipitation and the solid formed was recovered by filtration; washed with water, and dried. Recrystallization from chloroform–petroleum ether (b.p. 30–60°) yielded 4.0 g (93%) of pure 3,4-dimethoxybenzyl *p*-methoxyphenyl ether (m.p. 86–87°). The ether had the following spectral data: n.m.r. ($CDCl_3$) δ (p.p.m.) 6.92 (7H unresolved aromatic multiplet centered at 6.92), 4.92 (2H singlet, methylene), 3.84 (9H singlet, CH_3O—), 3.76 (3H singlet, phenyl CH_3O—); i.r. (CCl_4) 1230 cm^{-1} (C—O—C stretch).

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.06; H, 6.61. Found: C, 70.25; H, 6.59.

All the thermal decompositions were carried out in a similar manner with use of toluene as a solvent being the only variation. Details are shown in Table 2. The assigned structures for the ethers prepared were supported by spectral data.

The authors wish to thank the National Research Council of Canada for financial support of this research and the Department of University Affairs for the award of an Ontario Graduate Fellowship to T. H. Breckles. We also wish to thank Dow Chemical of Canada Ltd. for a generous supply of HMP.

The Chlorination of Pyrroles. Part II[1]

G. R. BIRCHALL AND A. H. REES
Department of Chemistry, Trent University, Peterborough, Ontario

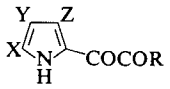
Received August 27, 1970

We report the chlorination of pyrryl-2-glyoxylic acid and derivatives and hence a synthesis of *O,O'*-dimethylpyoluteorin and 5-dechloro-*O,O'*-dimethylpyoluteorin. The different behavior of these compounds on demethylation is described and explained.

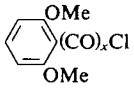
La chloruration de l'acide pyrolleglyoxylique-2 et quelques-uns de ses dérivés est rapportée; ces réactions constituent une synthèse de l'*O,O'*-diméthylpyolutéorine et du dechloro-5 *O,O'*-diméthylpyolutéorine. Le comportement différent de ces composés vis-à-vis de la réaction de déméthylation est décrit et expliqué.

Canadian Journal of Chemistry, 49, 919 (1971)

We found during the synthesis of pyoluteorin (2, 3) that the preparation (4) of pure 4,5-dichloropyrrole-2-carboxylate was troublesome. We therefore prepared pyrryl-2-glyoxylyl chloride (**1**, X = Y = Z = H; R = Cl) (5) and hence the acid (**1**, X = Y = Z = H; R = OH) and its isobutylamide **2**. We anticipated that chlorination at the 3-position would be blocked. This expectation was not fully met but we found that the products were more easily separated. We thus obtained the chloroamides **3**, **4**, and **5** and hence some of the corresponding ketoacids.



1



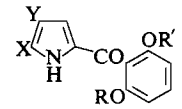
6

R = $NHCH_2CHMe$	
X = Y = Z = H	**2**
X = Y = Cl; Z = H	**3**
X = Z = Cl; Y = H	**4**
X = Z = H; Y = Cl	**5**

Before oxidation to the carboxylic acids, we used the salts of the ketoacids in reaction with **6** ($x = 1$) (2, 3). This went in poor yield when X = Y = Z = H. There was no improvement when we used 2,6-dimethoxyphenylglyoxylyl chloride (**6**, $x = 2$).

By reaction of **1** (X = Y = Cl; Z = H; R = Na) with **6** ($x = 1$) we obtained a pure sample of **8** (3) and hence of pyoluteorin.

Hydrolysis of **5** and oxidation gave 4-chloropyrrole-2-carboxylic acid. From this acid or the parent ketoacid we made 5-dechloro-*O,O'*-dimethylpyoluteorin **9** (6), identical with the compound obtained by partial hydrogenation of **8**. Demethylation with boron trichloride stopped at **10** in contrast to the complete demethylation of **8** under the same mild conditions. This resembled our earlier demethylation of **7** with this reagent which gave **11**. Complete demethylation to **12** (6) was done with aluminum bromide. The latter reagent converted **9** to 5-dechloropyoluteorin (**13**) (7).



7 X = Y = H; R = R′ = Me
8 X = Y = Cl; R = R′ = Me
9 X = H; Y = Cl; R = R′ = Me
10 X = H; Y = Cl; R = Me; R′ = H
11 X = Y = R = H; R′ = Me
12 X = Y = R = R′ = H
13 X = R = R′ = H; Y = Cl

This difference is attributed to the acidity of the pyrrole NH whose anion can donate to the boron atom and promote a second mild demethylation in cases where there are sufficient electronegative groups in the heterocyclic ring or where the Lewis acid is sufficiently polar.

We prepared the ester **14** but neither it nor chloro-derivatives **15**, **16**, and **17** underwent thermal decarbonylation, probably because of NH to carbonyl bonding.

1 R = OCH_2CHMe_2	
X = Y = Z = H	**14**
X = Z = H; Y = Cl	**15**
X = Z = Cl; Y = H	**16**
X = Y = Cl; Z = H	**17**

TABLE 1. The n.m.r. spectra ($CDCl_3$) of 2-pyrryl glyoxylic acid derivatives

Compound	1H	3H	4H	5H	CH_2CHMe_2	$—CHMe_2$	$—CHMe_2$	Amide H
2	−1.6m	2.81m	3.6m	2.48m	6.77t	8.1m	9.05d	2.3
3	−1.6m	2.55d			6.75t	8.1m	9.05d	2.5
4	−1.6d		3.81d		6.84t	8.2m	9.05d	2.5
	←———	$J_{1,4}$ 1.8Hz	———→					
5	−1.6m	2.92m		2.65m	6.78t	8.2m	9.05d	2.4
		←———	After D_2O J 1.6Hz	———→				
15	−0.5	2.8m		2.7m	5.83d	7.9m	8.94d	—

Finally we investigated the dichlorination in acetic acid of pyrryl-2-glyoxylic acid **1** (R = OH; X = Y = Z = H) to the 4,5-dichloro-derivative (plus minor amounts of 4-chloro-derivative). We attribute the absence of any other isomers to strong solvation of the ketoacid function, effectively blocking the 3-position. Taking advantage of the different NH acidities, we were able to selectively oxidize the monochloroketoacid to the easily separable monochloroacid with alkaline peroxide. We attribute the stability of the dichloroketoacid to the formation of an O,N-dianion, not attacked by HOO^- whereas in the monochloro-analogue there must be appreciable quantities of mono-anion present so that attack by HOO^- gives **18** which breaks down as indicated (8). This affords a convenient route to pure dichloroketoacid and hence by further oxidation to 4,5-dichloropyrrole-2-carboxylic acid.

Experimental

2-Pyrrylglyoxylic Acid and Isobutylamide

Pyrrole, 10.7 g in 50 ml dry ether was added dropwise with stirring to 16 ml oxalyl chloride in 200 ml ether at −70° over 3 h. The mixture was poured slowly into a vigorously stirred solution of 24 g sodium hydroxide in 240 ml ice-water and the aqueous layer was separated and acidified, giving ketoacid **1** (X = Y = Z = H; R = OH). This crude acid, in ether solution, was washed with water to remove oxalic acid and the solution dried ($MgSO_4$) and evaporated at 20° giving 15.4 g, 70% ketoacid, m.p. 112° crystallized from benzene (lit. m.p. 113° (9)).

When the ketoacid chloride, prepared as above, was poured into a stirred solution of 50 ml isobutylamine in 200 ml ether at −70° and the system allowed to warm up, the residue after filtration was crude amide. It was taken up in dichloromethane, filtered, dried ($MgSO_4$), and evaporated giving 28 g crystalline amide. This was chromatographed on 750 g neutral alumina. Elution with light petroleum/ether 4:1 gave 5 g di-isobutyloxamide, m.p. 168° (18%). Further elution, solvent ratio 20:7, gave *N*-isobutyl-2-pyrrylglyoxylamide, 20 g (70%), m.p. 90°, crystallized from aqueous ethanol; i.r. (Nujol) 3480 (NH), 1672, 1630 (CO bands) cm^{-1}.

Anal. Calcd. for $C_{10}H_{14}N_2O_2$: C, 61.8; H, 7.3; N, 14.4. Found: C, 61.65; H, 7.3; N, 14.5.

Chlorination of 2

Amide **2** (2% in acetic acid) was treated with 2.1 mol chlorine and left overnight at room temperature. Evaporation of the solvent and chromatography of the residue on silica, eluting with light petroleum/ether (increasing ratio), gave (*a*) 3,5-dichloro-derivative **4**, 6%, m.p. 118–119° crystallized from benzene/light petroleum; mass spectrum *m/e* 264 (20), 262 (40), 164 (64), 162 (100).

Anal. Calcd. for $C_{10}H_{12}Cl_2N_2O_2$: C, 45.6; H, 4.6; Cl, 26.9; N, 10.6. Found: C, 45.3; H, 4.2; Cl, 26.7; N, 10.6.

(*b*) 4,5-Dichloro-derivative **3**, 50%, m.p. 132°; mass spectrum *m/e* 264 (20), 262 (32), 57 (100).

Anal. Calcd. for $C_{10}H_{12}Cl_2N_2O_2$: C, 45.6; H, 4.6; Cl, 26.9; N, 10.6. Found: C, 45.7; H, 4.6; Cl, 27.2; N, 10.8.

(*c*) 4-Chloro-derivative **5**, 20%, m.p. 134°; mass spectrum *m/e* 230 (12), 228 (38), 130 (34), 128 (100), 57 (100).

Anal. Calcd. for $C_{10}H_{13}ClN_2O_3$: Cl, 15.5. Found: Cl, 15.1.

A mixture of products (12%), was also obtained, containing the trichloroderivative, *m/e* 296 (M^+).

Chlorination (1.2 mol) under the same conditions, gave as above 5% **4**, 22% **3**, and 50% **5** after chromatography.

The orientations of the chlorinated amides (and esters) follow from their n.m.r. spectra, Table 1.

4,5-Dichloro-2-pyrrylglyoxylic Acid

Amide **3**, 1.8 g, and potassium hydroxide, 2.3 g in 10 ml ethanol and 50 ml water, were refluxed 2 h. After evaporation of the solvent, water was added and the alkaline solution extracted with ether and acidified giving 1.2 g (90%) of the acid m.p. 177°, yellow needles crystallized from benzene/light petroleum, i.r. (Nujol) 1710, 1643 (CO bands); mass spectrum *m/e* 209 (24), 207 (40), 164 (40), 162 (100).

Anal. Calcd. for $C_6H_3Cl_2NO_3$: N, 6.75. Found: N, 7.0.

4-Chloro-2-pyrrylglyoxylic Acid

Amide **5**, by the method above, gave the acid (90%), m.p. 160° crystallized from benzene/light petroleum; mass spectrum *m/e* 175 (16), 173 (48), 130 (34), 128 (100).

Anal. Calcd. for $C_5H_4ClNO_3$: Cl, 20.4. Found, Cl, 20.4.

2,6-Dimethoxybenzoyl Cyanide

Compound **6** ($x = 1$) (10), 20 g, was refluxed 20 h in 100 ml dry benzene with 10.3 g cuprous cyanide. After filtration, the organic layer was washed with sodium bicarbonate solution, then with water, dried ($MgSO_4$), and evaporated. The residue was crystallized from benzene/light petroleum to give 11 g (60%) of ketonitrile, light yellow needles m.p. 69–70°, i.r. (Nujol) 2300 cm^{-1} (CN); mass spectrum *m/e* 191 (100%, M^+).

Anal. Calcd. for $C_{10}H_9NO_3$: C, 62.8; H, 4.75; N, 7.3. Found: C, 62.9; H, 4.8; N, 7.4.

2,6-Dimethoxyphenylglyoxylamide

The above cyanide (9 g) was left for 5 days at 20° in 100 ml concentrated hydrochloric acid solution. Dilution with water gave the amide, 7.5 g (80%) m.p. 148–150°, crystallized from benzene/light petroleum, i.r. 3500, 3320, 1690, 1643 cm^{-1}; mass spectrum *m/e* 209 (4), 165 (100).

Anal. Calcd. for $C_{10}H_{11}NO_4$: C, 57.4; H, 5.3; N, 6.7. Found: C, 56.8; H, 5.2; N, 6.3.

New Synthesis of 2,6-Dimethoxyphenylglyoxylic Acid

The above amide (7.5 g) was refluxed 1 h with 300 ml 5% potassium hydroxide solution. The cold solution was extracted with methylene chloride then acidified giving the acid, 5 g (66%), as an oil which slowly crystallized, m.p. 92–95° from benzene/petroleum ether (lit. m.p. 98° (11)); i.r. (Nujol) 1705, 1665 cm^{-1}; mass spectrum *m/e* 210 (14), 165 (100).

Monodechloro-O,O'-dimethylpyoluteorin (9)

Table 2 summarizes the syntheses of **9**. It formed colorless needles m.p. 150° from benzene/light petroleum, i.r. (Nujol) 3300, 1625, 1600 cm^{-1}; u.v. max (ethanol) 295 mμ.

Anal. Calcd. for $C_{13}H_{12}ClNO_3$: C, 58.6; H, 4.6; Cl, 13.4; N, 5.3. Found: C, 59.0; H, 4.6; Cl, 13.3; N, 5.1.

O,O'-Dimethylpyoluteorin (8)

The method of Table 2, after preparative t.l.c. and crystallization from benzene/light petroleum, gave 4% pure **8**, m.p. 193–196°; u.v. max (ethanol) 305 mμ; i.r. 1630, 1603 cm^{-1}.

Anal. Calcd. for $C_{13}H_{11}Cl_2NO_3$: C, 52.0; H, 3.7; Cl, 23.7; N, 4.7. Found: C, 52.4; H, 3.8; Cl, 23.4; N, 4.5.

Hydrogenation of O,O'-Dimethylpyoluteorin (8)

Compound **8**, 480 mg in 40 ml acetic acid containing 650 mg sodium acetate, was shaken in hydrogen with 1 g 5% palladium-on-charcoal. One molar equivalent was taken up in 1.5 h. After filtration and evaporation of the solvent, the residue was resolved by t.l.c. giving **8**, 180 mg and monodechloro-*O,O'*-dimethylpyoluteorin, **9**, 200 mg, identical with the material synthesized above.

5-Dechloro-O-monomethylpyoluteorin (10)

Compound **9** (80 mg) was demethylated with boron trichloride (3). The product, from the n.m.r. and mass spectrum was the monomethyl ether **10**, m.p. 148°, crystallized from benzene/light petroleum, 60 mg (80%), i.r. (Nujol) 3400, 3200, 1615, 1598 cm^{-1}.

Anal. Calcd. for $C_{12}H_{10}ClNO_3$: Cl, 14.1. Found: Cl, 13.9.

TABLE 2. Reactions of pyrrole acid salts with acid chlorides **6**

Pyrrole salt	Acid Chloride **6** x	Product	Yield (%)
2-COCOONa	1	**7**	5
2-COONa	2	**7**	5
4-Cl-2-COONa	1	9	5
4-Cl-2-COCOONa	1	**9**	2
4-Cl-2-COCOONa	2	**9**	1
4,5-di-Cl-2-COCOONa	1	**8**	4

Didechloro-O-monomethylpyoluteorin (11)

Didechloro-*O,O'*-dimethylpyoluteorin, 80 mg, was treated with boron trichloride as described (3). The product, after crystallization from benzene/light petroleum, had m.p. 129°, 60 mg (80%); i.r. (Nujol) 1613 cm^{-1}.

Anal. Calcd. for $C_{12}H_{11}NO_3$: C, 66.35; H, 5.1; N, 6.45. Found: C, 66.1; H, 4.8; N, 6.3.

The same product was obtained using aluminum chloride under mild conditions. Aluminum bromide effected removal of both methyl groups. So did boron tribromide (12).

5-Dechloropyoluteorin (13)

The dimethyl ether **9**, 135 mg, in 20 ml dry benzene, was treated with 400 mg anhydrous aluminum bromide, After stirring for 2 h at 20°, water was added and the organic layer separated and dried ($MgSO_4$). After evaporation of the solvent, the residue was recrystallized from benzene giving 110 mg (90%) 5-dechloropyoluteorin, m.p. 197°; i.r. 3500–3400, 1633, 1598, 1560 cm^{-1}; u.v. max (ethanol) 330 mμ, log ε = 4.25; n.m.r. see Table 3.

Isobutyl Pyrryl-2-glyoxylate (1, X = Y = Z = H; R = i-Bu)

Pyrrole, 10.7 g was converted to the glyoxylyl chloride as above. The mixture, at −70° was poured slowly into a solution of sodium, 3.4 g, in excess isobutanol. The system was allowed to warm up with stirring and left for 24 h. Evaporation of the solvent left a residue which was absorbed onto 600 g silica and eluted with light petroleum/ether, 10:1, giving 25 g, 75% of ester **14**, i.r. 1740, 1655 cm^{-1}.

Chlorination of the Above Ester

The ester, 12.5 g, was treated with 1.2 mol chlorine in acetic acid. Work-up, as above, gave after column chromatography on silica, 7.5 g (50%) isobutyl 4-chloropyrryl-2-glyoxylate as colorless needles, m.p. 75°; mass spectrum *m/e* 231 (8), 229 (24), 130 (33), 128 (100).

Anal. Calcd. for $C_{10}H_{12}ClNO_3$: C, 52.7; H, 5.3; Cl, 15.4; N, 6.1. Found: C, 52.3; H, 5.3; Cl, 15.3; N, 6.3.

Hydrolysis with 40% potassium hydroxide solution gave pure 4-chloropyrryl-2-glyoxylic acid in quantitative yield.

TABLE 3. The n.m.r. spectra of pyoluteorins

Compound	Solvent	1H	3H	4H	5H	3′	4′	5′	Me	OH
9*	$CDCl_3$	0.0	3.54m	—	3.0 m	3.43d†	2.66m	3.43d	6.25	—
10	DMSO-d_6	−2.0	3.8 m		2.9 m	3.58d	2.9 m	3.58d	6.4	0.4
11*	$CDCl_3$	0.1	3.14m	3.75m	2.98m	3.4 d	2.7 m	3.14d	6.3	0.2
			After D_2O $J = 3.6$ Hz		$J = 2.4$ Hz					
					$J_{3,5} = 1.2$ Hz					
13*	DMSO-d_6	−2.0	3.8 m	—	2.97m	3.75d	3.12m	3.75d	—	0.63

*After D_2O, $J_{3,5} = 1.6$ Hz.
†The 3′,4′,5′ protons form an AB_2 system, $J_{A,B} = 7$–7.5 Hz (K. Bailey, personal communication; compare J. R. Dyer, ref. 13).

A mixture of isobutyl 3,5- and 4,5-dichloropyrryl-2-glyoxylates, 5.0 g (30%) was also obtained, shown by n.m.r. to be in the ratio of 1:3.

4-Chloropyrrole-2-carboxylic Acid

4-Chloropyrryl-2-glyoxylic acid, 3.2 g in 60 ml 2 *N* sodium hydroxide solution, was treated dropwise with 18 ml 3% hydrogen peroxide solution at 5°. The stirred solution was allowed to warm to room temperature over 20 h then acidified and extracted with ether. The ether solution was extracted with sodium bicarbonate solution and the latter acidified giving a precipitate of 2.2 g (83%) of 4-chloropyrrole-2-carboxylic acid; m.p. 195° not sharp; i.r. (Nujol) 1700 cm^{-1} (CO); mass spectrum *m/e* 147 (20), 145 (60), 129 (35), 127 (100).

Anal. Calcd. for $C_5H_4ClNO_2$: C, 41.3; H, 2.8; Cl, 24.4; N, 9.6. Found: C, 41.4; H, 2.8; Cl, 24.2; N, 9.5.

The mass spectra of pyrrole acids, ketoacids, and their derivatives show cleavage to the pyrrol cation, loss of carbon monoxide to a pyrryl ion and then loss of HCN to give a cyclopropenyl ion (1).

Chlorination of Pyrryl-2-glyoxylic Acid

The above acid, 1 g, in 5 ml acetic acid was treated dropwise with 2.2 mol chlorine in 25 ml acetic acid. The system was stirred 20 h at 20° and the solvent taken off under vacuum. The residue, crystallized from benzene/light petroleum gave a 0.7 g cocrystalline mixture of 4- and 4,5-dichloroketoacids, analyzed by n.m.r. in NaOD solution as being in the ratio 1:4. There was no signal above 3 τ, indicating a total lack of 4-H protons.

Oxidation of the Mixture of Chloroketoacids

The acid mixture above, 240 mg, was oxidized with excess alkaline peroxide as described previously. Preparative t.l.c. on silica, chloroform/methanol/acetic acid (50:5:1) then gave bands at R_f 0.4 and 0.1 due to the chloropyrrole-2-carboxylic acid, 20 mg and the dichloropyrroleketoacid, 150 mg, respectively, after recrystallization, identical with pure authentic specimens obtained earlier, above.

Oxidation of 4,5-Dichloropyrryl-2-glyoxylic Acid (1, X = Y = Cl; Z = H; R = OH)

The dichloroketoacid, 20 mg, in 4 ml 50% aqueous acetic acid was treated with 45 mg lead tetraacetate at 20°. After 1 h the solvent was removed and the residue was shaken with ether and dilute sulfuric acid. The ether extract was dried ($MgSO_4$) and evaporated and the residue purified by t.l.c. giving, after recrystallization from benzene/light petroleum, 8 mg 4,5-dichloropyrrole-2-carboxylic acid.

Electronic Excited States of the Cyclic 1,4-Diaza-1,3-diene (Cyclic α-Diimine) System. Photochemical Reactions of 2*H*-Isoimidazole, 5,6-Dihydropyrazine, and 1,4-Diazepine Derivatives[1]

D. R. ARNOLD,[2] V. Y. ABRAITYS, AND D. MCLEOD, JR.
Union Carbide Research Institute, P.O. Box 278, Tarrytown, New York 10591

Received September 17, 1970

The five-, six-, and seven-membered cyclic 1,4-diaza-1,3-dienes have been irradiated under a variety of conditions. The six-membered ring (dihydropyrazine) opens in a 6π e valence isomerization reaction. The resulting enediimine is stable at low temperatures and has been characterized (i.r.). Irradiation of 2,3,5,5-tetramethyl-5,6-dihydropyrazine (**1***b*) results in formation of the enediimine **2***b* which reacts further to give the rearranged monomer **12** and/or dimers **13** depending upon the temperature. The five- and seven-membered systems are stable to irradiation in inert solvents. However, irradiation of 2,2-dimethyl-4,5-diphenylisoimidazole (**10***h*) in isopropyl alcohol gives the dihydroderivative **19** and in tetramethylethylene the one-to-one adduct **25**.

The u.v. spectrum of the six-membered ring (5,6-dihydropyrazine) is very different from that of the five- and seven-membered rings. The long wavelength maximum (*ca.* 350 nm) of the six-membered ring is attributed to a transition directly into an excited state common to the enediimine **2** (*i.e.*, the excited state has a node between C-5 and -6 of the dihydropyrazine).

Les diaza-1,4 dienes-1,3 cycliques à cinq, six, et sept chaînons ont été irradiés sous plusieurs conditions. Le cycle à six chaînons (la dihydropyrazine) s'ouvre par une réaction impliquant une isomérisation de valence de 6π e. L'ènediimine résultante est stable à basse température et a été caractérisée (i.r.). L'irradiation de la tétraméthyl-2,3,5,5 dihydro-5,6-pyrazine (**1***b*) conduit à l'ènediimine **2***b* qui, selon la température, réagit pour donner le monomère réarrangé **12** et/ou le dimère **13**. Les systèmes à cinq et sept chaînons sont stables vis-à-vis de l'irradiation dans des solvants inertes. Cependant, l'irradiation du diméthyl-2,2 diphényl-4,5 isoimidazole (**10***h*) dans l'alcool isopropylique conduit au dérivé dihydro **19** et à un produit d'addition 1:1 **25** dans le tétraméthyléthylène.

Le spectre u.v. du cycle à six chaînons (dihydro-5,6 pyrazine) est très différent de celui des cycles à cinq et sept chaînons. L'importance de la longueur d'onde maximum (*ca.* 350 nm) du cycle à six chaînons est attribuée à une transition directement vers un état excité commun à l'ènediimine **2** (*i.e.*, l'état excité a un noeud entre les C-5 et -6 de la dihydropyrazine).

Canadian Journal of Chemistry, 49, 923 (1971)

Introduction

Photo- and thermal valence isomerization has proven to be a useful reaction for the synthesis of a variety of carbocyclic and heterocyclic systems (1). Scheme 1 illustrates some of the possible valence isomerizations of the 1,4-diazadiene system. The reactions shown with dark arrows have been observed.

The first report of a reaction in this series, starting with **1**, was by Beak and Miesel (2). It was found that several derivatives of **1** rearranged upon irradiation either to the imidazoles **9** (if R_4 was hydrogen) or to the isoimidazoles **10** (if neither R_3 nor R_4 were hydrogen) (see Scheme 2). These results were explained on the basis of the involvement of the intermediates **2** and **8**. While the intermediates were not detected, these products and the minor products, which were those expected from the addition of alcohol to **8**, made this mechanism plausible.

We report here details of our studies with **1** where the final products are consistent with the proposed mechanism. Furthermore, we have detected an intermediate, stable at low temperatures,[3] to which we assign structure **2**. Padwa *et al.*, have recently shown that some derivatives of **2**, which are stable at room temperature, can also be prepared in this way (4).

This system has also been approached from **3**. Heine and co-workers found that derivatives of **3** were photochromic and behaved like **8** toward dipolarophiles upon heating (5). The irradiation of derivatives of **3** has recently been reinvestigated, and both **2** and **8** were detected among the

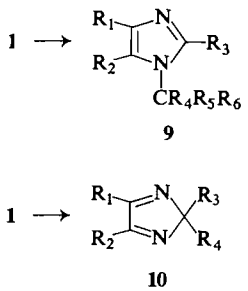

SCHEME 2

intermediates (4, 6). Table 1 summarizes the reported results of irradiations of this system.

There are no reported examples of the 4πe ring closure reaction (**7** from **1**) with a 1,4-diazadiene system. This reaction is of particular interest since the unknown 1,2-diazacyclobutene is predicted to have some aromatic character due to the presence of six electrons in a planar conjugated system (7). In a quest for an example of this reaction we have irradiated the isoimidazole **10***h* and the 1,4-diazepine **11** where the 6πe ring-opening reaction is prevented. The 4πe ring closure does occur in 1,3-cycloheptadiene (8) and cyclopentadiene (9) and in fact with some similar heterocyclic systems (10).

In the course of this work we were struck by the differences in the u.v. absorption spectrum of the seemingly identical chromophores contained in the five-, six-, and seven-membered ring. While some difference is expected due to strain and planarity variations through this series, the long wavelength (*ca.* 350 nm) absorption of the six-membered ring seems anomalous.[4] We interpret this absorption as a transition which involves the σ electrons of the 5,6-bond of **1**.

[4]The variation of absorption in the α-diketone series as a function of planarity has been studied in detail by N. J. Leonard and co-workers (11).

Results

The cyclic 1,4-diaza-1,3-dienes used in this study were readily prepared by condensation of the α-diketone with the appropriate amine. The syntheses of isoimidazoles (2, 12) and 5,6-dihydropyrazines (2, 13) are well known. The diazepine **11** was prepared in like manner from benzil and 1,3-propanediamine with little of the difficulty experienced by others (14). The analytical and spectral data for these compounds are given in

detail in the Experimental and, with the exception of the u.v. spectrum to be discussed later, were in accord with the structures.

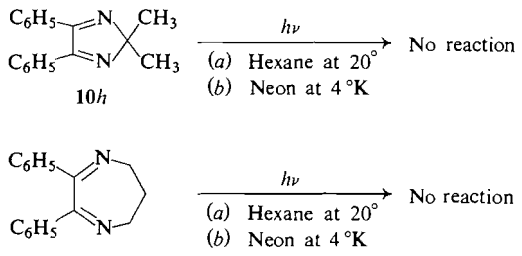
Irradiation of a benzene or methylcyclohexane: isopentane, (4:1), solution of 2,3,5,5-tetramethyl-5,6-dihydropyrazine (**1***b*) at room temperature (reaction 2, Table 1) gave a good yield of a rearranged product, to which we have assigned structure **12**, along with a mixture of less volatile products, presumably dimeric in nature. A major component of the less volatile mixture has been obtained pure and assigned structure **13**. The structural assignment of **12** rests primarily on spectral data and on deuterium exchange studies in acid solution. The i.r. spectrum of **12** shows strong absorption at 876 (hydrogen out-of-plane deformation of terminal methylene) and 1635 cm^{-1} (C=N stretching). The u.v. spectrum (λ_{max} 301 nm, ε 6000) reflects the conjugation in the system (14). The n.m.r. spectrum (C_6D_6) has absorption at δ 1.19 (the equivalent methyls), 1.99 (methyl on C=N), 2.39 (methyl on nitrogen), and a pair of doublets (J = 1.5 Hz) at 3.53 and 3.95 (the methylene group) consistent with the assigned structure. When the n.m.r. spectrum is taken in trifluoroacetic acid the spectrum of **12** protonated at the methylene group is obtained; δ 0.91 (the equivalent methyls), 1.34 (methyl on C=N), 1.41 (the methyl which was the methylene), and 1.94 (methyl on nitrogen). Deuterotrifluoroacetic acid exchanges the protons at δ 1.41 rapidly and those at δ 1.34 more slowly. The exchange of the hydrogens of the methyl C=N undoubtedly involves a diprotonated species which deprotonates from the methyl.

The molecular weight (mass spectrum and osmometric) requires a dimeric composition for **13**. The similarity in the i.r. and n.m.r. spectrum with that of **12** led to the assigned structure.

When the irradiation of **1***b* is carried out at low temperatures (reactions 3 and 4, Table 1), a different product is obtained which is stable at $-180°$ but which reacts when allowed to warm to $-80°$ (reaction 5). Little or no **12** is obtained in this way; instead the reaction mixture consists of the dimeric products (containing **13**) which were obtained in minor amounts in the room temperature irradiation.

The i.r. spectrum of the initial product (stable $< -180°$), and the subsequent reactions it undergoes upon warming, led to the tentative assignment of structure **2***b*. The i.r. absorption at 1677 cm^{-1} (C=N stretching) for **2***b* is consistent with the reported value for **2***l* (1625 cm^{-1}) where the imine is conjugated with the phenyl ring (4). The irradiation of **1***d* and *f* at low temperatures also forms the corresponding intermediates **2***d* and *f* with imine stretching frequencies of 1656 and 1675 cm^{-1} respectively.

The isoimidazole **10***h* and diazepine **11** were irradiated in inert solvents (hexane at 20°, neon at 4 °K, Scheme 3) under conditions which brought about isomerization of 1; however, no reaction was observed.

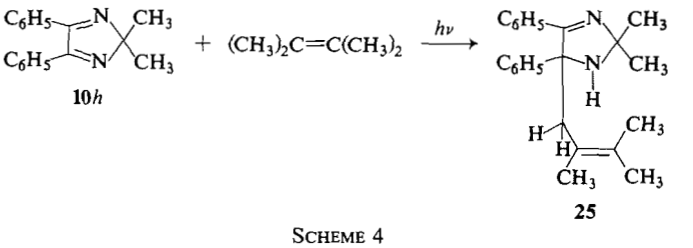


SCHEME 3

When the irradiation of **10***h* was carried out in isopropyl alcohol, the dihydroisoimidazole **19** was obtained in high yield. Compound **19** is reported as a direct irradiation product of **1***h* in ethanol, with **10***h* as a secondary product resulting from air oxidation of **19** upon work-up (reaction 14, Table 1) (2). The ease with which **10***h* is reduced in this solvent suggests the possibility of **10***h* being the precursor of **19**.

The diazepine **11** is also reduced upon irradiation in isopropyl alcohol although the reaction appears to be less efficient, and the product has not been fully characterized. Both of these photochemical reductions stop at the mono imine stage.

Irradiation of **10***h* in tetramethylethylene solution (Scheme 4) affords a one-to-one adduct in high yield. The structure **25** is assigned to the adduct on the basis of the analytical and spectral data reported in detail in the Experimental. The i.r. spectrum has absorption at 1630 (C=N stretch) and 3360 cm^{-1} (N—H stretch). The n.m.r. is consistent with the assigned structure with five nonequivalent methyl groups, a doublet attributed to the nonequivalent hydrogens of the methylene group, and a broad peak (δ 2.01) for the hydrogen attached to nitrogen. The hydrogen on nitrogen in the dihydroisoimidazole **19** appears in the same region (δ 2.08).



SCHEME 4

Discussion

The photo-valence isomerization of **1** to **2** appears to be a general reaction. The ultimate fate of the enediimine **2** depends upon substitution and temperature. This suggests competing reactions with low activation energies. For example, the formation of **12** upon irradiation of **1** at 20° can be explained by hydrogen migration within the intermediate **8***b*. If the irradiation is carried out at low temperatures, the enediimine **2***b* or the imine ylide **8***b* can react with each other or dimerize in competition with hydrogen migration.

The dimerization is a thermal reaction of the intermediate **2***b* and/or **8***b* since **2***b* is stable to the irradiation at low temperatures and yields dimers only, upon warming even in the dark. A photochemical dimerization of the enediimine **2***l* to give **22** (reaction 16, Table 1) has been suggested (2), and the reported formation of 4,4′-dimethylaminostilbene and azobenzene upon irradiation of 4-dimethylaminobenzaldehydeanil was given as an analogy (15). We have been unable to reproduce this reaction, however, and find the anil rather stable to irradiation.[5]

The ring closure of the enediimine **2***l* back to the dihydropyrazine **1***l* occurs to the exclusion of products derived from **8***l* (reaction 23, Table 1). In other cases studied where this reaction might have been observed, (reactions 5, 13, 15, Table 1) formation of **1** was, at most, a minor reaction. This may be the result of the decreased electrophilicity of the imine carbon when the imine moiety bears a phenyl group.

In the carbocyclic series, when the 6πe photovalence isomerization of cyclohexadiene to hexatriene is prevented, the 4πe reaction has been observed. Thus, irradiation of cyclopentadiene yields bicyclo[2.1.0]pentene, and 1,3-cycloheptadiene yields bicyclo[3.2.0]hept-6-ene (8, 9). The formally analogous reactions do not occur in the case of the 1,4-diaza-1,3-diene systems studied. Even at low temperatures, where thermal reversal of the bicyclic products would be prevented, no such product was detected.[6]

The u.v. absorption spectrum of the 1,4-diaza-1,3-diene chromophore is very different for the 5,6-dihydropyrazine **1**, and the isoimidazole **10***h* and diazepine **11**. Typical spectra are shown in Fig. 1. The long wavelength absorption maxima for several 5,6-dihydropyrazines are tabulated in Table 2. This maximum has been assigned to an $n \rightarrow \pi^*$ band (2). While it is certainly true that the geometry of the chromophore is dependent upon ring size and that the absorption spectrum is effected by the extent of planarity through the whole chromophore (11), it seemed desirable to look for another explanation for a difference as pronounced as this.

The first possibility which must be considered is that small concentrations of the enediimine **2** are present in the sample of **1**. This may seem reasonable since the enediimine **2** does have absorption in this region [**2***l* λ_{max} (cyclohexane) 360 nm, ε 12 000 (4*b*)]. However, it seems unlikely that even small concentrations of **2** are present since **2** is, in most cases, quite unstable, giving products in a thermal reaction, and no such products are obtained even upon heating **1**.[7]

Another possibility is that small amounts of a tautomeric structure, the 2,5-dihydroisomer, causes the anomalous absorption. This can easily be ruled out since **1***c* and *h*, which cannot tautomerize, have the long wavelength maximum.

The explanation that we favor attributes this long wavelength absorption to a transition between the ground state 5,6-dihydropyrazine and

[5]Azobenzene is produced if oxygen is not excluded.

[6]The 2,3-diaza-1,3-diene system is similarly reluctant to close to the azo compound. For example, 1,4-diphenyl-5,5-dimethylisopyrazole and 1,4-diphenyl-2,3-diazepine are stable to irradiation in inert solvents. In this case, even the 6πe reaction is not observed; 1,4-diphenyl-5,5,6,6-tetramethyl pyridizine is stable to irradiation (16).

[7]For example, **1***d* is stable in refluxing benzene for many hours. When heated to 200°, **1***d* apparently isomerizes to the 1,4-dihydropyrazine (17).

an electronic excited state of the enediimine. That is, the electronic excited state has a node between C-5 and -6 of the 5,6-dihydropyrazine.

Of course the geometry of the initially formed excited state is the same as that of the ground state dihydropyrazine (Franck–Condon principle). In this geometry the nonbonding electrons on C-5 and -6 can interact with the nonbonding pair of electrons on the adjacent nitrogens. This is, thus, undoubtedly a less energetic structure than the initial state which would result from excitation of a planar enediimine and may, in fact, be the 0-vibrational, rotational structure of the excited state of the enediimine.[8]

[8]The 0-vibrational, rotational structure for the excited state of the analogous 1,3,5-hexatriene has one terminal methylene twisted out of the plane (18).

The suggestion that the σ-electrons of the 5,6-carbon–carbon bond are involved in this transition receives some support from the study of the anomalous absorption of triethylenediamine and from the study of the interaction of nonconjugated chromophores in general (19). Triethylenediamine has an absorption band at long wavelengths (λ_{max} 251 nm, ε 1000) (20) which has been assigned to the interaction of the nonbonding pairs of electrons on the nitrogens through the carbon–carbon σ-bonds (19). Calculations show that the carbon–carbon σ-bond in triethylenediamine is weakened in the low-lying excited state (19*a*).

The electronic transition from the ground state of one valence isomer to the electronic excited state of another valence isomer, described here

for the special case of 5,6-dihydropyrazine is undoubtedly a more general phenomena.[9] Indeed, the suggestion that the electrons of the 5,6-single bond are involved in the anomalously long wavelength absorption of 1,3-cyclohexadiene was made long ago (22) but abandoned in favor of an interpretation based on steric and hyperconjugative effects (23).

Experimental

The i.r. spectra (crystalline compounds, KBr; liquids, neat) were taken on a Beckman IR 5A spectrometer unless otherwise noted. The u.v. spectra were taken in spectral grade hexane or 95% ethanol using 10 mm cells on a Cary spectrophotometer model 14.

The n.m.r. spectra were determined on *ca.* 10% solutions with tetramethylsilane as internal standard on a Varian A 60 instrument.

The mol. wt. determinations (osmometric using benzene solution) and combustion analysis were by Schwarzkopf Microanalytical Laboratories, New York. Mass spectral analyses were by Morgan Schaffer Corp., Quebec City, Quebec, and utilized an ionization voltage of 70 eV. Melting points were taken on a Nalge apparatus and are not corrected.

*Preparation of 2,3,5,5-Tetramethyl-5,6-dihydropyrazine (**1b**)*

A solution of 8.8 g (0.1 mol) 1,2-diamino-2-methylpropane in 10 ml benzene was cooled in an ice bath and treated dropwise with 8.6 g (0.1 mol) biacetyl in 10 ml benzene. The reaction mixture became warm and homogeneous during the addition. This solution was refluxed for 30 min and then 3.6 ml of water was removed by a Dean–Stark trap. The benzene was removed on a rotary evaporator, and the oily residue was chromatographed on aluminia. The first fractions eluted with benzene contained 8.7 g (0.06 mol) 2,3,5,5-tetramethyl-5,6-dihydropyrazine (b.p. 60–61°/29 mm). This compound rapidly air oxidizes (turns purple) and was stored under nitrogen in a refrigerator. Pertinent analytical and spectral data for **1***b* are: n.m.r. (C_6D_6): δ 1.07 (6H, s), 1.82 (3H, s), 1.88 (3H, t, J = 1.5 Hz), 3.33 (2H, quartet, J = 1.5 Hz); (neat): δ 0.72 (6H, s), 1.42 (3H, s), 1.47 (3H, t, J = 2 Hz), 2.98 (2H, q, J = 2 Hz). The u.v. (hexane): 225 (ε 8900), 354 nm (190); (ethanol): 340 nm (200). The i.r. spectrum of a neat sample coincided with the spectrum taken in a xenon matrix which is reported in detail below.

Anal. Calcd. for $C_8H_{14}N_2$ (mol. wt. 138): C, 69.52; H, 10.21; N, 20.27. Found: (156 (osmetric)): C, 69.74; H, 10.23; N, 19.99.

*2,2-Dimethyl-4,5-diphenylisoimidazole (**10h**)*

This compound was prepared by a procedure similar to that reported (12). A solution of 10.5 g (0.05 mol) benzil, 40 g ammonium acetate, and 5 ml acetone in 100 ml glacial acetic acid was refluxed for 2 h. The solution was cooled, poured into 150 ml of ice–water, and then extracted with ether. The ether extract was washed with water until the washings were neutral, dried over magnesium sulfate, and evaporated to dryness. The resulting crude product was chromatographed on alumina with hexane eluent followed by short-path distillation (sublimation apparatus; 100°/10–15 mm) to afford 10 g (80%) of colorless crystals (m.p. 76–76.5°). The reported m.p. was 79–80° (12).

Pertinent spectral characteristics are: u.v. (hexane) 254 (ε 11 720), 215–220 (sh); (ethanol): 262 nm (ε 9700); n.m.r. (CCl_4) δ 7.20–7.62 (10H, m), 1.57 (6H, s); (acetic acid - d_4): δ 7.15–7.70 (10H, m), 1.70 (6H, s). No fluorescence or phosphorescence emission (methanol: ethanol, 4:1, 77°K) was observed from material purified in this way. Less pure samples showed emission believed due to trace amounts of triphenyloxazole and benzil. The i.r. spectrum taken in KBr coincided with the spectrum taken in a neon matrix which is reported in detail below.

*Preparation of 2,3-Diphenyl-1,4-diazepine (**11**)*

An equimolar benzene solution (3000 ml) of benzil (21 g) and 1,3-diaminopropane (7.4 g) and a trace of *p*-toluenesulfonic acid (0.5 g) was refluxed 3 days. Water (2.6 ml) was azeotroped out using a Dean–Stark trap and the benzene evaporated on a rotary evaporator. The oily residue (28.4 g) was crystallized from ethanol to obtain a crude solid (25 g, m.p. 111–115°) which was then chromatographed on alumina. The product (20.37 g) was eluted with 25% benzene in hexane. Further purification by recrystallization from hexane–ether gave **11** (m.p. 115–116.5°).

The following spectral and analytical data were obtained for **11**: u.v. (hexane); 234 (ε 15 824), 254 (16 213), shoulder 326 nm (240); (EtOH): 233 (17 890), 257 nm (16 720). The n.m.r. (CCl_4): δ 2.26 (pentet, 2H, J = 6.5 Hz), 3.49 (t, 4H, J = 6.5 Hz), 7.15–7.20 (m, 10H); ($CDCl_3$): δ 2.30 (pentet, 2H, J = 6.5 Hz), 3.53 (t, 4H, J = 6.5 Hz), and 7.15–7.75 (m, 10H). The i.r. spectrum taken in KBr coincides with the spectrum taken in a neon matrix which is reported in detail below.

Anal. Calcd. for $C_{17}H_{16}N_2$ (mol. wt. 248.3): C, 82.22; H, 6.50; N, 11.28. Found (251 (osmetric)): C, 82.24, 82.18; H, 6.60, 6.62; N, 11.30, 11.37.

*Irradiation of 2,3,5,5-Tetramethyl-5,6-dihydropyrazine (**1b**) at 20°*

A benzene (250 ml) solution of 2,3,5,5-tetramethyl-5,6-dihydropyrazine (3.4 g, 0.02 mol) was purged with nitrogen and irradiated with a 450 W Hanovia medium-pressure mercury vapor lamp through a Pyrex filter in an immersion well. The temperature of the solution was maintained at 20° by means of a water bath. After 1 day the benzene was removed on a rotary evaporatory at room temperature. The residue (3.7 g) was distilled on a spinning band column, and the fraction boiling 53–54° at 25 mm, $n_D^{18°}$ 1.4916 (2.7 g, 80%) was shown to be **12** on the basis of the following spectral and analytical data.

The i.r.: 2955 (s), 2920 (s), 1635 (s), 1430 (m), 1403 (s), 1363 (s), 1281 (s), 1266 (s), 1190 (s), 1160 (m), 1107 (m) 1030 (w), 1015 (w), 983 (w), 940 (m), 876 (s), 802 (w), 738–746 (s), and 694 (m) cm^{-1}. The u.v. (hexane): 301 nm (ε 6000); (ethanol): 312 nm (5400). The n.m.r. (neat): δ 1.10 (s, 6H), 1.91 (s, 3H), 2.47 (s, 3H), 3.34 (d, 1H, J = 1.5 Hz), 3.72 (d, 1H, J = 1.5 Hz); (C_6D_6): δ 1.19 (s, 3H), 1.99 (s, 3H), 2.39 (s, 3H), 3.53 (d, 1H, J = 1.5 Hz), 3.95 (d, 1H,

[9]For example, the long wavelength absorption of 2*H*-chromenes and 2*H*-pyrans may involve a transition into the excited states of the α,β, and γ,δ unsaturated carbonyl compound (21).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

J = 1.5 Hz). The n.m.r. was also taken in trifluoroacetic acid (H and D) with internal standard (DDS). The tube containing the acid was purged with nitrogen and cooled prior to the addition of **12**. These spectra are described in the Results.

Anal. Calcd. for $C_8H_{14}N_2$ (mol. wt. 138): C, 69.52; H, 10.21; N, 20.27. Found (167 (osmetric)): C, 69.78; H, 10.19; N, 20.07.

