The fully protected nucleoside derivatives **4** were obtained in greater than 90% yields (Table 1) within 6 h by treating compounds **1** with levulinic acid and dicyclohexylcarbodiimide (DCC) in dioxane (Scheme 2). Isomerization of the silyl group did not occur during this reaction. This was verified by the preparation of the isomeric compounds **6** from the 3′,5′-diprotected nucleosides **5**. It is interesting to note that with the adenosine derivative **1***b* no levulination occurred at the exocyclic amino group. In fact an attempt to produce *N*-acylation was marginally successful: 2′,3′,5′-tri-TBDMS adenosine (2) was only 10% acylated at the 6-amino group when treated with a 3-fold excess of levulinic acid and DCC.

The 5′-methoxytrityl group can be removed from **4** and **5** using 80% acetic acid at either room temperature for 15 h or at 90°C for 30 min. Yields on detritylation were 80–90%. In preparative conversions of **1** to **2** there is no need to isolate compound **4**.

The isomeric pair **4** and **6** as well as the pair **2** and **7** have different chromatographic properties and are easily distinguished (Table 1). Their nmr spectra are also clearly different. The chemical shift of the H-1′ signal is greatest in all cases for the isomer having the levulinyl group in the 2′-position. This trend corresponds to the general observation made several years ago by Reese and co-workers (13) who also noted that $J_{1',2'}$ is greater for the 3′-isomer than for the 2′-isomer. For the levulinated nucleosides described in this paper $J_{1',2'}$ is greater when the levulinyl group is on the 3′-position for A and G derivatives or on the 2′-position for C and U derivatives. It is also interesting that the magnitude of the coupling constants is greater for the purine derivatives than for the

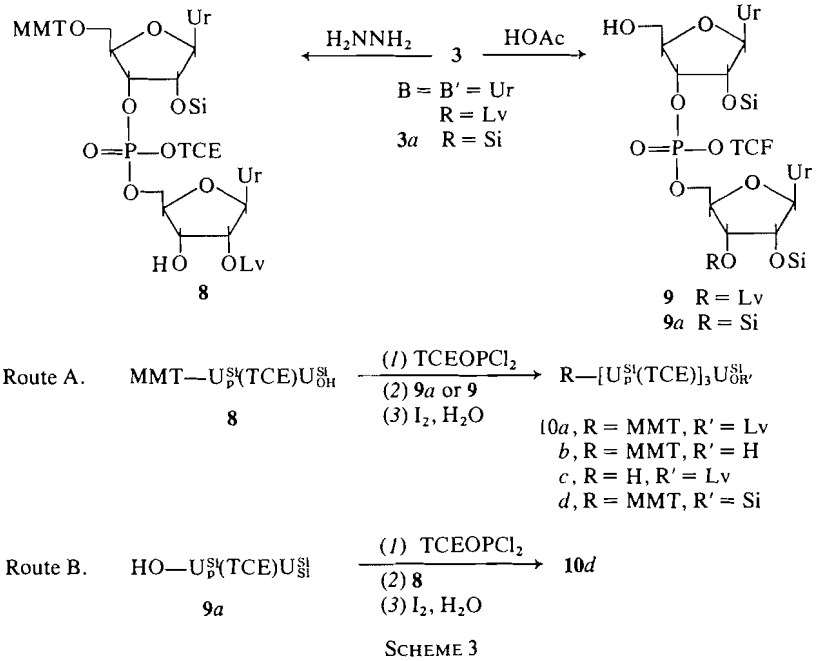
SCHEME 2

pyrimidine derivatives. This trend is also true for the silyl derivatives that we have previously reported (2, 3).

Nucleosides having a 5′-methoxytrityl group and a 2′ or 3′-TBDMS group show interesting chemical shifts for the methyl and *tert*-butyl protons of the TBDMS group. For pyrimidine nucleosides (C, U), the 3′-TBDMS protons are significantly shielded relative to the 2′-TBDMS isomer. For purines (A, G) the trend is just the reverse (2, 3). The same observation is made for the compounds reported in this manuscript which also contain a levulinyl group. Thus in MMT-U^{Si}_{Lv} and MMT-$C^{Bz}{}^{Lv}_{Si}$ the 3′-TBDMS protons are shielded relative to their 2′-TBDMS isomers **4***a* and **4***c* while the reverse is true for MMTA^{Si}_{Lv} and MMT-$G^{Bz}{}^{Lv}_{Si}$. For the untritylated compounds **2** and **7**, the 3′-TBDMS protons (**7***a–d*) all have greater chemical shifts than the 2′-TBDMS isomer (**2***a–d*).

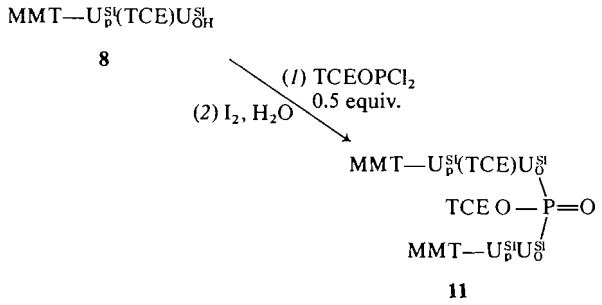
Compounds **6** and **7** are not only useful in confirming the structure of **4** and **2** but are obvi-



ously useful in the synthesis of 2′–5′ linked ribonucleotides. With the observation of the production of 2′–5′ linked oligoadenylates during the interferon process (14) it has become essential to be able to synthesize such linkages. We have reported the synthesis of a trinucleotide of adenosine possessing 2′–5′ linkages (15) and the development of compounds **6** and **7** will permit the rapid synthesis of any desired sequence involving 2′–5′ linkages.

The levulinyl group is removed rapidly from the fully protected nucleosides. Reactions using pyridine – acetic acid – hydrazine result in complete cleavage of the levulinyl group in less than five minutes. These conditions do not affect *N*-protecting groups nor do they cause isomerization of silyl groups (e.g. in **1**). Using the normal ratio of hydrazine (10 equiv.) with **1***a* resulted in detectable isomerization of the silyl group only after 2 h of stirring. Using 50 equiv. of hydrazine resulted in detectable isomerization after 2 h and led to 30% isomerization after 17 h. Since removal of the levulinyl group requires 5 min or less, there is obviously no problem with isomerization during the conversion of **4** to **1** and none has been detected. Furthermore, these conditions do not affect benzoyl groups on the amino groups of cytidine and guanosine.

Nucleotide Synthesis and Block Condensations



The utility of the above described combination of protecting groups was tested through the synthesis of oligonucleotides of uridine. The dinucleotide **3** (B = B′ = Ur, R = Lv) was prepared on numerous occasions by the phosphite coupling reaction using **1***a* and **2***a*. Yields ranged from 75 to 86% on reaction scales involving from 300 mg up to 7 g of **1***a*. Compound **3** provided the key intermediate for testing the phosphite procedure in block condensations (Scheme 3).

Treatment of **3** with hydrazine gave **8** in over 90% yield while treatment of **3** with acetic acid gave **9** in greater than 85% yield. In an attempt to determine the best conditions for block condensations, compounds **8** and **9***a* were condensed by two different routes to produce the tetranucleotide **10***d*. Route A (Scheme 3) is the route we have normally used (2–4) and involves phosphorylation at the 3′-hydroxyl (of **8**) followed by coupling to the 5′-hydroxyl (of **9***a*). The alternate procedure, Route B, involves phosphorylation first at the 5′-hydroxyl (of **9***a*) followed by coupling to the 3′-hydroxyl (of **8**). We found that Route A gave consistently better yields than Route B. Further we have found that in

SCHEME 3

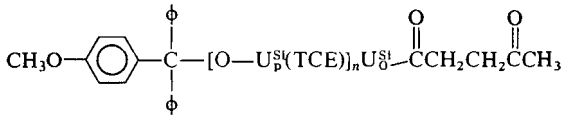
For personal use only.

block condensations better yields are obtained in reactions conducted at 0°C than in those conducted at −78°C.



One of the side reactions in the synthesis of short nucleotides via the Route A approach is the formation of 3′–3′ linked nucleotides (2–4). While this seldom represents a separation problem we felt it to be essential to determine the probability of 3′–3′ coupling in block condensations. Consequently an attempt was made to determine the maximum amount of 3′–3′ linked tetramer that could be formed from compound **8**. Compound **8** was treated with 0.5 equiv. of phosphodichloridite at 0°C for 1 h. After work-up, starting material **8** was recovered to the extent of 46%. Compound **11** was obtained in only 10% yield and a large amount of material (presumably phosphorylated **8**) remained at the origin on tlc. The compound **11** was clearly distinguishable from the correct tetranucleotide **10***a*.

Compound **10***a* was converted into the two tetranucleotide units **10***b* and **10***c* which were condensed to form the octamer **12***a* (Scheme 4) in 76% yield. Repeating the hydrazine and acetic acid deprotections on **12***a* gave the units **12***b* and **12***c* which were condensed to produce the fully protected hexadecamer **13***a* in 51% yield. The noteworthy features of this sequence include: (*1*) total reactions times for condensing any two blocks was kept at 90 min, and (*2*) the ratio of 5′-protected unit (e.g. **12***b*) to 5′-unprotected unit (e.g. **12***c*) remained at 1:0.8 throughout the series. Yields and properties of nucleotide units are collected in Tables 2 and 5.

SCHEME 4

While the above results clearly demonstrate the compatibility of this group of protecting groups and their suitability for block extension of chains, there is one additional feature that is very useful. Both the methoxytrityl and levulinyl groups contain an isolated methyl group. Since the methoxytrityl and levulinyl groups occur at opposite ends of the

growing chain, and since the methyl resonances occur at different chemical shifts in the nmr (typically δ 3.85 ppm for CH_3O— and δ 2.26 ppm for CH_3C—) the appearance of these two signals confirms a successful coupling of two units in the correct fashion. Only the formation of a 3′–5′ bridge between two units can result in a molecule possessing both signals. They therefore serve as internal labels. Thus in the condensation of **12***b* and **12***c* to form the hexadecamer, only the desired product **13***a* could contain singlets corresponding to the CH_3O— and CH_3C— groupings. These singlets are easily observed even on small quantities of large molecules such as **13***a*. The disappearance of one of these signals also serves to establish the removal of one or the other of the protecting groups during a deprotection step.

The oligomers **10**, **12**, and **13** were deprotected to the free nucleotides which were completely degraded by pancreatic ribonuclease to uridine 3′-phosphate and uridine in the correct ratios. The sequence for deprotection consists of (*1*) removal of the levulinyl group (hydrazine, 5 min), (2) removal of the methoxytrityl group (80% HOAc, 20–30 min, 80–90°C), (*3*) removal of the trichloroethyl group (Zn/Cu in DMF at 55°C for 8–13 h), and (*4*) removal of the silyl protecting groups with TBAF. In previous reports we had isolated the nucleotidic material after the Zn/Cu

†Entries 1–4 were all conducted on the same scale. Entry 5 represents an average over six separate preparations ranging in scale from 300 mg to 7.0 g of **1***a*. Entry 6 represents an average over five preparations ranging from 250 mg to 3.0 g of **8**. Entry 7 represents an average over three condensations ranging from 190 to 420 mg of **10***b*.

treatment by paper chromatography. This procedure had worked well for short nucleotides but as chain length increased so did the difficulty in eliminating salts. We have found that this problem is nicely resolved by applying the products of step (*3*) to pre-adsorbant Analtech silica gel plates. These plates were developed in chloroform–methanol solvents and under these conditions the oligonucleotide separates cleanly as a tight band and the salts remain at the origin.

Conclusion

In this manuscript we have detailed a procedure for the synthesis of oligoribonucleotides using a block condensation approach. This manuscript in conjunction with our previous detailed reports (2–4) completes the basic development of a protection group – condensation procedure that permits the synthesis of oligoribonucleotides on a large scale. The procedure is rapid and the reaction mixtures are clean relative to any of the alternative procedures for oligonucleotide synthesis. We believe that the series of procedures we have developed, and in particular the use of the *tert*-butyldimethylsilyl protecting group, allow, for the first time, the synthesis of oligoribonucleotides at least as rapidly as oligodeoxynucleotides. We will further explore the limits of this procedure through an attempt to synthesize by chemical procedures the sequence of nucleotides corresponding to that of the transfer RNA^{fMet} from *E. coli*.

Experimental

General Methods

All general procedures and techniques including chromatography, uv, nmr, mass spectrometry, elemental analyses, melting points, electrophoresis, and enzyme assays are as previously described (2) with the following exceptions.

Thin layer chromatographic data (R_f values) are recorded from Brinkman Polygram SIL G UV 254 analytical sheets. High pressure liquid chromatography results of enzyme degradations were obtained on a Spectrophysics SP 8000 microprocessor based hplc unit using a Brownlee Labs anion exchange column AX10A (4.1 × 250 mm, 10 micron particles) and an acetonitrile–ammonium phosphate gradient. The nmr measurements were made on a Varian T60 spectrometer.

All starting nucleosides **1***a–d* and **5***a–d* were prepared as previously described (2, 3). The preparation of the TBAF reagent has been previously described (2).

Levulination of Compounds 1 and 5. The Preparation of the Fully Protected Nucleosides 4 and 6

The preparation of both series of compounds **4** and **6** followed the same general procedure. Compound **1** or **5** was dissolved in dry dioxane (10 mL/mmol) and 1.5–2 equivalents of levulinic acid, 3–4 equivalents of dicyclohexylcarbodiimide, and 10 mg/mmol of **1** or **5** of 4-dimethylaminopyridine were added. The solution was stirred at room temperature from 6–13 h although tlc indicated that all reactions were over in 6 h. The solution was filtered from dicyclohexylurea and extracted with 10% sodium bicarbonate in water. The organic layer was concentrated at reduced pressure and the residue was applied to thick layer plates. Solvents used for development of the plates are listed in Table 3. Yields and properties of the products **4**(*a–d*) and **6**(*a–d*) are listed in Table 1.

Preparation of Compounds 2 and 7

These series of compounds were obtained by treating compounds **4** or **6** respectively with 80% acetic acid (10 mL/mmol) at 80–90°C for 20–30 min. Solvents were removed at reduced pressure and the residue was applied to tlc plates developed in the solvents recorded in Table 3. The properties of compounds **2***a–d* and **7***a–d* are collected in Table 1. This same procedure was used for the removal of the methoxytrityl group from nucleotides.

General Procedure for the Removal of the Levulinyl Group

This procedure was general for the removal of the levulinyl group from nucleosides and nucleotides. The compound was dissolved in pyridine (1 mL/mmol) and 10 equiv. of 0.5 *M* hydrazine hydrate in pyridine – acetic acid (3:2) were added. After 5 min, 2,4-pentanedione (10 equiv.) was added with cooling. Solvents were removed by coevaporation with pyridine and the residue was dissolved in chloroform which was washed with water. The organic layer was concentrated and triturated with petroleum ether. Products were isolated by tlc. For oligonucleotides the isolated yields of the compounds **8**, **10***b*, and **12***b* were 92–94, 92–95, and 92–94% respectively. Solvents used for isolating **8**, **10***b*, and **12***b* on tlc are listed in Table 4.

Tests for Isomerization of TBDMS in the Presence of Hydrazine

5′-*O*-Monomethoxytrityl-2′-*O*-TBDMS uridine (**1***a*) was dissolved in two different concentrations of hydrazine hydrate and

the solutions were monitored by tlc. At the times indicated the composition of the solution was determined from preparative tlc plates developed in ether–hexane (3:1). (*1*) Compound **1***a* (189 mg, 0.3 mmol) was treated with 10 equivalents (3 mL) of hydrazine hydrate solution as per the above general procedure. Thin layer chromatography gave the first indication of isomerization (trace presence of **5***a*) after 2½ h. The degree of isomerization had reached 10% after 6 h. (*2*) The above test was repeated except that 50 equivalents of hydrazine hydrate (15 mL) solution was added. Isomerization was detectable after 2 h and had reached 30% after 17 h.

General Procedure for Nucleotide Condensations

This procedure is essentially as has been previously described (2–4). In the current reactions a ratio of 1:0.8 of 3′-unblocked to 5′-unblocked units has been used. The procedure is illustrated by example experiments for each of the blocks synthesized. Solvents used in isolating products by thick layer chromatography are listed in Table 4.

Synthesis of MMT-U_p^{Si}(TCE)U_{Lv}^{Si} (3, B = B′ = Ur, R = Lv)

Compound **3** was prepared several times at different scales of reactions. As an example, compound **1***a* (300 mg, 0.47 mmol) in THF (0.65 mL) was added dropwise to a solution of THF (0.5 mL) containing 78 μL (0.52 mmol) of trichloroethyldichlorophosphite and 0.28 mL (2 mmol) of collidine maintained at −78°C. After a total of 10 min at −78°C compound **2***a* (172 mg, 0.38 mmol) in THF (1 mL) was added and the reaction mixture was stirred for 30 min at −78°C and allowed to warm up to room temperature (total 30 min). Iodine (228 mg, 0.88 mmol) in 3 mL of THF–H_2O (2:1) was added and the solution stirred for 5 min. The solvents were removed at reduced pressure and the residue was dissolved in $CHCl_3$ (50 mL) which was extracted with water (40 mL), 5% $NaHSO_3$ (10 mL), and finally with water. Products were isolated by tlc.

Synthesis of the Tetranucleotide MMT-U_p^{Si}(TCE)U_p^{Si}(TCE)U_{Si}^{Si}(10d)

Route A

(*1*) Compound **8** (200 mg, 0.17 mmol) in THF (0.5 mL) was added dropwise to a solution of THF (0.2 mL) containing $TCEOPCl_2$ (27 μL, 0.17 mmol) and collidine (0.1 mL, 0.9 mmol) maintained at −78°C. After a total of 15 min the second component, compound **9***a* (140 mg, 0.135 mmol) in THF (1 mL) was added and stirring was continued for 30 min and allowed to warm to room temperature. Iodine (90 mg, 0.3 mmol) in THF–H_2O (2:1, 1.5 mL) was added and after 5 min the reaction was worked up in the usual fashion. Results of all these condensations are recorded in Table 2.

(*2*) The above reaction was repeated except that the temperature was raised from −78°C to 0°C.

Route B

(*1*) Compound **9***a* (175 mg, 0.17 mmol) in THF (0.8 mL) was added dropwise to a solution of THF (0.1 mL) containing $TCEOPCl_2$ (27 μL, 0.183 mmol) and collidine (0.1 mL, 0.9 mmol) maintained at 0°C. After 15 min, compound **8** (160 mg, 0.135 mmol) in THF (0.5 mL) was added and stirring was continued for 30 min at 0°C followed by warming to room temperature for 15 min. The reaction was treated with iodine and worked up as in the usual fashion.

(*2*) The above reaction was repeated at −78°C.

Synthesis of the 3′–3′ Linked Tetramer, 11

Compound **8** (250 mg, 0.21 mmol) in THF (0.5 mL) was added to a solution of THF (0.3 mL) containing collidine (0.1 mL) and $TCEOPCl_2$ (16 μL, 0.11 mmol) maintained at 0°C. The solution was stirred at 0°C for a total of 1 h followed by warming to room temperature for an additional hour. The reaction mixture was treated with iodine and worked up in the usual fashion (Table 4 for tlc solvents). The desired product, **11**, was obtained in a 10% yield (32 mg) along with 112 mg (45%) of the starting material **8**. Properties of compound **11** are collected in Table 5.

Synthesis of the Octanucleotide MMT-[U_p^{Si}(TCE)]$_7U_{Lv}^{Si}$ (10a)

The general procedure was followed. As an example, compound **10***b* (210 mg, 0.092 mmol) in THF (0.5 mL) was added dropwise to a solution of THF (0.2 mL) containing collidine (0.09 mL) and $TCEOPCl_2$ (16.5 μL, 0.1 mmol) maintained at 0°C. The solution was stirred for a total of 15 min at 0°C where-

upon compound **10***c* (150 mg, 0.072 mmol) in THF (0.35 mL) was added and the solution was stirred at 0°C for 30 min followed by warming to room temperature (30 min). The solution was treated with iodine (50 mg, 0.18 mmol) in THF–H_2O (2:1, 1.5 mol) for 5 min and worked up in the usual manner. The yield of **10***a* in this reaction was 76%. Yields and properties are collected in Tables 2, 4, and 5.

*Synthesis of the Hexadecamer MMT-[U_p^{Si}(TCE)]$_{15}U_{Lp}^{Si}$ (**13**a)*

Compound **12***b* (45 mg, 0.01 mmol) in THF (0.3 mL) was added dropwise to a solution of THF (0.1 mL) containing collidine (6.4 μL, 0.045 mmol) and $TCEOPCl_2$ (1.8 μL, 0.012 mmol) at 0°C. The solution was stirred at 0°C for 20 min whereupon compound **12***c* (30 mg, 0.006 mmol) in THF (0.3 mL) was added and stirring was continued at 0°C for 30 min. The solution was allowed to warm up to room temperature for a total of 30 min. Iodine (10 mg, 0.04 mmol) in THF–H_2O (2:1, 0.6 mL) was added and after 5 min the products were isolated in the usual fashion. From this experiment compound **13***a* was obtained in 36% yield. Results and properties are collected in Tables 2, 4, and 5. On a slightly larger scale reaction starting with 75 mg (0.016 mmol) of **12***b*, the yield of **13***a* was 51%.

Complete Deprotection of Oligonucleotides

The first step in complete deprotection was removal of the levulinyl group as previously described. The product of this reaction, without further purification, was subjected to 80% HOAc at 80–90°C during 20–30 min. Reactions were easily followed by tlc using chloroform–ethanol. (9:1). Solvents were removed at reduced pressure and the last traces of acetic acid were removed by coevaporation with ethanol. The residue was dissolved in DMF (0.4 mL/10 mg of starting nucleotide) and 50 mg of freshly prepared Zn/Cu reagent was added and the reaction was stirred at 55°C for 8–13 h. Again the course of the reaction could be followed by tlc using chloroform–ethanol (9:1). The crude mixture was applied directly to a pre-absorbent Analtech silica gel plate (250 micron, 20 × 20 cm, No. 3251, silica gel GH). The plate was developed first in ether and then in chloroform–methanol (4:1). The nucleotide band ($R_f \sim 0.3$–0.6) was eluted with methanol. The solvent was removed at reduced pressure and the product was precipitated from acetone with hexane. The solid was stirred for 1.5 h with TBAF. The solution was passed through a Dowex 50W–X8 (Na^+ form) ion exchange column. The eluant was collected, concentrated, and applied to Whatmann 3MM paper developed in solvent F. Only one nucleotide band was obtained in each case. The product was eluted with water and collected by lyophilization. Yields were 80–90% determined spectrophotometrically. Properties of the deprotected oligonucleotides are collected in Table 6. Each nucleotide was treated with pancreatic ribonuclease and was degraded to 3′-uridylic acid and uridine in the expected ratios as shown in Table 6.

TABLE 6. Properties of oligonucleotides

Compound	*R_f^F	†R_m^{Tp}	Enzyme degradation‡ Up/U

REGINALD H. MITCHELL. Can. J. Chem. **58**, 1398 (1980).

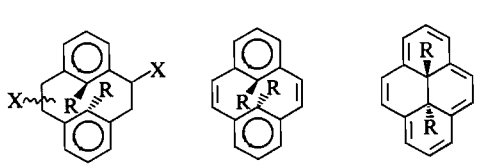
2,11-Diselena[3,3]metacyclophane and its 9,18-dimethyl derivative are prepared in ca. 7% yield from Na_2Se and xylylene bromide. Wittig rearrangement and benzyne induced Stevens rearrangement gave the ring contracted [2,2]metacyclophane derivative. Attempted selenoxide elimination to produce metacyclophane-diene failed. The ^{1}Hmr spectra of the selenametacyclophane indicate that the *syn*-conformer is the more stable. A general synthesis of aryl-alkenes in an 80% yield starting from benzyl phenyl selenide, alkylation with an alkyl halide, and then selenoxide elimination is given.

REGINALD H. MITCHELL. Can. J. Chem. **58**, 1398 (1980).

On a préparé le diséléna-2,11[3,3] métacyclophane et son dérivé diméthylé en positions 9 et 18 avec un rendement d'environ 7% à partir du Na_2Se et du bromure de xylylène. Les transpositions successives de Wittig et de Stevens induites par le benzyne ont conduit à la formation du dérivé cyclique contracté: [2.2] métacyclophane. Une tentative d'éliminer le sélénoxyde en vue d'obtenir le métacyclophane diène a échoué. Les spectres rmn du ^{1}H du sélénamétacyclophane indiquent que le conformère *syn* est le plus stable. On présente une synthèse générale d'aryl-alcènes qui procède avec un rendement de 80% impliquant une alkylation en partant du séléniure de benzyle et de phényle et d'un halogénure d'alkyle et une élimination de sélénoxyde.

[Traduit par le journal]

Introduction



Dithiacyclophanes[1] have attracted much attention in recent years both because of their interesting fluxional properties (1) and because of their ready conversion into both the cyclophanes themselves (2) and into many novel derived polycyclic aromatic compounds (3). However, until our initial report (4), the analagous diselenaphanes were unknown.

There was some considerable incentive to investigate the properties of such compounds because of the early reports (5) on the ease of the selenoxide elimination relative to the well known, but relatively high temperature, sulfoxide elimination. This was pertinent in that conversion of cyclophane **1***Da* into the cyclophane-diene **2***a* could not be achieved in very good yield (6).

We had previously discovered (7) that cyclophane **1***Fb* undergoes Hofmann elimination readily to give diene **2***b* and dihydropyrene **3***b* in excellent yield (>80%) under a variety of base–solvent conditions. The yield of **2***a*, however, from the corresponding **1***Fa* was much poorer (<40%); a competing Stevens rearrangement to give **1***Ha* occurred (6). In other related systems the yields were much worse (8). At the start of this work the sulfoxide elimination had not been reported for these systems, but subsequently Otsubo and Boekelheide (9) have shown that sulfoxides **1***Kb* and **1***Ka* give dihydropyrene **3***b* (34%) and pyrene **4** (37%) respectively on pyrolysis under vacuum. The internal hydrogen substituents of the initially formed **3***a* were evidently lost at the temperature of the pyrolysis. Indeed it has been shown (6) that such hydrogens undergo migration out of the centre of the ring at temperatures above 60°C, and hence the possibility that the selenoxide **1***La* or **1***Na* might undergo elimination at room temperature to give **2***a* was very attractive. We thus decided to investigate the synthesis and reactions of 2,11-diselena[3,3]metacyclophane **5***Aa* and its 9,18-dimethyl derivative **5***Ab*.

Numbering of Compounds

Where a single letter *a* or *b* follows a number, the *a* refers to the series with internal hydrogen atoms, the *b* to the series with internal $-CH_3$ groups. Where two letters follow a number the first capital letter relates to the substituent X or Y in the formulae below and the second small letter to the —H, or $-CH_3$ series.

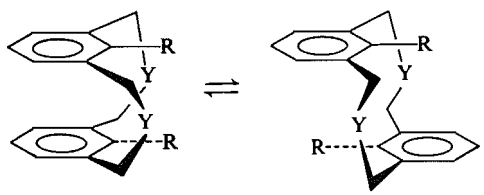
Syntheses



The analogous thiacyclophanes, **5***Ba* and **5***Bb* are best prepared (3, 10) by slowly adding an equimolar solution of bromide **6***A* and thiol **6***B* to dilute potassium hydroxide in 90% aqueous ethanol. Unfortunately selenols are not nearly as easy to prepare and handle as the corresponding thiols (11), and when prepared readily oxidize to diselenides. Solutions containing the selenol **6***Ca* could be generated from the selenocyanate **6***Ia* (12) or from bromide **6***Aa* and NaSeH using the method of Klayman and Griffin (13), and in the presence of excess bromide **6***Aa* form some of the desired selenaphane **5***Aa*, along with tetraselenaphane **7** (12), polymer, and other products. Pure **5***Aa* is, however, difficult to separate from this mixture.

A similar result was obtained when Na_2Se was used in aqueous or ethanolic solvent with bromide **6***Aa*, a procedure which works reasonably well (6) with Na_2S. The best method to prepare the selenaphane **5***Aa* proved to be addition of anhydrous Na_2Se (Alfa) to a solution of *m*-xylylene dibromide **6***Aa* in dry DMF, DMSO, or HMPT (hexamethylphosphoric triamide) under nitrogen. After chromatography on silica gel, 2,11-diselena-[3,3]metacyclophane **5***Aa* was thus obtained in an average 7% yield as pale yellow crystals, mp 121–122°C. There was also obtained 8% of the cyclic trimer **8***Aa*, mp 130–132°C. The identity of these was established by analysis and mass spectrometry, where **5***Aa* gave a molecular ion at *m/e* 368 (97%) with a correct (14) isotope pattern for two Se atoms per molecule, and showed fragment peaks corresponding to loss of one (23%) and two (100%) Se atoms. The trimer **8***Aa* gave a weak molecular ion at *m/e* 552 with correct isotope pattern for three Se atoms per molecule.

A similar reaction between bromide **6***Ab* and Na_2Se gave 7% yield of the dimethylselenaphane **5***Ab*, mp 185–187°C, and the trimer (~5%) **8***Ab*, mp 186°C, again identified by their mass spectra (molecular ions at *m/e* 396 and 594 respectively, with correct Se isotope patterns).

Nuclear Magnetic Resonance Spectra

Despite much previous interest (1) in the conformational equilibrium between the *syn*- and *anti*-isomers of various 2,11-dithia[3,3]-metacyclophanes, the preference for the *syn*-conformer for the parent **5***Ba* has only recently (15) been established by X-ray crystallography in the solid state and by nuclear magnetic resonance spectroscopy in solution. The dimethyl compound **5***Bb* on the other hand exists as discrete *syn*- and *anti*-conformers which are not interconvertible and can be readily distinguished by ^{1}Hmr spectroscopy (6). The *anti*-conformer of **5***Bb* has the internal $-CH_3$ hydrogens at δ 1.30 shielded by the adjacent benzene ring with the aryl hydrogens normal at δ 7.0–7.4. *Syn*-**5***Bb* on the other hand shows the aryl hydrogens shielded by the adjacent ring at δ 6.66 and the $-CH_3$ hydrogens normal for a toluene at δ 2.54. This assignment has been confirmed by X-ray data (16). The conformer of selenaphane **5***Ab* that is isolated shows ^{1}Hmr peaks for the aryl hydrogens at δ 6.97 and for the $-CH_3$ hydrogens at δ 1.77 and

syn-5 *anti*-5

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

thus by comparison to the thiacyclophane series is clearly the *anti*-conformer.

The $-CH_3$ hydrogens, however, are 0.47 ppm less shielded in the selenaphane than in the thiaphane. Similarly the selena-trimer **8***Ab* shows its $-CH_3$ hydrogens at δ 2.05, 0.25 ppm less shielded than those of the thia-trimer **8***Bb* at δ 1.80 (6). This reduction of shielding in the selenaphane series is probably a reflection of the longer C—Se bond lengths, 198 pm (17), relative to those of C—S, 182 pm (18), which allow the $-CH_3$ hydrogens to take up a position further away from the opposite benzene ring in the selenaphanes than in the thiaphanes, rather than an electronegativity effect which is minimal (19) and cannot be observed for the methylene bridge hydrogens.

The ^{1}Hmr spectrum for the parent selenaphane **5***Aa* shows the aryl hydrogens at δ 7.04 with the internal hydrogens at δ 6.46 and the bridge protons at δ 3.78. In the thiaphane **5***Ba* these are at δ 6.91, 6.82, and 3.71 respectively. The latter compound is thought to undergo a rapid conformational equilibrium with the *syn*-conformer being preponderant (>90%) (15). If this is the case for selenaphane **5***Aa* the proportion of *anti*-conformer present must be higher in order to yield an average chemical shift of δ 6.46 for the internal hydrogens. Since the difference in chemical shifts between the selena-trimer **8***Aa* and the thia-trimer **8***Ba* is <0.1 ppm for all protons, the chemical shifts for all protons of the *syn*-conformers of **5***Aa* and **5***Ba* might also be expected to be similar, and for the aryl hydrogens to be close to δ 7. For the *anti*-conformer of **5***Aa* the case is not so clear. For *anti*-thiaphane **5***Ba*, the shielded internal hydrogen has been estimated (15) to have (if it could be observed) a chemical shift of ca. δ 5. Considering the Se vs. S size argument that was made above for the dimethyl compounds **5***Ab* and **5***Bb*, the chemical shift of the internal hydrogen of selenaphane **5***Aa* should be greater (i.e. less shielded) than that estimated for **5***Ba*. We have previously reported (4) the variable temperature ^{1}Hmr spectrum of **5***Aa* and have shown that the signal due to the internal hydrogens collapses into the baseline at ca. −96°C. At that time we observed at ca. −110°C a small signal (ca. 0.8H) at δ 4.5 which we assigned to a shielded internal proton of an *anti*-conformer of **5***Aa*. Unfortunately we have not been able to repeat this observation. The probe of our spectrometer was at that time cracked (unknown to us) and we now do not know if the observed peak was real or an artefact of the spectrometer or experiment. It should be pointed out that at that temperature, much of the dissolved material has precipitated out and the solution is on the verge of freezing. We now observe a small peak (ca. 0.6H) at δ 6.0 at ca. −110° to −115°C both on a 90 MHz and 60 MHz instrument (see Fig. 1), which is not a spinning side band, which we were not able to see previously. The sample of **5***Aa* used is identical to the previous samples in all other respects. Examination of molecular models of **5***a* and **5***b* indicates immediately the considerably lower steric demand of an —H than of a $-CH_3$. The models of *anti*-**5***Aa* and **5***Ba* are considerably less stepped than those of the methyl derivatives **5***Ab* and **5***Bb* (see Fig. 2), and hence a chemical shift of δ 6 for the internal hydrogen of *anti*-**5***Aa* is not unreasonable.[2]

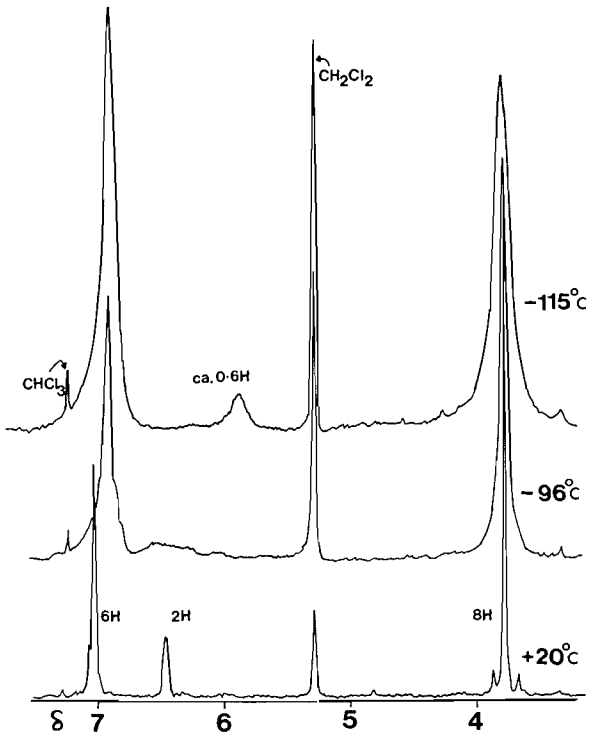


FIG. 1. The ^{1}Hmr spectrum (90 MHz) of **5***Aa* at +20°C, −96°C, and ca. −115°C in $CDCl_3$–CD_2Cl_2 (1:3).

Without being certain as to the exact chemical shift of the internal hydrogens of *anti*-**5***Aa* it is not possible to calculate exactly the relative contributions of the *syn*- and *anti*-conformers. If the δ 6 peak is definitely due to *anti*-**5***Aa*, then from the position of the fast exchanging peak at room temperature of δ 6.5, the relative contributions of *syn*:*anti* would be ca. 1:1. If the previously observed peak at δ 4.5 is correct, the contributions of *syn*:*anti* would be about 4:1. In either case, and together with the

[2]Since many conformers of *anti*-**5***Aa* are possible, which vary depending on the relative orientation of the methylene bridges and selenium atoms, it is possible that now a different conformer than previously is being frozen out.

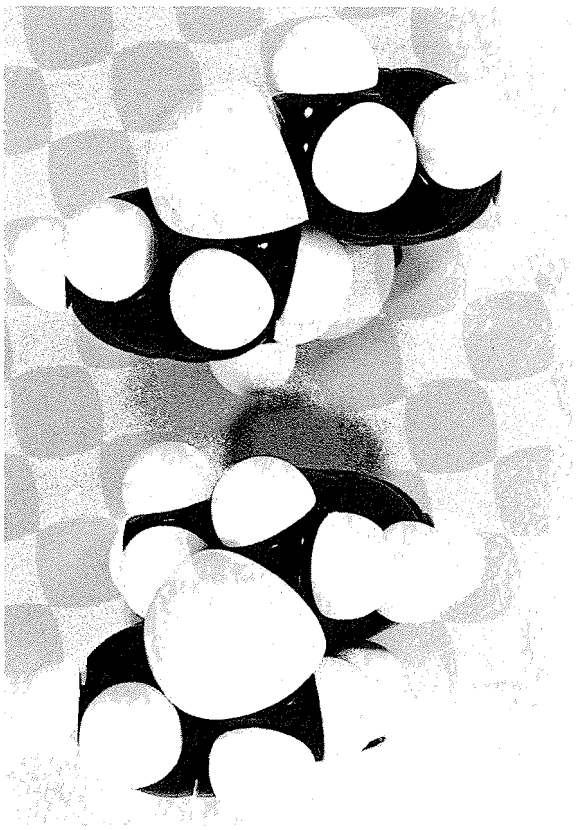

FIG. 2. CPK Models of anti-cyclophanes **5***Ba* (top) and **5***Bb* (bottom).

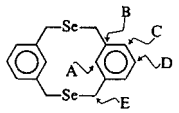
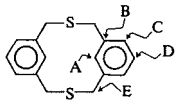
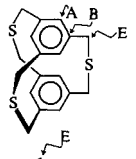
information that the integrated peak areas for the δ 4.5 peak were 0.8H[3] and for the δ 6 peak 0.6H,[3] we can conclude that as in the case of thiacyclophane **5***Ba*, the *syn*-conformer seems to be preferred. We hope to verify this by X-ray measurements, and also gain some insight as to why *anti*-selenaphane **5***Aa* may be a greater contributor to the *syn–anti* equilibrium than *anti*-thiaphane **5***Ba*. When an ^{1}Hmr sample of selenaphane **5***Aa* is heated (in hexachlorobutadiene) the chemical shift[4] of the internal hydrogens increases from δ 6.32 to δ 6.47, somewhat more than the 0.03 ppm observed for **5***Ba* (15). This possibly indicates a larger change in the position of the *syn–anti* equilibrium in this case than for the thiacyclophanes (which are nearly pure *syn*), consistent with the shift data discussed above. Pertinent also is that the chemical shifts[4] of the dimethyl derivative **5***Ab* over the same temperature range in the same solvent are almost invariant (< ±0.02 ppm). The internal —CH_3 hydrogen signal remains sharp over the range −40°C to +160°C indicating no major conformational change is taking place. The signal for the —CH_2— bridge protons is sharper at −30°C and at +150°C than it is at 60°C when it has partially collapsed into the baseline (Supplementary Figure deposited[4]) indicating that these protons are undergoing a conformational change, possibly a bridge wobble. No significant change[4] is observed in the ^{1}Hmr spectrum of the trimer **8***Aa* over the temperature range +35°C to −110°C.

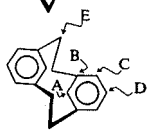
The ^{13}Cmr spectrum is shown in Table 1 in comparison to several related cyclophanes. The internal aryl carbons (A) are strongly deshielded in the known *anti*-cyclophanes **10** and **11** (1*f*) by about 6–8 ppm from their position in *m*-xylene. In the *syn*-cyclophanes, **5***Ba* and **9**, this is much reduced to 2–3 ppm. Clearly selenaphane, **5***Aa*, most closely resembles the *syn*-series in this respect, consistent with the ^{1}Hmr data. Considering the closeness in chemical shift of the methylene protons of **5***A* and **5***B*, it is somewhat surprising that the chemical shift of the methylene bridge carbons (E) of the selenaphane **5***Aa* are at 9.9 ppm higher field than those of the thiaphane **5***Ba*. The $^1J_{(^{13}C—^{77}Se)}$ coupling constant can be determined from the small side bands to this peak and in **5***Aa* is 65.3 Hz. The $^1J_{(^{13}C—H)}$ coupling constants can be readily determined from the gated spectra and are given in Table 1. Our assignments from these spectra are consistent with those of the thiaphane **5***Ba* (1*f*).

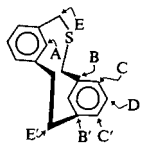
Reactions











The initial route (7,6) from **5***Bb* to **3***b* involved a Stevens rearrangement of the sulphonium salt **5***Db* to give **1***Db*. While the selenaphane **5***Aa* could be readily methylated with dimethoxycarbonium fluoroborate (20) to give the bis-selenonium salt **5***Ca* in 62% yield, the salt, on attempted rearrangement with either potassium *tert*-butoxide or sodium hydride in tetrahydrofuran (THF), failed to give **1***Ea*, but rather the molecule cleaved to give an oily product, which by ^{1}Hmr contained αα′-bis(methylseleno)-*m*-xylene **6***Ea*. Cleavage of the C—Se bond by strong bases such as butyl lithium was first discovered by Gilman (20) and has been extensively studied by Seebach and Peleties (21) and Krief and co-workers (22) and subsequently avoided by ourselves (23) as well as others (24) by use of lithium dialkylamides when deprotonation of a selenide was required. We were, however, somewhat surprised that easy cleavage occurred with poorer nucleophiles such as *tert*-butoxide and hydride. At that time, no alternative to the Stevens

[3]Average of five spectra. Entirely *anti*-conformer would yield a 2H integration value.

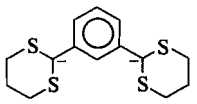
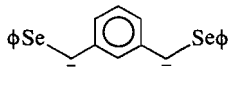
[b]Values for $^1J_{^{13}C-H}$ are given in parentheses, in Hz.

rearrangement was known. We thus decided that it might be possible to synthesize the desired cyclophane **1***Ea* by an alternate route. It occurred to us then that the selenide function might not only be used in the elimination step but also to build up the carbon skeleton. Since Sharpless *et al.* (25) had been able to alkylate the anion of $\phi SeCH_2CO_2Et$ with alkyl halides, it seemed reasonable to expect that $\phi SeCH_2\phi$, **12**, would behave similarly.[5]

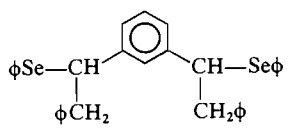


Benzyl phenyl selenide, **12**, was prepared in essentially quantitative yield by reaction of benzyl bromide with NaSeϕ (prepared from ϕSeSeϕ and $NaBH_4$ (13)) in refluxing ethanol, as white plates, mp 32–33°C. This could be benzylated by treatment with lithium di-isopropylamide at 0°C in dry THF, followed by more benzyl bromide, and gave an 87% yield of the selenide **12***a*. The latter on treatment with 30% H_2O_2 in THF at room temperature gave a quantitative yield of *trans*-stilbene **13***a*. There was no need to isolate the intermediate selenide, **12***a*, and the whole sequence could be effected easily in one pot. Thus reaction of the anion of **12** with benzyl bromide, ethyl bromide, and methyl iodide respectively followed by H_2O_2 gave **13***a* (81%), **13***b* (80%), and **13***c* (76%). Subsequently many similar reactions have been reported by others and the whole area has been covered by an excellent review (26). Hylton and Boekelheide (27) had shown that it was possible to alkylate the dianion **14** with *m*-xylylene dibromide

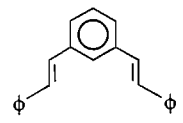


12 Z = H
12*a* Z = $CH_2\phi$
12*b* Z = CH_2CH_3
12*c* Z = CH_3

13*a* Z = ϕ
13*b* Z = CH_3
13*c* Z = H



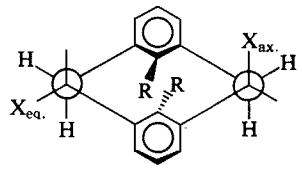
14



15

6*Aa*, hence we anticipated no problem with similar alkylation of **15** provided that the dianion could be generated. α,α′-Bis(phenylseleno)-*m*-xylene **6***Ma* was obtained in 91% yield as colourless plates mp 41–42°C from *m*-xylylene bromide and NaSeϕ. Treatment with lithium di-isopropylamide and then D_2O indicated that a dianion had formed (^{1}Hmr, ms analysis). That this was the desired dianion **15**, and

[5]Preliminary report: ref. 23.



16

17

that this could be bis-alkylated, was shown by addition of benzyl bromide to give the selenide **16**, which showed a molecular ion at *m/e* 598 and gave in its ^{1}Hmr spectrum the 24 aryl hydrogens at δ 6.4–7.8, the 2 methine hydrogens as a triplet at δ 4.39, and the 4 methylene hydrogens as a doublet at δ 3.19. Further treatment of **16** with H_2O_2 at room temperature in THF gave a quantitative yield of *trans-m*-distyryl benzene, **17**, mp 169–170°C (lit. (28) mp 169.5–170°C). When a solution of the dianion **15** (bright yellow) was added dropwise to THF at the same rate as a solution of the bromide **6***Aa*, the colour of the anion was immediately discharged. Chromatography of the reaction mixture yielded only a few mg of the desired cyclophane **1***Ma*, recognised by comparison to an authentic sample prepared by a different route (described below). The major products of this reaction appeared to be higher linear oligomers on the basis of mass spectroscopy. Although this route had failed to yield **1***Ma* in any great yield, it led us to the realisation that it should be possible to generate the dianion of **5** by treatment with a strong base, and that such a dianion might undergo a (Wittig) rearrangement analogous to the Stevens rearrangement of sulphonium salts. Such rearrangement of **5***B* and a number of related compounds to **1***D* occurred (10) smoothly with either butyl lithium or lithium diisopropylamide. When the latter was added to selenaphane **5***Aa*, rearrangement occurred rapidly and after addition of MeI, cyclophane **1***Ea* was obtained as a waxy, foul smelling solid. Its structure was confirmed by the molecular ion at *m/e* 396 in its mass spectrum and by its ^{1}Hmr spectrum which showed the 6 aryl hydrogens at δ 7.5–6.9, the internal hydrogens at δ 5.10 and δ 5.50, and the —$SeCH_3$ hydrogens at δ 1.92 with the remaining hydrogens as a multiplet at δ 4.1–2.0, very similar to the spectrum observed for the analogous **1***Da*. However, after conversion of this product to the selenoxide, no spontaneous elimination occurred, either at room temperature, at 80°C, or on stirring with anhydrous $MgSO_4$. We considered at this time whether this might be due to the fact that we were attempting the elimination of MeSeOH, whereas nearly all the previous literature examples had eliminated φSeOH. We thus decided that the elimination should be tried on the phenyl selenoxide **1***Na*. Attempted generation of selenide **1***Ma* from **1***Fa* by treatment with NaSeφ failed; however, at that time Otsubo and Boekelheide (9) reported the benzyne induced Stevens rearrangement of **5***Ba* to give **1***Ja*, and subsequent thermolysis of its sulfoxide, **1***Ka* to give pyrene in 37% yield.

Reaction of selenaphane **5***Aa* with benzyne (generated from anthranilic acid and butyl nitrite) gave, after chromatography, 75% of the desired cyclophane **1***Ma*, mp 189–191°C. Its structure was readily confirmed by analysis, molecular ion at *m/e* 520, and ^{1}Hmr spectrum. Similarly the dimethyl cyclophane **5***Ab* gave **1***Mb*, in which the characteristic internal —CH_3 signals in the ^{1}Hmr spectrum could be clearly seen at δ 0.9 and 1.2. However, when **1***Ma* was stirred with H_2O_2 in THF at room temperature, only a very low yield of pyrene was obtained. No dihydropyrene **3***b* was obtained from **1***Mb*. Clearly the selenoxide elimination in the cyclophanes **1** is a much less facile elimination than in alicyclic examples. Fragmentation of selenoxides is a *syn* elimination process (25). Attainment of the *syn*-conformation of **1** may be difficult in the case of the cyclophanes because of the rigidity of the molecule caused by the strain in these systems (1*a*, 29). On examination of models, it does not much matter whether the substituents X in **1** are in the axial or equatorial positions as shown, since rotation about the C—C bridge bond, to bring X *syn* with H, thrusts one benzene ring into the other in either case. That this may be less serious when R = H, may be the reason why some pyrene was isolated from **1***Na*, yet no **3***b* from **1***Nb* when R = CH_3. Presumably this barrier can be overcome by going to high temperatures, as is the case in the sulfoxide pyrolysis (9), but then the method offers no advantage since the selenium compounds are significantly less accessible.

SCHEME 1. Newman projection of an isomer of **1**.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The ^{1}Hmr spectra were determined in $CDCl_3$ (unless otherwise stated) on a Perkin-Elmer R12A (60 MHz) or R32 (90 MHz) spectrometer and are reported in ppm downfield from tetramethylsilane as internal standard. The ^{13}Cmr spectra were determined in $CDCl_3$ on a Nicolet TT-14 Fourier transform spectrometer operating at 15.1 MHz. Mass spectra were determined on a Hitachi-Perkin-Elmer RMU-7 or Finnigan 3300 mass spectrometer at 70 eV. Microanalyses were performed by this department. All evaporations were carried out under reduced

pressure on a rotary evaporator at ca. 40°C. Extracts were dried with anhydrous sodium sulfate.

*2,11-Diselena[3,3]metacyclophane, 5*Aa

A solution of *m*-xylylene dibromide, **6***Aa*, (10.6 g, 40 mmol) in dry N_2-purged DMF (50 mL) was added under N_2 at room temperature in one portion to a well stirred solution of anhydrous Na_2Se (Alfa, 6.0 g, 48 mmol) in dry DMF (100 mL). After 12 h, the solvent was removed under vacuum, and water and dichloromethane were added. The organic layer was washed well with water, dried, and evaporated. The residue was chromatographed on silica gel (200 g) using pentane–benzene (or CH_2Cl_2) (85:15) as eluant to yield firstly the dimer, ~520 mg (7.1%) as pale yellow crystals from ethanol or cyclohexane, mp 121–122°C; ^{1}Hmr (90 MHz) δ: 7.04 (bs, 6H, ArH), 6.46 (bs, 2H, internal ArH), and 3.78 (s, 8H, —CH_2—); ms, molecular ion at *m/e* 368 ($C_{16}H_{16}{}^{80}Se_2$) with correct isotope pattern for Se_2 (14). *Anal.* calcd. for $C_{16}H_{16}Se_2$: C 52.48, H 4.40; found: C 52.16, H 4.47.

Eluted next was the cyclic trimer, 2,11,19-triselena-[3,3,3]metacyclophane, **8***Aa*, 600 mg (8%), as pale yellow crystals from cyclohexane, mp 130–132°C; ^{1}Hmr (90 MHz) δ: 7.20 (s, 9h, ArH), 7.06 (bs, 3H, internal ArH), and 3.60 (s, 12H, —CH_2—); ms, molecular ion at *m/e* 552 (correct isotope pattern for Se_3). *Anal.* calcd. for $C_{24}H_{24}Se_3$: C 52.48, H 4.40; found: C 52.37, H 4.36. Essentially the same results were obtained when either dimethyl sulphoxide or hexamethylphosphorictriamide were used as solvents.

*Stevens Rearrangement of Selenide 5*Aa

*(a) Bis-selenonium Salt 5*Ca

A solution of the selenide **5***Aa* (800 mg, 2.18 mmol) in CH_2Cl_2 (10 mL) was added to a stirred suspension of dimethoxycarbonium fluoroborate (20) (6.1 mmol) in CH_2Cl_2 (10 mL) under N_2 at −30°C. The mixture was stirred without further cooling for 4 h, when ethyl acetate was added. The mixture was stirred with ethyl acetate until a clean precipitate of bis-salt **5***Ca* formed, which was collected by filtration and dried to yield 767 mg (62%) of powder, dec. ~200°C. *Anal.* calcd. for $C_{18}H_{18}B_2Se_2F_8$: C 38.20, H 3.21; found: C 38.46, H 3.46.

(b) Rearrangement

Potassium *tert*-butoxide (148 mg, 1.33 mmol) was added under N_2 to a stirred suspension of the bis-salt from (*a*) above (250 mg, 0.44 mmol) in dry THF (10 mL). After 15 min, H_2O, aqueous HCl, and CH_2Cl_2 were added, and the organic layer was washed, dried, and evaporated. The residual oil gave ^{1}Hmr (60 MHz) δ: 7.1 (bs, 4H, ArH), 3.62 (s, 4H, Ar*CH*$_2$Se—), and 1.83 (s, 6H, —$SeCH_3$) which indicated its structure to be αα′-bis(methylseleno)-*m*-xylene, **6***Ea*.

*Wittig Rearrangement of Selenide 5*Aa

(a) Using Lithium Diisopropylamide

A solution of *i*-Pr_2NLi (1.1 mmol, prepared from *n*-BuLi and *i*-Pr_2NH) in dry THF (5 mL) was added under N_2 at 0°C to a solution of the diselenide **5***Aa* (183 mg, 0.50 mmol) in dry THF (10 mL). After ca. 2 min, methyl iodide was added until the dark green-brown colour was just discharged. Water, CH_2Cl_2, and aqueous HCl were then added, and the organic layer was washed, dried, and evaporated. The residue was chromatographed on silica gel (140 g) using pentane–benzene (4:1) as eluant to yield firstly mixed isomers of cyclophane **1***Ea*, 95 mg (48%) as a waxy, foul smelling solid; ^{1}Hmr (90 MHz) δ: 7.5–6.9 (m, 6H, ArH), 5.50 and 5.10 (bs, ~1H each, internal ArH), 4.1–2.0 (m, 6H, —CH—CH_2—), and 1.92 (s, 6H, —$SeCH_3$); ms, molecular ion at *m/e* 396 (correct isotope pattern).

When this product was dissolved in THF (60 mL) and 30% H_2O_2 (6 mL) was added, the mixture first became cloudy and then clarified. Thin layer chromatography indicated no cyclophane diene **2***a* or pyrene to be present. This result was not changed on stirring with anhydrous $MgSO_4$ for 24 h or on reflux for 4 h.

(b) Using Benzyne

A solution of anthranilic acid (250 mg) in dry THF (5 mL) was added dropwise over 1 h to a refluxing solution of selenide **5***Aa* (127 mg, 0.35 mmol) and butyl nitrite (500 mg) in dry THF (20 mL) under N_2. After heating under reflux for a further hour, the reaction mixture was cooled and H_2O, aqueous HCl, and CH_2Cl_2 were added. The organic layer was washed, dried, and evaporated. The residue was chromatographed on silica gel (35 g) using pentane–benzene (7:3) as eluant to yield crystalline product **1***Ma*, 136 mg (75%) as white crystals from cyclohexane, mp 189–191°C; ^{1}Hmr (60 MHz) δ: 7.8–6.5 (m, ~16H, ArH), 5.7–5.2 (m, ~2H, internal ArH), and 5.0–2.0 (m, ~6H, —CH—CH_2—); ms, molecular ion at *m/e* 520 (correct isotope pattern). *Anal.* calcd. for $C_{28}H_{24}Se_2$: C 64.87, H 4.67; found: C 64.61, H 4.58.

Oxidation and Elimination

The selenide **1***Ma* from (*b*) above (130 mg) was stirred at room temperature in THF (15 mL) with 30% H_2O_2 (5 mL) for 50 h. The products were extracted into ether and chromatographed on silica gel to yield 1 mg (2%) of pyrene, identified by tlc, uv, and ^{1}Hmr comparison to an authentic sample.

*9,18-Dimethyl-2,11-diselena[3,3]metacyclophane, 5*Ab

From 2,6-bis(bromomethyl)toluene **6***Ab* (6) (11.1 g) and Na_2Se (6.0 g) in DMF as described above for **5***Aa*, there was obtained after chromatography, firstly 555 mg (7%) of dimer **5***Ab*, as very pale yellow crystals from cyclohexane, mp 185–187°C; ^{1}Hmr (90 MHz) δ: 6.97 (s, 6H, ArH), 3.69 (s, 8H, —CH_2—), and 1.77 (s, 6H, —$ArCH_3$); ms, correct molecular ion and isotope pattern for $C_{18}H_{20}Se_2$ at *m/e* 396.

Eluted next was the cyclic trimer (9,17,26-trimethyl-2,11,19-triselena[3,3,3]metacyclophane) **8***Ab*, mp ~186°C from benzene; ^{1}Hmr (60 MHz) δ: 7.00 (s, 9H, ArH), 3.67 (s, 12H, —CH_2—), and 2.05 (s, 9H, $ArCH_3$); ms, correct molecular ion for $C_{27}H_{30}Se_3$ at *m/e* 594.

*Wittig Rearrangement and Attempted Elimination of 5*Ab

From the dimer **5***Ab* (300 mg) and benzyne (excess) as described above for **5***Aa*, there was obtained 525 mg of oily residue, which contained the mixed cyclophane isomers **1***Mb* as indicated by ^{1}Hmr (60 MHz) δ: 7.7–6.9 (m, ArH), 4.0 and 3.7 (t, —*CH*—CH_2—), 2.3–1.7 (m, —CH—*CH*$_2$), and 1.2 and 0.9 (s, internal —CH_3). When these were stirred at room temperature or heated under reflux with 30% H_2O_2 in THF solution, no dimethyldihydropyrene **3***b* could be detected.

Benzyl Phenyl Selenide, 12

Sodium borohydride (3.87 g, 102 mmol) was added in batches to a solution of diphenyl diselenide (15.6 g, 50 mmol) in absolute ethanol (250 mL). Benzyl bromide (17.1 g, 100 mmol) in benzene (50 mL) was then added to the resultant colourless solution of NaSeφ. After refluxing for 2 h, the reaction mixture was cooled and evaporated. The residue was extracted with water and ether, and the organic layer washed, dried, and evaporated to yield quantitatively the product **12**, as an oil, which solidifies on standing and gives white plates from ethanol, mp 32–33°C; ^{1}Hmr (90 MHz) δ: 7.5–6.8 (m, 10H, ArH) and 4.00 (s, 2H, —CH_2—); ms, molecular ion (correct isotope pattern) at *m/e* 248. *Anal.* calcd. for $C_{13}H_{12}Se$: C 63.16, H 4.89; found: C 62.87, H 4.92.

Benzylation of Benzyl Phenyl Selenide to Give **12**a

A solution of selenide **12** (4.94 g, 20 mmol) in dry THF (20 mL) was added dropwise under N_2 at 0°C to a solution of *i*-Pr_2NLi (20 mmol, prepared from *n*-BuLi and *i*-Pr_2NH) in dry THF (30 mL). Benzyl bromide (3.42 g, 20 mmol) in dry THF (10 mL) was then added dropwise to the dark green reaction mixture at 0°C, which was immediately decolorized. Ether, water, and aqueous HCl were then added, and the organic layer was washed, dried, and evaporated. Chromatography of the residual oil on silica gel (140 g) using pentane as eluant gave the pure product **12***a*, 5.87 g (87%) as a colourless oil; ^{1}Hmr (60 MHz) δ: 7.5–6.8 (m, 15H, ArH), 4.43 (t, J = 8 Hz, 1H, —C*H*—CH_2), and 3.26 (d, J = 8 Hz, 2H, —CH—C*H*$_2$—); ms, molecular ion (correct isotope pattern) at *m/e* 338. *Anal.* calcd. for $C_{20}H_{18}Se$: C 71.21, H 5.38; found: C 70.89, H 5.25.

Oxidation and Elimination to Stilbene

30% H_2O_2 (20 mL) was added to a solution of the selenide **12***a* in THF (100 mL) at room temperature. The reaction mixture was then either stirred at room temperature for 18 h, or in the presence of anhydrous $MgSO_4$ for 4 h, or refluxed for 2 h. In each case the yield of *trans*-stilbene (identical mp, ^{1}Hmr, tlc to an authentic sample) isolated after extraction into ether was quantitative.

General Procedure for in-situ *Alkylation, Oxidation, and Elimination to Yield* trans-*Alkenes*

The selenide **12** (10 mmol) in dry THF (10 mL) was added dropwise under N_2 at 0°C to a soln of *i*-Pr_2NLi (10 mmol) in dry THF (15 mL), followed by the halide (10 mmol), also dropwise in dry THF (5 mL). After 10 min, THF (50 mL) and 30% H_2O_2 (20 mL) were added. The reaction was stirred for 12 h and then ether, water, and aqueous HCl were added. The organic layer was washed, dried, and evaporated (or fractionally distilled) to yield virtually pure product, identical to authentic samples. (See text for yields.)

α,α′-*Bis(phenylseleno)*-m-*xylene* **6**Ma

From diphenyl diselenide (15.6 g, 50 mmol), $NaBH_4$ (3.87 g, 100 mmol), and *m*-xylylene dibromide **6***Aa* (13.2 g, 50 mmol), using the procedure described above for benzyl phenyl selenide **12**, there was obtained 18.8 g (91%) of product **6***Ma*, as colourless plates from ethanol–benzene, mp 41–42°C; ^{1}Hmr (60 MHz) δ: 7.6–6.9 (m, 14H, ArH) and 3.99 (s, 4H, —CH_2—); ms, molecular ion at *m/e* 418 ($^{80}Se_2$, correct isotope pattern). *Anal.* calcd. for $C_{20}H_{18}Se_2$: C 57.70, H 4.36; found: C 57.39, H 4.41.

Bis-benzylation of **6**Ma

From the selenide **6***Ma* (2.5 g, 6 mmol), *i*-Pr_2NLi (12 mmol), and benzyl bromide (12 mmol) in dry THF (35 mL), using the procedure described above for **12**, there was obtained a 90% yield of product **16**, as an oil; ^{1}Hmr (90 MHz) δ: 7.8–6.4 (m, 24H, ArH), 4.39 (t, J = 8 Hz, 2H, —C*H*—CH_2—), and 3.19 (d, J = 8 Hz, 4H, —CH—C*H*$_2$—); ms, molecular ion at *m/e* 598 ($^{80}Se_2$, correct isotope pattern). *Anal.* calcd. for $C_{34}H_{30}Se_2$: C 68.46, H 5.07; found: C 68.84, H 5.13

Oxidative elimination using H_2O_2–THF as described above gave an essentially quantitative yield of *m*-distyrylbenzene, **17**, mp 169–170°C (lit. (28) mp 169.5–170°C); ^{1}Hmr (60 MHz) δ: 7.2–7.7 (m, 14H, ArH) and 7.11 (s, 4H, —CH=CH—).

Cycloalkylation of **6**Ma *with* m-*Xylylene Dibromide,* **6**Aa*; Cyclophane* **1**Ma

A solution of dianion **15** in dry THF (50 mL) was prepared in a needle valve dropping funnel from selenide **6***Ma* (6 mmol) and *i*-Pr_2NLi (12 mmol), and was added dropwise over 2 h at the same rate as a solution of *m*-xylylene dibromide **6***Aa* (6 mmol) in dry THF (50 mL) was added from a second funnel, to vigorously stirred dry THF (50 mL) under N_2. The strong colour of the dianion was decolorized by the bromide on each drop. After 12 h the solvents were evaporated, and water, aqueous HCl, and CH_2Cl_2 were added. The organic layer was washed, dried, and evaporated. The residue was chromatographed on silica gel and yielded a few mg of the product **1***Ma*, recognised by tlc and ^{1}Hmr comparison to that obtained above. Several products were also obtained which on the basis of ms/^{1}Hmr were probably linear tri, tetra, and polymer.

Complex fluoroanions in solution. XI. Complexes of silicon, germanium, and titanium tetrafluorides with simple anions[1]

S. BROWNSTEIN

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received February 22, 1980

S. BROWNSTEIN. Can. J. Chem. **58**, 1407 (1980).

A fluorine-bridged silicon fluoroanion and many hexa-co-ordinate germanium and titanium fluoroanions have been identified in solution via fluorine magnetic resonance. A generalized shceme is used to correlate all fluorine chemical shift data for hexa-co-ordinate fluorine containing species.

S. BROWNSTEIN. Can. J. Chem. **58**, 1407 (1980).

Nous avons identifié en solution, à l'aide de la resonance magnétique nucleaire de fluor, un fluoroanion du silicium ponté par une atome de fluor ainsi que plusiers fluoroanions du germanium et du titane hexa coordonnés. On utilise un schéma général pour mettre en corrélation toutes les donnés concernant le déplacement chimique de fluors pour les espéces hexa coordonnées contenant du fluor.

Introduction

Complexes of SiF_4 have been reported with some organic bases (1) and with the anions of a few dibasic organic acids (2). A complex was observed with trifluoroacetate (3) but not with fluorosulfate nor trifluoromethanesulfonate anions (4). In the present study the reaction of SiF_4 with a wide range of anions was investigated. Although fluorine bridged complex fluoroanions have been identified with tin and titanium they have not been observed for silicon (5).

There have been more extensive studies of GeF_4 complexes, including complexes with neutral oxygen- and nitrogen-containing organic compounds (1, 6), the anions of some carboxyllic acids (2), and SCN^- and OCN^- (7, 8). Complexes of SnF_4 have been thoroughly studied (9). Homopolymeric fluoroanions of titanium have been described (5), as well as heterospecies with partially oxygenated molybdenum and tungsten species (10). Complexes with the ligands SCN^- and OCN^- have been described (11), as well as with trifluoroacetate, fluorosulfate, and trifluoromethanesulfonate (3, 4). The purpose of the present article is to identify new fluorine bridged complex fluoroanions and to correlate the fluorine chemical shifts of all hexa-co-ordinate fluoride species, regardless of central atom.

Some of the anions employed in this study are potentially bidentate. As an example acetate ion has been shown, by X-ray diffraction studies, to co-ordinate with a central atom via one (12) or both (13) of its oxygen atoms. It does not appear that infrared frequency shifts are adequate to unambiguously decide between the two kinds of co-ordination (14).

Experimental

Fluorine resonance spectra were obtained at 94.18 MHz on a "Varian Associates" XL-100A spectrometer coupled with a "Nicolet Instruments" TT100A Fourier Transform unit. Spectral widths of 20 kHz were accumulated in 16K of memory using an rf pulse of 5 μs (45°). Normally 1000 transients were accumulated and averaged. Chemical shifts are reported in ppm with respect to internal $CFCl_3$ as zero and with shifts to high field considered negative. Samples were prepared with great care to exclude moisture using standard vacuum line and dry box techniques. Infrared spectra were recorded with potassium bromide pellets on a "Beckman Acculab 4" spectrometer.

Silicon and germanium tetrafluorides were employed directly from the cylinders. Titanium tetrafluoride was vacuum sublimed immediately before use. The tetramethyl ammonium salts were employed as previously described (15). Sulfur dioxide, methylene chloride, and acetonitrile were used as solvents (15).

Results and Discussion

Silicon tetrafluoride does not complex with bromide, chloride, perchlorate, fluorosulfate, nor trifluoromethanesulfonate anions. It forms 1:1 complexes with trifluoroacetate, acetate, thiophenolate, chlorate, formate, nitrite, nitrate, azide, cyanide, and thiocyanate ions. The chemical shifts and spin coupling constants for these complexes are listed in Table 1. The values reported are for sulfur dioxide solutions at −75°C unless otherwise noted. In every case except one, to be discussed further in this presentation, change in the ratio of anion-to-SiF_4 from 1:1 to 4:1 has no effect on the chemical shift measured for the complex. Therefore it is safe to assume that formation of the 1:1 complex is essentially complete with stoichiometric quantities of reactants and that no further complex formation occurs. Only a single fluorine resonance line is observed for each of the complexes so it is not possible to assign their stereochemistry. A pentagonal bipyramid with the ligand binding at only one location seems most likely since such structures are often fluxional.

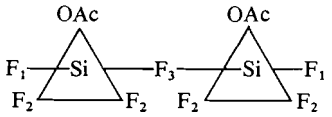
TABLE 1. Chemical shifts and spin coupling constants of complexed SiF_4 anions



Species	δ_F	J_{Si-F}
SiF_4	−158.8	172
SiF_6^{2-}	−125.0	110
$SiF_4CF_3COO^-$	−124.9	92
$SiF_4CH_3COO^-$	−120.8	155
$SiF_4SC_6H_5^-$	−125.5	
$SiF_4ClO_3^-$	−135.7[a]	
SiF_4OOCH^-	−117.8	
$SiF_4NO_2^-$	−136.5[a]	150
$SiF_4NO_3^-$	−142.3[a]	
$SiF_4N_3^-$	−136.0[a]	132
SiF_4CN^-	−130.1	105
SiF_4SCN^-	−148.7	

[a]In CH_2Cl_2 as solvent.

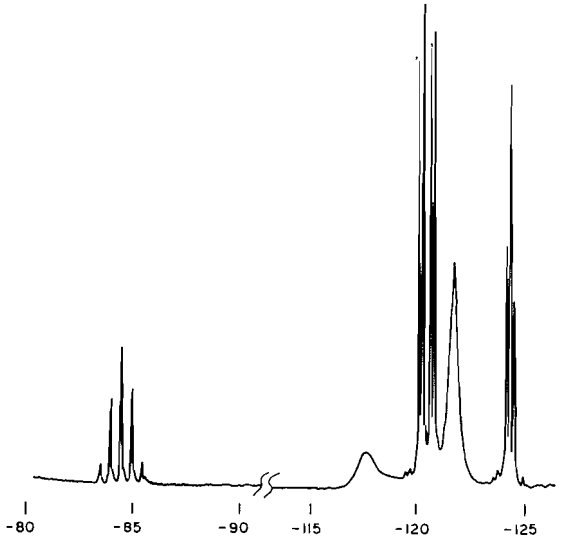
In the case of acetate ion, if there is more than one equivalent of SiF_4 the fluorine resonance spectra of the solutions may be interpreted according to reaction [1].

[1] $5SiF_4 + 4OAc^- \rightleftharpoons 2[Si_2F_7(OAc)_2]^- + SiF_6^{2-}$

The species $Si_2F_7(OAc)_2^-$ is assigned the structure **I** in terms of the relationships of its fluorine

I

atoms. Similar results would be obtained if the acetate group were bidentate and attached as to give two octahedra joined at a corner. Its fluorine magnetic resonance spectrum is shown in Fig. 1.



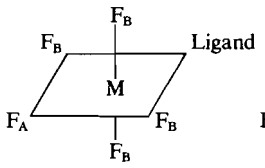


FIG. 1. The fluorine resonance spectrum of a sulfur dioxide solution of tetramethylammonium acetate and 1.20 equivalents of SiF_4 at −70°C.

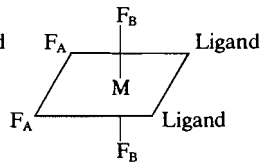
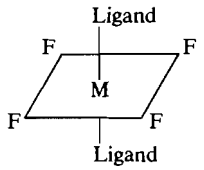


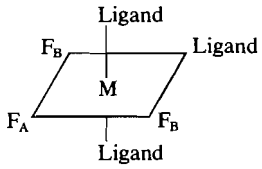
The fluorine resonance parameters of **I** are: $\delta_1 = -128.1$, $\delta_2 = -123.9$, $\delta_3 = -84.6$; $J_{1-2} = 18$ Hz, $J_{1-3} = 0$ Hz, $J_{2-3} = 52$ Hz; $J_{Si-F_1} = 120$ Hz; $J_{Si-F_2} = 120$ Hz; and were obtained by a first-order analysis. The broadened lines at −120.8 and −125.4 are from the 1:1 complex and SiF_6^{2-}. They are broadened by rapid exchange with a small quantity of unreacted SiF_4 since reaction [1] does not quite go to completion.

When 1.5 equivalents of SiF_4 are used the line from the 1:1 complex is no longer observed and the broad line which is the averaged signal of SiF_6^{2-} and SiF_4 is shifted towards the position of free SiF_4 at higher field. In Table 2 are shown the area ratios and chemical shift to be expected if reaction [1] proceeds to completion, and also the experimental values. When a solution containing more than one equivalent of SiF_4 for each acetate is evaporated to dryness under vacuum the resultant solid is SiF_4-OAc^- according to its infrared spectrum and fluorine resonance spectrum. Additional lines are sometimes observed with the other anions but it was not possible to sufficiently slow down exchange reactions to assign the lines.

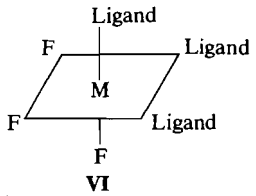
Complexes of GeF_4 with various simple anions frequently disproportionate to give, amongst other products, complex anions of structure **II**.



II



III



Chemical shifts and spin coupling constants for this species with a variety of ligands are listed in Table 3. The 2:1 adduct of structure **III** is the most commonly observed species. Fluorine resonance parameters for this species are listed in Table 4. Three other species which can sometimes be positively identified have structures **IV**, **V**, and **VI**.

Their fluorine resonance parameters are listed in Table 5.

The spectrum of a representative sample is shown in Fig. 2 along with the assignments. If there are less than two equivalents of anion for each GeF_4 one observes rapid fluorine exchange between the various environments and it is not possible to further interpret the spectra. Two exceptions to the preceding statement are samples with a 1:1 ratio of GeF_4 and the anions nitrite or azide. In both these cases one gets a pair of triplets with different chemical shifts and spin coupling constants than those found in samples containing two equivalents of the anion. The symmetry required by the fluorine resonance spectra is obtained with structures **VII** and **VIII** or a trigonal bipyramid with the ligand in

VII **VIII**

an equatorial position. The latter seems least likely since it would probably be fluxional. Although the bent nitrite ion could be accommodated in either **VII** or **VIII** the linear azide ion would probably require structure **VIII**. It was found impossible to obtain pure 2:1 and 1:1 complexes of structures **III** and **VIII**, uncontaminated by the other adducts, in order to compare and further characterize the 1:1 complex. Therefore the assignment of structure **VIII** to these species must be considered tentative. Their fluorine resonance parameters are listed in Table 5.

Complexes of SnF_4 with simple anions have been reported in considerable detail (9). A scheme was devised to fit the chemical shift data for the tin fluoro complexes to the equation

$$[2] \quad \delta F = pC + qT$$

where δF is the chemical shift difference from MF_6^{2-} and p and q are the number of substituents *cis* and *trans* to the fluorine atom whose shift is calculated. This scheme also works with germanium as central atom and values for C and T are listed in Table 6. Calculated values of the chemical

shifts are also given in Tables 3–5. These results will be discussed in conjunction with those for titanium.

Stannous fluoride, plumbous fluoride and lead tetrafluoride do not appear to give soluble complexes under the conditions of this study. Titanium tetrafluoride gives *cis* and *trans* disubstituted hexafluoroanions of structures **III** and **IV** with CF_3COO^-, SCN^-, and N_3^-. Their chemical shifts are listed in Table 7 and the derived *C* and *T* values in Table 6. It should be noted that the principal lines in the fluorine resonance spectra of the reaction products of TiF_4 with tetramethylammonium and tetrabutylammonium thiocyanate in SO_2 and CH_3CN as solvents are different than those reported for the reaction between di-*n*-propylammonium hexafluorotitanate and tetrabutylammonium hexathiocyanato-*N*-titanate (11). It is assumed that under the somewhat different experimental conditions of this study sulfur–titanium rather than nitrogen–titanium bonding is being observed. Very weak lines from the nitrogen bonded species are also observed in this study. Because of the possibility for binding via nitrogen versus oxygen or sulfur for OCN^- and SCN^-, it is possible that the numbers associated with the entries for these anions might sometimes not refer to effectively the same species.

Condensed species with at least two TiF_4 units joined by fluorine bridges were also observed in the fluorine resonance spectra. Although their spectra could be fitted with plausible structures and parameters the assignments are too tentative to report.

TiF_4 is insoluble in sulfur dioxide but is brought into solution by complexing with the anions listed in Table 7. TiF_4 dissolves in acetonitrile and remains in solution upon addition of a considerable excess of methylene chloride or sulfur dioxide. The two triplets of structure **III** with acetonitrile as ligand (δ = 154.3 and 162.5, J = 34.9) are clearly resolved at −80°C in sulfur dioxide as solvent. Fluorine resonance lines, attributed to polymeric species, are the only ones observed in methylene chloride as solvent. It is possible by prior dissolution in acetonitrile to produce the perchlorate complex of structure **III** in sulfur dioxide as solvent. Only polymeric species are observed in methylene chloride as solvent. Nitrite, nitrate, and chlorate ions appear to react with TiF_4 in sulfur dioxide as solvent. Only polymeric species are observed when they are brought into solution in methylene chloride with the aid of acetonitrile.

Zirconium and hafnium tetrafluorides could not be brought into solution under the conditions used in these studies.

In addition to correlating fluorine chemical shifts

for hexa-co-ordinate fluorine substituted species eq. [2] can also be used to correlate observations for different ligands and different central elements. If the ligands are ordered according to the value $C - T$ for a given central element, the same order is maintained for other hexa-co-ordinate elements (16). This has been demonstrated for Group V (16), and is illustrated for Group IV in Table 8. Of the 36 values listed only 5 are out of order and 3 of these involve SCN^- or OCN^-. However, as previously noted, the bonding mode of SCN^- in the complexes is not always clear.

Potentiometric properties of trialkylammonium ion-exchangers

MICHEL GÉRIN AND JAMES FRESCO[1]

Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received February 4, 1980

MICHEL GÉRIN and JAMES FRESCO. Can. J. Chem. **58**, 1412 (1980).

The potentiometric behaviour of nitrobenzene solutions of 21 trialkylammonium salts employed as membrane material has been investigated. Deviations from ideal Nernst response curves for chloride, bromide, iodide, and perchlorate sensors were explicable on the basis of partition and hydrolysis of the ion exchangers. Interference coefficients for the anion selective electrochemical sensor tridodecylammonium perchlorate could be related to the ion-exchange constant of the salt.

MICHEL GÉRIN et JAMES FRESCO. Can. J. Chem. **58**, 1412 (1980).

On a étudié les propriétés potentiométriques des solutions de 21 sels de trialkylammonium utilisés comme matériaux de membrane dans le nitrobenzène. On a expliqué les déviations de la réponse idéale Nernstienne pour ces senseurs aux ions chlorure, bromure, iodure et perchlorate à partir de la partition et de l'hydrolyse des échangeurs ioniques. Un rapport pourrait être établi entre les cœfficients d'interférence du senseur électrochimique au perchlorate de tridodécylammonium et la constante d'échange ionique de ce sel.

Introduction

Interest in the use of liquid ion exchangers in anion-selective electrochemical sensors has resulted in the examination of a variety of organic salt–solvent combinations as active membrane materials (1). Certain high molecular weight quaternary ammonium salts, in particular, have been successfully applied as exchangers in several studies (2–12). Development of satisfactory electrochemical sensors for ions such as sulphate, chromate, and carbonate has not matched the rapid progress in measurements of other divalent and univalent ions. Membrane electrodes based on trioctylamine and trilaurylamine sulphates in nitrobenzene, however, have been reported to be reversible to sulphate ion over a certain concentration range (13).

Limits of detection and ion selectivity of the electrochemical sensors are generally a focus of most investigations. In a number of cases these properties have been linked to physico-chemical constants of the liquid ion exchangers. The results of previous studies of the partition constants, hydrolysis constants, and ion exchange constants of trialkylammonium salts (14–16) have suggested that these salts may be considered model compounds for testing the effect of molecular structure on the response of anionic electrochemical sensors.

Experimental

Chemicals and Solutions

The preparation of nitrobenzene saturated aqueous solutions of potassium halides and soidum perchlorate has been described (16). Trialkylammonium salts and their 0.1 *M* solutions in nitrobenzene were also prepared as previously described (14, 15).

[1]To whom all correspondence should be addressed.

Experimental Cell

The electrochemical cell was designed to provide maximum flexibility and rapidity of use. Suggested by a design of Eisenman (10) it consisted of a Teflon block divided in two parts connected to each other through a machined key. Each block contained a drilled-out compartment that could be filled with an aqueous solution. The two blocks and compartments were separated by a liquid ion exchanger compartment. Three Teflon O-rings sandwiched two Millipore filter membranes and could be positioned to separate the two compartments. The central space in between the two filters could be filled with liquid ion exchanger.

Two 4 cm long pieces of polyethylene "spaghetti tubing" were inserted in the top part of the central O-ring through fine holes. These allowed the injection of liquid ion exchanger by a syringe in the central space in between the two filters. The aqueous cylindrical compartments were ca. eight cm long with a one cm diameter. The O-rings (Millipore XX3001201) were of 1 cm internal diameter. Reference electrodes (1 *M* calomel electrodes Fisher 13-639-51) contacted the solutions on each side of the membrane through holes drilled in the block.

Several types of filters were tested for the central liquid ion exchanger compartment. Millipore Solvinert filters (UGHP01300) were found to be adequate to retain the nitrobenzene ion exchanger solutions. These filters are described by the manufacturer as solvent resistant hydrophobic filters of 0.25 μ pore size. They were found to swell slightly in nitrobenzene and were adjusted in the compartment after pre-soaking in the organic solutions. The volume of the exchanger compartment was approximately 150 mm^3.

The electrochemical cell was placed in a constant temperature environment. This consisted of a double-walled lucite box through the lid of which reference electrodes could be lowered. The temperature was maintained at 25°C by circulation of water.

Measurements of the potential were performed by a calibrated Accumet Expanded Scale Research pH-meter (model 320) in the expanded mV mode. The potentiometric error was estimated at ±0.2 to 0.3 mV.

Procedure

For each salt tested as a liquid ion exchanger a potential response curve was obtained. First the membranes, after soaking 1 min in the organic liquid, were placed in between the O-rings. The block thus formed was positioned in the cell using

an external centering device. The two blocks were tightened in order to support the exchanger compartment. The 0.1 *M* liquid exchanger was introduced. One of the aqueous compartments was filled with a 0.1 *M* solution of MX, where M is an alkali metal ion and X is the anion of the salt used as exchanger (e.g. $NaClO_4$ for the tridodecylammonium perchlorate, $TLAHClO_4$, exchanger). In the other compartment a series of MX solutions were tested consecutively. Concentration levels usually were 10^{-1} *M*, 10^{-2} *M*, 10^{-3} *M*, and 10^{-4} *M*. In the perchlorate series intermediate concentrations were also tested. For interference measurements the solutions tested were decimolar in KI, KBr, or KCl and contained a range of perchlorate concentrations from 10^{-4} to 10^{-1} *M*.

Solutions were removed from the compartments by drainage through a plug situated on the side of each block. Compartments were refilled from the holes provided on the top of the blocks. Reproducibility was checked by testing duplicate solutions first from dilute to concentrated then in the reverse order. All organic solutions were decimolar (within 5%) in ion exchanger except the TLAHCl solution which was 0.06 *M* and saturated.

The notation TPRAH, TBAH, TPTH, THAH, TOAH, and TLAH denotes tripropylammonium, tributylammonium, tripentylammonium, trihexylammonium, trioctylammonium, and tridodecylammonium, respectively.

Results

The response curves of the electrochemical cell for the four series of salts, perchlorates, iodides, bromides, and chlorides studied appear in Fig. 1. In Fig. 2 the response curve of the $TLAHClO_4$-based electrode in the presence of anion interferences is presented. In these figures the potential *E* is plotted against the log reciprocal of the anion activity. The value for *E* was corrected for the small potential obtained when the two aqueous compartments of the cell contained identical 0.1 *M* MX solution. The anion activity was calculated from the concentration employing the Debye–Hückel equation. In Fig. 1 the straight lines extended by short dashes were calculated from the Nernst equation.

Solutions of pure water tested in the electrode were not recorded since they gave drifty, unstable, and nonreproducible potentials. Generally the response times increased with increasing dilution of the test solutions. Solutions in the range 3×10^{-4} *M* to 10^{-4} *M* frequently required 10–15 min to achieve a stable value. Other more concentrated solutions reached a stable reading within a few minutes. Reproducibility varied with the concentration level and the exchanger tested. High molecular weight ammonium salts usually gave reproducible potentials while low molecular weight exchangers were poorly reproducible. Vertical bars extend to a value of one standard deviation above and below each plotted point.

Potential values obtained for the low molecular weight salts $TPRAHClO_4$, TPRAHI, TBAHI, TBAHBr, and TPTAHBr were stable for a few minutes after which the potential drifted continuously to lower values. For the salts TPRAHBr, TBAHCl, and TPRAHCl no stable value could be recorded. In the case of the $TLAHClO_4$ electrode, response times were found to be longer when interfering ions were present especially at low concentrations of the main ion.

Discussion

Response Curves

High molecular weight ammonium salts in each series usually gave more Nernstian response curves than their low molecular weight homologues. In general the order of increasing deviation from an ideal Nernstian response curve was $ClO_4^- < I^- < Br^- < Cl^-$. Over the range of concentration studied all curves showed deviation from the theoretical slope at low concentrations. These deviations were assignable to contamination of the test aqueous phase by anion migration from the contiguous ion exchanger (1, 10).

Two processes can be examined as the basis for deviations from the ideal Nernst slope. One is the partition of the organic ammonium salt from nitrobenzene into water and the other, hydrolysis of the ion exchanger.

The extent of solubilization of the ion exchanger in an aqueous phase by partition is a function of the K_p value corresponding to the equilibrium

$$\overline{R_3NHX} \rightleftarrows R_3NH^+ + X^-$$

These constants have been measured for various exchangers (15) and were of increasing magnitude in the order

$$TPTAHI < THAHCl < TBAHClO_4 < TPTAHBr < TBAHI < TPRAHClO_4, TPTAHCl < TBAHBr < TPRAHI$$

considering only those salts with K_p values greater than 10^{-4}.

If the deviation from Nernstian slope is due in large part to solubilization, this deviation would follow the same order as K_p (12). For an activity level of 0.01 the order of increasing deviation is (see Fig. 1)

$$TPTAHI\ (\text{no deviation}) < THAHCl, TBAHClO_4 < TBAHI < TPTAHBr < TPRAHClO_4, TPTAHCl, TBAHBr < TPRAHI$$

This is essentially the same order as that of K_p values. No deviation is found for TPTAHI and other salts of higher molecular weight in each series. Thus deviations from the theoretical slope at this concentration level arise from the process of solubilization of the exchanger by partition into the aqueous phase.

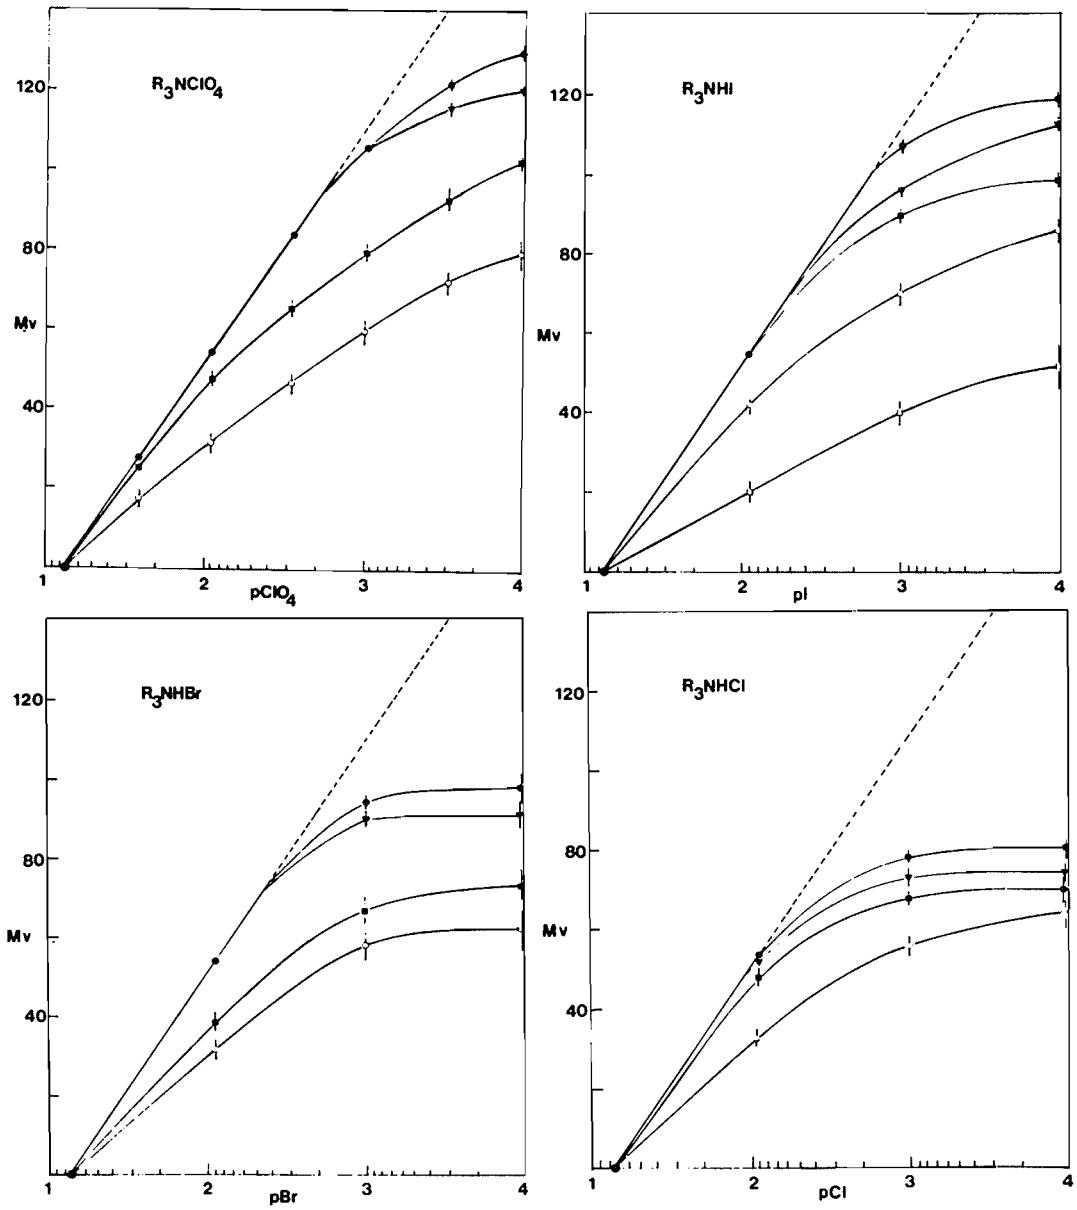

FIG. 1. Response curves of electrodes employing trialkylammonium salts R_3NHX as liquid anion exchangers. ●: $TLAHClO_4$, $TOAHClO_4$, $THAHClO_4$, TLAHI, TOAHI, TLAHBr, TOAHBr, TLAHCl; ▼: $TPTAHClO_4$, THAHI, THAHBr, TOAHCl; ■: $TBAHClO_4$, TPTAHI, TPTAHBr, THAHCl; ○: $TPRAHClO_4$, TBAHI, TBAHBr, TPTAHCl; □: TPRAHI.

It is of interest to compare deviations from Nernst-type behaviour, ΔE_{ex}, at this activity level with those predictable from the theory of Kamo, Hazemoto, and Kobatake (17). The theory relates the potential, E, of a liquid membrane electrode to the partition and dissociation constants of the organic ion exchanger according to

$$E^0 - (RT/F) \ln [(c \sqrt{c^2 + A_x})/2]$$

where c represents the initial anion concentration of the test solution and

$$A_x = 4K_p\bar{c}_{sx}$$

The partition coefficient of the ion exchanger is K_p and $\bar{c}_{sx}$ or $\overline{[R_3NHX]}$ represents the concentration of the undissociated ion exchanger in the membrane. An expression for the deviation from the theoretical slope is easily obtained in the form

$$\Delta E = (RT/F) \ln [(1 + \sqrt{1 + A_x/c^2})/2]$$

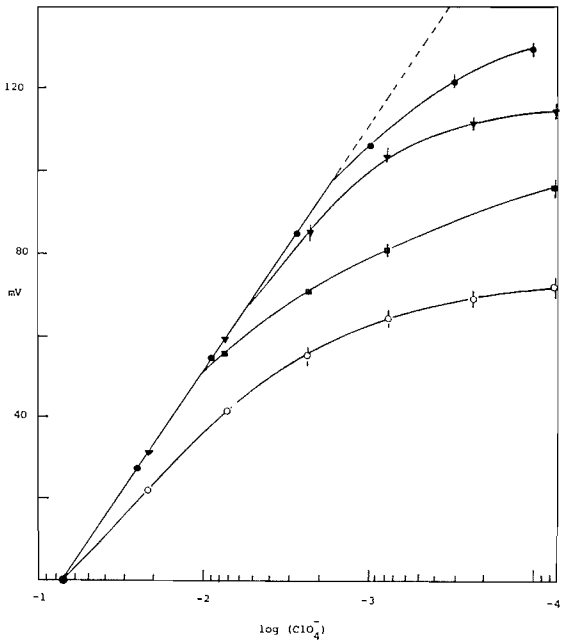

FIG. 2. Response curves of the $TLAHClO_4$ electrode in the presence of extraneous ions. ●: no extraneous salt; ▽: 0.1 *M* potassium chloride; ■: 0.1 *M* potassium bromide; ○: 0.1 *M* potassium iodide.

Theoretical values, ΔE, were calculated for c equals 0.01 and $\bar{c}_{sx}$ equals 0.1 for all the salts studied. These results and the corresponding observed values appear in Table 1. Exchanger dissociation in nitrobenzene was ignored since it is less than 15% for the most extreme case. The 21 ion exchangers could be distributed among three groups according to the data presented in Table 1.

Calculated and experimental deviations are negligibly small for all ion-exchangers with K_p values below 10^{-4}. These include the long chain salts beginning with $TPTAHClO_4$ for the perchlorate series and THAHI, THAHBr, and TOAHCl respectively for the other series. Ion exchangers with intermediate partition coefficients

$$\sim 10^{-4} < K_p < 2 \times 10^{-3}$$

show comparatively small but significant emf deviations. Fair agreement exists between calculated and experimental values for the four salts, $TBAHClO_4$, TPTAHI, TPTAHBr, and THAHCl, comprising this group.

Large deviations exist for ion exchangers with K_p values higher than $\sim 2 \times 10^{-3}$. Calculated ΔE values are considerably greater than the corresponding experimental values. In these cases ΔE has been overestimated by unaccounted loss of ion exchangers to the aqueous test solution through partition.

TABLE 1. Comparison of deviation from ideal Nernst-type response for trialkylammonium ion exchangers

Exchangers*	$K_p(15)$	ΔE, mV	ΔE_{ex}, mV
$TPRAHClO_4$	2.5×10^{-2}	44	23±3
$TBAHClO_4$	8.2×10^{-4}	11	7±3
$TPTAHClO_4$	1.6×10^{-3}	<1	1±1
R'_3NHClO_4	$<10^{-6}$	<1	<1
TPRAHI	2.1×10^{-1}	70	35±3
TBAHI	5.4×10^{-3}	27	13±3
TPTAHI	1.2×10^{-4}	3	1±1
THAHI	2.1×10^{-6}	<1	<1
R'_3NHI	$<10^{-7}$	<1	<1
TBAHBr	1.2×10^{-1}	62	23±3
TPTAHBr	2.1×10^{-3}	18	15±3
THAHBr	3.5×10^{-5}	1	1±1
R'_3NHBr	$<10^{-6}$	<1	<1
TPTAHCl	2.2×10^{-2}	42	22±3
THAHCl	4.4×10^{-4}	7	6±2
TOAHCl	7.1×10^{-7}	<1	2±2
R'_3NHCl	$<10^{-8}$	<1	<1

*R′ denotes the higher members of the series.

When deviations at low concentration levels are analysed (10^{-3}–10^{-4} *M* ion concentration), partition alone would not be sufficient to explain the trends. Response curves for the salts $TLAHClO_4$, $TOAHClO_4$, and $THAHClO_4$ were indistinguishable. The same behaviour was observed for TLAHI and TOAHI, also TLAHBr and TOAHBr. These salts are, however, expected to have different aqueous partition constants. It was also noted that the extent of deviation increases in the order

$$ClO_4^- < I^- < Br^- < Cl^-$$

This is the order expected if this deviation was based on hydrolysis of these high molecular weight salts. Two-phase hydrolysis constants (16) for R_3NHX were shown to increase from perchlorate to chloride and were independent of carbon chain length beyond C_4. Thus the high molecular weight salts cited which have very low partition constants would, however, hydrolyze to the same extent within each series and to a different extent from series to series. This would explain the observed trends.

At all concentrations a combination of the aforementioned effects is undoubtedly largely responsible for the observed behaviour of the electrodes.

Reproducibility, drift and response time are better understood if the reactions mentioned are considered. Occurrence of important partition or hydrolysis is expected to create drift and worsen the reproducibility by changing the composition of the ion exchanger phase. The constant drift encountered in the TPRAHCl, TBAHCl, TPRAHI sys-

tems can be assigned to their comparatively large K_p values which will favour depletion of the organic phase of ion exchanger immediately after introduction of the aqueous phases. For the higher molecular weight salts partition is less important. Since hydrolysis or partition are repressed at high aqueous concentration levels, no drift is observed and reproducibility is of the same order as the potentiometric error.

Selectivity

The $TLAHClO_4$ system was chosen for selectivity studies since it represented the exchanger having the most Nernstian response and the best reproducibility. From the plots in Fig. 2 the effect of extraneous halide ions could be assessed. Qualitatively the iodide anion appears to have the most influence on the potential of the perchlorate electrode since the response curve in the presence of a constant level of iodide (0.1 *M*) deviated most from the interference-free perchlorate response curve. Bromide interfered less than iodide, while chloride gave the least interference. The trend in anion interference parallels the trend in the corresponding ion exchange constants (16). The selectivity constant K_{S12} is easily related to ΔE, the difference in mV between the theoretical Nernstian interference-free potential and the actual recorded potential in the presence of interference, according to

$$K_{S12} = a_1 (10^{\Delta E/59} - 1)/a_2$$

The activities of main and interfering monovalent anions are a_1 and a_2 respectively (18, 19).

Values of K_{S12} for the $TLAHClO_4$ electrode were computed at different perchlorate activity levels in the presence of the halide ions. These values varied with the activity level in agreement with previous studies of other ion selective electrodes (20). The average value corresponding to activity levels below 2×10^{-3} was used since in this activity range the response of the electrode was Nernstian. The selectivity constants K_{S12} were ClO_4^-/I^-, ~0.1; ClO_4^-/Br^-, ~0.03; and ClO_4^-/Cl^-, ~0.005. These values are approximate and should be considered as empirical parameters (1) describing interference under specified experimental conditions. Interference clearly increases from Cl^- to Br^- to I^-.

Several authors have attempted to correlate electrochemical selectivity constants with ion exchange constants (5, 8, 10, 12, 21). James *et al.* (8) studied the interference properties of electrodes using tetrahexylammonium iodide dissolved in various organic alcohols as liquid anion exchangers. They found a good correlation between

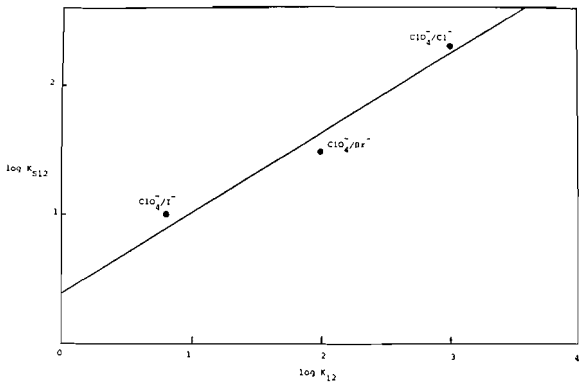

FIG. 3. Comparison of ion-exchange constants, K_{12}, and selectivity constants, K_{S12} for tridodecylammonium perchlorate.

selectivity constants and ion exchange constants in this system. Scibona *et al.* (5) and Fabiani (9) used tetraheptylammonium salts dissolved in various solvents. Applying theoretical equations developed by Eisenman *et al.* (21) they related semiquantitatively interference constants to ion-exchange constants, dissociation constants, and the mobility of the anions in the organic phase. Eisenman (10, 21) mentioned a membrane made of dodecylamine dissolved in nitrobenzene which in an electrochemical cell was selective for I^- in the presence of Br^- and Cl^-. In a more detailed study on di-2-ethylhexyl phosphoric acid in *n*-amyl alcohol, theoretical equations (21) predicted the order of selectivities; however, the agreement was only qualitative.

For the trialkylammonium salts no theoretical equation is available which could relate the interference response curves to the chemical properties of the ion exchanger. The system does not fall in the category of a completely dissociated ion exchanger nor a strongly associated one (~15% of the ion exchanger is ionized). However, a correlation was found between K_{S12} and K_{12} values. In Fig. 3 a plot of log K_{S12} vs. log K_{12} is presented. Values of ion-exchange constants K_{12} were obtained from Table 2 in ref. 16. The slope of the plot is ca. 0.6. A similar correlation with a slope of ca. 0.5 was observed by Bäck and Sandblom (12) with tetraalkylammonium salts in methylene chloride. James *et al.* (8) observed the same phenomenon but with a slope close to one.

The selectivity constants obtained for the tridodecylammonium perchlorate exchanger are of the same order of magnitude as values tabulated by Koryta (22) for other liquid anion exchangers.

Octahedral–tetrahedral equilibria in aqueous cobalt(II) solutions at high temperatures

THOMAS WILSON SWADDLE[1] AND LEONARD FABES

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received February 27, 1980

THOMAS WILSON SWADDLE and LEONARD FABES. Can. J. Chem. **58**, 1418 (1980).

Evidence is presented to indicate that aqueous Co^{2+} exists as the hexaaquo-ion in equilibrium with minor amounts (upper limits 0.08% at 298 K, 7% at 625 K, at 16–25 MPa) of tetraaquocobalt(II), with $\Delta H \sim +17$ kJ mol^{-1}. The single visible absorption band of the supposed $Co(H_2O)_4^{2+}$ has maxima at 552 nm and 486 nm in the intensity ratio 2:1. Hydrogen sulfate ion (up to 0.5 *M* at least) does not complex Co^{2+}(aq) detectably in acidic media, 290–625 K, and sulfuric acid therefore holds promise as a non-complexing strong monobasic acid for high-temperature aqueous studies. In water containing 2.0 *M* or more Cl^-, the tetrahedral form of cobalt(II) is $CoCl_4^{2-}$, ΔH for the octahedral → tetrahedral equilibrium being +62 kJ mol^{-1}; for $CoBr_4^{2-}$, the corresponding ΔH is +70 kJ mol^{-1}, the greater endothermicity accounting entirely for the lower stability relative to $CoCl_4^{2-}$.

THOMAS WILSON SWADDLE et LEONARD FABES. Can. J. Chem. **58**, 1418 (1980).

Dans cet article, on montre que le Co^{2+} en milieu aqueux existe sous forme de l'ion hexahydraté en équilibre avec de petites quantités de tétraquocobalt(II) (limite supérieure: 0.08% à 298 K et 7% à 625 K à 16–25 MPa; $\Delta H \sim +17$ kJ mol^{-1}). L'unique bande d'absorption dans le visible pour l'ion proposé $Co(H_2O)_4^{2+}$ possède un maximum à 552 nm et un à 486 nm dans un rapport d'intensité 2:1. L'ion HSO_4^- ne complexe pas de façon détectable le Co^{2+}(aq) en milieu acide (jusqu'à 0.5 *M* tout au moins, de 290 à 625 K), et ainsi l'acide sulfurique est très prometteur comme acide fort monobasique non-complexant pour les études à haute température dans l'eau. En solution aqueuse 2 *M* ou plus en Cl^-, la forme tétrahédrique du cobalt(II) est $CoCl_4^{2-}$, et le ΔH de l'équilibre octahédrique–tétrahédrique est de +62 kJ mol^{-1}. Pour $CoBr_4^{2-}$, la valeur correspondante de ΔH est +70 kJ mol^{-1}, la relativement faible stabilité du $CoBr_4^{2-}$ par rapport au $CoCl_4^{2-}$ étant due entièrement à la différence des ΔH.

Introduction

The chemistry of cobalt(II) in water at elevated temperatures has attracted attention because of the spectacular thermochromism exhibited when halide ions are present (1–3), and because of its relevance to the understanding of the mechanism of ^{60}Co transport in the heat transfer systems of water-cooled nuclear reactors (4, 5). The present study was therefore undertaken to evaluate visible-region spectrophotometry as a quantitative tool for the study of the high-temperature aqueous chemistry of cobalt(II). In effect, this required the design of a corrosion-resistant optical cell serviceable to at least 30 MPa at 650 K, the identification of the complex species present and the detailed analysis of the temperature dependence of their spectra, and the demonstration of the "inertness" of the supporting electrolytes used.

Several optical cells for high-temperature aqueous studies have been described (1, 3, 6–13). The cell described below has the advantage of simplicity of construction at the expense of permitting contact between the solution sample and the structural metal, but by fabricating the cell body out of titanium – 0.2% palladium alloy corrosive interactions are minimal, even at high chloride concentrations. This alloy is attacked by trifluoromethanesulfonic acid, however, and so this acid and its salts could not be used as noncomplexing supporting electrolytes in place of the usual perchloric acid and perchlorates, which, though intrinsically surprisingly stable kinetically in water at high temperatures, can be catalytically decomposed to a significant extent when transition metal ions are present (14, 15). We have therefore investigated HSO_4^- as a non-complexing supporting anion, as it is isoelectronic with ClO_4^- and has not been reported to form complexes of any significant thermodynamic stability with metal ions in aqueous solution at near-ambient temperatures. The basicity of SO_4^{2-} rises markedly with increasing temperature, so that at 570 K and above sulfuric acid is effectively monobasic (16); thus, in these experiments, free SO_4^{2-} was effectively eliminated simply by having a small stoichiometric excess of H^+ over total sulfate.

Special interest in the spectrum of the aqueous hexaaquocobalt(II) ion was stimulated by the suggestion of Swift and Connick (17, 18) that some tetrahedral $Co(H_2O)_4^{2+}$ might also be present at elevated temperatures. Subsequent work by Fiat *et al.* (19, 20) indicated that the ^{17}O-nmr data (which originally had led Swift and Connick to postulate the existence of $Co(H_2O)_4^{2+}$) are in fact consistent within the experimental uncertainty with the exclusive existence of the hexaaquo-species over the temperature range 263–456 K at least. This did not completely settle the issue, however, since observations of the visible spectrum (17) and temperature-jump relaxation kinetics (18) of

aquocobalt(II) solutions, made by Swift and Connick in support of their proposal, then remained unexplained. We now present evidence that Swift and Connick were correct, and that the observations of Fiat *et al.* (19, 20) can be accommodated.

Experimental

All chemicals were Baker Analyzed or Fisher Certified reagents. Distilled water was passed through Barnstead deionizer and organic removal cartridges before use.

The spectrophotometer cell (path length 3.42 cm) is shown in Fig. 1. The cell body and K-cross-section seals are of ATL-40 Ti – 0.2% Pd alloy (Atlas Titanium Ltd.), but the end plates, bolts, and pressure connection gland nuts are of type 316 stainless steel. The lower pressure connection facilitates filling, etc., but is not necessary. A prototype using screw-in end-plugs rather than bolted closures was unsuccessful because residual torque on the windows often led to their fracture, usually in the cooling portion of a temperature cycle. Attempts to use commercial K-seals of gold-plated Inconel were unsuccessful, as the smallest penetration of the plating resulted in catastrophic galvanic corrosion of the nickel alloy by the hot salt solutions. The Ti – 0.2% Pd alloy showed excellent corrosion resistance, however, and etching of the sapphire windows (3, 10) was slow enough to be accommodated quite economically by their periodic replacement. Nevertheless, only those sets of spectra which were accurately reproducible in the cooling part of the temperature cycle were accepted; such discrepancies as occasionally occurred were generally attributable to leaks rather than corrosion. The temperature of the cell was measured (±0.25 K) with two thermocouples inserted in 5 cm wells (not shown) drilled parallel to the optical axis, with reference to junctions at 273.2 K. The response of the thermocouples was checked periodically against Fisher T421 Ther-Metric fusion point standards.

The solution samples were permitted to expand into an overflow chamber (Fig. 2), where a free piston loosely separated the liquid phase from the pressurizing fluid (high-pressure argon) to minimize distillation of the solvent. All parts shown with single cross-hatching in Fig. 2 were Ti – 0.2% Pd, so that solutions contacted only titanium alloy and sapphire; the bottom closure nut and all further high-pressure connections were of type 316 stainless steel.

The optical cell is heated with the furnace shown in Fig. 3. Each interlocking half contains an electrical winding of 5 m of 21 AWG chromel-A wire, and a sheath of copper coils to allow cooling water to be circulated in a countercurrent fashion to protect the spectrophotometer from thermal damage. The shells are of aluminum, and the insulation is Sauereisen No. 1 cement. Temperatures can be held constant to within 0.5 K using simply a rheostat or variable transformer in conjunction with a voltage regulator. A heating jacket was also provided for the overflow vessel, but this is unnecessary, particularly if this vessel can be placed lower than the sample cavity in the optical cell to eliminate convective exchange of solution.

The optical cell and its furnace were designed to fit inside the sample compartment of a Cary Model 15 spectrophotometer, although most of the measurements reported here were made with a Model 17H instrument which has a large open sample compartment and excellent baseline stability. Neutral density filters were used as desired to help balance the sample and reference beams, and spectra were referred to baselines obtained in blank runs.

Throughout this article, the symbol M means mol dm^{-3} as measured at 293 K and 0.1 MPa, i.e., it represents a temperature- and pressure-independent concentration scale based on the conditions of preparation of the solutions by volume as a standard state. This is more convenient than the mol kg^{-1} scale where mixed-electrolyte solutions are involved. Corrections for the linear expansion of the cell (9.0×10^{-6} K^{-1}) were generally smaller than the uncertainty in the absorbance measurements and were ignored.

Results

Cobalt(II) Sulfate in Dilute Aqueous Sulfuric Acid

The dependence of the visible absorption spectrum of a typical cobalt(II) sulfate solution in dilute sulfuric acid on temperature T is shown in Fig. 4, just as obtained from the spectrometer. The measured absorbance A must be corrected (A_{corr}) for the thermal expansion of the solutions, which, for these dilute systems, can be equated to the interpolated thermal expansion of water at the appropriate pressures (21). Where necessary, spectra were also corrected for a low intensity absorption which developed to a maximum at ~730 nm, as the temperature rose, while an even weaker absorption around 800 nm decreased concomitantly; this phenomenon appeared in all solutions including plain water, and probably derived from vibrational overtones of H_2O (in which case $\varepsilon_{H_2O} \sim 3 \times 10^{-4}$ M^{-1} cm^{-1} at 730 nm around 500 K, cf. Bell and Krohn (22)).

So long as a sufficient excess of H^+ was present to convert in principle all SO_4^{2-} to HSO_4^- and to suppress the hydrolysis of Co^{2+}(aq) (5), the spectra were quantitatively reproducible to ±2% in molar absorbance ε (= $A_{corr}/3.42[Co]$, M^{-1} cm^{-1}) and ±0.2% in wavelength λ or wavenumber $\bar{\nu}$, for a given temperature and pressure. No significant dependence on the stoichiometric $[H^+]$ or $[SO_4^{2-}]$ could be detected, over the temperature (290–625 K) and concentration (0.1–0.5 M H_2SO_4 or H_2SO_4/$NaHSO_4$) ranges investigated. Thus, *neither complexing by HSO_4^- nor hydrolysis of Co^{2+}(aq) were detectable under these conditions.*

If, however, the stoichiometric $[H^+]$ was *less* than the stoichiometric $[SO_4^{2-}]$, anomalously large red shifts were seen above 400 K, evidently because of hydrolysis of Co^{2+} in the HSO_4^-–SO_4^{2-} buffer; a solid, probably $CoSO_4 \cdot H_2O$ (23), was often precipitated, e.g. above 525 K when $[CoSO_4] = 0.0317$ M and $[H_2SO_4] = 0.0099$ M, and in any case spectral changes occurred which were not reversible over the temperature cycle.

The vastly predominant form of Co^{2+}(aq) in the solutions containing excess stoichiometric H^+ over sulfate was undoubtedly $Co(H_2O)_6^{2+}$, at least near 300 K (17–20), and the absorption band corres-

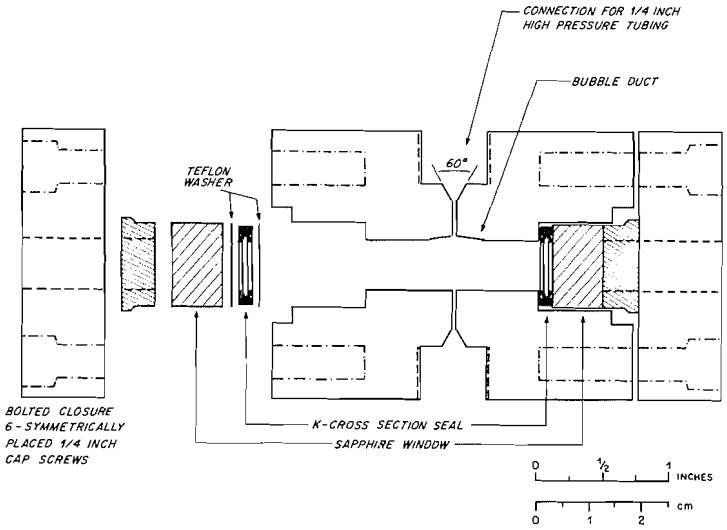

FIG. 1. Pressurizable optical cell.

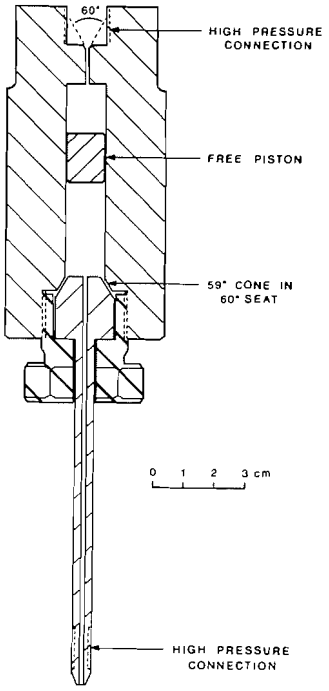

FIG. 2. Expansion chamber.

ponds to the Laporte-forbidden $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ transition (with some admixture of spin-forbidden excitations to states derived from ^2G and ^2H terms of Co^{2+}) (ref. 24, pp. 318–324). This band should therefore derive essentially all its oscillator strength f

$$[1] \quad f = 4.315 \times 10^{-9} \int_0^\infty \varepsilon_{\bar{\nu}}\, d\bar{\nu} \quad (\bar{\nu} \text{ in } cm^{-1})$$

from vibronic coupling, in which case the temperature dependence of f would be expected (25) to follow the equation

$$[2] \quad f = \sum_i C_i \coth (h\nu_i/2kT)$$

where ν_i is the ith normal vibrational mode contributing to vibronic coupling and C_i is a proportionality constant. For $Co(H_2O)_6^{2+}$, the relevant modes are ν_3, ν_4, and ν_6, but ν_6 is inactive and only ν_3 is seen (364 cm^{-1}) (26), possibly because ν_4 lies close; in any event, the hyperbolic cotangent terms are not very sensitive to the choice of ν_i for $\bar{\nu}_i <$ 400 cm^{-1} when $T >$ 300 K, and one can take the ν_3 term alone to obtain

$$[3] \quad f = C \coth (262/T)$$

In fact, the measured whole-band f values increase much more rapidly with rising T than eq. [3] predicts, and even faster again than allowed by the simplified equation

$$[4] \quad f = f_0(1 + \exp (200/T))$$

used by Holmes and McClure (27) to describe the low-temperature behavior of f in solid $CoSO_4 \cdot 7H_2O$. This sharply T-dependent excess oscillator strength might be interpretable in terms of changes in the solvent effect on f as the aqueous medium expands thermally, but the various attempts (28–33) to account for such solvent effects theoretically have either been overly simplistic or led to expressions containing too many parameters, and in any case have dealt only with fully-allowed transitions, primarily in non-polar solvents. These treatments do, however, suggest that a relevant variable is the square of the refractive index of the

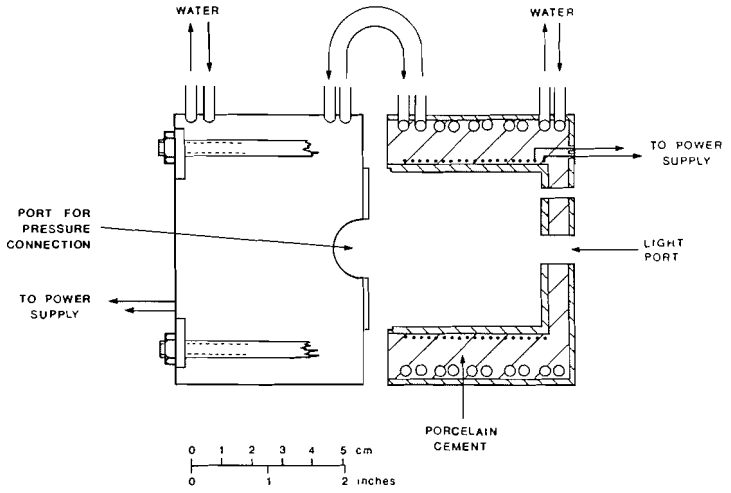

FIG. 3. Furnace for optical cell.

solvent, which in turn suggests that eq. [3] needs to be supplemented with some function of the square of the solution density ρ (34). Bayliss's work (30) links the variation of f with that of the wavenumber $\bar{\nu}_{max}$ of the band maximum, as observed here (empirically, $10^5 f \sim 0.0159\ (20054 - \bar{\nu}_{max})$ for $\bar{\nu}_{max}$ in cm^{-1}), while Robertson and King's suggestion, that pressure (i.e., solvent density) effects on f act through influencing the *populations* of the various solvation spheres around a dissolved absorber, provides a further link with the proposal which follows.

Correction of the spectra of Fig. 4 for expansion, followed by subtraction of the 291 K spectrum, yields the difference spectra of Fig. 5.[2] The striking constancy of the wavelengths (552 ± 2 and 486 ± 1 nm) and relative intensities (1:0.5) of the principal features of these difference spectra over the range of 128 K confirms Swift and Connick's interpretation of their single, lower-temperature difference spectrum (17) as evidence for the presence of a new aquocobalt species at elevated temperatures. The band shape is as expected for the $^4T_1(P) \leftarrow {}^4A_2$ transition of tetrahedral cobalt(II) (see below) at low resolution. Furthermore, taking $Dq = 920$ and $B = 825\ cm^{-1}$ for $Co(H_2O)_6^{2+}$ (ref. 24, pp. 318–324) and, after Smith (35), setting $Dq(T_d)$ to ~0.48 $Dq(O_h)$, we calculate (ref. 24, p. 182) that the $^4T_1(P) \leftarrow {}^4A_2$ maximum of $Co(H_2O)_4^{2+}$ should occur at 17990 cm^{-1} or 556 nm, very close to that observed.

[2]Strictly, the 291 K band should be corrected according to eq. [3] to each of the other four temperatures, but the absorption at 291 K near the maximum of the difference spectra is small and so this correction cannot materially affect the essential features revealed in Fig. 5. Conversely, the extrapolated contribution to the 291 K spectrum of the species having the absorption maximum at 552 nm can be neglected in this context.

In addition, experience with nitratoaquochromium(III) ion (37) suggests that the ligand-field spectrum of $Co(H_2O)_4^{2+}$ should be very similar to that of $Co(NO_3)_4^{2-}$, for which the $^4T_1(P) \leftarrow {}^4A_2$ maximum occurs at 535 nm with $Dq = 466\ cm^{-1}$ and $B = 855\ cm^{-1}$ (38), so lending support to the foregoing estimate and its implicit assumption that $B(T_d) \sim B(O_h)$. It is, therefore, very likely that the excess oscillator strength over that predicted by eq. [3] is indeed due to small amounts of tetraaquocobalt(II) formed in an endothermic equilibrium

$$[5] \quad Co(H_2O)_6^{2+} \rightleftharpoons Co(H_2O)_4^{2+} + 2H_2O$$

whence, taking the activity of solvent water with respect to the 298 K, 0.1 MPa reference state to be given by the relative density $\rho_r (= \rho_{T,P}/\rho_{293,0.1})$, and assuming equal activity coefficients for the hexa- and tetra-aquo ions, we have

$$[6] \quad [Co(H_2O)_4^{2+}]/[Co(H_2O)_6^{2+}] = \rho_r^{-2} \exp(\Delta S/R - \Delta H/RT)$$

$$[7] \quad f = f_{O_h}[Co(H_2O)_6^{2+}]/[Co_{total}] + f_{T_d}[Co(H_2O)_4^{2+}]/[Co_{total}] \approx f_{O_h} + f_{T_d}[Co(H_2O)_4^{2+}]/[Co(H_2O)_6^{2+}]$$

Combination of eqs. [3], [6], and [7] then gives

$$[8] \quad f = C \coth(262/T) + D\rho_r^{-2} \exp(-\Delta H/RT)$$

where

$$[9] \quad D = f_{T_d} \exp(\Delta S/R)$$

and a non-linear least-squares regression gave an excellent fit of a set of 19 data points for $[CoSO_4] = 0.0336\ M$, $[H_2SO_4] = 0.0990\ M$, and $P = 16$ MPa to eq. [7] over the entire range 298–614 K with $C =$

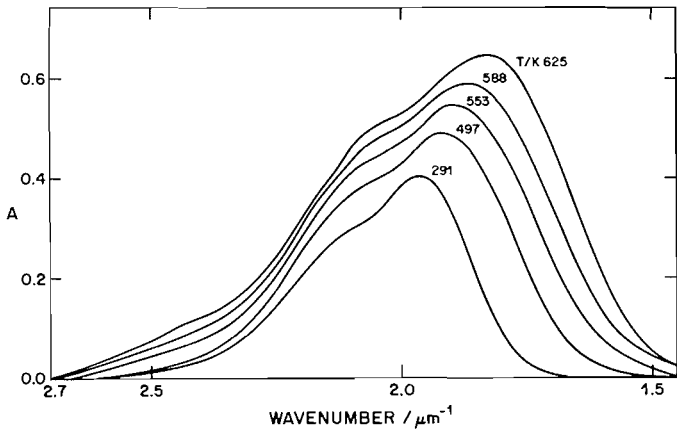

FIG. 4. Spectra of 0.0238 *M* $CoSO_4$ in 0.478 *M* H_2SO_4 at 25 MPa, uncorrected for thermal expansion of solution. Optical path length 3.42 cm.

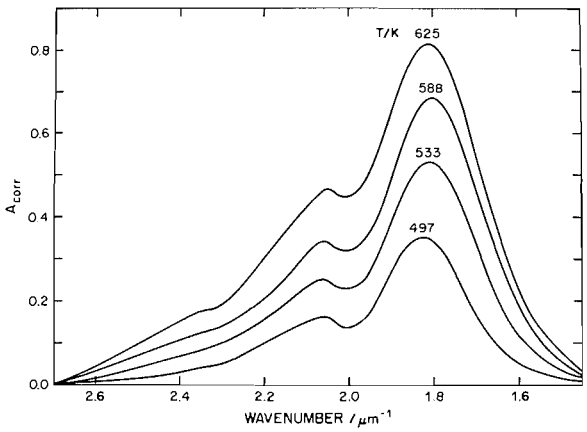

FIG. 5. Difference spectra from Fig. 4, after correction for thermal expansion of solution.

$(5.20 \pm 0.15) \times 10^{-5}\ M^{-1}\ cm^{-2}$, $D = (132 \pm 51) \times 10^{-5}\ M^{-1}\ cm^{-2}$, and the enthalpy of reaction $\Delta H = +16.6 \pm 2.0\ kJ\ mol^{-1}$ (uncertainties are standard deviations).

A plot of eq. [8] with these parameters is shown in Fig. 6, together with the calculated contributions to f of the octahedral and tetrahedral aquocomplexes. The actual concentrations of tetraaquocobalt(II) present cannot be calculated unless f_{T_d} is known; values of 3×10^{-3} to 8×10^{-3} are typical of tetrahedral cobalt(II) (ref. 24, pp. 318–324), but, as argued above, tetranitratocobaltate(II), with the f value of 1.94×10^{-3} for the $^4T_1(P) \leftarrow {}^4A_2$ maximum (38), is probably a better analogue for $Co(OH_2)_4^{2+}$. In that case, about 0.08% of the total aquocobalt(II) is present as $Co(OH_2)_4^{2+}$ at 298 K and ~7% at 625 K,[3] and $\Delta S \sim$

[3]These percentages may at least be taken as upper limits, as the f value chosen for $Co(OH_2)_4^{2+}$ is the lowest of those for tetrahedral cobalt(II) that have appeared in the literature. Similarly, the ΔS cited is the most positive likely value.

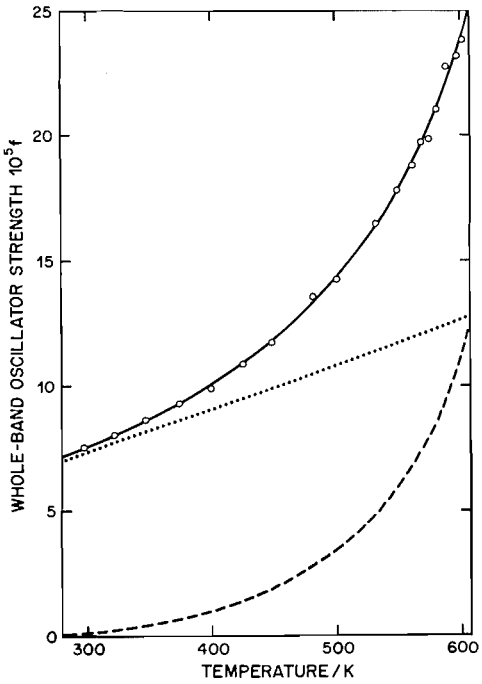

FIG. 6. Temperature dependence of expansion-corrected oscillator strength of 510 nm band of 0.0336 *M* $CoSO_4$ in 0.0990 *M* H_2SO_4 at 16 MPa. Solid curve: eq. [8] with parameters given in text. Dotted curve: estimated contribution of $Co(H_2O)_6^{2+}$ (eq. [3]). Dashed curve: estimated contribution of $Co(H_2O)_4^{2+}$.

$-3\ J\ K^{-1}\ mol^{-1}$. Thus, although the lower-temperature $Co(H_2O)_4^{2+}$ levels are low enough to escape detection by the method of Fiat *et al.* (19, 20), enough $Co(H_2O)_4^{2+}$ is present in aquocobalt(II) solutions to provide a dissociative pathway (D mechanism) for solvent exchange and net substitution in $Co(H_2O)_6^{2+}$. These results also suggest that an endothermic equilibrium similar to eq. [5] may be responsible for the high-temperature broadening of the Raman spectrum of aqueous

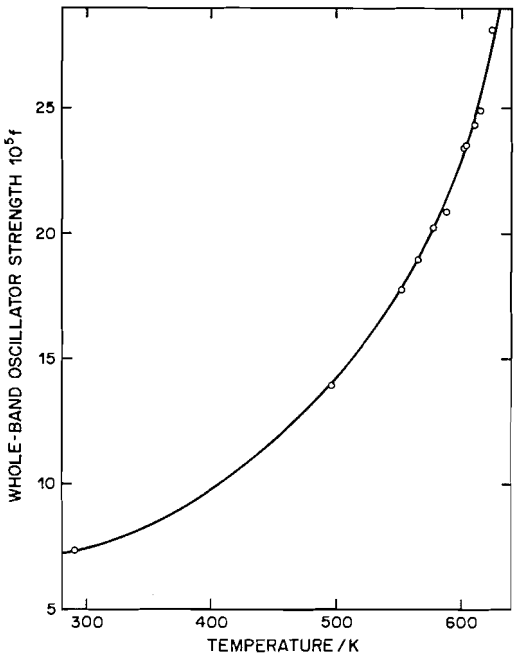

FIG. 7. Temperature dependence of oscillator strength of 510 nm band of 0.0238 *M* $CoSO_4$ in 0.478 *M* H_2SO_4 at 25 MPa. Curve represents eq. [8] with parameters for 0.099 *M* H_2So_4 (see text).

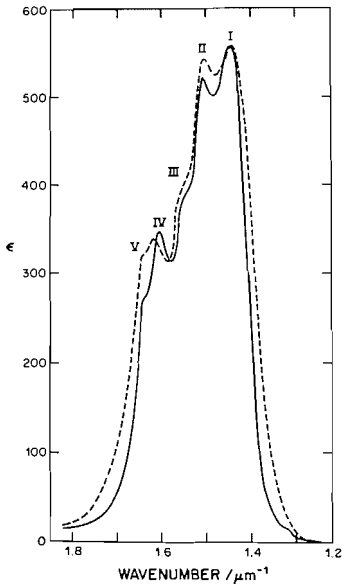

FIG. 8. Expansion-corrected spectra of 5.78 × 10^{-4} *M* $CoSO_4$ in 9.83 *M* LiCl with 1.8 × 10^{-3} *M* HCl at 24 MPa. Solid curve: 346 K. Broken curve: 534 K.

$Mg(H_2O)_6^{2+}$ (ionic radius 72 pm, cf. 73 pm for Co^{2+} (39)), as reported by Irish *et al.* (40); these authors favored an alternative explanation, but did not discount this possibility.

Figure 7 shows that the above parameters for $[H_2SO_4]$ = 0.099 *M* fit the data for $[H_2SO_4]$ = 0.478 *M* equally well (and to a higher upper temperature), so confirming that complexing by SO_4^{2-} or HSO_4^- is negligible and hydrolysis of Co^{2+}(aq) is completely suppressed. Similar results were obtained with other dilute acidic hydrogen sulfate media. This clearly demonstrates the potential usefulness of hydrogen sulfates as "inert" supporting electrolytes for high temperature aqueous chemistry.

Cobalt(II) in Excess Aqueous Chloride

The salient features of the spectra of cobalt(II) chloro-complexes in high temperature aqueous media have been well documented by Lüdemann *et al.* (1–3), while work by Bjerrum *et al.* (41, 42), Krauss and Lehmann (43), and Zeltmann *et al.* (44) has provided a more detailed understanding of these systems at temperatures below 360 K. It is now clear that, contrary to earlier reports suggesting that $CoCl_3OH_2^-$ was the major tetrahedral cobalt(II) species in aqueous chloride media (45), the tetrachlorocobaltate is the only important four-coordinate species in concentrated (~10 *M*) aqueous halide media (3, 41, 42, 44, 46). In more dilute solutions, $Co(H_2O)_4Cl_2^0$ may well be important at near-ambient temperatures (43, 47) and di- and tri-chloro aquocobalt complexes at high temperatures (1, 2).

The present study confirms that the only important tetrahedral Co species in 10 *M* aqueous LiCl at elevated temperatures is $CoCl_4^{2-}$. The spectra of such solutions had the shape and wavelengths characteristic of $CoCl_4^{2-}$ even at 293 K, and intensified with rising temperature, without significant shifts of maxima wavelengths, to reach an almost temperature-independent expansion-corrected intensity at ~ 340 K. Figure 8 shows spectra of $CoCl_4^{2-}$ in 9.8 *M* (52.3%, ρ^{293} = 1.213 g cm^{-3}) LiCl at 346 and 534 K, with expansion corrections based on Maksimova's (48) equation

$$[10] \quad \rho_r = (\rho_{H_2O}{}^T + 0.314)/(\rho_{H_2O}{}^{293} + 0.314)$$

The intensities of the features II and V are somewhat *T*-dependent (ε_{II} actually exceeds ε_I slightly, above about 550 K) and the wholeband oscillator strength rises 20% from 5.06 × 10^{-3} to 6.08 × 10^{-3} M^{-1} cm^{-2}, primarily because of a slight broadening over this 188 K range, but the striking constancy of ε_I (556 ± 7 M^{-1} cm^{-1}) and λ_I (692 ± 1 nm) contrasts with the aquocobalt(II) case considered above and lends itself to quantitative estimation of $CoCl_4^{2-}$ where this is the only tetrahedral halo-species present. The relative insensitivity of this nominally Laporte-forbidden $^4T_1(P) \leftarrow {}^4A_2$

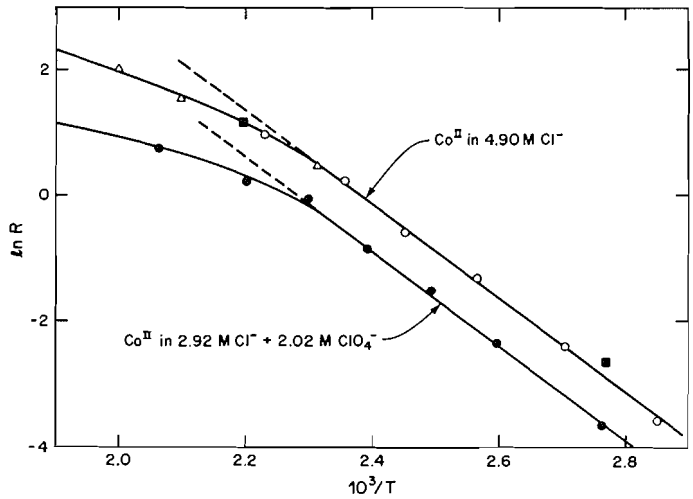

FIG. 9. Temperature dependence of tetrahedral–octahedral ratio R for $CoCl_2$ at 25 MPa in (upper curve) 4.80 M NaCl + 0.098 M HCl and (lower curve) 2.92 M NaCl + 2.024 M $NaClO_4$ + 0.43 mM HCl. $CoCl_2$ concentrations are 0.16 (triangles), 0.32 (squares), 1.32 (filled circles), and 1.60 (open circles) mM.

band of $CoCl_4^{2-}$ to temperature arises because it gains intensity through electronic, rather than vibronic, interactions of Co^{2+} with its ligands (49).

In acidified NaCl solutions, 2.0–5.0 M, the high-temperature densities of which were estimated by the method of Khaibullin and Borisov (36), $CoCl_4^{2-}$ was shown to be the only important absorbing species in the 700 nm region, so that one can use the apparent molar absorbance ε_I^* at 697 nm to measure the ratio R of $CoCl_4^{2-}$ to non-tetrahedral Co species.

$$[11] \quad R = [CoCl_4^{2-}]/[\text{Co(octahedral)}] = \varepsilon_I^*/(\varepsilon_I - \varepsilon_I^*)$$

The equilibrium constant K for the reaction

$$[12] \quad Co(H_2O)_{6-n}Cl_n^{(2-n)+} + (4-n)Cl^- \rightleftharpoons CoCl_4^{2-} + (6-n)H_2O$$

would be given by

$$[13] \quad K = a_{CoCl_4^{2-}} \cdot a_{H_2O}^{(6-n)}/(a_{Cl^-}^{(4-n)} \cdot a_{CoCl_n})$$

or, at constant ionic strength,

$$[14] \quad K' = R a_{H_2O}^{(6-n)}/[Cl^-]^{(4-n)} = \exp(\Delta S/R - \Delta H/RT)$$

Unfortunately, n is not known (but is scarcely likely to be zero at these halide concentrations and high temperatures, a_{H_2O} cannot be set to unity, and there is doubt concerning the validity of the ionic strength principle at these high concentrations and temperatures. Nevertheless, Fig. 9 shows that, at a given $[Cl^-]$, a plot of ln R vs. $1/T$ is linear up to about 50% completion of reaction with the same slope, corresponding to $\Delta H = +62 \pm 2$ kJ mol^{-1} for $[Cl^-]$ = 2.9, 4.0 (not shown), and 4.9 M at ionic strength 4.9 M. Krauss and Lehmann (43) report $\Delta H \sim$ 46 kJ mol^{-1} for the cobalt(II)–chloride octahedral–tetrahedral equilibrium over a smaller (75 K) range of temperatures. At a given temperature, R is dependent on $[Cl^-]$ to the power of about 1.5 at this ionic strength; this does not warrant detailed consideration, for the reasons given above, but suggests that $n = 2$, i.e., that the equilibrium observed is

$$[15] \quad Co(H_2O)_4Cl_2^0 + 2Cl^- \rightleftharpoons CoCl_4^{2-} + 4H_2O$$

This is not unreasonable for conditions of moderate $[Cl^-]$ and elevated temperature, which favor neutral species by virtue of the lowered dielectric constant (see also Krauss and Lehmann's evidence for $Co(H_2O)_4Cl_2^0$ (43)).

For acidic NaCl solutions with $[Cl^-]$ less than about 0.1 M but 2 to 5 × $[Co^{II}]$, broad, rather featureless bands with markedly *temperature-dependent* maxima were observed near 650 nm at elevated temperatures; these were attributed to mixtures of $CoCl_2(OH_2)_2^0$ and $CoCl_3(OH_2)^-$, the spectra being quite distinct from that of $CoCl_4^{2-}$ or any octahedral species, but no further information could be extracted. Similarly, at chloride-to-cobalt ratios of less than unity ($[Cl^-] \sim 0.03$ M or less), shifts and intensifications of the octahedral (510 nm) band showed that $Co(H_2O)_5Cl^+$ was probably important at elevated temperatures, but this was not pursued in detail.

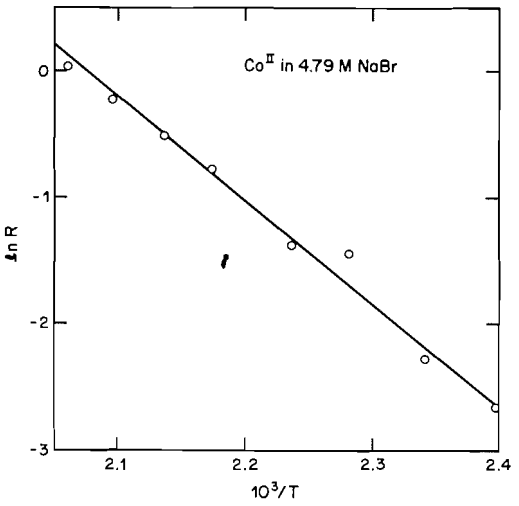

FIG. 10. Temperature dependence of tetrahedral–octahedral ratio for $CoSO_4$ (1.6 m*M*) in 4.79 *M* NaBr with 1.6 m*M* HBr at 24 MPa.

Cobalt in Excess Aqueous Bromide

The visible spectrum of 1.0 m*M* cobalt(II) sulfate in 9.0 *M* HBr shows a band with four well-defined maxima at 723, 697, 664, and 640 nm which reach temperature-independent expansion-corrected molar absorbances of 724, 720, 430, and 330 M^{-1} cm^{-1} respectively as the temperature is increased beyond 345 K. These data evidently characterize $CoBr_4^{2-}$. The same spectrum develops in solutions of cobalt(II) in aqueous NaBr (4.79 *M*, 36.2%, ρ^{293} = 1.364 g cm^{-3}) containing 1.0 m*M* HBr, as the temperature is raised. As with $CoCl_4^{2-}$, we can determine the ratio *R* of $CoBr_4^{2-}$ to octahedral cobalt(II) from the expansion-corrected (47) molar absorbance at 723 or 697 nm, and Fig. 10 shows that ln *R* is in effect a linear function of $1/T$ at least as far as $R \sim 1$, giving $\Delta H = +70 \pm 3$ kJ mol^{-1} for the octahedral → tetrahedral reaction.

The dependence of *R* on $[Br^-]$ was not studied, partly because of doubts regarding the validity of calculations made without direct knowledge of the activity coefficients involved (cf. $CoCl_4^{2-}$) but also because of the lower stability of $CoBr_4^{2-}$ relative to $CoCl_4^{2-}$. At 450 K, for example, $R = 0.30$ for 4.8 *M* NaBr and 3.0 for 4.9 *M* NaCl; the difference amounts to 8 kJ mol^{-1} in free energy, and is completely accounted for by the difference in ΔH.

JOHN A. FINDLAY, PAUL MEBE, MICHAEL D. STERN, and M. L. GIVNER. Can. J. Chem. **58**, 1427 (1980).

3,17β-Dihydroxy-6-oxaestra-1,3,5(10),7-tetraen and related steroidal compounds have been synthesized in high yield via condensation of 7-methoxy-4-vinyl coumarin and 2-methyl-1,3-pentanedione. The approximate uterotrophic activity of the synthetic compounds relative to 17β-estradiol has been determined.

JOHN A. FINDLAY, PAUL MEBE, MICHAEL D. STERN et M. L. GIVNER. Can. J. Chem. **58**, 1427 (1980).

On a synthétisé avec des rendements élevés les dihydroxy-3,17β oxa-6 estra tétraène-1,3,5(10),7 ainsi que des stéroides apparentés en faisant appel à la condensation de la méthoxy-7 vinyl-4 coumarin sur la méthyl-2 pentanedione-1,3. On a déterminé l'activité utérotrophique approximative des produits synthétiques par rapport à celle de l'estradiol-17β.

While miroestrol **1**, one of the most potent naturally occurring estrogens discovered (1), has been the subject of two synthetic studies (2) no successful synthesis has been reported to date. Since the compound possesses the 6-oxa-7-ene feature we considered it of interest to synthesize some steroidal analogues possessing this novel B ring enol ether function for pharmacological evaluation. This paper reports an efficient total synthesis of 3,17β-dihydroxy-6-oxaestra-1,3,5(10),7-tetraen, **10***c*, and related compounds.

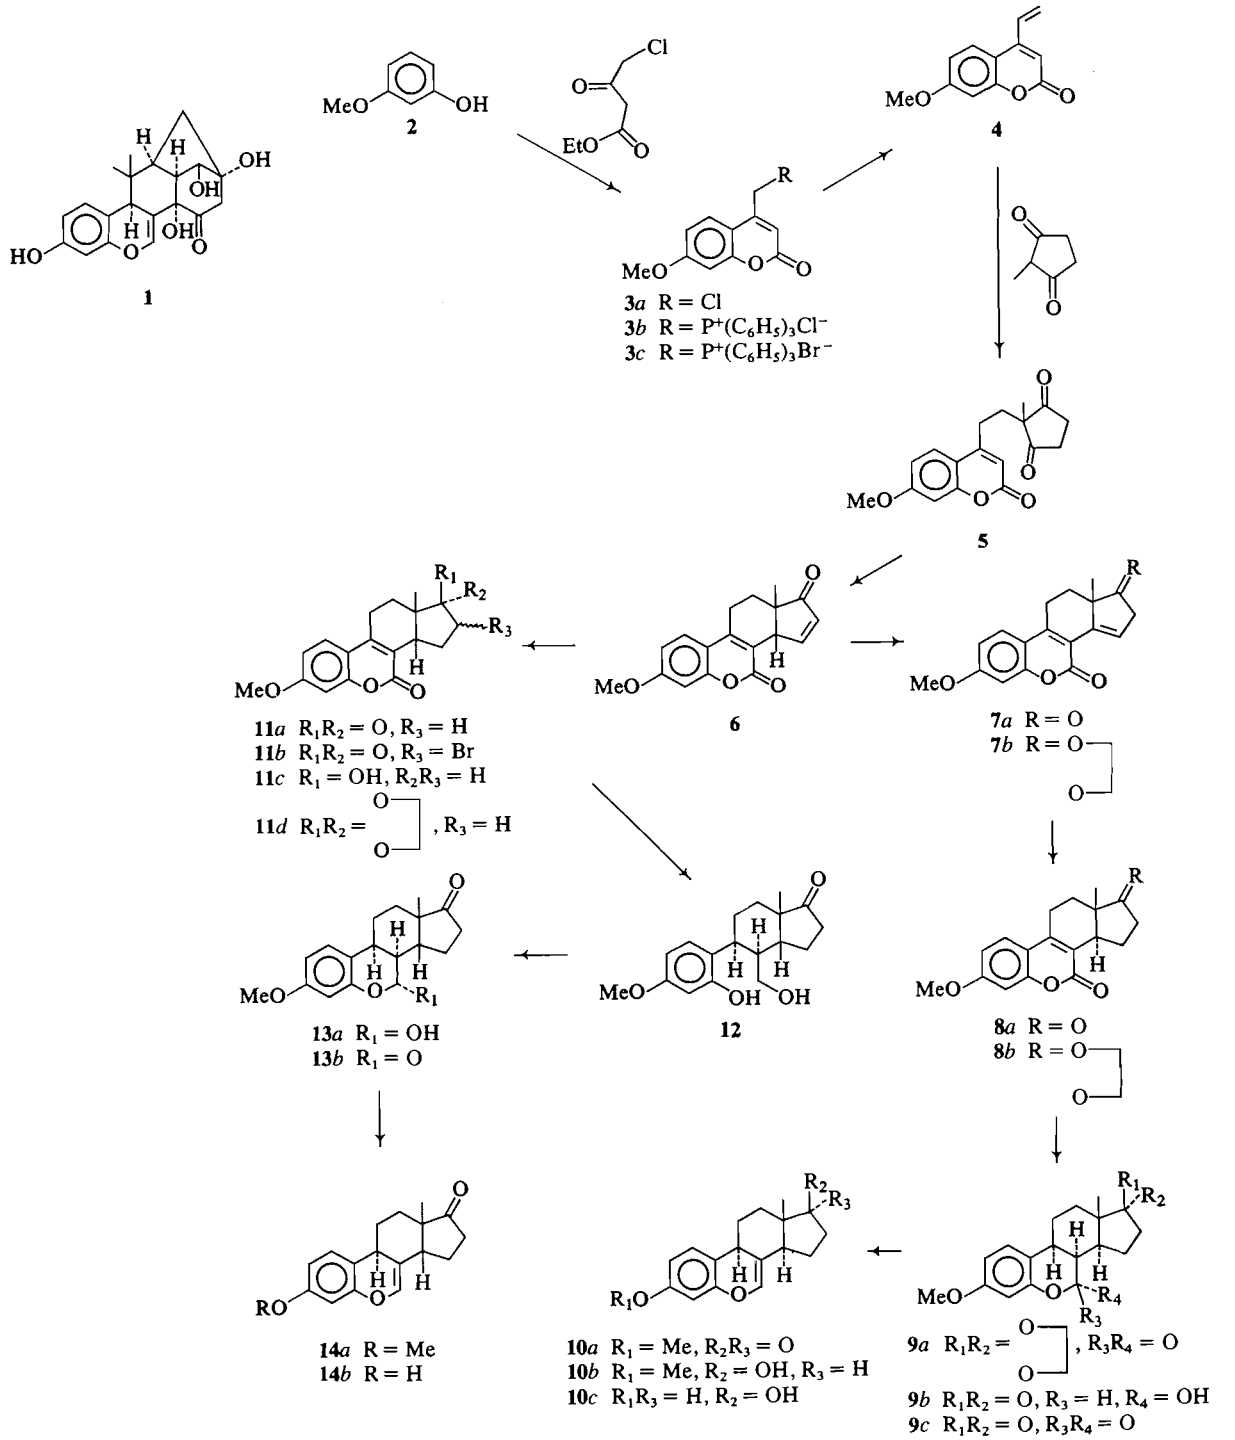
Our synthesis contains a variant of the Torgov approach (3) involving a Michael type addition of 2-methyl-1,3-cyclopentanedione on the key intermediate 7-methoxy-4-vinyl coumarin **4** leading to the tetracyclic 3-methoxy-6-oxaestra-1,3,5(10),8(9),15-pentaen-7,17-dione, **6**, which by further functional group manipulation gave the prototype target compound **10***a* in 24% overall yield from *m*-methoxyphenol, **2**.

The vinyl coumarin **4** was prepared by condensing *m*-methoxyphenol **2** with ethyl-4-chloroacetoacetate in the presence of concentrated H_2SO_4 to give 7-methoxy-4-chloromethyl coumarin **3***a* which was readily transformed into the triphenylphosphonium salt **3***b*. The latter underwent Wittig condensation with aqueous formaldehyde in the presence of Na_2CO_3 to provide crystalline 7-methoxy-4-vinylcoumarin, **4** in 68% overall yield from **2**.

Compound **4** can also be prepared by oxidation of 7-methoxy-4-methyl coumarin with SeO_2 in refluxing diglyme/benzene to 7-methoxy-4-formyl coumarin which after reduction to the corresponding alcohol, displacement with bromide ion, and triphenylphosphonium salt formation provided **3***c* and an alternate route to **4** in a 50% overall yield. Attempted direct conversion of 7-methoxy-4-formyl coumarin to **4** via Wittig reaction under a variety of conditions was unsuccessful (4).

Condensation of **4** with 2-methyl-1,3-cyclopentanedione in acetonitrile containing KF and 18-crown-6, under N_2, gave the seco steroid **5** in 68% yield. Cyclization of the latter to the α,β-unsaturated ketone **6** was achieved in 80% yield by refluxing with *p*-toluenesulfonic acid in benzene. The ^1H nmr spectrum of **6** shows two sets of double doublets, one at δ 6.20 ($J = 5$ Hz, $J = 2$ Hz) and the other at δ 7.80 ($J = 5$ Hz, $J = 3$ Hz) assigned to C(15)H and C(16)H and constituting an AMX system with C(14)H.

Chemical corroboration of the location of the double bond between C(15) and C(16) is derived from the bromination of **11***a* to **11***b* and the dehydrobromination of **11***b* to give a single product, identical to **6**. The cyclopentanone **11***a* can be obtained by sodium borohydride reduction of **6** to the alcohol **11***c* followed by oxidation with CrO_3/H_2SO_4 or by catalytic hydrogenation of **6**.



The C/D ring junction in **6** was shown to be *cis* via the following sequence: ketalization gave **7***b* (96% yield) whose ^1H nmr spectrum features a multiplet at δ 6.92 due to the olefinic C(15)H. Deketalization

afforded the β,γ-unsaturated ketone **7***a* (96% yield) which on hydrogenation using 10% Pd/C in benzene gave the single tetraenone **8***a* in 93% yield, different from the isomer **11***a* obtainable by direct catalytic reduction of **6**. The *trans* C/D ring junction stereochemistry of **8***a* was confirmed by X-ray studies (5) on the reduction product **9***a* of its ketal **8***b* (*vide infra*). Development of the trans C/D ring junction via the H_2/Pd/C/benzene reducing medium has been successfully employed in similar steroidal systems (6).

Direct confirmation of the *cis* C/D ring junction in

TABLE 1. Uterotropic activity of miroestrol analogues

Compound (racemic)	No.	Uterotrophic activity relative to 17β-estradiol
8α-3-Methoxy-7-hydroxy-6-oxaestra-1,3,5(10)trien-17-one	**9***b*	Inactive
8α-3-Methoxy-6-oxaestra-1,3,5(10)-trien-7,17-dione	**9***c*	Slightly active
3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17-one	**10***a*	Slightly active
3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17β-ol	**10***b*	Slightly active
3-Hydroxy-6-oxaestra-1,3,5(10),7-tetraen-17β-ol	**10***c*	Quite active, but less than 17β-estradiol
14β-3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17-one	**14***a*	Inactive

6 and **11***a* comes from X-ray diffraction studies (7) on the hemi-acetal ketone **13***a*, obtained by $Na_2Cr_2O_7$/DMSO oxidation of the major Li/NH_3 reduction product **12** of **11***d*, which revealed the existence of the *cis–anti–cis* ring junction stereochemistry for **13***a*. The ethylene ketal of dione **13***b* was also obtained (17%) in the reduction of **11***d* by Li/NH_3.

Compound **14***a* was obtained in quantitative yield from **13***a* by dehydration with *p*-toluenesulfonic acid in refluxing benzene while **14***b* was available directly from **13***a* in 85% yield by treatment with boron tribromide in dichloromethane at 0°C.

With the stereochemistry of the C/D ring junction now under rigorous control, the α,β-unsaturated lactone ketal **8***b* was transformed into the saturated lactone ketal **9***a* in 93% yield by means of Li/NH_3. Further reduction with one equivalent of diisobutylaluminum hydride at −70°C followed by acidic work up gave the crystalline hemi-acetal ketone **9***b* (85% yield). The ^{1}H nmr spectrum of the latter shows a doublet at δ 5.60 (J = 9 Hz) indicative of a *trans* diaxial relationship of C(7)H/C(8)H.

The keto lactone **9***c* was prepared in quantitative yield by deketalization of **9***a* using *p*-toluenesulfonic acid in acetone.

Dehydration of **9***b* using *p*-toluenesulfonic acid–benzene gave a quantitative yield of the 6-oxa-7-ene steroid **10***a* whose ^{1}H nmr spectrum displays a signal at δ 6.23 for the vinylic C(7)H. Infrared absorptions at 1730 and 1685 cm^{-1} attest to the presence of five-membered ketone and vinyl ether functionalities. 17β-Hydroxy-3-methoxy-6-oxaestra-1,3,5(10)7-tetraen, **10***b*, was obtained from **10***a* in quantitative yield by reduction with sodium borohydride in benzene/methanol. The ^{1}H nmr spectrum displays a signal at δ 3.80 (t, J = 8 Hz) characteristic (8) of the α configuration for C(17)H. Demethylation of **10***b* to 3,17β-dihydroxy-6-oxaestra-1,3,5(10),7-tetraen, **10***c*, was accomplished in 68% yield by heating it at 180–190°C with CH_3MgI. Attempted demethylation of **10***b* using boron tribromide led to intractable mixtures.

The racemic compounds **9***b*, **9***c*, **10***a*, **10***b*, **10***c*, and **14***a* prepared by this route have been tested for uterotrophic activity using the procedure of Rubin *et al.* (9) with minor modification and the results are contained in Table 1. Compound **10***c* was the most potent of the series but less active than 17β-estradiol. Herr *et al.* (10) have shown that the Δ^7-estrogens are more active than those which are saturated in ring B. The results indicate that formation of 6-cyclo-ether analogues of Δ^7-estrogens results in a decrease of uterotrophic activity.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Mass spectra were obtained with an Hitachi-Perkin-Elmer RMU-6D spectrometer. The ^{1}H nmr spectra were recorded in $CDCl_3$ with a Varian T-60 instrument employing tetramethylsilane as internal standard. Line positions are reported in ppm from this standard. The ir spectra were recorded with a Perkin-Elmer 457 grating infrared spectrophotometer.

7-Methoxy-4-chloromethylcoumarin, 3a from 2

Concentrated H_2SO_4 (200 mL) in a two necked 1-L round bottom flask fitted with dropping funnel and thermometer was cooled below 10°C and a mixture of *m*-methoxyphenol (10 g, 81 mmol) and ethyl 4-chloroacetoacetate (13.15 g, 85 mmol) was slowly added to the stirred solution maintaining the temperature below 15°C. The mixture was then stirred at room temperature for 15 h and the reaction mixture poured into ice/water (800 mL) with vigorous stirring. The precipitated product was filtered off and washed with water to neutrality and then treated with aqueous 5% NaOH (80 mL) to remove phenolic impurities. The residue was washed with water (3 × 50 mL) affording white crystalline 7-methoxy-4-chloromethylcoumarin **3***a* (17.02 g, 94%). Recrystallization from ethanol gave analytically pure material mp 195°C. *Anal.* calcd. for $C_{11}H_9O_3Cl$: C 58.79, H 4.01; found: C 58.48, H 4.30. The mass spectrum *m/e* 226 (32, M + 2), 224 (100, M^+), 196 (43, M − CO), 189 (26, M − Cl), 161 (36). The ^{1}H nmr spectrum δ_{TMS} ($CDCl_3$): 3.90 (s, 3H, CH_3O), 4.63 (s, 2H, $ClCH_2$—), 6.40 (s, 1H, C(3)H), 6.80–7.67 (m, 3H, aromatic). The ir spectrum ν_{max} (KBr): 1725 (carbonyl), 1610 (aromatic), 1400, 1357, 1294, 1269, 1219, 1144, 1061, 1030, 1000, 880, 859, 831 cm^{-1}.

((7-Methoxy-2-oxo-2H-1-benzopyran-4-yl)methyl)triphenylphosphonium Bromide 3c

A mixture of 7-methoxy-4-bromomethylcoumarin (**4**) (0.25 g, 0.93 mmol) and triphenylphosphine (0.24 g, 0.95 mmol) was suspended in dry acetonitrile (15 mL). The mixture was stirred and refluxed under N_2 and the suspended mixture dissolved after 30 min. Refluxing was continued for 18 h, during which

time the white phosphonium salt precipitated. The mixture was cooled, filtered, and the salt **3***c* was washed several times with boiling benzene, then dried *in vacuo*, affording pure product (0.44 g, 90%) mp 272–274°C. The product was also obtained (79%) when benzene was used instead of acetonitrile as reaction solvent.

*((7-Methoxy-2-oxo-2*H*-1-benzopyran-4-yl)methyl)triphenylphosphonium Chloride* **3***b*

The phosphonium chloride salt **3***b* was prepared in 82% yield from chloromethylcoumarin **3***a* and excess triphenylphosphine in acetonitrile as previously described for the phosphonium bromide salt **3***c*. The salt, a white powder, was dried *in vacuo* and melted at 266–268°C.

7-Methoxy-4-vinylcoumarin **4** *from* **3***c*

(*a*) The triphenylphosphonium bromide **3***c* (0.61 g, 1.14 mmol) was suspended in 37% formaldehyde (2.2 mL). A solution of 15% Na_2CO_3 (1.5 mL) was added intermittently by a dropping funnel. Each subsequent addition was made after the orange-yellow color of the phosphorane formed had disappeared. When the addition of the base was complete, the mixture was stirred at room temperature for 2 h. The suspended white crystalline product containing triphenylphosphine oxide by-product was extracted three times with ether (100, 50, and 30 mL). The ethereal layer was dried (anhydrous Na_2SO_4) and evaporated. The white residue obtained was chromatographically purified on a short column of silica gel. Elution with ethyl acetate – cyclohexane (2:5) gave pure white crystalline vinylcoumarin **4** (0.20 g, 98%), mp 98°C. Attempts to recrystallize this compound in several solvents were unsuccessful.

Anal. calcd. for $C_{12}H_{10}O_3$: C 71.30, H 4.95; found: C 70.80, H 5.07. The mass spectrum *m/e*: 202 (100, M^+), 174 (78, $M - CO$), 159 (62, $M - CO - CH_3$). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 3.90 (s, 3H, CH_3O—), 5.63–6.12 (m, 2H, vinylic), 6.30 (s, 1H, C(3)H), 6.43–7.71 (complex m, 4H, aromatic and vinylic). The ir spectrum ν_{max} (KBr): 1720 (C=O), 1610, 1500, 1155, 861, 814 cm^{-1}.

(*b*) Vinylcoumarin **4** was synthesized as described above in 91% yield from phosphonium chloride salt **3***b* instead of phosphonium bromide salt **3***c*.

3-Methoxy-8,14-seco-6-oxaestra-1,3,5(10),8-tetraen-7,14,17-trione **5** *from* **4**

To a stirred solution of 18-crown-6 (80 mg) in acetonitrile (15 mL) was added KF (310 mg) and the mixture was dried by heating *in vacuo* at 135°C for 1.5 h. Vinylcoumarin **4** (1.73 g, 8.56 mmol) and 2-methylcyclopentane-1,3-dione (1.10 g, 9.81 mmol) were then added to the stirred mixture. The mixture was refluxed under N_2 and the suspended material dissolved. The mixture was refluxed overnight and the resulting white precipitate containing excess diketone reagent was removed by filtration while the reaction mixture was hot. The precipitate was washed with acetonitrile (2 × 10 mL). The filtrate and the washings were combined and acetonitrile was evaporated under reduced pressure. The residue was dissolved in chloroform (100 mL) and washed with 5% $NaHCO_3$ (2 × 20 mL) to remove excess cyclopentanedione. The organic layer was worked up in the usual manner. The pale orange residue was purified by chromatography on silica gel (100 g). Elution with ethyl acetate – cyclohexane (1:2) furnished the pale orange crystalline seco-steroid **5** (1.83 g, 68%). An analytical sample recrystallized from ethyl acetate had mp 128°C.

