Isotopic exchanges in the treatment of cyclobutane with tritiated or deuterated trifluoromethanesulfonic acid or with tritiated sulfuric acid

CHOI CHUCK LEE AND ERIC C. F. KO
Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0
Received May 1, 1979

CHOI CHUCK LEE and ERIC C. F. KO. Can. J. Chem. **58**, 1 (1980).

When cyclobutane (**1**) is shaken at 0°C with $[^3H]CF_3SO_3H$ (**2**-*t*) or with $(^2H)CF_3SO_3H$ (**2**-*d*), incorporation of T or D into the hydrocarbon layer readily occurred. All eight H atoms of **1** can be involved in the exchange since polydeuterated species including octadeuterated hydrocarbons were observed by mass spectrometry. In an experiment with **1** and **2**-*t*, quenching of the acid layer with H_2O gave a mixture of cyclobutanol, cyclopropylcarbinol, and allylcarbinol in the ratio of 61:37:2, respectively, as estimated by isotopic dilution, while vpc analysis of the hydrocarbon layer showed the presence of **1**, methylcyclopropane, and 1-butene in the ratio of 66:30:4. The results are explained by a carbocationic chain mechanism, involving the formation of equilibrating bicyclobutonium ions. Similar but slower incorporation of T into the hydrocarbon layer was observed when **1** was treated with $[^3H]H_2SO_4$.

CHOI CHUCK LEE et ERIC C. F. KO. Can. J. Chem. **58**, 1 (1980).

Quand on agite le cyclobutane **1** à 0°C avec de l'acide trifluorométhane sulfonique tritié $[^3H]CF_3SO_3H$ (**2**-*t*) ou deutéré $[^2H]CF_3SO_3H$ (**2**-*d*) l'incorporation du tritium ou du deutérium dans la phase hydrocarbonée se produit facilement. Tous les huit atomes d'hydrogène de **1** peuvent être impliqués dans l'échange puisqu'on observe par spectrométrie de masse des espèces polydeutérées incluant des hydrocarbures octodeutérés. Dans une expérience avec **1** et **2**-*t* la brusque dilution de la phase acide avec de l'eau donne un mélange de cyclobutanol, de cyclopropylcarbinol et d'allylcarbinol dans un rapport de 61:37:2 respectivement tel qu'évalué par dilution isotopique, tandis que l'analyse par cpg de la phase hydrocarbonée révèle la présence de **1**, du méthylcyclopropane et du butène-1 dans un rapport de: 66:30:4. On explique ces résultats selon un mécanisme en chaîne carbocationique impliquant la formation d'ions bicyclobutonium en équilibre. On observe une incorporation similaire mais plus lente du tritium dans la phase hydrocarbonée quand on traite **1** avec du $[^3H]H_2SO_4$.

[Traduit par le journal]

By analogy with the protonation of cyclopropane with deuterated or tritiated H_2SO_4 (1, 2) to give protonated cyclopropane intermediates, which led to the formation of 1-propyl products with the isotopic label scrambled over all three carbon positions (3, 4), we had attempted to obtain evidence for protonated cyclobutane intermediates by treating cyclobutane (**1**) with tritiated acids such as $[^3H]H_2SO_4$ or $[^3H]CF_3SO_3H$ (5). Since no tritiated butyl product was detectable from the treatment of **1** with $[^3H]H_2SO_4$ and an upper limit of no more than 1% ring cleavage was observed in the treatment of **1** with $[^3H]CF_3SO_3H$, it was concluded that processes via protonated cyclobutane intermediates are not likely to be major reaction pathways (5). In accord with this conclusion, the isotopic scramblings observed in the trifluoroacetolysis of 1-[1-^{14}C]butyl tosylate (6) or 1-[1-^{14}C]butylmercuric perchlorate (7), and in the deamination of 1-[1-^{14}C]butylamine (8), were interpreted by invoking some contribution from protonated methylcyclopropane intermediates rather than from protonated cyclobutane.

In the treatment of **1** with $[^3H]CF_3SO_3H$ (5), after the mixture was shaken at 75°C for 3 days, isotopic H–T exchange was observed and the recovered **1** was found to have the same specific activity as that of the original $[^3H]CF_3SO_3H$. Since treatment of cyclopropane with D_2SO_4 resulted in the formation of monodeuterocyclopropane (9), the H–T exchange was assumed to be due to monotritiation of **1**, giving rise to an active **1** with essentially the same specific activity as the original $[^3H]CF_3SO_3H$. We have now found that this interpretation is incorrect and this paper reports on the results obtained from further studies on isotopic exchanges when **1** is

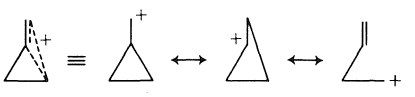
[a]From mass spectral analysis of 0.2-mL aliquots of the hydrocarbon layer withdrawn periodically from an initial mixture of 2.0 mL of cyclobutane (**1**) and 4.0 mL of CF_3SO_3D (**2**-*d*) being shaken at 0°C.
[b]There was an induction period and no D incorporation into the hydrocarbon was observed at reaction times of up to 25 min.
[c]Corrected for P + 1 and P + 2 due to ^{13}C.

treated with $[^3H]CF_3SO_3H$ (**2**-*t*), $(^2H)CF_3SO_3H$ (**2**-*d*), or $[^3H]H_2SO_4$ (**3**-*t*).



In the earlier work (5), the exchange was measured after **1** was shaken with **2**-*t* at 75°C for 3 days because these were the conditions used in the attempt to obtain open chain butyl products. In the present study, it was found that the H–T exchange can occur under much milder conditions. For example, when a 1:2 (by volume) mixture of **1** and **2**-*t* was shaken at 0°C, after a variable induction period of about 10–30 min, incorporation of T into the hydrocarbon layer took place and the specific activity of the recovered tritiated hydrocarbon rose above the specific activity of the original **2**-*t* in less than an hour. This finding alone suggests that monotritiation is certainly not sufficient to account for the extent of exchange.

It is of interest to note that years ago, Stevenson and co-workers (10, 11) studied the H–D exchange between saturated hydrocarbons and H_2SO_4. For example, when hydrocarbons such as isobutane or isopentane were passed through D_2SO_4, polydeuterated hydrocarbons were obtained and the exchange was interpreted by means of a carbocationic chain mechanism. The mass spectral analysis of the hydrocarbon layer on treatment of **1** with **2**-*d* also showed the occurrence of polydeuteration. A typical set of data, obtained from analyzing sample aliquots withdrawn at different times from a mixture of **1** and **2**-*d* that was being shaken at 0°C, is given in Table 1.

Since exchange could involve all H atoms of **1**, at infinite time, a complete mixing of all H isotopes would result. Under the conditions of the previous experiment reported in 1976 (5), the calculated specific activity of the recovered hydrocarbon at infinite time, x_∞, was 1.76×10^7 dpm/mmol (see Experimental section for illustrations of the calculation). After **1** and **2**-*t* were shaken at 75°C for 3 days, the specific activity of the resulting hydrocarbon, x, was coincidentally the same as that of the original **2**-*t*, namely, 1.42×10^7 dpm/mmol. Thus the ratio x/x_∞ was 1.42/1.76 = 0.81 or the exchange was about 81% complete.

Utilizing the method of data treatment described by Stevenson and co-workers (10) in their study on the exchange between isobutane and H_2SO_4, for the reaction of **1** with **2**-*t*, a plot of $\ln [1 - (x/x_\infty)]$ vs. reaction time would give a straight line the negative slope of which is the initial first order rate constant, k, for the appearance of tritium in the hydrocarbon layer. The observed results from duplicate sets of such experiments, carried out at 0°C, are summarized in Table 2, and these gave k values of $2.4 - 2.5 \times 10^{-4}$ s^{-1}. When **1** was treated with $[^3H]H_2SO_4$ (**3**-*t*), tritium was also incorporated into the hydrocarbon layer, but at a much slower rate than in the reaction with **2**-*t*. A typical set of results obtained from an experiment carried out at 40°C is summarized in Table 3, giving a k value of 1.3×10^{-6} s^{-1}.

If the exchange during the treatment of **1** with **2**-*t* or **3**-*t* were to proceed via a carbocationic mechanism, formation of the cyclobutyl cation would likely result in rearrangements since cyclobutyl, cyclopropylcarbinyl, and allylcarbinyl cations are known to interconvert readily via equilibrating bicyclobutonium ions (**4**) (12–14). Indeed, Olah and Lukas (15) have observed by nmr that treatment of cycloalkanes at low temperature in the super-acids FSO_3H–SbF_5 and HF–SbF_5, with or without SO_2-ClF as diluent, resulted in hydride ion abstraction to give cycloalkyl cations. When a solution of **1** in SO_2ClF–FSO_3H–SbF_5 was quenched with CH_3OH, an 80% yield of a 9:1 mixture of methyl cyclopropylcarbinyl ether and methyl cyclobutyl ether was obtained (15).

24	8.42	0.123
41	12.4	0.181
48	14.4	0.210
	k (s^{-1})	1.3×10^{-6}

[a]Samples each containing 0.25 mL of **1** and 1.0 mL of **3**-*t* with specific activity of 2.82×10^6 dpm/mmol were shaken in sealed tubes at 40°C. The calculated x_∞ was 6.85×10^6 dpm/mmol.
[b]To allow for the induction period, each sample was shaken for 1.5 h before being regarded as having reached its zero time.

In order to ascertain whether rearrangement via bicyclobutonium ions have occurred in the present study, a mixture of 1.0 mL of **1** and 4.0 mL of **2**-*t* was shaken at 0°C for 4 h. After 1.0-mL aliquots of the acid layer were quenched in H_2O containing cyclobutanol (**5**), cyclopropylcarbinol (**6**), or allylcarbinol (**7**) as carrier, the recovered activities in the urethane derivations fo **5**, **6**, and **7**, respectively, were in the ratio of 61:37:2. Similarly, vpc analysis of the hydrocarbon layer showed the presence of three peaks with relative areas of 66:30:4, and these were assigned, respectively, to cyclobutane, methylcyclopropane, and 1-butene.

All the above observations may be accommodated by a carbocationic chain mechanism as was originally suggested by Stevenson and co-workers (10, 11). The initiation step is the formation of the carbocation. In the reaction of isobutane with H_2SO_4, for example, it was suggested (10) that initiation could arise either from oxidation of isobutane to the *t*-butyl cation or from protonation of traces of olefinic impurity such as isobutene. In the present work, **1** was freshly prepared and there is probably no olefinic impurity.. Oxidation, or abstraction of hydride ion, the term used by Olah and Lukas (15), could be responsible for the initiation. The slow initiation could then account for the induction period which was also observed by Stevenson and co-workers (10). It is of interest to note that Setkina *et al.* (16) have also reported the observation of H–D exchanges between saturated hydrocarbons and D_2SO_4. A free radical mechanism was proposed (16); but subsequently, evidence was obtained for the formation of carbocations from the reaction of saturated hydrocarbons with H_2SO_4 (17).

Olah and co-workers (18) have more recently proposed a variant to hydride abstraction, which involves an electrophilic protolysis of a C—H bond, giving a two-electron three-center bonded carbonium ion, which subsequently loses H_2 to give the tricoordinated carbenium ion. The fact that the stronger acid, [^{3}H]CF_3SO_3H, could react with **1** faster than [^{3}H]H_2SO_4 might be regarded as in accord with electrophilic protolysis. However, an attempt to detect the liberated H_2 by mass spectrometry in the reaction of **1** with CF_3SO_3H has failed to give positive results. This is not surprising since the amount of H_2 produced may be very small as its liberation would take place only in the initiation step of a chain mechanism.

As proposed by Stevenson and co-workers (10, 11), the carbocationic chains are propagated through intermolecular transfers of hydride ions between carbocation and hydrocarbon molecules ($R^+ + RH \rightleftharpoons RH + R^+$), and the chains are terminated by some irreversible side reactions of the cations. The hydride ion transfers could take place between the cations and the dissolved hydrocarbon molecules or hydrocarbon molecules in the interface. In the exchange between isobutane and H_2SO_4, it was suggested (10) that during the existence of the *t*-butyl cation, any of its α-hydrocarbons may exchange with the protons of the acid. It was assumed that this exchange occurred at a

rate such that equilibrium between carbocation hydrogens and acid hydrogens was established during the life of each ion. Since the *t*-butyl cation does not undergo intramolecular hydrogen shifts, the exchanges will involve only the nine primary hydrogens. Consequently, a maximum extent of deuteration by D_2SO_4 will produce isobutane-d_9, with the tertiary hydrogen unaffected (10).

In the present study with **1**, the bicyclobutonium ion, **4**, will be formed, either directly from **1** or as a result of a rearrangement of the cyclobutyl cation. It is known (13, 14) that different bicyclobutonium ions can arise from 1,2-shifts of neighboring σ-bonds, and equilibration of these bicyclobutonium ions will eventually cause all three methylene groups in **4** to become equivalent. Thus the H atoms are intramolecularly rearranged among the methylene groups. This intramolecular rearrangement, together with the possibility of 1,2-hydride shifts in the cyclobutyl cation, the many cycles of intermolecular hydride transfers between cations and hydrocarbon molecules, and exchanges between the α-H, D, or T of the cation and the H, D, or T of the acid during the lifetime of the cation, will lead to the involvement of all eight hydrogen atoms of the C_4H_8 molecule in the exchange. This mechanism is borne out by the data in Table 1. The intermolecular hydride transfer reactions involving bicyclobutonium ion **4** will also lead to the formation of the rearranged hydrocarbons, methylcyclopropane, and 1-butene, as well as cyclobutane, and this again is in agreement with observation.

The actual mechanism for the exchange between the α-hydrogens of the cation and the acid hydrogens has not been elucidated either in the early work of Stevenson and co-workers (10) or in the present study. One possibility (suggested by a referee and an editor) is the involvement of an olefinic intermediate, $R^+ \rightleftharpoons$ alkene + H^+. In that event, polymerization of the olefinic intermediate followed by fragmentation conceivably might account for some of the d_1 to d_8 species recorded in the mass spectra (Table 1). However, such possible contributions from a polymerization–fragmentation process likely did not account for all of the observed d_1 to d_8 species and would not invalidate the conclusion that polydeuteration occurred during the treatment of **1** with **2**-*d*, especially when the reaction of **1** with **2**-*t* may be reasonably interpreted on the basis of a complete exchange between the eight H atoms of **1** and the *t*-label of **2**-*t*.

Experimental

Reaction of Cyclobutane (1) with (^2H)CF_3SO_3H (2-d)

A mixture of 2.0 mL (26 mmol) of **1**, bp 12–13°C, prepared from 1,4-dibromobutane (19), and 4.0 mL (46 mmol) of **2**-*d*, prepared from trifluoromethanesulfonic acid anhydride and D_2O, was shaken mechanically in a stoppered glass tube kept at 0°C in an ice-water bath. Periodically, 0.2-mL aliquots of the hydrocarbon layer were withdrawn and analyzed by mass spectrometry to give the results recorded in Table 1, showing the presence of polydeuterated species in the hydrocarbon layer. In this experiment, the amount of hydrocarbon relative to the amount of acid in the reaction mixture would decrease as aliquots of the hydrocarbon layer were withdrawn, hence no kinetic treatment was attempted.

Reaction of 1 with [^3H]CF_4SO_4H (2-t)

In preliminary studies, when mixtures of **1** and **2**-*t*, the latter being prepared by adding [^{3}H]H_2O and the calculated amount of trifluoromethanesulfonic acid anhydride to ordinary **2**, were placed in individual sealed tubes and shaken at 0°C for different lengths of time, the incorporation of T into the hydrocarbon layer was found to be not reproducible quantitively. This difficulty arose because of the variability of the initial induction period. To obtain the results recorded in Table 2, the following procedure was adopted.

A mixture of 1.0 mL (718 mg, 12.8 mmol) of **1** and 4.0 mL (6860 mg, 45.7 mmol) of **2**-*t*, with a specific activity of 2.10×10^7 dpm/mmol, was shaken in a stoppered glass tube at 0°C as in the experiment with **2**-*d*. After the induction period has passed, 0.2-mL and 0.8-mL aliquots, respectively, of the hydrocarbon and acid layers were withdrawn at different times and the T incorporation into the hydrocarbon layer was measured. In this way, the relative amounts of hydrocarbon to acid, and hence the theoretical specific activity in the C_4H_8 hydrocarbon layer at complete exchange, x_∞, would remain constant throughout the experiment.

In this experiment, the total amount of activity involved was $45.7 \times 2.10 \times 10^7 = 9.60 \times 10^8$ dpm, and the total amount of H involved was $(12.8 \times 8) + 45.7 = 148$ mg atoms.

When exchange is complete, the specific activity, x_∞, would be $(9.60 \times 10^8)/148 = 6.49 \times 10^6$ dpm/mg atom H or $6.49 \times 10^6 \times 8 = 5.18 \times 10^7$ dpm/mmol C_4H_8.

From the observed specific activities, x, that were incorporated into the hydrocarbon layer at different reaction times, x/x_∞ were calculated and plots of $\ln [1 - (x/x_\infty)]$ vs. time gave the k values of 2.4×10^{-4} and 2.5×10^{-4} s^{-1} for the duplicate runs (Table 2).

In the earlier experiment reported in 1976 (5), 18 mmol of **1** was shaken with 22.8 mmol of **2**-*t* whose specific activity was 1.42×10^7 dpm/mmol. At complete exchange, x_∞ would be $8(1.42 \times 10^7 \times 22.8)/(22.8 + 8 \times 18) = 1.76 \times 10^7$ dpm/mmol C_4H_8.

Quenching and Product Studies

A mixture of 1.0 mL of **1** and 4.0 mL of **2**-*t* (2.10×10^7 dpm/mmol) was shaken at 0°C for 4 h. One-mL aliquots of the acid layer were quenched separately by shaking with 10 mL of H_2O containing 0.5 mL of cyclobutanol (**5**, 461 mg, 6.4 mmol), cyclopropylcarbinol (**6**, 444 mg, 6.1 mmol), or allylcarbinol (**7**, 429 mg, 6.0 mmol) as carrier. The alcohol was then recovered by ether extraction and purified by preparative vpc (1/4 in. × 8 ft copper column packed with 25% β,β′-oxydipropionitrile on chromosorb P at 80°C). The phenylurethanes of **5** and **6** and the α-naphthylurethane of **7** were prepared (12) and these were repeatedly recrystallized to give constant specific activities of 1.83×10^5, 1.19×10^5, and 7.03×10^3 dpm/mmol, respectively, for the derivatives of **5**, **6**, and **7**. Making the reasonable assumption that essentially all the weight of each alcohol was due to the added carrier, the total activities recovered were $1.83 \times 10^5 \times 6.4 = 1.2 \times 10^6$ dpm, $1.19 \times 10^5 \times 6.1 = 7.3 \times 10^5$ dpm, and $7.03 \times 10^3 \times 6.0 = 4.2 \times 10^4$ dpm, respectively, for **5**, **6**, and **7**, corresponding to a ratio of 61:37:2.

The hydrocarbon layer from the above experiment was analyzed by vpc (1/4 in. × 8 ft copper column packed with 15% silicone gum rubber on chromosorb W at 20°C). Three peaks were obtained with retention times of 30, 40, and 75 s and with relative areas of 30:66:4, respectively. Comparison with a sample of **1** showed that the largest peak with retention time of 40 s was **1**, and by analogy with the results from the quenching experiment, the other two peaks are assigned to methylcyclopropane and 1-butene, with a relative ratio of 66:30:4 for cyclobutane:methylcyclopropane:1-butene.

Reaction of ***1*** *with* $[^3H]H_2SO_4$ (***3***-t)

The **3**-*t* was prepared by adding $[^3H]H_2O$ to a calculated amount of fuming H_2SO_4. The reaction was carried out at 40°C in individual sealed tubes each containing 1940 mg (19.8 mmol, about 1.0 mL) of **3**-*t* (2.82×10^6 dpm/mmol) and 180 mg (3.2 mmol, about 0.25 mL) of **1**. From preliminary trials under these conditions, the induction time was about 1.5 h. The reaction mixtures were, therefore, allowed to shake at 40°C for 1.5 h before being regarded as having reached the zero time. At different times after this arbitrarily chosen induction period, the incorporation of T into the hydrocarbon layer was measured to give the results of Table 3. In this experiment, the specific activity at complete exchange, x_∞, would be $8(2.82 \times 10^6 \times 19.8)/(19.8 \times 2 + 2.3 \times 8) = 6.85 \times 10^6$ dpm/mmol C_4H_8.

Acknowledgments

We wish to express our sincere thanks to Professor M. Saunders of Yale University and Professor P. von R. Schleyer of Universität Erlangen-Nürnberg for suggesting to us that the exchange between **1** and **2**-*t* should be further investigated and for their valuable comments. The financial support given by the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

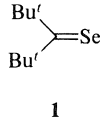
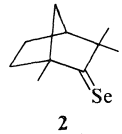
NORMAN Y. M. FUNG, PAUL DE MAYO, BERND RUGE, ALAN C. WEEDON, and S. KING WONG. Can. J. Chem. **58**, 6 (1980).



The photochemistry of di-*tert*-butylselenoketone **1** and selenofenchone **2** has been examined. Their photochemical properties resemble those of thioketones rather than ketones in that hydrogen abstraction occurs from an upper excited state and not from the lowest ($n \rightarrow \pi^*$) excited state. Di-*tert*-butylselenoketone, **1**, on irradiation into the S_2 band forms the diselenide **3**. The quantum yield for this process was found to be 0.0055 and was increased in the presence of a good hydrogen atom donor. No reaction was observed following excitation into the S_1 state unless a good hydrogen atom donor was present, and even then the photoreaction was very inefficient. Quenching experiments with biacetyl demonstrated the lifetime of the abstracting state to be in the order of 10^{-11} s. The formation of the diselenide **3** has been rationalized in terms of hydrogen abstraction from solvent by photoexcited **1** and trapping of the radicals produced by ground state **1**, leading to the radical **6**. The mechanism is supported by esr evidence for the existence of **6**. Selenofenchone, **2**, also, did not react following excitation into the S_1 state, but underwent intramolecular cyclization in a similar manner to bicyclic thioketones following excitation into the S_2 state.

NORMAN Y. M. FUNG, PAUL DE MAYO, BERND RUGE, ALAN C. WEEDON et S. KING WONG. Can. J. Chem. **58**, 6 (1980).



On a examiné la stéréochimie de la di-*tert*-butylsélénocétone **1** et de la sélénofenchone **2**. Leurs propriétés photochimiques sont semblables à celles des thiocétones plutôt qu'à celles des cétones où il se produit une élimination d'hydrogène à partir de l'état excité supérieur et non à partir de l'état excité le plus faible ($n \rightarrow \pi^*$). L'irradiation de la di-*tert*-butylsélénocétone **1** dans la bande S_2 conduit au disélénure **3**. On a trouvé que le rendement quantique de cette réaction est de 0.0055 et qu'il augmente en présence d'un bon donneur d'hydrogène. L'irradiation dans la bande S_1 ne donne pas de réaction à moins qu'un donneur d'hydrogène soit présent et, même dans ces conditions, la réaction photochimique n'est pas efficace. L'interruption brusque des réactions à l'aide du biacétyle a montré que la durée de vie de l'état où il y a élimination d'hydrogène est de l'ordre de 10^{-11} s. On a rationalisé la formation du disélénure **3** en fonction d'une élimination d'hydrogène à partir du solvant par le composé **1** photoexcité et en fonction du piégeage des radicaux produits dans l'état fondamental, conduisant au radical **6**. Les preuves de l'existence du dérivé **6** apportées par la rpe confirment le mécanisme proposé. La sélénofenchone **2** ne réagit pas non plus à la suite d'une excitation dans l'état S_1 mais il subit une cyclisation intramoléculaire de façon similaire aux thiocétones bicycliques après une excitation dans l'état S_2.
[Traduit par le journal]

Introduction

Recently Barton and colleagues (1) reported the preparation of the first isolable selenoketones, namely di-*tert*-butylselenoketone, **1**, and selenofenchone **2**. As is the case with the related thioketones (2), selenoketones possess a low energy electronic transition giving rise to a weak intensity band, $S_1(T_1)$, in the visible region of the absorption spectrum. There are also higher energy electronic transitions which result in strong absorption in the ultraviolet. Whereas ketones abstract hydrogen atoms when excited into the $S_1(T_1; n \rightarrow \pi^*)$ electronic state, thioketones have been shown to abstract hydrogen atoms more efficiently when excited into the S_2 state, which is probably of $\pi \rightarrow \pi^*$ character (2). This ability to abstract hydrogen whilst in a higher excited state is a property deriving, at least in part, from the lifetime of the S_2 state of thioketones (10^{-10}–10^{-11} s) which is long enough to allow both intra- and intermolecular reactions to occur. These lifetimes may owe their longevity to slow internal conversion, itself arising, in part, from the large energy separation between the S_2 and S_1 states; this is of the order of 40–60 kcal/mol for thioketones. The energy separation between the S_1 and S_2 states of selenoketones **1** and **2** is comparable (ca. 60–65 kcal/mol) suggesting that they too might possess comparatively long lived upper excited states despite the presence of the heavy atom. We report here the results of an investigation into the photochemistry of the selenoketones **1** and **2** undertaken to determine if their reactions paralleled those of thioketones, so extending the class of compounds known to react from an upper excited state (3).

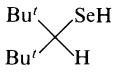
of the selenoketone **1** into both the S_1 and S_2 states[2] in the presence of any one of acrylonitrile, ethyl vinyl ether, fumaronitrile, and dimethylmaleate failed to produce detectable amounts of adducts, possibly merely a consequence of steric hindrance (4*b*).

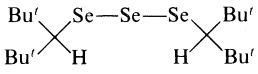


Barton and colleagues (1) reported that irradiation, through quartz, of a solution of selenoketone **1** in benzene gave the diselenide, **3** in high yield. We

3

have found that by irradiation, through both Pyrex and quartz, of **1** in a variety of solvents (cyclohexane, hexanes, dioxane, benzene, and acetonitrile), in all cases formation of the diselenide **3** occurred. The diselenide was identified by comparison with an authentic sample prepared in high yield by lithium aluminium hydride reduction of the selenoketone followed by air oxidation of the intermediate selenol **4**.

In these solvents, excepting benzene, other reactions also occurred, to give substantial quantities of unidentified compounds along with selenium metal, reducing the diselenide yield to less than 50%. However, in benzene as solvent, or in the presence of added selenol **4**, the photochemical reaction to yield diselenide was much cleaner and proceeded in high chemical yield (85%).



4

In Table 1 the quantum yields of disappearance of **1** in the presence of varying amounts of selenol **4** are shown; increasing the concentration of **4** enhances the quantum yield considerably. The data also demonstrate that the photoreaction is wavelength dependant; reaction of **1** following excitation into the S_1 state is extremely inefficient, indicating that the selenoketone mimics thioketones in that it reacts more readily from an upper excited state. The nature of the "S_1" band is uncertain. In thiones the $S_0 \rightarrow T_1$ transition has about 20% of the strength of the $S_0 \rightarrow S_1$ transition and occurs as a shoulder on the long wavelength side of the latter. In **1** the band is very broad and suggests comparable intensities perhaps and considerable mixing. Hence excitation may well give the triplet directly. The reactive state attained after excitation into the S_2 is assigned only by analogy as $S_2(\pi \rightarrow \pi^*)$.

The quantum yields of disappearance of **1** obtained in the presence of selenol, following excitation into S_1, are very scattered. This is because of a competing ground state reaction between the selenoketone and the selenol which occurs at a rate comparable to that of the photochemical process: correction was made, but the errors are large.

Investigation of the dark reaction showed that in the absence of air the only product is the diselenide **3**, presumably arising from nucleophilic attack by selenol upon the selenoketone; thioketones can also undergo nucleophilic attack at the sulphur atom (5). If the ground state reaction between **1** and **4** was performed in the presence of oxygen, a second product was produced, which was identified as the triselenide **5**. The structure of **5** has been proved by X-ray crystallographic analysis and this, along with a discussion of its mode of formation, has been reported elsewhere (6).

5

In Figs. 1 and 2 are shown the esr signals observed when selenoketone **1** was irradiated in pentane at −110°C under conditions such that the diselenide **3** is formed. These signals are assigned to

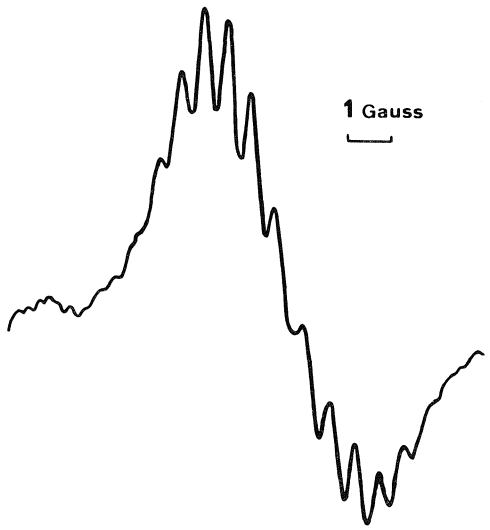


FIG. 1. Hyperfine splitting by γ-protons in radical **6***a*; a_H = 0.50 G.

[2]The electronic spectrum of **1** in hexanes possesses maxima at 698 nm (ε 25), 266 nm (ε 7400), and 229 (ε 3000). The 266 nm band tails to wavelengths beyond 300 nm and consequently irradiation of **1** in Pyrex using a medium pressure mercury lamp allows excitation into both S_1 and S_2 states in the same experiment.

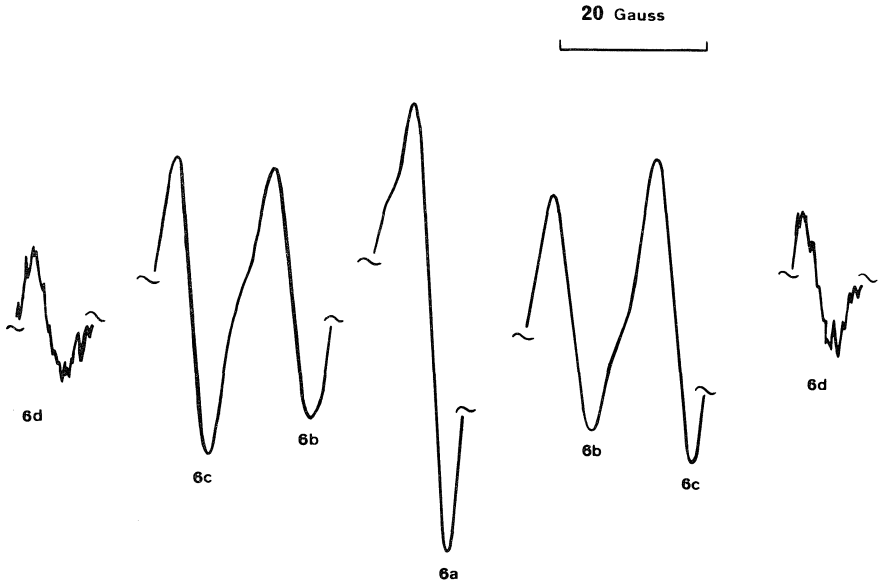

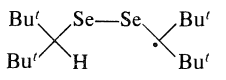

FIG. 2. Hyperfine splittings by ^{77}Se in radicals **6***b*, **6***c*, and **6***d*; a_{Se} = 38.1 and 65.3 G. Discontinuities signify changes in instrument sensitivity (amplification factors 1×, 10×, and 16× for signals assigned to **6***a*, **6***b* and **6***c*, and **6***d* respectively). Assignments for **6***b* and **6***c* may be reversed.

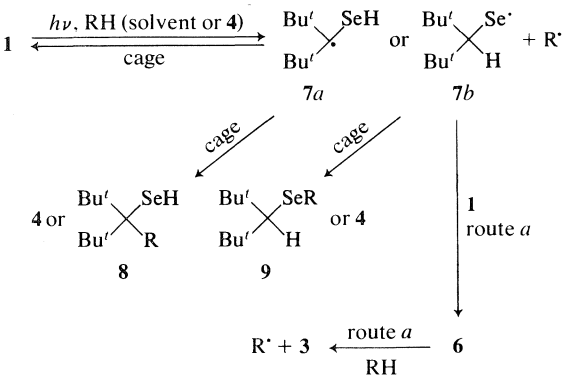
the radical **6** which was subsequently observed by Scaino and Ingold (7). The hyperfine splittings (a_H = 0.50 G, a_{Se} = 38.1 and 65.3 G) are similar to those reported by Scaino and Ingold as is the *g*-factor which was determined to be 2.0021. No signals were observed following irradiation into the S_1 band of **1** (with light of wavelength greater than 460 nm) unless selenol **4** was present. Allowing for the wavelength dependence of the intensity of the irradiation source, the ratio of intensities of the esr signals produced when **1** was irradiated in the S_1 or S_2 bands was approximately 1:60 respectively. Similarly, the esr signal intensities were in the ratio of approximately 20:1 depending upon the presence or absence of the selenol **4** during irradiation into S_2.[3]

6

In the absence of selenol **4**, the esr signal produced upon excitation into the S_2 state decayed in a first order manner ($t_{1/2} \sim 1.8$ s at −110°C), whilst in the presence of **4** the decay was more complex, and, initially, faster. This is consistent with quenching of the radical by solvent (pentane) in the absence of **4** to give apparent first order kinetics of



[3]This ratio is concentration dependent; 0.1–0.2 *M* solutions of **1** and **4** were used.

TABLE 2. Comparison of calculated and measured esr signal strengths for all possible ^{77}Se distributions in radical **6**

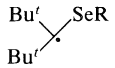
†Signal height was used. Mean of several determinations.
‡Only the outer two lines were observed.

decay, whereas quenching by **4** may be initially faster but sets up a chain: radical **7***b* is produced, which can generate more of **6** when trapped by **1** (see Scheme 1; Scaino and Ingold (7) have demonstrated the efficiency of **1** as a radical trap).

SCHEME 1

The assignment of the structure **6** to the radical observed is based upon the hyperfine splitting pattern in the esr spectrum. The only stable selenium isotope to possess a nuclear spin (^{77}Se, $I = \frac{1}{2}$) has a natural abundance of 7.58%. Thus coupling of the unpaired electron in **6** can occur with none (structure **6***a* in Fig. 2), one (structure **6***b* or **6***c*), or two selenium atoms (structure **6***d*) to give rise to a set of



lines with a predictable ratio of intensities. The calculated and measured ratios are given in Table 2 and show reasonable agreement. Only the outer pair of the four lines expected for the radical **6***d* were observed, the inner two presumably being hidden under the stronger signals of **6***b* and **6***c*. That the lines observed were due to the same radical containing different numbers of ^{77}Se atoms was further supported by the observation of identical decay rates for the lines assigned to **6***a*, **6***b*, and **6***c* following irradiation of **1** in pentane at − 110°C.

The results described are rationalized in terms of the processes shown in Scheme 1. By analogy with the reactions of photoexcited ketones and thioketones, and because of the observed acceleration by selenol (ascribed to the presumed good hydrogen atom donating ability of the selenium–hydrogen bond, which has a bond dissociation energy of 90 kcal/mol in H_2Se (13)), the primary act of the photoexcited selenoketone is proposed to be hydrogen abstraction to give either of the radicals **7***a* or **7***b*. Neither of these are observed in the esr spectrum; in the case of **7***b* this is to be expected since the spectrum would be very broad (sulphur centred radicals have never been observed for this reason). In the case of **7***a* the non-observation may reflect its rapid trapping either within or outside the solvent cage in which it is formed. The latter process appears unlikely to be faster than the analogous trapping of radical **6** by hydrogen atom donation from solvent; since **6** *is* observed, this may indicate that **7***a* is not formed or undergoes rapid recombination or disproportionation within the solvent cage. The fates of **7***a*, if formed, within the solvent cage could be disproportionation with the accompanying solvent (or selenol) derived radical to give the selenol **4**, or alternatively combination to give selenol **8**. The latter process should be slow because of steric hindrance. Similarly **7***b* would be expected to disproportionate or combine with its partner radical within the solvent cage to give **4** or the selenide **9**. If **7***b* escapes from its solvent cage then its most probable fates are reaction with selenoketone **1**, a good radical trap (7), or hydrogen abstraction from solvent or selenol **4**. Reaction with **1** yields the observed radical **6**, which can proceed to the isolated product **3**, whilst hydrogen abstraction yields selenol **4**. If **4** reaches a high enough concentration, or if it is added to the system, then a chain sequence may be expected since hydrogen

For personal use only.

atom abstraction from **4** by photoexcited **1** to give one molecule of **3** yields two **7***b* radicals each of which can be trapped by **1** to give more of **6** and hence more of **3** and **7***b* (path *a* in Scheme 1). It is possible that any selenol **4** produced may all be consumed by ground state reaction with **1** to give diselenide **3**; in this case, and in the absence of added **4**, the solvent derived radical should be trapped by **1** to give radical **10**, which may abstract from

10

solvent and set up a chain sequence. The fact that in the absence of added **4** approximately 50% of the product is diselenide **3** suggests that any chain reactions set up by quenching of solvent derived radicals by **1** must be very short. Selenol **4** generated in the reaction may be partly responsible for this chain terminating step. That none of the radical **10** was observed in the esr experiment may also be relevant, although Scaino and Ingold (7) do report the presence of a second radical, other than **6**, in lower concentration.

More information about the abstracting state of **1** following excitation into the S_2 band was obtained by determinations of relative quantum yields in the presence of a quencher. In Figs. 3 and 4 are shown Stern–Volmer plots for the quantum yields of disappearance of **1** and formation of **3** in the presence of various concentrations of biacetyl. From Fig. 3 the lifetime of the excited state being quenched is $(1.5 \pm 0.6) \times 10^{-10}$ s whilst from Fig. 4 it is $(0.5 \pm 0.2) \times 10^{-11}$ s, which are of the same order as the reactive state of thioketones following excitation into S_2 (2).

The errors in the lifetimes are large and hence the

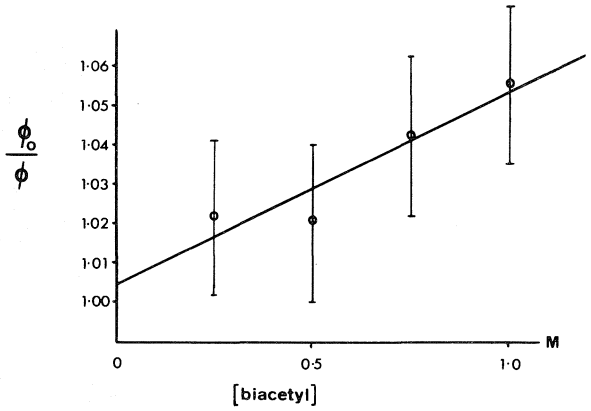

FIG. 3. Stern–Volmer plot for quantum yield of formation of **3** from **1** in hexanes in the presence of biacetyl. Slope = 1.5 ± 0.6 L/mol, whence $\tau = (15 \pm 6) \times 10^{-11}$ s assuming $k_q = 10^{10}$ L/mol s.

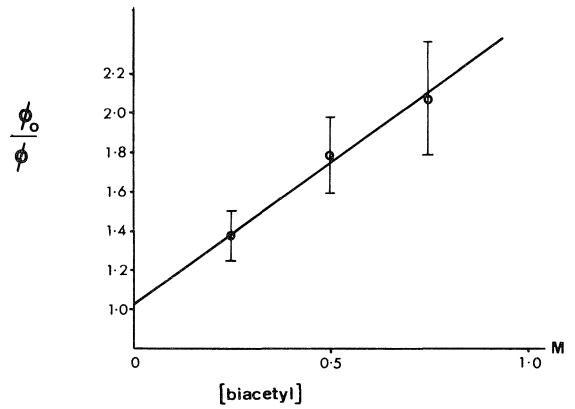

FIG. 4. Stern–Volmer plot for quantum yield of disappearance of **1** in hexanes in the presence of biacetyl. Slope = 0.06 ± 0.02 L/mol, whence $\tau = (0.6 \pm 0.2) \times 10^{-11}$ s assuming $k_q = 10^{10}$ L/mol s.

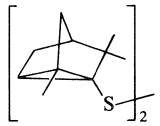

τ are essentially only order of magnitude determinations. Also, quenching of the excited state of **1** only has an indirect effect upon the quantum yields of disappearance of **1** and appearance of **3**, and the exact effect cannot be predicted. Further, the amount of **3** formed was determined by uv spectrophotometry; **3** may have been contaminated by the triselenide **5** whose extinction coefficient at the wavelengths monitored is much greater than that of **3** (ε_{254} for **3** $\approx$ 300; for **5** $>$ 2000), resulting in overestimation of the yield of **3**.

Irradiation of Selenofenchone, 2

Thiofenchone possesses maxima at 490 nm and 235 nm in the electronic absorption spectrum, and irradiation into the S_2 band results in intramolecular hydrogen abstraction and conversion to the thiol **11** and the disulphide **12** in 56 and 38%

11

12

yield respectively. No intermolecular hydrogen abstraction is observed, even in reasonably good hydrogen atom donating solvents such as pentane. The disulphide **12** only appears at high conversion, suggesting that it is a secondary photoproduct (8).

Selenofenchone, **2**, possesses maxima at 616 nm (ε 42), 272 nm (ε 9600), and 224 nm (ε 3700) in hexanes, and thus resembles di-*tert*-butylselenoketone, **1**. When a benzene solution of **2** was irradiated through Pyrex, under which conditions both the S_1 and S_2 states are populated, clean conversion to a mixture of the diselenides **13**, **14**, and possibly **15** was observed. Conversion was high but

not complete, presumably because of light absorption by the products, and no deposition of selenium metal was observed. Chromatography of the reaction mixture on silica gel did not allow separation of the diselenides, but the mass spectrum confirmed the composition of the mixture. The molecular weights of the diselenides **13**, **14**, and **15** are 430, 432, and 434 respectively (based upon ^{80}Se) and

13 **14** **15**

selenium has six stable isotopes of appreciable natural abundance; analysis of the family of molecular ion peaks ascribed to **13**, **14**, and **15** molecules indicates that they are present in the approximate ratio 1:1:0.1 (Table 3), although the errors are sufficiently large that little, or no **15** may be present.[4] This was supported by the ^1H-nmr spectrum of the mixture of diselenides where the hydrogen atom adjacent to the selenium atom is observed at δ 3.2; the ratio of this signal to all others was approx. 1:50 (a 1:1:0.1 ratio of **13**:**14**:**15** requires 1:54). Whilst the extremely non-polar diselenides could not be separated by normal chromatography on silica gel, repeated, careful high pressure liquid chromatography on a reverse phase column allowed partial separation into fractions from which small amounts of the diselenide **13** could be obtained in pure crystalline form. The mass spectrum of the pure diselenide **13** exhibited the correct molecular ion at 430 mass units and the isotopic pattern was consistent with the presence of two selenium atoms (Table 3). The ^1H-nmr spectrum of **13** was extremely similar to that of the sulphur analogue **12** and the characteristic C—H stretching vibration of a cyclopropyl methine was observed at 3080 cm^{-1} in the infrared spectrum.

Since the diselenides **14** and **15** could not be isolated pure, the mixture of **13**, **14**, and **15** was further characterized by reduction of the Se–Se bond with lithium aluminium hydride (9) and trapping of the resultant selenols with methyl iodide to give the selenides **16** and **17**; these were easily

16 **17**

separable by chromatography. Isolation of the intermediate selenols was not attempted because of their extremely rapid air oxidation to give diselenides. The mass spectrum of the selenide **16** possessed the correct molecular ion and isotopic pattern for one selenium atom (Table 3) and the ^1H-nmr spectrum exhibited the cyclopropyl hydrogen atom at 1.01 ppm. Similarly, the selenide **17** exhibited the correct molecular ion and isotopic

[4]This analysis, of course, assumes that the molecular ion intensities reflect the ratio of **13**, **14**, and **15** present in the crude reaction mixture.

distribution (Table 3) and in the ^{1}H-nmr spectrum the methine adjacent to the selenium atom appeared as a doublet at δ 2.57 (J = 2.5 Hz). Two isomers of **17** are possible (*exo* or *endo*); in the ^{1}H-nmr spectrum of unpurified **17** a second, but lower intensity doublet at 2.47 ppm (J = 2.5 Hz) was observed. If the minor product is an isomer at position 2, then the major product may be the *endo*-isomer by analogy with the relative chemical shift of the hydrogen in position 2 of *exo* and *endo* isomers of fenchol and norborneol (10). The coupling constant of the methine at 2.57 ppm cannot be used reliably for stereochemical assignment; the J values for the corresponding hydrogens in *exo* and *endo* fenchol are 1.85 and 1.35 Hz, respectively (11). Confirmation of the bicyclic and tricyclic structures of **17** and **16** was obtained from the ^{13}C-nmr spectra (Table 4); whilst it is not possible to assign specific positions to the signals unambiguously, the number of quaternary, tertiary, and secondary carbons in each spectrum clearly indicates the structural differences.

As mentioned above, irradiation of thiofenchone gives as the primary product of irradiation the cyclopropylthiol **11**, which, apparently, on further reaction yields the disulphide **12**. In the case of selenofenchone the situation is complicated by the fact that the presumed primary product, the selenol **18** may, by analogy with **1**, undergo a dark reaction with the starting material to give diselenide **14**. If its concentration becomes high enough, **18** may also act as a hydrogen donor for excited **2**. Two experiments were performed to estimate the concentration of **18** at different times during the reaction: an oxygen free solution of **2** was irradiated to 50% conversion and then allowed to stand in the dark.

18

No dark reaction was observed, indicating that little or no **18** was present, or that the dark reaction does not occur. In the second experiment irradiation was continued to ~90% conversion and the reaction mixture was treated with methyl iodide/sodium hydride in the absence of oxygen to trap any **18** formed. Only a trace of the selenide **16** was detected indicating that selenol concentration was very low. These results suggest that the selenol **18** is consumed rapidly during the irradiation, presumably by ground state reaction with **2**, to give **14**. The diselenide **15** may be formed by photolysis of **13** or **14** at high conversion, or it may arise from abstraction from solvent by excited **2** and trapping of the radical produced by ground state **2** in a similar manner to the formation of **3** from **1**. Attempted observation of an esr spectrum during irradiation of **2** under the same conditions used for **1** was unsuccessful, indicating that any radical intermediates, other than those centred on selenium, are either extremely short-lived or formed in concentrations at least 100 times lower than when **1** was irradiated.

From the data and observations described, the formation of **13** as a major product is difficult to explain; it is not formed by air oxidation of selenol **18** during work-up since little **18** was trapped by methyl iodide. Also it cannot be formed by photolysis of diselenide **14** since little of **15** is formed, and photolysis of **14** would lead to a statistical ratio of **13**:**14**:**15** of 1:2:1. Furthermore photolysis of **18**, the presumed primary photoproduct, would appear unlikely since its concentration appears to be low at 50% and 90% conversion and also since the extinction coefficient of **18** should be small in comparison with that of the diselenides.

The state from which selenoketone **2** reacts was also investigated by measuring the absolute quantum yield of disappearance in benzene solution. Irradiating with light of wavelength 602 nm resulted in no conversion of selenoketone requiring a quantum yield of disappearance following excita-

For personal use only.

tion into the S_1 state of less than 6×10^{-4}. Irradiating with light of wavelength 268 nm gave a quantum yield of disappearance of $5.0 \times 10^{-3} \pm 0.2 \times 10^{-3}$; thus selenofenchone resembles thiofenchone in that it undergoes intramolecular H-abstraction following excitation into the S_2 state to give products arising from β-insertion, but not following excitation into the S_1 state. Fenchone itself does not undergo β-insertion, presumably because the $S_2(\pi \rightarrow \pi^*)$ state is too short lived and the $S_1(n \rightarrow \pi^*)$ state possesses the wrong geometry for abstraction to occur (in excited fenchone the n orbital, rendered electrophilic because of its electron deficiency, cannot reach the β C—H bond). In thio- and selenofenchone, if the S_2 state is of $\pi \rightarrow \pi^*$ nature, the partially filled, and hence electrophilic, π orbital is of the right geometry to insert into the β C—H bond.

Experimental

Di-*tert*-butylselenoketone **1** was prepared by the method of Barton and co-workers (1) in 69% yield. Natural fenchone was purified by the literature method (12) and converted to selenofenchone by the method of Barton and co-workers (1) in 31% yield. Di-*tert*-butylselenol **4** and the triselenide **5** were prepared as previously described (6). All irradiations were performed on solutions which had been degassed by at least three freeze–pump–thaw cycles to a residual pressure better than 5×10^{-4} Torr. Quantum yield determination irradiations were performed in a merry-go-round apparatus with a 450 W medium pressure Hg lamp, or in a JASCO spectroirradiator. Light intensities were determined in the latter at 278 nm by ferrioxalate actinometry and related to intensity at 689 nm using a thermopile. The disappearance of the selenoketones **1** and **2** was monitored by decline of the optical density of the visible band at ~698 nm (**1**) and 606 nm (**2**). All ^{1}H-nmr spectra were recorded at 100 MHz on a Varian XL100 spectrometer. ^{13}C-nmr spectra were recorded on the same machine at 25.2 MHz. Electron spin resonance spectra were obtained on a Varian E12 spectrometer equipped with a variable temperature accessory.

High pressure liquid chromatography was performed on a Varian 8500 instrument using a Whatman Partisil PX210/25 ODS-2 reverse phase column and methanol/water (98.2:1.8) as eluent.

Diselenide (3)

Selenoketone **1** (2.0 g) under nitrogen and in ether (15 mL) was added to lithium aluminum hydride (300 mg) in ether (15 mL). After a few minutes the mixture was acidified and the product isolated with methylene chloride (200 mL). Concentrated aqueous ammonia (15 mL) was added and air was bubbled through the stirred solution for 24 h after which time the originally colourless solution had turned yellow. The mixture was neutralized with aqueous hydrochloric acid and the aqueous phase was extracted with methylene chloride. The combined organic phases were dried (Na_2SO_4) and evaporated. The residue was crystallized from methanol to give 1.03 g of **3** as yellow crystals mp 58–59°C (lit. (1) 56.5°C); nmr (CCl_4) 1.22 (s), 3.08 (s) ppm, in the ratio 18:1; uv λ_{max} 319 nm (ε 287).

Irradiation of Selenoketone 1 in Hexanes

A degassed solution of selenoketone **1** (234 mg) in hexanes (mixture of isomers, 5 mL) was irradiated through quartz with a low pressure mercury lamp for 6 days, after which time red selenium metal had begun to deposit upon walls of the reaction vessel. The reaction mixture was diluted to 10 mL and the visible electronic spectrum was recorded; from the optical density at 700 nm it was calculated that 61% (142 mg) of the selenoketone remained. The solvent was removed and unconverted selenoketone was distilled out; the residue was chromatographed (silica gel/petroleum ether) to give a yellow material (48 mg) found by nmr to be the diselenide **3** contaminated to the extent of 15% by the triselenide **5**. Crystallization from methanol gave a sample of the yellow diselenide **3**, identical with an authentic specimen.

Irradiation of Selenoketone 1 in Hexanes in the Presence of Selenol 4

The selenoketone **1** (120 mg) and the selenol **4** (100 mg), each in hexanes (3 mL), were degassed in separate, but connected quartz vessels and mixed directly before being irradiated with a low pressure mercury lamp for 7 h, after which time selenium metal began to be deposited on the vessel walls. The reaction mixture was diluted to 10 mL and the optical density was measured at 700 nm, whence the selenoketone was found to be 60% converted. The solvent was removed and most of the excess selenoketone was distilled out (0.1 mm/50°C). The residue (147 mg) was chromatographed (silica gel/petroleum ether) to give a yellow material (132 mg) found to comprise the diselenide **3** (85%) and the triselenide **5** (15%) by nmr.

Reaction of Selenoketone 1 with Selenol 4 in the Presence of Air

Selenoketone **1** (157 mg) and selenol **4** (127 mg) were dissolved in hexanes (6 mL) and allowed to stand for 15 h during which time the solution changed in colour from blue to green to yellow. The solvent was removed and the nmr spectrum of the residue indicated a 1:1 mixture of diselenide **3** and triselenide **5**. Crystallization from isopentane/methanol gave orange crystals of **5** (55 mg). Recrystallization from ethanol gave pure **5** (27 mg) mp 85–88°C (lit. (6) 86–88°C).

Reaction of Selenoketone 1 with Selenol 4 in the Absence of Air

Selenoketone **1** (124 mg) and selenol **4** (100 mg) each in hexanes (3 mL) were degassed in separate, but connected vessels and mixed together. After 10 days at 70°C and one month at room temperature, the optical density of the solution at 700 nm following dilution to 10 mL indicated that 65% of the selenoketone had been converted. Removal of solvent and distillation of excess **1** and **4** yielded crystalline diselenide **3**, 130 mg. Recrystallization from methanol gave pure **3** (100 mg), identical with an authentic sample.

Irradiation of Selenofenchone 2 in Benzene

Selenofenchone **2** (120 mg) in benzene (10 mL) was irradiated through Pyrex with a medium pressure mercury lamp for 36 h and the resulting green solution was chromatographed (silica gel/pentane) to give unchanged starting material (8 mg) and a yellow oil (105 mg) which travelled near the solvent front. High pressure liquid chromatography of this material indicated the presence of two major components, the faster moving of which was separated in sufficiently pure form to allow crystallization to give a sample of the diselenide **13**, mp 70–77°C; ir (CCl_4) 3080, 2980, 2940, 2890, 1540, 1460, 1360, 1320 cm^{-1}; ^{1}H-nmr ($CDCl_3$) 1.82 (1 H, broad d, $J = 9$ Hz), 1.69 (1 H, broad d, $J = 9$ Hz), 1.57 (1 H, m), 1.41 (3 H, s), 1.28 (1 H, broad d, $J = 9$ Hz), 1.22 (1 H, broad m), 1.16 (1 H, broad d, $J = 9$ Hz), 0.92 (3 H, s), 0.88 (3 H, s); ms *m/e* (for Se containing fragments, the peak corresponding to ^{80}Se is given) 430 (m^+, 27%), 215 (39, containing 1 Se atom), 173 (18, containing 1 Se atom), 159 (34, containing 1 Se atom), 137 (14), 135 (40), 134 (100), 133 (54), 121 (23), 119 (49), 108 (40), 106 (27), 94 (25), 92 (39), 82 (59 $H_2{}^{80}$Se), 80 (54, $H_2{}^{78}$Se), 78 (27, $H_2{}^{76}$Se), for analysis of isotopic distribution of selenium in the

molecular ion see Table 3; precise mass determination: $C_{20}H_{30}{}^{80}Se_2$ requires *m/e* 430.0677; $C_{20}H_{30}{}^{78}Se^{82}Se$ requires *m/e* 430.0687. Found, 430.0682, 430.0687.

Reduction and Alkylation of Diselenides ***13, 14, and 15***

A degassed solution of selenofenchone (185 mg) in benzene (10 mL) was irradiated through Pyrex with a medium pressure mercury lamp for 34 h. The solvent was removed from the greenish yellow solution and the residue was chromatographed (silica gel/pentane) to give the mixture of diselenides (110 mg) which was dissolved in ether and added, under nitrogen, to lithium aluminum hydride (61 mg) in ether. At completion of the addition the yellow colour of the diselenides had disappeared. Methyl iodide (1.4 g) was added and the solution was stirred for 16 h. Following an aqueous work-up the product was chromatographed twice (silica gel/pentane) to give starting material (37 mg), selenide **16** (44 mg), and selenide **17** (25 mg) as oils. For **16**; ^{13}C-nmr see Table 4; ^{1}H-nmr (CDCl) 1.95 (3 H, s), 1.75 (1 H, broad d, J = 10.5 Hz), 1.70 (broad dt, 1 H, J = 10.5, 1.5 Hz), 1.49 (1 H, m, J = 1.5 Hz), 1.41 (3 H, s), 1.28 (1 H, broad dt, J = 10.5, 1.5 Hz), 1.17 (1 H, broad d, J = 10.5 Hz), 1.01 (1 H, broad s), 0.91 (6 H, s); ms, *m/e* (for Se containing fragments, only the largest peak, corresponding to ^{80}Se, is given) 230 (M^+, 31), 215 (25, contains Se), 187 (12, contains Se), 171 (11, contains Se), 159 (4, contains Se), 135 (16), 119 (100), 108 (30), 106 (31), 94 (36), 93 (23), 92 (75), 80 (42), 78 (41), 69 (40); precise mass determination: $C_{11}H_{18}{}^{80}Se$ requires *m/e* 230.0573; found, 230.0577; *Anal.* calcd. for $C_{11}H_{18}{}^{80}Se$: C 57.64, H 7.91; found: C 57.45, H 8.10. For **17**; ^{1}H-nmr ($CDCl_3$) 2.56 (1 H, d, J = 2.5 Hz), 1.95 (3 H, s), 1.78–1.05 (7 H, superimposed multiplets), 1.15 (3 H, s), 1.03 (6 H, s); ^{13}C-nmr, see Table 4; ms, *m/e* (for Se-containing fragments, only the largest peak corresponding to ^{80}Se is given) 232 (M^+, 5.5), 217 (0.5, contains Se), 149 (2, contains Se), 137 (29), 96 (21), 82 (100), 69 (19), 52 (19); precise mass determination: $C_{11}H_{20}{}^{80}Se$ requires 232.0730; found 232.0725.

Preparation and ^{31}P nuclear magnetic resonance studies of chiral phosphines

NICHOLAS C. PAYNE[1] AND DOUGLAS W. STEPHAN

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 2, 1979

NICHOLAS C. PAYNE and DOUGLAS W. STEPHAN. Can. J. Chem. **58**, 15 (1980).

The reaction of Li metal with alkyldiphenylphosphines generates the alkylphenylphosphide anions, which can undergo subsequent reactions with alkyl halides to give chiral phosphines (RR′R″P). The ^{31}P nmr chemical shifts have been measured for these phosphines, and show greater deviations from the values predicted by the first order additivity model than do those of more symmetrical phosphines (i.e., R_3P and $R_2R'P$). The shifts for these chiral molecules, and for a wide range of other phosphines, can be accurately predicted using a second order pairwise additivity scheme. The dependence of the observed and calculated chemical shifts upon electronegativity and steric factors is discussed.

NICHOLAS C. PAYNE et DOUGLAS W. STEPHAN. Can. J. Chem. **58**, 15 (1980).

La réaction du lithium métallique avec les alkyldiphénylphosphines produit des anions alkylphénylphosphures qui, par des réactions subséquentes avec les halogénures d'alkyle, peuvent conduire à des phosphines chirales (RR′R″P). La mesure des déplacements chimiques du ^{31}P révèle que ces phosphines ont, par rapport aux valeurs prévues du modèle d'additivité de premier ordre, des déviations plus grandes que celles d'autres phosphines plus symétriques (i.e., R_3P et $R_2R'P$). Pour ces molécules chirales et un grand nombre d'autres phosphines, on peut prédire, avec précision, les déplacements chimiques en utilisant un modèle apparié d'additivité de deuxième ordre. On discute du fait que les déplacements chimiques observés et calculés dépendent des facteurs d'électronégativité et stérique.

[Traduit par le journal]

Introduction

Catalytic asymmetric hydrogenation has received considerable attention of late (1–10). The common component in these studies has been the use of metal complexes of chiral phosphines to hydrogenate unsaturated prochiral substrates. It has been shown by both crystallographic studies (2, 11) and chemical modification of the chiral phosphine (12) that the orientation of the substituents on the phosphorus atoms dictates the degree of asymmetric induction. In initiating further research in this area, we have undertaken the preparation of some phosphines containing one phenyl substituent, with the chiral centre at the phosphorus atom. Previously used routes to the racemic modifications of such phosphines are in general tedious, with poor yields (reactions [1] to [4]) (13–16).

$$[1]\quad RR'R''P{=}O \xrightarrow{LiAlH_4} RR'R''P$$

$$[2]\quad RR'R''_2PI \xrightarrow{Na} RR'R''P$$

$$[3]\quad RR'HP \xrightarrow{Li} RR'P^- \xrightarrow{R''X} RR'R''P$$

$$[4]\quad RR'PCl \xrightarrow{R''MgX} RR'R''P$$

In each of these cases the preparation of the starting material is not trivial. In contrast, we have prepared the racemic modifications of chiral phosphines from the commonly available alkyldiphenylphosphines.

Chiral phosphines provide an excellent test for the validity of a ^{31}P chemical shift additivity scheme. The observed chemical shifts for these phosphines deviate from the first order calculation (17) to a greater extent than those of the more symmetrically substituted phosphines (i.e. R_3P and $R_2R'P$). This led us to propose an alternative scheme, a second order pairwise additivity model, which proves to be both more accurate and applicable to a wider range of phosphines.

Experimental

All preparations were done under an atmosphere of dry nitrogen. The ^{31}P nmr spectra were recorded for ether solutions of the purified phosphines and methylene chloride solutions of the phosphonium salt derivatives. Samples were sealed in 10 mm tubes under a nitrogen atmosphere. $(CH_3O)_3PO$ was used as the external reference, though the reported chemical shifts are relative to 85% phosphoric acid. The spectra were recorded on a Varian Associates XL 100 instrument operating at 40.5 Mc s^{-1}, and broad band proton decoupling was employed. Proton nmr spectra were recorded on both the XL 100 and T60 spectrometers. Infrared spectra were obtained on a Perkin-Elmer 621 infrared spectrometer. Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. Analyses were performed by the Spang Microanalytical Lab., Eagle Harbor, Michigan and Gygli Microanalysis Lab., Toronto, Ontario.

Preparation of Starting Materials

Diphenylmethylphosphine (18) and diphenylcyclohexylphosphine were prepared by the standard Grignard routes, using freshly distilled ether (from $LiAlH_4$), the appropriate Grignard reagent and chlorodiphenylphosphine obtained from Aldrich Chem. Co. Inc.

A. Preparation of Ethylmethylphenylphosphine, PPhMeEt

Diphenylmethylphosphine (30 mL) was dissolved in freshly

[a]These chemical shifts are reported in ppm relative to 85% H_3PO_4 such that a downfield shift is positive.
[b]Temperatures reported are uncorrected.
[c]Since this phosphine was an air stable solid, no derivative was prepared.
[d]Yields were not recorded.

distilled tetrahydrofuran (from Na/benzophenone) and 2.5 g of Li metal, freshly cut, were added. The mixture was stirred for 5 h. Within the first 15 min an intense red colour appeared. After stirring, the solution was cooled in a salt/ice bath and 24.6 mL of bromoethane (35.9 g) was added dropwise over a 45 min period with stirring. Gradually the solution faded in colour and was allowed to warm to room temperature. It was then stirred for an additional hour. Degassed H_2O (150 mL) was added slowly to the solution which was cooled in an ice bath. After only a few drops were added the colour changed from red to pale yellow. After completion of the hydrolysis, the THF layer was removed and the aqueous layer extracted with ether. The THF layer and the ether extracts were combined and dried overnight over magnesium sulfate. The magnesium sulfate was filtered off and the THF and ether removed by distillation. Vacuum distillation of the remaining solution yielded 9.2 g of ethylmethylphenylphosphine (37%) bp 108–112°C/20 mm.

In an analogous manner methylphenylpropylphosphine, PPhMePr, was prepared by reaction of the phosphide anion with 1-bromopropane. By generating the phenylcyclohexylphosphide anion from diphenylcyclohexylphosphine, the preparations of cyclohexylmethylphenylphosphine, PPhMeCy, cyclohexylethylphenylphosphine, PPhEtCy, and cyclohexylphenylpropylphosphine, PPhPrCy, were achieved. Details are given in Table 1.

B. Preparation of Benzylmethylphenylphosphine, PPhMeBz

Attempts to prepare benzylmethylphenylphosphine from lithium methylphenylphosphide and benzyl chloride were hindered by difficulties in separation of the product from unreacted starting material (i.e. diphenylmethylphosphine). Because of this, an alternative route was used. Benzyldiphenylmethylphosphonium iodide was prepared by the route of Bailey *et al.* (10); 44 g of this salt were dissolved in freshly distilled THF and 3.87 g of lithium aluminum hydride added. The mixture was refluxed for 30 h. The major portion of the THF was then distilled off. Sodium potassium tartrate solution (20%, 385 mL) was added slowly with cooling (ice bath). Following this hydrolysis the solution was stirred for 30 min and extracted with two 325 mL portions of ether. The extracts were combined, dried over magnesium sulfate, filtered, and the ether distilled off. Vacuum distillation gave 9.0 g (41%) benzylmethylphenylphosphine, bp 120°C/5 mm.

C. Preparation of 1,4-Di(cyclohexylphenylphosphino)butane

The starting material was the dimesylate of 1,4-butanediol. This was prepared by analogy to the work of Crossland and Servis (19). 1,4-Butanediol (19.28 g) was dissolved in 450 mL of methylene chloride and 90 mL of triethylamine was added. Methanesulfonylchloride (54 mL) was added dropwise with cooling (ice bath), and the mixture stirred for 4 h. The solution was extracted successively with 250 mL each of water, 10% HCl solution, saturated bicarbonate solution, and saturated brine solution. The methylene chloride layer was dried over magnesium sulfate. The solution was then filtered, the solvent removed by rotary evaporation, and the oil crystallized by addition of ether. The product was filtered and washed with cold THF. The formulation as the dimesylate of 1,4-butanediol was supported by the ^1H nmr and mass spectra.

As before lithium cyclohexylphenylphosphide was prepared from 62.9 g of diphenylcyclohexylphosphine and Li metal (3.25 g). To this solution, 25.8 mL of freshly distilled *tert*-butyl chloride was added slowly over a 50 min period. Dimesylate (19 g) was added over a period of half an hour. The red colour faded to orange-yellow during an additional half hour of stirring. H_2O (125 mL) was added slowly, and the THF was distilled off. The aqueous layer was extracted three times with 125 mL of ether, and the ether layers combined and filtered. To

the ethereal solution 22.75 g of $Ni(NO_3)_2 \cdot 6H_2O$ in absolute alcohol was added. Sodium thiocyanate (29 g) in absolute alcohol was also added and the resulting mixture stirred overnight. The crude nickel complex (40 g) was filtered off, suspended in 165 mL of ethanol, treated with 19 g of sodium cyanide, and stirred for 24 h. The solution was then extracted with three portions (250 mL) of ether, and the extracts dried over magnesium sulfate. The ether layer was filtered and the solvent removed by rotary evaporation. The resulting coloured oil was passed down a 20 cm column of alumina with ether elution. Removal of the solvent yielded a colourless oil which crystallized in ethanol. The yield was 3.4 g (10%) of 1,4-di(cyclohexylphenylphosphino)butane.

D. Preparation of Dipropylmethylphosphine, Dibenzylmethylphosphine, Dicyclohexylethylphosphine, and Dicyclohexylpropylphosphine

These phosphines were prepared from the appropriate Grignard reagent and either dichloromethylphosphine, chlorodicyclohexylphosphine, or dichloroethylphosphine, which were purchased from the Pressure Chemical Co.

E. Preparation of the Phosphonium Salts

To an ether solution of the appropriate phosphine, excess iodomethane was added. Crystallization occurred rapidly. The solutions were cooled, filtered, the white salt isolated and washed with excess ether.

Results and Discussion

Preparative Route

The chiral phosphines reported here were synthesized via reaction [5].

$$[5]\quad PPh_2R + 2Li \rightarrow PPhR^-Li^+ + Li^+Ph^-$$
$$\downarrow R'X$$
$$PPhRR' \text{ (33–56%)} + LiX + PhR'$$

Cleavage of a phenyl ring from the alkyldiphenylphosphine was accomplished with lithium metal in THF under a dry, oxygen free, nitrogen atmosphere. Subsequent reaction of the alkylphenylphosphide anion with a suitable alkyl halide, followed by distillation, yielded the racemic modification of the trisubstituted phosphine. This route has the advantage that a commonly available starting material exists, whereas previous routes required chiral phosphorus precursors.

Attempts to prepare PPhMeR by the same route, where R is benzyl (Bz) or substituted phenyl groups, proved unsuccessful. ^1H and ^{31}P nmr spectra clearly illustrated the presence of a mixture of product and unreacted starting material in the distillate.

To prepare a sample of PPhMeBz, a method analogous to that used by Bailey *et al.* (16) was employed. The reaction route is shown in reaction [6].

$$[6]\quad PPhCl_2 + BzMgX \xrightarrow{Et_2O} PPhBz_2 \xrightarrow[Et_2O]{MeI} PPhBz_2MeI$$
$$\downarrow LiAlH_4/THF$$
$$PPhMeBz\ (22\%)$$

In addition to the monophosphines, a chiral bidentate phosphine was also prepared by reaction [5]. In order to achieve disubstitution, a better leaving group than a halide ion is required. Use of the dimesylate of 1,4-butanediol resulted in the product $(PhCyPCH_2CH_2)_2$. Purification of the ligand by formation of the nickel thiocyanate complex, followed by subsequent displacement from the metal with cyanide ion was successful, since the desired product is removed from the organic impurities present resulting from incomplete or elimination reactions.

All the phosphines were characterized by their ^{31}P, ^1H nmr, and ir spectra. The purity of the phosphines was indicated by the presence of only singlets in the ^1H decoupled ^{31}P nmr spectra. Observed chemical shifts are given in Table 1. Proton spectral integrations were consistent with the formulated products. Overlapping of signals, particularly when a cyclohexyl group was present, precluded the observation of many of the expected coupling constants. Methyl–phosphorus coupling (J_{P-CH_3}) is reported, as the resonances are sharp and intense doublets. As has been observed for other phosphines (20), the coupling of the phosphorus to the β methyl group in PPhMeEt was observed to be stronger than to the α methyl group. Infrared spectra showed the expected absorptions and in addition indicated that no oxidation had occurred. Analytical data, ^{31}P and ^1H nmr spectra were obtained for the methyl iodide derivatives of the monophosphines. These results are listed in Tables 1 and 2. For the phosphonium salts, ^{31}P nmr spectra showed singlets with the expected downfield shift of the resonances relative to the precursor phosphines. Proton spectra of the phosphonium salts were as expected, with a marked increase in the phosphorus–hydrogen coupling constant relative to those seen for the corresponding phosphines.

The proton spectra of PPhMeBz and $PPhBz_2MeI$ illustrated the magnetic inequivalence of the benzyl protons. With the chiral centre at the phosphorus atom, these protons become diastereotopic and thus geminal coupling is observed.

^{31}P nmr Additivity Schemes to Account for Chemical Shifts

The concept of an empirical additivity scheme has been applied to a variety of spectroscopic parameters (21, 22). Grim *et al.* (17) proposed a first order group contribution additivity scheme for the ^{31}P chemical shifts of trivalent phosphorus species. Tabulated in Table 5 are the observed and calculated ^{31}P chemical shifts for a large number of phosphines. The approach of Grim *et al.* showed significant deviations from the observed ^{31}P chemical shift for phosphines with substituents whose electronegativity

is markedly different from that of a typical alkyl or aryl group (i.e. H, CF_3, $SnMe_3$).

The ^{31}P chemical shifts of the common alkyl or aryl phosphines have been observed to be qualitatively dominated by the steric bulk of the substituents (23, 28). An attempt was made to demonstrate this in a quantitative fashion by correlating the first order ^{31}P chemical shift group contribution of a substituent to its cone angle. The substituent cone angles were defined from crystallographic positional parameters. Phosphorus–carbon and carbon–hydrogen bond lengths were assumed to be 1.8 and 1.0 Å respectively, and phosphorus, carbon, and hydrogen atoms were assumed to be spherical with atomic radii of 1.9, 1.4, and 1.2 Å, respectively. The intersections of all atoms of the substituent with planes normal to the P—C bond were calculated at 0.2 Å intervals along the P—C vector in the region between 1.0 Å and 4.0 Å from the phosphorus atom. At 5° intervals about the P—C bond the maximum breadth of intersection was considered to subtend an angle at the phosphorus nucleus. The reported cone angles (Table 4) are an average of the maximum values calculated at each of the 5° intervals. The plot of the substituent cone angles versus the ^{31}P chemical shift group contributions is shown in Fig. 1. In general, a steric dependence of ^{31}P chemical shift for alkyl/aryl phosphines is observed, though significant deviations from linearity occur, which can be attributed to the electronic factors that affect the contribution of a group to the chemical shift.

TABLE 4. Substituent cone angle

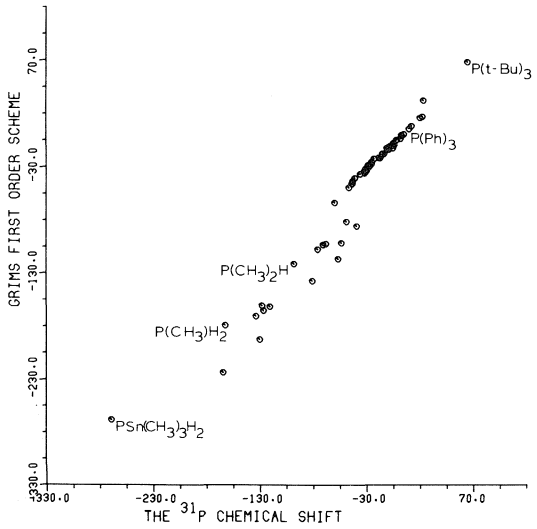

FIG. 2. First order calculation of the ^{31}P chemical shift versus the observed values.

aryl phosphines, the discrepancy between calculated and observed ^{31}P chemical shifts is significantly larger than that seen for the more symmetric phosphines. In light of this we propose an alternative additivity scheme. Our approach considers three substituent pairwise contributions to the chemical shift. Thus, for PPhMeEt the sum of the Ph–Me, Ph–Et, and Me–Et pairwise contributions would yield the observed ^{31}P chemical shift. Pairwise contributions involving the lone pair of electrons as one 'substituent' were not included, so to calculate the R–R′ pairwise contribution constant (PC), eqs. [7] and [8] were solved using the observed chemical shifts (CS) for PR_3 and PR_2R'

$$[7]\quad CS_{PR_3} = 3PC_{R-R}$$

$$[8]\quad CS_{PR_2R'} = 2PC_{R-R'} + PC_{R-R}$$

Repetition of such calculations yielded the pairwise contribution constants tabulated in Table 3.

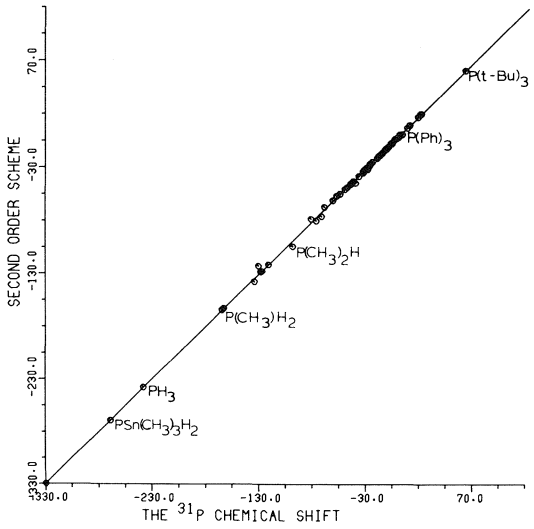

FIG. 3. Second order pairwise calculation of the ^{31}P chemical shift versus the observed values. The straight line is an unweighted least-squares fit of the plotted data. The correlation coefficient here is 1.000.

Table 5 shows the calculated chemical shifts for a wide range of phosphines using this second order approach. These data are also illustrated graphically in Figs. 2 and 3. Not only for alkyl/aryl phosphines or phosphines with electronegative substituents, but even for phosphines that contain a $SnMe_3$ group, for which no consistent group contribution constant could previously be assigned (27), the agreement between observed and calculated ^{31}P chemical shifts is significantly better using the second order pairwise additivity scheme. The improvement can be attributed to the fact that this scheme takes account of the environment of the substituent, and in that way better reflects the steric and electronic factors that alter the ^{31}P chemical shifts.

Studies on trifluoromethanesulfonic acid. Part 2. Conductivities of solutions of metal trifluoromethanesulfonates and other bases in trifluoromethanesulfonic acid

DAVID G. RUSSELL AND JOHN B. SENIOR[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received May 29, 1979

DAVID G. RUSSELL and JOHN B. SENIOR. Can. J. Chem. **58**, 22 (1980).

Electrical conductivity measurements are reported for solutions in trifluoromethanesulfonic acid of a number of simple and complex bases, including univalent and divalent metal trifluoromethanesulfonates. The univalent metal salts, water, aniline, and acetic acid behave as fully dissociated bases, while the alkaline earth metal salts show considerable ion association. The trifluoromethanesulfonate anion appears to have an abnormally high mobility, as compared to the metal cations, and is believed to conduct by a proton-transfer mechanism. Dissociation constants for some weak organic bases and association constants for strontium and barium trifluoromethanesulfonates are estimated. Sulfuric acid behaves as a weak electrolyte, while sulfur trioxide is effectively a non-electrolyte. The conductivities of potassium nitrate and potassium dihydrogenphosphate are consistent with the formation of the nitryl cation and the phosphate acidium ion, respectively.

DAVID G. RUSSELL et JOHN B. SENIOR. Can. J. Chem. **58**, 22 (1980).

On rapporte les mesures de conductivité électrique d'un certain nombre de bases simples et complexes incluant les trifluorométhane sulfonates de métaux mono et bivalents en solution dans l'acide trifluorométhane sulfonique. Les sels de métaux monovalents, l'eau, l'aniline et l'acide acétique se comportent comme des bases totalement dissociées alors que les sels de métaux alcalino terreux montrent une très grande association d'ions. L'anion trifluorométhanesulfonique semble avoir une grande mobilité qui est anormale si on la compare à celle des cations métalliques et on pense que cette mobilité est due à un mécanisme de transfert de proton. On évalue les constantes de dissociation de quelques bases organiques faibles et les constantes d'association des trifluorométhanesulfonates de strontium et de barium. L'acide sulfurique se comporte comme un électrolyte faible alors que l'anhydride sulfurique est effectivement un non électrolyte. Les conductivités du nitrate et du phosphate diacide de potassium sont en accord avec la formation du cation nitryle et de l'ion phosphate acidium respectivement.

[Traduit par le journal]

Introduction

Trifluoromethanesulfonic acid (HTFMS) was first prepared in 1954 (1). Since that time, and especially since the acid has become commercially available, there has been considerable interest in this very strong acid as a solvent and reaction medium. An extensive review was recently published covering the literature prior to 1976 (2). Since the majority of solutes may be expected to give rise to ionic species in solution in HTFMS, electrical conductivity measurements should prove valuable in studying solute behavior. Although conductivity measurements have been made on mixtures of HTFMS with sulfuric acid (3), carboxylic acids (4), and water (5), no previous systematic study has been made of solutions in HTFMS itself as solvent. In this paper we report the conductivities of solutions in HTFMS of Group IA and IIA metal trifluoromethanesulfonates and of a number of other simple and complex bases.

Experimental

HTFMS (3M Company) was purified by double distillation at atmospheric pressure with rigorous exclusion of moisture. The fraction boiling at 162°C was collected directly in the conductivity cell. This acid was free from H_2SO_4 (a significant impurity in the commercial acid) and all samples had specific conductivities less than 1.6×10^{-4} ohm^{-1} cm^{-1} at 25°C. In later experiments a small amount of P_2O_5 was added prior to the first distillation. This resulted in a significant reduction of the specific conductivity to values within the range 3.48 to 7.0×10^{-5} ohm^{-1} cm^{-1}. Some HTFMS anhydride was produced, it was discarded in the lower boiling fractions.

Barium trifluoromethanesulfonate (3M Company) was recrystallized from water. *Alkali metal and thallium(I) trifluoromethanesulfonates* were prepared by addition of a slight excess of the appropriate metal sulfate to an aqueous solution of barium trifluoromethanesulfonate.. The reaction mixture was allowed to stand for 1 day, and filtered to remove the precipitate of barium sulfate. The filtrate was evaporated to dryness and the product recrystallized from dried acetone. All the salts were

tested and found to be free from Ba^{2+} and SO_4^{2-} ions. *Ammonium trifluoromethanesulfonate* was prepared by the addition of ammonia to an aqueous solution of HTFMS to give a neutral solution, followed by careful evaporation of the solvent. *Calcium, strontium, and silver trifluoromethanesulfonates* were prepared by the addition of a slight excess of the appropriate carbonate to aqueous HTFMS. After filtration and evaporation to dryness, the calcium and strontium salts were recrystallized from dried acetone and the silver salt was recrystallized from a dried benzene – carbon tetrachloride mixture. All of the salts were dried under vacuum at 110°C.

Analyses: lithium, sodium, strontium, and barium were determined gravimetrically as their sulfates. Potassium, rubidium, caesium, and thallium were precipitated and weighed as their tetraphenylborates. Silver was determined gravimetrically as the chloride. Calcium was precipitated as the oxalate and after ignition was weighed as the carbonate. The ammonium salt was analyzed by determining its ammonia content. Analytical data and melting points are shown in Table 1. Infrared spectra of the salts (Nujol mulls) showed only bands characteristic of the $CF_3SO_3^-$ ion (6). The absence of bands at 1610, 3600, and 3750 cm^{-1} showed that the samples were free from water.

Nitrobenzene was purified by fractional freezing (mp 6°C). *Nitromethane* was fractionally distilled twice (bp 97.5/735 mm Hg). *Aniline* was refluxed with stannous chloride, then distilled. Glacial *acetic acid* was refluxed with acetic anhydride followed by fractional distillation. p-*Nitrochlorobenzene* was recrystallized twice from methanol and stored over P_2O_5 in a vacuum desiccator (mp 83°C). *1,3,5-Trinitrobenzene* was recrystallized from glacial acetic acid, washed with water, then dried and stored over P_2O_5 in a vacuum desiccator (mp 122–123°C).

Reagent grade *potassium nitrate* and *potassium dihydrogenphosphate* were dried at 120°C. Anhydrous *sulfuric acid* was prepared by adding sufficient dilute oleum to minimum-conducting sulfuric acid to increase its conductivity to 1.0439×10^{-2} ohm^{-1} cm^{-1}. *Sulfur trioxide* was distilled from 65% fuming sulfuric acid.

Conductance measurements were made in an oil thermostat at 25 ± 0.002°C using an Industrial Instruments Inc. RC 18 conductivity bridge. Conductivity cells were similar to those described by Barr *et al.* (7), with platinized platinum electrodes. Cell constants were determined using minimum-conducting sulfuric acid as a secondary standard (8). Solid and liquid solutes were added to the conductivity cell from weight burettes, with minimum exposure to the atmosphere.

Densities were measured at 25 ± 0.002°C using a 25 mL specific gravity bottle.

Results and Discussion

Some properties of HTFMS are summarized in Table 2. By analogy with other protonic solvents it may be assumed that HTFMS undergoes autoprotolysis

$$2CF_3SO_3H \rightleftharpoons CF_3SO_3H_2^+ + CF_3SO_3^-$$

The lowest value we measured for the conductivity of HTFMS, 3.48×10^{-5} ohm^{-1} cm^{-1}, is significantly lower than previously reported values (4, 5), and thus represents an upper limit for the conductivity of the pure acid. We provisionally adopt this value for the conductivity of pure HTFMS, due to the autoprotolysis ions. If a sample of HTFMS has a conductivity in excess of this value, the excess must be ascribed to impurities; the most probable of these being water, which acts as a strong base. From the measured initial conductivities of the solvent, we estimate the maximum concentrations of water to be 5×10^{-4} *m* and 2×10^{-3} *m* respectively, for samples prepared with and without P_2O_5 addition in the first distillation step. Conductivities reported in Tables 3, 4, and 6 have been corrected for the conductivity due to impurities in the solvent using the expression:

$$\kappa_{corr} = \kappa_{obs} - (\kappa_{solv} - \kappa_{ap})$$

where κ_{obs} and κ_{corr} are respectively the observed and corrected conductivities of the given solution, κ_{solv} is the initial conductivity of the solvent and $\kappa_{ap} = 3.48 \times 10^{-5}$ ohm^{-1} cm^{-1}.

Bases in HTFMS as solvent may be defined as substances which increase the concentration of the trifluoromethanesulfonate ion, $CF_3SO_3^-$, and acids as substances which increase the concentration of the acidium ion $CF_3SO_3H_2^+$. By analogy with the behavior of the corresponding salts in other strong acid solvents, the Group IA and IIA metal trifluoromethanesulfonates might be expected to behave as strong bases of the HTFMS solvent system.

tions of metal trifluoromethanesulfonates are given in Table 3. The original experimental results are available as supplementary material.[2] The conductivity curves of the univalent metal salts are very similar (Fig. 1), suggesting that these salts do in fact behave as fully dissociated bases of the HTFMS system. The conductivities decrease slightly, at any given concentration, in the order

$$Ag > Tl \sim NH_4 \sim Cs > Rb > K > Na > Li$$

The relatively small dependence of the conductivity on the nature of the cation suggests that the major part of the current is carried by the $CF_3SO_3^-$ anion, which could conduct by a proton-transfer mechanism as well as by the normal ion-migration mechanism, and thus have an abnormally large mobility. This has been shown to be the case for the anions HSO_4^- (9), SO_3F^- (7), and SO_3Cl^- (10) ions in their respective parent solvents. Estimates of normal ionic mobilities in HTFMS using Walden's rule suggests strongly that the $CF_3SO_3^-$ ion does indeed have an abnormally large mobility in HTFMS solution. In fluorosulfuric acid (viscosity 1.56 cP), the limiting ionic mobility of the potassium ion, $\lambda^0_{K^+}$, has been found from transport number measurements to be 17 ohm^{-1} cm^2 equiv^{-1} (7). Using the value of 2.97 cP for the viscosity of HTFMS (5) we estimate $\lambda^0_{K^+}$ in HTFMS to be 9. The limiting equivalent conductance Λ_0 of CF_3SO_3K in HTFMS, obtained by linear extrapolation of the curve of Λ vs. $c^{1/2}$ to zero concentration is 44.5, from which $\lambda^0_{CF_3SO_3^-}$ is 35.5. Similarly $\lambda^0_{Na^+}$ in chlorosulfuric acid (viscosity 2.43 cP) has been reported to be 9 (10), from which we deduce $\lambda^0_{Na^+}$ in HTFMS to be 7. We find $\Lambda_0(CF_3SO_3Na)$ to be 44.8, giving $\lambda^0_{CF_3SO_3^-} = 37.8$. These two estimates agree reasonably well, considering the approximate nature of Walden's rule, and indicate that the $CF_3SO_3^-$ ion carries approximately 80% of the total current in these solutions, about the same fraction carried by the abnormally-conducting hydroxide ion in aqueous solutions of alkali metal hydroxides. At the same time, the mobility of $CF_3SO_3^-$ is considerably lower than those of SO_3F^- and SO_3Cl^- in their parent solvents, which suggests that the proton-transfer mechanism is less effective in HTFMS than in these other solvents. It is possible that the more bulky CF_3 group in some way hinders the reorientation of solvent molecules, which is an essential, and possibly rate-limiting, step in the proton-transfer conduction process. More definite conclusions concerning individual ionic mobilities must await the results of transport

[2]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

number measurements. Fialkov and Ligus (4) have reported transport fractions for some carboxylic acid – HTFMS mixtures. Although these refer to much more concentrated solutions than any studied in the present work, it is perhaps of interest that for an approximately 1.0 *m* solution of acetic acid (a strong base in HTFMS), the transport fraction for the $CH_3COOH_2^+$ ion is reported to be 0.181, which is just the magnitude predicted by our calculations.

The order of conductivities of the univalent salts is similar to that found in other strong acid solvents (7, 9, 10) and may be explained in an analogous manner in terms of an increase in the extent of cation solvation in the order

$$Ag < Tl \sim NH_4 \sim Cs < Rb < K < Na < Li$$

Cation solvation could affect the conductivity in two ways. Firstly, the more highly solvated cations will have larger Stokes radii and thus lower mobilities. Secondly, solvent molecules which are "tied up" in the solvation shells of cations are less available to participate in the proton-transfer mechanism of conduction by the anion, and the most highly solvated cations will interfere with this mechanism to the greatest extent. The latter effect may be the more important, especially at high concentrations, if the cations conduct a rather small fraction of the total current.

Plots of equivalent conductivity, Λ, vs. the square root of the molar concentration, $c^{1/2}$, for the univalent metal trifluoromethanesulfonates were linear up to the highest concentrations studied. Since density data were not available for most of the solutions studied, the conversion from molal to molar concentrations was made assuming the solutions to have the same density (1.696 g cm^{-3}) as the pure solvent. In the case of the potassium salt, for which the following densities were measured: $m = 0.0786, d = 1.705$; $m = 0.169, d = 1.715$ g cm^{-3}, this approximation appeared to be satisfactory and no significant difference was found either in the slope of the Λ vs. $c^{1/2}$ plot or in the value of the limiting equivalent conductance obtained by extrapolation to zero concentration, when interpolated densities of the solution were used instead of that of the pure solvent. Plots of Λ vs. $c^{1/2}$ are not usually linear over such a wide concentration range for fully dissociated electrolytes, and such behavior might be taken to indicate some degree of ion association. However, similar behaviour observed in aqueous hydrochloric acid solutions (11), and for solutions in sulfuric (9) and fluorosulfuric (7) acids has been attributed (7) to interference with the proton-transfer mechanism of conductance, as solvent molecules are increasingly "tied up" in the solvation shells of cations at higher concentrations.

For sufficiently dilute solutions, the variation of equivalent conductivity with concentration is described by the Debye–Hückel–Onsager limiting law

$$\Lambda = \Lambda_0 - AI^{1/2}$$

where I is the ionic strength, and A depends on the temperature, the charges on the ions, and on the viscosity and dielectric constant of the solvent. The

Nitromethane	2.7	0.76	0.25	Very feebly ionized
1,3,5-Trinitrobenzene	0.004	0.04	—	—

dielectric constant of HTFMS is not known, so it is not possible to compare the observed slopes of the Λ vs. $c^{1/2}$ curves with that predicted by the above equation. Agreement with the observed slopes can be obtained, for the lithium and sodium salts, by inserting into the limiting law equation a value of 58 for the dielectric constant, and for the salts of the other alkali metals, ammonium and thallium(I) by using values in the range 68–71, along with the value of 0.0297 P for the viscosity. A dielectric constant of this order of magnitude would be reasonable for a solvent of this type, and would be consistent both with essentially complete dissociation of uni-univalent salts and the extensive ion association which is found for the salts of divalent cations.

Other Bases

In interpreting the conductivities of solutions of complex bases, and of incompletely ionized bases, we make the assumption that solutions of different bases having equal conductivities contain equal concentrations of the $CF_3SO_3^-$ anion. The ratio, γ, of the concentrations of a fully dissociated reference base and of a base B, having equal conductivities, then gives the number of moles of $CF_3SO_3^-$ ion produced in solution, per mole of B. This method, which is valid if the mobility of the abnormally conducting anion is sufficiently high that differences in cation mobilities may to a good approximation be neglected, has been used successfully for solutions in related solvents such as sulfuric (12), fluorosulfuric (7), and chlorosulfuric (10) acids. With a suitable choice of reference base, so that cation mobilities are as similar as possible, the method appears to give reasonable results in HTFMS also.

Organic Bases

For a weak, monoprotic base, ionizing according to the equation

$$B + CF_3SO_3H \rightleftharpoons BH^+ + CF_3SO_3^-$$

the degree of dissociation is equal to the value of γ as defined above. The dissociation constant K_b may be calculated from the relation

$$K_b = [BH^+][CF_3SO_3^-]/[B] = \gamma^2 m/(1 - \gamma)$$

Brackets denote actual concentrations in molal units and m is the stoichiometric molal concentration of the weak base.

The results of conductivity measurements at 25°C on solutions of acetic acid, aniline, nitrobenzene, *p*-nitrochlorobenzene, nitromethane, and 1,3,5-trinitrobenzene are given in Table 4 and Fig. 2. Acetic acid and aniline give conductivity curves which are very similar to those for the univalent metal trifluoromethanesulphonates, and evidently behave as strong bases.

The other solutes give lower conductivities, and behave as weak bases. Values of K_b for these bases, calculated from the γ-values obtained using aniline as the reference base, are given in Table 5, along with K_b-values for the same bases in other strong acid solvent systems (7, 12–14). It can be seen that in general, for any given base, the K_b-value decreases in the order

$$FSO_3H > CF_3SO_3H > H_2SO_4 > CH_3SO_3H$$

40.0	137.4				
45.0	146.5				

We have shown elsewhere (15) that trifluoromethanesulfonic acid behaves as a weaker acid in sulfuric acid than does fluorosulfuric acid, and it appears that this order of acid strengths holds also for the bulk solvents. 1,3,5-Trinitrobenzene, however, appears to behave as a slightly stronger base in trifluoromethanesulfonic acid than it does in fluorosulfuric acid. We have no explanation for this apparent anomaly.

Group IIA Metal Trifluoromethanesulfonates

Conductivity data for calcium, strontium, and barium trifluoromethanesulfonates are given in Table 3 and Fig. 3. These substances are of limited solubility, and in each case conductivities have been measured up to the most concentrated solutions which could be obtained. Solubility decreases in the order

$$Ba > Sr > Ca > Mg$$

It was not possible to obtain a sufficiently concentrated solution of the magnesium salt to give a meaningful conductivity measurement.

If the divalent metal salts were fully dissociated in solution, they would be expected to produce solutions of a given conductivity at about half the molal concentration required for univalent metal salts, i.e. their γ-values should be close to 2.0. In fact, as Fig. 3 shows, the conductivity curves for the barium and strontium salts, while they do indeed lie above that for the potassium salt at lower concentrations, show considerable curvature, and actually fall below the potassium curve at higher concentrations. The curve for the calcium salt, over its very limited solubility range, never rises above that for potassium. It is evident that these salts undergo extensive ion association in solution, and the formation of both ion pairs

$$M^{2+} + CF_3SO_3^- \rightleftharpoons CF_3SO_3M^+$$

and neutral species

$$CF_3SO_3M^+ + CF_3SO_3^- \rightleftharpoons (CF_3SO_3)_2M$$

must be postulated.

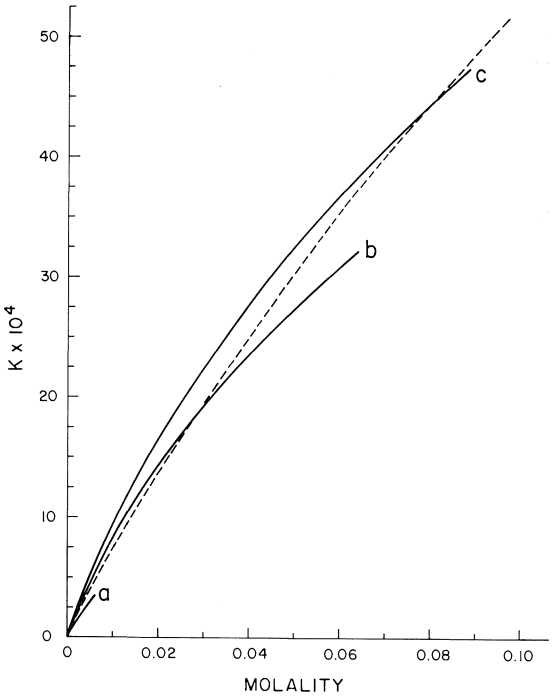

FIG. 3. Specific conductivities of solutions of trifluoromethanesulfonates, $(CF_3SO_3)_2M$. M = *a*, Ca; *b*, Sr; *c*, Ba. Dashed curve, CF_3SO_3K.

The equilibria can be expressed in terms of the association constants as

$$K_1 = [MX^+]/[M^{2+}][X^-]$$

$$K_2 = [MX_2]/[MX^+][X^-] \qquad (X = CF_3SO_3)$$

With γ as defined above, and making the same assumptions, it can be shown that

$$K_1 + \frac{K_1K_2\gamma^2 m}{\gamma - 1} = \frac{2 - \gamma}{\gamma m(\gamma - 1)}$$

Thus a plot of $(2 - \gamma)/\gamma m(\gamma - 1)$ vs. $\gamma^2 m/(\gamma - 1)$ should be a straight line with intercept K_1 and slope K_1K_2. Linear plots were obtained for the barium and strontium salts, using γ-values obtained with CF_3SO_3K as reference base. A least-squares analysis gave the following values for the associa-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tion constants: $Ba(CF_3SO_3)_2$, $K_1 = 51 \pm 3$, $K_2 = 3.2 \pm 0.2$; $Sr(CF_3SO_3)_2$, $K_1 = 250 \pm 20$, $K_2 = 4.7 \pm 0.5$.

The extent of ion association increases with decreasing crystal radius of the divalent metal cation. This is the same order as found for hydroxides in aqueous solution (16) and for chlorosulfates in chlorosulfuric acid (10) and is what would be expected for purely electrostatic anion–cation interaction, and contact ion-pairs. The reverse order might be expected if solvent molecules separated the anion and the cation, since the crystallographically smaller cations would have the larger solvated radii. It has been pointed out (16) that solvent-separated ion pairs formed by metal hydroxides in aqueous solution, M^{n+},H_2O,OH^- would tend to pass over into M^{n+},OH^-,H_2O by proton transfer along a hydrogen bond, and a similar effect would be expected to occur in the present case, so that solvent-separated ion pairs would not be stable.

Inorganic Solutes

Conductivity data for a number of inorganic solutes are given in Table 4 and Fig. 2. The conductivity curve for water is almost identical to that for potassium trifluoromethanesulfonate. Water thus behaves as a strong base, ionizing according to

$$H_2O + CF_3SO_3H \rightleftharpoons H_3O^+ + CF_3SO_3^-$$

Sulfuric acid is a very weak electrolyte in HTFMS. Since HTFMS has been shown to behave as a weak acid in sulfuric acid (15), it is probable that sulfuric acid in turn behaves as a weak base in HTFMS:

$$H_2SO_4 + CF_3SO_3H \rightleftharpoons H_3SO_4^+ + CF_3SO_3^-$$

The K_b-value for sulfuric acid in this solvent is estimated from the conductivity data to be about 1.0×10^{-4}. In the light of these results, the ionic formulation, $H_3SO_4^+CF_3SO_3^-$, proposed by Fialkov and Ligus (3) for the 1:1 compound found by them in the HTFMS – sulfuric acid system, is most unlikely to be correct.

Sulfur trioxide behaves as an extremely weak electrolyte in HTFMS. By analogy with its reactions with sulfuric, fluorosulfuric, and methanesulfonic acids, sulfur trioxide would be expected to form trifluoromethanedisulfonic acid, $CF_3S_2O_6H$, which is expected to be a very weak acid of the HTFMS solvent system. However, no conductivity minimum could be observed on titration with potassium trifluoromethanesulfonate, and this, plus the very low conductivity of the solutions, shows that $CF_3S_2O_6H$, if formed, is extremely weakly ionized. Preliminary studies of nmr spectra of CF_3SO_3H–SO_3 mixtures suggest that $CF_3S_2O_6H$ is formed initially, but the solutions are unstable and decompose slowly over a period of several days, to give a complicated mixture of products.[3] SO_3 was not studied at a low enough concentration to permit detection of the initial decrease in conductivity which might have been expected due to its reaction with the trace amount of water in the solvent.

In order to test the usefulness of conductance measurements for the study of more complex electrolytes, we studied solutions of potassium nitrate and potassium dihydrogenphosphate. The modes of ionization of these two solutes are well established in other strong acid solvents, and there is no reason to suppose that they would behave differently in HTFMS.

Potassium nitrate gives γ-values close to 3, consistent with ionization to give the nitryl cation

$$KNO_3 + 3CF_3SO_3H \rightleftharpoons K^+ + NO_2^+ + H_3O^+ + 3CF_3SO_3^-$$

Potassium nitrate has been shown to ionize similarly in sulfuric acid (17) and in fluorosulfuric acid (18), and the preparation of a mixture of $CF_3SO_3^-NO_2^+$ and $CF_3SO_3^-H_3O^+$ by the reaction of anhydrous nitric acid with HTFMS has been reported (19).

Potassium dihydrogenphosphate gives γ-values close to 2, consistent with ionization to give the phosphate acidium ion

$$KH_2PO_4 + 2CF_3SO_3H \rightleftharpoons K^+ + H_4PO_4^+ + 2CF_3SO_3^-$$

as found for this solute in sulfuric acid (20).

Conclusions

This work demonstrates that conductivity measurements can play a useful role in studies of solute behavior in HTFMS. So long as only singly-charged cations are present, it is possible both to determine the mode of ionization of simple and complex bases, and to estimate, at least semi-quantitatively, the degree of dissociation of weak bases. Some difficulty may be anticipated in the interpretation of results for complex systems in which doubly-charged cations are produced, because of the occurrence of ion association, the extent of which varies considerably with the nature of the ions involved. It would be most desirable to have a reliable value for the dielectric constant of HTFMS, obtained by direct measurement, as this would permit the use of more sophisticated treatments of the data, taking account of non-ideality effects.

Reçu le 18 juin 1979

ROBERT-LOUIS BROSSARD et DOMINIQUE-LOUIS PIRON. Can. J. Chem. **58**, 30 (1980).

L'étude de l'oxydation anodique du magnésium a été entreprise en milieu légèrement alcalin dont l'eau de mer simulée. Les analyses du produit de corrosion, formé en présence d'une forte concentration en ions chlorures, sont compatibles avec la formation d'un composé dont la formule chimique est voisine de $5\,Mg(OH)_2 \cdot MgCl_2$. Cependant, ce chloro-complexe de magnésium se transforme en $Mg(OH)_2$ après un contact de plusieurs heures avec la solution.

Cette étude a conduit à l'élaboration d'un modèle qui permet d'expliquer le comportement anodique du magnésium sans faire appel à la formation d'intermédiaires. Ce modèle lie étroitement les caractéristiques du comportement anodique aux propriétés du produit de corrosion qui se voit traversé par un réseau de pores dans toute son épaisseur. Le courant et l'hydrogène gazeux circulent par les pores tandis que la nature poreuse de ce film explique qu'il soit faiblement protecteur. Par ailleurs, la surconsommation de magnésium qu'entraine le dégagement d'hydrogène s'explique à partir de la dissolution de fines particules de magnésium prisonnières dans le produit de corrosion. De plus, l'activation de l'électrode dès le retour à l'abandon est attribué à la mise à nu du métal à l'extrémité des pores durant la dissolution anodique.

Enfin, la substitution des chlorures par les sulfates comme électrolyte n'affecte nullement la valeur de la tension corrigée de l'anode pour la chute ohmique qui demeure constante à -1.65 V (/E.C.S.) approximativement.

ROBERT-LOUIS BROSSARD and DOMINIQUE-LOUIS PIRON. Can. J. Chem. **58**, 30 (1980).

This study of the anodic behavior of magnesium in simulated seawater has shown that the corrosion product formed at the surface of the electrode depends mainly on the nature of ions dissolved in the electrolyte. Analyses of the corrosion product, formed in the presence of a high concentration of chloride ions, are compatible with the formation of a compound having approximately the formula $5Mg(OH)_2 \cdot MgCl_2$. However, this complex is gradually transformed over a period of several hours into $Mg(OH)_2$.

A model of the oxidation mechanism is presented in which the characteristics of the anodic behavior of magnesium are related to the structure of the oxidation layer. For example, the activation of the surface of the anode, the kinetics of the hydrogen evolution reaction, and the large difference between values of corrected and uncorrected electrode potential can all be explained by this model. It is the resistance of the film to the flow of current which controls the kinetics of anodic dissolution of magnesium.

Introduction

Le magnésium est l'un des métaux les plus actifs du point de vue électrochimique (1). L'utilisation de ce métal offre donc une alternative intéressante dans les systèmes de protection des structures métalliques où il fait avantageusement office d'anode sacrificielle (2). L'anode de magnésium se rencontre aussi dans les piles qui servent, par exemple, à la propulsion des torpilles ainsi qu'à l'alimentation des circuits électroniques que l'on retrouve dans les détecteurs de sous-marins, les ballons météorologiques et les émetteurs de secours (3–17).

La dissolution anodique du magnésium s'accompagne d'un dégagement d'hydrogène qui consomme une fraction des électrons libérés (18–24). Ceci se traduit par un faible rendement faradaique des anodes de Mg généralement observé.

Un procédé d'oxydation en deux étapes intermédiaires a été imaginé pour expliquer ce phénomène. Il comporte la formation initiale d'un intermédiaire: l'ion de magnésium monovalent (Mg^+) (23, 24) ou le dihydrure de Mg (25, 26). La réaction ultérieure de cet intermédiaire avec la solution génèrent les électrons qui servent au dégagement de l'hydrogène (23–26). Par contre, un dernier groupe de chercheurs (27–34) attribue au phénomène de désintégration de l'anode, la surconsommation de métal tandis qu'ils soutiennent que le dégagement d'hydrogène résulte de la réaction de ces particules avec la solution. Les modèles suggérés dans la littérature ont été élaborés principalement à partir de mesures de dégagement d'hydrogène et de pertes de poids dans des milieux alcalins ou s'approchant de la neutralité. Les solutions contenaient généralement des ions chlorures en faible ou forte concentration.

Ainsi, les modèles proposés dans la littérature traduisent des points de vue fort différents et souvent même contradictoires. Le présent travail se propose donc d'approfondir l'étude de l'oxydation anodique de ce métal à partir d'un éventail de tech-

niques expérimentales variées dans les solutions qui simulent les milieux réels d'utilisation dont le plus répandu est l'eau de mer.

Programme expérimental

La cellule et ses organes (fig. 1)

La solution (environ 2 L) repose dans une jarre en Pyrex percée latéralement et recouverte d'un couvercle en Téflon. Celui-ci voit de nombreux tubes le traverser: l'hydrogène pénètre par un long tube de verre (E); un thermomètre permet de relever la température; deux électrodes auxiliaires en platine platinisée assurent le passage du courant vers l'électrode de travail en magnésium (T); une électrode au calomel saturé sert de référence. Elle baigne dans l'électrolyte contenu dans la partie supérieure du capillaire de Luggin; le capillaire traverse complètement la cellule et vient à près de 1 mm de la surface de l'électrode de magnésium; l'hydrogène qui se dégage de l'anode de Mg monte dans une burette graduée partiellement remplie d'électrolyte.

C'est à partir du volume d'électrolyte déplacé qu'on déduit la quantité d'hydrogène dégagée.

L'électrode de magnésium (A) se présente sous forme d'une tige de 1 cm de diamètre par 1.5 cm de profondeur (fig. 2). L'électrode est en contact avec une vis d'acier soudée à un fil de cuivre. Un tube de Tygon serre l'électrode de magnésium tandis que l'époxy remplit l'espace vide entre le tube et les conducteurs.

La pureté des échantillons

L'analyse spectrographique[1] des échantillons révèle la présence de quelques impuretés: Cu: 30 ppm, Fe: 116 ppm, Si: 3 ppm tandis que le magnésium est pur à 99.95%.

Par ailleurs, les échantillons n'ont subit aucun traitement thermique ou autre visant à modifier la grosseur des grains. L'examen de quelques échantillons au microscope a révélé que le diamètre des grains était de l'ordre de 1 mm.

Une eau doublement distillée dont la conductivité spécifique était voisine de $10^{-6}\ \Omega^{-1}\ cm^{-1}$ a été utilisée dans la préparation des solutions.

La préparation des essais

De la solution

Les solutions utilisées ont été soigneusement préparées par des méthodes gravimétriques et volumétriques usuelles. La cellule d'électrolyse et ses divers organes ont subit plusieurs rinçage à l'eau distillée avant de recevoir près de 2 L de solutions.

L'hydrogène gazeux barbottait plus de 12 h dans la solution avant l'immersion de l'électrode de travail. Les solutions étaient légèrement alcalines (le pH étant compris entre 8 et 11) et contenaient une forte concentration en ions sulfates ou chlorures. Les chlorures ont surtout été utilisées.

De l'électrode de Mg

La méthode utilisée par Blanchet (35) a été retenue: l'échantillon subissait préalablement un polissage mécanique avant de subir une attaque chimique.

Une immersion de une demi-heure dans la solution de travail précédait l'imposition du courant ou de la tension à l'électrode de magnésium.

Les techniques expérimentales utilisées

Les courbes de polarisation potentiostatiques et galvanostatiques ont été obtenues par les méthodes courantes.

[1]Certificat d'analyse fourni par Ventron Corp., Chem. Div., Congress St., Beverly, MA.

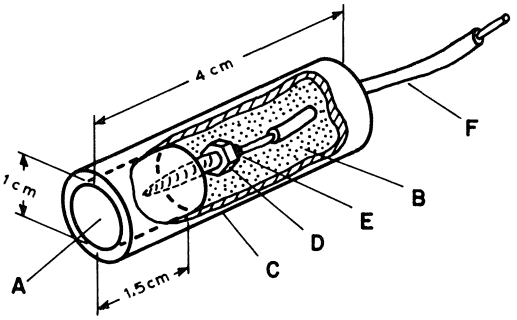

FIG. 2. L'électrode de magnésium et son support. A: disque de magnésium; B: époxy; C: gaine en tygon recouverte extérieurement de ruban de Téflon; D: vis en acier; E: soudure; F: fils de cuivre recouvert d'une gaine de plastique.

En chronopotentiométrie, le courant imposé demeurait constant tandis que la tension d'électrode était enregistrée sur un enregistreur deux plumes Moseley 7100-B de Hewlett-Packard ou à l'aide d'un oscilloscope à mémoire Tektronix No 7623-A pour les variations rapides.

Par ailleurs, la tension d'électrode imposée demeurait constante en chronoampérométrie grâce à l'emploi d'un potentiostat Tacussel PRT 2U-2X tandis que le courant était enregistré en fonction du temps.

Enfin, la tension corrigée de l'électrode a été obtenue par interruption instantanée du courant.

Résultats expérimentaux et discussion

L'analyse des courbes de polarisation potentiostatique, des micrographies montrant les modifications que subit la surface de l'anode et les mesures de la cinétique du dégagement d'hydrogène fournit de précieuses indications sur le processus

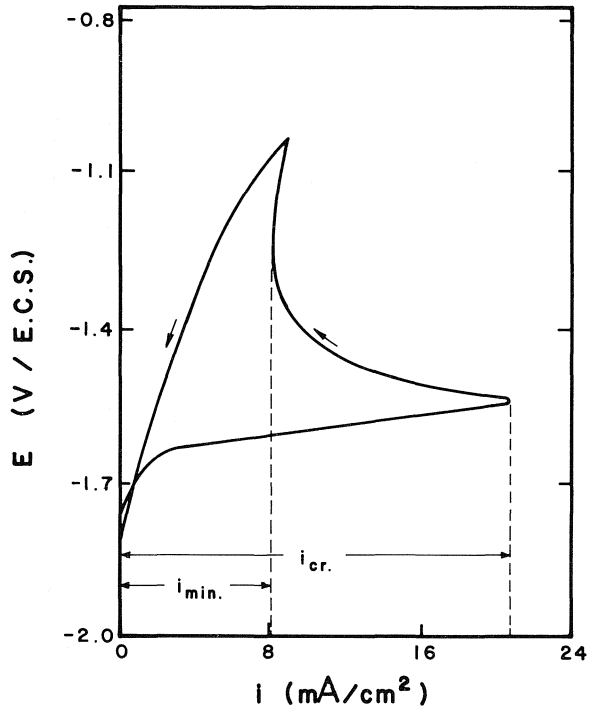

FIG. 3. Courbe de polarisation potentiostatique. E: tension d'électrode; i: densité de courant. Composition de la solution: H_3BO_3: 0.15 M; KOH: 0.086 M; KCl: 1 M; pH: 9.8; T: 25°C; ΔE: +20 mV; Δt: 5 min.

d'électrode. Elles nous ont conduit à l'élaboration d'un modèle qui permet d'expliquer le comportement de l'anode de magnésium.

Elaboration du modèle

L'examen de la courbe de la fig. 3, représentative du comportement anodique du magnésium, révèle un accroissement soudain de la vitesse de dissolution alors que la tension de polarisation est de l'ordre de 100 mV seulement. Pour des valeurs de tension croissantes (convention d'oxydo-réduction) elle passe par un maximum, 20 mA/cm² approximativement, pour décroître ensuite progressivement jusqu'à une valeur voisine de 8 mA/cm². L'allure de cette courbe rappelle la formation de films protecteurs qui sont observés lors de la passivation du nickel (36) et du fer (37) entre autres. Le recouvrement de la surface de l'anode de Mg par un film est nettement visible à l'œil nu.

Cependant, la faible décroissante du courant suggère que la protection offerte par ce dernier est beaucoup moins parfaite que dans le cas du Ni (36) et du Fe (37). Par ailleurs, le phénomène d'hystérésis prononcé (fig. 3) est attribuable à la lenteur ou à l'absence de redissolution du film.

La surface de l'anode a été examinée dans les instants qui précèdent son recouvrement complet par le produit de corrosion. Les examens au microscope optique (50×–300×) révèlent la formation de cavités plus ou moins étendues et profondes où les produits de corrosion ont tendance à s'accumuler. Elles se traduisent par la présence de zones sombres sur les micrographies obtenues (fig. 4). De plus, la portion de surface couverte par ces zones sombres s'accroît avec une augmentation de la quantité d'électricité qui a traversée l'électrode. Par ailleurs, les zones claires sont constituées de petits points d'éclat métallique qui correspondent au magnésium lui-même. Ces observations suggèrent que la dissolution est très localisée tandis que la rugosité de la surface augmente avec la quantité de courant ayant traversé l'anode. La rugosité devient telle qu'il est raisonnable d'envisager que des particules de magnésium se séparent complètement de l'anode pour demeurer captives dans le produit de corrosion.

Ces particules sont sujettes à la corrosion métallique suivant les réactions globales (38):

[1] $Mg \rightarrow Mg^{2+} + 2e^-$

[2] $2H_2O + 2e^- \rightarrow 2OH^- + H_2$

au même titre que la surface de l'anode de Mg en contact avec l'électrolyte. Néanmoins, on a ob-

FIG. 4. Apparence de la surface d'une anode de Mg. Grossissement: 300×; densité de courant imposée: 15 mA/cm²; durée de la polarisation: 3 min. 15 s.

servé qu'un dégagement d'hydrogène gazeux abondant se produit durant plusieurs secondes sur un flocon d'oxyde qui se détache complètement de l'anode de Mg. Ceci suggère que l'hydrogène gazeux résulte surtout de la dissolution des particules métalliques.

Mentionnons que Hoey et Cohen (39) ont aussi observé la dissolution localisée du magnésium dans des solutions de pH = 10 contenant 110 ppm de NaCl tandis que Staumanis et Bhatia (33) ont observé la présence de particules de Mg dans le film d'oxydation anodique formé en solution neutre ou légèrement alcaline.

Revenons aux réactions [1] et [2]. Le dégagement d'hydrogène qui en résulte explique la consommation de magnésium sans produire d'électrons utiles. De plus, une augmentation de la densité de courant doit se traduire par un accroissement proportionnel de la vitesse de dissolution de l'anode métallique. Ce qui entraîne la séparation d'un plus grand nombre de particules de magnésium par unité de temps et, par conséquent, un dégagement d'hydrogène plus abondant. Les mesures expérimentales de la vitesse du dégagement d'hydrogène à différentes valeurs de densité de courant anodique constantes ($1\,mA/cm^2 \leq i_a \leq 50\,mA/cm^2$) tendent à confirmer cette prévision du modèle. En effet, nous avons observé que la vitesse du dégagement d'hydrogène demeure constante à densité de courant anodique imposée constante ($1\,mA \leq i_a \leq 50\,mA/cm^2$) comme le montre la courbe de la fig. 5. Dans l'exemple choisi, le courant anodique est de 30 mA/cm² tandis que la solution contient plusieurs espèces ioniques dont les ions Na^+ et Cl^- qui prédominent largement en terme de concentration. Par ailleurs, la fig. 6 révèle que l'accroissement du débit d'hydrogène dégagé est approximativement de 0.2×10^{-6} mol/cm² min. pour une augmentation de courant de 1 mA/cm² dans ces solutions. Cette observation est en parfait accord avec le modèle proposé. De plus, la vitesse du dégagement d'hydrogène est indépendante de la concentration en électrolyte (figs 6 et 7). Néanmoins, la substitution des ions Cl^- par les ions $(SO_4)^{2-}$ se traduit par une diminution de la vitesse du dégagement d'hydrogène (fig. 6): elle est respectivement égale à 0.6 et 0.4×10^{-5} mol/min cm² alors que la densité de courant est de 30 mA/cm².

Par ailleurs, le dégagement de l'hydrogène nécessite la présence d'un réseau de pores dans le film formé par l'accumulation des produits de corrosion. Cette couche protectrice serait donc traversée dans toute son épaisseur par un réseau de pores constitué d'une multitude de canaux (fig. 8) tandis que la surface métallique de l'anode est, par

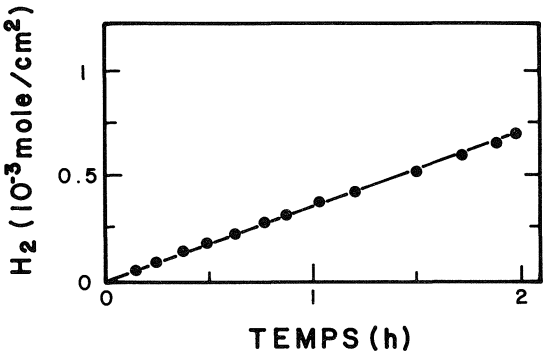

FIG. 5. Quantité d'hydrogène dégagée sur une anode de Mg en fonction du temps. Densité de courant imposée: 30 mA/cm². Composition de la solution: NaCl: 25 g/L; KCl: 0.7 g/L; $MgCl_2$: 5 g/L; Na_2SO_4: 4 g/L; $NaHCO_3$: 0.2 g/L.

ailleurs, fort rugueuse. La formation de multiple cavités entraîne le détachement de particules de magnésium métallique qui demeurent prisonnières du produit de corrosion.

Les résultats chronoampérométriques et chronopotentiométriques commentés plus loin tendent à confirmer et préciser le modèle présenté.

Nature du produit de corrosion

On a observé que le produit de corrosion dépend des espèces ioniques présentes dans l'électrolyte. En solutions fortement concentrées en chlorure, les résultats des analyses au spectromètre Auger sont caractéristiques de la formation d'un chlorocomplexe de magnésium dont la formule chimique est voisine de $5Mg(OH)_2 \cdot MgCl_2$ (40). De plus, pour des durées de polarisation de plusieurs heures, seul l'hydroxyde de magnésium $Mg(OH)_2$ était présent. Enfin, du carbonate, du sulfate et de l'hydroxyde de magnésium ont aussi été détectés dans le film lorsque la solution contenait des carbonates et des sulfates.

Analyse des résultats chronopotentiométriques

Le produit de corrosion fait obstacle au passage de courant d'où l'apparition d'une chute ohmique non négligeable qui coincide avec le recouvrement total de l'anode. Nos mesures indiquent que la chute ohmique est responsable de l'accroissement de la tension d'électrode au-delà de −1.65 V (/E.C.S.) environ alors que le film s'épaissit et que des changements s'y manifestent (fig. 9). La courbe de la fig. 9 montre la valeur de la tension d'électrode non-corrigée pour la chute ohmique en fonction du temps. On observe que la tension d'électrode corrigée pour la chute ohmique est constante à une valeur voisine de −1.65 V (/E.C.S.) tandis que la chute ohmique peut dépasser 2.5 V.

Par contre, l'écaillement du film, souvent ob-

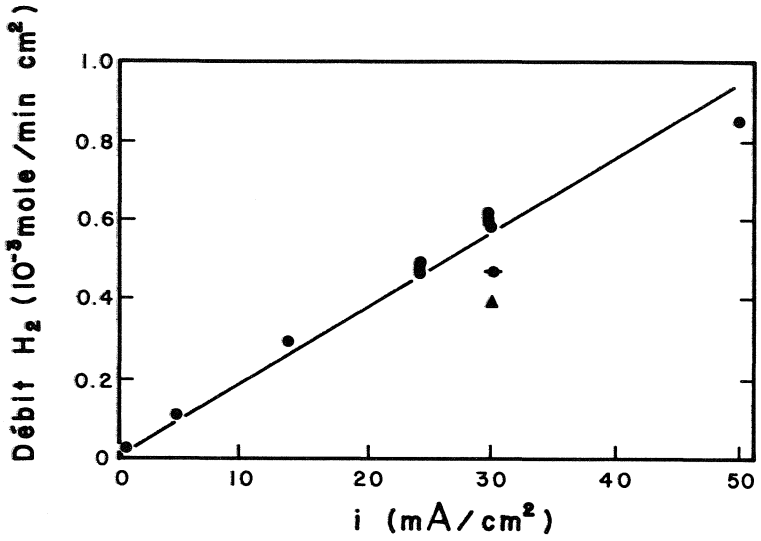

FIG. 6. Débit d'hydrogène dégagé en fonction de la densité de courant anodique pour différents électrolytes: ●, $MgSO_4$, 6.31 g/L, Na_2SO_4, 73.36 g/L, $NaHCO_3$, 4 g/L; △$MgSO_4$, 6.31 g/L, Na_2SO_4, 4 g/L, $NaHCO_3$, 4 g/L; ○ KCl entre 0.5 et 2.5 *M*.

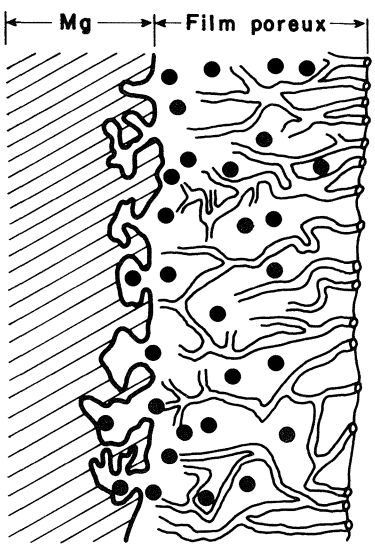

FIG. 8. Coupe schématique du produit de corrosion formé sur l'anode de Mg.

servable à l'œil nu, abaisse la barrière offerte au passage du courant ce qui entraîne des baisses substantielles de la tension d'électrode. Elles peuvent atteindre plusieurs centaines de mV: environ 1200 mV dans l'exemple de la fig. 9. De plus, la chute quasi-instantanée de la tension correspondant au point (*a*) (fig. 9) coïncide avec le détachement complet d'un disque formé par l'accumulation du produit de corrosion à la surface de l'anode. L'épaisseur de ce disque est évaluée à 1 mm approximativement.

On déduit de l'ensemble de ces observations que la résistance offerte par le film tend à freiner considérablement la vitesse de dissolution anodique du magnésium.

Mode de croissance du film poreux

Rappelons que le réseau de pores est considéré comme étant partiellement rempli d'électrolyte. Le chemin le plus facile offert au passage du courant est alors l'électrolyte contenu dans le réseau. Par ailleurs, les densités du courant apparentes im-

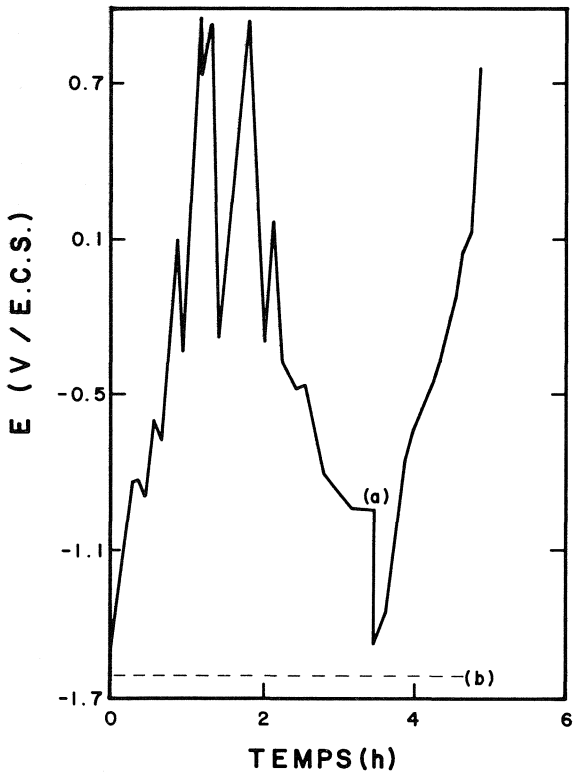

FIG. 9. Allure typique d'un enregistrement chronopotentiométrique. *E*: tension d'électrode; densité de courant: 50 mA/cm²; force ionique: 1.086; *T*: 25°C. Composition de la solution: H_3BO_3: 0.15 *M*; KCl: 1 *M*; KOH: 0.086. (*a*) Correspond à un disque d'oxyde qui se détache de l'électrode; (*b*) valeur de la tension d'électrode corrigée pour la chute ohmique. Elle est égale à −1.65 V.

posées étaient égales ou supérieures à 1 mA/cm² environ. Par conséquent, la densité de courant à l'extrémité des pores est susceptible d'être élevée. La vitesse de dissolution rapide du magnésium devrait donc entraîner la destruction locale d'un mince film protecteur initialement présent à la surface de l'anode de Mg. C'est ainsi que l'on explique l'activation de la surface de l'électrode de Mg dès le retour à l'abandon, qui peut atteindre jusqu'à 300 mV par rapport à la tension de −1.65 V (/E.C.S.) (fig. 10). La tension corrigée de l'anode pour la chute ohmique est voisine de −1.65 V à l'interruption du courant en (*c*).

Le grattage de l'anode de Mg révèle effectivement la présence d'un film qui est en contact direct avec le magnésium; il est très mince et de couleur gris-noir. Bien que Huber et Fleukiger (42) aient fait une observation identique et ait identifié l'oxyde de magnésium (MgO), la nature et le rôle exact de ce mince film demeurent cependant obscurs. Greenblatt (18) considère ce film comme un mauvais conducteur tandis que l'oxyde de magnésium alors identifié pourrait aussi être le résultat du contact du magnésium avec l'air lors du grattage.

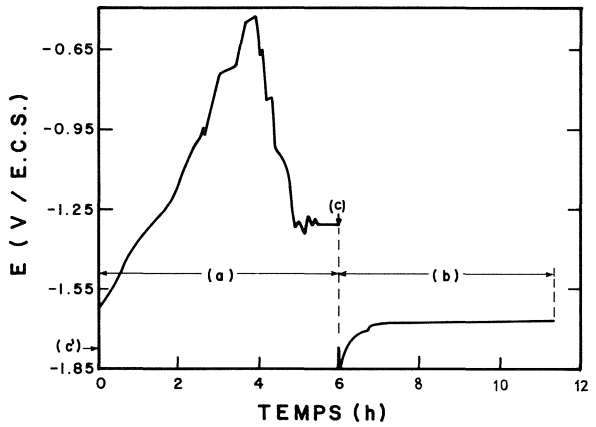

FIG. 10. Tension d'électrode en fonction du temps durant et après polarisation: (*a*) durant la polarisation, (*b*) à l'abandon, (*c*) valeur initiale de la tension d'électrode à l'abandon. *E*: tension d'électrode; densité de courant imposée durant la polarisation: 12 mA/cm²; composition de la solution: KCl: 1 *M*, H_3BO_3: 0.15 *M*, KOH: 0.086 *M*.

L'extrémité des pores est aussi susceptible de s'enrichir notablement en ions Mg^{2+}. Les ions de signe contraire vont donc devoir se déplacer afin de préserver la neutralité électrique. Un précipité est donc susceptible de se former suite à cet enrichissement (un chloro-complexe, par exemple) et de se déposer sur les parois des pores qui se retrouvent alors partiellement bloquées.

Par ailleurs, dans une fourchette de temps comprise entre 200 et 2500 s les courbes chronoampérométrique vérifient les relations suivantes (fig. 11):

$$[3] \quad i = A' t^{-1}$$

ce qui se ramène a

$$[4] \quad \int_{t=t_0}^{t=t} i \, dt = a + 2.303 A' \log_{10} t$$

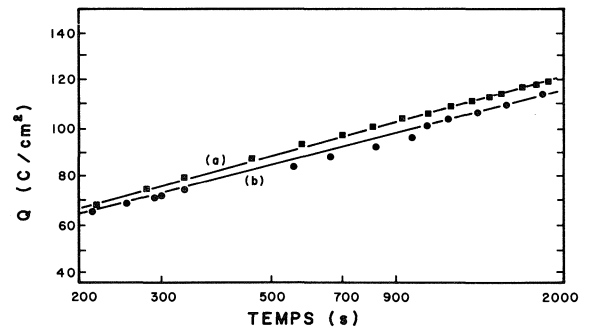

FIG. 11. Quantité d'électricité ayant traversé l'anode de magnésium en fonction du temps: (*a*) $E = -1.32$ V(/E.C.S.), (*b*) $E = -1.2$ V(/E.C.S.). Composition de la solution: KCl: 1 *M*, H_3BO_3:0.15 *M*, KOH: 0.086 *M*.

TABLEAU 1. Valeurs des constantes A' déduites des courbes chronoampérométriques

E (V/E.C.S.)[a]	A' (C/cm²)[b]
−1.57	22.2
−1.32	24.4
−1.20	22.2
−1.15	23.9
−1.06	25.0
−0.91	24.3

[a]Non corrigé pour la chute ohmique.
[b]$A' = i \cdot t$.

où a et A' sont des constantes avec A' indépendante de la tension anodique imposée (tableau 1).

La pente des droites définies par la relation [4] est de 55 ± 2 C/cm² dans les conditions expérimentales figurant sur la fig. 11. Elle correspond à $2.303A'$.

Un tel comportement est compatible avec le mécanisme du blocage partiel des pores (41). Par conséquent, le mécanisme de croissance du film en serait un de dissolution–précipitation. L'effet d'étranglement créé par l'accumulation du précipité sur les parois des pores contribuerait alors à freiner la dissolution du magnésium.

Influence de l'électrolyte et du courant

Jusqu'ici, l'influence de la concentration en électrolyte et du courant imposé sur le comportement électrochimique de l'anode de magnésium n'a pas encore été abordée. Tel que l'illustre les enregistrements chronopotentiométriques reproduite à la fig. 12, une élévation de la concentration en électrolyte fort, qui est notamment le KCl dans l'exemple choisi, se traduit par une diminution substantielle de la résistance offerte par le film au passage du courant. Cette diminution de résistance est attribuée à une augmentation de la conductivité électrique de l'électrolyte contenu dans les pores.

Par ailleurs, la tension corrigée d'électrode reste constante à une valeur voisine de −1.65 V (/E.C.S.). Cette valeur est inaffectée par une variation de la concentration en électrolyte fort que celui-ci soit un chlorure ou un sulfate.

Enfin, la vitesse avec laquelle le produit de corrosion s'accumule à la surface de l'anode doit être proportionnelle à la vitesse de dissolution des ions Mg^{2+}. De plus, une augmentation de la quantité de produit de corrosion accumulé doit se traduire par un accroissement de la chute ohmique. Par conséquent, la vitesse de croissance de la chute ohmique devient plus rapide avec une augmentation du courant anodique (fig. 13). Cependant, d'autres phénomènes contribuent à diminuer ou à

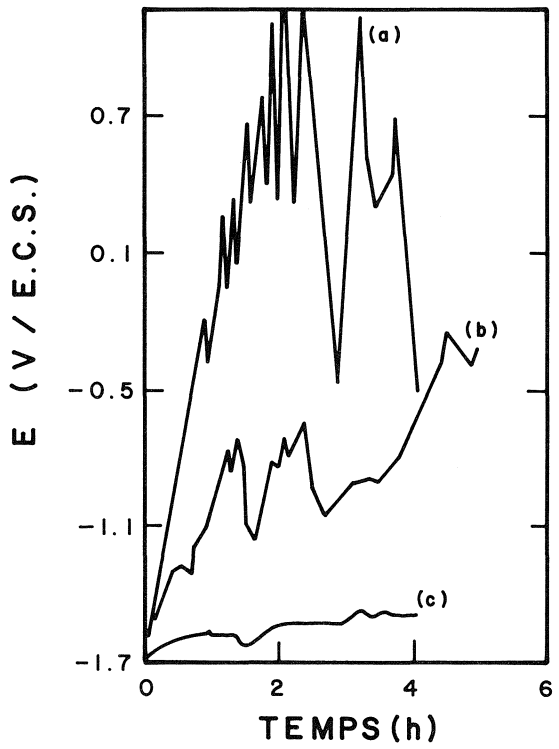

FIG. 12. Enregistrements chronopotentiométriques sur une anode de magnésium pour différentes concentrations en électrolyte fort. (*a*) $I = 0.586$ pour KCl = 0.5 *M*, (*b*) $I = 1.086$ pour KCl = 1 *M*, (*c*) $I = 2.586$ pour KCl = 2.5 *M* où I = force ionique. Densité de courant imposée: 24.62 mA/cm². Sont présents dans ces solutions: H_3BO_3: 0.15 *M*, KOH: 0.086 *M*.

augmenter la valeur de la chute ohmique comme, par exemple, le blocage partiel des pores par l'hydrogène gazeux et l'écaillement du film poreux. C'est à ce dernier que l'on attribue l'allure en dents de scie des courbes chronopotentiométriques.

Conclusions générales

1. La nature du produit de corrosion qui s'accumule à la surface de l'électrode de magnésium dépend de la nature des ions présents dans l'électrolyte. En solution fortement concentrées en chlorure, les analyses du film sont compatibles avec la formation d'un chloro-complexe de magnésium dont la formule chimique est voisine de $5Mg(OH)_2 \cdot MgCl_2$. Au contact prolongé avec la solution, il se transforme en $Mg(OH)_2$ tandis que du carbonate et du sulfate sont aussi présents lorsque l'électrolyte contient des carbonates et des sulfates.

2. Le modèle présenté permet d'expliquer le comportement anodique du magnésium sans faire appel à la formation d'intermédiaires. Ce modèle lie

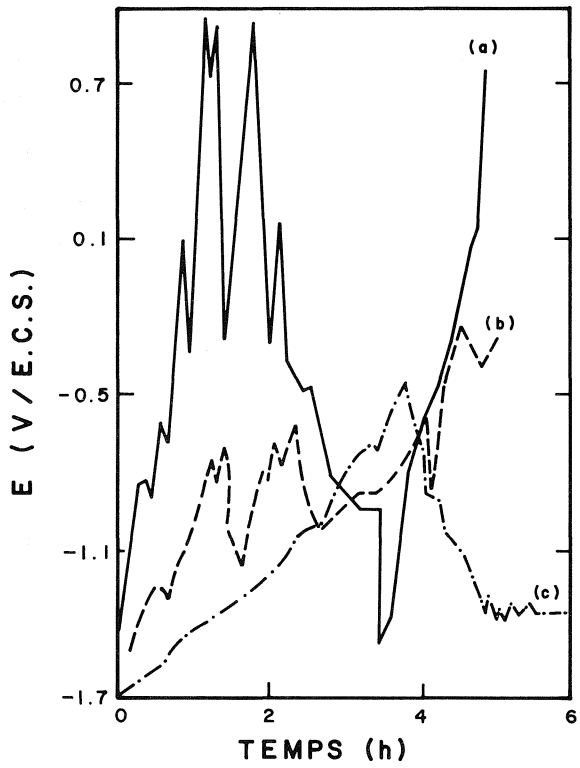

FIG. 13. Enregistrements chronopotentiométriques pour différentes densités de courant anodique. Densité de courant (mA/cm^2): (*a*) 50, (*b*) 24.6, (*c*) 12. Composition de la solution: H_3BO_3: 0.15 *M*, KOH: 0.086 *M*, KCl: 1 *M*. Force ionique: 1.086.

étroitement les caractéristiques du comportement anodique aux propriétés du produit de corrosion. Ce dernier se voit traversé complètement par un réseau de pores par où circule le courant et l'hydrogène gazeux. La nature poreuse de ce film explique qu'il soit faiblement protecteur.

3. Le surconsommation de magnésium qu'entraîne le dégagement d'hydrogène résulte de la dissolution des fines particules de Mg prisonnières du produit de corrosion.

4. L'activation de l'électrode dès le retour à l'abandon est attribuée à la mise à nu du métal à l'extrémité des pores durant la dissolution anodique.

5. Les variations de la tension apparent d'électrode (au-dessus de −1.65 V (/E.C.S.)) sont attribuées à des variations de la chute ohmique conséquente à l'épaississement du film et aux changements qui s'y manifestent dont le blocage partiel des pores et l'écaillement du film. La substitution des chlorures par les sulfates comme électrolyte n'affecte nullement la valeur de la tension corrigée de l'anode de magnésium qui demeure constante à −1.65 V (/E.C.S.) approximativement.

Influence des groupes *tert*-butyle, triméthylsilyle et triméthylgermyle sur la stéréochimie de réactions d'addition en série cyclohexénique. III. Epoxydation de cyclohexènes substitués en position allylique et réduction des époxydes par $LiAlH_4$

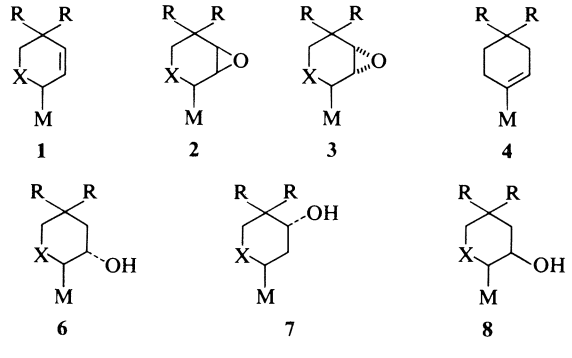
JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI et GEORGES MANUEL. Can. J. Chem. **58**, 39 (1980).

On a étudié la réaction d'époxydation des *tert*-butyl-6 (ou triméthylsilyl-6 ou triméthylgermyl-6) diméthyl-3,3 cyclohexènes; on note que la stéréochimie de ces réactions est gouvernée principalement par des facteurs stériques. On rapporte aussi les résultats obtenus lors de la réduction par l'hydrure double de lithium et d'aluminium des époxydes *cis* ainsi que *trans*; on remarque que la stéréochimie et la régiochimie des réactions de réduction sont influencées par des facteurs stériques ainsi que par les effets électroniques du groupe triméthylsilyle.



JEAN-CLAUDE RICHER, MARC-ANDRÉ POIRIER, YVETTE MARONI, and GEORGES MANUEL. Can. J. Chem. **58**, 39 (1980).

The epoxidation of allylic alkenes in the 6-*tert*-butyl (or 6-trimethylsilyl or 6-trimethylgermyl) 3,3-dimethylcyclohexenes is examined; it has been found that the stereochemistry of these reactions is governed mostly by steric factors. The results obtained by the reduction of *cis* and *trans* epoxides by lithium aluminium hydride are also reported, the regiochemistry and the stereochemistry of the reactions of reduction are governed by steric factors as well as by the electronic effects of the trimethylsilyl group.

Introduction

Dans un travail antérieur (1), on a décrit la synthèse des alcènes **1***a*, **1***b*, **1***c* et **4***a*, **4***b*, **4***c*. Plus récemment (2), on a examiné la stéréochimie de l'ouverture des époxydes dérivés des alcènes vinyliques du type **4** par différents réactifs. On a montré que ces réactions sont gouvernées, d'une part, par l'influence stérique des divers substituants et, d'autre part, par les effets électroniques des groupes triméthylsilyle et triméthylgermyle.

Dans la première partie de cette communication, on examine la stéréochimie de la réaction d'époxydation, par l'acide *m*-chloroperbenzoïque (AMCP), des alcènes allyliques **1***a*, **1***b* et **1***c*. Dans une seconde partie, on étudie la réduction des époxydes correspondants *cis* (**2***a*, **2***b*, **2***c*) et *trans* (**3***a*, **3***b*, **3***c*) par l'hydrure double de lithium et d'aluminium ($LiAlH_4$). Les résultats obtenus sont regroupés dans le Tableau 2 où figurent aussi ceux rapportés par Richer et Freppel (3) pour les composés **2***d* et **3***d*, ceux obtenus par Rickborn et Lamke (4) pour les composés **2***e* et **3***e*, les résultats de Moir et coll. (5) et Hartman et Rickborn (6) pour les époxydes **2***f* et **3***f* et enfin les résultats de Berti *et al.* (7) pour les composés **2***g* et **3***g*.

Résultats et discussion

Les résultats obtenus lors de l'époxydation (3, 8) des alcènes du type **1** sont regroupés dans le Tableau 1. On note, en série carbonée et siliciée, la formation d'un fort pourcentage d'isomère *trans*. Ce fait expérimental doit essentiellement résulter de la présence du groupe *tert*-butyle (ou du groupe triméthylsilyle) et du méthyle pseudo-axial. Ces

TABLEAU 1. Pourcentages relatifs des produits obtenus lors de l'époxydation des alcènes du type **1**

Alcène	% Epoxyde 2 (*cis*)	% Epoxyde 3 (*trans*)	% Produit de clivage 5
1*a*	6	94	—
1*b*	24	76	—
1*c*	—	—	100

M = Me_3C, Me_3Si, Me ou OMe
R_a = Me_a ou H_a
R_e = Me_e ou H_e

SCHÉMA 1

groupes masquent la face *cis* de la molécule et orientent la réaction d'époxydation vers l'autre face (flèche 3 du schéma 1). On note également une nette augmentation du pourcentage en isomère *cis* quand on passe de la série carbonée à la série siliciée. On peut donner une explication à ce résultat en remarquant que la liaison C—Si, plus longue que la liaison C—C (9), permet une diminution des interactions 1,3 diaxiales dans l'état de transition, entre le réactif et l'un des méthyles du groupe $SiMe_3$. On remarque que les pourcentages relatifs d'addition *cis*/*trans* lors des réactions d'époxydation discutées ici sont similaires à ceux observés lors de l'hydroboration de ces mêmes alcènes (1). En effet, la stéréochimie de l'époxydation ressemble beaucoup à celle de l'hydroboration et les réactions sont contrôlées par des facteurs stériques intervenant dans l'état de transition.

Lors de la réaction de l'acide *m*-chloroperbenzoïque avec l'alcène germylé **1***c*, il n'a pas été possible d'isoler les époxydes **2***c* et **3***c* attendus, même en présence de carbonate de potassium nécessaire à l'obtention des époxydes silylés **2***b* et **3***b*. L'alcool allylique isolé **5** résulte d'une β-décomposition (schéma 2) beaucoup plus prononcée en série germylée qu'en série silylée dans la généralité des cas (10, 11).

Réduction des époxydes par $LiAlH_4$

Les résultats obtenus lors de la réduction par $LiAlH_4$ de mélanges d'époxydes des types **2** et **3** sont résumés dans le Tableau 2. L'interprétation générale des résultats est basée sur le fait que l'ouverture des époxydes se fait toujours d'une façon *trans* et généralement diaxiale selon la généralisation de Furst et Plattner (12) soit sous les formes chaise-croisée ou bateau-croisé conduisant respectivement aux produits d'ouvertures normale (produit diaxial) et anormale (produit diéquatorial). Les résultats sont discutés à l'aide des équilibres conformationnels représentés dans les schémas 3 et 4.

La réduction de l'époxyde *cis* (**2***d*) du *tert*-butyl-3 cyclohexène (X = CH_2, M = Me_3C, R = H) conduit à 100% d'isomère *cis* **8***d*. L'examen du schéma 3 indique que cet époxyde réagit essentiellement sous les formes *A* et *B*. En effet, le conformère *C* comportant des groupes aussi volumineux

SCHÉMA 2

que $(CH_3)_3C$ ou $(CH_3)_3Si$ en position pseudo-axiale est très improbable. Qui plus est, on peut, dans le cas particulier où R = H, admettre que le conformère *B*, moins stable que le conformère *A*, n'intervient pas. Les interactions entre R (R = H pour l'époxyde **2***d*) et l'hydrure entrant doivent être faibles. Dans ces conditions, l'ouverture de **2***d* se ferait exclusivement selon l'état de transition *A* conduisant à l'alcool **8***d* par une ouverture normale.

La réduction de l'époxyde *cis* (**2***a*) du *tert*-butyl-6 diméthyl-3,3 cyclohexène (X = CH_2, M = Me_3C, R = CH_3) conduit à 35% de l'alcool **9***a* correspondant à une ouverture anormale résultant du conformère *B*. Dans ce cas, l'énergie de l'état de transition *A* doit être suffisamment élevée (par suit des interactions 1,2 qui existent entre le réactif et le méthyle pseudo-équatorial ou comme l'a suggéré un des arbitres, à cause de l'interaction diaxiale-1,3 entre le méthyle axial et l'oxygène négatif qui se développe en axial dans l'état de transition *A*) pour qu'un état de transition différent, impliquant la forme bateau-croisé *B*, puisse devenir compétitif.

La réduction de l'époxyde silylé (**2***b*) conduit à un pourcentage d'ouverture anormale (**9***b*: 50%) plus élevé qu'en série carbonée analogue (**9***a*: 35%). Cette variation du pourcentage peut résulter de l'accroissement de la longueur de la liaison interatomique quand on passe du C—C au motif Si—C. Ce phénomène favorise l'attaque en α du groupe Me_3Si (formation de **9***b*) par rapport à l'attaque en α du groupe Me_3C (formation de **9***a*).

Le comportement de l'époxyde *cis* (**2***e*) issu du méthyl-3 cyclohexène (**1***e*) lors de la réduction par $LiAlH_4$ est analogue à celui de l'époxyde *cis* (**2***d*) formé à partir du *tert*-butyl-3 cyclohexène (**1***d*). L'interprétation des résultats observés dans ce cas est donc, pour l'essentiel, celle déjà indiquée pour le composé **2***d*.

L'époxyde *cis* (**2***f*) du méthoxy-3 cyclohexène (**1***f*) conduit à 57% d'alcool **9***f* provenant d'une ouverture anormale du conformère *B*. Pour interpréter cette régiosélectivité, on peut, à côté des facteurs stériques déjà énoncés pour rendre compte des résultats précédents, suggérer que la conformation *C* (schéma 3) est favorisée par l'association avec une molécule d'hydrure (conformation *C* du schéma 5). Une explication de cet ordre (conformation *A* du schéma 5) pourrait être avancée pour rationaliser les résultats obtenus par Berti *et al.* (7) lors de la réduction de l'époxyde *cis* (**2***g*).

La réduction de l'époxyde silylé *trans* (**3***b*) conduit exclusivement au produit **7***b* issu de l'ouver-

SCHÉMA 4

ture normale du conformère *C'* (schéma 4). L'alcool **9***b* provient vraisemblablement de la réduction de la cétone **10***b* qui pourrait se former par réarrangement (13, 14) de l'époxyde. Pour des raisons d'ordre stérique, la présence du conformère *A'* semble improbable. Le niveau énergétique de l'état de transition *C'* (schéma 4) est élevé car il implique de fortes interactions entre le réactif et l'un des méthyles du groupe triméthylsilyle d'une part et le méthyl pseudo-axial, d'autre part. Le fait qu'une ouverture normale se produise par l'intermédiaire de cet état de transition malgré ces interactions donne une idée de l'ordre de grandeur des énergies nécessaires pour parvenir à la forme bateau-croisé *B'* et forcer l'entrée du réactif en α du groupe méthyl (R) équatorial.

L'époxyde *trans* (**3***a*) du *tert*-butyl-6 diméthyl-3,3 cyclohexène **1***a* a le même comportement que son analogue silylé (**3***b*) et implique les mêmes interactions.

Par contre, l'époxyde *trans* (**3***d*) du *tert*-butyl-3 cyclohexène **1***d* conduit à 35% de l'alcool **6***d* résultant d'une ouverture anormale. Le conformère *A'* n'étant pas plus favorisé dans ce cas que dans les cas mentionnés précédemment, on doit faire l'hypothèse que le produit anormal provient d'une attaque du conformère *B'*. Cette attaque serait favorisée par l'absence de l'interaction entre le réactif et le méthyle (R) en position pseudo-équatoriale.

Pour l'époxyde *trans* (**3***e*) du méthyl-3 cyclohexène, on observe pratiquement les mêmes résultats que pour l'époxyde **3***d*. On ne peut, dans ce cas, exclure une participation du conformère *A'*.

En ce qui concerne l'époxyde *trans* (**3***g*), on invoque à nouveau le fait que le conformère *A'* permet une chélation dans l'état de transition (schéma 5) pour expliquer la formation presque univoque d'alcool **6***g* résultant d'une ouverture anormale.

Dans le cas de l'époxyde *trans* (**3***f*) du méthoxy-3 cyclohexène (**1***f*) pour lequel il n'existe aucun conformère permettant ce type d'association, la réduction conduit à 47% d'alcool (**7***f*) provenant d'une ouverture normale (état de transition *C'* du schéma 5) et 53% de (**6***f*) correspondant à une ouverture anormale (états de transition *A'* ou *B'*). L'effet inductif du groupe OCH_3 favorise la conformation *A'*. Les énergies du même ordre de grandeur impliquées dans les états de transition A' et C'

doivent donc permettre la rationalisation de l'ensemble des résultats.

En conclusion, on peut indiquer que la stéréochimie des réactions d'époxydation examinées est essentiellement sous le contrôle de facteurs stériques. D'autre part, la réduction des époxydes par $LiAlH_4$ conduit généralement à des ouvertures *trans* et diaxiales. Dans certains cas, cependant, la coordination d'un hydrure entre deux atomes d'oxygène (bases) orientés favorablement permet de modifier ce comportement.

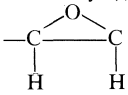
Partie expérimentale

Les points de fusion ont été mesurés sur un appareil Cole-Parmer de la compagnie Instrument & Equipment.

Les spectres ir ont été enregistrés à l'aide d'un spectrophotomètre Beckman modèle IR-8 à double faisceau et sauf indication contraire, tous les spectres ont été pris entre deux plaques de NaCl.

Les spectres de résonance magnétique nucléaire ont été déterminés sur un spectromètre modèle C-60-H de la compagnie JEOL. Le solvant choisi est le chloroforme deutéré pour les composés carbonés et le tétrachlorure de carbone pour les produits silylés et germylés.

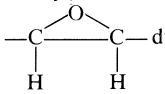
Les indices de réfraction ont été déterminés à l'aide d'un réfractomètre du type Abbé. La pureté de tous les nouveaux produits décrits dans ce travail a été déterminée par chromatographie en phase gazeuse et leur identité confirmée par spectrométrie de masse à l'aide d'un spectromètre Hitachi Perkin-Elmer modèle RMU 6-D opérant avec une énergie de faisceau d'électrons ionisant de 70 eV et d'un spectromètre AEI MS-902 relié à un ordinateur PDP-8; toutes les masses moléculaires expérimentales déterminées correspondent à ± 0.0015 unités de masses aux valeurs calculées.



Synthèse de alcènes

La synthèse des alcènes **1***a*, **1***b*, **1***c* est décrite dans un travail antérieur (1).

Epoxydation des alcènes

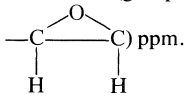


Epoxydation du tert*-butyl-6 diméthyl-3,3 cyclohexène* **1***a*

On obtient les époxydes **2***a* et **3***a* (rendement de 90%) en utilisant le même mode opératoire que pour l'alcène vinylique **4***a* (2).

Les deux époxydes ont été séparés (d'un mélange contenant 6 et 94% respectivement de **2***a* et **3***a*) en faisant appel à la chromatographie en phase gazeuse préparative à 140°C pour un débit de 55 mL/min et utilisant une colonne de 8 pi sur ¼ de po de diamètre remplie de tris-cyanoéthoxypropane à 20% sur Chromosorb R (80–100). A la suite de 25 injections de 50 μL, on isole 500 mg d'époxyde *trans* (**3***a*) ayant les caractéristiques suivantes: pé 52°C/0.2 Torr; n_D^{26} 1.6934; ir: 1255, 915, 695, 645 cm^{-1}; rmn ($CDCl_3$): 0.98 (s, 9H, groupe *tert*-butyle), 1.02 (s, 6H, méthyle), 2.90 (d, 1H) et 2.52 (d, 1H,  du pont époxyde) ppm.

Préparation de l'époxyde cis *2*a



Dans un ballon de 50 mL, muni d'un refrigérant, on introduit 1.66 g d'alcène **1***a* (0.01 mol) dans 40 mL de diméthylsulfoxyde contenant 10 gouttes d'eau (15, 16). Le ballon étant maintenu sous atmosphère d'azote, on ajoute en une seule fois 3.1 g de *N*-bromosuccinimide. On laisse à 50°C pendant deux heures. Le mélange réactionnel est extrait de la manière habituelle et les bromhydrines résultantes sont traitées par 60 mL de *tert*-butylate de potassium dans le DMSO et laissés sous atmosphère d'azote à 50°C pendant une heure (17). Le mélange réactionnel conduit, après extraction à 0.75 g d'un mélange des époxydes **2***a* et **3***a* (40% du rendement théorique).

La séparation du mélange d'époxydes (contenant respectivement 42% et 58% de **2***a* et **3***a*) est effectuée comme précédemment par chromatographie en phase gazeuse préparative. Les caractéristiques de l'époxyde *cis* **2***a* sont les suivantes: pé 56°C/0.3 Torr; n_D^{25} 1.6943; ir: 795, 830, 860, 900 cm^{-1}; rmn ($CDCl_3$): 0.97 (s, 9H, *tert*-butyle), 1.00 (doublet mal résolu, 6H, méthyl), 3.25 (d, 1H) et 2.65 (d, 1H pour les protons  du pont époxyde) ppm.

Epoxydation du diméthyl-3,3 triméthylsilyl-6 cyclohexène **1***b*

Dans un ballon refroidi à −5°C contenant 15 mL de chloroforme et 40 mL de chlorure de méthylène, on ajoute 2.0 g d'alcène **1***b* (11 mmol) suivi de 4.0 g de carbonate de potassium anhydre et 4.0 g d'acide *m*-chloroperbenzoïque (8). On maintient cette température pendant 35 min, puis on filtre. Le filtrat

est lavé avec une solution de soude à 5%, extrait à l'éther selon la méthode habituelle. On obtient ainsi 1.9 g d'un mélange des composés **2***b* et **3***b* (90% du rendement théorique) dans lequel le rapport de **2***b*/**3***b* déterminé par rmn est de 24/76; ir (mélange): 1380, 1360, 1245, 870, 740 cm^{-1}; rmn (CCl_4): 0.06 (s, Me_3Si), 1.06 et 0.93 (groupe *gem*-diméthyle), 2.96 (d, 1H) et 2.56 (d, 1H,

ppm.

Epoxydation du diméthyl-3,3 triméthylgermyl-6 cyclohexène **1***c*

Le traitement de l'alcène **1***c* par la méthode décrite pour le composé **1***b* ne conduit pas aux époxydes **2***c* et **3***c*, mais au composé **5** (rendement 79%); pé 78–79°C/9 Torr; ir: 3380, 3040 cm^{-1}; rmn (CCl_4): 0.93 et 1.00 (groupe *gem*-diméthyle), 4.00 (proton carbinolique) et 5.50 (m, 2H, proton oléfinique) ppm.

Réduction des époxydes et analyse des alcools obtenus

Réduction

La réduction de 5.5 mmol des époxydes des types **2** et **3** par 0.5 g d'hydrure double de lithium et d'aluminium en suspension dans 10 mL d'éther anhydre est effectuée à 0°C. Après avoir chauffé le mélange réactionnel au reflux pendant 20 h, on l'hydrolyse à 0°C par une solution de soude à 50%. On extrait à l'éther et on obtient les alcools correspondants (rendements moyens 85%).

Analyse des produits

Les mélanges d'alcools provenant des réactions de réduction des époxydes **2** et **3** ont été analysés par chromatographie en phase gazeuse à l'aide d'un chromatographe à ionisation de flamme Research Chromatograph 700 de la compagnie F et M muni d'une colonne de 6 pi × $\frac{1}{8}$ de po remplie de Diatoport 5750 (80–100) supportant 6% de son poids de LAC 728. Les temps de rétention (en min) des alcools dans ces conditions sont résumés au Tableau 3. L'identification des pics a été réalisée par superposition avec des échantillons authentiques dont le propriétés sont décrites dans le Tableau 4.

Remerciements

Les auteurs remercient vivement le Conseil National de Recherches du Canada, le CNRS, et les autorités chargées d'administrer les accords Franco–Québécois pour l'aide financière apportée sous forme d'octroi de recherches, de bourse d'études et de frais de mission. Les auteurs tiennent à remercier le Dr Pierre Maroni pour l'accueil chaleureux réservé à M. Marc-André Poirier durant son stage à Toulouse. Les auteurs tiennent aussi à exprimer leur reconnaissance aux Dr Mazerolles et Lesbre pour leur compréhension et leurs discussions utiles.

A proton magnetic resonance relaxation time study of several vitamin D derivatives

GEORGE KOTOWYCZ, TOM T. NAKASHIMA, M. KIRK GREEN,[1] AND GERDY H. M. AARTS
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 23, 1979

GEORGE KOTOWYCZ, TOM T. NAKASHIMA, M. KIRK GREEN, and GERDY H. M. AARTS. Can. J. Chem. **58**, 45 (1980).

Proton magnetic resonance relaxation time studies at 200 and 400 MHz have been measured for vitamins D_2, D_3, as well as the biologically active 1α,25-$(OH)_2D_3$. A comparison of these relaxation times at the two frequencies allows the evaluation of the dipolar correlation times for the different protons in the molecule. These are very short, and range from $< 0.7 \times 10^{-10}$ s to 1.2×10^{-10} s. Application of the Solomon equation to the relaxation times of the 19*Z* and 19*E* protons allows a calculation of the internuclear distance since these two geminal protons relax each other predominantly by the dipolar mechanism. Using the T_1 values, the calculated distances are 1.98 ± 0.10 Å for 1α,25-$(OH)_2D_3$, 2.01 ± 0.10 Å for D_3, and 1.95 ± 0.10 Å for D_2. The calculated distance based on a neutron diffraction distance for the C—H bond is 1.91 Å. The measurement of the relaxation times also allows a definitive spectral assignment of the 21- and 28-methyl protons for vitamin D_2.

GEORGE KOTOWYCZ, TOM T. NAKASHIMA, M. KIRK GREEN et GERDY H. M. AARTS. Can. J. Chem. **58**, 45 (1980).

On a étudié et mesuré le temps de relaxation pour la résonance magnétique du proton à 200 et 400 MHz des vitamines D_2, D_3 et également du composé biologiquement actif 1α,25-$(OH)_2D_3$. La comparaison de ces temps de relaxation à ces deux fréquences permet une évaluation des temps de corrélation dipolaire des différents protons de la molécule. Les temps sont très courts et s'échelonnent entre $< 0.7 \times 10^{-10}$ s et 1.2×10^{-10} s. L'application des équations de Solomon aux temps de relaxation des protons 19*Z* et 19*E* permet le calcul des distances internucléaires puisque ces deux protons portés par le même carbone relâchent tous deux de façon prédominante selon un mécanisme dipolaire. En utilisant les valeurs de T_1 les distances calculées sont: 1.98 ± 0.10 Å pour 1α,25-$(OH)_2D_3$, 2.01 ± 0.10 Å pour D_3 et 1.95 ± 0.10 Å pour D_2. La distance de la liaison C—H est de 1.91 Å. Cette distance est calculée en se basant sur la distance de diffraction d'un neutron. La mesure des temps de relaxation permet également une identification définitive des protons des méthyles en positions 21 et 28 de la vitamine D_2.

[Traduit par le journal]

Introduction

One of the three most important biological regulators for calcium and phosphorus metabolism is vitamin D (1). Vitamin D and its derivatives have been studied extensively as witnessed by a recent workshop on the biochemical, chemical, and clinical aspects of vitamin D (2). A large number of review articles has now been published on this vitamin and on its metabolism (1–4), to list only a few. Vitamin D is a steroid, whose structure differs from that observed for other steroids. The main difference is the fact that its B ring is cleaved and the preferred conformation about the C6—C7 bond is *S-trans* instead of an *S-cis* (5). The hormonally active form of the vitamin is 1α,25-$(OH)_2D_3$ (1–4). The structural formulae for this molecule as well as for vitamins D_2 and D_3 are given in Fig. 1.

Some conformational studies have been carried out on vitamin D compounds and their derivatives, especially since the development and availability of high-field, nmr cryospectrometers. For example, proton magnetic resonance studies of vitamin D_3, 1α,25-$(OH)_2D_3$, and several structural analogs have established that the A ring exists in solution as an equilibrium mixture of roughly equal populations of two chair conformers (1, 6, 7). Shift reagents have also been used to study this equilibrium in vitamins D_2 (8) and D_3 (7). As Norman and coworkers (1) point out "Thus, while it is definitely a fact that all vitamin D-seco steroids undergo the

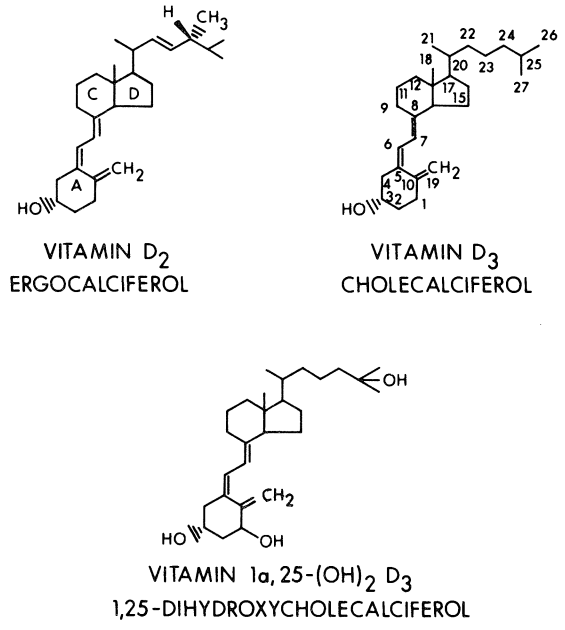

FIG. 1. Structures of vitamins D_2, D_3, and 1α,25-$(OH)_2D_3$.

dynamic equilibration between the two conformers, it remains to the future to delineate the implications of this phenomenon of vitamin D-related molecules to their detailed biochemical mode of action. The concept of conformational optimization of biological activity of vitamin D-like compounds is clearly one that bears further examination in the future''.

Other conformational analyses using a variety of techniques have been carried out by Berman *et al.* (ref. 2, pp. 19–28) and Okamura *et al.* (ref. 2, pp. 33–45, 9, 10). Both ^{13}C and ^{1}H nmr techniques have been applied by Mazur and co-workers (5, 11) and ^{13}C nmr techniques have also been applied by Tsukida *et al.* (12). DeLuca and co-workers (ref. 2, p. 927) and Knobler *et al.* (14) have obtained the solid-state conformations of vitamin D and related molecules. Quantum mechanical calculations (15) have also been applied in deriving structure–activity relationships. Finally, Wing (ref. 2, pp. 71–83) has carried out both nmr and force field calculations on vitamin D compounds. His critical analysis of the conformational equilibria data as well as of the theoretical calculations indicates that all of the results are in very good agreement.

We chose to study the vitamin D system, especially the 1α,25-$(OH)_2D_3$ derivative, since this appears to be the hormonally active form of this vitamin. There are many diseases which are known to be related in some fashion to vitamin D. These include (1) chronic renal disease, vitamin D-dependent rickets, hypoparathyroidism, drug induced metabolism of vitamin D as in the case of chronic administration of anti-convulsant drugs, and a host of bone diseases. The above compound is especially important in the kidney, where the biologically active form of this vitamin is produced.

In the present study, we have measured proton magnetic resonance longitudinal relaxation times both at 200 MHz and at 400 MHz. From the frequency dependence of the proton relaxation times, using the Solomon equation (16), the correlation times are obtained for the protons of vitamin D_2, D_3, and 1α,25-$(OH)_2D_3$. Distances in solution between the two C-19 protons for these three vitamins are calculated and compared with the neutron diffraction distance.

Experimental

Solutions of vitamins D_2 (Sigma Chemical Co.) and D_3 (Aldrich Chemical Co.) were prepared by dissolving 20.0 mg and 20.5 mg of each compound, respectively, in 5.0 mL of $CDCl_3$ (Scientific Graphics) so that the vitamin concentration was 0.010 *M*. Before use, the $CDCl_3$ was treated with Al_2O_3 (BDH Chemicals Ltd.) to remove acidic impurities. The solutions for the nmr experiments were vacuum degassed using the freeze–pump–thaw technique and were sealed.

The 1α,25-$(OH)_2D_3$ derivative was a gift from Dr. M. Uskokovic. About 0.9 mg (close to saturation) of this derivative were dissolved in 0.35 mL of degassed $CDCl_3$ and then the sample was vacuum degassed and sealed. Whenever possible, the solutions were prepared in the dark and kept in the freezer right up to the time that the experiments were run. To eliminate paramagnetic materials, all glassware was extensively cleaned following procedures previously reported (17).

The proton magnetic resonance experiments were obtained at 28°C on a Bruker WH-200/DS (200 MHz) and a Bruker WH-400/DS (400 MHz) nmr spectrometer operating in the pulsed Fourier transform mode using the Bruker Aspect 2000 computer, and 16 K data points. The deuterium resonance of the $CDCl_3$ was used as the lock signal. The longitudinal relaxation times (T_1) were obtained using the 180°–τ–90° two-pulse sequence and 9 to 10 τ values were included in the analysis of the T_1 data, based on the initial slope of a plot of $\ln((M_\infty - M_\tau)/(M_\infty))$ vs. τ. In this plot, M_∞ is the equilibrium value of the magnetization, and M_τ is the value of the magnetization at time τ between the 180° and 90° pulse. These *M* values were obtained from the measurement of the peak heights. The T_1 data were obtained from a computer analysis of the intensities as a function of the τ value using a least-squares program. The standard deviations at 400 MHz and 200 MHz were about 2% and 4%, respectively. For two different samples of vitamins D_2 and D_3, T_1 values varied by 5%.

Results

A 400 MHz spectrum of vitamins D_2 and D_3 is shown in Fig. 2 and a spectrum for 1α,25-$(OH)_2D_3$ is given in Fig. 3. Typical 180°–τ–90° inversion recovery spectra are shown in Fig. 4 for 1α,25-$(OH)_2D_3$ and the T_1 data for the isolated proton resonances are given in Table 1, both at 200 and 400 MHz. The proton resonances were assigned according to the work of Wing *et al.* (7). However, for D_2, they assign the C-28 methyl resonance to low field of the C-21 methyl resonance. We have changed this assignment, since the C-21 methyl protons are expected to have the same relaxation times in all three molecules. This can only be true if the C-21 methyl resonances are assigned to low field of the C-28 methyl resonances. In addition, the assignment of the 19*Z* and 19*E* proton resonances is interchanged for vitamins D_2 and D_3, based on proton magnetic resonance nOe difference studies (G. Kotowycz, G. H. M. Aarts, and K. Bock, in preparation). This in no way affects the present results since a distance is calculated only between these two protons.

A comparison of the spectra in Figs. 2 and 3 indicates that the C-19 protons shift to low field in 1α,25-$(OH)_2D_3$ with respect to these protons in D_3. In addition, proton 6 experiences a shift to low field with respect to proton 7. Similar results have been previously observed (7). Chemical shift and coupling constant analyses have been published for vitamins D_3 (7) and D_2 (8).

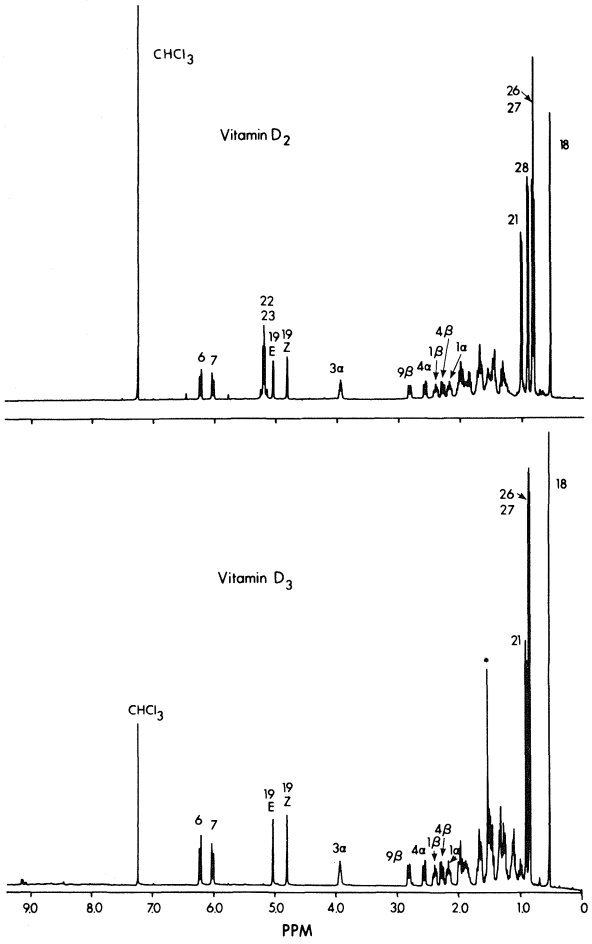

FIG. 2. The 400 MHz proton magnetic resonance spectra of vitamins D_2 and D_3 in $CDCl_3$. The * indicates a water impurity peak.

Discussion

The Solomon equation for the longitudinal relaxation times due to the dipolar interaction is given by (16)

$$[1] \quad \frac{1}{T_{1D}} = \frac{C^6}{r^6}\left(\frac{\tau_R}{1 + \omega_I^2\tau_R^2} + \frac{4\tau_R}{1 + 4\omega_I^2\tau_R^2}\right)$$

In this equation, C is a product of physical constants equal to 74.48 Å $s^{-\frac{1}{6}}$ for two interacting protons (18), r is the interproton distance in Å, ω_I is the proton resonance frequency in rad/s, and τ_R is the rotational correlation time ($C^6 = (3/10)(\hbar^2\gamma_H^4/10^{-48})$ where $\hbar$ is Planck's constant divided by 2π, γ_H is the magnetogyric ratio for a proton, and 10^{-48} converts units of cm to Å). Taking the ratio of this equation at two frequencies, namely 200 and 400 MHz, and rearranging, one obtains eq. [2]:

$$[2] \quad \frac{T_{1D}(400)}{T_{1D}(200)} = \frac{\left(\frac{5 + 8\omega_I^2\tau_R^2}{1 + 5\omega_I^2\tau_R^2 + 4\omega_I^4\tau_R^4}\right)_{200\ MHz}}{\left(\frac{5 + 8\omega_I^2\tau_R^2}{1 + 5\omega_I^2\tau_R^2 + 4\omega_I^4\tau_R^4}\right)_{400\ MHz}}$$

Hence, from a knowledge of the T_1 value at 400 MHz, $T_{1D}(400)$ for a given proton and the corresponding value at 200 MHz, $T_{1D}(200)$, τ_R for any proton can be evaluated. A plot of τ_R vs. the $T_{1D}(400)/T_{1D}(200)$ quotient is shown in Fig. 5. This approach has been previously applied by Fung *et al.* (18) to obtain the correlation times for the propionyl-CoA protons. They worked both at 220 MHz and 100 MHz. However, the form of eq. [2] is slightly different from that quoted in ref. 18.

Using the graph shown in Fig. 5, the correlation times for the protons are given in Table 1 for the three molecules. The correlation times range from $< 0.7 \times 10^{-10}$ s to 1.2×10^{-10} s.

Distance calculations between the 19*Z* and 19*E* protons can now be carried out, as these geminal protons are relaxed foremost by each other by the dipolar mechanism while contributions to their relaxation from neighboring protons are expected to be small. Using the average values of the T_1 results at 400 MHz for both protons for each molecule, and the average correlation times (0.99×10^{-10} s for 1α,25-$(OH)_2D_3$, 0.88×10^{-10} s for D_3, and 0.70×10^{-10} s for D_2), 19*Z* to 19*E* interproton distances were calculated using eq. [1]. These are 1.98 ± 0.10 Å for 1α,25-$(OH)_2D_3$, 2.01 ± 0.10 Å for D_3, and 1.95 ± 0.10 Å for D_2. Using a neutron diffraction value for the C—H bond distance of 1.10 Å (13), and a bond angle of 120°, the calculated distance between these two protons is 1.91 Å. The calculated and measured interproton distances are in excellent agreement, considering the fact that other protons can contribute slightly to the relaxation. The error limits on the measured interproton distances are 5%. Sykes and co-workers (19) have carried out a detailed study of the calculation of absolute interproton distances of *cis*- and *trans*-crotonaldehyde in solution and also present a detailed bibliography of earlier studies.

The data in Table 1 show two additional interesting features. The T_1 value for protons 26 and 27 for 1α,25-$(OH)_2D_3$ at 400 MHz is 0.85 s, whereas for D_3 it is 1.57 s. The former molecule contains an OH group attached to the C-25 carbon. The shorter T_1 values for the 1α,25-$(OH)_2D_3$ molecule are probably due to changes in internal motion due to some steric hindrance arising from the OH group. This effect will decrease the T_1 value for the 26- and

[a]Since very small changes in these short T_1 values cause extensive changes in the $T_1(400)/T_1(200)$ quotient, τ_R values were not evaluated.
[b]Reliable T_1 values were not obtained due to multiplet overlap.

27-methyl protons in comparison with those for D_3. Secondly, the shorter T_1 value for proton 1β in D_3 with respect to the 1β proton in 1α,25-$(OH)_2D_3$ is due to the substitution of a geminal proton by the OH group in the latter compound. The difference in T_1 for these two values could not give us an accurate distance between the 1α and the 1β protons for D_3.

In the present study, the initial rates have been calculated. The experiments were carried out at the lowest possible concentration (0.01 *M* and less) so that only *intra*molecular dipolar interactions are important. Relaxation mechanisms due to paramagnetic impurities have been minimized by careful cleaning of all glassware, and the degassing of all samples. A deuterated solvent was used to eliminate solute–solvent dipolar interactions. Consequently, the initial rates are very nearly equal to $1/T_{1D}$ providing that other relaxation mechanisms, such as spin–rotation, do not contribute to the T_1. The effects of cross-relaxation are minimized by the initial slope approximation (20). The discussion of cross-relaxation effects has now been well documented (21, 22). Campbell and Freeman (23) investigated the effects of cross-relaxation in weakly and strongly coupled two-spin systems. For

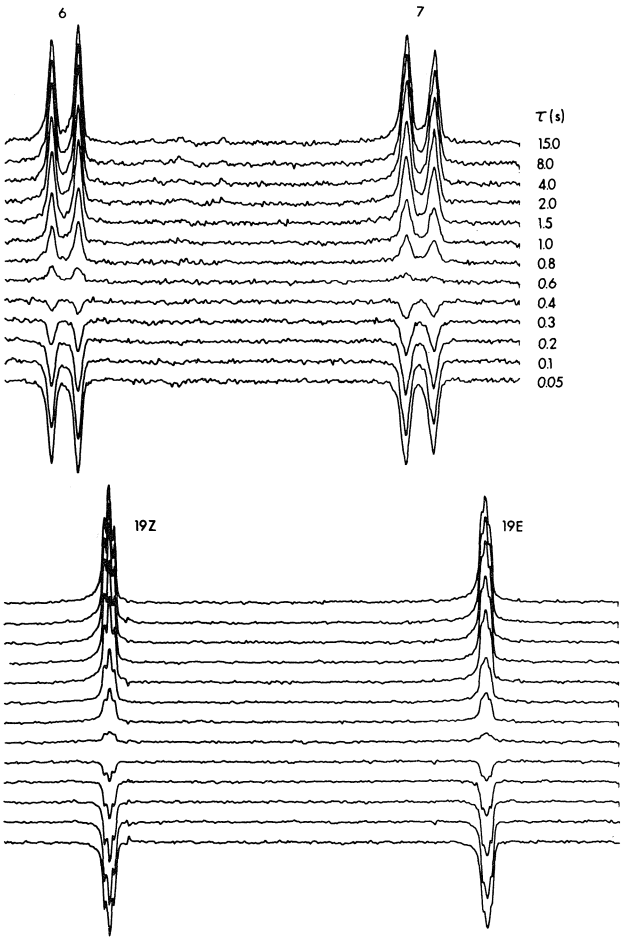

FIG. 4. The 180°–τ–90° inversion recovery spectra obtained at 400 MHz for protons 6, 7, 19*Z*, and 19*E* of 1α,25-$(OH)_2D_3$. The τ values are indicated in the figure. The delay time between the pulse sequences was 15 s; 16 000 data points were used together with 40 scans.

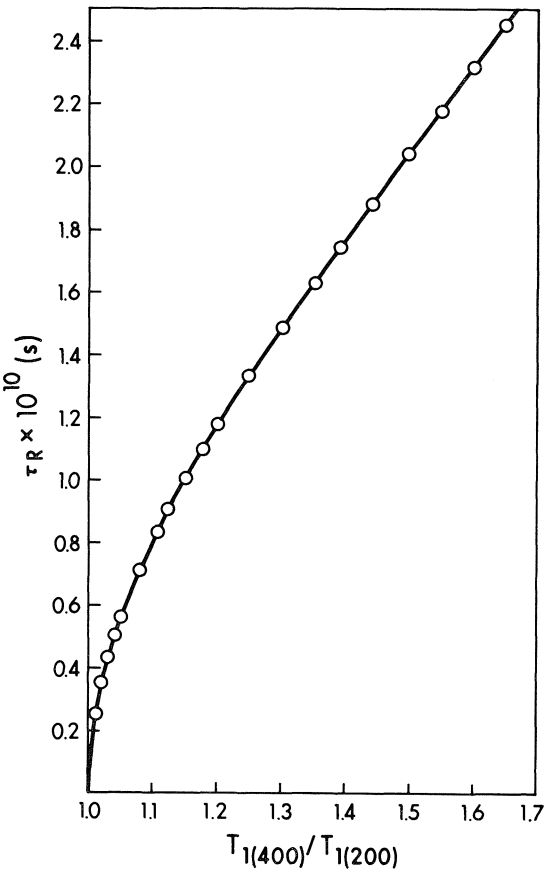

FIG. 5. A plot of τ_R vs. the $T_{1D}(400\ MHz)/T_{1D}$ (200 MHz) quotient. The curve was computed according to eq. [2].

the weakly coupled case, the maximum error in the derived spin–lattice relaxation time is of the order of 10%, and the authors conclude that it may be safely neglected for many applications (23). For the strongly coupled case, deviations from exponential spin–lattice relaxation due to cross-relaxation requires (*a*) strong dipolar relaxation, (*b*) strong spin–spin coupling, and (*c*) asymmetrical external relaxation. As the authors acknowledge (23), these three criteria are not easily satisfied simultaneously. In the systems involved in the present study, because of the high magnetic field strengths employed, many of the protons are weakly coupled. In addition, the small range of T_1 values indicates that condition (*c*) is not fulfilled for any strongly-coupled protons.

In summary, solution geometry based on high resolution proton T_1 values is now being obtained for a range of organic molecules (19, 24, 25), and various selective and non-selective relaxation measurements provide valuable information of the solution conformation. The study of the role of vitamins in nutrition and in health is now increasing, as evidenced by a recent review article (26). The presence of the two extra hydroxyl groups in the active form of vitamin D is extremely important. The cellular mechanism by which 1α,25-$(OH)_2D_3$ increases intestinal calcium absorption in several hours in the rat, while vitamin D_3 takes 12–24 h, is not well understood (27). The results of the present study can be used as a basis for further studies involving the binding of Ca(II) ions, interactions with calcium binding proteins, and 1α,25-$(OH)_2D_3$.

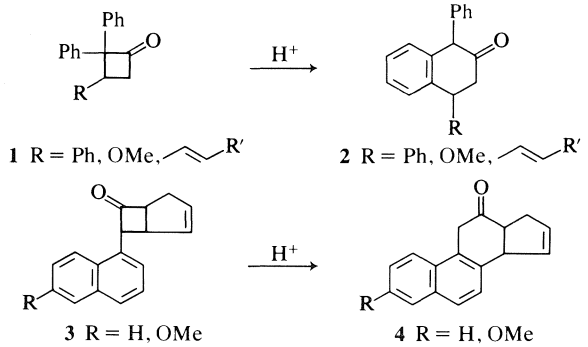
Acid-catalyzed rearrangement of cyclobutanones. V. Preparation of polycyclic aromatic dihydrofurans and dihydropyrans

PAUL DUPERROUZEL AND EDWARD LEE-RUFF
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received July 19, 1979

PAUL DUPERROUZEL and EDWARD LEE-RUFF. Can. J. Chem. **58**, 51 (1980).

Cyclobutanones derived from α-phenyl, α,α-diphenyl, and bisphenyleneketene cycloaddition to dihydrofuran and dihydropyran were rearranged under acidic conditions to polycyclic aromatic dihydrofurans and dihydropyrans respectively. A mechanism for these rearrangements is proposed.



PAUL DUPERROUZEL et EDWARD LEE-RUFF. Can. J. Chem. **58**, 51 (1980).

Les cyclobutanones provenant de la cycloaddition de l'α-phényle, de l'α,α-diphényle et du bisphénylènecétène sur le dihydrofuranne et le dihydropyranne sont transposés en milieu acide respectivement en dihydrofurannes et dihydropyrannes polycycliques aromatiques. On propose un mécanisme pour ces transpositions.

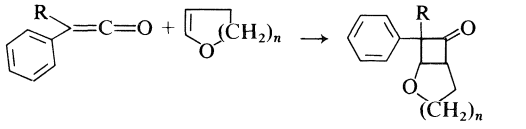
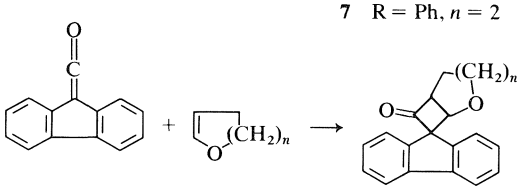
Protonated cyclobutanones undergo a wide variety of ring opening reactions (1–4). The ease of preparation of these derivatives by a number of classical (5) as well as contemporary (6) methods makes this class of compounds potentially useful synthetic intermediates. We have reported (3, 4) that 2-aryl-cyclobutanones possessing positive charge stabilizing groups at carbon-3, i.e., **1** undergo acid rearrangement to β-tetralones, i.e., **2**. By this method steroid derivatives such as **4** were



1 R = Ph, OMe, R′ **2** R = Ph, OMe, R′

3 R = H, OMe **4** R = H, OMe



prepared from cyclobutanones **3**. With the increased reactivity of enol ethers towards ketene cycloadditions (7) and the ready availability of dihydrofuran and dihydropyran we were interested in widening the scope of such rearrangement towards the synthesis of polycyclic derivatives incorporating such ring systems.

Cyclobutanones **5–9** were prepared by cycloaddition of dihydrofuran or dihydropyran with the respective ketene. The yields of these derivatives depend on the mode of preparation in instances where the ketene is not stable, however under optimised conditions the yields of cyclobutanones **5–9** exceeded 80%. Due to the extreme reactive nature of phenylketene towards homopolymerization, the preparation of **5** was accomplished by the addition of 1 equiv. of triethylamine to an ethereal solution of phenylacetylchloride containing 3 equiv. of dihydrofuran. In the reverse mode of addition only trace amounts of **5** were obtained with the principal product being a crystalline 2:1 ketene–dihydrofuran adduct. Cyclobutanones **6** and **7** had been previously described (7). Ketones **5**, **8**, and **9** were assigned structures based on the spectral data and comparison of these with those of ketones **6** and **7**.

Cyclobutanones **5–9** were rearranged under acidic conditions using either 1 equiv. of P_2O_5 at ambient temperature in benzene or preferably catalytic amounts of *p*-toluenesulphonic acid at reflux temperature. The principal products of these reactions are the aromatic dihydrofurans **10–12**, **15**, **16** in yields ranging from 30 to 90% (see Table 1). The structural assignments of these compounds were based on their spectral data as well as in

certain instances, i.e., **10** and **11**, conversion to the aromatic furans **13** and **14** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (12). Naphthofuran **13** had an identical uv spectrum and mp of picrate to those reported for **13** obtained by an alternate synthesis (8). The fluoranthene chromophore in **15** and **16** was established by the close correspondence of their uv spectra to that of fluoranthene (see Fig. 1).

The acid rearrangements of cyclobutanones **5–9** appear to follow a different course when compared to ketones **1** and **3** in that β-tetralones are not formed as principal products in the former case. However the formation of aromatic dihydrofurans **12**, **15**, and **16** formally involves a dehydration step and it is conceivable that β-tetralones are precursors to these dihydrofurans. In one study on the acid rearrangement of **16** with *p*-toluenesulphonic acid in benzene solution the ir absorption of the reaction mixture was monitored for carbonyl absorption. Peaks at 1725 and 1620 cm^{-1} appeared in the early stages of the reaction and then decreased in intensity as the reaction progressed. We were not successful in the isolation of any intermediates prior to completion of the reaction. Given that β-tetralones **17** are primary reaction products in these rearrangements and are formed by a mechanism previously reported for ketones **1** and **3** (3), the subsequent dehydration of **17** could involve a hydride shift of the protonated species to form a more

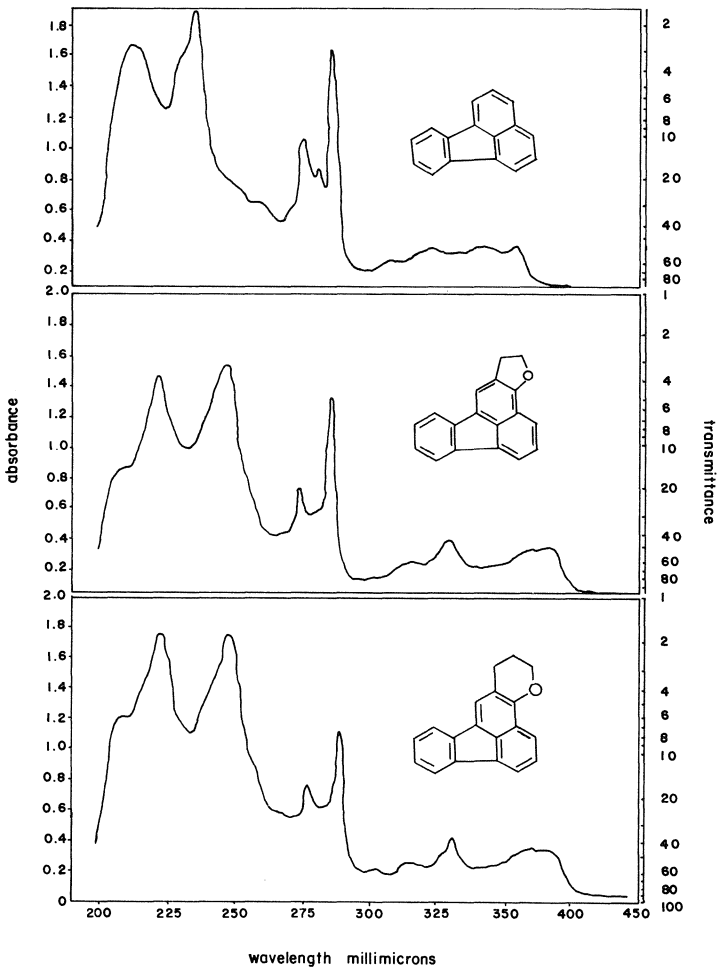

FIG. 1. Ultraviolet spectra of fluoranthenes (for ε values see Experimental).

stabilized carbonium ion **18**. An ensuing proton loss to **19** and dehydration leads to the observed products. Evidence for such a mechanism could be obtained from suitable labelling experiments.

With the current interest in the synthesis of polycyclic aromatic hydrocarbons and their oxidative metabolites, our cyclobutanone rearrangement reactions constitute a novel and useful addition to this area. Furthermore, polycyclic furans such as **13** and **14** posses a "bay region" (8) and may possibly increase the carcinogenic character of naphthalene derivatives. These compounds are currently being screened for mutagenic properties by standard tests.

Experimental

The melting points were determined on a Reichert melting point apparatus and are uncorrected. Infrared spectra were recorded on a Unicam SP1000 instrument as thin films (neat) or KBr pellets. Nuclear magnetic resonance spectra were recorded on a Varian EM-360 instrument in $CDCl_3$ solution containing 1% tetramethylsilane as internal standard. Ultraviolet spectra were obtained on a Unicam SP800A spectrometer using ethanol solutions. All starting materials were obtained from Aldrich Chemicals. Microanalyses were performed by Gygli Microanalysis Laboratories of Toronto.

Preparation of Acid Chlorides

The carboxylic acids were refluxed in 3-fold excess of thionyl chloride for 2–4 hours. The excess thionyl chloride was evaporated. The acid chlorides were crystallized from hexane solutions (9-fluorenylcarbonyl chloride mp 74–75°C (lit. (9) mp 76°C)) or distilled (2-phenylacetyl chloride bp 98°C/12 Torr (lit. (10) bp 100°C/12 Torr)).

Preparation of Cyclobutanones

Cis *7,7-Diphenyl-2-oxabicycloheptan-6-one (**6**) and* Cis *8,8-Diphenyl-2-oxabicyclooctan-7-one (**7**)*

These were prepared according to the procedures of Huisgen (7) with no modifications.

*7-Phenyl-2-oxabicycloheptan-6-one (**5**)*

To a solution containing 2 g of 2-phenylacetyl chloride in 70 mL of anhydrous ether and 5 g of dihydrofuran was slowly added 1.31 g of triethylamine in 10 mL of ether under nitrogen at

room temperature. When the addition was complete the solution was stirred for a further 30 min. The reaction mixture was filtered and the filtrate evaporated to give an oily residue. Infrared ν: 1785 (C=O stretch), 1085 (C—O stretch) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.3 (s, 5H), 5.2 (q, 1H, J = 4 Hz), 4.5 (d, 1H, J = 4 Hz), 3.9 (m, 3H), 2.1 (m, 2H); ms $M^+ - 70$ (C_4H_6O) base peak m/e: 70 ($C_4H_6{}^+O$).

7,7-Bisphenylene-2-oxabicycloheptan-6-one (8)

To 1 g of 9-fluorenylcarbonyl chloride in 50 mL of anhydrous ether cooled to −60°C was slowly added 0.442 g of triethylamine in 10 mL of ether. An orange coloured solution was immediately formed. To this solution was added 3 g of dihydrofuran and the solution was warmed to 0°C and stirred for one hour. The solution was filtered and the precipitate was washed with 3 × 50 mL of distilled water.

The precipitate was recrystallized in ether–methanol mp 114–116°C; ir ν: 1775 (C=O stretch), 1090 (C—O stretch) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.2–8.0 (m, 8H), 4.9 (d, J = 6 Hz, 1H), 4.0–4.5 (m, 3H), 2.0–2.7 (m, 2H); ms m/e: 262 (M^+), base peak 70 ($C_4H_6O^+$). *Anal.* calcd. for $C_{18}H_{14}O_2$: C 82.44, H 5.34; found: C 82.23, H 5.51.

8,8-Bisphenylene-2-oxabicyclooctan-7-one (9)

The same procedure as for the preparation of ketone **8** was used, except dihydropyran was used in place of dihydrofuran. Ketone **9** was found to be soluble in ether and the following workup procedure was used. The solution was filtered and the filtrate was evaporated to dryness. The residue was crystallized in ether mp 121–123°C; ir ν: 1774 (C=O stretch), 1050 (C—O stretch) cm^{-1}, ^{1}Hmr ($CDCl_3$) δ: 7.3–7.9 (m, 8H), 4.6 (d, J = 6 Hz, 1H), 3.2–4.2 (m, 3H), 1.3–2.5 (m, 4H); ms m/e: 276 (M^+), base peak 84 ($C_5H_8O^+$). *Anal.* calcd. for $C_{19}H_{16}O_2$: C 82.61, H 5.80; found: C 82.58, H 5.75.

Acid-catalyzed Rearrangement. General Procedure

P_2O_5/C_6H_6

The cyclobutanone (200–500 mg) was dissolved in dry benzene (40 mL). To this solution was added 2 equiv. of P_2O_5 and the suspension was stirred from 2–24 h. The suspension was filtered and the solid was washed with benzene and ether. The filtrate and washing were evaporated. In certain instances (**10**, **15**, and **16**) the residue was chromatographed on silica gel thin layer plates. Yields and specific details of the reactions are given in Table 1.

TsOH/C_6H_6

To a solution of benzene (30–40 mL) containing the cyclobutanone (200–500 mg) was added a few crystals of toluenesulphonic acid. The solution was heated to reflux for 2–24 hours. The solution was washed with 10% aqueous sodium bicarbonate, then dried with anhydrous magnesium sulphate and evaporated. The residue in certain instances was chromatographed on silica gel thin layer plates.

Spectral Data of Dihydrofurans and Dihydropyrans

Reçu le 30 avril 1979

BERNARD BOYER, GÉRARD LAMATY, JEAN-PIERRE ROQUE et PATRICK GENESTE. Can. J. Chem. **58**, 55 (1980).

L'étude cinétique des réactions d'addition de l'ion borohydrure, de l'ion sulfite et de l'hydroxylamine sur un certain nombre de composés carbonylés stéréospécifiquement deutériés (tétraméthyl-3,3,5,5 cyclohexanone, bicyclo[2,2,1]norbornanone-2 d_2-7,7), a permis de mettre en évidence un effet isotopique secondaire lointain du deutérium. Les résultats obtenus révèlent l'intervention d'un effet directionnel dans l'origine stérique de ces effets isotopiques. En particulier, cette étude montre l'importance de la nature et de l'orientation des vibrations mises en jeu par une liaison C—D au cours du processus réactionnel.

BERNARD BOYER, GÉRARD LAMATY, JEAN-PIERRE ROQUE and PATRICK GENESTE. Can. J. Chem. **58**, 55 (1980).

A kinetic study of the addition reactions of borohydride and sulfite ions and of hydroxylamine to a number of stereospecifically deuterated carbonyl compounds (3,3,5,5-tetramethyl cyclohexanone, 7,7-d_2-bicyclo[2,2,1]-2-bornanone) leads to the observation of a distant secondary deuterium isotope effect. The results obtained reveal the intervention of a directional effect in the steric origin of these isotope effects. In particular, this study shows the importance of the orientation of the vibrations brought into play by a C—D bond during the reaction process.

(Journal translation)

Introduction

Dans un article précédent (1), nous avions remarqué l'absence d'effet isotopique secondaire du deutérium dans la réaction d'addition de BH_4^- sur la bicyclo[2,2,1]heptanone-2 d_2-5,6 *endo* (**1**) et dans la réaction de décomposition de la combinaison bisulfitique de cette même cétone. Sur la base classique de l'origine stérique des effets isotopiques (4, 5), ces résultats sont surprenants. En effet, la réaction de réduction est connue pour avoir un état de transition très tardif (2, 6) entraînant des interactions stériques importantes entre l'oxygène et les hydrogènes (ou deutériums) 5,6 *endo* (fig. 1*a*).

Par ailleurs, la décomposition de la combinaison bisulfitique (fig. 1*b*) passe par un état de transition proche de la cétone (3) dans lequel sont supprimées les interactions de non-liaison entre le groupe hydroxyle et les hydrogènes (ou deutériums) 5,6 *endo*. On pouvait s'attendre à trouver un effet isotopique inverse dans le premier cas ($k^H/k^D < 1$) et direct dans le second ($k^H/k^D > 1$), puisque le deutérium est supposé "moins volumineux" que l'hydrogène (4).

Par contre, nous avons observé que la réduction de la diphényl-2,6 pipéridone-4, (**2**), deutériée en position 2,6 axiale (fig. 2), donne lieu à un effet isotopique secondaire $k^H/k^D = 0.96_3$ (7).

Nous avons suggéré que cette différence de comportement pouvait être due au fait que dans le premier composé (fig. 1) les interactions de non-liaison se produisent "par le flanc" des liaisons C—H (ou C—D) et affectent donc les mouvements de déformation ("bending") de ces liaisons, alors que dans le second (fig. 2) ces mêmes interactions se produisent essentiellement par "la pointe des liaisons" et affectent ainsi leurs mouvements d'élongation ("stretching"). Nous avions conclu qu'il devait exister un effet directionnel dans l'effet isotopique d'origine stérique: les vibrations de déformation seraient peu affectées par la substitution isotopique, seules les vibrations d'élongation le seraient.

TABLEAU 1. Valeurs des rapports k^H/k^D pour les réactions d'addition de BH_4^-, NH_2OH et SO_3H^- et pour la réaction de décomposition des combinaisons bisulfitiques

Produits	k^H/k^D			
	BH_4^-	Addition de NH_2OH	SO_3HNa	Décomposition de la combinaison bisulfitique
 **1**	1.00_4[a]	—	—	1.00_5[a]
 **2**	0.96_3[b]	—	—	—
 **3a**	0.98_7[c]	—	—	—
 **3b**[f]	0.96_4[c]	0.97[d]	0.98_4[e]	1.01_3[e]
 **4**	0.95_9[c]	0.97[d]	—	—

[a]Voir réf. 1.
[b]Voir réf. 7.
[c]Effets isotopiques mesurés à 25.0 ± 0.1°C dans le mélange eau–dioxanne 50/50 avec une précision meilleure que 1%.
[d]Effets isotopiques mesurés à 25.0 ± 0.1°C dans des solutions aqueuses d'acides chlorhydrique de concentrations variables, avec une précision meilleure que 2%.
[e]Effets isotopiques mesurés à 25.0 ± 0.1°C dans un tampon acide acétique–acétate de sodium à pH = 5.41 dans le solvant H_2O–EtOH (60/40 en volume). La précision sur les valeurs du rapport k^H/k^D est meilleure que 1%.
[f]La présence de 2 atomes de deutérium en position 4 n'apporte aucune contribution supplémentaire à l'effet isotopique observé. La cohérence des résultats obtenus pour **3***a* et **3***b* (voir texte) montre bien qu'il y a additivité de l'effet isotopique quand on passe du mono-CD_3 au di-CD_3 et que les deux deutériums en 4 ne modifient pas le résultat.

Dans le cadre d'une étude plus générale portant sur l'addition de divers nucléophiles sur les cétones cyclaniques, nous avons utilisé deux modèles qui se prêtent bien à la vérification de cette hypothèse. Il s'agit, d'une part de la tétraméthyl-3,3,5,5 cyclohexanone (**3**) substituée en 3 par un, **3***a*, ou deux groupes CD_3, **3***b*, et d'autre part de la méthyl-1 bicyclo[2,2,1]heptanone-2 (**4**) deutériée en position 7.

Résultats et discussion

Sur toutes ces cétones nous avons mesuré la vitesse d'addition de l'ion borohydrure dans l'eau–dioxanne 50/50 à 25°C, et, pour certaines d'entre elles, la vitesse de décomposition de la combinaison bisulfitique.

Les résultats expérimentaux sont reportés dans le tableau 1.

L'examen des résultats fait apparaître que la substitution isotopique sur le(s) groupe(s) méthyle(s) en position 3 de la tétraméthyl-3,3,5,5 cyclohexanone, composés **3***a* et **3***b*, entraîne un effet isotopique inverse dans les réactions d'addition des trois nucléophiles et un effet isotopique direct dans le cas de la réaction de décomposition de la combinaison bisulfitique.

Ces effets isotopiques sont faibles, comme on pouvait s'y attendre, et avant de les discuter il convient de savoir s'ils sont significatifs ou non. Chaque constante de vitesse est la moyenne de 6 déterminations indépendantes, la déviation standard étant, dans tous les cas, $\leq 0.3\%$; l'incertitude sur le rapport k^H/k^D est donc légèrement inférieure à 0.01. La comparaison des effets isotopiques observés avec **3***a* et **3***b* confirme la confiance que nous pouvons avoir dans nos données; le composé **3***a*, qui ne possède qu'un seul groupe méthyle en position 3 est en réalité un mélange à parties pratiquement égales des deux conformères (fig. 3).

Seule la conformation **3**′*a* donnera un effet isotopique stérique lors de l'addition de l'ion borohydrure car on ne peut raisonnablement envisager

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

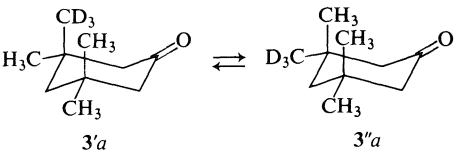

FIG. 3.

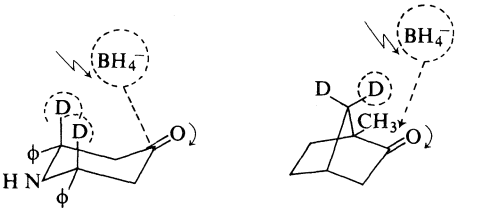
que le CD_3 équatorial de **3″*a*** modifie tant soit peu la vitesse de la réaction; la variation de l'énergie libre d'activation due à la substitution isotopique sera donc deux fois plus faible pour **3*a*** que pour **3*b*** et on devra donc avoir

$$(k^H/k^D)_{3b} = (k^H/k^D)^2_{3a}$$



C'est ce que confirme l'expérience puisque $(0.987)^2 = 0.97_3$, compatible avec la valeur trouver pour **3*b*** aux erreurs expérimentales près.

Les réactions conduisent essentiellement aux composés à groupe —OH axial. Au fur et à mesure de l'avancement de la réaction, il y a donc apparition d'un effet stérique de compression dû aux interactions de non-liaison entre l'oxygène de la cétone et les groupes méthyles axiaux; l'existence d'un effet isotopique inverse indique que cette interaction est moindre dans le cas des composés deutériés (**3*a*** et **3*b***). On remarque que l'effet isotopique varie légèrement d'un nucléophile à l'autre; on doit s'attendre à ce qu'il soit d'autant plus important que l'état de transition de la réaction est plus tardif (plus proche des produits finaux). Nous avons montré par ailleurs que l'addition de l'ion sulfite et de l'hydroxylamine conduisait à un état de transition précoce (3, 6, 8) tandis que l'addition de BH_4^- conduit à un état de transition tardif (2, 6); on retrouve bien ici cette différence puisque l'effet isotopique avec l'ion borohydrure est sensiblement plus élevé qu'avec les deux autres nucléophiles.

On peut remarquer également que la décomposition de la combinaison bisulfitique de la cétone, **3*b***, s'accompagne d'un relâchement des interactions 1,3 diaxiales qui se traduit par effet isotopique direct.

Examinons à présent les résultats obtenus lors de l'addition de BH_4^- sur les cétones **1**, **2**, **3*b*** et **4**. Ces 4 modèles peuvent être subdivisés en 2 groupes si l'on considère la nature de la contribution stérique à l'effet isotopique.

Dans le premier groupe, réunissant les composés **2** et **4**, nous pouvons constater (fig. 4) que les liaisons C—H (C—D) en position 3,5 diaxiale pour **2** et la liaison C—H (C—D) en position *syn*-7 pour **4**, se trouvent dans la direction la plus propice à une interaction avec le nucléophile lors de son approche par la face axiale pour **2** et par la face *exo* pour **4** (additions largement prépondérantes).

2 $k^H/k^D = 0.96_3$ **4** $k^H/k^D = 0.95_9$

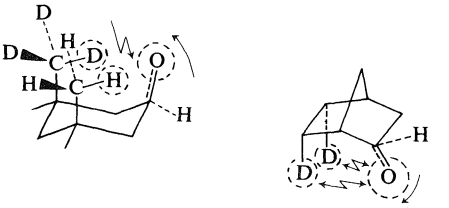


FIG. 4. Effets stériques d'approche dans la réduction par l'ion borohydrure.

Ainsi la présence de 2 atomes de deutérium dans la pipéridone **2** conduit à une diminution de l'énergie d'activation de 22 cal soit 11 cal par deutérium. Par contre, un seul atome de deutérium conduit à $\Delta\Delta G^{\neq}$ égal à 25 cal pour **4**. Bien qu'il s'agisse dans les deux cas d'un effet stérique d'approche, l'orientation de la liaison C—D dans le composé **4** est telle que les interactions stériques mettent davantage en jeu la vibration d'élongation de cette liaison que dans le cas du composé **2**.

Par contre dans le deuxième groupe (**3*b*** et **1**), l'orientation des liaisons C—H (C—D) est favorable à l'intervention d'un "effet stérique de compression" lié au développement, dans l'état de transition tardif, d'interactions de non-liaison entre l'oxygène du carbonyle et, d'une part le groupe CD_3 axial (addition équatoriale) pour **3*b***, et d'autre part les liaisons C—H (C—D) 5,6 *endo* pour **1** (fig. 5).

L'examen des valeurs observées au sein de ce groupe est révélateur de l'importance de l'orientation de la liaison C—D sur l'effet isotopique d'origine stérique.

Dans le cas de la tétraméthyl-3,3,5,5 cyclohexanone **3*b***, un seul atome de deutérium du CD_3 axial apporte une contribution à l'effet isotopique; l'orientation de la liaison C—D est telle que les interactions de non-liaison qui se développent dans l'état de transition affectent essentiellement la vibration d'élongation de cette liaison; ceci conduit à

3 $k^H/k^D = 0.96_4$ **1** $k^H/k^D = 1.00_4$

FIG. 5. Effets stériques de compression dans la réduction par l'ion borohydrure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

un effet isotopique de 4% environ, correspondant à un $\Delta\Delta G^{\neq}$ égal à 22 cal, identique à celui observé pour la cétone **4**.

La littérature nous fournit un certain nombre d'exemple de l'influence des interactions de non-liaison liées aux variations des vibrations d'élongation. C'est le cas, en particulier, des résultats obtenus dans la série des dérivés du biphényle par Mislow *et al.* (9), Melander et Carter (10), Carter et Dahlgren (11) pour lesquels la réaction d'inversion configurationnelle donne lieu à un rapport k^H/k^D compris entre 0.87_6 et 0.83_3 selon la température et la nature du substrat.

Un exemple plus récent est celui donné par la solvolyse de *p*-nitrobenzoate de tertiobutyl-2 adamantyle-2 (**5**) qui s'accompagne d'un effet isotopique direct $k^H/k^D = 1.11$ (12) ($\Delta\Delta G^{\neq} = -62$ cal) lorsqu'on substitue les hydrogènes du groupe tertiobutyle par des deutériums. Or, au cours de cette réaction, de type S_N1, il y a suppression des interactions 1,3 diaxiales du groupe tertiobutyle avec deux atomes d'hydrogène. Statistiquement on peut dire qu'en première approximation, la substitution isotopique n'affecte que l'interaction d'un seul hydrogène (ou deutérium) avec deux atomes d'hydrogène (fig. 6).

Pour une seule interaction H(D)–H, on peut donc estimer à 31 cal l'augmentation de l'énergie d'activation provoquée par la substitution isotopique. Cette valeur est dans le même sens bien que légèrement plus élevée que dans le cas des composés **3***b* et **4**.

L'hypothèse d'une dépendance directionnelle de l'effet isotopique stérique semble parfaitement justifiée lorsque l'on considère la nature et l'origine même des interactions mises en jeu au cours du processus réactionnel. En effet, ces interactions de non-liaison, réunissant sous le même vocable les effets stériques d'approche et les effets stériques de compression, représentent en fait des interactions qui se produisent entre atomes non liés lorsqu'ils arrivent à une distance supérieure à la somme de leurs rayons de van der Waals. Ces contacts peuvent se produire selon diverses directions suivant

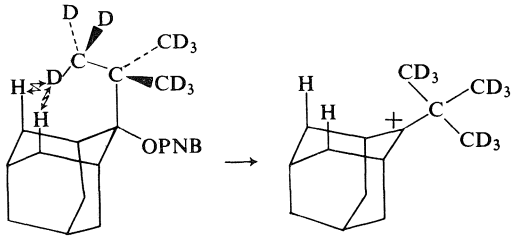

FIG. 6. Solvolyse du *p*-nitrobenzoate de tertiobutyl-2 adamantyle-2 (**5**).

l'orientation dans l'espace des atomes impliqués dans ces interactions de non-liaison.

Or, d'après la représentation de Pauling de la liaison covalente (13), une liaison C—H (ou C—D) est anisotrope et présente un aplatissement sur le flanc du lobe orbitalaire (fig. 7); il sera donc plus facile, pour un autre atome, de s'approcher à une distance donnée d'un atome d'hydrogène par "le flanc" que par "la pointe". En outre, les fréquences de vibration de déformation (bending) étant beaucoup plus faibles que celles d'élongation (stretching), une "gène stérique identique en amplitude" mettra en jeu des énergies moindre lorsqu'elle se produira sur "le flanc" du lobe que sur "la pointe".

C'est en effet ce que l'on observe expérimentalement puisqu'en ne considérant que l'interaction créée par un seul atome de deutérium, les $\Delta\Delta G^{\neq}$ vairent de 0 à 31 cal quand on passe du composé **1**, pour lequel n'interviennent que les vibrations de déformation, au composé **5** où les interactions 1,3 diaxiales mettent en jeu les vibrations d'élongation.

Il est hors de doute que la substitution d'un hydrogène par un deutérium entraîne une variation des contraintes stériques au sein de la molécule. Toutefois, nous pensons avoir montré que cet effet ne peut affecter sensiblement la vitesse d'une réaction que si les atomes qui viennent au contact de la liaison C—H (ou C—D) le font suivant l'axe de cette liaison et non selon une direction perpendiculaire.

Partie expérimentale

Obtention des produits

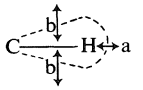
Le composé **3***b* a été synthétisé selon le schéma réactionnel suivant:

L'isophorone d_8 (14) a été préparé selon la méthode de Starks (15) par échange en milieu basique ($NaOD/D_2O$) en présence de bromure de cétyltriméthylammonium (CTAB). L'addition de ICD_3Mg sur cette cétone éthylénique conduit après hydrolyse au composé **3**. Après dédeutériation sélective ($NaOH/H_2O$) (15), nous avons isolé **3***b* avec un rendement de 63%, pé: 94°C/20 Torr.

Par un procédé analogue au précédent mais en utilisant l'isophorone non deutériée comme produit de départ, nous avons obtenu l'homologue mono-trideutériée en 3 (**3***a*).

Le composé bicyclique **4** a été préparé selon la méthode de Berson et coll. (16) en utilisant comme produit de départ la norbornanone-2 sélectivement deutériée en α du carbonyle par CF_3CO_2D (17) pé: 65°C/20 Torr.

La teneur isotopique a été contrôlée par spectrométrie de masse. Le taux de deutérium est dans tous les cas supérieur à 98%.



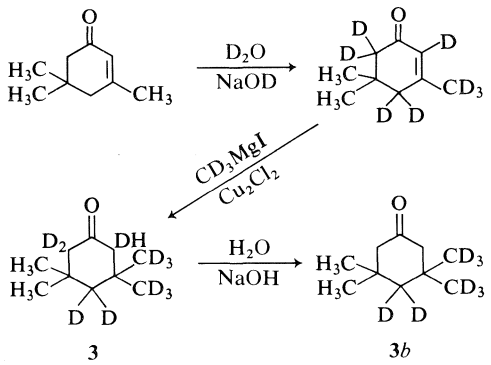


FIG. 7. Liaison C—H selon le modèle de Pauling (13).

SCHÉMA 1

Mesures cinétiques

Cinétiques de réduction des cétones par l'ion borohydrure

Les conditions de concentration et de solvant sont les mêmes que celles de Geneste et Lamaty (2): eau–dioxanne 50/50 en volume, 0.05 *N* en soude. La réaction est suivie à 25.0 ± 0.1°C par spectrophotométrie uv à une longueur d'onde (285 nm) pour laquelle seule la cétone de départ absorbe (1).