The residue (0.3 g) from the above distillation of **12** was distilled under higher vacuum. The fraction boiling 96–98°/0.1 mm, n_D^{18} 1.50 (0.3 g, 19%) was shown to be a mixture of dimers with **13** as a major component, assigned on the basis of spectral and analytical data. This mixture was unstable toward air (turns purple), and **13** was not obtained free of the other isomers. One sample of the mixture was observed to partially crystallize, and the i.r. and n.m.r. reported below were taken on this sample.

The i.r.: 2960 (s), 2920 (m), 2855 (w), 2760 (w), 1690 (w), 1650 (w, shoulder), 1645 (m, shoulder), 1627 (C=N) (s), 1615 (s), 1450 (w), 1373 ($C(CH_3)_2$) (s), 1300 (w), 1280 (s), 1260 (w), 1220 (w), 1188 (m), 1162 (w), 1120 (w), 1036 (w), 878 (=C^H_H) (m), 820 (w), 737 (s), 696 (w), and 657 (w) cm^{-1}. The n.m.r. (C_6D_6): δ 1.28 (s, 12H), 1.99 (s, 6H), 3.24 (s, 4H), 3.78 (broad s, 2H), 3.95 (broad s, 2H).

The mass spectrum had a parent peak at 276 and peaks at 274 and 272. The ratio of these peaks varied with the temperature of the inlet. This is taken as evidence for loss of hydrogen (one and two molecules) in the inlet.

Anal. Calcd. for $C_{16}H_{28}N_4$ (mol. wt. 276): C, 69.52; H, 10.21; N, 20.27. Found (246 (osmetric)): C, 69.78; N, 10.30; N, 20.12.

The irradiation of neat **1***b* was carried out in a Pyrex n.m.r. tube kept at 20° by means of a water bath. The irradiation source was the 450 W Hanovia medium-pressure mercury vapor lamp 2 in. away. After 1 day of irradiation the n.m.r. indicated essentially complete conversion to monomer **12**. No dimers were detected.

Irradiation of 2,3,5,5-Tetramethyl-5,6-dihydropyrazine (1b) at Low Temperatures

A 1.0 g sample of the dihydropyrazine dissolved in 10 ml of methylcyclohexane:isopentane, 4:1, in a Pyrex tube, was purged with nitrogen, sealed, and cooled in liquid nitrogen in a Pyrex dewar to form a glass. This sample was irradiated at liquid nitrogen temperatures with a 1 kW high-pressure, mercury vapor lamp (General Electric AH6). After 6 h irradiation the tube was allowed to warm to room temperature, and the solvent was removed on a rotary evaporator. The n.m.r. and i.r. of the crude reaction mixture showed starting material and the mixture of dimeric material obtained in minor amounts from the irradiation at room temperature mentioned previously.

When the irradiation was carried out as above except at −50°, the rearranged monomer **12** was the major product (rearranged monomer: dimer mixture, *ca.* 6:1). Irradiation at room temperature for 19 h gave essentially complete conversion to the rearrangement monomer **12**.

Irradiation of 2,3-Diphenyl-1,4-diazepine (11) in Hexane at 20°

2,3-Diphenyl-1,4-diazepine (**11**) (3 g) was dissolved in hexane (275 ml), purged with nitrogen, and irradiated with a 450 W Hanovia medium-pressure mercury vapor lamp through a quartz immersion well. The temperature of the irradiation was maintained at 20° by means of a water bath. After 15 days irradiation, the solvent was removed on a rotary evaporator, and the residue (3 g) was found to be essentially pure starting material (t.l.c., i.r., n.m.r.).

Irradiation of 2,2-Dimethyl-4,5-diphenylisoimidazole (10h) in Hexane

A solution of 0.5 g of **10***h* in 5 ml of hexane in a quartz tube (9″ × 3/8″ i.d.) was purged with nitrogen, sealed, and irradiated with a 450 W Hanovia medium-pressure lamp *ca.* 2 in. away for 2 weeks. During the irradiation the temperature of the solution was maintained at 15° using a water bath. The solvent was evaporated leaving a crystalline residue which was shown by n.m.r. and i.r. to be essentially pure starting material.

A 4×10^{-5} *M* solution of **10***h* in hexane was irradiated in a 10 mm quartz tube through a Pyrex filter using the above conditions. No change in the u.v. absorption spectrum was observed after 16 h.

Procedure for Irradiation of Cyclic 1,4-Diazadienes in Inert Matrices at Low Temperatures

Inert gas matrices of 2,3,5,5-tetramethyl-5,6-dihydropyrazine (**1***b*), 2,3-diphenyl-5,5-dimethyl-5,6-dihydropyrazine (**1***f*), 2,3-diphenyl-5,6-dihydropyrazine (**1***d*), 2,3-diphenyl-1,4-diazepine (**11**), and 2,3-diphenyl-5,5-dimethylisoimidazole (**10***h*) were prepared by deposition of the vapors on a cesium bromide window in an apparatus described previously (24). The temperature of the sample was 4°K (liquid helium) for neon and 63°K (solidified nitrogen) for the xenon matrix. The i.r. spectrum was recorded on a Perkin–Elmer 225 spectrometer before and after irradiation with a General Electric AH-6 1 kW high-pressure, mercury vapor lamp through a Corning 7-54 filter (transmission 2300–4200 Å) and quartz focusing lenses. The reaction was complete after *ca.* 30 min irradiation of **1***b*, *f*, and *d*; while no reaction was observed after 1 h with **11** and **10***h*.

In one experiment a matrix of 2,3,5,5-tetramethyl-5,6-dihydropyrazine (**1***b*) in methylcyclohexane:isopentane, 4:1, was irradiated at 77 °K (liquid nitrogen) using a more conventional variable-temperature apparatus (Beckman VLT-2). This solvent is essentially transparent between 1500–1700 cm^{-1}, and the progress of the irradiation could be followed by scanning this region.

2,3,5,5-Tetramethyl-5,6-dihydropyrazine (1b) in Xenon

Starting material: 1657 (w), 1606 (m), 1595 (s), 1460 (m), 1440 (s), 1422 (m), 1377 (m), 1372 (w), 1365 (m), 1358 (m), 1330 (w), 1275 (m), 1260 (m), 1235 (m), 1213 (s), 1157 (m), 1145 (s), 1074 (s), 950 (s), 895 (s), 885 (s), 800 (s), 780 (w), 775 (w), 698 (s), 630 (w), 535 (m), and 478 (s) cm^{-1}. After irradiation: 1677 (s), 1628 (m), 1580 (m), 1455 (w), 1439 (s), 1429 (s), 1375 (w), 1367 (m), 1361 (m), 1358 (s), 1237 (s), 1208 (s), 1145 (m), 1108 (m), 1070 (w), 1065 (w), 1059 (w), 972 (s), 900 (w), 791 (w), 745 (w), 707 (m), 609 (w), and 588 (w) cm^{-1}.

2,3-Diphenyl-5,5-dimethyl-5,6-dihydropyrazine (1f) in Xenon

Starting material: 1560 (s), 1491 (w), 1444 (s), 1378 (w), 1360 (m), 1330 (m), 1315 (w), 1295 (w), 1275 (s), 1253 (m), 1185 (s), 1175 (w), 1152 (w), 1148 (w), 1085 (m), 1070 (w), 1062 (w), 1027 (m), 1018 (w), 1007 (w), 988 (s), 950 (w),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

915 (w), 905 (w), 791 (s), 785 (w), 755 (s), 729 (s), 690 (s), 584 (w), 568 (s), and 551 (s) cm^{-1}. After irradiation: 1675 (b, s), 1495 (w), 1485 (w), 1443 (s), 1430 (m), 1368 (s), 1360 (s), 1227 (s), 1074 (w), 1030 (w), 990 (w), 971 (s), 888 (m), 769 (s), 755 (m), 699 (s), 690 (s), 661 (w), and 650 (m) cm^{-1}.

*2,3-Diphenyl-5,6-dihydropyrazine (**1d**) in Neon*

Starting material: 1560 (s), 1496 (m), 1440 (w), 1340 (w), 1330 (w), 1320 (b, m), 1300 (w), 1270 (s), 1234 (w), 1230 (w), 1175 (m), 1150 (w), 1090 (m), 1070 (w), 1035 (w), 1027 (m), 985 (s), 912 (w), 890 (w), 787 (s), 758 (s), 721 (s), 689 (s), 681 (w), 670 (w), 569 (s), and 550 (s) cm^{-1}. After irradiation: 1656 (m), 1601 (w), 1462 (m), 1458 (m), 1221 (s), 1195 (s), 1067 (w), 1029 (m), 1000 (s), 969 (s), 920 (w), 898 (m), 829 (w), 765 (s), 740 (w), 709 (w), 695 (s), 690 (s), 660 (w), and 589 (w) cm^{-1}.

*2,3,5,5-Tetramethyl-5,6-dihydropyrazine (**1b**) in MCIP*

Starting material: 1658 (w), 1610 (m, shoulder), and 1598 (s) cm^{-1}. After irradiation: 1675 (s), 1630 (m), and 1581 (m) cm^{-1}. Further irradiation had no effect. The initial irradiation product disappeared upon warming to 195 °K to give the product with i.r. absorption listed below: 1675 (w, shoulder), 1660 (m), 1640 (m), 1620 (s), and 1660 (w, shoulder) cm^{-1}.

*2,2-Dimethyl-4,5-diphenylisoimidazole **10h** in Neon*

Starting material: 1610 (w), 1561 (w), 1551 (s), 1495 (w), 1491 (s), 1480 (w), 1464 (w), 1446 (s), 1355 (w), 1338 (w), 1313 (w), 1300 (w), 1288 (m), 1271 (s), 1218 (s), 1182 (m), 1175 (m), 1169 (m), 1080 (m), 1071 (m), 1021 (m), 969 (s), 918 (w), 890 (w), 881 (m), 840 (w), 791 (s), 759 (s), 738 (s), 690 (s), 661 (m), 581 (s), 579 (s), and 534 (m) cm^{-1}. The spectrum was not affected by 1.5 h irradiation.

*2,3-Diphenyl-1,4-diazepine **11** in Neon*

Starting material: 1615 (w), 1609 (s), 1600 (m), 1581 (s), 1495 (m), 1479 (m), 1449 (s), 1340 (m), 1338 (w), 1333 (w), 1320 (s), 1315 (w), 1303 (m), 1291 (m), 1272 (s), 1260 (m), 1200 (m), 1175 (m), 1101 (w), 1090 (m), 1084 (m), 1071 (m), 1050 (w), 1029 (m), 951 (w), 945 (s), 920 (w), 791 (s), 767 (s), 760 (w), 731 (s), 690 (s), 689 (s), 672 (w), and 586 (s) cm^{-1}. No change in the spectrum was observed following 1.5 h irradiation.

*Irradiation of 2,2-Dimethyl-4,5-diphenylisoimidazole (**10h**) in Isopropyl Alcohol*

2,2-Dimethyl-4,5-diphenylisoimidazole (3.2 g) in isopropyl alcohol (275 ml) was purged with argon and irradiated with a 450 W Hanovia medium-pressure mercury vapor lamp in a quartz immersion well. After 1 day the n.m.r. spectrum of an aliquot indicated that only a small amount of the starting isoimidazole remained, the major signals being attributed to the dihydroisoimidazole **19**. The extent of reaction could also be determined by v.p.c. using a silicon oil column (SE 30/Chromsorb W, 1/2″ × 5′, 180°, 75 ml He/min, retention time **10*h***, 17; **19** 21 min). The solvent was removed to give an oil (3.4 g) which was dihydroisoimidazole (90% pure) contaminated with the isoimidazole (i.r. and n.m.r.). An attempt was made to purify this mixture by chromatography on alumina; however, even though manipulations were carried out under argon, the amount of isoimidazole increased.

This reaction may involve the hydrogen atom transfer mechanism shown to occur with ordinary imines (25).

*Irradiation of 2,3-Diphenyl-1,4-diazepine (**11**) in Isopropyl Alcohol*

The diazepine is not very soluble in isopropyl alcohol so dilute solutions were used. An isopropyl alcohol solution (2 ml) of the diazepine (**11**) (0.01 g) was irradiated in a quartz tube for 2 days with a 450 W Hanovia medium-pressure, mercury vapor lamp held 2 in. away. The temperature of the irradiated mixture was kept at 20°. The irradiation solution was light yellow; however, the color was discharged upon exposure to air. Evaporation of the solvent on a rotary evaporator gave a crystalline residue (0.01 g, m.p. 105–113°) shown (i.r.) to be essentially pure starting material.

More concentrated solution could be made if the mixed solvent isopropyl alcohol – dioxane was used. Then the progress of the reaction could be followed by n.m.r. Even when the solution was yellow, no change was observed in the aromatic region of the spectrum (the spectrum of **19** is very different from **10*h*** in this region); again, exposure to air led to a rapid loss of color.

Catalytic Hydrogenation of 2,2-Dimethyl-4,5-diphenylisoimidazole

A solution of **10*h*** (1 g) in 95% ethanol (100 ml) with 0.5 g of Pd/C (5%) was reduced in a Parr hydrogenation apparatus. After 1 day under a hydrogen pressure of 50 lb the solution was filtered rapidly and the solvent evaporated under vacuum to a yellow oil. The oil was taken up in methylcyclohexane, and crystalline (m.p. 90–92°) dihydroisoimidazole was deposited upon cooling. The reported m.p. of this compound is 85–88.5° (2). Pertinent spectral data for **19** are: i.r. 3300 (w), 3000 (w), 2950 (s), 2920 (w), 2830 (w), 1630 (s), 1570 (m), 1490 (s), 1450 (s), 1435 (m), 1370 (w), 1355 (m), 1320 (m), 1300 (w), 1245 (w), 1210 (s), 1195 (s), 1175 (s), 1150 (w), 1068 (s), 1050 (w), 1025 (w), 1015 (m), 922 (w), 875 (w), 845 (s), 760 (s), 720 (w), 696 (s), 694 (s), 672 (w), and 654 (w) cm^{-1}; u.v. (hexane): 230 (ε 15 400), 286 nm (Sh, ε = 720); n.m.r. ($CDCl_3$): δ 7.0–7.7 (m 10H), 544 (s, 1H), 2.08 (broad s, 1H), 1.60 (s, 3H), and 1.47 (s, 3H). The broad singlet at δ 2.08 is assigned to N–H since it disappears upon addition of 10% acetic acid - *d*; the singlet at δ 5.44, assigned to the benzylic hydrogen, shifts down field to δ 6.30.

Anal. Calcd: ($C_{17}H_{18}N_2$): C, 81.56; H, 7.25; N, 11.19. Found: C, 81.76; H, 7.45; N, 11.03.

*Catalytic Hydrogenation of 2,3-Diphenyl-1,4-diazepine (**11**)*

The diazepine (1.2 g) in ethanol (200 ml) was shaken under hydrogen (45 lb) with Pd/C (5%, 0.5 g) in a Parr hydrogenation apparatus. After 18 h the solution had turned yellow and after 64 h was colorless. The solution was filtered and concentrated to colorless crystals (1.2 g, m.p. 100–109°) which were recrystallized from hexane–ethanol giving the tetrahydro derivative (m.p. 109–110°). The gross structure of this compound was assigned on the basis of the following analytical and spectral evidence. The n.m.r. spectrum is consistent with formation of only one of the two possible stereoisomers.

The n.m.r. ($CDCl_3$): δ 7.0 (aromatic, 10H), 4.2 (ben-

For personal use only.

zylic, sharp s, 2H), 1.7–2.1 (N–H, broad s, 2H), 3.3–3.8 (m, not symmetrical, 6H); (CCl_4): δ 6.97 (10H), 4.11 (benzylic, sharp s, 2H), 2.5–3.5 (m, 4H), 1.65–2.07 (m, 2H), and 1.57 (s, N–H, 2H). The i.r. 3320 (w), 3020 (w), 2920 (s), 2845 (m), 1600 (w), 1580 (w), 1460 (s), 1445 (s), 1420 (m), 1370 (m), 1279 (w), 1163 (s), 1155 (m), 1113 (m), 1072 (w), 1026 (w), 963 (w), 909 (w), 770 (s), 747 (s), 735 (w), 720 (w), 708 (s), 698 (s), 680 (m), and 670 (m) cm^{-1}.

Anal. Calcd. for $C_{17}H_{20}N_2$ (mol. wt. 252.35): C, 80.91; H, 7.99; N, 11.10. Found (242 (osmetric)): C, 81.04; H, 8.09; N, 10.97.

Several attempts were made to isolate the dihydroderivative from the reaction mixture before complete reduction; however, the yellow color was rapidly discharged upon exposure to air and the crude reaction mixture contained only diazepine and the tetrahydroderivative (i.r. and n.m.r.).

*Irradiation of 2,2-Dimethyl-4,5-diphenylisoimidazole (**10h**) in Tetramethylethylene*

A solution of 1.5 g of the isoimidazole **10*h*** in 10 ml of tetramethylethylene in a Pyrex tube (5/8″ o.d. × 9 1/2″) was irradiated 2 in. from a 450 W Hanovia medium-pressure mercury vapor lamp. The temperature of the solution was maintained at 20° by means of a water bath. After 2 days irradiation the excess tetramethylethylene was evaporated leaving 1.9 g of oil shown by n.m.r. to be *ca.* 70% adduct and 30% unreacted isoimidazole.

This mixture was difficult to separate by column chromatography; however, an analytical sample of the adduct (m.p. 92–96°) was obtained from the first fractions eluting with hexane and increasing amounts of benzene. The adduct could also be obtained by evaporating the unreacted isoimidazole (sublimation apparatus, 135°/11 mm) leaving 1.3 g (m.p. 85–95°) of adduct. We were unable to find a good solvent for recrystallization of the adduct. The following analytical and spectral properties led to the assigned structure **25**.

Anal. Calcd. for $C_{23}H_{28}N_2$ (mol. wt. 332): C, 83.08; H, 8.49; N, 8.43. Found (305 (osmetric)): C, 82.98; H, 8.29; N, 8.73.

The n.m.r. (CCl_4): δ 1.13 (s, 3H), 1.18 (m, 3H), 1.26 (s, 3H), 1.57 (s, 3H), 1.68 (bd, s, 3H), 2.01 (bd, s, 1H), 2.75 (d, J = 14 Hz, 1H), 3.26 (d, J = 14 Hz, 1H), 6.97–7.72 (m, 10H).

The i.r.: 3050 (w), 2970 (s), 2930 (s), 2870 (w), 1620 (s), 1570 (m), 1496 (m), 1448 (s), 1412 (m), 1375 (m), 1358 (m), 1330 (w), 1310 (w), 1278 (w), 1220 (s), 1180 (w), 1156 (w), 1075 (m), 1032 (w), 984 (w), 972 (w), 905 (w), 880 (w), 840 (w), 777 (s), 764 (s), 728 (w), 694 (s), 685 (m), and 652 (m) cm^{-1}.

The parent peak (*m/e* 332) is detected, but smaller than 331 and 333 (the P–H and P + H peaks). The base peak is 249, which can arrive through loss of the tetramethylethylene radical. Other prominent fragments are 145 ($C_{10}H_{11}N$) and 104 (C_7H_6N).

Synthesis and Thermolysis of 2*H*-1,2,3-Benzothiadiazine 1,1-Dioxide and 2,1-Benzoxathiin-3-one 1,1-Dioxide[1,2]

J. F. KING, B. L. HUSTON, ANNE HAWSON, J. KOMERY, DONNA M. DEAKEN, AND D. R. K. HARDING
Department of Chemistry, University of Western Ontario, London 72, Ontario

Received September 14, 1970

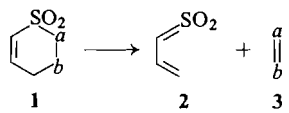
2*H*-1,2,3-Benzothiadiazine 1,1-dioxide (**6**) and 2,1-benzoxathiin-3-one 1,1-dioxide (**5**), representatives of little-known heterocyclic systems, have been synthesized from sodium *o*-formylbenzenesulfonate (**7**). Thermolysis of **5** and **6** was investigated in the hope of finding evidence for the formation of a sulfene. No characterized product was obtained from **5**, but **6** gave the sultine 3*H*-2,1-benzoxathiole 1-oxide (**21**), the compound expected from the sulfene **20**.

La 2*H*-benzothiadiazine-1,2,3 dioxyde-1,1 (**6**) et la benzoxathiin-2,1 one-3 dioxyde-1,1 (**5**), des représentants de systèmes hétérocycliques peu connus, ont été synthétisés à partir de l'*o*-formylbenzènesulfonate de sodium (**7**). La thermolyse de **5** et **6** a été examinée dans l'espoir de trouver des indications concernant la formation d'un sulfène. Aucun produit caractérisé ne fut obtenu à partir de **5**, mais **6** a donné la sultine 3*H*-benzoxathiole-2,1 oxyde-1 (**21**), le composé prévu du sulfène **20**.

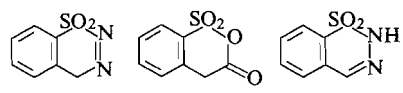
Canadian Journal of Chemistry, 49, 936 (1971)

Introduction

Sulfenes ($RR'C{=}SO_2$) may now be regarded as established and respectable intermediates,[3] in certain reactions at least, even though they have thus far eluded all of the numerous attempts at their isolation and characterization. As a possible route leading to new information on sulfenes, and possibly even their isolation, we contemplated the synthesis of compounds which by the action of heat or light might fragment to give sulfenes. One tested recipe for the frangibility required to form high energy species requires the construction of a molecule so arranged that the other fragment of the reaction is a particularly stable species, *e.g.* molecular nitrogen, carbon dioxide, sulfur dioxide, and so on.[4] Among the possible ways of applying this notion to the formation of sulfenes is the synthesis of species of the general formula **1** which could undergo cycloreversion of the reverse Diels–Alder type to give vinylsulfene (**2**) and a stable fragment **3**. For reasons of synthetic convenience we focussed our attention on benz–fused analogues of **1**, the specific objectives in the work reported herein being 4*H*-1,2,3-benzothiadiazine 1,1-dioxide (**4**) and 2,1-benzoxathiin-3-one 1,1-dioxide (**5**), alias "*o*-sulfophenylacetic anhydride".



1 **2** **3**



4 **5** **6**

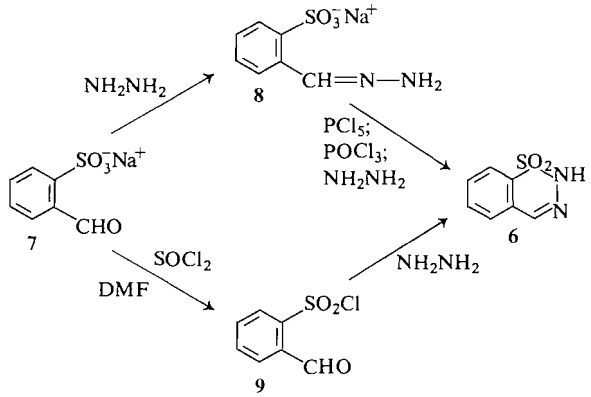
The cyclic anhydride **5** was synthesized without difficulty but gave none of the hoped for fragmentation. The cyclic azo compound **4** was not obtained but its isomer **6** was prepared and found to extrude nitrogen on thermolysis with formation of a sultine (cyclic sulfinic ester); **6** is the parent of a heterocyclic system previously known only in the form of some 4-hydrazino-derivatives (3 and references cited) and the very recently reported 4-phenyl compounds (4). In the course of this work it was found that reaction of **6** with chlorine led to an interesting transformation possibly involving a sulfene; this is described in detail in the accompanying paper. Part of the substance of these two papers has already been reported in preliminary form (5).

[1]Organic Sulfur Mechanisms. Part 8. For part 7 see ref. 1.

[2]Some of the work recorded in this and the following paper is taken from the following theses (University of Western Ontario): D. M. Deaken (Honors B.Sc., 1964), A. Hawson (M.Sc. 1968), J. Komery (M.Sc. 1969).

[3]For a summary of the chemistry of sulfenes up to 1967 see Opitz' review (2); access to more recent work may be obtained from ref. 1 and papers cited therein.

[4]Thermolysis of four-membered rings, with and without fragmentation, has also been explored and appears to lead to sulfenes (1).



SCHEME 1

Results and Discussion

Synthesis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6)

The starting material for all of the syntheses described in this paper is sodium *o*-formylbenzenesulfonate (**7**), a material which is commercially available in a "practical" grade apparently as the monohydrate (*cf.* ref. 6). Reaction of **7** with hydrazine hydrate gave the hydrazone **8**, which when treated without purification with a mixture of phosphorus oxychloride and phosphorus pentachloride, gave **6** in about 5–10% yield (see Scheme 1). Attempts to improve the yield led to the observation that recrystallization of the hydrazone led to an even poorer yield of **6**. Acting on the inference that residual hydrazine was responsible for the difference, hydrazine was added to the reaction of **8** with $POCl_3$–PCl_5. The yields of **6** were much improved, though erratic; the best yield in a number of such experiments was 80% (based on **8**) but repetition of the procedure as recorded gave only low yields. Further study led to a procedure which incorporated minor changes in conditions and which gave yields of 30–50% with some consistency (see Experimental).

The structure **6** for the material thus obtained follows from elemental analysis and the following spectroscopic features: (*a*) bands at 3.1 (1H, N*H*), 7.9 (m, four aromatic hydrogens), and 8.2 p.p.m. (s, 1H, —C*H*=N—) in the n.m.r. spectrum, (*b*) i.r. peaks at 3280 (NH), 1657 (w, C=N—), 1345 (vs) and 1165 cm^{-1} (vs) (—SO_2—). Final confirmation of the structure (**6**) is provided by its synthesis from *o*-formylbenzenesulfonyl chloride (**9**) as described below.

Because of the erratic yields of **6** from **7** on treatment with the phosphorus chloride – hydrazine mixture, the *p*-toluidine anil **10** and the tosylhydrazone **13** (prepared from **7** via **12**) were investigated as possible precursors of **6** (see Scheme 2). The anil **10** apparently gave **11**, whereas the tosylhydrazone **13** gave a 3% yield of **6**. No attempt was made to improve the tosylhydrazone route because of the discovery of another, and evidently better, way of making **6**.

An obvious precursor of **6** is *o*-formylbenzenesulfonyl chloride (**9**), a compound which, prior

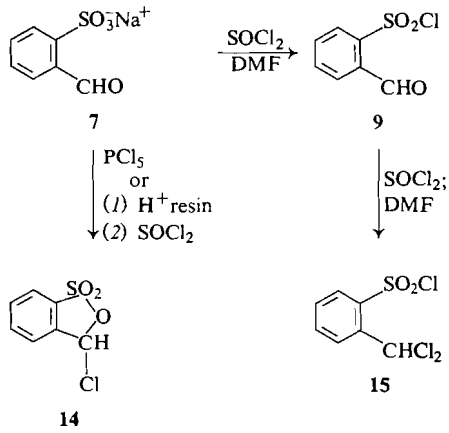
to this study, was unknown. The reaction of **7** with PCl_5–$POCl_3$ has been known for many years (6, 7) to lead, not to **9**, but to its cyclic isomer **14**, which does not give **6** on reaction with hydrazine hydrate. As is described in detail in the following paper we have found that chlorination of **6** in the presence of water gives **9**. As a route for the synthesis of **6**, this procedure is, of course, valueless, but it did lead to the characterization of **9** so that it could be readily recognized when made in other ways, even when mixed with other materials. In addition, by treating a sample of **9** prepared from **6** with hydrazine, it was possible to get **6** back in very good yield; this, as has been mentioned above, confirmed the structure of **6**.

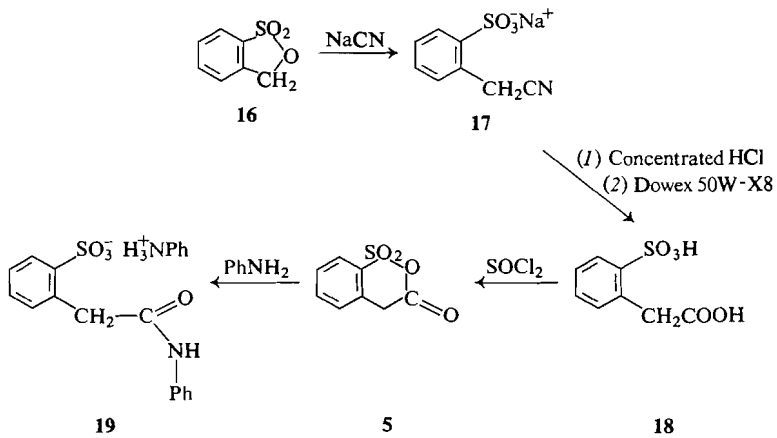
Treatment of **7** with thionyl chloride gave no reaction, and conversion of **7** to *o*-formylbenzenesulfonic acid followed by reaction with thionyl chloride gave the cyclic chloride **14**. When **7** was allowed to react with thionyl chloride in the presence of a catalytic amount of dimethylformamide, however, the product was evidently mainly *o*-formylbenzenesulfonyl chloride (**9**) mixed with a little of the cyclic isomer (**14**) (Scheme 3). Reaction of this mixture with hydrazine hydrate led to the isolation of **6** in an overall yield of about 50% from **7**. The crude product also contains **14**, but this is readily separated by taking advantage of the acidity of **6**. This procedure is simple and gives reasonably consistent yields, and became our method of choice for the synthesis of **6**. It was found that only a short reaction time was required to convert **7** to **9**, longer times (or treatment of **9** with thionyl chloride) led to the benzal chloride **15**, which did not yield **6** under the conditions used to convert **9** to **6**.



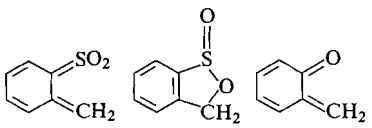
SCHEME 3

Synthesis of 2,1-Benzoxathiin-3-one 1,1-Dioxide (5) ("o-Sulfophenylacetic Anhydride")

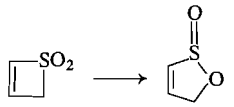
The synthesis of **5** is straightforward and is summarized in Scheme 4. The starting material (**16**) was obtained from **7** via **14**, following the method of List and Stein (7) as described in detail by Helberger *et al.* (8). The structure of **5** follows from its mode of synthesis and is confirmed by elemental analysis and spectra; a conspicuous feature in the i.r. is a strong band at 1818 cm^{-1}. As would be expected of a mixed carboxylic–sulfonic anhydride, **5** is very easily hydrolyzed, for example, by atmospheric moisture, to *o*-sulfophenylacetic acid (**18**), and reacts very readily with aniline to give **19**.



SCHEME 4



20 21 22



23 24

Thermolysis of 5 and 6

All attempts at thermal fragmentation of **5** to give **20** or materials evidently derived from **20** were without avail. On the basis of the results (1, 9) with thermolysis of thiete 1,1-dioxide (**23**), which appears to rearrange via vinylsulfene (CH_2=CH—CH=SO_2), we might have expected that **20** below 700–800° would have given the "sultine" (cyclic sulfinic ester) **21**, and at higher temperatures the "desulfinylation" (1) product, *o*-quinone methide (**22**). An authentic specimen of **21** was available from work connected with the chlorinolysis of **6** (see the following paper), and **22** and its trimerization product have been described (10) and should have been readily recognizable, if present. In either the simple quartz tube at 380–550° and pressures of 5–7 μ, or the flash thermolysis apparatus (1) at 600°, **5** was recovered substantially unchanged. In the flash apparatus at 1000°, only general decomposition was observed.

Thermolysis of the thiadiazine (**6**) at 600–620° in the flash apparatus gave back starting material and at 750° yielded only an uncharacterized gum. In a quartz tube at 500° and about 1 mm, **6** gave a roughly 25% yield of the sultine **21**; the yields appeared to be improved by the presence of a plug of glass wool in the tube. It has also been noted by Dr. L. J. Danks in these laboratories (private communication) that **21** is formed (in addition to black tar) in an estimated 10% yield on heating **6** in the melt at 180°. The sultine (**21**) is the product expected at these temperatures from **20** if, in fact, it were formed. When taken with our evidence (1) for the intermediacy of vinylsulfene in the rearrangement of **23** to **24**, and also the formation of the 4-chloro analogue of **21** on chlorinolysis of **6** as described in the following paper, this result would suggest that the simplest route to **21** from **6** is via **20**, though the present evidence does not exclude other pathways. Formation of **20** from **6** formally requires migration of a hydrogen from nitrogen to carbon; this could perhaps take place via **4**, followed by fragmentation as originally visualized, or conceivably by cleavage of one of the ring bonds in **6**, with formation of the diazene (diimide), followed by hydrogen migration accompanying loss of nitrogen. With either of these processes it is not surprising that the quartz tube apparatus and the melt, with their much greater likelihood of collisions with the walls and other molecules, would be more favorable conditions for a two (or more) step process than the flash apparatus.

Experimental

Sodium *o*-formylbenzenesulfonate (**7**) was obtained from Koch-Light Laboratories Limited, Colnbrook, England, under the designation "*o*-sulfobenzaldehyde Na salt" and indicated as "75–89%" or "practical" grade. No attempt was made either to assay or to purify the **7** before use; the yields given are based on the assumption that it is the pure mono-hydrate and would presumably be somewhat higher if pure **7** were used. All other reagents and solvents were of commercial reagent grade unless otherwise indicated.

Unless otherwise specified melting points were determined on a Kofler hot stage and are uncorrected. The i.r. spectra were obtained with Beckman IR-7 or IR-10 instruments using sodium chloride cells. The n.m.r. values given were determined on a Varian A60 instrument using tetramethylsilane as internal standard; a Varian T60 spectrometer was used in some instances to ascertain product composition. The t.l.c. was carried out using Camag Kieselgel DF5 or "GF-254 (acc. to Stahl)" silica gel supplied by E. Merck, Darmstadt, Germany. Petroleum ether refers to the fraction of boiling range 35–60°. Unless otherwise stated magnesium sulfate was used to dry the organic phase following extraction in a separatory funnel.

Preparation of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6) from Sodium o-Formylbenzenesulfonate (7) via the Hydrazone (8)

Sodium *o*-formylbenzenesulfonate (**7**) (40.0 g) and hydrazine hydrate (99%) (50 ml) were refluxed together for 2 h. The hydrazine hydrate was then evaporated off under reduced pressure and the crude product was dissolved in methanol. The methanol insoluble material was removed by filtration and the methanol soluble material recrystallized from methanol–ether giving 24.0 g (56%) of white crystals.

The crude hydrazone **8** (10 g) obtained as above, was placed in a three-necked round-bottomed flask fitted with a condenser, mechanical stirrer, and dropping funnel. Hydrazine hydrate (99%, 5 ml) was added and the mixture stirred and cooled to 0° in an ice bath. Phosphorus oxychloride (50 ml) was added dropwise over a period of 45 min, followed by phosphorus pentachloride (10 g), and the mixture warmed to 60° and stirred until the mixture became smooth (about 4.5 h). The mixture

For personal use only.

was poured onto crushed ice and allowed to stand until the phosphorus oxychloride appeared to have hydrolyzed completely, and extracted with chloroform. The extracts were washed with water, dried with anhydrous sodium sulfate, and the solvent evaporated leaving a pale yellow solid 2.4 g (30%). Recrystallization from chloroform gave crystals of **3** (1.35 g, 17%) melting at 142–143°.

A number of repetitions of this procedure with varying quantities of **8** gave erratic results with crude yields sometimes as low as 5–10% and on one occasion as high as 80%. The use of benzene or dimethylformamide as solvent led to little or no **6**. In one experiment with this general method, starting with a smaller quantity (3.9 g) of **8** and appropriately reduced amounts of the other reagents, further hydrazine hydrate (5 ml) was added after the addition of the phosphorus oxychloride was complete; this led to a 50% yield of crude product (25% after recrystallization).

The i.r. spectrum of **6** (Nujol mull) showed the following bands: 3280, 1657 (w), 1598 (w), 1565 (m), 1479 (w), 1448 (m), 1360 (sh), 1345 (vs), 1268 (m), 1225 (m), a very strong band with peaks at 1183, 1165, and 1145, 1080 (m), 993 (s), 970 (m), 915 (s), 883 (m), 858 (m), 780 (w), 785 (s), 735 (m), 690 (w), 640 (s). The n.m.r. spectrum (in acetone-d_6) showed a broad hump at 3.1 which disappeared on addition of D_2O, a singlet at 8.1, and a complex band from 7.8–8.0 p.p.m.

Anal. Calcd. for $C_7H_6SO_2N_2$: C, 46.14; H, 3.32; N, 15.38; S, 17.59. Found: C, 46.19; H, 3.29; N, 15.24; S, 17.42.

The pK_a of **6** was determined in 50% ethanol–water (by weight) by titration with 0.1 *N* sodium hydroxide measuring the p*H* with a Radiometer 25 p*H* meter with glass and calomel electrodes standardized with aqueous buffer solution, p*H* 7.00; to obtain the hydrogen ion activity in the aqueous alcohol medium 0.18 was subtracted from meter readings of the p*H* (*cf.* Bates *et al.* (11)). By this technique the following pK_a values were obtained: **6**, 7.2; benzaldehyde tosylhydrazone, 8.6; benzenesulfon-*p*-toluidide, 10.1. Dauphin *et al.* (12) report a pK_a value of 10.17 for benzenesulfon-*p*-toluidide in the same medium.

Preparation of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6) via o-Formylbenzenesulfonyl Chloride (9)

Sodium *o*-formylbenzenesulfonate (**7**) (5 g, 0.24 mol) was suspended in thionyl chloride (20 ml) and dimethylformamide (12 drops) added. The mixture was refluxed for 1 h and then evaporated to dryness. The residue was extracted with methylene chloride and filtered. The filtrate was concentrated to about 25 ml and hydrazine hydrate (99%) (3 ml) cautiously added dropwise with stirring. The mixture was stirred at room temperature for 10 min, then diluted with water, cooled in an ice bath and acidified with concentrated HCl. The aqueous mixture was extracted with chloroform, the chloroform extract was extracted with 5% NaOH. The chloroform layer was dried, and the solvent evaporated, leaving a pale yellow solid (0.59 g) which melted at 113–115° and had the same i.r. spectrum as a sample of the "pseudo acid chloride" (**14**) prepared by the method of Helberger *et al.* (10). The sodium hydroxide extracts were acidified and extracted with chloroform; the chloroform extracts were dried and the solvent removed to give a crude 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**6**) (2.08 g, 50%), which after one recrystallization from chloroform melted at 141–142°.

It was found that best conversion of **4** to *o*-formylbenzenesulfonyl chloride (**9**) was obtained using only a very brief reaction time with thionyl chloride (*e.g.* 3 min reflux). Under such conditions using 7 (5 g), thionyl chloride (20 ml) and dimethylformamide (25 drops) and taking the product up in pentane and washing with water, **9** was obtained as a pale yellow oil (3.7 g, 76%), identified by i.r. and n.m.r. spectra. With longer reaction times **9** was further transformed to **15** (see below).

Attempted Synthesis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6) via the Anil 10. Formation of the Carbinolamine Ether 11

Sodium *o*-formylbenzenesulfonate (**7**) (10.4 g, 0.05 mol) and *p*-toluidine (5.4 g, 0.05 mol) were partially dissolved in absolute ethanol (50 ml) and gently refluxed for 20 min. The hot solution was filtered and the filtrate evaporated to dryness. Ether was added to the oily residue and the colorless crystals, presumed to be **10** (11 g 74%), collected by filtration. The i.r. spectrum (Nujol) showed bands at 1620 (w), 1565 (w), 1500 (w), 1190 (vs), 1140 (m), 1090 (m), 1045 (w), 1025 (s), 970 (w), 880 (w), 820 (m), 760 (m), 716 (s).

The anil (**10**) (5 g) was mixed with phosphorus pentachloride (5 g) and ground in a mortar for 5 min, and then left at room temperature for 0.5 h. The mixture was poured into ice–water and extracted with methylene chloride. The extracts were dried over anhydrous sodium sulfate and the solvent evaporated to give a yellow solid (4.3 g). Extensive recrystallization from methylene chloride – petroleum ether and methanol gave crystals melting at 129–130°, for which structure **11** is assigned. The i.r. spectrum showed peaks at 3000 (w), 1510 (m), 1450 (w), 1310 (s), 1270 (m), 1170 (s), 1130 (m), 1090 (m), 1040 (s), 970 (m), 600 (m), 580 (m) and the n.m.r. spectrum showed complex aromatic absorption from 7.1–8.0 (8H), and singlets at 6.40 (1H), 3.12 (3H) and 2.37 p.p.m. (3H).

Anal. Calcd. for $C_{15}H_{15}NO_3S$: C, 62.27; H, 5.23; N, 4.84; S, 11.06. Found: C, 62.46; H, 5.34; N, 4.91; S, 11.06.

Synthesis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6) via the Tosylhydrazones 12 and 13

p-Toluenesulfonylhydrazine (tosylhydrazine) (4.7 g) and sodium *o*-formylbenzenesulfonate (**7**) were partially dissolved in methanol (25 ml) and refluxed for 1 h. The hot solution was filtered and the filtrate treated with ether to give a white, crystalline solid (**12**) (6.1 g) which showed the following peaks in the i.r. (Nujol); 3350 (m), 1600 (w), 1320 (m), 1205 and 1170 (vs), 1140 (sh), 1090 (m), 1065 and 1045 (m), 1025 (m), 965 (m), 835 (m), 810 (m), 787 and 780 (w), 760 (w), 730 and 720 (m), and 700 (w).

The tosylhydrazone **12** was mixed with phosphorus pentachloride (2 g) and ground in a mortar. The resultant yellow paste was left at room temperature for 10 min whereupon it was mixed with water (50 ml) and the mixture extracted with ether. The extracts were dried over anhydrous sodium sulfate and the solvent removed leaving a colorless oil (1.2 g, 61%) which solidified on standing. The i.r. spectrum showed characteristic bands at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1375 and 1325 and 1174 ascribable to the SO_2Cl and $-SO_2N$ functions. Recrystallization from methylene chloride – petroleum ether gave colorless crystals (presumed to be **13**) (768 mg), m.p. 136–140° (dec) which were not further characterized.

The sulfonyl chloride – hydrazone (**13**) (3 g) was mixed with hydrazine hydrate (99%, 10 ml) and warmed at 60° for 1.5 h. The pale yellow solution was cooled, diluted with water, and acidified with concentrated hydrochloric acid. The mixture was extracted with chloroform and the extracts dried over anhydrous sodium sulfate. Removal of the solvent gave an orange oil (1.25 g), which on trituration with chloroform gave a small amount (105 mg) of colorless crystals, m.p. 137–410°, which gave no depression of m.p. on admixture with authentic **6**. The remaining products were not investigated further.

*Preparation of o-Dichloromethylbenzenesulfonyl Chloride (**15**)*

Sodium *o*-formylbenzenesulfonate (**7**) (5 g, 0.024 mol) was suspended in thionyl chloride (20 ml) and dimethylformamide (25 drops) added. The mixture was refluxed for 0.5 h. The excess thionyl chloride was then removed under reduced pressure, the residue was taken up in methylene chloride and the mixture filtered. Removal of the methylene chloride gave an oily residue which partially dissolved in pentane. The pentane solution was washed with water and dried; removal of the solvent gave a yellow oil (4.2 g) which crystallized on cooling in a Dry Ice – acetone mixture. Recrystallization from carbon tetrachloride – pentane at −60° gave colorless crystals (3.4 g, 55%) melting at 50–52°; recrystallization gave the analytical specimen, m.p. 54–55°. The i.r. spectrum showed bands at 3000 (w), 1570 (w), 1470 (w), 1445 (m), 1380 (vs), 1320 (w), 1285 (w), 1180 (vs), 1120 (m), 1060 (w), 980 (w), 840 (s), and 680 cm^{-1} (m). The n.m.r. spectrum showed only complex absorption from 7.4–8.4 with a prominent peak at 7.86 p.p.m.; the mass spectrum indicated a molecular weight of 258 with another peak at 260 of the same intensity.

Anal. Calcd. for $C_7H_5Cl_3O_2S$: C, 32.39; H, 1.94; Cl, 40.98; S, 12.35. Found: C, 32.58; H, 1.95; Cl, 41.18; S, 12.45.

o-Formylbenzenesulfonyl chloride (**9**) (1.01 g), thionyl chloride (5 ml), and dimethylformamide (5 drops) were refluxed for 0.5 h. The excess thionyl chloride was removed under reduced pressure and water and pentane added to the residue. The pentane extract was dried and the solvent evaporated leaving colorless crystals; the i.r. spectrum was virtually identical with that of **15** prepared as above except for a rather small peak at 1700 cm^{-1}, presumably due to a small amount of **9**. Recrystallization from carbon tetrachloride – pentane gave crystals melting at 49–52°.

*Reaction of 3H-2,1-Benzoxathiole 1,1-Dioxide (**16**) with Sodium Cyanide*

3*H*-2,1-Benzoxathiole 1,1-dioxide (**16**) (10) (5 g, 0.029 mol) was dissolved in absolute alcohol (150 ml) and was added slowly with stirring over a period of 30 min to a solution of sodium cyanide (1.48 g, 0.03 mol) in water (15 ml). The reaction mixture was refluxed for 4 h. Evaporation of solvent yielded sodium *o*-cyanomethylbenzenesulfonate (**17**) (6.4 g, 100%). The product was recrystallized three times from methanol, m.p. 298–301°.

Anal. Calcd. for $C_8H_6NaNO_3S$: C, 43.84; H, 2.76; N, 6.39; S, 14.63. Found: C, 43.95; H, 2.70; N, 6.41; S, 14.32.

The i.r. spectrum (Nujol) showed absorption bands at 3060 (w), 2240 (w), 1408 (w), 1235 (s), 1215 (s), 1195 (s), 1180 (s), 1145 (m), 1095 (m), 1050 (w), 1030 (m), 955 (w), 755 (m), 725 (m), 705 (m), 625 cm^{-1} (m). The n.m.r. spectrum (dimethyl sulfoxide-d_6) showed absorption bands at 4.43 (s, 2H) and 7.25–8.0 p.p.m. (aromatic hydrogen absorption, 4H).