Anal. calcd. for $C_{18}H_{18}O_5$: C 68.80, H 5.73; found: C 68.14, H 5.66. The mass spectrum *m/e*: 314 (100, M^+), 277 (17), 203 (64, M – H – methylcyclopentanedione), 202 (67, M – methylcyclopentanedione), 190 (29), 174 (36). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.23 (s, 3H, CH_3—), 1.85–2.30 (m, 2H, C(12)H), 2.40–2.73 (m, 2H, C(13)H), 2.90 (s, 2H, C(15)H and C(16)H), 3.90 (s, 3H, CH_3O—), 6.07 (s, 1H, C(8)H), 6.79–7.98 (m, 2H, aromatic C(2)H and C(4)H), 7.53 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1718 (broad, lactone, ketone, C=O), 1612, 1429 cm^{-1}.

*14*β*-3-Methoxy-6-oxaestra-1,3,5(10),8,15-pentaen-7,17-dione* **6** *from* **5**

The secosteroid **5** (2.24 g, 7.13 mmol) was suspended in dry benzene (20 mL) and *p*-toluenesulfonic acid monohydrate (430 mg) was added to the mixture. The mixture was stirred and refluxed under N_2 for 15 h. Water was removed azeotropically employing a Dean–Stark trap filled with Linde molecular sieves, type 5A. The resulting reddish brown mixture was cooled and diluted with benzene (20 mL). The mixture was then washed with 5% $NaHCO_3$ (2 × 20 mL) to remove *p*-toluenesulfonic acid. The organic layer after drying (anhydrous Na_2SO_4) and evaporation gave a reddish brown residue which was chromatographed on a silica gel (100 g) column and elution with ethyl acetate – cyclohexane (2:5) afforded **6** (1.69 g, 80%), mp 143–145°C (recrystallized from ethyl acetate). An analytical sample was homogeneous on tlc and proved to be sensitive to light and moist air resulting in a bright purple color.

Anal. calcd. for $C_{18}H_{16}O_4$: C 72.97, H 5.40; found: C 72.61, H 5.40. The mass spectrum *m/e*: 296 (100, M^+), 281 (13, $M - CH_3$), 269 (12), 268 (76, M – CO), 253 (21). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 12.7 (s, 3H, CH_3—), 1.40–3.33 (complex m, 6H), 3.90 (s, 3H, CH_3O—) 6.20 (q, 1H, J = 5 Hz, J = 2 Hz, C(15)H), 6.90 (m, 2H, aromatic C(2)H and C(4)H), 7.48 (d, J = 8 Hz, 1H, aromatic C(1)H), 7.80 (q, 1H, J = 5 Hz, J = 3 Hz, C(16)H). The ir spectrum ν_{max} (KBr): 1730 (shoulder, ketone C=O), 1710 (broad, lactone C=O), 1615, 1520, 1460 cm^{-1}.

3-Methoxy-6-oxaestra-1,3,5(10),8,14-pentaen-7-oxo-17-ethylene acetal **7***b* *from* **6**

To a solution of tetracyclic pentaene **6** (1 g, 3.38 mmol) in benzene (50 mL) was added ethylene glycol (3 mL) and *p*-toluenesulfonic acid (30 mg). The solution was refluxed (while water was removed azeotropically) for 4 h and then cooled to room temperature. The solution was diluted with benzene (50 mL) and the organic layer was evaporated to give the ketal **7***b* in 96% yield, homogeneous on tlc. An analytical sample was recrystallized from ethyl acetate (mp 168°C).

Anal. calcd. for $C_{20}H_{20}O_5$: C 70.59, H 5.88; found: C 70.70, H 5.92. The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.06 (s, 3H, CH_3—), 1.50–3.26 (complex m, 6H), 3.86 (s, 3H, CH_3O—), 4.00 (s, 4H, —OCH_2CH_2O—), 6.92 (m, 1H, C(15)H), 6.84 (m, 2H, aromatic C(2)H and C(4)H), 7.43 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1725 (lactone C=O), 1620, 1600 (aromatic), 1300, 1160, 1030, 885, 850, 810 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 221 (22 422), 250 (13 918), 350 (25 773).

3-Methoxy-6-oxaestra-1,3,5(10),8,14-pentaen-7,17-dione **7**a

A solution of the tetracyclic ketal **7***b* (1 g, 2.94 mmol) in acetone (30 mL) was treated with a catalytic amount of *p*-toluenesulfonic acid monohydrate. The solution was stirred overnight at room temperature. Most of the product precipitated out of the solution and this fraction was filtered out and washed with 5% $NaHCO_3$ and water to give a pure product **7***a*. The filtrate was concentrated and diluted with benzene (50 mL). The organic layer was washed with 5% $NaHCO_3$ (20 mL) and water. The dried organic layer was evaporated to give a crude residue which was purified on silica gel column and eluted with *n*-hexane – ethyl acetate (1:1). The two fractions were combined to give a total yield of the pentaendione **7***a* (0.835 g, 96%). An analytical sample was recrystallized in acetone – petroleum ether (2:1) to give light orange crystals (mp 212°C dec.).

The mass spectrum *m/e*: 296 (65, M^+), 269 (19, $M^+ - CH_2{=}CH$), 268 (100, $M^+ - CO$), 267 (12), 253 (26), 240 (13), 239 (13). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.17 (s, 3H, CH_3—), 1.44–3.33 (complex m, 6H), 3.90 (s, 3H, CH_3O—), 6.90 (multiplet, 2H, aromatic C(2)H and C(4)H), 7.03 (t, J = 2 Hz, 1H, C(15)H), 7.60 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1746 (ketone C=O), 1710 (α,β-unsaturated lactone C=O), 1625, 1610, 1595 (aromatic), 1460, 1450, 1400, 1290, 1260, 1210, 1170, 1140, 1030, 830, 820 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 216 (18 179), 247 (8 848), 350 (18 179).

3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7,17-dione **8**a *from* **7**a

A suspension of 10% palladium on charcoal (50 mg) in sulfur-free benzene (10 mL) was degassed and saturated with H_2. To this catalyst mixture was added a purplish solution of the tetracyclic pentaen **7***a* (100 mg, 0.34 mmol) in benzene (15 mL). The mixture was vigorously stirred and hydrogenation was stopped after about 7 mL of H_2 (required to saturate one double bond) was absorbed. The catalyst was filtered and the clear solution evaporated to dryness to give pure tetraen dione **8***a* (0.094 g, 93%). An analytical sample was recrystallized from benzene to afford white crystals, mp 223–225°C.

Anal. calcd. for $C_{18}H_{18}O_4$: C 72.48, H 6.04; found: C 72.70, H 6.09. The mass spectrum *m/e*: 299 (15, M + 1), 298 (100, M^+), 270 (19, $M^+ - CO$), 255 (50), 243 (39), 242 (55), 241 (44), 229 (28), 227 (20). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 0.90 (s, 3H, CH_3O—), 6.90 (m, 2H, aromatic C(2)H and C(4)H), 7.50 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1735 (ketone C=O), 1720 (lactone C=O), 1620, 1610 (aromatic), 1510, 1450, 1395, 1295, 1275, 1260, 1230, 1215, 1185 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 225 (11 569), 328 (14 204).

3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7-oxo-17-ethylene Acetal **8**b *from* **8**a

The tetracyclic ketone **8***a* was ketalized as described in the procedure for compound **7***b* to give the ketal **8***b* in 88% yield. Analytical sample was recrystallized in acetone to give white crystals, mp 184°C. The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 0.87 (s, 3H, CH_3—), 1.50–3.23 (complex m, 9H), 3.87 (s, 3H, CH_3O—), 3.95 (s, 4H, —OCH_2CH_2O—), 6.42 (m, 2H, aromatic C(2)H and C(4)H), 7.47 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1710 (broad lactone C=O), 1610, 1385, 1320, 1300, 1285, 1200, 1160 (broad), 1070 (broad), 970, 855, 810, 790, 780 cm^{-1}. The mass spectrum *m/e*: 342 (17, M^+), 298 (98, $M^+ - CH_2CH_2O$—), 283 (18, $M^+ - CH_2CH_2O + CH_3$), 270 (21, $M^+ - CH_2CH_2O - CO$), 256 (42), 255 (20), 243 (88), 242 (100), 241 (93), 227 (47), 226 (25).

8α-3-Methoxy-6-oxaestra-1,3,5(10)-trien-7-oxo-17-ethylene Acetal **9**a *from* **8**b

Into dry liquid ammonia (300 mL) was added lithium (45 mg), cut into small pieces. The deep blue solution thus formed was stirred vigorously with a magnetic stirrer for 10 min and a suspension of ketalized tetraen **8***b* (1 g, 2.92 mmol) in anhydrous ether (75 mL) was quickly added. The mixture was vigorously stirred for an additional 30 min and quenched with dry NH_4Cl (500 mg) carefully. The ammonia condenser was removed and ammonia allowed to evaporate in a stream of nitrogen. The residual ammonia and ether were evaporated under reduced pressure. The white residue was treated with 5% NaOH solution (25 mL) to remove over-reduced phenolic material. The mixture was stirred, filtered, and washed with water several times and dried. The white crystalline triene **9***a* (0.94 g, 93%) was recrystallized from benzene to give white needles, mp 164°C.

Anal. calcd. for $C_{20}H_{24}O_5$: C 69.76, H 6.97; found: C 69.36, H 6.82. The mass spectrum *m/e*: 344 (88, M^+), 259 (18), 258 (100), 256 (21), 190 (18), 177 (27), 139 (54). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.00 (s, 3H, CH_3—), 1.33–3.00 (complex m, 11H), 3.80 (s, 3H, CH_3O—), 3.90 (s, 4H, OCH_2CH_2O), 6.63 (m, 2H, aromatic C(2)H and C(4)H), 7.70 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1770 (lactone C=O), 1630, 1600 (aromatic), 1515, 1460, 1285, 1240, 1170, 1150 (broad), 1040, 985, 850 cm^{-1}.

8α-3-Methoxy-6-oxaestra-1,3,5(10)-trien-7,17-dione **9**c

The tetracyclic ketal **9***a* was deketalized by stirring in acetone with a catalytic amount of *p*-toluenesulfonic acid monohydrate overnight to give a quantitative yield of the tetracyclic dione **9***c*. An analytical sample was recrystallized from benzene to give white crystals, mp 171°C.

The mass spectrum *m/e*: 301 (20, M + 1), 300 (100, M^+), 229 (18), 216 (14), 215 (12), 177 (27), 176 (20), 163 (24), 150 (38), 148 (20), 137 (31), 124 (20). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.00 (s, 3H, CH_3—), 1.33–3.23 (complex m, 11H), 3.80 (s, 3H, CH_3O—), 6.60–6.80 (m, 2H, aromatic C(2)H and C(4)H), 7.10 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1770 (lactone C=O), 1730 (ketone C=O), 1620, 1590 (aromatic), 1510 (broad), 1450, 1430, 1360, 1330, 1278, 1240, 1201, 1170, 1130 (broad), 1055, 1035, 975, 876, 835 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 220 (11 491), 280 (2 771), 285 (2 608).

8α-3-Methoxy-7-hydroxy-6-oxaestra-1,3,5(10)-trien-17-one **9**b *from* **9**a

Into an oven dried pear-shaped flask was added the ethylene ketal lactone **9***a* (0.1 g, 0.29 mmol) and dry toluene (5 mL). The solution was cooled to −70°C and a 1 *M* diisobutylaluminium hydride solution (0.3 mL) was added from a syringe through a septum. The reaction mixture was stirred for 20 min at −70°C and then quenched with methanol (0.5 mL). The mixture was allowed to warm to 0°C and cold 5% HCl (20 mL) was added. The product was extracted twice with chloroform (30 ml, 25 ml) and the organic layer was washed with water twice and dried with $MgSO_4$. Evaporation of the solvent left white crystals which were subsequently deketalized as before affording pure white tetracyclic hemiacetal **9***b* in 85% yield. Recrystallization in ethyl acetate – *n*-hexane (2:1) afforded white needles melting at 175°C.

Anal. calcd. for $C_{18}H_{22}O_4$: C 71.52, H 7.28; found: C 71.56, H 7.30. The mass spectrum *m/e*: 302 (45, M^+), 164 (15), 163 (93), 161 (19), 150 (100), 137 (33). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.07 (s, 3H, CH_3—), 1.40–3.00 (complex m, 11H), 3.87 (s, 3H, CH_3O—), 5.60 (t, J = 6 Hz, 1H, C(7)H; D_2O added, d, J = 9 Hz), 6.43 (m, 2H, aromatic C(2)H and C(4)H), 6.60 (d, J = 7 Hz, 1H, C(7)OH), 7.00 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 3420 (OH), 1730 (ketone C=O), 1620, 1590, 1510, 1460, 1450, 1340, 1275, 1200, 1180, 1160, 1124, 1040, 1000, 935, 830 cm^{-1}.

3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17-one **10**a *from* **9**b

To a solution of the tetracyclic hemiacetal **9***b* (0.1 g, 0.33 mmol) in benzene (15 mL) was added *p*-toluenesulfonic acid monohydride (30 mg). The mixture was refluxed azeotropically under nitrogen for 1 h. The mixture was cooled to room temperature and diluted with benzene (30 mL). It was washed with 5% $NaHCO_3$ (20 mL), with water, and then dried. Evaporation of the solvent gave a pure white crystalline tetracyclic vinyl ether **10***a* in quantitative yield. A sample was recrystallized from ethyl acetate – *n*-hexane (1:1) giving white crystals, mp 175°C.

Anal. calcd. for $C_{18}H_{20}O_3$: C 76.05, H 7.04; found: C 75.93, H 7.14. The mass spectrum *m/e*: 284 (100, M^+), 269 (9, $M^+ - CH_3$), 256 (35, $M^+ - CO$), 255 (39), 241 (67), 228 (34), 227 (26), 213 (22), 188 (23), 187 (40), 160 (27). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

0.87 (s, 3H, CH_3—), 1.23–2.70 (complex m, 9H), 3.23 (broad m, 1H, benzylic), 3.80 (s, 3H, CH_3O—), 6.23 (t, J = 2 Hz, 1H, C(7)H), 6.60 (m, 2H, aromatic C(2)H and C(4)H), 7.05 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1730 (ketone C=O), 1685 (medium, vinyl ether O—CH=C), 1615, 1575, 1500, 1440, 1250, 1240, 1210, 1205, 1175, 1150, 1125, 1040, 935, 860, 830 cm^{-1}. The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 225 (11 410), 250 (5 167), 290 (4 629).

3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17β-ol ***10b*** *from* ***10a***

To a solution of the tetracyclic ketone **10*a*** (0.412 g, 1.45 mmol) in benzene (15 mL) was added methanol (15 mL). The solution was cooled in an ice-water bath and sodium borohydride (100 mg) was added at once. The mixture was stirred for 5 min and gradually allowed to warm to room temperature. After 45 min the mixture was poured into ice-cold 5% HCl solution (20 mL) and the product was extracted with benzene and the organic layer washed twice with water and dried with $MgSO_4$. Evaporation of the solvent left a white crystalline alcohol **10*b*** (96% yield), pure by ^1H nmr spectrum. A sample was recrystallized from ethyl acetate – *n*-hexane (2:1) to give white crystals melting at 124°C.

Anal. calcd. for $C_{18}H_{22}O_3$: C 75.52, H 7.69; found: C 75.96, H 7.56. The mass spectrum *m/e*: 286 (100, M^+), 257 (50), 241 (49), 187 (82), 161 (48), 137 (25). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 0.73 (s, 3H, CH_3—), 1.20–2.50 (complex m, 10H), 3.17 (broad m, 1H, benzylic), 3.80 (s, 3H, CH_3O—), 3.80 (t, 1H, C(17)H), 6.10 (t, J = 2 Hz, 1H, C(7)H), 6.33–6.60 (m, 2H, aromatic C(2)H and C(4)H), 7.00 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 3420 (broad, OH), 1700 (weak, vinyl ether O—CH=C), 1620, 1585 (aromatic), 1510, 1450, 1210, 1200, 1180, 1135, 1040, 940, 865, 840 cm^{-1}.

3-8Hydroxy-6-oxaestra-1,3,5(10),7-tetraen-17β-ol ***10c*** *from* ***10b***

To methylmagnesium iodide (1.59 mmol) in anhydrous ether (20 mL) was added methyl ether **10*b*** (0.228 g, 0.80 mmol) under nitrogen. The mixture was stirred and ether was removed with a stream of nitrogen. The solid mixture was heated at 180–190°C for 3 h. The mixture was cooled to room temperature and hydrolysed with ice-cold 5% HCl (25 mL). The product was extracted with chloroform (20 mL × 4) and the organic layer was washed several times and dried with $MgSO_4$. Evaporation of the solvent left a crude brown residue which was purified by silica gel preparative tlc (using ethyl acetate – *n*-hexane (1:1)) to give yellowish crystals of the diol **10*c*** (0.148 g, 68%). An analytical sample was recrystallized from 95% ethanol to give white needles, mp 196–201°C (dec.).

The mass spectrum *m/e*: 272 (95, M^+), 243 (48, M^+ – CHO), 227 (35), 173 (100), 147 (52), 123 (24). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$–DMSO-d_6, two drops): 0.73 (s, 3H, CH_3—), 1.00–3.33 (complex m, 9H), 3.33 (broad m, 1H, benzylic C(9)H), 3.80 (broad m, 1H, C(17)OH), 6.10 (broad s, 1H, C(7)H), 6.33–6.60 (m, 2H, aromatic C(2)H and C(4)H), 7.00 (d, J = 8 Hz, 1H, aromatic C(1)H), 8.70 (s, 1H, phenolic OH). The ir spectrum ν_{max} (KBr): 3410 (OH), 3240 (broad, phenolic OH), 1700 (weak, vinyl ether O—CH=C), 1620 (aromatic), 1510, 1460, 1350, 1260, 1180 (sharp), 1135, 1050 cm^{-1}.

14β-3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7,17-dione ***11a*** *from* ***6***

Into a 100 mL round-bottomed flask was added 10% Pd/C (100 mg) and dry benzene (15 mL). The mixture was degassed by pumping at reduced pressure and prehydrogenated. A solution of the tetracyclic pentaene **6** (200 mg, 0.68 mmol) in dry benzene (915 mL) was added at once to the catalyst–benzene mixture in a hydrogen atmosphere. The mixture was stirred until one equivalent of hydrogen was absorbed (~15 min). The catalyst was filtered and removal of benzene under reduced pressure gave white crystalline tetracyclic tetraen **11*a*** (200 mg, 98%). An analytical sample, crystallized from benzene–cyclohexane (1:1), had mp 156–159°C.

Anal. calcd. for $C_{18}H_{18}O_4$: C 72.48, H 6.04; found: C 72.11, H 6.06. The mass spectrum *m/e*: 298 (100, M^+), 283 (15, M – CH_3), 270 (16, M – CO), 255 (17), 244 (50), 243 (50), 242 (38), 227 (38). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.10 (s, 3H, CH_3—), 1.39–3.32 (complex m, 9H), 3.90 (s, 3H, CH_3O—), 6.83–7.00 (m, 2H, aromatic C(2)H and C(4)H), 7.50 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1730 (shoulder ketone C=O), 1701 (lactone C=O) cm^{-1}.

14β-3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7,17-dione ***11a***

The chromic acid solution (prepared by dissolving CrO_3 (5.298 g) in 10 mL water and then adding H_2SO_4 (5 mL)) was added to a cooled (20°C) solution of the tetracyclic alcohol **11*c*** (0.5 g, 1.67 mmol) in acetone (15 mL). The oxidizing solution (1 mL) was added dropwise, so that the temperature of the reaction mixture did not exceed 35°C. The addition was stopped when the orange color of the oxidizing solution persisted. The mixture was stirred for 30 min and excess oxidant was destroyed with isopropyl alcohol (1/2 mL). The liquid was decanted and the green salts washed with acetone (30 mL) twice. To the combined washings was added $NaHCO_3$ until the solution was neutral. The mixture was filtered and the filtrate evaporated under reduced pressure. The residue was dissolved in $CHCl_3$ (50 mL) and washed with water, saturated sodium chloride solution, and dried with $MgSO_4$. Evaporation of the solution left a residue which was recrystallized to give white crystals of the ketone **11*a*** (0.408 g) in 82% yield, identical with material obtained by catalytic reduction of **6**.

The uv spectrum (95% EtOH) λ_{max} nm (ε_{max}): 222 (11 455), 323 (20 124).

14β-3-Methoxy-16-bromo-6-oxaestra-1,3,5(10),8-tetraen-7,17-dione ***11b***

A solution of the tetracyclic ketone **11*a*** (0.469 g, 1.57 mmol) in dry THF (15 mL) cooled in an ice-water bath was stirred and bromine (0.25 g) in methylene chloride (5 mL) was added dropwise, keeping the temperature of the reaction mixture below 10°C. The yellow mixture was then stirred for 1 h and the reaction was found to be complete on tlc. The mixture was treated with 10 mL of 5% $NaHCO_3$ and then cold water (50 mL) was added. The product was extracted twice with methylene chloride (100 mL, 50 mL). The combined organic layer was washed once with water and dried. Evaporation of the solvent left yellowish crystals which after column purification gave the bromide **11*b*** (0.49 g, 79%). A sample was recrystallized from benzene to give light yellow crystals melting at 222°C.

Anal. calcd. for $C_{18}H_{17}O_4Br$: C 57.29, H 4.51; found: C 57.15, H 4.56. The ^1H nmr spectrum δ_{TMS} (DMSO-d_6): 1.23 (s, 3H, CH_3—), 1.50–3.30 (complex m, 8H), 3.90 (s, 3H, CH_3O—), 4.73 (m, 1H, C(16)H), 7.00 (m, 2H, aromatic C(2)H and C(4)H), 7.73 (d, J = 10 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1750 (ketone C=O), 1710 (α,β-unsaturated lactone C=O), 1610 (aromatic), 1405, 1280, 1212, 1165, 1100, 1045, 838 cm^{-1}. The mass spectrum *m/e*: 378 (83, M + 2), 376 (83, M^+), 298 (49, M + 2 – HBr), 297 (49, M^+ – Br), 244 (56), 243 (100), 242 (65), 241 (35), 227 (39).

14β-3-Methoxy-6-oxaestra-1,3,5(10),8,15-pentaen-7,17-dione ***6*** *from* ***11b***

A solution of the tetracyclic bromoketone **11*b*** (0.147 g, 0.39 mmol) in dimethylformamide (5 mL) was added to a stirred hot (150°C) suspension of magnesium oxide (0.05 g) in dimethylformamide (20 mL). The mixture was stirred at 150°C for 30 min under nitrogen atmosphere. The red solution was cooled to room temperature and ice-cold 5% HCl (20 mL) was added

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

and the product extracted with benzene (25 mL) three times. The combined organic layer was washed with 5% $NaHCO_3$ and finally with water and dried. The red solution was decolorized by adding a pinch of activated carbon. Evaporation of the solvent left a purplish residue which after purification on preparative tlc gave the tetracyclic pentaen **6** (0.87 g, 76%) identical with material prepared directly from **5** as previously described.

14β-3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7-oxo-17-ol **11***c*

To the solution of the tetracyclic ketone **6** (4.91 g, 16.6 mmol) in benzene (55 mL) was added methanol (55 mL). The solution was cooled in an ice-water bath and sodium borohydride (2.23 g, 55.60 mmol) was added at once. The mixture was stirred for 5 min and the ice-water bath was replaced by a water bath and allowed to warm to room temperature. The yellow mixture was stirred for 2 h and neutralized with ice-cold 5% HCl. The solvent was evaporated under reduced pressure to 1/3 of the original volume. The residue was diluted with ether (150 mL) and washed with water twice. The ethereal layer was dried (anhydrous $MgSO_4$). Evaporation of the solvent gave a quantitative yield of yellow crystalline product **11***c*. Recrystallization in benzene–cyclohexane (1 : 1) gave white crystals, mp 99–101°C.

Anal. calcd. for $C_{18}H_{20}O_4$: C 72.60, H 6.67; found: C 72.90, H 6.64. The mass spectrum *m/e*: 300 (100, M^+), 282 (27, $M^+ - H_2O$), 267 (52, $M^+ - (CH_3$ and $H_2O)$), 243 (72), 241 (40), 240 (21), 227 (19). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.07 (s, 3H, CH_3—), 1.83 (s, 1H, —OH), 1.40–3.00 (complex m, 9H), 3.90 (s, 3H, CH_3O—), 4.10 (t, J = 8 Hz, 1H, 17αH), 6.82–7.00 (m, 2H, aromatic C(2)H and C(4)H), 7.53 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 3320 (broad OH), 1710 (lactone C=O), 1615 (aromatic), 1520, 1285, 1170, 840, 685 cm^{-1}.

14β-3-Methoxy-6-oxaestra-1,3,5(10),8-tetraen-7-oxo-17-ethylene Acetal **11***d*

To a solution of the tetraen dione **11***a* (200 mg, 0.67 mmol) in dry benzene (20 mL) was added ethylene glycol (2 mL), and a catalytic amount of *p*-toluenesulfonic acid monohydrate. The mixture was refluxed for 2.5 h and water was removed with aid of a Dean–Stark trap. The mixture was then washed with 5% $NaHCO_3$ (2 × 15 mL) and worked up in the usual manner. The residue was concentrated in benzene (5 mL) and filtered without suction through silica gel (10 g). The adsorbent was washed with ethyl acetate (50 mL) and the combined washings were evaporated under reduced pressure to give a white crystalline ketal **11***d* (210 mg, 95%), homogeneous on tlc.

The ^1H nmr spectrum δ_{TMS}: 0.97 (s, 3H, CH_3—), 1.59–3.18 (complex m, 9H), 3.93 (s, 3H, CH_3O—), 3.98 (s, 4H, OCH_2CH_2O), 6.78–7.56 (m, 3H, aromatic). The ir spectrum ν_{max} (KBr): 1710 (C=O), 1610, 1281, 1199 cm^{-1}.

14β-3-Methoxy-5,7-dihydroxy-5,6-seco-6-oxaestra-1,3,5(10)-trien-17-one **12** *from* **11***d*

Into a two-necked 1 litre round-bottomed flask ammonia (600 mL) was condensed using a Dewar condenser. Excess lithium (619 mg, 88.42 mmol), cut into small pieces, was added against a countercurrent of N_2. The resulting deep blue solution was stirred vigorously for 15 min. Tetracyclic tetraen **11***d* (7.56 g, 22.11 mmol) was added at once from a dropping funnel under N_2 atmosphere. The blue mixture was stirred for another 30 min and then quenched with excess ammonium chloride (5 g). Ammonia was allowed to evaporate in a stream of N_2 and a white residue was obtained. Residual ammonia was removed under reduced pressure. The residue was treated with 5% NaOH (180 mL) and stirred to dissolve the phenolic product. The undissolved material was filtered and washed with water until the washings were not basic, affording the ethylene ketal of **13***b* (1.39 g, 17%), *vide infra*. The basic layer was washed with ether (2 × 30 mL) and after acidification, the product was extracted with ether (3 × 30 mL). After the usual work up, the residue was deketalized to afford a less soluble tricyclic ketone **12** (5.29 g, 79%). An analytical sample recrystallized in acetone melted at 226–228°C.

Anal. calcd. for $C_{18}H_{24}O_4$: C 71.05, H 7.89; found: C 70.93, H 7.64. The mass spectrum *m/e*: 304 (100, M^+), 286 (7, $M - H_2O$), 164 (26), 163 (61), 150 (64), 137 (25). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$ + DMSO-d_6): 1.20 (s, 3H, CH_3—), 1.33–3.58 (complex m, 14H), 3.73 (s, 3H, CH_3O—), 6.21–7.00 (m, 3H, aromatic), 8.90 (s, 1H, phenolic —OH). The ir spectrum ν_{max} (KBr): 3420–3100 (broad —OH), 1720 (C=O), 1614, 1520 cm^{-1}.

8α,14β-3-Methoxy-6-oxaestra-1,3,5(10)-trien-7,17-dione **13**b

The ketal of **13***b*, the minor product of Na/NH_3 reduction of **11***d*, was deketalized by dissolving it in acetone (20 mL) and adding a catalytic amount of *p*-toluenesulfonic acid. The solution was stirred at room temperature overnight. Acetone was evaporated and the pinkish residue, in a minimum amount of benzene, was filtered without suction and washed with ethyl acetate to afford white crystalline tetracyclic ketone **13***b* in 90% yield. An analytical sample recrystallized from benzene melted at 204°C.

Anal. calcd. for $C_{18}H_{20}O_4$: C 72.00, H 6.66; found: C 72.05, H 6.65. The mass spectrum *m/e*: 300 (100, M^+), 204 (43), 203 (97), 202 (84), 174 (52). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 1.19 (s, 3H, CH_3—), 1.33–3.21 (complex m, 11H), 3.80 (s, 3H, CH_3O—), 6.60–6.76 (m, 2H, aromatic C(2)H and C(4)H), 7.10 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 1771 (lactone C=O), 1732 (ketone C=O), 1630, 1596 cm^{-1}.

8α,14β-3-Methoxy-7-hydroxy-6-oxaestra-1,3,5(10)-trien-17-one **13**a *from* **12**

To a stirred solution of $Na_2Cr_2O_7 \cdot 2H_2O$ (2.60 g, 8.82 mmol) in dimethylsulfoxide (25 mL) was added the tricyclic dihydroxytriene **12** (4.10 g, 13.5 mmol) in dimethylsulfoxide (2 mL). Concentrated H_2SO_4 (5 mL) was added slowly keeping the temperature below 70°C. The mixture was cooled, poured into crushed ice-water mixture, and extracted with chloroform (2 × 50 mL). The organic layer was washed with 5% NaOH (2 × 20 mL) and water (3 × 30 mL). The usual work up afforded a brown residue which was purified via a column of silica gel (125 g). Elution with ethyl acetate – cyclohexane (2:5) gave pure white crystalline hemiacetal **13***a* (3.50 g, 86%), mp 192°C (recrystallized from ethyl acetate).

Anal. calcd. for $C_{18}H_{22}O_4$: C 71.52, H 7.28; found: C 71.69, H 7.29. The mass spectrum *m/e*: 302 (64, M^+), 163 (100), 150 (77), 137 (30), 124 (91). The ^1H nmr spectrum δ_{TMS} ($CDCl_3$): 0.97 (s, 3H, CH_3—), 1.32–3.33 (complex m, 11H), 3.59 (d, J = 4.4 Hz, 1H, —OH), 3.80 (s, 3H, CH_3O—), 5.53 (t, J = 4 Hz, 1H, —OCHO—), 6.40–6.63 (m, 2H, aromatic C(2)H and C(4)H), 7.10 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 3370 (OH), 1715 (C=O), 1612, 1575, 1504 cm^{-1}.

14β-3-Methoxy-6-oxaestra-1,3,5(10),7-tetraen-17-one **14**a *from* **13**b

A solution of the tetracyclic hemiacetal **13***b* (120 mg, 3.97 mmol) in dry benzene (10 mL) was treated with a catalytic amount of *p*-toluenesulfonic acid monohydrate (50 mg). The solution was refluxed for 1 h and water was removed azeotropically with a Dean–Stark trap. The mixture was cooled and diluted with benzene (20 mL), washed with 5% $NaHCO_3$ (30 mL) and water (2 × 20 mL). The usual work up afforded a pure oily vinyl ether **14***a* in quantitative yield. An analytical sample was crystallized from cyclohexane to give white crystals, mp 76–85°C.

Anal. calcd. for $C_{18}H_{20}O_3$: C 76.06, H 7.04; found: C 76.10, H 6.98. The mass spectrum *m/e*: 284 (62, M^+), 269 (22, $M - CH_3$),

188 (55), 187 (90), 86 (23), 85 (67), 84 (38), 83 (100). The ^{1}H nmr spectrum δ_{TMS} ($CDCl_3$): 1.10 (s, 3H, CH_3—), 1.32–3.50 (complex m, 10H), 3.77 (s, 3H, CH_3O—), 6.40–6.72 (m, 3H, aromatic and vinylic), 7.07 (d, J = 8 Hz, aromatic at C(1)H). The ir spectrum ν_{max} (KBr): 1735 (C=O), 1680 (C=C—O), 1620, 1580 cm^{-1}.

3-Hydroxy-6-oxaestra-1,3,5(10),7-tetraen-17-one ***14****b from* ***14****a and from* ***13***

(*a*) To an ice-water cooled solution of boron tribromide (0.72 mL, 7.47 mmol) in dry dichloromethane under N_2 (3 mL) was added slowly a solution of methyl ether **14***a* (753 mg, 2.49 mmol) in dry dichloromethane (6 mL) via a syringe. The mixture was stirred at 0°C for an hour and a yellow precipitate was observed to form. The yellow mixture was further stirred at room temperature for another hour and then quenched with ether (10 mL) and water (5 mL). The mixture was extracted with ether and the ether layer was washed with 5% sodium hydroxide solution to extract the phenolic product. After acidification of the basic aqueous layer and extraction with ether, the dried organic layer on evaporation gave a crude product. Crystallization from ethyl acetate afforded the product **14***b* (412 mg), plus mother liquors which upon chromatography on silica gave additional 103 mg of product. The total yield was 615 mg (92%), mp 160–164°C.

(*b*) In one step the hemiacetal **13***a* (502 mg, 1.66 mmol) was demethylated and dehydrated as described above (*a*) to afford **14***b* (369 mg, 85%).

Anal. calcd. for $C_{17}H_{18}O_3$: C 75.56, H 6.67; found: C 75.52, H 6.69. The mass spectrum *m/e*: 270 (68, M^+), 255 (28, $M-15$), 213 (10), 174 (72), 173 (100). The ^{1}H nmr spectrum δ_{TMS} ($CDCl_3$): 1.10 (s, 3H, CH_3—), 1.32–3.50 (complex m, 10H), 3.5 (complex m, 1H, benzylic), 6.38–6.70 (m, 4H, aromatic C(2)H and C(4)H, vinylic C(7)H and phenolic), 7.00 (d, J = 8 Hz, 1H, aromatic C(1)H). The ir spectrum ν_{max} (KBr): 3380 (broad, OH), 1720 (C=O), 1680 (O—C=C), 1620 and 1595 cm^{-1} (aromatic).

Determination of Uterotrophic Activity of ***9****b,* ***9****c,* ***10****a,* ***10****b,* ***10****c, and* ***14****a*

Immature 21-day old Sprague–Dawley rats weighing 30–40 g were obtained from Canadian Breeding Laboratories, St. Constant, Quebec. The animals were housed in an air-conditioned room 24 to 25°C, 45 to 50% humidity, and given Purina Chow and water *ad libitum*. Test substances (0.01–10 μg per rat) were administered subcutaneously in 0.2 mL sesame oil. Control animals received vehicle only. The work was divided into four experiments, each with control group and three groups receiving fixed amounts of 17β-estradiol (0.02, 0.1, 0.5 μg per rat) as standard.

The rats (10 per group) received three daily injections, and were sacrificed by cervical dislocation 24 h after the last injection. The uteri were excised free of fat and mesentery blotted and weighed to the nearest milligram on a torsion balance.

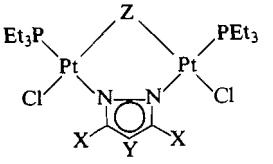
Azole derivatives of metals. VI. Binuclear platinum(II) derivatives having both μ-pyrazolato-*N*,*N*′ and methoxy or chloride as bridging groups

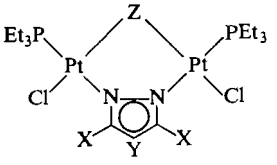


FLAVIO BONATI, HOWARD C. CLARK, and CHUN S. WONG

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, University of Guelph, Guelph, Ont., Canada N1G2W1

Received August 22, 1979[1]

FLAVIO BONATI, HOWARD C. CLARK, and CHUN S. WONG. Can. J. Chem. **58**, 1435 (1980).



Binuclear platinum(II) complexes of the type

where X = H, CH_3, Y = H, Br, Z = Cl, OCH_3, are synthesized by the reaction of $Pt_2Cl_4(PEt_3)_2$ with the pyrazole and sodium hydroxide in methanol. The nature of the product depends on the amount of sodium hydroxide used.

FLAVIO BONATI, HOWARD C. CLARK et CHUN S. WONG. Can. J. Chem. **58**, 1435 (1980).

En faisant réagir du $Pt_2Cl_4(PEt_3)_2$ avec le pyrazole et l'hydroxyde de sodium dans le méthanol, on a synthétisé des complexes binucléaires du platine(II) du type

où X = H, CH_3, Y = H, Br, Z = Cl, OCH_3. La nature du produit dépend de la quantité d'hydroxyde de sodium utilisée.

[Traduit par le journal]

Introduction

While a pyrazole (*P*zH) is only a monodentate ligand, a pyrazolate anion (Pz^-) can be either monodentate or exobidentate (1, 2).[2] In the last case, two (or more) coordination centers are generally bridged by μ-pyrazolato-*N*,*N*′ groups: e.g. one, or two, or three such groups in the cases of $[Au(pz)]_3$ (3) and $[h^5\text{-}C_5H_5Ni(pz)]_2$ (4), or $[R_2Ga(pz)]_2$ (5) and metal(II) bispyrazolylborates (1), or octahedral metal(II) trispyrazolylborates (1) and $[EtB(\mu\text{-pz-}N,N')_3BEt]BF_4$ (6), respectively.

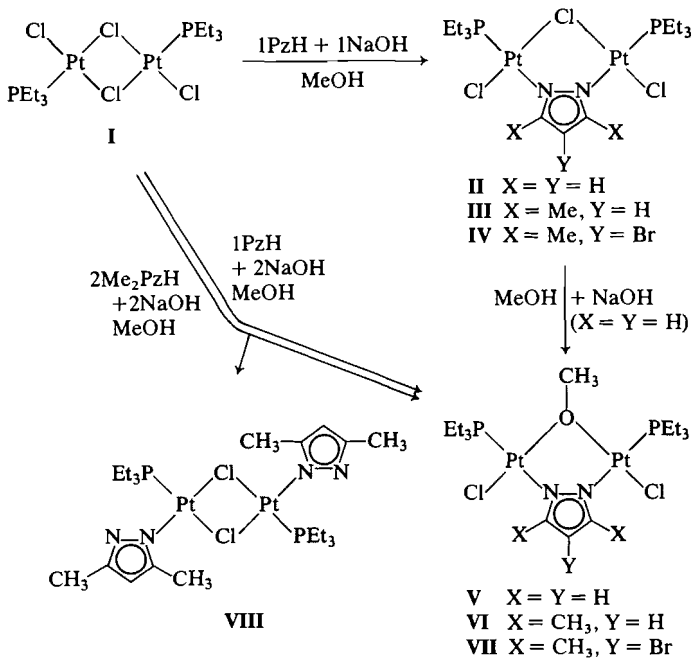
In pursuing our interest in pyrazolato-bridged compounds (7) and in platinum chemistry (8), we now show that two coordination centers (here Pt(II)) can be simultaneously bridged by a pyrazolato-*N*,*N*′ together with a chloride- or methoxy-groups and that the resulting, asymmetric, five-membered ring Pt-N-N-Pt-Z (Z = Cl or O) is stable.

Results and Discussion

The reaction between bis(triethylphosphine)-dichloro(μ-dichloro) diplatinum, **I**, and one mole of pyrazole in methanol gives different products according to the quantity of alkali present. If only one mole of sodium hydroxide is employed, a binuclear complex, **II**, in which chloride and exobidentate pyrazolato-*N*,*N*′ ligands bridge the two platinum atoms, is obtained (Scheme 1).

Upon treatment of **II** with a second mole of sodium hydroxide in methanol, another binuclear complex, **V**, in which the two metal atoms are bridged by a methoxy and an exobidentate pyrazolato-*N*,*N*′ ligand, is obtained. The same type of compound can be obtained directly by allowing **I** to react with one equivalent of pyrazole dissolved in two equivalents of methanolic sodium hydroxide.

The reaction was found to follow the same courses even when more sterically demanding pyrazoles were employed, such as 3,5-Me_2pzH (9), or an azole with a different basicity, such as 3,5-Me_2-4-BrpzH. Both ligands give the corresponding compounds **III** and **VI**, or **IV** and **VII**, respectively,



[1]Revision received March 27, 1980.

[2]PzH means $C_3H_4N_2$, i.e. unsubstituted pyrazole, while 3,5-Me_2pzH or 3,5-Me_2-4-Br-pzH mean the pyrazole molecule having the indicated substituents at the designated ring position; a generical pyrazole is indicated by *P*zH.

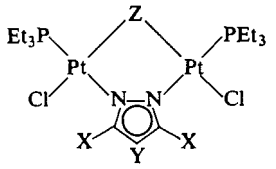
*Cl analysis was carried out on very small sample, the results are invariably high.

characterized through analyses (Table 1) and through infrared and nmr spectroscopic data (Table 2). The isolation of derivatives of 3,5-Me_2-4-Br-PzH proves that the bonding to platinum may take place only through the 1-position of the ring, in this case the only unsubstituted one.

When two moles of 3,5-Me_2PzH and of sodium hydroxide were employed, besides **VI**, another binuclear compound was isolated from the mother liquor and identified as **VIII** through analytical and spectral data.



The ^{31}P and ^{1}H nmr spectra (Table 2) show the required resonances, the assignment of which is helped by the coupling to ^{195}Pt (33% abundance; spin = 1/2). Thus, in the case of the methoxy bridged compounds a 1:8:16:8:1 pattern is expected for the protons in the Pt—OMe—Pt system owing to the presence of molecules having two (11.36%) or one (44.68%) ^{195}Pt nucleus together with molecules (43.95%) having no nmr-active platinum isotope. Such a pattern is indeed observed in the spectrum of **V**, although the two weakest signals were detected with some difficulty; ^{3}J(Pt—H) being 46–48 Hz in these cases.

The same pattern is expected for the 4-CH signal of the heterocyclic ring in all the Pt(μ-Pz-*N*,*N'*)Pt system. Nevertheless, only a broadening of the pertinent signal is observed because ^{4}J(Pt—H) is one order of magnitude smaller than ^{3}J; in addition the signal is weak because only one proton is involved.

When the azolato is connected to only one

[a]Nuclear magnetic resonance spectra were recorded on a Brüker instrument operating at 24.88 or 60 MHz for ^{31}P or ^1H respectively; s = singlet; q = 1:8:18:8:1 quintet (see text).
[b]Coupling undetected due to broadness of signal.
[c]See text.

platinum atom (i.e. is monodentate) no such pattern is observed, but just the expected two satellites, as for the 4-CH protons of the 3,5-Me_2Pz^- group in compound **VIII**.

The ^{31}P nmr spectra show a singlet flanked by two ^{195}Pt satellites with ^1J(PtP) = 3.0 to 3.5 kHz, and in one case, **I**, a value of 29.3 Hz is also observed for ^3J(PtP). The singlet pattern implies that the two phosphines are equivalent, i.e. they have the same *trans* ligand. Further, in the ^1H nmr spectra of **V**, **VI**, and **VIII**, the $-OCH_3$ groups exhibit no P—H coupling; the phosphines are therefore *trans* (10) to the exobidentate–pyrazolato bridge (as shown in Scheme 1).

Finally, the reaction of **I** with 3,5-dimethylpyrazole in the absence of added alkali was investigated by ^1H nmr spectroscopy. Immediately after mixing in $CDCl_3$, the methyl singlet due to the ligand was replaced by two equally intense resonances at δ2.52 and 2.23. The high field resonance appeared as a singlet, while the low field one exhibited ^{195}Pt satellites with ^4J(Pt—H) = 4 Hz. The coupling with the ^{195}Pt nuclei is probably also felt by the 4-CH proton, which produces a broad singlet at δ5.95. All these data suggest a monodentate pyrazole ligand, bonded through the 2-N atom,

The colour of the solution is yellow, suggesting *trans* geometry of the two chlorides. This is also consistent with the observed formation of *trans* products in the bridge splitting reaction of the dimer, **I**, with amines (11).

The above results confirm that a pyrazolato group may be either a monodentate or an exobidentate ligand. In the former case, the mode of attachment is the same as that found in $(Ph_2PCH_2)_2Pt(pz)_2$ (12); in the latter case the heterocyclic anion may be accompanied by a second and different bridging group either Cl or OCH_3, affording the stable, homobinuclear complexes, **II–VII** having a novel type of arrangement of ligands.

Experimental

$Pt_2(PEt_3)_2Cl_4$ was prepared according to the literature method (13). ^1H nmr spectra was recorded on a varian A60 spectrometer. ^{31}P nmr spectra were recorded in a Brüker PW60 and were ^1H decoupled; the chemical shifts are relative to 85% H_3PO_4. Infrared spectra were obtained on a Beckmann IR12 instrument. Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis, IN. The substituted pyrazoles were prepared by the method of Morgan and Ackermann (14).

Preparation of VI

4-Bromo-3,5-dimethylpyrazole (88 mg, 0.5 m*M*) was dissolved in 0.5 mL of 1 *N* 90% acqueous methanolic NaOH (0.5 m*M*). The resulting solution was then added to a suspension of 384 mg (0.5 m*M*) of $Pt_2(PEt_3)_2Cl_4$ in 10 mL methanol. The reaction mixture was stirred magnetically for 3 h. The creamy yellow precipitate was filtered, washed with methanol, water, methanol, and ether. Recrystallization from CH_2Cl_2/ethanol afforded yellow needles 397 mg (87%).

The methods of preparation of **II** and **IV** are similar. Both compounds are recrystallized from CH_2Cl_2/aqueous ethanol (yield: **II**, 74%; **IV**, 63%).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Preparation of VII

(*A*) To a suspension of (0.14 m*M*) 115 mg of **VI** in 2 mL of methanol was added 0.15 mL of 1 *N* NaOH. After stirring for 24 h, the yellow solid was filtered and washed with methanol, water, methanol, and ether. The complex was recrystallized from CH_2Cl_2/ethanol. Yield 70 mg (60%).

(*B*) Alternatively, **III**, **V**, **VII** can be prepared directly from $Pt_2(PEt_3)_2Cl_4$ as follows: a solution of 3,5-dimethylpyrazole (9.6 mg, 0.1 m*M*) in 0.2 mL 1 *M* aqueous methanolic NaOH (0.2 m*M*) was added to a suspension of 76.8 mg of $Pt_2(PEt_3)_2Cl_4$ (0.1 m*M*) in 2 mL of MeOH. After stirring for 24 h, the yellow solid was filtered, washed with methanol, H_2O, methanol, and ether. Recrystallization from CH_2Cl_2/ethanol afforded crystals of **III**, 55 mg (66%).

Compound VIII

To a methanol suspension (10 mL) of the compound **I** (223.5 mg, 0.29 mmol), 3,5-Me_2pzH (58.4 mg; 0.61 mmol) and sodium hydroxide (1 mL of a 90% methanolic solution, 0.614 *M* diluted to 5 mL with methanol) were added, whereupon a yellow solution formed. After overnight standing, yellow crystals of **VI** (73 mg) were filtered off, and the solution was evaporated to dryness, leaving an oily residue which solidified upon standing under ether. The solid was dissolved in warm methanol (8 mL) and the compound **VIII** (34.3 mg) crystallized upon slow evaporation to a volume of 2 mL.

Metal binding to N(9), N(7), and N(3) of adenine. Crystal structure of μ-(adeninato-*N*3,*N*7,*N*9)tris(methylmercury(II)) perchlorate

JOSEPH HUBERT AND ANDRÉ L. BEAUCHAMP

Département de Chimie, Université de Montréal, C.P. 6210, Succ. A., Montréal (Qué.), Canada H3C 3V1

Received December 31, 1979

JOSEPH HUBERT and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **58**, 1439 (1980).

The title compound belongs to space group $P\bar{1}$ with the following cell parameters: $a = 6.304$, $b = 11.925$, $c = 25.946$ Å, $\alpha = 85.76$, $\beta = 89.78$, $\gamma = 83.57°$, and $Z = 4$. The structure was solved by the heavy-atom method and refined on 2570 nonzero reflections to an R factor of 0.044. In the two crystallographically independent $[Adeninato(CH_3Hg)_3]^{2+}$ ions, methylmercury groups are linearly bonded to N(3), N(7), and N(9) of a deprotonated adenine ring, forming Hg—N bonds of normal lengths (ave. 2.08 Å) for two-coordinated mercury. One half of the complex cations are associated in a dimeric unit by a pair of strong N(6)—H(6) ···N(1) hydrogen bonds, while the others are packed as individual species in the crystal. The structure is stabilized by a number of contacts between mercury and perchlorate oxygens.

JOSEPH HUBERT et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **58**, 1439 (1980).

Le composé appartient au groupe d'espace $P\bar{1}$ et possède les constantes réticulaires suivantes: $a = 6.304$, $b = 11.925$, $c = 25.946$ Å, $\alpha = 85.76$, $\beta = 89.78$, $\gamma = 83.57°$ et $Z = 4$. La structure a été résolue par la méthode de l'atome lourd et l'affinement effectué au moyen de 2570 réflexions d'intensité non nulle a convergé jusqu'à $R = 0.044$. Les deux ions complexes $[Adéninato(CH_3Hg)_3]^{2+}$ cristallographiquement indépendants possèdent des groupes méthylmercure à coordination linéaire liés aux atomes N(3), N(7) et N(9) d'une molécule d'adénine déprotonée. Les liaisons Hg—N sont de longueur normale (moy. 2.08 Å) pour un mercure bicoordonné. La moitié des cations complexes sont associés en dimères au moyen d'une paire de liaisons hydrogène fortes N(6)—H(6)···N(1), tandis que les autres s'empilent individuellement dans le cristal. Plusieurs contacts entre le mercure et les atomes d'oxygène des ions perchlorates contribuent à la stabilisation du cristal.

Introduction

Donor basicity in polydentate ligands is affected by metal coordination somewhere else in the molecule. Purines are quite sensitive to such effects because their donor atoms are interconnected by a fluid system of π-electrons. Detailed knowledge of those effects is required to understand the interaction of nucleic acids with metallic species like platinum anticancer drugs, since metal binding at one position is likely to change the ability of other portions of the ligand to form hydrogen bonds, accept more metal atoms, and so on. Direct information of that sort on series of related compounds is still missing.

That problem is investigated using the CH_3Hg^+ ion, a uniligating Lewis acid in which the linear coordination of mercury leads to minimal steric hindrance. The interdependence of donor sites has already been mentioned for adenosine (1) and clear evidence has recently been provided by X-ray work on 9-methyladenine (MAd) complexes. Indeed, the N(1),N(6)-bonded $[(CH_3Hg)_2(MAd—H)]^+$ species is isolated from acidic solutions (2), even though mercury has to displace an amino hydrogen that does not spontaneously dissociate even at high pH. Substitution of that hydrogen is probably facilitated by simultaneous coordination of another CH_3Hg^+ group to position N(1), which was found to be attacked first by mercury (3). Unsubstituted adenine reacts differently because the acidic H(9) proton is readily displaced by CH_3Hg^+. Neutral adenine (HAd) and the neutral CH_3HgAd complex, in which the N(9) sites are occupied by H and CH_3Hg respectively, clearly show changes in the basic character of the remaining nitrogen atoms: adenine accepts the extra proton at N(1) (4), whereas CH_3HgAd accepts a second CH_3Hg^+ group at N(7) (2).

The title compound contains three CH_3Hg^+ groups per ligand. The corresponding protonic species (H_3Ad^{2+}) has hydrogen atoms attached to N(1), N(7), and N(9) (5), but from the above discussion, it is clear that the coordination sites cannot be predicted from the corresponding protonic compound. Inasmuch as no reliable information could be extracted from the vibrational spectra (6) and no other 3:1 complexes had been reported, a crystallographic investigation was undertaken to determine the pattern of site occupancy.

Experimental

Crystal Data

$C_8H_{13}Cl_2Hg_3N_5O_8$ fw = 979.9

Triclinic, space group $P\bar{1}$, $a = 6.304(7)$, $b = 11.925(4)$, $c = 25.946(4)$ Å, $\alpha = 85.76(2)$, $\beta = 89.78(5)$, $\gamma = 83.57(6)°$, $V = 1933$ Å^3, $Z = 4$ formula units per cell, $D_c = 3.362$ g cm^{-3}, $\mu(MoK\alpha) = 240.5$ cm^{-1}, $\lambda(MoK\bar{\alpha}) = 0.71068$ Å, $t = 23°C$.

Crystallographic Measurements

Crystals suitable for X-ray work were obtained directly from

the reaction mixture as described elsewhere (6). The specimen used had the following distances between the indicated pairs of faces: 0.06 mm (001 and 00$\bar{1}$), 0.14 mm (010 and 0$\bar{1}$0), and 0.17 mm (100 and $\bar{1}$00).

A set of precession and cone axis photographs indicated a triclinic Laue symmetry (space groups $P1$ or $P\bar{1}$) and provided starting cell parameters. According to the estimated density, that cell would contain four formula units, that is, two independent formulas per asymmetric unit in $P\bar{1}$. Such cases have to be carefully checked in order to make sure that the crystal does not belong to a space group of higher symmetry. The triclinic cell is believed to be correct for the following reasons:

(*i*) The set of orientation photographs taken at 10° intervals around the dial axis of the precession camera failed to reveal any symmetry.

(*ii*) A cell with the same dimensions was deduced by the autoindexing routine of the ENRAF-NONIUS CAD4 software from two independent samples of 25 centred reflections found by the SEARCH routine procedure.

(*iii*) The cell provided by the CAD4 software (Reduced cell, type I (7)) has only one apparently specialized Niggli element ($S_{13} = ac \cos\beta \sim 0$) as a consequence of the β angle being close to 90°. A greater specialization of the Niggli elements is necessary to lead to higher symmetry (7). The same conclusion is reached by using TRACER II (8), a computer program working with the slightly different Delauney cell.

(*iv*) Oscillation photographs were recorded with the crystal mounted on the CAD4 diffractometer by placing a Polaroid cassette behind the beam catcher. With a real axis along the vertical direction (z axis) of the instrument, the crystal was allowed to oscillate ±13° about ω and pictures were taken (45 min exposures) about two median ω positions for each of the three axes. The photographs showed the expected layer line separations, but no symmetry. If either *a* or *c* actually belonged to a cell of higher symmetry, the mirror of the Laue group would introduce a top–bottom mirror symmetry in the oscillation photograph.

(*v*) The solved structure (see below) shows that one half of the complex cations form hydrogen-bonded dimeric groups, whereas the others are packed individually. Those strikingly different, but chemically reasonable, packing modes confirm that the two formula units are crystallographically independent and could not belong to a cell of higher symmetry, where they would have to become symmetrically equivalent.

Intensity measurements were collected using the $\omega/2\theta$ scan technique. A fixed slit of 3.0 mm was used and the scan range (ω) was $(0.90 + 0.35 \tan\theta)°$ extended 25% on each side for background. Scan speed S between 6.7 and 0.67 deg min^{-1} was automatically selected to make $I/\sigma(I) = 100$, but a maximum scan time of 120 s was imposed. Prescans at 6.7° min^{-1} were done and all the weak reflections ($I/\sigma(I) < 1$) were not remeasured at low speed. Their F_o and $\sigma(F_o)$ values were taken from the prescan counts. Three standard reflections were monitored as a check on instrument and crystal stability. They showed random fluctuations within ±4% about their respective means. Crystal orientation was checked every 100 reflections by recentering three reflections. Misorientation was always <0.1° and no crystal recentering was done.

A total of 4989 independent reflections (hkl, $\bar{h}kl$, $h\bar{k}l$, and $\bar{h}\bar{k}l$, $2\theta \leq 45°$) were measured using Enraf–Nonius option FLAT, a procedure to measure intensity at the ψ angle where absorption is minimum for a plate-like crystal. Net intensity I was obtained from $I = (P - B/0.50)S$, where P is the total scan count and B is the total background count measured during one half of scanning time. The standard deviation was calculated from $\sigma(I) = (P + B/0.25)S^2 + (0.02I)^2$. A set of 2570 reflections with $I/\sigma(I) \geq 3$ was retained for structure determination. The crystal was highly absorbing and an absorption correction was applied (Gaussian integration, grid 8 × 8 × 8). For most of the measurements, the transmission factors ranged from 0.15 to 0.30. For the six $h00$ and three more reflections, diffractometer geometry allowed measurement only at the most unfavorable ψ position. Their transmission coefficients were < 0.02 and they were arbitrarily assigned zero weight. The data were finally corrected for Lorentz and polarization effects.

Resolution of the Structure

The structure was solved by the heavy-atom method. In space group $P\bar{1}$, there are six crystallographically independent Hg atoms, two of which were first located from a Patterson synthesis. The four remaining Hg atoms were visible on a Fourier map. All nonhydrogen atoms were finally located from a subsequent Fourier map phased on the six Hg atoms. Full-matrix least-squares refinement of positional and isotropic thermal parameters with unit weights converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.098$. The Hg atoms were then anisotropically refined and the R factor reduced to 0.059. At this point, the structure was essentially correct and refinement was continued by using block-diagonal least-squares to save computer time. The hydrogen atoms on C(2), C(8), and the N(6) amino group of each ring were then fixed at their calculated positions (C(N)—H = 0.95 Å, sp^2 hybridization) with isotropic temperature factors B of 6.0 Å^2 (U = 0.076 Å^2). Hydrogen parameters were not refined, but the coordinates were recalculated after each cycle. The methyl hydrogens were not found. In the last cycles of refinement, individual weights $w = 1/\sigma(F)^2$ were used for each reflection. Anisotropic refinement of all nonhydrogen atoms converged to $R = 0.044$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.051$. The goodness-of-fit ratio was 1.52. There were no indications in the final ΔF map that the space group might be $P1$ instead of $P\bar{1}$. The map showed a general background ≤0.8 e/Å^3, except for a few peaks of 1.1–1.8 e/Å^3 within 1.1 Å from Hg.

The refined coordinates are listed in Table 1. Lists of structure factors and temperature factors are available upon request.[1] The scattering curves were those of Cromer and Waber (9), except for hydrogen (10). Anomalous scattering coefficients $\Delta f'$ and $\Delta f''$ for Hg and Cl were taken from Cromer (11).

Description of the Structure

In the 2:1 complex, imidazolic nitrogen atoms N(7) and N(9) are occupied by CH_3Hg groups (2). This first example of a 3:1 adenine complex shows that the third binding site is N(3). In all known N(3)-bonded compounds, the ligand is bridging via N(9) and N(3) and the species that most closely resemble the present situation are the dimeric cations $[Cu_2(HAd)_4Cl_2]^{2+}$ (12) and $[Cu_2(HAd)_4(H_2O)_2]^{4+}$ (13) in which N(7) is protonated. However, other cases of N(3),N(9)-bridging are known in which N(1) and N(7) are either both free (14) or both protonated (15, 16).

Interatomic distances and bond angles are schematically represented in Fig. 1. Unless otherwise stated, they correspond to average values

[1]The supplementary material includes lists of observed and calculated structure factors, anisotropic temperature factors of nonhydrogen atoms, coordinates of hydrogen atoms, individual interatomic distances and bond angles, and details of best-plane calculations. Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

over the two independent complex cations.[2] Mercury exhibits the expected linear two-coordination within experimental error (C—Hg—N = 177(1)°).

[2]The conventional one-digit numbering scheme is used to discuss features common to both independent complex cations in the cell. Whenever reference is made to a specific cation, symbols N(11), C(12) ... (cation No. 1) or N(21), C(22) ... (cation No. 2) are used.

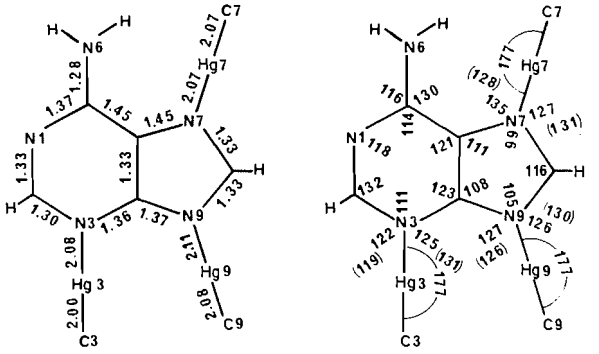

FIG. 1. Average interatomic distances and bond angles in [Adeninato(CH_3Hg)$_3$](ClO_4)$_2$. The two values for C—N—Hg angles refer to cation No. 1 (unparenthesized) and cation No. 2 (parenthesized), respectively. The standard deviations on bond lengths are 0.04–0.05 Å, except for Hg—N(C), 0.02–0.04 Å, and on bond angles, 3°, except for C—Hg—N, 1°.

All three nitrogen atoms bind the metal equally strongly with a normal average Hg—N bond length (2.08(3) Å) (17). The Hg—CH_3 distances (ave. 2.05(4) Å) also agree with previous studies (17).

Because electron density is largely concentrated in a few mercury atoms, the light atom portion of the structure is defined with limited accuracy. Corresponding distances and angles in the two independent cations are equal within experimental errors. The average results given in Fig. 1 agree with 2σ with the normal geometry of the ligand (18).[1] Both adenine rings are planar within 0.05 Å (1.5σ) and the amino groups do not significantly deviate from their respective planes.[1] The greater out-of-plane bending of the CH_3Hg group as a whole (Hg–plane distance = 0.07–0.35 Å) is undoubtedly due to molecular packing.

The four perchlorate ions have the expected tetrahedral geometry. The O—Cl—O angles range from 105 to 116° (σ = 2°, ave. 109°). The Cl—O bonds lengths are spread between 1.33 and 1.47 Å (σ = 0.03 Å) with a normal average value of 1.40 Å.

Packing efficiency is achieved by parallel positioning of the flat complex cations (Fig. 2). However, in contrast with free ligands and a number of complexes, adenine rings are not in direct contact. Two different packing patterns can be recognized. In layers parallel to *ab* at z = 1/2, complex cations (black atoms) form centrosymmetric "dimers" via a pair of strong N(26)—H(26)···N(21) hydrogen bonds: N(26)···N(21) = 2.92(4) Å, C(26)—N(26)—N(21) = 117(2)°, C(22)—N(21)—N(26) = 116(2)°. In layers at z = 0, the cations (white atoms) pack as individual units and their amino groups form only weak hydrogen bonds with a perchlorate ion: N(16)···O(12) = 3.10(4) Å, C(16)—N(16)—O(12) = 149(2)°, Cl(1)—O(12)—N(16) = 107(2)°. An

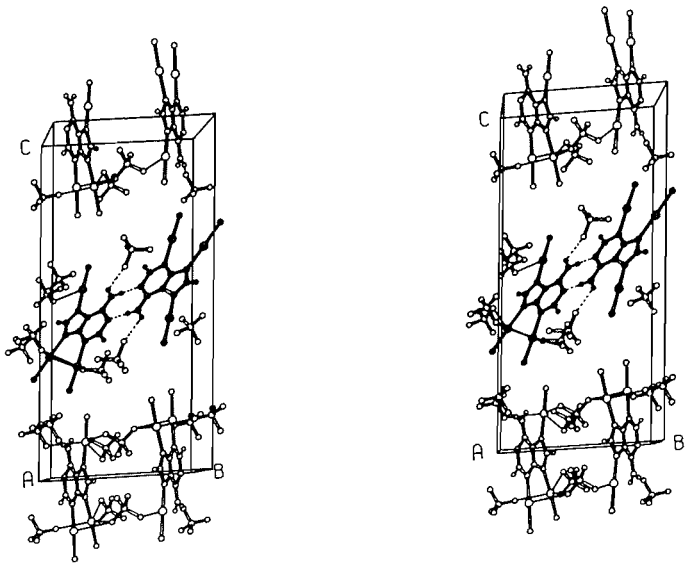

FIG. 2. Stereoscopic projection of the molecular packing in [Adeninato$(CH_3Hg)_3$]$(ClO_4)_2$. Mercury and chlorine atoms are represented by larger spheres of arbitrary sizes. Dotted lines represent H-bonds, and Hg—O contacts are shown as thin bonds. The two independent complex cations are shown with white (No. 1) and black atoms (No. 2), respectively.

important contribution to crystal stabilization results from mercury–perchlorate interactions. Contacts commonly exist between linearly coordinated mercury and extra donors in the equatorial plane. Such contacts may be moderately strong with halogeno–mercury compounds, for instance, but they tend to be much weaker with CH_3Hg groups. In fact, only three Hg···O contacts are found to be shorter than 2.9 Å, the sum of the admitted van der Waals radii of mercury (1.5 Å) (19) and oxygen (1.4 Å) (20). However, Grdenic (19) suggests that a radius as high as 1.73 Å can be used for mercury if very weak interactions are taken into account. There are 11 more Hg—O contacts in the 2.9–3.1 Å interval and they are all located within ±15° from the equatorial plane (Fig. 2). Although those interactions are individually weak, they probably have a determining effect on molecular packing.

Discussion

The most significant characteristic of the present crystal structure is the apparent absence of affinity of N(1) for mercury. Indeed, the latter site is the first to react with CH_3Hg^+ in adenosine (21) and 9-methyladenine (3) and the first to protonate in neutral adenine and the above derivatives (1, 4). Because of the availability of N(9) for coordination, adenine was expected to differ in reactivity from its N(9)-substituted analogues. Nevertheless, it was not anticipated that N(1) would become the worst heterocyclic nitrogen donor, poorer than N(3).

The lack of reactivity of N(3) in N(9)-substituted adenines is mainly due to steric hindrance (see ref. 3, Fig. 3). Replacement of bulky N(9)-alkyl or -ribosyl by either copper (12–15), silver (16) or as the present case, mercury leaves enough space for a second metal atom to bind to N(3) without experiencing appreciable strain. The Hg(3)—Hg(9) distances (3.270(2) and 3.310(2) Å) are slightly lower than the long contacts in solid mercury (3.47 Å) (19), but the lack of Hg–Hg repulsion is evidenced from the nearly equal Hg—N—C angle pairs for each CH_3Hg group bonded to N(3) or N(9).

Even if the presence of CH_3Hg instead of a bulkier group at N(9) makes N(3) sterically more available, it must be remembered that N(1) is not hindered either. Hence, steric hindrance alone cannot explain that N(3) reacts better than N(1). We have proposed (2) that the replacement of H(9) by a less electronegative Hg atom should spread more electron density into the ligand, increasing the basicity of other nitrogen donors. Assuming that such a basicity enhancement should be more pronounced for nitrogen atoms closer to N(9), we were able to explain that the second CH_3Hg^+ ion was bound to N(7) instead of N(1) in the 2:1 complex. Inasmuch as N(7) and N(3) are separated from N(9) by the same number of bonds and, according to theoretical work by Pullman and co-workers (22), there should be only small differences in electrostatic potential at N(3) and N(1) in the free neutral ligand, the basicity enhancement experienced by N(3)

could be sufficient to make it a better binding position than N(1).

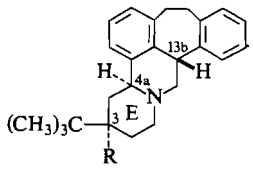
S. FORTIER, M. PRZYBYLSKA, and L. G. HUMBER. Can. J. Chem. **58**, 1444 (1980).

(±)-Deoxybutaclamol, $C_{25}H_{31}N$, crystallizes in space group $P2_1/a$ with cell dimensions: a = 16.626(3), b = 10.646(2), c = 11.278(3) Å, β = 90.47(4)°. The structure was solved by direct methods using the QTAN program. The coordinates were refined by block-diagonal least-squares calculations to R = 0.052 for 3147 observed reflections.

The structure of (±)-deoxybutaclamol was found to be very similar to that of equipotent (±)-butaclamol and is in agreement with that assigned on the basis of chemical, spectral, crystallographic, and pharmacological studies. This confirmation validates the coordinates of a lipophilic accessory binding site in a proposed model of the central dopamine receptor.

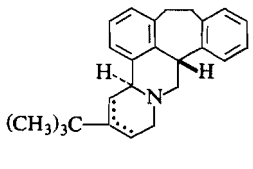
S. FORTIER, M. PRZYBYLSKA, et L. G. HUMBER. Can. J. Chem. **58**, 1444 (1980).

Le (±)-désoxybutaclamol, $C_{25}H_{31}N$, cristallise dans le groupe d'espace $P2_1/a$ et les dimensions de la maille sont: a = 16.626(3), b = 10.646(2), c = 11.278(3) Å, β = 90.47(4)°. On a résolu la structure par des méthodes directes en faisant appel au programme QTAN. On a affiné les coordonnées par la méthode des moindres carrés (blocs diagonaux) jusqu'à une valeur de R = 0.052 pour 3147 réflexions observées.



On a trouvé que la structure du (±)-désoxybutaclamol est très semblable à celle du (±)-butaclamol de puissance semblable et qu'elle est en accord avec celle attribuée en se basant sur des études chimiques spectrales, cristallographiques et pharmacologiques. Cette confirmation rend valable les coordonnées d'un site récepteur accessoire lipophile dans un modèle proposé du récepteur central de la dopamine.

[Traduit par le journal]



Introduction

Recent studies have shown that (±)-butaclamol, **1**, (1) is a clinically active antipsychotic agent in man (2–7), and in animals exhibits a psychopharmacological profile typical of antipsychotic agents (8). These effects of antipsychotic agents are believed to be mediated via the blockade, in the brain, of the receptors for the endogenous neurotransmitter dopamine (for a review of the dopamine hypothesis of schizophrenia, see ref. 9).

(±)-Butaclamol has been demonstrated to be a high-affinity dopamine receptor antagonist (10, 11), and its ability to bind to the dopamine receptor has been ascribed to the presence in its semirigid benzocycloheptapyridoisoquinoline nucleus of an extended phenylethylamine pharmacophore (12), the nitrogen atom and phenyl ring of which bind to primary binding sites on the receptor macromolecule (13, 14). It was suggested (12) that the hydroxyl and *tert*-butyl groups of (±)-butaclamol contribute to the affinity between ligand and receptor through binding to accessory binding sites on the receptor macromolecule. Further studies, however, have demonstrated (13) that the hydroxyl group does not contribute to binding affinity since (±)-deoxybutaclamol, **2**, was found to be virtually equipotent to (±)-butaclamol using *in vivo* (13) and *in vitro* (15) models of dopamine receptor blockade. In contrast, the presence of the *tert*-butyl or other similar lipophilic group at the 3-position of the benzocycloheptapyridoisoquinoline nucleus was found to be critical for dopamine receptor antagonist activity (13).

1 (R = OH)
2 (R = H)

3

This necessity for the presence of a lipophilic group confirmed the existence of a lipophilic accessory binding site and has led to the proposal (13, 14) of a model of the dopamine receptor which incorporates primary as well as accessory binding sites. The coordinates of the lipophilic accessory binding site were assigned with the assumptions that the *tert*-butyl group at position-3 of (±)-deoxybutaclamol, **2**, was attached equatorially, that ring

E assumed a chair conformation, and, that the molecule possessed a 4a,13b-*trans* relative configuration.

While the latter assumption was verified by proton magnetic resonance spectral evidence (13), there remained uncertainties with respect to the first two. These uncertainties existed since in the synthesis of (±)-deoxybutaclamol by the catalytic reduction of the olefin mixture **3** with platinum oxide as catalyst, apart from a 34% yield of (±)-deoxybutaclamol, there was also obtained a 30% yield of an isomeric compound (mass spectrum and elemental analysis) which retained a 4a,13b-*trans* relative configuration (pmr spectrum) (13).

On the basis of equipotency between (±)-butaclamol and (±)-deoxybutaclamol (13, 15), and the absence of activity with the isomer, (±)-deoxybutaclamol was assigned a structure with an equatorial *tert*-butyl configuration and a ring E-chair conformation, similar to that observed in the crystal structure of (±)-butaclamol (16).

Since the validity of the coordinates for the lipophilic accessory binding site in the proposed model of the dopamine receptor are critically dependent on the correctness of the above configurational and conformational assignments, we have undertaken a crystal structure analysis of (±)-deoxybutaclamol.

Experimental

(±)-Deoxybutaclamol hydrochloride was converted to the free base which was crystallized from 2-propanol and had mp 110–113°C. The crystal data of (±)-deoxybutaclamol are as follows:

$C_{25}H_{31}N$ fw = 345.5
Monoclinic, $P2_1/a$, a = 16.626(3), b = 10.646(2), c = 11.278(3) Å, β = 90.47(4)°, V = 1996.1 Å^3, Z = 4, ρ_o = 1.150 (by flotation at 24°C), ρ_c = 1.150 g cm^{-3}, Cu Kα(λ(α_1) = 1.54050, λ(α_2) = 1.54434 Å).

The space group was established from precession films. The data were measured on an automatic Picker diffractometer with Ni-filtered Cu radiation using an almost spherical crystal of diameter 0.61 mm. The unit cell parameters were derived from the angular settings of five high-order axial reflections (2θ = 80–111°) and their equivalents. The intensities were measured by the θ–2θ scan procedure at 3.5° take-off angle and with 2θ scanning speed of 2° min^{-1}. The backgrounds were recorded for 20 s with a stationary counter at the start and end of each scan. The intensities of two standard reflections were examined at regular intervals for scaling. Of the 3396 non-equivalent reflections ($2\theta_{max}$ = 130°), 3147 (93%) had significant net counts and were considered observed. Net intensities were corrected for Lorentz and polarization effects, but not for absorption (μ(Cu) = 4.59 cm^{-1}).

The structure was solved by direct methods using the program QTAN (17). An E map computed from the solution with the most negative NQEST figure of merit (18) showed two images of the molecule, each with 24 out of the 26 non-hydrogen atoms, and translated by about 1.5 Å from one another along the y axis (19). Averaging the y coordinates gave the correct structure. The hydrogen atoms were located from a difference map computed at a later stage.

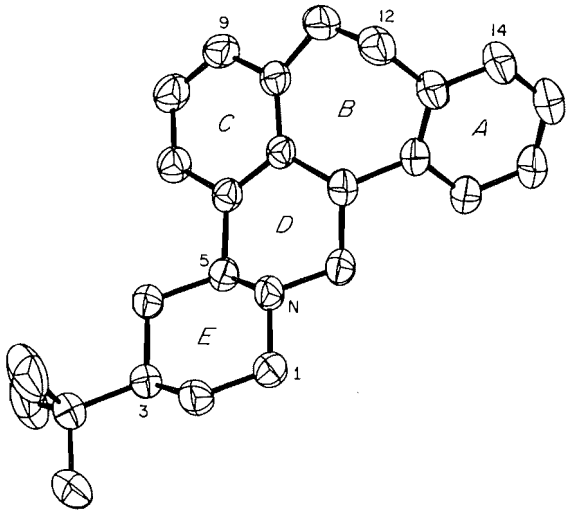

FIG. 1. The molecular structure of deoxybutaclamol with 50% probability thermal ellipsoids.

Refinement was carried out by block-diagonal least-squares with only the observed reflections, minimizing $\Sigma w(|F_o| - |F_d|)^2$ with weights $w = 1/[\sigma^2(F) + 0.002\,F^2]$, where $\sigma(F)$ is the esd in the observed amplitude based on counting statistics.

Anisotropic thermal parameters were used for C and N atoms, but H atoms were treated isotropically. Three hydrogen atoms of the butyl group (H(23, 3), H(24, 3), and H(25, 1)) did not refine well, resulting in unacceptably long C—H bond lengths and consequently they were included at the fixed positions deduced from molecular geometry.

All the reflections with highest net counts were corrected for extinction and three planes which suffered from multiple diffraction (724, 152, and $\bar{7}82$) were excluded from the final stages of refinement.

All calculations were carried out with the NRCC crystallographic computer programs by Ahmed, Hall, Pippy, and Huber (20). The scattering factor curves were those of Hanson, Herman, Lea, and Skillman (21) for C and N; and of Stewart, Davidson, and Simpson (22) for H. The refinement converged to R = 0.052 and Rw = 0.100 for the 3147 observed reflections and the mean and maximum shifts/esd were 0.16 and 0.90, respectively. The refined atomic coordinates are presented in Table 1.[2] A final difference map revealed no significant peaks, as the values were within −0.22 and 0.20 e Å^{-3}.

Results and Discussion

A view of one of the two enantiomorphs of (±)-deoxybutaclamol present in the crystal structure, drawn by ORTEP program (23), is shown in Fig. 1.

*Identifies atoms not included in the mean plane calculation.

the lone pair of electrons of N is pointing up. The *tert*-butyl group is attached equatorially.

Bond lengths and angles are presented in Fig. 2(*a* and *b*). The mean value of 1.525 Å for C(sp^3)—C(sp^3) bonds came close to that for C(sp^3)—C(sp^2) bonds (1.522 Å). This overall slight shortening for C—C single bonds is comparable to that found in (+)-isobutaclamol hydrobromide (24), where C(sp^3)—C(sp^3) bonds gave the mean of 1.527 Å. The longest bond is C(3)—C(22) (1.554 Å), an expected result due to the substitution by the large *tert*-butyl group. The mean value for C(sp^2)—C(sp^2) bonds is 1.390 Å and the mean of C—N bonds is 1.462 Å, which is in agreement with the value for the C to three-covalent N distance. The C—H are in the range 0.94–1.08 Å (mean = 1.00 and esd = 0.03 Å). The valency angles have normal values with the exception of three endocyclic angles in the cycloheptane ring. The values for C(21)—C(10)—C(11), C(10)—C(11)—C(12), and C(18)—C(19)—C(21) are considerably larger than normal (126.7, 119.2, and 114.1°). They agree with the corresponding angles in (+)-dexclamol hydrobromide (16) which are 129, 118, and 112°, respectively.

The angles at the attachment of the *tert*-butyl group are also abnormally large (113.5 and 115.5.°). Since some of the hydrogen atoms attached to C(24) and C(25) make short intermolecular contacts with hydrogen atoms of neighbouring molecules, these increases may be caused by the crystal packing.

The C—C—H and H—C—H angles vary from 101.9 to 122.8° and give the average 110.9°.

Endocyclic torsion angles are shown in Fig. 2(*c*) and mean plane calculations in Table 2. Ring A is almost planar with $\chi^2 = 47.2$, but ring C is not, showing large atomic displacements up to 0.039 Å. The dihedral angle between their mean planes is 63.2°.

Ring E has a regular chair conformation, but ring D is a half-chair with C(20) and N distances of −0.34 and 0.51 Å from the plane of the other four atoms of the ring. The cycloheptane ring B is of V shape, folded along C(12)···C(19) line. The displacements of the atoms from the mean planes of the two portions of the ring B are given in Table 2. The dihedral angle between them is 61.4°. Atoms H(12, 2) and H(19) exhibit a flagpole-bowsprit interaction between them, being separated by 2.15 Å.

The molecules are separated by normal van der Waals contacts. There are no C···H distances below 2.89 Å and the shortest H···H contact is H(12, 2) to H(2, 2) of 2.45 Å.

In summary, (±)-deoxybutaclamol possesses a molecular structure in agreement with that as-

Aromatic fluorination with xenon difluoride: L-3,4-dihydroxy-6-fluoro-phenylalanine

GUNTER FIRNAU,[1] RAMAN CHIRAKAL, SUDESH SOOD, AND STEPHEN GARNETT

Department of Nuclear Medicine, McMaster University Medical Centre Division, Chedoke–McMaster Hospital, M.P.O. Box 2000, Hamilton, Ont., Canada L8N 3Z5

Received March 10, 1980

GUNTER FIRNAU, RAMAN CHIRAKAL, SUDESH SOOD, and STEPHEN GARNETT. Can. J. Chem. **58**, 1449 (1980).

L-3-Methoxy-4-hydroxyphenylalanine was fluorinated directly with XeF_2 in CH_2Cl_2 at −60°C *in vacuo*. After hydrolysis with 48% aqueous HBr, L-6-fluorodopa was obtained. The yield, based on XeF_2, was 25%. This reaction might be applied when chiral biomolecules are to be tagged with fluorine-18.

GUNTER FIRNAU, RAMAN CHIRAKAL, SUDESH SOOD et STEPHEN GARNETT. Can. J. Chem. **58**, 1449 (1980).

Le produit de la réaction de L-3-methoxy-4-hydroxyphenylalanine avec le difluorure de xénon en chlorure de methylène sous vide à −60°C a été hydrolisé par le l'acide bromique aqueux (48%) pour produire exclusivement du L-6-fluorodopa. Le rendement de cette réaction est de l'ordre de 25% (basé sur XeF_2). Cette réaction pourrait être utilisée lors du marquage de molecules biochimiques chirales avec du fluor-18.

The radioactive tracer DL[^{18}F]3,4- dihydroxy-5-fluorophenylalanine (DL[^{18}F]-5-fluorodopa) has enabled us to make novel measurements of intracerebral dopamine metabolism, non-invasively in primates, by means of simple gamma ray detectors placed over the head (1). The synthesis of DL-5-fluorodopa is cumbersome (2) and, from a biological point of view, the L-stereoisomer would be much preferred. In this communication we describe a simple and rapid fluorination with xenon difluoride that yields the unique molecule L-6-fluorodopa. This procedure could be adapted to make the ^{18}F labelled analogue.

The direct fluorination of L-dopa with XeF_2 is not possible. XeF_2 oxidizes the catechol in L-dopa to *o*-quinone. Further, fluorinations with XeF_2 are reported to proceed best in methylene chloride (3) but L-dopa does not dissolve in it. Because L-3-methoxy-4-hydroxyphenylalanine ethyl ester is soluble in methylene chloride and it is not oxidized, it was reacted with XeF_2 in methylene chloride at −60°C *in vacuo* and the reaction products hydrolysed immediately with 48% HBr. The reaction mixture was chromatographed by reversed phase hplc and 6-fluorodopa was the only fluorinated product. The 6-fluorodopa was identified by ms and ^{19}Fmr.

In order to prove that 6-fluorodopa was the L-enantiomer, it was used as a substrate for the stereospecific L-amino acid decarboxylase (E.C.4.1.1.26). This enzyme is known to decarboxylate 5-fluorodopa (4) and a wide variety of other aromatic amino acids. The product of the enzymatic reaction of 6-fluorodopa was isolated by reversed phase hplc and shown to be 6-fluorodopamine.

Fluorinations with XeF_2 usually yield isomeric mixtures of fluoroaromatics (3). Only one of the three possible fluorodopa isomers was detected from our synthesis. The exclusive fluorination of dopa in the 6-position is in accord with the suggested electrophilic character of the reaction (3). This mild fluorination reaction may be applicable to other fragile and chiral biomolecules, such as L-hydroxytryptophan.

Experimental

Preparation of L-3-Methoxy-4-hydroxyphenylalanine Ethyl Ester

L-3-Methoxytyrosine (7.83 g, 40 mmol, SIGMA Chemical Company) was suspended in absolute ethanol (150 mL) and HCl gas was passed through for 30 min. The reaction mixture was kept at room temperature overnight before the ethanol was evaporated. The remainder was twice redissolved in water (50 mL each) and evaporated. Recrystallizations from methanol–ether gave 10 g L-3-methoxy-4-hydroxyphenylalanine ethyl ester hydrochloride. This hydrochloride (9.7 g, 35 mmol), dissolved in 15 mL of water, was neutralized with 1.4 g sodium hydroxide. The neutralized solution was extracted three times with hot ethyl acetate. The combined extracts were dried over anhydrous Na_2SO_4. Evaporation of ethyl acetate left 7.0 g of white crystals, yield 73%, based on L-3-methoxy-4-hydroxyphenylalanine, mp 93–94°C, uncorrected. *Anal.* calcd. for $C_{12}H_{17}NO_4$ (239.3): C 60.23, H 7.18, N 5.85; found: C 60.22, H 7.14, N 5.83 (Microanalysis Laboratories, A. B. Gygli, Toronto).

Preparation of L-6-Fluorodopa

A solution of 17 mg (0.1 mmol) xenon difluoride (PCR, Research, Inc.) in 2 mL methylene chloride was placed in a Kel-F tube and frozen with liquid nitrogen. The pressure in the tube was reduced to about 10 μm Hg. Anhydrous hydrogen fluoride (10 μL) and a solution of 71 mg (0.3 mmol) L-3-methoxy-4-hydroxyphenylalanine ethyl ester in 1 mL methylene chloride was added. The Kel-F tube was warmed up to −60°C. The

colour of the reaction mixture changed from green to yellow-brown over a period of 10 min. The methylene chloride was evaporated at room temperature *in vacuo*. To the yellow remainder 10 mL of 48% hydrobromic acid was added. The hydrolysis mixture was treated at 140°C for 15 min while hydrogen gas was passed through. The hydrobromic acid was removed by evaporation *in vacuo*. The dry residue was twice redissolved in water and evaporated. Finally, the residue was dissolved in 5 mL water. This solution was chromatographed in aliquots with hplc (column: μBondapak™/C-18, 7.8 mm × 300 mm; mobile phase: 0.1% acetic acid in water at 2 mL/min; detector: uv at 280 nm). The fluorodopa fraction was collected and the solvent evaporated. Yield 5.4 mg or 25% based on XeF_2; $^{19}Fmr(D_2O)$ δ: 36.4 (s) ppm downfield from hexafluorobenzene, measured with a Bruker WH 90 FT nmr spectrometer at 84.66 MHz at 25°C. In comparison, 6-fluorodopamine has a chemical shift of 37 ppm downfield from hexafluorobenzene (6). Gas chromatography – mass spectroscopy: the trimethylsilyl derivative of 6-fluorodopa was prepared (7). The gas chromatograph (Varian 2700) was fitted with a 1800 mm × 2 mm column (1.5% OV-17 on Chromosorb W, 80–100 mesh). The operating conditions were: injector at 305°C, column at 270°C, interface and Watson–Biemann separator at 300°C, flow rate 50 mL of He/min. The mass spectrograph was a Varian Mat CH7, which was operated with an ionization voltage of 70 eV, and an emission current of 300 μA. The ion source was maintained at 300°C. The observed mass fragments at 218 and 219 are typical for trimethylsilylated amino acids (8). Those at 197 and 285 are consistent with the structure of a fluorinated bistrimethylsilylated methyl catechol cation (7). The uv absorption: λ_{max}: 284 nm in 0.1% acetic acid.

Proof that the L-*Stereoisomer of 6-Fluorodopa had been Produced*

L-Amino acid decarboxylase was prepared from rabbit kidney cortex by the method of Lancaster and Sourkes (5) and purified up to the $(NH_4)_2SO_4$ fractionation. A chromatographically pure sample of 6-fluorodopa, derived from the XeF_2 reaction, was incubated for 2 h with the decarboxylase. The enzyme reaction was terminated by addition of 5% phosphotungstic acid in 2 *N* HCl and then heated at 100°C for 1 min. After the precipitated proteins had been removed by centrifugation, an aliquot of that solution was chromatographed with hplc (column: μBondapak™/C-18, 7.8 mm × 300 mm; mobile phase: 0.05 *M* NaH_2PO_4 buffer pH 3.5 at 2.0 mL/min; detector: uv at 280 nm). The presence of 6-fluorodopamine was confirmed by spiking with the authentic material. During the enzymatic reaction the amount of 6-fluorodopa was reduced by 90%. The appropriateness of the enzymatic assay was established by showing that under the above conditions (4) authentic L-dopa and L-5-fluorodopa were completely converted to dopamine and 5-fluorodopamine, respectively.

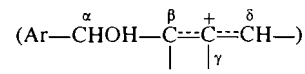
Reçu le 27 août 1979

GILBERT DANA, JOSYANE GHARBI-BENAROUS et SA LE THI THUAN. Can. J. Chem. **58**, 1451 (1980).

L'évolution du carbocation allylique hydroxylé du type *C*

issus des diols du type *A*



peut se dérouler suivant cinq processus: trois attaques nucléophiles, (en β ou en δ, par une molécule du solvant ou en δ par l'hydroxyle intramoléculaire), une réaction de dégradation, et la transposition pinacolique.

Les attaques nucléophiles sur le pôle δ aussi bien intramoléculaires (formation de dihydrofurannes) que par une molécule de solvant (formation de cétone de type *B*), sont des processus très sélectifs qui s'excluent mutuellement dans le cas d'un substituant unique en β, γ, ou δ. Pour les carbocations disubstitués en γ et en δ, la sélectivité est moindre et on obtient des mélanges différents de ces deux types de produits, suivant l'encombrement des substituants. On a pu ainsi analyser le rôle des différents facteurs stériques qui régissent l'équilibre de stéréomutation du carbocation allylique et par là, déterminent l'orientation de la déshydratation.

GILBERT DANA, JOSYANE GHARBI-BENAROUS, and SA LE THI THUAN. Can. J. Chem. **58**, 1451 (1980).

The allylic carbocations

formed during the dehydration of diols of type *A*

are found to react by five different processes: three nucleophilic attacks (by solvent at the β or δ positions, or by the intramolecular hydroxyl group at δ), a degradation reaction between C_α and C_β and the classical pinacol rearrangement.

Nucleophilic attack at the carbon δ is a very efficient reaction and sometimes (for monosubstituted substrates in β, γ or δ) gives quasi-exclusive products: a ketone for the reaction with H_2O in δ or a 2,5-dihydrofuran product for the intramolecular reaction.

In the case of γ and δ disubstituted carbocations, the selectivity is less and we show that it is possible to analyze the different steric effects commanding the stereomutation equilibrium of the allylic carbocation and so determining the orientation in the dehydration.

Introduction

L'étude de la réactivité des carbocations allyliques α-hydroxylés du type *C*, issus des diols-1,2 du type *A*, effectuée dans trois précédents mémoires (1, 2, 3) a permis de mettre en évidence cinq réactions possibles bien distinctes (schéma 1). Ces réactions, observées de façon souvent sélective pour des carbocations non-substitués ($R_\alpha = R_\beta = R_\gamma = R_\delta = H$) ou monosubstitués par un méthyle dans l'une des trois positions β, γ ou δ, sont les suivantes.[2]

(*a*) Une attaque nucléophile du solvant en δ conduisant à une cétone (cétone *B*) et observée essentiellement dans le cas des diols Ar—CHOH—CHOH—CH=CH—CH_3 (diols **1**) et Ar—CMeOH—CHOH—CH=CH—CH_3 (diols **2**) ($R_\delta = CH_3$) (1, 4).

[1]Précédent mémoire de la série, réf. 3.

[2]La numérotation des différents diols fait suite à celle utilisée pour les premiers mémoires (1, 2, 3).

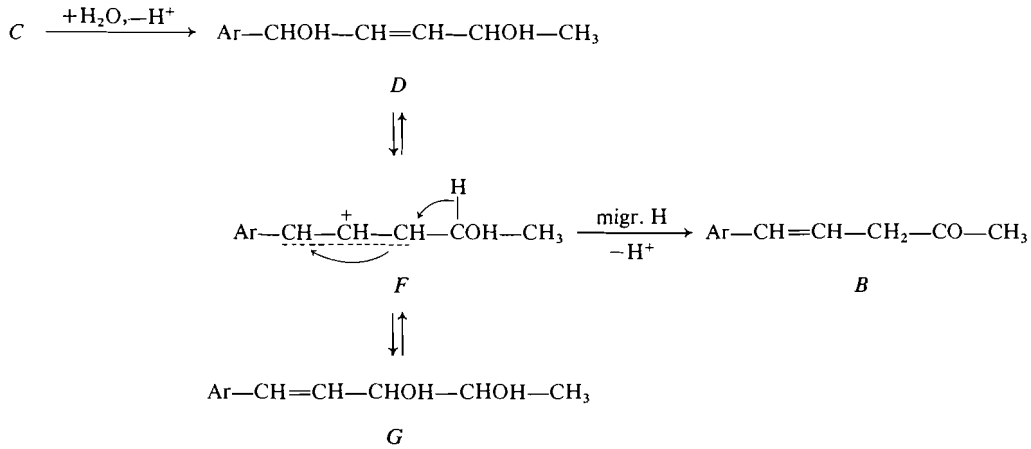
SCHÉMA 1. Les cinq évolutions observées du carbocation allylique *C*



Cette formation de la cétone de type *B* est donc finalement le résultat de la transposition pinacolique (migr. H) du carbocation *F* et apparaît effectivement (1, 4) sous sa forme carbonyle non conjugué.

(*b*) Une attaque nucléophile intramoléculaire de l'hydroxyle en α sur le carbone δ (cyclisation en dihydrofuranne et éventuellement transformation en naphtalène), observée essentiellement dans le cas des diols Ar—CHOH—CMeOH—CH=CH_2 (diols **4**) ($R_\beta = CH_3$) (2, 5).

(*c*) La transposition pinacolique (tp), plus ou moins observée dans tous les cas, mais surtout importante pour les diols Ar—CHOH—CHOH—CH=CH_2 (diols **3**) ($R_\alpha = R_\beta = R_\gamma = H$) (2).

(*d*) Une réaction de dégradation (6) (coupure de la liaison C_α—C_β) observée essentiellement avec les diols Ar—CHOH—CHOH—CMe=CH_2 (diols **5**) ($R_\gamma = CH_3$) (3).

(*e*) Une attaque nucléophile du solvant en β (retour interne (7)), réaction inverse de l'ionisation du diol de départ et matérialisée par l'établissement

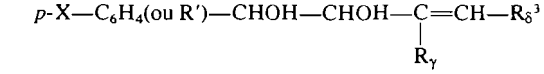
rapide d'un équilibre *érythro–thréo* de ce diol. Cette réaction est observée uniquement lorsque $R_\beta = CH_3$ (diols **4**) (8).

L'influence des substituants donneurs ou attracteurs du noyau aromatique sur la (ou les) réaction(s) observée(s) nous a permis chaque fois d'interpréter l'évolution du système. Toutefois, le caractère quasi-exclusif des différentes réactions interdisait d'apprécier l'importance relative des différents facteurs (électroniques ou stériques) dûs à la présence du méthyle dans les différentes positions envisagées.

Dans le présent mémoire, nous nous proposons d'étudier les réactions observables lorsque les carbocations portent deux substituants en γ et en δ, dont les effets spécifiques sont, dans une certaine mesure antagonistes. L'effet des différents substituants étant plus nuancé, les réactions observées sont moins sélectives et la comparaison des différents facteurs devient possible.

Nous introduirons alors quelques uns des résultats antérieurs dans la discussion générale en vue d'illustrer notamment le rôle de la configuration du carbocation allylique résultant de l'équilibre de stéréomutation (9).



Forme ArCHOH *exo* Forme ArCHOH *endo*

Résultats

Déshydratation des diols γ-δ disubstitués (schémas 2, 3 et tableau 1)

La déshydratation est effectuée dans les mêmes conditions que pour les séries précédentes (1, 2, 3) dans l'acide sulfurique normal (entraînement à la vapeur d'eau), sur le mélange équimolaire des diols *érythro* et *thréo*. Seuls apparaissent des produits de déshydratation sans perte de carbone. Trois types de substances sont identifiés.[4]

6: $R_\gamma = R_\delta = CH_3$ *b* X = H, *c* X = CH_3, *d* X = OCH_3 et *e* R' = C_2H_5
7: $R_\gamma = CH_3$, $R_\delta = C_2H_5$ *b* X = H, *c* X = CH_3
8: $R_\gamma = C_2H_5$, $R_\delta = CH_3$ *c* X = CH_3
9: $R_\gamma = C_2H_5$, $R_\delta = C_3H_7$ *e* R' = C_2H_5

[3]Voir note 2. Les lettres *a*, *b*, *c* ... désignant le substituant X du groupe aromatique (*e* désigne le remplacement du groupe aromatique entier par le reste saturé éthyle) sont également repris des mémoires précédents et ont la même signification pour les neuf séries de diols.

[4]Les dérivés des diols sont désignés par un numéro dont le premier chiffre désigne le diol de départ (1 à 9) et le deuxième chiffre, le type du dérivé.

(*a*) *La cétone du type* B ***(62, 72, 82 ou 92)*** sous sa forme conjuguée ou non conjuguée (isomère *E* unique). En ce qui concerne la réaction de formation de ces cétones *B*, elles apparaissent dans ces séries, généralement sous forme d'un mélange (quasi)équilibré; dans le cas des cétones **62***b* ⇄ **62′***b*, le mélange obtenu dans la réaction a, en fait, la même composition que le mélange équilibré (équilibration de chacun des isomères, conjugué et non conjugué dans les conditions de la déshydratation, par l'acide sulfurique normal à reflux). Toutefois en l'absence du groupe aromatique (pour les diols **6***e* ou **9***e*, R' = C_2H_5) la forme non conjugée **62′***e* ou **92′***e* domine dans le mélange réactionnel (tableau 1 et schéma 3) alors qu'elle est presque absente à l'équilibre.

(*b*) *Les produits de cyclisation, dihydrofurannes* cis *et* trans *(**63**, **73** ou **83**) ou naphtalènes (**64**, **74** ou **84**) (tableau 1)*

Ces dérivés cyclisés, observés déjà de façon importante pour la série de diols **4** ($R_\beta = CH_3$, $R_\gamma = R_\delta = H$) (2), apparaissent dans les trois séries des diols **6**, **7** et **8**, surtout sous forme de dérivés dihydro-2,5 furanniques, alors que les dérivés naphtaléniques ne constituent que des traces détectables par cpv (ou par rmn après enrichissement).

(*c*) *Un aldéhyde de transposition pinacolique (**61**, **71** ou **81**)* résultant de la migration du groupe aryle sur le carbocation allylique (formes *Z* ou *E* conjuguées, schéma 2, tableau 1). Dans le cas du diol **9***e* (schéma 3) ne comportant pas de groupe aromatique, on observe la migration d'un hydrogène (cétones **96***e* et **96′***e* 14%) plutôt que celle de C_2H_5 (cétones **91***e*, 5%), moins favorable.

Discussion

Etude des attaques nucléophiles en δ

(A) Rôle des facteurs électroniques

Il est intéressant de noter pour les quatre séries de diols étudiés dans ce mémoire, que les produits de coupure cessent d'être observés (malgré la présence du méthyle en γ (3)) et que la transposition pinacolique diminue chaque fois au profit d'une attaque nucléophile en δ, soit intermoléculaire (formation des cétones *B*) soit intramoléculaire (produits cyclisés). La polarité du carbone δ se prête donc bien à ce type d'attaque, ce qui confirme les prévisions que l'on pouvait faire à partir des charges totales ($\sigma + \pi$) calculées pour des substrats analogues comportant ou pas un méthyle en γ ou en δ. Nous avons vu (3) en effet qu'un méthyle en γ polarise négativement le carbone δ d'environ 9 à 12 $\times 10^{-3}$ unités de charge et constitue donc un substituant défavorable aux attaques nucléophiles en δ. En revanche, un méthyle en δ, polarise positivement ce carbone δ de 23 à 25 $\times 10^{-3}$ unités de charge

et constitue donc un substituant très favorable aux attaques nucléophiles en δ. Ces effets apparaissent de manière très claire pour les diols **1** ou **2** (R_γ = H, R_δ = CH_3) qui donnent de façon privilégiée les cétones *B* (1), et pour les diols **5** (R_γ = CH_3, R_δ = H) qui évoluent vers des réactions de coupure (3). Les valeurs des charges indiquées montrent que l'influence favorable du méthyle en δ est plus importante que l'influence défavorable du méthyle en γ; aussi pour les diols **6** à **9** on n'observe pas de coupure mais seulement des attaques nucléophiles en δ. D'ailleurs le calcul des charges totales (σ + π) montre bien qu'il y a additivité des effets de méthyles en γ et δ puisqu'en présence des deux substituants R_γ = R_δ = CH_3, on trouve une polarisation positive de 15 à 13 × 10^{-3} unités de charge sur le carbone δ.[5]

Il n'est donc pas étonnant d'observer pour les diols disubstitués en γ et δ que les produits de coupure ne se forment pas. Il en est de même pour le retour interne. En effet, la charge partielle positive, relativement faible sur le pôle β du carbocation semble aussi insuffisante pour qu'on observe la fixation d'un hydroxyle du solvant sur ce pôle. L'attaque nucléophile en β se trouve masquée (10) par les attaques nucléophiles en δ, plus rapides, en

[5]Y. L. Pascal, communication personnelle. Calculs effectués par la méthode IEHT sur IBM 3600. Nous remercions vivement l'auteur qui a mis à notre disposition les résultats obtenus au cours de ses travaux.

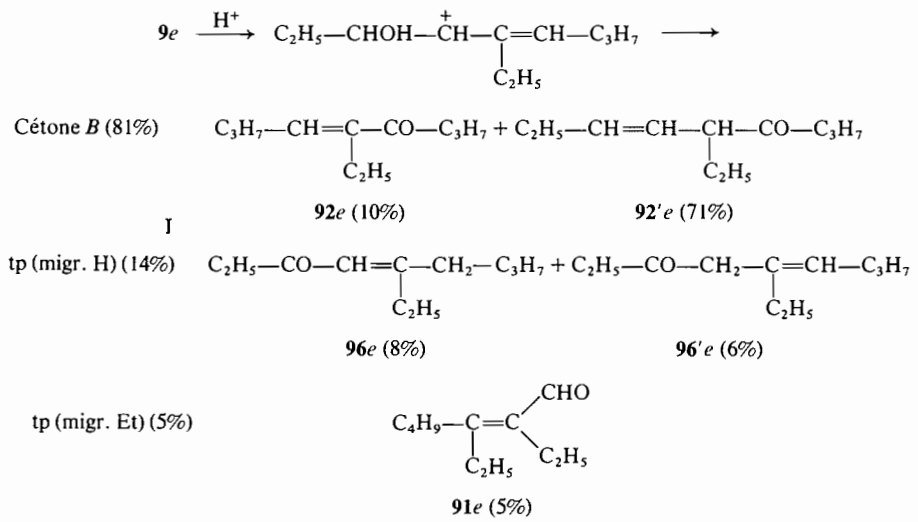

SCHÉMA 3. Produits de déshydratation du diol **9***e*. Pour la désignation des substances, cf. note schéma 2.

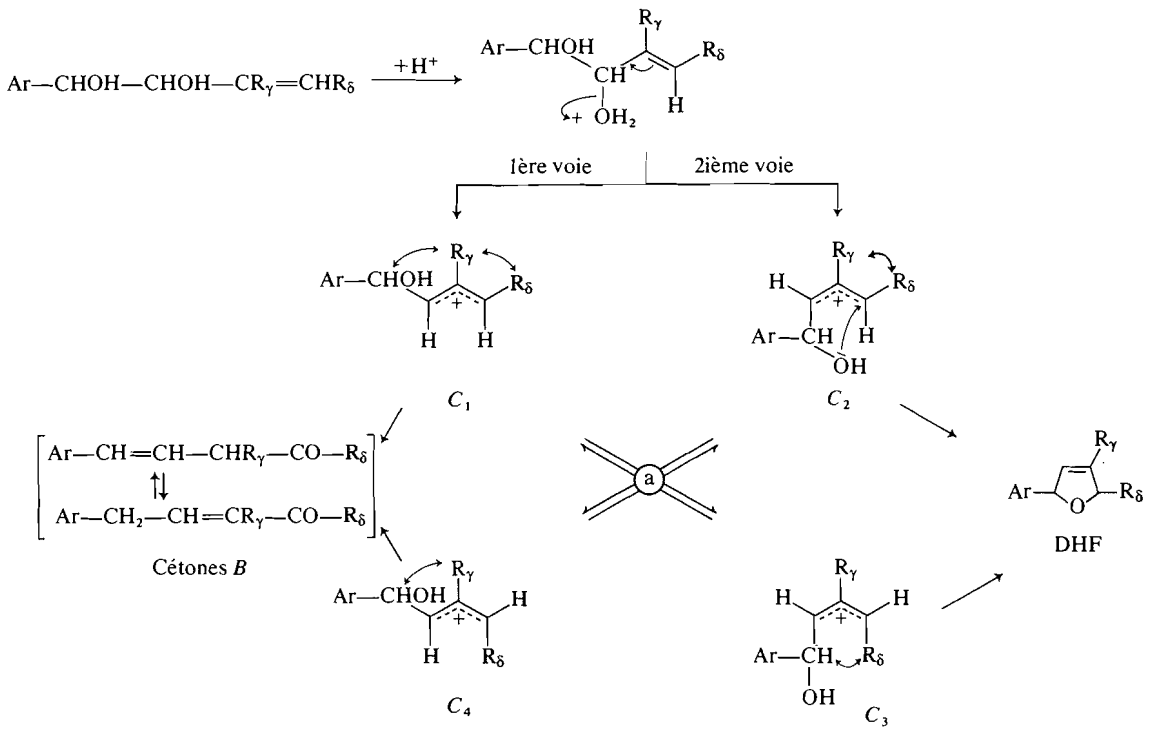
raison de la différence des charges partielles sur les deux extrémités du carbocation.

Un problème intéressant dans le cas de ces diols, est la compétition entre la réaction inter ou intramoléculaire. Dans cette compétition, la configuration du carbocation allylique joue un rôle déterminant.

(B) Rôle des effets stériques

On sait que les substrats allyliques subissent une solvolyse 10^4 à 10^5 fois plus rapide que les substrats saturés de même classe (11). Cette accélération résulte de l'assistance du doublet π au départ du groupe partant. Il est donc probable que l'ionisation du diol conduit directement à l'une des formes délocalisées C_1, C_2, C_3 ou C_4 (schéma 4).



Bien que les doubles liaisons trisubstituées des α-diols aient dans des cas analogues et pour une petite partie la configuration *Z* (12), on peut admettre une configuration majoritairement *E* de la double liaison des diols **6**, **7**, **8** et **9**. Il en résulte que, seules deux formes isomères C_1 ou C_2 semblent devoir prendre naissance directement par ionisation. Les deux autres formes isomères C_3 et C_4 résultent des précédentes par stéréomutation (schéma 4). Des calculs effectués dans des cas plus simples semblent indiquer que cette stéréomutation est possible par deux voies différentes (9) suivant que $R_\gamma = CH_3$ (passage par un ion cyclopropylium avec fermeture et ouverture disrotatoires, schéma 4) ou que $R_\gamma = H$ (passage par un carbocation à double liaison localisée, schéma 5).

On peut noter sur le schéma 4 que les formes C_2 et C_3 dans lesquelles le groupe ArCHOH occupe une position *endo*, peuvent *a priori* conduire indifféremment aux cétones *B* par attaque d'une molécule de solvant H_2O sur le pôle δ, ou aux dérivés dihydrofuranniques par attaque de l'hydroxyle en α bien placé, sur le carbone δ. En revanche les formes C_1 et C_4 (groupe ArCHOH *exo*) ne peuvent, en absence de stéréomutation, conduire qu'aux cétones *B*. Mais comme nous allons le voir, en fait, chaque fois que les effets stériques sont favorables à la forme C_1 ou C_4, la formation des cétones *B* est accrue, alors qu'elle peut éventuellement disparaître lorsque ce sont les formes C_2 ou C_3 qui sont favorisées (cas des diols **4**, $R_\beta = CH_3$, schéma 5). Tout se passe comme si les formes C_2 et C_3 capables d'évoluer aussi bien vers les cétones *B* que vers les dérivés dihydrofuranniques, donnent de préférence ces derniers. On comprend d'ailleurs aisément que dans ce cas, les facteurs entropiques soient plus favorables à la réaction intramoléculaire qu'intermoléculaire, et cela d'autant plus que des interactions de stabilisation entre l'hydroxyle et le site cationique du type solvatation de l'ion (13) favorisent une géométrie moléculaire (ArCHOH *endo*) qui préfigure l'attaque nucléophile et y conduit donc de façon très naturelle.

De plus, il est probable que dans cette configuration le noyau benzénique puisse aussi interagir favorablement avec la charge +, électrophile, par formation d'un complexe du type π. Le fait est qu'en l'absence de groupe aryle ($R' = C_2H_5$, **6***e*, **9***e*, schéma 6) cette configuration C_2 ne semble pas intervenir.

Ces interactions stabilisatrices sont d'ailleurs en compétition avec les interactions stériques qui poussent au contraire le groupe ArCHOH volumineux, à se placer, comme nous le verrons dans le cas des diols **1**, en position *exo*. De telles interac-

Formes C_1 et C_4 ArCHOH en position *exo*

Formes C_2 et C_3: ArCHOH en position *endo*

SCHÉMA 4

Equilibre de stéréomutation des carbocations allyliques Ar—CHOH—$\overset{+}{C}$H—$\overset{+}{C}$R$_\gamma$—CHR$_\delta$

65 R$_\gamma$ = R$_\delta$ = CH$_3$; **75** R$_\gamma$ = CH$_3$, R$_\delta$ = C$_2$H$_5$; **85** R$_\gamma$ = C$_2$H$_5$, R$_\delta$ = CH$_3$; **95** R$_\gamma$ = C$_2$H$_5$, R$_\delta$ = C$_3$H$_7$.

(a): Inversion simultanée de deux extrémités du carbocation dans l'hypothèse du passage par un ion cyclopropylium (ref. 9) (fermeture et ouverture disrotatoire) si R$_\gamma$ = CH$_3$($C_1 \rightleftarrows C_3$ et $C_2 \rightleftarrows C_4$) ou passage par un carbocation localisé si R$_\gamma$ = H ($C_1 \rightleftarrows C_4$ et $C_3 \rightleftarrows C_2$). .

tions stabilisatrices n'interviennent pas pour le groupe R$_\delta$ lorsqu'il occupe la position *endo*, stériquement très gênée, et nous verrons que, sauf interaction stérique R$_\gamma$ ↔ R$_\delta$ exceptionnellement

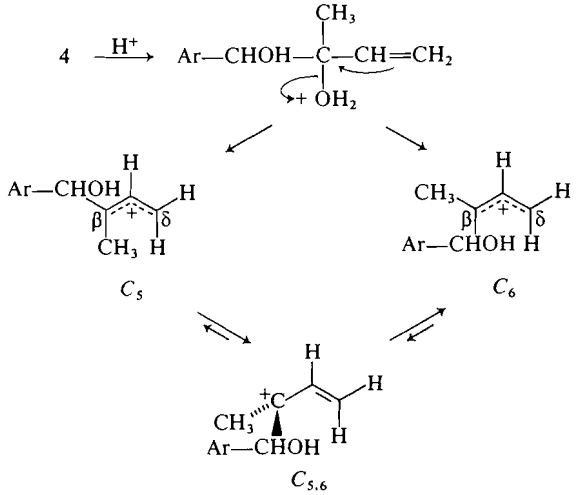

SCHÉMA 5. Stéréomutation du carbocation allylique très dissymétrique (primaire–tertiaire) issu du diol **4**.

importante (R$_\gamma$ = Et, R$_\delta$ = Pr), R$_\delta$ reste de préférence en position *exo* (formes C_1 ou C_2). Il a bien été observé qu'un méthyle (14*a*) ou un phényle seul (14*b*) occupent de préférence la position *exo*.

Nous admettrons donc (et les résultats suivants le confirment) que les cétones *B* se forment essentiellement à partir des seuls carbocations C_1 (ou C_4) alors que C_2 (et C_3) sont les précurseurs des dérivés cyclisés. En fait, pour la formation des cétones *B*, il existe entre ce carbocation allylique C_1 et la cétone *B*, un autre intermédiaire obligatoire *D*, qui est un γ-diol éthylénique (1), dont l'ionisation elle-même va conduire à un nouveau carbocation allylique *F* (voir Introduction et schéma 7).

D'après la configuration du carbocation précurseur C_1 ce γ-diol *D* a obligatoirement la configuration *E*. Il apparait donc que ce diol évolue en raison de cette configuration vers la cétone *B*. De tels exemples de sélectivité sont connus (4*a*, 15).

En ce qui concerne les dérivés dihydrofuranniques, il est possible également que l'on passe par l'intermédiaire d'un γ diol éthylénique. En raison de la structure de son précurseur C_2, ce

SCHÉMA 6. Rôle de la configuration C_4 en l'absence du groupe aromatique et pour un diol très encombré (diol **9***e*).

diol *D'* isomère du précédent *D*, doit avoir la configuration *Z*.

La déshydratation de tels diols conduit généralement à des mélanges de dérivés dihydrofuranniques et de cétones (16). Les réactions sont alors peu sélectives et souvent même les cétones prédominent (17). Ceci ne correspond pas aux observations dans notre cas. En effet, l'examen des résultats observés pour les diols de la série **4**, montre que dans le cas où la formation des dérivés dihydrofuranniques est privilégiée, il ne se forme pas de produits *B*. Il apparaît donc légitime d'admettre la cyclisation directe du carbocation C_2 en DHF.

Nous allons montrer que l'évolution du taux de cyclisation par rapport à la somme des attaques

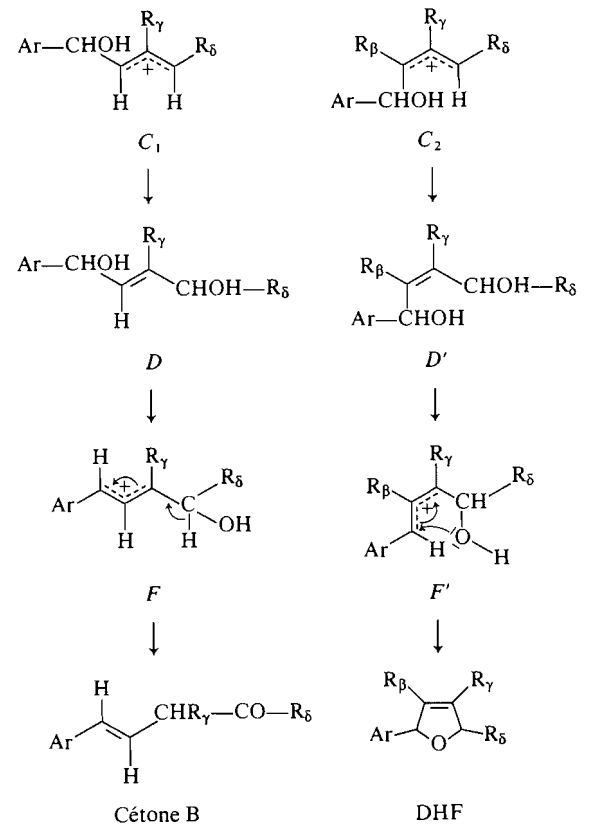

SCHÉMA 7. Importance de la stéréochimie des γ-diols intermédiaires éventuels.

nucléophiles en δ (produits cyclisés + cétones *B*), dans les diverses séries de diols étudiés, est en bon accord avec l'attribution des cations précurseurs des cétones *B* et des dihydrofurannes.

(a) Rôle de R_γ

On peut noter d'abord que pour $R_\delta = CH_3$, plus R_γ est gros, plus il favorise la réaction de cyclisation, en déplaçant l'équilibre de stéréomutation de C_1 vers C_2. Dans ces cas (avec $R_\delta = CH_3$), les interactions stériques $R_\delta \leftrightarrow R_\gamma$ restent en effet modérées et nous pouvons négliger le rôle des configurations C_3 ou C_4. L'examen des résultats du tableau 2 montre, en effet, que pour Ar donné (Ar = *p*-CH_3—C_6H_4) le taux de cyclisation augmente progressivement pour $R_\gamma = H$, CH_3 ou C_2H_5. Ainsi dans le cas des diols **1** ($R_\delta = CH_3$, $R_\gamma = H$), le carbocation allylique peut prendre naissance sous deux formes délocalisées C_1 ou C_2 (schéma 4). En l'absence du méthyle central R_γ, l'isomère C_1 est plus stable que C_2 (les effets stériques favorables à la forme ArCHOH *exo* étant plus importants que les interactions de stabilisation de la forme ArCHOH *endo*) et la première voie, conduisant directement à la cétone *B* devient le processus privilégié (taux de cyclisation du diol **1***c*: 13%).

En revanche pour le diol **6***c* ($R_\gamma = R_\delta = CH_3$), la présence d'un méthyle en γ, déplace l'équilibre de stéréomutation vers la forme C_2 apte à se cycliser (schéma 4) et sur les 70% de produits résultant des attaques nucléophiles en δ, on trouve 20% de produits dihydrofuranniques (soit un taux de cyclisation de 29%). De la même façon, pour le diol correspondant de la série **8** (diol **8***c*: $R_\gamma = C_2H_5$, $R_\delta = CH_3$), la présence de l'éthyle en γ rend la forme C_2 encore plus abondante et on trouve pour ce même taux, 46% (tableau 2).

Sur l'effet stérique de R_γ, on peut conclure qu'en présence d'un substituant en cette position, la réaction intramoléculaire, quand elle est possible (polarisation + en C_δ, $R_\delta \neq H$), est toujours privilégiée. Plus R_γ est gros, plus la formation du cation précurseur des dérivés cyclisés est favorisée par les facteurs stériques et on observe un accroissement du rendement de ces derniers par rapport aux cétones *B*.

(b) Rôle de R_δ

Si dans le diol **6** ($R_\gamma = CH_3$, $R_\delta = CH_3$), on remplace le méthyle en δ par un éthyle: diol **7** ($R_\gamma = CH_3$, $R_\delta = C_2H_5$) on favorise la formation des dérivés cyclisés au détriment des cétones *B*. Ainsi pour Ar = *p*-CH_3—C_6H_4, diol **7***c*, le taux de cyclisation atteint la valeur de 60% au lieu de 29% pour le diol **6***c* (tableau 2).

On a donc favorisé C_2 au détriment de C_1 (schéma 4), R_δ étant plus encombrant, l'effet

For personal use only.

TABLEAU 2. Comparaison générale de l'orientation des déshydratations et des taux de cyclisation dans les attaques nucléophiles en fonction de l'encombrement stérique du carbocation allylique (cas Ar = p-CH_3—C_6H_4)

	Présence d'un substituant en δ (R_β = H)					Absence d'un substituant en δ		
Série de diols	Diol **1***c*	Diol **6***c*	Diol **8***c*	Diol **7***c*	Diol **9***e*[a]	Diol **4***c*	Diol **5***c*	Diol **3***c*
Position des substituants	R_γ = H	R_γ = CH_3	R_γ = C_2H_5	R_γ = CH_3	R_γ = C_2H_5	R_γ = H	R_γ = CH_3	R_γ = H
						R_β = CH_3	R_β = H	R_β = H
	R_δ = CH_3	R_δ = CH_3	R_δ = CH_3	R_δ = C_2H_5	R_δ = C_3H_7	R_δ = H	R_δ = H	R_δ = H
Transposition pinacolique	37%	30%	25%	26%	19%	47%	65%	100%
Attaque nucléophile en δ	(63)	(70)	(75)	(74)	(81)	(53)	(0)	(0)
Cétone *B*	55	50	40	30	81			
Cyclisation	8	20	35	44	0	53		
Taux de cyclisation[b]	13%	29%	46%	60%	0%	100%	—	—
Coupure							35	

La totalité des produits de déshydratation récupérés représente environ 80% du diol consommé.
[a]Le diol 9*c*, avec Ar = CH_3—C_6H_4, a été déshydraté, mais le mélange obtenu, n'a pu être analysé avec assez de précision (mélange complexe de substances peu volatiles).
[b]Taux de cyclisation = $\frac{\text{Cyclisation}}{\text{Cétones } B + \text{Cyclisation}} \times 100$ (par rapport au total des attaques nucléophiles en δ).

"d'arc-boutant" qu'il exerce sur le méthyle central en γ va en fait aggraver l'interaction de ce dernier avec le groupe ArCHOH *exo* dans la forme C_1 au profit de C_2. Le rôle de cet effet "d'arc-boutant" de R_δ dans l'équilibre de stéréomutation apparaît même très important puisqu'il semble aussi efficace de remplacer méthyle par éthyle en δ (diols **6** et **7**, 29 à 60%) que de remplacer H par méthyle en γ (diols **1** et **6**, 13 à 29%).

(c) Effet stérique croissant de R_γ et R_δ

Dans le cas du diol **9** (R_γ = C_2H_5, R_δ = C_3H_7), on augmente simultanément la grosseur des substituants en γ et en δ. On crée alors une telle compression stérique que la forme C_4 apparaît comme la seule forme possible stable et ainsi comme le seul précurseur privilégié des cétones du type *B* (schéma 6).

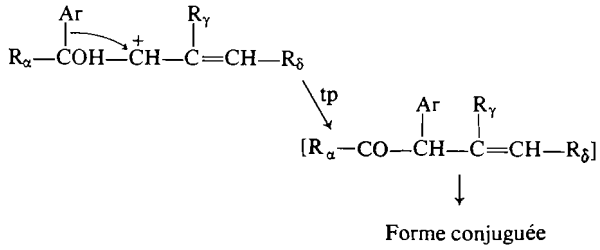
Cet effet de compression stérique excessif dans le diol **9***e* explique donc l'apparition des produits *B* en grande quantité (81%) alors que les dérivés cyclisés sont absents, leurs ions précurseurs C_2 ou C_3 étant improbables. En conclusion, les résultats observés montrent qu'en augmentant à la fois et de manière trop importante, l'encombrement stérique des substituants R_γ central et R_δ, on favorise la formation exclusive des cétones *B*, alors qu'en augmentant seulement R_γ, on favorise la cyclisation.

(d) Retour sur le rôle de R_β

Cette importance de la configuration du carbocation allylique dans l'orientation des réactions observées permet de comprendre certains résultats antérieurement décrits. Aussi, dans le cas des diols de la série **4** (R_β = CH_3, R_γ = R_δ = H) (2), il y avait formation de dérivés cyclisés sans trace de cétones *B* (**4***c*, 53% de cyclisation) (tableau 2).

Dans ce cas, il n'existe que deux ions stéréoisomères C_5 et C_6 (schéma 5), se transformant l'un en l'autre par l'intermédiaire de la forme localisée $C_{5,6}$ puisque R_γ = H. On peut d'ailleurs noter que ces diols **4** sont les seuls pour lesquels nous avons observé l'existence d'une réaction d'isomérisation *érythro–thréo* (retour interne) au cours de la déshydratation. Cette possibilité de réversibilité de l'ionisation du diol, est liée à la polarité + importante sur le pôle β tertiaire. Peut être le retour se produit-il justement lors du passage du carbocation par sa forme localisée $C_{5,6}$ (9*a*).

Entre ces deux ions C_5 et C_6, les facteurs stériques qui différencient les formes Me_β ou ArCHOH en position *exo* sont minimisés par rapport au cas H_β ou ArCHOH *exo*. Seules les interactions stabilisatrices, spécifiques à ArCHOH sont bien différentes entre les deux isomères. Ces interactions sont favorables à la forme C_6 (précurseur des dihydrofurannes) qui apparaît donc seule jouer un rôle dans les attaques nucléophiles (polarisation + trop faible en δ pour donner lieu à une attaque du solvant comme dans le cas des diols **3**, R_α = R_β = R_γ = R_δ = H qui ne donnent lieu qu'à la transposition pinacolique).



La discussion sur l'équilibre de stéréomutation permet donc d'interpréter les résultats observés en ce qui concerne la compétition entre la formation des cétones *B* et celle de dérivés cyclisés. La compétition entre la transposition pinacolique et l'ensemble de ces attaques nucléophiles en δ résulte elle, de l'intervention de facteurs stériques et électroniques plus classiques.

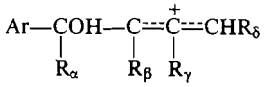
Etude de la transposition pinacolique (tp). Importance des facteurs stériques

Nous avons montré dans le 1er mémoire (1) que par un effet de décompression au cours de la trans-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

position, un groupe méthyle en R_α accélére la migration du groupe aromatique:

L'effet inverse dû à R_γ peut être mis en évidence dans la présente étude. Remarquons que pour le diol **6***d* (X = OCH_3), on observe 20% de cétones *B* (tableau 1). Le carbocation allylique existe donc bien, malgré la grande stabilisation du carbocation concurrent en α (due à la présence du groupe anisyle). Cependant ce carbocation allylique est loin d'évoluer exclusivement dans le sens de la migration du groupe anisyle pourtant si mobile. En fait la présence d'un substituant méthyle en γ introduit un accroissement de la compression stérique dans la molécule au cours de la transposition, et ralentit la migration au profit des attaques nucléophiles en δ. Cette diminution de la transposition pinacolique est régulière lorsque R_γ augmente de volume. On peut suivre cette évolution dans le tableau 2 pour R_δ = CH_3 dans le cas du groupe migrant Ar = *p*-CH_3—C_6H_4 (**1***c*, R_γ = H, tp = 37%; **6***c*, R_γ = CH_3, tp = 30%; **8***c*, R_γ = C_2H_5, tp = 25%).



Nous avons aperçu le même effet défavorable à la transposition pinacolique et trouvé les mêmes évolutions lorsque le substituant encombrant se trouve sur le carbone γ (**3***c*, R_γ = H, tp = 100%; **5***c*, R_γ = CH_3, tp = 65 à 75%) ou sur le carbone β lui-même (**3***c*, R_β = H, tp = 100%; **4***c*, R_β = CH_3, tp = 47% seulement).

Evidemment cet effet stérique se superpose à l'effet électronique classique de X sur l'aptitude migratrice du groupe Ar.

Il convient de rappeler toutefois que dans le cas des diols bisecondaires, l'aldéhyde de transposition pinacolique peut provenir soit du carbocation allylique avec migration du groupe Ar, soit du carbocation benzylique avec migration du groupe éthylénique. Donc les valeurs signalées constituent la limite supérieure du taux de transposition dans l'évolution du carbocation allylique.

Conclusion

La configuration du carbocation allylique α-hydroxylé de formule générale

apparaît comme un facteur déterminant dans l'orientation de la déshydratation des diols 1,2 α-β éthyléniques correspondants.

Cette configuration est très sensible à l'effet stérique des substituants, qui peut s'exercer soit directement, soit par effet "d' arc-boutant", pour modifier l'équilibre de stéréomutation et probablement, par là, la configuration *Z* ou *E* du γ-diol intermédiaire, notamment en ce qui concerne la formation de cétones du type *B*. Des effets stériques plus classiques interviennent aussi (effets de compression ou de décompression) au cours de la transposition pinacolique.

Toutefois, les effets électroniques des substituants sont loin d'être négligeables et il s'y ajoute probablement des interactions à distance de la lacune électronique du carbocation avec le groupe hydroxyle et avec le groupe aromatique.

De la conjugaison de ces différents effets résultent les modifications spectaculaires observées dans l'orientation de la déshydratation entre les cinq schémas réactionnels mis en évidence.

Partie expérimentale

La préparation et la déshydratation dans H_2SO_4 normal des diols ont été réalisées selon la méthode exposée dans la réf. 1. Les rendements obtenus pour la déshydratation sont toujours voisins de 75%. On détermine la composition des mélanges de produits transposés, par rmn dans le distillat brut après avoir purifié les différents produits par chromatographie en phase vapeur (cpv) sur colonne de XF 1150 et établi les structures par voie spectroscopique. Les analyses ont été effectuées sur les échantillons chromatographiés, après une rapide distillation sous vide. (Laboratoire de Microanalyse du Centre de Spectrochimie de Paris-Centre.)

Les spectres rmn ont été réalisés sur appareil Varian-A60, (solution $CDCl_3$, δ en ppm par rapport au TMS, référence interne). Les mêmes solutions ont été utilisées pour les spectres ir (spectrographe Perkin-Elmer, modèle 357, étalonnage par film de polystyrène).

Les spectres d'absorption uv sont enregistrés (appareil Varian modèle 635) en solution dans l'éthanol à 95%.

1. Déshydratation des diols 6: Ar (ou R')—CHOH—CHOH—C(CH_3)=$CHCH_3$

1. Déshydratation du diol **6e** *(R' = éthyle)*

La réduction par le Zn et l'acide acétique du mélange acroléine et aldéhyde tiglique, donne le *méthyl-3 heptadiène-2,6 diol-4,5* (18) (pé 122°C/0.02 Torr) dont la semi-hydrogénation (Ni de Raney dans l'alcool) permet d'obtenir le *méthyl-3 heptène-2 diol-4,5*, **6a** (18).

La déshydratation de ce diol conduit aux deux cétones *B* isomères:

la E-*méthyl-3 heptène-3 one-2*, **62e** (isomère conjugué prédominant). Sa configuration *E* et sa conformation transoïde sont déterminées par utilisation des chélates de terres rares en rmn. On observe en effet que ΔvMe(3) > ΔvH(4) > ΔvCH$_2$(5) (tableau 3); ir: 1665 cm^{-1}; rmn δ(ppm): 2.20 (s, H1), 1.70 (d, *J* = 1.2 Hz, Me 3), 6.56 (H4), 2.23 (q, *J* = 7 Hz, H5), 1.50 (H6), 0.97 (t, *J* = 7 Hz, H7).

la *méthyl-3 heptène-4 one-2*, **62'e**, ir: 1715 cm^{-1}; rmn δ (ppm): 2.03 (s, H1), 3.06 (quintuplet, H3), 1.08 (d, *J* = 6.5 Hz, Me 3), 5.1–5.9 (m, H4, H5), 2.06 (quintuplet, H6), 1.00 (t, *J* = 6.5 Hz, H7).

2. Déshydratation des diols **6**b, **6**c *et* **6**d *(Ar = p-X—C_6H_4)*

(a) Aldéhydes **61** *(transposition pinacolique).* La configuration *Z* ou *E* de ces aldéhydes et leur conformation transoïde ont été établies par l'utilisation des chélates de terres rares en rmn (tableau 3). On note en effet pour les $\Delta\nu Ar > CH_3(3) > CH_2(4)$ pour les isomères *E* et $Ar > CH_2(4) > CH_3(3)$ pour les isomères *Z*. Nous avons obtenu les liquides jaune clair suivants; les analyses sont effectuees sur des mélanges d'isomères *Z* et *E*.

Le *méthyl-3 phényl-2 pentène-2 al (61*b), *isomère* Z; ir: 1665 cm^{-1}; rmn δ(ppm): 10.11 (s, H1), 1.81 (s, H3), 2.75 (q, H4), 1.25 (t, *J* = 7 Hz, H5). *Isomère* E; ir: 1670 cm^{-1}; rmn δ(ppm): 10.11 (s, H1), 2.30 (s, H3), 2.10 (q, H4), 1.01 (t, *J* = 7 Hz, H5). *Anal.* calc. pour $C_{12}H_{14}O$: C 82.72, H 8.10; trouvé: C 82.85, H 7.89.

Le *méthyl-3 paratolyl-2 pentène-2 al (61*c), *isomere* Z; ir: 1660 cm^{-1}; rmn δ(ppm): 9.63 (s, H1), 1.85 (s, H3), 2.77 (q, H4), 1.25 (t, *J* = 7 Hz, H5). *Isomère* E; ir: 1665 cm^{-1}; rmn δ(ppm): 9.63 (s, H1), 2.31 (s, H3), 2.15 (q, H4), 1.02 (t, *J* = 7 Hz, H5). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 82.78, H 8.62.

Le *méthyl-3 paraanisyl-2 pentène-2 al (61*d), *isomère* Z; ir: 1670 cm^{-1}; rmn δ(ppm): 9.48 (s, H1), 1.85 (s, H3), 2.76 (q, H4), 1.25 (t, *J* = 7 Hz, H5). *Isomère* E; ir: 1675 cm^{-1}; rmn δ(ppm): 9.63 (s, H1), 2.31 (s, H3), 2.15 (q, H4), 1.02 (t, *J* = 7 Hz, H5). *Anal.* calc. pour $C_{13}H_{16}O_2$: C 76.44, H 7.90; trouvé: C 76.59, H 7.66.

(b) Cétones **62** *(cétones du type* B). Un isomère est prédominant. Sa configuration *E* et sa conformation transoïde sont établies par utilisation des chélates de terre rares en rmn (tableau 3). On observe en effet l'ordre suivant de déplacement des protons: $CH_3(1) > CH_3(3) > H(4) > CH_2(5) > Ar$. Nous avons ainsi obtenu les liquides suivants.

Le *méthyl-3 phényl-5 pentène-3 one-2 (62*b), ir: 1675 et 1635 cm^{-1}; uv: 236 nm (ε = 12 440); rmn δ(ppm): 2.21 (s, H1), 1.85 (Me 3), 6.69 (*J* = 7 et 1.2 Hz, H4), 3.61 (d, H5). *Anal.* calc. pour $C_{12}H_{14}O$: C 82.72, H 8.10; trouvé: C 82.63, H 8.29.

Le *méthyl-3 paratolyl-5 pentène-3 one-2 (62*c), ir: 1670 et 1635 cm^{-1}; uv: 239 nm (ε = 12 660) (inflexion); rmn δ(ppm): 2.26 (s, H1), 1.88 (Me 3), 6.76 (*J* = 7 et 1.2 Hz, H4), 3.55 (d, H5). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 82.81, H 8.75.

Le *méthyl-3 paraanisyl-5 pentène-3 one-2 (62*d), ir: 1670 et 1635 cm^{-1}; uv: 234 nm (ε = 12 000); rmn δ(ppm): 2.21 (s, H1), 1.83 (Me 3), 6.70 (*J* = 7 et 1.2 Hz, H4), 3.50 (d, H5). *Anal.* calc. pour $C_{13}H_{16}O_2$: C 76.44, H 7.90; trouvé: C 76.31, H 7.97.

(c) Cétones 62' (cétones du type B). Nous avons obtenu les isomères suivants.

Le *méthyl-3 phényl-5 pentène-4 one-2 (62'*b), ir: 1720 et 1625 cm^{-1}; uv: 243 nm (ε = 11 140); rmn δ(ppm): 2.09 (s, H1), 1.22 (d, *J* = 7 Hz, Me 3), 3.26 (H3), 6.02 (dd, *J* = 16 et 7 Hz, H4), 6.51 (d, *J* = 16 Hz, H5). *Anal.* calc. pour $C_{12}H_{14}O$: C 82.72, H 8.10; trouvé: C 82.75, H 8.04.

Le *méthyl-3 paratolyl-5 pentène-4 one-2 (62'*c), ir: 1730 et 1625 cm^{-1}; uv: 255 nm (ε = 16 300); rmn δ(ppm): 2.16 (s, H1), 1.25 (d, *J* = 7 Hz, Me 3), 3.35 (H3), 6.11 (dd, *J* = 16 et 7 Hz, H4), 6.56 (d, *J* = 16 Hz, H5). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 82.98, H 8.51.

Le *méthyl-3 paraanisyl-5 pentène-4 one-2 (62'*d), ir: 1720 et 1635 cm^{-1}; uv: 248 nm (ε = 10 950); rmn δ(ppm): 2.10 (s, H1), 1.2 (d, *J* = 7 Hz, Me 3), 3.23 (H3), 5.93 (dd, *J* = 16 et 7 Hz, H4), 6.45 (d, *J* = 16 Hz, H5). *Anal.* calc. pour $C_{13}H_{16}O_2$: C 76.44, H 7.90; trouvé: C 76.29, H 7.95.

(d) Dihydro-2,5 furanne (63)

Le *diméthyl-4,5 phényl-2 dihydro-2,5 furanne (63*b), ir: 1660 cm^{-1}; uv: 307 nm (ε = 1780) et 290 nm (ε = 2660); rmn δ(ppm): 5.4–5.7 (m, H2, H3), 1.75 (m, Me 4), 4.8 (m, H5), 1.28 (d, Me 5, 45% *cis*) et 1.32 (d, Me 5, 55% *trans*). *Anal.* calc. pour $C_{12}H_{14}O$: C 82.72, H 8.10; trouvé: C 82.90, H 8.05.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

Le *diméthyl-4,5 paratolyl-2 dihydro-2,5 furanne (63c)*, ir: 1665 cm^{-1}; uv: 255 nm (ε = 3090); rmn δ(ppm): 5.35–5.85 (m, H2, H3), 1.75 (m, Me 4), 4.88 (m, H5), 1.31 (d, Me 5, 45% *cis*) et 1.35 (d, Me 5, 55% *trans*). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 82.77, H 8.59.

(e) Naphtalènes 64

Le *diméthyl-1,2 naphtalène-(64b)*, le *triméthyl-1,2,7 naphtalène (64c)* et le *diméthyl-1,2 méthoxy-7 naphtalène (64d)*.

Ces produits sont identifiés par leurs propriétés spectroscopiques (19, 20).

II. Déshydratation des diols 7:

p-*X*—C_6H_4—*CHOH—CHOH—C*(CH_3)=*CH—*CH_2—CH_3

1. Aldéhyde 71 (transposition pinacolique)

On obtient deux isomères *Z* et *E* pour l'aldéhyde **71**; leur configuration a été attribuée par analogie avec les déplacements chimiques des protons des aldéhydes **61**. Les analyses sont effectuées sur des mélanges d'isomères *Z* et *E*.

Le *méthyl-3 phényl-2 hexène-2 al (71b)*, *isomère* Z; ir: 1665 cm^{-1}; rmn δ(ppm): 10.25 (s, H1), 1.80 (s, Me 3), 2.73 (t, *J* = 7 Hz, H4), 1.65 (H5), 1.02 (t, *J* = 7 Hz, H6). *Isomère* E; ir: 1670 cm^{-1}; rmn δ(ppm): 10.25 (s, H1), 2.30 (s, Me 3), 2.10 (t, *J* = 7 Hz, H4), 1.50 (H5), 0.80 (t, *J* = 7 Hz, H6). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 83.10, H 8.48.

Le *méthyl-3 paratolyl-2 hexène-2 al (71c)*, *isomère* Z; ir: 1660 cm^{-1}; rmn δ(ppm): 10.25 (s, H1), 1.81 (s, Me 3), 2.80 (t, *J* = 7 Hz, H4), 1.66 (H5), 1.03 (t, *J* = 7 Hz, H6). *Isomère* E; ir: 1660 cm^{-1}; rmn δ(ppm): 10.25 (s, H1), 2.28 (s, Me 3), 2.13 (t, *J* = 7 Hz, H4), 1.50 (H5), 0.82 (t, *J* = 7 Hz, H6). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.33, H 8.81.

2. Cétones 72E et 72' trans *(cétones du type* B*)*

La *méthyl-4 phényl-6 hexène-4 one-3 (72b)*, ir: 1670 cm^{-1}; rmn δ(ppm): 1.08 (H1), 2.52 (H2), 1.90 (Me 4), 6.75 (tq, *J* = 7 et 1.2 Hz, H5), 3.53 (d, H6). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 82.80, H 8.61.

La *méthyl-4 phényl-6 hexène-5 one-3 (72'b)*, ir: 1715 cm^{-1}; rmn δ(ppm): 1.03 (H1), 2.54 (H2), 3.35 (H4), 1.23 (d, Me 4), 6.12 (dd, *J* = 16 et 7 Hz, H5), 6.55 (d, *J* = 16 Hz, H6). *Anal.* calc. pour $C_{13}H_{16}O$: C 82.93, H 8.57; trouvé: C 83.07, H 8.69.

La *méthyl-4 paratolyl-6 hexène-4 one-3 (72c)*, ir: 1665 cm^{-1}; rmn δ(ppm): 1.08 (H1), 2.53 (H2), 1.91 (Me 4), 6.75 (tq, *J* = 7 et 1.2 Hz, H5), 3.53 (d, H6). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 82.95, H 8.83.

La *méthyl-4 paratolyl-6 hexène-5 one-3 (72'c)*, ir: 1710 cm^{-1}; rmn δ(ppm): 1.05 (H1), 2.57 (H2), 3.36 (H4), 1.26 (Me 4), 6.10 (dd, *J* = 16 et 7 Hz, H5), 6.55 (d, *J* = 16 Hz, H6). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.20, H 8.78.

3. Dihydro-2,5 furanne (73)

L'*éthyl-5 méthyl-4 phényl-2 dihydro-2,5 furanne (73b)*, rmn δ(ppm): 5.5–5.8 (H2, H3), 1.71 (Me 4), 4.75 (H5), 1.51 et 0.95 (50% *cis*, CH_2CH_3) et 1.63 et 0.97 (50% *trans*, CH_2CH_3).

L'*éthyl-5 méthyl-4 paratolyl-2 dihydro-2,5 furanne (73c)*, rmn δ(ppm): 5.4–5.8 (H2, H3), 1.71 (Me 4), 4.75 (H5), 1.48 et 0.95 (CH_2CH_3, 50% *cis*) et 1.60 et 0.97 (CH_2CH_3, 50% *trans*). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.25, H 8.76.

4. Naphtalènes (74) (22, 23)

L'*éthyl-1 méthyl-2 naphtalène (74b)* et l'*éthyl-1 diméthyl-2,7 naphtalène (74c)*

III. Déshydratation du paratolyl-1 éthyl-3 penténe-3 diol-1,2 (8c)

Nous avons d'abord préparé le *trans*-éthyl-2 butène-2-al par crotonisation de l'éthanal et du butanal par la soude normale.

Dans un ballon de 2 L à 0°C muni d'un agitateur rodé, d'un réfrigérant, d'un thermomètre et d'une ampoule à brome, on met 520 cm^3 de NaOH (*N*). On verse par l'ampoule les deux aldéhydes (10 mol de butanal et 10 mol d'éthanal fraîchement distillés) préalablement refroidis vers −30°C.

La réaction est exothermique et il faut maintenir la température du ballon au dessous de 40°C.

Lorsque la température redescend vers 20°C, on arrête l'agitation, décante, extrait à l'éther et lave à l'eau jusqu'à neutralité. On sèche, on sépare par distillation une fraction de 400 g (pé 110–150°C/1 Torr) que l'on redistille à la colonne à bande tournante, pour séparer le *trans* éthyl-2 butène-2-al (300 g pur, pé 135°C/1 Torr); rmn δ(ppm): 0.96 (t, Me) et 2 (d, Me), 2.20 (CH_2), 6.6 (CH=C), 9.41 (s, $CH_{(ald)}$).

Le diol **8***c* a été obtenu par réduction du *trans*-éthyl-2 butène-2-al avec le paratolylaldéhyde par la poudre de zinc et l'acide acétique.

Par déshydratation, on obtient l'*éthyl-3 paratolyl-2 pentène-2 al (81c)*, ir: 1685 cm^{-1}; rmn δ(ppm): 10.2 (s, H1), 1.96 et 2.66 (CH_2), 0.96 et 1.20 (Me). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.24, H 8.74.

E-*éthyl-3 paratolyl-5 pentène-3 one-2 (82c)*, ir: 1665 et 1630 cm^{-1}; rmn δ(ppm): 2.23 (s, H1), 6.68 (tt, *J* = 7 et 1.3 Hz, H4), 3.51 (d, *J* = 7 Hz, H5), 2.25 et 0.93 (CH_2CH_3). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.29, H 8.85.

L'*éthyl-3 paratolyl-5 pentène-4 one-2 (82'c)*, ir: 1705 et 1630 cm^{-1}; rmn δ(ppm): 2.13 (s, H1), 3.06 (q, H3), 5.96 (dd, *J* = 16 et 7 Hz, H4), 6.49 (d, H5), 1.6 et 0.85 (CH_2CH_3). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.09, H 9.03.

L'*éthyl-3 méthyl-2 paratolyl-5 dihydro-2,5 furanne (83c)*, rmn δ(ppm): 4.83 (H2), 5.3 à 5.7 (H4, H5), 1.25 (d, Me 2, *cis*), 1.31 (d, Me 2, *trans*), 2.0 et 1.05 (CH_2CH_3). *Anal.* calc. pour $C_{14}H_{18}O$: C 83.12, H 8.97; trouvé: C 83.32, H 8.84.

L'*éthyl-2 diméthyl-1,7 naphtalène (84c)*. Il ne constitue qu'une trace détectable par cpv et identifié par rmn après enrichissement par comparaison avec les produits décrits (20, 21).

IV. Déshydratation de l'éthyl-5 nonène-5 diol-3,4 (9e)

Par réduction des deux aldéhydes, acroléine et éthyl-2 hexène-2 al, nous avons obtenu l'*éthyl-5 nonadiène-1,5 diol-3,4* (18), pé 132°C/0.01 Torr. Nous avons réalisé une semi-hydrogénation de ce diol en présence de Ni de Raney pour obtenir ainsi l'*éthyl-5 nonène-5 diol-3,4* (**9***e*, pé 128°C/0.007 Torr). La déshydratation de ce diol conduit aux produits suivants.

1. Produits de transposition pinacolique

Le *diéthyl-2,3 heptène-2 al (91e)*, 5%, détectable sur cpv et identifié (après enrichissement) par ir et rmn (δ: 9.3 (s, CHO))ppm.

L'*éthyl-5 nonène-4 one-2 (96e)*, ir: 1680 cm^{-1}; rmn δ(ppm): 2.40 (q, H2), 5.98 (t, *J* = 1.2 Hz, H4).

L'*éthyl-5 nonène-5 one-3 (96'e)* E, ir: 1715 cm^{-1}; rmn δ(ppm): 2.5 (q, *J* = 6.5 Hz, $CH_2$2), 3.03 (s, $CH_2$4), 6.55 (t, *J* = 7 Hz, H6).

La configuration *E* de cet isomère est démontrée par la règle d'additivité des déplacements chimiques (21), δ H6 (E_{calc}) = 6.55; δ H6 (Z_{calc}) = 6.26 ppm.

2. Cétones du type B

L'*éthyl-5 nonène-5 one-4 (92e)* E (attribution par analogie avec la cétone **62***e*), ir: 1670 cm^{-1}; rmn δ(ppm): 6.4 (tt, *J* = 7 et 1.2 Hz, H6).

L'*éthyl-5 nonène-6 one-4, (92'e)*, isomère *E* prédominant, ir: 1710 cm^{-1}; rmn δ(ppm): 2.42 (t, *J* = 7 Hz, $CH_2$3), 2.83 (q, *J* = 7 Hz, H5), 5.26 (2d, H6), et 5.63 (2t, H7): partie AB d'un système $ABMX_2$ analysable à 80 MHz, *J* (H6, H7) = 16 Hz; ^{13}C rmn: 11.74(CH_3), 13.83(2CH_3), 17.20($CH_2$2), 24.39(CH_2, Et), 25.67 (CH_2 8), 43.42 (CH_2 3), 58.44 (CH 5), 127.26 (CH 7), 135.90 (CH 6), 212 (CO 4) ppm.

NORMAN H. SAGERT and WOON LEE. Can. J. Chem. **58**, 1463 (1980).

The distribution of the four lower trialkylphosphates, triethyl, trimethyl, tripropyl, and tributylphosphates, between dodecane and water has been measured as a function of temperature between 293.15 K and 313.15 K, and as a function of trialkylphosphate concentration at concentrations below 0.1 mol/dm^3. From these results, the thermodynamic functions associated with the transfer of each of these trialkylphosphates from water to dodecane were calculated. With the exception of trimethylphosphate, free energies of transfer changed by −3.5 kJ/mol for each methylene group added to the solute. The enthalpies of transfer for all the trialkylphosphates were in the range of 26 to 30 kJ/mol, so that most of the differences in the free energies of transfer arise from entropic differences.

Dimerization constants for the trialkylphosphates in dodecane were consistent with those available in the literature.

NORMAN H. SAGERT et WOON LEE. Can. J. Chem. **58**, 1463 (1980).

On a mesuré la distribution des 4 trialkylphosphates inférieurs, triéthyl-, triméthyl-, tripropyl- et tributylphosphates, entre le dodécane et l'eau, en fonction de la température entre 293.15 et 313.15 K et en fonction de la concentration de trialkylphosphate pour des concentrations inférieurs à 0.1 mol/dm^3. A partir de ces résultats, on a calculé les fonctions thermodynamiques associées au transfert de chacun de ces trialkylphosphates de l'eau au docécane. A l'exception du cas du triméthylphosphate, l'addition d'un groupe méthylénique au soluté provoque une variation de −3.5 kJ/mol dans l'énergie libre de transfert. Les enthalpies de transfert de tous les trialkylphosphates sont de l'ordre de 26 à 30 kJ/mol de telle sorte que la plupart des différences des énergies libres de transfert proviennent de différences entropiques.

Les constantes de dimérisation des trialkylphosphates dans le dodécane sont en accord avec celles rapportées dans la littérature.

[Traduit par le journal]

Introduction

Tributylphosphate has been widely used in extraction processes for separating the components of irradiated nuclear fuel (1). As part of a program to study the interfacial properties relevant to such solvent extraction systems, we have studied the adsorption of trimethylphosphate (TMP), triethylphosphate (TEP), tripropylphosphate (TPP), and tributylphosphate (TBP) (2) at the dodecane–water interface. In order to interpret these adsorption results, it is necessary to have a good thermodynamic description of the process in which solute is transferred from the aqueous phase to the organic phase. The thermodynamics of this transfer process may then be compared with the thermodynamics of adsorption from the organic phase or from the aqueous phase to the interface.

Unfortunately, good thermodynamic descriptions of the transfer processes are not available. Distribution ratios for TBP and TPP are known at room temperature (3, 4). If the enthalpies of solution of these solutes in both dodecane and water were known, complete thermodynamic descriptions of the transfer processes could be obtained. However, the enthalpy of solution of TBP in water has not been measured because TBP is not very soluble in water (5, 6). Enthalpies of solution of TBP have been measured in hexane and dodecane (7) and enthalpies of solution of TPP are available for water (6), and *i*-octane (8). The distribution ratios of TEP and TMP between water and dodecane have not been measured. For both solutes good calorimetric data on enthalpies of solution in water (5) are available but little is known about their enthalpies of solution in alkanes. The only data available are for TEP in *i*-octane (8).

It therefore seemed appropriate to make a complete study of the distribution ratios of the four lower trialkylphosphates at solute concentrations low enough that the ratios can be extrapolated to infinite dilution with some confidence. Free energies of transfer can then be calculated, and from their variation with temperature, enthalpies and entropies of transfer can be calculated, albeit with less precision than from direct calorimetric measurements.

Although the primary purpose of this work is to examine the thermodynamics of transfer, an analysis of the data should give some information on the state of aggregation of trialkylphosphates in the dodecane.

Experimental

Vials containing 5.0 cm^3 dodecane, 5.0 cm^3 water, and varying amounts of one of the trialkylphosphates were prepared as previously described (2) and were shaken for at least 40 h in a thermostatted water bath. Temperatures of the water bath were

controlled to ±0.1 K. Samples were withdrawn for analysis while keeping the vials thermostatted. Analyses were done by gas chromatography on a Varian model 1800 gas chromatograph fitted with hydrogen flame detectors and on-column injectors. The sample size was 1 mm³. For TEP analyses a 2 m × 3 mm column of 80–100 mesh Poropak P was used at 493 K. For analyses of the other trialkylphosphates, a 3 m × 3 mm column of 3% nitrile silicone gum XE50 on Chromosorb G was used at 493 K.

The sources and purification of dodecane and water have been described (2). The TMP, TEP, and TPP were purchased from Aldrich, and the source and preliminary purification of TBP have been described (2). The trialkylphosphates were further purified by distillation at reduced pressure using a spinning band distillation column. They were stored over activated molecular sieve 4A.

Results and Discussion

Distribution ratios were measured at 293.15 K, 298.15 K, 303.15 K, 308.15 K, and 313.15 K for TMP, TEP, TPP, and TBP distribution between dodecane and water. The TEP and TMP concentration ranges were 0 to 0.1 mol/dm³ in the aqueous phases and TPP and TBP concentration ranges were 0 to 0.1 mol/dm³ in the dodecane. Results[2] for TEP are shown in Fig. 1, where the distribution ratio, D, is defined as (molarity of TEP in the dodecane)/(molarity of TEP in the water). Consideration of the chromatographic techniques used would allow error estimates of ±2% at higher concentrations rising to ±10% at lower concentrations for values of D. The distribution ratios increase very slightly with increasing TEP concentration in the water, but can easily be extrapolated back to zero molarity to give the distribution coefficient K_D.

Table 1 lists all the measured distribution coefficients, K_D, and these are valid to within ±5%. Table 1 also includes mole fraction distribution coefficients K_D^X since it is usual to express results in terms of mole fractions and to employ mole fraction standard states for calculations involving thermodynamics of transfer (9, 10, 11). These have the advantage that the reference base is temperature independent so that enthalpies are equivalent to those measured calorimetrically (12). Since K_D and K_D^X refer to infinite dilution conditions, they are related by eq. [1]

$$[1] \quad K_D^X/K_D = V^{0,\beta}/V^{0,\alpha}$$

where $V^{0,\alpha}$ and $V^{0,\beta}$ are the molar volumes of water and dodecane respectively.

Following Aveyard and Mitchell (9), the standard free energies of transfer of the trialkylphosphates from water to dodecane can be calculated

[2]All the measured distribution ratios are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

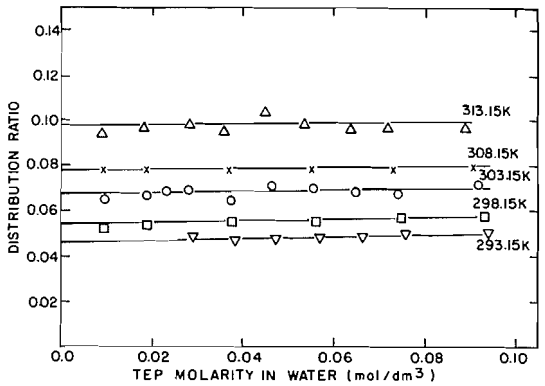

FIG. 1. Distribution ratios, D, for TEP plotted against TEP molarity in the aqueous phase at the five indicated temperatures.

from the value of K_D^X. If the trialkylphosphate is designated as component 1, the aqueous phase called the α phase, and the dodecane phase the β phase, then chemical potentials of solute 1 in the two phases are given by [2] and [3],

$$[2] \quad \mu_1^{\alpha} = \mu_1^{\theta,\alpha} + RT \ln f_1^{\alpha} X_1^{\alpha}$$

$$[3] \quad \mu_1^{\beta} = \mu_1^{\theta,\beta} + RT \ln f_1^{\beta} X_1^{\beta}$$

in which $\mu_1^{\theta,\alpha}$ and $\mu_1^{\theta,\beta}$ are the standard chemical potentials, f_1^{α} and f_1^{β} are the activity coefficients, and X_1^{α} and X_1^{β} are the mole fractions of 1 in the α and β phase respectively. The activity coefficients are chosen to become unity as the mole fractions approach zero. Thus, at infinite dilution, the standard free energy of transfer from water to dodecane is given by eq. [4],

$$[4] \quad \mu_1^{\theta,\beta} - \mu_1^{\theta,\alpha} = \Delta_{\alpha}^{\beta}\bar{G}_1^{\theta} = -RT \ln K_D^X$$

provided the standard state is chosen to be the hypothetical standard state of unit solute mole fraction with unit activity coefficient.

The standard enthalpy of transfer may then be calculated from the temperature variation of the standard free energy of transfer using eq. [5].

$$[5] \quad \Delta_{\alpha}^{\beta}\bar{H}_1^{\theta} = \partial(\Delta_{\alpha}^{\beta}\bar{G}_1^{\theta}/T)/\partial(1/T)$$

Figure 2 shows a plot of $\Delta_{\alpha}^{\beta}\bar{G}_1^{\theta}/T$ against $1/T$ for the solute TEP. Over the small range of temperature investigated, a reasonably linear relationship is obtained, indicating a constant enthalpy of transfer over this range. Values for the standard entropies of transfer may then be calculated easily, and Table 2 lists all the free energies, enthalpies, and entropies of transfer for the four solutes studied. The errors in the enthalpies are at least ± 1 kJ/mol from random deviations and may be as high as ±2 kJ/mol if undetected systematic deviations occur.

As has been noted for many other systems (9, 10), the standard free energies of transfer for these

TBP	−20.0±0.9	26.8±1.2	157.2±4.7

trialkylphosphates are a linear function of the number of methylene groups in the molecule. The free energies are shown in Fig. 3 as a function of the number of carbon atoms in the solute. Also shown is the result for TPP in *n*-hexane at 298.15 K given by Dyrssen and Petković (4) as well as the value for TBP in dodecane given by Marcus (3). The results

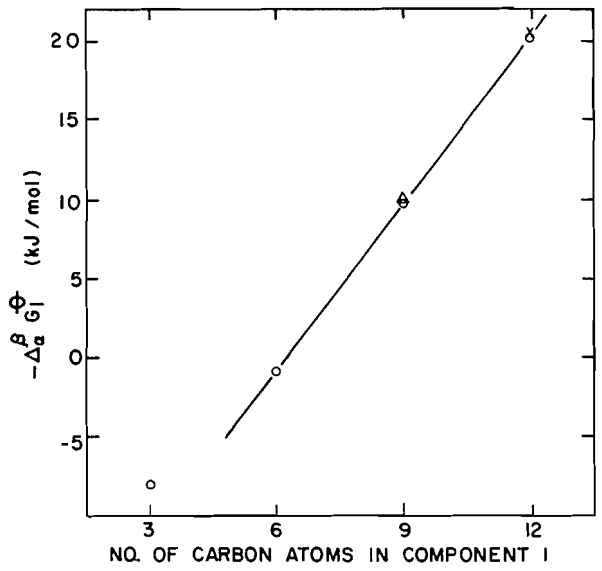

FIG. 3. Variation of standard free energy of transfer with number of carbon atoms in trialkylphosphate solute. The circles (O) refer to this work, the triangle (Δ) to ref. 4, and the cross (×) to ref. 3. The line has a slope of 3.5 kJ/mol per CH_2 unit.

of Aveyard and Mitchell (9) show that, for alcohols at least, the chain length of the hydrocarbon used as the organic phase does not greatly affect the standard free energies of transfer. Our results, when compared to those of Dyrssen and Petković (4), suggest that this is the case for the trialkylphosphates as well.

The solid line in Fig. 3 has a slope corresponding to −3.5 kJ/mol per CH_2 group. This value is almost in the middle of the range, −3.56 ± 0.1 kJ/mol per CH_2 group, quoted by Tanford (11) as expected for transfer of a large variety of organic solutes from water to hydrocarbons. The constancy of this value is one of the bases for the postulate of the "hydrophobic effect" (10). The standard free energy of transfer of TMP is not on the line, but it is reasonable to expect the addition of the first methylene group to the chains to be somewhat anomalous (13).

In contrast to the standard free energies of transfer, the standard enthalpies of transfer do not show a large variation with chain length, although there appears to be some lowering with increased chain length. Similar behaviour has been observed for alcohols (14). Thus the changes in the standard free energies of transfer result largely from changes in the standard entropies of transfer (Table 2). The enthalpies of solution are very large and negative, implying a distinct enthalpic preference for the water phase. Since these are much larger than the enthalpies of transfer of the pure hydrocarbons from water to hydrocarbons (10), the phosphate group is probably responsible for most of the enthalpic effects. A similar suggestion has been made for the OH groups in alcohols (9).

For some solutes, our standard enthalpies of transfer may be compared with direct calorimetric measurements, since the enthalpy of transfer from water to hydrocarbon will be equal to the enthalpy of solution in the hydrocarbon minus that in the water (8, 14). Kertes *et al.* (7) give 7.4 kJ/mol and 7.2 kJ/mol for the enthalpies of solution of TBP in dodecane and hexane respectively, and Rytting *et al.* (8) give 7.6 and 10.8 kJ/mol for the enthalpies of solution of TPP and TEP respectively in *i*-octane. Kertes and Tsimering (5) found enthalpies of solution in water to be −21.2 and −25.2 kJ/mol for TMP and TEP respectively, while, earlier, Lindenbaum *et al.* (6) had found enthalpies of solution in water of −21.1 and −22.6 kJ/mol for TEP and TPP. Thus, if the enthalpies of solution in *i*-octane can be taken as applicable to dodecane, then from Kertes *et al.* the enthalpy of transfer should be 35.9 kJ/mol for TEP whereas, from Lindenbaum *et al.*, it should be 32.0 kJ/mol for TEP and 30.3 kJ for TPP. Our results, which are 29.5 kJ/mol for TEP and 26.6 kJ/mol for TPP are rather lower than these calorimetric results.

A number of reasons may be considered for our lower results. First of all, strictly speaking the systems are not the same since our experiments measure the thermodynamics of transfer from mutually saturated phases, whereas the calorimetric experiments measured the thermodynamics of solution into pure solvents. It is unlikely that the small solubility of dodecane in water is very important. However, water solubility in dodecane is known to be altered by TBP, with one mole of TBP carrying along one mole of water into the organic phase (3). A loose complex has been proposed (3, 15). Thus water solubility in the dodecane could well result in lower enthalpies of transfer, which perhaps may be more accurately thought of as enthalpies of transfer for trialkylphosphate–water complexes. Secondly, we have used enthalpies of solution in *i*-octane because none were available for dodecane, although the differences should be small. Thirdly, for the calorimetry, agreement between reputable workers is none too good and is outside estimated error limits. Thus, if error limits, including our own, are much larger than estimated, much of the disagreement may be illusory.