Etude cinétique de la réaction d'oximation

Les conditions de détermination des constantes de vitesse sont identiques à celles décrites par Petitjean et coll. (18).

Etude cinétique de l'addition de l'ion sulfite. Décomposition des combinaisons bisulfitiques

Nous avons utilisé la méthode spectrophotométrique uv mise au point au Laboratoire et décrite par ailleurs (19).

Received July 16, 1979

ALEXANDER F. JANZEN, GERALD N. LYPKA, and RODERICK E. WASYLISHEN. Can. J. Chem. **58**, 60 (1980).

N-tert-Butyldimethylsilyl derivatives of imidazole, 2-methylimidazole, 4-methylimidazole, benzimidazole, pyrazole, 1,2,4-triazole, and benzotriazole were prepared from *tert*-butyldimethylsilyl chloride and the corresponding heterocyclic compound. The products were identified by carbon and proton nmr, mass spectrometry, and elemental analysis. The carbon nmr spectra confirmed the absence of intermolecular silyl exchange at ambient temperature. Silyl exchange did occur at elevated temperatures, 130–160°C.

Reaction of *N-tert*-butyldimethylsilyl or *N*-trimethylsilyl heterocycles with dimethylsulfoxide gave *N*-(methylthio)methyl derivatives of imidazole, 2-methylimidazole, 4-methylimidazole, benzimidazole, pyrazole, and 1,2,4-triazole. The products were characterized by carbon and proton nmr, mass spectrometry, and elemental analysis. A mechanism involving a Pummerer rearrangement is proposed to account for the results.

ALEXANDER F. JANZEN, GERALD N. LYPKA et RODERICK E. WASYLISHEN. Can. J. Chem. **58**, 60 (1980).

On a préparé des dérivés *N-tert*-butyldiméthylsilyles de l'imidazole, de la benzimidazole, des Me-2 et Me-4 imidazoles, du pyrazole, du triazole-1,2,4 et du benzotriazole, à partir du chlorure de *tert*-butyldiméthylsilyle et des composés hétérocycliques correspondants. On a identifié les produits par rmn du ^1H et du ^{13}C, par spectrométrie de masse et par analyse élémentaire. Les spectres rmn du ^{13}C confirment l'absence d'un échange intermoléculaire du groupe silyle à température ambiante. L'échange se produit à température élevée, 130–160°C. Les hétérocycles ayant des substituants *tert*-butyldiméthylsilyle ou triméthylsilyle sur l'azote réagissent avec le diméthylsulfoxyde pour donner des dérivés *N*-(méthylthio) méthyle de l'imidazole, des méthyl-2 et méthyl-4 imidazoles, du benzimidazole, du pyrazole et du triazole-1,2,4. On a caractérisé les produits par rmn du ^1H et du ^{13}C, par spectrométrie de masse et par analyse élémentaire. Tenant compte de ces résultats, on propose un mécanisme réactionnel qui implique une transposition de Pummerer.

[Traduit par le journal]

Silyl exchange in *N*-(trimethylsilyl)pyrazoles occurs with activation energies of 24–32 kcal/mol, except in dilute solutions of diphenyl ether where inordinately low (3–6 kcal/mol) activation energies were observed (1). The low energy pathway of intermolecular silyl exchange in *N*-(trimethylsilyl)imidazole (~7.7 kcal/mol) and *N*-(trimethylsilyl)-2-methylimidazole was attributed to rapid hydrolysis; silyl exchange was slowed down in two ways: firstly, by re-distillation of products under anhydrous conditions and, secondly, by addition of a large excess of triethylamine which presumably inhibited further exchange reactions at silicon (2).

Since bulky substituents are known to inhibit reaction at silicon (3), it seemed reasonable that introduction of the *tert*-butyl group would reduce the problem of catalyzed silyl exchange in *N*-trialkylsilyl heterocycles. Consequently, a variety of *tert*-butyldimethylsilyl derivatives of imidazole, 2- and 4-methylimidazole, benzimidazole, pyrazole, 1,2,4-triazole, and benzotriazole were prepared and investigated by means of ^{13}C and ^1H nmr.

During the course of this work, it was observed that *N*-trialkylsilyl heterocycles interacted with dimethylsulfoxide to give *N*-(methylthio)methyl derivatives. These derivatives were presumably formed via a Pummerer rearrangement.

Experimental

Natural abundance ^{13}C nmr spectra were measured at 20 MHz using a Varian CFT-20 Fourier Transform nmr spectrometer. Gated proton decoupling was used in order to retain nuclear Overhauser enhancements of the proton coupled spectra. Typically, flip angles of 40 to 60° were used with acquisition time > 1 s and a pulse delay of 2–5 s. Proton nmr spectra were obtained on a Varian A-56/60A spectrometer. Mass spectra were obtained on a Finnigan 1015 quadrupole mass spectrometer. Elemental analyses were performed by Micro-Tech Laboratories, Skokie, Illinois.

Imidazole (Aldrich), 2-methylimidazole (Sigma), 4-methylimidazole (ROC/RIC), benzimidazole (Aldrich), pyrazole (Eastman), 1,2,4-triazole (Aldrich), benzotriazole (Aldrich) were used without further purification. Me_2SiCl_2 (PCR) and $(Me_3Si)_2NH$ (MCB) were redistilled prior to use. Methylene chloride, triethylamine, cyclohexane, and dimethylsulfoxide were dried, redistilled, and stored over molecular sieve. *t*-$BuMe_2SiCl$ was prepared from *t*-BuLi and Me_2SiCl_2 (3) and 1-(trimethylsilyl)imidazole, 1-(trimethylsilyl)pyrazole, and 1-(trimethylsilyl)-1,2,4-triazole were prepared from $(Me_3Si)_2NH$ and the corresponding heterocycle (4).

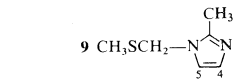
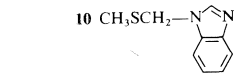
[a]Error ±0.5 Hz, unless otherwise indicated.





N-tert-*Butyldimethylsilyl Heterocycles*

Compounds **1**–**7** were prepared on a 0.02 mol scale by mixing equimolar amounts of *t*-$BuMe_2SiCl$ and the corresponding heterocycle in the presence of excess triethylamine (5, 6). The reaction mixture was either stirred at room temperature for 3–6 days or refluxed for 5–20 h until reaction was complete, as determined by nmr. $Et_3N{\cdot}HCl$ was filtered off and Et_3N was removed under vacuum. A trace of $Et_3N{\cdot}HCl$ was removed by adding cyclohexane, refiltering and removing cyclohexane under vacuum. All products (except **6**) were purified by distillation at 10^{-2} Torr and were clear, viscous liquids. Recrystallization of **6** from cyclohexane gave a white solid mp 87–89°C. Yields of final products were 50% or greater.

The products **1** to **7** were identified by ^{13}C nmr (Tables 1 and

2), ^1H nmr, and mass spectrometry. Compound **1** has been studied previously (5, 6) and **6** was identified by elemental analysis.

Anal. calcd. for $C_8H_{17}N_3Si$: C 52.41, H 9.35, N 22.92; found: C 51.69, H 9.27, N 22.64.

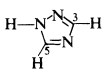
Reaction with DMSO

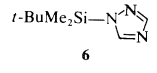
N-(Methylthio)methyl derivatives **8–13** were prepared at 140–180°C for 8–24 h in three ways: (*a*) *N*-trimethylsilyl heterocycle and DMSO, (*b*) *N-tert*-butyldimethylsilyl heterocycle and DMSO, (*c*) hexamethyldisilazane, heterocycle, and DMSO. Yields of products were 40–60%.

In a typical reaction, benzimidazole (15 g, 0.13 mol), DMSO (5.0 g, 0.063 mol), and $(Me_3Si)_2NH$ (10.3 g, 0.064 mol) were refluxed for 20 h. The colourless top layer ($Me_3SiOSiMe_3$) was decanted. CCl_4 was added and a white precipitate (benzimidazole, 8.4 g) was removed. The CCl_4 fraction was washed with 3 × 20 mL portions of H_2O and the CCl_4 layer dried ($MgSO_4$) and rotary evaporated to yield a yellow oil which was extracted once more with CCl_4/hexane and dried under vacuum. The oil was identified as *N*-[(methylthio)methyl]benzimidazole on the basis of elemental analysis, carbon nmr (Table 3), proton nmr, and mass spectrometry.

In another reaction, 2-methylimidazole (10 g, 0.12 mol), DMSO (4.8 g, 0.061 mol), and $(Me_3Si)_2NH$ (10 g, 0.062 mol) were refluxed for 8 h. The colourless top layer ($Me_3SiOSiMe_3$) was decanted. CCl_4 was added and the white precipitate (2-methylimidazole) removed. The CCl_4 fraction was rotary evaporated and the product purified by gas chromatography and identified as *N*-[(methylthio)methyl]-2-methylimidazole on the basis of elemental analysis, carbon nmr (Table 3), proton nmr, and mass spectrometry.

Results and Discussion





N-(tert-*Butyldimethylsilyl)imidazole and Related Heterocycles*

The ^{13}C nmr spectra (Tables 1 and 2) of compounds **1–7** show clearly that the introduction of the bulky *tert*-butyl substituent gives non-fluxional molecules. In each case, separate signals are observed for non-equivalent ring carbons, as required in the absence of intermolecular silyl exchange. (Only the spectrum of **3** is insensitive to chemical exchange effects.)

The carbon spectra were assigned on the basis of nmr data reported for *N*-methyl analogues of **1–7** (7–9). For the methyl group directly bonded to silicon, $^1J_{C,H}$ = 120.3[5] ± 0.2[5] Hz which is only slightly larger than the value of 118.4 Hz observed for $^1J_{C,H}$ in TMS (10). The $^1J_{C,H}$ values for the methyl carbons of the *tert*-butyl moiety were also the same for all compounds within experimental error, 125.5[5] ± 0.25 Hz, slightly larger than the value of 124.04 ± 0.10 Hz observed in neopentane.[1]

$^nJ_{C,H}$ values involving the ring carbons of **1** and **2** are similar to those reported previously for the corresponding *N*-trimethylsilyl derivatives of **1** and **2** (2), while values for **5** and **6** are similar to those observed in 1-methylpyrazole (7, 8) and 1-methyl-1,2,4-triazole (7).

In order to help confirm the assignment of C-3 and C-5 in 1,2,4-triazole derivatives, INDO-MO-FPT level molecular orbital calculations (11) of the various $^nJ_{C,H}$ values in 1,2,4-triazole were carried out. Atomic coordinates were calculated from the bond lengths and angles derived from an X-ray study (12). The results are summarized below.

Parameter	 (Calcd)	 (Obsd, ref. 7)	*t*-BuMe$_2$Si—  **6** (Obsd, this study)
$^1J_{(C\text{-}3,H)}$	180.7 Hz	205.3 Hz	203.8 Hz
$^3J_{(C\text{-}3,H\text{-}5)}$	14.5	11.9	11.8
$^1J_{(C\text{-}5,H)}$	184.4	210.1	206.6
$^3J_{(C\text{-}5,H\text{-}3)}$	11.8	7.3	8.4

some *N*-(methylthio)methyl derivatives

^{13}C,H coupling constants, Hz			
$^1J_{(CH_3)} = 139.4$ $^1J_{(C\text{-}4,H)} = 189.4$ $^2J_{(C\text{-}4,H\text{-}5)} = 10.4$	$^1J_{(CH_2S)} = 152.7$ $^1J_{(C\text{-}5,H)} = 186.5$ $^3J_{(CH_3SCH_2)} = 4.8$	$^1J_{(C\text{-}2,H)} = 203.8$ $^2J_{(C\text{-}5,H\text{-}4)} = 17.4$ $^3J_{(CH_2SCH_3)} = 4.5$	$^3J_{(C\text{-}4,H\text{-}2)} = 10.4$
$^1J_{(CH_3\text{-}C\text{-}2)} = 128.7$ $^1J_{(C\text{-}5,H)} = 188.8$ $^3J_{(CH_3SCH_2)} = 4.5$	$^1J_{(CH_3S)} = 139.2$ $^2J_{(C\text{-}4,H\text{-}5)} = 9.2$ $^3J_{(CH_2SCH_3)} = 4.8$	$^1J_{(CH_2S)} = 151.8$ $^2J_{(C\text{-}5,H\text{-}4)} = 15.9$ $^3J_{(C\text{-}5,CH_2S)} = 3.3$	$^1J_{(C\text{-}4,H)} = 188.8$
$^1J_{(CH_3)} = 139.3$ $^3J_{(CH_3SCH_2)} = 4.7$	$^1J_{(CH_2S)} = 152.2$ $^3J_{(CH_2SCH_3)} = 4.8$	$^1J_{(C\text{-}2,H)} = 206.0$ $^3J_{(C\text{-}2,CH_2S)} = 3.1$	

The relative magnitudes of calculated $^1J_{C,H}$ and $^3J_{C,H}$ values are in agreement with the assignments made on the basis of chemical shifts.

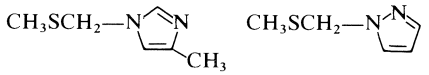
The ^{13}C nmr spectra of **1–7** were recorded at elevated temperature. Compounds **1**, **4**, and **6** showed no broadening of the lines at 150°C but **2** and **3** showed broadening at 130°C. In the case of **5**, no exchange was observed at 125°C, but considerable exchange was evident at 150°C and coalescence of C-3 and C-5 occurred at 175 ± 10°C from which we estimate $\Delta G_c^{\ddagger} = 21.2 \pm 1.0$ kcal/mol (C-4 remained unchanged during this process, as expected).

The proton nmr spectra of **1–7** at 40°C are consistent with rigid structures; however, because of small chemical shift differences the assignment of ring hydrogens could not be made unambiguously.

Reaction of DMSO with N-*Trialkylsilyl Heterocycles*[2]

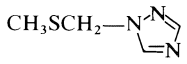
DMSO was found to react with *N-tert*-butyldimethylsilyl or *N*-trimethylsilyl heterocycles at elevated temperature 140–180°C in the absence of solvent to give the corresponding *N*-(methylthio)-methyl heterocycles **8–13**. Heating a mixture of DMSO, heterocycle, and $(Me_3Si)_2NH$ also gave the same products since, in this case, the *N*-trimethylsilyl heterocycle was formed *in situ* from $(Me_3Si)_2NH$ and heterocycle (4), followed by reaction with DMSO.

[1] $2R_3Si\text{—}N\langle\!\rangle N + (CH_3)_2S{=}O \longrightarrow CH_3SCH_2\text{—}N\langle\!\rangle N + R_3SiOSiR_3 + HN\langle\!\rangle N$



8

The products **8–10** were identified by elemental analysis, carbon nmr (Table 3), proton nmr, and mass spectrometry. Compounds **11–13** were identified by proton nmr and mass spectrometry.



[2]For a preliminary account, see ref. 19.

The mass spectra of **8–13** showed prominent peaks at M^+, $M - SCH_3^+$, and *m/e* 61 ($CH_3SCH_2^+$).

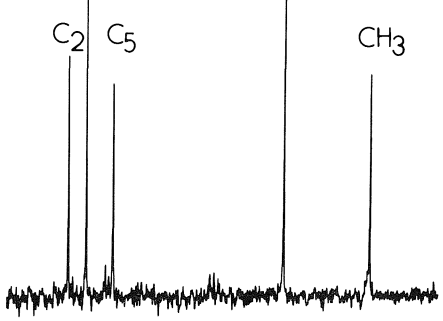
A typical ^{13}C nmr spectrum is shown in Fig. 1. The carbon nmr data confirm the structures of **8–13**

11 **12**

13

since the chemical shifts and coupling constants of the ring carbons (Table 3) are very similar to those of the corresponding *tert*-butyldimethylsilyl heterocycles (Table 1 and 2) while the CH_3SCH_2 group in **8–13** is similar to CH_3SCH_2F (13) and CH_3SCH_2Cl (14). The proton nmr of **8–13** showed the CH_3S group at 1.93 to 2.13 ppm and the CH_2 group at 4.78 to 5.37 ppm.

The formation of **8–13** is an example of a Pummerer rearrangement in which a nitrogen, rather than the more familiar oxygen or halogen (15), substituent migrates to the α-position. A possible mechanism is described in Scheme 1. Insertion of



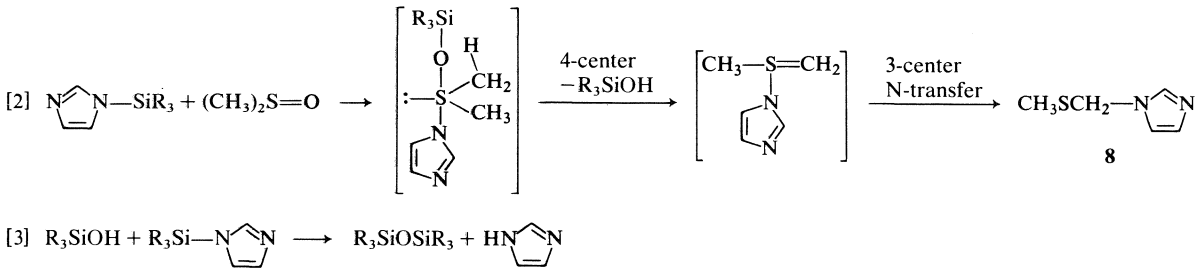


FIG. 1. ^{13}C nmr spectrum of *N*-[(methylthio)methyl]imidazole **8**.

SCHEME 1

DMSO into the Si—N bond is analogous to SO_2 or SO_3 insertion into Si—N compounds (16) and the 4-center and 3-center steps are similar to the postulated conversion of Me_2SF_2 to $MeSCH_2F$ (13) and Me_2SCl_2 to $MeSCH_2Cl$ (17). Equation [3] is analogous to the reaction of alcohols with Si—N compounds (18).

Trifluoromethylsulfonyl aryl derivatives: competitive nucleophilic attack at an aromatic carbon and at the sulfur atom of an aromatic SO_2CF_3 group

FRANÇOIS TERRIER AND JEAN MOREL

Laboratoire de Physicochimie des Solutions (LA CNRS 161), Ecole nationale supérieure de chimie de Paris, 11 rue Pierre et Marie Curie, 75231 Paris Cedex 05 and Faculté des Sciences de Rouen, 76130 Mont Saint Aignan, France

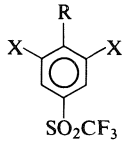
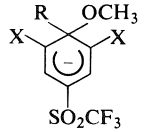
Received July 5, 1979

FRANÇOIS TERRIER, JEAN MOREL, MARIE-JOSÉ POUET, and MARIE-PAULE SIMONNIN. Can. J. Chem. **58**, 65 (1980).

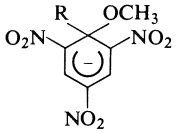
The reaction of methoxide ion with 2-nitro-4-trifluoromethylsulfonylanisole, 4-nitro-2-trifluoromethylsulfonylanisole and 2,4-bis(trifluoromethylsulfonyl)anisole in DMSO has been studied by ^1H and ^{19}F nmr. Evidence for the transient formation of *gem*-dimethoxy σ-adducts arising from nucleophilic attack at the aromatic C1 carbon is given. Concurrent methoxide ion attack occurs at the sulfur atom of the SO_2CF_3 group to give the aryl methyl sulfonates $ArSO_3CH_3$, which are slowly converted into aryl sulfonates $ArSO_3^-$. The ^1H chemical shifts of the anisoles are consistent with a greater electron-withdrawing effect of the SO_2CF_3 group compared to the nitro group. In contrast, a 4-nitro group appears to be more efficient than a 4-SO_2CF_3 group in delocalizing the negative charge of the σ-adducts.



FRANÇOIS TERRIER, JEAN MOREL, MARIE-JOSÉ POUET et MARIE-PAULE SIMONNIN. Can. J. Chem. **58**, 65 (1980).

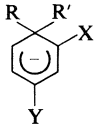


La réaction des ions méthoxyde avec les nitro-2-trifluorométhylsulfonyl-4, nitro-4 trifluorométhylsulfonyl-2 et bis(trifluorométhylsulfonyl)-2,4 anisoles a été étudiée en milieu DMSO par rmn du proton et du fluor. Les résultats mettent en évidence la formation transitoire des complexes-σ *gem*-diméthoxylés résultant de l'attaque nucléophile des ions CH_3O^- sur le carbone aromatique C1. Une attaque nucléophile intervient simultanément sur l'atome de soufre du groupe SO_2CF_3 et conduit aux aryl sulfonates de méthyle $ArSO_3CH_3$ correspondants, qui sont eux-mêmes progressivement transformés en sulfonates $ArSO_3^-$. Les déplacements chimiques δ_H des anisoles confirment que l'effet attracteur d'un groupe SO_2CF_3 est plus important que celui d'un groupe nitro. Par contre, ce dernier présente une aptitude plus importante à délocaliser la charge négative des complexes-σ.



Introduction

The trifluoromethylsulfonyl function is the most powerful neutral electron-withdrawing group known, as evidenced by its Taft and Hammett constants (1–3). Not surprisingly this substituent greatly facilitates formation of Meisenheimer-type complexes from aromatic substrates. Thus, tris-1,3,5-(trifluoromethylsulfonyl)benzene, **1**, gives the monomethoxyl σ-complex, **2**, which is 2×10^6-fold more stable than its trinitro analogue **3** in methanol (4, 5). Similarly, 2,6-dinitro-4-trifluoromethylsulfonylanisole, **4**, reacts with CH_3O^- ion to give the σ-complex **5**, which is about 10^2-fold more stable than the trinitro complex **6** (6).



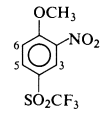
The stability of Meisenheimer adducts is strongly decreased when the parent aromatic substrates are activated by two instead of three electron withdrawing groups (7). As a consequence

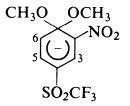
1 R = H X = SO_2CF_3 **2** R = H X = SO_2CF_3 **3** R = H
4 R = OCH_3 X = NO_2 **5** R = OCH_3 X = NO_2 **6** R = OCH_3

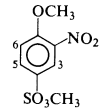
a R = R′ = OCH_3
b R = R′ = OC_2H_5
7 X = Y = NO_2 *c* R = H R′ = CH_2COCH_3
d R = H R′ = CH_2NO_2

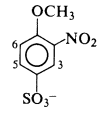
8 X = NO_2 Y = CN, CF_3, SO_2CH_3
9 X = CN, CF_3, SO_2CH_3 Y = NO_2

only 2,4-dinitro adducts **7** have been unambiguously identified (7–10), while 2,4-disubstituted adducts like **8** or **9** could not be observed.









However, the presence of a powerful electron-withdrawing substituent such as SO_2CF_3 might be expected to enhance the stability of such adducts and allow their identification.

We now report an nmr identification of the trifluoromethylsulfonyl σ-adducts **11**, **15**, and **19** which arise from methoxide ion attack at the aromatic C1 carbon of 2-nitro-4-trifluoromethylsulfonylanisole **10**, 4-nitro-2-trifluoromethylsulfonylanisole **14**, and 2,4-bis(trifluoromethylsulfonyl)anisole **18**, respectively. This study also reveals the occurrence of a competitive nucleophilic substitution at the sulfur atom of the SO_2CF_3 group of **10** and **14** to form the methylsulfonates **12** and **16**; these products are unstable and irreversibly converted into the sulfonates **13** and **17**.

14 **15** **16** **17**

Results

The reactions of CH_3O^- with the anisoles **10**, **14**, and **18** in DMSO solution were followed by repetitively scanning ¹H nmr spectra at 100 MHz and ¹⁹F nmr spectra at 94.1 MHz (Varian XL-100). Meisenheimer complexes **11**, **15**, and **19** were observed when less than 1 equiv. of CH_3OK was used. The species have too short a half-life to be observed at higher base concentrations.

The ring protons of all the compounds studied, except **16**, gave an AMX system with coupling constants allowing an unambiguous assignment of individual protons: $^3J_{5-6}=8$–10 Hz, $^4J_{3-5}=2$–3 Hz, $^5J_{3-6}<0.5$ Hz (see Tables 1 and 2). Moreover, a long-range coupling between H6 and the methoxyl protons was observed in aromatic derivatives, so that $^5J_{3-6}$ could be resolved only when irradiating the methoxyl protons.

2-Nitro-4-trifluoromethylsulfonylanisole

The ¹H nmr spectrum of **10** in DMSO-d_6 exhibits a methoxyl singlet at 4.17 ppm, a doublet at 7.80 (H6), a doublet of doublets at 8.39 (H5), and a doublet at 8.62 (H3) (Table 1). The fluorine signal appears as a singlet at −78.1 ppm (upfield from $CFCl_3$).

Addition of less than 1 equiv. of concentrated methanolic potassium methoxide (4.4 *M*) to a DMSO-d_6 solution of **10** resulted in an almost complete disappearance of the signals from **10** and the concomitant appearance of four new products (Fig. 1). One set of signals, which is observed only for a few minutes, consists of a singlet at 2.87 and an AMX system with a high field doublet at 5.07 (H6), a doublet of doublets at 6.55 (H5), and a doublet at 8.15 (H3). Integration showed that the relative intensities are in a 6:1:1:1 ratio. These results point out the formation of the σ-adduct **11**. In agreement with this structure, the ¹⁹F spectrum shows a new singlet at −79.3 ppm, which is at slightly higher field than that of the parent molecule.

The presence of fluoroform is evidenced from both ¹H spectra (quadruplet at δ = 7.28 ppm, $^2J_{FH}$ = 79 Hz) and ¹⁹F spectra (doublet at δ = −78.3 ppm, $^2J_{FH}=79$ Hz).

The two other products are aromatic and contain

For personal use only.

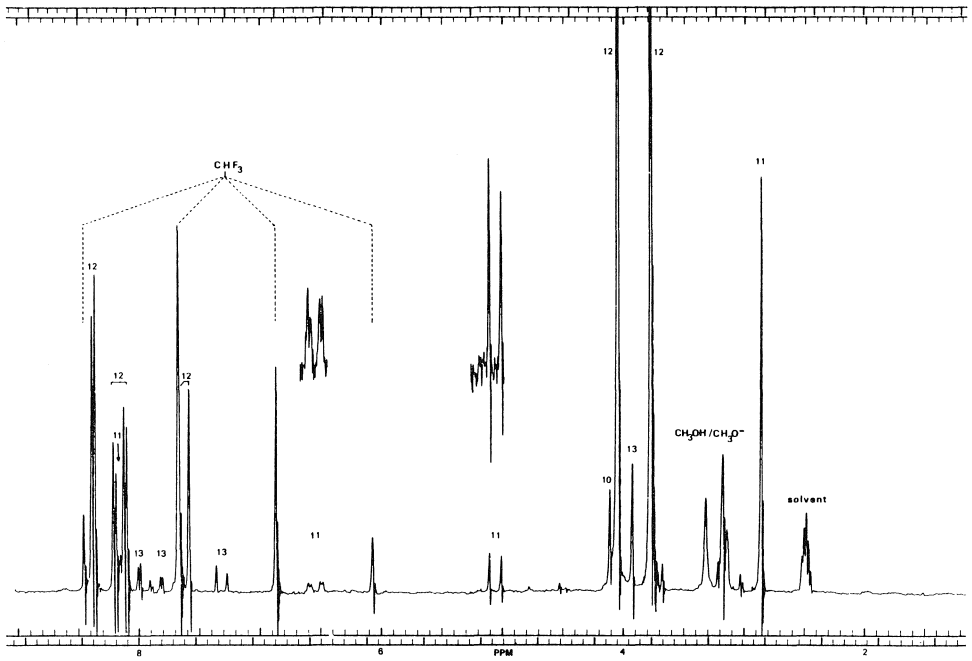

FIG. 1. ^{1}H nmr spectrum of the *in situ* generation of the σ-adduct **11**, the methylsulfonate **12**, and the sulfonate **13**, by addition of methanolic potassium methoxide to the anisole **10** in DMSO-d_6. Resonances are identified by structure numbers.

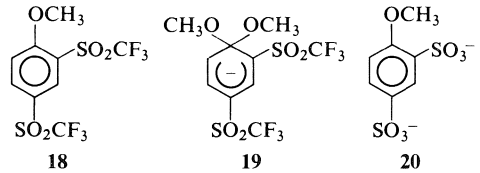


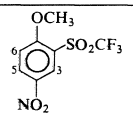
no fluorine, as deduced from ^{19}F spectra. They may be identified as the methylsulfonate **12** and the sulfonate anion **13**, respectively, which both exhibit an AMX pattern in the aromatic region. Moreover, **12** gives two methoxyl singlets at 4.06 and 3.79 ppm, while **13** has only one OCH_3 signal at 3.95 ppm. With time, the signals belonging to **12** decrease while those of **13** increase; after a few days, **13** is the only product in the solution. A definitive proof of the formation of **13** comes from a comparison of its ^{1}H nmr spectrum with that of an authentic sample of the corresponding ammonium salt dissolved in DMSO-d_6 (see Experimental).

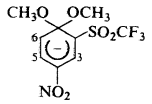
4-Nitro-2-trifluoromethylsulfonylanisole

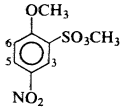
The general features for the reaction of **14** with methoxide ion are similar to those observed with **10**. Four products are also formed with **14**, one of which is CHF_3. Differences in the nmr spectra of the various species are of interest. In the parent anisoles **10** and **14**, H3 has almost identical chemical shifts but H5 is less shielded in **14** than in **10**, leading to an inversion in the field position of H3 and H5 resonances. In a similar way, H5 is less shielded than H3 in the methylsulfonate **16**, but the differences between these shifts is smaller than in **14**. As a result, the spectrum of **16** is of the ABX type and the H6 resonance exhibits a six line pattern. A second order analysis yields the parameters indicated in Table 2 and has been confirmed by a simulation of the spectrum (Fig. 2). Moreover, as can be seen in Fig. 2, the AB part of **16** overlaps with the H3 doublet of **17**.

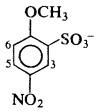
2,4-Bis(trifluoromethylsulfonyl)anisole

A similar study of the reaction of CH_3O^- with 2,4-bis(trifluoromethylsulfonyl)anisole **18** has been performed, but we were not able to identify all the various species involved in this system. The formation of CHF_3 and the characterization of the disulfonate **20** (Table 3) as the final product show, however, that we are dealing with an analogous sequence of reactions. Indeed, due to the presence of two SO_2CF_3 moieties, up to ten products may be expected to coexist in the solution, explaining the complexity of the observed nmr spectra.









18 **19** **20**

However, immediately after the addition of CH_3O^- to a solution of **18** in DMSO, the high-field part of the ^{1}H spectra exhibits a doublet of doublets at 6.58 ppm, a doublet at 5.17 ppm, and an intense singlet at 2.91 ppm, which can be observed only for a few minutes. Though the low-field signal could not be identified, due to the overlap of many signals

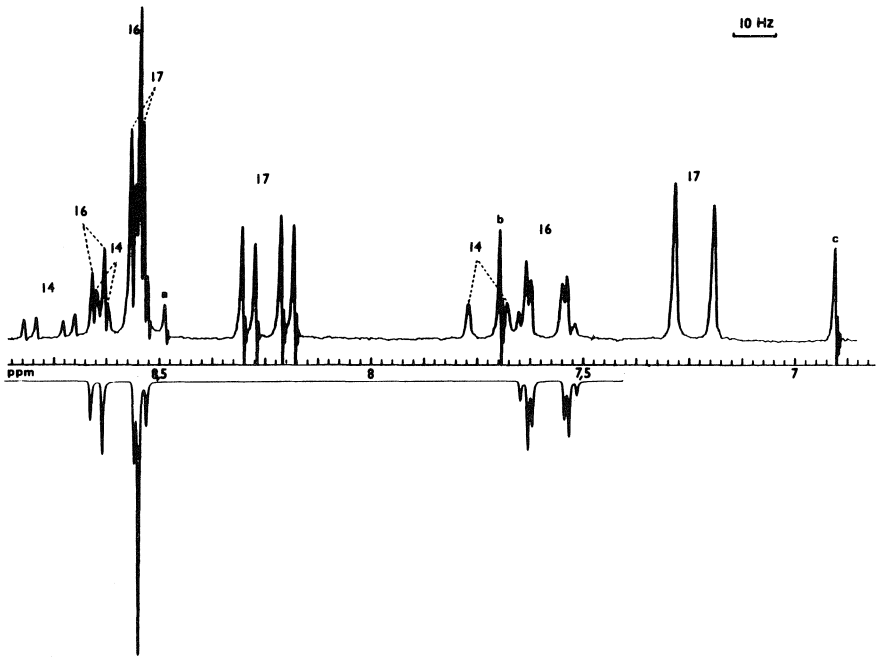

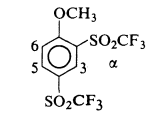

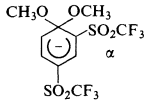

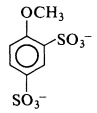

FIG. 2. Low-field part of the ¹H nmr spectrum of the methylsulfonate **16** and the sulfonate **17** and the simulated ABX system of **16**. Resonances are identified by structure numbers. Signals noted *a*, *b*, *c*, are three components of the quartet from CHF_3.

in this region, these results clearly point out the initial formation of the σ-adduct **19**. Further evidence comes from the ¹⁹F spectra: addition of CH_3O^- to a solution of **18** in DMSO-d_6 results in an almost complete disappearance of the signals from **18** at −76.10 and −78.16 ppm and the appearance of two equally intense absorptions at −78.23 and −79.53 ppm, which quickly disappear. These ¹⁹F shifts are in agreement with those expected for the σ-adduct **19**. The formation of CHF_3 and of other fluorinated species can also be observed by ¹⁹F nmr.

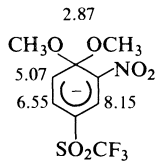
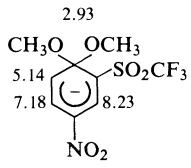
 **19**	α: -78.2_3 β: -79.5_3		6.58	5.17	2.91	2.4	10	
 **20**		8.05	7.58	6.93	3.79	2.3	8.5	



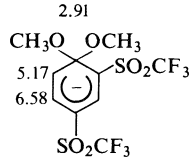
[a]δ in ppm relative to internal TMS (¹H) and internal $CFCl_3$ (¹⁹F). Negative values are upfield from the reference compound. *J* in Hz.

The structure of the final product **20** has been proved by a comparison of its ¹H spectrum with that of an authentic sample of the corresponding barium salt, dissolved in DMSO-d_6 (see Experimental).

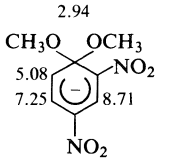


Discussion

Proton Chemical Shifts



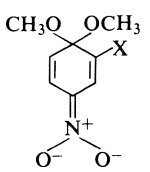
The formation of the σ-adducts **11**, **15**, and **19** from nucleophilic attack of CH_3O^- at the aromatic C1 carbon of the anisoles **10**, **14**, and **18** is confirmed by a comparison of the observed nmr parameters with those previously reported for the dinitro-analogue **7***a* (7).



11

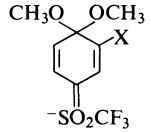
15

19



7a

In particular, the high-field shift of H6, which resonates at about 5.1 ppm, appears to be diagnostic of such *gem*-dialkoxyl-2,4-disubstituted adducts. Also, the resonance of the methoxyl protons is seen near 2.9 ppm while it is shifted to ~3 ppm in the *gem*-dimethoxyl trisubstituted adducts.



Comparing the OCH_3, H3, and H5 shifts in **11** and ***7a*** shows that the replacement of the SO_2CF_3 substituent by a nitro group at the 4-position results in a low-field shift of all of these resonances. Similarly, the OCH_3 and H5 resonances are at lower field in **15** than in **19**. This suggests that the 4-nitro group is more efficient than SO_2CF_3 in delocalizing the negative charge of the σ-adducts. This result is in agreement with our previous study of 4-X-substituted 2,6-dinitro-1,1-dimethoxyl adducts (11). In this case a linear plot of $\delta_{H3,5}$ versus the σ_R constant of the 4-X substituent was observed; however, to fit the above correlation for X = NO_2, σ_{Rp^-} has to be used. It thus appears that the resonance contributor, **21**, is of a much greater importance than the analogous one, **22**, which involves the *d* orbital participation of the sulfur atom, at least in this type of negatively charged species.

A quite different trend is observed in the parent anisoles **10** and **18**. H5, which is *ortho* to the same SO_2CF_3 substituent, is less shielded when *para* to a SO_2CF_3 group, as in **18**, than when *para* to a nitro group, as in **10**. This shows that SO_2CF_3 is more electron-withdrawing than NO_2 in aromatic substrates, as expected from the σ_p constants: (NO_2: $\sigma_p = 0.778$; SO_2CF_3: $\sigma_p = 0.93$) (12).

A similar comparison of H5 chemical shift in the

21

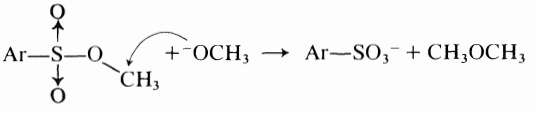
sulfonates **13** and **20**, where H5 is *ortho* to the same SO_3^- substituent but *para* to NO_2 in **13** and to SO_3^- in **20**, indicates that, as expected, SO_3^- has a much less electron-attractive influence than NO_2 (SO_3^-: $\sigma_p = 0.090$) (12).

Fluorine Chemical Shifts

Both the anisole **18** and the σ-complex **19** exhibit two fluorine signals which may be assigned to the 2-SO_2CF_3 and 4-SO_2CF_3 groups respectively in the following way. Long range coupling constants $^5J_{F-H5}$ and $^5J_{F-H3}$ are observed in the anisole **10**, where the SO_2CF_3 group is *para* to the methoxyl substituent. No such F—H coupling constant is present in the anisole **14**, where the SO_2CF_3 group is *ortho* to the methoxyl substituent. The spectrum of **18** shows that H5 is spin-coupled with the three fluorines of one of the SO_2CF_3 groups, the ^{19}F resonance of which appears at −78.16 ppm. This allows us to assign this high-field fluorine signal (δ = −78.16 ppm) to the 4-SO_2CF_3 group and the low-field resonance (δ = −76.10 ppm) to the 2-SO_2CF_3 group.

A comparison of the ^{19}F chemical shifts in the three anisoles **10**, **14**, and **18** indicates that the fluorines of 4-SO_2CF_3 groups in **10** and **18** are shielded relative to those of 2-SO_2CF_3 groups in **14** and **18**, suggesting that the donor effect of the methoxyl group is more important in the *para* than in the *ortho* position.



An assignment of the fluorine resonances in the σ-adduct **19** can be made on the basis of the upfield ^{19}F shifts observed on going from anisoles **10** and **14** to σ-complexes **11** and **15** ($\delta_{11} - \delta_{10} = -1.2$ ppm) and ($\delta_{15} - \delta_{14} = -1.9$ ppm), respectively. If the high-field fluorine resonance of **19** is assigned to the 4-SO_2CF_3 group, similar upfield shifts are obtained on going from **18** to **19**: 4-SO_2CF_3, $\Delta\delta = -1.37$ ppm and 2-SO_2CF_3, $\Delta\delta = -2.13$ ppm.

Conclusion

The occurrence of a competitive nucleophilic attack of methoxide ion at the aromatic C1 carbon of the anisoles **10**, **14**, and **18** to give the σ-adducts **11**, **15**, and **19** and at the sulfur atom of the SO_2CF_3 group of **10** and **14** to form the methylsulfonates **12** and **16** is clearly established by our experimental nmr data. This result is fully consistent with the well-known leaving group ability of the CF_3 substituent and the reaction certainly proceeds via a direct bimolecular nucleophilic displacement mechanism. Such a mechanism has been proved to operate in the hydrolysis or methanolysis of sulfonyl derivatives, which have a poorer leaving group, such as chlorine or dialkylamino (13, 14). The identification of **12** and **16** is, however, of interest since several authors have postulated, but not observed, the formation of methylsulfonates as intermediates in the conversion of trifluoromethylsulfonyl aromatic derivatives into benzene sulfonates in strongly basic medium (15, 16).

As to the formation of sulfonates as final products, it may be formulated, in agreement with previous results of Tommila and Lindholm (17), in terms of an Sn2 displacement at the methoxyl carbon of the SO_3CH_3 moiety. The good leaving group ability of the arylsulfonate moiety should favor such a reaction, which may be compared to the methoxide ion Sn2 attack on the methoxyl carbon of activated polynitroanisoles (18–20). In this latter case, the corresponding phenoxides and dimethylether are obtained. The nonobservation of dimethylether in the nmr spectra is probably due to its high volatility at the probe temperature of the nmr spectrometer (32°C).

During the completion of this work, an nmr identification of the σ-adduct **19** has been reported (21). A comparison of the published parameters for **19** with those found in this work for this adduct and for **11** and **15** makes these results (21) somewhat questionable. In particular, the reported OCH_3 and H6 chemical shifts $\delta_{OCH_3} = 3.75$, $\delta_{H6} = 6.61$ from HMDS ($\delta_{OCH_3} = 3.81$, $\delta_{H6} = 6.67$ from TMS) are not consistent with values generally found for *gem*-dimethoxyl-2,4-disubstituted σ-adducts (*vide supra*).

Experimental

2-Nitro-4-trifluoromethylsulfonylanisole **10**, 4-nitro-2-trifluoromethylsulfonylanisole **14**, and 2,4-bis(trifluoromethylsulfonyl)anisole **18** were prepared as previously described (22, 23, 24): **10** mp = 81°C, **14** mp = 71°C, **18** mp = 119°C. The ammonium salt of **13** was prepared from the corresponding acid, which was obtained by sulfonation of *o*-nitroanisole with chlorosulfonic acid, as previously described (25, 26). Its ^1H nmr spectrum was identical to that of the final product obtained in the reaction of CH_3O^- with **10**. An authentic sample of 1-methoxybenzenedisulfonate **20** was prepared according to the method of Svanholm and Parker (27). Its ^1H nmr spectrum was identical to that of the final product obtained in the reaction of CH_3O^- with **18**.

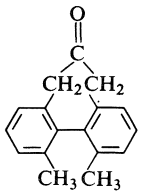
Unequal primary kinetic isotope effects in the base-catalysed H–D exchange of diastereotopic protons

ROBERT R. FRASER AND PHILIPPE J. CHAMPAGNE
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received July 16, 1979

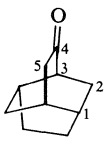
ROBERT R. FRASER and PHILIPPE J. CHAMPAGNE. Can. J. Chem. **58**, 72 (1980).

Primary kinetic isotope effects have been measured for the base-catalyzed exchange reaction of 4′,1″-dimethyl-1,2,3,4-dibenzcyclohepta-1,3-diene-6-one, **1**. It was found that the isotope effects k^H/k^T and k^D/k^T for the faster exchanging protons (13.6 and 3.8 respectively) are significantly larger than the corresponding values for the slower exchanging protons (4.6 and 1.6 respectively). These differences could result from truly unequal isotope effects due to transition state differences or intrusion of a second pathway for exchange of the less reactive proton in the dedeuteration reaction. The data appear to support the latter interpretation. The secondary deuterium isotope effect was found to be 1.18.



ROBERT R. FRASER et PHILIPPE J. CHAMPAGNE. Can. J. Chem. **58**, 72 (1980).

On a mesuré l'effet isotopique cinétique primaire de la réaction d'échange catalysée par les bases de la diméthyl-4′,1″ dibenz-1,2,3,4 cycloheptadiène-1,3 one-6 **1**. On a trouvé que l'effet isotopique k^H/k^T et k^D/k^T pour les échanges les plus rapides de proton (13.6 et 3.8 respectivement) sont d'une manière significative plus grandes que les valeurs correspondantes pour les échanges les plus lents de proton (4.6 et 1.6 respectivement). Ces différences peuvent provenir d'un effet isotopique vraiment inégal dû à des différences d'état de transition ou à l'intrusion d'un second modèle d'échange du proton moins réactif dans la réaction de dédeutération. Les données semblent confirmer la deuxième interprétation. On a trouvé que l'effet isotopique secondaire du deutérium est de 1.18.



[Traduit par le journal]

Introduction

We have previously described the measurement of markedly different rates of hydrogen–deuterium exchange of the diastereotopic protons α to the carbonyl function in ketones **1** (1) and **2** (2). The reported rate ratios of 73 and 290 were interpreted as evidence for the importance of stereoelectronic control in the reactions of enolates. In order to substantiate the validity of this conclusion it is important to obtain evidence regarding the occurrence of internal return during the exchange reaction. To this end we wish to describe in this paper the measurement of the primary isotope effects k^H/k^T and k^D/k^T for each of the diastereotopic protons of **1**. These isotope effects have been found to

1

2

differ by factors of 3 and 2.5 respectively for the two protons. The difference can be attributed either to unequal proportions of internal return or to intrinsically different primary kinetic isotope effects. Arguments in support of the former interpretation of the data will be presented.

Internal Return

In its simplest form internal return refers to the process by which an anion produced by proton abstraction reverts to starting material. For example, in eq. [1] the reverse reaction defined by k_{-1} represents the internal return process which is expressed quantitatively as the ratio $a^H = k_{-1}/k_2$.

$$[1]\quad R_3C{-}H + SO^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R_3C^- \ldots H{-}OS \xrightarrow[SOD]{k_2} R_3CD + SO^- + SOH$$

Tests for the presence of internal return have thus far been of two types. One indication of its occurrence in a stereoselective isotopic exchange reaction is the observation of a significant influence of added crown ether on the stereoselectivity (3, 4). Another clearly predictable consequence of a large value for a^H would be an isotope effect which approaches unity as a^H becomes much greater than one. For smaller values of a^H one expects to observe a decrease from the normal primary isotope effect, whose magnitude cannot be measured. An ingenious solution to this problem was achieved by Streitwieser *et al.* (5) who have utilized the Swain–Schaad relations (6) between hydrogen, deuterium, and tritium exchange rates.

Streitwieser's Equations

The basis for the calculation of internal return is the relationship [2] below derived by Swain *et al.* (6) who assumed all isotope effects arise from zero

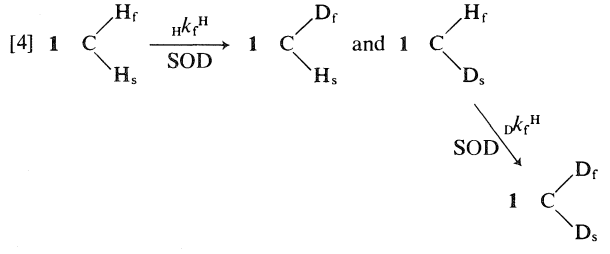
point vibrational energy differences (no tunnelling).

[2] $$k^H/k^T = (k^D/k^T)^{x+1} = (k^H/k^D)^{(x+1)/x}$$



The value assigned to x (2.26) was revised to 2.344 by Streitwieser and co-workers (5) to include the effects of reduced mass. These relations were then used to test for internal return in a number of isotope exchange reactions of aryl, diaryl, and triarylmethanes (5, 7). In essence, the approach was to determine $(k^H/k^T)_{SOD}$ and $(k^D/k^T)_{SOH}$ by experiment. If the difference in isotope effects gave a value for x of 2.344, it could be concluded that internal return was absent. Any diminution in x could be converted, using the quantitative relations given in the Appendix, into a value of a^H. By this method, a significant amount of internal return ($a^T = 0.66$, where a^T refers to internal return during exchange of tritium for hydrogen) was detected in the exchange of triphenylmethane in methanol containing sodium methoxide (5). In contrast, the amount of internal return in the exchange of the same compound in cyclohexylamine (plus lithium amide) was negligible; $a^T = 0.02$ (7). More recently the same method was utilized in our laboratory to establish the absence of internal return in the exchange of the benzylic protons of benzyl methyl sulfoxide (8). The equations derived by Streitwieser appear in the Appendix.

For application of these equations to ketone **1** two additional sets of experimental data are required. One is the equilibrium constant $K^{T'}$ described in eq. [3].

[3] $$\mathbf{1}\,C{-}T + CH_3OH \rightleftharpoons \mathbf{1}\,C{-}H + CH_3OT$$

Tritium analysis of solvent and ketone after equilibration gave a value for $K^{T'} = 1.23 \pm 3\%$. Previously, values of similar magnitude had been observed for 9-phenylfluorene in methanol, $K^{T'} = 1.3$ (5), and for benzyl methyl sulfoxide in methanol $K^{T'} = 1.27$ (8).

The second requirement is a knowledge of the secondary deuterium isotope effect which represents the ratio of the rates of H–D exchange when the diastereotopic partner is hydrogen versus deuterium, i.e., ${}_Hk_f^H/{}_Dk_f^H$ as illustrated in eq. [4].

[4] 

Results and Discussion

Measurement of Secondary Isotope Effect in 1

In the case of the biarylcycloheptadienone, **1**, the high stereoselectivity between abstraction of H_f and H_s of 62:1 in the H–D exchange and the stereoselectivity of 12:1 in the D–H exchange of **1**-d_4 (to be described in detail later) allows preparation of **1**, selectively labelled with deuterium in 50% of the H_s position, and only 4% in the H_f position.

In the H–D exchange of this sample one monitors by ^1H nmr the exchange of both types of fast protons (the extent of exchange of H_s being negligible over the time interval used). The isotope effect ${}_Hk_f^H/{}_Dk_f^H$ was thereby found to be 1.18 (see Table 1) in good agreement with those secondary isotope effects previously reported for fluorene 9,9-d_2, i = 1.18 (5*a*), and for toluene-d_3, i = 1.18 (16). The secondary isotope effect for exchange in the slow position of **1** is not determinable and can only be assumed to have the same magnitude.

Measurements of Isotope Effects in 1

The orientation of the two diastereotopic protons of **1** was established previously to be that shown in Fig. 1. The pro R in R protons, the more labile towards base, will be referred to as the "fast" protons and the pro S in R protons referred to as the "slow" protons. These are labelled H_f and H_s respectively. Their relative rates of exchange k_f/k_s have been measured in methanol-*O*-*d* in the presence and absence of crown ether and found to be about 60:1[1] in both instances. These rate data are given in Table 2. The lack of effect of crown ether can be interpreted as an indication that internal return is not of importance in this exchange reaction. Nevertheless, the more quantitative indications of isotope effects were sought. The very large difference in proton abstraction rates made possible the measurement of isotope effects for each proton. Several examples of the methods used to measure the isotopic exchange rates are given in the Appendix.

Primary Isotope Effects and Internal Return

The rate constants in Table 2 give rise to the following primary isotope effects;

$$(k_f^H/k_f^T)_{CH_3OD} = 13.6 \qquad (k_f^D/k_f^T)_{CH_3OD} \geqq 3.8$$

$$(k_s^H/k_s^T)_{CH_3OH} = 4.6 \qquad (k_s^D/k_s^T)_{CH_3OH} = 1.6$$

From these kinetic isotope effects and $K^{T'}$, the

[1] In our preliminary communication (1) the individual rate constants reported were in error by the conversion factor 2.303. In addition, the rate data has been reanalyzed using the more exact treatment of Sachs (9) thereby leading to the modified rate constants which are included in Table 2.

TABLE 1. Secondary isotope effect measurement for **1** (in CH_3OD, 0.002 *M* in sodium methoxide)*

Time (s)	${}_DA_f^H$	${}_HA_f^H$	A_e^H	B	${}_Dk_f^H$ (s^{-1})	${}_Hk_f^H$ (s^{-1})	i_f
0	0.840	1.080					
60	0.556	0.654	0.028	0.121	7.14	8.61	1.20

*The superscripts denote bond being broken, left hand subscripts denote the nature of the geminal nucleus.

TABLE 2. Kinetics of H–D (D–H) exchange in the ketone **1**

Run	Solvent/base (conc.)	Rate constants (L M^{-1} s^{-1}) Fast position	Slow position
1	CH_3OD/CH_3ONa (2.9×10^{-3} *M*)	$k_f^H = 6.3$	$k_s^H = 0.095$
2	CH_3OD/CH_3ONa-C.E.*(1.6×10^{-3} *M*)	$k_f^H = 6.2$	$k_s^H = 0.10$
3	CH_3OD/CH_3ONa (1.3×10^{-3} *M*)	$k_f^H = 7.1$ $k_f^T = 0.52$	
4	CH_3OD/CH_3ONa (6.0×10^{-3} *M*)		$k_s^H = 0.15$ $k_s^T = 0.033$
5	CH_3OH/CH_3ONa (6.1×10^{-3} *M*)	$k_f^D = 0.65$ $k_f^T = 0.17$	$k_s^D = 0.054$ $k_s^T = 0.033$

*C.E. refers to dicyclohexyl-18-crown-6.

internal return is calculated to be 11.7 for a_f^H and 0.32 for a_s^H. The resultant a_f^H of 11.7 representing 92% internal return is particularly remarkable. Any large amount of internal return in methanol is unexpected, for as Hunter has pointed out (10), previous exchanges in this solvent have indicated little if any internal return. A more disturbing aspect associated with this internal return is the value for the H–D isotope effect for proton abstraction which can be calculated from k_f^H/k_f^T and a_f^H. This value representing the primary H–D isotope effect for step 1, eq. [1], is 36.

Such a high value for a primary isotope effect in base catalysed carbanion formation is without precedence; a number of examples of normal primary kinetic isotope effects are reported by Jones (11). We are therefore led to question the validity of Streitwieser's equations as applied to ketone **1**. The most significant assumption inherent in their application is that there will be no solvent effect on internal return. However, this assumption cannot be tested directly. Tunnelling is assumed to be absent as well (12).[2] Failure of the method could also result from difficulties specific to **1**. For example, since **1** possesses two of each type of diastereotopic proton, the accuracy of the mass spectral analysis is decreased from a normal precision of ±2% to an estimated 4 to 6% due to the measurement of intensity ratios involving five isotopic molecular ions. Since the rate constants are usually the average of only two measurements, due to a practical limitation on the amount of **1** synthesized, the combined errors could lead to uncertainties in isotope effects of up to 8% or more. Also, because of repeated exponential relations between the measured isotope effects and a^H, the uncertainty range calculated for a^H is 3 to 13 for the labile proton and 0.25 to 1.2 for the slowly exchanging proton. Equally important is the question of the proper choice of exponent (12). Errors in temperature, measurement of $K^{T'}$ and i, and additional approximations in the Sachs equation reduce the quantitative assessment of a^H to a qualitative status of indeterminate accuracy.[3]

Nevertheless, the experimentally determined

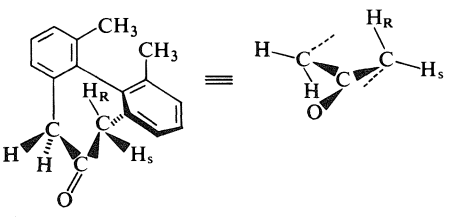

FIG. 1. A three-dimensional representation of 4′,1″-dimethyl-1,2,3,4-dibenzcyclohepta-1,3-diene-6-one, **1**.

[2]Any value for k^H/k^D in excess of ten is considered to require a contribution from tunnelling, and appears to be associated with steric hindrance.

[3]One further uncertainty could not be avoided. It was found that minor amounts of water in the solvent had a substantial effect on the rates of exchange. For the practical consideration of time, runs 3, 4, and 5 could not be performed on the same days. Although all possible precautions were taken to avoid exposure to moisture, small differences in traces of water in the solvent possibly occur.

kinetic isotope effects do provide some valuable mechanistic information. From k_f^H/k_f^T, *assuming no internal return*, one can calculate the primary isotope effect k_f^H/k_f^D to be 6.2 and, by the same method, k_s^H/k_s^D to be 2.9. This divergence of the two primary isotope effects may be interpreted as either a reflection of intrinsically different isotope effects since any two C—H bonds involving diastereotopic protons are different, *or* the smaller isotope effect exhibited by H_s results from diminution of its true isotope effect by internal return. A special type of internal return has already been proposed independently by two groups. Work by Lamaty (13) and by Banerjee and Werstiuk (14) has clearly established a much greater selectivity in the deuteration of a chiral ketone than in the dedeuteration of the same α,α-dideuterated chiral ketone. Their results and those for ketones **1** and **2** are summarized in Table 3. The scheme, first put forward by Banerjee and Werstiuk (14), is represented in Fig. 2. Essentially, the explanation for the fact that k_f^H/k_s^H on deuteration of norbornanone is 740 but that k_f^D/k_s^D for the dedeuteration of 3,3-dideutero-2-norbornanone is only 100 is as follows. In the reverse exchange, i.e., **1** $d_2 \rightarrow d_0$, the faster exchange (side f) produces d_{1s}. The second dedeuteration step k_{-2s} will experience more effective competition from k_{3f} than in the deuteration process since k_{-2s} will be retarded by the primary isotope effect, whereas in deuteration k_{-2f} experiences the retarded isotope effect. This explanation, involving reversible monodeuteration and resultant exchange with inversion is plausible but contains in it certain questionable assumptions. First, it assumes no secondary isotope effect and no solvent effects on isotope effects. In addition, it utilizes a symmetrical enol or enolate as the intermediate, although the involvement of two enolates or one or more asymmetrically solvated intermediates is also possible.[4] It also assumes no internal return of the type we sought to detect, i.e., formation and collapse of an anion to starting material as indicated in eq. [1].

All of the isotope effects revealed by the data in Table 2 are consistent with the schemes of Werstiuk and Lamaty. Indeed the further reduction in stereoselectivity in the tritium exchange to $k_f^T/k_s^T = 5.1$ is predicted as a result of the inversion pathway in Fig. 2. In addition, the fact that the solvent isotope effect for the rapidly exchanging proton is 2.6 (see runs 3 and 5 and secondary isotope effect) while that for the slow proton is 1.2 (see runs 4 and 5) can also be readily accounted for by the presence of inversion during the exchange of the slow tritium.

There is another possible interpretation[5] that all the observed rate constants represent exchanges in the absence of any inversion. Consequently the

[4]Tidwell and co-workers discuss the difficulties in distinguishing between enol and enolate intermediates (15). Even though the exchange of the fast proton via a mandatory retention pathway must involve an asymmetric intermediate this factor is not represented in the figure.

[5]It is important to note that regardless of the interpretation of these isotope effects the observed stereoselectivity of 63:1 is a minimum value and is not the result of internal return in the slow position. Thus the conclusions of refs. 1 and 2 remain valid.

primary kinetic isotope effects and solvent isotope effects would differ by surprisingly large amounts for the two diastereotopic protons. Work is in progress to test this interpretation.

Experimental

Heavy water (99.9 at.% D) and methanol-*O*-*d* (99 at.% D) were obtained from Merck, Sharp and Dohme Canada Limited. Tritiated water (25 mCi/mL) and standard tritiated toluene (4.5 × 10^6 dpm/mL) were obtained from New England Nuclear Corporation. Solutions of lower specific activity were prepared by volumetric dilution. Tritiated methanol and methanol-*O*-*d* were prepared by dilution with tritiated water and the respective solvents. Dicyclohexyl-18-crown-6 cyclic polyether obtained from Aldrich was used without further purification.

Diphenyloxazole (PPO) and 2,2′-*p*-phenylene-bis(5-phenyloxazole) (POPOP), liquid scintillation counter grade, were obtained from Baker Co. Scintanalyzed toluene was obtained from Fisher Scientific.

All weighings for scintillation counting were done on an E. Mettler Zurich Type H-16 balance accurate to 0.05 mg. The nmr spectra were taken in deuterochloroform solution (unless otherwise stated) on a Varian T-60 spectrometer or a Varian HA-100 spectrometer equipped with an SD-100 deuterium spin decoupler. Control tests showed the T-60 integration to be as accurate as the HA-100 integration so the T-60 nmr was used for analysis unless otherwise stated. Tritium counting was carried out in a Beckman LS-150 scintillation counter equipped with an external standard channels ratio function. Kinetic samples which involved mass spectrometric analysis were run on an AEI MS-903 mass spectrometer. The experimental conditions reported are those found to give the most accurate and reliable results after a minimum of two pre-trials for each rate determination.

Unless otherwise stated, the experimental data were treated by the Sachs equation (9) for equilibrating pseudo-first order reactions as given below.

$$\frac{d_0 + h_0}{d_0 + h_0 + B} \ln \frac{A_0 - A_e}{A_t - A_e} = kT$$

where d_0 = initial concentration of exchangeable deuterium in solvent, h_0 = initial concentration of exchangeable hydrogen in solvent, B = concentration of hydrogen (or deuterium or tritium) in solvent due to exchange with substrate, A = concentration of hydrogen (or deuterium or tritium) in substrate, A_e = equilibrium concentration of hydrogen (or deuterium or tritium) in substrate.

Preparation of Solutions For Kinetic Measurements

Sodium methoxide solutions in methanol or methanol-*O*-*d* were prepared by adding methanol volumetrically by syringe to the required amount of clean, dry sodium in a cooled serum capped flask which had been flushed with nitrogen. The deuterium gas formed was allowed to escape through a second syringe needle. The base was then titrated with standard hydrochloric acid solution. Alternatively, solutions were prepared by dissolving a weighed amount of fresh, dry sodium methoxide in methanol-*O*-*d*. Both methods gave base solutions which remained clear and colourless and maintained their base strength for periods up to three months when stored in the refrigerator under nitrogen and with the serum caps taped and wrapped with Parafilm.

Toluene scintillation liquid was prepared by dissolving 4 g of PPO and 1 g of POPOP in 1 L of Scintanalyzed toluene.

Sample Preparation

For Nuclear Magnetic Resonance

When extraction was to be used for recovery of the partially exchanged ketone, the reaction mixture was quenched with 0.1 *N* HCl and the resulting suspension was extracted three times with spectral grade methylene chloride. The organic phase was dried over anhydrous magnesium sulphate, filtered, and the solvent removed on the rotary evaporator. Traces of solvent were removed by drying under a vacuum of about 0.2 Torr for at least one hour. Control tests using deuterated acid indicated no isotope exchange due to this work-up procedure.

Since the partially exchanged ketone samples were unstable in their isotope content towards chromatographic purification, and recrystallization resulted in large losses, samples for nmr analysis were prepared as above unless otherwise specified. Ketone **1** was not sublimable below its melting temperature with the available vacuum.

For Mass Spectrometry

Each sample for scintillation counting and for mass spectrometry was prepared in the following way. The aliquot to be quenched was withdrawn from the reaction by syringe and added to three times its volume of distilled water containing hydrochloric acid 10% in excess of the base present. The resulting suspension was covered and stored in the refrigerator overnight, after which time the pure, white ketone had precipitated out. This precipitate was filtered, washed with distilled water, and dried under vacuum to constant weight.

For Scintillation Counting

The purified aliquot (5–25 mg) was weighed out accurately in a 20 mL polyethylene scintillation vial (Fisher) and was dissolved in 10 mL of the toluene scintillation liquid. With each set of quenched samples was included a set of standards for calibrating the counting efficiency of the machine. Samples were counted with an ^3H window for varying times depending on the sample size and specific activity to give maximum 1.0% statistical error except in a few cases where, due to small sample size, the error rose to 1.5%.

Due to a shortage of available ketone **1**, the standard samples used to calibrate the counting efficiency of the scintillation counter were made up by adding increasing amounts (0 to 0.2 mL) of chloroform to solutions of 0.01 mL of standard tritiated toluene in 10 mL of toluene scintillation liquid, such that the range of standard sample quenching was greater than the range involved in tritium counting of quenched samples.

For each standard sample counted, the machine registered an external standard ratio which allows conversion of the counting rate into a specific activity for each sample.

Method of Treatment of Mass Spectral Data

For all measurements of primary isotope effects the proton and deuterium content were determined by mass spectrometric analysis. Each sample was analyzed at least eight times over a range of six *m/e* units above and below the parent molecular ion (M^+). Each set of peak heights was normalized to a total of 100, then averages were taken for each *m/e* value. The spectra of pure **1** showed a large PMI (M^+), and $(M + 1)^+$ and $(M + 2)^+$ peaks which were 20.27% and 2.54% respectively of the M^+ peak. Therefore, each peak height in an analytical sample was corrected accordingly. The concentrations of the d_0, d_1, d_2, d_3, and d_4 species could then be calculated from these corrected peak heights. The details of this treatment of the spectral data appear in the thesis of P.J.C. (17). All proton concentrations (or deuterium for the reverse exchange) are expressed as the number of protons (or deuterons) remaining out of the 4 originally available for exchange.

This treatment gives individual rate constants with a precision of ±4–6%. Comparable accuracy is obtained when rate constants are obtained from several quenched aliquots.

*Determination of the Secondary Isotope Effect (*i*) for the Fast Methylene Position in* **1**

Preparation of **1** *Specifically Deuterated in 50% of the Slow Position*

Reaction conditions were based on previous pre-trial estimates of deuteration and dedeuteration rates.

To 100 mg (0.424 mmol) of **1** in 2.46 mL of methanol-*O-d* was added 0.01 mL of sodium methoxide/methanol-*O-d* (0.18 *M*) under nitrogen with stirring. The reaction was stirred at 29.4 ± 0.1°C for 2 780 s, after which time the reaction was quenched and the ketone (76 mg) recovered by extraction. The nmr of this ketone showed only 0.8 protons remaining, all of them in the high field (slow) position. The ketone was redissolved in 1.83 mL of methanol under nitrogen and 0.065 mL of sodium methoxide/methanol solution (0.045 *M*) was added with stirring at 29.0 ± 0.1°C. This reaction was quenched after 6 980 s and the ketone isolated. The nmr of this product showed a total of 3.08 hydrogens in the two methylene positions. The 100 MHz spectrum on 250 Hz sweep width with deuterium decoupling gave the following breakdown for this 3.08 hydrogens: CD_fH_s = 0.08 H; CH_fD_s = 0.84 H; CH_fH_s = 2.16 H (see Table 2).

Measurement of Secondary Isotope Effect, i_f

To 40 mg (0.17 mmol) of the monodeutero **1** from above in 0.99 mL of methanol-*O-d* under nitrogen was added, with stirring, 0.01 mL of sodium methoxide/methanol-*O-d* solution (0.18 *M*) at 29.0 ± 0.1°C. After 60 s 0.5 mL was withdrawn by syringe and quenched. The remainder was quenched after 120 s. The samples of ketone were recovered by extraction and examined by 100 MHz nmr as above. The results of the proton analysis of these samples[6] are presented in Table 1 and show the secondary isotope to be 1.18.

Measurement of Rates in Runs 1 to 5 in Table 2

The details of these rate measurements have been placed in the Depository of Unpublished Data.[7]

Appendix

Determination of k_f^H *and* k_f^T *in Methanol*-O-d

To prepare a sample of **1** selectively tritiated in the fast position an exchange was carried out in tritiated methanol until 5% of the equilibrium tritium content was incorporated in **1**. Under these conditions (see Experimental for details) the distribution between fast and slow positions will still be 63:1.

Exchange of this sample of **1** was carried out in methanol-*O-d* containing sodium methoxide (1.3×10^{-3} *M*). Aliquots for deuterium were taken at times considered optimum on the basis of three previous experiments on the same sample under the same conditions. Only the first two of four aliquots analyzed for deuterium content contained sufficient remaining protons to yield an accurate k_f^H. This exemplifies a problem in reproducing conditions for a given set of rates due to limitations in the accuracy with which a solution of desired base concentration can be prepared and also to the difficulty in maintaining a reproducible water content in the solvent. For the same reason only two of three aliquots subjected to tritium analysis were used in calculating k_f^T.

Determination of k_s^H *and* k_s^T *in Methanol*-O-d

A sample of **1** equilibrated in methanol-*O-t* con-

[6]The measurements were made during simultaneous irradiation using an SD-100 deuterium spin decoupler.

[7]Copies may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

taining methoxide catalyst was shown by tritium analysis to be fully labelled in both positions. Exchange of this sample in methanol-*O-d* (6.03 *M* in $NaOCH_3$) was monitored by taking of aliquots at times determined from three previous experiments to be optimum. This required all fast proton and tritium contents to have attained equilibrium values and for aliquots to possess contents of H_s and T_s in the range of 20 to 75% of their starting values. For both k_s^H and k_s^T only two aliquots analysed proved to be in this range.

Determination of k_f^D, k_f^T, k_s^D, *and* k_s^T *in Light Solvent*

Because of the isotope effects being smaller and also the selectivity being reduced to about 12 (observed in preliminary exchanges) it was possible to take aliquots at times optimum for measuring each of the four rate constants during a single reverse exchange reaction. The sample of **1**, fully deuterated (96%) and fully tritiated (11 429 dpm/mg) by exchange to equilibrium in tritiated methanol-*O-d* was exchanged in methanol-*O-h* containing sodium methoxide (6.1×10^{-3} *M*). The results of isotope content determination gave the derived rate constants appearing in Table 2.

Aliquots taken at intermediate times could not be used for calculation of k_s^D since it was not certain that all of D_f had exchanged and also since a significant part of the D_s exchange at these points had taken place under the influence of the secondary isotope effect caused by deuterium in the fast positions. As a result only three of six aliquots were used to obtain the value of $k_s^D = 0.32 \times 10^{-3}\ s^{-1}$ with good agreement between samples (standard deviation = ±2%). For the fast exchange, the first five samples were used in the calculation of $k_f^D = 3.97 \times 10^{-3}\ s^{-1}$, (the sixth sample had exchanged more than 90%) but the agreement between the rate constants calculated from these samples was not as good (standard deviation = ±6.8%). These two results give rise to a stereoselectivity of $k_f^D/k_s^D = 12.1 \pm 9\%$ which has decreased by a factor of 5.1 from the forward exchange stereoselectivity of 63.

Streitwieser's Equations

The value for $a^H = (k_{-1}/k_2)$ (1) can be obtained (5) from the relationships between the following experimental measurements:

$$A = (k_{ex}^D/k_{ex}^T)^{x+1} \cdot k_{ex}^T/k_{ex}^H$$

$$B = (k_{ex}^D/k_{ex}^T)^{x+1} \cdot K^{T'}$$

where $K^{T'}$ represents the equilibrium given in eq. [3],

$$a^T(A - B) = [1 - a^T(B^{1/x+1} - 1)]^{x+1} - A$$

$$a^H = a^T k_{-1}^H/k_{-1}^T$$

$$= a^T K^T k_1^H/k_1^T$$

where k_1^H refers to carbanion formation from light isotope loss, and

$$k_1^T/k_1^H = k_{ex}^T/k_{ex}^H + a^T\left(\frac{k_{ex}^T}{k_{ex}^H} - K^{T'}\right)$$

Similar expressions for k^T/k^D relations appear in ref. 5.

Transfer free energies of alkali metal chlorides and of some individual ions in glycerol and water mixtures

INDRA N. BASUMULLICK[1] AND KIRON K. KUNDU[2]

Physical Chemistry Laboratories, Jadavpur University, Calcutta – 700032, India

Received May 29, 1979

INDRA N. BASUMULLICK and KIRON K. KUNDU. Can. J. Chem. **58**, 79 (1980).

Standard free energies of transfer, ΔG_t^0, of alkali metal chlorides from water to aqueous mixtures of 10, 30, 50, and 70 wt.% glycerol have been determined from emf measurements of the double cell comprising Ag–AgCl and K(Hg) electrodes at 25°C. These values were divided into individual ion contributions by use of tetraphenyl arsonium tetraphenyl boride (Ph_4AsBPh_4) assumption, the required ΔG_t^0 values of the reference electrolyte (Ph_4AsPh_4B), obtained by measuring solubilities of $KBPh_4$, Ph_4AsPi, and KPi (Pi = picrate) in the solvents. The solvation behaviour of the involved ions, as dictated by their respective $\Delta G_t^0(i)$ values, in this as well as in systems of other similar co-solvents like ethanol, ethylene glycol, and urea, suggests that it is determined by one or several effects of acid–base, Born-type, and dispersion interactions. Moreover, comparable stability of Ph_4B^-, particularly in aqueous glycerol and urea, suggests that "specific interactions" are possibly responsible for the well-known folding–unfolding phenomenon of native conformation of proteins in presence of co-solvents.

INDRA N. BASUMULLICK et KIRON K. KUNDU. Can. J. Chem. **58**, 79 (1980).

On a déterminé les énergies libres normales de transfert ΔG_t^0 des chlorures métalliques alcalins dans l'eau et dans des mélanges aqueux à 10, 30, 50 et 70% en poids de glycérol à partir des mesures fem d'une double cellule comprenant des électrodes Ag–AgCl et K(Hg) à 25°C. Ces valeurs sont divisées en contributions individuelles d'ions en faisant appel à l'hypothèse du tétraphénylborure de tétraphényle arsonium (Ph_4AsBPh_4); on a obtenu les valeurs requises de ΔG_t^0 de l'électrolyte de référence (Ph_4AsPh_4B) en mesurant les solubilités du $KBPh_4$, Ph_4AsPi et du KPi (Pi = picrate) dans les solvants. Les valeurs respectives de $\Delta G_t^0(i)$ obtenues dans ce système de solvants aussi bien que dans d'autres systèmes de cosolvants similaires comme l'éthanol, l'éthylèneglycol et l'urée, suggèrent que du point de vue de la solvatation les comportements des ions impliqués sont dictés principalement par des effets combinés acide–base du type Born ou par des interactions de dispersion. De plus, la stabilité comparable du Ph_4B^-, particulièrement dans le glycérol aqueux et dans l'urée, suggère que des interactions spécifiques sont responsables du phénomène bien connu de plissement–déplissement de la conformation naturelle des protéines en présence de co-solvants.

[Traduit par le journal]

Introduction

It is well recognized that glycerol has a striking ability of stabilizing (1–3) the native conformation of proteins as oppose the well-known destabilizing effect of urea (4–6). The genesis of these differences in the stability of protein is yet a conflicting issue (1). It is, however, widely believed that unfolding action of urea and stabilizing action of glycerol possibly stem from their effects on water structure (1, 3, 7, 8). Dipaola and Belleau (1, 9), from their apparent molar volume and heat capacity studies, increasingly emphasized that "specific interactions" rather than structural changes of water are the key to the stabilizing action of glycerol.

Recent studies of transfer energies of hydrogen halides (HX) and those accompanying the ionization of water in aqueous mixtures of urea (10, 11) and glycerol (12) have revealed that the structural order induced by both glycerol and urea are significantly less compared to those of aqueous alcohols, possibly due to the "specific-site hydration" (13) through hydrogen bonding centres of these co-solvents. Also, while urea acts more like a statistical structure breaker (14), glycerol lies on the border line of the structure making mono-ols (15) and structure breaking poly-ols (9). At any rate the observed differences in the structural order induced by these two co-solvents are not significantly different to be ascribed as the genesis of the converse behaviour of these co-solvents on thermodynamic stability of native proteins. Consequently, it should be of particular interest to investigate further if solvating behaviour of these two co-solvents on the different constituent groups of proteins or interactions of "specific nature" by the respective co-solvents play an important role in dictating the folding–unfolding phenomena of proteins caused by these co-solvents.

Previously, Kundu and co-workers have reported free energies, ΔG_t^0 of H^+X^- (10), H^+OH^- (11), M^+Cl^- (16*a*) and of the individual ions obtained by the Ph_4AsBPh_4 or TATB assumption (16*b*) in aqueous urea solutions and have drawn important reflections on the relative acid–base properties and solvating capacities of the solvents and on the nature of ion–solvent interactions in the solvents (10, 11, 16, 17). As a part of the parallel studies in glycerol and water mixtures we now re-

port ΔG_t^0 values of alkali metal chlorides and of the individual ions obtained by using same TATB assumption. It is hoped that comparison of these results with those in aqueous solutions of urea as well as of a mono-ol like ethanol (EtOH) (18) and a di-ol like ethylene glycol (EG) (19) will help reveal the essential differences in the relative stability of these simple hydrophilic ions on the one hand and hydrophobic Ph_4As^+/Ph_4B^- on the other in these solvents. Moreover, since either of the latter ions is often used as a model solute for hydrophobic hydration (20), ΔG_t^0 values of these ions will help reflect the relative interactions between the hydrophobic sites like apolar side chains of protein molecules and hence on the genesis of the relative stabilization of proteins in the respective co-solvent systems.

ΔG_t^0 values of MCl (M = Li, Na, K, Rb, or Cs) have been evaluated at 25°C in aqueous mixtures of 10, 30, 50, and 70 wt.% glycerol from the standard emf's (ΔE^0) of the double cell [1]

[1] Ag–AgCl/MCl(m), solvent/M(Hg)/MCl(m), water/AgCl–Ag

that have been determined by measuring the emf of the cell at different molalities (m) of MCl. ΔG_t^0 values were then divided into individual contributions by the widely used (21) and amply justified (22, 23) "TATB" assumption [2]:

$$[2] \quad \Delta G_t^0(Ph_4As^+) = \Delta G_t^0(Ph_4B^-) = \tfrac{1}{2}\Delta G_t^0(Ph_4AsBPh_4)$$

The ΔG_t^0 values for the reference electrolyte (R.E.) have been determined by equation:

$$[3] \quad \Delta G_t^0(Ph_4AsBPh_4) = \Delta G_t^0(Ph_4AsPi) + \Delta G_t^0(KBPh_4) - \Delta G_t^0(KPi)$$

the corresponding values of the salts Ph_4AsPi, $KBPh_4$, and KPi being evaluated by the solubility method described earlier (16*b*).

Experimental

Purification of the solvents has been described (12). The origin of and pretreatment for alkali metal chlorides (MCl) used and preparation cell solutions were similar to those described earlier (16, 24*a*). Metal amalgams were prepared by the electrolysis of a fairly concentrated solution of the corresponding alkali metal salts: hydroxides (G.R., Merck) in the case of Na and K and carbonates (G.R., Merck) in the case of Rb and Cs. Li amalgam was prepared from a moderately concentrated solution of LiCl (G.R., Merck). Electrolysis was performed at 0.5–1.0 A between a mercury pool cathode and a Pt-foil anode for 30–40 min (less for Li), after which the amalgam was drained off, washed quickly with purified water and then methanol, dried *in vacuo* at about 50°C, and stored in a vacuum desiccator. Before use the amalgam was first diluted with mercury, if required, in a closed vessel, then passed through a long capillary tube fitted at the bottom of the vessel to free it from the scum and transferred directly into the dropping amalgam reservoir. These operations were performed in a dry H_2 atmosphere. The concentration of the metal in the amalgam was estimated by adding excess standard HCl and titrating back with standard alkali. For "Li" amalgam best behaviour was obtained at a concentration of about 0.001 m whereas for the amalgams of other metals, a concentration near 0.005 m was found to be more suitable. While in use the dropping amalgam reservoir (DAR) was disturbed as little as possible to preserve the homogeneity of the amalgam. Before each experiment, time was allowed for the impurities to rise to the surface. While in use, dry H_2 gas was occasionally passed into the DAR to fill the vacant space left by the out-flowing amalgam and thus to ensure easy flow.

The dropping amalgam reservoir consists of a vertical glass cylinder with two parallel tubes fused vertically into its tapering bottom. Each tube ends in a fine capillary with an upcurving tip and is fitted with a stop-cock, as well as a provision for electrical contact. Standard joints provide for smooth and air-tight introduction of the tubes into the cell vessels. A funnel and a stop-cock arrangement at the top allows filling the DAR with amalgam. A water-circulating jacket around the cylindrical body ensures that the amalgam remains at the desired operating temperature. The two glass cell vessels resemble that used by Izmailov and Ivanova (25). Electromotive force values were measured with the help of a Leeds and Northrup K_4-potentiometer in conjunction with a moving coil galvanometer (Cambridge Inst. Co.). General experimental procedures were similar to those of previous measurements (16, 24*a*).

Preparation of the salts viz. $KBPh_4$, Ph_4AsPi, and KPi and measurement of their saturated solubilities by spectrophotometric method were essentially similar to those described earlier (19, 24*b*). Constancy of the absorbance to within 1% was taken as the criterion of the attainment of the saturated solubility of the salts. At least two sets of measurements were made for all the solutes and the results were found to agree to within 1%. The required dilution of the saturated solution of the salts, the molar extinction coefficient (ε) values of the salts in the media, and the wavelength of light used are given elsewhere.[3]

Results

The observed emf (ΔE) values of cell [1] at different molalities m (mol kg^{-1}) of MCl for the different solvent mixtures are given in the Depository.[3] The standard ΔE^0 values (Table 1) were obtained by extrapolating the function $\Delta E^{0\prime}$ described by [4] against m to $m = 0$ (24*a*)

$$[4] \quad \Delta E^{0\prime} = \Delta E - 2k[f_s(m) - f_w(m)] = \Delta E^0 - 2k\Delta bm$$

where

$$f(m) = -A_0B_0m^{1/2}(1 + a^0B_0m^{1/2})^{-1} - \ln(1 + 0.002Mm)$$

Here subscripts s and w indicate the mixed solvents and water respectively, $k = RT/F$, Δb is the differ-

*Reference 12*a*; maximum uncertainties in ΔE^0 values are ±0.5 mV and in ΔG_t^0 values, ±0.05 kJ mol^{-1}.

ence between the coefficients of the first power of m in the extended Debye–Hückel equation in the two solvents and a constant depending upon the solute and solvent properties and ion-size parameter a^0, and M is the mean or the simple molecular weight of the mixed solvents or water, respectively. A_0B_0 and B_0 are the conventional Debye–Hückel constants as described earlier (12). Since alteration of the value of a^0 caused no significant change in ΔE^0, $a^0 = 0$ was used in all cases. The estimated standard deviation in ΔE^0 values for all the cases lie within ±0.5 mV. Standard free energies of transfer ΔG_t^0 of MCl from water to the mixed solvents on mole fraction scale were derived at 25°C from [5]

$$[5] \quad \Delta G_t^0 = F\Delta E^0 - 2RT \ln (M_s/M_w)$$

where F = Faraday. The values of ΔG_t^0(MCl) are given in Table 1. The average uncertainty is about ±0.05 kJ mol^{-1}.

Since the salts $KBPh_4$, Ph_4AsPi, and KPi are found to be sparingly soluble in these solvents and dielectric constants of these mixed solvents are fairly large, their ΔG_t^0 values were evaluated on mole fraction scale by use of [6], assuming complete ionization.

$$[6] \quad \Delta G_t^0 = 2.303RT[p({}_sK_{sp}{}^c) - p({}_wK_{sp}{}^c)] + 4.606RT \log M_w d_s/M_s d_w$$
$$= 4.606RT \log {}_wS_wY_{\pm}/{}_sS_sY_{\pm} + 4.606RT \log M_w d_s/M_s d_w$$

where $K_{sp}{}^c$ is the solubility product in molar scale, S is the solubility in mol dm^{-3}, and $Y_{\pm}$ is the mean molar activity coefficient of the saturated solutions. The $Y_{\pm}$ values were calculated by [7] using the familiar standard form of the Debye–Hückel equation

$$[7] \quad -\ln Y_{\pm} = \tfrac{1}{2}A_0B_0d_s^{-1/2}S^{1/2} \times [(1 + a_+{}^0B_0d_s^{-1/2}S^{1/2})^{-1} + (1 + a_-{}^0B_0d_s^{-1/2}S^{1/2})^{-1}] + \log [(d_S - 0.001SM + 0.002SM_s)/d_s]$$

where the terms have their usual meaning (19). Density d_s of the solutions were assumed to be approximately equal to that d_S of the respective solvents. Most of the parameters were taken from the previous paper (12*a*). As before (19), the ion-size parameters $a_+{}^0$ and $a_-{}^0$ for the cations and anions, respectively, are taken as (18)

$$a_{K^+}{}^0 = a_{Pi^-}{}^0 = 0.3 \text{ nm}$$

and

$$a_{Ph_4B^-}{}^0 = a_{Ph_4As^+}{}^0 = 0.5 \text{ nm}$$

The observed solubilities, calculated $pK_{sp}{}^c$ and also ΔG_t^0 values are given in Table 2. The $pK_{sp}{}^c$ values were found reproducible to within ±0.01 unit. The ΔG_t^0 values of Ph_4B^-/Ph_4As^+ were then computed by use of [2] and are presented in Table 3. Those of other individual ions were then derived from the ΔG_t^0 values of the appropriate salts listed in Table 1 and those of HX reported earlier (12*a*). These values of $\Delta G_t^0(i)$ with a maximum uncertainty of ±0.1 kJ mol^{-1} are presented in Table 3.

Discussion

Figure 1 illustrates the variation of the ΔG_t^0 values of the individual ions with the co-solvent composition. For the sake of comparison the profile for H^+ obtained by Wells' method (26) is also shown. It is worth noting that the $\Delta G_t^0(H^+)$ values obtained by Wells' method are less than those obtained by the present RE Method. The discrepancy possibly lies in the fact that the equilibrium constant K_c of the reaction

$$[8] \quad H^+(H_2O)_5 + ROH \rightleftharpoons H^+(ROH)(H_2O)_4 + H_2O$$

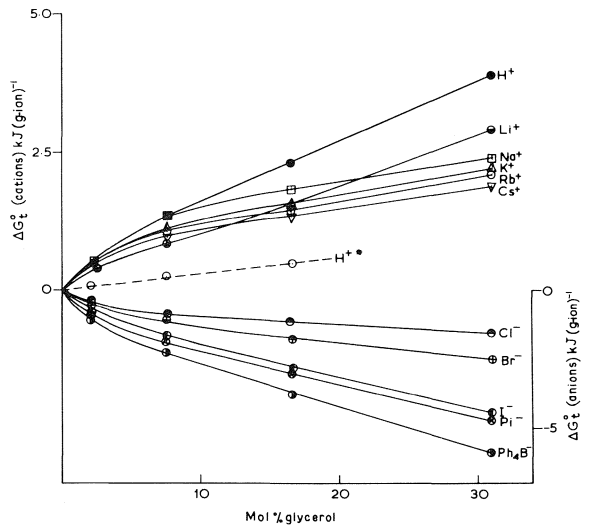

FIG. 1. Variation of $\Delta G_t^0(i)$ of some individual ions from water to glycerol + water mixtures at 25°C. * Wells' data (26).

where ROH denotes co-solvent, is negligibly small for this system, Wells equated $\Delta G_t^0(H^+)$ with the Born-type electrostatic (27) contribution only, neglecting the chemical or basicity effects (27). This leads us to suspect if the very basis of Wells' method is valid for less basic co-solvents like glycerol. However, the small values of K_c for these mixed solvents corroborate that the observed pronounced destabilization of H^+ is the result of decreased basicity of the mixed solvents compared to water.

The observed increasing destabilization of other simple cations and increasing stabilization of simple anions also conform to what is expected from the acid–base type interactions (28, 29), between "anion-acidic H-centre" and "cation-basic O-centre" of these more acidic (30, 31) and less basic (26) co-solvents. For alkali metal cations the observed relative order of destabilization also follows the sequence $Na^+ > K^+ > Rb^+ > Cs^+$, as expected from acid–base type interactions. For Li^+, however, the observed sharp destabilization beyond 50% glycerol can be attributed to the fact that in water-rich regions the smooth exchange of water molecules from the strong hydration cosphere of Li^+ (32) by the added co-solvent molecules is likely to be somewhat difficult. But at co-solvent-rich compositions where glycerol molecules are prone to exchange H_2O molecules from the primary solvation zone, they change the solvation number untowardly, possibly due to steric ef-

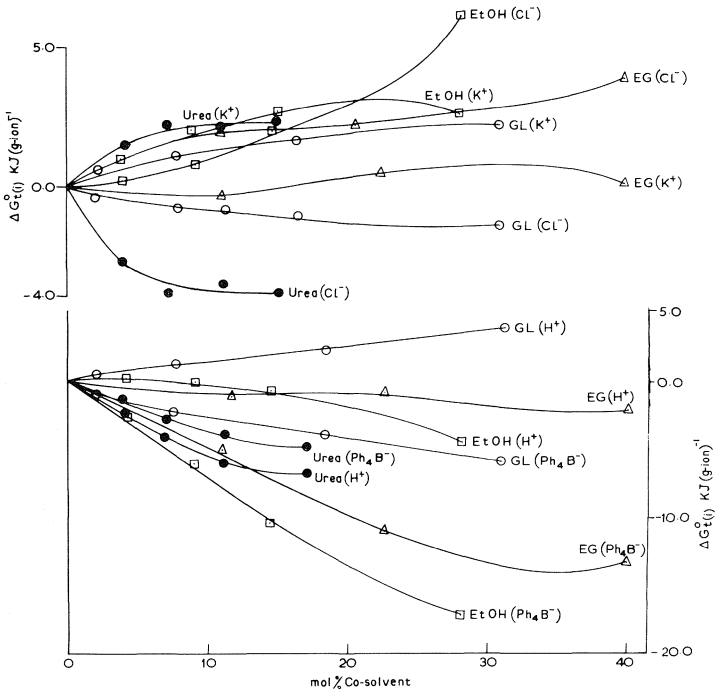

FIG. 2. Comparison of $\Delta G_t^0(i)$ of H^+, K^+, Cl^-, and Ph_4B^- from water to aqueous mixtures of ethanol (EtOH), ethylene glycol (EG), glycerol (GL), and urea (UH).

fect of their large size compared to water. Recently Choi and Criss (33) also contended that the large $\Delta H^0_{TMS \leftarrow AN}$ values (TMS = sulpholane and AN = acetonitrile) for the Li salt are the result of a greater change in solvation number for Li^+ relative to other alkali metal ions when they are transferred from AN to TMS. The large size of TMS molecules compared to ACN brings about the relatively low degree of solvation of Li^+ in TMS than in ACN.

The observed increased stability of the halide ions though conforms to the increased acid–base interaction resulting from the increased acidity of the solvents their order $Cl^- > Br^- > I^-$ does not. This is possibly due to the superimposed effects of dipole-induced polarization of the halide ion as indicated by Wells (26). Alternatively, the feasibility of the crowding of the larger number of co-solvent dipoles or their hydrogen bonded aquo-complexes (29) round the larger sized I^- compared to those round Br^- and Cl^- may be partly responsible for the observed order of stabilization of the halide ions.

In the case of organic ions, however, the observed pronounced stabilization of Ph_4As^+/Ph_4B^- is indicative of the effect of large dispersion interactions of hydrophobic phenyl groups (34). But the increased stabilization of Pi^- is the result of combined effects of increased acidity of the solvents and the increased dispersion interaction with the phenyl group of Pi^- ion. Notably, dispersion interaction effects on four phenyl groups of Ph_4As^+/Ph_4B^- exceed the combined effects of acidity and dispersion interactions on Pi^- ion.

Again, from Fig. 2 where ΔG_t^0–composition profiles of some typical simple ions like H^+, Cl^-, and K^+ and large hydrophobic ion Ph_4B^- have been compared with those in the aqueous mixtures of EtOH (18), EG (19) as well as urea, UH (16*b*), it may be observed that the order of increased stabilization of H^+ is UH + water > EtOH + water > EG + water > glycerol (GL) + water. In fact, this is also the order in which the negative charge density on the basic $\equiv C—O^-$-group of UH or —O-atom of other co-solvents varies. Thus, proton stabilization appears to be so strongly guided by charge densities of basic centres of the co-solvents that other effects including Born-type electrostatic interactions are frequently masked and this provides a firm support to $\Delta G_t^0(H^+)$ as a measure of the Brønsted basicity of the co-solvents relative to water (27).

On the other hand, $\Delta G_t^0(Cl^-)$ composition profiles indicate that while Cl^- is increasingly destabilized in the cases of EtOH and EG, it is increasingly stabilized in GL and UH and relative order of stability increases in the aqueous mixtures of EtOH < EG < GL < UH. Leaving aside UH, since the acidity increases in the same order (27), one should expect that the observed order is the

For personal use only.

result of increased acidity and decreased Born-type electrostatic effects of the co-solvents. In the case of urea, however, since the dielectric constant increases with the addition of urea, Born-type electrostatic effects augment the stabilization of Cl^- due to the possible ion–dipole interactions through the positive charge centre of the zwitterionic form of urea.

Unlike Cl^-, the behaviour of K^+ and other alkali metal cations in the aqueous mixtures of these co-solvents appears to be somewhat involved, for no regular order in $\Delta G_t^0(K^+)$–composition profiles is discernable. Apparently, as indicated earlier (19), the behaviour of alkali metal cations is guided by the combined effects of pronounced Born-type electrostatic contribution, acid–base type interaction, and also "structural" interaction (35) of the solvents.

As Fig. 2 illustrates, $\Delta G_t^0(Ph_4B^-)$ values for these aqueous co-solvents are increasingly negative, indicating the increased stability of these hydrophobic ions in each of these mixed solvents. Since the Born-type electrostatic effects associated with the transfer of this large hydrophobic ion in all the solvent systems are likely to be fairly small and its relative stability is expected to be chiefly guided by the dispersion forces arising from the hydrophobic propensities of the respective co-solvents, the relative positions of the $\Delta G_t^0(Ph_4B)$–composition profiles suggest that the order of hydrophobicity of the co-solvents is EtOH > EG > UH > GL.

Since the solvation of model hydrophobic solutes Ph_4B^-/Ph_4As^+ in urea–water mixtures exceeds that in glycerol–water mixtures, it appears to suggest that in the latter solvents the hydrophobic solutes are likely to be relatively less solvated and hence more prone to undergo hydrophobic interactions among themselves than in the former solvents. Moreover, if hydrophobic interaction (HI) (36) through the apolar side chain of a protein molecule is a major contributor to protein stabilization, the results of the present study may lead one to conclude that the protein molecules are likely to be more stabilized in glycerol–water mixtures than in urea–water mixtures. Also HI among the apolar side chains of a protein molecule is possibly one of the guiding factors for the relative stabilization of proteins by these two co-solvents.

However, since the $\Delta G_t^0(Ph_4B^-)$ values in these two co-solvent systems do not seem significantly different from each other, one may wonder if the little difference in hydrophobic propensity of these two co-solvents could induce sufficient hydrophobic interactions in the apolar side chains of a protein molecule so as to result in the observed relative stabilization of proteins. Evidently, some other factors, including "specific interactions" as emphasized by Belleau *et al.* (9), possibly serve as the key to the relative stabilization of the native confirmation of proteins.

Electrostatic effects of substrate charge on base-catalyzed proton exchange in purines. Implications for the involvement of zwitterions

SPENCER E. TAYLOR

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received July 26, 1979

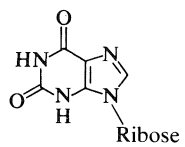
SPENCER E. TAYLOR. Can. J. Chem. **58**, 86 (1980).

Rates of detritiation from the C-8 position of various ionized purine molecules have been shown to reflect electrostatic interactions occurring within the transition state of the exchange reaction. The purines are capable of existing as protonated, anionic, neutral, and zwitterionic species in aqueous solution, each of which have been shown previously to undergo specific hydroxide ion-catalyzed detritiation. The effects of substrate charge are quantified as the *proton activating factor*, *anion deactivating factor*, and *zwitterion activating factor*. Localized charge and not net charge is shown to govern the reactivities of the various species, especially the zwitterions.

Estimation of rate constants for the zwitterionic species (hitherto only postulated to account for the observed rate behaviour) has enabled the calculation of the corresponding zwitterionic equilibrium constants (K_{zw}). K_{zw} values calculated in this manner agree with those estimated from suitable literature pK_a data.

SPENCER E. TAYLOR. Can. J. Chem. **58**, 86 (1980).

On a montré que les vitesses de détritiation à partir de la position C-8 de différentes molécules purines ionisées, reflètent les interactions électrostatiques se produisant à l'intérieur de l'état de transition de la réaction d'échange. Les purines peuvent exister en solution aqueuse sous forme d'espèces protonées, anioniques, neutres et hermaphrodites. On a montré antérieurement que chacune de ces espèces subit une détritiation catalysée spécifiquement par l'ion hydroxyde. On a quantifié les effets de la charge du substrat sous forme de facteur activant le proton, facteur désactivant l'anion et facteur activant l'ion hermaphrodite. On a montré que la charge localisée et non la charge résultante, gouverne les réactivités des différentes espèces et spécialement celle des zwitterions.



Une évaluation des constantes de vitesse des espèces hermaphrodites (postulée seulement jusqu'à date pour tenir compte du comportement de la vitesse observée) a permis de calculer les constantes d'équilibre (K_{zw}) du zwitterion correspondant. Les valeurs de K_{zw} calculées de cette façon concordent avec celles évaluées à partir des données appropriées de pK_a de la littérature.

[Traduit par le journal]

The specific hydroxide ion-catalyzed isotopic hydrogen exchange from the C-8 position of purines has been shown to involve different ionized species, ranging from the N-7- or 9-protonated molecule through to the mono- and di-anions (ionization having occurred in the pyrimidine ring) (1). In addition, strong evidence has been put forward in favour of the involvement of zwitterionic species (2).

Based solely on a consideration of the coulombic interaction between the reactants, it would be expected that base and nucleophilic catalysis would be facilitated after protonation of the neutral purine molecule; deprotonation, on the other hand, would lead to decreased reactivity. However, complications to this simplified scheme can be envisaged for aromatic systems in which extensive charge delocalization and the presence of several potential protonation/deprotonation sites may preclude a rigorous theoretical treatment. Quantitative data on the effects of the charged state of the substrate can nevertheless be obtained. Stewart and Srinivasan (3) defined the term "proton activating factor" (**paf**) as the relative rate enhancement resulting from protonation (or alkylation (4)) of the substrate molecule, and Jones and Taylor (5) introduced the "metal activating factor" to quantify the similar effects of metal ion co-ordination. These ideas are taken a stage further in the present paper in which the effects of anion formation in purines are also considered, and the "anion deactivating factor" (**adf**) is introduced accordingly.

Few systems possess the capability of the purines to exist in as many different ionized forms within a relatively narrow pH range. The additional involvement of zwitterion species has only served to extend the number of possible structures available in aqueous solution (e.g. the case of xanthosine, **1** (1*a*)).

1

In the present paper, a quantitative examination is made to assess the effects of molecular charge on the rates of the hydroxide ion-catalyzed detritiation of a number of ionized purine species. The discussion is restricted to consequences of protonation or

ionization occurring in the purine base moiety, but the considerations are equally valid for charge modifications in the ribose or ribose-phosphate groups of nucleosides and nucleotides, respectively. The magnitudes of the **paf** and **adf** values are interpreted on the basis of simple electrostatic interactions in the transition state. In addition, a method for the estimation of zwitterionic equilibrium constants from the kinetic data is outlined.

Results and Discussion

Paf and Adf Values in the Detritiation of Xanthines

The detritiation of [8-^{3}H]-labelled xanthines represent the most extensively-studied purine system so far reported (1*a*). Rate constants at 85°C have been obtained for the reactions involving the neutral and several ionic forms of this class of purine, and data for caffeine (**2**), theobromine (**3**), and paraxanthine (**4**) are summarized in Table 1. The two dimethylxanthines **3** and **4** can exist in three

2; $R_1 = R_2 = CH_3$
3; $R_1 = H, R_2 = CH_3$
4; $R_1 = CH_3, R_2 = H$

predominant forms within the pH range 0–12 at 85°C (1*a*), viz. the N-9-protonated (BH_2^+), neutral (BH), and monoanionic (B^-) molecules, each of which have been shown to contribute to the pH-rate behaviour (1*a*). In addition, zwitterionic species ($BH^{\pm}$) formed by proton migration from the pyrimidine to imidazole rings have been implicated as being the major contributors to the rate at intermediate pH (1*a*), following the original suggestion by Tomasz *et al.* (6), such that the measured rate constant (k') is a composite function comprising contributions from the neutral (k_b) and zwitterionic (k_c) molecules, according to the equation (1*a*, 2)

$$[1] \quad k' = k_b + K_{zw}k_c$$

in which K_{zw} is the zwitterionic equilibrium constant (= $[BH^{\pm}]/[BH]$). In view of this complication, the 1,3,7-trimethyl derivative **2** was studied. Owing to the lack of an ionizable proton in the pyrimidine ring, **2** cannot exist as a zwitterion, and thus serves as a suitable "model" for neutral **3** and **4**, assuming the effects of the additional methyl group are similar to those of hydrogen (3), and enables the calculation of satisfactory **paf** values (= k_a/k_b)[1] free from contributions from zwitterionic species. Calculated **paf** and the corresponding **adf** (= k_d/k_b)[1] values are summarized in Table 1. Second-order rate constants for reactions involving the zwitterions of **3** and **4** are calculated from the relationship

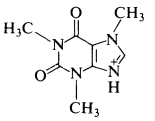
$$[2] \quad k_c = k_a \times \mathbf{adf} \quad (\equiv k_d \times \mathbf{paf})$$

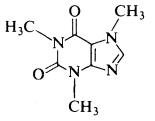
which assumes that the **adf** for the protonated molecule is the same as that for the neutral molecule (and that the **paf** for the neutral molecule is the same as for the anion).

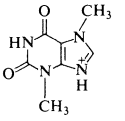
The **paf** values found for **2***a*, **3***a*, and **4***a* (9.3×10^7, 1.4×10^8, and 2.0×10^8, respectively) are similar in magnitude to the values found previously (3*a*, 7) for 9-alkylpurines (1.3×10^8) and illustrate the effect of protonation at the site adjacent to the reaction centre (3*b*).

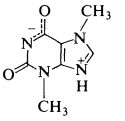
Anion formation at the N-3 position (in **4**) is seen to have a greater influence on the detritiation rate at C-8 than anion formation at N-1 (in **3**) by the larger **adf** value in the latter case (Table 1). Still larger effects of anion formation occur as a result of ionization in the imidazole ring (relevant to purine bases such as adenine (8), guanine (9), hypoxxanthine (9), and xanthine (1*a*), and to imidazole itself (10)). Previous analyses (1*a*, 8–11) have not accounted for an exchange mechanism involving such anions, but it seems reasonable to expect a rate reduction of similar magnitude to the rate enhancement observed for protonation of the imidazole ring (i.e., an **adf** value of $\sim 10^{-8}$); such a value would be difficult to measure experimentally.

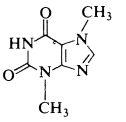
Origin of the Paf and Adf Values

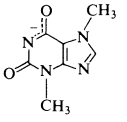


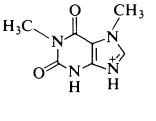


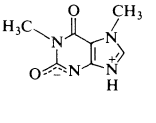


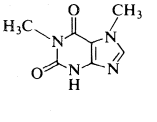


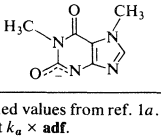












For reactions between ions, electrostatic control of reaction rate is usually the dominant factor. However, where different protonation and/or ionization sites exist within a molecule, it is not possible to treat the reactants as simple charged spheres, nor is it valid to consider overall (net) charge as the major influence on the reaction rate. In consideration of these points, we have constructed a model to illustrate that the observed effects of substrate charge can possibly originate from simple electrostatic interactions within the transition state of the exchange process. Assuming a highly product-like transition state[2] in which virtually complete triton transfer to hydroxide has occurred, with concomitant localization of a full negative charge

[1]The subscripts *a*, *b*, *c*, and *d* refer to the protonated, neutral, zwitterionic, and monoanionic purine species, respectively, corresponding to the symbolism employed in Table 1.

[2]An interpretation consistent with low kinetic isotope effects and near-unity Brønsted β-coefficients (12).

on C-8 (Fig. 1), it is envisaged that protonation of N-7/9 would serve to stabilize the transition state whereas anion formation would produce the opposite effect. In this model, it is assumed that protonation and ionization localizes full charges on the *N* atoms concerned, some justification for which comes from the finding that protonation and alkylation of the imidazole ring produce similar rate-enhancing effects, suggesting a certain independence of the *nature* of the substituent.

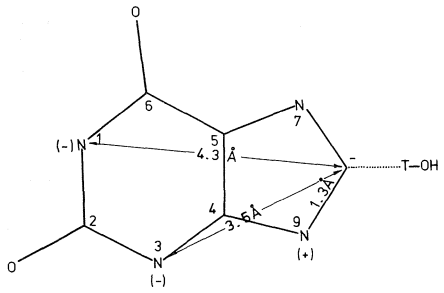

FIG. 1. The geometry of a typical xanthine molecule used for the calculation of intercharge distances in the transition state model.

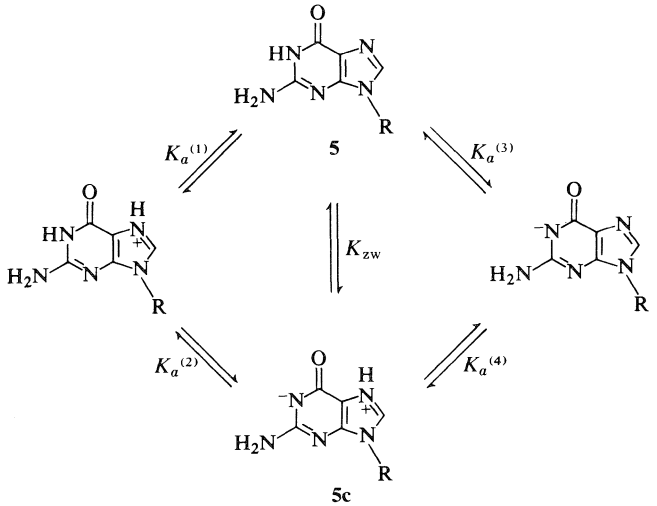
Electrostatic effects on the rate of detritiation based on the above model can therefore be described by (ref. 13, ref. 14, chapt. 9):

$$[3] \quad \log k_a/k_b = \log (\mathbf{paf}) = \frac{\varepsilon^2}{2.303kTr_{-+}D_{\text{eff}}}$$

for the effect of protonation, and

$$[4] \quad \log k_d/k_b = \log (\mathbf{adf}) = -\frac{\varepsilon^2}{2.303kTr_{--}D_{\text{eff}}}$$

for the effect of ionization, where k is Boltzmann's constant, T the absolute temperature, r_{-+} and r_{--} the distances between the assumed point charges ($-\varepsilon$ and $+\varepsilon$, and $-\varepsilon$ and $-\varepsilon$, respectively, located on C-8 and the relevant N atoms), ε the electronic charge, and D_{eff} the effective (microscopic) permittivity of the region between the charges.



Equations [3] and [4] reduce to [5] at 85°C, after substitution of the various constants, $\mathring{r}_{-\pm}$ being expressed in Ångstroms.

$$[5] \quad \log (\mathbf{paf}) \text{ or } \log (\mathbf{adf}) = \pm\frac{205.8}{\mathring{r}_{-\pm}D_{\text{eff}}}$$

Although a small change in the geometry of the imidazole ring in 7-methylxanthine occurs as a result of N-9 protonation (15), generally the crystal structures of caffeine (16), the xanthine N-3 anion (17), theobromine (18), and theophylline (19) exhibit a reasonably constant geometry of the xanthine ring system. We have therefore arbitrarily chosen the xanthine anion (17) as the geometrical basis of our model xanthine, shown in Fig. 1. Based on this model, the distances $r_{\text{C-8-N-9}}$, $r_{\text{C-8-N-3}}$, and $r_{\text{C-8-N-1}}$ are found to be 1.3, 3.5, and 4.3 Å, respectively. Substitution of these values into eq. [5], together with the corresponding log (**paf**) or log (**adf**) values, permits the calculation of D_{eff} in each case. Thus, D_{eff} values of 19 (C-8 – N-9, based on an average **paf** value for **2**, **3**, and **4**), 34 (C-8 – N-3 for **4**), and 42 (C-8 – N-1 for **3**) are found. These values are intermediate between the permittivity of water at 85°C (60 (ref. 14, p. 178)) and the much lower value generally regarded (14) as typical of a hydrocarbon molecular framework. That D_{eff} appears to vary with intercharge distance may be an inherent feature of this oversimplified model, or it may genuinely reflect the increasing solvent participation with increasing charge separation. The fact that the measured D_{eff} values are found to be of reasonable magnitudes lends support to the transition state model chosen.

*Zwitterionic Equilibrium Constants and the "Zwitterion Activating Factor" (**Zaf**)*

For the purpose of calculating k_c for guanosine from the high pH value of k', Tomasz *et al.* (16) first derived a value for K_{zw} using the method of Tucker and Irvin (21). Since we presently adopt the same approach in the present paper, a brief account of the principles involved will be given at this stage. The ionization sequence of, e.g. guanosine (**5**, R = ribose) is considered to be as shown in Scheme 1.

‖Reference 6, at 37°C.

The measured K_a for N-7 protonation is thus given by:

[6] $K_a = K_a^{(1)} + K_a^{(2)}$

Similarly, the zwitterionic equilibrium constant is given by:

[7] $K_{zw} = K_a^{(2)}/K_a^{(1)} \quad (= K_a^{(4)}/K_a^{(3)})$

Combination of eqs. [6] and [7] leads to [8].

[8] $K_{zw} = K_a^{(2)}/(K_a - K_a^{(2)})$

If $K_a^{(2)}$ is small compared with K_a, K_{zw} can be calculated from the simplified expression,

[9] $pK_{zw} = pK_a^{(2)} - pK_a$

By using the corresponding N-7 methylated compound as a model for the zwitterionic species, a value of $K_a^{(2)}$ can be obtained. Thus Tomasz *et al.* (6) compared the pK_a values for guanosine and 7-methylguanosine in order to estimate K_{zw} for guanosine, a value of 1.9×10^{-5} being obtained at 37°C. These workers then proceeded to evaluate k_c (from eq. [1] with $k_b = 0$).

In addition to this method, however, our present considerations of the quantitative effects of protonation and deprotonation on the rate of detritiation in purine systems provides a measure of k_c which we can use in conjunction with eq. [1] and the known values of k' and k_b to evaluate K_{zw}. A summary of k_c and derived K_{zw} values for the xanthines and other purine systems (assuming the same **adf** for N-1 deprotonation as found for **3**) is presented in Table 2. These K_{zw} values can be compared with those calculated using Tucker and Irvin's method. Although there is a paucity of literature $pK_a^{(2)}$ measurements, suitable data (22) are available for the 9-methyl derivatives of **3** and **4**, and for 7,9-dimethylxanthine (assumed to be a reasonable model for the xanthinium ion), in addition to the data used by Tomasz *et al.* (6). Data from the latter source, together with the K_{zw} values calculated using eq. [9], are given in Table 3.

A comparison of the K_{zw} data given in Tables 2 and 3 calculated using the present "kinetic" approach and Tucker and Irvin's "equilibrium" method shows there to be remarkable agreement, and indicates little change in K_{zw} with temperature. The magnitude of the K_{zw} values deserves some comment. Intuitively, a major determinant of the magnitude of K_{zw} is considered to be the basicity

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

difference between proton donor and acceptor sites. This can be exemplified by comparing the paraxanthine and theobromine systems. Using ΔpK_a (= pK_a (donor site) − pK_a (acceptor site)) as a measure of the difference in basicity, the greater (by $\sim 10^4$) K_{zw} value in the former case can be correlated with a smaller ΔpK_a (by ~2.6 at 25°C (23)).

Even though the concentration of neutral molecules far exceeds the zwitterion concentration, the much greater reactivity of the latter, expressed in terms of the "zwitterion activating factor" (**zaf** = k_c/k_b), accounts for its dominance in the reaction pathway. The **zaf** values are intermediate between the corresponding **paf** and **adf** values, as would be expected, and range from 3.7×10^6 for paraxanthine to 8.9×10^7 for guanosine.

Concluding Remarks

In the present paper it has been shown that it is possible to quantitatively dissect the electrostatic effects of molecular charge on the rate of the hydroxide ion-catalyzed detritiation from purines. This also applies to situations in which more than one localized charged site is present in the molecule, such as for zwitterionic species hitherto only postulated to account for the observed rate behaviour.

In addition, one final point is worthy of note. In adenine and purine derivatives, the major protonation site is N-1 and not N-7 as is the case for most other purines (20), although detritiation is suggested as proceeding via the N-7-protonated molecules (7, 8). Different relative degrees of N-7- and N-1-protonation may therefore exist in solution, which would necessarily make any conclusions based on the effects of single-site protonation hazardous. Such considerations account for the lower-than-average **paf** values observed for adenosine (3*a*, 8).

Acknowledgement

I would like to express my gratitude to Dr. J. R. Jones, University of Surrey, Guildford, U.K., for his help and encouragement which made this study possible.

Metal complexes as antioxidants. 7. Kinetics of inhibition of styrene autoxidation by zinc di-isopropyldithiophosphate[1]

J. A. HOWARD AND S-B. TONG[2]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received August 14, 1979

J. A. HOWARD and S-B. TONG. Can. J. Chem. **58**, 92 (1980).

Rates of oxygen absorption by styrene (RH) containing 2,2,3,3-tetraphenylbutane and zinc di-isopropyldithiophosphate at 30°C obey the rate law $-d[O_2]/dt \propto [RH]^{1.4} R_i^{0.79}/[Zn[(i\text{-}PrO)_2PS_2]_2]^{0.54}$, where R_i is the rate of free-radical chain initiation. This order with respect to the styrene concentration implies extensive chain transfer from the poly(peroxystyryl)peroxy radical to a radical derived from the inhibitor. Reaction products confirm the displacement of a di-isopropyldithiophosphoryl radical in the chain termination reaction.

Diethyldithiophosphoric acid also inhibits styrene autoxidation by a mechanism which involves extensive chain transfer.

J. A. HOWARD et S-B. TONG. Can. J. Chem. **58**, 92 (1980).

Les vitesses d'absorption de l'oxygène par le styrène (RH) contenant du tétraphényl-2,2,3,3 butane et du diisopropyldithiophosphate de zinc à 30°C obéissent à la loi de vitesse: $-d[O_2]/dt \propto [RH]^{1.4} R_i^{0.79}/[Zn[(i\text{-}PrO)_2PS_2]_2]^{0.54}$, où R_i est la vitesse d'initiation d'une chaîne de radicaux libres. Cet ordre par rapport à la concentration du styrène implique des transferts de chaîne importants du radical polyperoxy(peroxystyryle) au radical dérivé de l'inhibiteur. Les produits de la réaction confirment le déplacement du radical diisopropyldithiophosphoryle dans le blocage de la réaction en chaîne.

L'acide diéthyldithiophosphorique inhibe également l'autoxydation du styrène selon un mécanisme qui implique des transferts de chaîne importants.

[Traduit par le journal]

Introduction

In the first part of this series it was reported (1) that rates of inhibited autoxidation of several hydrocarbons (styrene, cyclohexene, tetralin, etc.) by a number of zinc dialkyldithiophosphates, xanthates, and dialkyldithiocarbamates at 30° and 50°C obey the rate expression

$$[1] \qquad \frac{-d[O_2]}{dt} = \frac{k_p[RH]R_i}{nk_{inh}[ZnL_2]}$$

where $-d[O_2]/dt$ is the inhibited rate of oxygen absorption, k_p is the rate controlling homopropagation rate constant for the hydrocarbon, RH, R_i is the rate of chain initiation, k_{inh} is the rate constant for reaction of the chain-carrying alkylperoxy radical with the metal complex, ZnL_2, and n is the total number of alkylperoxy radicals destroyed by each molecule of ZnL_2.

A linear dependence of $-d[O_2]/dt$ on R_i and an inverse dependence on $[ZnL_2]$ gave support to the following mechanism for the termination reaction

$$[2] \qquad RO_2^{\cdot} + ZnL_2 \xrightarrow{k_{inh}} X$$

$$[3] \qquad (n-1)RO_2^{\cdot} + X \xrightarrow{fast} \text{non-radical products}$$

where X is a transient intermediate. We tentatively concluded at that time that the peroxy radical reacts with the complex at the metal centre either by an electron transfer reaction [4] or an S_H2 process [5]

$$[4] \qquad RO_2^{\cdot} + ZnL_2 \xrightarrow{k_{inh}} RO_2^{-} + ZnL_2^{+\cdot} \longrightarrow RO_2ZnL + L^{\cdot}$$

$$[5] \qquad RO_2^{\cdot} + ZnL_2 \longrightarrow RO_2ZnL_2 \longrightarrow RO_2ZnL + L^{\cdot}$$

which would mean that the ligand radical $L^{\cdot}$ is the transient intermediate X.

Burn had, however, previously argued (2, 3) that inhibition of olefins such as styrene, cyclohexene, and indene by ZnL_2 was not consistent with this mechanism because of the known rapidity with which sulphur radicals add to double bonds (4–6).

Although kinetic electron spin resonance spectroscopy has been used to show that alkylperoxy radicals do indeed react with ZnL_2 (1, 7) the reaction kinetics have not been established. Thus it was originally reported that rates of decay of $t\text{-}BuO_2^{\cdot}$ are first-order with respect to the concentration of the radical *and* the complex (1) while it has since been demonstrated that, although radical decays are exponential, rates of reaction are virtually independent of the complex concentration.

Because of the apparent inconsistencies in the reported kinetics for reaction of alkylperoxy radicals with $Zn[(i\text{-}PrO)_2PS_2]_2$ we decided to reinvestigate the inhibition kinetics using styrene as a model substrate. The results of this work, which are reported here, are consistent with either mechanism [4] or [5] and also with the ability of $(i\text{-}PrO)_2PS_2^{\cdot}$ to add to vinyl compounds.

Experimental

Materials

Styrene (Aldrich) was passed down a column of basic alumina to remove stabilizer and trap-to-trap distilled onto the initiator (2,2,3,3-tetraphenylbutane) and the inhibitor from cupric diethyldithiocarbamate. This latter procedure was performed to ensure complete removal of adventitious hydroperoxidic impurities. Chlorobenzene (solvent) and *tert*-butyl hydroperoxide were purified by standard methods. 2,2,3,3-Tetraphenylbutane was obtained from Dr. L. R. Mahoney (Ford Motor Co., Dearborn, MI) and zinc di-isopropyldithiophosphate was obtained from several sources, and it was also prepared in our laboratory, mp 149–150°C. Diethyldithiophosphoric acid (Aldrich) was purified by distillation.

Kinetic Procedure

All rate measurements reported in this paper were performed at 30°C using a previously described apparatus (8).

Products

Polyperoxides produced after autoxidation of styrene (7.8 *M*) containing tetraphenylbutane (4.3×10^{-4} *M*) and inhibitor were isolated by slow addition of the reaction mixture to a large excess of *n*-hexane. The viscous oils which were precipitated were dissolved in benzene and freeze-dried to give white powders which were analyzed for percentage zinc, sulphur, and phosphorus by atomic absorption, a turbidimetric method, and an inductively coupled plasma emission method respectively. Pulsed Fourier transform ^{31}P nmr spectra of the polymeric peroxides in $CDCl_3$ were obtained with a Varian XL-100 spectrometer. Chemical shifts were measured relative to $(MeO)_3P$ in $CDCl_3$.

Results

The Kinetics of Inhibited Autoxidation

Initial rates of oxygen absorption by solutions of styrene in chlorobenzene containing 2,2,3,3-tetraphenylbutane (TPB) and $Zn[(i\text{-}PrO)_2PS_2]_2$ were measured at 30°C and inhibited rates of autoxidation were calculated from the observed rates by subtracting the rate of oxygen absorption by the initiator ($R_i = 2 \times 2 \times 10^{-6}$[TPB]*M* s^{-1}). Inhibited rates were measured over as wide a range of styrene, TPB, and $Zn[(i\text{-}PrO)_2PS_2]_2$ concentrations as possible, and the results are presented as log (inhibited rate) against log (reactant concentration) plots in Figures 1, 2, and 3.

The order with respect to styrene was determined at two concentrations of $Zn[(i\text{-}PrO)_2PS_2]_2$ (0.015 and 0.041 *M*) and the gradients of the log–log plots gave substrate concentration exponents of 1.45 ± 0.13 and 1.36 ± 0.05 respectively. The order with respect to the initiator concentration was also determined at these two inhibitor concentrations and found to be 0.79 ± 0.05. The gradient of the plot of log $(-d[O_2]/dt)$ against log $[Zn[(i\text{-}PrO)_2PS_2]_2]$ gave an inhibitor concentration exponent of 0.54 ± 0.09.

These results indicate that rates of oxidation of styrene containing $Zn[(i\text{-}PrO)_2PS_2]_2$ obey the rate

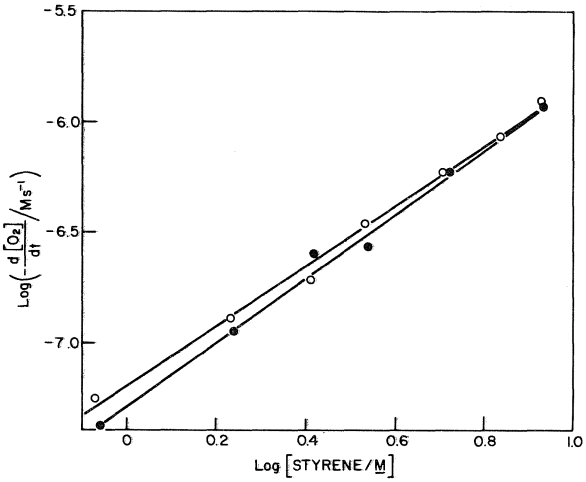

FIG. 1. A plot of the logarithm of the inhibited rate of autoxidation of styrene against the logarithm of the styrene concentration. Open circles, [TPB] = 9.8×10^{-4} *M*, $Zn[(i\text{-}PrO)_2PS_2]_2$ = 0.041 *M*; filled circles, [TPB] = 4.5×10^{-4} *M*, $Zn[(i\text{-}PrO)_2PS_2]_2$ = 0.015 *M*.

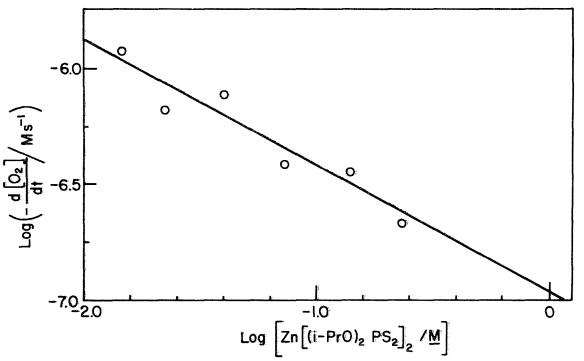

FIG. 2. A plot of the logarithm of the inhibited rate of oxidation of styrene ([TPB] = 4.3×10^{-4} *M*) against the logarithm of the $Zn[(i\text{-}PrO)_2PS_2]_2$ concentration.

expression

$$[6] \qquad \frac{-d[O_2]}{dt} \propto \frac{[RH]^{1.4} R_i^{0.79}}{[ZnL_2]^{0.54}}$$

which is almost identical with the rate laws that have been found for the inhibited autoxidation of 9,10-dihydroanthracene and tetralin by phenol at 60°C (9), tetralin by 1,1′-bis(*N*-phenyl-2-naphthylamine) at 60°C (10), and styrene by 2,4,6-tri-*tert*-butylaniline at 65°C (4).

A rate expression of this form is indicative of a mechanism in which there is extensive involvement of radicals derived from the inhibitor in rate controlling propagation reactions, i.e., extensive chain transfer (11, 12). Based on this kinetic evidence inhibition of autoxidation of styrene by $Zn[(i\text{-}PrO)_2PS_2]_2$ can be represented by the elementary

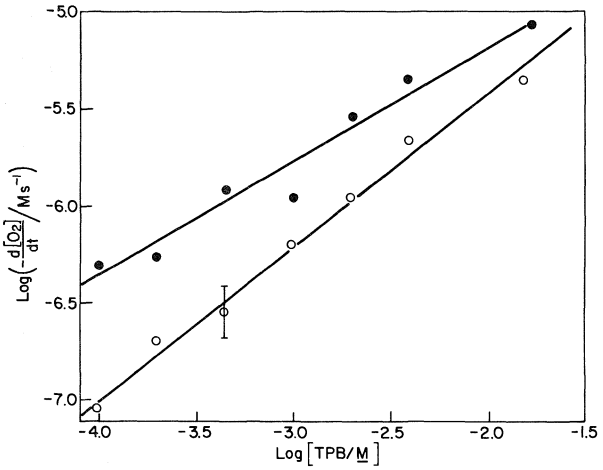

FIG. 3. A log–log plot of the inhibited rate of oxidation of styrene against the TPB concentration. Open circles, $Zn[(i\text{-}PrO)_2PS_2]_2$ = 0.072 *M*; filled circles $Zn[(i\text{-}PrO)_2PS_2]_2$ = 0.015 *M*.

reactions

[7] $R'\text{–}R' \longrightarrow 2R'^{\bullet}$

[8] $R'^{\bullet} + O_2 \xrightarrow{k_0} R'O_2^{\bullet}$

[9] $R'O_2 + RH \xrightarrow{k'_p} R'O_2RH^{\bullet}$

[10] $R'O_2RH^{\bullet} + O_2 \xrightarrow{k_0} R'O_2RHO_2^{\bullet}$

[11] $R'O_2RHO_2^{\bullet} + RH \xrightarrow{k_p} R'O_2RHO_2RH^{\bullet}$

[12] $R'O_2RHO_2^{\bullet} + ZnL_2 \xrightarrow{k_{inh}} R'O_2RHO_2ZnL + L^{\bullet}$

[13] $L^{\bullet} + RH \xrightarrow{k_{13}} LRH^{\bullet}$

[14] $L^{\bullet} + R'O_2RHO_2^{\bullet} \xrightarrow{k_{14}}$ inert products

where R′–R′ represents TPB, RH is styrene, and L• is $(i\text{-}PrO)_2PS_2$.

Making the usual steady state assumptions that the rate of initiation is equal to the rate of termination and that $k_p[R'O_2RHO_2][RH] = k_0[R'O_2RH^{\bullet}][O_2]$ along with the further approximations that $k_p[RH] \gg k_{inh}[ZnL_2]$ and $k_p[RH] \gg k_{14}[RO_2^{\bullet}]$, the inhibited rate is given by

$$[15] \quad \frac{-d[O_2]}{dt} = k_p\left(\frac{k_{13}R_i}{2k_{inh}k_{14}}\right)^{\frac{1}{2}}\frac{[RH]^{\frac{3}{2}}}{[ZnL_2]^{\frac{1}{2}}}$$

Substitution of all the inhibited rates and reactant concentrations into this expression gives $k_{13}/2k_{inh}k_{14} \sim 10^{-11}$ *M* s.

This reaction mechanism does, of course, require a termination reaction between $(i\text{-}PrO)_2PS_2^{\bullet}$ and $RO_2^{\bullet}$ and that the styrene polyperoxide produced in rate controlling propagation reactions contains $Zn(i\text{-}PrO)_2PS_2$ and $(i\text{-}PrO)_2PS_2$ end groups.

Styrene polyperoxide produced after prolonged autoxidation of styrene in the presence of zinc diisopropyldithiophosphate was isolated and found to contain zinc (0.85 ± 0.02%), sulphur (2.19 ± 0.11%), and phosphorus (0.88 ± 0.04%). $Zn[(i\text{-}PrO)_2PS_2]_2$ would, therefore, appear to have been incorporated into the polymer by the inhibition reaction [12] and the chain transfer reaction [13].

Effect of Hydroperoxide

Several groups of workers have shown by radical scavenging (13, 14) and aromatic amine destruction (15, 16) experiments that there is a reaction between $Zn[(i\text{-}PrO)_2PS_2]_2$ and alkyl hydroperoxides which produces free radicals capable of initiating autoxidation. We found, however, that when *tert*-butyl hydroperoxide (0.008 *M*) was added to styrene containing TPB (0.001 *M*) and $Zn[(i\text{-}PrO)_2PS_2]_2$ (0.04 *M*) the inhibited rate was reduced by a factor of ~3.5. Furthermore, the inhibited rate was independent of the hydroperoxide concentration from 0.00005 to 0.001 *M*.

Inhibited rates in the presence of *t*-BuOOH (0.0002 *M*) were found to obey the rate expression

$$\frac{-d[O_2]}{dt} = \frac{[RH]^{1.47\pm0.13}R_i^{0.86\pm0.1}}{[Zn[(i\text{-}PrO)_2PS_2]_2]^{0.58\pm0.1}}$$

which is very similar to the rate in the absence of *t*-BuOOH implying that chain transfer is still important in the presence of hydroperoxide.

Effect of Dialkyldithiophosphoric Acid

Although it has been reported (1) that dialkyldithiophosphoric acids inhibit the autoxidation of styrene and cyclohexene, reactant exponents have not previously been determined. We now report that diethyldithiophosphoric acid is about 5 times more efficient than $Zn[(i\text{-}PrO)_2PS_2]_2$ in styrene and that the order with respect to the substrate concentration is 1.45 ± 0.17 for styrene containing TPB (6×10^{-4} *M*) and $(EtO)_2PS_2H$ (5.6×10^{-3} *M*). This indicates that inhibition of this hydrocarbon by the free acid can probably be described by the elementary reactions [7] to [14], with reaction [12] taking the form

$$RO_2^{\bullet} + (EtO)_2PS_2H \rightarrow RO_2H + (EtO)_2PS_2^{\bullet}$$

This mechanism was substantiated by the observation that the polyperoxide produced by autoxidation of styrene in the presence of $(EtO)_2PS_2H$ contained low percentages of phosphorus and sulphur and that the ^{31}P nmr spectrum in $CDCl_3$ showed a major transition at −51.65 ppm, a somewhat less

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

intense transition at −145.35 ppm and minor transitions at −79.41 ppm and −122 ppm relative to $(MeO)_3P$ in $CDCl_3$.[3] The major transition had a chemical shift quite different from the chemical shift for $(EtO)_2PS_2H$ (−61.21 ppm) and is tentatively assigned to the phosphorus nucleus in a diethyldithiophosphoryl end group in polystyrene peroxide. The occurrence of a fairly major peak at $\delta\ ^{31}P = -145.35$ suggests that the polystyrene peroxide contained some type of phosphate group produced by replacement of sulphur by oxygen. This type of reaction, although poorly understood, is common in lubricants containing zinc dialkyldithiophosphates.[4]

Conclusions

There appears to be no doubt that an alkylperoxy radical can displace a di-isopropyldithiophosphoryl radical from zinc di-isopropyldithiophosphate and that this radical has the ability to add to styrene and also to undergo a chain termination reaction. It is, therefore, not surprising that inhibition of styrene autoxidation by diethyldithiophosphoric acid also involves extensive chain transfer. The generality of this mechanism has, however, not yet been demonstrated and work is in progress in our laboratory on the kinetics and products of the inhibition of styrene autoxidation by other dialkyldithiophosphates and dialkyldithiocarbamates.

The influence of *tert*-butyl hydroperoxide on autoxidation of styrene in the presence of zinc di-isopropyldithiophosphate is not at the present time clear. Enhanced inhibition could perhaps be the result of interception of ligand radicals by the hydroperoxide to give *tert*-butylperoxy radicals which are known to be less reactive towards styrene than the poly(peroxystyryl)peroxy radical (17).

$$(i\text{-PrO})_2PS_2^{\cdot} + t\text{-BuOOH} \rightarrow (i\text{-PrO})_2PS_2H + t\text{-BuO}_2^{\cdot}$$

In addition this reaction gives di-isopropyldithiophosphoric acid which is a better inhibitor than $Zn[(i\text{-PrO})_2PS_2]_2$.

[3]Downfield shifts are positive, relative to internal $(MeO)_3P$ using Ξ (^{31}P in $(MeO)_3P$) = 40 486 459 Hz at 100 MHz relative to TMS. Chemical shifts relative to the more familiar but less reproducible standard H_3PO_4 can be calculated from $\delta\ H_3PO_4 = -141$.

[4]We thank a referee for bringing this point to our attention.

The molecular and crystal structure of *trans*-dichloro(dimethylformamide)(2,6-lutidine)platinum(II)

F. D. ROCHON, P. C. KONG, and R. MELANSON
Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Received June 15, 1979

F. D. ROCHON, P. C. KONG, and R. MELANSON. Can. J. Chem. **58**, 97 (1980).

The crystal structure of *trans*-[Pt(DMF)(2,6-lutidine)Cl_2] has been determined by X-ray diffraction. The crystals are orthorhombic, space group *Pbca*, with $a = 11.612(13)$, $b = 26.504(33)$, $c = 9.271(9)$ Å, and $Z = 8$. The structure was refined by full matrix least-squares analysis to a conventional R factor of 0.051 and a weighted $R_w = 0.044$. The coordination around the platinum atom is square planar. The 2,6-lutidine ring is perpendicular to the platinum plane. DMF is bonded to platinum through the oxygen atom. It is planar and makes an angle of 71° with the platinum plane. The *cis–trans* configuration of the [Pt(DMF)(L)Cl_2] (L = pyridine derivative) complexes in DMF solution is discussed.

F. D. ROCHON, P. C. KONG et R. MELANSON. Can. J. Chem. **58**, 97 (1980).

La structure cristalline de *trans*-[Pt(DMF)(lutidine-2,6)Cl_2] a été déterminée par diffraction des rayons-X. Les cristaux appartiennent au groupe spatial orthorhombique *Pbca*, avec $a = 11.612(13)$, $b = 26.504(33)$, $c = 9.271(9)$ Å et $Z = 8$. Les coordonnées et les facteurs thermiques anisotropes ont été affinés par moindres-carrés (matrice entière) jusqu'à $R = 0.051$ et $R_w = 0.044$. La coordination autour de l'atome de platine est plane. Le noyau lutidine-2,6 est perpendiculaire au plan du platine. DMF est lié au platine par l'atome d'oxygène. Le ligand DMF est plan et forme un angle de 71° avec la plan du platine. La configuration *cis–trans* des complexes [Pt(DMF)(L)Cl_2] (L = dérivé de la pyridine) en solution dans le DMF, est discutée.

Introduction

In an attempt to prepare compounds of the type *cis*-[Pt(am)(am′)Cl_2] (am = amine, am′ = amine ≠ am) in a view of increasing the screening range for antitumour properties of platinum complexes, we have isolated a series of compounds [Pt(DMF)(L)Cl_2] where L = pyridine derivative and DMF = dimethylformamide (1). The compounds were first prepared by the following reaction:

$$[1]\quad K[Pt(L)Cl_3] \xrightarrow[DMF]{Ag^+} [Pt(L)(DMF)Cl_2]$$

The compounds were assumed to have the *cis* configuration for two reasons: (*i*) The *trans* effect of chlorine is greater than the *trans* effect of pyridine derivatives. (*ii*) The following reactions were observed (except when L = 2,6-lutidine):

$$[2]\quad \begin{aligned} K[Pt(L)Cl_3] + L &\xrightarrow[DMF]{Ag^+} \textit{cis}\text{-}[Pt(L)_2Cl_2] \\ [Pt(DMF)(L)Cl_2] + L &\xrightarrow{DMF} \textit{cis}\text{-}[Pt(L)_2Cl_2] + DMF \end{aligned}$$

Therefore [Pt(DMF)(L)Cl_2] was assumed to be an intermediate in the above overall reaction [2]. Since [Pt$(L)_2Cl_2$] has the *cis* configuration, [Pt(DMF)(L)Cl_2] was also assumed to be the *cis*-isomer. When L = 2,6-lutidine (2,6-lut), the reaction stops at [Pt(DMF)(2,6-lut)Cl_2]. We have already reported that the steric hindrance of 2,6-lut to its *cis* position is so large that *cis*-[Pt$(2,6\text{-lut})_2Cl_2$] cannot be obtained from the reaction of K[Pt(2,6-lut)Cl_3] and 2,6-lut (2).

In order to confirm our hypothesis, we decided to undertake a crystal structure analysis of one of the compounds. Only [Pt(DMF)(2,6-lut)Cl_2] gave suitable crystals for X-ray analysis. Even we realized that this compound was not necessarily representative of the series, we have decided to determine its structure. We were surprised to find out that it had the *trans*-configuration.

The DMF compounds can also be prepared by dissolving the bridged compounds [Pt(L)$Cl_2]_2$ in DMF (1). Infrared spectroscopy has shown that the products obtained by both methods were identical.

Experimental

[Pt(DMF)(2,6-lut)Cl_2] was synthesized according to ref. 1 and recrystallized as plates from a DMF–ether solution.

The orthorhombic standard centrosymmetric space group *Pbca* was established unambiguously from precession photographs. The cell parameters were calculated by least-squares refinement of the setting angles of 15 independent peaks centered on a Syntex $P\bar{1}$ diffractometer using graphite monochromatized MoKα radiation.

Crystal data are as follows:

$PtCl_2C_{10}H_{16}N_2O$ mw = 446.25
Orthorhombic *Pbca*, a = 11.612(13), b = 26.504(33), c = 9.271(9) Å, V = 2853(5) Å^3, Z = 8, D_x = 2.078 g cm^{-3}, D_m = 2.07(2) g cm^{-3} (flotation), λ(MoKα) = 0.71069 Å, μ(MoKα) = 107.01 cm^{-1}, and T = 22°C.

Collection and Reduction of Intensity Data

The intensity data were collected from a crystal of dimensions 0.76 × 0.358 × 0.076 mm. A total of 4196 independent reflections were measured in the region of $2\theta < 60°$ by the $2\theta/\theta$ scan technique using MoKα radiation. The scan rate was 1° (2θ) min^{-1} for most reflections, but rates as high as 24° min^{-1} were selected for strong reflections by the autocollection program. A 2θ scan range of 1° below $K\alpha_1$ and 1° above $K\alpha_2$ was selected. The background time to scan time ratio was 0.40. Three standard reflections were measured after every 47 reflections. They showed fluctuations of ±3% during the data collection.

The reflections for which the intensity was less than $2.5\sigma(I)$ were considered as unobserved. The standard deviation $\sigma(I)$ was calculated as already described (3). An absorption correction based on the equations of the crystal faces was applied to all the reflections. The transmission factors varied from 0.058 to 0.443. The data were then corrected for the Lorentz and polarization effects. This set of 2125 observed reflections was used for the structure determination.

The atomic scattering factors of Cromer and Waber (4) were used for Pt, Cl, O, N, and C atoms, those of Stewart, Davidson, and Simpson (5) were used for hydrogen. The anomalous dispersion terms (6) of platinum and chlorine were included in the calculations.

Structure Determination

The structure was solved by the heavy atom method. The refinement of the parameters was carried out by full-matrix least-squares methods. In the early stages of refinement, unit weights were assigned to all observed reflections. Later, individual weights $w = 1/\sigma^2(F)$ (7) were applied. The hydrogen atoms on the lutidine ring and the aldehyde hydrogen atom were fixed at their calculated position (C—H = 0.95 Å, angle = 120°) and assigned isotropic temperature factors of β = 6.0 Å^2. An isotropic secondary extinction coefficient (8) was also applied. The refinement of the scale factor, the coordinates and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = \sum ||F_o| - |F_c|| / \sum |F_o| = 0.051$ and $R_w = [\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2]^{1/2} = 0.044$. The final difference Fourier map did not show peaks higher than ±0.7 e Å^{-3}. Attempts to find the hydrogen atoms on the methyl groups were not successful.

The calculations were carried out with a Cyber 73 computer and the programs used have already been described (3). A table of observed and calculated structure factors is available from the Depository of Unpublished Data.[1]

[1]Complete set of data (lists of structure factors and anisotropic thermal parameters) is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion

The refined atomic parameters are listed in Table 1. A list of the anisotropic temperature factors is available. A labelled diagram of the molecule is shown in Fig. 1. The bond distances and angles within the molecule are listed in Table 2.

As mentioned earlier, we expected the compound to be the *cis* isomer, but we were surprised to find out that it had the *trans* configuration. The DMF ligand is bonded to platinum through the oxygen atom which confirmed our previous hypothesis based on infrared and nmr spectroscopy (1).

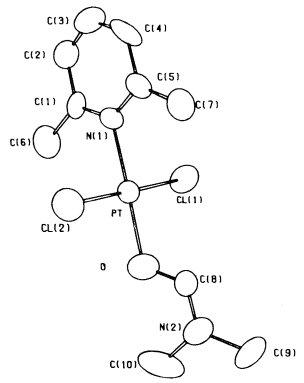

FIG. 1. Labelled view of the molecule *trans*-[Pt(dimethylformamide)(2,6-lutidine)Cl_2].

As expected, the coordination around the platinum atom is square planar. The weighted best plane was calculated through the five atoms. The deviations from this plane are: Pt, 0.0007; Cl(1), −0.026; Cl(2), −0.035; O, 0.033; and N(1), 0.034 Å. The angles around the platinum atom are close to the expected 90° and 180°.

The Pt—Cl bonds (2.297 Å) are normal and agree well with the published values (3, 10, 11). The Pt—O bond of 2.051 Å also seems normal. Infrared spectroscopy has already shown that [Pt(DMF)$_2$Cl$_2$], [Pt(dimethylacetamide)$_2$Cl$_2$] (12), and the analyzed compound (1) were bonded to platinum through the oxygen atom. But to our knowledge, this study is the first structure determination of platinum–DMF complex. Platinum does not usually form bonds with oxygen atoms. For example, DMSO coordinates to platinum through the sulphur atom (3, 10, 11) and not through the oxygen atom like most other metals.

DMF exists as a resonance structure of the two mesomeric forms $(CH_3)_2NCHO$ and $(CH_3)_2N^+CHO^+$. Because of the ionic form, platinum will form bonds more easily with the oxygen atom than with the nitrogen atom. The decrease in multiplicity of the C—O bond and the increased multiplicity of the C—N bond resulting from the resonance structures, have been observed in all published crystal structures involving DMF molecules. Table 3 shows a brief summary of several DMF crystal structure determinations.

Since the ionic form is favored when DMF is coordinated to a metal, a more pronounced decrease in multiplicity of the C—O bond along with an increase of multiplicity of the C—N bond would be expected. But it is interesting to observe that DMF has the same structure, whether it is coordinated to a metal or uncomplexed as a molecule of crystallization. The structure of DMF in the gas phase has been determined in 1962 by electron diffraction (13). The C—O distance (1.20 Å) seems shorter than the distances found in crystal structures of DMF compounds (1.21–1.30 Å). But in many determinations, including DMF, the standard deviations are very high. Therefore the difference might not be significant. The C—N distance in DMF (1.34 Å) is the same as the distances found in crystalline DMF compounds (1.28–1.35 Å). Therefore the structure of DMF seems unaltered whether it is free, crystallized as a molecule of solvent or bonded to a metal.

All the published structures show that DMF is planar. In our study of *trans*-[Pt(DMF)(2,6-lut)Cl_2], DMF is also planar. The deviations from the weighed best plane are: O, −0.01(1); N(2), 0.02(1); C(8), 0.02(1); C(9), −0.03(2); and C(10), 0.00(2) Å. The C(8)—O bond distance of 1.253(12) Å agrees well with the published data (Table 3). It is slightly longer than a normal C=O bond. The N(2)—C(8) bond (1.326(13) Å) also agrees with the data shown on Table 3. It is shorter than a normal N—C bond showing an increase in multiplicity of the bond resulting from the resonance structures. The angles around the nitrogen atom are close to 120° and agree with the data published on DMF structures of Table 3.

The Pt—N(1) distance of 2.013 Å agrees well with published Pt—N distances in pyridine derivative compounds (10, 11). The 2,6-lutidine ligand is planar and is perpendicular to the platinum coordination plane (88.4°). The distances within the ligand are normal and agree with published data (10, 11). The angles are close to the expected 120°.

A stereoscopic view of the packing in the *trans*-[Pt(DMF)(2,6-lut)Cl_2] crystal is shown in Fig. 2. The molecules are packed in planes parallel to the *bc* plane. All the hydrogen atoms being bonded to carbon atoms, no strong hydrogen bonding was expected, but one interaction involving the aldehyde proton with a chlorine atom is worth mentioning. The distances and angles involved are shown in Table 4. The H···Cl(2) distance (2.67 Å) is shorter than the Van der Waals distance (3.0 Å). The angles are good, but the long distance C(8)···Cl(2) (3.62 Å) indicates that this interaction is fairly weak.

Since the *trans* effect of chlorine is greater than pyridine derivatives, the products of reactions [1] and [3] should have the *cis*-configuration, at least, the initial products should be the *cis* isomers.

$$[3]\quad [Pt(L)Cl_2]_2 + 2DMF \xrightarrow{DMF} 2[Pt(L)(DMF)Cl_2]$$

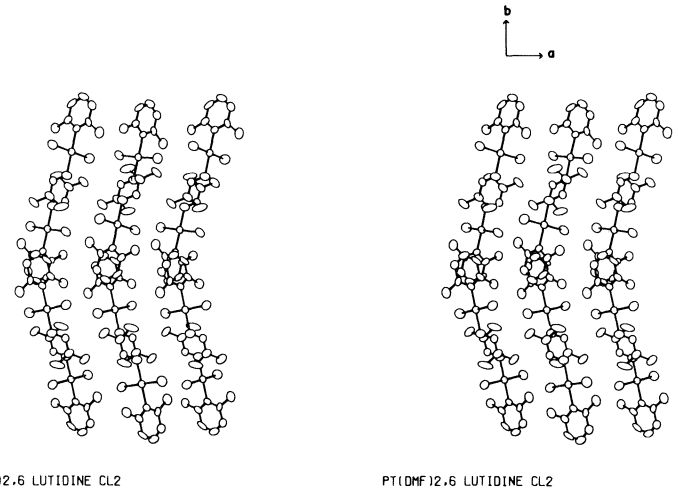

FIG. 2. Stereoscopic view of the packing in the *trans*-$[Pt(DMF)(2,6\text{-lut})Cl_2]$ crystal.

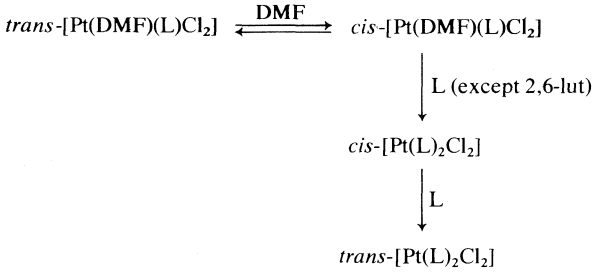
The *trans*-isomers could be formed from the subsequent isomerization of the *cis*-isomers, as is $[Pt(DMSO)(L)Cl_2]$ in dimethylsulphoxide (DMSO) solution (9). The nmr signals of the ortho-protons of $[Pt(DMSO)(4\text{-picoline})Cl_2]$ in DMSO, appeared at 8.52 ppm for the *trans*-isomer and at 8.76 ppm for the *cis*-isomer. The nmr spectrum of $[Pt(2,4\text{-lut})(DMF)Cl_2]$ in DMF-d_6 does not give positive evidence of two isomers in solution (only one doublet for the ortho proton of 2,4-lut with half width of 2.5 Hz). This may be because the *trans* effect of DMF is smaller than the *trans* effect of DMSO. Therefore the influence of the DMF ligand on the ortho proton of 2,4-lut might be the same, whether it is in the *cis* or *trans* position.



cis-$[Pt(DMF)(L)Cl_2]$ is suggested to exist in solution because of the following observations. No $[Pt(2,6\text{-lut})_2Cl_2]$ can be obtained from the reaction of *trans*-$[Pt(DMF)(2,6\text{-lut})Cl_2]$ and 2,6-lut in DMF. Since 2,6-lut causes no steric hindrance in the *trans* position, the inability to displace DMF is presumably due to the stability of *trans*-[Pt(DMF)(2,6-

TABLE 4. Possible hydrogen bonds

Atoms	Transformation (on last atom)	Distance (Å)	Atoms	Angle (deg)
C(8)—H...Cl(2)	$\frac{1}{2}+x, y, \frac{1}{2}-z$	3.620(1)	O(8)—C(8)...Cl(2)	124.2(7)
H...Cl(2)	$\frac{1}{2}+x, y, \frac{1}{2}-z$	2.673	N(2)—C(8)...Cl(2)	113.9(7)
			C(8)—H...Cl(2)	167.2(7)

lut)Cl_2]. This explanation should also apply to other *trans*-[Pt(DMF)(L)Cl_2]. However, when L = pyridine, 2-picoline, and 4-picoline, *cis*-[Pt(L)$_2Cl_2$] can be obtained from the reaction of [Pt(DMF)(L)Cl_2] and L in DMF or $CHCl_3$ at room temperature (Pt: L = 1:1, concentration 0.05 *M*, and time = 1.5 h). Since *trans*-[Pt(L)$_2Cl_2$] cannot isomerize to *cis*-[Pt(L)$_2Cl_2$], the formation of the *cis* isomer should come from the direct reaction of *cis*-[Pt(DMF)(L)Cl_2] and L. The failure to obtain [Pt(2,6-lut)$_2Cl_2$] does not contradict the existence of *cis*-[Pt(DMF)(2,6-lut)Cl_2] in solution. It has already been found that the steric hindrance of 2,6-lut to its *cis* position is so large that *cis*-[Pt(2,6-lut)$_2Cl_2$] cannot be obtained from the reaction of K[Pt(2,6-lut)Cl_3] and 2,6-lut (2). Therefore, in DMF solution, [Pt(DMF)(L)Cl_2] should be a mixture of *cis*- and *trans*-isomers. The scheme of the reactions is thus as follows.

Molecular motion and methyl group rotation barriers from ^{13}C nmr relaxation times. Norbornane and adamantane derivatives in solution

HELMUT BEIERBECK, ROBERT MARTINO, [1] AND JOHN K. SAUNDERS
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received June 8, 1979

HELMUT BEIERBECK, ROBERT MARTINO, and JOHN K. SAUNDERS. Can. J. Chem. **58**, 102 (1980).

The carbon-13 relaxation time data for several norbornane and adamantane derivatives are presented. It is shown that the most probable principal axis of the rotational diffusion tensor is an axis which contains the centre of mass of the molecule and the heterosubstituent. The influence of the C—Ĉ—H bond angle on the calculation of methyl group rotation barriers from relaxation time data and on the barrier is discussed.

HELMUT BEIERBECK, ROBERT MARTINO et JOHN K. SAUNDERS. Can. J. Chem. **58**, 102 (1980).

Le temps de relaxation du carbone-13 de plusieurs dérivés de norbornane et d'adamantane sont présenté. On démontre que l'axe principale le plus probable de la tensor de la diffusion rotationnel est celle que contient le centre de masse de la molécule et l'hétérosubstituant. On discute l'influence de l'angle C—Ĉ—H sur le calcul de la barrière de rotation d'un groupement méthyle à partir du temps de relaxation et aussi sur la barrière elle-même.

The analysis of ^{13}C nmr spin lattice relaxation times (T_1) provides insight into the dynamic behaviour of organic molecules in solution, including the overall diffusion constants for the molecules (1) and diffusion constants for rotation about single bonds (2–4). The simplest case of overall motion is isotropic motion. In such a case the diffusion constant can be obtained directly from T_1 data using eq. [1], since most models of molecular reorientation

$$[1]\quad \frac{1}{T_1} = \frac{N\gamma_H{}^2\gamma_C{}^2\hbar^2}{(r_{C-H})^6}\,\tau_c$$

assume that the rotational diffusion constant R_i about the ith axis is related to the correlation time about this axis (τ_{ci}) by the expression $(1/6R_i) = \tau_{ci}$ (5).

The internal reorientation rate of a CH_3 group rotation can be calculated using eq. [2] (6), where

$$[2]\quad \frac{1}{T_1} = \frac{3\gamma_H{}^2\gamma_C{}^2\hbar^2}{(r_{C-H})^6} \times \left[\frac{A}{6R} + \frac{B}{6R + R_{int}} + \frac{C}{6R + R_{int}}\right]$$

A, B, and C are geometrical terms, R is the overall diffusion constant obtained by application of eq. [1] to the T_1 data of rigid carbons, and R_{int} is the diffusion constant for reorientation about the carbon—CH_3 bond. Equation [2] is the stochastic diffusion model. The relaxation rate constant for CH_3 groups jumping between three equivalent positions separated by 120° is given by eq. [3] (7)

$$[3]\quad \frac{1}{T_1} = \frac{3\gamma_H{}^2\gamma_C{}^2\hbar^2}{(r_{C-H})^6}\left[\frac{A}{6R} + \frac{B + C}{6R + R_{int}}\right]$$

In an earlier publication (8) we have shown that the values of R_{int} for CH_3 groups in steroids depend on the number of 1,3 diaxial CH_3–hydrogen interactions to which the CH_3 group is subjected. In order to further explore the factors which influence R_{int}, we have studied several methylated bicyclo-[2,2,1]heptanes and adamantanes, the results of which are presented in Table 1. The T_1 values represent the dipole–dipole contributions since the nOe was 2.0 ± 0.1 for all carbons in all molecules. Inspection of the results given in Table 1 reveals that the T_1 data cannot be analysed by application of eqs. [1] and [2] since the NT_1 values of ring carbons in most compounds are not constant. For example, C-5 has a significantly shorter T_1 than C-6 for compound **1** when $CDCl_3$ is employed as solvent. This implies that the overall motion of the molecules is anisotropic. Previously reported data for norbornene (9, 10) showed non uniform NT_1 values for ring carbons, particularly at C-4, which was interpreted in terms of anisotropic motion (9) and different C—H bond lengths (10). A shorter C—H bond length than normal at C-4 is plausible but it appears very unlikely that the difference in T_1 between C-5 and C-6 in **1**, **2**, and **3** can be attributed to bond length differences.

In systems undergoing anisotropic motion, τ_c of eq. [1] must be replaced by an expression containing the diffusion constants about the various molecular axes. The simplest case of an anisotropic system is that of a symmetric top molecule in which τ_c is expressed in terms of R_1 and R_2, where R_1 describes the rotation about the C_3 axis and R_2 the

rotation about the two mutually perpendicular axes. The equation necessary to convert T_1 data into R_1 and R_2 was developed by Woessner (6) and is shown as eq. [4]. The constants A, B, and C are

$$[4]\quad \frac{1}{T_1} = \frac{N\hbar^2\gamma_C{}^2\gamma_H{}^2}{r_{C-H}} \times \left[\frac{A}{6R_2} + \frac{B}{5R_2 + R_1} + \frac{C}{2R_1 + 4R_2}\right]$$

again geometrical constants which are functions of the angles between the C—H bond vectors and the symmetry axes. The definition of the geometrical constants, together with the equation for determining the three principal values of the rotational diffusion constants for an asymmetric top molecule, can be found in ref. 6.

Woessner's equations have been successfully applied to simple molecules (11), molecules containing only carbon and hydrogen (12), and to molecules containing heterosubstituents (13, 14), where the carbon–heterosubstituent bond is coincident with the symmetry axis of the molecule. Molecules containing heterosubstituents, which are not on the symmetry axis, pose a much more serious problem in that the calculation of diffusion constants about various axes requires *a priori* that the axes have been defined. The normal method based on Woessner's equation assumes that the principal axes of diffusion coincide with the principal axes of the moment of inertia. This is a reasonable assumption for the above mentioned cases, but may not be valid for heterosubstituted molecules, where the substituent is not on an axis (15). First of all, if the motion is controlled by diffusion rather than by inertial properties, it is the volume rather than the moment of inertia that must be considered (10). Secondly, heterosubstituents are often more strongly solvated and can be involved in solute–solute interactions.

We have calculated T_1 values for each carbon by optimizing the diffusion constants using three different principal axes. The first series (*A*) of T_1 values was calculated using the principal axes of the moment of inertia as the principal axes of the diffusion tensor. The second assumption (*B*) also used the moment of inertia but placed the heterosubstituent on the principal axis of rotation. In other words, this method assumes that the rotation of the hydrocarbon moiety is controlled by inertial effects (which correspond to volume effects as this part of the molecule contains only carbon and hydrogen), and that movement of the heterosubstituent is more restricted. The final method (*C*) was to assume that the carbon–heterosubstituent bond is the principal axis of molecular rotation. This method assumes that the heterosubstituent is "fixed" in solution by intermolecular interactions and that the most energetically favored path for molecular rotation is that about the carbon–oxygen bond. The values were calculated by assuming that the molecules behave as symmetric tops in solution. It is evident that the difference between observed and calculated values would be reduced by the use of three axes, since an additional variable would be introduced. However, in view of the experimental error in T_1 measurements and the limited number of C—H bond vectors in some molecules, it was felt

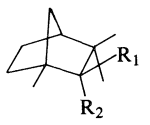
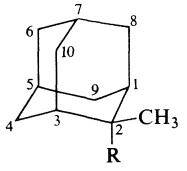
that more meaningful results would be obtained using the symmetric top model. Verification of this was found by inspection of calculated moment of inertia data and from calculations using an asymmetric top model for several compounds.

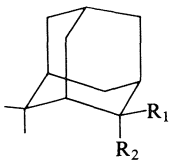


Discussion

Overall Motion



The carbon-13 T_1 values calculated using the three assumptions are compared with those obtained experimentally in Table 2. Compounds **1** and **6** are illustrated in Figs. 1 and 2 as a function of the three principal axes chosen. The T_1 values for **1** calculated by *A* or *B* correlate reasonably well with those observed in $CDCl_3$ whereas those calculated using *C* do not. Inspection of Fig. 1 shows that the position of the principal axis in *B* does not differ significantly from *A* and in both cases the C-5—H_{exo} vector is almost parallel with the principal axis, whereas this is not the case using the C—O bond as the principal axis. In acetone-d_6 isoborneol **1** displays isotropic motion, which is calculated equally well by all three assumptions. For compound **2**, the CH_2 carbon relaxation times increase in the order C-6 < C-5 < C-3, which is reproduced by both *A* and *B*, but not by *C*. Also the difference between calculated and experimental suggests that *B* is the superior assumption. The values for the other compounds are inconclusive, in that each assumption gives much the same values and similar differences. The one possible exception is camphor, in which it appears that the best correlation is obtained by utilizing assumption *C*. The main reason for this is the abnormally short value for C-4. Examination of the data for the other compounds shows that T_1 (C-4) is always smaller than calculated, and in most cases this difference is quite significant. This implies that the C—H bond length



1 R_1 = OH, R_2 = H
2 R_1 = H, R_2 = OH
3 $R_1 + R_2$ = O

4 R_1 = H, R_2 = OH
5 $R_1 + R_2$ = O

6 R = OH
7 R = Br

8 R_1 = OH, R_2 = H
9 R_1 = H, R_2 = OH
10 $R_1 + R_2$ = O

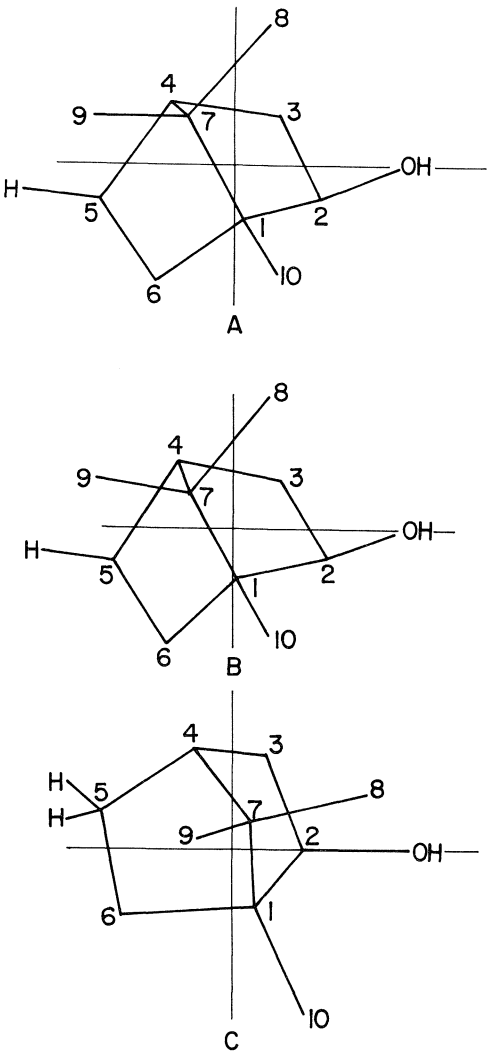


FIG. 1. Representation of isoborneol relative to the various principal axes of rotation tensor. *A*: principal axes of the moment of inertia. *B*: principal axis of rotation tensor passes through oxygen and the centre of mass of the molecule. *C*: principal axis is coincident with the C—O bond.

for C-4 is less than the normally accepted value, as had been suggested earlier (10), and that this shortening is even more pronounced when there is a carbonyl group at C-2. For compounds **3** and **5** the number of different C—H bond vectors is even more limited. The conclusion that can be drawn from the data on compounds **1**–**5** is that both *A* or *B* result in satisfactory correlation of calculated with observed relaxation times, whereas *C* does not give as good a correlation.

The T_1 values for **6** indicate significant anisotropic motion, since C-4 and C-9 have shorter relaxation times than other CH_2 carbons and C-7 has a shorter T_1 value than other CH carbons. The

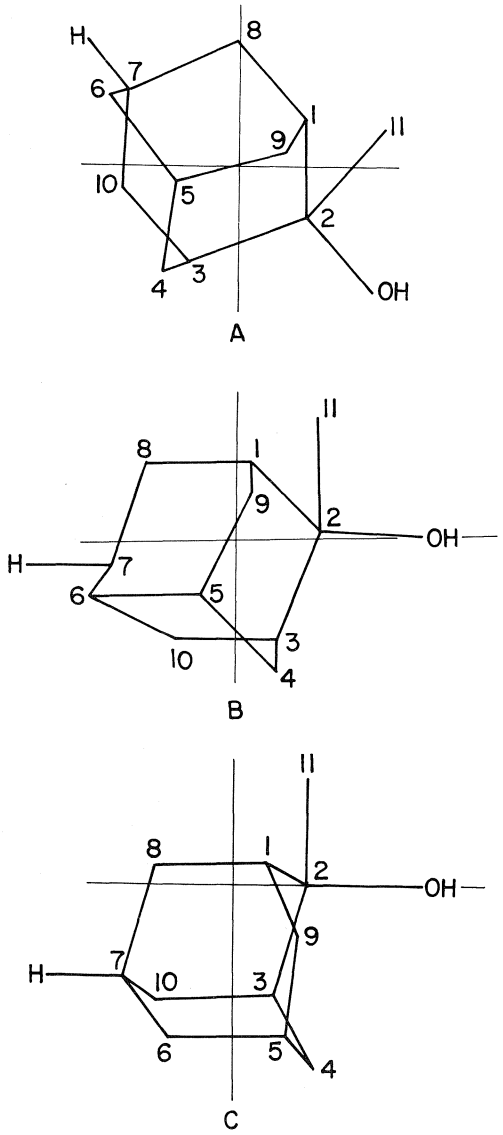

FIG. 2. Representation of 2 methyl adamantan-2-ol relative to the various axes of rotation tensor. *A*: principal axes of the moment of inertia. *B*: principal axis of rotation tensor passes through oxygen and the centre of mass of the molecule. *C*: principal axis is coincident with the C—O bond.

calculations using *A* cannot reproduce these differences. The lack of correlation for *A* is readily explained by inspection of Fig. 2, where it can be seen that the C-7—H bond vector is nowhere near parallel to the principal axis. The results for compounds **8–10** are inconclusive with respect to the choice of a principal axis, although generally *B* and *C* result in slightly better correlations. For example, the differences between observed and calculated values for C-5 and C-9 using *A* are at the limit and just outside the limit of experimental error, respectively. It is of interest to note that the experimental value for an oxygen bearing carbon is always less than that calculated. The rotation rates calculated for **10**, using method *C*, show that the result cannot be interpreted in terms of the C—O bond being the principal axis of rotation. The conclusion that can be drawn from the adamantane derivatives is that *B* and *C* (with the exception of *C* for **10**) give reasonable correlation between calculated and experimental values, whereas *A* fails for compound **6**.

It should be emphasized that a measured T_1 value is an average. For example, the T_1 value of a molecule which forms an associated species will only measure the diffusion constant of the associated species if its lifetime is longer than R^{-1}. If the lifetime is much shorter than R^{-1}, then we will observe the T_1 values of the monomer (14). Intermediate values of lifetime relative to R^{-1} result in both monomeric and associated species contributing to the observed T_1 value. If the results presented here represent the rotation of a monomer (without specific solvation) then the degree of anisotropy from volume considerations would have a maximum value of $R_1/R_2 = 1.5$ and it would be reasonable to assume that the inertia and diffusion axes are coincident. It is possible that **1** (in acetone), **5**, **7**, and **10** rotate essentially as monomers since the degree of anisotropy is small. The compounds **1** (in $CDCl_3$), **2**, and **6** are observed as associated species either due to solute–solute interactions or strong solvation. Both interactions will be centered at oxygen and it is therefore reasonable to assume that oxygen is on the principal axis of diffusion. The actual degree of anisotropy (R_1/R_2) depends on many factors. These include the type of association, the lifetime of the associated species relative to R^{-1}, the barrier to rotation about the C—O bond, and also the strength of solvent–solvent interactions. It is thus not prudent to discuss the type of associated species formed from a simple T_1 measurement.

The conclusion that can be drawn is that the most probable principal axis of the diffusion tensor is that which passes through oxygen and the centre of mass of the molecule. The difference between calculated and experimental values, using this axis, is within experimental error (10%) for all carbons in all molecules. Use of *A* or *B* does not result in a significant variation in R_2 for the compounds **1–5** nor does the use of *B* or *C* result in a large difference for R_2 in **6–10**. The variation in R_1 is more significant (up to 30%).

Methyl Group Energy Barriers

[c] From Zens and Ellis (3).

riers (V_R) to this rotation are given in Table 3. R_{int} was calculated using eq. [3] modified to take into account the anisotropy in the overall motion (16). The barriers were then calculated using $R_{int} = R_0 e^{-V_R/RT}$ where R_0 is given by

$$R_0 = \frac{3}{2}\sqrt{\frac{kT}{I}}$$

and I is the moment of inertia. The barriers are recorded for C—C—H angles of 109.47° and 112° since the latter is the value obtained from a neutron diffraction study of durene (17). Stothers and Blunt (4) have shown the effect of varying this angle on R_{int} and hence on V_R. The effect of angle on the calculated value of R_{int} depends on the ratio $T_1(CH_3)/T_1(CH)$ and becomes more important the larger this ratio becomes. The limit of rapid rotation for an angle of 109.47° is $T_1(CH_3) = 3T_1(CH)$ whereas that for an angle of 112° is $T_1(CH_3) \simeq 4T_1(CH)$.

The barriers to rotation for camphor have been reported previously by Zens and Ellis (3) from a study of T_{ISR} (SR ≡ spin rotation). They obtained a linear plot from a graph of $T_{ISR} = K(1 + \alpha V_R)$ for a number of compounds where V_R was known and then used T_{ISR} to calculate V_R for the CH_3 groups in camphor. More recently, Ellis and co-workers (18) have published a second article in which they showed dependence to be exponential rather than linear. The apparent reason for the difference in behaviour is due to a systematic error in the determination of the nOe in the first publication. The results in the second article do not invalidate the conclusions of the first (18). The results presented by Zens and Ellis (3) for camphor are significantly higher than those presented here. An error in our nOe measurements implies a longer T_{IDD} and hence a smaller V_R, which is opposite to that observed. The calculation of V_R from T_{ISR} data contains a term $I^{3/2}$ which, as shown by Stothers and Blunt (4), will depend on the value of the C—Ĉ—H angle. The values calculated for camphor using an angle of 112° and eq. [13] of ref. 3 are also given in Table 3. The values for C-8 from the two laboratories using 112° as the angle are within experimental error. The calculation from the spin rotation data assumes that the C—Ĉ—H angles of the model compounds are the normal tetrahedral values. Correlation between the values of V_R for C-9 and C-10 occurs at angles of 114° and 113.5°, respectively, with the respective barriers being 10.6 and 10.7 kJ/mol.

It is of interest to compare the T_1 values used in the two sets of calculation. The order is the same, T_1(C-8) < T_1(C-10) < T_1(C-9) as are the dipolar and the spin rotation contributions. An increase in T_{IDD} implies a decrease in V_R. However, an increase in bond angle results in a larger calculated barrier of V_R from T_{IDD} and a smaller barrier when calculated using T_{ISR}. Thus a combination of both T_{ISR} and T_{IDD} will furnish the barrier to rotation about the methyl–carbon bond and the valency angle C—Ĉ—H. The spin rotation contribution becomes more important at higher temperatures and lower

concentrations. The calculations of R_{INT} and V_R for the compounds reported here are fairly insensitive to variations in the C—Ĉ—H angle, since the ratio $T_1(CH_3)/T_1(CH)$ is in the range 0.4–2.4 (7).

The results for the adamantane derivatives, together with those obtained from steroids (8), given in Table 4, show a decrease in the barrier, as the number of 1,3 diaxial methyl–hydrogen interactions increases. The results for **3** show the same trend in that V_R for C-8 is higher than for C-9, which has an additional *pseudo* 1,3-diaxial methyl–hydrogen interaction. The lower barriers in camphor than in the adamantanes is no doubt due to the C-1—C-7—C-4 angle being significantly less than 109.47° in the former. Inspection of the rotation path of a methyl group implies that the energy difference between the preferred (*gauche*) and highest (eclipsed) energy conformation should be independent of the number of such interactions since the 1,3-diaxial interactions are equivalent in both conformations. It is reasonable to assume, however, that an increase in the number of 1,3-diaxial interactions increases the C—Ĉ—H angle. This will have two consequences on the barrier. First of all the calculated value will increase as the C—Ĉ—H angle increases, which will decrease the differences observed as a function of the number of interactions. Calculation of V_R as a function of angle shows that this is not sufficient, however, to account completely for the differences. Secondly, an increase in the C—Ĉ—H angle will decrease the repulsive interaction in the eclipsed conformation and therefore decrease the barrier.

The methyl group rotation barriers in the rigid compounds are essentially the same, whether the methyl group is subjected to 1,3-diaxial (or *pseudo* diaxial) methyl–hydrogen or methyl–hydroxyl interactions. In the steroids the barrier is higher for the methyl–hydroxyl interaction. Ring A of the steroids is quite flexible. The reduction of a keto group to an alcohol increases the barrier to rotation for a methyl group on the carbon β to the substituted ring carbon.

Experimental

All T_1 measurements and data analyses were performed as described previously (14). Sweep widths of 2000 Hz (8 K data points) were used. The errors are estimated to be ±10%, although the relative accuracy is better (±5%). The errors in R_1, R_2, and R_{int} vary, depending on the relative rates. For example, R_{int} for isotropic motion is given by $R_{int} = (48/X - 6)$ where $X = 3T_1(CH)/T_1(CH_3) - 1$. When $T_1(CH_3)$ approaches $\frac{1}{3}T_1(CH)$, X approaches 8, and the term $48/X$ approaches 6. A small percentage error in T_1 causes a large percentage error in R_{int}. An error of ±5% in the T_1 values can lead to an error in R_{int} of ±50%, when the ratio approaches this limit. Small errors in T_1 also result in large errors in R_{int} when $T_1(CH_3)$ approaches $3T_1(CH)$. In the examples described herein, $T_1(CH_3)$ is in the range 0.8–2.4 $T_1(CH)$ and errors of ±5% in $T_1(CH_3)$ result in average ±10% error of R_{int}. The average overall error in R_{int} is then ±15% and that in V_R ±5%.

The nOe measurements were obtained using the suppressed nOe technique (*1a*). Only hydrogen-bearing carbons were examined and the nOe was in all cases 2.0 ± 0.1. A good indication of a methyl group possessing an nOe of less than 2.0 in reasonably sized molecules can be ascertained from comparisons of peak areas of the signal corresponding to the methyl group carbon to those corresponding to methylene and methine carbons. All nOe and T_1 measurements were performed at 32°C.

The compounds used were either obtained from commercial sources or prepared using literature methods. Compounds **1–3** and **5** were commercial samples. Compound **4** was obtained by $LiAlH_4$ reduction of **5** (19). The preparation of compounds **6** and **7** was reported previously (20). Compounds **9–11** were prepared as described by McKervey *et al.* (21).

The ^{13}C nmr chemical shifts were assigned according to literature values, **1–5** (22); **6**, **7** (20). The spectra for the other compounds were assigned using standard techniques such as off-resonance decoupling, $Pr(fod)_3$ induced shifts, and comparison with other adamantane derivatives. The recorded shifts are found in Table 5.

TABLE 5. Chemical shift data[a] for compounds **8–10**

YUNKO LEE, LEONARD W. REEVES, and ALAN S. TRACEY. Can. J. Chem. **58**, 110 (1980).

Nematic lyotropic liquid crystalline materials, which spontaneously align in a magnetic field (Type II) have been prepared from a mixed detergent system consisting of potassium dodecanoate and decyltrimethylammonium bromide. This system has an advantage that the charge on the interface of the finite disc micelles can be readily varied. Sodium and bromide ion interactions with the interface have been investigated by nuclear magnetic resonance of the ions. Deuterium magnetic resonance spectra of deuteriated water and specifically deuteriated detergent chains have been obtained. The results show that there is a water structure built around the carboxylate headgroups which ceases to be stable when about 30% of potassium dodecanoate is replaced by decyltrimethylammonium bromide. Bromine magnetic resonance studies show that the bromide ion interacts only weakly with carboxylate but indicates, as would be expected, much stronger interaction with the trimethylammonium groups. The sodium ion in contrast was found to bind strongly with carboxylate and weakly with trimethylammonium. The sodium spectra indicate that the association of sodium with carboxylate is complex, involving two specific binding sites. Deuterium spectra from deuteriated hydrocarbon chains are interpreted in terms of the motional freedom of the individual chains. The results re-emphasize that the motional properties of a particular hydrocarbon chain of an amphiphile in the micellar bilayer is determined to a large extent by its headgroup and that the behaviour of one chemical species cannot be inferred from that of another.

YUNKO LEE, LEONARD W. REEVES et ALAN S. TRACEY. Can. J. Chem. **58**, 110 (1980).

On a préparé des composés à cristaux liquides du type nématique et lyotropique, qui s'alignent spontanément dans un champ magnétique (type II), à partir d'un mélange de détergents formé de dodécanoate de potassium et de bromure de décyltriméthylammonium. L'avantage de ce système réside dans le fait que l'on peut facilement faire varier la charge à l'interface des disques finis de micelles. On a utilisé la résonance magnétique des ions pour étudier les interactions des ions sodium et bromures avec l'interface. On a obtenu les spectres de résonance magnétique du deutérium de l'eau deutérée et des chaînes de détergents deutérées d'une façon spécifique. Les résultats indiquent qu'il se forme un arrangement des molécules d'eau autour du carboxylate de la tête polaire et que cette structure perd sa stabilité quand on remplace 30% de dodécanoate de potassium par du bromure de décyltriméthylammonium. Les études de résonance magnétique du brome montrent que les ions bromures sont en interaction faible avec le carboxylate mais comme on s'y attendait, cette interaction est beaucoup plus forte avec le groupement triméthylammonium. On trouve au contraire que les ions sodium sont liés plus fortement au carboxylate et faiblement au groupement triméthylammonium. On interprète les spectres du sodium obtenus à partir des chaînes hydrocarbonées deutérés, en fonction du mouvement libre des chaînes individuelles. Ces résultats mettent d'avantage l'accent sur le fait que les propriétés de mouvement d'une chaîne hydrocarbonée particulière d'un composé amphiphile dans la double phase micellaire sont déterminés dans une large mesure par la tête polaire et que le comportement d'une espèce chimique ne peut être déduit de celui d'une autre.

Introduction

The spontaneous formation of bilayer structures by aqueous dispersions of amphiphiles is a well known phenomenon (1) which was discovered by the colloid chemists (2) interested in soap solutions and their ability to solubilize substances not otherwise soluble in water. The term bilayer has usually been reserved for the lamellar arrangement of two polar interfaces separated by approximately extended hydrocarbon chains (3) between the two interfaces. In this case the bilayer has a plane of symmetry bisecting the distance between the headgroups or polar interfaces. The bilayer concept can be extended to include an axis of symmetry for the bilayer, in which case the interface forms a cylindrical surface, or even a centre of symmetry where there is a spherical shaped interface (4).

Bilayers occur widely in biology (5) and a great deal of current activity derives from this fact. On the one hand chemically homogeneous planar bilayers of lipids (6) or soaps have been studied by physicists (7) interested in the phases formed and state of motion of hydrocarbon chains in these various phases (8). The methods used have with one exception (9) not been addressed, indeed they are often inappropriate, to bilayers which contain more than one chemical component. In this one exception the emphasis of the study was directed toward the provocation of phase changes in bilayer structures where the polar headgroups are homogeneous in chemistry but the chains in a binary mixture have different lengths (9). The biochemical aspects of bilayers are only accessible in systems

where there is a wide variety of lipids, and sometimes proteins as well (5).

The shapes and sizes of bilayer architectures lead to a wide variety of liquid crystalline mixtures (4) and thus the work on bilayers has a strong link with the fluid crystalline state, which is otherwise based on positional and orientational order of molecules rather than micelles (4). Most liquid crystalline manifestations of the hydrophobic effect derive their properties from infinitely repeating structures with positional order (4) such as the L_α, H_α, or isotropic phases (4). The extensive studies from our own laboratories have derived from liquid crystals based on micellar units which have an extended but finite bilayer structure where long range orientational but not positional order is maintained. These materials spontaneously align in magnetic fields, the first such system having been reported in 1967 by Lawson and Flautt (10).

An extensive literature now exists from our previous studies, which have been addressed to several different aspects of bilayer and liquid crystal chemistry. These studies include (*a*) synthesis of new lyotropic nematic phases (11–16); (*b*) the discovery of methods to obtain the structure of ions in fluids (17, 18); (*c*) the solution chemistry of micellar bilayers at the level of segmental motions of hydrocarbon chains (19, 20); (*d*) the study of degree of order of solubilized guests (21, 22); (*e*) the behaviour of ions and water at the micelle interface (23, 24); (*f*) investigation of induced chemical shift anisotropy in ions (25); (*g*) a magnetic classification of the new liquid crystalline materials (11), etc.

The present study of a Type II (11) mesophase is directed both toward the structure of the micelle interface as well as the behaviour of hydrocarbon chain motions in a bilayer micelle. The finite micelle unit is a binary solution of two amphiphiles, with decanol a minor component, added in low concentration in order to sustain the integrity of the same phase. The binary bilayer solution is of special interest because it combines both cationic and anionic polar headgroups and because the mesophase is a novel one.

Type II mesophases that spontaneously align in magnetic fields of a few thousand gauss (11) at room temperature are composed of disc shaped lamellar, but finite, micelles which retain orientational order over long distances. They have negative diamagnetic anisotropy (26). The magnetic field tends to align along the polar interface of the micelle which is of course in a dynamical sense in anisotropic motion about this orientation. The mean direction of the normal to the micelles is the director of the liquid crystal. The nature of the Type II nematic phases is suggested by the evidence of diamagnetic anisotropy (13) and studies of phase diagrams near the related L_α phase (27), but it has been confirmed by the low angle X-ray diffraction studies of Queiroz de Amaral *et al.* (28).

The present investigation includes sodium-23, bromine-79, bromine-81, and proton resonance of ions and deuterium magnetic resonance studies of water (DOH) and specifically and massively labelled hydrocarbon chains. In Type II nematic mesophases composed of sodium decylsulphate, decanol, water, and sodium sulphate the disc micelles are 38 Å in bilayer thickness, greater than 1000 Å in extent, and immersed in an aqueous matrix of about 90 Å in average thickness (28).

Results and Discussion

Water and Ions at the Interface of the Micelle

We have been particularly concerned with two aspects of the properties of nematic bilayer systems. One of these has been the mechanism by which quadrupole splittings arise for normally spherical ions at the micelle interface, the other has been the motional properties of the hydrocarbon chains of the constituent detergents of the anisotropic bilayer solution.

Should sodium quadrupole splittings arise from ion-binding to specific sites then a systematic elimination of such binding sites will give rise to a steady decrease in the sodium quadrupole splitting. A chemical variation of the content of the micelles without a phase change occurring provides a means of accomplishing this. We have found that the potassium dodecanoate of the lyotropic mesophase prepared from potassium dodecanoate/NaBr/D_2O can, within rather broad limits, be replaced with decyltrimethylammonium bromide on a mole for mole basis without provoking a phase change. Each bilayer disc-like micelle is thus a binary solution of two amphiphiles with the possibility of variation of composition in a continuous manner. When this replacement was made, it was found that the sodium quadrupole splitting decreased linearly with decrease in mole fraction of potassium dodecanoate. The splitting becomes zero when about 25% of the dodecanoate has been replaced. The magnitude of the splitting then increases to a maximum when somewhat less than 50% replacement of dodecanoate has occurred. That no phase change was responsible for this behaviour was established by observing the deuterium quadrupole splitting of the D_2O in the sample. The results are displayed in Fig. 1. At the point where the sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

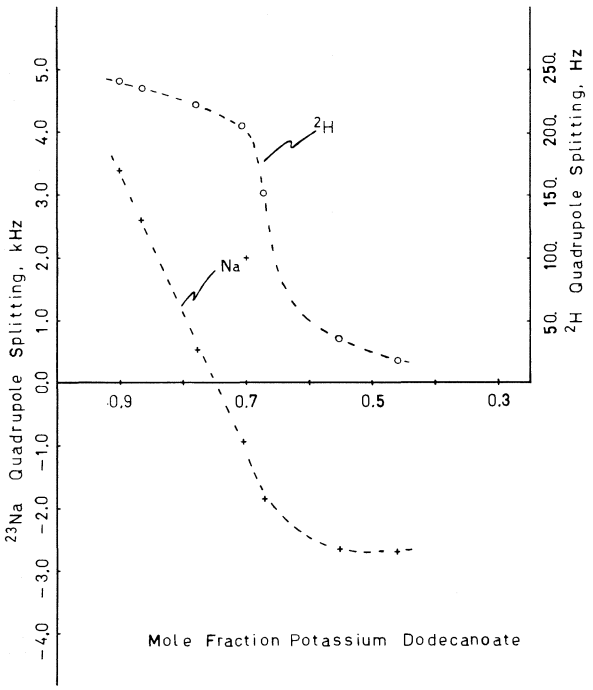

FIG. 1. Sodium and deuterium quadrupole splittings are plotted as a function of the mole fraction of potassium dodecanoate in total detergent where the second component is decyltrimethylammonium bromide. The mesophase was prepared using D_2O.

splitting is zero the deuterium splitting has decreased only slightly from its initial value at high dodecanoate concentration. These results indicate a change in *sign* of the sodium quadrupole splitting. The *absolute* signs of sodium quadrupole splittings have previously been ascertained by utilizing the direction of change in magnitude of the splitting as a function of temperature (29). By using such criteria the sodium splittings in entries 1 and 3 of Table 1 should have opposite signs because the temperature dependencies are opposite. The results displayed in Figs. 1 and 2 show that this is not true because the concentration dependence shows the signs of the sodium splittings to be the same. The mesophases studied here are all Type II nematic liquid crystals made up of disc micelles (11), that is, they align in the magnetic field so that the director is perpendicular to the direction of the field. This means that signs of any splittings are opposite to and the magnitudes one-half as large as those which would normally be assigned for spectra from mesophases which orient with their directors aligned along the magnetic field direction.

A remarkable feature of Fig. 1 is the large decrease in the magnitude of the deuterium quadrupole splitting, from deuteriated water, which begins at about 70 mol% potassium dodecanoate. It is evident that a hydration structure, built around the carboxylate headgroups cannot remain stable after 30% of the dodecanoate in the bilayer has been replaced by the cationic detergent. There follows a rapid decrease to small values of the deuterium splitting. The value obtained at high mole fractions of trimethylammonium in the bilayer, of 18 Hz, is typical of values we have obtained for cationic lyotropic phases prepared from hexadecyltrimethylammonium or hexadecylpyridinium chlorides (14). This small value was found when only about 50% of the dodecanoate had been replaced by trimethylammonium.

With the above results in view it was decided to investigate the behaviour of the hydrocarbon chains in order to study chemical effects on the whole bilayer as well as simultaneously monitoring both the sodium and water splittings. In order to do this, the D_2O in the above phase was replaced with H_2O containing 0.1 wt.% D_2O. Because of deuterium isotope effects, which have not been studied here, the molar proportion of water was varied to accommodate replacement of ^2H with ^1H without causing a phase change. In this second mesophase there was about 18 mol% less H_2O (0.1% D_2O) than D_2O and also there was a 14% decrease in the amount of sodium bromide used. In spite of these changes in the composition of the mesophase, which also change the proportion of K^+ counter- and Na^+ co-ions, the sodium splitting (Fig. 2) goes to zero at the same bilayer composition as in the first phase and the curve follows quite closely that of Fig. 1. This confirms that the integrity of the mesophase has been maintained and indicates that the distribution of sodium and potassium ions between the interface and interstitial water is unchanged.

Since the water deuterium splittings displayed in Fig. 2 appear substantially different from those of Fig. 1, it should be pointed out that the range of stability of this latter mesophase with only two detergents lies in the range of 58 to 78 mol% dodecanoate. Outside this range some decanol is required. The decanol simply stabilizes the type II nematic mesophase, extends its range, and in all cases is a minor component of the constituent micelles. Without decanol an isotropic material is obtained. The sudden decrease in the water splittings of Fig. 1 is obscured in Fig. 2 by the limited range of the stability of the second mesophase.

As indicated by the fifth column of Table 1, the deuterium quadrupole splitting of the water signal for the mesophase composition range of 1.0 to 0.7 mol fraction dodecanoate is insensitive to tem-

TABLE 1. Some parameters[a] obtained for the potassium dodecanoate/decyltrimethylammonium bromide mixed detergent system. Magnitudes of splittings are given and the temperature dependence reflects the direction of change in magnitude as the mesophase warms to magnet temperature

[a]Measured parameters are reproducible to better than 2% of the values reported, except the 74.1 mol% sodium splitting which varies about 10 Hz from phase to phase.

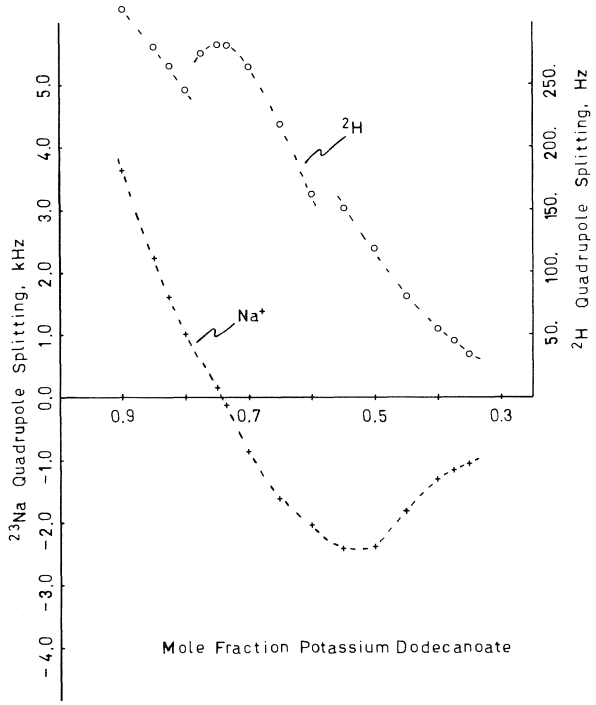

FIG. 2. Sodium and deuterium quadrupole splittings are plotted as a function of the mole fraction of potassium dodecanoate in total detergent. The second detergent is decyltrimethylammonium bromide and the mesophase was prepared using H_2O containing 0.1 wt.% D_2O.

perature changes. This region corresponds to the quadrupole splittings of large magnitude in Fig. 1. The larger magnitude of the D_2O quadrupole splitting throughout this range shows that there is a stable hydration of the carboxylate groups at the bilayer interface. At bilayer compositions less than 65 to 70 mol% dodecanoate, the interface is unable to accommodate tight binding of the water. The water quadrupole splittings decrease substantially in magnitude and simultaneously become quite temperature sensitive with quadrupole splittings increasing 10–20% over a 10° rise in temperature through the range 20–30°C. The headgroup, $-N(CH_3)_3^+$, does not bind the water as strongly because of the more shielded charge and permits water near the interface to tumble in an almost isotropic manner.

In spite of small decanol additions to preserve the Type II nematic phase a rapid drop in water splittings at about 70 mol% dodecanoate in total detergent is still observed (Fig. 2). Increasing the decanol content and slightly extending the range for its usage was sufficient to remove any discontinuity in the nmr parameters, which are plotted in Fig. 2.

The sodium quadrupole splittings on the other hand, (Figs. 1 and 2), are not sensitive to the replacement of D_2O by H_2O. The curves closely follow each other and the zero splitting occurs at the same mole fraction of potassium dodecanoate in the bilayer (~74 mol% in total detergent). The Na^+ and K^+ ions are distributed in the same proportion between the interface and interstitial water and thus the sodium splitting represents the population weighted average for both. Figure 2 shows that there is a decrease in magnitude of the sodium quadrupole splitting in the range 0.5 to 0.3 mol% dodecanoate, a point not evident from Fig. 1 because of restrictions in the range of the desired mesophase.

Changes in the water content of the mesophases have minimal effect on the sodium splittings, but the variation of co-ion concentrations (by using more or less sodium bromide in the preparation of the mesophase) does have a very small but observable effect on the position of zero splitting. With 74.0 mol% potassium dodecanoate and a magnet temperature of 31.4°C a −30 Hz sodium quad-

rupole splitting is observed when sodium bromide is 3.1 wt.% of the mesophase. At twice this value (6.0 wt.%) the splitting is −20 Hz, at 8.7 wt.% it is +72 Hz, and at 11.3 wt.% of the mesophase is +250 Hz. Thus a four-fold increase in the amount of sodium bromide present has changed the sodium splitting by +280 Hz, with the major increase in splitting occurring at high salt concentration, which concentration change incidently also induces a phase transition at 31°C. The temperature dependence of the sodium splittings was used in order to suggest their *relative* signs. As seen from Table 1, at 90 and 75 mol% potassium dodecanoate the magnitudes of the sodium splittings increase with temperature. This is determined by placing a room temperature sample in the probe and observing the change in quadrupole splittings with rise in temperature to that of the magnet. At 65 and 50 mol% potassium dodecanoate the magnitude of the splittings decreases with increasing temperature. At 74.0 mol% potassium dodecanoate and 3.1 wt.% sodium bromide the sodium splitting starts at ~ −225 Hz and increases to −30 Hz. In the 6.0 wt.% mesophase the splitting starts at ~ −190 Hz and rises to −20 Hz. For the 8.7 wt.% phase the splitting starts at ~ −75 Hz, passes through zero (a measured line width of about 20 Hz), then rises to +72 Hz. No attempt to determine an accurate temperature dependence was made. Significant observations concerning these results are that an 8–10 degree rise in temperature has as large an effect on the sodium splittings as has a change in sodium bromide concentration from 3.1 to 11.3 wt.% of the mesophase and also that the direction of change is the same in both cases.

The small deviations from zero with large change in concentration of sodium ions shows that sodium ions not residing in the interface region of the micelle, i.e., those located in the interstitial water, have a very small or zero quadrupole splitting corresponding to almost isotropic sodium ion. As a consequence, exchange with those ions located in the interface has a minimal effect on the zero position. In this regard it should be noted from Fig. 2 that when the detergent interface of the micelle has a large positive charge, the sodium quadrupole splittings are about −1 kHz. In cationic mesophases prepared from hexadecyltrimethylammonium bromide or hexadecylpyridinium chloride, sodium splittings are typically in the order of +0.7 to +1.2 kHz (14). Clearly this shows that the induced quadrupole splitting for sodium ions becomes small when the sodium is combined with a micelle structure whose charge limit corresponds to a cationic detergent interface.

The description of the variation of the sodium quadrupole splitting as the amphiphile composition of the bilayer is varied *requires* at least three well designated sites for the location of the sodium ion. We propose that the three sites correspond to the following. In site I the sodium ions are located mainly within the plane of the interface, their location being determined by hydrogen bond interactions between the hydration sphere of the sodium and two carboxylate residues. With the partial replacement of carboxylate by trimethylammonium some of these bridging sites are no longer available and they are replaced by weakly hydrated sites involving a single carboxylate group. In this case the sodium ions are displaced from the plane of the interface but are still bound to it via the single carboxylates. In the third site sodium ions are remote from the interface region in an aqueous environment. The observed quadrupole splitting is then a population weighted average of splittings for the three sites. In the population weighted average the sodium and potassium ions are included because their distribution between interface and interstitial water is the same. The sign of the quadrupole splitting at each site is determined by the average orientation of the constraint axis as in eq. [1]

$$[1] \quad \Delta\gamma_{Na} = 2Q_{Na}\tfrac{1}{2}(3\cos^2\phi - 1)S_{con}$$

where $\Delta\gamma_{Na}$ is the sodium quadrupole splitting, Q_{Na} the sodium quadrupole coupling constant at the site in question, and ϕ is the angle between the constraint axis and direction of the electric field gradient. S_{con} is the order parameter describing the alignment of the constraint axis and is given by $\frac{1}{2} \times \langle 3\cos^2\theta - 1\rangle$ where the angular brackets indicate a value averaged over all θ where θ is the instantaneous angle between the constraint axis and the magnetic field. As the angle ϕ changes, the value of $\frac{1}{2}(3\cos^2\phi - 1)$ can change sign and consequently so will the sodium quadrupole splitting, $\Delta\gamma_{Na}$.

Collecting together the two angular terms of eq. [1] we can rewrite it in a simplified manner as

$$[2] \quad \Delta\gamma_{Na} = 2Q_{Na}S$$

Taking into account a multisite model we have $\Delta\gamma_{Na}$ as a summation over X_i, the fraction of molecules in site i as

$$[3] \quad \Delta\gamma_{Na} = 2\sum_i X_i Q_i S_i$$

or equivalently we can write for the case of the particular situation here that

$$[4] \quad \Delta\gamma_{Na} = X_I\Delta\gamma_I + X_{II}\Delta\gamma_{II} + X_{III}\Delta\gamma_{III}$$

where $\Delta\gamma_I$, $\Delta\gamma_{II}$, and $\Delta\gamma_{III}$ are quadrupole splittings characteristic of the individual sites.

For personal use only.

From Figs. 1 and 2 a value of +5.8 kHz for the value of $\Delta\gamma_{Na}$ in a pure dodecanoate mesophase can be estimated and since X_{II} is assumed to be zero in our model on a pure dodecanoate interface this value is given by

$$[5] \quad \Delta\gamma_{Na} = X_I\Delta\gamma_I + X_{III}\Delta\gamma_{III}$$

From the Experimental it is seen that there are 2.980 sodium and potassium ions for 2.105 carboxylate headgroups. If we make the reasonable assumption that on an average one carboxylate accommodates one sodium or one potassium ion then $X_I = 0.71$ and $X_{III} = 0.29$. We have shown that sodium and potassium ions are sufficiently alike that there is no preference for one over the other in any of the three sites. The sodium quadrupole splitting then monitors the mean location of either ion. $\Delta\gamma_{III}$ must be estimated but it should correspond reasonably closely to the observed splittings for the cationic mesophases prepared from hexadecyltrimethylammonium for which splittings of ~0.90 kHz were obtained (30). Using these numbers we can calculate that the characteristic coupling for site I is +7.8 kHz. A characteristic value for $\Delta\gamma_{II}$ is more difficult to assess. In our model, the replacement of a dodecanoate ion by a decyltrimethylammonium ion should result in two alkali metal ions being displaced to a site II. The model also predicts that there are no alkali metal ions in site I when 50% of the dodecanoate has been replaced by decyltrimethylammonium. It is reasonable to assume an interface of alternating negative and positive charge arrangements rather than any appreciable two dimensional phase separations giving areas of negative and positive charges. Consequently the sodium splitting in the bilayer with no net charge can be written as

$$[6] \quad \Delta\gamma_{Na} = X_{II}\Delta\gamma_{II} + X_{III}\Delta\gamma_{III}$$

From the observed values for $\Delta\gamma_{Na}$ of −2.6 kHz (Figs. 1, 2) and the appropriate X_{II} and X_{III} (Experimental) the characteristic splitting for site II is −5.5 kHz. Thus the characteristic splittings for sites I, II, and III are +7.8, −5.5, and +0.9 kHz respectively. It is possible to test our model by calculating the mole fraction of dodecanoate in total detergent at which a zero sodium splitting occurs, and to compare this to the experimental value. In the general case corresponding to our model, eq. [4] can be rewritten as

$$[7] \quad \Delta\gamma_{Na} = [\Delta\gamma_I C_D(3x - 2) + 2\Delta\gamma_{II}C_D(1 - x) + \Delta\gamma_{III}C_E]/[xC_D + C_E]$$

where x is the mole fraction potassium dodecanoate, C_D is the total number of moles of amphiphile, and C_E is the number of moles of the electrolyte (sodium bromide). With $\Delta\gamma_{Na}$ equal to zero and C_D and C_E equal to 2.105 and 0.875 respectively, from the Experimental, and $\Delta\gamma_I$, $\Delta\gamma_{II}$, and $\Delta\gamma_{III}$ taking the previously derived values, the mole fraction, x, calculated is 0.76. This value agrees extremely well with the value actually obtained (Figs. 1, 2) of 0.74–0.75.

A problem with the model adopted is that it assumes that site I in the pure dodecanoate mesophase is fully occupied with alkali metal ions. However, the sodium splitting in the pure mesophase decreases with rise in temperature (Table 1) indicating that some alkali ions are being displaced into either site II or III. The result is that $\Delta\gamma_I$ could be underestimated.

The model also ignores the possibility that site III actually consists of two sites, one containing truly isotropic cations in the interstitial water and one with cations in a diffuse water layer loosely bound to the interface (31). This should be unimportant since the number of excess alkali metal ions and the amount of water present is constant. The division of site III into two sites would probably be required if an attempt to explain the temperature dependence throughout the complete concentration range were made. As previously discussed some sodium ion concentration studies were made in the mesophase region of zero sodium quadrupole splitting. The number of moles of sodium bromide present was varied by a factor of 4, from 0.437 to 1.75 mmol. A positive shift in quadrupole splitting of nearly 300 Hz was observed. The corresponding calculated shift, using eq. [7], was close to 400 Hz. The agreement is good and the discrepancy can probably be accounted for in terms of a truly isotropic region within site III.

The change in sign of the quadrupole splitting on going from site I to II or II to III is described by eq. [2] where S has changed sign because of the displacement of cations from one site to another. In terms of our model, S and thus the induced quadrupole splitting, in a pure dodecanoate mesophase, should be positive in sign. The signs of the other splittings follow as shown in Figs. 1 and 2. The signs of the water splittings have arbitrarily been assigned as positive.

In the hope that bromine magnetic resonance would provide information concerning the interactions occurring for the bromide ion at the micellar interface, both ^{79}Br and ^{81}Br spectra were obtained. Only ^{81}Br parameters are quoted. ^{79}Br magnetic resonance was used as a check whenever required. As a further check ^{23}Na quadrupole split-

For personal use only.

tings were obtained to ensure they corresponded to those of Fig. 2 assuring us of mesophase integrity. At a concentration of 90 mol% potassium dodecanoate in total detergent, ^{81}Br had a small quadrupole splitting of 15.5 ± 0.1 kHz. As can be seen from Fig. 3, the bromine transitions were well resolved. It is worth mentioning that the chemical shift of this bromide ion is 90 ± 40 Hz from that of the bromide ion in a concentrated aqueous sodium bromide solution. In view of the extreme sensitivity of bromine chemical shifts to solvent environment, this small shift indicates an almost isotropic aqueous environment. At 100, 74, and 65 mol% of dodecanoate, ^{81}Br quadrupole splittings of 10.2 ± 0.1, 30.6 ± 0.2, and 30.4 ± 0.2 kHz respectively were obtained while a 74 mol% mesophase containing one-half the normal sodium bromide concentration gave an ^{81}Br splitting of 21.7 ± 0.2 kHz. Substantial broadening both of the centre and outer transitions over those of Fig. 3 both in ^{79}Br and ^{81}Br was observed as the proportion of decyltrimethylammonium bromide was increased. With 50 and 35 mol% of potassium dodecanoate the central transitions of the triplet were 3.3 and 4.4 kHz wide respectively and the outer transitions extremely difficult to observe (see Table 1). Sodium transitions were, under identical conditions (i.e., nothing changed but the transmitter frequency), as sharp as was normally found. It is known that ^{81}Br quadrupole coupling constants are typically in the order of 300–400 MHz (31, 32) although it has been estimated that $^{81}Br^-$ bound to $-N(CH_3)_3^+$ headgroups has a quadrupole coupling constant of 1.8 MHz (30). In either case the results here indicate that bromine interacts weakly with dodecanoate headgroups, behaving in a near isotropic manner when no decyltrimethylammonium is present but behaving more and more anisotropically as the decyltrimethylammonium content is increased. The increased broadening of the bromine transitions with increased decyltrimethylammonium content can be attributed to more efficient relaxation of the bromine nucleus as interactions with the increasingly positively charged interface become more important (30), a mechanism which leads also to the enhanced quadrupole splittings. These results provide no evidence that the bromide ion undergoes complex interactions similar to those of the sodium ion.

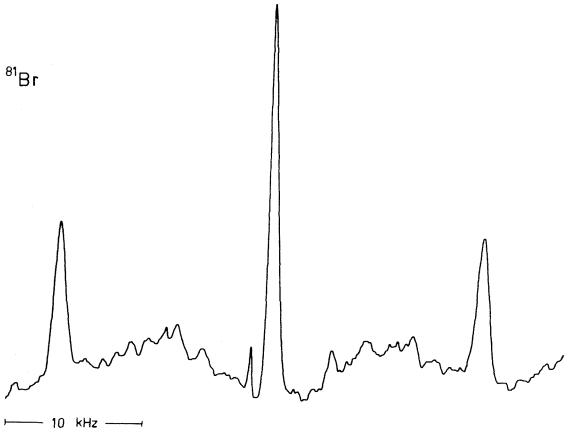

FIG. 3. An ^{81}Br spectrum taken at a mesophase composition of 90 mol% potassium dodecanoate (see Fig. 2) in the total detergent.

Another negatively charged ion which possibly could help resolve the problems of ion-interface binding is acetate. In this case the anisotropic motion of the ion can be measured through the proton–proton or proton–carbon dipolar interactions. The dipolar coupling, D_{HH}, is given by eq. [8].

$$[8] \quad D_{HH} = \frac{h \cdot \gamma_H^2}{4\pi^2 r_{HH}^3} S_{C_3}$$

S_{C_3} is the degree of alignment of the major axis of the acetate ion, γ_H is the magnetogyric ratio for protons, r_{HH} is the proton internuclear distance and h is Planck's constant. In conjunction with the acetate dipolar splittings both ^{23}Na and ^{2}H quadrupole splittings were obtained. The composition of the first set of mesophases studied was potassium dodecanoate/decyltrimethylammonium bromide/sodium acetate of molar proportions 1.17:1.17:1.0 with D_2O content varied between 51.2 and 61.3 wt.% of the mesophase. The results are shown in Fig. 4. Of major significance in these results is the fact that the ratio of quadrupole splittings of sodium to deuterium remains relatively constant, at least to very high water content. On the other hand, the ratio of the sodium or deuterium splitting to the acetate splitting decreases with water content. This is seen from the ratios entered into Table 2. The linearity between the sodium and deuterium quadrupole splittings can be explained if it is assumed that the sodium and the water splittings originate from a common interface interaction involving both species. On the other hand, the results for the 90 mole fraction dodecanoate micelle produced no linearity between any of the parameters measured (Table 3). These results give support to the three-site model for the behaviour of the sodium ions. In this model those ions in site II will behave differently with respect to water than those at site I. There is no evidence that the ^{81}Br splittings undergo a sign change and investigation of ^{13}C acetate unequivocally shows that D_{HH} does not undergo a change in sign.

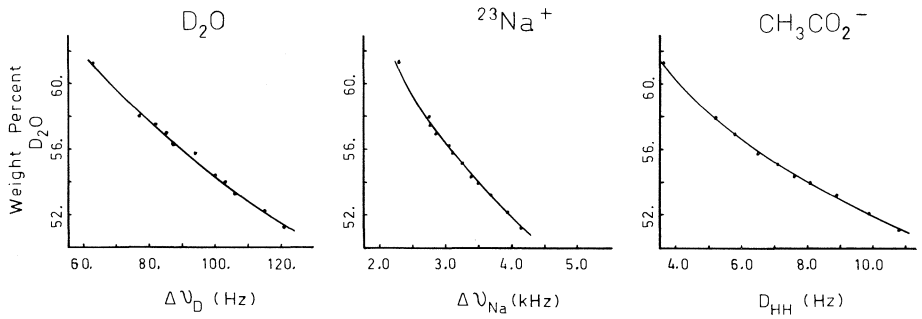

FIG. 4. Quadrupole splittings (^2H, ^{23}Na) and dipolar coupling (D_{HH}) in acetate ion plotted as a function of water content of the mesophase. Absolute values are plotted.

TABLE 2. Nuclear magnetic resonance parameters, $\Delta\nu_D$ deuterium splitting for D_2O, $\Delta\nu_{Na}$ for sodium, and D_{HH} the intramethyl proton dipole–dipole coupling for acetate ions. The values for the splittings at the various concentrations of D_2O were taken from the smooth curves of Fig. 4. The mesophase compositions are given in the text. Ratios of nuclear magnetic resonance parameters are listed in the last columns

In the hope that the acetate ion might provide further information, the vibrationally uncorrected structure of the methyl group has carefully been determined at various molar ratios of potassium dodecanoate to decyltrimethylammonium bromide. The results are given in Table 4 which also includes a structure determined for acetate ion in a cationic phase prepared from decylammonium chloride (24). An HCH angle of 109.9° within the error of all measurements was obtained. This is important because it establishes that the extremely small dipolar couplings observed here derive from a truly small order parameter rather than from an average between two large parameters of opposite sign. This latter averaging often occurs in thermotropic systems and leads to the determination of anomalous geometries, chemical shift anisotropies, and quadrupole coupling constants (33). The absence of such averaging for acetate and the obvious presence of it for sodium indicates clearly that the interaction sites occupied by the positively charged sodium ions are very different from those of the negatively charged acetate.

The Hydrophobic Region of the Micellar Bilayer

Deuterium quadrupole splittings from deuterium labelled hydrocarbon chains provide information concerning the non-aqueous region of the bilayer. Deuterium quadrupole splittings have been assigned to all positions in the dodecanoate, decyltrimethylammonium, and decanol chains. Assignments were made by preparing specifically deuteriated compounds and using those splittings to assign resonances from perdeuteriated species. Four mesophases were thoroughly investigated. They were: (1) 90 mol%, (2) 74 mol%, (3) 50 mol%, and (4) 45 mol%, potassium dodecanoate. Table 5 gives the collected results of the measurements. All values are normalized to an average ^2H splitting for the $—N(CD_3)_3^+$ headgroup of deuteriated decyltrimethylammonium, a small amount of which was incorporated into all mesophases. This was done because the CD_3 splitting varied slightly from sample to sample. The most obvious observation which can be made from Table 5 is that the magnitude of the quadrupole splittings does not change a great deal throughout the range studied, i.e., the average

alignment of the components of the hydrophobic region at 90 mol% dodecanoate is not much different from the alignment at 74, 50, or 35 mol%. A second general observation is that the quadrupole splittings are very sensitive to the nature of the headgroup on the hydrocarbon chain, and that this sensitivity is propagated even down to the terminal position of a chain at least ten carbons long. This is a point well worth stressing since it is clear that if information concerning a particular species in a bilayer is desired one should not base conclusions on observations made on closely related compounds in the same bilayer.

It is interesting in this regard to note the relative change in magnitude of the quadrupole splitting from the decyltrimethylammonium and dodecanoate ions labelled at the α position. The values go in the order of 11, 17, 40, and 50% larger quadrupole splitting of dodecanoate over decyltrimethylammonium for the phases of 90, 74, 50, and 35 mol% dodecanoate respectively. Decanol shows an opposite behaviour being 21% greater at

90 mol%, only 96% as large at 50 mol% and dropping to 89% of the dodecanoate splitting at 35 mol%. These results are illustrated by Fig. 5. Only the two extremes are shown, 90 mol% (Fig. 5*A*) and 35 mol% potassium dodecanoate (Fig. 5*B*).

The degree of order S_i, of a carbon–deuterium bond in the hydrocarbon component of the bilayer derives from motions affecting the chain as a whole, as well as from motions particular to the given methylene segment containing that bond. Consequently the order parameter measured is a product of two such parameters which are related to the deuterium quadrupole splitting observed, by eq. [9]

$$[9] \quad \Delta\gamma_i = \tfrac{3}{2}Q_D S_i = \tfrac{3}{2}Q_D S_i(\mathrm{RB}).S_i(\mathrm{I})$$

S_i(RB) is associated with rigid body motion and S_i(I) with the intrinsic degree of alignment. Contributions to rigid body motion are motions such as oscillations of the disc-like micelle, chain diffusion, and chain rotations, which affect all chains of the same chemical identity equally. The major motions reducing S_i(I) from the value of 1 are *trans/gauche* rotations (34, 35) which can in general have a different effect on each methylene segment. The rigid body motion of the chain does not affect individual methylene segments differently and as a conse-

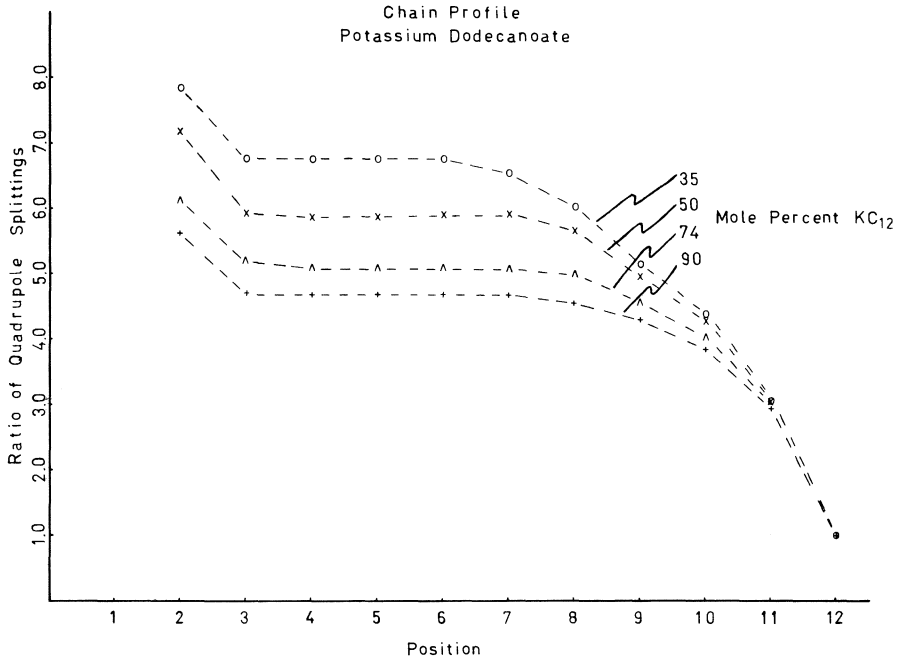

FIG. 6. The chain order profiles for potassium dodecanoate at the various mesophase compositions shown (refer to Fig. 2). KC_{12} refers to potassium dodecanoate and the parameter plotted is $\Delta\nu_x/\Delta\nu_{12}$ versus methylene position (x).

quence, by division of one quadrupole splitting by another from a position within the same hydrocarbon chain, the expression [10] is obtained. Any set of ratios of deuterium splittings provides

$$[10] \quad \Delta\gamma_i/\Delta\gamma_k = S_i(\mathrm{I})/S_k(\mathrm{I})$$

the same information. We use the splitting of the deuteriomethyl group as the reference and compare all the splittings from the same chain to it. The results provide a profile for the relative motions of the various methylene segments of the hydrocarbon chain. This incidentally provides a simple test to determine whether changes in magnitude of quadrupole splittings as a function, say, of water content or temperature variation reflect changes in rigid body motion rather than changes in the internal motions of the individual detergent molecules. In the first case the profile remains constant, and in the second it should change.