*Hydrolysis of Sodium o-Cyanomethylbenzenesulfonate (**17**)*

Sodium *o*-cyanomethylbenzenesulfonate (**17**) (2 g, 9.1 mmol) was dissolved in water (20 ml). Concentrated hydrochloric acid (20 ml) was added dropwise with stirring. The reaction mixture was refluxed for 45 min and then evaporated to dryness. The material (2.2 g) obtained was not characterized but was dissolved in water and passed through a column of Dowex 50W-X8 ion exchange resin in the acid form. The aqueous solution was immediately evaporated under reduced pressure (0.1 mm) without heating, to yield *o*-sulfophenylacetic acid (**18**) (2.2 g, 94%, assuming one molecule of water of crystallization). The product was recrystallized three times from methanol, m.p. 215–219°.

Anal. Calcd. for $C_8H_8O_5S \cdot CH_3OH$: C, 43.51; H, 4.87; S, 12.91. Found: C, 43.55; H, 5.17; S, 12.95.

The i.r. spectrum (Nujol) showed bands at 3200 (s), 1705 (s), 1680 (s), 1315 (w), 1285 (m), 1270 (s), 1210 (s), 1195 (s), 1145 (m), 1085 (m), 1020 (s), 970 (w), 925 (w), 880 (w), 830 (w), 780 (m), 755 (m), 715 (m), 670 (w), 625 (m), 605 (m), 585 (m), and 575 cm^{-1} (m). The n.m.r. (dimethyl sulfoxide-d_6) bands were at 3.57 (s, 3H), 4.13 (s, 2H) 6.30 (s, 1H) 7.06–7.45 (complex aromatic hydrogen absorption and a hydroxyl group, 4H), 7.7–7.95 (complex aromatic absorption, 1H), and 8.01 p.p.m. (s, 1H); on addition of D_2O, peaks at 6.30, 7.15, and 8.01 p.p.m. disappeared.

*Reaction of o-Sulfophenylacetic Acid (**18**) with Thionyl Chloride*

Freshly distilled thionyl chloride (15 ml) was added to *o*-sulfophenylacetic acid (**18**) (0.3 g, 1.39 mmol). The reaction mixture was heated under reflux for 1 h under anhydrous conditions. The thionyl chloride was decanted from a sludge of 50 mg and was evaporated under reduced pressure without heating. The yield of crude solid material was 250 mg. Recrystallization from dried methylene chloride and pentane in a water-free atmosphere, yielded 2,1-benzoxathiin-3-one 1,1-dioxide ("*o*-sulfophenylacetic anhydride") (**5**) (160 mg, 60%), m.p. 107.5–108.5° (vacuum capillary). The product (**5**) had to be dried and stored over phosphorus pentoxide to prevent hydrolysis.

Anal. Calcd. for $C_8H_6O_4S$: C, 48.48; H, 3.05; S, 16.17. Found: C, 48.15; H, 3.24; S, 16.04.

The i.r. spectrum (CH_2Cl_2) showed absorption bands at 2900 (w), 1818 (s), 1600 (w), 1585 (w), 1480 (m), 1455 (w), 1385 (w), 1205 (s), 1195 (s), 1150 (w), 1085 (m), 1070 (m), 1015 (w), 965 (w), 940 (w), 845 (s), 790 (m), and 655 cm^{-1} (w). The n.m.r. spectrum ($CDCl_3$) showed bands at 4.28 (s, 2H) and 7.25–8.15 p.p.m. (aromatic absorption, 4H).

A similar yield of 2,1-benzoxathiin-3-one 1,1-dioxide (**5**) was obtained when the reaction was carried out at room temperature.

Reaction of 2,1-Benzoxathiin-3-one 1,1-Dioxide (5) with Aniline in Methylene Chloride

In a water–free atmosphere, 2,1-benzoxathiin-3-one 1,1-dioxide (5) (0.1 g, 0.51 mmol) was dissolved in dried methylene chloride (1 ml). Distilled aniline (0.096 g, 1.03 mmol) was added. The reaction mixture was left for 30 min at 5°, after which the methylene chloride was evaporated. The product was recrystallized from methanol to yield the anilinium derivative (19) (153 mg, 78%), m.p. 229–231°.

Anal. Calcd. for $C_{20}H_{20}N_2O_4S$: C, 62.48; H, 5.25; N, 7.29; S, 8.34. Found: C, 62.48; H, 4.99; N, 7.38; S, 8.42.

The i.r. spectrum (Nujol) showed absorption bands at 3270 (m), 2600 (w), 1650 (s), 1600 (s), 1560 (s), 1520 (m), 1500 (s), 1355 (m), 1320 (w), 1290 (w), 1260 (w), 1220 (s), 1185 (s), 1160 (s), 1140 (s), 1080 (m), 1050 (w), 1030 (w), 1020 (s), 970 (w), 910 (w), 855 (w), 845 (w), 820 (w), 800 (w), 780 (w), 760 (s), 745 (m), 720 (m), 710 (m), 700 (m), 660 (m), and 620 cm^{-1} (s). The n.m.r. spectrum (dimethyl sulfoxide-d_6) showed bands at 4.6 (s, 2H), 6.8–8.9 (aromatic absorption plus ammonium protons, 17H), 10.53–10.71 p.p.m. (broad band, 1H).

Quartz Tube Thermolysis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (6)

The thermolyses were carried out in a tubulated quartz tube essentially as previously described (1) except that a 1–2 in. plug of glass wool was placed roughly in the center of the heated zone of the tube. The tube was heated for 12″ of its length by a Lindberg/Hevi-Duty oven (made by Hevi-Duty Heating Equipment Co., Watertown, Wisconsin). A sample of **6** was placed in one end of the tube and sublimed into the hot zone of the apparatus using a microburner and an i.r. heating lamp. In one run 106 mg of **6** gave 69 mg of crude product which on t.l.c. gave a fraction (22 mg, 25%) which appeared spectroscopically to be almost entirely the sultine **21**. A second run with 103 mg of **6** gave 60 mg of crude product which afforded 24 mg (27%) of the t.l.c. fraction. Combination of these two t.l.c.-purified specimens of **21**, followed by treatment with decolorizing charcoal and crystallization, gave **21** (21 mg) melting at 39–40°; mixed m.p. with an authentic specimen of **21** prepared as described in the following paper 39–42°. The i.r. and n.m.r. spectra were identical with those of the authentic material.

We gratefully acknowledge the support of the National Research Council of Canada, the Petroleum Research Fund (administered by the American Chemical Society), and the Alfred P. Sloan Foundation.

Chlorination of Heterocyclic and Acyclic Sulfonhydrazones[1]

J. F. KING, ANNE HAWSON, B. L. HUSTON, L. J. DANKS, AND J. KOMERY
Department of Chemistry, University of Western Ontario, London 72, Ontario

Received September 14, 1970

Chlorination of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) in wet methylene chloride gives *o*-formylbenzenesulfonyl chloride (**4**), but in dry methylene chloride at 0° yields the chlorosultine 3-chloro-3*H*-2,1-benzoxathiole 1-oxide (**2**); the latter is readily hydrolyzed to the "pseudo-acid" 3*H*-2,1-benzoxathiol-3-ol 1-oxide (**3**) which on further chlorination forms **4**. In 1,2-dichloroethane at −20° chlorination of **1** gave the "coupled product" **14**, whereas in dimethylformamide at room temperature the cyclic acyl chloride hydrazone 4-chloro-2*H*-1,2,3-benzothiadiazine was isolated in poor yield. The acyl chloride hydrazones (**16**) were the products obtained following chlorination of some representative aromatic acyclic tosylhydrazones (**15**). 3*H*-2,3,4-Benzothiadiazepine 2,2-dioxide (**19**), a previously unknown heterocyclic system, was synthesized in two steps from 1,3-dihydrobenzo[*c*]thiophene (**17**). Chlorinolysis of **19** gave *o*-chloromethylbenzal chloride (**21**). These reactions are believed to involve formation of the α-chloroazo compound (*e.g.* **22**) as the first step. The formation of **2** from **1** is discussed in terms of three possible routes, two which involve the sulfene **23**.

La chloration de la 2*H*-benzothiadiazine-1,2,3 dioxyde-1,1 (**1**) dans du chlorure de méthylène humide conduit au chlorure de l'*o*-formylbenzènesulfonyle (**4**), mais donne dans le chlorure de méthylène sec à 0 °C une chlorosultine à savoir la chloro-3 3*H*-benzoxathiole-1,2 oxyde-1 (**2**); celle-ci est rapidement hydrolysée en "pseudo acide" 3*H*-benzoxathiol-1,2 ol-3 oxyde-1 (**3**) qui est transformé en **4** par chloration ultérieure. La chloration de **1** à −20° dans le dichloro-1,2 éthane donne un "produit couplé" **14** alors que dans la diméthylformamide à la température de la pièce, l'hydrazone cyclique du chlorure d'acyle, la chloro-4 2*H*-benzothiadiazine-1,2,3 est obtenue avec un faible rendement. Les hydrazones (**16**) des chlorures d'acyle sont les produits obtenus par chloration de tosylhydrazones (**15**) aromatiques et acycliques caractéristiques. Un système hétérocyclique inconnu jusqu'à présent, la 3*H*-benzothiadiazépine-2,3,4 dioxyde-2,2 (**19**) a été synthétisé en deux étapes à partir du dihydro-1,3 benzo[*c*]thiophène (**17**).

L'ouverture de **19** par le chlore conduit au chlorure de l'*o*-chlorométhylbenzal (**21**). Il est supposé que ces réactions procèdent dans la première étape, par la formation de composés α-chloroazo (*e.g.* **22**). La formation de **2** à partir de **1** est discutée en considérant trois voies possibles, dont deux impliquant le sulfène **23**.

Canadian Journal of Chemistry, 49, 943 (1971)

As described in the preceding paper (1), our interest in the generation of sulfenes led us to synthesize 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**). Some observations made in the course of attempting to improve our early synthetic procedure led us to examine the effect of chlorine on **1**. Once we had determined the general features of this reaction, it appeared that one of the more likely mechanisms involved a sulfene. This prompted us to carry out a comparatively detailed investigation of the course of this transformation and also a study of the chlorination of other sulfonhydrazones, to find out whether the reaction of **1** was typical or exceptional. Some of the earlier results in this study have been described in a preliminary communication (2).

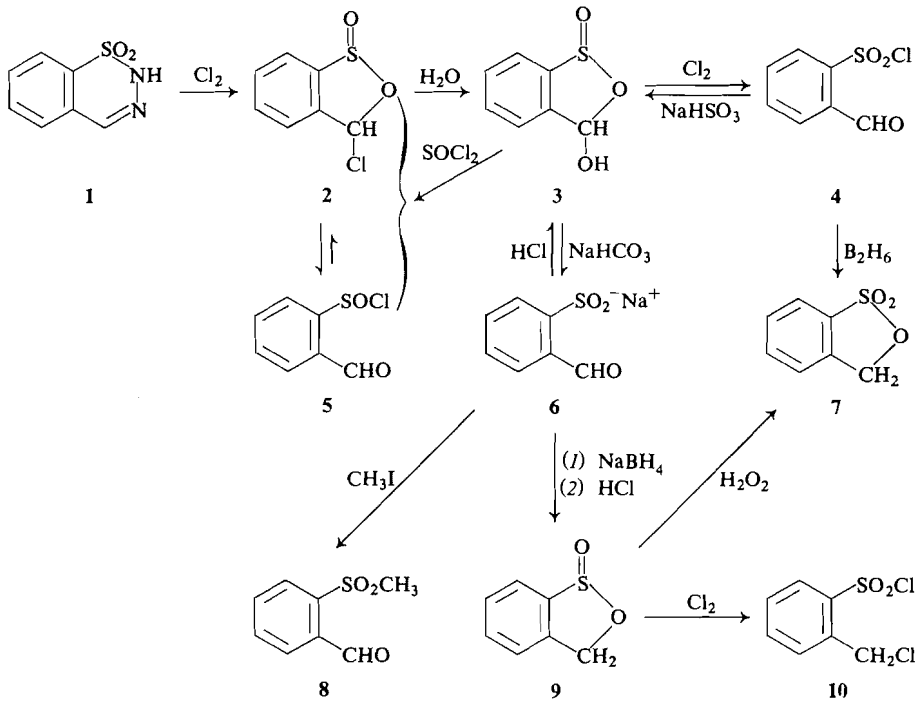
Results and Discussion

The Products of the Chlorinolysis and Subsequent Interconversions (Scheme 1)

When chlorine was bubbled into a solution of **1** in chloroform (reagent grade, containing 0.75% ethanol) or wet methylene chloride at room temperature, we observed effervescence (presumably due to nitrogen) and isolated a white crystalline solid melting at 33–35°. Structure **4** for the product readily follows from elemental analysis and spectra, the latter showing a singlet (1*H*) at 10.9 p.p.m. in addition to aromatic proton signals (4*H*) around 7.9 p.p.m. in the n.m.r., and bands at 1700 and 2900 due to the aldehyde group and at 1385, 1192, and 366 cm^{-1} characteristic (3, 4) of the $—SO_2Cl$ function. The peak at 2900 cm^{-1}, though at the high end of the range for such absorption was confirmed as due to the formyl group by observation of the combination band (5, 6) at 4600 cm^{-1} in the near i.r.

On adding a solution of **1** to a solution of chlorine in methylene chloride with careful exclusion of water, we again observed effervescence but the product obtained on evaporating the solvent showed only a small carbonyl maximum in the i.r., no significant bands attributable to a sulfonyl group, but absorption at 1140 and 960 cm^{-1} suggestive of a sulfinic ester (3). After shaking this material with a mixture of water and methylene chloride and evaporating the

[1]Organic Sulfur Mechanisms. Part 9. For part 8 see the accompanying paper (1).



SCHEME 1

organic phase, we obtained a good yield of a crystalline solid, m.p. 98–102°, shown as described below to be 3*H*-2,1-benzoxathiol-3-ol 1-oxide (**3**). This structure is the cyclic tautomer of *o*-formylbenzenesulfinic acid, and because of the complexity of the systematic name **3** is referred to here as the "pseudo-acid".

The pseudo-acid character of this material is shown by titration with base, which gave an equivalent weight of 171 (theoretical for **3** is 170); this taken with the elemental analysis establishes the empirical formula $C_7H_6O_3S$. The i.r. spectrum of the sodium salt (**6**) shows bands at 2750, 1706, and 1686, and a very strong complex absorption centered around 1020 cm^{-1}, as expected for the aldehyde and sulfinate (3) functions. Structure **6** is confirmed by conversion of the sodium salt to *o*-methylsulfonylbenzaldehyde (**8**) by reaction with methyl iodide; **8** had previously been made (7) by oxidation of the sulfide. The pseudo-acid (**3**) itself is not very soluble in the usual solvents for i.r. spectroscopy. A Nujol mull spectrum showed strong bands at 3180, 1137 (sh), 1125, and 1085 and no absorption around 1700 cm^{-1}, whereas the spectrum of a dilute (but saturated) solution in methylene chloride showed absorption at 3540 and 3300, a strong band centered around 1140, and a rather weak peak at 1705 cm^{-1}. This last peak is presumably due to a small amount of aldehyde in the methylene chloride solution, though whether this means the presence of *o*-formylbenzenesulfinic acid itself or the conjugate base is not certain. The very strong absorption around 1140 cm^{-1} is in agreement with the cyclic sulfinate formulation (**3**) (3); the differences between the solid and liquid phase spectra could merely be a reflection of the differences in phase, but ring–chain tautomerism (acid $\rightleftharpoons$ pseudo-acid), ionization, and *cis–trans* isomerism in **3** may well contribute also.

The n.m.r. spectrum of the pseudo-acid (**3**) in D_2O showed complex aromatic absorption from 7.7–8.0 (4H) and an apparent singlet at 8.11 p.p.m. (1H). Addition of 1 equiv of sodium bicarbonate resulted in a broadening of the four-hydrogen aromatic absorption, complete removal of the singlet at 8.11, and its replacement by a sharp singlet at 10.60 p.p.m. (1H); with 0.5 equiv of $NaHCO_3$ the one-hydrogen peak is a broadened singlet at 9.33 p.p.m. Addition of perchloric acid caused a small upfield shift of the 8.11 p.p.m. peak so that it became superimposed

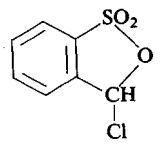
on the aromatic absorption. In acetone-d_6 **3** showed absorption in the aromatic region (5H) as well as a signal at 5.7 p.p.m. (1H) which disappeared on adding D_2O. The above results indicate that the pseudo-acid (**3**) and the conjugate base (and perhaps the "true" acid) are in rapid equilibrium with **3** predominating in the absence of added base. Phthalaldehydic acid shows comparable behavior (8).

Reduction of a solution of **3** in sodium hydroxide (*i.e.* **6**) with sodium borohydride, followed by acidification with hydrochloric acid led to **9**, a cyclic sulfinic ester or "sultine" (*cf.* refs. 9 and 10). Sultine **9** is also produced on thermolysis of **1**, as described in the accompanying paper (1), and its formation and n.m.r. spectrum were of interest in connection with the formation of sultines by thermal rearrangement of thiete 1,1-dioxide and derivatives (10). The anisotropy of the sulfinyl group is such that in a group of these sultines (10) the chemical shifts of the two methylene protons were found to differ by as much as 0.67 p.p.m. Confirmation of the sultine formulation (**9**) was obtained by oxidation to the sultone (**7**), identical to a specimen prepared from the cyclic chloride **11** by the procedure of Helberger *et al.* (11), and also from **4** by reduction with diborane.

It seemed from the results already described that **3** was probably the precursor of **4** in the chlorination of **1** in wet methylene chloride and that chlorination of **3** should yield **4**; this was found to be so. In addition, reduction of **4** with sodium bisulfite gave back **3**. Chlorination of the sultine **9** led to **10**, a previously unknown material which would appear to have potential as a synthetic intermediate. Chlorinolysis of a sulfinic ester has been observed before in the formation of methyl chloride from methyl methanesulfinate (12), and would also appear to have analogy in the cleavage of sulfite esters (13). *o*-Chloromethylbenzenesulfonyl chloride (**10**) is more conveniently prepared from sodium *o*-formylbenzenesulfonate by reduction with sodium borohydride followed by treatment with $POCl_3$–PCl_5.

Remaining to be discussed are the transformations involving **2** and **5**. The material obtained on chlorination of **1** in dry methylene chloride at room temperature proved intractable but when the reaction was carried out at 0–2°, again with exclusion of moisture, careful removal of solvent left a crystalline product melting at 64–66°. Structure **2** for this material follows from elemental analysis and spectra, the latter showing strong bands at 1150 and 970 cm^{-1} in the i.r., characteristic of sulfinic esters (3), while in addition to the aromatic absorption (4H) in the n.m.r. there was a sharp singlet (1H) at 7.08 p.p.m. appropriate to the methine hydrogen. When the n.m.r. sample was allowed to stand for a time, the singlet at 7.08 diminished and one at 9.88 p.p.m. grew. The latter peak is due (as is shown below) to presence of some of the ring–chain isomer **5**. On further standing (and addition of HCl) the 7.08 peak diminished further and the 9.88 grew until an equilibrium mixture consisting of about 17% of **2** and 83% of **5** was obtained. The equilibration was evidently catalyzed by hydrogen chloride and since the absence of HCl was difficult to ensure (or its concentration difficult to control) owing to the ease with which **2** and **5** may be hydrolyzed, no attempt was made to determine the rate of spontaneous equilibration.

The same equilibrium mixture of **2** and **5** is obtained by treatment of the pseudo-acid (**3**) with thionyl chloride. From the mixture so obtained we isolated a sample of **5** (m.p. 103–105°); the structure again follows from elemental analysis and spectra (see Experimental). A solution of **5**, showing initially no sign of **2** in the n.m.r., was found gradually to develop a small peak due to **2** at 7.08 p.p.m., eventually giving the spectrum of the equilibrium mixture. It should perhaps be mentioned that the purest specimen of **2** obtained showed no sign of the 9.88 peak in the n.m.r. but did show a very small carbonyl absorption at 1700 cm^{-1}; the i.r. sample at least would appear to have been contaminated with a small amount of **5**.



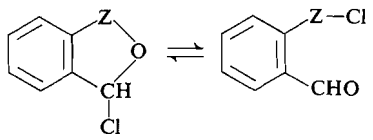
11

The ring–chain isomerism (**2** ⇌ **5**) observed here offers an interesting contrast with related systems. The analogous sulfonyl compounds **4** and **11** are reasonably stable species which show no sign of equilibrating under any circumstances in which we have observed them. With the carbonyl system on the other hand the only form that has been observed (see for example ref. 14)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

has the cyclic (phthalide) structure; the failure to observe the open form ("normal" acid chloride) is assumed to be due to rapid conversion to the ring tautomer.

It is of interest to consider the variation in relative stabilities of "ring" *vs.* "chain" isomers in the light of Pearson's "hard–soft–acid–base" (HSAB) theory (15). If we symbolize the general situation by the equilibrium **12** ⇌ **13** and focus

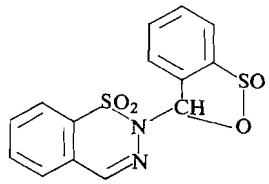


12 **13**

attention initially only on bond energies, it is evident that any change in equilibrium constant accompanying changing from one Z to another, reflects as a first approximation a change in the bond energy difference, $E_{Z-Cl} - E_{Z-O}$. Kice and Guaraldi have shown (16) that the sulfinyl group is a distinctly "softer" Lewis acid than the sulfonyl and carbonyl groups, which are "hard" (15, 17). Since Cl^- is "softer" than RO^- (15), we would expect the difference $(E_{Z-Cl} - E_{Z-O})$ to be larger for the sulfinyl compounds than for the sulfonyl or carbonyl analogues. With the sulfinyl *vs.* the carbonyl compounds this is evidently so, the equilibrium proportion of the open form **13** being much higher for the former than the latter. This would in turn suggest that the equilibrium mixture of **4** and **11** would be almost entirely **11**, but the point has not been tested. Another factor which could influence the position of the equilibrium **12** ⇌ **13** is variation in ring strain associated with change from one Z group to another, but the ring strain in these compounds is probably not large and its variation would not seem to us to be the most important influence.

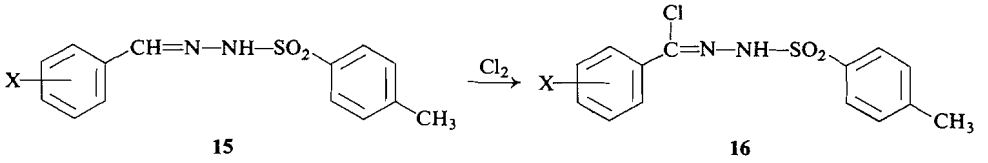
A similar comparison of the isomerization **2** ⇌ **5** with the ring–chain tautomerization "pseudo-acid" (**3**) ⇌ *o*-formylbenzenesulfinic acid is also explicable in HSAB terms. The change in equilibrium constant in this case is a direct function of the change in the quantity $E_{S-X} - E_{C-X}$, where X may be Cl or OH. By the same reasoning as before the equilibrium proportion of the open-chain isomer is predicted to be greater with the acid chlorides than the acids; the same conclusion is drawn from experiment. Steric effects would be expected to be of even less significance in this case, since the cyclic compounds are derived from the same ring system.

Finally, mention should be made of two further variations in the course of the chlorination of the benzothiadiazine (**1**) accompanying change in reaction conditions. In 1,2-dichloroethane at −20°, a product melting at 198–200° was obtained; the yield of this high-melting material was improved (to 82%) by adding the chlorine to **1**, rather than the other way around. This material analyzed for $C_{14}H_{10}S_2O_4N_2$ and showed i.r. bands characteristic of both sulfinyl and sulfonyl groups, but no sign of N–H absorption. These points suggested that the material arose from reaction of **2** (or **5**) with unreacted **1**. In confirmation of this the mixture of **2** and **5** obtained by reaction of **3** with thionyl chloride, gave, when treated with an equimolar quantity of **1**, a 90% yield of the compound melting at 198–200°. Also, alkaline hydrolysis of the high-melting material gave back **3** and **1** in good yield. The simplest formulation for this "coupled product" that fits the above data is **14**, though the zwitterionic structure with the "sultinyl" residue attached to the other nitrogen is not excluded.



14

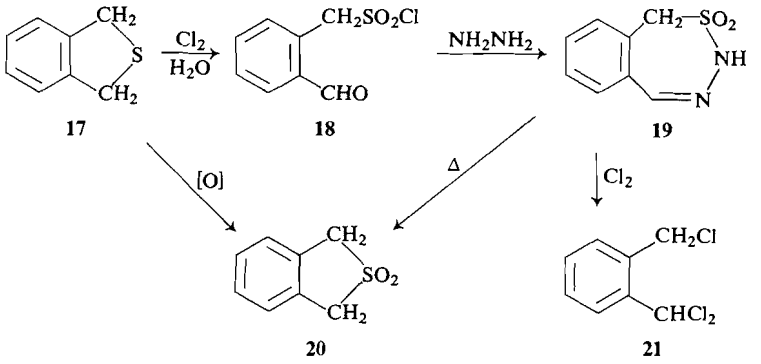
Use of cold dimethylformamide as the solvent in the chlorination of **1** led to another result. Part of the material suffered loss of nitrogen and, presumably via solvolysis, led to *o*-formylbenzenesulfonic acid, which was characterized by conversion to **11**. Some of the material, however, retained the nitrogen to give a material which, on the basis of analytical, i.r., n.m.r., and mass spectrometric data is evidently 4-chloro-2*H*-1,2,3-benzothiadiazine 1,1-dioxide, *i.e.* the cyclic acyl chloride hydrazone. As is described immediately below, the formation of acyl chloride hydrazones is the reaction found with acyclic sulfonhydrazones in both methylene chloride or dimethylformamide, though the yield is higher with the latter solvent. The properties of the 4-chloro-derivative of **1** are such that if it had been formed



15 16

a X = H
b X = *p*-OCH_3
c X = *o*-SO_2CH_3

SCHEME 2



17 18 19 20 21

SCHEME 3

in significant amount in the chlorinations in the other solvents then it would probably have been readily detected.

Chlorination of Acyclic Sulfonhydrazones (Scheme 2)

It appeared that the reaction of aromatic sulfonhydrazones with chlorine had not been studied before, and that information on this reaction might be of use in helping to understand the nature of the chlorinolysis of the thiadiazine (**1**). Accordingly the sulfonhydrazones **15***a–c* were treated with chlorine at room temperature. The principal product in each case was the acyl chloride hydrazone (hydrazonoyl chloride) (**16***a–c*); this is the expected result on the basis of previous workers' findings on the halogenation of other hydrazones (18). In addition, small amounts of the aldehyde and *p*-toluenesulfonyl chloride were also formed.

Synthesis and Chlorinolysis of 3H-2,3,4-Benzothiadiazepine 2,2-Dioxide (19) (Scheme 3)

For reasons described more fully in the discussion of the mechanism (below) we decided to synthesize the previously unknown heterocycle 3*H*-2,3,4-benzothiadiazepine 2,2-dioxide (**19**) and to treat it with chlorine. The thiadiazepine **19** was readily obtained from the dihydrothiophene **17** via the sulfonyl chloride (**18**) produced by treatment of an aqueous suspension of **17** with chlorine. The thiadiazepine (**19**) was obtained as a white solid melting (with evolution of gas) at 169–170°, the mode of synthesis and its analytical and spectroscopic properties of which (see Experimental) support the thiadiazepine formulation (**19**). On heating just above its melting point for a few minutes the evolution of gas ceases and the sulfone (**20**) is obtained in good yield. The latter compound (**20**) on further heating (at 280°) has been previously shown (19) to undergo loss of sulfur dioxide to give products derivable from *o*-quinodimethane.

3*H*-2,3,4-Benzothiadiazepine 2,2-dioxide (**19**) reacts readily with chlorine at 0° with loss of both nitrogen and sulfur dioxide to give *o*-chloromethylbenzal chloride (**21**).

The Mechanism of the Chlorinolysis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (1)

Three possible routes from **1** to the chlorosultine (**2**) are summarized in Scheme 4. The first step is common to the three mechanisms and

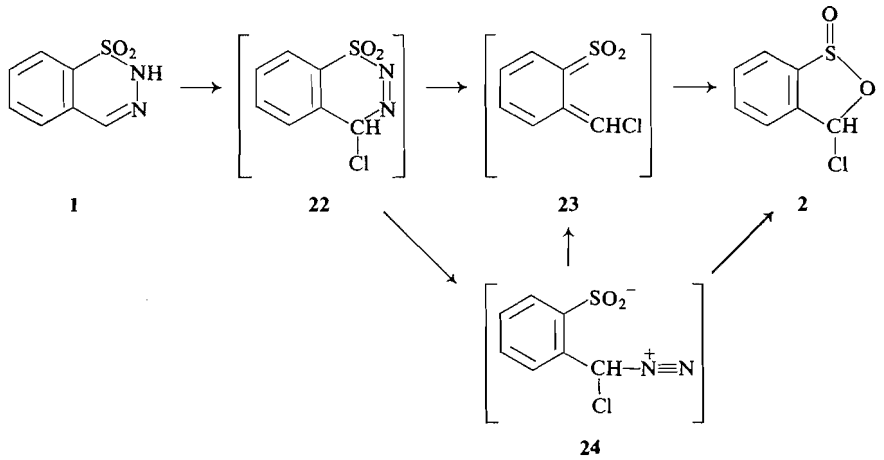

SCHEME 4

involves attack of chlorine at the α-carbon with formation of the α-chloroazosulfone (**22**), a reaction for which there is precedent from different quarters. As has been mentioned above halogenation of aldehyde hydrazones, including sulfonhydrazones, gives the acyl chloride hydrazone, most probably via the α-chloroazo compound. In agreement with such a formulation is the actual isolation of the azo compound on chlorination of ketazines (20, 21).

The cyclic α-chloroazo compound **22**, once formed, is well set up to undergo cycloreversion to the sulfene (**23**), which, following the route proposed for the formation of the sultines (1, 10), would be expected to give the chlorosultine **2**. Reverse Diels–Alder reactions with extrusion of nitrogen can be estimated to be strongly exothermic (by about 45 kcal/mol), and, though apparently not very frequently observed, would appear to be facile reactions taking place readily below room temperature (for examples see reference 22). A particularly close analogy to the present case is the formation of *o*-quinodimethane dimer by mercuric oxide oxidation of 1,2,3,4-tetrahydrophthalazine observed by Carpino (23). This reaction is believed to involve oxidation to the cyclic azo compound followed by extrusion of nitrogen to give *o*-quinodimethane.

Though the formulation **22** → **23** → **2** is attractive to us, it is not the only imaginable route from **22** to **2**. To judge from the work of Overberger and co-workers (24, 25) and more recently by Kice and Gabrielsen (26), azosulfones react by free radical processes under certain circumstances, but heating is normally required to induce the homolysis even in apparent free radical chain processes; such reaction would seem unlikely under the conditions of the chlorinolysis of **1**. Ionic cleavage of azosulfones to form the diazonium sulfinate is well-known; from **22** this would lead to **24** which could go to the chlorosultine (**2**), either directly or via the sulfene (**23**). Lewis and co-workers (27) have estimated that the half-life for the formation of benzenediazonium benzenesulfinate ($PhN^{+}{\equiv}N\ {}^{-}SO_2{-}Ph$) from the azosulfone ($PhN{=}NSO_2Ph$) in methanol is about 5 min at 29°. The formation of an aliphatic diazonium ion would not be expected to be much faster and at first glance such a process (*i.e.* via **24**) would seem a little slow to account for the rapid formation of **2** from **22** in non-polar solvents even at 0° and lower. These observations are also consistent with the formation of the hydrazonoyl chlorides (**16**), the prototropic shift in the presumed intermediate α-chloroazo compound taking place faster than the heterolysis to the *p*-toluenesulfinate and benzylic diazonium ions. In these chlorinations, however, small amounts of both *p*-toluenesulfonyl chloride and the aromatic aldehyde are, in fact, observed, suggesting that the decomposition to the diazonium sulfinate does compete to some extent. However, substituents on the azo group in **22** are held in a *cis* configuration whereas it is likely that in the azo compound from **15** they are *trans*, and it is by no means impossible that a *cis*-azosulfone (*e.g.* **22**) because of the favorable *anti* arrangement of the sulfonyl group and the free electron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

pair, could undergo heterolysis a good deal more quickly than the *trans* analogues. Unfortunately, unlike a number of other azo compounds (including the closely related diazosulfonates), there is comparatively little information on geometrical isomerism in azosulfones, and in no instance has a pair of *cis–trans* isomers been isolated, or even been unambiguously shown to exist (27, 28); a study of the dipole moments of a number of azosulfones led to the conclusion that each of these compounds had the *trans* configuration (28).

It was hoped that the chlorination of 2*H*-2,3,4-benzothiadiazepine 2,2-dioxide (**19**) might be instructive, since the α-chloroazosulfone presumably formed initially would have a *cis* azo double bond but at the same time be less favorably arranged for cycloreversion than **22**. The result shows that the six-membered ring arrangement as in **22** is not *required* for easy loss of nitrogen, though, at the same time, it does not exclude the reverse Diels–Alder mechanism when the molecule is well set up for it. It would appear that it is not possible to determine at this stage which reaction path the reaction is actually proceeding by, and further discussion should await further information.

Experimental

Experimental procedures, materials, and apparatus are the same as in the accompanying paper. The i.r. spectra below 600 cm^{-1} were determined on a Beckman IR-5A spectrometer equipped with CsBr optics and using KBr cells; the near i.r. determination was made on a Cary 14 spectrophotometer.

Chlorinolysis of 2H-1,2,3-Benzothiadiazine 1,1-Dioxide (1)

(i) In Hydroxylic Media

2*H*-1,2,3-Benzothiadiazine 1,1-dioxide (**1**) (1) (1.005 g) was dissolved in chloroform (55 ml; Fisher Spectranalyzed, containing 0.75% ethanol), and dry chlorine gas was bubbled through. When the solution began to effervesce the passage of chlorine was stopped and when no more gas was given off (about 5 min) the solvent was evaporated under reduced pressure. The product, 1.265 g of a colorless oil, was recrystallized four times from carbon tetrachloride – petroleum ether (35–60°) cooled in an acetone – Dry Ice mixture, giving **4** as fine white crystals melting at 33–35°. The i.r. spectrum showed peaks at: 2900 (w), 2770 (vw), 1700 (s), 1585 (m), 1570 (m), 1445 (w), 1400 (sh), 1380 (vs), 1300 (w), 1265 (m), 1180 (vs), 1120 (m), 1060 (m), 1035 (w), 995 (w), 965 (vw), 820 (m), 700 (m), 640 (w), 570 (s), 505 (w), 470 (m), 435 (vw), and 370 (m) cm^{-1}. The n.m.r. spectrum (CCl_4) showed multiplets in the aromatic region at 7.9 p.p.m. (4H) and a singlet (1H) at 10.9 p.p.m.

Anal. Calcd. for $C_7H_5SO_3Cl$: C, 41.08; H, 2.46; S, 15.67; Cl, 17.23. Found: C, 41.05; H, 2.76; S, 15.47; Cl, 17.16.

In another experiment chlorine (~ 0.5 g) was dissolved in methylene chloride (50 ml) and water (0.1 ml) was added. To this mixture a solution of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) (387 mg) in methylene chloride (20 ml) was added dropwise over a period of about 10 min. When the strong effervescence, which accompanied addition of **1**, had subsided, a portion of the reaction mixture was examined by i.r. spectroscopy which showed the presence of unreacted **1**. The mixture was then left overnight, dried, and the solvent evaporated giving a colorless oil (251 mg, 52%) shown by its i.r. spectrum to be *o*-formylbenzenesulfonyl chloride (**4**). Recrystallization from cold petroleum ether–carbon tetrachloride gave crystals melting at 31–35°.

(ii) In Dry Methylene Chloride Followed by Aqueous Work-up

A solution of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) (1.02 g) in methylene chloride previously dried by distillation from lithium aluminum hydride, was added dropwise over a period of 20 min to a solution of chlorine (about 2.0 g) in dry methylene chloride (50 ml). Within a few minutes the mixture began to bubble and when the effervescence had stopped (1 h) the solvent was evaporated leaving a colorless oil showing bands at 1710, 1140, and 960 cm^{-1} in the i.r. Water (10 ml) was added to the product and the mixture warmed on the water bath (10 min) before being extracted with methylene chloride. The methylene chloride extract was dried and the solvent evaporated giving crude **3** as white crystals (75%), which after recrystallization from methylene chloride melted at 98–102°. The i.r. spectrum of a Nujol mull of **3** showed bands at 3180 (s), 1598 (w), 1585 (w), 1337 (m), 1325 (w), 1295 (s), 1253 (s), 1213 (s), 1137 and 1125 (vs), 1085 (vs), 1055 (s), 1020 (w), 957 (w), 888 (m), 840 (vs), 770 (s), 725 and 713 (vs), and 678 (m) with no absorption around 1700 ± 25 cm^{-1}, whereas a dilute (saturated) solution in methylene chloride showed bands at 3540 and 3300 (w), 3080 (w), 1705 (w), 1452 (w), 1425 and 1420 (w), 1305 (w), 1280 (w), 1220 (m), 1140 and 1125 (s and broad), 1055 (w), 883 (m), 850 (w), and 790 (m) cm^{-1}.

Anal. Calcd. for $C_7H_6SO_3$: C, 49.34; H, 3.55; S, 18.89. Found: C, 49.46; H, 3.78; S, 18.83.

The n.m.r. spectrum of **3** in acetone-d_6 showed complex absorption from 7.2 to 7.9 and a broad singlet at 5.7; the latter band disappeared in addition of D_2O. In D_2O solution, using external tetramethylsilane as the standard, **3** showed aromatic absorption as a relatively narrow band from 7.8 to 8.0 (4H) and a slightly broadened singlet (1H) due to the methine hydrogen at 8.11 p.p.m. Upon addition of 1 equiv of $NaHCO_3$ the aromatic absorption broadened 7.6–8.2 (4H) and a new sharp singlet appeared at 10.60 p.p.m. With only 0.5 equiv of $NaHCO_3$ there was aromatic absorption at 7.7–8.2 (4H) and a broadened singlet at 9.33 p.p.m. (1H). After addition of a few drops of 30% perchloric acid to the solution of **3** in D_2O, the n.m.r. spectrum showed only a relatively narrow band between 7.7 and 8.0 p.p.m. The integrated intensity of the 7.8–8.3 region (5H) in the spectrum of **3**, relative to that of a small amount of acetone added to the D_2O to serve as an integration standard, was found to be about the same as the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

integrated intensity of the 7.7–8.0 band found after addition of perchloric acid; this was interpreted as showing that the band at 8.11 in **3** had moved upfield upon addition of perchloric acid and was obscured by the aromatic hydrogens.

Titration of **3** (18.9 mg) with 0.01 *N* sodium hydroxide led to consumption of 11.05 ml, corresponding to an equivalent weight of 171; theoretical equivalent weight, 170. On evaporation of the water sodium *o*-formylbenzenesulfinate (**6**) was left as a crystalline solid. The i.r. spectrum of this material (Nujol mull) showed peaks at 3060 (w), 2750 (w), 1710 and 1686 (vs), 1586 (s), 1567 (m), 1304 (m), 1255 (m), 1200 (s), 1162 (w), 1133 (w), 1118 (w), a very strong complex absorption with the following peaks, 1063, 1045, 1018, 1000, 987 and 972, 888 (w), 837 (m), 825 (m), 763 (s), 725 (m), 695 (m), and 682 (m) cm^{-1}.

When sodium *o*-formylbenzenesulfinate (**6**) (31 mg) was suspended in methylene chloride and hydrogen chloride bubbled through the mixture, the yellow salt disappeared and a white precipitate formed. After 15 min when there were no traces of **6** remaining, the solution was filtered and the solvent removed from the filtrate under reduced pressure without heating leaving a colorless oil (24 mg) the i.r. spectrum of which showed it to be the pseudo-acid (**3**). After crystallization from methylene chloride, the product melted at 92–96°.

(iii) In Dry Methylene Chloride at 1 ± 1°

A solution of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) (589 mg) in a mixture of dry methylene chloride (25 ml) and dry chloroform (5 ml) was added slowly to a stirred solution of chlorine (636 mg) in methylene chloride (15 ml), maintained at 0–2° by means of an ice-bath, over a period of 1 h. After addition was complete, the mixture was stirred for a further 1/2 h and then the solution was evaporated to about 5 ml under reduced pressure at room temperature. The concentrated solution was transferred to a Craig tube and solvent removed in a stream of dry nitrogen until crystallization took place. The white crystals of **2** (269 mg) were collected. The n.m.r. spectrum showed a singlet (1H) at 7.25 p.p.m. and a multiplet (4H) at 7.7 p.p.m. The i.r. spectrum (CH_2Cl_2) showed the following peaks: 3040 (w), 1700 (w), 1585 (w), 1465 (w), 1450 (m), 1300 (w), 1235 (w), 1200 (m), 1145 (vs), 1060 (m), 1020 (w), 970 (vs), 880 (w), 865 (s), 640 (s); the peak at 1700 cm^{-1} (and perhaps also that at 1200 cm^{-1}) is probably due to the aldehyde – sulfinyl chloride (**5**) present as impurity.

The analytical sample, prepared by recrystallization (twice) from methylene chloride, melted at 64–66°.

Anal. Calcd. for $C_7H_5SO_2Cl$: C, 44.57; H, 2.67; S, 16.99. Found: C, 44.49; H, 2.87; S, 17.11.

In some preparations the crude crystalline product showed a small peak at 9.88 p.p.m. in the n.m.r. due to the presence of **5**. One such sample, in which integration of the 7.08 and 9.88 peaks indicated a ratio of **2** to **5** of 94:6 was let stand at room temperature for 80 min. The n.m.r. showed a change in the intensities of the 7.08 and 9.88 peaks corresponding to a change in composition to 74% **2** and 26% **5**; the aromatic region also became broader. Dry hydrogen chloride was then bubbled into the sample and the mixture let stand for 10 min; the ratio of **2** to **5** was judged from the n.m.r. spectrum to be 49:51, and after a further 15 min to be 35:65. After standing overnight the above ratio was estimated as 17:83.

(iv) In 1,2-Dichloroethane at −20°

A solution of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) 364 mg, 2 mmol in dichloroethane (55 ml) was added dropwise with stirring to a solution of chlorine (168 mg) in dichloroethane (14 ml) cooled to −20°. The mixture was stirred for 1 h at −20°, and the solvent removed under reduced pressure at room temperature to give a sticky, colorless solid (317 mg). Recrystallization from methylene chloride gave crystals (177 mg) melting at 194–196° (dec.); further recrystallization from methylene chloride – acetone gave an analytical sample of the coupled product (**14**) melting at 198–200° (dec.). The i.r. spectrum of a dilute (saturated) solution in $CHCl_3$ showed prominent bands at 1350, 1185, and 1130 with weaker bands at 3000, 1440, 905, 890, and 655 cm^{-1}.

Anal. Calcd. for $C_{14}H_{10}N_2O_4S_2$: C, 50.28; H, 3.01; N, 8.38; S, 19.17. Found: C, 50.15; H, 2.89; N, 8.34; S, 19.35.

In another experiment in which chlorine (1 mmol) in dichloroethane (14 ml) was added to **1** (366 mg, 2 mmol) in dichloroethane at −20° as above, a higher yield (82%) of recrystallized **14** was obtained.

(v) In Dimethylformamide

2*H*-1,2,3-Benzothiadiazine 1,1-dioxide (**1**) (1.31 g) was dissolved in a mixture of dimethylformamide (18 ml) and water (3 ml) and the solution was cooled to 0°. Chlorine was passed into the solution until the yellow color persisted and after a further 2 min the reaction mixture was evacuated on a water aspirator to remove much of the excess chlorine. It was then poured into water (300 ml) and the product extracted with methylene chloride (4 × 100 ml, 2 × 50 ml). The combined extracts were dried and evaporated to give an oil which on standing overnight *in vacuo* partly solidified. Crystallization from methylene chloride gave 4-chloro-2*H*-1,2,3-benzothiadiazine 1,1-dioxide (327 mg, 21%), melting at 143–144°. The i.r. spectrum (CH_2Cl_2) showed absorption at 3310 (m), 1585 (w), 1560 (w), 1370 (m), 1345 (s), 1245 (w), 1185 (s), 1145 (m), 1040 (m), 990 (m), 865 (m), and 630 (m) cm^{-1}. The n.m.r. spectrum (CD_2Cl_2) exhibited a multiplet (4H) at 7.8–8.2 and a broad signal (1H) at 8.3–9.2 p.p.m. removed by addition of D_2O. In the mass spectrum the molecular ion was principally a doublet at 216 (Cl^{35}) and 218 mu (Cl^{37}), relative abundance 29:12.

Anal. Calcd. for $C_7H_5ClN_2O_2S$: C, 38.81; H, 2.33; Cl, 16.36; N, 12.93; S, 14.80. Found: C, 38.72; H, 2.23; Cl, 16.53; N, 12.93; S, 14.74.