There do not seem to be any reliable data on enthalpies of solution of TMP in dodecane, probably because of the low limiting solubility. However, if an enthalpy of solution of about 12 kJ/mol is inferred from the TEP and TPP data, then the enthalpies of solution measured by Kertes *et al.* (5) and Lindenbaum *et al.* (6) yield enthalpies of transfer of 34 kJ/mol and 24 kJ/mol respectively. Our value of 29.0 is thus exactly midway between these estimates. If our results really are expected to be lower than the calorimetric results as outlined in the above paragraph, our value of 29.0 kJ/mol for an enthalpy of transfer supports the higher estimate of the enthalpy of solution obtained by Kertes and Tsimering (5). No calorimetric data on the enthalpies of solution of TBP in water are available because of the low solubility of TBP in water (5, 16).

Generally one would expect some finite change in heat capacity to be associated with the transfer of these trialkylphosphates (10). However, with the large experimental error and the small temperature range examined, it is perhaps not surprising that there is no curvature in the plot of $\Delta_{\alpha}^{\beta}\bar{G}^{\theta}/T$ against $1/T$ (Fig. 2), and thus no observable change in heat capacity.

Finally, we would like to see if our data can be used to say anything about the aggregation of trialkylphosphate molecules in dodecane. In principle, the slopes of the lines in Fig. 1 can be used to determine the extent of association in the dodecane. Following Woolley *et al.* (12), the general association reaction is written as eq. [6]

$$[6] \quad nP \overset{K_n}{\rightleftharpoons} P_n$$

if monomer is the predominant species in the aqueous phase. The distribution ratio D has been defined as the total trialkylphosphate molarity in the dodecane divided by that in the aqueous phase. This quantity D is the ratio plotted in Fig. 1. The distribution coefficient K_D is defined at infinite dilution and thus represents the ratio of trialkylphosphate monomers in the dodecane to trialkylphosphate in the aqueous phase.

Dimers are thought to be the predominant associated trialkylphosphate species in alkane solvents, and it is not usually necessary to consider

higher degrees of association (4, 8, 17). Thus, from eq. [6] we obtain eq. [7]

$$[7] \quad D = K_D + 2K_2K_D^2[\mathrm{TAP}]_{aq}.$$

where K_2 is, of course, the equilibrium constant for dimerization as given in eq. [6]. Our experiments were not planned for the purpose of obtaining K_2 and were limited to low concentrations. For the two lower trialkylphosphates with low K_D's, our slopes in plots like Fig. 1 are not significantly different from zero. This is consistent with a K_2 of 0.7 for TEP in hexane as observed by Petković (17) since any observable slope in our plots would imply a very much higher value for K_2.

The situation is somewhat better for TPP and TBP. Here, for TPP we obtain an estimate for K_2 of 1.3 at 294.15 K and 1.5 at 298.15 K. This can be compared with 1.2 at 295.15 K in hexane as measured by Dyrssen and Petković (4) using solvent extraction techniques. Similarly, for TBP, we obtain 2.0 to be compared with 2.9 by Petković (18) in hexane and 2.6 and 2.5 by the same author (17) in dodecane and cyclohexane respectively. In view of the small concentration range used in this work, all that can be said is that our dimerization constants are not inconsistent with those found in the literature.

Thermodynamics of molecular interactions between nitromethane and aromatic hydrocarbons

RAM K. NIGAM,[1] PREM P. SINGH,[1] RUCHI MISHRA, AND MOHAN SINGH
Department of Chemistry, Maharshi Dayanand University, Rohtak- 124001, Haryana, India
Received March 26, 1979[2]

RAM K. NIGAM, PREM P. SINGH, RUCHI MISHRA, and MOHAN SINGH. Can. J. Chem. 58, 1468 (1980).

Excess volumes of mixing V^E, excess enthalpies H^E, and excess Gibbs free energies of mixing G^E, of binary mixtures of nitromethane with aromatic hydrocarbons have been measured at 303.15 and 313.15 K. The V^E, H^E, and G^E data, which are positive throughout the entire range of concentrations, have been examined with Winnick's theory. The calculated V^E, H^E, and G^E values compare reasonably well with the corresponding experimental values. The theory also correctly predicts the influence of temperature on these excess functions.

RAM K. NIGAM, PREM P. SINGH, RUCHI MISHRA et MOHAN SINGH. Can. J. Chem. 58, 1468 (1980).

On a mesuré à 303.15 et à 313.15 K les volumes de mélange en excès, V^E, les enthalpies en excès, H^E, et les énergies libres de Gibbs de mélange en excès, G^E, de mélanges binaires formés de nitrométhane et d'hydrocarbures aromatiques. On a examiné à l'aide de la théorie de Winnick les données de V^E, H^E et G^E qui ont des valeurs positives dans tout l'intervalle de concentration utilisée. Les valeurs calculées de V^E, H^E et G^E se comparent raisonnablement bien aux valeurs expérimentales. La théorie prédit également d'une façon précise l'influence de la température sur ces fonctions d'excès.

[Traduit par le journal]

Introduction

Renon *et al.* (1), following Prigogine (2), have proposed a semi-empirical partition function for simple liquids based on a three parameter theory of corresponding states. Winnick and Prausnitz (3) have recently extended this partition function to mixtures using Scott's two fluid theory (4) and have tested the resulting expressions for the excess thermodynamic functions against the corresponding experimental data for some polar–polar and polar–non-polar mixtures. It would, therefore, be interesting to see if the V^E, H^E, and G^E data of the binary mixtures of nitromethane with aromatic hydrocarbons can aptly be described by this theory.

Experimental

Analytical grade benzene, toluene, *o*-, *m*-, and *p*-xylenes were purified as described earlier (5) while nitromethane (B.D.H., A.R. Grade) was purified as suggested by Saunders and Spaull (6). The purity of the final samples was checked by measuring their density at 298.15 ± 0.01 K which agreed to within ±0.00005 g/cm³ with the corresponding literature values (refs. 7–10, ref. 28, p. 165).

Excess volumes of mixing were measured as a function of composition using the direct dilatometric method (11). The temperature of the thermostatic bath was controlled to ±0.01 K. The uncertainty in experimental V^E values is about 0.5%.

Heats of mixing measurements were made in an adiabatic calorimeter which has been described elsewhere (12). The time was recorded by an electronic timer (type 701 SR.No.010, Systronic, Ahmedabad, India) which could read to ±0.0001 s. The temperature variations of the thermostatic bath were found to be within ±0.01 K. The uncertainty in H^E values is about 1.1%.

Vapour pressures of these mixtures were determined by a static method described previously (13). The apparatus was placed in a water thermostat which in turn was placed in another water thermostat. The temperature of the outer thermostat was controlled to ±0.01 K and the temperature drift in the inner thermostat was found to be less than ±0.003 K. The mercury heights in the manometer were read by a cathetometer which could read to ±0.001 cm. All vapour pressure measurements were reproducible to better than ±0.02 Torr.

Our measured vapour pressures of aromatic hydrocarbons and nitromethane at 303.15 K compare to within 0.3% with that obtained from the corresponding data (refs. 14–17, ref. 28, pp. 143, 577) reported for these compounds at various temperatures.

Results

The experimental V^E, H^E, and G^E data for binary mixtures of nitromethane with benzene, toluene, *o*-xylene, *p*-xylene, and *m*-xylene at 303.15 and 313.15 K as function of composition are recorded in Tables 1 to 3.[3]

V^E data were fitted to the equation

$$[1]\quad V^E/x_1(1-x_1)\ \text{cm}^3\ \text{mol}^{-1} = [V_0 + V_1(2x_1 - 1) + V_2(2x_1 - 1)^2]$$

while H^E data were fitted to the equation

$$[2]\quad H^E/x_1(1-x_1)\ \text{J mol}^{-1} = [h_0 + h_1(2x_1 - 1) + h_2(2x_1 - 1)^2]$$

where V_0, V_1, V_2, h_0, h_1, and h_2 are adjustable parameters of [1] and [2] respectively and x_1 is the mole fraction of nitromethane. These parameters were evaluated by fitting $V^E/x_1(1 - x_1)$ and $H^E/x_1(1 - x_1)$ to [1] and [2] respectively by the method of least squares and are recorded along

with the standard deviations, $\sigma(V^E)$ and $\sigma(H^E)$, of the molar excess volumes and molar excess enthalpies respectively in Table 1.

The vapour pressure data for these mixtures at 303.15 and 313.15 K were used to evaluate the molar excess Gibbs free energies of mixing, G^E, by Barker's method (18). The form of the function used for G^E, following Redlich and Kister (19), is

$$[3] \quad G^E/RT = x_1(1 - x_1)[G_0 + G_1(2x_1 - 1) + G_2(2x_1 - 1)^2]$$

where G_0, G_1, and G_2 are adjustable parameters. These parameters are recorded in Table 1. All calculations were made on an I.B.M. 1620 computer. The second virial coefficient of benzene was taken from literature (20) while those for nitromethane, toluene, *o*-xylene, *p*-xylene, and *m*-xylene were calculated from Berthelot's equation (21); the necessary critical constant data were taken from the literature (22).

Discussion

Suri (23) has determined the V^E values for benzene + nitromethane mixtures at 298.15 and 303.15 K. While our V^E values at 303.15 K for this mixture are more positive in the concentration range $0 < x_1 < 0.53$ (the values differ by as much as 0.035 cm^3 mol^{-1} at $x_1 = 0.3$), they are more negative (maximum difference being 0.025 cm^3 mol^{-1} at $x_1 = 0.7$) in the rest of the nitromethane concentration range. Again Brown and Fock (24) have determined the H^E values of benzene + nitromethane mixtures at 318.15 K. Assuming that H^E varies linearly with temperature in the temperature range 303.15–318.15 K, our H^E values at 318.15 K agree to within ±10 J mol^{-1} with those reported by Brown and Fock (24). The same, however, is not true of the G^E data reported (25) for this mixture at 318.15 K (our extrapolated G^E values at 318.15 K are more negative by as much as 250 J mol^{-1} at $x_1 = 0.6$ from those reported by Brown and Smith (25)). We are unaware of any V^E, H^E, and G^E data at 303.15 or 313.15 K with which to compare our results for the remaining binary mixtures. The H^E values for the various mixtures as evaluated from the corresponding G^E values did not agree with the corresponding experimental H^E values. This is consistent with the earlier observation (21, 26) regarding the evaluation of H^E data from the corresponding G^E data. Further V^E, H^E, and G^E values

are positive throughout the entire concentration range for all the mixtures studied here. Again while V^E data vary in the order

toluene < benzene < *p*-xylene < *o*-xylene < *m*-xylene

H^E and G^E data follow the sequence

benzene < toluene < *p*-xylene < *m*-xylene ≈ *o*-xylene

At the simplest qualitative level the V^E data can be explained if it is assumed that these mixtures are characterised by (*a*) steric repulsion and (*b*) dipole – induced dipole interactions between the components of these mixtures. Such a scheme of molecular interactions would suggest that, compared to benzene, the electron-rich end of the toluene moiety would interact strongly with electron deficient $-CH_3$ end of the nitromethane moiety so that V^E values for nitromethane + toluene mixtures should be less positive than that for nitromethane + benzene mixtures. The experimental V^E data support this conjecture. For nitromethane + xylene mixtures the dipole – induced dipole interactions would be of the same order of magnitude as that for nitromethane + toluene mixtures but the steric repulsion between nitromethane on the one hand and the two bulky CH_3 substituents in xylenes on the other would increase considerably. This would require that the V^E values for xylenes + nitromethane mixtures should be more positive than that for benzene + nitromethane mixtures. The experimental V^E data lend further support to this conjecture. Further within the xylenes the steric repulsion between the nitromethane and xylenes would vary in the order

p-xylene < *o*-xylene < *m*-xylene

so that V^E values for *p*-xylene + nitromethane mixtures should be less positive than that for *o*-xylene + nitromethane or *m*-xylene + nitromethane mixtures. This has, in fact, been observed.

The enthalpic effect on the other hand is the cumulative sum of the contribution due to interactions (*a*) (which are always endothermic) and (*b*) (which are exothermic) mentioned above. Our H^E data suggest that the contribution due to the factor (*a*) always outweighs those due to factor (*b*) for the mixtures studied here so that the H^E values should vary in the order

benzene < toluene < *p*-xylene < *m*-xylene < *o*-xylene

The present study thus suggests that binary mixtures of nitromethane with aromatic hydrocarbons are characterised by dipole – induced dipole interactions and that steric repulsion also plays an important part.

We next examined our V^E, H^E, and G^E data for Winnick theory (26). Based on a configurational partition function (27) of a pure liquid suggested by cell theory, Winnick (26) expressed the configurational partition function for a polar–non-polar mixture of mole fraction x_1 by the expression

$$[4]\quad Q_m = \frac{\prod_{i=1}^{2} \{[V_{im}^*(\tilde{V}_{im}^{1/3} - 1)^{3C_i} J(\tilde{T}_{im})]^{N_i} \exp(-x_i E_{im}/kT)\}}{N_i!}$$

where

$$[5]\quad E_{im} = -[(U_{im}^*/\tilde{V}_{im}) + M_{im}]$$

$$[6]\quad M_{im} = \sum_{i=1}^{2} p_j M_{ij}$$

$$[7]\quad M_{ij} = m_{im}'\mu_1^2\left(\frac{\varepsilon - 1}{\varepsilon + 2}\right) V_2^*/(V_{12}^*)^2$$

and

$$[8]\quad V_{12}^* = N_A\xi[\tfrac{1}{2}(\sigma_{1m} + \sigma_{2m})^3]$$

All the quantities in eqs. [4] to [8] have the same significance as suggested by Winnick and Prausnitz (3, 26). V^E, G^E, and H^E, according to this theory, were calculated from the following expressions

$$[9]\quad V^E = V_m - \sum_{i=1}^{2} x_i V_i = \sum_{i=1}^{2} (x_i \tilde{V}_{im} V_{im}^*) - \sum_{i=1}^{2} x_i V_i$$

$$[10]\quad A^E \approx G^E = A_m - \sum_{i=1}^{2} x_i A_i - RT \sum_{i=1}^{2} x_i \ln x_i$$

and

$$[11]\quad U^E \approx H^E = U_m - \sum_{i=1}^{2} x_i U_i$$

with

$$[12]\quad U_{mi} = RT^2 \ln Q_{mi}$$

and

$$[13]\quad A_{mi} = -kT \ln Q_{mi}$$

$$[14]\quad J(\tilde{T}) = \exp\left[-28.025 \exp\left(-\frac{4.84}{\tilde{T}_i}\right) - \frac{2.320}{\tilde{T}_i} + \zeta\right]$$

In order to evaluate V^E, H^E, and G^E according to the Winnick theory (26), we evaluated the various parameters in the following manner: the reduced

volume of the component i in the mixture was evaluated by solving the expression

[15] $\tilde{V}_{im}^{4/3} = 9.008(\tilde{V}_{im}^{1/3} - 1)/\tilde{T}_{im}$

where

[16] $T_{im}^* = (aU^*)_{im}/(ak)_i RC_i$

while the characteristic volume of the components i in the mixture, V_{im}^*, was evaluated from the equation

[17] $V_{im}^* = N_A \xi \sigma_{im}^3$

where N_A is Avogadro's number, K is a constant having a value of 9.008, and ξ is the packing factor which is assumed to have the same values in pure components and also in mixtures. Further, U_{im}^* and σ_{im} for the component i in the mixture were calculated using the relations

[18] $U_{im}^* = \frac{1}{2} N_A S_{im} E_{im}$

[19] $\sigma_{im} = \Sigma p_j \sigma_{ij}$

where

[20] $$S_{im} = S_i \sigma_{im}^2 \Big/ \sum_{i=1}^{2} p_j \sigma_{jm}^2$$

[21] $$P_j = x_j \sigma_j^d \Big/ \sum_{j=1}^{2} x_i \sigma_{ij}^d$$

[22] $$E_{im} = \sum_{j=1}^{2} p_j (E_{ii} \cdot E_{jj})^{1/2} (1 - K_{ij})$$

[23] $\sigma_{ij} = \frac{1}{2}(\sigma_{ii} + \sigma_{jj})$

and K_{ij} in [22] is a parameter that takes into account the deviation of E_{ij} from the geometric mean of E_{ii} and E_{jj} and for the present investigations has been assumed to be zero. The choice of S_i in eq. [18] is not critical and for the present analysis we have taken $S_1 = 8$ for hydrocarbons and 6 for nitromethane. The parameter m_{12}' which is the only one not predetermined in [7] was assumed to be independent of temperature, and was evaluated in the manner suggested by Winnick (26). Its value is listed in Table 3. All other parameters are given in Table 2 while V^E, H^E, and G^E values for all the binary mixtures studied here at $x_1 = 0.3$, 0.5, and 0.7 are given in Table 3. An examination of Table 3 reveals that the theoretical V^E, H^E, and G^E values compare reasonably well with the corresponding experimental values. The theory also correctly predicts the influence of temperature on these excess thermodynamic functions of these binary mixtures.

Received November 2, 1979

DIMITAR G. KLISSURSKI, IVAN G. MITOV, and TRIFON TOMOV. Can. J. Chem. 58, 1473 (1980).

The kinetics and mechanism of reduction of α-Fe_2O_3 by hydrogen has been studied by a static circulation method in the temperature range 220–350°C. It has been established that the reaction order with respect to the hydrogen pressure is 0.86 ± 0.07 and the activation energy of the process is 17.9 ± 0.7 kcal/mol. The kinetic results and the Mössbauer spectra of specimens reduced to different degrees have shown no accumulation of wüstite phase during the reaction.

DIMITAR G. KLISSURSKI, IVAN G. MITOV et TRIFON TOMOV. Can. J. Chem. 58, 1473 (1980).

On a étudié la cinétique et le mécanisme de la réduction du α-Fe_2O_3 par l'hydrogène par la méthode de circulation statique dans l'intervalle de température 220–350°C. On a établi que l'ordre de la réaction, en fonction de la pression d'hydrogène, est de 0.86 ± 0.07 et que l'énergie d'activation de la réaction est de 17.9 ± 0.7 kcal mol^{-1}. Les résultats cinétiques et les spectres Mössbauer de quelques échantillons réduits à des degrés différents ont montré qu'il n'y a pas d'accumulation de wüstite pendant la réaction.

[Traduit par le journal]

Introduction

The kinetics and mechanism of reduction of α-Fe_2O_3 (hematite) with hydrogen have been the subject of a number of studies (1–9). However, in many cases the effects of internal and external diffusion on the kinetic data have not been eliminated. In addition, there are contradictions in the conclusions on the basic stages of reduction (1, 2, 6–9).

The present paper aimed at studying the reduction of α-Fe_2O_3 at relatively low temperatures using a static-circulation method.

Experimental

The α-Fe_2O_3 used for the kinetic investigations was prepared by thermal decomposition of ferric hydroxide in air at 400°C followed by calcination for 5 h at 800°C. The ferric hydroxide was precipitated at pH 9 from solutions of $Fe(NO_3)_3 \cdot 9H_2O$ and NH_4OH. The specific surface area of the specimen as measured and calculated according to the BET method using low-temperature adsorption of krypton was $0.29\ m^2\ g^{-1}$. The phase identity of the initial α-Fe_2O_3 was confirmed by X-ray phase analysis and Mössbauer spectroscopy. The reduction was carried out with an all-glass static-circulation system (1) which enabled us to make measurements at a constant pressure or at a constant volume of hydrogen. Most of the measurements were carried out at constant pressure of hydrogen during the reduction. In order to establish the conditions under which the results are influenced neither by internal nor by external diffusion, we first studied the effect of the sample grain size and the speed of hydrogen circulation on the rate of reduction. Sample fractions with grain sizes of 0.100–0.125 mm were chosen and used in the kinetic measurements.

Immediately before the measurements the samples were heated for 2 h under vacuum. The water vapour formed during the reduction was frozen by a trap cooled with liquid nitrogen. The amount of hydrogen consumed during the reduction at a constant pressure was measured volumetrically by a mercury-filled gas burette. The rate of reduction R was calculated by graphic differentiation of the kinetic curves. For determination of the reduction rate at different pressures of hydrogen (R^1) the reciprocical time needed for 3% degree of reduction of the samples was also taken.

Results and Discussion

The temperature dependence of the deduction rate is shown in Arrhenius coordinates in Fig. 1. The calculated activation energy of the process was found to be 17.9 ± 0.7 kcal/mol. This value is close to the values obtained by other authors (1, 4). Boreskov (4) and Rostovtsev *et al.* (1) have found the values of 21.0 kcal/mol and 17.7 kcal/mol, respectively.

The dependence of the rate of the reduction process on the hydrogen pressure is shown in Fig. 2. The calculated order of the reduction reaction with respect to the hydrogen pressure was 0.86 ± 0.07. In studies on the initial stage of the reduction of

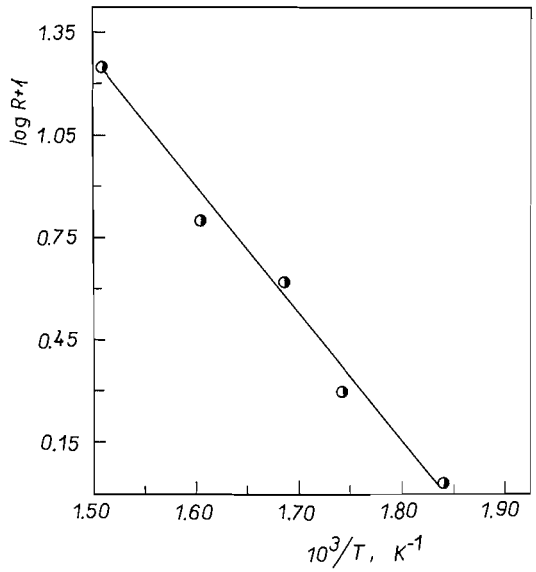

FIG. 1. Temperature dependence of the rate of reduction R, mL H_2/min (NTP); P_{H_2} = 80 Torr; α-Fe_2O_3, 0.200 g.

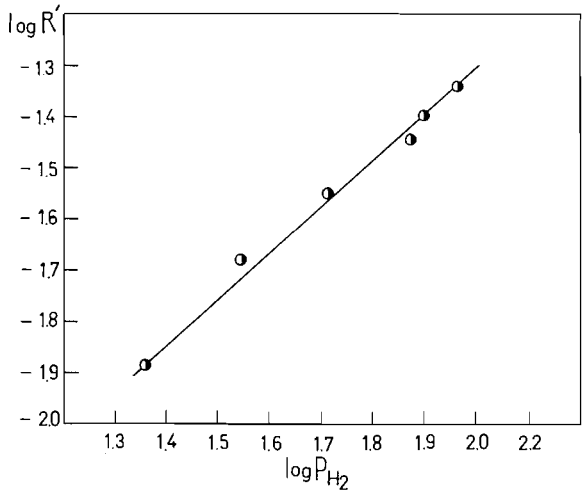

FIG. 2. Dependence of the rate of reduction R^1 on the hydrogen pressure (Torr) ($R^1 = 1/\tau_{0.03}$; where 0.03 is the time for reaching a reduction degree α = 3%); T = 300°C; α-Fe_2O_3, 0.200 g.

α-Fe_2O_3 Boreskov (4) have found a value very close to that established in the present work.

A number of previous studies showed that when α-Fe_2O_3 is reduced to iron, it successively passes into magnetite (Fe_3O_4) and then to wüstite (FeO). As a rule these phase transitions are accompanied by changes in the rate of reduction. The curves of reduction rate vs. reduction degree show characteristic minima at reduction degrees of 11% and 33%, which correspond to the iron/oxygen atomic ratio in magnetite (1:1.33) and wüstite (1:1).

As is evident from Fig. 3, the characteristic minimum for a reduction degree of 11% is clearly expressed under our experimental conditions.

Figure 4 (curve 2) shows the Mössbauer spectrum of an α-Fe_2O_3 sample reduced to 11%. As can be seen, the basic component is magnetite. Traces of α-Fe_2O_3 are also discernible. The spectrum obtained corresponds to non-stoichiometric magnetite ($Fe_{3-v}O_4$). The value of v can be determined from the ratio of the areas of lines A and B (Fig. 4).

According to Topsöe (10):

$$v = \frac{2 - S_B/S_A}{6 + 5(S_B/S_A)}$$

where S_A and S_B are the areas of lines A and B.

For samples of α-Fe_2O_3 reduced to 11% and 33%, v = 0.06 and 0.09, respectively. This enables one to determine the degrees of reduction. The calculated values are 10% and 35%. They are in good agreement with the data for the degrees of reduction calculated on the basis of volumetric measurements.

It is worth noting that at a reduction degree of 33%, there is no pronounced minimum in the curves of reduction rate vs. reduction degree. As was already pointed out, this minimum is associated with the appearance of the wüstite phase. The possibility of wüstite formation with reduction proceeding under our experimental conditions has not been clarified by previous investigations. According to the phase diagram of the iron–oxygen system, wüstite may exist as a stable phase only at temperatures higher than the point of eutectoid transition (570°C). Below this point the wüstite should decompose to magnetite and iron, i.e. the reduction process should take place without formation of wüstite phase. However, as was already pointed out, the available experimental data are very contradictory. Romanov *et al.* (6) have observed the formation of wüstite phase at 520°C whereas Rostovtsev and co-workers (1, 2) described the appearance of wüstite at temperatures of 400°C as well.

Our investigations showed that the Mössbauer spectrum of α-Fe_2O_3 reduced to 33% (Fig. 4, curve 3) corresponded to the spectra of α-Fe and of the magnetite phase (Fe_3O_4) with traces of α-Fe_2O_3. This indicates that under our experimental conditions no accumulation of the wüstite phase is observed, i.e. the reduction of magnetite to α-Fe proceeds without a pronounced phase transition to wüstite.

Some of the contradictory results of previous investigations on the reduction of α-Fe_2O_3 with hydrogen can be connected with the great differ-

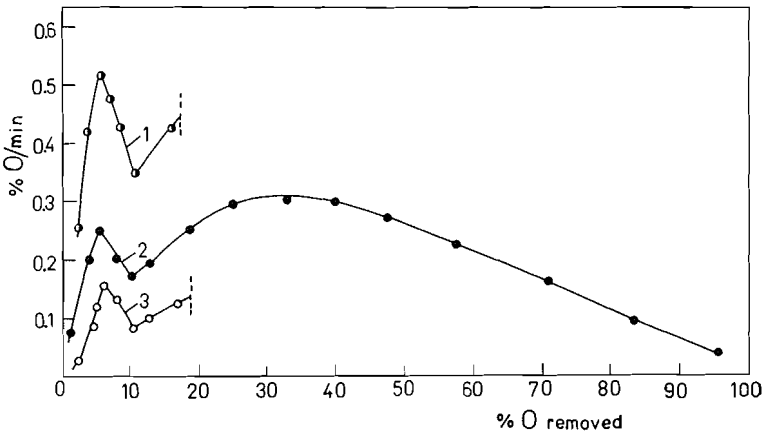

FIG. 3. Dependence of the reduction rate, in % O removed per min, on the degree of reduction, in % O removed.

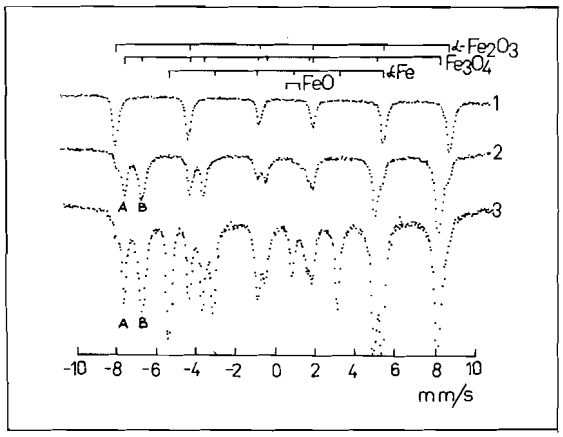

FIG. 4. Mössbauer spectra of: (*1*) α-Fe_2O_3; (*2*) α-Fe_2O_3 reduced to a degree of 11%; (*3*) α-Fe_2O_3 reduced to α = 33%.

ence between the experimental conditions. Our results are in good agreement with the results of the thermodynamic studies of the Fe–O system. This implies that at temperatures below the eutectoid transition point of 570°C, the probability of the formation and accumulation of a wüstite phase during the reduction process would strongly decrease.

SAMUEL O. GRIM, EDWARD D. WALTON, and LARRY C. SATEK. Can. J. Chem. **58**, 1476 (1980).

Phosphorus-31 nmr data are reported for tri-*n*-butylphosphine selenide complexes of mercury(II) and cadmium halides and for some miscellaneous complexes of tertiary phosphine sulfides and selenides with the same metal halides. The ligands in the complexes are labile in solution at room temperature but the exchange can be "frozen out" in certain cases at reduced temperature. Selenium-77–phosphorus-31 coupling constants are less in the complexes than in the free ligands and $^1J_{PSe}$ decreases in each observable case with decreasing temperature. Two bond mercury-199–phosphorus-31 coupling is observed in some of the cooled solutions of the complexes.

SAMUEL O. GRIM, EDWARD D. WALTON et LARRY C. SATEK. Can. J. Chem. **58**, 1476 (1980).

On présente les données de la rmn du ^{31}P des complexes du séléniure de tri-*n*-butylphosphine avec les halogénures de mercure(II) et de cadmium ainsi que celles obtenues pour des complexes divers de sulfures de phosphines tertiaires avec les mêmes halogénures métalliques. Les ligands de ces complexes sont labiles en solution, à la température ambiante, mais l'échange peut être bloqué dans certains cas à des températures plus basses. Les constantes de couplage sélénium-77–phosphore-31 sont plus faibles dans les complexes que dans les ligands libres et la valeur de $^1J_{PSe}$ décroît avec la température dans tous les cas où l'on peut faire des observations. Dans les cas de certaines solutions refroidies de complexes on observe le couplage ^{199}Hg–^{31}P à travers deux liaisons.

[Traduit par le journal]

The research activity in phosphine selenide coordination chemistry has not been nearly as exhaustive as that of phosphine oxides and sulfides (1). However, since selenium has an nmr-active isotope (^{77}Se, 7.58%, $I = 1/2$) of reasonable abundance, a new dimension for examining the properties of the phosphorus–selenium bond is available (2, 3), which is important because of the continuing interest in the nature of the phosphorus chalcogen bond (4, 5). We report here the results of an nmr (^{31}P) study on the complexes of some tertiary phosphine selenide and sulfide complexes with mercury(II) and cadmium(II) halides. A preliminary communication of this work has already appeared (6). In spite of the fact that these coordination complexes are very simple addition compounds, many of them have not been previously reported and characterized.

Results and Discussion

Tertiary phosphine selenides are prepared by reaction of a tertiary phosphine with potassium selenocyanate in acetonitrile (7) or perhaps more conveniently by the reaction of red elemental selenium and the tertiary phosphine in refluxing toluene (8). Triphenylphosphine selenide reacts with mercuric halides to produce primarily the 1:1 molar adduct, i.e., $(Ph_3PSe)_2Hg_2X_4$, even when 3:1 (ligand:Hg) reaction ratios are used. These compounds are not very soluble in common organic solvents and thus were not investigated further. However, tri-*n*-butylphosphine selenide reacts with mercury(II) and cadmium halides in a 2:1 molar ratio to produce the six pure compounds, $(n\text{-}Bu_3PSe)_2MX_2$, where M is Hg or Cd, and X is Cl, Br, or I, in good isolated yield. The 2:1 adducts with $n\text{-}Bu_3PSe$ even form preferentially if the ligand:metal ratio is 1:1. In addition, several miscellaneous compounds, including $(n\text{-}BuPh_2PSe)_2Hg_2I_4$, $(n\text{-}Bu_2PhPSe)_2HgCl_2$, $(n\text{-}Bu_2PhPSe)_2HgI_2$, $(n\text{-}Bu_2PhPSe)_2HgBr_2$, $(n\text{-}Bu_2PhPSe)_2CdI_2$, $(Ph_3PSe)_2Hg_2Br_4$, and $(Ph_3PSe)_2Hg_2I_4$ were prepared. Phosphorus-31 nmr data for the soluble phosphine selenide complexes and also two phosphine sulfide complexes, viz., $(n\text{-}Bu_3PS)_2HgCl_2$ and $(n\text{-}Bu_3PS)_2HgBr_2$, are given in Table 1. The observations from these data are: (*a*) at room temperature, the phosphine sulfide and phosphine selenide ligands in solutions of L_2HgX_2 and L_2CdX_2 are labile, i.e., they exchange rapidly on the nmr time scale. This is demonstrated by the results shown in Fig. 1. For $(n\text{-}Bu_3PSe)_2HgI_2$ in concentrated CH_2Cl_2 solution at room temperature, J_{PSe} is 584 Hz and δ_P is 42.7 ppm. The free

[a]Temperatures are accurate to ±3°; δ_P's to ±0.01 ppm; J's to ±2 Hz unless otherwise indicated.
[b]The reference (85% H_3PO_4) freezes so that accurate δ's are not recorded.

ligand values are 693 Hz and 37.0 ppm, respectively. As excess n-Bu_3PSe is added to the solution of complex only one phosphorus resonance (with ^{77}Se satellites) is observed, but J_{PSe} increases and δ_P decreases to reflect the weighted average of the complexed and free ligand values in the equilibrium:

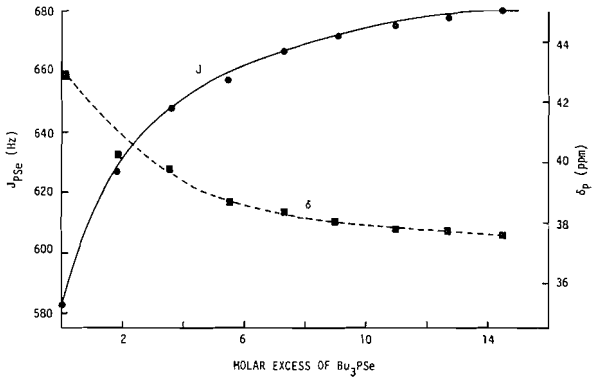

FIG. 1. The variation of $^1J_{PSe}$ (●, left ordinate, solid line) and δ_P (■, right ordinate, dashed line) with the excess moles of ligand in a solution of $(n\text{-}Bu_3PSe)_2HgI_2$.

[1] $n\text{-}Bu_3PSe^* + (n\text{-}Bu_3PSe)_2HgI_2 \rightleftarrows (n\text{-}Bu_3PSe)(n\text{-}Bu_3PSe^*)HgI_2 + n\text{-}Bu_3PSe$

Previous studies which have noted the lability of ligands by ^{31}P nmr measurements include phosphine complexes of cadmium (9) and mercury(II) (10–14) and phosphine oxide complexes of zinc, cadmium, and mercury(II) salts (15). (*b*) J_{PSe} decreases upon complexation, and the magnitude of the decrease is greatest for the most acidic of the mercury Lewis acids, i.e., $HgCl_2$ (ΔJ = 142 Hz) > $HgBr_2$ (ΔJ = 133 Hz) > HgI_2 (ΔJ = 110 Hz). The trend is the same for the CdX_2 compounds, but the differences among the compounds is not as great as for the mercury compounds. (*c*) The ligand exchange rate decreases with decreasing temperature, so that some of the complexes become "frozen out" on the nmr time scale. This is demonstrated by the appearance of two separate ^{31}P resonances (one due to ligand and one due to complex) when excess n-Bu_3PSe is added to a solution of $(n\text{-}Bu_3PSe)_2HgBr_2$ in CH_2Cl_2–$CDCl_3$ at −89°C. In the mercury series, the HgI_2 complexes are most labile and the $HgCl_2$ the least, as indicated by the temperature at which the exchange is slow on the nmr time scale. The $(n\text{-}Bu_3PSe)_2HgCl_2$ exchange is frozen out at about −50°C, the $HgBr_2$ complex at about −70°C, and the experimental conditions were not reached to stop the ligand exchange in the HgI_2 complex. In the cadmium series, crystallization of the complexes at reduced temperature hampered similar experiments but the $(n\text{-}Bu_3PSe)_2CdBr_2$ exchange was "stopped" at about −70°C also. By comparison, the corresponding phosphine sulfide complexes, i.e., $(n\text{-}Bu_3PS)_2HgCl_2$ and $(n\text{-}Bu_3PS)_2HgBr_2$ became inert at about −65°C and −87°C, respectively, roughly 15° lower in temper-

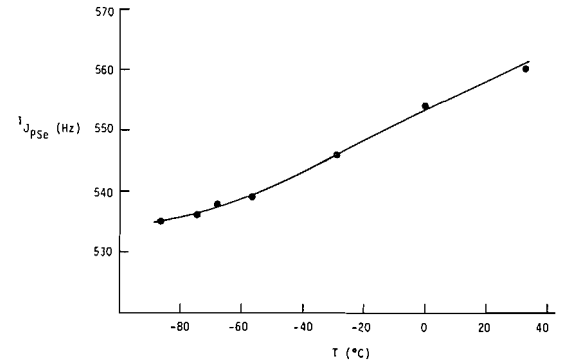

FIG. 2. The variation of $^1J_{PSe}$ with temperature in a solution of $(n\text{-}Bu_3PSe)_2HgBr_2$.

ature than the selenide analogues. (*d*) As the temperature is decreased, J_{PSe} decreases also. The rate of change of J_{PSe} is shown graphically for $(n\text{-}Bu_3PSe)_2HgBr_2$ in Fig. 2. It can be seen that J_{PSe} approaches a minimum value, which is presumably that of the non-exchanging complex. Possible rationalization for the decrease of J_{PSe} with decreasing temperature include: a decrease in the equilibrium constant, $K_{[2]}$, of a dissociation equilibrium such as represented in eq. [2]

[2] $(n\text{-}Bu_3PSe)_2HgBr_2 \rightleftarrows (n\text{-}Bu_3PSe)HgBr_2 + n\text{-}Bu_3PSe$

a weakening of the P—Se bond due to the strengthening of the Hg—Se bond; and hybridization changes at Se which would change the *s*-character of the P—Se bond. A dilution study (from 0.4 *M* to 0.04 *M* in five steps) of $(n\text{-}Bu_3PSe)_2HgBr_2$ in CH_2Cl_2 at ambient temperature resulted in an approximate increase in J_{PSe} of only about 2 Hz over this ten-fold concentration range. Although it is difficult to predict what J_{PSe} would be in the tricoordinated species of eq. [2], if it is assumed to be approximately the same as in the tetracoordinated species, then a change in J_{PSe} of the experimentally observed magnitude upon a ten-fold dilution would result only if $K_{[2]} < 10^{-4}$. If $K_{[2]}$ is this small (4.9% dissociation for the 0.04 *M* case and 1.6% dissociation for the 0.4 *M* case), a further decrease of $K_{[2]}$ at reduced temperature would not produce the observed changes in the magnitude of J_{PSe} upon cooling. Therefore, the correct explanation for the decrease of J_{PSe} in $(n\text{-}Bu_3PSe)_2HgBr_2$ with decreasing temperature is not clear from these data. (*e*) At low temperatures, two bond mercury-199–phosphorus-31 coupling is observed in the complexes $(n\text{-}Bu_3PSe)_2HgCl_2$, $(n\text{-}Bu_3PSe)_2HgBr_2$, $(n\text{-}Bu_3PS)_2HgCl_2$, and $(n\text{-}Bu_3PS)_2HgBr_2$. The values are, respectively, 157 Hz, 141 Hz, 115 Hz, and 103 Hz, i.e., coupling through selenium is greater than through sulphur. Weak satellites appear in the spectrum of $(n\text{-}Bu_3PS)_2CdBr_2$ at −70°C which we believe are due to two bond coupling of cadmium-111 and cadmium-113 to phosphorus, with $^2J_{CdP}$ equal to 40 Hz. This value and corresponding $^2J_{HgP}$ value give a reduced coupling constant (16) ratio $^2K_{CdP}/^2K_{HgP}$ of 0.27 which is close to the range expected (0.28–0.36) for analogous compounds of mercury and cadmium (9).

The J_{PSe} values in the free ligands, $n\text{-}Bu_3PSe$, $n\text{-}Bu_2PhPSe$, $n\text{-}BuPh_2PSe$, and Ph_3PSe vary in the manner (693, 715, 730, and 740 Hz, respectively) expected based on the electron drawing ability of the organic substituents. This was also the same order reported earlier (3) for the $Et_nPh_{3-n}PSe$ compounds.

In summary, we have shown that a study of phosphorus–selenium coupling constants in complexes of phosphine selenide ligands adds an interesting new dimension to the investigation of phosphorus chalcogen bonds.

Experimental

Phosphorus-31 nmr spectra were obtained with a Varian XL-100 Fourier Transform spectrometer equipped with a Nicolet Multi-Observe Nuclei Accessory (MONA) unit operating at 40.5 MHz using broad band proton decoupling. Samples were contained in spinning 10 mm tubes with a mixture of CH_2Cl_2:$CDCl_3$ (1:1 or 2:1) as the solvent system with a 1 mm capillary tube containing 85% H_3PO_4 as reference concentrically inserted in the sample tube. Deuterium in the solvent provided the frequency lock. Temperatures were determined by inserting a pentane thermometer directly into the solutions before and after each measurement.

Microanalyses were performed by Dr. F. Kasler of the University of Maryland.

$n\text{-}Bu_3P$ (Aldrich) and Ph_3P (M and T Chemicals) were used as supplied commercially. $n\text{-}Bu_2PhP$ and $n\text{-}BuPh_2P$ were prepared by *n*-butyl Grignard reaction with $PhPCl_2$(Aldrich) and Ph_2PCl (Aldrich), respectively (17). Tertiary phosphine sulfides were prepared by direct reaction of S with the phosphine in refluxing toluene. Tertiary phosphine selenides were prepared from the phosphine and KSeCN in CH_3CN (7) or by direct reaction of elemental red Se with the phosphine in refluxing toluene (8). ^{31}P nmr data are: Ph_3PSe, δ 36.9 ppm, J_{PSe} 740 Hz (lit. (3) δ36.1, J_{PSe} 738); $n\text{-}BuPh_2PSe$, δ 34.6, J_{PSe} 730; $n\text{-}Bu_2PhPSe$, δ 37.6, J_{PSe} 715; $n\text{-}Bu_3PSe$, δ 37.0, J_{PSe} 693.

(n-Bu$_3$PS)$_2$HgCl$_2$. Mercuric chloride (1.36 g, 5 mmol) in 50 mL of EtOH was added to 2.34 g (10 mmol) of Bu_3PS in 50 mL of EtOH. The volume was reduced to 25 mL by rotary evaporation and the solution was cooled, whereupon 3.1 g (83%) of crystals were formed. The product, mp 79–81°C, was recrystallized from EtOH. *Anal.* calcd. for $C_{24}H_{54}Cl_2HgP_2S_2$: C 38.94, H 7.35; found: C 39.07, H 7.55.

(n-Bu$_3$PS)$_2$HgBr$_2$ was prepared in a similar manner and was recrystallized from CH_2Cl_2/EtOH. The product, mp 75–76°C, was produced in 63% yield. *Anal.* calcd. for $C_{24}H_{54}Br_2HgP_2S_2$: C 34.77, H 6.56; found: C 34.67, H 6.82.

(n-Bu$_3$PSe)$_2$HgI$_2$. To a solution of HgI_2 (1.74 g, 3.8 mmol) in 300 mL of EtOH was added 2.20 g (7.8 mmol) of $n\text{-}Bu_3PSe$ in 10 mL of EtOH. The solution was concentrated by evaporation at room temperature by a stream of N_2 until crystals, mp 68.5–70°C, 3.1 g (80%) formed. *Anal.* calcd. for $C_{24}H_{54}HgI_2P_2Se_2$: C 28.35, H 5.35; found: C 28.21, H 5.57.

Reçu le 20 février 1980

MARIE-CHRISTINE ABRAHAM, MAURICE ABRAHAM et JAMES SANGSTER. Can. J. Chem. **58**, 1480 (1980).

Nous avons étudié l'influence de la température sur les constantes B.E.T. de dissolution de l'eau dans un mélange fondu [$AgNO_3$ + $TlNO_3$], contenant $AgNO_3$ à la fraction molaire 0.515, dans l'intervalle de température 85–110°C, pour des fractions molaires d'eau comprises entre 0 et 0.5 environ. Ces constantes B.E.T. sont: r: rapport molaire des sites d'adsorption aux sels; ΔE: différence entre l'énergie molaire d'adsorption de l'eau sur un site disponible dans les sels fondus et l'énergie molaire de condensation de l'eau.

Nous avons observé, dans ce travail, que l'influence de la température peut se résumer dans les énoncés des deux propriétés suivantes: (*1*) r est une fonction linéaire croissante de la température; (*2*) le produit $r\Delta E$ est sensiblement indépendant de la température.

MARIE-CHRISTINE ABRAHAM, MAURICE ABRAHAM, and JAMES SANGSTER. Can. J. Chem. **58**, 1480 (1980).

The temperature dependence of the B.E.T. constants for water dissolved in the melt (0.515 $AgNO_3$ + 0.485 $TlNO_3$) has been studied in the range 85–110°C at water mole fractions between 0 and 0.5. The B.E.T. constants are: r: the mole ratio of adsorption sites to salt; ΔE: the difference between the molar energy of adsorption of water on an available site in the melt and the molar energy of liquefaction of water.

It was found in this work that (*1*) r increases linearly with temperature and (*2*) the product $r\Delta E$ is perceptibly independent of temperature.

Introduction

Au cours de travaux récents (1–5) nous avons mesuré les pressions de vapeur d'eau de quelques mélanges eau–nitrates fondus pouvant contenir de l'eau à toute concentration à des températures relativement basses, au voisinage de 100°C et à des pressions inférieures à celle de l'atmosphère. Nous avons alors trouvé que la théorie B.E.T. adaptée aux solutions d'électrolytes forts (6, 7) permet de prévoir l'existence de certaines propriétés des solutions d'eau dans les sels fondus. Par exemple, nous avons montré que les constantes B.E.T. de dissolution de l'eau suivent des règles d'additivité quand on fait varier la concentration d'un des constituants des mélanges de nitrates fondus, dans certaines limites, suivant les cas. Après avoir ainsi étudié en particulier l'influence du facteur concentration, nous poursuivons en examinant l'influence de la température sur les constantes B.E.T. de dissolution de l'eau relative à un mélange ($AgNO_3$ + $TlNO_3$) de composition eutectique.

Résultats expérimentaux

La méthode de mesure des pressions de vapeur et la détermination des activités ont été décrits dans un travail précédent (1). La fraction molaire de $AgNO_3$ dans le mélange de sels fondus anhydres a été fixée à 0.515. Les mesures ont été faites à 87, 93 et 105°C. A ces températures, le deuxième coefficient du viriel pour la vapeur d'eau a respectivement pour valeurs: −525, −492 et −435 cm^3/mol. Les valeurs correspondantes de la fugacité sont: 463.62, 581.31 et 891.1 Torr. Le même système ayant été étudié auparavant à 98.5 et 111°C (2, 3), les données expérimentales ainsi réunies ont permis de tirer des conclusions quant à l'influence de la température sur la pression de vapeur d'eau et des paramètres thermodynamiques utiles qui lui sont reliés. Les valeurs mesurées de la pression p ainsi que les valeurs correspondantes de la fugacité f, de l'activité a et du coefficient d'activité γ sont disponibles ailleurs.[2]

Discussion

Les isothermes et les constantes B.E.T.

L'équation B.E.T. adaptée aux solutions d'électrolytes (7) s'écrit

$$[1] \quad \frac{a_e(1 - x_e)}{x_e(1 - a_e)} = \frac{1}{cr} + \frac{c - 1}{cr} a_e$$

où a_e *et* x_e = activité et fraction molaire de l'eau; r = rapport molaire des sites d'adsorption aux sels; c est donnée approximativement par l'expression

$$[2] \quad c = \exp(-\Delta E/RT)$$

avec $\Delta E = E - E_L$.

Dans [2], E et E_L ont les significations suivantes: E = énergie molaire d'adsorption de l'eau sur un site disponible dans le sel fondu; E_L = énergie molaire de condensation de l'eau.

A l'aide des valeurs de x_e et a_e la fonction

$$f(a_e) = \frac{a_e(1 - x_e)}{x_e(1 - a_e)}$$

est représentée graphiquement. Les droites isothermes de la fig. 1 sont ainsi obtenues, dans l'intervalle $0 < a_e < 0.7$, par la méthode des moindres carrés, avec un coefficient de corrélation supérieur à 0.999. En appliquant les éqs [1] et [2], l'ordonnée à l'origine et la pente des isothermes donnent les valeurs des constantes c, r et ΔE groupées dans le tableau 1, qui contient également celles obtenues antérieurement (2, 3). L'examen de ce tableau montre qu'une élévation de température augmente r et diminue c ainsi que $-\Delta E$. La dernière colonne du tableau montre que r augmente et $-\Delta E$ diminue de manière à fixer le produit $-r\Delta E$ pratiquement indépendant de la température, dans l'intervalle étudié. D'où la relation:

[3] $r\Delta E \cong -0.155$ kcal mol^{-1}

Sur la fig. 2 sont représentés r et $-r\Delta E$ en fonction de la température. r apparaît comme droite. Son équation, en utilisant les températures en Kelvin, est:

[4] $r = 2.38 \times 10^{-3}T - 0.401$

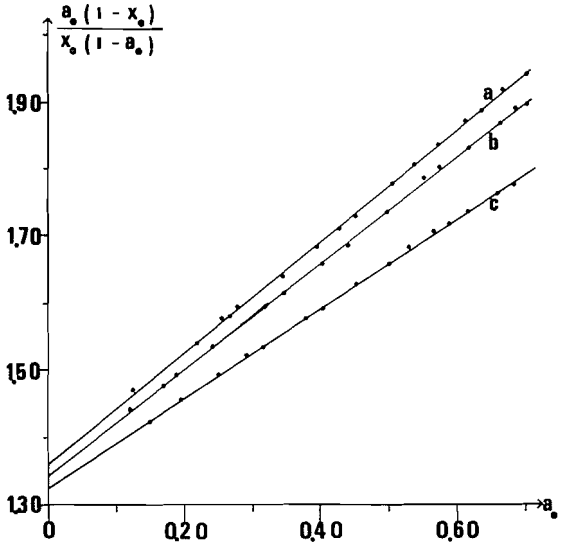

FIG. 1. Les isothermes B.E.T. de dissolution de l'eau dans le mélange de sels fondus [$AgNO_3$ + $TlNO_3$] contenant $AgNO_3$ à la fraction molaire 0.515, à 87.0°C (*a*), 93.0°C (*b*) et 105.0°C (*c*).

TABLEAU 1. Les constantes B.E.T. pour le système [$AgNO_3$ + $TlNO_3$ + H_2O] à cinq températures. Fraction molaire de $AgNO_3$ dans le mélange de sels fondus: 0.515

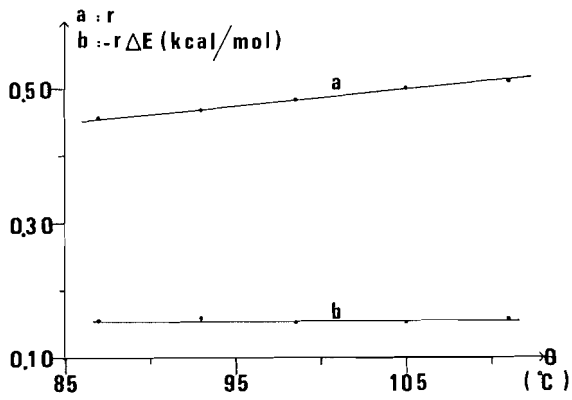

FIG. 2. Les expressions B.E.T. "r" et "$r\Delta E$" en fonction de la température, relatives aux solutions d'eau dans le mélange de sels fondus [$AgNO_3$ + $TlNO_3$] contenant $AgNO_3$ à la fraction molaire 0.515.

Les grandeurs molaires d'excès de l'eau à dilution infinie dans les sels fondus

Ces paramètres peuvent être calculés par les relations suivantes:

[5] $\Delta\mu_e^\infty = RT \ln \gamma^\infty$

[6] $\Delta s_e^\infty = -\frac{\partial}{\partial T}(RT \ln \gamma^\infty)$

[7] $\Delta h^\infty = \Delta\mu_e^\infty + T\Delta s_e^\infty$

γ^∞, $\Delta\mu_e^\infty$, Δs_e^∞ et Δh^∞ coefficient d'activité, enthalpie libre molaire d'excès, entropie molaire d'excès et enthalpie de transfert de l'eau à dilution infinie dans les sels fondus.

γ^∞ s'exprime en fonction des constantes B.E.T. (8) par:

[8] $\gamma^\infty = 1/cr$

Les relations [5]–[8] et [2] donnent:

[9] $\Delta\mu_e^\infty = \Delta E - RT \ln r$

[10] $\Delta s_e^\infty = \frac{RT}{r}\frac{\partial r}{\partial T} + R \ln r - \frac{\partial \Delta E}{\partial T}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

$$[11] \quad \Delta h^{\infty} = \Delta E - T\frac{\partial \Delta E}{\partial T} + \frac{RT^2}{r}\frac{\partial r}{\partial T}$$

Le tableau 2 donne les valeurs de $\Delta\mu_e^{\infty}$, Δs_e^{∞} et Δh^{∞} calculées par les relations [3], [4], [9], [10] et [11].

La constante rigoureuse de la loi de Henry

Cette constante K_H^{∞} s'exprime en fonction du coefficient d'activité de l'eau à dilution infinie dans les sels fondus γ^{∞}, et de la fugacité de l'eau pure f_0 par la relation suivante:

$$[12] \quad K_H^{\infty} = \gamma^{\infty} f_0$$

Les valeurs de γ^{∞}, f_0 et K_H^{∞} aux températures étudiées sont données dans le tableau 3. La température influence dans le même sens f_0 et K_H^{∞}. Elle influence en sens contraire γ^{∞} et K_H^{∞}. Le sens de variation de f_0 avec la température impose celui de K_H^{∞}. Ceci provient de la petitesse relative de l'enthalpie de transfert de l'eau de la phase eau pure à la phase sels fondus contenant une quantité infiniment petite d'eau. En effet, la relation [12] donne:

$$[13] \quad \frac{\partial \ln K_H^{\infty}}{\partial(1/T)} = \frac{\partial \ln \gamma^{\infty}}{\partial(1/T)} + \frac{\partial \ln f_0}{\partial(1/T)}$$

Or, on a les relations ci-dessous [14]–[16]

$$[14] \quad \frac{\partial \ln \gamma^{\infty}}{\partial(1/T)} = \frac{\Delta h^{\infty}}{R}$$

TABLEAU 2. Grandeurs molaires d'excès de l'eau à dilution infinie dans le mélange fondu [$AgNO_3$ + $TlNO_3$] en fonction de la température. Fraction molaire de $AgNO_3$ dans le mélange fondu: 0.515

θ (°C)	$\Delta\mu_e^{\infty}$ (kcal/mol)	Δh^{∞} (kcal/mol)	Δs_e^{∞} (u.e.)
87.0	0.22	0.36	0.4
93.0	0.23	0.41	0.5
98.5	0.22	0.44	0.6

[c]Référence 3.

$$[15] \quad \frac{\partial \ln f_0}{\partial(1/T)} = \frac{-\Delta H_v^0}{R}$$

où ΔH_v^0 est l'enthalpie molaire de vaporisation de l'eau pure.

$$[16] \quad \Delta H_v^{\infty} = \Delta H_v^0 - \Delta h^{\infty}$$

où ΔH_v^{∞} est l'enthalpie molaire de vaporisation de l'eau à dilution infinie dans les sels fondus. Des relations [13]–[16], on obtient la relation [17].

$$[17] \quad \frac{\partial \ln K_H^{\infty}}{\partial(1/T)} = -\frac{\Delta H_v^{\infty}}{R}$$

La pente de la droite $\ln K_H^{\infty} = f(1/T)$ représentée à la fig. 3 est imposée par la valeur moyenne de ΔH_v^{∞} qui est 9.4 kcal/mol. Elle est proche de la valeur moyenne de ΔH_v^0 dans le même intervalle de température: 9.8 kcal/mol.

Le coefficient d'activité de l'eau

La fig. 4 ne reproduit les résultats que pour les deux températures extrêmes étudiées afin d'en faciliter l'examen. Essentiellement on constate que la courbe représentative de la fonction $\gamma_e = f(a_e)$ passe par un maximum. L'élévation de température abaisse la courbe en l'aplatissant. Le tableau 4 donne

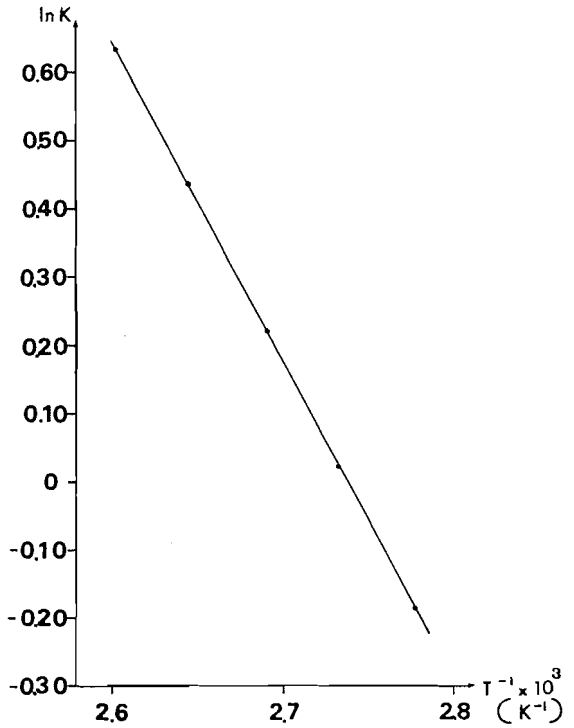

FIG. 3. Influence de la température sur la constante de la loi de Henry de dissolution de l'eau dans le mélange de sels fondus [$AgNO_3$ + $TlNO_3$] contenant $AgNO_3$ à la fraction molaire 0.515.

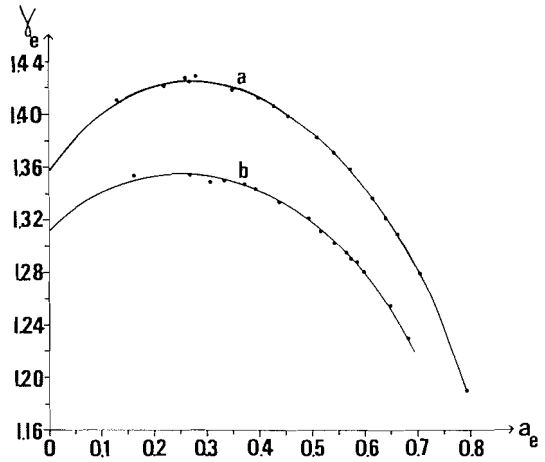

FIG. 4. Le coefficient d'activité de l'eau en fonction de son activité dans le système [$AgNO_3$ + $TlNO_3$ + H_2O] pour une fraction molaire 0.515 de $AgNO_3$ dans le mélange fondu [$AgNO_3$ + $TlNO_3$] à 87.0°C (*a*) et 111.0°C (*b*).

le maximum γ_m et l'activité correspondante a_m, en fonction de la température, calculés par les formules [18] et [19] établies précédemment (9)

$$[18] \quad \gamma_m = \frac{(c - 2 + cr)^2}{4cr(c - 1)} + \frac{1}{cr}$$

$$[19] \quad a_m = \frac{c - 2 + cr}{2(c - 1)}$$

On voit que a_m est comprise dans l'intervalle de validité de l'éq. [1] et que γ_m diminue quand la température augmente. On a aussi (3) la relation [20].

$$[20] \quad \frac{d^2\gamma_e}{da_e^2} = -\frac{2(c - 1)}{cr}$$

TABLEAU 4. Le coefficient d'activité maximum de l'eau γ_m, l'activité correspondante a_m et la dérivée seconde $d^2\gamma/da^2$ en fonction de la température. Solutions d'eau dans le mélange de sels fondus [$AgNO_3$ + $TlNO_3$] contenant $AgNO_3$ à la fraction molaire 0.515

θ (°C)	γ_m	a_m	$-d^2\gamma/da^2$
87.0	1.43	0.28	1.66
93.0	1.41	0.28	1.58
98.5	1.39	0.27	1.44
105.0	1.37	0.25	1.33
111.0	1.36	0.26	1.29

Or, comme l'indique le tableau 4, la valeur absolue de $d^2\gamma_e/da_e^2$ diminue en restant plus grande que un, quand la température augmente.

Les relations [18]–[20] issues du modèle B.E.T. expliquent bien les caractéristiques principales des courbes $\gamma_e = f(a_e)$ à l'aide de deux paramètres expérimentaux dont les définitions sont simples.

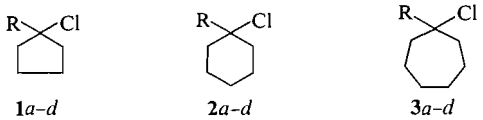
The effect of the bulk of the sidechain on the rate of solvolysis of 1-alkyl cyclopentyl, cyclohexyl, and cycloheptyl chlorides has been studied. With the exception of the *t*-butyl systems, the ratio of solvolysis rates for the three ring systems falls in a given series. The slower rate of solvolysis in the six-membered ring system may be due to an extra activation energy contribution caused by the conversion of a neutral chair form to the twist boat or half chair conformation, prior to the actual solvolysis. In the case of five- and seven-membered ring systems the formation of an intermediate carbonium ion is sterically favoured (I-strain or eclipsing interaction) consistent with earlier findings. The faster rate of solvolysis of 1-*t*-butylcycloalkyl chlorides is likely due to a rearrangement reaction where alkyl participation enhances the rate of solvolysis.



K. RANGANAYAKULU, M. VASUMATHI DEVI, R. BALAJI RAO et K. RAJESWARI. Can. J. Chem. **58**, 1484 (1980).

On a étudié l'effet de l'encombrement de la chaîne latérale sur la vitesse de solvolyse des chlorures d'alkyl-1 cyclopentyle, cyclohexyle et cycloheptyle. A l'exception des systèmes *tert*-butyle, le rapport des vitesses de solvolyse des trois systèmes cycliques correspond à une série donnée. Le fait que la vitesse de solvolyse est plus lente dans les cycles à 6 chaînons peut être due à une contribution supplémentaire de l'énergie d'activation provoquée par l'interconversion d'une forme chaise neutre en une forme bateau-croisée ou demi-chaise avant la solvolyse. Dans le cas des systèmes cycliques à 5 et 7 chaînons, la formation d'un carbocation intermédiaire est favorisée par des facteurs stériques (tension-I ou interaction éclipsée) en accord avec les résultats obtenus antérieurement. Le fait que la vitesse de solvolyse des chlorures de *tert*-butyl-1 cycloalkyle soit plus grande est probablement due à une réaction de transposition où la participation du groupe alkyle augmente la vitesse de solvolyse.

[Traduit par le journal]

Introduction

The solvolyses rates of various ring halides have been extensively studied (1–5). A 125-fold increase in the rate of solvolysis of **1***a* relative to **2***a* has been attributed to relief in steric strain in the transition state of the chloride **1***a* and an increase in steric strain in the transition state of the chloride **2***a*. Since strain effects could originate from the ring as well as the sidechain, we have studied the effect of the bulk of the sidechain on the rate of solvolysis of 1-alkyl cyclopentyl **1***a–d*, cyclohexyl **2***a–d*, and cycloheptyl chlorides **3***a–d*.

1*a–d* **2***a–d* **3***a–d*

a, R = Me; *c*, R = *i*-Pr
b, R = Et; *d*, R = *t*-Bu

Experimental

All the compounds used in this study were prepared using procedures reported in the literature (5–10). All solvolysis experiments were carried out in 80% aqueous ethanol at 30°C. The rate constants for compounds **1***a–c*, **2***a–c*, and **3***a–c* were measured using the procedure adopted by Brown *et al.* (11). The rate constants for compounds **1***d*, **2***d*, and **3***d* were measured using an automatic capacitance bridge with a digital control unit (type 1673A, General Radio Company, Concord, MA, U.S.A.).

Product analysis in each case was done by carrying out the solvolysis reaction in water. The chloride (500 mg) was added to 10 cm^3 of water and allowed to stir at room temperature for 3 days. The reaction mixture was extracted with pentane (4 × 30 mL) and dried over anhydrous magnesium sulphate. The solvent was removed using a fractionating column (24 in.) and the residue was analysed by nmr spectroscopy and glc. The residue in the case of Me, Et, and *i*-Pr substituted compounds was found to be a mixture of unrearranged alkene and alcohol by nmr analysis.

In the case of *t*-butyl systems the residue in each case appeared to contain more than two products and these were separated by preparative glc on a Varian Aerograph model 90-P with a 3/8 in. × 6 ft, 10% SE-30 on 60/80 chromosorb P column. A column temperature of 125°C was used to separate products of **1***d* and **2***d* and a temperature of 135°C was used in case of **3***d*. Each glc separated fraction was analysed by its nmr spectrum (obtained on a Varian XL-200 spectrometer) in $CDCl_3$ using tetramethylsilane as the internal standard. The nmr spectra were consistent with the structures proposed and the chemical shifts of the characteristic peaks are reported (on the product structures) in ppm (δ) downfield from TMS. The peaks reported are sharp singlets unless otherwise mentioned and integrate well for the number of protons. The results are given in detail subsequently.

Results and Discussion

The results of the solvolyses experiments are given in Table 1. The solvolysis data for 3-chloro-3-alkylpentanes have also been included for com-

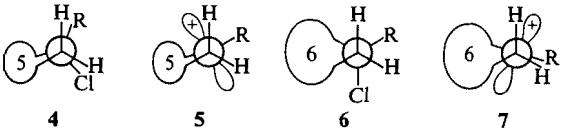
TABLE 2. Rate ratios for the solvolyses of 1-chloro-1-alkyl cycloalkanes

Ratio	Value			
	Methyl	Ethyl	*i*-Propyl	*t*-Butyl
$\frac{\text{5-membered}}{\text{6-membered}}$	67.70	66.70	40.83	57.61
$\frac{\text{7-membered}}{\text{6-membered}}$	63.03	62.83	35.55	127.09



parison purposes (11). The kinetics show first order behaviour in all the cases studied. The rate ratios for the solvolyses of five-, six-, and seven-membered ring compounds are given in Table 2.

The rate of solvolysis in any given ring system where the R sidechain is changed could be affected by one or more of the following factors:

(*i*) In going from the reactant to the transition state leading to the carbonium ion intermediate, there should be a decrease in the eclipsing interaction in the case of the five-membered ring system, **4** → **5**, whereas in the case of the six-membered ring system, **6** → **7**, there should be an increase (I-strain) (12). This will have the effect of increasing the rate with increase in the bulk of the 1-alkyl group in the five-membered ring system, and correspondingly decreasing the rate in the six-membered ring system. However, the near constancy of the relative rates of the five- and the six-membered ring systems in going from the methyl to the *t*-butyl sidechain suggests that this is not an important contributing factor in causing the basic differences in solvolysis rates between these two ring systems.

(*ii*) In the case of the five-membered ring system, there are four α-hydrogens (ring) in a favourable orientation for hyperconjugative stabilization, see **5**, while in the case of the six-membered ring system there are only two such hydrogens, **7** (13). This latter statement assumes that the solvolysis reaction in the six-membered ring system proceeds via a chair conformation in the transition state. Brown *et al.* (14) have made a detailed study of the solvolyses of 1-aryl-1-cycloalkyl and 1-aryl-1-alkylcarbinyl 3,5-dinitrobenzoates. Their results reveal a close similarity in the ρ^+ values for methyl, isopropyl, cyclobutyl, and cyclohexyl groups indicating no significant difference in the electronic contributions to an electron deficient centre. However, the ρ^+ values for cyclopentyl and cycloheptyl groups are considerably less negative and this has been attributed to a combination of I-strain and superior hyperconjugative contributions by the cyclopentyl group, and to I-strain alone in the case of the cycloheptyl group. β-Deuterium isotope effects involving ring hydrogens are known for the solvolysis of both cyclopentyl (2,2,5,5-d_4) tosylate (15*a*) and cyclohexyl (2,2,6,6-d_4) tosylate (15*b*), $k_H/k_D = 2.06$ and 2.34, respectively. This isotope effect implies that hyperconjugative stabilization is more important in the cyclohexyl case so that this hyperconjugative argument can hardly explain the faster rate of solvolysis found for the cyclopentyl system.

(*iii*) Conformational preference for hyperconjugative participation by the C—H hydrogens of the alkyl group in the five- and seven-membered ring systems. From electron spin resonance results and from the observation of secondary β-deuterium isotope effects in bridgehead systems (16), one can show that hyperconjugation is dependent on the angle (θ) between the "*p*" orbital on the trigonal carbon and the neighboring C—H bond (Fig. 1). If indeed this is the reason for the observed difference in solvolysis rates of five- and six-membered ring compounds, then there should be a large difference

in the isotope effect of the 1-CD_3-cycloalkyl substituted compounds. The Me-d_3 isotope effects for the solvolysis of methylcyclopentyl chloride and methylcyclohexyl chloride are given in Table 3. Since the isotope effects are temperature dependent, one can assign a rough value of 1.3 for k_{CH_3}/k_{CD_3} at 25°C for methyl cyclohexyl chloride. Thus, it can be concluded that the 1-alkyl group stabilises the intermediate carbonium ion better in a six-membered ring system than in the five-membered ring. Therefore, this factor also seems not to be responsible for the observed rate differences in the solvolysis of five- and six-membered ring compounds.

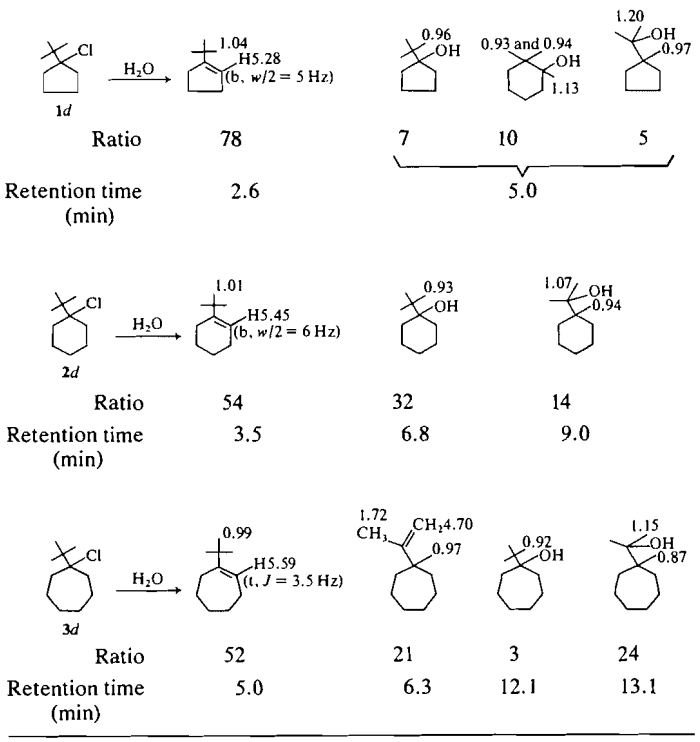
(*iv*) An increase in Baeyer strain in the formation of a five-membered ring cation (109° to 115°) compared to a six-membered ring cation (109° to 120°). This effect is likely to reverse the rates of solvolysis of five- and six-membered ring systems from the observed results, and therefore may not be the significant factor in changing the rates of solvolysis in different ring systems.

(*v*) Decreasing solvation in all the ring systems with increase in the bulk of the alkyl group.

To summarize, the regular decrease in the solvolysis rates of all the three ring systems with the increase in the bulk of the alkyl group suggests relief of eclipsing interactions in the chloride, differential hyperconjugative participation of the β-hydrogens of the ring or of the 1-alkyl sidechain, and Baeyer strain are not the major contributing factors accounting for the differences in solvolysis rates of the different ring systems. However, in a given series **1***a–c*, **2***a–c*, and **3***a–c* the results could very well be explained by considering hyperconjugative participation of β-hydrogens of the 1-alkyl group, in addition to solvation effects.

Solvolysis of *t*-Butyl Systems

The *t*-butyl chlorides **1***d*, **2***d*, and **3***d* all solvolyse much faster than the methyl systems **1***a*, **2***a*, and **3***a*. Obviously some new factor must be involved here and as a first step we have carried out a product analysis. For the product study, the solvolysis of **1***d*, **2***d*, **3***d* was carried out in water in order to simplify the nature of the products, specifically to avoid the formation of ethers which will only complicate the analysis. In each case both the nmr (200 MHz) and glc analyses showed the presence of rearranged products.



The products from the chloride **1***d* could not be separated in glc under the conditions used. The first fraction contained the unrearranged alkene but the second fraction consisted of a mixture of three alcohols, 1-*t*-butylcyclopentanol, 1,2,2-trimethylcyclohexanol, and 2-(1-methylcyclopentyl)-2-propanol. The identity of these alcohols was confirmed by synthesizing these, 1-*t*-butylcyclopentanol and 1,2,2-trimethylcyclohexanol according to the literature procedures (10, 18*a*) and 2-(1-methylcyclopentyl)-2-propanol by adding methyllithium to 1-acetyl-1-methylcyclopentane (kindly supplied by Dr. T. S. Sorensen). The nmr spectrum of the mixture of these authentic alcohols matched well with that of the second fraction.

In the case of the chlorides **2***d* and **3***d* the solvolysis products could be separated well under the glc conditions used and the products could be easily identified.

The ratios of each of the products, the chemical shifts of the characteristic proton signals, and the retention times are given in Table 4. Recovery experiments have also been carried out for the solvolysis of the Me, Et, and *i*-propyl compounds and these show no rearranged products. The faster rate of solvolysis in the *t*-butyl compounds can therefore be correlated with the appearance of rearrangement products. Brown *et al.* (10) have studied the rate of solvolysis of 1-*t*-butylcycloalkylcarbinyl *p*-nitrobenzoates and the results are as follows: cyclopentyl, $k_1 = 0.236\ s^{-1}$, cyclohexyl, $k_1 = 7.35 \times 10^{-3}\ s^{-1}$, cycloheptyl, $k_1 = 1.15\ s^{-1}$. The corre-

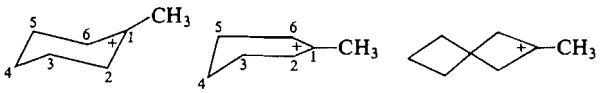
TABLE 4. Solvolyses of 1*d*, 2*d*, and 3*d*

sponding ratios, $k_{t\text{-butyl}}/k_{\text{methyl}}$, are 112, 134, and 273. Using the chlorides the corresponding ratios are $k_{t\text{-butyl}}/k_{\text{methyl}} = 2.8$, 3.28, and 6.62. In the *p*-nitrobenzoates there is a large rate difference between the methyl and *t*-butyl substituents and this has been atrributed by Brown *et al.* (10) to the relief of steric strain in going to the transition state. On first glance these results seem to be different from those obtained by us using 1-*t*-butylcycloalkyl chlorides. However, the F-strain involving ionisation of *p*-nitrobenzoates is larger than for the corresponding chlorides (19) and therefore the chlorides appear to be better for studies of structural effects in which large F-strain factors should be avoided (10). Also, introduction of two or three bulky groups at a tertiary center can result in far larger rate enhancements (20). However, the significant factor is that the relative reactivities of five-, six-, and seven-membered ring compounds are not very different, irrespective of the leaving group. Thus:

$$(k_5(t\text{-Bu})/k_6(t\text{-Bu}))_{Cl} = 57.67$$

$$(k_5(t\text{-Bu})/k_6(t\text{-Bu}))_{OPNB} = 32.10$$

$$(k_7(t\text{-Bu})/k_6(t\text{-Bu}))_{Cl} = 127.09$$



$$(k_7(t\text{-Bu})/k_6(t\text{-Bu}))_{OPNB} = 156.46$$

It seems to us that the dramatic rate increase in *t*-butyl substituted cycloalkyl chlorides is not primarily of F-strain origin because: (*a*) the chlorides are much less susceptible to this factor as shown above and (*b*) there should be a steady progression from R = Me to R = *t*-butyl, if this phenomenon is involved. It has been suggested that methyl participation in *t*-butyl substituted systems enhances the rate of solvolysis (21). Our results are consistent with this argument although it is somewhat peculiar that in the cyclopentyl and cyclohexyl series the rearranged products only account for 15% and 14% respectively of the total. Thus the participation does not involve the complete breaking of the methyl carbon bond in the solvolysis transition state.

Solvolysis Rate Comparisons Between the Three Ring Systems

Up to now we have discussed two phenomena: a slight rate decrease in all the three rings in going from Me to *i*-Pr; secondly, the fairly large increase in all cases with the *t*-butyl substitutent. Neither of these factors relates directly to the question of why the six-membered ring system solvolyses slower than its counterparts. We have previously suggested that eclipsing interactions are not of primary importance in causing the rapid rate in the five-

8 9 10

membered ring system, since a rate increase would have been expected with increasing bulk. This relief of eclipsing interactions is the usual argument given, e.g. work of Brown (5, 10), for this rate increase and this could still be possible if compensating factors were at work, i.e. a large rate decrease on going from methyl to isopropyl due to solvation and/or hyperconjugation effects, balanced by a smaller increase caused by the eclipsing relief. The rate increase in the seven-membered case seems to fit Brown's I-strain concept. One possibility for the cyclohexyl system could be that the solvolysis might not involve the chair form and in this case the large rate decrease predicted on going from Me to *i*-Pr would not necessarily apply, i.e. development of eclipsing interactions in a chair cation intermediate **8**. In the case of the six-membered cation several conformations, **8–13**, could be considered. Taking steric factors alone into consideration, the carbonium ion intermediate in the six-membered ring system is more crowded than the neutral molecule. Recently Sorensen *et al.* (22) have shown that the twist boat form of methylcyclohexyl cation **10** is more stable (ca. 500 cal/mol) than the chair form **8**, although there is a rapid equilibration of the two conformers even at low temperatures. With an increase in the bulk of the 1-alkyl group it is likely that the equilibrium would be shifted even more towards the half chair or the twist boat form since there is a smaller eclipsing interaction of the alkyl group with C_2-hydrogens. In the ground state chlorides, the difference in energy between the chair form and the half chair or twist boat form will be even higher (ca. 3–4 kcal/mol). Although the chair conformation is undoubtedly the ground state for the chlorides, the eclipsing interaction in the chair cation may make it more economical for the molecule to solvolyse via a twist boat ground state as long as the energy gain through forming a better cation transition state is enough to counter-balance the energy differences between the neutral chair and the twist boat chlorides. In any case, the solvolysis rate would be slower than in the other two ring systems since it is a matter of deciding between the best of two bad situations.

In some ways the conformational argument involving a twist boat transition state seems better, since this fits with the small rate decrease observed in going from methyl to isopropyl, and it should be noted that some solvolysis data on secondary cyclohexyl systems have already been rationalised by involving a non-chair conformation transition state (15*a*, 23).

Cation mobilities in liquid and supercritical C_1–C_4 hydrocarbons

NORMAN GEE AND GORDON R. FREEMAN

Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 18, 1980

NORMAN GEE and GORDON R. FREEMAN. Can. J. Chem. **58**, 1490 (1980).

The relationship between ion mobility and liquid viscosity is commonly expressed as $\mu \propto \eta^{-m}$. In hydrocarbons the value of m tends to be near 1.0 at $\eta > 5$ mP, $m > 1.0$ at $\sim 5 < \eta < 1$ mP, and $m < 1.0$ at $\eta < 0.5$ mP. Thus there is a maximum in a plot of $\mu\eta$ against η^{-1} and Walden's rule ($m = 1.0$) is only a rough approximation. The decrease of $\mu\eta$ as the critical region is approached is accompanied by an increase in the ratio of diffusion coefficients $D_{\text{molec}}/D_{\text{ion}}$. Ion mobilities in the liquids well below their normal boiling points are chiefly controlled by the fluidity. At higher temperatures and concomitant lower liquid densities and viscosities $\mu\eta$ first increases, due to an increasing ion mean free path, then decreases as the critical region is approached, due to the increasing liquid compressibility and consequent electrostriction about the ion.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **58**, 1490 (1980).

On exprime communément la relation entre la mobilité de l'ion et la viscosité du liquide par $\mu \propto \eta^{-m}$. Dans les hydrocarbures, la valeur de m tend vers 1.0 à $\eta > 5$ mP, $m > 1.0$ à $\sim 5 < \eta < 1$ mP et $m < 1.0$ à $\eta < 0.5$ mP. Ainsi il existe un maximum dans la courbe $\mu\eta$ en fonction de η^{-1} et la règle de Walden ($m = 1.0$) n'est qu'une grossière approximation. Lorsqu'on s'approche de la région critique, la diminution de $\mu\eta$ s'accompagne d'une augmentation du rapport des coefficients de diffusion $D_{\text{molécule}}/D_{\text{ion}}$. Les mobilités ioniques dans les liquides à des températures bien au-dessous de leur point d'ébullition sont principalement contrôlées par la fluidité. A des températures plus élevées et à des viscosités et des densités concomitantes plus faibles, $\mu\eta$ décroît d'abord, grâce à une augmentation du libre parcours moyen de l'ion, puis diminue lorsqu'on s'approche de la région critique par suite de l'augmentation de la compressibilité du liquide et d'une électrostriction conséquente autour de l'ion.

[Traduit par le journal]

Introduction

Ion mobilities μ in liquid hydrocarbons are often compared with the viscosity η, since by Walden's rule $\mu\eta$ should be constant and independent of temperature (1–9). In general this is not true. Earlier results, which were restricted to temperatures near or below the normal boiling points of the measured liquids, indicate that $\mu\eta$ increases with temperature in many systems (1, 2). This is equivalent to saying that μ varies as η^{-m}, $m > 1.0$ (6–9). Recent development of high pressure conductance cells has allowed mobility measurements over the entire liquid range at temperatures up to the critical (7–9). The effects of molecular structure and temperature on $\mu\eta$ are now examined by measurements of μ in eight small hydrocarbons (the C_1 to C_4 alkanes and alkenes, with the exceptions of the butenes). Ion mobilities in the butenes have been reported (7), but measured liquid viscosities are not available for three of the isomers and are only reported for temperatures below 239 K in 1-butene. The butenes are therefore not included in the present discussion.

Experimental

Purification of methane and ethane samples is described in ref. 10, and of propane, propene, and cyclopropane in ref. 11. The remaining samples were all Phillips Research Grade of > 99.90% purity. Further purification of ethene was effected by holding the liquid on KOH pellets overnight at 195 K and subsequent treatment as for ethane. The butanes were purified at room temperature in the same vacuum line described in refs. 10 and 11, except that Davison 4A Molecular Sieves were used instead of Davison 3A and a sodium–potassium alloy was used instead of potassium mirrors.

The conductance cells were described in refs. 8 and 9, the cooling system in ref. 6 and the heating system in ref. 9.

Mobilities were measured by a time-of-flight method (6). Electrons were swept from the liquids by the electric field, so there was no interference from anions. The liquids were under their vapor pressure.

Viscosities for the compounds were taken from ref. 12, except for isobutane and cyclopropane. Values were only used for temperature ranges where experimental data exist. For isobutane, ref. 12 did not give experimental results over the entire liquid range. A composite of the results in refs. 13 and 14 was used instead. The data in Fig. 1 of ref. 13*d* are incorrect; Figs. 4 and 5 should be used. For cyclopropane no liquid viscosities to our knowledge have been measured. At $T < 300$ K values have been estimated by the method of Morris (15).

Results

The ion mobilities μ are plotted against the temperature in Fig. 1. Increasing the temperature towards the critical region leads to a monotonic increase of the mobility for all the compounds except cyclopropane. The cyclopropane curve exhibits a small maximum at ~393 K (~5 K below the critical temperature). The ion mobilities in all of the present hydrocarbons at ~1 K above T_c are in the range $(4.9 \pm 0.6) \times 10^{-3}$ cm²/V s, except in methane, where it is 7.8×10^{-3} cm²/V s.

Figure 2 shows the product of the ion mobility and the fluid viscosity, $\mu\eta$, plotted against η^{-1}. Figure 2A includes the present results except those for propene, cyclopropane, and isobutane. The mobilities in *n*-hexane are from ref. 8 and the vis-

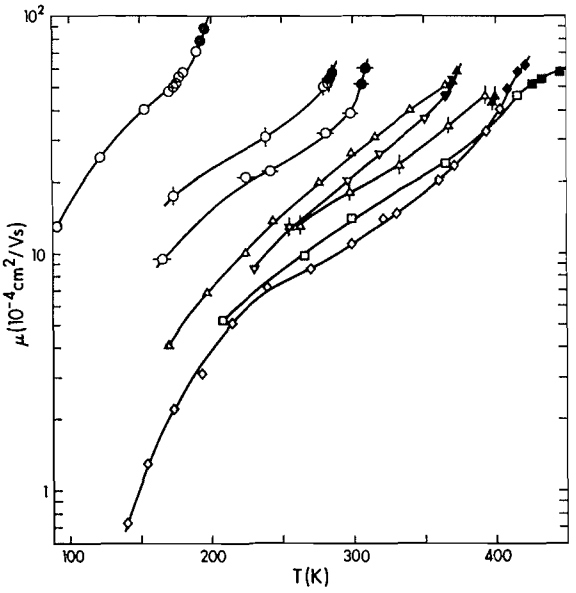

FIG. 1. Mobility μ plotted against temperature. Liquids: methane, O; ethane, —O—; ethene, ○; propane, △; propene, ▽; cyclopropane, ▲; *n*-butane, □; isobutane, ◇. Closed symbols represent supercritical fluids at the critical densities.

cosities are from ref. 14. Figure 2*B* includes the isobutane and propene results, plus *n*-pentane mobilities from ref. 9 and viscosities from ref. 14. Results are only shown for ranges where experimental viscosity values are available. The value of m in $\mu \propto \eta^{-m}$ tends to be approximately 1.0 at $\eta^{-1} < 200\ P^{-1}$, while at $\eta^{-1} > 200\ P^{-1}$ m can either > 1.0 or < 1.0. As the critical region is approached ($\eta^{-1} > 2000\ P^{-1}$) we always observe $m < 1.0$ (Fig. 2). It has previously been found that in many $C_{n\geq 5}$ hydrocarbons below their normal boiling points, in the range $40 < \eta^{-1} < 400\ P^{-1}$, the value of m is > 1.0 (1, 9).

There is a distinct maximum in the μη plots for

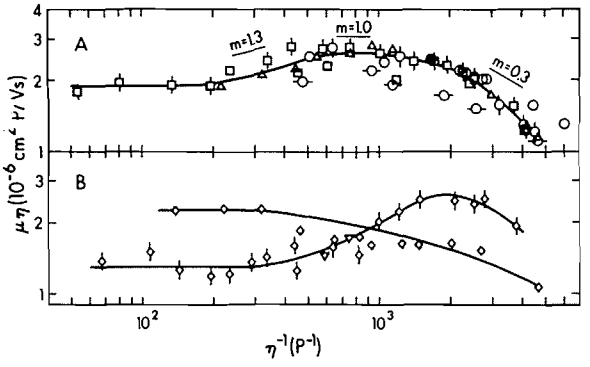

FIG. 2. Plot of μη against the inverse viscosity η^{-1}. The symbols are the same as in Fig. 1, with the addition of *n*-pentane (◇, ref. 9) and *n*-hexane (□, ref. 8). The dashed lines and values of m illustrate $\mu \propto \eta^{-m}$.

propane, *n*-pentane, and *n*-hexane (Fig. 2). The possibility of a maximum for the other liquids cannot be ruled out.

The mobility in cyclopropane is plotted against T^{-1} in Fig. 3. The dashed line represents $E_\mu = 4.6$ kJ/mol. Although no experimental viscosity data are available for cyclopropane, from Fig. 2 it can be expected that the value of m will be much closer to 1 than to 2. Hence we conclude that $E_\eta \approx 4$–5 kJ/mol for liquid cyclopropane well away from the critical region. The values of η for cyclopropane given in ref. 16 were estimated by the method of Souders and they yield a value of E_η that is too small (2.3 kJ/mol). The method of Morris is

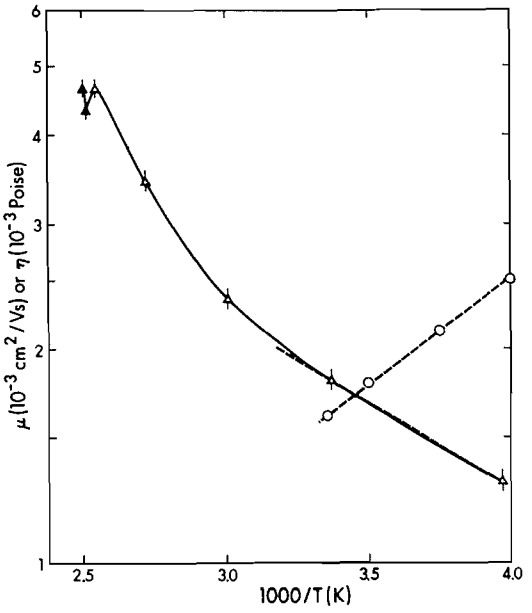

FIG. 3. Arrhenius plots of mobility and viscosity for cyclopropane. Mobilities: liquid, △; supercritical fluid at critical density, ▲. The viscosities (O) were estimated by the method of Morris (15). The dashed lines were used to estimate the values of E_μ and E_η given in the text.

recommended for small cyclic compounds (15), and it gives $E_\eta = 5.7$ kJ/mol for cyclopropane at the temperatures in question (Fig. 3), in satisfactory agreement with the estimate based upon the cation mobilities.

It should be mentioned that the viscosities of a number of liquids given in ref. 16 were estimated by the method of Souders, and these should not be used. The viscosity values are probably accurate to within 25% (not the 3–5% stated), but the activation energies might be wrong by a factor of 2. The method of van Velzen is recommended for open chain hydrocarbons (15).

Discussion

The plot of cation mobility against temperature contains a small dip in the critical region for cyclopropane, but not for the other hydrocarbons (Fig. 1). In earlier work a dip was also noticed only for cyclic hydrocarbons (8, 17). In all the other systems there is a monotonic increase of cation mobility with temperature. The reason for the difference in behavior is not known. The dip in cation mobility is not related to the much larger decrease in electron mobility in the high temperature portion of the liquid range of spherelike and globular hydrocarbons (7, 9, 10, 18, 19). The latter has been attributed to the break up of a conduction band, which participates in the transport of the electrons (9, 20) but not of the ions. The extent of electrostriction about the ions should be similar in all the hydrocarbon critical fluids, so it is unclear why the cyclic hydrocarbons display slightly different behavior.

It should be mentioned that the very large fluctuations in density that are characteristic of the critical fluid have correlation lengths much greater than the electron or ion interaction distances, so the mobilities of electrons and ions in the critical fluid are not much different from those in the adjacent fluids on either side of the critical region.

While Walden's rule is not generally true in detail (Fig. 2), all of the present results can be represented to within a factor of two by the approximation:

$$[1] \quad \mu\eta \approx 2 \times 10^{-6}\ \text{cm}^2\ \text{P/V s}$$

It is surprising that the same approximation applies to within a factor of two to cation mobilities in widely differing liquids (1, 21), from viscous paraffin oils (21), through C_{16} (21) to C_1 alkanes, to liquid nitrogen (22), hydrogen (23), argon (22, 24), neon (25), helium (26, 27) and even ammonia (calculated from data in refs. 22 and 28). Although any particular solvent has been measured over a relatively small range of viscosities (21), approximation [1] is valid in the extensive zone $0.2 < \eta^{-1} < 40\,000\ \text{P}^{-1}$.

Stokes' law, or some treatment from which Stokes' law is recoverable, is the more usual starting point for examination of ion mobilities (24, 29–35). An early attempt to connect liquid and gas behavior, that is, to account for the effect of changing the fluid density, involves modification of Stokes' law to (29, 30):

$$[2] \quad \mu\eta = \frac{e}{6\pi r}\left(1 + \frac{c\lambda}{r}\right)$$

where r is the ion radius, λ is the mean free path, and c a constant. The 6π indicates that the medium "wets" the ion (perfect stick). If the ion moves through the fluid by pushing molecules out of its path, the factor 6π would be 4π (perfect slip).

It may be mentioned that the semihydrodynamic equation used successfully to explain the mobility of electrons (large-bubble state) in dense helium gas at low temperatures (ref. 36 and subsequent work on electrons in dense helium gas) corresponds to eq. [2] with $c = 3/2$ and λ given by:

$$[3] \quad \lambda = 3\eta/\rho\bar{v}$$

where ρ is the density in g/cm^3 and $\bar{v}$ is the mean speed of the Maxwellian distribution of molecular velocities. However, [2] with [3] was not used for the electron bubble state in liquid helium (37) and is unsuitable for the liquid state in general. The attempt to use this semihydrodynamic equation to describe the mobility of electrons in the localized state in liquid hydrocarbons (38) is inappropriate. A reason in addition to those given previously (39) is the following. Equation [3] applies to dilute gases. At higher densities λ is smaller than indicated by [3] (40). The use of realistic values for ionic or electron bubble radii in liquids, with λ from [3], always gives $(c\lambda/r) \gg 1$. Thus [3] leads to $\mu\eta$ that are much too large for ions or localized electrons in liquids.

In dense liquids one has $(c\lambda/r) < 1$ and Stokes' law is a reasonable approximation of [2]. This is the situation at low values of η^{-1} (Fig. 2). The value of η^{-1} was increased experimentally by heating the liquid under its vapor pressure. This also decreased the liquid density and thereby increased λ. When $(c\lambda/r)$ approaches unity eq. [2] indicates that $\mu\eta$ should increase above that expected from Stokes' law, in qualitative agreement with the results at $\eta^{-1} > 200\ \text{P}^{-1}$ (Fig. 2). However, the subsequent decrease of $\mu\eta$ at $\eta^{-1} > 10^3\ \text{P}^{-1}$ must have a different cause, because one might expect λ to continue to increase with decreasing density.

The charged ion interacts more strongly with neighboring molecules than would a neutral particle (31–35, 41). There are two main sources of friction in addition to that expected from a hard core (Stokes' law). One is the electrostriction of the solvent about the ion (34, 35, 41), which increases the local density and thereby the local viscosity. This effect occurs in both nonpolar and polar solvents and increases with increasing compressibility of the liquid. The other is the interaction between the ion charge and the electric dipoles of the solvent molecules, which produces a drag on the translational motion of the ion (31, 33). This effect increases with increasing solvent dipole moment (or dielectric constant) and decreasing ion radius.

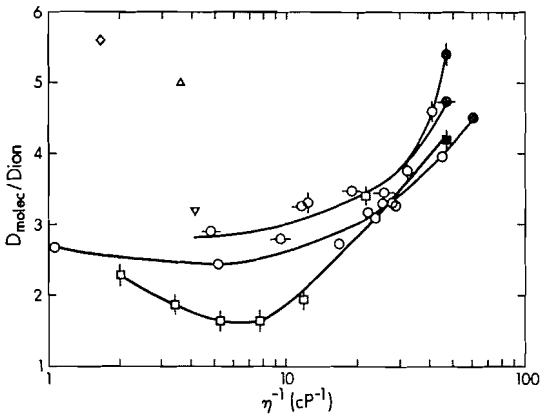

FIG. 4. Ratio of diffusion coefficients D_{molec}/D_{ion} plotted against the inverse viscosity. Methane, O; ethane, —O—; ethene, ○; *n*-hexane, □, ref. 8. The closed symbols represent ratios for molecules in the critical fluid and ions in the gas at the critical density and 1–2 K above T_c. The ratios for the noble liquids are for a pressure of 15 atm, ref. 24: argon, △; krypton, ▽; xenon, ◇. The argon viscosity value is from ref. 46, and those for krypton and xenon are from ref. 47. The viscosity increases by ~2% on going from 1 to 15 atm (46*b*).

The behavior of the ion can be compared with that of the neutral solvent molecules through the ratio of their diffusion coefficients D.

$$[4] \quad D_{molec}/D_{ion} = eD_{molec}/\mu kT$$

where e is the number of protonic charges on the ion, $k = 8.6 \times 10^{-5}$ eV/K is Boltzmann's constant, and T is the absolute temperature. In the noble liquids argon, krypton, and xenon at 15 atm pressure and temperatures slightly above their normal boiling points, the ratio D_{molec}/D_{ion} has values from 3.2 to 5.6 (24, 35). The values were accounted for by assuming that the ions were dimeric (the hard core radius of M_2^+ is greater than that of M^+), and considering the effect of the ion–molecule polarization interaction upon the local density (electrostriction).

Self diffusion coefficients have been measured up to the critical point in methane (42), ethane (43, 44), and ethene (45). The ratio D_{molec}/D_{ion} is plotted against η^{-1} in Fig. 4 for these liquids and for *n*-hexane (8). The ratio has values of 2–3 in the liquids at or below their normal boiling points ($\eta^{-1} \leq 800$ P^{-1}), but they increase to 4–5 in the near critical fluids. The ratios in the hydrocarbons are lower than those in the noble liquids at the same value of η^{-1} (Fig. 4 and refs. 46 and 47). This may imply that the relative effect of electrostriction is smaller when the molecule and ions are larger and more complex, or that the ions are smaller than solvent dimers, or both.

The earlier suggestion that the cation in liquid ethane drags with it a solvent shell comprised of eleven additional ethane molecules (4) is not correct. Furthermore, the values of $\mu\eta$ in the earlier work were 35% lower than the present values at the same η^{-1}; the sample treatment (4) might have generated olefins which could form relatively large (multimeric) cations.

The fact that $\mu\eta$ for radiolytic ions is relatively insensitive to the molar volume of the hydrocarbon (Fig. 2 and ref. 1) may be attributed to a smaller role of electrostriction when the ions and solvent molecules are larger.

The value of D_{molec}/D_{ion} is also increased by the presence of a permanent dipole moment on the molecules (17), which contributes to the drag on the ion. The value of the ratio for the nonpolar benzene is 2.0 ± 0.1 at temperatures from 290 to 550 K (17, 48), while in the polar toluene (dipole moment = 0.4–0.6 D in the liquid phase, ref. 49) the ratio is 3.8 ± 0.2 over the temperature range 180 to 380 K (17, 48*c*, 50).

The decrease of $\mu\eta$ and increase of D_{molec}/D_{ion} at high η^{-1} (Figs. 2 and 4, respectively) are attributed to increased electrostriction in the high temperature liquids. The extent of electrostriction increases with the liquid compressibility (41). As the critical region is approached the compressibility increases rapidly.

In summary, ion mobilities in liquid hydrocarbons well below their normal boiling points are chiefly controlled by the fluidity. The value of $\mu\eta$ is not very sensitive to the size of the hydrocarbon molecule, and hence of the ion in these radiolytic systems. This is attributed to a smaller relative effect of electrostriction when the ions and molecules are larger. At higher temperatures and concomitant lower densities $\mu\eta$ first increases due to an increasing mean free path of the ion, then decreases as the critical region is approached, due to the increasing liquid compressibility and consequent electrostriction about the ion.

MICHAEL FALK. Can. J. Chem. **58**, 1495 (1980).

We have studied the infrared spectra of H_2O, D_2O, and HDO in hydrated Nafion membranes in the sodium form. The spectrum of isotopically isolated HDO exhibits two distinct absorption bands in the OH stretching region and similarly in the OD stretching region. These bands have been taken to correspond to two distinct environments of the OH groups in Nafion, identified as O—H···O and O—H···CF_2. It appears that a substantial proportion of water molecules have an OH group (or occasionally both OH groups) exposed to the fluorocarbon environment. This implies that the hydrated ion clusters are either much smaller than previously estimated or, more likely, are non-spherical in shape with frequent local intrusions of the fluorocarbon phase. Water in Nafion is much less strongly hydrogen-bonded than water in aqueous salt solutions at the same temperature and may be expected to have distinct physical properties.

MICHAEL FALK. Can. J. Chem. **58**, 1495 (1980).

Nous avons étudié les spectres infrarouge de H_2O, D_2O et HDO dans des membranes hydratées de Nafion sous forme de sel de sodium. Le spectre du HDO isotopiquement isolé montre deux bandes distinctes d'absorption dans la région de vibration de valence OH et de même dans la région de valence OD. On admet que ces bandes correspondent à deux environnements distincts des groupements OH dans le Nafion, identifiés comme étant: O—H···O et O—H···CF_2. Il semble qu'une proportion appréciable des molécules d'eau ont un groupement OH (ou occasionnellement les deux groupements OH) exposés à l'environnement du fluorocarbone. Ceci indique que les groupes d'ions hydratés sont ou bien plus petits que prévu ou, plus probablement, possèdent une forme non sphérique avec de fréquentes intrusions locales de la phase fluorocarbone. L'eau dans le Nafion a des liaisons hydrogène moins fortes que celles de l'eau dans les solutions salines à la même température et on doit s'attendre à lui trouver des propriétés physiques différentes.

[Traduit par le journal]

Infrared spectroscopy can be an effective tool in the investigation of water dispersed in other media. As a part of a program of spectroscopic studies on water in different molecular environments, we have investigated water in hydrated Nafion membranes. Nafion is a perfluorosulfonate resin developed by the Plastics Department of du Pont (1). This polymer consists of a perfluorinated polyethylene backbone with pendant side-chains terminating with —$SO_3^-M^+$ groups, where M^+ is an exchangeable cation. The incidence and length of the side-chains is variable within limits and Nafion membranes used in electrochemical applications usually have equivalent weights of 1100 to 1500 per —$SO_3^-M^+$ group. Nafion membranes are used extensively as separators in electrolytic cells, their industrial importance being due to their exceptional chemical, thermal, and mechanical stability, combined with high permeability to cations (2).

The mechanism of cation transport, which holds the key to the membranes' performance, is not yet well understood, largely because of the lack of knowledge about the detailed microstructure of hydrated Nafion. Hydrated membranes of equivalent weight 1200, in the sodium form, contain up to 21% of water by weight or 18 H_2O per —$SO_3^-Na^+$ pair, the exact amount of water depending on pretreatment and on the thermal history of the sample (1). Studies of low-angle X-ray scattering and of other physical properties by Yeo and Eisenberg (3), Gierke (4), and others (5), as well as analogy with other ionomers (6), suggest that hydrated Nafion is a two-phase system, consisting of hydrated clusters of ions embedded in the surrounding fluorocarbon medium. Observed Bragg spacings are taken to indicate that the hydrated clusters are about 50 Å apart. Assuming that they are spherical in shape, and considering the volume changes occurring during the hydration process, Gierke estimated that the clusters are about 40 Å in diameter (4). Apart from this rough estimate of size, little is known to-date about the geometry of these hydrated ion clusters or about the state of water within them.

Some structural deductions may be made *a priori*. In the hydrated sodium form of Nafion there is sufficient water to complete the coordination of the sodium ion (which requires six H_2O) and of the polymer-bound sulfonate ion (which also requires about six H_2O), especially as water molecules may be shared between the cation and the anion. The ion pairs —$SO_3^-Na^+$ can therefore be expected to be fully surrounded by water, with the individual ions separated most of the time. This is indeed confirmed by the infrared study of the stretching vibrations of the —SO_3^- ion in Nafion by Mauritz and Lowry (7) and by the sodium-23 nmr study by

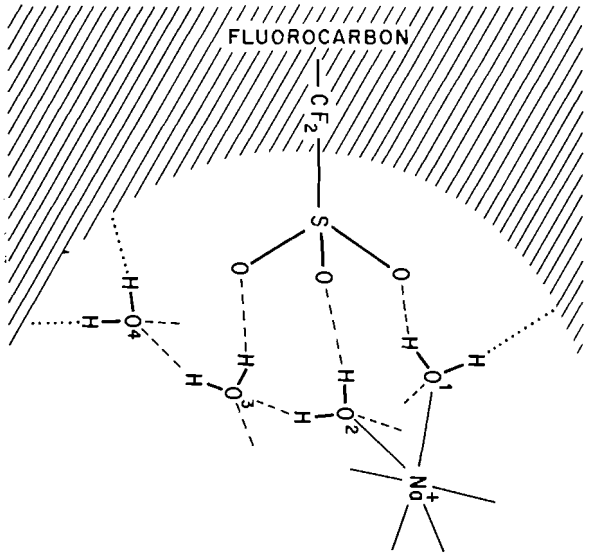

FIG. 1. Hydrogen-bonded (---) and non-hydrogen-bonded (···) interactions of water molecules in a portion of a hydrated ion cluster in Nafion.

Komoroski and Mauritz (8). The lone pairs of electrons on the water molecules within the clusters may interact either with a sodium ion or with an OH group of another water molecule. Similarly, the OH groups may interact either with an oxygen atom of an anion or with the oxygen of another water molecule (Fig. 1). Because of electrostatic repulsion, the periphery of the cluster is not likely to be completely lined with $—SO_3^-$ ions, so that some peripheral water molecules may find themselves in direct contact with the fluorocarbon phase. This would lead to the occurrence of a certain proportion of non-hydrogen-bonded OH groups, which should be detected and, in principle, quantitatively estimated by infrared spectroscopy.

Infrared spectra of Nafion have already been reported by Mauritz and Lowry (7), by Lopez *et al.* (9), and by Heitner-Wirguin (10), but these authors did not concern themselves in detail with the absorption bands due to water. Lopez *et al.* did not comment on the presence of a high-frequency shoulder in their spectra of H_2O in Nafion (Fig. 1 of ref. 9), while Heitner-Wirguin simply assigned such high-frequency shoulders to "free H_2O" (Table 3 of ref. 10), without any discussion of the structural implications of such an assignment. The present investigation deals specifically with the bands due to OH and OD stretching of the isotopic molecules H_2O, D_2O, and HDO, and those due to the bending fundamental of H_2O in the sodium form of Nafion (a similar study of other cationic forms will be presented separately). Special attention has been paid to the spectral profiles of the stretching bands of isotopically isolated HDO, which are most directly interpretable structurally (11, 12).

Experimental

Homogeneous Nafion films bearing product designations 125 (equivalent weight 1200, thickness 127 μm) and 142 E (equivalent weight 1400, thickness 51 μm) were obtained from the Plastics Department, E. I. du Pont de Nemours and Co. These films were supplied in the protonated form. Prior to use they were submitted to a standard pre-treatment (1) by boiling in distilled water for 30 min. They were then converted to the sodium form by immersion in 1 *N* NaCl solution for 1 h or more, rinsed, and dried over sulfuric acid.

The films were mounted in an infrared cell with silver chloride windows. The cell formed a part of a hygrostatic system in which moist air was continuously circulated, keeping the sample temperature at about 30°C and maintaining a constant relative humidity (rh) level and D/H ratio. The infrared absorption of the H_2O/D_2O vapor in the sample cell was compensated by a matched reference cell. A low rh level of about 3% was maintained with concentrated sulfuric acid. Higher levels of rh were obtained with saturated solutions in H_2O/D_2O of one of the following salts: $MgCl_2$ (about 33% rh), $NaNO_2$ (about 66% rh), or KBr (about 84% rh). High value of rh, approaching 100%, was maintained with an appropriate mixture of neat H_2O and D_2O. The films which have been equilibrated at 100% rh will be referred to as "hydrated", though their water content (found for Nafion 125 to be about 9% H_2O by weight) was substantially lower than that of fully hydrated Nafion as reported in ref. 1.

The spectra were recorded on a model 180 Perkin-Elmer spectrophotometer. The thickness of Nafion films was suitable for the study of the OH stretching fundamental of HDO when the films were about 90–95% deuterated, and for the study of the OD stretching fundamental of HDO when they were about 10% deuterated. The much more intense H_2O stretching fundamental in undeuterated films could only be studied at lower water contents, up to about 84% rh in Nafion 142 E and up to about 33% rh in the thicker films of Nafion 125. In recording the spectra in the region of the OD stretching fundamental, the absorption of dry Nafion due to overtones of the CF stretching vibrations was compensated by a matching dry film of undeuterated Nafion, placed in the reference beam outside of the hygrostatic system. In the regions of the OH stretching and HOH bending fundamentals, dry Nafion has no appreciable absorption bands and there was no need for compensation. The regions of the D_2O and HDO bending fundamentals were too strongly obscured by Nafion absorption to yield useful spectra.

Results and Band Assignments

HDO Stretching

Figure 2 shows the region of the OH stretching fundamental in the infrared spectrum of HDO in fully hydrated films of Nafion 125 and 142 E. The spectral profiles are very nearly the same, indicating that the state of water in Nafion does not change appreciably with the sulfonate content. The same conclusion was derived from the observations on the other water bands investigated.

The infrared spectrum of HDO in liquid water has a single broad OH stretching band, with a maximum, at 30°C, near 3404 cm^{-1} (13). Spectra of HDO in aqueous salt solutions (13) and those of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

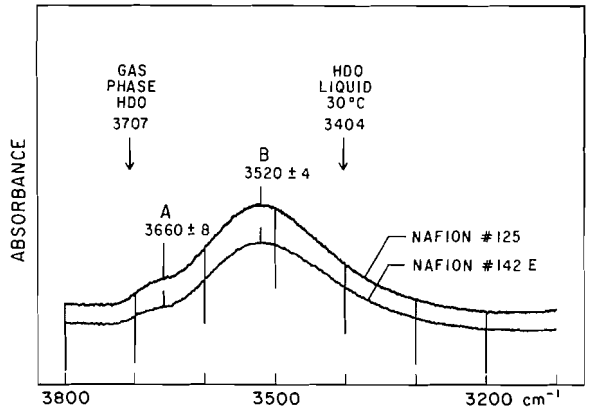

FIG. 2. The OH stretching region of HDO in the spectrum of two fully hydrated Nafion films (100% rh; 5% H, 95% D).

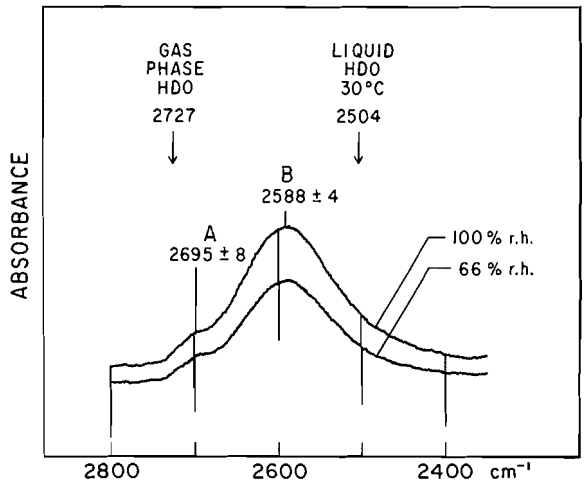

FIG. 3. The OD stretching region of HDO in the spectrum of Nafion 125 at two degrees of hydration (90% H, 10% D).

HDO in hydrophilic polymers such as nucleic acids (14) resemble the spectrum of the pure liquid at the corresponding temperature. In sharp contrast, the spectrum of HDO in hydrated Nafion consists of *two bands*, marked A and B in Fig. 2, whose frequencies, 3660 and 3520 cm^{-1}, are *much higher* than those of HDO in liquid water. Apparently OH groups in hydrated Nafion occur in two distinct types of surroundings, which we shall refer to as A and B, pending further discussion below.

Figure 3 shows the corresponding OD stretching absorption of HDO in Nafion 142 E at two water contents. The upper spectrum corresponds to fully hydrated Nafion and is analogous to the OH stretching spectra in Fig. 2. The OH/OD frequency ratios are $(3660 \pm 8)/(2695 \pm 8) = 1.358 \pm 0.005$ for band A, and $(3520 \pm 4)/(2588 \pm 4) = 1.360 \pm 0.003$ for band B, the same within experimental error as the ratio for HDO in the gas phase, 3707.5/2726.7 = 1.360 (15).

The lower spectrum in Fig. 3 shows that upon partial dehydration of Nafion small changes occur in the band shape. These changes are consistent with the frequencies of bands A and B remaining unchanged, and the ratio of the intensity of band A relative to band B increasing slightly upon dehydration. Similar observations were made for Nafion 125 and for the OH stretching band of HDO.

Structural Identification of Bands A and B

The main band in the spectrum of HDO in Nafion, labelled B, is clearly associated with those OH (or OD) groups of water in Nafion which form hydrogen bonds. Two types of hydrogen bonds are possible, water···water and water···sulfonate (Fig. 1). The occurrence of only one band with no resolved sub-structure indicates that these two possible types of O—H···O bonds are of similar average strength. Similarly, there is no spectroscopic distinction between the stretching frequencies of those water molecules which are interacting through their lone electron pairs with the sodium ions (H_2O^1 and H_2O^2 in Fig. 1) and those which only interact with other water molecules (H_2O^3 and H_2O^4 in Fig. 1). The situation is not unlike that observed in the spectra of HDO in salt solutions, discussed in ref. 13. The large shift of band B to high frequency with respect to the liquid-phase value (cf. Figs. 2 and 3) shows that the mean strength of hydrogen bonds is substantially lower than in liquid water.

The smaller band, labelled A, is at a frequency sufficiently close to that of gas-phase HDO (cf. Figs. 2 and 3) that is must be considered due to OH groups not involved in O—H···O hydrogen bonding. We believe that this band originates in the OH groups exposed to the fluorocarbon environment. The frequencies of HDO in monomeric water dissolved in perfluorinated solvents may be deduced from the data in refs. 16 and 17 to be about 3680 cm^{-1} for OH stretch and about 2705 cm^{-1} for OD stretch. The slightly lower observed frequencies of band A in Nafion (3660 cm^{-1} for OH stretch and 2695 cm^{-1} for OD stretch) are what would be expected for water molecules on the periphery of the flurocarbon medium, with one or both OH groups exposed to the flurocarbon, but also engaging in some water–water and water–ion interactions (cf. Fig. 1).

H_2O and D_2O Stretching

Figure 4 shows the OH stretching region of the spectrum of H_2O in undeuterated Nafion 142 E at different hydrations. Four distinct bands are re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

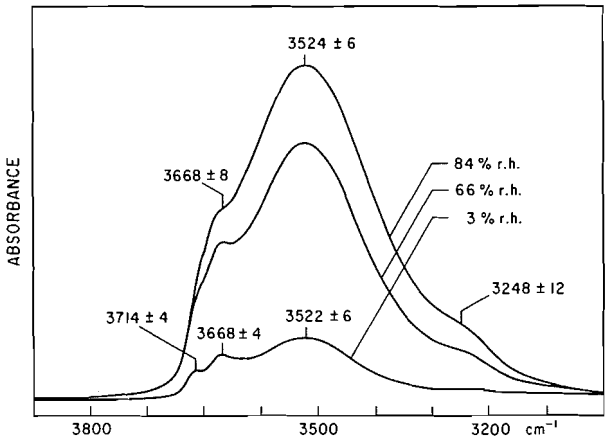

FIG. 4. The OH stretching region of H_2O in the spectrum of undeuterated Nafion 142 E at three degrees of hydration.

solved at low hydrations, three of them being still detectable at 84% rh. Figure 5 shows the corresponding OD stretching region of D_2O in the same Nafion sample in a nearly fully deuterated state. The D_2O features do not exactly correspond to the H_2O features of Fig. 4. For D_2O five distinct bands are evident at low hydrations and four at higher hydrations. The assignment of these H_2O and D_2O absorption bands, as well as their correspondence to the HDO bands A and B, require the following analysis.

If, as has been concluded from the HDO spectrum, OH groups in Nafion occur in two types of spectroscopically distinct surroundings, A and B, which differ widely as to the strength of hydrogen bonding, then the corresponding H_2O spectrum should consist of a superposition of contributions from two stretching fundamentals, ν_1 and ν_3, of H_2O molecules in each of three distinct types of

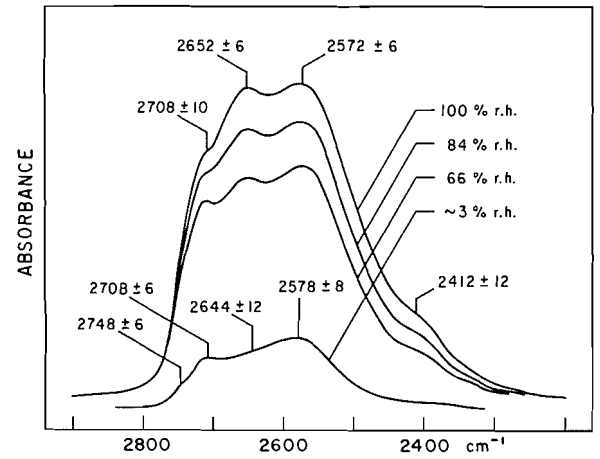

FIG. 5. The OD stretching region of D_2O in the spectrum of Nafion 142 E at four degrees of hydration (about 5% H, 95% D).

surroundings: A···HOH···A, A···HOH···B, and B···HOH···B. For brevity we shall refer to them as AA, AB, and BB. In addition, the lower-frequency portion of the OH stretching region of the H_2O spectrum may also contain a contribution from the overtone $2\nu_2$ of the HOH bending vibration, at about $2 \times 1630 = 3260\ cm^{-1}$. This overtone may complicate the observed spectrum by entering into Fermi resonance with the lower-frequency H_2O stretching fundamental, ν_1, resulting in intensity redistribution and frequency shifts (17). An analogous situation may be expected to occur for D_2O.

Schiffer *et al.* (18) have established a correlation between stretching frequencies of HDO and the

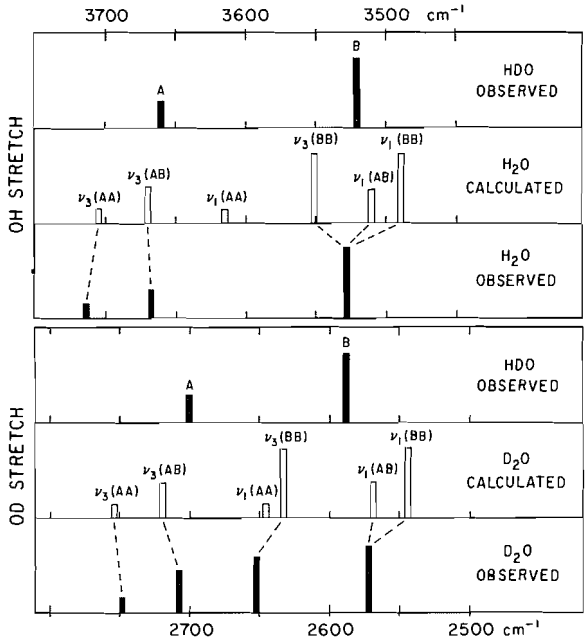

FIG. 6. Comparison of the observed stretching frequencies of H_2O and D_2O in Nafion with those calculated from the corresponding HDO frequencies.

corresponding frequencies of H_2O and D_2O. Using eqs. [1], [2], [15], and [16] in ref. 18, and the observed values of HDO frequencies, we have calculated the ν_1 and ν_3 frequencies of the H_2O and D_2O molecules of type AA, BB, and AB in Nafion. These calculated frequencies, which must be considered first-order approximations, since they neglect Fermi resonance with $2\nu_2$ and the coupling of like vibrations on neighboring molecules, are shown schematically in Fig. 6.

The observed H_2O spectrum (Fig. 4) shows a broad band at about $3248\ cm^{-1}$, which clearly corresponds to the $2\nu_2$ overtone, allowing for a small downward shift due to Fermi resonance. The remaining three observed features, at 3714, 3668, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

3524 cm^{-1}, are then assigned to the ν_1 and ν_3 fundamentals of AA, AB, and BB molecules as shown by broken lines in the upper part of Fig. 6. Apparently the bands due to ν_3(BB), ν_1(AB), and ν_1(BB) overlap into a single unresolved band, while ν_1(AA) is too weak to be observed in the midst of other, more intense absorptions. As may be expected from the HDO spectrum, most of the intensity arises from absorptions due to molecules of type BB, with a smaller contribution from AB, and a very small but observable contribution from AA.

Similarly, the observed D_2O spectrum (Fig. 5) shows a band at about 2412 cm^{-1}, which is due to the $2\nu_2$ overtone. This leaves four features which are then assigned to the partly superposed ν_1 and ν_3 fundamentals of the three types of D_2O molecules, as shown by broken lines in the lower part of Fig. 6. The reason for one more band being resolved in the D_2O spectrum than in the H_2O spectrum is the larger separation between the ν_1 and ν_3 fundamentals in molecules of type BB. As a result, D_2O and H_2O spectra present a different appearance in the stretching region. As before, the observation of the D_2O band at 2748 cm^{-1} shows the non-negligible occurrence of water molecules of type AA, at least at lower hydrations.

H_2O Bending

Figure 7 shows the region of the HOH bending fundamental in the spectrum of undeuterated Nafion at different degrees of hydration. Only one band is resolved in all cases, its maximum shifting slightly from about 1625 cm^{-1} in nearly dry Nafion to 1630 cm^{-1} in the fully hydrated material. The halfwidth varies from about 40 cm^{-1} to about 60 cm^{-1} with increasing hydration.

We interpret the single band as an unresolved envelope resulting from the superposition of bands due to HOH bending of the different types of water molecules. In general, increased hydrogen bonding increases the HOH bending frequency, hence the frequencies of molecules AA, AB, and BB may be expected to increase in that order. The observed small increase in frequency and bandwidth with increasing hydration may therefore reflect a minor increase in the relative proportions of the more strongly hydrogen-bonded molecules BB with respect to those of types AB and AA.

Discussion

Fraction of OH Groups Exposed to the Fluorocarbon Environment

The ratio of areas of bands A and B of HDO in Nafion should in principle provide a measure of the relative proportions of O—H···CF_2 and O—H···O

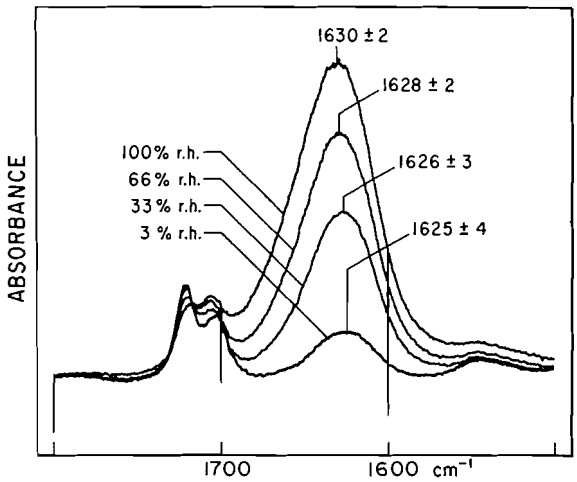

FIG. 7. The HOH bending region in the spectrum of undeuterated Nafion 142 E at four degrees of hydration. The small bands at 1545, 1705, and 1722 cm^{-1} are absorptions of dry Nafion.

environments. Unfortunately, a quantitative estimation is not possible but nevertheless a useful order-of-magnitude estimate can be made.

The individual areas of bands A and B are difficult to determine accurately because of severe overlap and uncertain profiles of the component bands. The best possible estimate is that bands A and B have an area ratio of the order of 1:13. In order to calculate the actual ratio of OH groups in the two environments, we have to allow for the well-known increase of the infrared absorptivity of OH (or OD) oscillators with hydrogen bonding. Glew and Rath found that the integrated absorptivity of the OH stretching fundamental is proportional to the frequency shift from the gas-phase frequency (16). Irregularities in such behavior are sometimes found (19), but assuming that the linear relation of Glew and Rath holds, we estimate that the OH groups giving rise to band B at 3520 cm^{-1} (2580 cm^{-1} for OD) probably absorb four times more intensely than those which give rise to band A at 3660 cm^{-1} (2695 cm^{-1} for OD). This means that the ratio of OH groups in OH···CF_2 environments to those in OH···O environments is of the order of 4:13. In other words, a fraction 4/(13 + 4) or roughly one quarter of all OH groups do not participate in OH···O bonding.

Geometry of the Hydrated Ion Clusters

We have deduced a rather surprising fact that a high proportion of water molecules in Nafion are exposed to the fluorocarbon medium, with somewhere of the order of a quarter of all OH groups so exposed. This finding has important implications for the size and shape of the hydrated ion clusters.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

We must first of all assert that most of the water in hydrated Nafion is indeed in the clusters and is not dispersed in the fluorocarbon medium at the molecular level. Three observations point strongly to this being the case. Firstly, the solubility of water in the fluorocarbon medium may be expected to be very low. We have been unable to detect water spectroscopically in Teflon sheets thoroughly soaked in water (20). Secondly, the OH stretching frequencies of band A of HDO as well as the stretching frequencies of H_2O and D_2O assigned to ν_3(AA), are lower by 10–20 cm^{-1} than the frequencies reported for H_2O (16, 17) or calculated for D_2O for monomeric water molecules completely surrounded by liquid fluorocarbon. Thirdly, in the spectrum of Nafion at higher hydrations the relative intensity of bands assigned to ν_3(AA) of H_2O and D_2O is very small, showing that water molecules in $CF_2\cdots HOH\cdots CF_2$ environments are uncommon relative to those in $CF_2\cdots HOH\cdots O$ environments. Hence it is possible to conclude that most of the $OH\cdots CF_2$ interactions occur at the interface between the aqueous regions and the non-polar fluorocarbon phase, and not totally within the fluorocarbon phase. This implies a high surface-to-volume ratio for the hydrated clusters and points either to their small size or to a highly non-spherical shape.

If we assume that the clusters are approximately spherical, and are sharply defined from the surrounding phase, then the high surface-to-volume ratio requires that they have an average diameter of the order of 12 Å. This is much smaller than Gierke's estimate of 40 Å, (4) even after allowing for some diminution of cluster size with lowering of water content.[2]

If the clusters are indeed 30–40 Å in diameter, then the present results imply large-scale deviations from spherical geometry. The picture that emerges is that of the aqueous phase forming irregularly shaped bodies with numerous interconnections and local intrusions of the fluorocarbon phase. The side-chains, which due to their ether links are much less hydrophobic than the main fluorocarbon chain, are most likely to form such intrusions.

State of Water in Nafion

Our results indicate not only that a sizable fraction of OH groups of water in Nafion are exposed to the fluorocarbon medium and thus do not participate in hydrogen bonding, but also that those OH groups which do participate in the hydrogen bonding, do so weakly. Using the well-known linear relation between the lowering of the OH stretching frequency from the gas-phase value and the strength of the hydrogen bond, due to Badger and Bauer (21), the average strength of the remaining hydrogen bonds of water in Nafion can be estimated as about 62% of the value for liquid water at the same temperature: $(3707 - 3520)/(3707 - 3404) = (2727 - 2588)/(2727 - 2504) = 0.62$.

The cooperativity of hydrogen bonding between water molecules has been recognized long ago (22) and has been stressed again recently (23). Single water molecules are poor hydrogen-bond donors and acceptors, and the strength of hydrogen bonding increases rapidly with the size of the water cluster (24). Water in cellulose acetate membranes has recently been found to be relatively weakly hydrogen-bonded, which has been explained by the small average size of the clusters of water molecules in that medium (25). Judging from the OH or OD stretching frequencies of water in Nafion, hydrogen bonding in this medium appears to be even weaker than in cellulose acetate. This appears to be due not so much to the small size of the water clusters, as to the incompleteness of the hydrogen bonding in the aqueous phase, caused by what must be very frequent local intrusions of the fluorocarbon phase. In any event, it is clear that water in Nafion is in a state quite distinct from the liquid phase and may be expected to have physical properties widely different from those of bulk water or aqueous solutions.

Conclusions

1. Infrared spectra indicate that hydrogen bonding of water in fully hydrated Nafion is considerably weaker than in liquid water at the same temperature.

2. A substantial proportion of water molecules have one OH (or occasionally both OH groups) exposed to the fluorocarbon environment.

3. The hydrated ion clusters are either much smaller than previously estimated or, more likely, are highly non-spherical in shape with frequent local intrusions of the fluorocarbon phase.

4. Water absorbed in Nafion appears to be in a state quite unlike the liquid phase and may be expected to have physical properties widely different from those of water in aqueous solutions of electrolytes.

[2]Gierke's more recent results lead to the cluster diameter of about 30 Å for sodium Nafion of 1200 equivalent weight and a water content of 9% by weight, corresponding to the "hydrated" films used in the present study. I wish to thank Dr. Gierke for communicating these results to me prior to publication.

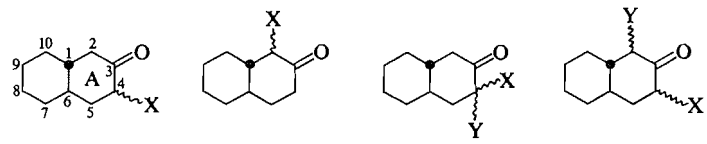
Reçu le 9 janvier 1980

PIERRE METZGER, ELIETTE CASADEVALL, ANDRÉ CASADEVALL et MARIE-JOSÉ POUET. Can. J. Chem. **58**, 1503 (1980).

Les spectres rmn ^{13}C de 31 bicyclo[4,*n*,0]alcanones-3, à jonction de cycle *trans*, α substituées, αα′ et αα disubstituées ont été déterminés. Les effets des substituants sont analysés en fonction de leur nature électronique, de leur configuration axiale ou équatoriale et du degré de déformation du cycle portant la fonction carbonyle. L'influence du substituant sur le déplacement chimique du $^{13}C{=}O$ est discutée sur la base de l'existence de formes de résonance du carbonyle, et des interactions de non liaison entre C=O et X. Comme les spectroscopies ir et uv, la rmn ^{13}C s'avère un bon outil pour déterminer la configuration d'un substituant en α du C=O dans les systèmes figés.

PIERRE METZGER, ELIETTE CASADEVALL, ANDRÉ CASADEVALL, and MARIE-JOSÉ POUET. Can. J. Chem. **58**, 1503 (1980).

The ^{13}C nmr spectra of α, αα, and αα′ substituted *trans-fused* bicyclo[4,*n*,0]alkan-3 ones, are described. Substituent effects are discussed in terms of their electron withdrawing character, axial or equatorial configuration, and cyclohexane deformation. $^{13}C{=}O$ chemical shifts are shown to be based on the polarization of π bond and on C=O/X non-bonded interactions. As in ir and uv spectroscopy, ^{13}C nmr is a convenient method for detecting an α substituent configuration in fixed ring ketones.



Les déplacements chimiques des carbones d'une molécule sont des données qui traduisent à la fois la géométrie moléculaire et l'environnement électronique. Au premier titre la rmn ^{13}C, tout comme la rmn ^{1}H qu'elle complète efficacement, a été utilisée pour résoudre des problèmes d'analyse conformationnelle de cyclanones et de leurs dérivés substitués (1, 2). Au second titre, l'influence du carbonyle sur les déplacements chimiques des autres carbones du cycle a été étudiée (3). Toutefois, la variation du déplacement chimique du $^{13}C{=}O$ en fonction de la nature électronique du substituant et de sa configuration axiale ou équatoriale, a été jusqu'ici peu explorée (4). C'est pourquoi il nous a paru intéressant de rapporter et de comparer les données rmn ^{13}C relatives à une série de 31 bicyclo[4,*n*,0]alcanones-3, α substituées, à jonction de cycle *trans*, avec $n = 4$, 3 ou 2 (Schéma 1 et Tableaux 1, 2, 3) et de dégager les relations qu'une telle comparaison peut mettre en évidence.

L'emploi d'un système figé permettant de distinguer plus aisément les effets électroniques, nous avons déterminé dans un premier temps, l'influence de la nature des substituants et de leur orientation axiale ou équatoriale sur le déplacement chimique des ^{13}C de la molécule, dans le cas de la bicyclo[4,4,0]décanone-3 *trans* avec X-4 = H, CH_3, OCH_3, $OCOCH_3$, C_6H_5, Br, Cl, F, NO_2, CN, $CO_2C_2H_5$ et C≡CH (composés **1** à **12** du Tableau 1). Cette étude a été étendue à quelques dérivés disubstitués -4,4 et -2,4 (composés **13** à **16**, du Tableau 2).[1]

Le système décanique à jonction *trans* étant un

[1]Bien qu'une nomenclature analogue à celle des cycles A et B des stéroïdes soit plus couramment utilisée pour la série décalinique, nous avons préféré utiliser une numérotation homogène pour les trois séries.

SCHÉMA I

système cyclohexanique non déformé, il était par ailleurs intéressant de connaître l'influence d'une déformation géométrique du cycle sur les effets des substituants. Pour cela nous disposions de dérivés bicyclononaniques et bicyclooctaniques *trans* (composés **20** à **23** du Tableau 3 et Schéma 1). On sait en effet que la tension qui résulte d'une jonction 1–2 *trans* entraîne une déformation du cycle A qui est d'autant plus grande que le cycle qui lui est joint est plus petit (5, 6). Cette déformation qui se manifeste par un applatissement du cycle A au niveau du dièdre en *para* de la jonction, se traduit en particulier par la perte du caractère purement axial ou équatorial des liaisons *exocycliques* des carbones C_3 et C_4 délimitant ce dièdre.

Déplacements chimiques ^{13}C

Les carbones primaires, secondaires, tertiaires ou quaternaires ont été identifiés à l'aide de la méthode d'off-resonance. Selon les cas, un échange proton–deutérium en α' et (ou) en α du C=O, ou une irradiation sélective des protons H-2 et H-4 ont permis de différencier les carbones 2 et 4. Par ailleurs les effets γ d'un substituant axial d'une part, β et γ du deutérium (7) d'autre part, ont aidé à l'attribution des signaux correspondants aux carbones situés en β et γ du substituant. La caractérisation des signaux des ^{13}C en position 7, 8, 9 et 10 pour les composés décaniques, 7, 8 et 9 pour les composés nonaniques, 7 et 8 pour les composés octaniques a été réalisée sur la base de l'atténuation des effets δ, ε et ζ du substituant et des effets β du cycle A.

Les effets des substituants sur le déplacement chimique des différents carbones sont portés dans le Tableau 1 pour les dérivés monosubstitués de la bicyclo[4,4,0]décanone-3 *trans*, dans le Tableau 2 pour les dérivés disubstitués. Dans la Tableau 3 est établie une comparaison des déplacements chimiques ^{13}C des cétones appartenant aux trois séries bicycliques ainsi que de ceux de leurs dérivés chlorés.

Enfin dans le Tableau 4 nous mentionnons à titre indicatif le déplacement chimique des carbones 3 et 4 des cétones spontanément énolisables dans le solvant utilisé et de leurs énols respectifs: cyano-4*e*, nitro-4*e* et carbethoxy-4*e* bicyclo[4,4,0]-décanones-3 *trans*. Les autres carbones des formes énoliques n'ont pu être identifiés avec certitude, en raison même de l'existence de l'équilibre céto–énolique (environ 80:20). Si les $\delta^{13}C$ énoliques sont conformes à ce qui a déjà été observé (8), il faut noter que les signaux des $^{13}C_4$ des dérivés cyano et carbéthoxy se situent à des champs relativement forts pour des carbones de type sp^2.

Discussion des effets de substituants sur le déplacement chimique des carbones sp^3

(A) Bicyclo[4,4,0]décanones-3 trans *substituées en position-4*

1. Effet α C_4

La nature inductive de l'effet α se manifeste par la variation des valeurs des $\delta^{13}C_{\alpha X} - \delta^{13}C_{\alpha H}$ qui suit sensiblement l'échelle d'électronégativité des substituants (Tableau 5), avec cependant deux exceptions, déjà relevées pour les systèmes cyclohexaniques (10), celles des groupements C≡N et C≡C—H.

La comparaison des résultats figurant dans le Tableau 1, à ceux rapportés dans la littérature pour les cyclohexanes monosubstitués (10, 11) montre, comme cela a été antérieurement souligné (2), que la présence du carbonyle entraîne un affaiblissement de l'effet α.

CN	enol.	165,46	81,19
	Δ*	−34,15	39,66
NO_2	enol.	171,18	124,26
	Δ	−29,97	32,07
$CO_2C_2H_5$	enol.	172,07	97,21
	Δ	−32,41	39,79

*$\Delta = \delta^{13}C_{enol} - \delta^{13}C_{cétone}$.

Une autre observation, bien que n'ayant pas de lien direct avec l'effet α, découle de cette comparaison. En considérant que l'adjonction d'un cycle en C_6 au cyclohexane ne modifie que très peu le déplacement chimique des carbones situés en *para* de la jonction de cycle nouvellement formée, ce qui est le cas lorsque X = H, on peut calculer pour chaque substituant X un effet du carbonyle en β du substituant (effet βC=O) sur le carbone α portant le substituant:

$$\beta C{=}O = \delta^{13}C_4 - \delta^{13}C_{\alpha\ (cyclohexane\ monosubstitué)}$$

Les valeurs ainsi obtenues permettent de mesurer l'importance des interactions intramoléculaires C=O/X ressenties par le carbone α. Les valeurs de βC=O rassemblées dans le Tableau 6 montrent que les composés se classent suivant deux catégories par rapport à la cétone non substituée: (*1*) les composés dont le carbone α ne ressent pas plus de perturbation que lorsqu'il existe une interaction C=O/H. Il s'agit en particulier des composés à $CH_3(e)$, CN(*e*), et C≡C—H (*a*); (*2*) ceux dont le carbone α ressent une perturbation plus ou moins grande suivant le substituant, perturbation qui est nominalement supérieure ou inférieure à celle observée pour une interaction C=O/H.

TABLEAU 5. Variation de l'effet α du substituant en fonction de son électronégativité pour les bicyclo[4,4,0]décanones-3 substituées en position-4

X	Electronégativité (9)	$\delta^{13}C_X - \delta^{13}C_H$ X axial	X équatorial
H	2,28	0

F	3,95	52,08	50,74

TABLEAU 6. Effets du C=O sur le carbone α de bicyclo[4,4,0]-décanones-3 substitués en position-4

X	Effet $\beta_{C=O}$
H	14,7
$CH_3(a)$	17,8
C≡C—H(*a*)	14,8
C≡N (*e*)	13,8
CH_3 (*e*)	12,3
OCH_3 (*a*)	9,7
OAc (*a*)	7,7
NO_2 (*e*)	7,2
F (*a*)	5,7
Br (*e*)	4,4
Cl (*e*)	4,4
OCH_3 (*e*)	4,0
OAc (*e*)	2,7
Cl (*a*)	1,9
F (*e*)	0,9
Br (*a*)	−2,1

Il est intéressant de noter que pour un substituant X, le maximum de perturbation enregistrée sur C_α intervient pour celui des deux épimères (axial ou équatorial) qui est thermodynamiquement le plus stable. Il a été montré dans le cas des halogèno cétones (12), que la stabilisation des isomères à F(*e*), Cl(*a*) et Br(*a*) par rapport à leurs épimères respectifs provient d'une plus grande interaction orbitalaire entre les paires d'électrons libres de l'halogène et les orbitales

$$\sigma^*\left(\begin{array}{c} (X)\quad (O) \\ \diagdown\ \diagup\!\!\diagup \\ C\text{—}C \end{array}\right) \text{ ou } \pi^*(C{=}O)$$

Nous verrons plus loin que ces mêmes interactions peuvent permettre d'interpréter l'influence de l'halogène sur les déplacements chimiques $^{13}C{=}O$ relatifs, des halogéno-cétones épimères.

2. Effet β C_5

Tous les substituants ont un effet de déblindage sur le C_5, en général amplifié par rapport à l'effet de champ électrique $\langle E^2 \rangle$ observé en série cyclohexanique (13). Mis à part le cas des halogènes (2), il ne semble pas y avoir de lien entre l'intensité de cet effet et l'encombrement du substituant.

3. Effets γ

Dans tous les cas les effets γ des substituants axiaux produisent un blindage des signaux des carbones considérés ; cependant quelques différences apparaissent selon que le carbone est séparé de

TABLEAU 7. Influence de l'isomérie de position-2*e* et -4*e*, sur les effets Δ des substituants dans le cas des chloro et bromo bicyclo-[4,4,0]décanones-3 *trans* ($\Delta = \delta^{13}C_{\text{cétone halogénée}} - \delta^{13}C_{\text{cétone}}$)

	X-2	αC_2	βC_3	βC_1	$\gamma' C_4$	γC_6	γC_{10}	δC_5	δC_7	δC_9	εC_8
17	Cl-2*e*	21,98	−8,61	8,17	−0,82	0,45	−2,31	−0,29	−0,10	−0,46	−0,45
18	Br-2*e*	16,65	−9,15	8,41	−0,77	1,32	−1,35	0,24	0,37	−0,23	−0,24
	X-4	αC_4	βC_3	βC_5	$\gamma' C_2$	γC_6	δC_7	δC_1	εC_8	εC_{10}	ζC_9
7*e*	Cl-4*e*	22,39	−8,65	11,38	−0,89	−0,14	−0,71	0,18	−0,46	−0,76	−0,31
6*e*	Br-4*e*	14,74	−9,35	12,24	−1,06	1,41	−0,76	0,06	−0,46	−0,74	−0,34

celui portant le substituant par C=O (γ') ou non (γ). On peut noter qu'en valeur absolue $|\gamma C_6| > |\gamma' C_2|$, et que $\gamma' C_2$ est plus sensible à la nature du substituant que γC_6:

$$-5{,}70 < \gamma C_6 < -4{,}45 \quad -5{,}95 < \gamma' C_2 < -2{,}20$$

A l'inverse, les effets γ des substituants équatoriaux sont nettement moins marqués: (*1*) effet de déblindage faible ou nul dans le cas de CH_3 et C_6H_5 sur C_2 et C_6, et de Br et CN sur C_6, et (*2*) effet de blindage faible dans tous les autres cas.

4. Effets δ, ε *et* ζ

Ces effets sont peu importants comparativement aux autres effets et à leurs analogues déterminés en série cyclohexanique (10). Néanmoins les tendances suivantes sont relevées : effet de déblindage sur $\delta' C_1$; effet de blindage sur δC_7; effet de blindage sur $\varepsilon' C_{10}$ et εC_8, avec $|\varepsilon' C_{10}| > |\varepsilon C_8|$; effet de blindage faible sur le carbone ζC_9.

(B) Bicyclo[4,4,0]décanones-3 trans αα *et* αα' *disubstituées*

Les déplacement chimiques des dérivés αα et αα' disubstitués de la bicyclo[4,4,0]décanone-3 *trans* sont rapportés dans le Tableau 2. Les valeurs expérimentales sont comparées aux valeurs calculées à partir des incréments des dérivés monosubstitués en position-4 pour les dérivés αα, en position-4 et -2 pour les dérivés αα'. A ce titre les incréments des chloro-2*e* et -4*e* et bromo-2*e* et -4*e* bicyclo[4,4,0]décanones-3 *trans* sont rapportés dans le Tableau 7. On peut y noter pour chaque halogène une assez bonne concordance entre les valeurs d'incréments des deux isomères de position avec cependant trois déviations, celles: des effets α sur les carbones C_2 et C_4, des effets γ sur les carbones C_{10} et C_7, et des effects β sur les carbones C_1 et C_5. Ces déviations résultent pour les deux premières de l'interaction 1–3 de type diaxial entre X-2*e* et H-10*e*, interaction qui n'a pas son équivalent pour les isomères X-4*e*. Pour la troisième de ces déviations, elle trouve vraisemblablement son origine dans la différence de degré de substitution entre les carbones C_1 (tertiaire) et C_5 (secondaire). Revenons maintenant aux dérivés disubstitués **13** à **16** (Tableau 2); pour ces quatre composés un bon accord n'est observé entre valeurs calculées et expérimentales que pour le composé **15** (chloro-2*e* méthyl-4*e*). Dans les autres cas on n'observe pas d'additivité des incréments pour les carbones C_1 à C_7 du composé **16** (dibromo-2*e*, 4*e*) et C_2, C_3, C_6 et surtout C_4 des composés **13** et **14** (méthyl-4*e* chloro-4*a* et méthyl-4*a* chloro-4*e*). Ce manque de concordance peut être imputé à des déformations moléculaires provenant pour **16** de l'interaction stérique $H_{10e}/Br_{2e}/O_3/Br_{4e}$ qui doit être plus importante que $H_{10e}/Cl_{2e}/O_3/(CH_3)_{4e}$, dans le cas de **15**, et pour **13** et **14**, d'une disubstitution sur le même atome de carbone, comme cela a déjà été observé dans le cas de *gem* diméthyl ou dichloro substitution (1*c* et références citées). Les interactions de type dipole–dipole introduites par la disubstitution (14) et orbitalaires, à travers les liaisons pour le dérivé dibromé **16** (15), sont aussi susceptibles de rendre compte de la non-additivité des incréments.

(C) Influence de la déformation du cycle

Les déplacements chimiques $\delta^{13}C$ pour les bicyclo[4,4,0]alcanones-3 *trans* et les valeurs de $\Delta\delta^{13}C$ pour leurs dérivés α chlorés (chlore axial et équatorial) sont rassemblés dans le Tableau 3. A partir de ces données, il est difficile de définir une tendance générale de variation des déplacements chimiques en fonction de la déformation de cycle, comme dans le cas analogue des benzo[1,2 : 4,5]dicycloalcènes (16). Cependant si on limite la discussion aux carbones sp^3 C_2 et C_4, on peut noter que l'effet γ du chlore axial d'une part et la différence $^{Cl}\Delta$ = effet $\alpha_{eq.}$ − effet $\alpha_{ax.}$ diminuent lorsque la déformation du cycle A croît. Ces deux résultats sont en accord avec la perte de caractère axial ou équatorial du substituant sur le cycle en C_6 résultant de la modification des angles de torsion $X_4C_4C_3O$ (Tableau 8) lorsque le nombre d'atomes de carbone du cycle joint diminue (5, 6, 17).

Effets des substituants sur le déplacement chimique du $^{13}C{=}O$

L'examen des déplacements chimiques des $^{13}C{=}O$ rapportés dans les Tableaux 1, 2 et 3 permet de mettre en évidence plusieurs résultats: (*1*) la substitution d'un hydrogène en α du C=O par un atome ou un groupement électroattracteur se traduit par un blindage du $^{13}C{=}O$, généralement d'autant plus important que le pouvoir inductif du substituant est plus élevé. Inversement un groupe tel que CH_3, provoque un déblindage du $^{13}C{=}O$. Les déplacements chimiques extrêmes sont séparés de 14 ppm; (*2*) Pour un même substituant attracteur d'électron, une orientation équatoriale a un effet de blindage supérieur à celui d'une orientation axiale; (*3*) Une déformation de cycle croissante tend à diminuer l'écart $\Delta\beta C_3$ défini dans le Tableau 9.

Si l'effet de blindage d'un $^{13}C{=}O$ par les substituants électroattracteurs est relativement bien connu (réf. 4, voir aussi réf. 3, p. 279) par contre l'effet de l'orientation axiale ou équatoriale dans le cas de composés cycliques l'est beaucoup moins. Pour rendre compte de ces résultats deux interprétations basées l'une sur la polarisation de la double liaison C=O l'autre sur les interactions de non liaison C=O/X, sont envisageables.

Considérons en premier lieu les deux formes de résonance, *a* et *b*, généralement admises pour les cétones (19)

Ces deux formes contribuent à la distribution électronique totale autour du carbonyle, dont dépend le $\delta^{13}C{=}O$. Un atome d'halogène par ses électrons non partagés, en apportant une contribution électronique à l'environnement immédiat du carbonyle tendra à contrebalancer l'effet de la forme *b* et l'on observera un blindage du carbonyle pour les cétones halogénées par rapport aux cétones non substituées. Cette participation des électrons non partagés de l'halogène à la densité électronique sur le carbonyle, dépendra directement, pour des cétones de structure figée, des orientations relatives des liaisons C=O et C—X, une déviation à la coplanéarité ayant pour effet de réduire les interactions de résonance. Ceci se traduira par un blindage du $^{13}C{=}O$ plus important pour l'épimère à halogène équatorial que pour celui à halogène axial.

TABLEAU 9. $\Delta\beta C_3$ = effet $\beta_{eq.}$ − effet $\beta_{ax.}$, cas des chloro-4 bicyclo[4,*n*,0]alcanones-3 *trans*

n	4	3	2
$\Delta\beta C_3$	−3,01	−2,42	−1,22

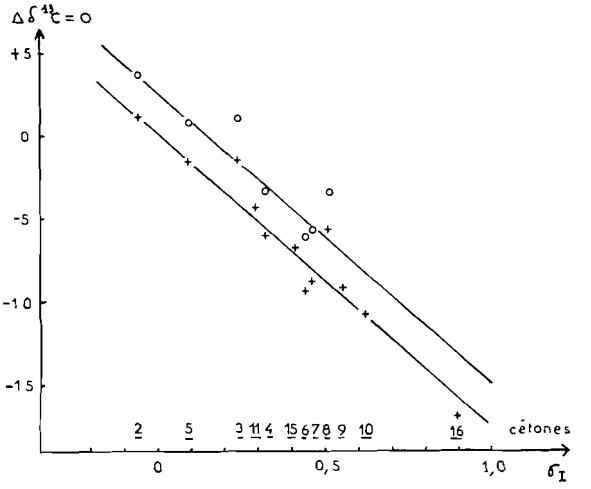

FIG. 1. Relations linéaires entre $\Delta\delta^{13}C{=}O$ et σ_I; ○: X axial, +: X équatorial.

L'existence de deux corrélations linéaires et parallèles, une pour chaque série d'épimères, entre le blindage de $^{13}C{=}O$ et les paramètres d'énergie libre σ_I des substituants[2] (Fig. 1) vient d'appuyer cette interprétation. (Ce même type de corrélation a précédemment été observée (*4c*) avec les dérivés du camphre substitués en position-4.) Il faut noter cependant deux exceptions: avec OCH_3 et F, les $^{13}C{=}O$ sont moins blindés que ne laissent prévoir les valeurs de σ_I. L'appartenance à cette corrélation des composés αα′ disubstitués, en tenant compte des valeurs de σ_I de chaque substituant montre que si une modification structurale par rapport aux dérivés monosubstitués existe, elle doit être très peu importante. Par contre les composés αα disubstitués, en raison de la double orientation de leurs substituants ne se situent sur aucune des deux droites.

La théorie des orbitales offre une autre méthode plus quantitative, méthode déjà utilisée par d'autres auteurs (*1d*, 2, 22), pour interpréter le blindage

[2] Les valeurs de σ_I sont celles indiquées dans la littérature (19), sauf pour $OCOCH_3$ (20), CN et $CO_2C_2H_5$ (21).

For personal use only.

du $^{13}C{=}O$ par les substituants électroattracteurs sur la base d'interactions orbitalaires entre atomes non liés. Dans le cas des halogénocétones il a été montré que l'un des facteurs régissant la stabilité relative de deux épimères est lié à la grandeur des interactions orbitalaires qui existent entre les groupes non liés C=O et X (12).

Received July 25, 1979[1]

NIBARAN C. DEY, BIRENDRA K. SAIKIA, and INAMUL HAQUE. Can. J. Chem. **58**, 1512 (1980).

The relative viscosities and densities of glycine in 5%, 10%, 15%, and 20% w/w acetonitrile–water mixtures at 25, 30, 35, and 40°C and of DL-alanine in water, 5%, 15%, and 20% w/w acetonitrile water mixtures at 30 and 40°C have been determined. The viscosity *B* coefficients have been found to increase with increase in concentration of acetonitrile and also with the increase of temperature in both cases.

The limiting apparent molar volumes and limiting value of effective flow volumes have also been calculated.

NIBARAN C. DEY, BIRENDRA K. SAIKIA et INAMUL HAQUE. Can. J. Chem. **58**, 1512 (1980).

On a déterminé les viscosités et les densités relatives de la glycine dans des mélanges d'acétonitrile–eau à 5, 10, 15 et 20% (w/w), à 25, 30, 35 et 40°C et celle de la DL-alanine dans des mélanges d'acétonitrile–eau à 5, 15 et 20% (w/w), à 30 et 40°C. On a trouvé que les coefficients de viscosité *B* dans les deux cas augmentent avec la concentration de l'acétonitrile et également avec la température.

On a également calculé les volumes molaires apparents limites et la valeur limite des volumes d'écoulement effectif.

[Traduit par le journal]

Viscosity measurement provides valuable information about the size and state of solvation of molecules in solution (1). Such measurements on dipolar ions, particularly of the amino acids, have been carried out by a number of workers (2–5), namely, in aqueous solutions. However, the work has not been extended to nonaqueous or mixed aqueous solvents. The temperature effect on the solvation has also not been extensively studied. The present work reports viscosity and density measurements between 25 and 40°C in aqueous acetonitrile solutions of glycine and DL-alanine.

Experimental

Glycine and DL-alanine (A.R. Grade) were purified and dried by usual methods and stored in a desiccator over P_2O_5. Acetonitrile (reagent grade) was dried over anhydrous copper sulfate for several days with frequent agitation. It was doubly distilled each time collecting only the middle fraction. Its refractive index, density, and viscosity compared well with the literature values (6). Doubly distilled water was used for making up solutions. All the solutions were prepared by weight and vacuum correction was made for each weight.

Viscosity was measured with a Cannon Fenske direct flow viscometer having a viscosity constant of about 0.003 at 25°C. The kinetic energy correction term was found to fall in the region of experimental error for the solutions under study and, therefore, was neglected. Flow time measurement was repeated for each solution until three successive measurements agreed to within ±0.02%. Loading error was minimised by using capillary head pipette.

All the viscosity and density measurements were carried out in a thermostatic water bath, the temperature of which was kept constant to within ±0.01°C.

[1]Revision received March 30, 1980.

Results and Discussion

The relative viscosity η_r was calculated by using the equation (1)

$$[1] \quad \eta_r = (\eta/\eta_0) = (\rho t/\rho_0 t_0)$$

where η, ρ, "t" represent the viscosity, density, and flow time respectively of the solution and η_0, ρ_0, and "t_0" refer to those of the solvent.

Experimental values of relative viscosity were fitted into eq. [2] by the method of least squares.

$$[2] \quad \eta_r = (\eta/\eta_0) = 1 + BC + DC^2$$

The constant B measures the size and shape effect of the solute as well as structural modification, induced by solute solvent interaction, and is the major contributor to relative viscosity in eq. [2]. The constant D is relatively small in magnitude and its significance is not clearly understood (5). The contribution of D in the relative viscosity for the concentrations under study is small and, therefore, could not be evaluated with sufficient precision for a comparative study. In general, the values of D for glycine in water–acetonitrile solution lie between 0.015 to 0.03 and for DL-alanine between 0.03 to 0.07, for the concentration and temperature ranges covered in the present study.

In order to compare our results with those of others (5), we determined the density and viscosity of glycine in water at 25°C. The overall reproducibility in the individual viscosity measurement was found to be better than 0.1%. Figure 1 shows the

variation of B and D constants with concentration of glycine in different water–acetonitrile mixtures at 25°C.

The B value[2] of glycine increases with the increase in temperature up to 35°C in all the solvent compositions. Since (dB/dT) is positive for a structure-breaking solute (7–9), we easily classify glycine as a structure breaker in water–acetonitrile solvent mixtures. In structured solvents, a solute with or without a primary solvation sheath can apparently affect the degree of "structure" of solvent molecules at relatively large distances. Tyrrell and Kennerley (4) proposed that in aqueous solution, glycine has a primary solvation shell and that the solvated solute is a net structure breaker. Devine and Lowe (5) classified glycine as a net structure breaker in aqueous solution assuming that the electrostrictive solvation of NH_3^+ and CO_2^- varies little with temperature. This assumption is likely to be valid at relatively lower temperature. We observed a negative (dB/dT) at 40°C for 15% and 20% acetonitrile solutions and this might be a result of decrease in solvation.

For DL-alanine we observe a negative (dB/dT) in pure water. At 5% acetonitrile solution, (dB/dT) is insignificant and at higher acetonitrile concentration (dB/dT) is positive. Devine and Lowe (5) from a study of the viscosity of aqueous β-alanine concluded that β-alanine is a structure breaker. Phang (10) has proposed that DL-alanine is a structure breaker in aqueous dimethylformamide solution. Mason *et al.* (2), however, classified both α-alanine and β-alanine as structure makers from a study of differential entropies of dilution and the differential activation energy for viscous flow. The controversy seems to arise from the hydrophobic structure stabilization by the apolar groups and the structure breaking by NH_3^+ and CO_2^- groups, the net effect of which might vary under experimental conditions. It has been shown (5) that the contribution per CH_2 group of the aminoacids towards viscosity B coefficient (ΔB) in water at 25°C is 0.084 $dm^3\ mol^{-1}$, instead of the hydrodynamically predicted value of 0.038. This implies that CH_2 groups lead to stabilization of water structure. In glycine the hydrophobic stabilization effect is overcompensated by structure breaking. In case of DL-alanine in pure water structure stabilization is higher and we observe a negative (dB/dT). In aqueous acetonitrile solution the hydrophobic stabilization is less effective and we observe a positive (dB/dT) at higher acetonitrile concentration as a result of net structure-breaking effect.

The B value of glycine increases with increase in acetonitrile concentration. In aqueous solution the B value of glycine at 25°C as given by Devine and Lowe (5) is 0.143 ± 0.002. The corresponding value at 20% acetonitrile solution is 0.187. For DL-alanine also, the B value increases with increase in acetonitrile concentration. The B value of DL-alanine at 30°C is 0.241 and 0.261 in pure water and 20% acetonitrile solution, respectively. In view of the opposite nature of glycine and DL-alanine in pure water, this increase in B value in aqueous acetonitrile solution cannot alone be due to disruption of water structure by acetonitrile. The solutes might, therefore, be solvated by acetonitrile. Since positive (dB/dT) was observed as discussed above, acetonitrile must be strongly attached to the solutes. Zana *et al.* (11) have recently shown that electrostriction of ions in acetonitrile is larger than in water. The steep increase of B value between 15% and 20% acetonitrile solution must be con-

[2]The experimental values of density, relative viscosity, and the B coefficient values for glycine in 5%, 10%, 15%, and 20% acetonitrile solutions at 25°C, 30°C, 35°C, and 40°C; for DL-alanine in water, 5%, 15%, and 20% acetonitrile solutions at 30°C and 40°C and the density and viscosity of mixed solvents are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

nected, at least partially, with water-structure breaking by acetonitrile. Gorbunov *et al.* (12) found from ir spectroscopic study that the hydrogen bond of H_2O molecules becomes weaker in the presence of acetonitrile.

In both the solutes, the B coefficient increases more rapidly with increase in acetonitrile concentration than in the case of aqueous dimethylformamide solution (10). The graphically obtained B values of glycine for 0.05 mole fraction of acetonitrile and dimethylformamide in aqueous solution is found to be 0.157 and 0.152 respectively. This higher B value in acetonitrile solution might be connected with stronger solvation by acetonitrile.

The apparent molar volumes (ϕ_v) were calculated from the experimental density data. The limiting apparent molar volumes (ϕ_v^0) were then calculated by the method of least squares from the equation.

$$[3]\quad \phi_v = \phi_v^0 + AC$$

where A is a constant and C is the molarity. The values of ϕ_v^0 at 25°C are close to those reported in water (2, 5) and aqueous dimethylformamide solution (10). Within experimental error ϕ_v^0 varies little. A small increase is observed with rise in temperature. The values of ϕ_v^0 and B/ϕ_v^0 are shown in Tables 1 and 2.