Figures 6, 7, and 8 show the chain profiles obtained for the various components of the bilayer. A comparison of the figures shows that there are large differences in the shape of the profiles between the three components. On the other hand, large changes in the composition of the mesophase bilayer have rather small effects on the shape of profiles for chains of the same chemical identity, the major effect being a scaling of all segment splitting values with respect to those of the terminal methyl group. Chain profiles are determined *mainly* by the headgroup and often rather large changes in bilayer composition have minimal effect on the profile as is observed in the figures. We have never observed the same degree of order profile from aliphatic chains with different headgroups. The headgroup of the hydrocarbon chain is anchored more or less securely in the interface region of the micelles of the mesophase by its own peculiar hydration and counter ion interactions. Chemically distinct headgroups are anchored differently. This is an important experimental result bearing on bilayer solution chemistry.

Equal quadrupole splittings, three times greater than for the terminal methyl group, would be obtained for the methylene deuteriums if the hydrocarbon chain were extended, rigid, and rapidly rotating about its long axis. In this case the profile would be perfectly flat until the methyl group is reached. The hydrocarbon chain of course is not rigid and internal rotations about carbon–carbon bonds do occur. It has been shown that a flat chain profile is maintained if rotations occur as complementary *gauche* pairs which cause formation of "kinks" ((±)-*gauche*/*trans*/(∓)-*gauche* sequences) and "jogs" ((±)-*gauche*/multiple *trans*/(∓)-*gauche* sequences), which oscillate along the length of the chain (34, 35). Random single *gauche* rotations produce a rapid decrease in the quadrupole splittings and since they occur most easily near the terminal carbons of the hydrocarbon

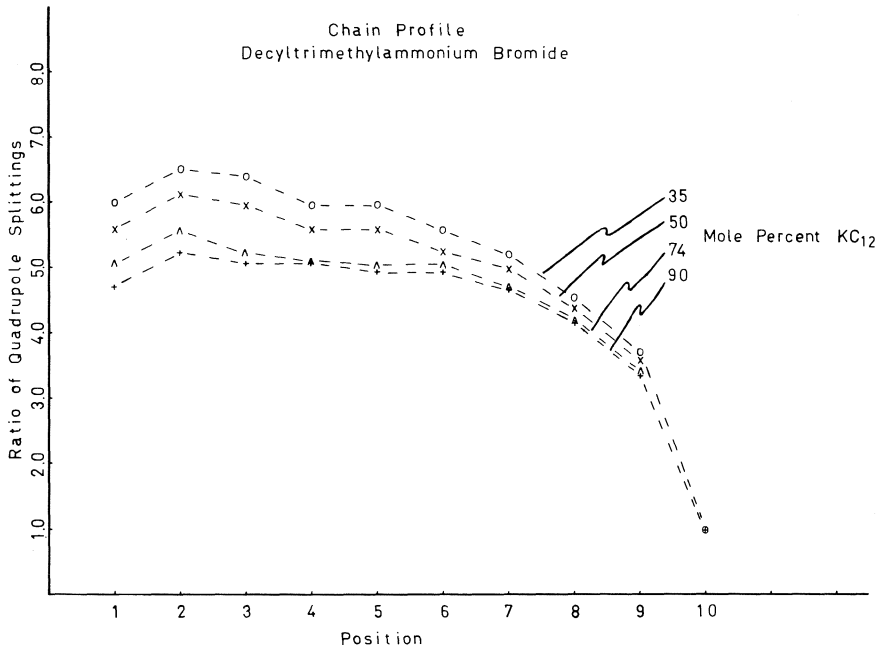

FIG. 7. The chain order profiles for decyltrimethylammonium bromide at the mesophase compositions shown (refer to Fig. 2). $\Delta\nu_x/\Delta\nu_{10}$ versus methylene position (x) is the parameter plotted. KC_{12} refers to potassium dodecanoate.

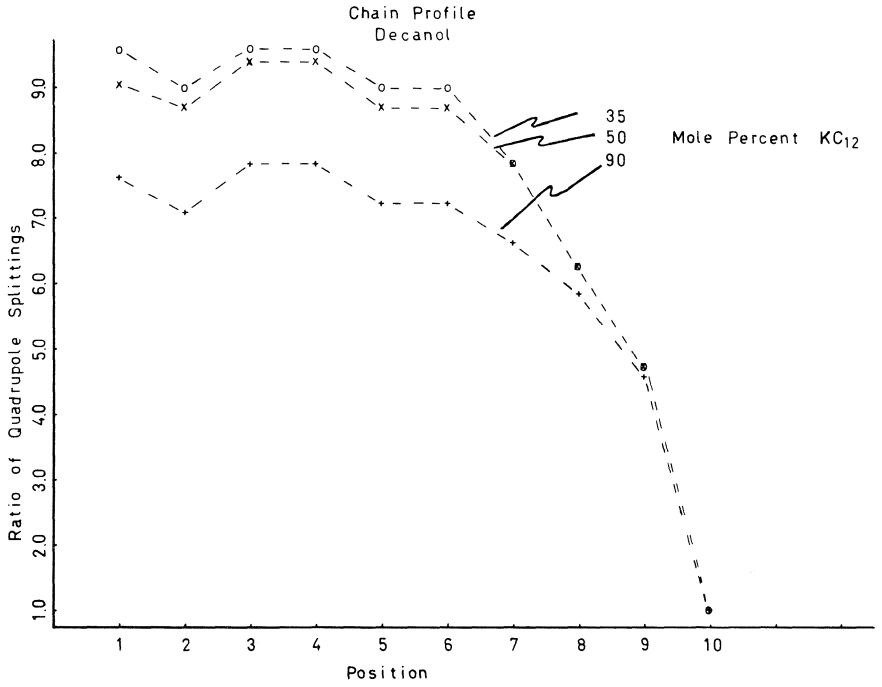

FIG. 8. The chain order profiles for decanol at the various mesophase compositions shown. KC_{12} refers to potassium dodecanoate and the parameter plotted is the methylene position (x) versus $\Delta\nu_x/\Delta\nu_{10}$.

chains the chain profile usually has a plateau-like region extending from the initial methylene group then terminated by a rapid decay resulting in a methyl splitting much less than one-third that of the plateau value. This behaviour is clearly seen for the profiles of Figs. 6, 7, and 8. If the plateau region of the profile is not flat it will be because the "kinks" and "jogs" are preferentially formed at one posi-

tion rather than another. Formation of a "kink" results in certain carbon–deuterium bonds being directed at different average angles with respect to the magnetic field of the nmr spectrometer, thus giving rise to varying quadrupole splittings for different deuteriums. These differences will disappear only if averaging over all positions is complete. The most obvious cause of positions of preferential formation of "kinks" or "jogs" is that the initial segments of the hydrocarbon chain are being held by the headgroup at an angle different from that which would be preferred in the absence of such a constraint. The preferred angle is generally accepted to be perpendicular to the interface but this has been questioned (36, 37, 38). In this regard it has been found that increasing the length of the hydrocarbon chain but retaining the same headgroup has only a small effect on the chain profile, within the relevant region (38).

Examination of Fig. 6 provides considerable information concerning the behaviour of the dodecanoate hydrocarbon chain. Characteristic of the four profiles is an initial large value of the quadrupole splitting at position 2 dropping considerably to a plateau of values which extends, in the case of the 90 mol% profile, essentially to carbon 8. With increase in decyltrimethylammonium content, this plateau embraces fewer segments, finally extending to carbon 6 for the 35 mol% profile. These results show that the dodecanoate chain is more constrained (i.e., the ratio of plateau/terminal CD_3 splitting decreases) with respect to neighbouring chains at the higher concentrations of dodecanoate.

The formation of single *gauche* rotations near the nonpolar end of the chains is interpreted as less probable when the chains are more tightly packed. An extended chain which is rotating freely about its long axis has a theoretical ratio of 3 between chain methylene deuterium splittings and the terminal $-CD_3$ doublet separations. A ratio which approaches 3 for the methyl $-CD_3$ group to the $-CD_2$-plateau value indicates a small population of single *gauche* rotamers as does an extension of the plateau region to include more segments. In Fig. 7 the decyl chain of the substituted ammonium ion behaves in a similar manner to the profiles of the dodecanoate chains shown in Fig. 6, a minimum probability of *gauche* rotations in both chains occurring at 90 mol% dodecanoate bilayers.

Experimental

Spectra

Deuterium and sodium nuclear magnetic resonance spectra were obtained either from a Varian VF-16 wide-line nmr spectrometer (results in Figs. 1 and 4, and Table 2) observing at 4.7 and 8.1 MHz respectively, or from a Bruker SXP FT spectrometer (results in Figs. 2, 5, 6, 7, and 8, and Table 4) observing at 9.2 and 15.8 MHz for deuterium and sodium. ^{79}Br and ^{81}Br spectra were obtained using the SXP spectrometer at carrier frequencies of 15.1 and 16.2 MHz respectively. The maximum spectral window on the FT spectrometer is 50 kHz. In the case of large spectral widths, transitions which were folded were unambiguously identified by changing the carrier frequency and observing the relative shifts in peak positions. Proton spectra were recorded using a Varian HA-100 spectrometer operating in the locked mode.

Materials

The lyotropic mesophases which were used to obtain the results in Figs. 2, 3, 5, 6, 7, and 8, and Table 4 had the following composition, in millimoles for each component: total detergent/sodium bromide/water (0.1 wt.% D_2O)/decanol (maximum) = 2.105:0.875:49.0:0.42. The mole fraction of potassium dodecanoate in total detergent was varied from 100 mol% to 35 mol%, consequently the proportion of decyltrimethylammonium bromide varied from 0 to 65 mol%. Decanol was required in the ranges (*a*) 100.0–77.5 mol% potassium dodecanoate, 0.40–0.0 mmol decanol; (*b*) 57.0–35.0 mol% potassium dodecanoate, 0.0–0.42 mmol decanol.

A second series of mesophases containing D_2O instead of H_2O was utilized to obtain the results for Fig. 1. The molar proportions were: total detergent/sodium bromide/D_2O = 2.105:1.02:60. The compositions of all other mesophases are given in the text.

The specifically deuteriated compounds were prepared by standard techniques from commercially available materials (19, 39). Perdeuteriated decanol and decyltrimethylammonium bromide were prepared from perdeuteriated decanoic acid by the following sequence of elementary reactions.

[11] $CD_3(CD_2)_8C(=O)OH \xrightarrow{SOCl_2} CD_3(CD_2)_8C(=O)Cl \xrightarrow{LiAlD_4} CD_3(CD_2)_8CD_2OH$

[12] $CD_3(CD_2)_8CD_2OH \xrightarrow{TsCl/pyridine} CD_3(CD_2)_8CD_2OTs \xrightarrow[MeOH/H_2O]{NaN_3} CD_3(CD_2)_8CD_2N_3 \xrightarrow{LiAlH_4} CD_3(CD_2)_8CD_2NH_2$

[13] $CD_3(CD_2)_9NH_2 \xrightarrow[MeOH/NaHCO_3]{CH_3I} CD_3(CD_2)_8CD_2N(CH_3)_3I \xrightarrow[MeOH]{Ag_2O} CD_3(CD_2)_8CD_2N(CH_3)_3OH \xrightarrow{HBr} CD_3(CD_2)_8CD_2N(CH_3)_3Br$

Overall yields of the pure decyltrimethylammonium bromide (recrystallized from ethylacetate/ethanol (~20/1)), ranged between 50 and 70% from the starting decanoic acid. Where required, steps of the reaction sequence were checked for completion using thin layer chromatography. Iodine vapour or 10% sulfuric acid and heat were used to visualize the plates.

Perdeuteriated decanoic and dodecanoic acids were prepared using an adaption of the process of Stenhagen and Dinh-Nguyen (40) as has been described (14). After one cycle the deuterium enrichment was found to be approximately 90%.

Vinyl ether hydrolysis. XIII. The failure of I-strain to produce a change in rate-determining step[1]

Y. CHIANG, W. K. CHWANG, A. J. KRESGE,[2] AND S. SZILAGYI

Department of Chemistry, University of Toronto, Scarborough College, West Hill, Ont., Canada M1C 1A4

Received July 30, 1979

Y. CHIANG, W. K. CHWANG, A. J. KRESGE, and S. SZILAGYI. Can. J. Chem. **58**, 124 (1980).

Rates of hydrolysis of 1-ethoxy-3,3,5,5-tetramethylcyclopentene and 1-methoxy-2,3,3,5,5-pentamethylcyclopentene measured in mineral acid and formic and acetic acid buffer solutions show general acid catalysis and give large kinetic isotope effects in the normal direction ($k_H/k_D > 1$). This indicates that these reactions proceed by the conventional mechanism for vinyl ether hydrolysis in which proton transfer from the catalyzing acid to the substrate is rate-determining, and that the I-strain in these substrates is insufficiently great to shift the reaction mechanism to rapidly reversible substrate protonation followed by rate-determining hydration of the ensuing cationic intermediate.

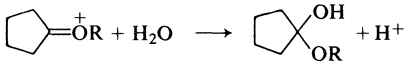
Y. CHIANG, W. K. CHWANG, A. J. KRESGE et S. SZILAGYI. Can. J. Chem. **58**, 124 (1980).

On a mesuré les vitesses d'hydrolyse de l'éthoxy-1 tétraméthyl-3,3,5,5 et du méthoxy-1 pentaméthyl-2,3,3,5,5 cyclopentène en utilisant un acide minéral et des solutions tampons d'acides formique et acétique. Ces vitesses montrent l'effet d'une catalyse générale par les acides et donnent de grands effets isotopiques cinétiques dans la direction normale ($k_H/k_D > 1$). Ceci indique d'une part que ces réactions se déroulent suivant le mécanisme conventionnel d'hydrolyse d'un éther vinylique dans lequel le transfert d'un proton de l'acide au substrat est l'étape déterminante et d'autre part que la tension I dans ces substrats n'est pas suffisamment importante pour faire évoluer le mécanisme de la réaction vers une protonation réversible du substrat suivie d'une étape déterminante impliquant l'hydratation de l'intermédiaire cationique qui en résulte.

[Traduit par le journal]

The acid-catalyzed hydrolysis of simple vinyl ethers is known to occur through rate-determining protonation of the double bond of the substrate (eq. [1]) followed by rapid hydration of the ensuing carbonium ion (eq. [2]) and subsequent fast breakdown of the hemiacetal intermediate (eq. [3]).

[1] $CH_2{=}CHOR + HA \rightarrow CH_3\overset{+}{C}HOR + A^-$



[2] $CH_3\overset{+}{C}HOR + H_2O \rightarrow CH_3\underset{OH}{C}HOR + H^+$

[3] $CH_3\underset{OH}{C}HOR \rightarrow CH_3CHO + HOR$

There is reason to believe, however, that the protonation step is close to being reversible (1), and in fact a system has been discovered in which the reaction mechanism appears to change from rate-determining protonation in mineral acid solutions to rate-determining hydration preceded by rapid and reversible protonation in carboxylic acid buffers (2).

In an effort to explore this mechanistic change we have been searching, so far in vain, for other examples of rate-determining hydration in vinyl ether hydrolysis (1, 3). We report here the results of an attempt to bring internal steric effects in cyclic substrates, I-strain (4), to bear upon the problem.

The substrates we used are derivatives of 1-alkoxycyclopentene. It is known that eclipsing strain in saturated five-membered carbocyclic systems impedes chemical processes which convert the hybridization of ring atoms from sp^2 to sp^3, and this effect should therefore make the reaction of 1-alkoxycyclopentyl cations with water (eq. [4])

[4] 

more difficult than it would otherwise be. Eclipsing strain is known also to favour introduction of a carbon–carbon double bond into a cyclopentane ring (5), and this effect should therefore facilitate deprotonation of the cation to regenerate vinyl ether (eq. [5]). These two effects taken together can

[5] 

thus be expected to slow hydration relative to deprotonation, and, if the effects are sufficiently great, the result might be a change in rate-determining step.

Our previous work shows that this does not happen with 1-ethoxycyclopentene itself; all of the available evidence indicates that this substrate hydrolyses by the normal rate-determining proton transfer mechanism (6). Substitution of methyl groups for ring hydrogens in this system, however, might increase eclipsing strain significantly, and we have therefore extended our previous work by

examining the behavior of 1-ethoxy-3,3,5,5-tetramethylcyclopentene, **1**, and 1-methoxy-2,3,3,5,5-pentamethylcyclopentene, **2**.

1 **2**

Experimental

Materials

1-Ethoxy-3,3,5,5-tetramethylcyclopentene was prepared from the corresponding ketal, which in turn was made by treating 2,2,4,4-tetramethylcyclopentanone (Chemical Samples Co.) with triethyl orthoformate in ethanol solution in the presence of a catalytic amount of sulfuric acid. Heating this mixture under reflux for one day followed by neutralization of the sulfuric acid (with sodium ethoxide), removal of the solvent, and vacuum distillation of the residue gave a mixture of ketal and vinyl ether which was separated into pure components by gas chromatography. Both products were characterized by nmr and mass spectroscopy; ^{1}H nmr ketal, δ: 3.45 (q, 4H), 1.78 (s, 2H), 1.43 (s, 2H), 1.15 (t, 6H), 1.03 (s, 12H); vinyl ether, δ: 4.02 (s, 1H), 3.63 (q, 2H), 1.55 (s, 2H), 1.25 (t, 3H), 1.05 (s, 12H).

1-Methoxy-2,3,3,5,5-pentamethylcyclopentene was made in a similar fashion from trimethyl orthoformate and 2,2,4,4,5-pentamethylcyclopentanone. In this case, the vacuum distillate contained only the vinyl ether and starting ketone; no ketal was isolated. The starting ketone was prepared by methylating 2,2,-4,4-tetramethylcyclopentanone using methyl iodide and an equivalent amount of sodium hydride. This ketone as well as the vinyl ether were characterized by nmr and mass spectroscopy; ^{1}H nmr ketone, δ: 2.07 (m, 1H), 1.67 (s, 2H), 1.07 (s, 3H), 1.03 (s, 6H), 0.89 (s, 3H), 0.75 (s, 3H); vinyl ether, δ: 3.74 (s, 3H), 1.63 (s, 5H), 1.04 (s, 6H), 1.02 (s, 6H).

Solutions were prepared using best available commercial grades of acids and bases and either deionized H_2O purified further by distillation from alkaline permanganate or D_2O as received (Merck).

Kinetics

Rates of reaction were measured spectroscopically by following the decrease of the intense vinyl ether absorption in the region 200–220 nm. Measurements were made using a Cary 118 C spectrometer with thermostatted cell compartment (25.0 ± 0.02°C). Substrates dissolved in ethanol were added to acid or buffer solutions contained in quartz cuvettes after these solutions had come to temperature equilibrium with the cell compartment; the amount of ethanol used was such that its final concentration in the reaction mixtures was of the order of 0.1%. Both substrates were only very sparingly soluble in water, and care had to be taken to shake the reaction mixtures sufficiently vigorously to effect complete solution.

Data so obtained followed the first-order rate law accurately. Rate constants were evaluated graphically, either using infinite-time readings taken after 10–12 half-lives or, in the case of the slower runs, by the Guggenheim (7) or Swinbourne (8) methods.

Results

1-Ethoxy-3,3,5,5-tetramethylcyclopentene

First-order rate constants for the hydrolysis of this substrate were measured in acetic acid buffer solutions using H_2O and D_2O as the solvents. The data are summarized in Table 1.

These observed first-order rate constants proved to be accurately proportional to acetic acid concentration in buffer solutions of constant hydrogen ion concentration, maintained by keeping the buffer ratio constant, and, when the buffer ratio was changed, the proportionality constant relating observed rate constants to acetic acid concentration remained invariant. This indicates that only the acid component of the buffer and not the buffer base is catalytically effective, which implies that the system is undergoing general acid catalysis. The rate law for such a process is given by eq. [6].

$$[6] \quad k_1 = k_H + [H^+] + k_{HA}[HA]$$

The data were fitted to this expression by linear least-squares analysis, and the results (Table 1) showed good constancy of k_{HA}: $(1.90 \pm 0.05) \times 10^{-1}\ M^{-1}\ s^{-1}$ at a buffer ratio of 1.0 and $(1.91 \pm 0.04) \times 10^{-1}\ M^{-1}\ s^{-1}$ at a buffer ratio of 0.5.

Hydronium ion catalytic coefficients were evaluated from the intercepts of these least-squares

relationships using hydronium ion concentrations calculated from the thermodynamic dissociation constant of acetic acid and activity coefficients for the hydronium and acetate ions recommended by Bates (9). These catalytic coefficients also showed good consistency: $k_{H^+} = (2.67 \pm 0.06) \times 10^2 M^{-1}$ s^{-1} and $k_{H^+} = (2.74 \pm 0.04) \times 10^2 M^{-1} s^{-1}$, indicating that the system conforms to the rate law of eq. [6] quite well.

The data obtained in D_2O solution were treated similarly. The results (Table 1), when combined with those provided by the H_2O measurements, give the following isotope effects: $k_{H^+}/k_{D^+} = 3.32 \pm 0.07$ and $k_{HA}/k_{DA} = 4.88 \pm 0.17$.

1-Methoxy-2,3,3,5,5-pentamethylcyclopentene

Rates of hydrolysis of this substrate were measured in perchloric and hydrochloric acid solutions as well as in formic and acetic acid buffers. The data are summarized in Tables 2 and 3.

In the mineral acid solutions first-order rate constants proved to be accurately proportional to hydronium ion concentration, with no indication of catalysis by water species. Second-order rate constants were therefore evaluated simply by dividing the first-order constants by acid concentration and taking averages of the values so obtained. The results showed good agreement between perchloric and hydrochloric acid solutions: $k_{H^+} = 3.06 \pm 0.08$ $M^{-1} s^{-1}$ and 2.92 ± 0.10 $M^{-1} s^{-1}$, respectively. The measurements in HCl/H_2O and DCl/D_2O gave the isotope effect $k_{H^+}/k_{D^+} = 2.70 \pm 0.12$.

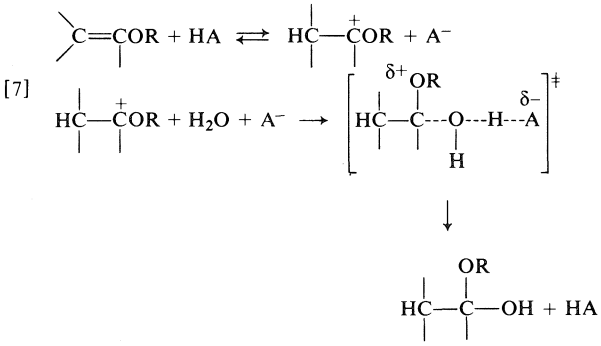
$k_{H^+} = 2.96 \pm 0.02$ $M^{-1} s^{-1}$	

[a]Ionic strength maintained at 0.040 M by adding sodium chloride; indicated error limits are standard deviations of mean values.

The data obtained in acetic acid buffers were treated as described above for the other substrate; this produced a value of $k_{H^+} = 2.96 \pm 0.02$ $M^{-1} s^{-1}$, which is nicely consistent with the mineral acid results. The formic acid solution data, on the other hand, had to be corrected for "buffer failure", inasmuch as significant ionization of this (stronger) buffer acid occurred at the lowest buffer concentrations used, and actual (as opposed to stoichiometric) buffer ratios, and therefore hydronium ion concentrations, consequently did not remain constant along a series of solutions of constant stoichiometric buffer ratio. This correction was performed as before (6*a*) using activity coefficients recommended by Bates (9) and the hydronium ion catalytic coefficients determined in perchloric and hydrochloric acids. This treatment produced a value of $k_{H^+} = 2.99 \pm 0.02$ $M^{-1} s^{-1}$, in very good agreement with results from the measurements in other acids.

Discussion

Reaction Mechanism



The hydrolysis of both of the vinyl ethers examined here shows general acid catalysis. This is the behavior expected for a reaction in which proton transfer from the catalyst to the substrate (eq. [1]) is rate-determining. A process in which proton transfer is rapid and reversible and hydration of the ensuing carbonium ion (eq. [2]) is the slow step would, on the other hand, lead to specific hydronium ion catalysis. The form of acid catalysis observed therefore suggests that the hydrolysis of these substrates proceeds by the conventional

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

mechanism in which substrate protonation is the rate-determining step.

This conclusion is supported by the large kinetic isotope effects found for the hydrolysis of these substrates when the catalyst is the hydronium ion, $k_{H^+}/k_{D^+} \simeq 3$. Isotope effects of this magnitude are to be expected for rate-determining proton transfer from the hydronium ion to a substrate which is a carbon base, and such isotope effects have in fact been found for a number of vinyl ether hydrolyses known to proceed by the conventional, rate-determining proton-transfer mechanism (6*b*). Rate-determining hydration preceded by rapidly reversible protonation, on the other hand, would be expected to give inverse isotope effects, $k_{H^+}/k_{D^+} < 1$, due principally to inverse isotope effects on the reversible pre-equilibrium protonation step. Since this prediction is quite at variance with the experimental findings, reversible protonation followed by rate-determining hydration must be rejected as a mechanistic possibility.

There is, however, a variant of the rejected mechanism which could produce hydronium ion isotope effects of the observed magnitude. In this mechanistic variation, rapidly reversible substrate protonation is followed by a hydration step in which the attacking water molecule gives up one of its protons to a general base simultaneously with C—O bond formation (eq. [7]). The primary isotope effect which such a process might show would offset the inverse isotope effect on the pre-equilibrium step, and the overall isotope effect could well be as great as $k_{H^+}/k_{D^+} = 3$. This scheme would also show overall general acid catalysis, which is consistent with the experimental observation.

[7]

This mechanism, however, is inconsistent with the fact that the isotope effects found for hydration of one of the present substrates, 1-ethoxy-3,3,-5,5-tetramethylcyclopentene, catalyzed by two different acids are both quite large: $k_H/k_D = 3.3$ for the hydronium ion and $k_H/k_D = 4.9$ for acetic acid. It has recently been discovered that isotope effects on proton transfer between electronegative atoms, such as the oxygens of the proton donor and proton acceptor in the scheme of eq. [7] under catalysis by hydronium ion and acetic acid, pass through a very narrow maximum as the pK_a difference between donor and acceptor is changed systematically (10). The width of this maximum is considerably less than the difference of seven pK_a units between the acid strengths of acetic acid and the hydronium ion, and it follows, therefore, that if one of these catalysts shows a large isotope effect in the present reaction operating through the mechanism of eq. [7], the other should not. The mechanism of eq. [7] must thus be inoperative.

Further support for a conventional mechanism with rate-determining substrate protonation comes from the good agreement between the presently observed hydronium ion isotope effects and values expected from a correlation of such isotope effects for a number of other vinyl ether hydrolyses. We found recently that hydronium ion isotope effects for the hydrolysis of some 30 vinyl ethers could be related to the free energies of activation of these reactions using a relationship suggested by Marcus rate theory (6*b*). This correlation predicts $k_{H^+}/k_{D^+} = 3.68$ for the hydrolysis of 1-ethoxy-3,3,5,5-tetramethylcyclopentene, whereas the observed value is $k_{H^+}/k_{D^+} = 3.32$, and it predicts $k_{H^+}/k_{D^+} = 3.06$ for the hydrolysis of 1-methoxy-2,3,3,5,5-pentamethylcyclopentene, whereas the observed value is $k_{H^+}/k_{D^+} = 2.70$.

It can be argued, moreover, that general base-catalyzed hydration of a carbocation such as that shown in eq. [7], would be unlikely in the present situation. Catalyzed hydrations of this kind have been found only in the case of relatively stable cations such as methoxy- or amino-substituted triarylmethyl ions (11), aryltropilium ions (12), and phthalimidinium ions (13). This is presumably because in these cases removal of a proton from the attacking water molecule simultaneously with C—O bond formation avoids generation of an unfavorable reaction intermediate (14); the protonated alcohol which would be formed in the absence of proton removal is less stable than either the carbocation or the alcohol itself, and provision of a route which bypasses this substance removes an unnecessary reaction barrier. The carbocations formed in vinyl ether hydrolysis, however, are considerably less stable than the ions listed above, and it is likely that they are less stable also than the protonated alcohols formed by their hydration. Bypassing these protonated alcohols via general base catalysis would therefore provide no particular mechanistic advantage, and the entropic requirement of a process of higher molecularity would militate against it.

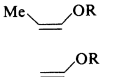
Relative Reactivities

The arguments presented above show that the hydrolysis of the cyclopentenyl vinyl ethers investigated here occurs by the conventional, rate-determining substrate protonation mechanism which operates in the hydrolysis of most other vinyl ethers, and that I-strain has not succeeded in producing a mechanistic change. This result could not have been predicted beforehand, but it can now be rationalized after the fact using data which this study has provided.

1-Ethoxy-3,3,5,5-tetramethylcyclopentene is only slightly less reactive than its unmethylated analog, 1-ethoxycyclopentene; the rate constants for hydrolysis catalyzed by the hydronium ion are 270 M^{-1} s^{-1} and 454 M^{-1} s^{-1} (6*a*) respectively. This amounts to a rate reduction of only 0.59. The smallness of this change suggests that introduction of these four methyl groups into the system does not raise eclipsing strain very much at all, and that there is no appreciable difference in I-strain between 1-ethoxycyclopentene and its tetramethyl analog.



Further substitution of a fifth methyl group has a much greater rate effect: k_{H^+} for 1-methoxy-2,3,-3,5,5-pentamethylcyclopentene is only 2.98 M^{-1} s^{-1}, which makes this substrate 150 times less reactive than 1-ethoxycyclopentene and 90 times less reactive than 1-ethoxy-3,3,5,5-tetramethylcyclopentene. However, not all of this difference can be assigned to an increase in I-strain. The fifth methyl group introduced here is placed on the β-carbon atom of the vinyl ether function where it can stabilize the double bond and reduce the rate of reaction by lowering the free energy of the initial state; such substitution is known to slow vinyl ether hydrolysis in acyclic systems where I-strain is not a factor. Furthermore, the pentamethyl substrate is a methyl vinyl ether whereas the substances with which it is being compared are ethyl vinyl ethers, and methyl vinyl ethers have proved to be less reactive than their ethyl counterparts.

The effect of changing the saturated group from ethyl to methyl can be estimated by comparing rates of hydrolysis of ethyl and methyl vinyl ethers reported in the literature. Data for five such pairs are available; these (Table 4) show rate reductions in the range 0.43 to 0.53 and give an average value of 0.48 ± 0.02.

The effect of β-methyl substitution on double bond stability can also be evaluated by using information from the literature. The data here (Table 5) show significantly different rate retardations for *cis* than for *trans* methyl substitution, which can be understood in terms of unfavorable steric interference between methyl and alkoxy groups in the *cis* isomer. The quantity of interest in the present situation is of course the effect of *cis*-β-methyl substitution, and the data of Table 5 put this rate reduction at 0.31 ± 0.03.

Use of these two factors to correct for the change in saturated alkoxy group and to eliminate the double-bond stabilizing effect gives (1/90)/(0.48 × 0.31) = 0.074 as the rate retardation attributable to the increase in I-strain in 1-methoxy-2,3,3,5,5-pentamethylcyclopentene over that in 1-ethoxy-3,3,5,5-tetramethylcyclopentene. This is considerably greater than the reduction of 0.59 found in

going from 1-methoxycyclopentene to 1-methoxy-3,3,5,5-tetramethylcyclopentene. But the effect is still quite small: a rate factor of 0.074 corresponds to a free energy difference of only 1.5 kcal/mol. This could well be too little to effect a mechanistic change even in the present system where the free energies of the two transition states being affected are presumably quite similar.

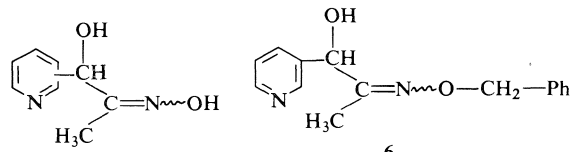
The phenethyl group is a common structural feature present in many classes of drugs such as β-adrenergic blocking agents, bronchodilators, CNS stimulants, and vasoconstrictors (1). To date there have been very few studies involving the synthesis of bioisosteric compounds having the pyridinyl ethyl structural feature (2, 3). The reaction of α-methoxy and α-ethoxyvinyllithium with aryl (alkyl) aldehydes and ketones as a method of preparing aryl (alkyl) α-hydroxyketones has been reported (4, 5). It would be of interest, therefore, to prepare medicinal precursors which could subsequently be elaborated to compounds having the pyridinyl moiety as part of a freely rotating, semi-rigid, or rigid conformation. We now describe the synthesis of pyridinyl α-hydroxyketones and α-diketones, and their reaction with amines.

Reaction of 4-pyridinecarboxaldehyde **1***a* with the masked acyl anion α-ethoxyvinyllithium **2**, obtained by treatment of ethyl vinyl ether with *tert*-butyllithium (4, 5), at −65°C under nitrogen afforded 2-ethoxy-1-(4-pyridinyl) -2- propen-1-ol (**3***a*, 82%). Similar reactions of **1***b* and **1***c* with **2** gave the respective hydroxy enol ethers **3***b* (65%) and **3***c* (50%). Hydrolysis of hydroxy enol ethers **3***a* and **3***b* using 44% aqueous formic acid with ether methylene chloride (14:11 v/v) as solvent at 25°C for 4 h gave rise to the respective α-hydroxyketones **4***a* (62.9%) and **4***b* (82.9%). A similar hydrolysis of the 2-substituted pyridine **3***c* resulted in complete cleavage of the enol ether. The ^{1}H nmr spectrum of the unpurified reaction mixture exhibited those absorptions expected for the α-diketone

a 4-Pyridyl, *b* 3-Pyridyl, *c* 2-Pyridyl



9*c* rather than the α-hydroxyketone **4***c*. All attempts to purify this reaction mixture resulted in extensive decomposition. An impure sample of the α-diketone **9***c* was obtained after neutral alumina oxide column chromatography (about 12% from **3***c*). The mass spectrum of **9***c* exhibited a molecular ion at *m/e* 149 (*Exact Mass* calcd. for $C_8H_7NO_2$: 149.0477; found (high resolution ms): 149.0475) while the ^{1}H nmr spectrum displayed a 3H singlet at 2.58 due to the methyl absorption as well as the absorptions due to those of a 2-substituted pyridine ring. Other hydrolytic procedures investigated indicated that **3***b* was inert to 0.2 *N* aqueous methanolic HCl at 25°C for 12 h whereas treatment with 3 *N* aqueous methanolic HCl afforded a complex mixture of products.

Reaction of α-hydroxyketones **4***a* and **4***b* with hydroxyl amines gave rise to oximes. For example, reaction of **4***a* and **4***b* with hydroxylamine afforded **5***a* (27.6%) and **5***b* (63.3%) respectively, while treatment of **4***b* with *O*-benzylhydroxylamine yielded oxime **6** (62.5%). The respective ^{1}H nmr

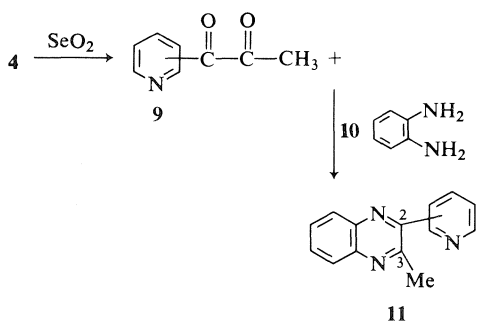
5 6

a 4-Pyridyl, *b* 3-Pyridyl

spectra of **5***a*, **5***b*, and **6** exhibited dual methyl absorptions at δ 1.68 and 1.76, 1.7 and 1.83, and 1.7 and 1.88 in ratios of 5:1, 3:1, and 12:1. These spectral data suggest that oximes **5** and **6** exist as a mixture of *E*- and *Z*-isomers. Oximes **5** and **6** were not elaborated further.

The reductive amination of the α-hydroxyketone **4***b* with morpholine hydrochloride **7** in the presence of sodium cyanoborohydride over the pH range 4–7.5 was investigated as a method to prepare the aminoalcohol **8**. The reaction gave a complex mix-



7 8

ture of products which did not contain **8**. Other attempts to generate the iminium species by reaction of **4***b* with morpholine using molecular sieves or titanium tetrachloride as water scavengers were also unsuccessful (6). The failure of **4***b* to react with secondary amines such as morpholine or pyrrolidine may be due to strong hydrogen bonding between the hydroxyl and carbonyl groups of **4***b*.

Oxidation of α-hydroxyketones **4***a* and **4***b* using selenium dioxide afforded the α-diketones **9***a* (42.9%) and **9***b* (32%) respectively. Condensation of the α-diketones **9***a* and **9***b* with *o*-phenylenediamine **10** gave the quinoxalines **11***a* (72%) and **11***b* (79.2%) respectively.

The pyridyl α-hydroxyketones **4** and α-diketones **9** will be used in subsequent studies involving the

9 10 11

a 4-Pyridyl, *b* 3-Pyridyl, *c* 2-Pyridyl

design of new nitrogen heterocycles with pharmacological activity.

Experimental

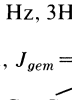
Melting points were determined with a Büchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra were determined in deuterochloroform (unless otherwise noted) with TMS as internal standard with a Varian EM-360 A spectrometer. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Unicam SP-1000 or Perkin Elmer 267 spectrometer. Mass spectra were measured with an AEI-MS-50 mass spectrometer and these exact mass measurements are used almost exclusively in lieu of elemental analyses. All of the products described gave rise to a single spot on tlc using a solvent system less polar and more polar than the specific solvent system described for purification of the reaction mixture. No residue remained after combustion of the products purified by tlc or column chromatography.

*2-Ethoxy-1-(4-pyridinyl)-2-propen-1-ol (***3***a)*

General Procedure A

To a solution of ethyl vinyl ether (5.04 g, 70 mmol) in 30 mL anhydrous tetrahydrofuran, under a nitrogen atmosphere at −65°C, *tert*-butyllithium (3.01 g, 47 mmol) in pentane (29.4 mL) was added dropwise with stirring during 25 min. The cooling bath was removed and the yellow solid slowly redissolved as the temperature was allowed to warm from −65°C to 0°C over a period of 20 min. This solution was cooled to −65°C and a solution of 4-pyridinecarboxaldehyde (5 g, 46.7 mmol) in 30 mL dry tetrahydrofuran was added dropwise over a period of 45 min. The resulting dark brown mixture was allowed to warm gradually to 25°C over a 2 h period. The mixture was then cooled to 0°C and 50 mL of 20% aqueous ammonium chloride was added with stirring for 5 min followed by an additional 50 mL water. The organic layer was separated and the aqueous fraction was extracted with ether – methylene chloride (14:11 v/v) (3 × 30 mL). The combined organic extracts were washed with water and brine. Drying (Na_2SO_4) and removal of the solvent *in vacuo* gave **3***a* along with an impurity as indicated by ^{1}H nmr. Dissolution of the reaction mixture in 20 mL ether – methylene chloride (14:11 v/v) and then washing with 2.5 *N* sodium hydroxide (3 × 20 mL) removes the impurity. Drying the ether – methylene chloride layer (Na_2SO_4) and removal of the solvent *in vacuo* afforded **3***a* as a white solid (6.85 g, 82%); mp: 72–73°C; ir: 1420 and 1660 (s, C=CH_2) cm^{-1}; ^{1}H nmr δ: 1.21 (t, $J_{CH_2CH_3}$ = 7 Hz, 3H, CH_3), 3.72 (q, $J_{CH_2CH_3}$ = 7 Hz, 2H, —CH_2CH_3), 4.11 (d, J_{gem} = 2.5 Hz, 1H, C=C(H)(H)), 4.36 (d, J_{gem} = 2.5 Hz, 1H, C=C(H)(H)), 5.12 (s, 1H, —C*H*), 5.45 (broad s, 1H, OH, exchanges with deuterium oxide), 7.42 (d, $J_{2,3} = J_{5,6}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 2H, H-3, H-5), 8.5 (d, $J_{2,3} = J_{5,6}$ = 5 Hz of d, $J_{2,5} = J_{3,6}$ = 1 Hz, 2H, H-2, H-6). *Exact Mass* calcd. for $C_{10}H_{13}NO_2$: 179.0946; found (high resolution ms): 179.0954.

*2-Ethoxy-1-(3-pyridinyl)-2-propen-1-ol (***3***b)*



Reaction of 3-pyridinecarboxaldehyde (5 g, 46.7 mmol) with α-ethoxyvinyllithium (47 mmol) and completion of the reaction as described under General Procedure *A* gave **3***b* as a pale yellow semi-solid (5.43 g, 65%); ir (neat): 3300 (br m, OH), 1430, and 1660 (m, C=CH_2) cm^{-1}; ^{1}H nmr δ: 1.2 (t, $J_{CH_2CH_3}$ = 7 Hz, 3H, CH_3), 3.71 (q, $J_{CH_2CH_3}$ = 7 Hz, 2H, —CH_2CH_3), 4.08 (d, J_{gem} = 2.5 Hz, 1H, C=C(H)(H)), 4.35 (d, J_{gem} = 2.5 Hz, 1H,

), 5.12 (s, 1H, —CH—), 5.42 (broad s, 1H, OH, exchanges with deuterium oxide), 7.23 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 7.82 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{4,6}$ = 1.75 Hz of d, $J_{2,4}$ = 1.75 Hz, 1H, H-4), 8.4 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 1.75 Hz, 1H, H-6), 8.56 (d, $J_{2,4}$ = 1.75 Hz, 1H, H-2). *Exact Mass* calcd. for $C_{10}H_{13}NO_2$: 179.0946; found (high resolution ms): 179.0950.

*2-Ethoxy-1-(2-pyridinyl)-2-propen-1-ol (**3**c)*

Reaction of 2-pyridinecarboxaldehyde (5 g, 46.7 mmol) with α-ethoxyvinyllithium (47 mmol) and completion of the reaction as described under General Procedure *A* gave **3***c* as a pale yellow semi-solid (4.24 g, 50.7%); ir: 1445 and 1630 (m, C=CH_2) cm^{-1}; ^1H nmr δ: 1.23 (t, $J_{CH_2CH_3}$ = 7 Hz, 3H, CH_3), 3.8 (q, $J_{CH_2CH_3}$ = 7 Hz, 2H, —CH_2CH_3), 4.1 (d, J_{gem} = 2.5 Hz, 1H, ), 4.41 (d, J_{gem} = 2.5 Hz, 1H, ), 5.15 (broad s, 2H, —CH—, OH, exchanges with deuterium oxide), 7.1–7.58 (complex m, 2H, H-3, H-5), 7.72 (d, $J_{4,5}$ = 8 Hz of d, $J_{3,4}$ = 8 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6). *Exact Mass* calcd. for $C_{10}H_{12}NO$ (M^+ − OH): 162.0873; found (high resolution ms): 162.0922 (base peak).

*1-Hydroxy-1-(4-pyridinyl)-2-propanone (**4**a)*

General Procedure B

To a solution of the enol ether **3***a* (1 g, 5.58 mmol) in 10 mL ether – methylene chloride (14:11 v/v) was added 2 mL 88% formic acid and 2 mL water. Solid sodium carbonate was added until the reaction mixture was just alkaline to litmus paper and the mixture was allowed to stir for a further 30 min. The reaction mixture was eluted from a 2.5 × 20 cm column of sodium sulfate using 600 mL ether – methylene chloride (14:11 v/v) to yield **4***a* as a pale yellow semi-solid (0.531 g, 62.9%); ir (neat): 3400 (m, OH) and 1725 (s, CO) cm^{-1}; ^1H nmr δ: 2.23 (s, 3H, CH_3), 5.28 (s, 1H, —CH—), 6.64 (broad s, 1H, OH, exchanges with deuterium oxide), 7.5 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 2H, H-3, H-5), 8.64 (d, $J_{5,6}$ = 5 Hz of d, $J_{3,6}$ = $J_{2,5}$ = 1 Hz, 2H, H-2, H-6). *Exact Mass* calcd. for $C_8H_9NO_2$: 151.0633; found (high resolution ms): 151.0631.

*1-Hydroxy-1-(3-pyridinyl)-2-propanone (**4**b)*

Hydrolysis of the enol ether **3***b* (1 g, 5.58 mmol) using aqueous formic acid and completion of the reaction as described under General Procedure *B* afforded **4***b* as a yellow semi-solid (0.70 g, 82.9%); ir: 3400 (m, OH) and 1725 (s, CO) cm^{-1}; ^1H nmr δ: 2.17 (s, 3H, CH_3), 5.19 (s, 1H, —CH—), 5.4 (s, 1H, OH, exchanges with deuterium oxide), 7.32 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 7.71 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{4,6}$ = 2 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 8.57 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6), 8.65 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_8H_9NO_2$: 151.0633; found (high resolution ms): 151.0635.

*1-Hydroxy-1-(4-pyridinyl)-2-propanone oxime (**5**a)*

General Procedure C

To a stirred solution of α-hydroxyketone **4***a* (0.27 g, 1.788 mmol) in 40 mL methanol at 0°C was added sodium acetate (0.149 g, 1.817 mmol) and hydroxylamine hydrochloride (0.124 g, 1.788 mmol). The reaction mixture was allowed to stir for 2 h at 25°C prior to pouring onto 100 mL water. Extraction with chloroform (4 × 100 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* gave a pale yellow solid which was purified using six 20 cm × 20 cm silica gel G plates, 0.75 mm in thickness, with ethyl acetate as development solvent. Extraction of the fraction having R_f 0.29 using 200 mL warm methanol afforded **5***a* (0.082 g, 27.63%); mp 149–151°C; ir: 3240 (m, C—OH), 2805 and 2680 (m, =N—OH), and 1610 (s, C=N—) cm^{-1}; ^1H nmr δ ($CDCl_3$ + DMSO-d_6): 1.68 and 1.76 (s, 3H, CH_3), 3.34 (s, 1H, =N—OH, exchanges with deuterium oxide), 5.28 (s, 1H, C*H*—OH), 5.88 (broad s, 1H, C—O*H*, exchanges with deuterium oxide), 7.41 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 2H, H-3, H-5), 8.6 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{2,5}$ = $J_{3,6}$ = 1 Hz, 2H, H-2, H-6). *Exact Mass* calcd. for $C_8H_{10}N_2O_2$: 166.0743; found (high resolution ms): 166.0745. *Anal.* calcd. for $C_8H_{10}N_2O_2$: C 57.82, H 6.06; found: C 58.02, H 6.02.

*1-Hydroxy-1-(3-pyridinyl)-2-propanone oxime (**5**b)*

Reaction of the α-hydroxyketone **4***b* (0.283 g, 1.87 mmol) with hydroxylamine hydrochloride (0.131 g, 1.87 mmol) in the presence of sodium acetate (0.307 g, 3.74 mmol) and completion of the reaction as described under General Procedure *C* including purification by preparative tlc gave **5***b*, having R_f 0.5, as a white solid (0.197 g, 63.3%); mp 133–135°C; ir: 3250 (m, C—OH), 2720 (m, =N—OH), and 1590 (m, C=N) cm^{-1}; ^1H nmr (DMSO-d_6) δ: 1.7 and 1.83 (s, 3H, C*H*$_3$), 3.48 (s, 1H, =NOH, exchanges with deuterium oxide), 5.3 (s, 1H, —CH—), 5.9 (broad s, 1H, CH—OH, exchanges with deuterium oxide), 7.38 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 7.8 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{4,6}$ = 2 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 8.51 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6), 8.6 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_8H_{10}N_2O_2$: 166.0743; found (high resolution ms): 166.0744. *Anal.* calcd. for $C_8H_{10}N_2O_2$: C 57.82, H 6.06; found: C 57.73, H 6.04.

*1-Hydroxy-1-(3-pyridinyl)-2-propanone O-(Phenylmethyl)oxime (**6**)*

O-Benzylhydroxylamine hydrochloride (0.318 g, 1.99 mmol) was added to a solution of α-hydroxyketone **4***b* (0.304 g, 2.01 mmol) in 30 mL methanol at 0°C and the reaction was allowed to proceed at 0°C for 1 h and then at 25°C for 6 h with stirring. The reaction mixture was poured onto 100 mL water. Extraction with chloroform (4 × 50 mL), drying (Na_2SO_4), and removal of the solvent *in vacuo* yielded **6** as a pale yellow solid (0.323 g, 62.5%); mp 92–94°C; ir: 3150–3200 (m, C—OH), 2700 (m, =NOH), 1590, and 1660 (s, C=N) cm^{-1}; ^1H nmr δ: 1.7 and 1.88 (s, 3H, CH_3), 4.56 (s, 1H, OH, exchanges with deuterium oxide), 5.18 and 5.27 (s, 2H, —OCH_2—), 7.32 (m, 6H, H-5, C_6H_5), 7.7 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{4,6}$ = 2 Hz of d, $J_{2,4}$ = 2 Hz, 1H, H-4), 8.55 (m, 2H, H-2, H-6). *Exact Mass* calcd. for $C_{15}H_{16}N_2O_2$: 256.1212; found (high resolution ms): 256.1214.

*1-(4-Pyridinyl)-2,3-propanedione (**9**a)*

General Procedure D

To a solution of selenium dioxide (1.11 g, 10 mmol) in 40 mL dioxane and 1 mL water was added at once a solution of the α-hydroxyketone **4***a* (2.42 g, 16 mmol) in 20 mL dioxane. The reaction mixture changes from white to orange during the addition of **4***a* and a dark red precipitate soon begins to separate. The reaction was allowed to continue 12 h with stirring. The solvent dioxane was removed by decantation and transferred to another flask. The residual dark red solid deposited on the sides of the reaction flask was washed with methylene chloride (2 × 10 mL). Removal of the solvent *in vacuo* from the combined dioxane and methylene chloride fractions gave a dark reddish-black liquid containing suspended solid which was purified on a neutral alumina column (30 g). Elution with benzene – ethyl acetate (1:1 v/v, 100 mL) afforded **9***a* (1.02 g, 42.9%) as a pale yellow solid; mp 86–88°C; ir: 1730 and 1740 (s, CO) cm^{-1}; ^1H nmr δ: 2.57 (s, 3H, CH_3), 7.88 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{3,5}$ = 1.5 Hz, 2H, H-3, H-5), 8.9 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{2,5}$ = $J_{3,6}$ = 1 Hz, 2H, H-2, H-6). *Exact Mass* calcd. for $C_8H_7NO_2$: 149.0477; found (high resolution ms): 149.0477.

*1-(3-Pyridinyl)-2,3-propanedione (**9**b)*

Oxidation of the α-hydroxyketone **4***b* (2.42 g, 16 mmol) using

selenium dioxide (1.11 g, 10 mmol), completion of the reaction and neutral alumina oxide chromatography of the reaction mixture as described under General Procedure *D* gave **9***b* as a pale yellow oil (0.76 g, 32%); ir (film): 1680, 1720, and 1775 (s, CO) cm^{-1}; ^1H nmr δ: 2.52 (s, 3H, CH_3), 7.42 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5), 8.36 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{2,4}$ = 2 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-4), 8.84 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6), 9.26 (d, $J_{2,4}$ = 2 Hz, 1H, H-2). *Exact Mass* calcd. for $C_8H_7NO_2$: 149.0477; found (high resolution ms): 149.0478.

*3-Methyl-2-(4-pyridinyl)quinoxaline (**11**a)*

General Procedure E

A solution of the α-diketone **9***a* (0.215 g, 1.44 mmol) and *o*-phenylenediamine **10** (0.16 g, 1.48 mmol) in 20 mL absolute ethanol was boiled under reflux for 6 h. Removal of the solvent *in vacuo* gave a light yellow-green solid which was purified on a neutral alumina column (10 g). Elution with ethyl acetate (25 mL) afforded **11***a* (0.23 g, 72.33%); mp 135–137°C; ir: 1595 (s, C=N) cm^{-1}; ^1H nmr δ: 2.84 (s, 3H, CH_3), 7.55–8.4 (complex m, 6H, phenyl hydrogens, H-3, H-5, pyridine), 8.9 (d, $J_{2,3}$ = $J_{5,6}$ = 5 Hz of d, $J_{2,5}$ = $J_{3,6}$ = 1 Hz, 2H, H-2, H-6, pyridine). *Exact Mass* calcd. for $C_{14}H_{11}N_3$: 221.0953; found (high resolution ms): 221.0948.

*3-Methyl-2-(3-pyridinyl)quinoxaline (**11**b)*

Reaction of the α-diketone **9***b* (0.309 g, 2.08 mmol) with *o*-phenylenediamine (0.227 g, 2.1 mmol) in 30 mL absolute ethanol followed by purification as described under General Procedure *E* gave **11***b* as a pale yellow solid (0.364 g, 79.2%); mp 95–97°C; ir: 1550, 1560, 1575, and 1590 (s, C=N) cm^{-1}; ^1H nmr δ: 2.82 (s, 3H, CH_3), 7.56 (d, $J_{4,5}$ = 8.5 Hz of d, $J_{5,6}$ = 5 Hz, 1H, H-5, pyridine), 7.7–8.3 (complex m, 5H, phenyl hydrogens, H-4, pyridine), 8.78 (d, $J_{5,6}$ = 5 Hz of d, $J_{4,6}$ = 2 Hz, 1H, H-6, pyridine), 9.0 (d, $J_{2,4}$ = 2 Hz, 1H, H-2, pyridine). *Exact Mass* calcd. for $C_{14}H_{11}N_3$: 221.0953; found (high resolution ms): 221.0940.

Carbon catalyzed organic reactions: carbon promoted solvolysis of a phosphate ester derived from 1,1′-bi-2-naphthol

YUMIKO Y. HOYANO AND RICHARD E. PINCOCK

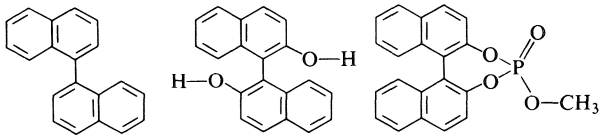
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received July 11, 1979

YUMIKO Y. HOYANO and RICHARD E. PINCOCK. Can. J. Chem. **58**, 134 (1980).

Active carbons which catalyze the racemization of 1,1′-binaphthyl are not effective in racemizing the 2,2′-dihydroxyl and the 8,8′-dicarbomethoxyl derivatives of binaphthyl. The 2,2′-binaphthyl methyl phosphate ester derived from optically active 1,1′-bi-2-naphthol undergoes slow thermal racemization at 190°C ($t_{1/2}$ 100 min, $\Delta H^{\neq}$ 26.1 kcal/mol, $\Delta S^{\neq}$ −21 cal/mol deg) in triglyme and this racemization rate is also unaffected by active carbon. However, in the hydroxylic solvent 2-(2-ethoxyethoxy)ethanol at 130°C the rate of solvolysis of the phosphate ester is increased ca. tenfold by carbon blacks or decolorizing carbon at 1 mg/mL concentration. Control experiments show that the acceleration is not due to soluble impurities released by the carbons; heterogeneous catalysis, probably by acidic and/or nucleophilic functional groups on the carbon surfaces, is involved.

YUMIKO Y. HOYANO et RICHARD E. PINCOCK. Can. J. Chem. **58**, 134 (1980).



Les charbons actifs qui catalysent la racémisation du binaphtyle-1,1′ ne sont pas efficaces dans le cas des dérivés dihydroxyl-2,2′ et dicarbométhoxyl-8,8′ du binaphtyle. L'ester méthylique du binaphtyl-2,2′ phosphate derivé du bi-2 naphtol-1,1′ optiquement actif subit une racémisation lente à 190°C ($t_{1/2}$ 100 min, $\Delta H^{\neq}$ 26.1 kcal/mol, $\Delta S^{\neq}$ −21 cal/mol deg) dans le triglyme et cette vitesse de racémisation n'est pas affectée par le charbon actif. Cependant dans un solvant hydroxylé comme le (éthoxyéthoxy-2)-2 éthanol à 130°C, le charbon noir ou le charbon décolorant à une concentration de 1 mg/mL augmente d'environ 10 fois la vitesse de solvolyse de l'ester phosphorique. Des expériences de contrôle mettent en relief le fait que l'augmentation de vitesse n'est pas due aux impuretés solubles libérées par les charbons. On pense plutôt à une catalyse hétérogène due probablement à des groupes fonctionnels acides ou nucléophiles présents sur la surface du charbon.

[Traduit par le journal]

1,1′-Binaphthyl, **1**, is sufficiently hindered around the interannular bond so that thermal rotation of this bond is slow at room temperature. However, the rotation can be very effectively promoted by suspensions of carbon blacks or activated carbons and catalytic racemization of optically active binaphthyl is thereby rapidly achieved (1). The kinetics of this heterogeneous catalytic reaction have been presented in some detail (2) but extensions of this interesting reaction type remain unexplored.

We have investigated the possibility that the barrier to rotation in a highly hindered binaphthyl derivative, such as in 1,1′-bi-2-naphthol **2**, where the presence of the two hydroxyl groups prevents rotation except at high temperatures (3), might be lowered by the catalytic power of adsorption on carbon blacks. Also the multitude of functional groups on part of the active carbon surface (4) suggested, in addition, that both electrophilic and nucleophilic catalysis of some reactions (e.g., ester hydrolysis) may occur during adsorption on carbon. Indeed, together with the many examples of catalysis by carbon of inorganic reactions, of oxidations, and of hydrocarbon isomerizations, there are a few reports of solvolysis reactions catalyzed by carbon (5).

We have therefore extended our catalytic studies to the methyl phosphate ester **3** derived from optically active binaphthol **2**. This compound presents the possibilities both of catalyzed racemization related to that of 1,1′-binaphthyl as well as ester solvolysis of the phosphate moiety. It was hoped that a demonstration of solvolytic activity by carbon could supply an initial model for possible catalytic properties of carbon (in addition to its well-known adsorption properties) during removal of pesticides and other contaminates from water (6). The phosphate ester **3** was therefore chosen to be investigated both because of its relationship to binaphthyl and its likely adsorption due to the presence of larger aromatic groups, but also as a model for potential reactions of biological phosphate esters and related insecticides.

1 **2** **3**

Results and Discussion

The 2,2′-dihydroxyl derivative of 1,1′-binaphthyl is optically stable over long periods at 100°C in neutral solvents but is considerably racemized within a day in basic or acidic conditions near this temperature (3). At 150°C in diglyme the compound

is only 10% racemized after 20 h and, in spite of sensitivity of the racemization rate to acidic and basic catalysis, the addition of active carbons (Norite or Spheron 6) had no effect on this slow racemization.

The phosphate ester **3** derived from bi-2-naphthol, **2**, is also highly optically stable. The phosphate ring compels the rotation to proceed only by passage of the 8 and 8′ positions past each other rather than the less hindering 8′ and 2 (and 8 and 2′) positions as a binaphthyl and its 2,2′-dihydroxyl derivative. Slow racemization of **3** in triglyme proceeds only near 190°C ($t_{1/2}$ 100 min) with $\Delta H^{\ddagger}$ 26.1 kcal/mol, $\Delta S^{\ddagger}$ −21 cal/mol deg. Addition of Norite or Spheron 6 to solutions of the phosphate ester had no effect on the loss of optical activity in this solvent.

Similarly, another derivative of 1,1′-binaphthyl, this one with carbomethoxy groups in the 8 and 8′ positions and a low barrier to rotation corresponding to a half life of 23 min at 50°C (7), showed no catalysis of racemization by Norite under conditions where binaphthyl itself is very rapidly racemized by carbon surfaces.

The lack of any effect of carbon in the racemization of these compounds shows that the catalytic racemization reaction of binaphthyls is not a very general phenomenon. It can be expected that the adsorption process, with a possible flattening of the binaphthyl rings as it approaches the graphitic planes of active carbons (1, 2) should be a rather specific process which is easily disrupted by functional groups on the aromatic rings.

Although the binaphthyl methyl phosphate **3** is not catalytically racemized by suspensions of carbon in nonhydroxylic solvents, it does undergo a reaction promoted by carbon in a hydroxylic solvent. When ester **3** is present in the monoethyl ether of diethylene glycol, a slow loss of optical activity occurs at 130°C due to solvolysis. Addition of a variety of different carbons of both acidic and basic character (i.e., Carbolac 1 "pH 3", Spheron 6 "pH 6", and Sterling FT "pH 9") increased the rate of loss of optical rotation to about the same degree. That solvolysis rather than a simple racemization was occurring was shown by isolation of 1,1′-bi-2-naphthol from a larger scale catalyzed run. The naphthol retained its optical purity but its greatly lower specific rotation results in essentially complete loss of measured activity during a kinetic run.

Figure 1 shows first order plots for the loss of optical activity at three concentrations of ester and with Norite as catalyst at ca. 1.0 mg/mL. The rate

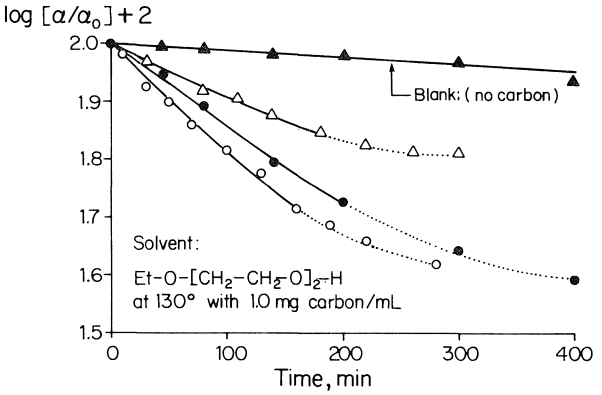

FIG. 1. First order plots of the loss of optical activity at 130°C for phosphate ester **3** in diethyleneglycol monoethyl ether with and without carbon black (Norite) at 0.9–1.1 mg/mL. The ester concentration (× 10^3) and Norite concentration were, respectively, ▲ 5.76 with no carbon, △ 11.6 with 1 mg/mL, ● 5.76 with 0.9 mg/mL, and ○ 2.97 with 1.1 mg/mL.

constants calculated from the initial portions of such plots are collected in Table 1. The initial rate of loss of optical rotation can be over ten times greater with carbon than without. Although this catalytic effect of carbon was reproducible with different batches of ester and of carbon and with measurement by either polarimetry or ultraviolet spectrometry, the results do not allow a satisfying kinetic analysis. Unfortunately the carbon-promoted reaction always slowed and sometimes essentially stopped (see Fig. 1) during a run. This

deactivation also showed up in a decrease in the initial first order rate constant at higher ester concentration. It is possible that some active sites on carbon, say hydroxyl groups, might be irretrievably covered up and inactivated by transfer of the phosphate group from naphthyl to the carbon surface; this would occur more effectively at high ester concentrations. However, such a noncatalytic, "bimolecular" reaction of functional groups on carbon with the ester can be eliminated as the major reaction since no loss of ester occurred in the similar, but otherwise non-hydroxylic, solvent diglyme at 130°C in the presence of carbon over 13 h. The catalytic reaction in the hydroxylic solvent has a half life of about 3 h under these conditions.

Most disturbing to a more complete kinetic treatment of the reaction was that the rate was very insensitive to the amount and type of suspended carbon. This suggested that an impurity in the carbons, possibly low molecular weight (and soluble) acids or bases, might be extracted into the solvent where it reached a constant saturated concentration. A homogeneous reaction at constant rate rather than a heterogeneous catalytic reaction would then occur. Several experiments were carried out to investigate this possibility.

First a suspension of the carbon in the hydroxylic solvent was held at 150°C, filtered hot, and the filtrate used for a normal kinetic control run (i.e., without carbon present). No especially accelerated rate of solvolysis was found. It is possible, however, that an active soluble agent at 150°C had precipitated and been lost during the preparation of the control solution at room temperature, so a further more definitive test was carried out.

A U-shaped tube with a fine sintered glass filter at the centre bottom, dividing the tube into equal sections, was employed. A normal kinetic solution of the ester complete with suspended carbon was heated and introduced into one side of the U-tube placed in a 130°C bath. By applying a little air pressure above the solution about half of the solution was then filtered into the other section of the tube; samples from both sides of the tube could be taken separately and measured as usual. The reaction in the filtered side, free from carbon, showed the normal, slow, uncatalyzed solvolysis; the reaction in the side with suspended carbon showed the catalytically enhanced rate of loss of ester. The results definitely show that a heterogeneous reaction of the suspended carbon particles is involved in the more rapid loss of ester. The rate of about 10-fold is not large and its origin is unknown, but since some aromatic phosphate esters are subject to nucleophilic, general base and acid catalysis (8, 9), it seems that groups on carbon blacks such as hydroxyl, carboxyl, and phenolic must be involved. Unlike the catalytic effect of carbon in the racemization of 1,1′-binaphthyl (2), the catalysis by carbon of this phosphate ester solvolysis is not inhibited by naphthalene. Relatively nonpolar, graphitic planes, which may competitively adsorb naphthalene, may be involved in the former catalysis while polar functional groups, not influenced by the presence of naphthalene, are active with the latter substrate. The example of catalytic activity reported here at least shows that if a way to prevent the deactivation of the catalyst could be found, and indeed, if an increased activity could be affected by modification of the catalyst, carbon black could be an interesting and useful catalyst of some solvolytic reactions.

Unfortunately, an extension to the reaction of another aromatic phosphate ester with a hydroxylic solvent in the presence of carbon failed to show any catalytic effects. The insecticide Paraoxon (i.e., *p*-nitrophenyl diethyl phosphate) is stable in monomethyl diethylene glycol at 80°C over 4 h with or without Norite at 1 mg/mL. At 130°C slow reaction of Paraoxon occurs, but the rate remains unaffected by the presence of active carbon particles. Therefore, both the catalyzed racemization of binaphthyl and the catalyzed solvolysis of phosphate ester **3** so far remain unique examples of these types of catalytic activity of carbon.

Experimental

The cyclic phosphate diester of 1,1′-bi-2-naphthol was prepared by methods similar to that mentioned (10) except that binaphthol, phosphorus oxychloride, and pyridine (mole ratios 1:1:2) were reacted in benzene and then refluxed overnight. The crude binaphthylphosphorus chloride, isolated by ether extraction, was hydrolyzed in 50% dioxane–water at 50°C until (ca. 30 min) no chloride was detected by thin layer chromatography. After extraction into dichloromethane, the solid was recrystallized from methanol to give the binaphthylphosphoric acid, mp 344–346°C. *Anal.* calcd. for $C_{20}H_{13}PO_4$: C 68.96, H 3.73; found: C 68.44, H 3.90.

Rather than cinchonine (10), strychnine was used in methanol as the resolving agent. After recrystallizations from large volumes of methanol (by concentration through evaporation to bring about crystallization) the salt, mp 245–247°C, was taken up in ethanol and decomposed by treatment at 70°C with Dowex 50W-X12 acid ion exchange resin. Evaporation of the decanted solution gave an oily residue which crystallized from methanol to give a solid, mp 335–337°C, $[\alpha]_D$ −609° (2.4 mg/mL in methanol), (lit. (9) 530°). A private communication from Prof. D. J. Cram and K. P. Shepherd reported $[\alpha]_D$ 601° for the plus enantiomer. *Anal.* calcd. for $C_{20}H_{13}PO_4$: C 68.96, H 3.73; found: C 68.68, H 3.70.

The methylbinaphthylphosphate ester **3** was prepared from the binaphthylphosphoric acid in methanol by treatment with diazomethane in ether. After recrystallization from benzene – petroleum ether it gave mp 210–212°C, $[\alpha]_D$ −490° (1.94 mg/mL

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

in methanol), (lit. (10) mp 210°C and $[\alpha]_D$ 544°). Optically active 1,1′-bi-2-naphthol was kindly supplied by Professor D. J. Cram.

1,1′-Binaphthyl-8,8′-dicarboxylic acid was resolved with brucine (11) and reacted with diazomethane to give the diester, mp 125–126°C, (lit. (7) mp 123–125°C). Paraoxon (bp 150–158°C/0.5 Torr) (lit. (12) bp 155°C/0.1 Torr) was prepared by reaction of *p*-nitrophenol with diethylchlorophosphate and triethylamine in benzene. Diglyme (i.e., bis(2-methoxyethyl)-ether) and triglyme (i.e., 1, 2-bis(2-methoxyethoxy)ethane) were refluxed and distilled from calcium hydride or lithium aluminum hydride. Diethyleneglycol monoethyl ether (i.e., 2-(2-ethoxy-ethoxy)ethanol was distilled and a centre portion, bp 210°C, collected for use. Sources of the carbon blacks have been described (2).

For kinetic studies the usual conditions were a suspension of carbon black in 9 mL of solvent containing 18 mg of phosphate ester. The rate of stirring was not critical as the carbon particles were readily suspended by light agitation. The kinetic sample was heated in a constant temperature oil bath and samples periodically withdrawn, cooled, and filtered using a Swinny syringe filter. Polarimetric analysis was with a Bendix type 143A automatic polarimeter. The rate constants were obtained from the initial slopes of the plots of log α/α_0 = log (fraction of reaction) versus time; the optical rotations of infinity samples were essentially zero and negligible. The plots were usually sufficiently straight to the first half-life, but showed considerable slowing thereafter (see Fig. 1). The rate of loss of rotation in a solution of 2.97×10^{-3} *M* ester with 1.1 mg of Norite/mL was unaffected by the presence of 0.134 *M* naphthalene.

The rate of reaction was also measured by loss of uv absorption of ester **3** at 302 nm in filtered aliquots of the kinetic run after dilution with ethanol. At the concentration of ester employed in the kinetic studies there was no measurable loss of the ester by adsorption onto the carbon. This was determined by comparison of uv spectra at room temperature before and after addition (and filtering) of the carbon. Under the higher temperature conditions of the kinetic runs even less ester would be reversibly adsorbed.

The thermal racemization of ester **3** at 0.0046–0.006 *M* in triglyme was determined at 190, 180, and 170°C. Good first order plots with rate constants 11.8, 5.60, and 3.43×10^{-5} s^{-1}, respectively, were obtained. Assuming a 5% error in k_{obs}, values of $\Delta H^{\ddagger}$ 26.1 ± 2.3 kcal/mol and $\Delta S^{\ddagger}$ −21 ± 6 cal/mol deg were calculated.

Product studies were carried out with 150 mg of ester in 7.5 mL of diethyleneglycol monoethyl ether containing 67 mg of Norite at 130°C for 70 h. Addition of water, extraction with benzene, and preparative thin layer chromatography showed 1,1′-bi-2-naphthol (identified by infrared and ultraviolet spectra) as the only noticeable product. For quantitative analysis a sample of ester, 28.6 mg, in 1 mL of solvent with 12 mg of Norite heated 20 h at 130°C showed a rotation of −0.069 in a 1 cm cell. With the specific rotation of binaphthol at −33.8 (3) this measured rotation corresponds to production of binaphthol with 90% retention of activity.

Chemistry of hexamethyldisilazane. Silylation of β-diketones and amination of β-triketones

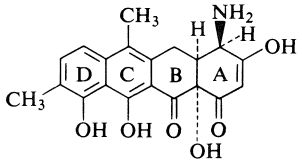
DANIEL T. W. CHU[1,2] AND STUART N. HUCKIN[3]

Abbott Laboratories, Limited, P.O. Box 6150, Montreal, P.Q., Canada H3C 3K6

Received August 8, 1979

DANIEL T. W. CHU and STUART N. HUCKIN. Can. J. Chem. **58**, 138 (1980).

It is discovered that hexamethyldisilazane, a reagent generally used to silylate amino, hydroxyl, sulfhydryl, and carbonyl groups, reacts with β-diketones to form their trimethylsilyl enol ethers in high yield.



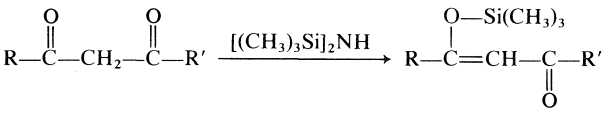
An efficient and simple procedure for aminating β-triketones to their enaminodiketones by the use of hexamethyldisilazane is also described.

DANIEL T. W. CHU et STUART N. HUCKIN. Can. J. Chem. **58**, 138 (1980).

On a découvert que l'hexaméthyldisilazane, un réactif utilisé habituellement dans la silylation des groupements amino, hydroxyle, sulfhydryle et carbonyle, réagit avec les β-dicétones pour former leur éthers énoliques triméthylsilylés avec des rendements élevés, On décrit également une méthode simple et efficace d'amination de β-tricétones en énaminodicétones correspondantes à l'aide de l'hexaméthyldisilazane.

[Traduit par le journal]

During the course of our investigation on chemical modification of 2-deacetylchelocardin (**1**) (1, 2), we were interested in protecting the enolized ketone group of the β-diketone in ring A by a silyl group.

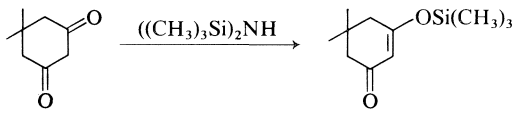


1

β-Diketones, under standard procedures (3, 4) do not undergo silylation readily. Silylation of carbonyl compounds has been reported using chlorotrimethylsilane and strong base (3, 4), bis(trimethylsilyl)acetamide (5), triethylsilylthiobenzene (6), trimethylsilyl trifluoromethanesulfonate (7), and ethyl trimethylsilylacetate and tetra-*n*-butylammonium fluoride (8). Attempted silylation of 1,3-dicarbonyl compounds by standard silylation methods (3, 4) resulted in relatively low yields.

To avoid loss of a substantial amount of 2-deacetylchelocardin (**1**), we used simple β-diketones as model compounds in the search for a mild silylation procedure.

It has now been found that silylation of β-diketones to their corresponding trimethylsilyl enol ethers is effected in very high yield by the use of hexamethyldisilazane as illustrated in Schemes 1



2*a*, *b* **3***a*, *b*

a R = R′ = CH_3
b R = R′ = C_6H_5

SCHEME 1

and 2. This procedure involves the reaction of the β-diketone in an aprotic solvent with a slight excess of hexamethyldisilazane at room temperature. The product is isolated by evaporating the excess hexamethyldisilazane and solvent under reduced pressure, yielding essentially pure residue. The reaction appears to be general for enolizable β-diketones as illustrated in Table 1.

4 **5**

SCHEME 2

While our investigation was in progress, it was claimed that 1,3-dicarbonyl compounds can be silylated by 1-(trimethylsilyl)imidazole (9). This procedure involves heating a mixture of the 1,3-dicarbonyl compound, hexamethyldisilazane, and a catalytic amount of imidazole at refluxing temperature (126°C) for several hours followed by fractional distillation. The authors also reported that reaction of 1,3-dicarbonyl compounds with 1-(trimethylsilyl)imidazole in pentane and ligroin resulted in low yields of the corresponding trimethylsilyl enol ethers. These results may be explained by

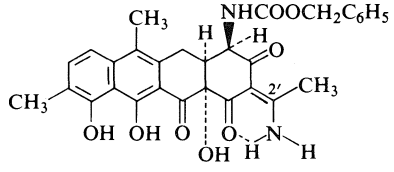
the possibility that the effecting agent in this silylation procedure is hexamethyldisilazane itself.

Since our present procedure involves no heating and all the by-products are highly volatile, it offers the advantage of being mild, efficient, and simple. It is particularly useful when the silylated product is extremely high boiling since it avoids fractional distillation. Purification by chromatographic techniques is not feasible since the silylated β-diketones are very readily hydrolyzed.

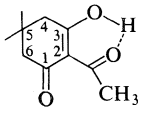
Amination of β-Triketones



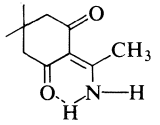
Chelocardin, a broad spectrum antibiotic, was first described in 1961 (10) and subsequently shown to be (**6**) (11). During our investigation on the chemical modification of chelocardin (**6**), it became apparent that protection of the enolized ketone group of the β-triketone system in ring A would yield a versatile intermediate for the synthesis of various chelocardin analogs.

With the discovery of an efficient procedure for silylation of β-diketones by the use of hexamethyl-

6 R = H
7 R = $COOCH_2C_6H_5$



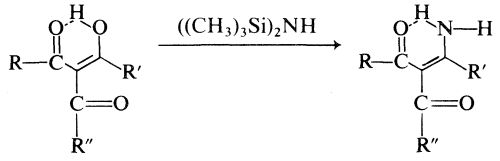
disilazane, we explored the effect of hexamethyldisilazane on β-triketones, particularly on chelocardin derivatives. Successful extension of this silylation procedure on *N*-carbobenzoxychelocardin (**7**) (12) would have produced the desired ring A intermediate. Treatment of *N*-carbobenzoxychelocardin (**7**) with hexamethyldisilazane in methylene chloride gave a crude product having two trimethylsilyl groups in its nmr spectrum. As the phenolic hydroxyl groups were expected to be silylated, it seemed that silylation of the β-diketone system in ring A had not occurred. In order to identify the product further, it was then subjected to hydrolysis to see whether we recovered *N*-carbobenzoxychelocardin (**7**). However, treatment of the crude product with methanolic hydrogen chloride yielded, unexpectedly, 2′-amino-*N*-carbobenzoxychelocardin (**8**), a product which was previously prepared by reaction of (**7**) with ammonium acetate (13). Thus the 2′-enol group in *N*-carbobenzoxychelocardin (**7**) was replaced by an enamine.



8

2-Acetyldimedone was used as a model compound to study this transformation of the β-triketone to the enaminodiketone by the use of hexamethyldisilazane. 2-Acetyldimedone (**9**) (14) possesses two singlets at δ 2.32 and 2.50 in its nuclear magnetic resonance (nmr) spectrum taken in $CDCl_3$ corresponding to the four methylene protons at C-4 and C-6. Reaction of **9** with hexamethyldisilazane in dry chloroform gave the 2-

aminoacetyldimedone (**10**). Replacement of the enol by an enamine had occurred exclusively on the 2-acetyl side chain. Its structure was confirmed by having a singlet at δ 2.34 (4 protons) corresponding to two chemically equivalent methylene groups at



9

10

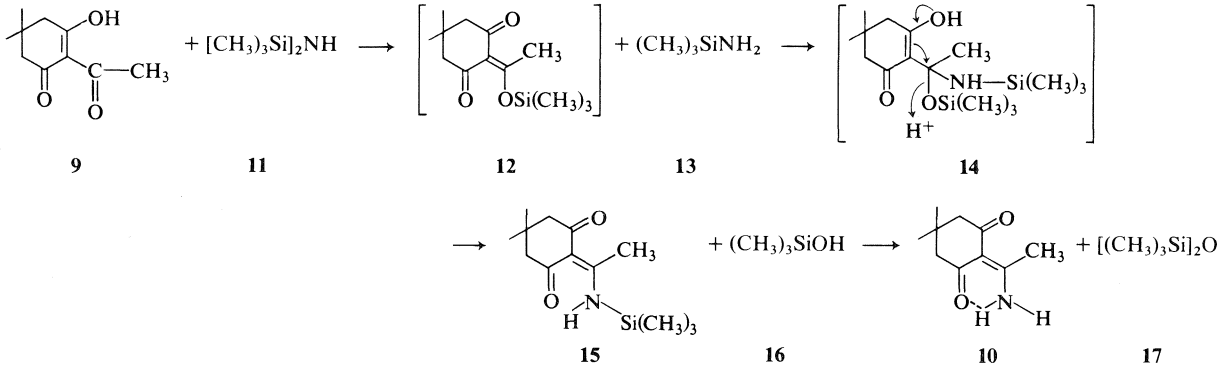
C-4 and C-6 in its nmr spectrum. A broad singlet at δ 11.57 shows the presence of one of the amino protons hydrogen bonded with the keto group. The other non-hydrogen bonded amino proton shows a broad singlet at δ 7.65. It possesses a correct molecular ion, *m/e*, at 181 in its mass spectrum. Further confirmation of its structure was obtained by synthesizing **10** by the use of ammonium acetate. The product synthesized by both procedures was identical in all respects.

The amination of β-triketones to their corresponding enaminodiketones by the use of hexamethyldisilazane (Scheme 3) appears to be general for enolizable β-triketones. It is an efficient, simple, and high yield reaction and seems to be superior to the ammonium acetate aminating pro-

SCHEME 3

cedure. We have successfully applied this procedure to several β-triketones and the results are illustrated in Table 2.

Using 2-acetyldimedone as an example, a possible mechanism for this reaction is illustrated in Scheme 4.



2-Acetyldimedone (**9**) was first silylated by hexamethyldisilazane (**11**) to give the unstable enol silyl ether (**12**) by a process parallel to the silylation of β-diketones. The trimethylsilazane (**13**) formed during the reaction underwent a Michael addition to the highly reactive double bond because it is doubly activated by two carbonyl groups at C-1 and C-3 to give the intermediate (**14**). This compound was then stabilized by elimination of the trimethylsilanol (**16**) by a retrograde Michael reaction to yield compound **15**. Nucleophilic attack on **15** by the trimethylsilanol (**16**) gave the 2-aminoacetyldimedone (**10**). As the proposed by-product, hexamethyldisiloxane (**17**) has a boiling point of 100–101°C (15), it was not isolated by our work-up procedure.

An alternative mechanism may involve compound **12** as an initial product which is subsequently aminated by ammonia derived from hydrolysis of trimethylsilazane (**13**) to give **10**. Since all experiments were performed under absolute dry conditions, it seems unlikely that the transformation involves this alternative mechanism.

Experimental

The ir spectra were recorded on a Perkin-Elmer Model 710A infrared spectrophotometer. The nmr spectra were recorded on a Varian Associates A-60 spectrometer in deuterated solvents; resonance positions are given on the δ scale (ppm) relative to internal tetramethylsilane. The nmr peaks were designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiple; b, broad. The high resolution mass spectra were determined on an Associated Electrical Industries MS-902 Double Focussing mass spectrometer and were processed on an IBM 1800 computer. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The ^{13}C nmr spectra were recorded on a Varian Associates XL-100-15/TT-100 spectrometer system in DMSO; resonance positions are given in ppm relative to internal tetramethylsilane. Parameters used were pulse width (30°) 3.5 μs, pulse delay 0.5–1.0 s, and sweep width 6K and 8K data table.

Since the ir absorption spectra of various derivatives reported here have a β-amino-, β-unsaturated carbonyl function which would have similar absorption to the β-triketone system, very

[a]Work-up procedure differs from others (see Experimental).
[b]Only A ring in ^{13}C nmr data is reported here for comparison.

little change in the carbonyl absorption region (1580–1680 cm^{-1}) was observed. Hence their absorption bands are not reported.

Silylation of β-Diketones

Other than reaction time (see Table 1), the conditions used for the silylation of the three β-diketones to their corresponding trimethylsilyl enol ethers were identical to those illustrated below with dimedone (**4**). Physical data and yields of all the products are compiled in Table 1.

Hexamethyldisilazane (1.5 g, 9.44 mmol) was added to a solution of dimedone (**4**) (1 g, 7.14 mmol) in dry dichloromethane (20 mL) under a nitrogen atmosphere. After stirring at room temperature (20°C) for 1½ h, the excess hexamethyldisilazane and by-products were evaporated at 10 Torr at room temperature. The residue solidified after standing overnight under dry nitrogen atmosphere yielding 1.49 g (98%) of pure **5**.

Amination of β-Triketones

Other than reaction time (see Table 2), the conditions used for the amination of the four β-triketones studied to their corresponding enaminodiketones were identical to those illustrated below with 2-acetyldimedone (**9**). Since there was a difference in work-up procedure for 2′-amino-*N*-carbobenzoxychelocardin (**8**), its experimental procedure is also reported. Physical data and yields of all products are compiled in Table 2.

Hexamethyldisilazane (600 mg, 3.72 mmol) was added to a solution of 2-acetyldimedone (500 mg, 2.75 mmol) in dry chloroform (10 mL) and the resulting solution was stirred under a nitrogen atmosphere at room temperature (20°C) for 14 h. It was evaporated to dryness under reduced pressure. Nuclear magnetic resonance spectra of the crude product showed the absence of enolsilyl or silylamino groups. It was then redissolved in chloroform (50 mL) and washed with water. The organic layer was dried over magnesium sulfate. Evaporation to dryness yielded 485 mg (**10**) (98%), mp 127.5–128.5°C.

*Preparation of 2-Aminoacetyldimedone (**10**) by the use of Ammonium Acetate*

Ammonium acetate (500 mg, 6.33 mmol) was added to a solution of 2-acetyldimedone (300 mg, 1.65 mmol) in tetrahydrofuran (20 mL) and the resulting mixture was stirred at room temperature (20°C) for 16 h. It was filtered and evaporated under reduced pressure to dryness. It was taken up in chloroform (50 mL) and washed with water. The crude product obtained was chromatographed on silica gel column to give 230 mg pure product (**10**) identical to the one prepared above. The yield was 76%.

*2′-Amino-N-carbobenzoxychelocardin (**8**)*

Hexamethyldisilazane (380 mg, 2.37 mmol) was added to a solution of *N*-carbobenzoxychelocardin (**7**) (450 mg, 0.83 mmol) in dry chloroform (20 mL) and the resulting solution was stirred under nitrogen atmosphere at room temperature for 2 h. It was evaporated under reduced pressure to dryness. The residue was refluxed in 0.01 *M* methanolic hydrogen chloride solution (25 mL) for 1 h. After concentrating to small volume, a precipitate appeared. It was filtered and washed with cold methanol yielding 365 mg **8**.

Acknowledgements

We thank G. Nettleship for recording nmr spectra and Sandra L. Mueller and her associates and Ruth S. Stanaszek of Abbott Laboratories, North Chicago, for recording the mass spectra and ^{13}C nmr spectra, respectively, and the staff of the microanalytical department of Abbot Laboratories for the elemental analyses. We also thank David L. Garmaise for his interest and encouragement throughout the course of this work.

The reaction of $R_2PC{=}CCl(CF_2)_n$ with iron carbonyls. Unusual complexes formed by ligand cleavage reactions

WILLIAM R. CULLEN AND MANGAYARKARASY WILLIAMS

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received June 19, 1979

WILLIAM R. CULLEN and MANGAYARKARASY WILLIAMS. Can. J. Chem. **58**, 143 (1980).

The phosphines $R_2PC{=}CCl(CF_2)_n$ and arsine $(CH_3)_2AsC{=}CCl(CF_2)_3$ (L; R = C_6H_5 or C_6H_{11}; n = 2, 3, 4) react with iron carbonyls to afford a range of products. Simple substitution yields (L)Fe(CO)$_4$ and $L_2Fe(CO)_3$. Loss of chlorine from the ligands, symbolized (L − Cl), gives coupled complexes of formula $[(L - Cl)Fe(CO)_4]_2$ and loss of chlorine and fluorine gives the η^3-allyl bridged derivatives (L − Cl − F)$Fe_2(CO)_6$. Only substitution products are obtained from the cyclobutenes.

WILLIAM R. CULLEN et MANGAYARKARASY WILLIAMS. Can. J. Chem. **58**, 143 (1980).

Les phosphines $R_2PC{=}CCl(CF_2)_n$ et l'arsine $(CH_3)_2AsC{=}CCl(CF_2)_3$ (L; R = C_6H_5 ou C_6H_{11}; n = 2, 3, 4) réagissent avec les carbonyles de fer pour conduire à une variété de produits. La substitution simple donne (L)Fe(CO)$_4$ et $L_2Fe(CO_3)$. La perte de chlore à partir des ligands symbolisés (L − Cl) donne des complexes couplés de formule $[(L - Cl)Fe(CO)_4]_2$ et la perte de chlore et de fluor donne les dérivées ayant un groupement η^3-allyle en position de pont (L − Cl − F)$Fe_2(CO)_6$. A partir des cyclobutènes, on obtient seulement des produits de substitution.

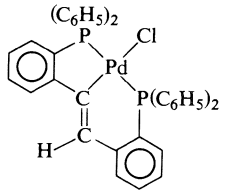
There is considerable current interest in the reactions of tertiary phosphines and arsines of the type R_2ER' (E = P, As; R′ = unsaturated hydrocarbon group) with transition metal complexes (1–18). The general thrust of these studies has been to establish what can happen to the unsaturated group held in close proximity to a transition metal by a bond formed between the metal and the Group V donor. Many types of behaviour have been observed which can be described as follows (only typical examples are given):

(*1*) Coordination by E with R′ being unaffected (1, 3), e.g.

$(C_6H_5)_2PC{=}CCl(CF_2)_3Mo(CO)_5$

and **1**.

(*2*) Coordination of both E and R′ to give a chelate derivative (3, 4), e.g. **1**.



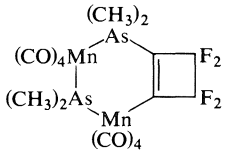
1

(*3*) Coordination of both E and R′ to different metal atoms (5–8), e.g.,

$(CO)_3FeP(C_6H_5)_2C{\equiv}C_6H_5 \quad (CO)_3FeP(C_6H_5)_2C{\equiv}C_6H_5$

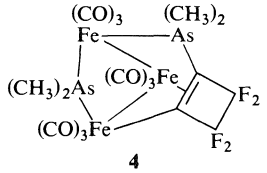
(*4*) Modification of R′ to an η^1-bonding species by cleavage of an appropriate group such that (*a*) E and modified R′ are bonded to the same metal (9), e.g., **2** (by loss of H), (*b*) E and modified R′ are

2



bonded to different metal atoms (10), e.g., **3** from

$(CH_3)_2AsC{=}CAs(CH_3)_2(CF_2)_2$



and (*c*) E is bonded to one metal, and the modified R′ is η^1-bonded to one metal and η^2-bonded to a third resulting in a cluster (11), e.g., **4** from

$(CH_3)_2AsC{=}CAs(CH_3)_2(CF_2)_2$

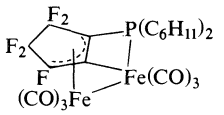
(*5*) Modification of R′ to an η^n-bonding species, $n > 2$, by cleavage of the appropriate groups with

3

4

concomitant formation of a cluster (2, 12), e.g., **5** from

$(C_6H_{11})_2PC{=}CCl(CF_2)_3$



(this is also an example of class 4(*a*)).

(*6*) Coupling of ligands through R′ to give a new ligand which coordinates to the metal using the Group V donors and two σ-bonds from the newly formed bridging group (3, 13), e.g., **6**.

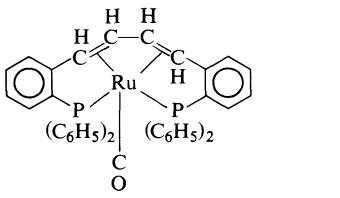
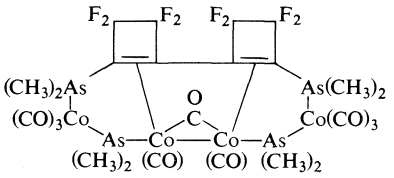
5



6



(*7*) Coupling of the ligand through R′ with cleavage of groups to give a new unsaturated ligand which bonds to (*a*) one metal (3, 13) using E and the bridging group, e.g., **7** and (*b*) two or more metal centres using E and the bridging group producing a cluster (14, 15), e.g., **8** from

$(CH_3)_3AsC{=}CAs(CH_3)_2(CF_2)_2$

(*8*) Cleavage of R′ from E associated with coupling reaction of the fragment with R_2PR' to yield clusters in which E and the new unsaturated systems bind (16, 17), e.g., **9** from

7

8

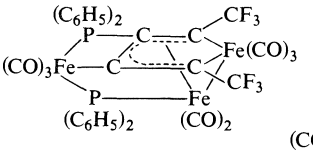
$(C_6H_5)_2PC{\equiv}CCF_3$

(*9*) Others (18), e.g.,

$(C_6H_5)_2PCH_2C(CF_3){=}CHP(C_6H_5)_2PtCl_2$

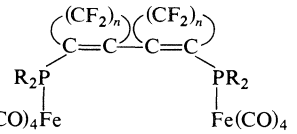
from $(C_6H_5)_2PC{\equiv}CCF_3$.

In this paper we describe the reaction of the unsaturated ligands



$R_2EC{=}CCl(CF_2)_n$

with $Fe(CO)_5$. In particular we describe the preparation and properties of a number of compounds related to **5**, however, other compounds belonging to class 1 are identified. We also report examples **10** of compounds which belong to a new subsection of class 7 (7*c*): **10** is formed by coupling the ligand through R′ with cleavage of groups to give a new unsaturated ligand which bonds to metal centres using the E donors alone.



This work arose because it was recognized (1, 2) that unusual reactivity seems to be associated with ligands with the structure

$R_2EC{=}CX$

where X is a potential leaving group.

9

10

Experimental

Reactions with iron carbonyls were carried out in sealed Carius tubes. A standard vacuum system was used for the manipulation of volatile reactants. Involatile phosphines were handled in a nitrogen-filled glove bag.

Infrared spectra were recorded using a Perkin-Elmer 457 spectrophotometer. The KBr cell had a path length of 0.1 mm and the solvent was cyclohexane. Only selected bands are quoted in the text. Nuclear magnetic resonance spectra were run ($CDCl_3$ solution) on Varian T-60 and XL-100 instruments; chemical shifts are given in ppm downfield from internal TMS (^1H spectra), upfield from internal $CFCl_3$ (^{19}F spectra), and upfield from external 85% H_3PO_4 (^{31}P spectra, ^1H decoupled).[1] Mass spectra were obtained using an AEI MS-9 spectrometer. Microanalyses were performed by Mr. Peter Borda of the Chemistry Department, University of British Columbia.

Fluorocarbons and phosphine starting materials were obtained from Peninsular Chem Research Inc. and Strem Chemical Co. respectively. Pentacarbonyl iron also came from Strem. The ligands

$R_2EC{=}CCl(CF_2)_n$

were prepared as previously described (1, 19).

Reaction of the Tertiary Phosphines $R_2EC{=}CCl(CF_2)_n L$, with Iron Carbonyls

The following general procedure was used for all reactions of the phosphines with iron pentacarbonyl and triiron dodecacarbonyl. The details applying to specific complexes are listed in Table 1.

A benzene solution containing a 1:10 mole ratio of ligand-to-pentacarbonyliron (or 1:2 ratio when $Fe_3(CO)_{12}$ was used) was heated at the indicated temperature for 3–52 h. At the end of the reaction period the solvent was removed at reduced pressure. The residue was dissolved in petroleum ether (bp 40–60°C) and chromatographed on a Florisil column. The colored bands were eluted with mixtures of diethyl ether – petroleum ether. The eluate was evaporated leaving the crude products which were recrystallized from hexane.

Table 2 shows the percentage yield of various compounds

[1]The nmr data are listed in Table 5 which is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

isolated from the reaction of

$(C_6H_5)_2PC{=}CCl(CF_2)_3$

with $Fe(CO)_5$ after different time intervals.

Reaction of $(C_6H_5)_2PC{=}CCl(CF_2)_3Fe(CO)_4$ with the Iron Pentacarbonyl

Iron pentacarbonyl (2.1 g, 10.7 mmol) and the iron complex (0.6 g, 1.06 mmol) in benzene (8 mL) were heated at 150°C for 48 h. The procedure for working up the products was similar to that described above. Chromatography on a Florisil column gave a yellow band when eluted with petroleum ether. This was identified as unreacted complex $(L)Fe(CO)_4$ (0.21 g, 33% recovery). A 1% diethyl ether – 99% petroleum ether mixture eluted an orange band. Evaporation of solvent and recrystallization from hexane afforded orange-red crystals of the $(L-Cl-F)Fe_2(CO)_6$ derivative of known spectroscopic properties (0.22 g, 33%).[2]

[2]See footnote to Table 1.

Pyrolysis of $(C_6H_5)_2PC{=}CCl(CF_2)_3Fe(CO)_4$

When a solution of the iron complex (0.213 g, 0.38 mmol) in benzene (8 mL) was heated at 150°C for 48 h the solution turned orange. The tube contents were treated as described above. Chromatography on a Florisil column gave $(L)Fe(CO)_4$ (0.08 g, 37% recovery) as the only product.

Reaction of $(C_6H_5)_2PC{=}CCl(CF_2)_3W(CO)_5$ with Iron Pentacarbonyl

Iron pentacarbonyl (0.54 g, 2.75 mmol) and the tungsten complex (1) (0.2 g, 0.28 mmol) in benzene (10 mL) were heated at 150°C for 46 h. At the end of the reaction period the solution was orange with white solid particles. The usual procedure followed by chromatography on a Florisil column gave a yellow band which was eluted with petroleum ether. This was identified as

$(C_6H_5)_2PC{=}CCl(CF_2)_3Fe(CO)_4$

(0.015 g, 9.6%) of known spectroscopic properties. A 1% diethyl

ether – 99% petroleum ether mixture eluted an orange band. This was identified as the corresponding $(L - Cl - F)Fe_2(CO)_6$ species (0.011 g, 6.3%) of known spectroscopic properties.

Results and Discussion

The simplest possible products anticipated from the reaction of a ligand

$R_2EC{=}CCl(CF_2)_n$

L, with an iron carbonyl are the mono-substituted derivatives

$R_2EC{=}CCl(CF_2)_nFe(CO)_4$

$(L)Fe(CO)_4$, where the group V donor has displaced one CO group from the parent carbonyl $Fe(CO)_5$.[3] As can be seen from Tables 1 and 2 both cyclobutene derivatives

$R_2PC{=}CCl(CF_2)_2$

($R = C_6H_5$ or C_6H_{11}) afford only these derivatives when reacted with $Fe(CO)_5$ at 140°C. At higher temperatures charring occurs.

This type of mono-substituted product is the one isolated when those ligands are reacted with the group VI hexacarbonyls (1). However,

$(C_6H_{11})_2PC{=}CCl(CF_2)_3$

reacts with iron pentacarbonyl to afford two novel products one of formula $(L - Cl - F)Fe_2(CO)_6$ (see footnote *a*, Table 1) and the other $(L - Cl)_2Fe_2(CO)_8$. The tetracarbonyl derivative $(L)Fe(CO)_4$ in this case is isolated from the reaction of L with $Fe_3(CO)_{12}$: the other two complexes are also produced.

The analogous diphenylphosphine complexes $(L - Cl - F)Fe_2(CO)_6$ and $(L)Fe(CO)_4$ (but not $(L - Cl)_2Fe_2(CO)_8$) are produced in the reaction of

$(C_6H_5)_2PC{=}CCl(CF_2)_3$

with $Fe(CO)_5$ at 150°C for 48 h. A shorter reaction time (3 h) affords a greater yield of the $(L)Fe(CO)_4$ complex and a disubstituted derivative $L_2Fe(CO)_3$ can also be isolated. The $(L)Fe(CO)_4$ and $(L - Cl - F)Fe_2(CO)_6$ complexes are also formed on ultraviolet irradiation of a benzene solution of the ligand and $Fe(CO)_5$.

In a similar manner

$(C_6H_5)_2PC{=}CCl(CF_2)_4$

affords a coupled $(L - Cl)_2Fe_2(CO)_8$ derivative and a cluster $(L - Cl - F)Fe_2(CO)_6$ (but no simple $(L)Fe(CO)_4$ derivative). The dicyclohexylphosphino analogue

$(C_6H_{11})_2PC{=}CCl(CF_2)_4$

yields the $(L)Fe(CO)_4$ and $(L - Cl - F)Fe_2(CO)_6$ complexes but not the coupled $(L - Cl)_2Fe_2(CO)_8$. Arsenic compounds apparently behave in a similar manner since

$(CH_3)_2AsC{=}CCl(CF_2)_3$

reacts with $Fe(CO)_5$ to give the $(L)Fe(CO)_4$ and $(L - Cl - F)Fe_2(CO)_6$ derivatives.

Characterization of the New Complexes

Analytical data are given in Table 3.

(L)Fe(CO)$_4$

$L = R_2PC{=}CCl(CF_2)_n$ ($R = C_6H_5$ or C_6H_{11}, $n = 2, 3, 4$) except

$(C_6H_5)_2PC{=}CCl(CF_2)_4$ and $(CH_3)_2AsC{=}CCl(CF_2)_3$

The mass spectra of these complexes show a parent ion followed by peaks corresponding to the loss of four carbonyl groups. The infrared spectra outside the ν(CO) region are similar to those of the free ligand and ν(C—F), ν(C=C), and ν(C—Cl) are essentially unshifted indicating that only the phosphorus (or arsenic) atom is involved in the bonding of L to the $Fe(CO)_4$ fragment. The ^{19}F nmr spectra are consistent with this interpretation.[1] In the ν(CO) region of the infrared spectra the $(L)Fe(CO)_4$ complexes show four bands one of which appears as a shoulder. This is to be expected if $(L)Fe(CO)_4$ is an axially substituted trigonal bipyramid and L is an asymmetric ligand (20). As can be seen from Table 4, the frequency of the ν(CO) bands for the

[3]These $(L)Fe(CO)_4$ complexes belong to class 1 described above.

[a]Calculated for $C_{24}H_{22}F_7Fe_2O_6P.\ 0.5\ C_6H_{14}$.

diphenylphosphino derivatives are slightly higher than those of the dicyclohexylphosphino analogues. This feature is also observed for the $(L)M(CO)_5$ complexes (M = Cr, Mo, W) (1) and indicates that the diphenylphosphino complexes are the better π-acceptors (or σ-donors).

$(L)_2Fe(CO)_3$

L = $(C_6H_5)_2PC{=}CCl(CF_2)_3$. The mass spectrum confirms the formula and the nmr spectra indicate that the ligand is bound only through the phosphorus. The two ν(CO) bands suggest that the structure of $(L)_2Fe(CO)_3$ is a diaxially substituted trigonal bipyramid.

$(L - Cl)_2Fe_2(CO)_8$

L = $(C_6H_5)_2PC{=}CCl(CF_2)_4$, $(C_6H_{11})_2PC{=}CCl(CF_2)_3$. The infrared spectra of these complexes show no ν(C—Cl) bands and only weak ν(C=C) bands. The ν(CO) region shows four bands and the pattern is very similar to that of the $(L)Fe(CO)_4$ compounds described above. The absence of Cl is seen in both mass spectra. A peak corresponding to the molecular ion is present in the case of the diphenylphosphino derivative however the most intense peak corresponds to the ion $(L - Cl)Fe(CO)_4^+$ from which loss of four CO groups takes place. In the case of the dicyclohexylphosphino analogue, the parent ion is not seen in the mass spectrum and only peaks associated with $(L - Cl)Fe(CO)_4$ are observed. These data suggest that two complexes have the structure **10** (R = C_6H_5, n = 4; R = C_6H_{11}, n = 3) which is consistent with their ^{19}F nmr spectra.[1]

$(L - Cl - F)Fe_2(CO)_6$

L = $R_2PC{=}CCl(CF_2)_n$ R = C_6H_{11}, n = 3, 4; R = C_6H_5, n = 3, 4; and $(CH_3)_2AsC{=}CCl(CF_2)_3$.

It is easiest to describe this group of compounds in terms of the known structure of

$(C_6H_{11})_2PC{=}C{=}CF(CF_2)_2Fe_2(CO)_6$

5 even though the X-ray determination confirmed the structure deduced on the basis of the spectroscopic properties. Thus the infrared spectrum of **5** shows the absence of ν(C=C) and ν(C—Cl) and has a very different ν(C—F) pattern from the parent ligand. The ν(CO) region has six bands with a pattern similar to that reported for (L—L)-$Fe_2(CO)_6$ (6) (L—L =

$(CH_3)_2AsC{=}CAs(CH_3)_2(CF_2)_2$

and similar ligands) which have a similar structure. The Mössbauer spectrum shows the presence of two inequivalent iron atoms. The ^{19}F nmr (Fig. 1

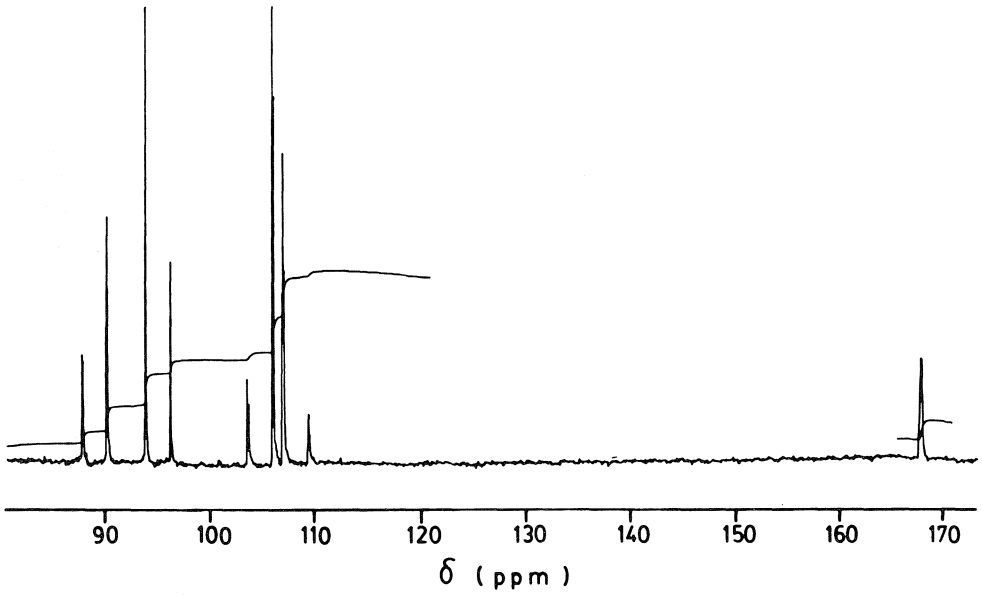

FIG. 1. The ^{19}F nmr spectrum of $(C_6H_{11})_2PC{=}C{=}CF(CF_2)_2Fe_2(CO)_6$.

and Table 5[1]) shows two "AB quartets" centred at 106.6 (J(F,F) = 224.7 Hz) and 92.06 ppm (J(F,F) = 224.9 Hz) and one up-field multiplet. The up-field shift of the single fluorine atom is probably due to a shielding effect of the allyl linkage (21, 22). The quartet with fewer additional couplings at 92.06 ppm can be assigned to the CF_2 group nearest the phosphorus atom. The ^{31}P nmr spectrum of **5** consists of a single multiplet (due to P–F coupling) but the down-field shift on complexing (Table 5) is much less than in the related $(L)Fe(CO)_4$ and $[(L-Cl)Fe(CO)_4]_2$ complexes indicating that the loss of electrons from the phosphorus atoms, because of donation to the metal, must be partly compensated by cluster formation.

The spectroscopic properties of the other complexes of formula $(L - Cl - F)Fe_2(CO)_6$ are very similar to those of **5** and they all undoubtedly have

For personal use only.

the same basic skeleton. In the case of the cyclohexenyl derivative the ^{19}F nmr spectra show three sets of "AB quartets" but these cannot be assigned with any certainty to a particular CF_2 group.[1]

Coupling reactions of halocarbons in the presence of $Fe(CO)_5$ are well known, e.g. eq. [1] (23). The interesting feature of the reactions

[1] $(C_6H_5)_2CCl_2 + Fe(CO)_5 \rightarrow (C_6H_5)_2C{=}C(C_6H_5)_2$

which give rise to the two derivatives **10** is that the basic ligands

$$R_2\overline{PC{=}C(CF_2)_n}\,\overline{C{=}CPR_2(CF_2)_n}$$

have not been reported previously. Attempts to prepare them by reacting the appropriate phosphine R_2PH with

$$Cl\overline{C{=}C(CF_2)_n}\,\overline{C{=}CCl(CF_2)_n}$$

give disubstitution only when $n = 2$ (24). Related coupling reactions to give **8** and **7** have already been described in the Introduction. In these cases coupling occurs by loss of $-As(CH_3)_2$ and H respectively from the ligands, and the unsaturated bridging groups are coordinated to a metal center or metal centers. In **10** the newly formed unsaturated bridge is not involved in further bonding.

A compound of structure **10** $R = C_6H_5$, $n = 2$ is produced in low yield from the reaction of the free ligand with $Fe(CO)_5$ although in this case the main products are isomers of formula $(L)Fe_2(CO)_6$ in which the ligand has undergone considerable rearrangement (25).

There are numerous known η^3-allyl complexes of iron (26) including some which are partly fluorocarbon. However, only one example was previously known in which the allyl group is a fluorocarbon moiety (27), this is the (η^3-nonafluorocyclohexenyl)tricarbonyliron anion obtained from (η^4-octafluorocyclohexa-1,3-diene)tricarbonyliron by fluoride ion addition. The compounds of structure **5** (and **4**) are also very unusual in that they contain a ligand which is η^n-bonded with respect to one metal and η^1-bonded to another.

In an attempt to gain some insight into the mechanism of formation of these $(L - Cl - F)Fe_2(CO)_6$ complexes some studies were conducted with

$$(C_6H_5)_2P\overline{C{=}CCl(CF_2)_3}$$

In the presence of $Fe(CO)_5$ reaction occurs (Table 2) with the first formed product being $(L)Fe(CO)_4$. As the reaction time increases the first formed $(L)Fe(CO)_4$ appears to react with the excess $Fe(CO)_5$ to give $(L - Cl - F)Fe_2(CO)_6$. This is confirmed by a separate experiment. Thus heating $(L)Fe(CO)_4$ and $Fe(CO)_5$ at 150°C gives a 33% yield of $(L - Cl - F)Fe_2(CO)_6$. Because of these results, we hoped that a mixed metal derivative might be formed by reacting (150°C)

$$(C_6H_5)_2P\overline{C{=}CCl(CF_2)_3}W(CO)_5$$

with $Fe(CO)_5$. Only low yields of the appropriate $LFe(CO)_4$ and $(L - Cl - F)Fe_2(CO)_6$ were obtained. The reaction probably proceeds by ligand exchange followed by further reaction of the $(L)Fe(CO)_4$ with $Fe(CO)_5$.

The properties of complexes of structure **5** are of interest since potential sites of activation are the Fe—Fe bond the CO groups and the η^3-allyl group. A preliminary study has shown that the diphenylphosphino analogue of **5** is an efficient catalyst for the photochemical isomerization of olefins, though not their photochemical hydrogenation (28).

In conclusion it should be pointed out that it is difficult to explain why the derivatives of the cyclobutenes

$$R_2P\overline{C{=}CCl(CF_2)_2}Fe(CO)_4$$

do not react further to give the $Fe_2(CO)_6$ derivatives since there are numerous examples known of η^3-allyl groups derived from 4-carbon rings (26).

3,5-Dimethylpyrazolylphosphine molybdenum(0) and tungsten(0) carbonyl complexes

HARRY B. DAVIS, JAMES K. HOYANO, PING YUEN LEUNG,
LOUIS K. PETERSON, AND BRIAN WOLSTENHOLME
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received July 9, 1979

HARRY B. DAVIS, JAMES K. HOYANO, PING YUEN LEUNG, LOUIS K. PETERSON, and BRIAN WOLSTENHOLME. Can. J. Chem. **58**, 151 (1980).

Complexes with the general formula $[L_nM(CO)_m]$, where $L = \phi_xP(Me_2pz)_{3-x}$, $x = 0$–2, $n = 1$ or 2, M = Mo(0) or W(0), $m = 3$ or 4, were prepared by thermal or photolytic methods by the reaction of the appropriate 3,5-dimethylpyrazolyl phosphine ligand with $M(CO)_6$, norbornadienemetaltetracarbonyl $[C_7H_8M(CO)_4]$, cycloheptatrienylmetaltricarbonyl $[C_7H_8M(CO)_3]$, $[(Me_2N(CH_2)_3NMe_2)M(CO)_4]$, $[(CH_3CN)_2M(CO)_4]$, or $[CH_3CN)_3M(CO)_3]$. Structural evidence indicates octahedral geometry about the metal atom centre, and several modes of coordination for the ligands in those complexes isolated and characterized. For $x = 2$, the ligand $\phi_2P(Me_2pz)$ was monodentate, via phosphorus in $[(\phi_2P(Me_2pz))_2M(CO)_4]$ (**I**, **II**), and bidentate in $[\phi_2P(Me_2pz)M(CO)_4]$ (**III**, **IV**) where coordination by P and the 2N site of the pyrazolyl ring yielded four-membered $\overline{MPNN}$ metallocycles. For $x = 1$, the $\phi P(Me_2pz)_2$ ligand was bidentate, via the phosphorus atom and one of the 2N sites of one of the pyrazolyl substituents, thus giving the four-membered $\overline{MNNP}$ metallocycle in $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**), and tridentate in $[\phi P(Me_2pz)_2M(CO)_3]$ (**VI**, **VII**) where three *facial* CO's, two 2N atoms of the pyrazolyl rings, and a part of the phenyl ring occupy the six coordination sites. For $x = 0$, the $P(Me_2pz)_3$ ligand was tridentate via the 2N atoms of all three pyrazolyl rings, thus giving tricyclic systems $[P(Me_2pz)_3M(CO)_3]$ (**VIII**, **IX**).

HARRY B. DAVIS, JAMES K. HOYANO, PING YUEN LEUNG, LOUIS K. PETERSON et BRIAN WOLSTENHOLME. Can. J. Chem. **58**, 151 (1980).

Les complexes de formule générale $[L_nM(CO)_m]$ où $L = \phi_xP(Me_2pz)_{3-x}$, $x = 0$–2, $n = 1$ ou 2, M = Mo(0) ou W(0), $m = 3$ ou 4 sont préparés au moyen de méthodes thermiques ou photolytiques par la réaction du ligand approprié: diméthyl-3,5 pyrazolyle phosphine avec $M(CO)_6$, norbornadiènemétaltétracarbonyle $[C_7H_8M(CO)_4]$ cycloheptatrièmylmétaltricarbonyle $[C_7H_8M(CO)_3]$, $[(Me_2N(CH_2)_3NMe_2)M(CO)_4]$, $[(CH_3CN)_2M(CO)_4]$ ou $[(CH_3CN)_3M(CO)_3]$. Les données structurales indiquent qu'il existe une géométrie octaèdrique autour de l'atome de métal central et plusieurs modes de coordination des ligands dans les complexes isolés et caractérisés. Pour $x = 2$, le ligand $\phi_2P(Me_2pz)$ est monodentate par l'intermédiaire du phosphore dans $[\phi_2P(Me_2pz))_2M(CO)_4]$ (**I**, **II**) et bidentate dans $[\phi_2P(Me_2pz)M(CO)_4]$ (**III**, **IV**) où la coordination par le phosphore et l'azote 2 du cycle pyrazolyle donne les métallocycles à 4 chaînons $\overline{MPNN}$. Pour $x = 1$ le ligand $\phi P(Me_2pz)_2$ est bidentate par l'intermédiaire de l'atome de phosphore et un des deux azote des substituants pyrazolyles donnant ainsi un métallocycle à 4 chaînons $\overline{MNNP}$ dans le complexe $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**). Le ligand $\phi P(Me_2pz)_2$ est tridentate dans le complexe $[\phi P(Me_2pz)_2M(CO)_3]$ (**VI**, **VII**) où les trois CO en position faciale, deux atomes d'azote 2 des cycles pyrazolyles et une partie du cycle phényle occupent les six sites de coordination. Pour $x = 0$ le ligand $P(Me_2pz)_3$ est tridentate par l'intermédiaire des atomes d'azote 2 des trois cycles pyrazolyles donnant ainsi des systèmes tricycliques $[P(Me_2pz)_3M(CO)_3]$ (**VIII**, **IX**).

[Traduit par le journal]

Introduction

There is currently an interest in the chemistry of transition metal complexes formed by polydentate ligands containing different donor atoms, including various structural combinations of phosphine and amine type centres (1). The potential of such systems to exhibit subtle variations in properties, with possible applications in homogeneous catalytic processes, has stimulated much interest and research effort in this field. We have previously described the syntheses of pyrrolyl- (2) and pyrazolyl-phosphine (3) ligand systems, and the formation of complexes of the latter with manganese(I) and rhenium(I) (4).

We report here our investigations of 3,5-dimethylpyrazolylphosphine complexes of molybdenum(0) and tungsten(0).

Discussion

In general, the reactions of the dimethylpyrazolylphosphine ligands $\phi_xP(Me_2pz)_{3-x}$ ($x = 0$–2) with the substituted metal carbonyls $[C_7H_8M(CO)_4]$, $[(Me_2NCH_2CH_2CH_2NMe_2)M(CO)_4]$, $[(CH_3CN)_2M(CO)_4]$, $[C_7H_8M(CO)_3]$, and $[(CH_3CN)_3M(CO)_3]$ (M = Mo or W) proceed under relatively mild conditions, and the derivatives of molybdenum react more readily than those of tungsten. When hexacarbonyl $M(CO)_6$ was used, more vigorous reaction conditions were required. Preliminary studies showed that prolonged heating (> 12 h) of the pyrazolylphosphine ligands $\phi_xP(H_2pz)_{3-x}$ with $Mo(CO)_6$ in refluxing benzene gave highly insoluble products, with analyses and ir data (ν_{CO} region) consistent for tricarbonyl formulations $[LM(CO)_3]$, possibly with polymeric structures.[1] Prolonged heating of $[\phi_2P(Me_2pz)Mo(CO)_4]$ (**III**) under similar conditions also gave insoluble products.

The products **I**–**IX** were characterized according to elemental analyses, mass, infrared (Table 1), ^1H (Table 2), and ^{31}P (Table 3) nmr spectroscopic data. The pure complexes are moderately air-stable crystalline solids, whereas the free ligands are readily oxidized and hydrolysed in air (3).

Complexes of Diphenyl(3,5-dimethylpyrazolyl)-phosphine, $\phi_2P(Me_2pz)$

Six isomeric octahedral structures are possible for the $[L_2M(CO)_4]$ complexes $[(\phi_2P(Me_2pz))_2M(CO)_4]$ (M = Mo, **I**; W, **II**) where the pyrazolylphosphine ligands may coordinate via phosphorus or via nitrogen in *cis*- or *trans*-configurations. The ^{31}P spectra of **I** and **II** (Table 3) indicated equivalent phosphorus nuclei, and the coordination shifts (−66 and −44 ppm, respectively) suggest direct phosphorus–metal bonding. This conclusion is corroborated by evidence of a doublet satellite resonance in the ^{31}P spectrum of **II**, arising from coupling between phosphorus and the ^{183}W nucleus ($I = \frac{1}{2}$, natural abundance, 14.3%, giving a 7:86:7 triplet (5)). The coupling constant ($J_{^{31}P-^{183}W}$ = 320 Hz) is of a magnitude comparable to literature values for phosphine–tungsten complexes (5–7). Also, ^1H nmr evidence indicated equivalent 3,5-dimethylpyrazolyl rings in **I** and in **II**. The ir spectra of **I** and **II** show only one strong ν(CO) band, indicative of a *trans*-octahedral D_{4h} structure, and with essentially the same energy as the E_u mode of *trans*-$[(\phi_3P)_2M(CO)_4]$ complexes (M = Mo (8), W (9)). Similarly, the pyrrolylphosphine com-

plexes $[(\phi_2P(R_2py))_2Mo(CO)_4]$ (R = H, pyrrolyl; R = Me, 2,5-dimethylpyrrolyl) prefer a *trans* rather than a *cis*-configuration.[2]

The complexes of $[\phi_2P(Me_2pz)M(CO)_4]$ (M = Mo, **III**; W, **IV**) showed mononuclear parent ions and loss of four CO groups in their mass spectra, and four ir bands were observed in the carbonyl stretching region (Table 1). In both cases the ^{31}P coordination shifts were appreciably downfield (Table 3) and, for **IV**, direct phosphorus–tungsten coupling ($J_{^{31}P-^{183}W}$ = 267 Hz) was observed. These data indicate a mononuclear, *cis*-tetracarbonyl pseudo-C_{2v} structure (10–12) for **III** and **IV**, containing coordinated phosphorus (5–7) in a four-membered $\overline{MPNN}$ metallocycle. Structurally similar $\overline{MPNN}$ and $\overline{MPCC}$ metallo-rings are found in $[\phi_2P(Me_2pz)Mn(CO)_3Cl]$ (13) and in *ortho*-metallated insertion products of the type $(CH_3C_6H_4)_2\overline{PC_6H_3(CH_3)Mn}(CO)_4]$ (14), respectively.

Whereas the phosphorus bonded *trans*-$[(\phi_2P(Me_2pz))_2M(CO)_4]$ (**I** and **II**) derivatives were readily obtained by employing excess ligand in solution, corresponding attempts to prepare bis-ligand manganese and rhenium analogs yielded only $[\phi_2P(Me_2pz)M(CO)_3X]$ (M = Mn, Re; X = Cl, Br). The latter compounds are also resistant to nucleophilic attack by excess $\phi_2P(Me_2pz)$, ϕ_3P, and CO (4).

Complexes of bis(3,5-Dimethylpyrazolyl)phenylphosphine, $\phi P(Me_2pz)_2$

The reaction of $\phi P(Me_2pz)_2$ with [(nbd)Mo(CO)$_4$],[3] $[(CH_3CN)_3Mo(CO)_3]$, or [(cht)Mo(CO)$_3$][4]

[2]L. K. Peterson and B. Gour, unpublished observations.

[3]nbd = norbornadiene.

[4]cht = cycloheptatriene.

gave the same complex $[\phi P(Me_2pz)_2Mo(CO)_3]$ (**VI**, orange-red). The reaction of $\phi P(Me_2pz)_2$ with $[(CH_3CN)_3W(CO)_3]$ gave $[\phi P(Me_2pz)_2W(CO)_3]$ (**VII**, dark red).

A crystal structure determination of **VII** (15) shows a monomeric species, with an octahedral tungsten centre coordinated by three facial carbonyl groups, by two 2N centres of the pyrazolyl rings, and by a portion of the phenyl group. The latter appears to function in a novel fashion as a "2-electron donor" in this structure, presumably in order to achieve an 18-electron configuration.

In the complexes $[H_2B(Me_2pz)_2Mo(CO)_2(C_7H_7)]$ (16) and $[(C_2H_5)_2B(pz)_2Mo(CO)_2(\eta^2\text{-allyl})]$ (17, 18), Cotton *et al.* have found that 16-electron configurations are avoided by virtue of B---H---Mo or αC---H---Mo three centre-two electron bridge bonding, respectively. The seemingly three-coordinate cation $[(\phi_3P)_3Rh]^+$ is apparently stabilized in a similar fashion, by interactions between Rh and two proximal carbon atoms and one *ortho* hydrogen of a phenyl ring (19). Interestingly, the steric requirements about four-coordinate boron in $[(C_6H_5)_2B(pz)_2(CO)_2(2\text{-methylallyl})Mo]$ (20) preclude a Mo---H---C interaction, thus leaving the metal with a 16-electron valence shell configuration. Three-coordinate phosphorus in our compound $[\phi P(Me_2pz)_2W(CO)_3]$ (**VII**) is less sterically demanding, allowing the phenyl ring to orient itself so as to interact with the metal centre.

On the basis of spectroscopic evidence, compounds **VI** and **VII** have essentially similar structures. Both species exhibit mononuclear parent ions and loss of three CO groups in their mass spectra. Their solution ir spectra show two strong bands in the carbonyl stretching region, indicative of pseudo C_{3v} structures. The relatively low frequencies of the ir bands, as compared to $[MeC(CH_2P\phi_2)_3M(CO)_3]$ (21) complexes (Table 1), suggest coordination by weak π-accepting centres (viz., the 2N's of the pyrazolyl rings and either the phenyl ring or a solvent molecule occupying the sixth coordination site). ^1H nmr spectra show that the pyrazolyl rings are equivalent at ambient temperature, and compounds **VI** and **VII** exhibit singlet ^{31}P resonances with positive coordination shifts (+17 and +19 ppm respectively). This latter effect may be attributed to changes in bond angles about phosphorus (7, 22, 23).

The compounds $[\phi P(Me_2pz)_2M(CO)_3]$ (**VI** and **VII**) slowly react with chloroform, but are stable under nitrogen in benzene, toluene, and tetrahydrofuran. Freshly prepared solutions of **VI** and **VII** react readily with carbon monoxide, as shown by a change in colour, from orange-red to yellow, and by the appearance of new ^{31}P nmr signals. The reactions of **VI** and **VII** with donor molecules will be reported later.

The reaction of $\phi P(Me_2pz)_2$ with $[(CH_3CN)_2W(CO)_4]$ yielded $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**, yellow). Four ir bands were observed in the carbonyl stretching region, indicating a *cis*-tetracarbonyl pseudo C_{2v} configuration (10–12). Structures based on a six-membered $P(N—N)_2W$ metallocycle (Fig. 1) or on a four-membered $\overline{PNNW}$ metallocycle (Fig. 2) are possible. The ^1H nmr spectrum of **V** (Table 2) showed four equal intensity methyl and two equal intensity 4-H resonances, indicative of non-equivalent pyrazolyl rings. The ^{31}P spectrum consisted of a downfield singlet resonance, with tungsten satellites, indicating direct phosphorus-to-metal bonding (5–7). These data are consistent for a *cis*-tetracarbonyl, four-membered metallocycle, containing one coordinated and one free pyrazolyl moiety (Fig. 2). The alternative six-membered metallocycle arrangement (Fig. 1) is precluded.

The molybdenum analog $[\phi P(Me_2pz)_2Mo(CO)_4]$ of **V** is readily formed by the reaction of CO with a solution of $[\phi P(Me_2pz)_2Mo(CO)_3]$ (**VI**) in toluene, but has not yet been isolated pure. Its infrared, ^1H and ^{31}P nmr spectra indicate a structure analogous to that of $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**). In fact, the ir spectra (ν_{CO} region) of the tetracarbonyl complexes $[\phi_2P(Me_2pz)M(CO)_4]$, $[\phi P(Me_2pz)_2M(CO)_4]$, and $[(\phi_2PC_2H_4P\phi_2)M(CO)_4]$ (21) are quite similar, but differ significantly from the spectra of *cis*-$[(pyridine)_2M(CO)_4]$ (24) and $[(dipyridyl)M(CO)_4]$ (24), in which two *cis* coordination sites are occupied by weakly π-bonding ligands that are similar to pyrazolyl moieties. Thus the ligands $\phi_2P(Me_2pz)$ and $\phi P(Me_2pz)_2$ closely resemble $\phi_2PC_2H_4P\phi_2$, in terms of σ donor and π acceptor behaviour, in molybdenum and tungsten tetracarbonyl complexes.

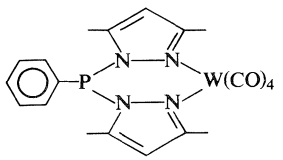

FIG. 1. Six-membered $P(N—N)_2W$ metallocycle.

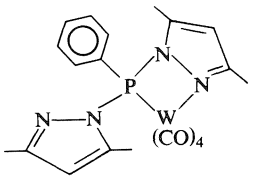

FIG. 2. Four-membered $\overline{PNNW}$ metallocycle.

Interestingly, the d^6 rhenium(I) complex $[\phi P(Me_2pz)_2Re(CO)_3Br]$ is structurally different from **V**. The former adopts a six-membered $P(N—N)_2Re$ boat metallocyclic form (15), a structure common among complexes of pyrazolylborate (25, 26) and pyrazolylgallate (27, 28) ligands, whereas **V** contains a four-membered metallocycle (Fig. 2). Using CPK Atomic Models,[5] we constructed molecular structures based on Figs. 1 and 2. Two boat configurations are possible for Fig. 1. One structure, with the phosphorus lone pair and a carbonyl group (say group "A") in "*endo*" positions, shows severe steric interaction between the phenyl ring and the two 5-methyl groups of the pyrazolyl rings. The second structure, with the phenyl ring and carbonyl group "B" ("B" being *trans* to "A") in "*endo*" positions, shows steric interference between the phenyl ring and group "B", and neatly accounts for the formation of the tricarbonyl derivatives $[\phi P(Me_2Pz)_2M(CO)_3]$ (**VI** and **VII**), via a sterically assisted elimination of CO. Note that in the analogous structure for $[\phi P(Me_2pz)_2Re(CO)_3Br]$ group "B" is CO, rather than Br, for steric reasons, and, being *trans* to the bromide ligand (corresponding to group "A"), is not as readily displaced as in the molybdenum- and tungsten-tetracarbonyl cases.

A study of the models also shows that the steric congestion of the boat forms of Fig. 1 is released when the four-membered metallocyclic structure (Fig. 2) is formed. This occurs because one of the 3,5-dimethylpyrazolyl rings is free to rotate. It also appears that an analogous metallocyclic structure would be accessible to $[\phi P(Me_2pz)_2Re(CO)_3Br]$, but would require the bromide ligand to orient *cis*, rather than *trans*, to a carbonyl group. The resulting structure would have an energy disadvantage associated with two *trans* carbonyl groups, and is presumably less stable than the all *cis* arrangement actually observed in the $P(N—N)_2Re$ boat form (15).

Complexes of tris-(3,4-Dimethylpyrazolyl) phosphine, $P(Me_2pz)_3$

The ligand $P(Me_2pz)_3$ was found to react with tetracarbonyl and with tricarbonyl derivatives of molybdenum and tungsten to yield highly insoluble products formulated as $[P(Me_2pz)_3M(CO)_3]$ (M = Mo, **VIII**; M = W, **IX**).

The complexes **VIII** and **IX** exhibit two strong ν(CO) bands in their ir spectra, and the pyrazolyl rings were found to be equivalent according to ^1H nmr spectra. Mass spectra showed mononuclear parent ions, and species corresponding to the consecutive loss of three CO groups. Hence, a C_{3v} tricyclic structure is indicated, with three *facial* CO groups, and the $P(Me_2pz)_3$ ligand coordinated symmetrically via the 2N atoms of all three pyrazolyl rings. Similar tridentate chelating character has also been reported for pyrazolylborate (25, 26, 29) and pyrazolylgallate (30) ligands.

The relatively low ν_{CO} stretching frequencies for **VIII** and **IX** (~1750–1770 and 1880–1900 cm^{-1}, Table 1) are consistent with the weak π-accepting character of the pyrazolyl ligands. Likewise, two low energy bands are observed for *fac*-$[(pyridine)_3Mo(CO)_3]$ (31) and for tri-(2-pyridyl)-aminemolybdenumtricarbonyl complexes (32), in which the pyridine ligands have coordination properties similar to those of pyrazolyl moieties (24). By contrast, the phosphorus bonded C_{3v} tricyclic structures $[MeC(CH_2P\phi_2)_3M(CO)_3]$ (M = Mo, W (21)) exhibit substantially higher ν_{CO} stretching frequencies.

Nuclear Magnetic Resonance Spectra

The ^1H nmr spectra of the ligands $\phi_2P(Me_2pz)$ and $\phi P(Me_2pz)_2$, and of the complexes **I–IV**, **VI**, and **VII** (Table 2) consisted of a phenyl multiplet (τ 2.5–2.8), a 4-H resonance (τ ~ 4), and two methyl resonances (τ 7.4–8.6). Complex **V** showed four equally intense methyl and two equally intense 4-H resonances, arising from the non-equivalence of the two 3,5-dimethylpyrazolyl groups (already discussed). The relative intensities of the bands corroborate the given formulations of the listed complexes.

The methyl resonances of $\phi_2P(Me_2pz)$ and $\phi P(Me_2pz)_2$ are quite sensitive to complexation. For the ligands themselves, the higher field resonance is assigned to the 5-Me group, on the basis of relatively greater paramagnetic shielding by the phenyl rings (33, 34).

The factors affecting the methyl ^1H chemical shifts in the complexes **I–VII** (Table 2) include (*a*) changes in C—H δ electron density, transmitted inductively as a result of coordination of phosphorus alone (**I**, **II**), or of phosphorus and one 2N site (**III–V**), or of two 2N sites and a portion of the phenyl ring (**VI**, **VII**); (*b*) changes in the π and/or π* electron density of the aromatic phenyl ring(s), the pseudo-aromatic pyrazolyl ring(s) and the carbonyl groups; (*c*) changes in the ring currents, and hence the anisotropic shielding effects (33, 34) associated with (*b*) above; and (*d*) paramagnetic shielding effects attributable to the *d* electrons of the Mo or W metal atom. While the individual shielding contributions of the above factors are

[5]CPK Atomic Models, Ealing Scientific Limited, 23 Leman Street, London, E.1., England.

For personal use only.

difficult to assess, a study of CPK molecular models suggests the following: (*i*) in the *trans* complexes **I** and **II**, the Me_2pz ring is free to rotate about the P—N bond (Fig. 3). During rotation, the 5-methyl group encounters a steric interaction with carbonyl groups that are *cis* to the ligand, and the interaction with the phenyl ring is increased. These effects result in enhanced paramagnetic shielding, as observed. The much smaller shielding of the 3-methyl group, relative to free ligand, is attributable to a long range effect of the carbonyl groups that are *cis* to the ligands. (*ii*) In the metallocyclic systems **III** and **IV**, the 5-methyl group is "locked" in place, in close proximity to two phenyl rings (Fig. 4), and may again be assigned the higher field resonance. The 3-methyl group is similarly "locked" adjacent to a carbonyl group, and again experiences a small shielding effect. The 3- and 5-methyl resonances of $[\phi_2P(Me_2pz)M(CO)_4]$ are effected to a much greater extent in the tungsten complex (**IV**) than in its molybdenum analog (**III**). (*iii*) In $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**) there is one free and one coordinated Me_2pz ring. The four methyl resonances can be paired to correspond closely with resonances of the free ligand (the two lower field signals), and to resonances typical of the Me_2pz ring in PNNM metallocyclic structures (**III**, **IV**) (the two higher field resonances). (*iv*) In the tricarbonyl complexes $[\phi P(Me_2pz)_2M(CO)_3]$ (**VI**, **VII**), the metal---phenyl interaction has three significant effects: first, it causes a deepening of the $P(N—N)_2W$ boat metallocycle; second, the steric interaction between the 5-methyl and the phenyl moieties is decreased; and third, the 3-methyl group is moved away from the carbonyl groups. These structural changes are consistent with the observed deshielding of the 3- and 5-Me protons,

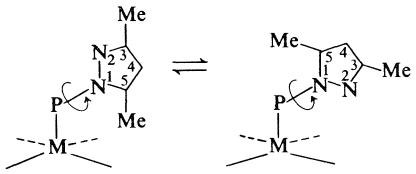

FIG. 3. Rotation about P—N bond.

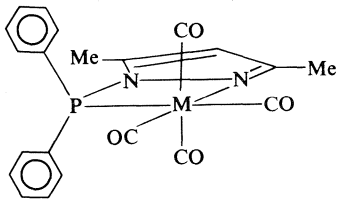

FIG. 4. Metallocycle systems **III** and **IV**.

but since the chemical shifts are now very similar (within ~0.04 ppm), the assignment of the resonances cannot be made with confidence.

In the free ligands $\phi_2P(Me_2pz)$ and $\phi P(Me_2pz)_2$, and in most of the complexes **I**–**VII**, the 4-H chemical shift variation is small, and the resonance is broad due to unresolved ^{31}P–H coupling. In two cases (**VI** and **VII**), however, the resonance was resolved into a doublet ($J_{^{31}P-H}$ = ~3 Hz). Similar couplings were reported for $[\phi P(Me_2pz)_2Re(CO)_3Br]$ and $[P(Me_2pz)_3Re(CO)_3Br]$ (4). Factors affecting long range phosphorus–hydrogen coupling have been discussed (7, 35, 36). Also in two cases an appreciable shielding of the 4-H proton is observed, in $[\phi_2P(Me_2pz)W(CO)_4]$ (**IV**) and for the coordinated Me_2pz ring in $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**); these two 4-H resonances are further broadened, suggestive of both long range ^{183}W–H and ^{31}P–H unresolved coupling. The main factor affecting the 4-H resonance is probably attributable to changes in the shielding effects of the Me_2pz ring π electrons (37, 38).

The proton decoupled ^{31}P nmr spectra of complexes **I**–**VII** are listed in Table 3. The effects which influence the chemical shift of phosphorus include: (*a*) a local diamagnetic term, (*b*) a paramagnetic term, (*c*) neighbour anisotropy effects, and (*d*) interatomic currents (39, 40). Grim *et al.* (40) consider (*c*) and (*d*) to be the most important factors, at least in tertiary phosphine complexes of group VI metal carbonyls.

The phosphorus coordination shifts ($\Delta^{31}P$) for various *trans*-$L_2M(CO)_4$ complexes (41, 42) are listed in Table 4, for comparison with our compounds **I** and **II**. The ^{31}P values for $[(\phi_2P(Me_2pz))_2M(CO)_4]$ (**I**, **II**) are consistent with trends reported in the literature (41, 42), in that the greater numerical value is found in the molybdenum complexes.

For bis-phosphine chelate complexes $[\phi P(R)(CH_2)_nP(R)\phi M(CO)_4]$ (M = Mo, W), the ^{31}P coordination shift is small for four-membered chelate rings (6), but is unusually large for five-membered rings (43–45), the molybdenum complexes having the larger numerical values (typically −67 ppm for Mo and −52 ppm for W). By contrast, the $\Delta^{31}P$ values for our four-membered chelate systems are relatively large ($[\phi_2P(Me_2pz)Mo(CO)_4]$ (**III**), −58 ppm; $[\phi_2P(Me_2pz)W(CO)_4]$ (**IV**), −52 ppm; $[\phi P(Me_2pz)_2W(CO)_4]$ (**V**), −45 ppm) and differences between Mo and W are much less marked than in bidentate phosphine complexes.

Variable temperature nmr studies of the above complexes will be reported in a subsequent paper.

Experimental

All experimental operations were carried out under anhydrous and oxygen-free conditions using high vacuum or inert atmosphere systems. In preparations where carbon monoxide evolution was monitored, heavy-walled Pyrex or quartz Teflon-valved reaction tubes were used, and reaction mixtures were initially outgassed in a series of three freeze–pump–thaw cycles. Evolved carbon monoxide was measured intermittently, or on completion of reaction, by means of a Sprengel pump (46). A water-jacketed Hanovia lamp was utilized in photochemical synthesis.

Solvents were dried by standard methods, distilled, and deaerated prior to use. Common reagents were purchased from commercial suppliers.

The pyrazolylphosphine ligands (2, 3) and the following transition metal complexes were prepared according to published procedures: [(nbd)Mo(CO)$_4$] (ref. 47, pp. 124, 125), [(cht)Mo(CO)$_3$] (ref. 47, pp. 125, 126), [(tmpda)W(CO)$_4$] (48), [(nbd)W(CO)$_4$] (49), [$(CH_3CN)_2$W(CO)$_4$] (50), [$(CH_3CN)_3$W(CO)$_3$] (51), and [(cht)W(CO)$_3$] (49) (nbd = norbornadiene, cht = cycloheptatriene, tmpda = *N*,*N*,*N*′,*N*′-tetramethylpropylene-1,3-diamine).

Elemental analyses for C, H, and N were performed by the University analyst, Simon Fraser University. ^1H and ^{31}P nuclear magnetic resonance spectra were obtained using Varian A56/50 and XL100 instruments, the latter having Fourier transform and nuclear decoupling facilities. Infrared spectra were recorded with a Perkin-Elmer 457 spectrophotometer and were calibrated against standard polystyrene film. Mass spectra were determined with the double-focussing Hitachi-Perkin-Elmer RMU-6E instrument.

*(a) Preparation of [$(\phi_2P(Me_2pz))_2Mo(CO)_4$] (**I**)*

A solution of [(nbd)Mo(CO)$_4$] (0.65 mmol) and $\phi_2P(Me_2pz)$ (1.80 mmol) in benzene (20 mL) was heated at 60°C for 15 h. The solution was evaporated to dryness and the residue recrystallized twice from chloroform–hexane to yield white crystals of [$(\phi_2P(Me_2pz))_2$Mo(CO)$_4$] (**I**). Yield 40%. *Anal.* calcd. for $C_{38}H_{34}N_4MoO_4P_2$: C 59.4, H 4.46, N 7.29; found: C 60.0, H 4.60, N 7.50.

*(b) Preparation of [$(\phi_2P(Me_2pz))_2W(CO)_4$] (**II**)*

A solution of [(tmpda)W(CO)$_4$] (0.82 mmol) and $\phi_2P(Me_2pz)$ (1.80 mmol) in 15 mL of benzene was heated at 80°C for 18 h. The evolved carbon monoxide (0.12 mmol) was collected, the reaction mixture was evaporated to dryness under vacuum, and the residue was crystallized from chloroform–hexane to yield white crystals of [$(\phi_2P(Me_2pz))_2$W(CO)$_4$] (**II**). Yield 50%. *Anal.* calcd. for $C_{38}H_{34}N_4O_4P_2W$: C 54.1, H 3.72, N 5.46; found: C 54.5, H 4.72, N 6.35.

*(c) Preparation of [$\phi_2P(Me_2pz)Mo(CO)_4$] (**III**)*

A solution of [(nbd)Mo(CO)$_4$] (0.50 mmol) and $\phi_2P(Me_2pz)$ (0.50 mmol) in benzene (10 mL) was stirred at room temperature for 3 h. The yellow solution was evaporated to dryness under reduced pressure, yielding a residue which was crystallized from benzene–hexane and identified as [$\phi_2P(Me_2pz)$Mo(CO)$_4$] (**III**) golden-yellow crystals, mp 90°C (dec.). Yield 80%. *Anal.* calcd. for $C_{21}H_{17}MoN_2O_4P$: C 51.7, H 3.51, N 5.74; found: C 51.9, H 3.64, N 5.80.

*(d) Preparation of [$\phi_2P(Me_2pz)W(CO)_4$] (**IV**)*

A mixture of [$(CH_3CN)_2$W(CO)$_4$] (1.5 mmol) and $\phi_2P(Me_2pz)$ in 20 mL of benzene was stirred under nitrogen at room temperature for 60 h. The solvent was removed under reduced pressure, and the light brown residue was chromotographed, under nitrogen, on a florisil column, using benzene/ether as eluant. The appropriate fraction of eluant was collected, the solvent was removed under vacuum, and the product was recrystallized from benzene/hexane, and identified as [$\phi_2P(Me_2pz)$W(CO)$_4$] (**IV**). Yellow crystals; mp 109°C (dec.). Yield 40–50%. *Anal.* calcd. for $C_{21}H_{17}N_2O_4PW$: C 43.8, H 2.97, N 4.86; found: C 44.0, H 3.10, N 4.97.

*(e) Preparation of [$\phi P(Me_2pz)_2W(CO)_4$] (**V**)*

A mixture of [$(CH_3CN)_2$W(CO)$_4$] (1.3 mmol) and $\phi P(Me_2pz)_2$ (1.3 mmol) in benzene was stirred under nitrogen at room temperature for 20 h. During this time, the yellow crystals of [$(CH_3CN)_2$W(CO)$_4$] gradually disappeared and the solution became brownish yellow. The solvent was removed under reduced pressure and the residue was chromatographed under nitrogen on a florisil column (80–100 mesh), using diethyl ether as eluant. The appropriate fraction of eluant was collected, the solvent was removed under vacuum, the product was recrystallized from Et_2O/hexane and identified as [$\phi P(Me_2pz)_2$W(CO)$_4$] (**V**). Yellow crystals. Yield ~40%. *Anal.* calcd. for $C_{20}H_{19}N_4O_4PW$: C 40.4, H 3.22, N 9.43; found: C 41.0, H 3.50, N 9.80.

*(f) Preparation of [$\phi P(Me_2pz)_2Mo(CO)_3$] (**VI**)*

A solution of [(nbd)Mo(CO)$_4$] (0.50 mmol) and $\phi P(Me_2pz)_2$ (0.50 mmol) in 15 mL of benzene was stirred for 2 h at room temperature, giving a clear orange solution. Hexane (30 mL) was added carefully on top and allowed to diffuse slowly into the benzene layer (overnight). The orange solid precipitate was collected and recrystallized from benzene–hexane to yield orange crystals identified as [$\phi P(Me_2pz)_2$Mo(CO)$_3$] (**VI**). Yield 60%. *Anal.* calcd. for $C_{19}H_{19}MoN_4O_3P$: C 47.7, H 4.00, N 11.7; found: C 48.1, H 4.10, N 12.0. The mass spectrum showed the molecular ion and the loss of 3 carbonyl groups.

*(g) Preparation of [$\phi P(Me_2pz)_2W(CO)_3$] (**VII**)*

A mixture of [$(CH_3CN)_3$W(CO)$_3$] (1.7 mmol) and $\phi P(Me_2pz)_2$ (1.7 mmol) in 20 mL of benzene was stirred under nitrogen at 75°C for 30 min. The deep red solution was filtered, the filtrate was concentrated to about 5 mL under vacuum, yielding orange-red crystals that were collected and recrystallized from benzene/hexane. The product was identified as [$\phi P(Me_2pz)_2$-W(CO)$_3$] (**VII**); yield, 45%. *Anal.* calcd. for $C_{19}H_{19}N_4O_3PW$: C 40.3, H 3.38, N 9.90; found: C 39.8, H 4.01, N 9.32. The mass spectrum showed the molecular ion and the loss of 3 carbonyl groups.

*(h) Preparation of [P(Me$_2$pz)$_3$Mo(CO)$_3$] (**VIII**)*

Solutions of P(Me$_2$pz)$_3$ (0.50 mmol) in benzene (10 mL) and of (nbd)Mo(CO)$_4$ (0.50 mmol) in benzene (5 mL) were mixed together and stirred at room temperature for 20 h. The yellow precipitate was collected, dried under vacuum, and identified as [P(Me$_2$pz)$_3$Mo(CO)$_3$] (**VIII**). Yield 80%. *Anal.* calcd. for $C_{18}H_{21}MoN_6O_3P$: C 43.6, H 4.26, N 16.9; found: C 43.9, H 4.50, N 16.9.

The identical product was obtained by reaction of [(cht)Mo(CO)$_3$] with P(Me$_2$pz)$_3$ in benzene at room temperature.

*(i) Preparation of [P(Me$_2$pz)$_3$W(CO)$_3$] (**IX**)*

A mixture of [(CH$_3$CN)$_3$W(CO)$_3$] (0.51 mmol) and P(Me$_2$pz)$_3$ (0.51 mmol) in 10 mL of benzene was stirred at room temperature for 18 h. The yellow precipitate was collected, washed with benzene (10 mL) and with tetrahydrofuran (10 mL), dried under vacuum, and identified as [P(Me$_2$pz)$_3$W(CO)$_3$] (**IX**). Yield 80%. *Anal.* calcd. for $C_{18}H_{21}N_6O_3PW$: C 37.0, H 3.62, N 14.4; found: C 37.6, H 3.91, N 13.9.

Heating equimolar amounts of [(tmpda)W(CO)$_4$] and P(Me$_2$pz)$_3$ in benzene solution at 60–70°C for 80 h gave **IX** in 95% yield.

A kinetic study of the oxidation of N(III) by ClO_2^- in aqueous acidic media

SAMIR S. EMEISH[1] AND KEITH E. HOWLETT
Department of Chemistry, Bedford College, London NW1 4NS, U.K.

Received July 5, 1979

SAMIR S. EMEISH and KEITH E. HOWLETT. Can. J. Chem. **58**, 159 (1980).

Kinetics of the reaction between nitrous acid and chlorite have been studied spectrophotometrically. The rate equation involves terms $[HNO_2]^{1.5}$ and $[ClO_2^-]^{0.5}$, and both an uncatalysed and a chloride ion-catalysed path have been identified. A mechanism involving peroxonitrite and hypochlorous acid as intermediates is shown to be consistent with the observations.

SAMIR S. EMEISH et KEITH E. HOWLETT. Can. J. Chem. **58**, 159 (1980).

On a étudié par spectrophotométrie la cinétique des réactions entre l'acide nitreux et l'ion chlorite. L'équation de vitesse fait intervenir les terms $[HNO_2]^{1.5}$ et $[ClO_2^-]^{0.5}$ et on a identifié deux types de réaction: l'une non catalysée et l'autre catalysée par l'ion chlorite. Ces observations sont compatibles avec un mécanisme impliquant un peroxynitrite et l'acide hypochloreux comme intermédiaires.

Introduction

Although the kinetics of the redox reactions involving N(III) and halate anions have been reported before, and the reactivities of the various species and the mechanistic steps have been reviewed (1–3) further work on these systems is necessary. As a corollary to that work we now report a first study of the reaction between N(III) and Cl(III), a possible intermediate step in the N(III)/Cl(V) reaction.

Experimental

Preliminary work indicated no technical difficulties which would hinder a spectrophotometric study of this reaction.

When possible, Analar grade chemicals were used without further purification. Sodium chlorite was recrystallised from warm, slightly alkaline solution, the crystals being dried at 120°C for 2 h. The purity was checked iodometrically. Stock solutions of sodium nitrite and of sodium chlorite were stabilised by traces of NaOH (4) (and were discarded after a week).

Reaction was initiated in thermostatted solutions by thoroughly mixing first N(III) with Cl(III) and finally by adding buffer. Samples were withdrawn at intervals and analysed for [N(III)] by the Shinn method (5), here further modified from its use by Kershaw and Chamberlin (6). In the present instance, experimental samples (typically 2 cm^3) were quenched in ~80 cm^3 of 0.0025 mol dm^{-3} HCl containing 0.03 g sulphanilamide. After 5 min, 2 cm^3 of 3 mol dm^{-3} HCl was added to complete the diazotisation, and after a further 2 min, 1 cm^3 of 0.1% *N*(-1-naphthyl)-ethylenediamine dihydrochloride was added, the solution made up to 100 cm^3 and its absorbance determined at 538 nm between 10 and 60 min later.

Results

The reaction is immeasurably slow at 25°C and pH ≈ 7, but has a convenient speed at pH ≈ 4.5 (maintained in our work by either potassium hydrogen phthalate or acetate buffers) with [N(III)] ≈ [Cl(III)] ≈ 10^{-4} mol dm^{-3}. Minor observed irregularities in rates were removed by the presence of 10^{-3} mol dm^{-3} Na_2EDTA (see later) in all runs used to deduce kinetic parameters.

That N(III) and Cl(III) react in the molar ratio 2:1 to produce exclusively nitrate and chloride was variously confirmed. Firstly, the molar reacting ratio was determined by measuring the N(III) remaining after complete reaction, starting with excess N(III); the mean result was 1.99:1. Secondly, near 47 000 cm^{-1}, chlorite, hypochlorous acid, chloride, and nitrous acid are transparent or weakly absorbing whereas nitrate is more strongly absorbing. Reaction mixtures, acidified with HCl were allowed to react to completion and shown to have absorption spectra identical with corresponding solutions of $NaNO_3$ + HCl over the whole range 40 000 – 50 000 cm^{-1}. Thirdly, Cl^- in normal reaction products was determined by potentiometric titration, and it was shown that Cl^- was produced mole for mole from chlorite in its reaction with nitrite.

Cations such as Na^+ or K^+ have no specific effect upon the rate of reaction, even when present in 500-fold excess compared with the reactants, although there is a general decelerating effect of ionic strength *I* (see later). Distinct from this, the deliberate addition of ions such as Ni^{2+}, Cr^{3+}, Cu^{2+}, Co^{2+} at concentrations comparable with those of the reactants (4×10^{-4} mol dm^{-3}) produced a noticeable increase in rate of 10% or more. These catalytic effects are partially removed by 10^{-3} mol dm^{-3} Na_2EDTA. Similar additions of Fe^{2+} introduce a completely different, fast reaction path. It therefore seems probable that the consistent results observed in the presence of EDTA correspond to

*Acetate buffer, all others phthalate.

reactions uncatalysed by adventitious traces of transitional or polyvalent ions.

Preliminary experiments showed that the rate of reaction is uninfluenced by variation of intensity of illumination, surface/volume ratio, or oxygen-content of the solution.

Since the kinetics of the main reaction are not of a simple order, elucidation was begun by use of initial rates. At constant T, I, and $[H^+]$ these indicated

$$-\mathrm{d}[N(III)]/\mathrm{d}t = k_2[NO_2^-]^{1.5}[ClO_2^-]^{0.5}$$

which may be integrated to

$$k_2 t = \{2/([ClO_2^-]_0 - 0.5[NO_2^-]_0)\} \times \{([ClO_2^-]_t/[NO_2^-]_t)^{1/2} - ([ClO_2^-]_0/[NO_2^-]_0)^{1/2}\}$$

from which the rate constant, k_2, for an individual experiment may be derived from the variation of $([ClO_2^-]_t/[NO_2^-]_t)^{1/2}$ with t. This test showed that individual runs followed these kinetics to beyond 75% consumption of either reactant, as is illustrated by the results of Table 1.

Variation of $[H^+]$ alone showed that the order with respect to H^+ is 1.5. Values of $[H^+]$ were calculated from measurements of pH, e.g. at 25°C via

$$-\log H^+ = \mathrm{pH} - 0.509\{I^{1/2}/(1 + I^{1/2}) - 0.25I\}$$

Table 2 shows a selection of kinetic runs and the values of the 3.5 order rate constant, obtained at 25°C, $I = 0.016$ mol dm^{-3}, using two different buffer systems.

The effect of variation in I upon rate constant was investigated using additions of KNO_3 (deliberate additions of NO_3^- and of Cl^- in concentrations comparable with the reactants have no detectable effect). Table 3 lists one set of experimental results.

These results correspond closely to the equation

$$\log k(298) = 6.27 - 1.4_0 F(I)$$

where

$$F(I) = I^{1/2}/(1 + I^{1/2}) - 0.25I$$

and

$$k = k_2/[H^+]^{1.5}$$

When the temperature was varied, at constant I, the results given in Table 4 were obtained.

These results correspond to an activation energy of 42 kJ mol^{-1} for the N(III)/Cl(III) reaction.

The presence of one simple ion, namely chloride, has a specific catalytic effect upon the reaction when present in relatively large concentration. Table 5 records results obtained at 25°C when Cl^- is

added as NaCl, I being maintained constant with $NaNO_3$.

Added chloride ion produces a first order catalytic effect which is maintained throughout a reaction (chloride produced in the reaction is present at concentrations 100-fold less than the deliberate additions and is insignificant in this respect). Since the order of reaction throughout each Cl^--catalysed experiment remains 1.5, 0.5, and 1.5 in NO_2^-, ClO_2^-, and H^+ respectively, the total rate equation becomes

$$\text{Rate} = k[NO_2^-]^{1.5}[ClO_2^-]^{0.5}[H^+]^{1.5} + k'[NO_2^-]^{1.5}[ClO_2^-]^{0.5}[H^+]^{1.5}[Cl^-]$$

Values of k and k' at 25°C are given in Table 5.

The results of variation of k' with temperature for the Cl^--catalysed process are given in Table 6.

These results correspond to an activation energy of 38 kJ mol^{-1}.

Discussion

The reactants are mixed as nitrite and chlorite but these two ions do not react together. At least one must be protonated before reaction. The acid ionisation constant for $HClO_2$ is about 20 times that of HNO_2 so that at our working pH, HNO_2 is a more important species than $HClO_2$. Since rate is directly proportional to $[NO_2^-]^{1.5}$, $[H^+]^{1.5}$, and $[ClO_2^-]^{0.5}$ the rate determining step must therefore involve species which are stoichiometrically related to $[HNO_2]$ in the ratio 1.5:1 and to $[ClO_2^-]$ in the ratio 0.5:1.

The two acid species, other than H^+, in the two buffer systems used, are present in very different concentrations, both well in excess of $[H^+]$. Since rates are unaffected by a change of buffer, the N(III)/Cl(III) reaction is specifically catalysed by H^+, not by acids in general.

The kinetic form thus puts definite restrictions upon the mechanism for which we propose:

$$HNO_2 + H_2O \rightleftharpoons H_3O^+ + NO_2^-$$

Step *1* $HNO_2 + ClO_2^- \rightleftharpoons ONOO^- + HOCl$

Step *2* $ONOO^- \rightarrow NO_3^-$

Step *3* $HOCl + HNO_2 \rightarrow NO_3^- + 2H^+ + Cl^-$

together with steps *4* and *5* in the presence of excess Cl^-

Step *4* $HOCl + Cl^- \rightleftharpoons HOCl_2^-$

Step *5* $HOCl_2^- + HNO_2 \rightarrow NO_3^- + 2H^+ + 2Cl^-$

(with appropriately numbered rate and equilibrium constants).

The proposed oxygen-transfer step *1* is essentially the means whereby the kinetic results can be understood. We assume that this equilibrium is relatively rapidly established with the position of equilibrium well to the left. In a steady state the species $ONOO^-$ and HOCl are produced and lost at equal rates, and since their initial concentrations are zero, their concentrations will always be either the same or in a constant ratio. Thus ignoring this ratio factor,

$$[HOCl] = [ONOO^-] = (K_1[HNO_2][ClO_2^-])^{0.5}$$

whence for the overall uncatalysed rate

$$d[NO_3^-]/dt = 2k_3K_1^{0.5}[HNO_2]^{1.5}[ClO_2^-]^{0.5}$$

and for the Cl^--catalysed component of the rate

$$d[NO_3^-]/dt = 2k_5K_4K_1^{0.5}[HNO_2]^{1.5} \times [ClO_2^-]^{0.5}[Cl^-]$$

Combining these equations with K_a, viz.

[1] $K_a = [H^+][NO_2^-]\gamma_{H^+}\gamma_{NO_2^-}/[HNO_2]\gamma_{HNO_2}$

where γ_A is the activity coefficient of A, and assuming that γ for an uncharged species is unity and further that those for singly charged species, γ_1, are all equal at constant I, we have

[2] $\text{Uncatalysed rate} = k[NO_2^-]^{1.5} \times [H^+]^{1.5}[ClO_2^-]^{0.5}$

where

[3] $k = 2k_3K_1^{0.5}K_a^{-1.5}\gamma_1^3$

TABLE 5. Variation of initial rate with $[Cl^-]$ at $I = 0.215$ mol dm^{-3} and 25°C, using initial concentrations, $[NaNO_2] = 6.71 \times 10^{-4}$ mol dm^{-3}, $[NaClO_2] = 2.45 \times 10^{-4}$ mol dm^{-3}, and $[H^+] = 8.80 \times 10^{-5}$ mol dm^{-3}, k and k' refer to eqs. [2] and [4]

and

[4] Catalysed rate component

$$= k'[NO_2^-]^{1.5}[H^+]^{1.5}[ClO_2^-]^{0.5}[Cl^-]$$

where

$$k' = 2k_5K_1^{0.5}K_4K_a^{-1.5}\gamma_1^3$$

We must note that the concentrations in eqs. [2] and [4] refer to equilibrium values whereas the experimental equation refers to "made up" concentrations. The experimental observations are of rates of loss of total [N(III)]. At pH 4–5

$$\text{Total [N(III)]} = [NO_2^-] + [HNO_2]$$

thus substituting for $[NO_2^-]$ in eq. [1] inserts the following extra term,

$$(1 + [H^+]\gamma_1^2/K_a)^{-1.5}$$

into both eqs. [2] and [4], and converts $[NO_2^-]$ into the measured quantity [N(III)]. Since $K_a \approx 10^{-3}$ mol dm^{-3}, this extra term varies by only some 10% over the range of experimental conditions of acidity. Thus the proposed mechanism is consistent with the experimental observations, and this consistency extends to the effect of variation of ionic strength. The activity coefficient terms of eqs. [2] and [3] imply that the theoretically expected variation of rate with I is

$$\log k = \log k_0 - 1.53F(I)$$

Returning to a consideration of the proposed mechanism, step *2* could involve participation of HNO_2. This would not affect the kinetics but the idea has been rejected. It is reported (7) that the probability of XOO species to undergo substitution varies directly with the negative inductive effect of X^- and that the nucleophilic strength for displacement at oxygen (8) in XOO decreases in the order $Br^- > NO_2^-$. Hence if HNO_2 were reacting with $ONOO^-$, Br^- would be expected to affect the rate of reaction. We have found that Br^-, present in 4-fold excess over N(III), has no effect upon rates. Further, Halfpenny and Robinson (9) observed that Br^- is oxidised by $ONOO^-$ but not by its isomerisation products. Thus $ONOO^-$ does not last very long in the present system otherwise Br_2 and HOBr would have been produced and these would have further oxidised N(III) at our acidities (10).

Peroxonitrite has long been recognised as a yellow species, although there is still debate about the mechanism of its isomerisation and about pK_a for peroxonitrous acid (9, 11–18). If our mechanism is correct, it seems to support a value for pK_a for HOONO smaller than 4 in order to keep the substance mainly in the anionic form under our working conditions. If this were not so the N(III)/Cl(III) reaction would have an order with respect to H^+ different from that observed.

Confirmation that peroxonitrite is a probable intermediate has been obtained by carrying out a rapid reaction between N(III) and Cl(III) at pH ≈ 1, when a transient orange-yellow colour characteristic of peroxonitrite was observed. Further, potentially useful information about peroxonitrite was obtained by reacting N(III) and Cl(III) together with a half life of about 3 min, and passing the reacting mixture through the cavity cell of a Varian E4 esr spectrometer. Although a wide range band (~5000 G, X band) was explored, no signals were detected. This apparent absence of radicals applies to all

For personal use only.

steps of the N(III)/Cl(III) reaction including the isomerisation of peroxonitrite. This latter would therefore seem to be heterolytic in nature.

The species $HOCl_2^-$ postulated in the Cl^--catalysed process is one of a type of intermediates put forward frequently by others (19–21) in the reactions of chlorine oxyacids. The present kinetic form requires that the intervention of Cl^- occurs mechanistically after steps which determine the other kinetic orders.

S_N2 iodide displacement on unsymmetrical cyclic dioxenium salts. A stereoelectronically controlled reaction

NORMAND BEAULIEU[1] AND PIERRE DESLONGCHAMPS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received August 28, 1979

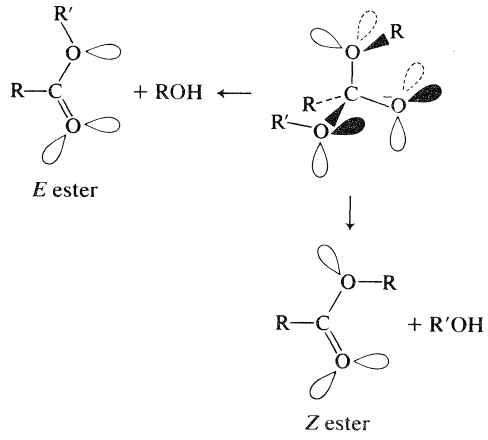
NORMAND BEAULIEU AND PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 164 (1980).

Iodide ion reacts with the cyclic dioxenium salts **1–6** to yield mixtures of iodoester and lactone plus alkyl iodide (Table 1). The formation of iodoester competing with the formation of lactone appears to be an unexpected result. It can, however, be explained by a stereoelectronic effect, similar to the anomeric effect in acetals, which is also responsible for the greater stability of the *Z* over the *E* form in dioxenium salts and in esters.

NORMAND BEAULIEU et PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 164 (1980).

Les sels cycliques dioxeniums **1–6** réagissent avec l'ion iodure pour donner un mélange d'iodoester, de lactone et d'iodure d'alkyle (Tableau 1). La formation d'iodoester en compétition avec celle de la lactone est un résultat inattendu. Ce résultat peut cependant être expliqué par un effet stéréoélectronique semblable à l'effet anomère que l'on retrouve dans les acétals. Cet effet stéréoélectronique serait aussi responsable de la plus grande stabilité des formes *Z* par rapport aux formes *E* dans les sels dioxeniums et les esters.

Our recent studies on the oxidative cleavage of conformationally rigid vinyl orthoesters[2] have provided evidence that when a tetrahedral intermediate (hemiorthoester) can break down with primary stereoelectronic control to give either a *Z* or an *E* ester, it yields preferentially the *Z* ester (Scheme 1).



This preference was explained by a secondary electronic effect which lowers specifically the energy of the transition state leading to the *Z* ester. This secondary electronic effect in hemiorthoesters is equivalent to the classic anomeric effect observed in acetals (2).

The above analysis has led us also to realize that (*a*) this secondary electronic effect (or anomeric effect) exists in the ester function itself and (*b*) it is the major electronic parameter which stabilizes the *Z* form in preference to the *E* form in esters (3).

In order to provide evidence to show the importance of this electronic effect in esters, we have studied the S_N2 displacement reaction, by iodide ion, on a series of cyclic dioxenium salts. We wish to report this study.

Experimental Results

The cyclic dioxenium salts **1–6** (Table 1) were prepared by the reaction of trimethyl or triethyloxonium tetrafluoroborate salt with the appropriate lactone (4, 5). The products expected by the reaction of iodide ion on these dioxenium salts are the corresponding lactone plus methyl or ethyl iodide, and/or the corresponding iodoethyl or iodomethyl ester.[3] An instantaneous reaction was observed when the salts **1–6** dissolved in dichloromethane were treated with a solution of sodium iodide in acetonitrile at room temperature. A mixture of lactone, alkyl iodide, and iodoester was obtained in all cases. The iodoesters were found to be stable under the reaction conditions. The results are summarized in Table 1.

SCHEME 1

Discussion

The experimental results show clearly that the formation of iodoester (process A) can compete effectively with the formation of lactone and alkyl

[a]Average of four experiments.
[b]Average of two experiments.

iodide (process B). We considered that this is a very unusual result because, if all the classic parameters are considered in both processes, we would have predicted that only process B would have taken place. In process B, two molecules are formed and the ring is not broken while in process A, only one molecule is formed and the ring is cleaved. Process A should therefore require more energy than process B. Furthermore, in the dioxenium salts having a methoxy group, iodide displacement on the primary methyl group should be favored over that on the secondary methylene group of the dioxenium ring. This factor favors again the formation of lactone and methyl iodide, yet important quantities of iodoester are observed (cf. **3**).

Thus, in resumé, good arguments can be found which favor process B and none for process A, yet process A remains competitive. It is also reasonable to assume that the combination of the factors discussed above should lower the energy of the transition state of process B to the point (≃3 kcal/mol) where process A would not be observed. It is therefore clear that there must be a new parameter which operates in process A only, lowering the energy of its transition state, so that it can compete with process B.

There is indeed an electronic effect which can

SCHEME 2

lower specifically the energy barrier of process A. We will see that this electronic effect is of the same nature as the anomeric effect (2) observed in acetals.

There is good evidence (X-ray supported by calculation) that dioxenium salts are planar (7, 8). The cyclic dioxenium salts **1–6** can exist theoretically in the *Z* form **7** or the *E* form **8** (Scheme 2). There is, however, good evidence that these salts exist in the *Z* form only.[4] It is known (by nmr, ref. 9) that dimethyl dioxenium salts exist in the *Z* (**9**) rather than the *E* form (**10**), and that protonation of esters in super acid medium yields the ion **11** (10). Similar results were obtained with carboxylic acids (11).

We therefore assume that the salts **1–6** exist in the *Z* form **7** with which iodine will react to give either the iodoester or the lactone plus alkyl iodide.

Structures **12** and **13** represent the two transition states (yielding **14** and **15** respectively). It can be seen that in **12** the bond to be broken (R—O1) is antiperiplanar to the non polar C1—C2 bond whereas in **13**, the bond to be broken (C5—O5) is antiperiplanar to the C1—O1 polar bond. In other words, in **13** the electron pair of the C5—O5 bond can be delocalized by an interaction with the an-

[4]The greater stability of the *Z* form over the *E* form in these compounds is also due to an electronic effect (*vide infra*).

For personal use only.

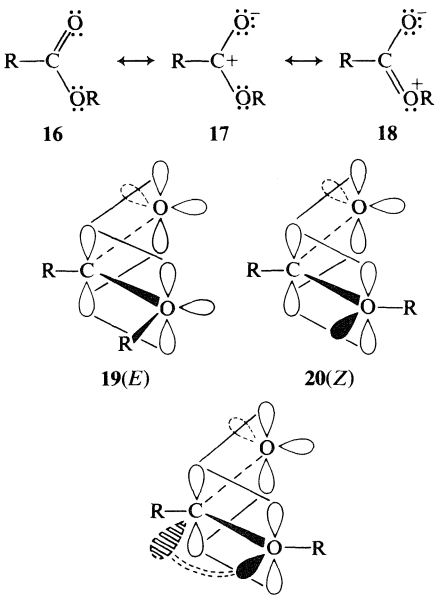
tibonding orbital (σ^*) of the polar C1—O1 bond (12), whereas in **12**, the electron pair of the R—O1 bond cannot be delocalized into an antibonding orbital of a polar bond. Consequently, there is an electronic factor which can lower the energy barrier for the formation of the iodoester only.[5]



We believe that it is this electronic effect which makes iodoester formation competitive with the otherwise favored formation of lactone and alkyl iodide.

This electronic effect is similar to the anomeric effect in acetals (2). It only differs by the fact that the carbon C1 is trigonal (sp^2 hybridized) in dioxenium salts and tetrahedral (sp^3 hybridized) in acetals. We also believe that it is this kind of electronic effect which renders the *Z* form more stable than the *E* form in dioxenium salts as well as in esters (3).

In the *E* form of dioxenium salts **8**, the non-bonded electron pairs of O5 and O1 are not oriented antiperiplanar to a polar C—O bond whereas in the *Z* form **7**, the non-bonded electron pair of O1 is antiperiplanar to the polar C1—O5 bond. The electron pair on O1 in **7** can therefore be delocalized into the antibonding orbital of the sigma C1—O5 bond, lowering the energy content of this form.

It is also well known that esters are planar and that the *Z* form is much more stable than the *E* form (3). The *E* form is of course observed in small ring lactones but as soon as the size of the lactone ring allows the *Z* form, the *E* form is no longer observed (13). Even in the case of *tert*-butyl formate, the *Z* form predominates (≃90%) over the *E* form (14). Again, in the *Z* form of an ester, the ether oxygen has an electron pair properly oriented so that it can be delocalized into the antibonding orbital (σ^*) of the C—O sigma bond of the carbonyl group. This is not the case in the *E* form. We think that this electronic factor is the driving force which makes the *Z* form more stable.

Thus, as we have previously discussed (1), there are two different types of stereoelectronic effects in esters, a primary and a secondary one. In the primary electronic effect, one electron pair of the ether oxygen is delocalized with the π orbital of the C=O bond. This electron pair (*p* orbital) is therefore parallel to the π C=O bond. This primary electronic delocalization is usually expressed by the resonance structures **16**, **17**, and **18** (Scheme 3).

16 **17** **18**

19(*E*) **20**(*Z*)

21

SCHEME 3

This electronic delocalization conveys an sp^2 character on the two oxygens as well as the central carbon of the ester function. It is therefore responsible for the two geometrical forms *E* and *Z* of an ester function which can be represented respectively by structures **19** and **20**. In the *Z* form, there is an extra electronic delocalization which can occur between the other electron pair (sp^2 hybridized) of the ether oxygen and the antibonding orbital of the sigma bond of the carbonyl group as shown in **21**.[6,7]

The larger proportion of iodoester in the case of salts **2**, **4**, and **6** as compared with salts **1**, **3**, and **5** respectively can be readily explained because it is more difficult for iodine to attack an ethyl rather than a methyl group. Comparison of ring-size, **1** (or **2**) with **3** (or **4**), indicates that it takes more energy to break a five than a six-membered ring. Finally, the lower percentage of iodoester in the case of the bicyclic dioxenium salts **5** and **6** as compared with **3** and **4** respectively, can be explained by the presence of the second ring in **5** and **6** which causes

[5]Transition state **13** leads to an iodoester **15** having the stable *Z* conformation, whereas transition state **12** leads to a lactone **14** having the less stable *E* conformation. Consequently, the above results can be rationalized in this manner. However, we then arrive at the same conclusion, because *Z* esters are more stable than *E* esters for the same electronic reason (*vide infra*).

[6]This stabilizing electronic effect might be larger (≳3 kcal/mol) than the one (≃1.2 kcal/mol (2, 15)) observed in acetals, the reason being that the carbonyl C=O bond in esters is a more polarized bond than the C—OR bond in acetals. The very large difference in stability between *Z* and *E* esters could therefore be understood on that basis.

[7]If this electronic effect exists, it means that the CO—OR bond should be shorter in aliphatic esters (*Z* ester) than in lactones (*E* ester). X-ray analysis however, shows no difference (J. D. Dunitz, Eidgenossiche Technische Hochschule, personal communication).

extra steric hindrance to the attack by iodine on the methylene group of the dioxenium ring.

Experimental

Vapor-phase chromatographic (vpc) analyses and separations were carried out on a Varian aerograph instrument model 2800 with thermal conductivity detector (SE-30-5%; 5 ft × ¼ in.; Chromosorb W 100—120 mesh). The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton nmr spectra were recorded on a Varian A-60 or a Bruker WP-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. Mass spectral assays were obtained using a Hitachi-Perkin-Elmer RMU-6-A instrument at 70 eV.

Syntheses of the Dioxenium Salts

The dioxenium salts **2**, **4**, **5**, and **6** are known compounds; they were prepared by following the published procedure (4). The dioxenium salts **1** and **3** were prepared by the same method.

γ-Butyrolactone (0.5 mmol), or δ-valerolactone, and trimethyloxonium tetrafluoroborate (0.8 mmol) were mixed in anhydrous dichloromethane (5 mL) and left at room temperature for 15 h. Excess trimethyloxonium tetrafluoroborate salt was removed by filtration and the solution was evaporated. Nuclear magnetic resonance analyses indicated the presence of the expected dioxenium salt **1** or **3** only, the corresponding lactones were not detected. These salts were used without further purification.

Methyl Dioxenium Salt 1: nmr (CD_2Cl_2) δ: 2.5–3.0 (2H, multiplet), 3.3–3.6 (2H, triplet, J = 9 Hz), 4.4 (3H, singlet, CH_3O), and 5.4–5.7 (2H, triplet, J = 8 Hz, CH_2O).

Methyl Dioxenium Salt 3: nmr (CD_2Cl_2) δ: 2.0–2.4 (4H, multiplet), 2.9–3.3 (2H, multiplet), 4.45 (3H, singlet, CH_3O), and 5.1–5.4 (2H, broad triplet, CH_2O).

Reaction of Iodide Ion on the Dioxenium Salts

The dioxenium salts **1–6** (≈0.5 mmol) were dissolved in anhydrous dichloromethane (5 mL) and sodium iodide (≈1 mmol) dissolved in anhydrous acetonitrile (5 mL) was added. An instantaneous reaction was observed, the reaction mixture was filtered, concentrated, and analyzed by ^1H nmr spectroscopy, and by vpc (Table 1). In the case of dioxenium salts **1**, **2**, **3**, **4**, and **6**, the mixtures of the corresponding lactone and iodoester were separated by vpc. The lactones were properly identified with authentic samples and the iodoesters were characterized by spectroscopic methods (infrared, ^1H nmr, and ms). In the case of the dioxenium salt **5**, the corresponding iodoester and lactone were identified by vpc and ^1H nmr but were not isolated.

Methyl 4-Iodobutyrate: vpc (retention time) 18 min (100°C); ir ν_{max} ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 2.0–2.8 (4H, multiplet), 3.35 (2H, triplet, J = 8 Hz, CH_2I), and 3.9 (3H, singlet, CH_3O); ms m/e: 228 (M^+, absent), 197 ($M^+ - OCH_3$), 169 ($M^+ - CO_2CH_3$), and 101 ($M^+ - I$).

Ethyl 4-Iodobutyrate: vpc (retention time) 11.8 min (110°C); ir ν_{max} ($CHCl_3$): 1735 cm^{-1}; nmr ($CDCl_3$) δ: 1.33 (3H, triplet, J = 7 Hz, CH_3), 2.0–2.8 (4H, multiplet), 3.4 (2H, triplet, J = 8 Hz, CH_2I), and 4.3 (2H, quadruplet, J = 7 Hz, CH_2O); ms m/e: 242 (M^+, absent), 197 ($M^+ - OC_2H_5$), 169 ($M^+ - CO_2C_2H_5$), and 115 ($M^+ - I$).

Received May 22, 1979

M. H. BROOKER and C.-H. HUANG. Can. J. Chem. **58**, 168 (1980).

Raman spectra have been recorded for solids and melts of composition $MgCl_2 + nACl$ (n = 0–4 and A = Cs, Rb, K, Na, Li). Characteristic spectra have been observed for each of the solids predicted from phase diagram studies and an additional two compounds formulated as Rb_3MgCl_5 and K_3MgCl_5 were detected. The compounds Cs_2MgCl_4, Cs_3MgCl_5, and Rb_3MgCl_5 contain the discrete $MgCl_4^{2-}$ tetrahedral ion which has been characterized by its Raman spectrum. These compounds melt with retention of the $MgCl_4^{2-}$ ion. Most other solids appear to contain distorted network octahedra with face-, edge-, or corner-shared chlorides. These solids melt to give the more stable tetrahedral $MgCl_4^{2-}$ ion. In melts of high $MgCl_2$ concentration a new peak was detected which appears to be characteristic of the dimeric $Mg_2Cl_7^{3-}$ ion which exists in equilibrium with the $MgCl_4^{2-}$ ion. The results are compared to similar studies on the better characterized $CsCl–AlCl_3$ system.

M. H. BROOKER et C.-H. HUANG. Can. J. Chem. **58**, 168 (1980).

On a enregistré les spectres Raman des sels à l'état solide et à l'état fondu ayant la composition suivante: $MgCl_2 + nACl$ (n = 0–4 et A = Cs, Rb, K, Na, Li). On a observé des spectres caractéristiques pour chacun des solides prédits à partir d'études de diagramme de phase et on a décelé deux composés additionnels identifiés comme étant: Rb_3MgCl_5 et K_3MgCl_5. Les composés Cs_2MgCl_4, Cs_3MgCl_5 et $RbMgCl_5$ contiennent un ion tétraédrique discret $MgCl_4^{2-}$ qu'on a identifié par son spectre Raman. Ces composés fondent avec rétention de l'ion $MgCl_4^{2-}$. La plupart des autres solides semblent contenir un système octaédrique déformé portant des ions chlorures sur la face, l'arête ou le coin. Les solides fondent en donnant l'ion tétraédrique $MgCl_4^{2-}$ le plus stable. Dans les sels fondus à forte concentration de $MgCl_2$, on a décelé un nouveau pic qui semble être caractéristique de l'ion dimère $Mg_2Cl_7^{3-}$ qui existe en équilibre avec l'ion $MgCl_4^{2-}$. On a comparé les résultats à des études similaires faites sur le système le mieux caractérisé $CsCl–AlCl_3$.

Introduction

The concept of complex ion formation in molten salts has been the subject of considerable controversy. Evidence for MX_4^{2-} anions from phase diagram calculations was first noted by Flood and Urnes (1) for the $MgCl_2$ – alkali metal chloride system. Lumsden (2) has shown that solutions of up to about 30 mol% of MCl_2 (M = Mg, Mn, Fe, Zn) in KCl can be treated as ideal Temkin solutions of K^+ cations and the anions Cl^- and MCl_4^{2-}. Lumsden has argued that phase diagram calculations did not imply real $MgCl_4^{2-}$ entities but only a statistical order of ions. Failure of the calculations to extend into the MCl_2-rich region of the phase diagram has also been used as an argument against complex entities in the melt.

A number of species and polymeric structures have been proposed (3) but our recent Raman studies of the K_2MgCl_4 and Cs_2MgCl_4 as oriented single crystals and in the molten state were strongly in favour of the tetrahedral $MgCl_4^{2-}$ ion proposed by Maroni and co-workers (4, 5) for magnesium halide melts. Additional studies (6) on molten $MgCl_2$ suggested the presence of discrete polyatomic species, including $MgCl_4^{2-}$, and did not favour the residual ionic lattice model proposed by Capwell (7). The present study represents a continuation of our work to include the solids and molten salts of composition $MgCl_2 + nACl$, for n = 0 to 4, A = Cs, Rb, K, Na, Li. An attempt has been made to use Raman spectroscopy to identify and characterize the solids predicted by the phase diagram studies and to determine if information from the solids can be used to deduce structural properties of the melts. Generally it was found that the structure of species present in the melts was not related to the structure present in the solid but three compounds Rb_3MgCl_5, Cs_2MgCl_4, and Cs_3MgCl_5 did melt with retention of the tetrahedral $MgCl_4^{2-}$ coordination. The network lattice structures with distorted octahedral coordination of magnesium gave way to the smaller, melt-stabilized tetrahedral coordination on fusion.

Experimental

Anhydrous $MgCl_2$(Alpha) was dried under vacuum at 30°C for 24 h then the temperature was raised slowly (over 8 h) to 180°C where the solid was further dried under vacuum for 24 h. Reagent grade alkali metal chlorides were dried under vacuum at 180°C for 24 h before use. The salts and salt mixtures are somewhat hygroscopic so all manipulations were performed in a glove bag under dry N_2 or under vacuum. Appropriate quantities of the salts were placed in 6 mm id quartz tubes, further heated at

about 200°C under vacuum for 2 h, then the temperature was slowly raised until the sample melted. At this stage the melts were clear-colorless quiet liquids and showed no evidence of any impurities, in particular, MgO, the most likely impurity in $MgCl_2$. The samples were slowly cooled to room temperature and sealed under vacuum. Some of the tubes containing the sodium salts had a tendency to fracture on cooling. Attempts were made to grow single crystals of the salt mixtures by slowly passing the samples through a temperature gradient (vertical Bridgeman method). This technique also served to zone refine the materials.

Raman spectra of the solids and melts were obtained directly from these tubes. Results presented in the present study are for melts and unoriented polycrystalline samples (no depolarization properties were observed). Results for several oriented single crystals have been presented elsewhere (8). Raman spectra were measured with a Coderg PHO spectrometer after excitation with the 488.0 nm line of a Control Laser model 553A argon ion laser operating on the light control mode with about 1 W of power at the sample. Plasma lines were removed with a narrow-band-pass interference filter. Peak positions were calibrated against laser plasma lines. Polarization of the incident beam was controlled by a half-wave plate and the 90° scattered light was analyzed with a polaroid film placed before the monochromator slit. Depolarization measurements for the melts were made by analyzing the scattered light parallel ($I_{||}$) and perpendicular ($I_{\perp}$) to the incident laser beam. The large diameter (6 mm id) sample tubes helped to reduce the stray light and were employed even though they did not fit in the constant temperature furnace available. Stray-light and ghosts were reduced to a satisfactory low levels by employing a solution of 0.5 *M* $Pr(EDTA)^-$ complex as a post sample filter and by carefully adjusting the focus to ensure that a minimum of reflected laser light fell on the entrance slit of the monochrometer. These methods allowed distortion-free spectra to be recorded to within 20 cm^{-1} of the exciting line for these highly reflecting samples. Spectra recorded with and without these precautions showed no difference in peak positions or relative intensities but a much improved background was possible with the post-sample filter. Studies of KNO_3 and $CsNO_3$ with and without the post sample filter showed no appreciable alterations in the shapes or relative intensities of low frequency modes above 40 cm^{-1}. Generally 2 cm^{-1} slits were employed for the solids and 4 cm^{-1} slits for the melts.

Spectra of the melts were obtained in a simple nichrome heating coil with temperatures monitored with a chromel–alumel thermocouple on the sample container. Subsequent temperature variation studies revealed that the spectra were insensitive to sample temperature so that the ±15° uncertainty in the temperature actually in the laser beam would have little influence on the measured peak positions and halfwidths of the melts. Changes in cation and concentration caused the most significant spectral changes for the melts for the temperature range employed (600–700°C). Spectra of the solids were recorded at 25°C and no attempt was made to investigate possible phase transitions. Spectra of the solids and melts were recorded on two different occasions to establish the consistency of the band shapes and frequencies. Raman envelopes for the melts were manually digitallized, base-line corrected with a polynomial function, and the envelopes curve resolved into Gaussian components with a least-squares refinement. The number of components was kept to the minimum number that could be justified on the basis of visual inspection of the spectra. The primary concern of the curve resolving procedures was to obtain the ratio of the intensity of the peak at about 250 cm^{-1} (due to tetrahedral $MgCl_4^{2-}$) to that of the low frequency mode about 225 cm^{-1}. In this way one could obtain the ratio, $I = I_{225}/I_{250}$, or the fraction of the total intensity of the 160–260 cm^{-1} region which comes from the I_{250} peak, $f = I_{250}/I_{total}$. If one makes the approximation that the different intensities in the ν_1 portion are directly related to different polyatomic species concentrations then f represents the fraction of the total species concentration which comes from $MgCl_4^{2-}$. Serious band overlap and base-line uncertainties limit the accuracy of the ratio to about 15%. The computer resolved results were consistant with and probably not much better than results obtained by manual graphical methods. Although more precise data collection and treatment would be desirable one would still be faced with the lack of information on molar scattering efficiencies of the two species and species concentrations would remain uncertain.

Results and Discussion

Raman spectra for the solids of the $MgCl_2$–ACl systems are shown (Figs. 1–5) with peak frequencies, halfwidths, relative intensities, and assignments collected in Tables 1–5. Except for our recent work (3, 8) on single crystals the spectra of the solid compounds have not been reported previously. The results are in excellent agreement with

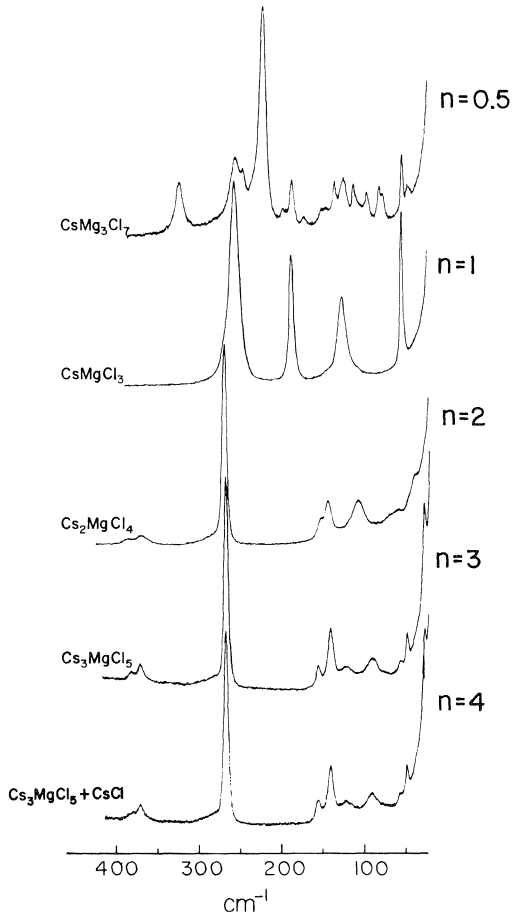

FIG. 1. Raman spectra of solids formed from the CsCl–$MgCl_2$ system.

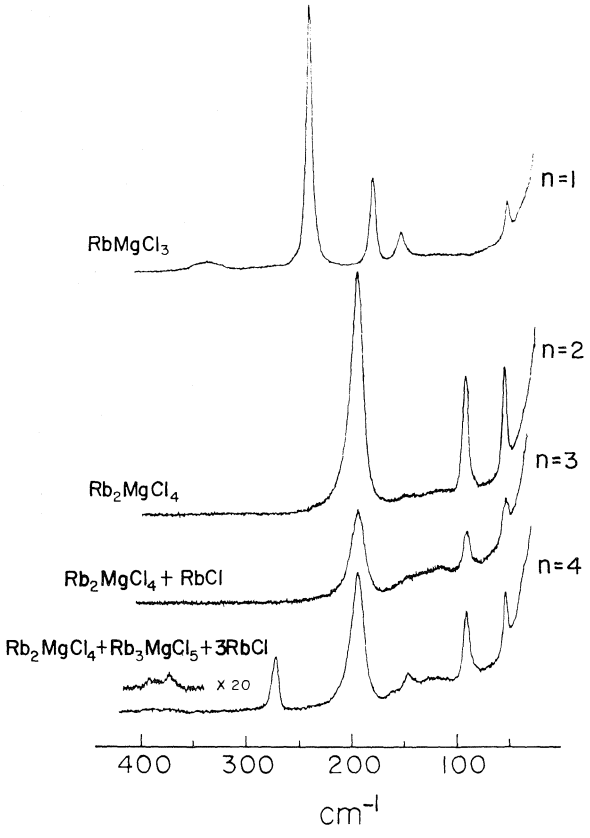

FIG. 2. Raman spectra of solids formed from the RbCl–$MgCl_2$ system.

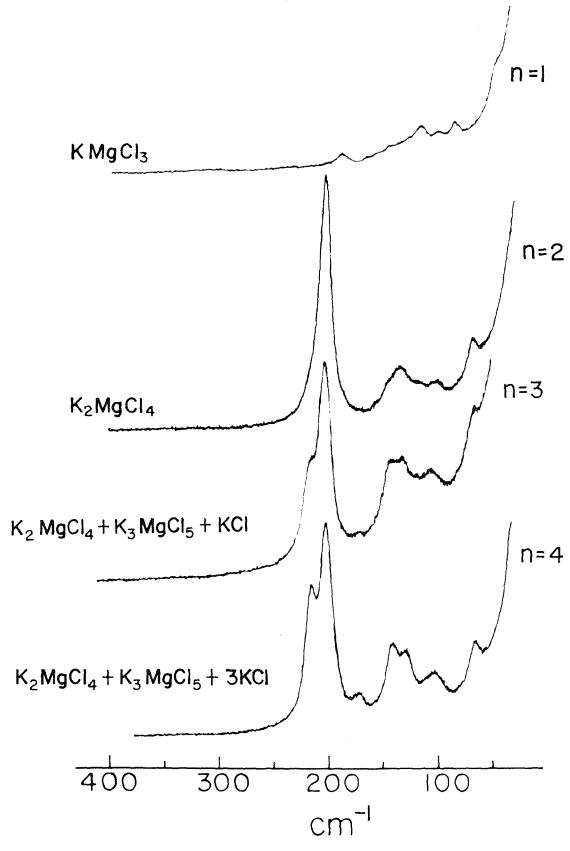

FIG. 3. Raman spectra of solids formed from the KCl–$MgCl_2$ system.

phase separation studies and characteristic peak frequencies have been assigned to each of the predicted double salts. Additional new compounds or solid solutions have been identified in the alkali metal-rich region of the RbCl–$MgCl_2$ and KCl–$MgCl_2$ systems. Previous studies (3–5, 8) have shown that the $MgCl_4^{2-}$ ion can be characterized by the typical spectrum of a tetrahedral molecule with T_d point-group symmetry, similar to CCl_4 but with peak frequencies: $\nu_1(A_1)$, 250 cm^{-1}; $\nu_2(E)$, 110 cm^{-1}; $\nu_3(F_2)$, 360 cm^{-1}; $\nu_4(F_2)$, 145 cm^{-1}. This ion has been identified in the Cs_2MgCl_4, Cs_3MgCl_5 salts and in the new salt of rubidium which has the probable formula Rb_3MgCl_5. Raman spectra of the other salts suggest that extended lattice structures with the Mg^{2+} in a distorted octahedral site with shared corners, faces, or edges are most probable. A discussion of the results for the pure-component starting materials and the solid mixtures follows.

Pure Components

First-order Raman scattering is not allowed for either the NaCl or CsCl forms of the alkali metal chlorides (9, 10). Weak second order scattering can occur (9, 11) but in the Raman spectra of the polycrystalline samples employed in the present study it appeared as a weak–broad structureless feature from 100 to 200 cm^{-1} with intensity an order of magnitude less than the processes reported (11). Magnesium chloride does have a first order Raman spectrum. On the basis of the crystal structure: space group, $R\,\bar{3}m$ (D_{3d}^5), $z = 1$ (12), two Raman active peaks are predicted, A_{1g} and E_g. These have been assigned to sharp peaks at 240 and 155 cm^{-1} respectively (6, 7). The assignment is consistent with partial polarization measurements (7) and analogous studies of isomorphous MCl_2 structures (13). The crystal has layers of chlorine ions which are nearly cubic close packed with magnesium ions between the layers with distorted octahedral coordination (D_{3d} sites). The A_{1g} mode at 240 cm^{-1} corresponds to the in-plane symmetric stretching motion of the chlorides while the E_g mode corresponds to the in-plane anti-symmetric stretch. Temperature variation studies from 77 to 973 K indicated that the peak positions decreased with increased temperature but no phase change was

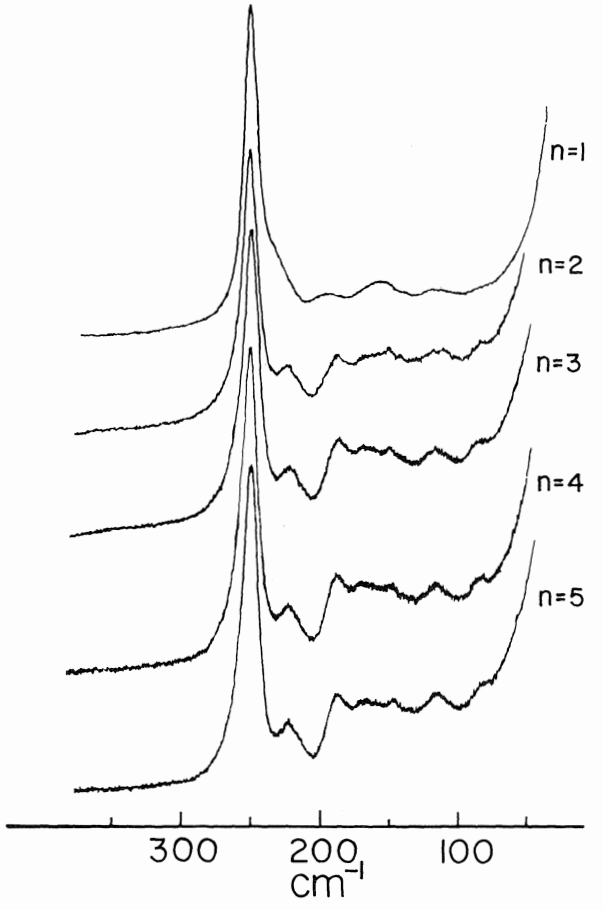

FIG. 5. Raman spectra of solids formed from the LiCl–$MgCl_2$ system.

detected (6, 7). In the $MgCl_2$–ACl systems we were unable to detect peaks which could clearly be assigned to $MgCl_2$ solid but in the results which follow it is possible that intensity in the 240 and 150 cm^{-1} region for the $MgCl_2$-rich solids could be due to pure $MgCl_2$.

CsCl–$MgCl_2$ System

The phase diagram of the CsCl–$MgCl_2$ system (14, 15) indicates the presence of four double salts, the incongruent melting $CsMg_3Cl_7$, stable below 565°C, and three congruent melting compounds; $CsMgCl_3$, mp 610°C; Cs_2MgCl_4, mp 545°C; and Cs_3MgCl_5, mp 527°C. All four compounds have been detected and characterized by their Raman spectra (Fig. 1, Table 1). The solid of composition $MgCl_2$ + 4CsCl can be seen to be a mixture of the Cs_3MgCl_5 salt and CsCl while the incongruent melting $CsMg_3Cl_7$ also contains some of the $CsMgCl_3$ salt.

$CsMgCl_3$ crystallizes with hexagonal symmetry, space group $P6_3/mmc$ (D_{6h}^4); $a = b = 7.269$ Å, $c = 6.187$ Å; 2 formula units per unit cell (16). There are no discrete molecular ions but a basic feature is the linear array of $MgCl_6$ octahedra sharing faces directed along the hexagonal c axis. Five Raman-active modes are predicted from the factor-group analysis: A_{1g}, E_{1g}, and $3E_{2g}$ modes. Four Raman peaks are clearly visible (Fig. 1) and depolarization measurements (8) indicate that the peak at 126 cm^{-1} has both E_{1g} and E_{2g} symmetry. The peak at 254 cm^{-1} of A_g symmetry corresponds to the symmetric stretching motion of the Cl^- ions in the σ_h (ab) plane of the crystal. A more complete discussion of the Raman results has been given elsewhere (8).

Cs_2MgCl_4 is orthorhombic; space group $Pnma$ (D_{2h}^{16}); $a = 9.777$, $b = 7.514$, $c = 13.234$ Å; 4 formula units per unit cell (17). Magnesium is tetrahedrally coordinated with distinct $MgCl_4^{2-}$ ions present in the lattice. The structure is isomorphous with Cs_2SO_4. Raman results for oriented single crystals have been presented in detail in a previous publication (3). Not all of the peaks reported previously have been observed in the present work (Table 1,

[a]Assignments for compounds III and IV are based on the tetrahedral $MgCl_4^{2-}$ unit in these solids. Assignments for compound II are based on the factor group (D_{6h}^4) analysis of this extended lattice structure. More complete assignments have been given elsewhere (8).
[b]Peak frequency in cm^{-1}.
[c]Halfwidths and relative intensities based on the most intense peak given a value of 10 are listed in parentheses.
[d]Pure $MgCl_2$ has peaks at 155 and 240 cm^{-1} and may contribute in this region.

Fig. 1), but this is due to the fact that the previous work was done on oriented crystals at 77 K. Nevertheless, the typical four line spectrum of the $MgCl_4^{2-}$ species can be identified and the assignments (Table 1) are based on the oriented single crystal data.

The complete structure of Cs_3MgCl_5 has not been reported but Couch and Smith (18) deduced from X-ray powder patterns that the structure was isomorphous with Cs_3CoCl_5; space group $I4/mcm$ (D_{4h}^{18}); $a = b = 9.23$ Å, $c = 14.88$ Å; 2 formula units per primitive unit cell. Discrete $MgCl_4^{2-}$ tetrahedral are predicted and the Raman results are in excellent agreement with this prediction. Results of a full factor group analysis and depolarization measurements have been presented (8). The ν_3 mode (380, 369 cm^{-1}) and the ν_4 mode (142, 157 cm^{-1}) of the tetrahedral ion have been split by crystal field effects (Fig. 1, Table 1).

The crystal structure of $CsMg_3Cl_7$ is not known. Indeed it will be difficult to obtain structural information on this incongruent melting compound. A large number of Raman peaks have been detected with the intense peaks at 219.5 and 320 cm^{-1} the most prominent (Table 1, Fig. 1). Our samples also contained peaks due to $CsMgCl_3$ (Fig. 1) and a

[a]Assignment of I should be based on the D_{2h}^{16} space group but data are too scarce. Assignment of II is based on the D_{4h}^{17} structure. Intensity in the 100–200 cm^{-1} region may have a large second order component (3).
[b]Peak frequency in cm^{-1}.
[c]Halfwidths, and relative intensities based on the most intense peak given a value of 10 are listed in parentheses.

weak peak at 244 cm^{-1} may be due to $MgCl_2$. It seems doubtful that the structure contains a discrete species, such as $MgCl_4^{2-}$ or $MgCl_6^{4-}$ since the characteristic peaks are absent. Further speculation on the structure is not warranted.

RbCl–$MgCl_2$ System

The phase diagram of the RbCl–$MgCl_2$ system is characterized by two congruent melting compounds $RbMgCl_3$ and Rb_2MgCl_4 (15, 19). Full crystal structure data are not available but it has been suggested that the $RbMgCl_3$ salt is isostructural with $CsMgCl_3$ (20, 21) while the Rb_2MgCl_4 salt may have a tetragonal structure similar to K_2MgCl_4 (20). Raman results for $RbMgCl_3$ are consistent with the $CsMgCl_3$ structure and it can be seen (Figs. 1 and 2) that the spectra are quite similar. The assignments for $RbMgCl_3$ (Table 2) have been made by analogy with the cesium salt. The origin of the weak peak at 335 cm^{-1} is uncertain although it has been assigned to a combination mode. The lowest frequency mode in $CsMgCl_3$ (54 cm^{-1}) has been assigned to the Cs^+ sublattice (8) which would suggest that the mode at 54 cm^{-1} in the $RbMgCl_3$ should be due to the Rb^+ sublattice but this is not in keeping with mass differences. Possibly the modes at 152.8 and 124.6 cm^{-1} in the rubidium and cesium salts are due to the alkali metal sublattice mode.

The Rb_2MgCl_4 spectrum resembles the K_2MgCl_4

[b]Peak frequency in cm^{-1}.
[c]Halfwidths, and relative intensities based on the most intense peak given a value of 10 are listed in parentheses.

spectrum (Figs. 2, 3) insofar as the most intense peak at 194 cm^{-1} is close to the value of 205 cm^{-1} observed for K_2MgCl_4. The peaks at 56.0 and 92.6 cm^{-1} are much sharper than possible corresponding peaks at 70 and 103 cm^{-1} in the K_2MgCl_4 spectrum. Sharpening of peaks is to be expected on going to larger cations since environmental broadening is expected to be less. The peak at 92.6 cm^{-1} may be due to an A_{1g} mode predicted but not observed for the potassium salt. Assignments (Table 2) are based on the uncertain analogy with the K_2MgCl_4 salt which has been studied in more detail (3).

The spectrum of the solid of composition $n = 3$ resembles that of the Rb_2MgCl_4 salt which indicates that this solid is really $Rb_2MgCl_4 + RbCl$. However, the solid formed from the melt composition $n = 4$ shows several new features in addition to the Rb_2MgCl_4 peaks. The peaks at 147, 261.8, 374, and 390 cm^{-1} are similar in peak position and relative intensity to the ν_4, ν_1, and ν_3 (split by lattice forces) of the tetrahedral $MgCl_4^{2-}$ species as observed for Cs_2MgCl_4 and Cs_3MgCl_5 (Tables 1, 2). Markov and Panchenko (19) noted the peculiar behaviour of the line of crystallization extending up to 29 mol% $MgCl_2$ but their cooling curves indicated only one eutectic. Raman results suggest the presence of a new incongruent melting compound Rb_3MgCl_5. Presence of a solid solution cannot be ruled out but the clarity of the Rb_2MgCl_4 part of the spectrum suggests that this is not the case.

KCl–$MgCl_2$ System

Two congruent melting compounds have been reported from phase diagram studies of the KCl–$MgCl_2$ system (22). X-ray diffraction data are available for both salts and neither contains the $MgCl_4^{2-}$ ion. Brynestad *et al.* (23) reported that $KMgCl_3$ has an orthorhombically distorted

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

perovskite structure at room temperature which transforms to a cubic perovskite-type structure at 448 K. The room temperature structure has space group *Pbnm* (D_{2h}^{16}); $a = 6.954$ Å, $b = 6.971$ Å, $c = 9.922$ Å; 4 formula units per unit cell. Magnesium has approximately octahedral symmetry with face-shared chloride ions. Factor group analysis predicts the following mode distribution:

$$\Gamma_{total} = 7A_{1g} + 7B_{1g} + 5B_{2g} + 5B_{3g} + 8A_u + 8B_{1u} + 10B_{2u} + 10B_{3u}$$

$$\Gamma_{acoustic} = B_{1u} + B_{2u} + B_{3u}$$

Twenty-four Raman active modes are predicted and since no discrete structural units exist, the assignment of Raman peaks must await oriented single crystal studies. Raman scattering from this sample was weak and the peaks were broad and poorly defined (Fig. 3, Table 3). The spectrum does not resemble either $CsMgCl_3$ or $RbMgCl_3$ and is clearly distinguishable from the K_2MgCl_4 spectrum. There was no evidence of any $MgCl_2$ or K_2MgCl_4 in the sample.

K_2MgCl_4 has a tetragonal structure: space group I_4/mmm (D_{4h}^{17}); $a = b = 4.94$ Å, $c = 15.58$ Å; one formula unit per primitive unit cell (17). Magnesium is in a distorted octahedral site in a network structure with neighbouring octahedra sharing corners. Previous Raman results for oriented single crystals were in good agreement with the factor-group analysis based on this structure. Assignments (Table 3) are based on the previous study (3). The strong peak at 205 cm^{-1} is due to the out-of-plane rotatory motion of the Cl^- sublattice while the peak at 73 cm^{-1} has been assigned to a similar mode of the K^+ sublattice. Predicted A_{1g} modes were not observed but moderately strong second-order scattering was present between 100 and 160 cm^{-1} (Fig. 3).

Spectra of solids obtained from melts in the high KCl region of the phase diagram indicate the presence of an additional compound tentatively formulated K_3MgCl_5 (Fig. 3, Table 3). The most intense of the new peaks occurs at 219 cm^{-1} which is too low to be due to a $MgCl_4^{2-}$ species. It seems most likely that the new compound also contains a network octahedral coordination for the magnesium. The fact that the spectrum of K_2MgCl_4 persists into the solids of composition $n = 3$ and $n = 4$ suggests that the new compound melts incongruently. Presence of a solid solution cannot be ruled out.

NaCl–$MgCl_2$ System

Two incongruent melting compounds, $NaMgCl_3$ and Na_2MgCl_4 are proposed by phase diagram studies (22). No diffraction data are available for either salt. Characteristic Raman spectra have been assigned for each salt (Fig. 4, Table 4) but, as expected, for incongruent melting compounds it is difficult to obtain pure compounds. The spectrum of $NaMgCl_3$ seems to be less intense than that of Na_2MgCl_4 and may contain intensity due to $MgCl_2$ which is expected from phase diagram information. Raman spectra do suggest a network octahedral coordination for magnesium.

LiCl–$MgCl_2$ System

The LiCl–$MgCl_2$ system has been reported to form a solid solution over the whole composition range (24). Raman results (Table 5, Fig. 5) are in excellent agreement with this proposal. Spectra of the solids obtained for each composition were essentially identical (Fig. 5). There was no evidence for sharp peaks due to $MgCl_2$ which would have suggested that the solid had separated into a mixture of crystalline $MgCl_2$ and LiCl. In fact, the broad nature of all of the peaks is consistent with solid solution formation over the entire concentration range. It is difficult to assess possible local structure from the spectra but the presence of the strong peak at 250 cm^{-1} could be due to the presence of a local $MgCl_4^{2-}$ environment. A weak peak at 345 cm^{-1} was also observed which could be due to the ν_3 mode of the T_d species. The presence of the 250 cm^{-1} peak even in the solid of composition $LiMgCl_3$ would only seem possible if the tetrahedral geometry about magnesium was a network array with shared Cl^- ions over a lattice that included the Li^+ ions.

Melts

Raman spectra for melts of composition $MgCl_2 + n$ACl are shown (Figs. 6–10) while data for the $n = 4$ and $n = 1$ compositions are collected in Table 6. Peak positions were relatively constant over the concentration range studied as were the halfwidths except for the halfwidths of the peaks in the 200–250 cm^{-1} region which increased with increased $MgCl_2$ concentration. Peaks at about 110, 145, and 350 cm^{-1} were depolarized, whereas the peaks in the 200–250 cm^{-1} region were strongly polarized with depolarization ratios less than 0.02. For melts of low $MgCl_2$ concentration ($n = 4$), a four line spectrum was observed and there seems little doubt about the assignment of these peaks to the four lines expected for the tetrahedral $MgCl_4^{2-}$ ion (Table 6) (3–5). The similarity of the spectrum to that of CCl_4 has been noted (3). A marked cation dependence on the ν_1 mode can be seen by com-

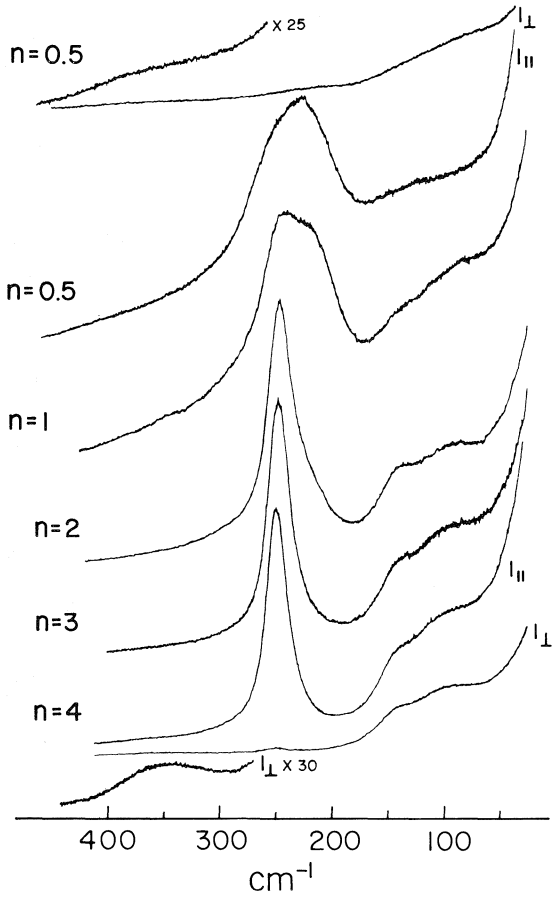

FIG. 6. Raman spectra of melts of the $CsCl–MgCl_2$ system. Depolarized spectra are shown for the highest and lowest $MgCl_2$ concentrations with the ν_3 region of $MgCl_4^{2-}$ considerably scale expanded.

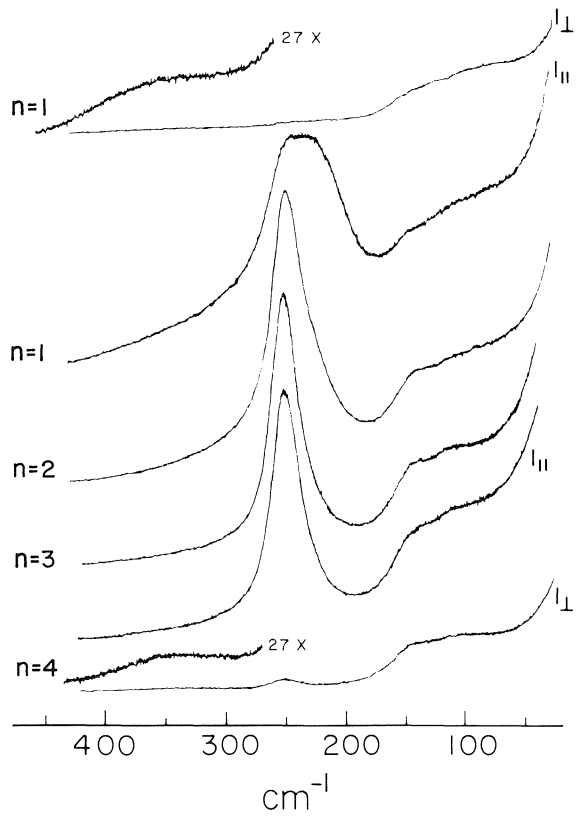

FIG. 7. Raman spectra of melts of the $RbCl–MgCl_2$ system (see Fig. 6).

parison of the melts of low $MgCl_2$ concentration. The peak maximum shifts to slightly lower frequencies while the halfwidth of the band increases considerably over the cation series Cs^+ to Li^+. This is not unexpected since the small Li^+ ion can compete quite favourably for the chloride ion which will weaken the Mg—Cl force constant and lower the frequency. Halfwidth variations of the ν_1 mode at about 250 cm^{-1} are probably due to vibrational relaxation caused by environmental broadening. The symmetric stretching mode of $MgCl_4^{2-}$ will occur in a greater range of environmental conditions in the neighborhood of the smaller, lighter Li^+ and Na^+ ions than for the larger Rb^+ and Cs^+ and this could explain the larger halfwidth for the lithium melt. Exchange broadening may also be a factor since the expected lifetime of the Cl^- ions in $MgCl_4^{2-}$ would be 10^{-10} to 10^{-12} s which is the correct range for these effects (25). The lifetime of the Cl^- in $MgCl_4^{2-}$ in the cesium melt is expected to be considerably longer than for the lithium melt.