In another experiment 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) (239 mg) was dissolved in dimethylformamide (4.6 g) and solid calcium carbonate (480 mg) was added to the solution. The mixture was then cooled to 0° and added to a cooled, freshly prepared solution of chlorine (460 mg) in dimethylformamide (4.4 g). After 5 min the reaction mixture was filtered and the filtrate evaporated to give an oil which was partitioned between chloroform and water in three stages. The organic phase on evaporation gave an oil (104 mg) which was crystallized from chloroform–pentane to give needles of 4-chloro-2*H*-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1,2,3-benzothiadiazine 1,1-dioxide (52 mg, 18%), identified by direct comparison (i.r., mixed m.p., t.l.c.) with a specimen prepared as described above. Evaporation of the aqueous phase also gave an oil (456 mg) which was dissolved in water (5 ml) and passed through Dowex 50W-X8 ion exchange resin. Evaporation of the eluate gave an acidic oil (195 mg) whose i.r. absorption at 1020 (s) and 1240 (s) cm^{-1} suggested the presence of some sulfonic acid. It was treated with thionyl chloride (5 ml) on the steam bath for 15 min and evaporated to dryness under reduced pressure; crystallization of the resultant oil from chloroform gave **11** (55 mg, 22%), m.p. 111–114°, identified by direct comparison (mixed m.p., i.r.) with an authentic specimen (29).

Preparation of o-Formylbenzenesulfinyl Chloride (5) from the Pseudo-acid (3)

The pseudo-acid (**3**) (522 mg) was dissolved in thionyl chloride (5 ml) and left at room temperature for 0.5 h. The excess thionyl chloride was removed under reduced pressure leaving a pale yellow crystalline product (530 mg), which on recrystallization five times from methylene chloride containing a few drops of thionyl chloride and evaporating the excess solvent under a stream of dry nitrogen, gave *o*-formylbenzenesulfinyl chloride (**5**), m.p. 103–105° (vacuum capillary). The i.r. spectrum (CH_2Cl_2) showed bands at 3060 (w), 2850 (m), 2750 (w), 1700 (vs), and 1680 (sh), 1585 (m), 1575 (m), 1390 (w), 1305 (m), 1205 (s), 1145 (vs), 1050 (w), 1030 (w), 845 (s), and 650 cm^{-1} (s). The n.m.r. spectrum (CD_2Cl_2) showed complex aromatic absorption in the range 7.5–8.3 (4H) and a sharp singlet at 9.88 p.p.m. (1H).

Anal. Calcd. for $C_7H_5ClO_2S$: C, 44.57; H, 2.67; S, 16.99. Found: C, 44.54; H, 2.93; S, 17.04.

In other experiments the n.m.r. spectrum of the material obtained by dissolving **3** in thionyl chloride showed in addition to the peaks characteristic of **5**, a singlet at 7.08 p.p.m. and a prominent peak around 7.5 p.p.m. ascribable to the presence of about 20% of **2**.

Chlorination of 3H-2,1-Benzoxathiol-3-ol 1-Oxide (3) (the "Pseudo-acid")

The "pseudo-acid" **3** (84 mg) was dissolved in methylene chloride (25 ml) and a solution of chlorine (about 0.2 g) in methylene chloride (8 ml) was added. The mixture was shaken for 5 min and then allowed to stand for 1 h. When the solvent was evaporated 85 mg (83%) of a colorless oil was obtained. An i.r. spectrum (CCl_4) of the product was identical to that of *o*-formylbenzenesulfonyl chloride (**4**) prepared as above. The product was crystallized from carbon tetrachloride – petroleum ether cooled in an acetone – Dry Ice mixture; m.p. 31–35°.

Reduction of o-Formylbenzenesulfonyl Chloride (4) to the "Pseudo-acid" 3

o-Formylbenzenesulfonyl chloride (1.94 g, 9.5 mmol), sodium sulfite (2.5 g), and water (20 ml) were stirred at room temperature for 4.5 h. The solution was acidified with concentrated sulfuric acid and heated to 90–100° on the steam bath for 1 h. The solution was cooled and extracted with methylene chloride. The extracts were dried and the solvent evaporated under reduced pressure giving a colorless solid (1.01 g, 63%), melting at 97–98°. After recrystallization, it melted at 97–100°; mixed m.p. with a specimen of **3** prepared from **1**, 97–100°. The i.r. was also identical with that of authentic **3**.

Formation of o-Methylsulfonylbenzaldehyde (8) from the "Pseudo-acid" 3

A solution of sodium bicarbonate (504 mg, 6 mmol) in water (8 ml) was added to a solution of the "pseudo-acid" **3** (1.02 g, 6 mmol) in ethanol (10 ml) and the mixture let stand for 5 min. The mixture was then evaporated to dryness, benzene was added and the mixture evaporated again to dryness (3 ×); the last traces of volatile material were removed by means of an oil pump. The pale yellow solid (**6**) was then dissolved in absolute ethanol and methyl iodide (1 ml) added. The mixture was refluxed for 4.5 h, whereupon the dark red mixture was allowed to cool and was poured into water and extracted with methylene chloride. The extracts were washed with 0.1 *N* sodium thiosulfate (10 ml) and then with saturated potassium chloride solution. Evaporation of the solvent gave a colorless oil (1.39 g), the spectrum of which indicated the major portion of the material to be the diethyl acetal of **8**. The oil was suspended in 5% hydrochloric acid (10 ml) and warmed on the steam bath for 0.5 h. The mixture was then cooled in an ice-bath and the crystals of **8** (832 mg; 75%) removed by filtration. The crystals melted at 97–99°; reported for **8**, 97–98° (7). The i.r. spectrum ($CHCl_3$) showed peaks at 3000 (m), 1695 (s), 1585 (m), 1570 (w), 1395 (m), 1315 (vs), 1260 (w), 1185 (m), 1150 (vs), 1115 (w), 1060 (w), and 955 (m); the n.m.r. spectrum showed a singlet at 3.25 (3H), a complex multiplet around 7.6–8.2 (4H), and a singlet at 10.52 p.p.m. (1H).

Reduction of the "Pseudo-acid" 3 with Sodium Borohydride

3*H*-2,1-Benzoxathiol-3-ol 1-oxide (**3**) (1.76 g, 0.010 mol) was dissolved in 1.0 *N* sodium hydroxide (10.3 ml) and water (70 ml). Sodium borohydride (4 g, 0.106 mol) was added and the reaction mixture was left stirring overnight at room temperature. Concentrated hydrochloric acid (120 ml) was added slowly. The reaction mixture was extracted with methylene chloride which in turn was dried and evaporated under reduced pressure to yield 3*H*-2,1-benzoxathiole 1-oxide (**9**) (1.4 g, 88%). The crude product was distilled, b.p. 165°/0.005 mm. The distillate when cooled to −30° crystallized; recrystallization from ether and pentane yielded crystals of **9** melting at 40–41°.

Anal. Calcd. for $C_7H_6O_2S$: C, 54.52; H, 3.92; S, 20.80. Found: C, 54.60; H, 3.96; S, 20.78.

The i.r. spectrum (CCl_4) showed absorption bands at 3070 (w), 2930 (w), 2870 (w), 1580 (w), 1468 (m), 1450 (m), 1340 (w), 1298 (w), 1255 (w), 1210 (m), 1185 (w), 1130 (s), 1060 (m), 1020 (w), 1005 (w), 950 (s), 710 (s), 705 (s), 690 (s), 645 (s), and 560 cm^{-1} (m). The n.m.r. spectrum (CCl_4) showed an AB quartet, $\delta_A = 5.42$ and $\delta_B = 5.78$ p.p.m., $J_{AB} = 13.5$ Hz., and aromatic hydrogen absorption between 7.3–7.75 p.p.m., relative areas 1:2.

Oxidation of 3H-2,1-Benzoxathiole 1-Oxide (9) with Hydrogen Peroxide in Acetic Acid

A 2.1 ml aliquot of a solution made by mixing glacial

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

acetic acid (3 ml) with hydrogen peroxide (30%) (0.8 ml), was added to **9** (0.10 g, 0.65 mmol). The reaction mixture was heated under reflux for 1½ h, and was then poured into water (4 ml) and extracted three times with methylene chloride. The methylene chloride solution was washed with sodium carbonate solution, dried, and the solvent evaporated to yield 3*H*-2,1-benzoxathiole 1,1-dioxide (**7**) (0.06 g, 55%). Recrystallization from benzene gave white crystals, m.p. 113–114°, identified by mixed m.p. and comparison of i.r. and n.m.r. spectra with an authentic specimen prepared as described by Helberger *et al.* (11); reported m.p. 112.5° (11).

*Reduction of o-Formylbenzenesulfonyl Chloride (**4**) with Diborane*

o-Formylbenzenesulfonyl chloride (**4**) (0.14 g, 0.72 mol) was dissolved in diglyme (15 ml) which had been dried by distilling from calcium hydride. Diborane (13 mmol), generated by mixing sodium borohydride and boron trifluoride etherate in diglyme, was bubbled slowly into the diglyme solution under anhydrous conditions. The reaction mixture was poured into water (150 ml) to destroy unreacted diborane, and the water was evaporated from the diglyme under reduced pressure. Methylene chloride (30 ml) was added and then the solution was washed five times with water (25 ml portions). The methylene chloride was dried and evaporated to yield crude 3*H*-2,1-benzoxathiole 1,1-dioxide (**7**) (0.042 g, 35%). Recrystallization from methylene chloride and petroleum ether yielded crystals melting at 110–113°, and with an i.r. spectrum identical to that of an authentic specimen prepared by the method of Helberger *et al.* (11); reported m.p. 112.5° (11).

*Chlorination of 3H-2,1-Benzoxathiole 1-Oxide (**9**)*

3*H*-2,1-Benzoxathiole 1-oxide (**9**) (2.2 g, 14 mmol) was dissolved in methylene chloride which had been dried by distillation from lithium aluminum hydride. Chlorine was dissolved in methylene chloride (0°) until the solution was 0.6 *N*, as determined by titration with sodium thiosulfate. An aliquot of 48 ml (14.4 mmol of chlorine) was added dropwise under anhydrous conditions to the magnetically stirred solution of **9**. The reaction mixture was stirred for 3 h at room temperature. The methylene chloride was evaporated under reduced pressure without heating, to yield *o*-chloromethylbenzenesulfonyl chloride (**10**) (3.15 g, 98%). Recrystallization from methylene chloride and petroleum ether yielded short thin crystals (2.56 g, 80%), m.p. 46–47°.

Anal. Calcd. for $C_7H_6Cl_2O_2S$: C, 37.36; H, 2.69; Cl, 31.50; S, 14.24. Found: C, 37.25; H, 2.83; Cl, 31.16; S, 14.41.

The i.r. absorption bands (CH_2Cl_2) were found at 3060 (w), 1590 (w), 1570 (w), 1470 (m), 1442 (m), 1372 (s), 1305 (m), 1180 (s), 1115 (w), 1060 (m), 1040 (w), 962 (w), 820 (m), 675 (m), 585 (s), 570 (s), 547 (s), 490 (m), 445 (w), 373 cm^{-1} (w); n.m.r. spectrum (CCl_4) showed absorption bands at 5.10 (s, 2H) and 7.35–8.2 p.p.m. (4 aromatic hydrogens).

*Preparation of o-Chloromethylbenzenesulfonyl Chloride (**10**) from Sodium o-Formylbenzenesulfonate*

Sodium *o*-formylbenzenesulfonate (practical grade) (1 g, 0.048 mol) was dissolved in water (60 ml). Sodium borohydride (0.18 g, 4.74 mmol) was added. The reaction was stirred for 20 h at room temperature. Hydrochloric acid was added until the solution was slightly acidic. The water was evaporated under reduced pressure with heating. The white residue was leached with hot ethanol (70 ml) and the ethanol evaporated to yield crude sodium *o*-hydroxymethylbenzenesulfonate (0.75 g, 75%); i.r. bands (Nujol) at 3560 (w), 3490 (w), 3280 (m), 3060 (w), 1300 (w), 1240–1140 (s), (partially resolved), 1095 (m), 1058 (w), 1035 (s), 1010 (s), 955 (w), 890 (w), 835 (w), 760 (s), 710 (s), and 625 cm^{-1} (s).

The crude sodium *o*-hydroxymethylbenzenesulfonate as prepared above (12.2 g, 58 mmol) was cooled in ice. Phosphorus oxychloride (60 ml, 0.66 mol) was added slowly with stirring. Phosphorus pentachloride (12.2 g, 59 mmol) was added. The reaction was stirred at 50° for 3 days and then poured slowly with stirring onto ice. After the evolution of heat had subsided (3 h), the aqueous mixture was extracted with methylene chloride (400 ml). The methylene chloride solution was washed with water, dried, and the solvent evaporated under reduced pressure without heating. The crude yield of yellow viscous liquid was 12.7 g. Crystallization from methylene chloride and petroleum ether at −60° yielded *o*-chloromethylbenzenesulfonyl chloride (**10**) (6.1 g, 46%). Recrystallization from the same solvents gave 2.81 g, m.p. 46–47°. The i.r. spectrum and m.p. were identical to the sample of *o*-chloromethylbenzenesulfonyl chloride (**10**) prepared from **9**.

*Formation of the "Coupled Product" **14** by Reaction of **1** with the Chlorosultine – Sulfinyl Chloride (**2** ⇌ **5**) Mixture*

The pseudo-acid **3** (73 mg, 0.43 mmol) was added to thionyl chloride (5 ml) and left at room temperature for 15 min. The pale yellow solution was evaporated to dryness. The residual pale yellow solid (a mixture of **2** and **5**) was dissolved in dry methylene chloride and a solution of 2*H*-1,2,3-benzothiadiazine 1,1-dioxide (**1**) (78 mg, 0.43 mmol) in dry methylene chloride (5 ml) added. The mixture was left at room temperature for 1 h. Evaporation of the solvent gave colorless crystals which on recrystallization from methylene chloride – pentane melted at 197–198°; yield 122 mg (90%). The i.r. spectrum was identical to that of the "coupled product" **14** prepared by chlorination of **1** in dichloroethane at −20°.

*Hydrolysis of the "Coupled Product" **14***

The coupled product **14** (100 mg) was suspended in 5% sodium hydroxide solution (5 ml) and swirled for 10 min, whereupon most of the solid had dissolved to give a pale yellow solution. The mixture was left at room temperature for 1 h, and then acidified with 20% hydrochloric acid to give a white precipitate (41 mg, m.p. 135–140°). Recrystallization from chloroform gave **1**, m.p. 139–140°, mixed m.p. with a specimen of **1** prepared as described above 138–141°.

The filtrate was extracted with methylene chloride; removal of the solvent from the extracts gave a colorless oil (45 mg), which on recrystallization from methylene chloride gave crystals identified as the pseudo-acid **3** by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

m.p. (97–100°) and mixed m.p. with an authentic specimen (98–101°).

Preparation of the Tosylhydrazones ***15***

Approximately equimolar amounts of the aldehyde and *p*-toluenesulfonylhydrazine were refluxed in absolute ethanol. The crude product was obtained either by cooling the reaction mixture and filtering off the crystalline product or by evaporating the solvent. Recrystallization from the indicated solvent gave the following samples with the indicated melting points: benzaldehyde tosylhydrazone (**15***a*) (ethanol), m.p. 128–129°, reported m.p. 127–128° (30); anisaldehyde tosylhydrazone (**15***b*) (methylene chloride – pentane), m.p. 109–111°, reported m.p. 112–114° (30); *o*-methylsulfonylbenzaldehyde tosylhydrazone (**15***c*) (ethanol), m.p. 209.5–211°, with the following elemental analysis.

Anal. Calcd. for $C_{15}H_{16}N_2O_4S_2$: C, 51.11; H, 4.57; N, 7.95; S, 18.19. Found: C, 50.96; H, 4.53; N, 7.85; S, 18.05.

Chlorination of the Tosylhydrazones ***15****: Formation of the Acyl Chloride Hydrazones*

*(a) Benzoyl Chloride Tosylhydrazone (**16a**)*

(*i*) A solution of benzaldehyde tosylhydrazone (**15***a*) (549 mg, 2.0 mmol) in dry methylene chloride (25 ml) was cooled to −20° and added dropwise to a stirred solution of chlorine (154 mg, 2.2 mmol) in dry methylene chloride (19 ml) maintained at −20°. The mixture was stirred for 1 h and the solvent then removed at reduced pressure and room temperature. The dark yellow oily residue was dissolved in methylene chloride and filtered from a trace of insoluble residue. Removal of the solvent gave a dark brown oil (342 mg) which was dissolved in benzene and filtered through a column of silica gel (B.D.H. Reagent). Removal of the solvent gave a colorless solid which was recrystallized from methylene chloride – pentane to give colorless crystals of **16***a* (163 mg, 26%), m.p. 112–114°, mixture m.p. with authentic **16***a* (prepared as described below) 112–114°; the i.r. spectra were indistinguishable.

(*ii*) To a solution of benzaldehyde tosylhydrazone (**15***a*) (367 mg, 1.34 mmol) in dimethylformamide (DMF) (3.0 ml, dried over Linde 4A molecular sieves) at 0° was added a solution of chlorine in DMF (0.23 *M*) to a permanent end point. After 5 min, the reaction mixture was evaporated to dryness to give a colorless oil (469 mg). Crystallization from methylene chloride gave **16***a* (295 mg, 71%), m.p. 112–114°, identical to an authentic sample (i.r., mixed m.p.).

*(b) Anisoyl Chloride Tosylhydrazone (**16b**)*

A solution of anisaldehyde tosylhydrazone (**15***b*) (238 mg, 0.78 mmol) in the minimum quantity of DMF was titrated to a permanent end point with a solution of chlorine (0.63 *M*) in the same solvent. When t.l.c. showed that all the starting material had been consumed, the reaction mixture was evaporated to dryness to give a yellow oil, which crystallized from methylene chloride to give **16***b* (143 mg, 54%), m.p. 146–149°. The i.r. ($CHCl_3$) showed peaks at 3245 (w), 1610 (s), 1510 (m), 1410 (m), 1310 (m), 1255 (s), 1175 (s), 1075 (m), 1040 (m), 975 (m), 910 (m), 865 (m), 840 (m), 815 (m), 705 (w), 675 (m), and 660 (m) cm^{-1}. The n.m.r. ($CDCl_3$) comprised a singlet (3H) at 2.4, a singlet (3H) at 3.8, an apparent AB quartet (4H), $\delta_A = 6.9$, $\delta_B = 7.75$, $J_{AB} = 10$ Hz, another apparent AB quartet (4H), $\delta_A = 7.3$, $\delta_B = 7.9$, $J_{AB} = 8$ Hz, and a broad singlet (1H), removed by addition of D_2O, at 8.2 p.p.m.

Anal. Calcd. for $C_{15}H_{15}ClN_2O_3$: C, 53.17; H, 4.46; Cl, 10.47; N, 8.27; S, 9.46. Found: C, 53.22; H, 4.40; Cl, 10.66; N, 8.24; S, 9.63.

*(c) o-Methylsulfonylbenzoyl Chloride Tosylhydrazone (**16c**)*

A solution of *o*-methylsulfonylbenzaldehyde tosylhydrazone (**15***c*) (352 mg, 1.0 mmol) in dichloroethane (65 ml) was added dropwise to a stirred solution of chlorine (75 mg, 1.05 mmol) in dichloroethane (7.5 ml), cooled to −20°. The solution was stirred for 1 h and the solvent then removed at room temperature and reduced pressure to give a pale yellow oil (369 mg). Trituration with methylene chloride gave some colorless solid (81.8 mg, m.p. 209–211°) which was removed by filtration. Addition of pentane to the filtrate afforded pale yellow crystals, recrystallized from acetone to give colorless crystals of **16***c* (108 mg, 28%), melting at 166.5–168° (dec.). Absorption in the i.r. (Nujol) occurred at 3200 (w), 1590 (w), 1295 (s), 1240 (m), 1170 (s), 1150 (s), 1125 (m), 1070 (m), 955 (m), 850 (m), 820 (w), 765 (m), 705 (w), 665 (m), 630 (w) cm^{-1}.

Anal. Calcd. for $C_{15}H_{15}ClN_2O_4S_2$: C, 46.56; H, 3.91; Cl, 9.16; N, 7.24; S, 16.57. Found: C, 46.68; H, 3.84; Cl, 9.23; N, 7.18; S, 16.64.

*Benzoyl Chloride Tosylhydrazone (**16a**)*

1-Benzoyl-2-(*p*-tolylsulfonyl)-hydrazine (31) (100 mg) was dissolved in thionyl chloride (5 ml) and the solution was refluxed for 2 h. The excess thionyl chloride was evaporated at reduced pressure and the residue was pumped *in vacuo*. The solid product was recrystallized from methylene chloride – pentane to give colorless needles of **16***a* (68 mg, 64%), m.p. 113–115°. The i.r. spectrum ($CHCl_3$) showed bands at 3280 (m), 1605 (m), 1500 (w), 1455 (w), 1400 (s), 1360 (s), 1265 (m), 1180 (s), 1090 (s), 1075 (s), 980 (m), 870 (s), 630 (m), 620 (m), 545 (m) cm^{-1}. The n.m.r. spectrum ($CDCl_3$) showed a singlet (3H) at 2.4, a multiplet (5H) at 7.35, a multiplet (4H) at 7.8, and a broad singlet (1H) at 8.3 p.p.m.

Anal. Calcd. for $C_{14}H_{13}ClN_2O_2S$: C, 54.45; H, 4.24; Cl, 11.48; N, 9.07; S, 10.38. Found: C, 54.26; H, 4.31; Cl, 11.62; N, 9.08; S, 10.22.

*Preparation of 1,3-Dihydrobenzo[c]thiophene (**17**)*

Sodium sulfide nonahydrate (51 g, 0.21 mol) was partially dissolved in a mixture of alcohol (500 ml) and water (100 ml) in a 1 l round-bottomed flask. The flask was fitted with a Soxhlet extraction apparatus (sintered disc type) charged with α,α′-dichloro-*o*-xylene (Aldrich 25 g, 0.14 mmol). The solution was heated to reflux and the α,α′-dichloro-*o*-xylene extracted into the solution. The mixture was refluxed for a further 0.75 h and then steam distilled until the distillate was clear. The distillate was extracted with ether and the extracts washed with water and dried. Evaporation of the solvent gave a colorless oil (16.49 g, 87%) showing i.r. and n.m.r. absorption

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

appropriate to 1,3-dihydrobenzo[*c*]thiophene (**17**). The oil solidified on cooling in the refrigerator, the solid melting at 23–24.5°; reported m.p. 22.5–23.5° (32).

*o-Formylphenylmethanesulfonyl Chloride (**18**)*

Ice water (2 l) was saturated with chlorine gas. The solution was rapidly stirred and a suspension of 1,3-dihydrobenzo[*c*]thiophene (**17**) (5.50 g) in water (50 ml) was injected below the surface over a period of 15 min. The reaction was stirred for a further 45 min with slow passage of chlorine and addition of more ice as necessary. The white crystalline solid (mixed with a little black tar) was collected, washed with water, and dissolved in methylene chloride. The solution was dried (Na_2SO_4), treated with animal charcoal, and the solvent evaporated to leave a dark solid (7.22 g). Crystallization from benzene–pentane gave a material (5.7 g, 70%) melting at 72–76°. To obtain the analytical specimen a methylene chloride solution was filtered through silica gel and the material recrystallized twice from carbon tetrachloride to give **18** m.p. 76.5–78°. The i.r. spectrum ($CHCl_3$) showed peaks at 2840 (w), 2750 (w), 1705 (s), 1600 (w), 1585 (m), 1380 (s), 1170 (s), 865 (m), and 625 (m) cm^{-1}. The n.m.r. spectrum ($CDCl_3$) showed a singlet (2H) at 5.6, a multiplet (4H) at 7.5–8.0, and a singlet (1H) at 10.1 p.p.m.

Anal. Calcd. for $C_8H_7ClO_3S$: C, 43.94; H, 3.22; Cl, 16.21; S, 14.66. Found: C, 43.84; H, 3.32; Cl, 15.99; S, 14.52.

*3H-2,3,4-Benzothiadiazepine 2,2-Dioxide (**19**)*

o-Formylphenylmethanesulfonyl chloride (**18**) (2.0 g, 9.2 mmol) was dissolved in methylene chloride (20 ml) and added dropwise at room temperature to a stirred solution of hydrazine hydrate (5.0 g, 100 mmol) in methylene chloride (50 ml) over a period of 20 min. After a further 10 min, the reaction mixture was poured into aqueous sodium hydroxide (2.0 g NaOH, 150 ml H_2O), shaken, and the brown organic phase discarded. The aqueous phase was added to methylene chloride (300 ml) and the rapidly stirred mixture treated dropwise with 8% hydrochloric acid until it was distinctly acidic. The layers were then separated, the aqueous phase re-extracted with methylene chloride (100 ml), and the combined extracts washed once with water (100 ml), dried, and concentrated to *ca.* 5 ml. The crystalline **19** (1.36 g, 76%) was collected by filtration; m.p. 163–167° (dec.). Repeated crystallization from ethanol gave material melting at 169–170° (dec.). The i.r. spectrum (Nujol) showed peaks at 3250 (m), 1325 (s), 1310 (s), 1170 (s), 1135 (s), 1005 (m), 885 (m), and 770 cm^{-1}.

Anal. Calcd. for $C_8H_8N_2O_2S$: C, 48.91; H, 4.11; N, 14.32; S, 16.33. Found: C, 48.76; H, 4.09; N, 14.09; S, 16.18.

*Thermolysis of 3H-2,3,4-Benzothiadiazepine 2,2-Dioxide (**19**)*

The benzothiadiazepine **19** (250 mg) was heated at 175–180° under slightly reduced pressure to remove evolving gases. After 5 min, gas evolution had ceased and the reaction product was cooled to room temperature, dissolved in methylene chloride (40 ml), and filtered through silica to remove colored impurities. Evaporation of the eluate gave a colorless solid (181 mg) whose i.r. and n.m.r. spectra were identical to those of an authentic sample of 1,3-dihydrobenzo[*c*]thiophene 2,2-dioxide (**20**) obtained by oxidation of **17** (19); yield 85%. On recrystallization from methylene chloride – hexane it melted at 151–151.5°; mixed m.p. with authentic **20**, 148–150.5°.

*Chlorinolysis of 3H-2,3,4-Benzothiadiazepine 2,2-Dioxide (**19**)*

The benzothiadiazepine **19** (250 mg) was stirred in dry methylene chloride (25 ml) and the suspension was cooled in an ice-bath. Chlorine gas was passed through the mixture until all the material had dissolved, and the solution was then diluted with methylene chloride (50 ml) and washed with sodium thiosulfate solution (50 ml, 10%) and water (2 × 50 ml). The organic phase was dried and evaporated to give a liquid (280 mg) whose n.m.r. spectrum indicated that it was essentially pure α,α,α′-trichloro-*o*-xylene (**21**) (100% yield). A redistilled sample (73°/0.05 mm) had n_D^{29} 1.5695 (reported (33) n_D^{18} 1.5740). In the i.r. ($CHCl_3$) it showed bands at 1490 (w), 1460 (m), 1270 (s), 1210 (w), 1185 (m), 860 (s), 695 (vs), and 680 (vs) cm^{-1}. The n.m.r. spectrum ($CDCl_3$) showed a singlet (2H) at 4.7, a singlet (1H) at 7.1, a multiplet (3H) at 7.3–7.5, and a further multiplet (1H) at 7.8–8.0 p.p.m.

Anal. Calcd. for $C_8H_7Cl_3$: C, 45.85; H, 3.37; Cl, 50.77. Found: C, 45.83; H, 3.48; Cl, 50.89.

Reaction of **19** with only 1 equiv of Cl_2 under similar conditions to the above, afforded a mixture of starting material and α,α,α′-trichloro-*o*-xylene (**21**).

We gratefully acknowledge the support of the National Research Council of Canada, the Petroleum Research Fund (administered by the American Chemical Society), and the Alfred P. Sloan Foundation.

Etude des spectres de vibration du benzothiazole et des oscillations des liaisons CH de quelques uns de ses dérivés

JEAN-CLAUDE PANIZZI,[1] GISÈLE DAVIDOVICS,[1] ROBERT GUGLIELMETTI,[2] GILBERT MILLE,[1] JACQUES METZGER,[2] ET JACQUES CHOUTEAU[1]

Département de Chimie Organique, Faculté des Sciences de Marseille, Marseille, France

Reçu le 13 juillet, 1970

Les spectres i.r. du benzothiazole et de 29 de ses dérivés mono, di, et trisubstitués ont été analysés. Dans chaque série, un composé au moins a été examiné à l'état vapeur, à l'exception des hétérocycles ayant un substituant en position 7. Trois spectres Raman, dont celui du benzothiazole, ont aussi été étudiés. Les vibrations de valence ν(CH) et de déformation hors du plan γ(CH) ont été attribuées, ainsi que la plupart des autres oscillations fondamentales du benzothiazole.

Quatre dérivés dichlorés et un dérivé trichloré ont été spécialement synthétisés pour faciliter l'interprétation des vibrations γ(CH).

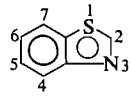
The i.r. spectra of benzothiazole and those of 29 of its derivatives, mono, di, and trisubstituted have been analyzed. In each series, at least one compound has been studied in the vapor state, except the heterocycles having a substituent in position 7. Three Raman spectra, one of which is the benzothiazole, have also been examined. The ν(CH) stretching and γ(CH) out-of-plane deformation vibrations have been assigned, as well as the majority of the other fundamentals of benzothiazole.

Four dichloro and one trichloro derivatives have been synthetized, in order to make easy the interpretation of the γ(CH) vibrations.

Canadian Journal of Chemistry, 49, 956 (1971)

Introduction

Dans les travaux spectroscopiques relatifs au benzothiazole et à ses dérivés, publiés jusqu'ici (1–16), il n'existe aucune analyse détaillée des



spectres de vibration de ces molécules pour lesquelles les attributions antérieures concernent quelques fréquences seulement (2–16) et sont très souvent imprécises.

Dans le cadre de recherches en série hétérocyclique, il nous a paru intéressant d'étudier les spectres i.r. sous différents états physiques, gazeux en particulier, ainsi que le spectre Raman à l'état liquide, du benzothiazole.

Afin d'identifier les vibrations des liaisons CH, nous avons comparé les spectres i.r. du benzothiazole et de 29 de ses dérivés substitués en position 2, disubstitués en -2,4, -2,5, -2,6, et -2,7 et trisubstitués en -2,6,7 et -2,4,6. Un certain nombre de ces composés ont également été examinés à l'état vapeur. Les spectres Raman de quelques dérivés monosubstitués ont aussi été enregistrés.

L'exposé des conditions expérimentales sera suivi d'un court chapitre consacré à la géométrie du benzothiazole. Après avoir indiqué nos résultats expérimentaux, nous discuterons l'interprétation des vibrations des liaisons CH du benzothiazole et de ses dérivés, puis celle des oscillations de noyau du benzothiazole.

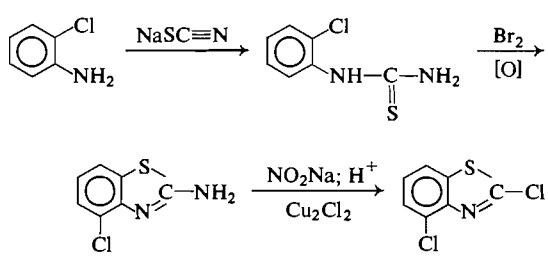
Conditions expérimentales

Préparation des composés benzothiazoliques

Les alcoyl-2 et benzyl-2 benzothiazoles, ainsi que la série des éthyl-2 benzothiazoles substitués, principalement en position 6, par divers groupements fonctionnels, ont été synthétisés au Laboratoire de Chimie Organique (17, 18) en vue de la préparation de composés spiropyranniques du type benzothiazolique (17, 19). En outre, nous avons entrepris la synthèse des dichloro -2,4, -2,5, -2,6, et -2,7 benzothiazoles et du trichloro-2,4,6 benzothiazole qui est un produit nouveau.

Nous indiquons succinctement les schémas réactionnels choisis et les références bibliographiques correspondantes. Pour certains composés déjà connus, nous avons amélioré les méthodes de synthèse et les rendements.

(1) Dichloro-2,4 benzothiazole (20–22)

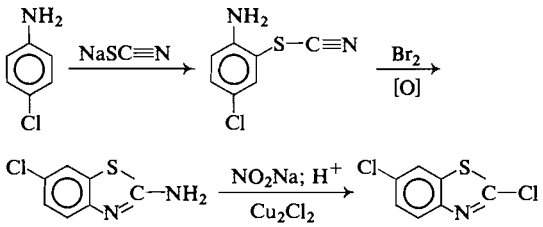


Solvant de recristallisation: éther de pétrole
F = 97° (litt. F = 97–98° (23))

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

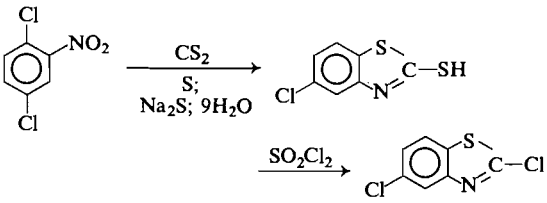
(2) Dichloro-2,6 benzothiazole (22, 24)

Nous avons utilisé une méthode assez générale de thiocyanation spécifique des amines aromatiques substituées en position para (24).



Solvant de recristallisation: éther de pétrole
F = 98° (litt. F = 98–99° (25))

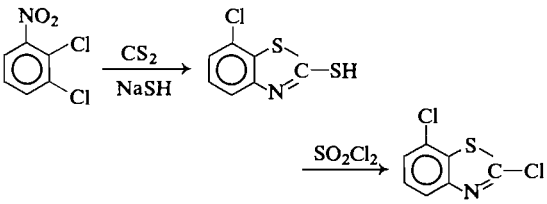
(3) Dichloro-2,5 benzothiazole (25–27)



Solvant de recristallisation : méthanol en présence de charbon actif
F = 68° (litt. F = 70–71° (25))

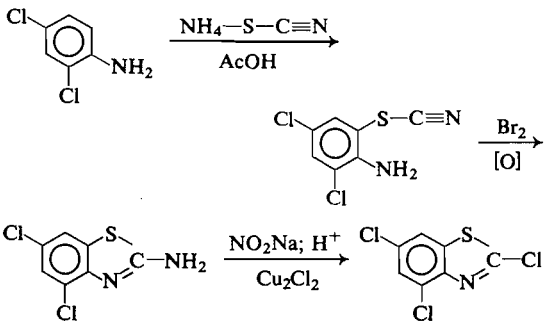
Ce processus de synthèse, lorsqu'il peut être appliqué, donne de bien meilleurs résultats que celui faisant intervenir un dérivé aminé en position 2.

(4) Dichloro-2,7 benzothiazole (25, 28, 29)



Solvant de recristallisation: éther de pétrole en présence de charbon actif et d'alumine
F = 53–54° (litt. F = 53–54° (29))

(5) Trichloro-2,4,6 benzothiazole (22, 30)



Nous avons utilisé la méthode de thiocyanation de Brewster (29) applicable aux amines aromatiques polysubstituées et possédant au moins une position disponible en ortho du groupement amine. Le rendement de cette séquence de synthèse a été amélioré en opérant en milieu moins dilué (rendement en amino-2 dichloro-4,6 benzothiazole: 61%, F = 268°; litt.: 45%, F = 260° (30)).

Solvant de recristallisation: éther de pétrole, le composé se présente sous forme de cristaux blancs de F = 108°.

Anal. calc. pour $C_7H_2NSCl_3$ (238.5 g): C, 33.22; H, 0.84; N, 5.87; S, 13.41; Cl, 44.65. Trouvé: C, 33.51; H, 0.82; N, 5.97; S, 13.25; Cl, 44.10.

La structure du composé est confirmée par r.m.n. Les déplacements chimiques observés pour les protons H-5 et -7 sont, respectivement, de 7.38 et 7.55 p.p.m. La constante de couplage $J_{H_5-H_7} = 2.2$ Hz, est caractéristique d'un couplage de type méta.

Spectres infrarouges

Les spectres i.r. des composés gazeux ont été mesurés à l'aide d'une cellule à gaz chauffante Perkin–Elmer de 5 cm d'épaisseur à fenêtres de KBr ou d'ICs.

Les concentrations des solutions, pour les spectres i.r. à l'état dissous étaient voisines de 0.2 mol/l. Le tétrachlorure de carbone a été utilisé dans les régions de 3000 et de 1500 à 1250 cm^{-1}, le tétrachlorure d'éthylène entre 1800 et 1500 et de 400 à 200 cm^{-1}, le sulfure de carbone entre 1250 et 400 cm^{-1}. Les coefficients d'extinction molaire apparents ont été mesurés au maximum des bandes d'absorption.

Les spectres i.r. des composés solides à la température ordinaire ont été réalisés, à l'état fondu, dans une cellule chauffante Perkin–Elmer, à des températures voisines de leurs points de fusion.

Les spectres i.r. ont été enregistrés sur spectrographes Perkin–Elmer, modèles 125 ou 225, double faisceau, équipés de deux réseaux et d'un prémonochromateur en KBr.

Spectres Raman

Le tube utilisé pour réaliser les spectres Raman du benzothiazole, du chloro-2, et du méthyl-2 benzothiazole à l'état liquide avait 22 cm de long et 9 mm de diamètre intérieur.

Les spectres ont été effectués avec un spectrographe Hilger et Watts, type E 612 et enregistrés à l'aide d'un microphotomètre Hilger L 470. La raie excitatrice 4358 Å du mercure a été sélectionnée avec un filtre de nitrite de sodium.

Les facteurs de dépolarisation ont été mesurés par la technique d'Edsall et Wilson (31) et corrigés d'après la méthode de Rank et Kagarise (32).

Structure géométrique du benzothiazole

La structure déterminée pour l'anhydrobase du diméthyl -2,3 benzothiazole (33) apporte un argument en faveur de la planéité du benzothiazole. Dans l'hypothèse de la symétrie maximale Cs, les 36 vibrations normales de cette molécule se décomposent en 25 mouvements de classe A′, devant donner lieu à des raies Raman plutôt fortes et polarisées et 11 oscillations de

*Fréquences observées: α, à l'état liquide; σ, à l'état dissous, suivies entre parenthèses du coefficient d'extinction molaire apparent; ϕ, à l'état gazeux, (C) indique une structure de vibration rotation de type C.
Pr, propyle; *i*-Bu, isobutyle; *t*-Bu, tertiobutyle; P, pentyle.
FF, très forte; F, forte; m, moyenne; f, faible; ff, très faible; e, épaulement.

mode A'', caractérisées par des raies de diffusion généralement faibles et dépolarisées.

Les moments principaux d'inertie petit, moyen et grand du benzothiazole, calculés avec des paramètres choisis par comparaison avec le thiazole, pour l'hétérocycle pentagonal (34) et avec les dérivés benzéniques (35) et la *N*-méthyl benzothiazoline (33), ont les valeurs respectives 152, 367, et 519 u.m.a. $Å^2$. Le grand axe d'inertie étant perpendiculaire au plan de l'hétérocycle, aux vibrations de symétrie A'' doivent correspondre, dans le spectre i.r. du composé à l'état vapeur, des enveloppes de type C et à celles de symétrie A', des bandes de vibration rotation de type A, B ou hybride A + B (36).

Les séparations approximatives $\Delta\nu_{PR}$ cm^{-1} des branches P et R des bandes de vibration rotation, déterminées à l'aide des formules proposées par Seth-Paul et de Meyer (37), sont de 12 cm^{-1} pour les bandes A, de 7 cm^{-1} pour celles de type B, et de 19 cm^{-1} pour les enveloppes de type C.

*ε, Coefficient d'extinction molaire apparent; I, intensité relative; ρ, facteur de dépolarisation; D, dépolarisée. Les fréquences en italiques ont été observées à l'état liquide: e, épaulement; f, faible; ff, très faible. §, Attribution suggerée.

Pour les dérivés du benzothiazole, on peut s'attendre à ce que les vibrations entraînant une variation de moment électrique perpendiculaire au noyau benzothiazolique soient de type C, avec des séparations $\Delta\nu_{PR}$ cm^{-1} différentes suivant les composés.

Résultats expérimentaux

L'ensemble des résultats expérimentaux sur le benzothiazole est résumé dans le tableau 2. Les séparations $\Delta\nu_{PR}$ cm^{-1} observées dans le spectre i.r. du benzothiazole à l'état vapeur, représenté sur la fig. 1, sont respectivement, de 12, 9, et 19 cm^{-1}, en moyenne, pour les bandes de type A, B et C, en bon accord avec les valeurs calculées. Dans les spectres des dérivés du benzothiazole, lorsque le contour des bandes de vibration rotation de type C a pu être déterminé, leur structure, ainsi que la fréquence de la branche Q correspondante ont été mentionnées dans le tableau 1.

Analyse des spectres

A. Vibrations mettant en jeu les liaisons CH dans le benzothiazole et ses dérivés

Dans l'approximation des vibrations de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

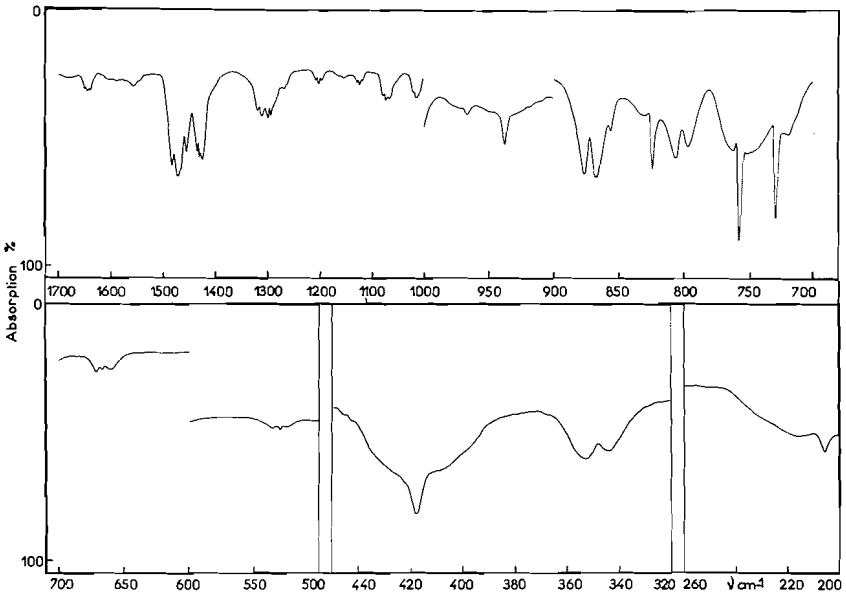

FIG. 1. Spectre i.r. entre 1700 et 200 cm^{-1} du benzothiazole à l'état vapeur.

groupe, on peut distinguer, pour le benzothiazole, 15 oscillations des liaisons CH, dont dix de symétrie A′ (5 ν(CH) + 5 δ(CH)) et cinq de symétrie A″ (5 γ(CH)).

(1) Vibrations de valence ν(CH)

La liaison CH en position 2 du benzothiazole n'étant pas adjacente aux liaisons CH de l'homocycle, l'interaction entre les oscillations de valence ν(CH) respectives du cycle benzénique et de l'hétérocycle pourrait être faible. La comparaison des spectres i.r. du benzothiazole et de ses dérivés substitués en position 2 ne permet pas, cependant, d'assigner une fréquence particulière à la vibration $\nu(C_2H)$ qui est observée vers 3080 cm^{-1} dans les spectres des composés thiazoliques (38).

Les vibrations des CH benzéniques du benzothiazole qui peuvent également être, soit couplées mécaniquement, soit à peu près indépendantes, doivent, dans les deux cas, donner naissance à quatre mouvements de valence ν(CH) distincts. Les oscillations ν(CH) aromatiques sont prévues par Scherer et Evans (39), entre 3086 et 3093 cm^{-1}, dans l'orthodichlorobenzène. Lebas (40) leur rattache, dans les dérivés orthodisubstitués du benzène, trois fréquences assez variables, entre 3111 et 3018 cm^{-1}. On peut, en outre, attendre dans la région de 3160 à 3000 cm^{-1}, des bandes harmoniques et de combinaison des vibrations fondamentales de noyau du benzothiazole. Quatre suites de fréquences, dont trois à 3129 ± 15, 3008 ± 11, 2991 ± 4 cm^{-1} se rapportant à de faibles bandes d'absorption du spectre du benzothiazole (*cf.* tableau 2) et une autre suite, plus élevée, vers 3163 ± 23 cm^{-1}, observée seulement pour certains dérivés, peuvent, effectivement, être reliées à des combinaisons binaires de mouvements de noyau (41).

En dehors des précédents, le spectre i.r. du benzothiazole dissous dans un solvant neutre ne montre, au dessus de 3000 cm^{-1}, que trois autres maximums à 3080, 3068, et 3032 cm^{-1} dont le deuxième, qui seul est assez intense, est aussi le seul qui soit vu dans le spectre Raman du benzothiazole. Aux deux premières de ces fréquences correspondent, dans les spectres des dérivés du benzothiazole, deux suites à 3078 ± 15 et 3064 ± 13 cm^{-1}, composées uniquement de bandes i.r., pour la plus élevée, et également de raies Raman, lorsque les spectres de diffusion ont été réalisés, dans le cas de la plus basse. Par analogie avec les benzènes orthodisubstitués (39, 40), ces deux suites doivent pouvoir être reliées à des vibrations de valence ν(CH). L'attribution à un mouvement ν(CH) de l'absorption à 3032 cm^{-1}, à laquelle on peut aussi rattacher une suite de bandes i.r. à 3027 ± 13

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

cm^{-1}, est moins sûre, plusieurs bandes de combinaison de vibrations de noyau étant prévues au voisinage de cette fréquence.

Un épaulement observé à 3065 cm^{-1}, dans les spectres i.r. des chloro-2 et dichloro-2,5 benzothiazoles, pourrait peut-être, appartenir aussi à une oscillation ν(CH).

(2) Vibrations de déformation dans le plan δ(CH)

On attend, pour le benzothiazole, cinq vibrations de déformation dans le plan δ(CH).