In order to treat the aminoacids as suspension of rigid particles, we made use of the Vand (13) equation, as modified by Eagland and Pilling (14), shown in eq. [4],

$$[4]\quad C/[\log \eta/\eta_0] = 2.303/2.5V_h - 2.303QC/2.5$$

where Q is a particle interaction coefficient and V_h is the effective flow volume. V_h includes that part of the solvent molecules which are immobilized inside the cavities of the solute molecules. It will also include the solvent molecules in a primary solvation layer for a solvated species. A plot of $C/(\log \eta/\eta_0)$ against C should be linear with a slope of $2.303Q/2.5$ and an intercept of $2.303/2.5V_h$ when $C \rightarrow 0$. This effective flow volume as $C \rightarrow 0$ is

Pure water	61.0	3.95	61.7	3.77
5% acetonitrile	59.9	4.12	60.1	4.08
15% acetonitrile	60.0	4.19	60.2	4.33
20% acetonitrile	60.5	4.31	60.7	4.45

termed as the "limiting value of effective flow volume" (V_h^0). For spherical suspension it has been shown by Eagland and Pilling (14) that

$$[5]\quad B = 2.5V_h^0$$

The variation of V_h^0 with temperature and acetonitrile concentration for glycine and DL-alanine is shown[3] in Fig. 2. It was found that V_h^0 obtained from eq. [4] also satisfied eq. [5], within experimental error. Therefore, the spherical approximation is valid for both glycine and DL-alanine.

The large value of the ratio B/ϕ_v^0 as shown in Tables 1 and 2 and also the large value of V_h^0 compared to ϕ_v^0 undoubtedly suggest primary solvation of glycine and DL-alanine. As seen in Fig. 2, V_h^0 is larger in mixed solvent than in pure water. Further increase in V_h^0 with increase in acetonitrile concentration is more significant in case of glycine than in DL-alanine. The steep increase in V_h^0 between 15% and 20% acetonitrile is quite distinguishable. It is interesting to note that the solvent viscosity decreases at this concentration. We conclude that at this concentration acetonitrile is capable of quickly destroying the prevailing "water structure" in the mixed solvent.

Hereby we conclude that acetonitrile breaks water strucuture, particularly at concentrations above 15%. Glycine and DL-alanine, which are normally solvated in aqueous solution, are also sol-

vated by acetonitrile in aqueous acetonitrile solution. Both glycine and DL-alanine behave as net structure breakers in aqueous acetonitrile solution and this behaviour is the result of long range structure breaking beyond the structure forming solvation zone. Assumption of rigid spherical suspension is valid for both solvated glycine and DL-alanine.

Specific decomposition rate constants in unimolecular reactions[1]

HUW O. PRITCHARD AND GALINA M. DIKER
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3
AND
ANDREW W. YAU
Herzberg Institute of Astrophysics, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6
Received January 11, 1980

HUW O. PRITCHARD, GALINA M. DIKER, and ANDREW W. YAU. Can. J. Chem. 58, 1516 (1980).

The original treatment of unimolecular reactions given by Polanyi and Wigner in 1928 is recast in quantum terms. It is found that very simple and natural choices for the oscillation which is assumed to cause reaction lead to good predictions of the specific reaction rate constant $k(E)$, and also the overall rate of reaction: nitrous oxide, carbon dioxide, methyl isocyanide, trideuteriomethyl isocyanide, ethyl isocyanide, ethyl chloride, cyclopropane, cyclobutane, and ethane are treated as illustrations.

HUW O. PRITCHARD, GALINA M. DIKER et ANDREW W. YAU. Can. J. Chem. 58, 1516 (1980).

Le travail original de Polanyi et Wigner (1928) sur les réactions unimoléculaires est revu en termes quantiques. Un choix naturel et simple de l'oscillation qui cause présumément la réaction fournit de bonnes prédictions pour les constantes de vitesse spécifiques de réaction $k(E)$ aussi bien que la vitesse globale de réaction. Comme examples, on utilise l'oxide nitreux, l'oxide carbonique, l'isocyanure de méthyle, l'isocyanure de trideutérométhyle, l'isocyanure d'éthyle, le chlorure d'éthyle, le cyclopropane, le cyclobutane et l'éthane.

[Traduit par le journal]

Introduction

In 1928, Polanyi and Wigner proposed the first molecular-dynamic picture of a unimolecular reaction (1). They imagined the molecule to consist of n atoms of essentially equal mass, held together by roughly equally strong forces; they then analysed in simple terms the vibrational motions of such a collection of atoms and concluded that an amount of energy greater than ε would be concentrated in a particular bond approximately $\nu e^{-\varepsilon/kT}$ times per second, where ν is the fastest vibrational frequency in the molecule, and $\varepsilon \gg kT$. Thus, if ε is identified as the critical energy required for dissociation or for transformation to another species (we shall use E_{crit} for this quantity in our reformulation), then it follows naturally that the rate constant for the reaction is, in its simplest form,

$$[1] \quad k \simeq \nu e^{-\varepsilon/kT}$$

This expression applies only if the critical energy ε is assumed to be confined in one linear dimension, but Polanyi and Wigner also derived formulae applicable to the cases where ε was assumed to be concentrated in either two or three linear dimensions, the latter yielding the rate constant expression

$$[2] \quad k \simeq \frac{2\nu\varepsilon}{kT} e^{-\varepsilon/kT}$$

This primitive treatment of molecular vibration was developed extensively by Slater (2) in a slightly different form, but nevertheless one which was foreseen by Polanyi and Wigner in their original discussion: he defined a critical coordinate, and attempted to calculate the mean frequency with which, in an oscillating molecule, this coordinate would exceed a certain length, and reaction was assumed to have taken place at this point. Using a harmonic-oscillator model for cyclopropane, Slater calculated the shape of the fall-off curve for the isomerisation to propylene (3) simultaneously with and independently of (ref. 2, p. 181) our measurements (5) on this reaction, and his theory was received with tremendous enthusiasm as the result of the remarkable agreement between his predictions and the experiment. Later, however, as Slater tried to extend his approach to anharmonic oscillators and to quantised oscillators (ref. 2, Chapt. 10), and because of insuperable difficulties relating to degeneracy changes upon partial isotopic substitution of highly symmetrical molecules, e.g., *cyclo*-C_3H_6 and *cyclo*-$C_3H_4D_2$, or CH_3NC and CH_2DNC (7), the theory has fallen into disrepute. This, taken together with other unsuccessful attempts based upon eq. [2] to account for high frequency factors (8, 9), seems an unfitting fate for such an attractive concept.

In this paper, we present a quantum formulation for the approximate rate of decomposition of a vibrationally excited molecule, based upon the origi-

nal concept of Polanyi and Wigner (1), and we show, within the limitations of the available spectroscopic data and our understanding of the nature of molecular vibrations, that acceptable results can be obtained.

Basic Formulation

We begin by regarding the molecule as a collection of s independent oscillators and rigid rotors, with a set of vibration–rotation states $i = \{n_1, n_2, n_3, \cdots, n_s\}$ at energies

$$[3] \quad E_i = \sum_{j=1}^{s} \varepsilon_j(n_j)$$

where $\varepsilon_j(n_j)$ is the energy associated with the jth oscillator/rotor in the quantum state n_j. We then attempt to represent the reaction process by the motion of a particular oscillator, r, and assume that reaction can occur if more energy than the critical energy of the reaction, E_{crit}, is found in this oscillator, i.e.

$$[4] \quad \varepsilon_r \geq E_{crit}$$

Furthermore, we assume, in the spirit of Polanyi and Wigner (1), that if a molecule finds itself in a state in which it has more energy than E_{crit} in oscillator r, it will decompose within the vibrational period of that oscillator: for either a harmonic or a Morse oscillator, this is

$$[5] \quad \tau = (2c\nu_r)^{-1} \text{ seconds}$$

where c is the velocity of light and ν_r is the vibrational frequency of the oscillator r in wavenumber units.

If we now denote the state density of the molecule at energy E by $\rho_s(E)$ and the corresponding state density of a *hypothetical submolecule* with oscillator r removed by $\rho^r_{s-1}(E)$, then the fraction of states at E that decompose to products with time constant τ^{-1} is

$$[6a] \quad \alpha_1(E) = \Sigma \rho^r_{s-1}[E - \varepsilon_r(n_r)]/\rho_s(E)$$

where the summation is over n_r for which $E_{crit} \leq \varepsilon_r(n_r) \leq E$; in the quantity $\rho^r_{s-1}(E)$, the subscript $s-1$ refers to the remaining $(s-1)$ oscillators in the hypothetical submolecule when the oscillator r has been removed. The specific rate constant is then

$$[7a] \quad k_1(E) = 2c\nu_r\alpha_1(E)$$

Equations [6a] and [7a] are based on the postulate that the critical energy is localised in one oscillator, and are thus the quantum analogue of eq. [1]. In a more complex molecule where we may envisage the critical energy to be shared between m of the s oscillators, eq. [6a] is generalised to

$$[6b] \quad \alpha_m(E) = \Sigma \rho^{r_1 r_2 \cdots r_m}_{s-m}(E - \varepsilon_R) g_m(\varepsilon_R)/\rho_s(E)$$

where $\rho^{r_1 r_2 \cdots r_m}_{s-m}(E)$ is the state density of the hypothetical submolecule with the oscillators $r_1, r_2, \cdots, r_m$ removed,

$$\varepsilon_R = \varepsilon_{r_1}(n_{r_1}) + \varepsilon_{r_2}(n_{r_2}) + \ldots \varepsilon_{r_m}(n_{r_m})$$

is the energy in the reactive oscillators $r_1, r_2, \cdots, r_m$ in the state $\{n_{r_1}, n_{r_2}, \ldots, n_{r_m}\}$, $g_m(\varepsilon_R)$ is the state degeneracy of the group of m interesting oscillators at energy ε_R, and the summation is over all values of n_r for which $E_{crit} \leq \varepsilon_R \leq E$. The average lifetime of these states is, following Polanyi and Wigner (1), that of the oscillator with the highest frequency, viz. $|\nu_r|_{max}$, whence [7a] is generalised to

$$[7b] \quad k_m(E) = 2c|\nu_r|_{max}\alpha_m(E)$$

The computation of $k(E)$ using eqs. [6] and [7] requires as input parameters the relevant vibration–rotation constants of the molecule and the critical energy of the reaction. Since, except for the simplest of molecules, we have no *a priori* knowledge of E_{crit}, we will use the observed infinite-pressure activation energy, E_∞, as the critical energy, E_{crit}. In addition, for the sake of logical consistency, we adjust the chosen value of ν_r (or else $|\nu_r|_{min}$, the smallest of the group of m frequencies) very slightly to ensure that there is a reactive level *exactly* at E_{crit}; typically, this adjustment amounts only to a few percent of the value of ν_r (or $|\nu_r|_{min}$). We will proceed to examine the behaviour of eqs. [6] and [7] in considerable detail for two test cases, the thermal isomerisations of methyl isocyanide and of cyclopropane, and thereafter will present more briefly applications to other reactions, and discussions of various points which arise in respect of the formulation and of the results.

Some Preliminaries

In the discussion which follows, we will always compare our synthetic $k(E)$ function with those derived for the same molecular model using the Slater–Forst and RRKM procedures; moreover, with a single exception noted below, we will always regard the molecule as a collection of rigid rotating Morse oscillators. Thus, before tests of eqs. [6] and [7] can be made, it is necessary to describe the nature of such tests.

(i) Slater–Forst Procedure

We take as the target against which to compare our synthetic $k(E)$ function, the empirical specific rate function $k(E)$ derived from the experimental

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

rate law by the Slater–Forst procedure (10, 11), i.e.

$$[8] \quad \bar{k}(E) = A_\infty \rho(E - E_\infty)/\rho(E)$$

where E_∞ and A_∞ are respectively the infinite-pressure activation energy and frequency factor: we have given detailed arguments (12) why [8] should provide a reasonable estimate for the specific rate function, and more recently, we have made detailed numerical tests of its accuracy (13).

The specific rate function $\bar{k}(E)$ given by eq. [8] is not entirely unique, but depends slightly upon the assumed molecular model, as is shown in Fig. 1 for methyl isocyanide. Of the three curves shown, the topmost one assumes that the molecular oscillations are harmonic, whereas the bottom one assumes that they are Morse oscillators with the anharmonicity factors we estimated previously (12): we have concluded since that those empirical anharmonicity factors were much too severe, and we have evolved a new empirical scheme (which is described in the Appendix), based upon the assumed dissociation behaviour of the oscillator in question; this scheme will be used throughout this paper, and the resulting $\bar{k}(E)$ function for methyl isocyanide lies between the other two curves.

(ii) RRKM Calculations

The RRKM specific rate functions $k^*(E)$ shown for comparison in the following sections are computed by a relatively simple procedure, roughly equivalent in its degree of sophistication to our model described by eqs. [6] and [7]: $k^*(E)$ is calculated using eq. [6.20] of ref. 7, assuming no adiabatic rotations; the program used was essentially that supplied by Holbrook (ref. 7, p. 149), but modified for Morse oscillators, and with the sums and densities of states calculated by our own techniques (15). The calculations of $k(E)$, $\bar{k}(E)$, and $k^*(E)$ are always mutually consistent in the sense that they use the same set of frequencies, anharmonicities, and rotational constants for the molecule in question; likewise, all calculations use the same value of E_∞, and the same value of A_∞ is used in the Slater–Forst procedure and in the RRKM frequency adjustment. In the latter case, after the choice of the reaction coordinate (which is usually taken to be one of the frequencies chosen as ν_r), the two lowest frequencies remaining in the molecule were always adjusted to achieve the matching with the entropy of activation: the results for $k^*(E)$, of course, are insensitive to the choice of reaction coordinate (cf. Fig. 3 below) provided the assumed activated complex has the required entropy.

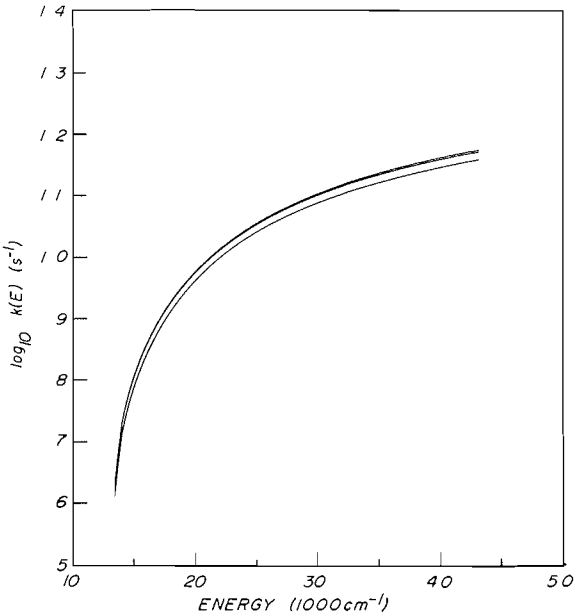

FIG. 1. Comparison of three empirical $\bar{k}(E)$ functions for methyl isocyanide, which are, in order: topmost curve, harmonic oscillators; middle curve, Morse oscillators with anharmonicities defined by eq. [A1]; bottom curve, Morse oscillators with anharmonicities from ref. 12.

(iii) The Overall Rate Constant

As is shown in Fig. 1, the numerical magnitudes of $\bar{k}(E)$, and also $k^*(E)$, are model-dependent and as can be seen in subsequent diagrams, $\bar{k}(E)$ and $k^*(E)$ can often be markedly different although they always correspond to the same value of the rate constant at the RRKM fitting temperature. Thus, whilst our primary aim in this work has been to compare the synthetic $k(E)$ function with the empirical $\bar{k}(E)$ function, a complete test of the synthetic $k(E)$ function requires that it also give acceptable values for the overall activation energy and frequency factor. Consequently, for each synthetic $k(E)$ function, (and also for each empirical $\bar{k}(E)$ function), we have always reconstructed the overall rate constant for the reaction using

$$[9] \quad k_\infty(T) = [Q(T)]^{-1} \int_0^\infty \rho(E) k(E)\, e^{-E/RT}\, dE$$

where $Q(T)$ is the reactant partition function, and compared the synthetic overall rate constant with the observed value. We also examined the derived Arrhenius parameters A_∞ and E_∞ for constancy with temperature. In the case of the $\bar{k}(E)$ function, this simply served as a check on the correctness and consistency of the partition functions and densities of states used in the calculations. On the other hand, using the synthetic $k(E)$ functions there were small, and real, variations of up to 0.2 or 0.3 kcal mol^{-1} in E_∞ and up to about ±30% in A_∞ over

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

a temperature range of a factor of two in T. Consequently, to complete the test of each model calculation, the computed values of A_∞ and E_∞ in the appropriate experimental temperature range are listed in the caption of each diagram, along with the observed values, the latter in italics.

Methyl Isocyanide

There have been several theoretical studies of the potential energy surface for the transition between methyl isocyanide and methyl cyanide (16–18), and it is clear that if one had to postulate a single vibrational mode which, if sufficiently excited, would lead to reaction, one would naturally choose the C—N—C bending mode $\nu_8 = 263\ cm^{-1}$ (19). Figure 2 shows the result of the application of eqs. [6*a*] and [7*a*] for this model, with $\nu_8 = 263\ cm^{-1}$ adjusted slightly to $\nu_r = 267\ cm^{-1}$ to ensure that a reactive level occurs exactly at the value of the critical energy. Also shown on the same diagram are the RRKM $k^*(E)$ function and the empirical $\bar{k}(E)$ function, and the agreement with the latter is remarkable; likewise, the agreement of the overall rate constant with experiment, as documented in the legend to the diagram, is excellent.

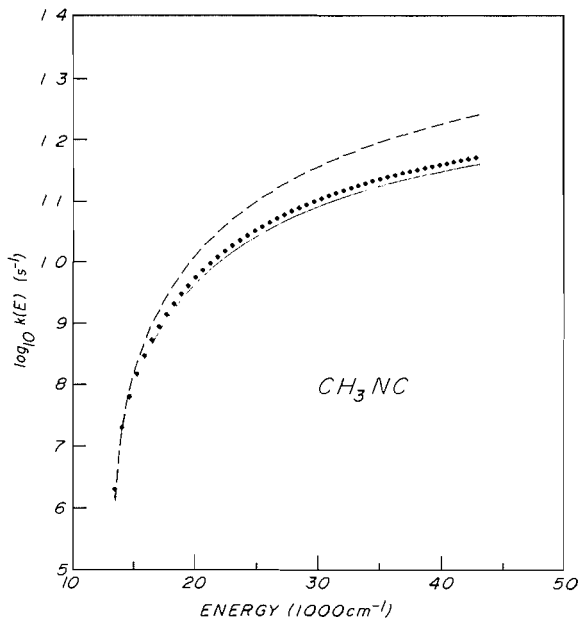

FIG. 2. Comparison of synthetic $k(E)$, empirical $\bar{k}(E)$, and RRKM $k^*(E)$ functions for methyl isocyanide using anharmonicities defined by eq. [A1]: solid line, $k(E)$ using $\nu_r = 263\ cm^{-1}$; individual points, $\bar{k}(E)$; dashed line, $k^*(E)$. The rate constants calculated from $k(E)$ using eq. [9] give the following Arrhenius parameters: $E_\infty = 38.2$ (*38.2*) kcal mol^{-1}, $A_\infty = 1.9$ (*2.2*) $\times 10^{13}\ s^{-1}$ at 500 K.

Sensitivity of the Computed Results to the Nature of the Assumed Model

As we noted above, and showed in Fig. 1, the computed values of $\bar{k}(E)$ depend very slightly upon the oscillator model assumed for the reacting molecule, but nevertheless, any of these functions will reproduce the observed rate constant when substituted in eq. [9]; likewise, the $k^*(E)$ function calculated by the RRKM prescription, although significantly different from $\bar{k}(E)$, still corresponds to the same value of the rate constant at the matching temperature.[2] Inspection of eqs. [6*a*] and [7*a*], however, shows that our synthetic $k(E)$, and the derived overall rate constant, should be quite sensitive to the choice of the reactive oscillator ν_r, and the nature of this sensitivity is shown in Fig. 3*a*. In this diagram, [6*a*] and [7*a*] were applied to the rotating *harmonic*-oscillator model of methyl isocyanide and ν_r was considered to be, in turn, $\nu_8 = 263$, $\nu_4 = 945$, $\nu_3 = 1429$, $\nu_2 = 2166$, and $\nu_1 = 2966\ cm^{-1}$. Most of the sensitivity of $k(E)$ to ν_r arises in eq. [7*a*] and, in fact, for harmonic oscillators $k(E)$ is directly proportional (to within about 3 or 4%) to ν_r at any value of E: thus, the computed overall rate constant is also approximately proportional to ν_r, with $A_\infty \simeq (1.9 \times 10^{13}) \times (\nu_r/267)\ s^{-1}$ in this case; this proportionality does not hold, however, as we shall see below for strongly anharmonic oscillators.

In contrast, Fig. 3*b* shows the RRKM results for $k^*(E)$ where, in turn, each of the five frequencies treated as ν_r in Fig. 3*a* is regarded as the critical reaction coordinate; this figure again demonstrates the now well-known insensitivity of the RRKM $k^*(E)$ function to the choice of reaction coordinate, which arises through the frequency adjustment procedure to match the experimental A-factor (12). Thus, we see that the present formulation, using eqs. [6] and [7], has the *potential* for making predictions, whereas the RRKM method does not possess this capability.

[2]The RRKM $k^*(E)$ functions are always lower than the empirical $\bar{k}(E)$ functions at low energy: this is because the threshold occurs at an energy E_0 which is lower than E_∞ in RRKM theory (eq. [6.5] of ref. 7), so that eq. [9] will only give the same value of $k_\infty(T)$ at the matching temperature if the mean value of $k^*(E)$ is below the mean value of $\bar{k}(E)$ in the significant energy range. The magnitudes of these differences viz. between E_0 and E_∞, or between $k^*(E)$ and $\bar{k}(E)$, become more marked the greater is the required extent of the frequency adjustment in the RRKM entropy matching procedure (cf. eq. [6.4] of ref. 7): thus, if there is a large frequency adjustment (as in Figs. 4, 6, and 10), $k^*(E)$ will always be below $\bar{k}(E)$ in the useful energy range, but if there is only a small frequency adjustment (as in Figs. 2, 7, 8, and 9) $k^*(E)$ will cross $\bar{k}(E)$ at high energy because it has a slightly smaller curvature, corresponding to the fact that the RRKM k_∞ increases with increasing temperature more quickly than strict Arrhenius (12).

Cyclopropane

A property of eq. [6*a*] is that if the critical energy and critical frequency ν_r are held constant, but the complexity of the molecule is increased, the ratio of active to passive states decreases somewhat; thus, it is clear that if the critical energy is considered to be localised in only one oscillator, one will not compute frequency factors much in excess of 2×10^{14} s^{-1}, the value obtained for methyl isocyanide using the asymmetric C—H stretch $\nu_1 = 2966$ cm^{-1} for ν_r, as in Fig. 3*a*. However, if the critical energy does not have to be localised in one degree of freedom but can be distributed in some other way then, as Polanyi and Wigner recognised, frequency factors greater than 10^{15} s^{-1} are possible, via eq. [2]; our quantum reformulation of this concept is embodied in eqs. [6*b*] and [7*b*], and we will now demonstrate their application to the cyclopropane isomerisation reaction.

According to calculations by Jug (20), the reaction coordinate in the isomerisation of cyclopropane to propylene can be visualised as a superposition of the torsional vibration ν_3 and an asymmetric stretch ν_{6b}, where these are the normal modes of vibration of a simplified model of cyclopropane, i.e. X_3Y_3 and the notation is that of Herzberg (21). Extending, and being guided by, this idea, we show in Fig. 4 the results of a series of calculations for cyclopropane. We chose two normal vibrations of cyclopropane, $\nu_3 = 1188$ cm^{-1}, the ring stretch, and $\nu_6 = 3103$ cm^{-1}, an asymmetric CH_2 stretch (19) to represent the critical motion in this reaction. The lowest two synthetic curves show that localisation of the critical energy in either one of these oscillators cannot generate the high observed reaction rate for this molecule. However, if we allow the critical energy to be shared *in any fashion* between these two oscillators of frequency 1188 and 3103 cm^{-1}, and accept Polanyi and Wigner's suggestion (1) that the lifetime for this complex oscillator is simply the lifetime of the oscillator having the higher frequency, then agreement with the empirical $k(E)$ is remarkable; also, the computed frequency factor of 1.4×10^{15} s^{-1} is in excellent agreement with experiment.

Although, as noted above, the present procedure provides us with the potential for exploring different "reaction co-ordinates" in a way which is not possible using the RRKM procedure, our choice in Fig. 4 for the reaction co-ordinate for cyclopropane is not unique. We notice that Jug's picture (20) of the reaction process also includes some rotational motion of one of the CH_2 groups: thus if we had chosen to share the critical energy between the ring stretch ν_3 at 1188 cm^{-1} with *one or other* of the degenerate pair of CH_2 twists, also at 1188 cm^{-1} (19), we would have calculated a synthetic $k(E)$ function only slightly below our first choice, as shown in Fig. 4, and with a frequency factor[3] of 1.6×10^{15} s^{-1}. However, were we to share the energy equally among all three oscillators of frequency 1188 cm^{-1}, the calculated $k(E)$ function would be about an order of magnitude larger than the result of sharing between two.

Non-adiabatic Reactions

The use of eq. [5] to give the rate of disruption of an oscillator involves the assumption that the process is an adiabatic one and, in general, we do not know whether this is or is not the case. The dissociation of CO_2 into CO+O is, however, clearly a non-adiabatic reaction and so it is interesting at this juncture to examine the application of eqs. [6] and [7] to this reaction. The molecule has two stretching modes, a symmetric one ν_1 leading to simultaneous dissociation of both C—O bonds, and an asymmetric one ν_3 which will lead to dissociation into O and CO; it also has a pair of bending modes ν_2 which, for the time being (see Appendix), are treated as being harmonic. Moreover, it appears from our recent calculations (22) that both in N_2O and CO_2, the transmission efficiency for curve crossing is about 1 in every 100 oscillations: the results presented in Fig. 5 assume therefore that ν_3 is the critical oscillator ($\nu_r = \nu_3 = 2349$ cm^{-1}) and that a transmission coefficient $\kappa = 0.01$ is included in eq. [5] to take rough account of the non-adiabatic problem. The agreement is reasonable, as also it is for N_2O using again ν_3 as the critical frequency ($\nu_r = \nu_3 = 2283$ cm^{-1}) and the same value of 0.01 for the transmission coefficient.

For the remainder of the paper, we will assume that the reactions we consider are adiabatic processes, although in general we have no way of knowing whether or not this is strictly true: thus, it should be kept in mind that we are always in danger of overestimating the rate constant through the neglect of a non-adiabatic transmission coefficient κ in eqs. [5]–[7].

Other Molecules

In this section, we will inspect briefly the extent to which eqs. [6] and [7] are successful in reproducing the specific rate functions and observed rate constants for the usual selection of other test-case thermal unimolecular reactions.

Cyclobutane

We proceed here by analogy with the treatment

[3]Although the lower $k(E)$ function gives the higher A-factor, there is no inconsistency since it also gives a slightly higher activation energy, see legend to Fig. 4.

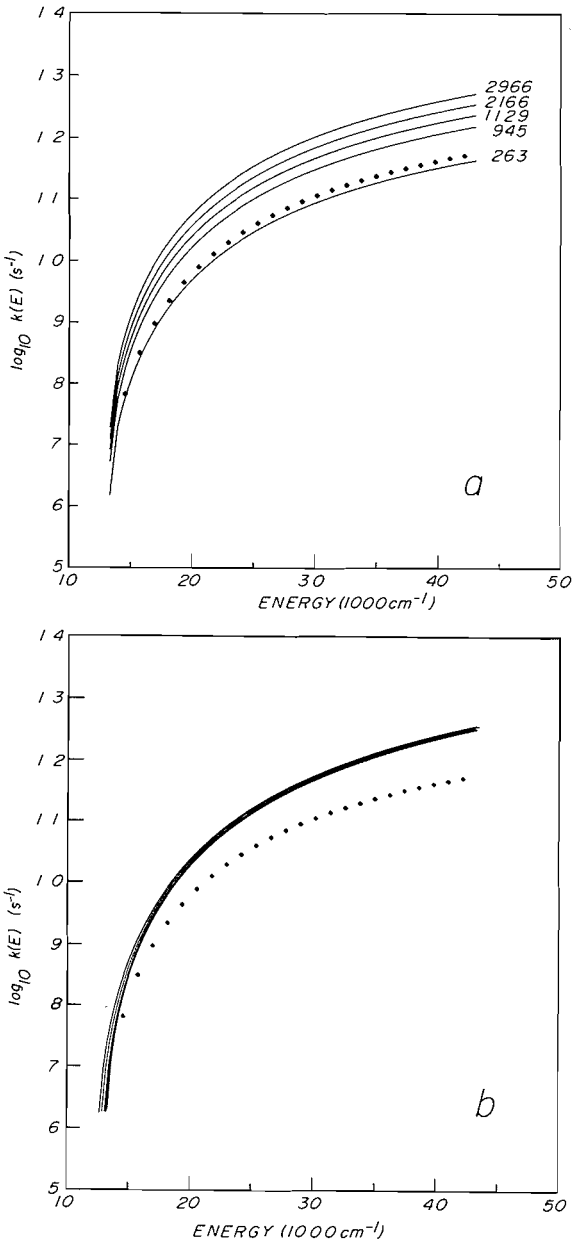

FIG. 3. (*a*) Comparison of five synthetic rate functions calculated according to eq. [7*a*] for methyl isocyanide, in the harmonic-oscillator approximation; the lines are labelled by the value of the frequency, in cm^{-1}, chosen for ν_r. (*b*) Five RRKM $k^*(E)$ functions using, in turn, the same five frequencies for the reaction co-ordinate. On both diagrams, the individual points represent the empirical $\bar{k}(E)$ function calculated according to eq. [8], also in the harmonic-oscillator approximation.

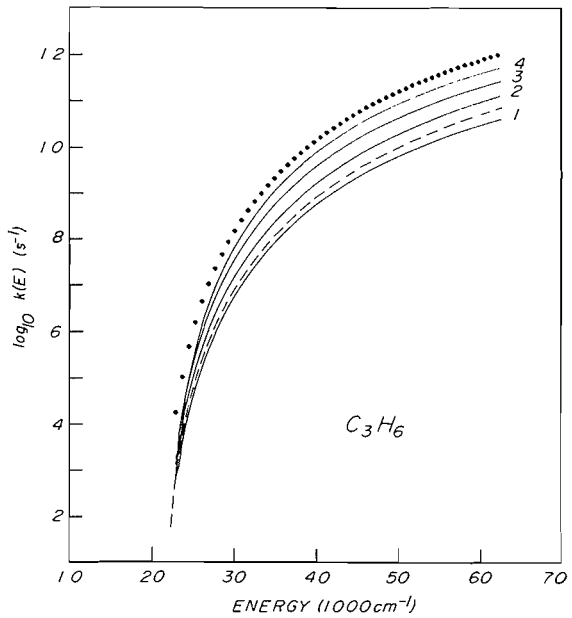

FIG. 4. Comparison of four synthetic $k(E)$ functions (solid lines) with the empirical $\bar{k}(E)$ function (points) and the RRKM $k^*(E)$ function (dashed line) for cyclopropane. Curves 1 and 2 use eq. [7*a*] with ν_r = 1188 and 3103 cm^{-1} respectively; curves 3 and 4 use eq. [7*b*] and share 1188 (g = 1) with 1188 (g = 2) and 1188 (g = 1) with 3103 (g = 1) cm^{-1} respectively. The rate constants calculated from the synthetic functions using eq. [9] give the following Arrhenius parameters (in order 1, 2, 3, 4): E_∞ = 65.5, 65.5, 67.2, 66.0 (*65.6*) kcal mol^{-1}, A_∞ = 0.07, 0.19, 1.6, 1.4 (*1.9*) × 10^{15} s^{-1} respectively, at 700 K.

of cyclopropane we gave above: the concentration of the critical energy in any single skeletal motion (having frequencies in the range 200–1000 cm^{-1}) gives rather low rates, and so we assume that the critical energy needs to be shared between two oscillational modes. Inspection of the normal modes of vibration of cyclobutane (23) shows that there is a pair having B_{1g} symmetry which form a natural choice for the reaction co-ordinate: one is the ring deformation ν_9 at 926 cm^{-1} in which the C_1—C_2 and C_3—C_4 lengths extend simultaneously while the C_2—C_3 and C_4—C_1 lengths decrease; the other is the CH_2 wagging ν_8 at 1219 cm^{-1} which simultaneously moves the H_2 pairs towards (and away from) the line of the C—C bonds, as required by the end of the dissociation process. Figure 6 compares the computed $k(E)$ function based on this assumption with the empirical $\bar{k}(E)$ and RRKM $k^*(E)$ functions: the computed rate constants are about a factor of 3.5 too high when compared with the experimental values between 700 and 800 K.

Ethyl Chloride

Figure 7 shows the results of choosing the critical coordinate to be one of the C—C—Cl deformation ν_{11} = 336 cm^{-1}, the C—Cl stretch ν_{10} = 671 cm^{-1} or the CH_3 degenerate stretch ν_2 = 2946 cm^{-1} (19). The choice of the C—Cl stretch ν_{10} gives almost exact agreement for the $k(E)$ function with the calculated rate constant some 20–25% below the ob-

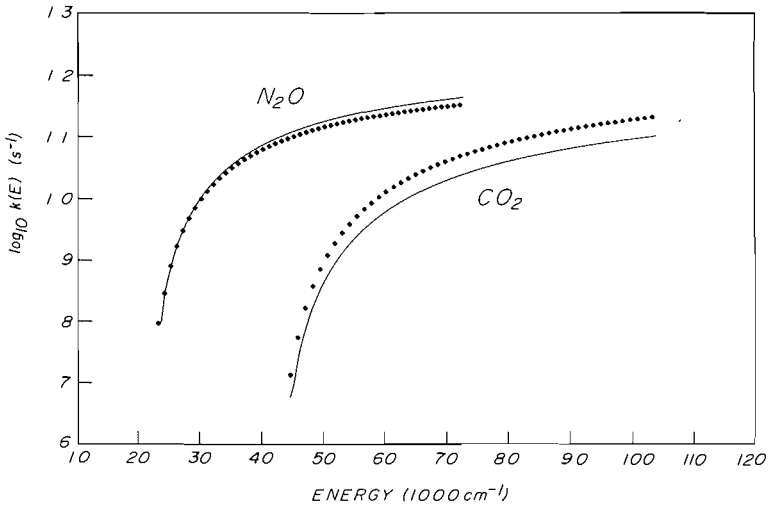

FIG. 5. Comparison of synthetic and empirical rate functions for carbon dioxide and nitrous oxide. The rate constants calculated from the synthetic functions using eq. [9] give the following Arrhenius parameters: CO_2, $E_\infty = 124\,(127)$ kcal mol^{-1}, $A_\infty = 1.2\,(2.0) \times 10^{12}$ s^{-1} at 3000 K; N_2O, $E_\infty = 66\,(66)$ kcal mol^{-1}, $A_\infty = 1.9\,(1.5) \times 10^{12}$ s^{-1} at 2000 K.

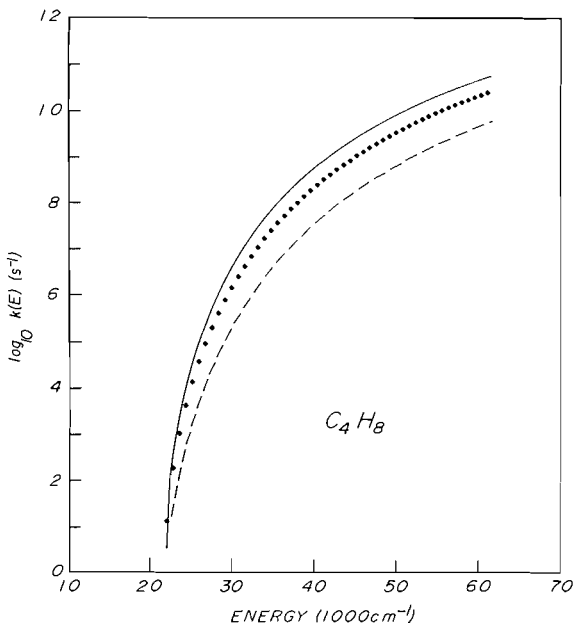

FIG. 6. Comparison of synthetic, empirical, and RRKM rate functions for cyclobutane. The rate constants calculated from the synthetic rate function according to eq. [9] give the following Arrhenius parameters: $E_\infty = 62.9\,(62.5)$ kcal mol^{-1}, $A_\infty = 16\,(3.7) \times 10^{14}$ s^{-1} at 700 K.

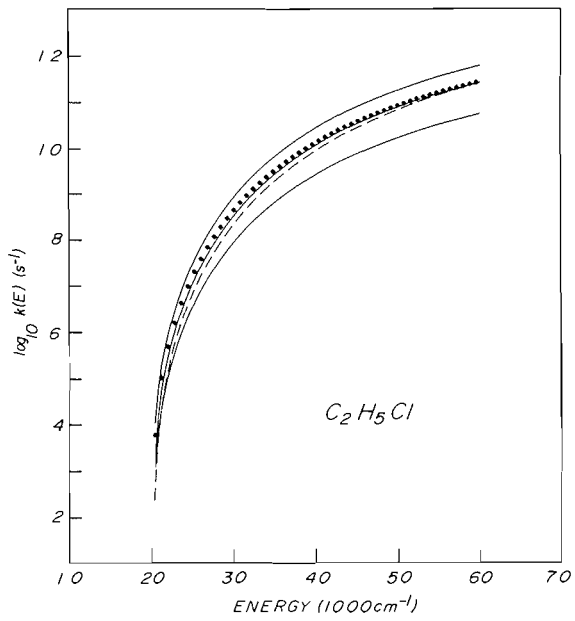

FIG. 7. Comparison of three synthetic rate functions, calculated according to eq. [7*a*] with the empirical and RRKM rate functions for ethyl chloride: the synthetic functions, from top to bottom, use $\nu_r = 2946$, 676, and 336 cm^{-1} respectively, and using eq. [9], give rise to the following Arrhenius parameters: $E_\infty = 58.4$, 58.6, 58.4 (*58.4*) kcal mol^{-1}, $A_\infty = 2.0$, 0.9, 0.2 (*1.1*) $\times 10^{14}$ s^{-1} at 600 K.

served values. In this calculation, the synthetic $k(E)$ curves do not fall exactly into a sequence as happens in Fig. 3*a*: this is because $\nu_{11} = 336$ cm^{-1} is treated as being harmonic, whereas $\nu_{10} = 676$ is assigned an anharmonicity $x_e = 0.006$ and $\nu_2 = 2946$ cm^{-1} has $x_e = 0.018$; in fact, were we to imagine that any one of $\nu_4 = 1463$ cm^{-1} (CH_3 degenerate deformation) or $\nu_5 = 1448$ cm^{-1} (scissors) or $\nu_{14} = 1448$ cm^{-1} (CH_3 degenerate deformation) (19), all treated as harmonic in our empirical assignment of anharmonicity, was the critical oscillator, the computed $k(E)$ function would be indistinguishable on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

the scale of the diagram from the one shown for $\nu_{10} = 676\,cm^{-1}$, $x_e = 0.006$. Thus, although Fig. 1 shows that the deduction of the Slater–Forst $\bar{k}(E)$ function is relatively insensitive to the anharmonicities chosen for the various oscillators in the molecule, our computed $k(E)$ function is sensitive to the anharmonicity chosen for the critical oscillator itself; the reason for this is quite clear on inspection of eq. [6*a*], since the spacings of the $\varepsilon_r(n_r)$ depend strongly upon the value of x_e in the reactive region.

Ethyl Isocyanide

Ethyl isocyanide possesses two bending frequencies, cf., ethyl cyanide (19), $\nu_{13} = 226\,cm^{-1}$ and $\nu_{20} = 270\,cm^{-1}$ (24). Figure 8 shows the empirical $\bar{k}(E)$ function, the RRKM $k^{\ddagger}(E)$ function and two synthetic $k(E)$ functions, one for a single oscillator ($\nu_r = \nu_{13} = 226\,cm^{-1}$) and the other for which the critical energy is shared between the two bending motions: the latter is rather better.

Trideuteriomethyl Isocyanide

Figure 9 shows the results for CD_3NC analogous to the calculations presented for CH_3NC in Fig. 2: considering the excellent agreement with experiment for CH_3NC, the results shown in Fig. 9 for CD_3NC are somewhat disappointing, but nevertheless the predicted rate is well within a factor of 3 of the correct result.

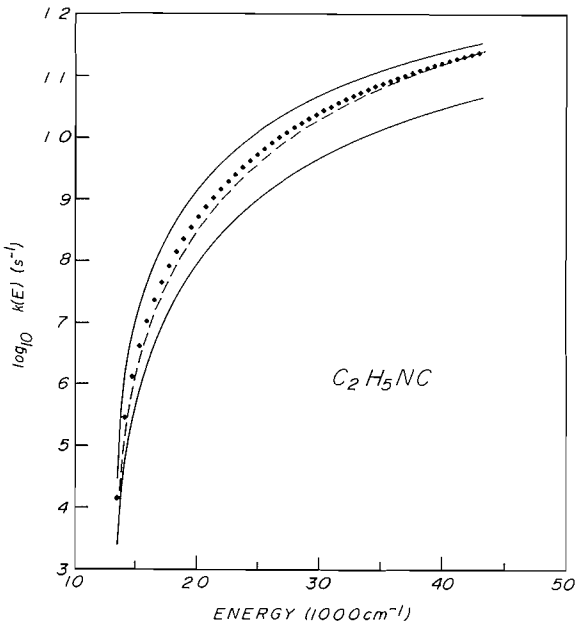

FIG. 8. Comparison of two synthetic rate functions with the empirical and RRKM rate functions for ethyl isocyanide: the lower synthetic function uses eq. [7*a*] and one bending frequency, the upper one uses eq. [7*b*] and both bending frequencies. The rate constants calculated from these synthetic rate functions according to eq. [9] give the following Arrhenius parameters: $E_\infty = 38.3, 38.1$ (*38.4*) kcal mol^{-1}, $A_\infty = 1.5, 31$ (*7.8*) $\times 10^{13}\,s^{-1}$ at 500 K.

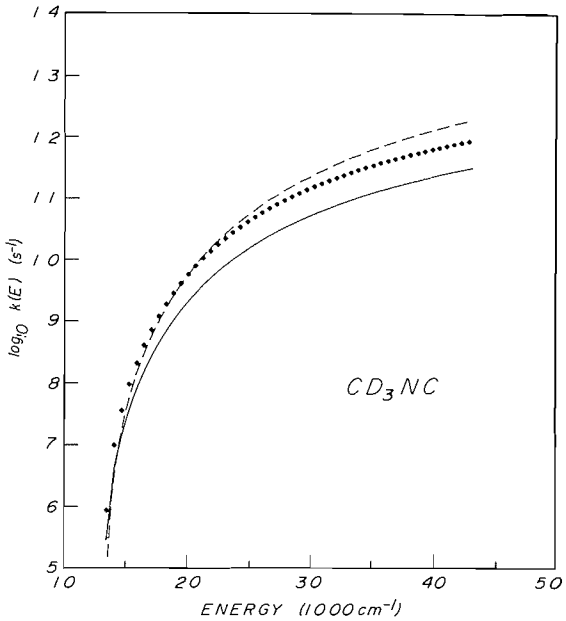

FIG. 9. Comparison of synthetic, empirical, and RRKM rate functions for trideuteriomethyl isocyanide. The rate constants calculated from the synthetic rate function according to eq. [9] give the following Arrhenius parameters: $E_\infty = 38.5$ (*38.5*) kcal mol^{-1}, $A_\infty = 1.7$, (*4.5*) $\times 10^{13}\,s^{-1}$ at 500 K.

Ethane

The ethane molecule possesses 6 singly degenerate and 6 doubly degenerate normal modes of vibration (ref. 21, p. 115). The ethane decomposition also has a very high frequency factor (26) of about $6.3 \times 10^{16}\,s^{-1}$, so it is clear that $m > 1$ in eq. [6*b*]. Examination of the normal-mode diagrams shows that there are only three of them which lead to any significant extension and contraction of the C—C bond, namely $\nu_1 = 2954\,cm^{-1}$ (CH_3 symmetric stretch), $\nu_2 = 1388\,cm^{-1}$ (CH_3 symmetric deformation), and $\nu_3 = 995\,cm^{-1}$ (C—C stretch) (19). Sharing of the critical energy of reaction between these three degrees of freedom yields a synthetic $k(E)$ function remarkably close to the empirical one, with the rate constant only about a factor of 3 too low.

Discussion

In this paper, we have taken the original concept of Polanyi and Wigner and reformulated it in discrete or quantised form.[4] As a result, we have

[4]As such, this reformulation is probably the nearest attainable approach to the quantum (anharmonic) form of the Slater theory, which so eluded Noel Slater, and others, over the years.

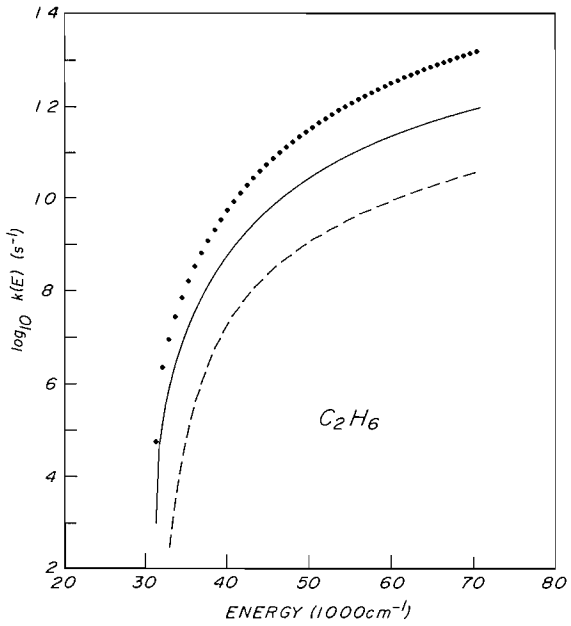

FIG. 10. Comparison of synthetic, empirical, and RRKM rate functions for ethane. The rate constants calculated from the synthetic rate function according to eq. [9] give the following Arrhenius parameters: 89.8 (*89.2*) kcal mol^{-1}, $A_\infty = 2.7$ (*6.3*) $\times$ 10^{16} s^{-1} at 900 K.

found that the rate of the unimolecular disruption of a rotationally and vibrationally excited molecule can be calculated with reasonable accuracy (usually within a factor of 3 or 4) by a very simple procedure. One first identifies the type of vibrational motion which, if carried to its limit, will result in the required reaction process. For simple molecules, it appears that this is always a simple process, and can be represented as the concentration of the critical energy in a *single* oscillator; for more complicated molecules it appears that, in general, the critical energy can be shared among two or perhaps three oscillators, and the choice of such oscillators is not very difficult in certain cases, e.g. cyclobutane, or possibly ethane. Then one enumerates the states of the molecule which have more than the critical energy localised in the critical oscillator(s) and assigns to them a mean lifetime which is simply half the vibrational period of the fastest critical oscillator: the remainder of the states are treated as being passive, and the synthetic $k(E)$ function is just the product of the mean decay rate constant for an active state with the ratio of the number of active to passive states.

It would be wise not to read too much physical significance into the apparent success of this simple model at this early stage, for several reasons. First, each state is treated as being discrete and infinitely narrow, whereas in reality each level is broadened from a number of causes, and in fact each level is overlapped by many of its neighbours: we intend to address this problem in a later publication.

Second, we have used a normal-mode representation of the internal motions of the molecule, whereas at these moderately high levels of excitation, a local-mode representation may be more appropriate: we are assuming here, of course, that the normal-mode and local-mode representations are commensurable in the sense that either will give us about the same densities of passive and active states in the given energy region. Hence, the mapping of the normal modes into the local modes would be a prerequisite for the proper choice of the critical oscillator for each reaction. It is clear, however, that the actual disruption process is often going to be representable by the concentration of the critical energy into a single local mode: as examples, we have in this paper the cases of methyl isocyanide and ethyl chloride: the latter result is rather surprising in view of the amount of effort which has been expended in the past trying to formulate the nature of the transition state[5] in such four-centre reactions! For such cases, the principal requirement is a knowledge of the frequency of the local mode leading to reaction[6]. For more complicated molecules, the critical energy can be shared between two, or perhaps even three vibrational degrees of freedom, and by using (not illogical) combinations of such oscillations, it is fairly easy to generate acceptable $k(E)$ functions and rate constants: this sharing of the critical energy among two or more oscillators leads directly to the prediction of "high" frequency factors (1, 8, 9, 27).

Third, our knowledge of the energy-level density in any molecule must be very imperfect because, in general, we have very scant knowledge of anharmonicities and of rotation–vibration interaction constants, both of which affect the level densities

[5]We always have to keep in mind, of course, that a curve-crossing may be involved, and that we are really dealing with a more complex (and therefore faster) process moderated by a non-adiabatic transmission factor κ.

[6]In this context, the apparent discrepancy noted above between the success of the method for methyl isocyanide and for its isotopic variant becomes explicable. In methyl isocyanide, we have assumed equally spaced harmonic levels of the 263 cm^{-1} oscillation in evaluating eq. [6*a*], whereas, above threshold, this oscillation must degenerate into a rotation with *increasing* level spacings as the energy increases. Likewise, in the deuteriated molecule, the analogous bending at 249 cm^{-1} also degenerates into a rotation, but because of the increased effective moment of inertia for this rotation, the level spacings will be closer than for the normal molecule. Thus, in the final analysis, the $k(E)$ function for the heavier molecule will not be a factor of three below that for the normal molecule, as we find here using our normal-mode approximations; similar considerations might apply also to ethyl isocyanide.

significantly. We have tried to allow for the former in a very empirical manner, but have ignored completely the problem of rotation–vibration interaction, although we have allowed for the density of rotational states at all stages in the formulation: this is analogous to the approximations we have made previously in treating the dissociations of CO_2 and N_2O, both at high (22) and low (4) pressures, but it is clear, especially in the former case, that the neglect of rotation–vibration interaction has an adverse effect on the quality of the computed rate constants; there is, of course, no *a priori* reason why one should not consider the critical energy to be shared between rotation and vibration, but we have not explored the behaviour of such calculations.

In conclusion, we believe that the present approach has a number of favourable qualities. It is simple in concept, and simple to use: moreover, for simple molecules (fewer than 5 or 6 atoms, say) there usually appears to be a fairly unambiguous choice of critical oscillator which causes eqs. [6] and [7] to give results within a factor of about 3 of the empirical Slater–Forst $\bar{k}(E)$ function. For such molecules, it is now becoming possible to compute, *ab initio*, potential surfaces of "chemical accuracy" from which all the required molecular parameters, i.e. potential barrier, vibration frequencies, moments of inertia, and so on can be derived: thus, a true *ab initio* calculation of a unimolecular rate constant becomes a possibility. For more complicated molecules, this approach gives hope that we will be able eventually to distinguish between alternative pathways in a manner which is not possible with the RRKM method: this is because we do not have to adjust the frequencies of the molecule to match the observed frequency factor, but rather we take the natural frequencies as best we can determine them, and by the appropriate choice of a reaction co-ordinate are led to the unambiguous calculation of the frequency factor. Thus, this approach has considerably greater predictive potential when one is interested in the rates of reactions for which no measurements are possible at infinite pressure; however, before true predictions can be made for reactions in general, a period of exploration is required in which we examine, for a series of reaction types, the correspondence between the structure of the molecule and the nature of the appropriate reaction co-ordinate.

Appendix
Anharmonicities and Other Molecular Constants

In general, the calculations reported in this paper use the same set of molecular and reaction rate constants as we used previously, viz. Tables 2 and 3 of ref. 12; ethane was not considered in that paper, but the vibration frequencies (19), moments of inertia (6), the barrier to internal rotation (6) and the rate parameters (26) are taken from recent reliable sources. However, the anharmonicities we used previously are rather unsatisfactory for the present application. In that work (12) we examined the variation in density of states for methyl isocyanide and for cyclopropane as a function of the anharmonicity chosen for certain oscillators, and from the extent of that variation, it became clear that the choice of anharmonicities would have only a moderate effect on the derived $\bar{k}(E)$ function,

essentially since eq. [8] contains a ratio of terms which are changed in the same sense by changes in anharmonicity. Based on Cyvin's treatment of cyclopropane (14), we had recommended some empirical anharmonicity factors for use in these calculations (12) but these anharmonicities are, in general, too large: for example, the bending frequency of 263 cm^{-1} in methyl isocyanide would "dissociate" before the critical energy of 13 361 cm^{-1} is reached, making the application of eq. [6*a*] impossible. These large anharmonicities, although acceptable for general statistical calculations, are unreasonable for molecular-dynamic applications. Consequently, we have adopted an empirical method of assigning anharmonicity factors based upon the nature of the vibration in question and its estimated dissociation limit. We assign an effective dissociation limit D_i to each vibration: for example, the C—C stretch in ethane would have $D_i \simeq 90$ kcal mol^{-1}, the symmetric stretch of a CH_3 group would have $D_i \simeq 300$ kcal mol^{-1} and the asymmetric stretch of the same group about 100 kcal mol^{-1}; all bending or deformation degrees of freedom, which cannot be assigned a dissociation energy in this simple way, were assumed to be harmonic. To simplify the procedure even more, it matters very little what effective dissociation energy D_i is assigned to an oscillator once $D_i > 2E_{crit}$; consequently, all anharmonic oscillators were given a number N_i in the range $1 \leq N_i \leq 2$ where $N_i = D_i/E_{crit}$ for $D_i \leq 2E_{crit}$ or $N_i = 2$ for $D_i > 2E_{crit}$, and the anharmonicity factor was then calculated according to the standard Morse-oscillator equation (25).

$$[A1] \quad \omega_e x_e = \omega_e^2/4N_i E_{crit}$$

The only exception to the use of this recipe was in the case of N_2O, where reliable values for the anharmonicities exist, cf. Table 1 of ref. 4.

Received July 11, 1979[1]

NERIYANURI MANOHARA MURTHY and SARASWATULA VENKATA SUBRAHMANYAM. Can. J. Chem. **58**, 1527 (1980).

The effect of NaCl, KCl, RbCl, KBr, and KI on the temperature corresponding to the sound velocity maximum (TSVM) of aqueous *t*-butanol has been studied. The structural contribution to the shift in the TSVM of aqueous *t*-butanol by the addition of alkali halides was found to be in the order NaCl > KCl > RbCl and KCl > KBr > KI, thereby indicating that $Na^+ > K^+ > Rb^+$ and $Cl^- > Br^- > I^-$ in disrupting the hydrogen-bonded structure of water. The results also indicate an enhancement in the structure-breaking characteristic of both cations and anions in the presence of *t*-butanol. However, the order is the reverse of that found for pure water, i.e. $Rb^+ > K^+ > Na^+$ and $I^- > Br^- > Cl^-$. The results have been explained on the basis of hydrophobic–hydrophilic interactions prevalent in the ternary systems.

NERIYANURI MANOHARA MURTHY et SARASWATULA VENKATA SUBRAHMANYAM. Can. J. Chem. **58**, 1527 (1980).

On a étudié l'effet des sels suivants NaCl, KCl, RbCl, KBr et KI sur la température correspondant à la vitesse maximale du son (VMS) dans des solutions aqueuses de *tert*-butanol. On a trouvé que la contribution structurale au déplacement de la VSM du *tert*-butanol aqueux par l'addition d'halogénures de métaux alcalins varie dans l'ordre NaCl > KCl > RbCl et KCl > KBr > KI indiquant ainsi que la destruction des liaisons hydrogènes dans l'eau se fait dans l'ordre: $Na^+ > K^+ > Rb^+$ et $Cl^- > Br^- > I^-$. Les résultats indiquent également une augmentation caractéristique dans la dislocation de la structure pour les cations et les anions en présence du *tert*-butanol. Cependant l'ordre est l'inverse de celui trouvé pour l'eau pure soit $Rb^+ > K^+ > Na^+$ et $I^- > Br^- > Cl^-$. On a expliqué les résultats en fonction des interactions hydrophobe–hydrophyle qui existent finalement dans les systèmes tertiaires.

[Traduit par le journal]

Introduction

The viscosity *B*-coefficient (1), activation energy of viscous flow (2), compressibility data (3, 4), and the data on the structural contribution to the shift in the temperature of sound velocity maximum in water (5) for alkali halides indicate a structure-ordering effect for Li^+ and Na^+ and a structure-breaking effect for Rb^+ and K^+. Li^+ was found to be more effective than Na^+ in structure-making, i.e. enhancement of long range order in water, and Rb^+ was found to be more effective than K^+ in structure-breaking, i.e. disruption of the hydrogen-bonded structure of water. For anions the structure-breaking effect was found to be in the order $I^- > Br^- > Cl^-$.

Conductivity measurements by Broadwater and Kay (6) on KCl, CsCl, LiBr, KBr, Me_4NBr, Bu_4NBr, and Me_4NI in aqueous mixtures containing *t*-butanol at 25°C indicate that the structural effects of cations and anions are modified significantly in the presence of *t*-butanol. Structure-breaking ions were found to be more effective and this effect was found to be maximum around 10 mol% of *t*-butanol, the concentration at which maximum enhancement of water structure by *t*-butanol is believed to take place. It was also observed that the order found in the structure-breaking power of both cations and anions to be reverse of the order found for the same ions in pure water.

The behaviour of water + *t*-butanol system has been extensively studied from different angles, particularly in the water-rich region in view of the highly hydrophobic character of *t*-butanol. The various studies (7–21) indicate an enhancement in the hydrogen-bonded structure of water by *t*-butanol when present in small amounts. The maximum in the hydrophobic interactions between *t*-butanol and water molecules occurs in the region 3 to 8 mol% of *t*-butanol as evidenced by the existence of extrema in many of the physical properties. But, Hepler (22) points out that there is no unambiguous numerical measure of structure-making or -breaking by a solute. However, since a shift in the equilibrium between the hydrogen-bonded bulk form and non-hydrogen-bonded dense form of water is accompanied by a volume change, one can take the partial molar volume of the solute to provide a rough measure of the effect of that solute on the structure of water (23). The minimum in ϕ_v occurs at 25°C near 0.04 mole fraction of *t*-butanol (12), the concentration at which most of the properties (9, 13, 18) exhibit maxima or minima.

The strength of the hydrophobic interaction of *t*-butanol is sensitive to temperature. The sharp minimum in the hydroxyl-proton chemical shift (16) as a function of concentration of *t*-butanol in aqueous *t*-butanol rapidly diminishes on heating, being entirely lost in the region of 67°C. The minimum in ϕ_v versus X_2 and the maximum in ϕ_c versus X_2 (X_2 is the mole fraction of *t*-butanol) are more pronounced in the water-rich region of aqueous *t*-

butanol (12), reflecting promotion of ordered structure of water, which shift to lower concentrations as the temperature is increased (the minimum in ϕ_v and maximum in ϕ_c versus X_2 occur around $X_2 \simeq 0.02$ at 55°C).

Our earlier studies on the effect of isomeric butanols on the temperature of adiabatic compressibility minimum (24) and sound velocity maximum (25) indicate *t*-butanol to promote the hydrogen-bonded structure of water. These studies indicate maximum enhancement in the structure of water to occur around $X_2 \simeq 0.0193$ and 0.0046, respectively. It may be noted that the compressibility and velocity studies are confined to 64 and 74°C respectively.

Studies on the effect of electrolytes on the solution structure of aqueous *t*-butanol have been made extensively (26–30) by measuring the thermodynamic functions such as free energies, enthalpies, entropies, heat capacities, and volumes, and evaluating the corresponding transfer functions of the concerned solutes from water to water + *t*-butanol. The large concentration dependence of the transfer functions observed in the water-rich region has been explained in terms of the solute–solute interactions between the reference solute and the cosolvent taking into account the ordered structure of the aqueous *t*-butanol.

In order to understand the influence of alkali halides on the solution structure of aqueous *t*-butanol in the water-rich region through ultrasonic velocity measurements and also to see whether the findings of Broadwater and Kay (6) regarding the structure-breakings power of anions and cations still persist even at high temperatures, we have taken up the study of the effect of alkali halides on the temperature of sound velocity maximum (TSVM) of water and the results are reported here.

Experimental

Triply distilled degassed water was used to prepare stock solution of aqueous *t*-butanol. The mole fraction of *t*-butanol in the stock solution is 0.0046, the concentration at which maximum enhancement of water structure is supposed to occur as revealed from TSVM studies. Each time about 1 L solution was prepared by weighing the samples using a triple beam balance. This stock solution was used to prepare solutions of desired concentration of the electrolytes under study, namely AR grade NaCl, KCl, RbCl, KBr, and KI.

Ultrasonic velocity in the ternary system (electrolyte + aqueous *t*-butanol) was determined with an accuracy of ±0.003% using a single crystal variable path interferometer working at 3 MHz, the details of which are discussed elsewhere (24), over a range of 5°C on either side of TSVM at an interval of 2 to 3°C.

Results

The experimentally determined ultrasonic velocity data at different temperatures in the ternary solutions (water + *t*-butanol + electrolyte) at different concentrations of electrolytes have been used, after effecting diffraction correction (31), to determine the temperature of the sound velocity maximum in the ternary solution. In all cases, since the shape of the velocity temperature curves are similar to that of aqueous *t*-butanol and also to that of pure water, a transparent template of the velocity–temperature curve of pure water itself was used to fix the TSVM of the ternary solution and the accuracy in fixing TSVM is ±0.2°C. Typical results are shown graphically in Fig. 1 and the values of TSVM obtained at different concentrations of electrolytes in the ternary solutions are given in Table 1.

Discussion

The shift in the temperature corresponding to the sound velocity maximum in the solution of aqueous *t*-butanol caused by the addition of an electrolyte is given by

$$[1] \quad \Delta T' = T_{\text{ternary sol.}} - T_{\text{binary sol.}}$$

$\Delta T'$ may be thought of as arising due to two effects, namely, dilution effect and structural effect. The dilution effect is always negative while the structural effect may be positive or negative depending on the change in the solution structure towards

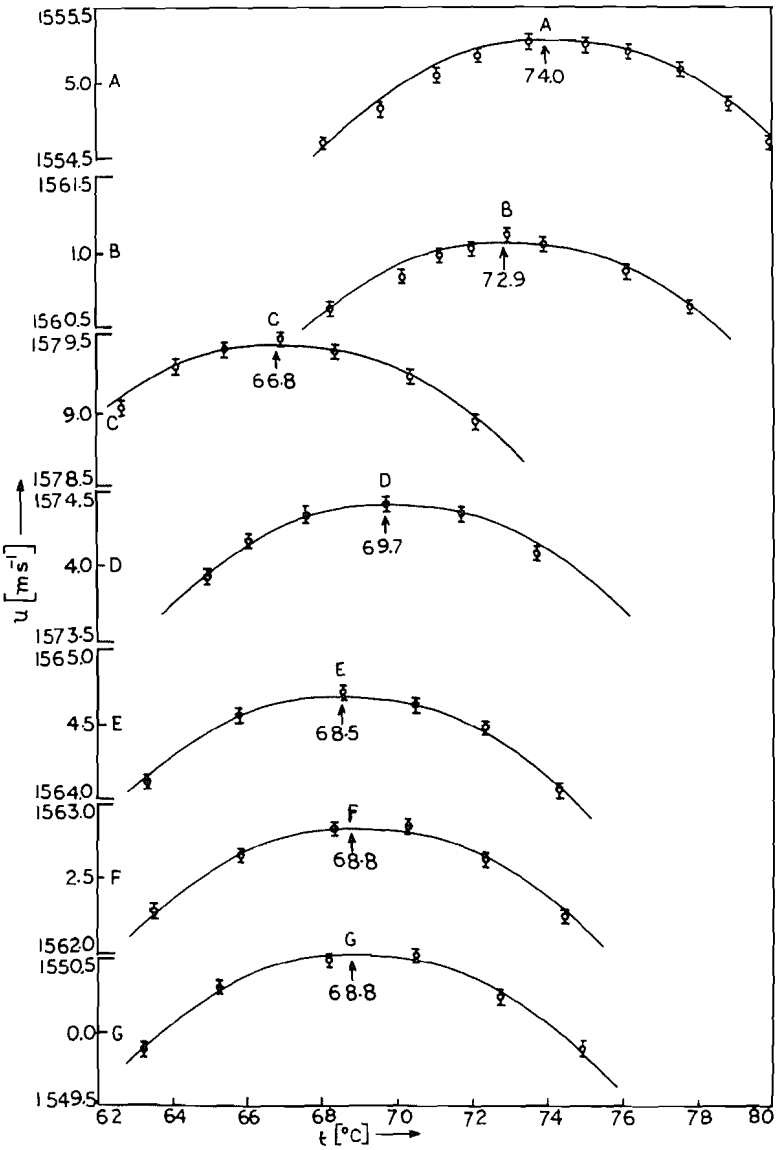

FIG. 1. Ultrasonic velocity versus temperature in aqueous *t*-butanol at different concentrations of electrolytes. *A*, pure water; *B*, $w = 0.0000$ aqueous *t*-butanol, $X_2 = 0.0046$; *C*, water + *t*-butanol + NaCl, $w = 0.0204$; *D*, water + *t*-butanol + KCl, $w = 0.0234$; *E*, water + *t*-butanol + RbCl, $w = 0.0450$; *F*, water + *t*-butanol + KBr, $w = 0.0339$; *G*, water + *t*-butanol + KI, $w = 0.0474$.

more order or less order owing to the interaction of the electrolyte with water molecules. It is necessary to separate these two effects to delineate the structural propensities of different ions. The effect of dilution in lowering the TSVM of aqueous *t*-butanol can be obtained by considering the expressions representing the temperature dependence of sound velocity in aqueous *t*-butanol and in the solute (electrolyte).

The velocity in aqueous *t*-butanol in which the mole fraction of *t*-butanol is 0.0046 conforms to the relation

$$[2] \quad u_{12} = 1561.02 - 0.0196[73.0 - t]^2$$

where t represents the temperature in °C. The velocity in the solute can be written as

$$[3] \quad u_2 = u_2^0 - \alpha_u t$$

where u_2^0 is the velocity at 0°C and α_u represents the temperature coefficient of sound velocity.

Considering the internal energy U of a mixture is additive on mole fraction basis (32), we can write

$$[4] \quad U = (1 - x)U_1 + xU_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

where U_1 and U_2 are the internal energies of the components 1 and 2 respectively and x represents the mole fraction of component 2 in the mixture. Differentiating eq. [4] with respect to volume (V) at constant entropy (S) and using the relation

$$[5] \quad \left[\frac{\partial^2 U}{\partial V^2}\right]_S = \frac{u^2 M}{V^2}$$

where u and M represent the ultrasonic velocity in the liquid and molecular weight of the liquid respectively, we get

$$[6] \quad u^2 = \frac{(1-x)M_1}{\bar{M}} u_1^2 + \frac{xM_2}{\bar{M}} u_2^2$$

In the above equation $\bar{M}$ represents the molecular weight of the mixture given by

$$[7] \quad \bar{M} = (1-x)M_1 + xM_2$$

Equation [6] can be rewritten as

$$[8] \quad u^2 = (1-w)u_1^2 + wu_2^2$$

where w represents the weight fraction of the second component in the solution.

Equation [8] has been applied by Kudriavtsev (32) to calculate the sound velocities in aqueous solutions of electrolytes. The same relation has also been utilized (5, 33) to obtain an expression for the ideal shift in the temperature of sound velocity maximum in water due to the addition of an electrolyte.

In view of the fact that in the water-rich region aqueous t-butanol behaves as pure water, in respect of velocity–temperature profile, we can use the following relation to represent the velocity in the ternary solution containing an electrolyte

$$[9] \quad u^2 = wu_2^2 + (1-w)u_{12}^2$$

where w represents the weight fraction of the electrolyte in the ternary solution. Substituting eqs. [2] and [3] in eq. [9] and differentiating the resulting equation with respect to temperature and using the condition $du/dt = 0$ at $t =$ TSVM of the solution, we get

$$[10] \quad [1561.02 - 0.0196(73.0 - T')^2] \times 0.0392(73.0 - T') = -\frac{w}{(1-w)} \times [(u_2^0 - \alpha_u T')\alpha_u]$$

where T' represents the TSVM in the ternary solution. The term within the square bracket on the left hand side of eq. [10] represents the velocity in aqueous t-butanol at the TSVM of the ternary solution and can be replaced by 1561.02 ms^{-1} provided T' does not differ from 73.0°C appreciably which is true. Hence

$$[11] \quad T' = T'_{id.} = \frac{4467 - bu_2^0\alpha_u}{61.2 - b\alpha_u^2}$$

Here $T'_{id.}$ represents the ideal value of TSVM when no structural changes are involved and $b = w/(1-w)$. The structural contribution to the shift in TSVM can be written as

$$[12] \quad [\Delta T'_{str.}]_{exp.} = T'_{exp.} - T'_{id.}$$

In order to evaluate the structural contribution to the shift in TSVM we have to calculate $T'_{id.}$. As per eq. [11] we need α_u and u_2^0 in the solute. Since the solutes used are solid electrolytes which have cubic structure, we have three velocities associated with sound wave propagation, namely, one longitudinal and two torsional. The problem now is which one of these velocities we have to take to evaluate u_2^0 and α_u that may be used in eq. [11] to obtain $T'_{id.}$. Since there is no reason to prefer any one of these velocities we may use the mean velocity $\bar{u}_m$ for u_2 in the electrolyte given by the following relation

$$[13] \quad u_2 = \bar{u}_m = \frac{1}{3}\left[\frac{2}{\bar{u}_s^3} + \frac{1}{\bar{u}_l^3}\right]^{-1/3}$$

where $\bar{u}_l$ and $\bar{u}_s$ represent the longitudinal and torsional wave velocities in the polycrystalline aggregates of the electrolytes. Indeed to evaluate the Debye characteristic temperature of polycrystalline samples the average velocity normally used is the one given by eq. [13] and we feel our preference to use $\bar{u}_m$ instead of any one of the u_l or u_s to evaluate $T'_{id.}$ is reasonable. The values of u_2^0 and α_u calculated using the elastic constants and their temperature dependence (34–36) for the electrolytes under study are given in Table 2.

The observed shift $\Delta T'$ and the values of the structural contribution to the shift in TSVM, $[\Delta T'_{str.}]_{exp.}$, evaluated using eqs. [1] and [11] and [12] respectively at different concentrations of NaCl, KCl, RbCl, KBr, and KI are presented in Table 1 along with $T'_{exp.}$ and $T'_{id.}$ values. Since weight fraction of the electrolyte is involved in the evaluation of the ideal shift and hence the structural shift, it is more appropriate to see how the structural shifts change with weight fraction of the electrolyte in the ternary solution rather than the molality or volume fraction and there by delineate the structural propensities of individual ions. In view of this the values of $[\Delta T'_{str.}]_{exp.}$ for NaCl, KCl, and RbCl and KCl, KBr, and KI as a function of weight fraction are represented graphically in Figs. 2 and 3, respectively. The values of the structural contribution to the shift in TSVM of water, $[\Delta T_{str.}]_{exp.}$,

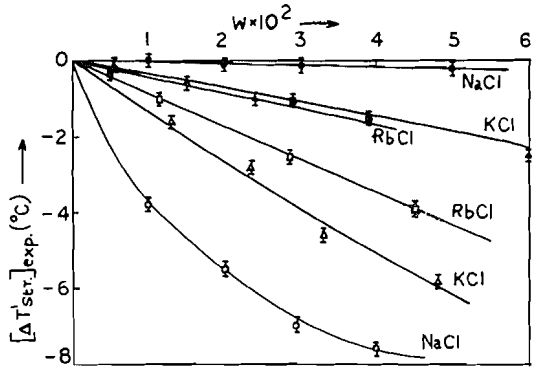

FIG. 2. $[\Delta T'_{str.}]_{exp.}$ versus weight fraction w of NaCl, KCl, and RbCl in aqueous t-butanol. ●, ■, ▲ correspond to pure water.

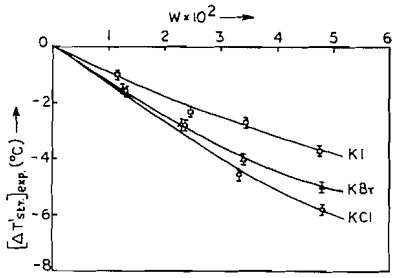

FIG. 3. $[\Delta T'_{str.}]_{exp.}$ versus weight fraction w of KCl, KBr, and KI in aqueous t-butanol.

as a function of weight fraction of NaCl, KCl, and RbCl available in literature (5) are also included in Fig. 2. An examination of the data presented in Fig. 2 indicates that the values of $[\Delta T'_{str.}]_{exp.}$ for NaCl, KCl, and RbCl are negative and also greater than $[\Delta T_{str.}]_{exp.}$, indicating that the structure-breaking efficiency of these solutes gets enhanced in the presence of t-butanol. The values of $[\Delta T'_{str.}]_{exp.}$ and $[\Delta T_{str.}]_{exp.}$ are accurate to ±0.2°C. Within the limits of experimental error we clearly see that at any given concentration $[\Delta T'_{str.}]_{exp.}$ for NaCl > KCl > RbCl, indicating that in the presence of t-butanol the structure-breaking efficiency of $Na^+ > K^+ > Rb^+$ whereas in pure water the TSVM studies indicate that the structure-breaking efficiency of $Rb^+ \geq K^+ > Na^+$. The viscosity B-coefficient for Na^+, K^+, and Rb^+ respectively are +0.086, −0.007, and −0.029, indicating that the structure-breaking efficiency of these ions are in the order $Rb^+ > K^+ > Na^+$ (1).

From Fig. 3 we notice that within the limits of experimental error the values of $[\Delta T'_{str.}]_{exp.}$ for KCl ≥ KBr > KI up to $w \simeq 0.025$. But as the concentration of the solute increases ($w > 0.025$) we definitely see that at any given concentration $[\Delta T'_{str.}]_{exp.}$ for KCl > KBr > KI. From these observations we may conclude that in general the structure-breaking efficiency of $Cl^- > Br^- > I^-$ in the presence of t-butanol. In pure water the structure-breaking efficiency of these ions are in the order $I^- > Br^- > Cl^-$ as revealed from TSVM studies on halides of lithium (5) and viscosity data. The viscosity B-coefficient for Cl^-, Br^-, and I^- respectively are −0.007, −0.032, and −0.080 (1).

The results of the present study are in line with the observation made by Broadwater and Kay (6). This indicates that the interactions responsible for enhancement in the structure-breaking nature of both cations and anions such as hydrophobic–hydrophilic interactions between cosolvent and the solute and dehydration of the ions due to the presence of t-butanol persist even at high temperatures. The collapse of the three dimensional structure of the solution readily due to the addition of hydrophilic solutes may be related to the strong solute–water, cosolvent–water, and solute–cosolvent structural interactions (30, 37). It is also worthwhile to note that the enhancement in the hydrophobic interactions of n-Am_4NBr, Bu_4NBr, and $NaBPh_4$ at 30°C around $X_2 \simeq 0.03$ to 0.04 of t-butanol has been attributed to a mechanism of mutual enhancement of water structure by both the hydrophobic solutes (38). Hence it may be inferred that t-butanol enhances the hydrophilic or hydrophobic interactions respectively of structure-breaking or structure-making solutes in aqueous ternary systems when present in small amounts at which the binary cosolvent structure is more ordered than pure water.

A type II aqueous cholesteric lyomesophase

MAHMUT ACIMIS[1] AND LEONARD W. REEVES[2]

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received January 15, 1979[3]

MAHMUT ACIMIS and LEONARD W. REEVES. Can. J. Chem. **58**, 1533 (1980).

The lyotropic liquid crystals formed by optically active detergents, water, and electrolyte have been investigated near and above the water-rich limit of the lamellar mesophase by using nuclear magnetic resonance, relative density observations, and polarized microscopy. The racemic mixture of α-alanine decyl ester forms a lamellar phase, a disc-micelle type II phase (which may co-exist in equilibrium), followed by an isotropic material as the water content increases. The resolved *d* or *l* detergent also forms a lamellar mesophase which may coexist with a type II disc-micelle system; however, as water content increases a transition occurs to a cholesteric lyotropic mesophase which itself passes over to an isotropic phase at the highest water contents studied. The range of existence, as a function of water content, for these intermediate type II DM and cholesteric phases is very narrow. The screw axis of the cholesteric mesophase aligns parallel to the magnetic field. A tentative structure of the cholesteric phase based on disc micelles distorted into a partial helix is suggested.

MAHMUT ACIMIS et LEONARD W. REEVES. Can. J. Chem. **58**, 1533 (1980).

Opérant dans la zone située tout près et au-dessus de la limite riche en eau de la mésophase lamellaire et faisant appel à la rmn, à des observations de densité relative et à la microscopie polarisée, on a étudié les cristaux liquides lyotropes formés par les détergents optiquement actifs, l'eau et un électrolyte. Le mélange racémique de l'ester décyclique de l'α alanine forme une phase lamellaire, une phase disque-micelle de type II (qui peut coexister en équilibre) qui est suivie d'un produit isotrope lorsque la teneur en eau augmente. Le détergent résolu (*d* ou *l*) forme également une mésophase lamellaire qui peut coexister avec un système disque-micelle de type II; cependant lorsque la teneur en eau augmente, il se produit une transition en une mésophase cholestérique lyotrope qui elle-même se transforme en une phase isotrope pour la plus haute teneur en eau étudiée. Le domaine d'existence, en fonction de la teneur en eau, de ces intermédiaires de type II DM et des phases cholestériques est très étroit. L'axe sans fin de la mésophase cholestérique s'aligne parallèlement au champ magnétique. On suggère une structure non définitive pour la phase cholestérique basée sur les disques micellaires déformés en une hélice partielle.

[Traduit par le journal]

Introduction

Lawson and Flautt (1) discovered lyotropic liquid crystals that spontaneously align in the static magnetic fields used for nuclear magnetic resonance (nmr) studies. These uniaxial fluids may be prepared using chemical variations, either with positive (type I) or negative (type II) diamagnetic anisotropy (2). We have investigated the effect of chemical changes in the composition of such systems, and a recent overview article summarizes the results of these extensive studies (3). The type II lyomesophases can have the infinite lamellar structure, in which case they are not spontaneously aligned by magnetic fields, or they can be nematic[4] with a disc bilayer structure of finite micelles with orientational order only (3, 13). The possibility of preparing an aqueous chiral lyotropic mesophase has been one of our continuing investigations since the aligning mesophases attracted our attention some ten years ago (3). The biological membrane bilayer is made up of optically active amphiphiles (4, 12).

Two previous co-workers (5, 6) have studied the effect of optically active amphiphile components as guests in these mesophases. Radley and Saupe (7) used the decylammonium chloride – cholesterol system (9) in order to investigate an induced twisted structure by optical methods. In their quantitative study of the induced twist in a type II DM lyomesophase, the chemical system was ex-

[4]Footnote added in proof. While this article was in press, an article by Charvolin *et al.*, J. Phys. Lett. **40**, 587 (1979), has appeared on the low angle X-ray diffraction of a type II DM mesophase. These authors conclude that this mesophase is nematic with disc-micelles. The Laue camera, used by these workers, obscures the observation of the inner diffraction reported by Lia Q. do Amaral (13) using full low angle X-ray diffraction apparatus. Furthermore, the experimental conditions of Charvolin *et al.* with respect to sample thickness, so important in the detection of residual magnetic orientation, are not stated. More recently, Lia Q. do Amaral and co-workers (Mol. Cryst. Liq. Cryst. Lett., in press) have seriously questioned the use of the word "nematic" for these intermediate mesophases. The outer sharp maxima have been assigned as a Bragg diffraction arising from regions of positionally ordered disc-micelles. We feel that the notation Type II DM and Type I CM mesophases accommodates the lack of nematic behaviour (19) and avoids the necessity of implying nematic structures. Our notation (19) also accommodates the formation of Type II CM and Type I DM mesophases, which have yet to be experimentally realised. The reversal of the diamagnetic anisotropy sign for the amphiphiles in constituent micelles is a chemically accessible variable and we can expect reports on these predicted mesophases in the future.

tended to include brucine sulphate and tartaric acid guests (7). Tracey and Diehl (8) prepared a mesophase similar to that of Flautt and Lawson (1) but with optically active sodium decyl-2-sulphate as a guest amphiphile.

There is no report on aqueous lyotropic mesophases that exhibit polymorphism with chiral amphiphiles, however, two non-aqueous systems (10, 11, 14) have been investigated. These liquid crystalline systems are not related to the aqueous bilayer micelle structures in any simple way (12).

The present study is directed toward the first synthesis of cholesteric aqueous lyotropic systems which are related to the type II DM systems, but prepared with a pure optically resolved amphiphile. The results will show that true cholesteric phases can be prepared as well as their nematic[4] racemate. A polymorphism of liquid crystalline forms occurs because the transition to the cholesteric state requires a critical water content.

The paper is divided into two parts, first the nmr study of the cholesteric mesophases and their nematic[4] racemate at higher water content, and secondly, a polarized microscopic investigation with parallel nmr studies at lower water contents to illustrate the relationship and polymorphism of the mesophases formed with chiral detergents.

Experimental

Materials

α-Alanine hydrochloride decylester (α-ADE) was synthesized in the following manner. HCl gas was passed into 31.5 g (~0.2 mol) *n*-decanol in a 3-necked flask at a temperature of 60–65°C and agitated by a bar magnet. After 10 min, 5 g (~0.056 mol) α-alanine was poured into the flask (Aldrich Chemical Co.), and solution of the solid took place over a 2 h period. At this point the stream of HCl gas was stopped and the reaction mixture stored overnight at room temperature. The next day, the excess HCl was removed by reducing the pressure with a water pump; crude α-ADE crystallized out and was filtered from excess *n*-decanol. The crude product was recrystallized three times from ethylacetate and dried several hours in a vacuum oven (15 Torr) at 50°C to give an 80% or better yield. The purified α-ADE gave the following physical constants. L-alanine hydrochloride decylester (*l*-ADE), mp 105°C; $[\alpha]_{578}^{24}$ −6.8° (*c* 2.1, H_2O), *d*-alanine hydrochloride decylester (*d*-ADE), mp 105°C; $[\alpha]_{578}^{24}$ +6.8° (*c* 2.1, H_2O); the racemic mixture (d*l*-ADE), mp 73°C. The rotation angles were measured on a Carl Zeiss 340740 polarimeter.

Compositions of Mesophases with α-ADE

The racemic mixture and separate enantiomers of the *d*- and *l*-alanine hydrochloride decylester were used respectively to form type II DM and cholesteric lyomesophases with the following composition:

	α-ADE's	Na_2SO_4	D_2O
Weight %	50.955	5.095	43.949
Moles	1.000	0.187	11.450

The ingredients were weighed in test-tubes, which were sealed in order to prevent evaporation and homogenized by warming on a water bath with intervening periods of centrifugation through small constrictions in the tube. It was found that α-alanine hydrochloride decylesters (α-ADE's) form different mesophases, dependent on water content. This polymorphism was independent of the sign of the chirality. The range of stability of the different mesophases on changing the water content is given below. By keeping the moles of the α-ADE's and Na_2SO_4 constant as above, we use the term "Moles of water per one mole of amphiphile, MWPA" to describe the composition of mixtures.

(*i*) Lamellar phases of all the α-ADE's exist at and below 10.600 MWPA. (*ii*) Co-existent lamellar and type II DM mesophases exist between 10.700 and 11.250 MWPA. (*iii*) Cholesteric mesophases of the chiral α-ADE's and a type II DM mesophase of the racemic mixture exist between 11.300 and 11.850 MWPA. At 12.000 MWPA an anisotropic and an isotropic phase coexist, providing the temperature is less than 30°C. All these phases are liquid crystalline at 0°C.

Nuclear Magnetic Resonance Measurements

The deuterium nmr of D_2O in the liquid crystals was performed in a Bruker SXP 60 pulse spectrometer, with a high resolution probe at 9.21 MHz as described previously (3). The probe temperature was 27 ± 1°C, and microscopic studies were made at the same ambient temperature. Na-23 nmr spectra were measured at 15.781 MHz. Both nuclei measured can be observed with good signals at less than 20 pulses.

Preparation of the Microscope Slides

The preparation of the microscope slides was achieved by using a Teflon spacer allowing 0.05 mm sample thickness between the slide and coverglass.

Results

Types of Mesophases Formed

Lamellar Phases

At low water contents, 10.600 MWPA, the *l*-, *d*-, and *dl*-alanine hydrochloride decylesters form lamellar phases. The nmr samples of these lamellar phases did not spontaneously align in the magnetic field at room temperature. The sealed nmr sample tubes were heated above the isotropic point ~85°C and then allowed to cool in the magnetic field to the probe temperature. This manner of aligning lamellar phases has been used previously by Tiddy *et al.* (21). For the aligned samples, the D_2O signals were a doublet of splitting 1010 ± 30 Hz for all three α-ADE's if the same concentrations were used and they were assigned as type II behaviour ($\Delta\chi < 0$) (15). These nmr samples were investigated in the polarizing microscope. The three mesophase samples of α-ADE's exhibited approximately the same texture as shown in Plate 1. This texture was assigned by Rosevear (18) as "Coarse mosaic texture" of the neat phase (Fig. 4 in ref. 18).

Coexistent Lamellar and Type II DM Phases

In the range 10.700–11.250 MWPA the three α-ADE's form two coexistent phases. In this region of coexistence both phases became aligned after a

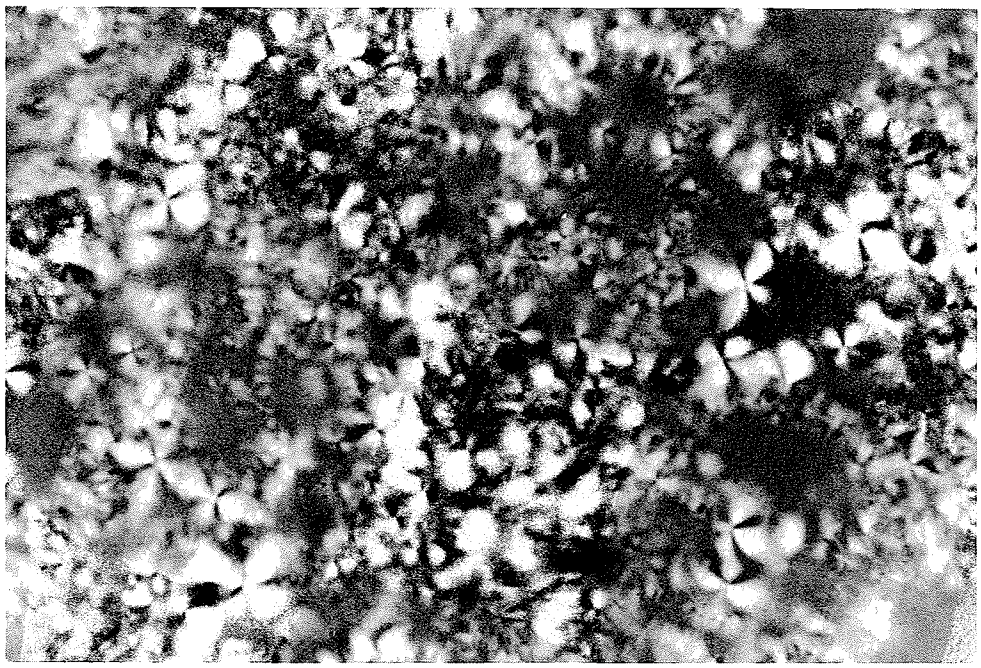

PLATE 1. A coarse mosaic texture of lamellar phases formed by α-alanine hydrochloride decylesters. Crossed polarizers. Magnification 400 ×.

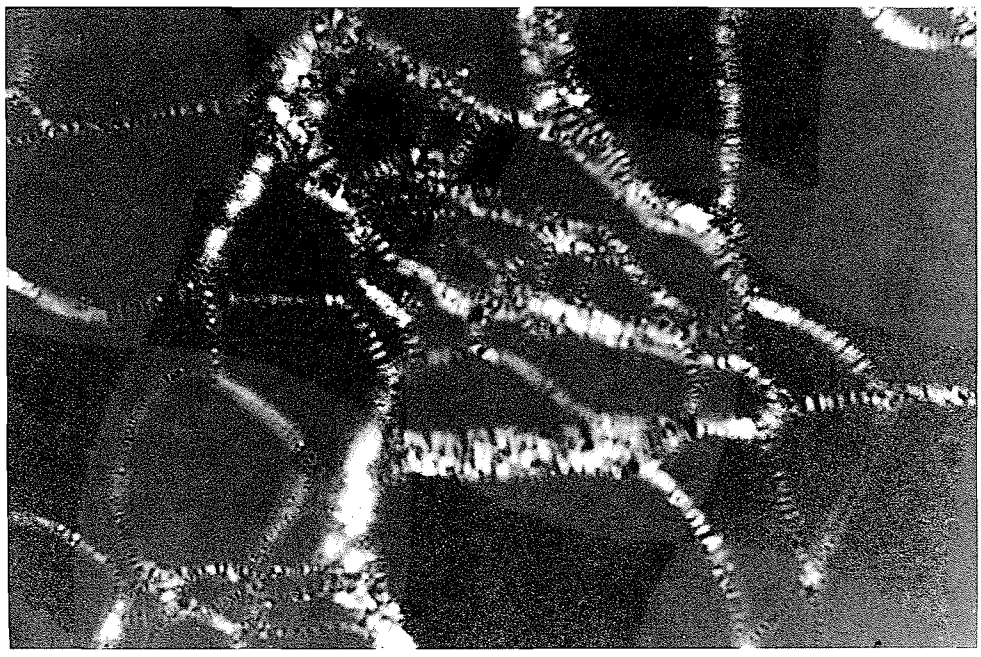

PLATE 2. Two phase region formed by α-alanine hydrochloride decylesters. The texture shown in the photomicrograph pertains to a lamellar phase whereas the black areas contained "threaded" texture as in Plate 3 which appears dark, since, after a few minutes, it aligned perpendicular to microscope slide glass surface.

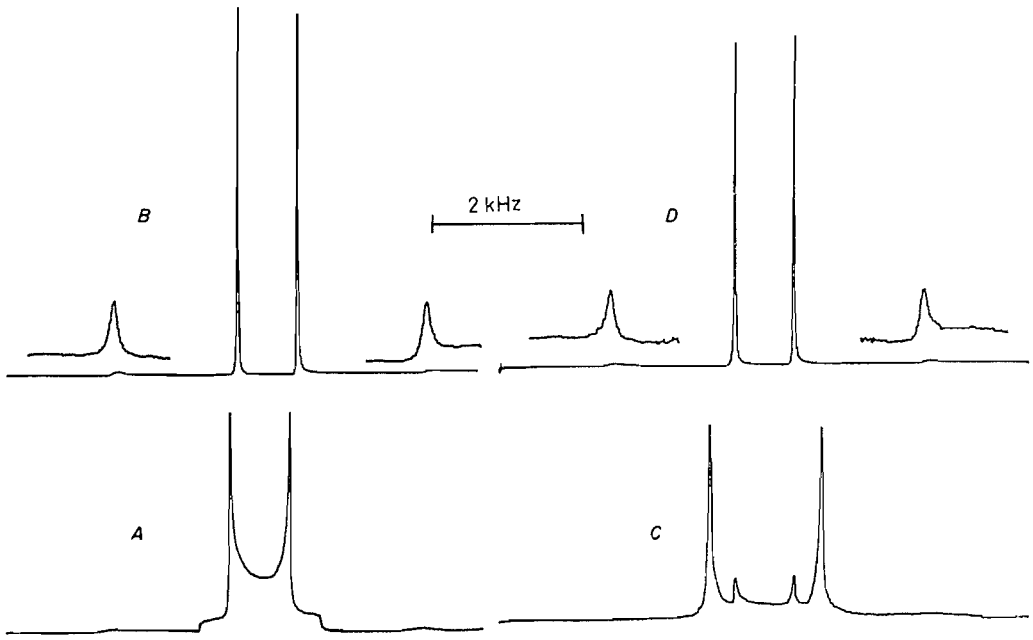

FIG. 1. Deuterium nuclear magnetic resonance spectra of D_2O in α-alaninehydrochloride decylester mesophases. *A*. Compensated mesophase immediately on immersion in the magnetic field. *B*. Spectrum taken a few minutes later after alignment in the field without spinning. *C*. Spectrum after a $\pi/2$ rotation of the nmr sample tube to rotate the perpendicular plane into the field. *D*. During spinning of the sample tube. Amplified peaks above the spectra are assigned to the $-ND_3^+$ group.

few hours at room temperature. The D_2O signals consisted of two doublets of 930 ± 10 Hz for the outer peaks and 770 ± 10 Hz for the inner peaks if 11.120 MWPA were used. Accordingly, the outer doublet can be attributed to a lamellar phase which has the lower density, and the inner doublet to a type II DM phase. Microscopic investigations confirmed the existence of two phases (Plate 2). The texture in Plate 2 shows some resemblance to Figs. 14, 15, and 16 in ref. 18. These textures were assigned by Rosevear (18) as "Additional textures of neat phase". We have assigned the black parts in Plate 2 to the type II DM phase (19). The type II DM phase aligns in a few minutes perpendicular to the microscope glass surface; it is viewed along the optic axis, and thus appears dark through crossed polarizers, i.e. the phase has an isotropic plane perpendicular to this direction.

Type II DM Phase and Cholesteric Phases

Between 11.300 and 11.850 MWPA the racemic mixture of α-ADE forms a type II disc micelle DM mesophase, and the enantiomers form cholesteric phases with opposite helicity. The pitch of the screw axis of these cholesteric phases depends on the water content. A quantitative study of this subject is in progress. In the case of the type II DM phases the mean size of the disc probably becomes smaller at higher water content.

Nuclear Magnetic Resonance Studies of the Mesophases Formed

Mesophases Formed from the Racemic Mixture of α-ADE

The racemic mixture of α-ADE forms lamellar mesophases at lower water contents, which are characterized by the photomicrograph studies, as well as having the property of lower density and higher quadrupole splitting for the deuterium magnetic resonance signal of D_2O in the system than the mesophase, which occurs in coexistence at higher water contents. The mesophase occurring at the higher water contents investigated is characterized by the property of rapid alignment in the magnetic field, higher density, and lower quadrupole splitting for the D_2O. This mesophase is also type II $\Delta\chi < 0$ in diamagnetic properties and is clearly identifiable with the previously assigned type II DM phase (15). Figure 1 shows the deuterium magnetic resonance signals for the intermediate type II DM mesophases with differing alignment procedures. The figure reproduces exactly the behaviour previously observed (15). In Fig. 1*A*, the initial spectrum on placing the sample in the magnetic field is typical for random orientation of the directors in having the powder pattern form for 3 dimensions. After a short time, in the neighborhood of a few minutes, the directors align in a plane perpendicular to the magnetic field and a

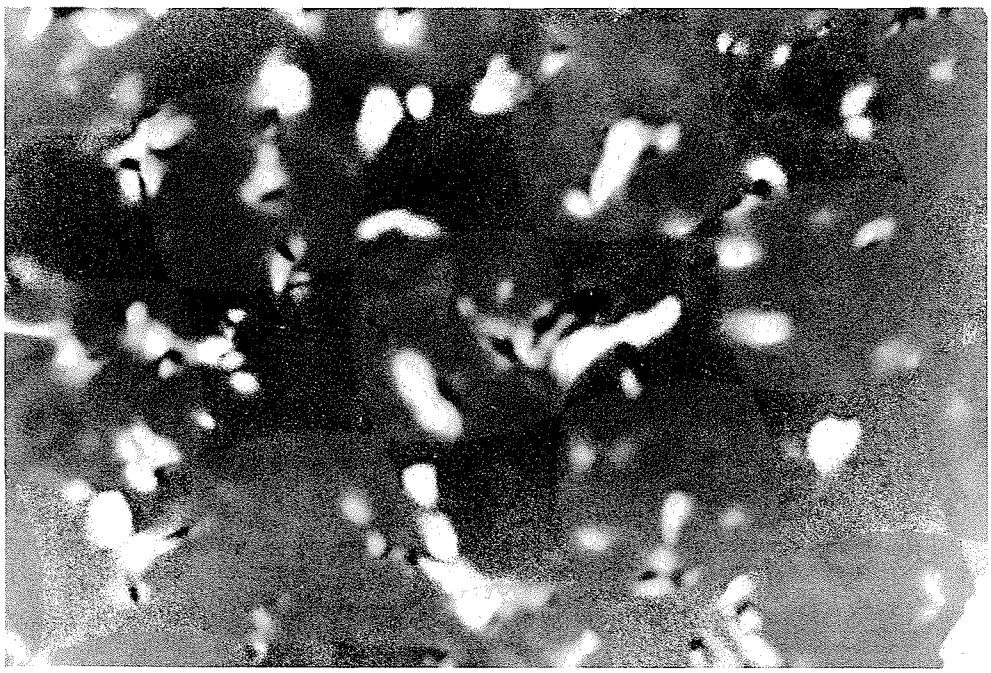

PLATE 3. "Threaded" or "Schlieren" texture of type II (DM) phase formed by *dl*-alanine hydrochloride decylester. This texture disappears in a few minutes. Crossed polarizers. Magnification 100 ×.

sharp doublet is observed, which is equal to the doublet splitting in the powder pattern (2). If the distribution of directors in this perpendicular plane is monitored by rotating the sample tube by 90° (Fig. 1*C*) so that the perpendicular plane is turned into the magnetic field, the spectrum indicates an unsymmetrical distribution of directors in this plane. Such behaviour has been described previously for the type II DM mesophases. If sample spinning is set in motion, the directors rapidly align along the spinning axis of the tube (15) (Fig. 1*D*).

It is interesting to note that separate signals for the more highly ordered $-ND_3^+$ group in the amino-acid residue are clearly resolved, and for Figs. 1*B* and *D* they have been amplified above the recorded spectrum. These amino-acid residues are located at the bilayer interface with the aqueous compartment and are thus more highly ordered than the D_2O. Table 1 includes details of all quadrupole splittings measured.

The results of microscopic investigations of the type II DM phases prepared from the racemic mixture are shown in Plate 3. The texture of type II DM (19) with a negative diamagnetic anisotropy is nematic-like and shows "threaded" or "schlieren" texture (Plate 3) (1, 20). This texture is not stable because of the tendency of the director to align perpendicular to the microscope slide glass surface. This alignment occurs in a few minutes if such microscope samples are placed in the magnetic field

(14.1 kG), with the direction of the aligning magnetic field parallel to the surface of the microscope slide glass. (The optic axis of the type II DM phase aligns perpendicular to the magnetic field direction.)

Mesophases Derived from l-*ADE and* d-*ADE*

The cholesteric mesophases which occur at higher water contents with optically resolved α-ADE's are significantly different in their behaviour in the magnetic field. In Figs. 2*A* and 3*A*, the powder diagram for the *l*-ADE and *d*-ADE mesophases obtained on first immersion in the magnetic field are the same as the compensated type II DM phase. The alignment of the cholesteric liquid crystals is slow compared to the compensated phase, and the final alignment never becomes as homogeneous. In Figs. 2*B* and 3*B* the doublet of the quadrupole splitting for D_2O is on the order of 30 Hz in half width for each peak after 5 h alignment time. For the compensated type II DM mesophase, corresponding

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

For personal use only.

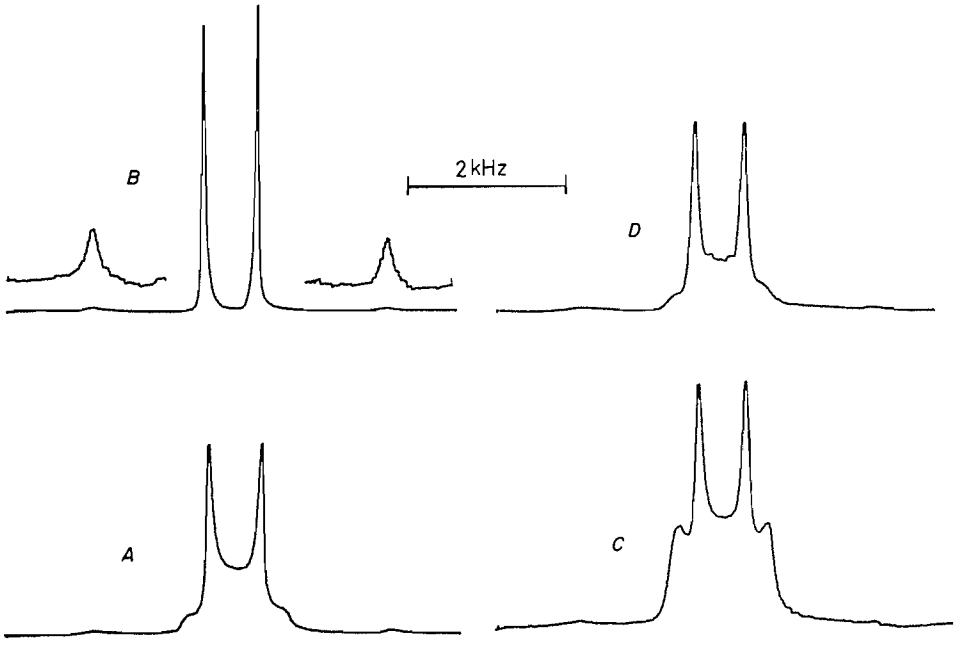

FIG. 2. *A*, *B*, *C*, and *D* are corresponding spectra (as in Fig. 1) for the cholesteric *l*-alanine ester mesophase. Orientation time is on the order of 5 h in these cases.

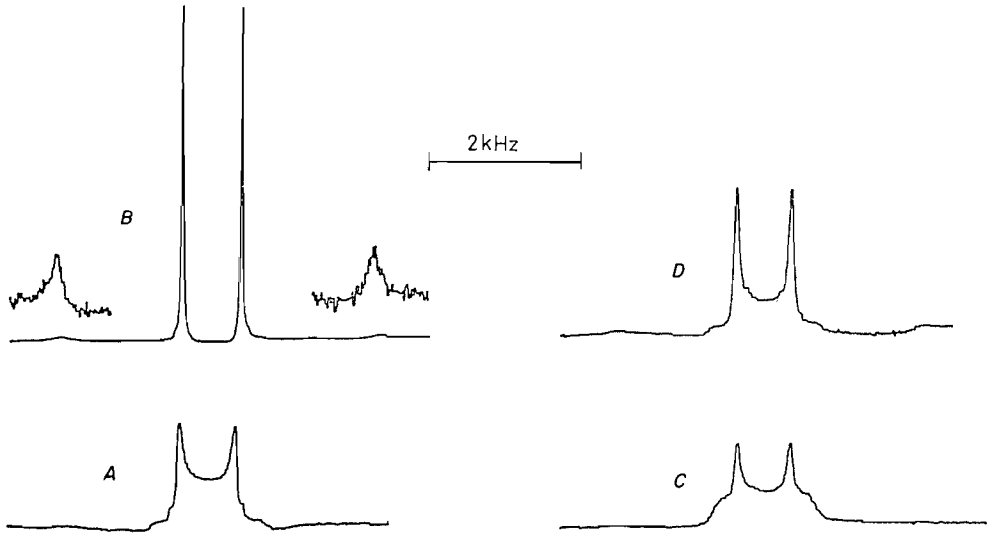

FIG. 3. *A*, *B*, *C*, and *D* corresponding spectra (as in Fig. 1) for the *d*-alanine ester cholesteric mesophase, alignment time 5 h.

peaks are on the order 10 Hz in half width for stationary samples in 8 mm nmr tubes. The experiment which monitors the director distribution in a perpendicular plane to the magnetic field (Figs. 2*C* and 3*C*) gives a quite different result compared to the compensated type II DM mesophase. The director distribution after rotating the nmr tube by $\pi/2$ is much more uniform than the compensated nematic phase and resembles the true 2-dimensional powder pattern spectrum with the plane in the magnetic field (Fig. 4, ref. 15). Figures 2*D* and 3*D* are a clear contrast to the behaviour of the compensated nematic mesophase. On spinning the sample tube there is no alignment along the tube axis of the director, instead the random distribution in the perpendicular plane (yz) to the magnetic field

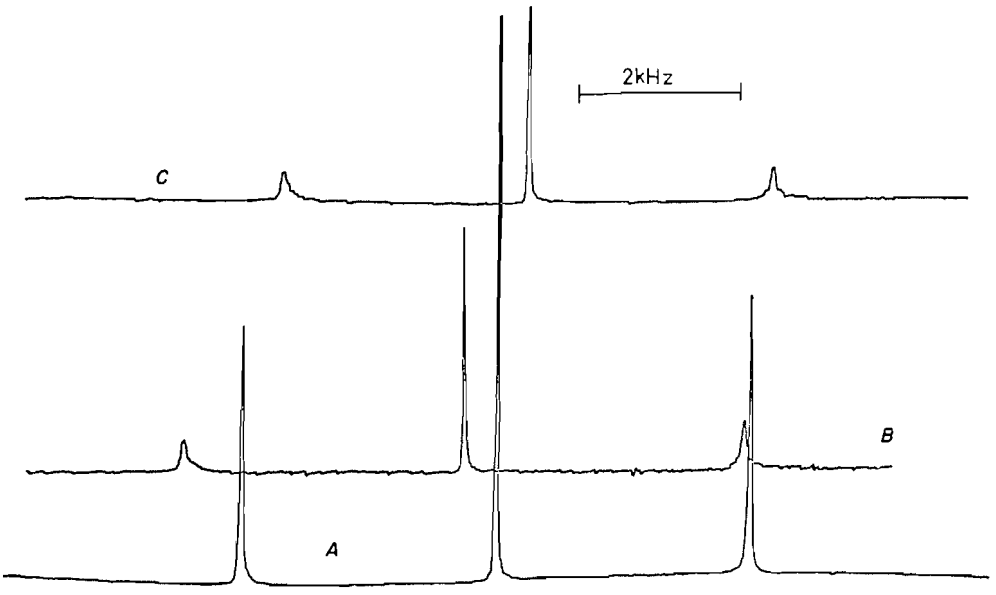

FIG. 4. Sodium nuclear magnetic resonance spectra; *A* for the aligned compensated type II mesophases; *B* the cholesteric *d*-alanine ester mesophase; and *C* the *l*-alanine ester mesophase.

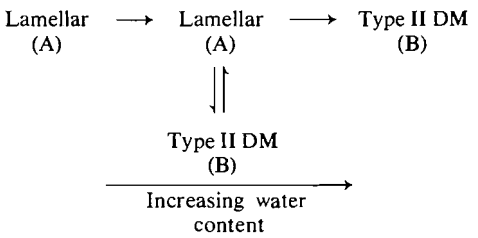
(z direction) is rotated about the y axis to give an effective 3-dimensional random distribution of directors. This reproduces a typical powder spectrum like series *A* of the figures; however, unlike the type II DM mesophases, subsequent alignment under the spinning constraint never occurs. The additional signals in Figs. 2*B* and 3*B* are assigned to the $-ND_3^+$ group of the amino-acid residues in the head groups as before.



The sodium-23 nmr spectra of non-spinning samples for liquid crystals prepared from *dl*-ADE in a compensated mesophase are shown as Fig. 4*A*, the *d*-ADE mesophase as spectrum 4*B*, and the *l*-ADE mesophase as spectrum 4*C*. The samples were allowed to align for 5 h in the case of the cholesteric liquid crystals. The broadening of the satellites in Figs. 4*B* and 4*C* show the distribution of alignment of the directors in the cholesteric mesophase (16). The separation of the quadrupole splittings for sodium are all listed in Table 1.

The results of polarizing microscope studies of *l*- and *d*-alanine hydrochloride decylester mesophases are shown in Plates 4(*a*) and 4(*b*). Plate 4(*a*) shows non-aligned cholesteric bands, after the microscope sample was equilibrated for 2 h. The ordering in the magnetic field produces a regular direction of the screw axis along the magnetic field as in Plate 4(*b*).

Discussion

The mixtures of water, α-ADE's, and sodium sulphate studied in this work evidently embrace a series of mesophases of distinctly different structure. The two investigative tools, polarized microscopy and deuterium nmr, are not sufficient to determine the structure of these liquid crystals, but they are sufficient together to distinguish between different mesophases and identify some previously known phases. The relative density of the mesophases is an important piece of corroborative evidence, because water being more dense than the inner core of hydrophobic chains, the more water-rich of two coexisting phases becomes the lower layer in a two phase system. In view of the evidence presented in the Experimental, we conclude that there is a regular progression in the polymorphism of the mesophase, which differs for resolved *l*- or *d*-α-ADE and racemic α-ADE. This progression can be separately considered, as (I) for racemic α-ADE and (II) for *l*- or *d*-α-ADE as below. The mesophase with the lowest water content is stated first.

(I) Racemic α-ADE

The type II DM mesophase is composed of disc-

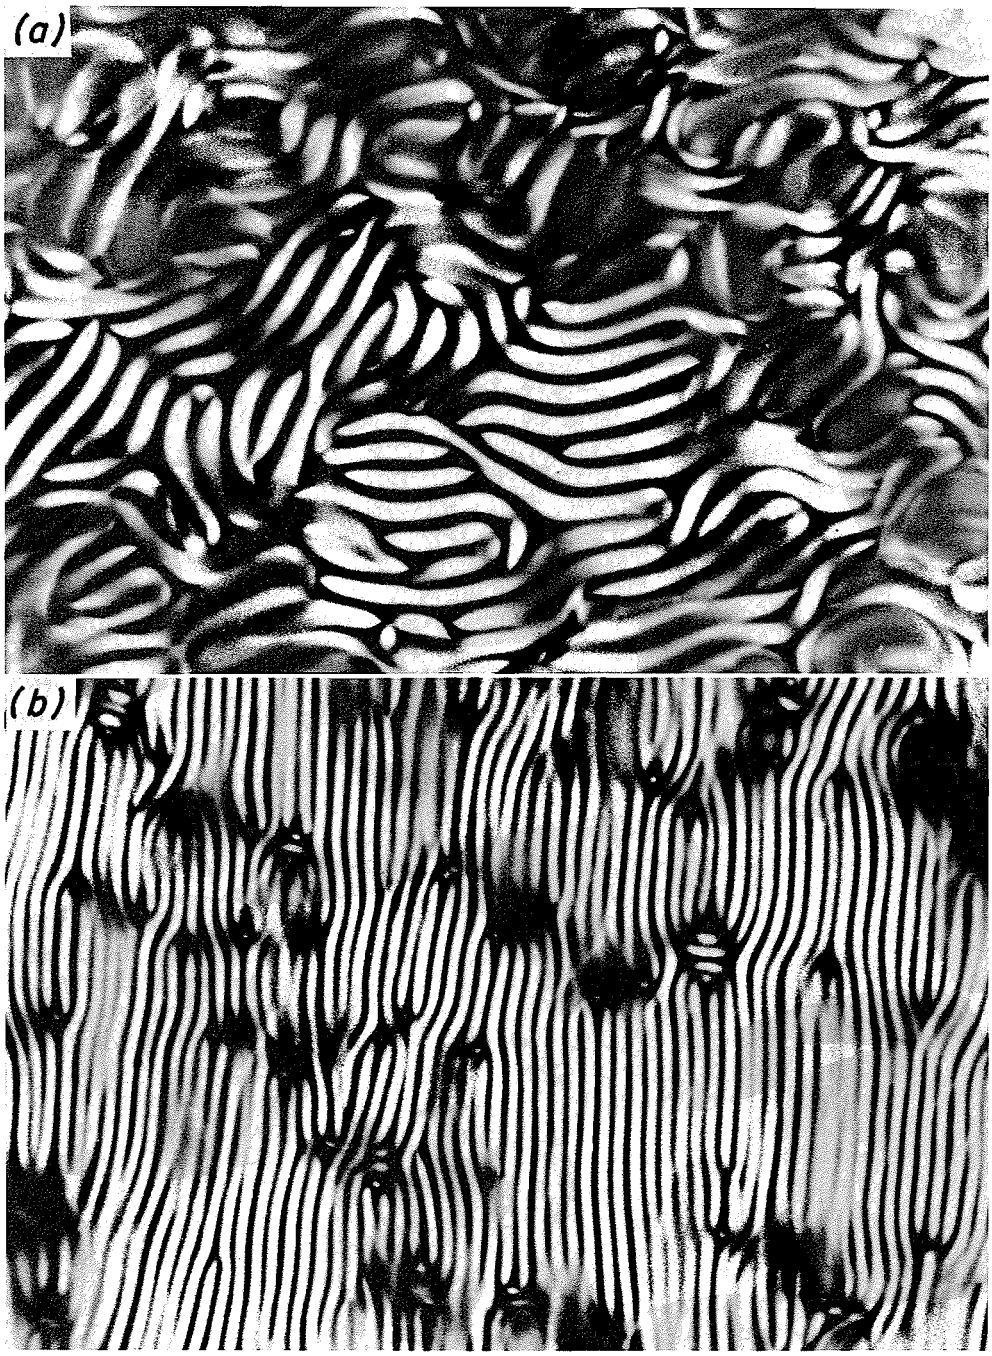

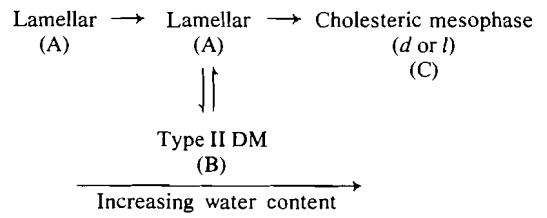

PLATE 4. (*a*) Non-aligned cholesteric texture. The mesophase was equilibrated two hours on the microscope slide. (*b*) Aligned cholesteric texture. The above microscope sample was placed two hours in the 14.1 kG magnetic field. The direction of the magnetic field was parallel to the surface of the microscope slide glass from left to right. Crossed polarizers. Magnification 100 ×.

like bilayer micelles of finite size disposed with long range orientational, but little[4] long range positional order (13, 15).

(II) *l* or *d* α-ADE

The nmr and microscopic evidence does not distinguish between the lamellar (A) phases in I and II nor the type II DM mesophases in I and II, but we assume that these phases have the same structure in both cases. Three different mesophase structures are encountered, the third type is a cholesteric type mesophase. The compensated type II DM mesophase has negative diamagnetic anisotropy (2, 22) and thus the derived cholesteric phase, prepared using the resolved detergent, has a screw or helical axis, which is parallel to the magnetic field direction (17). The directors are arranged in each successive plane perpendicular to the screw axis with regular angular displacement and thus although still close to being perpendicular to the field direction they are fanned out evenly in their projections on this perpendicular plane. The even distribution of the directors in this perpendicular plane has been demonstrated (Figs. 2*C* and 3*C*) by rotating this plane into the magnetic field and observing the two dimensional powder pattern. Plates 4(*a*) and 4(*b*) confirm the twisted structure and the texture illustrates the fact that the screw axis is parallel to the applied magnetic field direction. This cholesteric mesophase, because it is prepared using a single optically active amphiphile and can be prepared with opposite helical forms as well as in the compensated *d*/*l* mixture, represents the *first* report of the aqueous lyotropic analogue of the thermotropic cholesteric liquid crystal. The quantitative study of the effect of water content on unbalanced mixtures of *d* and *l* forms and impurities on the pitch of the screw axis is in progress. The origin of the cholesteric behaviour is an interesting question. A good postulate for the structure can be made by considering the relationship to the type II DM mesophase. In the one case where the structure has been determined by low angle X-ray diffraction (13) the type II DM mesophase has been shown to consist of large disc micelles of bilayer thickness, disposed without long range positional order but retaining orientational order.[4]

It is reasonable to assume that at a critical water content, i.e. at a critical average inter-micelle distance, the inter-micelle forces fall off sufficiently to allow a helical type distortion of the disc-shape to occur because of more efficient packing of the optically active head groups within the micelle units of the structure. The packing of these micelles can lead to a helical structure of the mesophase and thus typical cholesteric properties.

Disc micelles in type II DM phases: short chains in long chain host bilayers

MAHMUT ACIMIS[1] AND LEONARD W. REEVES[2]
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1
Received December 13, 1979

MAHMUT ACIMIS and LEONARD W. REEVES. Can. J. Chem. **58**, 1542 (1980).

Host bilayers of the large disc shaped micelles in type II DM phases have been prepared with two detergents having a 16 carbon chain. Studies of small quantities of 10 carbon guest amphiphiles have been made using deuterium magnetic resonance. The host bilayer solution is only slightly perturbed by changes in simple counter and co-ions. The only major change in host chain order profiles is obtained when its pyridinium head groups are changed for *N*-trimethyl head groups. The guest chain motions near the non-polar chain terminus are considerably more restricted than in bilayers prepared from hosts of shorter chain length conforming closely to the guest chain length. The small changes observed in motion behaviour of the chains as a function of simple counter and co-ions can be a standard to test the effect of specific complexing agents on guest chain motions in the present system.

MAHMUT ACIMIS et LEONARD W. REEVES. Can. J. Chem. **58**, 1542 (1980).

On a préparé des doubles couches pouvant servir de cages aux micelles ayant la forme de disque dans des phases DM de type II en utilisant deux détergents ayant une chaîne à 16 atomes de carbone. On a étudié des petites quantités d'amphiphiles susceptibles d'être encagées à 10 atomes de carbone en utilisant la rmn du ^2H. La solution réceptrice à double couches est légèrement perturbée par les changements dans les ions simples opposés et les ions simples de même signe. On obtient le seul changement important dans l'ordre de la chaîne réceptrice lorsque ses têtes de groupe pyridinium sont remplacées par des têtes de groupe *N*-triméthyle. Les mouvements de la chaîne encagée près du bout de chaîne non polaire sont considérablement plus restreints que dans les doubles couches préparées à partir des récepteurs à chaîne plus courte se rapprochant de très près de la longueur de chaîne encagée. Les petits changements observés dans le comportement des chaînes en fonction des ions simples opposés et des ions simples de mêmes signes peuvent servir de référence pour vérifier l'effet des agents complexants spécifiques sur les mouvements de la chaîne encagée dans le présent système.

Introduction

Intermediate phases in aqueous lyotropic systems (1, 2) are formed when a hexagonal or lamellar structure is diluted with water and a quantity of electrolyte is added (3, 4). These phases align spontaneously in an applied magnetic field and for type II DM ($\Delta\chi < 0$) systems the constituent disc-micelles align with the normal to their interfaces perpendicular to the applied field (5, 6). The structure of one type II DM mesophase has been determined by low-angle X-ray diffraction methods (7). The micelles are of bilayer thickness and the dimension of their planar extent in the case studied (7) is in excess of 1000 Å.

The present study is designed to investigate the following aspects of the bilayer of the constituent micelles in the Type II DM phase. (*a*) The degree of order profiles of guest amphiphiles of short length (10 segments) in a disc bilayer micelle of longer chain amphiphiles (16 segments). (*b*) The variation of chemistry of the polar or ionic head group in the guests to include cationic, anionic, and neutral groups. (*c*) The study of two 16 carbon chain host systems with *N*-trimethyl and pyridinium head groups. (*d*) The variation of the chemical identity of simple counter and co-ions. We have recently completed a rather thorough study of the reverse case where the host bilayer is prepared from amphiphiles of short chain length compared to the guests (6).

Experimental

Materials

1-Hexadecylpyridinium chloride and 1-hexadecyltrimethylammonium bromide were purchased from J. T. Baker Co., and purified by recrystallization, hexadecylpyridinium chloride from cyclohexane–ethanol and hexadecyltrimethylammonium bromide from ethyl acetate.

1-Hexadecyltrimethylammonium chloride and 1-hexadecyltrimethylammonium nitrate were synthesized by converting 1-hexadecyltrimethylammonium bromide to 1-hexadecyltrimethylammonium hydroxide by treatments with silver oxide (Ag_2O) in methanol (8). After filtering the precipitated AgBr, the 1-hexadecyltrimethylammonium hydroxide was neutralized by appropriate acids.

All perdeuteriated compounds were made from potassium salts of fatty acids according to a variation of the procedure of Dinh-Nguyen *et al.* (9) in a steel bomb. Perdeuteriated 1-decanol, sodium 1-decylsulfate, 1-decylammonium chloride, 1-hexadecylpyridinium chloride, 1-hexadecyltrimethylammonium chloride, 1-hexadecyltrimethylammonium bromide, and 1-hexadecyltrimethylammonium nitrate were made from the appropriate perdeuteriated potassium salts of the fatty acids. The deuteriated fatty acid salts were converted to fatty acids and these were reacted to give acid chlorides by means of thionyl chloride ($SOCl_2$). The acid chlorides were then reduced with lithium aluminum deuteride ($LiAlD_4$) to the appropriate perdeuteriated alcohols (10).

[a]Composition of studied systems are given in weight percent and moles. Abbreviations of the components are listed in Experimental.

Perdeuteriated Sodium 1-Decylsulfate

Perdeuteriated 1-decanol was converted to sodium 1-decylsulfate using chlorosulfuric acid and subsequent neutralization with NaOH.

Perdeuteriated 1-Decylammonium Chloride

Perdeuteriated 1-decanol was converted to decylamine as previously described (11). The prepared amine was then neutralized by hydrochloric acid.

Perdeuteriated Hexadecyl Compounds

Perdeuteriated 1-hexadecyltrimethylammonium chloride, bromide, and nitrate were synthesized from 1-perdeuteriated hexadecyliodide with aqueous trimethylamine (25–30%). Perdeuteriated hexadecyliodide was made from perdeuteriated hexadecylalcohol (12). The prepared perdeuteriated 1-hexadecyltrimethylammonium iodide was converted to perdeuteriated 1-hexadecyltrimethylammonium hydroxide by means of silver oxide (Ag_2O) as described above. The perdeuteriated 1-hexadecyltrimethyl hydroxide was then neutralized by appropriate acids. Perdeuteriated 1-hexadecylpyridinium chloride was synthesized from perdeuteriated 1-hexadecyl iodide and pyridine. 1-Hexadecylpyridinium iodide was converted to the chloride by means of silver oxide and subsequent neutralization with hydrochloric acid. The purity of the compounds was checked by thin layer chromatography and sometimes by proton nmr as well.

Composition of the Mesophases

All samples were prepared by weighing the required amounts of the components into test tubes. In order to keep the contents of the mesophases constant, the tubes were sealed, and the samples homogenized by warming on a water bath and centrifuging. The homogenized samples were opened and poured into 10 mm nmr tubes. The compositions are given in moles (host detergent normalized to one mole) and weight percent (Table 1). The given moles and percentage of sodium 1-decylsulfate and 1-decylammonium chloride originate from deuteriated molecules, assuming a 90% deuteriation. The water used contained 0.1% D_2O. In order to avoid long repetitions, some abbreviations of the compounds are introduced.

1-Hexadecyltrimethylammonium chloride, HDTACl
1-Hexadecyltrimethylammonium bromide, HDTABr
1-Hexadecyltrimethylammonium nitrate, $HDTANO_3$
1-Hexadecylpyridinium chloride, HDPCl
} Hosts

Sodium-1-decylsuphate, NaDS
1-Decanol, Dec.
1-Decylammonium chloride, DaCl
} Guests

All nmr spectra were determined at 9.1 MHz on a Bruker SXP pulse nmr spectrometer using an external proton water lock. The ambient temperature was 32 ± 1°C. Spectral widths on the order of 20–30 kHz were used, and approximately 5 000 to 60 000 transients were required.

Results

Systems Studied

In this study the host mesophase is based on the hexadecylhydrocarbon chain while the guests are 1-decylsulphate, 1-decylammonium, and 1-decanol, these being respectively negative, positive, and no net charge on the head group. The

host head group has been varied between trimethylammonium and pyridinium, the first with chloride, bromide, and nitrate counter ions and the second with only chloride counter ions. In this systematic manner, the chemical changes at the interface can be studied for both changes in the order of the water and the totally deuteriated hydrocarbon chains of the guests and hosts.

The study for comparison of three guests in type II DM bilayers was made in two steps. Mesophases labelled "A" contain both the NaDS guest and small amounts of 1-decanol. However, since replacement of the same mol% of 1-decylsulphate in the mesophase by 1-decylammonium ion provoked a phase change, a set of mesophases labelled "B" contain the 1-decylammonium ion with slightly different mole percentages of 1-decanol, in order to preserve the type II nematic mesophase. The effects on the hosts were monitored by including some perdeuteriated host detergent in each mesophase. The deuterium quadrupole splittings measured for the 0.1% D_2O in H_2O were always very low in the range 20–50 Hz. This is entirely consistent with the recent studies from this laboratory on mixed bilayers with carboxylate and pyridinium or trimethylammonium head groups (8). It is evident that the strong hydration of carboxylate groups at the interface imposes a strong ordering effect on the interface water, but the more shielded positive charges and lack of donor or acceptor sites for hydrogen bonding for the $-N(CH_3)_3^+$ and pyridinium head groups leads to transfer of little ordering effect to the water at the interface (8). The host mesophases here all fall into the latter class.

Deuterium Magnetic Resonance Studies

The use of the residual deuterium quadrupole splittings to measure degrees of order along C—D bonds in the hydrocarbon chains of liquid crystals has already been adequately described in the literature (14–17). The measurements reported here consist of determining and assigning the quadrupole splittings of specifically deuteriated chains, both for hosts and guests. This quadrupole splitting is proportional to the degree of order along the C—D bonds. Since the proportionality is always the same, we use the quadrupole splitting directly as a measure of the degrees of order.

Mesophases A

The deuterium quadrupole splittings for mesophases A may be obtained from the supplementary data[3] and are plotted in Figs. 1 to 4 against the carbon number of the respective $-CD_2-$ group in the hydrocarbon chains. An undesirable transition to an isotropic phase predicated some small variations from the A mesophases in the mole fraction of components which make up the B mesophases (Table 1). These small differences are not important as we shall show in the discussion.

Mesophases A with the host HDTA were prepared with different counter ions, Cl^-, Br^-, and NO_3^-. The plateau of uniform order extends to the carbon 9 segment, followed by a rapidly decreasing quadrupole splitting for segments 10 to 16. The chloride counter ion does affect the order of the segment of carbon 1 in this mesophase, the degree of order being displaced above the plateau. For mesophases containing HDPCl the uniform degree of order extends to the 10th carbon (Fig. 4).

Some general observations are possible with respect to the relative degrees of order of hosts and guests in the same bilayer solution of mesophases A. The 1-decylsulphate has a short plateau of uniform order of 4 carbon segments, which lies above the corresponding host segments in all mesophases while the same region for 1-decanol segments always lies well below that of the host. There are differences in the magnitude of this relative ordering which depend primarily on the identity of the counter ion. Changes in the absolute values of de-

grees of order, that affect all components of the bilayer solution of the extended micelle, can be associated with the overall changes in motion of the micelle as a body (6). On the other hand, relative changes in the motion of host and guest in different mesophases must derive from changes in the bilayer solution of amphiphiles which make up the

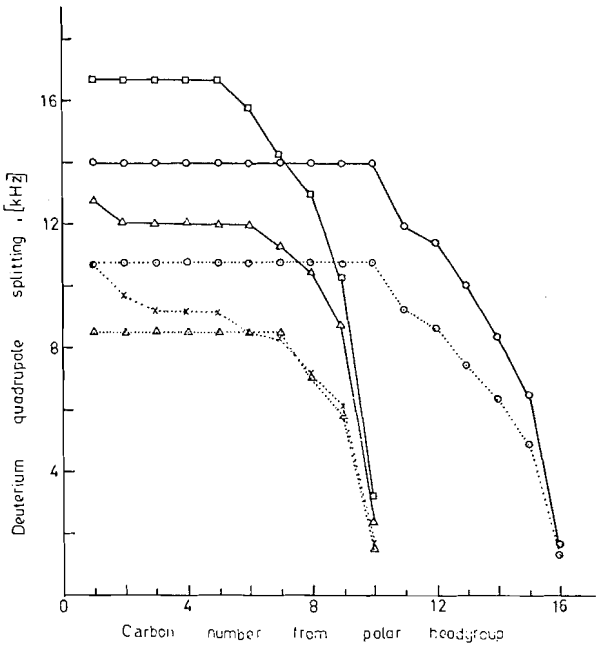

FIG. 4. Host is 1-hexadecylpyridinium chloride, HDPCl-d_{33}, otherwise as in Fig. 1.

micelle. The magnitudes of plateau degrees of order for HDTA ion segments decrease slightly for the three mesophases A with the effect for $Cl^- > Br^- > NO_3^-$ counter ions (Figs. 1–3). They correspond to 16.8 kHz, 15.8 kHz, and 14.5 kHz, respectively, in terms of quadrupole splittings.

Mesophases B

These liquid crystals contain the neutral guest amphiphiles, 1-decanol, and the cation, 1-decylammonium.

With a cationic guest amphiphile for series B the plateau of order in the host HDTA is always lower than in series A with an anionic guest, but the difference depends on the choice of the small counter and co-ion. The difference is large with Cl^- and smaller with Br^- and NO_3^-. This change in absolute order can be accounted for by assuming that mean micelle diameter is in general smaller with the cationic guest allowing larger amplitude motions of the micelle as a body. The same decrease in plateau order of the host on changing the nature of the guest is seen in Fig. 4 where results on HDPCl are summarized. The 1-decylammonium ion segments do not in general have a well developed plateau of uniform order, but they always appear of lower order than the host.

Discussion

General Consideration of Degrees of Order

The degree of order along a C—D bond may be

written as a product of the different angular contributions about different axes (11, 13). For the type II mesophases studied here, the disc-shaped micelles of bilayer thickness have a symmetry axis normal to the disc, which oscillates about the director, i.e., optic axis of the uniaxial liquid crystal. The optic axis in the aligned type II mesophases is disposed in a perpendicular direction to the applied magnetic field. The experimental degree of order for —CD_2— segment i in mesophase α is therefore written:

$$[1] \quad S^{\alpha}_{\text{expt}(i)} = S^{\alpha}_{\text{mo}(i)} \cdot S^{\alpha}_{\text{co}(i)} \cdot S^{\alpha}_{k/j(i)} \cdot S^{\alpha}_{\text{dif}(i)} \cdot 1/2(3\cos^2\Omega - 1)$$

where $S^{\alpha}_{\text{expt}(i)}$ = experimentally measured degree of order in mesophase α. $S^{\alpha}_{\text{mo}(i)}$ = contribution to the measured degree of order from oscillation of the normal to the disc micelle, about the director or optic axis of the mesophase. $S^{\alpha}_{\text{co}(i)}$ = contribution of the oscillation of the pseudo-rigid hydrocarbon chain as a unit about the normal to the micelle interface. The separation of internal motions of the chain from the motions of the pseudo-rigid chain is a reasonable and common assumption. $S^{\alpha}_{\text{dif}(i)}$ = contribution from diffusive motions of the pseudo-rigid chain in the micelle bilayer. Normally in the present situation only diffusive motion around the edge of the finite bilayer disc can make a contribution. This term therefore does vary with the size of the disc micelle as does $S^{\alpha}_{\text{mo}(i)}$, but if we assume the disc micelle is very large compared to its thickness (7), the diffusion term becomes very small and $S^{\alpha}_{\text{dif}(i)} \simeq 1$. $S^{\alpha}_{k/j(i)}$ = contributions derived from internal motions of the chain. $\Omega = 90°$, the angle between the mesophase director and the magnetic field. Thus [1] may be shortened to:

$$[2] \quad S^{\alpha}_{\text{expt}(i)} = -1/2\, S^{\alpha}_{\text{mo}(i)} \cdot S^{\alpha}_{\text{co}(i)} \cdot S^{\alpha}_{k/j(i)}$$

For the same mesophase α, it is clear that since $S^{\alpha}_{\text{mo}(i)}$ and $S^{\alpha}_{\text{co}(i)}$ are rigid chain motions, they are the same for all segments with the same chain and therefore:

$$[3] \quad S^{\alpha}_{\text{expt}(i)}/S^{\alpha}_{\text{expt}(j)} = S^{\alpha}_{k/j(i)}/S^{\alpha}_{k/j(j)}$$

The relative contributions to the internal motions at segments i and j in the same chain are directly comparable in the ratio profile by eq. [3]. These ratio profiles are known to be independent of water content of mesophases within the variations possible for type II aligning mesophases (6, 11). This reasonable experimental result is explicable in terms of changes in micelle size and water thickness but not of internal packing of amphiphiles in disc micelles, within the limits that these are large enough to make negligible the small proportion of amphiphiles at the disc edges (6). Table 2 lists the quadrupole splitting ratios as in eq. [3] where segment i is arbitrary and segment j is the terminal methyl segment.

If there is no change in the averaged segmental motion of a given amphiphile in two different mesophases, we should obtain an experimental result according to [4], where α and β denote mesophase change for the same amphiphile:

$$[4] \quad S^{\alpha}_{k/j(i)}/S^{\alpha}_{k/j(j)} = S^{\beta}_{k/j(i)}/S^{\beta}_{k/j(j)}$$

The only differences in the composition of mesophases listed in Table 1 are associated with the counter ions and the nature of a minor guest. It is instructive to examine the quadrupole splitting ratios in [4] as the mesophases are altered. The differences in ratios [4] from phase to phase for the hexadecyltrimethylammonium segments are small, e.g., the ratios of the plateau order to the terminal methyl degree of order are 10.59, 9.85, 9.90, 10.74, 10.31, and 10.13 (Table 2). This is a much smaller range than the parent quadrupole splittings, which vary widely for a given segment in different mesophases. The variation in the ratios of the host segments from mesophase to mesophase does indicate some very minor changes in the kink/jog motions and thus of packing of the host amphiphile in the bilayer. Both the change of counter and co-ion and the small quantity of guest appear to be factors in these small changes of the bilayer solvent.

The ratios of quadrupole splittings for the hexadecylpyridinium ion are quite distinct from the hexadecyltrimethylammonium[3] confirming that the chemical effect of prime importance is the change of identity of the polar head group. On the other hand for mesophase A and B in this system, the ratios as defined in eq. [4] are the same within experimental error.[3] The change of the minor amount of guest between 1-decylsulphate and 1-decylammonium, with conservation of the chloride counter ion, has absolutely no effect on the chain motions of this host.

These interesting quantitative results on the degree of order profile of the host amphiphile chain segments assure us that the bilayer solvent chain motions are almost unchanged, although the micelle size may change from mesophase to mesophase. With this fact in mind we can pass on to discuss the dilute solutes in this host bilayer.

Concentrating now on the changes, if any, in the motion of the 1-decanol guest or solute chain as the mesophase is altered with respect to counter ion and other guest, we see from Table 2 that within the mesophases containing HDTA ions the variations in ratios are small. These small variations in ratios

[a]The components of each system are arranged vertically so that the hosts and guests in all mesophases can be directly compared by moving from left to right. The ratios were calculated according to eq. [3] using the measured quadrupole splittings. The ratios are normalized to the quadrupole splitting of the terminal methyl group, which splitting includes the effect of methyl group rotations. The carbon number in the chains is placed in parentheses after each ratio, e.g. 9.90 (1–9) means ratio constant for carbon segments 1–9 at a value 9.90.

cannot be associated specifically with counter ion change or the nature of other guest. A large change in the 1-decanol ratios occurs, when this amphiphile is transferred to a bilayer whose solvent detergent is HDPCl. The kink/jog motion of 1-decanol is thus altered a great deal in this process, showing us that the internal packing of the micelle unit changes near this decanol guest. The primary cause is evidently the specific effect of change in the host amphiphile.

The 1-decylsulphate ion is somewhat sensitive to the change in counter ion to a minor degree in mesophases A, but the ratios for a given segment do not vary more than 10% in changing the counter ion. The guest 1-decylammonium ion behaves in a similar fashion.

Comparison with Prior Studies of Counter Ion Effects

A simple substitution in the sodium counter ion of a type I (cylindrical micelle) mesophase by 5% cesium ion with the composition otherwise unchanged is sufficient to change the liquid crystal to a type II (disc-micelle) mesophase (3). It is reasonable to investigate therefore any influence of the counter ion on the bilayer solutions of constituent micelles. Fujiwara and Reeves (11) have shown that the quadrupole coupling ratios are somewhat affected by the change Cl^-, BF_4^-, and F^- as counter ions in mesophases based on the decylammonium ion (See Table 1, ref. 11). These 1-decylammonium phases are now known to be type II disc-micelles (DM) with orientational but no positional order (6). A study of the methyl-substituted ammonium counter and co-ions and their effect on quadrupole splitting ratios for the 1-decylsulphate chain in a type II DM mesophase showed that, in this case, the balance between methyl groups, which are non polar, and hydrogen bonding N—H bonds does affect the ratios in a systematic manner (14).

The present study is the first which attempts to investigate the whole motion profiles of guests and hosts in a disc-micelle nematic phase as a function of counter ion. Very minor changes in the motions of the bilayer solution have been found as a result of those counter and co-ion changes for simple hydrophilic negative ions. This rather remarkable result provides us with a standard so that real chemical interface interactions, such as complexing of a metal ion, can be safely embarked upon in this system. A polar or ionic head group of a guest solute in the bilayer can be changed in the formation of a complex without affecting the host amphiphiles simply from a careful choice of the chemistry. Such studies are now in progress.

The Aspects of Mis-fit Guest Chains

The host bilayers correspond to 16 carbon chain lengths while the guests have 10 hydrocarbon segments. There is a considerable increase in motional freedom (fall off in degrees of order) of the short guest chains within the region carbons 1–9 of the host of high uniform order (Figs. 1–4). Superficially at least, the guest chains appear to have a motion profile similar to one for a 10-segment half-bilayer (11, 14).

The region of carbon segments 6–10 for the guests exemplifies motions which therefore are to a first approximation not determined by the host bilayer. Similar results have been reported recently by Charvolin and Mely (15) for bilayers of fatty acids in non-aligned lamellar mesophases.

Comparison with 10-segment half-bilayers is possible using our previously published data (11, 14). The ratio of deuterium quadrupole splittings in aligned mesophases of 1-decylammonium chloride (11) for plateau to penultimate $—CD_2—$ segment is about 1.9, while decylammonium guests in the present studies have a corresponding ratio of the order of 1.51 for all host bilayers (Figs. 1–4). This is a significant change and corresponds to a less flexible chain (closer to a rigid all *trans* chain) in the present cases. The fall in degrees of order towards the bilayer centre is known to be determined by an increasing probability of single *gauche* rotations (16, 17). For 1-decylsulphate chains in aligned mesophases of this amphiphile, the ratio of plateau to penultimate $—CD_2$-quadrupole splittings is also $\sim$1.90 but the 1-decylsulphate guests in the present systems studies have ratios 1.80 in Fig. 1; 1.67 in Fig. 2; 1.70 in Fig. 3; and 1.62 in Fig. 4. The higher probability of all *trans* segments for a short misfit chain near its non-polar terminus is clearly demonstrated. 1-Decanol is a major component of the type II mesophase based on 1-decylsulphate; and it shows in this 10-segment half-bilayer the ratio 1.8 (14). The 1-decanol guests in mesophases A and B of the present series show the same ratio between 1.57 and 1.64 depending on the particular system. There is, in all cases of the misfit short chains studied here, a higher probability of extended all *trans*-arrangements or lower probability of single *gauche* rotations in host bilayers of 16 carbon segments in length.

Received January 10, 1980

F. Y. FUJIWARA and L. W. REEVES. Can. J. Chem. **58**, 1550 (1980).

Type II DM mesophases with disc-shaped micelles have been synthesized from decylammonium chloride and sodium decylsulphate – decanol amphiphiles with added water and electrolyte. Small amounts of guest amphiphiles have been added in the form of lauric acid or laurate ion. Specific and perdeuterated amphiphiles have been prepared and included in small quantities in the mesophases. The deuterium magnetic resonance spectra of the magnetically aligned phases has been studied and quadrupole splitting doublets assigned to all segments of both host and guest hydrocarbon chains. The mesophases have been diluted with water over the stable range of type II DM behaviour at 34 ± 0.2°C.

The quadrupole splittings of all hydrocarbon chain segments, which reflect the degrees of order along C—D bonds in these segments, are accurately reproduced at all water contents by a knowledge of one quadrupole splitting in the chain and a simple proportionality constant which is derived for each segment of the chain. This further extends the previous results for host chains to those of guest chains studied here. The absolute degrees of order of chain segments are greatly influenced by water content because motion of the constituent disc micelles depends on the volume of interstitial water and they also vary in size as water is added. The packing in the bilayer solution of the disc micelles of the amphiphiles is therefore not a function of the interstitial water content in so far as the detailed *trans/gauche* motions of the hydrocarbon chains are not affected by changes in water content.

The lauric acid-d_{23} chain in the decylammonium chloride bilayer has the same degree of order along the D—D axis and the C—D bond, confirming that the motion of the pseudo rigid chain in the bilayer is cylindrically symmetric. The degree of order profiles of hosts and guests are all quite distinct indicating that chemical identity of the head group and its anchoring in the interface is the main determinant of the motion profiles.

F. Y. FUJIWARA et L. W. REEVES. Can. J. Chem. **58**, 1550 (1980).

On a synthétisé des mésophases DM de type II ayant des micelles en forme de disques à partir des composés amphiphiles: chlorure de décylammonium et décylsulfate de sodium – décanol en présence d'eau et d'un électrolyte. On a ajouté des petites quantités d'amphiphiles susceptibles d'être encagées sous forme d'acide laurique ou d'ions laurate. On a préparé des composés amphiphiles spécifiques et perdeutérés et on les a introduit en petites quantités dans les mésophases. On a étudié les spectres de rmn du ^{2}H des phases magnétiques alignées et on a identifié le dédoublement quadrupolaire des doublets de toutes les portions des chaînes hydrocarbonées des récepteurs et des molécules encagées. On a dilué les mésophases avec de l'eau dans le domaine de comportement stable du DM de type II à 34 ± 0.2°C.

On a reproduit avec précision les dédoublements quadrupolaires de toutes les portions de chaîne hydrocarbonées qui réflètent le degré de l'ordre le long des liaisons C—D de ces fragments pour toutes les teneurs en eau à partir de la connaissance d'un dédoublement quadrupolaire dans la chaîne et d'une constante simple de proportionnalité qui est déduite pour chaque segment des chaînes. Ceci permet d'étendre les résultats antérieurs pour les chaînes réceptrices aux chaînes encagées étudiées ici. Les dégrés absolus de l'ordre des segments de chaînes sont grandement influencés par la teneur en eau parce que le mouvement des micelles constituantes en forme de disque dépend du volume d'eau interstitielle et leur taille varie lorsqu'on ajoute de l'eau. Le tassement dans la solution à double couche des micelles en forme de disques des amphiphiles n'est toutefois par une fonction de la teneur en eau interstitielle dans la mesure où les mouvements détaillés *trans/gauche* des chaînes hydrocarbonées ne sont pas affectées par les variations de la teneur en eau.

La chaîne d'acide laurique d_{23} dans la double couche de chlorure de décylammonium a le même degré d'ordre le long de l'axe D—D et de la liaison C—D confirmant ainsi que le mouvement de la chaîne pseudo rigide dans la double couche est cylindriquement symétrique. Les profils du degré d'ordre des molécules réceptrices et des molécules encagées sont tout à fait distincts, indiquant par là que l'identité chimique du groupe de tête et de son point d'attache à l'interface détermine principalement le profil du mouvement.

Introduction

Lyotropic mesophases, obtained by diluting the hexagonal or lamellar phases with water and adding small amounts of electrolyte, are nematic in character (1). The type II DM liquid crystal is derived from the lamellar phase and has finite bilayer disc-like micelles disposed with orientational long range order, but little positional order of their centres of gravity (2). The present study is confined to this type of mesophase. Recently a variety of investigations, using deuterium magnetic resonance, have sought to probe several aspects of the hydrocarbon chain segment order profiles in the micelles as a function of chemical change (3, 4). The first major study of degrees of order profiles in

Type II DM lyotropic systems[3] (5) utilized specific deuteriation techniques to assign the —CD_2— resonances to specific segments in decanol and decyl sulphate ions. The principal conclusion of this first detailed study was that degrees of order profiles are a function primarily of the polar or ionic head group identity.

Carboxylic acids and carboxylates labelled at the α position and of chain length 2–16 were then studied as guests in the nematic type II sodium decyl sulphate – decanol–water–Na_2SO_4 system (6). Apart from some water dispersion of shorter chain carboxylates, the degree of order of the —αCD_2— position increased linearly with the carbon chain length (6) but no further increase in degree of order of the —αCD_2— accompanied chain lengths beyond the half-bilayer distance. A nematic type II DM mesophase composed of hexadecylpyridinium and hexadecyltrimethylammonium ions can be prepared in all proportions of the two amphiphiles and deuteriated decanol can be added in small amounts (7). The segmental order profiles of both host amphiphiles are remarkably insensitive to the mole fraction of each amphiphile in the micelle. Decanol, however, in the 16-carbon host bilayer, is noticeably affected near the non-polar terminus, where single *gauche* rotations are less probable than in host bilayers of shorter chain length (7) Studies of complete order profiles of guest and host have been completed for cases where the guest chain exceeds the host chain in length (4). Several types of behaviour have been noted depending on the chemistry of the interface (4). Phospholipid chains included in 16-carbon chain host bilayers differ only to a small extent in order profile from the homogeneous lipid bilayers prepared as membrane models (8, 9, 10). For butyric acid and butyrate ion guests the assignment of quadrupole splittings for the three segments has been made (11). In the form of butyric acid the all-*trans* form predominates to 63% (11). The systematic study of short chain length guests in longer chain host bilayers further confirmed that in all cases investigated the probability of single *gauche* rotations near the non-polar terminus of the guest chain are less probable than in host bilayers composed of amphiphiles with shorter chain lengths (12).

The purpose of the present study is (*a*) to further verify and statistically test the simple proportionality between degrees of order for different —CD_2— segments in the guest chains as water content is varied (1); (*b*) to obtain a measure of the degree of order along the D—D axis of a —CD_2— group and compare it to the value obtained from deuterium quadrupole splitting along the C—D bond; (*c*) to study, qualitatively at least, the degree of order profile of an acid amphiphile and its conjugate base in both cationic and anionic host bilayers, i.e., to probe the anchoring as a function of changes in interface chemistry.

[3]Notation Type II DM assigned in ref. 1 at a later date.

Experimental

The chemical syntheses of the specifically and massively deuteriated amphiphiles used in this study have been described clearly in other papers (1, 13) in which references are located to original methods and those adopted by us. A complete set of references is appended to a recent overview article (3).

The nuclear magnetic resonance (nmr) methods are standard. Deuterium nmr was observed using a Varian XL-100 spectrometer with Gyrocode option. Very good signal to noise was obtained from the low concentrations of deuteriated hydrocarbon chains with about 20–50 000 transients. Spectrometer settings were always optimized for each case by considerable previous experience.

In order to relieve the congestion of signals, which occurs when both host and guest chains are deuteriated in the same mesophase, the host chain segments were deuteriated in one system and the guests in another but the composition of both phases was the same. The care in permuting specifically deuteriated chains of the host in equivalent mesophases allows unequivocal assignment of the quadrupole doublets to specific segments (5, 15). The results for lauric acid-d_{23} and laurate ion-d_{23} in type II DM mesophases prepared originally by Lawson and Flautt (16) have been discussed previously (4) in another context, but the results for the same guests in mesophases of decylammonium chloride (17) are presented here for the first time. The compositions of mesophases are given in Table 1 in order that others may reproduce these rather difficult systems. Purification procedures can be found in our previously published work (see ref. 3 for a list of references). Experimental temperature of nmr observations was 34°C.

Results

The deuterium magnetic resonance spectra of sodium laurate-d_{23} and lauric acid-d_{23} have been discussed previously (1) in the context of a set of experiments designed to study the effect of a lengthening chain on degree of order profiles in SDS–decanol mesophases. The other acids and carboxylates of the same head group chemistry had longer chains as in myristic, palmitic, and stearic acids (1). These results are important in this new context, where a common carboxylate and carboxylic acid, laurate and lauric acid are used as small concentrations of guests in two host mesophases, one based on the cationic detergent decylammonium and the other based on the anionic detergent decyl sulphate (with a small amount of decanol). In the present case all amphiphiles have approximately the same chain length. The results

TABLE 1. Composition of mesophases used in this study

(*a*) Lauric acid in SDS (11) mesophase

Standard phase (D7):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	92.02
Lauric acid-d_{23}	0.12
Decanol	1.40
Sodium decylsulphate (SDS)	5.44
Sodium sulphate	1.04

Diluted phases: D7, as above, D7-1, 92.62 mol% water; D7-2, 93.10 mol% H_2O; D7-3, 93.54 mol% H_2O; D7-4, 93.95 mol% H_2O.

The diluted phases were merely obtained by adding water to the standard D7 mesophase so as to achieve the overall mol% water in the diluted mesophases. This procedure applies to the other entries below for other systems.

Standard phase (D6):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	92.00
Lauric acid	0.12
Decanol	1.39
SDS (17.45% 3, 3, 4, 4-d_4)	5.43
Na_2SO_4	1.06

Diluted phases: D6-1, 92.71 mol% H_2O; D6-2, 93.18 mol% H_2O; D6-3, 93.59 mol% H_2O; and D6-4, 93.97 mol% H_2O.

Standard phase (D30):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	92.01
Lauric acid	0.12
Decanol	1.40
SDS (10.04% 1, 1, 9, 9, 10, 10, 10-d_7, 9.6% 22-d_2)	5.44
Na_2SO_4	1.04

Standard phase (D32):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	92.00
Lauric acid	0.12
Decanol	1.40
SDS (9.3% 1, 1, 9, 9, 10, 10, 10-d_7, 9.7% 3, 3, 4, 4-d_4)	5.44
Na_2SO_4	1.04

Diluted phases: D32-1, 92.6 mol% H_2O; D32-2, 93.09 mol% H_2O; D32-3, 93.54 mol% H_2O; D32-4, 93.93 mol% H_2O.

(*b*) Lauric acid in decylammonium chloride mesophase

Standard phase (D5):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	91.906
Lauric acid-d_{23}	0.140
Decylammonium chloride	5.854
Sodium chloride	2.100

Diluted phases: D5-1, 92.23 mol% H_2O; D5-2, 92.58 mol% H_2O; D5-3, 92.89 mol% H_2O; and D5-4, 93.07 mol% H_2O.

Standard phase (D4):	Mol%
H_2O (pH ~ 2, 0.1% D_2O)	91.917
Decylammonium chloride (3.2% 2, 2-d_2, 5.1% 1, 1, 9, 9, 10, 10, 10-d_7)	5.846
Sodium chloride	2.097
Lauric acid	0.140

pertinent to the cationic amphiphile type II DM system have not been previously reported.

Lauric Acid-d_{23} *in Decylammonium Chloride Mesophases*

The deuterium quadrupole splittings measured for each segment in the standard and diluted mesophases (see Table 1) decrease for both guest and host as water is added within the stable existence of the type II DM mesophase system. The curves of degree of order of C—D bonds in segments (1) are very similar to those published before (1, 3, 15). For the host segments (16) we have shown that the decrease is at first linear with water concentration, but afterwards falls off much more steeply, until the mixture undergoes a phase separation to form two layers with the lower layer isotropic in properties (15). In the coexistence region of the type II DM and the isotropic phase the deuterium splittings of the host do not depend on overall water content.

The strict proportionality between deuterium quadrupole splittings, which we have previously reported for this host mesophase (15), as the water content is varied, has been confirmed during the present study for both guests and hosts. Figure 1 illustrates that segmental order ratios (3) for the guest are independent of water concentration in the phase. The degrees of order of DOH measured from the doublet splitting in the water are linear with the splitting for the αCD_2 group of the chain. The intercept for zero splitting in the water occurs at about +750 Hz for the αCD_2 group splitting. The spectrum of lauric acid-d_{23} is shown as Fig. 2 for the standard mesophase. It shows resolution of each segment and in the first few segments the dipole–dipole coupling effect between the two deuterium nuclei in each —CD_2— group. Such dipole–dipole coupling lends itself to the determination of the degree of order of the D—D axis in the —CD_2— group. The analysis of two spin 1 particles in the nmr spectra of oriented species was published some time ago (18). Assuming the two spins are equivalent and thus scalar coupling is zero, each quadrupole doublet component is split into 3 resolvable transitions (18) of significant intensity. One splitting between the three peaks is four times the dipole–dipole coupling and the other twice (18). The dipole–dipole coupling is given by:

$$[1] \quad D_{12} = -2829/r_{12}^3 S_{12}$$

where D_{12} is the dipole–dipole coupling constant; −2829 is a factor of nuclear constants designed to express the result of D_{12} in Hz; r_{12} is the distance between deuterium nuclei in Å; S_{12} is the degree of order of the internuclear axis. Taking r_{12} = 1.8 Å, we obtain D_{12} = 485 S_{12}. Assuming the nuclear quadrupole coupling constant for the C—D bond to be 170 kHz and that the asymmetry parameter η = 0, we can express the degree of order along the C—D bond in the segment as:

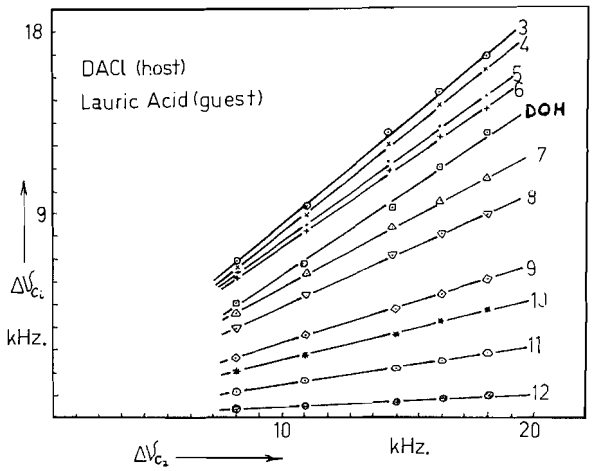

FIG. 1. Deuterium quadrupole splittings of an arbitrary segment $\Delta\nu_{C_i}$, denoted by the value of i placed against each line at the right, and the use of different distinguishing symbols for each set of points, plotted against the quadrupole splitting in the segment of carbon 2 of the chains, denoted as $\Delta\nu_{C2}$. The values of $\Delta\nu_{Ci}$ and $\Delta\nu_{C2}$ are strictly proportional and independent of the water content of the type II DM mesophases. The data corresponds to the mesophases D5 to D5-4 of Table 1. The quadrupole splittings of the water (DOH) are also included as square points ⊡ and the line so marked at the right hand side.

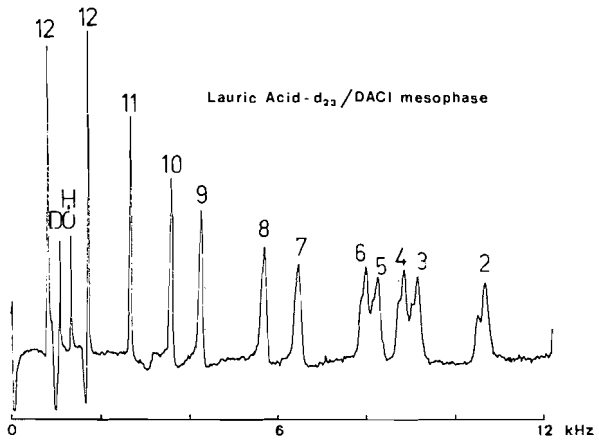

FIG. 2. Deuterium spectrum of sample D5. Spectral width 12341 Hz; aquisition time 0.1 s; pulse width 40 μs; number of transients 21 676. All eleven —CD_2— segments of lauric acid-d_{23} are resolved separately in increasing segment number from the right. The DOH doublet appears as the second and third peaks from the left. The spectrum is symmetric about this point. The left hand doublet components are not observed. On the right hand side of the half spectrum, resolution of dipole–dipole splittings between segmental —CD_2— deuteriums is seen.

[2] $\Delta\gamma_Q = 255\, S_{CD}$

where $\Delta\gamma_Q$ is the quadrupole splitting in kHz.

The simultaneous measurement of degrees of order S_{CD} along the C—D bond and S_{12} along the DD axis from the same spectrum enables us to compare degrees of order in different perpendicular directions to the axis of the pseudo-extended chain. It is assumed in the pseudo-rigid chain model of packing of amphiphiles in bilayers, that the anisotropic motion of the chain is cylindrically symmetric (19), i.e. all directions perpendicular to the pseudo-extended chain axis are equivalent. These spectra are therefore an important test of this point. The low and high field components of the quadrupole doublets have been used to determine an average for four independent values $S_{12} = S_{DD}$ from each spectrum. The comparisons are: (*a*) segment at carbon 2, αCD_2, $S_{CD} = 0.158$, $S_{DD} = 0.168$; (*b*) segment 3, $S_{CD} = 0.124$, $S_{DD} = 0.130$; (*c*) segment 4, $S_{CD} = 0.120$, $S_{DD} = 0.118$; (*d*) segment 5, $S_{CD} = 0.110$, $S_{DD} = 0.118$; (*e*) segment 6, $S_{CD} = 0.106$, $S_{DD} = 0.106$.

The error in the value of S_{DD} is large because of the small value of the dipole–dipole coupling. The best estimate of this error is ± 0.01 in the value S_{DD}. Having taken this into account it is clear that the degrees of order in the two directions are, within this error, the same.

The quadrupole splittings for the standard D5 mesophase (Table 1) were observed to be: 2, 19.01 {1} kHz; 3, 15.91 {1}; 4, 15.32 {1}; 5, 14.13 {1}; 6, 13.57 {1}; 7, 10.52 {1}; 8, 8.954 {5}; 9, 6.066 {5}; 10, 4.712 {5}; 11, 2.859 {5}; 12, 0.908 {5}. The first number is the segment corresponding to the carbon number in the chain, the values are all in kilo-Hertz and the bracketed numbers after the splittings are the random error in the last significant figure. Thus the entry 4. 15.32 {1} means that for the —CD_2— segment at carbon number 4 in standard mesophase D5 (see Table 1) the deuterium quadrupole splitting is 15.32 kHz with a random error ± 0.01 kHz. The quadrupole splittings in all mesophases of the D5 series can be reproduced by giving one value of the splitting in the chain for each diluted mesophase of D5-1–D5-4 and the slopes of the proportionality in Fig. 1. The values for splittings of the αCD_2 positions (segment at carbon 2) are the following for designated diluted phases (Table 1); D5-1, 16.99 {1}; D5-2, 14.75 {1}; D5-3, 11.14 {2}; D5-4, 8.10 {5}. The mean proportionality constants are expressed as $\Delta\nu_{C_x}/\Delta\nu_{C2}$, (the splitting of the xth segment divided by that of carbon 2) are: $x = 3$, 0.8442; $x = 4$, 0.8107; $x = 5$, 0.7521; $x = 6$, 0.7242; $x = 7$, 0.5610; $x = 8$, 0.4808; $x = 9$, 0.3239; $x = 10$, 0.2481; $x = 11$, 0.1477; $x = 12$, 0.0464.

In order to clearly illustrate this way of presenting the data in its most compact form, the quadrupole splitting of carbon segment 4 for mesophase D5-2 is computed and compared to the experimental value measured. The required splitting is evidently $(\Delta\nu_{C4}/\Delta\nu_{C2}) \times \Delta\nu_{C2} = 0.8107 \times 14.75 = 11.96$ kHz which compares to the measured value 11.98 kHz.

The same procedure can be used to describe the array of quadrupole splittings for the host chains. Taking the series D4, D15, and D16 together the proportionality ratios in decylammonium chains can be averaged for all determinations. The ratio computed is again that for arbitrary segment C_x divided by that for the first carbon: Values $\Delta\nu_{C_x}/\Delta\nu_{C1}$ are: $x = 2$, 0.9180; $x = 3$, 0.9040; $x = 4$, 0.8743; $x = 8$, 0.6358; $x = 9$, 0.5194; and $x = 10$, 0.1216. The single quadrupole couplings which will facilitate the computation of all others in the diluted mesophases are: D4, 16.11 {2}; D4-1, 14.07 {2}; D4-2, 11.72 {2}; D4-3, 7.98 {5} for the first carbon segment in kHz with errors in the last significant figures in brackets. For the D15 series values are: D15, 16.08 {2}; D15-1, 14.22 {2}; D15-3, 6.49 {5}, again for the first carbon CD_2 segment in kHz. For the D16 series, D16, 16.76 {2}; D16-1, 14.35 {2}; D16-2, 12.12 {2}; and D16-3, 9.03 {2}.

The complete array of data on quadrupole couplings for the lauric acid guest, decylammonium chloride host, can be reconstructed from the compact listings above, for the corresponding compositions given in Table 1.