An increase in the $MgCl_2$ concentration results in additional Raman scattering about 225 cm^{-1}. A second component at ~225 cm^{-1} is *clearly resolved* for the Cs, Rb, and K salts (Figs. 6–8) and there can be little doubt that there are two peaks in this region, i.e., the change in the envelope is not just simple broadening of the ν_1 mode. The formation of a new equilibrium species in the melts of high $MgCl_2$ concentration is suggested. It should be noted that the peaks due to the $MgCl_4^{2-}$ tetrahedron persist for all of the melts and can be detected in melts of high $MgCl_2$ concentration and even the pure $MgCl_2$ melts (Figs. 6–10, Table 6) (6). This is particularly obvious in the $I_\perp$ spectrum where the depolarized intensity remains in the 350, 145, and 110 cm^{-1} regions due to the ν_3, ν_4, and ν_2 modes. Relative intensities of these modes remained constant within experimental error over the concentration range studied. The ν_3 mode has been detected in the spectrum of molten $MgCl_2$ (6). If one makes the crude assumption that the molar scattering efficiencies of the ν_1 mode of $MgCl_4^{2-}$ at 250 cm^{-1} is equal to the molar scattering efficiency of the mode of the new species at 225 cm^{-1} then the intensity of the ν_1 mode divided by the total inten-

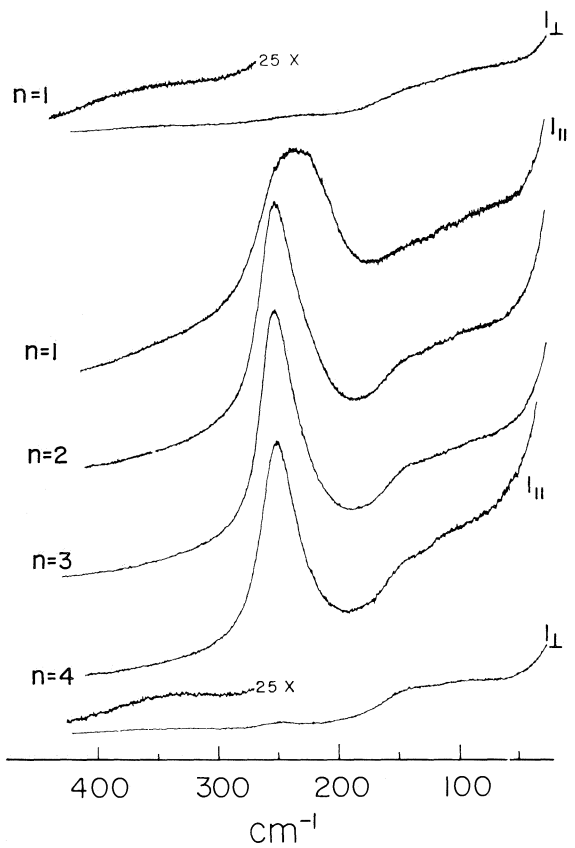

FIG. 8. Raman spectra of melts of the KCl–$MgCl_2$ system (see Fig. 6).

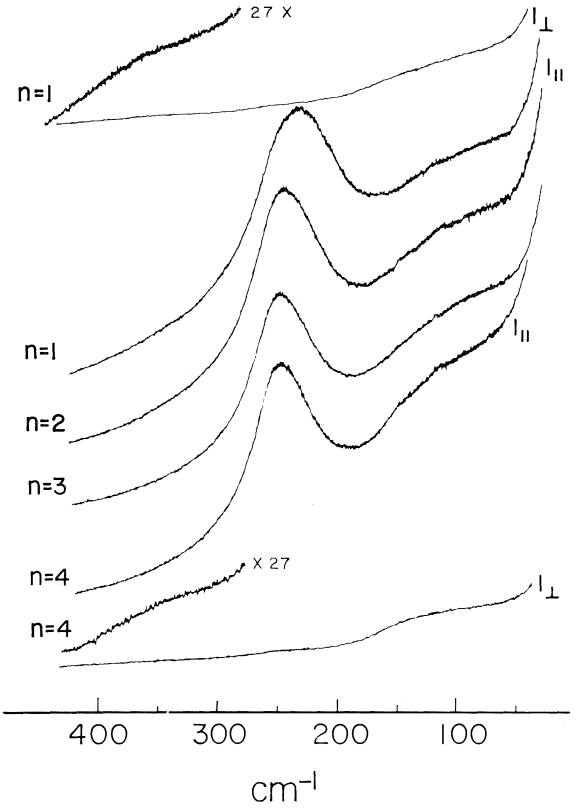

FIG. 9. Raman spectra of melts of the NaCl–$MgCl_2$ system (see Fig. 6).

sity in the 160–250 cm^{-1} region corresponds to the fraction of $MgCl_4^{2-}$ present in the melt. On this basis one finds that only $MgCl_4^{2-}$ is present at low $MgCl_2$ concentrations but this decreases slowly with increasing $MgCl_2$ concentration until only about 30% is left in pure $MgCl_2$ (Fig. 11). Possibly a third species exists in pure $MgCl_2$ since an additional polarized peak has been resolved at 130 cm^{-1} (6). The failure of simple mixture models to account for the phase diagrams of the $MgCl_2$–ACl systems would appear to be due to the presence of a new species in the high $MgCl_2$ region.

It is difficult to identify the species which gives rise to the polarized peak at 225 cm^{-1} since no other peaks have been detected. However, the present studies are quite analogous to those for the more stable, low melting CsCl–$AlCl_3$ system where two clearly resolved peaks at 350 and 312 cm^{-1} have been assigned to the $AlCl_4^-$ and $Al_2Cl_7^-$ ions on the basis of concentration studies and normal coordinate analysis. The $Al_2Cl_7^-$ ion is composed of two corner-shared tetrahedrons with probable D_{3d} symmetry (26, 27). It seems quite possible that in the present study the peak at 225 cm^{-1} is due to the $Mg_2Cl_7^{3-}$ ion since this would allow the magnesium to retain its tetrahedral coordination through corner-sharing with other magnesium centered tetrahedrons. An edge-shared $Mg_2Cl_6^{2-}$ would also be consistent with the results. $Mg_2Cl_6^{2-}$ ions, which we have preposed previously (3, 6), would be favoured by the lower charge but formation of $Mg_2Cl_7^{3-}$ would be statistically more favourable. A melt of composition $CsMgCl_3$ could possibly be described by the simplistic equilibrium although many others could be written.

$$8CsMgCl_{3(s)} \rightleftharpoons 8Cs^+ + 2Mg^{2+} + 6MgCl_4^{2-} \rightleftharpoons 3Mg_2Cl_7^{3-} + 3Cl^-$$

In the short time period of the Raman process smaller aggregates probably occur but with low concentration and/or with low intensity. It appears as if the tetrahedral coordination of Mg is highly favoured. Aggregates with 3Mg ions would be possible and have been proposed for molten $MgCl_2$ (6) but larger aggregates would probably have lifetimes shorter than Cl^- diffusion times. The presence of the $Al_2Cl_7^-$ ion was not predicted by phase diagram studies (28) and although the presence of the $CsMg_3Cl_7$ solid may suggest the presence of a dis-

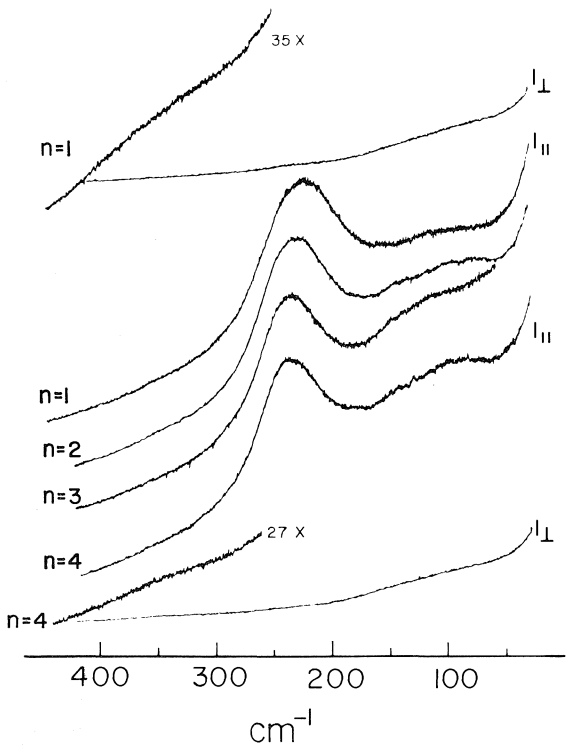

FIG. 10. Raman spectra of melts of the LiCl–$MgCl_2$ system (see Fig. 6).

crete dimeric or trimeric ion it appears that the $Al_2Cl_7^-$ and $Mg_2Cl_7^{3-}$ ions are melt stabilized. Spectroscopic studies of the $MnCl_2$–ACl and $ZnCl_2$–ACl systems indicate that tetrahedral coordination of the divalent metal cation is maintained over the whole concentration range and similar polynuclear tetrahedral species have been proposed for the concentrated melts (29, 30).

It does not seem likely that octahedral coordination occurs. A discrete $MgCl_6^{4-}$ ion seems extremely unlikely since even in the solids the octahedral coordination could only be stabilized by sharing of chlorides in a network lattice. Dimeric species with octahedral coordination and shared chlorides would require unrealistically large species charges and a discontinuous change in coordination when formed from the $MgCl_4^{2-}$ ion. There is no evidence to suggest the presence of $MgCl_3^-$ which would be expected to have a symmetric stretching mode at higher frequencies than ν_1 of $MgCl_4^{2-}$. An Mg_2Cl_4 molecule would require either improbable Mg–Mg contact or unfilled coordination sites.

An increase in $MgCl_2$ concentration appears to cause an increase in the halfwidths of both the 250 and 225 cm^{-1} components. The explanation of this effect is probably similar to that given above for the cation effect at fixed $MgCl_2$ concentration ($n = 4$), i.e., inhomogeneous broadening or lifetime broadening caused by the greater symmetry of the attraction of Cl^- ions between two magnesium ions than between a magnesium and cesium ion.

In summary the present results present a reasonably clear picture of the coordination behaviour of magnesium in the alkali metal chloride – magnesium chloride solids and melts. In solids the discrete tetrahedral $MgCl_4^{2-}$ species can only be stabilized by large cations such as Cs^+ or Rb^+ and then only when there is sufficient chloride. Edge-, face-, and corner-shared octahedral appear more often in the solid state structures. Nevertheless the fusion of the salts inevitably leads to stabilization of the $MgCl_4^{2-}$ ion which can probably coexist in equilibrium with an ionic dimer $Mg_2Cl_7^{3-}$. There is generally no reason to expect the species present in the melt to persist into the solid state although this does appear to be the case for Cs_2MgCl_4, Cs_3MgCl_5, and Rb_3MgCl_5. From a vibrational spectroscopic point of view there is little doubt that the presence of discrete equilibrium ionic species dominates the melt structure. Lattice-like structural models are not supported by this work. The

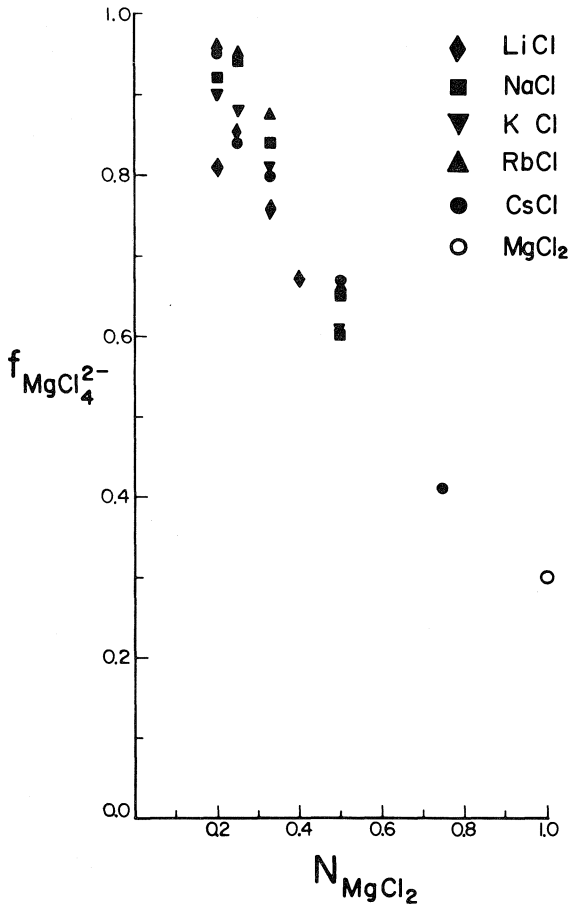

FIG. 11. Fraction of magnesium in the $MgCl_4^{2-}$ ion form obtained from the ratio of the intensity of the ν_1 mode at about 250 cm^{-1} to the total polarized intensity in the region.

moderately high conductivity of pure $MgCl_2$ (31) is consistent with the presence of the ions proposed above (the equivalent conductance for molten $MgCl_2$ at 1060 K is 33.2 ohm^{-1}). Improved data collection and treatment of the ionic melts over the critical concentration range ($n = 2$ to $n = 0$) would help to improve the determination of the relative species concentrations but lack of information on the relative scattering efficiencies would still need to be overcome. The halfwidths of the ν_1 peaks for the different melts suggest that the $MgCl_4^{2-}$ and $Mg_2Cl_7^{3-}$ ions have kinetic stability relative to chloride diffusion. The species lifetimes are considerably larger in the CsCl–$MgCl_2$ melts (probably 10^{-10} to 10^{-11} s) but decrease with increasing $MgCl_2$ concentration and with decreasing size of alkali metal cation.

A ^{31}P nuclear magnetic resonance spectroscopic study of complexes of cadmium(II) with some phosphine oxides, sulfides, and selenides[1,2]

PHILIP A. W. DEAN[3] AND MARY K. HUGHES

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 18, 1979

PHILIP A. W. DEAN and MARY K. HUGHES. Can. J. Chem. **58**, 180 (1980).

Complexation between $Cd(SbF_6)_2$ and the ligands Ph_3PE (E = S or Se), $Ph_2P(E)(CH_2)_nP(E)Ph_2$ (n = 1 or 2, E = O, S or Se; n = 3, E = Se), $[Ph_2P(E)CH_2]_3CMe$ (E = S or Se) and $Ph_2P(E)(CH_2)_2PPh(E)(CH_2)_2P(E)Ph_2$ (E = O, S, or Se) in liquid SO_2 has been studied, mainly by low-temperature ^{31}P nmr spectroscopy. With the sulfides and selenides the maximum donor atom/Cd ratio observed is four, as shown by the limiting low temperature spectra of $(Ph_3PE)_4Cd^{2+}$ (E = S or Se), $[CH_2(PPh_2(Se))_2]_2Cd^{2+}$, and $[Ph_2P(E)CH_2CMe(CH_2PPh_2(E))_2]_2Cd^{2+}$ (E = S or Se). The last two complexes both contain a potentially tridentate ligand behaving in a bidentate manner and their spectra are unexpectedly complicated due, perhaps, to conformational effects. Slow exchange spectra of $[Ph_2P(E)(CH_2)_2PPh(E)(CH_2)_2PPh_2(E)]Cd^{2+}$ (E = S or Se) show that in each complex the ligand behaves in a tridentate manner. For the preceding complexes, two-bond $^{111/113}Cd$–^{31}P coupling is observed at the donor sites, and for the selenides a reduction in $|{}^1J(^{31}P—^{77}Se)|$ on complexation further identifies the bound —PSe groups.

The maximum coordination number appears to be six in the complexes of the phosphine oxides. Both 2:1 and 3:1 L:Cd complexes exist for both of the bidentate ligands $Ph_2P(O)(CH_2)_nP(O)Ph_2$ (n = 1 or 2) whereas in the system $Ph_2P(O)(CH_2)_2P(O)Ph(CH_2)_2P(O)Ph_2$–$Cd^{2+}$ the species identified is the presumably six-coordinate 2:1 complex. For comparison, the six-coordinate complex $[\{CH_2(PPh_2(O))_2\}_3Hg]^{2+}$ has been identified in solution also.

Competition studies between the dioxides, disulfides, and diselenides of the diphosphines show that the disulfides and diselenides cannot compete with the dioxides for cadmium, but that the diselenides can compete with the disulfides to a limited extent.

PHILIP A. W. DEAN et MARY K. HUGHES. Can. J. Chem. **58**, 180 (1980).

On a étudié la complexation entre $Cd(SbF_6)_2$ et les ligands: Ph_3PE (E = S ou Se), $Ph_2P(E)(CH_2)_nP(E)Ph_2$ (n = 1 ou 2, E = O, S ou Se; n = 3, E = Se), $[Ph_2P(E)CH_2]_3CMe$ (E = S ou Se) et $Ph_2P(E)(CH_2)_2PPh(E)(CH_2)_2P(E)Ph_2$ (E = O, S ou Se) dans le SO_2 liquide en utilisant principalement la rmn du ^{31}P à basse température. Avec les sulfures et les sélénures le rapport maximum atome–donneur Cd observé est 4 tel que montré par les spectres à basse température du $(Ph_3PE)_4CD^{2+}$ (E = S ou Se), du $[CH_2(PPh_2(Se))_2]_2Cd^{2+}$ et du $[Ph_2P(E)CH_2CMe(CH_2PPh_2(E))_2]_2Cd^{2+}$ (E = S ou Se). Les deux derniers complexes contiennent un ligand potentiellement tridentate se comportant de manière bidendate et leurs spectres sont compliqués de manière inattendue probablement à cause d'effets conformationnels. Les spectres d'échange lents du $[Ph_2P(E)(CH_2)_2PPh(E)(CH_2)_2PPh_2(E)]Cd^{2+}$ (E = S ou Se) montrent que dans chaque complexe le ligand se comporte de manière tridentate. Pour les complexes précédents on observe au niveau des sites donneurs un couplage à travers deux liaisons $^{111/113}Cd$–^{31}P et pour les sélénures la réduction de $|{}^1J(^{31}P–^{77}Se)|$ dans la complexation identifie d'avantage les groupes —^{2}PSe liés.

Le nombre maximum de coordination semble être 6 dans les complexes de phosphine oxydes. Les deux complexes 2:1 et 3:1 L:Cd existent pour les deux ligands bidentates $Ph_2P(O)(CH_2)_nP(O)Ph_2$ (n = 1 ou 2) alors que dans le système $Ph_2P(O)(CH_2)_2P(O)Ph(CH_2)_2P(O)Ph_2$–$Cd^{2+}$ l'espèce identifiée est probablement le complexe hexacoordonné 2:1. On a identifié en solution également pour fins de comparaison le complexe hexacoordonné $[\{CH_2(PPh_2(O))_2\}_3Hg]^{2+}$.

Les études de compétition entre les dioxydes, les disulfures et les disélénures des diphosphines montrent que les disulfures et les disélénures ne peuvent entrer en compétition avec les dioxydes dans le cas du cadmium mais que les disélénures peuvent jusqu'à une certaine limite entrer en compétition avec les disulfures.

[Traduit par le journal]

Introduction

The potential of Fourier Transform ^{113}Cd nmr for the study of cadmium complexes in solution has already been amply demonstrated (1–16). There is general agreement, however, that a lack of good "fingerprint" data on well-defined species is holding back development in this area (7, 13–15). As part of a project aimed towards identification of the regions where cadmium resonance of complexes with various numbers and types of Group VIA donor atoms should occur, we have used ^{31}P nmr to characterize, in solution, cadmium complexes with a range of phosphine oxides, sulfides, and selenides as model Group VIA donors. To try and reduce coordination by the anion or solvent, which may lead to undesired mixed-ligand complexes, we have used a strong acid salt, $Cd(SbF_6)_2$, in a weak-donor solvent, SO_2.

One previous room temperature ^{31}P nmr study involved the complexes $[Ph_2P(O)CH_2P(O)Ph_2]CdX_2$ (X = Cl, Br, or I) (17) and another complex $[Ph_2P(O)CHPr^nPPh_2]CdBr_2$ (18). (The related $[Ph_2P(O)CH_2PPh_2]CdBr_2$ was not soluble enough for study.) In both cases deshielding of the phosphoryl phosphorus occurred on complexation and in both cases rapid intermolecular ligand exchange

[d]Data for free ligand from ref. 23.
[e]This 2:1 complex gave very broad lines at low temperatures. The spectral parameters at 308 K were determined by extrapolation from the exchange-averaged spectra of samples with L/Cd > 2.
[f]Signal overlap prevents accurate determination of satellite splitting.
[g]At 308 K, the exchange-averaged spectrum yields $\lvert^1J(PSe)\rvert \approx 570$ Hz for the complex.
[h]Broadening of the satellites, but not the centre band, suggests $\lvert^5J(PSe)\rvert \approx 5$ Hz.

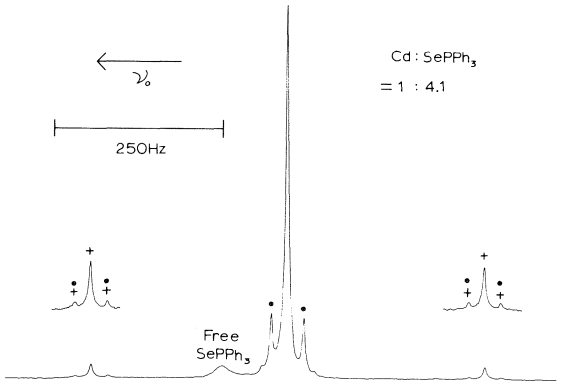
was thought to be occurring: no ^{31}P–$^{111/113}Cd$ coupling was evident. Complexation of the phosphoryl group to cadmium also occurs in $(Ph_3PO)_2CdX_2$ (X = Cl or Br) (19) and in the 1:1 complex of Ph_3PO with bis(thenoyltrifluoroacetonato)cadmium (20). To our knowledge the only phosphine chalcogenide complexes of cadmium reported are $(Et_3PSe)_2CdI_2$ (21) and $[(Ph_3PE)CdX_2]_n$ (E = S, X = I; E = Se, X = Br or I) (22). These are non-conductors in MeCN, but the Ph_3PE complexes, at least, dissociate in solution (22).

Results and Discussion

The Systems $Cd(SbF_6)_2$–Ph_3PE–SO_2 (E = O, S, or Se)

Key ^{31}P nmr spectral parameters for the complexes identified in these systems are given in Table 1.

In the 209 K spectra of solutions in which Ph_3PSe:Cd(II) > 4, separate signals from free and bound ligand are observed, as shown in Fig. 1. Integral analysis shows that the latter is present in a 4:1 complex. The signals from the complex are comprised of a centre band containing ca. 65% of the total bound ligand intensity, flanked by one pair of satellites with ca. 25% of the total intensity and a second more widely spaced pair of satellites with ca. 10% of the total intensity. The amplitude of the more closely spaced satellites make it clear that these are a superimposition of ^{111}Cd and ^{113}Cd satellites (^{111}Cd and ^{113}Cd have $I = \frac{1}{2}$, natural abundances of 12.75 and 12.26% and magnetic moments of −0.5922 and −0.6195 nuclear magnetons, close enough that overlap of signals will occur at small satellite splittings). The more widely spaced satellites are from molecules containing ^{77}Se. (^{77}Se:7.58% natural abundance, $I = \frac{1}{2}$). $^2J(^{31}P—^{111/113}Cd)$ in the 4:1 complex is more than an order of magnitude smaller than known values of $^1J(^{31}P—^{111/113}Cd)$ (24) (e.g. $^1J(^{31}P—^{113}Cd)$ = 1124–1308 Hz in a series of bis(phosphine) complexes of CdI_2 in CH_2Cl_2 at 183 K). This is good evidence for two-bond coupling in the $SePPh_3$ species. In addition, $\lvert^1J(^{31}P—^{77}Se)\rvert$ in the complex is reduced from the free ligand value, and such



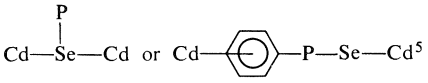


FIG. 1. The 209 K 40.5 MHz ^{31}P nmr spectrum of an SO_2 solution in which $Cd(SbF_6)_2$:$SePPh_3$ = 1:4.1. Filled circles indicate $^{111/113}Cd$ satellites, and crosses ^{77}Se satellites.

a change is known to accompany coordination of phosphine selenides through the selenium atom (23, 25). Hence the spectrum is consistent with the formation of $Cd(SePPh_3)_4^{2+}$ with a regular, presumably tetrahedral (at least on a time average), $CdSe_4$ core.

At ambient probe temperature,[4] or at 209 K in metal-rich mixtures, an intermolecular-exchange averaged spectrum is observed showing coupling to ^{77}Se but not to $^{111/113}Cd$. In the ligand-deficient mixtures $|^1J(^{31}P—^{77}Se)|$ is less than found in $Cd(SePPh_3)_4^{2+}$ (e.g. at 209 K $|^1J(^{31}P—^{77}Se)| = 528$ Hz in a mixture containing Ph_3PSe:Cd = 2.5:1), so that additional species, perhaps of lower coordination number are formed. In the metal-rich mixtures, the rapid intermolecular exchange may occur through formation of either

bridges, or both.

The Ph_3PS-containing system behaves in a manner identical to the selenide analog. The ^{31}P nmr spectral parameters of $Cd(SPPh_3)_4^{2+}$ are given in Table 1.

In contrast to the preceding, poorly-soluble products are formed in the system $Cd(SbF_6)_2$–$OPPh_3$–SO_2, and these could not be studied in detail by ^{31}P nmr. However, the 220 K spectrum of a saturated solution in which Cd:$OPPh_3$ = 1:3.8 shows a weak line deshielded by 6.8 ppm from the free ligand signal ($\delta_{OP(OMe)_3} = 31.8$ ppm), and in the corresponding spectrum of a saturated solution wherein Cd:$OPPh_3$ = 1:8.5, exchange is evidently occurring at an intermediate rate between free ligand and a species deshielded by ca. 2.7 ppm from it. By analogy with our findings for the diphosphine dioxides (see below) we tentatively suggest that the more deshielded signal might be due to $Cd(OPPh_3)_4^{2+}$ and the less deshielded to $Cd(OPPh_3)_6^{2+}$.

The Systems $Cd(SbF_6)_2$–$Ph_2P(E)(CH_2)_nP(E)Ph_2$–SO_2 (n = 1 or 2, E = O, S, or Se; n = 3, E = Se) and $Hg(SbF_6)_2$–$Ph_2P(O)(CH_2)_nP(O)Ph_2$ (n = 1 or 2)

The ^{31}P nmr spectral parameters for the species identified in solutions containing the diselenides are included in Table 1, while the data for the complexes of the diphosphine dioxides are given in Table 2.

At 220 K the behaviour of the system $Cd(SbF_6)_2$–$Ph_2P(Se)CH_2P(Se)Ph_2$–SO_2 is similar to that of the Ph_3PSe system at reduced temperature (see above) except that intermolecular exchange is slow only when L:Cd $\approx$ 2:1. At or near this ratio a $^{111/113}Cd$ satellite splitting of 45 Hz is observed, similar in magnitude to that found in $Cd(SePPh_3)_4^{2+}$ (see Table 1). Thus it is evident that a four-coordinate (in selenium atoms) bis(chelate) complex, $Cd[(SePPh_2)_2CH_2]_2^{2+}$, is formed. When L:Cd > 2:1, the spectrum is the weighted average of the spectra of the free ligand and the 2:1 complex: there is no significant formation of stable complexes with more than two ligands. When L:Cd < 2 the magnitude of $^1J(P—Se)$ is less than that of the 2:1 complex (e.g., at 220 K, $J \approx 550$ Hz when L:Cd = 1:1.26) and it is clear that other species are being formed. However, the rapid exchange-averaging prevents study of these. At ambient probe temperatures rapid exchange-averaging occurs at all L:Cd ratios.

Like samples containing $Ph_2P(Se)CH_2P(Se)Ph_2$, samples containing $Ph_2P(Se)(CH_2)_2P(Se)Ph_2$ exhibit fast-exchange spectra at ambient probe temperature for all L:Cd ratios. These spectra are consistent with $Cd[(SePPh_2(CH_2))_2]_2^{2+}$ being the species of highest coordination number formed. (The observation of the characteristic yellow colour of the free ligand in SO_2 only when L:Cd > 2 supports this conclusion.) However, in contrast to the behaviour of the system with the shorter-chain diselenide, intermediate-, not slow-, exchange spectra are observed at 220 K for samples with L:Cd $\approx$ 2. For example, a sample with L:Cd $\approx$ 2.1:1 exhibits two approximately equally intense lines, both with $w_{1/2} \approx 60$ Hz, and with $\delta_{OP(OMe)_3} \approx 41.1$ and 42.7 ppm together with a third, broader line ($w_{1/2} \approx 160$ Hz), at $\delta_{OP(OMe)_3} \approx 37.4$ ppm. The higher field signal is not greatly shifted from the free ligand resonance ($\delta_{OP(OMe)_3} = 35.4$ ppm). This spectrum is best interpreted in terms of either exchange between free ligand and two other species, or, more likely, exchange between free ligand and a second species with two inequivalent sites. The second interpretation receives considerable support from behaviour of complexes containing chelating unsubstituted or substituted

rings (see below). For samples containing the unsubstituted propylene ligand, as for the other diselenides, rapid exchange occurs at ambient probe temperature and at low temperatures when

[4]All the phosphine selenide – Cd^{2+} mixtures are unstable at room temperature: over a period of hours red selenium begins to form.

[5]Cadmium(II)–arene complexes are known to be formed in liquid SO_2 (16).

TABLE 2. ^{31}P nmr spectra of $(O)Ph_2P(CH_2)_nPPh_2(O)$ ($n = 1$ or 2) and their complexes with Cd^{2+} and Hg^{2+} and of $(O)PhP(CH_2CH_2PPh_2(O))_2$ and its complex with Cd^{2+}

Ligand	Metal cation	L/M	T (K)	δ_P[a] (ppm)	Comment
$Ph_2P(O)(CH_2)P(O)Ph_2$	—	—	220	27.2	
	Cd^{2+}	2	220	36.8	^2J(CdOP) is not observed. At 313 K, ligand exchange is fast in mixtures of the 1:2 and 1:3 complexes, but not in mixtures of the 1:3 complex and excess free ligand.
	Cd^{2+}	3	220	35.4	
	Hg^{2+}	2	220	~39.5	^2J(HgOP) is not observed; $w_{1/2} > 30$ Hz. Ligand exchange between 3:1 and large amounts of the 2:1 complex occurs at an intermediate rate at 210 K and rapidly at 313 K. Exchange between the 3:1 and excess free ligand is slow at 220 K but rapid at 313 K.
		3	220	37.0	$\lvert^2J(HgOP)\rvert = 46 \pm 1$ Hz
$Ph_2P(O)(CH_2)_2P(O)Ph_2$	—	—	220	36.7	
	Cd^{2+}	2	200	4.15	^2J(CdOP) is not observed. At 313 K, ligand exchange is fast both in mixtures of the 1:2 and 1:3 complexes and mixtures of the 1:3 complex with excess free ligand.
	Cd^{2+}	3	200	39.4	
	Hg^{2+}	2	205	~49.2	^2J(HgOP) is not observed; $w_{1/2}$ ~50 Hz
		3	205	40.8	$\lvert^2J(HgOP)\rvert$ ~30 Hz

[c]Terminal phosphorus atoms.

L:Cd exceeds 2:1. When L:Cd ≈ 2, however, a slow-exchange spectrum can be observed at 205 K. This consists of two equally intense lines,[6] both with both $^{111/113}Cd$ and ^{77}Se satellites (see Table 3). The most plausible interpretation of this spectrum is in terms of a bis(chelate) complex, $Cd[(SePPh_2)_2(CH_2)_3]_2^{2+}$, in which the conformation of each eight-membered chelate ring is rigid at this low temperature and is such that C_2 symmetry exists about the cadmium.[7]

Downfield ^{31}P complexation shifts and blanching of pale yellow diphosphine disulfide – SO_2 solutions by $Cd(SbF_6)_2$[8] provide good evidence for complexation of cadmium by $Ph_2P(S)(CH_2)_nP(S)Ph_2$ ($n = 1$ or 2) but the exact nature of the complexes could not be established with certainty. With the shorter-chain ligand, intermolecular exchange was rapid for all L:Cd ratios both at ambient probe and reduced temperatures. Unfortunately the maximum downfield complexation shift (ca. 5.3 ppm from the free ligand signal ($\delta_{OP(OMe)_3}$ = 33.0 ppm at 220 K)) was too small to allow accurate determination of the stoichiometry of the complex(es) formed from the exchange-averaged shifts. With the ligand $Ph_2P(S)(CH_2)_2P(S)Ph_2$, intermolecular ligand exchange could be slowed, but incompletely and only in the absence of excess ligand. Thus the 220 K spectrum of a solution in which L:Cd = 2.0:1 showed two partially-coalesced, approximately equally intense, broad ($\omega_{1/2} \approx 30$ Hz) lines deshielded by 3.4 and 5.2 ppm from the free ligand resonance ($\delta_{OP(OMe)_3}$ = 43.7 ppm). A tentative explanation of this spectrum is in terms of the formation of a four-coordinate bis(chelate) complex of C_2 symmetry (see above)

[6]In most spectra an unassigned line of variable intensity was observed at $\delta_{OP(OMe)_3} \approx 32.1$ ppm.

[7]We note that in the tetrahedral complexes $[CHR(CH_2PPh_2)_2]_2Pt$ (R = H or $—CH_2PPh_2$), the puckered chelate rings give rise to two inequivalent pairs of phosphorus atoms, at reduced temperature when R = H, and at room temperature when R = $—CH_2PPh_2$ (26, 27).

[8]The $Ph_2P(S)(CH_2)_nP(S)Ph_2 - Cd(SbF_6)_2 - SO_2$ solutions were initially clear but on standing at room temperature became cloudy in about 1 h.

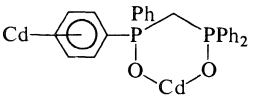
in which there occurs either conformational "flipping" or ligand exchange (or both) at an intermediate rate.

Two sharp single lines can be seen in the 200 K spectra of samples in which $Ph_2P(O)(CH_2)_2P(O)Ph_2$:Cd > 3:1. That at higher field is due to the free ligand and the other, deshielded by 2.7 ppm, is, by integral analysis, from the complex $Cd[(OPPh_2(CH_2))_2]_3^{2+}$ with, presumably, a CdO_6 octahedral core. The free ligand signal disappears when L:Cd = 3:1, and as the molar ratio is decreased further, there appears a second sharp line a further 2.1 ppm downfield, which becomes dominant at L:Cd = 2:1. Evidently a second, 2:1, complex, probably with tetrahedral coordination, is formed in this system. At still lower L:Cd ratios, very complicated multi-line spectra occur, and incompletely soluble species are eventually formed.

In the region $2{:}1 \gtrsim$ L:Cd $\gtrsim 1$, one or more poorly soluble species are formed, but otherwise the behaviour of the system $Cd(SbF_6)_2$–$Ph_2P(O)CH_2P(O)Ph_2$–SO_2 is very similar to that just described, and evidently both 3:1 and 2:1 species occur here too. These are characterized by the chemical shifts given in Table 2. In extremely cadmium-rich solutions (L:Cd < 1:1) a soluble species is formed which gives rise to two equally intense doublets deshielded by 13.6 and 29.3 ppm from the free ligand and with a common 14 Hz coupling. The more shielded doublet occurs in the same regions as the signals of the 3:1 and 2:1 complexes (Table 2). However the less shielded must represent a more severely perturbed phosphoryl group. Possibly a species of the type



$(n \geqslant 1)$

is being formed in this region.[9]

Surprisingly,[10] no two-bond cadmium–phosphorus coupling is observed in the spectra of the complexes of the chelating diphosphine dioxides even under slow exchange conditions.[11] To determine whether ^2J(M—O—P) is generally very small, we have examined complexation of mercury(II) with $Ph_2P(O)(CH_2)_nP(O)Ph_2$ (n = 1 or 2), anticipating that in slow-exchange spectra coupling to ^{199}Hg might be visible (^{199}Hg; 16.84% natural abundance, $I = \frac{1}{2}$). This expectation was realized for the complex $Hg[(OPPh_2)_2CH_2]_3^{2+}$ (see Table 2) which, at 220 K in the presence of excess ligand, gives a

[9]No chemical change in the ligand occurs: the 313 K spectrum shows a single line with $\delta_{OP(OMe)_3} = 46.2$ ppm. It is unlikely that the observed low temperature spectrum is due to formation of an arene complex such as

as cadmium arene complexes are labile (16) so that both ends of the chelate would be equivalent on a time-average.

[10]Two-bond cadmium–phosphorus coupling is thought to occur in some complexes of CdX_2 with R_3PO (28).

[11]Downfield ^{31}P complexation shifts but not cadmium satellites were observed in the systems CdX_2–$Ph_2P(O)CH_2P(O)Ph_2$–DMSO (17). The absence of satellites was attributed to either rapid ligand exchange or a small value of ^2J(Cd—O—P) with a preference for the former. Rapid ligand exchange probably does occur in these systems, but our results show that ^2J(Cd—O—P) may well be small also.

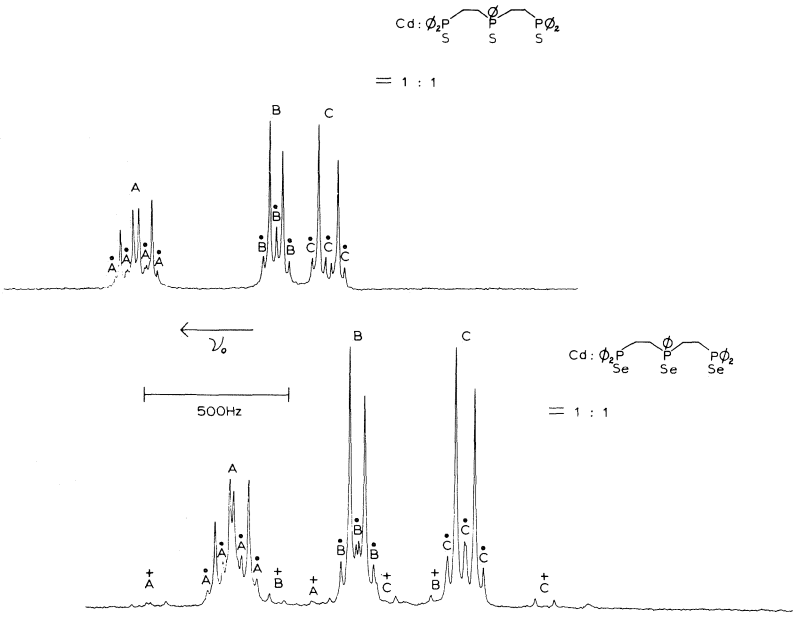

FIG. 2. The 220 K 40.5 MHz ^{31}P nmr spectra of SO_2 solutions containing (top) $Cd(SbF_6)_2$:triphosS_3 = 1:1 and (bottom) $Cd(SbF_6)_2$:triphosS_3 = 1:1. Satellites are indicated as in Fig. 1.

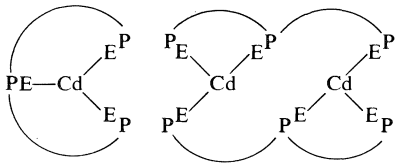
sharp line with ^{199}Hg satellites. On a time average, at least, this complex probably contains the comparatively rare (29) octahedral HgO_6 core. With a slight deficiency of ligand below the 3:1 ratio (e.g. L:Hg = 2.8:1) sharp signals from both the 3:1 and a second, presumably 2:1, complex can be seen. A greater deficiency of ligand leads to more rapid exchange, with much broader, though still separate, lines for the two complexes. At L:Hg $\approx$ 2:1 it is clear that an appreciable amount of the 3:1 complex occurs: this must be the preferred complex in the system. At ambient probe temperature rapid intermolecular exchange occurs for all ratios of $Ph_2P(O)CH_2P(O)Ph_2$:Hg.

The behaviour of the system $Hg(SbF_6)_2$–$Ph_2P(O)(CH_2)_2P(O)Ph_2$–SO_2 is similar: rapid intermolecular exchange occurs at ambient probe temperature but in the 205 K spectra, by variation of the L:Hg ratio it was possible to observe well-separated signals attributable to 3:1 and 2:1 complexes (see Table 2). Shoulders on the signal from the 3:1 complex suggest that ^2J(HgOP) is ca. 30 Hz. As with the preceding diphosphoryl ligand, the 2:1 complex is incompletely formed at L/Hg = 2:1, e.g. a weak signal from the 3:1 complex is evident in the spectrum of a solution with L:Hg = 1.74:1. Where 2:1 and 3:1 complexes coexist, the former gives a broader signal, suggesting it is the more labile species. The presence of trace amounts of the labile 2:1 complex might account for our observation that in ligand-rich samples at 205 K, the free ligand signal is considerably broader than the signal of the 3:1 complex.

The Systems $Cd(SbF_6)_2$–$Ph_2P(E)(CH_2)_2P(E)Ph$-$(CH_2)_2P(E)Ph_2$–SO_2 (E = O(triphosO_3), S(triphosS_3), or Se(triphosSe_3))



Pertinent ^{31}P spectra data for the trioxide containing system are included in Table 2. The corresponding data for the trichalcogenide-containing systems are given in Table 3.

The behaviour of the system containing triphosS_3 is straightforward. At ambient probe temperature, rapid intermolecular exchange occurs regardless of L:M ratio. Exchange is also rapid at 220 K if L:Cd > 1:1. However, when triphosS_3:Cd = 1:1, the spectrum shown in Fig. 2 (top) is obtained. In contrast to the AB_2 spectrum of the free ligand (Table 3), the spectrum of the 1:1 complex shows three regions of resonance, each of equal intensity. By analogy with the spectrum of the corresponding free triselenide the value of ^6J(PP) should be near zero (23). Therefore the double-doublet A must be due to the central $\geq$PS group and the doublets B and C must be signals from chemically-inequivalent terminal —P(S)Ph_2 groups. A, B, and C each exhibit $^{111/113}Cd$ satellites showing that all the sulfur atoms are bound to cadmium and that intermolecular exchange involving the 1:1 species is slow at this temperature. The

spectrum can be accounted for in terms of the formation of a mononuclear species **I**, provided, as seems probable, that conformational equilibration in the relatively rigid bicyclic system is slow at 220 K. Alternatively the ligand could be behaving in a bridging manner to give **II**, in which the terminal groups are clearly chemically inequivalent. Our prejudice is for the first of these species since conformational rigidity evidently occurs in the 2:1 complexes of $Ph_2P(Se)(CH_2)_3P(Se)Ph_2$ (see above) and $triphosO_3$ and $(Ph_2P(E)CH_2)_3CMe$ (E = S or Se) (see below) also. Both **I** and **II** involve coordination of three sulfur atoms to cadmium, but this does not necessarily mean that the total coordination number of the metal is three: the solvent or anion could be coordinated also. Work is presently underway to determine which ligands, if any, can coordinate to $Cd(triphosS_3)^{2+}$ and its $triphosSe_3$ analog (see below). With $triphosS_3$ itself, significant coordination beyond 1:1 does not occur: the exchange-averaged spectra observed when L:Cd > 1:1 are just the weighted average of the 1:1 complex and free ligand. Further, the 1:1 complex persists in the presence of excess cadmium.

I **II**

The behaviour of the system $Cd(SbF_6)_2$–$triphosSe_3$–SO_2 is similar to, but more complicated than, the preceding. The best-characterized species is a 1:1 complex giving the spectrum shown in Fig. 2 (bottom). This spectrum shows not only $^{111/113}Cd$ satellites but also the expected ^{77}Se satellites. Consistent with coordination of all three selenium atoms (see above), the values of $|{}^1J(^{31}P—^{77}Se)|$ are reduced from the free ligand values; significantly the values of $^1J(^{31}P_B—^{77}Se)$ and $^1J(^{31}P_C—^{77}Se)$ are not greatly different, suggesting no great distinction in the way the inequivalent PSe groups bind to the metal(s). Again this spectrum can be interpreted in terms of **I** or **II**.

At ambient probe temperature, a 1:1 $triphosSe_3$:Cd^{2+} mixture gives a spectrum in which the non-terminal PSe group gives rise to a sharp triplet but in which the terminal PSe groups give rise to a considerably broader doublet. As the signal of non-terminal PSe group is shifted further by complexation than those of the terminal PSe groups (Table 3), it is improbable that the former could be sharpened by intermolecular exchange while the latter are not. A more logical interpretation is in terms of fast exchange between traces of free ligand and an incompletely conformationally-averaged structure **I**.

When excess $triphosSe_3$ is present, intermolecular exchange is rapid even at 220 K and the exchange-averaged spectrum confirms that further coordination of $triphosSe_3$ beyond 1:1 does not occur. In the presence of excess cadmium, intermolecular exchange is rapid at ambient temperature, but at reduced temperatures quite complicated behaviour occurs. For example, a solution containing $triphosSe_3$:Cd = 1:2.0 has a spectrum which, at 220 K, consists of a sharp triplet with $\delta_{OP(OMe)_3} = 52.1$ ppm, close to the shift of resonance A of the 1:1 complex, and ^1J(P—P) and $^1J(^{31}P—^{77}Se)$ of 58 and ca. 556 Hz, respectively, and a broad doublet centred at $\delta_{OP(OMe)_3} \approx 38.6$ ppm, roughly the average position of resonances B and C of the 1:1 complex. On further lowering the temperature, to 200 K, the triplet broadens without shifting, while the doublet does not broaden significantly but splits into a strong central doublet and two weaker flanking doublets at $\delta_{OP(OMe)_3} \approx$ 34.3 and 43.4 ppm approximately the positions of B and C. Possibly the 1:1 complex and a further unidentified metal-rich species coexist in this solution and above 200 K undergo rapid intermolecular exchange of metal.

Both ambient probe and reduced temperature spectra provided evidence for the formation of the complex $Cd(triphosO_3)_2^{2+}$ in solutions in which triphos O_3:Cd $\geq$ 2. Even at ambient probe temperature, exchange with excess free ligand is slow and in ligand-rich solutions separate spectra of the bound and free trioxide can be seen as shown in Fig. 3. As B and C coalesce at the higher temperature these resonances must arise from the terminal PO groups of the bound $triphosO_3$, and A is therefore a signal from the non-terminal PO group; these assignments are consistent with the spectrum of the free ligand. At low temperatures B and C are doublets and A shows the incompletely-resolved fine structure of, presumably, a double-doublet (Fig. 3, bottom). At ambient probe temperature B and C coalesce and no A–B or A–C spin coupling is evident (Fig. 3, top). On complexation of the ligand then, there is not only the expected complexation shift, but also a marked reduction in ^3J(P—P) (Table 2 and Fig. 3). We have found such reductions to occur in both $triphosO_3$ and the parent triphosphine on *fac* coordination (30) and therefore we suggest that if, as expected, $Cd(triphosO_3)_2^{2+}$ is an octahedral complex, the tridentate ligand coordinates facially. Thus both *s*- and *u-fac* structure (as opposed to the *mer* structure) are possibilities.

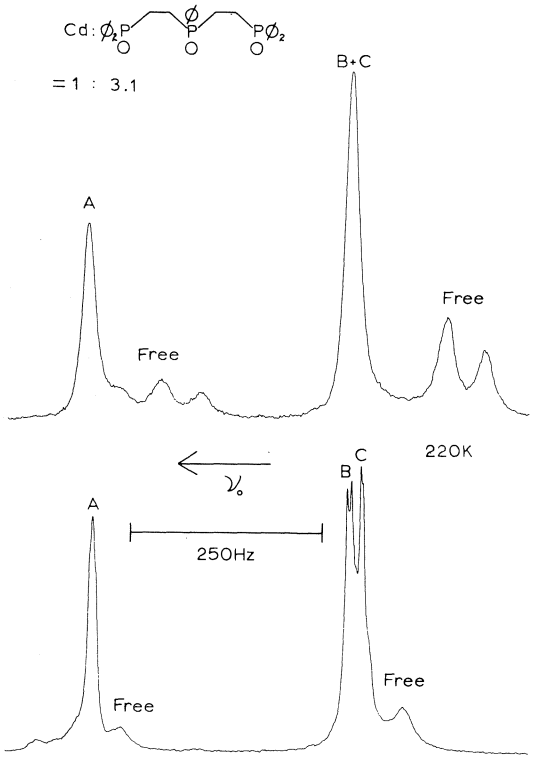

FIG. 3. The 40.5 MHz ^{31}P nmr spectra of an SO_2 solution containing $Cd(SbF_6)_2$:triphosO_3 = 1:3.1 at (top) 308 K and (bottom) 220 K.

Both the *fac* structures can account for the magnetic inequivalence of the terminal PO groups which is observed in the low temperature spectrum (Table 2 and Fig. 3). In the *s-fac* structure the two groups occupy chemically equivalent sites, and their inequivalence must arise from a rigid conformation of the bicyclic metal-chelate system, whereas in the *u-fac* structure, the groups occupy chemically inequivalent sites. At ambient probe temperature the signals from the terminal groups coalesce (Fig. 3, top). In the *s-fac* structure the coalescence of B and C which occurs at room temperature would be a natural consequence of fast conformational equilibration and for this reason we favour the symmetrical structure. However, a rapid partial ligand dissociation[12] – intramolecular rearrangement – recoordination process in the *u-fac* structure might also account for the observed room temperature equivalence of the terminal groups.

When triphosO_3:Cd < 2:1, many lines are observed in the low temperature spectra and no analysis was attempted. The spectra at ambient probe temperature are consistent with an intermediate rate of exchange between various triphosO_3-containing species.

The Systems $Cd(SbF_6)_2$–$(Ph_2P(E)CH_2)_3CMe$–SO_2 (E = S(tripodS_3) or Se(tripodSe_3))[13]

The 220 K spectra of samples containing tripodSe_3:Cd > 2:1 show a signal from the free ligand, as exemplified in Fig. 4 (bottom). Thus a 2:1 complex is the most highly ligated species formed in this system. The 220 K spectrum of the 2:1 complex has three regions of resonance, A, B, and C, each equally intense. The singlet A has a ^{77}Se satellite splitting of *larger* magnitude than that of the free ligand. This fact, and the absence of observable $^{111/113}Cd$ satellites about A, make it clear that A must be the resonance of an *unbound* PSe group. In contrast, the doublets B and C both have both observable $^{111/113}Cd$ satellites and ^{31}P—^{77}Se spin–spin coupling *smaller* in magnitude than in the free ligand. They must therefore be signals from bound PSe groups. Thus in the complex Cd(tripodSe_3)$_2^{2+}$ the potentially tridentate ligands are behaving in a bidentate manner and have one arm "dangling": the complex possesses a $CdSe_4$ core.

Each chelate ring in Cd(tripodSe_3)$_2^{2+}$ is 8-membered. By analogy with Cd[$(SePPh_2)_2(CH_2)_3]_2^{2+}$ (see above) we might then expect the signals from the bound PSe groups to be *singlets*, chemically shifted by their dissimilar orientations relative to the puckered chelate rings. In fact, as seen in Fig. 4 (bottom), B and C are *doublets*, though not, apparently, because of spin-coupling. It seems likely that with the $—CH_2P(Se)Ph_2$ substituent on the propylene backbone of the ligand a small distortion from C_2 symmetry occurs, leading to inequivalence of all four bound PSe groups in the presumably approximately tetrahedral coordinated complex.

In samples containing tripodSe_3:Cd < 2:1, the feature most noticeable in the 220 K spectra is the large relative broadening of resonance A. This is consistent with the expectation that the dangling PSe group will be involved in coordination in metal-rich mixtures. In these samples, as well as ligand-rich samples, the spectra at ambient probe temperature exhibit broad lines indicating exchange at an intermediate rate.

The tripodS_3 system behaves very like the tripodSe_3 system except that excess free ligand is only poorly soluble in SO_2. Close to the 2:1 tripodS_3:Cd ratio the 220 K spectrum (Fig. 4, top) shows features which, by analogy with the Cd(tri-

[12]Complete dissociation is ruled out by the absence of bound-free ligand exchange.

[13]TripodO_3 decomposes in the solid state on standing at room temperature and because of this instability was not used as a ligand.

podSe$_3$)$_2^{2+}$ spectrum, can be interpreted in terms of a low-symmetry, but approximately tetrahedral, complex Cd(tripodS$_3$)$_2^{2+}$ in which the ligands behave in a bidentate manner.

The ^{31}P spectral parameters of Cd(tripodS$_3$)$_2^{2+}$ and Cd(tripodSe$_3$)$_2^{2+}$ are listed in Table 4.

Competition between Binary Mixtures of Diphosphine Dioxide, Disphosphine Disulfide, and Diphosphine Diselenide for Coordination to Cadmium(II)

As we (this work and ref. 30) and others (17, 31) have shown, complexation of phosphine oxides often leads to quite large ^{31}P complexation shifts. Thus if the chemical shift of a phosphine oxide complex is known and exchange-averaging with excess ligand occurs, the percentage complexation of the ligand in the presence of the acceptor can be assessed. Although the ^{31}P complexation shifts of phosphine selenides are usually smaller than those of phosphine oxides, a large change in $|^1J(^{31}P—^{77}Se)|$ accompanies complexation (this work and refs. 23, 25) and so, if the complexed value is known or can be estimated, the exchange-averaged value of this coupling constant allows determination of the extent of complexation of a phosphine selenide.

Using the preceding two indicators we have made semiquantitative measurements of the extent to which the two ligands compete in the ternary mixtures $Cd(SbF_6)_2$–$Ph_2P(E)(CH_2)_nP(E)Ph_2$–$Ph_2P(E')(CH_2)_nP(E')Ph_2$ (n = 1 or 2; E and E′ are O and S, or O and Se, or S and Se). The data and a brief summary of the conclusions are given in Table 5. In the interpretation of the results our principal assumption is that bound diphosphine diselenides, even in mixed ligand complexes, will have approximately the same value of $^1J(^{31}P—^{77}Se)$ as in the bis(diphosphine diselenide) complexes. From our study we conclude that neither diphosphine disulfides nor diphosphine diselenides can compete with homologous diphosphine dioxides for coordination to cadmium, but that diphosphine diselenides compete appreciably with diphosphine disulfides. This latter result is interesting since selenium compounds are antagonists for cadmium poisoning (32) and in biological systems cadmium is usually found bound to sulfur ligands (33).

Experimental

Materials

1,3-Bis(diphenylphosphino)propane, 1,1,1-tris(diphenylphosphinomethyl)ethane, and bis(2-diphenylphosphinoethyl)phenylphosphine (all from Strem Chemicals Inc.) showed no significant impurities by ^{31}P nmr and were used as received. Triphenylphosphine (Eastman Kodak Co.) was recrystallized from ethanol. Bis(diphenylphosphino)methane and 1,2-bis(diphenylphosphino)ethane were synthesized by the literature method (34).

Antimony pentafluoride (PCR) was distilled twice under dry nitrogen. Anhydrous cadmium fluoride (Alfa "Ultrapure") and anhydrous mercuric fluoride (Alfa) were used as received to prepare $Cd(SbF_6)_2$ (16) and $Hg(SbF_6)_2$ (35).

[d]Integral analysis gives free:complexed ligand $\approx$ 1:5.5.
[e]From the exchange-averaged spectrum of the system $Cd(SbF_6)_2$ – excess P_2Se_2 – SO_2 at 313 K, $\lvert^1J(PSe)\rvert \sim 598$ Hz in $Cd(P_2Se_2)_2^{2+}$.
[f]From the exchange-averaged spectrum of the system $Cd(SbF_6)_2$ – excess P_2O_2 – SO_2 at 313 K, $\delta_P = 37.8$ ppm for $Cd(P_2O_2)_3^{2+}$.
[g]For complexation by P_2O_2 only, $\delta_{PO}(calcd) \sim 37.0$ ppm.
[h]For complexation by P_2O_2 only, $\delta_{PO}(calcd) \sim 37.2$ ppm.
[i]$\lvert^1J(PSe)\rvert \sim 596$ Hz and $\delta_{PSe} \sim 42.6$ ppm for $Cd(P_2Se_2)^{2+}$ at 313 K (see Table 1).

The phosphine oxides were prepared by I_2/OH^- treatment of the phosphines (36). The phosphine sulfides resulted from the reflux of a slight excess of the phosphine with sulfur in benzene solution (37–39) (excess sulfur proves difficult to remove); the phosphine selenides were prepared in an earlier study (23) by an analogous procedure using an excess of selenium shot. The purity of the ligands was checked by mp and by ^{31}P nmr.

Sulfur dioxide (Matheson Anhydrous Grade) was dried by standing in the gas phase over 3A molecular sieves for 12–24 h.

Preparation of Nuclear Magnetic Resonance Samples

In a dry-nitrogen filled glove box, appropriate amounts of ligand and $Cd(SbF_6)_2$ were transferred to previously-described (16, 23) baked-out (140°C) 10 mm od nmr tubes made from standard-wall 10 mm tubing having attached a section of 9 mm special wall tubing. The tubes were capped for removal from the inert atmosphere. For addition of solvent, the cap was quickly removed, the tube attached to a standard glass/Teflon vacuum line via a $\frac{3}{8}$ in. "Ultratorr" fitting and evacuated, SO_2 (ca. 2 mL) condensed in from a storage tube, and a flame-seal made at the 9 mm tubing. The samples were stored at −196°C until run.

$^{31}P\{^1H\}$ Nuclear Magnetic Resonance Spectra

All nmr spectra were obtained using a Varian XL-100-12 spectrometer system operating at 40.54 MHz. The use of the $(CD_3)_2CO$–$OP(OMe)_3$ external lock-reference sample and the method of temperature measurement were described in a preceding publication (23).

NOTE ADDED IN PROOF

In more recent studies (40) both 1:4 and 1:3 Cd:EPR_3 (E = S or Se) complexes have been characterized by ^{31}P for a variety of groups R, including R = Ph. For R = *o*-tolyl apparent 1:2 complexes have also been identified.

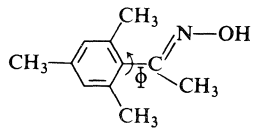
SUZANNE FORTIER, GEORGE I. BIRNBAUM, GERALD W. BUCHANAN, and BRIAN A. DAWSON. Can. J. Chem. **58**, 191 (1980).



From an X-ray analysis of the title compound it is found that the dihedral angle between the plane of the aromatic ring and the oxime plane is 70.8°. This large angle precludes a significant π electron overlap between the oxime function and the benzene ring. The distortions of the internal ring angles attributable to the four substituents are examined in detail, and parameters are derived for the oxime group. The aryl–oxime C—C bond length (1.491 Å) is the longest yet reported for an aromatic oxime. Using the X-ray derived geometry as input for the calculation of $^{13}C—^{15}N$ coupling constants, one obtains markedly better agreement between calculated and observed couplings than was the case when a force-field calculated molecular geometry was employed. The barrier to rotation about the aryl–oxime bond is estimated to be about 5.8 kcal/mol.

SUZANNE FORTIER, GEORGE I. BIRNBAUM, GERALD W. BUCHANAN et BRIAN A. DAWSON. Can. J. Chem. **58**, 191 (1980).

Une analyse de diffraction aux rayons-X du composé de la présente étude montre que l'angle dièdre entre le plan de l'anneau aromatique et le plan du groupement oxime est de 70.8°. La dimension de cet angle empêche un recouvrement significatif des électrons-π entre la fonction oxime et l'anneau de benzène. Les déformations des angles, à l'intérieur de l'anneau, attribuables aux quatre substituants, sont examinées en détail et les paramètres de déformation du groupement oxime sont dérivés. La longueur de la liaison C—C entre les groupements aryle et oxime (1.491 Å) est la plus grande observée jusqu'à présent pour un oxime aromatique. L'accord entre les valeurs expérimentales et théoriques des constantes de couplage $^{13}C—^{15}N$ est sensiblement amélioré par l'utilisation de la géometrie moléculaire dérivée de l'étude aux rayons-X, comparativement au cas où la géometrie employée était calculée à partir des champs de force. La barrière de rotation autour du lien aryle–oxime est estimée à 5.8 kcal/mol.

Introduction

A recent publication from one of these laboratories (1) reported calculations of $^{13}C—^{15}N$ nmr coupling constants for aromatic oximes. Input for the coupling constant program were geometries as calculated from a force-field approach. In general, the agreement between observed and calculated couplings was rather poor, and therefore more accurate structural information was deemed desirable. Accordingly, we have obtained the X-ray crystal structure of *E*-1-(2,4,6-trimethylphenyl)ethanone oxime **1**, a compound for which the dihedral angle Φ between the plane of the aromatic ring and the oxime function is of particular interest.

1

The X-ray derived geometry, when used as input for the coupling constant program, results in markedly improved agreement between the experimental and calculated $^{13}C—^{15}N$ couplings. Also some conclusions, not previously available, regarding the magnitude of the rotational barrier about the aryl–oxime bond can be drawn.

Experimental

The title compound was prepared as described before (1) and crystallized from *n*-hexane to give colorless prisms, mp 98–99°C. Precession photographs indicated monoclinic symmetry and the following systematic absences: *h0l* for odd *h* and *0k0* for odd *k*. The space group was thus uniquely determined to be $P2_1/a$. A crystal fragment measuring 0.25 × 0.25 × 0.30 mm was mounted along the unique (*b*) axis on a card-controlled Picker four-circle diffractometer and the following crystal data were obtained.

$C_{11}H_{15}NO$ mw = 177.24
Monoclinic, a = 15.516(4), b = 8.702(2), c = 7.852(2) Å, β = 94.04(2)°; V = 1057.54 Å^3, D_m = 1.107 g cm^{-3}, Z = 4, D_c = 1.113 g cm^{-3} (21°C; CuKα$_1$, λ = 1.54051 Å, CuKα$_2$, λ = 1.54433 Å), F(000) = 384, μ(CuKα) = 5.3 cm^{-1}.

The moving-crystal – moving-counter method (θ–2θ scan) was used to measure the intensity data. Monochromatization was achieved by the use of a nickel filter and a pulse height analyzer. Two standard reflections were monitored at regular intervals; their intensities decreased by 15% during the data collection. A net count of 80 or 8% of the background,

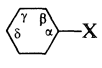
[a]All parameters were multiplied by 10^3.

whichever was higher, was determined as threshold intensity below which reflections were considered unobserved. There were 1796 unique reflections accessible to the diffractometer ($2\theta \leq 130°$) of which 1522 (84%) had intensities above threshold values. The intensities were corrected for Lorentz and polarization factors; absorption corrections were considered unnecessary in view of the low value of μ.

The structure was determined by direct methods and the atomic parameters were refined by block-diagonal least-squares. All scattering factors were taken from the International tables for X-ray crystallography (2). The hydrogen atoms were located on difference Fourier maps and their parameters were refined isotropically. Throughout the refinement the function $\sum w(|F_o| - |F_c|)^2$ was minimized and the following weighting scheme was used during the final stages: $w = w_1w_2$, where $w_1 = 1$ for $|F_o| \leq 8.0$, $w_1 = 8.0/|F_o|$ for $|F_o| > 8.0$; $w_2 = \sin^2\theta/0.4$ for $\sin^2\theta < 0.4$, $w_2 = 1$ for $\sin^2\theta \geq 0.4$. Three strong, low-order reflections suffered severely from extinction effects and they were given zero weights. After the final cycle the average parameter shift equalled 0.05σ and the largest one 0.61σ. The conventional residual index R ($\sum|\Delta F|/\sum|F_o|$) is 0.049 and the weighted index R' ($\sum w\Delta F^2/\sum wF_o^2$) is 0.058 for 1545 reflections, including 26 unobserved ones for which $|F_o| < |F_c|$. A final difference Fourier map was featureless.

The final coordinates and temperature parameters, as well as their estimated standard deviations, are listed in Table 1. Table 2 lists the observed and calculated structure factors.[4] Bond lengths and bond angles are shown in Fig. 1.



[4]Table 2 may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussion

(*a*) *X-ray Results*

A stereoscopic view of the molecule is shown in Fig. 2. Contrary to our previous estimate (1), the dihedral angle between the aromatic ring and the oxime plane is 70.8°. The ring itself is almost completely planar (Table 3), but its substituents are significantly displaced from the mean plane.

Bond lengths and angles in the mesityl moiety show excellent agreement with the expected C_{2v} symmetry, the substituents having distorted the original D_{6h} symmetry of the benzene ring. The angular distortions in benzene rings caused by various substituents have been studied extensively by Domenicano and co-workers (3–6) and by Norrestam and Schepper (7–9). These distortions affect the angles $\alpha, \beta, \gamma, \delta$, and they depend, in most cases, on the electronegativity of the substituent X.

A least-squares refinement of data obtained from five accurately determined crystal structures yielded the following values for the methyl substituent (7): $\Delta\alpha = -1.9(1)$, $\Delta\beta = 1.0(1)$, $\Delta\gamma = 0.3(1)$, $\Delta\delta = -0.7(1)°$. These values are in very good

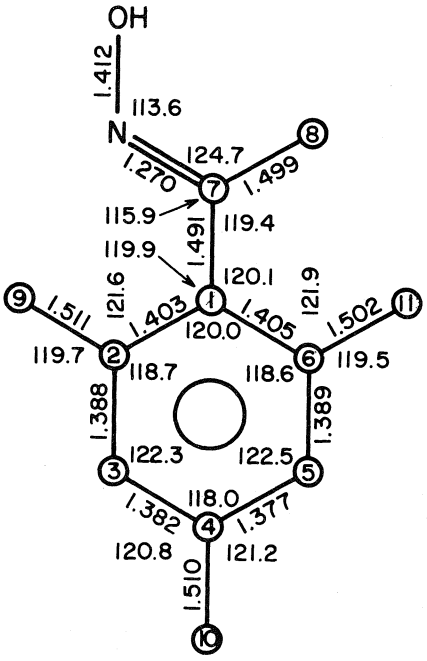

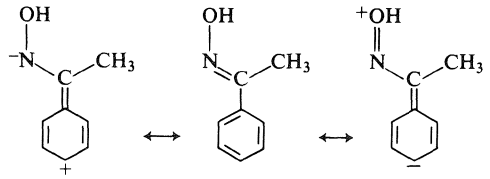

FIG. 1. Bond lengths (Å) and bond angles (deg); their esd are 0.002–0.003 Å and 0.14–0.21°, respectively.

agreement with those derived by Domenicano and Murray-Rust (6). Since the deformations have been shown to be additive (7), one can calculate that in a mesityl group the deviations from 120° would be ±1.3°, with smaller angles at the substituted and larger angles at the unsubstituted ring atoms. Consequently, the angles which we found in the present structure analysis enable us to derive the following distortions attributable to the oxime substituent: $\Delta\alpha = -1.3$, $\Delta\beta = 0$, $\Delta\gamma = 1.1$, $\Delta\delta = -0.7°$.

In the case of $-NO_2$ and —COOH substituents different parameters were found, depending on whether these groups were roughly coplanar with the benzene ring or highly twisted and thus unable to withdraw electrons from the ring (9). Therefore, in considering whether and how the deformation parameters which we obtained for the oxime group would change if that group was coplanar, we must determine whether this group donates or withdraws electrons from the ring. Although one can envisage three general types of resonance forms for acetophenone oxime, it is unlikely that the charged forms contribute much to the ground state. This

view is supported by ^{13}C nmr chemical shift evidence. In *E*-acetophenone oxime the *para*-carbon chemical shift is essentially identical to that of benzene itself (10). This indicates that, in the case of a nearly planar compound, there is no net electron withdrawal or release by the oxime function bonded to the benzene ring. Consequently, the distortion parameters for the oxime group are not likely to be affected by the dihedral angle between that group and the aromatic ring.

A methyl substituent also causes changes of the bond lengths in the benzene ring (3). However, the symmetrical substitution by the three methyl groups in our structure cancels out these changes. On the other hand, the inductive effect of the oxime group causes a polarization of the ring electrons. As a result, the aromatic bonds are longest near this substituent, C(1)—C(2) and C(1)—C(6), and shortest on the opposite side of the ring, C(3)—C(4) and C(4)—C(5). The absence of π electrons in the C(1)—C(7) bond accounts for the fact that this bond is longer in our structure than in any other aromatic oxime. Furthermore, while there is no interaction between N and the C(9) methyl group, one of the hydrogens attached to C(8) makes short contacts with N (2.58 Å) and with O (2.31 Å). This may explain the unusually low value of the N=C(7)—C(1) angle which is 8.8° smaller than the N=C(7)—C(8) angle. The C=N—O angles in oximes have been observed to be as small as 108.4° (11) and as large as 125.2° (12), therefore our value of 113.6° is not unusual.

There is an intermolecular hydrogen bond formed by a donation of the hydroxyl proton to the nitrogen atom of the molecule related by a center of symmetry. The geometry of this hydrogen bond is as follows: O···N 2.813(2), H···N 1.98(3), H···N_{corr}

1.89 Å (9), O—H···N 156, H—O···N 17°. Apart from this there are no intermolecular distances shorter than van der Waals contacts.

(b) Rotational Barrier Problem

No experimental measurement of the rotational barrier about the aryl–oxime bond is presently available. Our attempts to "freeze out" this rotation on the nmr time scale to −100°C in both ^1H and ^{13}C spectra were unsuccessful. Input for the GEMO (14) program requires some estimate of this barrier, which essentially represents the conjugation energy between the aromatic ring and the oxime group. Using ketone results as an analogy (15), we estimated this barrier at 9.0 kcal/mol for **1**, and found the calculated dihedral angle to be 35.5° (1) with standard geometries as input (16). This angle is considerably lower than that found in the X-ray crystal structure, which suggests that our estimate of the rotational barrier may have been too high. A lower estimate of the conjugation energy between the oxime group and the aromatic ring would permit more facile deformation of the dihedral angle toward 90°, since it is known that the conjugation energy for two unsaturated networks varies in general as the square of the cosine of the dihedral angle between the networks (17).

In order to determine the dependence of the calculated dihedral angle on the barrier height for **1**, some further calculations were performed using GEMO. Input for GEMO in this approach was the X-ray derived bond lengths and angles, with only the dihedral angle Φ not being specified. The program then calculated the dihedral angle Φ for a series of barriers ranging from 0.0 to 9.0 kcal/mol. The results are presented in Fig. 3 in graphical form.

Interestingly, for a dihedral angle similar to that found in the X-ray analysis (i.e. 70°), the rotational barrier is about 5.8 kcal/mol. This low value is certainly consistent with our inability to freeze out the rotational process on the nmr time scale at −100°C. A very crude estimate of the barrier can also be obtained from electronegativity considerations. One might expect that the rotational barrier for an oxime function bonded to a benzene ring should lie in the range between 9.0 kcal/mol (observed for acetophenone) (15) and that calculated for styrene of 2.0 kcal/mol (18). Such indeed appears to be the case for **1**, although strict comparison of compounds is not valid due to the presence of the *ortho* methyl substituents in **1**.

(c) Coupling Constants

The Fermi contact contributions to the $^{13}C—^{15}N$ couplings, as calculated via the INDO MO approach (19), are presented in Table 4. Values obtained previously using standard geometries as input are included in parentheses for comparison. In three cases out of four, there is markedly better agreement between observed and calculated values using the X-ray geometry as input. For the other case, of geminal coupling to the C position, only slightly poorer agreement is found using the revised geometries.

The only instance for which sign determinations

[a]This work.
[b]Parenthesized values are results of previous calculations (1).

are available for these couplings is for the system shown below,

$^2J_{N—C—CH_3} = +1.0$ Hz

where the sign of $^2J_{N—C—CH_3}$ was found to be positive (20), and the magnitude is small, i.e. 1.0 Hz. Interestingly for **1**, the calculated $^2J_{N—C—CH_3}$ is +1.1 Hz, while the observed value is also small, being less than 0.6 Hz.

The reasonably good agreement between calculated and observed $^{13}C—^{15}N$ couplings using this approach suggests an important contribution from the Fermi contact mechanism in one, two, and three bond couplings involving ^{13}C and ^{15}N.

COMMUNICATION

Long-range phosphorus hyperfine coupling in a persistent nitroxide radical

P. LIVANT[1]

Department of Chemistry, Auburn University, Auburn, AL 36830, U.S.A.

AND

R. L. DUDLEY

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 12, 1979

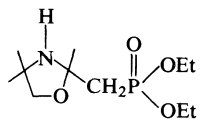
P. LIVANT and R. L. DUDLEY. Can. J. Chem. **58**, 197 (1980).

An unusually large long-range hyperfine coupling to γ-phosphorus has been observed in nitroxide **2**. The magnitude of the coupling is ascribed to the rigidity of the ring system and the consequent importance of conformations like **7**. The radical forms upon lengthy exposure of **1** to air. It may also be prepared by standard methods, and is stable over a period of months at 0°C. Transient and as yet unidentified radicals are observed during the oxidation of **1** to **2** with aryl peracids.

P. LIVANT et R. L. DUDLEY. Can. J. Chem. **58**, 197 (1980).

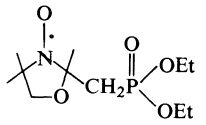
On a observé dans le nitroxyde **2** un grand couplage hyperfin peu usuel à longue distance avec le phosphore en position γ. On a attribué l'importance de ce couplage à la rigidité du système cyclique et à l'importance résultante de la conformation du composé **7**. Le radical se forme après une longue exposition du produit **1** à l'air. On peut également le préparer par des méthodes classiques et il est stable pendant plusieurs mois à 0°C. On observe des radicaux transients (non encore identifiés) lors de l'oxydation du composé **1** par les peracides acycliques qui conduit au composé **2**.

[Traduit par le journal]



A number of studies have reported the spectra of phosphorus-containing nitroxides. The magnitude of the phosphorus hyperfine splitting constant (P-hfsc) was found to vary considerably as a function of the position of the phosphorus atom with respect to nitroxyl function, viz. α-position (—N(—O·)—P), 1.73–13.2 G(1–7); β-position (—N(—O·)—C—P), 0.0–41.8 G for acyclic cases (6–11), 29.6–54.7 G for cyclic cases (12); γ-position (—N(—O·)—C—C—P), 0.0–1.75 G (8).[2]

Phosphorus-containing iminoxyl radicals (13, 14) and aci-anions (8, 9) exhibit similar magnitudes of P-hfsc's as a function of position of phosphorus relative to the radical center.



Though not stated explicitly, these nitroxides appear to be relatively short lived. Rassat and coworkers (4) have described a nitroxide that should be relatively persistent, but because of low yields in the preparation of this nitroxide, isolation of the pure material was not possible.

We would like to report the synthesis of diethyl 2,4,4-trimethyl-1,3-oxazolidin-2-ylmethylphosphonate *N*-oxyl. **2**. To our knowledge, this persistent radical shows the largest γ-P-hfsc yet reported for an aliphatic nitroxide.

Oxazolidine **1** was prepared from diethyl-β-

1

2

keto-propylphosphonate and 2-amino-2-methyl-1-propanol by the method of Keana *et al.* (15). This colorless liquid gave a satisfactory elemental analysis and nmr for the structure assigned.[3]

After three months exposure to air, compound **1** turned pale yellow. A benzene solution of the yellow material gave a six-line esr spectrum which is ascribed to **2**.[4] The splitting pattern consists of a triplet of doublets, with a N-hfsc of 14.06 G, typical for nitroxides. The doublet splitting of 1.81 G is consistent with the splitting for a γ-phosphorus. In more polar solvents **2** gave additional splitting due to three γ-hydrogens. These probably arise from one of the methyl groups on the oxazolidine ring.

[1]Author to whom correspondence should be addressed.

[2]Although further examples of coupling to remote phosphorus have been reported (K. Torssell. Tetrahedron, **33**, 2287 (1977)), these involve aromatic nitroxides and are therefore not directly comparable to the aliphatic systems under discussion here.

[3]For **1**: *Anal.* calcd.: C 49.07, H 10.40, N 5.20; found: C 49.47, H 10.24, N 5.12. P- and H-nmr agree with previously published data (P. Livant and M. Cocivera. J. Org. Chem. **43**, 3011 (1978)).

[4]Electron spin resonance spectra were obtained on a Varian E 104 esr spectrometer.

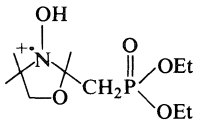
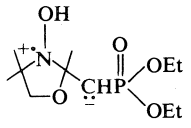
TABLE 1. Electron spin resonance parameters for **2**[a]



Solvent	a^N	a_γ^P	a_γ^H
C_6H_6	14.06	1.81	—
CH_2Cl_2	14.96	1.87	0.39(3H)
H_2O or D_2O	15.87	3.22	0.39(3H)

[a]In gauss.

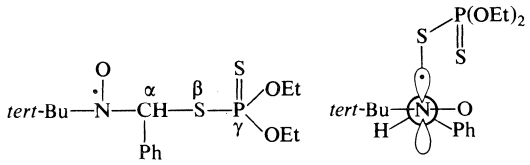


The esr findings are summarized in Table 1. The increase in the nitrogen and γ-phosphorus splittings in polar solvents is due to a solvent polarity effect (16, 17).

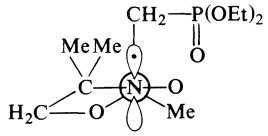
Conceivably, the doublet splitting in the esr spectrum of **2** might have been assigned to a H-hfsc in the protonated nitroxide **3**, or the zwitterionic radical **4** (18). This possibility was ruled out since both the hydroxyl proton and nitrogen hyperfine splitting should be significantly larger in such a radical (21). Either protonated radical should undergo deuterium exchange in D_2O, but identical spectra were obtained in both H_2O and D_2O solvent.

Why is the γ-P-hfsc in **2** so large? The only reported nitroxide with γ-P-hfsc nearly as large as that of **2** is **5** (γ-P-hfsc = 1.75 G). Radicals similar to **5**, however, lacking the α-phenyl substituent, have much lower γ-P-hfsc's (8). In **5**, rotation about the N—C_α bond is probably somewhat hindered, due to the bulky *tert*-butyl and phenyl groups, with the result that phosphorus spends more time in conformations such as **6**. The analogous rotation about the N—C_α bond in **2** is eliminated by the incorporation of the bond into the oxazolidine ring. Thus we have for **2** a large population of conformation **7**, resulting in a large γ-P-hfsc.

3



4



The air oxidation of aliphatic secondary amines to persistent nitroxides appears to be an uncommon reaction. The air oxidation of diaryl amines to nitroxides has been observed more widely (19).

In addition to air oxidation, **1** may be converted to **2** by oxidation with Na_2WO_4/H_2O_2 (20) followed by chromatography on silica gel with chloroform eluant. The orange oil obtained in this way gives an esr spectrum identical to that assigned to **2**, and is stable for months at 0°C.

Oxidation of **1** with either *m*-chloroperbenzoic acid or *m*-nitroperbenzoic acid in CH_2Cl_2 also gave **2**, and in addition two new radicals were observed

5 **6**

7

during the oxidation. For the first: $a^N = 15.87$ G and $a_\beta^H = 12.77$ G (3H). These coupling constants are similar to those of *N*-*t*-butyl-*N*-methyl nitroxide (21) and, therefore, the radical is probably of similar structure. For the second: $a^N = 15.48$ G, $a_\beta^H = 21.54$ G, and $a_\gamma^H = 0.39$ G (3H). The doublet splitting of 21.54 G is assigned to a hydrogen coupling since it is too large for an α-phosphorus splitting and too small for a cyclic β-phosphorus splitting. Since $a^N < a_\beta^H$, this radical is probably a cyclic nitroxide (22). The two radicals observed in addition to **2** in the aryl peracid oxidations are short-lived; at the end of the reaction only **2** ($a^N = 14.96$ G, $a_\gamma^P = 1.87$ G, $a_\gamma^H = 0.39$ G (3H)) is in evidence.

Akhrem *et al.* (23) found no esr signal during or after the reaction of perbenzoic or peracetic acid with piperidine, and proposed a non-radical route. The identity of the transient radicals observed in the present system and the mechanism operative here are under investigation.

Acknowledgments

On Ruhemann's Purple

DONALD C. WIGFIELD, GERALD W. BUCHANAN, AND STEPHEN M. CROTEAU
Department of Chemistry, E.W.R. Steacie Laboratories, Carleton University, Ottawa, Ont., Canada K1S 5B7

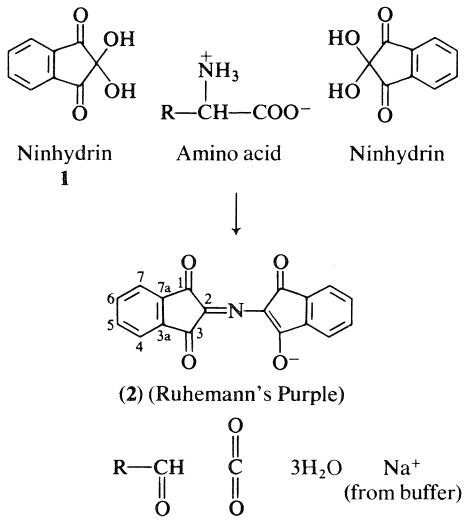
Received May 24, 1979

DONALD C. WIGFIELD, GERALD W. BUCHANAN, and STEPHEN M. CROTEAU. Can. J. Chem. **58**, 201 (1980).

The ^1H nmr spectrum previously reported for Ruhemann's Purple is shown to be inconsistent with the accepted structure of this material. The discrepancy with the reported ^1H nmr spectrum is shown to be due to the presence of a major impurity, identified as hydrindantin. Spectra (^1H nmr, ^{13}C nmr, ir, uv–visible) of Ruhemann's Purple, its protonated analogue DYDA, and other ninhydrin relatives are reported, and structural conclusions are based on these spectral data.

DONALD C. WIGFIELD, GERALD W. BUCHANAN et STEPHEN M. CROTEAU. Can. J. Chem. **58**, 201 (1980).

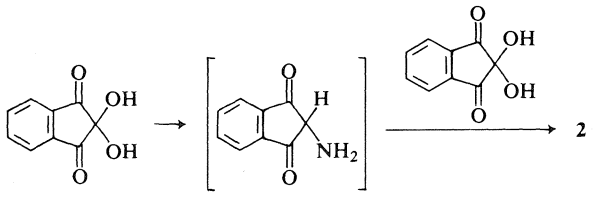
On montre que le spectre rmn du ^1H attribué antérieurement au pourpre de Ruhemann ne correspond pas à la structure proposée pour ce produit. On démontre que la différence par rapport au spectre rmn du ^1H est due à la présence de l'hydrindantine identifiée comme impureté principale. On a rapporté les spectres (rmn du ^1H et du ^{13}C, ir, uv–visible) du pourpre de Ruhemann, de ses analogues protonés DYDA et d'autres ninhydrines apparentées et les conclusions structurales décrites sont basées sur ces données spectrales.



[Traduit par le journal]

The reaction of amino acids with ninhydrin is one that has been known for a long time (1), and which for thirty years has been used for the quantitative determination of amino acids (2). The reaction is shown in Scheme 1. Various inconsistencies in the literature, and, in particular, the reported ^1H nmr spectrum for Ruhemann's Purple (3), have led to our own investigations in this area.

Results and Discussion



Evaluation of Previous Data

Extensive effort has been expended to elucidate the mechanism of formation of Ruhemann's Purple (4–8). Despite this, a recent review has pointed out that major texts are still at variance with each other regarding this mechanism of formation (9). In contrast to this concern with mechanism, the actual structure of Ruhemann's Purple appears to have received unquestioned acceptance. Ruhemann, in his extensive studies in this area in the early 1900's, discovered ninhydrin (**1**) (1), and uncovered the fact that it gave a purple colour with skin (1), and with amino acids (10). Based on analogy with the structure for purpuric acid (11, 12) (which had six years earlier been revised from Beilstein's 1858 suggestion involving an aziridine ring (13)), Ruhemann in 1911 proposed the structure **2** for the purple substance formed from ninhydrin (14). Ruhemann also converted ninhydrin to the unstable 1,3-diketohydrindamine (**3**), (15) from which he

SCHEME 1. Reaction of ninhydrin with amino acids to yield Ruhemann's Purple.

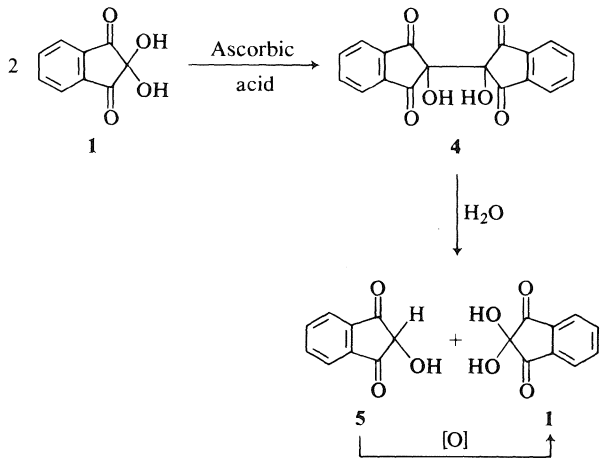
SCHEME 2. Ruhemann's synthetic route to **2**.

subsequently also produced a purple substance by reaction with ninhydrin (14) (see Scheme 2). However, there was apparently no experimental evidence that this purple substance and the purple material produced by the ninhydrin – amino acid reaction were indeed one and the same thing. Nearly forty years later, elemental analysis confirmed the empirical formula corresponding to that of **2** (2), and later still the ir spectrum revealed a peak at 1670 cm^{-1} (16), consistent with the delocalized carbonyl system. Because of volatility problems, no mass spectrum has been reported.



The proton nmr spectrum of Ruhemann's Purple in dimethyl sulfoxide-d_6 has been reported to consist of "two peaks of equal intensity which originate in the aromatic protons of the two nonequivalent indanedione rings" (3). Despite the fact that, in the structure **2** as written, the two benzene rings are different, this difference is completely eliminated by resonance delocalization of the negative charge. An alternative explanation of two peaks of equal intensity would be differentiation of the protons *ortho* and *meta* to the five-membered ring (i.e., C-4H vs. C-5H, etc.), but all ninhydrin derivatives appear to have accidental chemical shift equivalence of these two sets of protons (see Experimental). Because of this unsatisfactory situation regarding the interpretation of the reported nmr spectrum, we were led to consider that either (*a*) the spectrum reported was not that of Ruhemann's Purple, or (*b*) the structure long accepted for Ruhemann's Purple was incorrect.

Spectra of Ruhemann's Purple

Multiple reactions of ninhydrin with glycine under standard conditions (2) were performed, the purple precipitates collected, and the ^1H nmr spectra recorded. In contrast to the report of Friedman (3), that the spectrum consists of two peaks (δ 7.65 and 8.00) of equal intensity, we observe the following. (*1*) Spectra are not reproducible from one reaction to another. Some spectra have the two peaks (δ 7.65 and 8.00) of equal intensity, others have the δ 7.65 peak considerably more intense; in some spectra the peak at δ 8.00 is entirely absent. (*2*) There is an additional peak at δ 6.5. This peak has an intensity 25% that of the δ 8.00 peak. (*3*) The peaks at δ 6.5 and 8.00 slowly decrease with time and are replaced by peaks at δ 8.07 and 7.5, respectively. (*4*) The peaks at δ 6.5 and 7.5 disappear upon addition of D_2O.

These observations are most easily rationalized in the following way. Ruhemann's Purple gives rise to the single peak at δ 7.65. As previously discussed, a single-peak spectrum is consistent with structure **2**. The other two peaks (δ 6.5 and 8.00) are due to hydrindantin, **4**, a compound that has figured prominently in discussions of the mechanism of the ninhydrin reaction (9). Authentic samples of hydrindantin, **4**, prepared by reduction of ninhydrin with ascorbic acid (17), give these same two peaks. The decay of these peaks (δ 8.00 and 6.5) and their replacement by peaks at δ 8.07 and 7.5 is consistent with the known chemistry of hydrindantin (7) – retroaldol cleavage to give **5** and **1** (see Scheme 3), followed by rapid air oxidation (15) of hydroxydiketohydrindene **5** to ninhydrin, **1**. The final product is therefore ninhydrin, an authentic sample of which gives the same two spectral peaks at δ 8.07 and 7.5.

The ^{13}C nmr spectrum of Ruhemann's Purple should lead to a simple 5-line spectrum if structure **2** is correct. This is, in fact, observed, although one of the peaks (138.4 ppm) is extremely weak.[1] This signal was eventually detected by running the spectrum in non-deuterated dimethyl sulfoxide solvent (82 000 scans). Of the five peaks, two, 120.7 and 132.8 ppm, are immediately assignable to the aromatic C—H groups *ortho* and *meta* to the ring

SCHEME 3. Deliberate reduction of ninhydrin to hydrindantin and its spontaneous conversion back to ninhydrin.

[1]In connection with this problem, we also prepared indantrione (18), (dehydrated ninhydrin). This compound also exhibits very weak carbonyl ^{13}C signals.

junction, respectively, on the basis of their high intensity, their multiplicity in off-resonance decoupled spectra, and the analogy to other, rigorously assigned, ring structures (19). A third peak (134.0 ppm) is assignable to C-2 (C—N) of the indanedione ring. The final two peaks (138.4 and 139.9 ppm) correspond to the ring junction carbon and the carbonyl carbons, the latter occurring at higher field than usual due to the resonance delocalization of the negative charge. A firm distinction between the two does not seem possible without further experimentation. The intensity of the peak at 138.4 ppm is very dependent on experimental conditions, being more intense than the 139.9 ppm peak for spectra taken in non-deuterated dimethyl sulfoxide, and essentially non-detectable for spectra taken in DMSO-d_6. On this basis, it seems probable that the peak at 138.4 ppm is due to the carbonyl carbons, and that at 139.9 ppm is due to the ring junction carbons. Either position is acceptably close to chemical shifts for the ring junction carbons in the other ninhydrin derivatives. The low intensity of the C=O resonance of **2** recorded in DMSO-d_6 solution is probably due to the absence of spatially proximate H's available for relaxation of this carbon, since there are no nearby H's in the same molecule and none available in the solvent. This problem is overcome when a protonated solvent is used, since intermolecular dipole – dipole relaxation of the C=O carbon can now occur via the solvent protons giving rise to a positive nuclear Overhauser effect and a shortened T_1 for the C=O resonance. Both these factors result in increased peak intensity in the Fourier transform ^{13}C spectrum (20). Although it is difficult quantitatively to predict the chemical shift of the C—O, due to lack of appropriate model compounds, one can suggest that the shift to higher field, relative to normal carbonyl resonances, results from averaging of keto and enol environments.

In summary, the spectral evidence on Ruhemann's Purple is consistent with the long-accepted structure **2**. The previously reported ^1H nmr spectrum (3) appears to have been obtained on a sample containing an equal amount of hydrindantin impurity, giving rise to the spurious peak at δ 8.00.

Spectra of DYDA

In addition to Ruhemann's Purple, **2**, spectra were also obtained on its unstable parent acid (diketohydrindylidenediketohydrindamine, DYDA), that arises from protonation of **2**, by subjecting **2** to mildly acidic solution. These spectra are recorded in the Experimental and we comment here only on the significant points.

SCHEME 4. Possible structures for DYDA.

Since the mass spectrum of Ruhemann's Purple is unavailable, the mass spectrum of DYDA is especially valuable. As expected, this shows peaks at *m/e* 303 (molecular ion), 275, 247 (successive losses of CO) and also *m/e* 132, 104, 76 (successive loss of CO from *m/e* 132) which also occur in the mass spectrum of ninhydrin. Metastable ions corresponding to all four steps involving loss of CO mentioned above were apparent, occurring at *m/e* 55.6 (104 → 76), 82.0 (132 → 104), 222.1 (275 → 247), and 250.0 (303 → 275). These data are clearly consistent with a species corresponding to a protonated **2**.

Three possible structures **6**, **7**, and **8**,[2] for DYDA are indicated in Scheme 4, depending on whether there is C, O, or N protonation, respectively. The ^{13}C nmr spectrum consists only of 5 signals, showing equivalence about the central nitrogen; this can be accommodated in structures **6** and **7** by rapid equilibration between equivalent structures, and is demanded by resonance in structure **8**. The δ_c value of the carbonyl carbons, 181.7, is consistent only with the tetracarbonyl structure **6**. For structures **7** and **8**, the 25% enol content for any one carbon would be expected to provide a substantial upfield shift, as in the case of Ruhemann's Purple itself (138.4). As a model for structure **6** it is noteworthy that the δ_c shift of the corresponding carbons of the structurally unambiguous indantrione (183.4) is very similar to those of DYDA.

There is further evidence against structures **7** and

[2]A referee urged us to consider this structure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

8. No evidence of an O—H or a $\overset{+}{N}$—H stretch in the ir spectrum is evident and there is not a strong M − 1 peak in the mass spectrum. Furthermore, in the case of **8**, the carbonyl absorption frequency would be expected to be low, due to the delocalized system (1655 cm^{-1} in the case of Ruhemann's Purple); in fact the absorption is at 1680 cm^{-1}, consistent with the unsaturated carbonyl system present in **6**. Finally, DYDA is soluble in organic solvents and does not exhibit zwitterionic behaviour expected of **8**.

In summary, the spectral data appear to be substantially in favour of the tetracarbonyl structure **6**. Initially we felt that the non-aromatic proton in the ^1H nmr spectrum (δ 5.0) was at low field for the C—H. However, the corresponding shift in a β-diketone is about δ 3.6, to which must be added as much as 1.7 ppm for the carbon–nitrogen substitution.[3] Wherever the proton is attached, it is highly acidic, and possibly hydrogen-bonded, and thus the variation in chemical shift is unremarkable.

Mechanistic Aspects

Two mechanistic aspects should briefly be mentioned.

The interconversion of hydroxydiketohydrindene (**5**) and the corresponding amine (**3**) figures prominently in various mechanistic proposals, particularly in relation to hydrindantin formation. (See ref. 9 and references therein.) It does not seem to have been mentioned previously that such a step is rarely encountered in organic chemistry. If and how this step occurs is an intriguing question.

A second point regarding mechanism of Ruhemann's Purple formation is a definition of the reaction itself. If current mechanistic thought is correct (9), it follows that the formation of a molecule of hydrindantin is tied to the formation of one *less* molecule of Ruhemann's Purple. Thus one would expect the use of Ruhemann's Purple as a quantitative measure of amino acid content to be highly irreproducible, paralleling the irreproducible quantities of hydrindantin we have observed. Biochemically, this has, in fact, been recognized to be the case for a long time, and is circumvented, in automatic amino acid analyzers, by addition of excess stannous chloride, as reducing agent (21). Mechanistic studies on the reaction, however, have not employed this experimental modification, and we wish to emphasize the unfortunate situation that conclusions on mechanism are, for the most part, based on experimental conditions significantly different from those used in actual biochemical practice.

[3]We are very grateful to another referee for pointing this out.

Experimental

General

Infrared spectra were recorded on a Perkin-Elmer 237B grating infrared spectrophotometer using a polystyrene film as a reference. Ultraviolet and visible spectra were recorded on a Beckman Model 25 spectrophotometer. Nuclear magnetic resonance spectra were obtained, using dimethyl sulfoxide-d_6 as solvent, unless otherwise noted, and TMS as internal standard, on a Varian Model T-60 instrument for proton spectra and on a Varian Model XL-100-12 instrument equipped with a Nicolet Technology Corporation Fourier transform data system for ^{13}C spectra. Sweep widths were routinely 6000 Hz, with 8192 data points being employed. Pulse angles were normally 45° and a pulse delay of 2 s was used. The number of spectral accumulations varied from 35 000 to 80 000. Mass spectra were obtained on an AEI MS-12 mass spectrometer at Trent University, Peterborough, Ont. Melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected.

Ninhydrin (1)

This compound, obtained from Bio-Rad Laboratories, was recrystallized from water before use. Glycine, reagent grade (Fisher Scientific Co.), was used without further purification.

Ruhemann's Purple (2)

The reaction between glycine (75 mg, 1.0 mmol) and ninhydrin (700 mg, 3.93 mmol) was conducted in citrate buffer under the conditions of Moore and Stein (2). The product (150 to 290 mg), obtained on a medium mesh sintered glass funnel and dried *in vacuo* over sulfuric acid, was a brownish solid having superficial metallic lustre, λ_{max}(EtOH): 253 (ε, 44 000), 409 (ε, 21 400), and 575 (ε, 19 000) nm; ν_{max}(KBr): 1655 (delocalized carbonyl) cm^{-1}; ^1H nmr δ: 7.65 (s); ^{13}C nmr (in non-deuterated DMSO) δ: 120.7 (C-4, C-7), 132.8 (C-5, C-6), 134.0 (C-2), 138.4, 139.9 (C-1, C-3, and C-3a, C-7a).

Diketohydrindylidenediketohydrindamine (DYDA) (6)

Ruhemann's Purple (100 mg) in water (40 mL) was acidified with 4–5 drops of concentrated hydrochloric acid. The reddish precipitate was collected on a medium mesh sintered glass funnel and dried *in vacuo* over sulfuric acid, $\lambda_{max}(CHCl_3)$: 485 (ε, 16 000) nm; $\nu_{max}(CHCl_3)$: 1680 (C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.0 (1H, s, position concentration dependent, non-aromatic hydrogen), and 7.9 (8H, m, aromatic H's); ^{13}C nmr ($CDCl_3$) δ: 124.0 (C-4, C-7), 136.1 (C-5, C-6), 137.4 (C-2), 140.7 (C-3a, C-7a), and 181.7 (C-1, C-3); *m/e*: 303 (M^+), 275, 247, 132, 104, 76, with metastable transitions at 250.0 (303 → 275), 222.1 (275 → 247), 82.0 (132 → 104), and 55.6 (104 → 76).

Hydrindantin (4)

Ninhydrin (4.00 g, 2.24×10^{-2} mol) was reduced by ascorbic acid (2.00 g, 1.14×10^{-2} mol) in 0.5 *N* acetic acid solution following the conditions of Connell *et al.* (17). The product was collected on a coarse mesh sintered glass funnel, washed with water, and dried *in vacuo* over sulfuric acid yielding 3.08 g (1.91×10^{-2} mol, 85%) of crystalline material, λ_{max}(EtOH): 229 (ε, 80 000) and 246 (ε, 20 000) nm; ^1H nmr δ: 6.5 (2H, s, OH), and 8.00 (8H, s, aromatic H); ^{13}C nmr δ: 79.4 (C-2), 122.3 (C-4, C-7), 136.1 (C-5, C-6), 141.2 (C-3a, C-7a), and 196.3 (C-1, C-3).

Indantrione

Ninhydrin was dehydrated by overnight exposure to 125°C in a drying oven to produce the magenta-coloured crystals of indantrione (which rapidly reverted to ninhydrin upon exposure to moist air), mp 255–257°C (lit. (18) mp 254–256°C), ^1H nmr δ: 8.10 (s); ^{13}C nmr δ: 123.8 (C-4, C-7), 136.6 (C-5, C-6), 140.1 (C-3a, C-7a), 183.4 (C-1, C-3), and 187.0 (C-2).

The reaction of *cis*-$Ru(CO)_4(SiCl_3)_2$ with bidentate ligands

R. K. POMEROY AND K. S. WIJESEKERA
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received September 7, 1979

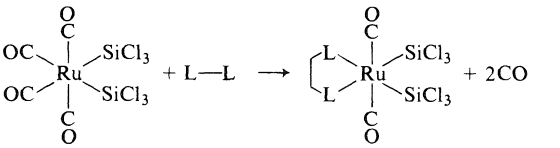
R. K. POMEROY and K. S. WIJESEKERA. Can. J. Chem. **58**, 206 (1980).

The substitution of the equatorial carbonyl groups in *cis*-$Ru(CO)_4(SiCl_3)_2$ by a variety of bidentate ligands (L—L) to give compounds of the type $Ru(L—L)(CO)_2(SiCl_3)_2$ is described. With $Ph_2E(CH_2)_2EPh_2$ (E = P, As) it was also possible to isolate the bridging derivatives, $(Cl_3Si)_2(OC)_3Ru(L—L)Ru(CO)_3(SiCl_3)_2$. The ^{31}P nmr spectra (of the phosphorus compounds) are discussed.

R. K. POMEROY et K. S. WIJESEKERA. Can. J. Chem. **58**, 206 (1980).

On décrit la substitution des groupes carbonyles équatoriaux du $Ru(CO)_4(SiCl_3)_2$ *cis* par une variété de ligands bidendates (L—L) conduisant aux composés de type $Ru(L—L)(CO)_2(SiCl_3)_2$. Avec le $Ph_2E(CH_2)_2EPh_2$ (E = P, As) on peut aussi isoler les dérivés pontés $(Cl_3Si)_2(OC)_3Ru(L—L)Ru(CO)_3(SiCl_3)_2$. On discute des spectres rmn du ^{31}P des composés du phosphore.

[Traduit par le journal]



Introduction

The compound *cis*-$Ru(CO)_4(SiCl_3)_2$ is unusual in metal carbonyl chemistry in that the carbonyl ligands *trans* to the $SiCl_3$ groups undergo facile exchange with ^{13}CO at room temperature (1). The kinetics of the exchange was consistent with the reaction proceeding by a dissociative mechanism. It was expected that this compound would react with donor ligands to give the corresponding equatorially substituted derivatives. A preliminary investigation with monodentate ligands has indicated this to be the case (2). Herein we report the reaction of *cis*-$Ru(CO)_4(SiCl_3)_2$ with a variety of bidentate ligands (L—L) to give compounds of the type $Ru(L—L)(CO)_2(SiCl_3)_2$. In some cases it has also been possible to isolate the bridging derivatives, $(Cl_3Si)_2(OC)_3Ru(L—L)Ru(CO)_3(SiCl_3)_2$.

Results and Discussion

Sulfur Derivatives

The reaction of *cis*-$Ru(CO)_4(SiCl_3)_2$ with the sulfur chelates $CH_3S(CH_2)_2SCH_3$ and $R_2P(S)P(S)R_2$ (R = CH_3, C_2H_5) proceeds smoothly in solution at room temperature to give $Ru(L—L)(CO)_2(SiCl_3)_2$ derivatives (L—L = chelate ligand). These compounds, and the other $Ru(L—L)(CO)_2(SiCl_3)_2$ derivatives reported here, are white, moderately air-stable, crystalline solids which exhibit one absorption in the infrared carbonyl stretching region. The single carbonyl absorption is consistent with a *trans* arrangement of the carbonyl groups. This in turn agrees with the ^{13}CO exchange studies which indicated that only the carbonyl groups *trans* to the $SiCl_3$ ligands are labile (1). The synthesis of these derivatives may therefore be summarized in the following equation:

Although not measured accurately, the rate of substitution (except for dienes) appeared the same as that found for the CO exchange.

Substitution in metal carbonyl derivatives usually occurs *cis* to the non-carbonyl substituent (3). The unusual *trans* substitution which occurs in *cis*-$Ru(CO)_4(SiCl_3)_2$ may be attributed to the strong π-acceptor properties of the $SiCl_3$ group (1).[1]

Phosphorus Derivatives

The compounds $Ru(Ph_2P(CH_2)_nPPh_2)(CO)_2(SiCl_3)_2$ (n = 1, 2) were prepared in a similar manner to the sulfur chelates. However, unlike the sulfur compounds there was infrared evidence for the monodentate intermediates $Ru(L—L)(CO)_3(SiCl_3)_2$. These compounds could not be isolated due to their rapid conversion to $Ru(L—L)(CO)_2(SiCl_3)_2$. The intermediates (not unexpectedly) had identical carbonyl stretching frequencies to the corresponding bridged compounds $(L—L)[Ru(CO)_3(SiCl_3)_2]_2$ (*vide infra*). They were not compounds of this type, however, since the bridged derivatives do not give $Ru(L—L)(CO)_2(SiCl_3)_2$ under the same conditions.

For the case of L—L = $Ph_2P(CH_2)_2PPh_2$ it was verified that the same $Ru(L—L)(CO)_2(SiCl_3)_2$ derivative could be prepared by heating *trans*-$Ru(CO)_4(SiCl_3)_2$ with L—L in solution at 80°C. It has been found previously that *trans*-$Ru(CO)_4(SiCl_3)_2$

isomerizes to the *cis* isomer (to give an equilibrium mixture of the two forms) at 80°C (4). It is also known that the *trans* isomer does not exchange with ^{13}CO under normal conditions (1).

The dinuclear derivatives $(Cl_3Si)_2(OC)_3RuPh_2P(CH_2)_nPPh_2Ru(CO)_3(SiCl_3)_2$ (n = 1, 2) containing the phosphorus ligand in a bridging position were prepared by slowly adding a solution of the ligand dropwise to a solution containing excess *cis*-$Ru(CO)_4(SiCl_3)_2$. The identity of these compounds was established by infrared spectroscopy (which was typical of compounds of the type $RuL(CO)_3(SiCl_3)_2$ (5)), carbon and hydrogen analysis, and by the fact that they exhibit only one ^{31}P nmr resonance. The other reasonable possibility, $Ru(L—L)(CO)_3(SiCl_3)_2$, can be rejected from the analytical data and the fact that such compounds would exhibit two ^{31}P nmr resonances.

It is surprising that the reaction to form the chelate derivative:

$$Ru(L—L)(CO)_3(SiCl_3)_2 \rightarrow Ru(L—L)(CO)_2(SiCl_3)_2$$

does not occur, even though this process is known to be reasonably fast in CH_2Cl_2 solution. The formation of the bridged complex is presumed to involve combination of $Ru(L—L)(CO)_3(SiCl_3)_2$ with the five-coordinate intermediate $Ru(CO)_3(SiCl_3)_2$:

$$Ru(CO)_3(SiCl_3)_2 + (L—L)Ru(CO)_3(SiCl_3)_2 \rightarrow (L—L)[Ru(CO)_3(SiCl_3)_2]_2$$

A second order reaction between $Ru(L—L)(CO)_3(SiCl_3)_2$ and $Ru(CO)_4(SiCl_3)_2$ is thought unlikely since it would involve a seven-coordinate, 20-electron, transition species. It may be that in hexane the intermediate $Ru(L—L)(CO)_3(SiCl_3)_2$ initially precipitates from solution[2] such that its effective concentration is less than that of $Ru(CO)_3(SiCl_3)_2$ which is relatively high due to the large excess of $Ru(CO)_4(SiCl_3)_2$ employed. Under these conditions the formation of the bridged derivative would be the preferred reaction. Some support for this explanation is the observation that the bridged compound could not be prepared in CH_2Cl_2 solution in which the compounds are more soluble.

The ^{31}P nmr spectral data of these and the other phosphorus-containing derivatives are reported in Table 3. It has been observed previously that there is a large downfield shift of the ^{31}P signal on forming a chelate ring (6). This is also observed in the present molecules. From a comparison of the bridged with the chelate derivatives it is possible to say that in these compounds approximately half the downfield shift may be accounted for as due to coordination of the phosphorus to the transition metal and the other half of the shift as due to formation of the chelate ring.

Arsenic Derivatives

The preparation (in excellent yield) of $Ru(C_6H_4[As(CH_3)_2]_2)(CO)_2(SiCl_3)_2$ was similar to the preparation of the sulfur chelate derivatives. There was infrared evidence for the intermediate $Ru(C_6H_4[As(CH_3)_2]_2)(CO)_3(SiCl_3)_2$, but it could not be isolated. However, the reaction at room temperature (in CH_2Cl_2) of $Ph_2As(CH_2)_2AsPh_2$(As—As) with *cis*-$Ru(CO)_4(SiCl_3)_2$ in a 1:1 mole ratio gave approximately a 1:1 mixture of $Ru(As—As)(CO)_2(SiCl_3)_2$ and the bridged derivative $(Cl_3Si)_2(OC)_3Ru(As—As)Ru(CO)_3(SiCl_3)_2$. This mixture remained almost unchanged on stirring for a further four days. The pure mononuclear compound could be obtained at 80°C whereas the pure dinuclear compound could be prepared by reacting the arsine ligand

[2]Compounds such as $Ru(PPh_2Me)(CO)_3(SiCl_3)_2$ are insoluble in hexane (5).

TABLE 2. Analytical and infrared data for (L—L)[$Ru(CO)_3(SiCl_3)_2]_2$ compounds

L—L	%C Calcd.	%C Found	%H Calcd.	%H Found	ν(CO), CH_2Cl_2 soln. (cm^{-1})
$(C_6H_5)_2P(CH_2)_2P(C_6H_5)_2$	29.42	29.90	1.85	1.93	2117 m, 2075 s, 2049 vs
$(C_6H_5)_2PCH_2P(C_6H_5)_2$	28.81	29.13	1.72	2.25	2116 m, 2075 s, 2049 vs
$(C_6H_5)_2As(CH_2)_2As(C_6H_5)_2$	27.56	28.22	1.74	1.68	2117 m, 2072 s, 2049 vs

with a large excess of *cis*-$Ru(CO)_4(SiCl_3)_2$ in solution at room temperature.

Diene Derivatives

The reaction of the dienes, norbornadiene and cyclooctadiene, with *cis*-$Ru(CO)_4(SiCl_3)_2$ to give Ru(diene)$(CO)_2(SiCl_3)_2$ takes up to four days to go to completion even when the diene is used as a solvent. This is considerably longer than the preparation of the other derivatives reported here. There is no evidence for a monosubstituted derivative during the reaction which suggests that it is the initial attack on the presumed intermediate, $Ru(CO)_3(SiCl_3)_2$, which is the rate-determining step. It is probable that there is competition for the intermediate by the diene and the carbon monoxide produced from the reaction. In support of this suggestion is the fact that the reaction proceeds at the normal rate when the carbon monoxide is removed by continuously passing a slow stream of nitrogen over the stirred reaction solution.

Diene could not be displaced from Ru(diene)$(CO)_2(SiCl_3)_2$ by passing carbon monoxide through a solution of the appropriate compound. In contrast cyclooctatetraene (COT) was displaced from Ru(COT)$(CO)_2(SiCl_3)_2$ on treatment (in solution) with carbon monoxide. The much lower yield of the cyclooctatetraene derivative suggests it is less stable than the diene derivatives.

In the solid state the compounds are reasonably air-stable crystals which can be sublimed under vacuum at elevated temperatures. The mass spectra of these molecules exhibit a weak parent ion and a stronger set of peaks due to $[P—Cl]^+$. This behaviour is frequently observed in this type of compound (7). Similar to other molecules reported here the diene derivatives exhibit one strong carbonyl stretch in the infrared spectrum. However, Ru(norbornadiene)$(CO)_2(SiCl_3)_2$ did show (in hexane solution) two additional, very weak absorptions to higher frequency of the main CO stretching peak. These bands remained unchanged on recrystallization and sublimation. It is possible that these minor peaks are due to trace amounts of the isomer having one of the alkene linkages coordinated in the axial position.

TABLE 3. Phosphorus nuclear magnetic resonance data for new complexes

Compound	δ (ppm)	Δ_{cs} (ppm)[a]
$Ru(Ph_2P(CH_2)_2PPh_2)(CO)_2(SiCl_3)_2$	−48.1	−60.95
$Ru(Ph_2PCH_2PPh_2)(CO)_2(SiCl_3)_2$	−48.4	−61.5
$Ph_2P(CH_2)_2PPh_2[Ru(CO)_3(SiCl_3)_2]_2$	−15.3	−28.15
$Ph_2PCH_2PPh_2[Ru(CO)_3(SiCl_3)_2]_2$	−15.4	−28.7
$Ru[(C_2H_5)_2P(S)P(S)(C_2H_5)_2](CO)_2(SiCl_3)_2$[b]	−67.2	−16.3

[a]Δ_{cs} is the coordination chemical shift defined as (δ complex − δ ligand), where δ complex and δ ligand are the chemical shifts of the complexed and free ligand, respectively.
[b]Coordination of the ligand is through sulfur.

Experimental

Unless otherwise stated reactions were carried out under a nitrogen atmosphere. As a further precaution some of the reactions were carried out in a dry box (Vacuum Atmospheres). Solvents were meticulously dried and stored under nitrogen before use. Melting points were measured in sealed capillaries using a Gallenkamp apparatus; they are uncorrected. Infrared spectra were recorded on a Perkin-Elmer 237 spectrometer fitted with an external recorder. The spectra were calibrated using carbon monoxide. Proton nuclear magnetic resonance spectra were obtained on a Varian A56/60 or XL100 spectrometer using $CDCl_3$ as solvent and TMS as internal standard (δ = 0) unless otherwise stated. Phosphorus nmr spectra were obtained on the latter instrument (operating in the Fourier transform mode) using CH_2Cl_2 as solvent and H_3PO_4 (85%) as an external reference (δ = 0, downfield negative). Mass spectra were obtained on a Hitachi/Perkin-Elmer RMU-6E double focusing mass spectrometer using an ionization voltage of 80 eV. Microanalyses were performed by M. K Yang of the microanalytical laboratory of Simon Fraser University. Dodecacarbonyltriruthenium was prepared according to the literature (8). Ligands were commercially available and were used without further purification.

Preparation of cis-*Ru(CO)$_4$(SiCl$_3$)$_2$*

A quartz tube (30 cm × 3 cm, fitted with a Teflon valve) containing $Ru_3(CO)_{12}$ (0.64 g, 1.0 mmol) and Cl_3SiH (3 mL, 30 mmol) in hexane (20 mL) was evacuated and pressurized with carbon monoxide (2 atm). The stirred solution was irradiated for 3 days at a distance of 3 cm by a 200 W mercury arc lamp (contained in a quartz, water-cooled jacket). The colorless solution was then transferred to a Schlenk tube and cooled for 2 h at −78°C. The hexane and excess Cl_3SiH were then removed from the white, crystalline *cis*-$Ru(CO)_4(SiCl_3)_2$ (1.37 g, 95%) which was dried on the vacuum line. The compound at this stage is sufficiently pure for most purposes, however it may be further purified by sublimation at 40°C, 0.02 Torr onto a probe cooled to −78°C.

Preparation of Ru(CH$_3$S(CH$_2$)$_2$SCH$_3$)(CO)$_2$(SiCl$_3$)$_2$ and Related Derivatives

A solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.24 g, 0.5 mmol) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

dithiahexane (0.07 g, 0.6 mmol) in *n*-hexane (15 mL) was stirred at room temperature for 6 h. The solvent was then removed from the white solid which was washed (hexane) and dried under vacuum. The product $Ru(CH_3SCH_2CH_2SCH_3)(CO)_2(SiCl_3)_2$ (0.22 g, 80%) was analytically pure as obtained. Proton nmr δ: 2.60 (CH_2), 2.90 (CH_3) ppm. The corresponding $R_2P(S)P(S)R_2$ (R = CH_3, C_2H_5) derivatives were similarly prepared (85% and 90% yields, respectively). There was no spectroscopic evidence for the monocoordinated intermediate during these reactions.

Preparation of $Ru(Ph_2PCH_2CH_2PPh_2)(CO)_2(SiCl_3)_2$

A solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.273 g, 0.566 mmol) and $Ph_2PCH_2CH_2PPh_2$ (0.225 g, 0.565 mmol) in benzene (15 mL) was stirred overnight at 50°C. Hexane (15 mL) was then added and the solution placed in the refrigerator to complete precipitation. Solvent was removed from the white product which was further washed with *n*-hexane and dried on the vacuum line. The yield of $Ru(Ph_2PCH_2CH_2PPh_2)(CO)_2(SiCl_3)_2$ (0.460 g) was essentially quantitative. The analytical sample was obtained as fine white needles by recrystallization from benzene. The compound $Ru(Ph_2PCH_2PPh_2)(CO)_2(SiCl_3)_2$ was similarly prepared.

It was subsequently found that these reactions could be conveniently carried out at room temperature with reaction times of approximately 8 h. In these reactions there was infrared evidence for the monosubstituted derivatives $Ru(L—L)(CO)_3(SiCl_3)_2$ but the bands thought to be due to these compounds were never very intense and as the reaction progressed they weakened with a corresponding increase in the intensity of the band due to the dicarbonyl derivative.

It was also found that $Ru(Ph_2P(CH_2)_2PPh_2)(CO)_2(SiCl_3)_2$ could be prepared by heating molar proportions of $Ph_2P(CH_2)_2PPh_2$ and *trans*-$Ru(CO)_4(SiCl_3)_2$ (1) in heptane solution at 80°C. The reaction was complete after 6 h and was essentially quantitative.

Preparation of $Ph_2P(CH_2)_2PPh_2[Ru(CO)_3(SiCl_3)_2]_2$

To a stirred solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.70 g, 1.45 mmol) in *n*-hexane (30 mL), was added dropwise over 8 h $Ph_2P(CH_2)_2PPh_2$ (0.25 g, 0.63 mmol) in *n*-hexane (200 mL). After the addition was complete the solution was stirred for a further two hours. The supernatant liquid was then removed from the white solid of product, $Ph_2P(CH_2)_2PPh_2[Ru(CO)_3(SiCl_3)_2]_2$, which was washed with four 10 mL portions of *n*-hexane and dried under vacuum. The yield was essentially quantitative (based on $Ph_2P(CH_2)_2PPh_2$); the compound was analytically pure as prepared. The $Ph_2PCH_2PPh_2$ analogue was prepared similarly.

Preparation of $Ru[(CH_3)_2AsC_6H_4As(CH_3)_2](CO)_2(SiCl_3)_2$

A solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.24 g, 0.50 mmol) and *ortho*-$(CH_3)_2AsC_6H_4As(CH_3)_2$ (0.14 g, 0.70 mmol) in CH_2Cl_2 (15 mL) was stirred at room temperature for 24 h. The solution was then filtered, *n*-hexane added (15 mL), and cooled at −78°C. The solvent was removed from the product which was washed and dried as before. The white crystals so obtained were analytically pure. The ^1H nmr spectrum showed resonances at δ 7.2–8.2 (CH) and 2.05 (CH_3) ppm.

Preparation of $Ru(Ph_2AsCH_2CH_2AsPh_2)(CO)_2(SiCl_3)_2$

A solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.482 g, 1 mmol) and $Ph_2AsCH_2CH_2AsPh_2$ (0.486 g, 1 mmol) in benzene was heated at 75–80°C in an evacuated sealed tube (fitted with a Teflon valve). Approximately every 12 h the tube was cooled and reevacuated. After four days the tube was cooled and worked up in a similar manner to the derivatives of the phosphorus chelates. The yield was essentially quantitative.

When the reaction was carried out in CH_2Cl_2 solution at room temperature an infrared spectrum after 18 h showed approximately equal amounts of $Ru(Ph_2AsCH_2CH_2AsPh_2)(CO)_2(SiCl_3)_2$ and $(Ph_2AsCH_2CH_2AsPh_2)[Ru(CO)_3(SiCl_3)_2]_2$. A spectrum of the solution after it had been stirred for a further three days was virtually unchanged.

Preparation of $Ph_2As(CH_2)_2AsPh_2[Ru(CO)_3(SiCl_3)_2]_2$

A solution containing *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.150 g, 0.31 mmol) and $Ph_2As(CH_2)_2AsPh_2$ (0.050 g, 0.10 mmol) in *n*-hexane (15 mL) was stirred overnight. The white precipitate of $Ph_2As(CH_2)_2AsPh_2[Ru(CO)_3(SiCl_3)_2]_2$ (0.12 g, 85%) was separated from the mother liquor, washed with *n*-hexane (five 10 mL portions), and dried on the vacuum line. The analytical sample was obtained by recrystallization from CH_2Cl_2/*n*-hexane.

Preparation of $Ru(C_8H_{12})(CO)_2(SiCl_3)_2$

A solution of *cis*-$Ru(CO)_4(SiCl_3)_2$ (0.482 g, 1 mmol) in cyclooctadiene (5 mL) was stirred at room temperature for four days. After this time *n*-hexane (10 mL) was added and the resulting solution stored in the refrigerator to complete precipitation. Excess diene and *n*-hexane was removed from the white crystalline product which was washed with further *n*-hexane and dried on the vacuum line. The yield of $Ru(C_8H_{12})(CO)_2(SiCl_3)_2$ was 80%, and appeared pure by infrared spectrum. The analytical sample was obtained by recrystallization from CH_2Cl_2/*n*-hexane; ^1H nmr δ: 2.55 and 5.35 ppm (ratio 2:1). The norbornadiene analogue was prepared similarly (75% yield) as was the cyclooctatetraene derivative $(Ru(C_8H_8)(CO)_2(SiCl_3)_2)$. However, in the latter case the initial compound was brown and was purified by stirring with decolorizing charcoal. The ^1H nmr of this compound showed two singlets at 6.05 and 6.50 ppm.

The compounds appeared stable in air for short periods, the norbornadiene derivative sublimes at 110°C (0.02 Torr). When carbon monoxide was bubbled through a solution of $Ru(C_8H_8)(CO)_2(SiCl_3)_2$ in CH_2Cl_2 it reverted to *cis*-$Ru(CO)_4(SiCl_3)_2$ over 18 h.

Preparation of $Ru[2,2'\text{-}(C_5H_4N)_2](CO)_2(SiCl_3)_2$

The preparation of this compound was essentially that given for the dithiahexane derivative. The compound was very air sensitive and decomposed rapidly in solution, preventing adequate study.

Thermal rearrangement of 5,6,6-triphenylbicyclo[3.1.0]hex-2-ene to 6,7-benzo-1,5-diphenyltricyclo[3.2.1.$0^{2,8}$]octane

STEFAN WEIGL[1] AND JOHN WARKENTIN[2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

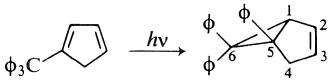
Received September 13, 1979

STEFAN WEIGL and JOHN WARKENTIN. Can. J. Chem. **58**, 210 (1980).

The triphenyl vinylcyclopropane system, 5,6,6-triphenylbicyclo[3.1.0]hex-2-ene, **1**, undergoes clean thermal rearrangement, at 210°C, to 6,7-benzo-1,4-diphenyltricyclo[3.2.1.$0^{2,8}$]octane, **9**. This result indicates that **1** behaves like a phenylcyclopropane and not like a vinylcyclopropane in the thermal ring opening. The proposed mechanism involves initial formation of a 1,3-diradical, one site of which is benzyl as well as homoallyl and the other site of which is both benzhydryl and homoallyl. Subsequent steps involve coupling of the radical sites through one of the phenyl groups and a suprafacial 1,5-hydrogen shift concerted with generation of a new cyclopropane ring.

The ^{1}Hmr and ^{13}Cmr spectra of **9** are reported and discussed in terms of the shielding properties of cyclopropane and benzene rings.

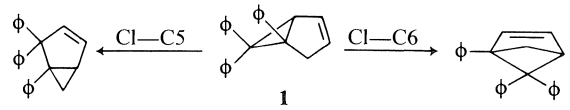
STEFAN WEIGL et JOHN WARKENTIN. Can. J. Chem. **58**, 210 (1980).



Le système triphényle vinylcyclopropane, triphényl-5,6,6 bicyclo[3.1.0]hexène-2 (**1**), se transpose thermiquement de façon très nette à 210°C en benzo-6,7 diphényl-1,4 bicyclo[3.2.1.$0^{2,8}$]octane (**9**). Ce résultat indique que ce système lors de l'ouverture thermique du cycle se comporte comme un phénylcyclopropane et non comme un vinylcyclopropane. Le mécanisme proposé fait intervenir la formation initiale d'un diradical-1,3 dont un site comporte le groupe benzyle aussi bien que le groupe homoallyle et dont l'autre contient les deux groupes benzhydryle et homoallyle. Les étapes subséquentes impliquent le couplage des sites du radical à travers l'un des groupes phényle et une transposition 1,5 suprafaciale concertée d'hydrogène avec formation d'un nouveau cycle cyclopropane.

On rapporte des spectres rmn du ^{1}H et du ^{13}C et on les discute en fonction des propriétés de blindage des cycles cyclopropane et benzène.

[Traduit par le journal]



Introduction

Recently we reported (1) a convenient synthesis of 5,6,6-triphenylbicyclo[3.1.0]hex-2-ene, **1**, based on the photochemical di-π-methane rearrangement of 1-triphenylmethylcyclopentadiene (eq. [1]).

[1] 

1

That product has several structural features which were expected to make it thermally unstable. First, as a vinylcyclopropane system, it has the potential to rearrange in the vinylcyclopropane-to-cyclopentene sense.[3] In the present case the possible products would include a bicyclo[2.1.1]hexene from C1—C6 bond breaking and a new bicyclo[3.1.0]hex-2-ene (eq. [2]), from C1—C5 bond breaking. In addition to rearrangements from the vinylcyclopropane moiety, **1** might also be expected to undergo the thermolysis chemistry of phenylated cyclopropanes.[3] Thus, homolytic breaking of the C5—C6 bond of **1** would relieve ring strain and non-bonded interactions while leading to a relatively stabilized benzyl and benzhydryl diradical. Both of the radical sites of the latter would also be homoallylic.

[2] 

1

For each of the three ways of opening the cyclopropane ring one can envision a number of subsequent steps, including phenyl migration, aromatic substitution, and reclosure to new ring systems such as those of eq. [2]. The doubly homoallylic diradical referred to above is also capable, in principle at least, of rearrangement through cyclopropylcarbinyl radical intermediates (16).

In this paper we report the thermal rearrangement of **1** to **9**. The ^{1}Hmr and ^{13}Cmr spectra of **9** are reported and some unusual features of the former are discussed.[4,5]

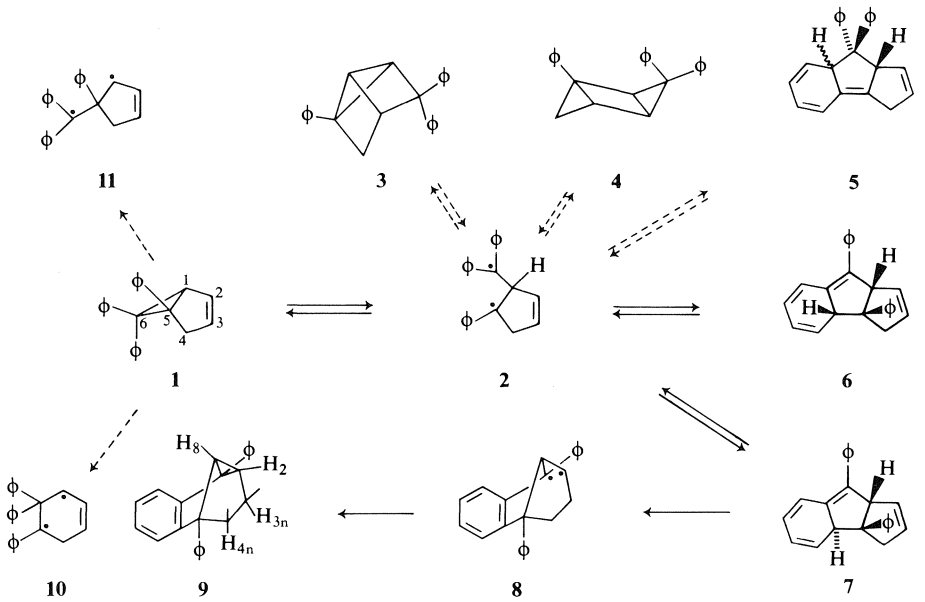
[3]Thermal reactions involving ring opening of cyclopropane and substituted cyclopropanes (vinyl and aryl substituents in particular) have been studied extensively as well as intensively and it is not appropriate to review the subject here. Recent reviews and selected recent papers can be found in refs. 2–7 and 8–15 respectively.



[4]The structure of **9** was determined by X-ray crystallography and the nmr spectra were assigned on the basis of that structure.

SCHEME 1

Discussion

In view of the large number of precedented thermal rearrangement pathways available to **1** (see above) it was surprising to find that only one product, **9**, is actually obtained. In the following paragraphs a mechanism for the formation of **9** is proposed and possible reasons for the failure of reasonable alternative pathways are discussed briefly.

A rationale for the rearrangement of **1** to **9** is depicted in Scheme 1, where full arrows are used to designate reactions that are part of the proposed mechanism and where dashed arrows show intermediates and products from potential competitive processes that were not realized. We discuss the main features (full arrows) of the scheme first and return later to examine its peripheral features.

The first step in the proposed mechanism is to cleave the C5—C6 bond of **1**, converting it to diradical **2** in which both free radical sites are delocalized. Of the options available to the latter, intramolecular radical coupling to the geometric isomers **6** and **7** is favoured. This coupling involves bond formation between the benzyl carbon and an *ortho* carbon of a phenyl ring of the benzhydryl group. Isomer **7** is geometrically suited for a suprafacial 1,5 hydrogen transfer, concerted with ring formation,[6] leading to the observed product, **9**, in which H3n was originally an *ortho* benzenoid hydrogen. Structure **8** is included only to aid with visualization of the **7**–**9** rearrangement; it would be an intermediate if H-migration were a discrete step preceding formation of the C1—C2 bond of **9**.

Compound **6** is the wrong stereoisomer for a concerted process analogous to that leading from **7** to **9**. To accommodate the clean formation of **9** we must either postulate that **6** is formed in trace amounts only or that it too finds a path to **9**. There is no good reason to expect a highly preferred sense of ring closure (**7** favoured greatly over **6**) from a radical coupling reaction, which must have a small activation energy. Therefore we suggest the alternative explanation, that **6** is formed and that it reverts to **2** under the conditions of the reaction.

Turning now to the alternative pathways leading from **1**, it is clear that the thermochemically most favoured intermediate, other than **2**, is diradical **11**. The main difference between **2** and **11** is the difference between benzyl and allyl radical stabilization. Its magnitude can be estimated from the C—H bond dissociation energies of toluene and propene (17) and works out to about 4 kcal mol^{-1}; the bond in toluene being the weaker. The uncertainty of that number (ca. ± 2 kcal mol^{-1}) together with the knowledge that only a part of it would be manifest at the transition states leading to **2** and **11**, made prediction of the direction of the ring opening quite risky. Although we had expected products from **11**, such as the diene resulting from phenyl migration, none were found. This result suggests that **11** was

[6]The rearrangement of **7** to **9** may also be viewed as a retro-"ene" reaction.

For personal use only.

not formed, possibly because there really is a significant thermochemical advantage from benzylic, rather than allylic, resonance (see above) and/or because there is greater relief of non-bonded interactions among phenyl groups at the transition state leading to **2**.

Ring opening of **1** to form **10** has precedents from both vinylcyclopropane and phenylcyclopropane chemistry.[3] In the present case it could be excluded from serious consideration, however, because **1** is also a *gem* diphenylcyclopropane. It would have been surprising if benzhydryl radical stabilization had been insufficient to make either C5—C6 or C1—C6 bond homolysis the pathway of lowest activation energy.

There are at least five alternative pathways that **2** might follow instead of the proposed closures to **6** and **7**. Those routes (Scheme 1) lead to **3**, **4** (two isomers), and **5** (two isomers). Compounds **3** and **4** may be viewed as products derived, formally, from initial homoallyl-to-cyclopropylcarbinyl rearrangement of the benzyl site of **2**. Since that site is homoallylic in two senses, the rearrangement could involve either end of the double bond. The diradicals resulting from those formal rearrangements might then ring close to **3** and **4**.[7] In the present case there is no evidence for those processes, possibly because of the adverse thermochemistry associated with making both cyclobutane and cyclopropane rings. We point out the potential for forming **3** and **4** because it may be feasible to prepare those ring systems from starting materials of type **1**, possibly by blocking aromatic substitution with *ortho* substituents or by favouring homoallyl–cyclopropylcarbinyl rearrangement with other substituent changes.[8]

Compounds **5** would result from coupling of the benzhydryl radical site with an *ortho* carbon of the benzyl radical site. One isomer of **5** should be capable of the type of rearrangement shown by **7**. Since **9** was the only product detected, it seems reasonable to assume that **2** does not cyclize to either of the isomers **5** rather than that the expected 1,5 hydrogen shift fails for some unknown reason. Although cyclization to **5**, like the corresponding paths to **6** and **7**, is a radical coupling reaction, there are two features of **5** which suggest that there ought to be a significantly higher barrier to it than to **6** or **7**. First, **5** is a conjugated triene without further conjugation whereas **6** and **7** are phenyl-conjugated trienes. Second, **5** is a more crowded species than either **6** or **7**. If these features together contribute to an enhancement of E_a for formation of **5**,[9] amounting to only 3 kcal mol^{-1}, then about 4% of **2** would leak into **5** and as much as half of that might return to **2** by virtue of being the wrong isomer for sigmatropic rearrangement. Thus, the absence of readily detectable amounts of products from **5** can be accounted for, since barriers to ring closure of diradicals can vary by more than 5 kcal mol^{-1} with changes in substituents.[10]

TABLE 1. Nuclear magnetic resonance spectra of **9**[a–d]

Nucleus	Chemical shift (δ)	Coupling constants (Hz)
H3n	1.27	$J_{3n,3x} = -13.2$; $J_{3n,4x} = 11.2$
H3x	2.09	$J_{3x,2} = 7.1$; $J_{3x,4n} = 0.0$
H4n	2.12	$J_{4n,4x} = -9.5$; $J_{4n,3n} = 6.0$
H2	2.55	$J_{2,3n} = 2.0$
H4x	2.67	$J_{4x,3x} = 10.4$
H8	3.01	$J_{8,2} = 7.4$
C3	23.47	
C2	35.01	
C4	47.53	
C1	47.98	
C8	52.63	
C5	62.87	

[a] ^{1}Hmr spectrum at 220 MHz; ^{13}Cmr spectrum at 90 MHz; both with $CDCl_3$ and TMS reference.
[b] Spectral simulation of the ^{1}Hmr spectrum using the above chemical shifts and coupling constants gave an RMS error of < 0.5 Hz.
[c] Assignment of the ^{13}Cmr spectrum is based on the chemical shifts (see text) and on the degree of substitution inferred from the multiplicity of signals in a spectrum taken with partial decoupling ^{13}C from ^{1}H.
[d] The benzenoid carbon resonances have not been assigned but they are listed below. The first 10 signals are for H-bearing carbons and signals followed by (2) indicate two equivalent carbons. The last 4 signals are those of fully-substituted sp^2 carbons. ^{13}Cmr(aromatic): 122.76, 123.89, 126.20, 126.30, 126.66, 126.75, 127.73(2), 128.31(2), 128.51(2), 129.94(2), 141.70, 144.70, 145.15, 151.40.

In summary, the above analysis suggests that some of the potential reactions of **1**, and also **2**, may be nearly isoenergetic. Thus the rearrangement **1** → **9** is not only of interest for itself but also for the potential use of suitably substituted bicyclo[3.1.0]-hex-2-enes as precursors of other polycyclic compounds. Moreover, it seems likely that intermediates like **6** and **7** could be trapped with some dienophiles.

The ^{1}Hmr and ^{13}Cmr spectra of **9** (Table 1) deserve brief comment. The most striking feature of the ^{1}Hmr spectrum is the chemical shift of cyclopropyl hydrogen H8 (3.01 δ). Cyclopropane itself absorbs at 0.22 δ (18) and tertiary cyclopropyl hydrogens do not normally give signals below 1.0 δ in the absence of an electron-withdrawing α-substituent. Examination of a model of **9** suggests that the two phenyl groups have to avoid coplanarity (approximate) with the benzo function. Con-

[7] This description is intended as an aid to visualization of the relationships between **2** and **3** or **4** rather than as a description of a likely mechanism.

[8] A milder method (e.g., photochemical) for generating intermediates of type **2** might also be necessary, in order to preserve products like **3** and **4**.

[9] Relative to the E_a value for formation of **7**. This calculation involves the reasonable assumption that the pre-exponential factors for closure of **2** to **5** and **7** are not significantly different.

[10] For 1,3-diradicals (5).

formations that minimize non-bonded interactions between the benzo group and the phenyl ring at C1 leave H8 and H2 in the deshielding zone of that ring. Similarly, the phenyl ring at C5 deshields H8 also, as well as H4x. Thus, H8 is twice deshielded as a result of steric hindrance to rotation of the phenyl groups. On the other hand, H3n is shielded because it lies over the π-system of the benzo ring and the signal from it appears at the highest field in spite of a small deshielding effect exerted on it by the cyclopropane ring.[11]

The ^{13}Cmr shifts for the nonbenzenoid carbons of **9** show features analogous to those in the ^{1}Hmr spectrum. Thus, of the two secondary carbons, C3 is upfield from C4 and, of the two tertiary carbons, C8 is downfield from C2. The signals from the two quaternary carbons were assigned on the basis of the shielding shown by cyclopropane carbons (C1 > C5) (20).

Experimental

A solution of 5,6,6-triphenylbicyclo[3.1.0]hex-2-ene (**1**, 140.2 mg, 4.55×10^{-4} mol, mp 108–109°C) in 13 mL of spectro-quality cyclohexane was degassed and sealed into a thick-walled glass tube. The latter was heated at 210 ± 10°C in a steel pressure bomb for 46 h. The tube was cooled and opened, and the cyclohexane was evaporated with a rotary evaporator. A ^{1}Hmr spectrum (high gain) of the solid residue was indistinguishable from the corresponding spectrum of **9** that was subsequently recrystallized from benzene; yield estimated on the basis of nmr detection limit ≥ 95%.

Recrystallized **9** had mp 170°C; uv (cyclohexane) λ_{max} (log ε_{max}): 230 plateau (4.29), 259 (3.00), 262 (3.01), 264 (3.01), 269 (2.97), 280 (2.87); ir (μ, CCl_4, strong and medium bands listed): 3.24 m, 3.27 s, 3.30 s, 3.40 s, 3.42 s, 3.45 m, 3.49 m, 3.51 m, 6.27 m, 6.71 m, 6.80 m, 6.89 m, 6.93 s, 9.74 m, 9.86 m, 11.74 m, 12.84 m, 13.40 s, 13.87 m, 14.49 s, 14.81 m; ms *m/e*: 308; *Mol.Wt.* calcd. for $C_{24}H_{20}$: 308; found (osmometric): 307. *Anal.* calcd. for $C_{24}H_{20}$: C 93.46, H 6.54; found: C 93.53, H 6.67.

The ^{1}Hmr and ^{13}Cmr spectra of **9** are listed in Table 1.

[11] *cis*-Cyclopropylcarbinyl hydrogens in bicyclo[3.1.0]hexanes are deshielded by about 0.11 δ whereas corresponding *trans*-hydrogens are slightly shielded (0.07 δ) (19).

Acknowledgements

This work was supported by the National Research Council of Canada. We are grateful to Dr. Arthur Grey for the 220 MHz spectrum of **9** and to Mr. Brian Sayer for the simulation of that spectrum.

Cell surface carbohydrates for targeting studies[1]

M. M. PONPIPOM,[2] R. L. BUGIANESI, AND T. Y. SHEN
Merck Sharp & Dohme Research Laboratories, Rahway, NJ 07065 U.S.A.

Received June 14, 1979

M. M. PONPIPOM, R. L. BUGIANESI, and T. Y. SHEN. Can. J. Chem. **58**, 214 (1980).

Syntheses of a series of glycolipids with 6-(5-cholesten-3β-yloxy)-1-thiohexane as the aglycon and the following carbohydrates as surface determinants are described: D-glucose, D-mannose, D-galactose, 2-acetamido-2-deoxy-D-glucose, 2-acetamido-2-deoxy-D-galactose, L-fucose, L-arabinose, D-xylose, *N*-acetyl-D-neuraminic acid, lactose, and cellobiose. These 6-(5-cholesten-3β-yloxy)hexyl 1-thioglycopyranosides have been incorporated into phospholipid vesicles for *in vivo* tissue distribution studies.

M. M. PONPIPOM, R. L. BUGIANESI et T. Y. SHEN. Can. J. Chem. **58**, 214 (1980).

On décrit la synthèse d'une série de glycolipides comportant le (cholesten-5 yloxy-3β)-6 thio-1 hexane comme aglycone et les carbohydrates suivants comme déterminant de surface: D-glucose, D-mannose, D-galactose, acétamido-2 déoxy-2 D-glucose, acétamido-2 déoxy-2 D-galactose, L-fucose, L-arabinose, D-xylose, acide *N*-acétyl-D-neuraminique, lactose et cellobiose. On a incorporé ces thio-1 glycopyrannosides de (cholesten-5 yloxy-3β)-6 hexyle dans les vésicules de phospholipides en vue d'en étudier *in vivo* la distribution dans les tissus.

[Traduit par le journal]

Liposomes have been used as carriers to introduce biologically active materials into cells (1–4). These lipid vesicles are formed when mixtures of phospholipid, cholesterol, and a charged amphiphile in varying molecular ratios are agitated or sonicated in an aqueous solution. Water-soluble and lipid-soluble chemotherapeutic agents can be accommodated in aqueous and lipid phases of liposomes, respectively. A wide variety of materials, e.g. enzymes (5, 6), antigens (7, 8), antibiotics (9), chelating agents (10, 11), small molecules, ions, etc., have been encapsulated in liposomes. The tissue distribution and clearance kinetics of drugs entrapped in liposomes are known to be affected by the liposome composition, particle size, and surface charge (12). Natural ligands such as aggregated immunoglobulins coated onto liposomes (4) have been used with partial success to direct vesicles to specific target organs and tissues. Saccharide determinants, such as glycolipids and glycoproteins present at the cell surface, are known to participate in intercellular recognition process. Alveolar macrophages have been shown to bind glycoproteins and synthetic glycoconjugates that have D-mannose, 2-acetamido-2-deoxy-D-glucose, or D-glucose in the exposed, nonreducing position (13). Mammalian hepatic receptors are specific for terminal D-galactose of desialylated serum glycoproteins, whereas in avian liver, the receptors recognize terminal 2-acetamido-2-deoxy-D-glucose (14). Neuraminidase-treated erythrocytes which have D-galactose as the terminal sugar are shown to be susceptible to rapid elimination and are sequestered in the liver and spleen (15). The specific binding of macrophages to MIF (migration inhibitory factor) involves the recognition of L-fucose (16). The uptake of some lysosomal enzymes by fibroblasts in culture involves recognition of D-mannose phosphate on the enzyme molecules (17). Following these and other examples, it would seem that synthetic glycolipids incorporated in liposomes may well change the *in vivo* tissue distribution and clearance kinetics of drugs. To extend a previous communication (18) from these laboratories, we report the syntheses of a series of glycolipids with 6-(5-cholesten-3β-yloxy)-1-thiohexane as the aglycon and the following carbohydrates which occur naturally in membrane oligosaccharides (19) as surface determinants: D-glucose, D-mannose (18), D-galactose (18), 2-acetamido-2-deoxy-D-glucose, 2-acetamido-2-deoxy-D-galactose, L-fucose, L-arabinose, D-xylose, and *N*-acetyl-D-neuraminic acid. Glycolipids with lactose and cellobiose as the surface determinants were also prepared for this study.

Initially, cholesteryl and stigmasteryl α-D-mannopyranosides (**3** and **5** respectively) were prepared for comparisons with 6-(5-cholesten-3β-yloxy)-hexyl 1-thio-α-D-mannopyranoside (**1**) (18) as synthetic ingredients for liposomes. In contrast to **1**, compounds **3** and **5** could not be incorporated at a concentration of 15–18% (by weight) into 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC) liposomes by probe sonication of lipid mixtures in aqueous 0.1 *M* KCl and 10 m*M* Tris buffer at pH 8.0. This may be due to the more rigid structures of **3** and **5**. Therefore, 6-(5-cholesten-3β-yloxy)-1-thiohexane was chosen as a lipid tail for our

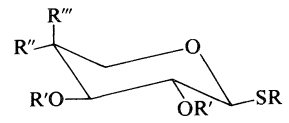
systematic studies on the effects of external carbohydrate determinants on liposome distribution. Thioglycosidic linkage was used because it is more stable towards acid and enzymatic hydrolysis than *O*-glycosides (20, 21). These thioglycosides were prepared from 6-(5-cholesten-3β-yloxy)hexyl iodide (**32**) (18) and per-*O*-acetyl-1-thioglycopyranoses in dichloromethane containing triethylamine (18) or better in tetrahydrofuran using 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) as a base. The coupling reactions were more rapid in the presence of DBU and usually completed within 0.5–3 h.[3] The per-*O*-acetylated analogs **7**, **10**, **14**, **17**, **20**, **23**, **37**, and **40** were synthesized by the above procedures in high yields. Trace amounts of the 1,2-*cis* isomers were also isolated in some cases. The α and β anomers can be determined in most cases, from their nmr spectra. For example, the H-1 signal of 6-(5-cholesten-3β-yloxy)hexyl 2,3,4-tri-*O*-acetyl-1-thio-α-L-arabinopyranoside (**23**) appears as a doublet at δ 4.52 ($J_{1,2}$ = 8.5 Hz) whereas in the β-L-anomer, it resonates at δ 5.64 ($J_{1,2}$ = 5.0 Hz). The chemical shifts and coupling constants of other protons are all in agreement with the assigned structures (see Experimental).



The synthesis of 5-acetamido-2-*S*-[6-(5-cholesten-3β-yloxy)hexyl]-3,5-dideoxy-2-thio-β-D-*glycero*-D-*galacto*-2-nonulopyranosonic acid (**29**) was more elusive. Difficulties were encountered in the preparation of the intermediates **26** and **27**. The reported R_f 0.58 (chloroform–methanol 92:8) for the thiouronium salt **26** was rather high in comparison with the mobility of its precursor **25** (R_f 0.67) (22). Because of our difficulties and the fact that the intermediates **26** and **27** were not well characterized (22), we decided instead to couple **25** with 6-(5-cholesten-3β-yloxy)-1-thiohexane (**34**) under various conditions (23, 24). Unfortunately, only methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-2,3-dehydro-2,3,5-trideoxy-D-*glycero*-D-*galacto*-2-nonulopyranosonate was isolated as a major product. Recently, Ferrier and Furneaux (25) used boron trifluoride etherate to catalyse the condensation of carbohydrate peresters and thiols to provide a convenient synthesis of thioglycosides. When methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3,5-dideoxy-D-*glycero*-D-*galacto*-2-nonulopyranosonate (26) and **34** were reacted in the presence of

boron trifluoride etherate, a major product was isolated and the structure was tentatively assigned as **28**. The nmr spectrum of this material has many features in common with that of methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-dideoxy-2-*O*-methyl-β-D-*glycero*-D-*galacto*-2-nonulopyranosonate (**30**) which is quite different from the spectrum of **31** (see Tables 1 and 2). The anomeric configurations of *N*-acetyl-D-neuraminic acid analogs can generally be established from the chemical shifts of H-3e which resonate at a lower field in α anomers when compared with the corresponding β anomers (27), e.g., the H-3e of **31** is at δ 2.58 whereas that of **30** is at δ 2.45 (see Table 1). In the synthesis of **28**, a minor amount of the α anomer was also isolated as a mixture with **28** (see Experimental). The assignment of these products was verified by the chemical shifts of H-3e, i.e., δ 2.54 for **28** and δ 2.73 for the corresponding α anomer. It is noteworthy that the coupling constants ($J_{7,8}$) for **28**, **30**, and **31** are reflected by the anomeric configuration and possibly by the size of the aglycon (see Table 2). For example, $J_{7,8}$ for **31** is large (9.0 Hz) as expected for *N*-acetyl-α-D-neuraminic acid analogs (27) whereas $J_{7,8}$ for **30** and **28** are only 4.0 and 2.5 Hz, respectively. Although *N*-acetyl-D-neuraminic acid occurs almost exclusively as the α anomer in glycoproteins, glycolipids, and polysaccharides, we thought it would still be of interest to use the β-thioglycoside **29** (isolated as a major product) for our biological studies.

The deblocked 6-(5-cholesten-3β-yloxy)hexyl 1-thioglycosides have been incorporated into egg lecithin, dioleyl-(DOPC), dipalmitoyl-, and distearoylphosphatidylcholine vesicles (18, 28). Up to concentrations of 50 mol% of these synthetic glycolipids have been incorporated in DOPC multilamellar liposomes. For sonicated vesicles, the glycolipids have been incorporated up to 15 mol% in phosphatidylcholine. The average size of DOPC/glycolipid vesicles is not significantly changed by the nature of the carbohydrate deter-

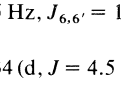
minants. Similar observations were recently reported with other synthetic mannose-containing glycolipids (29).



The *in vivo* tissue distribution studies of liposomes containing these synthetic glycolipids have been examined.[4] Some recognition of the carbohydrate determinants by specific organs and tissues was demonstrated. For example, liver took up injected liposomes much more readily if they contained the lactosyllipid **38** than if they contained the galactosyl analog **12** or no glycolipid, suggesting that the glucosyl moiety of the disaccharide **38** allowed better interaction of the terminal galactose with the putative cell-surface receptor. The importance of disaccharides was also demonstrated in the study of the influence of cerebrosides on the interaction of liposomes with HeLa cells (30). On the other hand, liposomes containing the sialyllipid **29** reduced the uptake of liposomes by liver. Similar observations were also reported on the tissue distribution of EDTA encapsulated within liposomes containing glycolipids (31). Details will be published elsewhere.

Experimental

Melting points were determined with a Thomas-Hoover "Unimelt" apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer Model 241 polarimeter. Thin-layer chromatography (tlc) was performed on silica gel GF_{254} (Analtech) plates, and the spots were detected by a ceric sulfate (1%) – sulfuric acid (10%) spray. Column chromatography was conducted on silica gel 60 (70–230 mesh ASTM). Nuclear magnetic resonance spectra were recorded for solutions in chloroform-*d* (unless stated otherwise) at 60 or 300 MHz, with tetramethylsilane as the internal standard. Conventional processing consisted in drying organic solutions with anhydrous sodium sulfate, filtration, and evaporation of the filtrate under diminished pressure.

The following per-*O*-acetyl-1-thioglycopyranoses were prepared via 2-*S*-(per-*O*-acetylglycopyranosyl)-2-thiopseudourea hydrobromides according to known procedures: 2,3,4,6-Tetra-*O*-acetyl-1-thio-β-D-glucopyranose (**6**) (32); 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-β-D-glucopyranose (**9**) (33, 34); 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-β-D-galactopyranose (**13**), mp 188–189°C, $[\alpha]_D^{27}$ −2.5° (*c* 1.2, chloroform) (*Anal.* calcd. for $C_{14}H_{21}NSO_8$: C 46.27, H 5.83, N 3.38, S 8.83; found: C 46.55, H 5.86, N 3.68, S 8.73); 2,3,4-tri-*O*-acetyl-1-thio-β-L-fucopyranose (**16**) (35); 2,3,4-tri-*O*-acetyl-1-thio-β-D-xylopyranose (**19**) (36); 2,3,4-tri-*O*-acetyl-1-thio-α-L-arabinopyranose (**22**) (37, 38); 2,3,6-tri-*O*-acetyl-4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-1-thio-β-D-glucopyranose (**36**) (39); and 2,3,6-tri-*O*-acetyl-4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-1-thio-β-D-glucopyranose (**39**) (40, 41).

*Stigmasteryl 2,3,4,6-Tetra-O-acetyl-α-D-mannopyranoside (**4**)*

A solution of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (1.0 g) in dry benzene (7.5 mL) was added to a solution of stigmasterol (1.1 g) in benzene (65 mL) and nitromethane (65 mL) containing mercuric cyanide (0.7 g) and calcium sulfate (0.7 g). The mixture was stirred for 4 h at room temperature. Another batch of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide (1.0 g) was added and the mixture was stirred for another 4 h. The solid was filtered and the filtrate was concentrated to a residue which was taken up in chloroform and washed successively with water, aqueous sodium hydrogencarbonate, and water. The dried solution was evaporated to an oil which was triturated with methanol to give crystals (1.85 g, two spots). The crude material was put on a column of silica gel and eluted with 3% 2-propanol in chloroform. The desired fractions were pooled and evaporated *in vacuo* to give **4** (1.3 g, 60%), mp 80–82°C, $[\alpha]_D^{27}$ +19° (*c* 1.5, chloroform); nmr (chloroform-*d*) δ: 4.95 (d, $J_{1,2}$ = 1.5 Hz, H-1), 5.19 (d, d, $J_{2,3}$ = 3.5 Hz, H-2), 5.38 (d, d, $J_{3,4}$ = 10.0 Hz, H-3), 5.25 (t, $J_{4,5}$ = 10.0 Hz, H-4), 4.24 (d, d, $J_{6,5}$ = 5.5 Hz, $J_{6,6'}$ = 12.0 Hz, H-6), 1.97, 2.02, 2.06, and 2.12 (4 OAc), 5.34 (d, *J* = 4.5 Hz, olefinic), 3.47 (m, ), 0.82 (d, *J* = 6.0 Hz, CH_3-21), 0.76, 0.78 (CH_3-26 and CH_3-27), and 0.67 (s, CH_3-18). *Anal.* calcd. for $C_{43}H_{66}O_{10}$: C 69.51, H 8.95; found: C 69.51, H 9.10.

*Stigmasteryl α-D-Mannopyranoside (**5**)*

A suspension of **4** (500 mg) in methanol was warmed until dissolution. Sodium methoxide (25 mg) was added and the solution was kept at room temperature overnight. The product

For personal use only.

crystallized from the medium and was collected by filtration and washed successively with methanol, water, and ethyl ether to give **5** (300 mg), mp 220°C (dec.), $[\alpha]_D^{27}$ +26° (*c* 1.0, pyridine); nmr (dimethylsulfoxide-d_6) δ: 4.76 (H-1), 5.30 (H-6 olefinic), 4.99–5.20 (m, H-22 and H-23 olefinic), 0.99 (d, J = 6.0 Hz, CH_3-21), 0.95 (s, CH_3-19), 0.81, 0.83 (CH_3-26 and CH_3-27), 0.77 (CH_2—CH_3), 0.67 (s, CH_3-18). This material is insoluble in most organic solvents. *Anal.* calcd. for $C_{35}H_{58}O_6$: C 73.13, H 10.17; found: C 72.72, H 10.08.

Cholesteryl α-D-*Mannopyranoside* (*3*)

Cholesteryl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (**2**), mp 89–92°C, $[\alpha]_D^{27}$ +25° (*c* 1.0, chloroform) was prepared in a similar manner to **4**. Deblocking of **2** afforded **3** in a near quantitative yield, mp 213–216°C, $[\alpha]_D^{27}$ +31° (*c* 0.8, pyridine); nmr (dimethylsulfoxide-d_6) δ: 4.76 (H-1), 5.31 (olefinic), 0.94 (s, CH_3-19), 0.89 (d, J = 6.0 Hz, CH_3-21), 0.82, 0.84 (CH_3-26 and CH_3-27), 0.64 (s, CH_3-18). *Anal.* calcd. for $C_{33}H_{56}O_6$: C 72.22, H 10.29; found: C 72.24, H 10.18.

*6-(5-Cholesten-3*β*-yloxy)hexyl 1-Thioglycopyranosides*

Per-*O*-acetyl-1-thioglycopyranose (10 mmol) was reacted with **32** (18) (10 mmol) in dichloromethane (30 ml) containing triethylamine (10 mmol) under nitrogen for 1–3 days at room temperature. If DBU was used as a base in tetrahydrofuran, the condensation was usually complete within 0.5–3 h. Tetrahydrofuran was removed *in vacuo* and the residue was partitioned between dichloromethane and water. The organic layer was dried and concentrated to a syrup which was put on a column of silica gel and eluted with chloroform followed by 1–2% ethanol in chloroform. The desired fractions were combined and evaporated to give 6-(5-cholesten-3β-yloxy)hexyl per-*O*-acetyl-1-thioglycopyranoside which was deblocked either by Bio-Rad AG 1-x2 (OH) ion exchange resin in ethanol–tetrahydrofuran or by sodium methoxide in methanol. 6-(5-Cholesten-3β-yloxy)hexyl 1-thioglycopyranosides were usually isolated as crystalline materials.

*6-(5-Cholesten-3*β*-yloxy)hexyl 2,3,4-Tri-*O*-acetyl-1-thio-*α*-L-arabinopyranoside* (***23***)

This compound was prepared in 64% yield, $[\alpha]_D^{27}$ −22° (*c* 1.88, chloroform); nmr (chloroform-*d*) δ: 4.52 (d, $J_{1,2}$ = 8.5 Hz, H-1), 5.24 (t, $J_{2,3}$ = 8.5 Hz, H-2), 5.09 (d, d, $J_{3,4}$ = 3.5 Hz, H-3), 5.13 (b, H-4), 4.12 (q, $J_{5,5'}$ = 13.0 Hz, $J_{5,4}$ = 3.5 Hz, H-5), 3.68 (q, $J_{5',4}$ = 1.0 Hz, H-5′), 2.05, 2.09, and 2.14 (3 OAc), 5.36 (d, J = 4.5 Hz, olefinic), 3.46 (t, J = 6.5 Hz, C—CH_2—O— ), 3.14 (m, —O— ), 2.70 (m, —S—CH_2—C), 0.99 (s, CH_3-19), 0.91 (d, J = 6.0 Hz, CH_3-21), 0.84, 0.87 (CH_3-26 and CH_3-27), and 0.66 (s, CH_3-18). *Anal.* calcd. for $C_{44}H_{72}SO_8$: C 69.44, H 9.54, S 4.21, found: C 69.62, H 9.80, S 4.50.

A minor amount of the α anomer of **23** (higher R_f) was also isolated, nmr (chloroform-*d*) δ: 5.64 (d, $J_{1,2}$ = 5.0 Hz, H-1), 5.31 (q, $J_{2,3}$ = 10.0 Hz, H-2), and 5.22 (q, $J_{3,4}$ = 3.5 Hz, H-3). *Anal.* calcd. for $C_{44}H_{72}SO_8$: C 69.44, H 9.54, S 4.21; found: C 69.53, H 9.84, S 4.50.

*6-(5-Cholesten-3*β*-yloxy)hexyl 1-Thio-*α*-L-arabinopyranoside* (***24***)

This compound was obtained in 83% yield, $[\alpha]_D^{27}$ −18° (*c* 2.0, chloroform); nmr ($CDCl_3$ with D_2O spike) δ: 5.36 (d, J = 4.5 Hz, olefinic), 4.25 (d, $J_{1,2}$ = 8.5 Hz, H-1), 4.10 (q, $J_{3,2}$ = 12.5 Hz, $J_{3,4}$ = 2.0 Hz, H-3), 3.99 (b, H-4), 3.68 (q, H-2). *Anal.* calcd. for $C_{38}H_{66}SO_5$: C 71.88, H 10.48, S 5.05; found: C 71.85, H 10.70, S 5.12.

*6-(5-Cholesten-3*β*-yloxy)hexyl 2,3,4-Tri-O-acetyl-1-thio-*β*-D-xylopyranoside* (***20***)

Compound **20** was prepared in 65% yield, mp 106–108°C (methanol), $[\alpha]_D^{27}$ −56° (*c* 1.55, chloroform); nmr (chloroform-*d*) δ: 4.51 (d, $J_{1,2}$ = 9.0 Hz, H-1), 4.97 (t, $J_{2,3}$ = 8.5 Hz, H-2), 5.19 (t, $J_{3,4}$ = 8.5 Hz, H-3), 4.23 (d, d, $J_{5e,4}$ = 5.0 Hz, $J_{5e,5a}$ = 12.0 Hz, H-5e), 3.38 (d, d, $J_{5a,4}$ = 9.0 Hz, H-5a), 4.97 (H-4), 2.04 and 2.06 (3 OAc), 5.35 (d, J = 4.5 Hz, olefinic), 3.45 (t, J = 6.5 Hz, C—CH_2—O— ), 3.13 (m, —O— ), 2.66 (m, —S—CH_2—C), 0.98 (s, CH_3-19), 0.90 (d, CH_3-21), 0.85 and 0.87 (d, d, CH_3-26 and CH_3-27), and 0.67 (s, CH_3-18). *Anal.* calcd. for $C_{44}H_{72}SO_8$: C 69.44, H 9.54, S 4.21; found: C 69.35, H 9.82, S 4.25.

*6-(5-Cholesten-3*β*-yloxy)hexyl 1-Thio-*β*-D-xylopyranoside* (***21***)

Compound **21** was obtained as a crystalline material, mp 115°C (methanol), $[\alpha]_D^{27}$−45° (*c* 1.47, chloroform); nmr ($CDCl_3$ with D_2O spike) δ: 4.29 (d, $J_{1,2}$ = 9.5 Hz, H-1), 3.35 (t, $J_{2,3}$ = 9.0 Hz, H-2), 3.50 (t, $J_{3,4}$ = 9.0 Hz, H-3), 5.37 (d, J = 4.5 Hz, olefinic). *Anal.* calcd. for $C_{38}H_{66}SO_5$: C 71.88, H 10.48, S 5.05; found: C 71.77, H 10.26, S 5.09.

*6-(5-Cholesten-3*β*-yloxy)hexyl 2,3,4-Tri-*O*-acetyl-1-thio-*β*-L-fucopyranoside* (***17***)

This compound was prepared in 81% yield, $[\alpha]_D^{27}$ −4° (*c* 1.5, chloroform); nmr (chloroform-*d*) δ: 4.46 (d, $J_{1,2}$ = 10.0 Hz, H-1), 5.25 (t, $J_{2,3}$ = 10.0 Hz, H-2), 5.07 (d, d, $J_{3,4}$ = 3.5 Hz, H-3), 5.30 (d, H-4), 3.84 (q, J = 6.0 Hz, H-5), 1.22 (d, CH_3-5), 2.0, 2.08, and 2.19 (3 OAc), 5.37 (d, J = 4.5 Hz, olefinic), 3.48 (t, J = 6.5 Hz, C—CH_2—O— ), 3.15 (m, —O— ), 2.72 (m, —S—CH_2—C), 1.0 (s, CH_3-19), 0.91 (d, CH_3-21), 0.85 and 0.87 (d, d, CH_3-26 and CH_3-27), 0.67 (s, CH_3-18). *Anal.* calcd. for $C_{45}H_{74}SO_8$: C 69.73, H 9.62, S 4.14; found: C 69.62, H 9.68, S 4.09.

*6-(5-Cholesten-3*β*-yloxy)hexyl 1-Thio-*β*-L-fucopyranoside* (***18***)

This compound was obtained as needles in 80% yield, mp 110–112°C (EtOAc), $[\alpha]_D^{27}$ −11° (*c* 1.43, chloroform); nmr ($CDCl_3$ with D_2O spike) δ: 5.36 (d, J = 4.5 Hz, olefinic), 4.27 (H-1 and H-2), 3.78 (b, H-4), 3.68 (q, J = 6.5 Hz, H-5), 3.60 (H-3). *Anal.* calcd. for $C_{39}H_{68}SO_5 \cdot 0.5\ CH_3COOCH_2CH_3$: C 71.05, H 10.47, S 4.63; found: C 70.84, H 10.68, S 5.00.

*6-(5-Cholesten-3*β*-yloxy)hexyl 2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranoside* (***7***)

Compound **7** was prepared in 86% yield, mp 101–102.5°C (methanol), $[\alpha]_D^{27}$ −36° (*c* 1.59, chloroform). *Anal.* calcd. for $C_{47}H_{76}SO_{10}$: C 67.75, H 9.19, S 3.85; found: C 67.72, H 9.44, S 3.71.

*6-(5-Cholesten-3*β*-yloxy)hexyl 1-Thio-*β*-D-glucopyranoside* (***8***)

Compound **8** was obtained as a crystalline material, mp 110°C (aqueous isopropanol), $[\alpha]_D^{27}$ −41° (*c* 1.07, chloroform), R_f 0.27 (chloroform–methanol, 9:1); nmr ($CDCl_3$, with D_2O spike) δ: 5.34 (d, J = 4.5 Hz, olefinic), 4.43 (d, $J_{1,2}$ = 9.5 Hz, H-1). *Anal.* calcd. for $C_{39}H_{68}SO_6$: C 70.44, H 10.31, S 4.82; found: C 70.43, H 10.36, S 4.63.

*6-(5-Cholesten-3*β*-yloxy)hexyl 2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-1-thio-*β*-D-glucopyranoside* (***10***)

This compound was prepared in 85% yield, mp 176–179°C,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$[\alpha]_D^{27}$ −43° (*c* 1.5, chloroform). *Anal.* calcd. for $C_{47}H_{77}NSO_9$: C 67.83, H 9.33, N 1.68, S 3.85; found: C 67.54, H 9.78, N 1.80, S 3.90.

*6-(5-Cholesten-3β-yloxy)hexyl 2-Acetamido-2-deoxy-1-thio-β-D-glucopyranoside (**11**)*

Compound **11** was obtained in 77% yield, mp 183–187°C (dec.) (methanol), $[\alpha]_D^{27}$ −36° (*c* 1.5, dimethylsulfoxide), R_f 0.48 (chloroform–methanol–water, 80:20:2). *Anal.* calcd. for $C_{41}H_{71}NSO_6$: C 69.74, H 10.14, N 1.98, S 4.54; found: C 69.57, H 10.27, N 1.86, S 4.66.

*6-(5-Cholesten-3β-yloxy)hexyl 2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-1-thio-β-D-galactopyranoside (**14**)*

This compound was isolated as a crystalline material in 63% yield, mp 130–133°C (ethanol), $[\alpha]_D^{27}$ −37° (*c* 1.5, chloroform). *Anal.* calcd. for $C_{47}H_{77}NSO_9$: C 67.83, H 9.33, N 1.68, S 3.85; found: C 67.69, H 9.37, N 1.67, S 4.02.

*6-(5-Cholesten-3β-yloxy)hexyl 2-Acetamido-2-deoxy-1-thio-β-D-galactopyranoside (**15**)*

Compound **15** was obtained in 85% yield, mp 241–243°C, $[\alpha]_D^{27}$ −35° (*c* 1.5, *N*,*N*-dimethylformamide). *Anal.* calcd. for $C_{41}H_{71}NSO_6$: C 69.74, H 10.14, N 1.98, S 4.54; found: C 69.57, H 10.44, N 2.20, S 4.90.

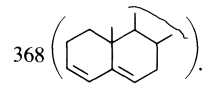
*6-(5-Cholesten-3β-yloxy)hexyl 2,3,6-Tri-O-acetyl-4-O-(2,3,4,6-tetra-O-acetyl-βD-galactopyranosyl)-1-thio-β-D-glucopyranoside (**37**)*

This compound was prepared in 60% yield, $[\alpha]_D^{27}$ −22° (*c* 1.55, chloroform). *Anal.* calcd. for $C_{59}H_{92}SO_{18}$: C 63.19, H 8.27, S 2.86; found: C 63.27, H 8.46, S 2.88.

*6-(5-Cholesten-3β-yloxy)hexyl 4-O-(β-D-Galactopyranosyl)-1-thio-β-D-glucopyranoside (**38**)*

Compound **38** was obtained as a crystalline material, mp 189–192°C (aqueous isopropanol), $[\alpha]_D^{27}$ −21° (*c* 1.63, dimethylsulfoxide), R_f 0.26 (chloroform–methanol–water, 80:20:2). *Anal.* calcd. for $C_{45}H_{78}SO_{11}$: C 65.34, H 9.51, S 3.88; found: C 65.42, H 9.51, S 4.11.

*6-(5-Cholesten-3β-yloxy)hexyl 2,3,6-Tri-O-acetyl-4-O-(2,3,4,6-tetra-O-acetyl-β-D-glucopyranosyl)-1-thio-β-D-glucopyranoside (**40**)*



This compound was prepared in 76% yield, mp 178–180°C (ethyl ether – 95% ethanol), $[\alpha]_D^{27}$ −27.5° (*c* 1.0, chloroform). *Anal.* calcd. for $C_{59}H_{92}SO_{18}$: C 63.19, H 8.27, S 2.86; found: C 63.15, H 8.50, S 2.91.

*6-(5-Cholesten-3β-yloxy)hexyl 4-O-(β-D-Glucopyranosyl)-1-thio-β-D-glucopyranoside (**41**)*

This compound was obtained as a crystalline material, mp 197–201°C (aqueous isopropanol), $[\alpha]_D^{27}$ −32° (*c* 1.0, dimethylsulfoxide). *Anal.* calcd. for $C_{45}H_{78}SO_{11}\cdot H_2O$: C 63.95, H 9.54, S 3.79; found: C 63.87, H 9.86, S 3.91.

*6-(5-Cholesten-3β-yloxy)-1-thiohexane (**34**)*

Thiourea (7.5 g) was added to a solution of **32** (15 g, 25.3 mmol) in tetrahydrofuran (200 mL), and the mixture was heated under reflux with vigorous stirring for 6 h. The solution was concentrated to a residue which was triturated with anhydrous ethyl ether. The solid was filtered and dissolved in chloroform (100 mL), and the solution was added to a solution of potassium metabisulfite (15 g) in water (100 mL). The mixture was refluxed under nitrogen for 20 min. The cooled solution was separated and the organic layer was dried and evaporated *in vacuo* to a crude material which was put on a column of silica gel and eluted with 5% ethyl ether in petroleum ether. The desired fractions were pooled and evaporated to give **34** (11 g, 86%), mp 89–90°C; ms *m/e*: 502 ($M^{+\cdot}$), 487 ($M^{+\cdot}-CH_3$),

Anal. calcd. for $C_{33}H_{58}SO$: C 78.82, H 11.63, S 6.38; found: C 78.91, H 11.64, S 6.25.

A portion of **34** was acetylated with acetic anhydride in pyridine to give **35**, mp 81–81.5°C. *Anal.* calcd. for $C_{35}H_{60}SO_2$: C 77.14, H 11.10, S 5.89; found: C 77.20, H 11.23, S 6.13.

*Methyl 5-Acetamido-4,7,8,9-tetra-O-acetyl-2-S-[6-(5-cholesten-3β-yloxy)hexyl]-3,5-dideoxy-2-thio-β-D-glycero-D-galacto-2-nonulopyranosonate (**28**)*

Boron trifluoride etherate (0.7 mL, 5.5 mmol) was added to a solution of **34** (0.98 g, 1.96 mmol) and methyl 5-acetamido-2,4,7,8,9-penta-*O*-acetyl-3,5-dideoxy-β-D-*glycero*-D-*galacto*-2-nonulopyranosonate (**25**) (1.01 g, 1.96 mmol) in dry chloroform (5 mL). The mixture was stirred under nitrogen for 5 h at room temperature. Chloroform (25 mL) was added to the reaction mixture and the solution was washed with aqueous sodium hydrogencarbonate (20 mL) and water (20 mL). The dried solution was concentrated to a residue which was put on a column of silica gel and eluted with chloroform – ethyl ether – methanol (30:10:1). The desired fractions were pooled and evaporated to give **28** as a foam (400 mg), $[\alpha]_D^{27}$ −38.5° (*c* 1.5, chloroform); nmr (chloroform-*d*) δ: 5.44 (t, $J_{7,6} = J_{7,8} = 2.5$ Hz, H-7), 5.35 (d, $J = 4.5$ Hz, olefinic), 5.27 (o, $J_{4,5} = 10.5$ Hz, $J_{4,3a} = 12.0$ Hz, $J_{4,3e} = 5.0$ Hz, H-4), 5.28 (d, $J_{NH,5} = 10.5$ Hz, N—H), 5.12 (t, t, $J_{8,9} = 8.0$ Hz, $J_{8,9'} = 2.5$ Hz, H-8), 4.82 (d, d, $J_{9,9'} = 12.5$ Hz, H-9′), 4.34 (d, d, $J_{6,5} = 10.5$ Hz, H-6), 4.18 (d, d, H-9), 4.10 (q, H-5), 3.80 (s, $COOCH_3$), 3.44 (t, $J = 6.5$ Hz, C—CH_2—O— ), 3.13 (m, —O— ), 2.54 (H-3e), 2.13, 2.07, 2.04, 2.02, and 1.88 (5s, 4 OAc and NAc), 0.98 (s, CH_3-19), 0.91 (d, $J = 6.0$ Hz, CH_3-21), 0.84 and 0.86 (CH_3-26 and CH_3-27), 0.66 (s, CH_3-18). *Anal.* calcd. for $C_{53}H_{85}SNO_{13}$: C 65.20, H 8.78, N 1.44, S 3.28; found: C 65.20, H 9.03, N 1.97, S 3.68.

The overlapping fractions were combined and concentrated to give a mixture (60 mg) of **38** and the corresponding α anomer; nmr (chloroform-*d*) δ: 2.54 (H-3e of **28**), 2.73 (d, d, $J_{3e,4} = 4.5$ Hz, $J_{3e,3a} = 13.0$ Hz, H-3e of the α anomer of **28**).

*5-Acetamido-2-S-[6-(5-cholesten-3β-yloxy)hexyl]-3,5-dideoxy-2-thio-β-D-glycero-D-galacto-2-nonulopyranosonic acid (**29**)*

A solution of **28** (46 mg) in dry methanol (8 mL) containing sodium methoxide (3 mg) was kept for 3 h at room temperature. The solution was then adjusted to pH 9.0 by gradual addition of 2.5 *N* sodium hydroxide (~10 drops). The suspension was stirred for 16 h, and tetrahydrofuran (20 mL) was added to dissolve the precipitate. The solution was stirred with Bio-Rad AG50W-X2 (H^+) ion exchange resin, filtered, and the filtrate was concentrated to a residue which was triturated with ethyl ether – petroleum ether to give **29** as a sodium salt (30 mg, 80%), $[\alpha]_D^{27}$ −73° (*c* 1.0, dimethylsulfoxide; ms *m/e*: 816 ($M^{+\cdot}$ + Na). *Anal.* calcd. for $C_{44}H_{74}NSO_9Na\cdot H_2O$: C 63.35, H 9.18, N 1.67, S 3.84; found: C 63.45, H 9.19, N 1.72, S 4.00.

Acknowledgements

The authors thank Dr. J. V. Heck for samples of methyl 5-acetamido-4,7,8,9-tetra-*O*-acetyl-3,5-

dideoxy-2-*O*-methyl-α, and β-D-glycero-D-galacto-2-nonulopyranosonates, Dr. B. H. Arison and Mr. H. Flynn for recording 300 MHz spectra, and Mr. J. P. Gilbert and his associates for microanalyses.

Binuclear and mononuclear nickel(II) and zinc(II) complexes of the tetradentate ligand 1,4-di(2′-pyridyl)aminophthalazine

JAMES ALFRED DOULL AND LAURENCE KENNETH THOMPSON[1]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received February 5, 1979

JAMES ALFRED DOULL and LAURENCE KENNETH THOMPSON. Can. J. Chem. **58**, 221 (1980).

Previous studies with the title ligand, PAP, have shown a predominance of binuclear complexes with cobalt and copper in which the ligand-to-metal ratio is 1:2. The nickel complexes produced are more varied in composition; e.g., 1:2 binuclear systems $[PAPNi_2X(OH)(H_2O)_4]X_2$ (X = Cl, Br); 1:1 binuclear systems $[PAP_2Ni_2(H_2O)_4]X_4$ (X = Cl, Br), $[PAP_2Ni_2(NCS)_3]NCS$, $[PAP_2Ni_2(OH)I_2]I\cdot 2H_2O$, $[PAP_2Ni_2(OH)(H_2O)_2]X_3$ (X = ClO_4, BF_4, I); and 2:1 mononuclear systems $[(PAPH)_2Ni(H_2O)_2]X_4$ (X = I, BF_4). Zinc forms both mononuclear, $[PAPZnX_2]\cdot H_2O$ (X = Br, I), and a 1:1 binuclear system, $[PAP_2Zn_2Cl_4]$. Triple bridges are suggested between the nickel atoms in all binuclear systems involving bridging hydroxy groups. Weak antiferromagnetic exchange is observed ($-J < 10\ cm^{-1}$) in two binuclear nickel complexes, which is enhanced in the presence of a hydroxy bridge. Spin–spin coupling is assumed to occur via a superexchange mechanism. In all cases nickel appears to be six-coordinate while for the zinc complexes both four- and six-coordination are observed.

JAMES ALFRED DOULL et LAURENCE KENNETH THOMPSON. Can. J. Chem. **58**, 221 (1980).

Les études antérieures sur le ligand PAP ont révélé la formation prépondérante de complexes binucléaires avec le cobalt et le cuivre, dans lesquels le rapport ligand/métal est 1:2. On a préparé des complexes de nickel qui ont une composition plus variée i.e. des systèmes binucléaires 1:2 $[PAPNi_2X(OH)(H_2O)_4]X_2$ (X = Cl, Br), des systèmes binucléaires 1:1 $[PAP_2Ni_2(H_2O)_4]X_4$ (X = Cl, Br), $[PAP_2Ni_2(NCS)_3]NCS$, $[PAP_2Ni_2(OH)I_2]I\cdot 2H_2O$, $[PAP_2Ni_2(OH)(H_2O)_2]X_3$ (X = ClO_4, BF_4, I) et des systèmes mononucléaires 2:1 $[(PAPH)_2Ni(H_2O)_2]X_4$ (X = I, BF_4). Le zinc forme deux types de complexes: l'un mononucléaire $[PAPZnX_2]\cdot H_2O$ (X = Br, I) et l'autre binucléaire 1:1 $[PAP_2Zn_2Cl_4]$. On suggère un triple pont entre l'atome de nickel et tous les systèmes binucléaires faisant intervenir un groupe hydroxyle en position de pont. On observe un faible échange antiferromagnétique ($-J < 10\ cm^{-1}$) entre des complexes binucléaires du nickel. Cet échange est favorisé par la présence d'un groupe hydroxyle en position de pont. On pense que le couplage de spin se produit par l'intermédiaire d'un mécanisme de superéchange. Dans tous les cas le nickel semble être hexacoordonné alors que dans le cas des complexes de zinc on observe des composés tétra ainsi que hexacoordonnés.

Introduction

Potentially binucleating ligands are important in model studies of metalloproteins containing two metal ions in close proximity, e.g., Type III copper systems, hemocyanin, and hemerythrin. Binuclear complexes, in which two metals are brought into close proximity, require bridging groups that generally involve one or two donor atoms. The binucleating ligand 2-pyridinealdazine (PAA), investigated by Stratton and Busch (1), was an early example of a system involving a two atom azine bridge. More recent examples of binuclear complexes involving azine type ligands include disubstituted pyrazole, pyridazine, and phthalazine systems (2–7). Binuclear Schiff base complexes involving single atom oxygen bridges have also been reported (8).

In previous papers (9, 10) we described some binuclear copper and cobalt complexes of the ligand 1,4-di(2′-pyridyl)aminophthalazine (Fig. 1, ligand abbreviated PAP). In all cases binuclear species were obtained with double or triple bridging units connecting the two metal centres. Strong antiferromagnetic exchange was observed for the complex $[PAPCu_2(OH)(H_2O)_4](IO_3)_3$ ($-J$ = 167 cm^{-1}) and much weaker exchange for the cobalt complexes $[PAPCo_2X_3]$ (X = Cl, Br, I), $[PAPCo_2(OH)(NCS)_2]\cdot H_2O$ ($-J$ = 3.3–5.5 cm^{-1}). We report here a series of binuclear 1:1 nickel and zinc derivatives of PAP, in which two metals are bound simultaneously to two adjacent ligands, 1:2 binuclear derivatives and also some mononuclear derivatives. For the binuclear complexes, bridging groups include just the phthalazine framework in some cases, while in others additional bridging groups, e.g., hydroxide and halide are proposed. Preliminary variable temperature magnetic susceptibility studies indicate weak antiferromagnetic exchange for two binuclear nickel complexes.

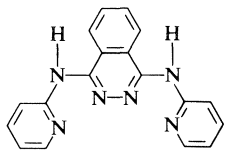

FIG. 1. 1,4-Di(2′-pyridyl)aminophthalazine.

Experimental

Electronic spectra were recorded with a Cary 17 spectrometer and infrared spectra with a Perkin-Elmer model 283 spectrometer. Magnetic susceptibilities were obtained at room tem-

perature by the Faraday method using a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance. Variable temperature magnetic susceptibilities were measured in the Chemistry Department, University of British Columbia, by the Gouy method on equipment previously described (11). The molar susceptibilities, χ_{Ni}, were corrected for the diamagnetism of all atoms and temperature independent paramagnetism. Conductance data were obtained with a General Radio Company bridge with impedance comparator and a constant temperature bath adjusted to 25°C.

Microanalyses were carried out in part in the Chemistry Department at Memorial University using a Perkin-Elmer model #240 Elemental Analyzer and by Atlantic Microlab, Inc., Atlanta, GA. Metal analyses were determined by atomic absorption with a Varian Techtron AA-5, after digestion of the samples in concentrated HNO_3 or aqua regia.

Nickel Complexes of PAP

The ligand, 1,4-di(2′-pyridyl)aminophthalazine was prepared as described previously (9).

*$[PAP_2Ni_2(H_2O)_4]Cl_4 \cdot 3H_2O$ (**I**)*

PAP (1.50 g, 4.77 mmol) was added to a solution of $NiCl_2 \cdot 6H_2O$ (1.13 g, 4.77 mmol) in water (50 mL) and the mixture heated with stirring until all the ligand dissolved. The resulting purple solution was filtered and reduced in volume. A mixture of purple and green crystals was obtained on standing. On drying both crystalline forms at 80°C under vacuum for 1 h, green powders were obtained which were shown to be the same compound according to electronic and infrared spectral data. Recrystallization was effected from water giving a crystalline mixture as before. The two crystalline forms appear to be different hydrated species of the same basic structure. Controlled dehydration by heating under vacuum was difficult and various hydrates can be obtained, according to analytical data, depending on the temperature and the drying time. The air-dried purple complex (**I**) contained seven water molecules, whereas on drying under vacuum (0.05 mm Hg) at 80°C for 3 h a green complex (**II**) containing two water molecules (see Table 1) was obtained. The purple bromide salt (**III**) was prepared similarly and again differing hydrated species were obtained.

*$[PAP_2Ni_2(OH)I_2]I \cdot 2H_2O$ (**V**)*

PAP (1.00 g, 3.18 mmol) was added to a solution of NiI_2 (1.0 g, 3.19 mmol) in methanol (175 mL) and the mixture refluxed until a clear green solution was obtained. On filtering the solution and allowing it to stand for a week green crystals were obtained. The product was filtered, washed with methanol/ether (50/50), and dried under vacuum at 80°C for 2 h.

*$[PAP_2Ni_2(NCS)_3]NCS$ (**VI**)*

PAP (1.00 g, 3.18 mmol) was dissolved in a minimum volume of refluxing ethanol and $Ni(NCS)_2$ (1.20 g, 6.86 mmol) dissolved in ethanol containing a small amount of water. The solutions were mixed and refluxed until a pale green precipitate formed. The reaction mixture was allowed to stand overnight and the green powdery product filtered, washed with ethanol, and air dried. Recrystallization was effected from methanol and the product dried under vacuum at 80°C for 3 h.

*$[PAP_2Ni_2(OH)(H_2O)_2](ClO_4)_3$ (**VII**)*

PAP (1.50 g, 4.77 mmol) was added to a solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (1.80 g, 4.92 mmol) in water (600 mL) and the mixture refluxed until a pale green solution was obtained. The solution was filtered and reduced in volume until green crystals formed. The product was recrystallized from water and dried under vacuum at 80°C for 3 h.

*$[PAP_2Ni_2(OH)(H_2O)_2](BF_4)_3$ (**VIII**), $[(PAPH)_2Ni(H_2O)_2](BF_4)_4$ (**XII**)*

PAP (0.750 g, 2.39 mmol) was added to $Ni(BF_4)_2 \cdot 6H_2O$ (0.850 g, 2.49 mmol) in water (75 mL) and the mixture refluxed for 2 h. The green solution was filtered and reduced in volume until a greyish green crystalline solid formed (**XII**). This product was filtered, washed with water, and dried under vacuum at room temperature for 1 h. The purple–blue mother liquor was reduced further in volume and allowed to stand at room temperature. Turquoise–green crystals (**VIII**) were obtained, and were filtered, washed with water, and dried under vacuum at room temperature. The binuclear derivative (**VIII**) was obtained as the sole product by adjusting the pH of the nickel tetrafluoroborate solution to 5.5 by addition of fluoride (see Discussion).

*$[PAP_2Ni_2(OH)(H_2O)_2]I_3 \cdot 3H_2O$ (**IX**), $[(PAPH)_2Ni(H_2O)_2]I_4$ (**XIII**)*

PAP (1.00 g, 3.18 mmol) was added to a solution of NiI_2 (1.00 g, 3.19 mmol) in water (100 mL) and the mixture refluxed until a purple–blue solution was formed. The solution was filtered and allowed to stand until yellow–green crystals formed

(**XIII**). The product was filtered, washed with water, and dried under vacuum at 80°C for 2 h. The mother liquor was reduced in volume on a steam bath until more product (**XIII**) formed. The mixture was cooled and treated as before. At this stage a total of about 0.4 g of material had been collected. Further reduction in volume produced a khaki–green crystalline material (**IX**) (0.8 g) which was filtered, washed with water, and dried under vacuum at 60°C for 2 h.

*[PAPNi$_2$Cl(OH)(H$_2$O)$_4$]Cl$_2$ (**X**)*

PAP (1.00 g, 3.18 mmol) was added to a solution of $NiCl_2 \cdot 6H_2O$ (1.55 g, 6.51 mmol) in 80% acetic acid (12 mL) and the mixture refluxed for 1 h. A pale green solid formed which was filtered, washed with ethanol and ether, and dried under vacuum at room temperature for 3 h.

The analogous bromide complex (**XI**) was prepared similarly as a green solid. On drying under vacuum at 80°C for 6 h the bromide complex was obtained as a buff–yellow solid while the chloride derivative changed to a yellow–green solid. On exposure to air both compounds reverted to their original green forms.

*[PAP$_2$Zn$_2$Cl$_4$] (**XIV**)*

PAP (1.00 g, 3.18 mmol) was dissolved in hot ethanol (100 mL) and added to a hot solution of anhydrous zinc chloride (1.00 g, 7.33 mmol) in ethanol (60 mL). A pale yellow precipitate formed in the hot solution. The product was purified by soxhlet extraction in methanol and dried under vacuum at 80°C for 2 h.

The other zinc complexes were prepared similarly from methanol using anhydrous zinc salts.

Results and Discussion

Characterization of the Complexes

Nickel Complexes

PAP preferentially binds two metal ions and mononuclear complexes are not common. Previously reported binuclear complexes of PAP with cobalt and copper include just systems in which the ligand-to-metal ratio is 1:2 (9, 10). The nickel complexes, however, are different in that 1:1 binuclear systems involving two ligands bridging two metals are most common. In these binuclear systems PAP behaves as a tetradentate ligand coordinating through two phthalazine and two pyridine nitrogen atoms and the nickel ions adopt pseudo-octahedral stereochemistries. 1:2 Binuclear derivatives can also be produced but are hydrolytically unstable. A 2:1 pseudo-octahedral mononuclear complex cation is formed in the reaction between PAP and both nickel tetrafluoroborate and nickel iodide in water. This system involves the coordination of two protonated bidentate ligands in which one phthalazine and an adjacent pyridine nitrogen are involved in bonding to the metal.

Electronic Spectra and Structure

Two major absorptions are observed in the solid state mull transmittance spectra of all the 1:1 binuclear nickel complexes corresponding to the ν_1 and ν_2 transitions for pseudo-octahedral nickel(II) (Table 2). The ν_3 transition, which should occur above 25 000 cm^{-1} for predominantly nitrogen bound systems, is obscured in all cases by charge transfer absorption associated with the ligand itself. In addition a shoulder is observed in some cases on the low energy side of ν_2, which is assigned to a spin-forbidden transition. No splitting of ν_2 is observed in these systems and only in the case of the iodide complex (**V**) is there any splitting of ν_1. This is perhaps surprising, since the symmetry of the crystal field around the nickel ion in these systems will be lower than octahedral. Other 1:1

binuclear nickel complexes involving similar ligands, e.g., 1,4-dihydrazinophthalazine and 3,6-di(2′-pyridyl) pyridazine (4) exhibit electronic spectra in which large splittings of ν_1 (1500–5900 cm^{-1}) and ν_2 (900–5100 cm^{-1}) are observed. These spectra are interpreted in terms of a tetragonal crystal field. The absence of splitting of ν_1 or ν_2 is perhaps indicative of *cis*- rather than *trans*-NiN_4X_2 chromophores (12). A splitting of ν_1 of 1800 cm^{-1} is observed for the iodide complex (**V**) which suggests a possible *trans* structure.

The binuclear 1:1 perchlorate (**VII**), tetrafluoroborate (**VIII**), and iodide (**IX**) complexes are assigned *cis*-NiN_4O_2 structures involving bridging phthalazines and bridging hydroxy groups, the sixth coordination site at each metal being occupied by water (Fig. 2). The solid state spectra of the purple 1:1 binuclear chloride (**I**) and bromide (**III**) complexes are identical, and since the aqueous solution spectrum of the chloride complex is the same as its solid state spectrum, *cis*-NiN_4O_2 solid state structures are proposed in which water molecules occupy the fifth and sixth coordination sites at each nickel centre.

In the case of the green chloride complex **II** obtained by heating **I** under vacuum, a slight lowering in energy of the ν_1 and ν_2 bands is observed in keeping with a system containing some coordinated halide. A more pronounced lowering of ν_1 is observed for the corresponding bromide complex (**IV**), while ν_2 decreases by only 200 cm^{-1}. It is clear that water is again displaced by halogen in the metal coordination sphere. Heating the purple hydrated chloride and bromide complexes under vacuum gives various lower hydrates. When the number of water molecules per nickel atom is less than two, green or khaki–green coloured complexes are obtained. However, determining just how many coordinated halide groups exist in these dried complexes and whether or not bridging halides are to be found is difficult. Far infrared spectra have not been useful and conductivity studies are of no use since solvated species are produced in solution.

The 1:2 binuclear chloride and bromide complexes (**X**, **XI**) have solid state spectra in which there is a significant splitting of ν_1 (Table 2) and the band positions are shifted to lower energy compared with the 1:1 systems. In a six-coordinate 1:2 binuclear species only two coordination sites per metal would be occupied by ligand nitrogen atoms and the remaining sites could be occupied by water, hydroxide, and possibly halide, in keeping with the lower energy absorptions. Analytical and infrared data indicate the presence of a hydroxy group in these compounds and binuclear structures involving both bridging phthalazine and hydroxy groups are suggested. An X-ray study on the complex $[PAPCu_2Cl_3(OH)]\cdot H_2O$ has shown the presence of a triple bridge between square pyramidal copper atoms, involving bridging phthalazine, hydroxy, and chloro groups (9, 13). Molecular models indicate that such a structure would be possible for the 1:2 nickel halide complexes and that including a sixth ligand (i.e. water) at each pseudo-octahedral metal centre would present no steric problems. Both ν_1 and ν_2 for the bromide complex occur at lower energy than corresponding bands for the chloride complex suggesting the presence of a halide bridge in both systems (Fig. 3) (see also discussion on infrared data). Prolonged drying of the complexes, by heating under vacuum, produced colour changes (Cl, yellow–green; Br, buff–yellow) which suggested a change in the metal coordination sphere. This was reflected in their electronic spectra in which shifts to lower energy were observed on drying, suggesting the presence of coordinated terminal halide groups. On exposure to air again the original spectra were obtained indicating that water had displaced halogen in the coordination sphere.

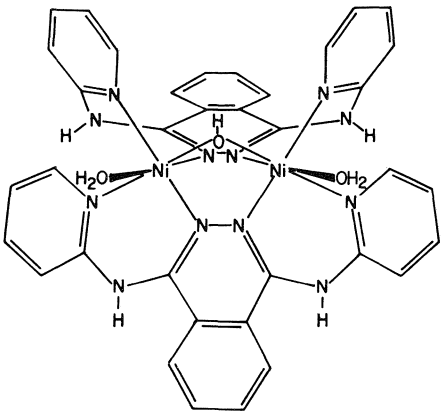

FIG. 2. A proposed structure for the cation in the complex $[PAP_2Ni_2(OH)(H_2O)_2](ClO_4)_3$.

Addition of the 1:2 binuclear derivatives to water produced an insoluble pale green precipitate, identified as nickel hydroxide, and purple solu-

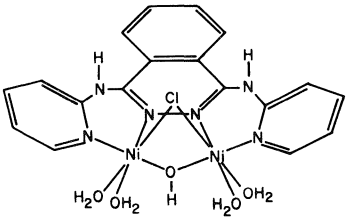

FIG. 3. A proposed structure for the cation in the complex $[PAPNi_2Cl(OH)(H_2O)_4]Cl_2$.

tions. Electronic spectra of these solutions exhibited bands due to $[PAP_2Ni_2(H_2O)_4]^{4+}$ and also an additional band around 9000 cm^{-1} assigned to ν_1 for $[Ni(H_2O)_6]^{2+}$. It appears therefore that the 1:2 binuclear complexes disproportionate in aqueous solution, possibly as follows:

$$2[PAPNi_2X(OH)(H_2O)_4]X_2 \rightarrow [PAP_2Ni_2(H_2O)_4]X_4 + NiX_{2\,(aq)} + Ni(OH)_{2\,(s)} + 4H_2O$$

The 1:1 binuclear complexes are clearly more stable in aqueous solutions. In concentrated acetic acid the minimal water present is sufficient to provide a source of ligands, but not to destroy the 1:2 system.

The 1:1 binuclear iodide complex (**V**) exhibits a splitting of ν_1 of 1800 cm^{-1}, suggesting the possibility of a *trans* structure involving four equatorial nitrogen donors. The lower energy absorptions indicate coordinated iodine and since PAP appears to be neutral (9) a hydroxide bridge is also proposed. The structure of this complex would thus be the *trans* equivalent of that proposed for **VII**, **VIII**, and **IX** (Fig. 2), but would have at least one axial site occupied by iodine. A *trans* structure is appropriate in this case in view of the bulk of the iodine atom. In aqueous solution ν_1 and ν_2 are observed at higher energy, consistent with an aquated species.

No splitting is observed for ν_1 or ν_2 in the case of the 1:1 binuclear thiocyanate complex (**VI**). ν_2 occurs at approximately the same energy as it does in the 1:1 halide complexes involving *cis*-NiN_4O_2 chromophores. However, ν_1 is reduced by 900 cm^{-1}, suggesting a somewhat weaker crystal field at the nickel centre.

The mononuclear 2:1 derivatives (**XII**, **XIII**) exhibit no splitting of ν_1 or ν_2 and the band energies are consistent with a Ni–N_4O_2 chromophore. The absence of splitting may be indicative of a *cis* rather than a *trans* structure. However, the tetrafluoroborate complex (**XII**) has an almost identical infrared spectrum to an analogous copper complex, $[(PAPH)_2Cu(H_2O)_2](BF_4)_4$, which has a tetragonal structure involving bidentate ligands coordinating via one pyridine and one nitrogen atom (the other pyridine nitrogen appears to be protonated) according to recent X-ray studies (14). It seems likely therefore that the nickel systems have a similar *trans* Ni—N_4O_2 structure.

In aqueous solution the nickel complexes exhibit an intense charge transfer absorption in the range 28 600–28 900 cm^{-1} (Table 2). In some cases this band can be observed in the solid state spectrum, but at slightly lower energies. This absorption is assigned to a π–π^* transition and has been used previously (9) to assess the charged state of the ligand. In a series of copper complexes, in which a neutral ligand species was involved, this band was found in the range 27 400–29 600 cm^{-1}. It is thus apparent, in keeping with other data, that PAP is a neutral species in all the nickel complexes.

The solution spectrum of the purple 1:1 chloride complex (**I**) is the same as its solid state spectrum, indicating a system involving two coordinated water molecules per nickel in both states. However, in the case of the purple bromide complex (**III**) the solution spectrum differs somewhat from its solid state spectrum. ν_1 occurs as a broad single band at 11 400 cm^{-1} in the solid state but in solution is replaced by a peak at 10 300 cm^{-1} and a shoulder of comparable intensity at 11 600 cm^{-1}. The component of ν_1 at 11 600 cm^{-1} corresponds almost exactly with ν_1 for the purple tetraaquo complex (**III**), while that at 10 300 cm^{-1} is close to ν_1 for the green bromo complex (**IV**). The bromide complex (**III**) may exist as a mixture of the tetraaquo complex and a bromo derivative in aqueous solution. The same spectrum is obtained by dissolving the green bromide complex (**IV**) in water.

Infrared Data

In a previous paper we assigned an absorption at 989 cm^{-1} in PAP to a ring breathing mode associated with the pyridine residues (9). A shift of this band above 1000 cm^{-1} indicated a coordinated pyridine ring. In most of the binuclear complexes this band is observed above 1000 cm^{-1} (Table 3) with no residual band associated with uncoordinated pyridine. In the case of the binuclear tetrafluoroborate complex (**VIII**) the ν_3 absorption associated with the tetrafluoroborate ion masked the coordinated pyridine band. However no absorption due to free pyridine was observed.

Rather broad absorptions are observed for the 1:1 binuclear halide complexes (**I**, **III**) in the range 3600–3200 cm^{-1}. However, a band at 3550 cm^{-1} in the bromide complex is assigned to coordinated water. The general similarity of the spectra of these species, especially in the far infrared region, suggests the same solid state cations involving coordinated water rather than halide. In the case of the 1:1 binuclear tetrafluoroborate complex (**VIII**) peaks at 3625 and 3550 cm^{-1} are assigned to coordinated water and bridging hydroxide, although distinction between the two may not be possible. The analogous perchlorate complex (**VII**) exhibits a broad shoulder in this region and assignments due to coordinated water and bridging hydroxide could not be made. Peaks at 3370 cm^{-1} (BF_4^-) and 3360 cm^{-1} (ClO_4^-) are assigned to NH stretch and absorptions associated with the tetrafluoroborate and per-

chlorate groups themselves indicate that these anions are uncoordinated.

The 1:1 binuclear iodide complexes (**V**, **IX**) have very similar infrared spectra and both bear a close resemblance to the spectra of the binuclear hydroxo bridged derivatives **VII** and **VIII**. $[PAP_2Ni_2(OH)(H_2O)_2]I_3 \cdot 3H_2O$ (**IX**) exhibits an OH stretching absorption at 3550 cm^{-1} and an absorption at 3380 cm^{-1} due to NH stretching. These peaks are close to those observed for **VII** and **VIII** and support a hydroxy bridged structure involving two coordinated water molecules. The iodide complex (**V**), prepared in methanol, exhibits only a broad absorption in this region with a peak at 3270 cm^{-1}, which can be associated with NH stretch. No peak due to OH stretch could be discerned. The differences in the range 3200–3600 cm^{-1} could be associated with a system having the same basic structure as **IX** but involving coordinated iodine rather than water.

The 1:2 binuclear halide complexes (**X**, **XI**) exhibit a sharp absorption at 3530 cm^{-1}, which is assigned to OH stretching associated with a bridging hydroxy group, while a broad absorption around 3360–3370 cm^{-1} is assigned to NH stretch. In the far infrared a comparison of the spectra of the hydrated complexes (**X**, **XI**) with their dried counterparts allowed certain assignments to be made. Bands in the range 308–328 cm^{-1}, common to all four species, are assigned to Ni—N stretch. Absorptions at 275, 282 cm^{-1} (Cl) and 231 cm^{-1} (Br) in the dried compounds disappear on exposure to air and are assigned to terminal nickel–halogen stretch, and a strong absorption around 242–246 cm^{-1}, common to all species, may be associated with nickel–oxygen stretch in the bridging hydroxy group. The absence of terminal nickel halogen stretching vibrations in **X**, **XI** suggests the coordination of two water molecules at each nickel centre.

The thiocyanate complex (**VI**) exhibits a most unusual infrared spectral region due to CN(NCS) stretching. Strong absorptions at 2098 and 2048 cm^{-1} are assigned to nitrogen bound and ionic thiocyanate respectively while a strong, low energy absorption at 2002 cm^{-1} cannot be assigned to a normal thiocyanate group. The complex is clearly a 1:1 binuclear derivative involving six-coordinate nickel which leaves four coordination sites available for thiocyanate coordination. Assuming the presence of one ionic thiocyanate a reasonable way for the other three groups to be accommodated would involve two isothiocyanates and a thiocyanate bridge. Molecular models and other data suggest that a three atom bridge between the two metal centres would be unlikely, but a single atom bridge would, of course, be possible. The low energy thiocyanate absorption could therefore be associated with a single atom nitrogen bridged thiocyanate in which the CN bond order is somewhat lower than usual. Further studies, including an X-ray structural determination, are necessary to confirm this.

NOTE ADDED IN PROOF: A recent X-ray structure of the complex $(n\text{-}Bu_4N)_3[Re_2(NCS)_{10}]$ reveals the presence of two solely N-bonded bridging thiocyanate groups (17). Infrared absorptions at 1920 and 1885 cm^{-1} are assigned to CN stretching in these bridging groups.

In the protonated mononuclear complexes (**XII**, **XIII**) PAP coordinates as a bidentate ligand via one phthalazine and one pyridine nitrogen atom. The ν_3

vibration associated with the tetrafluoroborate anion masks the pyridine ring breathing vibrations in **XII**, but three bands (Table 3) are observed in this region for the iodide complex. Bands at 1015 and 1008 cm^{-1} can be associated with coordinated pyridine moieties while the band at 998 cm^{-1} is consistent with a protonated pyridine ring (a hydrochloride salt of PAP in which both pyridine rings appear to be protonated has just one absorption in this region at 1003 cm^{-1}).

Magnetism and Conductance

The binuclear perchlorate (**VII**), tetrafluoroborate (**VIII**), and iodide (**V**) complexes have room temperature magnetic moments close to the spin only value, which are comparable with those observed for 1:1 binuclear complexes of 1,4-dihydrazinophthalazine (4) for which $-J$ values fall in the range 20–24 cm^{-1}. Variable temperature susceptibility studies have been carried out on the chloride (**I**) and perchlorate (**VII**) complexes in the temperature range 80–300 K and preliminary results using the conventional model for two interacting $S = 1$ states (4) (Table 4) indicate smaller J values ($-J$ less than 10 cm^{-1}) than were found for other disubstituted diazine systems (4). This difference may be due to the fact that in the PAP complexes six-membered chelate rings are formed, as opposed to five in the other diazine systems, with the result that orbital overlap between the metal centres and the π-molecular orbital system of the phthalazine bridge will be reduced because of the non-planarity of the ligand. Direct orbital overlap between the metal centres seems unlikely and a superexchange mechanism is suggested via the bridging groups. It is significant that a larger exchange is observed for the perchlorate complex which is assumed to have a hydroxy bridge in addition to the phthalazine bridge. Further studies on the spin–spin exchange in these systems are planned down to liquid helium rather than liquid nitrogen temperatures.

Conductance data (Table 4) were obtained for some systems in aqueous solution as a function of concentration and the slopes of Kohlrausch plots for the chloride (**I**) and perchlorate (**VII**) complexes indicate 1:4 and 1:3 electrolytes respectively (15). An anomalously large slope was observed for the mononuclear tetrafluoroborate complex (**XII**) indicating the presence of more ions in solution than expected. The tetrafluoroborate ion hydrolyses in aqueous solution are as follows (16):

$$BF_4^- + H_2O \rightleftharpoons BF_3(OH)^- + HF \qquad K = 2.3 \times 10^{-3}$$

Subsequent dissociation of HF and possible dissociation of protonated PAP could be responsible for the high conductance of this system. The pH of an approximately 0.1 mol dm^{-3} solution of nickel tetrafluoroborate was found to be 2.5 (calculated pH 2.3). It is thus no surprise that a protonated mononuclear complex is obtained from the reaction of PAP with $Ni(BF_4)_2$ in water. Adjustment of the pH of nickel tetrafluoroborate solution can be achieved by controlled addition of fluoride ion. Reaction of PAP with an aqueous solution of nickel tetrafluoroborate (pH adjusted to 5.5 by addition of fluoride) gave only the 1:1 binuclear derivative (**VIII**).

A similar mixture of compounds was obtained from the reaction between nickel iodide and PAP in water. In this case the formation of a protonated complex is somewhat surprising, since the aqueous nickel iodide used in our studies was only slightly acidic (approximately 0.1 mol dm^{-3}, pH = 6.0). However, if the hydroxy bridged species is the most thermodynamically favoured binuclear system, protons would be present in solution, which would be responsible for the formation of the protonated complex. That such a species is not observed for the perchlorate system may simply be a reflection on its solubility. In the case of the tetrafluoroborate system the hydrolysis of BF_4^- just enhances the acidity.

[b]$-J = 3.2$ cm^{-1}, $g = 2.20$.
[c]$-J = 7.3$ cm^{-1}, $g = 1.93$.

Zinc Complexes

The zinc complexes of PAP were obtained as fairly insoluble yellow or pale yellow solids from ethanol or methanol. Elemental analyses indicate that in all the complexes the ligand-to-metal ratio is 1:1.

Infrared data (Table 3) indicate that in the chloro complex (**XIV**) PAP is acting as a tetradentate

ligand and so a 1:1 binuclear structure is proposed. Two sharp bands are observed in the far infrared spectrum of the chloro complex, which are assigned to Zn—Cl stretch, suggesting that each zinc ion is in a six-coordinate *cis*-N_4Cl_2 environment.

The other zinc complexes exhibit two pyridine ring breathing mode absorptions, which indicate that PAP coordinates as a bidentate ligand through one phthalazine and one pyridine nitrogen. Absorptions in the far infrared at 238, 210 cm^{-1} for the bromo-complex (**XV**) suggest a tetrahedral ZnN_2Br_2 chromophore, with water bound in the lattice. The similarity between the infrared spectrum of this system and that of the iodo-complex (**XVI**) suggests a tetrahedral ZnN_2I_2 structure for the iodide complex.

Excess volumes of toluene mixtures with some alcohols at 303.15 K

GOOLLA NARAYANA SWAMY, GOLLA DHARMARAJU, AND GURAJALA KODANDA RAMAN
Department of Chemistry, College of Engineering, Sri Venkateswara University, Tirupati 517 502, India

Received July 30, 1979

GOOLLA NARAYANA SWAMY, GOLLA DHARMARAJU, and GURAJALA KODANDA RAMAN. Can. J. Chem. **58**, 229 (1980).

Excess volumes for binary mixtures of toluene with 1-propanol, 2-propanol, 1-butanol, 2-methyl-1-propanol, 1-pentanol, 1-hexanol, 1-heptanol, and cyclohexanol have been measured as a function of composition at 303.15 K by a dilatometric method. The excess volume curves for 1-propanol and 1-butanol are sigmoid. For other alcohols V^E values are positive over the entire composition range.

GOOLLA NARAYANA SWAMY, GOLLA DHARMARAJU et GURAJALA KODANDA RAMAN. Can. J. Chem. **58**, 229 (1980).

On a mesuré les volumes d'excès des mélanges binaires du toluène avec les alcools suivants: propanol-1, propanol-2, butanol-1, méthyl-2 propanol-1, pentanol-1, hexanol-1, heptanol-1 et le cyclohexanol en fonction de la composition à 303.15 K en utilisant une méthode dilatométrique. Les courbes de volume d'excès du propanol-1 et du butanol-1 sont sigmoides. Dans le cas des autres alcools, les valeurs de V^E sont positives pour toutes les échelles de composition.

Introduction

Alcohols are strongly self-associated (1) and for binary solutions rich in alcohol a three dimensional network of hydrogen bonded alcohol molecules is believed to be present (2, 3). A good deal of work has been reported by Washburn and Lightbody (4) on the excess volumes of mixtures of methanol, ethanol, and 2-propanol with toluene and benzene as common components. The purpose of the present investigation is to study the effect of a non-polar solvent like toluene on excess volumes of some alcohols. The alcohols selected were 1-propanol, 2-propanol, 1-butanol, 2-methyl-1-propanol, 1-pentanol, 1-hexanol, 1-heptanol, and cyclohexanol.

Experimental

Materials

Analytical grade toluene was purified in accordance with the procedure suggested in literature (5). All alcohols except 1-heptanol were dried by refluxing with fused calcium oxide and distilling from it. Heptanol (Koch-Light Laboratories Ltd., England) was used without further purification. The purities of the liquids were checked by comparing measured densities with those reported in the literature (6). Excess volumes as a function of composition were determined dilatometrically by the method described by Rao and Naidu (7). The experimental method was previously checked (8) against cyclohexane + benzene at 303.15 K, and the results obtained showed a standard deviation of ± 0.003 cm^3 mol^{-1}.

Results

The results[1] at 303.15 K are graphically represented in Fig. 1. The experimental values of V^E may

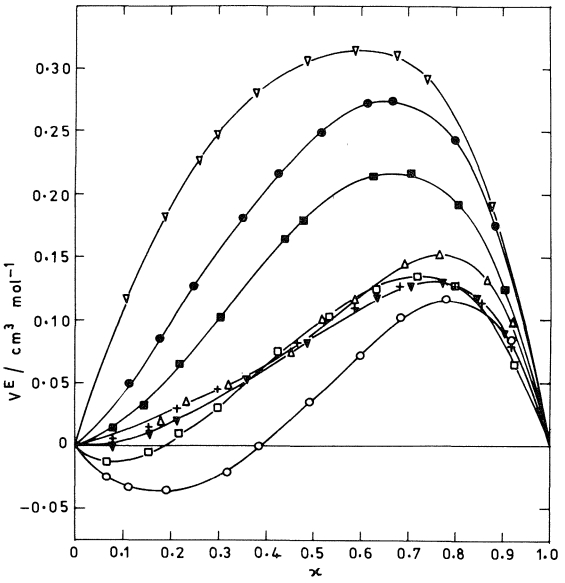

FIG. 1. Excess volumes V^E plotted against mole fraction x of toluene at 303.15 K for the mixtures of toluene with alcohols: ○, 1-propanol; ●, 2-propanol; □, 1-butanol; ■, 2-methyl-1-propanol; △, 1-pentanol; ▼, 1-hexanol; +, 1-heptanol; ▽, cyclohexanol.

be represented by an empirical equation

$$[1] \quad V^E/\text{cm}^3\,\text{mol}^{-1} = x(1-x)[a_0 + a_1(2x-1) + a_2(2x-1)^2]$$

where x is the mole fraction of toluene. The values of the parameters a_0, a_1, and a_2 evaluated by the method of least-squares are given in Table 1 along with standard deviation $\sigma(V^E)$.

Discussion

The curves for mixtures of toluene with 1-

Toluene + 2-methyl-1-propanol	0.738	0.754	0.145	0.004
Toluene + 1-pentanol	0.359	0.645	0.577	0.002
Toluene + 1-hexanol	0.348	0.590	0.280	0.003
Toluene + 1-heptanol	0.367	0.573	0.306	0.004
Toluene + cyclohexanol	1.229	0.368	0.486	0.001

propanol and 1-butanol are sigmoid. The excess volumes for mixtures of toluene with 1-propanol and 1-butanol are negative at lower mole fractions of toluene and positive at higher mole fractions. For other mixtures the values of V^E are positive over the entire concentration range. V^E values for 2-propanol, 2-methyl-1-propanol, and cyclohexanol are larger than normal alcohols. For equimolar mixtures V^E values fall in the order 1-propanol < 1-butanol ≈ 1-pentanol ≈ 1-hexanol ≈ 1-heptanol < 2-methyl-1-propanol < 2-propanol < cyclohexanol.

Numerous studies (9–11) indicate that alcohols are associated through hydrogen-bonded linear chains (with restricted rotation about hydrogen bonds) into variable degrees of polymerisation. According to Treszczanowicz and Benson (12) the observed V^E data may be explained qualitatively by postulating that V^E is the resultant of opposing effects. The positive V^E values arise due to the breaking of hydrogen bonds in self-associated alcohols and physical dipole–dipole interactions between alcohol monomers and multimers. Negative contributions arise from changes of "free volume" in the real mixture and the presence of π-electrons in toluene resulting in the formation of weak intermolecular complexes. The results show that the negative contributions decrease with increase in chain length. But the positive values of V^E for 1-butanol, 1-pentanol, 1-hexanol, and 1-heptanol which are almost equal suggest that the positive V^E values are insensitive to the chain length. Negative contributions get more and more sterically hindered when the alkyl group in the alcohol becomes more and more branched, which is observed in the behaviour of mixtures with 2-propanol and 2-methyl-1-propanol. Washburn and Lightbody (4) have reported excess volumes of toluene + 2-propanol at 298.15 K using density measurements which also show similar trend. The maximum value of V^E for cyclohexanol may be due to less self-association than other alcohols.