Dans les spectres des dérivés thiazoliques disubstitués en positions 4 et 5, la vibration $\delta(C_2H)$ est attribuée vers 1200 cm^{-1} (38), tandis que dans ceux des dérivés orthodisubstitués du benzène, les vibrations δ(CH) se situent vers 1200, 1150, 1130, et 1040 cm^{-1} (42–46).

Les spectres i.r. et Raman du benzothiazole présentent, vers 1200 cm^{-1}, une bande d'absorption faible et une forte raie de diffusion qui, du fait qu'elles n'apparaissent pas dans les spectres des dérivés benzothiazoliques substitués en position 2 (41, 47) pourraient être dues à la vibration $\delta(C_2H)$ notée ν_9 (tableau 2). Dans la région de 1260 à 1040 cm^{-1}, on relève encore, dans les spectres i.r. et Raman du benzothiazole quatre maximums: ν_8, ν_{10}, ν_{11}, et ν_{12} (*cf.* tableau 2) susceptibles d'appartenir à des mouvements δ(CH). Il semble, en effet, que certains d'entr'eux ne soient pas observés dans les spectres des benzothiazoles di ou trisubstitués (41, 47). Toutefois, un seul dérivé substitué sur les carbones en -2,5, -2,7, -2,4,6, et -2,6,7 ayant été étudié, il ne peut s'agir d'une interprétation définitive. C'est pourquoi nous n'avons pas établi, dans ce travail, de suites δ(CH) pour les dérivés du benzothiazole. Nous ferons cependant remarquer, à propos des bandes i.r. à 1267 (ν_8) et 1072 cm^{-1} (ν_{12}) qui ont été reliées précédemment, la première, à un mouvement ν(C–N), la deuxième, à une vibration propre à l'hétérocycle thiazolique du benzothiazole (13), qu'aucune des vibrations de noyau du thiazole ne possédant de telles fréquences (38, 48), ces attributions ne paraissent pas très convaincantes.

(3) Vibrations de déformation hors du plan γ(CH) (tableau 1)

Le benzothiazole doit donner lieu à cinq vibrations γ(CH) de type A''. En l'absence de couplage important entre les vibrateurs CH de l'hétérocycle et de l'homocycle, leurs oscillations respectives pourraient être attendues vers 810 cm^{-1} comme dans les dérivés thiazoliques (38) et vers 977, 934, 865 et 750 cm^{-1} (42, 44), puisque d'après O'Sullivan (49) et Derkosch et Specht (50) les fréquences des mouvements γ(CH) varient peu dans un cycle benzénique orthodisubstitué, même s'il est adjacent à un noyau pentagonal aromatique ou hétérocyclique. Dans la région de 1000 à 750 cm^{-1}, le spectre i.r. du benzothiazole à l'état vapeur (fig. 1) présente trois enveloppes de vibration rotation de type C à 938, 824, et 756 cm^{-1}, ainsi que deux autres bandes à 966 et 856 cm^{-1} dont la structure, bien que plus difficile à préciser, paraît cependant être également de type C. On note, qu'à l'exception de celle vers 760 cm^{-1}, à laquelle correspond une raie Raman faible, ces diverses fréquences ne sont pas observées dans le spectre de diffusion.

Le maximum vers 825 cm^{-1}, qui disparaît lors d'une monosubstitution en position 2 (41), semblant dû, en première approximation, à la vibration $\gamma(C_2H)$, les oscillations γ(CH) de l'homocycle doivent être responsables des quatre autres, à 966, 938, 856, et 756 cm^{-1}.

Dans les spectres i.r. des dérivés benzothiazoliques monosubstitués en position 2, quatre suites de fréquences pouvant être rapprochées des vibrations γ(CH) du benzothiazole à 966, 938, 856, et 756 cm^{-1} peuvent être constituées. Les structures de vibration rotation observées, dans les spectres i.r. des chloro-2, méthyl-2 et éthyl-2 benzothiazoles à l'état vapeur, confirment l'attribution des absorptions de la suite vers 760 cm^{-1}, déjà envisagée antérieurement (9, 11), ainsi que celle du sommet vers 940 cm^{-1}, dans le cas du chloro-2 benzothiazole (*cf.* tableau 1)

La faible influence de l'hétérocycle sur les mouvements de déformation γ(CH) de l'homocycle, dans le benzothiazole, étant vérifiée, nous avons cru pouvoir affecter (*cf.* tableau 1) aux oscillations γ(CH) des dérivés benzothiazoliques disubstitués en -2,4, -2,5, -2,6, et -2,7, des suites de bandes i.r. ayant des positions voisines de celles des vibrations homologues des benzènes trisubstitués correspondants (42). Cette interprétation, conforme en ce qui concerne la suite vers 800 cm^{-1}, à celle de Bassignana *et al.* dans les diméthyl-2,5 et -2,6 benzothiazoles (9) est en partie justifiée par les structures de vibration

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

rotation de type C de certaines des bandes d'absorption composant les deux suites vers 870 et 803 ± 36 cm^{-1} (*cf.* tableau 1).

L'étude du spectre i.r. du trichloro-2,4,6 benzothiazole à l'état vapeur, permet d'assigner les deux vibrations γ(CH) de cet hétérocycle à 850 et 766 cm^{-1} ce qui, pour la plus élevée, est en accord avec les résultats de Randle et Whiffen qui, pour les dérivés benzéniques tétrasubstitués en -1,2,3,5 ne proposent qu'une seule fréquence γ(CH) à 851 cm^{-1} (42). Ces auteurs (42) ayant également affecté un sommet i.r. ou Raman seulement, aux oscillations γ(CH) des benzènes tétrasubstitués en -1,2,3,4, nous n'avons, dans le spectre i.r. de l'éthyl-2, méthoxy-6, nitro-7 benzothiazole, qui n'a pas été examiné à l'état gazeux, retenu qu'un seul maximum γ(CH) à 820 cm^{-1} (*cf.* tableau 1).

B. Vibrations de noyau du benzothiazole

On attend, pour le benzothiazole, 15 vibrations de squelette dans le plan et six oscillations de noyau hors du plan, qui seront respectivement notées ν_1 à ν_7 et ν_{13} à ν_{20} d'une part et Γ_1 à Γ_6 d'autre part; nous les analyserons successivement. Nos attributions, ainsi que celles que nous suggérons pour les fréquences ne pouvant être considérées comme appartenant à des modes fondamentaux, sont indiquées dans le tableau 2.

(1) Vibrations de symétrie A'

Dans les travaux précédents consacrés au benzothiazole, Chambonnet (6) ainsi que Larivé *et al.* (8) pensent que l'on peut affecter entre 1588 et 1015 cm^{-1} dix absorptions aux vibrations de noyau ou de déformation δ(CH) de l'hétérocycle benzothiazolique. Les deux plus hautes, à 1588 et 1555 cm^{-1}, dénommées bandes thiazole I et II par Randall *et al.* (3), ont déjà été reliées, par ces auteurs, à des mouvements de noyau, celle à 1555 cm^{-1} étant, par ailleurs, rattachée simultanément à une oscillation ν(C=C) par Bassignana *et al.* (10) et à une vibration ν(C=N) par Chambonnet (6). Par ailleurs, outre ceux à 1065 et 1260 cm^{-1} qui ont déjà été discutés dans ce travail, Bonnier *et al.* (13) considèrent comme étant dus respectivement à une vibration du cycle thiazolique et à des mouvements ν(C=N) et ν(C—S) trois maximums à 1420, 1470, et 660 cm^{-1}.

Le spectre i.r. de vibration rotation du benzothiazole à l'état vapeur montre treize bandes de type A ou hybride A + B vers 1551, 1476, 1460, 1429, 1313, 1292, 1266, 1200, 1123, 1071, 1012, 667, et 530 cm^{-1} et cinq bandes de type B vers 1600, 1157, 872, 801 et 350 cm^{-1}. Ces fréquences, sauf celles vers 1460 et 1429 cm^{-1} sont également observées dans le spectre de diffusion, la plupart appartiennent à des raies Raman fortes et polarisées (*cf.* tableau 2). Le spectre Raman comporte encore deux autres raies intenses et polarisées à 709 et 505 cm^{-1}, auxquelles ne correspondent que des bandes i.r. faibles (tableau 2).

Ainsi que les 18 suivants, les deux maximums à 1595 et 1557 cm^{-1} sont, en accord avec les travaux précédents (3, 6, 8, 10) et bien qu'ils apparaissent dans une région où l'on observe des combinaisons des oscillations γ(CH), certainement attribuables à des vibrations fondamentales. S'il s'agissait de combinaisons, en effet, on les attendrait très faibles ou inactives dans le spectre de diffusion, ce qui n'est pas le cas (*cf.* tableau 2). De plus, il est à noter que ces deux fréquences sont très voisines de celles des deux vibrations de noyau de symétrie A' les plus élevées du benzothiophène (51, 52). Dans la mesure où les cinq fréquences 1266, 1200, 1157, 1123, et 1071 cm^{-1} appartiennent bien aux oscillations de déformation δ(CH), les quinze autres doivent être dues aux mouvements de noyau dans le plan ν_1 à ν_7 et ν_{13} à ν_{20}. On peut souligner, en faveur de cette interprétation, l'excellente concordance existant entre les positions de toutes les vibrations de noyau de symétrie A' du benzothiazole et du benzothiophène (51, 52).

(2) Vibrations de symétrie A''

En dehors de celles attribuées à des oscillations γ(CH), le spectre i.r. à l'état vapeur du benzothiazole montre trois autres bandes de vibration rotation de type C, à 728, 420, et 206 cm^{-1} (*cf.* tableau 2, fig. 1), qui peuvent être affectées à des mouvements de noyau hors du plan Γ_1, Γ_5, et Γ_6. En outre, les spectres Raman et i.r. du benzothiazole comportent, respectivement, une raie faible et partiellement dépolarisée et un épaulement vers 671 cm^{-1}, susceptibles d'appartenir à une vibration de noyau hors du plan, que nous désignerons par Γ_2. En effet, les spectres i.r. à l'état vapeur des dichloro-2,5, -2,6, et -2,7 benzothiazoles montrent, vers cette fréquence, une bande de vibration rotation de type C (41, 47). Les oscillations de noyau Γ_3 et Γ_4 pourraient peut-être, par analogie avec le benzothiophène qui possède deux vibrations de

noyau hors du plan à 558 et 471 cm^{-1} (51, 52) donner lieu aux faibles raies Raman à 584 et 452 cm^{-1}.

The Spontaneous Resolution of Oxalatobis(ethylenediamine)cobalt(III) Chloride

D. G. BREWER AND K. T. KAN
Department of Chemistry, University of New Brunswick, Fredericton, New Brunswick

Received October 6, 1970

The spontaneous partial resolution of oxalatobis(ethylenediamine)cobalt(III) chloride was affected by the crystallization of the complex compound from a supersaturated aqueous solution (1 g/25 ml) at 20 °C without the influence of any dissymmetric agent. Crystals exhibiting in some cases dextro-rotatory properties, and in the others levo-rotatory were obtained with up to 25% optical purity.

La résolution spontanée partielle du chlorure d'oxalatobis(éthylènediamine)cobalt a été effectuée par cristallisation du complexe sans l'influence d'aucun agent dissymétrique, d'une solution aqueuse sursaturée (1 g/25 ml à 20 °C). Suivant les cas, des cristaux droits et des cristaux gauches ont été obtenus avec des rendements optiques allant jusqu'à 25%.

Canadian Journal of Chemistry, 49, 965 (1971)

Introduction

Since Pasteur's first resolution of optical isomers, various methods such as hand-picking, preferential crystallization, diastereoisomer formation, and chromatography have been utilized for the resolution of enantiomers. Detailed reviews of this subject have been given by Eliel (1), Secord (2), and Buss and Vermeulen (3).

Most of the methods for the resolution of racemic modifications require the presence of optically active environments, achieved by the use of other optically active substances, or polarized radiation. For a closed system not influenced by any dissymmetric agent, the probability of its becoming optically active will always be very low. However, there have been a couple of reports on the spontaneous resolution of organic isomers (4, 5).

In this work, we were able to effect a spontaneous resolution of the oxalatobis(ethylenediamine)cobalt(III) chloride from a supersaturated aqueous solution by a crystallization method without any dissymmetric influence.

Experimental

Oxalatobis(ethylenediamine)cobalt(III) chloride was prepared by two different methods. The first method involved the substitution of an oxalate ion with the chloride ions in a *cis*-dichlorobis(ethylenediamine)cobalt chloride molecule reported by Werner (6). The second method was a direct synthesis described by Dwyer *et al.* (7). Both methods yielded clear red crystals of oxalatobis(ethylenediamine)cobalt chloride with four hydrated waters at the time of their separation from the mother liquors (8). The compound lost part of its water of crystallization and the transparency of the crystals disappeared gradually when it was air dried. Dwyer *et al.* reported that this compound had only one hydrated water (7). The resolution of $[Co(en)_2(C_2O_4)]^+$ ion was affected by using the method described in ref. 7. The optical active isomers of $[Co(en)_2(C_2O_4)]I$ thus obtained was transformed into chloride form by shaking the iodide salt with freshly prepared silver chloride. The specific rotation of $[Co(en)_2(C_2O_4)]Cl.H_2O$ was found to be $[\alpha]_D = +920°$, which is close to the value reported by Dwyer *et al.*, *viz.*, $[\alpha]_D = +930°$ (7).

Optical rotations were determined on a Rudolph Model 200A photoelectric polarimeter equipped with a high intensity mercury lamp. A Honeywell Electronik 19 recorder was used to help obtain the polarimeter reading. The optical rotatory dispersion curves were measured with a Durum-Jasco ORD/UV-5 recording spectropolarimeter.

$[Co(en)_2(C_2O_4)]Cl.H_2O$ (1.00 g) dissolved in warm water (25 ml) was introduced into a clean test tube, which was then properly sealed. The temperature of the solution was kept at 25 ± 0.5 °C for 2 h by putting the test tube in a thermostated water bath, and it was lowered manually at a rate of 1 °C per 2 h until a temperature of 20 °C was reached. At this final temperature, the solution became barely supersaturated and initially a few clear red crystals of $[Co(en)_2(C_2O_4)]Cl$ slowly appeared. The solution was then allowed to stay at 20 °C for 12 h before the crystals were removed from the solution by quick filtration. The crystals were washed with 80% methanol, absolute methanol, and then air dried. The optical activity of the crystals, as well as the mother liquor, was then checked with the Rudolph spectropolarimeter at the wavelengths of 404.7 and 577.0 mμ using a high intensity mercury lamp. At these two wavelengths, $[Co(en)_2(C_2O_4)]Cl$ showed opposite rotation. By comparing the optical

activities measured at these two wavelengths, it is possible to detect and confirm small rotations exhibited by the crystals. To avoid accidentally picking up a fraction of the crystals containing an unequal amount of enantiomers, the whole crop of crystals was ground and mixed completely in a motar before the examination of optical activity.

Results

The results of several consecutive experiments were tabulated in Table 1. The optical rotatory dispersion (o.r.d.) of the crystals from these experiments were identical with that of the optically pure complex resolved conventionally (Fig. 1). The mother liquors always showed a rotation opposite to that of the crystals, although when the resolutions were poor, the optical activities of the mother liquors could not be detected with our instrument. To ascertain that the observed optical activity did not come from the original complex, the compound was prepared in two entirely different ways, as described in the Experimental section, and it was found that in both cases the same compound obtained was optically inactive.

The same experiment was repeated more than 50 times, and no consistency was observed in the optical activities of the crystals. Sometimes the dextro-rotatory crystals were obtained, sometimes the levo ones, and, in the remainder, racemic mixtures. The yield of the crystals from 1 g starting material ranged from 0.2–0.05 g, with a trend towards better resolution at lower yields. The best resolution was about 25% optically pure. The largest crystal obtained

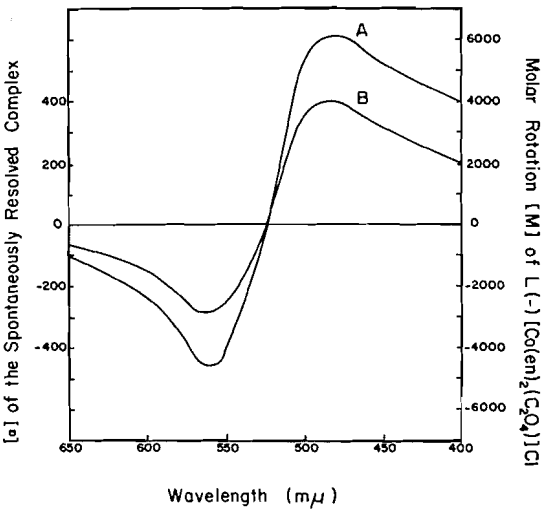

FIG. 1. The optical rotatory dispersion curves of the conventionally resolved (*A*), and the spontaneously resolved (*B*) $[Co(en)_2(C_2O_4)]Cl.H_2O$.

weighed 0.5 m and hence the minimum number of crystals in the larger batches is approximately 400.

There have been reports (9, 10) that optically active atmospheric dust would induce resolution. Special cares have therefore been taken to clean and seal the reaction tubes. An independent experiment by one of our colleagues in another part of the Chemistry Building, using separate facilities never exposed to any optically active substances, produced similar results.

All these experimental facts indicated that a

spontaneous resolution of the oxalatobis(ethylenediamine)cobalt ion had occurred.

Discussion

The mechanism for the spontaneous resolution of oxalatobis(ethylenediamine)cobalt chloride is not the same as that described by Havinga (4). For one thing, the methyl-ethyl-allyl-anilinium iodide is optically labile, and $[Co(en)_2(C_2O_4)]Cl$ is not. It was found that $[Co(en)_2(C_2O_4)]Cl$ did not racemize or undergo photoracemization in aqueous solution at room temperature (11, 12).

Yamasaki *et al.* (8) reported that $[Co(en)_2(C_2O_4)]Cl$ when crystallized from water formed a racemic mixture with crystals without distinguishable facets between 15–25 °C. Like that of any typical mixture, the solubility of a racemic mixture is higher than that of the pure components (1, 2). This is also true for $[Co(en)_2(C_2O_4)]Br$. Werner (6) observed that the solubility of the optically active bromide (1.05 g/100 ml at 17 °C) was much lower than that of the inactive form (1.85 g/100 ml at 17 °C). This difference in solubility is also expected to exist between the optical active and inactive chloride form of the same cation. If a supersaturated solution of oxalatobis(ethylenediamine)cobalt chloride is allowed to crystallize very slowly in solutions, the first nucleus, or the few nuclei formed will consist of one enantiomer only, or will be composed of an unequal amount of the two enantiomers. This nucleus or these nuclei will grow by the addition of molecules of its own configuration to form crystals, which, in turn, will act as seeds to induce an asymmetric separation of crystals from the solution in favor of their own kind, until the solution is sufficiently supersaturated with the other form for it to commence to separate. The mechanism for this asymmetric separation of crystals, we believe, is analogous to the partial resolution of $[Co(en)_2(C_2O_4)]Br$ by Werner (6) by the seeding of a supersaturated solution of this complex with an optically active crystal of one of the isomers. The chance for either one of the enantiomers to deposit first is the same and explains why the resolutions sometimes yielded crystals enriched in one of the forms. The spontaneous crystallization process is always very delicate. Any slight fluctuation in the system, such as temperature variation, vibration, dust, etc., will affect the process tremendously. It is understandable then that reproducible results were not obtained and also why no resolution was observed in some experiments. Some experiments were performed involving the rapid crystallization of the complex from a supersaturated solution by lowering the temperature quickly, and no optical activity was found in the products. On the other hand, in some experiments, the temperature was allowed to drop below 20 to 18 °C, and a large amount of crystals (0.4–0.5 g) showing very small rotations, or no rotation at all, was obtained. Thus, the process of crystallization is all important in the spontaneous resolution of oxalatobis(ethylenediamine)cobalt chloride.

The basic requirements for the spontaneous resolution of $[Co(en)_2(C_2O_4)]Cl$ appear to be: (*i*) the compound form a racemic mixture; (*ii*) the solubility of the pure enantiomers is lower than that of the racemic mixture; (*iii*) the crystallization process is very slow, and without, preferably, perturbation of any kind, so that only one of a few nuclei will form and grow at the early stage of the crystallization process; and (*iv*) last but not least, the compound should respond readily to a dissymmetric influence, such as those described by Werner(6), Schweitzer and Talbott (13), and Broomhead (14).

The authors wish to thank Dr. D. Idler and Mr. D. Ellis of the Fisheries Research Board in Halifax for the use of their Durum-Jasco Spectropolarimeter, and the National Research Council of Canada for financial support.

Synthesis and Stereochemical Assignments of Some Trifluoromethylphenylcyclopropanes

L. J. ALTMAN, M. R. BRAMWELL, AND J. C. VEDERAS
Department of Chemistry, Stanford University, Stanford, California 94305

Received September 28, 1970

Stereochemical assignments of a series of substituted *cis*- and *trans*-1-trifluoromethyl-2-phenylcyclopropanes (unsubstituted, bromide, carbonitrile, and carboxamide) based on a detailed analysis of the n.m.r. spectra and on the ten-fold difference in rates in the reaction of *cis*- and *trans*-1-trifluoromethyl-2-phenylcyclopropyl carbonitrile with basic hydrogen peroxide are presented.

Des attributions de stéréochimie pour une série de trifluorométhyl-1 phényl-2 cyclopropanes substitués (non-substitué, bromo, carbonitrile, et carboxamide) *cis* et *trans* sont présentées; les conclusions sont basées sur analyse détaillée des spectres r.m.n. et sur le fait que le rapport des vitesses de réaction des trifluorométhyl-1 phényl-1 cyclopropylcarbonitriles *cis* et *trans* avec le peroxyde d'hydrogène en milieu basique est de 10/1.

In connection with our work on the configurational stability of the α-trifluoromethylcyclopropyl radical (1), it was necessary to synthesize and assign the stereochemistry of a number of trifluoromethylphenylcyclopropanes. The stereochemical assignments are based to a large part on analysis of the n.m.r. spectra of these compounds. We present here the results of the analyses.

The synthesis of the compounds **1***a–c* and **2***a–c* was accomplished through a 1,3-dipolar addition (2) of phenyldiazomethane to an electron deficient olefin followed by pyrolysis of the resulting pyrazoline (Scheme 1). The isomers were separated by v.p.c. The amides **1***d* and **2***d* were prepared from the corresponding nitriles, **1***c* and **2***c*, by treatment with basic hydrogen peroxide (3).

The analyses of the 100 MHz n.m.r. spectra were accomplished with the LAOCN 3 computer program (4). In order to resolve the coupling between the fluorine nuclei and the benzylic protons in **1***a–d* it was found necessary to decouple the aromatic protons. The analysis of **2***c* was verified by obtaining a satisfactory agreement between the derived parameters from both the 60 and 100 MHz spectra. The relative sign of the geminal coupling constant was confirmed in **1***b* and **2***b* by means of a spin tickling experiment (5). The refined spectral parameters are presented in Tables 1 and 2.

The assignment of the relative stereochemistry in **1***a* and **2***a* is based on the well verified assumption (6) that in cyclopropanes the *cis* vicinal coupling is larger than the *trans* vicinal coupling. The comparison of the derived coupling constants between the hydrogen α to the trifluoromethyl group (X = H) and H-2 and -3 in **1***a* and **2***a* places H-2 *cis* to the α-proton in **1***a* and H-3 *cis* to the α-proton in **2***a*. Since H-2 is *cis* to the benzylic proton in both **1***a* and **2***a*, this allows the assignment of **1***a* as *cis*-trifluoromethylphenyl cyclopropane[1] and **2***a* as *trans*-trifluoromethylphenylcyclopropane. This assignment is confirmed by a comparison of the derived coupling constants between the α-proton and H-1 in **1***a* (8.97 Hz) and **2***a* (4.63 Hz).

The stereochemical assignments of the nitriles **1***c* and **2***c* come from a competition experiment in which the nitriles were converted to amides by the action of basic hydrogen peroxide. It was expected that the rate of reaction of the compound with the nitrile *cis* to the phenyl would be slower than the unhindered isomer with the nitrile *trans* to the phenyl based on experiments with the model compounds *cis*- and *trans*-1-methyl-2-phenylcyclopropyl carbonitrile. A rate difference of approximately 10 was found between the two isomers and therefore allows the assignment of nitriles (**1***c* as *cis*- and **2***c* as *trans*-1-trifluoromethyl-2-phenylcyclopropyl carbonitrile) as well as the corresponding amides **1***d* and **2***d*. This assignment is also corroborated by the relative v.p.c. retention times of the nitriles (**1***c* = 31 min, **2***c* = 25 min) and the t.l.c. R_f's of the amides (ether eluant, **1***d* = 0.5, **2***d* = 0.7).

[1]All compounds are named as derivatives of cyclopropane for convenience in following the stereochemical assignments; *cis* and *trans* refer to the relative orientation of the trifluoromethyl and phenyl substituents.

c X = CN

SCHEME 1

With this series of six compounds in hand it was now possible to assign the bromides **1***b* and **2***b* on the basis of the four–bond fluorine proton coupling constants (J_{F2} and J_{F3}). It is observed that this four bond coupling is larger when the CF_3 and proton are *trans* to each other. Indeed, in the nitriles the spectra could only be fitted with a negative value of the *cis* coupling constant. Thus it was possible to assign **1***b* as *cis*- and **2***b* as *trans*-1-trifluoromethyl-2-phenylcyclopropyl bromide. This assignment is also consistent with the empirical observation that the fluorines on a CF_3 *cis* to a phenyl are deshielded by approximately 6 p.p.m. relative to those on a CF_3 *trans* to the phenyl.

Experimental

The n.m.r. spectra were taken of $CDCl_3$ solutions (≈20%) on a Varian HA-100 spectrometer. Peak positions were obtained to 0.1 Hz by means of charts calibrated by a Hewlett Packard 5512A frequency counter. The v.p.c.'s were run on an F&M model 700 with a 20 ft by 1/4 in. column of 20% carbowax 20 M on Chromosorb W with a gas flow of 100 ml/min at 145°.

1-Trifluoromethyl-2-phenylcyclopropane

A mixture of phenyldiazomethane (7) and excess trifluoropropene[2] at reflux was irradiated with two 300 W unfrosted incandescent lamps until all the phenyldiazomethane had reacted. The resulting crude pyrazoline was pyrolyzed directly in the v.p.c. injection port (200°) to give *cis*- and *trans*-1-trifluoromethyl-2-phenylcyclopropane. The v.p.c. retention times: *cis* 20 min, *trans* 13 min.

1-Trifluoromethyl-2-phenylcyclopropanecarbonitrile

A crude mixture of *cis*- and *trans*-1-trifluoromethyl-2-phenylcyclopropanecarbonitrile, prepared by the addition of a solution of phenyldiazomethane in petroleum ether to a solution of α-trifluoromethylacrylonitrile[3] in petroleum ether at 0° followed by evaporation of the solvent under reduced pressure, was separated by preparative v.p.c. (retention times: *trans* 25 min, *cis* 31 min).

Anal. Calcd. for $C_{11}H_8F_3N$: C, 62.56; H, 3.82; N, 6.63. Found (*trans*): C, 62.67, H, 3.85; N, 6.55; (*cis*): C, 62.58; H, 3.89; N, 6.58.

1-Trifluoromethyl-2-phenylcyclopropanecarboxamide

cis-1-Trifluoromethyl-2-phenylcyclopropanecarboxamide was prepared from the reaction of *cis*-1-trifluoromethyl-2-phenylcyclopropanecarbonitrile (30 mg) in NaOH (0.3 ml) and 30% H_2O_2 (0.3 ml) in acetone (1 ml) at room temperature for 16 h followed by partitioning of the crude product between methylene chloride and water, preparative t.l.c. (silica gel HF; ether as eluant), and sublimation (80° at 10^{-3} mm Hg).

The *trans*-isomer was analogously prepared except for a longer reaction time (40 h). A mixture of the two amides could be separated by preparative t.l.c. (ether as eluant) with the *trans*-isomer having the highest R_f (0.5, 0.7).

Anal. Calcd. for $C_{11}H_{10}F_3NO$: C, 57.64; H, 4.40; N, 6.11. Found (*cis*): C, 57.44; H, 4.44; N, 6.04; (*trans*): C, 57.60; H, 4.44; N, 6.00.

Competition Experiment

To a stirred mixture of *cis*- (20.5 mg) and *trans*-1-trifluoromethyl-2-phenylcyclopropanecarbonitrile (20.5 mg) acetone (0.4 ml), 1.0 *N* NaOH (0.1 ml), and *o*-dichlorobenzene (15.9 mg) at 20° was added in one portion 30% H_2O_2 (0.80 ml). Aliquots were withdrawn and analyzed directly by v.p.c. by comparing the areas of the nitrile peaks and that of *o*-dichlorobenzene. After 1 h 4.8% of the *trans*-isomer had reacted whereas 53% of the *cis*-isomer had reacted.

We thank the donors of the Petroleum Research Fund, administered by the American Chemical Society, Eli Lilly and Company, and the Rohm and Haas Company for partial support of this research.

2-Arylimino-1,3-thiaazacycloalkanes

D. L. GARMAISE, G. Y. PARIS, AND G. EFTHYMIADIS
Abbott Laboratories Limited, Montreal, Quebec

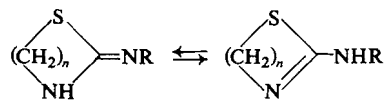
Received October 14, 1970

The reaction of ω-bromoalkyl isothiocyanates with aromatic amines served as a general preparative method for homologous 2-arylimino-1,3-thiaazacycloalkanes. Rings containing seven to thirteen members were prepared in this way. The isothiocyanates and some of the thiaazacycloalkanes had anthelmintic activity.

La réaction d'isothiocyanates d'ω-bromoalkyles avec les amines aromatiques s'avère une méthode générale de préparation d'arylimino-2 thiaaza-1,3 cycloalcanes. Des cycles contenant de sept à treize atomes ont été préparés de cette manière. Les isothiocyanates et quelques-un des thiaazacycloalcanes possèdent une activité anthelmintique.

Canadian Journal of Chemistry, 49, 971 (1971)

Five- and six-membered ring compounds having the general structures **A** and **B** have been extensively studied; the thiazine derivatives have



A **B**

shown potentially useful pharmacological properties (1) and the thiazolidines have anthelmintic action (2). Compounds in which $n > 3$ have not been previously reported; the preparation and some biological properties of compounds of general structure **A** where $n = 4$, 5, 6, 8, and 10 are described in this paper.

The methods commonly used for the preparation of 2-aryliminotetrahydro-1,3-thiazines were examined for possible applicability to the synthesis of larger rings. The most common procedure for preparing the six-membered rings is the acid-catalyzed cyclization of ω-hydroxyalkylthioureas (eq. 1). The reaction proceeded smoothly when $n = 3$ (or 2) but when $n = 4$, no cyclization occurred. Of the other methods which have been reported (1, 3, 4) for the synthesis of the six-membered rings, the reaction of 3-bromopropyl isothiocyanate with aromatic amines (1, 4) was the most readily adaptable to the synthesis of larger rings. The reaction of ω-bromopropylalkyl isothiocyanates with aromatic amines (eq. 2) was found to be a convenient general method.

[1] $$RNH\,C(=S)\,NH(CH_2)_nOH \xrightarrow[\text{HCl}]{\text{concentrated}} A$$

[2] $$Br(CH_2)nNCS + ArNH_2 \rightarrow A$$

(n = 4, 5, 6, 8, and 10)

The ω-bromoalkyl isothiocyanates (listed in Table 1) were obtained by the reaction of thiophosgene with ω-bromoalkylamine hydrobromides. In the case of the preparation of 4-bromopropyl isothiocyanate, it was observed that a variable amount (10–25%) of 4-chloropropyl isothiocyanate was also obtained, apparently by halogen exchange with thiophosgene. The ω-bromoalkylamines were obtained by standard methods from α,ω-dibromoalkanes via the monophthalimido derivatives.

et al. (6, 7), and Rabinowitz (8) on the use of n.m.r. spectra to distinguish between the tautomeric forms **A** and **B** in the thiazine series has cleared up the confusion resulting from earlier attempts to make this distinction on the basis of i.r. (3) and u.v. (9) spectra. Using model compounds of unequivocal structure, it has been shown that for given substituents on the aromatic ring, δ N—CH_2 is higher when the double bond is endocyclic. The presence of strongly electron-withdrawing substituents, such as the nitro group, on the aromatic ring tends to lower the value of δ N—CH_2; in general, however, tautomers of structure **A** have δ N—CH_2 ~ 3.32 and those of structure **B** have δ N—CH_2 ~ 3.57. Since the larger ring compounds prepared in this program had δ N—CH_2 = 3.30–3.35, it is assumed that the products are best represented by structure **A** and are named accordingly. In the absence of model compounds, however, this evidence can not be regarded as conclusive.

Biological Results

The ω-bromoalkyl isothiocyanates showed the anthelmintic activity characteristic of many isothiocyanates. 6-Bromohexyl isothiocyanate was particularly effective; at 400 mg/k, it eliminated 99% of the burden of *Nematospiroides dubius* from mice; at 250 mg/k, it reduced the number of larvae of *Ascaris suum* in mice by 81%, and at 100 mg/k, it reduced the number of eggs of gastro-intestinal nematodes of sheep by 76%. The other isothiocyanates listed in Table 1 also showed activity against the helminths tested and some fungistatic and bacteriostatic activity was also shown. None of them, however, was effective in doses low enough to warrant further interest.

Of the thiaazaalkanes, compounds **6**, **7**, **9**, and **16** showed activity against *N. dubius* and against the nematodes of sheep, but at too high dosages to warrant further interest.

Experimental

All melting points are uncorrected. Microanalyses were performed by the Microanalytical Department, Abbott Laboratories, North Chicago, Illinois.

4-Bromobutyl Isothiocyanate

Triethylamine (66 g, 0.66 mol) was added over a period of 2 h to a stirred solution of 4-bromobutylamine hydrobromide (70.0 g, 0.30 mol) and thiophosgene (35.8 g, 0.30 mol) in 500 ml chloroform at 5 °C. The reaction mixture was stirred at 25 °C for 2 h, and was then washed with 4% NaOH (2 × 500 ml), 5% HCl (2 × 500 ml), and water (2 × 500 ml).

The chloroform layer was dried and evaporated, and the residue was fractionated to yield 38.1 g (65%) of a mixture of 4-chlorobutyl isothiocyanate (20%) and 4-bromobutyl isothiocyanate (80%), b.p. 91–94°/0.2 mm. Pure samples of the two products could be obtained by preparative g.l.c. However, the unresolved mixture was adequate for the preparation of the 2-aryliminohexahydro-1,3-thiazepines.

The other isothiocyanates listed in Table 1 were prepared in the same way; with the longer-chain compounds, the presence of the chloro isomer was not detected.

2-Phenyliminohexahydro-1,3-thiazepine (6)

A solution of 4-bromobutyl isothiocyanate (4.81 g) and aniline (1.86 g) in ethanol (20 ml) was refluxed for 30 min. The solution was evaporated and the residue was dissolved in water (30 ml). The aqueous solution was washed with ether and was then neutralized with NaOH, giving the product m.p. 122–125°, yield 3.5 g (85%). Recrystallization from ether raised the melting point to 125–127°.

The other thiazepines listed in Table 2 were prepared in the same way; in most cases, the products were isolated as the hydrobromide salts. The course of the reaction was followed by the disappearance of the characteristic i.r. peak of the isothiocyanate (2150 cm^{-1}).

The thiazocine, thiazonine, thiaazacycloundecane, and thiaazacyclotridecane derivatives (compounds **16–27**) were also prepared in the same way. The reaction times were from 8–12 h for the larger rings; in several cases, some of the starting isothiocyanate remained unreacted.

The Mechanism of Oxygenation Reactions Catalyzed by Rhodium(I) Complexes in Solution

B. R. JAMES AND E. OCHIAI
Department of Chemistry, University of British Columbia, Vancouver 8, British Columbia

Received December 17, 1970

The mechanism of oxygenation reactions catalyzed by a rhodium complex which forms a 1:1 molecular oxygen adduct has been elucidated by infrared spectroscopy. Hydrogen abstraction from the substrate by the coordinated oxygen is involved, and the data give the first direct evidence for hydroperoxide intermediates in such reactions of d^8 metal complexes.

On a déterminé, par spectroscopie infrarouge, le mécanisme des réactions d'oxygénation catalysées par des complexes de rhodium pouvant donner des composés d'addition 1:1 avec l'oxygène. Un processus qui intervient, implique l'enlèvement, par de l'oxygène coordonné, d'un hydrogène du substrat; les résultats obtenus fournissent la première preuve directe que des hydroperoxydes se forment au cours de réactions de complexes métalliques d^8.

Canadian Journal of Chemistry, 49, 975 (1971)

Considerable interest has been aroused in the mechanism of oxidation catalyzed by molecular oxygen complexes since the discovery of Vaska's oxygen complex (1). Mechanisms involving oxygen–oxygen bond splitting and subsequent transfer to accepting ligand (2, 3) or free radical intermediates (4) have been proposed for square planar d^8 metal systems. A report by Stern (5) on the autoxidation of cumene catalyzed by palladium(0) phosphine complexes and other platinum metal complexes suggested that a free radical reaction might be initiated by hydrogen abstraction by the molecular oxygen complex with formation of a hydroperoxide complex. We have obtained direct evidence for a hydroperoxide intermediate in such oxidations involving a rhodium(I) cyclooctene complex.

Previous work from this laboratory (6) reported on the formation of a 1:1 molecular oxygen complex for $[RhCl(C_8H_{14})_2]_2$ in *N*,*N*-dimethylacetamide (DMA) containing lithium chloride (one O_2 per Rh atom) and its catalytic activity for oxidation of the solvent at 80°. We now find that this complex when dissolved in benzene, toluene, dichloromethane, or 1,2-dichloroethane rapidly absorbs oxygen to the same 1:1 mole ratio at 35°; a further uptake occurs very slowly for the toluene system. A brown precipitate, which forms at the completion of the rapid uptake, shows bands at 1690 and 1550 cm^{-1}, attributed to carbonyl and coordinated water,

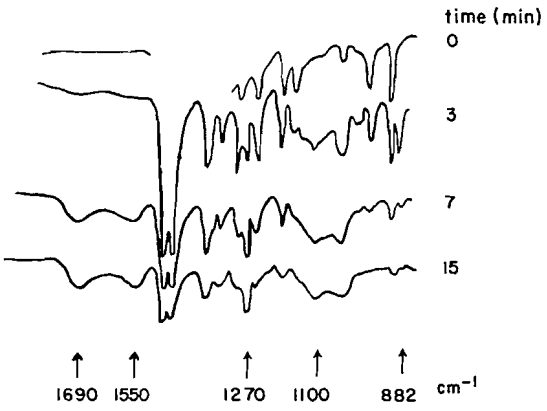

FIG. 1. Reaction of rhodium complex with oxygen in 1,2-dichloroethane as followed by infrared spectroscopy.

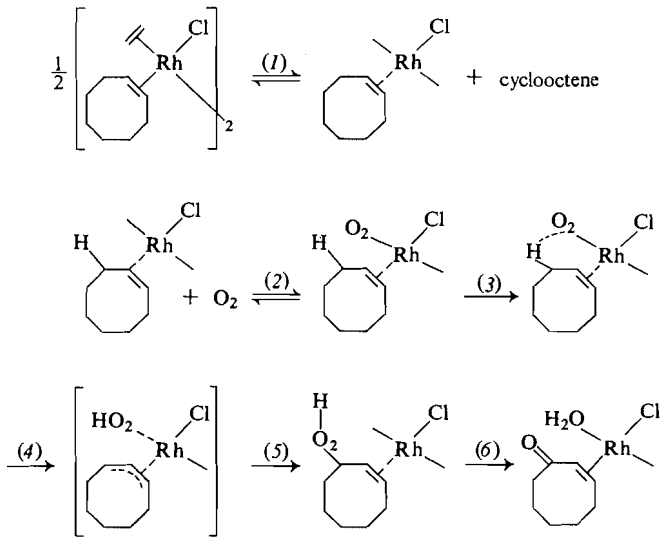
respectively, and around 3400 cm^{-1}, attributed to hydroxide. Oxidation of the cyclooctene seemed likely and some cyclooctenone was detected in the filtrate.

The reaction of the complex itself with oxygen in 1,2-dichloroethane was followed at room temperature (23°) using infrared spectroscopy by sampling onto a sodium chloride plate followed by rapid evaporation (see Fig. 1). A solution prepared under vacuum was exposed to air. At *ca.* 3 min, there appear the broad band centered at 3400 cm^{-1} and small peaks at 1270, 1100, and 882 cm^{-1}; at *ca.* 7 min, the peaks at 3400, 1270, and 1100 cm^{-1} intensify while the peak at 882 cm^{-1}



SCHEME 1

diminishes and weak peaks show up at 1690 and 1550 cm^{-1}; at *ca.* 15 min the same overall trend continues while the brown solid starts to precipitate. On assignment of the peaks: ν_{OH} at 3400 cm^{-1}, δ_{OH} (of hydroperoxide) at 1270 cm^{-1} (7), coordinated water at 1550 cm^{-1}, $\nu_{C=O}$ at 1690 cm^{-1}, ν_{C-O} at 1100 cm^{-1}, and ν_{O-O} at 882 cm^{-1} (coordinated), the observations could fit the reaction scheme shown, although it should be emphasized that neither the hydroperoxide moiety nor the cyclooctene substrate need remain coordinated to the rhodium (designated by broken lines to the rhodium atom). Indeed, cumene is also readily oxidized by this system with no induction period at 50 cm oxygen and 35° suggesting that coordination of the substrate is not essential for these oxidation processes. All that is necessary is hydrogen abstraction from the substrate by the coordinated oxygen (*cf.* step 4).

The mechanism shown readily explains the formation of cyclohexen-3-one from the catalyzed oxidation of cyclohexene with $RhCl(PPh_3)_3$ (8).

In the presence of a large excess of cyclooctene, no oxygen uptake is observed due to repression of the initial dissociation, which could involve loss of one or two cyclooctene ligands. The brown solid obtained from the cyclooctene system has not yet been obtained in a pure state and has not been identified but elemental analysis shows that it contains one coordinated C_8 unit per rhodium.

The formation of the allylic hydroperoxide intermediate suggested here is characteristic of the photochemical reaction by singlet oxygen ($^1\Delta_g$) (9). However, cyclohexadiene and anthracene, which are known to be good acceptors of singlet oxygen, are not oxidized by this catalyst system, and it is not clear at this stage how far the analogy between coordinated oxygen and singlet oxygen (10) in these systems can be drawn.

We thank the National Research Council of Canada for support of this research and Johnson Matthey Ltd. for loan of the rhodium.

Potential Energy- Sheets for the $n\pi^*$ and $\pi\pi^*$ Triplet States of Acrolein

Dedicated to Professor Paul de Mayo

A. DEVAQUET[1] AND L. SALEM

Laboratoire de Chimie Théorique,[2] Faculté des Sciences 91-Orsay, France

Received November 13, 1970

The energy of the $n\pi^*$ and $\pi\pi^*$ triplet states of acrolein as a function of the twist of the CH_2 terminal groups and relaxation of the three skeletal σ bonds has been investigated in an "*ab initio*" self-consistent field formalism. The potential energy sheets of these triplets show that the *cis* photoadducts of cyclic enones may arise from "planar, relaxed" triplet states whereas the *trans* photoadducts are given by "twisted, unrelaxed" triplet states.

Utilisant un formalisme SCF "ab initio" on étudie les niveaux énergétiques des états triplets $n\pi^*$ et $\pi\pi^*$ de l'acroleine en fonction de l'angle de torsion des groupes CH_2 terminaux et des temps de relaxation des trois liens σ de la chaîne. D'après les potentiels d'énergie de ces triplets, la formation de produits *cis* de photoaddition de cétones cycliques insaturées proviendrait d'états triplets "plan et relaxed" alors que les produits *trans* seraient obtenus à partir d'état triplets "tordus et unrelaxed".

Canadian Journal of Chemistry, 49, 977 (1971)

The photochemical reactions of 2-cyclohexenone are characterized by the occurrence of marked orientational specificity. The photocycloaddition reaction sometimes leads to products in which the six- and four-membered rings are fused *trans* as well as to the thermodynamically more stable *cis* fused adducts (1). The problem of identifying the excited state(s) of the enone responsible for such photoadditions is a matter of fundamental importance. There is, however, every reason to believe that most photocycloaddition reactions of simple enones are brought about by a triplet state (2).

In the present communication the potential energy surfaces of the $n\pi^*$ and $\pi\pi^*$ triplet states of s-*trans* acrolein are briefly described. This conformation which is 4.96 kcal/mol more stable than the s-*cis* conformation (the barrier of internal rotation around the single bond being 7.02 kcal/mol (3)) may be considered as a model for the enone systems. The geometries of these two triplet states have been investigated by the open-shell s.c.f. method of Nesbet (4) using a program developed by Stevens (5). Two internal motions have been considered: the twist of the CH_2 terminal group (θ_1) and the relaxation of the three skeletal σ bonds ($R_1R_2R_3$) (Fig. 1). These motions cause severe orbital changes.

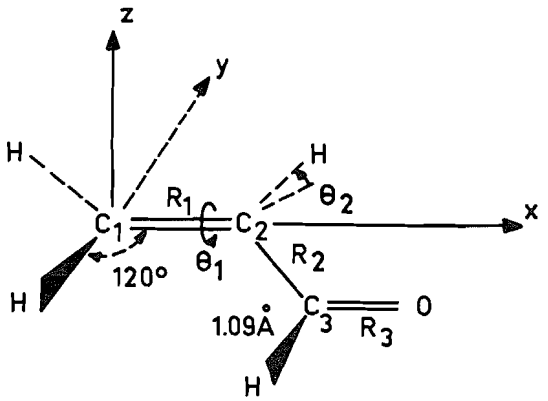

FIG. 1. Skeletal structure of acrolein.