An important feature of the quadrupole coupling ratios in a pseudo-extended chain is the ratio of splittings in the terminal —CD_2CD_3 segment. If the chain were really rigid and extended the ratio should be 3 (5, 15, 20). For the case of guest lauric acid chains, the value is 3.183, and for the host decylammonium chloride the value is 4.271, these being averages for all mesophases in this section.

The quadrupole splittings of the water (DOH) are somewhat lower than in mesophases based on decylsulphate ions (1, 5) but still much higher than mesophases prepared with head groups —$N(CH_3)_3^+$ and pyridinium (14). The values measured are: D5, 251 {2}; D5-1, 221 {2}; D5-2, 185 {2}; D5-3, 135 {2}; D5-4, 100 {5} partly isotropic; D4, 250 {2}; D4-1, 217 {2}; D4-2, 180 {2}; D4-3, 121 {2}; D15, 241 {2}; D15-1, 206 {2}; and D15-3, 92 {2} partly isotropic. The splittings are given in Hertz and errors in the last significant figure in brackets.

Sodium Laurate -d_{23} in Decylammonium Chloride Mesophases

The plateau of uniform degree of order is rather

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

well developed for laurate ion in decylammonium chloride, consequently Fig. 3 contains the quadrupole splittings of position 8 plotted against all other arbitrary segments where overlap of peaks did not occur. The variable is the usual chemical one of water content over the stable range of type II DM mesophases. Simple proportionality of order among —CD_2— segments is once again illustrated by the results in the figure.

The D22 series of the Experimental embraces the following deuterium quadrupole splittings for the segment 8 of the chain: D22, 13.87 {2}; D22-1. 12.63 {2}; D22-2. 10.96 {2}; D22-3. 8.80 {2}; and D22-4. 6.84 {5} partly isotropic. The following ratios obtained $\Delta\nu_{Cx}/\Delta\nu_{C8}$ facilitate the generation of all quadrupole splittings measured for the guest in the D22 series: $x = 1$, 1.428; $x = 3$, 4, 1.383; $x = 5$, 1.331; $x = 6$, 1.265; $x = 7$, 1.142; $x = 9$, 0.8029; $x = 10$, 0.6097; $x = 11$, 0.4041; and $x = 12$, 0.0897. The quadrupole splittings are in kHz.

The deuterium quadrupole splittings for the host may be generated from the following similar data for the αCD_2 splittings in kHz from the D21 series of the Experimental (Table 1): D21, 15.81 {2}; D21-1, 13.82 {2}; D21-2, 11.64 {2}; D21-3, 8.49 {2}; and D21-4, 6.69 {5} partly isotropic. The ratios of quadrupole couplings expressed as $\Delta\nu_{Cx}/\Delta\nu_{C1}$ for the decylammonium chain are: $x = 2$, 0.9306; $x = 8$, 0.6452; $x = 9$, 0.5223; and $x = 10$, 0.1223.

The ratios of the degrees of order for segments of the host chain are slightly different from values obtained with the lauric acid guest. The differences are of the order of 1%. This can be ascribed to the presence of a small amount of decylamine added in the mesophases containing sodium laurate. The agreement is satisfactory enough to regard the bilayer matrix unchanged as far as the guest is concerned. Ratios of splittings in the —CD_2CD_3 terminal fragments are: 4.27 for the host decylammonium chain and 4.58 for the guest laurate chains.

The data for lauric acid and laurate ion in host micelle bilayers of decylsulphate–decanol have been previously presented (1).

Comparison of Complete Order Profiles of Guests and Hosts in Standard Mesophases

The quadrupole splittings for host and guest segments in standard mesophases prepared here and presented previously (1) have been plotted against segment numbers in Fig. 4. In the case of decylsulphate and decylammonium chloride carbon 1 is plotted with the segment number 2 in order to compensate for the first carbon in the carboxyl moieties being in the head group —CO_2— or —COOH.

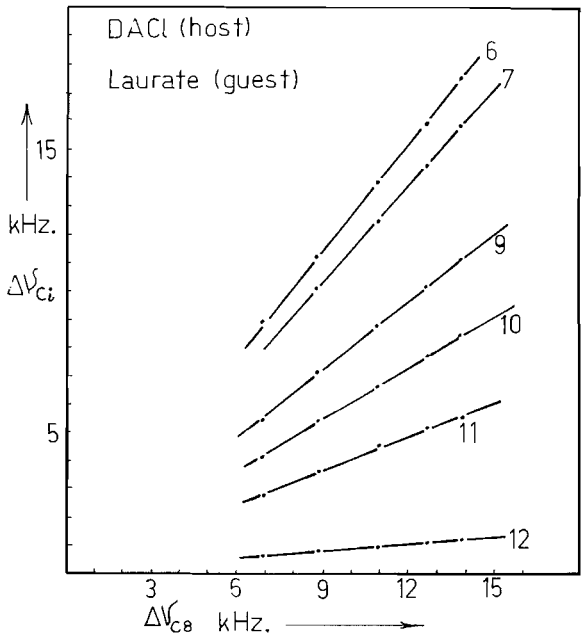

FIG. 3. Deuterium quadrupole splittings of arbitrary segment $\Delta\nu_{C_i}$ versus quadrupole splittings for the 8th segment $\Delta\nu_{C8}$ in perdeuteriated hydrocarbon chains of the laurate ion guests in a type II DM mesophase based on decylammonium chloride. Samples D22 to D22-4 in Table 1.

Discussion

Interpretation of Constant Ratios of Order in Segments

According to the recent low angle X-ray diffraction studies of Queiroz do Amaral and co-workers (2) the type II DM mesophase is a collection of disc-like micelles of diameter greater than 1000 Å and of bilayer thickness. The uniaxial properties of the fluid depend on the long range orientational order of these discs, but absence of positional order.[4] The aligned mesophases in a spinning nmr tube perpendicular to the magnetic field achieve a unique alignment along the axis of the spinning tube (13). The configuration for the present nmr experiments and all those for type II mesophases similarly aligned previously (3) is such that the planes of the discs are in the axis of the magnetic field direction and the normal to the flat faces is oriented along the axis of the nmr tube. This is diagrammatically pictured in the figure of a previous article (4). The micelle size is large enough to make negligible the influence of amphiphiles, which complete the edge of the disc.

If the degree of order measured for segments in

[4]Some positional ordering occurs, dependent on the nature and size of the sample tube. L. Q. do Amaral (Mol. Cryst. Liq. Cryst. Lett., in press).

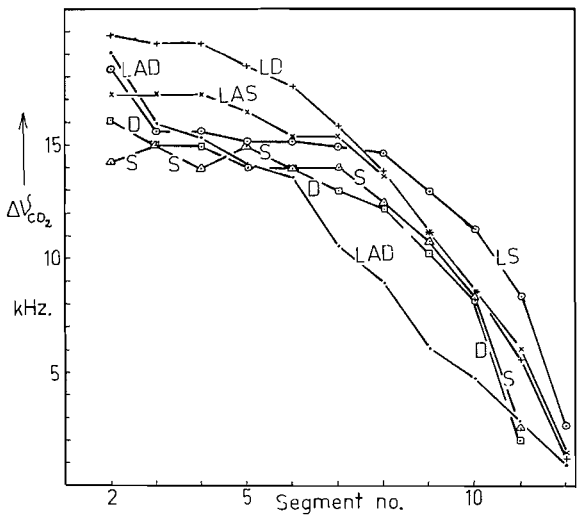

FIG. 4. A direct graphical comparison of quadrupole splittings in $—CD_2—$ segments (proportional to degrees of order along C—D bonds) in guests and hosts for the systems lauric acid and laurate ion guests in a micelle layer of decylsulphate–decanol, and the same guests in a bilayer of decylammonium ion – decylamine. The order profiles for the host bilayers are also plotted. The points correspond to the standard mesophases, the compositions of which are listed in Table 1. The profiles may be identified by both the type of point used and entries on each line, where distinction might be difficult. Temperature of experiments 34.0 ± 0.1°C. All mesophases type II DM. + Laurate ion in decylammonium mesophase (LD); ● lauric acid in decylammonium mesophase (LAD); ⊙ laurate ion in SDS/decanol mesophase (LS); × lauric acid in SDS/decanol mesophase (LAS); ⊡ profile of decylsulphate host chains (S); △ profile of decylammonium host chains (D). The segment numbers correspond to carbon number in the chain for guests and for the host chain segment 2 is the first carbon in the chain.

the same chain is separated into intra and extra chain contributions (1, 21) we may write:

$$[3] \quad (So)_n = (St/g)_n \cdot S_c$$

$(So)_n$ is the observed degree of order in the nth segment. $(St/g)_n$ is the intra chain contribution and S_c the contribution arising from the motion of the pseudo-rigid chain as a whole. A ratio for two segments in the same chain gives:

$$[4] \quad (So)_n/(So)_m = (St/g)_n/(St/g)_m$$

The intra chain contributions arise only because of the *trans/gauche* rotations along the chain (19). Since the ratio $(So)_n/(So)_m$ has been shown to be invariant it follows that the *trans/gauche* motions along the chain are not altered as water is added. The conclusion drawn is that the internal packing of the host and guest amphiphiles in the micelle does not change as the system is diluted with water. The lower degrees of order, measured as water dilutes the orientationally ordered micelles, owe their origin to larger amplitude movements of the micelle mostly deriving from changes in size of the micelle as more water is added (21). The results presented here do show very small differences in degrees of order of decylammonium chains between series D4, D15 and D6, and D21 but this is easily accounted for by the exchange process involving added decylamine in series D21. The guests are amphiphiles added in dilute solution in the micelle; the *trans/gauche* motions along these chains are also invariant to water content.

Motions Perpendicular to Pseudo-extended Chain Axes

The data presented in the Results, with respect to the lauric acid-d_{23} guest in the decylammonium chloride mesophase, show that for all perpendicular directions to the extended chain the degrees of order are the same. Cylindrical symmetry of motion about the long axis of the chain is a very useful assumption which is now justified by the present results. The uniaxial properties depend on long range orientational order of the rather large flat discs of the micelles.

Comments on Comparisons of Guest and Host Order

The plateau region of uniform degree of order in segments is not well developed for 10 or 12 carbon segment chains; this is especially the case for lauric acid guests in decylammonium bilayers (Fig. 4). The guest amphiphiles are either neutral at the polar head or negative. Oppositely charged head interactions occur for laurate guests in decylammonium chloride bilayers. The higher degree of order of the first five segments of this guest probably arises because of Coulombic attractions which induce a firmer anchoring at the guest head group site. On the other hand the segments 3–5 for laurate in decylsulphate–decanol bilayers have lower order than other guests. In so far as the absolute degrees of order carry the component of micelle motion which may differ from host to host, comparison of degrees of order of guest between host bilayers is not a reliable procedure. The main conclusion available is that the intrachain motions are peculiar to each guest and host amphiphile. This reflects the different anchoring of the head groups in the interface of the bilayer and confirms our earlier work in this respect on other systems (3). The individuality of these anchorings and profiles of order requires that studies on real membrane systems be aimed toward the behaviour of given lipids, to characterize their motion profiles, rather than designing experiments in the false hope that the motion profile of one lipid can be informative of the situation of the other lipids (8).

The lauric acid in decylammonium bilayers and laurate ion in decylsulphate–decanol bilayers are marked by a considerably higher order of the first $—CD_2—$ group over subsequent ones. The participation of this segment in the *trans/gauche* rotations of the carbon–carbon bonds is thus inhibited by head group anchoring.

With respect to the ratio of degrees of order in the $—CD_2CD_3$ terminal segments, treated in the manner reported before (20), the single *gauche* rotation about the last CD_2—CD_2 bond in the chain is more probable the higher the value of the ratio $\Delta\nu_{CD_2}/\Delta\nu_{CD_3}$. In decylammonium chains this ratio is 4.27, for guest laurate 4.58, for guest lauric acid in decylsulphate–decanol 4.29. These single *gauche* rotations are less probable in the other cases, ratios being 3.18 for lauric acid in decylammonium bilayers and 3.25 for decylsulphate chains. The participation of chain segments in terminal single *gauche* rotations is most highly developed for the lauric acid in decylammonium bilayers. This profile has no plateau of uniform order and the larger decreases in order per segment occur from carbon number 6 on.

Extraction of Zn(II) and Cd(II) with anthranilic acid in the presence of nitrogen-containing organic bases

BINA JAIN, J. M. SINGH, R. N. GOYAL, AND S. N. TANDON
Department of Chemistry, University of Roorkee, Roorkee-247672, India

Received October 11, 1979[1]

BINA JAIN, J. M. SINGH, R. N. GOYAL, and S. N. TANDON. Can. J. Chem. **58**, 1558 (1980).

Zinc and cadmium anthranilates do not extract into non-polar solvents alone in the pH range 4.5–6.5. But their extraction is synergistically enhanced in presence of N bases, apparently by displacement of coordinated water. The synergistic effect varies with the bases in the order β-picoline > pyridine > quinoline. The values of extraction constants suggest that cadmium forms more stable complexes than zinc.

BINA JAIN, J. M. SINGH, R. N. GOYAL et S. N. TANDON. Can. J. Chem. **58**, 1558 (1980).

Dans l'intervalle de pH 4,5 à 6,5, les anthranilates de zinc et de cadmium ne peuvent être extraits à l'aide de solvants non-polaires seuls. Mais leur extraction est activée synergétiquement en présence des bases azotées, apparemment par déplacement d'eau coordonnée. L'effet synergétique varie avec les bases dans l'ordre: β-picoline > pyridine > quinoléine. Les valeurs des constantes d'extractions suggèrent que le cadmium forme des complexes plus stables que ceux du zinc.

[Traduit par le journal]

Introduction

Anthranilic acid is known to be a good complexing agent and has found extensive applications as an analytical reagent. Some studies have also been reported on the use of anthranilic acid for the extraction of metals in oxygenated solvents. Harvey *et al.* (1) studied the extraction of Pu(IV) anthranilate into amyl acetate and reported the effect of pH on extraction. Hök (2) carried out extraction studies of some lanthanides using anthranilic acid and proposed their separations. Dinsel and Sweet (4) separated Fe(II) from Fe(III) using their extraction in the presence of anthranilic acid and determined the latter spectrophotometrically. Schweitzer and Howe (6) extracted Co(II) from anthranilic acid solution into different oxygenated solvents and reported $pH_{0.5}$ and maximum log D values. Sheyanova and Boyarkina (8) investigated the extraction of Co(II), Ni(II), Zn(II), and Cd(II) anthranilates and reported the pH values for their maximum extraction.

On the other hand, the anthranilates of some metals show poor extraction in non-polar solvents like chloroform (3) and benzene. However, the addition of neutral donors like heterocyclic nitrogen-containing organic bases to such systems increases the extraction significantly. The present article reports the extraction of Zn(II) and Cd(II) anthranilates into benzene in the presence of nitrogen-containing organic bases like pyridine, picolines, and quinoline. To the best knowledge of the authors it is the first report of a successful extraction of metal anthranilates into a non-polar solvent. The extracting species have been identified and the extraction constants calculated. On the basis of extraction data, the stability of the mixed complexes of zinc and cadmium has been computed. The study also gives an idea about the relative effectiveness of different bases as synergists. No attempts have been made to utilize the system for proposing separations. However, the investigations offer an entirely new system for achieving separations of metals as anthranilates.

Experimental

Reagents

The metal ion solutions were prepared by dissolving analytical grade sulphates of zinc and cadmium in doubly distilled water. The solutions were standardized by EDTA titrations. The nitrogen-containing organic bases pyridine, picolines, and quinoline were also of analytical grade. Freshly prepared aqueous solution of anthranilic acid (AR) was used throughout the investigation. ^{65}Zn and ^{115m}Cd isotopes of specific activity 321 mC/g Zn and 17 mC/g Cd were procured from Bhabha Atomic Research Centre, Bombay, India, and used for distribution studies. At around 55% extraction a precision of ±1% in the case of zinc and ±2% in the case of cadmium was obtained.

Analytical Procedure

In each set equal volumes of aqueous (1.0×10^{-4} M Zn(II) or Cd(II) and 0.04 M anthranilic acid or any other concentration) and organic phase (benzene) were shaken at room temperature 30 ± 2°C for half an hour which was found sufficient for complete equilibration. The pH of the aqueous phase was adjusted with perchloric acid or sodium hydroxide. After equilibration the two phases were separated and pH of the aqueous phase was determined. Suitable aliquots of each phase were pipetted out and counted using a well-type NaI(Tl) scintillation counter for ^{65}Zn and a G.M. counter for ^{115m}Cd. The pH range for the extraction of Zn(II) and Cd(II) lies between 4.5 and 6.5. The optimum concentration with regard to the bases are 0.25, 0.50, and 2.0 M for β-picoline, pyridine, and quinoline, respectively, for maximum extraction at an overall anthranilic acid concentration of

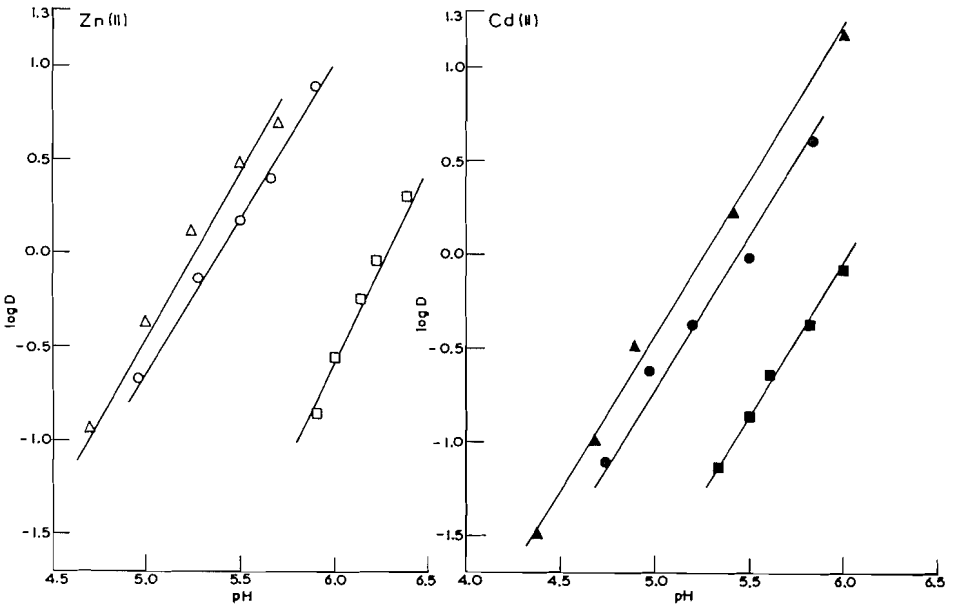

FIG. 1. Effect of pH on the extraction of Zn(II) and Cd(II) complexes with anthranilic acid (4×10^{-2} *M*) in presence of nitrogen-containing organic bases: ○, ●, pyridine, 0.35 *M*; △, ▲, β-picoline, 0.25 *M*; □, ■, quinoline; 2.0 *M*.

0.04 *M*. The ionic strength of aqueous phase was maintained constant (0.1 *M*) by adding sodium perchlorate.

Results and Discussion

The zinc and cadmium anthranilates in benzene alone show poor extraction (< 5%) over the pH range studied (4.5–6.5). But the addition of neutral donors like pyridine, picolines, and quinoline has a striking effect on the extraction and metal gets extracted to the extend of 80–90%. Obviously, this happens by the replacement of water molecules from the coordination sphere of the metal, rendering the species less hydrophilic, thereby enhancing its extraction into benzene.

For the extraction of Zn(II) and Cd(II) anthranilates into benzene in the presence of organic bases plots were drawn for log *D* vs. equilibrium pH of aqueous phase (Fig. 1) and log *D* vs. log of anthranilic acid concentration (Fig. 2). The straight lines with slope near 2 were obtained suggesting the release of two protons and the utilization of two acid molecules per metal atom. In order to find the ratio of metal-to-base, log *D* was plotted against log $[B]_{total}$ (Fig. 3). The straight lines with a slope of unity in the case of zinc and with a slope value near two for cadmium were obtained. Thus, the extracting species may be represented as $[Zn(anthra)_2 \cdot B \cdot H_2O]$ and $[Cd(anthra)_2 \cdot 2B]$ assuming the coordination number of zinc and cadmium to be four. It has been observed that out of the different nitrogen-containing organic bases used α-picoline is unable to enhance extraction. This may be explained on the basis of poor basicity of α-picoline; the steric factor may also play a role.

Tandon *et al.* (9, 10) studied the extraction of zinc and cadmium salicylates in the presence of some organic bases and reported similar species.

The reaction for mixed complex formation can be represented as

$$M_{aq}^{2+} + 2H_2A_{aq} + nB_{aq} \rightleftharpoons [M(HA)_2 \cdot nB]_{org} + 2H_{aq}^{+}$$

where M^{2+} represents Zn^{2+} or Cd^{2+} and H_2A stands for anthranilic acid. The equilibrium constant for extraction will be given by equation

$$K_{ex} = \frac{[M(HA)_2 \cdot nB]_{org}[H^+]_{aq}^2}{[M^{2+}]_{aq}[H_2A]_{aq}^2[B]_{aq}^n}$$

Hence

$$[1] \quad \log D = \log K_{ex} + 2 \log [H_2A]_{aq} + n \log [B]_{aq} + 2\,pH$$

where

$$D = \frac{[M(HA)_2 \cdot nB]_{org}}{[M^{2+}]_{aq}}$$

Mass balance for the base is given by the expression

$$[B]_{total} = [B]_{org} + [B]_{aq} + [BH^+]_{aq} + n[M(HA)_2 \cdot nB]_{org}$$

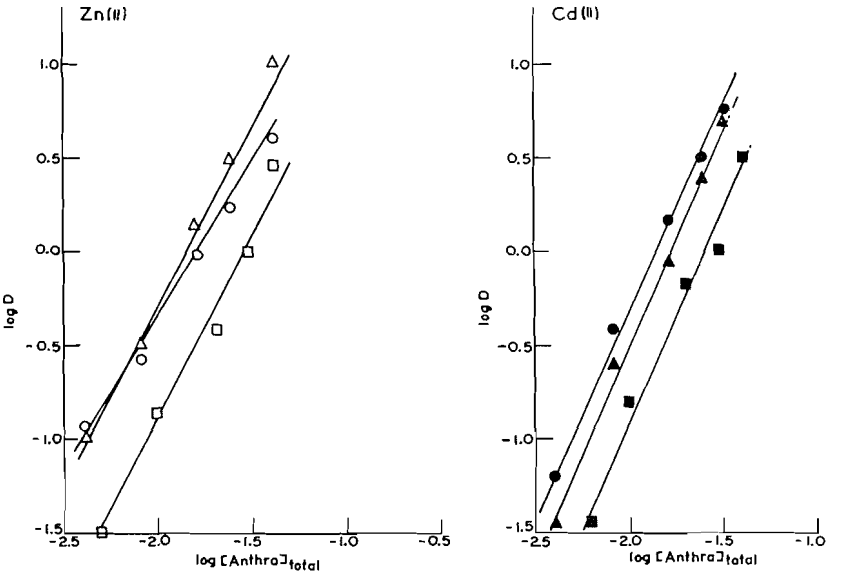

FIG. 2. Variation of distribution ratio for Zn(II) and Cd(II) as a function of anthranilic acid concentration at constant pH and base concentration: ○, pyridine, 0.35 *M*, pH = 6.3; △, β-picoline, 0.25 *M*, pH = 5.8; □, quinoline, 2.0 *M*, pH = 6.5; ●, pyridine, 0.35 *M*, pH = 6.3; ▲, β-picoline, 0.25 *M*, pH = 6.2; ■, quinoline, 2.0 *M*, pH = 6.4.

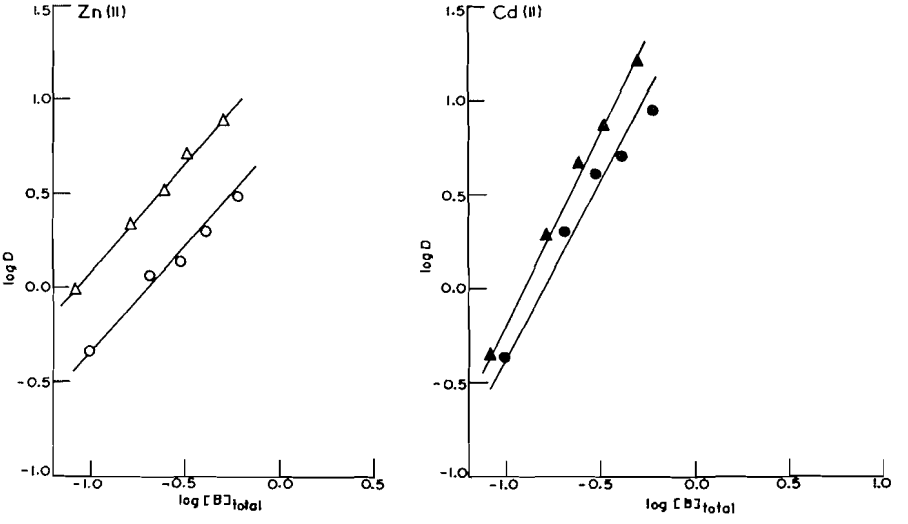

FIG. 3. Variation of distribution ratio as a function of base concentration at constant pH and anthranilic acid concentration (4×10^{-2} *M*): ○, pyridine, pH = 6.44; △, β-picoline, pH = 6.50; ●, pyridine, pH = 6.50; ▲, β-picoline, pH = 6.32.

Hence

$$[2] \quad [B]_{aq} = \frac{[B]_{total} - n[M(HA)_2 \cdot nB]_{org}}{\{P_B + 1 + [H^+]/K_{BH^+}\}}$$

where P_B and K_{BH^+} are the partition coefficient and ionisation constant respectively of BH^+ of the base. The average values of partition coefficient for pyridine and β-picoline are 1.95 and 1.85 respectively (10). K_{BH^+} values were taken from the literature (5, 7). Equilibrium concentration of base $[B]_{aq}$ was calculated using eq. [2]. Plot of log *D* vs. log $[B]_{aq}$ (Fig. 4) gave straight lines with a slope value of 1 in the case of zinc and 2 in the case of cadmium. These values again confirm the presence of one base molecule in zinc complex and two in cadmium complex.

The extraction constant (K_{ex}) is computed using eq. [1]. Values of extraction constant show that cadmium forms more stable complex with anthranilic acid than zinc. The results for pyridine and β-picoline are given in Tables 1 and 2. The data for quinoline are not given as in view of its distribution (5) being highly in favour of organic phase ($P_B >$

100) as compared to other bases, it is likely that a mixed complex is formed in the organic phase in this case.

The extraction data reveal that the effectiveness of the bases as synergists follows the sequence β-picoline > pyridine > quinoline, the concentrations required for a particular extraction (%) are in the reverse order. The stability of the complexes of β-picoline is higher than those of pyridine. A similar sequence of stability of complexes has been observed in other systems, also in consideration of both the strength of the base and steric factors (9, 10).

The infrared spectra give the usual peaks of anthranilate ion and bases, and no conclusive information is obtained from them.

Electrical conductivities of molten zinc chloride – lithium chloride mixtures between 320 and 450°C

SLIMANE BENHENDA[1] AND JEAN-BAPTISTE LESOURD

Laboratoire de Dynamique et de Thermophysique des Fluides, Université de Provence, Centre de Saint-Jérôme, 13397 Marseille Cedex 4, France

Received January 2, 1980

SLIMANE BENHENDA and JEAN-BAPTISTE LESOURD. Can. J. Chem. **58**, 1562 (1980).

Specific conductivities of $ZnCl_2$–LiCl liquid mixtures have been determined in the 320–450°C temperature interval and in the 0–0.54 LiCl mole fraction interval. They were found to increase steadily with both temperature and LiCl mole fraction, which was shown to be related to an increasing ionic character of the melt.

SILMANE BENHENDA et JEAN-BAPTISTE LESOURD. Can. J. Chem. **58**, 1562 (1980).

Les conductivités spécifiques des mélanges $ZnCl_2$–LiCl liquides ont été déterminées dans l'intervalle de temperature 320–450°C et dans l'intervalle 0–0,54 des fractions molaires de LiCl. On a observé une forte croissance de celles-ci à la fois avec la température et la fraction molaire de LiCl; la discussion montre que cette propriété est à rapprocher du caractère ionique croissant du liquide.

Introduction

Thermodynamic measurements in the $ZnCl_2$–LiCl liquid mixtures have been the object of several studies (1–6). In a previous work (7) we attempted to determine the internal transport numbers of the Zn^{2+} and Li^+ ions in these melts.

But no conductivity data concerning the $ZnCl_2$–LiCl liquid system have been reported, to our knowledge. It was therefore found desirable to investigate the latter data; the results of this investigation are the object of the present paper.

$ZnCl_2$-containing melts seem to be interesting owing to their peculiar structure which is characterized by partially covalent Zn—Cl bonds. Furthermore, high temperature electrochemical cells have recently been studied in view of possible applications (8, 9).

Experimental

The method used was a modification of the four-electrode method described previously (10).

Conductivity cell

The conductivity cell was made of Pyrex glass and such that the resistance of the melt be as high as possible. The useful part of the cell was a U-shaped tube (inner diameter: 1.5 mm; total length: 30 mm). Cells were calibrated with 0.1 *N* and 1 *N* KCl standard solutions at 20°C, and this was cross-checked with a 1 *N* NaCl solution at 20°C. Typical cell constants were of the order of 120 cm^{-1}.

Electrodes

Electrodes were made of platinum wire (0.5 mm in diameter, as supplied by Compagnie des Métaux Précieux, France) connected to pure silver leads (1 mm in diameter, as supplied by Compagnie des Métaux Précieux, France). All connections were made in the central hot part of the cell in order to avoid thermocouple effects. The leads were introduced in silica tubes for the sake of insulation.

Apparatus

The measuring circuit was composed of:

(*i*) A sine wave generator, with which a preliminary test was carried out at variable frequencies; it was thus ascertained that the effect of frequency was negligible above 1000 Hz. All other measurements were performed at 1500 Hz.

(*ii*) An insulator stepdown transformer, which protected the measuring circuit against any external noise.

(*iii*) A calibrated, variable R_0 resistor.

(*iv*) A recording millivoltmeter (M. E. C. I., France, equipment built under a Leeds and Northrup licence), selecting successively every one of six channels in the course of a 30-second cycle. The potentials across R_0 and the unknown R_x resistance, after rectification and amplification (rectifying probe and amplifier supplied by Lemouzy, France), were connected to the first two channels. A change over relay, triggered by the channel-switching device, connected alternately the potentials across R_0 and R_x to the meter. This ensured that both potentials were rectified and amplified rigorously in the same way, and were thus strictly comparable. Two other channels were used for recording the emf's of two calibrated Pt–(Pt – 10% Rh) thermocouple which served for the determination of the melt temperature. The last two channels were short-circuited for zero potential calibration.

(*v*) The cell was maintained at the desired temperature by an electric tube furnace supplied with a temperature control unit, as described previously (11).

Procedure

Mixtures were prepared and purified as previously (4, 12). Measurements were carried out at constant composition and the temperature varied in the course of a given run. All temperatures given were stable within ± 1°C for at least 30 min.

For the determination of R_x, the potentials across R_x and R_0 were set equal, whence, the impedance of the measuring circuit being very large, $R_x = R_0$ at equilibrium of the bridge, achieved by adjustment of R_0.

Miscellaneous

All calculations were carried out on the University of Provence PDP 11/45 computer. Equations given were fitted by using a non-linear least-squares regression method.

Results[2]

The specific conductivities (σ) of $ZnCl_2$–LiCl liquid mixtures may be represented satisfactorily as a function of temperature (T) at constant composition by an equation of the form

$$\sigma = a + bT + cT^2 + dT^3$$

σ in Ω^{-1} cm^{-1}; T in K. The values of a, b, c, and d as functions of LiCl mole fraction (x_{LiCl}) are given in Table 1. Figures 1 and 2 give the variation of σ against temperature.

These data may be compared with previous data at only one point: $x_{LiCl} = 0$, i.e. pure $ZnCl_2$, for which several previous studies are available (13–20). In Fig. 1, we have compared our results with some of these previous results. Our data appear to fall between the other ones, but closer to the values resulting from the compilation of Janz *et al.* (18) and the work of Doucet *et al.* (20) than to the less recent values of Biltz and Klemm (13).

The standard deviation on our data in pure $ZnCl_2$ with respect to the adjusted polynomial is about $1.5 \times 10^{-4}\ \Omega^{-1}$ cm^{-1}. From this, the possible relative error on our data in the middle of the range investigated is about 2.5% (at 377°C), with the hypothesis of a normal distribution of errors and within a 95% confidence level. This is consistent with experimental errors due to temperature fluctuations of ±1°C, and to the instrumental error. It is, however, higher than in similar measurements with typically ionic melts such as fused KNO_3. But the standard deviation given by Janz (19) (about $0.003\ \Omega^{-1}$ cm^{-1} between 700 and 900 K) leads to a relative error of the same order of magnitude as ours. It is clear that this error, due to peculiar experimental difficulties encountered with this system, is large enough to account for differences between our data and, say, those given by Janz *et al.* (18). At higher x_{LiCl} mole fractions, these difficulties appear less acute, and the relative errors calculated as above are much lower, and more in line with those observed in similar experiments with typically ionic molten salts. For instance, for $x_{LiCl} = 0.218$, the standard deviation is $1.625 \times 10^{-4}\ \Omega^{-1}$ cm^{-1}, which corresponds to a relative error of 0.3% at 350°C.

At 400°C, the specific conductivities of $ZnCl_2$–LiCl liquid mixtures may be represented by the equation

$$\sigma = 3.6676\, x_{LiCl}^3 + 0.590\, x_{LiCl} + 0.02$$

where σ is in Ω^{-1} cm^{-1}. Extrapolating to $x_{LiCl} = 1$, one obtains $\sigma = 4.28\ \Omega^{-1}$ cm^{-1}, whereas the extrapolated value, at 400°C, for the specific conductivity of molten LiCl is $\sigma = 4.43\ \Omega^{-1}$ cm^{-1}, according to Janz *et al.* (18). The relative difference is about 3%. If one considers the value of the relative error encountered here, and the fact that the extrapolated value of 4.43 refers to a metastable liquid, LiCl being normally a solid at 400°C, such an agreement may be considered as quite satisfactory.

If v_m stands for the molar volume of the system, one can also from our data calculate molar conductivities for $ZnCl_2$–LiCl liquid systems, as defined by the equation: $\Lambda = \sigma v_m$. This calculation was carried out using the density data of Bloom and Weeks (5), and those of Markov and Volkov (6). At 400°C, Λ was represented by the following equation:

$$\Lambda = 87.316\, x_{LiCl}^2 + 17.046\, x_{LiCl} + 1.15$$

with σ in Ω^{-1} cm^2 mol^{-1}.

TABLE 1. Coefficients a, b, c, and d of equation expressing σ as a function of T at various x_{LiCl} values*

x_{LiCl}	a	$b \times 10^2$	$c \times 10^5$	$d \times 10^8$
0.0	−3.1504	1.5355	−2.516	1.388
0.066	0.95537	−0.33978	0.30351	—
0.089	1.0271	−0.38062	0.35558	—
0.108	1.6002	−0.57325	0.51851	—
0.160	1.0545	−0.42616	0.43241	—
0.218	1.0546	−0.43847	0.46169	—
0.283	−0.99582	0.18472	—	—
0.365	−1.0934	0.21943	—	—
0.433	−1.6097	0.33041	—	—
0.540	−1.6075	0.37135	—	—

*Coefficient d is zero for $x_{LiCl} > 0$; coefficients c and d are zero for $x_{LiCl} > 0.218$, which amounts to linear behaviour.

Discussion

It appears that σ increases steadily with both temperature and LiCl mole fraction, and of course the same is true of Λ. Such a behaviour was expected, since pure $ZnCl_2$ is known for its partially covalent structure; its conductivity is, therefore, much lower than the conductivities of typically ionic molten salts (such as alkali nitrates) at the same temperature. However, upon heating, $ZnCl_2$ progressively shifts to an ionic structure, whereby its conductivity is considerably increased. Another piece of evidence for this behaviour is the convexity of the σ vs. temperature curves, as the latter are convex for melts with a low LiCl content. This means that these curves lie above any of their tangents, and, consequently, that σ increases much faster with temperature than in the case of typically

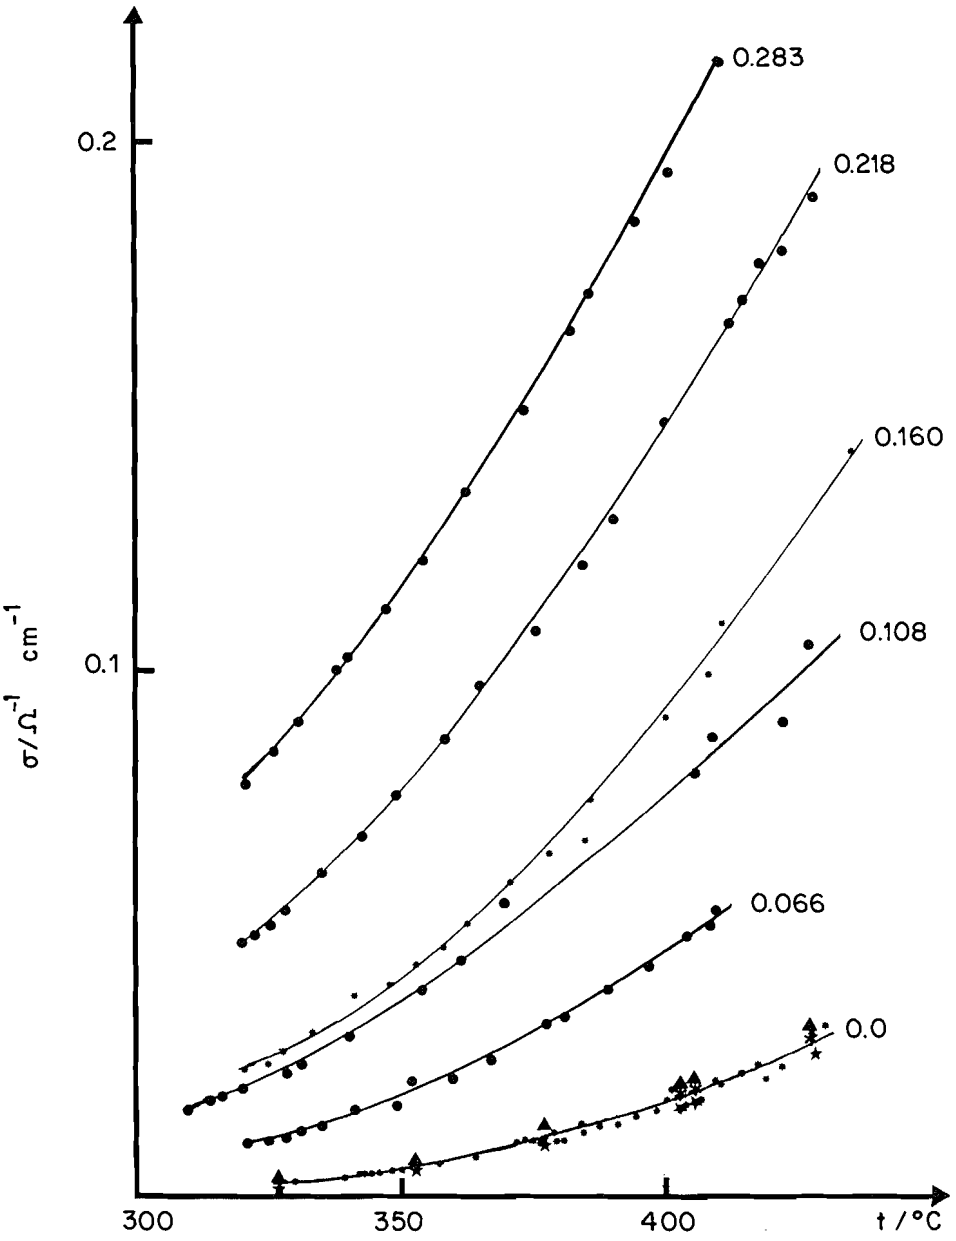

FIG. 1. Variation of $\sigma(\Omega^{-1}\,cm^{-1})$ against t (°C) ($0 \leq x_{LiCl} \leq 0.283$). Symbols: ∗ and ●: our data; ★: after ref. 13; ▲: after ref. 18; ∗: after ref. 20. Values of x_{LiCl} are given on various graphs.

ionic melts, for which σ generally exhibits a nearly linear behaviour on a 100°C temperature interval. Such a linear behaviour is observed, for example, in the case of the specific conductivities of molten $LiNO_3$ and $NaNO_3$ (21). We also observe this linear variation of σ against T here for melts with relatively high mole fractions ($x_{LiCl} > 0.25$). In these melts, the concentration in Li^+ ions (which are unable to enter in covalent bonds with neighbouring Cl^- ions) is large enough for the conductivity to behave as in a typically ionic liquid.

At constant temperature, one also encounters a strong increase in conductivity as the $ZnCl_2$–LiCl systems become more ionic upon LiCl addition.

Conclusion

Our conductivity measurements in $ZnCl_2$–LiCl liquid systems yield significant new experimental

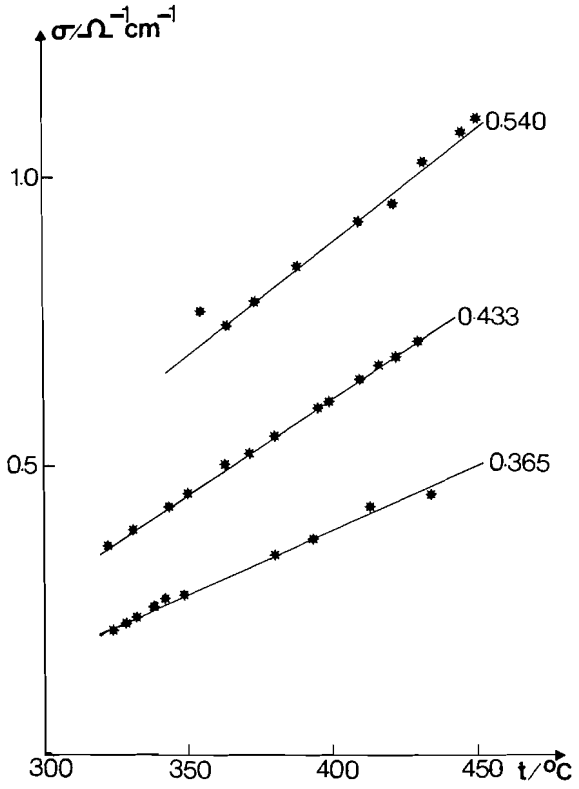

FIG. 2. Variation of $\sigma(\Omega^{-1}\ cm^{-1})$ against t (°C) ($x_{LiCl} \geq 0.365$). Values of x_{LiCl} are given on various graphs.

data which are interesting in that the mixtures shift progressively from a partially covalent structure to an ionic structure upon increasing temperature and LiCl mole fraction.

In the future, it might be desirable to extend the present study to higher temperatures (above 450°C) and to other transport phenomena such as shear viscosity and heat conductivity.

Furthermore, although some interesting spectroscopic data have been published about both pure $ZnCl_2$ (22–25) and $ZnCl_2$-containing melts (26–28), a complete understanding of the structure of these systems has not yet been reached. The molecular dynamics study of Rahman *et al.* (29) for BeF_2–LiF melts (BeF_2 being characterized, in the liquid state, by a covalent structure) indicates that computer simulation would perhaps be of interest for the study of the structure of $ZnCl_2$-containing melts.

Received February 25, 1980

LAURENCE K. THOMPSON, RICHARD G. BALL, and JAMES TROTTER. Can. J. Chem. **58**, 1566 (1980).

A series of copper(II) complexes of the title ligand are reported which exhibit both five-coordinate trigonal bipyramidal and pseudo-octahedral stereochemistries. Mixed stereochemistry complexes $[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br), $[Cu(NTBT)Br]_2[Cu_2Br_6]\cdot CH_3CN$, and the complexes $[Cu(NTBT)Cl]BPh_4(CH_3CN)_2\cdot\frac{1}{2}H_2O$, $[Cu(NTBT)(NO_3)]NO_3\cdot\frac{1}{2}H_2O$, contain trigonal bipyramidal cations while six-coordinate structures are implicated in the systems $[Cu(NTBT)Br_2]\cdot H_2O$ and $[Cu(NTBT)(H_2O)_2](ClO_4)_2\cdot MeOH\cdot H_2O$. The molecular structure of $[Cu(NTBT)(NO_3)]NO_3\cdot\frac{1}{2}H_2O$ has been determined by single crystal X-ray diffractometry. The crystal is monoclinic and belongs to the space group $C2/c$ with $Z = 8$, $a = 24.254(3)$, $b = 14.107(2)$, $c = 16.329(2)$ Å and $\beta = 105.94(1)°$. The complex adopts a distorted trigonal bipyramidal structure (no axial symmetry) with the ligand coordinating in a 'tripod' fashion as an N_4 donor. The fifth ligand is a monodentate nitrate. The mean Cu—N distance is 2.07(3)Å and the Cu—O distance is 1.938(3) Å. A second nitrate oxygen atom is close to the copper centre (Cu—O distance 2.783(4) Å) and may represent a weakly bound sixth ligand. Both infrared and electronic spectral data support the presence of a sixth ligand.

LAURENCE K. THOMPSON, RICHARD G. BALL et JAMES TROTTER. Can. J. Chem. **58**, 1566 (1980).

On a préparé une série de complexes de cuivre(II) avec le ligand mentionné dans le titre; ils se présentent sous des stéréochimies pentacoordonnées à la fois trigonale bipyramidale et pseudo-octaédriques. Les complexes à stéréochimie mixte: $[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br), $[Cu(NTBT)Br]_2[Cu_2Br_6]\cdot CH_3CN$ et les complexes $[Cu(NTBT)Cl]BPh_4(CH_3CN)_2\cdot\frac{1}{2}H_2O$, $[Cu(NTBT)(NO_3)]NO_3\cdot\frac{1}{2}H_2O$ contiennent des cations trigonaux bipyramidaux tandis que des structures hexacoordonnées sont impliquées dans les systèmes $[Cu(NTBT)Br_2]\cdot H_2O$ et $[Cu(NTBT)(H_2O)_2](ClO_4)_2\cdot MeOH\cdot H_2O$. On a déterminé la structure moléculaire du $[Cu(NTBT)(NO_3)]NO_3\cdot\frac{1}{2}H_2O$ par diffraction de rayons-X sur un monocristal. Le cristal est monoclinique et appartient au groupe d'espace $C2/c$ avec $Z = 8$, $a = 24.254(3)$, $b = 14.107(2)$, $c = 16.329(2)$ Å et $\beta = 105.94(1)°$. Le complexe adopte une structure déformée trigonale bipyramidale (pas d'axe de symétrie) avec le ligand coordonnée en un "trépied" comme un donneur de N_4. Le 5^e ligand est un nitrate monodentate. La distance moyenne Cu—N est de 2.07(3) Å et la distance Cu—O est de 1.938(3) Å. Un second atome d'oxygène du nitrate est près du centre du cuivre (distance Cu—O 2.783(4) Å) et peut représenter un sixième ligand faiblement lié. Les données spectrales électronique et infrarouge militent en faveur de la présence d'un sixième ligand.

[Traduit par le journal]

Introduction

The coordination chemistry of polyfunctional 'tripod' ligands with just nitrogen donors has received modest attention in recent years. However, for the most part, the ligands studied have been polyamines (1–5). We have recently studied the tetradentate 'tripod' ligand tris(2-benzimidazylmethyl)amine (NTB), which forms predominantly trigonal bipyramidal complexes with cobalt, copper, and zinc salts (6–8). In these systems the three pendant benzimidazole groups coordinate to the metal ion in the equatorial triangular plane. Electron spin resonance spectra of the copper complexes in frozen glass are characteristic of trigonal bipyramidal species with $g_{||} < g_{\perp}$ and low values of $A_{||}$. Similar spectra are observed for copper complexes of trenMe, trenEt (9, 10).

The coordination chemistry of monodentate and bidentate benzothiazoles has shown that in almost all cases involving complexes with first row transition metal ions (M = Fe, Co, Ni, Cu, Zn) the benzothiazole group is N-bonded (11–20). In the present study we have investigated copper complexes of the tris-benzothiazole, tripod, ligand tris(2-benzothiazolylmethyl)amine (NTBT) (Fig. 1) which is the benzothiazole analogue of NTB. This is the first report of coordination complexes of a

tris-benzothiazole ligand of this sort. In all cases NTBT appears to behave as an N_4 donor, similar to NTB, and forms both trigonal bipyramidal and pseudo-octahedral complexes. An X-ray structure confirms the molecular identity of NTBT itself (the ligand has not been previously reported) and the distorted trigonal bipyramidal nature of the nitrate complex $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$.

Experimental

Electronic spectra were recorded on a Cary 17 spectrometer, infrared spectra were obtained with a Perkin-Elmer model 283 spectrometer, and electron spin resonance spectra were recorded at −196°C on Varian E-3 and Jeolco ME-3X X-band spectrometers, the magnetic field strength being calibrated with an nmr probe or with Mn(II) in MgO powder. Magnetic susceptibilities were obtained at room temperature by the Faraday method with a Cahn model #7600 Faraday Magnetic Susceptibility system, coupled to a Cahn gram electrobalance and conductance data were obtained with a General Radio Company bridge with impedance comparator and a constant temperature bath adjusted to 25°C. Microanalyses were carried out in part by Canadian Microanalytical Service, Vancouver and by Atlantic Microlab, Inc., Atlanta, GA. Metal analyses were determined by Atomic Absorption with a Varian techtron AA-5, after digestion of the samples in concentrated HNO_3 or aqua-regia.

Tris(2-benzothiazolylmethyl)amine (NTBT)

Nitrilotriacetonitrile (15.0 g, 0.112 mol) and *o*-aminobenzenethiol (42.0 g, 0.336 mol) were mixed and heated slowly up to 190–200°C. At around 100°C an initial reaction occurs with frothing and rapid evolution of ammonia gas. The reaction mixture was maintained at 190–200°C for 7 h during which time ammonia gas was evolved. The product was cooled and the solid extracted into dichloromethane and refluxed with decolourizing charcoal. The solution was filtered and reduced in volume to give buff coloured crystals (28.0 g, 54.6%). Recrystallization was effected from dichloromethane and the product dried under vacuum (mp 191–192°C. Some preliminary softening occurred around 150–155°C, prior to melting, which could be associated with a phase change). *Anal.* calcd. for $C_{24}H_{18}N_4S_3$: C 62.9, H 3.93, N 12.2; found: C 62.7, H 4.00, N 12.2. Infrared spectrum (Nujol mull) 1626, 1596 (νCN) cm^{-1}; nmr ($CDCl_3$) (σ(relative intensity)) 7.94(28), 7.45(28) (complex multiplets, aromatic CH), 4.38(28) (CH_2); mass spectrum, major mass peaks (*m/e* (relative intensities)) 458(2)P, 324(2), 310(100), 283(15), 175(12), 149(78), 148(80), 137(3), 121(4), 108(8), 104(12).

Copper Complexes of NTBT

*$[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br) (**I**, **II**)*

NTBT (0.75 g, 0.0016 mol) was dissolved in dichloromethane (50 mL) and excess $CuBr_2$ (3.0 g, 0.013 mol) dissolved in methanol (150 mL). The solutions were warmed and mixed. Dark purple – black crystals formed after a few minutes, which were filtered, washed with methanol and dichloromethane and dried. The product was recrystallized from nitromethane and dried under vacuum.

The chloro-complex was prepared as a lime–green powder by refluxing NTBT with about 10 equiv. of $CuCl_2 \cdot 2H_2O$ in methanol for 4 h. The complex was filtered, washed with methanol and dichloromethane, and dried under vacuum. The mixed solvent method described above did not work consistently for the chloro-complex.

*$[Cu(NTBT)Cl]BPh_4 \cdot (CH_3CN)_2 \cdot \frac{1}{2}H_2O$ (**III**)*

NTBT (0.80 g, 0.0017 mol) and $NaBPh_4$ (0.61 g, 0.0018 mol) were dissolved in acetonitrile (125 mL). $CuCl_2 \cdot 2H_2O$ (0.30 g, 0.0018 mol) was dissolved in CH_3CN (50 mL) and the hot solutions mixed. After standing for 2 h a dirty white precipitate (identified as NaCl) was filtered off and the volume of the green filtrate reduced by half. Golden orange crystals formed, which were filtered, washed, with acetonitrile, and dried under vacuum.

*$[Cu(NTBT)Br]_2[Cu_2Br_6] \cdot CH_3CN$ (buff–brown, **IV**),*
*$[Cu(NTBT)Br_2] \cdot H_2O$ (lime–green, **V**)*

NTBT (0.75 g, 0.0016 mol) was dissolved in dichloromethane (75 mL). $CuBr_2$ (0.37 g, 0.0017 mol) was dissolved in hot methanol (15 mL) and filtered into the NTBT solution. A green coloured solution formed which deposited yellow–green crystals on cooling. The product was recrystallized from acetonitrile to give lime–green crystals which were filtered off, washed with acetonitrile, and dried under vacuum. This product was shown to be $[Cu(NTBT)Br_2] \cdot H_2O$ (**V**).

Attempts to produce $[Cu(NTB)Br]BPh_4$ by a similar route to that used for the analogous chloro-complex were largely unsuccessful (on one occasion golden brown crystals were obtained whose ir and electronic spectra suggested the formation of a tetraphenylborate analogue). In a typical reaction NTBT (0.80 g, 0.0017 mol) and $NaBPh_4$ (0.61 g, 0.0018 mol) were dissolved in hot acetonitrile (125 mL) and $CuBr_2$ (0.40 g, 0.0018 mol) dissolved in hot acetonitrile (50 mL). The two were mixed and stirred at room temperature for 15 min with the formation of a khaki–green solution (no precipitate formed), which was filtered and allowed to stand. Buff–brown crystals formed and were filtered off, washed with acetonitrile, ether, and dried under vacuum (0.5 g). This product was shown to be $[Cu(NTBT)Br]_2[Cu_2Br_6] \cdot CH_3CN$ (**IV**). On standing, the mother liquor deposited lime–green crystals, which were recrystallized from acetonitrile and dried under vacuum. This product was shown to be the same as the lime–green complex **V**. Reduction in volume of the mother liquor produced unreacted $NaBPh_4$.

A further attempt to produce $[Cu(NTBT)Br]BPh_4$, by reacting $[Cu(NTBT)Br]_2[CuBr_4]$ with two equivalents of $NaBPh_4$ in acetonitrile, failed. Buff–brown crystals of **IV** were produced initially followed by lime–green crystals (**V**) from the mother liquor. The attempted isolation of $[Cu(NTBT)Br]^+$ as the tetrafluoroborate or hexafluorophosphate salt also failed.

*$[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$ (**VI**),*
*$[Cu(NTBT)(H_2O)_2](ClO_4)_2 \cdot H_2O \cdot MeOH$ (**VII**)*

NTBT (0.8 g, 0.0017 mol) was dissolved in dichloromethane (50 mL) and $Cu(NO_3)_2 \cdot 3H_2O$ (0.45 g, 0.0019 mol) dissolved in methanol (50 mL) and the hot solutions mixed. The resulting green solution was heated to remove most of the dichloromethane and allowed to cool. A small quantity of buff crystals was removed by filtration and the green solution reduced in volume by heating on a steam bath to induce crystallization. Bright green crystals formed on standing. Recrystallization was effected from methanol and the product filtered, washed with methanol/ether (50/50), and dried under vacuum.

The perchlorate complex was produced similarly and recrystallized from methanol/TEOF.

Analytical data for the copper complexes are given in Table 1.

*Crystallographic Data for $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$ (**VI**)*

Preliminary photographic examination showed the crystals to be monoclinic. The systematic absences, $h + k$ odd for *hkl* and *l* odd for *h0l* indicated the space group to be either *C*2/*c* or *Cc*. As

the measured density indicated eight formula units per unit cell the centric space group $C2/c$ was chosen and this choice was confirmed by successful refinement of the structure.

The crystal chosen for data collection was mounted in a non-specific orientation on an Enraf-Nonius CAD-4 diffractometer. The unit cell constants and an orientation matrix were determined from a least-squares fit of 25 carefully centered reflections having $22 < 2\theta < 44°$. The crystal data are:

$C_{24}H_{18}CuN_6O_6S_3 \cdot \frac{1}{2}H_2O$ fw = 655.196

Monoclinic, $a = 24.254(3)$, $b = 14.107(2)$, $c = 16.329(2)$ Å, $\beta = 105.94(1)°$, $V = 5372.2$ Å^3, $Z = 8$ (22°C, MoKα, $\lambda = 0.71073$ Å); $\mu = 10.32$ cm^{-1}, $D_o = 1.637(2)$ g cm^{-3} (by flotation in CH_2Cl_2 and $CHBr_3$), $D_c = 1.62$ g cm^{-3}.

The experimental conditions for data collection and reduction were: MoKα radiation (graphite monochromator); ω–2θ scan with a range of $(0.5 + 0.347 \tan\theta)°$, extended 25% on either side for backgrounds; variable scan speed of 0.7 to 10.1 deg min^{-1} to give $I/\sigma(I) \geq 20$; $\sigma(I) = \{\text{Int} + 4(\text{BGL} + \text{BGH}) + (0.04I)^2\}^{1/2}$; 6367 data measured to $2\theta = 55°$ for $\pm h,k,l$; three reflections were monitored every hour of exposure time for intensity fluctuations and three reflections were recentered every 100 reflections to monitor crystal orientation.

Of the 6367 reflections measured, 3614 had $F > 3\sigma(F)$ and these were used in the structure solution and refinement.

Structure Solution and Refinement[2]

The positional parameters of the Cu atom were determined from a three-dimensional Patterson synthesis and the remaining non-hydrogen atoms were found using three iterations of the usual combination of least-squares refinement and difference Fourier synthesis.

Refinement of atomic parameters was carried out using full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes, respectively. The weighting factor w is given by $w = 4F_o^2/\sigma^2(F_o^2)$. The neutral atom scattering factors for all atoms were calculated from the analytical expression for the scattering factor curves (21). The f' and f'' components of anomalous dispersion were those of Cromer and Liberman (22) and were included in the calculations for the Cu and S atoms.

Refinement of all non-hydrogen atoms of the cation and anion, with anisotropic thermal ellipsoids, resulted in agreement factors of $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma F_o = 0.081$ and $R_2 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2)^{1/2} = 0.124$. A difference Fourier synthesis revealed 18 peaks corresponding to the H atoms in the cation and a peak at the special position $0y\frac{1}{4}$ which was assigned to the oxygen of a water molecule. In addition to these peaks there was evidence of disorder in the anion. A disorder model was constructed which had one nitrate (population of 0.85) refined anisotropically and a second nitrate, rotated, and slightly displaced from the first (population of 0.15), refined isotropically. Once the second nitrate had refined to its optimum position it was left fixed in subsequent refinement cycles.

The water molecule also appeared to be disordered among several orientations. This disorder could not be adequately defined nor could the hydrogen atom positions be determined, so only the oxygen atom corresponding to the most populated orientation was included in the refinement.

Refinement of the H atoms proceeded satisfactorily except for HC(14) and HC(23) which shifted to unrealistic positions. As a result these two were put in at their calculated positions (C—H 0.95 Å, C sp^2 geometry) and not refined in the last cycles.

In the final cycle 430 variables were refined using 3614 observations to final agreement factors of $R_1 = 0.044$ and $R_2 = 0.060$. The error in an observation of unit weight was 1.62e and the largest parameter shift was 0.8 times its estimated standard deviation. The largest peak in a difference Fourier, calculated from the final structure factors, with an electron density of 0.27 e Å^{-3} and located at (0.025, 0.226, 0.354) was not deemed chemically significant.

The final atomic positional and thermal parameters are given in Tables 2 and 3 while the list of observed and calculated structure factors is presented in Table 4.[3]

Results and Discussion

Characterization of the Ligand

In a previous paper (6) we reported the synthesis of the 'tripod' ligand tris(2-benzimidazylmethyl)amine by the high temperature condensation of nitrilotriacetonitrile with *o*-phenylenediamine. Extension of this reaction to the thermal fusion of nitrilotriacetonitrile and *o*-aminobenzenethiol led to the formation of the trisbenzothiazole analogue, tris(2-benzothiazolylmethyl)amine (NTBT, Fig. 1). This compound, which has not been previously reported in the literature, is characterized by elemental analysis, infrared, nmr, and mass spectral data (see Experimental). In the nmr spectrum a single methylene resonance occurs at 4.38 ppm and two complex multiplets at 7.45 and

†Solution decomposes on standing.

7.94 ppm, typical of 2-substituted benzothiazoles. X-ray crystallography confirms the molecular identity of NTBT in the complex $[Cu(NTBT)(NO_3)]\ NO_3 \cdot \frac{1}{2}H_2O$.

Characterization of the Complexes

Ligand Field and Electron Spin Resonance Spectra

The mixed stereochemistry complexes $[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br) (**I**, **II**) have solid state electronic spectra which comprise *d–d* bands associated with trigonal bypyramidal copper centres, $[Cu(NTBT)X]^+$ (1, 4, 7, 8), and also charge transfer absorptions associated with the tetrahalogenocuprate anions (23) (Table 5). *d–d* bands associated with these anions could not be clearly discerned in the solid state spectra, but would probably occur below 9000 cm^{-1} (24). The chloro-complex $[Cu(NTBT)Cl](BPh_4) \cdot (CH_3CN)_2 \cdot \frac{1}{2}H_2O$ (**III**) exhibits a solid state spectrum similar to compound **I**, associated with the trigonal bipyramidal cation $[Cu(NTBT)Cl]^+$.

Many attempts to synthesize the analogous bromide complex, $[Cu(NTBT)Br](BPh_4)$, were unsuccessful. In the reaction between copper bromide, NTBT, and sodium tetraphenylborate in acetonitrile two products were obtained. Initially a buff–brown crystalline solid (**IV**) was obtained followed by lime–green crystals (**V**). The buff–brown product (**IV**) has a major absorption at 9100 cm^{-1} with a shoulder at 12 300 cm^{-1} in its solid spectrum, suggesting the presence of the cation $[Cu(NTBT)Br]^+$. No other *d–d* or charge transfer absorptions were apparent in the spectrum below 25 000 cm^{-1}. The lime–green product (**V**) exhibits just one major absorption in the solid state at 10 900 cm^{-1}. The absence of a high energy shoulder in this case probably signals the presence of a six-coordinate species. A neutral derivative involving two coordinated bromine atoms is supported by other data. Reaction of $[Cu(NTBT)Br]_2[CuBr_4]$ (**II**) with sodium tetraphenylborate in acetonitrile led to the same mixture of products.

Compound **IV** appears to contain the five-coordinate cation $[Cu(NTBT)Br]^+$, but must also have a metal-containing anion (Table 1). A clue as to the identity of this anion comes from the solution spectrum of $[Cu(NTBT)Br]_2[CuBr_4]$ (**II**) in acetonitrile. This compound has a dark purple – black colour in the solid state but dissolves in acetonitrile to give a green solution. The electronic spectrum of this solution (Fig. 2*A*) has a *d–d* absorption at 10 000 cm^{-1}, with a high energy shoulder at 11 400 cm^{-1}, and an intense charge transfer band at 15 800 cm^{-1}. No absorptions due to $[CuBr_4]^{2-}$ are observed. The charge transfer absorption at 15 800 cm^{-1} corresponds very closely with an equivalent band observed for $[Cu_2Br_6]^{2-}$ in solution in glacial acetic acid (24) and in acetonitrile (Table 5). It is suggested that $[Cu(NTBT)Br]_2[CuBr_4]$ is undergoing an equilibrium disproportionation in acetonitrile according to the following

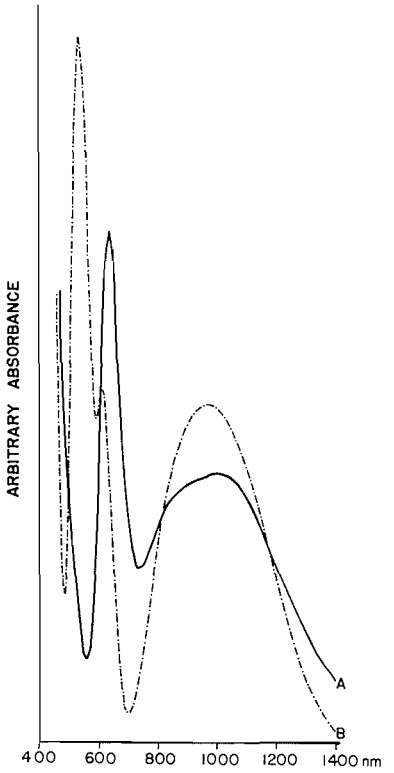

FIG. 2. Electronic spectrum of $[Cu(NTBT)Br]_2[CuBr_4]$ (*A*) in acetonitrile; (*B*) with added Br^-.

equation:

$$2[Cu(NTBT)Br]_2[CuBr_4] \quad \text{(purple)} \rightleftharpoons[CH_3CN] [Cu(NTBT)Br_2] + 2[Cu(NTBT)Br]^+ + [Cu_2Br_6]^{2-} \quad \text{(green)}$$

Addition of bromide ion to the green solution causes an immediate colour change to purple and a concomitant change in the spectrum (Fig. 2*B*) revealing the loss of $[Cu_2Br_6]^{2-}$ and the appearance of charge transfer bands associated with $[CuBr_4]^{2-}$. The absorption envelope around 10 000 cm^{-1}, which must contain components associated with $[Cu(NTBT)Br]^+$, $[Cu(NTBT)Br_2]$, and $[Cu_2Br_6]^{2-}$ increases in intensity on addition of bromide, with the loss of the shoulder at 11 400 cm^{-1}, and on further addition of bromide approaches the absorption energy associated with $[Cu(NTBT)Br_2]\cdot H_2O$. Addition of excess bromide causes enhancement of the bands associated with $[CuBr_4]^{2-}$ and a weakening of the absorption around 10 000 cm^{-1} indicating displacement of NTBT. A similar situation is observed in nitromethane.

The mixture of products (**IV** and **V**) obtained in these reactions in acetonitrile can be explained by the above equation. The lime-green crystalline product (**V**) is identified as $[Cu(NTBT)Br_2]\cdot H_2O$, a neutral six-coordinate species while compound **IV** is identified as $[Cu(NTBT)Br]_2[Cu_2Br_6]\cdot CH_3CN$. Since no charge transfer band is observed for $[Cu_2Br_6]^{2-}$ in the solid state (24) (Table 5) it is no surprise that only *d–d* bands are observed in the solid state spectrum of this compound.

The solution spectra of compound **IV** do not exhibit any charge transfer bands attributable to $[Cu_2Br_6]^{2-}$ in either acetonitrile or nitromethane. In acetonitrile the only absorption is a symmetrical single band at 10 500 cm^{-1}, corresponding almost exactly with the spectrum of $[Cu(NTBT)Br_2]\cdot H_2O$ (**V**) and it is perhaps no coincidence that this species is obtained as the sole product on recrystallization of $[Cu(NTBT)Br]_2[Cu_2Br_6]$ from acetonitrile. Although no spectral evidence exists for the presence of $[Cu_2Br_6]^{2-}$ in a nitromethane solution of **IV**, the band at 13 900 cm^{-1} is perhaps indicative of a partially solvated species derived from $[Cu_2Br_6]^{2-}$. On addition of bromide ion this band and the absorption at 9 400 cm^{-1}, due to $[Cu(NTBT)Br]^+$, rapidly coalesce with the formation of a single absorption at 10 600 cm^{-1}, followed by the appearance of charge transfer bands due to $[CuBr_4]^{2-}$.

Solution spectra of $[Cu(NTBT)Cl]_2[CuCl_4]$ (**I**) in acetonitrile and nitromethane exhibit bands attributable to $[Cu(NTBT)Cl]^+$ but no charge transfer bands are observed which can be associated with $[CuCl_4]^{2-}$ or $[Cu_2Cl_6]^{2-}$ (24). Presumably the major components in these solutions are [Cu(NTBT)Cl]Cl and solvated $CuCl_2$.

The solid state spectrum of the nitrate complex **VI** exhibits a major absorption at 11 800 cm^{-1} with a low energy shoulder, perhaps more typical of a six-coordinate derivative. X-ray structural data (see Discussion) indicate a highly distorted five-coordinate structure in which the close approach of a second oxygen atom from the coordinated nitrate group can possibly be considered as a weakly bound sixth ligand. In solution in nitromethane a single absorption is observed at 12 600 cm^{-1}, associated with a 1:1 electrolyte (see conductance discussion). A six-coordinate solution species with, e.g., a CuN_4O_2 chromophore would be expected to absorb at somewhat higher energy and so the nitromethane solution species is assumed to be $[Cu(NTBT)(NO_3)]^+$.

The solid state spectrum of the perchlorate complex reveals two quite widely separated bands at 15 000 and 9 500 cm^{-1}. The high energy absorption and the large separation of the two components

*Labels mean the following: *a*, powder spectrum (room temperature); *b*, frozen nitromethane glass (77 K); *c*, frozen methanol glass (77 K).
†Hyperfine coupling constants in units 10^{-4} cm^{-1}
‡$g_{\|} = 1.94$, $A_{\|} = 68 \times 10^{-4}$ cm^{-1} (estimated).

suggests a six-coordinate solid state structure (25) involving two coordinated water molecules. In nitromethane an absorption at 11 800 cm^{-1} with a high energy shoulder is indicative of a trigonal bipyramidal solution species involving either coordinated water or solvent.

In all the systems studied *d–d* absorptions associated with five- or six-coordinate complexes are comparable in energy with those observed for copper complexes of NTB (7, 8), in which the tripod ligand acts as an N_4 donor. This, combined with the absence of any absorption which could be associated with Cu–S interactions, suggests that NTBT is acting as a nitrogen donor in all cases. Confirmation of this, of course, is evident from the X-ray structure of $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$.

The 'tripod' ligand tris(2-benzimidazylmethyl)amine (NTB), which is structurally similar to NTBT, forms copper complexes with both five-coordinate trigonal bipyramidal and pseudo-octahedral stereochemistries (7, 8). Powder esr spectra recorded at X-band frequency and ambient temperature for the pseudo-octahedral systems in general exhibit three *g* values, while only one signal is observed in the powder spectra of the five-coordinate derivatives. In frozen methanol glass (77 K) all the copper/NTB complexes exhibit spectra typical of trigonal bipyramidal species in which $g_{\|} < g_{\perp}$ and low values of $A_{\|}$ are observed (7, 9, 10).

Broad isotropic resonances are observed in the powder spectra of the mixed stereochemistry complexes $[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br) (**I**, **II**) and also in the case of the nitrate complex $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$ (Table 6). The bromo-complex $[Cu(NTBT)Br]_2[Cu_2Br_6] \cdot CH_3CN$ has one major resonance at $g = 2.16$ with a weak additional feature at $g = 2.06$ which distinguishes this system from bromo-complex **II**. It is clear that in these systems intermolecular interactions are responsible for the exchange broadening apparent in the spectra. For the remaining complexes $g_{\|}$ and $g_{\perp}$ have been estimated, but again exchange broadening gives spectra which provide little definitive structural information.

In frozen glass at 77 K the esr spectra of some of these complexes are much more informative. The chloro-complex **III** has a typical trigonal bipyramidal spectrum in the $\perp$ region with a very low value of the hyperfine coupling constant (63×10^{-4} cm^{-1}) (Fig. 3). The lowest value previously reported for a trigonal bipyramidal system of this sort was for $[Cu(Et_6tren)Cl]Cl$ ($A_{\perp} = 79 \times 10^{-4}$ cm^{-1}) (9). No clearly defined features appear in the parallel region of the spectrum. A similar situation exists in the cases of the nitrate and perchlorate complexes (**VI**, **VII**). Typical trigonal bipyramidal features are observed in the $\perp$ region of the spectra with much larger values of $A_{\perp}$. Very weak features occur in the parallel region and only in the case of the perchlorate complex could an estimate of $g_{\|}$ and $A_{\|}$ be made. The close similarity between the spectra of these two systems suggests structurally similar species in the frozen glass.

The six-coordinate bromo-complex $[Cu(NTBT)Br_2] \cdot H_2O$ (**V**) exhibits a broad single

resonance in nitromethane at 77 K but in methanol the spectrum resembles that of a trigonal bipyramidal species. Copper hyperfine features are observed only in the $\perp$ region of the spectrum and it appears that in methanol at 77 K dissociation occurs to produce a five-coordinate species, possibly $[Cu(NTBT)Br]^+$. The complexes $[Cu(NTBT)X]_2[CuX_4]$ (X = Cl, Br) (**I**, **II**) exhibit essentially broad single resonances in nitromethane at 77 K with weak copper hyperfine splitting on the low field side of the resonance, suggesting the presence of a five-coordinate species. The weakness of these features prevented an estimate of g and A. It is evident that exchange effects in the glass are responsible for these largely structureless spectra. A similar situation is observed in the case of the complex $[Cu(NTBT)Br]_2[Cu_2Br_6]\cdot CH_3CN$ (**IV**). An examination of the half field region reveals signals at $g \simeq 4$ for compounds **I**, **II**, and **IV** suggesting the presence of spin-coupled dimeric species in all cases. For compound **IV** the antiferromagnetically coupled anion $[Cu_2Br_6]^{2-}$ could be responsible for the $g \simeq 4$ signal while in compound **II** it has already been shown that $[Cu_2Br_6]^{2-}$ is present in nitromethane. While it is not obvious from the room temperature electronic spectrum of $[Cu(NTBT)Cl]_2[CuCl_4]$ (**I**) in nitromethane that, e.g., $[Cu_2Cl_6]^{2-}$ is present, the appearance of a $g \simeq 4$ signal in the frozen glass esr spectrum does suggest the presence of an antiferromagnetically coupled species like $[Cu_2Cl_6]^{2-}$.

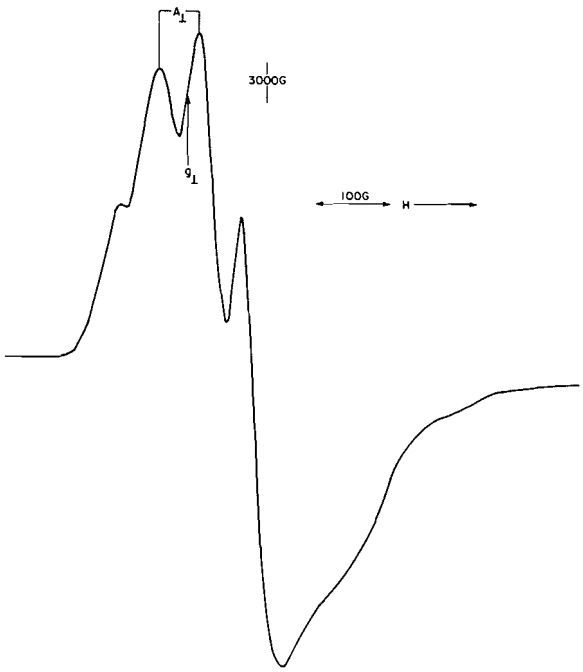

FIG. 3. Electron spin resonance spectrum (X-band) of frozen solution of $[Cu(NTBT)Cl]BPh_4\cdot(CH_3CN)_2\cdot\frac{1}{2}H_2O$ in nitromethane at 77 K.

Infrared Spectra

A comparison of compounds **I**–**V** allows the assignment of bands associated with metal–halogen and metal–nitrogen stretching (Table 7). Single absorptions are observed for ν(M—X) in the trigonal bipyramidal cations $[Cu(NTBT)X]^+$ (X = Cl, Br) while in the case of the pseudo-octahedral complex $[Cu(NTBT)Br_2]\cdot H_2O$ (**V**) two bands associated with Cu—Br stretching can be observed, consistent with a *cis*-structure. Absorptions at 272 (**I**) and 220 cm^{-1} (**II**) are assigned to Cu—X stretching in $[CuCl_4]^{2-}$ and $[CuBr_4]^{2-}$ respectively (26, 27), while for **IV** two absorptions at 240 (sh) and 225 cm^{-1} are associated with Cu—Br stretching in $[Cu_2Br_6]^{2-}$ (24).

Combination bands ($\nu_1 + \nu_4$) due to nitrate absorptions in **VI** occur at 1755, 1736, and 1719 cm^{-1}. The band at 1736 cm^{-1} can be associated with ionic nitrate while the other two bands are due to a coordinated nitrate group. The separation of these two bands is usually a reasonable indication of the bonding mode of such a group (28) and a difference of 36 cm^{-1} is large enough to suggest a bidentate nitrate. In this case, however, X-ray data formally define the coordinated nitrate as monodentate but weak involvement of a second nitrate oxygen to the copper centre is suggested from infrared data. In the perchlorate complex (**VII**) the ν_3 perchlorate absorption appears as a broad strong single band indicating the presence of ionic perchlorate and weak absorptions at 3580 and 3460 cm^{-1} are associated with coordinated water.

The complex $[Cu(NTBT)Cl]BPh_4(CH_3CN)_2\cdot\frac{1}{2}H_2O$ (**III**) has doublet absorptions at 2248, 2260 and 2290, 2300 cm^{-1} which are associated with lattice bound acetonitrile. No evidence exists for coordinated acetonitrile. Similar, but very weak, absorptions are found in the bromo-complex **IV** (29).

Magnetism and Conductance

Magnetic moments (Table 8) for compounds **I**–**III**, **V**–**VII** are normal for Cu(II) complexes of this sort. However, the moment associated with $[Cu(NTBT)Br]_2[Cu_2Br_6]\cdot CH_3CN$ falls below the spin only value at room temperature and is consistent with the presence of the antiferromagnetically coupled anion $[Cu_2Br_6]^{2-}$ (30). The room temperature moment of $KCuBr_3$ lies below the spin only value ($\mu_{eff(295\ K)} = 1.52$ BM) and so would be responsible for reducing the net moment of compound **IV**.

Conductance data are reported for several com-

TABLE 7. Infrared data (cm^{-1})

VII, $[Cu(NTBT)(H_2O)_2](ClO_4)_2 \cdot MeOH \cdot H_2O$		325	1100(ν_3, ClO_4^-)

TABLE 8. Magnetic moment and conductance data

Compound	μ(BM) (room temperature)	$\Lambda_M(MeNO_2)$ (Ω^{-1} mol^{-1} cm^2)
I, $[Cu(NTBT)Cl]_2[CuCl_4]$	1.90	
II, $[Cu(NTBT)Br]_2[CuBr_4]$	1.94	
III, $[Cu(NTBT)Cl]BPh_4 \cdot (CH_3CN)_2 \cdot \frac{1}{2}H_2O$	1.75	40
IV, $[Cu(NTBT)Br]_2[Cu_2Br_6] \cdot CH_3CN$	1.62	
V, $[Cu(NTBT)Br_2] \cdot H_2O$	1.84	36
VI, $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$	1.83	73
VII, $[Cu(NTBT)(H_2O)_2](ClO_4)_2 \cdot MeOH \cdot H_2O$	1.79	130

pounds (Table 8). $[Cu(NTBT)(H_2O)_2](ClO_4)_2 \cdot H_2O \cdot MeOH$ (**VII**) behaves as a 1:2 electrolyte in nitromethane. The lime-green neutral complex $[Cu(NTBT)Br_2] \cdot H_2O$ (**V**) has a low conductance, although it is largely undissociated. The low value associated with $[Cu(NTBT)Cl]BPh_4 \cdot (CH_3CN)_2 \cdot \frac{1}{2}H_2O$ (**III**) is consistent with a 1:1 electrolyte involving the large tetraphenylborate anion (31) and $[Cu(NTBT)(NO_3)]NO_3 \cdot \frac{1}{2}H_2O$ (**VI**) appears to be a 1:1 electrolyte also in nitromethane.

Structure Description

A perspective view of the cation, including the atom numbering scheme, is shown in Fig. 4. The Cu atom is coordinated to the four N atoms of NTBT and to an oxygen atom (O(1)) of one of the nitrate anions to form a distorted trigonal bipyramidal structure, with N(1) and O(1) axial. The ligand NTBT coordinates to the Cu atom in a tripod fashion similar to that observed in a series of Cu–tren and Cu–trenMe complexes (2, 3, 32, 33), and Cu–NTB complexes (7, 8). The 'backbone' of the NTBT ligand is a close structural analogue to tren, trenMe, and NTB and it is not surprising that a similar coordinating geometry should be adopted in the Cu complexes of these ligands.

The distortion from a regular trigonal bipyramid in the copper coordination polyhedron occurs in two ways. The bond angles N(1)—Cu—N(2), N(1)—Cu—N(3), and N(1)—Cu—N(4) are all less than 84°, indicating a tetrahedral distortion with the copper atom displaced below the equatorial plane. This sort of distortion is common in other systems

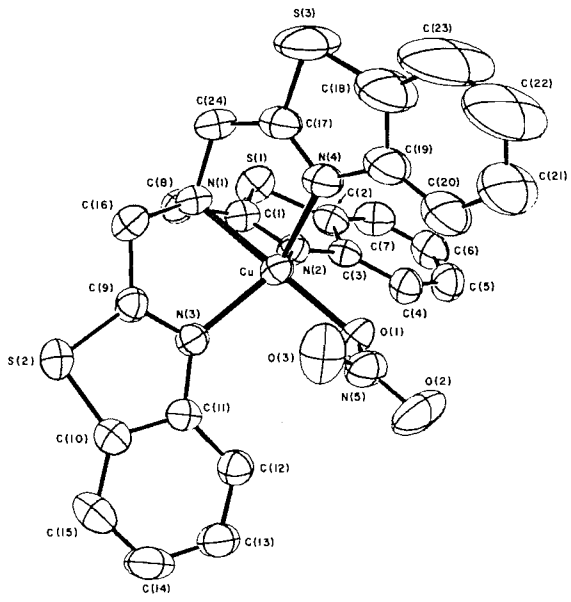

FIG. 4. Perspective view of the cation showing the atom numbering scheme. The atoms are represented by 50% probability thermal ellipsoids and the hydrogens have been omitted for clarity.

involving tren and trenMe (2, 3, 32, 33). Also the ligand does not possess C_3 crystallographic symmetry and is bent back with a large equatorial angle N(3)—Cu—N(4) of 137°. The other two equatorial angles are, as a consequence, significantly less than 120°. Although in the tren complex, [Cu(tren)NCS]NCS, a large equatorial angle of 130° is observed (2), angles closer to 120° are observed in other tren complexes, e.g., $[Cu_2(tren)_2X_2](BPh_4)_2$ (X = Cl, NCO, CN) (32, 33). In the case of the complex [Cu(trenMe)Br]Br (3) the ligand exhibits C_3 crystallographic symmetry, perhaps indicating the presence of a steric constraint due to the bulk of the N-methyl groups.

The Cu—N distances in $[Cu(NTBT)(NO_3)]\text{-}NO_3\cdot\frac{1}{2}H_2O$ (Table 9) range from 2.048(3) to 2.120(3) Å and do not differ significantly from the mean value of 2.07(3) Å. These distances are comparable to the Cu—N distances observed in the tren and trenMe complexes (2, 3, 32, 33) and are representative of normal Cu—N bond lengths.

The internal geometry of the NTBT ligand shows no unusual features, with the bond distances and angles of the benzothiazole rings similar to values

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

determined in a crystal structure of a Cu complex of another ligand containing these groups (34). The mean distances and angles within the phenyl rings are: for C(2)—C(7), 1.38(2) Å, 120(2)°; for C(10)—C(15), 1.39(2) Å, 120(1)°; for C(18)—C(23), 1.38(3) Å, 120(1)°. The C—H distances range from 0.7(1) to 1.10(5) Å with appropriate geometries for sp^2 and sp^3 C atoms.

When bonding to a single metal atom a nitrate group may behave as a unidentate ligand or a symmetrical or unsymmetrical bidentate ligand. In a review of metal–nitrate bonding (35) it is suggested that the nitrate is to be considered unidentate if the difference in the two closest metal–oxygen distances exceeds 0.7 Å. In the present complex the difference between Cu—O(1) and Cu—O(3) is 0.84(5) Å. While this exceeds the limit suggested by Addison *et al.* (35) it is not unambiguous, from the structural information, that the nitrate is unidentate.

One of the major distortion features of the structure is the large equatorial angle N(3)—Cu—N(4) of 137°. Oxygen atom O(3) is within 3.3 Å of N(3) and N(4) with N(3) and N(4) lying 1.82 and 1.98 Å respectively on opposite sides of the mean plane of Cu—O(1)—O(2)—O(3)—N(5). The nitrate plane therefore approximately bisects the N(3)—Cu—N(4) angle, being somewhat closer to N(3). If this structural perturbation can be considered to be the result of a close approach of oxygen O(3) to the copper centre, then a decision as to whether it should be considered a ligand may be difficult to make on the basis of X-ray data alone. According to Addison *et al.* (35) a decrease in the Cu—O(3) separation of only 0.14 Å would qualify the nitrate as a bidentate ligand. It is evident that the bending back of the N(3)—Cu—N(4) framework could be carried to a logical conclusion in which the N(3)—Cu—N(4) angle approached 180° and resulted in a pseudo-octahedral species. Under these circumstances the ambiguous structural results may be clarified by examining the spectroscopic properties of the complex. In this case there is evidence, *vide supra*, that the nitrate is acting as a pseudo-bidentate ligand, with a weak interaction from O(3), making the Cu complex almost six-coordinate.

The nitrate anions and the water molecule may be involved in a weak hydrogen bonding network, with the closest distances of approach being 2.57 Å between O(7) and O(4) and 2.96 Å between O(7) and O(5)′.

A high-field proton magnetic resonance and nuclear Overhauser effect study of prostaglandin E_2[1]

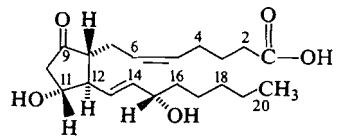
GEORGE KOTOVYCH,[2] GERDY H. M. AARTS, AND GLEN BIGAM
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 18, 1980

GEORGE KOTOVYCH, GERDY H. M. AARTS, and GLEN BIGAM. Can. J. Chem. **58**, 1577 (1980).

The proton magnetic resonance (^{1}H nmr) spectrum of prostaglandin E_2 (PGE_2) in $CDCl_3$ at 400 MHz has been completely analyzed utilizing homonuclear double resonance, inversion recovery, and nOe difference experiments. The nOe difference experiments are used to assign points of configuration, namely the H-10β and the H-10α proton resonances. A spectral analysis shows that the two protons at C-3 and the two protons at C-4 are nonequivalent, indicating a hindered rotation of the chain. This is possibly due to the hairpin conformation of PGE_2 in solution.

GEORGE KOTOVYCH, GERDY H. M. AARTS et GLEN BIGAM. Can. J. Chem. **58**, 1577 (1980).



On a analysé en détail le spectre de résonance magnétique du ^{1}H de la prostaglandine E_2 (PGE_2) dans le $CDCl_3$ à 400 MHz, en utilisant la double résonance homonucléaire, l'inversion de recouvrement et les expériences de différence d'effet Overhauser nucléaire (eOn). On a utilisé les expériences de différence de eOn pour établir la configuration en certaines positions de la molécule, par exemple les résonances du H-10β et du H-10α. L'analyse spectrale révèle que les deux protons en C-3 et en C-4 ne sont pas équivalents, indiquant ainsi que la rotation de la chaîne n'est pas libre. Ceci est probablement dû à une conformation en épingle à cheveux du PGE_2 en solution.

[Traduit par le journal]

Introduction

The prostaglandins, fatty acids with a wide range of biological activities, are being extensively studied from a structure–activity viewpoint (1–6). Many of the prostaglandins are characterized by a hairpin-like structure (5), which can be seen from the structural formula for prostaglandin E_2 (PGE_2). X-ray studies on a variety of prostaglandins including PGE_2 (8) have been carried out (P. Crabbé, ref. 2, pages 315–319; 7, and references therein), but since structure and activity are intimately related, the solution conformation may also be important.

One approach to the study of solution conformation involves nuclear Overhauser enhancement (nOe) experiments (9) which give information on molecular geometry. We have therefore undertaken a 400 MHz proton magnetic resonance study of PGE_2. The high-field instrument was required in order to separate the various resonances arising from the presence of a large number of similar protons in the molecule. A complete assignment of the resonances is achieved mainly by means of selective decoupling experiments. The nOe difference experiments are used to confirm several proton assignments. This technique was previously applied to gain information concerning the spatial structures of the basic pancreatic trypsin inhibitor (10), for spectral assignments in lysozyme (11), and in the study of the dependence of the homonuclear nOe, at two frequencies, on the correlation time (12). We have applied this technique in the study of vitamins D_2 and D_3 (13) and prostacyclin (14). Proton nOe difference experiments have the distinct advantage in that one experiment picks out all of the protons that are in close proximity to the irradiated proton even if these proton resonances are hidden by other multiplets.

In previous studies, the chemical shifts of prostaglandin A_2 methyl ester in the presence and absence of a lanthanide ion shift reagent have been measured in $CDCl_3$ at 100 MHz (15). Most of the protons could be assigned but H-3, H-18, and H-19 could only be assigned in the presence of the shift reagent. H-8, H-16, and H-17 could not be assigned. The nonequivalence of H-16 and 16* or H-7 and 7* could not be observed. Proton chemical shifts for prostaglandin $F_{2\alpha}$ in phosphate buffer were assigned at 270 MHz using decoupling techniques (16), but the chemical shift of the protons at C-3 and the nonequivalence of the protons at C-7 and C-16 were also not observed. Conover and Fried (16) analyzed the proton–proton coupling constants for the five-membered ring in terms of the Karplus curve (17, 18) and the analysis indicates a

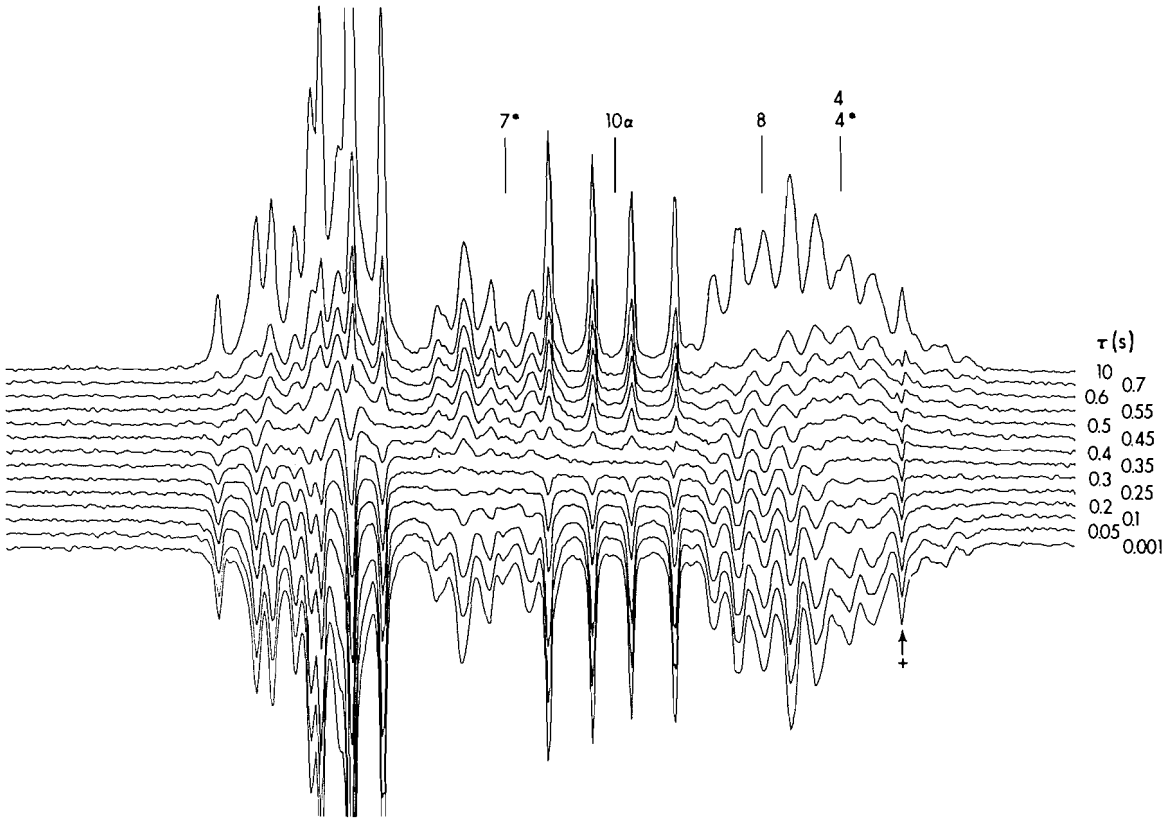

FIG. 2. The 180°—τ—90° inversion recovery spectra of PGE_2 in $CDCl_3$ at 297 K obtained at 400 MHz. The + indicates an instrumental artifact.

favored half-chair conformation for the ring which causes the maximum number of substituents of this ring to be pseudo-equatorial. Only the hydroxyl group at C-9 is in the pseudo-axial orientation.

In the present study, a complete, unambiguous assignment of the proton magnetic resonance spectrum of PGE_2 is obtained. The nOe difference experiments verify the assignment of the H-10α and H-10β resonances. Exact chemical shifts for some of the overlapping multiplets are obtained with the aid of inversion recovery measurements (19, 20). A spectral analysis shows that the protons at C-3 and C-4 are nonequivalent.

Materials and Methods

Prostaglandin E_2 was obtained from Sigma Chemical Co., St. Louis, MO, U.S.A. The samples were prepared in $CDCl_3$, 99.8% deuterated, obtained from SCI-Graphics at a concentration of 2 mg per 0.35 cc. The $CDCl_3$ was purified by treating it with Al_2O_3 (B.D.H. Chemicals Ltd.) and then vacuum degassing it several times before transferring it *in vacuo* into the nmr tube containing the solid prostaglandin, which was then sealed. All glassware was extensively cleaned to eliminate paramagnetic impurities following procedures previously reported (21).

The proton magnetic resonance spectra were obtained at 297 K on a Bruker WH-400/DS nmr spectrometer (400 MHz) operating in the pulsed Fourier transform mode using the Bruker Aspect 2000 computer, 16K data points, and a pulse width of 5 μs. The deuterium resonance of the solvent $CDCl_3$ was used as the lock signal. The homonuclear decoupling experiments were also performed in the pulse mode and these experiments allowed the assignment of all proton resonances in the molecule following standard procedures (22–24). The chemical shifts and coupling constants were calculated from normal spectra (except for H-2, 3, 3*, 4, 4*), obtained using 32K data points and expanded to a sweep width of 2 Hz/cm. Specific examples of some of the decoupling experiments are now summarized. The complete 400 MHz spectrum of PGE_2 is shown in Fig. 1A. Irradiation of H-5 and H-6 indicates the chemical shifts of H-7 and 7*, and H-4 and 4* (Fig. 1B). Upon irradiating H-11 (Fig. 1C), the H-10β and H-10α multiplets collapsed into doublets and were assigned, as was the multiplet for H-12. Upon irradiating H-13, the H-12 multiplet simplified and the centre of the multiplet could be determined. In Fig. 1D, the H-3 and 3* multiplet was irradiated, indicating the chemical shift of H-2 and H-4. Finally, irradiation of H-15 gives the position of the H-16 and 16* multiplets.

The chemical shifts, especially for the overlapping multiplets, can be confirmed by the inversion recovery experiments. In Fig. 2, for a time interval of 0.35 s between the 180° and the 90° pulses, the H-4 multiplet is nulled, whereas an excellent, but inverted spectrum is observed for H-8, confirming the chemical shift for this proton. As well, inversion recovery experiments were repeated with simultaneous decoupling of the protons at C-5 and C-6. Using a τ value of 0.57 s, an excellent spectrum is obtained for the two C-4 protons, which are nonequivalent. This

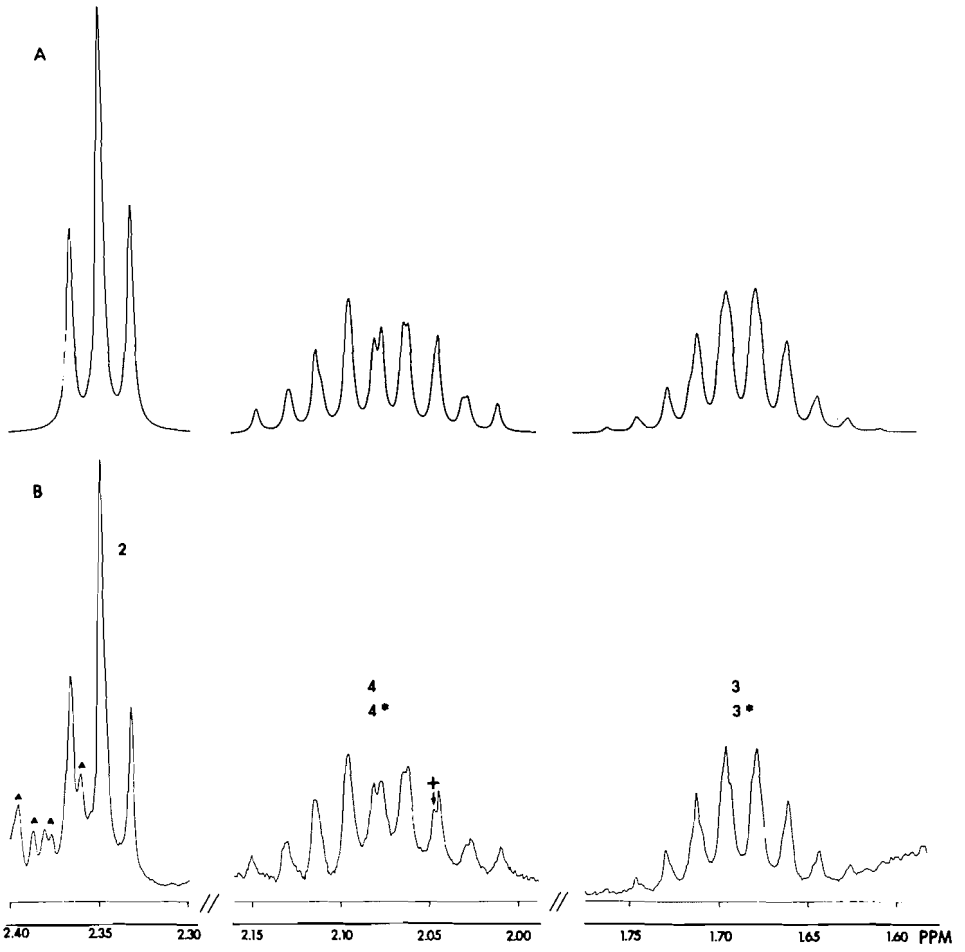

FIG. 3. (A) Simulated spectrum for the H-2, H-4*, 4, and the H-3*, 3 protons from low to high field, respectively. A line width at half height of 1.7 Hz was used. (B) The observed spectra for these protons, obtained with simultaneous decoupling of H-5 and H-6. The spectrum for H-4 and 4* was obtained from the 180°—τ—90° inversion recovery experiment ($\tau = 0.57$ s) also while irradiating H-5 and H-6. The delay time was 10.0 s; 32K data points were used to obtain maximum resolution. The + indicates an experimental artifact, seen in Fig. 2. The ▲ indicates peaks corresponding to protons 7 and 12.

was shown by a computer simulation of an $ABMNX_2$ system, where A and B refer to H-4 and 4*, M and N refer to H-3 and 3*, and X_2 refers to the two C-2 protons. The simulated spectrum is shown in Fig. 3A whereas the observed spectrum is shown in Fig. 3B. The observed spectrum for H-3 and 3* as well as for H-2 was obtained with simultaneous decoupling of the protons at C-5 and C-6. Considering the fact that the H-2 multiplet partially overlaps the H-7 multiplet, that the H-3 and 3* multiplet partially overlaps the H-16 and 16* multiplet, and the fact that the H-4 and 4* multiplet is obtained from an inversion recovery experiment, the agreement between the calculated and experimental spectra is very good. A computer iteration was not attempted but the shifts and coupling constants were varied to obtain a good visual match between the calculated and the observed spectra. 32K data points were used to obtain the best experimental spectrum and the computer analysis was carried out using the Bruker software package.

The results of the nOe difference experiments, carried out in the standard manner (10, 12) are shown in Fig. 4. 16K data points were used for these experiments, a pulse width of 10.7 μs (90° pulse) and a delay time of 6 s.

Results and Discussion

The complete proton magnetic resonance spectrum of prostaglandin E_2 is shown in Fig. 1. The assignments corresponding to the individual protons are indicated on the spectrum. The calculated chemical shifts in ppm and coupling constants in Hz are given in Table 1. These were obtained from the regular, coupled spectra as well as from the inversion recovery experiments. With the exception of the data for protons 2, 3 and 3*, and 4 and 4*, the chemical shifts and coupling constants are reported to first order, and error limits of ±0.01 ppm (±4 Hz) for the chemical shifts and ±0.2 Hz for the coupling constants are reported. However, for many of the protons these error limits are considerably smaller.

The nOe difference experiments in Fig. 4 make use of the fact that only those protons in close

14	5.69	$J(14—15) = 6.6$
15	4.14	$J(15—16) = J(15—16^*) = 6.6$
16, 16*	1.53, 1.59	
17, 18, 19	1.31	
20	0.90	$J(19—20) = 6.7$

[a]The chemical shifts, with respect to TMS, and the coupling constants are calculated to first order except for H-2, H-3 and 3*, and H-4 and H-4* where those parameters were obtained from the simulated spectrum. The conditions for the experimental spectra are in the Fig. 3 legend.
[b]The H-7 and H-7* multiplets cannot be analyzed to first order due to virtual coupling arising from the nearly equivalent shifts for H-5 and H-6. Therefore measured splittings are reported, and where relevant, averaged with the splitting obtained for the H-8 multiplet from the inversion recovery spectra.

physical proximity to the irradiated proton will be observed, even if these proton resonances are hidden by other multiplets. Resonances corresponding to protons further removed from the irradiated protons will not be observed. As seen in Fig. 4B, upon saturation of the H-10β multiplet (and inversion, since a difference experiment is carried out), the H-10α proton experiences a very large nOe, as it is nearest the H-10β proton. An nOe is also observed for H-11 which is β to the ring. This shows that the low-field H-10 multiplet corresponds to H-10β. The assignment of H-10β to low field of the H-10α multiplet was confirmed by an nOe experiment in which H-11 is saturated (Fig. 4C) and an nOe is observed for the other protons that are β to the ring, namely H-10β and H-8β. An enhancement was not observed for H-10α. Protons H-12, H-13, and H-14 also experience an nOe. The H-10β multiplet has also been assigned to low field of the H-10α multiplet in prostacyclin (14) and this assignment is consistent with the torsion angle dependence of chemical shifts due to OH groups in pentacyclic systems (25). Previously for $PGF_{2\alpha}$, H-10α was assigned to low field of H-10β (16).

Additional nOe difference experiments on a sample containing a drop of D_2O were carried out to check for the effect of irradiation of the broad OH resonance which appears between ~2.5 and 5.5 ppm. Similar results to those seen in Figs. 4B and 4C were obtained, and the very small peaks at 5.6 and 4.14 ppm, observed in Fig. 4B, are not seen. The presence of the OH signal does not affect the conclusions reached from the nOe difference experiments.

The nonequivalence of H-7, 7* and H-16 and 16* is expected as they are bonded to a carbon next to an asymmetric centre, but the nonequivalence of protons 3, 3* and 4, 4* is most interesting. This may arise from hindered rotation of the α-chain, possibly due to the hairpin conformation of PGE_2. In fact, Anderson and Ramwell (5) in discussing prostaglandin conformations, suggest "that the major change in conformation in transport from lipid to aqueous media is the restriction of free rotation of the carboxyl side chain, which is consistent with the hairpin model". We suggest that the nonequivalence of H-3, 3* and H-4, 4* is due to this restriction of free rotation.

In summary, high field nmr double resonance, inversion recovery, and nOe difference experiments have allowed the assignment of the complete spectrum of prostaglandin E_2. The protons at C-3 and C-4 are nonequivalent, indicating a hindered rotation of the α-chain, possibly due to the hairpin conformation of PGE_2.

The enthalpy of solution of NaI, NaCl, $NaClO_4$, and urea in water–tetrahydrofuran mixtures at 298.15 K

STEFANIA TANIEWSKA-OSIŃSKA, BOŻENA PIESTRZYŃSKA, AND ROMAN ŁOGWINIENKO

Department of Physical Chemistry, Institute of Chemistry, University of Łódź, 18 Nowotki Street, Poland

Received September 13, 1979[1]

STEFANIA TANIEWSKI-OSIŃSKA, BOŻENA PIESTRZYŃSKA, and ROMAN ŁOGWINIENKO. Can. J. Chem. **58**, 1584 (1980).

The integral enthalpy of solution of NaI, NaCl, $NaClO_4$, and urea was measured in the concentration range 0.01–0.5 mol/kg in mixtures of water and 2.5, 5, 7.5, 10, and 20 mol% of tetrahydrofuran at 298.15 K.

STEFANIA TANIEWSKA-OSIŃSKA, BOŻENA PIESTRZYŃSKA, et ROMAN ŁOGWINIENKO. Can. J. Chem. **58**, 1584 (1980).

On a mesurée l'enthalpie integrale de dissolution de NaI, NaCl, $NaClO_4$ et de l'urée dans l'intervalle des concentrations 0.01–0.5 mol/kg dans les mélanges contenant de l'eau et de 2.5, 5, 7.5, 10, et 20 mol % de tetrahydrofuranne à la temperature de 298.15 K.

Introduction

The addition of a small amount of monohydric alcohol to water causes the occurrence of the maximum of solution enthalpy for electrolytes and urea. So far, alcohols have constituted the only known group behaving like that. The examinations of urea solutions in water + THF which were carried out by Treiner and Tzias (1) have suggested to us a possibility of observing similar changes in the enthalpies of solution of inorganic salts in H_2O + THF mixtures. The chosen electrolytes are NaI, NaCl, and $NaClO_4$. The common cation of these salts permitted to investigate the influence of iodide, chloride, and perchlorate anions on the structure of the mixed solvent. Non-electrolyte, urea, was chosen for the examination to allow us a comparison of the results obtained with the data contained in the literature.

Materials

$NaClO_4 \cdot xH_2O$ "puriss" produced by Merck, BRD, was dried at 90°C. NaI "puriss" produced by POCh Gliwice, Poland, was crystallized from an acetone–water mixture and dried under vacuum at 60°C (2). NaCl "puriss" and urea "puriss" produced by POCh Gliwice, Poland, was crystallized from twice distilled water and dried under vacuum at 100°C and 70°C respectively (2, 3).

Tetrahydrofuran "pure" produced by POCh Gliwice, Poland, was used. Peroxides were removed from it by shaking THF with $FeSO_4$ and then left over sodium hydroxide for 10 days, then distilled from above sodium (1) and distilled each time before use. Impurities together with water content in THF was estimated using a gas chromatograph by "Perkin–Elmer–Hitachi" and it did not exceed 0.02%. The estimation of water content in THF by Karl Fisher's method gave similar results.

Relative index, n_D = 1.4047 of THF is in reasonable agreement with literature data n_D = 1.4051 (4), 1.4048 (5).

Aqueous solutions of THF were prepared by weight. Twice distilled water was used.

Apparatus

The enthalpy of solution was measured using an "isoperibol" calorimeter. A glass calorimetric vessel with a capacity of approximately 200 cm^3 was provided with a glass stirrer and a calorimeter heater made from constantan wire (R = 25). The stirrer ended with a funnel to attach a thin-walled ampoule containing the investigated substance. The ampoule was broken against the bottom of the calorimeter. The calorimeter temperature was measured by a 16-junction thermocouple system connected to a DC nanovoltmeter type 252 produced by "Unipan". The temperature sensitivity was 5×10^{-5} deg.

Results and Discussion

The values of enthalpy of solution for NaI, NaCl, $NaClO_4$, and urea in THF + H_2O mixtures are presented in Figs. 1, 2, 3, 4 respectively. The measured enthalpies of solution of salts were extrapolated to zero concentration by the method used by Criss and Cobble (6). The dielectric constants and densities necessary for the calculations were taken from the literature (7, 8). The values for compositions used in this work were interpolated graphically. Since in the literature there were no data on the temperature dependence of dielectric constants the derivatives dD/dT corresponding to the examined compositions of the mixed solvent were determined graphically from the data of Bury *et al.* (7). The accuracy of interpolation $dD/dT = f(x)$ introduces an error into the enthalpy values, which does not exceed 4 J. The solution enthalpies of urea were extrapolated graphically. The obtained heats of solution at infinite dilution of the investigated electrolytes and urea in THF–H_2O mixtures are presented in Table 1 and in Fig. 5.

The standard integral enthalpy of solution of urea in water determined by us is 15.39 kJ mol^{-1} whereas the data of Malec and Sarnowski (9) 15.41 kJ mol^{-1}; Łogwinienko (10), 15.49 kJ mol^{-1}; de Visser *et al.* (11), 15.28 kJ mol^{-1}; Schrier *et al.* (12), 15.29 kJ mol^{-1}; Desnoyers *et al.* (13), 15.30 kJ mol^{-1}; Egon and Luff (14), 15.31 kJ mol^{-1}; and Bury *et al.* (15), 15.32 kJ mol^{-1}.

Our value for ΔH^0 of NaCl in water is 3.79 kJ

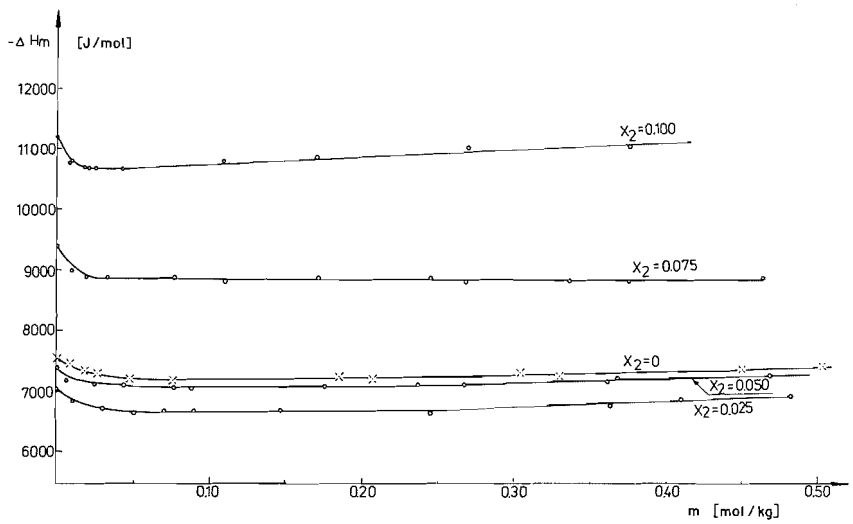

FIG. 1. Enthalpies of solution ΔH_m of NaI in THF + H_2O mixtures at 298.15 K; x_2 = mole fraction of THF.

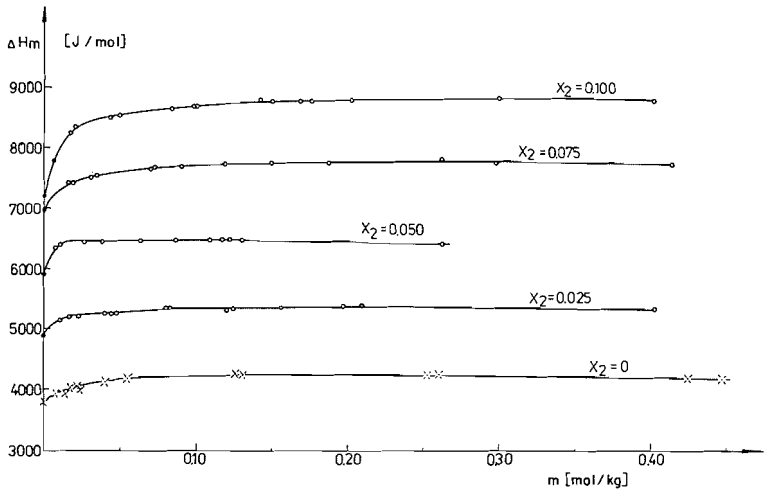

FIG. 2. Enthalpies of solution ΔH_m of NaCl in THF + H_2O mixtures at 298.15 K; x_2 = mole fraction of THF.

mol^{-1} whereas the literature values vary from 3.80 to 3.88 kJ mol^{-1} (6, 7, 16, 17). For ΔH^0 of NaI we obtained 7.54 kJ mol^{-1}, the literature values range from 7.58 to 7.79 kJ mol^{-1} (18–20). The standard ΔH^0 for $NaClO_4$ from our measurements is 14.57 kJ mol^{-1}. According to Lange and Martin (21), it amounts to 14.49 kJ mol^{-1}.

The heat of solution of NaCl and urea in H_2O + THF mixtures was also determined by Bury *et al.* (7, 15) and their data are also shown in Fig. 5. The reasons for disagreement between our data for urea and those of the above-mentioned authors are obscure.

Within the range of 0.035–0.045 mole fraction of THF the maximum of solution enthalpy for NaI, $NaClO_4$, and urea occurs. It is for the first time that in this work maxima of ΔH^0 within the water rich range have been observed for electrolytes in water–organic system not containing monohydric alcohol. It seems interesting that ΔH^0 maximum does not occur in NaCl solutions while in salt solutions in water–alcohol mixtures it occurs for all salts investigated up to now. Since the salts chosen have common cations we can compare the maxima of solution enthalpy regarding the relation between the anion size and the height of the observed maximum. As it is seen in Fig. 5 the height of maximum grows with increasing anion radius.

Dollet and Juillard (22, 23) examined the effect of substituents of benzoate ion on the transfer en-

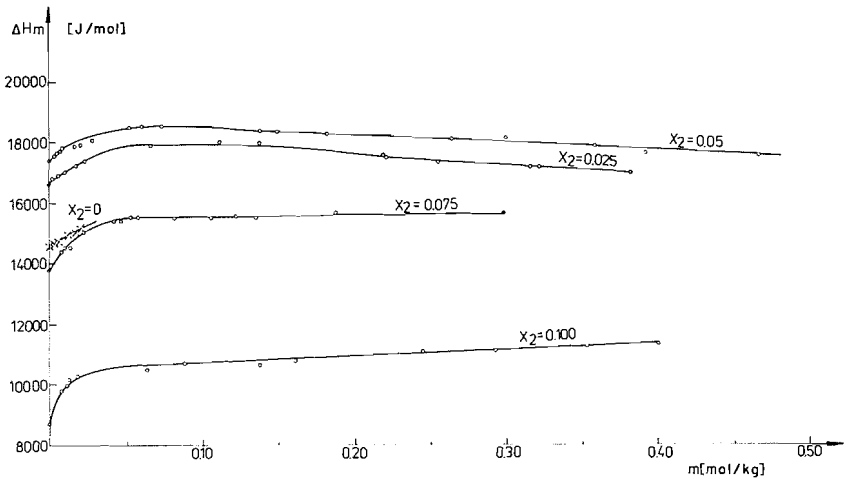

FIG. 3. Enthalpies of solution ΔH_m of $NaClO_4$ in THF + H_2O mixtures at 298.15 K; x_2 = mole fraction of THF.

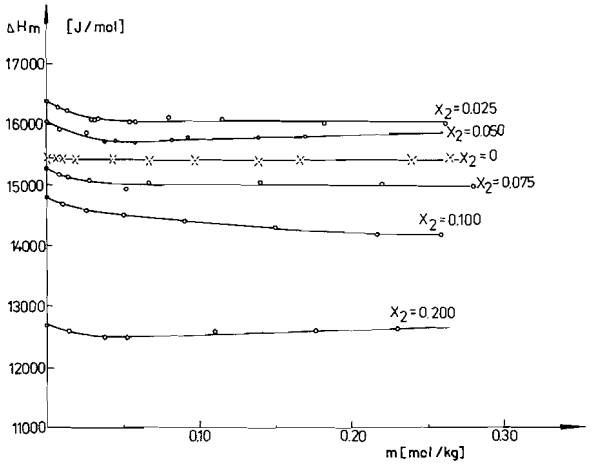

FIG. 4. Enthalpies of solution ΔH_m of urea in THF + H_2O mixtures at 298.15 K; x_2 = mole fraction of THF.

thalpy from water to water–*tert*-butanol mixtures. These authors observed the growth of the enthalpy maximum height with the substituent size. We have not found in the literature such observation in case of inorganic salt solutions, including electrolytes used in this work, in water–alcohol mixtures.

The maximum of the solution enthalpy of urea occurs due to the relatively large dimension of its molecule, half of the longest diameter, calculated according to the method of Kitaigorodsky (24) is 2.9 Å. The dimension of the urea molecule is smaller than the sum of the radii of the electrolytes exhibiting extrema, investigated in this work, and therefore the height of the maximum shown by the urea is smaller than the others.

It follows that the height of the maximum of solution enthalpy is affected only by the volume of the molecule solved and not by the presence or absence of the charges of ions.

The similarity of THF to alcohols arising from the observed maximum of the solution enthalpies of electrolytes in mixed solvents suggests that in the investigated system we deal with water structure ordering by small additions of THF. This is the reason why the lack of maximum for NaCl solutions is not clear. However, the values of entropy of transfer of NaCl from water to water + THF mixtures presented by Bury *et al.* (7) show a minimum.

Considering the fact that the entropy changes reflect the structure changes in the best way (19, 25), it can be assumed that NaCl behaviour does not differ from that of other solutes.

In many previous works (26–31), the conclusion on ordering and disordering effect of organic substances on water was drawn from the occurrence of maxima of the solution enthalpy of salts. It follows from the above that such reasoning may be misleading and the determination of entropy seems necessary as a criterion of structure changes.

Analogous course of mixing enthalpy of alcohols with water at 25°C, especially that of *n*-propanol (32) and of THF with water (33) reinforce the assumption about ordering effect of THF on water.

Kiyohara *et al.* (8) has observed a distinct maximum of partial molal excess thermal expansivity corresponding to 0.06 mol% of THF in water. The authors think that the physical sense of this extremum is not clear.

The analysis of nuclear magnetic relaxation times carried out by Goldammer and Hertz (34) has led to the conclusion that within the range of small THF content H_2O–H_2O interaction strengthens while THF–H_2O interaction can be neglected as

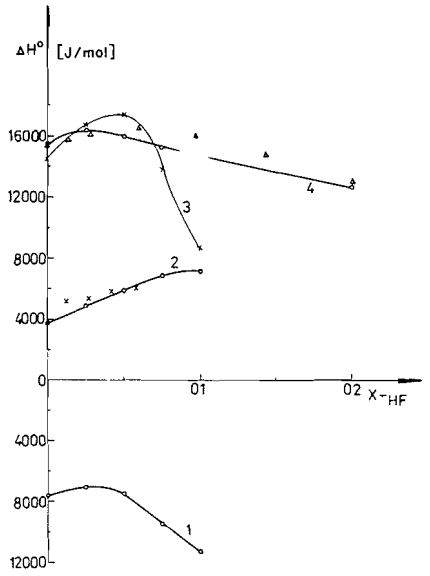

FIG. 5. Standard enthalpies of solution ΔH^0 of some solutes in THF + H_2O mixtures as a function of the mole fraction of THF at 298.15 K. *1*, NaI–THF + H_2O; *2*, NaCl–THF + H_2O; × NaCl–THF + H_2O (7); *3*, $NaClO_4$–THF + H_2O; *4*, urea–THF + H_2O; △ urea–THF + H_2O (1).

weak. This view speaks for the ordering effect of THF on water structure.

Analysing the physico-chemical properties of THF + H_2O mixtures, nmr spectra (35) and the shift of the temperature of maximum density of water affected by addition of THF, as well as the argon solubility data in THF + H_2O mixture (36), Kessler *et al.* (37) have come to the same conclusion as ours about water structure ordering by THF.

Extremum on curve $v = f(x)$ (38) (where v is the ultrasound velocity) corresponds, according to the authors, to the concentration 5 mol% at which the ordering of solvent is greatest but it is explained by the formation of clathrates with water by THF (one THF molecule – 17 water molecules).

Recently Iwasaki and Fujiyama (39) express their opinion on the existence of clathrates of THF in water and Gough (40) has the opposite opinion.

The extremes of solution enthalpy observed permit us to infer that the H_2O–H_2O interaction is amplified in the immediate vicinity of THF molecules, which are the guests of the II type clathrate-like cages.

Alkoxylation of 2,3-dialkylindoles utilizing iodosobenzene diacetate[1]

DENNIS V. C. AWANG[2] AND ANDRÉ VINCENT

Health and Welfare Canada, Drug Research Laboratories, Sir Frederick Banting Research Centre, Tunney's Pasture, Ottawa, Canada K1A 0L2

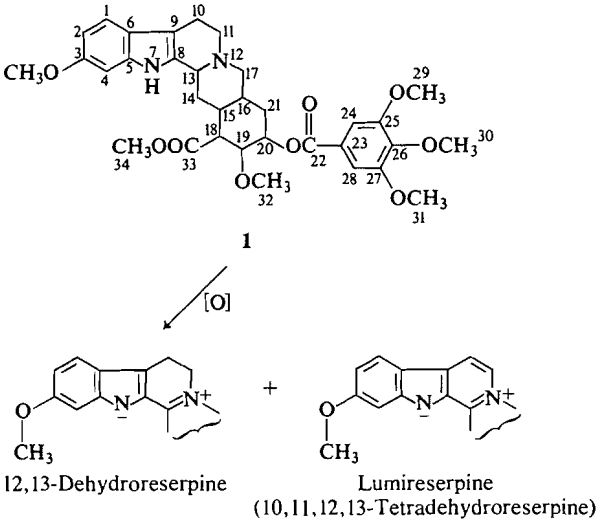
Received November 19, 1979

DENNIS V. C. AWANG and ANDRÉ VINCENT. Can. J. Chem. **58**, 1589 (1980).

Iodosobenzene diacetate has been employed in the development of a simple procedure for the production of 3-alkoxyindolenines from 2,3-disubstituted indoles, by treatment of the indoles with the reagent in alcoholic solvent.

Primary and secondary alkoxy functions have been incorporated at the β-site of 2,3-dimethylindole but the reaction with *tert*-butanol leads to other complex products. Good yields of 9-*n*-alkoxy-9*H*-reserpines have been realised but no reaction is observed in secondary alcohols.

DENNIS V. C. AWANG et ANDRÉ VINCENT. Can. J. Chem. **58**, 1589 (1980).



On a utilisé le diacétate de l'iodosobenzène dans la mise au point d'une méthode simple de production des alkoxy-3 indolénines impliquant le traitement d'indoles disubstitués en positions 2 et 3 par le réactif dans un solvant alcoolique.

On a incorporé les fonctions alkoxy primaire et secondaire au niveau du site β du diméthyl-2,3 indole mais la réaction avec l'alcool *tert*-butylique conduit à d'autres produits complexes. On a obtenu d'excellents rendements en *n*-alkoxy-9 réserpines 9*H* mais on n'a pas observé de réaction avec les alcools secondaires.

[Traduit par le journal]

The indole alkaloid reserpine (**1**) is oxidized in good yield by lead tetraacetate in acetic acid, generating predominantly 12,13-dehydroreserpine (**2**) or "lumireserpine" (**3**) depending on the molar ratio of reagent to substrate (1) (Scheme 1). Ajmalicine (2), 3-epi-α-yohimbine (3), and deserpidinediol (4) have similarly been converted to their tetradehydro derivatives. However, it has been reported (5) that reserpine could be converted in good yield (72%) to the corresponding acetoxyindolenine by treatment with lead tetraacetate *in cold methylene chloride solution*; also the indole dihydrocorynantheine was converted in 25% yield to the acetoxyindolenine upon treatment with lead tetraacetate *in benzene solution* (6). Reaction of reserpine with lead tetraacetate in methanol solution produced, following chromatography (5), roughly 10% of crude product from which the corresponding methoxyindolenine was obtained by recrystallization. The yields of acetoxy, benzoyloxy, and bromobenzoyloxy derivatives were variable.

The mechanisms of these reactions have not been elucidated and the stereochemistry of the substituted indolenines has not been determined; the latter authors (5), on the basis of the universally recognized proclivity of indoles towards *electrophilic* attack at the β-position, suggest an intermediate **4** which then suffers *nucleophilic* attack by

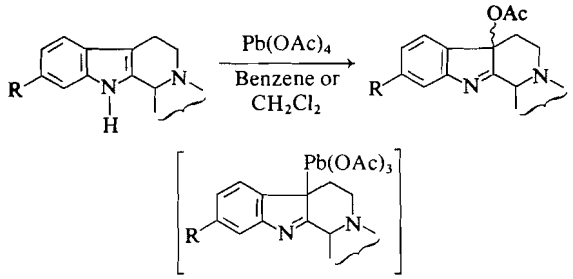
1 → **2** + **3**

SCHEME 1

acetic acid at the same site, a seemingly unlikely sequence (Scheme 2).[3]

In the present study, it has been found that iodosobenzene diacetate (IBD), less reactive than lead tetraacetate but a much more conveniently utilized reagent, effects similar oxidation of reserpine in acetic acid, but can also be employed in a simple procedure for introduction of primary alkoxy substituents at the β-position.

[1]Presented in part at the 176th National Meeting of the American Chemical Society, Miami Beach, Florida, September 11–17, 1978.



[2]Author to whom correspondence may be addressed.

[3]Examples of introduction of a nucleophile at this site are extremely rare; only two such reactions have been hitherto identified in the literature, namely, the silver ion assisted displacement of iodide by acetate (7), and intramolecular substitution by oxygen at the β-carbon of *N*-benzenesulfonylindoles (8).

SCHEME 2

Alkoxyindolenines have been derived in good yield and quality from reactions of reserpine with IBD in methanol, ethanol, and *n*-propanol solvent at room temperature, but upon treatment with IBD in solvent *i*-propanol the only reaction products generated, after several hours, were 3,4-dehydroreserpine and lumireserpine, in trace amounts.

It seems reasonable to conclude from the above data that the reactions of indole compounds with IBD and lead tetracarboxylates to produce substituted indolenines involve initial condensation reactions to form reactive *N*-substituted intermediates (9), which then undergo nucleophilic attack at the indole β-position (Scheme 3). In inert solvents such as benzene and methylene chloride, attack occurs by the liberated carboxylic acid, whereas solvent gains ascendancy when reactions are performed in alcoholic medium. The effectiveness of IBD and lead tetraacetate in oxidizing reserpine and related alkaloids to their dehydro derivatives in acetic acid medium likely reflects a more polar transition state for such reactions, which would therefore be promoted in the more polar acidic solvent.

2,3-Dimethylindole gives good yields of 3-alkoxy-2,3-dimethylindolenines upon reaction with IBD in methanol and *i*-propanol; tlc examination of the product of reaction with IBD in *tert*-butanol

SCHEME 3

indicates a gross mixture of compounds which have not been investigated further. The success of the *i*-propanol reaction (which fails with reserpine) is attributed to reduced steric hindrance to approach by the alcohol at the β-indole site of the 2,3-dimethylindole iodoso complex, as compared to relatively severe 1,3-diaxial interactions with the C-10 and C-13 hydrogens of reserpine.

The reactions of indoles, unsubstituted at the α- and/or β-carbons, are not as straightforward. In the case of indole itself, refractory high-molecular weight products are formed, whereas less-efficient and obviously more complex reactions result from monosubstituted substrates. 2-Methylindole and 3-methylindole, upon treatment with IBD in methanol, both give rise to at least four products as indicated by tlc; these gross mixtures were not investigated further on account of their apparent preparative inutility.

No contamination by epimers could be detected in the alkoxyindolenine products derived from the reaction of reserpine with IBD in methanol, ethanol, and *n*-propanol. The ir, ^{1}H nmr, and ^{13}C nmr spectra of 9-methoxy-9*H*-reserpine[4] are identical with those of the product of methanolysis of 9-chloro-9*H*-reserpine (**5**), the singular product of reaction of reserpine with *tert*-butyl hypochlorite. Steric considerations indicate the latter compound to be the 9β-compound resulting from attack by *tert*-butyl hypochlorite upon the less hindered face of the indole. Moreover, the identity of the methoxy product from IBD–methanol with the product of solvolysis of **5** suggests that methanol attack *beta* to indole nitrogen, upon both the IBD intermediate and the carbonium ion (undoubtedly easily generated at such an allylic–benzylic site), also takes place from the same less crowded side.

Further work on the chemistry of indolenine derivatives of indole alkaloids is in progress and should further elucidate the sterochemistry of their formation and transformations.

Experimental

General

Melting points are uncorrected. The ^{1}H and ^{13}C nmr spectra of reserpine and its derivatives were obtained on Varian A-60A and CFT-20 spectrometers respectively, using Me_4Si as internal standard. The ^{1}H and ^{13}C spectra of 2,3-dimethylindole products were recorded on a Bruker Spectrospin 80 MHz–20.1 MHz instrument. Elemental analyses were carried out by Mr. Hector Séguin of the National Research Council of Canada's Microanalytical Laboratory, Ottawa, Ontario.

[4]The numbering system is that employed by Wehrli (10) in recently published ^{13}C studies. The older system utilized by Levin, Lallemand, and Roberts (11) in their ^{13}C work originates from the indole nitrogen and would designate such compounds as C-7 substituted indolenines.

Materials

Reserpine, 2-methylindole, 3-methylindole, and 2,3-dimethylindole were all commercially obtained and their purity checked by tlc prior to use.

General Alkoxylation Procedure for Reserpine

To a solution of 500 mg (0.082 mol) of reserpine in 80 mL of the alcohol, was added in one portion 250 mg (0.082 mol) of IBD in 20 mL of the alcohol and the mixture stirred in the dark for ½h. The precipitated solid[5] was filtered, washed with cold methanol, and dried under vacuum. The product of methanol reaction had mp C_2H_5OH 231–232°C (lit. (5) (9-methoxy-9*H*-reserpine) mp from CH_2Cl_2–ether 233–235°C); ^1H nmr ($CDCl_3$) δ: 2.78[6] (s, 3H, C9–OCH_3); ^{13}C nmr ($CHCl_3$): 181.0[6] (C=N); ms (70 eV) *m/e*: 638 (parent). 9-Ethoxy-9*H*-reserpine had mp C_2H_5OH 234–236°C; ^{13}C nmr ($CHCl_3$):182.96 (C=N); ms (70 eV) *m/e*: 652 (M).

9-*n*-Propoxy-9*H*-reserpine had mp C_2H_5OH 239–241°C; ^{13}C nmr ($CHCl_3$):182.98 (C=N); ms (70 eV) *m/e*: 666 (parent).

3-Methoxy-2,3-dimethylindolenine

To a magnetically stirred solution of 249 mg (0.0017 mol) of 2,3-dimethylindole in 30 mL of methanol, cooled in an ice-bath and under nitrogen, was added dropwise 554 mg (0.0017 mol) of IBD dissolved in 10 mL of the same solvent, also ice-cooled over a period of 15 min. The resulting solution was stirred for a further 30 min, at the end of which it was diluted with 80 mL water and extracted with 3 × 60 mL portions of benzene. Preparative tlc on 1000 μ silica gel GF coated glass plates (Analtech) using benzene–ether–methanol 7:2:0.5 yielded 195 mg (35%) of light yellow oil which showed one spot on tlc using similar 250 μ plates. The product had ^1H nmr ($CDCl_3$) δ:1.45 (s, 3H, CH_3), 2.25 (s, 3H, =C—CH_3), 2.85 (s, 3H, OCH_3), 7.37 (m, 4H, aryl); ^{13}C nmr ($CHCl_3$) δ:183.2 (C2), 152.1 (C8), 136.1 (C9), 128.1, 124.3, 121.2, 118.8 (C4, 5, 6, 7), 87.4 (C3), 51.2 (OCH_3), 21.0 (C3, CH_3), 13.5 (C2, CH_3); ms (70 eV) *m/e*:175 (M).

3-Isopropoxy-2,3-dimethylindolenine

To a magnetically stirred solution of 451 mg (0.0031 mol) of 2,3-dimethylindole in 135 mL of isopropanol under nitrogen at room temperature was added in one portion 1.00 g (0.0031 mol) of IBD. The resulting solution was stirred at room temperature and monitored by tlc. After 45 min, at which time tlc of the solution indicated no appreciable reduction in the amount of residual starting material, solvent was evaporated and the major product (of lowest R_f save for minor secondary products) was isolated by preparative tlc. A yield of 114.5 mg of light brown solid was obtained which had ^1H nmr ($CDCl_3$) δ: 0.92 (d, 3H, $CHCH_3$, J = 6 Hz), 1.03 (d, 3H, $CHCH_3$), 1.43 (s, 3H, CH_3), 2.30 (s, 3H, =C—CH_3), 3.07 (m, 1H, OCH), 7.21 (m, 4H, aryl); ^{13}C nmr ($CHCl_3$) δ:186.2 (C=N), 153.8 (C8), 139.3 (C9), 129.7, 125.9, 123.5, 120.6 (C4, 5, 6, 7), 88.4 (C3), 68.9 (OCH), 24.5 ($CH(CH_3)$),[7] 23.7 (C3, $CH(CH_3)$),[7] 15.5 (C2); ms (70 eV) *m/e*: 203 (M), 160, 144, 117, 105, 91.

Satisfactory elemental analyses were obtained for all products.

[5]9-Propoxy-9*H*-reserpine was not precipitated readily and the reaction mixture was diluted with water and refrigerated in order to induce crystallization. The respective yields of precipitated solid, homogeneous by tlc analysis, were 76, 45, and 36% for methoxy-, ethoxy-, and *n*-propoxy derivatives, respectively.

[6]These chemical shifts are characteristic of fully substituted benzylic methoxyl protons and indolenine carbon, respectively. Complete details of a reinvestigation of the ^1H nmr and ^{13}C nmr spectra of reserpine and deserpidine, as well as elucidation of the spectra of a variety of their derivatives, will appear shortly.

[7]The accidental equivalence of the chemical shift of one of the isopropyl carbons with that of the methyl carbon attached to C3 was established by selective on-resonance decoupling.

Electron spin resonance study of spin-trapped azide radicals in aqueous solutions[1,2]

WALTER KREMERS AND AJIT SINGH[3]

Medical Biophysics Branch, Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Limited (Research Company), Pinawa, Man., Canada R0E 1L0

Received March 17, 1980

WALTER KREMERS and AJIT SINGH. Can. J. Chem. **58**, 1592 (1980).

Organic spin traps have been used to study the formation of azide radicals during the reaction of azide anions with hydroxyl radicals. The azide radicals have been successfully trapped with three spin traps: 5,5-dimethylpyrroline-1-oxide (DMPO), phenyl-*N-tert*-butyl nitrone (PBN), and 4-pyridyl-*N-tert*-butyl nitrone (PyBN). The azide radicals produced from ^{15}N sodium azide have also been trapped. The hyperfine splittings of the resulting radicals have been determined.

WALTER KREMERS et AJIT SINGH. Can. J. Chem. **58**, 1592 (1980).

On a utilisé des pièges à spin organique pour étudier la formation des radicaux azotures lors de la réaction des anions azotures avec les radicaux hydroxyles. On a piégé avec succès les radicaux azotures à l'aide de trois pièges à spin: le diméthyl-5,5 pyrroline oxyde-1 (DMPO), la phényl-N-*tert*-butyl nitrone (PBN) et la pyridyl-4-*N-tert*-butyl nitrone (PyBN). On a également piégé les radicaux azotures produits à partir de l'azoture de sodium marqué au ^{15}N. On a déterminé les couplages hyperfins des radicaux qui en résultent.

[Traduit par le journal]

Introduction

It has been suggested that azide anions react with hydroxyl radicals to generate $N_3^{\cdot}$ radicals [1] (1–5).

[1] $N_{3aq}^- + {}^{\cdot}OH \rightarrow N_3^{\cdot} + OH_{aq}^-$

The reaction continues to be studied by pulse radiolysis (6, 7). However, results on the formation of $N_3^{\cdot}$ radical by this reaction using the electron spin resonance (esr) technique have not been reported in the literature.[4] We described in this paper our work on the study of reaction [1] by the esr technique. Photolysis of azido cobalt(III) complexes also produces $N_3^{\cdot}$ radicals, which have been trapped with phenyl-*N-tert*-butyl nitrone (PBN) (8). The esr spectrum of the PBN–$N_3^{\cdot}$ adduct obtained by us agrees with that obtained by Rehorek *et al.* (8).

Experimental

5,5-Dimethylpyrroline-1-oxide (DMPO) and phenyl-*N-tert*-butyl nitrone (PBN) (Aldrich), 4-pyridyl-*N-tert*-butyl nitrone (PyBN) (Spin Trap Producers, Guelph, Ontario) and 100% ^{15}N-labelled sodium azide (Stohler Isotope Chemicals) were used as obtained. Other chemicals used were laboratory reagent quality or better; triple distilled water was used for all the experiments.

Electron spin resonance experiments were performed on a Varian V4500 spectrometer. Solutions containing a spin trap and sodium azide were deaerated and saturated with N_2O to increase the yield of $^{\cdot}OH$ (9) and irradiated with 3 MeV electrons from a nominally 4 MeV Van de Graaff accelerator, to a dose of ~4 Gy. The irradiated solution was then quickly transferred (within minutes) to the esr spectrometer cell and a spectrum recorded on a Nicolet 1074 signal averager. The esr spectrum of the DMPO–N_3 adduct was also obtained by *in situ* radiolysis. The equipment and the techniques used are essentially those described by Sargent and co-workers (10).

Hydroxyl radicals were also generated by the action of uv light on 1% hydrogen peroxide solutions (11). A 150 W Xenon arc lamp (Oriel) was used for irradiations, at a distance of 45 cm from the esr cell. Several spectra were normally accumulated during each photolysis run. In the case of PBN–N_3 adduct, the solution was found to be rather unstable so spectra were accumulated from several successive runs.

Results and Discussion

PBN

Photolysis of a 1% solution of H_2O_2 in the presence of PBN (5×10^{-2} mol dm^{-3}) and sodium azide (0.1 mol dm^{-3}) gives an esr spectrum consisting of a triplet of quartets (1:2:2:1) with the hyperfine splitting constants (hfsc) given in Table 1. This spectrum is identical to that reported by Rehorek *et al.* (8) and identified as the spin-trapped azide radical. In the absence of sodium azide, the PBN–OH adduct is obtained (Table 1).

PyBN

Photolysis of H_2O_2 (1%) in the presence of PyBN (5×10^{-2} mol dm^{-3}) and sodium azide (0.1 mol dm^{-3}) also gives an esr spectrum (Fig. 1*b*) consisting of a triplet of quartets with the hyperfine splitting constants (hfsc) given in Table 1. The simulation of this spectrum was computed with a

[1] AECL No. 6864.

[2] The work described in this paper was presented at the International Conference on ESR of Organic and Bio-organic Radicals, University of York, March 1980.

[3] To whom all correspondence should be addressed.

[4] A spectrum attributable to DMPO–N_3 adduct has been seen by Dr. G. R. Buettner (personal communication, 1979). Results similar to our own are being reported by Dr. E. G. Janzen and co-workers in an accompanying paper in this issue.

TABLE 1. Hyperfine splitting constants for the ·OH and N_3· spin adducts

Spin trap	·OH mT	N_3· mT
DMPO	$\alpha_H = 1.49$ $\alpha_N = 1.49$	$\alpha_H = 1.47$ $\alpha_{N1} = 1.47$ $\alpha_{N2} = 0.30$
PBN	$\alpha_H = 0.27$ $\alpha_N = 1.56$	$\alpha_H = 0.206$ $\alpha_{N1} = 1.505$ $\alpha_{N2} = 0.206$
PyBN	$\alpha_H = 0.19$ $\alpha_N = 1.50$	$\alpha_H = 0.195$ $\alpha_{N1} = 1.468$ $\alpha_{N2} = 0.195$

*$\alpha_{N1}(^{14}N) = 1.47$, $\alpha_{N2}(^{15}N) = 0.45$, and $\alpha_H = 1.47$, for the ^{15}N-labelled N_3· trapped with DMPO.

peak-to-peak linewidth of 0.92 G (0.092 mT) and is shown in Fig. 1*c*. The spectrum and hfsc for PyBN$\dot{}$–OH adduct are given in Fig. 1*a* and Table 1.

DMPO

With DMPO as the spin trap, we have obtained a series of esr spectra which show first the formation of the DMPO$\dot{}$–OH adduct (10, 12) (1% H_2O_2; DMPO, 5×10^{-2} mol dm^{-3}) (Fig. 2*a* and Table 1) and then its gradual replacement by the DMPO$\dot{}$–N_3 adduct as the concentration of sodium azide in the solution is increased to 5×10^{-2} mol dm^{-3} (Fig. 2*b–e* and Table 1). The esr spectrum of the DMPO$\dot{}$–N_3 adduct consists of a quartet of triplets; it is shown in Fig. 2*e* and the hfsc's are listed in Table 1. The quartet of triplets (1:1:1:2:2:2:2:2:2:1:1:1) is a result of overlap of the hfsc of the proton and the nitroxyl nitrogen, with further splitting by the azide nitrogen. The slight asymmetry of the spectum can be explained by a very small contribution of the DMPO$\dot{}$–OH adduct (Fig. 2*a*) to the DMPO$\dot{}$–N_3 spectrum (Fig. 2*e*). Simulation of this spectrum was computed with a peak-to-peak line width of 1.2 G (0.12 mT) and is shown in Fig. 2*f*. Comparative runs in H_2O vs. D_2O solutions gave identical esr spectra of the DMPO$\dot{}$–N_3 adduct.

Reaction of Fenton's reagent (ferrous ammonium sulfate and hydrogen peroxide), which is a known source of hydroxyl radicals [2] (13, 14 and references therein),

[2] $Fe_{aq}^{2+} + H_2O_2 \rightarrow Fe_{aq}^{3+} + \cdot OH + OH_{aq}^-$

with sodium azide, in the presence of DMPO gives an esr spectrum identical to that in Fig. 2*e*.

In situ radiolysis of an N_2O-saturated aqueous solution of sodium azide (0.1 mol dm^{-3}) and DMPO (5×10^{-2} mol dm^{-3}) produced an esr spectrum identical to that of Fig. 2*e*. This spectrum also consists of spectra of electrons trapped in the walls of the quartz cell and of DMPO$\dot{}$–H adduct (10).

Variation of sodium azide concentration, from 10^{-3} mol dm^{-3} up to 1 mol dm^{-3} did not change the shape of the observed spectrum of the DMPO$\dot{}$–N_3 adduct. The intensity of the peaks plateaued at ~5

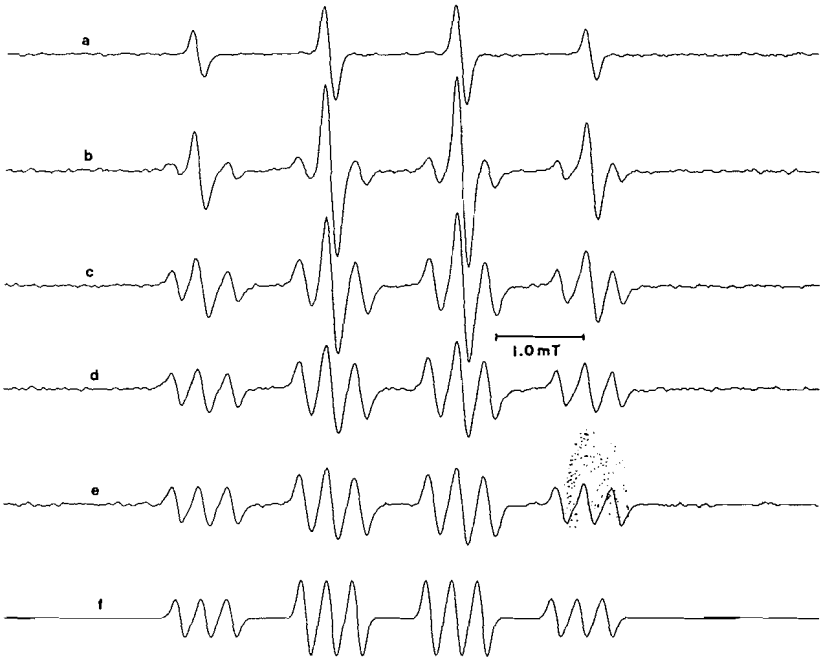

FIG. 2. Photolysis of 1% aqueous H_2O_2 in the presence of DMPO (5×10^{-2} mol dm^{-3}); esr spectra of spin-trapped $^{\cdot}OH$ and $N_3^{\cdot}$ radicals. (*a*) No additive, (*b*) NaN_3 (1×10^{-3} mol dm^{-3}), (*c*) NaN_3 (5×10^{-3} mol dm^{-3}), (*d*) NaN_3 (1×10^{-2} mol dm^{-3}), (*e*) NaN_3 (5×10^{-2} mol dm^{-3}), (*f*) computer simulation of DMPO$\dot{}$–N_3 adduct.

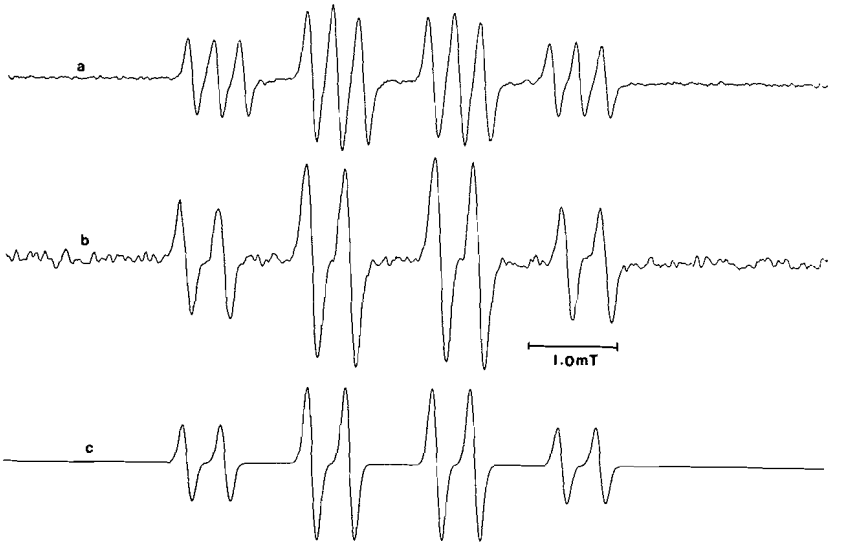

FIG. 3. Photolysis of 1% aqueous H_2O_2 in the presence of DMPO; esr spectra of spin-trapped ^{14}N and ^{15}N azide radicals. (*a*) NaN_3 (^{14}N, natural abundance) (5×10^{-2} mol dm^{-3}), (*b*) NaN_3 (^{15}N, 100%) (5×10^{-2} mol dm^{-3}), (*c*) computer simulation of DMPO$\dot{}$–(^{15}N)N_3 adduct.

$\times 10^{-2}$ mol dm^{-3}. It has been suggested that $N_3^{\cdot}$ adds on to the azide anion [3] (5) and recent pulse radiolysis work (7) strongly supports this suggestion.

[3] $N_3^{\cdot} + N_{3aq}^{-} \rightarrow (N_3)_{2aq}^{\cdot -}$

Thus at the higher concentrations of sodium azide, reaction [3] would compete with trappings of $N_3^{\cdot}$. The lack of any effect of sodium azide concentration suggests that the esr spectra of the DMPO$\dot{}$–N_3 and DMPO$\dot{}$–$(N_3)_{2aq}^{-}$ are identical. The possibility that $(N_3)_{2aq}^{\cdot -}$ is not trapped is ruled out by the fact that at 1 mol dm^{-3} concentration of sodium azide, where most of the $N_3^{\cdot}$ should exist as $(N_3)_{2aq}^{-\cdot}$ (7),

there is no reduction in the intensity of the DMPO̊–N_3 spectrum as compared to that at $\sim 5 \times 10^{-2}$ mol dm^{-3}.

In our work no secondary splittings due to the other two nitrogens (of N_3·) have been observed. Rehorek *et al.* (9) did observe these with nitrosodurene as a spin trap in methanol solutions. We plan to extend our work with the use of this spin trap.

^{15}N-labelled Azide Radical

The nuclear spin of ^{14}N is 1, which gives rise to the triplets observed in our spectra (15). The nuclear spin of ^{15}N is only 1/2; therefore, the spectra derived from ^{15}N-labelled azide radicals should consist of doublets instead of triplets (15). This was indeed observed. The spectrum of the DMPO̊–$^{15}N_3$ adduct (derived from 100% ^{15}N-labelled sodium azide) consists of a quartet of doublets (Fig. 3*b*, Table 1). The simulated spectrum (Fig. 3*c*) is computed with a peak-to-peak linewidth of 1.2 G (0.12 mT). The spectrum of the ^{14}N (natural abundance) DMPO̊–N_3 is shown in Fig. 3*a*, for comparison.

Untrapped N_3·

It has not been possible to observe the esr spectrum of N_3· in steady-state work. This is attributable to its short half-life (10^{-5}–10^{-6} s) (7).

Conclusion

Our work confirms that N_3· is formed in reaction of ·OH radicals with azide anions. The esr spectra of spin-trapped N_3· and $(N_3)_{2aq}^{-}$·, with DMPO, appear to be indistinguishable. The expected change in the number of peaks is seen in going from trapped ^{14}N azide radical (natural abundance) to the 100% ^{15}N-labelled one.

Azidyl, cyanatyl, and cyanyl radicals and chlorine atoms have been detected by spin trapping using α-phenyl *N-tert*-butyl nitrone (PBN) in the monoelectronic electrooxidations of azide, cyanate, cyanide, and chloride. Azidyl and cyanatyl radicals were also detected with PBN in the persulfate oxidations of azide and cyanate. Azidyl radicals could be detected in the reaction of azide with hydroxyl radicals in the presence of PBN.

On a décelé lors de l'électrooxydation monoélectronique de l'azoture, du cyanate, du cyanure et du chlorure des radicaux azotyle, cyanatyle et cyanyle et des atomes de chlore en piégeant des spins grâce à l'α-phényl *N-tert*-butyl nitrone (PBN). On a également pu déceler la présence des radicaux azotyle et cyanatyle lors de l'oxydation par les persulfate de l'azote et du cyanate. On a aussi mis en évidence la présence des radicaux azotyles lors de la réaction de l'azoture avec les radicaux hydroxyles en présence de PBN.
[Traduit par le journal]

Introduction

A recent paper by Rehorek, Thomas, and Hennig (1) which reports the detection of azidyl radicals in the photolysis of $K_3[Co(CN)_5N_3]$ and $[Co(NH_3)_5N_3]Cl_2$ in aqueous and methanolic solutions prompts us to communicate some preliminary results of the spin trapping chemistry observed in the one electron oxidations of azide ion and other pseudohalides in the presence of PBN. Because the reaction of hydroxyl and sulfatyl radicals with pseudohalides is very fast (2–4), both Fenton's reagent and persulfate were used in an attempt to produce the neutral radicals from the corresponding pseudohalides. Also, electrochemical oxidations were performed at potentials where the spin trap was electroinactive (5):

$$X^- - e^-(HO\cdot \text{ or } SO_4^{\cdot-} \text{ or electrochemical}) \longrightarrow X\cdot$$

where X = N_3, OCN, CN, Cl.

Experimental

Three different methods of oxidations were employed. All concentrations stated are final concentrations.

Reactions with Persulfate

Solutions of 1 *M* alkali metal pseudohalides containing 0.05 *M* PBN were mixed with 0.01 *M* $Na_2S_2O_8$ or $(NH_4)_2S_2O_8$ both previously outgassed with N_2 (10–15 min) and immediately monitored by esr. Conrol experiments (e.g. PbO_2 + NaN_3) indicated that spin adduct formation was not due to addition followed by oxidation. Photolysis experiments were performed with a medium pressure Hg arc which irradiated the quartz cell directly in the esr cavity.

Reactions with Fenton's Reagent

PBN (0.1 *M*) was added to a stock solution of 2×10^{-5} *M* $FeCl_3$ and 8×10^{-4} *M* adenosine diphosphate (ADP) shortly before performing the experiment and mixed with 0.1 *M* NaN_3 and 5×10^{-2} *M* H_2O_2 both previously outgassed with N_2. Control experiments gave no signal in the absence of any one component except for a weak signal when H_2O_2 and NaN_3 were mixed with PBN alone. This signal could be eliminated by the addition of EDTA.[1]

Apparatus

A description and figure showing the mixing chambers and esr cell arrangement have been published (6). For the electrolysis experiments a Varian E-256 cell was used.

[1]Trace metal ion impurities in water may catalyze the decomposition of H_2O_2 producing hydroxyl radicals. Complexation of these metal ions with EDTA appears to eliminate this problem.

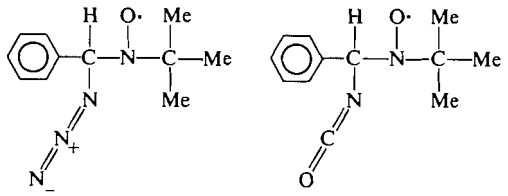
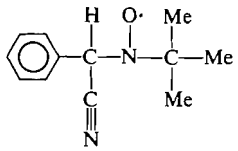
Electrochemical Oxidations



In situ electrochemical oxidations were carried out at a platinum gauze electrode in CH_3CN (AN)/0.10 *M* tetraethylammonium perchlorate solutions at potentials where substrate alone was oxidized (5). Sources of and purification procedures for AN and tetraethylammonium perchlorate have already been reported (7). Tetraethyl- or tetra-*n*-butylammonium (TEA or TBA) salts (TEA ClO_4, TEA CN, TBA N_3, TBA Cl, TEA NCO) were either commercially available or were prepared by standard methods (8). All potentials are reported relative to the aqueous saturation calomel electrode (sce).

Electron Spin Resonance

Three different Varian spectrometers were used in this work: V4502 (Georgia), E-9 (Oklahoma), and E-104 (Guelph). Hyperfine splitting constants (hfsc) were obtained by calibrating with Fremy's salt or stable "spin label" nitroxyl in solution.



Results

A spectrum consisting of a triplet of 1:2:2:1 quartets ($a_\beta^N = a_\beta^H$) is found when azide ions are oxidized electrochemically at 0.08 V in AN, by Fenton's reagent in H_2O, or upon photolysis in H_2O in the presence of PBN (see Table 1 for hfsc's). This spectrum is assigned to the adduct of the azidyl radical (**I**) and is in agreement with the results reported by Rehorek and co-workers (1).

I

II

III

Although the presence of splitting from a β-nitrogen is consistent with this assignment the spectrum does not give information about the nature of the remaining atoms in the group which was the radical. That this spectrum is not due to the amino adduct has been shown in independent experiments (9).

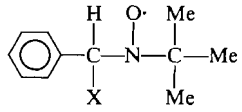
With persulfate three additional nitroxyl-type triplets are detected: $a_N = 13.03$ G due to Fremy's salt, $^-SO_3—\overset{O\cdot}{N}—SO_3^-$; $a_N = 17.03$ G due to $Me_3C—\overset{O\cdot}{N}—CMe_3$; $a_N = 14.58$ G perhaps due to $Me_3C—\overset{O\cdot}{N}—SO_3^-$. Fremy's salt is detected with 1 *M* NaN_3 plus 0.01 *M* $(NH_4)_2S_2O_8$ alone. The reaction between 0.1 *M* $Me_3C—N{=}O$, 0.1 *M* $(NH_4)_2S_2O_8$, and 1 *M* NaN_3 in H_2O produces the 13.0 G triplet, the 14.58 G triplet, and later the 17.03 G triplet. Much later (2 days) a 12.06 G triplet is found.

Photolysis or the persulfate oxidation of aqueous solutions of cyanate containing PBN produces a poorly resolved triplet of 1:1:1, 1:1:1 multiplets. A more well-resolved spectrum in which each multiplet becomes a doublet of triplets is obtained by electrooxidation of 0.90 V in AN. This spectrum is assigned to spin adduct **II** where the nitrogen atom of the cyanatyl group is bonded to an α-carbon of spin trap.

The electrochemical oxidation of cyanide produces a spin adduct spectrum only in the presence of high concentrations of PBN (~3.6 *M*). The assignment of this spectrum to the cyanyl radical adduct (**III**) is based on an independent spin trapping experiment:

$$Me_3COOC\overset{O}{\overset{\|}{C}}\overset{O}{\overset{\|}{C}}OOCMe_3 \longrightarrow 2Me_3CO\cdot + 2CO_2$$

$$Me_3CO\cdot + PhCH_2CN \longrightarrow Me_3COH + Ph\dot{C}HCN$$



$$Ph\dot{C}HCN + Me_3CN{=}O \longrightarrow PhCH(CN)\overset{O\cdot}{N}CMe_3$$

The spectra obtained (see Table 1 for hfsc's) are in good agreement with an earlier report by Forester and Hepburn (10): $a_N = 15.2$, $a_\beta^H = 2.4$ G from NaCN/HCl in H_2O/C_2H_5OH. However, two recent publications have assigned the following hfsc's to **III**: $a_N = 14.4$, $a_\beta^H = 5.5$, $a_\gamma^N = 1.2$ G (11) and $a_N = 14.6$, $a_\beta^H = 4.9$, $a_\gamma^N = 1.6$ G (12). Further experiments are planned to confirm this assignment.

The chlorine atom adduct is detectable in the electrochemical oxidation of chloride in the presence of PBN in AN. The assignment of the spin adduct is obvious from the relative large Cl-35, Cl-37 hfsc observed. The same spectrum can be obtained by photolysis of CCl_4 (see Table 1) or reaction with *tert*-butyl hypochlorite (13).

Electrooxidations of thiocyanate and bromide in the presence of PBN have produced triplets of doublets but the assignments are not clear at this time. Spin trapping experiments with PBN in the electrooxidation of selenocyanate have been unsuccessful to date.

TABLE 1. Hyperfine splitting constants of PBN spin adducts[a]

The mild rhodium(I), and phase transfer catalyzed, dehydrogenation of benzylic alcohols

HOWARD ALPER,[1] KHALED HACHEM, AND SANDRO GAMBAROTTA
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 7, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HOWARD ALPER, KHALED HACHEM, and SANDRO GAMBAROTTA. Can. J. Chem. **58**, 1599 (1980).

Benzylic alcohols can be dehydrogenated to carbonyl compounds by phase transfer catalyzed reaction (8 *M* NaOH, benzene, and $PhCH_2N(C_2H_5)_3^+Cl^-$ as the catalyst) in the presence of catalytic amounts of chlorodicarbonylrhodium(I) dimer. Evidence is presented for the intermediacy of *ortho*-metalated complexes in these reactions.

HOWARD ALPER, KHALED HACHEM et SANDRO GAMBAROTTA. Can. J. Chem. **58**, 1599 (1980).

Les alcools benzyliques peuvent être déshydrogénés en composés carbonylés par une réaction catalysée de transfert de phase (NaOH 8 *M*, benzène et $PhCH_2N(C_2H_5)_3^+Cl^-$ comme catalyseur) en présence de quantités catalytiques de dimère du chlorodicarbonylrhodium (I). On apporte les preuves de la présence de complexes orthométallés intermédiaires au cours de ces réactions.