Ion mobilities and collision frequencies in gaseous CH_3Cl, HCl, HBr, H_2S, NO, and SF_6: effects of polarity of the gas molecules

ERIC S. SENNHAUSER AND DAVID A. ARMSTRONG

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received August 13, 1979

ERIC S. SENNHAUSER and DAVID A. ARMSTRONG. Can. J. Chem. **58**, 231 (1980).

Mobilities of positive and negative ions at 296 K have been measured at pressures in the range 50 to 1200 Torr. Least-mean-squares analysis of the pressure dependences gave the following mobilities normalized to a density of 2.69×10^{19} molecules cm^{-3}: CH_3Cl $\mu_+ = 0.39$, $\mu_- = 0.37$; HCl 0.64, 0.59; HBr 0.48, 0.49; H_2S 0.59, 0.60; NO 0.97, 1.53; SF_6 $\mu_- = 0.49$ $cm^2 V^{-1} s^{-1}$. Except in one instance the ions exhibited a close to inverse dependence of mobility on gas density. The identities of the ions are discussed in the light of high pressure mass spectrometric data from the literature. The dependence of the collision frequencies of the ions on $\mu_D/\alpha^{1/2}$, the ratio of dipole moment to (polarizability)$^{1/2}$ for the neutral gas molecules, was very similar to that observed previously by the ion cyclotron resonance technique at much lower pressures. The magnitudes of the collision frequencies at unit concentration are in reasonable agreement with predictions based on the ion–molecule collision rate theory of Barker and Ridge, but the dependence on $\mu_D/\alpha^{1/2}$ is lower and closer to that predicted by ADO theory.

ERIC S. SENNHAUSER et DAVID A. ARMSTRONG. Can. J. Chem. **58**, 231 (1980).

On a mesuré les mobilités des ions positifs et négatifs à 296 K et à des pressions allant de 50 à 1200 Torr. Une analyse, par la méthode des moindres carrés, de l'effet de la pression conduit aux valeurs suivantes des mobilités normalisées à une densité de 2.69×10^{19} molécules cm^{-3}: CH_3Cl $\mu_+ = 0.39$, $\mu_- = 0.37$; HCl 0.64, 0.59; HBr 0.48, 0.49; H_2S 0.59, 0.60; NO 0.97, 1.53; SF_6 $\mu_- = 0.49$ $cm^2 V^{-1} s^{-1}$. A l'exception d'un seul cas, les ions montrent une tendance à inverser l'effet de la pression sur la mobilité dans le cas de la densité des gaz. On discute de l'identité des ions à la lumière des données sur la spectrométrie de masse à haute pression recueillies dans la littérature. L'effet de la fréquence des collisions sur $\mu_D/\alpha^{1/2}$, le rapport du moment dipolaire à une (polarisabilité)$^{1/2}$ pour les molécules de gaz neutre, ressemble beaucoup à celui observé antérieurement par la technique de résonance du cyclotron à des pressions plus faibles. L'ampleur de la fréquence des collisions à concentrations unitaires est raisonnablement en accord avec les prédictions basées sur la théorie de Barker et Ridge concernant la vitesse de collision ion–molécule, mais l'effet sur $\mu_D/\alpha^{1/2}$ est plus faible et plus près de celui prédit par la théorie "ADO".

[Traduit par le journal]

Introduction

The study of ion mobilities in gases leads to information on ion–neutral interaction potentials, and is also of importance for an understanding of ion transport and recombination mechanisms (1). A recent publication (2) from this laboratory described an ionization chamber-drift tube, which could be used at pressures in the range 50 to 1200 Torr. Mobilities for ions in ammonia vapor were reported, and compared to those calculated from ion–molecule collision rate theories (3, 4). This paper presents results for SF_6, H_2S, CH_3Cl, HBr, HCl, and NO. As well as being of interest in radiation chemistry, these gases possess dipole moments which cover a wide range. Therefore more extensive comparisons with ion–molecule rate theory predictions can be made. With the exception of CH_3Cl (5) all of the gases react rapidly with thermal electrons to form heavy negative ions.

Experimental

Materials

Sample preparation and material purification were performed in a mercury-free vacuum line. All gases were obtained from the Matheson Co. and subjected to several freeze–pump–thaw cycles to remove noncondensibles. In addition the NO (research grade), HCl (electronic grade, 99.99% minimum purity), and HBr (anhydrous, 99.8% minimum purity) were distilled several times from an alcohol slurry at 160 K; retaining only the first fractions. The H_2S (C.P., 99.5% minimum purity) was passed through a Linde molecular sieve (type 3A) at 0°C to remove traces of water. Mobility–current profiles were normally rerun after at least one repurification to make sure that no changes in the profile due to further removal of impurities occurred. Only with H_2S was any effect observed. The purified samples were stored at 77 K. Carbon tetrachloride was obtained from Baker Chemicals (spectrophotometric quality). A small quantity was stored in a tube after several freeze–pump–thaw cycles.

Apparatus

A diagram of the ionization chamber-drift tube is shown in Fig. 1. Details of its construction and of the associated electrical components were given in ref. 2. L_1 and L_2 are plane parallel electrodes, while G_1 and G_2 are nickel mesh grids. The radiation compartment of length d_1 (= 1.0 cm) is defined by L_1 and G_1 while the space between G_2 and L_2 of length d_3 (= 1.3 cm) is the collection compartment. The drift space between G_1 and G_2 has a length d_2 of 4.0 cm. The cell was pumped down to $\sim 10^{-6}$ Torr between fillings, and when a change to a new gas was made it was evacuated for several hours, while heated with a hot air blower.

During an experiment a constant intensity collimated 4 mm beam of 40 kV peak X-rays from a Müller MG 150 unit was centered in the radiation compartment. A constant potential, V_{dc}, was applied to G_2. Periodically a high voltage pulse (repetition frequency ~ 8 s^{-1}, rise time ~ 10 μs) of the same polarity as V_{dc} was applied to L_1 to produce fields E_r and E_d in the radiation and drift compartments. These fields could be varied by changing the magnitude of the high voltage pulse, or of R_1, R_2 and V_{dc}.

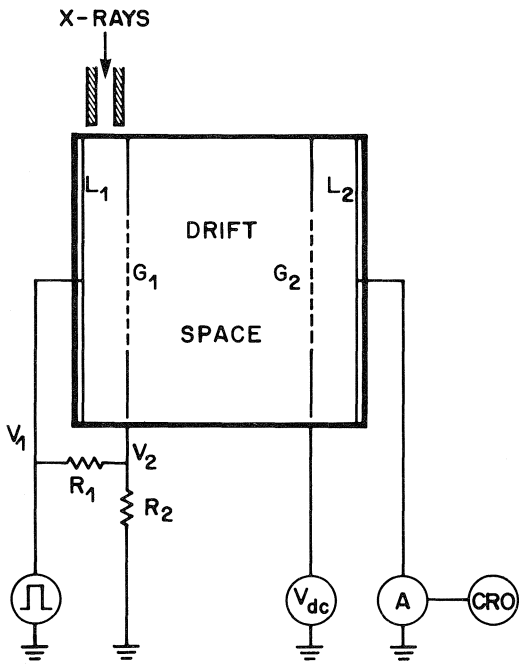

FIG. 1. Ionization chamber-drift tube. V_1 and V_2, pulsed high voltage applied to electrode L_1 and grid G_1; V_{dc}, steady potential applied to grid G_2; L_2, collecting electrode, A, amplifier.

The duration of the pulse was variable, and ions which crossed the 4.0 cm drift compartment before it ended were collected. Those which did not were returned to the irradiation compartment (or to grid G_1) by the potential on G_2. The "time off" of the high voltage was always long enough to allow steady state conditions to be reached in the radiation compartment.

In place of the Victoreen 475 A electrometer used in ref. 2 the output from electrode L_2 was fed into an Analog Device 46 J amplifier A. This has a high input impendance (10^{11} ohm) and high slew rate. It was connected as an inverting current amplifier with a current to voltage gain of $\sim 10^6$. The frequency response begins to drop at 20 kHz, but this was not a problem in following the present transients. The output from the amplifier was displayed on one beam of a Tektronix type 502 A dual beam oscilloscope. The second beam followed the profile of the square wave high voltage pulse, and provided a time base. When desired either trace from a single pulse could be recorded with a Model 8100 Biomation transient recorder and then reproduced on an X-Y recorder.

Data Analysis

In part (*c*) of Fig. 2 a typical trace of a current profile from the biomation recorder has been presented. The high voltage profile has been depicted by the solid line which crosses it and falls to zero just short of 20 ms, where the current profile also ends. As the duration of the high voltage pulse set by the time device (2) was shortened, the current profile was truncated correspondingly. In many experiments the time to peak maximum t_p was determined by shortening the voltage pulse until the "time off" coincided with it. Alternatively it could be measured from the abscissa of the oscilloscope or biomation traces.

In part (*a*) of Fig. 2 a representative detector signal of the type obtained with the electrometer used earlier (2) has been shown. This instrument measured the integrated charge per unit volume of the radiation compartment η/d_1, which reached the collection

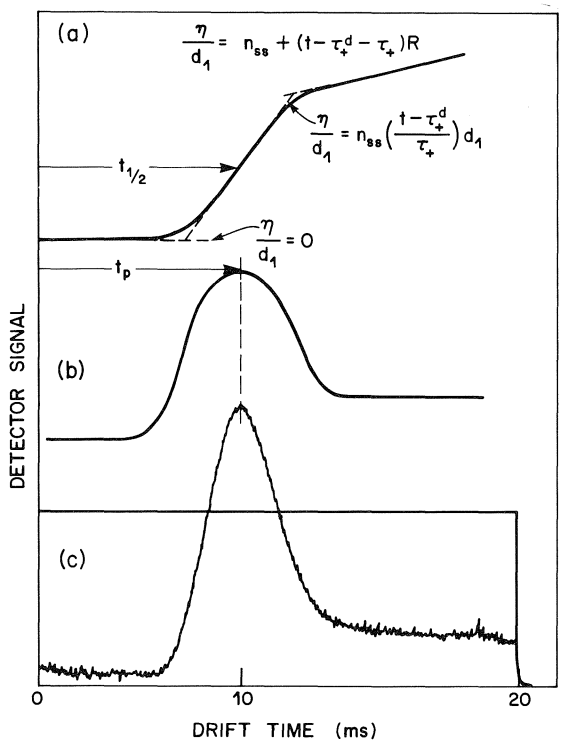

FIG. 2. Illustrations of detector signals. (*a*) Integrated charge reaching collecting electrode as a function of drift time or time on of the high voltage. (See text for explanation of dashed lines and equations.) (*b*) Differentiation of smooth curve in (*a*). (*c*) Smooth line, high voltage profile; line with noise, current–time profile for positive ions in HBr at 296 K and 191 Torr.

compartment as a function of drift time t. The charge–time profiles were analyzed in terms of the three straight lines shown. The equations for these lines, shown also in Fig. 2, were developed in ref. 2 on the assumption of no diffusional or space charge broadening of the ion cloud during drift. The smooth curve shows the effect of these processes.

The relation of the present detection method to the earlier one has been illustrated in part (*b*), which is a schematic differentiation of the smooth curve in (*a*). The time scale in (*a*) and (*b*) was somewhat expanded. The average ion drift time is now measured as t_p, rather than as $t_{1/2}$ in part (*a*) of Fig. 2. This was the time that an ion, starting its drift in the center of the irradiation compartment, would spend on average before detection. Therefore t_p is related to the ion mobility by eq. [1]:

$$[1] \quad t_p^{\pm} = \frac{1}{\mu_{\pm}}\left(\frac{d_1}{2E_r} + \frac{d_2}{E_d} + \frac{x}{E_c}\right)$$

Here, E_r, E_d, and E_c are the field strengths in the radiation, drift, and collection compartments and x is the distance into the collection compartment at which the ions are detected.

Results

The current profile in Fig. 2(*c*) was for the positive ions in 191 Torr of HBr at 296 K. The voltages at L_1 and G_1 were 1800 V and 1500 V respectively when the high voltage pulse was on and zero otherwise. The grid G_2 was kept at 400 V. This arrange-

ment gave rise to electric fields: $E_r = 300$, $E_d = 275$, and $E_c = 308$ V cm^{-1}.

For each ion and each pressure E_r and E_d were varied from about 110 to 400 V cm^{-1} with E_r being always somewhat larger. E_c was varied independently of E_r and E_d from ~120 to ~400 V cm^{-1}. To avoid any uncertainty in the parameter x eq. [1] was rearranged to:

$$[2] \quad t_p{}^{\pm}E_c = \frac{1}{\mu_{\pm}} E_c\left(\frac{0.5}{E_r} + \frac{4.0}{E_d}\right) + \frac{x}{\mu_{\pm}}$$

The ion mobility was then obtained from the reciprocal of the least-mean-squares slope of t_pE_c plotted against $E_c(0.5/E_r + 4.0/E_d)$. A typical plot of this has been shown in Fig. 3. It was for negative ions in HBr at 191 Torr. No systematic dependence of $\mu_{\pm}$ on field strength was observed for any of the conditions used. The E/P values ranged from 0.1 to 8 V cm^{-1} Torr^{-1} (E/N from 0.45 to 2.5 × 10^{-16}).

Values of the experimental mobilities are plotted against the neutral density in Fig. 4. Each point was derived from a least-mean-squares analysis of 10 to 20 points plotted as in Fig. 3. Except in NO, the mobilities of the positive and negative ions were similar. Table 1 summarizes the slopes of the solid lines in Fig. 4. They were obtained by the least-squares method. The reduced mobilities ($\mu_0 = \mu$ at $N = 2.69 \times 10^{19}$ cm^{-3}) are also given. With the exception of the positive ion in CH_3Cl the slopes all lay between −0.95 and −1.03.

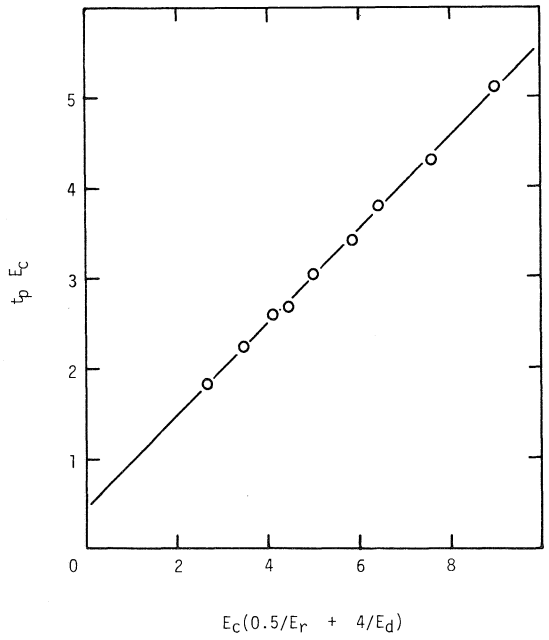

FIG. 3. Plot of t_pE_c against $E_c(0.5/E_r + 4.0/E_d)$ for negative ions in HBr at 191 Torr and 296 K.

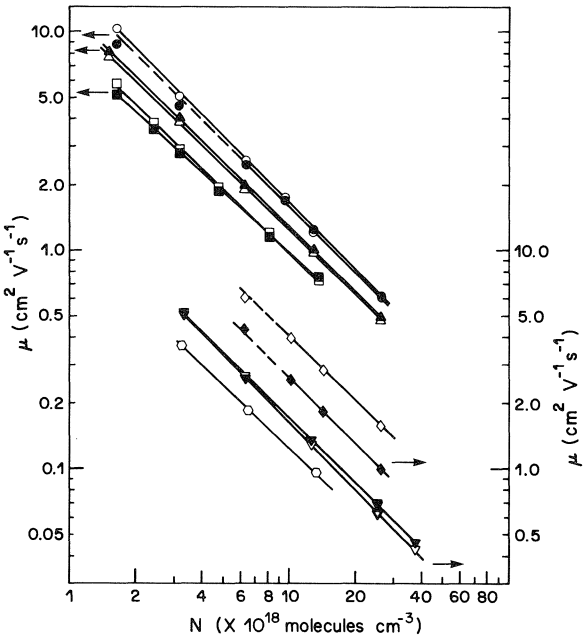

FIG. 4. Experimental mobilities plotted against gas densities. Filled symbols, positive ions; open symbols, negative ions: ○, H_2S; △, HBr; □, CH_3Cl; ◇, NO; ▽, HCl, ⬡, SF_6.

For H_2S, HCl, HBr, and CH_3Cl at one pressure, measurements were also made with a sample where a small amount (~1 Torr) of CCl_4 had been added. Within the experimental uncertainty positive and negative ion mobilities for samples with and without the e^- scavenger were the same. This molecule has a very large cross section for electron capture (6) and under the conditions used should have converted electrons to Cl^-:

$$[3] \quad CCl_4 + e \rightarrow \cdot CCl_3 + Cl^-$$

Thus the original negative ion would be replaced initially by Cl^-.

Discussion

The high pressures employed here would have caused a greater tendency for clustering of the ions than in the usual mobility studies carried out at or near 1 Torr. The Chapman–Enskog kinetic theory mobility equation (14), eq. [4]

$$[4] \quad \mu = \frac{3}{16}\left(\frac{1}{m} + \frac{1}{M}\right)^{1/2}\left(\frac{2\pi}{kT}\right)^{1/2}\frac{e}{N\omega}$$

shows the relation between μ, the masses m and M of the ion and neutral molecule, the ion charge e, and the averaged diffusion cross section ω. The dependence of μ on ion size (and clustering) arises from m and the contribution of hard sphere repulsive terms in ω. For large cluster sizes, as are likely

here, $(1/m + 1/M)^{1/2}$ would approach the limit $(1/M)^{1/2}$. Also from typical rate constant data (15) it is reasonable to assume that clusters would reach equilibrium distributions, which would be maintained during drift. When this condition holds only one mobility peak will be observed (8). This was the case for all ions reported. There was some evidence for two non-equilibrated positive species in SF_6, which may stem from different primary ions (16). These will be discussed elsewhere.

Our values of μ_0 for negative ions in SF_6 were: 0.45, 0.46, and 0.48 $cm^2\ V^{-1}\ s^{-1}$ at 100, 200, and 408 Torr respectively. The significance of the slight increase with pressure, if real, is not understood. The value of 0.45 ± 0.03 $cm^2\ V^{-1}\ s^{-1}$ at 100 Torr compares very favorably with 0.47 (17) and 0.54 (18) for $SF_6^-(SF_6)$ and 0.42 (17) and 0.47 (18) for $SF_6^-(SF_6)_2$ previously obtained at low pressures. Given that increasing m from the mass of the trimer to infinity in eq. [4] would only decrease μ_0 by 5%, it would appear that any effect on ω is also small for the cluster sizes occurring under our conditions. We assume that they are at least trimeric and maybe even larger.

Nitric oxide was the only gas in which the negative and positive ion mobilities differed widely, indicating very different ion masses and/or ω values. Mass analysis of ions in discharged NO showed $(NO)_2^+$ and NO_2^- to be the major species at pressures near 1 Torr (19), but the masses of these would only cause a 10% lower mobility of the positive ion. Therefore the results suggest that the positive ion is clustered much more strongly than the negative one or that some other factor is responsible.

Another effect of high pressure not mentioned above is the increased absolute concentration of trace impurities in the drift cell. If polar molecules like H_2O are present they may preferentially cluster the ions, when gases of lesser polarity are being studied. In the case of H_2S the positive ion current profile exhibited a doublet before the gas was completely purified. After purification the faster ion had disappeared, but it returned on the addition of a small trace of H_2O. This behavior is consistent with the observed displacement of H_2S from ion clusters by H_2O (15, 20). The presence of traces of H_2O in the NO could cause strong clustering of the positive ion (21), but we found no behavior like that for H_2S, which would support this suggestion.

The remaining gases used here are themselves so polar that the above effect should be unimportant. Indeed for H_2S, HCl, HBr, and CH_3Cl ion clustering is sufficiently strong that equilibria have been studied for either the positive or the negative ions, and species of the following formulae have been identified by mass analysis: $H_3S^+ \cdot nH_2S$ (15, 20), $Cl^- \cdot mHCl$ (22), $Br^- \cdot mHBr$ (23), and $CH_3ClCH_3^+ \cdot nCH_3Cl$ (24). In addition H_2Cl^+ and H_2Br^+ are formed from the parent ions (25), and should be clustered at the pressures used here. Reactions of electrons and ions occurring in the

hydrogen halides and H_2S under irradiation have been reviewed (26, 27). There is uncertainty about the negative ion species in H_2S (27, 28) and CH_3Cl. However, the low negative ion mobilities in these systems and the absence of any significant change on adding CCl_4 to capture electrons indicates that heavy ions were always present and some kind of electron capture process must operate. In the case of H_2S this agrees with the conclusions of others (27, 28).

A relatively simple relation exists between ion mobility and ξ, the collision frequency for momentum transfer between the ion and neutral molecules, viz.: $\xi = e/(m\mu)$ (4, 29). Therefore it is of interest to compare the present results with collision frequencies for other ion – polar molecule systems. For reasons which will become apparent we normalize ξ and μ to unit molecule concentration and compare the quantities $(\xi/N)(m/(M_r\alpha)^{1/2})$ and $e/\mu N(M_r\alpha)^{1/2}$, with M_r = reduced mass.

The points in Fig. 5 are values of $e/\{\mu N(M_r a)^{1/2}\}$ calculated from mobilities in Table 1 and plotted against $\mu_D/\alpha^{1/2}$, where μ_D is the dipole moment and α the polarizability of the neutral gas molecule. Values of these properties are given in Table 1. For the gases studied in this laboratory we chose to

For personal use only.

calculate $e/\mu N(M_r\alpha)^{1/2}$ for the ion of each system, for which the average cluster size could be estimated at 200 Torr from the mass spectrometric – thermodynamic data in the references noted above. Mobilities at 200 Torr were evaluated from μ_0 and y in Table 1. The mobilities for NH_3 systems are from refs. 2 and 7. The average ion cluster sizes were: $Cl^-\cdot 4HCl$, $NH_4^+\cdot 4NH_3$, $H_3S^+\cdot 4H_2S$, $CH_3ClCH_3^+\cdot 2CH_3Cl$, and $SF_6^-\cdot 2SF_6$. For HBr and NO there is not enough information for realistic estimates and we arbitrarily used cluster sizes of four. The bars about each point show the extreme values taking $m = M$ and $m = \infty$. Uncertainties in ion mass are seen not to affect the arguments below.

The mobility for $K^+\cdot 6H_2O$ in water vapor at a few Torr is taken from a compilation by Smirnov (8) and the ion identity based on data in ref. 30. Lowke and Rees' negative ion mobility of 0.67 in water vapor below saturation at a few Torr (9) was assumed to be $OH^-\cdot 4H_2O$, as identified in ref. 10 (see Fig. 10, ref. 10).

The dashed lines in Fig. 5 enclose the area covered by a total of eighteen points in a similar plot presented by Barker and Ridge (4), and based on collision frequencies determined by ion cyclotron resonance. The high pressure mobility results obtained here and the data for H_2O vapor are seen to follow the same approximately linear dependence on $\mu_D/\alpha^{1/2}$ and to agree quantitatively with the low pressure data.

The calculation of ion collision frequencies at unit concentration has been considered by Barker and Ridge (4). From their work it appears that eq. [5] should be a good approximation (within ~10%) for ion–neutral hard sphere radii less than 10 Å.

$$[5]\quad \xi = N\left(\frac{M}{m+M}\right)k_c$$

Here k_c is the "orbiting collision" frequency of ion–molecule reaction rate theory, which is given by eq. [6] (3, 4):

$$[6]\quad k_c = \frac{2\pi e}{M_r^{1/2}}\left\{\alpha^{1/2} + C\mu_D\left(\frac{2}{\pi kT}\right)^{1/2} + A\right\}$$

C is a function of $\mu_D/\alpha^{1/2}$, which allows for the ion–dipole interaction and is obtained from theory, and A is a relatively new term defined in ref. 31 and added to take account of the requirement for angular momentum conservation. Substituting [6] into [5] and multiplying by $m/(M_r\alpha)^{1/2}$ one obtains:

$$[7]\quad \frac{\xi}{N}\frac{m}{(M_r\alpha)^{1/2}} = 2\pi e\left\{1 + \frac{\mu_D}{\alpha^{1/2}}C\left(\frac{2}{\pi kT}\right)^{1/2} + \frac{A}{\alpha^{1/2}}\right\}$$

Su and Bowers (3) and Barker and Ridge (4) have developed different methods for averaging the ion–dipole interaction, which is contained in the second term in the braces. The upper solid line in Fig. 4 is based on Barker and Ridge's prediction of k_c from ref. 4. The lowest line is a calculation of $\xi m/N(M_r\alpha)^{1/2}$ based on revised values of C (31) for the ADO theory. Also for some specific molecules the A term has been included. The experimental points all fall well above the ADO line. Su *et al.* (31) claim that the reason for this may lie predominantly in the omission of repulsive potentials rather than in the ADO evaluation of the dipole–ion interaction, which they believe to be correct. On the other hand it is evident that the original Barker–Ridge calculation gives better agreement with experimental collision frequencies. However, although the data at present are somewhat limited and exhibit scatter, there appears to be a tendency for the Barker–Ridge theory to underestimate the collision frequency at low $\mu_D/\alpha^{1/2}$ and to overestimate it at high $\mu_D/\alpha^{1/2}$. A part of this may be due to the approximation $\sigma_d \simeq \sigma_0$ made in obtaining [5] (see ref. 4, Fig. 2). It would appear that this problem and the not unrelated question of short range repulsive interactions require attention before either theory can provide an accurate representation of experimental collision frequencies.

Evidence for anion coordination in hexafluorophosphate and hexafluoroarsenate complexes of nickel(II)

RAYMOND M. MORRISON, ROBERT C. THOMPSON, AND JAMES TROTTER

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received August 20, 1979

RAYMOND M. MORRISON, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **58**, 238 (1980).

Yellow crystals of tetrakis(4-methylpyridine)nickel(II)hexafluorophosphate, $C_{24}H_{28}F_{12}N_4NiP_2$, are monoclinic, $a = 19.709(5)$, $b = 9.866(2)$, $c = 16.515(9)$ Å, $\beta = 101.54(4)°$, $Z = 4$, space group $C2/c$. The structure was solved by Patterson methods and refined by full-matrix least-squares methods to $R = 0.071$ for 1002 observed reflections. The structure consists of a square-planar array of 4-methylpyridine ligands about nickel with hexafluorophosphate groups above and below the plane. The Ni—N distances are 1.916(9) and 1.919(10) Å with the pitch of the rings 102.06° and 97.32°. The shortest Ni—F distances are 3.031(8) Å. The structure shows that the anions are not fully coordinated to nickel but are nonetheless held in axial positions by weak, essentially ionic, interactions.

Tetrakis(pyridine)nickel(II)hexafluoroarsenate has been found to undergo a reversible structure change over the temperature range 180 to 200 K. Electronic and vibrational spectra and magnetic susceptibility studies suggest that the compound has a structure similar to that of $Ni(4\text{-mepy})_4(PF_6)_2$ with the anions only weakly interacting with cations in the high temperature form and fully coordinated in the low temperature form.

RAYMOND M. MORRISON, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **58**, 238 (1980).

Les cristaux jaunes de tétrakis(méthyl-4 pyridine) hexafluorophosphate de nickel(II) $C_{24}H_{28}F_{12}N_4NiP_2$ sont monocliniques $a = 19.709(5)$, $b = 9.866(2)$, $c = 16.515(9)$ Å, $\beta = 101.54(4)°$, $Z = 4$, groupe d'espace $C2/c$. On a résolu la structure par les méthodes de Patterson et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à une valeur de R 0.071 pour 1002 réflexions observées. La structure consiste en une rangée de ligands de méthyl-4 pyridine carré plan autour du nickel avec les groupes hexafluorophosphate au dessus et au dessous du plan. Les distances Ni—N sont de 1.916(9) et 1.919(10) Å alors que les cycles dévient du plan par 102.06° et 97.32°. Les distances Ni—F les plus faibles sont 3.031(8) Å. La structure montre que les anions ne sont pas complètement coordonnées au nickel, mais sont toutefois maintenus dans une position axiale par des interactions faibles essentiellement ioniques.

On a trouvé que le tétrakis(pyridine) hexafluoroarsenate de nickel(II) subit un changement reversible de structure sur une échelle de température allant de 180 à 200 K. L'étude des spectres de vibration, des spectres électroniques et de la susceptibilité magnétique suggère que le composé a une structure semblable à celle de $Ni(mepy\text{-}4)_4(PF_6)_2$. Cette structure se présente sous deux formes: l'une à haute température où les anions sont seulement en interaction faible avec les cations, l'autre à basse température où les anions sont complètement coordonnées.

[Traduit par le journal]

Introduction

The hexafluorophosphate and hexafluoroarsenate ions are commonly used as non-coordinating counter anions in coordination chemistry (1, 2). Examples of complexes in which there is evidence for PF_6^- and AsF_6^- coordination are scarce, consisting of a few unsolvated compounds, $CuAsF_6$ (3), $FeF(AsF_6)$ (4), and $Ni(AsF_6)_2$ (5) where there must be some anion—cation interaction and the pyridine complex, $Cu(py)_4(PF_6)_2$ (1, 6) where some spectral evidence for a form of anion coordination, termed semi-coordination, has been presented.

We previously described the 4-methylpyridine complexes, $Ni(4\text{-mepy})_4(PF_6)_2$ and $Ni(4\text{-mepy})_4(AsF_6)_2$, as consisting of square-planar $[Ni(4\text{-mepy})_4]^{2+}$ cations and non-coordinated or weakly semi-coordinated anions (2). This conclusion was based on electronic spectral and magnetic studies which indicated a spin-singlet electronic ground state and on infrared studies which indicated some lowering of anion symmetry possibly due to cation–anion interaction. More information on the nature of this interaction in $Ni(4\text{-mepy})_4(PF_6)_2$ is provided by the single-crystal X-ray diffraction study described in the present paper.

The original claim that the pyridine complex, $Ni(py)_4(PF_6)_2$, has anomalous magnetic properties (6) consistent with a singlet–triplet equilibrium and arising from anion coordination was later refuted (2). Further studies on this compound are reported here and we also describe the synthesis and characterization of the hexafluoroarsenate analogue, $Ni(py)_4(AsF_6)_2$. This latter compound is particularly interesting in that it has been found to undergo a reversible structure change over the temperature range 180 to 200 K. The strength of the anion-to-metal coordination in the low temperature form is significantly greater than in the room temperature form or in any other NiL_4A_2 hexafluoroarsenate or hexafluorophosphate complex.

Experimental

Preparations

Tetrakis(4-methylpyridine)nickel(II)hexafluorophosphate, $Ni(4\text{-mepy})_4(PF_6)_2$, was prepared as described previously (2) and crystals suitable for X-ray diffraction studies were obtained by slow evaporation (1 to 2 weeks in a nitrogen atmosphere

dry-box) of a saturated solution of the compound in an equal volume mixture of dichloromethane and chloroform.

Tetrakis(pyridine)nickel(II)hexafluorophosphate and -arsenate were prepared in a dry-box as follows. A sample of the appropriate hexakis(pyridine) derivative, $Ni(py)_6A_2$, prepared by published methods (6), was placed in a flask with a large excess of dichloromethane. Upon stirring the suspended solids changed from blue–green to orange–yellow in colour and the dichloromethane became faint blue–green in colour. The solid material was filtered and washed with dichloromethane until the washings were colourless. The product was then dried under vacuum for 24 h. As previously noted (2), thermal preparative methods involving heating the hexakis(pyridine) precursors were avoided as these lead to products containing variable amounts of paramagnetic impurities.

Anal. calcd. for $NiC_{20}H_{20}N_4P_2F_{12}$: C 36.16, H 3.03, N 8.43; found: C 36.12, H 2.99, N 8.49. *Anal.* calcd. for $NiC_{20}H_{20}N_4As_2F_{12}$: C 31.90, H 2.68, N 7.44; found: C 31.70, H 2.74, N 7.31.

Elemental analyses were done by P. Borda of the Department of Chemistry, The University of British Columbia.

Spectroscopic and Magnetic Measurements

Magnetic susceptibility measurements were made as described previously (2). Electronic spectra at room and liquid nitrogen temperatures were obtained on finely ground powders between silica glass plates using a Cary model 14 spectrophotometer. Infrared spectra were also obtained on powders pressed between KRS-5 (Harshaw Chemical Co.) plates using a Perkin-Elmer Model 225 spectrophotometer. The low temperature cell has been described elsewhere (7). It was outfitted with silica glass plates for the electronic spectra and BaF_2 windows for the infrared studies. The low temperature Raman spectrum was obtained using a Spex Ramalog 5 instrument equipped with a 514.5 nm argon ion laser and a low temperature cell designed by Lee and Aubke (8). The room temperature Raman spectrum was obtained using a Cary Model 81 spectrometer equipped with a He–Ne laser ($\lambda = 632.8$ nm).

X-ray Diffraction Experiment

Crystals of $Ni(4\text{-mepy})_4(PF_6)_2$ were hygroscopic and were sealed in 0.3 mm diameter Lindemann capillaries for study. Preliminary Weisenberg and precession photographs indicated a monoclinic space group. The crystal was mounted in a random orientation on an Enraf-Nonius CAD4 diffractometer. The unit cell parameters were determined by least-squares fit of 25 reflections. The crystal data are

$C_{24}H_{28}F_{12}N_4NiP_2$ fw = 721.15

Monoclinic, space group $C2/c$ (C_{2h}^6, No. 15) from absences and structure analysis, $a = 19.709(5)$, $b = 9.866(2)$, $c = 16.515(9)$ Å, $\beta = 101.54(4)°$, $V = 3146$ Å^3, $Z = 4$, $\rho_c = 1.523$ g cm^{-3}, $\mu = 8.2$ cm^{-1}.

Intensity data were measured in the range $2° \leq 2\theta \leq 45°$ with monochromatic Mo Kα ($\lambda = 0.71073$ Å) radiation with an ω scan. The scan angle was $(0.90 + 0.45 \tan\theta)°$, extended 25% on each side for background count, with a horizontal aperture of $(2.75 + \tan\theta)$ mm. Three intensity control reflections were checked every 5000 s of X-ray exposure and three orientation controls were measured every 150 reflections. In the data reduction, Lorentz-polarization (LP) corrections were applied and an estimated standard deviation was assigned by $\sigma^2(I) = S + 4(B_1 + B_2) + (0.05I)^2$ where S = scan count and B_1 and B_2 = background counts. During the data collection, the mean scale factor of the intensity controls varied randomly (±3%). Of the 2058 reflection data collected, 1002 (49%) had $I > 3\sigma(I)$ and were considered observed.

Structure Determination

The structure was determined by Patterson and Fourier methods, and corresponded to space group $C2/c$. With anisotropic thermal parameters for all of the atoms, inclusion of the anomalous scattering of nickel and phosphorus (9), and use of a weighting scheme ($F_o \leq F_{avg}$, $\omega = 1$, $F_o > F_{avg}$, $\omega = F_{avg}/F_o$; F_{avg} = averaged observed structure factor), full-matrix least-squares refinement led to R and R_ω of 0.071 and 0.096. Extinction and absorption corrections were not made, nor were hydrogen positions determined. A subsequent cycle of full-matrix least-squares refinement showed no shifts greater than 0.25σ for the parameters determined. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1] The final positional and thermal parameters are given in Tables 1 and 2.

Results and Discussion

The Crystal Structure of Ni(4-mepy)$_4$(PF$_6$)$_2$

The structure consists of nickel atoms on inversion centres with two pairs of crystallographically different 4-methylpyridine ligands defining a square-planar array around nickel. The hexafluorophosphate groups are crystallographically identical and situated above and below the square plane. Figure 1 shows a stereoview of the formula unit. The bond lengths and angles within the 4-methylpyridine rings (Table 3) are similar to those observed previously for coordinated 4-methylpyridine (10, 11). The rings are planar within experimental error. The PF_6 groups appear as somewhat distorted octahedra. The P—F distances vary from 1.466 to 1.593 Å, in the range normally observed (12) when uncorrected for thermal motion. The F—P—F angles range from 86.2 to 92.3° for adjacent fluorines and 175.7 to 177.8° for opposite fluorines. These apparent distortions and large thermal parameters which indicate a small amount of disorder are commonly observed in hexafluorophosphates (ref. 11 and references therein).

Clearly the hexafluorophosphate ions are not fully coordinated in this complex as evidenced by the fact that the Ni—F distance of 3.031 Å is only marginally less than the estimated sum of the van der Waals radii, 3.1 to 3.2 Å, and considerably greater than the sum of the covalent radii, 1.87 Å (13). This is consistent with the previously reported electronic properties of the molecule (2). On the other hand, we note that there is anion–cation interaction in the $Ni(4\text{-mepy})_4(PF_6)_2$ unit sufficiently strong to produce noticeable effects on the molecular structure. The anions occupy definite positions on the tetragonal axis, there is no evidence that they are rotating and, in addition, the

fluorine atoms closest to the nickel have the smallest thermal parameters. This interaction is weaker even than the anion–cation interaction in bis(tetrafluoroborato)bis(ethylenediamine)copper(II) for which the term semi-coordination was given (14); nonetheless, it no doubt causes the lowering in anion symmetry, the effects of which were observed previously in the infrared spectrum (2).

It is instructive to compare the bond parameters obtained here with those of related perchlorate complexes. The Ni—O distance in $Ni(4\text{-mepy})_4(ClO_4)_2$ and the analogous 3,4-dimethylpyridine derivative where the anions are considered to be non-coordinated (15, 16) are 3.290 and 3.343 Å respectively (compared to 3.10 Å for the sum of the van der Waals radii (13)); whereas, when the perchlorate is fully coordinated as in the 3,5-dimethylpyridine derivative (17) this distance is shortened to 2.187 Å. The anion–metal contact of 3.031 Å in $Ni(4\text{-mepy})_4(PF_6)_2$ is slightly less than that in the complexes with non-coordinated perchlorates. The Ni—N distances in the perchlorate complexes are affected by anion coordination; the distances increase from 1.90 Å to 2.05–2.15 Å on going from non-coordinated to coordinated anions. The short Ni—N distances (~1.92 Å) observed in the hexafluorophosphate derivative are again closest to those observed in perchlorate complexes with non-coordinated anions. Consistent too is the observed pitch of the 4-methylpyridine rings. The angles between the NiN_4 plane and the planes of the ligand rings in the perchlorate complexes are near 90° for non-coordinated anions and 45° for coordinated anions. The angles observed in $Ni(4\text{-mepy})(PF_6)_2$ (102.1 and 97.3°) are considerably greater than the 45° expected for fully coordinated anions. Overall this bond parameter comparison is consistent only with the hexafluorophosphate complex having non-interacting or, as is thought to be the case, having very weakly interacting anions.

Spectral and Magnetic Studies on $Ni(py)_4(AsF_6)_2$

The magnetic properties of $Ni(py)_4(AsF_6)_2$ and, for comparison, $Ni(py)_4(PF_6)_2$ are given in Fig. 2. The hexafluorophosphate derivative shows only very weak paramagnetism over the temperature range 80 to 300 K; whereas, the hexafluoroarsenate analogue shows a reversible change from what is only very weak paramagnetism above 200 K to strong paramagnetism (corresponding to approxi-

*The anisotropic thermal parameters employed in the refinement are U_{ij} in the expression: $f = f^0 \exp(-2\pi^2 \Sigma_i \Sigma_j U_{ij} h_i h_j a_i^* a_j^*)$.

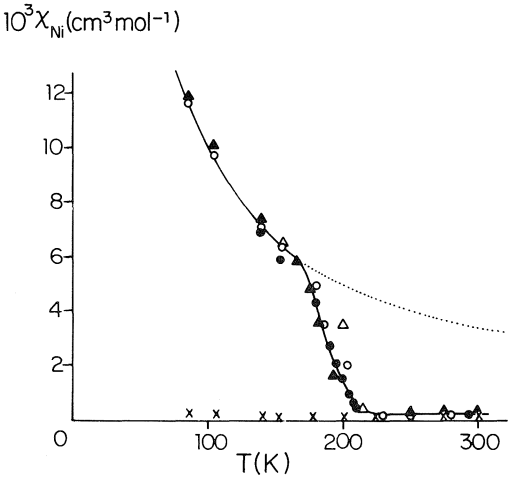

FIG. 2. Magnetic susceptibilities. ▲, ●, △, ○ are data points for $Ni(py)_4(AsF_6)_2$. Different symbols represent independent experiments. The solid line shows the trend of the data. The low temperature section which follows the Curie law is extended (dotted line) into the high temperature region for comparison with measured susceptibilities. × are data points for $Ni(py)_4(PF_6)_2$.

mately two unpaired electrons) at temperature below 180 K. Clearly the electronic ground state in $Ni(py)_4(AsF_6)_2$ changes from a spin-singlet to a spin-triplet at temperatures below the transition range. These magnetic properties show that, in the low temperature form, $Ni(py)_4(AsF_6)_2$ has fully coordinated AsF_6^- ions. This is confirmed by electronic spectral studies.

At room temperature the electronic spectrum of $Ni(py)_4(AsF_6)_2$ consists of a single band with a maximum at 450 nm consistent with a singlet ground state (18). At 80 K the spectrum changes (Fig. 3) to one which can be assigned as a superposition of two spectra: the original one-band spectrum plus a new one consisting of five bands assignable (Table 4) to the triplet–triplet transitions of a six-coordinate nickel(II) species with D_{4h} local symmetry. That this new species which forms at low temperatures has a structure involving *trans*-coordinated AsF_6^- is confirmed by comparison of the ligand field parameters calculated (including configuration interaction) for $Ni(py)_4(AsF_6)_2$, Dq = 1300, B = 887, Ds = 1588, and Dt = 568 (all in cm^{-1}), with those obtained for the known tetragonally distorted octahedral complexes $Ni(py)_4(BF_4)_2$ and $Ni(py)_4(ClO_4)_2$ (19). The parameters are comparable in magnitude with some differences (notably in Dt which is 540 cm^{-1} for the tetrafluoroborate and 500 cm^{-1} for the perchlorate derivative) which indicate a slightly higher degree of tetragonal distortion in the hexafluoroarsenate complex. The presence of a band at 450 nm shows that the conversion from the ground state singlet species to the ground state triplet species is not complete and this is borne out also by the magnetic studies. Six-coordinate nickel(II) complexes with triplet ground states normally have magnetic moments of the order of 3.1–3.2 BM. The observed values of ~2.85 BM suggests ~85% conversion to the triplet

form. The hexafluorophosphate analogue, $Ni(py)_4(PF_6)_2$, does not undergo a similar transformation at low temperatures. This is indicated by the magnetic studies and confirmed by the electronic spectrum of the complex which remains a single band spectrum with a maximum at 450 nm from room temperature to 80 K.

While the evidence for full anion coordination in the low temperature form of $Ni(py)_4(AsF_6)_2$ is clear the question remains as to whether the anions are weakly associated with the metal in the high temperature form of this complex and in the hexafluorophosphate derivative. The room temperature infrared spectra of both complexes (Table 5) show very broad ν_3 absorptions and medium intensity infrared-forbidden bands (ν_1 in the case of the hexafluorophosphate and ν_2 in the case of the hexafluoroarsenate). These results indicate some distortion of the anions below O_h symmetry resulting possibly from weak anion–cation interaction as discussed previously (2).

The effect of the structural change in $Ni(py)_4(AsF_6)_2$ on its vibrational spectrum is interesting to note (Table 5). The spectrum shows that as the anions become more strongly coordinated at 80 K,

ν_3 broadens and becomes more structured and ν_2 shifts to a lower frequency. The weak band at 562 cm^{-1} in the 80 K spectrum is due probably to the small amount of "room temperature" isomer which remains at this temperature. The pyridine bands show little change except, as would be expected, for the stereochemically sensitive 6*a* and 16*b* bands. As the anion coordination increases, 16*b* decreases from 471 to 432 cm^{-1} (a weak band at 465 cm^{-1} in the 80 K spectrum due to incomplete isomerization is again observed) and the 6*a* band is observed at 632 cm^{-1}. This band is probably at higher frequencies in the room-temperature species and no doubt hidden in the broad ν_3 absorption in the 300 K spectrum.

Attempts to obtain Raman spectra on these coloured complexes were not particularly successful; nonetheless, the bands which were observed for the hexafluoroarsenate complex and their tentative assignments are given in Table 5. In view of the fact that only a few bands (most of very low intensity) were observed, no attempt was made to analyze the changes in the Raman spectrum on cooling as was done for the infrared spectra.

Of all the complexes of the type NiL_4A_2, where L is pyridine or substituted pyridine and A is an anion such as Cl^-, Br^-, ClO_4^-, BF_4^-, PF_6^-, or AsF_6^-, only the complex reported here, $Ni(py)_4(AsF_6)_2$, has been found to exist in two isomeric forms. We are unable to explain why the particular combination of ligand and anion sizes and coordinating abilities gives rise to this phenomenon. At room temperature $Ni(py)_4(AsF_6)_2$ probably has a structure very similar to that of $Ni(4\text{-mepy})_4(PF_6)_2$ with

anions occupying positions above and below a square-planar $Ni(py)_4$ entity, Ni—F distances of the order of 3 Å and pyridine rings aligned with their planes at angles of ~90° with respect to the NiN_4 plane. On cooling the anions likely move to positions closer to the nickel atoms with a concomitant change of the pitch of the ligand rings to a value closer to 45°. It would be interesting to confirm this with X-ray crystallographic studies; unfortunately we have not been able to obtain large enough crystals of the complex for such studies.

The mechanism of hydrogenation of activated olefins, including prochiral ones, using *trans*-chlorohydridobis(diop)ruthenium(II)

BRIAN R. JAMES AND DANIEL K. W. WANG

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received May 24, 1979

BRIAN R. JAMES and DANIEL K. W. WANG. Can. J. Chem. **58**, 245 (1980).

Solutions of the title complex *trans*-$HRuCl(diop)_2$, where diop is an optically active chelating ditertiary, hydrogenate under mild conditions activated olefinic substrates, including prochiral ones in high optical yields. Kinetic and spectroscopic studies on hydrogenation of acrylamide and α-phenylacrylic acid indicate an "unsaturate" mechanism involving rapid coordination of the substrate to give an alkyl intermediate, that subsequently reacts with H_2 in a rate-determining step to yield the saturated product and the starting monohydride complex. A diop ligand dissociates to provide necessary coordination sites at the metal. The α-phenylacrylic acid coordinates more strongly than acrylamide, but hydrogenates more slowly.

BRIAN R. JAMES et DANIEL K. W. WANG. Can. J. Chem. **58**, 245 (1980).

Les solutions du complexe $HRuCl(diop)_2$ *trans*, où diop est un agent chélatant optiquement actif, provoquent l'hydrogénation, dans des conditions douces, de substrats oléfiniques activés, incluant ceux qui sont prochiraux avec de bons rendements optiques. Les études cinétiques et spectroscopiques faites sur l'hydrogénation de l'acrylamide et de l'acide α-phénylacrylique indiquent un mécanisme "insaturé" faisant intervenir une rapide coordination du substrat pour conduire à un intermédiaire alkyle. Ce dernier réagit ensuite avec H_2 dans l'étape déterminante pour donner le produit saturé et le monohydrure complexe de départ. Un ligand diop se dissocie pour fournir les sites de coordination nécessaires au métal. L'acide α-phénylacrylique se coordonne plus fortement que l'acrylamide, mais il s'hydrogène plus lentement.

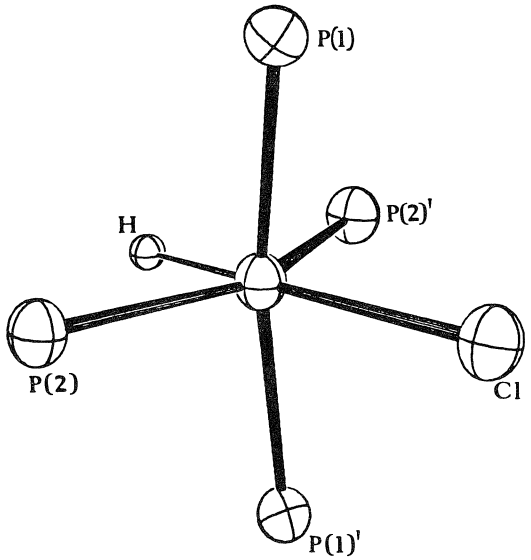
Introduction

There is currently a great deal of interest in the use of transition metal complexes with chiral ligands for catalytic asymmetric synthesis (1, 2). Rhodium complexes with chiral phosphine ligands have been used principally for hydrogenation (2, 3), and indeed some prochiral α,β-unsaturated carboxylic acid substrates have been hydrogenated catalytically to products with essentially 100% optical purity (4). Based on the known (5) high catalytic hydrogenating activity of the ruthenium(II) complex $HRuCl(PPh_3)_3$, we studied corresponding systems with chiral phosphine ligands and found that a dimeric $Ru_2Cl_4(diop)_3$ containing a bridging diop ligand (**I**) was effective for catalytic asymmetric hydrogenation (6). The dimer reacts with H_2 at ambient conditions to yield the isolable active hydride species $HRuCl(diop)_2$, **II** (reaction [1]), and based on ^1H and proton-decoupled ^{31}P nmr data, which showed inequivalent phosphines, the complex was considered (7) to have a *cis* configuration of hydrogen and chlorine (**III**), and we had attributed catalytic activity to labilization of a phosphorus atom *trans* to the hydride. We were thus surprised when a recent crystal structure determination (Fig. 1) revealed a distorted octahedral structure with a *trans* H—Ru—Cl arrangement, the inequivalence of the phosphorus atoms arising from a bending of P(2) and P(2)′ toward the H, and a bending of P(1) and P(1)′ toward the Cl. The dioxolane ring of the diop ligand fixes the configuration of the 7-membered ruthenium-containing chelate ring and the geometry appears to distort to minimize phenyl–phenyl interactions (8).



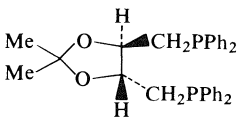


FIG. 1. The coordination geometry of the $HRuCl(diop)_2$ complex. Bond lengths (Å) and bond angles (deg) are: Ru—P(1), 2.393(1); Ru—P(2), 2.356(1); Ru—Cl, 2.548(2); and Ru—H, 1.65; ∠P(1)—Ru—P(1)′, 168.58(6); ∠P(2)—Ru—P(2)′, 149.52(7); and ∠P(2)—Ru—Cl, 105.24(3). P(1) and P(2) are part of the same diop molecule. A prime, e.g. P(1) and P(1)′, indicates atoms related by the 2-fold axis (8).

(I) 4*R*,5*R*-(−)diop

(III)

[1] $Ru_2Cl_4(diop)_3 + H_2 \rightarrow HRuCl(diop)_2 + \frac{1}{2}[RuCl_2(diop)]_2 + HCl$

(II)

This paper describes kinetic and spectroscopic studies on the $HRuCl(diop)_2$-catalyzed hydrogenation of acrylamide (acryl), and the prochiral α-phenylacrylic acid in *N*,*N*-dimethylacetamide (DMA) solution in attempts to elucidate reaction mechanisms, particularly since other *trans*-$HRuCl(diphosphine)_2$ complexes are inactive catalysts (7).

Experimental

Synthesis of **II**, materials used, the hydrogenation procedures in a constant pressure apparatus, H_2 solubility data, the work-up of products for determining optical yields, and the spectroscopic instrumentation used, have been reported elsewhere (7).

Results

Catalytic Hydrogenation of Acrylamide

Hydrogen uptake plots at 60°C are illustrated in Fig. 2, and the rates in the initial substantial linear regions were measured to yield kinetic data over the following concentration ranges (*M*): Ru (1.0–5.0) × 10^{-3}, acryl (1.0–6.0) × 10^{-1}, H_2 (0.8–2.2) × 10^{-3}, and added diop (0.0–6.0) × 10^{-3}. The kinetic data are summarized in Figs. 3–6.

The dependence on catalyst goes from first-order to about half-order with increasing concentration; with added diop, the dependence remains first-order (Fig. 3*A*, *B*). The dependence on acrylamide concentration shows very similar behaviour (Fig. 4*A*, *B*), while the rate is strictly first-order in H_2 (Fig. 4*C*). The inverse diop dependence (Fig. 5*A*) may be replotted as $(rate)^{-1}$ vs. added diop to yield a straight line passing through, or close to, the origin (Fig. 5*B*).

The total H_2 uptake could be followed to complete reduction of acrylamide to propionamide, which was readily identified.

Yellow DMA solutions of the $HRuCl(diop)_2$ complex **II** (λ_{max} 380 nm, $\varepsilon = 3150\ M^{-1}\ cm^{-1}$) were unreactive toward 1 atm H_2 at 60°C. Addition of acrylamide to a DMA solution of **II** under argon gave immediate changes in the 350–500 nm region, the absorption below 425 nm decreasing with loss of the absorption maximum, and that above 435 nm increasing somewhat. The solution remained yel-

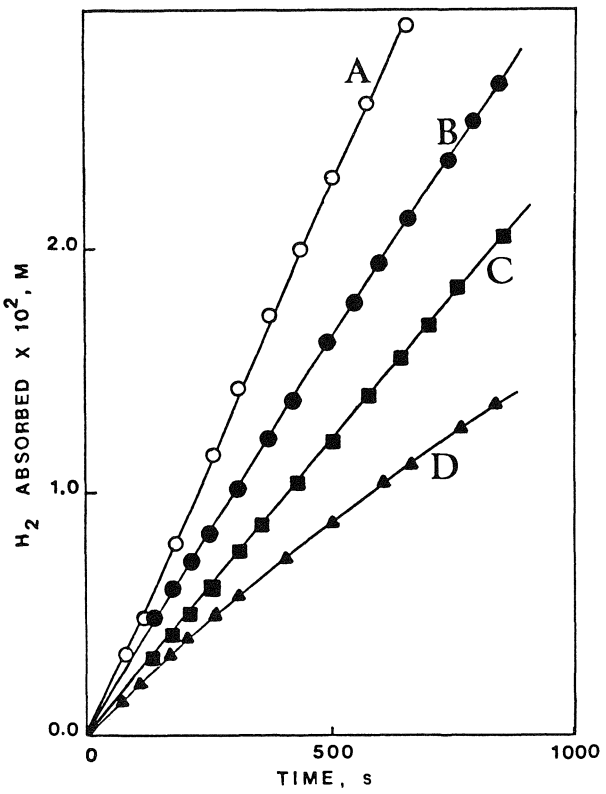

FIG. 2. Hydrogenation of acrylamide, DMA, 60°C; 0.2 *M* acryl, 2 × 10^{-3} *M* Ru. Pressure in Torr: *A*, 760; *B*, 600; *C*, 450; *D*, 300.

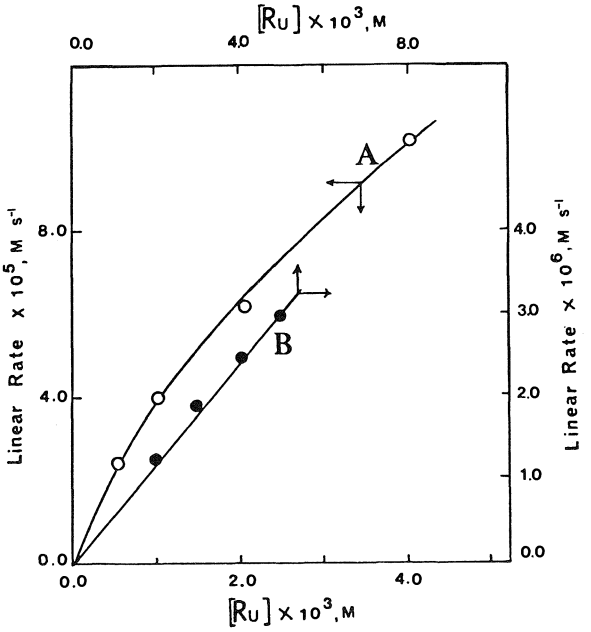

FIG. 3. Hydrogenation of acrylamide, DMA, 60°C. Curve *A*: 0.4 *M* acryl, 760 mm pressure. Curve *B*: 0.2 *M* acryl, 760 mm pressure, 6 × 10^{-3} *M* diop.

For personal use only.

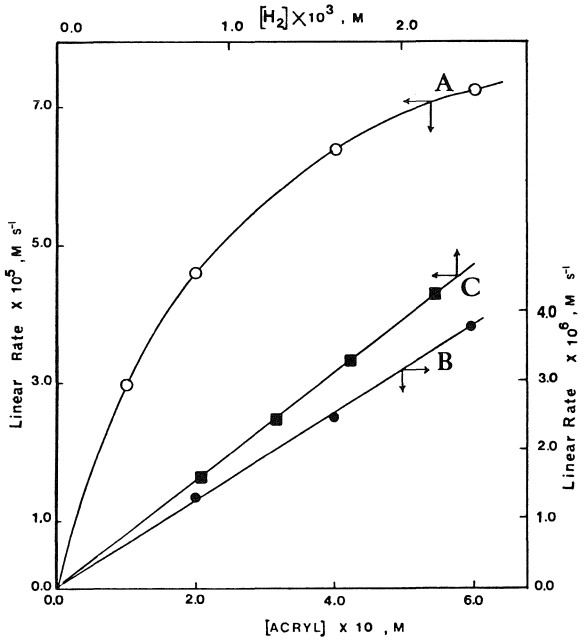

FIG. 4. Hydrogenation of acrylamide, DMA, 60°C. Curve *A*: 2 × 10^{-3} *M* Ru, 760 mm pressure. Curve *B*: 2 × 10^{-3} *M* Ru, 760 mm pressure, 6 × 10^{-3} *M* diop. Curve *C*: 0.2 *M* acryl, 2 × 10^{-3} *M* Ru.

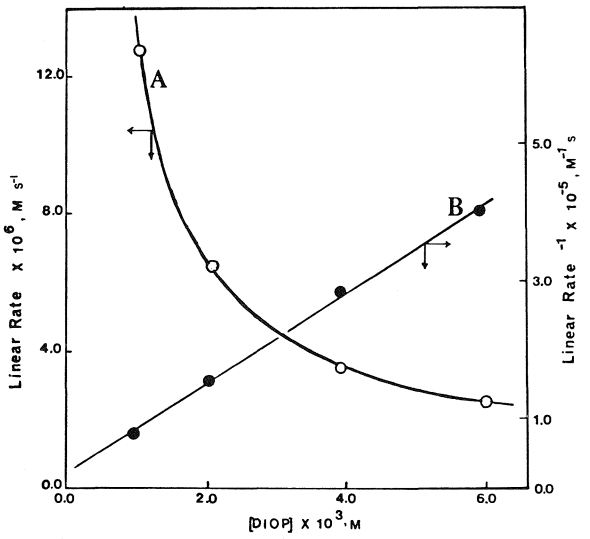

FIG. 5. Hydrogenation of acrylamide, DMA, 60°C. Curve *A*: 0.4 *M* acryl, 2 × 10^{-3} *M* Ru, 760 mm pressure. Curve *B*: curve *A* replotted as $(\text{rate})^{-1}$ vs. [diop] added.

low. A spectrophotometric titration yielded a set of spectra with a clean isosbestic point at 430 nm, and the data analyzed for the 1:1 equilibrium shown in reaction [2] with $K_1 = 3.8 \times 10^{-4}$:

[2] $\text{HRuCl(diop)}_2 + \text{acryl} \overset{K_1}{\rightleftharpoons} \text{complex} + \text{diop}$

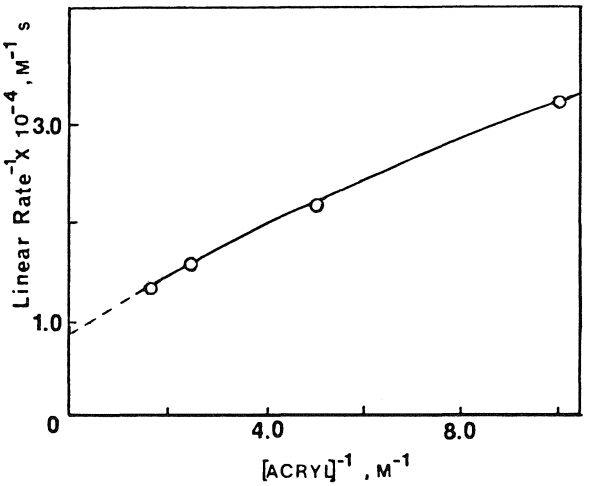

FIG. 6. Curve *A* of Fig. 4 replotted as $(\text{rate})^{-1}$ vs. $[\text{acryl}]^{-1}$.

The septet high-field ^{1}H resonance of **II** in $CDCl_3$ or DMA due to the coordinated hydride (7) disappears on the addition of acrylamide, and thus the complex formed in reaction [2] is considered to be an alkyl, although we have not been able to detect this by ^{1}H nmr in the amide solvent.

Catalytic Hydrogenation of α*-Phenylacrylic Acid*

The prochiral substrate α-phenylacrylic acid is readily hydrogenated catalytically to 2-phenylpropionic acid in 40% enantiomeric excess; use of the catalyst with (−)-diop yields the *S*(+) isomer, while the (+)-diop system gives the *R*(−) isomer (7).

[3] $\text{CH}_2{=}\text{C(C}_6\text{H}_5\text{)CO}_2\text{H} \rightarrow \text{CH}_3\text{CH(C}_6\text{H}_5\text{)CO}_2\text{H}$

The uptake plots resemble those for acrylamide but the rates are somewhat slower. The kinetics were determined as described above, and show a first-order dependence both on H_2 (Fig. 7*A*) and catalyst (Fig. 7*B*), a slight inverse dependence on added diop (Fig. 8*A*), and a first to zero-order in substrate (Fig. 8*B*).

The spectroscopic changes are similar to those for the acrylamide system, but K_1 is much larger (0.1).

Discussion

Acrylamide System

The kinetic and spectroscopic data are readily accommodated by the catalytic cycle outlined in reactions [4] to [6].

[4] $\text{HRuCl(diop)}_2 + \text{acryl} \overset{K_1}{\rightleftharpoons} \text{RuCl(alkyl)(diop)} + \text{diop}$

[5] $\text{HRuCl(alkyl)(diop)} + \text{H}_2 \xrightarrow{k} [\text{H}_2\text{RuCl(alkyl)(diop)}] \downarrow \text{HRuCl(diop)} + \text{propionamide}$

[6] $\text{HRuCl(diop)} + \text{diop} \xrightarrow{\text{fast}} \text{HRuCl(diop)}_2$

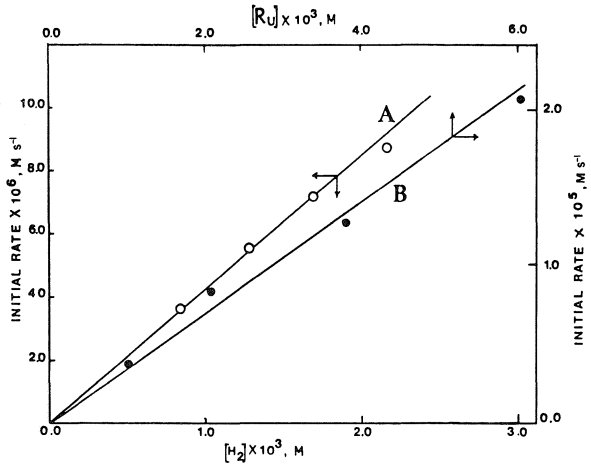

FIG. 7. Hydrogenation of α-phenylacrylic acid, DMA, 60°C. Curve *A*: 0.2 *M* phenylacrylic acid, 2×10^{-3} *M* Ru. Curve *B*: 0.4 *M* phenylacrylic acid, 760 mm pressure.

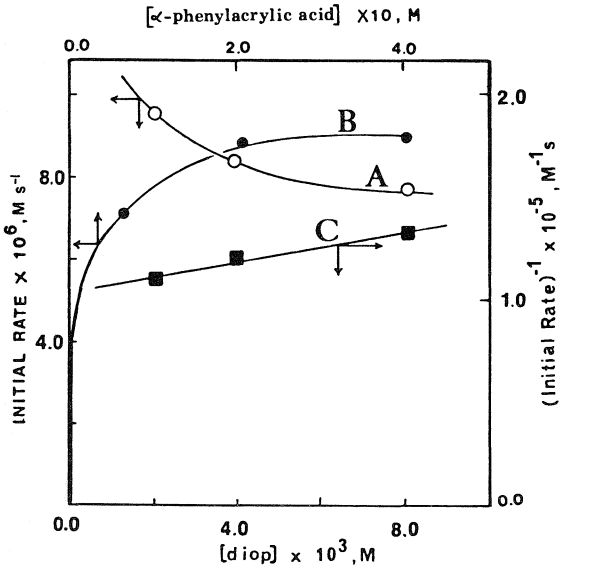

FIG. 8. Hydrogenation of α-phenylacrylic acid, DMA, 60°C. Curve *A*: 0.2 *M* phenylacrylic acid, 2×10^{-3} *M* Ru, 760 mm pressure. Curve *B*: 2×10^{-3} *M* Ru, 760 mm pressure. Curve *C*: curve *A* replotted as $(\text{rate})^{-1}$ vs. [diop] added.

The rapid alkyl formation is probably followed by a rate-determining oxidative addition of H_2 to give an octahedral ruthenium(IV) complex which then reductively eliminates the saturated product (see below). The dissociated diop may or may not reassociate to the HRuCl(diop) intermediate (which would be present as a solvated, likely 6-coordinate species) prior to commencement of the second catalytic cycle by further coordination of acrylamide.

The mechanism shown leads to the rate-law given in eq. [7], where a subscript "T" refers to the *total* concentration of species, e.g. $[\text{acryl}]_T$ refers to the free plus coordinated substrate.

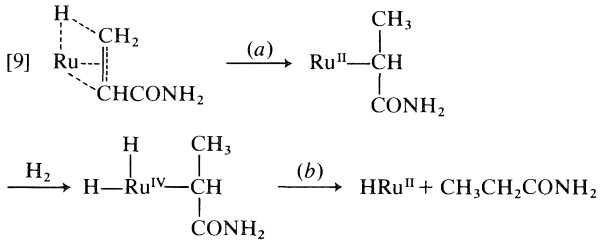
$$[7] \quad \text{Rate} = \frac{-d[H_2]}{dt} = \frac{kK_1[\text{Ru}]_T[H_2][\text{acryl}]_T}{K_1[\text{acryl}]_T + [\text{diop}] + K_1[\text{Ru}]_T}$$

The rate law shows the experimentally determined first-order dependence on $[H_2]$, between first- and zero-order in acrylamide, and between first- and zero-order in ruthenium. This catalyst dependence pertains even when $[\text{acryl}]_T \gg [\text{Ru}]_T$ (denominator of eq. [7]), since the [diop] term increases as $[\text{Ru}]_T$ increases (reaction [4]).

Although rate expression [7], or its inverse form (eq. [8]), is complex, some limiting forms that exist for some of the experimental conditions used are simple, and the data can be analyzed accordingly.

$$[8] \quad \frac{1}{\text{Rate}} = \frac{1}{k[H_2]}\left(\frac{1}{[\text{Ru}]_T} + \frac{1}{[\text{acryl}]_T}\right) + \frac{[\text{diop}]}{kK_1[\text{Ru}]_T[H_2][\text{acryl}]_T}$$

For example, at constant $[H_2]$, $[\text{Ru}]_T$, and $[\text{acryl}]_T$, the plot of $(\text{rate})^{-1}$ vs. added [diop] yields a straight line (Fig. 5*B*) whose slope yields a kK_1 value of $8.9 \times 10^{-3}\ M^{-1}\ s^{-1}$ (eq. [8]), although the intercept is too small to give a reliable k value.



The intercept of the plot drawn of $(\text{rate})^{-1}$ vs. $[\text{acryl}]^{-1}$ (Fig. 6) yields (eq. [8]) a k value of $\sim 27\ M^{-1}\ s^{-1}$. Use of the determined kK_1 value yields $K_1 = 3.3 \times 10^{-4}$ which is in good agreement with the spectroscopically determined value of 3.8×10^{-4}. For reactions with excess diop at constant $[\text{acryl}]_T$ and $[H_2]$, when $[\text{diop}] \gg K_1[\text{acryl}]_T + K_1[\text{Ru}]_T$, the plot of the rate vs. $[\text{Ru}]_T$ gives a straight line passing through the origin (eq. [7], Fig. 3*B*), the slope giving $kK_1 = 8.6 \times 10^{-3}\ M^{-1}\ s^{-1}$. Similarly, for conditions with excess diop, the slope of Fig. 4*B* yields a kK_1 value of $9.0 \times 10^{-3}\ M^{-1}\ s^{-1}$. The slope of Fig. 4*C* at the conditions used, close to first-order in acrylamide, is given by the expression $kK_1[\text{Ru}]_T[\text{acryl}]_T/[\text{diop}]$; rewriting [diop] in terms of equilibrium [4] gives for the slope the expression $kK_1^{1/2}[\text{Ru}]^{1/2}{}_T[\text{acryl}]^{1/2}{}_T$. The measured slope yields $kK_1^{1/2} \approx 1.0\ s^{-1}$, in comparison to a value of about $0.5\ s^{-1}$ determined from the other kinetic dependences; the agreement is considered reasonable.

In summary, all the kinetic data are internally consistent yielding at 60°C, $k = 27\ M^{-1}\ s^{-1}$ and $K_1 = (3.2 \pm 0.1) \times 10^{-4}$, and the latter value agrees

well with a spectroscopic K_1 value determined independently.

The mechanism closely resembles that of the $HRuCl(PPh_3)_3$-catalyzed systems, where a phosphine ligand dissociates to provide a coordination site for the unsaturated substrate (2). The $HRuCl(diop)_2$ complex alone does not detectably dissociate a diop ligand (7), while substrate coordination does cause loss of this ligand. Dissociation of one end of the chelating diphosphine could in principle allow for acrylamide coordination, and indeed monodentate diop ligand complexes are known (7); however, steric problems may force complete dissociation of a diop during formation of a *cis* hydrido-olefin intermediate. Subsequent hydride transfer is considered to proceed through a four-centre transition state (9); the direction of hydrometallation is uncertain but on electronic grounds it would be expected to proceed as shown in reaction [9] (other Cl, and diop ligand omitted):

In principle the rate-determining step could then be either the oxidative-addition of H_2 or the subsequent hydrogen transfer steps; the former is usually preferred since hydrido-alkyl species are relatively rare (2), although a greater difficulty in hydride transfer to coordinated alkyl in this case due to the conformational rigidity of the diop ligand cannot be ruled out.

The hydrogenation rates are about 1/50 as large as those using $HRuCl(PPh_3)_3$ under corresponding conditions (10), but are still reasonably efficient with a turnover number of about 100 h^{-1} at 1 atm H_2 at 60°C. The higher rates for the PPh_3 system result from more effective binding of substrates, i.e. higher K_1 values (10). More heavily substituted substrates, such as α- and β-methylcinnamic and methylfumaric acids (which are prochiral), are not hydrogenated at all by the diop catalyst likely because of steric problems in their coordination.

Of interest, the complexes $HRuCl[Ph_2P(CH_2)_nPPh_2]_2$, with n = 1–4, the n = 4 system being analogous to the diop system, are probably undistorted *trans* structures with C_{4v} symmetry, the P atoms all being equivalent at 30°C (11). None of these are effective for catalytic hydrogenation of olefins under mild conditions. The distortions imposed by the dioxolane ring of the diop ligands presumably make them more readily displaced by the substrate (higher K_1 values).

The nonlinearity of the H_2-uptake at lower pressure during hydrogenation of even 5–10% of the acrylamide (Fig. 2*D*) suggests the presence of some reaction that competes with step [5] under these conditions. Utilization of hydrogen from the phenyl rings of the phosphine is one possibility (12).

α-Phenylacrylic Acid System

The system parallels that of acrylamide after allowance is made for the much stronger binding by this acidic substrate. This results in a zero-order dependence on substrate even at 0.2 *M* (Fig. 8*B*); this means that the $K_1[\text{substrate}]_T$ term in the denominator of rate-law [7] then dominates, and the rate-law becomes simply $k[H_2][Ru]_T$ due to complete formation of the alkyl (reaction [4]). The average value of k determined from the slopes of Fig. 7*A*, *B* is 2.08 M^{-1} s^{-1}. The inverse dependence on diop is small (Fig. 8*A*) due to the relatively large K_1 value, but the limited inverse plot shown in Fig. 8*C* (eq. [8]) yields k = 2.2 M^{-1} s^{-1} from the intercept and a kK_1 value of 0.36 M^{-1} s^{-1} from the slope; these numbers give K_1 = 0.16 in reasonable agreement with the spectrophotometric data.

The much higher binding constant of the phenylacrylic acid compared to acrylamide could be due to differences in the electron-withdrawing properties of the substituent groups (C_6H_5, CO_2H vs. H, $CONH_2$), but coordination via the carboxylic acid or even the phenyl group is feasible (2). Binding of styrene to a solvated $Rh[Ph_2P(CH_2)_2PPh_2]^+$ species occurs primarily via the phenyl ring (13). The slower hydrogenation (k) step of the phenylacrylic acid system could be attributed to a less favourable oxidative addition of H_2 due to lower electron density at the metal centre and/or greater difficulty in a hydride transfer step (eq. [9]) due to steric reasons.

The overall catalytic addition of H_2 to olefins is nearly always *cis* (ref. 5, p. 407), and to the olefinic face coordinated to the metal. The hydrometallation step (reaction [9], step (*a*)) is necessarily *cis* and this is thought to determine the chirality of the final product since the reductive elimination step (reaction [9], step (*b*)) occurs with retention of configuration at the metal-bonded carbon (14). Thus, preferential coordination of one olefinic face of the substrate is required for asymmetric hydrogenation. These mono(diop) systems probably achieve preferred coordination of one olefinic face due to an alternating edge-face arrangement of the four phenyl groups (2, 15).

A tentative correlation between the extent of

For personal use only.

asymmetric induction and binding constants of prochiral olefinic substrates has been suggested for some Rh(diop)(solvent)$_2^+$ systems (16). The mechanism established in this work for the HRuCl(diop)$_2$ system should allow for a further testing of this hypothesis, studies that are in progress in this laboratory.

The structures of $[C_5H_7]^+$ ions produced by methyl loss from thirty isomeric C_6H_{10} molecular ions have been assessed from measurements of ionic heats of formation and the kinetic energy release associated with the fragmentation. It is proposed that the thermodynamically most stable $[C_5H_7]^+$ ions [cyclopentenium]$^+$ are formed at the dissociation threshold irrespective of the initial molecular ion structure. Mechanistic aspects of the fragmentations were studied by mean of deuterium labelling.

Observations of metastable peak shapes for labelled compounds permitted the identification of reaction pathways having different energy requirements. The lowest energy routes involved little or no positional mixing of H and D prior to fragmentation. It is proposed that the molecular ions with sufficient energy to fragment on the μs time scale undergo successive (and reversible) isomerization by allylic 1,3-hydrogen shifts to their isomeric isolated diene molecular ions which, by an allylic 1,2-hydrogen shift, may isomerize to a methylcyclopentene molecular ion prior to loss of methyl. The sequence of isomerization of the molecular ions is alkyne → allene → conjugated diene → isolated diene. The de-conjugation step has an activation energy of ca. 10 kcal mol^{-1}. We suggest, however, that allene molecular ions rearrange directly to isolated diene molecular ions.

PEDER WOLKOFF, JOHN L. HOLMES et F. P. LOSSING. Can. J. Chem. **58**, 251 (1980).

On a déterminé la structure des ions $[C_5H_7]^+$ provenant de la perte d'un méthyle par trente ions moléculaires isomères C_6H_{10}, à partir des mesures de chaleur ionique de formation et de l'énergie cinétique associées à la fragmentation. On propose que les ions [cyclopentènium]$^+$ $[C_5H_7]^+$ les plus stables thermodynamiquement, sont formés au début de la dissociation quelle que soit la structure de l'ion moléculaire initial. On a étudié le mécanisme de ces fragmentations par marquage isotopique au deutérium.

L'observation de la forme des pics métastables des composés marqués a permis d'identifier des mécanismes réactionnels requérant des énergies différentes. La voie exigeant la plus faible énergie implique peu ou pas de mélange de position de l'hydrogène ou du deutérium avant la fragmentation. On propose également que les ions moléculaires ayant suffisamment d'énergie pour se fragmenter dans des temps de l'ordre de la μs subissent des isomérisations successives, (et reversibles) par transpositions 1,3 d'hydrogènes allyliques conduisant à leurs ions moléculaires isomères comportant des dienes non conjugués, qui par une transposition allylique-1,2 peuvent s'isomériser en un ion moléculaire méthylcyclopentène avant la perte d'un méthyle. Les ions moléculaires s'isomérisent suivant la séquence: alcyne → allène → diène conjugué → diène non conjugué. L'étape de déconjugaison a une énergie d'activation de l'ordre de 10 kcal mol^{-1}. Nous suggérons cependant que l'ion moléculaire allénique se transpose en ion moléculaire comportant un diène non conjugué.

Introduction

Our understanding of the unimolecular decompositions of ionised unsaturated aliphatic hydrocarbons has improved only slowly during the last decade.

Although the development of new techniques (1) has made possible observations within well defined time frames, a fundamental and general understanding of the decomposition processes of alkenes has been rendered especially difficult by the extensive rearrangements which precede fragmentation. Levsen and Heimbrecht have examined non-decomposing molecular ions of alkenes by collisional activation mass spectrometry and they concluded that the isomerization of alkene molecular ions becomes less pronounced with increasing molecular size (2). Using metastable ion characteristics and thermochemical arguments Bowen and Williams have suggested (3) that up to a limiting chain length of six carbon atoms, complete interconversion takes place among isomeric monoalkene molecular ions prior to decomposition in the μs time frame.

Isotopic labelling studies have shown that the complete loss of positional identity of H and/or C atoms takes place prior to fragmentation in a wide variety of molecular ions of unsaturated hydrocarbons; examples have recently been reviewed (4). Incomplete atom randomization prior to fragmentation on the μs time scale only becomes prevalent in ions containing six or more C atoms, e.g., in dimethylpentenes (5), heptenes (6, 7), C_7H_{10} isomers (8), and octenes (9).

The structural integrity of ions which have insufficient internal energy to fragment in the μs time frame can be investigated by collisional activation

techniques. Varying degrees of isomerization have thus been identified among molecular ions of C_4H_8 (2), C_5H_{10} (10), C_6H_{10} (11), C_6H_{12} (10), C_7H_{14} (2), and C_8H_{16} (9). From the above it is evident that the relative rates of isomerization and fragmentation reactions are a complex function of internal energy and molecular size.

It has been shown recently (12) that isomeric cyclic C_6H_{10} molecular ions decompose by methyl loss via a methylcyclopentene molecular ion, producing cyclopentenium ions at their thermochemical threshold; the latter is the most stable $[C_5H_7]^+$ ion species, having a heat of formation (ΔH_f) of 199 kcal mol^{-1} (13).

In this paper, we describe methyl loss from *all* acyclic isomeric C_6H_{10} molecular ions; (*m/z* 67) is the base peak in the reported normal mass spectra of these compounds (14). The purpose of this investigation was to try to answer the following questions: What is the structure of the $[C_5H_7]^+$ ions and how are they formed? What influence has the position of unsaturation on the energetics and mechanism of $[C_5H_7]^+$ formation? How does loss of positional identity among H and D atoms come about?

Possible structures for $[C_5H_7]^+$ daughter ions whose thermochemistry has been investigated (13) are shown below, together with their heats of formation in kcal mol^{-1}. Methylcyclopentene

199 217 (est) 220 233 (est) 234

molecular ions with internal energy less than ca. 1 eV above the threshold for [cyclopentenium]$^+$ generation fragment (μs time scale) by a simple bond cleavage and there is no atom mixing (12). Ions having a greater internal energy and decomposing on the same time scale lose methyl containing randomly selected H atoms and the reaction is believed to proceed via a ring-opened species (12). We have measured ionization and appearance energies (AE) for *m/z* 67 using energy selected electrons (15) (molecular ion lifetime ~30 μs) and metastable peak shapes for $[C_5H_7]^+$ ion production. AE values afford $\Delta H_f(C_5H_7^+)$. The width of the metastable peak is directly related to the release of excess internal energy (which is made up of the non-fixed energy of the activated complex and any reverse activation energy (16)) into kinetic energy (T).

Results and Discussion

Thermochemistry

The heats of formation of the neutral C_6H_{10} molecules, molecular ions, and their $[C_5H_7]^+$ daughter ions are presented in Table 1, together with the kinetic energy releases evaluated from the half-height widths of the metastable peaks for $CH_3^\bullet$ loss. For convenience of presentation, Table 1 is subdivided according to the number and type of multiple bonds in the isomers.

(i) Molecular Ion Stability

The $\Delta H_f(C_6H_{10}^{+\bullet})$ values show that the relative stability of molecular ions having one unsaturated bond in a terminal position follows the order alkyne < allene < unconjugated diene < conjugated diene < cycloalkene. Stabilization by methyl substitution at a terminal unsaturated site is most significant for alkynes; thus the molecular ions of 2-hexyne and 3-hexyne have a $\Delta H_f(M^{+\bullet})$ 18 kcal mol^{-1} lower than that of 1-hexyne. This effect is smaller for conjugated and cumulated dienes; for example, $\Delta H_f(M^{+\bullet})$ of 2,3-hexadiene is 9 kcal mol^{-1} less than that of its 1,2-isomer.

The IE values of all terminal alkynes, 1,2- and 1,5-hexadiene, and 2-methyl-1,4-pentadiene are close to or above the calculated thresholds for the generation of $CH_3^\bullet$ and the most stable $[C_5H_7]^+$ daughter ion, [cyclopentenium]$^+$, e.g., for 1-hexyne, AE calculated for [cyclopentenium]$^+$ + $CH_3^\bullet$ = (199 + 34 − 29.6)/23.06 = 8.82 eV, IE = 9.95 eV; AE $[C_5H_7]^+$ = 10.04 eV. It is noteworthy that these molecular ions require less than 0.2 eV of internal energy (above their IE) for this fragmentation to be observed on the 30–50 μs time scale. Such ions then are all "hot" with respect to the above dissociation at their ionization thresholds.

(ii) Heats of Formation of $[C_5H_7]^+$ Daughter Ions

These, as can be seen from Table 1, fall into three general groups. Those with apparent heats of formation in the range 200 → 206 kcal mol^{-1} must have the [cyclopentenium]$^+$ structure and need not be further discussed. The excess energies of up to 5 kcal mol^{-1} may be ascribed to a kinetic shift effect (17). A second group have ΔH_f in the range 211 ± 3 kcal mol^{-1}. It is formally possible that these values relate to the formation of an isomeric $[C_5H_7]^+$ daughter ion with a ΔH_f about 12 kcal mol^{-1} above that of [cyclopentenium]$^+$. In view of the uncertainty of ΔH_f[dimethylcyclopropenium]$^+$ (13), this ion is a candidate. However, the energy release values for this group of compounds, the majority of which are conjugated dienes, all are significantly greater than those for the isolated dienes (and cycloalkenes (12)) which produce [cyclopentenium]$^+$ at or near to threshold. Thus these ΔH_f values may arise from the presence of an energy barrier for a common rearrangement (e.g., de-

conjugation of the double bonds) which precedes fragmentation to produce the most stable daughter ion; the larger $T_{0.5}$ values would thus reflect the higher internal energies of such ions (18). Indeed, the $[C_5H_7]^+$ daughter ion produced from 1,2,2-trimethylcyclopropene has a ΔH_f value too low for it to be [dimethylcyclopropenium]$^+$ and thus even this molecular ion undergoes rearrangement before fragmentation.

The alkynes form a third group. The terminal alkynes are "hot" ions (as discussed above) and the $T_{0.5}$ values are the largest for all compounds investigated. Although in principal two other daughter ions are thermochemically feasible, we suggest that again [cyclopentenium]$^+$ is being generated. The molecular ions of the non-terminal alkynes have significantly lower heats of formation and $CH_3^\bullet$ loss has an activation energy of 0.4–0.5 eV. The $T_{0.5}$ values and $\Delta H_f[C_5H_7]^+$ are also lower than for the terminal alkynes.

Two noteworthy exceptions to the above groupings should be discussed. 1,3-Hexadiene is the sole conjugated diene which has a low $\Delta H_f[C_5H_7]^+$ value. This is the only conjugated diene molecular ion which can formally lose a $CH_3^\bullet$ group by a favorable (19) allylic cleavage without the need of prior rearrangement.

1,2-Hexadiene also yields the same low $\Delta H_f[C_5H_7]^+$; this observation may be explained by proposing that the molecular ion may rapidly isomerize to that of 1,3-hexadiene with no appreciable energy barrier, because of the close similarity between their $\Delta H_f[C_5H_7]^+$ and energy release ($T_{0.5}$)values.

(iii) Kinetic Energy Releases

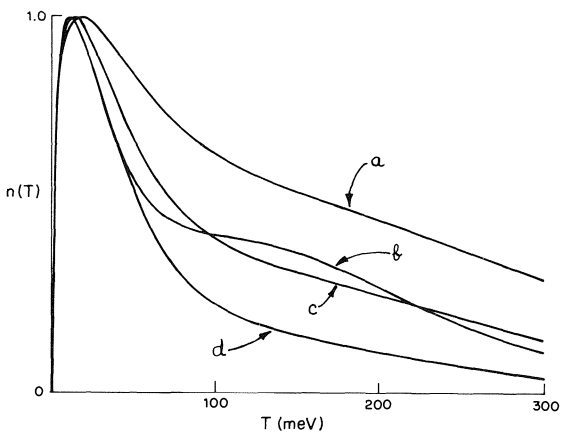
In previous work on cyclic $[C_6H_{10}]^{+\bullet}$, the difference in activation energies between two competing reactions leading to $[C_5H_7]^+$ could satisfactorily be related to the difference in their average released energies ($\Delta\langle T\rangle$) by use of Haney and Franklin's empirical equation (20), $\langle E\rangle^* = \Delta\langle T\rangle \times 0.44\ (3n - 6)$, where n is the number of atoms in the fragmenting ion.

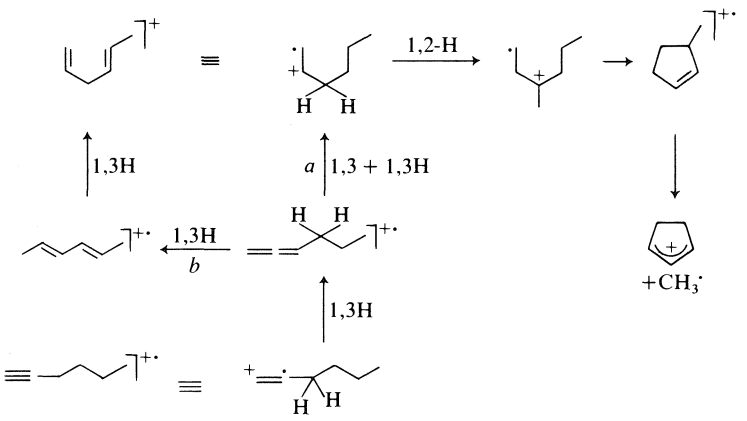
Although the released kinetic energies ($T_{0.5}$) (Table 1) roughly follow the same trend as $\Delta H_f[C_5H_7]^+$, no simple relationship exists between them. For example, $\Delta H_f[C_5H_7]^+$ for the majority of the conjugated dienes is 211 ± 3 kcal mol^{-1}, while $T_{0.5}$ ranges from 25–41 meV. These observations could result from the fragmentations taking place over more than one potential surface, i.e., that the metastable peaks consist of two (or more) superimposed gaussian-type peaks having different energy releases and being present in different relative abundances. Second components can clearly be seen in the distributions of released energies (21) for the fragmentations of 2-methyl-1,4-pentadiene, 2,3-dimethyl butadiene, 1-hexyne, and 3,3-dimethylbut-1-yne. These are shown in Fig. 1.

Fragmentation Mechanisms

(i) Isolated Dienes

For these isomers, $[C_5H_7]^+$ is produced at energies close to that for [cyclopentenium]$^+$. It is noteworthy that although the molecular ion of 3-methyl-1,4-pentadiene has a structure appropriate for the generation of the 1,4-pentadien-3-yl cation (ΔH_f = 220 kcal mol^{-1}) (13) by a simple allylic bond cleavage, nevertheless [cyclopentenium]$^+$ ions are generated. [Cyclopentenium]$^+$ formation (possibly via a methylcyclopentene molecular ion) from these isomers may be accomplished by *one* 1,2-hydrogen shift, followed by ring closure; the itinerant H atom is secondary (or tertiary) and allylic. (There is indeed experimental precedent for 1,2-H shifts in molecular ions of hydrocarbons (22, 23).) Two principles are thus required: (*a*) that the charge is preferentially located at the most highly substituted carbon atom and the odd electron at the least substituted carbon atom; (*b*) that the driving force for the H-shift is to achieve allylic stabilization of the charge (see Scheme 1). These principles do not apply to the 1,5-hexadiene molecular ion; isomerization to its 1,3- or 1,4-isomer is unlikely because of the low $\Delta H_f[C_5H_7]^+$ value. Further-





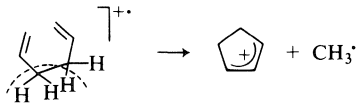


FIG. 1. Distributions of released energies ($n(T)$ represents the fraction of the energy released) derived from metastable peaks (21) for the fragmentation $C_6H_{10}^{+\bullet} \rightarrow C_5H_7^+ + CH_3^\bullet$ for (*a*) 1-hexyne, (*b*) 3,3-dimethylbut-1-yne, (*c*) 2,3-dimethyl-1,3-butadiene, and (*d*) 2-methyl-1,4-pentadiene.

SCHEME 1

more, this molecular ion has been shown to be stable with respect to isomerization at low internal energies (24). We propose that methyl is lost via the extrusion of a methylene group (C-3 or C-4) together with a neighboring secondary, allylic hydrogen atom leading to [cyclopentenium]$^+$ formation in a concerted manner (viz. internal methyl loss from alkane molecular ions (23) and the Cope rearrangement (see, for example, ref. 25)). The low $\Delta H_f[C_5H_7]^+$ value in the case of 2-propenylcyclopropane indicates that the ring opening has little or no activation energy, in keeping with recent studies of cycloalkanes (26).

(ii) Conjugated Dienes

With the exception of 1,3-hexadiene (discussed above) [cyclopentenium]$^+$ formation from the molecular ions of this group requires *two* H atom shifts if the above same two principles are applied. Isomerization of a 1,3-diene to its 1,4-isomer requires a 1,3-H shift, where the itinerant hydrogen atom is allylic and primary (cf., 1,3-H allylic shifts (27)), an additional 1,2-H shift then affords the methylcyclopentene molecular ion (see Scheme 1). The significantly higher $\Delta H_f[C_5H_7]^+$ values for the 1,3-dienes may arise from an activation energy for the deconjugation step, because the activation energy for a 1,3-allylic H-shift is negligible (12). $\Delta H_f[C_5H_7]^+$ for 2-ethyl-1,3-butadiene can be similarly explained even though two 1,3-allylic H-shifts are required for deconjugation. There are, however, (intuitively) alternative rationalizations for [cyclopentenium]$^+$ formation, e.g., a 1,4-H shift would afford the methylcyclopentene molecular ion directly from that of 2-methyl-1,3-pentadiene; indeed, the metastable peak was found to be composite from analysis of the peak shape (21), and thus indicative of competing fragmentation routes. The molecular ions of 2,3-dimethyl-1,3-butadiene and bicyclopropyl may rearrange via [2-propenylcyclopropane]$^{+\cdot}$ by a 1,2-H shift.

(iii) Allenes

$[C_5H_7]^+$ formations from allene molecular ions have ΔH_f and $T_{0.5}$ values lower than those of their conjugated isomers and so isomerization to the latter is unlikely (*b* in Scheme 1). Direct isomerization to a 1,4-isomer by two concerted 1,3-H shifts (*a* in Scheme 1) is a possible route.

(iv) Alkynes

We propose that these molecular ions first rearrange to an isomeric allene by a 1,3-H shift, a process for which there is a large thermodynamic driving force (see Table 1). This has been demonstrated for the [propyne]$^{+\cdot}$ → [allene]$^{+\cdot}$ system (28) and such a rearrangement has also been proposed for substituted acetylenes (29). However, the high $\Delta H_f[C_5H_7]^+$ values for 2- and 3-hexyne require either a substantial kinetic shift or an activation energy for the [alkyne]$^{+\cdot}$ → [allene]$^{+\cdot}$ step. (Note that the 1-ynes are "hot" ions as discussed earlier.) Only 3-methyl-2-pentyne produces $[C_5H_7]^+$ with a ΔH_f comparable to those from the allenes; this, however, is the *only* alkyne having a *tertiary* H-atom available for a 1,3-shift (to produce trimethylallene in this case); this may well have a lower energy requirement. The only deuterium-labelled alkyne studied in this work was 1-$^2H_1$-1-hexyne. The relative abundances of the metastable peaks for loss of $CH_3^\cdot$ and $CH_2D^\cdot$ were very close to the random statistical ratio (Table 2), in agreement with earlier work on ions of low internal energy content (30). Complete loss of positional identity among H atoms for $[C_6H_{10}]^{+\cdot}$ ions of such

high internal energy content is to be expected from our earlier investigations (12).

Deuterium Labelling

(i) 2-Methyl-1,4-pentadiene-1,1-$^2H_2$

Results for this compound have been reported earlier (12), but they have been revised and are presented here (as metastable peak areas) in Table 2. The observations were interpreted as arising from a random statistical loss of labelled methyl which requires an activation energy in excess of the threshold for [cyclopentenium]$^+$ generation, plus a threshold methyl loss which involves *mainly*, but not exclusively, $CH_3^{\cdot}$ loss prior to, or in concert with ring closure. The latter conclusion follows from the observation that the daughter ions *m/z* 67, 68, and 69 had the same AE as the unlabelled compound. Note that the $T_{0.5}$ value for $CH_3^{\cdot}$ loss (17.7 meV) is significantly higher than that for the specific loss of $CH_3^{\cdot}$ from methylcyclopentenes (15.5 meV) (12), but these results are compatible with a weighted summation of T values of 15.5 and 31 meV (12). Similarly, $T_{0.5}$ ($CH_2D^{\cdot}$) > $T_{0.5}$ ($CHD_2^{\cdot}$), an observation which is in keeping with the proposal that for this molecule, the threshold reaction involves partial mixing of H and D, i.e., the rates of H/D positional exchange processes are similar to or less than the rate of fragmentation. Loss of $CH_2D^{\cdot}$ represents a more mixed state than loss of $CHD_2^{\cdot}$; for example, H/D mixing resulting from successive 1,3-H shifts.

(ii) 2,4-Hexadiene-3,4-$^2H_2$ and 1,1,1-$^2H_3$

The relative abundances of the metastable peaks for these compounds are not in the random statistical ratio (see Table 2). There is, however, no major isotope effect operating here because the weighted $T_{0.5}$ values for the labelled compounds, 32.3 and 34.2 meV respectively, lie close to that for the unlabelled molecule, 34 ± 1 meV. The largest $T_{0.5}$ values are for the fragmentations corresponding to the greatest degree of label mixing and vice versa. The loss of $CD_3^{\cdot}$ from the 1,1,1-$^2H_3$ compound must represent the mechanistically least complex reaction because the statistical contribution to such a process is the smallest (see Table 2). Thus, the loss of terminal methyl group makes up ca. 20% of the overall fragmentation; it has the lowest $T_{0.5}$ value and corresponds to the minimum energy pathway, $\Delta H_f[C_5H_7]^+ = 212$ kcal mol^{-1}. If [cyclopentenium]$^+$ were the daughter ion, then the excess internal energy (13 kcal mol^{-1}) plus that required to achieve the rate constant for fragmentation is available for partitioning into translational energy. In our earlier work (12) average excess energies were estimated using the empirical relationship of Haney and Franklin (see above). In this case $\langle \varepsilon^* \rangle = 0.44 \times 42\ (0.078 - 0.046) = 0.59$ eV = 13.6 kcal mol^{-1}, in excellent agreement with the observed excess energy.

(iii) 1,2-Hexadiene-1-$^2H_1$

The metastable characteristics of this compound show the same trends as for those just described (Table 2), with substantial H/D mixing prior to methyl loss (cf. ref. 29*b*). $T_{0.5}$ ($CH_2D^{\cdot}$) possibly contains some contribution from high $T_{0.5}$ values from high randomization processes. At low electron energies the ratio $[M - CH_3^{\cdot}]^+/[M - CH_2D^{\cdot}]^+$ decreases; at nominal 12 eV it is 1:3.3 in the normal spectrum (1:1 at 20 eV) showing that methyl loss involving the terminal methylene group is the lower energy process.

Conclusions

We propose that irrespective of the structure of a $[C_6H_{10}]^{+\cdot}$ precursor molecular ion, the fragment ion $[C_5H_7]^+$, generated in the μs time frame, will have the [cyclopentenium]$^+$ structure. No evidence was found for the formation of $[C_5H_7]^+$ ions of any other structure. We further suggest that [cyclopentenium]$^+$ is the $[C_5H_7]^+$ ion generated at the dissociation threshold from isomeric $C_7H_{12}^{+\cdot}$, $C_8H_{14}^{+\cdot}$ and some higher homologous ions (14), in whose mass spectra *m/z* 67 is base, or second largest peak.

Experimental Section

Metastable peak shapes were measured at a fixed electric sector voltage on a Kratos AEI MS 902S mass spectrometer by sweeping the acceleration voltage using good energy resolution as described previously (31). For the labelled compounds each metastable peak was measured at the same acceleration potential to avoid errors arising from the sampling of slightly different ion lifetimes. Sample pressure was $3–5 \times 10^{-7}$ Torr. Kinetic energy release (T) was calculated in the usual way (16), correcting for main beam width and overlapping processes arising from natural isotopic abundances. Ionization and appearance energies were obtained as described previously using monoenergetic electrons, and a mini-computer for data accumulation and analysis (13, 15).

Unlabelled compounds were purchased from Chem. Samples Co. and Fluka, isomeric purity 98–99%. 1,2-Hexadiene was prepared as described (32) and purified by GC; 1,2-hexadiene-1-$^2H_1$ was made using $LiAlD_4$ ($^2H_1 \sim 98\%$). 2,3-Hexadiene (33) and 4-methyl-1,2-pentadiene (33) were gifts from Dr. D. G. Garratt. 1,2,2-Trimethylcyclopropene was prepared as described by Closs *et al.* (34). 2,4-Hexadiene-1,1,1-$^2H_3$ ($^2H_3 \sim 90\%$) and 2,4-hexadiene-3,4$^2H_2$ ($^2H_2 \sim 98\%$) were prepared according to Claesson (35) but the isolation procedure was slightly modified; the diene was distilled from the hydrolysis mixture and the fraction boiling from 45–95°C was collected; the organic layer was dried and 2,4-hexadiene (consisting of a mixture of all three geometric isomers) was collected by PGLC. 1-Hexyne-$^2H_1$ ($^2H_1 \sim 90\%$) was from Chem. Samples Co.

An INDO-MO study of the spectral properties and transannular interaction in [6]-helicene

B. M. Deb and Geetharani Kavu

Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India

Received December 22, 1978[1]

B. M. Deb and Geetharani Kavu. Can. J. Chem. **58**, 258 (1980).

The INDO-MO calculations on [6]-helicene reported here enable one to classify the four HOMO's as predominantly π, in contrast to other occupied MO's. A linear adjustment of these four HOMO's correlates well with the experimental photoelectron and optical spectra. Viewed through Mulliken's overlap population between overlapping rings, the transannular interaction in [6]-helicene appears to be unfavourable and therefore minimised. The use of a skeleton representation of the molecule is considered and found inadvisable.

B. M. Deb et Geetharani Kavu. Can. J. Chem. **58**, 258 (1980).

Les calculs des orbitales moléculaires INDO de l'hélicène-[6] que l'on rapporte ici permettent de confirmer que les 4 orbitales moléculaires HO sont d'une façon prédominante de type π, ce qui est à l'opposé des autres orbitales moléculaires occupées. Un ajustement linéaire de ces 4 orbitales moléculaires s'harmonise bien avec les spectres photoélectronique et optique expérimentaux. En se basant sur la population de recouvrement de Mulliken entre les deux cycles qui chevauchent, l'interaction transannulaire dans l'hélicène-[6] semble être défavorisé et de ce fait est minimisée. On a envisagé l'emploi d'un modèle pour représenter la molécule mais l'expérience montre que c'est à déconseiller.

Introduction

In recent years, a number of experimental and theoretical studies have been reported on [5]- to [14]-helicenes (1–3). The main objectives of the present INDO-MO calculations (4) are the following: (*1*) to examine the INDO-MO energy levels of [6]-helicene (X-ray geometry (5)) in relation to its experimental photoelectron (PE) and optical spectra; (*2*) to compare the agreement between INDO and PE and optical spectra of [6]-helicene with that for its constituent unit benzene (experimental geometry (6)); (*3*) to obtain a semi-quantitative account of transannular interaction (TI), i.e., secondary π delocalisation, between overlapping rings in the molecule; (*4*) to study the consequences of employing a skeleton model upon PE and optical spectra, σ–π mixing and TI in the molecule (see Fig. 1). The broad conclusions reached here might remain valid for higher members of the helicene series.

Results and Discussion

(1) Energy Levels of Benzene and [6]-Helicene (X-ray Geometry)

A comparison (Table 1) of INDO-MO energy levels of benzene with those from *ab initio* (7) and PE (8) spectral data[2] shows that the INDO ordering of the $a_{2u}\pi$ level (π_{11} in Table 1) is incorrect. Since the σ and π AO's do not mix in any benzene MO, Fig. 2 clearly indicates two separate dependences of the σ and π MO's instead of a collective dependence (9). The four π levels show a least-squares linear fit (in eV),

$$[1] \quad -(\mathrm{IP})_i = 0.276\varepsilon_i - 5.72$$

with an rms error of 0.07 eV (Fig. 2). The π–π* transition energies, calculated from INDO-MO levels adjusted by eq. [1], compare well with the corresponding experimental (10) results (Table 1).

The INDO lowering, $|\varepsilon_{\mathrm{INDO}}| - \mathrm{IP}$, of the HOMO (π) energy for benzene is quite high, 4.02 eV (Table 1). The calculated occupied π levels of benzene clearly reflect an exaggerated delocalisation energy which seems to be an artefact of INDO calculations on such planar systems. In contrast, the INDO lowering of the HOMO energy in [6]-helicene is 1.98 eV (Table 2), since extensive σ–π mixing[3] in this non-planar molecule raises the π orbitals in energy; in other words, non-planarity causes a loss in delocalisation energy. One therefore concludes that in planar aromatics where no mixing of σ and π AO's occurs, with increasing delocalisation the INDO method is likely to provide increasingly exaggerated delocalisation energies, whereas for non-planar molecules where extensive σ–π mixing occurs the INDO method would provide a more realistic description.

(2) Nature of the MO's in [6]-Helicene

In spite of extensive σ–π mixing it is possible to study the MO's of [6]-helicene in a manner which

[1]Revision received July 3, 1979.

[2]Used in conjunction with the Koopmans theorem, viz. $-(\mathrm{IP})_i = \varepsilon_i$, where $(\mathrm{IP})_i$ and ε_i are experimental ionisation potential and energy, respectively, of the *i*th MO.

[3]σ and π refer separately to each ring in [6]-helicene, and not to the whole molecule.

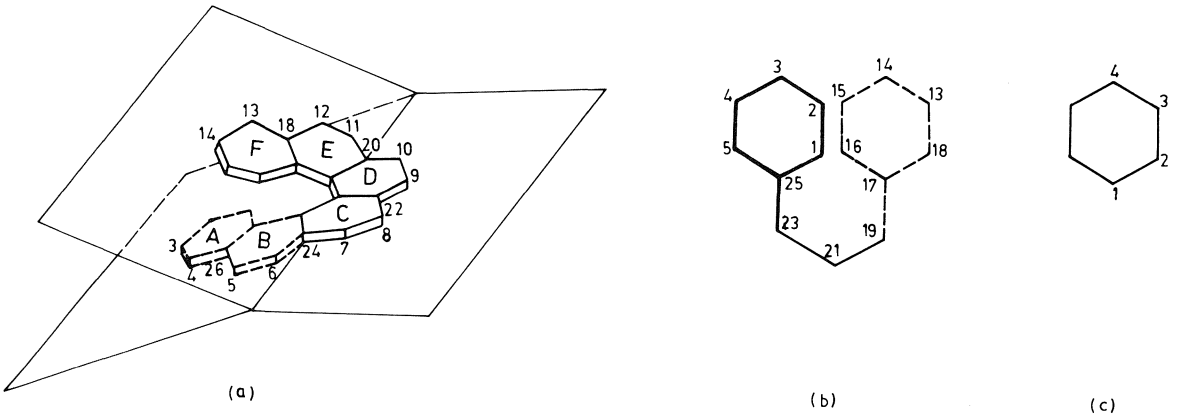

FIG. 1. (*a*) [6]-Helicence, (*b*) skeleton model of [6]-helicene, and (*c*) benzene. The same atom numbering is used for both (*a*) and (*b*) and hence some of those in (*b*) are not repeated in (*a*) for clarity. The H-atom numbering is the same as that of the C atom to which H is bonded. (*a*) is drawn after ref. 5. (*b*) is of C_2 symmetry with the two phenyl fragments, thick and dotted, respectively, above and below the plane of paper by 29.25°. In (*b*), the C—C and C—H bond lengths are taken as arithmetic means of the corresponding values in X-ray geometry, viz., 1.41 and 1.08 Å respectively, while all CCC angles are taken as 120°.

TABLE 1. INDO-MO and *ab initio* (7) MO energies compared with experimental ionisation potentials (8) of benzene. The "virtual orbital IP's" are *calculated* from PE and optical spectra (Koopmans theorem). The calculated and experimental (10) transition energies are given only for the first three bands. All values are in eV

MO type	INDO energy	*Ab initio* energy	−(IP)	α, *p*, β transition energies in ascending order	
				Calcd.	Expt.
π_{18}^*	9.71	—	−3.16	4.88	4.80
π_{16}^*, π_{17}^*	4.55	—	−4.56	6.29	6.14
π_{14}, π_{15}	−13.32	−9.25	−9.30	7.47	6.75
σ_{12}, σ_{13}	−13.63	−13.41	−11.40		
π_{11}	−22.81	−13.74	−12.1		
σ_9, σ_{10}	−18.63	−16.10	−13.8		
σ_8	−19.58	−16.95	−14.7		
σ_7	−20.80	−17.46	−15.4		
σ_6	−28.60	−19.48	−16.9		
σ_4, σ_5	−30.10	−22.50	−19.2		
σ_2, σ_3	−38.20	−27.79	−22.5		
σ_1	−51.60	−31.56	−25.9		

permits one to characterise the four HOMO's of the molecule as predominantly π, as follows. The orientation of the resultant *p* AO on a carbon atom with respect to the *X*-axis which is approximately perpendicular to the planes of the rings C, D (Fig. 1), together with an idea of the torsional angle of the planes[4] of A, B and E, F makes it possible to classify the resultant *p* AO in an MO as predominantly σ, π, or just σ–π. This permits classification of the four HOMO's as predominantly π, *in contrast to* the other occupied MO's whose σ character increases as one goes to higher binding energy. It may be noted that Obenland and Schmidt (3) empirically assign the π levels to be above 10 eV in the PE spectrum, thereby designating the first eight PE bands as π.

Although the nine HOMO's of [6]-helicene, for which PE spectral bands have been reported, apparently show a fairly good linear correlation (Fig. 3), such a correlation yields transition energies which are three to four times the corresponding experimental values. In accordance with the above observations on the π MO's of benzene and [6]-helicene, the four HOMO's and two LUMO's (Table 2) of the latter have been gathered into a

[4]It should be noted, however, that no two rings in the molecule are strictly coplanar.

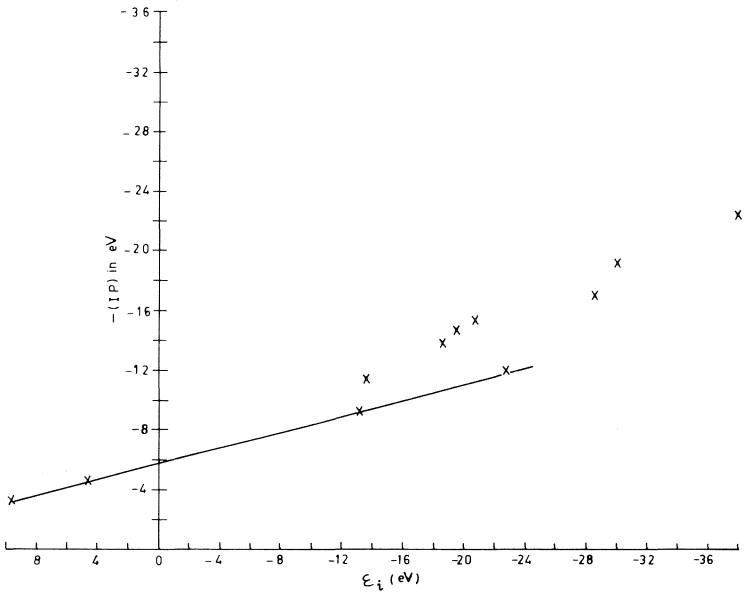

FIG. 2. Plot of experimental ionisation potentials $(IP)_i$ vs. INDO-MO energies (ε_i) of benzene. The "virtual orbital IP's" are calculated from observed PE and optical spectra (Koopmans theorem).

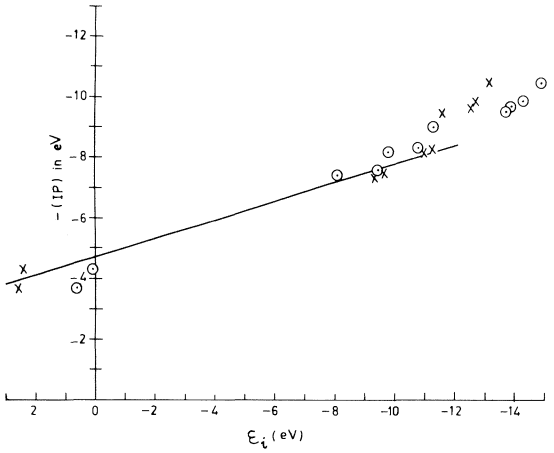

FIG. 3. Plot of experimental ionisation potentials $(IP)_i$ vs. INDO-MO energies (ε_i) of [6]-helicene in X-ray geometry (×) and skeleton model (○). The "virtual orbital IP's" are calculated from observed PE and optical spectra (Koopmans theorem).

least-squares linear (Fig. 3) expression,

$$[2] \quad -(IP)_i = 0.300\varepsilon_i - 4.74$$

with a slightly high rms error of 0.22 eV; this is due to a lack of perfect correlation between the MO's because of their differing π character, unlike benzene where the four MO levels are purely π. The close similarity between the slopes in eqs. [1] and [2] is quite significant, indicating that our characterisation of the four HOMO's as predominantly π is justified and a similar slope ($\sim$0.3) is likely to be encountered in INDO calculations on other helicenes. Since the agreement between the experimental and calculated (after adjustment according to eq. [2]) electronic transition energies is fairly good (Table 2), the identification of the α, p, and β bands as π–π^* transitions (2, 3, 11) is adequate.[5] In view of these observations, the skepticism (3) regarding INDO calculations on such molecules seems unjustified.

TABLE 2. Several INDO-MO energies, experimental (3) ionisation potentials and the first three transition energies of [6]-helicene. The "virtual orbital IP's" are *calculated* from PE and optical spectra (Koopmans theorem). All values are in eV and values in parentheses refer to the skeleton model

		α, p, β transition energies in ascending order

(3) Transannular Interaction

By virtue of their greater flexibility the helicenes can minimise TI which would otherwise increase their total energy, if the interaction is of the Möbius-type (3). An indication of the electron density between overlapping rings in [6]-helicene would help to assess the nature and extent of this interaction. It was found that of the three quantities given below, the Mulliken overlap population (MOP) is the most suitable index of overall electron distribution between a pair of bonded or non-bonded atoms (14). These quantities are:

$$[3] \quad d'(r,s) = \sum_{\mu\varepsilon r} \sum_{\nu\varepsilon s} P_{\mu\nu}$$

$$[4] \quad d(r,s) = \sum_{\mu\varepsilon r} \sum_{\nu\varepsilon s} |P_{\mu\nu}| \quad \text{(ref. 12)}^5$$

$$[5a] \quad n(r,s) = \sum_{i} \sum_{\mu\varepsilon r} \sum_{\nu\varepsilon s} n(i,\mu,\nu)$$

$$[5b] \quad n(i,\mu,\nu) = 2N_i C_\mu(i) C_\nu(i) S_{\mu\nu}$$

where $P_{\mu\nu}$ is a density matrix element of INDO calculations with the AO's μ and ν centred on the atoms r and s respectively; N_i is the occupation number of the ith MO; $C_\mu(i)$ is the LCAO coefficient of the μth AO of atom r in the ith MO and $S_{\mu\nu}$ is the overlap integral. Table 3 shows that there is no correspondence between $n(r,s)$ and either $d(r,s)$ or $d'(r,s)$, and Table 5 shows that, for benzene, $n(r,s)$ is the most reliable index of electron distribution. Tables 3 and 4 list the MOP values for a few atom pairs from overlapping rings in [6]-helicene. The sign of MOP indicates the favourable (positive sign) or unfavourable (negative sign) nature of TI while its magnitude is a measure of the strength of this interaction.

Table 3 indicates that the secondary π delocalisation between overlapping rings depends more sensitively on the relative orientations of the π orbitals concerned than on the interatomic distances. The values listed in Table 4 are quite small and confirm the earlier suggestion (3) that TI in [6]-helicene is unfavourable and therefore minimised. This is specifically reflected by the fact that the largest value of $n(r,s)$, viz., −0.0024, for the pair C_{17}, C_{23} is nearly equal in magnitude to the value of 0.0023 for C_1, H_3 in benzene.

(4) Effects of using a Skeleton Model for [6]-Helicene

Since the MO's of the skeleton model $C_{15}H_{10}$ (Fig. 1) show an overall linear correlation (Fig. 3), none of the occupied MO's can be classified as predominantly σ or π, in contrast to benzene or the X-ray geometry. Further, such a linear correlation embracing all the points does not reproduce the optical spectrum, although the five HOMO's of $C_{15}H_{10}$ have higher energies than the corresponding MO's of X-ray geometry because of an in-

TABLE 5. $n(r,s)$, $d(r,s)$, and $d'(r,s)$ values in au, calculated for non-bonded pairs of atoms in benzene (Fig. 1)

For personal use only.

creased $\sigma-\pi$ mixing in the former. Therefore, as with the X-ray geometry, a linear relationship was tested for only four HOMO's and two LUMO's, viz.

$$[6] \quad -(IP)_i = 0.382\varepsilon_i - 4.17$$

where the slope is considerably different from that in benzene or the X-ray geometry. Although eq. [6] well reproduces optical spectral results, such an agreement is superficial since there is no reason to differentiate the four HOMO's from other occupied MO's as far as $\sigma-\pi$ mixing is concerned. Furthermore, taken together, the skeleton energy levels show a worse agreement with experimental IP's and transition energies as compared with the unadjusted levels of X-ray geometry (Table 2).

The skeleton model also displays a different pattern of TI (Table 4) because of different orientations of the $p\pi$ AO's, as compared with the X-ray geometry. Except for two of the non-vanishing $n(r,s)$ values, the rest are negative, apparently indicating an unfavourable interaction. However, since the two largest $n(r,s)$ values, 0.0054 and -0.0065 for the atom pairs C_{16}, C_{25} and C_{17}, C_{23} respectively, are comparable in magnitude, one cannot conclude (*i*) whether TI in the skeleton is unfavourable or not, and (*ii*) if unfavourable, whether TI is minimised.

Thus we conclude that information and interpretations obtained from the skeleton model are not only quite different from those of the X-ray geometry, they are by and large unrealistic, although five skeleton HOMO's superficially show a "better" agreement with IP values (Table 2). Therefore in making semi-empirical MO calculations on large molecules, it is not always physically meaningful to replace the real molecules with certain skeleton ones.

Conclusion

The present INDO-MO calculations identify four HOMO's of [6]-helicene as predominantly π, in contrast to other occupied MO's. In a plot of $-(IP)_i$ of helicene against the corresponding ε_i(INDO), those MO's which are linearly correlated by a slope of ~ 0.3 should be predominantly π. Such a classification for [6]-helicene well reproduces its PE and optical spectra. The transannular interaction between overlapping rings in the molecule is examined by means of Mulliken overlap population. This confirms an earlier suggestion (3) that the TI in [6]-helicene is unfavourable and therefore minimised. The use of a skeleton model as a substitute for the real molecule was found to lead to unrealistic information and interpretation regarding $\sigma-\pi$ mixing, PE and optical spectra, and TI in the molecule. Therefore, one should be very careful in making such substitutions in semi-empirical calculations on large molecules.

SAFAA H. ETAIW, MOHAMED I. ISMAIL, and MOHAMED EL-BORAI. Can. J. Chem. **58**, 263 (1980).

The polarographic behaviour of some thiophenotropone derivatives were studied in DMF and in Thiel buffer solutions of varying pH values and μ of 0.1 at 25 ± 0.1°C. It was found that the carbonyl group is the active centre towards reduction. In strong acid media, the reduction proceeds via one reversible electron forming a free radical which dimerises to produce pinacol. In solutions of pH values from 4 to 9, the polarograms consist of two reduction waves of equal heights each corresponding to 1 F. In strong alkaline media, one wave is observed; in most cases, depending on the molecular structure, the wave corresponds to the uptake of two electrons. The first step involves the direct reduction of the basic form to the anion radical which undergoes a further reduction forming the corresponding thiophenotropolone. At pH values > 13, the height of the limiting current decreases until it attains the height corresponding to 1 F indicating that the anion radical is stable in such media. Also, the electron affinities of these compounds were calculated.

SAFAA H. ETAIW, MOHAMED I. ISMAIL et MOHAMED EL-BORAI. Can. J. Chem. **58**, 263 (1980).

On a étudié le comportement polarographique de quelques thiophénotropones dans le DMF et dans des solutions tampons de Thiel ayant différents pH et μ = 0.1 à 25 ± 0.1°C. On a trouvé que le groupe carbonyle est le centre actif lors de la réduction. En milieu acide fort, la réduction se produit par l'intermédiaire d'un électron réversible en formant un radical libre qui se dimérise pour donner un pinacol. Dans les solutions où le pH varie de 4 à 9, le polarogramme consiste en deux ondes de réduction d'égale hauteur correspondant chacune à 1 F. En milieu fortement basique on observe une onde. Dans la plupart des cas, dépendant de la structure moléculaire, l'onde correspond à la fixation de deux électrons. La première étape implique la réduction directe de la forme basique en un anion radicalaire qui, par réduction plus poussée, conduit à la thiophénotropolone correspondante. Pour des valeurs du pH > 13 la hauteur du courant de saturation décroît jusqu'à ce qu'elle atteigne celle correspondant à 1 F indiquant ainsi que l'anion radicalaire est stable dans un tel milieu. On a également calculé les affinités électroniques de ces composés.

[Traduit par le journal]

Introduction

The polarographic studies on the carbonyl compounds were the subject of many investigations (1–6). On the other hand, the quinonoid compounds of fused aromatic systems as well as those of fused heterocyclic systems were extensively studied in organic solvents or in media of different pH values (7–13). The reduction mechanism and the number of electrons involved in reduction process were found to depend on the nature of the compound and on the medium used. However, the electro-reduction of arenotropones has not been studied so far except the polarographic work done by Guilard *et al.* (14) to elucidate the structure of arenotropones and their metal tricarbonyl complexes. They claimed that the polarograms of arenotropones consist of two reduction waves (pH = 6.7) each corresponds to 1 F producing the corresponding arenotropolones. In the course of our research, a detailed study of the reduction of thiophenotropone derivatives (**I** and **II**) is performed in Thiel buffer solutions of varying pH values and in DMF.

Experimental

The thiophenotropones were prepared according to the recommended procedure described by Guilard and Fournari (15). The solids were purified by recrystallization from the appropriate solvents and their purity and individuality were checked by mp determination, pmr, elemental analysis, and thin-layer chromatography. The polarograms were recorded by Radiometer PO_4 type recording polarograph using a dropping electrode with $m = 2.45$ mg s^{-1} and $t = 3.6$ s at a height h of 52 cm Hg and a kalousek polarographic cell with a thermostating jacket. The temperature was maintained with an ultrathermostat at 25 ± 0.1°C. Buffers used were boric acid, sodium sulphate, succinic acid, and borax solutions (Thiel buffer). After pH 12 a concentrated solution of NaOH was used to raise the pH of the

medium. The thiophenotropones were dissolved in 20 vol% ethanol – water mixture. The polarograms in DMF were carried out using 0.1 mL^{-1} of *N*-tetrabutyl ammonium perchlorate as supporting electrolyte. Depolariser concentrations studied were 1×10^{-3} *M* at a μ of 0.1 (NaCl). A saturated calomel electrode (sce) was used as reference electrode. A Radiometer pH meter type 63 fitted with a combined glass electrode type GK 2301 C was employed for determination of pH. The instrument was accurate to ±0.01 pH unit. The electrolysis at controlled potential was made using a potentiostat TACUSSEL of type ASA 4/60. The electrolysis cell used was the same as that described by Peltier (16).

Results and Discussion

1. The Electro-reduction of Thiophenotropones

The polarograms of 1×10^{-3} *M* of **I***f* and **II***d* in Thiel buffer solutions of pH values 2.3–12.2 consist of one reduction wave corresponding to 2 F. The polarograms shift to more negative potentials and the limiting current decreases as the pH value of the medium increases. However, the polarograms of 1×10^{-3} *M* of the remaining compounds show a different behaviour depending on the molecular structure and the pH of the medium. In acid media, pH ≤ 5.9, the polarograms of **I***a*, *b* consist of one reduction wave *A* corresponds to 1 F while the remaining compounds show this behaviour at pH <4.0. Above these pH values, a new wave *B* is observed and the polarograms consist of two waves of equal heights. The total height of the two waves corresponds to 2 F. As the pH increases, wave *A* suffers a strong shift to more negative potentials than that of wave *B* until the two waves merge and appear as one wave (*C*) at pH ≥ 9.0. At pH > 12.5 the limiting current decreases until it attains the value corresponding to 1 F at pH ≃ 13.6 (wave *D*, Fig. 1). On the other hand, the polarograms of compounds **I***b*, *c* and **II***a*, *b* do not show this behaviour and they still consist of two reduction waves even in strong alkaline media. However, the polarograms of compounds **I***b*, *c* exhibit one reduction wave at pH ≃ 13.5 corresponding to 1 F while compounds **II***a*, *b* do not show this behaviour at all. These results are quite similar to those ob-

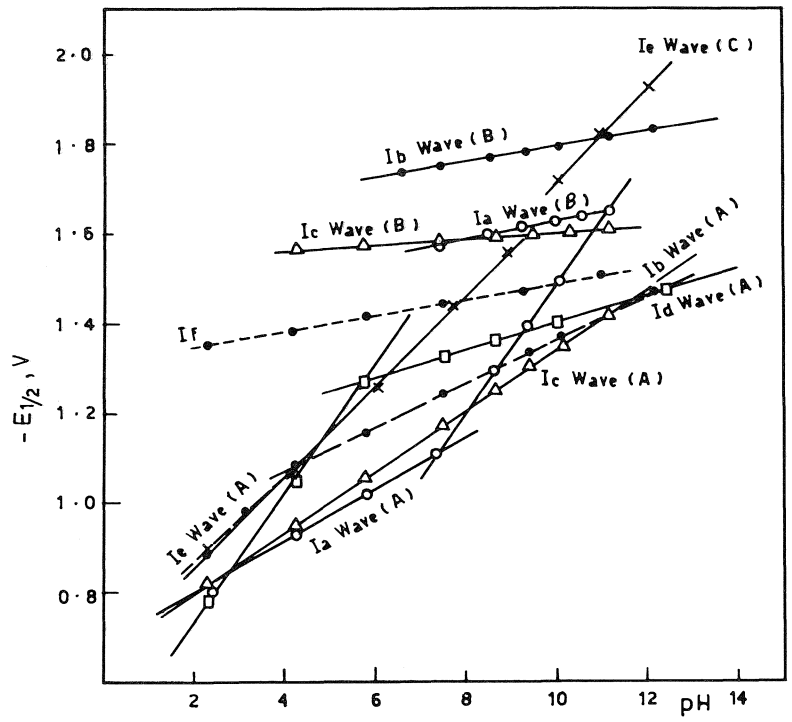

FIG. 2. Plot of $E_{1/2}$ vs. pH for **I**.

tained for the reduction of the carbonyl compounds (1). The values of n were determined coulometrically and using the Ilkovic equation (9). The diffusion coefficient (D_0) of the depolarizer has been experimentally determined (17) at pH values 2.3, 7.5, and 11.2 in Thiel buffer solutions. These pH values are particularly chosen so that well defined diffusion-controlled waves with least of other complications are obtained, as results obtained from the correlations between the pressure head of mercury and the limiting current (18) (Table 1) support this hypothesis.

In this case, Ilkovic equation could be applied for calculation of n using the mean values of D_0. Each of the waves (A, B, and D) corresponds to one electron while wave C exhibits two electrons. On the other hand, the reduction of **I***f* and **II***d* involves the uptake of 2 electrons while wave D corresponds to the uptake of one electron. These data are further supported by coulometry under controlled potential (19).

2. Reversibility of the Waves

Analysis of the waves was carried out by applying the fundamental equation for polarographic data (20). The correlations of E with log $[i/(i_1 - i)]$ are straight lines with somewhat varying slopes. Using the values of slope (Table 1), the values of the transfer coefficient α can be calculated. Wave A proceeds reversibly since the α values attain the unity. On the other hand, for waves B, C, and D and for compounds **I***f*, **II***d*, the α values equal to 0.31–0.77 (a quasi reversible reduction wave when α is more than 0.5; when α is less than 0.5, the reduction process proceeds irreversibly (21)).

3. Effect of pH on the Half-wave Potentials and the Limiting Current

The $E_{1/2}$ of the reduction waves shifts to more negative potentials as the pH of the medium increases, indicating that H^+ ions are involved in the electrode process. The correlation of $E_{1/2}$ with pH is straight lines for wave A of **I***c*, *e*, *f*, *g*, **II***c*, *d* while it is broken lines for compounds **I***a*, *b*, *d* and **II***a*, *b* (Figs. 2, 3). The plots of wave B in all compounds and wave C in compounds **I***e*, *g* are straight lines. The number of protons involved in the reduction process for each wave can be determined using the relation [1].

$$[1] \quad \Delta E_{1/2}/\Delta \mathrm{pH} = (0.059/\alpha n_a) Z(\mathrm{H}^+)$$

The values of H^+ ion indicate that one proton is consumed per electron for waves A and B, while the reduction process of **I***f* and **II***d* includes the uptake of two protons (Table 1).

The total limiting current decreases as the pH of the medium increases, the plots of i_1 vs. pH yield straight or curved lines. The reduction current of

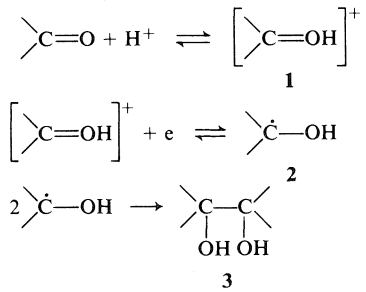
wave *A* is more or less constant in most cases, however, in a few cases it suffers a slight decrease as the pH of the medium increases.

4. Reduction Mechanism

Thiophenotropones may have two centres of reduction, the tropilidene ring and the carbonyl group. However, the reduction behaviour of these compounds resembles that of the carbonyl compounds (1). Firstly, we wish to investigate the reduction of tropilidene ring. For this purpose perchlorate salts of the type **III** or **IV** can be examined, but the unstability of these salts even in strong acidic media renders it difficult to carry out complete study on such salts. However, the salt **III**, $[(C_{11}H_{11}S)^+ClO_4^-]$, dissolved in 20 vol% ethanol – water mixture was studied in Thiel buffer solutions of varying pH values, since it is more stable than

III

IV



IV. In solutions of pH < 4, the polarograms consist of one reduction wave corresponding to 1 F. Within the pH range 4–7, a second wave appears which almost has equal height as that of the first wave. At pH > 7, the polarograms suffer deformation since the compound is hydrolysed. The polarographic characteristics are represented in Fig. 4. These results are in accordance with those obtained by Khopin and Zhdanov (22), who studied the electro-reduction of tropylium perchlorate salt. The first wave can be attributed to the formation of a free radical which undergoes dimerisation. At pH > 4, the new wave corresponds to the formation of thiophenotropilidene since the reduction process involves the uptake of two electrons and one proton.

$$(C_{11}H_{11}S)^+ + e \rightleftharpoons (C_{11}H_{11}S)^\cdot$$
$$2(C_{11}H_{11}S)^\cdot \rightarrow (C_{11}H_{11}S)_2 \quad \Big\} \text{ first wave, pH} < 4$$

$$(C_{11}H_{11}S)^+ + 2e \rightleftharpoons (C_{11}H_{11}S)^-$$
$$(C_{11}H_{11}S)^- + H^+ \rightarrow C_{11}H_{12}S \quad \Big\} \text{ pH} > 4$$

At pH > 4, the final product of reduction is the thiophenotropilidene itself as was supported by electrolysis at controlled potential (16). The electrolysis was carried out in aqueous solution at pH = 6 and at −1.38 V. After the extraction of the product of electrolysis, it was analysed by vapour phase chromatography. The electrochemical reduction was quantitative and the three isomers of **III** were separated in the proportions of 5:75:20%. These proportions are in agreement with those obtained chemically by Guilard and Fournari (15). Thus the tropilidene ring is inactive towards reduction at DME under these experimental conditions.

Wave *A* corresponds to the reduction of cation **1** and then forms the free radical **2** which dimerises to form pinacol **3**.

Wave *B* expresses the transformation of the radical **2** to the alcohol **4** as follows:

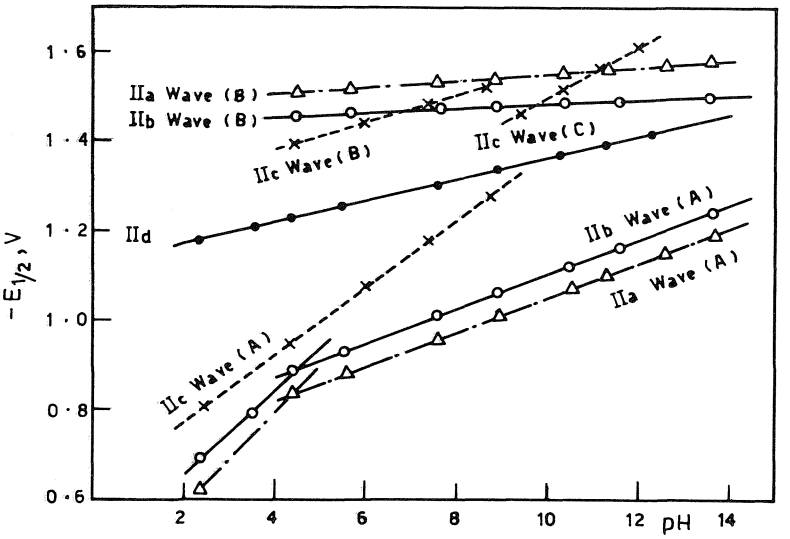

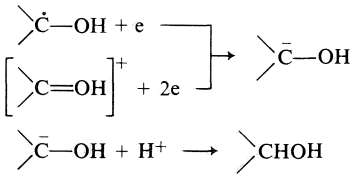

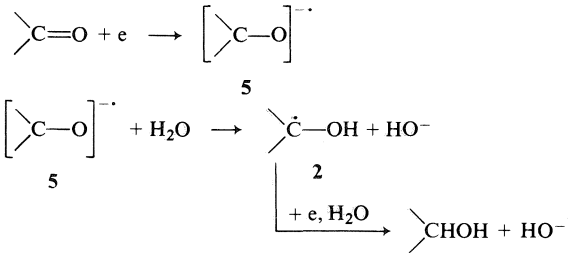

FIG. 3. Plot of $E_{1/2}$ vs. pH for **II**.

4

In strong alkaline media, pH > 10, as well as the reduction of **I***f* and **II***d* at different pH values, the first step involves the direct reduction of the basic form to the anion radical **5** which reacts with one molecule of water to reproduce **2**. The radical **2** can be reduced as follows:

5 **5** **2**

At pH > 12.5 and by increasing the pH of the solution, the anion **5** is predominant in solution and undergoes further reduction. This behaviour is not observed for compounds **II***a*, *b*.

5. The $E_{1/2}$*–Structure Correlation*

The $E_{1/2}$ values of thiophenotropone derivatives **I**, at one and the same pH value, are at more negative potentials than those of the corresponding thiophenotropones **II**. $\Delta E_{1/2}$ values equal 0.05–0.4 V depending on the nature of the wave, the molecular structure, and the pH value of the medium. Also, within one and the same series, the displacement in $E_{1/2}$ to less negative potentials goes in the order of decreasing donor character of the substituents. The increase of donor character of the substituent R or the increased delocalisation of π-electrons within the thiophenotropones **I** enhance the polarisation of the carbonyl group leading to easier formation of the anion **5**. This is the case which is substantiated by the direct formation of the anion **5** during the reduction of **I***f* and **II***d* even in strong acid media and by the appearance of two reduction waves for the polarograms of **I***b*, *c* and **II***a*, *b* in strong alkaline solutions. The last behaviour can be attributed to the decrease of the electron density of the tropilidene ring while it increases on the thiophene nucleus. This is the case which leads to localise the π-electrons of the carbonyl group.

6. The Correlation of Half Reduction Potentials ($E_{1/2}$) *with Absolute Electron Affinities (E.A.).*

The potential determining step in the polarographic reduction of a compound has been assumed to be the reversible addition of an electron to the molecule so that the half-wave reduction potential is a measure of the electron affinity of the compound according to eq. [2]

$$[2] \quad -E_{1/2} = \text{E.A.} - \Delta G_{sol} - \text{constant}$$

The constant term depends upon the reference electrode and is 5.07 eV for the saturated calomel electrode (23). The difference in solvation energies for the negative ion and the neutral, ΔG_{sol}, was determined by Briegleb (24) to have the value of −3.66 eV. Farragher and Page (25) assumed eq. [2] to be valid and calculated an average value of −2.37 eV for ΔG_{sol} for some charge transfer acceptors using the magnetron results for the absolute E.A. values of these compounds. Recently Chen (23, 26) proposed an average value for ΔG_{sol} to be

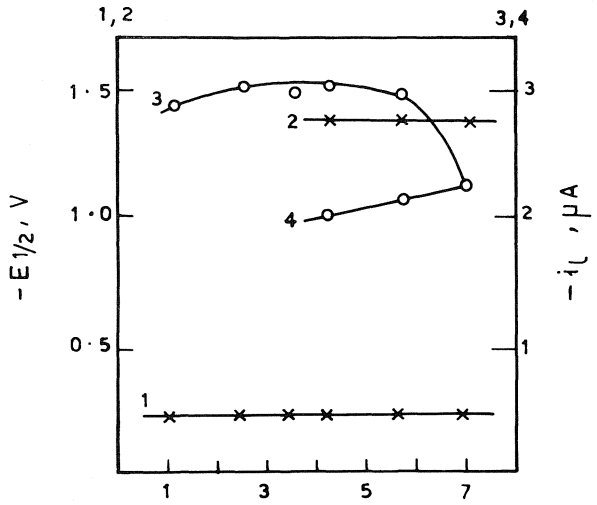

FIG. 4. Plot of $E_{1/2}$ and i_l vs. pH for **III** (0.5 m*M*).

equal to -2.58 ± 0.26 eV. Thus, the following equation can be used to calculate E.A. values from half-wave reduction potentials vs. the saturated calomel electrode (27–32).

[3] $\text{E.A.} = -E_{1/2} + 2.49 \pm 0.26$ eV

$E_{1/2}$ vs. sce, aprotic solvents

Received August 29, 1979

OSVALD KNOP, WOLFGANG J. WESTERHAUS, and MICHAEL FALK. Can. J. Chem. **58**, 270 (1980).

This investigation deals with the effect of temperature, between 10 and 293 K, on the ir spectrum of the NH_3D^+ probe ion in polycrystalline NH_4SnF_3, NH_4CuSO_3, cubic $(NH_4)_2SiF_6$, and $(NH_4)_2SnCl_6$. The results lead to the following conclusions. At 10 K these crystals contain symmetrically trifurcated N—H···3X bonds, i.e. bonds in which the N—H orientation of maximum probability is on the threefold axis. With increasing temperature these bonds lose progressively their symmetrically-trifurcated character to become highly bent, highly dynamic N—H···X bonds, and the strength of the hydrogen-bonding interaction increases. This is reflected in the decrease of the ND stretching frequency of the probe ion with increasing temperature, which is the opposite of the behaviour observed with normal (i.e. essentially straight) N—H···X bonds.

Re-determination of the room-temperature crystal structure of NH_4CuSO_3 has confirmed the correctness of the structure reported previously by Nyberg and Kierkegaard.

OSVALD KNOP, WOLFGANG J. WESTERHAUS et MICHAEL FALK. Can. J. Chem. **58**, 270 (1980).

Ce mémoire traite de l'effet de la température, entre 10 et 293 K, sur le spectre infrarouge de l'ion sonde NH_3D^+ dispersé dans les composés polycristallins NH_4SnF_3, NH_4CuSO_3, $(NH_4)_2SiF_6$ (phase cubique) ainsi que $(NH_4)_2SnCl_6$. Les résultats mènent aux conclusions suivantes. A 10 K ces cristaux contiennent des liaisons N—H···3X trifurquées symétriques, c'est-à-dire des liaisons dans lesquelles l'orientation la plus probable du vecteur N—H coïncide avec l'axe ternaire. Au fur et à mesure que la température augmente, ces liaisons perdent leur caractère trifurqué symétrique pour devenir des liaisons N—H···X dynamiques fortement coudées et l'interaction H···X devient plus forte. Conformément à ces changements, la fréquence de la vibration de valence ND de l'ion sonde diminue quand la température augmente, ce qui est à l'opposé du comportement des liaisons N—H···X normales, à savoir essentiellement droites.

La redétermination de la structure cristalline du NH_4CuSO_3 à la température de la pièce confirme la justesse de la structure rapportée antérieurement par Nyberg et Kierkegaard.

In Part VI (1) we pointed out that, in a crystal containing an NH_4^+ ion surrounded by potential hydrogen-bond acceptors X, a coordination geometry intuitively favourable to the formation of a symmetrically trifurcated N—H···3X bond does not guarantee the actual existence of such a bond, i.e. one in which the N—H orientation of maximum probability is demonstrably in a threefold axis. The distributions of proton density obtained in the only two neutron-diffraction studies bearing on the problem, those of cubic $(NH_4)_2SiF_6$ (2) and *fcc* $NH_4I(III)$ (3), both at room temperature, do not support the existence of symmetrically trifurcated N—H···3X bonds defined this way. However, they do indicate the presence of hydrogen-bonding interaction of pronounced dynamic character, associated with librational (and possibly also bending) motions of large amplitude ("fluxional" hydrogen bonds), and one may reasonably suppose that symmetrically trifurcated hydrogen *bonds* may exist in cubic $(NH_4)_2SiF_6$ at low temperatures.[3] At the time of writing Part VI the existence of such bonds was yet to be demonstrated.

We also called attention to the advantage which a variable-temperature study of the ir spectrum of the ammonium ion in NH_4SnF_3 would offer for an understanding of hydrogen bonding in trifurcated coordination geometries. Such a study of NH_4SnF_3 and of the companion compound NH_4CuSO_3 has now been carried out and the results are compared in the following to those, equally new, on cubic $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$ between 10 K and room temperature. We have again employed the NH_3D^+ ion at low concentration as a probe (cf. refs. 1 and 4). To assess the accuracy of the crystal-structure determination of NH_4CuSO_3 by photographic methods (5) we have also redetermined the room-temperature structure of the sulfite by X-ray diffractometry.

NH_4SnF_3

According to the determination of the room-tem-

perature crystal structure of NH_4SnF_3 from X-ray diffractometer data (6) the N atom in this crystal is at a site of symmetry C_3 and is coordinated by three F atoms (belonging to three different SnF_3^- ions) at 2.75 Å and another three F atoms (belonging to the same SnF_3^- ion) at 3.00 Å; the F atoms in each set are related by the threefold axis. The FNF angle of 108.2° corresponding to the shorter N···F distances is very close to tetrahedral, whereas that corresponding to the longer N···F distances, 54.4°, is almost exactly half the tetrahedral angle. This geometry (Fig. 1) implies that the three nonaxial hydrogen atoms H_n of the ammonium ion are strongly bonded to the first set of F atoms by normal, practically straight N—H···F bonds.[4] This portion of the N environment thus resembles the tetrahedral hydrogen-bonding network in NH_4F. The axial N—H_a vector, on the other hand, is constrained by symmetry to point, in its mean position, at the centre of the equilateral triangle formed by the F atoms at 3.00 Å from the N atom, the NH_aF angle being 134°. The N—H_a bond thus not only finds itself in a trifurcated *geometrical* situation, but in view of the strong constraint imposed by the three N—H_n···F bonds may be expected to constitute a true symmetrically trifurcated hydrogen *bond*, possibly different in its spectroscopic properties from the "fluxional" bonds in, for example, $(NH_4)_2SiF_6$ (cf. ref. 1). An indication that such a difference might exist is observed in Fig. 9 of ref. 1, in which the $\nu_{4bc}(a)$ frequency of the NH_3D^+ probe ion is plotted against the NHX* angle that would be required by symmetric trifurcation: the point for NH_4SnF_3 falls far off the regression line appropriate to cubic and trigonal $(NH_4)_2MX_6$ (X = F, Cl, Br, I), in which compounds the C.N. of the ammonium ion is 12 and the ammonium ions are not engaged in normal N—H···X bonds. It is one of the aims of the present study to determine whether such a difference in fact exists.

NH_4CuSO_3

A similar hydrogen-bonding geometry is found in NH_4CuSO_3 (Fig. 1), for which a crystal-structure determination by photographic methods has been reported (5). In this crystal ($R\bar{3}m$, No. 166, $Z = 2$) the N atom is located on a threefold axis, like in NH_4SnF_3,[5] but the coordination of the ammonium

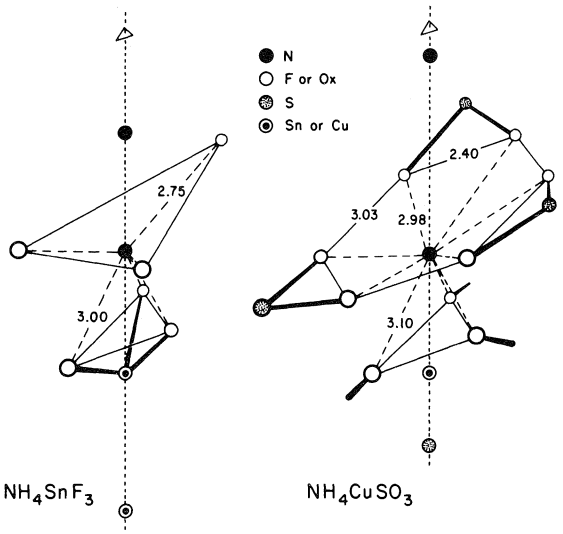

FIG. 1. Environments of the ammonium ion in NH_4SnF_3 and NH_4CuSO_3. Both drawings are on the same scale.

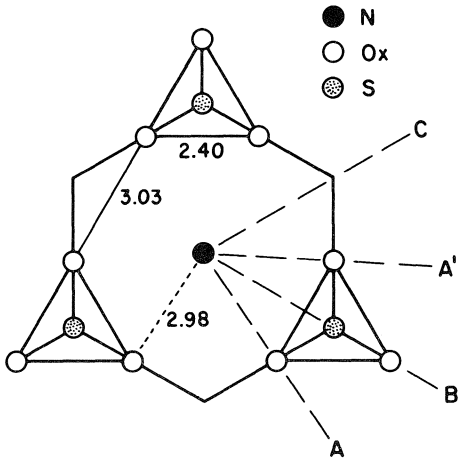

FIG. 2. Possible symmetric orientations of the ammonium ion in NH_4CuSO_3 about the threefold axis.

ion differs from that in the fluoride in the number of acceptor atoms available for the formation of strong hydrogen bonds. To the set of three F atoms at 2.75 Å from N there corresponds in NH_4CuSO_3 a set of six coplanar oxygens at 2.97(1) Å from the N atom. The six oxygens are arranged in three pairs, each pair belonging to an SO_3^{2-} ion (Fig. 2). The three O atoms constituting the trifurcated situation, at d(N···O) = 3.11(2) Å, each belong to a different sulfite ion. The NH_aO angle, 132°, is practically the same as the NH_aF angle in the fluoride, which suggests that the trifurcated hydrogen bonds in the two compounds may be expected to show similar behaviour. The mean positions of the hydrogen atoms H_n participating in the *strong* N—H_n···O bonds cannot, however, be surmised from the lo-

[4]In ref. 1 the orientation of the ammonium ion was erroneously stated to be the opposite of that proposed in ref. 6. See erratum (7) to ref. 1.

[5]The site symmetry of the N atom in NH_4CuSO_3 is C_{3v} but C_3 in NH_4SnF_3. Since *any* hexagonal or trigonal site symmetry produces the same number of component bands of $\nu_1(NH_3D^+)$ and $\nu_{4bc}(NH_3D^+)$ (4), no special mention of this difference will be required.

cation of the six coplanar O atoms. Inspection of Fig. 2 shows that a rigid $-NH_3$ triplet can in principle assume four orientations that might correspond to local energy minima: two symmetry-equivalent, A and A′, corresponding to normal N—H···O bonds, and two nonequivalent and bifurcated, B and C. Position B involves oxygens of the same sulfite ion; position C involves O atoms belonging to different SO_3^{2-} ions. A hydrogen bond corresponding to A would be somewhat bent, with an NH_nO angle of about 169°. It seems *a priori* probable that the ammonium ion in the crystal undergoes rapid reorientations about the threefold axis and that any one of the four orientations will be populated for some fraction of time, with the A and A′ orientations dominant.

$(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$

The environment of the NH_4^+ ion in these two cubic, isostructural crystals is illustrated in Fig. 1 of ref. 8. The N atom is surrounded by 12 equivalent halogen atoms X arranged at the corners of a coordination cuboctahedron of symmetry T_d. The tetrahedral distortion of the cuboctahedron from O_h symmetry is smaller in the chlorostannate. The N—H vectors point to alternate triangular faces of the cuboctahedron, away from the Si and Sn atoms (2). Spectra of the NH_3D^+ probe ion in the two compounds recorded previously (9) between 10 K and room temperature contained no indication of transitions.

Combination bands involving the librational mode $\nu_6(NH_4^+)$ are present in the ir spectra of the fluorosilicate even at room temperature, but in the spectra of the chlorostannate they emerge only on cooling below 80 K (1). This indicates that hydrogen bonding is considerably stronger in the fluorosilicate.

Experimental

Preparation

NH_4SnF_3 was prepared by dissolving SnF_2 and a slight excess of NH_4F in a minimum quantity of hot water, filtering, and allowing the filtrate to cool. The crystalline product was filtered off, washed with a minimum volume of cold water, and dried *in vacuo* (10). The SnF_2 was obtained by dissolving freshly precipitated Sn(II) hydroxide in aqueous HF. Deuterated NH_4SnF_3 was obtained by recrystallization from aqueous HF of the appropriate D content.

NH_4CuSO_3 was prepared as in ref. 11. Because of the insolubility of the sulfite in water deuterium had to be incorporated at the outset using a weakly deuterated solution of cupric sulfate.

The two hexahalometallates(IV) were prepared by recrystallization of commercial material from acidified aqueous solutions and were deuterated by crystallization from aqueous solutions of the appropriate D_2O content.

The authenticity of the preparations was checked by X-ray powder diffraction and by comparing their ir spectra with spectra reported previously (1, 12).

Infrared Spectra

Spectra were recorded on a Perkin-Elmer model 180 spectrophotometer fitted with a closed-cycle He refrigerator (Displex model 202, Air Products and Chemicals Co.). Suitable samples were obtained by mulling finely ground crystals with hydrocarbon oil (for spectra in the 1330–400 cm^{-1} range) or fluorocarbon oil (4000–1330 cm^{-1}). The mulls were sandwiched between CaF_2 or KBr plates. Survey spectra of undeuterated NH_4SnF_3 and NH_4CuSO_3 are presented in Fig. 3.

For the study of ND bands specimens deuterated to 1–3% were used. Spectra of the 3% D material, especially at low temperatures, contained small side bands originating in the secondary isotopic species $NH_2D_2^+$ and in the coupling of ND vibrations of neighbouring NH_3D^+ ions in the crystal (Figs. 4 and 5). Although the relative intensity of these side bands (which increases with the square of the D content) is much reduced at 1% D, the reduction is at the cost of diminished intensity of *all* ND absorptions and a relatively high noise level, especially at sample temperatures approaching room temperature, when the ND bands become broader and less intense. The band parameters reported in Tables 2 and 4 were obtained by extrapolation to 0% D of values measured in spectra of samples of different D contents.

The very pronounced Christiansen effect (13) present, especially at low sample temperatures, in the spectra of $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$ is responsible for the increased uncertainty in the values of peak positions and band halfwidths (cf. Table 4). The present values of the ND stretching frequencies 2416 cm^{-1} for NH_4SnF_3 and 2439 cm^{-1} for $(NH_4)_2SiF_6$ at liquid-nitrogen temperature differ somewhat from the values reported earlier (1), 2408 and 2432 cm^{-1}, respectively. This discrepancy is likely to originate in the greater uncertainty in the sample temperature in the previous study.

Re-determination of the Crystal Structure of NH_4CuSO_3

To re-determine the room-temperature structure of the sulfite, intensities were collected on an Enraf-Nonius CAD-4 automatic diffractometer (Mo Kα radiation) from a crystal approximately 0.4 × 0.4 × 0.1 mm^3 in size. They were reduced to a standard scale by a routine procedure and were corrected for Lorentz and polarization factors but not for absorption. 177 independent reflections with $I > 3\sigma(I)$ were used in the calculation. The atomic scattering factors were taken from ref. 14 and were corrected for the real part of anomalous dispersion.

The Cu and S positions were established from a Patterson function. A subsequent Fourier synthesis revealed all S and O locations. Comparison of the positional parameters with those of ref. 5 produced no significant differences. A full-matrix least-squares refinement (using programs of ref. 15) with anisotropic temperature factors gave $R = 0.048$, $R_w = 0.043$ ($w = \sigma^2|F_o| + 0.005|F_o|^2$, σ = individual esd calculated from the diffractometer counting statistics). A difference Fourier map computed at this stage for the region around the N atom showed a maximum on the threefold axis pointing to the centre of a triangle of O atoms, and a torus-shaped maximum containing three weak peaks in the region between the N and the six nearest O atoms. The latter feature is compatible with a distribution of the orientations represented in Fig. 2, the three weak peaks corresponding to orientation B. Fixing the H atoms in these positions resulted in $R = 0.044$, $R_w = 0.041$. Refinement of the H positions starting with the values obtained from the difference Fourier map gave almost identical R values and large esd values for the H parameters. The refined positional parameters of the H atoms are considered too uncertain to be reported here. A low-temperature structure determination is planned.

The bond distances shown in Figs. 1 and 2 were calculated from the final values of the positional parameters (Table 1) using

the unit-cell dimensions given in ref. 5. They differ only slightly from those reported by Nyberg and Kierkegaard and quoted in the Introduction.

Results

For brevity, the $\nu_1(NH_3D^+)$ (essentially ND stretching) and $\nu_{4bc}(NH_3D^+)$ (essentially ND bending) absorptions will be referred to as ν_1 and ν_{4bc} throughout.

NH_4SnF_3 and NH_4CuSO_3: General Features of the Spectra

As required (4) by the trigonal site symmetry of the ammonium ion, a 1:3 doublet was observed in the ND stretching region of the spectra of both compounds (Figs. 4 and 5). The weaker, higher-frequency component ν_1(a) corresponds clearly to the axial and the more intense, lower-frequency component ν_1(n) to the nonaxial N—D bond. The two ν_1 components, whose separation is of the order of 150–200 cm^{-1} (see below), are present at all temperatures between 10 and 293 K. The composite absorption observed in the ν_{4bc} region is incompletely resolved (Figs. 4 and 5) but is consistent with the 2:3:3 triplet expected for trigonal site symmetry. The assignments of the three components of the observed triplet to the two bending fundamentals of the nonaxial N—D and to the one doubly degenerate bending fundamental of the axial N—D given in Table 2 are tentative and no structural conclusions will be drawn from them. There was no indication of a transition in the NH_3D^+ spectra of either compound in the temperature range studied.

In the spectra of *undeuterated* samples (Fig. 3, Table 3) the absorption in the NH stretching region extends from 3200 to 2200 cm^{-1}. Most of it appears to arise from the nonaxial hydrogens which are strongly bonded to the F or O atoms. The large breadth, relatively high ir intensity, and rich fine structure at low temperatures are characteristic of strong hydrogen bonds (16). A part of the structure arises from the dynamic coupling of the vibrations of different NH_4^+ ions in the crystal, but some of it is a consequence of Fermi resonance with overtone and combination modes of NH_4^+. In particular, we note the occurrence of one or perhaps two sharp absorption minima in the 10 K spectrum of NH_4SnF_3. These are the so-called "Evans holes", a common Fermi-resonance phenomenon (17, 18) hitherto not reported in the spectra of solid ammonium compounds. The highest-frequency peaks in the 10 K spectra (NH_4SnF_3, 3290 cm^{-1}; NH_4CuSO_3, 3325 cm^{-1}) can be assigned to the stretching of the axial N—H bond, by analogy with ν_1(a). This assignment is supported both by the similarity of the effect of temperature on the frequency of this band in the NH and ND spectra and by the NH/ND frequency ratios, which approach the ideal ratio of 1.369 for diatomic harmonic NH and ND oscillators: 3290/2427 = 1.356, 3325/2437 = 1.364. Apparently the exceptionally large difference between the hydrogen-bonding strengths of H_a and H_n in these crystals is sufficient to decouple their stretching motions.

The *combination bands* $\nu_2 + \nu_6$ and $\nu_4 + \nu_6$ involving one of the bending modes, ν_2 or ν_4, and the librational mode ν_6 of the NH_4^+ ion, are seen as a series of intense, sharp bands in the spectra of both compounds at low temperatures. They are clearly observable even at room temperature, which reflects the presence of significant hydrogen bonding (cf. ref. 1). The $\nu_2(NH_4^+)$ fundamental, which is ir-inactive under cubic site symmetry but would be expected to appear when the symmetry is lowered, is in fact observed as a small band in the spectra of both compounds at room temperature (at 1695 cm^{-1} in NH_4SnF_3 and at 1680 cm^{-1} in NH_4CuSO_3) and sharpens considerably at low temperatures (Fig. 3).

In the spectrum of NH_4CuSO_3 three out of the four vibrational fundamentals of the sulfite ion are observed. They are assigned by analogy with the

spectra of other solid sulfites (cf. Table 6.32 of ref. 19). The remaining fundamental, the symmetric stretching vibration $\nu_1(A_1)$, is only weakly ir-active in a flat pyramidal SO_3^{2-} ion; the corresponding absorption band is probably obscured by the broad and intense band due to the degenerate stretching vibration $\nu_3(E)$.

NH_4SnF_3 and NH_4CuSO_3: Effect of Temperature on Frequencies

The ν_{4bc} component frequencies vary only slightly over the range of temperatures investigated: in NH_4SnF_3 they decrease by 2 cm^{-1} and in NH_4CuSO_3 by 5–7 cm^{-1} when the temperature is raised from 10 to 293 K. By contrast, the variation of the ν_1 frequencies in both compounds is not only pronounced (Figs. 4–6) but the ν_1(a) and ν_1(n) frequencies vary in *opposite directions*. As the temperature increases, ν_1(a) shifts to lower and ν_1(n) to higher frequencies. The decrease of the ν_1(a) frequency is roughly three times as great as the increase of the ν_1(n) frequency, so that the mean frequency (weighted in the 1:3 ratio of the axial to nonaxial hydrogens) remains nearly stationary with

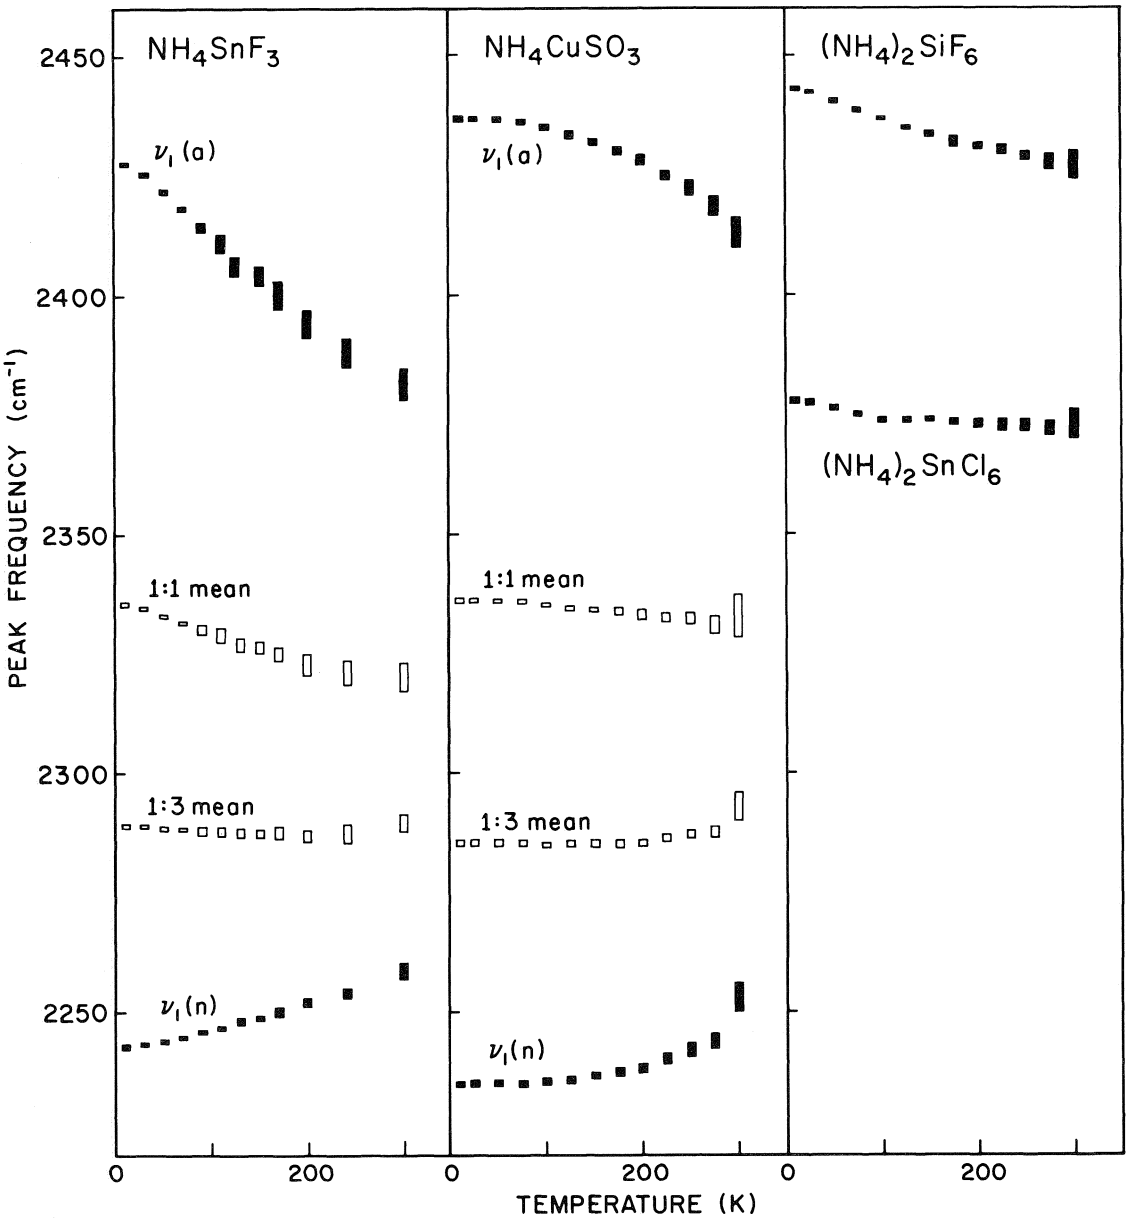

FIG. 6. Temperature variation of the ν_1(a) and ν_1(n) frequencies in NH_4SnF_3 and NH_4CuSO_3, compared with that of ν_1 in $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$.

temperature (Fig. 6). The range of variation of the ν_1(a) frequency in the fluoride in the 10–293 K range interval is 46 cm^{-1}, i.e. about 20% of the total ν_1 frequency range for ammonium halides (cf. ref. 1), and approximately twice as large as the corresponding range of variation in the sulfite. Furthermore, the decrease of the ν_1(a) frequency in NH_4SnF_3 begins to be appreciable at a much lower temperature than in NH_4CuSO_3.

Parallel shifts of frequency with temperature are observed for the NH stretching bands in the spectra of the undeuterated compounds. In the fluoride, cooling in fact shifts the axial frequency sufficiently away from the nonaxial frequency region to cause the axial vibration to uncouple from the nonaxial NH vibrations and the corresponding absorption band to become resolved (Fig. 3).

NH_4SnF_3 and NH_4CuSO_3: Effect of Temperature on Bandwidths

The halfwidths of the ν_1(n) absorptions in both compounds and of ν_1(a) in the sulfite remain nearly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

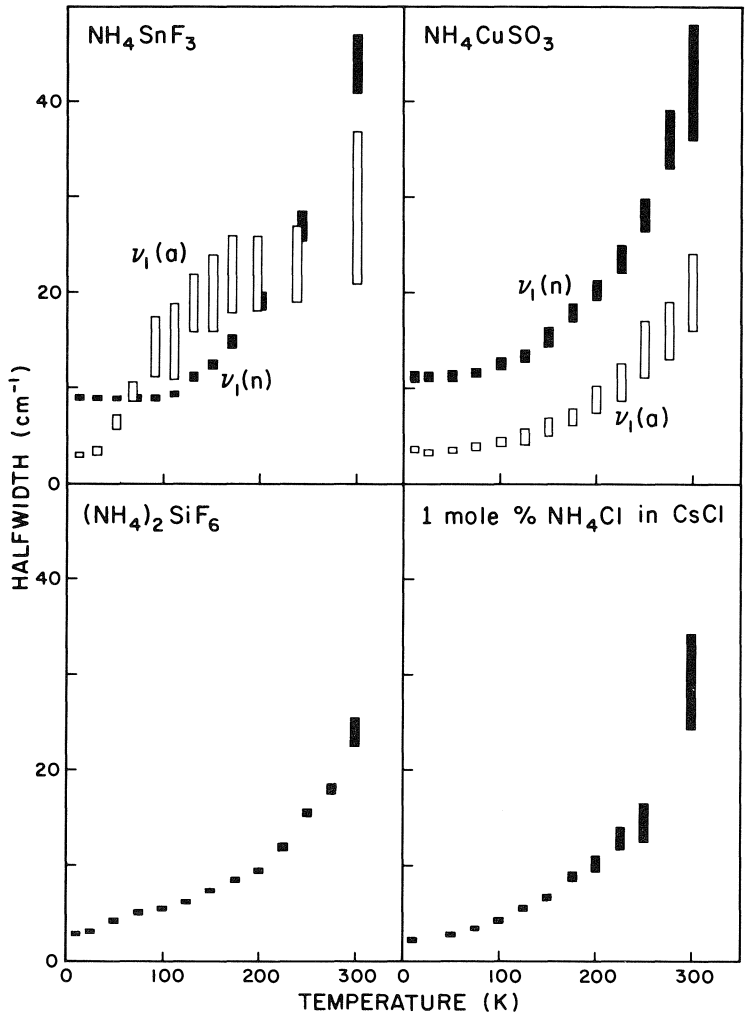

FIG. 7. Temperature variation of the halfwidths of the ν_1(a) and ν_1(n) absorption bands in NH_4SnF_3 and NH_4CuSO_3, compared with that of the halfwidth of the ν_1 absorption in $(NH_4)_2SiF_6$ and in a solid solution of NH_4Cl in CsCl.

constant up to about 100 K, after which they begin to increase at a progressively higher rate (Fig. 7). In this they resemble the ν_1 halfwidths in crystals containing NH_4^+ ions with four equivalent, normal (i.e. straight) N—H···X bonds and free from low-temperature transitions, such as NH_4F and solid solutions of NH_4Cl in CsCl at low ammonium concentrations (included in Fig. 7 for comparison).[6] However, the ν_1(a) halfwidth of NH_4SnF_3 follows an unusual pattern, with a steep initial increase at very low temperatures (about 30 K) and slowing down above 150 K. In both compounds the halfwidth of ν_1(n) at 10 K (the "residual" halfwidth) is greater than that of ν_1(a), the latter not exceeding 3 cm^{-1}.

[6]A detailed account of our study of NH_4F and of the "double-dilution" experiments on NH_4^+ dispersed in alkali halide matrices is scheduled to appear later in this series.

$(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$

The N atoms in both compounds are at sites of symmetry T_d over the entire temperature range of our study, hence a single ν_1 and a single ν_{4bc} absorption bands are expected and observed. The peak frequencies and halfwidths of these bands are recorded in Table 4 and their variation with temperature is compared with that of NH_4SnF_3 and NH_4CuSO_3 in Figs. 6 and 7.

The ν_1 frequency in $(NH_4)_2SnCl_6$ is appreciably lower than in $(NH_4)_2SiF_6$. This is a consequence of the volume effect (1) and not an indication of a strengthening of the hydrogen-bonding interaction. On the contrary, as pointed out above, the temperature dependence of the intensity of combination bands involving the librational fundamental $\nu_6(NH_4^+)$ shows that hydrogen bonding is much weaker in the chlorostannate.

Discussion

The surprising feature of the ν_1 absorption in NH_4SnF_3 and NH_4CuSO_3 is not that it is a doublet, for this is expected from the trigonal site symmetry of the ammonium ion, but the magnitude of the splitting, the difference between the $\nu_1(a)$ and $\nu_1(n)$ frequencies at 10 K being 202 cm^{-1} for the sulfite and 184 cm^{-1} for the fluoride. When these frequency differences, which are the largest on record for ammonium compounds, are compared to the ν_1 (80 K) frequencies observed in a variety of ammonium halides (1), it is found that they amount to 70–80% of the total ν_1 range bounded by the ν_1 values in NH_4F and NH_4BF_4. The magnitude of the splitting clearly indicates that the hydrogen-bonding interactions involving the three H_n are much stronger than that involving H_a, i.e. the hydrogen atom in trifurcated acceptor geometry.

However, even more remarkable is the temperature variation of the $\nu_1(a)$ and $\nu_1(n)$ frequencies, which is both pronounced and in opposite directions (Fig. 6). This is unlike in any ammonium compounds for which a detailed temperature study has been reported to date. The increase in the ν_1 frequency of normal N—H···X bonds, in the absence of phase transitions, may be as low as 2 cm^{-1} from 10 to 293 K, as exemplified by the ammonium ion dispersed at low concentrations in CsCl and CsBr matrices[6] (cf. also ref. 1). By contrast, the corresponding shift, to *lower* frequencies, of $\nu_1(a)$ with increasing temperature is 46 cm^{-1} in NH_4SnF_3 and 22 cm^{-1} in NH_4CuSO_3. For $\nu_1(n)$ the shifts, to *higher* frequencies, are less dramatic but at least comparable with those encountered for other straight N—H···X bonds (9) and several times the value in CsCl and CsBr matrices.

These observations make it difficult to avoid the conclusion that the effect of increased temperature is to *weaken* the strong N—H_n···X bonds (the normal expectation) and simultaneously to *strengthen* the weak hydrogen-bonding interactions involving the axial hydrogen. The near constancy of the $\nu_1(a)$, $\nu_1(n)$ mean (Fig. 6) implies that the *overall* hydrogen-bonding strength of the ion changes little with temperature and in this resembles the behaviour of the ion in the matrices.

The strengthening of the interaction of H_a with the three equidistant acceptor atoms can be explained, qualitatively, by an increase in the amplitude of the motions of the ammonium ion with temperature. The motions likely to be involved would be largely low-frequency, librational motions; internal (bending) motion may participate. As the amplitude increases, H_a is brought closer to its acceptor neighbours, the NH_aX angle increases, and the N—H_a···X geometry begins to assume increasingly the character of a straight hydrogen bond. The larger the amplitude, the greater the anharmonicity of the motion of H_a as a result of the correspondingly reduced H_a ···X distance. Conversely, at very low temperatures H_a will remain on or close to the threefold axis, and in such circumstances the N—H_a bond must be viewed as forming a true *symmetrically trifurcated* hydrogen bond.

A similar situation is obtained in $(NH_4)_2SiF_6$, with the difference that in this crystal none of the four equivalent hydrogens of the ammonium ion engages in a normal hydrogen bond. The decrease in the frequency of the unique ν_1 absorption is 16 cm^{-1} from 10 to 293 K, i.e. only about one third of the decrease in $\nu_1(a)$ in NH_4SnF_3. There is little doubt that the frequency decrease in the hexafluorosilicate is attributable to the same cause as the decrease in $\nu_1(a)$ in NH_4SnF_3 and NH_4CuSO_3.

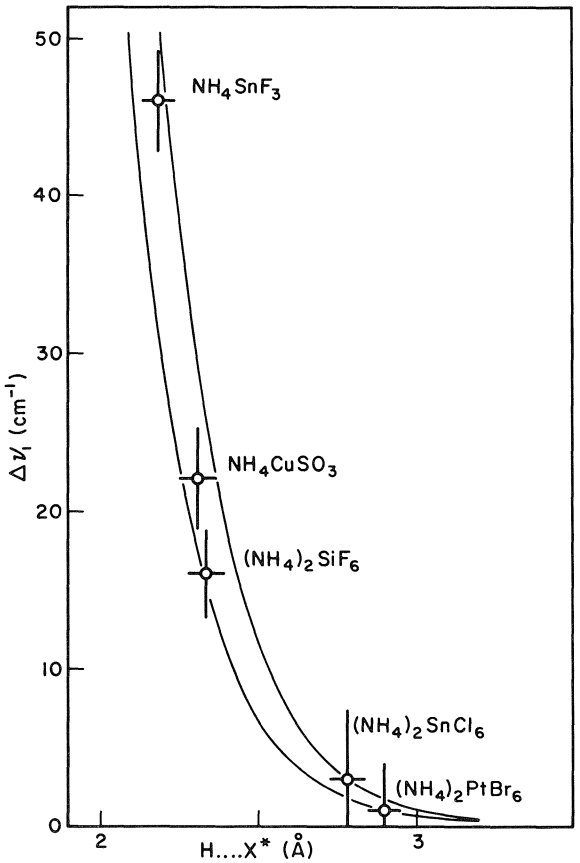

FIG. 8. Variation of $\Delta\nu_1 = \nu_1(10\text{ K}) - \nu_1(293\text{ K})$ with the H···X* distance corresponding to symmetric trifurcation. For NH_4SnF_3 and NH_4CuSO_3, $\nu_1 = \nu_1(a)$. The $\pm 1\sigma$ limits of the regression are shown.

However, in $(NH_4)_2SiF_6$ the ammonium ion is not anchored by strong normal hydrogen bonds. This and the cubic site symmetry must impart a different character to the thermal behaviour of the motions responsible for bringing the H atom closer to the F acceptors.

Although the structural situations in $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$ are completely analogous, the ν_1 frequency in the chloride decreases much less with increasing temperature than does the corresponding frequency in the fluoride; moreover, in the isostructural $(NH_4)_2PtBr_6$ it is known (9) to vary by only 1 cm^{-1} or less over the entire 10–293 K range. This supports the model proposed above for the response of a trifurcated hydrogen bond to temperature variation and shows the importance of the acceptor strength of the halogen atoms in the three compounds.[7] Raising the temperature of the three crystals by the same amount will, roughly speaking, cause the N—H bond to pivot about N by a comparable angle (and in any event by an angle which is not smaller in the chloride than in the fluoride), but as Cl is a weaker acceptor than F, the effect on ν_1 of the closer approach of the H atom to X will be considerably less in the chloride and even smaller in the bromide. Since the acceptor strength of X cannot be divorced from the effective size of X (and thus from the H···X* distance),[8] this means that decreasing the H···X distance by a certain amount produces a larger decrease in ν_1 when H···X is short than when it is long. When the $\Delta\nu_1 = \nu_1(10\text{ K}) - \nu_1(293\text{ K})$ values for the five compounds are regressed logarithmically on H···X* (Fig. 8), ln $\Delta\nu_1$ is found to be highly correlated with H···X*:

$$\ln \Delta\nu_1 = 14.41 - 4.89(\text{H}\cdots\text{X}^*)$$
$$r^2 = 0.98, \sigma = 0.27$$

i.e. $\Delta\nu_1$ can be approximated by a simple exponential function of the structural parameter H···X*. This is remarkable when one keeps in mind the various uncertainties involved and the structural dissimilarities, and considering the arbitrary choice of the temperature difference. It is possible that $\nu_1(10\text{ K})$ and $\nu_1(293\text{ K})$ in fact approximate, respectively, the "low-temperature" and the "high-temperature" limits of ν_1 and that the regression has a deeper meaning. The correlation is not very different when NH_4CuSO_3 is left out. Perhaps the reason that the sulfite is satisfactorily accommodated by the regression is the similarity of the formal charge on the oxygen of SO_3^{2-} and the fluorine of SnF_3^-.

We feel unable to discuss at present why the details of the temperature dependence of ν_1(a) and ν_1(n) are different in NH_4SnF_3 and NH_4CuSO_3. Apart from the obvious difference in the number of acceptors involved in the N—H_n···X bonds the structural situation is very similar in the two compounds.

The bandwidths at 10 K of the ν_1 absorptions corresponding to the trifurcated hydrogen bonds are comparable in all four compounds, not exceeding about 3 cm^{-1} (Fig. 7). The ν_1(n) absorptions in both NH_4SnF_3 and NH_4CuSO_3, however, have 10 K halfwidths about three times those of the respective ν_1(a) absorptions. The reason for this is not clear. On one hand we have the observation that the stronger the hydrogen-bonding interaction, the greater the halfwidth (as in ascorbic acid, ref. 16). On the other hand, the very strong hydrogen bonds in NH_4F have ν_1 halfwidths that at 10 K do not exceed 5 cm^{-1}.[6]

With the exception of ν_1(a) of NH_4SnF_3 the halfwidths of the ν_1 absorptions in all four compounds increase with temperature in a similar manner. The temperature dependence of these bandwidths cannot be very sensitive to the structure and chemistry of the individual crystal, as NH_4F and solid solutions of NH_4Cl in CsCl (Fig. 7) and of NH_4Br in CsBr behave in much the same way,[6] although the coordination of the ammonium ion and the hydrogen-bond strengths differ widely in these various cases. In view of this insensitivity the complex shape of the temperature dependence of the ν_1(a) halfwidth in NH_4SnF_3 is the more puzzling.

Conclusions

The most important conclusion from the present study of NH_4SnF_3, NH_4CuSO_3, cubic $(NH_4)_2SiF_6$, and $(NH_4)_2SnCl_6$ can be formulated as follows:

Where the geometry of the crystal structure of an ammonium compound provides an opportunity for the existence of a symmetrically trifurcated N—H···3X hydrogen bond, such a bond is likely to occur if the temperature is sufficiently low. With increasing temperature the strength of this bond will *increase*, but at the same time the bond will lose its symmetric trifurcation, the H atom will become progressively more associated with *one* acceptor

[7]The difference in the atomic mass of X undoubtedly plays a role in the lattice dynamics of the three crystals and may provide an additional contribution toward a strengthening of the H···X interaction in the fluoride.

[8]The H···X* distance is that between the H atom at rest on the C_3 axis and the acceptor atom X, i.e. corresponding to a symmetrically trifurcated bond. It depends on the metric properties of the crystal structure and varies from compound to compound. It should not be confused with the instantaneous H···X distance in a *particular* compound which varies with the amplitude of thermal motion of the axial hydrogen and hence with temperature.

atom at a time, and the hydrogen bond will acquire a more pronounced dynamic character.

Evidence for this conclusion is found in the decreasing frequency of the appropriate component of the ND stretching absorption ν_1 of the NH_3D^+ probe ion in the ir spectra of the four compounds as the temperature is raised from 10 to 293 K; in favourable circumstances the corresponding NH absorption in the spectrum of an undeuterated compound is resolved and a parallel frequency decrease is observable. In this respect the behaviour of the four compounds is quite similar, the main difference being in the magnitude of the frequency decrease. The magnitude appears to correlate with H···X*, the H···X distance for H in the symmetrically trifurcated position: the difference $\nu_1(10\ K) - \nu_1(293\ K)$ increases quasi-exponentially with decreasing H···X*. In contrast, the frequency of the ND stretching absorption corresponding to a *normal* N—H···X bond increases with temperature. The direction of the temperature variation, i.e. the sign of $d\nu_1/dT$, thus provides a diagnostic criterion for distinguishing between symmetrically trifurcated and normal N—H···X bonds.

The trifluoroacetic acid solvent system. Part VI. Density measurements

JOHN B. MILNE

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received July 25, 1979

JOHN B. MILNE. Can. J. Chem. **58**, 283 (1980).

The densities of solutions of several 1:1 trifluoroacetate electrolytes have been measured in 100% trifluoroacetic acid (HOTFA) and apparent molar volumes for their ion pairs have been determined. The density measurements coupled with limiting equivalent conductivities and dissociation constants, calculated by means of the Fuoss–Hsia equation, permit a more precise treatment of the conductivities of solutions at concentrations where the equivalent conductivity minimum occurs. The existence of triple ions in this solvent is not required to account for the conductivity minimum.

JOHN B. MILNE. Can. J. Chem. **58**, 283 (1980).

On a mesuré les densités de différents électrolytes de type trifluoroacétate 1:1 en solution dans l'acide trifluoroacétique pur (ATFA) et on a déterminé les volumes molaires apparents de leurs paires d'ions. Les mesures de densité utilisées conjointement avec les conductivités équivalentes limites et les constantes de dissociation, calculées au moyen de l'équation de Fuoss-Hsia permettent un traitement plus précis des conductivités des solutions à des concentrations où on atteint la conductivité minimum.

Il n'est pas nécessaire de faire appel à l'existence d'ions triples dans ce solvant, pour expliquer la conductivité minimum.

Introduction

For many solvents with dielectric constant less than 20, a plot of equivalent conductivity against concentration exhibits a minimum and this behaviour has been attributed to the formation of triple ions (1). Trifluoroacetic acid, with a dielectric constant of 8.4, shows this type of plot. This behaviour was explained originally in terms of triple ions (2). However, in view of cryoscopic results, this interpretation was later shown to be doubtful (3). A thorough reconsideration of the electrical conductivity work in the light of this finding required the measurement of the densities of the electrolyte solutions, since the solutions in the original work (3, 4) were made up in molal terms and converted to molar concentrations, using the density of the pure acid. This work concerns the measurement of the density of electrolyte solutions in trifluoroacetic acid, their use in improving the electrical conductivity results reported, and some discussion of the solvation properties of the solvent.

Experimental

Trifluoroacetic acid (Halocarbon) was purified and handled as described earlier (4) but without the addition of small amounts of trifluoroacetic anhydride. Similarily, the alkali metal and ammonium trifluoroacetates were prepared as described in ref. 4. Silver trifluoroacetate was crystallized from an equimolar mixture of silver carbonate (Fisher) and aqueous trifluoroacetic acid. The solution was protected from light during preparation. The tetramethyl- and tetraethylammonium trifluoroacetates were prepared by neutralization of an aqueous quaternary ammonium hydroxide solution (Eastman) with trifluoroacetic acid. The tetra-*n*-propyl- and tetra-*n*-butylammonium trifluoroacetates were made by a metathetic reaction of the quaternary ammonium bromide (Eastman) and silver trifluoroacetate in aqueous solution. The crude quaternary ammonium trifluoroacetates were recrystallized from ethanol (Me_4NOTFA), 3:1 benzene/ethanol (Et_4NOTFA), and propanol (n-Pr_4NOTFA and n-Bu_4NOTFA). Compositions were confirmed by C and H analysis as determined by Chemalytics Inc.

Densities were determined using an Anton Paar Digital Density Meter, Model DMA 40, calibrated with air and distilled water. A glove bag was attached to the inlet port of the meter and all transfers were made under dry conditions. Temperature was controlled at 25.00 ± 0.01°C. As a check on the accuracy of the density meter, the densities of pure acetonitrile and carbon tetrachloride were measured and found to be 0.7767 and 1.5844 g cm^{-3} respectively. Literature values for these solvents are 0.7766 and 1.58439 g cm^{-3} respectively (5). The precision of the DMA 40 Digital Density Meter is stated by the manufacturer to be 1×10^{-4} g cm^{-3} (6). The error given for the densities reported here is the average deviation and is based upon reproducibility for separate runs on the same compound.

Results and Discussion

Densities

The density of pure HOTFA at 25°C was 1.4774 ± 0.0001 g cm^{-3} and that at 0.00°C was 1.5353 ± 0.0001 g cm^{-3}. The density of pure acid at 25°C has been reported, ranging from 1.477 to 1.4885 g cm^{-3} (7). The densities of HOTFA solutions of lithium, sodium, potassium, cesium, silver, ammonium, and quaternary ammonium (R = Me, Et, n-Pr, and n-Bu) trifluoroacetates, each over the concentration range 0.015 to 0.200 molal at an average of 5 concentrations were measured at 25.00°C. The densities of lithium and ammonium trifluoroacetates were measured at 0.00°C also.[1] Apparent

molar volumes, ϕ_v, were calculated in the usual way (8) for each concentration. The average values of ϕ_v for each electrolyte, the average deviation, and the number of measurements are listed in Table 1. The ϕ_v showed little variation with concentration as indicated by the average deviations and the variation was essentially random although the deviations in ϕ_v appeared to be negative for the small, and positive for the large cations. The solutes studied exist predominantly as ion pairs in the concentration range studied as indicated by the degree of dissociation, α, at 0.05 *M* listed in Table 1. The α were calculated from ion pair dissociation constants, given below, except in the case of the quaternary ammonium trifluoroacetates, where K_d was estimated, using the Fuoss equation (9), from the sum of cation radii, as determined from ionic volumes for these cations in water (10), and the average trifluoroacetate anion contact radius (r = 3.48 Å) as estimated from the distance of closest approach for alkali metal trifluoroacetates, a_0, and the Pauling ionic radius of the alkali metal cation.

The ion pair apparent molar volumes listed in Table 1 provide evidence for electrostriction of solvent in as much as HOTFA itself has a molar volume of 77.2 cm^3 while the volumes of LiOTFA, NaOTFA, and KOTFA are less than this. Another interesting result is the equivalent volumes for LiOTFA and NaOTFA followed by a monotonic increase up to *n*-Bu_4NOTFA. Similar behaviour is also observed in the case of individual ionic volumes measured in H_2O, MeOH, and EtOH (10). The near constancy of the ϕ_v for LiOTFA and NaOTFA in HOTFA may be due to the formation of a solvent cage determined principally by intersolvent molecule contacts. The increase in ϕ_v with increasing cation size, except for KOTFA, is apparently determined by increased bare cation size and decreased electrostriction. In the case of ϕ_v for ion pairs, three influences must be considered, (*a*) that of the cation, (*b*) that of the anion, and (*c*) that of each ion in the ion pair on its counter ion. Interionic effects may be the cause of the small values of ϕ_v for KOTFA and NH_4OTFA. The intensity of the positive charge in LiOTFA and NaOTFA may favour the simple cation – trifluoroacetate anion pair but where the positive field strength is less intense, as with KOTFA, NH_4OTFA, and the heavier homologues, the hydrogen bis(trifluoroacetate), $H(OTFA)_2^-$, may take part in the ion pair. The additional decrease in anion size due to hydrogen bonding to the solvent could account for the smaller ϕ_v values relative to those of LiOTFA and NaOTFA. Solids containing the $H(OTFA)_2^-$ anion are well documented (7). Further evidence that the nature of the anion changes as the cation is varied is found in the alteration of the least distance in the ion pair discussed below.

Electrical Conductivity

The limiting equivalent conductivities, Λ_0, and dissociation constants, K_d, for the alkali metal and ammonium trifluoroacetates were recalculated, using molar concentrations calculated from the molalities by means of the measured densities, instead of the density of pure acid (4). The results were not significantly different from those originally reported. The extrapolation was also carried out using the Fuoss–Hsia equation (11), which should yield better values for Λ_0 and K_d for use with the electrical conductivities in the so-called "triple ion" region of concentration (2–4). These values of Λ_0 and K_d are listed in Table 2. Although these values differ slightly from those reported earlier (the K_d are ca. 20% larger and the Λ_0, ca. 10% smaller than the previously reported results), the basic conclusions of the original work remain unaffected. It should, however, be noted that either solvation or solvent relaxation plays an important role, since the combined mobility of cation and

trifluoroacetate anion (Λ_0) is smaller than that predicted for the cation alone from crystal ionic radii using Stokes' Law (λ_0^+) as shown in Table 2.

The variation in K_d with cation size is that expected for contact ion pairs (4) and the ion pair contact distances calculated by the Fuoss equation (9) approximate the sum of the ionic radii. Subtraction of the crystal radius of the cation from the contact distance should give the radius of the counter anion of the ion pair and this is listed for each solute in Table 2. Assuming that the $OTFA^-$ ion is the same size as the HOTFA molecule in the solvent (77.2 cm^3), $r(OTFA^-)$ is found to be 3.13 Å, while calculation of this radius from the density of NH_4OTFA (12) gives $r(OTFA^-) = 2.97$ Å. Estimation of $r(H(OTFA)_2^-)$, assuming the volume to be double that of HOTFA, gives 3.94 Å; calculation from the density of $K(H(OTFA)_2)$ (13) yields 3.59 Å. These estimates are close to the values for the anion radius calculated for the ion pairs and support the theory that the anion in the ion pair in the case of NaOTFA is the $OTFA^-$ anion but in the case of the larger cations, is the $H(OTFA)_2^-$ anion. This approach assumes, of course, that the anion is freely rotating in the ion pair, which may not be exactly true. Another possible explanation of the increase in anion radius with increasing cation size in the ion pair is the decrease in electrostatic compression on the anion as the positive field strength decreases. However, these effects are much smaller than the changes listed in Table 2, judging from the change in the size of the $H(OTFA)_2^-$ anion in the series $M(H(OTFA)_2)$ (M = K, Rb, and Cs) (13) and allowing for the Madelung effect in the crystalline solids. The $H(OTFA)_2^-$ anion radius increases from 3.59 to 3.70 Å on going from $K(H(OTFA)_2$ to $Cs(H(OTFA)_2)$ as calculated from molar volume of the crystal and cation size.

The limiting equivalent conductivities and dissociation constants were used in conjunction with the Fuoss–Hsia equation and an expression for the molar activity coefficient to explore the behaviour of Λ at higher concentrations ("triple ion region"). The degree of dissociation, α, was determined at each concentration by an iterative procedure from the equations:

$$K_d = c\, y_\pm^2\, \alpha^2/(1-\alpha)$$

$$y_\pm = (d_0/d)10^{-A\sqrt{c\alpha}/(1+Ba_0\sqrt{c\alpha})}$$

where c is molarity; $y_\pm$, the molar activity coefficient; d_0, the density of pure acid; d, the density of solution; a_0, the distance of closest approach calculated from K_d by the Fuoss expression (9); and A and B, constants defined in ref. 1, p. 230. The actual equivalent conductivity was then determined by

$$\Lambda = \alpha\Lambda'$$

where Λ', the equivalent conductivity corrected for ionic strength effects, was determined by the Fuoss–Hsia equation (11). A plot of the theoretical Λ vs. c is given in Fig. 1 along with the experimental points for NaOTFA, KOTFA, NH_4OTFA, and CsOTFA. It was found that the use of the more sophisticated expression for $y_\pm$ developed by Robinson and Stokes (ref. 1, p. 238), allowing for the effect of solvation on the activity coefficient, made virtually no change in the calculated values.

It may be seen from Fig. 1 that a minimum in Λ is expected from the theory without introducing triple ion equilibria (2). Cryoscopic results show that triple ions do not occur in the case of NaOTFA, KOTFA, and CsOTFA (3). The agreement between theory and experiment is quite good in the case of CsOTFA but becomes progressively poorer as the cation decreases in size. However, both the magnitude of Λ and the concentration at the minimum change as predicted by theory for the series of trifluoroacetates studied. It is interesting that LiOTFA has been shown to form triple ions and higher ion aggregates in propylene carbonate (14) and acetonitrile (15), both solvents of medium dielectric constant. The large discrepancy between

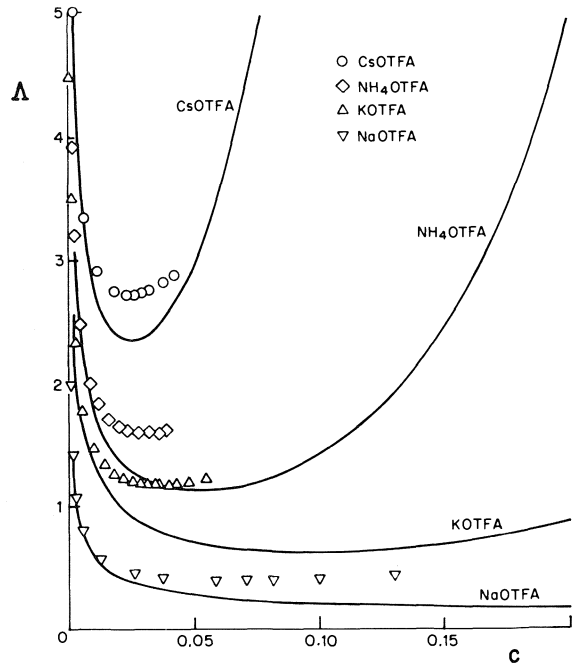

FIG. 1. Equivalent conductivity vs. molar concentration. The solid lines are calculated from theory; the points are experimental.

the minimum calculated for NaOTFA in HOTFA from theory (>0.25 *M*) and that observed (0.071 *M*) may be accounted for by the formation of triple ions.

The use of the measured densities in the calculation of freezing point depressions carried out in the cryoscopic study (3) has little effect on the conclusions of that work. The agreement of the calculation for the ion pair – simple ion model with the observed values is virtually unaffected while the agreement of the ion pair – simple and triple ions model with the measured values is worse.

A 1% crosslinked divinylbenzene–styrene copolymer, incorporating benzyl alcohol groups, was used to monoblock the symmetrical diacid chlorides, $ClOC(CH_2)_nCOCl$ (where $n = 4$ and 8). Further reaction of the polymer-bound monoester monoacid chloride with phenylmanganese iodide or butylmanganese iodide gave their respective polymer-bound tertiary hydroxyesters. Subsequent base cleavage and esterification yielded methyl 6-hydroxy-6,6-diphenylhexanoate, methyl 10-hydroxy-10,10-diphenyldecanoate, methyl 6-butyl-6-hydroxydecanoate, and methyl 10-butyl-10-hydroxytetradecanoate and some recovered dimethyl alkanoates. The reactions of some polymer-bound monoester monoacid chlorides with phenylcadmium chloride were also studied.

CLIFFORD C. LEZNOFF et VARDA YEDIDIA. Can. J. Chem. **58**, 287 (1980).

On a utilisé un copolymère styrène–divinylbenzène reticulé à 1% et contenant des groupes alcool benzylique pour bloquer une des fonctions des dichlorures de diacides symétriques $ClOC(CH_2)_nCOCl$ (où $n = 4$ et 8). La réaction de l'ester ainsi obtenu avec l'iodure de phénylmanganèse ou l'iodure de butylmanganèse conduit à leurs hydroxy-esters tertiaires respectifs fixés sur la résine. Le clivage subséquent par une base suivi d'une estérification conduit aux composés: hydroxy-6 diphényl-6,6 hexanoate de méthyle, hydroxy-10 diphényl-10,10 décanoate de méthyle, butyl-6 hydroxy-6 décanoate de méthyle et le butyl-10 hydroxy-10 tétradécanoate de méthyle et également à la récupération de quelques alkanoates de méthyle. On a également étudié les réactions de quelques monochlorures d'acides fixés sur la résine par une liaison ester avec le chlorure de phénylcadmium.

[Traduit par le journal]

Introduction

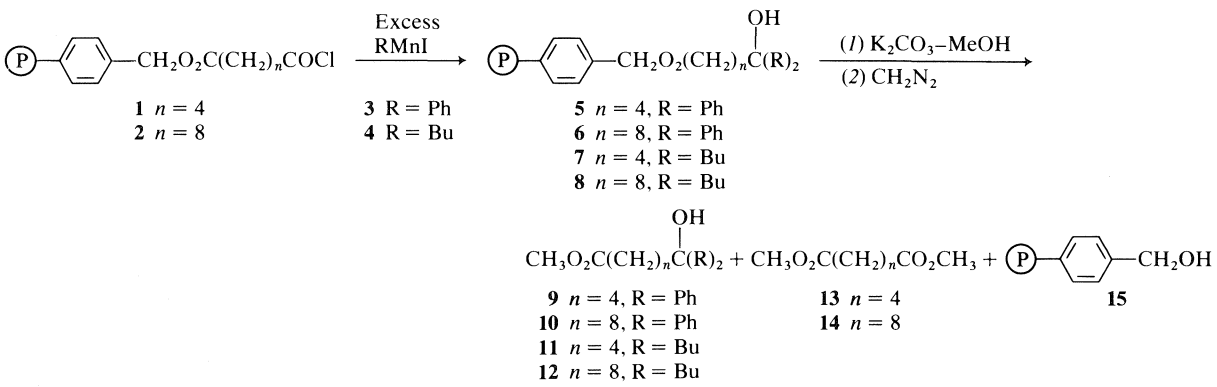
Tertiary hydroxyesters have been prepared before but in low yields and in multiple step reactions. Thus diethyl succinate reacted with benzophenone in a Stobbe condensation to give, after several further reactions, 4,4-diphenyl-γ-butyrolactone (5) useful against pathogenic viruses (6). Alternatively, reaction of succinic anhydride with phenylmagnesium bromide gave a mixture of products, one of which was 4-hydroxy-4,4-diphenylbutanoic acid (7).

It has been previously shown in our laboratory that insoluble polymer supports (8) can be used to monoprotect symmetrical diacid chlorides as the monoester monoacid chloride and several monoamide monoesters and primary hydroxyesters were prepared via solid phases (9, 10). In this paper we describe a general synthesis of hydroxyesters, disubstituted at the hydroxy position, from polymer-bound monoester monoacid chlorides.

Results and Discussion

The previously described (10) polymer-bound monoester monoacid chlorides (**1**) and (**2**), derived from adipyl and sebacyl chloride respectively, were treated in benzene at 0°C with an excess of phenylmanganese iodide (**3**) (11, 12) or butylmanganese iodide (**4**) (11, 12) in ether to give the polymer-bound tertiary hydroxyesters (**5–8**) respectively as shown in Scheme 1.

The infrared spectra of **5–8** exhibited strong absorptions at 1740 cm^{-1} and broad absorptions between 3200–3600 cm^{-1} indicative of ester and alcohol groups respectively. Cleavage of **5–8** with K_2CO_3 in methanol followed by esterification with diazomethane as previously described (10) yielded methyl 6,6-diphenyl-6-hydroxyhexanoate (**9**) (13), methyl 10,10-diphenyl-10-hydroxydecanoate (**10**), methyl 6-butyl-6-hydroxydecanoate (**11**), and methyl 10-butyl-10-hydroxytetradecanoate (**12**) respectively in good yield (Table 1). In addition, some dimethyl adipate (**13**) and dimethyl sebacate (**14**) were recovered from the reactions involving **1** and **2** respectively and separated from the products by preparative thin layer chromatography (tlc). The recovery of **13** and **14** is likely due to incomplete reaction of **1** and **2** with the organomanganese iodide reagents since our previous work (10) showed that most of the symmetrical diacid chlorides were monobound to the polymer although some double-binding of the diacid chlorides cannot be completely dismissed at this time (8, 14). The polymer itself was recovered as polymer-bound benzyl alcohol (**15**) and is recyclable by simple standard washing procedures as the organo-



[1]The use of polymer supports in organic synthesis. Part XXI. For parts XX, XIX, XVIII, and XVII, see refs. 1–4 respectively.

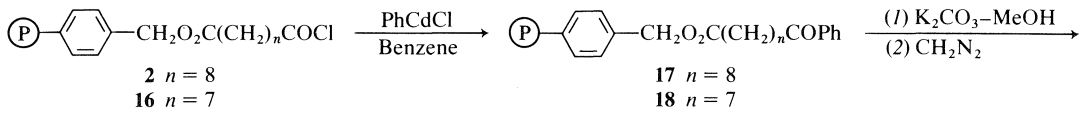
manganese and organocadmium reagents leave no insoluble impurities. The loading capacities of **1** and **2** were determined as previously described (10) and are given in Table 1. The spectroscopic and physical data of **9–12** are entirely consistent with the assigned structures and are given in the Experimental.

It should be noted that organomanganese iodide reagents were initially introduced as reacting selectively with acid chlorides to give ketones (11). It was later shown, however, that organomanganese iodide reagents do react with ketones albeit more slowly, but not at all with esters (12). Thus the syntheses of **5–8** utilized this selectivity for the first time so that the free acid chloride in the presence of an ester can react with two equivalents of **3** or **4** to give exclusively the tertiary hydroxyesters. The previously reported (13) synthesis of **5**, for example, was accomplished in 5 steps in ~20% overall yield from dimethyl adipate, compared to our 4-step synthesis in 85% yield (Table 1).



The possibility of preparing tertiary hydroxyesters with different substituents on the tertiary hydroxy carbon atom was then explored. Treatment of a polymer-bound monoester monoacid chloride (**16**) derived from azeloyl chloride with phenyl cadmium chloride (15) in benzene at 0°C yielded the polymer-bound keto esters **17** and **18** as shown in Scheme 2.

Cleavage and esterification of **17** and **18** as above gave methyl 10-oxo-10-phenyldecanoate (**19**) and methyl 9-oxo-9-phenylnonanoate (**20**) respectively. Unfortunately, **19** was contaminated with **13**, and **20** with dimethyl azelate (**21**), and in these cases the keto esters could not be readily separated from their respective diester precursors even by preparative tlc. The yields of **19** and **20** in the mixture obtained from the phenyl cadmium chloride reaction were estimated from the nmr spectrum of the fraction containing **19** and **13**, and **20** and **21**, respectively. Although a few attempts were made to synthesize unsymmetrical tertiary hydroxyesters by reaction of **18** with butylmanganese iodide, inseparable mixtures of products were obtained.

Conclusions

Hydroxyesters, symmetrically disubstituted at the carbon atom bearing the alcohol group, have been selectively prepared in good yield in a single key step from polymer-bound monoester monoacid chlorides. We have confirmed that the recently

described organomanganese iodide and organocadmium chloride reagents are easy to prepare, easy to use, give no sludges during or on completion of the reaction and should find wide use in synthetic organic chemistry. Since these reagents leave no residues as can occur with some organocopper reagents (16), they are particularly useful in conjunction with organic syntheses on solid phases.

Experimental

A chloromethylated 1% divinylbenzene (DVB)–styrene copolymer, containing 1.09 mequiv. Cl/g of resin, obtained from Sigma Chemical Company was used as the starting resin in all resin transformations. Filtration was done under vacuum using sintered glass Büchner funnels. Suspensions and solutions were stirred using magnetic stirrers. Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra were recorded on a Varian LM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).) Mass spectra (ms) were recorded at 70 eV on a Hitachi–Perkin-Elmer RMU 6E mass spectrometer. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Microanalyses were done by G. Gygli of Toronto. Spectral and analytical data are given for all new compounds and for known compounds where data are unreported.

*Preparation of Polymer-bound Acid Chlorides **1**, **2**, and **16***

A suspension of a 1% crosslinked divinylbenzene (DVB)–styrene copolymer containing benzyl alcohol groups (**15**) (17) in THF was treated with the corresponding diacid chlorides by a method previously described (10) to give the polymer-bound acid chlorides **1**, **2**, and **16**.

The quantities of the corresponding diacid chlorides bound to polymer **1** were determined by hydrolysis of **1**, **2**, or **16** as before (10) to give their respective polymer-bound monoester monoacids. They were then cleaved with K_2CO_3 in methanol and esterified to yield the respective dimethylesters (10) from which the loading capacities of **1**, **2**, and **16** were calculated and given in Table 1.

*Preparation of Polymer-bound Tertiary Hydroxyesters **5–8***

To a suspension of 2 g of polymer **1** or **2** in 50 mL of dry benzene at 0°C under an argon atmosphere was added 15 mmol of phenylmanganese iodide (**3**) or butylmanganese iodide (**4**) in 10 mL at Et_2O (11). After the addition the reaction mixture was allowed to warm to room temperature and was stirred for 12 h. The excess organomanganese iodide was decomposed with 50 mL of a saturated solution of ammonium chloride. The polymer was filtered and washed with water (twice), methanol (twice), THF (twice), and Et_2O (3 times), and air dried to give the polymer-bound tertiary hydroxyesters **5–8**; ir (KBr): 3200–3600 (broad, O—H) and 1740 (CO_2R) cm^{-1}.

*Preparation of the Tertiary Hydroxyesters **9–12***

A suspension of 2 g of polymer **5** was cleaved with K_2CO_3 in methanol (10) and the product was esterified with CH_2N_2. The reaction mixture (250 mg) was purified by preparative tlc using hexane–acetone (4:1) to give 208 mg of methyl 6,6-diphenyl-6-hydroxyhexanoate (**9**) as a solid. The solid was recrystallized from hexane to give pure **9**, mp 81–82°C (lit (13) mp 82–83°C); ir (KBr): 3450 (OH), 1715 (CO_2Me), and 1600 (phenyl) cm^{-1}; nmr δ: 7.1–7.6 (m, 10, aromatic H), 3.55 (s, 3, CH_3O), 2.2–2.5 (m, 4, CH_2CO and $CH_2\overset{\overset{OH}{|}}{C}Ph_2$), 2.17 (s, 1, OH), and 1.1–1.9 (m, 4, CH_2); ms *m/e*: 280 (40) ($M^+ - H_2O$), 206 (100), 115 (68), 91 (83).

Similarly **6** gave methyl 10,10-diphenyl-10-hydroxydecanoate (**10**), mp 47–48°C; ir (KBr): 3500 (O—H), 1710 (CO_2R), and 1600 (phenyl) cm^{-1}; nmr δ: 7.2–7.6 (m, 10, aromatic *H*), 3.7 (s, 3, OCH_3), 2.1–2.5 (m, 4, $CH_2C{=}O$ and CH_2COPh_2), 2.14 (s, 1, O—*H*), 1.1–1.6 (m, 12, CH_2); ms *m/e*: 336 (40) ($M^+ - H_2O$), 193 (100), 115 (88), 91 (55). *Anal.* calcd. for $C_{23}H_{30}O_3$: C 77.93, H 8.53; found: C 77.89, H 8.67.

Similarly **7** yielded methyl 6-butyl-6-hydroxydecanoate (**11**) as an oil after purification on preparative tlc using methanol–chloroform (1:99) as eluant; ir (neat): 3300–3600 (b, OH), and 1740 (CO_2CH_3) cm^{-1}; nmr δ: 3.65 (s, 3, OCH_3), 2.3 (t, J = 6 Hz, 2, $CH_2C{=}O$), 1.6 (s, 1, O—*H*), 1.1–1.5 (m, 19, CH_2), 0.9 (t, J = 6 Hz, CH_3); ms *m/e*: 230 (6) ($M^+ - H_2O$), 85 (100), 55 (79). *Anal.* calcd. for $C_{15}H_{30}O_3$: C 69.72, H 11.70; found: C 69.73, H 11.86.

Similarly **8** gave methyl 10-butyl-10-hydroxytetradecanoate (**12**) as an oil; ir (neat): 3350–3550 (O—H), and 1730–1750 (CO_2R) cm^{-1}; nmr δ: 3.67 (s, 3, O—CH_3), 2.32 (t, J = 7 Hz, 2, $CH_2C{=}O$), 1.3–1.4 (m, 27, —CH_2— and O*H*), 0.9 (t, J = 6 Hz, CH_3); ms *m/e*: 298 (9) ($M^+ - H_2O$), 55 (100), 41 (86). *Anal.* calcd. for $C_{19}H_{38}O_3$: C 72.55, H 12.18; found: C 72.14, H 12.19.

In the separation of the products the corresponding dimethyl esters were detected and separated from the monoester monotertiary alcohols by preparative tlc. The quantities of recovered dimethyl esters and the yields of monoester monotertiary alcohols are reported in Table 1.

*Preparation of Polymer-bound Ketoesters **17** and **18***

To a suspension of 2 g of polymer **2** or **16** in 40 mL of dry benzene at 0°C under an argon atmosphere was added 7 mmol of phenyl cadmium chloride (15) in 15 mL of dry benzene. The

For personal use only.

reaction mixture was allowed to warm to room temperature and was stirred for 24 h, after which 50 mL of 2% sulfuric acid was added and stirred for 10 min. The polymer was filtered and washed with benzene (twice), water (twice), methanol (twice), benzene (once), and ether (3 times), and air dried to give the polymer-bound ketoesters **17** or **18**; ir (KBr): 1735 (CO_2R) and 1690 (PhC=O) cm^{-1}.

*Preparation of Impure Ketoesters **19** and **20***

A suspension of 3 g of polymer **17** was cleaved with K_2CO_3 in methanol (10) and the product was esterified with CH_2N_2 to yield 400 mg of a mixture of 46% methyl 10-oxo-10-phenyldecanoate (**19**) (18) and 54% dimethyl sebacate (**14**) which was not further purified. Although the products **19** and **14** were inseparable by preparative tlc, the ratio of **19** to **14** could be readily determined from the nmr spectrum of the mixture using the nmr spectrum of pure **14** as a comparison. The ir (neat) spectrum of the mixture exhibited a strong absorbance at 1750–1730 (CO_2R), 1695 (PhCO), 1600 and 1590 (phenyl), and 1100 (C—O) cm^{-1}; nmr δ: 8.0 (m, *ortho* aromatic 2*H*), 7.4 (m, aromatic 3*H*), 3.7 (s, OCH_3), 3.0 (t, J = 7 Hz, CH_2COPh), 2.32 (t, J = 7.5 Hz, CH_2CO_2), and 1.1–1.9 (m, CH_2).

Similarly **18** yielded a mixture containing 54% methyl 9-oxo-9-phenylnonanoate (**20**) and 46% dimethyl azeloate (**21**), ir (neat): 1750–1730 (CO_2R), 1695 (PhCO), 1600 and 1590 (phenyl) cm^{-1}; nmr δ: 7.9 (m, *ortho* aromatic 2*H*), 7.4 (m, aromatic 3*H*), 3.7 (s, OCH_3), 2.98 (t, J = 7 Hz, CH_2COPh), 2.31 (t, J = 7 Hz, CH_2CO_2), and 1.2–1.8 (m, CH_2).

M. GRIGNON-DUBOIS, J. DUNOGUÈS et R. CALAS. Can. J. Chem. **58**, 291 (1980).

A l'exception du dérivé cyclopropanique, les cycloalkyltriméthylsilanes réagissent sur les électrophiles avec scission de la liaison Si—Me. Cette propriété peut être mise à profit pour la fonctionnalisation au niveau du silicium ce qui nous a conduits à une synthèse nouvelle des cycloalkyldiméthylfluoro (ou chloro-) silanes. L'acétylation par $MeCOCl/AlCl_3$ donne, dans le cas des cycles en C_5 et C_6, des résultats qui s'interprétent par l'arrachement initial d'un ion hydrure au substrat silicié.

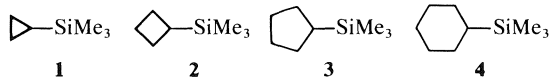
M. GRIGNON-DUBOIS, J. DUNOGUÈS, and R. CALAS. Can. J. Chem. **58**, 291 (1980).

Cycloalkyltrimethylsilanes, excepting cyclopropyl-, react with electrophiles by Si—Me bond splitting. Consequently silicon can be functionalized by this route. We also propose a new synthesis of cycloalkyldimethylfluoro (or chloro-)silanes. In the case of five or six member ring derivatives, the observed results are interpreted by a mechanism involving initial abstraction of hydride ion from the silicon substrate.

Introduction

Au cours de travaux antérieurs nous avons étudié la réactivité du cyclopropyltriméthylsilane vis-à-vis d'électrophiles et proposé la première synthèse de l'acide cyclopropane sulfonique (**1**) ainsi qu'une voie d'accès simple et pratique aux cyclopropylcétones (2). Par ailleurs nous avons montré que la sulfonation du cyclohexyltriméthylsilane avait lieu non par rupture de la liaison Si—$C_{alicyclique}$ mais au contraire par scission univoque d'une liaison Si—Me. Afin de déterminer d'une manière plus approfondie la réactivité de la liaison Me_3Si—$C_{alicyclique}$ en la comparant à celle de la liaison Si—Me, en vue d'éventuelles applications en synthèse, nous avons étudié le comportement de $(CH_2)_nCH$—$SiMe_3$ (n = 2, 3, 4, 5) vis-à-vis de quelques électrophiles. En particulier on pouvait se demander si, en série cyclobutanique, la fonctionnalisation serait possible comme en série cyclopropanique, par scission de la liaison Si—$C_{cyclobutanique}$ grâce à la tension du cycle à 4 chaînons. Cette étude nous a conduits à revoir la synthèse des substrats siliciés de départ pour n = 4 et 5 et à préparer le cyclobutyltriméthylsilane qui n'avait pas été décrit.

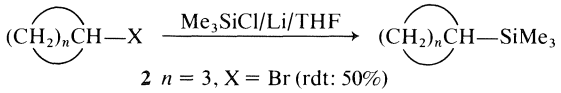
Nous rapportons ici les résultats que nous avons obtenus dans ce domaine.



[1]Avec la collaboration technique de B. Rezzonico.