In the 90° twisted acrolein, the $n\sigma$-type molecular orbital (m.o.) is a nearly pure $2p_y$ atomic orbital on the oxygen atom with little bonding character. There are also two non-bonding m.o.'s. The first one, namely y, is a nearly pure $2p_y$ atomic orbital on the C_1 carbon atom whereas the second one, which is the third π m.o., namely π_3, is of allylic type with a nodal plane passing near the C_3 carbon atom (Fig. 2).

Table 1 gives the various sets of values of the CC bond relaxations for which the total energy was calculated as a function of varying angle of twist θ_1. Figure 3 shows the resulting potential energy sheets for the two triplet states of acrolein (5). These sheets intersect along some curve passing points A and B. The true surfaces, of course, do not intersect even though they come

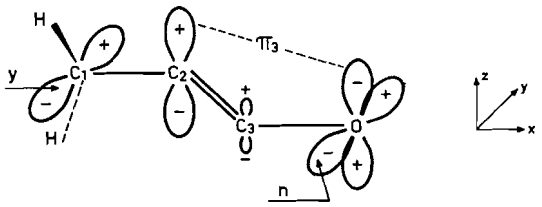

FIG. 2. "Frontier" orbitals in the 90° twisted acrolein.

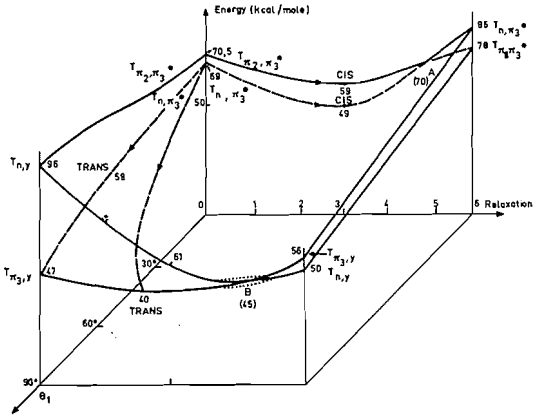

FIG. 3. Potential energy sheets of the two triplet states of acrolein (the origin of the vertical axis is the energy of the acrolein molecule in its ground state, geometry number zero of Table 1).

TABLE 1. Selected sets of bond lengths for R_1, R_2, and R_3

Geometry*	R_1(Å)	R_2(Å)	R_3(Å)
0	1.36	1.46	1.22
1	1.37	1.42	1.25
2	1.42	1.39	1.29
3	1.45	1.35	1.32
4	1.48	1.32	1.34
5	1.51	1.30	1.36
6	1.54	1.28	1.38

*These refer to positions on the "Relaxation" axis of Fig. 3.

very close: configuration interaction ultimately splits the states along the AB line as shown in the figure. Hence, whereas for instance the unrelaxed triplet π_2,π_3^* belongs to the *upper* sheet, the relaxed triplet belongs to the *lower* sheet.

A careful examination of these surfaces shows that it is not possible to distinguish any more between $n\pi^*$ and $\pi\pi^*$ states, only between highest and lowest triplet states. The "orbital" nature of these triplets is given by the detailed exploration of the sheet. For example, the highest relaxed and twisted triplet $T_{\pi_3,y}$, with energy 56 kcal/mol, has two paired electrons in the n oxygen orbital and one in each of the y and π_3 molecular orbitals. Because of the weak splitting throughout nearly the entire surface, the ordering of the potential energy sheets may be easily reversed by substitution with different electron donating or attracting groups, by use of different solvents, or by strain in cyclic compounds.

From a photochemical point of view these calculations lead to some hypotheses which may be useful in understanding the *cis* and *trans* cycloadditions of cyclic enones.

(*1*) the *cis* adduct may be found in either of the planar relaxed $n\pi^*$ and $\pi\pi^*$ triplet states with energies of 49 and 59 kcal/mol above the equilibrium ground state. These relaxed states need not twist immediately to decay respectively to the 90° twisted relaxed $T_{\pi_3,y}$ state (40 kcal/mol) and to point B (45 kcal/mol) because there appears to be small barriers for this motion. In the $n\pi^*$ state of acrolein there exists a 3 kcal/mol barrier to rotation about the double bond that can be explained in terms of a configuration interaction between the two triplets whereas the small rotational barrier in the $\pi\pi^*$ state should be increased in cyclic enones due to the strain energy associated with a twisted geometry. Therefore the molecule may remain in the relaxed (untwisted) triplet states for enough time to react.

(*2*) The *trans* adducts may arise from the 90° twisted and relaxed $T_{\pi_3,y}$ triplet state, whose energy is 40 kcal/mol. However, this state is nearly degenerate with the ground state at that particular nuclear configuration[3] and therefore intersystem crossing to this ground state should be very rapid.

(*3*) Alternatively the *trans* adduct may be formed near the 45° twisted but unrelaxed triplet state (58 kcal/mol). Indeed, an out-of-plane motion (θ_2) of the hydrogen atom adjacent to C_2 (Fig. 1) for this configuration provides an additional stabilization of 5 kcal/mol ($\theta_2 = -45°$ (5)). The C_1 and C_2 p orbital axes of the resulting triplet state are nearly perpendicular, and this should facilitate *trans* addition. Again in the cyclic case the strain energy arising from a twisted geometry can contribute to a "secondary minimum" in this region.

[3]Details will be published elsewhere.

All these possibilities are obviously strongly dependent on the ordering of the initial $n\pi^*$ and $\pi\pi^*$ triplet states and on their energetic separation in the specific cyclic enone.

The Gas-Phase Acidity Order of Some Inorganic Acids

L. BREWSTER YOUNG
Mobil Chemical Company, Edison, New Jersey 08817

AND

E. LEE-RUFF AND D. K. BOHME[1]
Department of Chemistry, York University, Toronto, Ontario

Received December 29, 1970

The gas-phase acidity order at 300 °K of the inorganic acids, water, ammonia, and hydrogen has been directly determined using the flowing afterglow technique. The order established is $H_2O > H_2 > NH_3$, water being the strongest acid in this series. This result is inconsistent with recent calculations, current available thermochemical data, and the order found in solution.

Utilisant une technique continue de luminescence retardée, on détermine directement l'ordre de l'acidité en phase gazeuse à 300 °K d'acides inorganiques, de l'eau, de l'ammoniac et de l'hydrogène. On trouve que l'eau est le produit le plus acide et que l'ordre décroissant est $H_2O > H_2 > NH_3$. Ce résultat n'est pas consistant avec les calculs théoriques récents, les données thermodynamiques disponibles actuellement et l'ordre trouvée en solution.

Canadian Journal of Chemistry, 49, 979 (1971)

As part of a program directed towards the determination of relative acidities of organic acids in the gas phase, experiments were recently performed to determine the gas-phase acidities of some simple inorganic acids. The flowing afterglow technique was employed to investigate the kinetics at 300 °K of proton transfer reactions of the type

$$[1] \qquad X^- + YH \rightleftharpoons Y^- + XH$$

The determination of the preferred direction of proton transfer at thermal energies identifies the sign of the free energy change of reaction 1 which, in turn, provides a measure of the relative gas-phase acidity of the acids YH and XH. Such information is valuable in formulating intrinsic reactivity functions, which should have an important bearing on reactivity functions measured in solution. Proton transfer reactions proceeding in the gas phase represent a limiting behavior that can be employed as a standard against which the performance of proton transfer reactions proceeding in the condensed phase may be related.

The experiments were performed in one of the flowing afterglow systems of the Environmental Science Services Administration Research Laboratories in Boulder, Colorado. Details of the method of operation and data analysis have been thoroughly described elsewhere (1, 2). Helium was again used as the buffer gas. The helium pressure in the tube was typically *ca.* 0.4 Torr. The NH_2^- and H^- ions were generated by 100

TABLE 1. Summary of acid–base reactions investigated in the gas phase at 300 °K

Acid–base reaction	k_f*	k_r*	K	$-\Delta G_{300}^{\circ}$ (kcal mol^{-1})
$H^- + H_2O \rightleftharpoons OH^- + H_2$	$\gtrsim 5(-11)$	$< 5(-12)$	> 10	> 1.4
$NH_2^- + H_2O \rightleftharpoons OH^- + NH_3$	$\gtrsim 5(-11)$	$< 5(-12)$	> 10	> 1.4
$NH_2^- + H_2 \rightleftharpoons H^- + NH_3$	$\geqslant 3.7(-11)$	$\sim 4(-12)$	$\gtrsim 10$	$\gtrsim 1.4$

*Units in cm^3 molecule^{-1} s^{-1}, (-11) denotes 10^{-11}.

and 25 eV electron impact on NH_3, respectively. The production of OH^- has been described previously (2). The reactant, H_2O, concentration could not be measured by metering it into the flow tube through calibrated flow elements, which is our conventional technique for measuring neutral concentration. The H_2O concentration was therefore measured by monitoring the increase in the total pressure in the reaction region as the vapor was bled into it. This method of measuring H_2O concentration is, however, both insensitive (the smallest partial pressure measurable with capacitance manometer with a 10 Torr sensing head was at best 0.1 microns) and inaccurate. Consequently, the rate constants for the fast reactions involving H_2O are necessarily limits and are considered reliable only to within a factor of 2.

A summary of the kinetic data obtained for this series of experiments is given in Table 1. The measured equilibrium constant, which was taken to be equal to the ratio of the forward and reverse reaction rate constants, will be equal to the thermodynamic equilibrium constant only if the energy distributions of the respective reactants of the forward and backward proton transfer reactions investigated follow Boltzmann energy distributions. We expect that this is the case in this series of experiments since the ionic species are allowed to undergo many thousand collisions with helium atoms before entering the reaction region where the neutral reactant species are added in thermodynamic equilibrium at room temperature. Thus the data shown in Table 1 clearly indicate the gas-phase acidity order $H_2O > H_2 > NH_3$, water being the strongest acid in this series. Whereas the observation that water is a stronger acid than ammonia in the gas phase has already been reported (3, 4), the position of hydrogen in this sequence has not, to our knowledge, been previously determined.

The gas-phase acidity order determined in this series of experiments is inconsistent with the recent theoretical studies of Ritchie and King who, on the basis of their computations of the potential energy surfaces of proton transfer reactions, predicted both NH_3 and H_2O to be stronger acids than H_2 (5, 6). The position of H_2 in our acidity scale is also inconsistent with the thermochemical data presently available. The value of 4.38 eV for $D(NH_2—H)$ (7) and 1.21 eV for the electron affinity of NH_2 (8) are probably least reliable and may be low or high, respectively, by as much as 0.5 eV.[2] Finally, the solution acidity order of this series is $H_2O > NH_3 > H_2$ since metal hydrides undergo facile proton transfer reactions with both water and ammonia to liberate hydrogen in solution (9, 10). Although the exchange reaction between amide and D_2 proceeds quite readily in solution, it has been found that the hydride ion is not involved in this exchange process. The reversal of the acidity order of NH_3 and H_2 in the gas phase suggests that solvation effects favor the right-hand side of the equilibrium

$$[2] \qquad NH_3 + H^- \rightleftharpoons NH_2^- + H_2$$

Similar acidity order reversals have been shown in the gas phase for alcohols and substituted amines (3, 11).

Utility of Shift Reagents in Nuclear Magnetic Resonance Studies of Polyfunctional Compounds: *N*- and *O*-Acetylated Carbohydrates and Nucleosides

R. F. BUTTERWORTH[1], A. G. PERNET[2], AND S. HANESSIAN[3]
Department of Chemistry, University of Montreal, Montreal, Quebec

Received December 30, 1970

The utility of n.m.r. shift reagents, $Eu(DPM)_3$ and $Pr(DPM)_3$, can be extended to polyfunctional molecules containing acetate and amide groups with significant spectral simplification and definitive peak assignments based on "signal crossover" phenomena.

On démontre que l'utilité des réactifs $Eu(DPM)_3$ et $Pr(DPM)_3$ qui induisent des déplacements en r.m.n. peut être étendue aux molécules polyfonctionnelles contenant des groupes acétate et amides; il en résulte que les spectres sont simplifiés d'une façon remarquable et que des attributions définitives de pics peuvent être faites.

Canadian Journal of Chemistry, 49, 981 (1971)

Recent work has demonstrated the ability of europium (1, 2) and praseodymium (3) chelates of dipivaloylmethane to produce remarkable shifts in the ^1H n.m.r. spectra of monofunctional compounds possessing simple and relatively complex structures (4). We report herein the effects of shift reagents on the n.m.r. spectra (at 100 and 60 MHz) of various classes of *polyfunctional* compounds, in which, *a priori*, multiple sites of complexation would be anticipated. We demonstrate the application of $Eu(DPM)_3$ and $Pr(DPM)_3$ chelates in the assignment of *O*-acetyl and *N*-acetyl resonance signals in polyacetylated carbohydrates as well as in the spectral simplification of various polyfunctional derivatives, including *nucleosides*.

Model studies[4] on the mechanism and preferential sites of complexation of Eu chelates with polyfunctional molecules were performed on methyl 2,3-*O*-isopropylidene-β-D-ribofuranoside (6), the corresponding 5-*O*-acetate, and 5-deoxy (7) analogs. The induced shifts decreased as expected in the order $\Delta Eu{:}OH > H_{5,5'} > H_4$, $H_3 > H_1$ in accordance with the generalization that protons remote from the site of complexation suffer smaller induced shifts than those of closer proximity (8). The 5-*O*-acetate and 5-deoxy analogs were found to complex to the extent of approximately 40–50% and 10–20% respectively, compared to the parent compound. Upfield shifts of approximately the same relative magnitudes were observed using $Pr(DPM)_3$ in CCl_4.

The significant interaction with the 5-*O*-acetate derivative cited above, prompted us to study substrates containing more than one acetyl group. In the case of α- and β-D-glucose pentaacetates, in which the relative chemical shifts of the respective acetyl signals are known by inference with other model compounds (9, 10) and in the case of β-D-galactose pentaacetate, the signal of the *primary* acetoxy group was in each case, shifted substantially more than secondary acetoxy signals. Incremental additions of $Eu(DPM)_3$ in minute portions to a solution of α-D-glucose pentaacetate

[4]Our initial studies with diacetone glucose revealed that at a defined concentration of $Eu(DPM)_3$ the order of chemical shifts increasing to higher field were $H_5 > H_3 > H_1 > H_4 > H_2 > H_{6,6'}$. Similar results have been reported on this compound while this work was in progress (5). We also note that the presence of two hydroxyl groups in a molecule as in 5-deoxy-1,2-*O*-isopropylidene-D-*xylo*-hexofuranose causes increased broadening of bands and presents some limitation on the method.

Upfield shifts of approximately the same relative magnitudes were observed using $Pr(DPM)_3$ in CCl_4.

The significant interaction with the 5-*O*-acetate derivative cited above, prompted us to study substrates containing more than one acetyl group. In the case of α- and β-D-glucose pentaacetates, in which the relative chemical shifts of the respective acetyl signals are known by inference with other model compounds (9, 10) and in the case of β-D-galactose pentaacetate, the signal of the *primary* acetoxy group was in each case, shifted substantially more than secondary acetoxy signals. Incremental additions of $Eu(DPM)_3$ in minute portions to a solution of α-D-glucose pentaacetate

[4]Our initial studies with diacetone glucose revealed that at a defined concentration of $Eu(DPM)_3$ the order of chemical shifts increasing to higher field were $H_5 > H_3 > H_1 > H_4 > H_2 > H_{6,6'}$. Similar results have been reported on this compound while this work was in progress (5). We also note that the presence of two hydroxyl groups in a molecule as in 5-deoxy-1,2-*O*-isopropylidene-D-*xylo*-hexofuranose causes increased broadening of bands and presents some limitation on the method.

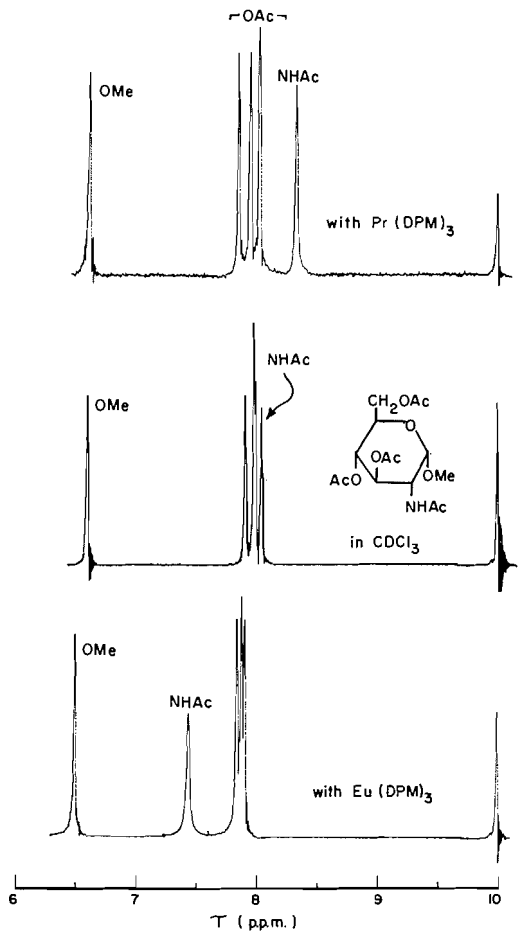

FIG. 1. The n.m.r. spectra (60 MHz) of methyl 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranoside in $CDCl_3$ solution (0.065 g in 0.6 ml). Normal spectrum (middle); after addition of 15 mg of $Pr(DPM)_3$ (upper); after addition of 15 mg of $Eu(DPM)_3$ (lower).

in $CDCl_3$ causes the net expansion of the acetyl signals region and the observation of a "signal crossover" phenomenon; that is the gradual shift of the signal due to the most affected acetyl group (at C-6) passing through a coalescence point (with the C-1 OAc signal) and emerging on the low field portion of the spectrum. Such increment-induced shifts provide a useful technique[5] to eventually assign all acetyl resonances in acetylated carbohydrates, based on their relative dispositions and their respective interaction with the shift reagents. We also point out that, in such derivatives, ΔEu is largest for the $H_{6,6'}$ protons compared to other ring protons which is a confirmatory tool for the identity of the corresponding shifting acetyl group.

Complexation of amide functions seems to be favored over esters by a factor of 4-5, as evidenced by our studies with α- and β-D-glucosamine pentaacetate and related compounds. In all cases, the *N*-acetyl resonance suffers a very large paramagnetic induced shift which is also reflected in the proportional shift of the NH doublet to lower field. The assignment of *N*-acetyl signals in the presence of acetoxy groups in carbohydrates has been resolved only recently by specific *N*- and *O*-deuterioacetylation and solvent-induced shift techniques (9, 11, 12). As can be clearly seen in Fig. 1 the characteristic downfield and upfield shifts of the *N*-acetyl signal can serve as a diagnostic tool in such assignments, utilizing $Eu(DPM)_3$ and $Pr(DPM)_3$ respectively. This preferential complexation with amide groups and their shift patterns was observed with other derivatives containing axial and equatorial amide and acetoxy functions.

Finally, application of the utility of $Eu(DPM)_3$ in the spectral simplification of certain nucleosides is demonstrated using *N*-acetyl cytidine triacetate and adenosine triacetate. Figure 2 shows the partial n.m.r. spectra of the former nucleoside derivative, in which the unresolved multiplet corresponding to the C-2′ and -3′ protons (lower spectrum) is clearly resolved into two triplets, $J_{2',3'} = 5$ Hz[6] (upper spectrum). The relatively large shift observed for the anomeric proton is reflective of the site of complexation and could aid in the assignment of anomeric configuration in such nucleosides, which is otherwise a difficult problem (13). The n.m.r. spectrum of adenosine triacetate in the presence of $Eu(DPM)_3$ also undergoes considerable simplification and expansion in the $C_{1'}$–$C_{3'}$ proton region. Progressive addition of reagent caused a rapid shift of the NH_2 signal indicating a preferential complexation and resulted in some broadening and exten-

[5]The general applicability of the incremental addition technique and the significance of the "signal crossover phenomenon" has been demonstrated with a variety of acetylated sugars and glycosides in this laboratory.

[6]Considerably higher resolution was observed when the spectra were run at slightly elevated temperatures (45–55° in $CDCl_3$) in tightly stoppered tubes. This effect which could be due to the viscosity of the solution at higher reagent concentration is under study.

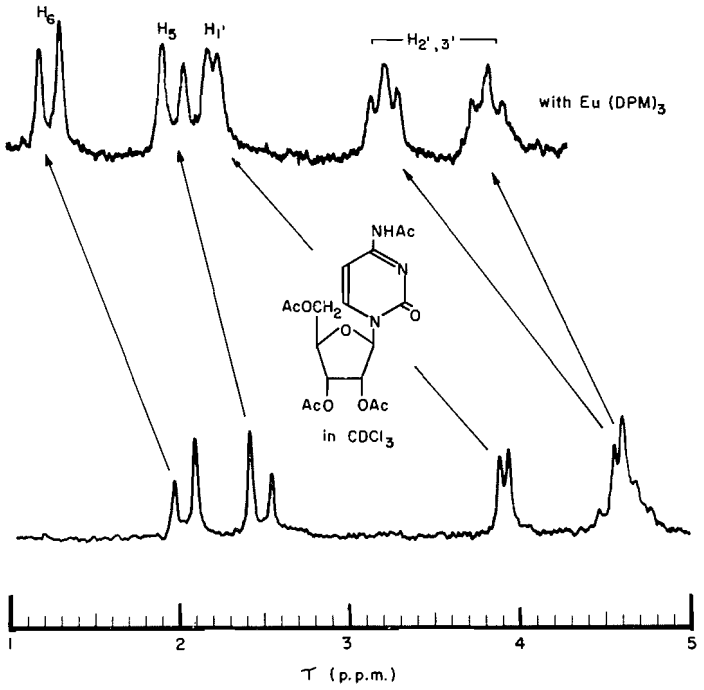

FIG. 2. Partial n.m.r. spectra (60 MHz) of *N*-acetyl cytidine triacetate in $CDCl_3$ solution before and after addition of $Eu(DPM)_3$.

sive downfield shift of the purine ring protons (C-2, -8). The anomeric and C-2′ protons were shifted considerably more than the C-3′ proton which, once again will have important implications in configurational assignments when further models are studied. Details concerning these and extended studies on the utility of shift reagents will be reported in this journal at a later date.[7]

Behavior of Extra Electrons in the Liquids Methane, Ethane, and Propane

M. G. ROBINSON, P. G. FUOCHI, AND G. R. FREEMAN
Chemistry Department, University of Alberta, Edmonton 7, Alberta

Received January 4, 1971

The radiation induced electrical conductances of liquids methane, ethane, and propane have been measured. At a field strength of 5 kV/cm the number of ion pairs collected at the electrodes per 100 eV absorbed by the liquid was 1.5 in methane (−160°), 0.20 in ethane (−90°), and 0.14 in propane (−90°). The short-lived conductance transient (k/u overshoot) observed at low field strengths in methane was 40% as large as that in argon. No transient was observable in ethane or propane. The freeness of motion of electrons in liquid methane is nearly as great as that in liquid argon and much greater than that in ethane or propane.

Les conductivités électriques provoquées sous irradiation ont été mesurées pour le méthane, l'éthane et le propane liquides. Pour une énergie de 100 eV absorbés par le liquide, le nombre de paires ioniques récoltées aux électrodes sous l'influence d'un champ électrique de 5 kV/cm est 1.5 pour le méthane à −160°, 0.20 pour l'éthane à −90° et 0.14 pour le propane à −90°. La conductivité tres éphémère (k/u overshoot) observée pour le méthane sous l'influence de champs peu élevés est 40% de celle de l'argon. Aucune conductivité éphémère semblable n'a été observée pour l'éthane ni le propane. La liberté de mouvement des électrons dans l'éthane ou le propane liquide est de beaucoup inférieure à celle qu'ils ont dans le méthane. Cette dernière est pratiquement aussi grande que la liberté de mouvement des électrons dans l'argon liquide.

The study of the behavior of extra electrons in liquids contributes to the understanding of low energy electron–molecule interactions, electronic states of liquids, radiation-induced electrical conductance, and radiation chemistry (1–3).

Electrons are quasifree in liquid argon (1). They also tend to be quasifree in liquid neopentane, though they are less free in neopentane than in argon (2). There is some question about whether electrons remain quasifree or form a localized state in liquid *n*-hexane, but the motion of electrons in *n*-hexane is much less free than that in neopentane (2–4).

There appears to be a correlation between the freeness of motion of an electron in a hydrocarbon liquid and the shape of the molecules: the more sphere-like the molecules the greater the freeness of the electron motion. To test this suggestion we have studied the radiation induced electrical conductance of the liquids methane, ethane, and propane. The induced conductance of liquid argon has been remeasured and used as a standard for comparison, since all of the generated ions become "free ions" in that liquid.

The experimental techniques were the same as those reported earlier (2). Microsecond pulses of X-rays from a 2 MeV Van de Graaff accelerator were used.

The 100 eV yields of ions of each sign collected at electrodes in the liquids are plotted against applied voltage in Fig. 1. The free ion yield in methane is about one third that in argon; that in ethane is one seventh that in methane; that in propane is 70% of that in ethane. Thus the greatest change in behavior occurs between methane and ethane.

The fraction ϕ_{fi} of the total ionization yield that becomes free ions is given by eq. 1 (5).

$$[1] \qquad \phi_{fi} = \frac{\int N(y) \exp(-\xi^2/\varepsilon y k T)\, dy}{\int N(y)\, dy}$$

where $N(y)$ is the relative number of secondary electrons that attain a separation distance y from their parent ions during the slowing down process, ξ is the charge on an electron, ε is the dielectric constant of the liquid, k is Boltzmann's constant, and T is the absolute temperature. The exact form of the $N(y)$ distribution function is not known, but a frequently used form that lends itself readily to calculations is the single parameter, three dimensional Gaussian [2] (6–8).

$$[2] \qquad N(y)/N_0 = (4y^2/\pi^{1/2}b^3) \exp(-y^2/b^2)$$

where $N(y)/N_0$ is the fraction of the ion–electron pairs that have a given value of y, and b is the dispersion parameter. In the simple function [2], b is also the most probable value of y.

Approximate values of b in the different liquids are: argon, ∞; methane, 700 Å; ethane, 140 Å; propane, 120 Å. The values in propane and ethane are similar to each other, but are much smaller than that in methane. This indicates that

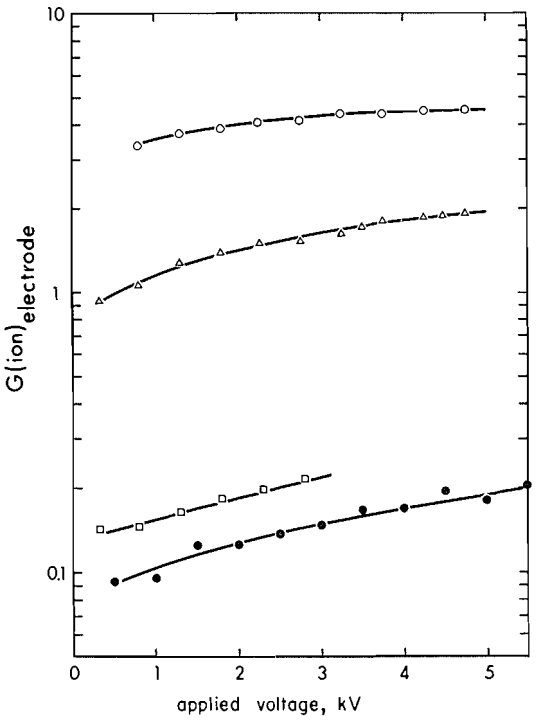

FIG. 1. G values of ions of each sign collected at the electrodes, as functions of the applied voltage. ○, argon, −186°; △, methane, −160°; □, ethane, −90°; ●, propane, −90°. Electrode spacing = 5 mm.

electron motion in liquid methane is much freer than that in ethane or propane.

The observation of a short-lived electrical conductance transient, previously called a k/u overshoot (2), after a pulse of radiation indicates the presence of quasifree electrons in the liquid. The transient in methane was 40% as large as that in argon, but was not observable in ethane or propane. This is further evidence that the freeness of motion of electrons is much greater in methane than in ethane or propane.

Thus the correlation between the molecular shape and the freeness of electron motion in the hydrocarbon liquid is substantiated. The contrast between the methane and ethane systems is striking.

This work is continuing and will be reported in detail at a later date.

Radiation and Radiationless Processes in 2,3-Pentanedione; Phosphorescence Lifetime in the Gas Phase

A. W. JACKSON AND A. J. YARWOOD

Department of Chemistry, McMaster University, Hamilton, Ontario

Received October 21, 1970

Fluorescence and phosphorescence are observed when 2,3-pentanedione in the gaseous state is excited at 365, 405, and 436 nm. The phosphorescence lifetime has been investigated as a function of temperature (298 to 363 °K) and concentration of the diketone (0.5 to 90 × 10^{-4} M). A mechanism that explains the experimental data is proposed. Apart from the radiative process and an intersystem crossing to the ground state, the triplet state 2,3-pentanedione molecules are removed by two other processes. One is a unimolecular reaction with a rate constant of $1 \times 10^{11} \exp(-11.0/RT)\,s^{-1}$ (consistent with an intramolecular hydrogen atom abstraction), and the other is an interaction with ground state molecules. The photochemistry of the triplet state of 2,3-pentanedione is compared with that of biacetyl to consider the effect of substitution of a hydrogen atom by the methyl group on the radiationless processes in diketones.

De la fluorescence et de la phosphorescence sont observées quand la pentanedione-2,3 est excitée à l'état gazeux à 365, 405 et 436 nm. Il a été déterminé que le temps de vie de phosphorescence est fonction de la température (298 à 363 °K) et de la concentration en dicétone (0.5 à 90 × 10^{-4} M). Un mécanisme permettant d'expliquer les données expérimentales est proposé. En plus du procédé radiatif et d'un passage intercistant vers l'état fondamental, la désactivation des états triplets des molécules de pentanedione-2,3 se fait par deux autres procédés. L'un par une réaction unimoléculaire avec une constante de vitesse de $1 \times 10^{11} \exp(-11.0/RT)\,s^{-1}$ (en accord avec une abstraction intramoléculaire d'atome d'hydrogène) et l'autre par une interaction avec des molécules à l'état fondamental. La photochimie de l'état triplet des pentanediones-2,3 est comparée à celle des biacétyles afin d'examiner l'effet de la substitution d'un atome d'hydrogène par un groupe méthyle sur le procédé radiatif dans les dicétones.

Canadian Journal of Chemistry, 49, 987 (1971)

Many molecules that are of great photochemical interest do not phosphoresce in the gaseous phase, and the presence of triplet states in the system must be deduced in an indirect manner. Two methods that are widely used are the triplet sensitized isomerization of *cis*-butene-2 introduced by Cundall *et al.* (1, 2), and the triplet sensitized phosphorescence of biacetyl, first demonstrated by Ishikawa and Noyes (3).

The advantages and disadvantages of the techniques have been considered by Noyes and Unger (4). One of the difficulties with biacetyl is the large ratio for emission from the triplet state as compared with that from the singlet state; about 60:1 (5) in the direct photolysis at long wavelengths. This implies that the possibility of singlet–singlet energy transfer (with subsequent phosphorescence) must be carefully considered in the system. A further complexity in the biacetyl photolysis is a product which can quench the triplet states very efficiently (6, 7); *e.g.* in the time required to scan the emission from biacetyl as a function of wavelength (excitation source a 1000 W Hg/Xe lamp with a 0.25 m monochromator), an appreciable decrease can occur in the intensity of the phosphorescence and in the lifetime of the triplet biacetyl.

The research of Richtol and Klappmeier (8) on 2,3-pentanedione in a matrix at 77 °K and in solution at 298 °K suggests that in the gaseous phase the ratio of phosphorescence to fluorescence would be smaller than for biacetyl. 2,3-Pentanedione might also be less sensitive to the quenching product and it could be an appropriate alternative to biacetyl in energy transfer studies. We have investigated the photochemistry of 2,3-pentanedione at temperatures between 298 and 363 °K and the pre-exponential factors and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

activation energies associated with some of the radiationless processes can be derived from the data. Also, a comparison with the rate constants for biacetyl photolysis shows the effect of substitution of a hydrogen atom by a methyl group on the rate processes in diketones in the gaseous phase.

Experimental

2,3-Pentanedione (Eastman Kodak, and Eastern Chemical Company) was purified (99.98%) by gas–liquid chromatography (on a 6 m 30% SE-30 on Chromosorb W column at 70 °C) and stored in a blackened bulb under vacuum at 77 °K. Mass spectral analysis showed no species with $m/e > 100$, and all fragments could be derived from 2,3-pentanedione. Only very pure diketone gave reproducible experimental results. The quinine sulfate (N. F. grade) was supplied by Fisher.

The luminescence spectrum of 2,3-pentanedione in the gas phase at 25 °C was obtained using a grating monochromator (Bausch and Lomb 0.25 m, 1200 lines/mm) to select the required incident wavelengths. The wavelength span of the exciting radiation was about 8 nm but a 1000 W Hg/Xe lamp (Hanovia) was used and a major portion of the radiation is that from the excited mecury. The emitted light was analyzed by a scanning Ebert monochromator (0.5 m Jarrell-Ash) and detected by a cooled photomultiplier (RCA 8575).

The corrected fluorescence and phosphorescence spectra as a function of wavelength were obtained using quinine sulfate to calibrate the monochromator–photomultiplier arrangement (9). The quantum yields were determined using quinine sulfate ($\phi_f = 0.55$) as a standard (10). The incident light intensities at 313, 405, and 436 nm were determined using potassium ferrioxalate actinometry (11).

The T shaped quartz cell (10 cm long) for the lifetime study was fitted with a Suprasil side window for viewing the emitted light. Gases were circulated through the cell by a teflon paddle which was rotated by an external magnet. The cell-stirrer arrangement was housed in an insulated air furnace which could be heated to greater than 100 °C. The temperature was measured using thermocouples attached to the cell and is precise to ±0.1 °C. The cell was isolated from the mercury-free gas handling line by a teflon O-ring stopcock (Delmar). The pentanedione was transferred from the chromatographic purification line through a trap held at −35° to minimize the mercury contamination of the system. Pressures were measured using a Bourdon spoon guage as a null-meter against a mercury manometer. Many experiments at the higher temperatures were performed at pressures which were greater than the saturated vapor pressure of the 2,3-pentanedione at 25 °C. In these cases, to attain the required concentration, the cell was filled the appropriate number of times at room temperature and then heated to a temperature at least 5 °C above the temperature at which the liquid and vapor were in equilibrium.

The excitation source for the lifetime study was a xenon discharge lamp (Strobotac Type 1531-AB, 0.018 J per flash) which had a decay time of 3.8×10^{-6} s. The lamp was triggered at about 2 Hz from the time base of an oscilloscope. The incident light was restricted to the region 360 to 520 nm by a glass filter (Corning CS5-60). The emitted light passed through a glass filter (Corning CS3-71) and was detected by a photomultiplier (1P28) with a response time of about 2×10^{-6} s. The output of the photomultiplier was displayed on an oscilloscope and photographed. (About 100 flashes per photograph were required.) No lifetimes shorter than 2×10^{-5} s are reported. In separate experiments, the effect of incident light intensity (100 to 15%) on the lifetime was determined using neutral density glass filters (Baird-Atomic).

For a particular concentration of pentanedione in the cell, the lifetime was measured at temperatures between 20 and 90 °C in about 10° intervals. (At the higher concentrations measurements were possible only at the higher temperature.) To ensure that quenching by decomposition products did not interfere, the lifetimes were occasionally remeasured at a low temperature after the usual sequence of experiments was complete. No attempt was made to reproduce the same temperatures for the different concentrations. The lifetimes at the experimental temperatures were calculated, and a cubic polynomial was fitted, using a least-squares technique, to the experimental data in the form $\log(1/\tau)$ *vs.* $1000/T$. From the polynomial that fitted the smoothly varying experimental data the lifetimes at 25, 30, 40, . . . 90° were calculated. There was no evidence of problems associated with liquid diketone using this procedure. The concentration of diketone in the cell was checked using the transmitted light intensity, which was essentially independent of temperature. If condensation were a problem, the amount of light absorbed might be expected to change at the higher temperature.

Results

In the region above 300 nm the absorption spectrum of 2,3-pentanedione extended from about 323 nm to about 480 nm with a maximum absorption in the range 415 to 433 nm. There was some structure in the absorption spectrum and bands were discernible at 442, 433, 423, 416, and possibly 410 nm.

The emission spectrum of 2,3-pentanedione (18.1 Torr) in the gas phase at 24 °C has been determined for excitation wavelengths of 405 and 436 nm. The emission spectrum was also recorded for a pentanedione (18.1 Torr)–oxygen (21 Torr) mixture. When oxygen was present the structureless emission extended from 426 nm to greater than 550 nm and had a maximum at 466 nm (the wavelengths quoted refer to the corrected emission spectrum). Through the use of quinine sulfate as a reference compound $\phi_r = 0.55$ (10) the quantum yield of the emission in the presence of oxygen was determined as $0.001 \pm 20\%$ for both 405 and 436 nm excitation. The emission which was quenched by oxygen was obtained as the difference between the total emission of pure

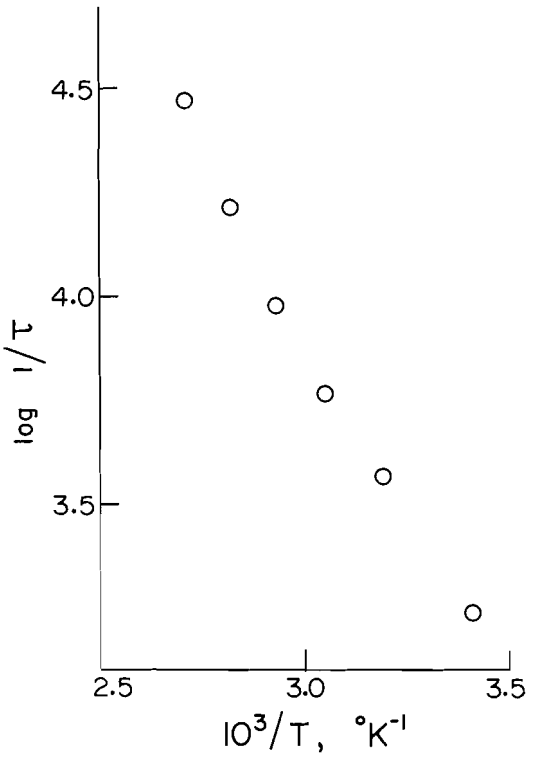

FIG. 1. Logarithm of the reciprocal of the lifetime of 2,3-pentanedione *vs.* the reciprocal of the temperature: pentanedione concentration, 0.66×10^{-4} *M*.

2,3-pentanedione (18.1 Torr) and the emission remaining when oxygen (21 Torr) was also present. It extended from 476 nm to greater than 610 nm (maxima at 520 and 568 nm) and at 24 °C had a quantum yield of 0.020 ± 20% for both 405 and 436 nm excitation. In all experiments the decays of the phosphorescence were well described by an exponential form, at times when the scattered light from the exciting flash was negligible. An example of the experimental results is shown in Fig. 1, where the lifetime data for a pentanedione concentration of 6.6×10^{-5} *M* are displayed at various temperatures. Data were obtained in separate experiments for concentrations in the range 6.6 to about 900×10^{-5} *M*. For some concentrations the lifetime was remeasured at low temperature after completing the sequence of lifetime measurements at increasing temperatures. In each case, the remeasured lifetime was in good agreement with the data obtained in the initial sequence, so that problems associated with the formation of a quenching product were not encountered. At each concentration the cubic equation was calculated which best fitted the experimental data, such as Fig. 1, and the lifetimes at 25, 30, 40, 50, 60, 70, 80, and 90 °C were derived. Figures 2 and 3 show how the reciprocals of the lifetimes obtained in this manner vary with concentration at each temperature.

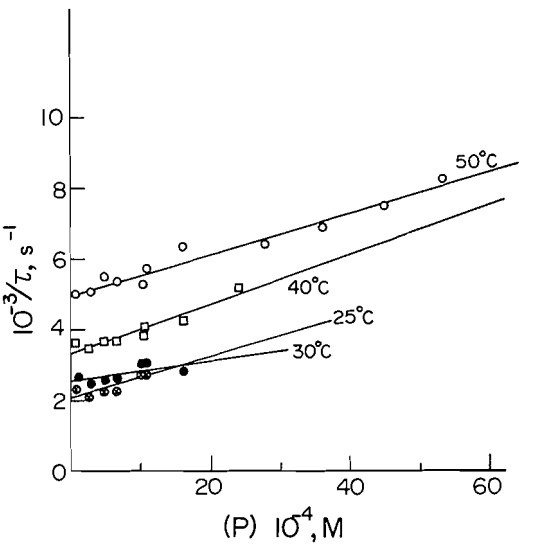

FIG. 2. Reciprocal of the lifetime of pentanedione *vs.* pentanedione concentration at temperatures between 25 and 50 °C.

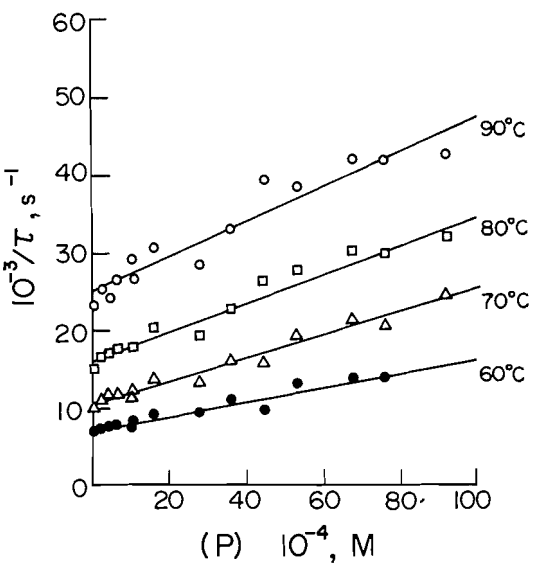

FIG. 3. Reciprocal of the lifetime of pentanedione *vs.* pentanedione concentration at temperatures between 60 and 90 °C.

For personal use only.

The effect of an inert gas on the triplet lifetime was studied by adding sulfur hexafluoride to pentanedione at a concentration of 1.0×10^{-3} M. Addition of 1.1 and 2.0×10^{-2} M of sulfur hexafluoride did not change the triplet lifetime from that of the pure pentanedione over the temperature range 25 to 90 °C.

The effect of incident light intensity on the lifetime was checked using a pentanedione concentration of 6.8×10^{-3} M. At relative incident intensities of 1.0, 0.50, 0.30, and 0.15 the lifetimes at 63.9 °C were 59.7, 61.4, 60.9, and 62.4×10^{-6} s, respectively. Since the lifetimes show no trend with incident intensity, and within experimental error are the same, there is no dependence of lifetime on intensity under these conditions.

Discussion

The electronic absorption spectra of the diketones biacetyl and glyoxal show that the longest wavelength spin allowed transitions lie at about 420 nm. The next region of absorption is usually at about 320–230 nm and there are other transitions at 200–185 nm and at about 170 nm. There is general agreement that the longest wavelength spin allowed transition in glyoxal and biacetyl corresponds to π^*,n excitation, and the excited state molecular configuration proposed (12, 13) is

$$\sigma_{core}\,(a_u)^2(b_g)^2(b_u)^2(a_g)^1(a_u)^1\ {}^1A_u\ (\pi^*,n)$$

The electronic absorption spectrum in the 480–320 nm region of 2,3-pentanedione is very similar in wavelength and intensity to that of biacetyl and excitation populates a π^*,n excited state.

On excitation in the π^*,n absorption band pentanedione emits in the blue and green regions of the spectrum. As usual, the emission in the blue which is still observed in the presence of oxygen is classed as fluorescence. The phosphorescence is the difference between the total emission and the fluorescence. The gaseous phase phosphorescence is shifted with respect to the spectrum observed in the condensed phase. Richtol and Klappmeier (8) report the maximum of the phosphorescence in hexane solution at 25 °C as 532 nm and in mixed alcohol glass at −196 °C as 508 nm, whereas the maximum in gaseous phase is at 520 nm. Apart from changes in the position of the wavelength of maximum phosphorescence with changes in phase and solvent, there are also significant differences in the ratio of the quantum yields of fluorescence and phosphorescene. For pentanedione in the gaseous phase at 24 °C excited at 405 and 436 nm the ratio ϕ_f/ϕ_p is about 0.05 for a concentration of 10^{-3} M, whereas Richtol and Klappmeier report that in hexane solution at 25 °C and a similar concentration, the ratio is about 0.6.

From the overlap of the absorption and fluorescence spectra in the gaseous phase the energy of the first excited singlet state can be estimated as about 63 kcal. The triplet–singlet splitting can be estimated as about 9 kcal from the onset of the fluorescence and the phosphorescence so the triplet state energy is about 54 kcal. The energy of the singlet state of biacetyl is at 64 kcal and of the triplet state at 55 to 57 kcal (14, 15).

The general character of the absorption and emission spectra, and energetics of the singlet and triplet states of 2,3-pentanedione is very similar to that of biacetyl. The photochemistry of pentanedione can be considered in terms of a mechanism which is a modification of that used to describe the photochemistry of biacetyl (16).