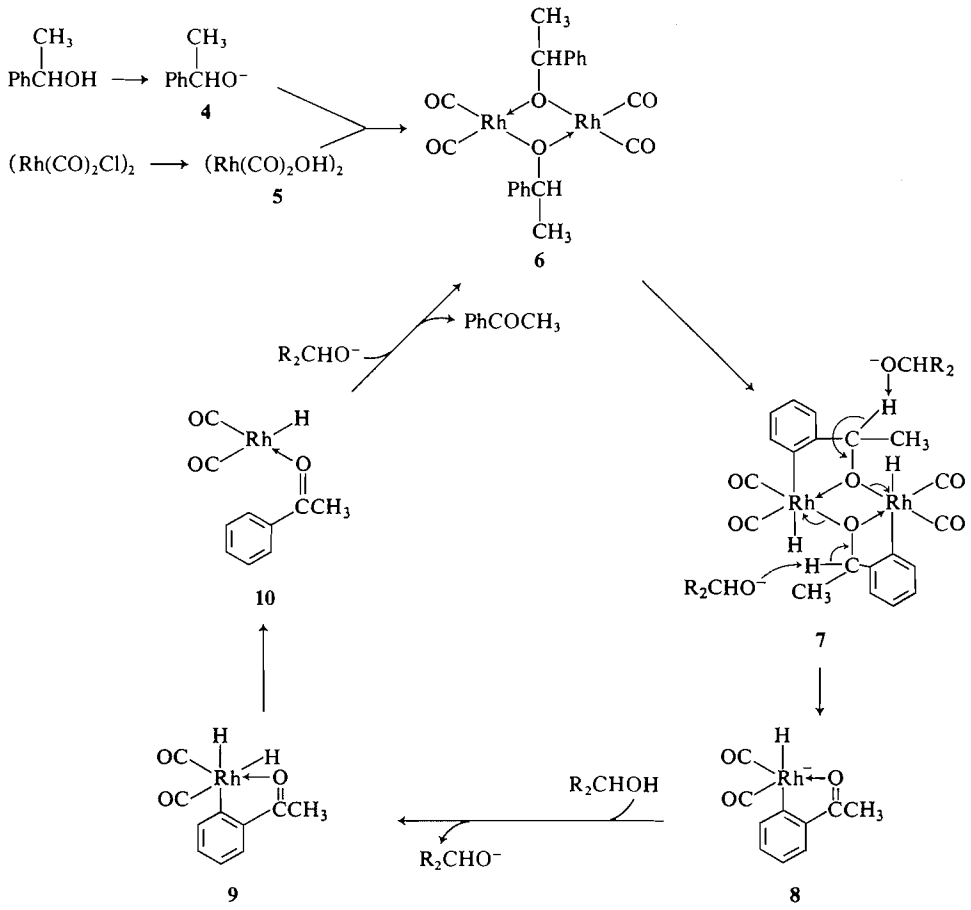
Phase transfer catalysis has recently become an important method for effecting reactions catalyzed by organometallic compounds (1). Examples include the cobalt carbonyl catalyzed carbonylation of dienes or trienes to unsaturated ketones (2), the palladium(II) catalyzed addition of benzene to α,β-unsaturated ketones (3), and the nickel(0) catalyzed cyanation of aryl halides (4). We now wish to demonstrate that phase transfer catalysis can be applied to the dehydrogenation of alcohols by rhodium(I) catalysts.

Treatment of a benzene solution of an alcohol (**1**) with a catalytic amount of chlorodicarbonylrhodium(I) dimer (**2**) ((25–100) : 1 mole ratio of **1**:**2**), sodium hydroxide (8 *M*), and benzyltriethylammonium chloride as the phase transfer catalyst, for 4 h at 55°C, or 18–30 h at room temperature, affords the dehydrogenated carbonyl compound (**3**). Reasonable yields (Table 1) of ketones were obtained from a variety of benzylic alcohols. Ethers were formed as by-products in two cases, with recovered alcohol as the only other organic species. Interestingly, primary alcohols were significantly less reactive than secondary alcohols. For example, 2-naphthalenemethanol was converted to 2-naphthaldehyde in 42% yield, and a small amount of naphthalene was also isolated. In addition, 1-adamantanemethanol and 3β-cholestanol failed to react under these conditions. One can take advantage of this difference in reactivity by selectively dehydrogenating a secondary alcohol in the presence of a primary one (e.g. 1-phenyl-1,3-propanediol).

$$\underset{\mathbf{1}}{R_2CHOH} \xrightarrow[PhCH_2N(C_2H_5)_3^+Cl^-]{[Rh(CO)_2Cl]_2\ (\mathbf{2})} \underset{\mathbf{3}}{R_2C{=}O}$$

C_6H_6, 8 *M* NaOH

Other rhodium(I) complexes could be used as catalysts, including chlorotris(triphenylphosphine)-rhodium(I) ($(Ph_3P)_3RHCl$, Wilkinson's catalyst), and chlorocarbonylbis(triphenylphosphine)rhodium(I) ($(Ph_3P)_2Rh(CO)Cl$), but conversions were significantly lower and the work-up of these reactions was not as simple as with $(Rh(CO)_2Cl)_2$. The same observations were noted when dichlorotris(triphenylphosphine)ruthenium ($RuCl_2(PPh_3)_3$) was employed as the catalyst.



Another useful phase transfer catalyst for the dehydrogenation reaction is Aliquat 336 (tricaprylmethylammonium chloride). Carbonyl compounds were also formed when the reaction was effected in the absence of a phase transfer catalyst (i.e. as a two-phase reaction), but with reduced product yields. No reaction occurred in the absence of both the phase transfer and rhodium(I) catalysts, or in the absence of only the latter.

A possible mechanism for the phase transfer catalyzed dehydrogenation of alcohols, catalyzed by complex **2**, is outlined in the catalytic cycle in Scheme 1 (illustrated with 1-phenylethanol). It is likely that the quarternary ammonium hydroxide, generated by hydroxide ion displacement of the chloride ion of the phase transfer catalyst in the aqueous phase, serves two functions in the overall process: (*1*) formation of the alkoxide **4**, and (*2*) displacement of the bridging chloride ligand of $(Rh(CO)_2Cl)_2$ to give **5**. These reactions likely

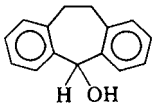
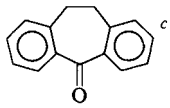
SCHEME 1





occur in the organic phase, and the phase transfer catalyzed substitution of hydroxo for chloride bridges has previously been described for several platinum complexes (5). Addition of the alkoxide to **5** would afford **6**, which by hydrogen transfer from an *ortho*-substituted carbon to each rhodium atom would give the rhodium(III) complex **7**. Carbon–hydrogen bond cleavage of **7** by alkoxide ion would generate **8**. Protonation of the latter would afford **9**, which is convertible to the rhodium(I) complex **10**. Acetophenone would then be formed by alkoxide ion displacement, regenerating **6**.

Solid evidence for the intermediacy of *ortho*-metalated complexes (6,7) in this reaction was obtained by the use of 1-pentafluorophenylethanol (**11**) as the substrate. Treatment of **11** with a catalytic amount of $(Rh(CO)_2Cl)_2$, under identical conditions to those described for 1-phenylethanol, gave the *ortho*-disubstituted compound **12** in 70% yield,[2] but no ketone (**13**). There is precedence for the removal of fluorine during *ortho*-metalation (8,9). The fluorine analog of **7** likely undergoes reductive elimination to give **12**, rather than conversion to the fluorinated derivative of **8**. The required formation of an *ortho*-metalated intermediate in the dehydrogenation reaction accounts for the failure to ob-

[2]Infrared spectra ($CHCl_3$) ν (OH): absent; ^1H nmr ($CDCl_3$) δ: 1.75 (d, CH_3), 5.63 (m,CH); ^{13}C nmr ($CDCl_3$) δ: 20.16 (CH_3), 74.05 (CH); ms *m/e*: 384 (M^+). *Anal.* calcd. for $C_{16}H_8O_2F_8$: C 50.01, H 2.10; found: C 50.17, H 2.13.

TABLE 1. Yields of carbonyl compounds obtained by phase transfer catalyzed dehydrogenation with **2**

Alcohol	Product[a]	Yield, %
2-Methylbenzhydrol	2-Methylbenzophenone	62
1-Phenylethanol	Acetophenone	78 (97)[e]
1-Ferrocenylethanol	Acetylferrocene[b]	81
1-*p*-Methoxyphenylethanol	*p*-Methoxyacetophenone	57
		64
2-Naphthalenemethanol	2-Naphthaldehyde[d]	42
$PhCH(OH)CH_2CH_2OH$	$PhCOCH_2CH_2OH$	46

[a] The structures of the products were characterized by comparison of physical data with those for authentic samples.
[b] $(C_5H_5FeC_5H_4CHCH_3)_2O$ was also formed in 6–7% yield.
[c] The ether $(C_{15}H_{13})_2O$ was isolated in 10% yield.
[d] Naphthalene was a low yield by-product (< 5%).
[e] Yield by gas chromatography.

serve dehydrogenation with simple alcohols such as 3β-cholestanol.

It is noteworthy that transfer hydrogenation was not observed when the dehydrogenation of 1-phenylethanol was effected in the presence of either cyclohexene or 1-decene, implying that hydrogen gas is not evolved during the reaction.[3] Finally, the dehydrogenation reaction is inhibited by the use of a carbon monoxide rather than a nitrogen atmosphere. This may be a consequence of the addition of carbon monoxide to each rhodium of **6** to give an 18-electron ligand complex, from which *ortho*-metalation would be unlikely to occur.

The following general procedure was used: a mixture of the alcohol, **1** (5.0 mmol), and **2** (0.05–0.20 mmol) in benzene (20–25 mL), 8 *M* NaOH (15–20 mL), and benzyltriethylammonium chloride (0.5–2.0 mmol) were stirred at room temperature (18–30 h) or at 55°C (4 h); the reaction was followed by thin-layer chromatography. The layers were separated, and the organic phase was dried ($MgSO_4$ or Na_2SO_4) and then concentrated to give the carbonyl compound. Further purification, if necessary, was effected by column chromatography, recrystallization, or distillation.

There are chronicled in the literature (1–16) a number of reports on base-catalyzed homoenolization of polycyclic monoketones. While several groups have quantified the rates of homoenolization and established propensities for rearrangement of monoketones, the homoenolization and rearrangement of polycyclic polyketones where remote C—H bonds are activated by two or more carbonyl groups have not been studied.

Our interest in the enolization of bicyclic diketones (17,18) led us to study the $K^+\bar{O}tBu$ catalyzed H–D exchange of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**) to establish whether or not bishomoenolization occurs at C-7. We reported previously that **1** undergoes unusually rapid H–D exchange at C-7 and the bridgeheads (19). We found also that **1** rearranges to an isomeric diketone via conversion of a methyl into a methylene. From ^1H nmr and ^{13}C nmr spectroscopic data and simple mechanistic considerations we speculated at that time that the isomeric diketone was **2**. We now report that **1**, in fact, rearranges to 1,3,3-trimethylbicyclo[2.2.2]-octane-2,5-dione (**3***a*)[1] via a novel β-homoenolate switch.

Table 1 lists a representative selection of isomerization studies of **3***a*. To establish conclusively the structure of the rearrangement product we converted it into the dibromide and determined the X-ray crystallographic structure (20). That the structure of the dibromide is **3***b* establishes 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione (**3***a*) as the rearrangement product. The formation of **3***a* is readily accounted for by a mechanism which involves a β-enolization of a methyl group of **1** to yield homoenolate **4**. Homoenolate **4** undergoes a novel β-enolate switch to homoenolate **5** (Scheme 1) that homoketonizes to **3***a*.[2] As far as we are aware this is only the second report of rearrangement that occurs via a homoenolate switch. Reusch and co-workers have shown that 6-methyl-5-hydroxytricyclo [4.4.0.0][1,5]decan- 9-one (**6**)[3] and several derivatives undergo rearrangement in base via a homoenolate switch (21,22). We plan to study other polycyclic diones to establish the generality and synthetic utility of the rearrangement.

SCHEME 1

TABLE 1. K^+-OtBu catalyzed isomerization of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**) in *tert*-butyl alcohol at 175°C

Concentration **1** (*M*)	Reaction time (h)	Concentration base (*M*)	Conversion* to **3***a* (%)
0.40	78.5	1.03	34
0.40	98	1.16	44
0.38	102	1.15	63

*The combined recovery of **1** and **3***a* generally was 70–85% after correction for preparative glpc collection efficiency.

Homoenolization of 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione. Unusually rapid H–D exchange of a bridgehead methyl

NICK HENRY WERSTIUK AND SHAHIN YEROUSHALMI

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 7, 1980

NICK WERSTIUK and SHAHIN YEROUSHALMI. Can. J. Chem. **58**, 1603 (1980).

The title compound **2***a* undergoes unusually rapid H–D exchange at the bridgehead methyl at a rate 5300 times faster than exchange of the bridgehead methyl of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one (fenchone). From the isotopic composition of partially deuterated **2***a*, we deduce that exchange occurs via an isomer, in equilibrium with **2***a*, which contains an active methylene derived from the bridgehead methyl.

NICK HENRY WERSTIUK et SHAHIN YEROUSHALMI. Can. J. Chem. **58**, 1603 (1980).

Le composé mentionné dans le titre subit un échange H–D au niveau du méthyle en tête de pont à une vitesse 5300 fois plus rapide que l'échange au niveau du méthyle en tête de pont de la triméthyl-1,3,3 bicyclo[2.2.1] heptanone-2 (fenchone). A partir de la composition isotopique du composé **2***a* partiellement deutéré, nous en déduisons que l'échange se produit par l'intermédiaire d'un isomère, en équilibre avec **2***a*, qui contient un méthylène activé provenant du méthyle en tête de pont.

[Traduit par le journal]

Over the past decade there has been a steady increase in the number of publications dealing with the homoenolization of polycyclic monoketones (1–16). Substantial progress has been made as regards the factors which control the rate of homoenolization and the rearrangement of polycyclic monoketones via homoenolate anions. However, there were no reports of studies of homoenolization of polycyclic polyketones prior to our report of the homoenolization and rearrangement of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**). We found that **1** rearranges to 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione (**2**) via a novel homoenolate switch (17). We found also that one of the methyl groups of **2** underwent unusually rapid H–D exchange under the conditions (~1 *M* $K^+\bar{O}t$Bu/*t*-BuOD, 175°C) used to homoenolize and rearrange **1**. In this communication we report on a preliminary study of the homoenolization of **2**. We present evidence that it is the bridgehead methyl of **2** that undergoes rapid exchange. Equally surprising is the unusual mechanism of H–D exchange which must involve conversion of the bridgehead methyl into an active methylene of an isomer which is in equilibrium with **2**.

Table 1 lists a representative selection of homoenolization experiments that illustrate the degree of deuterium incorporation of **2** as a function of base concentration, temperature, and reaction time. Equilibration of the hydrogens α to the carbonyl with the deuterium pool, as expected, occurs readily with the incorporation of 1.5–1.6 atoms of deuterium (entry 3). Additional deuterium is incorporated into **2** predominately by rapid exchange of

Homoenolization of 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione. Unusually rapid H–D exchange of a bridgehead methyl

NICK HENRY WERSTIUK AND SHAHIN YEROUSHALMI
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 7, 1980

NICK WERSTIUK and SHAHIN YEROUSHALMI. Can. J. Chem. **58**, 1603 (1980).

The title compound **2***a* undergoes unusually rapid H–D exchange at the bridgehead methyl at a rate 5300 times faster than exchange of the bridgehead methyl of 1,3,3-trimethylbicyclo[2.2.1]heptan-2-one (fenchone). From the isotopic composition of partially deuterated **2***a*, we deduce that exchange occurs via an isomer, in equilibrium with **2***a*, which contains an active methylene derived from the bridgehead methyl.

NICK HENRY WERSTIUK et SHAHIN YEROUSHALMI. Can. J. Chem. **58**, 1603 (1980).

Le composé mentionné dans le titre subit un échange H–D au niveau du méthyle en tête de pont à une vitesse 5300 fois plus rapide que l'échange au niveau du méthyle en tête de pont de la triméthyl-1,3,3 bicyclo[2.2.1] heptanone-2 (fenchone). A partir de la composition isotopique du composé **2***a* partiellement deutéré, nous en déduisons que l'échange se produit par l'intermédiaire d'un isomère, en équilibre avec **2***a*, qui contient un méthylène activé provenant du méthyle en tête de pont.

[Traduit par le journal]

Over the past decade there has been a steady increase in the number of publications dealing with the homoenolization of polycyclic monoketones (1–16). Substantial progress has been made as regards the factors which control the rate of homoenolization and the rearrangement of polycyclic monoketones via homoenolate anions. However, there were no reports of studies of homoenolization of polycyclic polyketones prior to our report of the homoenolization and rearrangement of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**). We found that **1** rearranges to 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione (**2**) via a novel homoenolate switch (17). We found also that one of the methyl groups of **2** underwent unusually rapid H–D exchange under the conditions (~1 *M* $K^+\bar{O}t$Bu/*t*-BuOD, 175°C) used to homoenolize and rearrange **1**. In this communication we report on a preliminary study of the homoenolization of **2**. We present evidence that it is the bridgehead methyl of **2** that undergoes rapid exchange. Equally surprising is the unusual mechanism of H–D exchange which must involve conversion of the bridgehead methyl into an active methylene of an isomer which is in equilibrium with **2**.

Table 1 lists a representative selection of homoenolization experiments that illustrate the degree of deuterium incorporation of **2** as a function of base concentration, temperature, and reaction time. Equilibration of the hydrogens α to the carbonyl with the deuterium pool, as expected, occurs readily with the incorporation of 1.5–1.6 atoms of deuterium (entry 3). Additional deuterium is incorporated into **2** predominately by rapid exchange of

TABLE 1. H–D Exchange of 1,3,3-trimethylbicyclo[2.2.2]octane-2,5-dione in $K^+\bar{O}t$Bu/*t*-BuOD

Entry	Concentration (*M*) **2***a*[a]	Concentration (*M*) base	Temperature °C	Reaction time (h)	Excess *d* per molecule[b] (*d* in methyl)
1	0.15	1.14	175	55	5.86 (2.31)[c]
2	0.12	1.05	150	4	4.10 (2.63)[c]
3	0.13	1.05	100	5	1.68 (0.13)[d]
4	0.11	1.03	100	25	2.01 (0.51)[d]
5	0.11	1.08	100	75	2.78 (1.06)[d]

[a]Recoveries of **2***a* were in the 80–90% range.
[b]Determined mass spectrometrically at low voltage (10–15 eV).
[c]Determined by ^{2}H nmr spectroscopy in the presence of Eu(fod)$_3$.
[d]Determined by ^{2}H nmr in the absence of Eu(fod)$_3$.

the bridgehead methyl. In fact, from a one-point kinetic analysis we find that the methyl of **2** exchanges 5300 times faster than the bridgehead methyl of fenchone (11). Although homoenolization occurs most readily at the bridgehead methyl, deuterium is also incorporated at C-7 and C-8 as is indicated by the data in entry 1. This conclusion is also supported by the ^{2}H nmr spectrum of deuterated **2** isolated from the reaction described in entry 1.

That a methyl undergoes exchange is established by the absence of a methyl signal at σ 1.04 in the ^{1}H nmr spectrum of deuterated **2***a* isolated from the experiment described in entry 1. That it is the bridgehead methyl that undergoes rapid exchange is supported by the following evidence. Irradiation of the C-3 methyls of **2***a* containing 4.9 excess deuterium atoms yielded an increase of 10.5% and 12.6% (average of three determinations) in the signal due to H-4. The nOe's (18) establish that the C-3 methyls must flank H-4. Also, that the ^{13}C signal due to C-1 of deuterated **2***b* obtained from a highly deuterated sample of **2***a* (6.5 excess deuterium atoms per molecule) was absent, an indication of a long relaxation time, establishes that C-1 must be attached to carbon atoms which bear oxygen, bromine, or deuterium as indicated in **3**. Furthermore, the signal at 19.4 ppm of the ^{13}C spectrum of **2***a* that we assign with certainty to the bridgehead methyl,[1] essentially disappears on deuteration.

Equally interesting is the fact that deuterium is incorporated into **2***a* in an unusual fashion. The expected sequence of exchange

$$d_0 \xrightarrow{k_1} d_1 \xrightarrow{k_2} d_2 \xrightarrow{k_2} d_3 \xrightarrow{k_3} d_4 \xrightarrow{k_4} k_5$$

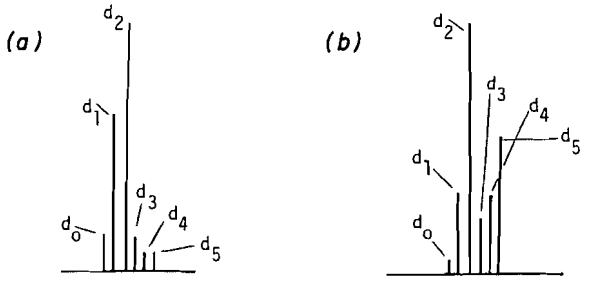
where

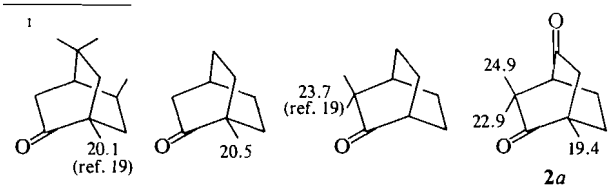
$$k_1 \sim k_2 \gg k_3 \sim k_4 \sim k_5$$

would lead to a build up and then a gradual decrease of d_3 and d_4 species as conversion to **2***a*-d_5 occurs. However, it is clear from the distribution of deuterated species (Fig. 1) that there is a slow conversion of **2***a*-d_2 to **2***a*-d_3 and then a fast conversion of **2***a*-d_3 to **2***a*-d_5. That is,

$$k_1 \sim k_2 \gg k_3 < k_4 \sim k_5$$

Even in the case where there is minimal exchange of the methyl (entry 3) it is clear that **2***a*-d_3 must be converted rapidly to **2***a*-d_5 (Fig. 1). When the peak intensities of **2***a* isolated from the experiment listed in entry 5 are corrected for $M + 1$ and $M + 2$ contributions, **2***a* is a composite of 2.4% d_0, 14.7% d_1, 43.7% d_2, 4.1% d_3, 12.5% d_4, 22.5% d_5, and $< 1\%$ d_6 species. These results suggest that exchange of the bridgehead methyl must occur predominately via an isomer which is in equilibrium with **2***a*[2] and the isomer probably has an active methylene group that is derived from the





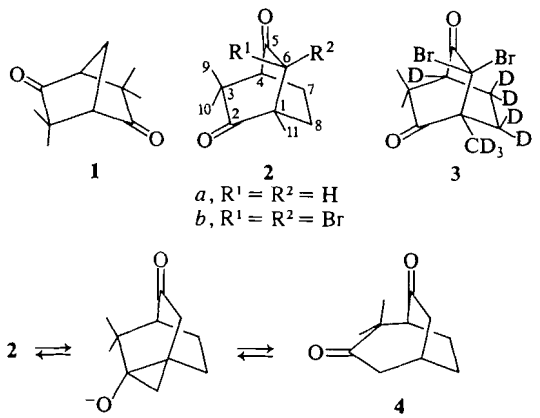


FIG. 1. (*a*) Molecular ion of deuterated **2**a from entry 3; (*b*) molecular ion of deuterated **2**a from entry 5.

We thank Professor C. Djerassi for providing us with a sample of 1-methylbicyclo[2.2.2]octan-2-one.

[2]The isomer which undergoes fast exchange must be present in a small amount because we cannot detect (< 1%) any other major components. If **4** is in fact the isomer of **2***a*, it must homoenolize rapidly as well.

SCHEME 1

bridgehead methyl. A possible candidate is 2,2-dimethylbicyclo[3.2.2]nonane-3,7-dione (**4**) (Scheme 1). We are currently investigating the homoenolization of other methylated bicyclo-[2.2.2]octanones and bicyclo[3.2.2]octanediones to establish the reason for the facile homoenolizations.

A highly asymmetric synthesis of the *O*-2-isocephem class of β-lactam antibiotics

SHEILA M. TENNESON AND BERNARD BELLEAU

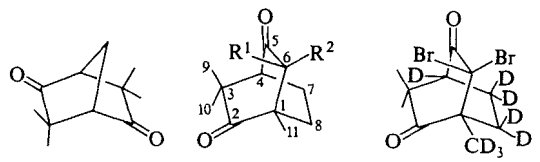
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received May 5, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

SHEILA M. TENNESON and BERNARD BELLEAU. Can. J. Chem. **58**, 1605 (1980).

Starting from D-threonine, an asymmetric synthesis of the dextrorotatory bioactive enantiomer of 3-methyl-7-phenylacetamido-*O*-2-isocephem was accomplished. The key step, where asymmetric cycloaddition of azidoacetyl chloride to the cinnamylidene Schiff base of protected D-threonine is induced, generates the desired *cis*-β-lactam in 90% optical yield. The absolute configuration of the final product was confirmed by comparing its antimicrobial activity with that of its corresponding racemate.



SHEILA M. TENNESON et BERNARD BELLEAU. Can. J. Chem. **58**, 1605 (1980).

En partant de la D-thréonine, on a réalisé une synthèse asymétrique de l'énantiomère dextrogyre biologiquement actif du méthyl-3 phénylacétamido-7 *O*-isocéphème-2. L'étape principale implique la cycloaddition asymétrique du chlorure d'azidoacétyle sur la base de Schiff de la cinnamaldéhyde avec la D-thréonine protégée et elle engendre la β-lactame *cis* désirée avec un rendement optique de 90%. On a confirmé la configuration absolue du produit final en comparant son activité antimicrobienne à celle du racémate correspondant. [Traduit par le journal]

Efficient and stereospecific syntheses of isocephems and the analogous *O*- and *N*-2-isocephems were recently reported by the Bristol Canada group (1). The *O*-2-isocephems in particular constitute a new class of β-lactam antibiotics whose effectiveness against some common pathogenic bacteria compare favorably with analogous cephalosporins currently in use. As is the case of all β-lactam antibiotics, antibacterial activity of a prototype *O*-2-isocephem was associated exclusively with one of the enantiomers (dextrorotatory) of the synthetic racemix mixture (1*f*). A single key step of the synthesis, the cycloaddition of azidoacetyl chloride to a cinnamylidene Schiff base introduces simultaneously the only two asymmetric centers appearing in the final product. However, only one racemate is obtained owing to the exclusive *cis*-stereospecificity of the cycloaddition. For obvious reasons of economics, a synthetic process leading mainly to the bioactive enantiomer from inexpensive starting materials became an important goal. Such an asymmetric process demands that the steric course of the cycloaddition be sensitive to chirality effects about an appropriate α-aminoester Schiff base. Although the chiral α-carbon of an aminoacid Schiff base is not proximal to the reacting aldimine carbon, preliminary observations by the Bristol group some time ago[1] strongly indicated that asymmetric cycloaddition was induced in some degree using a protected L-threonine Schiff base as the reaction partner. However, similar experiments by Just and Liak (2), but with a protected L-serine cinnamylidene Schiff base, led only to racemic material and thus could not yield any information on the possibility of asymmetric induction during the cycloaddition. This provided an additional incentive to reexamine, but in detail, the use of a protected enantiomer of a threonine Schiff base as a potential inducer of asymmetry. Mechanistic considerations allowed the prediction that, for the bioactive enantiomer of the end-product to be obtained, the D-isomer of threonine should be used as staring material. Thus, starting from D-threonine benzyl ester, the synthesis of optically pure (+)-3-methyl-7-phenyl-acetamido-*O*-2-isocephem of *cis*-configuration was accomplished as shown in Scheme 1.

Silylation (3) of D-Thr-ObzL·Hcl (4) (mp 126.5–127.5°C; $[\alpha]_D^{23}$ +10.1 (*c* 4.5, MeOh) in HMPT with *tert*-butyldimethylsilyl chloride gave the *O*-silyl ether[2] which was converted to Schiff base **1** on reaction with cinnamaldehyde (1*a*). The crude Schiff base plus triethylamine (1.3 equiv.) in dry CH_2Cl_2 was treated at −10°C with azidoacetyl chloride (1.2 equiv.) according to published procedures (1) to give β-lactams **2** and **3** (60% from D-Thr-ObzL·HCl), the azidoacetyl amide of protected threonine (~ 30%), and small amounts of unidentified material. The β-lactam fraction was submitted to hplc (Spherisorb, Si 100, 10 μm; MeOh–EtOAc–hexane (0.1:5:95)) to give pure **3** ($[\alpha]_D^{23}$ −150 (*c* 2.5, hexane)) and **2** ($[\alpha]_D^{23}$ +80 (*c*

1.5, hexane)) in a ratio of 9:1. That both **3** and **2** had *cis*-stereochemistry was inferred from their respective 200 MHz pmr spectra ($CDCl_3$)(**3**: $\delta = 4.90$ (d, $J = 5.3$ Hz, 1H, H-3) and 4.92 (dd, $J = 5.3$ and 8.8 Hz, 1H, H-4) ppm; **2**: $\delta = 4.89$ (d, $J = 5.2$ Hz, 1H, H-3) and 4.80 (dd, $J = 5.2$ and 8.8 Hz, 1H, H-4) ppm). Hence, the cycloaddition reaction proceeds asymmetrically to give a *cis* β-lactam in 90% optical yield.

The major β-lactam **3** was submitted to ozonolysis (CH_2Cl_2–MeOH, 9:1) at −70°C followed by reductive workup with $NaBH_4$–Alox (5) to give **4** (90%, $[\alpha]_D^{23}$ −158 (*c* 3.7)). Mesylation (6), then hydrolysis of the silyl ether with 95% TFA afforded alcohol mesylate **6** (85% from **4**, mp 100–101°C, $[\alpha]_D^{23}$ −112 (*c* 3) which on oxidation with Jones' reagent (7) (1.1 equiv.) at 15–20°C gave the enol mesylate **7** (1*b*) plus unreacted **6** which was recycled.[3] Without further purification, **7** was treated with triethylamine in refluxing CH_2Cl_2 (2.5 h) to give *O*-2-isocephem derivative **8** (1*b*) ($[\alpha]_D^{23}$ −22 (*c* 2.4)). Hydrogenation of **8** over Pt gave the amine **9** (1*b*) which was coupled with phenylacetic acid using EEDQ (8) to give the ester amide **10** (65% from **8**) ($[\alpha]_D^{23}$ +154 (*c* 0.6)). Hydrogenolysis (10% Pd/C) of **10** in EtOH–Thf (10:7) gave the *O*-2-isocephem acid **11**, (mp 95–105°C (dec.); $[\alpha]_D^{23}$ +155 (*c* 1, acetone)).

The respective *in vitro* antimicrobial activity (expressed as MIC's) of **11** and its corresponding racemate BC-L30 (9) against 5 typical strains of bacteria were as follows: *Streptococcus pneumoniae*, 0.25 and 0.5; *Streptococcus pyrogenes*, 0.5 and 0.5; *Staphylococcus aureus*, 0.5 and 1.0; *Escherichia coli*, 32 and 125; *Proteus mirabilis*, 8 and 16. These results establish the absolute configuration of **11** and its precursors. It appears to be the first time that a highly asymmetric cycloaddition on a Schiff base has been developed successfully for the production of the bioactive enantiomer of a β-lactam antibiotic. The mechanistic implications of this asymmetric cycloaddition, as well as other pertinent applications of this approach, will be described later.

[3]The oxidation was monitored by tlc and stopped at about 50% at which point side reactions became significant.

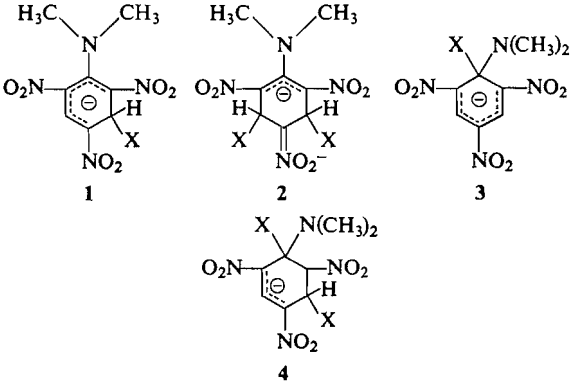
ERWIN BUNCEL, MASASHI HAMAGUCHI, and ALBERT R. NORRIS. Can. J. Chem. **58**, 1609 (1980).

The interactions of *N,N*-dimethylpicramide (DMP) with methoxide ion in dimethylsulfoxide–methanol media have been investigated spectrophotometrically at 25.0°C. Both the 1:1 and 2:1 σ-complexes of DMP and methoxide ion have been observed under the various reaction conditions employed. However, dimethylsulfoxide has been found to preferentially stabilize the 1:1 σ-complex relative to the 2:1 σ-complex. As a consequence, at low base concentrations in dimethylsulfoxide–methanol solutions rich in dimethylsulfoxide (i.e. 95/5, v/v, DMSO/MeOH), the 1:1 σ-complex can be formed in the absence of any 2:1 σ-complex. This observation has been used to obtain, for the first time, values of the absorption maxima and molar absorptivities at the absorption maxima of both the 1:1 and 2:1 σ-complexes.

ERWIN BUNCEL, MASASHI HAMAGUCHI et ALBERT R. NORRIS. Can. J. Chem. **58**, 1609 (1980).



On a étudié par spectrophotométrie à 25°C les interactions du *N,N*-diméthylpicramide (DMP) avec l'ion méthylate dans un milieu de diméthylsulfoxyde–méthanol. On a observé les deux complexes σ 1:1 et 2:1 du DMP avec l'ion méthylate dans les différentes conditions de réaction utilisées. Cependant on a trouvé que le diméthylsulfoxyde stabilise préférentiellement le complexe σ 1:1 par rapport au complexe σ 2:1. En conséquence, à de faibles concentrations de base dans les solutions de diméthylsulfoxyde–méthanol riches en diméthylsulfoxyde (i.e. 95/5, v/v DMSO/MeOH), le complexe σ 1:1 peut être formé en l'absence de tout complexe 2:1. On a utilisé cette observation en vue d'obtenir pour la première fois les valeurs d'absorption maximale et les absorptivités molaires à l'absorption maximale des deux complexes σ 1:1 et 2:1.

[Traduit par le journal]

Introduction

Investigations of several different types have been carried out on the reversible reactions of *N,N*-dimethylpicramide (DMP) with hydroxide ion (1, 2) and sulfite ion (3–5) in water and water–dimethylsulfoxide mixtures and with methoxide ion in methanol and methanol–dimethylsulfoxide mixtures (6–8).

^{1}H nmr studies (2, 4, 5, 7, 8) indicate that, in the solvents employed, at mole ratios of base-to-DMP less than one, all three bases add at C-3 (or C-5) to form 1:1 σ-complexes such as **1** (X = OH, OCH_3, SO_3^-). At mole ratios of base-to-DMP greater than 1, 2:1 σ-complexes such as **2** are observed (X = OH, OCH_3, SO_3^-). In no instance was there evidence for the formation of a C-1 adduct, **3** (X = OH, OCH_3, SO_3^-), or the formation of 2:1 σ-complexes involving addition of the base at both the C-1 and C-3 (or C-5) positions to yield complexes such as **4** (X = OH, OCH_3, SO_3^-).

However, although complexes of DMP such as **3** have not yet been reported, comparable species are known in systems closely related to *N*-methylpi-

cramide (9). Transient intermediates of structure type **3** have been reported in the reactions of picryl ethers with aliphatic amines (10).

While ultraviolet–visible studies clearly indicate a marked difference in the absorption spectra of complexes such as **1** and **2** (X = OH, OCH_3, SO_3^-) (1, 3–5), particularly in those cases in which X = OH and OCH_3, only in the case of **1** and **2** with X = SO_3^- have both the band shapes and molar absorptivity values (ε) at the absorption maxima (λ_{max}) been reported for both the 1:1 and 2:1 complexes (3–5).

We report here on our studies of the reaction of DMP with methoxide ion in dimethylsulfoxide–methanol (95/5, v/v) as solvent. Under our reaction conditions the stability constants which characterize the formation of the 1:1 and 2:1 σ-complexes are sufficiently different that good absorption data can be obtained for each complex.

Results and Discussion

In the wavelength region 200–900 nm, *N,N*-dimethylpicramide (DMP) in mixed dimethylsulfoxide–methanol (DMSO–MeOH, 95/5, v/v) as solvent exhibits a single, broad absorption band which displays a maximum at 383 nm ($\varepsilon_{383} = 1.41 \times 10^4\ M^{-1}\ cm^{-1}$).

The addition of progressively larger amounts of sodium methoxide in DMSO–MeOH solution (95/5, v/v) to a DMSO–MeOH (95/5, v/v) solution of fixed DMP concentration ($3.18 \times 10^{-4}\ M$) resulted in the simultaneous disappearance of the absorption band due to DMP and the appearance of a new absorption band possessing absorption maxima at 402 and 474 nm. Solutions containing only DMP and this new absorbing species, Q, were characterized by an isosbestic point at 370 nm (Fig. 1). The reaction of DMP to yield Q occurred well within the time required to mix the two solutions and record the absorption spectrum of the resulting mixture (<20 s). Conversion of DMP to Q was dependent on the mole ratio of $NaOCH_3$ to DMP and was essentially complete at a mole ratio of $NaOCH_3$ to DMP of 1.36. The addition of excess trifluoracetic acid (CF_3COOH) to the reaction mixtures rapidly and quantitatively converted Q to DMP.

If species Q is the result of a 1:1 interaction of DMP and CH_3O^-, we can write

[1] $\mathrm{DMP} + \mathrm{CH_3O^-} \rightleftharpoons \mathrm{Q}$

and

[2] $K_1 = [\mathrm{Q}]/[\mathrm{CH_3O^-}][\mathrm{DMP}]$

where [Q], [CH_3O^-], and [DMP] represent the equilibrium concentrations of Q, CH_3O^-, and DMP, respectively.

For a 1.00 cm cell the absorbance, A, at a specified wavelength is given by

[3] $A = \varepsilon_Q[\mathrm{Q}] + \varepsilon_{DMP}[\mathrm{DMP}]$

where ε_Q and ε_{DMP} are the molar absorptivities, in $M^{-1}\ cm^{-1}$, of species Q and DMP, respectively. At any given wavelength, ε_Q can be evaluated from the limiting absorbance value ($A_{limiting}$) in a plot of absorbance versus [CH_3O^-] under conditions of [CH_3O^-]/[DMP] $\simeq$ 1.1 to 1.4. Values of ε_Q, determined in this manner at selected wavelengths, are given in Table 1 together with values of ε_{DMP} at the same wavelengths.

Employing the material balance equations

[4] $[\mathrm{DMP}]_0 = [\mathrm{Q}] + [\mathrm{DMP}]$

and

[5] $[\mathrm{CH_3O^-}]_0 = [\mathrm{CH_3O^-}] + [\mathrm{Q}]$

where $[DPM]_0$ and $[CH_3O^-]_0$ represent total concentrations of DMP and CH_3O^- in solution, absorbance data collected at a given wavelength and values of ε_Q and ε_{DMP} at that wavelength one can, with the aid of eq. [3], evaluate [Q], [DMP], [CH_3O^-] and hence calculate K_1. From absorbance data collected at 402 nm, over the range of base concentrations in which DMP was being converted to Q, a mean K_1 of $1.4 \pm 0.4 \times 10^3\ M^{-1}$ at 25.0°C was obtained. Treatment in the same manner of absorbance data recorded at 444 and 474 nm yielded values of K_1 of comparable magnitude to that just quoted. The agreement among the values of K_1 calculated using absorbance data collected at the three wavelengths confirms the validity of eqs. [5], [4], and [3] and the 1:1 stoichiometry of species Q.

Quite independent of the wavelengths at which absorbances were recorded, the values of K_1, calculated in the manner described above, were found to increase slightly with increasing concentration of sodium methoxide in solution. This behavior was observed both when the reactions were carried out under conditions of varying ionic strength (0.50×10^{-4} to $9.00 \times 10^{-4}\ M$) and under conditions of a constant ionic strength of 0.20 M maintained with $(C_2H_5)_4NClO_4$.

Since the ^1H nmr studies (2, 7, 8) establish that the product formed as a result of the 1:1 interaction of CH_3O^- and DMP in both MeOH and DMSO–MeOH mixtures is **1** (X = OCH_3), and our value of λ_{max} for species Q (402 nm) agrees well with the λ_{max} value previously reported for the 1:1

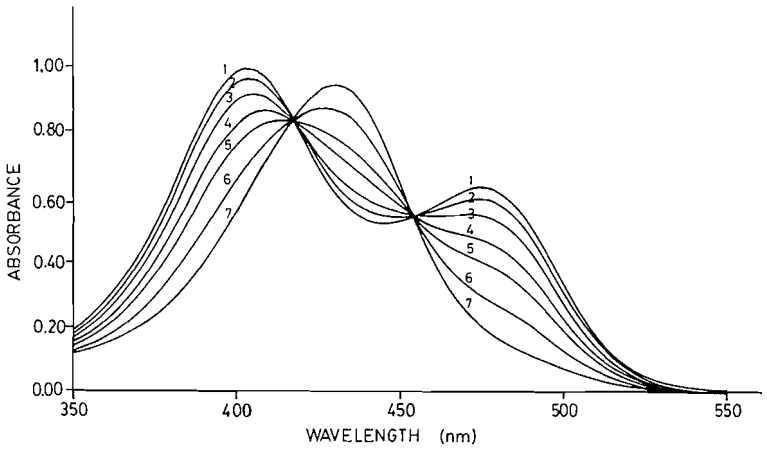
TABLE 1. Molar absorptivities, ε, at selected wavelengths for DMP and species Q and R in DMSO–MeOH (95/5, v/v) at 25.0°C

	ε (M^{-1} cm^{-1}) at the indicated λ (nm)			
Compound	384	402	430	474
DMP	1.41×10^4	1.08×10^4	0.52×10^4	0.06×10^4
Q	2.20×10^4	3.07×10^4	1.90×10^4	1.94×10^4
R	0.95×10^4	1.76×10^4	2.93×10^4	0.44×10^4

adduct in methanol (400 nm) (6), we can fairly confidently assign Q as having structure **1** (X = OCH_3). The similarities in the shapes of the absorption bands and the values of ε at λ_{max} of Q (complex **1**, X = OCH_3) and complex **6** (11)

lends support to our argument. Further, complex **7** (R = *i*-Pr) has been reported to possess a λ_{max} at 405 nm in methanol, although no mention is made by the authors (12) of either the value of ε at this wavelength or of a longer wavelength maximum associated with this species. Since complex **8** has a uv–visible absorption pattern and values of ε at λ_{max} very similar to those reported above for Q (13), our assignment of structure **1** rather than structure **3** to Q rests very heavily on the results of the ^1H nmr studies which show that species such as **3** are not formed in detectable concentrations in either methanol or methanol–dimethylsulfoxide mixtures (2, 4, 7, 8). That there are limitations associated with using only the shapes of absorption bands and values of ε at λ_{max} to differentiate the structures of related complexes in solution is further illustrated by the observation that the 1:1 σ-complexes **1** (X = OCH_3 in methanol as solvent) and **1** (X = SO_3^- in water or water–dimethylsulfoxide) have quite different band shapes and values of ε at λ_{max} (3, 4, 6).

The equilibrium constant for the formation of the 1:1 σ-complex **1** (X = OCH_3) in DMSO–MeOH (95/5, v/v) is substantially larger (1.4×10^3 M^{-1}) in this solvent than it is in methanol (7 M^{-1}) (1). Similar large increases in the values of *K* as a result of increasing the DMSO content of DMSO–MeOH mixtures have been noted in the formation reactions leading to **9** (X = CH_3O, C_2H_5S, and C_6H_5S) and a variety of related σ-complexes (14–17). The trend in *K* values is attributed primarily to a less effective solvation of methoxide ion by DMSO than by methanol; anionic σ-complex and the starting



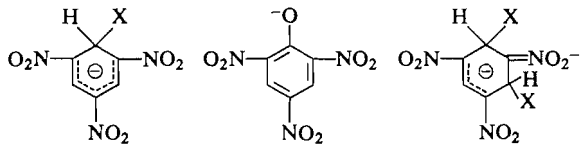


FIG. 2. Absorption spectra of dimethylsulfoxide–methanol solutions (95/5, v/v) 3.21×10^{-4} *M* in *N,N*-dimethylpicramide with $[NaOCH_3]_0$ (*M*) equal to: *1*, 4.34×10^{-4}; *2*, 16.3×10^{-4}; *3*, 28.7×10^{-4}; *4*, 46.7×10^{-4}; *5*, 62.6×10^{-4}; *6*, 99.8×10^{-4}; *7*, 153.0×10^{-4}.

nitroaromatic compound are considered to possess comparable solvation properties. Our lower ratio of *K* values (~200), as compared to values of 4×10^4 and 10^8 in other systems, may indicate that **1** (X = OCH_3) is far less effectively solvated by DMSO than is DMP. This is perhaps not surprising in view of the rather bulky nature of the dimethylamino group in the molecule.

The addition of NaOMe to solutions of fixed DMP concentration, beyond the mole ratio of CH_3O^- to DMP of 1.4, resulted in the disappearance of species Q and the appearance of a new species, R, characterized by a single absorption maximum at 430 nm ($\varepsilon = 2.93 \times 10^4\ M^{-1}\ cm^{-1}$). The spectra of solutions containing only species Q and R were characterized by isosbestic points at 417 and 454 nm (Fig. 2). Conversion of Q to R was effected within the time required to mix and record the spectrum of each solution (<20 s) at 25.0°C. Within minutes of mixing, the reaction of Q to yield R could be quantitatively reversed upon the addition of excess CF_3COOH. However, additional very slow spectral changes were noted in these solutions and, within 1 or 2 days of conversion of Q to R, complete recovery of DMP as a result of acidification of the solutions was not achieved. Similar observations of a very slow secondary reaction have been made by Gold and Rochester (1) in connection with the reaction of DMP and CH_3O^- in methanol. We find that the resulting spectra of the solutions are *not* consistent with the presence of either **8** or **10** in solution (18) and the reaction product(s) is (are), as yet, unidentified.

If species R is formed as a result of a 1:1 interaction of Q and CH_3O^- we have

[6] $Q + CH_3O^- \rightleftharpoons R$

and

[7] $K_2 = [R]/[Q][CH_3O^-]$

Employing absorbance data recorded at 402 nm and the arguments and procedures described earlier, a value of $K_2 = 1.4 \pm 0.2 \times 10^2\ M^{-1}$ was evaluated.[3] Values of K_2 of comparable magnitude were obtained from absorbance data collected at 430 and 474 nm. The invariance in the values of K_2, evaluated using the absorbance data obtained at the three wavelengths, offers strong support for the formulation of R as a species resulting from a 1:1 interaction of Q and CH_3O^-.

We note that the values of K_2 calculated using eq. [7] are not constant but increase slightly with increasing concentration of $NaOCH_3$. However, for the same range of $NaOCH_3$ concentrations, the variation in K_2 is significantly smaller than is the variation in K_1. This is somewhat surprising in the light of Crampton's observation that in the reaction

[3]Alternatively the experimental data could be treated using the Benesi–Hildebrand (19) equation in the form

[8] $\{A - \varepsilon_Q[Q]_0\}^{-1} = \{K(\varepsilon_Q - \varepsilon_R)[MeO^-]_0[Q]_0\}^{-1} + \{(\varepsilon_Q - \varepsilon_R)[Q]_0\}^{-1}$

The slope and intercept of the linear graph of the left-hand side of this equation versus $[MeO^-]_0^{-1}$ yielded values of *K* and ε_R in good agreement with those obtained using the procedure noted previously. Values of ε_R at selected wavelengths are listed in Table 1.

of sulfite ion and DMP in water, the formation constant for the 2:1 σ-complex was more susceptible to ionic strength effects than the formation constant of the 1:1 σ-complex (4). Perhaps, though, the systems are not comparable because of the differences in both charge types and the solvents employed in the two studies.

The ratio K_2/K_1 of $\sim10^{-2}$ for the reactions of DMP and CH_3O^- in our solvent system may be compared to the corresponding ratio of ~2 for the DMP–sulfite ion interactions in water (3, 4) and a value of $K_2/K_1 \gg 1$ for the DMP–hydroxide ion interactions in water (1). The results are completely in accord with earlier suggestions that, in the DMSO/MeOH solvent system, solvation of the diadduct by DMSO is far less favorable than is solvation of the monoadduct (4, 16). In contrast, solvation of the diadduct in water is comparable energetically to solvation of the monoadduct, irrespective of whether X = OH or SO_3^-.

Combining our mean values of K_1 and K_2 for the interactions of DMP and methoxide ion in DMSO/MeOH (95/5, v/v) we obtain a K for the overall reaction

[9] $\mathrm{DMP} + 2CH_3O^- \rightleftharpoons \mathrm{R}$

of 1.96×10^5 M^{-2} at 25.0°C. While Gold and Rochester (6) have also postulated the formation of the 2:1 σ-complex, **R**, in pure methanol, the K value they report (26 M^{-3} at 25.0°C) is formulated in terms of the apparent reaction

[10] $\mathrm{DMP} + 3CH_3O^- \rightleftharpoons \mathrm{R}$

and, as such, cannot be compared directly to our value of 1.96×10^5 M^{-2}. Based on the K_2/K_1 values quoted above, a ratio of K_2/K_1 for the DMP–CH_3O^- interaction in methanol of <1 might, however, be anticipated. Given that K_1 for the interaction is 6 M^{-1} at 25.0°C (12) a predicted value of $K_2 < 6$ M^{-1} is obtained. This then places an upper limit of <3.6 M^{-2} on the K for the overall reaction of DMP and $2CH_3O^-$ to yield R in methanol. On going from methanol as solvent to 95/5, v/v, DMSO–MeOH as solvent the increase in K_2 ($>10^5$) is clearly much larger than the increase in K_1 (~200).

In light of the ^1H nmr results, which show that 2:1 σ-complexes of DMP with HO^-, CH_3O^-, and SO_3^- possess structure **2** in solution, and the similarities in the ultraviolet–visible spectral characteristics of **2** (X = HO or SO_3^-) and species R, we propose structure **2** (X = CH_3O) for the 2:1 species, **R**, formed by the interaction of DMP and CH_3O^- in DMSO–MeOH.[4] Relevant spectral data are given in Table 2. We note that a number of 2:1 σ-complexes of TNB **11** (X = HO^-, SO_3^-, $C_2H_5S^-$, CH_3O^-) are also characterized by a single absorption maximum in the visible region and ε values, at λ_{max}, of magnitude $2.5 \pm 0.5 \times 10^4$ M^{-1} cm^{-1}.

Experimental

N,N-Dimethylpicramide was prepared by adding an excess of dimethylamine in ethanol to a 5% solution of 1-chloro-2,4,6-trinitrobenzene in ethanol and evaporating the resulting solution to dryness. The solution formed by extraction of the residue with acetone was filtered to remove the insoluble dimethylammonium chloride and evaporated to dryness. The resulting solid was recrystallized to constant melting point from absolute alcohol. After drying *in vacuo* over phosphorus(V) pentoxide, the product had a melting point of 138°C; lit. (21) 138°C. Sodium methoxide solutions were prepared by dissolving clean sodium in Analar methanol under nitrogen and were titrated with standard acid using phenolphthalein as an indicator. Dimethylsulfoxide (DMSO) was dried over calcium hydride and fractionated under reduced pressure, the middle fraction being collected. Eastman tetraethylammonium perchlorate was dried to constant weight *in vacuo* over phosphorus(V) pentoxide. Reagent grade trifluoroacetic acid was used as received.

Stock solutions of *N,N*-dimethylpicramide in DMSO, DABCO in DMSO, $(C_2H_5)_4NClO_4$ in DMSO, and $NaOCH_3$ in methanol were made up under nitrogen in a drybox and were protected from light. Solutions used in the equilibrium studies were also prepared in the drybox by adding appropriate volumes of the stock solutions to a known volume of DMSO. After thorough mixing, a portion of the solution was transferred to a clean dry spectrophotometric cell and the cell and its contents then placed in the spectrophotometer.

[4]A referee has suggested that simultaneously with the uv–visible study, one should also obtain ^1H nmr spectra on the same solutions, using pulse FT techniques. While in principle this may be possible, the observed slow decomposition of the dianionic species over the time period required to accumulate the necessary spectra, on solutions ca. 10^{-4} M, is likely to lead to ambiguous results. In a previous study we were able to obtain uv–visible, ir, and nmr spectral results on solutions having approximately equal concentrations and the results of all three techniques could consistently be interpreted as arising from the particular σ-complex species (20).

Optical measurements were carried out on a Beckman Acta IV spectrophotometer using matched silica cells of 1.0 mm and 5.0 mm path length. The temperature in the cells was maintained constant at 25.0 ± 0.1°C by circulating water from a constant temperature bath through a specially designed cell holder in the spectrophotometer.

N-Methylpicramide–methoxide ion interactions: proton abstraction versus σ-complex formation

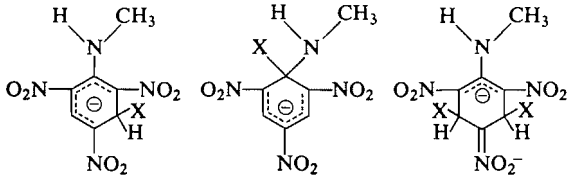
ERWIN BUNCEL,[1] MASASHI HAMAGUCHI,[2] AND ALBERT R. NORRIS[1]

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received January 21, 1980

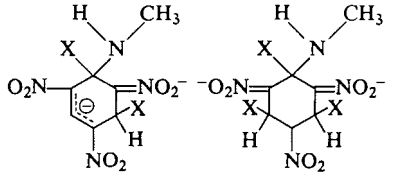
ERWIN BUNCEL, MASASHI HAMAGUCHI, and ALBERT R. NORRIS. Can. J. Chem. **58**, 1615 (1980).

The interactions of *N*-methylpicramide (NMP) with methoxide ion in dimethylsulfoxide–methanol media and with 1,4-diazabicyclooctane in dimethylsulfoxide have been investigated spectrophotometrically at 25.0°C. Dimethylsulfoxide has been found to stabilize the conjugate base of NMP, formed via loss of hydrogen ion from the methylamino group, with respect to the anionic σ-complex generated via addition of methoxide ion to a ring carbon position. As a result, methanol–dimethylsulfoxide solutions rich in dimethylsulfoxide (i.e., 95/5, v/v, DMSO/MeOH) contain the conjugate base of NMP as the sole product of the 1:1 interaction of NMP and methoxide ion. At mole ratios of methoxide ion to NMP > 1 a second interaction results, yielding a dianion formed via addition of methoxide ion to one of the H-bearing ring carbon atoms of the conjugate base. Values of absorption maxima and molar absorptivities at the absorption maxima for the conjugate base of NMP and the dianion are reported here for the first time.



ERWIN BUNCEL, MASASHI HAMAGUCHI et ALBERT R. NORRIS. Can. J. Chem. **58**, 1615 (1980).

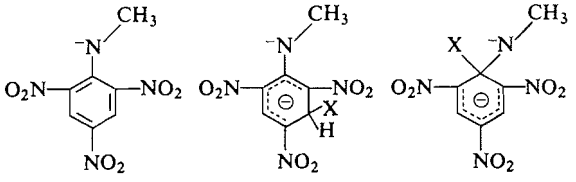
On a étudié par spectrophotométrie à 25°C les interactions du *N*-méthylpicramide (NMP) avec l'ion méthylate dans une solution de diméthylsulfoxyde–méthanol et également les interactions avec le diaza-1,4 bicyclooctane dans le diméthylsulfoxyde. On a trouvé que le diméthylsulfoxyde stabilise la base conjuguée du NMP formée par l'intermédiaire d'une élimination d'ion hydrogène du groupe méthylamino, par rapport au complexe σ anionique produit par l'addition de l'ion méthylate sur un carbone du cycle. En conséquence, les solutions de méthanoldiméthylsulfoxyde riches en diméthylsulfoxyde (i.e. 95/5 v/v DMSO/MeOH contiennent la base conjuguée du NMP comme produit unique de l'interaction 1:1 entre le NMP et l'ion méthylate. Pour des rapports molaires ion méthylate/NMP > 1, il en résulte une deuxième interaction conduisant à un dianion qui se forme par l'addition de l'ion méthylate sur l'un des atomes de carbone du cycle de la base conjuguée lié à un hydrogène. On présente pour la première fois les valeurs d'absorption maximale et les absorptivités molaires pour une absorption maximale de la base conjugée du NMP et du dianion.



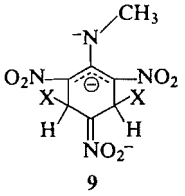
[Traduit par le journal]

Introduction

The interaction of *N*-methylpicramide (NMP) with base X^- can, in principle, lead to a variety of products. Thus, 1:1, 2:1, and 3:1 σ-complexes may be formed by the attachment of 1, 2, or 3 base ions to a variety of ring carbon centres to yield complexes **1–5**.



1 **2** **3**



4 **5**

In addition, the conjugate base of NMP, **6**, may be formed via the loss of a proton from the methylamino group and this anion may, in turn, add further base to form the additional complexes **7–9**.

6 **7** **8**

9

Previous studies (1–5) have established the existence, in solution, of species such as **1** (X = CH_3O, SO_3^-), **3** (X = CH_3O, SO_3^-), **6**, and **7** (X = HO, CH_3O). With X^- = HO^- and CH_3O^-, both the types of complexes formed and the equilibrium constants for the formation of a particular type of complex were found to depend strongly on the properties of the solvents used in the respective studies (3–6). While complexes such as **2** (X = CH_3O) have not been reported, comparable species

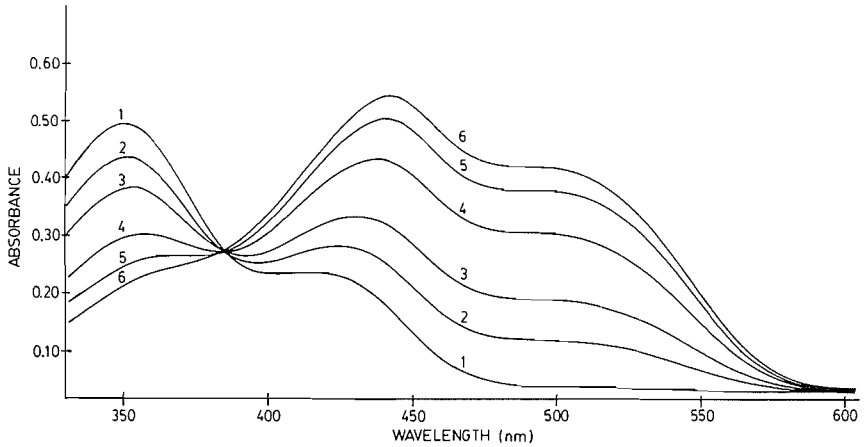

FIG. 1. Initial absorption spectra of *N*-methylpicramide in dimethylsulfoxide/methanol (95/5, v/v) containing various concentrations of sodium methoxide. [OMe^-] (*M*): , 0; *2*, 0.61×10^{-4}; *3*, 1.26×10^{-4}; *4*, 2.22×10^{-4}; *5*, 3.00×10^{-4}; *6*, 3.57×10^{-4}. [*N*-Methylpicramide] = 3.05×10^{-4} *M*; 10 cm cell; 25.0°C.

are known in systems closely related to NMP (7). Transient intermediates with structures analogous to **2** have also been observed in the reactions of picryl ethers with aliphatic amines (8, 9).

While species of types **1**, **3** and **7** (X = HO, CH_3O, SO_3^-), and **6** are fully characterized in terms of their ^1H nmr properties (1–4), they are less well characterized in terms of their ultraviolet–visible absorption properties, particularly in those cases in which X = HO and CH_3O (6). The reason for this is that, with these bases, the solvents utilized in the studies were such that the solutions invariably contained mixtures of the various σ-complexes and the conjugate base of NMP.

In this work we report on the interactions of NMP with 1,4-diazabicyclooctane (DABCO) in dimethylsulfoxide (DMSO) and also with methoxide ion in dimethylsulfoxide–methanol (95/5, v/v). The ultraviolet–visible spectra of species **6** and **7** (X = CH_3O) are reported here for the first time.

Results and Discussion

N-Methylpicramide (NMP) in a medium of dimethylsulfoxide–methanol (DMSO/MeOH, 95/5, v/v) exhibits a broad absorption band which displays an absorption maximum at 350 nm ($\varepsilon = 1.54 \times 10^4\ M^{-1}\ cm^{-1}$) and a shoulder with mid-point at 410 nm ($\varepsilon = 0.67 \times 10^4\ M^{-1}\ cm^{-1}$).

The addition of progressively larger amounts of sodium methoxide (NaOMe) to solutions of fixed concentration of NMP (3.00×10^{-4} *M*) lead to the simultaneous disappearance of the absorption maximum due to NMP and the appearance of a new absorption band possessing an absorption maximum at 442 nm and a shoulder with mid-point at 494 nm (Fig. 1). Formation of this second absorbing species, Y, was complete within the time required to mix the stock solutions of NaOMe and NMP and record the spectrum of the resulting mixture (<20 s). The extent of conversion of NMP to absorbing species Y was dependent on the concentration of NaOMe in solution; conversion was essentially complete with the addition of approximately 1.1 molar equivalents of NaOMe to the system. Throughout the course of the conversion of NMP to Y the solutions displayed a single isosbestic point at 385 nm (Fig. 1). The species whose absorption maximum occurred at 442 nm was stable for several days at room temperature. Over these periods of time addition of excess trifluoroacetic acid (CF_3COOH) rapidly and quantitatively converted this species to NMP.

The reaction of NMP with DABCO in pure, dry DMSO also resulted in the conversion of NMP to species Y as evidenced by the generation of a final spectrum identical to that obtained with $NaOCH_3$ above. Associated with the conversion of NMP to Y in pure DMSO is an isosbestic point at 388 nm. Formation of species Y again occurred within the time required to mix the stock solutions of the two reagents and record the spectrum of the resulting solution and the reaction to form Y was completely and rapidly reversed on the addition of excess CF_3COOH to the system. Complete conversion of NMP to species Y required the addition of more than 1 molar equivalent of DABCO to the system. Under identical experimental conditions, *N,N*-dimethylpicramide (*N,N*-DMP, 3.00×10^{-4} *M*) plus excess DABCO in pure, dry DMSO yielded no

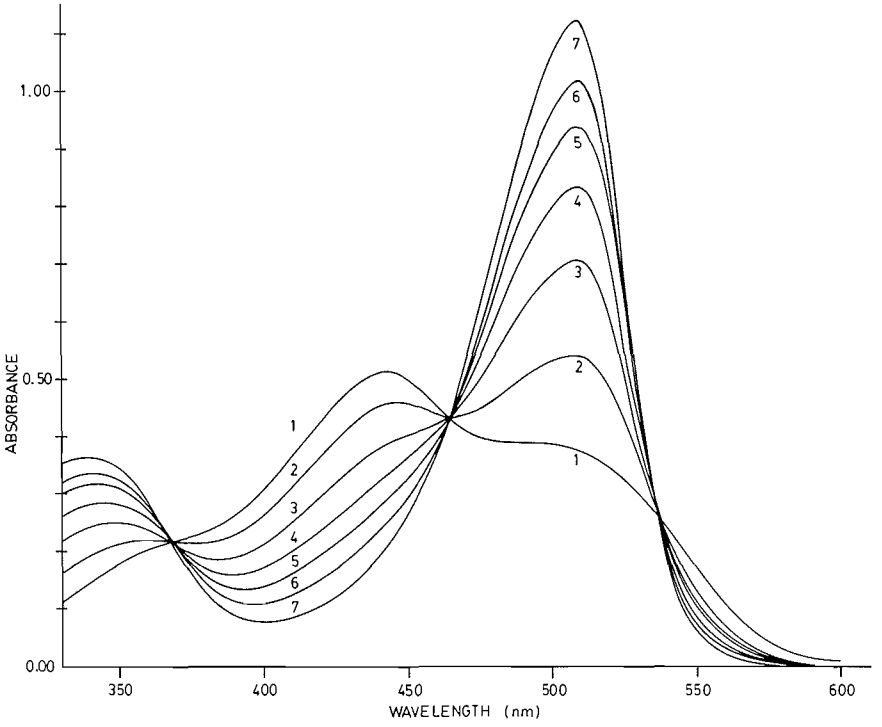

FIG. 2. Initial absorption spectra of *N*-methylpicramide in dimethylsulfoxide/methanol (95/5, v/v) containing various concentrations of sodium methoxide. [OMe^-] (*M*): *1*, 3.57×10^{-4}; *2*, 4.47×10^{-4}; *3*, 7.11×10^{-4}; *4*, 1.15×10^{-3}; *5*, 1.70×10^{-3}; *6*, 2.12×10^{-3}; *7*, 3.10×10^{-3}. [*N*-Methylpicramide] = 3.04×10^{-4} *M*; 0.10 cm cell; 25.0°C.

evidence of any reaction in solution, i.e. the spectrum due to *N,N*-DMP remained unchanged using DABCO concentrations of up to ~1 *M*.

Solutions of fixed NMP concentration (3.00×10^{-4} *M*) containing >1.1 molar equivalents of NaOMe underwent additional spectral changes as the concentration of NaOMe was increased. At concentrations of $MeO^- \sim 3.0 \times 10^{-2}$ *M*, the second sequence of spectral changes was essentially complete and a species possessing absorption maxima at 508 ($\varepsilon = 4.00 \times 10^4\ M^{-1}\ cm^{-1}$) and 335 nm ($\varepsilon = 1.23 \times 10^4\ M^{-1}\ cm^{-1}$) was observed (species Z). The spectra of solutions containing both Y and Z were characterized by isosbestic points at 366, 464, and 532 nm (Fig. 2). Conversion of Y to Z was rapid at room temperature ($t_{1/2} < 20$ s). At any fixed concentration of NaOMe, at room temperature, the concentration of Z decreased very slowly with time; $t_{1/2}$ for this decomposition was of the order of 1 day. However, within short periods of time (< 10 min after preparation) Z was converted quantitatively to Y (and, in the limit, to NMP) by the addition of appropriate amounts of CF_3COOH.

In pure, dry DMSO, even at DABCO concentrations up to the level of 1 *M*, there was no evidence for the formation of species Z from species Y. (The spectrum of Y was completely unaffected by the addition of DABCO up to this level of concentration.)

At fixed concentrations of NMP equal to 3.00×10^{-4} *M* and concentrations of $MeO^- > 3 \times 10^{-2}$ *M* the absorbance at 508 nm decreased in magnitude with increasing concentration of base. However, these decreases were not completely reversible upon the immediate addition of acid to the solution and the interaction of NMP and MeO^- under these conditions was therefore not studied quantitatively.

If species Y is the result of a 1:1 interaction of NMP and MeO^-, we can write

[1] $\text{NMP} + \text{MeO}^- \rightleftarrows \text{Y}$

and

[2] $K_1 = [\text{Y}]/[\text{NMP}][\text{MeO}^-]$

For a 0.10 cm cell, the absorbance, *A*, at a specified wavelength is given by

[3] $A = \{\varepsilon_Y[\text{Y}] + \varepsilon_{NMP}[\text{NMP}]\}0.10$

where ε_Y and ε_{NMP} are the molar absorptivities, in $M^{-1}\ cm^{-1}$, of species Y and NMP, respectively. At any given wavelength ε_Y can be evaluated from the

TABLE 1. Values of molar absorptivities, ε, at selected wavelengths for *N*-methylpicramide, species Y and species Z; 95/5 (v/v) dimethylsulfoxide/methanol solvent; $T = 25.0°C$

	ε (M^{-1} cm^{-1}) at λ (nm)				
Compound	335	350	420	442	508
NMP	1.33×10^4	1.54×10^4	0.67×10^4	0.46×10^4	0
Species Y	0.41×10^4	0.59×10^4	1.42×10^4	1.71×10^4	1.29×10^4
Species Z	1.22×10^4	1.11×10^4	0.24×10^4	0.56×10^4	4.00×10^4

limiting absorbance value (A_{limiting}) in a plot of absorbance versus [MeO$^-$]. Values of ε_{NMP} and ε_Y at selected wavelengths are given in Table 1.

In addition, we have the material balance equations

[4] $[NMP]_{Stoich} = [Y] + [NMP]$

and

[5] $[MeO^-]_{Stoich} = [OMe^-] + [Y]$

where $[NMP]_{Stoich}$ and $[MeO^-]_{Stoich}$ represent total concentrations of DMP and CH_3O^-, respectively, in solution.

Employing $\varepsilon_{NMP} = 0.46 \times 10^4\ M^{-1}\ cm^{-1}$ and $\varepsilon_Y = 1.71 \times 10^4\ M^{-1}\ cm^{-1}$ at 442 nm and absorbance data recorded at 442 nm, we can evaluate K_1, over the range of base concentrations in which NMP is being converted to Y, as $2 \pm 1 \times 10^5\ M^{-1}$. Treatment, in the same fashion, of absorbance data recorded at 464 and 500 nm yields K_1 values of comparable magnitude. The agreement among the values of K_1, calculated using absorbance data collected at the three wavelengths, confirms the validity of eq. [2] and 1:1 stoichiometry of species Y.

For solutions of fixed total concentration of NMP equal to $3.03 \times 10^{-4}\ M$, the values of K_1, determined using eq. [2], were found to increase by a factor of approximately four as the total base concentration in solution varied from $3.75 \times 10^{-5}\ M$ to $19.0 \times 10^{-5}\ M$. It seems unlikely that the variation in K_1 is due to an ionic strength effect because a comparable increase in K_1 values was observed when the experiments were carried out under conditions in which the base concentration varied from $3.75 \times 10^{-5}\ M$ to $20.0 \times 10^{-5}\ M$ but the ionic strength was maintained constant at $0.20\ M$ with added $(C_2H_5)_4NClO_4$.

If species Y also results from a 1:1 interaction of NMP and DABCO according to the equation

[6] $NMP + DABCO \rightleftarrows DABCOH^+ + Y$

we have

[7] $K_1' = [DABCOH^+][Y]/[NMP][DABCO]$

Utilizing absorbance data recorded at 442 nm and the values of ε_{NMP} and ε_Y at 442 nm quoted above, we find a constant value for K_1', over the entire range of DABCO concentrations employed, of 9.5×10^{-3}.

If complex Z is formed as a result of a 1:1 interaction of Y and MeO$^-$ we have

[8] $Y + MeO^- \rightleftarrows Z$

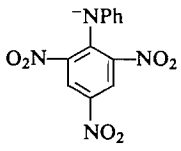
and

[9] $K_2 = [Z]/[Y][MeO^-]$

Using the arguments and procedures described above, the following parameters were obtained: $\varepsilon_Z = 4.00 \times 10^4\ M^{-1}\ cm^{-1}$ (508 nm), $\varepsilon_Y = 1.29 \times 10^4\ M^{-1}\ cm^{-1}$ (508 nm), and $K_2 = 1.5 \pm 0.2 \times 10^3\ M^{-1}$, over the range of base concentrations employed in these studies.

Although calculated values of K_2 showed a tendency to increase with increasing concentration of $NaOCH_3$ in solution, this tendency was much less marked than in the case of the K_1 values. Comparable variations in K_2 values were observed when the studies of the conversion of Y to Z were carried out in solutions whose ionic strength was maintained constant at $0.20\ M$ with added $(C_2H_5)_4NClO_4$ and in solutions in which the ionic strength was allowed to vary from $0.00032\ M$ to $0.0050\ M$.

It seems probable that the decrease in absorbance at 508 nm at concentrations of $MeO^- > 3 \times 10^{-2}\ M$ is due to both a 1:1 interaction of Z and MeO$^-$ and a slow decomposition of NMP. 3:1 σ-complexes such as **5** (X = CH_3O) have been observed in pure methanol and it has been noted that the stabilities of such complexes decrease markedly as the DMSO content of the solvent mixture increases (5, 6, 10).



The structure of the 1:1 complex Y is quite readily deduced by considering the results obtained from the reactions of NMP and DABCO in pure, dry DMSO and of NMP with MeO$^-$ in DMSO/MeOH. Thus, the observation that DABCO, which cannot form σ-complexes of any type (11), reacts with NMP to yield Y firmly establishes that Y is the anion **6**. The fact that the species generated by the reaction of NMP with 1 molar equivalent of MeO$^-$ in DMSO/MeOH has absorption properties identical to those of the species

For personal use only.

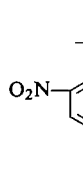
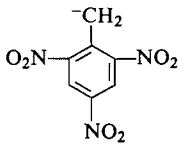
generated in pure, dry DMSO establishes that the anion **6** is also the exclusive species formed under these reaction conditions.

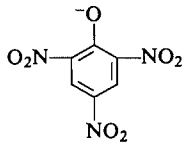
In agreement with this conclusion we note that Crampton and Gibson (12) have reported a λ_{max} of 435 nm for **10** which is the sole species formed in the reaction of MeO^- with *N*-phenylpicramide in methanol. Also in agreement with the above con-



10

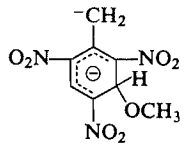


11



clusion is the general dissimilarity of the spectrum of Y (**6**) and the spectra of species such as **1** (X = OCH_3, SO_3^-, OH) and **11** (X = OCH_3, SO_3^-) (λ_{max} for X = OCH_3 species ~400 nm, $\varepsilon_{400} \simeq 3.2 \times 10^4\ M^{-1}\ cm^{-1}$). We note in passing the rather comparable shapes of the ultraviolet–visible absorption bands and values of ε at λ_{max} of the three closely related ions **6**, **12**, and **13** (13, 14).

6

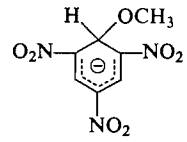


12

13

Parameter	Value		
	6	**12**	**13**
λ_{max} (nm)	442	520	360
$\varepsilon_{\lambda_{max}}$ ($M^{-1}\ cm^{-1}$)	1.71×10^4	1.7×10^4	1.5×10^4

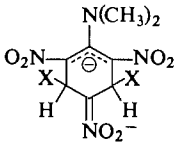
The exclusive formation of **6** under our reaction conditions is in accord with Crampton and Gibson's observations that, for a given *N*-alkylpicramide, the fraction of starting material converted to the conjugate base increases as the DMSO content of the solvent increases. Specifically for NMP they found this fraction to be 0.60 in pure MeOH and 0.90 in DMSO/MeOH (87/13, v/v) (12). Similar observations have been made by Fyfe *et al.* in connection with the reactions of 2,4,6-trinitrotoluene and methoxide ion to form **12** and **14** in DMSO/MeOH mixtures (15).



14

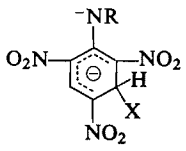
That increasing proportion of DMSO in the solvent will favor conjugate base formation over methoxide ion addition is to be expected since in reaction [10]

[10] $\mathbf{1} \rightleftharpoons \mathbf{6} + MeOH$



the two complexes differ by 1 molecule of MeOH. In addition, solvation of **6** by DMSO is probably more effective than solvation of **1** by this solvent.

15



Alternatively, one would expect that MeOH would less effectively solvate **1** than **6**.

A K_1 value of $20\ M^{-1}$ for the formation of **6** in pure methanol at 25.0°C has been reported (12). Our value of K for the same process in DMSO/MeOH (95/5, v/v) is $2 \pm 1 \times 10^5\ M^{-1}$ at 25.0°C. Similar large increases in K, as the result of increasing the DMSO content of DMSO–MeOH solvent systems, have been observed previously in the reactions of 1,3,5-trinitrobenzene with methoxide ion to form σ-complex **15** and in a number of related σ-complex forming reactions (16, 17). Preferential solvation by DMSO of the anion **15** as compared to CH_3O^- is considered to be the main factor leading to an increase in K as the proportion of DMSO in the solvent mixture increases (16, 17).

16

Since under the experimental conditions in which the 1:1 interaction predominates the exclusive 1:1 interaction product is **6**, it seems reasonable to assign the 1:2 adduct, species Z, as **7**. Support for this formulation comes from the observation that the spectral characteristics of the 2:1 adduct **16** (λ_{max} = 480 nm, $\varepsilon = 2.9 \times 10^4\ M^{-1}\ cm^{-1}$) are quite different from those of species Z. In addition, Z and complex **14** have very similar ultraviolet–visible absorption bands and ε values at λ_{max}. Crampton and Gibson (12) have reported λ_{max} values of 480 nm for a series of 2:1 adducts **17**

17

where X = OCH_3 and R = H, CH_3, i-C_3H_7, n-C_4H_9, t-C_4H_9, and C_6H_5 but make no mention of a second absorption maximum at wavelengths between 350 and 480 nm, or the magnitudes of the ε values at 480 nm.

Experimental

N-Methylpicramide was prepared by adding an excess of methylamine in ethanol to a 5% solution of 1-chloro-2,4,6-trinitrobenzene in ethanol and evaporating the resulting solution to dryness. The solution formed by extraction of the residue with acetone was filtered to remove the insoluble methylammonium chloride and evaporated to dryness. The resulting solid was recrystallized to constant melting point from absolute alcohol. After drying *in vacuo* over phosphorus(V) pentoxide, the product had a melting point 114–115°C; lit. (18) 115°C. Sodium methoxide solutions were prepared by dissolving clean sodium in Analar methanol under nitrogen and were titrated with standard acid using phenolphthalein as an indicator. Dimethylsulfoxide (DMSO) was dried over calcium hydride and fractionated under reduced pressure, the middle fraction being collected. DABCO was recrystallized twice from benzene and dried *in vacuo*. The resulting material was mixed with an equal amount of barium oxide and sublimed twice to yield white crystals, mp 157°C. Eastman tetraethylammonium perchlorate was dried to constant weight *in vacuo* over phosphorus(V) pentoxide. Reagent grade trifluoroacetic acid was used as received.

Stock solutions of *N*-methylpicramide in DMSO, DABCO in DMSO, $(C_2H_5)_4NClO_4$ in DMSO, and $NaOCH_3$ in methanol were made up under nitrogen in a drybox and were protected from light. Solutions used in the equilibrium studies were also prepared in the drybox by adding appropriate volumes of the stock solutions to a known volume of DMSO. After thorough mixing, a portion of the solution was transferred to a clean dry spectrophotometric cell and the cell and its contents then placed in the spectrophotometer.

Optical measurements were carried out on a Beckman Acta IV spectrophotometer using matched silica cells of 1.0 mm and 5.0 mm path length. The temperature in the cells was maintained constant at 25.0 ± 0.1°C by circulating water from a constant temperature bath through a specially designed cell holder in the spectrophotometer.

A wavelength specific photo-electric detector

R. STEPHENS

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada

Received January 17, 1980

R. STEPHENS. Can. J. Chem. **58**, 1621 (1980).

A photo-electric detector is described which is capable of showing selectivity towards atomic resonance radiation. Details are given of the construction of such a device suitable for use with the mercury 253.7 nm line. A possible mechanism for the operation of the detector is considered. Its spectral selectivity is illustrated by an examination of the atomic absorption signals obtained with a partially reversed line source.

R. STEPHENS. Can. J. Chem. **58**, 1621 (1980).

On décrit un détecteur photoélectrique capable d'être sélectif vis à vis la radiation de résonance atomique. On fournit les détails concernant la construction d'un tel appareil convenant à une utilisation dans la région de la raie du mercure à 253.7 nm. On considère un mécanisme possible d'utilisation du détecteur. La sélectivité spectrale est illustrée par un examen des signaux d'absorption atomique obtenus à l'aide d'une source de raies partiellement inversée.

Introduction

Recent work has shown the opto-galvanic effect to offer an ingenious and effective technique for the detection of low concentrations of atomic species, by the measurement of vapour phase ionisation currents produced under laser illumination (1–7). A natural question which arises from this work is whether the inverse process is also feasible; that is, can lower intensities of resonance radiation usefully be detected by the measurement of ionisation currents in atomic vapours of higher concentration? Such a detector would be of interest in analytical atomic spectroscopy in that it could provide a device with unusually high optical resolution, a large optical aperture, and automatic tolerance to stray light. It would also bring considerable simplification to the design of equipment intended for the measurement of resonance radiation.

At the present time there is no device available with all of these properties. The nearest approach is probably the resonance monochromator–photomultiplier combination described by Walsh and co-workers (8–11), which measures resonance fluorescence from a sputtered vapour. Even here, however, the functions of spectral isolation and photo-electric detection are carried out by separate instruments, which reduces both tolerance to stray light and the effective aperture of the system (since only a small fraction of fluorescent radiation can be collected).

This paper describes the construction and behaviour of a wavelength specific detector based on the opto-galvanic effect. For reasons of technical convenience the present device was designed for the detection of the mercury 253.7 nm line.

Experimental

Mercury was chosen as a suitable test element because high vapour pressures can be obtained readily and controllably, because intense discharge emission sources are available, and because the photon energy of the 253.7 nm line is sufficiently high to cause ionisation quite easily under the correct conditions.

Mercury vapour shows no useful ionisation upon irradiation by a resonance discharge source. Accordingly it was necessary to add an ionisation agent to the system. Potassium vapour was selected for this purpose, since its ionisation potential (4.3 eV) is just below that of a 253.7 nm photon (4.9 eV). It is of interest to record that sodium (ionisation potential = 5.1 eV) vapour can be used in place of potassium, although the resulting signals are smaller.

The source used in all the present experiments was an Oriel C-73-14 penlight discharge lamp. This gave sufficient intensity to examine the behaviour of the detector over a range of conditions. An ordinary mercury hollow cathode lamp driven at 2 or 3 mA also gave satisfactory signals provided all detector parameters were set reasonably close to the optimum.

Figures 1 and 2 show respectively the detector design used and the associated measuring apparatus. The detector was permanently attached to a vacuum line; no attempt was made to build a sealed system. Mercury vapour was supplied continuously at room temperature from (solid) zinc–mercury amalgam. Potassium was contained in a copper jacket, surrounded by an external heater. Constantin wire was welded to the bottom of the jacket to provide a thermocouple junction. The thermocouple readings were used to determine the vapour pressure of potassium in the jacket, and hence in the cell volume immediately above it. Ionisation was detected by two copper electrodes located over the exit of the potassium furnace. The electrodes were connected to a 0–300 V dc supply via a 10 MΩ load resistor. The signal developed across the resistor was ac coupled to a FET input pre-amplifier mounted directly on the end of the detector. Both the pre-amplifier and the detector (except for its front window) were covered by aluminum foil to provide electrical screening. An argon supply was available at the front of the detector, to sweep excess mercury vapour from the system, and also to permit the effect of inert gas pressure to be examined.

Construction of several detectors of this general type showed that their performance was not particularly affected by the extent of vacuum de-gassing of cell walls, electrodes, etc. (pre-

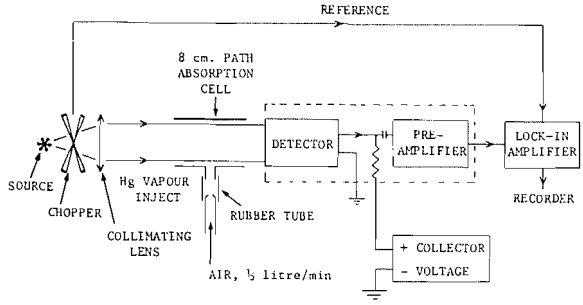

FIG. 2. Layout of the detector and associated equipment.

sumably because the potassium vapour acts as an effective getter in the ionisation region). However, it was essential to thoroughly melt and de-gas the potassium before use. This operation is most easily accomplished by initially introducing a piece of the metal into the copper jacket, then heating it under a few Torr of argon. This procedure minimizes migration of solid metal up the furnace walls.

It was found that careful design was necessary to avoid detection of spurious signals. Two causes of such signals were observed. The first occurred if solid potassium migrated onto either the electrodes or onto the glass walls surrounding them. The glass was effectively at ground potential, and could pass enough leakage current to enable the system to act as an ordinary vacuum photodiode. The second effect was observed in the event of the glass around the ionisation region becoming hot, in which case it showed photoconductivity. The detector design shown in Fig. 1 eliminated both of these processes quite effectively: however, as an added precaution the detector was operated under normal laboratory lighting throughout this work. Because both of the above effects show a wide spectral response, unlike the resonance response of present interest, their onset then was automatically signalled by a rapid increase of detector noise, followed by amplifier saturation. This mode of use also illustrates the tolerance of the detector towards stray light, mentioned previously. An additional effect that was observed even during proper operation of the detector was the existence of a dc background current. This was not easy to measure quantitatively, but it appeared to be of the same order of magnitude as the peak photo-current. The behaviour of this dc background was not examined here; nor was it included in any of the present measurements.

During operation the collector voltage (Fig. 2) and potassium furnace temperature were set to their required values, and a few millilitres of argon were allowed to enter the detector. The resulting signal form is shown in Fig. 3. An initial sharp rise occurs as mercury vapour is swept from the front of the detector, permitting more radiation to reach the ionisation region. Further argon flow then sweeps potassium and mercury vapours out of the ionisation region, and the signal falls to zero. When the argon flow stops the signal rises to a maximum as potassium and mercury vapours return, and finally falls again as mercury once more causes attenuation of the radiation reaching the ionisation region by re-diffusing to the front of the detector. The following measurements were all made on the signal peak observed after an injection of argon. Unless otherwise stated the detector remained continuously connected to the vacuum line, and therefore operated at the minimum pump pressure (about 0.2 Torr). When data were required at higher pressures the vacuum line was shut off and the detector filled with argon to a pressure somewhat beyond the required value. The line was then momentarily re-connected, to drop the pressure to the required value and simultaneously to sweep away excess mercury, and the reading was measured as described above.

Results and Discussion

The response characteristics of the device are shown in Figs. 4–6. Figure 4 shows the dependence of signal on the collector voltage applied to the detector electrodes. The initial rise of the signal from zero is consistent with an increasing efficiency of electron collection with increasing voltage. However, the curve shows no tendency to reach a plateau, which suggests that some degree of signal amplification may occur at higher voltages due to secondary electron production by collisional ionisation. The plot terminates at 270 V due to initiation of a continuous discharge.

Figure 5 shows the signal dependence on argon pressure. The signals are inversly proportional to argon pressure (slopes of both curves are −1.2)

except at low pressures, where the slope is reduced.

Figure 6 shows signal variations with the temperature of the potassium furnace. All readings were separated by a 3 min time interval for thermal equilibration. This interval was chosen as a compromise between thermal hysteresis (which is apparent in the results) and the need to minimize long term drift in the system. The results show an initial exponential increase, but appear to approach a maximum at about 600 K.

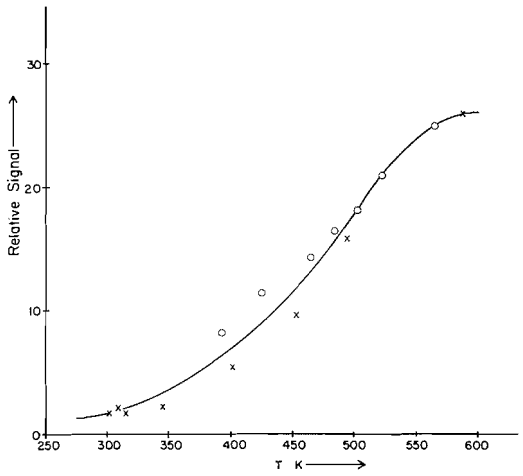

FIG. 6. Signal vs. potassium furnace temperature. Symbols ×, ○ represent respectively data taken with temperature increased from ambient, and that taken with temperature decreased from 600 K.

Comparison of the detector output with that of a conventional spectrometer showed (*a*) that the detector output was linearly dependent on source intensity (using neutral density filters); (*b*) that under optimum conditions the detector gave a p-p ac output of 60 mV across 3.9 MΩ. The source output measured by the spectrometer corresponded to an intensity of 8×10^{11} photons s^{-1}, about one third of which could be absorbed in a volume of saturated mercury vapour equivalent to the ionisation region in the detector. Hence it was estimated that the detector gave an output of about one electron for three photons absorbed in the ionisation region, or one electron for eight incident photons. This "quantum efficiency" is encouragingly high, being of the order of that given by a vacuum photodiode. There seems little doubt that it could be further improved upon by improved detector design.

Mechanism of the Detector

The behaviour described above can be accounted for as follows. Electrons are produced by collision between excited mercury and ground state potassium atoms. The state of the former ($^3P_1$ or metastable $^3P_0$) is not specified. Competition exists for the electrons between the applied electric field and vapour phase K^+ ions. The latter are produced according to the Saha equation (12) which, it is felt, will be displaced towards higher K^+ concentrations by the applied field. This arises because the field,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

being close to the limit set by plasma formation, will transport electrons very effectively and quite irrespective of whether those electrons are produced thermally (as a dc background current) or by photo-ionisation (the signal or interest). These processes are described quantitatively below.

[1] $Hg + h\nu \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Hg^*$

[2] $Hg^* + K \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Hg + K^+ + e^-$

[3] $Ar + K^+ + e^- \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Ar + K$

The reaction $2K \rightleftharpoons K_2$ is not included in this scheme. The equilibrium position of the reaction is reported to be well to the left (13), and the present results can be accounted for reasonably well without it.

Putting i_- as the current flow from the negative (ground) electrode and i_+ as the current flow to the positive electrode,

$$d[e^-]/dt = k_2[Hg^*][K] + k_{-3}[Ar][K] - k_{-2}[Hg][K^+][e^-] - k_3[Ar][K^+][e^-] + (i_- - i_+)$$

Under steady state conditions $d[e^-]/dt = 0$ and $i_+ = i_-$. Therefore provided the charge separation induced by the spatial separation of i_+ and i_- causes no major perturbation, and that no significant charge storage occurs in the device,

[4] $$k_2[Hg^*][K] + k_{-3}[Ar][K] - k_{-2}[Hg][K^+][e^-] - k_3[Ar][K^+][e^-] = 0$$

Putting I as the incident light intensity and again considering steady state conditions, eqs. [1] and [2] give

$$d[Hg^*]/dt = k_1 I[Hg] + k_{-2}[Hg][K^+][e^-] - k_{-1}[Hg^*] - k_2[Hg^*][K] = 0$$

$\therefore$

[5] $$[Hg^*] = (k_1 I + k_{-2}[K^+][e^-])[Hg]/(k_{-1} + k_2[K])$$

Equilibrium of eq. [3] requires

[6] $$k_3/k_{-3} = [K]/[K^+][e^-]$$

Charge balance requires

[7] $$[K^+] = [e^-]$$

Substitution of eqs. [5]–[7] into [4] leads to

$$[e^-]\left\{1 - \frac{k_2 k_{-2}[K][Hg]}{(k_{-1} + k_2[K])(k_{-2}[Hg] + k_3[Ar])}\right\} = \left(\frac{k_3[K]}{k_{-3}}\right)^{1/2} \frac{k_1 k_2 I[Hg]/(k_{-1} + k_2[K]) + k_{-3}[Ar]}{k_{-2}[Hg] + k_3[Ar]}$$

Assuming that the observed signal is proportional to $[e^-]$, and recognising that the output of the synchronous amplifier represents only the term containing I, this rather cumbersome expression can be re-cast as

$$S\left\{1 - \frac{k_2 k_{-2}[K][Hg]}{(k_{-1} + k_2[K])(k_{-2}[Hg] + k_3[Ar])}\right\} = \left(\frac{k_3[K]}{k_{-3}}\right)^{1/2} \frac{k_1 k_2 I[Hg]}{(k_{-1} + k_2[K])(k_{-2}[Hg] + k_3[Ar])}$$

where S is the output signal of the amplifier; i.e.

[8] $$S = \frac{k_1 k_2 (k_3/k_{-3})^{1/2} I[Hg][K]^{1/2}}{k_{-1}k_{-2}[Hg] + k_{-1}k_3[Ar] + k_2 k_3[K][Ar]}$$

Under the present conditions, [Hg] is constant. Assuming [K] and [Ar] respectively to be proportional to the pressures P_K and P_{Ar} determined in the potassium furnace and in the vacuum line (eq. [8]) now gives:

[9] $$S = IP_K^{1/2}/(a + bP_{Ar} + cP_{Ar}P_K)$$

where a, b, and c are constants.

Equation [9] can account for most of the results found here. Thus linearity on I and inverse proportionality to P_{Ar} at high argon pressures (P_K fixed) are self-evident, with a plateau in the log S vs. log P_{Ar} curve (Fig. 5) being reached when $a \sim (b + cP_K)P_{Ar}$. The signal dependence on potassium vapour pressure has the form $S \propto P_K^{1/2}(A + P_K)$, where A is a constant. Qualitatively this accounts for the behaviour observed in Fig. 6. Thus at low temperature the signal is approximately proportional to $P_K^{1/2}$, which leads to the initial exponential rise of the curve, while at higher temperatures a maximum is reached when P_K and A are equal. However, quantitative agreement is less satisfactory. Figure 7 shows a plot of log S vs. log $P_K^{1/2}/(A + P_K)$ for the data from Fig. 6, using a value of $A = 0.5$ (corresponding to the position of the maximum

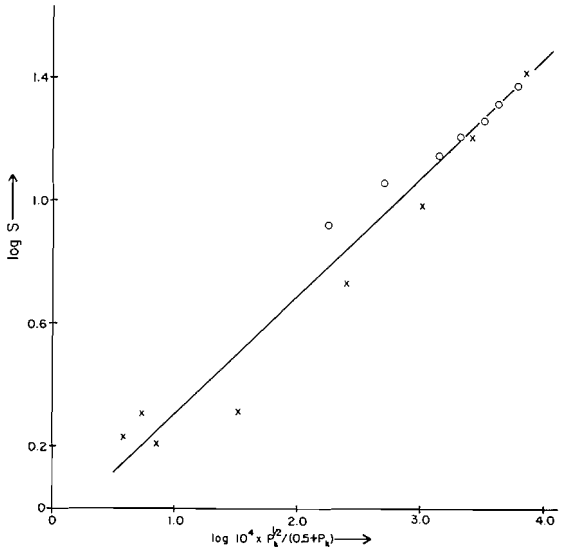

FIG. 7. Observed signals and potassium vapour pressure fitted to eq. [9]. Values of P_K were determined from the equation $\log_{10} P_{mm} = 7.45 - 4450/T$. Numerical constants in this equation are from the centre of a range given in ref. 13.

in the curve of Fig. 6, judged from the available data). Although the linearity of the curve is as expected, the value of the slope is closer to one third than to unity. One possible reason that can be suggested for this behaviour might be that, with the present cell design, potassium vapour pressure in the ionisation region where the photo-current originates is not in fact linearly related to the vapour pressure within the furnace, in contradiction to the assumption which connects eqs. [8] and [9].

Analytical Applicability of the Detector

From the viewpoint of the analytical spectroscopist the most interesting property of the present device is its optical selectivity. Thus the detector is expected to respond only to radiation that can be absorbed in the ionisation region, and to ignore all other incident frequencies. This property has been observed experimentally, as illustrated in Fig. 8. Figure 8(*a*) shows absorption signals caused by the injection of 1 mL of saturated mercury vapour into the absorption cell (Fig. 2). A 1 cm path sealed cell containing saturated mercury vapour was then inserted into the optical path. By selectively absorbing at the centre of the source emission profile this procedure caused in effect a large and reproducible broadening of the source emission line. The amplifier gain was then increased, to restore the output signal to its original value, and 1 mL of mercury vapour again injected into the absorption cell. The resulting signal is shown in Fig 8(*b*). Comparison of Fig. 8 (*a*) and (*b*) shows little difference between the two, as expected for a detector which is behaving selectively towards resonance radiation. For comparison the same procedure was carried out with the same source, etc., and using a conventional Varian-Techtron AA5 as the detection system. The resulting signals are shown in Fig. 8 (*c*) and (*d*). Again predictably, a marked difference is now observed.

The data in Fig. 8 (*a*), (*b*) were obtained after equilibration of mercury vapour had occurred, some minutes after an injection of argon, in order to obtain a flat baseline and hence to simplify comparison of repetitive results. This equilibration slightly biases the signals in Fig. 8 (*a*), (*b*) towards the observed condition of mutual agreement, because atomic absorption is already occurring in the detector ahead of the ionisation region even before the second cell is introduced. However, it is clear from the magnitudes of the signals in Fig. 8 that

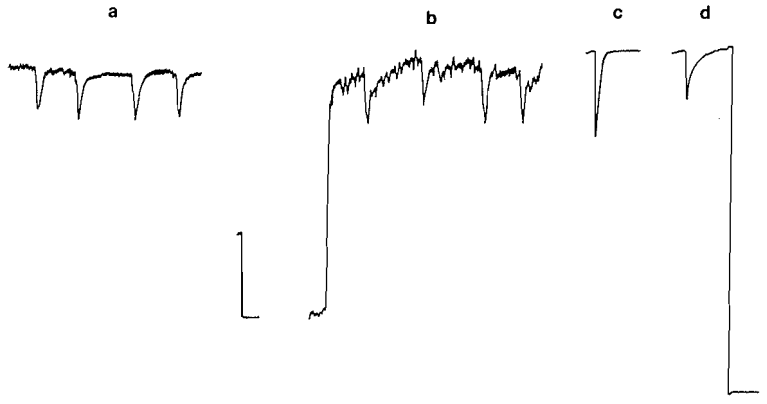

FIG. 8. (*a*) Absorption signal due to injection of 1 mL of mercury vapour into the absorption cell shown in Fig. 2. The ripple observed on the baseline is a beat frequency between the chopper and the rectified 60 Hz frequency of the fluorescent room lights. The latter show a measurable output at 253.7 nm. (*b*) Procedure in (*a*), repeated after placing a sealed absorption cell in front of the source. (*c*), (*d*) Procedure in (*a*) and (*b*) repeated on a conventional Varian-Techtron AA5 spectrometer.

such a bias does not affect either the nature or the validity of the preceding discussion.

Conclusions

The present results are considered to demonstrate the feasibility of obtaining selective detection of resonance radiation with a useful degree of optical sensitivity. The suggested detector mechanism involves ionisation of potassium vapour, both thermally and by collision with photo-excited mercury atoms. The K^+ population arising from thermal ionisation appears to act as an electron "buffer", by competing with the external electric field for the available electrons. The effect is thought to be enhanced due to electron loss to the external field in the form of a dc background current. This is not a useful process, since the existence of such a background automatically reduces the signal-to-noise ratio of the detector; for this reason the temperature in the ionisation region should be kept as low as possible.

The presence of argon is found to reduce signal magnitudes. It appears likely that other rare gases would show a similar effect. This does not represent a problem in the present apparatus, in which argon pressure can be reduced to zero if required. However, the effect is likely to be important if metal vapours are to be generated by sputtering rather than by thermal volatilisation, since a compromise would become necessary between the low gas pressure required to obtain a maximum signal and the finite value required to maintain a sputtering discharge.

The detector shows optical properties which include high resolving power, large aperture, good quantum efficiency, automatic tolerance towards stray light, and optical simplicity. This combination is felt to be of particular interest in the area of analytical atomic spectroscopy; an area where instrumental design problems involving some need for one or more of the above characteristics are encountered quite routinely at the present time.

Using low-temperature ^{31}P nmr, many new complexes formed between divalent cadmium (as $Cd(SbF_6)_2$) and monodentate phosphine chalcogenides in liquid SO_2 have been characterized. A 4:1 (L:M) complex is formed with Bu^t_3PS and, possibly, Bu^t_3PSe. 4:1 and 3:1 complexes are formed with Ph_3PE, $(o\text{-}C_6H_4Me)Ph_2PE$, $(p\text{-}C_6H_4Me)_3PE$, and $(C_6H_{11})_3PE$ (E = S or Se) as well as $(o\text{-}C_6H_4Me)_2PhPSe$, while 4:1, 3:1 and 2:1 complexes occur for $(o\text{-}C_6H_4Me)_3PE$ (E = S or Se), and, probably, $(o\text{-}C_6H_4Me)_2PhPS$. In addition, all the mixed ligand complexes in the series

$[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{4-n}]^{2+}$, $[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{3-n}]^{2+}$, and $[Cd(SeP(o\text{-}C_6H_4Me)_3)_n(SP(o\text{-}C_6H_4Me)_3)_{3-n}]^{2+}$

have been identified.

Trends in the ^{31}P nmr data are discussed.

PHILIP A. W. DEAN et LIJANA POLENSEK. Can. J. Chem. **58**, 1627 (1980).

On a caractérisé plusieurs nouveaux complexes entre le cadmium bivalent (sous forme de $Cd(SbF_6)_2$) et les chalcogénures de phosphine monodentates dans le SO_2 liquide en utilisant la rmn du ^{31}P à basse température. Un complexe du type 4:1 (L:M) se forme avec Bu^t_3PS et peut être avec Bu^t_3PSe. Des complexes du type 4:1 et 3:1 se forment avec Ph_3PE, $(o\text{-}C_6H_4Me)Ph_2PE$, $(p\text{-}C_6H_4Me)_3PE$ et $(C_6H_{11})_3PE$ (E = S ou Se) aussi bien qu'avec $(o\text{-}C_6H_4Me)_2PhPSe$, tandis que des complexes du type 4:1, 3:1 et 2:1 se forment avec $(o\text{-}C_6H_4Me)_3PE$ (E = S ou Se) et, probablement, $(o\text{-}C_6H_4Me)_2PhPS$. De plus, on a identifié tous les complexes de ligands mixtes dans les séries $[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{4-n}]^{2+}$, $[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{3-n}]^{2+}$, $[Cd(SeP(o\text{-}C_6H_4Me)_3)_n(SP(o\text{-}C_6H_4Me)_3)_{3-n}]^{2+}$.

On discute des tendances qui se manifestent dans les données de la rmn du ^{31}P.

[Traduit par le journal]

Introduction

A recent paper (1) has described the characterization, mainly by reduced temperature ^{31}P nmr, of a representative range of cadmium(II) complexes with monodentate, bidentate, and tridentate, or potentially tridentate, phosphine oxides, sulfides, and selenides. With the oxygen donors, the maximum coordination number was found to be six, while both the sulfur and the selenium donors gave a maximum coordination number of four. The ligands $Ph_2P(E)(CH_2)_2P(E)Ph(CH_2)_2P(E)Ph_2$ (E = S or Se) gave complexes in which only three Group VI donor atoms were bound to the metal, but with the monodentate ligands Ph_3PE (E = S or Se) only the 4:1 complexes, $[Cd(EPPh_3)_4]^{2+}$, were fully characterized, though the exchange-averaged ^{31}P nmr spectra of the system Ph_3PSe–$Cd(SbF_6)_2$–SO_2 at low Ph_3PSe/Cd ratios suggested the occurrence of lower coordinate species.

For our future ^{113}Cd nmr studies, it seemed particularly desirable that this earlier work with the triphenylphosphine chalcogenides should be extended to a wider range of phosphine chalcogenides and that the lower coordinate species should be completely characterized if possible. In this way, systematic variation of both the number and the type of donor groups about cadmium would become accessible. With these goals, in the present work we have used ^{31}P nmr to examine the systems R_3PS–$Cd(SbF_6)_2$–SO_2 and R_3PSe–$Cd(SbF_6)_2$–SO_2 (R_3 = Ph_3, $(o\text{-}C_6H_4Me)_3$, $(o\text{-}C_6H_4Me)_2Ph$, $(o\text{-}C_6H_4Me)Ph_2$, $(p\text{-}C_6H_4Me)_3$, Et_3, $(C_6H_{11})_3$, or Bu^t_3), as well as some systems likely to yield complexes with mixed ligands. Among the latter, $(o\text{-}C_6H_4Me)_3PS$–$(o\text{-}C_6H_4Me)_3PSe$–$Cd(SbF_6)_2$–SO_2 and $(C_6H_{11})_3PS$–$(C_6H_{11})_3PSe$–$Cd(SbF_6)_2$–SO_2 were studied in most detail.

Other than our previous paper (1), we could find only one other report dealing with the ^{31}P nmr spectra of cadmium complexes of phosphine chalcogenides (2):[3] in that report, the slow-exchange ^{31}P nmr spectrum of $CdCl_2(SePPh_3)_2$ in $CDCl_3$ at an unspecified temperature was presented, showing a 7 Hz reduction in $|^1J(^{31}P—^{77}Se)|$ on complexation and a value of 10.5 Hz for $|^2J(^{111/113}Cd—^{31}P)|$. In addition, there have been several studies of cadmium(II)–phosphine chalcogenide complexes in the solid state (e.g. refs. 3–6).

Results and Discussion

Complexes of a Single Ligand

In all of the systems studied, rapid intermolecular exchange occurs for all L/M ratios at ambient probe temperature. However, at reduced temperature, slow exchange spectra could be obtained for most of the systems at some values of L/M.

When L/M ≳ 3, the behaviour of the systems R_3PS–$Cd(SbF_6)_2$–SO_2 (R_3 = Ph_3, $(o\text{-}C_6H_4Me)_3$, $(o\text{-}C_6H_4Me)_2Ph$, $(o\text{-}C_6H_4Me)Ph_2$, $(p\text{-}C_6H_4Me)_3$, or $(C_6H_{11})_3$), and R_3PSe–$Cd(SbF_6)_2$–SO_2 (R_3 = Ph_3, $(o\text{-}C_6H_4Me)_2Ph$, $(o\text{-}C_6H_4Me)Ph_2$, $(p\text{-}C_6H_4Me)_3$, or $(C_6H_{11})_3$) is very similar. When L/M > 4, the systems behave as described earlier (1) for Ph_3PS and Ph_3PSe as ligands: the yellow colour of the free ligand – SO_2 charge transfer complex is visible, and the low temperature ^{31}P nmr spectra show a free ligand signal together with a signal with $^{111/113}Cd$ satellites, which, by integral analysis, is readily assigned to a 4:1 complex. The ^{31}P nmr spectral parameters of the 4:1 complexes of R_3PSe and R_3PS are given in Tables 1 and 2, respectively. At L/M ≃ 4 neither the yellow colour of the ligand–SO_2 complex nor the nmr signal of the free ligand is evident. The spectrum shows just the signal of the 4:1 complex. As L/M is decreased further, a new signal, with $^{111/113}Cd$ satellites, grows relative to that of the 4:1 complex, becoming dominant at L/M ≃ 3. Integral analysis in the range 4 > L/M > 3 confirms that this second signal is from a 3:1 complex. Details of the ^{31}P nmr spectra of the 3:1 complexes of R_3PSe and R_3PS are summarized in Tables 3 and 4, respectively.

The behaviour of the $(o\text{-}C_6H_4Me)_3PSe$-containing system is similar to that just described, except that when L/M ≳ 4, the spectra show some broadening, characteristic of slow intermolecular exchange, even at 196 K, the lowest accessible temperature. The value of $\lvert{}^2J(^{111/113}Cd—^{31}P)\rvert$ given in Table 1 for $[Cd(SeP(o\text{-tol})_3)_4]^{2+}$ should therefore be regarded as the minimum value.

The ligand Bu^t_3PS gives a 4:1 complex at L/M ≳ 4 as described above, but a second signal ($\delta_{OP(OMe)_3}$ ≈ 86.5 ppm), occurring when L/M < 4, had no cadmium satellites and so could not be attributed with certainty to $[Cd(SPBu^t_3)_3]^{2+}$.[4] Similarly, only one obvious cadmium-containing species $[Cd(SePBu^t_3)_n]^{2+}$ was identified with Bu^t_3PSe as ligand. In the system Bu^t_3PSe–$Cd(SbF_6)_2$–SO_2 the bright yellow colour of $Bu^t_3PSe{\cdot}SO_2$ persists to L/M ≈ 2.5, when at 196 K the broad spectrum shows partially-resolved cadmium satellites.[5] The odd behaviour of this system precluded direct determination of the number of ligands, but our prejudice is for n = 4, as in $Cd(SPBu^t_3)_4^{2+}$: neither $\lvert{}^2J(^{111/113}Cd—^{31}P)\rvert$ nor $\Delta^1J(^{31}P—^{77}Se)$ seem large

[4]This signal is not from a decomposition product: it collapses with the signal from $[Cd(SPBu^t_3)_4]^{2+}$ at ambient probe temperature.

[5]The decrease of 62 Hz in $\lvert{}^1J(^{31}P—^{77}Se)\rvert$ on changing from CH_2Cl_2 to SO_2 as solvent at 313 K indicates adduct formation (7).

enough, by comparison with possible analogues, for $n = 3$. Possibly the electron-rich Bu^t_3PSe is very strongly solvated, so the equilibrium

$$Cd^{2+}(solv) + SePBu^t_3(solv) \rightleftarrows [Cd(SePBu^t_3)_{4(?)}]^{2+}$$

is driven to the right only in the presence of a significant excess of Cd^{2+}.

Blanching of the colour of $Et_3PSe{\cdot}SO_2$ when $L/M \lesssim 4$, together with a reduction in $|^1J(^{31}P—^{77}Se)|$ in the cadmium-containing solutions, shows that Cd(II)–$SePEt_3$ complexes do form, but we were unable to stop rapid intermolecular exchange in either ligand-rich or metal-rich mixtures. $SPEt_3$ complexes were also labile, though in the ligand-rich systems the region of intermediate exchange was reached at 196 K, suggesting that for $[Cd(SPEt_3)_4]^{2+}$, $\delta_{OP(OMe)_3} \approx 63.4$ ppm ($\Delta\delta_P \approx 9.8$ ppm).

When L/M is decreased below three, an exchange-averaged spectrum is observed for systems containing Ph_3PSe or Ph_3PS, as noted earlier (1); systems containing $(p\text{-}C_6H_4Me)_3PSe$ and $(p\text{-}C_6H_4Me)_3PS$ behave similarly. However, the 3:1 spectrum persists to at least L/M = 2.5 when L = $(C_6H_{11})PS$, $(C_6H_{11})_3PSe$, $(o\text{-}C_6H_4Me)Ph_2PS$, $(o\text{-}C_6H_4Me)Ph_2PSe$, or $(o\text{-}C_6H_4Me)_2PhPSe$, though in all these cases a collapsed spectrum is observed by the time L/M = 1.5 is reached.

For all the selenides mentioned so far, $|^1J(^{31}P—^{77}Se)|$ is less in the collapsed spectrum than in the 3:1 complex, suggesting the occurrence of lower coordinate species as already noted (1). The resolved spectrum of the lower coordinate species is observed down to at least L/M = 1.5 when L is $(o\text{-}C_6H_4Me)_2PhPS$, $(o\text{-}C_6H_4Me)_3PS$, or $(o\text{-}C_6H_4Me)_3PSe$. For the first of these three, the new signal is shielded by 0.1_2 ppm relative to the signal of the 3:1 complex but no $^{111/113}Cd$ satellites were observed with certainty due to signal overlap. The full spectra of what we presume to be 2:1 complexes are observed for $(o\text{-}C_6H_4Me)_3PS$ and $(o\text{-}C_6H_4Me)_3PSe$. Details of the ^{31}P nmr spectra of these two 2:1 species are given in Table 5, and again it can be seen, by comparison with the data in Tables 2 and 4, that the shifts of the 2:1 complexes are very close to those of the corresponding 3:1 complexes.

Several noteworthy trends are exhibited by the data in Tables 1–5. The data in Tables 1, 3, and 5 show that for the same ligand, $|^1J(^{31}P—^{77}Se)|$ decreases as the number of coordinated phosphine selenides decreases. Grim and co-workers (8) have observed that in HgX_2 complexes of Bu^n_3PSe, $|^1J(^{31}P—^{77}Se)|$ decreases as the Lewis acidity of the acceptor increases. Our results are consistent with such an explanation, for the order of Lewis acidity will be $Cd(SePR_3)^{2+} > Cd(SePR_3)_2^{2+} > Cd(SePR_3)_3^{2+}$. Even in the 4:1 complexes, where the Lewis acidity of the metal centre is lowest, the change in $|^1J(^{31}P—^{77}Se)|$ on complexation is much larger than that observed in $CdCl_2(SePPh_3)_2$ (2).

In the 4:1 complexes of the triarylphosphine selenides (Table 1), the values of $|^1J(^{31}P—^{77}Se)|$ fall within a small range, in contrast to the corresponding couplings in the free ligands which are influenced by steric factors (9). Apparently in the 4:1 complexes there is little variation in the nature of the P—Se linkages. In view of this, the variation of $|^2J(^{111/113}Cd—^{31}P)|$ with different degrees of o-

methylation, shown also by the data in Tables 2–4, is surprising. However, the similarities of the data for corresponding complexes of Ph_3PE and $(p\text{-}C_6H_4Me)_3PE$ suggests that electronic effects on $^2J(^{111/113}Cd—^{31}P)$ are not important. Accordingly, it seems that $|^2J(^{111/113}Cd—^{31}P)|$ increases with increasing steric crowding between ligands, a suggestion supported by the relatively large two-bond couplings found in $(C_6H_{11})_3PE$ complexes and the very large couplings found in complexes of the sterically demanding $Bu^t{}_3PE$.

For both the sulfides and the selenides, it is found that for the same ligand, $|^2J(^{111/113}Cd—^{31}P)|$ increases as the number of ligands bonded decreases. For example, in the most complete series, those involving $(o\text{-}C_6H_4Me)_3PE$, ^2J is $\gtrsim$ 63, 67, and 83 Hz for E = Se, and 51, 54, and 70 Hz, for E = S, as n = 4, 3, and 2, respectively, in $[Cd(EP(o\text{-}C_6H_4Me)_3)_n]^{2+}$. These changes probably reflect changes in the hybridization of cadmium from approximately sp^3 in the 4:1 complexes, through approximately sp^2 in the 3:1 complexes towards approximately sp in the 2:1 complexes. However, two other effects may attenuate the two-fold reduction in ^2J expected to occur between the 4:1 and 2:1 complexes: firstly, there may be coordination, albeit weak, of either SO_2 or SbF_6^-, or both, and this coordination may divert "s" character from the Cd—E linkage and hence decrease $|^2J|$, and secondly, there should be release of steric crowding on reduction of the number of ligands coordinated, and our results suggest that this also leads to a decrease in $|^2J|$.

Complexes of Mixed Ligands

In their reduced temperature ^{31}P nmr spectra, most of the mixed ligand systems tried (both R_3PSe/R_3PS and $R_3PE/R_3'PE$ mixtures), gave evidence for the formation of complexes with mixed ligands. The complexes

$$[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{4-n}]^{2+}$$

$$[Cd(SeP(C_6H_{11})_3)_n(SP(C_6H_{11})_3)_{3-n}]^{2+}$$

and

$$[Cd(SeP(o\text{-}C_6H_4Me)_3)_n(SP(o\text{-}C_6H_4Me)_3)_{3-n}]^{2+}$$

provided the most useful combination of solubility and spectral resolution and therefore were studied in detail (Tables 6–8). The data for these complexes clearly establish the $CdSe_nS_{4-n}$ and $CdSe_nS_{3-n}$ kernels,[6] which we intend to study by ^{113}Cd nmr in the near future. In terms of the ^{31}P nmr spectra, perhaps the most noteworthy feature of the various spectra is the low sensitivity of the ^{31}P chemical shift and various coupling constants to replacement of R_3PSe by R_3PS, or vice-versa.

[6]Kernels of mixed Group VIA atoms are not widely known for cadmium (10).

Experimental

Materials

Triethylphosphine (PCR, Inc.), and tris(*t*-butyl)phosphine, tris(*o*-tolyl)phosphine, tris(*p*-tolyl)phosphine, bis(*o*-tolyl)-phenylphosphine, and *o*-tolyldiphenylphosphine (all from Strem Chemicals, Inc.) showed no significant impurities by ^{31}P nmr (11*a*, 12), and were used as received, as was the CS_2 adduct of tricyclohexylphosphine (Strem). Triphenylphosphine (Eastman Kodak Co.) was recrystallized from ethanol. $Cd(SbF_6)_2$ was prepared as described earlier (13).

Phosphine Sulfides and Selenides

Ph_3PS, Et_3PSe, $(C_6H_{11})_3PSe$, Ph_3PSe, $(o\text{-}C_6H_4Me)_3PSe$, and $(p\text{-}C_6H_4Me_3)PSe$ were prepared during prior studies (1, 7). The other sulfides and selenides were prepared analogously by reflux of the phosphine[7] with sulfur or selenium in benzene under nitrogen. Most of these compounds are known (11*b*), but Bu^t_3PSe, $(o\text{-}C_6H_4Me)_2PhPSe$, and $(o\text{-}C_6H_4Me)Ph_2PSe$ appear to be new compounds. The properties of the three compounds are:

Bu^t_3PSe: mp(uncorr.) 221–222°C (from Bu^nOH); exact mass calcd. for $C_{12}H_{27}PSe$: 282.1016; found (high resolution ms): 282.1015; ^{31}P nmr (CH_2Cl_2; 313 K): $\delta_{OP(OMe)_3}$ = 90.0 ppm; $\lvert^1J(^{31}P—^{77}Se)\rvert$ = 692 Hz.

$(o\text{-}C_6H_4Me)_2PhPSe$: mp(uncorr.) 161–162°C (from Bu^nOH); exact mass calcd. for $C_{20}H_{19}PSe$: 370.0389, found (high resolution ms): 370.0386; ^{31}P nmr (CH_2Cl_2; 313 K): $\delta_{OP(OMe)_3}$ = 26.2 ppm; $\lvert^1J(^{31}P—^{77}Se)\rvert$ = 719 Hz.

$(o\text{-}C_6H_4Me)Ph_2PSe$: mp(uncorr.) 149–150°C (from Bu^nOH); exact mass calcd. for $C_{19}H_{17}PSe$: 356.0233; found (high resolution ms): 356.0233; ^{31}P nmr (CH_2Cl_2; 313 K): $\delta_{OP(OMe)_3}$ = 28.8 ppm; $\lvert^1J(^{31}P—^{77}Se)\rvert$ = 732 Hz.

[7]$(C_6H_{11})_3P{\cdot}CS_2$ in the preparation of $(C_6H_{11})_3PS$.

Preparation of Nuclear Magnetic Resonance Samples

Samples containing one ligand were prepared in 10 mm od tubes as reported earlier (1). The ligand mixtures for preparation of complexes with two different ligands were made by mixing known amounts of methylene chloride solutions of the separate ligands in the 10 mm nmr tube, followed by removal of the solvent by evaporation under nitrogen, with final drying *in vacuo*. $Cd(SbF_6)_2$ was added in the glove box as before. For a given mixed ligand system, several different ratios of the two ligands were used to assist signal assignment.

^{31}P-{^1H} Nuclear Magnetic Resonance Spectra

The spectra were measured as reported in preceding publications (1, 7). The digital resolution was 0.3 Hz, but the natural broadness of the observed lines certainly leads to larger errors in line positions than is implied by this. We estimate that we can measure chemical shifts and values of $\lvert^2J(^{111/113}Cd—^{31}P)\rvert$ to ±1 Hz (0.025 ppm). $\lvert^1J(^{31}P—^{77}Se)\rvert$ probably has a maximum error of ±2 Hz.

Mass Spectra

High resolution mass spectra were obtained using a Varian MAT-311A spectrometer.

Acknowledgements

We wish to thank Mr. Doug Hairsine of this Department for measurement of the mass spectra, and both the Academic Development Fund of the University of Western Ontario and the Natural Sciences and Engineering Research Council of Canada for financial support.

Received March 10, 1980

GEORGE I. BIRNBAUM, KYOICHI A. WATANABE, and JACK J. FOX. Can. J. Chem. **58**, 1633 (1980).

The three-dimensional structure of pseudoisocytidine hydrochloride was determined by X-ray crystallography. The crystals belong to the triclinic space group $P\bar{1}$ and the cell dimensions are $a = 6.623(2)$, $b = 8.053(2)$, $c = 6.201(2)$ Å, $\alpha = 108.35(2)$, $\beta = 101.36(2)$, $\gamma = 93.54(2)°$. Intensity data were measured with a diffractometer and the structure was solved by a combination of heavy-atom and direct methods. Least-squares refinement, which included hydrogen atoms, converged at $R = 0.040$. The conformation about the glycosyl bond is *anti* ($\chi_{CC} = 21.6°$), the pucker of the furanose ring is C(1′)*exo*, and the conformation of the $-CH_2OH$ side chain is *gauche–trans* (t). An examination of bond lengths indicates that of the three main resonance forms of the isocytosine cation the fully conjugated one contributes more to the structure than the cross-conjugated one. Bond angles in the sugar ring reflect its rare conformation.

GEORGE I. BIRNBAUM, KYOICHI A. WATANABE et JACK J. FOX. Can. J. Chem. **58**, 1633 (1980).

On a déterminé la structure tridimensionnelle du chlorhydrate de pseudoisocytidine par diffraction de rayons-X. Les cristaux appartiennent au groupe spatial triclinique $P\bar{1}$ et les dimensions de la maille sont: $a = 6.623(2)$, $b = 8.053(2)$, $c = 6.201(2)$ Å, $\alpha = 108.35(2)$ $\beta = 101.36(2)$, $\gamma = 93.54(2)°$. On a mesuré les données d'intensité à l'aide d'un diffractomètre et on a résolu la structure à l'aide d'une combinaison de la méthode d'atome lourd et des méthodes directes. L'affinement des paramètres atomiques, qui inclut les atomes d'hydrogène, a été effectué par moindres carrés. L'indice final R est égal à 0.040. La conformation autour de la liaison glycosyle est *anti* ($\chi_{CC} = 21.6°$), le plissement du cycle furannose est C(1′)*exo* et la conformation de la chaîne latérale CH_2OH est *gauche-trans* (t). Un examen des longueurs de liaison indique que parmi les trois formes principales de résonance du cation isocytosine, la forme complètement conjuguée contribue plus à la structure que la forme où la conjugaison est opposée. Les angles de liaison dans le cycle furannose reflètent sa conformation rare.

[Traduit par le journal]

Among many naturally occurring nucleosides, a group of compounds, *C*-nucleosides, possess a unique structural feature in which the aglycon and sugar moieties are linked through a carbon-to-carbon (C—C) bond rather than the C—N glycosyl linkage. Most of these *C*-nucleosides are antibiotics, and many exhibit some anticancer and antiviral activities (1, 2). Recently, Chu *et al.* (3) synthesized a pyrimidine *C*-nucleoside, pseudoisocytidine, which was subsequently shown to be active in vitro and in vivo against various lines of mouse leukemia which are resistant to arabinosylcytosine (ara-C) (4).

The mechanism by which these substances act, whether as a result of being incorporated in DNA or RNA or by inhibiting cell activity at another stage of the cell growth, depends very much on their structure and conformation. Consequently, the solution conformations of pyrazomycin (5), formycin (6), and its analogs (7) have been studied in detail by nmr techniques. In addition, crystal structure determinations have been carried out for formycin monohydrate (8), formycin hydrobromide (9), 2-methylformycin (10), formycin B (11), oxoformycin B (11), showdomycin (12), α-pseudouridine (13), and pyrazomycin (14), but no details have been published about pyrazomycin. We now present the crystal structure of pseudoisocytidine hydrochloride, the first *C*-nucleoside with an isocytosine base to be so studied.

Experimental

Pseudoisocytidine hydrochloride was prepared as described by Hirota *et al.* (15). In order to obtain large crystals for the present study, the compound (200 mg) was dissolved in hot, concentrated hydrochloric acid (10 mL) and the solution diluted with hot ethanol (20 mL). The mixture was cooled slowly to room temperature, and the deposited crystals were filtered. The ^1H nmr spectrum of these crystals in D_2O was identical with that reported (3) for pseudoisocytidine hydrochloride, indicating that no *net* isomerization had occurred during the recrystallization procedure. All attempts to obtain large crystals from other solvent systems (e.g. MeOH, EtOH, MeOH–H_2O, EtOH–H_2O, etc.) were unsatisfactory. The colorless prisms belong to the triclinic space group $P\bar{1}$. A crystal fragment measuring 0.22 × 0.25 × 0.25 mm was mounted on a Picker four-circle diffractometer; it provided the following data:

$C_9H_{13}N_3O_5 \cdot HCl$ fw = 279.7

Triclinic, a = 6.623(2), b = 8.053(2), c = 6.201(2) Å, α = 108.35(2), β = 101.36(2), γ = 93.54(2)°, V = 305.0 Å^3, D_x = 1.52, D_m = 1.53 g cm^{-3} (flotation in bromobenzene–iodobenzene), Z = 1 (21°C; CuKα_1, λ = 1.54056; CuKα_2, λ = 1.54439 Å), F(000) = 146, μ (MoKα) = 3.3 cm^{-1}.

Intensities were measured with Nb-filtered MoKα radiation, using the moving-crystal/moving-counter method ($\theta/2\theta$ scan). Reflections with net counts < 100 or < 5% of background were categorized as unobserved. There were 1399 unique reflections with 2θ < 55° of which 1328 (95%) had intensities above threshold values. The intensities were corrected for Lorentz and polarization factors; absorption corrections were unnecessary.

A Fourier map, calculated with phases from the chloride ion at the origin, was not interpretable owing to the introduction of a false center of symmetry. However, two high peaks with a reasonable interatomic distance between them were selected, in addition to the chloride ion, as a partial structure. The positions of the 15 other nonhydrogen atoms were obtained after several cycles of tangent refinement (16). The structure was refined by block-diagonal least-squares with anisotropic temperature parameters. All hydrogen atoms were located on a difference Fourier map and refined with isotropic temperature parameters. The scattering factors were taken from the International tables for X-ray crystallography (17) and the chloride curve was corrected for anomalous dispersion. Throughout the refinement the function $\Sigma w(|F_o| - |F_c|)^2$ was minimized and a factor of 0.8 applied to all shifts. The following weighting scheme was used during the final stages: $w = |F_o|/4.8$ for $|F_o| \leq 4.8$ and $w = 4.8/|F_o|$ for $|F_o| > 4.8$. This scheme made the average values of $w(\Delta F^2)$ independent of $|F_o|$ and $\sin^2\theta$. The thermal vibration of O(3′) was found to be rather high perpendicular to the C(3′)—O(3′) bond. However, examination of a difference map showed no evidence of static disorder. After the final cycle the average parameter shift equalled 0.14σ and the largest 0.53σ. The conventional residual index R is 0.040 and the weighted index R' is 0.046. A final difference Fourier map was featureless. The coordinates are listed in Table 1; lists of anisotropic temperature parameters and of observed and calculated structure factors are available.[3] The overall conformation and the atomic numbering scheme are shown in Fig. 1.

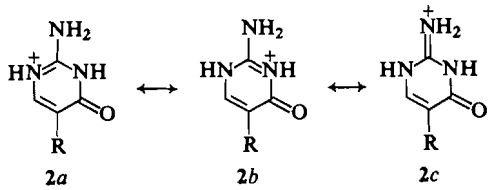
Results and Discussion

Isocytosine Moiety

Pseudoisocytidine (**1***a*) differs from cytidine in two respects: the ribose ring is attached to C(5) rather than to N(1) and the functions at C(2) and C(4) are interchanged. Both **1***a* and isocytosine (**1***b*) can exist in the two main tautomeric forms shown below.



1*a*: R = β-D-ribofuranosyl
1*b*: R = H

[3]These tables may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

In aqueous solution the two tautomers of **1***b* coexist in comparable amounts (18) and in the X-ray analysis of **1***b* both tautomers were found in the asymmetric unit (19). The ^{1}H nmr spectra of **1***b* and its cation have been studied by Wagner and von Philipsborn (20).

Protonation of the different tautomers of the isocytosine base (**1**) results in a common cation (**2**), present in our structure, for which three main resonance forms can be written.

2*a* **2***b* **2***c*

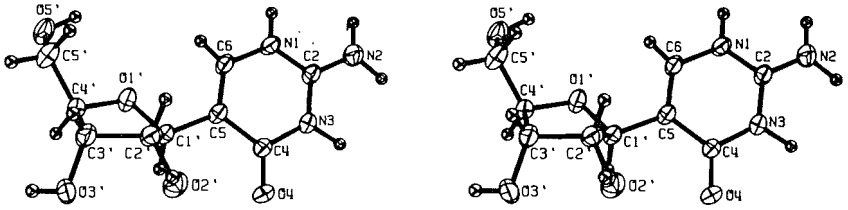


FIG. 1. Stereoscopic view of pseudoisocytidine hydrochloride; the ellipsoids include 50% probability.

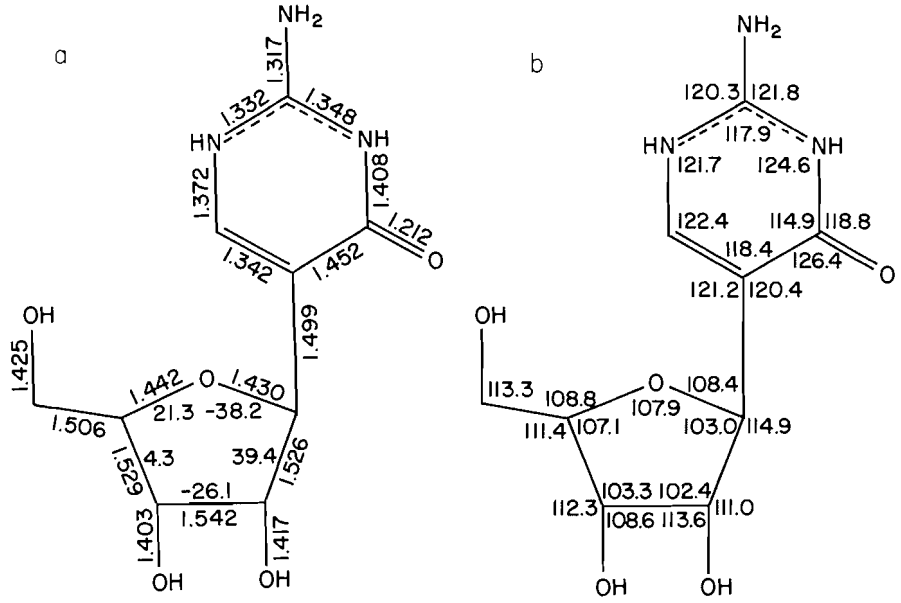

FIG. 2. Molecular geometry: (*a*) bond lengths and ribose ring torsion angles; esd's are 0.004–0.005 Å and 0.4°, respectively; (*b*) bond angles; esd's are 0.3°.

It is of interest to examine the contributions of these forms to the structure of the cation. This can be done by comparing the bond lengths in this structure (Fig. 2) with those in isocytosine (19) as well as in unprotonated and protonated cytosines (21–23). The exocyclic C—N bond in isocytosine (1.324(3) Å) is 0.010(3) Å shorter than the analogous C(4)—N(4) bond in cytosine, indicating more double bond character. When cytosine is protonated, this bond length decreases by 0.021 Å to 1.313 Å (21), suggesting a strong delocalization of the unshared electron pair from N(4) to N(3). Roberts and his colleagues arrived at the same conclusion on the basis of ^{15}N nmr spectroscopy (24). These observations agree with the previously determined energy barrier of ~15 kcal/mol which restricts the rotation about the exocyclic C—N bond in cytosine derivatives (25). Protonation of isocytosine decreases the length of C(2)—N(2) by only 0.007 Å; thus, there is relatively less delocalization of electrons into the ring in this system. However, we found this bond length (1.317 Å) to be very similar to the analogous bond lengths in protonated cytosines (21). Consequently, the contribution of the imino resonance from **2***c* must be similar in protonated cytosine and isocytosine systems. The relative contributions of the two other resonance forms (**2***a* and **2***b*) can be assessed by comparing the bond lengths N(1)—C(2) and C(2)—N(3). The latter is approximately equal to the analogous N(3)—C(4) bond lengths in protonated cytosines (21, 23). On the other hand, N(1)—C(2) has the same length as the more localized C=N bonds in unprotonated cytosine (26) and isocytosine (19). On the basis of these comparisons, and the relative lengths of these bonds, it appears that N(1)—C(2) has more double bond character than C(2)—N(3), i.e. **2***a* contributes more than **2***b*. This may be explained by the fact that **2***a* is fully conjugated, whereas there is unfavorable cross-conjugation in **2***b*.

The effects of protonation of cytosine and its

derivatives on bond angles are well established. Protonation occurs at N(3) and causes the endocyclic bond angle at that atom to increase by 4–5°, while the angles at the adjacent atoms C(2) and C(4) drecrease by the same amount (21–23). When we compare the geometry of our structure (Fig. 2) with that of isocytosine (19), we see the same changes of the bond angles in the ring. In fact, taking into account the interchange of functions at C(2) and C(4), the angles we found are in excellent agreement with the average values calculated from 12 protonated cytosine derivatives (22). There is, however, a difference in the exocyclic angles at the carbonyl carbon atom. In protonated cytosines N(1)—C(2)—O(2) is no more than 2.5° larger than N(3)—C(2)—O(2). On the other hand, in our structure C(5)—C(4)—O(4) is 7.6° larger than N(3)—C(4)—O(4). Exactly the same angles were found in isocytosine protonated at N(3) (19). This significant difference appears to be a peculiarity of the isocytosine system.

The six atoms of the pyrimidine ring are coplanar (Table 2) and the exocyclic amino group is in the same plane. However, O(4) and C(1′) are displaced from this plane, a phenomenon which is not unusual (27–29).

Ribose Moiety

The ribose ring adopts the rather unusual C(1′) *exo* conformation ($_1E$), the puckering at C(1′) displacing that atom by 0.571 Å (Table 2). The conformational parameters (30) $P = 130.3°$ and $\tau_m = 40.4°$ indicate that it is outside the usual ranges $P = 0$–36 and 144–180°. We have recently determined several nucleoside structures with unusual conformations of the deoxyribose ring (28, 29, 31), providing additional evidence of a relatively lower energy barrier between the C(2′)*endo* and C(3′)*endo* conformation of these rings (32–35). We have also shown that these conformations (O(1′)*endo*, C(1′)*exo*, C(1′)*exo*—C(2′)*endo*) very likely exist in solution as well, since this assumption results in a better agreement with observed J_{HH} coupling constants than the usual assumption of a C(2′)*endo* ⇄ C(3′)*endo* equilibrium. Thus, it appears probable that the C(1′)*exo* conformation which we found in the present crystal structure also contributes to the equilibrium population in solution. A study of the conformation of pseudoisocytidine in solution is now underway.

The ribose ring is attached to C(5) and the torsion angle about the glycosyl bond, C(6)—C(5)—C(1′)—O(1′), is 21.6° (Fig. 3), corresponding to the *anti* conformation (36). In pyrimidine *N*-nucleosides this is the more stable conformation, and it is almost always found in crystal structures unless a bulky substituent at C(6) imposes a *syn* conformation (29). The length of the C—C glycosyl bond (1.499 Å) is in very good agreement with values found in other *C*-nucleosides (8–13). It is interesting to note that C(4′)—O(1′) is just barely longer than C(1′)—O(1′) instead of by 0.03–0.05 Å. This reflects the fact that, in the present structure, C(1′) is bonded to only one electronegative atom (37). Other bond distances are normal and require no comments.

Bond angles in the furanose rings of nucleosides are known to depend on the conformation of the ring and, in the case of exocyclic angles, on the —OH substituent: whether "down" (ribose) or "up" (lyxose (38), xylose (39), or arabinose (27, 37)). Sundaralingam published average values for ribose and arabinose rings in the common C(2′)*endo* and C(3′)*endo* conformations (37). However, data on unusual sugars and/or conformations are relatively scarce. In a recently published statistical analysis of furanose bond angles in 110 ribo-, deoxyribo-, and arabino-nucleosides (40) there were no structures with the phase angle of pseudorotation (P) in the range 92–137°. Inclusion of such conformations will facilitate future analyses which are of great value in the interpretation of electron density maps of nucleic acids. The following observations can be made regarding the

TABLE 3. Distances and angles for hydrogen bonds

present structure (Fig. 2). The smallest endocyclic angle is, as usual in ribosides, at C(2′), but the angles at the puckered atom C(1′), as well as at C(3′), are not significantly larger. In fact, the angle at C(1′) is significantly smaller than 104.7°, the value which Westhof and Sundaralingam (41) recently derived for ribonucleosides in C(1′)*exo* conformation. However, these values were obtained on the basis of insufficient data from unusual ring conformations. The present structure analysis should therefore serve to improve the correlation between the bond angles and *P*. A similar situation was encountered in the structure of 5-hydroxymethyl-2′-deoxyuridine (hm⁵dU) where the deoxyribose ring also adopts a C(1′)*exo* conformation (28). The largest ring angle is, again as usual, at O(1′), but it is about 2° smaller than normal, reflecting the unusual ring pucker (40, 41). The difference between the smallest and largest ring angles is 5.5° in this structure and 5.0° in hm⁵dU; in C(2′)*endo* and in C(3′)*endo* ribosides that difference is about 9° (41).

There are also some unusual exocyclic bond angles. The two adjacent angles C(2′)—C(3′)—O(3′) and C(4′)—C(3′)—O(3′) are normally identical (37, 40), but sometimes the latter is much smaller (31, 42). In this structure, and in hm⁵dU (28), the reverse is true, indicating a possible correlation between these angles and the C(1′)*exo* ring conformation. The C(4′)—C(5′)—O(5′) angle (113.3°) is considerably larger than normal, but there is no obvious explanation for this distortion.

The conformation of the —CH_2OH side chain is *gauche–trans* (Fig. 3). Although not as common as *gauche–gauche* (g^+), this conformation (t) is not unusual. A correlation between the conformations of the side chain and of the sugar ring has been the subject of many studies. On the basis of crystal structures, Sundaralingam found the g^+ conformation to be the most preferred, regardless of the puckering of the sugar (43). A more recent and exhaustive survey found no correlation between the conformations of the side chain and the ring (40). On the other hand, from a survey of nmr data such a correlation for pyrimidine nucleosides and their 3′-monophosphates in *anti* conformation was postulated by Hruska (44) and was later described more quantitatively by Davies (45). However, the nmr data have always been interpreted by assuming a C(2′)*endo* ⇄ C(3′)*endo* equilibrium. As more unusual sugar puckers are being found, such correlations may have to be revised.

Hydrogen Bonding

There are seven protons capable of hydrogen bonding and all seven participate in such bonds. Details of the geometry are given in Table 3. As commonly observed in X-ray analyses, most O—H and N—H bonds appear shorter than their real values of 0.97 and 1.04 Å, respectively, which are obtained from neutron diffraction studies. By expanding the covalent bond lengths in the direction of the bond up to their real values, one obtains corrected H···*A* distances that express more accurately the strength of the hydrogen bond (46). Thus, it can be seen that one N—H···O, one N—H···Cl⁻, and one O—H···Cl⁻ bond are relatively weak (23). It should be noted that there are no hydrogen bonds between the pyrimidine bases. Also, the bases are not stacked, the shortest intermolecular distance between them being N(2)···O(4) 3.578 Å. Apart from the hydrogen bonds there are no intermolecular distances shorter than the sum of van der Waals radii.

Acknowledgments

All crystallographic computations were carried out with programs written by Ahmed *et al.* (47). Figure 1 was drawn with the ORTEP program of Johnson (48).

Thermolysis of alkylated 2-cyclohexenones and related monoterpenoid ketones

GORDON L. LANGE, VINCENT A. PEREIRA, AND MICHAEL WEEDLE

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received January 16, 1980

GORDON L. LANGE, VINCENT A. PEREIRA, and MICHAEL WEEDLE. Can. J. Chem. **58**, 1639 (1980).

2-Cyclohexenone and three methylated cyclohexenones were thermolyzed at 400°C for 20 hours to give conversions to products in the range 11 to 45%. When three monoterpenes containing the cyclohexenone moiety were thermolyzed under the same conditions the conversions were over 75%. The major products formed were alkylated benzenes, alkylated phenols, and double bond isomers of the starting enones. Mechanisms are proposed to account for these products.

GORDON L. LANGE, VINCENT A. PEREIRA et MICHAEL WEEDLE. Can. J. Chem. **58**, 1639 (1980).

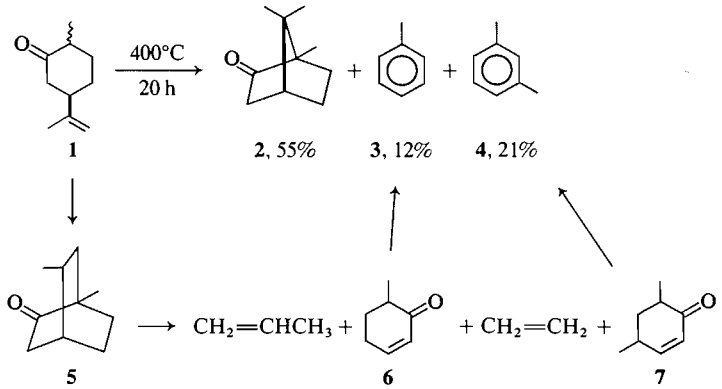
La cyclohexènone-2 et les trois méthyl-cyclohexènones thermolysées à 400°C pendant 20 heures conduisent aux produits de conversion dans la proportion de 11 à 45%. La thermolyse de trois monoterpènes contenant le noyau cyclohexènone dans les mêmes conditions conduit à des conversions avec des rendements supérieurs à 75%. Les produits principaux sont les benzènes et les phénols alkylés et les isomères de position des énones de départ. On propose un mécanisme qui tient compte de ces produits.

[Traduit par le journal]

Introduction

We wish to report our studies on the vapor phase thermolysis at 400°C of three methylated cyclohexenones and four monoterpenoid ketones. Our interest in this area of research was stimulated by an earlier investigation (1), in which the thermolysis of the monoterpene (+)-dihydrocarvone (**1**) yielded not only the desired (+)-camphor (**2**) but also significant amounts of toluene (**3**) and *m*-xylene (**4**) (Scheme 1). It was proposed that a retro-Diels–Alder reaction of the enol tautomer of **5** yielded cyclohexenones **6** and **7** which were then transformed to the aromatic hydrocarbons **3** and **4**, respectively. As a result of this investigation we felt two questions deserved closer scrutiny: (*i*) is the cyclohexenone → substituted benzene conversion a general thermal reaction? (*ii*) are aromatic hydrocarbons also formed on the thermolysis of other monoterpenoid ketones? This paper will outline the research that we have conducted to answer these questions.

Experimental



Instrumentation

Infrared (ir) spectra were recorded on a Beckman AccuLab 6 spectrophotometer, ultraviolet (uv) spectra on a Beckman Model 24 spectrophotometer with 95% ethanol as solvent, proton nuclear magnetic resonance (nmr) spectra on a Varian A-60A spectrometer with TMS (δ = 0.0) as internal standard, and mass spectra on a VG Micromass 7070F spectrometer coupled to a gas chromatography unit (gc–ms) equipped with a 6 ft × 0.25 in. 20% Carbowax 20 M column.

Gas chromatographic (gc) analyses were performed on an Aerograph Autoprep Model A-700 using the following columns: column A, 9 ft × 0.25 in. 20% Carbowax 20 M; column B, 6 ft × 0.125 in. 8% GE SF 96 silicone; column C, 6 ft × 0.125 in. 20% diethylene glycol succinate. In the analysis of the thermolysis products reported in Table 1 the areas of all peaks on the gc tracings were determined by triangulation and the areas were not corrected for differences in the thermal response of the detector. Each of the entries given in Table 1 is an average of at least two runs.

Thermolyses and Product Identification

Compounds **8**, **9**, **10**, **11**, **12**, and **15** were commercially available while **13** was prepared by acid treatment of camphor (2) and **14** was prepared by homogeneous catalytic hydrogenation of carvone (3). These compounds were purified by fractional dis-

tillation or preparative gc immediately prior to reaction and the sample size was 0.40 g for each run. The thermolyses were conducted at 400 ± 2°C for 20 h in a 650-mL evacuated (< 0.02 Torr) Pyrex reactor similar to that previously described (4). In some runs the surface area of the reaction was increased by a factor of ten (Table 1, large surface area) by filling the reactor with pieces of glass tubing (7 mm long × 6 mm od). The products were distilled into a cold finger cooled in liquid nitrogen and then analyzed by gc. The crude distillation recoveries were always high as very little tar formation was evident in any of the runs. The gc peaks were identified by coincident retention times with known samples on two or three columns, by the peak enhancement method, by gc–ms analysis, and in many instances by preparative gc collection and spectral analysis. Components more volatile than benzene were not analyzed but normally these were a relatively small percentage of the total products. The phenolic products had retention times longer than the starting enone and were routinely collected by preparative gc (column A) and their spectral data compared with authentic samples. In addition, the following compounds were collected and their spectra determined.

Experiment 1 3-Cyclohexenone was eluted before 2-cyclohexenone and its ir and nmr spectra were the same as those previously reported (5).

Experiment 3 3-Methyl-3-cyclohexenone was eluted before 3-methyl-2-cyclohexenone and its ir and nmr spectra were the same as those previously reported (5).

Experiments 6 and 7 (*a*) *m*-Xylene was collected and its ir spectrum determined to clearly establish that other xylene isomers were not present; (*b*) 2-ethyl-5-methylphenol eluted between *m*-cresol and 3,5-dimethylphenol and exhibited the following spectral data: nmr (CCl_4) δ: 1.2 (3H, t), 2.3 (3H, s), 2.6 (2H, quartet), 4.3 (1H, br s), 6.4–7.1 (3H, m); mass spectrum *m/e*: 136 (M^+).

Experiments 8 and 9 The collected sample of 5-isopropyl-2-methylphenol was identical to a sample prepared by treatment of carvone with $RhCl_3 \cdot 3H_2O$ (6).

Experiments 11 and 12 (*a*) The 3-methylcyclohexanone peak exhibited spectral properties identical to an authentic sample: (*b*) 2-ethylidene-5-methylcyclohexanone (**25**) eluted after menthone (**15**) but before a sample of pulegone (2-isopropylidene-5-methylcyclohexanone) which was added for

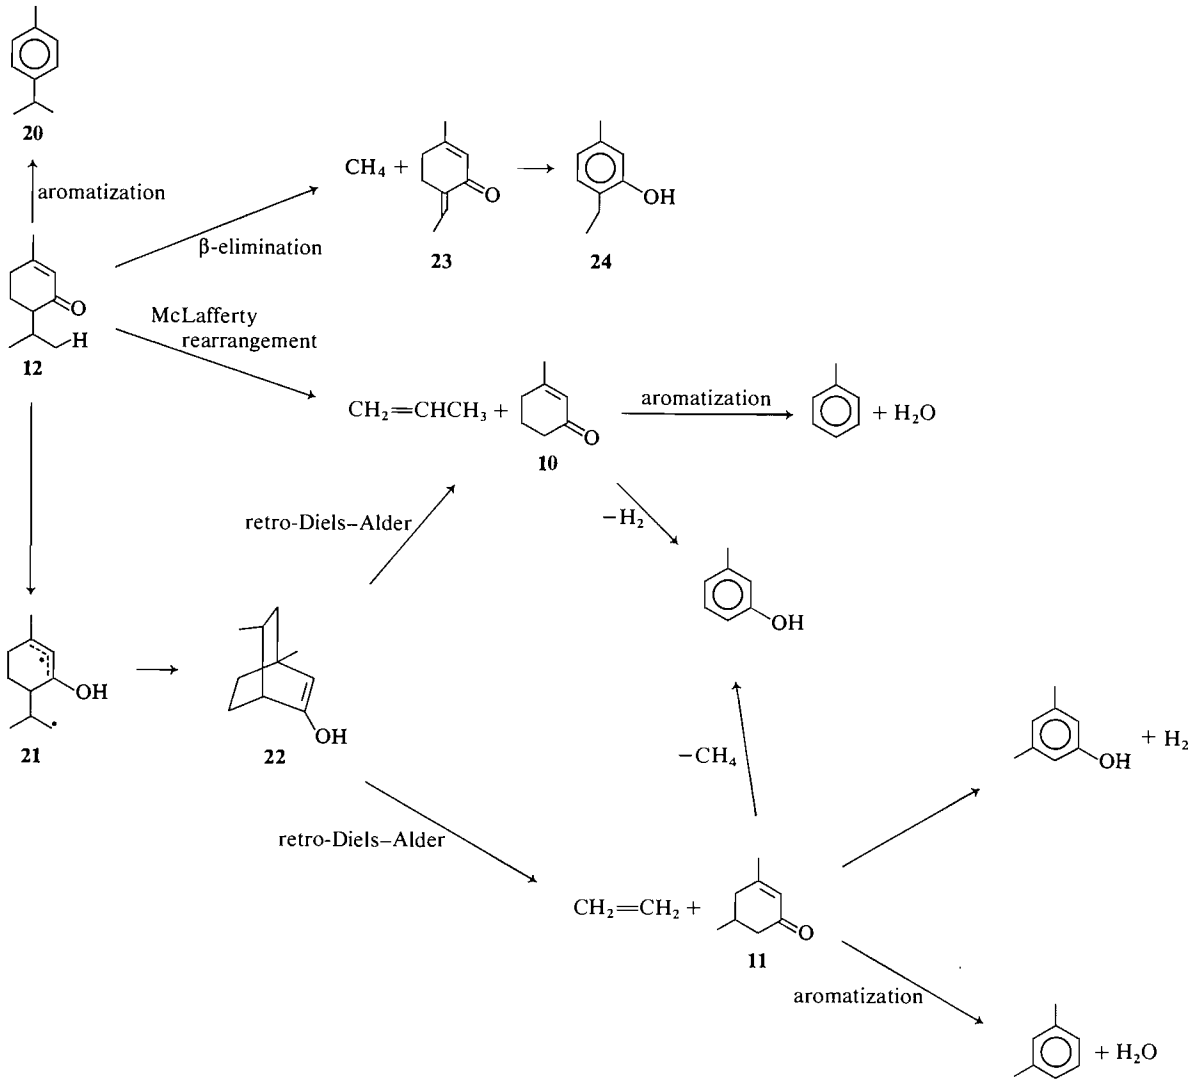
purposes of comparison. Compound **25** exhibited the following spectral data: uv λ_{max}: 244 nm; ir (CCl_4):1695, 1625 cm^{-1}; nmr (CCl_4) δ: 1.0 (3H, d), 1.7 (3H, d), 1.6–2.6 (7H, m), 6.6 (1H, m). These data are consistent with the reported data for the related compounds 2-ethylidene-6-methylcyclohexanone (7) and the available pulegone.

Results and Discussion



In the initial stages of our investigation, we examined the thermolysis of a number of methylated 2-cyclohexenones (**8–11**) to determine the effect of the position and of the number of substituents on the percentage conversion and the product composition (Table 1, Experiments 1–5). All thermolyses described were conducted in the vapor phase at 400°C for 20 h. The percentage conversions varied from 11 to 45% for these enones and the percentage of aromatization to a substituted benzene (e.g. 3-methyl-2-cyclohexene (**10**) → toluene) varied from 3 to 28%. Using either of these criteria of reaction, it appears that methyl substituents facilitate the conversions although the position of the substituents is also important (e.g. Experiment 2 vs. 3). Experiments 3 and 4 indicate that a ten-fold increase in the surface area within the reaction flask enhances the conversion slightly.

Scheme 2 outlines mechanisms to account for the products (Table 1, Experiments 3 and 4) formed by thermolysis of 3-methyl-2-cyclohexenone (**10**). Similar mechanisms would account for the products obtained from **8**, **9**, and **11**. Enolization of the enone is an essential step in almost all the transformations described and may be either a thermal or a catalyzed reaction on the glass surface of the reaction flask. Intermediate **16**, formed by enolization of **10**, may undergo the four possible reactions indicated in Scheme 2 to give the products isolated. First, a [1.5] sigmatropic hydrogen shift yields enol **17**, which then tautomerizes to give the unconjugated ketone **18**. Spangler and Hennis (8) have shown that these [1.5] shifts readily occur with 1,3-cyclohexadienes above 325°C. In the thermolysis of 2-cyclohexenone (**8**) the major product was also the unconjugated isomer (Experiment 1). In Scheme 2, the second pathway from **16** involves several [1.5] hydrogen shifts to give **19** which readily dehydrates to yield toluene. The driving force behind this aromatization sequence is presumably the formation of the stable benzene ring. Similarly, in the thermolysis of 3,5-dimethyl-2-cyclohexenone (**11**) the major product was *m*-xylene, formed by this aromatization process. The final two pathways from **16** involve elimination of a molecule of hydrogen or methane to give *m*-cresol or phenol, respectively. The very volatile products in these reactions were not analyzed so we have no direct evidence for the formation of products such as methane. In a similar manner, thermolysis of **11** yielded 3,5-dimethylphenol and *m*-cresol after loss of hydrogen or methane, respectively, while **9** yielded *o*-cresol and hydrogen.

Experiments 1 to 5 provided a better understanding of the types of processes to be expected upon thermolysis of methyl-substituted cyclohexenones. Next we proceeded to the thermolysis of more complex cyclohexenones, namely, the naturally occurring monoterpenes piperitone

SCHEME 2

SCHEME 3

(**12**), carvenone (**13**), and carvotanacetone (**14**). One striking feature of these reactions (Experiments 6–10) was the much higher conversions (>70%) which were attained. Evidently the isopropyl group of the monoterpenes enhances the reactivity of enones in these thermal transformations.

Scheme 3 outlines a number of pathways to explain the formation of the seven major components detected in the thermolysis of piperitone (**12**). Similar transformations will explain most of the products obtained from **13** and **14**. In this scheme, the enolization and [1.5] shifts are not shown in detail, but it is clear that *p*-cymene (**20**) is formed from **12** by the aromatization reaction discussed previously. A McLafferty-type rearrangement (9) is possible when an isopropyl group is on a carbon *alpha* to the carbonyl group. This fragmentation with **12** yields propene and **10**, which then gives toluene upon aromatization. Compound **10** also may be converted to *m*-cresol by loss of hydrogen. A pathway for the formation of *m*-xylene from **12** is not obvious but it should be emphasized at this point that the *meta* isomer is not formed by isomerization of either the *ortho* or *para* isomer. Thermolysis of either *o*- or *p*-xylene under the usual reaction conditions gave complete recovery of the starting material with no evidence of isomerization. We suggest that a primary hydrogen of the isopropyl group in **12** is transferred to the carbonyl group to give the allylic biradical **21**, which then cyclizes to form the bicyclo[2.2.2] system **22**.

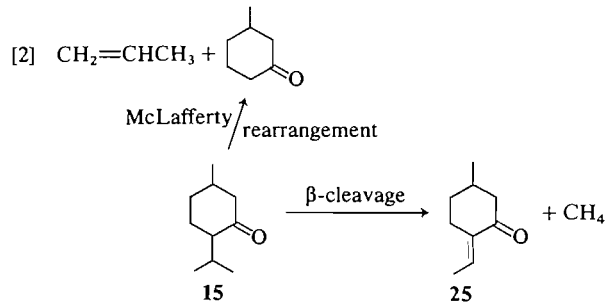
Retro-Diels–Alder fragmentation of **22** gives either propene and **10** or ethene and **11**. As observed in Experiment 5, **11** yields *m*-xylene, *m*-cresol, and 2,4-dimethylphenol, which are three of the products also formed from **12**. Retro-Diels–Alder reactions of bicyclo[2.2.2] systems previously were shown to occur under these reaction conditions (1).



The last pathway in Scheme 3 accounts for the formation of 2-ethyl-5-methylphenol (**24**) from piperitone (**12**). Judging from a limited number of examples, it appears that alkyl substituents at the 5-position in 2-cyclohexenones (i.e. *beta* to the carbonyl group) are most readily eliminated under our thermolysis conditions. For example, β-elimination of the methyl group of **11** yielded *m*-cresol (Experiment 5), which was one of the major products in that reaction. Likewise, elimination of a β-methyl group (along with an α-hydrogen) from **12** gives **23** (Scheme 3), which isomerizes to **24**. In the thermolysis of carvotanacetone (**14**), β-elimination of the isopropyl group gives the major product, *o*-cresol. The driving force in these reactions is presumably the formation of the new conjugated enone and ultimately the aromatic ring.

The double bond in the starting enone may isomerize from one side of the carbonyl group to the other via the enol and [1.5] sigmatropic shifts. For example, thermolysis of carvotanacetone (**14**) yields some carvenone (**13**) or thermolysis of **13** gives **14** (eq. [1]). Thus, the major product obtained in Experiments. 8 and 9 was *o*-cresol, formed by isomerization of **13** to **14** followed by β-elimination of the isopropyl group.

[1] 

14 **13**

To this point in our investigation, the only systems examined were substituted cyclohex*enones*. For purposes of comparison we thought it would be of interest to determine the products obtained from thermolysis of a naturally occurring cyclohex*anone*, namely the common monoterpene menthone (**15**). Experiments 11 and 12 indicated that the larger surface area increased the percentage conversion quite substantially but in both instances the major product was 3-methylcyclohexanone, formed by a McLafferty-type rearrangement as discussed earlier for piperitone (**12**). The other product formed in this thermolysis is proposed to be 2-ethylidene-5-methylcyclohexanone (**25**) (eq. [2]), on the basis of the spectral

[2] 

15 **25**

information reported in the Experimental. Compound **25** is formed by β-cleavage of one of the methyl groups of the isopropyl substituent. The menthone used in this study was a 2:1 mixture of the two epimers (actually menthone and isomenthone). Analysis of the menthone recovered after the thermolysis indicated the epimer ratio was 1.6:1. At a temperature of 400°C it would be expected that the equilibrium would be shifted towards the less stable epimer (10) and upon distillation of the products from the thermolysis flask the new equilibrium mixture would effectively be "trapped".

Summary and Conclusions

As a result of these studies it is possible to make several generalizations concerning the type of products to be anticipated upon thermolysis of substituted cyclohexenones. (*i*) At 400°C these enones readily undergo [1.5] sigmatropic hydrogen shifts via their enol tautomer to yield double bond isomers which may be isolated or be involved in further transformations. (*ii*) All of the cyclohexenones yielded varying amounts of substituted benzenes and thus this aromatization reaction is common to these systems. (*iii*) The enone may lose either a molecule of hydrogen or a simple alkane (e.g. methane or propane) to give a phenol. (*iv*) An alkyl group at the 5-position of a 2-cyclohexenone appears to be eliminated most readily in a so-called β-cleavage process. (*v*) Some transformations are more complex (e.g. **12** → *m*-xylene) and it is necessary to postulate an intermediate bicyclo[2.2.2] system, which then undergoes a retro-Diels–Alder reaction to give a new cyclohexenone and an alkene.

In conclusion, the thermal transformations of a variety of substituted cyclohexenones, including monoterpenoids, may be rationalized on the basis of a limited number of mechanistic pathways. These investigations may provide a better understanding of more complex thermal processes such as the conversion of terpenoids to aromatic hydrocarbons during the formation of petroleum (11) and other biomass conversions.

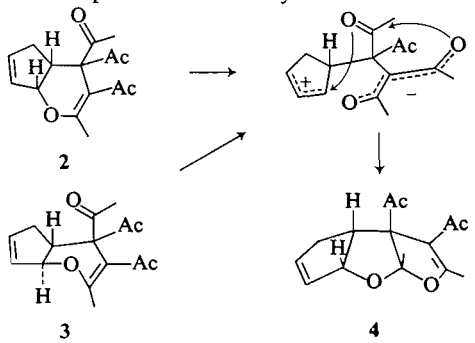
Received February 14, 1980

GIORGIO ADEMBRI, DONATO DONATI, RENZO CINI, RODOLFO NESI, and MIRELLA SCOTTON. Can. J. Chem. **58**, 1645 (1980).

Dimerization of tetraacetylethylene (TAE) **1** has led to a spiro[furan-2(5*H*),2′(3′*H*)-furo[2,3-*b*]furan], whose structure was established by X-ray analysis. The trend of TAE to furan ring closure was confirmed by the reaction with ethyl vinyl ether, where the first product of the reaction, the pyran adduct **8**, smoothly rearranged to a furo[2,3-*b*]furan derivative **9**.



GIORGIO ADEMBRI, DONATO DONATI, RENZO CINI, RODOLFO NESI et MIRELLA SCOTTON. Can. J. Chem. **58**, 1645 (1980).

La dimérisation du tétra-acétyléthylène (TAE) **1** conduit au dérivé spiro[furan-2(5*H*),2′(3′*H*)-furo[2,3-*b*]furanne] dont on a établi la structure par analyse aux rayons-X. On a confirmé la tendance du TAE à se transformer en un cycle furanne par la réaction avec l'éther éthylvinyle, où le premier produit de la réaction, l'adduit pyranne **8**, se transpose facilement en un dérivé furo[2,3-*b*] furanne **9**.