Résultats et discussion

Synthèse de $(CH_2)_nCH$—$SiMe_3$ (n = 2–5)



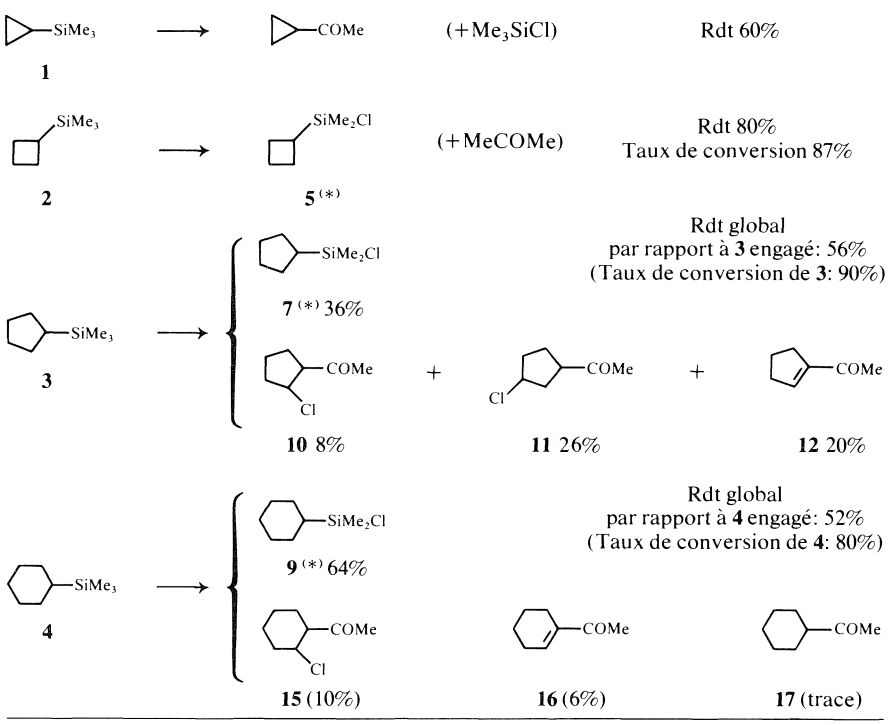
L'étude de **1** ne sera reprise qu'à titre comparatif puisque déjà publiée (1, 2).

Les composés **2**, **3** et **4** ont été synthétisés par silylation de $(CH_2)_nCH$—X (X = halogène) au

1 **2** **3** **4**

moyen du système $Me_3SiCl/Li/THF$ connu comme un excellent agent de silylation (3):

2 n = 3, X = Br (rdt: 50%)
3 n = 4, X = Br (rdt: 50%)
4 n = 5, X = Cl (rdt: 80%)



Acétylation avec $MeCOCl/AlCl_3$

Les résultats obtenus avec un équivalent de $MeCOCl/AlCl_3$ sont résumés dans le tableau 1.

Ce tableau appelle les commentaires suivants. (*a*) Seul le cyclopropyltriméthylsilane subit une scission univoque au niveau de la liaison Si—$C_{alicyclique}$. Le cyclobutyltriméthylsilane, au contraire ne réagit pas du tout à ce niveau et ne peut donc pas être comparé au dérivé cyclopropanique. (*b*) Avec les cycles en C_4, C_5 et C_6 le bilan réactionnel concernant les pourcentages relatifs de scission

TABLEAU 1. Acétylation des cycloalkyltriméthylsilanes par 1 équivalent de $MeCOCl/AlCl_3$

*L'hydrolyse des chlorosilanes conduit aux disiloxanes (**6** $n = 3$; **7** $n = 4$; **9** $n = 5$) selon:

$$(CH_2)_n\overset{\frown}{CH}—SiMe_2Cl \xrightarrow{H_2O} (CH_2)_n\overset{\frown}{CH}—SiMe_2OH \rightarrow [(CH_2)_n\overset{\frown}{CH}—Si—Me_2]_2O$$

Avec $n = 5$ le silanol résultant de l'hydrolyse de **9** est relativement stable et a été isolé même dans nos conditions. En présence de Me_3SiCl, on obtient en outre les dérivés mixtes $(CH_2)_n\overset{\frown}{CH}—SiMe_2OSiMe_3$.

des liaisons Si—Me et Si—$C_{alicyclique}$ peut être schématisé comme suit:

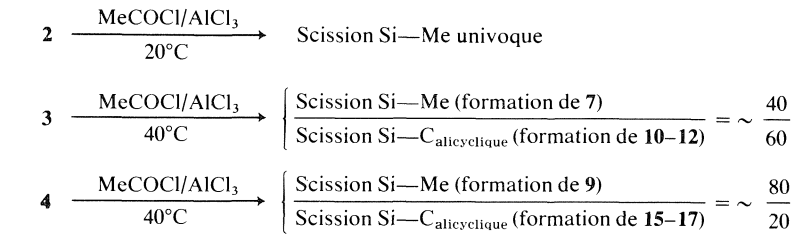

SCHÉMA 1. Bilan des scissions respectives Si—Me et Si—$C_{alicyclique}$ lors de l'acétylation de **2–4** par un équivalent de $MeCOCl/AlCl_3$.

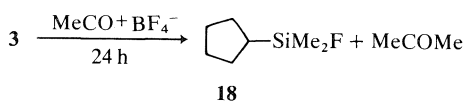
Ce bilan fait ressortir que **3** ne se situe pas entre **2** et **4** comme on aurait pu l'imaginer.

L'acétylcyclopentane est absent du mélange réactionnel et son homologue cyclohexanique n'est présent qu'à l'état de traces. Par contre, on trouve dans les deux cas des chlorocétones en quantité abondante. Elles se décomposent partiellement dans le milieu par perte d'HCl pour conduire respectivement à l'acétylcyclopentène et à l'acétylcyclohexène.



Nous avons vérifié que ces dérivés chlorés ne provenaient pas de la dégradation des méthylcycloalkylcétones dans le milieu, sous l'effet d'$AlCl_3$: l'acétylcyclopentane et l'acétylcyclohexane sont stables dans nos conditions opératoires. La formation des produits obtenus ne peut donc pas s'interpréter par une simple rupture de la liaison Si—$C_{alicyclique}$.

Ceci peut s'expliquer par l'intervention du chlorure d'aluminium . En effet l'acétylation de **3** par

$MeCO^+BF_4^-$ a lieu par scission univoque d'une liaison Si—Me:

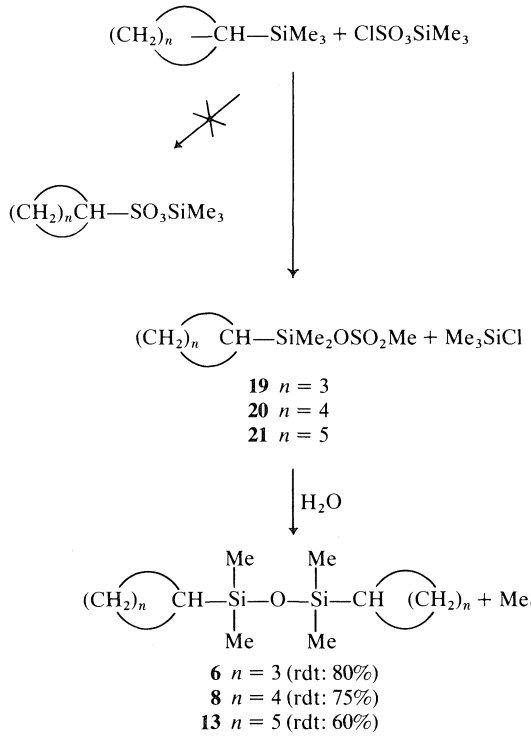
18

(ce qui constitue par ailleurs une voie d'accès pratique à **18**). Ceci suggère que les cétones formées lors de l'acétylation de **3** et **4** ne sont pas les produits primaires de la réaction. En fait nous pensons que $MeCOCl/AlCl_3$ produit un arrachement d'ion hydrure bien connu (4, 5) conduisant respectivement au cyclopentène et au cyclohexène dont l'acétylation peut expliquer la plupart des produits formés (6):

L'hypothèse de l'arrachement d'ion hydrure entraîne qu'une partie du chlorure d'acide engagé conduise à de l'éthanal puisqu'aucun dégagement gazeux (H_2 ou Me_3SiH) n'a été observé; celui-ci se polymériserait dans le milieu entraînant la formation de produits lourds dont nous avons noté la présence. En conséquence nous avons repris l'acétylation avec deux équivalents de complexe $MeCOCl/AlCl_3$. Les résultats observés sont rapportés dans le Tableau 2.

Il ressort de ces résultats que (*1*) le silane de départ réagit complètement; (*2*) le rendement global de l'acétylation augmente; (*3*) le rapport (scission Si—$C_{alicyclique}$/scission Si—Me) et le rendement en acétyl-1 chloro-3 cycloalcane augmentent. En effet, on sait que l'acétyl-1 chloro-3 cyclopentane se forme à partir de l'acétyl-1 chloro-2 cyclopentane par migration d'ion hydrure.

Avec 2 équivalents de complexe, on favorise donc la formation de cyclènes, ce qui est en accord avec l'interprétation proposée.



La formation de cyclène est moins importante pour le cycle en C_6 que pour celui en C_5. L'arrachement d'ion hydrure serait donc favorisé en série cyclopentanique. Il est bien connu que les réactions d'addition au carbonyle de la cyclohexanone transformant un carbone sp^2 en carbone sp^3 sont favorisées par rapport à celles de la cyclopentanone (7, 8), puisque la tension du cycle du cyclohexane est pratiquement nulle, ce qui n'est pas le cas du cyclopentane (6.5 kcal/mol) (9).

De ce fait on peut donc admettre que le passage d'un carbone sp^3 à un carbone sp^2 est plus facile en série cyclopentanique ce qui est corroboré par l'énergie de déstabilisation plus faible quand on passe du cyclopentane au cyclopentène (0.4 kcal/mol) que dans le cas du passage du cyclohexane au cyclohexène (2.6 kcal/mol) (9).

Ces considérations expliquent donc l'anomalie apparente du comportement du dérivé **3**, qui disparaît pour les réactions de substitution électrophile en l'absence de chlorure d'aluminium.

Sulfonation

La sulfonation, effectuée avec $ClSO_3SiMe_3$ (10), agent de sulfonation à la fois doux et efficace (11), a conduit à une scission de la liaison Si—Me, comme observé au cours d'essais préliminaires avec le cyclohexyltriméthylsilane (12). Ceci contraste avec les résultats que nous avons précédemment obtenus en série cyclopropanique (1):

Ceci confirme le caractère univoque de la scission Si—Me avec $n = 3$, 4 et 5 et donc que le cycle à 4 chaînons ne peut être comparé à celui à 3 chaînons, malgré son caractère π (13). Ce résultat est à rapprocher de ceux obtenus au Laboratoire par Bourgeois *et al.* (14) lors de la sulfonation de Bu-$SiMe_3$ qui s'effectue uniquement par scission de la liaison Si—Me. Les raisons stériques invoquées

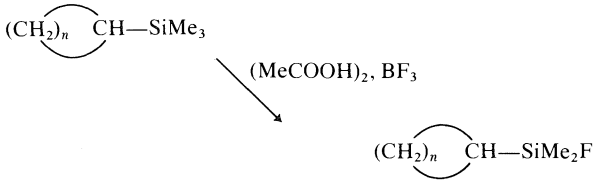


TABLEAU 2. Influence de la quantité de complexe sur l'acétylation de **3** et **4**

		Produits obtenus (Rdt %)

alors pour expliquer cette régiosélectivité sont applicables à notre cas.

Scission par $(MeCOOH)_2$, BF_3

Les conclusions des études précédentes permettaient de penser qu'avec les cycles en C_4, C_5 et C_6 la scission univoque de la liaison Si—Me permettait la fonctionnalisation au niveau du silicium. Nous avons donc appliqué cette réaction à la synthèse de cycloalkyldiméthylfluorosilanes en utilisant $(MeCOOH)_2$, BF_3 comme électrophile:

22 $n = 3$ (rdt: 50%)
18 $n = 4$ (rdt: 65%)
23 $n = 5$ (rdt: 70%)

Les rendements élevés confèrent à cette méthode une valeur synthétique pour accéder à des dérivés qui, à notre connaissance, n'avaient pas été décrits.

Conclusion

A l'exception du cyclopropyltriméthylsilane, les triméthylsilylcycloalcanes ne peuvent être utilisés comme précurseurs des dérivés alicycliques fonctionnels. En effet, dans les réactions de substitution électrophile, ce n'est pas le groupe silyle qui s'élimine mais seulement un groupe méthyle lié au silicium. Cette réactivité des liaisons Si—Me déjà mise en évidence au Laboratoire (14, 15) et généralisée aux liaisons silicium – groupe alkyle (16), peut être mise à profit pour transformer un groupe $—SiMe_3$ en $—SiMe_2X$, ce que nous avons illustré par la synthèse de cycloalkyldiméthylfluorosilanes.

En outre, nous avons proposé une interprétation cohérente de tous nos résultats, la réaction complexe observée entre **3** ou **4** et $MeCOCl/AlCl_3$ s'interprétant de façon satisfaisante par l'arrachement initial d'ion hydrure à ces deux substrats siliciés.

Partie expérimentale

Préparation du bromure de cyclobutyle

Nous l'avons obtenu à partir du cyclobutane carboxylate d'argent selon la méthode de Cason et Way (17) légèrement modifiée comme suit:

A une suspension refroidie à −25°C du sel d'argent dans le tétrachlorure de carbone (0.5 mol dans 500 cm^3) et vigoureusement agitée, on additionne, goutte à goutte, 0.5 mol de brome (séché sur P_2O_5). Il en résulte un important dégagement de CO_2. Lorsque le dégagement a cessé, on laisse remonter la température en maintenant l'agitation pendant 12 h. Le mélange réactionnel est alors filtré, le bromure d'argent lavé au tétrachlorure de carbone, puis l'ensemble des phases organiques est traité avec une solution saturée de thiosulfate de sodium et séché sur $MgSO_4$. Le solvant est distillé sous pression réduite (180 Torr) à l'aide d'une colonne à bande tournante, type Cadiot. Le rendement en bromocyclobutane (pé 63°C/180 Torr) est de 60%.

Silylation des halogénoalcanes

A une suspension de 0.2 at.g de lithium dans un mélange de 150 cm^3 de THF et 0.13 mol de Me_3SiCl, on additionne, goutte à goutte, 0.1 mol de dérivé halogéné, la température étant maintenue à −20°C. Les réactifs sont laissés en contact pendant 20 h. Le mélange réactionnel est alors filtré, les produits légers sont évaporés. Puis la phase organique est reprise deux fois au pentane afin d'éliminer toute trace de LiCl. Après élimination du solvant on obtient le dérivé silicié presque propre. Une filtration sur SiO_2 (2 cm de silice sur un verre fritté) permet d'isoler le produit pur; rdt: 50% à partir du bromocyclobutane et du bromocyclopentane, 80% à partir du chlorocyclohexane. La réaction donne de meilleurs résultats avec le dérivé chloré qu'avec les dérivés bromés; avec ces derniers, il se forme des produits lourds (séparés sur SiO_2).

Réactions d'acétylation

Elles ont été effectuées sous argon. A une suspension de 0.033 *M* de $AlCl_3$ dans 30 cm^3 de CH_2Cl_2 refroidie à 0°C, on additionne avec agitation 0.033 *M* de CH_3COCl. Après avoir maintenu pendant une heure cette température on ajoute, goutte à goutte, 0.03 mol de dérivé silicié en solution dans 10 cm^3 de CH_2Cl_2. Le milieu est maintenu à 0°C pendant une heure puis on laisse revenir à température ambiante avant de porter le mélange au reflux. Après 24 h de chauffage Me_3SiCl et le solvant sont éliminés sous vide (trompe à eau). Le résidu est versé sur un mélange glace–sel (−10°C) en présence de pentane, agité vigoureusement, puis extrait au pentane, lavé à l'eau jusqu'à neutralité et séché sur sulfate de magnésium.

Le mélange réactionnel est étudié en cpv, couplé à un spectrographe de masse (colonne S.E. 30, 10%, 3 m).

Une filtration rapide sur SiO_2 (éluant pentane) permet de séparer le produit de départ n'ayant pas réagi et les disiloxanes, des dérivés carbonylés. Le mélange de ces derniers est chromatographié sur colonne de silice afin d'isoler les différents constituants. Les essais effectués avec deux équivalents de $CH_3COCl/AlCl_3$ sont conduits de la même manière.

Réactions de sulfonation

Le triméthylsilylcycloalcane (0.05 mol) et $ClSO_3SiMe_3$ (0.05 mol) sont chauffés pendant une heure à 100°C. L'ester sulfonique est séparé par distillation.

L'hydrolyse est effectuée comme suit: 5 g de sulfonate de silyle sont versés dans 10 mL d'eau. L'addition est exothermique et il apparaît deux phases. La phase supérieure est constituée du disiloxane, la phase inférieure étant une solution aqueuse et $MeSO_3H$.

Scission par $(CH_3COOH)_2BF_3$

Un mélange de 0.05 mol de triméthylsilylcycloalcane et 0.05 mol du complexe $(CH_3COOH)_2BF_3$ sont chauffés à 100°C pendant 40 h. Le mélange est alors hydrolysé par une solution saturée de carbonate de sodium, extrait au pentane et séché sur $MgSO_4$. Après élimination du solvant on isole les fluorosilanes par distillation.

Description des produits obtenus

Les spectres de rmn (^1H) ont été enregistrés sur un appareil fonctionnant à 60 MHz (Perkin-Elmer R 24) (δ_{ppm}, solvant CCl_4, réf. int. $CHCl_3$ à 7.27).

En ir tous les composés triméthylsiliciés présentent les bandes d'absorption caractéristiques du groupe $SiMe_3$ à 1250, 840 et 755 cm^{-1} et les disiloxanes possèdent une absorption ν(Si—OSi) vers 1060 cm^{-1}.

Tous les produits nouveaux en particulier **2**, **6**, **18**, **19**, **20**, **21**, **22** et **23** ont des microanalyses C, H, Si en accord avec les formules proposées.

Bromure de cyclobutyle

Spectre de résonance magnétique nucléaire δ: 1.7 à 2.7 (massif complexe, 6 H); 4.4 (q élargi, 1 H); pé 63°C/170 Torr.

*Cyclobutyltriméthylsilane **2***

Point d'ébullition 84°C/270 Torr; rmn δ: 0 (1s, 9H); 1.7 à 2.5 (massif large, 7H).

*Dicycloalkyl tétraméthyl disiloxanes **6**, **8** et **13***

Point d'ébullition (**8**) 90°C/2 Torr; (**13**) 120°C/1 Torr. Ils présentent tous des spectres de rmn comparables, δ: 0.1 (1s, 12H, $SiMe_2$); entre 1 et 1.8 (1 massif, H du cycle).

*Acétyl-1 chloro-2 cyclopentane **10***

Infrarouge ν: 1710 (C═O), 760 (C—Cl) cm^{-1}; rmn δ: 1.6 à 2.1 (1 massif, 6H); 2 (1s, 3H); 2 à 2.8 (1m, 1H); 4 (1m, 1H); sm: pics moléculaires $M^+ = 146$ (^{35}Cl), $(M+2)^+ = 148$ (^{37}Cl) rapport 3/1; pic de base: $m/e = 43$ $(CH_3CO)^+$; **10** se décompose spontanément à température ambiante en **12** et HCl.

*Acétyl-1 chloro-3 cyclopentane **11***

Infrarouge ν: 1700 (C═O),760 (C—Cl) cm^{-1}; rmn δ: 1.5 à 1.9 (1 massif, 6H); 2 (1s, 3H); 3 (1m, 1H); 4.1 (1m, 1H); sm: pics moléculaires $M^+ = 146$ (^{35}Cl), $(M+2)^+ = 148$ (^{37}Cl) rapport 3/1; pic de base: $m/e = 43$ $(CH_3CO)^+$. Contrairement à **10**, **11** est stable à température ambiante.

*Acétylcyclopentène **12***

Infrarouge ν: 1680 (C═O), 1620 (C═C) cm^{-1}; rmn δ: 2 (1m, 2H); 2.2 (1s, 3H); 2.4 (1m, 4H); 6.6 (1 signal large, 1H); $M^+ = 110$.

*Acétyl 1-chloro-1 cyclohexane **15***

Infrarouge ν: 1710 (C═O), 750 (C—Cl) cm^{-1}; rmn δ: 1 à 1.8 (1 massif, 8H); 2 (1s, 3H), 2.2 à 2.8 (1 massif, 1H); 4 (1m, 1H); $M^+ = 160$.

*Acétyl cyclohexène **16***

Infrarouge ν: 1680 (C═O), 1650 (C═C) cm^{-1}; rmn δ: 1.2 à 2.2 (massif, 8H); 2.2 (1s, 3H); 6.8 (1 signal large, 1H); $M^+ = 124$.

*Esters sulfoniques **19**, **20** et **21***

Résonance magnétique nucléaire δ: 0.4 (1s, 6H); 1 à 2 (1 massif, CH du cycle); 3 (1s, 3H); pé (**20**) 90°C/1 Torr; (**21**) 100°C/0.4 Torr.

*Fluorosilanes **18**, **22**, **23***

En rmn du proton, outre les signaux dûs aux hydrogènes du cycle, ils se caractérisent par un doublet ($J \simeq 6$ Hz) dû au groupe $SiMe_2F$.

Viscosity of binary solutions of polar liquids[1]

ROBERT A. STAIRS
Department of Chemistry, Trent University, Peterborough, Ont., Canada K9J 7B8

Received June 4, 1979

ROBERT A. STAIRS. Can. J. Chem. **58**, 296 (1980).

The viscosity of mixtures of water with a number of organic liquids and of some mixtures of two organics has been analysed in terms of its deviation from "ideality", expressed as $\ln H = \ln \eta - (x_1 \ln \eta_1 + x_2 \ln \eta_2)$. For most of the systems the quantity $\ln H$ is a single-valued and linear, or nearly linear, function of the product $y_1 y_2$, where

$$y_1 = [1 + (V_2/V_1)^{\kappa}(x_1^{-1} - 1)]^{-1} \text{ and } y_2 = 1 - y_1$$

representing mole fractions (with $\kappa = 0$), or volume fractions ($\kappa = 1$), or various compromises ($0 < \kappa < 1$). Neither extreme, nor any single compromise, expresses the behaviour of all the systems. A linear relation between $1/H$ and the relative excess volume, suggested on the basis of the free-volume theory of fluidity, is shown to represent approximately the behaviour of the mixtures of two organic liquids. It fails with the water–organic mixtures.

ROBERT A. STAIRS. Can. J. Chem. **58**, 296 (1980).

La viscosité des mélanges de l'eau avec divers liquides organiques et des mélanges de deux produits organiques a été prise en compte afin d'étudier sa déviation par rapport à "l'idéalité" exprimée par la grandeur H, definie par: $\ln H = \ln \eta - (x_1 \ln \eta_1 + x_2 \ln \eta_2)$. Pour la plupart des systèmes $\ln H$ est une fonction à valeur unique, linéaire ou quasi-linéaire, du produit $y_1 y_2$, où

$$y_1 = [1 + (V_2/V_1)^{\kappa}(x_1^{-1} - 1)]^{-1} \text{ et } y_2 = 1 - y_1$$

représentant les fractions molaires pour $\kappa = 0$ ou les fractions volumiques pour $\kappa = 1$, ou des compromis divers pour $0 < \kappa < 1$. Cependant, ni l'un, ni l'autre des cas extrèmes, ni aucun des compromis n'exprime le comportement de tous les systèmes. Un parallèle entre $1/H$ et le volume d'excès relatif, suggéré à partir de la theorie du volume libre de la fluidité, représente approximativement le comportement des mélanges de deux liquides organiques. Il échoue avec les mélanges eau–organique.

Discussion of the viscosity behaviour of binary liquid solutions commonly starts from the concept of an "ideal" solution, with a view to considering particular systems as departing more or less from the ideal law. It is not clear, however, whether the ideal law should take the form of the (weighted) arithmetic, geometric, or harmonic mean of the viscosities of the pure components. The absolute rate theory, by focussing attention on excess thermodynamic functions of activation, most naturally works through the assumption that, in an ideal solution, the free enthalpy of activation, for instance, should be additive on a mole fraction basis

$$[1] \quad \Delta G^{\ddagger} = \Delta G_1^{\ddagger} x_1 + \Delta G_2^{\ddagger} x_2$$

where the subscripts refer to the two components, x is mole fraction, and the $\Delta G^{\ddagger}$ are standard free enthalpies of activation for flow. This implies the geometric mean law:

$$[2] \quad \ln \eta_g = x_1 \ln \eta_1 + x_2 \ln \eta_2$$

The free volume approach, as used, for example, by Hildebrand (1) leads naturally to a different choice. He writes, for the variation of both viscosity and density with temperature (following Batschinski (2) with modifications)

$$[3] \quad \eta^{-1} = a\rho^{-1} - b = B(V - V_0)/V_0$$

i.e. the fluidity η^{-1} is proportional to the "relative free volume". The constant B is an insensitive function of molecular size and shape, and V_0 is the intrinsic volume per mole.

An ideal solution, in the usual sense, shows no volume change on mixing. The assumption that there is also no free volume change on mixing leads to the expectation that, if the two kinds of molecules are similar in size and shape, as they must be if they are to form an ideal solution, the fluidities should be additive:

$$[4] \quad \eta_h^{-1} = \eta_1^{-1} x_1 + \eta_2^{-1} x_2$$

(The subscript h indicates the harmonic mean.)

There is no currently-favoured theory that leads naturally to the arithmetic mean:

$$[5] \quad \eta_a = \eta_1 x_1 + \eta_2 x_2$$

but a number of pairs of substances that might be expected to be nearly ideal most closely conform to this law, e.g. acetone and methylethylketone: Toropov's data (3) for the viscosity of mixtures of these at 20°C yield values of the quantity:

$$[6] \quad s = \left(\frac{\sum (\eta_{obs} - \eta_{theor})^2 / x_1 x_2)}{n - 2} \right)^{1/2}$$

[1]Presented in part at the 58th Canadian Chemical Conference, Toronto, May 1975.

equal to 0.071 with $\eta_{theor} = \eta_h$, 0.040 with η_g, and 0.007 with η_a.

Except where the two components differ very much in viscosity, there is in fact not a great deal of difference between these three means. It may readily be shown that they differ most when $x_1 = x_2 = 0.5$. If the ratio of the viscosities of the pure liquids $\eta_2/\eta_1 = a$, it may also be shown that the ratios of the means to each other are then:

$$[7] \quad \eta_a/\eta_g = \eta_g/\eta_h = \tfrac{1}{2}(1/\sqrt{a} + \sqrt{a})$$

For the pair water–methanol, $a = 0.626$ and each of the outer measures, η_a and η_h, differs from η_g by only 3%. The real viscosity in this system passes through a maximum that differs from any of the assumed "ideal" values by a factor of about 2, and it makes little difference which is chosen. Accordingly, we have followed the *aurea mediocritas* and chosen the geometric mean η_g, as our defined "ideal" viscosity, η_i, and have discussed deviations from the ideal law in terms of the quantity:

$$[8] \quad H = \eta/\eta_g = \eta/\eta_i$$

From the point of view of the free volume approach it is not surprising that those systems that show large positive viscosity deviations tend also to show large negative deviations from volume additivity. If it is true that free volume is necessary for flow, then shrinkage on mixing, which would appear to reduce the free volume, should be associated with an increase in viscosity. One would like to know, at each composition, the fractional change in the free volume, which should be related to our quantity H. The free volume per mole of the real solution must be obtained from the Hildebrand–Batschinski relation, eq. [3], through which V_0, the intrinsic volume, may be obtained from a graph of η^{-1} versus the molar volume V which, if the relation holds for a solution at constant composition,[2] should yield a straight line with volume-intercept V_0. Then the actual free volume at a particular temperature is $v = V - V_0$, and the "ideal" free volume, i.e. the free volume that would have existed had there been no shrinkage, will be $v_i = v - V^E$ (recall that V^E, the excess volume, is here negative). If eq. [3] is applied to both the real and the ideal viscosities, eq. [8] becomes

$$[9a] \quad H = (B_i v_i/V_{0i})/(Bv/V_0)$$

or, with the further assumptions that $B_i = B$ and $V_{0i} = V_0$, i.e. that all the non-ideality appears in the free volume,

$$[9b] \quad H = v_i/v = v_i/(v_i + V^E)$$

Correct use of this argument requires data for all the solutions over a range of temperatures, which are not available at present. For now we are using the relative excess volume, defined (as percentage) by:

$$[10] \quad V_r^E = 100\left(\frac{V - V_1x_1 - V_2x_2}{V_1x_1 + V_2x_2}\right) = 100\left(\frac{(x_2^{-1} - 1)M_1/M_2 + 1}{\rho(x_2^{-1} - 1)M_1/M_2\rho_1 + 1/\rho_2} - 1\right)$$

where V is the molar volume, ρ, M, and x are density, molecular weight, and mole fraction, and the subscripts 1 and 2 refer to the two components. Values of the (negative) excess volume are approximately proportional to the product of the mole fractions, x_1x_2, as suggested by Biron (6) or to the product of the volume fractions, $\phi_1\phi_2$, as suggested by Hildebrand and Scott (7). From eq. [9*b*], one would expect a linear dependence of the reciprocal of H on V^E, and hence a linear dependence of H^{-1} on x_1x_2 or on $\phi_1\phi_2$.

Figure 1 shows the result of plotting H^{-1} vs. x_1x_2 for water–methanol mixtures (outer, full curve) and vs. $\phi_1\phi_2$ (inner, dashed curve). The arrows represent the direction of increasing proportion of methanol. Neither abscissa gives a good fit. The change from mole fraction to volume fraction over-corrects.

We now define a pair of variables y_1 and y_2 by

$$[11] \quad y_1 = [1 + (V_2/V_1)^\kappa(x_1^{-1} - 1)]^{-1}$$
$$y_2 = 1 - y_1$$

Here V_1 and V_2 are the molar volumes of the pure liquids 1 and 2, and κ is an adjustable parameter. If $\kappa = 1$, y_1 and y_2 represent volume fractions; if $\kappa = 0$, they are mole fractions. Intermediate values of κ represent various compromises, of which two have particular significance. If $\kappa = \frac{1}{3}$, y_1 represents the "line fraction" of component 1 in the mixture, that is, the fraction of an arbitrary line in the mixture that is occupied by molecules of component 1. If $\kappa = \frac{2}{3}$, y_1 is the corresponding "area fraction". Since viscosity involves the transfer of momentum across surfaces within the fluid, this particular value of κ, if found to be favoured by the data, would have been pleasing. Alas, it was not to be, in spite of some early results which were suggestive. Figure 2 contains a plot of H^{-1} vs. y_1y_2 for water–methanol, with $\kappa = 0.82$. The data now fall on a single curve, but it is not very linear.

[2]Lutschinsky (4) and Kottler (5) each report that Batschinski's formula holds for solutions.

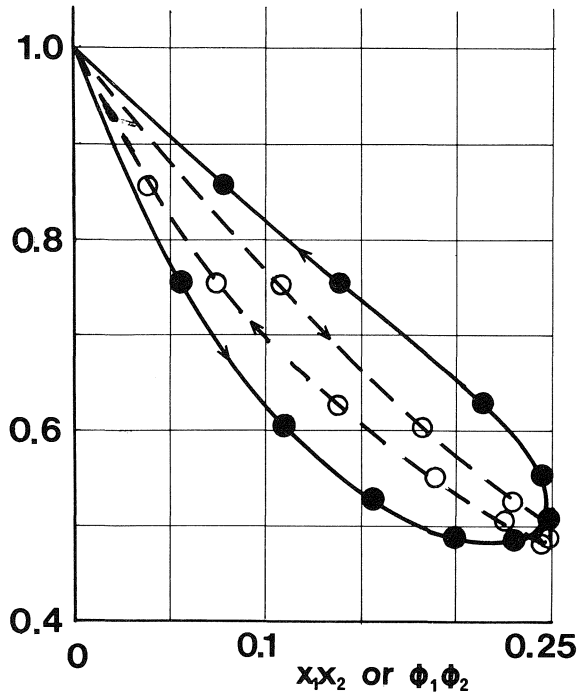

FIG. 1. Deviation of the viscosity of water–methanol mixtures from ideality, expressed as $H = \eta/\eta_i$ (where η_i is defined by log $\eta_i = x_1 \log \eta_1 + x_2 \log \eta_2$), plotted as H^{-1} against x_1x_2 (mole fractions, filled circles) and against $\phi_1\phi_2$ (volume fractions, open circles). The arrows indicate the direction of increasing proportion of methanol.

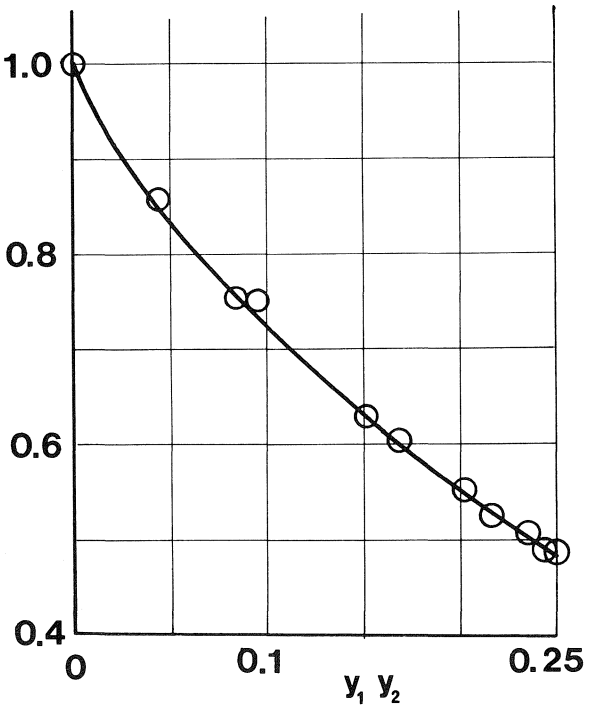

FIG. 2. H^{-1} (defined in Fig. 1) for water–methanol mixtures plotted against y_1y_2 (defined in text).

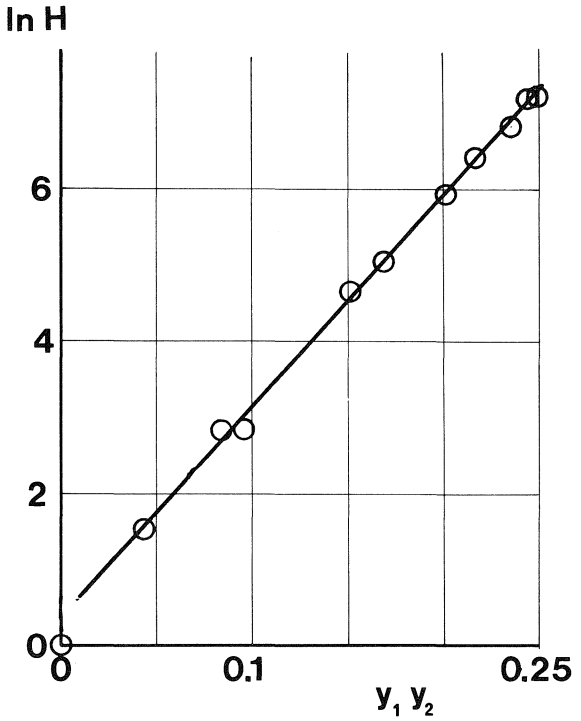

FIG. 3. Same data as in Fig. 2, plotted as ln H against y_1y_2.

An argument from the absolute rate theory has been used (8, 9) to predict a dependence of H on mole fraction of the form:

$$[12] \quad \ln H = -(W/RT)x_1x_2$$

where W is an interspecific interaction energy. This suggests trying a plot of ln H versus y_1y_2. This is shown, for the same data, in Fig. 3, and appears to yield a more nearly linear result. Not quite, however, for the best straight line fails to pass through the origin.[3] For practical purposes it seems the best.

Table 1 contains the results of applying similar treatments to data for a number of liquid pairs. The data are from a number of sources. Some are from our own laboratory (refs. 10, 11 and unpublished results), but most are from available tabulations (12–14). The fit obtained varies from satisfactory to poor, judged by the ability of the fitted equation to reproduce the original data as expressed by the relative standard error of estimate of viscosity,

$$[13] \quad S_{\ln\eta} = \{\sum (\ln \eta_i/\eta_{\text{calcd}})^2/(n-3)\}^{1/2}$$

Most of the published viscosity data are stated to three significant figures, which implies a relative precision of about 1%, i.e. $S_{\ln\eta} = 0.01$, though

[3]The best fit was obtained with an expression of the form ln $H = a(y_1y_2)^{1/2} + by_1y_2$. There seems to be no theoretical reason to expect this.

TABLE 1. Excess viscosity of liquid mixtures. Maximum values of $H = \eta/\eta_1^{x_1}\eta_2^{x_2}$, attained at $y_1y_2 = 0.25$ (where $y_2 = 1 - y_1 = [1 + k(x_2^{-1} - 1)]^{-1}$ and $k = (V_1/V_2)^{\kappa}$) with the maximum relative excess volume, V_r^E(max), for comparison, and the interaction parameter, $W = 4RT \ln H_{max}$

*Values in parentheses are k, entered for those cases where either scatter of the data or proximity of H or V_2/V_1 to unity rendered calculated values of κ meaningless. In those cases k replaces $(V_2/V_1)^{\kappa}$ in eq. [11].

some show more scatter than this. Fit was considered "poor" if the data were not reproduced to 3%. Aside from scatter, the main cause of poor fit appeared to be non-linearity of the graph of ln H versus y_1y_2. The largest deviations occur in mixtures of water with the non-hydroxylic liquids acetone and *N*,*N*-dimethylformamide and with the two propanols and *t*-butanol, the least "water-like" on the list. A closer look at the data for acetone revealed that with this non-donor (in the hydrogen-bonding sense) solvent, the viscosity was essentially ideal in all mixtures with acetone content greater than $x_2 = 0.8$, i.e. where the acetone-to-water ratio is greater than 4. Four acetone molecules are apparently enough to isolate each water molecule sufficiently to prevent formation of hydrogen-bonded chains. Below this ratio, a rather sudden rise occurs. This is most apparent when H is plotted against mole fraction of acetone, as in Fig. 4.

Leaving these anomalous cases aside, the remainder are reasonably well fitted, with values of κ ranging rather widely. Neither mole fraction nor volume fraction, nor any single compromise, best describes the data for all systems. Further, when a similar fit of excess-volume data to an analogous expression was tried for a few systems, it was found that the values of κ required differed from the best value for the viscosity (i.e. the maxima in H and V_r^E occur at different compositions).

Nevertheless, to pursue the suggested connection between the excess viscosity and the (negative) excess volume, the maximum value of H and the maximum value of V_r^E were computed, and the results for the liquid pairs in this study are plotted as $H_{(max)}^{-1}$ vs. V_r^E(max) in Fig. 5. There appears to be a correlation, especially for the mixtures of two organic liquids (omitting the nearly ideal mixtures of two alcohols and two ketones), where an approximate fit is possible with the linear expression

$$[14] \quad H_{(max)}^{-1} = 0.570 + 1.035 V_r^E(\text{max})$$

The mixtures of two alcohols appear to be essentially ideal both in their volume of mixing and in

An analysis of the factors contributing to the regioselectivity observed in the opening of oxiranes

MARGARET M. KAYSER AND PETER MORAND

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 23, 1979

MARGARET M. KAYSER and PETER MORAND. Can. J. Chem. **58**, 302 (1980).

The regioselectivity of epoxide ring opening can be analyzed in terms of hard–soft acid–base (HSAB) theory. The coordination of the hard acid with the oxygen atom of the oxirane ring produces a "pulling effect" which determines the direction of the ring opening. In the absence of a strong "pulling effect" the "pushing effect" of the approaching base is examined and the consequences of relative softness or hardness of the nucleophile on the regioselectivity of the ring opening are discussed.

MARGARET M. KAYSER et PETER MORAND. Can. J. Chem. **58**, 302 (1980).

La régiosélectivité de l'ouverture du cycle époxyde peut être analysé en fonction de la théorie acide–base dur–mou (ABDM). La coordination de l'acide dur avec l'atome d'oxygène du cycle oxiranne produit un "effet de traction" qui détermine la direction de l'ouverture du cycle. En l'absence d'un "effet de traction" assez fort, on évalue l'effet "repoussement" de la base qui s'approche. On discute des conséquences de la nature relative molle ou dure du nucléophile sur la régiosélectivité de l'ouverture du cycle.

Unsymmetrical epoxides have two possible sites at which nucleophilic substitution may occur. It has been generalized (1) that "nucleophiles attack at the less highly substituted carbon atom of the epoxide ring in neutral or basic media, as would be anticipated for a normal S_N2 process".

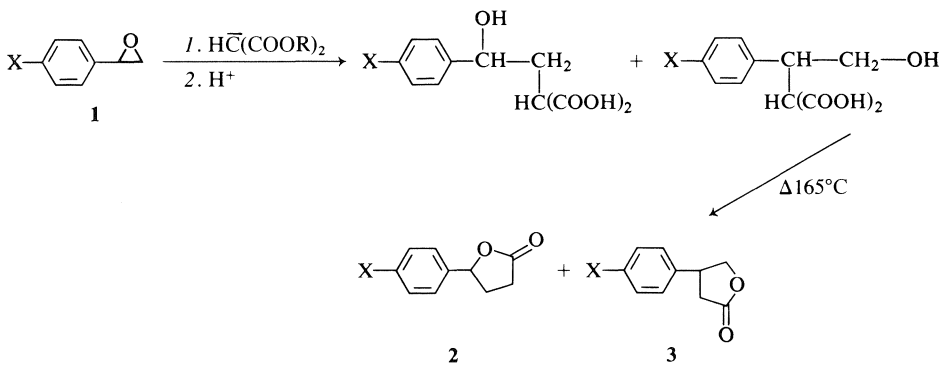
In the course of our work involving the preparation of β-substituted γ-butyrolactones, regioselective opening of the intermediate epoxide was of prime importance. The condensation of styrene oxide **1** with ethyl malonate under basic conditions according to the method described by DePuy, Breitbeil, and Eilers (2) yielded a mixture of two lactones. The major product was lactone **3** resulting from nucleophilic attack at the secondary carbon atom of the epoxide ring. In *para*-substituted styrenes **1***a* and **1***b*, the substituent exerted a significant effect on the direction of ring opening (Scheme 1). In the presence of the same counter ion (Na^+) and the same nucleophile (malonate anion), the electron-releasing methoxy group promoted nucleophilic attack at the secondary (more highly substituted) carbon atom, while the *p*-nitro substituent favoured reaction at the terminal carbon atom.

Similar substituent effects on the direction of ring opening in styrene oxides were observed for the reaction with sodium phenoxide in excess phenol (3). The percentage of product resulting from attack at the secondary carbon atom increased in the order $NO_2 < H < OCH_3$. These results contrast with the assumption (4, 5) that the effect of an electron-donating substituent on the direction of S_N2 ring opening in epoxides is to favour attack at the primary carbon atom (more disposed to accommodate a negative charge), while an electron-withdrawing group should promote attack at the secondary carbon atom. Also, the regioselectivity of these reactions cannot be attributed to steric factors (6) since the steric requirements of *p*-nitro- and *p*-methoxystyrene oxides resemble each other.

Regioselectivity of the Oxirane Ring Opening

By contrast with the results discussed above, the regioselectivity of $LiAlH_4$ reduction of substituted styrene oxides is much less sensitive to the influence of electron-releasing or electron-withdrawing groups (Table 1).

A search of the literature confirms that vastly different selectivities may be expected for the direction of ring opening in a series of substituted epoxides by different nucleophiles. A representative sample is included in Table 1. On the whole, the variations in regioselectivity of nucleophilic attack are particularly evident in the case of aromatic epoxides. Aliphatic epoxides (7, 8) conform better to the generalization stating that nucleophilic attack in basic media occurs at the least substituted carbon atom.



Since the commonly evoked electronic and steric effects do not adequately explain the observed results, the regioselectivity of epoxide ring opening should be reexamined in the light of more recent theories on molecular interactions.

Theoretical Considerations Applicable to Epoxide Ring Opening

CNDO/2 MO calculations (9) showed that in aromatic and conjugated epoxides the distribution of electric charges is very fluid (compared to aliphatic epoxides). This suggests that the direction

of ring opening may be understood better in terms of Klopman's (10) application of perturbation theory to the hard–soft acid–base (HSAB) principle (11).

Briefly, according to HSAB principle a reaction occurs most readily between a hard acid and a hard base or between a soft acid and a soft base. The hard–soft combination binds reluctantly. The reaction between a hard acid and a hard base is charge controlled. Here, the energy difference of the frontier orbitals (HOMO of the nucleophile and LUMO of the electrophile) is large and as a result little charge transfer occurs in the transition state. On the other hand, when the energies of HOMO and LUMO of the reacting species are similar there is significant electron transfer in the transition state. This type of interaction (under frontier orbital control) is associated with soft acid – soft base reactions (10).

4

The Effect of the Coordination of the Oxygen Atom with an Electrophile

Acid-catalyzed hydrolysis of the oxirane presupposes initial protonation of the oxygen atom[1] (hard acid – hard base interaction). This assump-

[1]Although acid-catalyzed epoxide ring opening is frequently assumed to be an S_N1 type reaction (while base-catalyzed ring opening is considered to be S_N2), it is not always the case. The opening of ethylene oxide with HCl or HBr has been found to exhibit third-order rate law. Moreover, a number of acid-catalyzed ring openings proceed with almost complete inversion of configuration (12).

tion is supported by an *ab initio* SCF (Gaussian 70) calculation (13) which shows that the association of the oxygen atom with an electrophile (H^+) weakens the C—O bond and changes the charge on the C-atom from negative to positive. But even under basic conditions the epoxide ring is subject to initial coordination with the counter ion (14), followed by nucleophilic attack by the anion. Evidently, the "harder" the electrophile present, the more important is its effect on the direction of ring opening. This can be illustrated by the results obtained in the reduction of substituted epoxides by $LiAlH_4$ with or without $AlCl_3$. Under the usual reaction conditions ($LiAlH_4$ in diethylether or THF) attack by the nucleophile (AlH_4^-) occurs exclusively or preferentially at the least substituted carbon atom of the oxirane ring (Table 1). However, in the presence of $AlCl_3$ (hard acid) the regioselectivity of the reaction is reversed (7).

"Pulling" and "Pushing" Effects

A somewhat similar effect of the association with a hard acid has been observed (15) in the cleavage of the benzyl protecting group. The mixture of the hard acid (BF_3) and soft nucleophile (thiol) proved to be a particularly successful combination for the recovery of parent alcohols in excellent yields. The authors showed (15) that the coordination of a hard acid with the oxygen atom, the "pulling" effect, was a determining factor in these reactions. In fact the "pulling" factor appeared to be more important than the subsequent attack by a soft nucleophile on the carbon atom (the "pushing" effect, Scheme 2).

SCHEME 2

A similar sequence of events may be envisaged in the case of oxirane ring opening. In the presence of a hard acid (such as $AlCl_3$) the association of the oxygen atom with the Lewis acid results in the "pulling" effect, which significantly increases the positive charge at the carbon atom. In unsymmetrically substituted epoxides the positive charge develops at the carbon atom best suited to accommodate it. Thus the site of nucleophilic addition is predetermined.[2]

[2]Also, since $LiAlH_4$-$AlCl_3$ combination yields hard aluminum hydrides AlH_xCl_{3-x} (16) which participate in hard–hard (more ionic in nature) interactions, the site of attack will coincide with the site of the developing positive charge on the secondary carbon atom of the styrene oxide ring.

Epoxide Ring Opening in the Absence of an Effective Hard Acid

In reactions where "hard acid" is not available the softness of an anion and of the two sites on the epoxide ring controls regioselectivity of nucleophilic addition.

Li^+ is a hard acid (17). It is "harder" than Na^+, yet both ions are less effective (as "pulling" agents) than BF_3 or $AlCl_3$. In ether solvents (such as diethylether or THF commonly used in reduction reactions) the counter ions are highly solvated. Consequently the solvent molecule has to be removed before an ion can approach and coordinate with the oxygen atom of the epoxide ring. The association with the oxygen atom of the epoxide ring is not particularly more favourable than coordination with the oxygen atoms of the solvent. As a result Li^+ and Na^+ are ineffectual "pulling" agents.[3] Consequently, the reduction with $LiAlH_4$ and the condensation with malonate anion of substituted styrene oxides represent cases where an effective "pulling" factor is absent.

Reaction with a Soft Nucleophile

All organic bases in which the donor atom is carbon are relatively "soft". Thus, the condensation of substituted styrene oxide with malonate anion represents a soft–soft interaction. In this type of interaction the frontier orbitals of the donor HOMO and the acceptor LUMO are of similar energy. A new orbital differs in energy and form from either of the original ones. Thus, even a subtle difference in energy between the two LUMO's (on the two carbon atoms of epoxide ring) will affect the selectivity of the reaction (Fig. 1).

In the *p*-methoxystyrene oxide the carbon atom α to the benzene ring is the "softer" of the two and as a result nucleophilic addition occurs there. In *p*-nitrostyrene oxide, the situation is reversed (Scheme 3).

Reaction with Complex Metal Hydrides

While malonate anion is a soft base, metal hydride ions form a scale of more borderline cases. In general, the more covalent the M—H bond, the softer is the hydride ion. Thus, BH_4^- is softer than AlH_4^- which in turn is softer than $AlH(OR)_3^-$

[3]Dimethoxyethane (DME) appears to trap Li^+ even more effectively than THF or diethylether; this may explain why lithium trimethylsilyl acetonitrile in DME attacks selectively the primary carbon atom of styrene oxide (18) in contrast to the relative lack of selectivity exhibited by malonate anion (Na/ethanol) (Scheme 1). It should be also pointed out that in more polar solvents the "pulling" effect and thus charge redistribution are favoured.

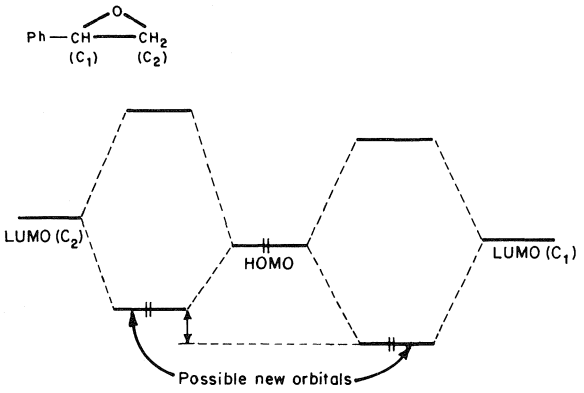

FIG. 1. Since the stabilization energy in the soft–soft interaction is large, even a small difference between LUMO (C1) and LUMO (C2) is significant.

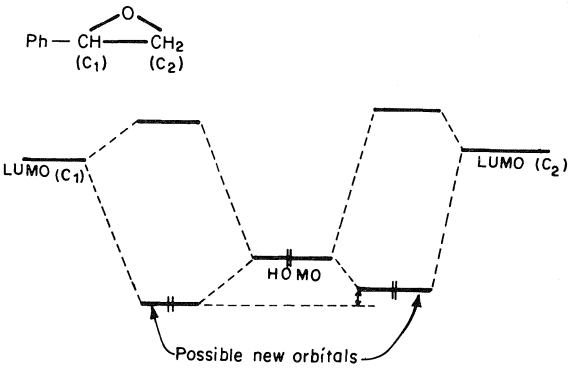

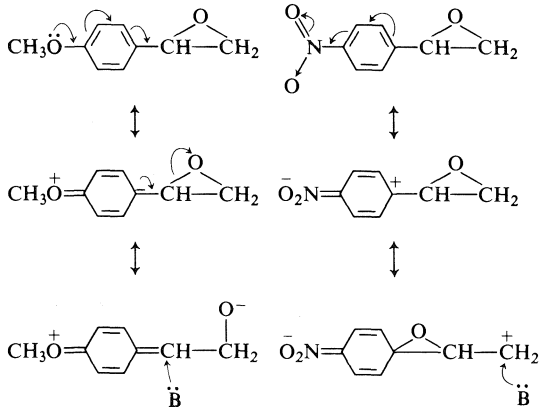

FIG. 2. The difference in stabilization energy between the two possible cases is small. It is therefore not an important driving force in this type of reaction.

SCHEME 3

where some of the soft hydride ions have been replaced by hard alkoxy groups (19).[4]

In effect AlH_4^- (a nucleophile harder than malonate anion or BH_4^-) is less sensitive to the nature of the substituents on the epoxide ring. Here, the energy difference between the frontier orbitals of the donor and acceptor is considerably larger. The new bonding orbital formed when the two species interact resembles that of the donor and the stabilization energy is small. The subtle difference in softness between the two carbon atoms of the epoxide ring does not have an important effect (Fig. 2). As a result, AlH_4^- is more sensitive to steric congestion than to a small difference in energy between the carbon atoms of the epoxide ring and the reaction takes place at the more accessible site.

Reductions with $LiBH_4$ (5) show quite a different order of selectivity (compared to $LiAlH_4$, see Table 1) principally due to the fact that BH_4^- is a softer nucleophile than AlH_4^- (18). The influence of the substituent on the phenyl ring is manifested in the ratios of products observed. The directive effect of the *p*-methoxy group is similar to that observed in reaction with malonate anion (i.e., the principal attack by nucleophile occurs at the secondary carbon atom). The distribution of isomers in the reduction of styrene oxide and *p*-bromostyrene oxide is also within the expected bounds. Quite unforeseen and intriguing, however, is the result of the reduction of *p*-nitrostyrene oxide. Here, one would have expected a higher percentage of the reaction taking place at the primary carbon atom.

The observed isomer distribution may be rationalized in the following manner. The powerful electron-withdrawing effect of the nitro group creates a diffuse positive charge in the epoxide ring. The LUMO energy levels on both carbon atoms are lowered considerably, thus promoting bond making over bond breaking in the transition state. BH_4^-, sterically less bulky and somewhat harder than malonate anion, shows preference for the secondary carbon atom which is slightly favoured towards bond making. The softer malonate anion forms the more thermodynamically stable bond.

A dramatic change in selectivity can be observed when reductions by $LiAlH_4$ are compared with reductions by lithium 9,9-di-*n*-butyl-9-borabicyclo-[3,3,1]nonate **4**. The latter provides H^-, a very soft nucleophile, as reducing agent. In reaction with styrene oxides, hydride addition occurs regiospecifically at the secondary carbon atom (Table 1).

Conclusions

Perturbation–HSAB theory correlates well the observed results and, although it can serve only as a rough guide, it is useful for a qualitative understanding of epoxide ring opening reactions.

The principal features of these reactions are (*1*) the importance of coordination with a hard acid and

[4] $LiAlH(SR)_3$ on the other hand is considerably softer due to softening of the reagent by the thio substituents.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the consequences of the "pulling" effect; (*2*) selectivity for the "softer" of the two carbon centres in reactions with soft nucleophiles; (*3*) preference for the sterically more accessible carbon atom in reactions with harder nucleophiles.

Experimental

Melting points were determined on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were obtained on a Beckman IR-20 spectrophotometer and proton nmr spectra in $CDCl_3$, with TMS as internal standard on a Varian HA-100 instrument.

Preparation of *p*-nitrostyrene oxide illustrates the general procedure for expoxide synthesis. *p*-Nitrobenzaldehyde (0.10 mol), trimethyl sulfonium chloride (0.15 mol), and triethylbenzyl ammonium chloride (TEBA chloride, phase transfer catalyst) were dissolved in methylene chloride (100 mL). The solution was placed in a 250 mL Erlenmeyer flask equipped with an efficient stirrer and cooled to 0°C. 50% Sodium hydroxide solution (60 g) was slowly added and the reaction mixture was stirred vigorously for 2 h. After dilution with distilled water, the layers were separated. The aqueous layer was extracted repeatedly with diethylether. The organic layers were washed separately with water, dried over anhydrous magnesium sulfate, and evaporated to dryness. The solid was recrystallized from ether to give orange crystalline *p*-nitrostyrene oxide (60%), mp 84–85°C. The nmr and ir spectra were consistent with the assigned structure.

Condensation of the substituted styrene oxides with ethyl malonate (Na, anhydrous ethanol) was performed according to the method described by Depuy *et al.* (2).

p-Methoxystyrene oxide, upon reaction with malonate ion, gave lactonic product in 66% yield. Only one structural isomer **3***a* was detected. Unequivocal proof of structure for the lactone was obtained by comparison of **3***a* with β-methoxyphenyl-γ-butyrolactone obtained from the $NaBH_4$ reduction of *p*-methoxyphenylsuccinic acid.

p-Nitrostyrene oxide treated with diethylmalonate gave γ-*p*-nitrophenyl-γ-butyrolactone **2***b*. This compound was identical with lactone obtained by nitration of γ-phenyl-γ-butyrolactone **2** (6).

The general procedure for $LiAlH_4$ reductions of styrene oxides is as follows. Epoxide (6.5 mmol) dissolved in dry THF (25 mL) was added slowly to a solution of $LiAlH_4$ (5.2 mmol) in THF (25 mL). The reaction mixture was stirred at ice-bath temperature and then allowed to warm to room temperature over a period of 3½ h. The reaction was cooled in an ice bath, quenched with 3 *N* HCl and stirred overnight. The layers were separated and the aqueous layer extracted with diethyl ether. Organic layers were combined, dried over anhydrous magnesium sulfate, and the solvents were evaporated. The products were analyzed by 100 Hz nmr.

COMMUNICATION

Hydrogen bond assisted reactions of carboxylic acids with alkyl halides in the gas phase by ion cyclotron resonance spectroscopy

R. L. CLAIR AND T. B. MCMAHON

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received November 23, 1979

R. L. CLAIR and T. B. MCMAHON. Can. J. Chem. **58**, 307 (1980).

The reactions of the strongly hydrogen bonded anions, $CH_3CO_2HF^-$ and $(CH_3CO_2)_2H^-$, with alkyl halides have been studied in the gas phase by ion cyclotron resonance spectroscopy. A novel reaction of nucleophilic attack by $(CH_3CO_2)_2H^-$ with alkyl chlorides to produce $CH_3CO_2HCl^-$ and alkyl acetates is reported. Parallels are drawn to synthetically important analogous reactions in glacial acetic acid solutions of alkali metal fluorides.

R. L. CLAIR et T. B. MCMAHON. Can. J. Chem. **58**, 307 (1980).

On a étudié les réactions des anions fortement liés par des liaisons hydrogènes tels que $CH_3CO_2HF^-$ et $(CH_3CO_2)_2H^-$ avec les halogénures d'alkyles en phase gazeuse, en utilisant la spectroscopie à trajectoire cycloidale résonante. On rapporte une nouvelle réaction qui consiste en une attaque nucléophile de $(CH_3CO_2)_2H^-$ sur les chlorures d'alkyles et conduisant à $CH_3CO_2HCl^-$ et à des acétates d'alkyles. On l'a comparé aux réactions analogues importantes en synthèse qui mettent en jeu les fluorures de métaux alcalins en solution dans l'acide acétique glacial.

[Traduit par le journal]

Solutions of alkali metal fluorides in carboxylic acids have recently been demonstrated to be extremely efficient carboxylating agents and, as a result, are of considerable synthetic utility (1–4). In the present communication we wish to report an investigation of analogous reactions of fluoride – carboxylic acid systems *in the gas phase* by ion cyclotron resonance spectroscopy (ICR), with the aim of providing mechanistic details of the solution phase reaction.[1]

The reaction of *n*-heptylchloride with glacial acetic acid is observed to proceed in 85% yield to *n*-heptylacetate after 10 h under reflux in the presence of stoichiometric amounts of KF, reaction [1] (7).

[1] $$nC_7H_{15}Cl + CH_3CO_2H \xrightarrow{KF} CH_3CO_2{\cdot}nC_7H_{15} + KHF_2 + KCl$$

In the absence of KF no reaction occurs, even after prolonged heating at elevated temperatures. The driving force for this reaction has been postulated to be the increased nucleophilic character of the hydroxyl oxygen of acetic acid resulting from formation of a fluoride ion – acetic acid adduct, reaction [2],

[2] $$CH_3CO_2H + F^- \rightarrow CH_3CO_2HF^-$$

which strongly localizes negative charge on the hydroxyl oxygen. This conjecture is supported by ir and nmr detection of such an adduct (8, 9) and *ab initio* calculations on HCO_2HF^- and $CH_3CO_2HF^-$ which demonstrate that the hydroxyl oxygen of these adducts has a greater electron density than either the corresponding carboxylic acid *or carboxylate anion* (10).

We have previously demonstrated that the fluoride – acetic acid adduct may be facilely generated in the gas phase by fluoride transfer from trifluoromethoxide ion, CF_3O^-, reaction [3] (11).

[3] $$CF_3O^- + CH_3CO_2H \rightarrow CH_3CO_2HF^- + F_2CO$$

In order to examine the acetoxylating ability of the $CH_3CO_2HF^-$ ion in the gas phase, mixtures of CF_3OF, CH_3CO_2H, and a wide variety of alkyl halides were examined. A typical example for results obtained with alkyl chlorides is shown in Fig. 1 for a 4:1.5:1 mixture of C_2H_5Cl, CH_3CO_2H, and CF_3OF at a total pressure of 5×10^{-6} Torr. The reactions found to occur, verified by double resonance experiments, are summarized by reactions [4] and [5].

[4] $$CH_3CO_2HF^- + CH_3CO_2H \rightarrow (CH_3CO_2)_2H^- + HF$$

[5] $$(CH_3CO_2)_2H^- + C_2H_5Cl \rightarrow CH_3CO_2HCl^- + CH_3CO_2C_2H_5$$

Reaction analogous to reaction [5] was also observed for methyl, *i*-propyl, and *t*-butyl chlorides. No direct nucleophilic displacement reactions were

[1]All ICR techniques used were identical to those described previously (5). Previous comparisons of solution and gas phase ionic reactions by ICR may be found in ref. 6.

0008-4042/80/030307-03$01.00/0

observed, however, for either $CH_3CO_2HF^-$ or $(CH_3CO_2)_2H^-$ with any of the alkyl chlorides, reactions [6] and [7]

[6] $CH_3CO_2HF^- + RCl \nrightarrow Cl^- + HF + CH_3CO_2R$

[7] $(CH_3CO_2)_2H^- + RCl \nrightarrow Cl^- + CH_3CO_2H + CH_3CO_2R$

On the basis of results of the solution phase studies it is these reactions which might initially be expected to occur. Solutions of alkali metal acetates in glacial acetic acid also lead to production of alkyl acetates in reactions with alkyl halides (1, 7). However, these reactions are generally observed to be much slower than those involving alkali metal fluorides and it therefore seems unlikely that the solution phase reaction proceeds via the sequence of reactions, [4] and [5], found in the gas phase.

Reactions of $CH_3CO_2HF^-$ with alkyl fluorides, bromides, and iodides were also investigated. Both $CH_3CO_2HF^-$ and $(CH_3CO_2)_2H^-$ were observed to be completely unreactive toward all alkyl fluorides examined. With both alkyl bromides and iodides, $CH_3CO_2HF^-$ was found to undergo nucleophilic displacement to produce the corresponding halide ion and alkyl acetate, reactions [8] and [9].

[8] $CH_3CO_2HF^- + RBr \rightarrow Br^- + HF + CH_3CO_2R$

[9] $CH_3CO_2HF^- + RI \rightarrow I^- + HF + CH_3CO_2R$

However, the biacetate ion, $(CH_3CO_2)_2H^-$, was found to be unreactive toward all bromides and iodides studied.

These apparently ambiguous results for the gas phase reactions of fluoride acetic acid systems with various halides may be more clearly understood from an examination of the thermochemistry for representative reactions outlined in Table 1. In order for a gas phase ion–molecule reaction to be observed the reaction must be exothermic and involve little or no activation energy. Since all possible reaction channels for alkyl fluorides are endothermic no reaction is observed. For alkyl chlorides the possible nucleophilic displacement reactions, reactions [6] and [7], are also endothermic and as a result cannot occur. However, alternative exothermic reaction channels do exist, resulting in either $FHCl^-$ or $CH_3CO_2HCl^-$ and the desired ester. The reaction producing $ClHF^-$ does not occur, likely because the proton in the $CH_3CO_2HF^-$ is displaced strongly toward the fluorine with D(O—HF) calculated to be 1.40 Å (10). In the biacetate ion the O—H distance is much shorter (1.17 Å (7)) and the geometry of the ion–molecule intermediate is thus more favorable for reaction, resulting in facile $CH_3CO_2HCl^-$ production (reaction [5]). For alkyl bromides and iodides nucleophilic displacement by $CH_3CO_2HF^-$ is exothermic and this reaction is observed. Conversely, nucleophilic displacement by $(CH_3CO_2)_2H^-$ remains endothermic and this species is observed to be unreactive, as expected. Failure to observe formation of $CH_3CO_2HBr^-$ and $CH_3CO_2HI^-$ via reaction analogous to reaction [5] is likely, due to the increased steric requirements of the bulkier halogens which prevent reorientation of the methyl halide in the ion–molecule intermediate to a geometry favorable for elimination of these species.

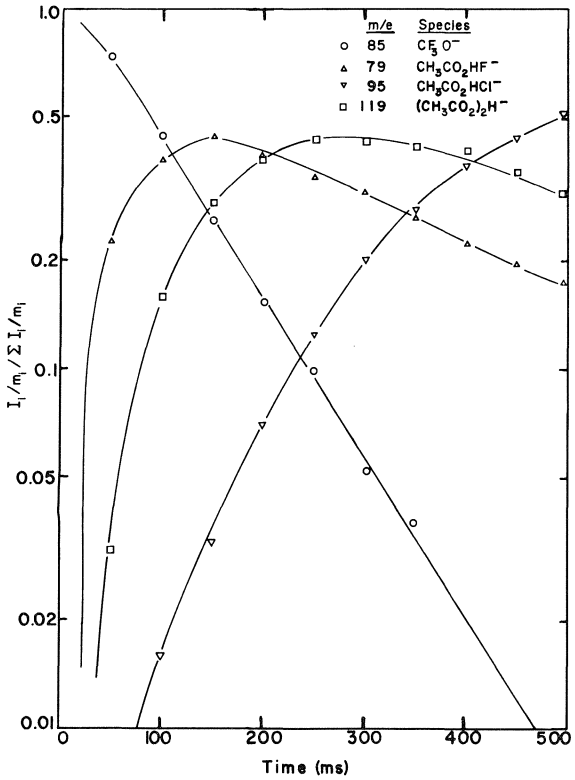

FIG. 1. Variation of relative ionic abundances with reaction time for a 4:1.5:1 mixture of C_2H_5Cl, CH_3CO_2H, and CF_3OF, following an 8 ms, 70 eV electron beam pulse. CF_3O^- is generated by dissociative electron attachment to CF_3OF.

In summary it appears that under the conditions where the esterification reactions have been examined in solution, the mechanism is exclusively direct nucleophilic displacement. The thermochemical data in Table 1 explain the decreasing time and temperature requirements for nucleophilic displacement as the size of the halogen increases (2, 3). It would be of interest, however, to examine solution phase reactions of alkali metal acetates in glacial acetic acid with alkyl chlorides at

TABLE 1. Enthalpy changes[a] for reactions of $CH_3CO_2HX^-$ with methyl halides, CH_3Y

$$CH_3CO_2HX^- + CH_3Y \xrightarrow{a} Y^- + HX + CH_3CO_2CH_3$$
$$CH_3CO_2HX^- + CH_3Y \xrightarrow{b} YHX^- + CH_3CO_2CH_3$$

		Enthalpy change	
$CH_3CO_2HX^-$	CH_3Y[b]	Channel *a*	Channel *b*
$CH_3CO_2HF^-$	CH_3F	38	3[c]
$(CH_3CO_2)_2H^-$	CH_3F	48	5
$CH_3CO_2HF^-$	CH_3Cl	9	−5
$(CH_3CO_2)_2H^-$	CH_3Cl	18	−3
$CH_3CO_2HF^-$	CH_3Br	−1	−13
$(CH_3CO_2)_2H^-$	CH_3Br	9	−6
$CH_3CO_2HF^-$	CH_3I	−7	−18
$(CH_3CO_2)_2H^-$	CH_3I	3	−8

[a] All reaction enthalpy changes in kcal/mol. Unless otherwise indicated $\Delta H_f^0(CH_3CO_2X^-)$ have been obtained from Yamdagni and Kebarle, ref. 16, or interpolated from gas phase acidity data as suggested by these authors. $\Delta H_f^0(CH_3CO_2HF^-)$ and $\Delta H_f^0((CH_3CO_2)_2H^-)$ are obtained in this fashion as outlined in ref. 11.

[b] Methylhalides are taken as representative of enthalpy changes for all alkyl halides studied. Available thermochemical data indicate that reaction enthalpies do not vary significantly with changes in alkyl group.

[c] $\Delta H_f^0(FHF^-)$ was calculated using $D(F^-—HF) = 35$ kcal/mol, obtained by interpolation from gas phase acidity data (see ref. 11). Recent studies of fluoride transfer reactions in our laboratory support a value of $D(F^-—HF) \leq 38$ kcal/mol.

relatively low temperatures to investigate the possibility of occurence of reaction analogous to [5] found in the gas phase. This possibility might be tested by monitoring such solutions by ir or nmr for presence of $CH_3CO_2HCl^-$.

More recent investigations have shown that fluoride ion is capable of enhancing nucleophilicity of a wide range of compounds with acidic hydrogens (12–15). We are currently extending our ICR studies to species such as fluoride bound to carbon acids and phenols to examine further parallels between reactivity in the gas phase and solution.

Easily polarizable hydrogen bonds and solvate structure in aqueous solutions of acids with $pK_a < 1$

MARTIN LEUCHS AND GEORG ZUNDEL
Physikalisch-Chemisches Institut der Universität München, Theresienstraße 41, D-8000 München 2, West Germany

Received August 2, 1979

MARTIN LEUCHS and GEORG ZUNDEL. Can. J. Chem. **58**, 311 (1980).

Aqueous solutions of 15 acids with $pK_a < 1$ were studied by ir spectroscopy. The ir bands of the acid molecules demonstrate that the proton acceptor strength of the anions increases in the series $CF_3SO_3^-$, HSO_4^-, ClO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$, NO_3^-. At very high concentrations (number of H_2O/acid molecules, $n < 1$) easily polarizable

$$\underset{\mathbf{I}}{AH\cdots OH_2} \rightleftharpoons \underset{\mathbf{II}}{A^-\cdots H^+OH_2}$$

hydrogen bonds are formed causing continuous absorption in the ir spectra. The deeper well of the double minimum energy surface of these hydrogen bonds at the beginning of the above series is present at the water molecule, and at the end of the series at the anion. The H_3O^+ character of the vibrations of the H^+OH_2 groups increases with increasing n. For $n > 1$ the weight of proton limiting structure **II** increases and more and more protons transfer from the acid–water into the water–water hydrogen bonds, i.e., they are present in $H_5O_2^+$ groupings which are embedded in the whole hydrate structure network. H_3O^+ vibrations are no longer found. The easily polarizable hydrogen bond in these groupings causes continuous absorption and the water molecules of these groupings cause broad bands. Of all acids studied, this group is the only cause of continuum in the more diluted solutions. The absorbance of the continuum per $H_5O_2^+$ group at $n = 2$ increases in the series $HClO_4$, CF_3SO_3H, H_2SO_4, H_2SeO_4, $C_6H_5SO_3H$. This is because of the increasing polarity of the environment of the $H_5O_2^+$ in this series of acids. The position of the water bands in solutions with $n = 6$ can be used to characterize the hydrogen bond acceptor strength of the anions. The H_2O scissor vibration shows that it increases in the series $AuCl_4^-$, $PtBr_6^{2-}$, $PtCl_6^{2-}$, ClO_4^-, BF_4^-, $CF_3SO_3^-$, J^-, HSO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$, $C_7H_7SO_3^-$, Cl^-. Finally molecular quantities which determine the pK_a values of the acids (proton acceptor strength, hydrogen bond acceptor strength, and special interaction properties of the anions) are discussed.

MARTIN LEUCHS et GEORG ZUNDEL. Can. J. Chem. **58**, 311 (1980).

On a étudié, par spectroscopie ir, les solutions aqueuses de 15 acides ayant un $pK_a < 1$. Les bandes ir des molécules d'acide démontrent que la force des anions accepteurs de proton augmente dans les séries: $CF_3SO_3^-$, HSO_4^-, ClO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$, NO_3^-. A de fortes concentrations (nombre de molécules H_2O/par nombre de molécules d'acides, $n < 1$), il y a formation de liaisons hydrogènes

$$\underset{\mathbf{I}}{AH\cdots OH_2} \rightleftharpoons \underset{\mathbf{II}}{A^-\cdots H^+OH_2}$$

facilement polarisables qui provoquent une absorption continue dans les spectres ir. Dans la surface à double minimum d'énergie de ces liaisons hydrogènes, le point le plus bas au début de la série ci-dessus est présent au niveau de la molécule d'eau et à la fin de la série il se situe au niveau de l'anion. Le caractère H_3O^+ des vibrations des groupes H^+OH_2 augmente avec n. Pour les valeurs de $n > 1$, le poids de la structure limite **II** du proton augmente et de plus en plus de protons passent des liaisons hydrogènes acide–eau aux liaisons hydrogènes eau–eau, i.e. ils sont présents dans les groupement $H_5O_2^+$ qui sont noyés dans toute la structure réticulaire de l'hydrate. On ne trouve plus les vibrations dues à H_3O^+. La liaisons hydrogène facilement polarisable de ces groupes provoque une absorption continue et les molécules d'eau de ces combinaisons donnent de larges bandes. Parmi tous les acides étudiés, ce groupe est la seule cause du continuum dans les solutions plus diluées. L'absorption du continuum par le groupe $H_5O_2^+$ pour $n = 2$ augmente dans la séries: $HClO_4$, CF_3SO_3H, H_2SO_4, H_2SeO_4, $C_6H_5SO_3H$. L'augmentation de la polarité de l'environnement de $H_5O_2^+$ dans cette série d'acide est responsable de cette observation. La position des bandes de l'eau dans les solutions où $n = 6$ peut être utilisée pour caractériser la force des anions en tant qu'accepteurs de liaison hydrogène. La vibration de cisaillement du H_2O montre qu'elle augmente dans la série $AuCl_4^-$, $PtBr_6^{2-}$, $PtCl_6^{2-}$, ClO_4^-, BF_4^-, $CF_3SO_3^-$, J^-, HSO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$, $C_7H_7SO_3^-$, Cl^-. Finalement on discute des quantités moléculaires qui déterminent les valeurs du pK_a des acides (capacité d'accepter des protons, capacité d'accepter des liaisons hydrogène et les propriétés spéciales d'interaction des anions).

Introduction

Molecular properties of strong acids in aqueous solutions were studied by ir (1–7) and Raman (8–14) spectroscopy. The degree of dissociation can be determined from bands of acid molecules and anions in the ir (1–7) and Raman spectra (11–14*a*). Infrared continuous absorption indicates the formation of easily polarizable hydrogen bonds (1, 15–20). Hydrogen bonds are easily polarizable when they have double minimum energy surfaces or energy surfaces with very broad flat wells, as shown by analytical (17) and SCF treatments (17–19). The continuous absorption can be directly calculated from the SCF transition moments (20, 21).

Due to their large polarizabilities and dipole moments these hydrogen bonds interact strongly with their environment (16). Thus, as discussed in ref. 16, pp. 731*ff*, the main cause of these continua is the large polarizability of hydrogen bonds which causes the following interaction effects: (*1*) The local electrical fields in solutions polarize these hydrogen bonds and shift the energy levels (induced dipole interaction). These local fields show a broad distribution and therefore a broad distribution of energy level differences occurs (see Fig. 6 in ref. 19). With these shifts resonances occurring between the various transitions are of particular significance. (*2*) Due to the large polarizability, transitions in the hydrogen bond couple with transitions in their environment, whereby the coupling with low wave number transitions is probably of particular importance. Furthermore, in liquid systems the equilibrium bond length shows more or less broad distributions (22), causing an additional distribution of the energy levels.

Interaction effect *1* (deformation of the energy surface by the local fields) and the length distribution of the hydrogen bonds were taken into account with our calculations of the continua (20, 21). With regard to interaction effect *2* only the coupling with the OO vibration was taken into account in our calculations of the continua.

Recently, Sokolov and co-workers (23*a*) calculated continua on the basis of coupling of transitions in charged hydrogen bonds and phonons in their environment. There is, however, strong experimental evidence that not the charge (as assumed by Sokolov and co-workers) but the symmetry of the proton potential is the essential feature for the appearance of the continua (23*a*). Thus a different interpretation of the coupling constant *S* in Sokolov's theory, mainly based on the high polarizability of largely symmetrical hydrogen bonds, seems more appropriate (23*b*). With this reinterpretation this theory describes very well interaction effect *2* and may explain some observations as discussed below.

Infrared continua are observed with structurally symmetrical charged hydrogen bonds of the types (16)

$$B^+H\cdots B \rightleftharpoons B\cdots H^+B$$

or

$$B^-\cdots HB \rightleftharpoons BH\cdots {}^-B$$

or with largely symmetrical non-charged proton transfer hydrogen bonds

$$B_1H\cdots B_2 \rightleftharpoons B_1{}^-\cdots H^+B_2$$

With aqueous solutions of acids and with acidic polyelectrolytes ir continua were already studied by various authors (for a summary see ref. 16). Recently, Librovich and co-workers (6, 7, 25–27) investigated the ir continua of aqueous acid solutions with the ATR technique which is particularly suitable when the absorbance of the acids is very strong.

Aqueous solutions of $HClO_4$, CF_3SO_3H (28), and HNO_3 (29) were already investigated in detail. In this paper these studies were extended to aqueous solutions of 15 strong acids. The results obtained are discussed in terms of the strength of the respective acids.

Material and Methods

The acids were purchased from Merck in Darmstadt, Germany, Riedl-de-Haen in Seelze, Germany and Fluka in Buchs, Switzerland (see Table 1). The purity was analytical grade except CF_3SO_3H, HBF_4, H_2SeO_4, $C_6H_5SO_3H$ (synthetic grade), and $HAuCl_4$ (Lab).

Pure perchloric acid was obtained by vacuum distillation (50 Torr) of a 2.5:1 volume mixture of H_2SO_4 (97%) and $HClO_4$ (70%). Pure sulfuric acid was prepared by mixing H_2SO_4 and oleum; H_2SeO_4 (97%) was dried with P_2O_5. The other acids could be obtained free of water. For all acids the highest concentration measured is given in Table 1.

The cell used for the liquid acid solutions had silicon windows and a wedge-shaped layer; the latter in order to avoid an interference pattern superimposed on the spectra caused by the high reflectivity of silicon.

The absorbance had to be corrected, since with the wedge-shaped layer Lambert–Beer's law is no longer valid. The true absorbance is obtained as described in ref. 2*a*. The absorbance of the continuum is determined as described in ref. 31, taking the background absorbance of water into account. The absorbance of the continuum is referred to the same background absorbance at 4700 cm^{-1}.

The degree of dissociation was determined in the following way: The absorbance of a characteristic band of the non-dissociated acid molecules was plotted against the acid molarity. The intensity of this band in the spectrum of the water-free acid yields the molar absorbance of this band. With this molar absorbance, the concentration of non-dissociated acid molecules in each solution could be determined, and thus the degree of dissociation.

Results and Discussion

Aqueous solutions of 15 acids (Table 1) with $pK_a < 1$ were studied by ir spectroscopy as a function of concentration. Selected examples of spectra are shown in Fig. 1. With all these acids, a strong continuum arises with increasing concentration. This continuum begins at the band of the H_2O stretching vibration and extends towards smaller wave numbers. For acids which can be studied up to very high concentrations, the intensity of this continuum reaches a maximum after which it decreases with increasing concentration. This is illustrated with selenic acid in Fig. 1*c*. The absorbance of this continuum is listed in Table 1 for 1*M* and 5 *M* solutions.

A large number of these acids could be studied over the whole concentration range up to the pure acid. The results obtained with these acids at very high concentrations are summarized in Table 2.

Degree of Dissociation

The degree of dissociation can be determined from the ir bands of the acid molecules. Figure 2 shows the bands demonstrating the removal of the proton from the anion. With CF_3SO_3H, ν(S—O) at 930 cm^{-1} vanishes in the spectrum of the solution and with $n = 1.6$ this band no longer occurs, indicating complete dissociation. Analogously complete dissociation is indicated by the disappearance of the following bands: H_2SO_4 (first dissociation step), $\nu_{as}(S—(OH)_2)$ at 960 cm^{-1} and $\nu_{as}(SO_2)$ at 1360 cm^{-1}; $HClO_4$, ν(Cl—O) at 740 cm^{-1}; H_2SeO_4 (first dissociation step), $\nu_{as}(SeO_2)$ at 975 cm^{-1}; $C_6H_5SO_3H$, ν(S—O) at 900 cm^{-1}; HNO_3, γ HNO_3 at 765 cm^{-1}. To obtain exact n values for complete dissociation in Fig. 3, the degree of dissociation is plotted as a function of n, the number of water molecules per acid molecule. With sulfuric acid, the bands in the ir spectra taken by the usual method do not allow quantitative evaluation in the whole range, therefore the Raman data of Young (11) are used. These results agree very well, however, with those obtained by Maiorov and Librovich (6) who studied aqueous sulfuric acid solutions using the ATR technique. With selenic acid, a quantitative evaluation in the whole range is also not possible due to the strong overlapping of the bands in the ir as well as in the Raman spectra (32), in the following therefore the n value for complete dissociation taken directly from the spectra is used. The following n values for complete removal of the protons from the anion are obtained: trifluoromethane – sulfonic acid, $n = 1.6$ (9.3 *M*); sulfuric acid (first step), $n = 1.6$ (13.6 *M*); perchloric acid, $n = 1.8$ (12.9 *M*); selenic acid (first step), $n \approx 2.0$; benzene sulfonic acid, $n = 5$ (4.9 *M*); and nitric acid, $n = 12$ (4.0 *M*). Hence in this series more and more water molecules are required for the removal of the protons from the anions.

With these spectroscopically determined degrees of dissociation one must keep in mind that the acid molecules observed as dissociated are not only those the protons of which are removed from the anion and present in $H_5O_2^+$, but also those with which the proton is present in proton-limiting structure **II** in the acid–water hydrogen bond (see following section).

Water–Acid Ratio Less Than One

Let us consider first the case of less than one water molecule per acid molecule ($n < 1$). With all these acids the absorbance of the continuum increases in proportion to the molarity of water, as shown by Fig. 4*a*. Simultaneously the OH stretching vibration (Table 2, column 1) of the acid, observed in the pure acids, vanishes. All these results taken together demonstrate the formation of easily polarizable acid–water hydrogen bonds, as represented by the two proton-limiting structures

$$\underset{\mathbf{I}}{AH\cdots OH_2} \rightleftharpoons \underset{\mathbf{II}}{A^-\cdots H^+OH_2}$$

In Fig. 4*b* the concentrations of protons removed from the anion (M_{H^+}) are plotted as a function of the molarity of water. From these results (as described in ref. 28) the weights of the proton-limiting structures at $n = 1$ were calculated and given in Table 2. For all acids under these conditions the proton can be present in both limiting positions. Thus in these acids acid–water hydrogen bonds with double minimum energy surfaces occur, as expected from the observed continuum.

In the series F_3CSO_2OH, H_2SO_4, $HClO_4$, C_6H_5-SO_2OH, HNO_3, the weight of proton-limiting structure **II** decreases and the weight of proton-limiting structure **I** increases. Thus in this series of acids, when one water molecule is present per acid molecule, the deeper well of the energy surface in the acid–water hydrogen bonds at the beginning of the series is present at the water molecule, and at the end of the series at the anion.

Let us now consider the bands of the water molecules in the acid–water groupings. The OH stretching vibration is observed as a very broad band with maximum in the region 3000–2600 cm^{-1}. Here and in the following, nitric acid will be considered separately. The maximum of the OH bending vibration is listed in Table 2, columns 7 and 8. With $HClO_4$ this vibration is observed at about 1700 cm^{-1}, largely independent of n, whereas with the other acids this band is found for $n \approx 0.5$ in the

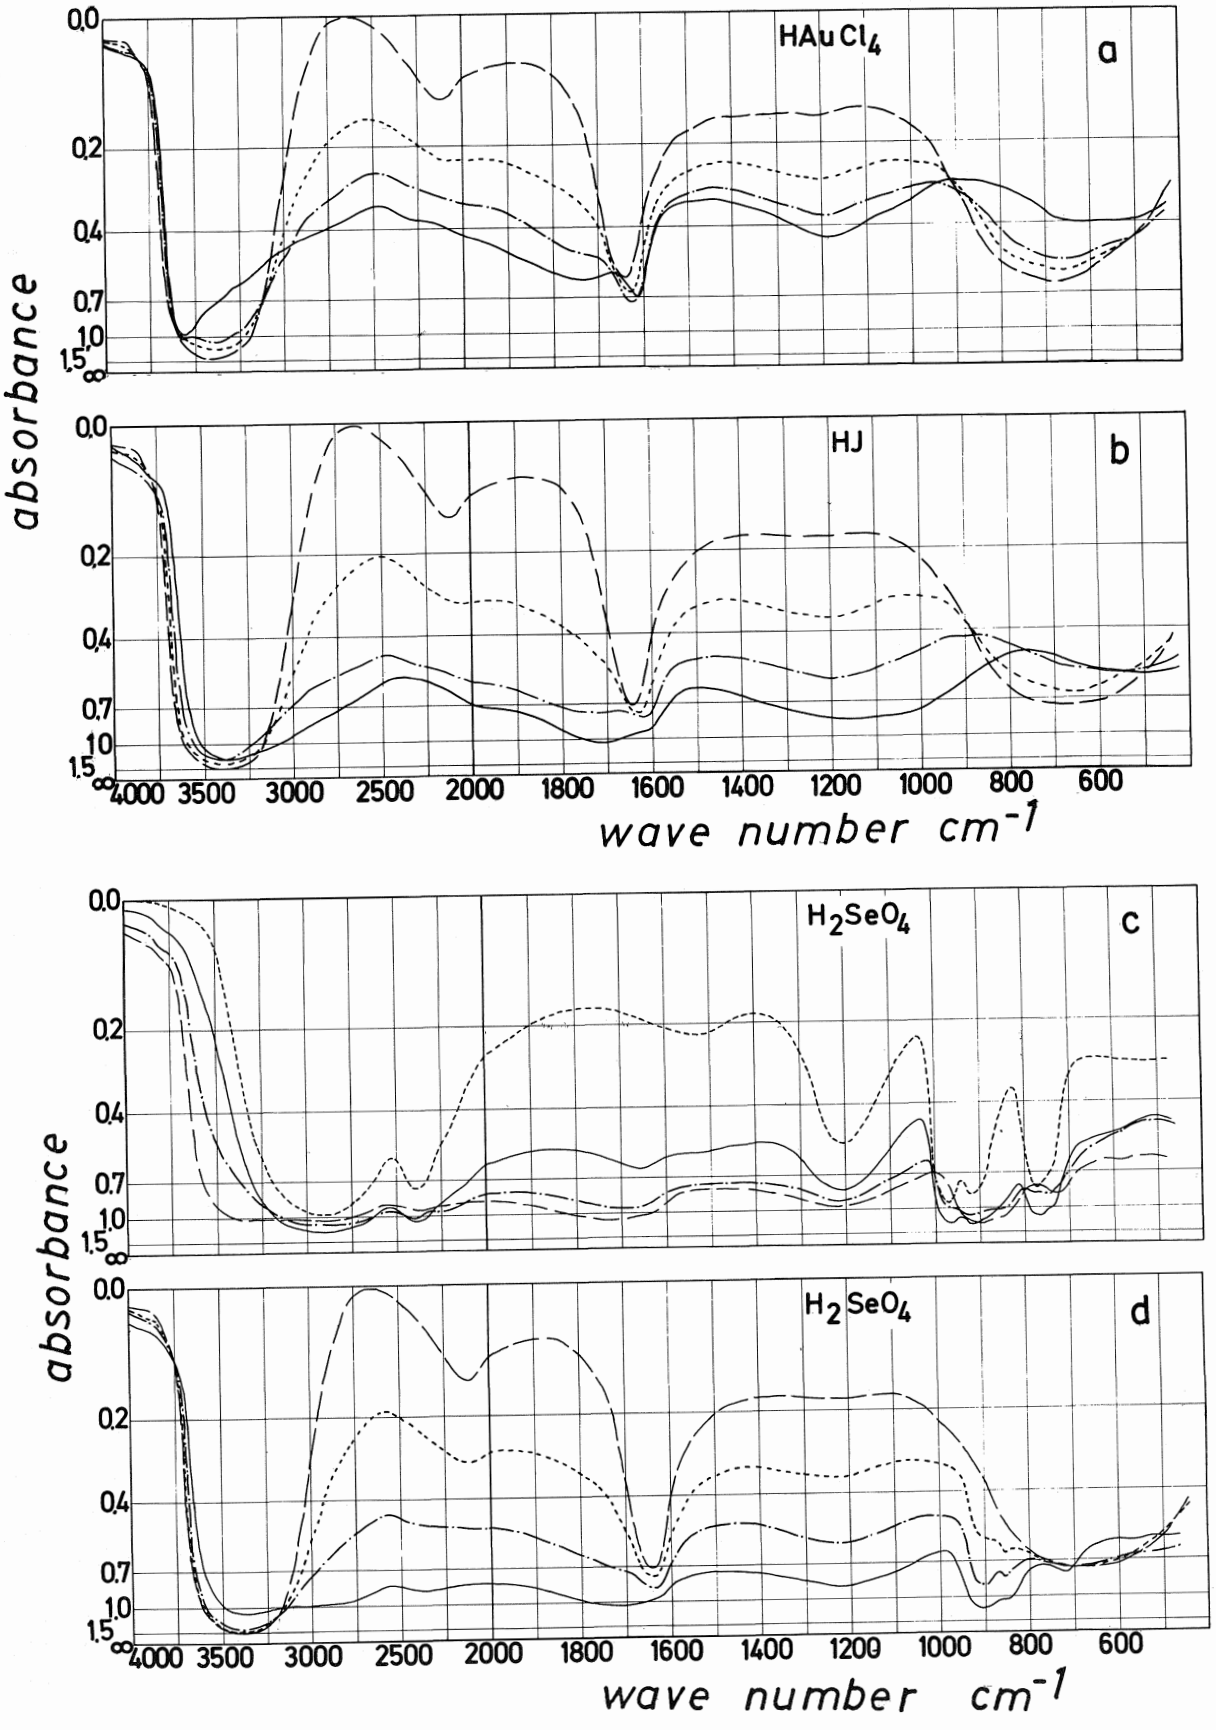
region 1640–1685 cm^{-1}, from $n = 0.5$ to $n = 1.2$ this band shifts to about 1710 cm^{-1}. Thus, with the exception of $HClO_4$, the OH bending vibration is observed, at $n = 0.5$, in the position of the scissor vibration of water molecules, whereby the shift from 1640 to 1685 cm^{-1} indicates that these water molecules in this series form increasingly stronger hydrogen bonds. As already discussed in ref. 28, the relatively high constant position of the OH bending vibration with $HClO_4$ is due to the strong influence of the proton on the H_2O molecule. This vibration shows H_3O^+ character. As discussed in detail in ref. 28, the H_3O^+ character of the vibrations increases with decreasing asymmetry of the environment of the H^+OH_2 grouping in the



$$AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$$

hydrogen bonds. This explains the shift of the OH bending vibration. From $n = 0.5$ to $n = 1.2$, this band shifts towards larger wave numbers, because of the fact that the acceptors of these water molecules now change from O atoms of non-dissociated acid molecules to O atoms of anions. Therefore, the environment of the H^+OH_2 grouping in proton limiting structure **II** becomes more symmetrical and thus the vibrations gain H_3O^+ character.

In the case of nitric acid (29), the H_2O stretching vibration is observed at 3580 cm^{-1} and the scissor vibration at 1615 cm^{-1}, i.e., the water molecules in the acid–water groupings form only very weak hydrogen bonds. This can be explained by the fact that nitric acid is only weakly dissociated for $n < 1$. Hence the acceptors of these hydrogen bonds are preferentially O atoms of non-dissociated acid molecules, which are less strong acceptors than O atoms of anions.

Water–Acid Ratio Greater Than One

With increasing n the degree of dissociation increases (Fig. 3). The addition of water molecules increases the weight of the polar proton limiting structure $A^- \cdots H^+OH_2$, an effect well known from other systems (2, 4). This increase of the weight of proton-limiting structure **II** is indicated by an increase of the intensity of the broad band of the OH stretching vibration in the region 3000–2600 cm^{-1}. With very strong acids, which are completely dissociated for $n = 2$, this band shows a maximum at about $n = 1.2$ (Fig. 7 in ref. 28).

With benzene sulfonic acid, i.e., an acid for which more water molecules must be present for

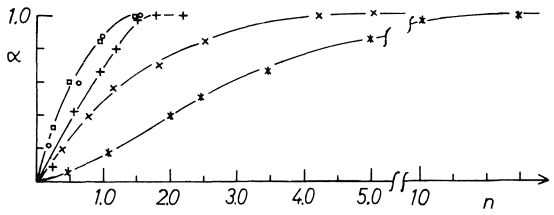

FIG. 3. Degree of dissociation of $HClO_4$: +; H_2SO_4: ○, CF_3SO_3H: □; $C_6H_5SO_3H$: ×; HNO_3: * depending on the mole ratio nH_2O/acid.

complete removal of the protons from the anions, this band has maximum intensity for $n = 2.0$. Finally, for nitric acid, this band is not observed as a pronounced band since at $n = 1$, the weight of proton limiting structure **II** is only 0.13. This weight of structure **II** increases slowly with increasing n. The presence of structure **II**, however, favours the transfer of the proton into the network of the hydrogen-bonded water molecules, i.e., the formation of $H_5O_2^+$. Thus, with nitric acid the concentration of proton-limiting structure **II** remains low.

The $H_5O_2^+$ Groupings

With the stronger acids, the ν(OH) band in the region 3000–2600 cm^{-1} is quite pronounced, but decreases for $n > 1.2$ and disappears with increasing n (Fig. 7 in ref. 28). This result indicates that in this case the protons transfer from the acid–water hydrogen bonds into hydrogen bonds between water molecules. As demonstrated earlier with acidic polyelectrolytes (1, 33) and aqueous solutions of strong acids (refs. 16, 26, see also ref. 23), the excess proton is present in $H_5O_2^+$ groupings which are embedded in the hydrate structure network.

The band observed with the strong acids for $n = 1$, with a maximum at about 1700 cm^{-1} caused by H^+OH_2 groupings of the proton limiting structure **II**, increases a little and shifts toward larger wave numbers. This band is found for $n = 2$ with a maximum at about 1740 cm^{-1}, caused by the bending vibration of the water molecules in $H_5O_2^+$ groupings. When more water molecules are added, i.e., with increasing n, the intensity of this band decreases, due to dilution of the acid solutions.

With all these acids, at $n = 2$, only one broad band of a H_2O scissor vibration is observed (Figs. 1*d* and 1*f* and in ref. 28 Figs. 1*a* and 1*b*). This clearly demonstrates, as discussed earlier (28, 34), that in $H_5O_2^+$, the proton is distributed between both water molecules, since otherwise, not only one but two bands ($\delta_{as}(H_3O^+)$ and $\delta(H_2O)$ of $H_3O^+H_2O$ grouping) should be observed. An additional OH bending vibration is only observed, however, with $n > 2$ (see following section). Thus, in aqueous solutions, in contrast to other statements (35–38), the H_3O^+ groups do not vibrate as an entity, when sufficient water molecules are present to form $H_5O_2^+$ groupings. The same conclusion was reached by Librovich, Maiorov, and Savalev comparing ir and Raman data (26).

In the liquid state, H_3O^+ vibrations (as mentioned above) may only be found when less than two water molecules per excess proton are present. In crystals, such vibrations are found when the excess proton is present at one water molecule (39). Finally, such vibrations can be observed when H_3O^+ is present in the gas phase (40).

The absorbance of the continuum at 1900 cm^{-1} is given for 1 *M* and 5 *M* solutions in Table 1, columns 1 and 2. Where pK_a values are known, the absorbance of these continua is plotted as a function of the pK_a values of the acids in Fig. 5.

The results in Table 1 and Fig. 5 demonstrate the following: for all acids completely dissociated at

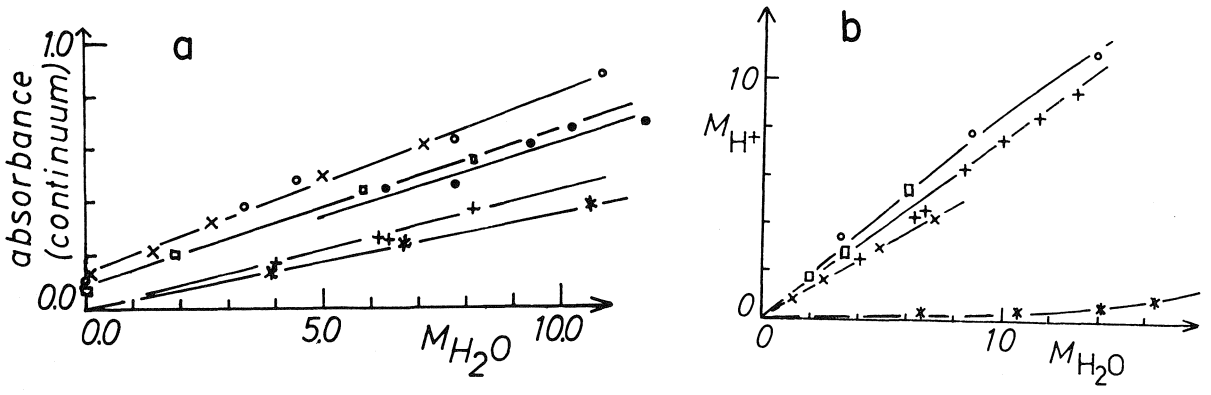

FIG. 4. (*a*) Absorbance of the continuum depending on the molarity of water. (*b*) Molarity of dissociated protons depending on the molarity of water $HClO_4$: +; H_2SO_4: ○; CF_3SO_3H: □; H_2SeO_4: ●; $C_6H_5SO_3H$: ×; HNO_3: *.

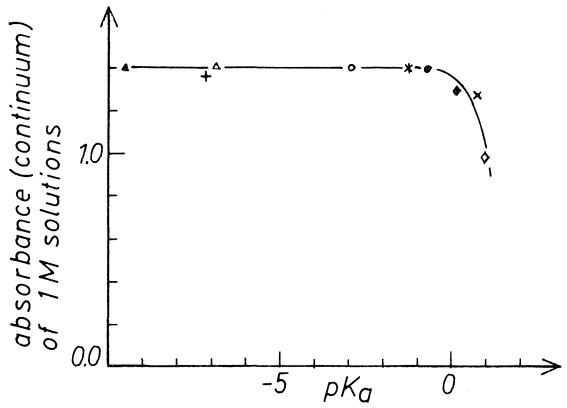

FIG. 5. Continuous absorption of 1 *M* solutions for HJ: ▲; HCl: △; $HClO_4$: +; H_2SO_4: ○; HNO_3: *; H_2SeO_4: ●; CF_3COOH: ◆; $H_2C_5O_4$: ×; HJO_3: ◇.

these concentrations, the absorbance of the continuum is the same, within experimental error. With increasing pK_a of the acids, the intensity of the continuum decreases since the acids are no longer completely dissociated. The fact that the strength of the absorbance of the continuum becomes independent of pK_a of the respective acid, for acids with $pK_a < 0$, suggests that in this pK_a region, with all acids at these concentrations, the same easily polarizable hydrogen bond causes the continuum. As discussed above and facts from the literature (1, 16, 20, 33), this polarizable hydrogen bond is the bond in $H_5O_2^+$ groupings.

The absorbance of these groupings, however, is equal, only if their interaction with the environment is the same. This will be demonstrated as follows. In Fig. 6, for $n > 2$, the absorbance of the continuum per proton removed from the anion is plotted as a function of n. As shown above, under these conditions, most of the protons of the strong acids are already present in easily polarizable hydrogen bonds of $H_5O_2^+$ groupings. Hence Fig. 6 shows the following: Result (*1*) For $n = 2$ to $n = 4$, the absorbance of the continuum per polarizable hydrogen bond increases in the series from perchloric acid to benzenesulfonic acid. Result (*2*) With increasing n in the region $n = 2$ to $n = 4$, the absorbance of the continuum per polarizable hydrogen bond increases. This increase is stronger the smaller the absorbance of the continuum per polarizable hydrogen bond at $n = 2$. Result (*3*) For larger n, the absorbance of the continuum per polarizable hydrogen bond becomes the same for all acids.

Theoretical calculations have shown that the interaction of the $H_5O_2^+$ groupings with their environment changes the intensity of the absorbance of the continuum per $H_5O_2^+$ grouping. These intensity

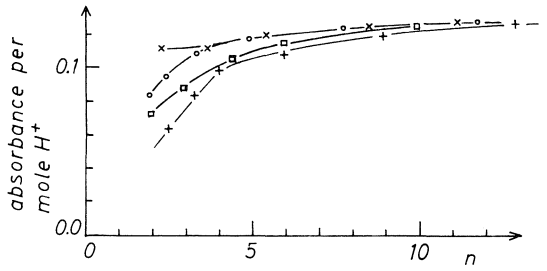

FIG. 6. Continuous absorption per mol of dissociated protons depending on the H_2O/acid mole ratio n. $HClO_4$: +; H_2SO_4: ○; CF_3SO_3H: □; $C_6H_5SO_3H$: ×.

changes have the following causes: firstly, when the $H_5O_2^+$ groupings are bound to stronger hydrogen bond acceptors, the OO distance in these groupings is stretched, and the barrier in the energy surfaces increased. From theory it is well known that many more transitions occur in the region 2500–1000 cm^{-1}, contributing to the continuum, when the mean OO distance of $H_5O_2^+$ is increased. This is shown by Fig. 6 in ref. 19 and demonstrated especially clearly by the calculated continua in ref. 20 (see Fig. 5 of ref. 20). Secondly, when the environment of $H_5O_2^+$ becomes more polar, transitions in the polarizable hydrogen bond may couple more strongly with low wave number vibrations in their environment. Thus, these vibrations may contribute and increase the intensity of the continuum. This intensity increase due to coupling with intermolecular vibrations can probably be described very well by the theory of Librovich, Sakun, and Sokolov (23).

These theoretical results explain the observed experimental findings: result *1*, the absorbance of the continuum per $H_5O_2^+$ in the series form $HClO_4$ to benzene sulfonic acid increases because the hydrogen bond acceptor strength of the anions and hence also the polarity of the environment of the $H_5O_2^+$ groupings increases in this series. Result *2*, the increase of the absorbance of the continuum per $H_5O_2^+$ with increasing n is analogously explained since the lone electron pairs of water molecules are much stronger acceptors than the O atoms of ClO_4^- ions. Therefore, when water molecules are added to $H_5O_2^+$ groupings the latter become more strongly bound to their environments and these environments become much more polar than when only the ClO_4^- ions are present. Thus, the absorbance of the continuum per polarizable hydrogen bond in $H_5O_2^+$ increases. This increase becomes less pronounced when the O atoms of the anions are stronger hydrogen bond acceptors, and vanishes when the acceptor strength becomes comparable to that of the lone pairs of the water molecules. At

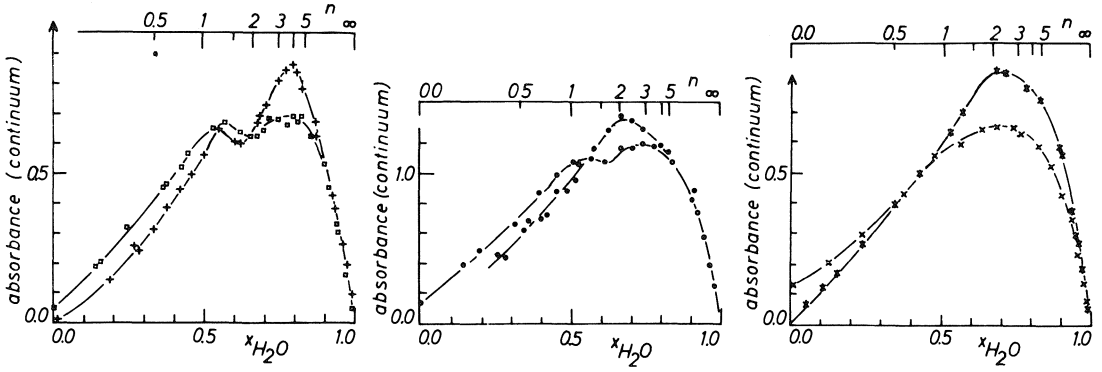

FIG. 7. Continuous absorption depending on the mole fraction of water x_{H_2O} and the water/acid mole ratio n: (*a*) $HClO_4$: +; CF_3SO_3H: □; (*b*) H_2SO_4: ○; H_2SeO_4: ●; (*c*) $C_6H_5SO_3H$: ×; HNO_3: *.

larger n, the absorbance of the continuum per proton becomes the same with all these acids (result *3*), since (as discussed above) $H_5O_2^+$ is then present, which is embedded in the network of hydrogen bonds formed by other water molecules.

In Fig. 7 the absorbance of the continuum at 1900 cm^{-1} is plotted as a function of mole fraction of water, X_{H_2O} and of n. In the case of acids with small pK_a a maximum of the absorbance is observed at $n = 1.2$, as already discussed in detail for $HClO_4$ and CF_3SO_3H in ref. 28. This maximum is caused by the slope of the broad band observed in the region 3000–2600 cm^{-1}. With these acids, a second maximum of the absorbance of the continuum is observed at larger n values, with $HClO_4$ at $n = 4.0$, with CF_3SO_3H at $n = 3.7$, and with H_2SO_4[1] at $n = 3.0$. The other acids show only one maximum, which is observed with H_2SeO_4 at $n = 2$, with $C_6H_5SO_3H$ at $n = 2.3$, and with HNO_3 at 2.3. This absorbance maximum is explained as follows: the increase of the absorbance is caused by the formation of $H_5O_2^+$ groupings. In the case of the acids with small pK_a, an additional increase of the absorbance is due to the above discussed increase of the absorbance per $H_5O_2^+$, caused by the addition of water molecules. The decrease of the absorbance of the continuum with increasing n is caused by decreasing concentration of $H_5O_2^+$ due to increasing dilution. Hence the shift of the maximum from $n = 4$ ($HClO_4$) to $n = 2$ (H_2SeO_4) is caused by the fact that the absorbance per $H_5O_2^+$ increases from $n = 2$ to $n = 4$ for $HClO_4$, whereas with H_2SeO_4 the absorbance per $H_5O_2^+$ is nearly the same for $n = 4$ and $n = 2$ (Fig. 6). The maximum of the absorbance with $C_6H_5SO_3H$ and HNO_3 is shifted towards larger n, since with these acids $H_5O_2^+$ groupings are still formed for $n > 2$.

Hydrogen Bond Acceptor Strength of the Anions

With increasing n at the low wave number slope of the band of the scissor vibration of the water molecules in the $H_5O_2^+$ grouping, the scissor vibration of the additional water molecules occurs. Some selected examples are shown in Fig. 8. This additional band is found in the region 1650–1615 cm^{-1}. The corresponding stretching vibration of these H_2O molecules is observed in the region 3580–3360 cm^{-1}. These water molecules are bound with their lone electron pairs to the OH groups of $H_5O_2^+$ and with their OH groups preferentially to acceptor groups of the anions. When these acceptors are very weak (as, for instance, it is the case with $AuCl_4^-$), the H_2O scissor vibration for $n = 6.9$ is observed at 1620 cm^{-1} and the stretching vibration at 3570 cm^{-1} (see Fig. 1*a*). The low position of the scissor vibration and the high position of the stretching vibration indicate that these water molecules are only very weakly bound to anions. In contrast to this result, with benzene sulfonic acid these bands are observed at 1640 and 3400 cm^{-1}, indicating that in this case the water molecules are bound to the anions via much stronger hydrogen bonds. In the following we consider the position of the scissor vibration, since the stretching vibration is very broad and in some cases superimposed on the OH stretching vibration of second OH groups of acid molecules. The position of the scissor vibration for $n = 6$ is given in Table 1, column 4. These band positions indicate the increase of the hydrogen bond acceptor strength in this series of anions from $AuCl_4^-$ to Cl^-.

The nitric acid solution is an exception since as long as the nitric acid is not completely dissociated, O atoms of non-dissociated acid molecules are acceptors for the OH groups of the water molecules.

[1]With previous measurements of aqueous H_2SO_4 solutions (34), the maxima of the intensity of the continuum at 1.2 and 3.0 could not be separated since the layer thickness of the samples was too great and the absorbance therefore too intense.

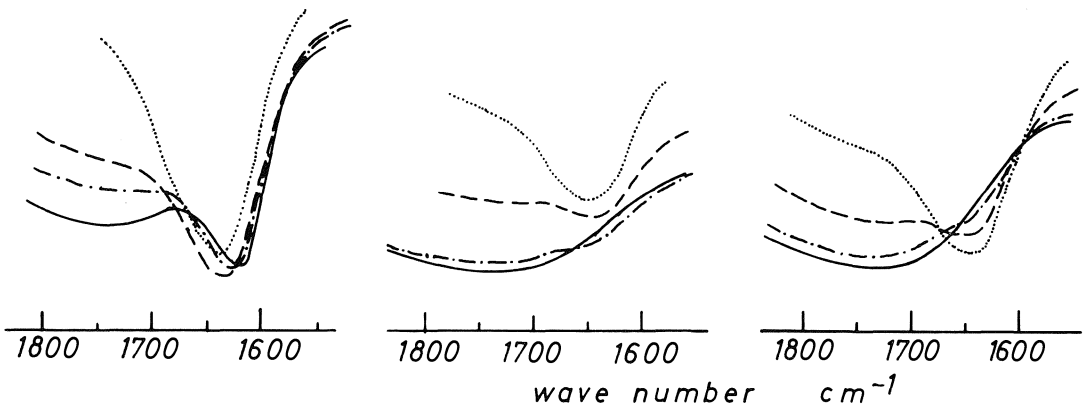

FIG. 8. (*a*) $HAuCl_4$: — $n = 6.9$; ····· $n = 9.9$; --- $n = 14.3$; ··· $n = 31.4$; (*b*) H_2SO_4: — $n = 2.4$; ····· $n = 4.9$; --- $n = 11.2$; ··· $n = 25.9$; (*c*) $C_6H_5SO_3H$: — $n = 2.2$; ····· $n = 3.5$; --- $n = 7.0$; ··· $n = 16.2$.

These O atoms are, however, much weaker acceptors than those of NO_3^- anions, and therefore the OH stretching vibration is observed at larger wave numbers, as already discussed in ref. 29.

With increasing n, for all these acids, the vibrations of the water molecules shift to the position in which these vibrations are observed in pure water, since more and more water–water hydrogen bonds are present in the solutions.

Conclusions

With acids ($pK_a < 1$), which are soluble up to concentrations at which one or less than one water molecule is present, the acid water hydrogen bonds formed under these conditions are easily polarizable proton transfer bonds

$$\underset{\mathbf{I}}{AH\cdots OH_2} \rightleftharpoons \underset{\mathbf{II}}{A^-\cdots H^+OH_2}$$

In the series CF_3SO_3H, H_2SO_4, $HClO_4$, H_2SeO_4, $C_6H_5SO_3H$, HNO_3, the weight of proton-limiting structure **I** increases and the weight of structure **II** decreases. The energy surfaces in these bonds are double minima, whereby with the stronger acids in the above series the deeper well is present at the water molecule and with the less strong acids at the anion.

Complete dissociation is reached with CF_3SO_3H at $n = 1.6$, H_2SO_4 (first step) at $n = 1.6$, $HClO_4$ at $n = 1.8$, H_2SeO_4 (first step) at $n \approx 2$, $C_6H_5SO_3H$ at $n = 5$, and HNO_3 at $n = 12$. Hence the acceptor strength of the anions for the proton in this series of acids increases.

The molecular processes associated with the removal of the proton from the anion are as follows: for $n = 0$ to $n = 1$, easily polarizable acid–water hydrogen bonds are formed. For $n > 1$, the weight of proton-limiting structure **II** increases due to the influence of the additional water molecules. The vibrations of the water molecules in the

$$AH\cdots OH_2 \rightleftharpoons A^-\cdots H^+OH_2$$

groupings gain more and more H_3O^+ character. Thereafter, the protons transfer from these acid—water hydrogen bonds into hydrogen bonds between water molecules, i.e., $H_5O_2^+$ groupings are formed. The excess proton in these groupings is distributed between both water molecules. H_3O^+ no longer vibrates as an entity. The easily polarizable hydrogen bond in $H_5O_2^+$ groupings causes strong ir continuous absorption, whereas the water molecules cause strong bands.

At $n = 2$, the continuous absorbance per $H_5O_2^+$ strongly depends on the acceptor strength of the O atoms of the anions, i.e. on the polarity of the environment. It increases with increasing acceptor strength in the series ClO_4^-, $CF_3SO_3^-$, HSO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$. In the case of acids with anions which are only weak hydrogen bond acceptors, the intensity of the continuum per $H_5O_2^+$ increases strongly with addition of water in the range $n = 2$ to $n = 4$, due to increasing interaction of the polarizable hydrogen bond in $H_5O_2^+$ with its environment.

With all acids studied, the hydrogen bond acceptor strength of the anions can be determined by considering the position of the bands of the water molecules. High wave number values of ν(OH) and low of δ(OH) indicate weak acceptor strength. From the positions of the H_2O scissor vibration at $n = 6$ (Table 1 column 6), the following series for increasing hydrogen bond acceptor strength of the anions is obtained: $AuCl_4^-$, $PtBr_6^{2-}$, ClO_4^-, BF_4^-, $CF_3SO_3^-$, I^-, HSO_4^-, $HSeO_4^-$, $C_6H_5SO_3^-$, $C_7H_7SO_3^-$, Cl^-.

The acceptor atoms of the non-dissociated acid molecules are much weaker hydrogen acceptors

than those of the anions. This is especially well demonstrated by nitric acid (29).

This series of the hydrogen bond acceptor strength of the anions of the respective acids does not agree with the series of the proton acceptor strength of the anions obtained as discussed above from the data in Table 2, columns 3–5. Complete dissociation occurs, for instance, with CF_3SO_3H and H_2SO_4 (first step) at smaller n values than with $HClO_4$, whereas the hydrogen bond acceptor strength of the O atoms of $CF_3SO_3^-$ and HSO_4^- is greater than that of ClO_4^-. As will be discussed in the following, both quantities determine the pK_a values of the acids.

The pK_a values are determined by measuring activities with potentiometric, indicator, or other classical methods. The aim of these methods is to obtain the number of dissolved particles. The macroscopic quantities measured with these procedures are determined, however, not only by the proton acceptor strength of the anions but also by the interactions of these ions with their environment, i.e., with the water molecules. Therefore, not only the proton acceptor strength of the anions but also the number and strength of the hydrogen bond acceptor sites of the anions, which are the decisive quantities for their hydration, determine the measured pK_a values.

In the case of $HClO_4$, a pK_a value smaller than that of H_2SO_4 is given in the literature (41–43) although the acceptor strength of ClO_4^- for the proton is greater than for HSO_4^-. The reason for the smaller pK_a value of $HClO_4$ is that ClO_4^- binds water molecules less strongly than HSO_4^-, due to the weaker hydrogen bond acceptor strength of the O atoms of ClO_4^- ions. In addition, the OH group of HSO_4^- also contributes to the interaction of HSO_4^- with the environment. Thus, the apparent particle number is smaller because of the stronger interaction of the water molecules with sulfuric acid. Hence a larger pK_a is measured with sulfuric acid than with $HClO_4$, although the proton acceptor strength of HSO_4^- is smaller than that of ClO_4^-.

The pK_a is smaller with HNO_3 ($pK_a = -1.4$ (43)) than with the sulfonic acids ($C_6H_5SO_3H$ ($pK_a = 1.5$ (42), 0.7 (44)), $C_7H_7SO_3H$ ($pK_a = 1.7$ (42), 0.9 (44))), whereas the ir spectroscopic results show that the proton acceptor strength is much stronger for nitric acid than for sulfonic acids. The latter is true not only for the sulfonic acids mentioned above but also for methane sulfonic acid as shown by Raman spectroscopy (12) and for polystyrene sulfonic acid as shown by ir (1), Raman (45), and nmr (46) studies. These discrepancies are caused by different interaction of the anions with their environment. NO_3^- is hydrophilic. In contrast to this property all mentioned sulfonic acids have hydrophobic groups besides the hydrophilic $—SO_3^-$ group. Because of these hydrophobic groups, the anions interact with one another, reducing the measured apparent particle number. Therefore the electrochemically observed pK_a is greater, although the removal of the proton from the anion, i.e., the spectroscopically observed dissociation is larger with the sulfonic acids than with nitric acid.

Thus the pK_a values are determined by various molecular quantities: *1*, the acceptor strength of the anions for the proton; *2*, the hydrogen bond acceptor strength of the anions, which determines the interaction of these anions with the water molecules; *3*, interactions due to hydrophobic groups causing association of the anions.

Thermodynamics of ionization of *trans*-crotonic and adipic acids in water; the silver – silver adipate electrode

UPENDRA NATH DASH AND UTTAM KUMAR NAYAK

Department of Chemistry, Gangadhar Meher College, Sambalpur (Orissa), India

Received June 18, 1979

UPENDRA NATH DASH and UTTAM KUMAR NAYAK. Can. J. Chem. **58**, 323 (1980).

The ionization constant, K, of *trans*-crotonic acid, and the first and second ionization constants, K_1 and K_2, of adipic acid have been determined in water at seven different temperatures ranging from 15 to 45°C with the help of the cells without liquid junction using silver – silver chloride and quinhydrone electrodes. The variations of pK, pK_1, and pK_2 with temperature have been expressed by the equations

$$pK = 105.54/T + 4.47 - 2.26 \times 10^{-2}T$$

$$pK_1 = 65.04/T + 4.65 - 1.52 \times 10^{-3}T$$

and

$$pK_2 = 4776.61/T - 27.98 + 6.01 \times 10^{-2}T$$

From the temperature coefficient of the ionization constants, the standard enthalpy, entropy, Gibbs energy, and heat capacity changes of the corresponding dissociation processes have been calculated. Using the values of ionization constants of adipic acid, the standard potential of the $Ag(s)/Ag_2Ad(s)/Ad^{2-}$ electrode, and the related standard thermodynamic quantities for the electrode process

$$Ag_2Ad(s) + 2e \rightleftharpoons 2Ag(s) + Ad^{2-}(solvated)$$

have been calculated in water at those temperatures.

UPENDRA NATH DASH et UTTAM KUMAR NAYAK. Can. J. Chem. **58**, 323 (1980).

On a déterminé la constante d'ionisation K de l'acide crotonique *trans* ainsi que les constantes de première et de deuxième ionisation K_1 et K_2 de l'acide adipique en solution aqueuse et à 7 températures différentes allant de 15 à 45°C. On a fait ces déterminations au moyen de cellules sans pont de jonction liquide et en utilisant des électrodes d'argent – chlorure d'argent et de quinhydrone. Les variations de pK, pK_1 et pK_2 en fonction de la température sont représentées par les équations suivantes:

$$pK = 105.54/T + 4.47 - 2.26 \times 10^{-2}T$$

$$pK_1 = 65.04/T + 4.65 - 1.52 \times 10^{-3}T$$

$$pK_2 = 4776.61/T - 27.98 + 6.01 \times 10^{-2}T$$

A partir du coefficient de température et des constantes d'ionisation, on a calculé, l'enthalpie normale, l'entropie, l'énergie de Gibbs et les variations de la capacité calorifique des réactions de dissociation correspondantes. En utilisant les valeurs des constantes d'ionisation de l'acide adipique, on a déterminé en solution dans l'eau et dans le même intervalle de température: le potentiel normal de l'électrode $Ag(s)/Ag_2Ad(s)/Ad^{2-}$ et les quantités thermodynamiques relatives à la réaction de l'électrode

$$Ag_2Ad(s) + 2e \rightleftharpoons 2Ag(s) + Ad^{2-}(solvaté)$$

[Traduit par le journal]

Introduction

Until quite recently, no work seems to have been done on the determination of ionization constants of *trans*-crotonic and adipic acids in aqueous medium over a range of temperature. A survey of the literature (1–3*a*, 4), however, shows that the pK values of these acids have been reported in water at 25°C, and the values of ΔH^0 and ΔS^0 are available (2, 5) at this temperature. The present work has been undertaken as a part of our programme of determining the ionization constants and the related thermodynamic quantities of organic acids in aqueous and mixed solvent media.

Electromotive force measurements of cells of the type

[A] $Ag,AgCl(s)/KCl(m_3),KA(m_2),HA(m_1),QH_2\text{–}Q/Pt$

[B] $Ag,AgCl(s)/KCl(m_3),KHAd(m_2),H_2Ad(m_1),QH_2\text{–}Q/Pt$

and

[C] $Ag,AgCl(s)/KCl(m_3),K_2Ad(m_2),KHAd(m_1),QH_2\text{–}Q/Pt$

where A stands for *trans*-crotonate ion, and Ad for adipate ion, were made in water at seven temperatures ranging from 15 to 45°C for determining the ionization constant of *trans*-crotonic and the first and second ionization constants of adipic acid, respectively.

Although the electrodes of the type, $Ag/Ag_2X(s)/X^{2-}$, where X^{2-} stands for oxalate, malonate, succinate, or chromate ion, have been studied by the authors (6–9) in aqueous, non-aqueous, and mixed media, the behaviour of the silver – silver adipate

electrode has not yet been studied in aqueous medium. The present work, therefore, aims at determining the standard potential of this electrode in water at different temperatures. The cell of the type

[D] Pt/QH_2–$Q,H_2Ad(m)/Ag_2Ad(s)/Ag$

was used for this purpose.

Experimental

trans-Crotonic acid (Fluka AG, Buchs SG 574253) was crystallised from boiling conductivity water, dried at 60°C for 2 h, and kept in a vacuum desiccator over anhydrous calcium chloride. Adipic acid (G.R., Proanalysis) was used without further purification. Potassium salts of *trans*-crotonic and adipic acids were prepared by the method similar to that described elsewhere (10, 11). The salts were dried at 110–120°C and stored in vacuum desiccator over anhydrous calcium chloride. Potassium chloride (BDH, AnalaR) was dried above 100°C and stored *in vacuo*. Quinhydrone and silver – silver chloride electrodes were prepared by the method similar to that described earlier (12, 13).

Silver adipate was prepared by adding silver nitrate (BDH, AnalaR) solution (0.2 mol dm^{-3}) slowly to equal volume of potassium adipate solution (0.11 mol dm^{-3}). The precipitate formed was carefully washed by decantation with conductivity water and stored in an amber-coloured glass-stoppered bottle for subsequent use.

Silver oxide was prepared by the method described elsewhere (14).

Silver – silver adipate electrode was prepared by the method similar to that of the silver – silver oxalate electrode (6). After preparation, the electrodes were stored in a 0.05 mol dm^{-3} aqueous solution of adipic acid for about 24 h and then rinsed with the cell solution containing adipic acid before use. Only those electrodes showing a potential difference of 0.1 mV or less when mutually compared with each other were used.

The cell vessels were of the type recommended by Harned and Wright (15).

Solutions for emf measurements were prepared in conductivity water. The cell measurements were carried out with electrodes set up as described earlier (6, 12, 16).

Results and Discussion

The method of calculation of the ionization constants of mono- and di-basic acids has been adequately described (6, 10, 11, 16).

The ionization constant, K, of *trans*-crotonic acid, or the first ionization constant, K_1, of adipic acid, corresponding to the equilibrium

$$H_xA + \text{solvent} \rightleftharpoons H^+(\text{solvated}) + H_{x-1}A^-(\text{solvated})$$

where A is the *trans*-crotonate ion when $x = 1$, and adipate ion when $x = 2$, is defined as

$$[1] \quad K \text{ or } K_1 = \frac{m_{H^+} m_{H_{x-1}A^-}}{m_{H_xA}} \frac{\gamma_{H^+}\gamma_{H_{x-1}A^-}}{\gamma_{H_xA}}$$

where m and γ are the molality and activity coefficient, respectively.

The "apparent" hydrogen ion molality, m_{H^+}' is related to the emf E of the cell [A] or [B] through the relation (16),

$$[2] \quad -\log m_{H^+}' = \frac{(E - E^0)F}{2.3026RT} + \log m_{Cl^-} - \frac{2A(Id_0)^{1/2}}{1 + a^0B(Id_0)^{1/2}}$$

where I and d_0 are the ionic strength of the solution and density of the solvent, respectively, and a^0 is the ion-size parameter. As a first approximation I was taken to be equal to $m_2 + m_3$ but subsequently an accurate value was obtained by successive approximation and refinement to a constant value of I ($\simeq m_2 + m_3 + m_{H^+}'$). The "apparent" ionization constant K' (for *trans*-crotonic acid) or K_1' (for the first ionization step of adipic acid) was calculated from the expression

$$[3] \quad \log K' \text{ or } \log K_1' = -\frac{2A(Id_0)^{1/2}}{1 + a^0B(Id_0)^{1/2}} + \log \frac{m_{H^+}'(m_2 + m_{H^+}')}{(m_1 - m_{H^+}')}$$

The true ionization constants, K and K_1, were obtained from the intercepts of the log K' vs. I, and log K_1' vs. I plots, respectively.

The second ionization constant, K_2, of adipic acid corresponding to the equilibrium

$$HAd^- + \text{solvent} \rightleftharpoons H^+(\text{solvated}) + Ad^{2-}(\text{solvated})$$

is given by

$$[4] \quad K_2 = \frac{m_{H^+} m_{Ad^{2-}}}{m_{HAd^-}} \frac{\gamma_{H^+}\gamma_{Ad^{2-}}}{\gamma_{HAd^-}}$$

and the "apparent" second ionization constant, K_2', was calculated from the expression

$$[5] \quad -\log K_2' = \frac{(E - E^0)F}{2.3026RT} + \log\left(\frac{m_1 m_3}{m_2}\right) + \frac{2A(Id_0)^{1/2}}{1 + a^0B(Id_0)^{1/2}}$$

where m_1 is the molality of HAd^-, m_2 is the molality of Ad^{2-}, and m_3 is the molality of Cl^- used in the cell [C], E is the observed emf of the cell, and I is the ionic strength of the solution given by

$$[6] \quad I = m_1 + 3m_2 + m_3$$

The second ionization constant was obtained by linear extrapolation to zero ionic strength ($I = 0$) of the function, $-\log K_2'$.

The values of E^0(Ag,AgCl), $E^0(QH_2$–$Q)$, the Debye–Hückel constants, and density, d_0, of the solvent needed for the calculation of log K', log

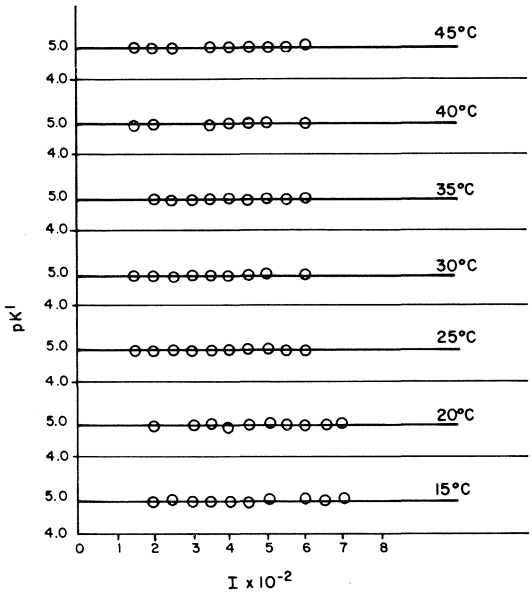

FIG. 1. Plot of $-\log K'$ versus ionic strength for *trans*-crotonic acid at different temperatures.

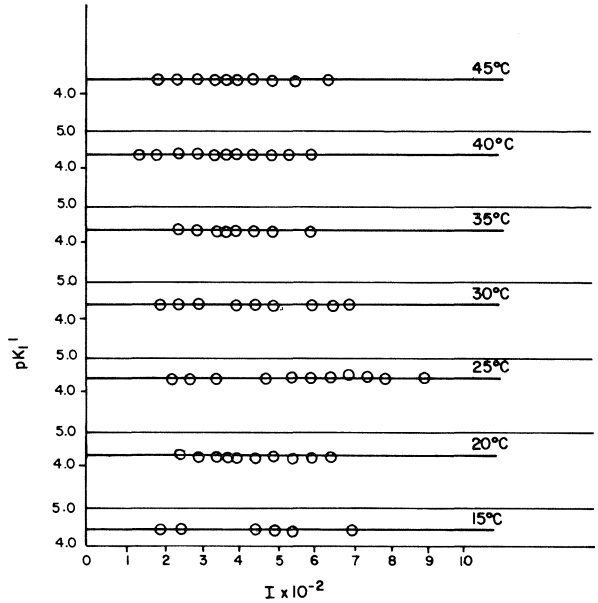

FIG. 2. Plot of $-\log K_1'$ versus ionic strength for the first step ionization process of adipic acid at different temperatures.

K_1', or $\log K_2'$ at different temperatures were obtained from the literature (17, 18). The values of the ion-size parameter a^0 were obtained by the method described earlier (16), and taken to be 0.6 and 0.55 nm for *trans*-crotonic and adipic acid, respectively.

The values of $\log K'$, $\log K_1'$, and $\log K_2'$ thus calculated were found to vary linearly with I (Figs. 1–3) for different temperatures and the linear extrapolation to $I = 0$ of values of $\log K'$, $\log K_1'$, or $\log K_2'$ yielded $\log K$, $\log K_1$, or $\log K_2$, respectively, for *trans*-crotonic and adipic acids. These values are presented in Table 1. The standard deviations calculated by the least-squares method are also shown in Table 1.

The standard molal potential, E_m^0 of silver – silver adipate electrode was obtained by the method of extrapolating (6, 8) the auxiliary function, $E^{0\prime}$, given by

$$[7] \quad E^{0\prime} = E + \left(\frac{2.3026RT}{2F}\right)\left(\frac{-6A(Id_0)^{1/2}}{1 + a^0B(Id_0)^{1/2}}\right) + \left(\frac{2.3026RT}{2F}\right)[2\log\{m\alpha(1+\beta)\} + \log(m\alpha\beta)]$$

to ionic strength, $I = 0$, where E is the observed emf of cell [D], m is the molality of adipic acid solution, and α and β are the degrees of first and second ionization constants of adipic acid, respectively, defined by the expressions

$$[8] \quad \alpha = \frac{[-K_1 + (K_1^2 + 4mK_1)^{1/2}]}{2m}$$

and

$$[9] \quad \beta = \frac{\{-(m\alpha + K_2) + [(m\alpha + K_2)^2 + 4m\alpha K_2]^{1/2}\}}{2m\alpha}$$

and the ionic strength I is given by

$$[10] \quad I = m\alpha(1 + 2\beta)$$

Using the K_1 and K_2 values of adipic acid obtained at different temperatures from emf measurements just described, the degrees of ionization α and β of adipic acid at the corresponding temperature were computed following a reiteration procedure. The values of E_m^0 are also included in Table 1 along with their standard deviations obtained by the least-squares method.

The variation of pK of *trans*-crotonic acid, pK_1 and pK_2 of adipic acid, and E_m^0 of the silver – silver adipate electrode with temperature has been expressed by the equations

$$[11] \quad \text{p}K = 105.54/T + 4.47 - 2.26 \times 10^{-2}T$$

$$[12] \quad \text{p}K_1 = 65.04/T + 4.65 - 1.52 \times 10^{-3}T$$

45	4.792±0.020	4.368±0.009	6.174±0.026	0.4194±0.0004

TABLE 2. Values of ΔG^0, ΔH^0, ΔS^0, and ΔC_p^0 for the ionization processes of *trans*-crotonic and adipic acid and the electrode process of the silver – silver adipate electrode in water at 25°C

Process	ΔG^0 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J deg^{-1} mol^{-1})	ΔC_p^0 (J deg^{-1} mol^{-1})
$HA \rightleftharpoons H^+ + A^-$	10.90	40.43	172.23	257.77
$H_2Ad \rightleftharpoons H^+ + HAd^-$	25.20	3.83	−71.72	17.34
$HAd^- \rightleftharpoons H^+ + Ad^{2-}$	34.03	−10.78	−150.36	−686.11
$Ag_2Ad(s) + 2e \rightleftharpoons 2Ag(s) + Ad^{2-}$	44.61	55.26	35.75	—

[13] $pK_2 = 4776.61/T - 27.98 + 6.01 \times 10^{-2}T$

and

[14] $E_m^0 = 0.4626 - 1.92 \times 10^{-3}(t - 25) - 1.42 \times 10^{-5}(t - 25)^2$

respectively, where T and t are the temperatures in K and °C, respectively.

The values obtained for the standard thermodynamic quantities, ΔG^0, ΔH^0, ΔS^0, and ΔC_p^0 associated with the reactions investigated are listed in Table 2.

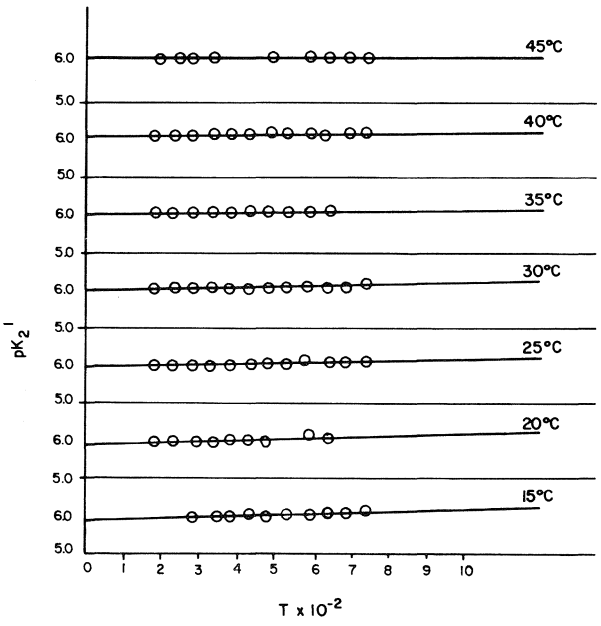

FIG. 3. Plot of − log K_2' versus ionic strength for the second step ionization process of adipic acid at different temperatures.

Since this work constitutes the first attempt to measure thermodynamic ionization constants for *trans*-crotonic and adipic acids in aqueous medium over a range of temperature using galvanic cells, a direct comparison with the results of other works is not possible. However, different values of dissociation constants for *trans*-crotonic and adipic acids are reported by various workers at 25°C. The values that have been reported earlier for *trans*-crotonic acid, pK = 4.698(1) and 4.686(4), and adipic acid, pK_1 = 4.418(5), 4.43(5), and 4.42(4), and pK_2 = 5.412(5), 5.42(5), and 5.277(3) at 25°C were determined from the studies of calorimetric and conductometric measurements. The different values of pK for *trans*-crotonic acid and pK_1 for adipic acid are in reasonably good agreement with each other, but the value pK_2 = 5.277 for adipic acid is found to be widely discrepant from the other values. The constants reported in Table 1 are somewhat higher than the constants reported earlier at 25°C excepting the pK_1 value for adipic acid. This discrepancy might be due to the use of ion-size parameter, a^0, in the calculation of pK values in the present work which was not considered in the previously reported values of pK of the investigated acids, since according to eq. [3] the pK is dependent on the ion-size parameter, and the pK values are expected to be higher than that calculated without considering the ion-size parameter (*3b*). Since the cells of the type [A], [B], and [C] have been employed satisfactorily for determination of pK values of a number of weak acids (19) and

the ion-size parameter was ascertained by following the method of Roy, Robinson, and Bates (20), it is believed that the present set of data is more trustworthy.

Constituents from *Salmalia malabaricum*

J. S. CHAUHAN, M. SULTAN, AND S. K. SRIVASTAVA
Chemical Laboratories, University of Allahabad, Allahabad, India

Received January 18, 1979

J. S. CHAUHAN, M. SULTAN, and S. K. SRIVASTAVA. Can. J. Chem. **58**, 328 (1980).

The phytochemical investigation of the root of *Salmalia malabaricum* has resulted in the isolation and identification of *n*-triacontanol, β-sitosterol, and a new glycoside which was characterized as 5,7,3′,4′-tetrahydroxy-6-methoxyflavan-3-*O*-β-D-glucopyranosyl-α-D-xylopyranoside on the basis of spectral and degradative studies.

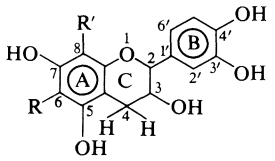
J. S. CHAUHAN, M. SULTAN et S. K. SRIVASTAVA. Can. J. Chem. **58**, 328 (1980).

La recherche phytochimique entreprise sur la racine du "*Salmalia malabaricum*" a permis d'isoler et d'identifier le *n*-triacontanol, le β-sistostérol et un nouveau glycoside que l'on a caractérisé comme étant l'α-D-xylopyrannoside du tétrahydroxy-5,7,3′,4′ méthoxy-6 flavan-3-*O*-β-D-glucopyranoxyle. Cette caractérisation est basée sur les études de dégradation et sur l'analyse spectrale.
[Traduit par le journal]

Introduction

Salmalia malabaricum (syn. *Salmalia malabarica*; Bombacaceae) is a member of a genus of highly medicinal plants (1, 2), especially in the indigenous system of medicine. The root of this plant has been found to contain proteins, fatty matter, tannins, sugars, starch, and a monogalactan (3). The products isolated from its stem bark include lupeol and β-sitosterol (4).

The ethanolic extract of the root of this plant afforded three compounds, compound A, mp 70–72°C, compound B, mp 185°C (dec.), and compound C, mp 135–136°C.



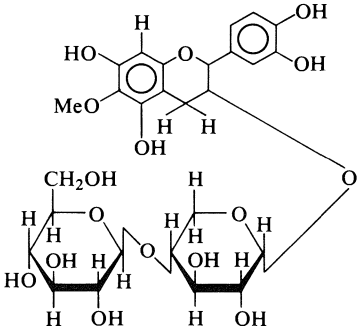
Results and Discussion

The alcoholic extract of the plant material on concentration afforded a white deposit (compound A) mp 80–82°C. It was characterized as *n*-triacontanol by its mp, ir, ^{1}H nmr, ms, oxidative degradation studies, and also by co-thin layer chromatography and superimposable ir spectra with an authentic sample.

The water-soluble portion of the alcoholic extract on extraction with ethyl acetate gave a compound B, $C_{27}H_{34}O_{16}$. This gave reactions characteristic of a catechin glycoside. The acid hydrolysis of the glycoside resulted in the isolation of one mol each of xylose and glucose and a flavan aglycone.

The aglycone, $C_{16}H_{16}O_7$, mp 176–177°C was found to contain five hydroxyl groups (penta-acetate; ir (KBr): 3340) and one methoxyl group (Zeisel; ir (KBr): 2832–2815 and 1190). The oxidative degradation of the aglycone with $KMnO_4$ yielded protocatechuic acid as one of the products, thereby confirming the presence of two hydroxyl groups at 3′ and 4′ positions in the ring B. The aglycone on alkaline degradation with 50% KOH gave two products which were identified as methoxyphloroglucinol and protocatechuic acid. The formation of these products in the degradation reactions could be explained by either of two possible structures of the aglycone.

Out of these two possibilities, the structure **1** was assigned to the aglycone on the basis of alkaline degradation of the completely methylated aglycone when antiarol (3,4,5-trimethoxyphenol) and veratric acid were obtained as the products of degradation. Only the structure **1** could furnish antiarol.



1 R = OCH_3, R′ = H
2 R = H, R′ = OCH_3

The periodate oxidation results showed the consumption of 3.1 mol of periodate with the liberation of 1.2 mol of formic acid per mole of the glycoside, thereby suggesting the presence of a disaccharide unit in pyranose form with either 1 → 4 or 1 → 2 linkage. The acid hydrolysis of the completely methylated glycoside gave 2-3-di-*O*-methyl xylose and 2,3,4,6-tetra-*O*-methyl glucose, indicating the sugars to be in pyranose form and that the disaccharide is glucopyranosyl xylose, C1 of glucose being linked to C4 of xylose. The glycoside on emulsin hydrolysis gave only glucose in the hydrolysate suggesting it to be terminal and β-linked with the other sugar moiety. The subsequent ready hydrolysis of this product with enzyme diastase to yield xylose confirmed the presence of an α-linkage between the aglycone and the xylose. The aqueous

For personal use only.

hydrolysate from partial hydrolysis of the glycoside with 1% HCl showed first the appearance of glucose, further suggesting its position to be terminal in the disaccharide unit. The location of the linkage of the sugar moiety in the glycoside was deduced to be at 3 in ring C from the study of the colour reactions (6–10), and further supported by the alkaline degradation of the completely methylated glycoside when antiarol and veratric acid were obtained. Thus keeping all the facts in view, the compound B has been assigned 5,7,3′,4′-tetrahydroxy-6-methoxyflavan-3-*O*-β-D-glucopyranosyl-α-D-xylopyranoside structure (**3**).

3

The water-insoluble fraction of the alcoholic extract on extraction with petroleum ether (40–60°C) gave a compound C which was characterized as β-sitosterol by ir, ^{1}H nmr, ms, acetyl and benzoyl derivatives, superimposable ir spectra, and co-thin layer chromatography with an authentic specimen.

Experimental

Melting points are uncorrected. Column, thin-layer, and paper chromatographic analyses were performed at room temperature. Sugars were characterized spectrophotometrically by PhOH–H_2SO_4 method (11, 12) using a Klett-Summerson photoelectric colorimeter and also by Whatmann filter paper No. 1, descending paper chromatography using butanol – acetic acid – water (4:1:5 v/v) as a developing solvent and aniline hydrogen phthalate for revealing the spots.

Plant Material

The root of *Salmalia malabaricum* was obtained from the local city, Allahabad, and was identified by the Botanical Survey of India, Allahabad.

Isolation Procedures

The air-dried and powdered root (2 kg) of *S. malabaricum* was extracted with EtOH under reflux for 20 days. The extract on refrigeration gave a white deposit (compound A) which was filtered and the filtrate concentrated in a Rotavapour to 100 mL. It was then poured into excess of distilled water (500 mL). The water-insoluble material was filtered off and the residue was extracted with a number of increasingly polar organic solvents. The petroleum ether fraction gave the compound C in a workable yield. The filtrate on extraction with EtOAc gave compound B.

Structural Determination

Compound A

The white deposit obtained by concentrating the alcoholic extract on column chromatography over neutral alumina and elution with petroleum ether – benzene (1:1 v/v) gave a solid which on crystallization ($CHCl_3$–MeOH, 1:3 v/v), furnished *n*-triacontanol, mp 80–82°C (lit. (5*e*) mp 86.5°C), acetate (Ac_2O/Pyridine) mp 66°C (lit. (5*e*) mp 69°C); ir (KBr): 3333, 2920, 2850, 1460, 1430, 1378, 1064 and 1124, 735, 724; ^{1}H nmr ($CDCl_3$) δ: 0.95 (1-CH_3), 1.25 (28-CH_2), 1.6 (—CH_2OH), and 4.24 (1-H, OH); ms *m/e*: 438 (M^+), 420, 393, 56, 55, 43, 41, 29, etc. The compound on oxidation with HNO_3 gave an acid, mp 92–93°C (lit. (5*e*) mp 93.5–94°C), which was identified as *n*-triacontanoic acid by co-paper chromatography and neutralization equivalent (13). Thus from the above data, the compound A was identified as *n*-triacontanol and confirmed by co-thin layer chromatography and superimposable ir spectra.

Compound B

The ethyl acetate extract of the water-soluble portion was purified over a column of silica gel and was crystallized as yellow needles from petroleum ether – EtOAc, mp 185°C (dec.). The homogeneity of the compound was checked by thin-layer as well as paper chromatography in different solvent systems. *Anal.* calcd. for $C_{27}H_{34}O_{16}$: C 52.77, H 5.58; found: C 52.66, H 5.47. The compound B gave positive Molische test but it neither reduced Fehlings solution nor gave colouration with aniline hydrogen phthalate reagent, thereby indicating its glycosidic nature. The colour reactions exhibited by the compound B, viz. yellow colouration with NaOH, dark red colouration with concentrated H_2SO_4, formation of a brown product soluble in isoamyl alcohol with concentrated HCl, yellow spot with *p*-toluene sulphonic acid, together with an absorption peak at λ_{max} 280 nm in the uv region, suggested the possibility of the compound being a catechin glycoside. The infrared spectrum of the sample (KBr) showed peaks at 3333, 2900, 2850, 1613, 1536, 1450, 1282, 1120, 825, and 769 cm^{-1}.

Acid Hydrolysis

The glycoside (500 mg) was hydrolysed with boiling 7% ethanolic H_2SO_4 (50 mL) for 6 h. After cooling, the contents were diluted to 50% with H_2O. The precipitated aglycone was separated by filtration. The aqueous solution was neutralized ($BaCO_3$), filtered, and evaporated under reduced pressure to a syrup which was found to contain xylose and glucose by paper co-chromatography with authentic samples. These were separated by column chromatography on cellulose in *n*-butanol – isopropanol – H_2O (11:6:3) (14) and characterized: xylose; osazone and *p*-nitrophenylhydrazone, mp and mixture mp, 158 and 156°C respectively; glucose; osazone and *p*-nitrophenylhydrazone, mp and mixed mp 204–205 and 184–186°C respectively. Quantitative analyses (15) revealed the presence of 1 mol of each sugar.

Methylation

The glycoside (600 mg) was methylated according to Kuhn's procedure with CH_3I and Ag_2O in dimethylformamide giving a semisolid. Methanolysis (16) followed by hydrolysis with 5% aqueous HCl at 100°C for 6 h gave the 2,3-di-*O*-methyl derivative of xylose and 2,3,4,6-tetra-*O*-methyl derivative of glucose in 1:1 molar ratio indicating 1 → 4 linkage of xylose to glucose. The aglycone obtained on hydrolysis, was subjected to alkaline degradation when antiarol, mp 145–147°C (lit. (5*b*) mp 148°C) and veratric acid, mp 178–179°C (lit. (5*c*) mp 181°C) were isolated as the products. The formation of antiarol is ample proof for the location of the —OCH_3 group at position 6 in the aglycone of the compound B.

Periodate Oxidation

The glycoside (30 mg) was oxidized by $NaIO_4$ at room temperature in 20 mL of 90% EtOH. A blank was run similarly. Results after 60 h showed the consumption of 3.1 mol of periodate with the liberation of 1.20 mol of formic acid per mol of the glycoside.

Enzymatic Hydrolyses

About 150 mg of the glycoside was suspended in an almond emulsin solution (20 mL) and kept at 45°C for 18 h. The sugar (50 mg) was separated from hydrolysate by preparative partition chromatography and was found to be only glucose (1 mol) as determined by colorimetry (12). Appearance of only glucose in this hydrolysate indicated it to be terminal and β-linked with xylose. Hydrolysis of the glycoside (100 mg) with diastase gave a disaccharide. This disaccharide when hydrolysed with acids or emulsion afforded two sugars characterized as xylose and glucose. This indicated that the disaccharide consisting of glucose and xylose is linked with the aglycone through an α-linkage.

Partial Hydrolysis

The glycoside (15 mg) was dissolved in dioxane (5 mL) containing HCl (1%) and allowed to stand at room temperature. Aliquots were taken at different intervals and examined by paper chromatography. The results indicated that glucose was liberated after 72 h while xylose appeared after 120 h.

Characterization of the Aglycone

The aglycone was purified by paper chromatography and crystallized from EtOAc – petroleum ether mixture as brown-yellow needles, mp 176–177°C. The homogeneity was checked by tlc and paper chromatography in different organic solvents; ir (KBr): 3350, 2900, 2870, 1615, 1460, 1280, 1125, and 770 cm^{-1}. *Anal.* calcd. for $C_{16}H_{16}O_7$: C 60.00, H 5.04; found: C 59.96, H 5.05.

Acetylation and Acetyl Percentage Determination

A sample of 50 mg of the aglycone was acetylated using Ac_2O (2 mL) and pyridine (5 mL) by the usual method. The acetyl derivative was crystallized from methanol, mp 120°C. The percentage of the acetyl groups in the acetylated product was determined by the method of Wiesenberger (17) as described by Belcher and Godbert (18). *Anal.* calcd. for $C_{26}H_{26}O_{12}$: C 58.87, H 4.94, acetyl 40.52; found: C 58.79, H 4.85, 5 × acetyl 40.56.

Methoxyl Percentage Determination

The percentage of methoxyl group in the aglycone (20 mg) was determined by Zeisel's method as described by Belcher *et al.* (19). *Anal.* calcd. for $C_{15}H_{13}O_6$: —OMe 9.40; found: —OMe 9.38.

$KMnO_4$ Oxidation

The aglycone (20 mg) was dissolved in acetone and oxidized with 10% $KMnO_4$ solution (30 mL) on a water bath for 4 h. The reaction mixture was cooled, sodium bisulphite added, and shaken with ether. The ethereal layer was then shaken with aqueous $NaHCO_3$. The bicarbonate solution was acidified with HCl and finally shaken with ether. The ethereal solution gave a product which was identified as protocatechuic acid, mp 196–197°C (lit. (5*a*) mp 199°C) and mixed mp.

KOH Degradation

A solution of aglycone (200 mg) in ethanolic KOH (50%, 10 mL) was refluxed for 10 h following the method of Briggs and Locker (20). The reaction mixture on cooling gave a precipitate (P) which was filtered. CO_2 was bubbled through the filtrate and the mixture again filtered. This filtrate was acidified with dilute HCl and extracted with ether to give a residue which on crystallization yielded protocatechuic acid, mp and mixed mp 196–197°C. The precipitate (P) in H_2O on acidification with dilute HCl and extraction with ether gave a crystalline solid which was identified as methoxyphloroglucinol (Iretol), mp 182–183°C (lit. (5*f*) mp 186°C) and by mixed mp and co-chromatography.

Compound C

The petroleum ether extract of the water-insoluble portion, on column chromatography over neutral alumina and elution with benzene–chloroform (3:1 v/v), gave an amorphous compound which on crystallization (benzene–chloroform, 3:2 v/v) gave white needles, mp. 135–136°C (lit. (5*d*) mp 136–137°C). It showed bluish-violet colouration with Liebermann-Burchardt reagent (21); ir (KBr): 3440 and 1649; ms *m/e*: 414 (M^+), 396, 273, and 255. It formed an acetate, mp 128°C (lit. (5*d*) mp 134°C), and benzoate, mp 142°C (lit. (5*d*) mp 145.5°C). The identity of the compound as β-sitosterol (22) was established by mixed mp, co-thinlayer chromatography, and co-ir with an authentic specimen of β-sitosterol.

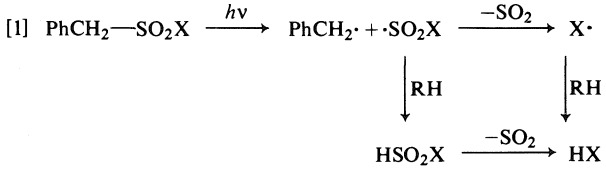
Received August 15, 1979

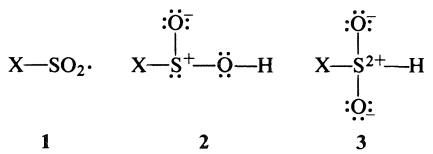
RUSSELL J. BOYD, ABHA GUPTA, RICHARD F. LANGLER, STEPHEN P. LOWNIE, and JAMES A. PINCOCK. Can. J. Chem. **58**, 331 (1980).

Extensive *ab initio* molecular orbital calculations on six sulfonyl radicals (XSO_2 where X = H, CH_3, NH_2, OH, F, and Cl), the simplest sulfinic acid HSO_2H[3] and its isomeric sulfone H_2SO_2, the HSO_2^- anion of sulfinic acid, the isomeric anion SO_2H^-, and for completeness, the SO_2H radical are presented. By use of the STO-3G* basis set, which includes *d*-type polarization functions on second-row atoms, all geometrical parameters are varied until the total energy is minimized, subject only to certain symmetry restrictions specified for each system. The inclusion of *d* orbitals on S is observed to affect the S—O bond lengths by as much as 0.45 Å. The calculations suggest that the radical site in sulfonyl radicals is significantly delocalized over the entire functional group and that the geometrical parameters of the SO_2 functional group in sulfonyl radicals are nearly independent of the substituent (r(S—O) = 1.47 ± 0.01 Å, < OSO = 123 ± 2°). Estimates of the X—S bond energy in CH_3SO_2, NH_2SO_2, and $OHSO_2$ are consistent with the chemistry of alkylsulfonyl and aminosulfonyl radicals and lead to an interesting prediction for alkoxylsulfonyl radicals. Furthermore the calculations yield lower total energies for HSO_2H, HSO_2^-, and SO_2H than for the respective isomeric forms H_2SO_2, SO_2H^-, and HSO_2.



RUSSELL J. BOYD, ABHA GUPTA, RICHARD F. LANGLER, STEPHEN P. LOWNIE et JAMES A. PINCOCK. Can. J. Chem. **58**, 331 (1980).

On présente les calculs *ab initio* approfondis d'orbitales moléculaires de six radicaux sulfonyles (XSO_2 où X = H, CH_3, NH_2, OH, F et Cl) de l'acide sulfonique le plus simple HSO_2H,[3] de sa sulfone isomère H_2SO_2, de l'anion HSO_2^- de l'acide sulfinique, de l'anion isomère SO_2H^- et pour compléter du radical SO_2H. Par l'utilisation de l'ensemble de base STO-3G* qui inclut les fonctions de polarisation de type *d* des atomes de la deuxième rangée, on a fait varier tous les paramètres géométriques jusqu'à ce que la quantité totale d'énergie soit minimale, tout en étant assujetie seulement à certaines restrictions de symétrie spécifiées pour chaque système. On observe que l'inclusion des orbitales *d* du soufre affecte les longueurs de liaison S—O d'environ 0.45 Å. Les calculs suggèrent que les sites des radicaux sulfonyles sont délocalisés de façon significative sur tout le groupe fonctionnel et que les paramètres géométriques du groupe fonctionnel SO_2 des radicaux sulfonyles sont presqu'indépendants des substituants (r(S—O) = 1.47 ± 0.01 Å, ∠OSO = 123 ± 2°). Les évaluations de l'énergie de liaison X—S dans CH_3SO_2, NH_2SO_2 et $OHSO_2$ sont en corrélation avec la chimie des radicaux alkylsulfonyles et aminosulfonyles et conduisent à des prédictions intéressantes au sujet des radicaux alkylsulfonyles. De plus, dans le cas de HSO_2H, HSO_2^- et SO_2H les calculs conduisent à des énergies totales plus faibles que celles obtenues pour les formes isomères H_2SO_2, SO_2H^- et HSO_2.



[Traduit par le journal]

Introduction

The photochemistry of benzylsulfonyl systems is characterized by homolytic cleavage of the C—S bond to benzyl and sulfonyl radicals (1). This is apparently general. However the products are variable because the fate of the sulfonyl radical depends on the nature of X and the H-atom donating ability of the solvent. If the sulfonyl radical readily loses SO_2, then hydrogen abstraction leads to HX. On the other hand if SO_2 is not readily lost, hydrogen abstraction leads to the corresponding sulfinic acid. Clearly the relative amounts of the two products are determined by the ease of loss of SO_2 from the sulfonyl radical and the relative stability of the sulfinic acid to desulfonylation.

In this paper we report the results of *ab initio* MO calculations on some simple models of the radicals and molecules shown in eq. [1]. In particular, extensive calculations on the sulfonyl radical **1**, the sulfinic acid **2**, and the sulfone **3** where X = H have been completed.

The calculations have been extended to include the bond strength of the X—S bond in **1** where X = H, CH_3, NH_2, OH, F, and Cl. For completeness several species derived from **2** are included.

Method

Standard single determinant *ab initio* molecular orbital theory was used in this work. Singlet states were treated by the closed-shell, spin-restricted Hartree–Fock (RHF) procedure (2) and the doublet ground states of radicals were treated by use of the spin-unrestricted (UHF) procedure (3).

The STO-3G* basis set (4) was used for all species containing second-row elements. In this basis set, a manifold of five *d*-type functions, consisting of one second-order Gaussian each, is added to the minimal STO-3G basis for second-row atoms only. For hydrogen and first-row elements, a minimal basis having one Slater-type orbital (STO), approximated by three Gaussian functions (5), for each canonical atomic orbital completes the STO-3G* basis. For species which do not contain one or more second-row elements the minimal STO-3G basis (5) was used. Although very much better basis sets, such as the 6-31G** (6), are available for some of the cases of interest in this study, the same basis set is used for a given atom throughout. Thus the energy change for the process shown in eq. [2] is estimated by use of the STO-3G* basis

[2] $CH_3SO_2\cdot \rightarrow CH_3\cdot + SO_2$

set for $CH_3SO_2\cdot$ and SO_2 and the STO-3G basis set for $CH_3\cdot$. Clearly, the methyl radical would be expected to be described more accurately by an extended basis set but this would require an identical extension of the basis set for $CH_3SO_2\cdot$ and lead to a prohibitive increase in the computations.

All the results reported in this paper were obtained by use of the GAUSSIAN 76 program (7). Some preliminary results on **1**, **2**, and **3** where X = H were obtained by use of PHANTOM (8), a CDC-oriented version of POLYATOM.

A full geometry optimization, subject to assumed symmetry constraints,[4] was carried out for each structure. This involves variation of all bond lengths and angles until variations of the order of 0.001 Å and 0.1° lead to no further lowering of the total energy. In a few cases the possibility of a lower symmetry was ruled out by appropriate calculations.

Before discussing the results, one important point should be made in connection with the choice of the basis set. Initially we intended to use the STO-3G basis set to minimize the total energy with respect to all geometrical parameters and then to use the final STO-3G geometry to carry out single calculations with a larger basis set to obtain the final energies. This approach has been used extensively in many applications by Pople and his co-workers (9). However our first few calculations showed that the S—O bonds are very sensitive to the inclusion of *d* orbitals on S. Indeed omission of the *d* functions leads to S—O bonds as much as 0.45 Å longer than the values reported in this paper. Such differences between STO-3G and STO-3G* geometries are very much greater than in the molecules treated by Pople and co-workers (4). Where comparison with experimental geometries is possible the inclusion of *d* orbitals on sulfur improves the agreement and, therefore, we have reported only the STO-3G* geometries in this paper.

Results and Discussion

Sulfonyl Radicals

The calculated equilibrium geometries of six sulfonyl radicals are illustrated in Fig. 1. Despite the variety of substituents the structural parameters of the SO_2 functional group remain essentially constant: r(S—O) = 1.47 ± 0.01 Å, ∠OSO = 123 ± 2° and a nonplanar arrangement about the sulfur atom. Unfortunately the geometries of sulfonyl radicals are not available from experiment, but it is worth noting that the STO-3G* calculated geometry (4) of SO_2 (r(S—O) = 1.446 Å, ∠OSO = 119.9°) agrees very well with the spectroscopic (10) results (r(S—O) = 1.431, ∠OSO = 119.3°). Relative to SO_2, our MO calculations at the STO-3G* level predict a substantial lengthening of the S—O bond and a small opening of the ∠OSO angle. This reflects the loss of the substantial amount of multiple bonding in SO_2. Even so, the sulfonyl radical bond lengths are substantially shorter than the S—O standard bond length of 1.54 Å and longer than the S=O value of 1.43 Å proposed by Hehre *et al.* (11).

Table 1 reveals the strong preference of the HSO_2 radical for the nonplanar conformation and suggests the possibility of a chiral thiosulfonyl radical in which one of the oxygens of **1** is replaced by a sulfur atom. Inversion not only changes the geometrical parameters but leads to substantial changes in the electronic structure. The fluoro- and chlorosulfonyl radicals also possess a high barrier to inversion.

In order to determine the preferred conformations of **1***b*, **1***c*, and **1***d*, model geometries based on assumed X—S bond lengths and structural parameters from the calculated geometries of HSO_2, CH_3, NH_2, and OH were used to complete a

[4]The point group and number of geometrical parameters optimized for each species are as follows: HSO_2 (**1***a*), C_s (4); CH_3SO_2 (**1***b*), C_s (7, all ∠HCS angles were optimized simultaneously); NH_2SO_2 (**1***c*), C_s (7); $OHSO_2$ (**1***d*), C_1 (9); FSO_2 (**1***e*), C_s (4); $ClSO_2$ (**1***f*), C_s (4); HSO_2H (**2**), C_1 (9); H_2SO_2 (**3**), C_{2v} (4); SO_2H (4), C_1 (6); HSO_2^- (**5**), C_s (4); SO_2H^- (**6**), C_1 (6).

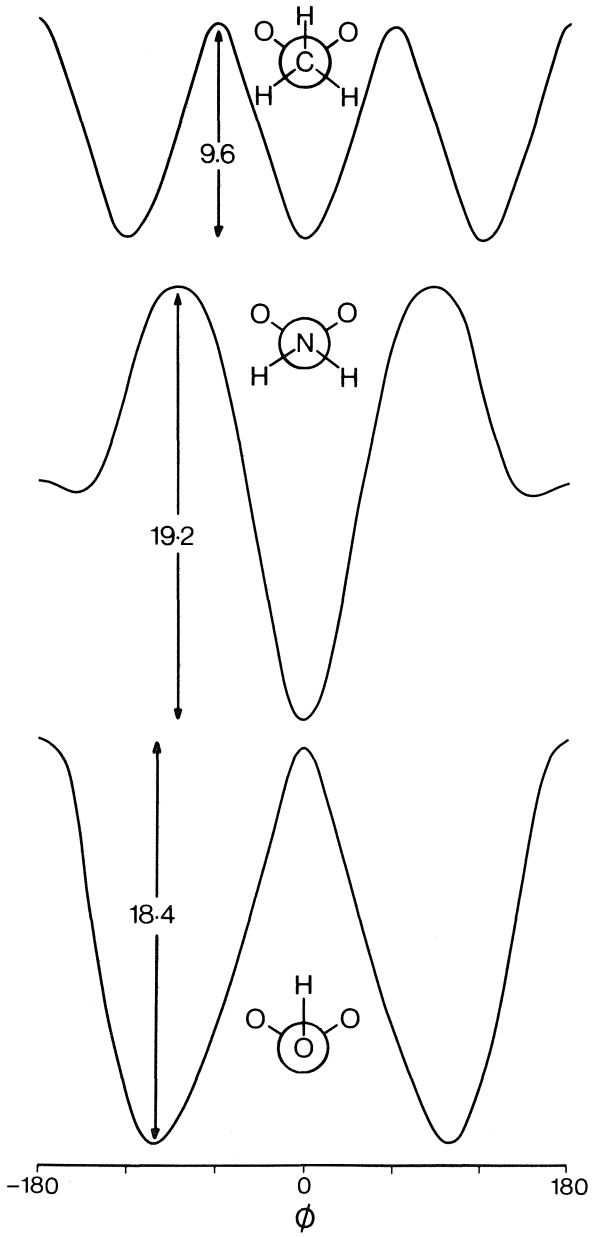
limited potential surface scan for rigid rotation about the X—S bond. The results are shown in Fig. 2. For the methyl- and aminosulfonyl radicals the staggered (C_s) conformations are preferred, while the hydroxylsulfonyl radical prefers an asymmetrical (C_1) conformation to either of the two possible symmetrical (C_s) conformations. Geometry optimization of the preferred conformations leads to the calculated structures shown in Fig. 1. The barriers shown in Fig. 2 refer to rigid rotation only. Optimization of the geometrical parameters at each value of the rotational angle would lower the barriers but would not destroy the qualitative features.



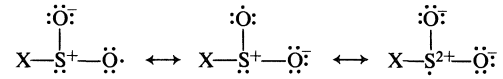


FIG. 2. One-dimensional cross-section of the conformational energy hypersurface of sulfonyl radicals. For each radical the origin of the rotational angle is defined by the conformation illustrated. Rotational barriers are in kJ/mol.

TABLE 2. Total energies and X—S bond properties of sulfonyl radicals

	Radical	Total energy (au)	Bond energy (kJ/mol)	Bond length (Å)	Force constant (mdyn/Å)
1*a*	HSO_2	−541.43082	142.1	1.362	5.3
1*b*	CH_3SO_2	−580.02986	112.2	1.818	4.4
1*c*	NH_2SO_2	−595.77788	74.7	1.713	5.5
1*d*	$OHSO_2$	−615.31484	104.6	1.629	6.7
1*e*	FSO_2	−638.95014	140.5	1.564	8.7
1*f*	$ClSO_2$	−995.49015	88.7	2.039	3.7

The conformations of **1***c* and **1***d* may be discussed in terms of the *gauche* effect (12). Analysis of *ab initio* calculations (13) on FCH_2OH has shown that the *gauche* effect in this molecule is dominated by the interactions between adjacent polar bonds (C—F and O—H) and not by the interactions between a polar bond (C—F) and the two adjacent lone pairs on the O atom. Apparently polar bonds play a similar role in the conformations of sulfonyl radicals. In **1***c* our results indicate a preferred conformation with the N lone pair *gauche* to the two O atoms, while the results for **1***d* correspond to the conformation with the maximum number of *gauche* interactions between the lone pairs of the hydroxyl O and the O atoms of the SO_2 functional group. Here it should be mentioned that the *gauche* effect has been studied in the case of a carbanion adjacent to SO_2 (14).

Before discussing the bond and electronic properties, we wish to comment further on the structure of sulfonyl radicals. In the literature, sulfonyl radicals are often (15) written simply as $RSO_2\cdot$ where the sulfur atom is understood to be bonded to two oxygens as well as substituent R. Evidently a more detailed description has not been proposed. Accordingly we have considered the results of a Mulliken population analysis (16) of the UHF wave functions for the sulfonyl radicals. Some relevant data are shown in Table 1 for the simplest sulfonyl radical. Although population analysis procedures are inherently arbitrary (17), we note that the net atomic charges of +0.33 and −0.21 on S and O, respectively, suggest a substantial polarization of the S—O bonds. Not surprisingly a positive charge is associated with the H atom. In order to comment on the radical site we now consider the spin densities. Bearing in mind that a positive spin density implies an excess of electrons of α spin, we observe significant net spin densities on all atoms, with the radical site appearing to be primarily on the O atoms. However, for the highest occupied MO we find a greater portion of the spin density on S. The difference between the two sets of spin densities is due to the use of an unrestricted wave function. We conclude[5] that the radical site is not on one particular atom but rather it extends over all three atoms of the SO_2 group. In terms of resonance forms, the sulfonyl radical may be represented by three principal contributors:

In view of the lone pair on S in the two equivalent resonance forms, the nonplanar arrangement about S in the sulfonyl radicals is not surprising. Also the formal charges are consistent with the polarity of the S—O bonds (see Table 1). Here it should be emphasized that our conclusion on the radical site is not entirely consistent with an esr study (18) according to which the radical site appears to be mainly centered on sulfur. Nevertheless our conclusion represents a combination of the practice whereby some authors (19) favour a S-centered radical and others (20) an O-centered radical.

The total energies and bond energies, defined by the dissociation process shown in eq. [2], are listed in Table 2 for the sulfonyl radicals included in this work. Although the STO-3G* values for bond energies are not expected to be as accurate as the calculated equilibrium geometries (4, 21, 22), the calculated bond energy of the methyl sulfonyl radical **1***b* agrees fairly well with the experimental value of 97.5 ± 7.5 kJ/mol reported by Busfield *et al.* (23). More recent work (24, 25) favours 84 ± 8 kJ/mol. It is interesting to note that the overestimation by theory in this case parallels a known regularity (22) in the six successive C—H dissociations of ethane to C2: STO-3G, and 4-31G calculations give too small a value for dissociations of a singlet molecule to a radical plus hydrogen atom, whereas the calculations give too large a value for dissociation of a radical. Insufficient thermochemical data prevents a similar analysis for sulfonyl radicals.

Photolysis of benzyl sulfonamides yields aminosulfonyl radicals which lose SO_2 to produce amines

[5]A RHF calculation yields a similar distribution for the unpaired electron.

(26) whereas alkylsulfonyl radicals generated by the photolysis of benzylic sulfones (1) abstract hydrogen to form sulfinic acids **2**. Evidently the C—S bond is stronger than the N—S bond in sulfonyl radicals. This conclusion is supported by the calculations reported in this paper. Here it is interesting to note that the hydroxylsulfonyl radical is predicted to be much more stable with respect to the loss of SO_2 than the aminosulfonyl radical and therefore derivatives of **1***d* would not be expected to produce alcohols as would be the case if the reaction proceeded by analogy with aminosulfonyl radicals which yield amines (26). This prediction regarding the chemistry of alkoxylsulfonyl radicals has not been tested experimentally.

To complete the series of isoelectronic first-row sulfonyl radicals we have included the fluorosulfonyl radical **1***e*. The results in Table 2 indicate that at the STO-3G* level, CH_3SO_2 may be regarded as the special case and not NH_2SO_2 as might be suspected in the absence of the calculations for **1***e*. In agreement with the general trends for sulfur–halogen bonds (27, 28), the bond energy of the chlorosulfonyl radical is predicted to be lower than the FSO_2 value. While direct comparison with experimental S—X bond energies is not possible for all the bonds considered in this work, it is interesting to note that the qualitative trend predicted in Table 2 is reflected by the available data for other series (28). For C—X bonds, the energies are 368, 305, 358, 485, and 327 kJ/mol for C, N, O, F, and Cl, respectively. The H—X bond energies are 411, 386, 459, 565, and 428 kJ/mol for C, N, O, F, and Cl, respectively. Thus in both series the nitrogen value is lower than the carbon and oxygen values.

Table 2 also includes the calculated bond lengths and force constants for X—S bonds. The bond lengths lie within the range of observed values (29, 30) and are surprisingly close to the standard bond lengths proposed by Hehre *et al.* (11). The largest discrepancies occur for N—S where the typical values (29) lie in the range 1.50 to 1.67 Å and O—S where a standard single bond length of 1.54 Å has been proposed (11).

Several electronic properties of sulfonyl radicals are reported in Table 3. The spin density on the oxygen atoms remains close to +0.4 and the net atomic charge at about −0.2. For the latter the largest departure from the mean occurs in $ClSO_2$ and is due to the inclusion of polarization functions on Cl. This anomaly would likely vanish at the Hartree–Fock limit. Even the S atom shows only a little more variation than O. Naturally the substituents show larger variations in electronic properties paralleling the substantial structural differences illustrated in Figs. 1 and 2. On the other hand the SO_2 functional group displays characteristic electronic and structural properties.

[c]This is the average of 0.407 for O2 and 0.353 for O3.

Sulfinic Acid, Sulfone, and Related Species

The STO-3G* calculated geometries of the simplest sulfinic acid, HSO_2H, (**2**), the sulfone, H_2SO_2, (**3**), the SO_2H (**4**) isomer of **1***a*, and the two possible anions, HSO_2^- (**5**) and SO_2H^- (**6**), formed in the dissociative ionization of **2** are summarized in Fig. 3. The corresponding point groups are listed in footnote 4. As in the structure of **1***d*, the S—O bonds of **2**, **4**, and **6** are significantly longer for hydroxyl groups than for terminal oxygen atoms. With the exception of anion **6**, the former are remarkably constant at 1.63 Å while the latter are observed to deviate substantially from the sulfonyl radical values (1.47 ± 0.01 Å). Again there is a paucity of experimental data with which to compare the theoretical structures. Sulfone **3** is not known but several sulfones have been studied by electron diffraction and microwave spectroscopy (30). In particular electron diffraction studies on sulfuryl fluoride (31), SO_2F_2, sulfuryl chloride (32), and dimethyl sulfone (33) have yielded 124.0, 123.5, and 119.7°, respectively, for the ∠OSO angle and 1.405, 1.404, and 1.435 Å, respectively, for the S—O bond length. Although further comparisons with experiment are not possible at present it is

[a]See Fig. 3 for structures.
[b]Atoms correspond to those identified by the subscripts in Fig. 3.
[c]1 au = 627.5095 kcal/mol = 2625.502 kJ/mol.

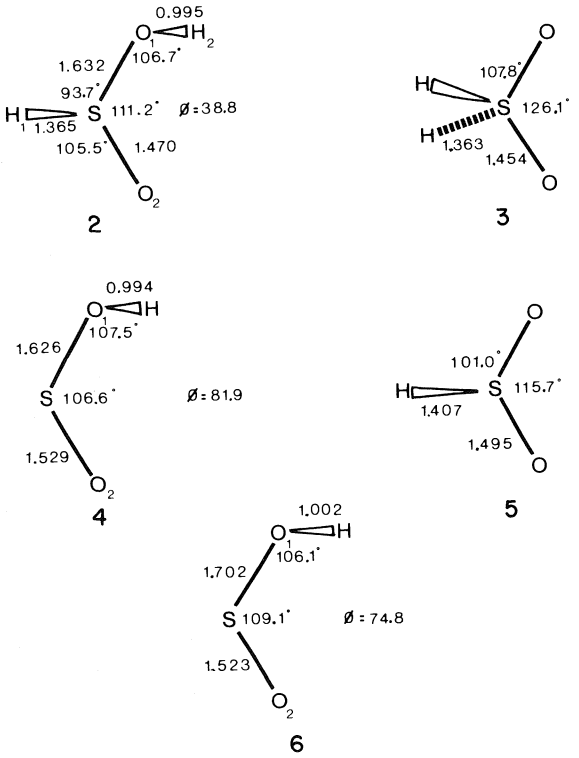

FIG. 3. Calculated geometries of sulfinic acid **2** and related species (bond lengths in Å, angles in degrees). ϕ refers to the $H_2O_1SO_2$ dihedral angle in **2** and to the HO_1SO_2 dihedral angle in **4** and **6**.

interesting to note some trends for the calculated structures. Removal of a hydrogen atom from sulphone **3** does not lead to a large geometry relaxation at S in the sulfonyl radical **1***a*. For the removal of H1 from **2** the only geometrical change is a lengthening of the S—O2 bond in radical **4**. And finally we note that **2**, **4**, and **6** adopt "staggered" conformations in which the dihedral angle differs considerably from the "ideal" 60° angle in ethane. These departures from ideality, which are also evident for the sulfonyl radicals shown in Fig. 1, are due to the low symmetry of the species included in this paper.

One of the objectives of our calculations was to compare the relative stabilities of the simplest sulfinic acid and its isomeric sulfone. From Table 4 it is clear that at the STO-3G* level the sulfinic acid **2** is predicted to be more stable by about 98.7 kJ/mol. Of course, our MO calculations pertain to the gas phase whereas sulfones and sulfinic acids are prepared in solution (1) where the solvent may have a major effect on the relative stabilities of the species of interest. Also the calculations do not account for kinetic factors.

The relatively high positive charge (see Table 4) on H2 of sulfinic acid **2** is consistent with the observed acidity. Loss of a proton at H2 leads to anion **5**. For comparison we have included the isomeric anion **6** formed by the dissociative ionization of the H—S bond in **2**. The much greater stability (~63 kJ/mol) of **5** is consistent with the charge distribution of **2** and the well-known chemistry of the oxy acids of sulfur (34). The net atomic charges listed in Table 4 suggest that sulfone **3** should not be appreciably acidic and that the negative charge on anions **5** and **6** resides primarily on the O atoms.

For completeness we have included the SO_2H radical **4**, which is isomeric with the sulfonyl radical **1***a*. Comparison of the respective total energies shown in Tables 2 and 4 indicates that **4** is more stable by about 0.065 au or 170 kJ/mol. Separation of the total energies into components yields 114.71488 au and 109.01803 au for the nuclear repulsion energy in **1***a* and **4**, respectively. The electronic energies are −656.14569 au and −650.51363 au, respectively. Thus the 5.63206 au difference in electronic energies is more than offset by the 5.69685 au difference in nuclear repulsion energies. Similar large differences occur in anions **5** and **6**: 113.79654 au and 106.68339 au, respectively, for the nuclear repulsion energies and −655.11413 au and −647.97681 au, respectively, for the electronic energies. However in the case of the anions the nuclear repulsion energy difference is insufficient to offset the lower electronic energy of **5**.

The large effect of *d*-type functions in the basis set for sulfur has been discussed in the previous

section. Here we note that it would be interesting to study the effect of further improvements in the basis set. Clearly a split-valence basis set would lead to lower total energies for all species (4). Further flexibility could be built in by including polarization functions on all atoms and not on S alone as in this paper. Here it should be mentioned that *ab initio* calculations on **3** have been reported by Van Wazer and Absar (35). With a larger basis and an assumed geometry a very much lower energy was obtained. No geometry optimizations were carried out. The inclusion of *d* orbitals on S lowered the energy by about 0.33 au and led to a large shift of electron density toward S. The resulting charge distribution (0.33 on S, −0.28 on O, and 0.11 on H) is very similar to the one listed for H_2SO_2 in Table 4. *Ab initio* calculations have not been reported for any of the other species included in this paper.

Conclusions

On the basis of the calculations reported in this paper, the following conclusions regarding sulfonyl radicals and related species may be drawn.

1. In agreement with previous studies (4, 36) on hypervalent molecules containing second-row atoms, *d* functions on sulfur are important for the prediction of S—O bond lengths. The STO-3G basis set yields values for S—O bonds which are as much as 0.45 Å longer than the STO-3G* basis set results which generally lead to better agreement with experiment.

2. The geometry of the SO_2 functional group in sulfonyl radicals XSO_2 is essentially independent of the nature of X: r(S—O) = 1.47 ± 0.01 Å, ∠OSO = 123 ± 2° and a nonplanar arrangement about the sulfur atom. The pyramidal geometry at S in sulfonyl radicals is consistent with recent electron spin resonance studies (37).

3. The radical site in sulfonyl radicals is significantly delocalized over the entire SO_2 functional group. This may be represented by three principal resonance contributors. Also the SO_2 functional group in sulfonyl radicals displays characteristic electronic properties which do not show a marked dependence on the choice of substituent.

4. The calculated X—S bond energy of CH_3SO_2 is ~38 kJ/mol greater than that of NH_2SO_2. This large difference is consistent with the chemistry of alkyl and aminosulfonyl radicals (1, 26). The corresponding bond energy in $OHSO_2$ is predicted to be ~30 kJ/mol greater than in NH_2SO_2. This suggests that alkoxylsulfonyl radicals might not react by analogy with the aminosulfonyl radicals.

5. At the STO-3G* level, sulfinic acid HSO_2H is predicted to be more stable than the simple sulfone H_2SO_2 by about 99 kJ/mol. Of the two possible anions formed by the dissociative ionization of sulfinic acid, HSO_2^- is predicted to be more stable than SO_2H^- by about 63 kJ/mol.

6. The SO_2H radical is predicted to be more stable than the isomeric sulfonyl radical HSO_2 by about 170 kJ/mol. As noted in the previous conclusion, the reverse situation is observed for the corresponding anions.

The structure of Schiff reagent aldehyde adducts and the mechanism of the Schiff reaction as determined by nuclear magnetic resonance spectroscopy

J. H. ROBINS, G. D. ABRAMS, AND J. A. PINCOCK[1]

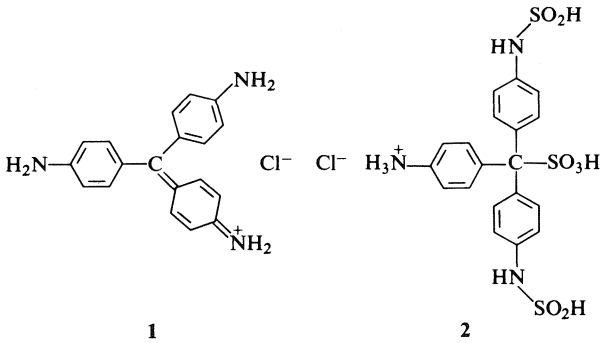
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 5, 1979

J. H. ROBINS, G. D. ABRAMS, and J. A. PINCOCK. Can. J. Chem. **58**, 339 (1980).

An nmr study of compounds isolated from the Schiff aldehyde reaction between pararosaniline hydrochloride, sulfur dioxide, and acetaldehyde has demonstrated that these adducts are α-anilinoalkylsulfonic acids. The evidence is incompatible with the other structures most often accepted in the literature, *N*-phenyl alkylsulfonamides. In combination with nmr spectra obtained from solutions of the Schiff reagent and the Schiff reaction and with literature spectrophotometric data, this result leads to a reasonable proposal for the mechanism of the colour development. The effects of the concentrations of the dye, acetaldehyde, and in particular, sulfur dioxide are explained and suggest that the dominant coloured species is a 2:1 acetaldehyde–dye adduct. The nmr results also reveal a kinetic/thermodynamic competition for acetaldehyde between the aniline of the dye and the aldehyde carbonyl leading to bisulfite addition. The relation of the Schiff test with acetaldehyde and the Feulgen test for aldehydes in biological samples is also discussed.

J. H. ROBINS, G. D. ABRAMS et J. A. PINCOCK. Can. J. Chem. **58**, 339 (1980).



Une étude par rmn des composés isolés de la réaction de l'aldéhyde de Schiff entre le chlorohydrate de pararosaniline, le bioxyde de soufre et l'acétaldéhyde a démontré que ces adduits sont les acides α-anilinoalkylsulfoniques. Cette démonstration est compatible avec les autres structures le plus souvent acceptées dans la littérature, *N*-phényl-alkylsulfonamides. Ce résultat, combiné aux spectres rmn des solutions du réactif de Schiff et de la réaction de Schiff et également aux données spectrophotométriques de la littérature, conduit à suggérer un mécanisme raisonnable pour le développement de la couleur. On a expliqué l'effet de la concentration du colorant, de l'acétaldéhyde et en particulier du bioxyde de soufre et on a suggéré que l'espèce colorée-dominant est l'adduit 2:1 acétaldéhyde–colorant. Les résultats de la rmn révèlent également une compétition cinétique/dynamique de l'acétaldéhyde entre l'aniline du colorant et le carbonyle de l'aldéhyde, conduisant ainsi à une addition de bisulfite. On discute également de la relation du test de Schiff avec l'acétaldéhyde et du test de Feulgen pour les aldéhydes dans les échantillons biologiques.

[Traduit par le journal]

Introduction

The use of the Schiff reagent as a test for aldehydes in biological samples was first suggested by Feulgen and Rossenbeck (1) and, in standard references on staining procedures (2, 3), is referred to as the Feulgen reagent. The full histochemical test is usually a combination of the Schiff reagent plus other reagents that produce aldehydes from naturally occurring molecules; for instance, acid hydrolysis of nucleic acids to remove the purine or pyrimidine bases and free the ribose sugar, or periodic acid oxidation of polysaccharides (4). Despite the fact that the complexity of the chemistry has often been recognized, many attempts have been made to make the staining quantitative (2). This work has often been successful particularly when relative values have been obtained using carefully standardized Schiff reagents and conditions. Our interest in the chemistry of the reagent began when one of us (J.R.) measured by Feulgen microspectrophotometry (2) the DNA content of a marine invertebrate.

Organic chemists have, of course, used Schiff's reagent for many years as a qualitative test for the presence of aldehydes. A positive test is indicated by a change from pale yellow (colourless) to deep red-violet upon addition of the aldehyde to the reagent. Although a recent review lists some sixty different methods of preparing the reagent (4), most rely on converting a red solution of pararosaniline hydrochloride, **1**, to colourless by addition of sulfurous acid from some source of S^{IV} (sulfur dioxide, sodium bisulfite, sodium sulfite, thionyl chloride, etc.). The review (4) also gives an extensive list of aldehydes that give positive tests and contains considerable discussion of the effect of variables such as pH, sulfurous acid, and aldehyde concentration on the intensity and stability of the colour formed.

This evidence demonstrates that the chemistry involved is neither simple nor clearly understood. Because such colour tests are now of less importance to organic chemists, the reaction is seldom discussed in modern texts.

In older references (5, 6) the leuco derivative of the dye is usually shown as **2** and the coloured adduct as **3**. The formulation **3** ignores the question of whether —NH—SO_2—CHR—OH is an α-hydroxyalkyl sulfonamide (—NH—$\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}$—CHR—OH) or a sulfite ester (—NH—$\overset{\overset{O}{\|}}{\underset{\underset{\cdot\cdot}{}}{S}}$—O—$\overset{\overset{R}{|}}{CH}$—OH). Both

3

4

have been proposed in the literature. The structures **2** and **3** are based mainly on the early work of Wieland and Scheuing (7). Although there is no doubt that the colour change results from conversion of the saturated central carbon of the triarylmethane system to a highly delocalized cation, the other features are less certain. The amino sulfinic acids in **2** are suggested because no colour results either from a reagent prepared using equimolar quantities of sulfur dioxide and pararosaniline hydrochloride (**1**) or by reaction of aldehyde bisulfite addition compounds with **1**. Therefore the reasonable pathway to a coloured species like **3** is via preformed amino sulfinic acid moieties. Other evidence for **3** is that the stoichiometry of the adduct is 2:1 aldehyde–pararosaniline, at least for acetaldehyde. As discussed by Kasten (4) and Puchtler *et al.* (8), the literature before 1920 contains other proposals, including Schiff's imine (Schiff base) formulation, which are not compatible with more recent findings.

On the basis of extensive spectrophotometric and kinetic work, Hörmann *et al.* (9) have proposed that the coloured Schiff adduct is an aminoalkyl sulfonic acid dication as in **4**. This suggestion was originally advanced by Rumpf (10) and has been adopted by others more recently (11). Again spectral evidence suggests a 2:1 adduct for acetaldehyde and formaldehyde. Others have proposed, for formaldehyde, ratios ranging from 3:1 (11) to 6:1 (12, 13, 14) usually without comment on actual structures. Regardless of stoichiometry, adducts like **4** cannot be formed directly from **2**.

In view of the interest in the use of the Schiff reagent in biological staining and the confusion about the chemistry (in particular stoichiometry), a more thorough study of the test using spectral methods (ir, ^{1}Hmr, ^{13}Cmr) seemed necessary. Wieland and Scheuing (7) isolated and characterized compounds from acetaldehyde pararosaniline reactions. In the present work, spectra were taken of three compounds prepared according to their methods. These spectra were then compared with those obtained from solutions of the Schiff test. The results give a much clearer picture of the chemistry involved and, as will become apparent, explain many of the ambiguities previously observed and, as well, reveal some intriguing kinetic phenomena.

Results and Discussion

Researchers have frequently used basic fuchsin when studying the Schiff reaction (7, 9, 10). This dye is often a mixture of several triarylmethane derivatives and the proportions may vary among commercial samples (1). Pararosaniline hydrochloride **1** was used throughout this study. ^{1}Hmr[2] spectra of the crude commercial dye gave a broad featureless signal from δ 6.2–7.2; simple recrystallization from water gave material of a single spot on tlc that showed the expected AB type doublet of doublets in the aromatic region. The known carbinol base **5**, obtained by adding hydroxide to **1**, was also prepared. The dye pararosaniline hydrochloride, **1**, the carbinol **5**, 4-methylaniline, and 4-methylanilinium cation serve as useful models for interpreting the spectra of the less well-understood pararosaniline derivatives. Two different effects are relevant to this study. The first can be illustrated by comparing the spectra of the simpler systems 4-methylaniline and the 4-methylanilinium cation, and concerns the effect of a protonated

[2]All ^{1}Hmr and ^{13}Cmr spectra are in DMSO-d_6 with δ values relative to internal TMS unless otherwise stated.

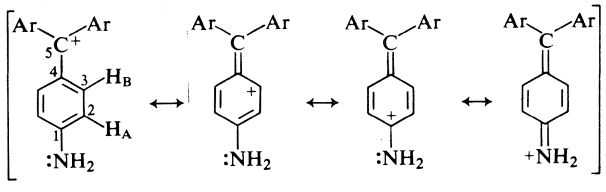
amino substituent on the chemical shifts of the aromatic hydrogens. The second effect, that of the influence on the aromatic proton shifts by the delocalized positive charge of the tris(4-aminophenyl)methyl cation, can be evaluated by comparison of the spectra of pararosaniline carbinol base (**5**) with pararosaniline hydrochloride (**1**). In the discussion that follows the δ values reported for *para*-substituted aromatic AB type systems are the centers of the doublets and are therefore not true chemical shifts.

Pararosaniline Carbinol Base (5)

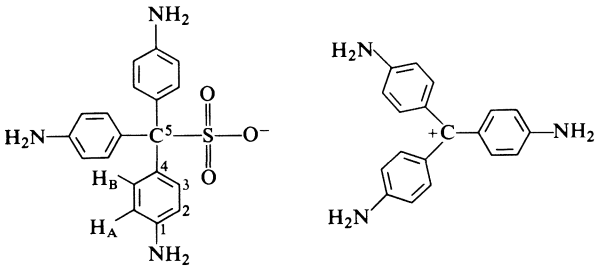


Since the central carbon is quaternary the substituent effect of the amino group should be similar to that in 4-methylaniline (MA). The ^{1}Hmr spectrum of **5**: δ 4.82 (NH_2; δ 4.70 in MA), 6.40 (H_A, J = 8 Hz; 6.48 in MA), and 6.78 (H_B, J = 8 Hz; 6.81 in MA) confirms this assertion. The chemical shifts also agree well with those expected on the basis of substituent additivity in aromatic rings (15). The ^{13}Cmr assignments are also straightforward; δ: 79.9 (C5), 112.6 (C2), 128.5 (C3), 137.0 (C4), and 146.1 (C1). Resonance delocalization from nitrogen puts negative charge on C2 and C4. Therefore of the quaternary pair C1/C4, C4 is at higher field and of the tertiary pair C2/C3, C2 is at higher field.

Pararosaniline Hydrochloride (1–6)

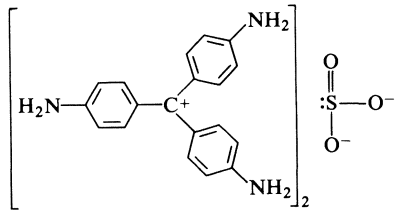
As shown in the resonance delocalized diagram of **6**, positive charge density is on C5, C3, C1, and NH_2. The ^{1}Hmr assignments of **6**: δ 6.84 (H_A, J = 9 Hz), 7.18 (H_B, J = 9 Hz), and 7.53 (NH_2) are then made on the basis that H_A is more shielded than H_B. Note as well the large downfield shift of the amino protons relative to those of the carbinol **5**. The ^{13}Cmr assignments for triarylmethyl cations have been made previously (16) according to parallel

5



6

arguments: δ: 114.5 (C2), 126.0 (C4), 140.1 (C3), 157.5 (C1), and 177.8 (C5). The conversion from the carbinol **5** to the cation **6** obviously gives the largest change in shift for C5 (sp^3 becoming sp^2 (+)).



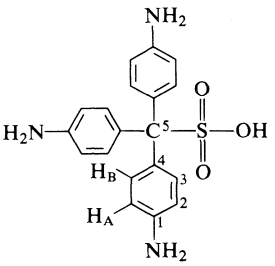
At this point it is worth mentioning that the ^{1}Hmr spectrum of an anilinium cation shows quite different behaviour for the aromatic protons. Electron donation by the resonance effect of the amino group is now removed and only an inductive electron-withdrawing effect remains. The signals of the aromatic protons coalesce to a singlet at δ 7.27 as can be observed in a spectrum of 1:1 molar ratio of 4-methylaniline – *p*-toluenesulfonic acid.

Pararosaniline Dye Salt, 7

This compound was originally prepared by Wieland and Scheuing (7) according to a procedure reported earlier (17). There has been some dispute about its structure with two of the favoured choices being **7** (the salt of a sulfonic acid) and **8** (a salt of sulfite anion). Although these two formulations are obviously very similar, the nmr evidence favours **7**. The ^{1}Hmr spectrum shows two AB sets of aromatic

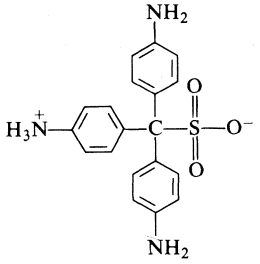
7

8



protons, one clearly from the cation: δ 6.78 (H_A), 7.18 (H_B), and 7.35 (NH_2), and one from the anion which has the central carbon quaternary in the triarylmethane system: δ 4.73 (NH_2), 6.34 (H_A), and 7.02 (H_B). The only significant change in the spectrum of the sulfonate anion from that of the carbinol **5** is the chemical shift of H_B, the proton nearest to the quaternary center. The two types of amino protons in the salt are different because of the slow exchange in DMSO. The ^{13}Cmr spectrum shows the same pair of ions. The cation spectrum is identical to that of **6** and the anion line positions are similar to those of **5**: δ 77.2 (C5), 112.2 (C2), 131.0

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



(C3), 133.7 (C4), and 145.7 (C1). There has been some discussion in the literature whether the attachment of the sulfur to the central carbon of these pararosaniline derivatives is a sulfonate (C—SO_2—O) or a sulfite ester (C—O—SO—O) (4). For this dye salt a choice can be made by consideration of the ir spectrum (KBr) which shows bands for sulfate, 1165 cm^{-1} and 1040 cm^{-1}, different from those expected for sulfite derivatives (18, 19). As well, Wieland and Scheuing (7) have demonstrated that the dye salt **7** is not oxidizable with iodine in agreement with the sulfonate formation. The ^{13}Cmr spectrum of **7** gives a resonance for C5 (δ 77.2) very similar to that for C5 (δ 79.9) of the carbinol base as expected from known chemical shifts of sulfonyl derivatives (20).

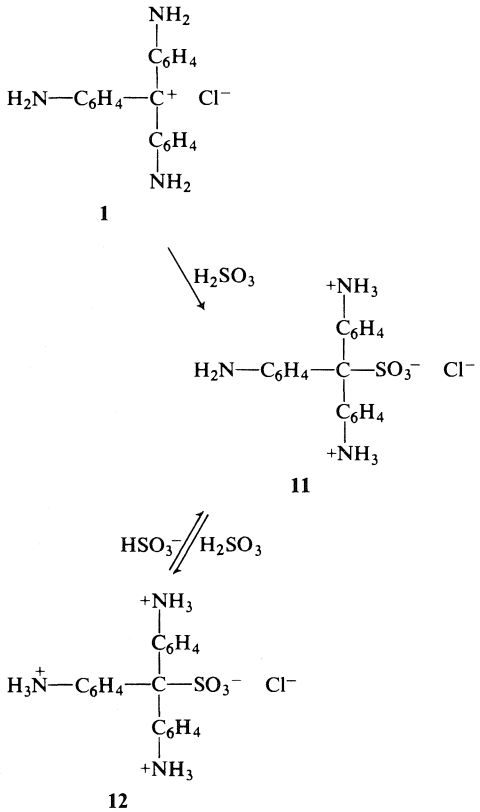
*Pararosaniline Leucosulfonic Acid (**9**)*

Several related compounds of this type have been prepared but they apparently only differ in the amount of water of crystallization (7, 17). Some difficulty was experienced obtaining nmr spectra for **9** since it was unstable in solution due to loss of sulfur dioxide. This is a well-known phenomenon since for solutions of pararosaniline hydrochloride there is an equilibrium between the coloured cation **1** and the colourless leuco derivative **9** which can be controlled by the sulfurous acid concentration. In fact, loss of SO_2 is the major problem in the stability of Schiff reagents (4). For **9**, spectra in DMSO could be obtained if run quickly but they were always those of mixtures of **9** and **1**. After several hours only **1** was present. This loss of sulfur dioxide could be slowed by adding D_2O to the DMSO solution. The ^{1}Hmr spectrum of **9** (δ 3.2–4.9 (—NH_2, H_2O of crystallization), 6.40 (H_A, J = 8 Hz), and 7.06 (H_B, J = 8 Hz)) gives values that are very similar to those of the anion portion of the dye salt **7**. The same relationship between **9** and **7** was observed in the ^{13}Cmr spectrum as well as the change of **9** to **1** with time. The pK_a of sulfonic acids, −2 to −3 (21), and anilinium ions, 4.6 (21), imply that **9** should exist predominantly as the zwitterion **10** in water. Even in DMSO where some changes in acidity from those in water might be expected, the very large difference in pK_a should favour **10**. A good model for **10** can be obtained from a solution consisting of a 3:1 molar ratio of 4-methylaniline – *p*-toluenesulfonic acid. The ^{1}Hmr spectrum of the aniline aromatic hydrogens, δ 6.76 (H_A, J = 8 Hz) and 6.95 (H_B, J = 8 Hz), is as expected for a 1:2 mixture of the protonated/unprotonated form with rapid exchange giving an average spectrum of the anilinium ion (δ 7.27, H_A and H_B) and the free amine (δ 6.48 (H_A) and 6.81 (H_B)). The ^{1}Hmr spectrum of

9

10

the leuco sulfonic acid is then consistent with the structure of the zwitterion **10**, the AB system at slightly lower field than in the carbinol, **5**. Finally, the ir (KBr) of **9**:**10** show the sulfonate pattern of bands at 1035 and 1170 cm^{-1}.



Schiff Reagent

The spectra of the previously described isolated compounds can now be compared to those of the Schiff reagent in D_2O. Peak positions for these spectra were assigned relative to δ HDO = 0. From the above discussion of the spectra in DMSO, it is the changes in chemical shift that are important. A solution (10 mg/mL) of pararosaniline hydrochloride **1** in D_2O shows the expected doublet of doublets in the ^{1}Hmr spectrum δ 2.08 (H_A, J = 9 Hz) and 2.50 (H_B, J = 9 Hz). The separation of the two doublets in D_2O (0.42 ppm) is similar to that observed in DMSO (0.34 ppm). In agreement with detailed experiments of triarylcarbinol pK_R values (23), there is no observable conversion of pararosaniline to its carbinol at pH = 7. On conversion to Schiff reagent by bubbling sulfur dioxide into the D_2O solution of **1** until the red colour just disappeared, the spectrum changed to a very close AB type system with the intense inner peaks at δ 2.70 and 2.74. Clearly that is not what is expected for formation of the leucosulfonic acid (**10**) where the separation of the doublets is 0.66 ppm and both H_A and H_B move to higher field. However, the change is compatible with saturation of the central carbon and more extensive protonation of the amino groups than in the zwitterion **10**.

It has been well established that excess sulfur dioxide or strong mineral acids (i.e., low pH) make the Schiff reagent inactive (4). This has always been a problem in the elaboration of a mechanism for the reagent's activity since more than one equivalent of sulfur dioxide is required for positive results and yet excess leads to no colour development on addition of the aldehyde. These facts can be explained by recognizing that extensive protonation of the amino groups will lower the effective concentration of nucleophilic nitrogens. Clearly any strong acid, including sulfurous acid, pK_1 =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

1.9, $pK_2 = 7.4$ (24, 25), will cause this behaviour; in contrast, weak acids such as acetic acid ($pK = 4.8$) do not have sufficiently low pK_a values to fully protonate all three nitrogens and therefore are not effective (4) in decreasing the sensitivity of the reagent. That pararosaniline derivatives can be triply protonated is evident from the behaviour of **1** itself which is converted to a yellow salt with a chromophore similar to that of the unsubstituted triphenylmethyl cation at pH = 0 (26). For a solution of pararosaniline hydrochloride at the usual concentration ($\sim 4 \times 10^{-4}$ *M*) and two equivalents of sulfur dioxide the pH $\simeq$ 2 (9). Therefore the solution is not acidic enough to convert **11** completely to **12** (26). The ^{1}Hmr spectrum in D_2O where exchange is rapid should be an average of **11** and **12** and should show the aromatic ring protons to be in an environment similar to the 4-methylanilinium ion. Wieland and Scheuing formulated the Schiff reagent with the excess sulfurous acid bound to nitrogen as in **2** (*N*-sulfinic acids) (7). However, compounds of this type are known to be unstable in water (27, 28) and there is no uv spectral evidence for this formation (11). The main reasons for their continued consideration in the literature are the assumption that the complex of aldehydes with Schiff's reagent is an alkyl sulfonamide **3** and the observation that Schiff's reagent does not give a colour test with preformed aldehyde bisulfite addition compound (7).

1 **11** **12**

Schiff Reagent Acetaldehyde Addition Product

Wieland and Scheuing prepared a solid 1:1:1 addition product of pararosaniline hydrochloride – sulfurous acid – acetaldehyde to which they assigned the structure **13** (7). The ^{1}Hmr spectrum in DMSO-d_6 of material prepared by this method, however, indicates that the correct structure is **14**: δ 1.50 (CH_3, doublet, $J = 6$ Hz), 4.53 (—CH, complex multiplet), 6.80 (H_A, H_A', doublet, $J = 9$ Hz), 7.12 (H_B, H_B' doublet, $J = 9$ Hz), 7.36 (broad singlet, NH_2), 8.16 (broad doublet, NH). Decoupling experiments clearly showed the —NH—CH—CH_3 group. The position of the aromatic doublet of doublets is characteristic of the delocalized triphenylmethyl cation, and the single hydrogen on the substituted nitrogen is at different chemical shift than the other NH_2 hydrogens. Although 2:1 aldehyde–pararosaniline adducts are usually suggested (7, 9), this isolated material is a 1:1 adduct as shown by integration of the signal intensities. The ir (KBr) is also compatible with a sulfonic acid derivative, exhibiting the bands expected at 1075 cm^{-1} and 1150 cm^{-1} (18, 19). The ^{13}Cmr spectrum for **14** has the advantage that the better resolution shows that there are two types of aromatic rings: δ 17.4 (CH_3), 64.1 (CH), 114.5 (C2, C2′), 126.0 (C4′), 126.3 (C4), 139.4 (C3′), 140.0 (C3), 155.6 (C1), 157.3 (C1′), and 177.3 (C5). Both sets of aromatic carbon line positions are consistent in chemical shift with a delocalized cation structure. Assignments of the primed and unprimed carbons are based on relative intensities.

The spectral evidence leaves no doubt that this complex is a 1:1 adduct of structure **14** in agreement with more recent formulations of the coloured Schiff product as an α-aminosulfonic acid (9, 11). However, Wieland and Scheuing state that the actual dye is a 2:1 (aldehyde–pararosaniline) adduct (7) and Hörmann *et al.* have found that the colour developed is proportional to the square of the acetaldehyde concentration (9). For the usual 4.5×10^{-3} *M* pararosaniline hydrochloride concentration and acetaldehyde at 4×10^{-4} *M* the statistical distribution of products (assuming all three amino groups are equally reactive) would be 91.4% unsubstituted, 8.4% monosubstituted, 0.26% disubstituted, and negligible trisubstituted. If only disubstituted products form coloured species efficiently and the extinction coefficient is $\sim 10^5$, as expected

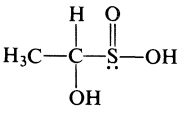
13



14 R = H
15 R = —CH(CH$_3$)SO$_3$H

for the pararosaniline derivative (23), the absorbance would be $4.5 \times 10^{-3} \times 2.6 \times 10^{-3} \times 10^5 \simeq 1.2\ cm^{-1}$ which is in reasonable agreement with, but about 60–70% of, the values observed by Hörmann *et al.* (9). Many workers have pointed out that there are probably at least two chromophores contributing to the total absorbance (4, 29, 30) and the simplest suggestion is that they are the cation of **14** and its disubstituted analogue **15**.

The complete mechanism for the Schiff reaction in water can then be written as in Fig. 1. Steps **9** → **16** → **18** and **11** → **17** → **19** are the well-known Schiff base or imine formation via a carbinolamine intermediate. The mechanism for these transformations has been studied extensively (31, 32) and the equilibrium constant for formation of imines from aromatic amines in water is known to be small (33, 34). The excess sulfurous acid is then required to shift the equilibria towards **20** and **21**. This, of course, lowers the sulfurous acid concentration of the solution and allows the final equilibria to be favorable i.e., **20** → **22** and **21** → **23**.[3] This explains the rather critical effect of sulfurous acid since more than one equivalent is required, but too high a concentration makes the final equilibria unfavorable (as well as increasing acidity to convert the pararosaniline to a fully protonated and unreactive derivative **12**). The discussion above on the stoichiometry of the complex suggests that loss of sulfur from the central carbon is much more favourable for **20** than **21**. This is reasonable because the pK_a of the amino group of α-aminosulfonic acids is lower by about 4 pK units than normal amines (35) and therefore will probably not be completely protonated under the reaction conditions. Therefore **22** has better resonance stabilization than **23**.

Finally, the observation that the Schiff reagent with acetaldehyde gives a positive test but that the colour slowly disappears with time should be explained (9). Again the ^{1}Hmr spectrum in D_2O is instructive since on adding acetaldehyde to the reagent the signals for the leuco sulfonic acid derivative **11**:**12** disappear immediately and signals for the new complex appear. After approximately two hours the signals for the leucosulfonic acid appear again and the aldehyde has been converted completely to the bisulfite addition compound **24**: δ − 0.32 (CH, quartet, J = 6 Hz) and −3.42 (CH_3, doublet, J = 6 Hz) (chemical shifts relative to HDO). This same spectrum can be duplicated with just acetaldehyde and sulfurous acid. If excess acetaldehyde is added, the sulfurous acid in solution is slowly converted entirely to **24** and the leucosulfonic acid is converted to pararosaniline hydrochloride. The colour of the solution is now stable but is the red (λ_{max}, 538 nm) of pararosaniline

24

hydrochloride rather than the red-violet (λ_{max}, 560 nm) of the Schiff aldehyde adduct. Clearly for qualitative tests this would still be considered positive.

These kinetic phenomena raise an interesting point. The amino groups of the dye react in kinetic preference with the aldehyde to give unstable carbinolamine or imine adducts whereas the thermodynamically favoured product is the bisulfite addition compound. The equilibrium constants for the first process are in the range 3–30 M^{-1} (36) whereas for bisulfite addition they are much higher, 10^4–10^5 M^{-1} (31, 34). As Young and Jencks (36) have demonstrated, the reactive species in bisulfite formation is the sulfite dianion and at pH ≃ 2 of the Schiff test, its concentration is 10^{-7} of the total concentration of S^{IV} species (24). The free amine concentration is given by the equilibria between **9**, **11**, and **12** in Fig. 1. The equilibrium between **11** ⇌ **19** can be estimated from the pK_a ≃ 2.0 for crystal violet (37) and therefore at the pH ≃ 2.0 the free amine concentration will be about half the total concentration of the dye. Therefore, in order for bisulfite to compete with the amine kinetically, the ratio of the second order rate constants, k_s/k_A, for reaction of bisulfite with acetaldehyde (k_s) and

[3]Note that **22** and **23** are the conjugate acids of **14** and **15** respectively and are the expected coloured species at the normal pH of 2 used for Schiff tests.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

amine with acetaldehyde (k_A), must exceed 10^7. Estimates of this rate ratio can be made from literature data using aniline as the amine, although not for acetaldehyde as the aldehyde. For instance, for formaldehyde: $k_s \simeq 5 \times 10^6\ M^{-1}\ s^{-1}$ (38), $k_A \simeq 2.75\ M^{-1}\ s^{-1}$ (34), $k_s/k_A \simeq 1.8 \times 10^5$; for 4-methoxybenzaldehyde: $k_s \simeq 10^3\ M^{-1}\ s^{-1}$ (38), $k_A \simeq 4.5 \times 10^{-3}\ M^{-1}\ s^{-1}$ (39), $k_s/k_A \simeq 2.2 \times 10^5$. Therefore the formation of **22** (or **23**) occurs in kinetic preference and the initially formed adducts are slowly converted to the bisulfite addition complex **24** by reversal of the equilibria to **9** (or **11**).

Summary

The coloured species formed in the Schiff reaction of acetaldehyde have been shown to be α-aminosulfonic acids which are unstable in solution due to loss of the aldehyde bisulfite addition compound. These Schiff complexes may be of 1:1 or 2:1 stoichiometry for acetaldehyde – pararosaniline hydrochloride if the relative concentration of the aldehyde is low. As Hörmann *et al.* (9) have stated, colour development for simple aldehydes will depend in a complex way on the concentrations of each of the dye, sulfur dioxide, and aldehyde and therefore for quantitative results careful calibration is required (9).

The staining of histological samples may be quite different since in this case disubstitution on the dye by aldehydes is less likely because of the rigid nature of the tissue samples. Moreover excess dye and sulfurous acid are always removed by water washing so that the equilibrium between the corresponding analogues of **21** and **23** will be shifted entirely to **23**. In fact, Hörmann *et al.* (9) have shown that for the PAS test (periodic acid, Schiff) a simple linear dependence between absorbance and starch concentration is observed (9) which can be used for relative but not absolute values. As well, the colour of the stained dried tissue samples might be stable since loss of aldehyde bisulfite compound is not likely outside of the aqueous acid test solutions.

Experimental

Proton magnetic resonance spectra were run on either a Varian T-60, Varian HA-100, or Varian CFT-20 spectrometer. Carbon spectra were from the CFT-20. The samples were run in either DMSO-d_6 with internal TMS or D_2O using the HDO signal as standard. Infrared spectra were recorded on a Perkin Elmer 237 or 521 spectrometer using KBr discs. Spectra are reported in the text.

Pararosaniline Hydrochloride

Commercial (J. T. Baker, C.I. 42500, lot number 310911) material was purified by recrystallization from water and showed only one spot with slight tailing on tlc (silica gel; 4:1:5 butanol – acetic acid – water).

Pararosaniline Carbinol Base

The method is similar to that of Jennings (40). A stirred suspension of 3.24 g (10 mmol) of pararosaniline hydrochloride in 500 mL of water was brought to boil. A boiling solution of 625 mL of 0.2 *N* sodium hydroxide (125 mmol) was added and the mixture boiled for 30 min and then filtered hot. After standing at room temperature overnight the solid was collected, washed with cold water, then ethanol–ether (1:10), and finally ether (28% yield); mp 208–210°C as a red liquid.

Pararosaniline Dye Salt

The method is similar to that of Dürrschnabel and Weil (17). Sulfur dioxide was bubbled through a solution of pararosaniline hydrochloride (10 g) in 40 mL of water until the colour changed from dark red to yellow. The solution was gravity filtered and then heated until it became red again. After cooling to room temperature, the crystals were collected, washed with ethanol–ether (1:10) and then ether, and finally dried *in vacuo* over sulphuric acid for two hours (53% yield).

Schiff Reagent Acetaldehyde Addition Product

The method used is that of Wieland and Scheuing (7). Pararosaniline hydrochloride, 0.326 g (1 mmol), was dissolved in 500 mL of 0.006 *N* (3 mmol) hydrochloric acid and the solution was filtered. Then 1.0 mL of an aqueous solution (0.044 g/mL, 1 mmol) of acetaldehyde and 10 mL of 0.1 *M* (1 mmol) sulfurous acid was added with stirring. The mixture was left at room temperature overnight. The precipitate was collected, washed with water, ethanol–ether (1:10), and ether, and dried for two hours *in vacuo* over concentrated sulfuric acid (61% yield).

A homopropargyl radical rearrangement. Kinetics of the rearrangement of the 2,2,5,5,-tetramethyl-3-hexyn-1-yl radical[1]

KEITH U. INGOLD

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

AND

JOHN WARKENTIN[2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 7, 1979

KEITH U. INGOLD and JOHN WARKENTIN. Can. J. Chem. **58**, 348 (1980).