[1]	$P + h\nu \rightarrow {}^1P_v \rightarrow {}^3P_0$	
[2]	${}^3P_0 \rightarrow P + h\nu_p$	k_2
[3]	${}^3P_0 \rightarrow P_n$	k_3
[4]	${}^3P_0 \rightarrow$ Product?	k_4
[5]	${}^3P_0 + P \rightarrow$ Removal	k_5

The subscripts n, v, and 0 indicate degree of vibrational excitation, while the superscripts 1 and 3 are the multiplicities of the electronic states, and the ground electronic state of pentanedione is indicated by P. The lowest concentration of diketone studied was about 6×10^{-5} M and the shortest triplet lifetime measured was about 2×10^{-5} s, so the relaxation can be assumed to be complete in the vibrational levels of the triplet before phosphorescence occurs. Accordingly, in this paper we are concerned with the kinetics of the triplet state in its lowest vibrational level. In the mechanism process 1 encompasses all photophysical processes prior to attainment of that level (*i.e.* light absorption, subsequent vibrational deactivation, intersystem crossing to the triplet and vibrational deactivation in the triplet state). Reaction 4 is added to the mechanism to account for the photochemical behavior in the gaseous phase and is in agreement with the rearrangement in solution (17) of 2,3-pentanedione to 1-hydroxy-1-methyl cyclobutanone.

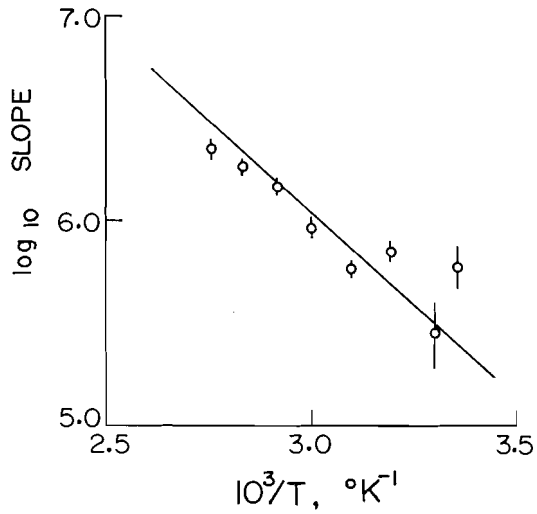

FIG. 4. Logarithm of the rate constants evaluated from the slopes of Figs. 2 and 3 *vs.* the reciprocal of the temperature.

A steady state treatment of this mechanism leads to the expression for the actual lifetime, τ, of the triplet state as $1/\tau = (k_2 + k_3 + k_4 + k_5P)$. Figures 2 and 3 show plots of the reciprocals of the triplet lifetimes *vs.* diketone concentration for temperatures between 25 and 90 °C. Clearly, the mechanism is consistent with the data. High concentrations of added sulfur hexafluoride do not change the triplet lifetime of the diketone. This shows that the photochemistry of pentanedione is quite unlike that of acetone (18), and does not involve a unimolecular reaction in its low pressure or fall-off region.

The slopes of the lines in Figs. 2 and 3 increase as the temperature increases, *i.e.* k_5 increases with temperature. A plot of the logarithm of the slopes from Figs. 2 and 3 *vs.* the reciprocal of the temperature is shown in Fig. 4, and the pre-exponential factor can be evaluated as 9×10^{10} M^{-1} s^{-1} and the activation energy as 7.5 kcal mol^{-1}. The value of the pre-exponential factor is larger than might be expected for the reaction of a polyatomic molecule with an activation energy of 7.5 kcal (20). However, a lower value of the pre-exponential factor is possible. The values derived from Fig. 4 depend significantly on the precision of the data at the lower temperatures. In that region, however, the precision of the data decreases rapidly. This is due to the low value of the rate constant for the bimolecular reaction at the lower temperature and to the concentration range investigated being severely limited by the low vapor pressure of the diketone at the low temperatures. (The error bars shown in Fig. 4 are the standard deviations of the slopes derived from Figs. 2 and 3.) This rate constant for the removal of triplet pentanedione by collision with a ground electronic state pentanedione molecule may be compared with the analogous rate constant in biacetyl photochemistry. At 25 °C the rate constant for 2,3-pentanedione is 3×10^5 M^{-1} s^{-1} and Garabedian and Dows report 7×10^4 M^{-1} s^{-1} for biacetyl (19). No studies have been made of the decomposition products of the system so the rate constant k_5 cannot at present be associated with product formation.

Another important aspect of Figs. 2 and 3 concerns the values of the intercepts of the lines corresponding to the various temperatures. The lowest concentration investigated in this research is about 6×10^{-5} M, however, Parmenter and Poland (21) found that the triplet emission of biacetyl at 25 °C excited at 436 nm is independent of pressure to at least 5×10^{-6} M. It is likely that the experimental data of Figs. 2 and 3 can be extrapolated to lower concentrations and intercepts evaluated that correspond to zero concentration of diketone. According to the steady state treatment of the mechanism, the intercepts on Figs. 2 and 3 are $(k_2 + k_3 + k_4)$ at the appropriate temperatures. From these data other interesting features of the system can be distinguished. It is usually assumed that the natural radiative rate constant does not depend on temperature. The rate constant for intersystem crossing from the triplet state to the ground electronic state can also be assumed to be independent of temperature. Although the temperature dependence of intersystem crossing rate constants has not been investigated extensively, there is theoretical and experimental evidence to validate the assumption. The theory of Siebrand (22) suggests a very small temperature effect on the intersystem crossing rate constants in molecules with a large energy gap between the states. This is corroborated by the experiments of Jones and Siegel (23) on aromatic compounds in a polymethylmethacrylate matrix. Also, the research of Kutschke and co-workers (24) on the triplet state of hexafluoroacetone in the gas phase has shown in that system a temperature independent k_{isc} can explain the experimental data. This leaves only the rate constant k_4 as a function of temperature, and the mechanism thus requires that a plot

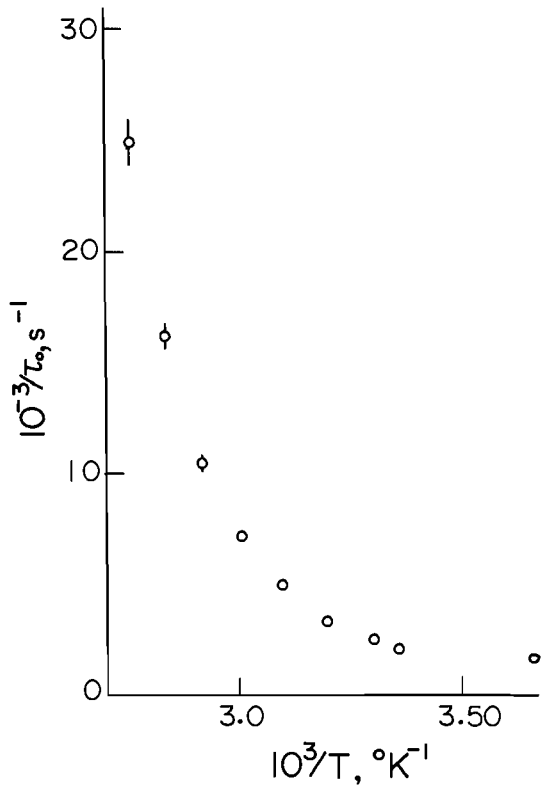

FIG. 5. Reciprocal of the rate constants evaluated from the intercepts of Figs. 2 and 3 *vs.* the reciprocal of the temperature.

of the intercepts of the lines of Figs. 2 and 3 *vs.* the reciprocal of the temperature be non-linear. Figure 5 shows that the experimental data do indeed behave in this manner. The data of Fig. 5 were fitted, using a weighted least-squares technique, to the form $a + b \exp(-C/RT)$; where "*a*" is the sum of the rate-constants k_2 and k_3 ($= 1.40 \times 10^3$ s^{-1}) and "*b*" and "*c*" are the pre-exponential factor and activation energy corresponding to rate constant k_4 (1.0×10^{11} s^{-1} and 11.0 kcal mol^{-1}). An explicit value for k_3 can be deduced if k_2 is derived from the quantum yield and lifetime data, $\phi_p = \phi_{isc}\tau_p k_2$ where ϕ_{isc} is the quantum yield of crossing from the first excited singlet state to the triplet state. Since the fluorescence yield is low ($\phi_f = 0.001$) and decomposition and internal conversion can be assumed to be small from the singlet formed on absorption at 405 and 436 nm, then ϕ_{isc} is approximately unity, k_2 about 47 s^{-1} and k_3, 1.3×10^3 s^{-1}. In a study of pentanedione in solution Richtol and Klappmeier (8) deduced a value for the total rate of removal of triplet molecules by unimolecular radiationless processes, *i.e.* $(k_3 + k_4)$. The data presented above yield individual values for k_3 and k_4 for pentanedione, and allow a comparison of the rate constants for intersystem crossing, k_3, from the triplet to the ground state in biacetyl and pentanedione. From the phosphorescence quantum yield determined by Gandini and Kutschke (25) and the triplet lifetime data of Kaskan and Duncan (26), $k_2 = 100$ s^{-1} and $k_3 = 460$ s^{-1} for biacetyl. So this work suggests that intersystem crossing increases with substitution of a hydrogen atom at an α-carbon by a methyl group in diketones. This effect in diketones is opposite to the trend noted in alkyl ketones (27) at low temperatures in a matrix. Apart from increasing the rate constant for intersystem crossing from the triplet to the ground state, an additional effect of substitution by the methyl group is to introduce another process (reaction 4) capable of removing the triplet state. Turro and Lee (17) have shown that photolysis of 2,3-pentanedione in solution at 25 °C forms 1-hydroxy-1-methyl cyclobutanone with a quantum yield of about 0.06. It is reasonable to associate the intramolecular photoreduction with the rate constant k_4, since the pre-exponential factor and activation energy are compatible with an internal hydrogen abstraction reaction.

In conclusion, the effect on the kinetics of the triplet state of substitution of a hydrogen atom in biacetyl by a methyl group is to decrease the radiative rate constant, increase the intersystem crossing rate constant, retain a bimolecular reaction for removal of the triplet state, and introduce an intramolecular reaction which is probably a photoreduction.

The Flash Photolysis of Tetraphenyldiphosphine, Triphenylphosphine, and Diphenylphosphine in Alcohols

S. K. WONG[1], W. SYTNYK, AND J. K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ontario

Received November 3, 1970

The photochemical reactions of tetraphenyldiphosphine, triphenylphosphine, and diphenylphosphine in alcohol were studied by flash photolysis and product analysis. The primary photochemical process of all three phosphines studied appeared to be the formation of diphenylphosphinyl radicals which subsequently abstract α-H atoms from the solvent alcohol. The relationship between the rate constants of the abstraction and the α-H bond energies of various alcohols was examined.

Les réactions photochimiques de la tétraphényldiphosphine et des di- et triphénylphosphines ont été étudiées, dans l'alcool, par photolyse "flash" et par analyse des produits. Le processus photochimique primaire pour les trois phosphines semble être la formation de radicaux diphénylphosphinyles qui arrachent subséquemment des atomes d'hydrogéne-α de l'alcool utilisé comme solvant. Une relation entre les constantes de vitesse d'abstraction et les énergies de liaison des hydrogènes-α de divers alcools a été examinée.

Canadian Journal of Chemistry, 49, 994 (1971)

The diphenylphosphinyl radical has been postulated as an intermediate in many organophosphorus reactions, such as in the photolysis of triphenylphosphine (1, 2), and in the reaction of tetraphenyldiphosphine with alcohols induced by light or heat (3). Some direct evidence of the existence of the radical has been obtained from an e.s.r. study of a combined effect of heat and light on tetraphenyldiphosphine and diphenylphosphine (4). More recently a better resolved e.s.r. spectrum was obtained from the u.v.-irradiation of a benzene solution of tetraphenyldiphosphine at liquid nitrogen temperature (5). We now wish to report the flash photolysis study of tetraphenyldiphosphine (TPDP), triphenylphosphine (TPP), and diphenylphosphine (DPP) in alcohols, presenting the electronic spectrum assigned to the diphenylphosphinyl radical and the kinetics of its reaction with alcohols.

Results and Discussion

The Electronic Spectrum of the Diphenylphosphinyl Radical

When a methanol solution of tetraphenyldiphosphine (TPDP) was flash photolyzed, a transient absorption spectrum of life-time about 160 μs was detected as shown in Fig. 1. Replacing TPDP by triphenylphosphine (TPP) or diphenylphosphine (DPP) gave identical transient spectra. The spectrum has its maximum around 3300 Å. The spectrum decayed when monitored at wavelengths between 3130 to 4350 Å with a similar time constant (Table 1). This suggests it arises from a single species. All three different substrates gave the same transient spectrum of similar life-time. With the complementary e.s.r. results (5) and the product analysis discussed below, the spectrum is assigned to the diphenylphosphinyl radical.

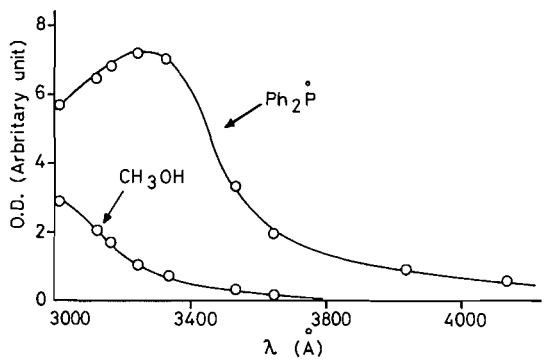

FIG. 1. The electronic absorption spectrum of diphenylphosphinyl radicals in methanol.

It should, however, be noted that methanol alone gave a transient spectrum under the same flash conditions. R. W. Yip has observed a similar transient spectrum by flashing methanol (private communication). The origin of this spectrum has not been investigated. The observation of some transients should not be too surprising when compared to the reported e.s.r. study of u.v.-irradiation of methanol (6). However, this methanol spectrum was much weaker

[1]Postdoctorate Fellow, 1969–1971.

TABLE 1. Rate constants for decay of transient spectrum in methanol

Substrate	$k_1 \times 10^{-3}$ (s^{-1})*				
	3130 Å	3330 Å	3650 Å	4050 Å	4350 Å
Tetraphenyldiphosphine	3.98	4.10	4.0	4.12	4.04
Triphenylphosphine	4.57	4.74	4.45	4.37	4.55
Diphenylphosphine	4.32	4.37	4.38	—	—

*Average values of 3 to 10 separate runs.

than that of diphenylphosphinyl radicals, and the shapes of the spectra are also different (Fig. 1).

The Reaction of Diphenylphosphinyl Radicals with Alcohols

Before we present and discuss the kinetic results of diphenylphosphinyl radicals with alcohols by flash photolysis, we first discuss the reaction mechanism based on reaction product analysis. In 1965 Horner and Dörges (1), and Kaufman and Griffin (2) simultaneously studied the photolysis of TPP. Methanol, 2-propanol, and dioxane were used as solvents by the former workers and benzene and benzene–ethanol mixtures by the latter workers. Both studies were in agreement regarding the primary photochemical process being the cleavage of the phosphorus–phenyl bond to produce a diphenylphosphinyl radical and a phenyl radical from a TPP molecule. Horner and Dörges isolated tetraphenylphosphonium salts (Ph_4P^+) and diphenylphosphinic acid ($Ph_2P(OH)O$) as major products by oxidizing the photolyzed methanol solution of 0.06 *M* TPP. They proposed the following mechanism

[1] $Ph_3P \xrightarrow{h\nu} Ph_2P\cdot + Ph\cdot$

[2] $Ph\cdot + Ph_3P \rightarrow Ph_4P\cdot$

[3] $Ph_4P\cdot + Ph_2P\cdot \rightarrow Ph_4P^+Ph_2P^-$

[4] $Ph_4P^+Ph_2P^- \xrightarrow{MeOH} Ph_4P^+OMe^- + Ph_2PH$

In more dilute methanol solution (0.03 *M*), or in 2-propanol, or in dioxane, the oxidation of the photolyzed TPP gave none or only traces of tetraphenylphosphonium salts. The major products in these cases were diphenylphosphinic acid and phenylphosphonic acid $PhP(OH)_2O$, which were presumably the oxidation products from diphenylphosphine and phenylphosphine. Horner and Dörges did not discuss in their note how these phosphines could be formed. On the other hand Kaufman and Griffin (2) observed diphenylphosphine and biphenyl as major products in benzene solution, and diphenylphosphine and ethyldiphenylphosphine were formed in benzene–ethanol mixture. They rationalized the results by proposing the following reactions

[1] $Ph_3P \xrightarrow{h\nu} Ph_2P\cdot + Ph\cdot$

[5] $Ph_2P\cdot + PhH \rightarrow Ph_2PH + Ph\cdot$

[6] $Ph\cdot + PhH \rightarrow Ph_2 + \frac{1}{2}H_2$

[7] $EtO\cdot + Ph_3P \rightarrow Ph_3\dot{P}OEt \rightarrow Ph_3PO + Et\cdot$

[8] $Et\cdot + Ph_3P \rightleftharpoons Ph_3\dot{P}Et \rightleftharpoons Ph_2PEt + Ph\cdot$

In 1966 Davidson, Sheldon, and Trippett (3) reported that diphenylphosphinyl radicals produced by u.v.-irradiation or thermal decomposition (>180 °C) of TPDP react with primary and secondary alcohols to give diphenylphosphine and alkyl phosphinites, the latter of which then either rearrange to give alkyl diphenylphosphine oxides or partially oxidize to the phosphinates according to conditions and substituents. Because they could not detect any products expected from the radical $R_2\dot{C}OH$, it was suggested that the apparent hydrogen abstraction of the O—H is initiated by the attack of the diphenylphosphinyl radical on the oxygen atom of the alcohol

[9] $Ph_2P—PPh_2 \xrightarrow[\text{or heat}]{h\nu} 2Ph_2P\cdot$

[10] $Ph_2P\cdot + R_2CHOH \rightarrow Ph_2\dot{P}^-—\overset{+}{O}(H)—CHR_2$

Thus, it appears that despite various reported studies, the reaction mechanism of diphenylphosphinyl radicals with alcohols is still uncertain and to some extent the experimental results are in disagreement. In order to provide a definite meaning to our kinetics study we undertook some product analysis experiments, with particular attention on the production of DPP, *i.e.* the hydrogen abstraction mechanism of diphenylphosphinyl radicals. We analyzed the products

immediately after the photolysis without any further chemical complication by oxidation (1) or by removal of the excess alcohols with other chemicals added (3). The major technique of analysis in these experiments was ^{31}P n.m.r., the experiments covering the range from +70 to −80 p.p.m. with respect to H_3PO_4. By ^{31}P n.m.r., diphenylphosphine, diphenylphosphine oxide, and triphenylphosphine oxide were the only detectable organophosphorus products in the photolysis of TPP in methanol, whereas diphenylphosphine and diphenylphosphine oxide were observed in the photolysis of TPDP in methanol. In the case of the photolysis of DPP in methanol, diphenylphosphine oxide was the only observable organophosphorus product. It should, however, be emphasized that because of the low sensitivity of ^{31}P n.m.r. compared with the proton magnetic resonance and the limited solubility of the reactants in methanol, it was not practical in our n.m.r. experiments to detect minor organophosphorus products (*e.g.* phenylphosphine was detected by g.l.c. as a minor product, but not by ^{31}P n.m.r.) and to perform mass balance calculations. Thus, methyldiphenylphosphine, tetraphenylphosphonium salt, methyldiphenylphosphinite, and methyldiphenylphosphinate, could escape n.m.r. detection if they were formed in minor amounts. Gas–liquid chromatographic analysis, however, confirmed all the products identified by ^{31}P n.m.r. and further showed that phenylphosphine was also present in minute amounts in the products. Benzene was shown by g.l.c. to be the major product in the photolysis of TPP but a minor product in the photolysis of TPDP or DPP. When 2-propanol was used as solvent, acetone was shown to be a product of the photolysis in agreement with Horner and Dörges' work (1) but in contrast to Davidson, Sheldon, and Trippett's results (3). Further mass balance experiments were performed on the photolysis of TPP in methanol followed by g.l.c. The results are shown in Table 2. Mass spectrometric analysis of the gaseous products of the photolysis of TPP in methanol showed the presence of H_2, CO, and CH_4. The above analysis is consistent with the postulate that the formation of diphenylphosphine is initiated by the generation of diphenylphosphinyl radicals via a photolytic cleavage of P—P, Ph—P, and P—H bonds of TPDP, TPP, and DPP respectively, and then followed by hydrogen abstraction from the solvent alcohols. Thus a generalized reaction scheme would be

$$[11]\quad \left.\begin{array}{l} Ph_2P{-}PPh_2 \xrightarrow{-Ph_2P\cdot} \\ Ph_3P \xrightarrow{-Ph\cdot} \\ Ph_2PH \xrightarrow{-H\cdot} \end{array}\right\} Ph_2P\cdot \underset{h\nu(-H\cdot)}{\overset{R_2CHOH}{\rightleftharpoons}} Ph_2PH \xrightarrow[-Ph\cdot]{h\nu} Ph\dot{P}H \underset{h\nu(-H\cdot)}{\overset{R_2CHOH}{\rightleftharpoons}} PhPH_2$$

In addition there were some oxidation reactions

$$[12]\quad Ph_3P \rightarrow Ph_3PO$$

$$[13]\quad Ph_2PH \rightarrow Ph_2P(O)H$$

or

$$[14]\quad Ph_3PO \xrightarrow[(-Ph\cdot)]{h\nu} Ph_2\dot{P}(O) \xrightarrow{R_2CHOH} Ph_2P(O)H$$

However, it remains to be determined whether the α-H or O—H hydrogen atom is abstracted by diphenylphosphinyl radicals. It was thought that if the photolysis was carried out in the solvent CH_3OD, the production of Ph_2PH would be an indication of α-H abstraction, and the production of Ph_2PD would indicate O—H abstraction. The best method to distinguish between Ph_2PH and

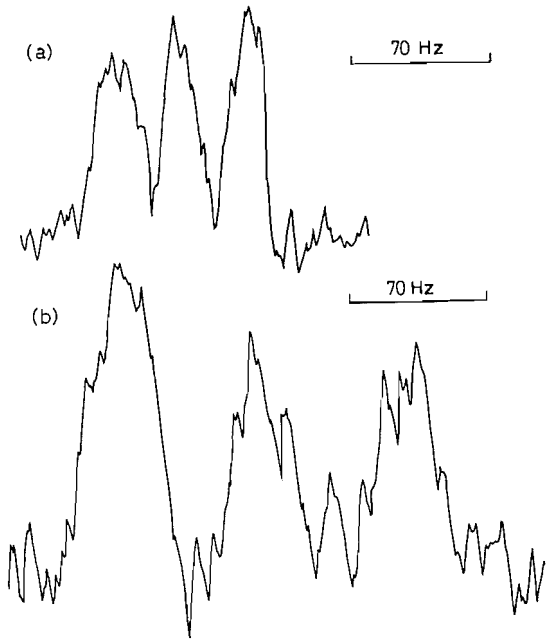

FIG. 2. The ^{31}P n.m.r. spectra of (*a*) Ph_2PD and (*b*) $Ph_2P(O)D$.

Ph_2PD, is probably ^{31}P n.m.r. (7, 8). The ^{31}P n.m.r. spectrum of Ph_2PH consists mainly of two lines separated by about 220 Hz, and that of Ph_2PD three lines separated by about 34 Hz (Fig. 2). However, we found that the hydrogen atom of Ph_2PH exchanged with the deuterium atom of CH_3OD. Thus the ^{31}P n.m.r. spectrum of Ph_2PH in CH_3OD with u.v.-irradiation gave three lines due to Ph_2PD by the exchange reaction

[15] $Ph_2PH + CH_3OD \rightleftharpoons Ph_2PD + CH_3OH$

When the proton magnetic resonance spectra of Ph_2PH in CH_3OD were carefully examined, it was found that O—H absorption of CH_3OH was increased by an observable amount. (There was about 1% CH_3OH in CH_3OD.) If TPDP or TPP is photolyzed in CH_3OD solution and the O—H absorption is increased, it may be concluded that the hydrogen abstraction occurs at α-H via the following schemes:

(*a*) If only α-H abstracted

[16] $Ph_2P\cdot + CH_3OD \rightarrow Ph_2PH + \dot{C}H_2OD$

[17] $Ph_2PH + CH_3OD \rightarrow Ph_2PD + \mathit{CH_3OH}$ (production of CH_3OH)

(*b*) If only O—D abstracted

[18] $Ph_2P\cdot + CH_3OD \rightarrow Ph_2PD + CH_3\dot{O}$

[19] $Ph_2PD + CH_3OD \rightarrow Ph_2PD + CH_3OD$ (no production of CH_3OH)

The experimental results are the following. When TPDP or TPP was irradiated in CH_3OD, ^{31}P n.m.r. indeed gave three lines due to Ph_2PD as well as another triplet due to $Ph_2P(O)D$. Most significantly ^1H n.m.r. spectra gave a large increase of CH_3OH signal (Fig. 3). The estimate of the amount of CH_3OH produced compared with the amounts of the substrates used and Ph_2PD and $Ph_2P(O)D$ formed might provide information about the relative importance of the two abstraction mechanisms. In fact, the amount of CH_3OH produced under the photolysis conditions was about 300 times as much as the number of moles of the substrates used. It is therefore concluded that diphenylphosphinyl radicals preferentially abstract α-H's of the alcohols. However, it must be pointed out that the labelling experiments do not exclude the possibility of minor O—H abstraction.

Kinetics Results

With the above conclusion, the kinetics data of the reaction involving diphenylphosphinyl

radicals can be presented to support the α-H abstraction mechanism.

A typical oscilloscope trace of the decay of the radicals in ethanol is shown in Fig. 4. Detailed analysis of the traces in methanol of all three substrates showed that the decay follows first order kinetics with respect to the radical concentration as seen in the log plot (Fig. 5) from which the rate constants were calculated. The first order kinetics was further confirmed by the fact that the rate constants are independent of the various initial concentrations over a 6-fold range. Since the life-times of the radicals are shorter in ethanol and in 2-propanol and are comparable to the duration of the flash, the rate constants involved a larger error and were determined by the half-life method (Table 3).

The first order kinetics with respect to diphenylphosphinyl radicals is consistent with the following expression

$$[20] \quad \text{Rate} = k_2[Ph_2P\cdot][\text{Alcohol}] = k_1[Ph_2P\cdot]$$

Alcohol was in excess amount and was considered to be practically constant. The results shown in Table 2 reveal an increase of apparent first order rate constant going from methanol, ethanol, to 2-propanol. This may be expected for the α-H abstraction since the bond dissociation energies of these α-H's decrease in that order. Whittle and co-workers (9, 10) determined the bond dissociation energies D(H—CH_2OH) and D[H—$CH(CH_3)OH$] by photobromination to be 92 and 90 kcal/mol, respectively. Benson and co-workers (11, 12) by the study of gas phase iodine-atom reactions estimated D(H—CH_2OH) and D[H—$C(CH_3)_2OH$] to be 95.9 ± 1.5 and 90.2 ± 1.1 kcal/mol, respectively. A relative difference of about 2–2.5 kcal/mol between D(H—CH_2OH)

†See text.

and D[H—$C(CH_3)OH$], and between D[H—$C(CH_3)OH$] and D[H—$C(CH_3)_2OH$] may be deduced from these two studies. In order to correlate more precisely the relation between the bond dissociation energies and the rate constants, we should consider the second order rate constants k_2 rather than k_1, *i.e.* making the correction for the different alcohol concentrations. In addition we should also correct for the statistical number of abstractable hydrogen atoms. If only the α-H's are considered, there are three in methanol, two in ethanol, and one in 2-propanol. The relationship between rate constants and bond energies of the C—H bond being abstracted is given in Table 4. This selectivity of radicals attacking primary, secondary, and tertiary C—H bonds is well established (13) and has been described in terms of the Polanyi equation which relates the activation energies of radical reactions to the strengths of the bond broken, and hence to the heats of reaction

$$[21] \qquad E = \alpha\{D(\text{C—H}) - \beta\}$$

where α, β are constants for the particular reactions. For example, α = 0.49, β = 74.3 kcal/mol for methyl radical abstracting reactions (14), and α = 0.86 and β = 82.5 kcal/mol for bromine atom attack on alkanes (14). In our case, if the frequency factor in the Arrhenius equation for abstraction per hydrogen is assumed to be 10^9 l mol^{-1} s^{-1}, the activation energies calculated are 11.5 kcal/mol for methanol, 10.4 kcal/mol for ethanol, and 9.3 kcal/mol for 2-propanol. Hence the α and β values in the Polanyi relation can be estimated to be 0.55 and 73 kcal/mol, respectively for diphenylphosphinyl radicals abstracting from alcohols.

Experimental

Triphenylphosphine (Aldrich) was recrystallized three times from ethanol. Tetraphenyldiphosphine (K & K) and diphenylphosphine (Alfa) were used without further purification. Methanol and 2-propanol were spectroscopic grade. Ethanol was absolute grade. Methanol-d_1 (99% D) was purchased from Stohler Isotope Chemicals. Diphenylphosphine oxide was prepared by autooxidation of diphenylphosphine (15).

The flash apparatus is of conventional design. The photolysis flash system consisted of two xenon-filled flash tubes, with input energies ranging from 100–5000 J and the corresponding flash durations (1/3 peak) ranging from 20–80 μs. A Garton-type flash tube of 200 J energy with a duration of 2.2 μs manufactured by Chelsea Instruments Limited, London, England, was coupled with a Spex (Model 1700-III) 3/4 m Czerny-Turner spectrometer/spectrograph in the flash spectroscopy. In the case of kinetic spectrophotometry, a Jarrell-Ash 17-721E photomultiplier with a quartz envelope fitted with a cathode follower was placed at the exit of the spectrometer and the spectro-flash was replaced by a 200 W high pressure mercury lamp. A Tektronic Type 564 B storage oscilloscope with plug-in accessories was used for trace recording. The detecting system has been tested for time response and linearity. The flash cells made of quartz had the following dimensions: 43 cm long, 1.3 cm in diameter; 28 cm long, 2.5 cm in diameter; and 15 cm long, 2.5 cm in diameter. Solutions for the flash experiments were extensively degassed by repetitive freeze–pump–thaw cycles under vacuum. The concentrations of the solutions ranged from 1×10^{-4} to 1×10^{-6} M. The flash study was carried out at room temperature (20° ± 2°).

In the analyses of the decay curves, and the construction of the diphenylphosphinyl radical spectrum, correction was made for the transients from the pure alcohol solvents. The correction was based on Beer's law. For simplicity, assume the transient from the solvent has concentration C_1 and extinction coefficient at the wavelength studied ε_1, and C_2 and ε_2 are the respective terms for diphenylphosphinyl radicals, then we have

$$[22] \qquad \log I_0/I = \varepsilon_1 C_1 l + \varepsilon_2 C_2 l$$

where l is the length of the cell, I_0 the light intensity with no absorption and I the light intensity with absorption. If one of the species is present, we have

$$[23] \qquad \log I_0/I_1 = \varepsilon_1 C_1 l$$

$$[24] \qquad \log I_0/I_2 = \varepsilon_2 C_2 l$$

where I_1, I_2 have usual meanings.

Solving these equations, we obtain

$$[25] \qquad \varepsilon_2 C_2 l = \log I_0/I_2 = \log I_1/I$$

In the product analysis experiments, solutions were thoroughly degassed and irradiated by a 200 W high

Nonequilibrium Thermodynamics in Chemical Kinetics

M. L. ANDERSON[1] AND R. K. BOYD
Department of Chemistry, University of Guelph, Guelph, Ontario

Received October 7, 1970

The description of chemical reaction rates, in terms of the language of nonequilibrium thermodynamics, is compared with the conventional language of chemical kinetics. It is concluded that the formalism of nonequilibrium thermodynamics possesses considerable disadvantages, even in the regime where the rate is a linear function of affinity; this conclusion also holds for cases where chemical rates are coupled to diffusion processes. Some of the difficulties involved are illustrated using the experimental data of Nebeker and Pings (28).

La description de la vitesse de réaction en termes du langage de la thermodynamique irréversible est comparée avec le langage conventionnel de la cinétique chimique. Il est conclu que le formalisme de la thermodynamique irréversible a des désavantages considérables et ceci même quand la vitesse est une fonction linéaire de l'affinité; cette conclusion est aussi valable dans les cas où la vitesse des réactions est liée aux processus de diffusion. Certaines des difficultés impliquées sont illustrées à l'aide des résultats expérimentaux de Nebeker et Pings (28).

Canadian Journal of Chemistry, 49, 1001 (1971)

I. Introduction

A large number of texts on nonequilibrium thermodynamics (n.t.) has appeared, particularly in the last ten years (1–7); the advantage of this formalism is that it treats all rate processes from a common point of view. This feature of n.t. has formed the basis of the claim that n.t. offers the ideal language for the description of systems in which different irreversible processes are occurring simultaneously; in particular, the claims of n.t. in the realm of biological systems have been strongly urged (5). In this case, at least, chemical change is one of the more important irreversible processes involved. Despite these compelling features, almost no experimental investigation of the rate of a chemical reaction has been interpreted in terms of the language of n.t.; to the knowledge of the present authors, the only exceptions (8, 9) were cases where the specific aim of the experiments was to test the n.t. formalism, rather than to investigate the kinetic behavior of the reaction systems.

It is clear that the great empirical success of the conventional chemical kinetic language, together with its persuasive theoretical rationale, provides a considerable barrier to the adoption of an alternative description; indeed, it does not seem unreasonable to insist that any such alternative must be consistent with the kinetic description. In the present work, the relationship between the two descriptions is investigated, and, where possible, the advantages and disadvantages of each are evaluated.

[1]Summer student, summer 1970.

II. Rate of a Single Chemical Reaction

In its present state of development, n.t. is essentially limited to processes whose rate is a linear function of a suitably defined thermodynamic force; however, second-order terms will also be included here. Scalar processes only will be considered

$$[1] \qquad J = LX + MX^2$$

where J and X are the conjugate thermodynamic flux and force, respectively, and L and M are phenomenological coefficients.

For the case of a chemical reaction, denoted by the stoichiometric equation

$$[2] \qquad \sum_i \nu_i M_i = 0$$

the usual definition of rate $= 1/\nu_i(dc_i/dt)$, satisfies the requirements for the thermodynamic flux, while the affinity $A = -\sum_i \nu_i \mu_i$ is the corresponding force (11). Here, ν_i is the stoichiometric coefficient of species M_i, conventionally defined as negative for reactants, positive for products; μ_i is the chemical potential of M_i.

The conditions, under which the usual chemical kinetic equations reduce to the form [1], have frequently (1–11) been deduced for special cases where the kinetic equation takes the form

$$[3] \quad v = 1/\nu_i(dc_i/dt) = k\beta \prod_{r=1}^{n_r} (a_r)^{-\nu_r} - k'\beta \prod_{p=1}^{n_p} (a_p)^{+\nu_p}$$

Here, a_i is the activity of M_i; n_r and n_p are the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

number of reactant and product species, respectively. The rate constants k and k′ are functions of temperature only, while β is a function of all thermodynamic variables; in terms of transition-state theory, β is the reciprocal of the activity coefficient of the transition complex (12). Equation 3 is a special case of a rate equation found to be satisfactory for a large number of systems (12); in general, however, the reaction orders α_i are not necessarily given by $\alpha_i = |\nu_i|$, as in eq. 3. A more general rate equation is

$$[4] \qquad v = k\beta \prod_{i=1}^{m} (a_i)^{\alpha_i} - k'\beta \prod_{i=1}^{m} (a_i)^{\alpha_i'}$$

when m is the total number of species whose activity affects the rate, other than via β. Now, the first term may contain the activities of species other than reactants, (*e.g.* products, catalysts), and the second term those of species other than products. It does not appear to have been demonstrated previously that empirically successful (12) rate expressions like [4] may be reduced to the form of eq. 1, suitable for treatment by n.t. In order to do this, it is necessary to discover the restrictions imposed upon the form of [4] by the requirement that *all* sets of equilibrium activities $\{a_i^{eq}\}$, which correspond to zero affinity, also make v vanish. All catalytic species, which do not affect the affinity, must have $\alpha_i = \alpha_i'$; for reactants and products, it may be shown (13–15) that a necessary and sufficient condition for A and v (given by eq. 4) to vanish together, is

$$[5] \qquad (\alpha_i' - \alpha_i)/\nu_i = n > 0, \text{ for all } i$$

It is readily shown, by considering [4] at equilibrium, that [5] implies;

$$[6] \qquad k/k' = K^n$$

where K is the thermodynamic equilibrium constant for reaction 2, given by

$$[7] \qquad K(T) = \prod_{i=1}^{N} (a_i^{eq})^{\nu_i}$$

In addition, the affinity may be expressed as

$$[8] \quad A = -\sum_{i=1}^{N} \nu_i \mu_i = RT \ln \prod_{i=1}^{N} (a_i^{eq}/a_i)^{\nu_i} = RT \ln \left[K \prod_{i=1}^{N} (1/a_i)^{\nu_i} \right]$$

where $N = n_r + n_p$ is the total number of species involved in reaction 2. Combination of eqs. 4–8 gives

$$[9] \quad v = \left[k\beta \prod_{i=1}^{m} (a_i)^{\alpha_i} \right] \times [1 - \exp(-nA/RT)]$$

recalling that $\alpha_i = \alpha_i'$ for species not appearing in [7] and [8]. In order to reduce [9] to the form of [1], the two factors in [9] may be expanded in Taylor Series in (A/RT). The second factor yields a series which converges for all real (nA/RT); the first factor may be written

$$[10] \quad k\beta \prod_{i=1}^{m} (a_i^{eq})^{\alpha_i} [1 + d_1(A/RT) + \cdots] = k\beta \prod_{i=1}^{m} (a_i)^{\alpha_i}$$

where

$$d_1 = \partial \left[\prod_{i=1}^{m} (a_i/a_i^{eq})^{\alpha_i} \right] \Big/ \partial [A/RT]_{A=0}$$

etc. It is not possible to give a general mathematical discussion of the region of convergence of [10]; however, on physical grounds, [10] must also converge for all real (A/RT), since even at the limit of infinite affinity, reactions are known to proceed with a finite velocity. Then

$$[11] \quad v = \left[k\beta \prod_{i=1}^{m} (a_i^{eq})^{\alpha_i} \right] \times [n(A/RT) + n(d_1 - n/2)(A/RT)^2 + \cdots]$$

Previous derivations (1–11) have involved the special case of [11] with $n = 1$. It may be pointed out that the common practice of identifying $[k\beta \prod_{i=1}^{m} (a_i^{eq})^{\alpha_i}]$ with v_{eq}, the one-way reactive flux at equilibrium, is not necessarily valid (16).

While eq. 4 is a very common rate equation (12), it does not include all known cases; a more general expression for v is

$$[12] \quad v = r(\{a_i\},T,x,y,\cdots) - r'(\{a_i\},T,x,y,\cdots)$$

where $\{a_i\}$ represents the set of activities defining the affinity of the reaction, and $x,y,\cdots$ are non-thermodynamic variables, such as catalyst concentration, area of active surface, etc. Hollingsworth (17) has elucidated necessary and sufficient conditions under which [12] shall vanish for all $\{a_i^{eq}\}$ which cause A to vanish. If f and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

θ are defined by

$$f(\{a_i\}, T,x,y, \cdots) \equiv r'/r$$

$$\theta \equiv \exp(-A/RT) = \prod_{i=1}^{N} (a_i/a_i^{eq})^{\nu_i}$$

then the function f must be (17) such that

$$[13] \qquad f-1 = (\theta-1)[(\partial f^*/\partial\theta)_{\theta=1} + \tfrac{1}{2}(\partial^2 f^*/\partial\theta^2)_{\theta=1}(\theta-1) + \cdots]$$

where $f^* = (r'/r)$ is the function obtained from f by eliminating any *one* a_i from the defining equations for f and θ. If $g \equiv (r/r_{eq})$ may be expanded in a Taylor Series, [13] becomes

$$[14] \qquad v = r_{eq}[(f^*)'(A/RT) + \{\tfrac{1}{2}(f^{*\prime\prime} - f^{*\prime}) + g'f^{*\prime}\}(A/RT)^2 + \cdots]$$

where

$$f^{*\prime} \equiv (\partial f^*/\partial\theta)_{\theta=1}$$

and

$$g' \equiv [\partial g/\partial(A/RT)]_{A=0}$$

etc. It is readily shown that [14] reduces to [11] if [12] has the special form [4].

Thus, even for very general kinetic descriptions, it is possible to show that the rate of a single chemical reaction, occurring in isolation, may be described by a power series in the affinity. This conclusion follows from thermodynamic constraints upon the form of the kinetic rate expression; if the latter is known, the phenomenological coefficients of the n.t. description may be identified kinetically. An assumption implicit in all the above concerns the existence of a unique degree of advancement, and thus of a reaction velocity, for reaction 2; this is not necessarily a trivial problem (18, 19).

III. Thermodynamic Coupling of Chemical Reactions

Thermodynamic coupling of macroscopically distinguishable processes represents the field in which n.t. is highly successful. If two such processes are occurring in the same system, the two rates are given by

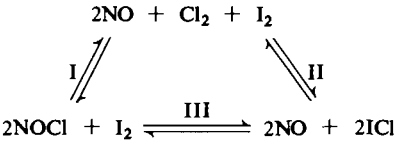
$$[15] \qquad J_1 = L_{11}X_1 + L_{12}X_2 + M_{111}X_1^2 + M_{122}X_2^2 + M_{112}X_1X_2 + \cdots$$

$$J_2 = L_{21}X_1 + L_{22}X_2 + M_{211}X_1^2 + M_{222}X_2^2 + M_{212}X_1X_2 + \cdots$$

If the coupling coefficients $L_{12}, L_{21}, M_{122}, M_{211}, M_{112}$ and M_{212} are nonzero, the two processes are said to be thermodynamically coupled; the Onsager Reciprocity Theorem (O.r.t.) then predicts $L_{12} = L_{21}$ (10). A glaring omission in the generally satisfactory experimental verification of O.r.t. (20) is the lack of any direct test for the chemical case. Previous work in this area has concentrated (1–11) on demonstrating the equivalence, for this case, of O.r.t. and the Principle of Detailed Balance (p.d.b.); these treatments have been restricted to triangular reaction schemes, in which the individual reaction steps follow simple mass-action expressions like [3]. To avoid the complexity of notation required for a completely general development, the particular reaction system, for which experimental data are available, will be treated here.

In an isothermal system, whose thermodynamic state is adequately represented in terms of the concentrations of five species NO, NOCl, Cl_2, ICl, and I_2, it is readily shown (ref. 12, pp. 169–171) that only *two* linearly independent stoichiometric equations may be written. This system may be written as a triangular scheme

[16]



Any two of the three stoichiometric reactions in [16] may be chosen for the thermodynamic description, say I and II. Unambiguous experimental measures of the independent thermodynamic fluxes J_1 and J_2, will then be given by $(+\frac{1}{2}dc_{NO}/dt)$ and $(-dc_{I_2}/dt)$, respectively, if the forward directions are arbitrarily chosen to correspond to the clockwise direction in [16], as written. Assuming that no problems exist concerning definitions of degrees of advancement (18, 19), the n.t. description of the rate of relaxation of [16] is given by eq. 15, with the fluxes defined as above, and the forces given by the affinities of reactions I and II.

If each individual step in [16] is considered independently of the others, the considerations of Section II above apply, so that

$$[17] \qquad v_1 = l_1A_1 + m_1A_1^2$$

$$v_2 = l_2A_2 + m_2A_2^2$$

$$v_3 = l_3A_3 + m_3A_3^2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

where v_1, v_2, and v_3 are the velocities of the individual steps, as distinct from the thermodynamic fluxes J_1 and J_2. As emphasized above, eqs. 17 are a consequence of thermodynamic constraints upon the form of the "true" rate equations at equilibrium. Equations 17 may thus be applied to the complex reaction mixture, in which all three reactions are occurring simultaneously, only if it is assumed that, when the whole system is at equilibrium, each mechanistic step in [16] is independently at equilibrium; this assumption is the Principle of Detailed Balance (p.d.b.).

For mechanism [16], assuming p.d.b., and noting that

$$A_3 = -(A_1 + A_2)$$

and

$$J_1 \equiv \tfrac{1}{2}\mathrm{d}c_{\mathrm{NO}}/\mathrm{d}t = v_1 - v_3$$
$$J_2 \equiv -\mathrm{d}c_{\mathrm{I}_2}/\mathrm{d}t = v_2 - v_3$$

eqs. 15 and 17 give

$$[18]\quad J_1 = (l_1 + l_3)A_1 + (l_3)A_2 + (m_1 - m_3)A_1^2 + (-m_3)A_2^2 + (2m_3)A_1A_2$$
$$J_2 = (l_3)A_1 + (l_2 + l_3)A_2 + (-m_3)A_1^2 + (m_2 - m_3)A_2^2 + (2m_3)A_1A_2$$

whence $L_{12} = L_{21}$, as has been demonstrated previously (1–11). However, extension of this widely-accepted treatment, to second order, shows that higher-order reciprocities are also predicted; should this be true, it would greatly extend the usefulness of n.t. for chemical kinetics. More general derivations of higher-order reciprocities have been given (21–23), independently of any particular mechanism.

It now seems certain that no such simple higher-order reciprocities exist, in general; Andrews (24) has elucidated the often subtle errors in these derivations (21–23), which are macroscopic arguments taking no account of the Principle of Microscopic Reversibility (p.m.r.), which underlies both O.r.t. (10) and p.d.b. (25). In addition, by extending Onsager's original treatment (10), Holmes and Mortimer (26) derived the rather complicated relationship between the higher-order coefficients and those of lower order. For the case of mechanism [16], the present authors have been unable to reduce this relationship (26) to any simple form. It appears, therefore, that the higher-order reciprocities evident in eq. 18 are incorrect, even though the derivation is an apparently trivial extension of standard treatments (1–11), which use p.d.b. explicitly. By considering a very special case, in which the exact kinetic equations could be unambiguously rearranged to the form of [15], Rastogi *et al.* (27) were able to confirm this general conclusion.