[Traduit par le journal]

Tetraacetylethylene (TAE) **1**, a conjugated system with a highly activated double bond, reacted with nucleophiles, electrophiles, and dienes to give homocycles, heterocycles, and cycloadducts respectively (1, 2). The cycloadducts obtained from cyclopentadiene easily converted into furan derivatives through a rearrangement which was promoted by steric hindrance and by the presence of an oxygen atom suitably placed with respect to an electron-deficient carbon atom. Thus, the *cis*-cyclopenta[*b*]pyran **2**, obtained from TAE and cyclopentadiene through a sigmatropic[3.3] rearrangement, and the *trans*-isomer **3** convert into the more stable cyclopenta[*d*]furo[2,3-*b*]furan **4** (3, 4).

Our interest in studying the reactivity of TAE led us to attempt some other cycloaddition reactions.

SCHEME 1

We found that they were sometimes slow or did not take place at all, for instance with butadiene, anthracene, hexachlorocyclopentadiene, diphenylfulvene. We attributed this behavior to the lack of planarity of TAE as follows from ir and Raman spectra (1). In all cases we isolated compound **5**, a dimer of TAE. The dimer **5** was prepared in 80% yield by refluxing TAE in an inert solvent, such as benzene, for 28 h. The ir spectrum showed a sharp band at 3420 cm^{-1} (OH), three bands at 1715, 1700, and 1685 cm^{-1} (CO groups), and a very strong band at 1605 cm^{-1}, which was indicative of a conjugated —CO—C=C—O— system (5, 6), confirmed by the uv absorption at 266 nm. The second maximum at 220 nm suggested the presence of a conjugated Ac—C=C—Ac system (7). The ^1H nmr spectrum, in deuterioacetone, displayed a singlet (1H) at δ5.85 for the OH group (the signal disappeared on deuteration) and two mutually coupled doublets (1H each, J = 14 Hz) at δ 3.36 and 2.15 attributable to methylene protons. There were also six singlets due to seven methyl groups; whereas five resonated at δ 2.36, 2.31, 2.15, and 2.04 (integral ratio 6:3:3:3), the other two showed a remarkable upfield shift (δ 1.56 and 1.47).

[a] Anisotropic thermal factors are of the form: $\exp(-2\pi^2(\sum_{i=j} h_i h_j a_i^* a_j^* U_{ij}))$.
[b] Isotropic thermal factor for hydrogen atoms was fixed to $U = 0.06$ Å^2.

The evidence presented above was not sufficient to choose among the variety of structures possible for compound **5**, keeping in mind the trend of TAE to furan ring closure which involves the introduction of several chiral centers. Consequently an X-ray structure determination was undertaken which established that it had the (2*R**,3′a*R**,5*R**,6′a*R**)3,3′a,4,4′-tetraacetyl-5-hydroxy-5,5′,6′a-trimethylspiro[furan-2(5*H*),2′(3′*H*)-furo[2,3-*b*]-furan] structure.

Details of the crystallographic analysis are reported in the Experimental.

A possible mechanism pathway would involve the dimerization of an intermediate such as **7** which could account for the stereochemistry of the dimer **5**. The same furan **7** could be invoked for the formation of 3,4-diacetyl-2-halomethyl-5-methylfuran **6** from TAE and concentrated haloacids (1).

TAE reacted with ethyl vinyl ether, an activated

electron-rich olefin, through an 1,4-dipolar addition to give 3,4,4-triacetyl-6-ethoxy-2-methyl-5,6-dihydro-4*H*-pyran **8** whose structure followed from spectral data. The presence of a —CO—C=C—O— system was revealed by the most intense band in the ir spectrum at 1620 cm^{-1} and confirmed by uv absorption at 259 nm. The ^1H nmr spectrum in deuteriochloroform showed four three-proton singlets at δ 2.11, 2.17, 2.31, and 2.45 for the methyl groups (the three signals at highest field partially overlapped a multiplet (2H) attributable to the methylene ring protons) and a doublet of doublets (1H, $J_{5',6}$ = 2.3 Hz, $J_{5'',6}$ = 4.0 Hz) at δ 5.08, which was assigned to the H-6 proton (this multiplet collapsed to a singlet by irradiation at 2.17). The spectrum also exhibited a triplet (3H), at δ 1.17 and a 16-component pattern (2H) centered at δ 3.68

8 9

SCHEME 3

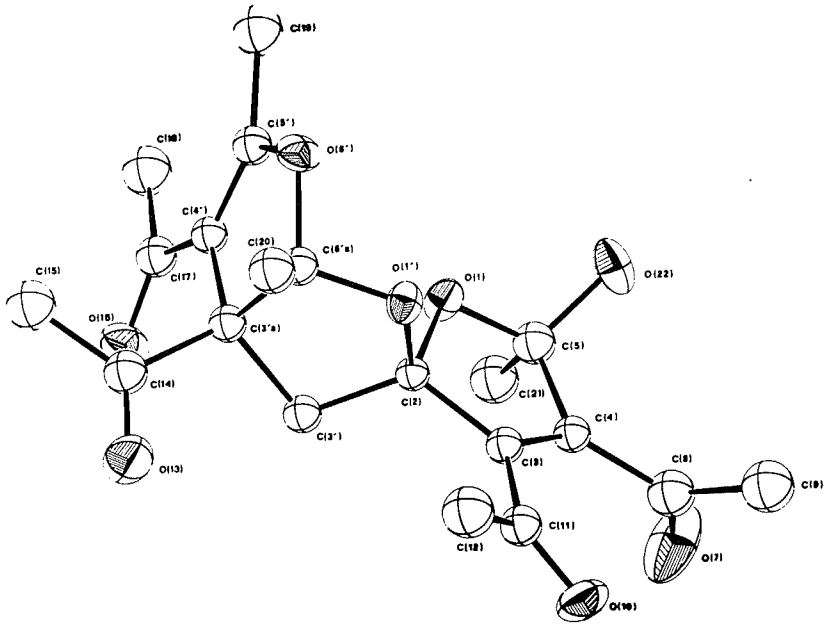

FIG. 1. ORTEP drawing of the molecule with 30% probability thermal ellipsoids and atom labelling system used in the crystallographic analysis.

for the ABX_3 system (J_{AB} = 9.5 Hz, $J_{AX} = J_{BX}$ = 7.0 Hz) of the O—CH_2—CH_3 group, according to the diastereotopic methylene protons (8, 9).

The pyran **8** was unstable and, both in the solid state and faster in solution, it rearranged intramolecularly to a compound, mp 65–67°C, which we assigned the structure of 3,3a-diacetyl-5-ethoxy-2,6a-dimethyl-*cis*,3a,4,5,6a-tetra-hydrofuro[2,3-*b*]furan **9** on the basis of spectral evidence and by analogy with foregoing cases. Both ir and uv spectra supported the presence of the same conjugated system as in isomer **8**. The same signals of the ABX_3 system (J_{AB} = 9.5 Hz, $J_{AX} = J_{BX}$ = 7.0 Hz) were also present in the ^{1}H nmr spectrum of this isomer at δ 1.2 (3H) and 3.67 (2H) respectively, whereas the H-5 and the methylene ring protons gave rise to three doublets of doublets (1H) at δ 5.16, 2.84, and 2.25 ($J_{4',4''}$ = 14.0 Hz, $J_{4',5}$ = 5.2 Hz, $J_{4'',5}$ = 6.3 Hz). The multiplet at highest field was partially obscured by three singlets (3H) at δ 1.32, 1.28, and 1.15 attributable to the methyl protons; as reported for compounds **4** and **5** the resonance of the methyl group at 6a position (δ 1.46) showed a remarkable upfield shift.

Experimental

Infrared spectra were measured for dispersions in potassium bromide with a Perkin-Elmer 457 spectrometer and uv spectra for solutions in methanol with a Cary 14 recording spectrophotometer. The ^{1}H nmr spectra were recorded with a Perkin-Elmer R 32; chemical shifts are reported in ppm downfield from tetramethylsilane as internal reference and coupling constants in Hz and are discussed in the Introduction. Molecular weight of compound **5** was determined with a Hitachi Perkin-Elmer 115 Apparatus.

(2R,3'aR*,5R*,6'aR*)3,3'a,4,4'-Tetraacetyl-5-hydroxy-5,5',6'a-trimethylspiro-[furan-2(5H),2'(3'H)-furo[2,3-b]furan]* **5**

TAE (0.4 g) was refluxed in benzene (2 mL) for 28 h. Evaporation of the solvent followed by crystallization of the resulting syrup with water gave the dimer **5** as colorless prisms, mp 144–146°C, (0.32 g, 80%); uv λ_{max} (log ε): 220(3.72) and 266 (3.96) nm; ir ν_{max}: 3420, 1715, 1700, 1685, 1645, 1605 cm^{-1}. *Anal.* calcd. for $C_{20}H_{24}O_8$: C 61.22, H 6.16, Mol. Wt. 392; found: C 61.48, H 6.14, Mol. Wt. 384.

3,4,4-Triacetyl-6-ethoxy-2-methyl-5,6-dihydro-4H-pyran **8**

TAE (0.8 g) was refluxed with ethyl vinyl ether (6 mL) for 28 h. The excess of the reagent was evaporated and the residue triturated with a little ether gave on filtration the pyran **8**, (0.88 g, 80%), mp 70–72°C (from light petroleum bp 40–70°C); uv λ_{max} (log ε): 259 (4.01) nm; ir ν_{max}: 1710, 1700, 1650, 1620 cm^{-1}. *Anal.* calcd. for $C_{14}H_{20}O_5$: C 62.67, H 7.51; found: C 62.83, H 7.52.

Preparative tlc of the ether solution (with ether as eluent) gave, in order of mobility, another crop of the pyran **8** (20 mg) and the dimer **5** (30 mg) (identical mp and ir spectrum with material obtained as above).

Isomerization of the Pyran **8**

The pyran **8** was not very stable and set aside in ether for a few days isomerized into 3,3a-diacetyl-5-ethoxy-2,6a-dimethyl-*cis*-3a,4,5,6a-tetrahydrofuro[2,3-*b*]furan **9**, mp 65–67°C, (from light petroleum bp 40–70°C); uv λ_{max} (log ε): 265 (4.08) nm); ir ν_{max}: 1710, 1615 cm^{-1}. *Anal.* calcd. for $C_{14}H_{20}O_5$: C 62.67, H 7.51; found: C 62.95, H 7.49.

Crystal Data of Compound **5**

$C_{20}H_{24}O_8$ fw = 392.4

Monoclinic, a = 20.30 (2), b = 7.80(1), c = 12.66(1) Å, β = 90.64(4)°, V = 2004.5 $Å^3$, ρ_c = 1.30 $g.cm^{-3}$, Z = 4, $F(000)$ = 832.0 (20°C, Mo-Kα, λ = 0.7107 Å), μ(Mo-Kα) = 1.08 cm^{-1}. Space group $P2_1/a$ from systematic absences $h0l$ for $h = 2n + 1$, $0k0$ for $k = 2n + 1$.

An irregular prism-shaped fragment of dimension ca. 0.2 × 0.25 × 0.15 mm^3 was mounted on a Philips automated diffractometer (graphite monochromator, Mo-Kα radiation). Cell constants were determined by least-squares treatment of angles of 25 reflections. The reflections were collected within $2\theta < 50°$ by ω-2θ step-scan at a scan speed of 0.04° s^{-1} and a scanwidth of 1.60° in ω. Background counts were measured at either end of the scan for 20 s. Two standard reflections monitored periodically showed no significant variation. After correction for Lorentz and polarization effects, 801 reflections with $I > 2\sigma(I)$ were considered observed and used in the structure solution and refinement. Absorption corrections were not applied.

Structure Analysis

The structure was solved by use of automatic centrosymmetric direct methods of the SHELX (1976) program system (10). Most of the non-hydrogen atoms were located in the E map, the remainder by Fourier maps of electron density. Two cycles of full matrix least-squares refinement with unit weight and isotropic temperature factors reduced R to 0.10. Two cycles of least-squares refinement with anisotropic temperature factors for all the oxygen atoms reduced the R factor to 0.081. The weighting scheme used was $w = (\sigma^2(F_0) + 0.005\ F_0^2)^{-1}$ where $\sigma(F_0)$ is the individual estimated standard deviation for each reflection from diffractometer counting statistics. A difference Fourier synthesis calculated at this point showed fifteen hydrogen atoms. These atoms were introduced in the calculation without further refinement of their position, with a temperature factor U of 0.06 $Å^2$. One additional least-squares cycle on non-hydrogen atom parameters gave an R factor of 0.056. At this stage a second difference Fourier synthesis showed seven new hydrogen atoms which were introduced in the final refinement. Three least-squares cycles gave the final disagreement indices R and R_w of 0.050 and 0.053 respectively. Final positional and thermal parameters with the estimated standard deviations are listed in Table 1. Observed and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

Description of the Structure

The ORTEP (11) drawing in Fig. 1 shows clearly the spiran system between a furan ring and a *cis*-fused furo[2, 3-*b*]furan system in the molecular structure of compound **5**.

Table 2 reports bond lengths and angles in the molecule, Table 3 the shortest significant intramolecular distances, and Table 4 equations of best least-squares planes through the rings and the angles between them. The rings A and C are essentially planar; evident puckering is present in ring B with the C(3') atom projecting (0.50 Å) out of the plane of the four other atoms.

[2]These tables are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

The most interesting feature in this molecule is the conjugated system O(16) = C(17)—C(4') = C(5')—O(6') in the ring C, which had been expected on the basis of the uv and ir spectra and by analogy with compound **4** (4). The conjugation is the driving force for the coplanarity of the acetyl group O(16)—C(17)—C(18) with the ring plane (about 5.7° between the two planes) and consequently, owing to the strong steric hindrance between the acetyl and the methyl group C(19), the angles C(17)—C(4')—C(5') and C(19)—C(5')—C(4') widen to 128.4° and 135.1° respectively.

The steric hindrance between the two acetyl groups O(10)—C(11)—C(12) and O(7)—C(8)—C(9) of the A ring is apparently more important than the conjugation and forces them out of coplanarity (17.8° and 67.0° respectively between the acetyl planes and the ring plane).

Received January 18, 1980

ANTHONY ANDERSON, CHUNG CHIEH, DONALD E. IRISH, and JAMES P. K. TONG. Can. J. Chem. **58**, 1651 (1980).

X-ray diffraction studies have revealed that $K_4UO_2(CO_3)_3$ is isostructural with $(NH_4)_4UO_2(CO_3)_3$; the crystal is monoclinic with a = 10.247(3), b = 9.202(2), c = 12.226(3) Å, β = 95.11(2)°, Z = 4, and space group $C2/c$. Three carbonate anions are arranged in bidentate fashion in the equatorial plane of UO_2^{2+}; one of these occupies a C_2 site and the other two occupy C_1 sites. All carbonates are significantly distorted from D_{3h} symmetry. The binding of carbonates to uranyl is strong and thus the lattice can be considered to be composed of $[UO_2(CO_3)_3]^{4-}$ anions and K^+ cations. The Raman and infrared spectra exhibit fewer lines than predicted for such a crystal. Tentative assignments are suggested for the more prominent bands of the constituent polyatomic species.

ANTHONY ANDERSON, CHUNG CHIEH, DONALD E. IRISH et JAMES P. K. TONG. Can. J. Chem. **58**, 1651 (1980).

Des études de diffraction de rayons-X révèlent que le $K_4UO_2(CO_3)_3$ a la même structure que le $(NH_4)UO_2(CO_3)$. Le cristal est monoclinique et appartient au groupe d'espace $C2/c$ avec a = 10.247(3), b = 9.202(2), c = 12.226(3) Å, β = 95.11(2)°, Z = 4. Les trois anions carbonates sont disposés de façon bidentate dans le plan équatorial de UO_2^{2+}; l'un d'eux est en position C_2 et les deux autres en position C_1. Tous les carbonates sont déformés de façon significative par rapport à une symétrie D_{3h}. La liaison carbonate-uranyle est forte et on peut alors considérer que le réseau est constitué d'anions $[UO_2(CO_3)_3]^{4-}$ et de cations K^+. Les spectres Raman et infrarouges montrent moins de raies que celles attendues pour ce genre de cristal. On a identifié provisoirement les bandes principales des constituants des espèces polyatomiques.

[Traduit par le journal]

Introduction

It is well known that in aqueous solution carbonate anions bind strongly to uranyl cations (1). Because the resulting complexes are very stable and interference from hydrolytic species is considerable it has been difficult to obtain accurate stability constants (2). The species $[UO_2(CO_3)_3]^{4-}$ is considered to predominate at 298 K when the carbonate ion is in large stoichiometric excess (2), although it carries the relatively uncommon four negative charges. This species is also known to occur in the crystalline state. Thus its structure has been reported for $(NH_4)_4UO_2(CO_3)_3$ (3). In this paper we report the structure of the complex as it is found in the potassium salt. Raman and infrared spectra, each measured at two temperatures, are also presented and assignments are proposed for the major bands.

Experimental

Sample Preparation

Uranyl carbonate (0.3 g) was dissolved in 60 mL of aqueous potassium carbonate solution containing an excess of the salt. Following dissolution by heating over a steam bath, filtration, and evaporation to about 16 mL, bright pale yellow crystals formed when left overnight at room temperature (298 K). The crystals were washed with cold water to free them from excess potassium carbonate and recrystallized. A yield of 90% (with respect to uranyl carbonate) was achieved.

X-ray Crystallography

Preliminary X-ray photographic studies indicated that the possible space groups of the crystal were $C2/c$ and Cc. The unit cell constants were found to be similar to those of tetraammonium uranyltricarbonate (3). Crystal data are as follows:

$C_3K_4O_{11}U$ fw = 606.4

Monoclinic, a = 10.247(3), b = 9.202(2), c = 12.226(3) Å, β = 95.11(2)°, V = 1148.2(6) Å^3, ρ_o = 3.5 (by liquid displacement), Z = 4, ρ_c = 3.507, μ(Mo-Kα) = 148 cm^{-1}, λ(Mo-K$\bar{\alpha}$) = 0.71069 Å, space group $C2/c$ (C_{2h}^6, No. 15).

The single crystal used for intensity measurements was cubic with ca. 0.08 mm edges. It was mounted on a Syntex $P2_1$ diffractometer and monochromatic (by graphite crystal) Mo-K$\bar{\alpha}$ radiation was used. Among 1693 independent reflections ($2\theta \leq 55°$), 1621 had net intensities greater than $\sigma(I)$; however, all reflections were included in the structural analysis. Lorentz and polarization factors were applied to derive the structure amplitudes. No absorption correction was made (μR = 0.6).

Because $K_4UO_2(CO_3)_3$ and $(NH_4)_4UO_2(CO_3)_3$, whose space group is $C2/c$, have similar cell constants, they were assumed to be isostructural. The K^+ ions were placed on NH_4^+ ion sites. This assumption was proven to be correct by the subsequent successful refinement. Atomic scattering factors for U, K, C, and O from Cromer and Waber (4) with anomalous dispersion corrections (5) for U and K were used. At the final stage, a weighting function $w^{-1} = 80 - F_o + 0.011F_o^2$ was introduced and the final R ($= \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$) and R_w($= (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$) were 0.038 and 0.045 respectively. *U is the average of the root-mean-square displacements (10^{-2} Å) and the values in parentheses are standard deviations from the average, $[\Sigma U_i^2 - (\Sigma U_i)^2/3]/2$; where $i = 1, 2$, and 3.

weighting scheme gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$.

On the final cycle of least-squares, the mean and maximum parameter shifts corresponded to 0.10σ and 0.72σ respectively. A final difference Fourier map showed no features of chemical significance. The final atomic parameters are given in Table 1.[1]

Raman and Infrared Spectroscopy

For the Raman spectra, polycrystalline samples were sealed in Pyrex glass melting point capillaries and placed at the focus of the 514.5 nm beam of a Spectra-Physics 165 argon ion laser. Light scattered at 90° was analyzed by a Jarrell-Ash 25-100 1.0 m double Czerny-Turner monochromator, equipped with an S.S.R. model 1105/1120 photon-counting system. Spectral resolutions of 1.5 to 3 cm^{-1} were used. For low temperature studies, the capillaries were placed in a simple double-walled glass cryostat and cooled by a controlled flow of nitrogen gas which passed through a copper coil immersed in liquid nitrogen. Temperatures were measured by a copper–constantan thermocouple in contact with the capillary.

Far infrared spectra were recorded with a Fourier Transform Spectrophotometer (Beckman RIIC 620), equipped with a 6 μm Mylar beam divider, quartz enveloped mercury lamp source, and germanium bolometer detector operating at 4 K. Digitized interferogram signals were transformed by a Data General (Nova 2) mini-computer, with a spectral resolution of 2.5 cm^{-1}. A thin layer of finely ground sample was sandwiched between two 3 mm sheets of polyethylene, and mounted on the cold finger of a simple glass cryostat. Spectra were recorded at ambient (~300 K) and low (~90 K) temperatures. Room temperature spectra were also obtained from Nujol mull samples on a polyethylene substrate.

Mid infrared spectra were recorded on three conventional grating spectrometers, Perkin Elmer 180, Beckman IR 12 and IR 9 using spectral resolutions of 1 to 2.5 cm^{-1}.

A variety of sampling techniques was used: mulls with Nujol or halocarbon grease were deposited on sodium chloride or silver bromide plates; dry powders were placed in contact with the KRS-5 prism of a Wilks model 9 multiple internal reflectance (MIR) attachment; and a thin layer of powder was sandwiched between silver bromide plates for transmission spectra. In the last case, the sample was also mounted in a cryostat and cooled to 83 K.

[1]Tables of structure factors and anisotropic thermal parameters are available from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Generally, the frequencies of sharp lines from room temperature samples agree to within ±2 cm^{-1} for all spectra. In a few cases the peak frequencies and band shapes of strong broad absorptions depend somewhat on the sampling technique used, and a weighted mean frequency was deduced for assignment purposes. In no case is the uncertainty greater than 5 cm^{-1}.

Results and Discussion

Crystal Structure

The structure consists of K^+ and $[UO_2(CO_3)_3]^{4-}$ ions. Atoms O(4), C(2), and U are located on a crystallographic two-fold axis; the other two carbonates are related to each other by a C_2 operation. Bond lengths and angles are incorporated with the ORTEP drawing, Fig. 1; the atomic numbering follows the scheme used for $(NH_4)_4UO_3(CO_3)_3$ (3) except that the labels for C(1) and C(2) are interchanged such that C(1) and C(2) are on C_1 and C_2 sites respectively.

The carbonates are bidentate with a mean U—O(carbonate) bond length of 2.430(5) Å. The U—O(uranyl) distance is 1.802(6) Å. This value is similar to that found in $(NH_4)_4UO_2(CO_3)_3$ (1.79(1) Å) and appears to be longer than that reported for UO_2CO_3 (1.67(9) Å) (6). Two types of C—O dis-

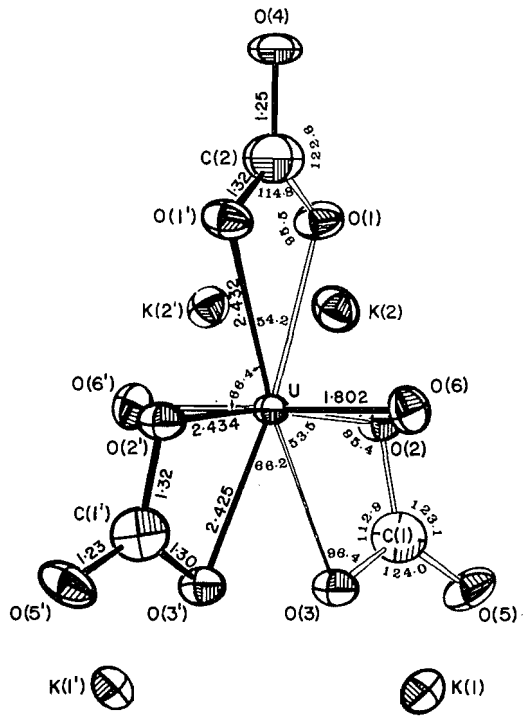

FIG. 1. Bond lengths and angles for the anion $UO_2(CO_3)_3^{4-}$. The anion has a 2-fold axis. Additional angles (deg) are: O(6)UO(1), 89.8; O(6)UO(1'), 89.5; O(6)UO(2), 87.7; O(6)UO(2'), 92.3; O(6)UO(3), 86.8; O(6)UO(3'), 93.9. Standard deviations: σ(U—O), 0.006 Å; σ(C—O), 0.01 Å; σ(OUO), 0.2°; σ(OCO), 0.3°; σ(COU), 0.2°.

tance are observed: a mean C—O (uncoordinated) equal to 1.24(1) Å and a mean C—O (coordinated) equal to 1.31(1) Å. From the standard deviations, the difference between the two types of OCO angle is significant; when only one oxygen atom is coordinated the mean OCO angle is 123.2(7)°. A smaller mean value, 113.9(1.3)°, is observed when both oxygens are coordinated. There is little difference between equivalent OUO angles: thus O(1)UO(2) and O(3)UO(3′) are equal (66.3(2)°) and O(1)UO(1′) and O(2)UO(3) are equal (53.7(4)°). For angles involving one uranyl oxygen, O(6), the OUO angles are given in the legend for Fig. 1. The two extreme values are 86.8(2)° and 93.9(2)° for O(6)UO(3) and O(6)UO(3′) respectively. The U—O(6) bond is not normal to the C(1)UC(2) plane but is inclined at an angle of 82.1(2)°; however, the C(2)UO(6) angle is 89.6(2)° and the O(6)UO(6′) angle is 179.2(2)°.

In order to determine the planarity of the atoms in the equatorial plane of the anionic species, four least-squares planes were calculated and are presented in Table 2. Giving equal weight to atoms, U, C(1), C(2), O(1), . . . O(5), the equation for plane *1* does not lead to a value of zero for coefficient m. Even though the number of atoms has been restricted to those designated above, the deviation from planarity is not insignificant; the three largest displacements from the plane are: U, 0.13 Å; O(2), −0.21 Å; and O(5), 0.16 Å whereas other atoms deviate less than 0.04 Å. Plane *2* passes through U and the centers of the carbonate ions, C(1) and C(2). The oxygen atoms of the carbonates are displaced from this plane by the following values: O(1), −0.16 Å; O(2), −0.24 Å; O(3), −0.03 Å; O(4), 0.00 Å; O(5), 0.24 Å. The carbonate centered on C(2), plane *3*, is planar as required by symmetry whereas the maximum displacement from the plane of the carbonate situated on the C_1 site, plane *4*, is 0.005 Å. The two planes, *3* and *4*, defined by the carbonates tilt slightly from the plane defined by UC(1)C(2), angles being 8.4 and 12.3°, Table 2. Thus the deviations of atoms in $U(CO_3)_3$ from planes *1* and *2* and the significant orientational differences between the carbonates centered on C(1) and C(2) indicate that the anion, $UO_2(CO_3)_3^{4-}$ does not have D_{3h} or D_3 symmetry. Additional evidence leading to this conclusion has already been given in the previous paragraph.

The packing of K^+ and $UO_2(CO_3)_3^{4-}$ ions, looking from the c^* direction is shown in Fig. 2. Because of the large anion, it is very difficult to define the number of K^+ ions around each anion and vice versa. Since the shortest K···C distance is 3.23 Å, we choose to list all K···O distances less than 3.30 Å in Table 3. The shortest of these is 2.673(7) Å (K(2)···O(5^6)). It is worthwhile noting that there are 8 oxygen atoms within 3.20 Å around K(2) and 9 around K(1). These interionic contacts correspond well with those of $(NH_4)_4UO_2(CO_3)_3$ (3) indicating that hydrogen bonding does not influence the crystal structure of the latter.

Vibrational Spectra

The Raman and infrared spectra are illustrated in Fig. 3 and tabulated in Table 4. An analysis of the vibrational spectra could start from the premise that within the lattice there are potassium cations and $[UO_2(CO_3)_3]^{4-}$ anions. In a first approximation the latter could be considered to have D_{3h} symmetry. From group theoretical considerations the species and activities of the normal modes would be $5A_1'(R) + 3A_2'(ia) + 9E'(R, ir) + A_1''(ia) + 4A_2''(ir) + 4E''(R)$. From the crystal structure it is clear that the anionic species departs significantly from D_{3h} and has in fact been reduced to C_2 symmetry. For this case 39 modes with frequencies coincident in

infrared and Raman spectra are predicted. The anion occupies a site of C_2 symmetry so no further complication arises from site splitting. There are two anions per primitive unit cell and the unit cell group is C_{2h}. Because of the centre of symmetry each band will be split by correlation field coupling into a Raman active component (A_g or B_g) and a noncoincident infrared active component (A_u or B_u).

Although the spectra are rich, the number of predicted lines was not observed and the complexity precludes a complete assignment. Instead a simpler approach has been taken. The primitive cell contains two approximately linear ($D_{\infty h}$) UO_2^{2+} cations on C_2 sites, 2 distorted (from D_{3h} to C_{2v}) CO_3^{2-} ions on C_2 sites, 4 distorted (from D_{3h} to approximately C_{2v}) CO_3^{2-} ions on C_1 sites, and $8K^+$ ions on C_1 sites. The vibrations of the polyatomic species can be assigned by analogy to similar groupings in other crystals or solutions and the crystal field splittings can be considered as perturbations.

For the uranyl ion (7) the symmetric UO_2^{2+} stretching vibration clearly occurs as a very strong sharp Raman band at 806 cm^{-1}. The infrared counterpart, forbidden under $D_{\infty h}$, is probably too weak to detect; the weak infrared bands in the 840–860 cm^{-1} region probably have a frequency too high to be considered to arise from correlation field coupling. The low value of the symmetric stretch suggests strong binding of carbonate to uranium. In aqueous perchlorate solution the band occurs at 872 cm^{-1}; replacement of water molecules by ligands such as nitrate and chloride lowers the frequency significantly (8). On the other hand for solid UO_2CO_3, we have observed a higher Raman frequency, equal to 884 cm^{-1}, consistent with a reported shorter U—O bond length (6).

The antisymmetric stretching vibration of UO_2^{2+} is clearly the intense infrared band at 882 cm^{-1}; there is no detectable Raman intensity and thus $D_{\infty h}$ selection rules hold. These two modes can be considered pure, involving little or no mixing (9). On the other hand the v_2 deformation mode, nominally expected in the 200 cm^{-1} region, involves changes in the oxygen–uranium–carbonate angles and thus is strongly coupled with low frequency external modes of the carbonate ions (9). No single frequency can be assigned and discussion is left until the lattice modes are considered.

The carbonate ions on the C_2 sites (designated C(2) after the carbon atom numbering) have C_{2v} symmetry and will vibrate largely independently of each other because of the orientations and distances involved. The carbonate ions on C_1 sites (designated C(1)) have C_1 symmetry (slightly distorted from C_{2v}). The two of these associated with a given uranyl ion will couple strongly and thus give rise to twice as many modes as C(2). For example,

considering the symmetric CO_3^{2-} stretching vibration, C(2) will generate A_g(R) and A_u(ir) whereas C(1) will generate A_g(R) + B_g(R) + A_u(ir) + B_u(ir). Assignments for these two classes of carbonate anions can be made starting from a D_{3h} model of an unperturbed carbonate anion. Such an anion would generate the following spectrum: $\nu_1(A_1')$ Raman active, symmetric stretch at about 1090 cm^{-1}; $\nu_2(A_2'')$ infrared-active, out-of-plane deformation at about 860 cm^{-1}; $\nu_3(E')$ and $\nu_4(E')$ both ir- and Raman-active antisymmetric stretching and bending modes at about 1400 and 700 cm^{-1} respectively (10). On changing to C_{2v} or C_1 symmetry the degeneracies of ν_3 and ν_4 are lifted and all modes are both Raman and infrared active and coincident. However, because of the centre of symmetry of the C_{2h} factor group which governs the selection rules for the correlation field coupling, the Raman and infrared bands may be slightly separated. One other guide to the assignments is the population ratio of 1:2 for the carbonates on C_2 and C_1 sites which should be reflected in the relative intensities.

Thus we assign 1046 (R,A_g) and 1045 (ir,A_u) to ν_1 of C(2); 1055 (R,A_g), 1065 (R,B_g), 1050 (ir,A_u), and 1055 (ir,B_u) to ν_1 of C(1). The higher frequency Raman and infrared lines are assigned to antisymmetric stretching modes: 1543 (R,A_g), 1600 (ir,A_u) and 1354 (R,B_g), 1360 (ir,B_u) are assigned to ν_3 of C(2); 1569 (R,A_g), 1550 (ir,A_u) and 1320 (R,B_g), 1340 (ir,B_u) are assigned to ν_3 of C(1). These bands are broad and the coupling of the C(1) ions is not resolved.

The weak Raman intensity of 879 cm^{-1} and the more intense infrared band at 855 cm^{-1} are probably the out-of-plane deformation (ν_2) of C(2) and similarly 863 and 847 cm^{-1} apply to C(1).

For the ν_4 deformation three Raman lines and three infrared lines are observed. Two possibilities occur. If site splitting is significant Raman bands at 719 and 693 with corresponding infrared bands at 724 and 694 can be assigned to C(2), based on the intensities. This indicates a site splitting of 26 cm^{-1} and a correlation field coupling of 2 to 5 cm^{-1}. For C(1) the Raman modes are 725 and 693 cm^{-1}, and the infrared modes are 720 and 694 cm^{-1}. The alternative scheme is to assign the 693, 694 cm^{-1} pair to A_g and A_u of C(2) and the 725, 724 and the 719, 720 pairs to A_g, A_u and B_g, B_u modes of two coupled carbonate anions for which the splitting due to loss of degeneracy of E' is too small to detect. (For distorted nitrates in solution the splitting of ν_4 is frequently not detectable even when ν_3 is split by 50 to 100 cm^{-1} (11).) In view of the 188 and 250 cm^{-1} splits in the ν_3 region the former analysis of ν_4 seems more probable, although the latter cannot be excluded. The frequencies and tentative assignments are summarized in Table 4.

With this approach to the assignments the uranyl–carbonate stretching and deformation modes will be classified as external modes. Analysis reveals that there will be 45 translatory modes, 22 librational modes, and 3 acoustic modes. Of the 22 librational modes, 11 are Raman-active ($5A_g$ and $6B_g$) and 11 are noncoincident infrared-active modes ($5A_u$ and $6B_u$).

The uranyl ion is nonpolar and therefore its librational modes are not expected to give intense infrared absorption; on the other hand the carbonate ions in their distorted form possess a dipole and hence their librations (except those about the dipole axis) will give moderate infrared absorption. All modes are mixed because of the low site symmetry and thus unique assignments are impossible. Furthermore the deformation of UO_2^{2+} (which involves a dipole change and hence appreciable infrared activity) is accompanied by motions of the carbonate ions and that internal mode cannot be uniquely designated (9). However, it is reasonable to attribute the grouping of bands from 240 to 320 cm^{-1} largely to motions involving uranyl deformation, bands from 150 to 240 cm^{-1} to carbonate librations and bands from 100 to 150 cm^{-1} to uranyl librations since the moment of inertia of UO_2^{2+} is larger than that of the carbonates. Translatory modes are expected to occur at low frequencies, some probably below the range of detection, because virtually all atoms including the massive uranium are involved in the motions. The representation of these translatory modes is $11A_g + 13B_g + 10A_u + 11B_u$, but only 7 peaks (6 Raman and 1 infrared) were observed.

Conclusions

The structure and vibrations of solid potassium uranyl carbonate have been studied by X-ray, Raman, and infrared techniques. A group theoretical analysis, based on the observed symmetries of the polyatomic ions (some of which are distorted from their free form), and those of their lattice sites and the monoclinic unit cell, has been applied in an attempt to assign the observed spectroscopic features. However, because of the low symmetry and subsequent mixing between modes, it is possible to categorize only the major features of the complex spectra. Spectroscopic confirmation is obtained for certain structural features such as the rather long U—O bond and the presence of distorted CO_3^{2-} ions on two types of sites.

Received February 4, 1980

DAVID C. FROST, NICHOLAS P. C. WESTWOOD, and NICK H. WERSTIUK. Can. J. Chem. **58**, 1659 (1980).

HeI photoelectron spectra are reported for a series of methyl-substituted monoketones and diketones based on 2-norbornanone. The effect of methyl substitution, and the inductive effect of a second carbonyl group has been studied. The diketones show a small separation between the two ketone moieties due to a through-bond interaction. Replacement with a thiocarbonyl group permits a comparison of the relative C=S and C=O interactions. The relative merits of the semi-empirical HAM/3 and CNDO/2 methods for such molecules are assessed.

DAVID C. FROST, NICHOLAS P. C. WESTWOOD et NICK H. WERSTIUK. Can. J. Chem. **58**, 1659 (1980).

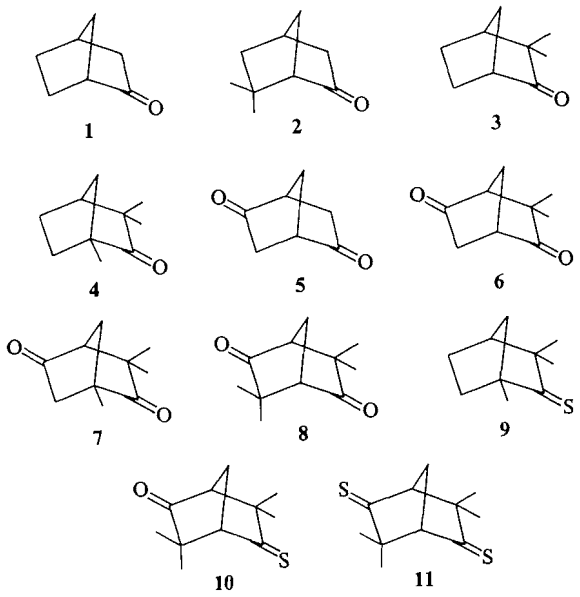
On rapporte les spectres photoélectroniques HeI d'une série de monocétones et de dicétones portant un substituant méthyle et dérivées de la norbornanone-2. On a étudié l'effet du substituant méthyle ainsi que l'effet inductif d'un second groupe carbonyle. Les dicétones montrent une faible séparation entre les deux fonctions cétones par suite d'une interaction à travers la liaison. Le remplacement par un groupe thiocarbonyle permet de comparer les interactions relatives C=S et C=O. On évalue les mérites relatifs des méthodes semi-empiriques de HAM/3 et de CNDO/2 pour ce type de molécules.

[Traduit par le journal]

Introduction

Carbonyl compounds provide a rich fund of information for the photoelectron (PE) spectroscopist (1, 2) since the carbonyl group exhibits a distinctive oxygen non-bonding type orbital which acts as a probe for electronic interactions within a molecule. We use the term "non-bonding" loosely here, since it is well established that considerable delocalization into the adjacent σ framework can occur.

A number of carbonyls and dicarbonyls have been investigated by ultraviolet photoelectron spectroscopy (UPS) (1, 2), although few γ-dicarbonyls have been studied except for benzoquinone and its substituted derivatives (3–6). For most dicarbonyl compounds, interest arises in the mechanism of the interaction between the two carbonyl groups, and whether it occurs through-space or through-bond (2, 3, 7–9). A typical case, particularly germane to the compounds studied in this work, is 1,4-cyclohexanedione which can exist in three conformations: boat (C_{2v}), chair (C_{2h}), and skew (or twist) (D_2). The twist configuration appears to be preferred (10), with a splitting of 0.15–0.2 eV between the n_- and n_+ oxygen lone pair combinations (2, 3) (see refs. 2 and 3 for the notation employed here).



Our interest in the bonding in the diones, ketothione, and dithione studied here stems from our systematic study of the base-catalyzed hydrogen isotope exchange of the substrates (11–13). In addition, the parent unsubstituted compound, norbornane, has been previously investigated by UPS and shows broad bands above 10 eV (14). The ketones and diketones investigated here are expected to have non-bonding orbitals primarily (although not entirely) localized on the C=O group, thereby showing a distinct, relatively sharp, ionization potential (IP) at less than 10 eV, well separated from those IP's belonging to the σ framework. We shall see later that interaction with the σ framework does occur to some extent.

The monosubstituted ketones in question are: 2-norbornanone (**1**); 6,6-dimethyl-2-norbornanone (**2**); 3,3-dimethyl-2-norbornanone (**3**), and 1,3,3-trimethyl-2-norbornanone (**4**). The diones are 2,5-norbornanedione (**5**); 3,3-dimethyl-2,5-norbornanedione (**6**); 1,3,3-trimethyl-2,5-norbornanedione (**7**), and 3,3,6,6,-tetramethyl-2,5-norbornanedione (**8**). Also studied were 1,3,3-trimethyl-2-norbornanethione (thiofenchone) (**9**); 3,3,6,6-tetramethyl-5-oxo-2-norbornanethione (**10**), and 3,3,6,6-tetramethyl-2,5-norbornanedithione (**11**). The series of monosubstituted ketones (**1–4**) thus provide an indication of the effect of successive alkylation upon the carbonyl lone pair ionization

energy. Addition of a second carbonyl group (**5–8**) provides a measure of the inductive effect of such a γ-carbonyl group, and the extent of interaction between the two groups. Finally, the thio-analogues (**9–11**) indicate if replacement of oxygen by sulphur alters the extent of interaction. Furthermore, the C=S π type orbital is no longer overlapped by the σ type orbitals (as in the case of the C=O compounds) and therefore provides additional information upon the interaction of the two C=S groups.

Experimental

Monoketones **2** and **3** were prepared via published procedures (15, 16), as were diones **5** and **7** (17, 18). **6** was prepared by oxidizing campheniyl acetate (19), hydrolyzing the ketoacetate, and oxidizing the ketol. Dione **8** was prepared by methylating **5** (11). The thio analogues **9**, **10**, and **11** were synthesized by heating **4** and **8** at reflux temperature in a P_2S_5 saturated solution of xylene. Each compound was carefully purified by preparative glpc before recording the photoelectron spectrum.

HeI photoelectron spectra were obtained on a PE spectrometer as previously described (20). Spectra were calibrated using the known IP's of CH_3I, N_2, and Ar. Although the resolution in these experiments is 35–40 meV, there is some vibrational structure unresolved on several of the first IP's. All quoted IP's are vertical IP's (band maxima).

Semiempirical calculations were performed with the standard CNDO/2 method (21), and the more recent HAM/3 method (22) which we have found to perform with good reliability in the prediction of IP's of organic molecules. Since the HAM/3 method uses a transition state concept and avoids problems associated with Koopmans' theorem (23), we prefer this method. Thus IP's for all ketones and diketones have been calculated using this procedure. HAM/3 is only parameterized for first row elements, and so calculations on the thio-compounds were performed using CNDO/2. Identical CNDO/2 calculations were also performed on all the ketones and diketones so that a direct comparison with the HAM/3 method could be made.

Results and Discussion

The HeI photoelectron spectra of compounds **1–11** are shown in Figs. 1 and 2. Values for the first few distinct IP's, and σ_{onset} are given in Tables 1–3, together with any associated vibrational structure and the full width at half maximum (fwhm) of the first band. Also included are the IP's calculated using the HAM/3 and CNDO/2 semiempirical methods. The HAM/3 results can be directly compared, however the CNDO/2 results (assuming the validity of Koopmans' theorem (23)) have been uniformly shifted by 3 eV to concur with the HAM/3 results and the experimental values.

Monoketones

IP's for 2-norbornanone (**1**) have been reported previously (24, 25), but no spectrum provided. This is shown in Fig. 1(*a*). There are some discrepancies in the values for the first vertical IP (9.17 eV (this work), 9.14 eV (25), and 8.94 eV (24)), probably due to difficulties in locating the adiabatic and vertical IP's (approximately the same intensity). This molecule provides the starting point for the methyl-substituted derivatives (**2–4**).

The interesting feature of these molecules is the absolute position of the first IP, and its corresponding fwhm, since these values provide a measure of the interaction of the methyl substituent with the carbonyl non-bonding orbital. Thus, this IP, as usual, shifts to lower bonding energy with increasing methyl substitution (particularly if methylation occurs adjacent to the C=O group), it becomes broader losing its sharp, non-bonding envelope and in some cases shows partially resolvable vibrational structure, typically between 750 and 1250 cm^{-1} (Table 1). These features are indicative of appreciable delocalization of the non-bonding orbital, and are followed by a decrease in the σ IP upon methyl substitution.

To assess these effects, we have performed semiempirical HAM/3 calculations (22) for norbornane (see ref. 14 for PE spectrum) and the monoketones **1–4**. The first two IP's obtained by the HAM/3 and CNDO/2 calculations are listed in Table 1. Geometries were based on that of norbornane (26, 27), with a C=O bond length of 1.24 Å and C—C(H-3) bond lengths of 1.53 Å. The C=O bond was constrained in the plane of C-1, C-2, and C-3, with the overall molecular framework kept symmetrical upon methyl substitution. This standard structure gave good agreement with the experimental IP's of all the monoketones using the HAM/3 method and no empirical shifting was necessary (compare CNDO/2). Therefore these geometries were used as a basis for the structures of the diketones.

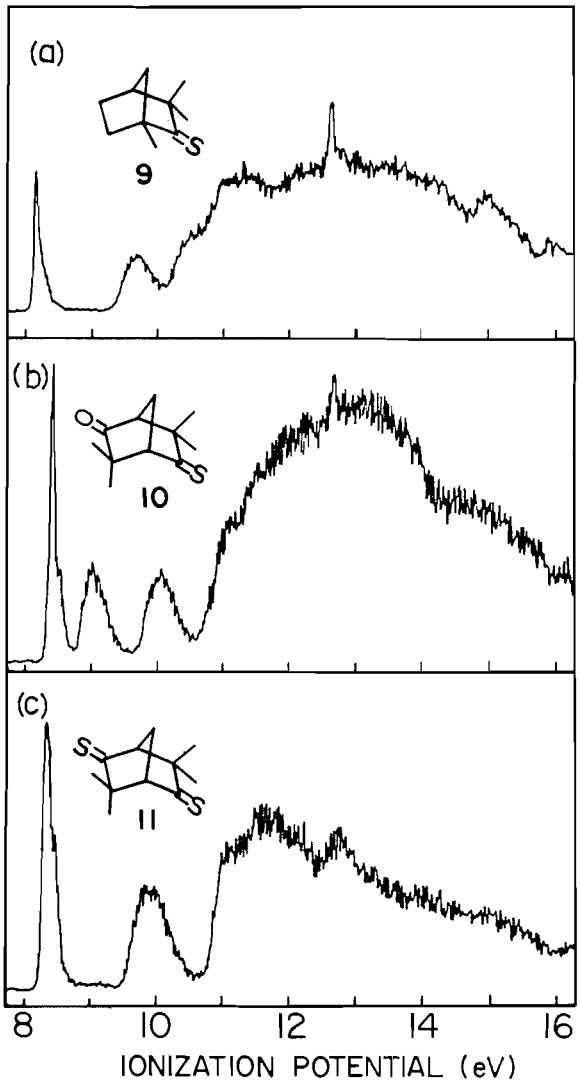

FIG. 2. (*a*), HeI photoelectron spectrum of **9**; (*b*), **10**; and (*c*), **11**.

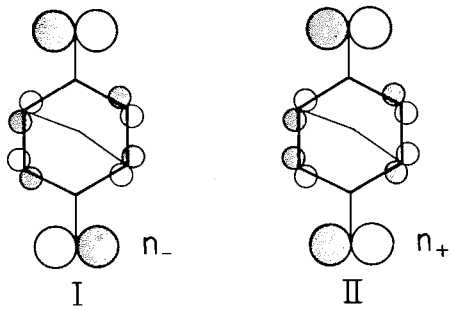
The second IP in **1** (maximum 11.1 eV) is mainly due to a C 2*p* orbital localized on C-7. This orbital corresponds to the highest occupied molecular orbital (HOMO) of norbornane (experimental IP, 10.7 eV (14), calculated IP, 10.64 eV (HAM/3)) inductively shifted to higher binding energy. The carbonyl π type orbital in **1** is predicted at 12.3 eV, and so is masked by the σ structure. The corresponding HAM/3 calculations for **2**, **3**, and **4** parallel the observed shift of the first IP to lower binding energy, and indicate a decreased oxygen 2*p* contribution confirming the further delocalization of the non-bonding orbital. The CNDO/2 calculations reproduce this shift and delocalization trend.



The first IP of **1** (9.17 eV) is 0.11 eV less than that of the non-bridged analogue, cyclopentanone (ca. 9.28 eV) (24, 28–30), but of a similar magnitude to that of cyclohexanone (ca. 9.15 eV) (29, 30). Bridging cyclohexanone, to give **1**, therefore has little effect upon the first IP and indeed, similar vibrational structure obtains for both cyclohexanone and **1**. However, the σ structure in cyclohexanone (vertical, 11.4 eV) is shifted to ca. 11.1 eV upon bridging. This is not surprising since the calculations indicate this orbital in **1** to be primarily C 2*p* in character and localized on C-7.

Diketones

Two main effects are observed when a second carbonyl group is introduced into **1** at C-5 giving the diketone **5**. Firstly, the vertical IP increases to 9.55 eV (average of n_- and n_+), and secondly, the two carbonyl groups interact to give a small but measurable splitting.

The observed stabilization of 0.38 eV arises from the inductive effect of introducing a second carbonyl group into the ring system. For the cyclohexanone, 1,4-cyclohexanedione molecules, Houk *et al.* (31) determine a value of 0.59 eV as the inductive shift of a second carbonyl group. This shift is thus larger than that found here for the bridged compounds **1** and **5**, indicative of a mediating influence by the bridge methylene group.

The observed splitting between the two oxygen non-bonding orbitals of **5** (0.16 eV) is due to a through-bond interaction (7, 8), i.e. a mixing of the n_0 orbitals with the skeletal σ orbitals. The two HOMO's can be represented by I and II, which show the phasing of the oxygen 2*p* orbitals and the σ ring orbitals as the molecule is viewed from above C-7.

The experimental magnitude of this splitting is partly confused by the presence of some partly resolved vibrational structure, but to all intents and purposes is identical to the first band of 1,4-cyclohexanedione. In both cases the coupling of the ring *p* orbitals with the carbonyl groups is poor, resulting in a small n_-/n_+ separation. However, the similarity of the two bands indicates that 1,4-cyclo-

hexanedione does exist predominately in one conformation (probably twist), since **5** is effectively locked into a similar configuration. Although the separation is small, compared, for example, to the planar *p*-benzoquinone and methyl derivatives (Δn = 0.3–0.5 eV), we prefer the assignment IP(n_-) < IP(n_+), since in II (n_+), the σ ring orbital has fewer nodes, and is subsequently more stabilized than in I (n_-). This also follows the generalization (2, 32) that the HOMO ordering should be IP(n_-) < IP(n_+) for any through-bond interaction over an odd number of intervening bonds when the carbonyl groups are coaxial.

The calculated values for the first two IP's of diones **5–8** are listed in Table 2. The ordering is confirmed by both the HAM/3 and the (shifted) CNDO/2 calculations with the splitting predicted by HAM/3 in excellent agreement with the experimental diketone n_-/n_+ separation. The CNDO/2 splitting is larger. Both the idealized geometry used here, and the X-ray geometry (33) give O---O distances of 5.21 and 4.92 Å respectively, indicating a negligible through-space overlap. The HAM/3 calculations predict the C=O π type orbitals at 12.0 and 12.5 eV, thus lying under the σ type orbitals and not observed on the spectra.

Substitution of the simple diketone **5** with methyl groups gives the unsymmetrical diketones **6** and **7**, and correspondingly, the Franck–Condon envelopes and fwhm's of the first bands reflect this asymmetry (Fig. 1 (*f*) and (*g*)). All IP's are decreased (Table 2) and the separation between n_- and n_+ is slightly increased since these two semilocalized orbitals are non-degenerate in zeroth order. HAM/3 gives reasonable values for the splitting in **6** and **7**, whereas CNDO/2 shows a wider margin between the n_- and n_+ orbitals.

The symmetric diketone **8** is substituted with four methyl groups, and so relative to **5** the mean of the n_-/n_+ IP's has decreased by 0.51 eV. This shift

is parallelled by the calculations (Table 2), which also predict a small decrease in the splitting.

Thioketones

IP's for thiofenchone, **9**, have been reported before (34), with the well separated sulphur non-bonding and sulphur π type orbitals measured at 8.1 and 9.6 eV, respectively. The spectrum is shown in Fig. 2(*a*) and we agree with the numerical values (Table 3) and with the vibrational structure ($1050 \pm 60\ cm^{-1}$) observed on the first band. The CNDO/2 calculations (shifted by the usual 3 eV) confirm this ordering although the n and π orbitals are placed closer together than the experimental values.

The ketothione **10**, with one oxygen and one sulphur atom, shows three bands below 10.5 eV. The first sharp band at 8.44 eV can easily be assigned to the sulphur non-bonding orbital (structure $= 890 \pm 60\ cm^{-1}$), with the IP inductively increased by the oxygen relative to the value in thiofenchone (**9**). The next IP at 9.05 eV shows some structure ($910 \pm 80\ cm^{-1}$), and the third IP at 10.06 eV is unresolved. From the separation between the S non-bonding and C=S π orbital in thiofenchone, and the position of the O non-bonding orbital in **8**, we assign the ordering of these three bands in **10** as S non-bonding, O non-bonding, and C=S π. The CNDO/2 calculations show extensive mixing between the second and third orbitals, albeit weighting the second orbital with more C=S π character.

If the remaining oxygen atom in **10** is replaced with a sulphur atom, we obtain the tetramethyldithione **11** which gives only two IP's below 10.5 eV. These are relatively more intense (with respect to the σ structure) than the corresponding two bands of thiofenchone (**9**). Each band may therefore be assigned to two orbitals the first with a maximum at 8.35 eV, to both the n_- and n_+ sulphur non-bonding orbitals. A precise value for the separation cannot be measured but the fwhm is much larger than the corresponding band in **10** (or even **9**). Some structure can be measured, viz. 370 ± 60 and $1160 \pm 60\ cm^{-1}$, but it is impossible to tell if part of this may result from the n_-/n_+ splitting. The second, broader band is centred at 9.95 eV and in this case shows a resolvable separation (0.17 eV) into two peaks. These correspond to the two C=S π orbitals, which in the oxygen analogue were masked by the σ structure. The increased separation of these two π orbitals compared to the n orbitals is followed by the CNDO/2 calculations (Table 3), viz. calculated $\Delta n_-/n_+ = 0.16$ eV, $\Delta \pi_-/\pi_+ = 0.37$ eV. It thus appears that the separation of the π orbitals in such thiocarbonyl compounds provides a more sensitive test of the interaction of these functional groups compared to the separation of the n orbitals. This is particularly true for the S non-bonding orbitals (which show no measurable splitting) since the through-bond interaction here will be quite small, as the S 3*p* orbitals are energetically far removed from the σ type orbitals and therefore do not overlap as efficiently. In fact the sharp nature of these S non-bonding orbitals illustrates that they are indeed more non-bonding than their oxygen counterparts.

Summary

UPS has been used to determine the carbonyl non-bonding energies in a series of 2-norbornanones and 2,5-norbornanediones. A reduction in binding energy with increasing methylation is observed, whereas introduction of a second carbonyl group inductively increases the IP. Additionally, there is a small (< 0.16 eV) n_-/n_+ separation in the diketones, arising from a through-bond interaction. Replacement of O by S indicates a reduced n_-/n_+ interaction, but permits observation of a larger π_-/π_+ separation. These results are supported by semiempirical (HAM/3 and CNDO/2) calculations; the former may be used without any scaling.

The formation and reactions of aromatic dimer cations in a high pressure photoionization source

JOHN A. STONE AND MARGARET S. LIN

Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received December 31, 1979

JOHN A. STONE and MARGARET S. LIN. Can. J. Chem. **58**, 1666 (1980).

Aromatic dimer cations (M_2^+) have been generated for a series of aromatic compounds in a high pressure photoionization source. Relative third order rate constants for formation of M_2^+ have been obtained for benzene (1.0), benzene-d_6 (2.7), toluene (0.8), *o*-xylene (1.5), *p*-xylene (0.7), fluorobenzene (0.3), *m*-fluorotoluene (0.5), *m*-chlorotoluene (0.7), *p*-chlorotoluene (0.5), and *o*-methoxytoluene (0.4). These values are consistent with and supplement previous data for such systems. Reagent ion monitoring has been used to determine the relative rates of reaction of both M_2^+ and the monomer ions, M^+, with a series of (mainly) aromatic compounds (X). Reaction of $C_6H_6^+$ is by charge transfer to compounds of lower ionization potential than C_6H_6. $(C_6H_6)_2^+$ reacts only by charge transfer, if the ionization potential of X is more than 0.5 eV lower than that of benzene. When the difference is smaller, mixed dimer cations are observed which are probably formed in a switching reaction $(C_6H_6)_2^+ + X \rightarrow (C_6H_6 \cdot X)^+ + C_6H_6$.

JOHN A. STONE et MARGARET S. LIN. Can. J. Chem. **58**, 1666 (1980).

Dans une source d'ionisation photochimique à haute pression, on a produit les cations aromatiques dimères (M_2^+) d'une série de composés aromatiques. On a obtenu les constantes de vitesse relative d'ordre 3 de la formation de M_2^+ du benzène (1.0), du benzène-d_6 (2.7), du toluène (0.8), des *o*- (1.5) et *p*-xylène (0.7), du fluorobenzène (0.3), du *m*-fluorotoluène (0.5), des *m*- (0.7) et *p*- (0.5) chlorotoluènes et du *o*-méthoxytoluène (0.4). Ces valeurs sont non seulement conformes aux donnés antérieures obtenues pour ce genre de systèmes (5) mais aussi elles en constituent un complément. On a utilisé le contrôle du réactif ionique pour déterminer les vitesses relatives de la réaction des ions dimères M_2^+ et monomères M^+ avec une série de composés (principalement) aromatiques (X). La réaction de $C_6H_6^+$ a lieu par transfert de charge aux composés ayant un potentiel d'ionisation plus faible que celui du C_6H_6. L'ion dimère $(C_6H_6)_2^+$ réagit seulement par transfert de charge si le potentiel d'ionisation de X est inférieur de plus de 0.5 eV à celui du benzène. Quand la différence est plus faible, on observe des cations dimères mixtes qui sont probablement formés par une réaction d'exchange: $(C_6H_6)_2^+ + X \rightarrow (C_6H_6 \cdot X)^+ + C_6H_6$.

[Traduit par le journal]

Introduction

The dimer cation of benzene $(C_6H_6)_2^+$ has been studied in the gas phase (1–5) and has been observed as an intermediate species in the radiolysis of benzene (6). Thermochemical determinations yielded a binding energy for this "sandwich" shaped complex of 17 kcal mol^{-1}, which is ~6 kcal mol^{-1} greater than that calculated for a purely electrostatic interaction (7). The observation that the binding energy for mixed dimers, e.g. $(C_6H_6 \cdot C_6H_5CH_3)^+$ is always less than for the symmetric dimer led to the suggestion that additional binding in $(C_6H_6)_2^+$ is obtained by electron delocalization, a contribution to the total binding energy that will be at a maximum for symmetric dimers. In mixed dimers containing benzene the binding energy decreases smoothly from the 17 kcal mol^{-1} for $(C_6H_6)_2^+$ to a minimum value of ~10 kcal mol^{-1} as the difference in ionization potential between benzene and the second aromatic constituent increases.

The stabilization of aromatic cations by dimer formation obviously has implications for the photochemistry and radiation chemistry of aromatics in the gaseous, liquid, and solid states. The reactions of such ions have received little attention. Important reactions of the dimer cations in such systems will be charge transfer to species of lower ionization potential and possibly exchange reactions of the form

[1] $(B_1 \cdot B_2)^+ + B_3 \rightarrow (B_1 \cdot B_3)^+ + B_2$

We report a study of the reactivity of some dimeric cations with a variety of neutrals, mainly aromatics and substituted aromatics, employing the technique of reactant ion monitoring (RIM) (8). The relative rates and the products of reaction have been determined. The third order relative rates of formation of some dimer cations have also been determined.

Experimental

The measurements were made using the high pressure instrument described previously (9) but with a new photoionization source (Fig. 1). The source was constructed from a cylindrical piece of stainless steel, 1.5 cm in diameter and 15 cm long. The cylinder is attached directly to a flange of the vacuum housing and is run at ground potential. The ionization chamber, a cavity of volume ~2 cm^3, has LiF windows and a circular ion exit 0.5 mm in diameter. The source may be heated by cartridge heaters embedded in blind holes drilled from outside the vacuum chamber. All gas connections to the chamber are of 1/8 in. OD stainless steel tubing. In the RIM mode a flow system is employed to prevent degradation of resolution in GC/MS work.

Reagent gas is led from a heated oven to the ion source via a

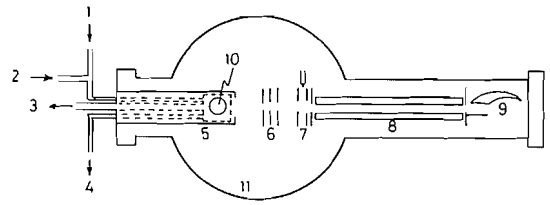

FIG. 1. Sketch of the instrument: *1*, inlet from gas chromatograph; *2*, inlet from heated reservoir; *3*, connection to capacitance manometer; *4*, connection to 1 in. diffusion pump; *5*, photoionization source; *6*, Einsel lens; *7*, electron impact ion source; *8*, quadrupole; *9*, continuous dynode electron multiplier; *10*, LiF window; *11*, vacuum housing leading to 6 in. diffusion pump.

heated Granville-Phillips variable leak valve. Between this leak valve and the ion source is a "T" connector which leads to a gas chromatograph via a Nupro fine metering valve. The chromatographic column effluent is split by a "T" connection inside the column oven, about 25% going to the ion source and 75% to a flame ionization detector. The internal volume of the tube connecting this "T" to the metering valve is only 40 μL which leads to practically simultaneous responses of flame ionization detector and mass spectrometer. All gas lines leading to the photoionization source are heated to ~100°C with heating tapes but for most experiments the ion source was operated at ambient temperature (25 ± 2°C). Cartridge heaters embedded in the ion source block allow operation at temperatures up to 200°C.

The 6 ft × 1/8 in. chromatographic columns contained 10% OV-1 or OV-11 on Chromosorb W. The column temperature was programmed from ambient temperature to 200°C. The benzene was J. T. Baker Ultrex (99.99%) and the toluene was Fisher Certified A.C.S. grade. All other chemicals were of the highest purity available. Solutions for the 1 μL chromatograph injections contained cyclohexane, cyclopentane, or *n*-hexane as solvents with solute concentrations in the range 10^{-2}–10^{-1} *M*.

Chromatographic and ion current signals were recorded simultaneously on a two channel, strip chart recorder. Peak area measurements for the ion current were made using a Nicolet 1170 signal processor.

Results and Discussion

The ionization potential of benzene is 9.24 eV (10) and the first electronic excited state of the ion is 2.25 eV higher (10) so that only ground state $C_6H_6^+$ will be formed initially by the krypton resonance radiation (10.03 eV (86%) and 10.64 eV (14%)). Up to 1.4 eV of vibrational excitation can be initially present but this excess energy will be rapidly degraded by collision and by bimolecular resonance charge transfer. The same relaxation processes will prevail for the other aromatics employed.

Third Order Relative Rate Constants

The initial experiments (non-RIM) were to obtain the relative rates of disappearance of the molecular ions in the pure reactants. In agreement with Sieck and Gorden (5), who also used a photoionization source, the only reaction of the molecular cation (M^+) observed in any single component system is the formation of the dimeric cation (M_2^+) in a third order process. A typical result is shown in Fig. 2 for C_6D_6. The decay of $C_6D_6^+$ is accompanied by a symmetrical increase in $(C_6D_6)_2^+$. Rate constant data are obtained from plots of $\log i_{M^+}/(i_{M^+} + i_{M_2^+})$ versus (pressure)^2, where i_{M^+} and $i_{M_2^+}$ are the ion currents due to monomeric and dimeric ions respectively at the same pressure. These plots are linear for decreases of up to 20% in the fractional yield of the molecular ion. The equation for such a line is $\ln i_{M^+}/(i_{M^+} + i_{M_2^+}) = -k[M]^2\tau$ where k is the rate constant for the reaction

[2] $M^+ + 2M \rightarrow M_2^+ + M$

τ is the average residence time for M^+ in the source and is not easily calculable since the ion path lengths are not well defined. However, relative rate constants are readily obtained from the relative slopes of such plots, a correction being made for the different residence times. Molecular flow is assumed so that $\tau_1/\tau_2 = (M_1/M_2)^{1/2}$ where M is the molecular weight. Reproducibility is ~± 10% and each of the results shown is the average of two or more determinations. The relative rate constants obtained are compared in Table 1 with those reported by Sieck and Gorden (5). (Their absolute value for $C_6H_6^+$ is 1.9×10^{-25} cm^6 molecule^{-2} s^{-1} compared with the value of 1.2×10^{-25} cm^6 molecule^{-2} s^{-1} of Anicich and Bowers (4).) The two sets of relative values are in good agreement and the observation of the high rate constant for $C_6D_6^+$ relative to that for $C_6H_6^+$ is confirmed. With the exception of *o*-xylene, substituents on the aromatic ring lead to a lowering of the rate constant, this being particularly noticeable for fluorobenzene. The rates of formation of these dimer cations are in

the same order as their stabilities measured by the enthalpy for dissociation of M_2^+, as shown in Table 1. Equilibrium constants K for the reaction

$$[2a] \quad M^+ + 2M \underset{k_r}{\overset{k_f}{\rightleftharpoons}} M_2^+ + M$$

determined by Meot-Ner *et al.* (7) are also shown in Table 1. If $K = k_f/k_r$, then it is apparent that the rate constant for the reverse reaction, k_r, increases much more rapidly with change of binding energy of M_2^+ than does the forward rate constant. Unfortunately there is no thermodynamic data for *o*-xylene, which has a very high value for k_f.

At pressures beyond the range shown in Fig. 2, ions appear which may be associated with impurities and their intensities increase with increasing pressure. The nature of these ions depends on the particular compound being studied and sometimes on the compounds just previously used in the instrument. The ions all arise from aromatic impurities of lower ionization potential than the compound under study, and may be the impurity molecular ion or a mixed dimer cation containing both the impurity and the compound under study. The relative yields of these products will be discussed later. In the low pressure region, where relative rate constants are determined, impurity peaks are not significant.

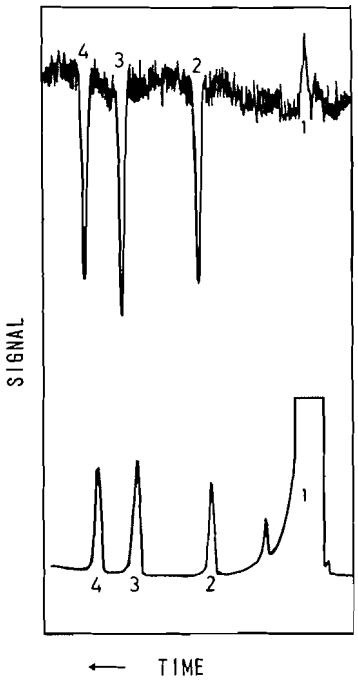

FIG. 3. Gas chromatogram (lower trace) and $(C_6H_6)_2^+$ ion current (upper trace). (*1*) *n*-hexane solvent, (*2*) toluene, (*3*) *o*-xylene, (*4*) mesitylene. The peaks in the upper trace correspond to about 15% decreases in the total ion intensity. Benzene pressure ~0.15 Torr, roughly 5×10^{-8} mol of each aromatic injected into the chromatograph.

Reagent Ion Monitoring (RIM)

The technique of reagent ion monitoring has been described in detail (8). Figure 3 shows the results obtained using $(C_6H_6)_2^+$ as the reagent ion. A steady flow of benzene from the heated reservoir gives a constant partial pressure (~0.15 Torr) in the ion source. Helium flowing at a constant rate from the chromatograph, gives a constant total pressure of ~0.8 Torr. Under these conditions the dominant ion is $(C_6H_6)_2^+$. The steady signal due to this ion is monitored. Components emerging from the chromatograph, which can react with $(C_6H_6)_2^+$, cause a decrease in the signal which generates an inverted "peak" similar to, and contemporaneous with, the chromatographic peak. It was ascertained in separate experiments that there is no mass dis-

For personal use only.

crimination in the gc/ms interface. Both the gc trace and that for the $(C_6H_6)_2^+$ ion current shown in Fig. 3 result from the injection into the chromatograph of 1 μL of a solution approximately 10^{-2} *M* in each of toluene, *o*-xylene, and mesitylene. The solvent, *n*-hexane, causes a slight increase in the $(C_6H_6)_2^+$ signal due to charge transfer from *n*-$C_6H_{14}^+$ formed by direct photoionization. Since the concentrations of the other constituents of the mixture are about 10^3 times less than that of the solvent, their direct photoionization is not of consequence. This was proved in a separate experiment in the absence of benzene when no ions, other than those from the solvent, were detected for compounds eluting from the chromatographic column.

The ratio of rate constants, k_1/k_2, for the reactions of compounds **1** and **2** with $(C_6H_6)_2^+$, is given by (11)

$$\frac{k_1}{k_2} = \frac{A_1}{A_2} \cdot \frac{X_2}{X_1} \cdot \left(\frac{M_2}{M_1}\right)^{1/2}$$

where A_1 and A_2 are the peak areas for compounds **1** and **2** respectively, obtained from the monitored reagent ion trace, and X_1/X_2 is the molar ratio of **1** and **2** in the chromatographic sample.

Figure 4 shows the RIM peak areas for *o*-xylene and mesitylene relative to that of toluene as functions of the amount of material injected into the chromatograph. The relative rate constant ratios computed as above are $k_{o\text{-xylene}}/k_{\text{toluene}} = 0.95$ and $k_{\text{mesitylene}}/k_{\text{toluene}} = 0.94$. As seen from Fig. 3, the low intensity of the ion signal causes some uncertainty in the base line and reproducibility of results is usually of the order of ±8%. Within this error limit, all three compounds have the same rate constant for reaction with $(C_6H_6)_2^+$. Figure 5*a* shows the rate constants relative to that of mesitylene for a series of compounds. The values are plotted against the ionization potentials of the compounds, which range from well above that of benzene (9.24 eV) to well below. For comparison, Fig. 5*b* shows the relative rates of reaction for many of the same compounds with $C_6H_6^+$. This ion was monitored under conditions where the concentration of $(C_6H_6)_2^+$ was small; the benzene pressure was lowered to ~30 mTorr and the ion source temperature was raised to ~120°C.

The shapes of the curves in Fig. 5 *a* and *b* are similar to those reported previously for the reaction of $C_6H_6^+$ (12, 13). For the low concentrations of reagents employed in the ion source no reaction is observed for compounds with ionization potentials above a well defined threshold. Below this threshold value the relative rate of reaction rises rapidly and soon attains a value which is little different for all the compounds. The threshold for $C_6H_6^+$ is very close to the ionization potential of benzene (9.24 eV) but that for $(C_6H_6)_2^+$ is about 0.2 eV lower. This difference, and kinetic considerations detailed below, show that these compounds are indeed reacting at high benzene pressure with $(C_6H_6)_2^+$, and not its precursor, $C_6H_6^+$.

If X is a reactive compound eluted from the

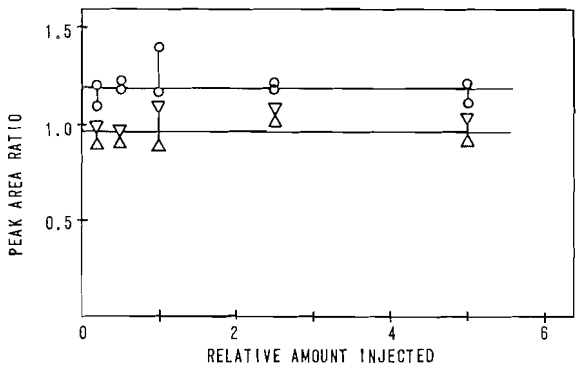

FIG. 4. RIM peak areas relative to those for toluene for *o*-xylene (△) and mesitylene (○) as functions of the amount of material injected into the chromatograph. Approximately equal concentrations of aromatics, with the maximum amount of each injected ~2 × 10^{-7} mol. Points show reproducibility of two separate runs.

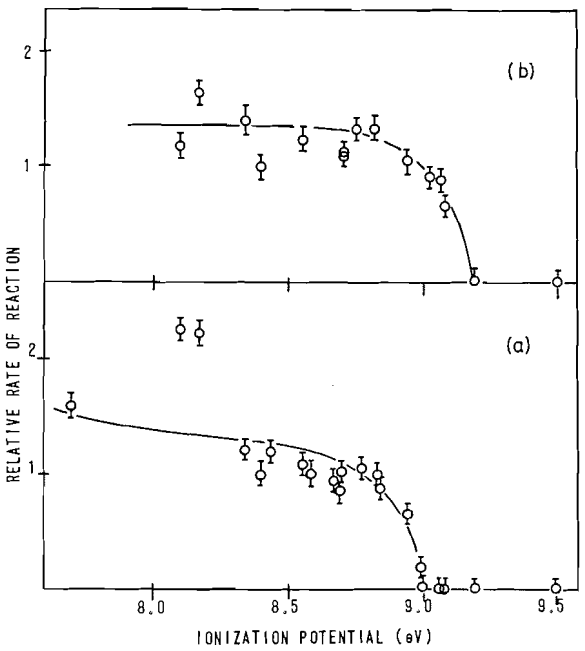

FIG. 5. (*a*) The relative rates of reaction of various compounds with $(C_6H_6)_2^+$; (*b*) the relative rates of reaction of various compounds with $C_6H_6^+$. The rate of reaction with mesitylene is taken as unity. Benzene pressure ~0.15 Torr.

chromatograph, then the competing reactions are

[3] $C_6H_6^+ + C_6H_6 \xrightarrow{M} (C_6H_6)_2^+$

[4] $C_6H_6^+ + X \xrightarrow{M} (C_6H_6 \cdot X)^+$

[5] $C_6H_6^+ + X \rightarrow$ Products

[6] $(C_6H_6)_2^+ + X \rightarrow$ Products

The rate constant for **3** is large ($\sim 2 \times 10^{-25}$ cm^6 molecule^{-2} s^{-1} (5)) and there is no reason for that for **4** to be any larger. The very small concentration of X relative to that of C_6H_6 ensures that reaction [4] does not compete effectively with reaction [3]. If a maximum rate constant equal to the Langevin collision rate constant ($\sim 1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}) is assigned to reaction [5], then the rate of reaction [3] relative to that of [5] is $2 \times 10^{-25}[C_6H_6]^2/1 \times 10^{-9}[X]$. At 0.1 Torr, $[C_6H_6]$ is 3×10^{15} molecules cm^{-3} and [X] is less than 0.1% of this value. The bimolecular reaction rate is therefore at least a factor of 100 less than the termolecular rate. The only reaction of X that need be considered at high benzene concentration is reaction [6].

Figures 6 and 7 show the results of similar experiments carried out with toluene and *m*-fluorotoluene. For toluene the threshold for reaction of $(C_6H_5CH_3)_2^+$ is about 0.1 eV lower than that for $(C_6H_5CH_3)^+$ whereas the thresholds for $(m\text{-}C_6H_4FCH_3)_2^+$ and $(m\text{-}C_6H_4FCH_3)^+$ are not experimentally distinguishable.

Reaction Products

The signal averager was employed to scan continuously the complete mass range (*m/e* 1–400) as each chromatographic peak was eluted. The ion signals due to products were not of sufficient intensity for quantitative determinations but accurate mass identifications could be made. The product observed for the reaction of all compounds with $C_6H_6^+$ i.e. at low benzene concentration, was the molecular ion, X^+, formed by charge transfer. Reaction with $(C_6H_6)_2^+$ leads to more than one product as shown in Table 2. The products are predominantly the molecular ion (X^+) and the mixed dimer $(C_6H_6 \cdot X)^+$. For every compound that reacts with $(C_6H_6)_2^+$, except bromobenzene which is very weakly reactive, the molecular ion is observed. It is the predominant product for all compounds except those with ionization potentials very close to the threshold for which the mixed dimer predominates. Since the ions suffer many potentially reactive collisions before leaving the ion source, the nature of the products observed does not necessarily show directly the products of the initial reaction with $(C_6H_6)_2^+$.

Sieck and Gorden (5) suggest that the initial

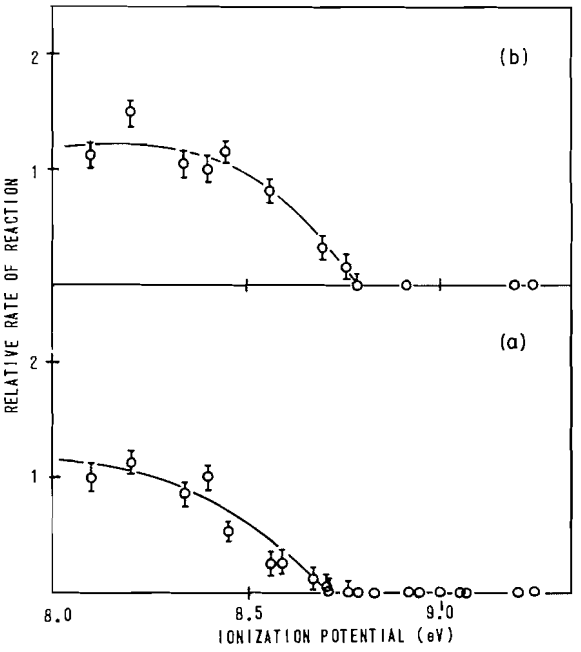

FIG. 6. (*a*) The relative rates of reaction of various compounds with $(C_6H_5CH_3)_2^+$; (*b*) the relative rates of reaction of various compounds with $C_6H_5CH_3^+$. The rate of reaction with mesitylene is taken as unity. Toluene pressure ~0.15 Torr.

reaction in benzene containing a very small amount of toluene, is the charge transfer reaction

[7] $(C_6H_6)_2^+ + C_6H_5CH_3 \rightarrow 2C_6H_6 + C_6H_5CH_3^+$

The suggestion is based on the observation that in benzene containing very small traces of toluene as impurity, the major initial impurity peak is $C_6H_5CH_3^+$ and not $(C_6H_6 \cdot C_6H_5CH_3)^+$. We have made a similar observation at benzene pressures of ~50 mTorr. However, Meot-Ner *et al.* (7) estimate a recombination energy of 8.55 eV for $(C_6H_6)_2^+$ so that reaction [7] is endothermic by ~6 kcal (IP($C_6H_5CH_3$) = 8.82 eV).

At the threshold potential of Fig. 5*a* only the mixed dimer ion is observed for C_6H_5Br. We suggest that for compounds of ionization potential given by this point, the switching reaction [8] is thermoneutral and for compounds of lower ionization potential it is exothermic.

$$[8]\quad X + (C_6H_6)_2^+ \xrightarrow{\Delta H_1} (C_6H_6 \cdot X)^+ + C_6H_6$$
$$\Delta H_2 \downarrow \qquad\qquad \uparrow \Delta H_4$$
$$[9]\quad X + C_6H_6^+ + C_6H_6 \xrightarrow{\Delta H_3} X^+ + 2C_6H_6$$

At the threshold $\Delta H_1 = 0$, i.e. $-\Delta H_3 = (\Delta H_2 + \Delta H_4)$. ΔH_3, the difference at the threshold in ionization potential between benzene and X, is (9.24 − 9.05) eV = 4.6 kcal mol^{-1} (see Fig. 5). $\Delta H_2 + \Delta H_4$ is the difference in binding energy between $(C_6H_6 \cdot X)^+$ and $(C_6H_6)_2^+$. This is entirely consistent with the results of Meot-Ner *et al.* (7) who give a value of ~4 kcal mol^{-1} for $(\Delta H_2 + \Delta H_4)$ when Δ(IP) is −5 kcal mol^{-1}. The switching mechanism is therefore energetically feasible.

As Δ(IP) increases ΔH_4 decreases (7) and reaches a limiting value of ~10 kcal mol^{-1}, corresponding to non-resonance stabilized binding. At the same time the possibility arises for competition between reaction [8] and the charge transfer reaction analogous to reaction [7]. The present results can only give a measure of the difference in binding energies $(\Delta H_2 + \Delta H_4)$ for the two dimer cations and not their absolute values. Meot-Ner *et al.* (7) obtain $\Delta G^0 = -4.6 \pm 1.5$ kcal mol^{-1} for the equilibrium

$$[10]\quad C_6H_5CH_3^+ + C_6H_6 \overset{M}{\rightleftharpoons} (C_6H_5CH_3 \cdot C_6H_6)^+$$

Therefore $K = 2.1 \times 10^3$ atm^{-1}, i.e. $[BT^+]/[T^+] = [(C_6H_5CH_3 \cdot C_6H_6)^+]/[C_6H_5CH_3^+)] = 2.1 \times 10^3 P_{C_6H_6}$. If the pressure of benzene is 0.15 Torr then $[BT^+]/[T^+] = 0.4$. If the actual value of ΔG^0 is

smaller but still within the assigned error limit then $[BT^+]/[T^+]$ can be as low as 0.05. The observation that when a very small concentration of toluene is present in benzene, then most of the toluene containing ions are T^+ rather than BT^+, is not inconsistent with the thermodynamic data of ref. 7 or the present results. A switching reaction produces $(C_6H_6 \cdot C_6H_5CH_3)^+$ which subsequently dissociates.

The difference between the thresholds for monomer and dimer cations is large for benzene, less for toluene, and not distinguishable from zero for *m*-fluorotoluene. At threshold for $(CH_3C_6H_4F)_2^+$, ΔH_5 is zero.

$$[11]\quad (CH_3C_6H_4F)_2^+ + X \xrightarrow{\Delta H_5} (CH_3C_6H_4F \cdot X)^+ + CH_3C_6H_4F$$
$$\downarrow \Delta H_6 \qquad\qquad \uparrow \Delta H_8$$
$$[12]\quad CH_3C_6H_4F^+ + CH_3C_6H_4F + X \xrightarrow{\Delta H_7} 2CH_3C_6H_4F + X^+$$

Then $-\Delta H_7 = \Delta H_6 + \Delta H_8$. Since $\Delta H_7 = \Delta(IP)$, the difference between $IP(CH_3C_6H_4F)$ and IP(X), the binding energies of $(CH_3C_6H_4F)_2^+$ and $(CH_3C_6H_4F \cdot X)^+$ are the same. The binding energy for *m*-fluorotoluene has not been measured but it will most probably be of the order of 12–14 kcal mol^{-1} as found for other halogenated aromatics (7). There can therefore be little stabilization of the dimer from electron delocalization and it follows that there can be only a small numerical difference between ΔH_6 and ΔH_8. The thresholds for the monomer and dimer cations are therefore close together. The difference between the thresholds for toluene is intermediate between that for benzene and that for *m*-fluorotoluene. This is consistent with the binding energy of the toluene dimer cation (16.0 kcal mol^{-1}) being lower than that of the benzene dimer (17.0 kcal mol^{-1}) (7) but higher than that of the *m*-fluorotoluene dimer.

The curves of Figs. 5–7 show that when the ionization potential of the compounds eluted from the gas chromatograph are well away from threshold, the relative rate constants tend to be comparable. This behaviour has been found for the benzene ion (8, 12) and also for charge transfer in gaseous alkane mixtures (14). In this latter case the reaction probability for collision was found to approach unity for $\Delta(IP) \sim 0.3$ eV. By analogy we suggest that the same is true in the present system. At the moment the precision of our relative rate constants is not sufficient for comparison of experimental and theoretical values. We hope that this situation may be changed by the improvements presently in hand to increase the signal-to-noise ratio by raising the efficiency of ion transmission. The only relative rate constant which is consistently anomalous is the one for the reaction of anisole with all the six ions studied. Since the final product of reaction, the anisole molecular ion, is no different in nature to those for other compounds of similar ionization potential, we do not at the moment understand this anomaly which is too large to be explained by the ADO theory.

Experiments with $C_6H_6^+$ led to suggestions that this ion is a useful reagent ion for chemical ionization mass spectrometry when operating in the RIM mode (8, 12). It can be used to discriminate between molecules according to their ionization potentials. The present results show that even greater versatility is available with benzene since $(C_6H_6)_2^+$ may also be used in a source operated at low temperature. Indeed a whole range of useful reagent ions is available if all the substituted benzenes are considered.

The electrochemical synthesis of organometallic halides of titanium, zirconium, and hafnium

FAROUQ F. SAID AND DENNIS G. TUCK

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 18, 1980

FAROUQ F. SAID and DENNIS G. TUCK. Can. J. Chem. **58**, 1673 (1980).

The electrochemical oxidation of titanium, zirconium, or hafnium (= M) in a cell containing an organic halide RX results in the formation of an organometallic halide of the metal concerned. These compounds are conveniently isolated as adducts of acetonitrile or 2,2′-bipyridine (bipy) also present in the electrolyte phase. The products most commonly isolated are the $R_2MX_2 \cdot L_2$ ($L = CH_3CN$ or $\frac{1}{2}$bipy), but other species were obtained in certain cases. Possible reasons for these findings are discussed.

FAROUQ F. SAID et DENNIS G. TUCK. Can. J. Chem. **58**, 1673 (1980).

L'oxydation électrochimique du titane, du zirconium ou de l'hafnium (= M) dans une cellule contenant un halogénure organique RX conduit à la formation d'un halogénure organométallique du métal concerné. Ces composés peuvent être isolés d'une façon convenable sous la forme de produits d'addition avec l'acétonitrile ou de la bipyridine-2,2′ (bipy) qui sont également présents dans la phase électrolytique. Les produits les plus communéments isolés sont le $R_2MX_2 \cdot L_2$ ($L = CH_3CN$ ou $\frac{1}{2}$bipy) mais dans certains cas on a obtenu d'autres espèces. On discute des causes probables qui expliquent ces résultats.

Introduction

The use of the direct electrochemical oxidation of metals in non-aqueous media has proven to be an effective route for the synthesis of organometallic halides of a number of main group metals (1). Less is known about the efficacy of such direct syntheses for transition metals, although the production of RMX adducts for M = Ni and Pd has been reported (2). We now describe the application of electrochemical methods in the direct synthesis of organohalides of titanium, zirconium, and hafnium. The oxidation of these metals to the corresponding tetrachlorides or tetrabromides, which were conveniently stabilized and handled as neutral adducts or anionic complexes, has already demonstrated the potential of the method for these elements (3).

The organometallic compounds of the Group IVA elements have been the subject of a number of reviews (4, 5). The standard preparative routes for the organometallic halides involve reaction of the appropriate halide with organolithium compounds, Grignard reagents, or zinc and aluminum alkyls. The stability of the resultant compounds apparently depends on the number and nature of the organic groups involved, on the particular halide, and on the presence of coordinating ligands. In view of this last consideration, we have carried out the electrochemical oxidation in the presence of a coordinating solvent (acetonitrile) and/or the ligand 2,2′-bipyridine in order to stabilize the products of the electrochemical oxidation.

Experimental

Materials, Analysis, Spectroscopic Methods

In all these respects, the experimental techniques were essentially identical to those described earlier (3).

Preparative Procedures

The general electrochemical techniques were as in previous work (6), with the metal to be oxidized forming the anode of a simple cell, which was sealed so that this and all other operations were performed under dry nitrogen. The total volume of the solution phase was 15–40 cm^3, comprised as follows: ethyl bromide, phenyl chloride, phenyl bromide, benzyl chloride, benzyl bromide: 20 cm^3 RX + 20 cm^3 acetonitrile (+ 2 cm^3 methanol in the case of Zr, or Hf, with benzyl bromide); benzyl iodide: 0.7 g RX + 40 cm^3 acetonitrile; phenyl iodide: 15 cm^3 RX + 15 cm^3 acetonitrile + 2 cm^3 methanol; methyl iodide: 20 cm^3 RX + 2 cm^3 methanol. Approximately 20 mg of tetraethylammonium halide was added in each experiment; in the preparation of 2,2′-bipyridine adducts, 0.5 g of this ligand was also added.

Table 1 gives the initial current for each system for an applied voltage of 50 V, the length of time of the electrolysis and the weight of metal dissolved from the anode. The method of isolation of the product depended on the individual circumstances as determined experimentally. For derivatives of benzyl chloride, bromide, and iodide, ethyl bromide, methyl iodide (with zirconium), and phenyl iodide, the products were those which precipitated from the solution phase as the electrolysis proceeded. The remainder was obtained from the solution by evaporation of solvent (phenyl bromide/titanium) or by the addition of benzene (phenyl bromide/zirconium), acetonitrile (methyl iodide/zirconium), or by acetonitrile followed by diethyl ether (methyl iodide/titanium). Table 1 also notes certain systems for which no identifiable product could be obtained. The overall yield of product was typically ca. 50%, based on the quantity of metal dissolved.

Electrolysis in which ethyl bromide was the parent organic halide provides typical examples of the preparation of R_2MX_2 adducts of zirconium and hafnium, and details of the procedures are given below. With titanium, detailed investigations showed that two products could be isolated from the electrolyte phase. Analytical results for all the compounds obtained in this work are listed in Tables 2 and 3.

Preparation of $(C_2H_5)_2MBr \cdot 2CH_3CN$ (M = Zr, Hf)

These electrochemical oxidations were amongst the fastest observed in this work. Almost immediately after beginning the electrolysis, a colorless crystalline solid deposited on the anode

[d]No identifiable compound could be isolated from this system.

surface, and subsequently settled on the bottom of the cell. This material was collected and dried *in vacuo*.

Preparation of $(C_2H_5)_2TiBr_2 \cdot 2CH_3CN$

When titanium metal was electrolyzed in a solution consisting of 10 cm³ C_2H_5Br, 20 cm³ CH_3CN, and 30 mg $(C_2H_5)_4NBr$, at a constant current of 30 mA (25 V), it appeared that two products were being formed. After the first few minutes of electrolysis, a yellow colour began to appear around the anode, and the colour of the solution progressively changed to brown. After about 45 min, a green solid started to deposit in the cell; this was collected and dried *in vacuo* (found: Ti 13.1, Br 44.0). When the filtrate was treated with diethyl ether, a brown solid precipitated (found: Ti 14.3, Br 45.4). We believe that the brown solid is indeed $(C_2H_5)_2TiBr_2 \cdot 2CH_3CN$ (cf. Table 2), whilst the green material may be a mixture of this and some reduction product (cf. bipy case below).

Preparation of $(C_2H_5)_2MBr \cdot bipy$ ($M = Zr, Hf$)

A pink colouration was observed around the anode at the beginning of the electrolysis, but this persisted for only a short time. A yellow solid subsequently began to deposit on the anode surface and in the bottom of the cell, and the overall colour of the solution progressively changed to yellow. At the end of the electrolysis the yellow solid was collected by filtration and dried *in vacuo*.

Electrochemical Preparation of $(C_2H_5)TiBr_2 \cdot 2bipy$ and $(C_2H_5)_2TiBr_2 \cdot bipy$

Titanium was electrolyzed in conditions similar to those above, and again two different compounds were seen to form, one green and the other brown. The brown compound which precipitated was collected, and identified as $(C_2H_5)_2TiBr_2 \cdot bipy$ (see Table 2). The green material which was precipitated by adding diethyl either to the filtrate analyzed as $(C_2H_5)TiBr_2 \cdot 2bipy$ (found: Ti 8.6, Br 28.9; calcd.: Ti 8.7, Br 29.1).

Characterization of Products

Each isolated substance was analyzed for metal and halogen, and in addition, infrared and nmr spectroscopy were used to confirm the presence of the appropriate donor ligand and organic group bonded to the metal. The proton nmr spectra, given in Table 4, call for little comment other than that they confirm the presence of the appropriate structural units.

The infrared spectra of the 2,2′-bipyridine adducts showed the spectral features associated with bidentate coordination of this ligand (7). The $\nu(C{\equiv}N)$ vibrations of the acetonitrile adducts are listed in Table 5. The values are similar to those reported for the MX_4 adducts (3), and show little dependence on R or X. The presence of the doublet indicates that the acetonitrile ligands have *cis* stereochemistry. We were not able to study the far infrared spectra of the compounds to establish the stereochemistry of these molecules.

Results and Discussion

General

As with previous electrochemical synthesis, the experiments show that the method is a simple and inexpensive route to a variety of organometallic halides. The method appears to be a general one, although there are certain systems (see Table 1) from which no reaction product could be isolated, even though significant quantities of metal dissolved. We attempted the preparation of anionic complexes by electrolysis of the metal in the presence of organic halide and excess (i.e. approximately 1 g) tetraalkyl ammonium halide, but obtained only on the salt of the corresponding anionic inorganic halogeno complex (cf. ref. 3).

The compounds obtained are sensitive to hydrolysis, but otherwise stable under nitrogen over some days. The presence of the complexing ligand during the preparative process, coupled with the immediate precipitation which occurs in many cases, is no doubt responsible for stabilizing the compounds, particularly against those processes arising from intermolecular interactions which are prevented by increasing the coordination number of the metal. Previous authors have shown that the thermal stabilities of benzyl zirconium iodides are improved by coordination with 2,2′-bipyridine (8); despite this approach, some of the results in Table 2 suggest that some decomposition may have occurred.

Reaction Pathway

The present work offers both interesting parallels and significant differences with that on the electrochemical synthesis of diorganotin(IV) dihalides (6). The most obvious point is that while with tin the products were invariably adducts of the R_2MX_2 compounds, the present experiments yield adducts of R_2MX_2, or adducts of R_3MX, or uncomplexed R_3MX, depending on R and X. We believe that the explanation is similar to that which we have given elsewhere (9) in terms of the electrochemical synthesis of organoindium(III) halides, namely anodic oxidation of the metal to a low oxidation state, followed by reaction with excess organic halide, followed by either complexation and precipitation or rearrangement reactions in solution.

In all our electrochemical work using organic halides, we have based the explanation on the first step of cathodic reduction (1).

[1] $RX + e \rightarrow R + X^-$

Migration of X^- to the anode is then followed by

[2] $X^- + M \rightarrow MX + e$

[3] $MX + RX \rightarrow RMX + X$

This sequence of reactions [2] and [3] can lead to a current efficiency (defined as moles of metal dissolved per Faraday) greater than unity, and non-integral. Examples of this have been found for tin (6) and cadmium (10), while for indium (9) reaction [3] is replaced by the formation of the indium(III) compound R_2MX. Attempts to measure the current efficiency were confounded by the formation of solids which adhered to the surface of the electrode; typical values were in the range 0.3–0.4 mol F^{-1}, which is higher than the value of 0.25 expected for Faradaic behaviour, but which gives no insight into the details of the electrode reactions. for the oxidative insertion of $(C_5H_5)_2Ti(CO)_2$ into the C—X bond of alkyl halides lends some support to the proposed reaction [4].

In the case of tin, it was suggested that the reaction

[4] $RMX + RX \rightarrow R_2MX_2$

followed by *in situ* complexation lead to the precipitation of $R_2MX_2 \cdot L_2$, whose insolubility prevented the redistribution reactions which otherwise result in R_2MX, RMX_3, etc. The importance of redistribution reaction in the present work is shown by the fact that when the product precipitates during the electrolysis, the products are generally the adducts $R_2MX_2 \cdot 2CH_3CN$ or $R_2MX_2 \cdot bipy$. The exceptions to this rule are $(C_6H_5)_3TiI$ and $(C_6H_5)_3ZrI$, which precipitated slowly as sticky solids during the electrolysis. There may be steric reasons why these compounds fail to complex with acetonitrile, and the slight solubility in this solvent may account for the formation of the triorganohalide by a redistribution reaction of $(C_6H_5)_2MI_2$. Similar arguments probably apply in the case of CH_3I/M systems, where adducts of the $(CH_3)_3MI$ species are formed with 2,2′-bipyridine; with hafnium, precipitation of the product occurs slowly during the electrolysis, whereas with titanium and zirconium addition of solvent(s) was required for precipitation. Here again, steric effects may mitigate against the stability of R_2MI_2 compounds, although in fairness one must note the formation of such species with $R = C_6H_5CH_2$.

One further piece of experimental evidence supports the proposed redistribution reactions. When zirconium was oxidized in the presence of phenyl iodide, the formation of iodine was observed, and subsequent analysis (thiosulphate titration) showed that 0.35 mmol I_2 was generated, and that 0.37 mmol Zr had dissolved. These results are compatible with the formation of $(C_6H_5)_3ZrI$ by either

[5] $C_6H_5ZrI + 2C_6H_5I \rightarrow (C_6H_5)_3ZrI + I_2$

or

[6] $(C_6H_5)_2ZrI_2 + C_6H_5I \rightarrow (C_6H_5)_3ZrI + I_2$

We have no reason to prefer one reaction over the other at the present time.

The final point about the solution chemistry which follows the electrochemical oxidation is that for titanium we observed some reduction of the M(IV) compounds. The synthesis was carried out in an undivided cell and reduction of solution species therefore is always a possibility, although clearly this cannot occur when the product precipitates. The evidence for this reduction is ambiguous for $Ti/C_2H_5Br/CH_3CN$ (cf. Experimental), but much better based for $Ti/C_2H_5Br/bipy$. Polarographic evidence (12, 13) for the reduction of $(C_5H_5)_2TiCl_2$ to give green $(C_5H_5)_2TiCl$ is in keeping with these observations.

In general then, the experimental results on the electrochemical preparation of organometallic halides of titanium, zirconium, and hafnium are in keeping both with the known properties of these elements, and with earlier work on direct electrochemical synthesis.

Fourier transform carbon-13 spin–lattice relaxation study of motion of cyclic hydrocarbons

DAVID E. AXELSON[1] AND CLIVE E. HOLLOWAY

Department of Chemistry, York University, 4700 Keele Street, Downsview, Ont., Canada M3J 1P3

Received July 30, 1979[2]

DAVID E. AXELSON and CLIVE E. HOLLOWAY. Can. J. Chem. **58**, 1679 (1980).

The molecular dynamics in solution for a series of cyclic and bicyclic hydrocarbon derivatives has been investigated by C-13 pulsed Fourier Transform nuclear magnetic resonance spin–lattice relaxation experiments. Molecular motion has been analysed in terms of an anisotropic rotational diffusion model, and an attempt has been made to assess the effects of structure on the observed rotational diffusion constants. Errors in the diffusion constants are discussed, and some of the other problems inherent in the use of these parameters to obtain structural information are outlined.

DAVID E. AXELSON et CLIVE E. HOLLOWAY. Can. J. Chem. **58**, 1679 (1980).

On a étudié la dynamique moléculaire d'une série d'hydrocarbures cycliques et bicycliques en solution en faisant appel à des expériences de relaxation spin–réseau par RMN du ^{13}C opérant par transformation de Fourier à impulsion. On a analysé le mouvement moléculaire en fonction d'un modèle de diffusion d'anisotropie rotationnelle et on a essayé d'évaluer les effets de structure sur les constantes de diffusion rotationnelle observées. On discute des erreurs sur les constantes de diffusion et on souligne quelques autres problèmes inhérents à l'utilisation de ces paramètres en vue d'obtenir des informations sur la structure.

[Traduit par le journal]

Introduction

Carbon-13 spin–lattice relaxation times (T_1) have been widely used to investigate details of molecular motion in solution (1). A major contribution to T_1 of a carbon-13 nucleus in an organic molecule arises from dipolar interactions with protons (T_1^{dd}). Under conditions of rapid molecular reorientation, and in the extreme narrowing limit of the ^{13}C resonances signal, the T_1^{dd} contribution is given by eq. [1], where τ_c is the correlation time for rotational motion and r_{CH} is the carbon–proton internuclear distance.

$$[1] \quad (T_1^{dd})^{-1} = \hbar^2 \gamma_C^2 \gamma_H^2 \sum_i r_{CH_i}^{-6} \tau_c$$

A molecule which is not spherically symmetric will probably undergo anisotropic rotation as it moves around in the magnetic field and eq. [1] will not be directly applicable. The anisotropy of rotation can arise because of inertial differences and because the ellipsoidal shape of the molecule causes differences in the barriers to diffusional motion about the rotation axes in solution. With relatively simple molecules the observed T_1^{dd} values are often interpreted qualitatively in terms of the geometry and assumed axes of rotation of the molecule. Thus carbons with unusually short T_1^{dd} values relative to similar carbons in the molecule are assumed to have their relevant C—H internuclear vectors lying on or close to the axis of fastest molecular rotation. This simple treatment can lead to misinterpretation of the observed relaxation data and may obscure useful dynamic and structural information.

When there are enough unique carbon–hydrogen vectors present in a molecule more detailed calculations (2) for anisotropic motion can be carried out. If a diffusion model can be assumed for molecular reorientation, the motion can be described by a rotational diffusion tensor analogous to the moment of inertia tensor for a free molecule (2–5). The intramolecular contributions to T_1^{dd} are then related to the elements of the diagonalized rotational diffusion tensor. For a structurally rigid molecule the three rotational diffusion constants, R_1, R_2, and R_3, indicate the relative rates of rotation about their respective axes. However, internal motions can also affect T_1^{dd} if the maximum in the frequency distribution of such modes lies in the region of the ^{13}C Larmor precession frequency. The analysis of the motion in terms of anisotropic rotational diffusion may then be misleading unless the effect of the internal motions can be factored out. The effect of internal or segmental motions is seen as an increase in T_1 for spinning methyl groups and for the carbons of flexible long chain substituents. These effects are usually analysed relative to the overall molecular motion as defined by a rigid part of the same molecule. In cyclic systems, such as those investigated here, the internal motions are ring flexing modes which involve the entire molecule and their effects are not readily separ-

able from rotational diffusion. Altering the rigidity of the ring system without changing the overall molecular shape can result in different relative values of R_1, R_2, and R_3 in a series of closely related derivatives. An attempt has been made to discern such effects in this study.

Calculation of the diffusion constants depends explicitly on molecular structure through the direction cosines of the relevant C—H vectors. It should therefore be possible to obtain structural information by determining the rotational diffusion tensor elements for various geometries, and using these to calculate T_1^{dd} values to compare with the observed values. In the exomethylene bicyclic systems there is evidence (6) that the methylene groups are skewed. Here an attempt has been made to assess the sensitivity of the motional analysis to minor modifications of this type.

We have also investigated the effect of errors in T_1^{dd} on the calculated rotational diffusion constants. Because each T_1^{dd} depends on the relative orientation of particular C—H vectors some motions may have little or no effect on a given T_1^{dd}. Conversely an error in any T_1^{dd} can affect each of the three R_i values quite differently. The degree to which the propagation of such errors interferes with the interpretation of molecular motion from T_1 data is discussed.

Experimental

Preparative methods for the less common derivatives examined are available in the literature (6, 7). Solutions for nmr were prepared in $CDCl_3$ and sealed in tubes. Samples were not degassed unless otherwise noted. Spectra were obtained on a Varian CFT 20 spectrometer with an 8 mm variable temperature probe (ambient temperature 37°C) and an 8K 620L-100 computer. All spectra were obtained under noise modulated proton decoupling conditions.

The T_1 data were obtained using the full inversion-recovery pulse sequence (8) for very short values, the progressive saturation technique (9) for longer values, and the intensity ratio approximation of this technique for very long values (10). The observed T_1 values were determined from a linear least-squares fit (11, 12) of intensity data to eq. [2],

$$[2] \quad \ln (M_\infty - M_\tau) = -\tau/T_1$$

where M_∞ is the equilibrium magnetisation, M_τ is the magnetisation at time τ, and τ is the pulse delay time.

Each T_1 value was measured at least three times and the estimated precision varies from ±5% for the shorter to ±10% for the longer values.

Nuclear Overhauser enhancements (nOe) were measured in the gated decoupling mode (13, 14) and repeated several times for each sample. The results have an estimated precision of from ±10% for a full nOe ($\eta = 2.0$) to ±14% for $\eta = 1$. The dipolar contribution to T_1 is given (15) by eq. [3].

$$[3] \quad \eta = 1.987\,(T_1^{dd})^{-1}/(T_1)\ \text{observed}))^{-1}$$

The error in T_1^{dd} becomes 14.5% ($\eta = 2.0$) for the least precise (longest) T_1 value. Since most of the T_1 values measured in this study at ambient temperatures are relatively short, with all the corresponding nOe values being 2.0 ± 10%, the T_1^{dd} precision probably lies closer to 11.5% in these cases. Because only T_1^{dd} is relevant to the motional analysis this is the value tabulated and referred to in the text. Where results from other studies are used, the relevant T_1(observed) and nOe values may be obtained from the appropriate references.

The analysis of the T_1^{dd} values was performed by a computer programme based on the equations of Woessner (2) for anisotropic rotational diffusion. The input to this programme is T_1^{dd} and the associated direction cosines of the relevant C—H vectors referred to a coordinate system which diagonalizes the moment of inertia tensor (*vide infra*). Starting values for the rotational diffusion constants (R_i) are also entered, a suitable choice of values being obtained by assuming isotropic reorientation.

Theory

(*i*) *The Choice of Principal Diffusion Axes (3, 5, 16)*

The orientation of the diffusion tensor principal axis system is the resultant of a number of forces acting on the system, reflecting the overall shape of the molecule and possible intermolecular interactions. Choosing the orientation is always difficult but can be simplified to some extent.

To a first approximation the principal axes of the moment of inertia tensor are the same as those of the diffusion tensor. This implies that overall molecular geometry is the primary factor involved in determining rotational diffusion constants, and this can only be true in the absence of polar groups and heavy atoms. Polar groups may also generate an electric dipole moment which can affect molecular motions (17). The overall symmetry of the system should be fairly high since it may not otherwise be possible to diagonalize the diffusion tensor (5, 16). At least three geometrically unique C—H vectors are necessary to determine the diffusion constants. It is important to recognize that the centre of the diffusion axes system cannot be located since the angles which appear in the equations for anisotropic rotational diffusion arise from a rotational transformation. Translational shifts of the centre of the diffusion axis coordinate system do not affect the relaxation times.

(*ii*) *Tests of the Applicability of the Diffusion Equation*

There are a number of criteria which can be used to test for the applicability of the small-angle rotational diffusion model for a particular axis of reorientation (17). The χ test proposed by Wallach and Huntress (18) compares the experimental correlation times (τ_c) with the theoretical reorientation time of a free gas molecule (τ_f),

$$\chi_i = \tau_{c_i}/\tau_{f_i} = (5/18D_i)(kT/I_i)^{1/2}$$

where I_i is the moment of inertia about axis i, and D_i

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the diffusion constant. If the former is much larger than the latter, the molecule is quite rigidly held relative to its neighbours and the reorientation process is characterized by a random walk of small angle steps. Conversely, if the molecule is rotating about an axis with a substantial angular momentum, the reorientation is said to be in the inertial limit. Such behaviour can sometimes lead to a spin rotation contribution (19) to T_1. Gillen and Noggle (17) have suggested the arbitrary distinction that for $\chi < 3$ the molecule is in the inertial limit, and for $\chi > 5$ it is in the diffusion region, and this is also used as guide in the present study. Values for I_i were obtained by a computer reconstruction of the molecule, from known X-ray data if possible or extrapolations from the data for similar compounds, and subsequent determination of the moment of inertia tensor.

(iii) Errors in Calculated Rotational Diffusion Constants

As pointed out in a recent communication (20), errors in T_1^{dd} can be greatly magnified in computed R_i values. Because of the dependence of T_1^{dd} on the relative orientations of the C—H vectors, some motions may have little effect on an observed T_1. Conversely, errors in T_1^{dd} are not necessarily transmitted equally in the three dimensions of R_i. There will also be an interdependence between the three axes such that positive errors along one axis require negative errors along another to maintain a calculated T_1^{dd} within the experimental error limit. However, in a study such as this, it is the ordering of the R_i values that is important. In each case we have allowed the computer programme to sample a range of R_i values, calculate the corresponding T_1^{dd} values and estimate a standard deviation. Although the variation of R_i values was found to be large, in cases where anisotropic reorientation was evident the axis of fastest rotation can be identified unambiguously. The ordering of the other two R_i values cannot always be determined, however. The errors in R_i do place a severe limit on the sensitivity of the analysis to structural changes. Consequently, the interpretation of such data in terms of conformational details should be viewed with extreme caution in most cases. A typical set of R_i values and their associated T_1^{dd} values are shown in Table 1 for compound **5** (see Fig. 2).

It has been suggested (20) that all C—H interactions out to 2.5 Å should be taken into account in the calculation of R_i values. We have investigated this for each of the monocyclic derivatives by including all intramolecular C—H interactions. We found no significant differences in the calculated R_i values from those obtained using only bonded C—H interactions. A representative bicyclic system (**3**, Fig. 2) was similarly investigated, with particular reference to the skewing of the exomethylene groups. No significant differences were observed. This result is probably largely due to the relatively few non-bonded C—H interactions closer than 2.5 Å in the molecules studied here.

Results and Discussion

(i) Monocyclic Systems

Experimental and calculated ^{13}C T_1^{dd} values and corresponding rotational diffusion constants (R_i) for some simple ring systems are given in Table 2. The definition of the principal diffusion axes used here and the numbering scheme are shown in Fig. 1. In all of these molecules the moments of inertia are in the order $I_1 > I_2 > I_3$.

Pure methylcyclohexane and methoxycyclohexane behave very similarly, R_1 being the fastest diffusion constant, followed by R_3, with R_2 being the smallest. The calculated rotational diffusion constants are insensitive to the conformational geometry of the substituted ring, both axial and equatorial conformations giving indistinguishable results within the error limits of the calculations. Dilution of methylcyclohexane in $CDCl_3$ changes the diffusion constants towards less anisotropic reorientation, R_1 decreasing and R_2 and R_3 increasing. The short value of T_1^{dd} for the C-4 carbon in each of these compounds has been previously assumed to be due to the close alignment of the

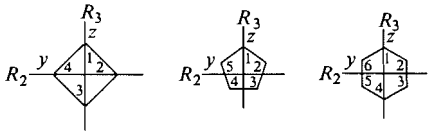

FIG. 1. Orientation of principal axes of diffusion in monosubstituted cyclic hydrocarbons: R_1 and x axis perpendicular to page; substituent at carbon 1.

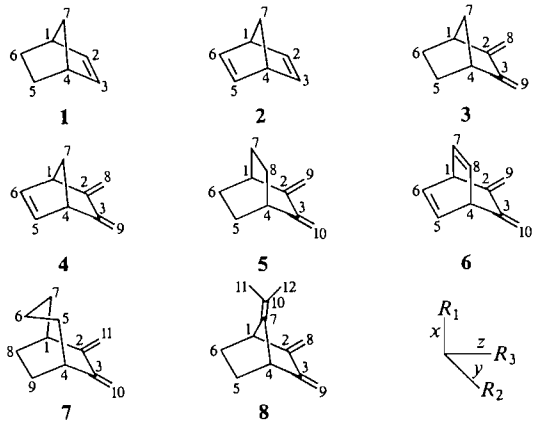

FIG. 2. Numbering scheme and orientation of principal axes of diffusion in bicyclic hydrocarbons.

C—H vector with the fastest axis of rotation (21). The present analysis shows this to be incorrect, as the T_1 difference between C-4 and C-2 or 3 must arise from a difference between the two slower axes of rotation, R_2 and R_3. This small difference may reflect differences in the moments of inertia (I_3 = 122 amu Å^2; I_2 = 414 amu Å^2). However, the slower motion about the y-axis (R_2) can also be due to the fact that this motion moves both the ring and the substituent, thereby sweeping out a greater volume. Similarly, the fastest motion (R_1) involves the axis with the highest moment of inertia, and this is best rationalized in terms of minimal disturbance of neighbouring molecules during this rotation. Application of the χ test shows that R_1 is near the inertial limit while R_2 and R_3 are essentially diffusion controlled (e.g. for methoxycyclohexane χ_1 = 1.7; χ_2 = 8.8; χ_3 = 5.4). The dominance of R_1 over R_2 and R_3 in planar or near planar ring systems seems to be fairly general in the absence of other complicating factors, for example in pyridine (22) and mesitylene (23).

The very short T_1 values for cyclohexanol reflect increased molecular association via hydrogen bonding. The ordering of the diffusion constants is also different, with R_3 the fastest. Qualitatively this is what one would expect for a hydrogen-bonded dimer. Quantitative conclusions about the motion of cyclohexanol are clouded by the probability that in such associated systems the principal diffusion axes and principal inertial axes are no longer aligned, and also the effect of the electric dipole moment in a molecule of this size has not been properly delineated. Dilution decreases the degree of self association and the ordering of the R_i values becomes similar to the other two derivatives. The closer resemblance between dilute cyclohexanol and methoxycyclohexane, rather than methylcyclohexane, may reflect the effect of the dipole moment.

The five membered ring of cyclopentene shows an appreciable contribution from spin-rotation to the T_1 values of the ethylenic carbons (16). Calculation of the motional characteristics from the T_1^{dd} contribution (Table 2) reveals fastest motion about the y-axis (R_2) followed closely by R_3 and R_1. The χ test is less than four in each case, suggesting at least partial inertial control of rotation. Grant and co-workers (16) have suggested that internal puckering vibrations also contribute substantially to the motions. Grandjean and co-workers (24) consider that the R_i values are essentially isotropic since previous calculations have ignored the shorter length of the olefinic C—H bond. While both considerations are valid, it should be emphasized that as inertial control becomes important the premises upon which the diffusion equations are based become increasingly inadequate.

Methylcyclopentane resembles methylcyclohexane in its rotational diffusion ($R_1 \gg R_3 > R_2$), while methoxycyclopentane and cyclopentanol differ in the relative ordering of R_2 and R_3. The χ test for methoxycyclopentane indicates that R_1 and R_2 are in the inertial limit (χ = 0.7 and 1.3 respectively) while R_3 is not (χ = 4.6). In all of these cases contributions to T_1^{dd} from ring flipping are possible, there being other evidence for large amplitude motions of this type in small rings (25–28). The T_1^{dd} values in cyclopentanol, compared to the other five membered ring derivatives, indicate considerable molecular association. It is interesting to note that changing from methyl to the more polar methoxy substituent substantially alters R_1 and R_3. The former is effectively perpendicular to the averaged dipole of the freely rotating methoxy group while the latter is colinear with the dipole. Introduction of hydrogen-bonding, with cyclopentanol, causes a major change in R_2 and a change in R_1, both of which are perpendicular to the direction of the interaction. As noted above, in such a case the principal axes of the diffusion tensor and the inertia tensor may no longer be aligned.

The fastest rotation in methylcyclobutane (R_3) appears to be governed by inertial considerations. The hydrogen-bonded neat cyclobutanol has very short T_1^{dd} values, characteristic of self-association, which give an ordering of rotation diffusion constants of $R_1 \gg R_2 > R_3$. A close similarity with cyclopentanol is noted, suggesting that internal puckering modes, if important, are similar in both ring systems. Dilution decreases the effect of hydrogen-bonding, and R_1 decreases while R_3 and R_2 both increase. Similar R_i values are noted for chlorocyclobutane, which does not associate ap-

precisely but does have a net electric dipole like cyclobutanol. Increasing the mass of the substituent while retaining the electric dipole, with bromocyclobutane, causes a reordering of the rates of rotational diffusion to $R_3 > R_2 > R_1$, which is in the inverse order of the moments of inertia. The complex interplay of effects upon which T_1^{dd} and R_i depend is effectively demonstrated by this series of related substituted cyclobutanes. It must be remembered that the defined orientation of the diffusion tensor principal axes in terms of the moment of inertia principal axes is a simplification which becomes invalid if either is subject to large perturbations. The presence of heavy atoms will perturb the latter and self-association and an electric dipole moment will perturb the former. Thus discussion of T_1^{dd} and R_i in terms of such effects is, at best, qualitative using the present approach. Similarly, the effect of other accompanying changes, structural or internal vibrational, for example, becomes impossible to specify.

(ii) Bicyclic Hydrocarbons

Experimental T_1^{dd} values and calculated R_i values are shown in Table 3 for a series of bicyclic hydrocarbons. Recalculated T_1^{dd} values have been omitted for clarity since the variations observed are similar to those shown in Table 2, and one derivative has been listed in detail in Table 1. The principal diffusion axes and numbering scheme for these derivatives are shown in Fig. 2. The moments of inertia are in the order $I_1 > I_2 > I_3$ for all of these derivatives.

Norbornane, norbornene, and norbornadiene have been previously investigated (16, 13, 29) and provide a convenient basis for comparison of the other bicyclic derivatives in this work. Differences in NT_1^{dd} are relatively small in these compounds and close to the experimental error. Concentration effects were found to be small for both T_1 and diffusion constants, and for norbornene increasing temperature causes a monotonic increase in T_1 for all carbons. If the spin–rotation mechanism were important in this temperature range, a levelling off of T_1 would be expected, such as observed for camphor (30) (above 315 K) and norbornadiene (28) (above 330 K). Under the conditions in this study the rotational diffusion constants for norbornene were in the order $R_3 > R_2 > R_1$, which is the inverse order of the moments of inertia. For the room temperature data, the χ test indicates inertial control for R_3 ($\chi = 1.5$) and R_2 ($\chi = 3.1$) and diffusion control for R_1 ($\chi = 8.5$). Assuming an Arrhenius temperature dependence for R_i, the energy barrier to rotation about the x and y axes is 9.2 kJ mol^{-1} (R_1 and R_2) and 10.5 kJ mol^{-1} for the z axis (R_3). These

values are similar to those reported by Sato and co-workers (29) for norbornadiene (10.5 kJ mol^{-1}) and slightly higher than the value reported (30) for a $CDCl_3$ solution. However, there is some discrepancy with these proton studies which report the motion of norbornadiene as isotropic at 25°C with $R = 7 \times 10^{10}$ s^{-1}. By contrast, data for the structurally similar norbornane (16) also indicates anisotropic motion, and a small observed anisotropy is not unexpected if the ellipticity factor ε is considered. This is the ratio of the maximum separation of atoms along axes perpendicular to the given rotation axis. The greater the value of ε, the slower the motion about that axis. Thus the axis of R_1, with the largest moment of inertia (183 amu Å^3) has an intermediate ε and the R_2 axis (I_2 = 145 amu Å^3) has the highest ε. Such opposing effects would tend to partially cancel out and minimize the net anisotropy of reorientation, making it more difficult to detect by a technique subject to quite large errors.

The derivatives **3** to **8** (Fig. 2) all contain exomethylene groups attached to a bicyclic skeleton. The immediate effect in **3** and **4** is a marked increase in the inertial anisotropy with I_1 increasing by a greater factor than I_2 greater than I_3. Subsequent changes, **5** to **8**, tend to decrease the inertial anisotropy again. The behaviour of **3** (2,3-dimethylene bicyclo(2.2.1)heptane) and **4** (2,3-dimethylene bicyclo(2.2.1)hept-5-ene) are quite different from the norbornane systems, as shown by the data in Table 3. The rotational diffusion constants for **3** do not correlate with moments of inertia, and the χ tests indicate that inertial effects are minimal for R_2 (χ = 8.6) and R_3(χ = 32.6), but may be important for R_1 (χ = 2.6). There is a similarity to the six membered ring systems in that the largest diffusion constant represents motion about an axis that appears to sweep out the least volume of solvent. The ε values for the three axes correlate with this effect, and a similar behaviour has been noted before (16) in the elongated molecule of *trans*-decalin. A low temperature study on **4** reveals a large change in R_1 and R_2 with temperature while R_3 changes only slightly. Steric, inertial, and electric dipole terms may be considered responsible for this observation. The relevant ellipticities relate to steric effects and should be more important for R_2 and R_3 than R_1. Inertial effects should give the order $R_3 > R_2 > R_1$, and a similar order is anticipated for the small electric dipole contribution aligned with the z axis. The χ test indicates that R_1 changes from diffusion (χ = 16) at low temperature to inertial (χ = 2) control at room temperature, R_2 moves in this direction also (χ = 39 to χ = 8) whereas R_3 remains under diffusional control (χ = 73 to χ = 56). The resulting nature of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the motion at any temperature thus represents a compromise between greater steric hindrance about the z axis and the less favourable inertial and electric dipole effects about the x axis. A similar trend has been found for *N,N*-dimethylformamide (5) in which steric and electric dipole effects compete, and in which there is also a marked shift of the principal diffusion tensor axes away from the principal inertial axes due to the large electric dipole. The present case is an interesting example involving a molecule with no large electric dipole moment, suggesting that such non-Arrhenius behaviour may be more common than hitherto believed.

Calculation of the diffusion constants depends explicitly on the molecular structure through the direction cosines of the relevant C—H vectors. Structural changes are therefore only detectable if there is a significant rotational shift of C—H vectors. In compounds **3** and **4** the orientation of the exomethylene groups may be skewed due to internal steric interactions of the inner C—H bonds. Compound **3** was used to estimate the variation in calculated diffusion constants on rotating the *sp* carbon bond angles between 114° and 130°. No significant changes in the diffusion constants were found.

Compound **5** (2,3-dimethylene bicyclo(2.2.2)-octane) illustrates another problem in delineating trends. The pure liquid has rotational diffusion constants in the order $R_2 > R_1 > R_3$ in contrast to the heptane analogue **3**. Bicyclo(2.2.2)octane itself exhibits a similar anisotropy with $R_{\|}(R_2) = 17 \pm 4 \times 10^{10}$ rad s^{-1} and $R_{\perp}(R_1, R_3) = 9 \pm 2 \times 10^{10}$ rad s^{-1}. Compound **6** (2,2-dimethylene bicyclo(2.2.2)octa-5,7-diene), however, was found to be similar to the heptane analogue **4** with $R_1 > R_2 > R_3$.

Explanation of the preferred axes of rotation in **5** and **6** is not straightforward. Considerations of ellipticity do not explain the differences between **5** and **6**, and in neither case do the R_i values relate inversely to the moments of inertia (e.g. for **6**, $I_1 = 386$; $I_2 = 337$; and $I_3 = 228$ amu Å^2). The parallel between compounds **4** and **6** was found to extend over a similar temperature range with a large change in R_1 and almost no change in R_3.

Compound **7** (2,3-dimethylene bicyclo(3.2.2)-nonane) introduces a further minor change in the bicyclo skeleton with little overall effect on the diffusional behaviour of the molecule. The ordering of the rotational diffusion constants is $R_1 > R_3 > R_2$ which correlates with the ellipticities ($\varepsilon_1 = 1.16$, $\varepsilon_2 = 1.42$, $\varepsilon_3 = 1.22$).

Compound **8** (2,3-dimethylene-7-isopropylidene bicyclo(2.2.1)heptane) is structurally different along the axis of R_1, and again the ordering of the diffusional constants essentially follows that of the ellipticities; ($\varepsilon_1 = 1.07$, $\varepsilon_3 = 1.15$, $\varepsilon_2 = 1.24$). Despite the structural modification, the relative magnitudes of the diffusion constants are similar to those of the related bicyclic systems **3** and **4**.

The structural change from the norbornyl skeleton to the exomethylene derivatives **3** and **4** causes a marked change in the rotational diffusion behaviour of the molecule. By contrast, the more flexible bicyclo(2.2.2)octane skeleton when similarly modified to give compound **5** shows considerably less change in diffusional behaviour. Also, while the norbornyl derivatives **3** and **4** are similar in behaviour, there is a substantial change in rotational behaviour between **5** and **6**. It is known (31–33) that bicyclo(2.2.2)octane and its derivatives undergo relatively large amplitude internal oscillations which can effect T_1^{dd}. Calculations (32) on the parent hydrocarbon indicate a barrier of 420 J mol^{-1} and a root-mean-square amplitude of 12° for twisting about the D_{3h} symmetry axis. Such a motional contribution to T_1^{dd} may overshadow the changes wrought by introduction of exomethylene groups to give compound **5**. Damping these oscillations by the introduction of double bonds in the ring, compound **6**, then gives the expected changes so that compounds **4** and **6** resemble each other. Going in the direction of increasing ring flexibility, compound **7**, also appears to have a similar effect on the R_i values, perhaps indicating that the flexing motions are now too facile and occurring too rapidly to affect T_1^{dd} under the present experimental conditions.

Conclusions

The errors introduced into the rotation diffusion constants from experimental errors of the relaxation times are often disturbingly large. These errors do not generally permit elucidation of effects other than major structural changes in a series of compounds. In addition, use of variable temperature T_1^{dd} data directly to estimate energy barriers to diffusional reorientation can also be misleading in view of the possible non-Arrhenius behaviour noted for the calculated R_i values. Large amplitude internal motions also contribute to T_1^{dd} and hence possibly affect R_i values. Dilution, temperature and viscosity changes can alter the relative contributions to T_1^{dd} of internal motions and rotational diffusion, and change the relative importance of electric dipole, inertial, and steric effects in the latter. Consequently, comparisons from one study to another can be risky unless all these effects can be taken into account. A recent study on 1-substituted adamantanes (34) has specifically looked at solvent effects.

However, we believe that in molecules where substantial anisotropic reorientation is occurring it is usually possible to identify the fastest axis of rotation. This axis is not always the one that might be picked intuitively from considerations of the molecular structure, or even from the observed T_1 values. Thus the calculations are of obvious value in such cases. The observed relative rates of rotational diffusion can, in many cases be correlated in a qualitative sense with either inertial effects or ellipticities. The former are most important in smaller molecules and are characterized by low values in the χ test and, in the extreme, spin rotation contributions to the observed relaxation rate.

Modification of HAM/3 excitation energies for $\pi\pi^*$ transitions of linear molecules

DELANO P. CHONG[1]

Department of Chemistry, 2545 The Mall, University of Hawaii at Manoa, Honolulu, HI 96822, U.S.A. and NASA-Ames Research Center, Moffett Field, CA 94035, U.S.A.

Received March 6, 1980

DELANO P. CHONG. Can. J. Chem. **58**, 1687 (1980).

The excitation energies calculated by the HAM/3 procedure for $\pi\pi^*$ transitions in linear molecules can be internally inconsistent by as much as ± 0.6 eV. In the recent study by Åsbrink *et al.*, the problem was avoided by adopting Recknagel's expressions and requiring the proper average $\pi\pi^*$ excitation energy. In this paper, we trace the small inconsistency back to its origin in HAM/3 theory and derive the analytical expression for the energy correction as well as Recknagel's formulas. Numerical examples studied include all seven linear molecules investigated by Åsbrink *et al.* The explicit expression for the correction enables us to perform meaningful configuration-interaction calculations on the excited states, as illustrated by the carbon suboxide molecule.

DELANO P. CHONG. Can. J. Chem. **58**, 1687 (1980).

Les énergies d'excitations des transitions $\pi\pi^*$ calculées par la technique HAM/3 pour les molécules linéaires peuvent contenir des erreurs internes pouvant aller jusqu'à $\pm$ 0.6 eV. Dans une étude récente, Åsbrink *et al.* ont contourné le problème en adoptant des expressions de Recknagel et en faisant appel à une moyenne appropriée de l'énergie d'excitation $\pi\pi^*$. Dans cet article nous avons retrouvé la cause des ces erreurs dans la théorie HAM/3 et nous déduisons l'expression analytique pour la correction de l'énergie ainsi que pour les formules de Recknagel. Les exemples numériques étudiés comprennent toutes les sept molécules linéaires étudiées par Åsbrink *et al.* L'expression explicite de la correction nous permet d'effectuer des calculs significatifs d'interaction de configuration des états excités tel qu'illustré par la molécule de sous-oxyde de carbone.

[Traduit par le journal]

1. Introduction

In a recent paper (1), Åsbrink *et al.* applied their new semi-empirical HAM/3 molecular orbital method (2) to calculate valence excitation energies of linear molecules. If they had used HAM/3 formalism throughout, the result would have shown that the two components of the $\pi\pi^*$ $^1\Delta$ state are split (by as much as 1.2 eV), as are those of $^3\Delta$. However, Åsbrink *et al.* (1) avoided the difficulty by adopting Recknagel's expression (3, 4) and by equating the average $\pi\pi^*$ excitation energy to the difference in HAM/3 orbital energies. Consequently, their numerical results are not affected by the present analysis.

In this paper, we first point out the origin of the deficiency in the HAM/3 procedure. Then, we obtain an explicit expression for the correction to HAM/3 excitation energies for $\pi\pi^*$ transitions of linear molecules. After the correction, Recknagel's formulas are recovered. Numerical results for the correction are confirmed for all seven linear molecules studied by Åsbrink *et al.* (1).

With the correction, it is now meaningful to perform configuration-interaction (CI) calculations to improve on the Recknagel energies. Numerical results of such calculations are reported for C_3O_2 in Section 3.

2. The Correction

To keep the notation simple, we shall consider a linear molecule belonging to the $C_{\infty v}$ point group. Appropriate subscripts u or g should be added for linear molecules with $D_{\infty h}$ symmetry. The degenerate π orbitals of interest are denoted by x and y and the π^* orbitals by X and Y. Following Åsbrink *et al.*, we define the electron repulsion integrals: $a = 2(\mathrm{xy}|\mathrm{XY})$, $b = 2(\mathrm{xY}|\mathrm{xY}) = 2(\mathrm{yX}|\mathrm{yX})$, $2c = K + \bar{K}$, $K = (\mathrm{xX}|\mathrm{xX}) = (\mathrm{yY}|\mathrm{yY})$, and $\bar{K} = (\mathrm{xX}|\mathrm{yY})$. The relative signs of the molecular orbitals are arbitrary and affect the signs of a and $\bar{K}$. To be consistent with Recknagel's expressions (3), we choose a to be positive so that if a computed value of a is negative, we would change the signs of a and $\bar{K}$ simultaneously ($\bar{K}$ may end up to be negative). Also we shall follow Åsbrink *et al.* (1) in using state symbols for excitation energies although it is not a standard practice.

The origin of the deficiency of HAM/3 theory when applied to $\pi\pi^*$ transitions of linear molecules lies in the fact that the average of the singlet and triplet excitation energies is given by $\Delta\varepsilon$ whether the transition is $\mathrm{x} \rightarrow \mathrm{X}$ or $\mathrm{x} \rightarrow \mathrm{Y}$, in contrast to standard Hartree–Fock theory (5).

The deficiency can be corrected in the following manner. Let the average of the singlet and triplet excitation energies be given by $\Delta\varepsilon + \delta$ for $\mathrm{x} \rightarrow \mathrm{X}$ or $\mathrm{y} \rightarrow \mathrm{Y}$ transition and $\Delta\varepsilon - \delta$ for $\mathrm{x} \rightarrow \mathrm{Y}$ or $\mathrm{y} \rightarrow \mathrm{X}$. Then, it can be shown that, when we do a simple 2

× 2 configuration-interaction calculation on the degenerate transitions, we get

$$[1] \quad K - b/2 = c = \bar{K} + b/2$$

$$[2] \quad \delta = c/2 - a/2$$

and recover Recknagel's expressions (3) which were used by Åsbrink *et al.* (1)

$$\begin{aligned} {}^1\Sigma^+ &= C - a + 4c \\ {}^1\Delta &= C + 2b \\ {}^{1,3}\Sigma^- &= C + a \\ {}^3\Delta &= C \\ {}^3\Sigma^+ &= C - a \end{aligned} \quad [3]$$

where

$$C = \Delta\varepsilon - b/2 - c/2$$

As noted by Åsbrink *et al.*, the INDO-like approximation formula for the repulsion integrals in HAM/3 makes $a = b$ for linear molecules. Consequently, eq. [2] can also be written as

$$[4] \quad \delta = K/2 - 3b/4$$

For the seven linear molecules[2] studied by Åsbrink *et al.* (1), the shift δ ranges from −0.0012 eV for $1\pi_u \rightarrow 2\pi_g$ of C_2N_2 to 0.6079 eV for $2\pi \rightarrow 3\pi$ of N_2O.

The $1e_{1g}(\pi)$ to $1e_{2u}(\pi^*)$ transition of benzene presents a similar situation. If one considers the $1a_2$, $2b_1$, $2a_2$, and $3b_1$ π-molecular orbitals (in C_{2v} representation) of benzene as the analogs of the x, y, X, and Y orbitals of linear molecules respectively, then the counterparts of the molecular levels ${}^1\Sigma^+$, ${}^1\Delta$, ${}^{1,3}\Sigma^-$, ${}^3\Delta$, and ${}^3\Sigma^+$ are ${}^1B_{1u}$, ${}^1E_{1u}$, ${}^{1,3}B_{2u}$, ${}^3E_{1u}$, and ${}^3B_{1u}$, respectively. However, the integral a for benzene is 0.4946 eV (according to HAM/3) compared to $b = 1.4533$ eV. In other words, eq. [4] is not valid for benzene and the δ-correction must be obtained from eq. [2]. For benzene, the δ-correction is found to be −0.0972 eV.

With the explicit expression for the δ-correction, it is now meaningful to perform CI calculations on the excited states. The carbon suboxide molecule is studied as an example.

3. Carbon Suboxide

The electronic structure of C_3O_2 has been the subject of a number of studies (7–16). The absorption spectrum (7–11) between 4–11 eV has been reviewed by Roebber (11). However, the peaks between 13 and 19 eV (10) remain unassigned. It is our hope that HAM/3 calculations can increase our understanding of the absorption spectrum.

The uv and X-ray photoelectron spectra have also been studied (12–14). There remains, however, a disagreement (at the same laboratory) on the ordering of the third to the fifth ionization potentials. The results of HAM/3 calculations are presented in Table 1, together with the experimental results and values from other calculations. It is not surprising that the HAM/3 results are very good (17).[3] As Table 1 shows, the HAM/3 results favor the ordering of Gelius *et al.* (13). On the other hand, C_3O_2 is one of 80 molecules used in the parametrization process (18), and there may be an inherent bias because that assignment was used in the parametrization procedure.

The absorption spectrum is not completely understood. Roebber (11) assigned the three bands between 4 and 8 eV based on effect of temperature and pressure, the Herzberg–Teller theory of vibrationally induced electronic transitions, and on INDO molecular orbital calculations. Figure 1 shows a composite spectrum from the studies of various workers (7, 10, 11). The energy scale is not linear and the absorption scale is not uniform. The first band at 4.67 eV (7) was assigned to the ${}^1\Sigma_u^-$ and ${}^1\Delta_u$ states arising from $2\pi_u$ to $2\pi_g$ excitation, both states calculated to be 3.71 eV above the ${}^1\Sigma_g^+$ ground state by the INDO method (11). The second band at 6.96 eV (10, 11) was first assigned to ${}^1\Sigma_u^+(2\pi_u \rightarrow 2\pi_g)$ (10), but was then changed to ${}^1\Sigma_g^-(2\pi_u \rightarrow 3\pi_u)$ and ${}^1\Delta_g(2\pi_u \rightarrow 3\pi_u)$ (11). This band can also be interpreted as the $n = 3$ member of first Rydberg series (δ = 1.00) as pointed out by Robin (19). The intensive ($f = 1.5$) band at 7.82 eV (10, 11) was assigned to the combination of ${}^1\Sigma_u^+(2\pi_u \rightarrow 2\pi_g)$ and ${}^1\Pi_u(2\pi_u \rightarrow 3s$ Rydberg). The 8–11 eV region was assigned (10) to $2\pi_u \rightarrow ns$ Rydberg series with either upper-state vibrations or a second Rydberg series. There remains some uncertainty and some unassigned peaks at higher energies, because of diffuseness of the bands and the unreliability of the INDO results.

The numerical results from HAM/3 are summarized in Table 2. There are two sets of unoccupied π* molecular orbitals $2\pi_g$ and $3\pi_u$. The molecular states arising from the one-electron transitions from $2\pi_u$, $1\pi_g$, and $1\pi_u$ to $2\pi_g$ are labelled as A, B, and C respectively, while those from $2\pi_u$, $1\pi_g$, and $1\pi_u$ to $3\pi_u$ are denoted by D, E, and F respectively in Table 2. While the results from HAM/3 are by no means definitive, they offer interesting alternatives to the INDO interpretations. There is little doubt concerning the assignment of

[2]The equilibrium geometry of all of the molecules studied in this paper has been taken from Hellwege's compilation (6).

[3]In ref. 17, the two consecutive entries at −0.30 and −0.30 in the column headed by HAM/3 in Table 1 should read −0.15 and −0.45, respectively.

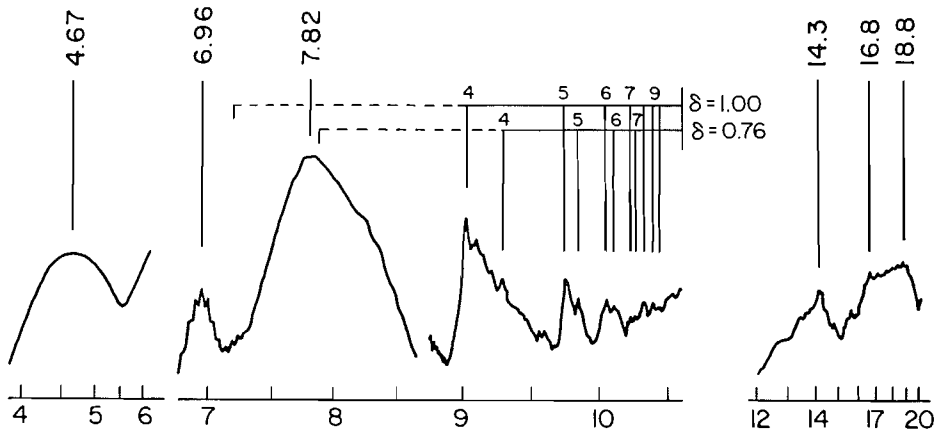

FIG. 1. Composite absorption spectrum of C_3O_2, taken from the studies of refs. 7, 10, and 11.

the 4.67 and 7.82 eV bands, although HAM/3 does poorly on those excitation energies, even after CI. The other results are quite different from INDO: (*a*) If the $^1\Sigma_g^-$ and $^1\Delta_g$ states are responsible for the 6.96 eV band they would seem to come from transition (B) $1\pi_g \rightarrow 2\pi_g$, rather than from (D) $2\pi_u \rightarrow 3\pi_u$, which was indicated by the INDO results. According to HAM/3, the latter states are about 9.8 eV above the $^1\Sigma_g^+$ ground state. (*b*) The assignment of the Rydberg region to one main series with upper-state vibrations was preferred (10) because the bands at 74.4 kK (9.22 eV) and 77.2 kK (9.57 eV) could not be fitted into any Rydberg series. The HAM/3 results offer some possible excited states for the alternative interpretation. There are two states with non-zero oscillator strengths at 10.5 and 10.6 eV according to HAM/3. (*c*) Between 14 and 19 eV there are four allowed transitions with *f*-value ranging from 0.006 to 0.45 which may contribute to the unassigned bands in that region.

4. Discussion

The preceding section shows that HAM/3 provides very good ionization potentials for C_3O_2, but the calculated excitation energies even after CI are not as accurate as those of other linear molecules (1). Leaving the example of carbon suboxide, let us examine the general performance of the semi-empirical HAM/3 molecular orbital method. Although the most frequent applications of HAM/3 have been the calculations of (*a*) vertical ionization potentials, (*b*) excitation energies, (*c*) electron affinities, and (*d*) anion excitations, the method has also been applied (see ref. 20) to (*e*) shake-up satellites in valence-electron photoelectron spectra, (*f*) core-electron binding energies in ESCA, (*g*) doubly charged cations, (*h*) core-electron excitation spectra, (*i*) X-ray emission spectra, and (*j*) shake-up satellites in core-electron ESCA. It can be seen that HAM/3 can be useful for a wide range of problems. Moreover, after some initial criticism

(21), a firmer theoretical basis of the HAM model has gradually emerged (22, 23). Because the cost of a HAM calculation is about the same as CNDO, it would be a powerful research tool when the extension (24) to molecules containing elements up to Br is completed.

Kinetic studies of the reactions of 4-nitrobenzofuroxan with cyanide ion and isopropoxide ion in isopropanol

MICHAEL E. MOIR AND ALBERT R. NORRIS[1]

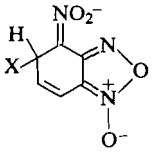
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received February 4, 1980

MICHAEL E. MOIR and ALBERT R. NORRIS. Can. J. Chem. **58**, 1691 (1980).

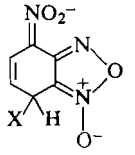
Kinetic studies of the reactions in isopropanol of 4-nitrobenzofuroxan with cyanide ion and isopropoxide ion have been carried out over the temperature range 15.0 to 35.0°C. For both bases, the first species identifiable using stopped-flow reaction techniques is postulated to be a C-7 σ-complex of 4-nitrobenzofuroxan and base. Specific rate constants and activation parameters for the formation of these σ-complexes are compared to corresponding data relating to the formation of cyanide ion and isopropoxide ion — σ-complexes of 1,3,5-trinitrobenzene in isopropanol.

MICHAEL E. MOIR et ALBERT R. NORRIS. Can. J. Chem. **58**, 1691 (1980).



On a effectué des études cinétiques relatives à la réaction du nitro-4 benzofuranne avec l'ion cyanure et l'ion isopropylate dans l'alcool isopropylique dans l'intervalle de température 15–35°C. Sur la base des techniques de réaction à flux stoppé on suppose dans les deux cas que la première espèce identifiable est un complexe σ entre le C-7 du nitro-4 benzofuranne et la base. On a comparé les constantes de vitesse spécifique et les paramètres d'activation de la formation de ces complexes σ aux données correspondantes se rapportant à la formation des complexes σ entre l'ion cyanure ainsi que l'ion isopropylate avec le trinitro-1,3,5 benzène dans l'alcool isopropylique.

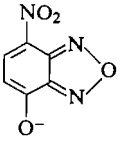
[Traduit par le journal]



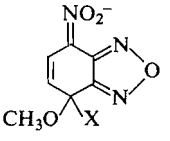
Introduction

The discovery (1) that certain benzofuroxan and benzofurazan derivatives act as powerful inhibitors of nucleic acid and protein biosynthesis in many types of animal cells has generated considerable interest in these classes of compounds (2–10). Especially noteworthy has been the observation that 4-nitrobenzofuroxan exhibits a toxic effect on the metabolism of leukocites in vitro (2), suggesting thereby the possibility that such compounds may act as potential antileukemic and immunosuppressive drugs. Since 4-nitrobenzofuroxan readily formed Meisenheimer type σ-complexes with nucleophiles and since drug action was abolished by preincubation with aliphatic thiols, it was concluded (2) that drug action was related to σ-complex formation of 4-nitrobenzofuroxan with intracellular thiol groups (9–11).

Previous studies (12, 13) of the interaction of 4-nitrobenzofuroxan and methoxide ion in methanol and methanol–dimethylsulfoxide mixtures have shown that both a kinetically controlled C-5 σ-complex, **1** (X = OCH_3), and a thermodynamically controlled C-7 σ-complex, **2** (X = OCH_3), are formed rapidly at 25.0°C. Slow reactions following the formation of these σ-complexes were shown to result in the generation of 7-hydroxy-4-nitrobenzofurazan, **3** (as the anion), and the 7,7′-dimethoxy-4-nitrobenzofurazan σ-complex, **4** (X = OCH_3) (12). Possible reaction pathways for the formation of these secondary products



1



2

via the σ-complexes and the implications of these observations as regards to the proposed mode of drug action of this compound have been presented (12).

As part of a comprehensive study designed to obtain kinetic and thermodynamic data relating to σ-complex formation reactions in these systems

3

4

and to establish the generality of the combined deoxygenation of the *N*-oxide function and substitution of the aromatic hydrogen at C-7 by nucleophiles, we have investigated the reactions of 4-nitrobenzofuroxan with cyanide ion and isopropoxide ion in isopropanol. We report here the results of our kinetic studies.

Results and Discussion

Above 250 nm the ultraviolet–visible absorption spectrum of 4-nitrobenzofuroxan (4NBFO), in isopropanol as solvent, displays a single broad ab-

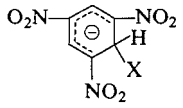
sorption band with absorption maximum at 408 nm ($\varepsilon = 8.50 \pm 0.05 \times 10^3\ M^{-1}\ cm^{-1}$).

The addition of progressively larger amounts of sodium isopropoxide (Na *i*-PrO) to solutions containing a fixed concentration of 4NBFO ($5.00 \times 10^{-4}\ M$) leads to a decrease in the absorption at 408 nm and the simultaneous appearance of two new absorption bands possessing absorption maxima at 338 and 275 nm. These two absorption bands were ascribed to the presence of a single new species, Y, in solution. Formation of Y was complete within the time required to mix the stock solutions of 4NBFO and Na *i*-PrO and record the spectrum of the resulting mixture (< 20 s). The extent of conversion of 4NBFO to Y was dependent on the concentration of *i*-PrO^- ion in solution; at 25.0°C the conversion was essentially complete after the addition of 10.5 molar equivalents of Na *i*-PrO to the system. Based on the formation of one molecule of Y per molecule of 4NBFO reacted, the molar absorptivity (ε) of Y at 338 nm was $1.30 \pm 0.05 \times 10^4\ M^{-1}\ cm^{-1}$. Throughout the course of the conversion of 4NBFO to Y, the spectra of the solutions displayed an isosbestic point at 372 nm.

Species Y was not stable for long periods of time at room temperature. Within several minutes of its formation, the addition of excess trifluoroacetic acid (CF_3COOH) to the solution rapidly and quantitatively regenerated 4NBFO. However, over a period of hours, Y apparently underwent additional reactions as indicated by the observations that the absorbances due to Y at 275 and 338 nm decreased in intensity and a new band (centered at 455 nm) slowly appeared in the visible region. The addition of excess CF_3COOH to solutions allowed to stand for a few hours at room temperature did not result in the complete regeneration of 4NBFO. Over still longer periods of time, the spectral changes observed in the reaction of 4NBFO and *i*-PrO^- ion in isopropanol closely paralleled those observed previously in the reactions of 4NBFO and methoxide ion in both methanol and methanol–dimethylsulfoxide mixtures (12).



For the reversible formation of species Y according to the equation

$$[1] \qquad 4NBFO + i\text{-}PrO^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Y$$

carried out under reaction conditions such that $[i\text{-}PrO^-]_0 \gg [4NBFO]_0$ ($[\ ]_0$ represents the total initial concentration), the k_{obs} obtained from the slope of the $\ln(A_\infty - A_t)$ or $\ln(A_t - A_\infty)$ versus time plots is related to the specific rate constants k_1 and k_{-1} and the $[i\text{-}PrO^-]_0$ as shown in eq: [2].

$$[2] \qquad k_{obs} = k_1[i\text{-}PrO^-]_0 + k_{-1}$$

At any given $[i\text{-}PrO^-]_0$ and temperature, k_{obs} values calculated using absorbance data recorded at 408 nm (disappearance of 4NBFO, $\ln(A_t - A_\infty)$ versus time plots) or absorbance data recorded at 338 nm or 275 nm (appearance of species Y, $\ln(A_\infty - A_t)$ versus time plots) were, within experimental error, equal. At a fixed temperature, plots of k_{obs} versus $[i\text{-}PrO^-]_0$ were strictly linear up to a $[i\text{-}PrO^-]_0$ of $3.2 \times 10^{-3}\ M$. Typical data are shown in Fig. 1 for the reactions of 4NBFO and *i*-PrO^- at 15.0, 25.0, and 35.0°C. The linearity of the k_{obs} versus $[i\text{-}PrO^-]_0$ plots strongly suggests that ion-pairing effects are not a problem at the concentrations of base employed in these studies. A similar absence of ion-pairing effects was noted previously in our studies of the reaction of 1,3,5-trinitrobenzene and isopropoxide ion to form σ-complex **5** (X = *i*-PrO) in isopropanol (14).

5

The slopes (k_1) and intercepts (k_{-1}) of the k_{obs} versus $[i\text{-}PrO^-]_0$ plots for the reaction of 4NBFO and *i*-PrO^- ion at 15.0, 25.0, and 35.0°C are given in Table 1. Values of K (k_1/k_{-1}) for the formation of Y are calculated to be 1.96×10^3, 2.43×10^3, and $3.01 \times 10^3\ M^{-1}$ at 15.0, 25.0, and 35.0°C, respectively. The magnitude of the calculated K at 25.0°C is completely in accord with the experimental observation that formation of Y is essentially complete at a $[i\text{-}PrO^-]_0/[4NBFO]_0$ ratio > 10.5. Plots of $\ln(k_1/T)$ versus $1/T$ and $\ln(k_{-1}/T)$ versus $1/T$ yielded the values of the activation parameters $\Delta H_1\dagger$, $\Delta S_1\dagger$, $\Delta H_{-1}\dagger$, and $\Delta S_{-1}\dagger$, respectively, listed in Table 2.

The reaction of 4NBFO and cyanide ion in isopropanol proceeded in two distinct fast steps sufficiently different in rate to enable a separate study of each step under available reaction conditions. The sequence of spectral changes described below was independent of whether the source of CN^- ions was ϕ_4AsCN, KCN plus an equimolar amount of 18-crown-6 or $(C_2H_5)_4NCN$.

The first stage in the reaction was, in many respects, similar to the fast reaction between 4NBFO and *i*-PrO^- described above. Thus, for solutions containing a fixed concentration of 4NBFO ($5.00 \times 10^{-4}\ M$), the addition of progressively larger amounts of ϕ_4AsCN leads to the disappearance of the absorption band at 408 nm and the simultaneous appearance of a new absorption band with absorption maximum at 340 nm. (A new absorption band with λ_{max} at 275 nm was not observed in these studies due to strong absorption of ϕ_4AsCN in this

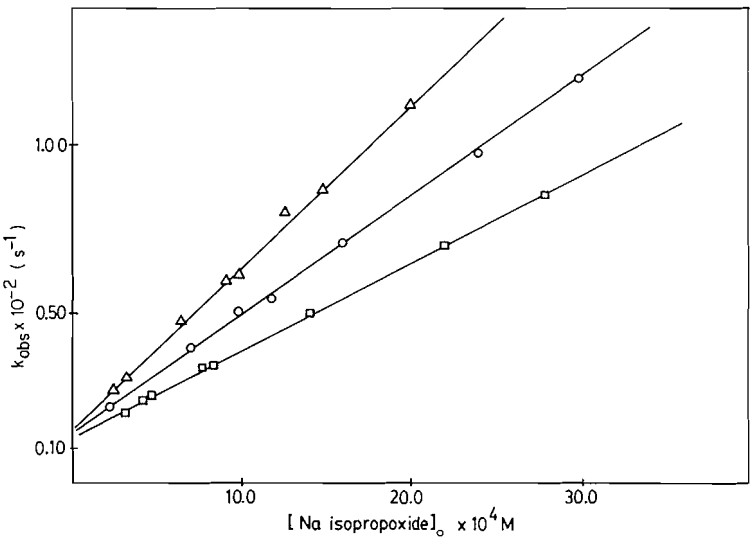


FIG. 1. Plot of k_{obs} versus concentration of isopropoxide ion for the σ-complex formation reactions between 4-nitrobenzofuroxan and isopropoxide ion in isopropanol at 15.0 (□), 25.0 (○), and 35.0°C (△).

TABLE 1. Specific rate constants for the reactions of 4-nitrobenzofuroxan with isopropoxide ion and cyanide ion in isopropanol[a]

	k_1 (M^{-1} s^{-1})		k_{-1} (s^{-1})

[a] k_1 and k_{-1} values obtained from the slopes and intercepts of the k_{obs} versus $[base]_o$ plots. In the 4-nitrobenzofuroxan – cyanide ion system only points at low $[CN^-]_o$ were used to evaluate k_1.

region). Formation of the species absorbing at 340 nm was again rapid, i.e. complete within the time required to mix the reagents and record the spectrum of the resulting solution. The extent of conversion of 4NBFO to the new absorbing species was dependent on the concentration of CN^- ion in solution with conversion being essentially complete upon the addition of 1.1 molar equivalents of ϕ_4AsCN to the solution. Based on a 1:1 conversion of 4NBFO to the new absorbing species the molar absorptivity (ε) of the new species at 340 nm was $1.30 \pm 0.05 \times 10^4$ M^{-1} cm^{-1}. Throughout the course of the conversion of 4NBFO to this new species, the uv–visible spectra of the solutions displayed an isosbestic point at 373 nm. Within several seconds of the complete conversion of 4NBFO to the species whose λ_{max} occurred at 340 nm, the addition of excess CF_3COOH or *p*-toluenesulphonic acid (PTSA) to the solution resulted in the rapid, quantitative regeneration of 4NBFO.

Following closely on the heels of this initial, fast, reaction was a somewhat slower (though still fast) reaction that led to a decrease in the absorption at 340 nm and the appearance of a new, very broad absorption band in the visible whose λ_{max} occurred at 540 nm. Associated with this second reaction was a color change of the solutions from colorless to purple. Based on the formation of one mole of this colored species per mole of 4NBFO reacted, the molar absorptivity (ε) of this colored species at 540 nm was 8.80×10^3 M^{-1} cm^{-1}. Once the absorbance at 540 nm was fully developed, the addition of excess CF_3COOH or TPSA to the solutions rapidly discharged the purple color of the solutions but did not quantitatively regenerate 4NBFO. The species whose absorption maximum occurred at 540 nm was also unstable at room temperature as evidenced by the fact that the absorption maximum of a solution containing this species slowly shifted to shorter wavelengths. The final product(s) of this reaction has (have) not yet been identified.

In the kinetic studies described below ϕ_4AsCN, KCN plus an equimolar amount of 18-crown-6 and $(C_2H_5)_4NCN$ were all utilized as sources of cyanide ion. The majority of the studies were carried out using ϕ_4AsCN.

At any given temperature and $[CN^-]_0$, k_{obs} values for the first reaction, calculated using absorbance data recorded at 408 nm (disappearance of 4NBFO) and absorbance data recorded at 340 nm (appearance of the new absorbing species) were, within experimental error, equal. For a specified $[CN^-]_0$, k_{obs} values were, within experimental error, independent of the source of the cyanide ion and, in runs using ϕ_4AsCN as a source of cyanide ion, independent of the total ionic strength of the solu-

TABLE 2. Kinetic and thermodynamic parameters for the formation of some σ-complexes of 4-nitrobenzofuroxan and 1,3,5-trinitrobenzene in isopropanol at 25.0°C[a]

Parameter	Value			
	2 (X = *i*-PrO)	**2** (X = CN)	**5** (X = *i*-PrO)[b]	**5** (X = CN)[c]
k_1 (M^{-1} s^{-1})	3.53×10^4	2.74×10^2	9.67×10^4	2.45×10^3
k_{-1} (s^{-1})	14.5	<0.01	1.7	0.048
k_1/k_{-1} (M^{-1})	2.43×10^3	$>2.74 \times 10^4$	5.6×10^4	5.1×10^4
$\Delta H_1\dagger$ (kJ mol^{-1})	20.9 ± 2.1	36.8 ± 2.5	24.3 ± 1.7	49.0 ± 2.1
$\Delta S_1\dagger$ (J mol^{-1} K^{-1})	-87.4 ± 4.6	-75.7 ± 6.7	-49.0 ± 5.9	-5.0 ± 5.9
$\Delta H_{-1}\dagger$ (kJ mol^{-1})	5.14 ± 3.3	—	66.9 ± 4.2	78.7 ± 5.4
$\Delta S_{-1}\dagger$ (J mol^{-1} K^{-1})	-205 ± 18	—	-8.4 ± 15.0	11.7 ± 14.2

[a]Error limits for $\Delta H\dagger$ values are based on the maximum and minimum slopes obtained in plots of log (k/T) versus $1/T$. Errors in $\Delta S\dagger$ are based on the maximum and minimum intercepts obtained, at $1/T = 0$, in plots of log (k/T) versus $1/T$.
[b]Data from ref. 14.
[c]Data from ref. 15.

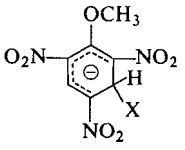
tion up to a $\mu = 5.02 \times 10^{-3}$ M (μ maintained constant with ϕ_4AsNO_2). Plots of k_{obs} versus $[CN^-]_0$ were linear at low concentrations of CN^- ion but curved slightly upwards at higher concentrations of CN^- ion. This curvature seemed to become more pronounced the higher the temperature. Similar observations relating to the dependence of k_{obs} on $[CN^-]_0$ have been noted previously in connection with the reactions of cyanide ion with 1,3,5-trinitrobenzene and 2,4,6-trinitrotoluene in isopropanol (15).

The slopes (k_1) of the k_{obs} versus $[CN^-]_0$ plots (obtained at low concentrations of cyanide ion) for the reactions of 4NBFO and CN^- at 15.0, 25.0, and 35.0°C are listed in Table 1. Values of the intercepts in the k_{obs} versus $[CN^-]_0$ plots were too small to permit an accurate evaluation of k_{-1} values at these temperatures. Based on an estimated value of K at 25.0°C of $>10^5$ M^{-1}, k_{-1} can be estimated to be $<10^{-3}$ at 25.0°C. A plot of $\ln(k_1/T)$ versus $1/T$ yielded the activation parameters $\Delta H_1\dagger$ and $\Delta S_1\dagger$ listed in Table 2.

At a given temperature and $[CN^-]_0$, k_{obs} values for the slow reaction, calculated using absorbance data recorded at 540 nm, were found to be independent of the source of the CN^- ion and, in runs utilizing ϕ_4AsCN as a source of CN^- ion, unaffected by changing the ionic strength up to a maximum μ of 5.02×10^{-3} M. Plots of k_{obs} for the slow reaction versus $[CN^-]_0$ were found to be strictly linear over the entire range of CN^- concentrations employed (5.02×10^{-3} M). The slopes (k_1^{slow}) of the k_{obs} versus $[CN^-]_0$ plots were 5.3×10^1, 1.09×10^2, and 2.25×10^2 M^{-1} s^{-1} at 15.0, 25.0, and 35.0°C, respectively. A plot of $\ln(k_1^{slow}/T)$ versus $1/T$ yielded values of $\Delta H_1\dagger$ and $\Delta S_1\dagger$ for the slow reaction of 53.1 ± 2.1 kJ mol^{-1} and -36.0 ± 5.9 J mol^{-1} K^{-1}, respectively.

Based on our previous ^1H nmr and uv–visible spectroscopic studies of the 4NBFO – methoxide ion reaction in methanol and methanol–dimethylsulfoxide mixtures (12), the species formed rapidly and reversibly as a result of the interactions of 4NBFO with *i*-PrO^- ion (λ_{max} 338 nm) and CN^- ion (λ_{max} 340 nm) in isopropanol are formulated as the σ-complexes **2** (X = *i*-PrO and CN), respectively. We have obtained no kinetic or spectroscopic evidence to suggest the formation of a C-5 σ-complex **1** (X = *i*-PrO or CN) in either system. However, in each case, a complex of this type could be formed more rapidly ($t_{1/2} < 1$ ms) and at low concentrations prior to the formation of the corresponding C-7 σ-complex and not be detected under our experimental conditions. We note that a species possessing a λ_{max} at 335 nm is also formed rapidly in the reaction of 4NBFO and sulfite ion in either water (at pH 8.5) or ethanol. On the addition of excess TFA acid or PTSA this species is rapidly and quantitatively converted to 4NBFO (16).

The markedly different spectra associated with the final reaction mixtures in the 4NBFO – cyanide ion and 4NBFO – isopropoxide ion interactions clearly indicate that different reaction products are formed in the two systems. We note that the final spectra observed in the reactions of 4NBFO and CN^- ion in isopropanol are very similar to the spectra generated in the initial, rapid, reversible reactions of cyanide ion and 4-nitrobenzofurazan in polar, aprotic solvents (17). The stoichiometries and structures of the colored species giving rise to these spectra have yet to be established.