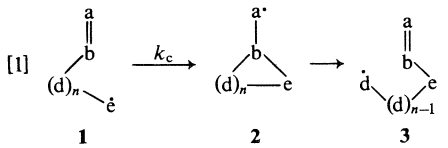
The rate constants for rearrangement of the 2,2,5,5-tetramethyl-3-hexyn-l-yl radical to the 2,6,6-trimethyl-4-heptyn-2-yl radical have been measured from 45 to 88°C by kinetic epr spectroscopy. The temperature dependence can be represented by

$$\log(k^{C\equiv C}/s^{-1}) = (12.4 \pm 1.5) - (14.6 \pm 2.4)/\theta$$

where $\theta = 2.3RT$ kcal mol^{-1}. This rearrangement, which must involve an intermediate vinyl radical of the methylenecyclopropane type, is much slower than analogous rearrangement of homoallyl radicals but comparable in rate to rearrangement of homobenzyl (neophyl) radicals.

KEITH U. INGOLD et JOHN WARKENTIN. Can. J. Chem. **58**, 348 (1980).

On a mesuré, les constantes de vitesse de la transposition du radical tétraméthyl-2,2,5,5 hexyne-3 yle en radical triméthyl-2,6,6-heptyne-4 yle-2, à des températures allant de 45 à 85°C en utilisant la spectroscopie de rpe cinétique. L'effet de la température peut être représenté par l'équation:



$$\log(k^{C\equiv C}/s^{-1}) = (12.4 \pm 1.5) - (14.6 \pm 2.4)/\theta$$

où $\theta = 2.3RT$ kcal mol^{-1}. Cette transposition, qui doit impliquer un radical vinylique du type méthylène-cyclopropane comme intermédiaire est beaucoup plus lent que la transposition analogue des radicaux homoallyliques, mais elle est comparable du point de vue vitesse à la transposition des radicaux homobenzyliques (néophyles).

[Traduit par le journal]

Introduction

The most common radical rearrangements are those involving intramolecular addition of the radical centre to a multiple bond situated β,γ, or further away, relative to the radical site (α).[3] In some cases this ring forming step completes the rearrangement of the initial radical **1** and the new radical **2** is a cyclic structural isomer, eq. [1]. In other cases the

1 **2** **3**

ring reopens in another sense, yielding an acyclic rearranged radical **3** from its acyclic progenitor **1**. A number of systems have been studied to date, including combinations of: (b=a) = aryl, C=C, C≡C, C=N, C≡N; n = 1, 3, 4, 5; d = carbon, heteroatoms; and e = carbon, nitrogen, oxygen, sulfur, silicon (1). Such rearrangements are not only potential steps in synthetic sequences but their rates can serve as reference points for measuring the rates of other radical processes (10,11).

Although rate constants for C5- and C6-ring closure (n = 4, 5; eq. [1]) of primary radical sites onto C≡C bonds (12)[4] and of C5-ring closure involving the C≡N bond (9) had been reported, there was no estimate of the rate constant for corresponding C3-ring closures involving triple bonds. The latter processes are of considerable interest because of the expected strain in the intermediate methylenecyclopropane system (e.g., **5**). It was not known, for example, whether that strain would provide a barrier to ring closure high enough to suppress completely the rearrangement of a homopropargyl radical relative to competing processes.

In this paper we report a study by kinetic epr spectroscopy of the homopropargyl radical 2,2,5,5-tetramethyl-3-hexyn-1-yl, **4**. This radical has been found to rearrange to 2,6,6-trimethyl-4-

heptyn-2-yl, **6**. The rate constants $k^{C\equiv C}$, and Arrhenius parameters for the overall rearrangement of **4** to **6** have been determined.

Experimental

The steady state and kinetic epr techniques applicable to the study of radical isomerizations have been described (13–15). Radicals **4** and **6** (eq. [2]) were generated by photolysis of di-*tert*-butyl peroxide (BOOB) in 2,2,5,5-tetramethyl-3-hexyne (v:v = 1:6) and, less successfully, by bromine abstraction from 1-bromo-2,2,5,5-tetramethyl-3-hexyne. Both tri-*n*-butyltin radicals, from photolysis of hexa-*n*-butylditin, and trimethylsilyl radicals, from photolysis of BOOB in the presence of trimethylsilane, were tried as bromine abstracting species.

2,2,5,5-Tetramethyl-3-hexyne (Farchan or Chemical Samples Co.) was purified by preparative glpc with an OV-1 column (20 ft × ⅜ in., 100°C) to remove an impurity (0.5% or more, batch dependent) which was eluted just after the alkyne. Analysis of collected alkyne with analytical glpc columns did not reveal any remaining impurity.

1-Bromo-2,2,5,5-tetramethyl-3-hexyne was prepared by photolysis of *tert*-butyl hypobromite (16) in the parent alkyne, followed by washing with bicarbonate solution and with water, drying, and vacuum distillation. The bromide distilled after unreacted alkyne at oil bath temperature 80–90°C (0.25 Torr); ^{1}Hmr (CCl_4) δ: 1.20 (s, 9H), 1.30 (s, 6H), 3.49 (s, 2H). *Mol. Wt.* calcd.: 218.0494, 216.0514; found (ms): 218.0497, 216.0528.

The kinetic epr technique was used, with BOOB and alkyne, to determine the rate constant for bimolecular self termination of **4**, $2k_t(\mathbf{4})$, at 15°C (Table 2). On the same day, with the same lamp and optical configuration, photolysis of di-*tert*-butyl ketone in hexadecane, at 26°C, gave $2k_t(t\text{-Bu}^\cdot) = 3.0 \times 10^9\ M^{-1}\ s^{-1}$, (lit. (17), $2k_t(t\text{-Bu}^\cdot) = 2.9 \times 10^9\ M^{-1}\ s^{-1}$), for the same conditions. This excellent agreement serves to confirm that the light was uniformly distributed across the sample in our epr cavity.

Results and Discussion

The epr signals from **4** and **6** (eq. [2]) were quite weak even under optimum conditions (carefully purified alkyne; see Experimental) and were swamped by other signals if crude alkyne was used directly. Use of the bromide and either tri-*n*-butyltin or trimethylsilyl radicals (Experimental) did not lead to improvement in the signal-to-noise ratio. Those conditions gave very weak spectra of the radicals of interest together with strong spectra from unidentified, persistent radicals.

Radicals **4** and **6** have proton coupling constants typical of hydrocarbon radicals. Thus **4** has $a^{H\alpha}$ (2H) = 23.7 and $a^{H\gamma}$ (6H) = 0.85 G while **6** has $a^{H\beta}$ (6H) = 22.5 and $a^{H\beta}$ (2H) = 21.6 G.

The ratio of the rate constant for the overall rearrangement to that for the bimolecular self-reaction of **6** can be calculated from the absolute concentrations of **4** and **6** according to the equation (13–15)

$$k^{C\equiv C}/2k_t(\mathbf{6}) = [\mathbf{6}]^2/[\mathbf{4}] + [\mathbf{6}]$$

The data used to derive $k^{C\equiv C}/2k_t(\mathbf{6})$ are listed in Table 1. Measurements were made as quickly as possible to minimize effects from buildup of long-lived free radicals and non-radical products. Reused samples gave results which were consistent with the results obtained with new samples, indi-

cating that accumulation of interfering species was negligible during the short illumination periods. To some, the results in this table may appear rather irreproducible. They are, nevertheless, the best that can be obtained using present day kinetic epr procedures. The scatter of the data serves as a reminder of the errors inherent in this type of measurement when, even at full light intensity, the signal-to-noise ratio is rather poor.

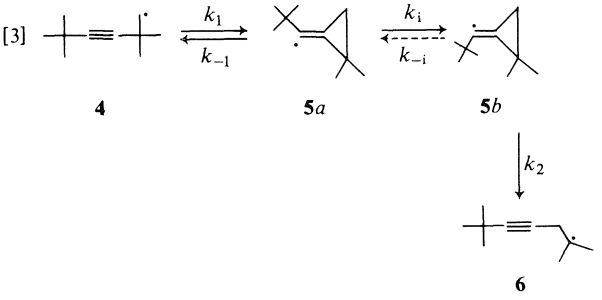

Table 2 lists the rate constants for the bimolecular self-reaction of **4**, $2k_t(\mathbf{4})$. These numbers were obtained as follows. The kinetic epr method was used to measure $2k_t(\mathbf{4})$ at 15°C, where its rate of rearrangement is very low. The resulting value, $5.2 \times 10^9\ M^{-1}\ s^{-1}$, indicates that **4** decays at the diffusion-controlled limit, as would be expected for this sterically unhindered radical. The value of $2k_t(\mathbf{4})$ at 15°C was then placed on the graph by Schuh and Fischer (17), of $2k_t$ against $1/T$ for *tert*-butyl radicals in various solvents. A line was drawn through that point and parallel to their line for *n*-decane solvent. Values of $2k_t(\mathbf{4})$, in the experimental temperature range for study of its rearrangement (Table 1), were then read from the ordinate of the graph. This procedure involves the reasonable assumption that the temperature (viscosity) dependence of $2k_t(\mathbf{4})$ in 2,2,5,5-tetramethyl-3-hexyne parallels that of $2k_t(t\text{-Bu}^\cdot)$ in *n*-decane. In view of the fact that the latter dependence is not very solvent sensitive (17) any error introduced through the above assumption is likely to be much smaller than other errors inherent in the kinetic epr method.

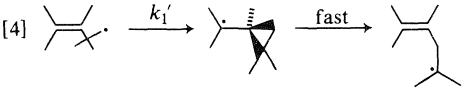
Since **6**, like **4**, is a sterically unhindered radical it also will undergo a bimolecular self-reaction at the diffusion-controlled limit. Because **6** and **4** are of equal molecular weight it is fairly safe to assume that $2k_t(\mathbf{6})$ and $2k_t(\mathbf{4})$ will be equal. The values of $2k_t(\mathbf{4})$ listed in Table 2 can therefore be combined with the data in Table 1 to obtain $k^{C\equiv C}$. A least-squares treatment leads to the Arrhenius equation

$$\log(k^{C\equiv C}/s^{-1}) = (12.40 \pm 1.5) - (14.6 \pm 2.4)/\theta$$



where the errors are standard deviations and $\theta = 2.3RT$ kcal mol^{-1}. These parameters give $k^{C\equiv C}$ (25°C) = 49 s^{-1}, which is nearly the same as the value for neophyl rearrangement (59 s^{-1} at 25°C) (15*e*).

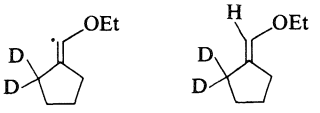
The question now arises as to whether the measured rate constants for **4** and for neophyl have similar meanings, since the rearrangement of homopropargyl radicals is potentially complicated by a factor not present in the rearrangement of homoallyl or homobenzyl systems. This complication arises out of the known preference for *trans* addition to acetylenes via radical intermediates (18). Thus, the intramolecular addition step in the overall rearrangement of **4** is expected to lead to radical **5***a* in preference to **5***b*,[5] eq. [3].

[3] 

It follows from the principle of microscopic reversibility that the stereoelectronically preferred ring opening pathway for **5***a* is that leading back to **4** rather than directly forward to **6**. *In order to reach* **6** *by the pathway of lowest activation energy, it is presumably necessary to invert* **5**a *to* **5**b.

A possible consequence of the expected stereoelectronic preference is significant return of **5***a* to **4**; that is, inversion of **5***a* might not be much faster than its reopening to starting radical. In that case the experimental rate constant, $k^{C\equiv C}$, would not be the k_1 of [3] but instead, $k^{C\equiv C} = k_1k_i/(k_i + k_{-1})$. Detailed comparison of $k^{C\equiv C}$ for the present homopropargyl radical rearrangement with rate constants for homoallyl and homobenzyl radical rearrangements could then be misleading since the latter have no stereoelectronic constraint against direct ring opening of the cyclic radical intermediate in the thermodynamically favoured direction. That is, for rearrangements such as that shown in eq. [4] it is probably safe to assume that the experimentally measured rate constant is equal to k_1'.

[4] 



Very little is known about inversion rates of vinyl radicals. Fessenden and Schuler (19*a*) concluded that the parent radical inverts with a barrier of ca. 2 kcal mol^{-1} and with rate constant between 3×10^7 and 3×10^9 s^{-1} at −133°C. The 2-propenyl radical also inverts readily although somewhat more slowly (19*a*)[6] than the vinyl radical. Other qualitative evidence for facile inversion of vinyl radicals includes the requirement for highly efficient traps in

[5]Vinyl radicals with H or alkyl substituents are known to be bent σ-radicals (19) even in the face of steric hindrance (20).

[6]The rate constant was not reported.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

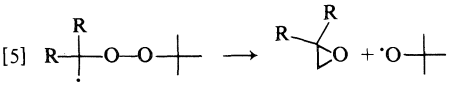
order to capture vinyl radicals with retention of configuration (18*a*, 18*b*, 21). An α-alkoxy substituent, on the other hand, greatly reduces the inversion rate constant of a vinyl radical. Even at 60°C, **7** is reduced cleanly to **8** (96%) in the presence of 0.065 *M* (initial) Bu_3SnH (18*a*, 18*b*).

7 8



In the present case, the substituents are not likely to have a large effect on inversion rates. Although steric hindrance must be greater in **5***b* than in **5***a*, the difference is expected to be much smaller than it would be in the corresponding alkenes because vinyl radicals have a C—C—R bond angle[7] of at least 151°. Consequently, the steric factor is not likely to reduce k_1 or to increase k_{-i} and k_2 greatly, relative to corresponding rate constants for less hindered vinyls. Moreover, the last step is expected to be fast and irreversible because **5***b* will probably feel some of the driving force of strain relief and of the vinyl-to-tertiary alkyl radical isomerization at the transition state. Consequently, we suggest that k_1 is largely or entirely rate-determining in the rearrangement of **4** and that $k^{C\equiv C}$ either equals k_1 or sets a lower limit not different from k_1 by more than an order of magnitude.

In theory, the assumption that ring closure is rate-determining can be checked by calculating a minimum activation energy, E_a, for this reaction using thermochemical data and additivity principles (22). We calculate ΔH_f^0 (**4**) = 43 kcal mol^{-1} and ΔH_f^0 (**5***a*) = 61 kcal mol^{-1} by taking the methylenecyclopropane strain energy as 41.7 kcal mol^{-1} (23) and ignoring small corrections for steric hindrance. These estimated heats of formation suggest that cyclization is endothermic by some 18 kcal mol^{-1} and that E_a (k_1 step) > 18 kcal mol^{-1}. Thus, the observed rate constant appears[8] to be much too high; not too low as would be predicted if $k^{C\equiv C} = k_1k_i/(k_i + k_{-1})$, with substantial attenuation from the factor multiplying k_1. Although this result is qualitatively the one required to support the above assumption, it cannot be regarded as strong support because of problems with the quantitative aspects of such thermochemical estimates (see below).

It is interesting to examine measured activation energies and thermochemically estimated minimum activation energies for other radical cyclizations to form three-membered rings. For cyclization of the neophyl radical, ΔH_r has been estimated at 16 kcal mol^{-1}, using thermochemical data and assuming that the cyclohexadienyl stabilization energy is 22 kcal mol^{-1} and that there is no spiro strain in the intermediate.[9] Since the experimental E_a for the overall rearrangement is only 13.6 kcal mol^{-1} (15*e*), the calculated endothermicity is also too high, as it is for the present homopropargyl case. For rearrangement of the β-phenylethyl radical the agreement is better since the estimated[9] ΔH_r is 17 kcal mol^{-1} and the experimental E_a (> 19 kcal mol^{-1})[10] at least exceeds the endothermicity, as it should.

Similarly, cyclization of the 2,2,5,5-tetramethyl-3-hexen-l-yl and the 3-buten-l-yl radicals has a calculated endothermicity of about 7 kcal mol^{-1} whereas the corresponding experimental E_a values[10,11] are ca. 7 and 9 kcal mol^{-1}. Again the rate of ring closure for the system with *gem* dimethyl substitution is higher than one would predict on the basis of the estimated endothermicity while the rate for the corresponding unsubstituted system is in qualitative agreement with the thermochemical estimate.

Finally, in the exothermic oxirane-forming cyclization shown in eq. [5], there is a similar accelerating effect of methyl groups (R = CH_3 compared to R = H) which amounts to a rate factor of 350 at

[5] 

25°C, or to a reduction of E_a by 3.5 kcal mol^{-1} (24).

It is fairly clear that the relief of steric compression which accompanies formation of a *gem* disubstituted, small ring (Thorpe–Ingold effect) (25), causes significant rate enhancement[12] in radical processes. Reaction enthalpies should be affected even more strongly than activation energies by such steric factors. Since calculated enthalpies, based on group equivalents and additivity (22), do not reflect such steric factors adequately,[13] it appears that thermochemical kinetics can not be used, even for "order of magnitude" estimates of absolute rates, in systems where the Thorpe–In-

[7]The CCH bond angle of vinyl radical is about 151° (19*a*).

[8]The error in thermochemical estimates of this sort could be several kcal mol^{-1}.

[12]By factors of 10^2–10^4.

[13]Another example illustrating this point comes from calculation of the heats of formation of neopentane and 1,1-dimethylcyclopropane. Both calculated values, based on group increments and ring strain but without any allowance for the different methyl–methyl group interactions in the two compounds, come close to the experimental values.

gold effect operates. On the other hand, thermochemical estimates can be used effectively to rank reactivities of systems of the same type; i.e., systems all of which are (or are not) *gem* disubstituted.

For the homoallyl rearrangement corresponding to the homopropargyl rearrangement (**4** → **6**) we estimate $\Delta H_r = 7$ kcal mol^{-1}. In spite of the uncertainty surrounding the use of such numbers, in isolation, to estimate the minimum value of E_a, it is clear from comparison with corresponding values for the homopropargyl and neophyl systems that the homoallyl rearrangement ought to be very fast indeed. Although a rate constant has not been measured, preliminary experiments suggest that it exceeds 10^3 s^{-1} at -100°C.[11] It is reasonable to attribute the slowness of the homopropargyl and neophyl radical rearrangements primarily to the strain energy of a methylenecyclopropane and to the loss of aromaticity, respectively, involved in attaining the appropriate transition states.

The large difference between homoallyl and homopropargyl radical rearrangement rates has practical consequences pertinent to synthetic procedures. To capture homoallyl radicals efficiently before they rearrange it is necessary to use very reactive reagents at relatively high concentration. Homopropargyl radicals, on the other hand, are more easily intercepted. The difference was demonstrated qualitatively with *tert*-butyl hypobromite as capturing reagent. Whereas 2,2,5,5-tetramethyl-3-hexyne gave unrearranged bromide quite cleanly (Experimental), *trans*-2,2,5,5-tetramethyl-3-hexene, under similar conditions, gave unrearranged bromide and 2,6,6-trimethyl-2,4-heptadiene.[11] The latter most likely came from dehydrohalogenation of rearranged, tertiary bromide.

Factor analysis as a complement to infrared band resolution. VII. The temperature dependence of the self association of phenol in carbon tetrachloride solution

B. U. PETELENZ[1] AND H. F. SHURVELL

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 20, 1979

B. U. PETELENZ and H. F. SHURVELL. Can. J. Chem. **58**, 353 (1980).

Infrared absorption bands in the OH stretching region of phenol in carbon tetrachloride solution have been recorded for various concentrations and at several temperatures between 25 and 60°C. Factor analysis of the digitized spectra was carried out and the presence of three absorbing components in the OH stretching band was indicated at all temperatures in the range of 25–60°C. The three components are assigned to monomer, linear dimer, and a polymeric species. It is suggested that the polymeric species is a cyclic trimer.

Band contour resolution was carried out to obtain areas of the component bands. The variation of the monomer and dimer band areas with temperature was used to obtain a value for the enthalpy of dimerization of -15.8 ± 0.6 kJ mol^{-1}.

B. U. PETELENZ et H. F. SHURVELL. Can. J. Chem. **58**, 353 (1980).

On a enregistré les bandes d'absorption, dans la région d'élongation du OH, du phénol en solution dans le tétrachlorure de carbone à différentes concentrations et à des températures variant de 25 à 60°C. On a effectué une analyse factorielle des spectres numériques et on a mis en évidence la présence des trois constituants qui absorbent dans la bande d'élongation du OH à toutes les températures comprises dans l'intervalle 25–60°C. Les trois constituants sont identifiés comme étant le monomère, le dimère linéaire et les espèces polymérisées. On suggère que les espèces polymérisées sont des trimères cycliques.

On a effectué la résolution des pics dans le but d'obtenir les surfaces des bandes des constituants. On a utilisé la variation des surfaces des pics du monomère et du dimère en fonction de la température afin d'obtenir une valeur de l'enthalpie de dimérisation de -15.8 ± 0.6 kJ mol^{-1}.

[Traduit par le journal]

Introduction

Factor analysis (principal component analysis) together with infrared band contour resolution has been used previously in various studies of equilibria in CCl_4 solution (1–5).

The application of factor analysis to digitized infrared spectra leads to the determination of the number of absorbing components (NC) in a complex band (1). Subsequent resolution of the spectra into NC components yields band areas, from which molar absorption coefficients and concentrations of the species present at equilibrium can be calculated using a non-linear least-squares method. Finally equilibrium constants can be calculated from the concentrations of the species.

In our previous studies (1–5) a constant temperature was maintained and spectra of solutions of various concentrations were recorded and analyzed. The only thermodynamic quantity available from this type of study is the equilibrium constant. On the other hand, the temperature dependence of the areas of component bands can lead to the determination of the enthalpy of reaction.

The thermodynamics of self association of phenol in inert solvents has been the subject of numerous studies employing various experimental techniques (4, 6–17) and the earlier work has been reviewed recently (7). There has been considerable controversy over the interpretation of experimental results. Several models have been proposed involving phenol monomer in equilibrium with various associated species, and the structure of these species has been discussed. The problem of end-group OH absorption has also received attention. It was felt that the methods of factor analysis and band resolution might resolve some of the problems encountered in studies of self association of phenol in CCl_4 solution.

In our own previous study on phenol in CCl_4 (4), the equilibrium constant K_d for the monomer–dimer equilibrium at 34°C was found to be 0.76 ± 0.05 L^{-1} mol. We report here an extension to this work, in which spectra have been recorded at various temperatures between 25 and 60°C for various concentrations of phenol in CCl_4. The spectra have been digitized and subjected to factor analysis and band contour resolution in order to obtain a value for the enthalpy of dimerization. End-group absorption has been taken into account in our calculations and the nature and structure of the most likely polymeric species are discussed here.

Experimental

Fisher Scientific Company spectroanalyzed carbon tetrachloride was dried over molecular sieve. Dryness was checked by monitoring water bands at 3709 and 3618 cm^{-1} in the infrared spectrum. Analytical reagent grade phenol was supplied by Mallinckrodt Chemical Company. Attempts were made to remove traces of moisture from the sample by refluxing a solution in benzene over molecular sieve. After distilling off the benzene–water azeotrope, the phenol was sublimed under reduced pressure and stored over P_2O_5. The effectiveness of the above treatment was checked by comparing the ir spectra of untreated and purified phenol in CCl_4 solution. Since there was no detectable difference in the spectra, it was concluded that the original sample probably contained less than 0.5% water.

All operations except weighing were performed in a dry-box in which the relative humidity was less than 20%. New solutions were prepared for each series of spectra. Details of solutions, pathlengths, and temperature ranges in which spectra were recorded are listed in Table 1.

Temperatures were precisely controlled with an RFL Industries Model 70 proportional controller. This device controls the electrical power supplied to a Beckman-R.I.I.C. model J3 heating jacket which surrounds a model FH-01 variable temperature NaCl cell supplied by the same company. The temperature was monitored by means of an iron–constantan thermocouple. The emf of the thermocouple was recorded on a Honeywell Electronik 194 recorder. The thermocouple was calibrated using standard thermometers made and calibrated to A.S.T.M. specifications.

Spectra were recorded on a Perkin-Elmer model 180 spectrometer without compensation in the reference beam. The spectral slit width was 2 cm^{-1} and a scanning rate of 15 cm^{-1}/min was used. Intensities were recorded as absorbance and the spectra were digitized manually at 2 cm^{-1} intervals.

Computational Methods

Factor Analysis

Factor analysis (principal component analysis) is a multivariate statistical technique, which can be used to determine the number of independent components contributing to an experimentally observed quantity, such as an infrared absorption band. Details of the method and its application to analysis of infrared and Raman spectra recorded for a series of solutions at a single temperature have been given in a recent review article (18). The present application to spectra recorded for a single solution at a series of temperatures differs only in notation.

If the number of temperatures at which spectra are recorded for a solution of fixed total phenol concentration is NT and if the number of wavenumber points at which intensity readings are taken is NW, then the absorbance matrix **A** (normalized to unit path length) will have NT rows and NW columns.

For the case where the temperature is fixed and spectra are recorded for NS solutions of various total phenol concentrations, a similar absorbance matrix is obtained with NS rows.

The method of factor analysis involves finding the rank of the absorbance matrix. Under the conditions of our experiments (NW > NT > NC), the rank of **A** may be interpreted as being equal to the number of absorbing components NC. To find the rank of **A**, the matrix $\mathbf{A}^T\mathbf{A}$ is formed, where $\mathbf{A}^T$ is the transpose of **A**. This matrix has the same rank as **A**, but has the advantage of being a square matrix with much smaller dimensions than **A** (NT × NT). The rank of **A** is given by the number of non-zero eigenvalues of $\mathbf{A}^T\mathbf{A}$. These can be determined using statistical tests (19–21).

Band Resolution

The computer programs for band contour resolution were written by Jones *et al.* (22). A Cauchy–Gauss product function was used to describe each component band in the envelope.

When the number of absorbing components NC is known, the fitting procedure consists of varying the peak position, height, and width parameters for all components until a satisfactory fit is obtained between the observed and computed contour. The quantity NC is obviously essential for this procedure and factor analysis provides this number.

TABLE 1. Concentrations, temperature ranges, and pathlengths for solutions of phenol in CCl_4

Total phenol concentration (*M*) at 20°C	Temperature range (K)	Cell pathlength (mm)
1.108	302–333	0.108
0.4542	298–323	0.188
0.4274	302–322	0.188
0.1147	298–323	0.52

Results and Discussion

The temperature dependence of the spectra of three solutions of phenol in CCl_4 in the OH stretching region is shown in Figs. 1–3. The sharp monomer peak at 3612 cm^{-1} increases in intensity relative to the broad dimer and polymer peaks as the temperature is increased. It is also evident in Fig. 2 that the dimer band at 3480 cm^{-1} gains intensity at the expense of the lower frequency polymer band centred near 3350 cm^{-1} as the temperature is increased.

Structures of Associated Species

In the subsequent paragraphs we will refer to dimer and higher polymers of phenol. Therefore some discussion of the structures of these species is necessary in order to justify our choice of the most likely self-associated species present in CCl_4 solutions.

It has been pointed out earlier (23) that the bent

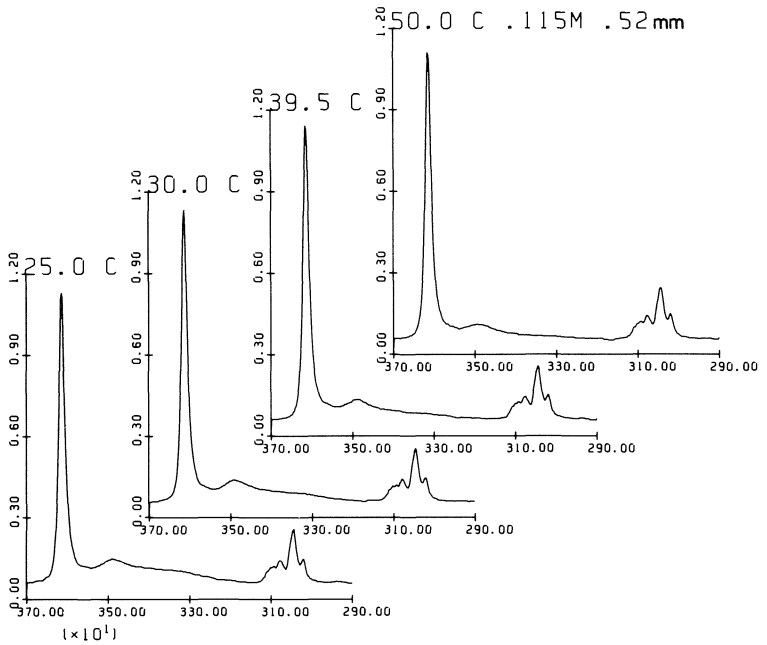

FIG. 1. The temperature dependence of the infrared spectrum of a 0.115 *M* solution of phenol in CCl_4.

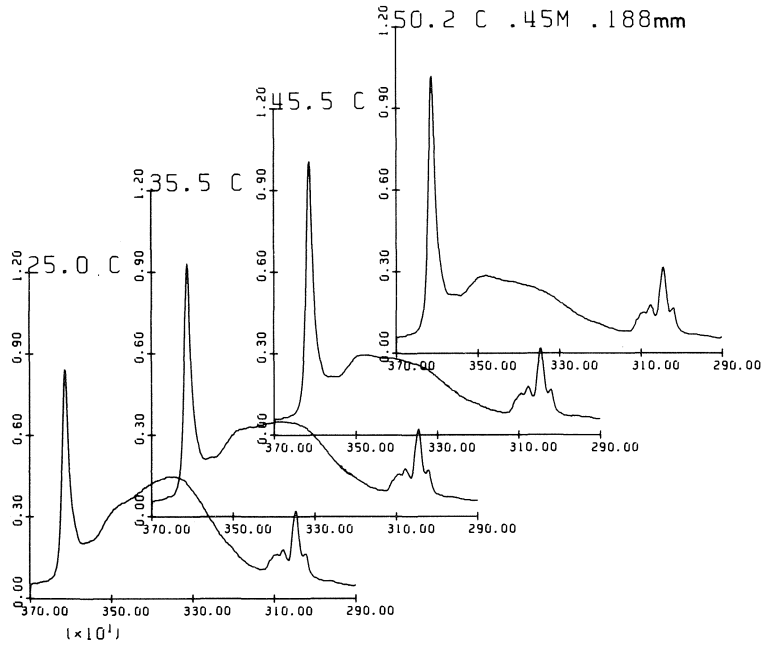

FIG. 2. The temperature dependence of the infrared spectrum of a 0.454 *M* solution of phenol in CCl_4.

hydrogen bonds in a cyclic dimer of phenol would be very weak and therefore the open-chain form is the most likely structure of the dimer.

Sterically the most favoured polymeric species appears to be the cyclic trimer, which has a planar strain-free six membered hydrogen bonded ring formed by the three OH groups. This structure is essentially the same as that found in the unit cell of crystalline phenol (24). The attack of a further phenol molecule to form a tetramer is sterically hindered and moreover, the formation of a tetramer would require ring opening which is energetically unfavoured. In solutions of low concentration in CCl_4 the formation of higher polymers is unlikely

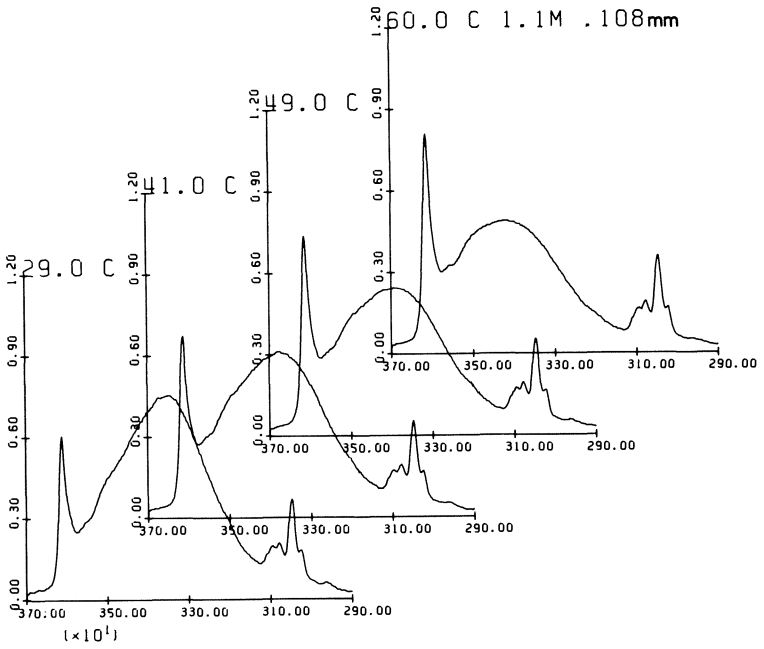

FIG. 3. The temperature dependence of the infrared spectrum of a 1.11 *M* solution of phenol in CCl_4.

and we assume that the species of phenol present under the experimental conditions used in this work are monomer, linear dimer, and cyclic trimer. This assumption appears to be in agreement with the results of factor analysis discussed below.

Factor Analysis Results

Spectra were recorded for several concentrations of phenol in CCl_4 at a series of temperatures. Factor analysis was carried out for each series of spectra. Table 2 lists the eigenvalues, and residual standard deviations (r.s.d.) (20) in the eigenvalues of $\mathbf{A}^T\mathbf{A}$ for a typical series of spectra recorded from a 1.108 *M* solution at six temperatures. Table 3 lists the eigenvalues of $\mathbf{A}^T\mathbf{A}$ and the corresponding standard errors (19) for a 0.4542 *M* solution of phenol for spectra recorded at seven temperatures.

In Table 3 it can be seen that the first three eigenvalues are larger than their standard errors. This indicates that three components are present. In Table 2 it is seen that the first three r.s.d. values are larger than the experimental standard deviation of 0.0015, while the fourth r.s.d. is close to this error estimate. However, examination of the eigenvalues reveals that there is a factor of 20 between the third and fourth eigenvalues, whereas there is only a factor of three between the fourth and subsequent eigenvalues. This surely indicates that only the first three eigenvalues are really non-zero.

Table 4 shows the distribution of misfit between

observed and regenerated absorbance matrix (19) using from one to seven eigenvectors. The last two columns list the computed values of χ^2 (19) and the expectation values calculated from the formula $(NW - m)(NT - m)$ (21), where NW is the number of points in a digitized spectrum (401 in the present case) and NT is the number of temperatures at which spectra were recorded. From Table 4 it can be seen that using two eigenvectors leaves 463 points with up to three standard deviations from the experimental values. Addition of a third eigenvalue brings all calculated points to within one standard deviation of the experimental values. Again, this indicates that the number of absorbing components is three. The χ^2 criterion is ambiguous in that it indicates two components. This can be seen from the comparison of the calculated values with the expectation values in columns 5 and 6 of Table 4.

The analysis was carried out for each solution of Table 1 with similar results. Spectra of the four solutions of Table 1 were also analyzed at a single fixed temperature (50°C) and again three components were indicated by all except the χ^2 test. At present we are unable to explain the failure of this criterion to indicate three components.

Band Contour Resolution

As suggested by factor analysis, we carried out band resolution using three Cauchy–Gauss product functions in the hydroxyl stretching region. Plots of typical resolved spectra are shown in Fig. 4, where it is seen that (after baseline removal) the fit between the observed and calculated spectra is quite good. Four band fits were also tried, to take end-group OH absorption into account. An example of a four band fit, with baseline removed, is shown in Fig. 5. End-group absorption is undoubtedly present, but does not appear as a separate component in the factor analysis. This is because there is a linear relationship between the intensity of bonded and free OH stretching absorption of the open chain dimer. For reasons discussed above, it is believed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

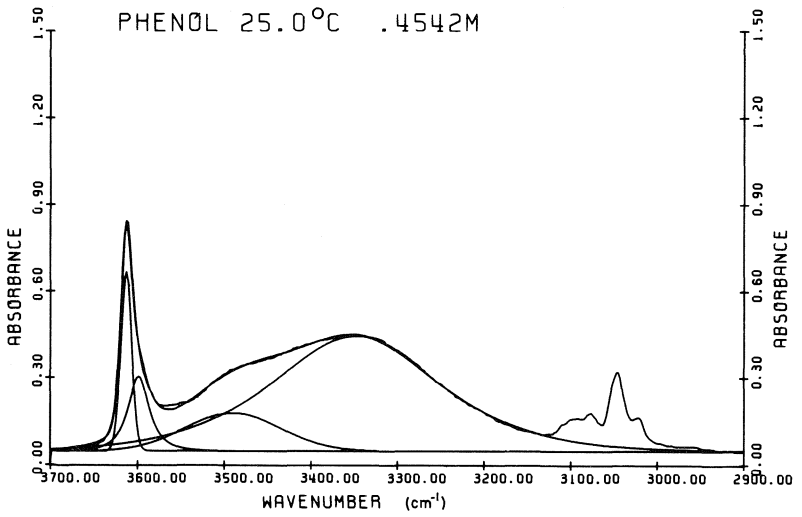

FIG. 5. A typical four-band fit to the spectrum of a 0.454 *M* solution on phenol in CCl_4 at 25°C. The baseline correction has not been subtracted from the experimental spectrum.

that a cyclic trimer is the most likely higher polymeric species. This trimer has no free OH end group. Open chain trimers and higher polymers would be expected to contribute to OH end-group absorption, but the concentration of these species is likely to be quite small.

Calculation of ΔH*(dimerization)*

Assuming that the activity coefficients of monomer and dimer are unity the equilibrium constant for the dimerization reaction is simply $K_d = C_2/C_1^2$ where C_1 and C_2 are the concentrations of monomer and dimer respectively. According to the Beer–Lambert law, the concentrations C_1 and C_2 are proportional to the absorbances of the corresponding resolved component bands and thus to the band areas A_1 and A_2.

If the dimerization constant is determined at several temperatures one can use the van't Hoff equation

$$[1] \quad d(\ln K_d)/d(1/T) = -\Delta H^0/R$$

But

$$[2] \quad \ln K_d = \ln (A_2/A_1^2) + \text{constant}$$

Thus, by plotting $\ln (A_2/A_1^2)$ versus inverse temperature one obtains the enthalpy of dimerization from the slope. The results obtained from four different total phenol concentrations are given in Table 5. It is assumed that neither ΔH^0 nor the molar absorption coefficients (ε_1 and ε_2) of monomer and dimer are temperature dependent in the small temperature range covered in the present study.

TABLE 5. Enthalpies of dimerization of phenol obtained for four different total concentrations of phenol in CCl_4

0.1147	15.242	29.480
	Ave. 15.804	

End-group Absorption

The effect of end-group OH absorption is difficult to assess. It does not appear as a separate absorbing component in the factor analysis. However, in the band fitting program the intensity of the fourth component must be somehow distributed by the computational procedure between the monomer and the dimer band. An estimate can be made of the effect of neglect of end-group absorption on the final results.

It may be assumed that the molar absorption coefficient of the end-group band is equal to that of the monomer (ε_1), since this is a similar type of vibration. The areas of the monomer and dimer bands obtained from the three-band fit each contain some contribution from the end-group absorption.

Suppose the contribution from the end-group absorption is x to the monomer absorbance and $(1 - x)$ to the dimer absorbance. Using the Beer–Lambert law the corrected normalized absorbances can be expressed as follows:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

Monomer:

[3] $A_1' = \varepsilon_1 C_1 + x\varepsilon_1 C_2$

Dimer:

[4] $A_2' = \varepsilon_2 C_2 + (1 - x)\varepsilon_1 C_2$

It is assumed here that the dimers are linear, i.e. the concentration of the end-group absorbing species is equal to the concentration of the dimer. Both the contribution of higher polymers to the end-group absorbance and the negative correction for the presence of cyclic dimers are neglected.

Thus, the dimerization constant becomes

$$[5] \quad K_d' = \frac{\varepsilon_1^2[\varepsilon_2 + (1 - x)\varepsilon_1]A_2'}{\{[\varepsilon_2 + (1 - x)\varepsilon_1]A_1' - x\varepsilon_1 A_2'\}^2}$$

Making use of eq. [5], it is found that calculated K_d values will be too high for low total concentration of phenol and too low in other cases. Consequently, there will be an error $\delta(\Delta H^0)$ in the calculated values of enthalpy of dimerization given by $-RT\delta K/K_d'$ where $\delta K = K_d' - K_d$.

If it is assumed that the intensity of the end-group band contributes equally to monomer and dimer intensities in the three-component fit, then $x = 1/2$. Three special cases will be considered: (*1*) an intermediate total concentration when $\mathbf{A}_1 = \mathbf{A}_2$; (*2*) a higher concentration when $\mathbf{A}_2 = 2\mathbf{A}_1$; (*3*) a low total concentration when $\mathbf{A}_2 = \mathbf{A}_1/2$.

The calculations were performed using the molar absorption coefficients determined in ref. 4 for monomer and dimer absorption bands. The results are presented in Table 6. Of course, due to the various assumptions made in the calculations, the results in Table 6 have a qualitative meaning only. Nevertheless, they seem to explain the concentration trend in the ΔH^0 values reported in Table 5.

Summary and Conclusions

Factor analysis (principal component analysis) has been used for the first time to study the temperature dependence of an infrared absorption band. The results for the OH stretching band in the infrared spectra of solutions of phenol in CCl_4 indicate the presence of three independent components in the spectra which are assigned to monomer, linear dimer, and one or more polymeric species. This conclusion is consistent with an earlier interpretation of the concentration dependence of the infrared spectra of phenol in CCl_4 solutions at a constant temperature (4).

It is possible to obtain a reasonable three-component fit to the observed spectra (Fig. 4). From the temperature dependence of the areas of the monomer and dimer components we have obtained an average value of $-15.8\,\text{kJ mol}^{-1}$ for the enthalpy of dimerization for four different concentrations of phenol in CCl_4 solution.

End-group absorption by the linear dimer, or higher linear polymers, contributes to the intensity of both monomer and dimer bands. The addition of a fourth component, due to end-group absorption, to the fitting procedure results in an improved fit between observed and computed band envelopes (Fig. 5). However, in this case the temperature dependence of the areas of the monomer and dimer component bands does not lead to consistent values of ΔH^0(dimerization) for solutions of different total phenol concentration. A slight trend with concentration might be noted in our reported values of ΔH^0(dimerization). This trend can be accounted for qualitatively by taking end-group absorption into account. It is not possible to assign definite structures to the polymeric species present in solutions of phenol in CCl_4, but we suggest that the predominant species is a cyclic trimer.

TABLE 6. Estimated error in ΔH^0 determined from the three-band fit

Case	Total phenol concentration	Error in ΔH^0 (kJ mol^{-1})
$\mathbf{A}_2 = 2\mathbf{A}_1$	High	−2.04
$\mathbf{A}_2 = \mathbf{A}_1$	Intermediate	−0.14
$\mathbf{A}_2 = \mathbf{A}_1/2$	Low	+0.05

CONSTANTINOS A. TSIPIS and CONSTANTINOS A. TSOLERIDIS. Can. J. Chem. **58**, 361 (1980).

Carbon-13 nmr chemical shifts of a number of *E*-silyl-alkenes containing the silyl substituent at an sp^2 carbon atom are presented. Assignments of the chemical shifts have been made by noting systematic variations in the spectra with changes in substituents and by comparison of the chemical shifts to those of the corresponding unsubstituted alkenes. The substituent effects observed were explained on the basis of the π-acceptor ability of the silyl substituents and the structure of the molecules. Comparing the ^{13}C nmr spectra of the *E*-silyl-alkenes and those of the corresponding unsubstituted alkenes, differential chemical shifts have been obtained which can be used as empirical substituent parameters for the prediction of the ^{13}C nmr spectra of other *E*-silyl-alkenes not yet studied. It was also demonstrated that ^{13}C nmr spectroscopy can be used without resorting to special techniques (gated decoupling and the addition of paramagnetics) as an alternative method to the ^1H nmr for the quantitative analysis of mixtures of regio-isomer *E*-silyl-alkenes.

CONSTANTINOS A. TSIPIS et CONSTANTINOS A. TSOLERIDIS. Can. J. Chem. **58**, 361 (1980).

On présente les déplacements chimiques en rmn du ^{13}C d'un certain nombre d'alcènes silylés-*E* portant le groupe silyle sur un atome de carbone sp^2. On a identifié le déplacements chimiques en notant les variations systématiques des spectres résultant des changements de substituants, et en les comparant à ceux des alcènes non substitués correspondants. On explique les effets des substituants en se basant sur la propriété π des substituants silylés et sur la structure des molécules. En comparant les spectres rmn du ^{13}C des alcènes silylés-*E* à ceux des alcènes non substitués correspondants, on a obtenu des déplacements chimiques différentiels qui peuvent être utilisés comme des paramètres additifs empiriques pour prédire les spectres rmn du ^{13}C d'autres alcènes silylés-*E* qui n'ont pas encore été étudiés. On a également démontré que la spectroscopie rmn du ^{13}C peut être utilisée, sans recourir à des techniques spéciales (découplage ou addition de substances paramagnétiques) comme une alternative pour la rmn du ^1H pour l'analyse quantitative des mélanges des régioisomères des alcènes silylés-*E*.

[Traduit par le journal]

Introduction

The number of publications dealing with ^{13}C nmr spectra of some model systems has grown in the past ten years. Thus, systematic studies on the ^{13}C nmr spectra of alkanes (1), alkenes (2–5), alkynes (6, 7), as well as some of their substituted derivatives (8–10) and other classes of organic compounds (11, 12) have been reported. However, as far as we know, the systematic studies of ^{13}C nmr spectra of model systems in organosilicon chemistry are rather limited.

Recently, a few papers dealing with ^{13}C nmr spectra of a variety of organosilanes including phenylsilanes (13, 14), benzylsilanes (15, 16), methylsilanes (17), alkoxysilanes (18), siloxanes (19), and siloxyethers (20–23) have been published. In most of them ^{13}C nmr spectroscopy was used to study the interaction between silicon and a substituent capable of p_π–d_π bonding, such as phenyl, oxygen, vinyl, etc. Also, in some cases, some empirical substituent – chemical shift (SCS) parameters were determined and correlated with observed chemical shifts (13–15).

Conspicuously absent from the growing volume of the ^{13}C nmr data on organosilanes is a systematic study of silyl-alkenes containing the silyl substituent in an sp^2 carbon atom. In the present paper we report our ^{13}C nmr measurements on a number of *E*-silyl-alkenes, either terminal or internal, and some hydroxy-derivatives. The aim of the paper is to fill this gap giving the ^{13}C nmr spectra of some model *E*-silyl-alkenes and to study the influence of the silyl substituent on the ^{13}C nmr signals of the alkene moiety.

Results and Discussion

In Table 1 are listed the chemical shifts (δ, ppm), the relative intensities, and the assignments of the ^{13}C nmr signals of some *E*-1-silyl-1-alkenes and hydroxyderivatives.

Chemical shift assignments were made using previously noted (2–5, 8, 10) ranges of resonances for analogous compounds, as well as by noting systematic variations in the spectra with changes in substituents.

The ^{13}C resonances of the two sp^2 carbon atoms (C1 and C2) of the *E*-1-silyl-1-alkenes appear, as one would expect, in the region of 120–160 ppm down-

*The comparison has been done between the ^{13}C nmr spectra, which were obtained in the same solvent ($CDCl_3$).

field from TMS. Comparing the chemical shifts of the sp^2 carbon atoms of the *E*-1-trichlorosilyl-1-alkenes under consideration with those of the vinyltrichlorosilane (8), which is the simplest 1-trichlorosilyl-1-alkene, we can make unambiguous assignments for the ^{13}C resonances of the two sp^2 carbon atoms. Thus, the signal at ca. 120 ppm is assigned unambiguously to the C1 and the signal at ca. 150 ppm to the C2 carbon atom. In order to support the above assignments of the ^{13}C resonances of the sp^2 carbon atoms of the *E*-1-silyl-1-alkenes, we also examined the ^{13}C nmr spectra of some internal *E*-silyl-alkenes. In the last case, it is clear from the comparison of the relative intensities of the ^{13}C nmr signals of the two sp^2 carbon atoms that the signal at higher field corresponds to the sp^2 carbon atom bearing the silyl group and that at lower field to the sp^2 carbon atom bearing the hydrogen. The signal at lower field has higher relative intensity than that at higher field because of the nuclear Overhauser enhancement effect (24). Details on the ^{13}C nmr spectra of the internal *E*-silyl-alkenes will be discussed later.

Assignments of the ^{13}C resonances of the saturated carbon atoms were made by comparison of their chemical shifts to those of the corresponding unsubstituted alkenes (2, 3, 5). It ought to be noted that it is possible to do this comparison, because, as it is known, the presence of a substituent causes small, usually, constant shifts of the resonances of the unsubstituted derivative, which can be expanded up to the fourth carbon atom relative to the carbon atom bearing the substituent (5).

Comparing the ^{13}C nmr spectra of the *E*-1-silyl-1-alkenes to those of the corresponding unsubstituted alkenes we noticed some remarkable trends concerning the sensitivity of the ^{13}C resonances of the alkene moiety to the organosilyl substituent.

In Table 2 are shown the differences ($\Delta\delta_C$) between the chemical shifts of the ^{13}C resonances of the *E*-1-silyl-1-alkenes and those of the corresponding unsubstituted 1-alkenes. In fact, the results reveal some patterns of chemical shift variations depending upon the nature of the silyl substituent.

Consideration of the substituent effects on the

*The ^{1}H nmr spectra were obtained in $CDCl_3$ or CCl_4 solutions using TMS as an internal standard.
†Values (a − d) and (b − c) are the differences between the resonance frequencies of the two outer and the two internal peaks of the quartet respectively.

chemical shifts of the sp^2 carbon atoms reveals that the silyl group introduces a downfield shift of the signals of both the sp^2 carbon atoms. These shifts for the three silyl substituents under consideration, e.g., $SiCl_3$, $SiMeCl_2$, and $SiEt_3$, are +7.69, +9.44, and +11.38 ppm for the C1 and +18.04, +15.09, and +9.60 ppm for the C2 carbon atoms respectively.

In the case of the trichlorosilyl and methyldichlorosilyl substituents the deshielding of the C2 is greater than that of the C1. In contrast, the triethylsilyl substituent introduces more deshielding on the C1 than on the C2.

Generally, as the number of chlorine atoms in the silyl substituent increases, the deshielding of the C2 increases, while just the opposite is true for the deshielding of the C1. This observation could be readily explained by considering the π-acceptor ability of the silyl substituents. Thus, as the number of chlorine atoms in the silyl substituent increases, its π-acceptor ability also increases, because of the −I inductive effect of the halogen. This, of course, has as a result the accumulation of more π-electron density on the C1 than on the C2 in the system C2⋯C1⋯SiX_3. In the case of the triethylsilyl substituent, although the +I inductive effect of the ethyl groups weakens its π-acceptor ability, there is still a net π-withdrawal registered at the C1 and C2. Therefore, in the three silyl substituents used the resonance effect predominates over the inductive effect. Of course, we cannot exclude the operation of other effects such as the "neighbor anisotropy" effect (25, 26) or the σ–π hyperconjugative effect, which has been postulated in many organosilicon compounds (14, 16, 27). These effects also contribute to the charge distribution on C1 and C2 and consequently to the observed ^{13}C resonances.

It ought to be specified that the same holds for the ^{1}H nmr spectra of the *E*-1-silyl-1-alkenes. The ^{1}H nmr parameters for the second order spectra of the olefinic protons of the compounds studied are listed in Table 3. As we can see from the data given in Table 3, the ^{1}H nmr parameters of the olefinic protons are independent of the nature of the alkyl chain of the alkene moiety but depend on the nature of the silyl group. The resonance frequency of the proton attached to the C1 (H_A proton) is lower than that of the proton attached to the C2 carbon atom (H_B proton). However, the resonance frequencies of both kinds of protons increase as the number of chlorine atoms in the silyl substituent increases. Also, it was observed that increasing the number of chlorine atoms in the silyl substituent increases the difference ($\nu_0\delta_{AB}$) between the resonance frequencies of the H_A and H_B protons. This is again in accordance with the π-acceptor ability of the silyl groups under consideration.

The effect of replacing H attached to the C1 with the silyl group on the ^{13}C nmr spectra of 1-alkenes is also a downfield shift at the C3 and an upfield shift at the C4 carbon atom. The carbon atoms C5, C6, and C7 which are further removed from the carbon bearing the silyl substituent are only slightly affected by the presence of the silyl group.

The magnitude of the deshielding of the C3 (1.5–3.0 ppm) depends on the nature of the silyl substituent and is proportional to the deshielding of the C1 and inversely proportional to the deshielding of the C2 carbon atom. The shielding of the C4, which also depends upon the nature of the silyl

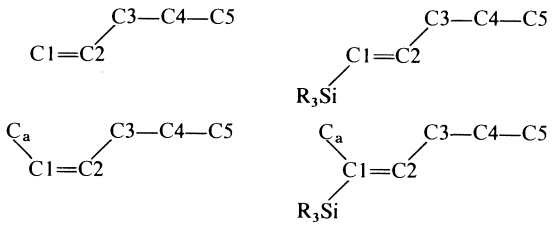
group and the alkene moiety, is the well known γ-effect, which is due to the non-bonded steric interactions.

The effects of substitution on the ^{13}C resonances of the alkene moiety presented here can be very useful in the analysis of ^{13}C nmr spectra. Reasonable predictions of ^{13}C nmr spectra for compounds not yet studied can be made. This could be achieved using the differential chemical shifts listed in Table 2 as empirical substituent parameters. On the basis of these parameters in correlation with the Lindeman–Adams rule (1) and the additivity parameters for alkenes (11) we can calculate the chemical shifts of other *E*-1-silyl-1-alkenes not yet studied. Thus, for *E*-1-silyl-2-cyclopentyl-ethylene the calculated values (δ, ppm) are, for $SiCl_3$: C1 = 119.80, C2 = 161.04; for $SiMeCl_2$: C1 = 121.55, C2 = 158.09; for $SiEt_3$: C1 = 123.49, C2 = 152.60. The calculated values are in good agreement with the experimental values shown in Table 2.

As a next step, it would be worth applying the empirical substituent parameters in order to predict the ^{13}C chemical shifts of internal *E*-silyl-alkenes containing the silyl substituent at an sp^2 carbon atom and to examine if it is necessary to introduce some corrective parameters.



In Table 4 are presented the chemical shifts, the relative intensities, and the assignments of the ^{13}C nmr signals of some internal *E*-silyl-alkenes and a few hydroxy derivatives. Included are the ^{13}C nmr spectra of some mixtures of regio-isomer internal *E*-silyl-alkenes. Also, in Table 4 are shown in parentheses the calculated chemical shifts on the basis of the empirical substituent parameters given in Table 2 and the known ^{13}C resonances of the corresponding unsubstituted *Z*-alkenes (2–5).

There is thus a satisfying agreement between the experimental and the calculated chemical shifts of the ^{13}C resonances of the internal *E*-silyl-alkenes under study, particularly in the case of the *E*-2-silyl-2-alkenes. There exists, however, a slight difference of the order of ~2 ppm between the experimental and the calculated chemical shift of the carbon atom bearing the silyl group, especially in the case of the $SiCl_3$ and $SiMeCl_2$ substituents. In the case of the *E*-3-silyl-3-alkenes and the *E*-3-silyl-2-alkenes the differences between the experimental and the calculated chemical shifts of the sp^2 carbon atoms tend to be larger for all three silyl groups under consideration. These differences become clearer from the comparison of the differential chemical shifts shown in Table 3 and those obtained for each subgroup of the internal *E*-silyl-alkenes studied (Table 5).

Supposing that the substituent effect on the ^{13}C resonances of either the terminal or the internal *E*-silyl-alkenes operates through the same mechanism, the observed differences between the experimental and the calculated chemical shifts of the sp^2 carbon atoms may be due to non-bonded steric interactions between geminal substituents or between substituents possessing *Z*-position. Therefore, the differential chemical shifts, which are valid for each subgroup of the internal *E*-silyl-alkenes (Table 5), also comprise a factor which expresses the extent of the non-bonded steric interactions. It must be noted that this factor depends upon the position of the double bond and the nature of the silyl substituent as well.

Comparing the differential chemical shifts given in Tables 3 and 5 it is observed that except for the sp^2 carbon atoms, where those vary, for the rest of the carbon atoms of the alkene moiety the shifts are very close. Thus, although differences between the experimental and the calculated chemical shifts of the sp^2 carbon atoms of the internal *E*-silyl-alkenes do exist, the differential chemical shifts discussed previously are proved to be rather useful for the correct assignment of the ^{13}C resonances for a great number of *E*-silyl-alkenes (either internal or terminal).

In order to justify the correctness of the assignments of the ^{13}C resonances that were made by the use of the aforementioned differential chemical shifts, the comparison of the shifts caused by the introduction of a methyl group at the C1 of a 1-alkene and the corresponding *E*-1-silyl-1-alkene was also used. The results of the comparison are shown schematically below:

$R_3Si = Cl_3SiCl_2MeSiEt_3Si$

ΔC1 = +9.49	ΔC1 = +7.18	+7.38	+9.89
ΔC2 = −8.23	ΔC2 = −7.85	−8.15	−7.38
ΔC3 = −7.02	ΔC3 = −6.92	−7.38	−7.18
ΔC4 = +0.61	ΔC4 = +0.77	+0.70	+1.25
ΔC5 = +0.22	ΔC5 = +0.23	+0.19	+0.27

The introduction of the methyl group causes a downfield shift at the C1, C4, and C5 and an upfield shift at the C2 and C3. The observed shifts in both cases are in good agreement, although some small differences appear again for the shifts of the carbon atom bearing the silyl substituent.

*The comparison has been done between the ^{13}C nmr spectra obtained in the same solvent ($CDCl_3$).

The trends of the substituent effect observed in the case of the internal *E*-silyl-alkenes are in accordance with those discussed previously for the terminal *E*-silyl-alkenes.

Considering the ^{13}C nmr spectra of the mixtures of the regio-isomer *E*-silyl-alkenes we found that it would be possible to quantify the mixtures using the peak heights of the ^{13}C resonances of certain of their carbon nuclei, without resorting to special techniques, such as gated decoupling (28) and the addition of paramagnetics (29). As is known, ^{13}C nmr spectroscopy has so far been little exploited for quantitative analysis because the signal areas rarely reflect carbon concentration. This is due to three factors which contribute to perturbing signal intensities. These factors are the differential relaxations, the nuclear Overhauser effect which does not always reach its theoretical maximum, and the failure to obtain sufficient pulse power to give a uniform excitation throughout the spectral region (12). However, in the case of the regio-isomers studied, there are carbon nuclei in each isomer with analogous chemical environments which also give ^{13}C resonances with very close chemical shifts. Such carbon atoms in the molecules of the regio-isomer *E*-silyl-alkenes are the C4, C5, and C6. For these carbon nuclei, it is reasonable to consider that the three factors contributing to the perturbation of the signal intensities are likely to be very similar and consequently the peak heights might reflect the concentration of each isomer in the mixture.

The results of the quantitative analysis of the mixtures studied, using the peak heights of the C4, C5, and C6 ^{13}C resonances of each isomer, are summarised in Table 6. Also, in Table 6 are shown the results obtained from the analysis of the mixtures by ^1H nmr spectroscopy. In fact, the results obtained by the two methods show a large measure of agreement. For some mixtures ^{13}C nmr spectroscopy gives better results than ^1H nmr spectroscopy because the separation of the ^1H signals of the two isomers is insufficient. Also, it can be noted that the analysis of the mixtures by glc, especially in the case of the chlorinated products, was unsuccessful. These products are very sensitive to the moisture and cause injection problems. Of course, we can get around these problems by converting the chlorinated products to the alkylated ones, via the Grignard reagents, but this method involves a chemical step which is destructive and takes some time.

Experimental

The silyl-alkenes studied were prepared by hydrosilylation of alkynes using *trans*-di-μ-hydrido-bis(tricyclohexylphosphine) bis(silyl)diplatinum complexes as catalysts, according to the method described elsewhere (30, 31).

*The calculation has been made using the peak heights of the ^{13}C resonances.

^{13}C nmr spectra were recorded on a Varian CFT-20 spectrometer operating in the Fourier transform mode at 20 MHz using 10 mm diameter sample tubes. An internal deuterium lock ($CDCl_3$) was employed with broad-band proton noise decoupling. The main parameters were: acquisition time 1.024 s; pulse delay 0 s; flip-angle 35° (7μs); noise bandwidth 1000 kHz; temperature 40°C. Samples were prepared as 20–40% v/v solutions in $CDCl_3$ containing 5–10% $CHCl_3$ with or without 1% TMS as an internal reference. In most cases, accumulation of 2000–3000 transient responses was sufficient to obtain adequate signals for all carbon atoms. Chemical shifts which were recorded with respect to internal $CHCl_3$ were converted to the TMS scale using the relationship $\delta_{(CHCl_3)} = +77.20$ ppm downfield from TMS. Positive shifts are reported downfield from TMS.

^{1}H nmr spectra were obtained with a Varian A 60A (60 MHz) spectrometer in CCl_4 or $CDCl_3$ solutions using TMS as an internal standard.

Photochemical rearrangements of 2-azido-4-thiochromanone 1-oxide and 1,1-dioxide: formation of 2*H*-benzo[f]-1,2-thiazepine derivatives

IAN W. J. STILL AND TOONG S. LEONG

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

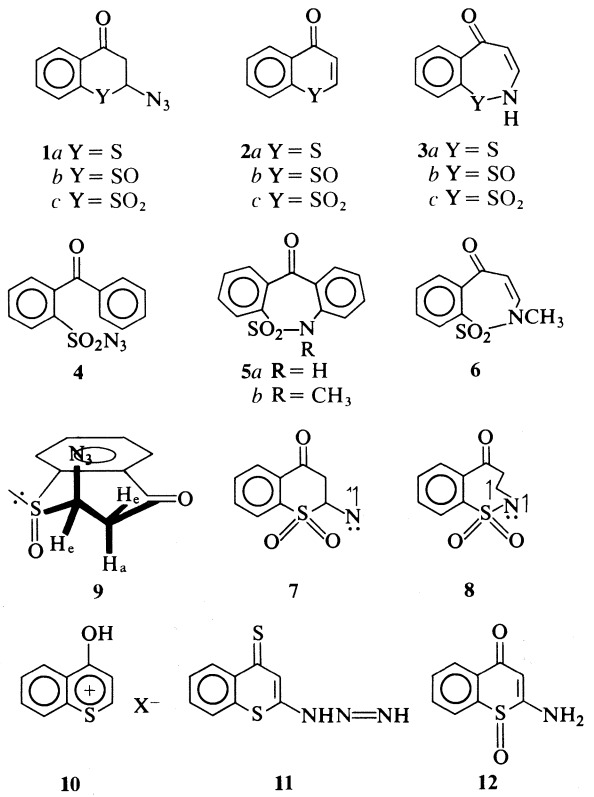
Received August 27, 1979

IAN W. J. STILL and TOONG S. LEONG. Can. J. Chem. **58**, 369 (1980).

Photolysis of 2-azido-4-thiochromanone 1,1-dioxide in benzene or dichloromethane leads to the formation of 2*H*-benzo[f]-1,2-thiazepin-5-one 1,1-dioxide, in very good yield. In contrast, the photolysis of the analogous sulfoxide was much more complex and no ring-expansion product could be isolated, although a small amount of a compound believed to be 2-aminothiochromone 1-oxide was formed. Several attempts to prepare the α-azidosulfide analogue, to compare its photochemical behavior, were unsuccessful and a rationale is proposed for the apparent instability of this member of the series.

IAN W. J. STILL et TOONG S. LEONG. Can. J. Chem. **58**, 369 (1980).

La photolyse du dioxyde-1,1 de l'azido-2 thio-4 chromanone en solution dans le benzène ou le dichlorométhane conduit à la formation du dioxyde-1,1 du 2*H* benzo[f] thiazépine-1,2 one-5 avec de bons rendements. Dans le cas de l'analogue sulfoxydé la photolyse est au contraire plus complexe et on n'a pas pu isoler de produits résultant d'une expansion de cycle, en dépit du fait que l'on croit à la formation de petites quantités d'oxyde-1 d'amino-2 thiochromone. Plusieurs tentatives de préparation de l'α-azidosulfure apparenté, dans le but de faire une étude comparative de son comportement photochimique, se sont révélées inefficaces. On propose une explication de l'instabilité apparente de ce composé.



[Traduit par le journal]

Introduction

In an earlier investigation (1) we reported the preparation of 2-azido-4-thiochromanone 1,1-dioxide **1***c* by the addition of hydrazoic acid to thiochromone 1,1-dioxide **2***c*. Representatives of the α-azidosulfone class of compounds have rarely been reported in the literature, although Böhme and Ziegler recently reported another example (2). The combination of functional groups represented by **1***a–c* therefore seemed to warrant a more detailed chemical investigation.

In particular, it appeared to us that the photochemical or thermal decomposition of the α-azidosulfone **1***c* might provide a convenient synthetic route to the 1,2-thiazepine **3***c*. Despite fairly intensive research interest in the 1,3- and 1,4-thiazepine series of heterocycles, stemming in part from their relatively easy synthetic availability and in part from the interesting medicinal properties of certain members of these series of compounds, virtually no work at all on the chemistry of 1,2-thiazepines had appeared until recently (2–5). In contrast to the isomeric thiazepines, 1,2-thiazepines of course are distinguished by being cyclic sulfenamides, sulfinamides, or sulfonamides respectively, depending on the oxidation state of the sulfur atom.

Very recently, Abramovitch *et al.* (6) described an interesting study of the thermal decomposition of a series of substituted arylsulfonyl azides. In particular, it was found that 2-azidosulfonylbenzophenone **4** underwent intramolecular aromatic substitution to produce the dibenzothiazepine derivative **5***a*. Under a variety of experimental conditions, however, the yields obtained did not exceed 7% and the sultam was invariably accompanied by

other products. Our expectation that the α-azidosulfone **1***c* should provide a convenient route to the 1,2-thiazepine system has been realized by an alternative photochemical rearrangement. We now present an account of our findings and also of the results of our attempts to extend this potentially useful reaction to the analogous conversions of the α-azidosulfoxide **1***b* and the α-azidosulfide **1***a* respectively.

Results and Discussion

The α-azidosulfone **1***c* first reported by us (1) was the first member of the series studied.[1] Photolysis of **1***c* in benzene ($\lambda_{irr} > 300$ nm) led to the isolation of 2*H*-benzo[f]-1,2-thiazepin-5-one 1,1-dioxide **3***c* in 39% yield. Surprisingly, after 10 h, starting material (33%) was also recovered but the only other product from the reaction appeared to be polymeric in nature. Lengthening the time of irradiation did not improve the yield of **3***c*, but led instead to increased formation of the polymeric product, so that after 35 h, for example, the yield of **3***c* had fallen to 2–3%, indicating that the product itself is photolabile. Irradiation of the azidosulfone in acetonitrile, or irradiation with light of shorter wavelength, failed to give any of the ring-expansion product.

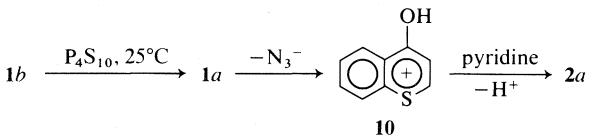
The structure of the 1,2-thiazepine was established by spectroscopic methods, including ^{13}C nmr. The compound shows a molecular ion in the mass spectrum at $m/e = 209$ and its infrared spectrum (solid state) indicates the presence of the tautomeric form (**3***c*), shown by a broad peak centred at 3100 (NH) cm^{-1}.[2] In addition, the ^1H nmr spectrum revealed a characteristic pair of vinylic hydrogens, with $J = 10$ Hz. Further confirmation that this representation, rather than the alternative O—H (or C—H) tautomeric forms, is correct, was provided as a result of methylation of **3***c* with diazomethane in ether. A single product ($m/e = 223$) was obtained, in 62% yield, with a uv spectrum virtually indistinguishable from that of **3***c*. The ^1H nmr spectrum revealed a new signal at $\delta = 3.40$, attributed to the N—CH_3 group. The analogous N-methyl derivative **5***b* prepared by Abramovitch *et al.* (6), the structure of which was confirmed by an unambiguous synthesis, shows a value of $\delta = 3.36$ for the N-methyl group and, in other relevant respects, the two series of 1,2-thiazepines show the expected similarity in spectral characteristics. Thus we feel that the structures of both our N-methyl derivative **6** and its precursor **3***c* are secure.

In an attempt to establish the nature of the excited state responsible for this photochemical ring expansion, we conducted the irradiation of **1***c* in acetophenone as the solvent, a method used previously to establish reaction pathways in other azide photolyses (8). After the same length of time a much higher yield (81%) of **3***c* was obtained in this experiment, with no evidence for recovered starting material, unlike the direct irradiation in benzene. This suggests a triplet mechanism for the formation of **3***c*. The triplet nitrene species **7** first formed must undergo ring expansion by preferential migration of the $ArSO_2$ residue to afford **8**.[3] Spin inversion, followed by prototropy, then leads to **3***c*.

An attempt to show that a singlet species could not be involved by using the so-called singlet-sensitization conditions employed by Suschitzky and his co-workers (8), i.e., irradiation in dichloromethane containing pyrene, gave only traces of photoproduct and essentially 100% recovery of starting material. However, this result was found to be attributable to essentially complete absorption of the light by the pyrene at the wavelengths employed in the irradiation. One side benefit to arise from this experiment, however, was the finding that when the irradiation of **1***c* was conducted in dichloromethane alone, a much cleaner reaction resulted than in the benzene irradiation. A comparable amount of starting material (38%) was recovered after 10 h but the isolated yield of the 1,2-thiazepine **3***c* rose from 39 to 81% (based on starting material actually consumed).

Attempts to carry out the ring expansion of the α-azidosulfone by ground-state decomposition pathways have also been investigated. Refluxing in aromatic solvents such as toluene, bromobenzene, and chlorobenzene, as well as heating the α-azidosulfone alone in the same temperature range (110–150°C) led to slow decomposition but gave no useful products. Likewise, attempts to carry out the acid-catalyzed decomposition of **3***c* by treatment with sulfuric acid at 0°C, or with trifluoroacetic acid at 25–65°C, did not lead to any of the 1,2-thiazepine ring-expansion product.

[1]It should be pointed out that the experimental conditions for the preparation of **1***c* from thiochromone 1,1-dioxide were incorrectly reported in reference (1) (see also Experimental).



[2]This remarkably low value for the NH stretch, observed in the solid state, is observed in other secondary sulfonamides, e.g., $C_6H_5SO_2NHSO_2C_6H_5$ (7), where the NH group is flanked by two electron-withdrawing groups, as is the case for **3***c*. We thank one of the referees for drawing our attention to this point.

[3]Although the possibility of direct conversion of the triplet azide to product, with rearrangement accompanying concerted loss of N_2, cannot be absolutely ruled out, the most frequently encountered pathway in azide photolyses is via the nitrene intermediate.

Since the preparation of thiochromone 1-oxide **2***b* had earlier been described by us (9), we decided to synthesize the analogous 2-azido-4-thiochromanone 1-oxide **1***b* and to examine its photochemical behavior. Acid-catalyzed addition of hydrazoic acid to **2***b* did in fact afford the expected α-azidosulfoxide **1***b*, in 50% yield. This compound was much more difficult to purify than the analogous α-azidosulfone, and is particularly susceptible to acid-catalyzed decomposition, for example, during chromatography. Nevertheless, a single pure isomer could be isolated, which showed an ABX pattern in the ^{1}H nmr spectrum characteristic of a *trans*-diaxial arrangement of the strongly polar sulfoxide and azide groups, as shown in structure **9**. The assignments of the two C-3 protons follow from both the magnitude of their respective vicinal coupling constants with H_e at C-2 and also from the fact that the H_a proton at C-3 should be the more strongly deshielded by the antiperiplanar electronegative N_3-substituent at C-2 (10). Interestingly, each of the three protons in the non-aromatic ring in **9** has a strongly electronegative substituent in an antiperiplanar relationship and hence we have assumed that the ^3J coupling reducing effects predicted by Booth (11) in such situations will be mutually cancelling. Had the individual coupling constants not been evident by a first-order analysis of the ^{1}H nmr spectrum, the line-width of the C-2 proton signal alone would have established the equatorial location for this proton (10). The 1,2-diaxial relationship of the sulfoxide and azide functional groups not only minimizes repulsive interactions but is also in accord with the well-known axial preference for S=O bonds in six-membered heterocyclic rings (12).

Photolysis of the α-azidosulfoxide **1***b* in benzene under similar conditions to those used in the photolysis of **1***c* appeared to lead, as expected, to a mixture of the ring-expanded 1,2-thiazepine **3***b* and the starting azide. Once again, a characteristic vinylic doublet pattern (J = 10 Hz) was evident in the ^{1}H nmr spectrum but the previously mentioned instability of the starting α-azidosulfoxide rendered the separation and purification of **3***b* by chromatographic means impossible.[4] Attempts to isolate the *N*-methyl derivative of **3***b* by treatment of the crude photolysate with diazomethane were likewise unsuccessful. Instead, we decided to treat the crude photolysate (containing about a 4:1 ratio of starting material – **3***b*) with phosphorus pentasulfide in pyridine. We had earlier observed that **1***b* could be converted almost quantitatively into thiochromone **2***a* by this reagent, and it was our expectation that this would allow us to effect a relatively easy separation (by chromatography) of **3***b*, although it was conceivable that **3***b* itself could be reduced under the reaction conditions to its cyclic sulfenamide counterpart **3***a*. Our earlier studies (13) have clearly demonstrated the effectiveness of phosphorus pentasulfide as a reagent for reducing sulfoxides to sulfides but the concomitant loss of the elements of HN_3 from 2-azido-4-thiochromanone 1-oxide on treatment with P_4S_{10}-pyridine was at first sight surprising, especially since our usual conditions for achieving deoxygenation of sulfoxides (P_4S_{10}–CH_2Cl_2, 25°C) left **1***b* quite unchanged. We believe that the conversion of **1***b* to **2***a* proceeds by initial deoxygenation of the azidosulfoxide to produce the highly unstable α-azidosulfide **1***a* (see later discussion). Ionization of **1***a*, possibly via a small percentage of the enol form present at equilibrium, would produce the 4-hydroxybenzothiopyrylium (azide) salt **10**, which in turn is rapidly deprotonated by the excess of pyridine present, producing thiochromone **2***a*. In support of this suggestion, **1***b* was found to be unaffected by treatment with pyridine alone under similar conditions.

10

In the event, our hope of being able to isolate **3***b* by this procedure was not realized because, although thiochromone **2***a* was indeed isolated, presumably from the reaction of starting **1***b* as outlined above, the 1,2-thiazepine product did not survive the treatment with phosphorus pentasulfide – pyridine. However, careful chromatography and recrystallization from acetone–hexane did produce a new yellow solid, mp 157–159°C, albeit in very low yield. This compound had the same molecular mass (m/e = 221) as the starting α-azidosulfoxide, although lacking any azide band in the infrared, and high resolution mass measurement on this ion and the elemental analysis confirmed the molecular formula, $C_9H_7N_3S_2$. The only reasonable structure for the new product which satisfies this formula, as well as the ir and ^{1}H nmr spectral characteristics, is that of the triazene, **11**, or one of its tautomers. (It was, for example, observed that only one proton was exchanged even after several hours exposure to D_2O; this would likely be the proton on the nitrogen next to the ring.) Although simple mono-

[4]Sudden decomposition of the starting azide invariably occurred at some point during the passage of the mixture down the column. The resulting rapid release of N_2 caused much cracking and bubbling within the column.

substituted triazenes are very uncommon, it does appear that the presence of an electron-withdrawing unit, as in **11**, significantly enhances the stability of this system (14). This product is not considered to be a photoproduct but a minor artifact of the procedure above, whereby phosphorus pentasulfide first deoxygenates the α-azidosulfoxide **1***b* and then subsequent thionation of the carbonyl group and pyridine-catalyzed prototropy (but not necessarily in that order) lead eventually to **11**.

Given the lack of success with the above photolysis, it was decided to repeat the photolysis of the α-azidosulfoxide in dichloromethane, since this solvent had been the solvent of choice for the α-azidosulfone photolysis. After 10 h, a reaction mixture resulted which looked (by ^{1}H nmr) generally similar to the one obtained in benzene, with the same ratio of starting material to product. It was found that the starting material could be removed by thick-layer chromatography, without the concomitant destruction of the products which occurred on column chromatography. Nevertheless, the reaction mixture was so complex that only one product could be isolated after extensive purification. A yellow solid, mp 172–174°C, was obtained in 13% yield, after repeated chromatography and fractional crystallization. This compound showed an apparent molecular ion at $m/e = 177$, but the elemental analysis indicated the formula $C_9H_7NO_2S$ and confirmation of this was obtained by high resolution mass measurement on the fragment at $m/e = 177$. Once again, NH (or OH) absorption was present in the ir spectrum, along with apparent carbonyl and sulfoxide bands at 1642 and 1070 cm^{-1}, respectively. All protons present were in the region from 7.1–8.1 ppm and thus D_2O exchange results were not meaningful. The ^{13}C nmr spectrum confirmed the presence of a carbonyl group at 184 ppm and the presence of four quaternary carbons. The structure which best accommodates these data, although it cannot be regarded as rigorously established, is that of 2-aminothiochromone 1-oxide **12**. The possibility that **12** exists as a mixture with the O—H and C—H tautomers of the corresponding imine is recognized, but the spectroscopic evidence, as well as analogy with related compounds, strongly favours this form. The formation of **12** can be accounted for by a well-precedented 1,2-hydrogen shift in the putative nitrene intermediate (most likely the singlet in this case) analogous to **7** (15). The ^{1}H nmr evidence cited earlier indicates that ring-expansion may also occur under these reaction conditions but clearly, if this is so, the 1,2-thiazepine 1-oxide (**3***b*) so formed must be more labile, photochemically as well as chemically, than **3***c*.

An additional photolysis of 2-azido-4-thiochromanone 1-oxide was conducted in acetophenone as solvent. Although this solvent had been successful in greatly improving the efficiency of the conversion of the analogous azidosulfone to **3***c*, in this instance a complex reaction mixture, similar in appearance (^{1}H nmr) to those from the direct irradiations, was obtained, with the single difference that there was no evidence for any recovered starting compound.

As the final representative of this series of 2-azido-4-thiochromanone derivatives, the α-azidosulfide **1***a* might be expected to lead by our photochemical route to the parent 2*H*-benzo[f]-1,2-thiazepin-5-one, **3***a*. The obvious route to **1***a* involving the conjugate addition of hydrazoic acid to thiochromone **3***a*, is not available in this instance, since the strong acid catalyst customarily required simply produces the unreactive thiopyrylium species **10** (1), which has proved to be inert towards nucleophilic substitution. Likewise, for the reasons discussed earlier, we were unable to convert the 2-azidosulfoxide **1***b* into **1***a* by simple deoxygenation, using either phosphorus pentasulfide (13) or thiophosphoryl bromide (16), thiochromone **2***a* being the only product obtained, in yields of 80–100%. The recent results of Chen *et al.* (17) indicated that it would be fruitless to attempt the direct chlorination of 4-thiochromanone with *N*-bromosuccinimide or *N*-chlorosuccinimide, but the treatment of 4-thiochromanone enol acetate **13** (18) with these reagents again led mainly to thiochromone (60–85%), although smaller amounts of the 3-halo derivatives **14***a*, *b* were also found.

13 **14***a* X = Cl, *b* X = Br **15**

We are forced to the conclusion that the presence of an effective leaving group at C-2 in the thiochromanone system is intrinsically destabilizing. Although Böhme and Ziegler (2) reported no difficulty in isolating and purifying the α-azidosulfide **15** derived from isothiochroman, this compound lacks the carbonyl group which is present in **1***a*. It is the apparent ease with which **1***a* is converted to the very stable aromatic 4-hydroxybenzothiopyrylium system (see earlier discussion), rather than any inherent instability associated with

For personal use only.

the α-azidosulfide functionality, which in our view accounts for the inability to isolate **1***a*.

Experimental

General

The infrared spectra were recorded on a Perkin-Elmer 337 grating spectrophotometer and the ultraviolet spectra on a Unicam SP-800A spectrometer. Low resolution mass spectra were obtained on a Bell and Howell 21-490 instrument. ^{1}H nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer with TMS as internal standard. Natural abundance ^{13}C nmr spectra were obtained on a Varian XL-100-15 instrument at 25.16 MHz in the pulsed Fourier transform mode, operating at 32 ± 3°C. Acquisition times of 0.666 s and pulse widths of 12 μs were employed. (A 90° "flip" angle is equivalent to ca. 55 μs.) Partially coupled spectra, as well as proton decoupled spectra, were recorded in all cases.

Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, DK2730 Herlev, Denmark or by A. B. Gygli, 329 St. George Street, Toronto, Ontario. Column chromatography and thin-layer chromatography (analytical and preparative) were conducted on silica gel using Fisher A.C.S. grade solvents. Melting points were recorded on an Electrothermal Mark II apparatus and are uncorrected.

*2-Azido-4-thiochromanone 1,1-Dioxide (**1**c)*

The preparation of **1***c* was adapted from the procedure previously reported by us (1). It was found, however, that the presence of a small quantity of a strong acid was essential for the reaction to proceed at a measurable rate, in contrast to the earlier report. A solution of thiochromone 1,1-dioxide (9.00 g, 46 mmol) in chloroform (120 mL) was mixed with a solution of hydrazoic acid in chloroform (140 mL, approx. 0.4 *M*) and concentrated H_2SO_4 (1.5 mL) was added to the resulting mixture. After stirring for 7 days at 25°C, the unsaturated C=O band (1667 cm^{-1}) in the ir spectrum of the starting sulfone had disappeared completely. The chloroform solution was washed with water and dried (Na_2SO_4). Evaporation of solvent afforded **1***c* as a pale yellow solid (10.10 g, 92%), mp 110–112°C (lit. (1) mp 110–111°C). The compound could be obtained as colorless needles by percolating through silica gel, followed by recrystallization from dichloromethane–hexane; uv (MeOH) λ_{max} (log ε): 247 (3.95), 287 (3.32), 295 (3.25) nm.

*Photolysis of 2-Azido-4-thiochromanone 1,1-Dioxide (**1**c) in Benzene*

A degassed solution of **1***c* (0.64 g, 2.71 mmol) in benzene (90 mL, freshly distilled from sodium) was irradiated through Pyrex with a 115 W medium pressure mercury arc lamp, in an immersion-well type of apparatus, under nitrogen for 10 h. The solvent was evaporated and the residual product was chromatographed on silica gel. Elution with dichloromethane gave **1***c* (0.21 g, 33%). Elution with 1–5% acetone in dichloromethane yielded a reddish-yellow product which was repeatedly washed with small amounts of acetone to give 2*H*-benzo[f]-1,2-thiazepin-5-one 1,1-dioxide (**3***c*) (150 mg, 39%), as a pale yellow solid.

The solid was decolorized with charcoal in acetone and recrystallized from acetone–hexane to give a colorless solid, mp 203–204°C (dec.). The compound could also be sublimed at 150–160°C/0.005 Torr; ir (KBr) ν_{max}: 3100 (broad, NH), 1618 (C=O), 1348, 1312, and 1178 (SO_2) cm^{-1}; uv (MeOH) λ_{max} (log ε): 298 (3.90) nm; ^{1}H nmr (acetone-d_6) δ: 5.73 (1H, d, J = 10 Hz, H-4), 7.05 (1H, d, J = 10 Hz, H-3), 7.77–8.10 (4H, m, aromatic, no signal observed for NH proton); ^{13}C nmr (acetone-d_6) δ: 191.5 (CO), 138.0, 136.1, 135.1, 134.8, 133.4, 131.1 (aromatic carbons), 124.3 (C-3), 112.8 (C-4); ms *m/e*: 209 (M^+). *Anal.* calcd. for $C_9H_7NO_3S$: C 51.66, H 3.38, N 6.70, S 15.32; found: C 52.30, H 3.70, N 6.27, S 15.18.

Further elution with higher percentages of acetone in dichloromethane afforded only polymeric material. The photolysis has been performed for various reaction times. The results are tabulated in Table 1.

*Photolysis of **1**c in Acetophenone*

A degassed solution of **1***c* (0.42 g, 1.76 mmol) in acetophenone (freshly distilled from K_2CO_3, bp 199–200°C, 80 mL) was irradiated under N_2 through Pyrex for 10 h. A pale yellow solution resulted. Acetophenone was removed (bp ~ 45°C/1 Torr, at bath temperature 80–85°C) to give a residue which was rather insoluble in chloroform and dichloromethane but soluble in acetone. The acetophenone-contaminated residue was triturated with chloroform and the $CHCl_3$ solution showed essentially only acetophenone absorptions in the ir. A yellowish solid (0.28 g, 75%) was filtered off and washed with chloroform. This product was shown to be identical with the photoproduct **3***c* obtained in benzene. Evaporation of the chloroform filtrate and elution from a preparative tlc plate with 30% acetone–CH_2Cl_2 afforded further **3***c* (22.1 mg, 6%).

*Photolysis of **1**c in Dichloromethane, in Presence of Pyrene*

A degassed solution of **1***c* (0.43 g, 1.79 mmol) and 1.28 g (6.30 mmol) pyrene (percolated through silica gel with pentane and recrystallized from ethanol, mp 154–155°C) in dry dichloromethane (80 mL) was irradiated under N_2 through Pyrex for 10 h. A brownish-yellow solution resulted. Evaporation of the solvent afforded a residue which consisted mainly of **1***c* and pyrene (identified by tlc). The residue was charged onto a column of silica gel (60 g). Elution with dichloromethane gave pyrene (1.25 g, 98%), followed by **1***c* (0.50 g, 95%). Elution with 5–30% acetone in dichloromethane afforded small amounts (14.8 mg) of a brownish-yellow residue which showed at least 3 spots on tlc examination. The R_f value of one of these spots matched that of the photoproduct **3***c*.

*Photolysis of **1**c in Dichloromethane*

A degassed solution of **1***c* (0.40 g, 1.70 mmol) in dry dichloromethane (80 mL) was irradiated under N_2 through Pyrex for 10 h. A yellow liquid together with a small amount of precipitate resulted. Evaporation of the solvent afforded a yellow residue which was charged onto a column of silica gel (60 g). Elution with dichloromethane gave **1***c* (0.16 g, 38%). Elution with 10–25% acetone in dichloromethane afforded **3***c* (0.18 g, 81%).

*2-Methyl-2H-benzo[f]-1,2-thiazepin-5-one 1,1-Dioxide (**6**)*

Compound **3***c* (116.2 mg, 0.56 mmol) was dissolved in absolute ethanol (50 mL) and the solution was cooled to 0–5°C. An ethereal solution of diazomethane was added dropwise until the yellow color persisted. The temperature of the solution was kept below 10°C during the addition. Thin-layer chromatography showed only a single product. Evaporation of the solvent gave a brownish-yellow oil. The oily residue was purified by preparative tlc. Elution with dichloromethane afforded **6** as a yellowish solid (76.2 mg, 62%), mp 46–48°C (pentane); ir ($CHCl_3$) ν_{max} 1624 (C=O), 1356, 1314, and 1133 (SO_2) cm^{-1}; uv (MeOH) λ_{max} (log ε): 306 (3.83) nm; ^{1}H nmr ($CDCl_3$) δ: 3.40 (3H, s, NCH_3),

5.80 (1H, d, J = 10 Hz, H-4), 6.70 (1H, d, J = 10 Hz, H-3), 7.60–8.10 (4H, m, aromatic); ^{13}C nmr (acetone-d_6) δ: 191.0 (CO), 139.9, 137.8, 136.7, 135.1, 133.5, 130.8 (aromatic carbons), 125.2 (C-3), 113.6 (C-4), 38.4 (NCH_3); ms *m/e*: 223 (M^+). *Anal.* calcd. for $C_{10}H_9NO_3S\cdot\frac{1}{2}H_2O$: C 51.71, H 4.34, N 6.03, S 13.81; found: C 51.65, H 4.41, N 5.90, S 13.68.

*(*trans*)-2-Azido-4-thiochromanone 1-Oxide (**1**b)*

A solution of HN_3 in $CHCl_3$ (prepared from 2.5 g, 0.04 mol NaN_3) was added dropwise to a solution of thiochromone 1-oxide **2***b* (9) (3.10 g, 0.01 mol) in $CHCl_3$ (30 mL). After the addition was complete, the solution was stirred at 25°C for 16 h. Evaporation of the solvent afforded a dark brown residue (3.81 g, 99%). This residue was repeatedly washed with small amounts of acetone to give **1***b* (1.92 g, 50%) as a pale yellow solid, mp 116–118°C; ir ($CHCl_3$) ν_{max}: 2122, 2095 (N_3), 1691 (C=O), 1060 (SO) cm^{-1}; uv (MeOH) λ_{max} (log ε): 243.5 (3.99), 297.5 (3.44) nm; ^{1}H nmr ($CDCl_3$) δ: 2.94 (1H, dd, J = 17 Hz, 3 Hz, H-3e), 3.37 (1H, dd, J = 17 Hz, 6 Hz, H-3a), 5.18 (1H, dd, J = 6 Hz, 3Hz, H-2e), 7.43–8.17 (4H, m, aromatic); ms *m/e*: 193($M^+ - N_2$). *Anal.* calcd. for $C_9H_7N_3O_2S$: C 48.87, H 3.19, N 19.00, S 14.47; found: C 49.14, H 3.25, N 18.91, S 14.55.

*Photolysis of (*trans*)-2-Azido-4-thiochromanone 1-Oxide (**1**b)*

A degassed solution of **1***b* (1.53 g, 6.89 mmol) in dry benzene (210 mL) was irradiated through Pyrex, using a 115 W medium pressure mercury arc lamp, for 6 h under nitrogen. A bright yellow solution together with traces of a yellow precipitate resulted. The filtrate was evaporated to dryness to give a brownish-yellow residue (1.55 g), which contained the starting material **1***b* and the photo-products, which had lower R_f values than **1***b* (10% acetone–CH_2Cl_2). ^{1}H nuclear magnetic resonance ($CDCl_3$) revealed the presence of two vinylic protons at δ 5.68 (d, J = 10 Hz) and 6.58 (d, J = 10 Hz), in the ratio 1:1. The ratio of vinylic to methylene protons (of **1***b*) was 1:4. An attempt to separate the crude products from the starting material by chromatography on silica gel resulted in the rapid decomposition of **1***b* and destruction of the column.

Attempted N*-Methylation of Above Photolysate*

An ethereal solution of CH_2N_2 was added dropwise to an ice-cooled solution of the crude product above (0.25 g) in EtOH (50 mL). After the addition was complete, the solvent was evaporated to give a brownish-yellow residue which did not show the nmr spectrum expected for the product. However, a singlet at δ 3.27 (possibly NCH_3) indicated that some *N*-methylated material may have been present.

*Treatment of the Crude Photolysate from **1**b with P_4S_{10}–Pyridine*

The crude photolysate (0.90 g, 4.06 mmol, based on **1***b*) from the photolysis of **1***b* in benzene was dissolved in pyridine (20 mL). To this solution was added phosphorus pentasulfide (0.90 g, 2.03 mmol). The mixture was stirred under N_2 at 25°C for 4 h. Most of the solvent was removed under vacuum. The dark brown residue was treated with dichloromethane (450 mL) and water (400 mL). Saturated sodium chloride solution (100 mL) was added to facilitate the separation. The organic layer (dark brown) was separated and the aqueous layer (yellow) was further extracted with dichloromethane (2 × 100 mL). The dichloromethane extracts were combined and washed with water (3 × 100 mL) and dried ($MgSO_4$). Evaporation of the solvent afforded a dark brown residue. The presence of thiochromone was strongly indicated by nmr.

The residue was chromatographed on silica gel. Elution with dichloromethane and 10% acetone in dichloromethane afforded sulfur (0.11 g), thiochromone (0.34 g, 2.10 mmol), and an unknown compound (0.17 g), as well as some pyridine. Further elution with 20–30% acetone in dichloromethane gave some deep red polymeric material. The crude unknown compound was then treated with charcoal in acetone. Recrystallization from acetone–hexane afforded some yellow solid (25 mg) **11**, mp 157–159°C; ir (KBr) ν_{max}: 3150, 3128 (NH), 1455, 1415 (N=N), 1125 (C=S) cm^{-1}; uv (MeOH) λ_{max} (log ε): 240 sh (3.65), 283 (2.91), 360–420 plateau (2.30) nm; ^{1}H nmr ($CDCl_3$) δ: 6.23 (1H, s), 7.12–7.49 (5H, m), 7.62 (1H, s); ms *m/e*: 221. *Anal.* calcd. for $C_9H_7N_3S_2$: C 48.86, H 3.19, N 19.00, S 14.49; found: C 49.14, H 3.25, N 18.91, S 14.55; calcd. for $C_9H_7N_3S_2$: 221.0081; found: 221.0081.

*Irradiation of (*trans*)-2-Azido-4-thiochromanone 1-Oxide **1**b in Dichloromethane*

Irradiation of a degassed solution of **1***b* (0.50 g, 2.67 mmol) in dichloromethane (100 mL) for 10 h led to the formation of a brownish-yellow solution. Evaporation of the solvent afforded a brownish-yellow residue consisting of **1***b* and a mixture of products. The acetone-insoluble material (19 mg) was filtered off. the ^{1}H nmr (acetone-d_6) of the acetone-soluble material revealed vinylic protons identical to those observed in the photolysis of **1***b* in benzene. (The ratio of the vinylic compound to **1***b* was approximately 1:4.) The acetone-soluble material was chromatographed on two preparative tlc plates and eluted with 30% acetone in dichloromethane to give a mixture of products. This material was reapplied on a preparative tlc plate and eluted with 30% acetone in dichloromethane. The major band on extraction with 40% acetone in dichloromethane gave a brownish-yellow residue (0.18 g) which was treated with charcoal in acetone. Filtration and evaporation afforded a yellow residue (0.12 g). The ^{1}H nmr (acetone-d_6) spectrum of this residue showed vinylic protons identical to those mentioned previously. The residue gave a yellow solid (14 mg, mp 172–174°C) upon precipitation with chloroform. Additional amounts (41 mg) of this yellow solid were obtained by extensive chromatography and fractional crystallization. The pure compound **12**[5] had the following characteristics:[6] ir: ($CHCl_3$) ν_{max}: 3492 (OH/NH), 1642 (C=O), 1070(S=O) cm^{-1}; uv (MeOH) λ_{max} (log ε): 308 (3.99), 415 (3.96) nm; ^{1}H nmr (DMSO-d_6) δ: 7.10–8.07 (m); ^{13}C nmr (DMSO-d_6) (21): 184.0 (CO), 150.1 (C-2), 145.0 (C-3), 142.9, 134.1, 132.5, 125.0, 124.4, 124.2 (aromatic); ms *m/e*: 177 (M^+ − 16). *Anal.* calcd. for $C_9H_7NO_2S$: C 55.96, H 3.65, N 7.25, S 16.57; found: C 55.64, H 3.84, N 7.16, S 16.26; calcd. for C_9H_7NOS (*m/e* = 177 fragment ion): 177.0248; found: 177.0250.

*Attempts to Prepare 2-Azido-4-thiochromanone, **1**a*

*(Non-catalyzed) Addition of Azide to Thiochromone (**2**a)*

Sodium azide (0.6 g, 9.31 mmol) was added in one portion to a solution of thiochromone (0.9 g, 5.6 mmol) in a 1:1 mixture of methanol–acetonitrile (6 mL). The reaction mixture was refluxed for 7 days. The solid (NaN_3) was filtered off and washed with dichloromethane. The washings and the filtrate were combined and evaporated to dryness. The residue was dissolved in ether and washed with water. Drying ($MgSO_4$) and evaporation of the solvent afforded only thiochromone (0.7 g, 78%).

*4-Thiochromanone Enol Acetate (**13**) and* N*-Chlorosuccinimide (NCS)*

A mixture of **13** (0.1 g, 0.5 mmol) and NCS (0.07 g, 0.5 mmol) in carbon tetrachloride (2 mL) was stirred at 25°C for 19 h. The floating material (succinimide) was filtered off and the residue

[5]Russian workers (19) recently reported the characterization of the analogous sulfide, 2-aminothiochromone. The two compounds show the expected spectral similarities.

[6]The vinylic compound could no longer be detected (^{1}H nmr in acetone-d_6) after this extensive chromatography and precipitation.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(0.09 g) obtained on evaporation of the filtrate was purified by preparative tlc, eluting with dichloromethane. Two major bands were observed. These were extracted with acetone to give (*i*) 3-chlorothiochromone (**14***a*) (10.4 mg, 11%) as yellowish needles, mp 148–149°C (lit. (20) mp 149°C); ir ($CHCl_3$) ν_{max}: 1625 (CO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.45–7.63 (3H, m), 8.01 (1H, s), 8.37–8.60 (1H, m); ms *m/e*: 198, 196 (M^+, ratio = 1:3). (*ii*) thiochromone (**2***a*) (68.1 mg, 85%).

Reaction of 4-Hydroxybenzothiopyrylium Perchlorate with Sodium Azide

A solution of the crude 4-hydroxybenzothiopyrylium perchlorate (21) (2.4 g, 9.4 mmol) in DMF (25 mL) was added to a solution of sodium azide (0.6 g, 9.2 mmol) in a minimum amount (250 mL) of DMF. The bright yellow mixture was stirred at 25°C for 18 h. It was then heated at 60–65°C for 6 h followed by a further period of heating at 95–100°C for 22 h. The DMF was evaporated *in vacuo* and the residue treated with ether–water mixture. The ether layer was separated and the aqueous layer re-extracted with ether. The ether extracts were combined and dried ($MgSO_4$). Evaporation gave thiochromone (1.1 g, 74%).

Reaction of 4-Acetoxybenzothiopyrylium Perchlorate with Sodium Azide

A mixture of 4-thiochromanone enol acetate **13** (0.5 g, 2.43 mmol) and triphenylmethyl perchlorate (1) (0.83 g, 2.42 mmol) in acetic acid (5 mL) was heated under reflux for 15 min. After cooling to 25°C the mixture was cooled in ice. The perchlorate salt (0.57 g, 77%) was filtered off and washed thoroughly with ether.

Sodium azide (0.12 g, 1.88 mmol) was added to a solution of the 4-acetoxybenzothiopyrylium perchlorate (0.57 g, 1.88 mmol) so prepared, in acetonitrile (5 mL). The reaction mixture was stirred at 25°C for 3 h. Sodium azide (0.12 g, 1.88 mmol) was again added. The mixture was stirred at 25°C for 3 h and an additional amount of sodium azide (0.24 g, 3.76 mmol) was added. The mixture was stirred at 25°C for 10 h and was then heated under reflux for 37 h. (Additional acetonitrile was added to maintain the liquid level.) The solid material was filtered off and washed with chloroform. The washings and the filtrate were combined and evaporated, affording only thiochromone (0.26 g, 87%).

Reaction of (trans)*-2-Azido-4-thiochromanone 1-Oxide* **1***b with Thiophosphoryl Bromide: Formation of Thiochromone* **2***a*

Thiophosphoryl bromide (0.024 mL, 0.23 mmol) was added dropwise (with a syringe) to a solution of **1***b* (50 mg, 0.23 mmol) in dry dichloromethane (2 mL) in a pre-dried two-neck flask equipped with magnetic stirrer, drying tube, and septum-cap inlet. The reaction mixture was stirred under N_2 at 25°C for 2 h. Some yellow precipitate (sulfur) was removed and the filtrate evaporated to afford a dark brown residue.

The residual material was stirred in a mixture of dichloromethane (50 mL) and 5% sodium carbonate (10 mL) for 0.5 h. The aqueous layer was discarded. The organic layer was extracted with 5% Na_2CO_3 (3 × 10 mL). Drying ($MgSO_4$) and evaporation afforded a yellowish residue (30.4 mg, 87%). The nmr ($CDCl_3$) and ir ($CHCl_3$) spectra indicated the residue consisted almost entirely of thiochromone **2***a*. The reaction was not further investigated.

Reactions of **1***b with Phosphorus Pentasulfide*

Phosphorus pentasulfide (40 mg, 0.09 mmol) was added in portions to a solution of **1***b* (40 mg, 0.18 mmol) in dry pyridine (2 mL). The reaction mixture was stirred under N_2 at 25°C for 4 h. The mixture was stirred briefly with water (10 mL) and dichloromethane (30 mL). The aqueous layer was discarded. The organic layer was repeatedly washed with water until the aqueous layer was colorless. Drying ($MgSO_4$) and evaporation afforded a yellowish residue (29.9 mg). Both nmr ($CDCl_3$) and ir ($CHCl_3$) indicated that this was mainly thiochromone in essentially quantitative yield.

Phosphorus pentasulfide (40 mg, 0.09 mmol) was added in portions to a solution of **1***b* (40 mg, 0.18 mmol) in dry dichloromethane (2 mL). The mixture was stirred under N_2 at 25°C for 4 h and diluted to 75 mL with dichloromethane. Water (25 mL) was added and the organic layer separated and washed with water (2 × 25 mL). Drying ($MgSO_4$) and evaporation of the solvent afforded a yellowish residue (39.4 mg, 98%). Nuclear magnetic resonance indicated that it was mainly the starting material, **1***b*.

Ion–molecule reactions in dimethylsulfoxide by high pressure photoionization mass spectrometry

JOHN A. STONE AND MARGARET S. LIN

Chemistry Department, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 14, 1979

JOHN A. STONE and MARGARET S. LIN. Can. J. Chem. **58**, 376 (1980).

Dimethylsulfoxide (DMSO) has been photoionized at 10.0 and 11.7 eV over the pressure range 0.3–210 mTorr. The rate constant for the disappearance of $DMSO^+$ is 1.0×10^{-9} cm^3 molecule^{-1} s^{-1}, independent of photon energy. The major products at low pressure are $CH_3SO(CH_3SO)CH_3^+$ and $CH_3SOHCH_3^+$ while at high pressure the ion series $(DMSO)_nH^+$ predominates with $n \leq 5$. In experiments with mixtures of DMSO and water or methanol very little mixed solvation of the proton was observed although isotopic D/H exchange between D_2O and $(DMSO)_2H^+$ is facile.

JOHN A. STONE et MARGARET S. LIN. Can. J. Chem. **58**, 376 (1980).

On a photoionisé le diméthylsulfoxyde (DMSO) à 10.0 et 11.7 eV sur une échelle de pression allant de 0.3 à 210 mTorr. La constante de vitesse de la disparition de l'ion $DMSO^+$ est de 1.0×10^{-9} cm^3 molécule^{-1} s^{-1} et est indépendante de l'énergie du photon. Les produits principaux à basse pression sont: $CH_3SO(CH_3SO)CH_3^+$ et $CH_3SOHCH_3^+$ tandis qu'à haute pression les ions de la série $(DMSO)_nH^+$ prédominent avec $n \leq 5$. On a observé, dans des expériences conduites avec des mélanges de DMSO avec de l'eau ou du méthanol, très peu de solvatation mixte du proton quoique l'échange isotopique D/H entre D_2O et $(DMSO)_2H^+$ soit facile.

[Traduit par le journal]

Introduction

The ion chemistry of dimethylsulfoxide (DMSO) received little attention for many years. Blais *et al.* (1, 2) studied both positive and negative ion reactions with a magnetic sector instrument at pressures around 10^{-4} Torr and first observed the products of positive ion reactions with *m/e* values greater than that of the molecular ion. It is now apparent that some of these *m/e* values were wrongly assigned so that the product designations are in error. Peers and Muller (3) obtained rate constants for the disappearance of the molecular ion and some primary ions formed by electron impact at pressures around 10^{-3} Torr. For the molecular ion, $k = 1.9 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} at ionizing electron energies of 11.0 and 16.0 eV. Reaction products were not identified.

Two ion cyclotron resonance (ICR) studies have recently helped identify some of the product ions and their precursors. McAllister (4) identified the major products originating from the reaction of the molecular ion (M^+) with the neutral molecule as the protonated molecule $(M+1)^+$ (reaction [1]), the proton bound dimer $(2M + 1)^+$ (reaction [2]), and a product obtained by transfer of CH_3SO^+ or CH_3SO (*m/e* 141) (reaction[3]).

[1] $CH_3SOCH_3^+ + CH_3SOCH_3 \rightarrow CH_3SOHCH_3^+ + CH_3SOCH_2^{\cdot}$

[2] $CH_3SOHCH_3^+ + CH_3SOCH_3 \rightarrow (CH_3SOCH_3)_2H^+$

[3] $CH_3SOCH_3^+ + CH_3SOCH_3 \rightarrow CH_3SO(SOCH_3)CH_3^+ + {}^{\cdot}CH_3$

Contemporaneously Nixon *et al.* (5) obtained qualitative results in general agreement with those of McAllister (4) and in addition obtained some rate constants and relative product yields. Their rate constant for the disappearance of M^+ (2.14×10^{-10} cm^3 molecule^{-1} s^{-1}) is an order of magnitude less than the value reported by Peers and Muller (3). M^+ disappeared to give mainly $(M+1)^+$ (95%), together with a small yield of the methylsulfinylated product arising from reaction [3]. Production of $(2M+1)^+$ from $(M+1)^+$ was found to be inefficient and further solvation of the proton was not observed. This slowness of reaction in the DMSO system was attributed to steric hindrance.

A quadrupole ion store (Quistor) was employed by Fulford *et al.* (6) in their study of DMSO. The major products obtained from M^+, $(M+1)^+$, and $(2M+1)^+$ were the same as those found by previous workers. However, other products were obtained which were either not reported by other workers or were present in yields far different from those reported previously.

The study of the reactions of the DMSO molecular ion is complicated to some extent by the reactions of fragment ions present in the initial spectrum. These latter ions do in most cases lead to the generation of the molecular ion (4). The present study was made using a photoionization source so that the reaction of the molecular ion alone could be examined, in the expectation that some of the inconsistencies of previous studies might be resolved.

Experimental

A photoionization source similar to the one described previously (7) was employed. It was machined from a stainless steel bar and had appropriate apertures for LiF windows, a Baratron pressure gauge, and a gas inlet. Cartridge heaters fitted into wells in the block. At very low pressures (~0.3 to 3 mTorr) the ions emerged through a circular aperture 1 mm diameter in a thin stainless steel plate. At higher pressures a slit was employed which was fabricated from razor blades and had dimensions 1.5 × 0.045 mm^2. The source was operated in the field free mode at ground potential. A conventional electron impact source facilitated accurate mass assignment. An ion counting system and a signal averager were used for data collection. The resolution of the quadrupole filter was adjusted so that there was little mass discrimination up to *m/e* 180 and above that value a correction was applied using factors obtained by comparisons with standard spectra of perfluorinated compounds. These corrections were not required for rate constant determinations.

Photoionization was by resonance radiation from either a krypton or argon low pressure, microwave-powered lamp. The former lamp supplies photons of energy 10.03 eV with a small contribution from those of energy 10.64 eV while the latter gives photons of energies 11.83 eV and 11.62 eV (8). Henceforth radiation from these lamps will be described as 10 eV and 11.7 eV, respectively.

The "Baker Analyzed" Reagent grade DMSO was dried by standing over 3 Å molecular sieve and was passed into the ion source from a heated reservoir via a heated Granville Phillips variable leak valve.

Results and Discussion

The vapour pressure of DMSO is ~0.6 Torr at 25°C so that in order to prevent condensation within the ion source the maximum pressure employed was less than half this value. Except where noted the ion source temperature was 298 ± 2 K.

(a) The Disappearance of the Molecular Ion (M^+)

Figure 1 shows that at 10 eV and low pressure there is a linear decrease in log fractional yield of M^+ with increasing pressure. The line extrapolates to unity at zero pressure which signifies that M^+ is the only significant initial ion. At 11.7 eV (Fig. 2) the curve extrapolates to 0.81, the ions observed, which account for the rest of the primary ionization, being *m/e* 61 ($C_2H_5S^+$), *m/e* 63 (CH_3SO^+), and *m/e* 62 ($C_2H_6S^+$ and CH_2SO^+) which has an extremely small yield. This is consistent with the determinations of Blais *et al.* (1) who give

$$IP(CH_3SOCH_3^+) = 9.9 \pm 0.1 \text{ eV}$$

$$AP(C_2H_5S^+) = 11.1 \pm 0.1 \text{ eV}$$

$$AP(CH_3SO^+) = 11.8 \pm 0.1 \text{ eV}$$

$$AP(C_2H_6S^+) = 11.6 \pm 0.1 \text{ eV}$$

and

$$AP(CH_2SO^+) = 11.8 \pm 0.1 \text{ eV}$$

Rate constants may be obtained from the slopes

of the lines for M^+ in Figs. 1 and 2 using the expression

$$\log I_{M^+}/\sum_i I_i = -kP\tau_{M^+}$$

where $I_{M^+}/\Sigma_i I_i$ is the fractional yield of the M^+ ions at a pressure P and τ_{M^+} is the average residence time of the M^+ ions in the source. Since the ion paths in the source are not well defined the value of τ_{M^+} was obtained by reference to a reaction with known rate constant. The disappearance of the molecular ion in propylene was measured and k was taken as 0.84×10^{-9} cm^3 molecule^{-1} s^{-1} at 10 eV and 0.68×10^{-9} cm^3 molecule^{-1} s^{-1} at 11.7 eV (9). $\tau_{M^+} = 1.36\tau_{C_3H_6^+}$, the correction factor being the square root of the ratio of molecular weights of DMSO and propylene.

The rate constant for the disappearance of the DMSO molecular ion is $1.0 \pm 0.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (four determinations) at 10 eV and $0.9 \pm 0.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1} (three determinations) at 11.7 eV. The error limits give the spread of the results. The non-dependence on ionizing energy is in agreement with the results of Peers and Muller (3) but their rate constant is higher by a factor of two (1.9×10^{-9} cm^3 molecule^{-1} s^{-1}). Such a large factor cannot be readily explained. Peers and Muller did not use a field-free source, the ions having a terminal kinetic energy of 0.71 eV, but it is expected that the rate constant will increase with decreasing ion kinetic energy for an exothermic reaction. The ICR value obtained by Nixon *et al.* (5) with 30 eV electrons, 2.14×10^{-10} cm^3 molecule^{-1} s^{-1}, appears to be too low. It is to be noted that on the graph showing typical kinetic data (Fig. 3 of ref. 5) the molecular ion constitutes less than 10% of total ionization at the shortest trapping time and the plot of log fractional yield of M^+ vs. time is decidedly non-linear.

The calculated ADO collision rate constant for M^+ is 2.5×10^{-9} cm^3 molecule^{-1} s^{-1} ($\alpha = 7.97 \times 10^{-24}$ cm^3 and $\mu_D = 4.11$ D). Our rate constant values show that reaction occurs with ~40% efficiency and therefore steric hindrance may play only a small role, if any, in the reaction.

A single experiment at 398 K using 11.7 eV photons yielded the same rate constant for the disappearance of M^+. The nature and yields of product ions were also not significantly changed.

(b) Product Ions at Low Pressure (0.3–3 mTorr)

The two major product ions at the lowest employable pressure are *m/e* 79, $CH_3SOHCH_3^+$ ($(M + 1)^+$) and *m/e* 141, $CH_3SO{\cdot}CH_3SOCH_3$ ($(2M - 15)^+$). Although the overall rate constant for the disappearance of M^+ appears independent of electronic excitation the relative yields of $(M + 1)^+$ and $(2M - 15)^+$ change with change of photon energy. The yield of $(2M - 15)^+$ decreases by roughly the same absolute amount that the initial yield of the molecular ion decreases in passing from 10 eV to 11.7 eV ionization energy. At the same time the yield of $(M + 1)^+$ increases. This behaviour suggests that none of the primary fragment ions produced at 11.7 eV leads to significant formation of $(2M - 15)^+$ and that electronic excitation of M^+ favours $(M+1)^+$ formation. This is consistent with the much higher relative yield of $(M + 1)^+$ observed when ionization is by electron impact with 30 eV electrons (5).

Nixon *et al.* (5) examined reaction [3] to determine whether the $(2M - 15)^+$ ion is formed in sufficiently large yield to serve as a methylsulfinium ion donor for analytical purposes, analogous to acetyl donation in acetone or 2,3-butanedione. They found that only 5% of the reactive collisons of M^+ lead to $(2M - 15)^+$. However, Fig. 1 shows that under present conditions, at the lowest pressure we employ, the methylsulfinylated product comprises 40% of total product, comparable with the 50% for self-acylation of 2,3-butanedione (10). With increasing pressure $(2M - 15)^+$ reacts further, by reaction [4] (5).

$$[4] \quad CH_3SO(CH_3SO)CH_3^+ + CH_3SOCH_3 \rightarrow (CH_3SOCH_3)_2H^+ + CH_2SO^{\cdot}$$

Since Nixon *et al.* (5) made observations only at times when most of M^+ had disappeared and since they were using 30 eV electrons for ionization, the small fraction of methylsulfinylated product observed by them is not surprising. We do still, however, concur with their conclusion that the utility of this ion as a chemical ionization reagent is severely limited, but this, under our conditions, is due to its rapid reaction with DMSO and not its low initial yield.

The failure to detect $(2M - 15)^+$ in the Quistor experiment cannot be, as suggested (6), that reaction [4] producing the proton bound dimer is endothermic for thermal ions since Figs. 1 and 2 clearly show that this reaction occurs. A more plausible explanation might be that the branching ratio for reactions [1] and [3] is dependent on ion kinetic energy as well as electronic excitation with [1] being favoured by the higher kinetic energies prevailing in the Quistor.

Very minor secondary ions at 10 eV are *m/e* 61 and 63. The yields are very low and only their sum is shown in Fig. 1. At 11.7 eV these ions are also primary fragment ions which are formed together with *m/e* 62. Measured as a composite peak they

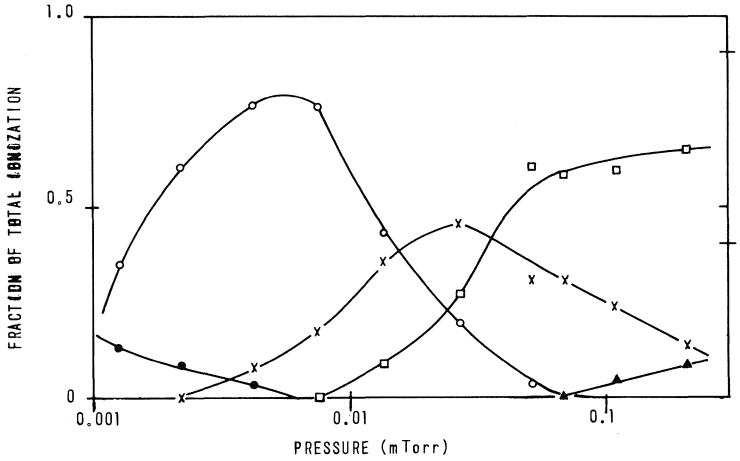

FIG. 3. Variation of the normalized ion abundances for the series $(CH_3SOCH_3)_nH^+$ at 10 eV and 298 K; values of n are ●*1*, ○*2*, × *3*, □*4*, and ▲*5*.

disappear with a rate constant very similar to that for the disappearance of the molecular ion (Fig. 2). The relative proportions of 61, 62, and 63 are 6/1/3, with a slight change in favour of *m/e* 63 at the highest pressures shown in Fig. 2.

The $(M+15)^+$ ion is present at both 10 and 11.7 eV and arises from the reaction of the molecular ion (4).

[5] $CH_3SOCH_3^+ + CH_3SOCH_3 \rightarrow CH_3SO(CH_3)CH_3^+ + CH_3SO^{\cdot}$

Its yield shows little dependence on photoionization energy.

(c) Product Ions at Higher Pressures (3–210 mTorr)

The major product ions in this pressure range belong to the series $(nM+1)^+$ with n = 2–5 which constitutes the progressive solvation of the proton. Figure 3 shows the relative yields of these ions at pressures up to 210 mTorr. Steric hindrance does not appear to be a factor in inhibiting solvation beyond $n = 2$ as has beeen suggested (5). It is probable that in the ICR experiments the pressure was not sufficient to observe the three body stabilization reactions for $n > 2$. The high yield of $(2M + 1)^+$ at low pressure shows that this ion is particularly stable. $(5M + 1)^+$ occurs at the limit of the mass range of the mass filter and its yield, although obviously small, is not accurately known. This ion, together with the $(4M + 1)^+$ ion, is completely absent at 210 mTorr when the temperature is raised to 398 K.

Two other ion series are present, corresponding to solvation of $(2M - 15)^+$ and $(M + 15)^+$. The maximum yield of any member of either series is less than 4% of total ionization. Most of the $(2M - 15)^+$ ions disappear via reaction [4] and are not solvated.

(d) Mixtures of DMSO with Water and Methanol

A separate inlet line was used to introduce a second gas into the ion chamber. With SF_6 (IP = 15.3 eV) the only effect observed with increasing total pressure up to 100 mTorr for a fixed small pressure of DMSO (< 2 mTorr) is a change in the yields of the product ions to those appropriate to a higher pressure of DMSO. No new ions are observed and the change in mass spectrum is due to an increase in ion reaction time.

Neither water nor methanol is ionized at 10 eV. Water behaves qualitatively in the same manner as SF_6. The only new product is $(CH_3SOCH_3 \cdot H_2O)^+$ which is in very low yield (< 0.5% total ionization). With D_2O the behaviour is very similar, there being a small $(CH_3SOCH_3 \cdot D_2O)^+$ peak and in addition an even smaller peak due to $(CH_3SOCH_3 \cdot H \cdot D_2O)^+$. At high D_2O pressures (> 50 mTorr) the $(M+1)^+$ and $(2M+1)^+$ peaks gradually change to $(M+2)^+$ and $(2M+2)^+$ as D replaces H. It is interesting that although this exchange occurs, essentially no mixed solvation is observed, even with water/DMSO ratios of 50:1. With methanol a prominent $(CH_3SOCH_3 \cdot H \cdot CH_3OH)^+$ peak constitutes 30% of total ionization in a mixture containing 0.3 mTorr DMSO and 60 mTorr methanol. With increasing DMSO pressure this fraction decreases and the yield constitutes only 2% of the total ionization at 2.1 mTorr DMSO.

The proton affinity of DMSO is 208.2 kcal mol^{-1} (11) so that proton transfer to water (PA 169 kcal mol^{-1}) or methanol (PA 182 kcal mol^{-1}) will not occur from $CH_3SOHCH_3^+$, which is formed only

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

via reaction [1]. The very limited mixed solvation of the $(2M + 1)^+$ ions is consistent with the relationship found between the hydrogen bond energies in $BH^+\cdots B_0$ and the proton affinity difference PA(B) − PA(B_0) where B and B_0 are gas phase bases (12). The maximum stabilization occurs when the difference in proton affinities is zero, in the present case when the second base is DMSO. Methanol, consistent with this thermodynamic argument, gives a greater yield of the mixed dimer than does water.

Binding sites between palladium(II) and nucleosides or nucleotides and crystal structure of [Pd(diethylenetriamine)(guanosine)]$(ClO_4)_2$

F. D. ROCHON, P. C. KONG, B. COULOMBE, AND R. MELANSON

Département de chimie, Université du Québec à Montréal, C.P. 8888, Montréal (Qué.), Canada H3C 3P8

Received August 23, 1979

F. D. ROCHON, P. C. KONG, B. COULOMBE, and R. MELANSON. Can. J. Chem. **58**, 381 (1980).

The interactions between [Pd(dien)Cl]Cl and some nucleosides and nucleotides were studied by nmr. The binding site of guanosine, guanosinemonophosphoric acid, xanthosine, and inosine is N(7). Cytidine is coordinated to palladium through N(3). Adenosinemonophosphate acts as a bidentate, binding two different palladium atoms at N(1) and N(7).

The crystal structure of [Pd(dien)(guanosine)]$(ClO_4)_2$ has been determined by X-ray diffraction. The crystals are orthorhombic, space group $P2_12_12_1$, with $a = 13.422$, $b = 14.587$, $c = 12.432$, and $Z = 4$. The structure was refined by block-diagonal least-squares analysis to a conventional R factor of 0.047 and a weighted $R_w = 0.043$. The coordination around the palladium atom is square planar. Guanosine is bonded to palladium through N(7). The planar purine ring makes an angle of 63.4° with the palladium coordination plane. The structure is stabilized by hydrogen bonding.

F. D. ROCHON, P. C. KONG, B. COULOMBE et R. MELANSON. Can. J. Chem. **58**, 381 (1980).

La réaction entre [Pd(dien)Cl]Cl et plusieurs nucléosides et nucléotides a été étudiée par rmn. Guanosine, l'acide guanosinemonophosphorique, xanthosine et inosine sont liés au palladium par N(7). Cytidine est coordinée au palladium par N(3). L'adénosinemonophosphate agit comme un bidentate, se liant à deux atomes de palladium différents par N(1) et N(7).

La structure cristalline de [Pd(dien)(guanosine)]$(ClO_4)_2$ a été déterminée par diffraction des rayons-X. Les cristaux appartiennent au groupe d'espace orthorhombique $P2_12_12_1$, avec $a = 13.422$, $b = 14.587$, $c = 12.432$ et $Z = 4$. Les coordonnées atomiques et les facteurs thermiques anisotropes ont été affinés par moindres-carrés (matrice diagonale) jusqu'à $R = 0.047$ et $R_w = 0.043$. La coordination autour de l'atome de palladium est plane. La guanosine est liée au palladium par N(7). Le plan du groupement purine fait un angle de 63.4° avec le plan de coordination du palladium. La structure cristalline est stabilisée par des ponts hydrogènes.

Introduction

The interaction of metals with nucleosides and nucleotides is of great biological importance. Recently, our work has been centered around platinum complexes because of their antitumour activity. The present work with palladium was undertaken in order to see if Pd(II) reacts in a way similar to Pt(II) with nucleosides and nucleotides. It is well known that Pd(II) complexes undergo ligand-exchange reactions much faster that Pt(II) complexes (1).

The interactions between [Pd(dien)Cl]Cl (dien = diethylenetriamine) and guanosine, guanosinemonophosphoric acid, xanthosine, inosine, cytidine, and adenosinemonophosphate were studied by nmr and compared to the results obtained with other palladium and platinum complexes (2–6). The reactions of the platinum and palladium complexes were found identical except for the faster rates of the palladium compounds.

A crystal structure determination was performed on one of the products. Since the chloro derivative did not give suitable crystals, the perchlorate complex was analysed by X-ray diffraction. Therefore in the second part of the publication we report the molecular and crystal structure of [Pd(dien)(guanosine)]$(ClO_4)_2$.

PART A

Experimental

[Pd(dien)Cl]Cl was synthesized according to the method described by Basolo, Gray, and Pearson (1).

The nucleosides and nucleotides were purchased from Raylo Chemicals Ltd.

The nmr spectra were measured on a Perkin-Elmer R-12 spectrometer at 27°C with DSS used as internal reference. All the solutions were stable since the spectra did not change with time.

Results and Discussion

The nmr spectra of the solutions formed from the interaction of [Pd(dien)Cl]Cl with different nucleosides and nucleotides are shown on Table 1. The interpretation of the spectra was based on several papers published on the nmr spectra of platinum and palladium nucleoside and nucleotide complexes (2–6).

Guanosine is insoluble in water but it reacts slowly with [Pd(dien)Cl] in D_2O to give a soluble compound [Pd(dien)(guanosine)]Cl. The downfield nmr spectrum consists of a doublet caused by H(1′) and a singlet caused by H(8). The signal of H(8) in $[Pd(dien)(guanosine)]^{2+}$ is more shifted downfield than H(1′) indicating that H(8) is close to Pd. Therefore we can conclude that the binding site of guanosine is N(7). This conclusion was confirmed later by an X-ray structure determina-

(1:3)	D_2O	8.91				6.23

tion of [Pd(dien)(guanosine)]$(ClO_4)_2$ (Part B of this publication). The experiment was repeated with guanosine 5′-monophosphoric acid (GuaMPA). Again the signal of H(1′) for the nucleotide and the complexed nucleotide is at about the same position, while the signal of H(8) is approximately at the same position as H(8) of $[Pd(dien)(guanosine)]^{2+}$ indicating that the binding site is N(7). But contrary to guanosine, this shift is upfield, since in the free ligand GuaMPA, the hydrogen ions interact with the nitrogen atoms of the base, causing a H(8) shift. This shift is pH-dependent as shown by Lim and Martin (4).

Since xanthosine is insoluble in D_2O, its reaction with [Pd(dien)Cl]Cl is slow. The nmr spectrum shows a reaction similar to guanosine. The signal of H(1′) is shifted downfield by 0.1 ppm while the signal of H(8) is shifted by 0.4 ppm indicating that N(7) is the binding site of xanthosine in [Pd(dien)(xanthosine)]Cl_2.

Inosine is soluble in D_2O. Its reaction with [Pd(dien)Cl]Cl is rapid. Table 1 shows that the signal of H(1′) is shifted by 0.07 ppm, the signal of H(2) by 0.17 ppm and H(8) by 0.51 ppm. Therefore the binding site of inosine in [Pd(dien)(inosine)]Cl_2 is again N(7).

Cytidine is slightly soluble in D_2O and reacts with [Pd(dien)Cl]Cl to give [Pd(dien)(cytidine)]Cl_2. The nmr spectrum of cytidine has already been published in DMSO (7). The signal of H(5) is a doublet close to the signal of H(1′) while the signal of H(6) is also a doublet at about 7.93 ppm. The signals of the three protons in [Pd(dien)(cytidine)]Cl_2 are shifted downfield by 0.03–0.05 ppm indicating that the binding site is far from H(1′), H(5), and H(6). N(3) was found to be the binding site in several platinum and palladium compounds (2, 6, 8). Therefore we can assume that N(3) is also the binding site of cytidine in [Pd(dien)(cytidine)]Cl_2.

Adenosine is not very soluble in D_2O. Therefore the reaction was studied with adenosine 5′ monophosphate disodium salt (AdoMPD). The reaction between AdoMPD and [Pd(dien)Cl]Cl was studied in 1:1, 1:2, and 1:3 proportions. In order to assign the signals of H(2) and H(8), AdoMPD was deuterated at H(8), and its reaction with [Pd(dien)(Cl)] was also studied by nmr. The nmr spectra are shown in Table 1. In 1:1 and 1:2 proportions the signals of H(1′), H(2), and H(8) were large, showing many peaks. When the proportion of Pd/ligand was 3:1, the signals were normal, that is a doublet for H(1′) and two singlets for H(2) and H(8). The shift of H(1′) in the complexed ligand is 0.06 ppm, while H(2) is shifted by 0.73 ppm and H(8) by 0.74 ppm. From these observations, we can conclude that AdoMPD acts as a bidentate, binding

two different atoms of palladium at N(1) and at N(7). The same conclusion was reached for the platinum analogue (2).

PART B

Experimental

[Pd(dien)(guanosine)]$(ClO_4)_2$ was prepared by the method already described for the platinum analogue (9).

A set of precession photographs indicated the $P2_12_12_1$ space group. The cell parameters were calculated by least-squares refinement of the setting angles of 15 independent peaks centered on a Syntex P$\bar{1}$ diffractometer using graphite monochromatized MoKA radiation.

Crystal Data

$PdCl_2C_{14}H_{26}N_8O_{13}$ mw = 691.71

Orthorhombic $P2_12_12_1$, a = 13.422(13), b = 14.587(7), c = 12.432(11) Å, Z = 4, V = 2434(4) Å^3, D_m = 1.89(2) g cm^{-3} (flotation), D_x = 1.887 g cm^{-3}, λMoKα = 0.71069 Å, μMoKα = 10.54 cm^{-1}, and T = 22°C.

Collection and Reduction of Intensity Data

The intensity data were collected from a crystal measuring about 0.3 × 0.3 × 0.2 mm and having approximately 15 faces. A total of 4043 MoKα independent reflections were measured up to a 2θ value of 60°. During the data collection, three standard reflections were measured after every 47 reflections as a test on crystal and instrument stability. No systematic changes were observed and the intensity fluctuations were within ±2%. The reflections (3234) for which the intensity was greater than 2.5σ(I) were considered as observed. The standard deviation σ(I) was calculated as already described (10). The data were corrected for the Lorentz and polarization effects. The scattering factors of Cromer and Waber (11) were used for palladium chlorine, oxygen, nitrogen, and carbon, those of Stewart *et al.* (12) were used for hydrogen. The anomalous dispersion terms (13) of palladium and chlorine were included in the calculations.

Structure Determination

The position of the palladium atom was easily located from the three-dimensional Patterson map. The positions of all the other atoms, except the hydrogen atoms, were obtained by structure factor and Fourier map calculations. The refinement of the parameters were carried out by block-diagonal least-squares methods. In the early stages of refinement, unit weight was assigned to all observed reflections. Later individual weights $1/w = a + bF_o + cF_o^2$ were calculated. The constants of the equation were adjusted to make the distribution of $w|\Delta F|^2$ almost constant with respect to $|F_o|$ and sin θ/λ (a = 12.30, b = −0.182, and c = 0.00095). The hydrogen atoms in the diethylenetriamine ligand and on the carbon atoms and on N(1) in the guanosine moiety were fixed at their calculated position[1] (C—H distance = 0.95 Å and N—H distance = 0.85 Å) and assigned isotropic thermal parameters of 6.0 Å^2. The refinement of the scale factor, the coordinates, and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = \sum ||F_o| - |F_c|| / \sum |F_o| = 0.047$ and $R_w = [\sum w(|F_o| - |F_c|)^2 / \sum w|F_o|^2]^{1/2} = 0.043$. The final difference Fourier map did not show peaks higher than ±0.4 e Å^{-3}. Attempts to find on the final difference Fourier map the hydrogen atoms that could not be calculated were not successful. The torsion angles within the ribose segment confirmed the expected D-configuration of the molecule. The R factor for the other enantiomorphic structure was higher (0.050) indicating that the coordinates of Table 2 correspond to the absolute structure.

The calculations were carried out with a Cyber 73 computer and the programs used have already been described (10). A table of observed and calculated structure factors is available.[1]

Results and Discussion

The refined atomic parameters are listed in Table 2. A list of the anisotropic temperature factors is available.[1] A labelled diagram of the ion [Pd(dien)(guanosine)]$^{2+}$ is shown on Fig. 1. (The size of the ellipsoids corresponds to a 50% probability.) The bond lengths within the ion are shown on Fig. 2, and the bond angles on Fig. 3.

As expected, guanosine is bonded to palladium through N(7). The coordination around the palladium atom is square planar. The deviations of the

[1]Lists of structure factors, calculated hydrogen positions, and anisotropic thermal parameters are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*The conventions suggested by Sundaralingam (19) and Trueblood and co-workers (20, 21) have been used.

five atoms from the weighted best plane are: Pd, −0.0009; N(5), 0.002; N(4), 0.071; N(6), 0.080, and N(7), 0.011 Å. The angles around palladium are close to the expected 90 and 180° but there are some distortions due to a slight strain caused by the tridentate ligand. The N(6)—Pd—N(5) and N(5)—Pd—N(4) angles (83.7 and 84.1°) are smaller than the N(6)—Pd—N(7) and N(7)—Pd—N(4) angles (93.6 and 98.6°). The N(4)—Pd—N(6) angle (167.1°) is also smaller than expected. The Pd—N bond lengths (1.99–2.03 Å) are normal and agree well with the published data (14, 15).

The purine ring is planar. The weighted best plane was calculated through the nine atoms. The deviations from this plane are: N(7), −0.015; N(1), −0.002; N(3), −0.005; N(9), 0.013; C(2), −0.016; C(4), 0.007; C(5), 0.001; C(6), 0.023; and C(8), −0.005 Å. The deviations of the substituents on the ring are as follows: N(2), −0.070; O(6), 0.022, and C(1′), −0.038 Å (esd = 0.005 to 0.008 Å). Since N(2) plays an important role in the hydrogen bonding system of the crystal, it might explain the slight deviation of N(2) from the purine plane. The latter plane makes an angle of 63.4° with the palladium coordination plane.

The bond lengths in the purine ring vary from 1.30 to 1.42 Å. They are similar to those found in guanosine rings mentioned in a review by Voet and Rich (16). They are identical to those found in guanosine dihydrate (17) and in [Pt(dien)-(guanosine)]$(ClO_4)_2$ (9). The bond angles also agree well with the published results mentioned above. The bond angles within the five member ring vary from 105 to 113°. In the six-membered ring, the range is from 111 to 128°. As pointed out by Singh (18) the internal ring angle at N(1) (125°) is greater than at N(3) (113°), the latter having no extra-annular attachment.

The glycosyl bond (1.46 Å) is normal (9, 16, 17).

The angles in the ribose ring are close to the tetrahedral values. O(1′), C(1′), C(3′), and C(4′) are coplanar and C(2′) is 0.54 Å distant from that plane, on the same side as C(5′) and N(9). This corresponds to the C(2′) *endo* conformation. The dihedral angle between the purine and the ribose planes is 30.4°. The torsion angles within the ribose group are listed in Table 3. The conventions suggested by Sundaralingam (19) and Trueblood and co-workers (20, 21) have been used. The torsion angle O(1′)C(1′)N(9)C(8), ϕ_{CN}, is −13° and defines an *anti* conformation about the glycosidic bond. The

C(5′)—O(5′) is in a *gauche–gauche* conformation relative to the ribose group: $\phi_{OO} = -66°$ and $\phi_{OC} = 52°$.

The bond lengths and the bond angles in the perchlorate ions are shown in Table 4. The distances vary from 1.35 to 1.43 Å. The bond angles are close to the tetrahedral values (107–112°).

A stereoscopic packing diagram is shown on Fig. 4. Base stacking plays an important role in most nucleoside crystal structures. In this structure, as in [Pt(dien)(guanosine)]$(ClO_4)_2$ (9), base stacking is not an important packing factor since the perchlorate ions are located between the bases. Hydrogen bonding is probably the predominant packing effect in this structure. The most important hydrogen bonds are listed in Table 5. All the hydrogen atoms attached to oxygen and nitrogen atoms in the guanosine group are involved in the hydrogen bonding system. O(2′)—H of each ribose group is intramolecularly hydrogen bonded to N(3). The other two hydroxyl groups O(3′)—H and O(5′)—H are involved in hydrogen bonds with the perchlorate ions. N(1) and N(2) form intermolecular hydrogen bonds, N(1)—H with O(2′) and N(2)$\begin{matrix}\diagup\\\diagdown\end{matrix}$N with both O(3′) and O(6). The role of the dien ligand in the hydrogen bonding system is doubtful. The most probable hydrogen bonds are shown on Table 5. The longer distances and the less favourable angles seem to suggest that these bonds are weaker.

Asymmetric reduction of α,β-unsaturated iminium salts with 1,4-dihydronicotinamide sugar pyranosides

NAOMICHI BABA, TAKETOSHI MAKINO, JUN'ICHI ODA, AND YUZO INOUYE

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611, Japan

Received August 31, 1979

NAOMICHI BABA, TAKETOSHI MAKINO, JUN'ICHI ODA, and YUZO INOUYE. Can. J. Chem. **58**. 387 (1980).

3;3,5-Trimethyl-2-cyclohexylidene iminium salts were reduced with 1,4-dihydronicotinamide sugar pyranosides to give optically active 3,3,5-trimethylcyclohexanone in enantiomeric excess ranging over 3–31%. The product stereochemistry changed sensitively with structural variation (including anomers, epimers, and deacetylation) of sugar residues. The reduction by more simplified chiral models, N^1-(1′*S*,2′*S*)-2′-hydroxy- or acetoxycyclohexyl-1,4-dihydronicotinamide revealed that operation of the functional groups on the sugar moiety is not merely steric in nature for induction of chirality in the product.

NAOMICHI BABA, TAKETOSHI MAKINO, JUN'ICHI ODA et YUZO INOUYE. Can. J. Chem. **58**, 387 (1980).

Les sels triméthyl-3,3,5 cyclohexylidène-2 iminium sont réduits par les pyrannosides du dihydro-1,4 nicotinamide pour donner la triméthyl-3,3,5 cyclohexanone optiquement active comportant un excès énantiomère allant de 3 à 31%. La stéréochimie du produit change d'une façon sensible avec les variations de structure (incluant les anomères les épimères et la déacétylation) des sucres. La réduction par des modèles chiraux plus simples N^1-(1′*S*,2′*S*)hydroxy-2′ ou acétoxycyclohexyldihydro-1,4 nicotinamides révèle que l'action des groupements fonctionnels sur les sucres n'est pas simplement de nature stérique lors de l'induction de la chiralité dans le produit.

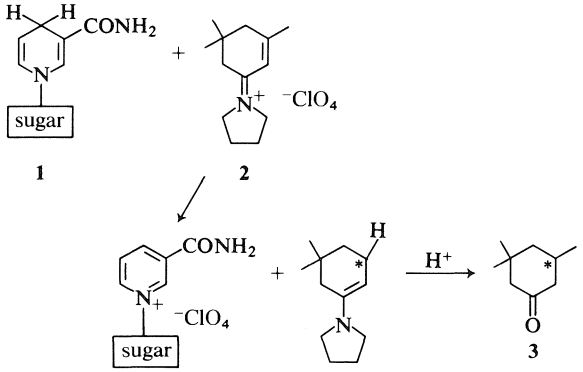
Introduction



In recent work directed toward co-enzyme models for NADH dependent dehydrogenase reductions, simulation of their salient stereospecificity by the use of simplified chiral NADH models (1) and chiral environment (2) has become one of the major interests for delving into a new method for asymmetric synthesis as well as studying the origin of stereospecificity of enzyme reactions. Pandit *et al.* (3) found that iminium salts could be potential substrates or direct hydrogen acceptors in non-enzymic NADH model reactions. We noticed that a similar reduction of iminium salt derived from prochiral α,β-unsaturated carbonyl compounds was effected by the use of simple chiral NADH models to give an optically active ketone bearing the chiral center at the β-position. This approach is worthy of note since there has been so far scanty precedent for asymmetric synthesis of optically active ketones with the chiral center at the β-position. Such compounds have been obtained conventionally by resolution (4). From this view, even partial asymmetric synthesis thus attained will greatly facilitate the first crystallization in resolution processes which sometimes impose difficulties.

In the present paper, we describe the reduction of prochiral iminium salt **2** with 1,4-dihydronicotinamide sugar pyranosides **1** as NADH models to afford an optically active ketone, 3,3,5-trimethylcyclohexanone **3**. The factors governing the stereochemistry of the product are discussed with respect to structural changes in the model compounds and substrate. Direct hydrogen transfer from **1** to **2** was established by the use of *N*-benzyl-4,4-dideuterionicotinamide and the reduction constitutes a sort of nucleophilic 1,4-addition reaction (formally a hydride attack in the present case).

Results and Discussion

Substrate Modification

Results on the reduction of substrate **2** with 1,4-dihydronicotinamide α- and β-D-glucopyranosides were reported in our previous communication (1*d*) and the data are in part reproduced in Table 2 for convenience. The pyrrolidine moiety and perchlorate anion of substrate **2** can easily be replaced by other amines and anions. To examine the dependence of product stereochemistry on substrate

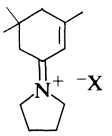
structure, modified substrates **4–9** were prepared and subjected to reduction with 1,4-dihydronicotinamide β-D-glucopyranosides. The results are summarized in Table 1. Substrates **4** and **5** were investigated in the expectation that hydrogen bonding and electrostatic attraction of oxygen in the former and additional positive charge on the nitrogen in the latter may possibly interact with hydroxyl groups of the glucose residue. Product ketones from the reduction with 1,4-dihydronicotinamide β-D-glucopyranoside under the same conditions showed rather inferior enantiomeric excess (e.e.) as compared with that found for the simple iminium salt **2**, which suggested the absence of substantial attractive interaction as expected above.



With **6–8**, a similar stereochemistry emerged, neither electronic nor steric participation of counter anions having been operative in the steric course as indicated by runs 5–7 in Table 1.

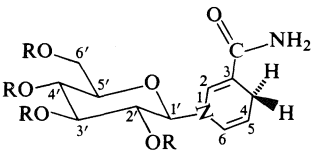
On the other hand, with the substrate **9**, which lacks the geminal dimethyl in the cyclohexenylidene moiety, (runs 8 and 9 in Table 1), the e.e. of the reduction product ketone was by far inferior to that with substrate **2** (runs 1 and 2 in Table 2). It then follows that structural change in proximity to the reaction center is important in the stereochemical process of hydrogen transfer in the present system.

Thus, practically, functionalization of the ketone with pyrrolidine was found to be the best method for the present system. Accordingly, **2** was chosen as a target substrate for the following study.



Structural Variation in Dihydronicotinamide Sugar Pyranosides

In Table 2 are listed the stereochemical results found for the reduction of substrate **2** with 1,4-dihydronicotinamide sugar pyranosides and their acetylated derivatives, **10–14**. Enantiomeric excess and configuration of the product were remarkably affected by structural difference in the sugar moiety despite the fact that the reaction center at

the 4-position of the dihydronicotinamide is apparently far removed from asymmetric carbons of the sugar moiety. The sole difference between β-D-glucopyranosides **10** and β-D-xylopyranosides **14** is that the latter lacks hydroxymethyl or acetoxymethyl groups at 5′-position of the pyranose ring. The reduction with acetyl-D-glucopyranoside, **10**-OAc, afforded the product ketone with preponderance of the *S*-enantiomer (run 1 in Table 2), whereas with acetyl-β-D-xylopyranoside, **14**-OAc, the *R*-counterpart was found in excess (run 9), so that the acetoxymethyl group at 5′-position of the pyranose ring functions to promote the *S*-chirality in the product. In contrast, both the OH-forms (runs 2 and 10) gave rise to the same *S*-product with higher e.e. in the former than in the latter case. As was also the case with OAc-forms, hydroxymethyl groups at 5′-position also favor the *S*-product. β-D-Galactopyranosides **13** are different from β-D-glucopyranosides **10** in that the configurations of the 4′-positions are opposite to each other. As can be seen from runs 1 and 7 in Table 2 for OAc-forms and runs 2 and 8 for OH-forms, this configurational difference did not cause substantial change in e.e. with the same *S*-product in preponderance. On the other hand, the configurational change from α to β at the anomeric carbons of OAc-forms of glucopyranosides resulted in a reversal of product configuration from *S* to *R*. With OH-forms, the α-anomer afforded a significantly higher e.e. of the product than the β-counterpart. Although the reduction data with D-mannopyranosides cannot be referred to with reasonable reliance because of the ambiguity in configurational integrity at the anomeric carbon, it is of interest to note that the OAc-form afforded much higher e.e. than the OH-form with reversal of configuration of the product. This change in product stereochemistry also suggests the importance of configuration at the epimeric 2′-carbon of the pyranose ring. Thus, the stereochemistry of reduction is greatly dependent on the structure of the sugar moiety as well as on whether or not the hydroxyl groups are acetylated. In addition, asymmetric centers adjacent to the nitrogen atom of the nicotinamide nucleus seem to exert more influence.

Hydroxyl groups at the 2′-position in nucleosides and nucleotides have been well documented to participate in determining their conformation through hydrogen bonding between the group and their base moiety (5), and also participate in enhancing the reactivity of dihydronicotinamide nucleoside by unidentified interaction between the group and dihydropyridine moiety (6). In this connection, we were particularly interested in the substituent at 2′-position of sugar pyranosides and prepared cyclohexanol derivatives of dihydronicotinamides **15**-OH and **15**-OAc as more simplified models for sugar pyranosides. Nicotinamide was incorporated in optically active amines **17** and **20** by the action of Zincke salt (7).

The stereochemical outcome (Table 2) revealed that the reduction of **2** with **15**-OH and **15**-OAc afforded the *R*-enantiomer with 6.3% e.e. and the *S*-counterpart with 17.7% e.e., respectively. Thus, OH and OAc groups at the 2′-position shifted the stereochemical course of the reduction in opposite directions despite the identical (1′*S*,2′*S*)-configuration in both reductants. This fact clearly shows that participation of these groups is not only steric but also electronic in nature. Molecular models revealed that the OH and OAc groups dispose spa-

tially within the range of hydrogen bonding with pyridine nitrogen. The same must hold for 1,4-dihydronicotinamide sugar pyranosides.

When the carbamoyl group was modified by *N*,*N*-diethylation, both the OH and OAc forms of β-D-glucopyranosides, **22**-OH and **22**-OAc, produced the same *S*-product in predominance to a comparable extent, which is in contrast to the reduction with the parent model compound **10**. This implies that the carbamoyl group is appreciably responsible for the difference in stereoselectivity observed in the reduction with **10**-OH and **10**-OAc, and that the mode of participation of the carbamoyl group as well as the modified *N*,*N*-diethylcarbamoyl group is not simply steric. Consistently, the ^{1}Hmr signal of the two carbamoyl protons is shifted to higher magnetic field with rising temperature (Fig. 1), clearly indicating the existence of hydrogen bonding between carbamoyl and sugar hydroxyls and/or solvent (9).

22-OH R = β-D-glucopyranosyl
22-OAc R = β-D-tetraacetylglucopyranosyl

When the substrate **2** was reduced with an achiral NADH model, 1-benzyl-1,4-dihydronicotinamide, in the presence of an equimolar amount of β-D-glucose, no asymmetric induction was obtained in the product ketone **3**. Accordingly, dihydronicotinamide should at least be connected with β-D-glucose through a covalent linkage for the asymmetric bias to be produced in the product ketone. This shows that, since solvation of β-D-glucose by *N*,*N*-dimethylformamide (solvent used for the present reaction system) may isolate the molecule from 1-benzyl-1,4-dihydronicotinamide and the substrate molecules in this instance, the asymmetric induction should be preceded by proximity of the chiral part to the reaction site prior to any non-covalent interactions responsible for enantiotopic recognition at the substrate.

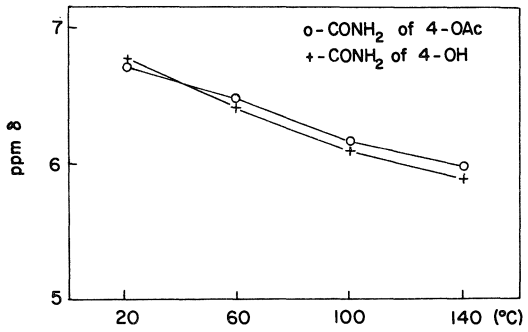

FIG. 1. Dependence of chemical shift of amide protons of 4-OAc and 4-OH on temperature (JEOL JNM-FX100 was used for the ^{1}Hmr spectra).

Finally, in view of the present data, the stereochemistry was very sensitive (including reversal of the stereochemistry) to structural variation in the sugar residue as well as the carbamoyl group, while the modification of substrate structure depressed the asymmetric bias equally with OAc- and OH-forms and the stereochemistry is virtually insensitive to the changes of the counter anions and external conditions (Table 3).

The present NADH model system is regarded as an example of asymmetric reaction in which the resulting stereochemistry cannot be understood without taking into account electronic factors, and the proximity effect of chiral source to reaction site is primarily important for the asymmetric induction. We prefer to leave the transition state topology open to speculation since insufficient stereochemical data is available at present. However, the information obtained here concerning the relationship between structure of NADH model compounds and stereochemistry of the reduction product ketone may help control and/or improve asymmetric syntheses in similar systems. The present system constitutes the first example of NADH model reaction by the use of sugars as chiral source to give optically active ketones with chirality at the β-position, and is applicable to other chiral α,β-unsaturated iminium salts as well.

Experimental

Infrared spectra were recorded with a Hitachi 215 spectrometer, ^{1}Hmr spectra with a Varian EM-360 spectrometer with tetramethylsilane as internal standard, and uv spectra were measured on a Hitachi EPS-3 spectrophotometer. Optical rotations were measured with a Perkin-Elmer 241 polarimeter and preparative vpc was performed on Varian Aerograph Model 920 with aluminum column (3 m) packed with 15% Apiezone at 170°C. Qualitative vpc was on a Shimadzu gas chromatograph GC-4CM with glass column (3 m) packed with 15% polyethylene glycol succinate at 170°C. The sugar pyranosides **10–14** were prepared according to the procedure of Haynes and Todd (10). Iminium salt **2** was prepared according to the method of Firrell and Hickmott (11). Counter anion analogues of **2**, *p*-nitro-, *p*-methoxybenzoate, and *d*-10-camphorsulfonate, **6–8**, were prepared (12) by exchange of the perchlorate anion with the carboxylate anions, stoichiometric quantity of potassium perchlorate having been separated out from a dry methanol solution of the corresponding potassium benzoates and **2**.

3,3,5-Trimethylcyclohexenylidenemorpholinium Perchlorate **4**

This salt was prepared by the same procedure as for **2** from a dienamine (from morpholine and isophorone, bp 80–90°C/0.35 Torr, 17.5 g, 84.4 mmol). Yield 17.1 g (65.8%). This salt was recrystallized from acetonitrile–ethanol–ether; mp 202–203°C; ^{1}Hmr (CF_3COOD) δ: 1.15 (6H, s, geminal CH_3), 2.3 (3H, s, CH_3 on vinyl group), 2.45 (2H, s), 2.75 (2H, s), 4.2 (8H, s.

TABLE 3. Results in reduction of **2** with **10**-OH under other specified conditions

Temperature (°C)	Reaction period (h)	Solvent	$[\alpha]_D^{25}$/°(*c*, *n*-Hexane)	e.e.[a] (%)	Configuration
140	1	DMF + TCE[a] (3:2)	+2.36 ± 0.35 (0.55)	23	*S*
180	0.5	No solvent	+2.31 ± 0.19 (1.04)	22	*S*

protons on morpholine ring), 8.7 (1H, s, vinyl proton). *Anal.* calcd. for $C_{13}H_{22}ClNO_5$: C 50.73, H 7.21, N 4.55; found: C 50.57, H 7.25, N 4.30.

3,3,5-Trimethylcyclohexenylidene-N-*methylpiperazinium Perchlorate* ***5***

This salt was prepared similarly by the quarternization of a dienamine (from isophorone and *N*-methylpiperazine, bp 86–87°C/0.15 Torr, 5.3 g, 24 mmol) with 70% perchloric acid. Yield 6.8 g (67%). The salt was recrystallized from acetonitrile – dry ether; mp 265–266°C; ^{1}Hmr (CF_3COOD) δ: 1.1 (3H, s, geminal CH_3), 1.2 (3H, s. another geminal CH_3), 2.3 (3H, s, CH_3 on vinyl group), 2.53 (2H, s), 2.84 (2H, s), 3.25 (3H, s, N—CH_3), 3.5–5.2 (8H, m, protons on piperazine ring), 6.85 (1H, s). *Anal.* calcd. for $C_{14}H_{26}Cl_2N_2O_8$: C 39.92, H 6.22, N 6.65; found: C 39.84, H 6.23, N 6.67.

3-Methylcyclohexenylidenepyrrolidinium Perchlorate ***9***

This salt was prepared by the same procedure as for **2** from a dienamine (from 3-methylcyclohexenone and pyrrolidine, bp 150–170°C/0.1 Torr, 10 g, 61 mmol). Yield 6.2 g (39%). The salt was recrystallized from methanol–ether; mp 84–86°C; ^{1}Hmr (CF_3COOD) δ: 1.15 (3H, s, CH_3), 1.3–2.8 (6H, m, methylene protons on cyclohexanone moiety), 2.8–4.4 (8H, m, methylene protons on pyrrolidine moiety). *Anal.* calcd. for $C_{12}H_{18}ClNO_4$: C 50.10, H 6.88, N 5.31; found: C 49.97, H 6.89, N 5.16.

N^1-β-D-*Triacetylxylopyranosyl-1,4-dihydronicotinamide* ***14***-*OAc*

The dihydro-form was obtained by sodium hydrosulfite reduction of its oxidized form which was prepared according to the method of Iff and Viscontini (13). Yield 5.4 g (59.3%); mp 175–177°C; $[\alpha]_D^{25}$, −29.3° (*c* 1.1, chloroform); uv (methanol) λ_{max}: 329 nm (ε 5 500). *Anal.* calcd. for $C_{17}H_{28}N_2O_8$: C 53.43, H 5.75, N 7.32; found: C 53.26, H 5.80, N 7.54.

N^1-β-D-*Xylopyranosyl-1,4-dihydronicotinamide* ***14***-*OH*

Deacetylation of **14**-OAc in methanol by ammonia (10) gave the OH-form. Melting point 177–178°C; $[\alpha]_D^{25}$ −18.8 ± 0.14° (*c* 1.12, water); uv (methanol) λ_{max}: 335 nm (ε 5 900). *Anal.* calcd. for $C_{11}H_{16}O_5N_2$: C 51.56, H 6.29, N 10.3; found: C 51.36, H 6.44, N 11.2.

N^1-*(1'S,2'S)-2'-Hydroxycyclohexylnicotinamide Chloride* ***18***

A solution of (*S*,*S*)-aminocyclohexanol (0.6 g, 5.2 mmol, 47.5% optical purity) in methanol (30 mL) was added dropwise to a solution of the Zincke salt (1.57 g, 4.4 mmol) in methanol (25 mL) with stirring. After the deep red color faded out, an excess of ether was added and the nicotinamide chloride separated from the solution was filtered, washed with ether, and dried over phosphorus pentoxide *in vacuo*. Yield 0.95 g (84%); mp 253–254°C; $[\alpha]_D^{25}$ 10.2 ± 0.15° (*c* 1.20, methanol); ^{1}Hmr (CF_3COOD) δ: 1.1–2.7 (8H, m, methylene protons on cyclohexane ring), 4.0–5.2 (2H, m, methyl protons on cyclohexane ring), 8.2 (1H, d of d, *J* = 8 Hz), 9.07 (1H, d, *J* = 8 Hz), 9.5 (1H, s). *Anal.* calcd. for $C_{12}H_{17}ClN_2O_2$: C 56.14, H 6.67, N 10.91; found: C 56.04, H 6.67, N 10.64.

N^1-*(1'S,2'S)-2'-Hydroxycyclohexyl-1,4-dihydronicotinamide* ***15***-*OH*

A solution of the chloride **18** (0.95 g, 3.7 mmol) in 5 mL of water was added dropwise to a solution of sodium hydrosulfite (1.31 g, 7.5 mmol) and sodium carbonate (1.55 g, 14.6 mmol) in water (8 mL) with stirring under ice-cooling in nitrogen atmosphere. After 30 min light yellow crystalline dihydronicotinamide separated from the reaction mixture, was filtered, washed with cold water, and dried over phosphorus pentoxide *in vacuo*. Yield 0.60 g (72.7%); mp 130–133°C (dec.); $[\alpha]_D^{25}$ 76.0 ± 0.03° (*c* 0.36, methanol); uv (methanol λ_{max}: 354 nm (ε 6 326); ^{1}Hmr (CD_3OD) δ: 0.9–2.3 (8H, m, methylene protons on cyclohexane ring), 3.1 (2H, d of d, *J* = 2 and 4 Hz, protons at 4-position), 5.85 (1H, d of d, *J* = 2 and 8 Hz, a proton at 6-position), 7.0 (1H, d, *J* = 2 Hz, a proton at 2-position). *Anal.* calcd. for $C_{12}H_{18}N_2O_2$: C 64.84, H 8.16, N 12.60; found: C 64.47, H 8.28, N 12.60.

(1S,2S)-2-Acetoxycyclohexylammonium Perchlorate ***19***

To the suspension of (1*S*,2*S*)-2-hydroxycyclohexylammonium chloride **16** (1.3 g, 8.6 mmol) in acetic anhydride (10 mL) was added 25 drops of 70% perchloric acid and the temperature was kept below 50°C by ice-cooling. The reaction mixture was stirred at room temperature overnight. Crystalline perchlorate **19** was separated from the solution by addition of ether. The perchlorate was recrystallized from acetonitrile–ether. Yield, 1.6 g (72%); mp 146–148°C. $[\alpha]_D^{25}$ 17.5 ± 0.14° (*c* 1.09, methanol). *Anal.* calcd. for $C_8H_{16}ClNO_6$: C 37.29, H 6.27, N 5.44; found: C 37.49, H 6.30, N 5.62.

N^1-*(1'S,2'S)-2'-Acetoxycyclohexyl-1,4-dihydronicotinamide* ***15***-*OAc*

A solution of the salt **19** (0.863 g, 3.37 mmol) in dry methanol (16.2 mL) was chilled in ice and added to 13.4 mL of 0.25 *N* methanolic potassium hydroxide. After a few min, a solution of Zincke salt (1.007 g, 2.82 mmol) in 16.2 mL of dry methanol was added dropwise and stirred gently at room temperature for 2 h. The reaction mixture was poured dropwise into about 2 L of ether with stirring and set aside until the ether phase became transparent. The bulk solvent was decanted, leaving very hygroscopic salt **21** which was dried over phosphorus pentoxide *in vacuo*. The crude yield was nearly quantitative; $[\alpha]_D^{25}$ 2.6 ± 0.15° (*c* 1.305, water); ^{1}Hmr (CD_3OD) δ: 1.8 (3H, s, acetyl protons), 1.1–2.6 (8H, m, methylene protons on cyclohexane ring), 5.2 (2H, amide protons), 8.0–9.4 (3H, m, protons at 4-, 5-, and 6-positions on pyridine ring), 9.5 (1H, s, protons at 2-position on pyridine ring). The salt **21** was dissolved in water (34 mL) and chilled in ice. This solution was added dropwise to a solution of sodium carbonate (1.042 g, 9.8 mmol) and sodium hydrosulfite (0.903 g, 5.2 mmol) in water (10 mL) under nitrogen atmosphere and stirred for 2 h at 0°C, followed by stirring for 1 h at room temperature. After this period, the organic phase was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

extracted with chloroform (20 mL × 3) and the extract was dried over anhydrous sodium sulfate. The solvent was removed completely under reduced pressure at room temperature leaving the nicotinamide **15**-OAc as light yellow oil. This product could not be purified to an analytical grade because of its instability but the integrity was confirmed by the following data and tlc analysis (silica gel, methanol–chloroform 10:1, $R_f = 0.5$, fluorescence). $[\alpha]_D^{25}$ 13.2 ± 0.04° (*c* 3.80, chloroform); ir ν_{max}: 1690 (amide carbonyl), 1740 (ester carbonyl) cm^{-1}; uv (ethanol) λ_{max}: 348 nm (ε 6 944); ^{1}Hmr ($CDCl_3$) δ: 1.0–2.7 (8H, m, methylene protons on cyclohexane ring), 2.0 (3H, s, protons of acetyl), 3.0 (2H, d of d, J = 2 and 4 Hz, protons at 4-position), 4.3 (1H, m, proton at 5-position), 5.55 (2H, amide protons), 5.75 (1H, d of d, J = 2 and 8 Hz, a proton at 6-position), 6.98 (1H, d, J = 2 Hz, a proton at 2-position).

N^1-β-D-*Tetraacetylglucopyranosyl*-N,N-*diethyl-1,4-dihydronicotinamide* ***22-OAc***

According to the method of Haynes and Todd (10), the oxidized form was prepared from *N,N*-diethylnicotinamide (4.4 g, 24.7 mmol) and acetobromoglucose (9 g, 21.9 mmol), and this glucopyranoside was confirmed as the β-anomer from the coupling constant (J = 8 Hz) of 1′H with 2′H (14). The noncrystalline bromide was reduced as such by sodium hydrosulfite to give **22**-OAc as white powder, yield 5.2 g (46%). This product was recrystallized from ethanol; mp 138–140°C (dec.); $[\alpha]_D^{25}$ 30.3 ± 0.08° (*c* 1.48, methanol); uv (methanol) λ_{max}: 307 nm (ε 2 800); ^{1}Hmr ($CDCl_3$) δ: 1.15 (6H, t, J = 8 Hz, CH_3 at ethyl groups), 2.0–2.1 (12H, s, $COCH_3$ × 4), 3.1 (2H, m, protons at 4-position), 3.4 (4H, q, J = 8 Hz, CH_2 at ethyl groups), 5.86 (1H, m, a proton at 6-position). *Anal.* calcd. for $C_{24}H_{34}N_2O_{10}$: C 56.46, H 6.71, N 5.49; found: C 56.09, H 6.71, N 5.12.

N^1-β-D-*Glucopyranosyl*-N,N-*diethyl-1,4-dihydronicotinamide* ***22-OH***

Compound **22**-OAc (1.8 g, 3.51 mmol) was deacetylated as described above and acetamide was removed by extraction with a mixture of chloroform and benzene (1: 10). After removal of the acetamide, the residue, **22**-OH, was used immediately for the reduction of substrate because of its instability and hygroscopic nature at ambient temperature. Purification was not feasible with this compound, but the integrity was confirmed by the following data and tlc analysis (silica gel, methanol–chloroform 10:2, R_f = 0.6, fluorescence). $[\alpha]_D^{25}$ 3.9 ± 0.15° (*c* 1.27, chloroform); uv (chloroform) λ_{max}: 310 nm (ε 2 500); ^{1}Hmr ($CDCl_3$) δ: 1.15 (6H, t, J = 8 Hz, CH_3 in ethyl groups), 3.1 (2H, m, protons at 4-position), 6.0 (1H, m, a proton at 6-position, 6.38 (1H, a proton at 2-position).

General Procedure for Asymmetric Reductions

Dihydronicotinamide (NADH model, 2.5 mmol) and substrate (2.5 mmol) in 10 mL of dry *N,N*-dimethylformamide was heated at 140°C for 1 h under nitrogen with stirring. The reaction mixture was cooled to room temperature and the enamine formed was hydrolyzed with 3 *N* hydrochloric acid (10 mL). Cyclohexanone thus liberated was extracted with *n*-pentane (20 mL × 4). The pentane solution was dried over anhydrous sodium sulfate and concentrated to about 1 mL. Quantitative determination of the ketone was done by vpc (15% polyethyleneglycol succinate, 170°C, 3 m). The ketone was isolated by preparative vpc (15% Apiezone L, 190°C, 3 m). After the identification and purity of the ketone were checked by ^{1}Hmr and vpc, the optical rotation was measured in *n*-hexane.

Oxygen exchange in methanol in acid solutions. Transition state activity coefficients

ROBERT A. MCCLELLAND

Department of Chemistry, Scarborough College, West Hill, Ont., Canada M1C 1A4

Received August 10, 1979

ROBERT A. MCCLELLAND. Can. J. Chem. **58**, 393 (1980).

Rate constants for oxygen exchange of methanol in sulfuric acid and perchloric acid solutions are reported, along with activity coefficients of methanol in sulfuric acid. Transition state activity coefficients ($f_{\neq}$*) for methanol exchange and *tert*-butanol exchange have been calculated. Values of $f_{\neq}$* for the latter behave very similarly to those for *tert*-butyl acetate hydrolysis, consistent with a carbonium ion-like transition state. Values for methanol exchange show considerably more salting-out, consistent with an oxonium ion-like transition state. A significant difference with the $A_{Ac}2$ hydrolyses of esters and amides is noted. For the latter the transition state is salted-out relative to its protonated precursor, whereas for methanol exchange, there is little difference between the activity coefficient of the protonated alcohol and the transition state, with the latter actually being somewhat salted-in. It is pointed out that the transition state activity coefficient approach can be rigorously applied even in the absence of protonation data.

ROBERT A. MCCLELLAND. Can. J. Chem. **58**, 393 (1980).

On rapporte les constantes de vitesse de la réaction d'échange d'oxygène du méthanol dans des solutions d'acides sulfurique et perchlorique, ainsi que les coefficients d'activité du méthanol dans l'acide sulfurique. On a calculé les coefficients d'activité de l'état de transition ($f_{\neq}$*) lors de la réaction d'échange du méthanol et du *tert*-butanol. Les valeurs de $f_{\neq}$* obtenues pour le *tert*-butanol se comportent comme celles relatives à l'hydrolyse de l'acétate de *tert*-butyle et sont en accord avec un état de transition impliquant un carbocation. Les valeurs dans le cas de l'échange de l'oxygène du méthanol montrent une diminution plus considérable qui est en accord avec un état de transition mettant en jeu un ion oxonium. On note une différence importe par rapport aux hydrolyses $A_{ac}2$ d'esters et d'amides. Dans ce dernier cas l'état de transition est relargué par rapport à son précurseur protoné alors que dans le cas de l'échange du méthanol il y a très peu de différence entre le coefficient d'activité de l'alcool protoné et l'état de transition, ce dernier étant actuellement quelque peu renforcé. On a mis en évidence le fait que l'approche du coefficient d'activité de l'état de transition peut être rigoureusement appliqué même en l'absence des données relatives à la protonation.

[Traduit par le journal]

We report here rate constants for the oxygen exchange reaction of methanol in aqueous sulfuric acid and perchloric acid solutions. Alcohol oxygen exchange reactions have been studied in the past (1), although no kinetic data appear to have been reported for methanol. With the exception of *tert*-butanol oxygen exchange, there also appears (1) to have been no kinetic study over a range of acidity sufficiently great to rigorously test the applicability of the various treatments now available for acid-catalyzed reactions (2–7). We in particular wished to test a new approach, the transition state activity coefficient method (7), on different types of reaction of known mechanism. For methanol exchange, there can be little mechanistic uncertainty; it is difficult to visualize a mechanism other than that involving an S_N2 displacement on the protonated alcohol by a solvent water molecule, proceeding through a symmetrical transition state.

[1] $CH_3—OH + H^+ \rightleftharpoons CH_3—{}^+OH_2 \rightleftharpoons$
$H_2O^{\delta+}\cdots CH_3\cdots{}^{\delta+}OH_2 \rightleftharpoons H_2O^+—CH_3 \rightleftharpoons HO—CH_3 + H^+$

Experimental

Sulfuric acid solutions and perchloric acid solutions were prepared and standardized as previously described (8, 9). [^{18}O]methanol (12.3% excess ^{18}O) was prepared from $H_2{}^{18}O$ (Miles Research) using the procedure of Sawyer (10).

Methanol exchange kinetics were initiated by dissolving [^{18}O]methanol (0.1 g) in the appropriate acid (10 mL) and placing this solution in a sealed tube in an oil bath thermostatted at 67.2°C. After an appropriate time interval the sealed tube was removed and immersed in an ice bath to quench the exchange. In the case of concentrated acids, a small quantity of water was also added. The solution was transferred to a small distillation apparatus, which was evacuated to 0.05 Torr. Volatile components were collected in a liquid nitrogen trap, until approximately 1–2 g of material had accumulated. Pyridine (50 mL) was added, followed by *p*-nitrobenzoyl chloride (20 g). This was stirred at 50–60°C for 10 min, at which point 5 mL of water was added to react with any excess acid chloride. After an additional 10 min stirring, the mixture was evaporated on a rotary evaporator. Ether (250 mL) and water were added, and the ether layer was washed with dilute aqueous hydrochloric acid, and three times with saturated sodium carbonate. Magnesium sulfate was added, and after filtration, the ether removed on a rotary evaporator. The remaining pale yellow solid was recrystallized from chloroform – petroleum ether. Based on its nmr spectrum this product is pure methyl *p*-nitrobenzoate, containing less than 5% *p*-nitrobenzoic acid. Between 20 and 50% of the methanol originally added can be accounted for in this product.

The methyl *p*-nitrobenzoate was analyzed for ^{18}O content directly on an AEI mass spectrometer, equipped with a Vacuumetrics Ratiometer. This use of this apparatus has been previously described (11). Methyl *p*-nitrobenzoate has a strong molecular ion peak in its mass spectrum, and this was chosen for analysis, the relative intensity of the two peaks at *m/e* 183 and *m/e* 181 being measured. The ester contains natural abundance ^{18}O in all oxygen atoms except, perhaps, the oxygen atom attached to the methyl group, that is, the oxygen derived from the methanol. The ^{18}O content in this oxygen was calculated from the formula

$$\%\ ^{18}O = 99.8\left(\frac{R - R_0}{1.002 + R - R_0}\right) + 0.2$$

where R = the 183/181 ratio in the sample in question, and R_0 =

[a]Mol percent of enriched methanol in mixture of enriched methanol and natural abundance methanol.
[b]$(183:181)_{calcd} = (\%Me^{18}OH/100)(0.1491 - 0.015) + 0.015$.
[c]The same value is obtained for a sample of methyl *p*-nitrobenzoate containing only natural abundance ^{18}O atoms. The calculated 183/181 ratio for $C_8H_7NO_4$ is 0.012 (J. H. Beynon and A. E. Williams (18)).

the 183/181 ratio in a sample of methyl *p*-nitrobenzoate containing only natural abundance ^{18}O atoms. As a check on the analysis, enriched methanol was accurately mixed with natural abundance methanol, dissolved in 30% H_2SO_4, and immediately subjected to the experimental procedure for isolation as the *p*-nitrobenzoate. Excellent agreement was found between the observed value of the 183/181 ratio, and the value calculated on the basis of the amount of enriched methanol actually present (Table 1). First order rate constants for methanol oxygen exchange were evaluated as the slopes of plots in ln (% ^{18}O − 0.2) vs. time. A typical set of data is provided in Table 1. The first-order kinetic plots were all excellently linear over one to two half-lives of exchange. In the case of the more concentrated acids, we checked for the possibility of decomposition of the methanol under the experimental conditions by taking the nmr spectra of the solutions. With the exception of solutions above about 80% H_2SO_4, there is no change in the spectra over a time period corresponding to one to two half-lives of exchange.

Distribution coefficients for methanol in carbon tetrachloride/aqueous H_2SO_4 mixtures were obtained in the following way. A standard solution in carbon tetrachloride containing known amounts of methanol and toluene was prepared, and the relative intensity of the two methyl peaks in the nmr spectrum obtained. A known amount of this solution was shaken with a known amount of aqueous solution for 15 min in a thermostatted water bath (25°C), and, after separation, the relative intensity of the two methyl peaks in the nmr spectrum of the carbon tetrachloride layer obtained. The difference before and after shaking was used to calculate the concentration of methanol remaining in the CCl_4, while the difference between this and the starting concentration was set equal to the concentration in the aqueous phase. This experiment requires that the toluene remains in the organic phase, an assumption which is probably valid, on the basis of distribution coefficients obtained previously (8, 12). Methanol has a strong preference for the aqueous phase. Conditions were arranged such that the concentrations of methanol in the carbon tetrachloride phase after distribution were of the order 0.005–0.01 *M*, meaning that concentrations in the aqueous phase were of the order of 1–3 *M*. Distribution coefficients with water were measured using several different concentrations of methanol and were found to be, within experimental error, the same.

Results and Discussion

Activity Coefficients

For the equilibrium partitioning of methanol between carbon tetrachloride and various aqueous sulfuric acid solutions, we have obtained distribution coefficients equal to the ratio of the concentration of methanol in the aqueous phase to the concentration in carbon tetrachloride. Activity coefficients (Table 2) were then calculated in the normal manner as $f_s = D^0/D$ (12), where D^0 and D are the distribution coefficients involving water/CCl_4 and acid/CCl_4, respectively. These values of f_s do not necessarily represent the activity coefficient of the neutral molecule, since the concentration of methanol in the aqueous phase refers to the total methanol present, and in the more concentrated acids a significant amount of this must be in the protonated form (13). The activity coefficient of the neutral molecule, f_{MeOH}, is related to f_s via eq. [2] where

$$[2] \quad f_{MeOH} = f_s[MeOH]_{tot}/[MeOH]$$

$[MeOH]/[MeOH]_{tot} \equiv$ fraction of methanol in the unprotonated form. Values of f_{MeOH} based on literature protonation data (13) are also listed in Table 2.

Figure 1 compares the activity coefficient behavior of methanol with that of other small organic molecules, including two other alcohols. We have chosen to compare f_s values in this figure, since all of the molecules are probably partially protonated in the more concentrated acids, and no correction for this fact has been made in their determination (12). As can be seen in Table 2, the activity coefficients based on the neutral molecule may be different from the measured activity coefficients, but the form of the $\log f_s$ vs. % H_2SO_4 curve remains unchanged. Figure 1 shows that methanol is not

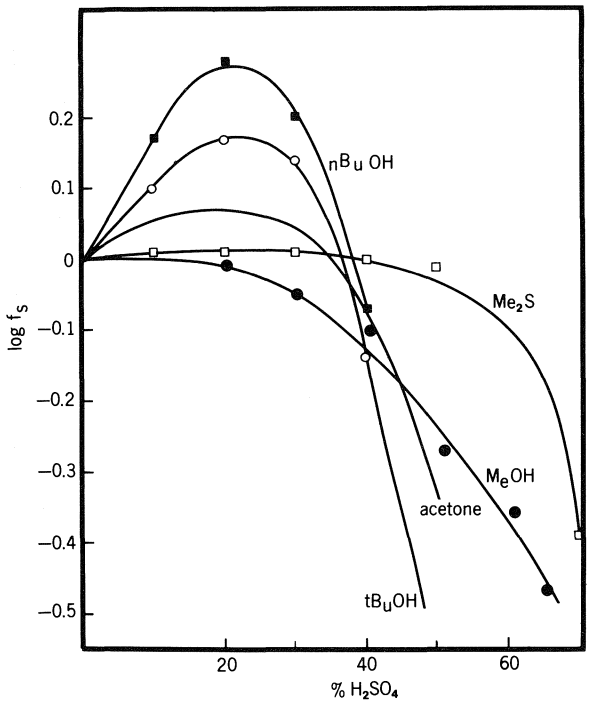

FIG. 1. Activity coefficients in sulfuric acid solutions. (Data taken from ref. 12, except for MeOH.)

unusual in its activity coefficient behavior. Neutral organic molecules generally show a small salting-out (positive log f_s) in dilute acids, followed by a pronounced salting-in in concentrated acids (12). This is also seen with methanol, with the minor difference that there is only little change in log f_s in dilute acids.

Kinetics of Oxygen Exchange

The oxygen exchange of methanol was studied by preparing an ^{18}O-labelled sample of the alcohol, and allowing this to exchange in natural abundance aqueous acids. The alcohol was separated and analyzed for ^{18}O content as its *p*-nitrobenzoate derivative. Observed first-order rate constants for exchange at 67.2°C are listed in Table 3, and plotted as a function of acid concentration in Fig. 2, along with literature data for *tert*-butanol exchange (14) and methyl acetate hydrolysis (4). One of the features of the methanol data is that unlike that of most A2 reactions (4, 15) the rate constants increase monotonically with increasing acid concentration and show no indication of reaching a maximum value. It is conceivable that in the more concentrated sulfuric acid solutions the rate increase could be due to the growing importance of a bisulfate ion catalyzed reaction, bisulfate displacing water from the protonated methanol, and then in turn being itself displaced by a solvent water molecule.[1] However the rate profile in perchloric acid solutions is very similar to that in sulfuric acid, and a similar reaction involving the less nucleophilic perchlorate ion is less likely. We presume therefore that at least up to 60–70% acid, the exchange occurs via the mechanism of eq. [1], with a solvent water molecule reacting with the protonated methanol.

69.3	19.7		

Transition State Activity Coefficients

Before proceeding further, we wish to point out a feature of the transition state activity coefficient approach which has not been recognized in its earlier applications (7, 16) and which permits an even wider range of applicability for this method. Taking the methanol exchange reaction to illustrate the point,

$$H^+ + MeOH \overset{1/K_a}{\rightleftharpoons} \overset{+}{MeOH_2}$$

$$\overset{+}{MeOH_2} (+ H_2O) \xrightarrow{k_2^0} \neq$$

the following expression can be obtained:

$$[3] \quad \log f_{\neq}^* + \log (K_a/k_2^0) = \log a_{H^+}^* + \log f_{MeOH} - \log k_{obsd} + \log [MeOH]/[MeOH]_{tot}$$

where $f_{\neq}^*$ is the activity coefficient of the transition state relative to the tetraethylammonium ion,[2] $a_{H^+}^*$ is the activity of the proton relative to the same ion, K_a is the dissociation constant of $MeOH_2$, k_2^0 is the rate constant for the second step, k_{obsd} is the observed first-order rate constant for exchange, and other terms are as described previously. As before (7), the water molecule which is present in the second step is not explicitly included in this expression, but is considered as part of $f_{\neq}^*$. The procedure to determine log $f_{\neq}^*$ is to plot the quantity on the right hand side of eq. [3] as a function of acidity, and extrapolate to zero acid concentration where log $f_{\neq}^* = 0$ to determine the constant log (K_a/k_2^0).

[1]We did in fact notice that in solutions more concentrated than 80% H_2SO_4 a second signal appears in the nmr spectrum of methanol, attributable to methyl hydrogen sulfate.

[2]Single ion activity coefficients cannot be measured directly. In the case of acid solutions the standard practice has been to refer these to the same standard ion, the tetraethylammonium ion (12), so that for various cationic species values are *relatively* correct.

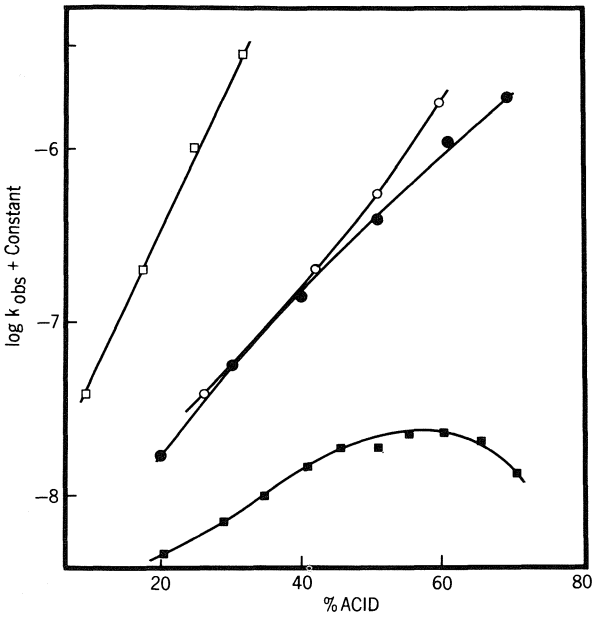

FIG. 2. Observed first-order rate constants in acid solutions. (○) MeOH exchange in perchloric acid at 67.2°C. (●) MeOH exchange in sulfuric acid at 67.2°C. (□) *t*-BuOH exchange in H_2SO_4 at 25°C (14); constant equals −2. (■) Methyl acetate hydrolysis in H_2SO_4 at 25°C (4); constant equals −5.

The final term in eq. [3] is important when the substrate is partially protonated, and in effect corrects k_{obsd} for that fact. What we would like to point out is that it is not necessary to apply this correction. From eq. [2]

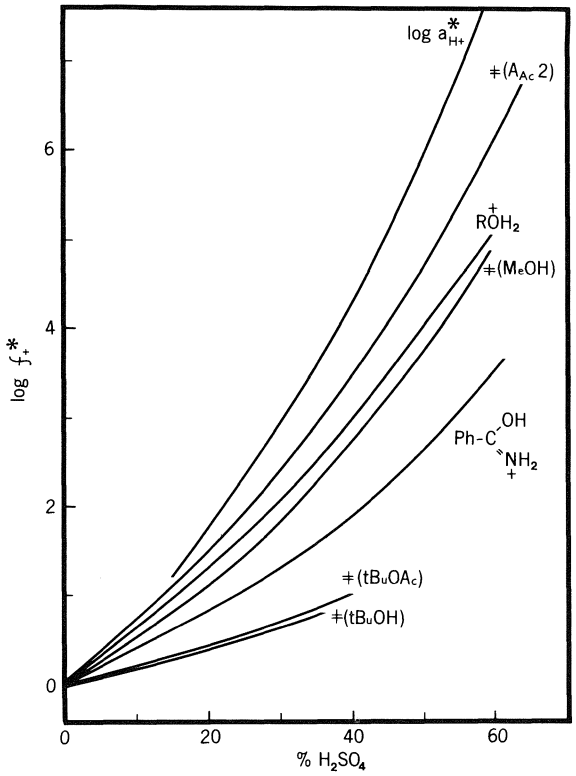
$$\log f_{MeOH} = \log f_s - \log [MeOH]/[MeOH]_{tot}$$

so that substituting in eq. [3] the protonation corrections cancel, giving

$$[4] \quad \log f_{\neq}^* + \log (K_a/k_2^0) = \log a_{H^+}^* + \log f_s - \log k_{obsd}$$

It is therefore equally as valid to use the measured f_s values based on total substrate concentration in the acid solution, and k_{obsd} values, with no correction in either for partial protonation. In fact the actual extent of protonation is irrelevant, and knowledge of this is not necessary to determine $\log f_{\neq}^*$.

Values of $\log f_{\neq}^*$ for methanol oxygen exchange based on eq. [4] and rate constants and activity coefficients determined in this work are plotted as a function of acid concentration in Fig. 3. Also plotted in this figure are activity coefficients for some related cations and transition states, including values of $\log f_{\neq}^*$ for *tert*-butanol oxygen exchange which we have calculated using literature rate (k_{obsd}) (14) and activity coefficient (f_s) (12) data.



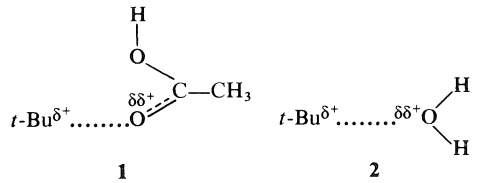


FIG. 3. Activity coefficients relative to the tetraethylammonium ion for cationic molecules and transition states. Values of log $a_{H^+}^*$ from ref. 17; ≠(A_{Ac}2), (7, 16*a*); ROH_2^+, (7); $PhC(OH)NH_2^+$, (12); ≠ (*t*-BuOAc), (7).

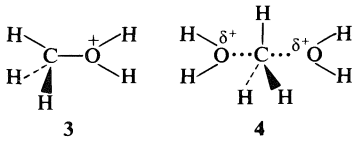
Values of ≠(A_{Ac}2) represent the normal bimolecular acid-catalyzed hydrolysis reactions of both esters and amides, for which there appears to be little difference in the behavior of $f_{\neq}^*$ (16*a*).



Values for ≠(*t*BuOAc) represent an $A_{Al}1$ hydrolysis reaction proceeding via the *tert*-butyl cation (7). One can note the very close similarity in the $f_{\neq}^*$ values for this latter reaction with the $f_{\neq}^*$ values for *tert*-butanol exchange. This exchange reaction has also been proposed to proceed via a *tert*-butyl carbonium ion (1), and its transition state is therefore very similar to that of the *t*-BuOAc hydrolysis (see **1** and **2**).

1 **2**

The transition state for methanol exchange is considerably more salted-out, in line with a change to a bimolecular reaction, and the transition state **4**.

3 4

This oxonium ion-like transition state with its $O^{\delta+}$—H bonds has a much greater requirement for water of solvation than the carbonium ion-like transition states and is therefore more destabilized by the increase in acidity and concomitant lower water activity. An interesting comparison involves the $f_{\neq}$* values for the methanol exchange reaction with the activity coefficients of the protonated alcohol itself. These show a similar variation, with the transition state being slightly less salted-out by increased acidity. The protonated alcohol has a highly localized charge and two hydrogens of the type O^{+}—H capable of strong hydrogen bonding to solvent water molecules. The transition state has four such hydrogens, but the positive charge is now more dispersed, being shared by two oxygen atoms. We propose therefore, and the activity coefficients support this, that the protonated methanol molecule with a full positive charge on one oxygen is more solvated by water molecules than the transition state with two partially charged oxygen atoms (although the difference is not very great).

This behavior can be contrasted with that of the $A_{Ac}2$ hydrolysis reactions, where a large increase in the value of f* is observed as the protonated substrate proceeds to the transition state. The characteristic large salting-out of the $A_{Ac}2$ transition state has been commented on previously (7), being explained in terms of an oxonium ion-like transition state **6** closely resembling the tetrahedral intermediate, with charge localized on an electron deficient oxygen atom which contains two strongly acidic protons which require solvent hydrogen bonding stabilization. The protonated ester or amide **5** has its positive charge delocalized over

X = OR, NR_2

5 6

several atoms, and is salted-out considerably less. The greater salting-out of the $A_{Ac}2$ transition state as compared to the exchange transition state is in fact one reason why rate constants for the exchange increase more rapidly with increasing acidity when compared to rate constants for the hydrolysis (Fig. 2).

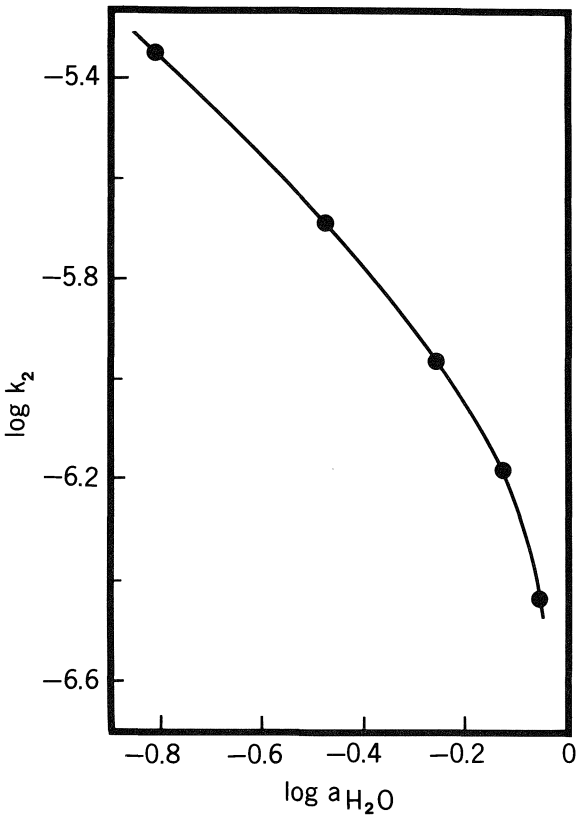

FIG. 4. "r" Hydration plot for methanol exchange in sulfuric acid solutions. Log k_2 = log k_{obsd} − log ($h_0^m/h_0^m + K'_{SH^+}{}^m$) where m = 0.22 and p$K'_{SH^+}$ = −6.88 (13).

The difference in the two types of reactions also shows up in a comparison of "r" hydration plots (4). This treatment plots log k_2 = log k_{obsd} − log {[SH^+]/([S] + [SH^+])} vs. log a_{H_2O}, and predicts that the slope of this plot (r) is equal to the number of water molecules in the transition state. For both ester and amide $A_{Ac}2$ hydrolysis, such plots produce positive "r" values, consistent with the presence of water molecules in the reaction with the protonated ester. The "r" plot (Fig. 4) for the methanol exchange reaction, using the literature protonation data (13), is significantly curved, *but* has a negative slope throughout. This is a somewhat surprising result since it implies that the methanol exchange reaction proceeds without the involvement of water. The explanation lies in the realization that what the "r" treatment actually represents is the variation in the difference in log $f_{\neq}$* and log f_{SH^+}* as a function of water activity. For most A2 reactions, such as the $A_{Ac}2$ hydrolyses,

this difference is positive and therefore the "r" value is positive. However for methanol exchange the difference is negative, and the apparently negative "r" value therefore results. In other words, the "r" value does not measure the number of water molecules, but rather a difference in activity coefficients.

Sulfur-bonded sulfoxide complexes of rhodium(III) and rhodium(I)

BRIAN R. JAMES AND ROBERT H. MORRIS

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received September 25, 1979

BRIAN R. JAMES and ROBERT H. MORRIS. Can. J. Chem. **58**, 399 (1980).

Aqueous 2-propanol solutions of $RhCl_3 \cdot 3H_2O$ on treatment with sulfoxides yield *mer*-$RhCl_3L_3$ complexes, the sulfoxide L being dimethyl (DMSO), tetramethylene (TMSO), methyl phenyl (MPSO), or (*R*)-methyl-*p*-tolyl (MPTSO); with diphenyl sulfoxide (DPSO), a $[RhCl(DPSO)_2]_2$ complex with S-bonded sulfoxide is obtained via the propanol reduction of a Rh(III) intermediate. The *mer*-rhodium(III) complexes in solution contain two sulfur-bonded sulfoxides (R_2SO), and one oxygen-bonded sulfoxide (R_2SO) that is *trans* to a (R_2SO) ligand. The DMS*O* ligand in *mer*-$RhCl_3(DMSO)_2(DMSO)$ is displaced by amides, amine oxides, and phosphine oxides; the DM*SO cis* to the oxygen-bonded ligands is identified in nmr by using the ring current shielding effects of $OPPh_2Me$. Salts of $[RhCl_4(R_2SO)_2]^-$ have been obtained with *n*-propyl sulfoxide and DMSO using several cations, including the symmetrically hydrogen-bridged species, $[R_2SO—H—OSR_2]^+$. The cyclooctene precursor $[RhCl(C_8H_{14})_2]_2$ has been used to synthesize $[RhCl(DPSO)(C_8H_{14})]_2$, $[RhCl(DMSO)_2]_2$, and $[RhCl(DIOS)_2]_2$, where DIOS is (2*R*,3*R*)-2,3-isopropylidene-2,3-dihydroxy-1,4-bis(methylsulfinyl)butane. The nature of rhodium–sulfur bonding is discussed, especially in terms of a contribution of metal–sulfur π-backbonding.

BRIAN R. JAMES et ROBERT H. MORRIS. Can. J. Chem. **58**, 399 (1980).

Lorsqu'on traite des solutions de $RhCl_3 \cdot 3H_2O$ avec des sulfoxydes dans le propanol-2 aqueux on obtient des complexes du type *mer*-$RhCl_3L_3$ où le groupe L est le sulfoxyde dérivant des radicaux suivants: diméthyle (DMSO), tétraméthylène (TMSO), méthylphényle (MPSO) ou (*R*)-méthyl-*p*-tolyle (MPTSO). On obtient avec le diphénylsulfoxyde (DPSO) un complexe $[RhCl(DPSO)_2]_2$ où le sulfoxyde est lié par le soufre, et qui résulte de la réduction par le propanol d'un intermédiaire Rh(III). Les complexes *mer*-rhodium(III) en solution contiennent deux sulfoxydes liés par l'atome de soufre (R_2SO) et un autre lié par l'atome d'oxygène (R_2SO) qui est en position *trans* par rapport au ligand (R_2SO). Les amides, les oxydes d'amines et les oxydes de phosphines déplacent le ligand DMS*O* du complexe *mer*-$RhCl_3(DMSO)_2$ (DM*SO*). On a identifié par la rmn le DM*SO* en position *cis* par rapport aux ligands liés par l'oxygène en utilisant les effets de blindage du courant de cycle du $OPPh_2Me$. On a obtenu les sels du type $[RhCl_4(R_2SO)_2]_2^-$ dérivés du *n*-propylsulfoxyde et du DMSO en utilisant plusieurs cations incluant les espèces liés symétriquement par un pont hydrogène: $[R_2SO—H—OSR_2]^+$. On a utilisé un précurseur cyclooctène $[RhCl(C_8H_{14})_2]_2$ pour synthétiser les complexes suivants: $[RhCl(DPSO)(C_8H_{14})]_2$, $[RhCl(DMSO)_2]_2$ et $[RhCl(DIOS)_2]_2$ où le groupe DIOS représente: (2*R*,3*R*) isopropylidène-2,3 dihydroxy-2,3 bis(méthylsulfinyl)-1,4 butane. On discute de la nature de la liaison Rh—S spécialement en fonction d'une contribution de retour π de la liaison métal–soufre.

[Traduit par le journal]

Introduction

Studies reported from this laboratory have described the successful use of ruthenium(II) complexes containing chiral sulfoxide ligands (L) as homogeneous catalysts for the asymmetric hydrogenation of some olefins (1–3). Some rhodium(I) complexes of the type Rh(diene)-$(PPh_3)(L)^+$, in which the chiral sulfoxide was oxygen-bonded (4), were found to be ineffective because of the relatively labile nature of the sulfoxide ligand in solution (1, 5). Anticipating that sulfur-bonded sulfoxides would be less labile (6), especially if metal $d_\pi \rightarrow$ sulfur d_π backbonding were significant (7, 8), we have synthesized several chlororhodium complexes containing such sulfoxides. We report here on an improved route to $RhCl_3(sulfoxide)_3$ complexes (9, 10), as well as on the preparation and characterization of other new Rh(III) and Rh(I) sulfoxide complexes.

Experimental

Synthetic procedures and solution measurements involving Rh(I) complexes were conducted under an argon atmosphere. All the Rh(I)–DMSO adducts were mulled in a glove bag under dry Ar. 2-Propanol with 0.1% water was used as supplied by Fisher Chem. Co. The phosphine oxides ($OPPh_2Me$, $OPPhMe_2$, $OPPhEt_2$) were prepared by oxidizing the phosphines in a slight excess of hot, dilute H_2O_2, and then extracting the product into $CHCl_3$, drying over $MgSO_4$, removing the solvent, and recrystallizing from EtOH. The sources of the sulfoxide ligands have been noted elsewhere (1, 4). Rhodium(III) trichloride trihydrate was obtained from Johnson Matthey Limited. The rhodium(I) complexes $[RhCl(cyclooctene)_2]_2$ and $[RhCl(C_2H_4)_2]_2$ were prepared according to literature procedures (11, 12).

Infrared data refer to Nujol mulls unless otherwise stated. Proton nmr data given to 3 decimals were acquired on a University-made 270 MHz spectrometer consisting of an Oxford Instruments superconducting magnet interfaced to a Nicolet 1080 computer. Other instruments used have been described previously (4). Microanalyses were performed by Mr. P. Borda of this department.

Preparation of the Complexes

$RhCl_3L_3$; L = DMSO, DMSO-d_6, TMSO, MPSO, R-*MPTSO*[1]

$RhCl_3 \cdot 3H_2O$ (0.2 g, 0.76 mmol) was dissolved and stirred for

[1]Sulfoxide abbreviations used are DMSO = dimethyl-, TMSO = tetramethylene-, MPSO = methyl phenyl(racemic)-, *R*-MPTSO = (*R*)-methyl *p*-tolyl-, DPSO = diphenyl-, NPSO = di-*n*-propyl-, DMSO and DMS*O*, for example, imply S- and O-bonded ligands, respectively. DIOS = (2*R*,3*R*)-2,3-*O*-isopropylidene-2,3-dihydroxy-1,4-bis)methyl sulfinyl)butane monohydrate (see ref. 2).

[a]Defined as ν(SO), coordinated sulfoxide − ν(SO), free sulfoxide; data under Ar is used for the Rh(I) systems.
[b]Mixture of isomers (see text).
[c]Measured in Nujol since complex insoluble in CH_2Cl_2.
[d]In CH_2Cl_2 rearrangement to $RhCl_3(NPSO)_2(NPSO)$ occurs (see text).
[e]ν(SO) of free sulfoxide.

30 min in 3 mL 2-propanol and 0.6 mL H_2O. On addition of L (2.3 mmol), the solution turned from red to yellow within 1 h. Brown suspensions sometimes formed intitially, but with stirring these were converted to suspensions of yellow product. Solutions for the L = DMSO, DMSO-d_6, and TMSO systems, sometimes remained clear, and deposited orange crystals (yield, 80–95%) on standing overnight. The L = MPSO and MPTSO systems yielded fine yellow powders on stirring for 18 h (90% yield). The products were filtered, washed with 2-propanol and ether, and dried *in vacuo*. All the complexes can be recrystallized from CH_2Cl_2 by addition of ether; the *R*-MPTSO adduct is obtained as feathery yellow crystals incorporating 0.5 mol CH_2Cl_2. The $RhCl_3(DMSO)_3$ compound can also be prepared by heating 0.2 g of $RhCl_3 \cdot 3H_2O$ in 1.0 mL DMSO at 70°C for 4 h, and then adding 100% EtOH until the microcrystalline solid precipitates. Table 1 lists some solution ir data for the compounds.

C_5H_5NO Complex. Anal. calcd. for $RhC_9H_{17}Cl_3O_3S_2N$: C 23.46, H 3.69, N 3.04; found: C 23.60, H 3.80, N 3.00. Nmr($CDCl_3$): 9.00 (m, 2, *ortho*), 7.85–7.50 (m, 3, *meta*, *para*), 3.57 (s, 6, *S*—CH_3), 3.51 (s, 6, *S*—CH_3).

$RhCl_3(DPSO)_2(^iPrOH)$

$RhCl_3 \cdot 3H_2O$ (0.050 g, 0.19 mmol) was dissolved and stirred in 1 mL dried 2-propanol for 30 min. The brown–orange product precipitated soon after the addition of 0.14 g (0.57 mmol) of DPSO. The suspension was stirred for 4 h, filtered, washed with 2-propanol and ether, and dried *in vacuo* (70%). *Anal.* calcd. for $RhC_{27}H_{28}Cl_3O_3S_2$: C 48.12, H 2.99; found: C 47.99, H 3.26. Nmr($CDCl_3$): δ 8.2–7.4 (m, 20, phenyl); 4.05 (m, 0.5, methine), 2.3–1.9 (broad singlet, 3, CH_3), 1.22 (d, 3, CH_3). Ir: ν(OH) 3400w; ν(SO) 1147m, 936s; ν(Rh—Cl) 350s.

$[(NPSO)_2H][RhCl_4(NPSO)_2]$

(*a*) $RhCl_3 \cdot 3H_2O$ (0.16 g, 0.72 mmol) was dissolved and stirred in 2 mL degassed 2-propanol for 30 min. The solution lightened to red–orange when 0.29 mL NPSO (2.5 mmol) was added. After 1 day the volume was reduced to 1 mL under vacuum; addition of 3 mL degassed hexane precipitated an orange microcrystalline solid that was filtered, washed with hexane, and dried *in vacuo*. Use of $CHCl_3$/hexane allowed recrystallization. Yield, 40%. *Anal.* calcd. for $RhC_{24}H_{57}Cl_4O_4S_4$: C 36.82, H 7.28; found: C 36.67, H 7.24. Nmr($CDCl_3$): δ 4.3–3.3 (m, 8,

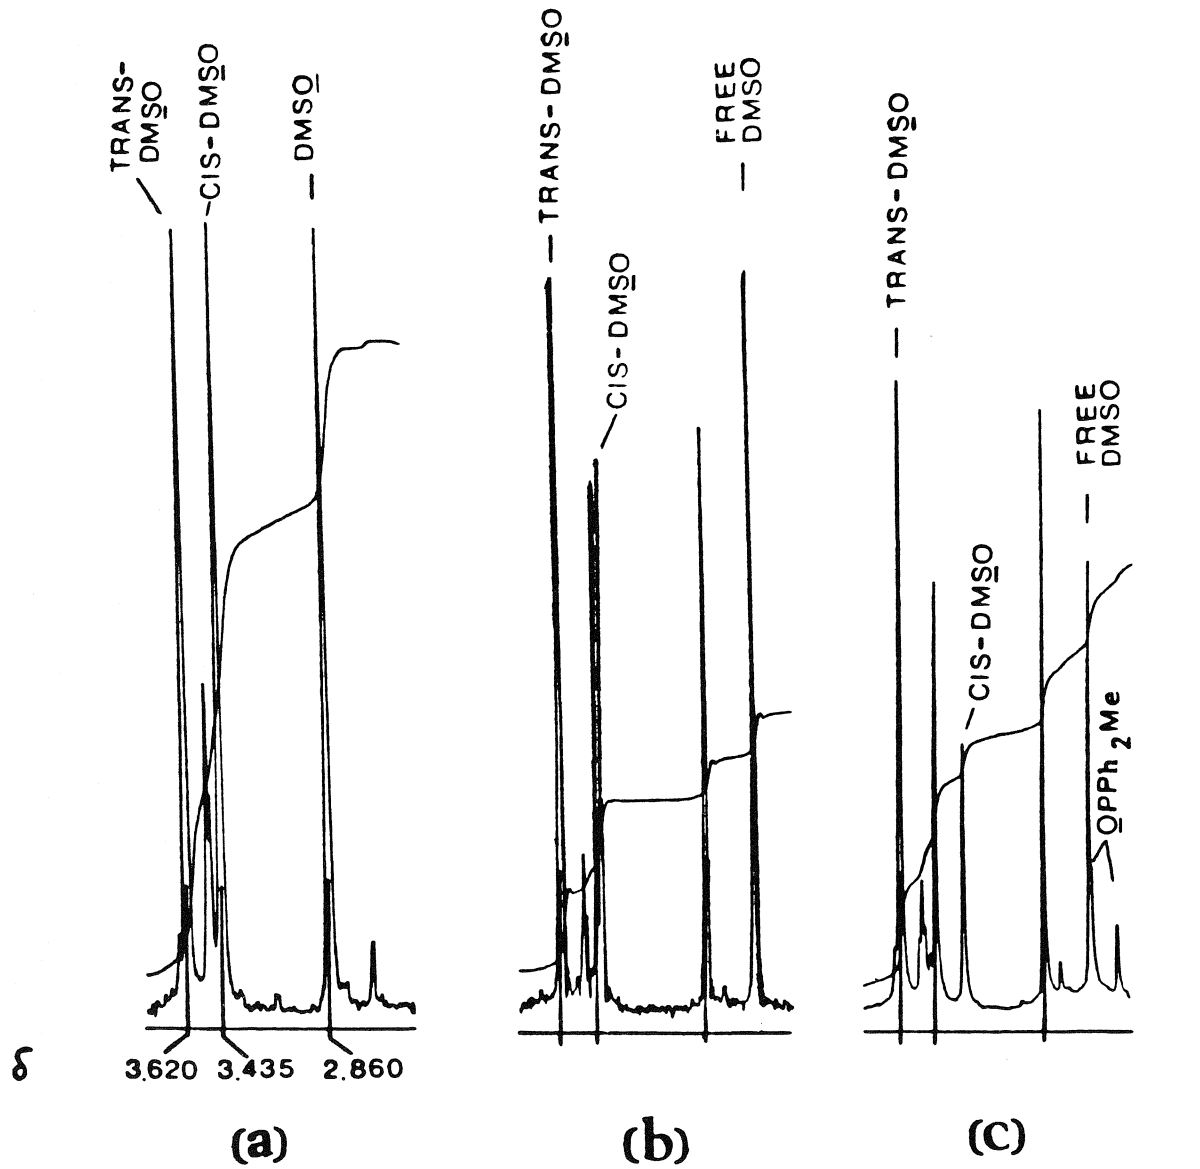

FIG. 1. 100 MHz ^{1}H nmr (δ 3.8–2.3 region) in $CDCl_3$ at 20°C of (*a*) $RhCl_3(DMSO)_3$, (*b*) $RhCl_3(DMSO)_3$ + 2 $OPPhMe_2$, and (*c*) $RhCl_3(DMSO)_3$ + 4.5 $OPPh_2Me$. The scale markings correspond to the peaks of $RhCl_3(DMSO)_2(DMSO)$ at δ 3.620, 3.435, and 2.860. The DMSO *cis* to O=L in the $RhCl_3(DMSO)_2(O{=}L)$ complexes in (*b*) and (*c*) (reaction [1]) are magnetically shielded by the phenyls of O=L.

S—C—H), 3.1–3.0 (m, 8, *O*—S—C—H + free O—S—C—H), 1.88 (m, 16, S—C—C—H), 1.1 (m, 24, S—C—C—C—H). Ir: ν(SO) 1122s; ν(S—O—H—O—S) 1600–1100 mb, 880–600 sb; ν(Rh—Cl) 350 m, 337s.

(*b*) A solution of $RhCl_3 \cdot 3H_2O$ (0.1 g, 0.38 mmol) in 0.15 mL concentrated HCl at 70°C was cooled to 25°C before 0.75 mL (5 mmol) of NPSO were added. The orange crystals that formed over 5 h were filtered, washed with a little 2-propanol, air-dried, and recrystallized as above. Yield, 65%. Spectral data agree with those given above in (*a*).

[H(DMSO)$_2$][RhCl$_4$(DMSO)$_2$]

A literature method (13) was used to prepare the compound as orange-red crystals. Nmr(D_2O): δ 3.56 (s, 4.2, *trans*-[$RhCl_4$(DMSO)(D_2O)]$^-$), 3.50 (s, 4.0, *trans*-[$RhCl_4(DMSO)_2]^-$), 2.70 (s, broad, 16, free DMSO). Ir: ν(SO) 1125; ν(S—O—H—O—S) 1600–1100 mb, 900–600 sb; $\rho_r(CH_3)$ 1020s, 972m; ν(Rh—Cl) 350s, 336s.

[NEt$_4$][RhCl$_4$(DMSO)$_2$]

After $RhCl_3(DMSO)_3$ (0.067 g, 0.15 mmol) and NEt_4Cl (0.025 g, 0.15 mmol) were warmed at 40°C for 30 min in CH_2Cl_2, solvent was pumped off until an orange precipitate formed. The mixture was cooled to 0°C and then filtered. Recrystallization from hot CH_2Cl_2/ether yielded a microcrystalline solid. Yield, 70%. *Anal.* calcd. for $RhC_{12}H_{32}Cl_4NO_2S_2$: C 27.13, H 6.07, N

[a]In $CDCl_3$ at 20°C using the peaks of $RhCl_3(DMSO)_3$ as an internal standard. Frequency shifts from these peaks to corresponding peaks of $RhCl_3(DMSO)_2(OL)$ are given in parentheses. All spectra contain "impurity" peaks at δ 3.503 and 3.492, possibly due to *mer*-$RhCl_3(DMSO)_3$ (see Fig. 1).
[b]K_1 is calculated from one spectrum and is accurate to ±50%.

2.63; found: C 27.25, H 6.0, N 2.50. Nmr(D_2O): δ 3.54 (s, 6, *S*—CH_3); 2.67 (s, 6, free DMSO); 3.19 (q, 8, N—CH), 1.25 (t, 12, N—C—CH). Nmr(CD_2Cl_2): 3.43 (s, 12, *S*—CH_3); 3.26 (q, 8, N—CH), 1.31 (t, 12, N—C—CH). Ir: ν(SO) 1140s; $\rho_r(CH_3)$ 1017m, 979m, 935m; ν(Rh—Cl) 345m, 335s.

[PS·H][$RhCl_4$(DMSO)$_2$]; PS = "Proton Sponge", 1,8-Bis(dimethylamino)naphthalene

[$H(DMSO)_2$][$RhCl_4(DMSO)_2$] (29 mg) was dissolved in 5 mL CH_2Cl_2 by adding 11 mg proton sponge. The orange–pink precipitate that formed when the solvent was gradually removed *in vacuo* was filtered, washed with ether, and air-dried. *Anal.* calcd. for $RhC_{18}H_{31}Cl_4N_2O_2S_2$: C 35.07, H 5.07, N 4.54; found: C 35.13, H 4.96, N 4.52. Nmr(D_2O): δ 7.9 (m, 6, aromatic H); 3.14 (s, 12, N—CH_3); 3.57 (s, 6, *S*—CH_3), 2.70 (s, 6, free DMSO). Nmr(CD_2Cl_2): 8.0–7.5 (m, 6, aromatic H); 3.29 (d, J = 2 Hz, 12, N—CH_3); 3.47 (s, 12, *S*—CH_3).

[RhCl(DPSO)$_2$]$_2$

To the red solution, obtained by stirring $RhCl_3 \cdot 3H_2O$ (0.1 g, 0.38 mmol) in degassed 2-propanol (1.5 mL) and H_2O (0.4 mL) for 30 min, was added DPSO (0.27 g, 1.3 mmol). The resulting solution deposited red crystals after standing from 8 to 24 h. The product was filtered under Ar, washed with degassed 2-propanol, and dried *in vacuo*. Yield, 65%. An attempt at recrystallization from degassed CH_2Cl_2/ether yielded brown, partially oxidized product. *Anal.* calcd. for $RhC_{24}H_{20}ClO_2S_2$: C 53.09, H 3.71, Cl 6.53; found: C 52.98, H 3.83, Cl 7.32. Ir: ν(SO) 1101s; ν(phenyl) 1068s; ν(Rh—Cl) < 250.

[RhCl(DPSO)(cyclooctene)]$_2$

(*a*) [RhCl(cyclooctene)$_2$]$_2$ (0.1 g, 0.14 mmol) was added to a degassed solution of DPSO (1.2 g, 6 mmol) in 3 mL CH_2Cl_2. After 8 mL of dry EtOH were added, the solution was warmed to 35°C, and concentrated by evacuation until a yellow powder formed. The air-sensitive microcrystalline solid obtained by cooling the mixture at −10°C was filtered under Ar, washed with dry EtOH, and dried *in vacuo*. *Anal.* calcd. for $RhC_{20}H_{24}ClOS$: C 53.28, H 5.26; found: C 52.97, H 5.26. Nmr($CDCl_3$): δ 7.8–7.2 (m, 20, phenyl); 3.9 (m, 4, olefinic H), 2.00 (m, 8, C=C—CH), 1.40 (m, 16, C=C—C—CH). Ir: ν(SO) 1109s; ν(phenyl) 1062s; ν(C_8H_{14}) 1180m, 1137m, 1128m, 960m, 922m, and others; ν(Rh—Cl) < 250.

(*b*) [RhCl(DPSO)$_2$]$_2$ (57 mg) was added to 14 μL *cis*-cyclooctene in 0.5 mL degassed CH_2Cl_2. Degassed EtOH (0.8 mL) was added and procedure (*a*) was followed. An orange oil first formed but soon crystallized yielding [RhCl(DPSO)-(C_8H_{14})]$_2$.

Other Olefin/Sulfoxide Complexes

The complex [RhCl(TMSO)(C_8H_{14})]$_2$ was likely prepared via procedure (*a*) above, but was too air-sensitive to obtain a good analysis. Ir: ν(SO) 1118s; ν(C_8H_{14}) 1175m, 1135m, etc.

Procedure (*a*), but using [RhCl(C_2H_4)$_2$]$_2$ and DPSO, gave an air-sensitive compound containing coordinated C_2H_4 (ir: 1217s, 997s) and DPSO (ν(SO) 1113s), but a good analysis was not obtained.

[RhCl(DMSO)$_2$]$_2$ and the Deuterated Derivative

To a degassed solution of excess sulfoxide (1.5 mL) in 5 mL of CH_2Cl_2 was added 0.25 g [RhCl(cyclooctene)$_2$]$_2$. After filtration under Ar, the solution was concentrated to 1.5 mL; 10 mL dry EtOH was added followed by 4 mL dry ether, and the resulting degassed solution was cooled to −10°C. The very hygroscopic and air-sensitive orange crystals were filtered and washed with dry ether under Ar; the nondeuterated complex is obtained with a solvate DMSO molecule, ν(SO) 1020s. *Anal.* calcd. for $RhC_4H_{12}ClO_2S_2 \cdot C_2H_6SO$: C 17.98, H 4.49; found: C 18.04, H 4.44. Nmr($CDCl_3$): δ 2.8 (s, broad, DMSO). Ir: ν(SO) 1101s; $\rho_r(CH_3)$ 1020s, 1007s, 972s, 937w; ν(Rh—Cl) < 250.

[RhCl(DMSO-d_6)$_2$]$_2$ was prepared similarly using DMSO-d_6. *Anal.* calcd. for $RhC_4D_{12}ClO_2S_2$: C 15.67, D 3.91; found: C 15.34, D 4.00. Ir: ν(SO) 1109s, 1099s, 1089s; $\delta_s(CD_3)$ 1022m,

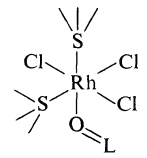
1008m; $\rho_r(CD_3)$ 820s, 767m; ν(Rh—Cl) <250 (the yellow mull turned black within 3 min on exposure to air).