The source of error is an ambiguity in the term "independently", as used in justifying eqs. 17. As emphasized in Section II, such rate equations are consistent with the "correct" kinetic equations as a result of thermodynamic constraints upon the latter, considered at the equilibrium state; but the equilibrium state involved is the infinite time-limit for the single reaction concerned, proceeding in isolation. In the complex system, on the other hand, the time variation of the affinity of a given reaction is due not only to the rate of that reaction, as was assumed in deriving [17], but to the rates of the other reactions also. The three reactions are still proceeding "independently", in the sense demanded by p.d.b.; it is the description of these "independent" rates, in terms of the simple eqs. 17, which breaks down. Equation 18 is valid to first order only, as a *consequence* of O.r.t.

As a practical example of some of the difficulties involved, experimental data obtained by Nebeker and Pings (9, 28) for reaction system [16] were reinterpreted; true thermodynamic coupling, as distinct from interference (29), was demonstrated to exist in this system. Reactions I and III were chosen (9) as the independent processes, and the rate data were fitted to second-order equations [15]; in the experiment considered by the original authors (9, 28) to be their best case, the linear coupling coefficients differed by a factor of about -200. As a first attempt to improve upon this result, the raw data (9) were reanalyzed in terms of reactions I and II, since the original treatment of the reverse of reaction III, as a fourth-order reaction, seemed unlikely to be valid. Table 1 shows the results obtained for this best case (270 to 500 s reaction time, run 16 (9)); all other runs (9) gave better fits when second-order terms were included, but this example happened to give the best fit using only linear terms, even though $A > 10RT$. In this case, $L_{21}/L_{12} \simeq -5$, well outside the standard errors; examination of the computed residuals showed alternating sequences of positive deviations and negative deviations, an indication of a poor fitting function (30) (see also Fig. 25, ref. 9).

TABLE 1. Phenomenological coefficients derived for run 16, ref. 11 (Velocities in mol l^{-1} s^{-1}; affinities in calories)

Parameter	Value	
L_{11}	$(7.4\pm1.3) \times 10^{-11}$	$-(32\pm26) \times 10^{-11}$
L_{22}	$-(24.9\pm1.8) \times 10^{-11}$	$(13\pm32) \times 10^{-11}$
L_{12}	$-(5.3\pm1.4) \times 10^{-11}$	$(23\pm23) \times 10^{-11}$
L_{21}	$(25.9\pm1.8) \times 10^{-11}$	$-(16\pm37) \times 10^{-11}$
M_{111}		$(1\pm2) \times 10^{-14}$
M_{222}		$(0.4\pm2) \times 10^{-14}$
M_{122}		$(2.3\pm1.8) \times 10^{-14}$
M_{211}		$(2.6\pm3.2) \times 10^{-14}$
M_{112}		$(1.7\pm2.9) \times 10^{-14}$
M_{212}		$(1.5\pm4.1) \times 10^{-14}$

It is clear that inclusion of only low-order terms in [15] is inadequate, and the first-order coefficients derived from such least squares treatments bear no resemblance to those governing the relaxation near equilibrium (10). Even if sufficient terms were included for [15] to converge, there is no guarantee that the least-squares criterion will yield the correct first-order coefficients, unless data are available well into the linear regime. Another feature of the statistical analysis was the uniformly high level of correlation coefficients between the affinities (0.93 to 0.99). This is merely a quantitative confirmation of Andrews' criticism (24) of treatments which consider affinities to be independent variables; for a given system evolving naturally towards equilibrium, time is the only independent variable.

Although the experimental data obtained by Nebeker and Pings (9) thus appear unsuitable for testing O.r.t., they do, in principle, offer an opportunity for a direct test of p.d.b. However, to do so requires that the rate laws for the reactions involved are either known, or can be reasonably estimated. Reaction I, at room temperature, although not an elementary reaction, does appear (31) to proceed according to the appropriate form of [3]. Reaction II is predicted (32) to proceed by a second-order, bimolecular mechanism, but unfortunately appears to be surface-catalyzed; it was here assumed to proceed according to the appropriate form of [3], with the heterogeneous contribution kinetically indistinguishable. The following mechanism was assumed for reaction III

$$2NO + I_2 \underset{k_{3a}}{\overset{K_{3a}}{\rightleftharpoons}} 2NOI$$

$$NOI + ICl \underset{k_{3b}'}{\overset{k_{3b}}{\rightleftharpoons}} NOCl + I_2$$

This assumed mechanism, with step (3*a*) essentially at equilibrium is an example of one of Hollingsworth's cases (19) where a unique degree of advancement exists for the overall reaction. The mechanism was proposed by analogy with that for the $NO–Cl_2–Br_2$ system (33), and leads to an overall rate law of the form of [6], with $n = 1/2$

$$v_3 = k_2 C_{NO} C_{ICl} C_{I_2}^{\frac{1}{2}} - k_2' C_{NOCl} C_{I_2}$$

assuming ideal gas behavior.

In order to express these assumed rate equations in a form suitable for testing p.d.b. eq. 6 is rewritten

$$[19]\quad v = \left[k\beta \prod_{i=1}^{N} (a_i^{eq})^{\alpha_i}\right]\left[\prod_{i=1}^{N} (a_i/a_i^{eq})^{\alpha_i}\right] - \left[k'\beta \prod_{i=1}^{N} (a_i^{eq})^{\alpha_i'}\right]\left[\prod_{i=1}^{N} (a_i/a_i^{eq})^{\alpha_i'}\right]$$

$$= C \exp(A_f/RT) + C' \exp(A_r/RT)$$

where A_f and A_r are the respective affinities for the process

$$\sum_i \alpha_i M_i(a_i) \rightarrow \sum_i \alpha_i M_i(a_i^{eq})$$

$$\sum_i \alpha_i' M_i(a_i) \rightarrow \sum_i \alpha_i' M_i(a_i^{eq})$$

Here, $M_i(a_i)$ denotes the ith. constituent in a state with activity a_i; also, $A_f - A_r = nA$. Applying [19] to the assumed rate laws for scheme [16], gives

$$[20]\quad J_1 \equiv -\tfrac{1}{2} dc_{NO}/dt = C_{11}\exp(A_{f1}/RT) + C_{11}'\exp(A_{r1}/RT) + C_{13}\exp(A_{f3}/RT) + C_{13}'\exp(A_{r3}/RT)$$

$$J_2 \equiv -dc_{I2}/dt = C_{22}\exp(A_{f2}/RT) + C_{22}'\exp(A_{r2}/RT) + C_{23}\exp(A_{f3}/RT) + C_{23}'\exp(A_{r3}/RT)$$

Although eqs. 20 are expressed in language similar to that of n.t., they are simply re-ex-

TABLE 2. Coefficients for run 13, ref. 11, fitted to eq. 20

Parameter	Value
C_{11}	$(1.3\pm0.1) \times 10^{-12}$
C_{11}'	$-(5.2\pm2.1) \times 10^{-8}$
C_{13}	$-(0.02\pm0.01) \times 10^{-12}$
C_{13}'	$(0.08\pm0.03) \times 10^{-12}$
C_{23}	$(0.019\pm0.005) \times 10^{-12}$
C_{23}'	$-(0.014\pm0.025) \times 10^{-12}$
C_{22}	$(0.002\pm0.001) \times 10^{-12}$
C_{22}'	$-(1.5\pm2.1) \times 10^{-8}$

pressions of the kinetic rate laws. If p.b.d. is obeyed, then

$$[21] \quad C_{11} = -C_{11}'; \; C_{22}' = -C_{22}'; \; C_{13}' = -C_{13}' = -C_{23}' = C_{23}'$$

As shown in the typical result given in Table 2, this analysis also yielded negative results. This was doubtless due to erroneous assumptions made in writing the appropriate rate laws.

IV. Discussion

It is clear that there are no shortcuts in chemical kinetics; regardless of the language chosen to describe the rate, there is no substitute for an experimental determination of the rate equation. The only partial exception to this conclusion is expected to involve systems sufficiently close to equilibrium that rates are linear functions of affinities. In practical terms, this is probably limited to electrode reactions, where affinities are precisely controllable and measurable electrically (34). The importance of the linear regime lies in the validity of O.r.t. only at first-order; for the conventional kinetic description, on the other hand, p.d.b. offers a simplification over the entire range of affinities.

Even in the linear regime, a fundamental disadvantage of the n.t. description arises from the fact, apparent from a comparison of eqs. 1 and 14, that the coefficients are functions of the equilibrium state of the system. This implies that phenomenological coefficients, measured in one reaction mixture, cannot be applied directly to another. The necessary transformation can be made, but, as shown in Section II above, this requires knowledge of the relevant *kinetic* rate laws. In the latter case, only correction factors, such as β in eq. 4, vary in this way.

It is possible that these disadvantages of the n.t. description could be outweighed, for example, if thermodynamic coupling should be important. For the case of coupled chemical reactions, examination of eq. 18 shows that the coupling coefficients vanish if $l_3 = 0 = m_3$. Such coupling is thus simply a consequence of the thermodynamically redundant, but mechanistically significant, reaction III, and is thus well within the realm of conventional chemical kinetics. However, it has been suggested that n.t. offers an ideal language for a description of systems in which chemical rates are coupled to other processes, such as diffusion. However, direct coupling coefficients between forces of different tensorial orders, are identically zero, according to the Curie–Prigogine Principle (ref. 5, pp. 88–89). In the present case, this simply implies that a local chemical rate is independent of the local composition gradient; proposed mechanisms for "indirect" coupling of chemical rates to diffusion processes, although expressed in the n.t. formalism, (ref. 5, Chap. 14), appear equally valid if the chemical rate is described differently.

The present work has thus resulted in generally negative conclusions concerning the suitability of the n.t. language for chemical kinetics. Similar opinions have been expressed previously (11, 35), although the treatment of the principal points, discussed above, was considerably less detailed. However, O.r.t. is a fundamental theorem, offering the possibility of a macroscopic test of p.m.r.; we are presently attempting to test O.r.t. for the chemical case, using a relaxation technique with phase-sensitive detection to aid in obtaining precise data in the linear regime.

Financial support by the National Research Council of Canada is gratefully acknowledged. The Institute of Computer Studies, University of Guelph, provided valuable assistance with the statistical analysis.

Use of a Gettering Material to obtain Oxygen-free Liquid Samples for Nuclear Spin Relaxation Studies

H. S. SANDHU
Physics Department, University of Victoria, Victoria, British Columbia

Received November 3, 1970

An investigation into the gettering powers of aluminum, barium, magnesium, and misch metal for removing oxygen from liquid samples has been carried out. The liquids treated with each getter are: H_2O, CH_2Br_2, CH_2Cl_2, CH_2I_2, and CH_3OH. The results show that aluminum is more suitable for all these liquids even though the other getters are also effective. It appears that as long as there is no strong reaction, any of these getters can be used to remove oxygen from any liquid.

Une étude a été faite de la valeur de l'aluminum, du barium, du magnésium et du métal Misch® comme getters pour l'élimination de l'oxygène d'échantillons liquides. Les liquides traités avec chaque getter sont: H_2O, CH_2Br_2, CH_2Cl_2, CH_2I_2 et CH_3OH. Les résultats montrent que l'aluminum est le plus approprié pour tous ces liquides quoique tous les autres métaux étaient aussi effectifs. Il apparaît qu'en autant qu'il n'y a pas de réaction violente, n'importe lequel de ces getters peut être utilisé pour l'élimination de l'oxygène de tout liquide.

Canadian Journal of Chemistry, 49, 1008 (1971)

It is well known that the nuclear spin – lattice relaxation time T_1 in liquids is extremely sensitive to small amounts of dissolved oxygen. It is, therefore, necessary to remove oxygen from the liquid sample in order to study T_1 of the pure liquid. In addition to methods involving bubbling of helium, distillation under vacuum, or freeze–pump–thaw techniques (1–5), misch metal (6) and barium (7) have been used for removing oxygen from liquid samples so that T_1 could be measured in pure liquids. Magnesium (1) has also been used to degas in certain instances but its use as a getter has not been investigated in any detail.

It is the purpose of this paper to report an investigation into the use of aluminum and magnesium as getters. A simple and reliable technique has been developed for preparing the samples and a detailed comparison of the gettering powers of aluminum, magnesium, misch metal, and barium for obtaining oxygen-free samples has been carried out.

Experimental Procedure

A $\frac{1}{2}$-liter flask has two tungsten electrodes E of 0.04 in. diameter sealed through one end of the ground glass joint G and a small tube B on one side as shown in Fig. 1. A tungsten wire of 0.015 in. diameter wound in the form of a coil of about $\frac{5}{16}$ in. i.d. and containing the metal to be used as a getter is connected to the electrodes by stainless steel clamps C. M_1, M_2, and M_3 are metal valves.

The system is evacuated to a pressure of about 10^{-6} mm and baked several times to remove oxygen adsorbed on the walls. After boiling the tube S for about 30 min in distilled water, it is filled with a small amount of liquid and connected to the system by the demountable vacuum union D. The sample is frozen in a liquid nitrogen bath and the air above the sample pumped out by opening M_1. When a pressure of about 10^{-6} mm has been attained again, M_1 is closed and the flask is filled with argon[1] to a pressure of $\frac{1}{2}$–1 mm. The metal is then evaporated by passing a current through the tungsten coil using a variac. After the metal has been deposited properly, the argon is pumped out and valve M_2 is closed.

The sample is now transferred to the tube B by immersing the tube in a liquid nitrogen bath. Once transfer is completed, the liquid nitrogen bath is removed in order to allow the getter to degas the sample. The sample is then transferred to the trap above the tube A by pumping on the liquid and freezing the vapors in the trap. The tube A is finally sealed off from the system after collecting the sample in it.

It may be pointed out that the variac is set at such a value so as to provide just enough current to cause evaporation of the metal. The current is passed intermittently to prevent the joint G and coil T from overheating. The joint G is also kept cool by wrapping it with a wet cloth. Since the depositing of each getter requires slightly different procedures, each getter will be discussed in turn.

Aluminum

Aluminum was tried both in the form of a wire of 5 mil diameter and foil of 1 mil thickness. Foil was found to be easier to heat. The 1 in. × 1 in. foil was rolled into a cylinder and inserted inside the coil of 12–13 turns in $\frac{3}{4}$ in. length. The ends of the foil were pushed over the coil edges to prevent it from slipping. Since aluminum reacts with tungsten, it was found necessary to heat the foil rather quickly. A dark grey deposit was obtained.

[1]Reagent Assayed Grade Argon supplied by Matheson Company of Canada, P. O. Box 322, Whitby, Ontario.

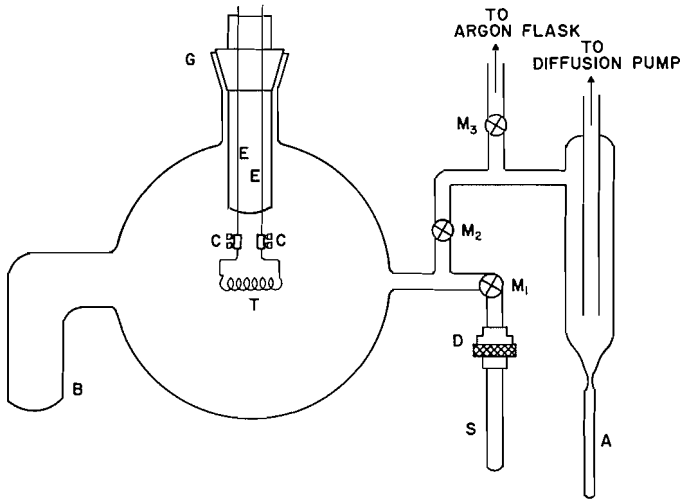

FIG. 1. Schematic diagram of the system for obtaining oxygen-free liquid samples.

TABLE 1. Nuclear spin – lattice relaxation time T_1 of oxygen-free liquids at 30 °C

	T_1 (s) with getter				
Liquid	Aluminum	Magnesium	Barium	Misch metal	Reported values
H_2O	3.91	3.89	3.79	3.93	3.96*
CH_2Br_2	14.40	14.50	14.20	14.20	14.70†
CH_2Cl_2	30.25	30.67	30.72	29.90	31.25‡
CH_2I_2	6.18	5.87	6.02	6.20	6.21†
CH_3OH	8.10	5.45	8.18	8.50	8.95§

*See ref. 10.
†See ref. 5.
‡See ref. 11.
§The sample was prepared using the technique described in ref. 5.

Barium

Barium was used in small pieces cut from a rod of 0.85 in. diameter. It was always kept immersed in paraffin oil to prevent oxidation. It was found necessary to place the metal pieces inside the flask as quickly as possible in order to minimize its contact with air. A tungsten coil of 20–22 turns in 1 in. length and containing closely packed barium pieces produced a good deposit of a dark grey-black color.

Magnesium

Small pieces of magnesium were closely packed in a tungsten coil of 12–14 turns in 1 in. length. Since magnesium has a lower melting point than the other getters, it was easy to produce a good diffused deposit of light grey color.

Misch Metal

Misch metal[2] was in rod form of diameter 0.165 in. Four to five small pieces in a tungsten coil of about 12 turns in 1 in. length generally produced a good deposit of dark black color. It was found easier to evaporate the metal by holding each piece between turns instead of placing the pieces inside the coil.

It may be pointed out that the getter was always deposited in the presence of argon because the gettering power of the diffused deposited layer is much higher (8) than the bright shiny deposit obtained without the presence of argon. Samples were taken after keeping the liquid in contact with the getter for (*i*) 2–4 h, (*ii*) 6–7 h, and (*iii*) 24 h.

Results and Discussion

The liquids investigated with each getter were H_2O, CH_3OH, CH_2Br_2, CH_2Cl_2, and CH_2I_2. The measurements of nuclear spin – lattice relaxation time T_1 were made at 30 °C using pulse techniques (9) and have an accuracy of $\pm 5\%$. The results are summarized in Table 1. These

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

results show that all getters are equally effective in removing oxygen except for those liquids which react strongly with the getter. It was found that the samples taken after 2–4 h gave the same T_1 values as the others taken after longer intervals. It was also observed that heating the getter did not improve its gettering power noticeably.

Lees *et al.* (6) expressed uncertainty in the applicability of their technique to the degassing of water. The technique mentioned in this paper does work effectively for water. Aluminum appears to be more suitable for water as well as the other liquids because no change in the color of the deposit was observed. Barium, magnesium, and misch metal deposits did change in color in the presence of water but T_1 values in each case agree with the previously reported values. Furthermore, no deterioration of any sample was observed even after several weeks.

All getters are equally effective for CH_2I_2, CH_2Cl_2, and CH_2Br_2 even though barium deposit showed some change in color for these liquids.

CH_3OH appears to react strongly with all getters except aluminum.

It may be pointed out that the technique described is quite different from that used by Moniz *et al.* (7) and is a considerable improvement over the one described by Lees *et al.* (6). Some of the features of this technique are: (*1*) The joint *G* (Fig. 1) simplifies the assembly of the gettering material; (*2*) the same flask can be reused after removing the deposit with chromic acid; and (*3*) since the sample is sealed from the system, it prevents any deterioration of the sample by the getter.

Aluminum appears to be a more suitable getter for these liquids. However, other getters are also equally effective except for those liquids which react strongly with the getter. It would, therefore, appear that any of these getters can be used for removing oxygen from any liquid as long as there is no strong reaction between the liquid and the getter.

This work was supported in part by a grant from the National Research Council of Canada and in part by a grant from the University of Victoria. I am indebted to M. J. Bulinckx for his assistance in this work. I also thank A. Eisenberg and D. Searle for their assistance in glass blowing.

Cyclic Imides. Preparation of Silylphthalimides and Characterization by Infrared and Mass Spectrometry

A. F. JANZEN AND E. A. KRAMER
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba

Received September 15, 1970

A series of silylphthalimides containing silicon substituents —H, —CH_3, —C_2H_5, —$CH_2CH{=}CH_2$, and —C_6H_5 have been prepared and characterized. The compounds are *N*-silylated and found to be monomeric in the liquid and gas phase. The i.r. spectroscopic studies in dilute (10^{-1} *M*) chloroform solution showed a decrease (approximately 40 cm^{-1}) in the carbonyl stretching frequency on silylation, but relatively small changes (± 7 cm^{-1}) on changing silicon substituents. The major effect appears to be electron donation by silyl groups. The N^{15} isotopomers were prepared and C—N and Si—N vibrations identified.

Mass spectrometric studies of methyl- and phenylsilylphthalimides, including N^{15} substitution, are reported. A possible mechanism of formation of methyl- and phenylbiphenylene silicon ions, involving loss of methyl or phenyl, carbon dioxide, and hydrogen cyanide, is suggested.

Une série de phtalimides sililés contenant des substituants liés au silicium —H, —CH_3, —C_2H_5, —$CH_2CH{=}CH_2$, et —C_6H_5 ont été préparés et caractérisés. Les composés sont *N*-sililés et se trouvent sous forme de monomères en phase liquide et gazeuse. Les études par spectroscopie i.r. en solution diluée dans le chloroforme indiquent une diminution (approximativement 40 cm^{-1}) de la fréquence de vibration du carbonyl, suite à la sililation, mais relativement peu de variation (± 7 cm^{-1}) si les substituants liés au silicium sont changés. L'effet principal apparaît comme étant l'effet donneur d'électrons des groupes sililés. Les isomères isotopiques N^{15} ont été préparés et les vibrations C—N et Si—N identifiés.

L'étude par spectrométrie de masse des méthyl et phényl phtalimides sililés, incluant les dérivés N^{15} substitués, est rapportée. Un mécanisme possible de la formation des ions méthyl- et phényl-biphénylène siliconium est suggéré et implique la perte de méthyle ou phényle, de dioxyde de carbone et de cyanure d'hydrogène.

Canadian Journal of Chemistry, 49, 1011 (1971)

Silicon–nitrogen compounds are useful synthetic intermediates in organic and organometallic chemistry (1). We have prepared a variety of silylphthalimides, including N^{15} isotopomers, and studied their i.r. and mass spectra. Although a number of silylphthalimides have been prepared previously (2) few details of their spectral properties or synthetic applications have been reported.

Table 1 lists compounds **1** to **7** prepared for this study. All are *N*-silylated and no evidence was found for *O*-silylation, although *O*-silylation may occur in cyclic imides if resonance stabilization is possible (3).

The compounds are monomeric in gas phase as determined by mass spectrometry, and monomeric in solution as confirmed by molecular weight measurements for **1** and **5**. The extent of association in the solid phase has not been established.

The silylphthalimides are relatively stable and may be handled in air, with the exception of **4** and **5**, where the presence of silicon–hydrogen bonds may account for more rapid hydrolysis.

Infrared Spectra

The i.r. spectra were examined in the region 4000–400 cm^{-1} with emphasis on those regions where C═O, Si—H, and Si—N vibrations normally occur.

In 10^{-1} *M* $CHCl_3$ solution, two bands were found in the carbonyl region, separated by 50 ± 7 cm^{-1}. These bands are generally assigned to the vibrationally coupled symmetric (higher frequency, weak intensity) and anti-symmetric (lower frequency, strong) modes of vibration (4). Values of C═O(asymmetric) for compounds **1** to **7** were found in the range 1700 ± 7 cm^{-1} as recorded in Table 1.

These C═O(asymmetric) values are lower than in phthalimide (1738 cm^{-1}, $CHCl_3$ solvent) or in phthalimide derivatives *e.g.N*-methylphthalimide (1720 cm^{-1}, CCl_4), 4-amino-*N*-methylphthalimide (1760 cm^{-1}, CCl_4 and 1766 cm^{-1}, $CHCl_3$) and 3,6-diamino-*N*-methylphthalimide (1748 cm^{-1}, CCl_4 and 1740 cm^{-1}, $CHCl_3$) (5).

The lowering in frequency on silylation may be ascribed to electron donation by the silyl group.

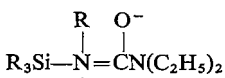
I

Polarization of the carbonyl bond, as in **I**, will be increased by electron donation resulting in a reduced bond order.[1] Metal complexing via the phthalimido carbonyl should result in a similar lowering as has been observed by Jain and Rivest (6). Analogous contributing structures such as **II** are considered important in describing the



II

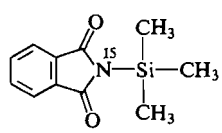
reactivity of silyl ureas (7).

Changing substituents on silicon has a relatively small effect on carbonyl absorptions (see Table 1). These effects could be accounted for by minor changes in molecular geometry, Si—N d_π—p_π bonding or intermolecular association.

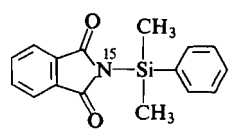
Compounds **4** and **5** showed strong Si—H absorptions at 2194 and 2188 cm^{-1}, respectively, in the region expected for Si—H stretching frequencies (9).

Vibrations characteristic of the Si—N bond may vary considerably. A band at 899 cm^{-1} has been assigned to the Si—N stretching frequency in trimethylsilylaniline (10) whereas a band at 945 cm^{-1} was found in bis-trimethylsilylacetamide (7) and the region 1170–1180 cm^{-1} was found characteristic of the Si—N bond in *N*-silyl-heterocycles (11).

Silylphthalimides prepared for this study showed a strong band at 1074 ± 9 cm^{-1}, as recorded in Table 1, which we assign to a Si—N vibration. This assignment is supported by the i.r. spectra of N^{15} isotopomers **8** and **9**.



8



9

Only two bands shift significantly on N^{15} substitution as shown in Table 2. The bands at

[1]The lowering of C=O(asymmetric) in platinum phthalimides has been explained in opposite terms *i.e.* electron withdrawal (8).

TABLE 2. The i.r. bands which shift on N^{15} substitution

Compound	C—N (cm^{-1})	Si—N (cm^{-1})
 8	N^{14} 1295 N^{15} 1285	N^{14} 1071 N^{15} 1047
 9	N^{14} 1295 N^{15} 1284	N^{14} 1072 N^{15} 1048

higher frequency, around 1290 cm^{-1}, are probably C—N vibrations or more complex mixed vibrations (12). Very similar bands were found for phthalimide-N^{15} and potassium phthalimide-N^{15}.

The band in the 1070 cm^{-1} region is then assigned to a Si—N stretching vibration. The N^{15} substitution shifts this band about 24 cm^{-1} to lower frequencies.[2] The Si—N band is generally broad, and in some cases additional bands are resolved. For example two bands are found in the 1070 cm^{-1} region of N^{14}-dimethylphenylsilylphthalimide, as shown in Fig. 1*a*. On N^{15} substitution, as shown in Fig. 1*b*, the more intense band at 1070 cm^{-1} shifts and therefore it is assigned to the Si—N stretching vibration.

Mass Spectra

There has been considerable interest recently in the mass spectra of organic phthalimides especially regarding the loss of CO_2 and the possibility of an imide–isoimide interconversion due to electron impact (13–15). We find that silylphthalimides also lose CO_2 but important differences are evident in their overall fragmentation schemes. Only methyl- and phenyl-silylphthalimides **1**, **2**, **3**, and the N^{15} isotopomer **9** will be discussed at this time since the remaining silylphthalimides showed more complex behavior not yet analyzed.

The mass spectra of compounds **1**, **2**, **3**, and **9** are shown in Fig. 2. Transitions supported by metastable peaks are indicated by an asterisk in

[2]The calculated frequency shift using the expression $\nu_i = \nu[\mu/\mu^1]$ is 25 cm^{-1}; if i = isotope, ν = 1070 cm^{-1}, μ = reduced mass.

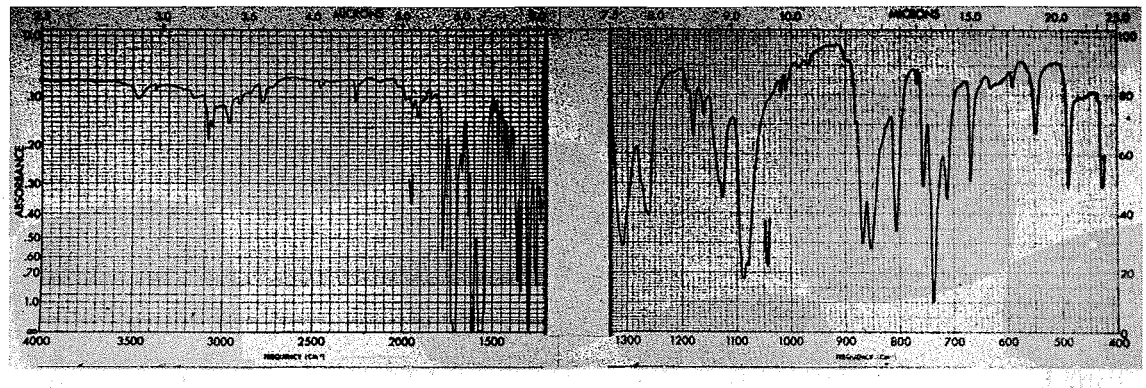

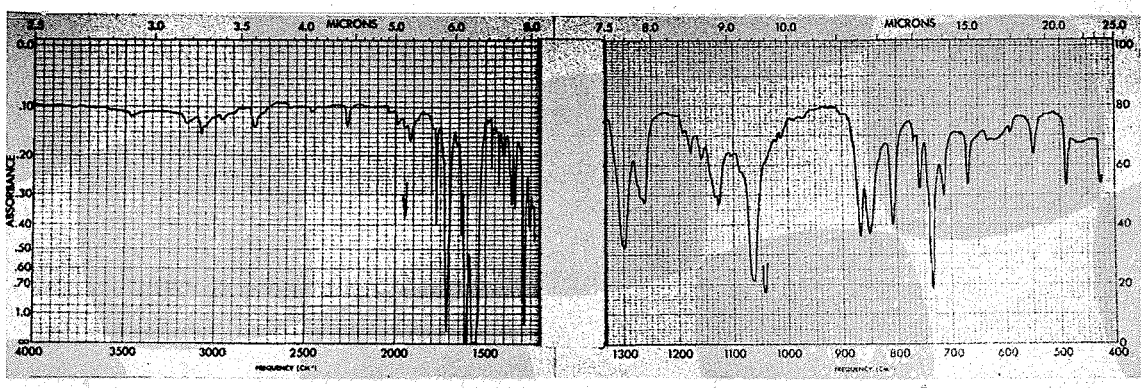

FIG. 1. The i.r. spectra of (*a*) *N*-(dimethylphenylsilyl)phthalimide (**2**) and (*b*) N^{15}-(dimethylphenylsilyl)phthalimide (**9**) recorded as mulls in hexachlorobutadiene (4000–1200 cm^{-1}) and Nujol (1330–400 cm^{-1}). Bands in region 1630–1550 cm^{-1} due to solvent.

TABLE 3. Some metastable peaks observed in the fragmentation of methyl- and phenyl-silylphthalimides

Compound	Observed	Calculated	Transitions
2	251.9	251.8	$281 \rightarrow 266 + CH_3$
9	253.0	252.8	$282 \rightarrow 267 + CH_3$
1	125.5	125.5	$204 \rightarrow 160 + CO_2$
9	126.5	126.4	$205 \rightarrow 161 + CO_2$
2	185.7	185.3	$266 \rightarrow 222 + CO_2$
9	186.5	186.3	$267 \rightarrow 223 + CO_2$
3	245.9	245.9	$328 \rightarrow 284 + CO_2$
2	171.1	171.3	$222 \rightarrow 195 + HCN$
9	170.8	170.5	$223 \rightarrow 195 + HCN^{15}$
2	80.1	80.0	$130 \rightarrow 102 + CO$
9	81.0	81.0	$131 \rightarrow 103 + CO$
9	55.0	56.1	$103 \rightarrow 76 + CN^{15}$

Fig. 2 and some metastable ions are listed in Table 3. These experimental results may be rationalized in terms of an overall fragmentation scheme shown in Fig. 3.

As seen in Fig. 3 the simplest fragmentation pattern is found for compound **1**. Molecular ion **a** loses CH_3 to give **b**. Ion **b** is analogous to **q** which has been suggested for *N*-*t*-butylphthalimide (14). Now **b** loses CO_2 to give **c** whereas **q** loses $CH_2{=}C{=}CH_2$.

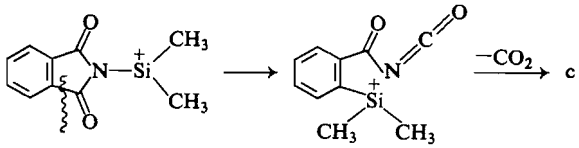
q **r** **s**

Loss of CO_2 may be preceded by electron impact induced isomerization. Anderson *et al.* suggested an imide–isoimide interconversion to explain the identical fragmentation patterns and loss of CO_2 for *N*-phenylphthalimide **r** and *N*-phenylisophthalimide **s** (15). Anderson *et al.* suggested the rearrangement occurs via an intermediate related to a spirolactam. For our purposes, however, their process could be described as breakage of a carbon–nitrogen bond followed by rotation and formation of oxygen–carbon bond.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Silylphthalimides could then lose CO_2 if a carbon–phenylene bond is broken, followed by rotation and formation of a phenylene–silicon bond.



b b′

At some stage rearrangement could result in a benzoyl isocyanate derivative **b′** since benzoyl isocyanate is known to lose CO_2 in the ground state under mild conditions (16).

Extension of the above scheme accounts adequately for the mass spectra of **2** and **3**. In particular, the process resulting in a biphenylene silicon

$$\mathbf{f} \xrightarrow{-HCN} \mathbf{g}$$

derivative, **g**, is readily explained. A peak at *m/e* 97.5, assigned to doubly-charged ion $(\mathbf{g})^{++}$, supports the highly aromatic structure suggested for **g**.

Additional ions **n**, **o**, and **p** were found in all silylphthalimides and these ions are also characteristic of organic phthalimides.

Experimental

General

All compounds were manipulated in a conventional vacuum system or under dry nitrogen atmosphere. Organochlorosilanes were purchased from Peninsular Chemresearch, phthalimide from Aldrich Chemical Co., and potassium phthalimide-N^{15} from Merck, Sharp and Dohme of Canada Ltd. All solvents were dried and distilled prior to use. Elemental analyses and molecular weights (Rast method) were carried out by Dr. A. Bernhardt, West Germany.

The i.r. spectra were determined on a Perkin–Elmer 337 spectrophotometer using KBr windows and calibrated against polystyrene film. Mass spectra were obtained on a Hitachi Perkin–Elmer RMU-6D mass spectrometer at 50 eV. Samples were introduced directly into ion source. The chamber temperature was approximately 230°.

Preparation of N-(Dimethylphenylsilyl)phthalimide

Potassium phthalimide (5.72 g, 30.9 mmol), made from potassium pentoxide and phthalimide according to the method of Hammick and Locket (17) (commercial potassium phthalimide gave impure final products) was added to 50 ml dry tetrahydrofuran in 150 ml flask with reflux condenser under nitrogen atmosphere. Dimethylphenylchlorosilane (5.72 g, 33.6 mmol) was added slowly with stirring. Reaction mixture was heated to 60° for 15 min then cooled to 0° and potassium chloride filtered off. Solvent and volatile components were pumped off leaving a white solid. By dissolving the latter in dry benzene the unreacted insoluble phthalimide was filtered off leaving product in solution. Recrystallization from benzene gave *N*-(dimethylphenylsilyl)phthalimide (5.1 g, 27.6 mmol).

N^{15}-(Dimethylphenylsilyl)phthalimide was prepared from potassium phthalimide-N^{15} (0.401 g, 2.16 mmol) and dimethylphenylchlorosilane (0.375 g, 2.20 mmol) according to the procedure above.

The typical procedure outlined for *N*-(dimethylphenylsilyl)phthalimide was repeated for each silylphthalimide. Products were recrystallized from benzene in yields of at least 50%. *N*-(Triethylsilyl)phthalimide was purified by vacuum distillation (b.p. 112° at 10^{-2} mm).

The ^1H n.m.r. spectra at 60 MHz were obtained for all compounds. Chemical shifts, coupling constants, and proton integrations were all consistent with structures shown in Table 1.

Polysaccharides of Soybeans. VI. Neutral Polysaccharides from Cotyledon Meal

G. O. Aspinall and I. W. Cottrell
Department of Chemistry, Trent University, Peterborough, Ontario

Received September 11, 1970

An arabinan and the previously characterized arabinogalactan and acidic polysaccharide complex have been isolated by extraction of defatted and deproteinized soybean cotyledon meal with water. Methylation analysis involving gas chromatography – mass spectrometry of methylated alditol acetates formed from the methylated arabinan has shown that the parent polysaccharide is highly branched and of the same structural type as other arabinans associated with pectins. Methylated derivatives of mustard seed and lemon-peel arabinans and of soybean arabinogalactan have been similarly analyzed.

Un arabinane ainsi qu'un arabinogalactane et un polysaccharide acide déjà connus ont été isolés par extraction à l'eau de fèves soya cotylédon dont on a préalablement éliminé les matières grasses et les protéines. L'analyse des alditols partiellement méthylés et acétylés obtenus à partir de l'arabinane méthylé par la technique de chromatographie en phase gazeuse et spectrométrie de masse, montre que le polysaccharide est hautement branché et qu'il a le même type de structure que d'autres arabinanes qui se trouvent dans les pectines. On a analysé de la même façon les dérivés méthylés des arabinanes obtenus de graines de moutarde, de pelures de citron et de l'arabinogalactane provenant des fèves soya.

Canadian Journal of Chemistry, 49, 1019 (1971)

In previous studies (1, 2) an arabinogalactan and an acidic polysaccharide complex have been isolated from soybean cotyledon meal and the main structural features of these polysaccharides have been established. In parallel investigations Morita and co-workers (3–5) have obtained similar evidence for the structure of the arabinogalactan. Morita also reported (3) that this polysaccharide, which was isolated by extraction of the meal with hot water after removal of the protein with cold dilute alkali, was accompanied by an arabinan whose structure was not examined. Arabinans of the type which are associated with pectins may be of genuine natural occurrence, *e.g.* in white mustard seeds (6–8), but polysaccharides containing a high proportion of arabinose residues in similar types of linkage, *e.g.* from sugar beet (9, 10) can also result from degradation during alkaline conditions of extraction. We have therefore re-examined the more readily soluble polysaccharides from soybean cotyledons isolated under the mildest possible conditions.

Defatted soybean cotyledon meal was extracted with (*i*) phenol – acetic acid – water (1:1:1) (11) to remove protein and (*ii*) water at 85° to remove the more soluble polysaccharides. Further removal of protein from the aqueous extract followed by fractional precipitation and chromatography on diethylaminoethylcellulose afforded an arabinan, an arabinogalactan, which contained arabinose and galactose residues in the proportions of 1:2.8, and an acidic polysaccharide complex. Paper chromatography of the neutral and acidic oligosaccharides formed on partial acid hydrolysis and acetolysis of the acidic polysaccharide complex showed that this preparation was at least qualitatively similar to the previously studied sample (1, 2) which had been extracted under harsher conditions. Likewise gas chromatography of the methyl glycosides formed on methanolysis of the methylated arabinogalactan showed that the parent polysaccharide was qualitatively similar to that studied previously by Morita and co-workers (3–5) and by ourselves (1, 2).

Evidence for the structure of the arabinan was obtained by methylation analysis. Methanolysis of the methylated arabinan gave components with the retention times of methyl glycosides of 2,3,5-tri- and 2,3-di-*O*-methylarabinose. Although no methyl glycosides of a mono-*O*-methylarabinose were detected by g.l.c., paper chromatography of the hydrolysate of the methylated polysaccharide showed the presence of 2,3,5-tri- , 2,3,-di-, and 2-*O*-methylarabinose in approximately equimolar proportions together with traces of 3-*O*-methylarabinose and the unsubstituted sugar. These results therefore indicate that the arabinan is a highly branched polysaccharide containing $1 \rightarrow 3$- and $1 \rightarrow 5$-linked arabinofuranose residues. Assuming that the constituent sugar is the L-enantiomer commonly found in plant polysaccharides, the highly negative specific optical rotations of the parent polysaccharide ($[\alpha]_D - 108°$) and the

TABLE 1. The g.l.c. of methylated alditol acetates from methylated polysaccharides

Acetate of	Retention time (T_E)*	Percentages of components from methylated derivatives of: Soybean arabinan	Soybean arabinogalactan	Lemon-peel arabinan	Mustard seed arabinan
2,3,5-Me_3 Arabinitol	0.57	39.2	6.1	30.0	39.6

2-Me Arabinitol	2.60	14.2		15.0	28.6
3-Me Arabinitol	2.89	6.0		4.6	tr
Arabinitol	3.62	10.5		12.0	6.3
2,3,6-Me_3 Galactitol	3.45		70.1		
2,6-Me_2 Galactitol	4.27		9.5		

*Relative to erythritol tetraacetate.
†Estimated as a single component. The presence of some 2,3,4,6-Me_4 galactitol acetate (with similar retention time on column *c*) as a minor component (< 20%) of the fraction was indicated by the appearance of a primary peak *m/e* 145 in the mass spectrum.

methylated derivative ($[\alpha]_D - 130°$) suggest that the majority, at least, of the sugar residues are those of α-L-arabinofuranose.

In view of our failure to detect methyl glycosides of 2-*O*-methylarabinose in the methanolysate from the methylated arabinan (presumably because of irreversible adsorption on the column) additional evidence for the identities of the sugars formed on hydrolysis of the methylated polysaccharide was obtained by examination of the products of reduction with sodium borohydride and subsequent acetylation. The identities of the major components of the mixture of methylated alditol acetates were established by combined g.l.c. – mass spectrometry (12) and by comparison with the components in a similar mixture derived from the previously characterized methylated mustard seed arabinan (6, 7). The presence of 3-*O*-methylarabinitol tetraacetate as a minor component of the mixture derived from the soybean arabinan was indicated by the appearance of a primary fragment *m/e* 189 in the mass spectrum (12). The cleavage products from methylated lemon-peel arabinan (13) were also examined by this procedure. The quantitative results are summarized in Table 1. The soybean arabinan is clearly of the same general type as other arabinans associated with pectins. The degree of branching in the soybean arabinan through *ca.* 30% of arabinose residues as indicated by the methylation data is in agreement with the observation that oxidation of the polysaccharide with periodate resulted in the consumption of 0.69 mol of reagent per sugar residue.

Previously examined samples of soybean arabinogalactan (1, 4) were shown to contain L-arabinofuranose residues as sidechains with every fourth or fifth β-D-galactopyranose residue carrying on the average two such residues in disaccharide units. The present arabinogalactan preparation contained a slightly lower ratio (1:2.8) of arabinose to galactose residues. The absence of mono-*O*-methylarabinose as a cleavage product from the methylated polysaccharide indicated the absence of branching through arabinose residues. The evidence on this point has now been re-assessed by examination by combined g.l.c. – mass spectrometry of the mixture of methylated alditol acetates formed from the methylated arabinogalactan (see Table 1). The rather lower ratio (1:4) of arabinose to galactose residues in the methylated polysaccharide than in the parent polysaccharide (1:2.8) may be explained if some contaminating arabinose in the original preparation had been lost during the methylation. Insofar as the present results again failed to provide any indication for branching through arabinose residues in the polysaccharide, the evidence requires that the main component of the polysaccharide preparation is a true arabinogalactan.

Experimental

Paper chromatography was carried out in the following solvent systems (v/v): (A) ethyl acetate – pyridine – water (10:4:3); (B) ethyl acetate – acetic acid – formic acid – water (18:3:1:4); (C) ethyl acetate – acetic acid – formic acid – water (18:8:3:9); and (D) butanone–water–ammonia (200:17:1). The g.l.c. was performed with a Hewlett–Packard model 5750 chromatograph using columns of (*a*) 5% by weight of neopentylglycol adipate polyester at 165°; (*b*) 10% by weight of Carbowax 20M at 190°; and (*c*) 3% by weight of silicone gum XE-60 at 170° on dichlorodimethylsilane treated Celite. were injected into column *c* in a Pye 104 chromatograph attached to an A.E.I. MS 12 mass spectrometer. The mass spectra were recorded at an inlet temperature of 200°, ionization potential of 70 eV, and a temperature of the ion source of *ca.* 150°. Electrophoresis of polysaccharide solutions (1%) were performed in 0.05 *M* sodium tetraborate buffer at p*H* 9.25, using a Tiselius type, Spinco Model H apparatus with Schlieren optics, and currents of 13 mA were maintained. Galacturonic acid contents were determined by a modified carbazole – sulfuric acid procedure (14). Protein was determined with the Folin phenol reagent (15). Optical rotations were measured on a Perkin–Elmer model 141 polarimeter at *ca.* 22° and, unless otherwise stated, were for aqueous solutions.

Extraction of Soybean Cotyledons and Fractionation of Polysaccharides

Soybean cotyledons (Lindarin variety, 1.5 kg) were extracted with boiling light petroleum (b.p. 60–80°) for 2 days, dried, and ground to a flour, and the flour was further extracted with boiling light petroleum for 2 days and then with boiling ethanol–water (4:1) for 2 days to remove coloring matter and soluble sugars (glucose, fructose, sucrose, raffinose, and higher oligosaccharides). Cotyledon meal (1 kg) was stirred for 2 days in phenol (6 kg), acetic acid (6 l), and water (6 l). The swollen meal was separated from the viscous supernatant liquid by high-speed centrifugation, and extraction of the resulting meal was repeated three times. The swollen residue was suspended in ethanol for several hours, the operation was repeated, and the deproteinized meal (440 g) was dried after further washing with ether. The combined extracts were dialyzed to remove phenol and acetic acid, and a portion of the resulting solution was hydrolyzed to give only traces of galactose and mannose.