[RhCl(DIOS)$_2$]$_2$

A degassed solution of DIOS (0.25 g, 0.92 mmol) in 5 mL CH_2Cl_2 was added to [RhCl(cyclooctene)$_2$]$_2$ (0.1 g, 0.14 mmol) under Ar. Solvent was removed under vacuum to yield a red–brown oil. After being washed with degassed ether (3 × 10 mL), the resulting light brown powder was taken up in 1 mL CH_2Cl_2 and reprecipitated by slowly adding ether. The product was filtered, and dried *in vacuo*. Yield, 90%. *Anal.* calcd. for $RhC_{18}H_{36}ClO_8S_4 \cdot H_2O$: C 31.63, H 5.85; found: C 31.76, H 5.70. Nmr($CDCl_3$): δ 4.6–4.0 (m, 4, methine); 3.9–3.2 (m, 6, *S*—CH_3 + *S*—CH_2); 3.0 (s, broad, 6, free S—CH_2); 2.65 (s, broad, 8, free S—CH_3); 1.45 (s, 12, O—C—CH_3). Ir: ν(OH) 3600–3200 mb; ν(*S*O), ν(SO), + $\rho_r(CH_3)$ 1150–1000 sb; $\rho_r(CH_3)$ 980–950sb, 890m; ν(Rh—Cl) <250.

Results and Discussion



Infrared and ^{1}H nmr spectroscopy have been widely used to distinguish between oxygen- and sulfur-bonded sulfoxide ligands (4 and references therein). On comparison with the free ligand, donation via oxygen causes a shift of ν(SO) to a lower range (1000–900 cm^{-1}), while S-bonding generally causes an increase of ν(SO) to above 1100 cm^{-1}; however, assignments of ν(SO) for O-bonded sulfoxides with α-methyl groups (DMSO and MPTSO in the present studies) are complicated by methyl rocking vibrations which appear at similar energies, and comparison with a deuterated analogue is often helpful. Downfield nmr shifts of protons in O-bonded complexes are usually small and close to the free values, while with S-bonded systems the α-protons are closer to the metal and experience shifts of up to 1 ppm.

All the complexes reported in this paper contain some S-bonded sulfoxides.

Neutral Rh(III) Complexes

A convenient preparation of $RhCl_3L_3$ complexes (L = DMSO, DMSO-d_6, TMSO, MPSO, and *R*–MPTSO) was discovered during attempts to generate Rh(I) complexes from $RhCl_3 \cdot 3H_2O$ and sulfoxides by using 2-propanol as the solvent and reductant (see below). The Rh(III) complexes are obtained in high yields (80–95%) simply by collecting after 1 day the yellow precipitate resulting from the addition of 3 equivalents of sulfoxide to one of $RhCl_3 \cdot 3H_2O$, predissolved for at least 15 min in 2-propanol containing 20% V/V water. The brown compounds that sometimes precipitated initially were found by ir to contain water or 2-propanol, but on stirring over several hours these intermediates were converted to $RhCl_3L_3$. Crystalline samples for L = DMSO, DMSO-d_6, and TMSO, were sometimes deposited on leaving the systems to stand.

The $RhCl_3L_3$ complexes (L = DMSO, DMSO-d_6, TMSO, and diethylsulfoxide) have been prepared previously from hot aqueous solutions of $Na_3[RhCl_6]$ (9). For L = DMSO, crystallographic (10) and ir analysis (14) show that in the solid state the isomer present is *mer*-$RhCl_3(DMSO)_2(DMSO)$ (see **1**), but solution spectra were not examined. When crystals of $RhCl_3(DMSO)_3$, prepared from 2-propanol, water, or DMSO media, are dissolved in $CHCl_3$ or CH_2Cl_2, the ir spectra show a broad ν(*S*O) band and a ν(S*O*) band (Table 1). The nmr spectrum (Table 2; Fig. 1*a*), however, displays more than the two DM*S*O methyl resonances expected for a *mer*-$RhCl_3(DMSO)_2(DMSO)$ species. Selective replacement of the O-bonded DMSO ligand by other oxygen donors (O = L) in solution occurs with the retention of *mer* stereochemistry in all cases (**1**, see below) and allows the assignment of the prominent nmr peaks of $RhCl_3(DMSO)_3$ in $CDCl_3$. The δ 3.620 resonance is attributed to DM*S*O *trans* to DMS*O*, the 3.435 signal to DM*S*O *trans* to Cl, and the 2.860 signal to DMS*O* (Table 2). A 5% impurity of *mer*-

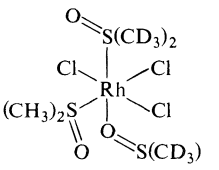
1

$RhCl_3(DMSO)_3$ could explain the smaller methyl resonances at δ 3.503 and 3.492 (intensity 2:1) observed in $CDCl_3$, and the corresponding degenerate single peak at δ 3.43 in CD_2Cl_2. This could also account for the observed DM*S*O/DMS*O* integration ratio of greater than 2:1, that is expected for *mer*-$RhCl_3(DMSO)_2(DMSO)$. The proportion of this "impurity" in solution increases slowly at 25°C over several days, along with a new species containing DMS*O* that resonates at δ 2.72. Attempts at separating the isomers by repeated recrystallizations from CH_2Cl_2/ether, or by thin layer chromatography on silica gel, failed. Analytical data, and the fact that added DMSO has no effect on the spectra, argue against the presence of chloride-bridged species. Since planes of symmetry of the molecule make the methyls of each DMSO equivalent, methyl inequivalence cannot account for the extra DM*S*O peaks (15). Autoionization to $[RhCl_2(DMSO)_4]^+[RhCl_4(DMSO)_2]^-$, similar to that observed for the analogous dimethyl sulfide complex (16), is also not consistent with the nmr data. A recent paper (17) that appeared after completion of the present work reports ^{1}H nmr and ^{1}H-{^{103}Rh} INDOR data on $[RhCl_{6-n}(DMSO)_n]^{n-3}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

species and also concludes that with $n = 3$, the major species in CH_2Cl_2 solution is *mer*-$RhCl_3(DMSO)_2(DMSO)$ with small amounts of *mer*-$RhCl_3(DMSO)_3$, interconversion being slow.

Table 2 presents nmr data for reaction [1] in $CDCl_3$ and rough estimates for the associated equilibria constants, K_1. All equilibria were shown to be established by warming the solutions at 40°C for 30 min. Addition of O=L has little influence on the peaks assigned to the *mer*-$RhCl_3(DMSO)_3$ impurity (see Fig. 1).



[1] *mer*-$RhCl_3(DMSO)_2(DMSO)$ + O=L

$$\overset{K_1}{\rightleftharpoons} \textit{mer}\text{-}RhCl_3(DMSO)_2(O{=}L) + DMSO$$

The nmr spectra of the isolated compounds, *mer*-$RhCl_3(DMSO)_2(O{=}L)$, where O=L is DMF, F·pip, and C_5H_5NO, show only the expected two equally intense, DMSO methyl resonances. A 30-fold excess of each of the weaker donors, DMA and $OPPh_2Me$, refluxed with $RhCl_3(DMSO)_3$ in 1,2-$C_2H_4Cl_2$ yields mixtures of the tris-DMSO and the desired bis-DMSO complexes. No reaction was observed with large excesses of $OPPh_3$, O_2SMe_2, and $OP(OEt)_3$. In all the studies of reaction [1], the ratio of methyl peak integrations for the S-bonded DMSO to the O-bonded DMSO plus free DMSO was 2.0. Strong donors such as PPh_3, pyridine, piperidine, and NEt_3, as well as greater than 1:1 excesses with respect to Rh of $OP(^nBu)_3$, C_5H_5NO, and NPSO, displace some DMSO as well as DMSO from $RhCl_3(DMSO)_3$.

In general, the O=L ligands cause greater shifts in the *cis*-DMSO resonances than in the *trans*. The diamagnetic shielding of the *cis*-DMSO methyl group by the phenyls of coordinated $OPPh_2Me$ is great enough to allow the unambiguous assignment of the upfield methyl peak to the *cis*-DMSO in the *mer*-$RhCl_3(DMSO)_2(O{=}L)$ complexes. The chemical shifts of the DMSO methyls *trans* to O=L might be explained by a *trans*-directed shielding of these methyl protons by the O=L ligand. Indeed the amount of shielding of these methyl protons, as judged by δ, correlates roughly with the oxygen donor strength of O=L (18–20): DMA < DMF < $OPPhMe_2$ ~ $OPPhEt_2$ ~ DMSO < $OPPh_2Me$ ~ NPSO < $OP(^nBu)_3$ < C_5H_5NO (see Table 2). By analogy, the downfield DMSO methyl peak of $IrCl_3(DMSO)_2(DMSO)$ (21) at δ 3.66 likely corresponds to DMSO *trans* to DMSO, and the other at 3.56, to DMSO *trans* to Cl. A similar technique, involving selective replacement of DMSO in the complex *trans*-$RuCl_2(DMSO)_3(DMSO)$ (22) by some O=L ligands, has been used (5) to explain the complex ^1H nmr spectrum of the tetrakis(dimethylsulfoxide) complex (15).

We have confirmed by nmr studies the earlier observation that the S-bonded ligands of $RhCl_3(DMSO)_3$ exchange at different rates (15), and can now state that it is the DMSO *trans* to DMSO that exchanges faster than the DMSO *trans* to Cl. Thus, after a solution of $RhCl_3(DMSO)_3$ (0.04 *M*) and DMSO-d_6 (0.4 *M*) in $CHCl_3$ is reacted at 35°C for 80 min, the yellow powder obtained on addition of ether contains 75% DMSO-d_6 *trans* to DMSO, <5% DMSO-d_6 *trans* to Cl, and 85% DMSO-d_6 (**2** shows the main product). Such labelled complexes could be useful in nmr studies of substitution reactions.

2

The ir (Table 1) and nmr data (see Experimental section) of the $RhCl_3L_3$ complexes with L = TMSO, MPSO, and *R*–MPTSO, are also consistent with two S- and one O-bonded ligands. The MPTSO complex shows just the two *S*-CH_3 ^1H nmr resonances expected for the *mer*-$RhCl_3(S$–MPTSO$)_2(R$–MPTSO$)$ structure.[2] The complex set of methyl peaks observed with the racemic MPSO ligand system must result from a mixture of "multistereoisomers", e.g. $RhCl_3(R$–MPSO$)_2(R$–MPSO$)$, $RhCl_3(S$–MPSO$)(R$–MPSO$)$-$(R$–MPSO$)$, etc. The detection of only two ν(Rh—Cl) for the L = TMSO, MPSO, and *R*-MPTSO complexes, is more consistent with a *fac* configuration, but in view of the nmr data for the *R*-MPTSO species, the *mer* formulation is favoured. The three metal–chloride bands are detected for the DMSO complex. Attempts at isolating $RhCl_3L_3$ complexes, or Rh(I) species (see below), with (*R*)-*t*-butyl-*p*-tolyl sulfoxide and (*S*)-*o*-tolyl-*p*-tolyl sulfoxide were unsuccessful, presumably because of steric problems, noted previously with Pt(II) centers (24). The $RhCl_3$-(sulfoxide)$_3$ complexes are useful starting materials for other complexes, for example, $RhCl_3$-$(DMSO)(py)_2$ which has anti-tumour properties (25).

Diphenylsulfoxide Complexes

On adding DPSO to $RhCl_3 \cdot 3H_2O$, predissolved in

[2] *R*–MPTSO becomes *S*–MPTSO when S-bonded to a metal.

wet 2-propanol (sulfoxide: Rh ~ 3), fairly air-stable, red crystals are deposited after 8–24 h, and these are formulated $[RhCl(DPSO)_2]_2$, ν(SO) indicating S-bonded sulfoxides (Table 1). The dimer formulation is consistent with the lack of a terminal ν(Rh—Cl), normally expected at >250 cm^{-1} (26), and the analytical data, since 3-coordinate Rh(I) is rare (27). The air-sensitivity of solutions of the complex (Table 1), and a stoichiometric reaction with cyclooctene in CH_2Cl_2 to give $[RhCl(DPSO)(C_8H_{14})]_2$ (see below), are consistent with a Rh(I) formulation. A brown product that precipitates out of an air-oxidized CH_2Cl_2 solution of the complex shows no ν(C—H) and is presumably some chlorooxide of Rh(III); free DPSO remains in solution.

Formation of $[RhCl(DPSO)_2]_2$ likely occurs according to reaction [2], as established for the cyclooctene dimer (11):

$$[2]\quad RhCl_3\cdot 3H_2O + 2L + (CH_3)_2CHOH \rightarrow \tfrac{1}{2}[RhClL]_2 + 3H_2O + 2HCl + (CH_3)_2CO$$

On using dry 2-propanol as solvent, we isolated a product analyzing correctly for $RhCl_3(DPSO)_2$(2-propanol), the ir (Table 1) showing the presence of both DP*S*O and DPS*O* (there could be one of each, or the compound could be a mixture of isomers). A broadening of the isopropyl methyl peaks in the nmr ($CDCl_3$) indicates exchange processes involving coordinated alcohol. The complex is likely an intermediate in reaction [2], since on suspension in 2-propanol/water under Ar, red crystals of $[RhCl(DPSO)_2]_2$ are deposited. The dehydrogenation of the alcohol is thought (28) to proceed via alkoxide formation and β-hydride elimination (reaction [3]):

$$[3]\quad Rh^{III}(^iPrOH) \xrightarrow[(a)]{-H^+} [Rh^{III}—O—\overset{\diagup}{C}H\overset{\diagdown}{}] \xrightarrow{-(CH_3)_2CO} HRh^{III} \xrightarrow[(b)]{-HCl} Rh^{I}$$

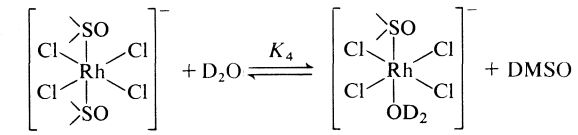
Water likely enhances elimination of H^+ (and Cl^-) in step (*a*) and the reductive elimination of HCl in step (*b*). Traces of a similar alcohol adduct containing only O-bonded sulfoxide were obtained using (*S*)-*o*-tolyl-*p*-tolyl sulfoxide, but the corresponding Rh(I) complex could not be isolated.

The milder conditions required for synthesis of the $RhCl_3L_3$ complexes in 2-propanol rather than water (9) may well result from a trace of Rh(I), generated by reaction [3], that is known to promote formation of Rh(III) species via a redox-catalyzed substitution process (29, 30).

Anionic Rhodium(III) Complexes

The $RhCl_3\cdot 3H_2O$/sulfoxide/wet 2-propanol reaction precipitated no neutral $RhCl_3L_3$ complex with L = NPSO, possibly because of solubilization by the alkyl chains. Addition of hexane, however, precipitated $[(NPSO)_2H][RhCl_4(NPSO)_2]$ in 40% yield. It is possible that some of the rhodium is converted by the alcohol to the univalent state, this reduction process (reaction [2]) furnishing the chloride required for the tetrachlororhodate(III) species. The complex is prepared in better yield in concentrated HCl media as initially described by Henbest and Trocha-Grimshaw (13) for the analogous $[(DMSO)_2H][RhCl_4(DMSO)_2]$ complex, although no spectral data were reported.

Both the NPSO and DMSO tetrachlororhodate(III) complexes have surprisingly intense and broad ir bands in the solid state at 1600–1100 and 900–600 cm^{-1} that are not due to the anion, as evidenced by the spectrum of the corresponding NEt_4^+ salt. Such bands can result from cations comprised of hydrogen-bonded bases (31), and a recent X-ray crystal structure of *trans*-$[(DMSO)_2H][RhCl_4(DMSO)_2]$ (32) has confirmed the existence of a proton bridge between the oxygen atoms of DMSO molecules in the cation $[(CH_3)_2SO—H—OS(CH_3)_2]^+$. The structure also confirms the S-bonded sulfoxides in the anion, as indicated by the nmr and ir (Experimental, Table 1, and ref. 17).



An approximate structure of the anion, as the sodium salt, has been reported by Sokol *et al.* (33). The *trans*-$RhCl_4L_2^-$ anions are readily formed via the $RhCl_3L_3$ complexes (L = DMSO, TMSO, MPSO) by treatment with NaCl in H_2O (14), or $[NEt_4]Cl$ in CH_2Cl_2 or H_2O. Other salts of the anions can be prepared from the $(R_2SO)_2H^+$ derivatives by adding strong bases, as reported previously (21) for $[(DMSO)_2H]$ $[IrCl_4(DMSO)_2]$, and we isolated in this way the protonated proton sponge[3] derivatives $[PS\cdot H][RhCl_4(R_2SO)_2]$ with DMSO (see Experimental section) and NPSO.

Spectroscopic observation of $(NPSO)_2H^+$ in CH_2Cl_2 or of $(DMSO)_2H^+$ in D_2O is not possible. The solution ir of the former suggests that HCl is eliminated when the tetrachlororhodate(III) salt is dissolved, since $RhCl_3(NPSO)_2(NPSO)$ appears to form (Table 1). The $(DMSO)_2H^+$ salt is insoluble in CH_2Cl_2, and in D_2O the DMSO of the cation appears in the nmr at the chemical shift for free DMSO.

[3]Proton sponge was chosen since we use this base to promote heterolytic cleavage of H_2 by Rh(III) complexes (to be published). For example, see ref. 23.

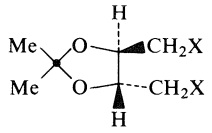
Dissolution of the NEt_4^+ or PS·H^+ salts of $RhCl_4(DMSO)_2^-$ in D_2O at 35°C gives complete formation of $RhCl_4(DMSO)(D_2O)^-$ within 30 s as evidenced by nmr (Experimental)

[4] 

δ3.50 δ3.56

Addition of DMSO moves equilibrium [4] to the left, and indeed when $[(DMSO)_2H][RhCl_4(DMSO)_2]$ is added to D_2O, both rhodate(III) species are detected due to the DMSO contributed by the cation. An nmr titration in the presence of added known amounts of DMSO yielded a K_4 value of $0.5 \pm 0.2\ M$ at 35°C. Reaction [4] illustrates the high kinetic *trans* effect of S-bonded sulfoxides (34). The monoaquated species is stable for weeks in aqueous solution at 20°C. The corresponding *trans*-$[IrCl_4(DMSO)_2]^-$ anions undergo aquation at a slower rate, $t_{1/2}$ being several minutes at 65°C (5).



Rhodium(I) Complexes from $[RhCl(olefin)_2]_2$ Precursors

The displacement of labile *cis*-cyclooctene or ethylene from the title Rh(I) dimers in CH_2Cl_2 by donor ligands provides convenient routes to $[RhClL_2]_2$ and $RhClL_3$ complexes, when L is a phosphine, arsine, etc., added at the required 2:1 or 3:1 ligand:metal ratios (35). However, even with a ten-fold excess of DPSO or TMSO per rhodium, only $[RhCl(C_8H_{14})L]_2$ complexes were isolated, L being the S-bonded ligand. Similar mixed olefin – chiral sulfoxide complexes of Pt(II) have been used to study the extent to which a Pt – chiral S moiety distinguishes between the prochiral faces of a coordinated olefin, which is important, for example, in considering catalytic asymmetric hydrogenation of the olefin (36). The $[RhCl(C_8H_{14})_2]_2$ precursor can be used to give complexes of the type $[RhCl(MPSO)(PPh_3)]_2$ (5).

Use of a large excess of sulfoxide with $[RhCl(C_8H_{14})_2]_2$ did lead to isolation of $[RhCl(DMSO)_2]_2$ and the DMSO-d_6 analogue. The complexes are extremely hygroscopic and air-sensitive in the solid state; on exposure to O_2, the ν(SO) at ~1100 cm^{-1} is rapidly replaced by one at 1140 cm^{-1} which must pertain to a higher oxidation state, Rh(II) or Rh(III). Formation of sulfone, $(CH_3)_2SO_2$, was not detected. In degassed water, the complexes rapidly disproportionate to Rh metal and a green filtrate likely containing Rh(II) (37, 38). Lack of a terminal ν(Rh—Cl) and the analytical data are again the criteria used for dimer formulation of the Rh(I) complexes.

The solution ir of $[RhCl(DMSO)_2]_2$ (Table 1) consists of peaks for S-bonded and free DMSO, but not O-bonded DMSO. The nmr spectrum in $CDCl_3$ is a single broad peak at δ2.80, a chemical shift intermediate between that of free and S-bonded ligand, showing that dissociation of DMSO is occurring rapidly on the nmr time scale. Such labile behaviour, not observed for *trans*-$PdCl_2(DMSO)_2$ (39), would in part account for the reactivity of the Rh(I) complex.

A complex, best formulated as $[RhCl(DIOS)_2]_2 \cdot 2H_2O$, was also prepared from the cyclooctene dimer. The ir and nmr data show S-bonded ligands are present, although they are clearly labile on the nmr time-scale. There is no good evidence for a O-bonded DIOS ligand, ν(SO) ~ 930 cm^{-1} (2) and the nmr shifts at δ 3.0, 2.65 are those of free ligand (either as such, or of a monodentate, "dangling" type). The lack of a terminal ν(Rh—Cl) indicates a chloride-bridged dimer, and we tentatively favour two monodentate S-bonded DIOS ligands completing the four-coordination. Such monodentate coordination has been realized with the analogous DIOP ligand (1).

X = $SOCH_3$ gives DIOS
X = PPh_2 gives DIOP

The Nature of Rhodium–Sulfur Bonding in Sulfoxide Complexes

Table 3 lists some spectroscopic and structural data for some S-bonded DMSO complexes. Considering the range of bonding modes illustrated in **I–III**, the S—O bond order likely increases from about 2 (that of free sulfoxide) in the Fe(II) and Ru(II) pentammine complexes to probably almost 3 for the Au(III) complex (7, 49); this seems reasonable in that in the low-spin d^6 systems metal $d_\pi \rightarrow$ sulfur d_π backbonding is optimized and competes successfully with backbonding from oxygen p_π (**I**), while the highly electronegative Au(III) has poor backbonding capacity (**III**). The other complexes listed, including those of Rh, lie in the intermediate range, presumably mainly of type **II** bonding with little metal–sulfur backbonding, although the two Rh(I) complexes have relatively small Δν(SO) values implying perhaps some type **I** contribution. The

[a] $\Delta\nu(SO) = \nu(SO) - 1055$ (free DMSO) in cm^{-1}. Data refer to Nujol mulls.
[b] The averaged S—O bond distance for DMSO in the molecule (Å).
[c] The average metal–sulfur distance in Å.
[d] $C_{15}H_{13}O$ is benzylacetophenone chelated to Ir by oxygen and benzyl carbon.

neutral Rh(III) complexes show $\nu(SO)$ at 20–40 cm^{-1} higher than similar Rh(I) adducts (and the same is true for DPSO and TMSO systems, see Table 1 and Experimental), and this could be rationalized in terms of either a small contribution of **I** in the Rh(I) systems or of **III** in the Rh(III) systems. *Ignoring metal–sulfur backbonding*, it is generally expected that a larger $\Delta\nu(SO)$ pertains to a stronger metal–S bond. There are insufficient structural data, but based on $\Delta\nu(SO)$, the metal–S bond strengths for the neutral d^8 systems decrease in the order Au(III) > Pt(II) ≈ Pd(II) > Rh(I), which would imply a relatively hard sulfur donor of sulfoxides (50). It is clearly difficult to estimate by spectroscopy the extent of metal–sulfur backbonding in the Rh(I) complexes. Chemical studies are likely to be more profitable: a greater resistance of $[RhCl(DPSO)_2]_2$ to disproportionate to metal (compared to $[RhCl(DMSO)_2]_2$) is strongly indicative of such backbonding, at least in the DPSO complex.

The relatively low $\Delta\nu(SO)$ value for the Rh(II) acetate complex probably results from the high *trans* influence of the metal–metal bond (51). Decreasing $\Delta\nu(SO)$ values on going from $RhClL_5^+$ (92–108 cm^{-1}), to $RhCl_3L_3$ (80–95 cm^{-1}) and $RhCl_4L_2^-$ (65–85 cm^{-1}) seem consistent with changes in the charges of the complexes.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support in terms of a research grant and a postgraduate scholarship (R.H.M.), and Johnson Matthey Ltd. for the loan of $RhCl_3 \cdot 3H_2O$. One of us (B.R.J.) wishes to thank Professor F. Calderazzo of the Instituto di Chimica Generale, Università di Pisa, for discussions and for the facilities and cooperation of the Institute during the writing of the paper.

Pyrrole chemistry. XXI. Synthetic approaches to cyanopyrroles

GRAHAM H. BARNETT, HUGH J. ANDERSON, AND CHARLES E. LOADER

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received October 2, 1979

GRAHAM H. BARNETT, HUGH J. ANDERSON, and CHARLES E. LOADER. Can. J. Chem. **58**, 409 (1980).

The Vilsmeier–Haack reaction with pyrrole and 1-methylpyrrole has been modified to provide a direct synthesis of the corresponding 2-nitriles. Chlorosulfonyl isocyanate may be used to prepare the same compounds, but less satisfactorily. The latter reagent does enable the synthesis of pyrrole-2,4-dicarbonitrile in one step. This dinitrile may be reduced to pyrrole-2,4-dicarboxaldehyde.

GRAHAM H. BARNETT, HUGH J. ANDERSON et CHARLES E. LOADER. Can. J. Chem. **58**, 409 (1980).

On a modifié la réaction de Vilsmeier–Haack appliquée aux pyrroles et le méthyl-1 pyrrole dans le but d'obtenir la synthèse directe des nitriles-2 correspondants. On peut utiliser l'isocyanate de chlorure de sulfonyle pour préparer les mêmes composés mais cette méthode donne de moins bons résultats. Le dernier réactif permet de réaliser la synthèse du pyrrole dicarbonitrile-2,4 en une seule étape. Ce dinitrile peut être réduit en pyrrole dicarboxaldéhyde-2,4.

[Traduit par le journal]

Recently we reported some further reactions of simple 2-cyanopyrroles (1). The synthetic usefulness of these compounds has caused us to investigate improved methods for the preparation of pyrrole-2-carbonitrile and its 1-methyl derivative. At present no direct synthesis from pyrrole gives the 2-nitrile in better than 50–60% yield (2) and, until recently, methods starting from the 2-aldehyde or 2-amide were no better (2*a*). The procedure of Streith *et al.* (3) appears to be the best conversion of 2-aldehyde to 2-nitrile reported so far. Taken together with the usual synthesis of the 2-aldehyde (4) it should give close to 70% of the 2-nitrile in two steps from pyrrole. The sequence from 2-aminopyridine used by Abramovitch and Cue (5) also gave good yields for each of several steps, but overall did not greatly improve the routine preparation of the 2-nitrile.

The recent use of chlorosulfonyl isocyanate (CSI) for the direct introduction of a cyano group onto activated aromatics (6, 7) prompted us to examine its use in the pyrrole series. However, although crude (2-pyrrolylcarbonyl)-sulfamoyl chloride could be obtained in excellent yield, and subsequent hydrolysis (8) gave a very good yield of pyrrole-2-carboxamide, the best preparation of the 2-nitrile was no better than 40%. There was a modest improvement in the yield in preparations of the 2-nitriles from 1-methyl- and 1-carbomethoxypyrroles. However, the overall results were not encouraging for an improved preparation of simple 2-cyanopyrroles. A number of modifications of the procedure using bases other than dimethylformamide (7*a*) were explored with no real success.

The use of 2.25 molar equivalents of CSI on pyrrole gave isolated yields of 53% 2,4- and 2.5% 2,5-dicyanopyrrole on quite a large scale. The availability of the 2,4-isomer in one step from pyrrole caused us to examine methods of selective reduction of this substance with a view to preparing 4-cyanopyrrole-2-carboxaldehyde. This should lead to an easy preparation of 3-cyanopyrrole through decarbonylation (1). Selectivity was not easily achieved, however. A mild reagent such as lithium triethoxyaluminohydride gave only starting material, while lithium aluminum hydride under a variety of conditions led to overreduction. The best isolated yields approached 50%. The use of the dissolving Raney nickel alloy method (1) was no more selective, but it was possible to prepare the 2,4-dialdehyde by this latter method in 55% yield on a moderate scale, although the reduction was much more successful on a small scale. Part of the difficulty lies with the low solubility of these compounds, all possessing electron-withdrawing groups in both 2- and 4-positions, making it time consuming to separate partially reduced mixtures of product and starting material.

A different approach to the synthesis of pyrrole-2-carbonitrile was suggested by the report of Liebscher and Hartmann (9). They used hydroxylammonium chloride in refluxing dimethylformamide (DMF) to convert aromatic aldehydes to nitriles in excellent yield, and were also successful in a reaction of the type:

$$\underset{\mathbf{1}}{Ar{-}CH{=}\overset{+}{N}(CH_3)_2ClO_4^-} \xrightarrow[DMF/\Delta]{NH_2OH\cdot HCl} Ar{-}CN$$

As these authors point out, immonium salts such as **1** are intermediates in the Vilsmeier–Haack formylation and may be isolated from that reaction (10).

We felt that, since the Vilsmeier aldehyde syn-

thesis is so successful with pyrrole (4), it should be possible to adapt that reaction to a direct nitrile synthesis using the above method. When we prepared the Vilsmeier complex in 1,2-dichloroethane solution using phosphorus oxychloride and DMF, the nuclear magnetic resonance (nmr) spectrum revealed a clean conversion to a 2-substituted pyrrole salt, corresponding to **1**. Thus, there seemed to be no real reason to isolate the perchlorate salt before proceeding. Hydroxylammonium chloride dissolved in warm excess DMF was added and the temperature raised to distil out the dichloroethane. When the boiling point of DMF was reached, the solution was refluxed and worked up according to Liebscher and Hartmann (9). There was a small yield of both 2-nitrile and 2-aldehyde and much destruction to a black tarry solid.

After several variations of the technique produced no real improvement, we decided to simplify the nature of the Vilsmeier intermediate in solution through the use of oxalyl chloride instead of phosphorus oxychloride. This avoided the possible complication of the presence of the phosphorus-containing by-product. We then obtained a solution of **2** in dichloroethane which showed a clean nmr spectrum.

2

As reflux with hydroxylammonium chloride in excess DMF still gave considerable destruction to tarry material, a molar equivalent of pyridine was added to the hydroxylammonium chloride solution in DMF. After addition of this mixture to the immonium salt, the solution was refluxed at the boiling point of dichloroethane. We were able to use nmr spectra to follow the conversion of the immonium salt, **2**, to the 2-nitrile over the course of about ten hours. On working up, there was much less tarry material and a yield of 64% of pyrrole-2-carbonitrile was obtained. The same procedure gave 67% of the 1-methyl analog from 1-methylpyrrole. Thus we have a "one-pot" synthesis of these two useful starting materials using simple reagents applicable on a large scale which gives satisfactory results.

Experimental

Melting points are uncorrected. Elemental analyses were by Atlantic Microlabs, GA, U.S.A. The ir spectra were recorded on a Perkin-Elmer 273B grating spectrophotometer. The ^{1}Hmr spectra were determined using a Varian EM360 instrument. Values are given on the δ scale using tetramethylsilane as internal reference. Mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6E spectrometer using a direct inlet system.

Reactions of Pyrrole and Chlorosulfonyl Isocyanate

Pyrrole-2-carboxamide

Chlorosulfonyl isocyanate (18.75 g, 132 mmol) in dichloromethane (35 mL) was added dropwise over 1 h to a stirred solution of pyrrole (6.7 g, 100 mmol) in dichloromethane (200 mL) kept about −24°C under dry nitrogen. Stirring was continued for a further 2 h while the bath temperature was allowed to rise slowly to ambient. The cream-colored powdery product was collected, washed with cold carbon tetrachloride, and dried in a vacuum desiccator. It was very sensitive to moisture. The crude product, (2-pyrrolylcarbonyl)-sulfamoyl chloride (17.9 g, 85%), had an nmr spectrum (acetone-d_6) δ: 7.25 (m, 2H), 6.30 (m, 1H).

The crude (2-pyrrolylcarbonyl)-sulfamoyl chloride was dissolved in ice water and filtered. The filtrate was warmed to ~80°C at which it turned red and precipitated some black solid. After a second filtration the solution was taken to pH 7 with saturated aqueous sodium hydrogen carbonate. The product, a white solid, then precipitated and was filtered off. More of the product was obtained by concentration of the filtrate. The crude product was easily sublimed to give pyrrole-2-carboxamide (8.12 g, 74% from pyrrole), mp 172–173.5°C (lit. (11) mp 172.5–174°C).

Pyrrole-2-carbonitrile

The adduct from CSI (53 mmol) and pyrrole (35 mmol) in 35 mL dichloromethane was prepared as above. To the stirred solution at −15 to −10°C was added DMF (5.7 mL, 73.5 mmol) over a period of 30 min. After 1 h further stirring, the reaction mixture was poured onto ice and, eventually, extracted with dichloromethane. The extract was washed successively with water and aqueous NaCl, dried (Na_2SO_4), and then evaporated to give a brown oil. Vacuum distillation of the oil gave pyrrole-2-carbonitrile (1.3 g, 40%), bp 118–120°C/14 Torr.

When acetonitrile was used as solvent and triethylamine as the base (*7a*) on a sample of (2-pyrrolylcarbonyl)-sulfamoyl chloride, the usual work-up gave 25% of 2-pyrrolecarbonitrile.

Pyrrole-2,4-dicarbonitrile and Pyrrole-2,5-dicarbonitrile

While the temperature was maintained at −24°C, a solution of CSI (318.4 g, 2.25 mol) in anhydrous ether (600 mL) was added over a period of 2 h to pyrrole (67 g, 1 mol) in anhydrous ether (400 mL) under an atmosphere of dry nitrogen. Over the following 2½ h the temperature was allowed to rise to ambient. DMF (320 mL, 4.14 mol) was then added over 1 h, keeping the temperature at about −12°C. After a further 1 h at room temperature, the reaction mixture was poured into ice-cold hydrochloric acid (3 *M*, 500 mL), and stirred for 20 min. This solution was extracted repeatedly with ethyl ether and finally with ethyl acetate. The combined layers were washed with dilute aqueous hydrochloric acid, aqueous sodium hydrogen carbonate, and with saturated aqueous NaCl, then dried ($MgSO_4$). After removal of the solvent the crude solid was extracted into toluene using a Soxhlet and, after crystallization from toluene, gave pyrrole-2,4-dicarbonitrile[1] (61.6 g, 53%), mp 181–183°C; ir ν: 2225 (CN) cm^{-1}; nmr (acetone-d_6) δ: 7.81 (1H, d), 7.28 (1H, d); *m/e*: 117. *Anal.* calcd. for $C_6H_3N_3$: C 61.54, H 2.58; found: C 61.55, H 2.61.

Evaporation of the toluene extract and residues from crystallization of the pyrrole-2,4-dicarbonitrile gave a crude solid which was recrystallized from ethyl ether – petroleum (bp 35–50°C), pyrrole-2,5-dicarbonitrile[1] (2.8 g, 2.5%), mp 148.5–149.5°C; ir ν: 2230, 2245 cm^{-1}; nmr ($CDCl_3$) δ: 6.93; *m/e*: 117. *Anal.* calcd. for $C_6H_3N_3$: C 61.54, H 2.58; found: C 61.46, H 2.59.

[1]Compound is referred to in ref. 12. No physical constants are given in that publication.

Reaction of 1-Methylpyrrole and Chlorosulfonyl Isocyanate

A solution of 1-methylpyrrole (11.34 g, 140 mmol) in dichloromethane (80 mL) was treated with CSI (24.80 g, 175 mmol) in dichloromethane (120 mL), followed 2 h later with DMF (22.7 mL, 29 mmol) as for pyrrole (above). The reaction product was poured into ice-cold 4 *M* HCl and worked up to give a yellow oil together with some white solid. Vacuum distillation then gave 1-methylpyrrole-2-carbonitrile (8.6 g, 58%) bp 82–87°C/10 Torr. The solid residue was chromatographed on EM Reagents neutral alumina Grade II using dry ethyl ether as eluant. The two products were recrystallized from ethyl ether – petroleum (bp 35–50°C): (*a*) 1-methylpyrrole-2,5-dicarbonitrile (0.46 g, 2.5%), mp 102–103°C; nmr ($CDCl_3$) δ: 6.82 (2H, s), 3.91 (3H, s); *m/e*: 131. *Anal.* calcd. for $C_7H_5N_3$: C 64.11, H 3.84; found: C 64.10, H 3.84; (*b*) 1-methylpyrrole-2,4-dicarbonitrile (0.51, 2.8%); mp 109–109.5°C; nmr ($CDCl_3$) δ: 7.35 (1H, d), 7.07 (1H, d), 3.96 (3H, s); *m/e*: 131. *Anal.* calcd. for $C_7H_5N_3$: C 64.11, H 3.84; found: C 64.11, H 3.87.

Reaction of Ethyl Pyrrole-1-carboxylate with Chlorosulfonyl Isocyanate

Following the procedure for pyrrole (above), ethyl pyrrole-1-carboxylate (4.17 g, 30 mmol), CSI (4.66 g, 33 mmol), and DMF (6.96 mL, 60 mmol) gave, upon working up, a purple oil which partly solidified on refrigeration. Vacuum distillation afforded ethyl 2-cyanopyrrole-1-carboxylate (2.9 g, 58%), bp 131–133°C/11 Torr; ir ν: 2220 (C≡N), 1760 (C=O) cm^{-1}; nmr ($CDCl_3$) δ: 7.35 (1H, m), 6.87 (1H, m), 6.19 (1H, m), 4.43 (2H, q), 1.46 (3H, t); *m/e*: 164. *Anal.* calcd. for $C_8H_8N_2O_2$: C 58.53, H 4.91, N 17.06; found: C 58.32, H 4.97, N 16.99.

Reductions of Pyrrole-2,4-dicarbonitrile

A solution of pyrrole-2,4-dicarbonitrile (0.117 g, 1 mmol) in tetrahydrofuran (2 mL, distilled from $LiAlH_4$) was added to a stirred suspension of $LiAlH_4$ (0.040 g, 1.06 mmol) in THF (5 mL) at 0°C under dry N_2. After 2½ h at 0°C the mixture was hydrolyzed with 2.5 *M* H_2SO_4 (6 mL). Extraction with ethyl ether was followed by washing with brine and drying ($MgSO_4$). Evaporation gave a cream-colored solid. This crude material was recrystallized from ethyl ether – petroleum (bp 35–50°C) affording 4-cyanopyrrole-2-carboxaldehyde (56 mg, 45%), mp 175–177°C (lit (13) mp 177–177.5°C).

When twice the amount of $LiAlH_4$ was used, the isolated product was about 80% 4-cyano-2-pyrrolecarboxyaldehyde, with the rest starting material, plus a trace of pyrrole-2,4-dicarboxaldehyde. Over half of the starting material was not accounted for.

Pyrrole-2,4-dicarbonitrile (2.0 g, 17.1 mmol) was added to a gently refluxing mixture of Raney nickel alloy (0.6 g) in formic acid (18 mL, 50% aqueous) which was evolving H_2 gas. Stirring and heating was continued for 1½ h. The hot solution was then continuously extracted with toluene. After drying ($MgSO_4$) and vacuum removal of solvent, the yellow solid was sublimed to give pyrrole-2,4-dicarboxaldehyde (1.18 g, 56%), mp 149–152°C (lit. (14) mp 151.5–152°C). The melting point of a mixture with authentic material was not depressed.

Modified Vilsmeier–Haack Synthesis for Pyrrolecarbonitriles

(a) Pyrrole-2-carbonitrile

A solution of dimethylformamide (20.1 g, 0.275 mol) in 1,2-dichloroethane (60 mL) in a 3-necked flask was cooled in an ice-salt bath. To the stirred and cooled solution was added a solution of oxalyl chloride (34.9 g, 0.275 mol) in 1,2-dichloroethane (40 mL) over a period of 20 min. The suspension of white solid was then allowed to stir at room temperature for 15 min. The suspension was cooled in ice and a solution of pyrrole (16.8 g, 0.25 mol) in 1,2-dichloroethane (50 mL) was added over 20 min. The light orange solution obtained was allowed to stir 15 min at room temperature.

Hydroxylammonium chloride (18.9 g, 0.275 mol) was dissolved in warm dimethylformamide (50 mL) and pyridine (21.7 g, 0.275 mol) was then added. This solution was added rapidly to the Vilsmeier complex prepared above. The reaction mixture, heated by an oil bath, was refluxed for 10 h. After cooling, about 500 mL saturated $NaHCO_3$ solution was added. The dark brown solution was extracted with ethyl ether. The ether extracts were washed with saturated aqueous NaCl and then with 1 *M* hydrochloric acid. The dark colored mixture was filtered through a thick pad of Celite. After several further washings with 1 *M* HCl, the ether layer was washed with saturated aqueous NaCl, several portions of 5% aqueous $NaHCO_3$, and with water. The ether layer was dried (K_2CO_3) and the solvent removed. Vacuum distillation gave pyrrole-2-carbonitrile (14.7 g, 64%), bp 74–76°C/1 Torr.

(b) 1-Methylpyrrole-2-carbonitrile

Following the procedure of (*a*) above using 1-methylpyrrole (20.3 g, 0.25 mol), vacuum distillation of the crude product gave 1-methyl-2-pyrrolecarbonitrile (17.7 g, 67%), bp 72–75°C/9 Torr.

σ^+ Substituent constants for the *ortho*- and *para*-vinyl group have been determined by the application of the linear free-energy relationship to the nitration of the β-substituted styrene derivatives.

Energy changes (relative to benzene system) for the proton and hydride ion transfer to individual positions in the styrene molecule have been calculated. Both approaches indicate that the vinyl group is capable of stabilizing both positively and negatively charged transition states. The interactions of the vinyl group with other substituents in the phenyl ring are also determined. Again, stabilizing effects with respect to both π-donor and π-acceptor substituents have been demonstrated for the vinyl group.

W. F. REYNOLDS, T. A. MODRO, P. G. MEZEY, E. SKORUPOWA et A. MARON. Can. J. Chem. **58**, 412 (1980).

On a déterminé les constantes de substituant σ^+ du groupe vinyle en position *ortho* et *para* en appliquant la relation linéaire d'énergie libre à la nitration des dérivés du styrène substitués en position β. On a calculé les variations d'énergie (par rapport au système benzénique) résultant du transfert du proton et de l'ion hydrure à des positions individuelles dans la molécule de styrène. Les deux approches indiquent que le groupe vinyle peut stabiliser de façon à la fois positive et négative les états de transition chargés. On a également déterminé les interactions du groupe vinyle avec les autres substituants du phényle. On a encore démontré l'effet stabilisateur du groupe vinyle par rapport aux substituants donneur π et accepteur π.

[Traduit par le journal]

Introduction

Most substituent groups attached to organic molecules can be classified as either electron donor or electron acceptor groups. Electron donor groups accelerate rates of reactions in which positive charge is developed in the transition state and slow down reactions involving development of negative charge, while electron withdrawing groups have the opposite effect. In the context of aromatic reactivity, substituent effects on a group X in a system RX can be predicted by the Hammett equation (1)

$$[1] \quad \log (k_X/k_H) = \rho\sigma_x$$

The substituent constant, σ_x, is respectively negative and positive for donor and acceptor groups while ρ is respectively negative and positive for reactions involving development of positive and negative charge in the transition state. A large number of σ constant scales have been proposed (2), including σ^+ (3) and σ^- (4) scales which are respectively intended for systems in which there is a large degree of positive or negative charge development in the transition state. Nevertheless, for most substituents σ^+ and σ^- have the same sign, characteristic of the donor or acceptor nature of the group.

However, there are a number of exceptions. For example, the halogens and most oxygen-bonded substituents have opposing field/inductive and resonance effects (e.g., $\sigma_I = +0.27, \sigma_R^0 = -0.45$ for OCH_3 and $\sigma_I = +0.50, \sigma_R^0 = -0.34$ for F according to Taft's dual substituent parameter scale (5)). Thus the net effect of the substituent depends upon the relative magnitudes of the two effects and may change sign for different positions of substituents (e.g., $\sigma_{meta} = +0.12, \sigma_{para} = -0.27$ for OCH_3 (6)) or for different types of reaction sites (e.g., $\sigma_p^- = +0.06, \sigma_p^+ = -0.07$ for F(6)).

Another more unusual class of exceptional substituents are those which have intrinsically small substituent effects in neutral systems but which are capable of stabilizing both negatively and positively charged species. For example, alkyl groups are both acid-strengthening and base-strengthening in gas phase proton transfer reactions, apparently due to the polarizability of these groups (7). However, for aromatic reactions in solution, this effect must be relatively unimportant since alkyl groups act as weak electron donors in this case (e.g., $\sigma_p^+ =$

[a]Reference 6.
[b]Reference 14.
[c]This value gives the relative rate of nitration of cinnamic acid (relative to benzene), $k_{rel} = 0.31$. Early value (16) estimated in acetic anhydride gives for cinnamic acid $k_{rel} = 0.11$.

-0.31, $\sigma_p^- = -0.17$ for CH_3 (6)). Two other substituents which should fall into this category even in solution are the phenyl and vinyl groups. In fact σ_p^+ ($= -0.20$ (6)) and σ_p^- ($\simeq \sigma_I + \sigma_R^- = +0.14$ (6)) constants for the phenyl group confirm that it will have a rate-accelerating effect on reactions involving the development of either positive or negative charge in the transition state. This presumably reflects the ability of the phenyl group to act as either a π-donor or a π-acceptor. Similarly, the vinyl group has a very small substituent effect in neutral systems (e.g., $\sigma_I = +(0.01\text{–}0.05)$, $\sigma_R^0 = -0.03$ (8)) but can act as a π-donor or π-acceptor, on demand:

[2] 

Thus one might expect opposite signs for σ_p^+ and σ_p^- for the vinyl group. The evidence on this point is contradictory. $\sigma_p^- = +0.14$ for the vinyl group (9). However, values of $\sigma_p^+ = -0.16$ and $+0.10$ have been reported for this substituent, based respectively on rates of solvolysis of cumyl chlorides (10) and ^{13}C chemical shifts of mono-substituted benzenes (11). Consequently, we decided to redetermine σ_p^+ for the vinyl group, based upon rates of nitration (12). One cannot investigate the nitration of styrene directly since the favoured site for electrophilic attack is the vinyl group. However, one can determine rates of nitration for *trans*-β-substituted styrenes, $C_6H_5CH{=}CHX$ where X is an electron withdrawing group. One can then plot rate of nitration vs. σ_X^+ and extrapolate to $\sigma^+ = 0.0$, i.e., X = H, using a Hammett plot.

It was also decided to carry out a theoretical investigation of the stabilizing effect of a vinyl group in aromatic systems, both for comparison with the experimental results and to check whether there was any relationship between induced charge densities and stabilization energies, such as has been recently noted in other systems (13).

Results of these investigations are reported below.

Results and Discussion

Experimental Data

Data for nitration of C_6H_5—CH=CH—X derivatives are summarized in Table 1. Rates of substitution at positions *para* and *ortho* correlate well with the values of σ^+ for the groups X:

$$\log k_p = -2.80\sigma_X^+ + 0.253 \; (r = 0.998)$$

$$\log k_o = -3.28\sigma_X^+ + 0.477 \; (r = 0.998)$$

(see Fig. 1.)[1] The plot yields $k_p = 1.79\ s^{-1} M^{-1}$ for nitration of the *para* position of styrene. Similarly $k_o = 3.00\ s^{-1}M^{-1}$ for nitration of the *ortho* position ($1.50\ s^{-1}M^{-1}$ for nitration at each carbon). By comparison, the determined value of k_2 for benzene = $0.832\ s^{-1}M^{-1}$ ($0.139\ s^{-1}M^{-1}$ at each carbon atom); ρ^+ for the nitration of benzene derivatives = -6.0 (14). Therefore,

[3] $$\log (k(\text{styrene})/k(1\text{H, benzene})) = -6.0\,\sigma_{(CH=CH_2)}^+$$

Using this equation the values of $\sigma_p^+ = -0.18$[2] and $\sigma_o^+ = -0.17$ are obtained for the vinyl group. The data also allow one to set a limit on the value of σ_m^+.

[1]Table 1 also includes nitration data obtained for the β-styrylphosphonic acid. From these data, together with Fig. 1, the (previously unreported) σ^+ value for the phosphonic group could be evaluated. It follows that $\sigma_{PO_3H_2}^+ = 0.44$, similar to that for the carboxylic group ($\sigma_{CO_2H}^+ = 0.42$ (14)). Close similarity of substituted effects of groups CO_2H and PO_3H_2 has been demonstrated before (15). The excellent correlations in Fig. 1 justify the use of σ_p^+ values for side-chain substituent groups.

[2]The different value estimated by Levy and co-workers (11) presumably is in error because *para* ^{13}C chemical shifts are not, in fact, related to σ_p^+ but rather must be correlated with σ_I and σ_R^0 (5).

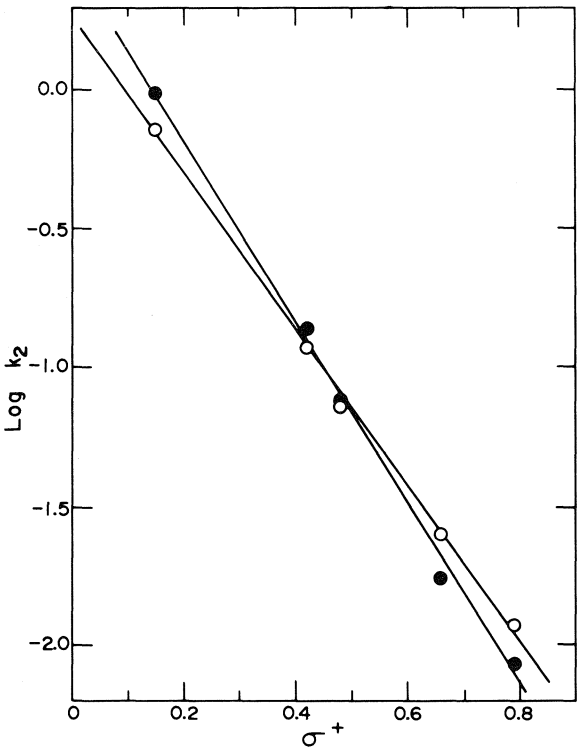

FIG. 1. Log k_2 for nitration of Ph—CH=CH—X vs. σ_x^+, TFA/H_2SO_4, 25°C. (○) *para* nitration; (●) *ortho* nitration.

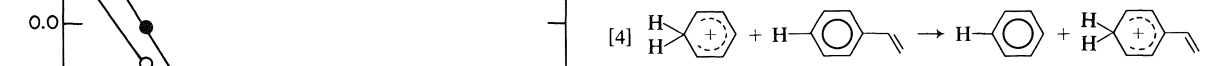
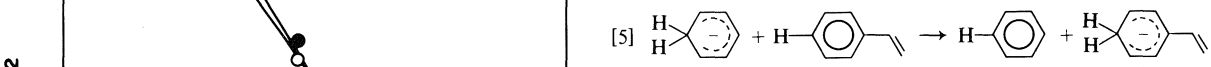


The maximum concentration of *meta*-nitro product is 2% (see Experimental). Thus, the rate constant for *ortho*-nitration is at least 30 times as great as for *meta*-nitration. This corresponds to $\sigma_m^+ > +0.06$.

The σ_p^+ and σ_m^+ values are close to those estimated from the solvolysis of *p*- and *m*-vinylcumyl chloride ($\sigma_p^+ = -0.16$, $\sigma_m^+ = +0.11$ (1)). Thus, σ_p^+ is in fact negative for the vinyl group. Comparison with σ_p^- (+0.14 (9)) confirms that, as suggested in the Introduction, the vinyl group can act as both a donor (to positively charged groups) and an acceptor (from negatively charged groups). In fact, the vinyl group appears to be almost equally effective at stabilizing positively and negatively charged transition states in solution, judging from the similar magnitudes of σ_p^+ and σ_p^-.



As shown in Table 1, the extent of *para* substitution increases with increasing polarity of X in C_6H_5—CH=CHX derivatives. This is consistent with the expected through-space field effect of X which should disfavour approach of an electrophile to the *ortho* position (17).

Theoretical (ab initio) *Calculations*

The effect of a vinyl group on electrophilic aromatic substitution can be estimated from the energy change for the isodesmic proton transfer reaction (18):

[4] 

and the similar reactions involving *ortho*- and *meta*-protonated styrenes. Similarly, the effect of a vinyl group on nucleophilic aromatic substitution can be estimated from the corresponding hydride transfer reactions:

[5] 

Results for these calculations are summarized in Table 2.

The calculations clearly demonstrate the ability of the vinyl group to stabilize positively and negatively charged transition states to a similar degree. They also show that this results from π charge transfer between the vinyl and phenyl groups. In fact, there is a close parallel between ΔE and $|q_\pi|$, the magnitude of π charge transfer. The calculations also indicate that the vinyl group stabilized the *para*-protonated intermediate slightly more than the *ortho*-protonated intermediate, consistent with the experimental σ_p^+ (−0.18) and σ_o^+ (−0.17) values. However, the calculations differ from the experimental results in predicting a slight stabilization of electrophilic substitution at the *meta* position. This may reflect a difference between gas phase and solution reactivity.

In view of the effect of a vinyl group on charged systems, it is also interesting to consider the effect of the vinyl group in neutral aromatic species. The calculated π charge distribution in styrene is shown in Fig. 2. It is seen that the group is essentially neutral (with only 0.0001 π electron transferred to the phenyl group, compared to almost ±0.2 π electron transfer between the vinyl group and charged

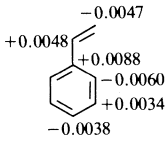
phenyl groups, see Table 2). However, there is significant π charge redistribution within the phenyl and vinyl groups. Within the orbital approximation, charge redistribution schemes may be modelled in terms of orbital interactions. It has previously been suggested in the case of halobenzenes and alkylbenzenes that repulsion between a filled orbital on the substituent and the phenyl π system will lead to an increase in π electron density at the *ortho* and *para* carbons (19). However, in these cases, it is difficult to separate this orbital repulsion effect from the electron donating resonance effects of these groups. With no net π electron transfer, the vinyl group provides very clear evidence for the existence of an orbital repulsion effect. This may account for the σ values of the vinyl group in neutral systems ($\sigma_m = +0.08$, $\sigma_p = -0.08$ (6)).



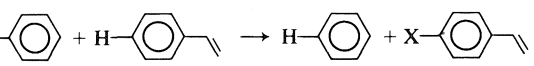


FIG. 2. Calculated π charge distribution in styrene.

It is also informative to consider the interaction of the vinyl substituent with other groups. This can be determined from the energy change for the isodesmic reaction:

[6] 

Results are summarized in Table 3. The interaction of the vinyl group with both electron donor groups (e.g., NH_2) and electron acceptor groups (e.g., NO_2) is stabilizing, although weak in the case of electron donor groups. The latter weak interaction may reflect a partial cancellation of the stabilizing π acceptor ability of the vinyl group by its orbital repulsion effect. The ability of the vinyl group to have stabilizing interactions with both donor and acceptor groups is most unusual. This can be seen by comparing with three other substituent groups with differing properties: a weak donor group, CH_3 ($\sigma_p^0 = -0.15$); a moderately strong acceptor group, CO_2H ($\sigma_p^0 = +0.44$); and a charged group CO_2^-. These data are shown in Table 3. The interactions of the methyl group with acceptor groups and donor groups are respectively stabilizing and destabilizing (as expected from the same signs for σ^+ and σ^-, see above). The CO_2H group shows the exact opposite pattern of stabilizing and destabilizing interactions, as expected from its opposite substituent effect. Finally, interactions of CO_2^- with acceptor and donor groups are respectively stabilizing and destabilizing. Interactions with highly polar groups (e.g., NO_2) are particularly strong. This presumably reflects the strong (through-space) field interaction between a polar and a charged group (20). This is also reflected in the apparently anomalous interactions with OH and F. These two groups have opposing field and resonance interactions (see Introduction). The former must dominate in the interaction with a

charged group while the latter dominates in the interaction with neutral groups (where field effects should be less important (20)). Finally, it is noteworthy that, of the various X groups, only vinyl shows stabilizing interactions with all three CH_3, CO_2H, and CO_2^-.

Summary and Conclusions

Experimental and theoretical investigations of the substituent effect of the vinyl group indicate that this group is capable of stabilizing both positively and negatively charged transition states by acting as either a π donor or a π acceptor, depending upon the demand of the system. A close parallel is noted between the stabilization energy and the extent of π charge transfer.

The vinyl group appears to have an intrinsically small substituent effect in neutral systems; mainly a weak orbital repulsion effect. However, the interaction of the vinyl group with both π donor and π acceptor substituents in *p*-disubstituted benzenes is a stabilizing interaction.

Experimental

Solvents were purified by conventional methods. AnalaR nitric acid (d. 1.42) was distilled from an equal volume of concentrated H_2SO_4 immediately before use. Trifluoroacetic acid was distilled from trifluoroacetic anhydride immediately before use. Ultraviolet spectra were determined with a Perkin-Elmer 402 spectrophotometer. ^1H nuclear magnetic resonance spectra were obtained with a Tesla BS-487 (80 MHz.) spectrometer. Gas chromatography was performed using a Pye Unicam, series 104 instrument.

Substrates

Benzene (**1**), β-bromostyrene (**2**), cinnamic acid (**3**), ethyl cinnamate (**4**), cinnamic nitrile (**5**), and β-nitrostyrene (**6**) were obtained commercially and were purified by distillation or crystallization until chromatographically pure (glc). β-Styrylphosphonic acid (**7**) was prepared according to Bergmann and Bondi (21); mp (from H_2O) 149–150°C (lit. (21), mp 146°C).

Product Determination

Substrate (ca. 10^{-2} *M*) was dissolved in TFA containing concentrated H_2SO_4 in the amount equimolar to that of the aromatic compound. The solution of nitric acid (slight excess) in TFA was added slowly at 0°C with stirring. The mixture was then left at room temperature until tlc showed that the reaction was complete. The product was then isolated by evaporation of TFA and extraction; in all cases the yield was practically quantitative and the elemental analysis (nitrogen) of the product agreed with the composition of a mononitro derivative. The nitration product was examined by tlc to determine the number of isomers formed and then oxidized with alkaline permanganate (22) to a mixture of nitrobenzoic acids (in all cases only *ortho* and *para* isomers were observed). The proportion of isomers was determined by quantitative separation of individual compounds and by comparison of the uv spectrum of the oxidation product with the spectra of model mixtures of known composition.

The oxidation product was also examined by nmr spectroscopy and the proportion of *ortho*- and *para*-nitrobenzoic acids was determined from the integrated signals of the aromatic protons of the *ortho* (δ 7.50–7.80) and *para* (δ 7.95–8.25) isomers. All determinations gave good internal agreement. Control experiments showed that the amount of *meta*-nitro product should not exceed 2%.

Rates of Nitration

A solution of HNO_3 in TFA was added to a stirred solution of an equimolar amount of substrate in TFA containing one equivalent of concentrated H_2SO_4 at 25.0°C, and aliquot portions were withdrawn at suitable times. For substrates **1**, **2**, **3**, **4**, **5**, and **7** aliquots were quenched in water and the concentration of nitro compounds in the reaction mixture was determined spectrophotometrically (uv) in the usual way. The following wavelengths and extinction coefficients of substrate (ε_s) and product (ε_p) were used: **1**, $\lambda = 258$ nm; $\varepsilon_s = 150$, $\varepsilon_p = 8500$; **2**, $\lambda = 265$ nm, $\varepsilon_s = 17000$, $\varepsilon_p = 4500$; **3**, $\lambda = 273$ nm, $\varepsilon_s = 21500$, $\varepsilon_p = 10800$; **4**, $\lambda = 275$ nm, $\varepsilon_s = 22000$, $\varepsilon_p = 11200$; **5**, $\lambda = 271$ nm, $\varepsilon_s = 22600$, $\varepsilon_p = 13100$; **7**, $\lambda = 258$ nm, $\varepsilon_s = 18700$, $\varepsilon_p = 11500$. For β-nitrostyrene (**5**) aliquots were extracted with *n*-hexane, extracts were evaporated under reduced pressure, and the residue was dissolved in *n*-hexane containing a known amount of 4-bromodiphenyl as a standard. The mixture was then separated by gas chromatography (column: 3% OV-225 on a Chromosorb W (AW-DMCS) 60/80 mesh, 1 m; temperature 115°C; flow rate (argon) 25 cm^3/min) and concentrations of individual nitro products were determined by the planimetric estimation of the peak areas.

Kinetic runs were followed to ca. 80% of conversion. Good second-order kinetics were obtained in all cases. Values of k_2 for nitration of benzene and substrates listed in Table 1 represent the average of 4–6 independent runs. Individual rate constants are reproducible to within ±5–15%.

Details of Calculations

A STO-3G basis set as contracted to a minimal basis set (23) was used for the *ab initio* molecular orbital calculations. Calculations were performed on an IBM 370/16S computer using a version of the Gaussian 70 program (24). Standard geometries were assumed for phenyl and vinyl groups (25) while the geometry of the protonated phenyl group was that given by McKelvey *et al.* (26). Other substituent geometries were identical to those previously reported (20).

A systematic investigation of the reaction of SiF_2 with ethylene and six methyl-substituted ethylenes. I. Product yields and mechanistic conclusions[1]

WILLIAM F. REYNOLDS, JAMES C. THOMPSON,[2] and A. P. GERALD WRIGHT
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received July 19, 1979

WILLIAM F. REYNOLDS, JAMES C. THOMPSON, and A. P. GERALD WRIGHT. Can. J. Chem. **58**, 419 (1980).

SiF_2 produced by the quartz tube reaction has been reacted with ethylene and six methyl-substituted ethylenes. All major products (polymers, disilacyclobutanes, disilacyclohexanes, and open chain compounds) have been characterized by a combination of ^{19}F, ^{1}H, ^{13}C, and ^{29}Si nmr spectroscopy. While polymer is always formed in highest yield, the relative proportions of other products vary significantly from alkene to alkene.

Key observations concerning structures and stereochemistries and product yields are summarized. Consideration of this evidence leads to a mechanism involving attack of SiF_2 on the olefin to form an excited silirane which either ring opens or relaxes to its ground state, followed in either case by further reaction.

WILLIAM F. REYNOLDS, JAMES C. THOMPSON et A. P. GERALD WRIGHT. Can. J. Chem. **58**, 419 (1980).

On a fait réagir le SiF_2, obtenu par la réaction du tube de quartz, avec de l'éthylène et six composés éthyléniques portant un substituant méthyle. On a identifié les produits principaux (polymères, disilacyclobutanes, disilacyclohexanes et des composés à chaîne linéaire) en utilisant les données de la rmn du ^{19}F, ^{1}H, ^{13}C et ^{29}Si. Tandis que le polymère se forme toujours avec de très bons rendements, les proportions relatives des autres produits varient de façon importante d'un alcène à l'autre.

On résume les observations fondamentales relatives aux structures et à la stéréochimie des produits obtenus. En tenant compte des preuves obtenues, on aboutit à un mécanisme qui fait intervenir une attaque de l'oléfine par du SiF_2 conduisant à la formation d'un siliranne excité dont le cycle s'ouvre ou revient à l'état fondamental; dans un cas comme dans l'autre une réaction subséquente se produit.

[Traduit par le journal]

Introduction

Since the initial report that SiF_2 could be generated in good yield by the reaction of SiF_4 with Si in a high temperature furnace (1), there have been numerous investigations of the reactions of SiF_2 with unsaturated organic compounds. These reactions yield a bizarre variety of compounds (e.g. see refs. 2–4). This has led to considerable speculation concerning the mechanism of these reactions (5–7). However, the mechanistic proposals were all based on incomplete information since the major polymeric products of these reactions had never been characterized.

Consequently, it was decided to carry out a systematic investigation of the reaction of SiF_2 with a series of methyl-substituted ethylenes, characterizing the products as completely as possible. It was hoped that this would provide a better understanding of this obviously complex reaction.

We have already published a preliminary account of the characterization of the polymeric products by ^{13}C and ^{29}Si nmr spectroscopy (8). This paper discusses product yields and stabilities, summarizes the key observations concerning structure, and presents a comprehensive mechanism which accounts for the structures and stereochemistry of the products as well as the product yields. Two subsequent papers (9, 10) will describe in detail the spectroscopic characterization of the products.

Experimental

SiF_2 was prepared in a greaseless vacuum line by the standard quartz tube method (1). In a typical reaction, 0.147 mol SiF_4 were converted to SiF_2 and co-condensed at −196°C with 0.139 mol *trans*-butene, using flow rates of about 170 mmol/h for each

IB	61	2	32	32	0	34
MB	51	2	14[b]	14	0	70
DB	28	Trace	2	25[d]	0	73

[a]Two isomers in 9:1 ratio. Minor component corresponded to TB four-membered ring.
[b]Two isomers in comparable yields.
[c]Two major isomers plus traces of other isomers.
[d]Two products in 4:1 ratio.
[e]At least two products.

reactant. The resultant condensate was allowed to warm to room temperature. Unreacted SiF_4, olefin, and volatile products were pumped to U traps or to a low temperature distillation column (11) for separation. The polymers, which varied in viscosity with olefin, were weighed and scraped into storage bottles in a glove bag. Some of the volatile products polymerized readily at room temperature. Any unstable product was condensed directly into an nmr tube glass-blown to the bottom of a U tube. The nmr tube was then sealed and stored in liquid nitrogen until use.

SiF_2 was reacted with ethylene (ET), propene (PR), *cis*-2-butene (CB), *trans*-2-butene (TB), isobutylene (2-methylpropene) (IB), 2-methyl-2-butene (MB), and 2,3-dimethyl-2-butene (DB). All olefins were of commercial purity. CB contained 0.2–0.5% of the *trans* isomer. Each reaction was repeated at least twice. Product yields were reproducible in all cases.

Elemental analyses could not be obtained since the products were thermally unstable and air sensitive (see below). In addition, complete separation of products was rarely possible. However, reaction products could be fully characterized by a combination of ^1H, ^{19}F, ^{13}C, and ^{29}Si nmr spectroscopy. ^1H spectra were obtained on Varian A56/60D, HA-100, and XL-100 spectrometers respectively operating at 60.0, 100.0, and 100.06 MHz. ^{19}F spectra were obtained on the A56/60D and XL-100 spectrometers operating at 56.4 and 94.16 MHz, respectively. The XL-100 was also used to obtain ^1H-decoupled ^{19}F spectra and ^{19}F-decoupled ^1H spectra. ^{13}C spectra were obtained on Varian XL-100 and CFT-20 spectrometers at 25.16 and 20.00 MHz while ^{29}Si spectra were obtained on a Bruker WP-80 spectrometer operating at 15.89 MHz. ^1H and ^{19}F spectra were generally obtained in continuous wave mode while other spectra were obtained in pulsed Fourier transform mode.

Results and Discussion

(a) Product Yields

In general, four types of products were observed in the olefin–SiF_2 reactions. In addition to polymeric products, 1,2-disilacyclobutanes and disilacyclohexanes were normally found as well as open chain products which usually were isomers of the disilacyclohexanes. However, a different open chain product was observed in the CB reaction. The disilacyclobutane and disilacyclohexane products produced from the reaction of ET with SiF_2 have been reported and characterized by mass spectrometry and ^1H and ^{19}F nmr spectroscopy (2). No chain isomer was found in that reaction but this type of product has been noted in other reactions of SiF_2 with unsaturated compounds (3, 12).

The overall and relative product yields for the various olefin–SiF_2 reactions are summarized in Table 1. Typically ca. 50% of olefin reacted while polymer usually constituted 60–90% (by weight) of isolated product. While there are some patterns to the overall product distribution, there are also a number of unusual results. For example, TB gave a high yield of disilacyclobutane but no disilacyclohexane or chain isomer. On the other hand, IB produced an unusually high yield of the latter two products but a low polymer yield while DB produced an unusually high yield of chain compound relative to disilacyclohexane. It is also noteworthy that several of the disilacyclohexanes were formed in two isomeric forms and that two different chain derivatives were found for the DB reaction. Finally, only one disilacyclobutane was formed in the TB reaction. However, two disilacyclobutane isomers were formed in the CB reaction, with the product of the TB reaction representing 10% of the yield and a new isomer (referred to as CB isomer) representing 90% of the yield. Since the yield of disilacyclobutane from the TB reaction is ca. 20 times as great as from the CB (see Table 1), the 10% TB isomer from the CB reaction probably comes from traces of TB in the starting CB (see Experimental). Thus the formation of disilacyclobutanes is essentially 100% stereospecific. Evidence is presented elsewhere that these derivatives are formed with retention of alkyl stereochemistry (9).

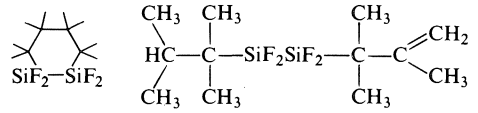
(b) Product Stabilities and Physical Properties

All products were air- and moisture-sensitive and were handled in vacuum. The polymers were yellow–white amorphous solids and were thermally stable at room temperature. All volatile products were clear liquids. The disilacyclohexanes were least volatile and were thermally stable at room temperature. Chain isomers were often sufficiently more volatile to allow partial column separation. A number of these compounds were thermally unstable. All of the disilacyclobutanes were unstable at room temperature, yielding clear polymeric products. The approximate order of the rate of polymerization was PR > IB > MB > ET > CB > TB with half-lives ranging from minutes to hours.

(c) Mechanism of Reaction of SiF_2 with Olefins

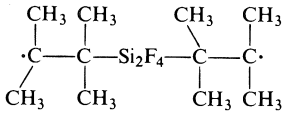
The main form of $(SiF_2)_n$ produced by the quartz tube method (11) is monomeric SiF_2 in its singlet state (13). However, Margrave and Perry suggested that the main reactive $(SiF_2)_n$ species in reactions with olefins and other unsaturated organic compounds is $F_2\dot{S}i—\dot{S}iF_2$, possibly produced via intermediate formation of $F_2Si{=}SiF_2$ (5). The main basis for this suggestion was the observation that most addition products from reaction of SiF_2 with unsaturated compounds contain Si_2F_4 units (2, 3), although insertion of SiF_2 into SiF and CF bonds is well established (6, 13). 2,2,3,3,7,7-Hexafluoro-2,3,7-trisilanorborn-5-ene (**V**) is the only well characterized compound with an isolated SiF_2 group (3, 14), resulting from reaction of SiF_2 with an unsaturated organic compound.

V



According to this suggestion, 1,2-disilacyclobutanes and 1,2-disilacyclohexanes are produced by the reaction of $F_2\dot{S}i—\dot{S}iF_2$ with 1 and 2 mol of olefin, respectively (5). If this mechanism is correct, then the reaction polymers should also contain mainly Si_2F_4 units.

Very recently, Seyferth and Duncan synthesized a difluorosilirane, **VI** (7)



VI

They observed that thermolysis of this product yielded two products (7) corresponding to those which have been observed from the reaction of SiF_2 with olefins (2, 3, 12).

VII **VIII**

This led them to suggest that the mechanism of the reaction of SiF_2 with olefins involved the initial formation of a silirane, followed by either ring opening or further reaction with SiF_2 (7). For example, ring opening of **VI** followed by dimerization should yield a biradical

which gives **VII** by ring closure and **VIII** by hydride transfer. Disilacyclobutanes could be formed by the reaction of SiF_2 with a silirane, by analogy with a similar reaction of dimethylsilyene (15).

This investigation has provided a significant amount of new information which can be used to test and modify these mechanistic proposals. Among the key points are: (*1*) the reaction polymers, which typically form 60–70% of isolated product, mainly contain isolated SiF_2 units (8, 9); (*2*) CB and TB produce 1,2-disilacyclobutanes with complete retention of configuration (9); (*3*) unsymmetric alkenes yield disilacyclohexanes with greater alkyl substitution at C(2) (10). More than one isomer is formed, whenever possible. For example, the disilacyclohexane from CB produces two major isomers, one with all-*cis* and the other with all-*trans* CH_3 groups (10); (*4*) the IB reaction gives a much smaller yield of polymer (34%) than other reactions plus a higher than normal yield of disilacyclohexane (32%) and its chain isomer (32%) (Table 1); (*5*) TB provides a much higher than normal yield of disilacyclobutane (37%) but no detectable amount of disilacyclohexane or chain isomer (Table 1). However, a mixed reaction of TB and PR with SiF_2 produces as one product a disilacyclohexane containing one TB and one PR unit (10); (*6*) TB (and to a lesser extent CB) yields a polymer with a significant proportion of Si_2F_4 units (8, 9). The polymerization reaction involves isomerization of the alkene linkages (9); (*7*) several alkenes yield open chain compounds which are isomers of 1,2-disilacyclohexanes while DB also yields a chain compound with an $(SiF_2)_3$ linkage (9); (*8*) a matrix isolation study of the reaction of SiF_2 with olefins has shown that when SiF_2 is co-

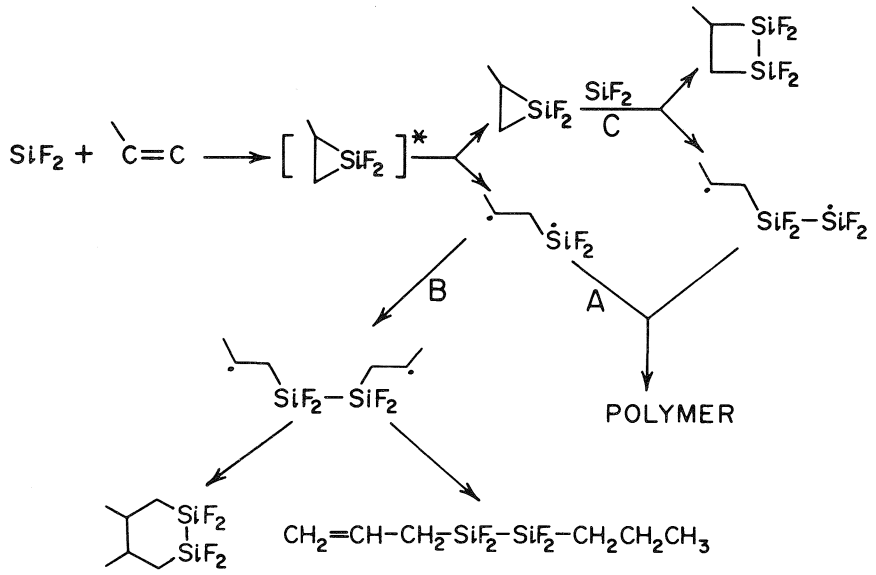


FIG. 1. Proposed mechanism to account for the reaction of SiF_2 with alkenes. Note that pathways *A* and *B* involve reaction of one of the biradicals with a silirane.

condensed with TB, a different esr signal is observed than for the $(SiF_2)_n$ polymer (16), suggesting the formation of radical intermediates in the SiF_2/olefin reaction.

Point *1* clearly demonstrates that SiF_2 is the major reactive $(SiF_2)_n$ species in this reaction series, in direct contradiction with the main assumption of the mechanism of Margrave and Perry (5). Point *2* also appears to be inconsistent with this mechanism since addition of $\dot{S}iF_2$—$\dot{S}iF_2$ to an olefin should either lead to scrambling of configuration if the reaction is stepwise or inversion of configuration if concerted (17).

However, points *1–4* as well as point *8* all appear to be consistent with the suggestion of Seyferth and Duncan that the reaction involves initial attack of singlet SiF_2 on the olefin. The one problem with the suggestion of Seyferth and Duncan concerns the observed stability of siliranes. **II** has a half-life in tetrahydrofuran solution of 1.75 h at 60°C (7), corresponding to a free energy of activation (presumably via ring opening) of 25 kcal/mol. The reactions under consideration here take place at −196°C in a frozen matrix. While some reaction may occur during subsequent warm-up, ring-opening of a ground state silirane appears improbable under these reaction conditions.

However, it appears possible to account for all of the observations for the unsymmetric alkenes by a minor modification of the mechanism of Seyferth and Duncan (7), shown in Fig. 1 for propene. The reaction of SiF_2 with alkenes should be strongly exothermic, leading to the formation of a vibrationally highly excited silirane. In a solid matrix, where normal mechanisms of energy relaxation such as collisional deactivation should be inefficient, some of the excited siliranes may open ring before they can drop down to the ground state. The probability of ring opening should be greatest for the reaction of unsymmetric alkenes since one of the Si—C bonds in the silirane should be weaker, corresponding to the carbon center which forms the more stable radical. There is direct evidence for the formation of an excited state product under identical experimental conditions for the analogous reaction of SiF_2 with C_6F_6 (18). In this case, chemiluminescence from excited $C_6F_5SiF_3$ can be observed visually as flashes of light in the solid matrix (18). There is also an analogy with the gaseous reaction of singlet CH_2 with alkenes. In this case, a "hot" cyclopropane is formed which partially isomerizes (19), presumably by ring opening. By contrast, the same reaction in solution, where collisional deactivation should be effective, yields unisomerized product (19).

The ring-opened silirane can attack a normal silirane, either initiating polymerization by carbon–silicon bond formation (path *A*) or forming a dimer by Si—Si bond formation (path *B*). Path *A* should normally be favoured due to the greater strength of C—Si bonds. However, in the IB reaction, path *B* must be the major reactive pathway (64% products derived from dimer as opposed to 34% polymer), probably because the dimer con-

tains two relatively stable tertiary carbon radical centers. The dimer from an unsymmetric alkene will yield disilacyclohexane with greater methyl substitution at C(2) and methyl isomerization at C(2) can occur by rotation about the C(1)—C(2) bond in the dimer.

Reaction of the silirane with a second mole of SiF_2 provides another reactive pathway (path *C*). Again one might obtain either a disilacyclobutane (formed with retention of configuration by SiF_2 bond insertion) or a ring-opened isomer. The latter could be incorporated into the polymer, accounting for the minor proportion of Si_2F_4 units.

In most reactions, no more than about 5% of the isolated products can be attributed to path *C*. The one major exception is TB where no products are observed corresponding to path *B* while disilacyclobutane is formed in 37% yield. Furthermore the polymer (63% yield) contains ca. 1/3 Si_2F_4 units which likely are due to path *C*. Thus in this case, it appears that the reaction proceeds by paths *A* and *C* in about a 40:60 ratio. The most likely explanation is that the TB silirane is particularly stable and a negligible amount of the ring-opened isomer is formed. The TB silirane might reasonably be expected to be the most stable silirane since the corresponding TB disilacyclobutane is the thermally most stable disilacyclobutane. However, formation of ring-opened disilacyclobutane is not unreasonable since all of the disilacyclobutanes are significantly less stable than **VI**. The ring-opened disilacyclobutane must have the structure shown since the alternative $\dot{S}iF_2$—C—C—$\dot{S}iF_2$ structure could not account for the observed isomerizations of alkene linkages in the TB reaction polymer. Kinetic factors may determine the structure of the ring-opened biradical. Polymerization presumably is initiated by the attack of a biradical on a silirane, yielding a polymer with both SiF_2 and Si_2F_4 units.

Other symmetric alkenes such as CB and DB appear to have reaction pathways intermediate between TB and the unsymmetric alkenes. It is significant that DB yields a relatively high yield of a chain isomer with Si_3F_6 units. This is most likely formed by attack of $(CH_3)_2\dot{C}$ — $C(CH_3)_2$ — SiF_2 — $\dot{S}iF_2$ on **VI** and is again favoured by the fact that the resultant biradical involves two tertiary carbon centers. CB reaction polymer contains about 10% Si_2F_4 units, suggesting a significant contribution from path *C* in this reaction. The only products whose origin cannot reasonably be attributed to this proposed mechanism are the fragments observed in the CB reaction. Basically the same mechanism can also account for the products of the acetylene/SiF_2 (5) and vinyl chloride/SiF_2 reactions (20), albeit with a different mode of hydride transfer to form the chain derivatives in the latter two cases.

Summary and Conclusions

The reaction of SiF_2 with olefins in a frozen matrix at −196°C produces four main types of products, with the relative yields varying significantly depending upon the olefin. The structures and stereochemistries of all of the observed disilacyclobutanes, disilacyclohexanes, chain isomers and polymers and the relative product yields can be accounted for by a mechanism in which the reaction of singlet SiF_2 with an alkene produces an activated silirane which can either open ring or relax to the ground state, followed in either case by subsequent reaction. While one cannot rule out the possibility of some involvement of $F_2\dot{S}i$—$\dot{S}iF_2$ in the reaction (5), we agree with the conclusion of Seyferth and Duncan that it is unnecessary to invoke this intermediate to account for the products (7).

The one obvious difficulty with this mechanism is the fact that no silirane has been directly detected in the reaction of SiF_2 with olefins (although small amounts of a compound of empirical formula $C_2H_4SiF_2$ was detected in the mass spectrum of the products of the reaction of SiF_2 with ET (2)). In view of the relative stability of ground state siliranes in solution (7), the failure to detect silirane might seem surprising. However, siliranes are also likely to be highly reactive (7). Since the reaction mixture likely contains SiF_2, ring-opened biradical isomers of the silirane and free radical polymer chains, all of which should be very reactive towards siliranes, the failure to observe siliranes as products is probably not surprising. It would appear that the best chance to detect silirane would be to condense SiF_2 into an excess of liquid olefin, where collisional deactivation may allow the silirane to relax rapidly to the ground state. This possibility is currently being investigated.

WILLIAM F. REYNOLDS, JAMES C. THOMPSON, and A. P. GERALD WRIGHT. Can. J. Chem. **58**, 425 (1980).

Polymers produced by the reaction of SiF_2 with olefins have been characterized by ^{13}C and ^{29}Si nmr spectroscopy and have been found to have a regular head-to-tail structure with isolated SiF_2 groups between olefin units. Only minor proportions of Si_2F_4 units are formed. The open chain organosilicon derivatives formed in the reaction are, with one exception, isomers of 1,2-disilacyclohexanes. The 1,2-disilacyclobutanes are formed stereospecifically with retention of alkyl stereochemistry. ^{19}F chemical shifts can be predicted by additive chemical shift parameters for the effect of alkyl substitution.

WILLIAM F. REYNOLDS, JAMES C. THOMPSON et A. P. GERALD WRIGHT. Can. J. Chem. **58**, 425 (1980).

La spectroscopie rmn du ^{13}C et du ^{29}Si a permis d'identifier les polymères issus de la réaction du SiF_2 avec les oléfines; on a trouvé qu'ils possèdent une structure régulière tête-queue avec des groupes SiF_2 isolés entre des unités oléfiniques. On rencontre de faibles proportions de groupes Si_2F_4. Les chaînes ouvertes de silanes formées au cours de la réaction sont, à une exception près, les isomères des disila-1,2 cyclohexanes. Les disila-1,2 cyclobutanes sont formés stéréospécifiquement avec rétention de la stéréochimie du groupe alkyle. Les déplacements chimiques du ^{19}F peuvent être prévus à l'aide des paramètres additifs de déplacement chimique relatif à l'effet des substituants alkyles.

Introduction

In the previous paper in this series, we have reported the product yields for the reaction of SiF_2 with a series of olefins (1). The evidence provided by both the product yields and the structures of the products was used to postulate a mechanism for this complex reaction (1). In this paper, we discuss the details of the spectroscopic characterization of three types of products: 1,2-disilacyclobutanes, open chain compounds, and polymers. These products were characterized by a combination of ^{19}F, ^{13}C, and ^{29}Si nmr spectroscopy.

The formation of disilacyclobutanes in the SiF_2–olefin reaction has been known for some time (2). Subsequently, reactions of SiF_2 with *cis*-2-butene (CB) and *trans*-2-butene (TB) were shown to be highly stereospecific with respect to alkyl configuration, although it was not known whether this involved retention or inversion of alkyl stereochemistry (3). This investigation has demonstrated that the reaction is 100% stereospecific (1). It is important to determine the absolute stereochemistry since it has been predicted that the reaction should involve inversion of configuration if it occurred by concerted addition of $\dot{S}iF_2$—$\dot{S}iF_2$ to the olefin (3).

The formation of open chain compounds has been observed in the reaction of SiF_2 with both alkenes (4) and alkynes (5), although the former have not been well characterized. Similarly, although polymers are usually the major products of the reaction of SiF_2 with unsaturated organic compounds (2, 4) (typically 60–70% for the olefin reaction (1)), these polymers have not been characterized. Rather, speculation concerning the mechanism of the reaction of SiF_2 with unsaturated organic compounds has been based upon the structures of the volatile products (6–8) which are in fact only minor products in these reactions. The structures of the polymers are obviously the key to answering the primary question of whether SiF_2 (8) or Si_2F_4 (6) is the major attacking species in this reaction. The answers to these structural questions are provided below.

Experimental

All experimental details are given in ref. 1.

Results and Discussion

(a) Nomenclature

The olefin used in the reaction is identified by capital letters, as shown above. Four-membered rings (1,2-disilacyclobutanes) and six-membered rings (1,2-disilacyclohexanes) are designated -c4 and -c6 respectively. Thus a disilacyclobutane from the reaction of SiF_2 with *cis*-2-butene is shown as CB-c4. Possible stereochemical variations of such compounds are discussed in the text.

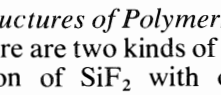
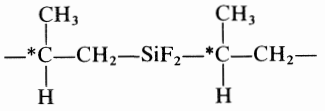
(b) Structures of Polymers[3]



There are two kinds of polymers produced in the reaction of SiF_2 with olefins. The first is the polymer which is produced directly in the reaction. This in each case was an amorphous yellow solid or highly viscous liquid. The polymers produced from propene (PR), *cis*-2-butene (CB), *trans*-2-butene (TB), and 2-methyl-2-butene (MB) reactions were all soluble in $CDCl_3$ while the isobutylene (2-methylpropene) (IB) polymer was sparingly soluble. The polymers from ethylene (ET) and 2,3-dimethyl-2-butene (DB) were insoluble in non-polar solvents and reacted with polar solvents.

In addition to the reaction polymers, the disilacyclobutanes also thermally polymerize (1). In a number of the cases, the initial yield of disilacyclobutane was so small that there was insufficient polymer to characterize. However, the polymers produced from the CB and TB disilacyclobutane derivatives (henceforth designated CB-c4 and TB-c4) were characterized. Since the ratio of alkene to SiF_2 is known (1:2) in these compounds, these compounds proved to be particularly useful in characterizing the CB and TB reaction polymers.



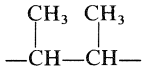
^1H and ^{19}F spectra of the polymers were generally uninformative with broad, poorly resolved peaks (the exception to this was the ^{19}F spectrum of the PR polymer, see below). However, ^{13}C and particularly ^{29}Si spectra proved to be very useful for polymer characterization. These spectra demonstrated that PR, IB, and MB reaction polymers all have surprisingly simple and regular structures. The PR polymer will be discussed in detail since it is typical. ^{29}Si and ^{13}C spectra for this polymer are shown in Fig. 1. The ^{29}Si spectrum is a 1:2:1 triplet with a 314 Hz coupling constant, typical of a one bond ^{29}Si–^{19}F coupling constant in organosilicon fluorides (10). No splitting is observed due to two-bond ^{29}Si–Si–^{19}F coupling. Consequently, the polymer must contain isolated SiF_2 units between alkene units. The ^{13}C spectrum is also simple, showing a singlet at δ15.3 assigned to methyl groups and two triplets ($J_{^{13}C-^{19}F}$ = 15 Hz) at δ11.3 and δ10.4, assigned to CH_2 and CH groups adjacent to SiF_2 units. This simple spectrum plus the fact that the ^{29}Si spectrum showed only one type of silicon demonstrates that the polymer has a regular

structure. More than one ^{29}Si signal and more than one ^{13}C methyl signal would be expected if the polymer contained a mixture of head-to-head and head-to-tail units or if it contained blocks of

and $-(SiF_2)_n-$ units. The ^{19}F spectrum of the PR polymer showed two AB quartets, indicative of two types of diastereotopic SiF_2 units (10). Since the propene linkage contains a chiral center, two types of SiF_2 units are possible, depending upon whether the SiF_2 is between two alkene linkages with the same or opposite stereochemistry (respectively labelled isotactic and syndiotactic diads (11))

The two AB quartets had essentially equal areas indicating that the polymer had an atactic (i.e. random) structure with respect to the stereochemistry of the alkene linkages (10).[4]

IB and MB reaction polymers show similar simple ^{29}Si and ^{13}C spectra (see Table 1 for ^{29}Si data) (9). However, the TB and CB reaction polymers have a more complicated structure. The TB polymer ^{29}Si spectrum shows not only the normal triplet spectrum but a significant additional component which is a triplet of triplets (Fig. 2*a*). This additional component exactly corresponds to the ^{29}Si spectrum of the polymer from the thermal polymerization of TB-c4 (Fig. 2*b*). Thus it can be attributed to Si_2F_4 units. Allowing for the fact that the spectrum due to Si_2F_4 units should be twice as intense, the ratio of SiF_2:Si_2F_4 is about 1:0.5 in the TB reaction polymer. The CB reaction polymer also has Si_2F_4 units but only in the ratio SiF_2:Si_2F_4 = 1:0.2 (Table 1). The other polymers contain only trace amounts (ca. 1–2%) of Si_2F_4 units (e.g. see Fig. 1).



The ^{13}C spectra of the CB and TB reaction polymers are complex (Fig. 3). Both polymers show four methyl peaks at δ13.6, 11.6, 10.0, and 8.9. By contrast, the polymers produced by polymerization of TB-c4 and CB-c4 each show a single methyl peak, respectively at δ8.9 and δ11.6 (precisely corresponding to two of the peaks in the reaction polymer spectra). The single peak methyl spectra indicated that TB-c4 and CB-c4 both polymerize with retention of configuration, as expected if the polymerization involves breaking of the weak Si—Si bond. Assuming that the polymer chains prefer to adopt an *anti* conformation, the CB methyl groups should be in *anti* conformation while the methyl groups are in a *gauche* conformation for

[3]A preliminary account of part of this work has appeared elsewhere (9).

[4]Liu has reached identical conclusions concerning the structure of these polymers based on their ^{19}F spectra (12).

the TB-c4 polymer. The methyl ^{13}C chemical shifts are consistent with this assumption since the methyl groups in the TB-c4 polymer show the expected high field shift due to a *gauche* γ interaction (13).

The methyl peaks in the CB and TB reaction polymers can be assigned by assuming that two types of

linkages are present with the same stereochemistries as the linkages in CB-c4 and TB-c4 polymers (respectively referred to as CB and TB linkages). In addition, different chemical shifts should be noted for CH_3 groups adjacent to SiF_2 and Si_2F_4 linkages, leading to four peaks. Methyl groups in CB and TB linkages and adjacent to Si_2F_4 units are assumed to have the same chemical shifts as methyl groups in CB-c4 and TB-c4 polymers (respectively δ11.6 and δ8.9). The remaining two peaks are assigned to CH_3 groups adjacent to SiF_2 units with the peak in a TB linkage again assumed to be at high field to the methyl group in a CB linkage. With this assignment, it is seen that the TB reaction polymer again contains a higher proportion of Si_2F_4 than the CB reaction polymer (see Fig. 3). However, it also indicates that both reaction polymers contain about the same ratio of CB linkages:TB linkages of about 2:1. This suggests that isomerization of the alkene linkages occurs during polymerization, apparently leading to a thermodynamic product distribution (the CB linkages should be more stable since there is a *gauche* methyl steric interaction in the TB linkage (see above)).

To summarize this section, PR, IB, and MB polymers show a regular structure with isolated SiF_2 units between alkene units oriented in a head-to-tail fashion. CB and particularly TB reaction polymers also contain Si_2F_4 units although SiF_2 units still predominate (SiF_2:Si_2F_4 = 1:0.5 for TB and 1:0.2 for CB). The polymerization involves isomerization of alkene linkages, yielding an apparent thermodynamic distribution with a ratio of CB linkages:TB linkages of about 2:1.

(c) Structure of Open Chain Organosilicon Derivatives

PR, IB, MB, and DB all give open chain organosilicon derivatives while ET and TB give no compounds of this type and CB yields different fragment compounds (1). The open chain organosilicon compounds all give complex ^1H spectra for the alkyl region, compounded by the fact that these

derivatives cannot be completely separated from the disilacyclohexane products. However, the ^1H spectra of the alkene region as well as ^{19}F and sometimes ^{13}C spectra all yield useful structural information (see Table 2). The chain derivative from PR clearly contains a terminal vinyl group **I**, while IB and MB chains have terminal vinylidene groups **II** (as indicated by the absence of large vicinal ^1H couplings):

I **II**

DB gives two isomers in a 4:1 ratio, each con-

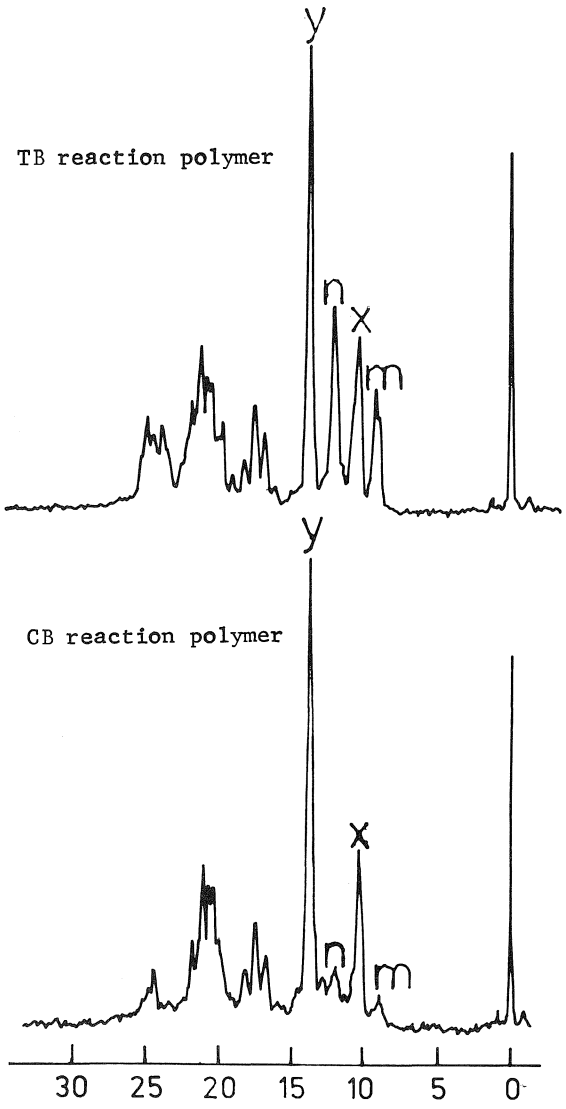

FIG. 3. ^{13}C spectra of TB and CB reaction polymers. Peaks m and n are CH_3 signals identical to those observed for the corresponding polymers from TB-c4 and CB-c4 while peaks x and y are CH_3 signals adjacent to SiF_2 units and with the same respective stereochemistry for the —CH(CH$_3$)—CH(CH$_3$)— linkage as in TB-c4 and CB-c4 (see text).

taining a vinylidene group. PR and IB chains give two SiF_2 signals in their ^{19}F spectra while DB gives two compounds with unsymmetric SiF_2SiF_2 and $(SiF_2)_3$ units in a 1:4 ratio. MB also gives a compound with an SiF_2—SiF_2 linkage but with four non-equivalent fluorines, indicating the presence of at least one chiral center in the molecule. Finally, the ^{13}C spectra of the PR chain shows two olefinic carbons and four saturated carbons, two with significant ^{13}C–^{19}F coupling (the olefinic carbons show no significant coupling).

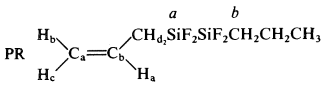
Structures for the chain derivatives which are consistent with all the spectral information are shown in Table 2. With the exception of the $(SiF_2)_3$ derivative from DB, all of these compounds are isomers of the corresponding disilacyclohexanes (14), suggesting a common intermediate (8). The proposed structure of the $(SiF_2)_2$ derivative of DB is identical to one of the products observed by thermolysis of a tetramethylsilirane (8). One other interesting observation is that the alkene group in each chain isomer is apparently formed between a carbon β to silicon plus a γ carbon which was an alkyl group in the starting alkene. This is apparently essential in this system since ET gives no chain isomer (1, 2). This contrasts with the reactions of acetylene (5) and vinyl chloride (15) with SiF_2 since these yield chain compounds with respective structures **III** and **IV**:

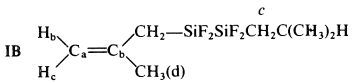
$HC{\equiv}C{-}Si_2F_4{-}CH{=}CH_2$ **III** $ClCH{=}CH{-}Si_2F_4{-}CH_2CH_2Cl$ **IV**

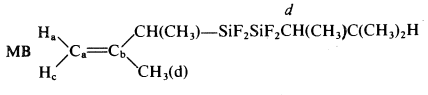
Apparently relatively subtle electronic effects determine the preference for formation of an unsaturated α,β or β,γ bond in these chain derivatives.

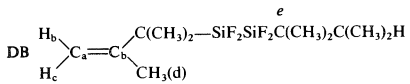
CB gives no chain derivatives similar to those shown in Table 1. Instead, a small amount of two other compounds are formed which cannot be completely separated and have not been fully characterized. However, one compound appears to contain a terminal vinyl group but no SiF_2 units. It is of too low volatility to be a butene isomer (10). The other compound contains apparent SiF_2H and SiF_3 units and saturated carbons but no vinyl groups (10). The origins of these derivatives are unknown.

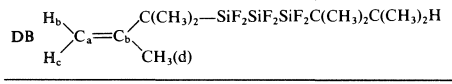
(d) Characterization of Disilacyclobutane Derivatives, Including Stereochemistry











(i) Establishment of Basic Structure

All compounds showed extensive ^{19}F–^{19}F coupling (see below), indicative of the presence of an SiF_2—SiF_2 unit and thus ruling out a 1,3-disilacyclobutane structure. The empirical formula of the ET derivative has already been established as $C_2H_4Si_2F_4$ by mass spectrometry (2). The ^{13}C spectrum of this derivative shows a single peak in the aliphatic region (δ8.9), ruling out a possible open chain structure such as $CH_2{=}CH{-}SiF_2{-}SiF_2H$. Thus it is clear that these products are 1,2-disilacyclobutanes.

Many cyclobutanes undergo rapid interconver-

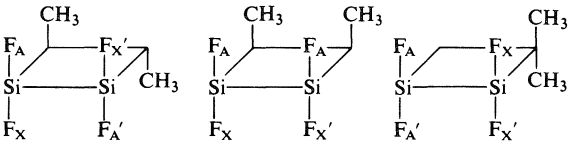
sion between non-planar forms (e.g. E_A = 1.3 kcal/mol for ring flipping in difluorosilacyclobutane (16)).

On the other hand, a recent X-ray crystal structure determination for a 1,2-disilacyclobutane has shown a planar ring (17). We have measured the ^{19}F spectra of disilacyclobutanes down to −113°C without seeing any evidence of "freezing out" of a conformational process. Since, in practical terms, it is impossible to distinguish between a planar ring and a rapidly interconverting non-planar structure, we will discuss these products as if they were planar.



(ii) Stereochemistry of Formation of Disilacyclobutanes

As noted above, the formation of a 1,2-disilacyclobutane from an alkene is a highly stereospecific reaction. This is very important from a mechanistic viewpoint since, if one assumes that $F_2\dot{S}i—\dot{S}iF_2$ is the attacking species in the formation of disilacyclobutane (6), orbital symmetry arguments predict inversion of configuration for a concerted thermal cycloaddition reaction (3). Thus it is important to establish the stereochemistry of the reaction.

^{19}F spectra proved most useful for determining the specific structures of disilacyclobutanes. All spectra were recorded at −40°C to minimize thermal polymerization. The disilacyclobutane from ethylene (thereforth designated ET-c4) gave an $A_4{}^{19}F$ spectrum but the ^{29}Si satellite peaks (due to ET-c4 containing one ^{29}Si atom) showed an AA′XX′ pattern. The products of propene (PR-c4) and methylbutene (MB-c4) reactions showed four non-equivalent ^{19}F peaks in essentially first order (AKRX) spectra. IB-c4 and TB-c4 gave AA′XX′ spectra while CB-c4 gave an AA′BB′ spectrum due to the smaller ^{19}F chemical shift difference in this compound (1.6 ppm).

The spectra were complicated by significant ^1H–^{19}F coupling. However, the ^1H-decoupled spectra showed simple splitting patterns (see Fig. 4). Although there are, in principle, two *gauche*, two *trans*-vicinal, and two *cis*-vicinal ^{19}F–^{19}F coupling constants in compounds such as PR-c4, pairs of coupling constants were similar in magnitude. PR-c4 showed three splittings of ca. 41 Hz, 15 Hz, and 2 Hz while MB-c4 showed splittings of ca. 44 Hz, 16 Hz, and 2 Hz. Similar splittings were observed in the ^{29}Si satellite spectra of CB-c4 and TB-c4 (the satellites give AKRX spectra due to the four non-equivalent fluorines in a singly-labelled compound). Thus ^{19}F–^{19}F coupling constants in disilacyclobutanes are relatively insensitive to methyl substitution and the observed splittings of ca. 42 Hz, 16 Hz, and 2 Hz can be assigned as geminal, *trans*-vicinal, and *cis*-vicinal couplings although not necessarily in that order.

TB-c4 must have either structure **VI** (retention of alkyl configuration) or **VII** (inversion of configuration) while CB-c4 has the other structure of this pair (IB-c4 must have structure **VIII**):

VI **VII** **VIII**

Note that the coupling between equivalent fluorines $J_{AA'}$ (and $J_{XX'}$) respectively corresponds to *trans*-vicinal, *cis*-vicinal, and geminal coupling constants in **VI**, **VII**, and **VIII**. $J_{AA'}$ for TB-c4, CB-c4, and IB-c4 can be determined by spectral analysis. Consequently, if the relative magnitudes of the *trans*- and *cis*-vicinal coupling constants are known, then it should be possible to assign unambiguously the structures of TB-c4 and CB-c4. Unfortunately, ^{19}F–^{19}F couplings in analogous carbon compounds provide no help in making this assignment since they vary in an extremely complex way with substitution and are of little value in assigning stereochemistry (18). However 2,2,3,3,7,7- heptafluoro-2,3,7-trisilanorborn-5-ene (5) (see Fig. 5) contains an Si_2F_4 unit in which *trans*- and *cis*-vicinal coupling constants can be assigned with confidence since the *cis*-vicinal coupling must be between equivalent fluorines. Detailed analysis of the AA′XX′ spectrum for the Si_2F_4 unit of this compound (including the use of ^{29}Si satellites) has shown that $|J_{trans\text{-vicinal}}| = 15$ Hz while $J_{cis\text{-vicinal}} = 0 \pm 0.5$ Hz (10). The geminal coupling has a magnitude of 33 Hz while the bridgehead SiF_2 shows a geminal coupling of 61 Hz. These are sufficiently close to the observed splittings of ca. 42 Hz, 15 Hz, and 2 Hz in disilacyclobutanes that the latter can be assigned with reasonable confidence as respectively geminal, *trans*-vicinal, and *cis*-vicinal coupling constants.

These splittings can be used to generate sample AA′XX′ spectra for comparison with the experimental AA′XX′ (or AA′BB′) spectra for IB-c4, CB-c4, and TB-c4. One problem is that it is not normally possible to determine relative signs of coupling constants by analysis of AA′XX′ spectra since different solutions are possible, corresponding to different signs and magnitudes of the cou-

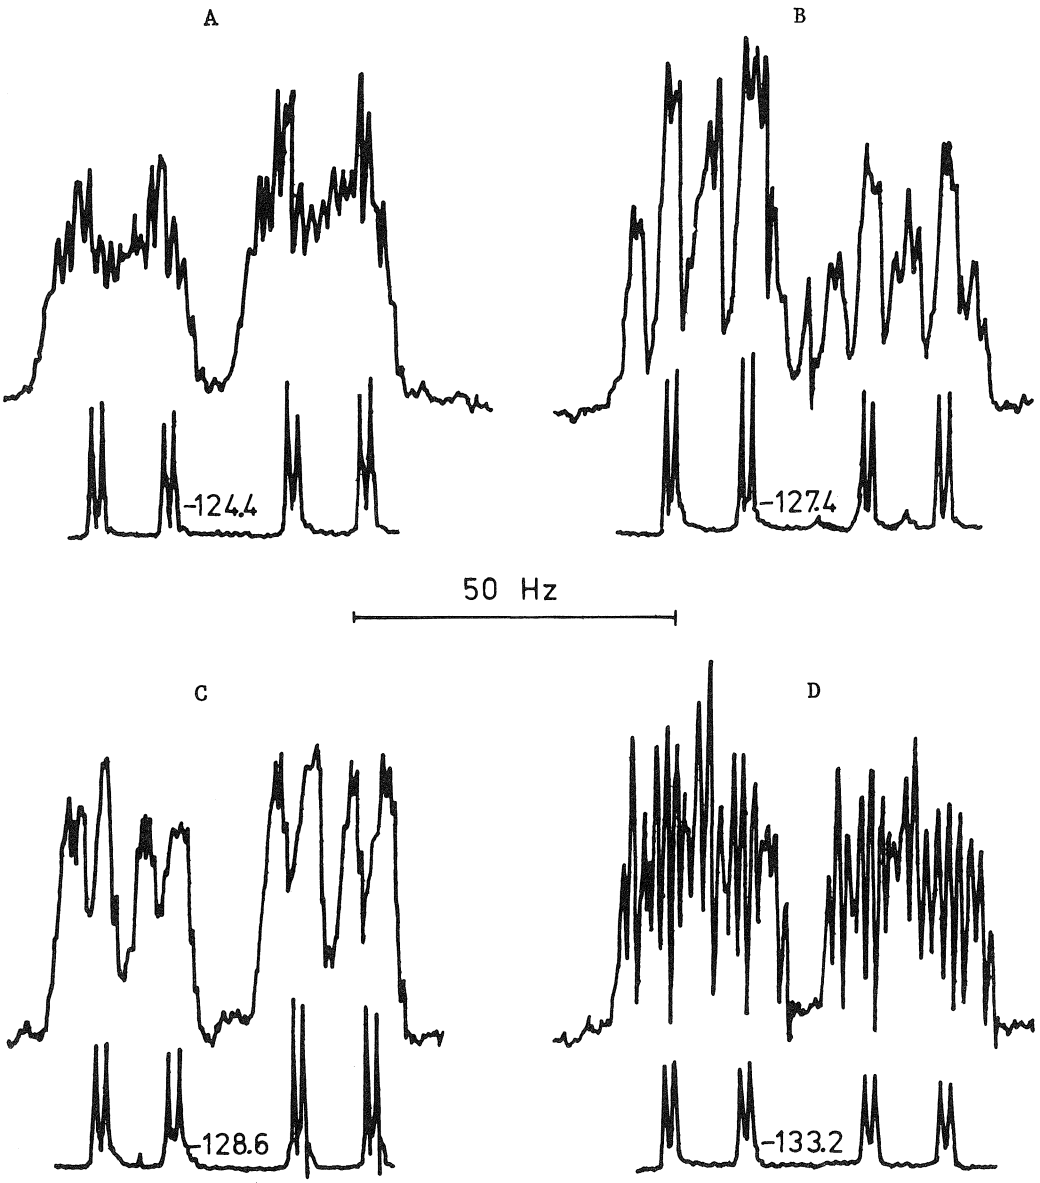

FIG. 4. ^{19}F peaks for four non-equivalent fluorines in PR-c4. The lower spectrum in each case is ^{19}F decoupled.

pling constants (19). However, in this case, it is possible to determine the relative signs of all three coupling constants because the magnitudes of the couplings are known and because three compounds of different symmetry are available for comparison. The sample spectra showed that the only combination which provided a good fit for all three experimental spectra was one in which the geminal coupling constant had the opposite sign to the two vicinal coupling constants (10). Since $J_{^{19}F-C-^{19}F}$ is typically ca. +200 Hz (18), it is likely that the geminal ^{19}F–Si–^{19}F coupling is also positive and that the vicinal coupling constants are negative.

More importantly, the TB-c4 spectrum could only be fitted if the coupling between equivalent fluorines was 15 Hz, corresponding to a *trans*-vicinal coupling constant. Consequently TB-c4 has structure **VI** and must be formed from TB with *retention of stereochemistry*. Similarly, the CB-c4 spectrum was only fitted with $|J_{AA'}| = 2$ Hz, i.e. a *cis*-vicinal coupling, indicating that CB-c4 had structure **VII**.

The above-mentioned signs and magnitudes of the three coupling constants were used as initial input parameters for an interative spectral analysis, using the computer program LAOCN3 (20). This

[a]In ppm relative to internal $CFCl_3$ (high field shifts negative).
[b]Coupling assumed positive by analogy with $^2J_{^{19}F-C-^{19}F}$ (see text).
[c]The ^{29}Si satellites of ET-c4 resembled the IB-c4 spectrum and allowed determination of only the *cis*-vicinal and *trans*-vicinal coupling.
[d]Iterative analysis gave identical values for this pair of coupling constants even though they could in principle be non-equivalent.
[e]Coupling between equivalent fluorines ($J_{AA'}$, $J_{XX'}$).
[f]The geminal couplings have a relatively larger uncertainty (ca. 5 Hz) since the spectrum is relatively insensitive to the magnitude of this coupling.

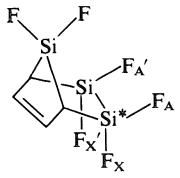

FIG. 5. Structure of trisilanobornene which was used to assign vicinal and geminal $^{19}F-^{19}F$ coupling constants. Note that when the molecule contains one ^{29}Si in the Si_2F_4 unit, all four fluorines in this unit are non-equivalent.

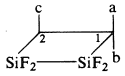

gave more precise values for the various coupling constants. The results are summarized in Table 3. It is particularly noteworthy that the vicinal coupling constants show little effect of alkyl substitution, lending further confidence to their use in stereochemical assignments. Similarly the geminal couplings fall in the range +41 ± 4 Hz.

Further support for the assigned structures of TB-c4 and CB-c4 is obtained from the ^{13}C chemical shift data for the disilacyclobutanes (see Table 4). The key point concerns the ^{13}C chemical shifts for the methyl groups of CB-c4 and TB-c4. The methyl peak for the former compound (δ7.5) is more than 5 ppm to high field to the methyl peak for the latter (δ12.6). It is well established that two methyl groups in a γ orientation are more shielded when they are spatially proximate (13). Thus the compound with *cis* methyl groups should give a methyl signal to high field of that with *trans* methyl groups. Thus the ^{13}C chemical shift data also indicate that CB-c4 and TB-c4 are formed with retention of alkyl stereochemistry.

TABLE 4. ^{13}C chemical shifts of 1,2-disilacyclobutanes[a]

	δ[b]				
	Ring carbon[c]		Methyl carbon[c]		
Compound	1	2	a	b	c

CB-c4	23.93	23.93	7.50	—	7.50
TB-c4	29.01	29.01	—	12.50	12.50

[a]Chemical shifts were not assigned for IB-c4 and MB-c4 due to low concentrations and because ^{13}C peaks were partially obscured by peaks from chain and disilacyclohexane derivatives.
[b]In ppm from internal $(CH_3)_4Si$. Low field shifts positive.
[c]Carbon labelled

This is also indicated by consideration of the ^{19}F chemical shifts. The ^{19}F chemical shift difference for TB-c4 (12.0 ppm) is much larger than for CB-c4 (1.6 ppm) while the four non-equivalent fluorines in PR-c4 give signals over an 8.8 ppm range. The relatively large effect of a methyl group upon individual

TABLE 5. Comparison of observed and predicted ^{19}F chemical shifts for disilacyclobutanes

Compound		Predicted and observed chemicals shifts (δ)[a]			
		A	B	C	D

	Predicted				−136.8 (−134.4)

[a]Relative to internal $CFCl_3$ in ppm. High field (low frequency) shifts are negative. Solutions contained ca. 10% compound in $CFCl_3$ with 10% $(CD_3)_4Si$ added to provide the internal lock signal.
[b]Predicted using additivity parameters from PR-c4 (see Fig. 3).
[c]Predicted using additivity parameters from PR-c4 for the effect of a $CHCH_3$ group and parameters for IB-c4 for the effect of $C(CH_3)_2$ (see Fig. 3).
[d]A minor peak was noted at this frequency which may be due to DB-c4 which is produced in a very low yield.

^{19}F chemical shifts in PR-c4 suggests the possibility of deriving additive chemical shift parameters to predict ^{19}F chemical shifts in **VI** and **VII** for comparison with CB-c4 and TB-c4. The average chemical shifts for ET-c4 (δ − 125.6), PR-c4 (δ − 128.4), CB-c4 (δ − 131.4), and TB-c4 (δ − 131.0) indicate that this procedure should be valid since they show an incremental shift of δ − 2.8 ± 0.2 for addition of each methyl group.

In order to derive an additivity scheme, one must first assign the individual ^{19}F resonances in PR-c4. There are sufficient differences in the two geminal couplings to allow one to conclude that fluorines A (δ − 124.4) and B (δ − 137.4) are on one silicon while fluorines C (δ − 128.6) and D (δ − 133.2) are on the other silicon (this was confirmed by homonuclear decoupling). A more complete assignment can be arrived at by making use of the ^1H–^{19}F coupling which is clearly visible in Fig. 4. Selective hydrogen decoupling plus consideration of the magnitudes of the individual ^1H–^{19}F coupling constants leads to the assignment shown in Fig. 6 (10). This assignment allows the derivation of parameters for the effect of CH_3 on individual ^{19}F chemical shifts. The chemical shift parameters in Fig. 6 indicate an upfield ^{19}F shift due to a proximate γ methyl and a downfield shift due to a proximate δ methyl. Similar effects were noted in disilacyclohexanes (14). Interestingly, ^{13}C spectra also show upfield γ

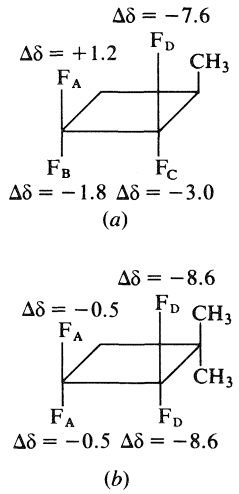

FIG. 6. Additive chemical shift parameters indicating the effect of (*a*) a single methyl group and (*b*) a $(CH_3)_2C$ group on the ^{19}F chemical shifts of 1,2-disilacyclobutanes.

(13) and downfield δ (21) shifts due to methyl–methyl steric interactions.

The parameters for Fig. 6 can be used to predict the chemical shifts of other disilacyclobutanes (Table 5). These predictions again indicate that CB-c4 and TB-c4 have respectively *cis* and *trans* methyl groups, i.e. they are formed with retention of stereochemistry. The additivity parameters are not as good at predicting MB-c4 ^{19}F chemical shifts. Additivity apparently breaks down when two methyls are substituted on the same carbon since the incremental contribution to the average chemical shifts is only -1.6 ± 0.2 ppm in this case (e.g. PR-c4 (δ − 128.4) → IB-c4 (δ − 130.1), CB-c4 (δ − 131.4) or TB-c4 (δ − 131.0) → MB-c4 (δ − 132.8)), compared to -2.8 ± 0.2 ppm for addition of a methyl group to an unsubstituted carbon. This may reflect either a saturation of substitutent effects or an alteration of the conformational equilibrium between different non-planar forms of the disilacyclobutane ring (see above). One way around this problem is to use IB-c4 shifts as a measure of the effects of a $(CH_3)_2C$ grouping (Fig. 6). When this is done, the agreement for MB-c4 is improved. In addition, the predicted ^{19}F chemical shift for DB-c4 is much closer to that observed for a minor peak tentatively assigned to this compound.

Summary and Conclusions

The polymers produced by the reaction of SiF_2 with olefins generally have a regular structure with isolated SiF_2 units between olefin linkages, with the olefin linkages in a regular head-to-tail fashion. This demonstrates that monomeric SiF_2 is the major reactive $(SiF_2)_n$ species in this reaction. The polymers from TB and, to a lesser extent, from CB also contain Si_2F_4 units. Polymerization occurs via a mechanism which allows scrambling of the alkene configuration.

Open chain derivatives have the general formula $R—(SiF_2)_n—R'$ where R is an alkyl group and R′ contains a terminal olefin function. With one exception, they contain Si_2F_4 units and are isomers of the corresponding 1,2-disilacyclohexane. DB also yields a derivative with an $(SiF_2)_3$ unit.

1,2-Disilacyclobutanes are formed with complete retention of stereochemistry of the alkyl groups in the starting olefin. This is clearly apparent from a consideration of ^{19}F–^{19}F coupling constants and ^{13}C and ^{19}F chemical shifts.

This information, along with further data concerning product yields (1) and structure of 1,2-disilacyclohexanes (14) are used to develop a detailed mechanism of the SiF_2–olefin reaction (1).

1,2-Disilacyclohexanes are generally formed as products in the reaction of SiF_2 with alkenes. Unsymmetric methyl-substituted alkenes yield disilacyclohexanes with greater methyl substitution at C(2). Often two (or more isomeric) products are formed, and the reaction proceeds by a mechanism which allows isomerization of the methyl configurations. The disilacyclohexanes exist in distorted chair conformations and the chair-to-chair interconversion can be observed at low temperature in many cases. Consideration of the variable temperature ^{19}F spectra and the effect of methyl groups on average and individual ^{19}F chemical shifts allows assignment of configurations and preferred conformations of all disilacyclohexane derivatives.

WILLIAM F. REYNOLDS, JAMES C. THOMPSON et A. P. GERALD WRIGHT. Can. J. Chem. **58**, 436 (1980).

La réaction du SiF_2 avec les alcènes conduit généralement aux disila-1,2 cyclohexanes. Les alcènes non symétriques portant un substituant méthyle conduisent à des disilacyclohexanes dans lesquels le groupe méthyle est porté de préférence par le carbone en position 2. Il se forme souvent deux (ou plusieurs) produits isomères et la réaction a lieu selon un mécanisme qui permet une isomérisation de la configuration des méthyles. Les disilacyclohexanes existent sous la forme chaise déformée, et dans plusieurs cas, on peut observer des interconversions chaise–chaise à basse température. On peut attribuer les configurations et les conformations préférentielles de tous les dérivés disilacyclohexanes en tenant compte des spectres du ^{19}F à des températures variables et de l'effet des substituants méthyles sur les déplacements chimiques moyens et individuelles du ^{19}F.

Introduction

Disilacyclohexanes are often formed in significant yield in the reaction of SiF_2 with alkenes (1–3). In our systematic investigation of the reaction of SiF_2 with ethylene and six methyl-substituted ethylenes, disilacyclohexane products were found in six of the seven reactions (3). In a number of cases, two or more isomeric disilacyclohexanes were formed (3). Furthermore, when a mixture of ethylene (ET) and propene (PR) was reacted with SiF_2, one of the major products was a mixed disilacyclohexane containing 1 mol ET and 1 mol PR (4). A similar mixed disilacyclohexane (in two isomeric forms) was obtained from the reaction of SiF_2 with a mixture of PR and *trans*-2-butene (TB) (4).

There are a number of possible structures for these derivatives. In addition, they would be expected to exist in chair conformations, with the possibility of observing the chair-to-chair interconversions from low temperature nmr spectra, just as in the case of cyclohexane (5).[3] Thus it is an interesting spectroscopic problem to determine the structures of these products and to investigate their conformational behavior. In addition the structures provide relevant information about the mechanism of the SiF_2–olefin reaction (6, 7). Fortunately it has proved possible to identify all of the major disilacyclohexane products and to determine their preferred conformations, using ^{13}C and variable temperature ^{19}F nmr spectroscopy, in conjunction with additive ^{19}F chemical shift parameters (4). These results are discussed below.

Experimental

Experimental details are given in ref. 3.

Results and Discussion

(a) Nomenclature

The olefin used in the reaction is identified by capital letters, as shown above. Four-membered rings (1,2-disilacyclobutanes) and six-membered rings (1,2-disilacyclohexanes) are designated -c4 and -c6 respectively. Thus, a disilacyclohexane resulting from the reaction of SiF_2 with a mixture of *trans*-2-butene and propene is shown as TBPR-c6. Further stereochemical differences between such compounds are shown in the tables and discussed in the text.

(b) Basic Structures of Disilacyclohexanes

The reaction of PR with SiF_2 is typical of alkene–SiF_2 reactions. The room temperature ^{19}F

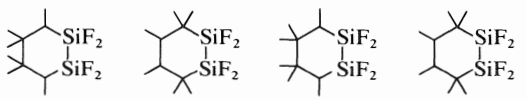
spectrum of the disilacyclohexane (henceforth designated as PR-c6) shows that two isomers were formed, each with two ^{19}F signals (see Fig. 1). Either 1,2 (**I**) or 1,4 (**II**) isomers could be formed:

I **II**

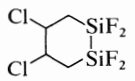
However, the spectrum shows large $^{19}F-^{19}F$ coupling for both isomers. Thus they both must have ring structure **I** since the 1,4 isomer would be expected to show very small (5-bond) $^{19}F-^{19}F$ coupling (8). In fact, all of the disilacyclohexanes detected in this investigation had the 1,2 structure. This is an interesting observation since the reaction of $SiCl_2$ with ethylene yields 1,4-disilacyclohexane (9).



There are three possible substitution patterns for the 1,2 PR-c6 isomers:

III **IV** **V**

In addition, there are two possible configurational isomers for each positional isomer: a *cis* (up,up or U,U) isomer, where both methyl groups are attached to the same face of the ring and a *trans* (up,down or U,D) isomer, where the two methyl groups are on opposite faces. Structure **IV** can be ruled out since each configurational isomer should show four non-equivalent fluorine peaks, rather than two. A choice can be made between structures **III** and **V** on the basis of ^{13}C spectral data. Each isomer gives three peaks. In each case, it is possible to assign C(1) (the carbon adjacent to Si) since it shows significant $^{13}C-^{19}F$ coupling. Off-resonance ^{1}H decoupling showed a complex multiplet for this peak while the remaining two peaks for each isomer appeared as a doublet and a quartet. The latter must be the methyl group while the former must be C(2). C(2) must be a tertiary carbon to account for the doublet splitting, indicating methyl substitution at C(2), i.e. structure **III**. Thus the two PR-c6 isomers must be the *cis* and *trans* isomers of **III**.



The 1,2-disilacyclohexanes produced from isobutylene (IB-c6) and 2-methyl-2-butene (MB-c6) also have two different possible structures (the ^{19}F spectra again ruled out unsymmetrically substituted isomers);

IB-c6 (**A**) IB-c6 (**B**) MB-c6 (**A**) MB-c6 (**B**)

Again, off-resonance decoupling indicated greater methyl substitution at C(2) in each case (structure **A**) (4).

Preferred methyl substitution at C(2) is also indicated by the ^{13}C chemical shift data. All of the disilacyclohexanes gave methyl peaks in the range δ17–29 (see Table 1) comparable with the methyl ^{13}C chemical shift in methylcyclohexane (δ23.8 (10)). However, the *cis*-2-butene derivative (CB-c6, MB-c6) and the mixed *trans*-2-butene-propene derivative (TBPR-c6) each gave an additional CH_3 signal in the range δ7–12, similar to the methyl chemical shifts in 1,2-disilacyclobutanes (3). In each case, the peak showed ^{19}F coupling. Thus the additional peak in the δ7–12 range can logically be assigned as a C(1) methyl while the peak at δ17–29 is a C(2) methyl signal. MB-c6 and TBPR-c6 gave C(2) and C(1) methyl peaks in a 2:1 ratio, again indicating greater methyl substitution at C(2). Thus, one can state, as a general rule that unsymmetric methyl-substituted alkenes give 1,2-disilacyclohexanes with greater methyl substitution at C(2). This may also apply to other substituents since vinyl chloride yields a disilacyclohexane with structure **VI** (2):

VI

(c) Variable Temperature ^{19}F Spectra and Identification of Configurational Isomers

As noted above, two isomers of PR-c6 were formed. These can be distinguished by their variable temperature ^{19}F nmr spectra (Fig. 2). The spectrum for one isomer remains essentially unchanged on cooling while the other changes from a two peak to a four peak spectrum (with each peak of equal area) on cooling. The *cis* (U,U) isomer should exist as two forms which are conformational enantiomers (each with one axial, a, and one equatorial, e, methyl group; see Fig. 3). At room temperature these will be rapidly interconverting, yielding an average spectrum with two peaks, equivalent to that for a planar ring. However, if cooling slows the chair-to-chair interconversion sufficiently, then one will see the spectrum of either mirror image chair in which there are four fluorine peaks of equal area. By contrast, the *trans* (U,D) isomer exists as two conformational diastereomers (with a,a and e,e methyl groups). The averaged spectrum will again show two peaks. However, on cooling, one should observe two unequal sets of two peaks (corresponding to a,a and e,e conforma-

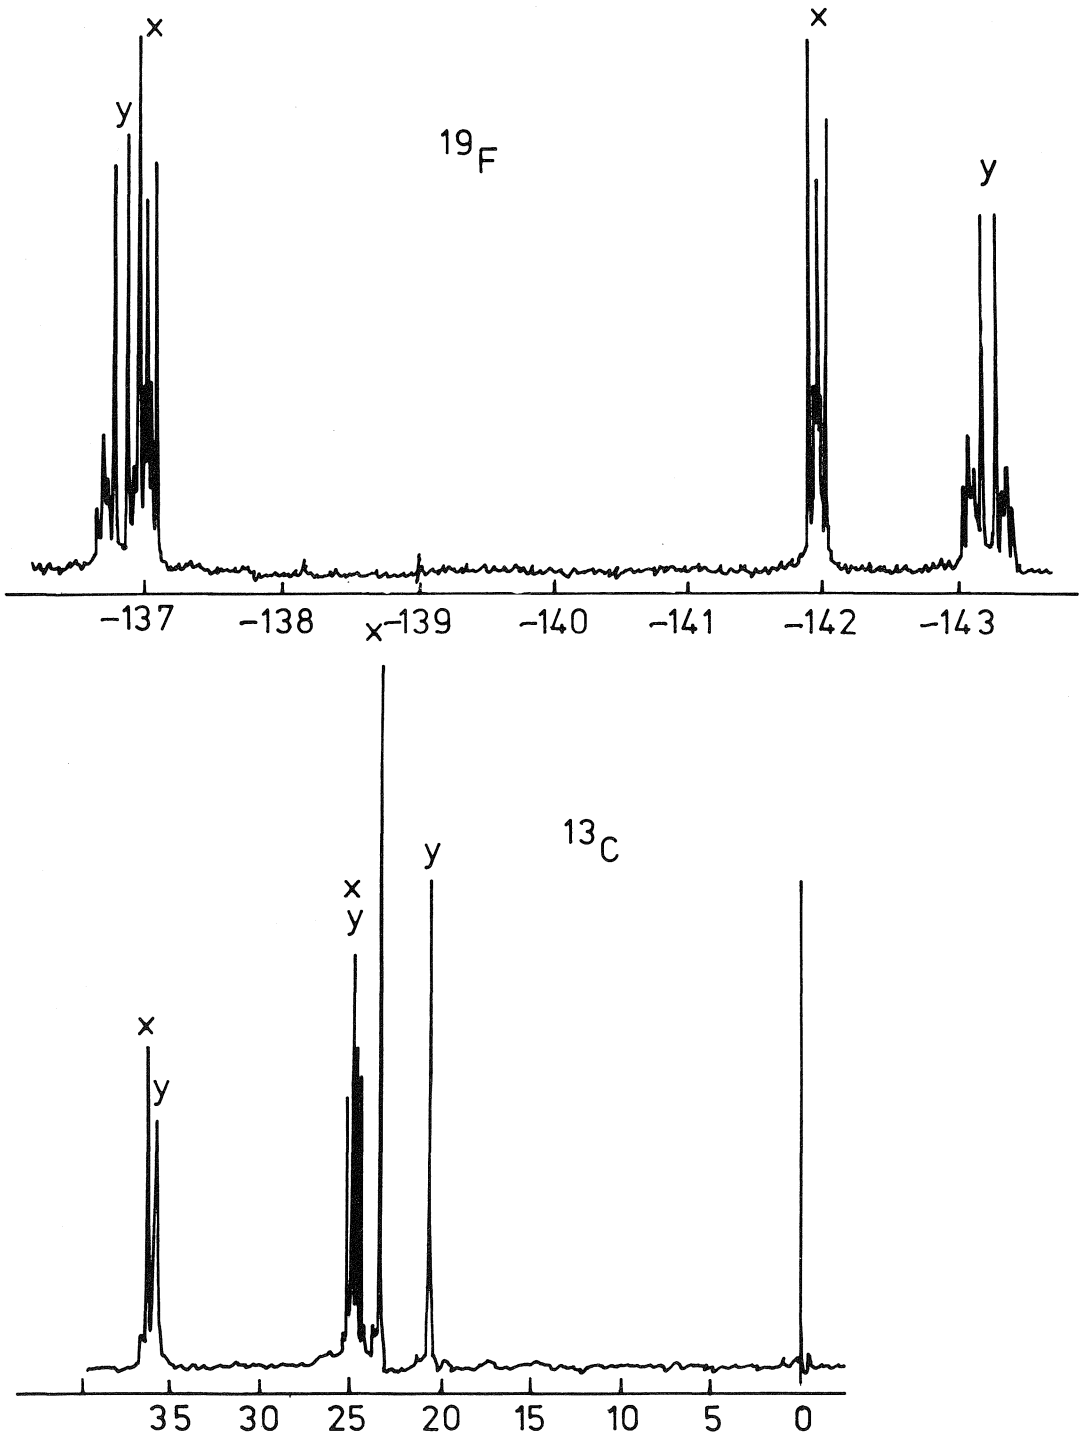

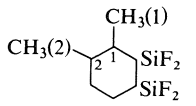

FIG. 1. ^{19}F and ^{13}C spectra of PR-c6 at 31°C (both spectra ^{1}H-decoupled): x = *trans*-PR-c6, y = *cis*-PR-c6.

tions, Fig. 3). Alternatively, if one conformation is strongly favoured and/or if the barrier to interconversion is low, one might observe a low temperature spectrum with only two peaks. Thus the compound which splits from two to four ^{19}F peaks on cooling can be assigned to the *cis* isomer while the compound whose spectrum remains unchanged on cooling can be assigned as the *trans* isomer.

TBPR-e,e,e	30.25 26.60	43.88 36.16	12.21	20.14 24.94

[a]In ppm relative to internal $(CH_3)_4Si$. Low field shifts positive.
[b]See text concerning assignments.
[c]Axial (a) and equatorial (e) conformations of methyl groups as determined in subsequent tables.
[d]Resonances assigned in this order since low temperature behaviour showed peak at δ20.34 split into a doublet $\Delta\delta = 10.4$ (257 Hz). Also PR-c6 ae has *gauche* methyls to high field.
[e]Assignment made on basis of variable temperature behaviour.
[f]Concentration too small relative to chain derivatives to make unambiguous assignment.
[g]Not observed due to overlap with other peaks in spectrum.

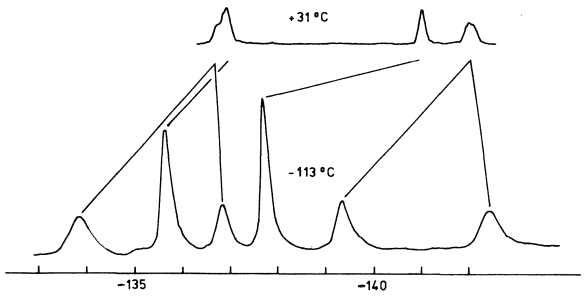

FIG. 2. Proton coupled ^{19}F spectra of PR-c6 at 31°C and −113°C.

Identical arguments have very recently been used to assign *cis* and *trans* isomers of **VI** (2). The ^{13}C spectra of the two PR-c6 isomers also showed similar variable temperature nmr behaviour, thus aiding in the assignment of the ^{13}C signals of these isomers (4).

Variable temperature ^{19}F spectra allowed assignment of the isomers of several of the other disilacyclohexane derivatives while in other cases the number of possible structures can be limited by symmetry considerations (see Table 2). Thus variable temperature ^{19}F spectra in conjunction with symmetry arguments provide a very useful method for assigning these isomers.

Free energies of activation, $\Delta G^{\ddagger}$, for chair-to-chair interconversion can be estimated from the coalescence temperatures of the ^{19}F spectra (Table 3). The values of $\Delta G^{\ddagger}$ show a rough trend with the number of possible eclipsing methyl–methyl steric interactions in the transition state (which can be estimated from the number of 1,2 eclipsing interactions in the planar form). $\Delta G^{\ddagger}$ for *cis*-PR-c6 (8.2 kcal/mol) is smaller than $\Delta G^{\ddagger}$ for the *cis* isomer of **VI** (11.2 kcal/mol (2)). This is reasonable since there should be additional electrostatic repulsion between the chlorines in the transition state of the latter compound. The failure to freeze out the chair-to-chair interconversions of ET-c6 and *trans*-PR-c6 is consistent with the lack of eclipsing CH_3–CH_3 interactions in those derivatives. The estimated axial–equatorial ^{19}F chemical shift difference for ET-c6 (see below) allows one to set a limit of $\Delta G^{\ddagger} < 6$ kcal/mol for this compound (4). This is considerably lower than $\Delta G^{\ddagger}$ for cyclohexane (10.3 kcal/mol (11)), indicating that the long Si—Si bonds significantly destabilize the ground state of 1,2-disilacyclohexane by ring distortion.

(d) Average ^{19}F Chemical Shifts and Assignment for Preferred Methyl Conformations

While many of the disilacyclohexane isomers have been assigned by variable temperature ^{19}F spectra, not all compounds could be assigned. In addition, the variable temperature behaviour provides no direct information about preferred methyl conformations (a or e). However, low temperature ^{19}F chemical shifts provide useful information about both configuration and conformation through the use of additive ^{19}F chemical shift parameters similar to those derived for 1,2-disilacyclobutanes (3). Average chemical shifts will be considered first (Table 4).

Comparison of ET-c6 and PRET-c6 indicates that a single methyl group at C(2) causes a very small change in average chemical shift ($\Delta\delta = -0.3$ ppm). By analogy with methylcyclohexane (12), the methyl group is very likely equatorial. By contrast, *cis*-c6, which has a,e methyl groups, shows a significant low field shift relative to ET-c6 ($\Delta\delta = +2.0$ ppm) which must reflect the effect of the axial methyl group. Thus, the large low field shift for *trans*-PR-c6 ($\Delta\delta = +3.3$ ppm) indicates that the methyl groups are a,a rather than e,e even though the latter conformation is favoured in *trans*-1,2-dimethylcyclohexane (12). Molecular models indicate that chair distortion by the long Si—Si bond decreases the dihedral angle between C(2) equatorial bonds to ca. 20°, introducing severe steric interactions in e,e-*trans*-PR-c6 which are not present in the cyclohexane analogue (Fig. 4). Mod-

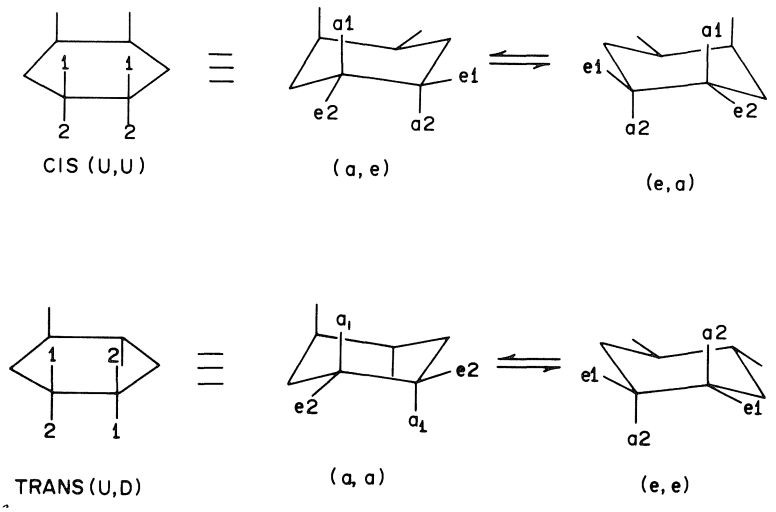

FIG. 3. Chair conformations of *cis*- and *trans*-PR-c6 isomers. Note that with rapid chair-to-chair interconversion, each isomer gives a spectrum similar to that expected for a planar ring.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

els also indicate that there is an even larger 1,3-diaxial CH_3–CH_3 steric interaction. Thus in TBPR-c6 and CB-c6, where there are isomers with either all e or all a methyl groups, the former should be favoured to avoid 1,3-diaxial interactions, even though this involves 1,2-diequatorial interactions. Also the isomer of MB-c6, which can have either an e(ae)(ea)e or an a(ae)(ae)a conformation, should favour the former conformation.

These ideas can be checked, using additive chemical shift parameters. $\Delta\delta = +3.3$ ppm for *trans*-PR-c6, indicating that the effect of a single axial methyl group at C(2), $\Delta\delta_{2a} = +1.7$ ppm (assuming an a,a conformation for *trans*-PR-c6). Similarly, $\Delta\delta$(*cis*-PR-c6) $= +2.0$ ppm $= \Delta\delta_{2a} + \Delta\delta_{2e}$ (where $\Delta\delta_{2e}$ is the effect of an equatorial methyl group at C(2)). Therefore $\Delta\delta_{2e} = 2.0 - \Delta\delta_{2a} = +0.3$ ppm. Alternatively $\Delta\delta_{2e} = \Delta\delta$(PRET-c6) $= -0.3$ ppm. On average, $\Delta\delta_{2e} = (+0.3 - 0.3)/2 = 0.0$. Similar calculations yield $\Delta\delta_{1e} = -3.3$ ppm and $\delta_{1a} = -1.4$ ppm for the effects of equatorial and axial C(1) methyl groups, with uncertainties comparable to that for δ_{2e} (4). Thus the average ^{19}F chemical shifts at -113°C can be estimated, assuming $\Delta\delta_{2e} = 0.0$, $\Delta\delta_{2a} = +1.7$ ppm, $\Delta\delta_{1e} = -3.3$ ppm, and $\Delta\delta_{1a} = -1.4$ ppm. Results of these calculations are summarized in Table 4. There is generally good agreement for 1,2-disilacyclohexanes with four or fewer CH_3 groups and in these cases all compounds can be assigned except for one TBPR-c6 and one CB-c6 isomer. The agreement is not as good for derivatives with six or eight CH_3 groups, possibly because the additivity of substituent effects begins to break down in these highly substituted derivatives (3).

Alternative conformations could be assigned. For example, *trans*-PR-c6 could have a preferred e,e conformation. However, in that case, the observed chemical shifts for PRET-c6, *cis*-PR-c6, and IB-c6 could only be rationalized by assuming an axial conformation of the methyl group in PRET-c6 and that $\Delta\delta_{2e} > \Delta\delta_{2a}$. However, this would lead to illogical results for the effects of CH_3 groups on individual ^{19}F chemical shifts (see below).

As noted above, several disilacyclohexanes which form conformational diastereomers give ^{19}F nmr spectra which do not "freeze out" on cooling. This could indicate either a low interconversion barrier or a predominance of one conformation (or both factors). This can be checked using additive chemical shift parameters. The majority of disilacyclohexanes show a change in average chemical shift of -1.0 ± 0.4 ppm on going from -113°C to $+31$°C (Table 4). However, three compounds give chemical shift changes which lie outside this range (the compounds assigned as a,aPR-c6, e,e,eTBPR-c6, and e,e,e,eCB-c6). In each case, calculations of the expected chemical shift for the two possible conformations indicate that the anomalous shift can be attributed to a small fraction of the less favoured conformation at higher temperature. Thus it is likely the failure to observe "frozen out" forms of these derivatives reflects both a low $\Delta G^{\ddagger}$ value (since all three derivatives have no CH_3–CH_3 eclipsing interactions in their transition states) and a predominance of one form at low temperature.

confirmation of the assignment of the individual isomers can be obtained from a consideration of the effect of CH_3 groups on individual ^{19}F chemical shifts. To accomplish this one must first assign individual ^{19}F resonances to axial or equatorial fluorines. The low temperature spectra must be used for this purpose since, in many of the high temperature spectra, axial and equatorial peaks are averaged due to chair-to-chair interconversion (see above).

One major aid in the assignment is the empirical observation that axial ^{19}F peaks in ^1H coupled spectra are always broader than equatorial peaks (4) (e.g. see Fig. 2). Two factors appear to contribute to this. First, detailed analysis of ^1H-decoupled ^{19}F spectra shows that $^{19}F-^{19}F$ coupling between the vicinal diaxial fluorines has a value of about −16 Hz while the corresponding diequatorial coupling is only −10 Hz (see Table 5). Second, there should be a large $^3J_{HF}$ coupling between an axial fluorine and an axial C(1) hydrogen while the corresponding $^3J_{HF}$ couplings involving an equatorial fluorines show much smaller splittings. Indiple, the axial fluorines in PRET-c6 show an 18 Hz splitting due to $^1H-^{19}F$ coupling while the equatorial fluorines show much smaller splittings. Individual axial and equatorial resonances can be assigned (4) using a combination of symmetry arguments (e.g. in *cis*-PR-c6 each pair of peaks in the low temperature spectrum which coalesce at high temperature must be due to an axial fluorine on one silicon and an equatorial fluorine on the second silicon, see Fig. 3), homonuclear $^{19}F-^{19}F$ decoupling and considerations of the effect of CH_3 groups on individual ^{19}F chemical shifts (see below). Assignments are given in Table 6.

The next problem is to assign ^{19}F chemical shifts for axial and equatorial fluorines in the absence of methyl substitution. Unfortunately, this cannot be determined directly since ET-c6 does not freeze out on cooling. However, reasonable assignments of δ_{axial} and $\delta_{equatorial}$ can be made from the data in Table 5, noting that $(\delta_{axial}+\delta_{equatorial})/2 = -140.00$, the average shift for ET-c6. The key observation is that for all four compounds with only C(2) methyl groups (PRET-c6, *cis*- and *trans*-PR-c6, and IB-c6), all eight equatorial fluorine signals come in the region $\delta - 138.0 \pm 1.2$. Thus it seems logical to assign $\delta_{equatorial} = -138$. Therefore, $\delta_{axial} = -142 \pm 1$. In fact three of the axial ^{19}F signals for the four compounds fall in this range (including both axial fluorines in PRET-c6). Thus this assignment also seems reasonable.

Having made this assignment, it is now possible to consider effects of individual methyl groups on ^{19}F chemical shifts. The following notation will be

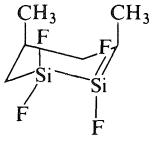
[a]In ppm relative to $CFCl_3$ (high field shifts negative).
[b]Conformation for which chemical shifts is calculated. Numbers refer to carbon to which methyl group is attached. Cl is adjacent to Si(l), Cl′ adjacent to Si(2).
[c]Predicted using parameters given in text.
[d]Axial fluorine attached to Si(l), etc.
[e]Probable conformation.
[f]Possible conformation.
[g]Assigned conformation.

used: the numbers 1,n (n = 2–4) will be used to designate the silicon and the carbon to which a particular fluorine and methyl are attached where n = 2 for the carbon next to silicon, etc. (see **VII**).

VII



(Note that there are two possible 1,3 interactions involving Si—C—C and Si—Si—C paths.) The symbols a and e will indicate axial or equatorial orientation and M and F refer to methyl and fluorine. Thus $\Delta\delta_{1,2aMaF}$ refers to the chemical shift change of an axial fluorine due to an axial methyl on the adjacent carbon.

In view of the complexity of the problem, we will only attempt to identify substituent effects which are greater in magnitude than 2 ppm. To begin, it is unlikely that any of the $\Delta\delta_{1,4}$ terms will exceed this magnitude since they involve fluorines and methyl groups which are far removed. Considering the compounds with only C(2) methyl groups, the fact that the equatorial fluorine shifts bunch so closely about −138 ppm suggests that $\Delta\delta_{1,3aMeF}$ and $\Delta\delta_{1,3eMeF}$ are both essentially zero. Considering axial fluorines, both signals in e-PRET-c6 come at δ − (142–143) ppm. In a,e-*cis*-PR-c6 one peak comes at δ − 142 while the other axial signal in this compound plus both axial fluorines in a,a-*trans*-PR-c6 and (a,e),(a,e)-IB-c6 comes in the range δ − 135 ± 1. Thus the logical assignments are $\Delta\delta_{1,3eMaF} \approx 0$ and $\Delta\delta_{1,3aMaF} \approx +7$ ppm, i.e. the only significant effect of a C(2) methyl is in the case of a 1,3 diaxial

interaction. This is logical since the methyl group and fluorine are much closer in this case than in any of the other combinations (see **VIII**).

VIII

A C(1) methyl also has 1,3 interactions with the fluorines on one Si (see **VIII**), in addition to 1,2 interactions with the other SiF_2 unit. The former are assumed to have the same magnitude as 1,3 interactions of a C(2) methyl group. Detailed consideration of the ^{19}F chemical shifts for C(1)-methyl substituted derivatives indicates that $\Delta\delta_{1,2aMeF} \approx \Delta\delta_{1,2eMaF} \approx -8$ ppm (average $\Delta\delta = -8.0 \pm 1.1$ ppm (4)) and $\Delta\delta_{1,2aMaF} \approx \Delta\delta_{1,2eMeF} \approx -4$ ppm (average $\Delta\delta = -3.9 \pm 2.3$ ppm (4)). Molecular models provide a rationalization for the fact that these parameters occur in pairs. The ring flattens about the silicons so that an axial fluorine and an equatorial methyl group or an equatorial fluorine and an axial methyl group are spatially proximate while diaxial and diequatorial pairs are more remote. Electron diffraction studies of other silacyclohexanes confirm flattening of the ring around silicon (13).[4]

Thus, the ^{19}F chemical shifts for silacyclohexanes can be accounted for by only three methyl substituent effects: a large low field shift due to 1,3 diaxial interactions ($\Delta\delta_{1,3aMaF} = +7$ ppm), a large high field shift due to spatially proximate 1,2 interactions ($\Delta\delta_{1,2aMeF} \approx \Delta\delta_{1,2eMaF} \approx -8$ ppm) and a smaller high field shift due to other 1,2 interactions (≈ -4 ppm). These values can be used to derive parameters for the effect of methyl groups on average chemical shifts ($\Delta\delta_{2e} = 0$, $\Delta\delta_{2a} = +1.75$, $\Delta\delta_{1e} = -3.0$, $\Delta\delta_{1a} = -1.25$) which are very similar to those developed above. The $\Delta\delta_{1,2}$ and $\Delta\delta_{1,3}$ parameters also show surprisingly close parallel with the corresponding ^{13}C chemical shift parameters for CH_3–CH_3 interactions in cyclohexane derivatives. In the latter case, $\Delta\delta_{1,2}(\gamma)$ parameters show maximum shielding (ca. -5 ppm (10)) for proximate methyl groups while 1,3 diaxial interactions cause low field shifts (+4.5 ppm (15)).

Calculated and observed ^{19}F chemical shifts are compared in Table 6. *All* of the equatorial shifts are predicted within 2 ppm along with the axial shifts for all derivatives with four or fewer methyl groups. The close agreement for the derivatives with four or less methyl groups allows one to conclude that the previously unidentified TBPR-c6 isomer probably has an a,a,e conformation while very clearly indicating that the CB-c6 isomer which freezes out on cooling is a,e,a,e rather than a,a,e,e. In this regard, it is interesting to note that the two main CB isomers respectively have all-*cis* (a,e,a,e or U,U,U,U) and all-*trans* (e,e,e,e or U,D,U,D) methyl groups, indicating that the mechanism of formation of disilacyclohexanes allows isomerization of alkene linkages. This contrasts with the disilacyclobutanes which are formed with complete retention of configuration (3).

It is surprising that the chemical shifts for these complex derivatives can be predicted with only three additive chemical shift parameters. Nevertheless, the very close agreement for derivatives with four or fewer methyl groups plus the close parallels with the ^{13}C additive parameters lends a great deal of confidence to the conformational and configurational assignments given in the previous sections. All other possible assignments seem less logical. For example, if *trans*-PR-c6 was assigned to e,e conformation (along with a for PRET-c6), then it would follow that $\delta_{1,3eMaF} \approx +7$ ppm and $\delta_{1,3eMaF} \approx 0$ ppm. This would be inconsistent with the corresponding additive ^{13}C chemical shift parameters and also with the CH_3—F distances in the two cases.

(f) ^{19}F–^{19}F and ^{29}Si–^{29}Si Coupling Constants in 1,2-Disilacyclohexanes

These coupling constants are summarized in Table 5. They are discussed elsewhere as part of a general discussion of trends in F–F and Si–F coupling constants (16).

Summary and Conclusions

Unsymmetric alkenes react with SiF_2 to form disilacyclohexanes with greater methyl substitution at C(2). The reaction of an alkene with SiF_2 often gives more than one disilacyclohexane derivative and the reaction proceeds by a pathway which allows isomerization of the alkene. These observations have been incorporated in a proposed comprehensive mechanism for the SiF_2–olefin reaction (3).

The disilacyclohexanes exist in distorted chair conformations. In a number of cases the chair-to-chair interconversion is sufficiently slow at low temperatures to observe the individual chair forms by ^{19}F nmr spectroscopy. The number of ^{19}F peaks in the low temperature spectra allows assignment of individual configurational isomers in several

[4]This is also indicated by an X-ray structure determination for **VI** (14).

cases. In addition, consideration of the effect of CH_3 groups on averaged ^{19}F chemical shifts allows further assignment of configurational isomers and determination of conformational preference. Individual ^{19}F chemical shifts can be predicted accurately using only three parameters to describe effects of 1,2 and 1,3 CH_3–F interactions. These parameters allow final assignment of all configurations and conformations of eleven 1,2 disilacyclohexane derivatives.

Carbocyclization in natural products. III.[1] Brominative cyclization of dehydrosaussurea lactone and costunolide[2,3]

TIKAM C. JAIN[4] AND CALVIN M. BANKS[5]

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 21, 1979

TIKAM C. JAIN and CALVIN M. BANKS. Can. J. Chem. **58**, 447 (1980).

Treatment of dehydrosaussurea lactone **4** and costunolide **1** with *N*-bromosuccinimide (NBS) in aqueous acetone at room temperature furnished bromolactones **6**, **7**, and **8**. Structural evidence for these bromolactones rests upon spectral data and transformation to the hydrogenated bromolactones **9**, **10**, and **11**. The latter were found identical with the corresponding products obtained by the brominative cyclization of dihydrocostunolide **2**.

TIKAM C. JAIN et CALVIN M. BANKS. Can. J. Chem. **58**, 447 (1980).

Le traitement de la dehydrosaussurea lactone **4** et de la costunolide **1** avec le *N*-bromosuccinimide dans acétone aqueux à la température ambiente a fourni les bromolactones **6**, **7** et **8**. L'évidence structurelle pour ces bromolactones reste sur des résultats spectraux et des transformations aux bromolactones hydrogénées **9**, **10** et **11**. Les derniers sont identiques aux produits correspondants obtenus par le cyclization brominatif de dihydrocostunolide **2**.

The anomalous ultraviolet absorption of costunolide **1** and other germacranolides has been attributed to the transannular interaction of the double bonds in the medium ring (3, 4). In contrast, dehydrosaussurea lactone **4** and saussurea lactone **3** differ from **1** in that there is freedom of rotation about the bonds that carry the olefinic linkages. Yet the ultraviolet spectra of these two compounds demonstrated an interaction of the double bonds (Table 1). Having compared the ultraviolet maximum of dehydrosaussurea lactone with that of saussurea lactone it was immediately apparent that the position of the maximum was not altered by the unsaturation in the lactone ring; however the extinction coefficient was increased. Thus the interactions of the double bonds in dehydrosaussurea lactone **4** indicated the strong possibility of cyclization in this molecule.[6]

Treatment of dehydrosaussurea lactone **4** with *N*-bromosuccinimide (NBS) furnished a crude semi-crystalline product which showed three spots on silica gel tlc plates in several solvent systems (2). Chromatography over a silica gel column gave the bromohydrin **6** and the bromolactones **7** and **8** in 43, 15, and 15% yields respectively.

TABLE 1. Ultraviolet data in EtOH

Substrate	Absorption maximum (nm)	Extinction coefficient ε
Costunolide **1**	214.5	11 841
Dihydrocostunolide **2**	214	6 166
Saussurea lactone **3**	209	741
Dehydrosaussurea lactone **4**	211.5	8 630
Tetrahydrodehydro-saussurea lactone **5**	213	6 300

The reaction was applied to costunolide **1** which when treated with NBS in aqueous acetone furnished the bromohydrin **6** and the bromolactones **7** and **8** in 50, 18, and 23% yields respectively. The three bromolactones derived from costunolide **1** were found identical to those made from dehydrosaussurea lactone **4** (ir, nmr, mixed melting point). For the hydrogenation experiments (*vide infra*) the compounds employed were those that were prepared from substrate **1**.

The bromohydrin **6**, mp 186–188°C, was analyzed for $C_{15}H_{21}O_3Br$ and further confirmed by high resolution mass spectrometry (Table 2). The major structural features were deduced by infrared and nmr spectroscopy. (For details, see Experimental.) The relative configuration of the molecule was established in a relatively simple manner. Catalytic hydrogenation in glacial acetic acid (PtO_2) of the bromohydrin **6** yielded the bromohydrin **9**, a compound of known stereochemistry (1, 6) prepared from dihydrocostunolide **2**. Mixed melting point and spectral comparison (ir and nmr) proved them to be identical.

SCHEME 1

The bromolactones **7** and **8** were analyzed for $C_{15}H_{19}O_2Br$, this being supported by high resolution mass measurement (Table 2). The spectroscopic data given in the Experimental were fully in accord with their structures portrayed as **7** and **8**. Final proof of the structures of the isomeric bromolactones **7** and **8** was secured through catalytic hydrogenation in ethanol (PtO_2) which provided the bromolactones **11** and **10** respectively.

Novelty of Cyclization

To the best of our knowledge, neither naturally occurring, nor synthetic, sesquiterpene lactones based on the elemane framework have hitherto been converted to bicyclic sesquiterpene lactones (2). The biogenetic significance of the facile carbocyclization in this class of compounds will be reported in due course.

Experimental[7]

N-*Bromosuccinimide (NBS) Cyclization of Dehydrosaussurea Lactone* ***4***

To a solution of dehydrosaussurea lactone **4** (1.0 g) in 5% acetone/H_2O (120 mL) an equimolar amount of *N*-bromosuccinimide (460 mg) was added and the solution was stirred magnetically for 42 h. Distillation of the solvent under reduced pressure furnished a crystalline product which was extracted with ether and washed with water (5 × 20 mL). The ethereal layer was dried over Na_2SO_4 and concentrated *in vacuo* to yield a semi-crystalline product (1.55 g) showing three spots on tlc plates. Silica gel chromatography of the crude reaction mixture followed by crystallization of the relevant fractions yielded three crystalline products **6**, **7**, and **8** described below.

Bromohydrin ***6***

The compound was recrystallized from ethyl acetate to yield flakes of **6**, mp 186–188°C; λ_{max} 206, ε 14 800; $[\alpha]_{589}$ +12.7°, $[\alpha]_{578}$ +13.0°, $[\alpha]_{546}$ +14.9°, $[\alpha]_{436}$ +25.0°, $[\alpha]_{365}$ +34.2° (*c* 1.01 at 25°C); ir: 3535 (hydroxyl) cm^{-1}, 1764, 1670, and 888 (α,β-unsaturated γ-lactone) cm^{-1}; nmr τ: 3.85, 4.50 (d, *J* = 3.0 Hz, 2H, —C=CH_2), 5.90 (m, 2H, HC—Br, HC—O—C=O), 8.62 (s, 3H, HO—C—CH_3), 8.88 (s, 3H, —C—CH_3). ms *m/e*: 313 (M^+ − CH_3, $\%\sum_{27}$ 1.73). *Anal.* calcd. for $C_{15}H_{21}O_3Br$: C 54.71, H 6.42; found: C 54.83, H 6.37.

Bromolactones ***7*** *and* ***8***

The mixture containing the bromolactones was rechromatographed on a silica gel column and the relatively nonpolar fractions were combined and crystallized from methanol to give bromolactone **7** (15% yield), mp 116–118°C; λ_{max} 206, ε 17 800; $[\alpha]_{589}$ +49.9°, $[\alpha]_{578}$ +52.7°, $[\alpha]_{546}$ +60.0°, $[\alpha]_{436}$ +104.0°, $[\alpha]_{365}$ +164.7° (*c* 1.12 at 25°C); ir: 1765, 1679, and 882 (α,β-unsaturated γ-lactone) cm^{-1}, 1624, 844, and 810 (trisubstituted double bond) cm^{-1}; nmr τ: 3.90, 4.57 (d, *J* = 3.0 Hz, 2H, —C=CH_2), 4.71 (s, broad, 1H, —C=CH), 5.90 (m, 2H, HC—Br, HC—O—C=O), 8.16 (t, broad, *J* = 1.0 Hz, 3H, HC=C—CH_3), 9.01 (s, 3H, —C—CH_3); ms *m/e*: 310 (M^+, $\%\sum_{27}$ 1.25). *Anal.* calcd. for $C_{15}H_{19}O_2Br$: C 57.88, H 6.15; found: C 57.94, H 6.17. The polar fractions were combined and crystallized from methanol to give bromolactone **8** (15% yield), mp 137–138°C; λ_{max} 206 nm, ε 18 400; $[\alpha]_{589}$ +106.2°, $[\alpha]_{578}$ +111.3°, $[\alpha]_{546}$ +126.9°, $[\alpha]_{436}$ +214.5°, $[\alpha]_{365}$ +331.8° (*c* 0.97 at 25°C); ir: 1771 (γ-lactone) cm^{-1}, 1673, 1650, and 920 (exocyclic methylene) cm^{-1}; nmr τ: 3.89, 4.55 (d, *J* = 3.0 Hz, 2H, —C=CH_2), 4.97, 5.09 (s, 2H, —C=CH_2), 5.98 (m, 2H, HC—Br and HC—O—C=O), 9.03 (s, 3H, —C—CH_3); ms *m/e*: 310 (M^+, $\%\sum_{27}$ 0.27). *Anal.* calcd. for $C_{15}H_{19}O_2Br$: C 57.88, H 6.15; found: C 57.82, H 6.20.

NBS Cyclization of Costunolide ***1***

Costunolide **1** (4.5 g) was dissolved in 5% acetone/H_2O (900 mL) and reacted with NBS (3.44 g) for 16.5 h. Removal of solvent at a reduced pressure produced a viscous gum which was taken up in ether and extracted with water (6 × 10 mL). The aqueous layer was back extracted and the combined ethereal solution was dried over Na_2SO_4 and the solvent was removed *in vacuo* yielding a crude gum (5.85 g). Thin layer chromatography (silica gel) in the following solvent systems, benzene, 5% methanol/benzene, and chloroform, revealed the presence of three compounds. The reaction mixture was expeditiously resolved into its three components **6**, **7**, and **8** by a simple silica gel column chromatography.

Bromohydrin ***6***

The bromohydrin **6** was crystallized from ethyl acetate, mp 186–188°C (undepressed upon mixing with the sample prepared from dehydrosaussurea lactone **4**), λ_{max} 208 nm, ε 15 600, their infrared spectra were superimposable; $[\alpha]_{589}$ +12.9°, $[\alpha]_{578}$ +13.4°, $[\alpha]_{546}$ +15.3°, $[\alpha]_{436}$ +25.8°, $[\alpha]_{365}$ +35.4° (*c* 1.58 at 30°C). *Anal.* calcd. for $C_{15}H_{21}O_3Br$: C 54.71, H 6.42, Br 24.27; found: C 55.08, H 6.47, Br 23.98.

Saturated Bromohydrin ***9***

The bromohydrin **6** (128 mg) was hydrogenated (12 h) with PtO_2 (50 mg) in ethanol (50 mL) to yield fully saturated bromohydrin **9**, mp 160–165°C (undepressed upon admixture with an authentic sample); the infrared spectrum was superimposable with that of authentic **9**; $[\alpha]_{589}$ −18.4°, $[\alpha]_{578}$ −19.9°, $[\alpha]_{546}$ −22.6°, $[\alpha]_{436}$ −40.4°, $[\alpha]_{365}$ −68.1° (*c* 1.14 at 28°C).

Studies on allylic peroxides. II.[1] Allyl-*t*-butyl peroxide

R. HIATT AND V. G. K. NAIR

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received August 21, 1979

R. HIATT and V. G. K. NAIR. Can. J. Chem. **58**, 450 (1980).

Allyl-*tert*-butyl peroxide decomposes thermally in toluene with $k_d = 10^{13.8} \exp(-33200/\theta)$ (s^{-1}). Product studies show the reaction to be a mixture of homolysis and radical-induced decomposition, the latter involving both radical addition to C=C and allyl hydrogen abstraction by alkoxy radicals. Computer modelling of the system gives good agreement with the experimental results and suggests that the overall decomposition is about 50% homolysis.

R. HIATT et V. G. K. NAIR. Can. J. Chem. **58**, 450 (1980).

Le peroxyde d'allyle et de *tert*-butyle se décompose thermiquement dans le toluène avec un $k_d = 10^{13.8} \exp(-33200/\theta)$ (s^{-1}). L'étude des produits obtenus montre que la réaction consiste en une homolyse et en une décomposition induite de façon radicalaire. Cette dernière implique à la fois l'addition du radical benzyle sur la double liaison carbone–carbone et l'enlèvement d'un hydrogène allylique par les radicaux alkoxy. Le modèle du système réalisé par ordinateur est en accord avec les résultats expérimentaux et suggère que la décomposition dans son ensemble est à 50% une homolyse.

[Traduit par le journal]

Introduction

Studies on the decomposition of 2,3-dimethyl-3-butenyl-2-hydroperoxide, (TMEH), have suggested a new mode of free radical initiation peculiar to allylic hydroperoxides (1). A follow-up investigation using allyl hydroperoxide was planned, but initial results with that substance proved extremely complicated. Allyl-*tert*-butyl peroxide seemed somewhat better behaved, and a useful vehicle for sorting out some of the peculiarities of allylic peroxide decompositions.

Experimental

Decompositions of the peroxide were carried out in evacuated, sealed pyrex ampoules, as previously (1). Residual peroxide and the volatile products were determined by glc, using known compounds as standards. Non-volatile residues were subjected to ir and nmr analysis.

Allyl-*tert*-butyl peroxide was prepared by the reaction of *t*-BuO_2H with allyl bromide in methanolic KOH at −5°C. *Tert*-BuO_2H (22.5 g, 0.250 mol) and allyl bromide (30.25 g, 0.250 mol) were mixed with 30 mL of methanol and the solution cooled in an ice-salt bath. A solution of 14 g of KOH in 100 mL of methanol was added dropwise over 20 min. The mixture was stirred for 5 h; 4.5 g (0.05 mol) of *t*-BuO_2H was added and stirring continued for 10 h. Extraction with pentane followed by distillation (55–56°C/75 Torr) gave 95% pure peroxide which was further purified by preparative glc (20% isodecyl phthalate on Chromosorb W). Yields averaged 16%.

Infrared: 815 (C—O—O), 1365 and 1385 (CMe_3), 1650 (C=C) cm^{-1}; nmr δ: 1.1 (s, 9H), 4.2 (d, 2H), 4.8–6.3 (m, 3H); ms *m/e*: 130 (M^+), 59 (Me_2COH^+?), 57 (CMe_3^+), 41 ($CH_2CHCH_2^+$), 28 ($CH_2CH_2^+$).

Results and Discussion

Rate constants for thermal decomposition of allyl *tert*-butyl peroxide, (*P*), in toluene are shown in Table 1. Although the first-order plots were linear, and the rate constants insensitive to initial concentration, the decompositions were relatively fast and the activation energy was ~5 kcal too low for simple homolysis (cf. *t*-Bu_2O_2, $k_{150°} = 1.9 \times 10^{-4}$ s^{-1} and $E_a = 37.8$ kcal (2)). Thus there appears to be a substantial amount of radical-induced decomposition.

Repeating the decompositions in the presence of 1.0 *M* α-methylstyrene gave only slightly different rate constants (Table 1). The Arrhenius parameters appear somewhat closer to normal for unimolecular homolysis but are not convincingly different from those obtained in pure toluene. The success of this

[a] Gram/mol dec., contains all the bibenzyl, but none of the other listed products.

attempt to suppress induced decomposition is questionable.

At 60°C in toluene the peroxide is stable but subject to attack by *tert*-butoxy radicals. After 2 h, a solution originally 0.166 *M* in peroxide and 0.332 *M* in DBPO (di-*tert*-butyl peroxyoxalate) contained no DBPO and 0.124 *M* peroxide, a 25% reduction. The yield of *t*-BuOH was nearly quantitative showing that attack of *t*-BuO· on the peroxide proceeded via abstraction rather than addition.

The products from thermolysis of the peroxide in toluene at 150°C (Table 2) are remarkable in several respects. All *t*-BuO· is found as either *t*-BuOH or acetone and the *t*-BuOH – acetone ratio, (2.7), is more than twice as large as found from *t*-Bu_2O_2 under the same conditions (3). Thus addition of *t*-BuO· to C=C is not significant, and more than half of the H-abstractions by *t*-BuO· are from species other than toluene. Some abstraction from the peroxide itself seems probable, but attack on

[1] $t\text{-BuO}\cdot + CH_2{=}CH{-}CH_2O_2t\text{-}Bu \longrightarrow t\text{-BuOH} + CH_2{=}CH{-}\dot{C}HO_2t\text{-Bu} \xrightarrow{O_2} CH_2{=}CH{-}CHO + t\text{-BuO}\cdot$

products, allyl alcohol, acrolein, and acrolein polymer must be considered as well. Cage disproportionation of *t*-BuO· and allyloxy radicals would also tend to increase *t*-BuOH yields.

[2] $t\text{-BuO}\cdot + CH_2{=}CH{-}CH_2OH \longrightarrow t\text{-BuOH} + CH_2{=}CH{-}\dot{C}HOH$

[3] $t\text{-BuO}\cdot + \underset{\|}{\overset{O}{C}}{-}H \longrightarrow t\text{-BuOH} + \underset{\|}{\overset{O}{C}}\cdot$

[4] $[CH_2{=}CH{-}CH_2{-}O\cdots O\text{-}t\text{-Bu}] \downarrow CH_2{=}CH{-}CHO + t\text{-BuOH}$

Evidence for benzyl radical attack on the peroxide is found in the 8% yield of 4-phenyl-1,2-epoxybutane. Benzyl radicals are also found as

[5] $PhCH_2\cdot + CH_2{=}CH{-}CH_2O_2t\text{-Bu} \longrightarrow Ph(CH_2)_2\dot{C}H{-}CH_2O_2t\text{-Bu} \xrightarrow{O_2} Ph(CH_2)_2\underset{\diagdown O \diagup}{CH}{-}CH_2 + t\text{-BuO}\cdot$

dimer and in the non-volatile residue (see below). Methyl radicals apparently do not add to the peroxide since no epoxypentane was found, and the methane yield is the same as acetone within experimental error.

Of the allyloxy portion of the peroxide, 30% is accounted for as allyl alcohol and 8% as epoxide. The remainder is presumably incorporated in the non-volatile residue. Infrared spectra of the latter revealed strong O—H and C=O absorptions, while nmr showed benzyl hydrogens superimposed on a broad, unresolved aliphatic absorption in a ratio of 1:5.2, but no vinyl C—*H*, nor any absorption due to *t*-Bu. Samples of residue taken after only 50% decomposition of peroxide showed a small amount of $\underset{\|}{\overset{O}{C}}{-}H$, but no aldehyde groups remained in material isolated after complete decomposition.

We surmise that the residue is a mixture of telomers, originally $PhCH_2(CH_2{-}\underset{|}{\overset{X}{C}}H)_nCH_2Ph$, where *n* is small and X is CH_2OH or CHO. Subsequent radical attack on —CHO yields $\underset{\|}{\overset{O}{C}}\cdot$ which may or may not decarbonylate prior to adding a few more monomer units and/or terminating. The possibility that "X" might be *t*-$BuCH_2O_2$ was worrisome since this would have biased the rate measurements. But while the peroxide itself is certainly a suitable monomer for the copolymerization, its absence from the polymer can be rationalized. The S_Hi to give epoxide + *t*-BuO· is probably much faster, under the circumstances, than addition of another monomer unit.

At this point, the general outlines of the thermal decomposition of allyl-*tert*-butyl peroxide in toluene are fairly clear. It is a mix of homolysis and radical-induced decomposition. At minimum, homolysis accounts for 15% (based on bibenzyl yield alone) or 22–23% if all the benzyl radicals found in the residue are counted. A maximum is impossible to assess, depending, as it does, both on

[e] Dead polymer.

acrolein yield, and the apportioning of the several routes for its production, neither of which can be assessed from the data.

Two kinds of radical-induced decomposition are evident, addition to C=C by alkyl radicals and allyl H-abstraction by alkoxy radicals. S_H2 displacement by alkyl radicals on the O—O bond is a third possibility but there is no evidence for it.

The foregoing conclusions, while instructive, seemed to underutilize the data at hand. The modelling exercise which follows suffers, however, from too little hard data, particularly in respect of residue structure. The basis set of reactions was chosen, after some experimentation, as the minimum number that with some stylization could match the significant products and the overall rate (Table 3).[2]

All polymer radicals were assumed to have the same free radical activity. Side chain reactivity was encompassed by an artificial device (CH, Table 3) used to indicate —CHO or CH_2OH in the polymer or polymer radical, and given an independent concentration.

Methyl radicals were included initially, but as this increased the number of equations by 6 or 7 and considerably enhanced the stiffness[3] of the set, all CH_3's were required to abstract from toluene (R4). This seemed fairly reasonable chemically, and did no violence to the fit. Prediction of CO yields was also deemed too complicated for similar reasons.

Toluene was taken to be constant at 9.4 *M* and its concentration incorporated into the rate constants where appropriate. Other conditions matched those of the experimental product studies; P_0 = 0.22 *M* and T = 150°C. Rate constants for H-abstractions and radical–radical combinations were assigned by reference to reviews by Hendry and co-workers (4, 5), and Ingold (6), respectively, while methyl acrylate (7) seemed to be the best available model for acrolein polymerization. Other rate constants were considered adjustable within reasonable limits. (In fact, all rate constants apart from free radical combinations could be so regarded since assignments for 150°C involved a substantial extrapolation from temperature ranges of the original data.)

Computations were carried out on a UNIX system, using Gear-type numerical integration, and were typically carried to 80–85% decomposition for comparison of predictions with the experimen-

[2] Table 3 and textual references to it are purposely stylized in order to make a clear distinction between chemistry and computational simulation. Adopting ordinary computer notation for the latter seems a readily comprehensible way of emphasizing the difference; Thus "E" for 10 to a power and *K* instead of *k* for rate constants.

[3] "Stiffness" is used in the mathematical sense, as a quality of differential equations that manifests itself in difficulty of numerical integration. Either the routine or the precision of the computer may be the limiting factor in the degree of stiffness that can be handled. In our case it was the computer, which had to be coaxed to solve even the 20 equations set.

tal results. Analytical minimization was not employed because the UNIX system proved incapable of handling both a minimization routine and Gear at the same time, and because minimization results for a scheme of this complexity have little credibility in any case. Instead a combination of intuition and hands-on experimental adjustment was used to produce a reasonable fit. The rate constants juxtaposed to the reactions (Table 3) produced the predicted product yields of Table 2 and an overall rate constant of 4.9×10^{-4} s^{-1} (cf. Table 1).

The predicted yields do approximate the experimental guide closely, the only serious inconsistencies being in the yields of acrolein (too high) and allyl alcohol (too low).[4] The model proved fairly rigid; attempts to improve the predictions for these products worsened the fit in other areas, and we suspect another reaction, perhaps a Diels–Alder, to be partly responsible for acrolein consumption.

Increasing the allyl alcohol yield is a more severe problem since it is generated only via the unimolecular homolysis and some of its is incorporated in the polymer. A partial solution to both difficulties would be to eliminate the cage disproportionation of t-BuO· with CH_2CHCH_2O· (R2), which was included with a rate constant arbitrarily set to equal 10% of all homolysis. It's difficult to see *why* cage disportionation should not be a factor, particularly as the t-BuO· + alkyl radical reaction is well documented (8), but perhaps it is not. Some years ago (9) we found that the thermal decomposition of $(MeEtCDO)_2$ in toluene yielded no MeEtCDOD. We were not wholly convinced at the time, nor are we now, but merely state our findings, to which as yet there has been no direct contradiction.

Generally speaking, the model lends support to the qualitative judgments about the course of the decomposition. The rate constants have little validity as yet, of course, but the important ones can be considered in the light of other data. A $K1$ of 2.4×10^{-4} s^{-1} is entirely believable. A value for $K10$ (and $K14$), abstraction of allyl-H from peroxide by alkoxy radicals, can be estimated for 60°C from the DBPO experiment. The relative concentrations of toluene and (average) peroxide, the efficiency of t-BuO· attack and k for t-BuO· + $PhCH_3$ (5)[5] give $K10_{60} = 1.28 \times 10^6$ M^{-1} s^{-1}. Comparing this to the model value of 4.4×10^6 M^{-1} s^{-1} at 150°C gives $K10 = 10^{8.62} \exp(-3840/RT)$, a value snugly between t-BuO· abstraction from a secondary alkene ($10^{8.2} \exp(-3350/RT)$) and from a secondary ether ($10^{8.7} \exp(-3910/RT)$) (5). The benzyl addition to peroxide is more difficult to gauge since good values for benzyl addition seem non-extant. A not unreasonable comparison can be made to RO_2· addition to 1-butene, however, which extrapolates to 157 M^{-1} s^{-1} at 150°C (5). The $K7$ value of 700 M^{-1} s^{-1} thus does not seem out of line.

In any case, we look forward to a forthcoming validity test when the numbers will be used in modelling a study of allyl hydroperoxide.

[4]Note that a comparison of polymer yields is not possible since the model doesn't assign a structure and permits initiation by radicals other than benzyl.

[5]We are not unaware of a more recent value of k for t-BuO· + $PhCH_3$ (10). However, (*a*) this value was not yet published when our computations were done, and (*b*) the new value does not have an associated activation energy; thus the necessary extrapolations to higher temperatures would be dubious. Since our conclusions are admittedly unprecise, it seems hardly worth jumping from one uncertainty to another just because the latter is newer.

Excitation spectrum of the near-ultraviolet bands of CS_2[1]

R. VASUDEV AND J. C. D. BRAND

Department of Chemistry, The Photochemistry Unit,[2] University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 5, 1979

R. VASUDEV and J. C. D. BRAND. Can. J. Chem. **58**, 454 (1980).

An excitation spectrum of the triplet–singlet band system of CS_2 vapor has been measured in the range 365–378 nm using a tunable laser source. Overall intensity is relatively insensitive to pressure in the range (150 mTorr – 340 Torr) tested in these observations. The results indicate that collisions with ground state molecules of CS_2 are efficient in promoting intersystem crossing to the ground state, and that the spontaneous emission observed is primarily resonance emission from the state populated by the radiation.

R. VASUDEV et J. C. D. BRAND. Can. J. Chem. **58**, 454 (1980).

On a mesuré le spectre d'excitation du système de bandes triplet–singulet du CS_2 gazeux entre 365 et 378 nm en utilisant une source réglable de laser. Entre 150 mTorr et 340 Torr la pression n'a relativement aucune influence sur l'intensité globale. Les résultats indiquent que les collisions avec les molécules de CS_2 dans l'état fondamental sont efficaces en ce sens qu'elles provoquent le passage d'un système à un autre vers l'état fondamental et que l'émission spontanée observée est essentiellement une émission de résonance à partir de l'état peuplé par la radiation.

Introduction

The near-ultraviolet $\tilde{a}$–$\tilde{X}$ band system (Kleman's R-system) of CS_2 in absorption is described in many papers. In the first comprehensive study, Kleman (1) established the vibration–rotation analysis and demonstrated that the $\tilde{a}$ state has a wide-angled equilibrium structure, $\theta \approx 136°$, with a low barrier, ~ 0.4 eV, to linearity. Zeeman measurements showed that the levels that combine radiatively with the ground state belong to the $B_2(\Sigma = 0)$ substate of a $^3A_2$ state split by case c coupling into $B_2(\Sigma = 0)$ and $A_1 + B_1(\Sigma = \pm 1)$ components (2–4). The electric dipole moment of the excited state is small, < 0.5 D, as expected from the wide-angle structure (5). Weak transitions to the $A_1 + B_1$ substates have been observed in the low-temperature crystal spectrum (6) but are apparently too weak to distinguish from the background of other transitions in the vapor absorption. As first suggested by Mulliken (7), $^3A_2$ is the lower-energy component of the $^3\Delta_u$ state of linear CS_2, split by Renner–Teller coupling into $^3B_2 + {}^3A_2$ (4, 6). No excited state of CS_2 has been found below $^3A_2$ in optical absorption or electron-impact studies (8–10).

In contrast to the absorption, emission from the $\tilde{a}$ state has hardly been studied at all. Hochstrasser and Wiersma (6) reported structureless emission from CS_2 in argon matrices, and similar unstructured emission results from thermal, shock-wave excitation of the vapor (11, 12). To the present, no report has appeared of optically-excited emission from the $\tilde{a}$ state of the vapor. This paper describes a laser-excitation vapor spectrum obtained by scanning the absorption in the region 365–378 nm with a pulsed laser. The results, though qualitative, indicate that rapid self-quenching by collision competes strongly with radiative emission from the $\tilde{a}$ state.

Experimental and Results

CS_2 emission was excited by an N_2-laser pumped tunable dye laser operated in the range 365–380 nm with PBD dye in toluene–ethanol mixtures as the lasing medium. The excitation spectrum (Fig. 1) was recorded with CS_2 vapor in a cell fitted with light baffles, using an EMI 9558 photomultiplier protected from residual scattered light by Corning 3-74 filters ($\lambda > 415$ nm), the PMT output being processed with a PAR boxcar averager. Peak power at the sample was 7–10 kW. Observation windows of different diameters were used to confirm that diffusion of molecules from the excitation region did not influence the results. A wavelength calibration (± 0.1 Å) was established by tuning a 0.5 m monochromator to a standard line in the Fe/Ne hollow cathode emission, then tuning the laser into coincidence.

The CS_2 sample was purified by freeze–pump–thaw cycles and the excitation spectrum (ES) recorded at pressures between 150 mTorr and 340 Torr. The high- and low-pressure ES show qualitatively similar though not identical intensity distribution, while the overall intensity was essentially independent of pressure (< 2-fold variation within the above range). Table 1 gives relative in-

tensities I_{es} in ES recorded through the $\lambda > 415$ nm blocking filters, corrected for the variation of laser power with excitation wavelength. The columns headed I_{ab} in Table 1 give relative numbers of photons absorbed from the exciting radiation,

$$[1] \quad I_{ab} = 100(I^0 - I)/I^0 = 100(1 - 10^{-d})$$

where $d = \log_{10} I^0/I$ is the optical density of the sample determined from separate measurements of the absorption spectrum recorded with the same bandpass used in ES experiments. In the case when the vibronic state pumped by the laser radiation relaxes first to a Boltzmann population in the electronic $\tilde{a}$ state, followed by spontaneous emission or collision-induced intersystem crossing to the ground state, the ratio I_{es}/I_{ab} is proportional to the quantum yield of emission. However, it is shown in the next section that vibrational relaxation of excited CS_2 does not precede emission; hence I_{es}/I_{ab} responds to changes in the Franck–Condon profile of emission as well as in quantum yield.

Errors due to overlapping bands are troublesome in both ES and absorption (see, e.g., re. 5), but the optical density data for Σ bands are in fair agreement with the intensity measurements of Barrow and Dixon (4). Peak frequencies in the ES correlate well with bandheads in absorption though a number of weak bands in absorption are relatively prominent in ES. The limits of the ES were determined by low absorbance of CS_2 on the long-wavelength side and by the gain profile of PBD at short wavelengths.

Although attempts to disperse the CS_2 emission were unsuccessful the frequency range in the emission was explored crudely by filters. Using a 580 nm cut-off filter the emission intensity for certain bands is reduced 50% (see Table 2); therefore, since the S-20 response of the photomultiplier drops sharply at $\lambda > 575$ nm, an important fraction of the total emission must occur in the red spectral region. However, not all bands are affected equally by the long-wavelength cut-off filter, and comparisons offer some insight to the relaxation of excited CS_2 as discussed in the following section.

Table 1 offers a number of new assignments in the band system. Since the resolution in ES, $\sim 0.7\ cm^{-1}$, is not sufficient to determine the value of the rotational quantum number K, these assignments are based on frequency considerations only and should be regarded as tentative.

Discussion

Table 2 summarizes relative intensity measurements in ES using 415 and 580 nm cut-off filters for a selected group of strong bands. The ratio $I(415)/I(575)$ shows a definite upward trend with

increasing values of v_2' in the emitting state. To the extent that a shift in this ratio indicates a shift in the center of gravity of the Franck–Condon distribution in emission, it follows that the frequency characteristics of the emission depend on the quantum numbers of the state populated by the radiation. This is surprising because, especially at 340 Torr pressure, one might expect that collisions would lead to a Boltzmann population of upper state levels. This cannot be the case however; instead, the excited state must be quenched rapidly by collisions so that an important fraction of spontaneous emission occurs from the state excited by the laser. We do not claim that the emission is exclusively resonance emission, though it appears that it is predominantly so. Taking into account the striking pressure-insensitivity of overall ES intensity (see above) the kinetic scheme, in lowest order, becomes:

$$[2] \quad CS_2 + h\nu = CS_2^* \qquad k_1$$

$$[3] \quad CS_2^* + M = CS_2 + M \qquad k_2$$

$$[4] \quad CS_2^* = CS_2 + h\nu \qquad k_3$$

where CS_2^* is a single vibronic state populated by the radiation, and $k_2(M) \gg k_3$ for $M = CS_2$. At high pressure the likelihood that a unimolecular radiationless decay channel will compete effectively with the collision-induced intersystem crossing [3] is remote, and this possibility is not considered in the scheme above.

Our explanation of the intensity shift between different cut-off filters can be outlined by reference to the potential energy section in Fig. 2. The ground state potential curve is based on the force field given by Suzuki (13); this curve is extrapolated far beyond its fitted range and should be considered

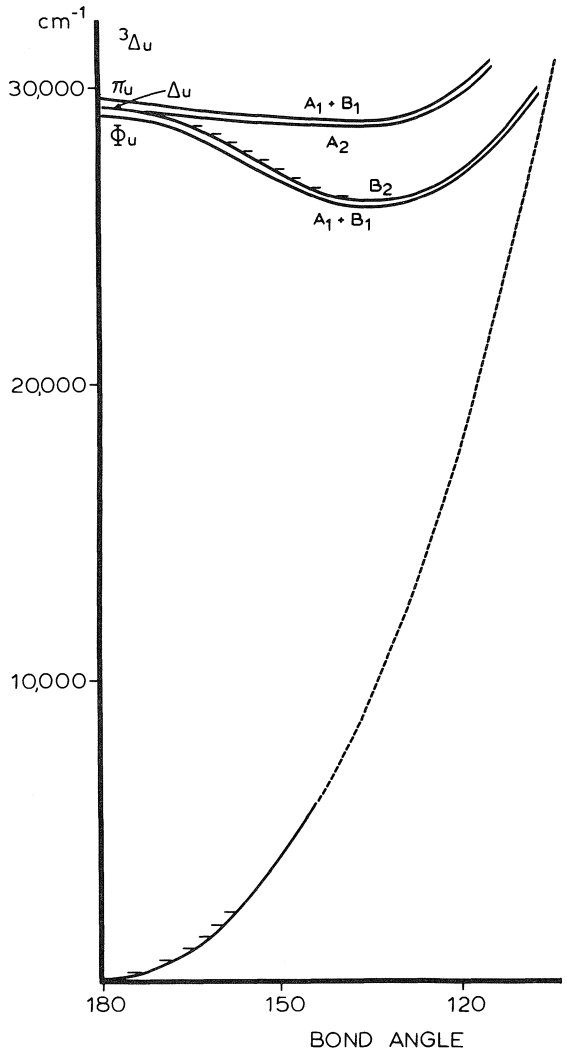

FIG. 2. Potential energy section in the plane of the bending coordinate. Spin splittings in the excited state (see refs. 3, 4, 6) are expanded to avoid congestion. Energy levels of the bending vibration are indicated in both states of the transition.

schematic at energies much above 5000 cm^{-1}. For the sake of argument, we also assume that emission from a given upper state with quantum number v_2' is concentrated in vertical transitions from the inner and outer turning points of the vibration, though this may not be a good quantitative description. Unless v_2' is small, the vertical transition from the outer turning point of the upper state potential occurs at an infrared frequency, whereas that from the inner turning point falls in the near-ultraviolet region; further, intensity will be distributed unequally since the ν^3 factor in the expression for spontaneous emission favors the higher-frequency transition. If we now relax the condition that the emission is concentrated into vertical transitions, it is reasonable to expect that the center of gravity of its Franck–Condon envelope will shift progressively towards higher frequencies with increasing v_2', which is also the direction of increasing phototube response. Consequently, in monitoring the total emission from different upper-states vibrational levels, the contribution of red wavelengths (transmitted by the $\lambda > 575$ nm filter) should fall as v_2' increases, which accords with the results in column 3 of Table 2.

Finally, the last column of Table 2 shows the variation of ES intensity relative to the absorption parameter I_{ab} defined in eq. [1]. This ratio changes considerably from one band to another, corresponding to the fact that the ES profile for CS_2 is by no means superimposable on the absorption spectrum. As mentioned earlier, I_{es}/I_{ab} is proportional to quantum yield *provided* the emission is preceded by vibrational relaxation in the upper electronic state, so that the large variation observed supports the conclusion that the self-quenching rate-constant is greater than that for vibrational energy transfer within the excited state. Since the ratios I_{es}/I_{ab} in Table 2 are un-normalized, the absolute values have no meaning; but trends are expected to be significant. Thus, the tendency for I_{es}/I_{ab} to increase with increasing v_2' is almost certainly due in part to the factors discussed in the previous paragraph, i.e., to the response of the detection system to the changing Franck–Condon envelope of the emission. However, we doubt if this is a complete explanation for two reasons: (*i*) the vibrational dependence is sharper than expected, and (*ii*) there is a suggestion that I_{es}/I_{ab} reaches a minimum in the $v_1' = 0$ series near $v_2' = 5$, which is not predicted from Franck–Condon arguments. At present, there is no clear indication of the reason for these anomalies and more experiments are needed.

Photoreactions of α-sulfonyloxyketones

JAMES LESLIE CHARLTON,[1] HOI KIONG LAI, AND GERALD NICHOLAS LYPKA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

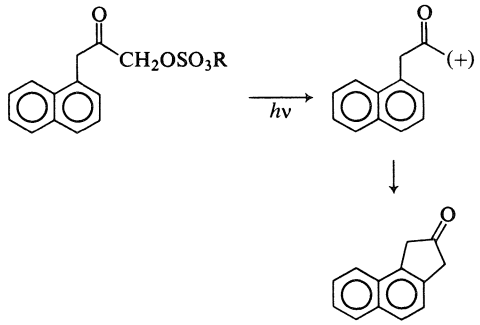
Received September 18, 1979

JAMES LESLIE CHARLTON, HOI KIONG LAI, and GERALD NICHOLAS LYPKA. Can. J. Chem. **58**, 458 (1980).

Earlier work on the photochemistry of α-sulfonyloxyketones uncovered their propensity to form the corresponding α-keto carbonium ions on photolysis. Typical reactions such as intramolecular cyclizations, carbonium ion rearrangements, and solvent trapping were found. This paper describes an attempt to extend this reaction to a general synthetic technique for polyene cyclizations. During the course of this work two other major reaction pathways were found. The first is an α-keto carbonium ion to acylium ion rearrangement and the second is a photoreduction–elimination process that leads to an α-keto radical rather than the corresponding cation.

JAMES LESLIE CHARLTON, HOI KIONG LAI et GERALD NICHOLAS LYPKA. Can. J. Chem. **58**, 458 (1980).

Des travaux antérieurs sur la photochimie des α-sulfonyloxycétones ont permis de mettre en évidence leur tendance à former les ions α-céto carbonium par photolyse. On a trouvé des réactions typiques telles que des cyclisation intramoléculaires, des transpositions de l'ion carbonium et sa capture par le solvant. Cette publication décrit une tentative d'étendre cette réaction à une technique générale de synthèse pour la cyclisation des polyènes. On a trouvé au cours de ce travail deux autres voies principales pour la réaction. La première est une transposition d'un ion α-céto carbonium en un ion acylium et la deuxième un procédé de photoréduction–élimination qui conduit au radical α-cétonique plutôt qu'au cation correspondant.

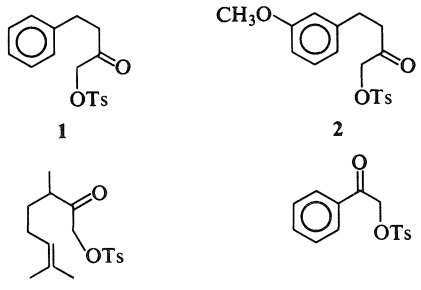


[Traduit par le journal]

Introduction

Concurrent with the discovery in 1966 that squalene oxide was enzymatically converted to lanosterol (1), several groups, notably those of Stork (2), Eschenmoser (3), Johnson (4), and van Tamelen (5) attempted to extend the scope of such reactions to provide a general nonenzymatic method for cyclization of polyenes. Most of the work has involved the intermediacy of cations (for example, see ref. 6) although both Breslow (7) and Julia (8) have demonstrated that free radical intermediates can also be used in initiating such polyene cyclizations.

Although the cationic or free radical intermediates of these reactions are usually generated by chemical and/or thermal catalysis, photochemical initiation has the advantage that the temperature can be kept low and no secondary chemical catalyst need be added. Witkop and co-workers have exploited this photochemical approach in their study of the cyclization reactions of *N*-chloroacetyl compounds (9). Schaffner and co-workers have also found that the photolysis of α-sulfonyloxyketones leads to cyclization, presumably via an α-keto carbonium ion as illustrated below (10).



This paper describes our attempt to extend the scope of the cyclization reactions of α-sulfonyloxyketones. In the course of this work we have encountered two major photochemical reaction pathways for these systems in addition to that described above.

Syntheses and Photolyses

In order to determine the scope of the photocyclization reaction of α-sulfonyloxyketones we have synthesized and photolysed the α-tosyloxyketones **1**, **2**, and **3** shown below. α-Tosyloxyketone **4** was synthesized and photolysed to investigate the competing side reactions.

The sequence shown in Scheme 1, wherein an acid chloride is converted to a diazoketone and thence to the α-tosyloxyketone, was found to be the

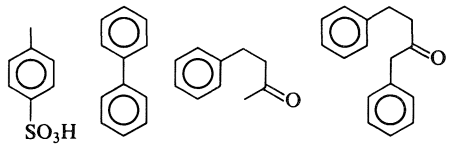
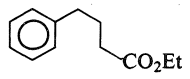


SCHEME 1

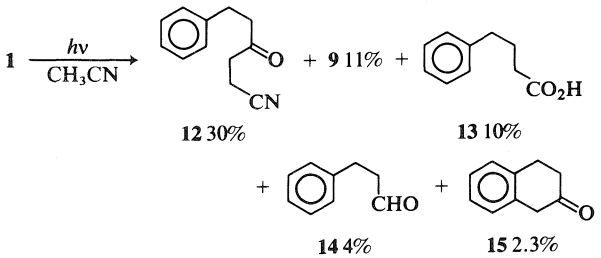
best generally applicable synthetic method for these compounds. The synthesis of the acid chlorides leading to the tosylates **1**, **2**, and **3** was accomplished using standard methods as described in the Experimental. Tosylate **4** was synthesized from benzoyl chloride.

1-Tosyloxy-4-phenyl-2-butanone 1



α-Tosyloxyketone **1** was irradiated in benzene, diethyl ether, ethanol, and acetonitrile. Compounds **7**, **8**, **9**, and **10**, shown below, were isolated after irradiation in benzene.

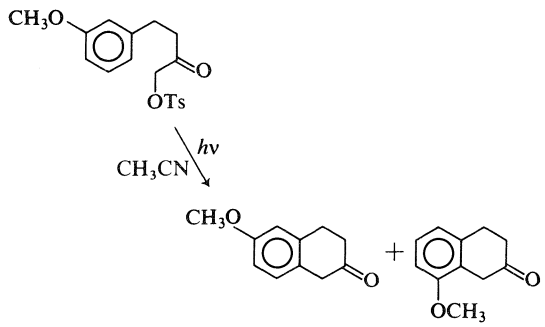
7 74% **8** 13% **9** 7% **10** 10%



All products were identified by comparison (gas chromatography and/or mass spectrometry) with authentic samples. The yield of toluenesulfonic acid was estimated from titration of total acid, while the yields of **8**, **9**, and **10** were determined by gas chromatography.

In ether solution, the yield of toluenesulfonic acid was 88% and the yield of methyl ketone **9** was 32%. Many minor components were also observed but not identified. In ethanol–acetonitrile the major products were the methyl ketone **9** (28%) and ethyl 4-phenylbutanoate **11** (10%, isolated yield).

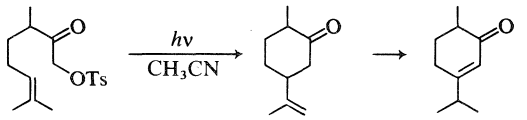
11



In dry acetonitrile, the major product had spectral data most consistent with the acetonitrile adduct **12**. This adduct was not identified by comparison with an authentic sample and hence its structural assignment is tentative. The remaining products were all identified unambiguously.

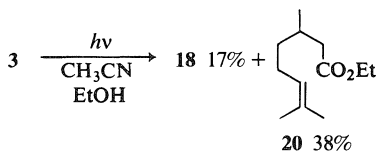
12 30% **13** 10% **14** 4% **15** 2.3%

1-Tosyloxy-4-(3-methoxyphenyl)-2-butanone



The irradiation of tosyloxyketone **2** was carried out in acetonitrile and benzene. The major products from irradiation in acetonitrile were the β-tetralones **16** and **17**, both identified by comparison with authentic samples. Photolysis in benzene and analysis of the volatile components by gas chromatography indicated that the product mixture was qualitatively similar to that obtained in acetonitrile.

16 24% **17** 23%



1-Tosyloxy-3,7-dimethyl-6-octene-3-one

Tosylate **3** was irradiated in acetonitrile in the presence of anhydrous potassium carbonate added to stop a slow, acid-catalysed decomposition of the tosylate. Gas chromatograph – mass spectrograph analysis showed the major product to be dihydrocarvone **18**, which isomerized very readily to 2-carvenone **19**.

dihydrocarvone **18** 2-carvenone **19**

Irradiation in acetonitrile containing ethanol gave dihydrocarvone **18** and ethyl 3,7-dimethyl-6-octenoate **20**.

20 38%

α-Tosyloxyketone 4

Photolysis of tosylate **4** in ethanol–acetonitrile gave increasing amounts of acetophenone and decreasing amounts of ethyl phenylacetate as the ethanol concentration was increased (Table 1).

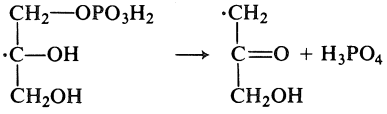
TABLE 1. Yields of acetophenone and ethyl phenylacetate

% Ethanol	% Acetophenone	% Ethyl phenylacetate
2	7.6	19
20	28	11
50	47	2.2

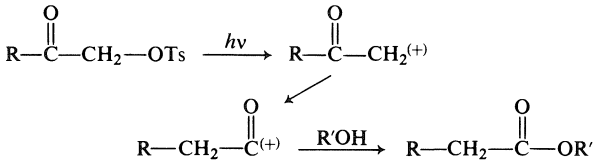
The products were found to be unstable under the reaction conditions. Maximum yields were obtained at less than full conversion of the tosylate and are not corrected for unreacted tosylate. The rate of photolysis was considerably increased at the higher ethanol concentration.



Discussion

From the first three tosyloxyketones studied, it appears that photocyclization yields are too variable to make this reaction a general synthetic method, but some conclusions regarding the general photoreactivity of these systems can be made. There seem to be two main reaction pathways, the first being a reduction–elimination route to the α-keto radical (Scheme 2).

SCHEME 2



This mechanism was first proposed by Szarek and Dmytraczenko (11) and is analogous to the elimination of phosphate from radical **23**, as reported by Schulte-Frohlinde and co-workers (12) and Samuni and Neta (13).

23

The results obtained from the photolysis of tosylate **4** in mixed acetonitrile–ethanol solvents are also consistent with the proposed mechanism. Ethanol, being a better hydrogen atom donor, increases the amount of photoreduction as its concentration is increased. Methyl ketone **9**, adducts **11** and **12**, and dihydrocarvone **18** (7) may all arise from the α-keto radical formed in the photoreduction–elimination reaction.

The second main reaction pathway for α-tosyloxyketones, as previously described by Schaffner and co-workers (10), is the heterolysis to the α-keto carbonium ion. However, we find that the major process following the formation of this ion is rearrangement to the acylium ion as shown in Scheme 3.

SCHEME 3

Thus from tosylates **1**, **3**, and **4** we obtain the butanoate ester **11**, the octenoate ester **20**, and ethyl phenylacetate, respectively. The rearrangement appears to compete effectively with cyclization reactions as the yield of tetralone from tosylate **1** is less than 3 percent under the best conditions. Only for compound **2** is cyclization the major process. Whether the cyclization process is free radical or ionic is unknown but it does appear that a very reactive center, such as the methoxyphenyl group, is necessary before cyclization is dominant.

Experimental

Mass spectra were recorded on a Finnegan 1015 mass spectrometer and only molecular ions and major fragments are reported. Nuclear magnetic resonance (nmr) spectra were obtained on a Varian EM360 or A-56/60 spectrometer using tetramethylsilane as internal standard. Camag Kieselgel DSF-5 and Davidson Chemical, grade H silica gel (60–200 mesh) were used for thin layer and column chromatography. Gas chromatographic analyses were performed on a Hewlett-Packard 700 instrument. Elemental analyses were performed by Chemalytics Inc., Tempe, AZ.

Hydrocinnamoyl and 3-Methoxyphenylhydrocinnamoyl Chloride

trans-Cinnamic acid (Eastman Kodak) and 3-methoxyphenyl cinnamic acid (Aldrich) were hydrogenated in ethanol over platinum to yield 83% and 95% of the hydro derivatives respectively. The acids were converted to the acid chlorides by refluxing in a mixture of thionyl chloride and benzene.

4-Phenyl-1-diazobutan-2-one

The 4-phenylbutanoyl chloride (hydrocinnamoyl chloride) was added to 3 equivalents of diazomethane in ether and followed by one equivalent of triethyl amine. The solution was stirred at room temperature for one hour, evaporated to dryness *in vacuo*, and chromatographed on silica gel using benzene–ether as eluant. The diazo ketone was obtained in 80% yield as a yellow oil; ir (neat): 2115 ($COCHN_2$), 1740 (C=O) cm^{-1}; nmr (CCl_4) δ: 7.1 (s, 5H), 4.93 (s, 1H), 2.40–2.85 (m, 4H); ms *m/e*: 174.

1-Tosyloxy-4-phenyl-2-butanone ***1***

p-Toluenesulfonic acid monohydrate (6.34 g, 0.033 mol) was added at room temperature to a solution of 4-phenyl-1-diazobutan-2-one (5.74 g, 0.033 mol) in anhydrous ether (50 mL). After 0.5 h the solution was washed with water, dried ($MgSO_4$), and evaporated to give crystals which recrystallized from benzene–pentane to yield 6.9 g (66%); mp 69–70°C; ir

(Nujol): 1730 (C=O) cm^{-1}; nmr δ: 7.1–7.7 (q, 4H), 7.05 (s, 5H), 4.25 (s, 2H), 2.78 (s, 4H), 2.45 (s, 3H); ms *m/e*: 318, 155, 146, 133, 105, 91, 77; *Anal.* calcd. for $C_{17}H_{18}O_4S$: C 64.15, H 5.66, S 10.06; found: C 64.40, H 5.76, S 10.15.

4-(3-Methoxyphenyl)-1-diazobutan-2-one

The procedure was identical to that found for the 4-phenyl derivative. The yield was 88% of yellow oil; ir (neat): 2125 ($COCHN_2$), 1730 (C=O) cm^{-1}; nmr (CCl_4) δ: 6.35–7.1 (m, 4H); ms *m/e*: 204.

1-Tosyloxy-4-(3-methoxyphenyl)butan-2-one

4-(3-Methoxyphenyl)-1-diazobutan-2-one (3.52 g, 0.017 mol) was reacted with *p*-toluenesulfonic acid monohydrate (3.61 g, 0.019 mol) as described above. After chromatography on silica gel (eluant benzene) 3.5 g (59%) of oil was obtained; ir (neat): 1740 cm^{-1}; nmr (CCl_4) δ: 7.2–7.66 (q, 4), 6.4–7.1 (m, 4), 4.25 (s, 2, $—COCH_2O—$), 3.6 (s, $—OCH_3$), 2.67 (broad s, 4, $—CH_2CH_2$), 2.3 (s, 3H, CH_3); ms *m/e*: 348, 194, 163, 155, 135, 121; *Anal.* calcd. for $C_{18}H_{20}O_5S$: C 62.07, H 5.75, S 9.20; found: C 62.51, H 5.86, S 9.43.

6-Methyl-5-hepten-2-ol

6-Methyl-5-hepten-2-one (12.6 g, 0.1 mol, Aldrich) was reduced in ether with $LiAlH_4$ (1.33 g, 0.035 mol) to give a quantitative yield of the alcohol; nmr (CCl_4) δ: 4.9 (broad t, 1H), 4.0 (broad s, 1H), 3.5 (m, 1H), 1.6–2.18 (m, 4H), 1.53 (s, 3H), 1.52 (s, 3H), 1.0 (d, 3H); ms *m/e*: 128, 110, 95.

2-Bromo-6-methyl-5-heptene

The alcohol above (4.65 g, 0.036 mol) was treated with pyridine (1.58 g) and PBr_3 (3.06 g, 0.018 mol) in ether. Work up and distillation yielded 2.9 g (42%) of colourless oil; nmr (CCl_4) δ: 4.9 (broad t, 1H), 4.1–4.4 (m, 1H), 1.75–2.3 (m, 4H), 1.54 (broad s, 6H), 1.2 (d, 3H).

2-Cyano-6-methyl-5-heptene

The 2-bromo-6-methyl-5-heptene was converted to the 2-cyano derivative using the method of Smiley and Arnold (14). Thus, the bromo compound (9.13 g, 0.048 mol) was reacted with NaCN (3.35 g) in DMSO (40 mL) to give the nitrile (3.91 g, 60%); nmr (CCl_4) δ: 4.8 (broad t, 1H), 2.1–2.3 (m, 1H), 1.4–1.9 (m, 4H), 1.3 (broad s, 6H), 0.9 (d, 3H); ms *m/e*: 137, 110, 95.

2,6-Dimethyl-5-heptenoic Acid

The nitrile from above (0.85 g, 6.2 mmol) in ethanol (2 mL) was added to a solution of KOH (3.36 g) in ethylene glycol (10 mL) and water (2 mL). After 18 h at reflux, the usual workup yielded the acid (0.65 g, 67%) with nmr and ir consistent with those reported in the literature (15).

2,6-Dimethyl-5-heptenoic Acid Chloride

A mixture of 2,6-dimethyl-5-heptenoic acid (0.16 g) and dry pyridine (3 drops) in dry benzene (25 mL) was treated at 0.5°C with freshly distilled oxalyl chloride (1.26 g) and then warmed to room temperature and left for 2 h. Filtration and evaporation gave the acid chloride 0.15 g (86%) (15).

1-Diaza-3,7-dimethyl-6-octene-2-one

The diazoketone was prepared by the method described for 4-phenyl-1-diazobutan-2-one in 76% yield. (See also ref. 15.)

1-Tosyloxy-3,7-dimethyl-6-octene-2-one

The diazoketone was converted to the tosyloxy derivative by treatment with ethereal *p*-toluenesulfonic acid (1.1 equivalents) in 82% yield; ir (neat): 1740, 1380, 1190, 780, 820 cm^{-1}; nmr (CCl_4) δ: 7.19–7.76 (q, 4H), 4.95 (bt, 1H), 4.46 (2H, s), 2.4 (s, 3H), 1.52 (s, 3H), 0.95 (d, 3H); ms *m/e*: 170, 155, 152, 139, 110, 95.

α-Tosyloxyacetophenone **4**

α-Diazoacetophenone was prepared according to the method described above (16) and converted to the α-tosyloxyacetophenone (17) with ethereal toluenesulfonic acid. The overall yield from benzoyl chloride was 51%.

Photolyses

All irradiations were carried out in water cooled quartz or Vycor vessels at 2537 Å (UV Products PCQX1 or Rayonet photochemical reactor).

Photolysis of 1-Tosyloxy-4-phenyl-2-butanone **1**

A solution of **1** (10 mg) in dry thiophene-free benzene (6 mL) was irradiated for 1 h, the solution washed with water, and the water evaporated. The residue, identified as *p*-toluenesulfonic acid by mass spectroscopy, was titrated with standard base and required 2.31×10^{-5} equivalents (73.5%). The organic layer was evaporated and analysed by a tandem gas chromatograph – mass spectrograph (gc–ms) (gc: 10% Se30 on Chromosorb W, 6 ft × 1/8 in., programmed from 100 to 220°C). The identity of products was confirmed by comparison with authentic samples (see below) and yields were determined by gc using 2-phenylacetophenone as internal calibrant. In order of gc retention times the products identified were: (*1*) 4-phenyl-2-butanone (7%); an authentic sample was prepared by hydrogenation of benzalacetone (18) in absolute ethanol in the presence of PtO_2 (100%); (*2*) 4-phenyltoluene (12%), identical to a commercial sample (Aldrich Chemicals); and (*3*) 1,4-diphenyl-2-butanone (10% yield). The authentic sample was prepared by reacting the Grignard of benzylchloride with hydrocinnamaldehyde in the usual way, giving the alcohol (24%) which was subsequently oxidized in ether to the ketone (88%) using 10% CrO_3 in 5% aqueous H_2SO_4 (19).

Irradiation of tosyloxyketone **1** (100 mg) in absolute ethanol (25 mL) led to a complex mixture of at least 6 volatile components. From among these, only two major components were identified by gc–ms as 4-phenyl-2-butanone and ethyl 4-phenylbutanoate. (The authentic ester was prepared from 4-phenylbutanoic acid and ethanol in the usual manner.) A solution of **1** (500 mg) in acetonitrile–ethanol (4:1, 100 mL) in the presence of anhydrous potassium carbonate (50 mg) was similarly irradiated and gc analysis indicated a higher yield of the ketone and ester. The solution was filtered, evaporated, the residue dissolved in ether, and this extracted with dilute aqueous bicarbonate. The ether layer after drying ($MgSO_4$) and evaporation yielded 190 mg which was chromatographed on tlc (benzene) to yield 4-phenyl-2-butanone (65 mg, 28%) and ethyl 4-phenyl-1-butanoate (32 mg, 10%).

Compound **1** (1.013 g), in dry acetonitrile (100 mL) with anhydrous potassium carbonate (500 mg), was irradiated under nitrogen for 18 h in a Rayonet photochemical reactor. The mixture was filtered, evaporated, and then dissolved in ether – aqueous bicarbonate. The aqueous layer was separated, acidified, and extracted with ether to yield 4-phenylbutanoic acid (50 mg, 10%), identified by comparison to a commercial sample (Aldrich). The ether layer was dried ($MgSO_4$), evaporated, and chromatographed on silica gel (benzene–ether, Camag DSF-5) to yield: (*1*) hydrocinnamaldehyde (14.5 mg, 3.7%), compared to commercial sample (Aldrich); (*2*) 4-phenyl-2-butanone (48 mg, 11%); (*3*) β-tetralone (9 mg, 2%) identified by comparison to commercial sample (Aldrich); (*4*) unreacted tosyloxyketone **1** (74 mg); and (*5*) a crystalline compound (168 mg, 30% as $C_{12}H_{13}NO$); nmr ($CHCl_3$) δ: 7.06 (s, 5H), 2.8 (s, 2H) 2.3–2.78 (m, 3H), 2.27 (s, 3H); ms *m/e*: 187, 164, 146, 104, 91.

Photolysis of 1-Tosyloxy-4-(3-methoxyphenyl)-2-butanone **2**

A mixture of tosyloxyketone **2** (395 mg), anhydrous potas-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

sium carbonate (400 mg), and acetonitrile (45 mL) was irradiated under nitrogen for 8 h in a Rayonet photochemical reactor. The mixture was filtered, evaporated (at room temperature), dissolved in ether – aqueous bicarbonate, the ether dried ($MgSO_4$), evaporated, and the residue chromatographed on tlc (ethyl acetate – benzene) to yield: (*1*) 6-methoxy-2-tetralone (44.3 mg, 24%), identified by comparison of gc retention time (10% Carbowax 20 m on Chromosorb W, 6 ft × 1/8 in., 180°C) and mass spectrum to a commercial sample (Aldrich), and (*2*) 8-methoxy-2-tetralone (42 mg, 23%), identical to a sample synthesized by the method of Robins and Walker (20).

Irradiation of tosyloxyketone **2** (10 mg) in benzene (6 mL) under nitrogen and analysis by gc (as above) indicated that the products were qualitatively similar to the results obtained in acetonitrile.

Photolysis of 1-Tosyloxy-3,7-dimethyl-6-octen-2-one ***3***

Tosyloxyketone **3** (410 mg) and anhydrous sodium carbonate (400 mg) were irradiated in acetonitrile (60 mL) under nitrogen for 2 h. The solution was then filtered, evaporated, and worked up by ether–water extraction. The crude product (160 mg) analyzed by gc–ms (10% Apiezon – 1% DEGS on Chromosorb W, 8 ft × 1/4 in., 160°C) showed the presence of both dihydrocarvone and 2-carvenone, synthesized as described by Wallach (21) and Buchi and Erickson (22). The 2-carvenone was subsequently shown to arise from isomerization on the gc column. The total yield of dihydrocarvone and 2-carvenone, isolated by gc, was 42 mg (22%).

Irradiation of **3** (2.91 g) in acetonitrile and ethanol (100 mL, 99:1) with potassium carbonate (3.0 g) under nitrogen, followed by the usual workup (see above) and chromatography on silica gel (Camag DSF-5, benzene–pentane) gave ethyl 3,7-dimethyl-6-octenoate (200 mg, 17% based on 65% conversion), dihydrocarvone (150 mg, 17% based on 65% conversion), starting tosyloxyketone **3** (1.0 g), and a mixed fraction (500 mg), eluted with ether, that still contained the tosyl group (nmr). This later fraction was not investigated further. An authentic sample of ethyl 3,7-dimethyl-6-octenoate was synthesized from citronellal (Chemical Service) by oxidation (23) and esterification with absolute ethanol.

A similar irradiation in acetonitrile–ethanol (4:1) yielded 38% of the ester.

Photolysis of α-Tosyloxyacetophenone ***4***

A mixture of the tosylate (300 mg), anhydrous potassium carbonate (500 mg), absolute ethanol, and purified acetonitrile (50 ml) was irradiated under nitrogen in a Vycor vessel using a low pressure mercury lamp (2537 Å). Yields of acetophenone and ethyl phenylacetate were obtained from gas chromatography (10% Se-30 on Chromosorb P, 10 ft × 1/8 in., 145°C) using diphenylmethane as an internal standard, and were determined at peak product concentrations. They were not corrected for any unreacted starting material. Yields are recorded in Table 1.