It is of interest to compare the specific rate constants and activation parameters for the formation of σ-complexes **2** (X = *i*-PrO) and **5** (X = *i*-PrO) and **2** (X = CN) and **5** (X = CN) in isopropanol. The specific rate constant for the formation of **2** (X =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

i-PrO) at 25.0°C is approximately one-third the specific rate constant for the formation of **5** (X = *i*-PrO) at 25.0°C. Since values of $\Delta H_1\dagger$ for the two reactions are comparable, the difference in k_1 values is related primarily to a difference in values of $\Delta S_1\dagger$. The more negative value of $\Delta S_1\dagger$ observed in the formation of **2** (X = *i*-PrO) suggests that ordering of solvent in going from reactants to the activated complex associated with formation of σ-complex is greater in the 4NBFO–*i*-PrO^- reaction than in the TNB–*i*-PrO^- reaction. Since desolvation of *i*-PrO^- is expected to be comparable in both reactions, the implication of the difference in $\Delta S_1\dagger$ values is that σ-complex **2** (X = *i*-PrO) is itself more strongly solvated than σ-complex **5** (X = *i*-PrO). Some support for this suggestion comes from a consideration of comparable data relating to the formation of **2** (X = CN) and **5** (X = CN). In this case k_1 for formation of **2** (X = CN) at 25.0°C is approximately one-tenth the k_1 for formation of **5** (X = CN) at this temperature. Although $\Delta H_1\dagger$ for the formation of **2** (X = CN) is somewhat less than $\Delta H_1\dagger$ for the formation of **5** (X = CN), this factor is outweighed by the $\Delta S_1\dagger$ value for the formation of **2** (X = CN) being far more negative than the $\Delta S_1\dagger$ for the formation of **5** (X = CN). Again, if one accepts that desolvation of the anion should proceed to comparable extents in both reactions, more extensive solvation of the activated complex leading to **2** (X = CN), than the activated complex leading to **5** (X = CN) is indicated. Further discussion of solvent effects clearly requires knowledge concerning enthalpies of solution of both TNB and 4NBFO in isopropanol.

Comparisons of the available kinetic data (15) suggest that, in terms of solvational changes, **2** (X = CN) and **6** (X = CN) might be far more comparable systems than **2** (X = CN) and **5** (X = CN). Unfortunately, no data are yet available for the formation of **6** (X = *i*-PrO) in isopropanol.

6

The curvature in the k_{obs} versus $[CN^-]_0$ plots observed in 1,3,5-trinitrobenzene–CN^- and 2,4,6-trinitrotoluene–CN^- ion interactions was ascribed to the operation of a weak stabilizing effect associated with the interaction of ϕ_4As^+ with the nitro groups or with the π-electron system of the substrate in the activated complex (15). A similar explanation might be invoked to explain the slight curvature in the k_{obs} versus $[CN^-]_0$ plots observed for the fast reaction between 4NBFO and CN^- ion. However, the observation that at a given $[CN^-]_0$, ϕ_4AsCN, KCN plus 18-crown-6 and $(C_2H_5)_4NCN$ all yield the same k_{obs} suggests that ϕ_4As^+, the 18-crown-6-K^+ complex and $(C_2H_5)_4N^+$ are all equally effective in stabilizing the activated complex for σ-complex formation. This seems rather unlikely in view of the rather different charge densities associated with these three cations. Further detailed studies of cation effects on the rates of reaction of CN^- ion with 4NBFO and the solubility of 4NBFO in isopropanol as a function of the concentration of ϕ_4AsCN and related salts are planned in order to shed more light on the reasons for the observed dependence of k_{obs} on cation concentration.

Experimental

Reagents

4-Nitrobenzofuroxan was prepared as described by Ghosh (3) (method B), mp 143°C.

Tetraphenylarsonium cyanide was prepared as previously described (18) and dried to constant weight *in vacuo* over phosphorus(V) pentoxide. Tetraphenylarsonium nitrite was prepared in a similar fashion but using sodium nitrite in place of sodium cyanide in both the initial preparation and the recrystallization procedures. After two recrystallizations the compound was dried to constant weight *in vacuo* over phosphorus(V) pentoxide.

Tetraethylammonium cyanide was prepared according to the method outlined by Andreades and Zahnow (19). After two recrystallizations from acetonitrile the compound was dried to constant weight *in vacuo* over phosphorus(V) pentoxide.

18-Crown-6 was used as received from PCR Research Chemicals, Inc.

All other reagents used in the study were A.R. grade or better.

Fisher Certified ACS isopropanol was normally dried by refluxing over Linde 4 Å Molecular Sieve overnight and then distilled under a dry nitrogen atmosphere. Only the middle portion of the distillate was retained. No discernible differences in rate constants were observed in those instances in which the preliminary drying of the isopropanol was effected according to Vogel's procedure (20).

Stock solutions of sodium isopropoxide were prepared by adding freshly cut sodium metal, pre-washed in dry isopropanol, to pure solvent maintained in an atmosphere of dry nitrogen. Solutions thus prepared were stored under nitrogen and standardized immediately before use by titration with 0.100 *M* HCl to the phenolphthalein end point. Stock solutions of sodium isopropoxide were usually 0.05 to 0.10 *M* in concentration. Solutions of lower concentration were prepared by dilution.

Stock solutions of 4-nitrobenzofuroxan and the various cyanide ion-containing salts were prepared by dissolving weighed quantities of each reagent in a known volume of isopropanol. Solutions of lower concentrations, used in the kinetic and equilibrium studies, were prepared by dilution.

Instruments

Ultraviolet–visible absorption spectra were obtained using Cary 14 and Unicam SP-1700 spectrophotometers and matched silica cells of 1.0 cm path length. The sample compartments of both spectrophotometers were kept at a constant temperature by circulating water from a constant temperature water bath through specially designed cell holders.

Kinetic measurements were carried out on a Durrum–Gibson stopped-flow spectrophotometer. A closed circuit temperature control system utilizing an Ultra Kryomat TK30D constant temperature bath kept the temperature in the valve-block, drive syringes and observation cell constant to within ±0.1°C. A stopped-flow cell of 2.0 cm path length and minimum "dead time" of 2 ms was used in all the kinetic runs.

Procedure

All kinetic runs were carried out with base in large excess over 4NBFO. Concentrations of 4NBFO varied from 1.0×10^{-5} to 7.0×10^{-5} *M*. Concentrations of *i*-PrO^- varied from 6.0×10^{-4} to 60.0×10^{-4} while concentrations of CN^- ion varied from 3.0×10^{-4} to 50.0×10^{-4} *M*. The ionic strength of the reaction mixtures was not maintained constant except as indicated.

Changes in concentration of 4NBFO were followed by means of the absorbance at 408 nm. Pseudo-first-order rate constants (k_{obs}) were obtained from the slopes of the $\ln(A_t - A_\infty)$ versus time plots where A_∞ and A_t refer to absorbances at times infinity and t respectively. Plots were normally linear to approximately 80% completion of the reaction. Individual k_{obs} values were reproducible to ±3% in the reaction of 4NBFO and isopropoxide ion and to ±5% in the reaction of 4NBFO and cyanide ion. Changes in concentration of σ-complex were followed by means of the absorbances at 338 and 275 nm (4NBFO–isopropoxide) and 340 (4NBFO–CN^-). In these cases pseudo-first-order rate constants were obtained from the slopes of $\ln(A_\infty - A_t)$ versus time plots.

Solution properties of the molten hydrates of zinc nitrate

SURENDER KUMAR JAIN[1] AND REITA TAMAMUSHI
The Institute of Physical and Chemical Research, Wako-shi, Saitama – 351, Japan

Received November 15, 1979

SURENDER KUMAR JAIN and REITA TAMAMUSHI. Can. J. Chem. **58**, 1697 (1980).

Density, conductivity, viscosity, refractive index, and surface tension of the molten $Zn(NO_3)_2 \cdot xH_2O$ ($2 \leq x \leq 6$) systems have been measured as a function of temperature. Both conductivity and fluidity exhibit a non-Arrhenius temperature dependence for all the compositions and have been described in terms of three parameter equations

$$Y(\Lambda, \phi) = A_Y T^{-1/2} \exp[-B_Y/(T - T_{0,Y})]$$
$$Y(\Lambda, \phi) = A_Y' \exp[-B_Y'/(V - V_{0,Y})]$$

based on the free volume model. The parameters $A_Y, A_Y', B_Y, B_Y', T_{0,Y}$, and $V_{0,Y}$ are the constants characteristic of the medium. The composition dependence of these parameters has been discussed. The temperature dependence of the Walden's product could be satisfactorily described by the equation

$$\Lambda\eta^p = \text{constant}$$

where p equals the ratio E_Λ/E_ϕ; E_Λ and E_ϕ being the apparent activation energy for the conductance and the viscous flow respectively. The molar polarisations (P_{LL}) computed using the Lorenz–Lorentz equation showed a slight temperature variation (< 0.2%) over the range 40–70°C. Thermal expansivity (α) and the ratio α/α_{GD} for the systems show a continuous fall with the decrease in the water content of the medium; the changes becoming more marked at $x < 4$. The surface tension – composition isotherms show a maximum near $x = 4$. The results are consistent with the change of configuration from octahedral to tetrahedral around Zn^{2+}, the increased covalent character in the Zn^{2+}—ONO_2^- bond and the water molecule acting as a bridging ligand in the melts containing less than 4 moles of water per mole of the salt.

SURENDER KUMAR JAIN et REITA TAMAMUSHI. Can. J. Chem. **58**, 1697 (1980).

On a mesuré en fonction de la température, la densité, la conductivité, la viscosité, l'indice de réfraction et la tension superficielle des systèmes $Zn(NO_3)_2 \cdot H_2O$ ($2 \leq x \leq 6$) à l'état fondu. La relation entre la conductivité et la fluidité d'une part et la température d'autre part ne correspond pas à la théorie d'Arrhénius pour toutes les compositions et on les a décrit selon des équations à trois paramètres basées sur le modèle de volume libre

$$Y(\Lambda, \phi) = A_Y T^{-1/2} \exp[-B_Y/(T - T_{0,Y})]$$
$$Y(\Lambda, \phi) = A_Y' \exp[-B_Y'/(V - V_{0,Y})]$$

Les paramètres $A_Y, A_Y', B_Y, B_Y', T_{0,Y}$ et $V_{0,Y}$ sont des constantes caractéristiques du milieu. On discute de l'effet de la composition sur ces paramètres. L'effet de la température sur les produits de Walden pourrait être décrit de façon satisfaisante par l'équation

$$\Lambda\eta^p = \text{constant}$$

où $p = E_\Lambda/E_\phi$; E_Λ et E_ϕ étant respectivement l'énergie d'activation apparente de la conductance et de l'écoulement visqueux. Les polarisations molaires (P_{LL}) calculées en utilisant l'équation de Lorenz–Lorentz indiquent une légère variation de la température (<0.2%) dans l'intervalle de 40–70°C. La dilatation thermique (α) et le rapport α/α_{GD} des systèmes diminuent continuellement avec la teneur en eau du milieu; les variations deviennent plus importantes pour $x < 4$. La tension superficielle isotherme de composition montre un maximum près de $x = 4$. Les résultats sont en accord avec un changement de configuration allant de octaédrique à tétraédrique autour de Zn^{2+}, l'augmentation du caractère covalent de la liaison Zn^{2+}—ONO_2^- et la molécule d'eau agissant comme ligand en position de pont dans les sels fondus contenant moins de 4 moles d'eau par mole de sel.

[Traduit par le journal]

Introduction

In the past few years the investigation of physico-chemical properties of the hydrated melts has attracted a good deal of attention. Of particular interest are the studies (1–9) of hydrated melts containing multivalent cations, such as Ca^{2+} and Mg^{2+}. Recently, Jain (10–15) has reported some physico-chemical measurements on a number of the molten hydrated nitrates of the metals belonging to the 3*d* series of transition elements. These studies were carried out at concentrations where sufficient water was present to fill the first or even the second (partially) coordination sphere of the cations. Solution properties of such systems at very low water content, insufficient even to fill the first coordination sphere where competitive solvation of cations and anions and the interionic interactions are expected to greatly influence the solution properties, have not been investigated. The solubility studies (16–18) indicate that the zinc nitrate – water system can be very conveniently studied up to

≃82% (by weight) of the salt concentration. Recently, the vibrational spectral studies of zinc nitrate – water system up to such high salt concentrations have been reported by Sze and Irish (19). For our interest in the solution properties at such high concentrations, we present some physico-chemical properties of this system with a view to see if there existed some correlation between the solution properties and the spectral studies.

Experimental

Material

Analytical grade (Wako Chemical Ind., Japan) hexahydrate of zinc nitrate was used in the study. The hexahydrate salt was fused in an airtight flask, maintained slightly above its melting temperature for a few hours, and then filtered through glass filter (porosity G-3). The filtered melt was then kept at ≃60°C for 2–3 h for maturing. On analysis the water content of the melt was found to correspond to a stoichiometry 6.01 ± 0.03. The melts with lower water contents were prepared by removing a calculated amount of water from the weighed quantity of the hexahydrate melts by continuous evacuation at ≃50°C. All the melts were transparent in the molten state.

Measurements

Densities were measured by measuring the volume of a known amount of the melt by using a precalibrated densitometer. The densitometer design, its calibration, and the measuring technique were similar to those reported earlier (9). The reported results are estimated to be accurate to ±0.1%.

Viscosities were measured with Ubbelohde type viscometers calibrated with aqueous solution of glycerol. The viscometer constants were 0.2352 and 0.08196 cP s^{-1} (1 cP = 10^{-3} N m^{-2} s). Inherent accuracy of these values is estimated to be better than ±0.5%.

The conductivity of the melts was measured by employing the four-electrode cell method. The details about the circuit design and the operational usefulness of this method have been described earlier (20). The cell resistance was observed to be independent of frequency over the range 10–1600 Hz. The reported results correspond to the measurements made at 1 kHz. The expected accuracy of the results is ±0.3%.

The refractive indices were measured on an Abbe type (Erma, Tokyo) refractometer, whose prisms were maintained at the highest (70°C) temperature by circulating water from a constant temperature bath through the prism compartments. A drop of the melt was directly placed onto the lower prism and the prisms were immediately clamped into the position and the measurement was made. The measurements were continued on the descending temperature scale at an interval of 10 deg, until the crystallization. The values were reproducible to ±0.0002.

The surface tensions were measured by the differential capillary rise method, as described earlier (11). The reported values are estimated to be accurate to ±0.5%.

The density, viscosity, and the conductivity measurements were carried out simultaneously in the same constant temperature bath (capacity 20 dm^3) and the temperatures were controlled and measured to ±0.1°C.

All measurements reported here were begun at high temperature and carried out downwards. At each temperature the constancy of the cell resistance for ≃10 min was taken as proof for the thermal equilibrium between the melt and the bath liquid. Reproducibility of results in heating and cooling cycles was taken as evidence that there was no appreciable loss of water during experiment.

Results and Discussion

Concentration Units

For the present results the compositions are expressed in terms of the water:salt mole ratios, designated as x. The normality (N) unit, which defines the concentration of electrostatic charge in equivalents per litre of the solution, has also been used for the interpretation of the present results. The normalities (at 60°C) corresponding to each x value are shown in Table 1.

Density and Equivalent Volume

The densities (ρ) and equivalent volumes (V_e) of the molten $Zn(NO_3)_2 \cdot xH_2O$ system corresponding to x ranging from 2.02 to 6.01 varied linearly with temperature and could be satisfactorily described by the equations

$$[1] \qquad \rho(\text{g cm}^{-3}) = a - bt(^\circ\text{C})$$

$$[2] \qquad V_e(\text{cm}^3 \text{ equiv.}^{-1}) = A + Bt(^\circ\text{C})$$

respectively. The coefficients a, b, A, and B are presented in Table 1. The present value of 82.4 cm^3 equiv.$^{-1}$ for V_e (at $x = 6.01$ and at 50°C) compares well with the value 82.0 cm^3 equiv.$^{-1}$, for $x = 6.00$, reported earlier (11). The density and equivalent volume at any temperature varied systematically with the changes in the water-to-salt mole ratio, and could be described by a second degree polynomial in x. The coefficients of the least-squares equations are presented in Table 2. The expansivities (α) expressed as

$$[3] \qquad \alpha = (1/V_e)\,(dV_e/dT)_p$$

show a regular decrease with the decrease in the water content of the medium; the decrease being more marked at water-to-salt mole ratios less than 4. This may be due to an increase in the electrostriction of the melt arising out of the increased effective electrostatic charge concentration (N) in the medium. Alternatively, because the total ligand concentration ($H_2O + NO_3^-$) is insufficient to allow a six coordination at these concentrations, this effect thus may be due to a configurational change from octahedral to tetrahedral coordination around Zn^{2+} ion. The spectral studies of Sze and Irish (19) on the zinc nitrate – water systems appear to support the latter possibility.

Conductivity and Fluidity

The conductivities and fluidities of the molten $Zn(NO_3)_2 \cdot xH_2O$ systems exhibited a non-Arrhenius temperature dependence and could be adequately described in terms of the equation

$$[4] \qquad Y(\Lambda, \phi) = A_Y T^{-1/2} \exp\left[-B_Y/(T - T_{0,Y})\right]$$

based on the free volume model of Cohen and Turnbull (21) or the cooperative rearrangement theory of Adam and Gibbs (22). The terms A_Y, B_Y, and $T_{0,Y}$ are constants characteristic of the system. The parameter $T_{0,Y}$ has been interpreted as theoretical glass transition temperature and its thermodynamic nature has been discussed by Cohen and Turnbull (21), Adam and Gibbs (22), and Angell and Rao (23). The exponential coefficient B_Y according to Adam and Gibbs (22) is expressed as

$$[5] \qquad B_Y = N_L \Delta\mu S_c^*/R\Delta C_p$$

where N_L is Avogadro's number, S_c^* is the minimum configurational entropy per particle required for a mass transporting rearrangement, $\Delta\mu$ is a free-energy barrier opposing the rearrangements, and ΔC_p is the change in heat capacity of the liquid at the glass transition. In view of the suggestion that the changes in $\Delta\mu$ from system to system may be offset, at least partially, by parallel changes in ΔC_p, it appears reasonable to consider B_Y to be composition independent. This empirical rule has been found to hold good for a large variety of the molten salt systems and concentrated electrolyte solutions (1, 3, 14, 15, 24–28). However, for $Ca(NO_3)_2 + H_2O$ system (29, 30) the parameter B_Y has been observed to vary systematically with composition. The present data accordingly were fitted into eq. [4] with all three parameters (A_Y, B_Y, and $T_{0,Y}$) as adjustable parameters. This method of data analysis did not give any meaningful composition dependence of these parameters. This might be due to the limited amount of the present data, and a strong interdependence of these parameters. It is probable that some clear and meaningful composition dependence of B_Y in the present system might become evident if extensive measurements are made with a sufficiently high precision. Under the circumstances, the present conductivity and fluidity data were fitted into [4], at near universal values of B_Λ (= 590 K) and B_ϕ (= 675 K). The best fit parameters are presented in Tables 3 and 4. For each process, the parameter $T_{0,Y}$ has a similar composition dependence and differs by ≃1 K in their absolute value. The experimental glass transition temperatures (T_g's) for some compositions were

estimated from the work of Angell and Sare (31) and are included in Table 3. Somewhat lower values for $T_{0,Y}$'s relative to T_g' are expected because of the long relaxation times encountered in the measurement of the latter quantity. A similar composition dependence of $T_{0,Y}$'s and T_g's confirms the belief that both are governed by similar forces; the electrostatic charge concentration being the most important (31). Figure 1 shows the variation of $T_{0,Y}$ and T_g with the normality (N) of the melt. The curvature in $T_{0,Y}$ vs. N plot can be interpreted as due to the increased penetration of the NO_3^- ion into the coordination sphere of the hydrated zinc ion, thereby resulting in a partial neutralization of the cationic charge and hence the effective electrostatic charge concentration. The presence of the bands at 750 and 760 cm^{-1} and the intensity analyses of the 950–1150 and 1150–1600 cm^{-1} regions in the Raman spectra (19) of the $Zn(NO_3)_2 \cdot xH_2O$ melts at low water content ($x < 4$) also indicate the increased interactions of the NO_3^- with Zn^{2+} at these concentrations.

The parameters A_Λ and A_ϕ show a regular decrease with a decrease in the water content of the medium. Obviously, the variations are in the reverse directions to that predicted by theory (21). Similar composition dependence of A_Λ's and A_ϕ's has also been observed earlier (14, 15, 32). The possibility that A_Y varies inversely with the rigidity of the medium (15) appears to be rather more convincing in light of the present results. However, the suggestion (32) that this discrepancy between

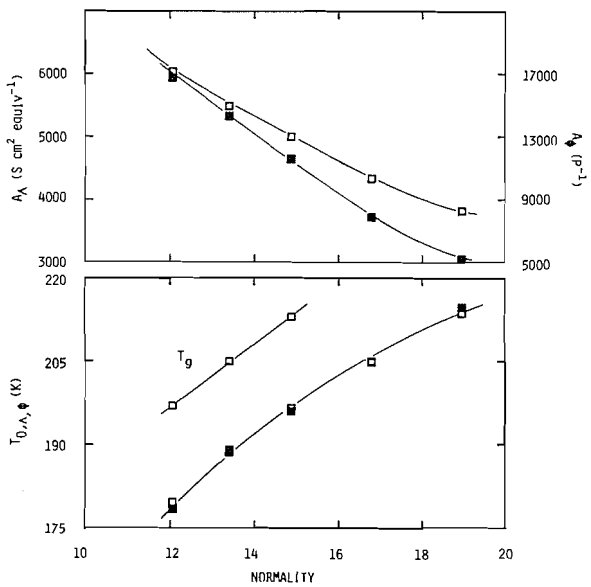

FIG. 1. The plots showing the variation of the parameters $T_{0,\Lambda}$ (■), $T_{0,\phi}$ (□), T_g, A_Λ (■), and A_ϕ (□) with the normality (N, at 60°C) for $Zn(NO_3)_2 \cdot xH_2O$ melts.

For personal use only.

the theory and experiment regarding the composition dependence of the pre-exponential coefficient (A_Y) may be related to the differences in the lability of water or nitrate ion in the coordination sphere of the cation also appears reasonable for the present system.

The Doolittle equation (33) in the form

[6] $$Y(\Lambda, \phi) = A_Y' \exp[-B_Y'/(V - V_{0,Y})]$$

has been found successful in describing the free volume (hence temperature) dependence of the transport properties (Λ and ϕ) of the present system. The terms A_Y' and B_Y' are empirical parameters, V is the molar volume at the temperature of property Y, and $V_{0,Y}$ is the intrinsic volume, i.e., the molar volume at the ideal glass transition temperature. The computed $V_{0,Y}$'s for the two processes (Tables 3 and 4) are almost equal and vary in the same fashion with composition. Like other systems (15, 27) here too, the intrinsic volumes are found to be nearly equal to the molar volumes at $T_{0,Y}$, obtained by extrapolation of the equation

[7] $$V(\text{cm}^3\ \text{mol}^{-1}) = \alpha + \beta(T - 273.15)$$

This is consistent with the view (21) that it is the region above $T_{0,Y}$ (K) and not 0 (K) which is of significance to the transport processes in such liquids.

A typical variation of Λ and ϕ (at 70°C) is shown as a function of normality (N) in Fig. 2. For the same change in concentration, the fluidity changes more rapidly than the conductivity. These variations in the magnitude of the transport properties are consistent with the changes postulated above. Low fluidities of the melts containing low water content ($x < 4$) may also arise owing to water molecules acting as bridging ligands at these concentrations. The intensity analysis of the Raman bands in the region 950–1150 cm^{-1} for $Zn(NO_3)_2 \cdot xH_2O$ melts of these concentrations led Sze and Irish (19) to postulate such a possibility at higher concentrations.

The log $\Lambda(\phi)$ vs. $1/N$ plots were curved. An attempt to describe the present results in terms of the equations (3)

[8] $$Y_T(\Lambda, \phi) = A_Y'' \exp[-B_Y''/(N_{0,Y} - N)]$$

yielded a value of ≃44 equiv. dm^{-3} for $N_{0,Y}$ (at 60°C), the limiting concentration at which $T_{0,Y}$ (K) equals the isothermal temperature, T (K). This value obviously is very high when compared with the charge concentration of ≃24.7 equiv. dm^{-3} in the anhydrous melt containing $KNO_3 + Ca(NO_3)_2$ (55:45), for which a value of 330 K (= 57°C) for T_0 has been reported (25).

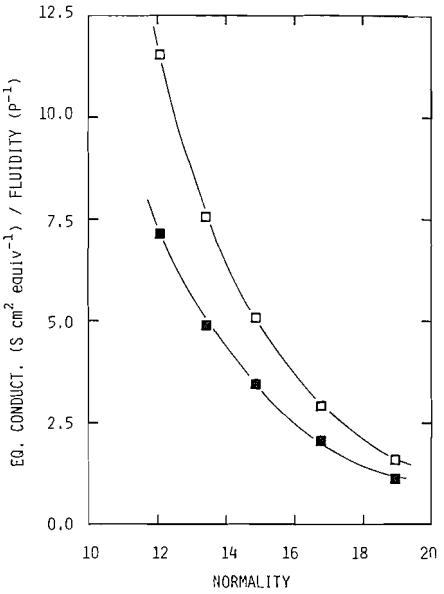

FIG. 2. Variations in the conductivity (■) and fluidity (□) values with the normality for the $Zn(NO_3)_2 \cdot xH_2O$ melts at 70°C.

The temperature dependence of Walden's product ($\Lambda\eta$) has been satisfactorily described by the equation (34)

[9] $$\Lambda\eta^p = \text{constant}$$

The computed parameters for the present system are recorded in Table 5. The value of p, which remains fairly constant at 0.87 ± 0.02, equals the average value of the ratio E_Λ/E_ϕ; E_Λ and E_ϕ being the apparent activation energy for the conductance and the viscous flow respectively.

Refractive Index

The refractive index (n) for all the compositions varied linearly with temperature. The n–t (°C) equations are presented in Table 6. The refractive index – x isotherms could be adequately described by a second degree polynomial in x. The corresponding equations are given in Table 7.

The molar polarisations at 60 and 40°C were calculated using the Lorenz–Lorentz equation

[10] $$P_{LL}(\text{cm}^3\ \text{mol}^{-1}) = [(n^2 - 1)/(n^2 + 2)]V$$

in which V is the molar volume. The calculated values are included in Table 6. The molar polarisation – composition (x) isotherms are given in Table 7. The P_{LL} values show a slight (< 0.2%) variation over the range 40–60°C. A systematic decrease in the temperature coefficient of P_{LL} with decreasing x values is worth noting. As a first approximation if this variation of P_{LL} with temperature is ignored, the expansivities of these melts may be calculated from the temperature coefficient of the refractive index and the differential forms of the Gladstone–Dale and the Lorenz–Lorentz equations, through the expressions (35)

$$[11] \quad \alpha_{GD} = [1/(n-1)]dn/dT$$

$$[12] \quad \alpha_{LL} = [6n/(n^2-1)(n^2+2)]dn/dT$$

The computed values of α_{GD} and α_{LL} are included in Table 6; α_{LL} always being smaller than α_{GD}. The ratio α/α_{GD} continues to decrease with the decrease in the water content of the medium. The values lower than 1 for the ratio α/α_{GD} are interpreted as a reflection of the increased covalent character in the Zn^{2+}–NO_3^- bonding. The appearance of 285 cm^{-1} Raman band in the spectra of zinc nitrate – water melts, below $x = 4$, has been ascribed by Sze and Irish (19) to the increased covalent character in the Zn^{2+}–ONO_2^- bond.

Surface Tension

The surface tension (σ) – temperature data were fitted into the equation

$$[13] \quad \sigma \text{ (mN m}^{-1}) = p - qt(°C)$$

The coefficients p and q are given in Table 8. The composition dependence of surface tension at 40 and 60°C is shown in Fig. 3. The corresponding

x	Data points	Temperature range (°C)	σ(mN m^{-1}) $= p - qt$(°C) p	$10q$	SE
6.01	2	40–60	93.80	1.08	—
5.02	3	40–70	98.47	1.76	0.4
4.06	3	50–70	100.98	1.91	0.04
3.07	3	50–70	95.78	1.11	0.1
2.02	2	60–70	93.60	0.94	—

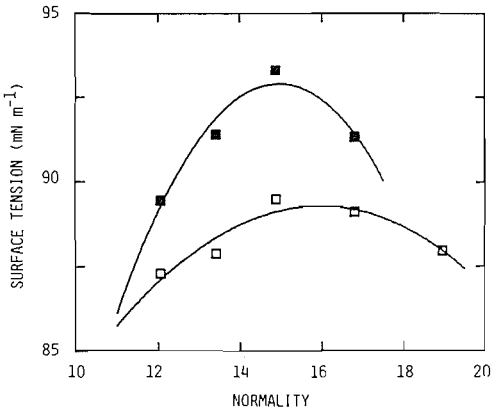

FIG. 3. Variation of the surface tension values with the normality for the $Zn(NO_3)_2 \cdot xH_2O$ melts; 60°C (□) and 40°C (■).

equations are tabulated in Table 9. The initial increase in the surface tension values may be seen as the effect of increased electrostatic charge concentration in the medium. The decrease in the σ values at concentrations corresponding to x below 4, in the light of above observations, is certainly a reflection of the increased covalent character in the zinc – nitrate ion bonding. The existence of maxima

Acid-catalyzed solvolysis: unusually rapid solvolysis of 3-fluoronortricyclene in $CD_3COOD - 0.1\ M\ D_2SO_4$

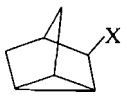
NICK HENRY WERSTIUK AND GEORGE TIMMINS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 1, 1980

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **58**, 1704 (1980).

3-Fluoronortricyclene (**1***a*) undergoes unusually facile solvolysis in $CD_3COOD - 0.1\ M\ D_2SO_4$ at 67°C and yields 3-acetoxynortricyclene-d_3 (**1***d*) which ring-opens to a mixture of deuterated norbornyl diacetates. This result contrasts with the behaviour of 3-chloro- (**1***b*) and 3-bromonortricyclene (**1***c*) that undergo cleavage of the three-membered ring in $CD_3COOD - 0.1\ M\ D_2SO_4$. The estimated rate accelaration for solvolysis of alkyl fluorides in acid media is 10^7-10^8.

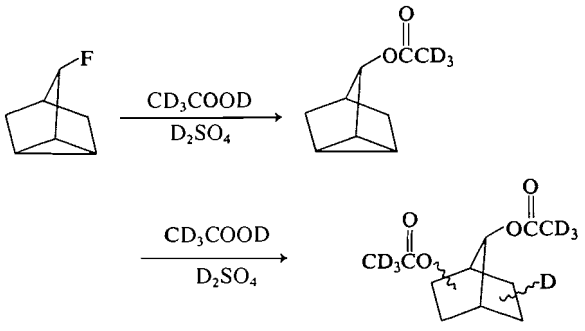


NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **58**, 1704 (1980).

Le fluoro-3 nortricyclène (**1***a*) se solvolyse avec une facilité surprenante dans le $CD_3COOD - D_2SO_4 - 0.1\ M$, à 67°C et conduit à l'acétoxy-3 nortricyclène-d_3 (**1***d*) qui subit une ouverture du cycle avec formation d'un mélange de diacétates de norbornyles deutérés. Ce résultat est contraire au comportement des chloro-3 (**1***b*) et bromo-3 (**1***e*) nortricyclène qui subissent une ouverture du cycle à 3 chaînons dans le $CD_3COOD - D_2SO_4 - 0.1\ M$. La vitesse d'accélération des fluorures d'alkyles en milieu acide est évaluée à 10^7-10^8.

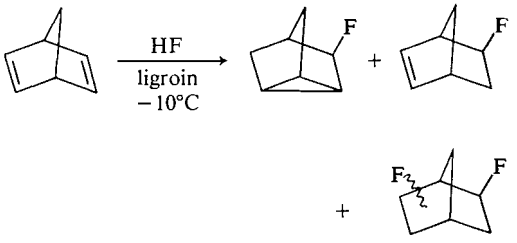
[Traduit par le journal]

Introduction



Although chloride and bromide are considered to be good leaving groups, in CD_3COOD containing D_2SO_4 (0.1 *M*), 3-chloro- (**1***b*) and 3-bromonortricyclene (**1***c*) ring-open, producing mainly *syn*- and *anti*-7-halo-2-*exo*-acetoxynorbornanes; no products due to solvolysis are detected (1). To complete our study of the effect of an electron-withdrawing group at C7 on the magnitude of the solvolytic γ-KIE of norbornyl sulfonates (1), we attempted to prepare 6-deuterated *syn*- and *anti*-7-fluoro-*exo*-2-norborneols — the brosylate precursors — by ring-opening 3-fluoronortricyclene (**1***a*). In contrast to the behaviour of **1***b* and **1***c* in acid medium, 3-fluoronortricyclene (**1***a*) undergoes rapid solvolysis followed by slow ring-opening of the 3-acetoxynortricyclene (**1***d*) (Scheme 1).

1*a*, X = F
b, X = Cl
c, X = Br
d, X = OAc



Results

For the ring-opening study we prepared **1***a* by addition of hydrogen fluoride to norbornadiene (Scheme 2). Side-reaction products, fluoronorbornene and difluoronorbornanes, were converted to norbornadiene by elimination with potassium *tert*-butoxide in DMSO, and solid **1***a* was isolated by sublimation and purified by preparative glpc. Its pmr spectrum (Fig. 1*a*) is consistent with the proposed structure ($^2J^{H,F} = 60$ Hz).

SCHEME 1

In CD_3COOD containing D_2SO_4, 3-chloro- and 3-bromonortricyclene ring-open, yielding halonorbornyl acetates with no detectable solvolysis products being formed (**1**). In contrast with this, **1***a* undergoes rapid solvolysis followed by a much slower ring-opening of **1***d* (Fig. 1*b*). This sequence of events is indicated in the pmr spectra illustrated in Fig. 1 *c* to *h*. The decreasing intensity of the doublet of **1***a* centered at δ 4.75 indicates almost

complete solvolysis after 2.04×10^4 s (Fig. 1*d*, *e*) with formation of **1***d*. The ring-opening of **1***d* that yields a mixture of four diacetates, as determined by analytical glpc, is monitored by the decrease in the peak at δ 1.7 in the pmr spectra shown in Fig. 1*f* to *h*. The pmr data also provided a rough measure of the solvolytic rate constant ($k \sim 6.5 \times 10^{-5}$ s^{-1} at 67°C) for **1***a*. This value is much higher than the values for 3-chloro- and 3-bromonortricyclene derived from published work (15, 16) (chloride, $k_1 \sim 0.33 \times 10^{-7}$ s^{-1} at 65°C, bromide, $k_1 \sim 2.1 \times 10^{-7}$ s^{-1} at 65°C).[1]

Discussion

The resistance of alkyl fluorides to displacement under alkaline conditions has been noted for many years (2–5, 12). In ethanolic sodium ethoxide primary alkyl fluorides undergo mainly substitution at rates which are 10^3–10^4 times slower than the corresponding bromides (5). Under the same conditions, secondary and tertiary fluorides react at rates which are 10^5–10^6 times slower than the corresponding bromides and produce predominately elimination products (5). This low reactivity of alkyl fluorides toward nucleophilic substitution is a reflection of the strength of the carbon–fluorine bond compared to carbon–bromine or carbon–chlorine bonds.

Although the rate of solvolysis of alkyl chlorides is usually not affected by the addition of acid (7, 8) exceptions have been noted in the case of chloroethers (9, 10) and the reaction of trityl chloride with phenol (11). With respect to alkyl fluorides, however, several workers (3, 6, 12–14) have discovered enhanced rates in the presence of acid. Berstein and Miller (4) observed that the rate of reaction of substituted benzyl fluorides in 70% aqueous ethanol containing various concentrations of hydrochloric acid was dependent on the initial concentration of acid. Addition of 0.1 *N* HCl resulted in slight rate increases; percent reaction after 10 h in the presence of 0.93 *N* HCl was approximately the same as after 120 h in the presence of an equal volume of 0.1 *N* HCl. Similar results were obtained by Chapman and Levy (6) for the solvolysis of *tert*-butyl and *tert*-amyl fluorides in aqueous ethanol containing hydrochloric acid. The latter authors also observed autocatalysis in initially neutral solutions or those with relatively high initial concentrations of alkyl fluoride (ratio of fluoride-to-HCl greater than 100). The autocatalytic effect was sufficient to produce apparent zero-order kinetics in some cases. Hydrolysis of benzoyl fluoride in aqueous acetone is also catalysed by acid (14). That alkyl fluorides undergo substitution much slower than alkyl chlorides or bromides in neutral or alkaline medium (*vide supra*) and **1***a* solvolyzes approximately 3×10^2 faster than **1***c* *establishes a rate acceleration of 10^7–10^8 for solvolysis of alkyl fluorides in acid media.*

Several authors have made suggestions about the nature of the rate-determining step and transition state involved in this acid-catalysed reaction. Bevan and Hudson (14) concluded that water was not strongly involved in the transition state of the rate-determining step. Likewise Swain and Spalding (13) suggested that a species similar to **2** with

$$RCH_2\overset{+}{F}H$$
2

water only loosely bound must be involved and that the rate-determining step may be

$$RCH_2\overset{+}{F}H \rightarrow R\overset{+}{C}H_2 + HF$$

The results of the solvolysis of **1***a* therefore confirm previous experimental observations of a large rate increase due to catalysis in acid media and allow us to estimate that the rate acceleration is in the order of 10^7–10^8. The reactivity of alkyl fluorides towards nucleophilic displacement appears to be controlled by two factors: in the absence of acid the strong fluorine–carbon bond results in slow rates of reaction relative to the corresponding alkyl chlorides and bromides whereas protonation (or hydrogen bonding) of fluorine results in relatively fast reaction rates in acid media.

Experimental

*Preparation of 3-Fluoronortricyclene (***1a***)*

Norbornadiene (25.2 g) was dissolved in purified ligroin (375 mL) contained in a 500 mL polyethylene bottle fitted with a stir-bar, a $CaCl_2$ drying tube, and a polyethylene inlet tube. The mixture was cooled in an ice–salt bath and HF (7.5 g) was bubbled into the solution over a period of 1 h. The black solution was stirred for 1 h and carefully poured onto 500 mL of ice–water containing K_2CO_3 (42 g). The organic layer was separated, washed with aqueous bicarbonate (2 × 50 mL) and water (2 × 50 mL), and dried. After the solution was treated with decolourizing carbon the solvent was removed by distillation through a 12 in. glass helicies column. Analytical glpc analysis of the residue (37.2 g) on a 1/8 in. × 10 ft 5% SE 30 column at 60°C established that three major products (>85%) were present in a ratio 2:2:1. To a solution of $K^+\bar{O}tBu$ (57.5 g) in DMSO (550 mL)

[1]Converted from data (15, 16) for the solvolysis rates in 80% EtOH – H_2O using the Winstein–Grunwald linear free energy relationship, $\log k/k_0 = mY$, with $Y = -1.64$ for 100% acetic acid. The rate comparison is necessarily approximate since the rate data for **1***a* is for fully deuterated acetic acid containing D_2SO_4. Temperature corrections were made assuming a rate doubling for each 10°C change.

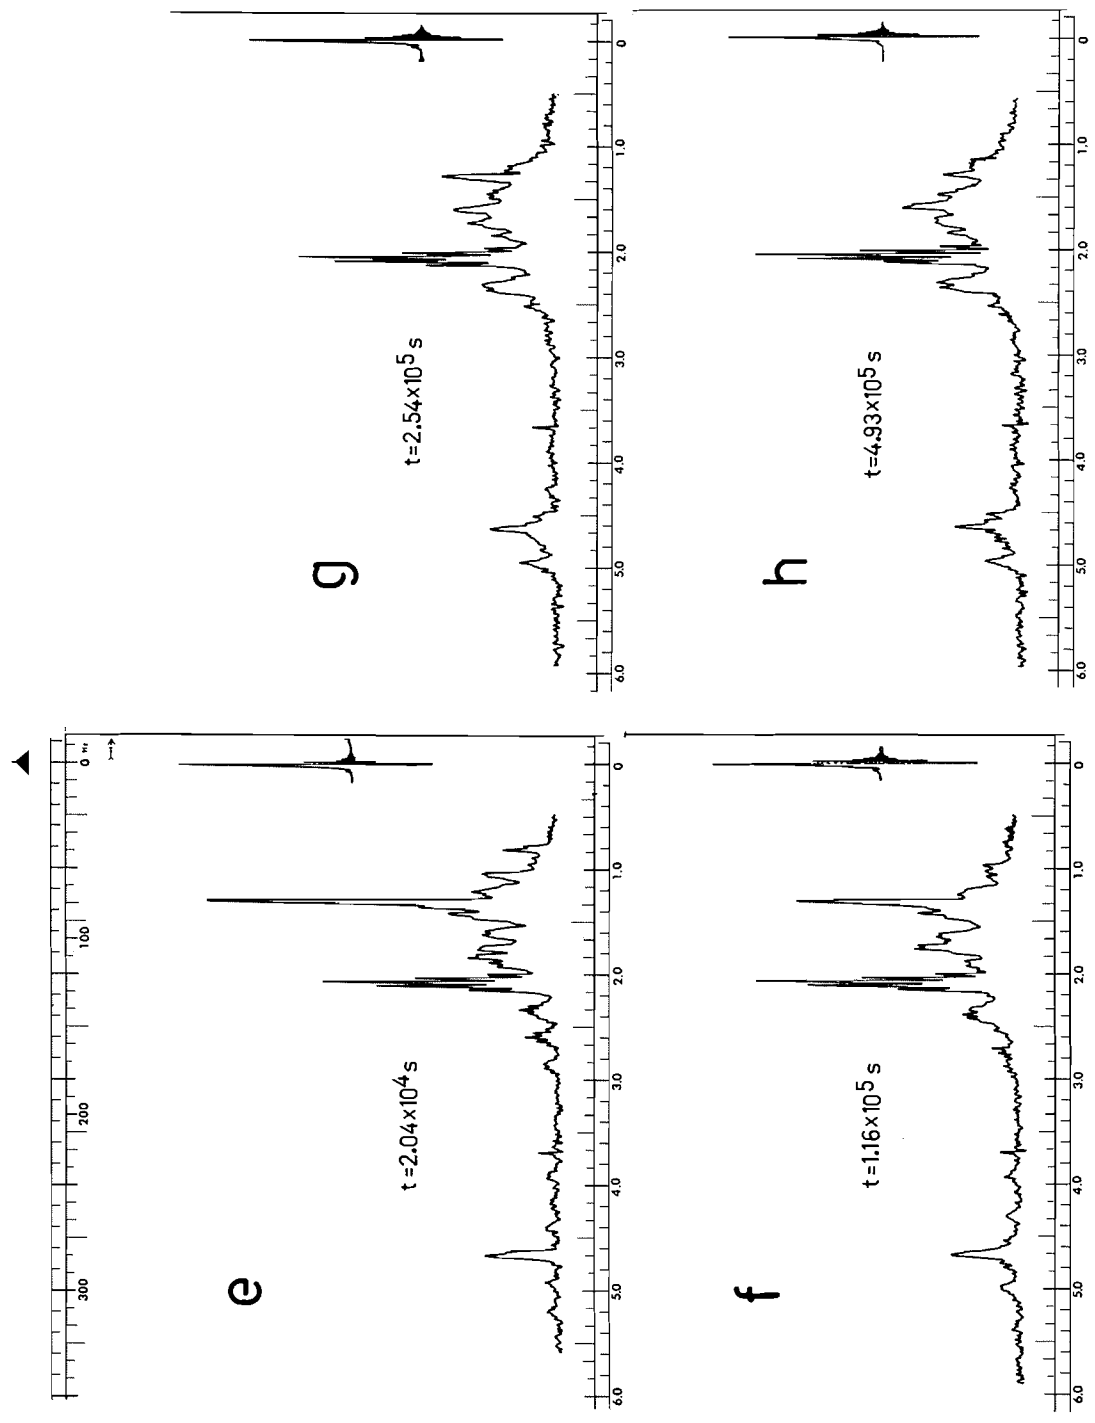

FIG. 1 (*Concluded*)

were added 31.7 g of the reaction mixture. The solution was stirred for 2.5 h at 80°C, water was added (1 L), and the mixture was extracted with ether (3 × 500 mL). The combined ether extracts were washed with water (2 × 300 mL), saturated aqueous NaCl (300 mL), and dried. Analytical glpc analysis on a 1/8 in. × 10 ft SE-30 column at 60°C showed that the peaks due to first and third major products had disappeared while the second product remained unchanged. The ether and most of the *tert*-BuOH were removed by distillation and the crude **1***a* was isolated from the tarry residue by sublimation. Solid **1***a* (0.94 g) was isolated from the sublimate by preparative glpc on a 1/4 in. × 12 ft 20% SE-30 column at 125°C; nmr (CS_2, 60 MHz) δ 4.75 (dt, 1H, J = 60 Hz, H-3), 2.3–1.9 (broad m, 2H, H-4 and H-7 *syn* to C—F), 1.8–1.1 (nortricyclyl envelope); ir (CS_2): 3075, 3000, 2950, 2875, 1348, 1360, 1308, 1288, 1134, 1063, 1040, 945, 907, 813, 802, 699.

D_2SO_4-catalyzed Ring-opening of 3-Fluoronortricyclene in CH_3COOD

3-Fluoronortricyclene (0.11 g) was dissolved in CH_3COOD (1 mL) that contained D_2SO_4 (0.02 g) and the solution was heated for 20 h at 85°C. The reaction mixture was poured onto saturated $NaHCO_3$ solution and the mixture was extracted with ether (3 × 25 mL). The combined ether extracts were washed with water (2 × 10 mL), dried, and the solvent was evaporated.

Analysis of the residue (0.13 g) by analytical glpc on a 1/8 in. × 10 ft FFAP column at 180°C established that four major products (>90%) were present in a ratio of 1:8:3:10; nmr (CH_3COOD, 60 MHz) δ 4.8 (broad m due to several peaks, —CHOAc), 2.5 (broad m, H-1 and H-4), 2.10 (broad s with shoulder, CH_3COO—), 2.2–1.1 (norbornyl envelope); ms M^+ *m/e* 213 $C_{11}H_{15}DO_4$ (deuterated norbornyl diacetates).

Kinetics of D_2SO_4-catalyzed Ring-opening of 3-Fluoronortricyclene in CD_3COOD

3-Fluoronortricyclene (0.022 g) was disolved in 1 mL of CD_3COOD that contained D_2SO_4 (0.010 g). The solution was transferred into an nmr tube, the tube was heated at 67 ± 3°C and 60 MHz pmr spectra were recorded at appropriate intervals. The spectra (Fig. 1) clearly indicated that **1***a*, after 5 h 40 min, was almost completely converted to 3-nortricyclyl acetate-d_3. After 137 h the conversion to deuterated norbornyl diacetates was essentially complete.

The approximate rate constant was determined by cutting and weighing the peaks for 3-H of 3-fluoro- and 3-acetoxynortricyclane. First-order kinetics were assumed and the rate constant ($k \sim 6.5 \times 10^{-5}\ s^{-1}$) was determined from the average of three weighings from each of two kinetic runs.

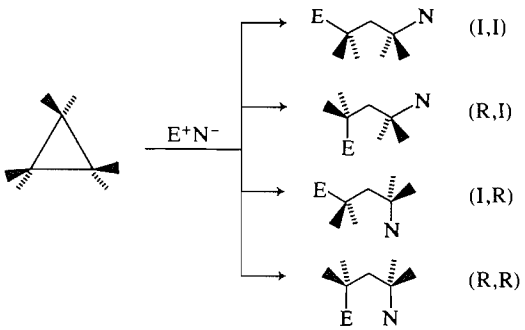
Stereochemistry of acid-catalyzed cleavage of 3-chloro- and 3-bromonortricyclene in deuterated medium. Evidence for edge protonation of nortricyclenes

NICK HENRY WERSTIUK, GEORGE TIMMINS, AND FRANK PETER CAPPELLI
McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 5, 1979

NICK HENRY WERSTIUK, GEORGE TIMMINS, and FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1709 (1980).

Cleavage of 3-chloronortricyclene (**4***c*) and 3-bromonortricyclene (**4***d*) occurs faster than solvolysis in D_2SO_4–DOAc at 70–75°C and yields *syn*-7-, *anti*-7-, *exo*-5-, and *endo*-5-halo-*exo*-2-norbornyl acetates as products. That the 7-chloroacetates comprise 70% of the reaction mixture, that 30% of the 5-chloro-*exo*-2-norbornyl acetates which comprised 28% of the reaction mixture are derived via rearrangement of the *syn*-7- and *anti*-7-chloronorbornyl cations, and that the deuterium at C-6 is at least 90% stereochemically pure *endo* is evidence that cleavage of the bond farthest removed from the electron withdrawing halogen is preferred 5:1 over the other bonds of the three-membered ring. The stereochemistry of the ring-opening is rationalized on the basis of cleavage via edge-deuteronation with formation of classical halocations as intermediates. The location of deuterium in the 5-halo-*exo*-norbornyl acetates is used to define the pathways whereby the 5-haloacetates are formed. This study also establishes that C-6 *endo* deuterated 7-chloro- and 7-bromo-*exo*-2-norbornyl brosylates can be synthesized from the corresponding 3-halonortricyclenes.



NICK HENRY WERSTIUK, GEORGE TIMMINS et FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1709 (1980).

Le clivage des chloro-3 et bromo-3 nortricyclènes (**4***c*) et (**4***d*) se produit plus rapidement que la solvolyse dans le mélange D_2SO_4–DOAc à 70–75°C et conduit aux acétates des halogèno-7-*syn*, 7-*anti*, 5-*exo* et 5-*endo* norbornyles-2-*exo*. Le fait que (*a*) les acétates des chloro-7 norbornyles constituent 70% du mélange réactionnel, (*b*) 30% des acétates des chloro-5 norbornyles-2-*exo*, qui constituent 28% du mélange réactionnel, proviennent de la transposition des cations chloro-7 *syn* et 7-*anti* norbornyles et (*c*) le deutérium en C-6 est au moins à 90% *endo* montre que le clivage de la liaison la plus éloignée de l'halogène électro-attracteur se fait préférentiellement et environ 5 fois plus rapidement que les autres liaisons du cycle à trois chaînons. On rationnalise la stéréochimie de l'ouverture du cycle en se basant sur une rupture par l'intermédiaire d'une deutération par l'arête avec formation d'halogènes cationiques comme intermédiaire. On utilise la position du deutérium dans les acétates des halogènes-5 *exo* norbornyles pour définir les voies de formation des acétates des halogènes-5. Cette étude établit également que les brosylates des chloro-7 et bromo-7 C-6 *endo* norbornyles-2 *exo* peuvent être synthétisés à partir des halogènes-3 nortricyclènes correspondants.

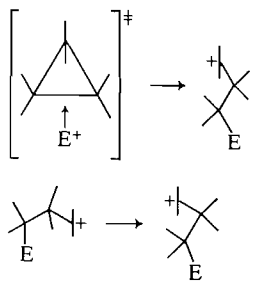
Introduction

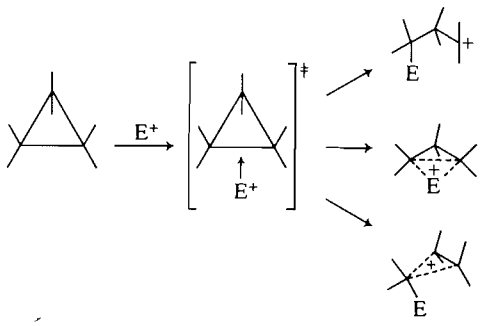
Over the past two decades the mechanistic details of the electrophilic cleavage of cyclopropanes have been elucidated by stereochemical and product studies. Generally, electrophilic cleavage occurs to yield products with either retention (R) or inversion (I) at the carbon atoms of the C—C bond which is cleaved by the electrophile (1–6). In general attempts have been made to establish how



substituents borne by a cyclopropane and the nature of the electrophile control the mechanism of the ring-opening. While a proton (deuteron) can attack cyclopropane face-wise, edge-wise, or

1 2 3

corner-wise as depicted in **1**, **2**, and **3**, respectively, face-wise attack does not occur because face-protonated cyclopropane is a high energy species (7, 8). Edge-wise attack can formally lead to open cations,[1] an edge-protonated cyclopropane, or a



[1]While retention of configuration is indicated in the above diagram, it is conceivable that the C—C bond adjacent to the bond being attacked by the electrophile is cleaved. It is also possible that the first formed ion undergoes a 1,2-alkyl shift and thereby yields products of ring-opening by inversion.

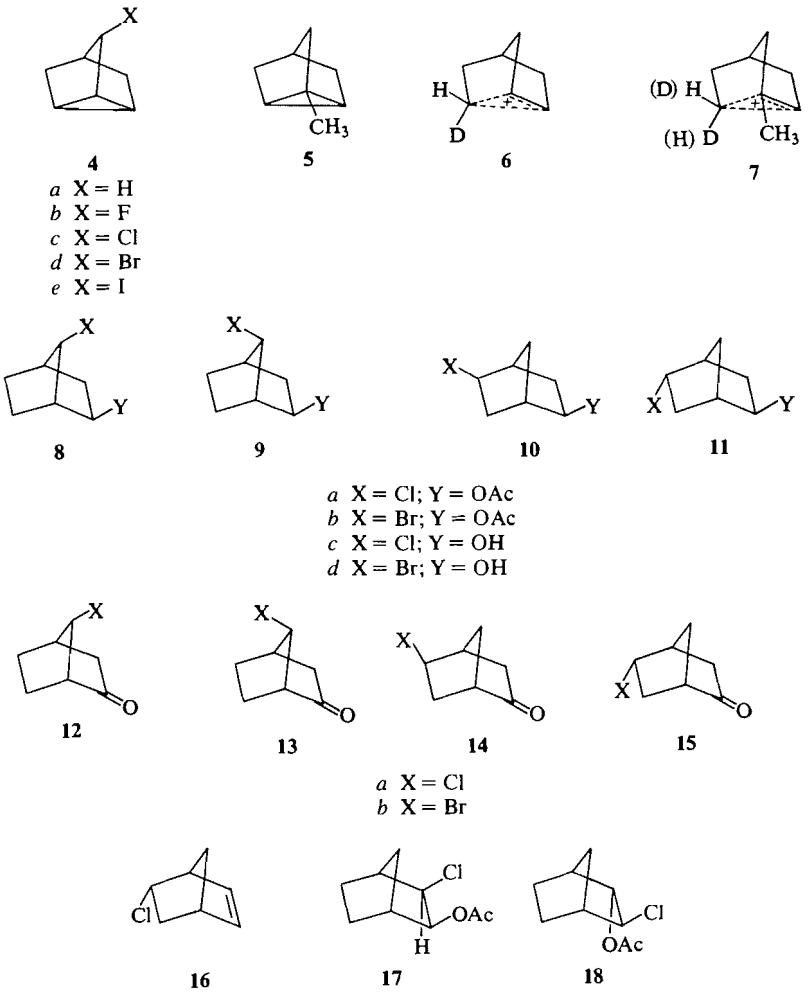
corner protonated cyclopropane which is formed by a proton-slide (9) to the corner after initial edge-approach.

Edge-wise attack is expected to be the preferred mode of cleavage because the majority of the polarizable electron density is located between the carbon atoms of the strained σ bonds. In the Walsh model, the degenerate e′ π type HOMO's of cyclopropane and nortricyclene (10) that are expected to bind with the incoming electrophile, contain four electrons and the a_1' MO, which is considerably lower in energy, contains two electrons.

It is clear from the MO's of cyclopropane documented by Jorgensen and Salem (11) that there is significant electron density at the corners in both the e′ and a_1' orbitals so that corner bonding of the electrophile with both types of MO's is possible.

It is not possible to predict the stereochemistry of such cleavage should it occur. It is possible, however, that cleavage occurs with both retention or inversion of configuration to yield classical cations. It is also possible that a corner-substituted cyclopropane that reacts to yield products of both retention and inversion of configuration is involved as an intermediate. From an electron density map of cyclopropane it is clear that there is less electron density localized at the corners than at the centres of the strained σ bonds. On this basis edge-wise attack would be preferred. This conclusion is in accord with LCAO SCF MO calculations of the electrostatic potential energy experienced by a positive charge as it interacts with the electrons and nuclei of cyclopropane (12).

The electrophilic cleavage of three-membered rings has been the subject of a number of reviews and as Cristol *et al.* (13) have stated " ... it is clear that inversion or retention of configuration by the nucleophile or electrophile may attend electrophilic addition to cyclopropanes and that no single mechanism can accommodate all data". It appears, however, that in most cases a proton (deuteron) cleaves a cyclopropane with retention of configuration. Of the studies involving a proton (deuteron) as the electrophile, investigations of the ring-opening of nortricyclene and several derivatives have generated considerable interest because the results relate to the long-standing norbornyl cation problem (14). Nickon and Hammons (15) and Hammons and co-workers (16) studied the D_2SO_4-catalysed acetolysis of nortricyclene (**4***a*) and 1-methylnortricyclene (**5**), respectively, and concluded that corner-protonated (deuterated) nortricyclenes **6** and **7**, the non-classical cations, were involved as intermediates.



Our interest in the non-classical ion problem (17, 18), and in the stereochemistry of 1,3-elimination in norbornyl systems (19), the reverse of protonation of nortricyclenes, led us to study the D_2SO_4-catalyzed ring-opening of the 3-halonortricyclenes **4***b–e*. We wished to determine whether the halonortricyclenes were ring-opened by edge or corner protonation and to prepare specifically C-6 deuterated *syn*- and *anti*-7-halo-*exo*-2-norbornyl brosylates which we required for a study of the effect of an electron withdrawing group on the unusually large γ-kinetic isotope effects (KIE's) observed in the solvolysis of *exo*-norbornyl sulfonate esters (2). In the following papers we expand on the preliminary reports of our work (17, 20).

exo-2-norbornyl acetates **8***a* and **8***b*, the *anti*-7-halo-*exo*-2-norbornyl acetates **9***a* and **9***b*, the *exo*-5-halo-*exo*-2-norbornyl acetates **10***a* and **10***b*, and the *endo*-5-halo-*exo*-2-norbornyl acetates **11***a* and **11***b*. Solvolysis (< 5%) of the nortricyclenes did not compete with ring-opening. The fluoride **4***b*, however, underwent unusually fast solvolysis, as documented in a following paper, and yielded nortricyclyl acetate that was slowly converted into diacetates. Iodide **4***e* liberated iodine and yielded two major products which we assumed were the corresponding 7-iodoacetates. However, the study of **4***e* was abandoned after several preliminary experiments.

Since the chloroacetates **8***a*, **10***a*, and **11***a* had virtually identical glpc retention times, the following procedure was used to establish that four major products were formed. The *anti*-acetate **9**a was isolated from the reaction mixture by preparative glpc and reduced to **9***c*. The remaining acetates were reduced to the chlorohydrins **8***c*, **10***c*, and **11***c* by LAH, and the *syn*-7-chlorohydrin **8***c*, that has a shorter retention time than other chlorohydrins, was isolated by preparative glpc. Chromic acid oxidation of the mixture of chlorohydrins obtained by LAH reduction of the total reaction mixture yielded the chloro-2-norbornanones **12***a* (26 ± 1%), **13***a* (44 ± 2%), **14***a* (14 ± 1%), **15***a* (14 ± 1%), and 2 ± 1% of two unidentified products. A sample of **9**a was prepared by acetylation of an authentic sample of **9***c* (21) and its ir and ^{1}H nmr spectra were identical to the spectra of **9***a* obtained from the ring-opening. A sample of *exo*-5-chloroketone **14***a* was prepared via the reaction of nortricyclanone with anhydrous HCl in CCl_4. Its ^{1}H nmr spectrum was identical to the spectrum of **14***a* obtained by chromic acid oxidation of the chlorohydrin mixture. To prepare an authentic sample of the *endo*-5-chloroketone **15***a*, *endo*-5-chloro-2-norbornene was hydroborated and the resulting mixture of

endo-5-chloro-*exo*-2- and *endo*-5-chloro-*exo*-3-norbornanols was oxidized to the chloroketones. The ^{1}H nmr spectrum of **15***a* isolated from a mixture of **15***a* (42%) and *endo*-6-chloro-2-norbornanone (58%) by preparative glpc was identical to the spectrum of **15***a* that was obtained by chromic acid oxidation of the chlorohydrin mixture (*vide supra*). To establish whether the isomeric 3-chloro-*exo*-2-norbornyl acetates **17** and **18** were significant products of the ring-opening, we prepared *exo*-3-chloro-2-norbornanone and *endo*-3-chloro-2-norbornanone (22, 23) and compared their glpc retention times with the retention times of the chloroketones. From the analysis we estimate that the 3-chloroacetates were formed in not more than 2% yield. By reducing the mixture of chloroacetates with Na in 2-propanol and analyzing the product by analytical glpc, we established an upper limit of 1% for the yield of *endo*-acetates. We checked the stability of the acetates **8***a*, **9***a*, **11***a*, **17**, and **18** under the reaction conditions by heating the compounds in 0.1 *M* H_2SO_4–HOAc at 70°C for 500 h. Compounds **8***a*, **9***a*, **11***a*, **17**, and **18** underwent 12 ± 1%, <3%, 15 ± 1%, <3%, and <2% rearrangement, respectively. Compound **8***a* rearranged to **9***a* and **11***a* rearranged to **10***a*. Acetates **17** and **18** used in the isomerization experiments were prepared by acetylation of the corresponding chlorohydrins that were obtained via a published route (22).

The products of the acid-catalyzed ring-opening of 3-bromonortricyclene, **8***b*, **9***b*, **10***b*, and **11***b*, were also characterized and their yields established basically by the procedure which we used to identify the products of the ring-opening of **4***b*. The relative yields of the bromoacetates **8***b*, **9***b*, **10***b*, and **11***b* were similar to the yields of the corresponding chloroacetates. The *syn*- and *anti*-7-bromo-*exo*-2-norbornyl acetates were converted to the corresponding bromoketones, **12***b* and **13***b*, and the bromoketones were identified as their 2,4-dinitrophenylhydrazones. An authentic sample of *exo*-5-bromo-2-norbornanone (**14***b*) was prepared by the addition of HBr to nortricyclanone and *endo*-5-bromo-2-norbornanone (**15***b*) was identified by the fact that its ^{1}H nmr spectrum was essentially identical to the spectrum of the corresponding chloroketone **15***a*.

Stereochemistry of Ring-opening: Cleavage in Deuterated Medium

To determine the stereochemistry of the electrophilic cleavage, **4***c* and **4***d* were ring-opened in deuterated medium. Since an extended reaction period (500 h) was required for **4***c* at 70°C, we avoided dilution of the deuterium pool by methyl exchange of CH_3COOD by carrying out the ring-opening in CD_3COOD. In CH_3COOD at 75 ± 1°C the ring-opening of **4***d* was essentially complete after 77 h. The haloacetates were converted to the corresponding ketones and the ketones were analyzed for deuterium mass spectrometrically (Table 1). To determine the deuterium distribution in the chloroacetates, the 2-norbornanols derived from the chloroketones were subjected to a lanthanide shift reagent (LSR) study. The ^{1}H nmr spectra of the natural abundance and deuterated *exo*-2- and *endo*-2-norbornanols are given in Figs. 1*a–f*. The LAH reduction of *syn*-chloroketone **12***a-d* gave predominately *exo*-2-norbornanol-*d* and reduction of **13***a-d* and **15***a-d* gave 85% of *endo*-2-norbornanol-*d* and 15% of *exo*-2-norbornanol-*d*. Surprisingly, **14***a-d* yielded predominately *exo*-2-norbornanol-*d*. Since hydride attacks the carbonyl group of **14***a-d* from the *exo* face to yield the *endo*-alkoxide and direct displacement of the chlorine by hydride is slow, solvolysis of the *exo*-5-chloro-*endo*-alkoxide must yield a pair of rapidly-equilibrating norbornyl cations that are trapped by hydride according to their equilibrium populations. Each norbornanol was carefully purified by preparative glpc before the ^{1}H nmr analysis was carried out.

The signal at δ 14.9 of the spectrum of *endo*-2-norbornanol (Fig. 1*a*) is clearly due to *endo*-6-H. That the signal at δ 6.9 of the spectrum of *exo*-2-

norbornanol (Fig. 1*d*) is due to *endo*-6-H was corroborated by a critical examination of the non-shifted 100 MHz spectra of **8***a*, **8***a-d*, and *syn*-7-chloro-*exo*-2-norbornanol-*exo*,*exo*-5,6-d_2 in the region of δ 1.5–2.8 where the *endo*-5-H and *endo*-6-H resonances appear. Since a decrease in the signal intensity corresponding to one proton is observed at the high field end of the spectrum of **8***a-d*, the deuterium must be located *endo* at C-6. The deuterated norbornanols were complexed with $Eu(thd)_3$ and the deuterium distribution was established by subtracting the integral for a proton at a specific site from the integral for a proton at a site bearing only natural abundance deuterium (*anti*-7-H and H-4 of *exo*-2-norbornanol-*d* and *anti*-7-H, *exo*-5-H and *endo*-5-H of *endo*-2-norbornanol-*d*). Figure 1*b* illustrates the shifted spectrum of deuterated *endo*-norbornanol obtained by LAH reduction of deuterated *anti*-7-chloro-2-norbornanone and Fig. 1*c* illustrates the spectrum of the deuterated *endo*-norbornanol derived from deuterated *endo*-5-chloro-2-norbornanone. Figure 1*e* shows the spectrum of deuterated *exo*-2-norbornanol obtained from *syn*-7-chloro-2-norbornanone and Fig. 1*f* is the spectrum of the deuterated *exo*-norbornanol obtained from deuterated *exo*-5-chloro-2-norbornanone. Since the accuracy of the integration is not better than ±5%, the error quoted is the sum of the errors in the specific-site and standard integrals. The deuterium content at C-2 was taken as the difference between the average deuterium content of the 7-chloroketones and the deuterium content of the appropriate 5-chloroketone (Table 1). The results of the ^{1}H nmr analysis are listed in Table 2. The deuterium content established by ^{1}H nmr considering the errors involved, compares favourably with the deuterium content determined by mass spectrometry. Thus, it is clear that the deuterium at C-6 of the 7-chloroacetates is at least 90% stereochemically pure *endo*.

The LSR analyses were not carried out in the case of the bromoketones. Instead, the ir fingerprint regions of the deuterated *exo*-2-norbornanols obtained from **8***d-d* and **9***d-d* were compared with the fingerprint regions of authentic samples[2] of *exo*-2-norbornanol-*exo*-6-*d* and *exo*-2-norbornanol-*endo*-6-*d*. From the spectra shown in Figs. 2*a–d*, it is clear that the deuterium in the 7-bromoacetates is at least 90% stereochemically pure *endo*. To corroborate this assignment we compared the spectra of **9***b* and **9***b-d* in the region of δ 1.2 where the *endo* proton resonances appear. That there was a decrease in intensity of the signal corresponding to approximately one proton indicates that the deuterium is located predominately *endo* at C-6. Since the 5-bromoketones contain less deuterium than the 7-bromoketones (Table 1) the deuterium distribution in the 5-bromoacetates must by similar to the deuterium distribution in the 5-chloroacetates.

Discussion

That the deuterium at C-6 of the *syn*-7- and *anti*-7-haloacetates **19***a*, **19***b*, **20***a*, and **20***b* is at least 90% stereochemically pure *endo*, in our view, establishes that the ring-opening occurs predominately by edge-deuteration of the bond farthest removed from the electron withdrawing halogen (Scheme 1). Although D^+ attacks the three-membered ring edge-wise, the question arises whether classical (Path a, Scheme 1) or non-classical (Path b, Scheme 1) intermediates are formed. In our view, classical[3] rather than non-classical cations are involved simply because participation of the C1—C6 bond should lead to development of positive charge at C-1 that is adjacent to the carbon bearing the electron withdrawing halogen.[4] It seems to us reasonable that this would

[2]We thank Professor A. Nickon for copies of the ir spectra of the deuterated *exo*-norbornanols.

[3]Since in our view (18) the norbornyl cation is a classical species, the 5- and 7-halonorbornyl cations are represented in that form in this and subsequent papers.

[4]Although Goering and Degani (24) suggest that non-classical 7-chlorocations are involved as intermediates in the acetolysis of 7-chloro-*exo*-2-norbornyl tosylates, they state that the low yield (≃ 2%) of 3-chloro-2-norbornyl acetates ... "is probably due to the low cationic character at C-1 because of the inductive effect of the adjacent chlorine atom."

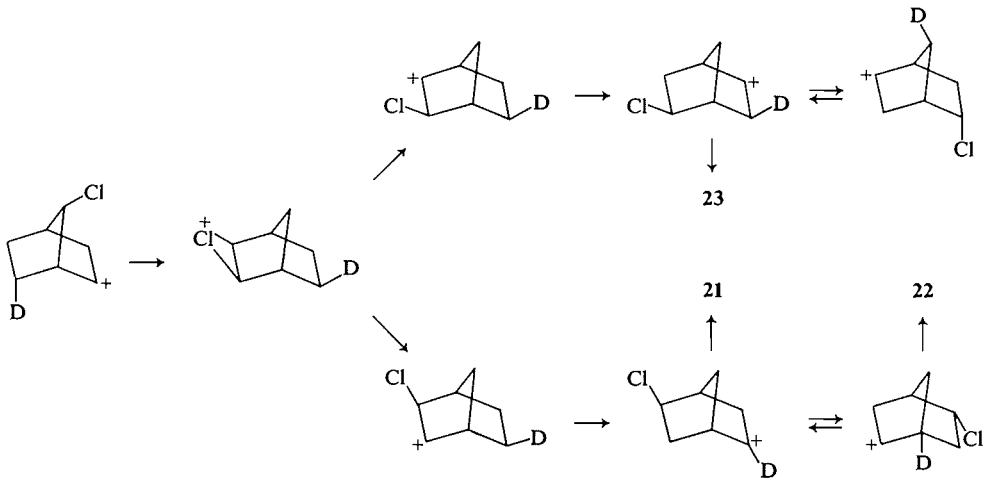
SCHEME 1

lead to a destabilization of the cation. That *exo*-3-chloro-*exo*-2-norbornyl tosylate is 250 times less reactive solvolytically than the 7-chloro tosylate supports our view. Thus ring-opening of **4***c* and **4***b* occurs predominately by deuteronation of the most basic C—C bond. The stereochemistry of the ring-opening is nicely accounted for on the basis of cleavage via edge-deuteronation with retention of configuration at C-6 and inversion of configuration at C-2 (Path a, Scheme 1). Although we consider that classical 7-halonorbornyl cations are the important intermediates, an edge deuteronated nortricyclene is a possible intermediate as well.



The pathways whereby the *syn*-7- and *anti*-7-halonorbornyl cations are converted to the 5-halonorbornyl cations are defined by the deuterium distribution in 5-chloronorbornyl acetates. Since **21** ($0.10 \pm 0.02 \times 14\%$) and **22** ($0.08 \pm 0.01 \times 14\%$) are formed, a 1,2-alkyl shift, a 6,2 hydride shift, and a 1,2-alkyl shift must occur in sequence to a minor extent to generate the cations that are the precursors of **21** and **22**. Since **23** ($0.25 \pm 0.03 \times 14\%$) is formed also, an *exo* chloronium ion (Scheme 2) is implicated as an intermediate. That we did not detect significant amounts of deuterium at C-7 of the *endo*-5-chloroacetate may be due to the fact that the *exo*-5-chlorocation is more stable than the *endo* isomer and that the integration method is inaccurate at low deuterium incorporations (< 0.05 *d*).

The presence of **24** ($0.08 \pm 0.01 \times 14\%$) and **25** ($0.10 \pm 0.02 \times 14\%$) indicates that the deuterated *anti*-7-chloronorbornyl cation rearranges, as depicted in Scheme 3, to the cations that are precursors of **24** and **25**. Since deuterium is not detected at C-3 of the *endo*-5-chloroacetate and at C-7 of the *exo*-5-chloroacetate, the *endo*-chloronium ion, as expected, is not an important intermediate.

Based on our analysis, the *exo*-5- and *endo*-5-chloroacetates formed by rearrangement of the *syn*-7- and *anti*-7-halocations comprise $8.5 \pm 1.7\%$ ($1.4 \pm 0.3\% + 1.1 \pm 0.2\% + 3.5 \pm 0.4\% + 1.1 \pm 0.2\% + 1.4 \pm 0.3\%$) of the reaction mixture. This result is nicely in accord with the work of Goering and Degani (24) which established that the *exo*-5- and *endo*-5-chloroacetates, in total, comprise 15.2% and 12.3% of the reaction products of the acetolysis of the *syn*-7- and *anti*-7-chloro-*exo*-2-norbornyl tosylates, respectively. Thus approxi-

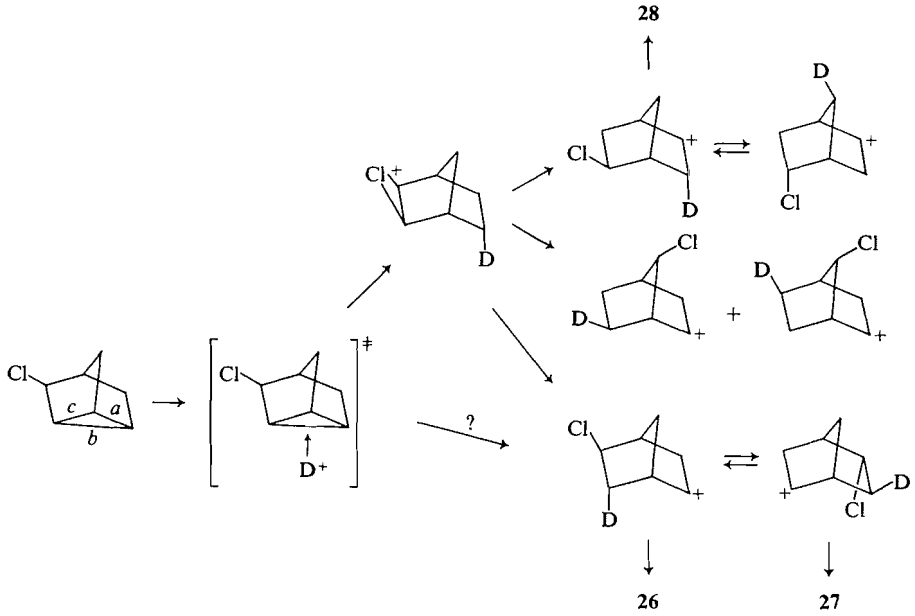
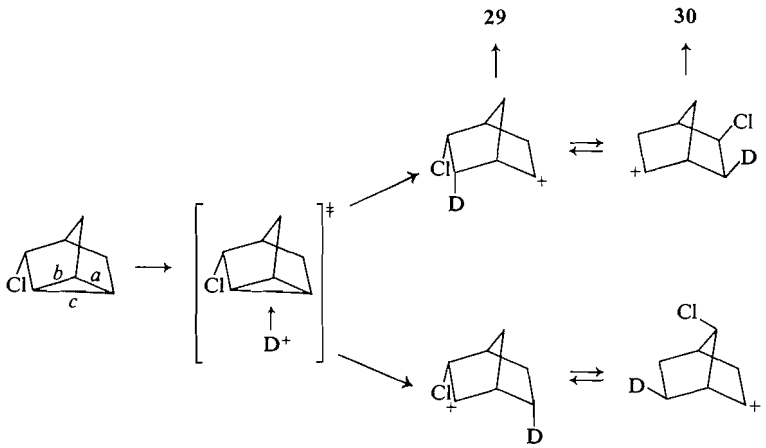
SCHEME 2

SCHEME 3



mately ((70% + 8.5%) × 0.9) or 71% of the chloroacetates result from edge-deuteronation of the bond farthest removed from the electron withdrawing chlorine atom. If deuteronation of the other two bonds is assumed to be equally likely, then deuteronation of the most basic bond is preferred by (71/29 × 2) or 5:1 over the other bonds. Since the *exo*-5- and *endo*-5-chloroacetates are formed in greater yield (28%) when **4***c* is ring-opened in acetic acid, the other bonds of the three-membered ring also must be cleaved. Here too, the deuterium distributions in the 5-chloroacetates define the mechanistic details. Edge-deuteration of bond *b* leads to several cations (Scheme 4) and, in fact, can introduce *exo*-deuterium at C-6 of the *syn*-7-chloroacetate. Chloroacetates **26** (0.15 ± 0.02 × 14%) and **27** (0.55 ± 0.05 × 14%) are formed directly by deuteronation of bond *b*. The formation of **28** (0.25 ± 0.03 × 14%) implicates an *exo* chloronium ion (Scheme 4) as an intermediate that possibly leads to a *syn*-7-chloronorbornyl cation with *exo* deuterium at C-6. That bond *c* is cleaved by edge-wise attack (Scheme 5) is indicated by the formation of acetate **29** (0.20 ± 0.04 × 14%). It is also possible that a small amount of the *anti*-7-chloronorbornyl cation with *exo* deuterium at C-6 is formed as well (Scheme 5).

Conclusions



We have established that the D_2SO_4-catalyzed ring-opening of 3-chloro- and 3-bromonortricyclene occurs faster than solvolysis in acetic acid and that the deuterium at C-6 of the major products is at least 90% stereochemically pure *endo*. Clearly

SCHEME 4

SCHEME 5

then, edge-deuteronation of the bond farthest removed from the chlorine is preferred over deuteronation of the other bonds by 5:1. Because the electronegativities of bromine and chlorine are comparable, we observe a similar preference for deuteronation of 3-bromonortricyclene. The small effect of the halogens on the regiochemistry is in keeping with the results of other studies which have established that substituent effects on the electrophilic cleavage of three-membered rings are usually small (6).

By determining the distribution of deuterium in the 5-chloroacetates we have elucidated the mechanisms of formation of the minor products as well.

Furthermore, this work has established that the ring-opening of **4***c* and **4***d* in deuterated medium, followed by LAH reduction of the acetates and a brosylation, is a viable route to C-6 *endo* deuterated *syn*-7-chloro-, *anti*-7-chloro-, *syn*-7-bromo-, and *anti*-7-bromo-*exo*-2-norbornyl brosylates. A study of the effect of an electron withdrawing group located at C-7 on the solvolytic γ-KIE's of *exo*-2-norbornyl sulfonate esters can now be realized.

Experimental

General

Proton magnetic resonance spectra were recorded on Varian T-60, A-60, and HA-100 spectrometers with tetramethylsilane (TMS) as the internal standard. Samples were dissolved in either carbon tetrachloride or carbon disulfide. Chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Infrared spectra were recorded on Perkin Elmer 337 and Beckman IR-5 infrared spectrometers and the samples were dissolved in carbon tetrachloride or carbon disulfide. Ab-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sorption frequencies were calibrated with polystyrene film and are expressed in reciprocal centimeters (cm^{-1}). For brevity, the notation cm^{-1} is omitted. Mass spectra were taken on a Hitachi-Perkin-Elmer RMU-6A spectrometer at 80 eV. Deuterium assay analyses were performed at 10 to 15 eV and are expressed as atoms of deuterium per molecule in excess of natural abundance deuterium. Analytical gas liquid partition chromatography was performed on a Varian Aerograph Model 204B dual column analytical gas chromatograph equipped with dual flame ionization detectors using helium as the carrier gas. The gas flow rate was usually 20–30 mL/min. Preparative gas liquid partition chromatography was carried out on a Varian Aerograph Model A-90-P gas chromatograph with a thermal conductivity detector and a helium flow rate of 50–60 mL/min. Spinning band distillations were performed on a Nester–Faust auto-annular Teflon spinning band distillation column. Melting points were recorded on a Kofler hot-stage apparatus and are uncorrected. Boiling points are also uncorrected.

All organic solutions were dried with either anhydrous sodium sulfate or magnesium sulfate.

*Sulfuric Acid-catalyzed Cleavage of 3-Chloronortricyclene (**4c**) in Acetic Acid*

3-Chloronortricyclene prepared by the method of Roberts *et al.* (21) (10.13 g, 79 mmol), sulfuric acid (1.31 g), and 150 mL of acetic acid (distilled from acetic anhydride) were mixed in a 250 mL flask fitted with a calcium chloride drying tube. The flask was placed in an oil bath maintained at 70 ± 3°C and the mixture was stirred magnetically. The reaction was monitored by glpc and after 120 h it was estimated to be >97% complete. Three-quarters of the reaction mixture was neutralized by slow addition to a saturated sodium bicarbonate solution and the products were extracted into ether (3 × 150 mL). The ethereal extracts were washed with water (75 mL), saturated bicarbonate solution (75 mL), and water (75 mL). After the solution was dried and the solvent was removed, there remained 10.9 g (98%) of chloroacetates. The glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 180°C showed three products, and only the product with the shortest retention time (7 min) was resolved from the others. It was isolated by preparative glpc on a 10 ft × 1/4 in. 15% Carbowax column maintained at 175°C and identified as *anti*-7-chloro-*exo*-2-norbornyl acetate (**9a**) by comparison of its spectral data to those of an authentic sample.

Lithium Aluminum Hydride Reduction of Chloroacetates

Into a 125 mL three-necked flask fitted with a condenser, a calcium chloride drying tube, an adding funnel, and a magnetic stirrer was placed a slurry of lithium aluminum hydride (1.92 g, 51 mmol) in dry ether (55 mL). The mixture of chloroacetates (4.46 g, 24 mmol) was dissolved in dry ether (10 mL) and slowly added to the slurry. After the mixture was refluxed for 4 h, the reaction flask was cooled in ice and excess hydride was carefully destroyed by the dropwise addition of water. The white precipitate was filtered off, the filtrate was acidified with hydrochloric acid (10%, 20 mL), and the ethereal layer was separated. The aqueous layer was extracted with ether (2 × 75 mL) and the combined ethereal layers were washed with water (50 mL), dried, and concentrated to yield 3.3 g (94%) of foul-smelling chlorohydrins. The glpc analysis on a 10 ft × 1/8 in. 10% Carbowax column at 178°C revealed at least three products with only the product of shortest retention time (5 min) being resolved from the others. This product was isolated by preparative glpc on a 1/4 in. × 10 ft. 15% Carbowax column at 175°C and identified as *syn*-7-chloro-*exo*-2-norbornanol (**4c**) by comparison of its spectra to those from an authentic sample (19).

Oxidation of Chlorohydrins

The oxidizing agent (24) was prepared in the following manner. Sodium dichromate (10 g) was dissolved in water (20 mL) and sulfuric acid (7.5 mL) was added. For each millimole of alcohol to be oxidized, 0.5 mL of solution was used.

To a solution of the mixture of chlorohydrins (0.20 g, 1.4 mmol) in ether (5 mL, pre-treated with oxidizing agent) in a 50 mL flask equipped with a condenser and magnetic stirrer, the oxidizing agent (0.8 mL) was slowly added. After the solution was vigorously stirred for 6.5 h, the ethereal layer was separated and the aqueous layer was extracted with ether (5 × 20 mL). The combined ethereal layers were washed with saturated bicarbonate (2 × 15 mL), water (2 × 20 mL), and then dried. Analytical glpc on 1/8 in. × 10 ft 10% Carbowax and 1/8 in. × 10 ft 20% Ucon Polar columns at 190°C and 180°C, respectively, showed three products that were isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 170°C. The product with shortest retention time was *anti*-7-chloro-2-norbornanone (**13a**); ir (CS_2): 1760 (C=O); nmr (CCl_4, 60 MHz) δ: 4.2 (s with fine structure, 1H, *syn*-7-H), 2.6 (broad s, 2H, H-1 and H-4), 2.5–1.5 (m, 6H, norbornyl envelope). The product of intermediate retention time (15 min) was *exo*-5-chloro-2-norbornanone (**12a**) and the product of longest retention time (19 min) was *endo*-5-chloro-2-norbornanone (**15a**). Chloroketones **12a** and **15a** were identified by comparison of their ir and nmr spectra to those obtained from authentic samples.

In a separate experiment, a small portion of the chlorohydrin mixture which was obtained from the chloroacetates by reduction was oxidized and the reaction mixture was analyzed by analytical glpc on a 1/8 in. × 10 ft 15% Carbowax column at 190°C. Compounds **13a** (44 ± 2%), **14a** (14 ± 1%), **12a** (26 ± 1%), and **15a** (14 ± 1%) were identified as the products.

Reduction of the Chlorohydrins by Sodium in 2-Propanol

To a magnetically stirred 2-propanol (50 mL, reagent grade) solution of the chlorohydrins (0.75 g, 5.2 mmol), small pieces of sodium metal (1.0 g, 43 mmol) were added at a sufficient rate to maintain the heated solution at reflux. After the sodium completely dissolved, the solution was refluxed for 3.0 h and the brown solid that formed when the mixture was cooled was dissolved in water (50 mL). The aqueous solution was extracted with pentane (4 × 70 mL) and the combined pentane extracts were washed with dilute hydrochloric acid (10%, 40 mL), water (2 × 40 mL), dried, and concentrated to yield 0.45 g (78%) of a white solid. Analytical glpc on 1/8 in. × 10 ft 10% Carbowax column at 130°C showed one major product (>95%) that was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 140°C. Its spectral properties were shown to be identical to those of *exo*-2-norbornanol; ir (CS_2): 3600 (free OH), 3600–3200 (hydrogen bonded OH); nmr (CCl_4, 60 MHz) δ:3.6 (d, 1H, *endo*-2-H), 2.2 (broad s, 1H, bridgehead), 2.0 (broad s, 1H, bridgehead), 1.9–0.7 (m, 9H, norbornyl envelope and OH). Another product (<5%) of slightly longer retention time than *exo*-2-norbornanol was not identified.

From an analysis on a 1/8 in. × 10 ft 10% FFAP column at 105°C that involved tracing and weighing the peaks, the ratio of *exo*-2-norbornanol to *endo*-2-norbornanol was 98 ± 1: 2 ± 1.

Preparation of Syn- *and* Anti-*7-chloro-exo-2-norbornanols*

The *syn*- and *anti*-7-chloro-*exo*-2-norbornanols were prepared by the addition of hypochlorous acid to norbornene according to the procedure of Roberts *et al.* (21) and purified by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 160°C. *Syn*-7-chloro-*exo*-2-norbornanol (**8c**) had the following properties: mp 87–91°C (lit. (18) mp 89–90°C); ir (CCl_4): 3590 (OH); nmr (CS_2, 100 MHz) δ:3.86 (m, 1H, *anti*-7-H), 3.60 (broad quintet, 1H, J = 6 Hz, *endo*-2-H), 2.25 (m, 2H, H-1 and H-4), 1.88 (m, 3H, *exo*-3-H, *endo*-3-H and -OH), 1.53 (m, 2H, *exo*-5-H and *exo*-6-H), 1.10 (m, 2H, *endo*-5-H and *endo*-6-H).

Anti-7-chloro-*exo*-2-norbornanol (**9c**) exhibited the following spectra: ir (CCl_4): 3620 (free OH), 3650–3200 (hydrogen bonded OH); nmr (CCl_4, 100 MHz): δ:4.19 (broad s with fine structure,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

1H, *syn*-7-H), 3.75 (d of d, 1H, J = 7.5 and 2.5 Hz, *endo*-2-H), 2.69 (broad s, 1H, OH), 2.26 and 2.14 (broad s, each 1H, bridgeheads), 2.00–1.67 (m, 3H, *exo*-3-H, *exo*-5-H and *exo*-6-H), 1.40 (broad d, 1H, J = 15 Hz, *endo*-3-H), 1.10 (m, 2H, *endo*-5-H and *endo*-6-H).

Exo-*3-chloro-2-norbornanone*

2-Norbornanone (11.7 g, 0.11 mol) was treated with sulfuryl chloride (15.0 g, 0.11 mol) in carbon tetrachloride (20 mL) at 25°C for 195 h (20). The major product, *exo*-3-chloro-2-norbornanone, was purified by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 168°C and exhibited the infrared absorptions previously reported (20); nmr (CS_2, 60 MHz) δ:3.5 (d, 1H, J = 3 Hz, *endo*-3-H), 2.6 (broad s, 2H, H-1 and H-4), 2.4–1.3 (m, 6H, norbornyl envelope).

Endo-*3-chloro-2-norbornanone*

Exo-3-chloro-2-norbornanone (0.64 g) was isomerized to the *endo* isomer in a refluxing aqueous solution (60 mL) of lithium carbonate (1.7 g).

Exo-*5-chloro-2-norbornanone* (***14***a)

Nortricyclanone (0.37 g, 3.4 mmol) was dissolved in carbon tetrachloride (25 mL) in a 50 mL round bottom flask fitted with a condenser and a magnetic stirrer. While the solution was heated to 70 ± 5°C in an oil bath, anhydrous hydrogen chloride was bubbled through the solution for 67 h. The mixture was neutralized with saturated sodium bicarbonate and the aqueous solution was extracted with carbon tetrachloride (4 × 55 mL). The combined extracts were washed with saturated bicarbonate (40 mL), water (3 × 25 mL), dried, and the organic solvent was removed by distillation through a 15 cm glass-helices column. Analysis of the residue by glpc on a 1/8 in. × 10 ft 10% Carbowax column at 185°C revealed one product.

Hydroboration of Endo-*5-chloronorbornene* (***16***)

Into a 250 mL flask fitted with a magnetic stirrer and a pressure equalizing funnel were placed **16** (192 g, 15.0 mmol) dissolved in tetrahydrofuran (40 mL, freshly distilled), and sodium borohydride (1.21 g, 31.8 mmol). After the flask was purged for 10 min with nitrogen, boron trifluoride etherate (6.5 g, 46 mmol, freshly distilled) in tetrahydrofuran (20 mL) was slowly added to the stirred solution containing olefin. After the addition was complete, the mixture was stirred for 1.5 h at room temperature. The funnel was replaced with a condenser, water was added to the mixture until hydrogen was no longer evolved, and sodium hydroxide (10%, 30 mL) was added. Hydrogen peroxide (30%, 6 mL) was slowly added to maintain a reflux and the solution was stirred for 3 h. The mixture was extracted with ether (3 × 80 mL), the extracts were washed with dilute hydrochloric acid (10%, 10 mL), water (2 × 20 mL), dried, and concentrated to yield a white solid (1.3 g, 59%). The two chlorohydrins, *endo*-5-chloro-*exo*-3-norbornanol and *endo*-6-chloro-*exo*-2-norbornanol, could not be separated by preparative glpc on a 1/4 in. × 10 ft 10% Carbowax column maintained at 180°C.

Endo-*5-chloro-2-norbornanone* (***15***a)

The mixture of chlorohydrins was oxidized as previously described to a mixture of chloroketones. Each chloroketone was purified by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column maintained at 170°C. The ketone of shortest retention time (17 min) was *endo*-5-chloro-2-norbornanone (42%); ir (CS_2): 1750 (C=O), 1310, 1280, 1260, 1180, 1150, 1075, 1060, 960, 940, 915, 890, 865, 770, 695, 675; nmr (CS_2, 100 MHz) δ: 4.30 (m, 1H, *exo*-5-H), 2.80–1.30 (m, 8H, norbornyl envelope). The ketone of longest retention time (23 min) was *endo*-6-chloro-2-norbornanone; ir (CS_2): 1760 (C=O), 1300, 1280, 1260, 1230, 1190, 1150(s), 1120, 1070(s), 1030, 970, 945, 925, 885, 865, 765, 735, 640; nmr (CS_2, 100 MHz) δ: 4.30 (m, 1H, *exo*-6-H), 2.70–1.40 (m, 8H, norbornyl envelope).

Exo-*2-chloro*-exo-*2-norbornyl* tert-*Butyl Ether and* Endo-*3-chloro*-exo-*2-norbornyl* tert-*Butyl Ether*

The *tert*-butyl ethers were prepared by the treatment of norbornene with *tert*-butyl hypochlorite (20). The *endo*-3-chloroether was isolated by preparative glpc on a 1/4 in. × 10 ft 15% FFAP column at 155°C; ir (neat): 1120 and 1075 (C—O); nmr (CCl_4, 60 MHz) δ: 3.8 (m, 1H, *exo*-3-H), 3.2 (t, 1H, *endo*-2-H), 1.2 (s, 9H, —$C(CH_3)_3$), 2.3–1.0 (m, 8H, norbornyl envelope). Similarly, the *exo*-3-chloroether was isolated by preparative glpc; ir (neat): 1090 (C—O); nmr (CCl_4, 60 MHz) δ: 3.8 (dd, 1H, J = 6 Hz and 1 Hz, *endo*-3-H), 3.5 (dd, 1H, J = 6 Hz and 1 Hz, *endo*-2-H), 1.2 (s, 9H, —$C(CH_3)_3$), 2.4–0.9 (m, 8H, norbornyl envelope).

Exo-*3-chloro*-exo-*2-norbornanol and* Endo-*3-chloro*-exo-*2-norbornanol*

The chlorohydrins were prepared according to the literature method (22) by treating the corresponding *tert*-butyl ethers with anhydrous hydrogen chloride. The nmr spectra of the chlorohydrins were identical to the reported spectra.

Exo-*3-chloro*-exo-*2-norbornyl Acetate and* Endo-*3-chloro*-exo-*2-norbornyl Acetate*

The chlorohydrins were acetylated by acetic anhydride in pyridine. Analytical glpc on a 1/8 in. × 10 ft. 10% Carbowax column at 190°C revealed that each acetate was >97% pure.

Endo-*5-chloro*-exo-*2-norbornyl Acetate* (***11***a)

Acetylation of a mixture of *endo*-5-chloro-*exo*-2-norbornanol and *endo*-6-chloro-*exo*-2-norbornanol prepared previously (*vide supra*) gave a mixture of the chloroacetates. *Endo*-5-chloro-*exo*-2-norbornyl acetate contaminated with 18% of the *endo*-6-isomer was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 175°C.

Stability of Chloroacetates

In a typical control reaction, 0.15 g of the chloroacetate was dissolved in acetic acid (5 mL) containing 0.10 M sulfuric acid and heated at 70 ± 5°C in an oil bath for 500 h. The extent of isomerization was monitored by analytical glpc on a 1/8 in. × 10 ft 15% Carbowax column programmed between 150 and 185°C and the following results were obtained. *Syn*-7-chloro-*exo*-2-norbornyl acetate underwent 12 ± 1% isomerization to *anti*-7-chloro-*exo*-2-norbornyl acetate, *endo*-5-chloro-*exo*-2-norbornyl acetate underwent 15 ± 1% isomerization to *exo*-5-chloro-*exo*-2-norbornyl acetate, *exo*-3-chloro-*exo*-2-norbornyl acetate, *endo*-3-chloro-*exo*-2-norbornyl acetate, and *anti*-7-chloro-*exo*-2-norbornyl acetate each underwent <3% rearrangement.

Deuterosulfuric Acid Catalyzed Cleavage of 3-Chloronortricyclene

3-Chloronortricyclene (18.5 g, 145 mmol) was dissolved in 80 mL of a mixture of acetic acid-d_4 (Merck, Sharp and Dohme of Canada Ltd., 99.5 at.% d) and 0.82 g of sulfuric acid-d_2 (Merck, Sharp and Dohme) in a 250 mL flask fitted with a calcium chloride drying tube. The mixture was heated in an oil bath at 70 ± 3°C for 504 h. Sodium acetate-d_3 (1.7 g) was added to the mixture and acetic acid-d_4 (55 mL) was removed by distillation under reduced pressure (5–7 Torr). The remaining solution was neutralized with saturated sodium bicarbonate and extracted with ether. After the extracts were washed with water and dried, evaporation of solvent left 26.5 g (95%) of deuterated chloroacetates.

Reduction of Deuterated Chloroacetates

The deuterated chloroacetate mixture (17.6 g, 92 mmol) was dissolved in dry ether (20 mL) and reduced by lithium aluminum hydride (1.89 g, 50 mmol) as previously described (*vide supra*). After workup, 12.7 g (94%) of deuterated chlorohydrins were obtained.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Oxidation of the Deuterated Chlorohydrins

The deuterated chlorohydrins from the previous reaction (12.7 g, 86 mmol) were oxidized by the method previously described (44 mL oxidizing agent) and 12.0 g (97%) of the deuterated chloroketones were isolated. Each chloroketone was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Ucon Polar column at 130°C and the deuterium was assayed by mass spectrometry; *anti*-7-chloro-2-norbornanone was a composite of 3.81 ± 0.01% d_0, 95.04 ± 0.18% d_1, 1.15 ± 0.18% d_2 species (0.976 ± 0.004 excess d per molecule) and *syn*-7-chloro-2-norbornanone was a composite 3.33 ± 0.02% d_0, 95.01 ± 0.21% d_1, 1.67 ± 0.24% d_2 species (0.985 ± 0.002 excess d per molecule); *exo*-5-chloro-2-norbornanone was a composite of 9.84 ± 0.25% d_0, 89.41 ± 0.59% d_1 and 0.67 ± 0.88% d_2 species (0.910 ± 0.015 excess d per molecule); *endo*-5-chloro-2-norbornanone was a composite of 12.87 ± 0.01% d_0, 84.65 ± 0.01% d_1, and 2.47 ± 0.01% d_2 species (0.894 ± 0.002 excess d per molecule).

Determination of the Deuterium Distribution

The deuterated chloroketones that had been previously separated by preparative glpc on a 1/4 in. × 10 ft 15% Ucon Polar column at 130°C were individually reduced by lithium aluminum hydride to a mixture of *exo*- and *endo*-2-norbornanol. In a typical reaction, the deuterated chloroketone (0.10 g) in ether (15 mL) was reduced by lithium aluminum hydride to the deuterated 2-norbornanols after a 15-day reflux. Whereas reduction of deuterated *anti*-7-chloro-2-norbornanone and *endo*-5-chloro-2-norbornanone gave *endo*-2-norbornanol-*d* as the major product and the *exo*-alcohol as the minor product, reduction of deuterated *syn*-7-chloro-2-norbornanone and *exo*-5-chloro-2-norbornanone gave *exo*-2-norbornanol-*d* as the major product. In each case about 0.020 g of the major isomer that was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 110°C was dissolved in CCl_4 (1 mL) solution of $Eu(thd)_3$ (0.030 g) and the pmr spectrum was recorded. The combined mass spectral and nmr data (Figs. 1*a–g*) established that >90% of deuterium in the *syn*-7- and *anti*-7-chloro-*exo*-2-norbornyl acetates was situated at C-6 with at least 90% *endo* stereochemical purity. The deuterium in *exo*-5-chloro-*exo*-2-norbornyl acetate was located at C-1 (0.10 ± 0.05), *endo* at C-2 (0.10 ± 0.05), *exo* at C-3 (0.20 ± 0.05), *endo* at C-3 (0.20 ± 0.05), *endo* at C-6 (0.20 ± 0.05), and the deuterium in *endo*-5-chloro-*exo*-2-norbornyl acetate was located at C-1 (0.10 ± 0.05), *endo* at C-2 (0.55 ± 0.05), and *endo* at C-6 (0.25 ± 0.05).

Check for Deuterium Loss During Preparative Gas–Liquid Partition Chromatography

A sample of *anti*-7-chloro-2-norbornanone that was collected by preparative glpc on a 1/4 in. × 10 ft Ucon Polar column at 130°C was analyzed for deuterium mass spectrometrically and was found to contain 0.95 excess deuterium atoms per molecule. Reinjection of a small portion of the chloroketone followed by a mass spectrometric analysis established that the deuterium content was 0.96 excess deuterium atoms per molecule.

Similarly, deuterated *exo*-5-chloro-2-norbornanone was tested for deuterium loss during isolation by preparative glpc. After a single injection and collection the norbornanone contained 0.90 excess d per molecule. After a reinjection and collection the ketone was found to contain 0.90 excess d per molecule.

Check for Deuterium Loss During Oxidation

Anti-7-chloro-2-norbornanone-*endo*-6-*d* (0.010 g, 0.95 excess d per molecule) in ether (3 mL, pretreated with oxidizing agent) and oxidizing agent (*vide supra*) (2 mL) were vigorously stirred together for 3.5 h at room temperature. The reaction was worked up and the product was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Ucon Polar column at 140°C. Mass spectral analysis established that the ketone contained 0.96 excess d per molecule and this was identical within experimental error, to the deuterium content of the starting ketone.

Deuterated *exo*-5-chloro-2-norbornanone (0.90 excess d per molecule) that contained deuterium *exo* at C-3 was subjected to the chromic acid oxidation reaction conditions and the deuterium was assayed by mass spectrometry. Within experimental error, the deuterium content was identical to the deuterium content of the starting material (0.90 excess d per molecule).

Sulfuric Acid Catalyzed Cleavage of 3-Bromonortricyclene

Freshly distilled 3-bromonortricyclene (5.00 g) was dissolved in glacial acetic acid (75 mL) that contained concentrated H_2SO_4 (0.74 g, 0.10 *M*) and the solution was heated at 74 ± 2°C for 30 h. The cooled solution was carefully poured onto a saturated sodium bicarbonate solution contained in a 2 L beaker and the aqueous layer was extracted with ether (4 × 80 mL). The combined extracts were dried and the ether was removed to yield 6.47 g of an oil. Analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C showed three peaks in a ratio of 4:54:42, the first peak being starting material. The major products were separated by preparative glpc on a 1/4 in. × 10 ft 20% DEGS column at 195°C. Seven fractions were collected with fractions 4 and 6 corresponding to the centre cuts of the main product peaks; fraction 4 was **9***b*; nmr (CS_2, 60 MHz) δ: 4.52 (q, 1H, J = 8, 3.5 Hz, H-2), 4.05 (m, 1H, *syn*-7-H), 2.3–1.0 (norbornyl envelope), 1.88 (s, 3H, CH_3CO—); fraction 6; nmr (CS_2, 60 MHz) δ: 4.5 (q, 1H, *endo*-2-H), 4.80 (m, 1H, *anti*-7-H), 2.5–1.1 (norbornyl envelope), 1.85 (s, 3H, CH_3CO—).

LAH Reduction of Fraction 4

The bromoacetate **9***b* (0.81 g) that was collected by preparative glpc was dissolved in dry ether (50 mL) and LAH was added in portions to the refluxing solution until reduction was complete as indicated by analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C. The excess LAH was quenched with wet ether and water (1 mL) and the salts were filtered off and washed with additional ether (3 × 15 mL). The ether solution was dried and the solvent was removed on the rotary evaporator to yield 0.55 g of a viscous oil. Analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C indicated that the bromohydrin **9***d* was approximately 85% pure.

LAH Reduction of Fraction 6

The bromoacetate (0.43 g) that was collected by preparative glpc was dissolved in dry ether (25 mL) and LAH was added in portions to the refluxing solution until reduction was complete. The excess LAH was quenched with wet ether and water (1 mL) and the filtered salts were washed with additional ether (3 × 10 mL). After the solution was dried, the solvent was removed on the rotary evaporator to yield 0.15 g of viscous oil. Analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C established that four major products were present in a ratio of 32:43:11:9. Two minor products, of longer retention time, comprised a total of 6% of the mixture. The retention time of the first component was identical to retention time of *exo*-2-norbornanol.

LAH Reduction of Bromoacetates

An ether solution (25 mL) of a mixture of bromoacetates (9.35 g) obtained from a large scale ring-opening of 15.0 g 3-bromonortricyclene was added dropwise to a vigorously stirred slurry of LAH (0.87 g) in dry ether (75 mL). After the addition was complete the solution was refluxed for 2 h and the excess LAH was quenched with wet ether. The filtered salts were washed with ether (3 × 10 mL), the ether layer was dried, and the solvent was evaporated to yield 7.06 g of a viscous oil. Analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C established the presence of five major products

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and the approximate relative yields were 7:27:3:11:51 in order of increasing retention time. The peaks due to the last three products overlapped considerably. The first peak had a retention time which was identical to the retention time of *exo*-2-norbornanol. The major components that comprised 27% and 51% of the reaction mixture, respectively, were isolated by preparative glpc on a 1/4 in. × 5 ft 15% Carbowax column at 175°C. From 6.17 g of reaction mixture 0.97 g of the 27% component and 1.34 g of the 51% component were isolated after the collected samples were reinjected and recollected. Analytical glpc analysis on a 1/8 in. × 10 ft 10% Carbowax column at 210°C established that both samples were >90% pure; *syn*-7-bromo-*exo*-2-norbornanol (**8***b*); nmr (CS_2, 60 MHz) δ: 3.86 (m, 1H, *anti*-7-H), 3.67 (m, 1H, *endo*-2-H), 2.35 (bs, 3H, H-1, H-4, and —OH), 2.1–1.0 (norbornyl envelope, 6H). *Anti*-7-bromo-*exo*-2-norbornanol (**9***b*); nmr (CS_2, 60 MHz) δ: 4.12 (m, 1H, *syn*-7-H), 3.70 (dd, 1H, *endo*-2-H), 3.63 (s, 1H, —OH), 2.3–0.9 (8H, norbornyl envelope).

Oxidation of Syn-*7-bromo*-exo-*2-norbornanol*

The *syn*-bromohydrin (**8***b*) (0.79 g) was dissolved in preoxidized ether (2.5 mL) and the solution was vigorously stirred for 3 h in the presence of 2.5 mL of Brown's reagent. Water was added (4 mL) and the mixture was extracted with ether (4 × 10 mL). The combined ether extracts were washed with saturated $NaHCO_3$ solution, water (10 mL), and dried. Evaporation of the solvent gave 0.69 g of a viscous liquid. The *syn*-7-bromoketone (**12***b*) (0.33 g, >90% pure) was isolated by preparative glpc on a 1/4 in. × 5 ft 15% Carbowax column at 165°C; ir (neat): 2970, 2880, 1752, 1402, 1302, 1080, 1045, 950, 808, 742; nmr (CS_2, 60 MHz) δ: 4.14 (m, 1H, *anti*-7-H), 2.8–1.3 (8H, norbornyl envelope). The 2,4-DNP that was recrystallized from 95% EtOH – ethyl acetate and chromatographed over neutral alumina had a mp 202.5–203.5°C (lit. (25) mp 201.5–202.5°C).

Oxidation of Anti-*7-bromo*-exo-*2-norbornanol*

The *anti*-bromohydrin (0.88 g) was dissolved in preoxidized ether (2.5 mL) and the solution was vigorously stirred for 5 h in the presence of 2.8 mL of Brown's reagent. Water was added (4 mL) and the aqueous layer was extracted with additional portions of ether (4 × 10 mL). The combined extracts were washed with saturated $NaHCO_3$ solution, water (2 × 10 mL), and dried. Evaporation of the solvent gave 0.62 g of a viscous oil. In addition to *anti*-7-bromo-2-norbornanone (55%) there were three other components (20:10:14) of longer retention times. The *anti*-7-bromo-2-norbornanone (0.10 g) was isolated by preparative glpc on a 1/4 in. × 5 ft 15% Carbowax column at 170°C; ir (neat): 2960, 2870, 1752, 1400, 1267, 1242, 1122, 1075, 922, 788, 730; nmr (CS_2, 60 MHz) δ: 4.18 (m, 1H, *syn*-7-H) 2.8–1.3 (8H, norbornyl envelope). The 2,4-DNP was recrystallized from 95% EtOH and had a mp 153–155.5°C (lit (26) mp 151.5–152.5°C).

Preparation of Acetic Acid-O-d

To 146.0 g of freshly distilled acetic anhydride was added 28.6 g of D_2O (99.77%). After the solution stood overnight at ambient temperature, it was stirred at 70°C for 1 h. The ^1H nmr analysis established that the CH_3COOD was 99% isotopically pure and that there remained 2% of acetic anhydride.

D_2SO_4 Catalyzed Ring-Opening of 3-Bromonortricyclene

3-Bromonortricyclene (20.0 g, freshly distilled) was dissolved in CH_3COOD (300 mL) that contained 3.0 g of D_2SO_4 and the solution was heated at 75 ± 2°C for 77 h. Analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 185°C indicated that the reaction was 95% complete. Two-thirds of the reaction mixture was removed and poured onto a saturated solution of $NaHCO_3$ in a 3 L beaker. The aqueous layer was extracted with ether (4 × 100 mL), the combined ether layers were dried, and the solvent was evaporated to yield 15.5 g of a mixture of bromoacetates. Analytical glpc analysis on the Carbowax column at 125°C showed by the presence of a shoulder on the peak of longest retention time that there were at least three components. The products from a portion (2.0 g) of the reaction mixture were separated on a 1/4 in. × 10 ft 15% Carbowax glass column at 170°C into two fractions. To minimize isomerization a glass tube was also inserted into the injection port of the glpc. The first fraction (0.89 g) consisted of deuterated *anti*-7-bromo-*exo*-2-norbornyl acetate and the second (0.77 g) was a composite of deuterated *syn*-7-bromo-*exo*-2-norbornyl acetate and the other two acetates. *Anti*-7-bromo-*exo*-2-norbornyl acetate-*d*; nmr (CS_2, 100 MHz) δ: 4.56 (dd, 1H, *endo*-2-H), 4.10 (m, 1H, *syn*-7-H), 2.33 (bm, 2H, H-1 and H-4), 2.1–1.1 (5H, norbornyl envelope), 1.93 (s, 3H, CH_3CO—).

LAH Reduction of Anti-*7-bromo-2*-exo-*norbornyl Acetate*-d

The *anti*-bromoacetate-*d* (1.05 g) was dissolved in dry ether (10 mL), and added to a stirred slurry of LAH (0.11 g) in ether (10 mL). The mixture was stirred at reflux for 4 h and the excess LAH was quenched by the addition of ether saturated with water (10 mL) and water (1 mL). The filtered salts were washed with ether (3 × 10 mL), the ether solution was dried, and the solvent was evaporated to yield 0.69 g of a viscous oil that was shown by analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 200°C to be composed of 94% of one component. The main component, *anti*-7-bromo-*exo*-2-norbornanol-*d* (0.46 g, >95% pure) was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax glass column at 180°C; mp 52–55°C; nmr (CS_2, 100 MHz) δ: 4.20 (narrow m, 1H, *syn*-7-H), 3.73 (dd, 1H, J = 7 and 3 Hz, *endo*-2-H), 2.28 (bm, 1H, bridgehead), 2.15 (m, 1H, bridgehead), 2.1–1.0 (5H, norbornyl envelope), 1.72 (s, 1H, —OH).

LAH Reduction of a Mixture of Syn-*7-bromo*-exo-*2-norbornyl Acetate*-d *and Other Acetates*

Run 1. A portion of fraction 2 (0.99 g) that was predominately *syn*-7-bromo-*exo*-2-norbornyl acetate-*d* was dissolved in dry ether (10 mL) and added to a LAH (0.10 g) slurry in ether. The excess LAH was destroyed by the addition of wet ether (10 mL) and water (1 mL). The filtered salts were washed with ether (2 × 10 mL), the combined ether extracts were dried, and the solvent was evaporated to yield 0.84 g of a viscous oil. Analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 200°C showed that three products, in order of increasing retention time, were present in a ratio of 55:19:26. The products were separated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax glass column at 150°C. *Syn*-7-bromo-*exo*-2-norbornanol-*d* (0.20 g), the product of shortest retention time had a mp 43.5–45.5°C (lit (25) mp 40–43°C); nmr (CS_2, 100 MHz) δ: 3.87 (narrow m, 1H, *anti*-7-H), 3.67 (m, 1H, *endo*-2-H), 2.38 (bm, 2H, H-1 and H-4), 2.06 (s, 1H, —OH), 2.10–1.0 (5H, norbornyl envelope).

Run 2. Additional bromoacetate mixture (1.65 g) was reduced and the three products were collected in two fractions. One fraction was *syn*-7-bromo-*exo*-2-norbornanol-*d* and the other consisted of the two products of longer retention time.

Oxidation of Bromohydrins and Mass Spectrometric Analysis of Deuterated Bromoketones

The *syn*-bromohydrin (0.23 g) isolated from Run 2 was dissolved in preoxidized ether (1.5 mL) and the mixture was stirred for 6 h in the presence of 1 mL of Brown's reagent. Water was added (5 mL), the mixture was extracted with ether (3 × 5 mL), the combined ether extracts were washed with aqueous $NaHCO_3$ (2 × 5 mL), and dried. The solvent was removed on a rotary evaporator to yield 0.19 g of a viscous oil that was shown by analytical glpc to be composed essentially of a single component (>95%). The bromoketone was purified by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax glass column at 165°C; ms *m/e*:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

189 (M^+); 4.27 ± 0.18% d_0, 94.03 ± 0.42% d_1, 1.71 ± 0.24% d_2 (0.967 ± 0.005 excess d per molecule).

The *anti*-bromohydrin (0.084 g) isolated from the reduction of bromoacetates was dissolved in preoxidized ether (0.5 mL) and treated with Brown's reagent (0.4 mL). After the usual work-up and preparative glpc on a 1/4 in. × 10 ft 15% Carbowax glass column at 160°C, a pure sample of the *anti*-bromoketone was isolated; ms *m/e*: 189 (M^+); 5.63 ± 0.12% d_0, 92.48 ± 0.28% d_1, 1.90 ± 0.20% d_2 (0.977 ± 0.007 excess d per molecule).

The second fraction (0.20 g) isolated from Run 2 was dissolved in preoxidized ether (1.5 mL) and stirred for 5 h in the presence of 0.5 mL of Brown's reagent. Work-up yielded 0.15 g of a viscous oil that was shown by analytical glpc to be comprised mainly of two components which were 47% and 34%, respectively, of the mixture. The bromoketones were separated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax glass column at 160°C. Compound **14**; nmr (CS_2, 100 MHz) δ: 4.10 (bt, 1H, *endo*-5-H), 2.80 (bm, 1H, H-4), 2.45 (m, 1H, H-1), 2.3–1.6 (norbornyl envelope); ms *m/e*: 189 (M^+); 15.24 ± 0.34% d_0, 81.04 ± 1.31% d_1, 2.25 ± 0.08% d_2 (0.867 ± 0.022 excess d per molecule). Compound **15**; nmr (CS_2, 100 MHz) δ: 2.53 (dd, 1H, J = 8 and 4 Hz, *exo*-3-H), 2.33 (bm, 1H, 1H, H-1), 2.15–1.5 (norbornyl envelope); ms *m/e*: 189 (M^+); 10.47 ± 0.56% d_0, 86.54 ± 0.40% d_1, 2.99 ± 0.67% d_2 (0.914 ± 0.033 excess d per molecule).

HBr-catalyzed Ring-opening of Nortricyclanone

Anhydrous HBr that was passed through concentrated H_2SO_4 was slowly bubbled through a magnetically stirred solution of nortricyclanone (0.28 g) in CCl_4 (15 mL) maintained at 70 ± 2°C. After 20 h the mixture was washed with water (10 mL), saturated aqueous $NaHCO_3$ (2 × 15 mL), aqueous $Na_2S_2O_7$ (10 mL), and dried. After the solution was treated once with Norit, the solvent was removd on the rotary evaporator to yield 0.32 g of a viscous oil. *Exo*-5-bromo-2-norbornanone that comprised >95% of the reaction mixture was isolated by preparative glpc on a 1/4 in. × 10 ft 15% Carbowax column at 175°C; nmr (CS_2, 100 MHz) δ: 4.12 (td, 1H, *endo*-5-H), 2.84 (m, 1H, H-4), 2.47 (m, 1H, H-1), 2.4–1.6 (norbornyl envelope).

Determination of the Deuterium Distribution

The *syn*-7-bromohydrin-*d* (0.090 g, >90% pure) was dissolved in 2-propanol (6 mL) and sodium (0.2 g) was added in small portions to the solution that was maintained at reflux. After a 2 h reflux most of the 2-propanol was removed by distillation, water was added (2 mL), the solution was extracted with ether (3 × 10 mL), and the combined ether extracts were dried. After one treatment with Norit the ether was removed on a rotary evaporator to yield a viscous oil. Analytical glpc on a 1/8 in. × 10 ft 10% Carbowax column at 150°C established that product was *exo*-2-norbornanol-*d* (>95%). A pure sample of the *exo*-2-norbornanol-6-*endo*-*d* was isolated by preparative glpc on a 1/4 in. × 5 ft 15% Carbowax column at 80°C; ir (CS_2): 948, 915, 878, 860, 835, 798, 770, 740, 705 (Fig. 2*c*). There was no significant absorption at 960, 890, and 780 that would indicate the presence of *exo*-2-norbornanol-6-*exo*-*d* (Fig. 2*a*).

The *anti*-bromohydrin-*d* (0.93 g) was dissolved in 2-propanol (50 mL) and sodium (1.0 g) was added in small portions to the solution. After a 2 h reflux the reaction mixture was worked up and the *exo*-2-norbornanol-6-*endo*-*d* was isolated by preparative glpc from the oily solid that remained after the solvent was evaporated; ir (CS_2): 948, 915, 878, 835, 798, 770, 740, 705 (Fig. 2*a*). There was no significant absorption at 960, 890, and 780 that would indicate the presence of a significant amount (>10%) of *exo*-2-norbornanol-6-*exo*-*d* (Fig. 2*a*).

Stereochemistry of acid-catalyzed cleavage of 7-chloro-1-methylnortricyclene in deuterated medium; evidence for edge protonation of nortricyclenes

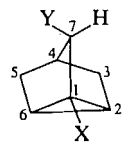
NICK HENRY WERSTIUK AND FRANK PETER CAPPELLI

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 5, 1979

NICK HENRY WERSTIUK and FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1725 (1980).

Cleavage of 7-chloro-1-methylnortricyclene (**1***e*) in D_2SO_4–DOAc yields deuterated *syn*-7-chloro-1-methyl-*exo*-2-norbornyl acetate (**3***a-d*) (1.04 excess *d* per molecule) and deuterated *anti*-7-chloro-1-methyl-*exo*-2-norbornyl acetate (**3***b-d*) (1.28 excess *d* per molecule) as the kinetic products. ^1H and ^2H nuclear magnetic resonance spectroscopic analysis of the corresponding alcohols complexed with $Eu(fod)_3$ shows that deuterium is located *endo* at C-6 and in the methyl group of the *syn*-7-chloroacetate, *endo* at C-6 and C-2, at C-7, and in the methyl group of the *anti*-7-chloroacetate. That the deuterium at C-6 of both acetates is 80-90% stereochemically pure *endo*, in our view, establishes that the bond farthest removed from the electron-withdrawing chlorine is preferentially cleaved via edge deuteronation.



NICK HENRY WERSTIUK et FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1725 (1980).

Les produits cinétiques du clivage du chloro-7-méthyl-1 nortricyclène (**1***e*) dans le mélange de D_2SO_4–DOAc sont les suivants: les acétates du chloro-7 *syn* méthyl-1 norbornyle-2 *exo* (**3***a–d*) deutérés (1.04 de *d* en excès par molécule) et les acétates du chloro-7 *anti* méthyl-1 norbornyle-2 *exo* (**3***b–d*) deutérés (1.28 de *d* en excès par molécule). L'analyse par spectroscopie de rmn du ^1H et du ^2H des alcools correspondants complexés avec $Eu(thd)_3$ révèle que le deutérium est situé en position *endo* du C-6 et dans le groupe méthyle de l'acétate du chloro-7 *syn* est en position *endo* des carbones-2,6 et 7 dans le groupe méthyle de l'acétate du chloro-7 *anti*. Le fait que 80 à 90% du deutérium en C-6 des deux acétates soit sous la forme *endo*, prouve, à notre avis, que la liaison la plus éloignée du chlore électro-attracteur est scindée préférentiellement par l'intermédiaire d'une deutération par l'arête.

Introduction

Over the past two decades the mechanisms of electrophilic cleavage of cyclopropanes have been probed by stereochemical studies. To determine the structures of transition states and intermediates involved in the ring-openings and to establish how substituents and the nature of the electrophile affect transition state structure is the usual objective of researchers (1–6). Although an electrophile can attack face-wise, edge-wise, or corner-wise, all results obtained have been interpreted on the basis of edge protonation or corner protonation because face-protonated cyclopropane is a high-energy species (7, 8). While inversion or retention may attend attack by an electrophile, a proton, in most cases, cleaves a three-membered ring with retention of configuration at the carbon bearing the proton. Studies involving the protonation of nortricyclene and several of its derivatives have generated considerable interest because the results relate to the long-standing norbornyl cation problem (9). From a study of the cleavage of nortricyclene (**1***a*) Nickon and Hammons (10) concluded that the cleavage of the three-membered ring yields the non-classical norbornyl cation. However, the results of our study (11) of 3-chloronortricyclene (**1***b*) and 3-bromonortricyclene (**1***c*) as documented in the preceding paper, point to ring cleavage via edge protonation (deuteronation) as the major reaction pathway and the classical *syn* and *anti*-7-halo-2-norbornyl cations are formed. In our view nortricyclene (**1***a*) also undergoes ring-opening via edge-wise attack and a rapidly-equilibrating norbornyl cation is formed. To determine quantitatively the stereochemistry of the ring opening of 1-methylnortricyclene (**1***d*) and to identify the kinetic products, Hammons *et al.* (12) studied the D^+ catalyzed ring-opening of **1***d*. They established that *endo*-2-methyl-*exo*-2-norbornyl acetate, in fact, is the kinetic product and that cleavage of the C1—C2 and C1—C6 bonds occurs with 62 ± 3% retention and 38 ± 3% inversion of configuration. The results were discussed on the basis of an intermediate non-classical 1-methylnorbornyl cation (**2**).

ation of the two different cyclopropane bonds to form classical cations rather than a non-classical ion we prepared 7-chloro-1-methylnortricyclene (**1***e*) and carried out the ring-opening in non-deuterated and deuterated medium. We were also interested in preparing specifically C-6 deuterated 1-methyl-*exo*-2- and 7-chloro-1-methyl-*exo*-2-norbornyl brosylates that we required to extend our study of the unusually large γ-KIE's observed for solvolysis of *exo*-norbornyl sulfonate esters (13, 14). The results of our study of the acid-catalyzed ring-opening of 7-chloro-1-methylnortricyclene are documented in this publication.

Results

Synthesis of 7-Chloro-1-methylnortricyclene (1e)

A Diels–Alder reaction between methylcyclopentadiene and ethene yielded a mixture of 1-methyl- and 2-methyl-2-norbornenes. Their spectral characteristics were identical to those published previously (15). Chlorination of 2-methyl-2-norbornene in CH_2Cl_2, in the presence of pyridine, gave previously unknown **1***e*. The ir and nmr spectra of **1***e* were consistent with the proposed structure.

Ring-opening in H_2SO_4–CH_3COOH; Identification of Products

When **1***e* was heated in 0.1 *M* H_2SO_4 – CH_3COOH at 62 ± 2°C for 105 h, it was converted into *syn*-7-chloro-1-methyl-*exo*-2-norbornyl acetate (**3***a*) (24%) and *anti*-7-chloro-1-methyl-*exo*-2-norbornyl acetate (**3***b*) (71%). We established, by analytical glpc, that the relative yields of the products did not change during the reaction and that the products did not rearrange in the injection block of the gas chromatograph. The analysis also showed that there were two very minor products, each < 2%, in the region of the chloroacetates and three very minor products, each < 2%, close in retention time to starting material. The minor components, which may have been tertiary acetates and isomeric alkenes (*vide infra*), were not isolated because they were present in very small amounts.

That there is a one-proton resonance at δ 4.50 in the ^1H nmr spectrum of **3***a* and a one-proton resonance at δ 4.55 in the spectrum of **3***b*, identified the products as secondary acetates. The chemical shifts of the *anti*-7-proton (δ 3.51) of **3***a* and the *syn*-7-proton (δ 3.77) of **3***b* are in agreement with assigned structures because a proton at C-7 *syn* to an *exo* acetoxyl group is deshielded relative to *anti*-proton by about 0.2–0.3 ppm (11, 16).

Reduction of the mixture of chloroacetates by sodium in 2-propanol gave 1-methyl-2-norbornanol (96%) and 4% of an unidentified product. From an analytical glpc analysis we established that < 5% of the *endo* alcohol was present. When the mixture of chloroacetates was reduced by LAH a mixture of the *syn*-7-chloro-1-methyl-*exo*-2-norbornanol (**3***c*) (22%) and *anti*-7-chloro-1-methyl-*exo*-2-norbornanol (**3***d*) (78%) was obtained. Analytical glpc analysis showed that **3***c* and **3***d* comprised > 95% of the reaction mixture. That **3***c* was the minor component (22%) was corroborated by the fact that its retention time, due to internal hydrogen bonding, was considerably shorter than the retention time of **3***d*.[1]

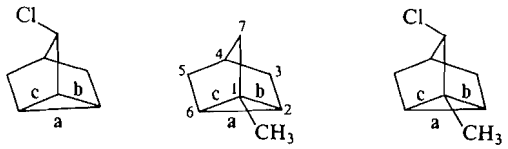
Cleavage in D_2SO_4–CD_3COOD; Determination of the Stereochemistry of Ring-opening

Compound **1***e* was ring-opened in 0.1 *M* D_2SO_4 – CD_3COOD (65 ± 2°C, 60 h) and yielded 27% of **3***a-d* and 73% of **3***b-d*. The acetates were reduced by LAH in ether, the deuterated chlorohydrins were isolated by preparative glpc, and a small portion of each chlorohydrin was oxidized to the corresponding chloroketone by Brown's reagent. The chloroketones, after being purified by preparative glpc, were assayed for deuterium mass spectrometrically. As in the case of the deuteronation of 1-methylnortricyclene the acetates contained greater than one deuterium atom per molecule (Table 1). To establish the location of the deuterium the ^1H nmr spectra of the chlorohydrins were obtained in the absence and presence of the lanthanide shift reagent Eu(fod)$_3$. To provide a check for the ^1H nmr analysis we also obtained ^2H nmr spectra of the deuterated chlorohydrins in the presence of Eu(fod)$_3$. In the ^1H nmr spectrum of the non-deuterated *syn*-chlorohydrin **3***c* given in Fig. 1*a*, it is interesting to note that the resonance due to *endo*-2-H, unlike the resonance of the *anti*-chlorohydrin **3***d* (Fig. 1*c*), is a broad multiplet. We believe that the coupling of *endo*-2-H to —O—H is observed in this case because internal hydrogen bonding to the chlorine reduces the rate of exchange of the —O—H. The spectrum of the deuterated *syn*-chlorohydrin **3***c-d* is given in Fig. 1*b* and the spectra of **3***c* and **3***c-d* complexed with Eu(fod)$_3$ are given in Figs. 2*a* and 2*b*, respectively. Assignment of the signals at δ 16.7 (*endo*-2-H), 10.7 (*exo*-3-H), 7.7 (CH_3—), 7.1 (*anti*-7-H), 6.1 (*endo*-3-H), and 5.1 (H-4) in Fig. 2*a* is straightforward. That the signal at δ 3.7 is due to the *endo*-proton at C-6 is established from a comparison of the non-shifted spectra of **3***c* (Fig. 1*a*) and **3***c-d*

[1]This behaviour parallels the behaviour of the *syn*-7- and *anti*-7-chloro-*exo*-2-norbornanols (11) on a Carbowax column.

TABLE 1. Deuterium content of *syn*-7- and *anti*-7-chloro-1-methyl-2-norbornanones

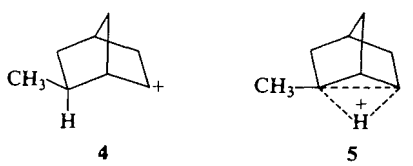
Ketone	Composition*				Excess *d* per molecule
	d_0	d_1	d_2	d_3	
syn-7-Chloro	3.72±0.42	86.19±0.86	9.09±0.27	—	1.044±0.016
anti-7-Chloro	5.24±0.14	65.95±0.47	22.10±0.18	5.98±0.22	1.281±0.007



*Mass spectrometric analyses were carried out at low voltage (10–15 eV). Averages of five determinations. Deviations are the standard deviations.

(Fig. 1*b*). Since *endo* protons at C-5 and C-6 of norbornanes generally appear at higher field (≃1 ppm) than *exo* protons (17,18) it is clear from the reduction of the signal intensity in the high field region, δ 1.1–1.2, of **3***c*-*d* (Fig. 1*b*) that the deuterium is located at an *endo* position. Since there is no viable mechanism for introducing *endo* deuterium at C-5, the deuterium must be located *endo* at C-6. While it is clear from the shifted spectrum of **3***c*-*d* (Fig. 2*b*) that most of the deuterium is located *endo* at C-6, we established by integration that deuterium was located in the methyl group as well.

The ^{1}H nmr spectra of the *anti*-chlorohydrins **3***d* and **3***d*-*d* are given in Figs. 1*c* and 1*d*, respectively. The spectrum of *anti*-chlorohydrin **3***d* complexed with Eu(fod)$_3$ is given in Fig. 2*c*. Here too, the assignment of the signals at δ 17.9 (*endo*-2-H), 12.9 (*exo*-3-H), 12.3 (*syn*-7-H), 7.4 (CH_3—), 7.0 (*endo*-3-H), and 5.1 (H-4) is straightforward. That the signal at δ 4.5 is due to the *endo*-proton at C-6 and that the deuterium in **3***d*-*d* is located predominantly at this position is established from a comparison of the spectra of **3***d* and **3***d*-*d* and from an inspection of the shifted spectrum of the deuterated *anti*-chlorohydrin **3***d*-*d* (Fig. 2*d*). As in the case of the *syn*-chlorohydrin, it is clear from a careful inspection of the high field regions (δ 0.7–1.0) of the spectra of **3***d* and **3***d*-*d* (Figs. 1*c* and 1*d*) that there is a significant reduction of the signal intensity in the spectrum of the latter. This is consistent with deuterium being located *endo* at C-6. While it is clear from the shifted spectrum of **3***d*-*d* (Fig. 2*d*) that the deuterium is located predominately *endo* at C-6, we established by integration that deuterium was also located at C-2, C-7, and in the methyl group. That the ^{1}H nmr integrals are a good measure of the deuterium distribution is confirmed by the ^{2}H nmr spectra of the deuterated *syn*- and *anti*-chlorohydrins obtained in the presence of Eu(fod)$_3$ (Figs. 3*a* and 3*b*). The deuterium distributions in the chloroacetates, as determined by ^{1}H and ^{2}H nmr are listed in Table 2. It should be noted that the deuterium content of **3***d*-*d* established by mass spectrometric assay of the corresponding ketone is slightly less than the actual deuterium content because the deuterium located at C-2 (Table 2) is lost during oxidation.



Discussion and Conclusions

In the preceding paper we showed that the deuterium at C-6 of the major products *syn*-7- and *anti*-7-chloro-*exo*-2-norbornyl acetates of ring-opening of 3-chloronortricyclene (**1***b*) is 85–90% stereochemically pure *endo* and thereby established that edge deuteronation of bond **a** of **1***b* is preferred over edge deuteronation of bonds **b** and **c** by 5:1. Hammons *et al.* (12) in a related study established that 1-methylnortricyclene (**1***d*) is ring-opened with 62 ± 3% retention and 38 ± 3% inversion of configuration and interpreted the results on the basis of a mechanism which involved formation of a non-classical 2-methylnorbornyl cation.

1*b* **1***d* **1***e*

In our view the ratio of 1.6:1, in favour of retention, is near the ratio which would be observed if bonds **a** and **b** of **1***d* are cleaved simply on the basis of a statistical edge-wise attack of D^+. This, of course, is possible only if the directing effect of the methyl group is small. That a methyl group enhances the rate of a 6,2-hydride shift in the 6-methyl-2-norbornyl cation **4** only by a factor between 5 and 15 (19) (the transition states for the hydride shift and ring-opening of **1***d*, both depicted by **5**, should be similar with respect to charge distribution) establishes that the directing effect of methyl in the ring-opening should be small.

4 **5**

To quantitatively establish the effect of a methyl group on the cleavage of **1***b*, we determined the rate

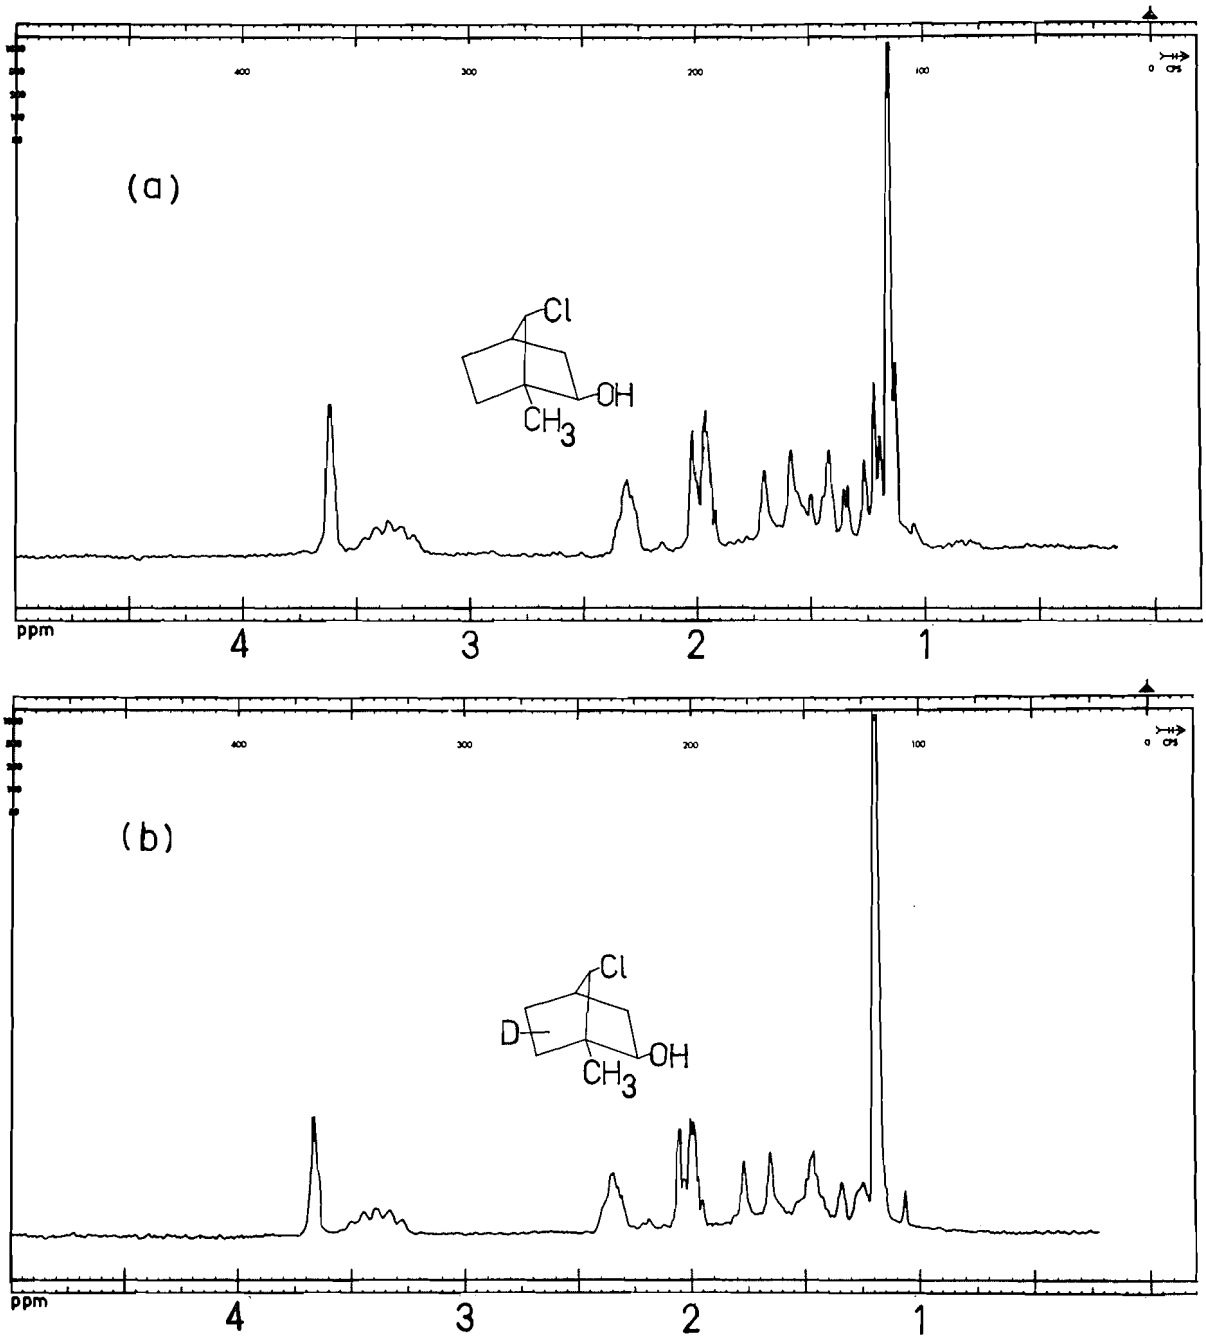

FIG. 1. (*a*) 100 MHz (CS_2) ^1H nmr spectrum of *syn*-7-chloro-1-methyl-*exo*-2-norbornanol; (*b*) *syn*-7-chloro-1-methyl-*exo*-2-norbornanol-*d*; (*c*) *anti*-7-chloro-1-methyl-*exo*-2-norbornanol; (*d*) *anti*-7-chloro-1-methyl-*exo*-2-norbornanol-*d*.

constants for ring opening of **1***b* and **1***e* in 0.1 *M* H_2SO_4 – CH_3COOH at 70°C (see Experimental). That a small rate acceleration of 3.9 is observed upon introduction of a methyl group is in accord with our view that the methyl group *does not control* the regiochemistry of the initial protonation (deuteronation) of nortricyclenes.

That phenylcyclopropane is 7.8 times less reactive than cyclopropane (20) provides further support that cation stabilizers borne by the cyclopropane do not significantly stabilize the transition state. In the case of 1-methylnortricyclene a small rate-retarding steric effect (1) of the methyl could mask a small preference for addition to the C1—C2

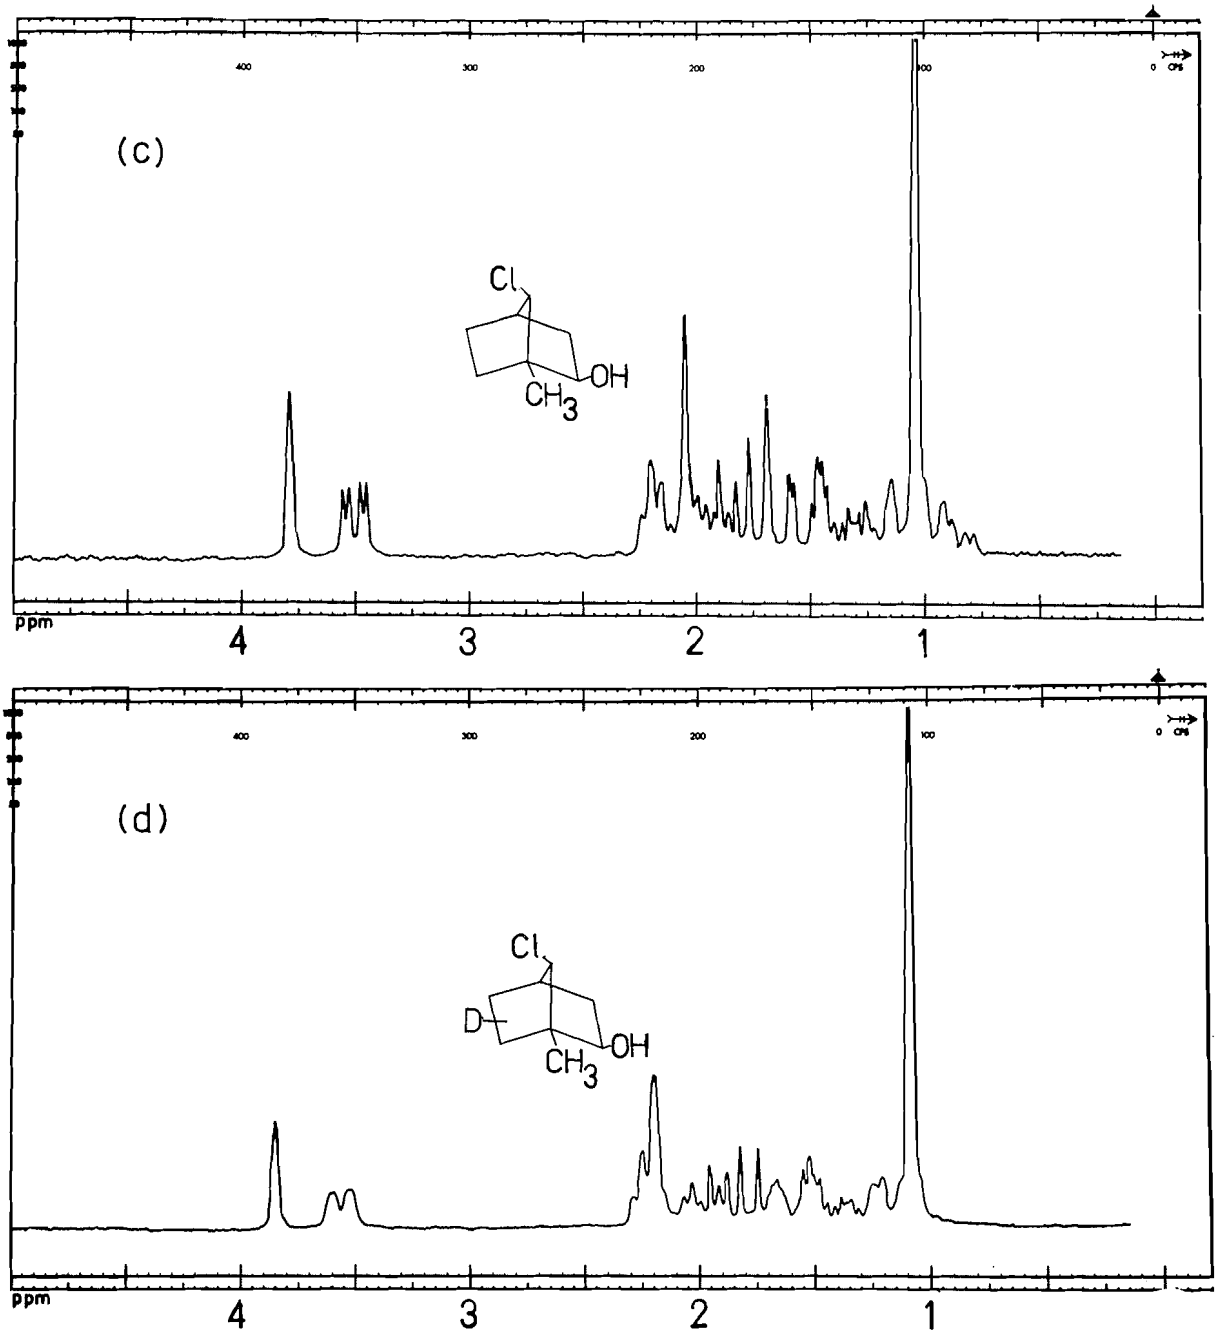

FIG. 1 (*concluded*)

and C1—C6 bonds so that protonation, and of course the stereochemical outcome of the reaction, would be controlled basically by the statistical factor. If this is indeed the case, then deuteronation (Scheme 1) of bond **a** of 7-chloro-1-methylnortricyclene, as in the case for 3-chloronortricyclene, should be preferred over deuteronation of bonds **b** and **c** by about 5:1. Since cations **6** and **7** are the initial intermediates, the stereochemistry of the cleavage should be similar to the stereochemistry of the ring-opening of 3-chloronortricyclene (11). From the data listed in Table 2 it is clear that this is indeed the case because the deuterium at C-6 of the 7-chloro-1-methyl-*exo*-2-norbornyl acetates is 80–90% stereochemically pure *endo*.

Clearly then, our studies have established that

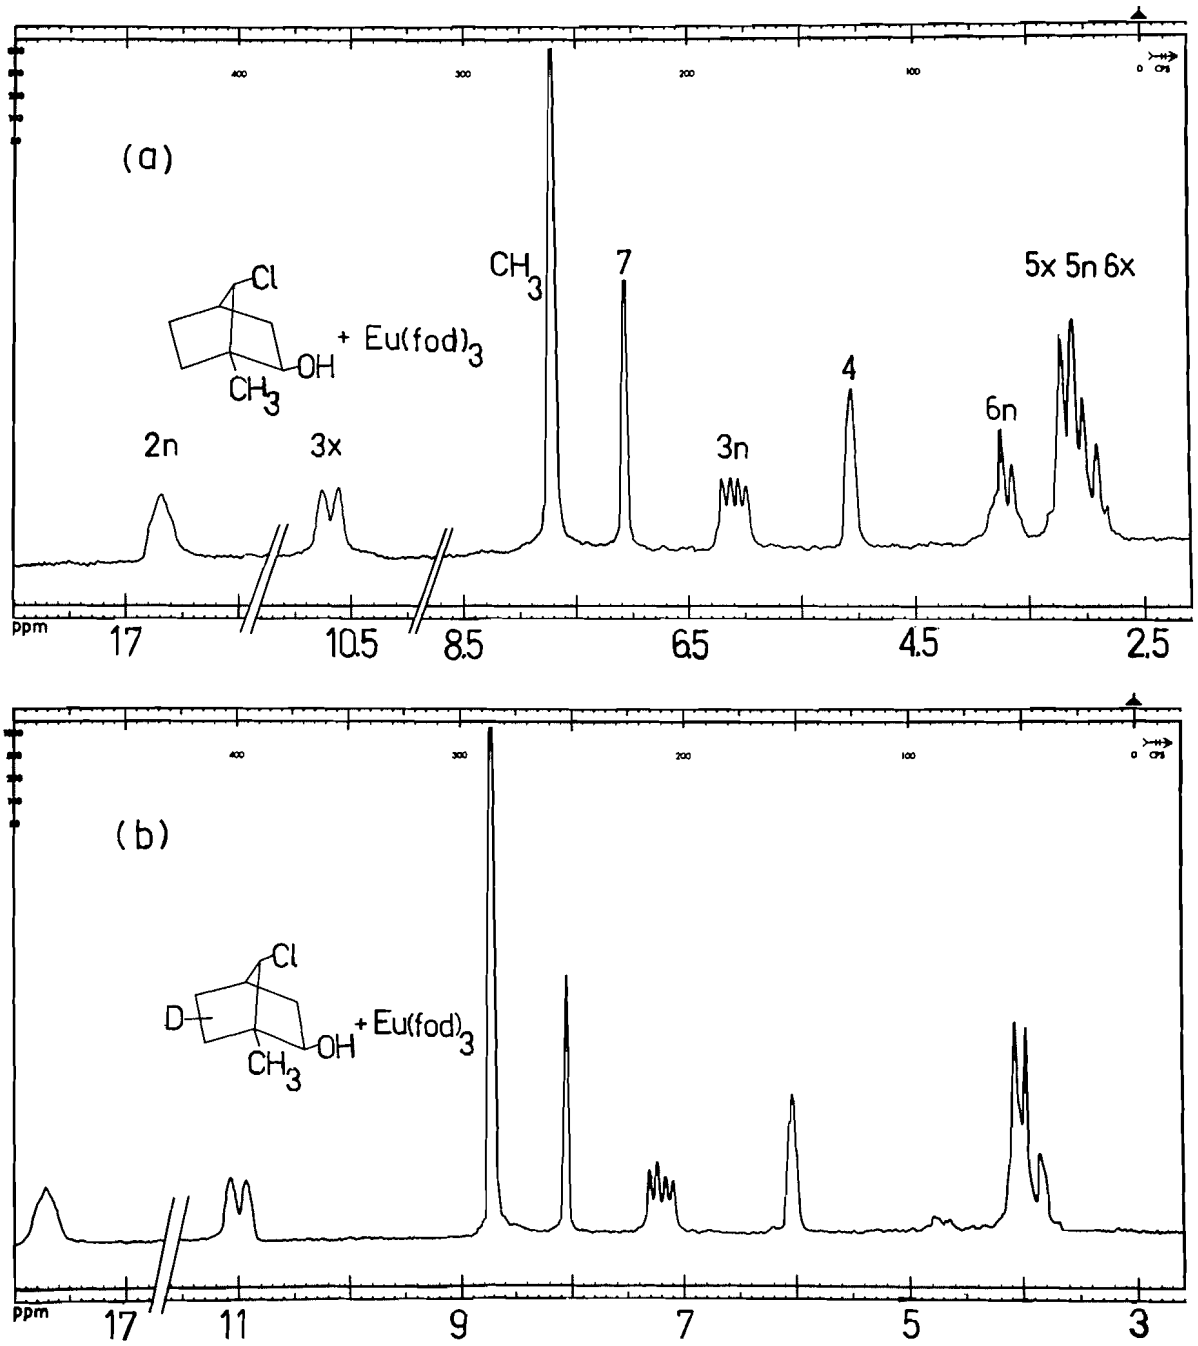

FIG. 2. (*a*) 100 MHz (CCl_4) ^1H nmr spectrum of *syn*-7-chloro-1-methyl-*exo*-2-norbornanol complexed with $Eu(fod)_3$; (*b*) *syn*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* complexed with $Eu(fod)_3$; (*c*) *anti*-7-chloro-1-methyl-*exo*-2-norbornanol complexed with $Eu(fod)_3$; (*d*) *anti*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* complexed with $Eu(fod)_3$.

there exists a common mechanism for the acid-catalyzed ring-opening of nortricyclene, 1-methylnortricyclene, and their halo-derivatives **1***b* and **1***e*.

That deuterium is located at C-7 and in the methyl group of the chloroacetates indicates that formation of the isomeric chloroalkenes **10**, **11**, **12**, **17**, **18**, and **19** attends the ring-opening. Possible routes to the chloroalkenes are listed in Schemes 1 and 2. The appearance of minor components which had glpc retention times very close to **1***e* is consistent with this requirement. The deuterated 2-

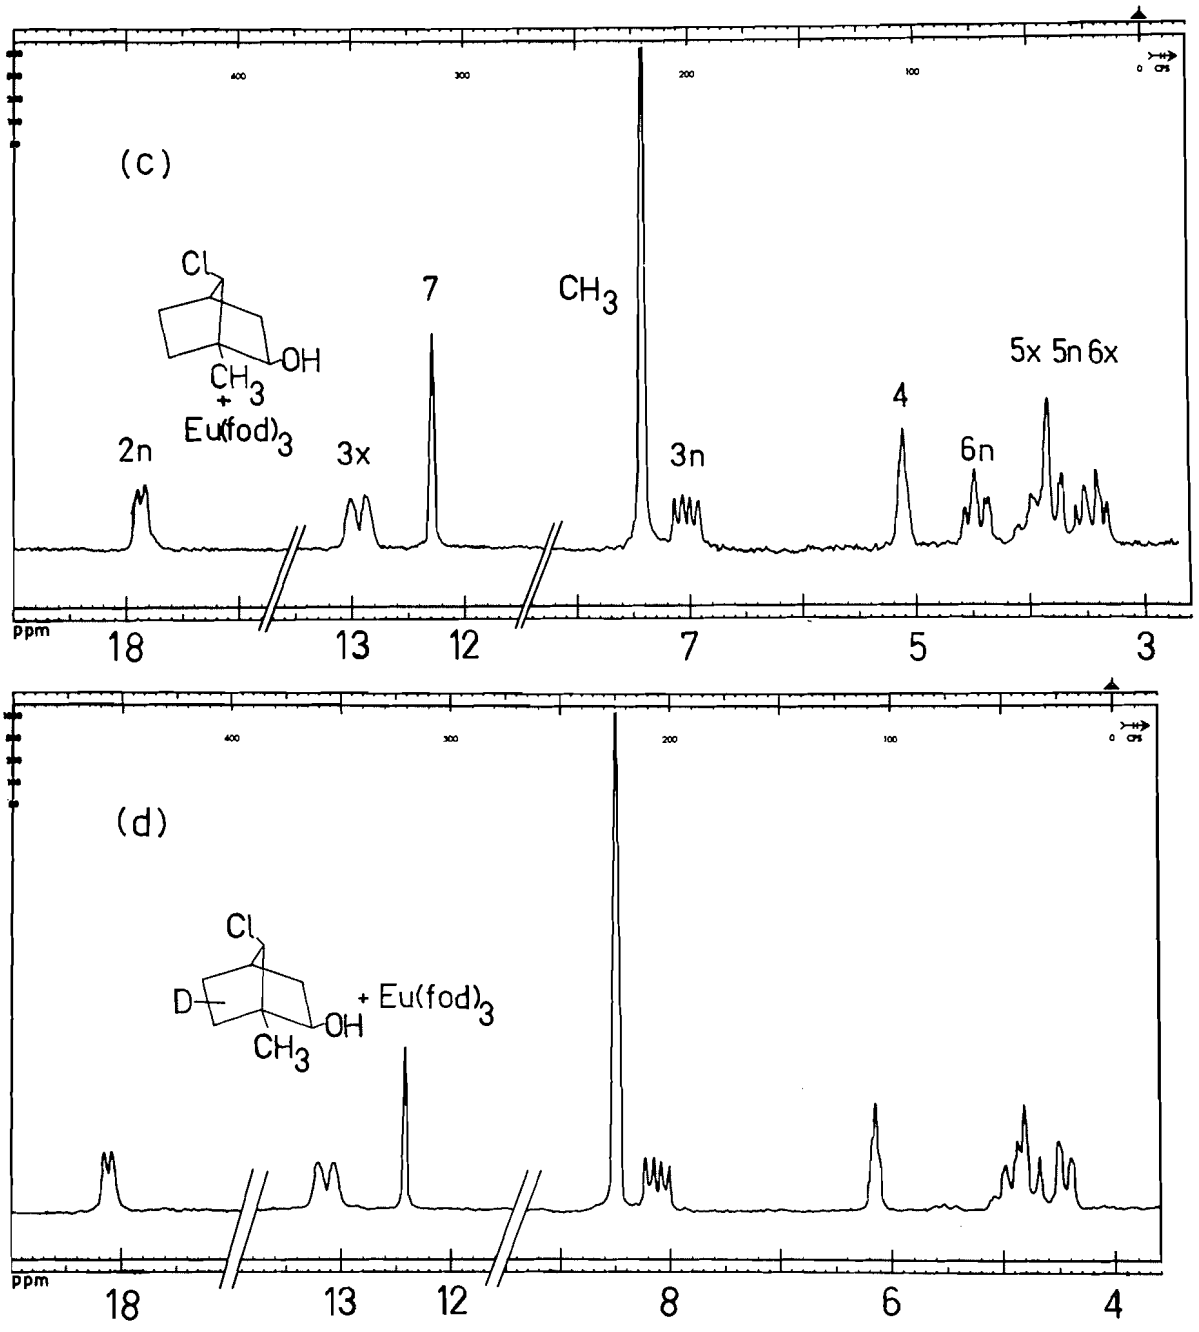

FIG. 2 (*concluded*)

chloro-3-methyl-2-norbornenes, **11** and/or **18**, are mandatory intermediates and it is clear that deuterium is incorporated at C-7 only in the *anti*-7-chloroacetate because deuteronation of **11** and/or **18** occurs predominately from the *exo* face (Scheme 3). While the chloroalkenes **10**, **11**, **12**, **17**, **18**, and **19** can be generated by deuteronation of bonds **a**, **b**, and **c** (Schemes 1 and 2), the deuterium distribution in the products and stereochemical outcome of the reaction points to their formation predominantly via deuteronation of bonds **b** and **c**. If, as we postulate, bonds **a**, **b**, and **c** of **1***e* are deuteronated with the same selectivities as bonds **a**, **b**, and **c** of **1***b* (11), then approximately 20% of the ring-opening of **1***e* should occur via cleavage of bonds **b** and **c**. Our claim that ring-opening of **1***e* occurs via deuteronation of bonds **b** and **c** to the same extent as in 3-chloronortricyclene is sup-

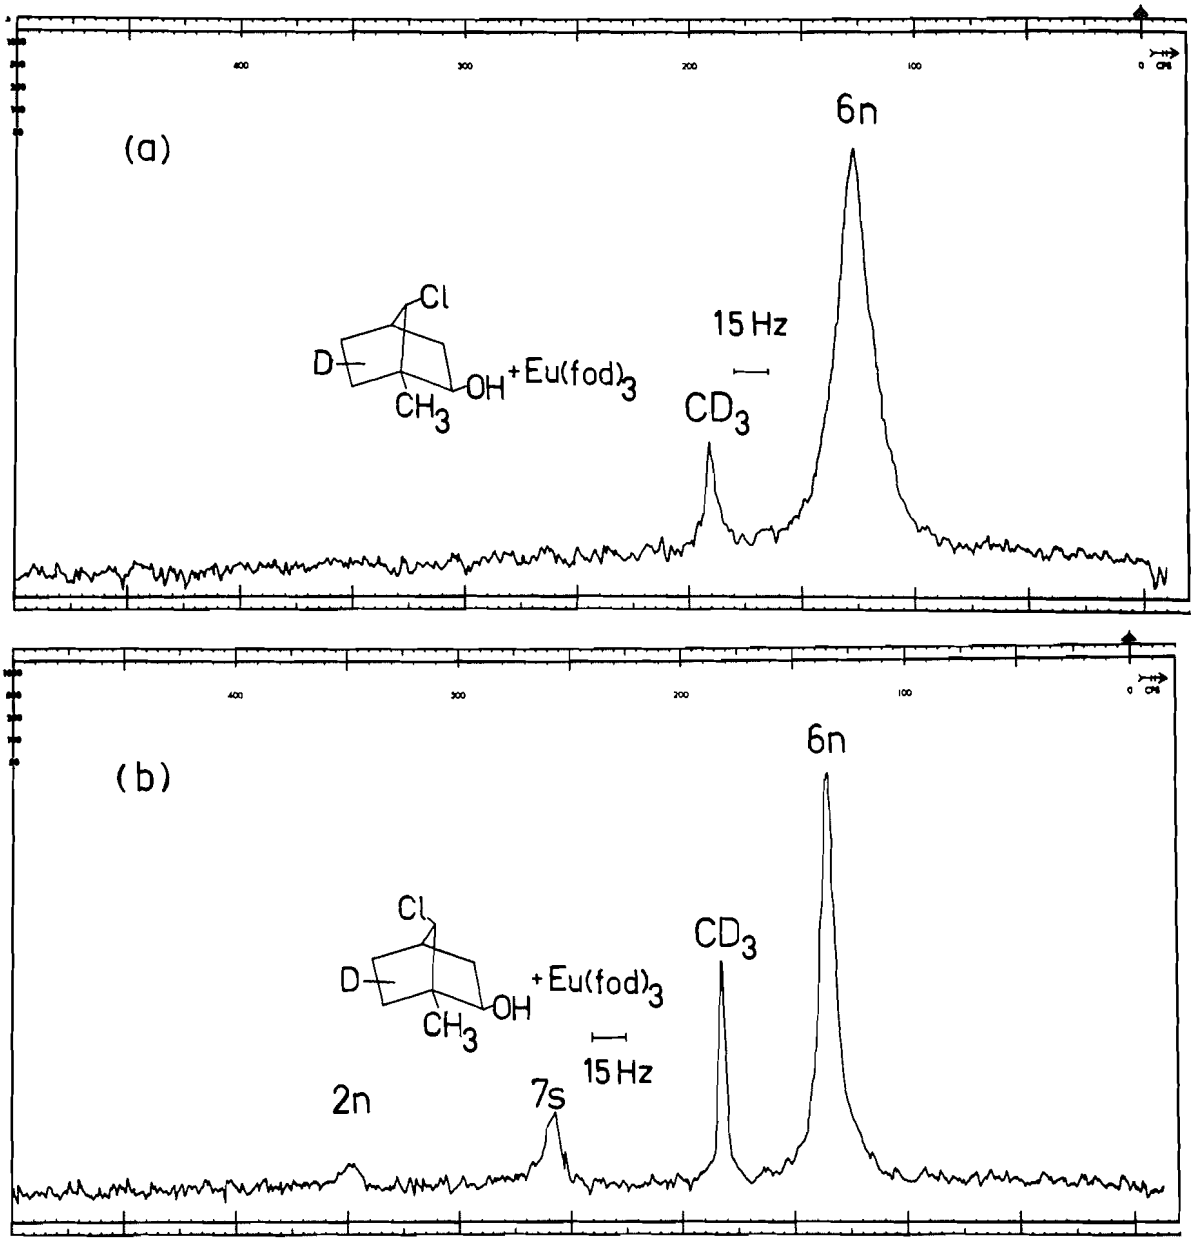

FIG. 3. (*a*) 15.4 MHz (CCl_4) ^2H nmr spectrum of *syn*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* complexed with $Eu(fod)_3$; (*b*) *anti*-7-chloro-*exo*-2-norbornanol-*d* complexed with $Eu(fod)_3$.

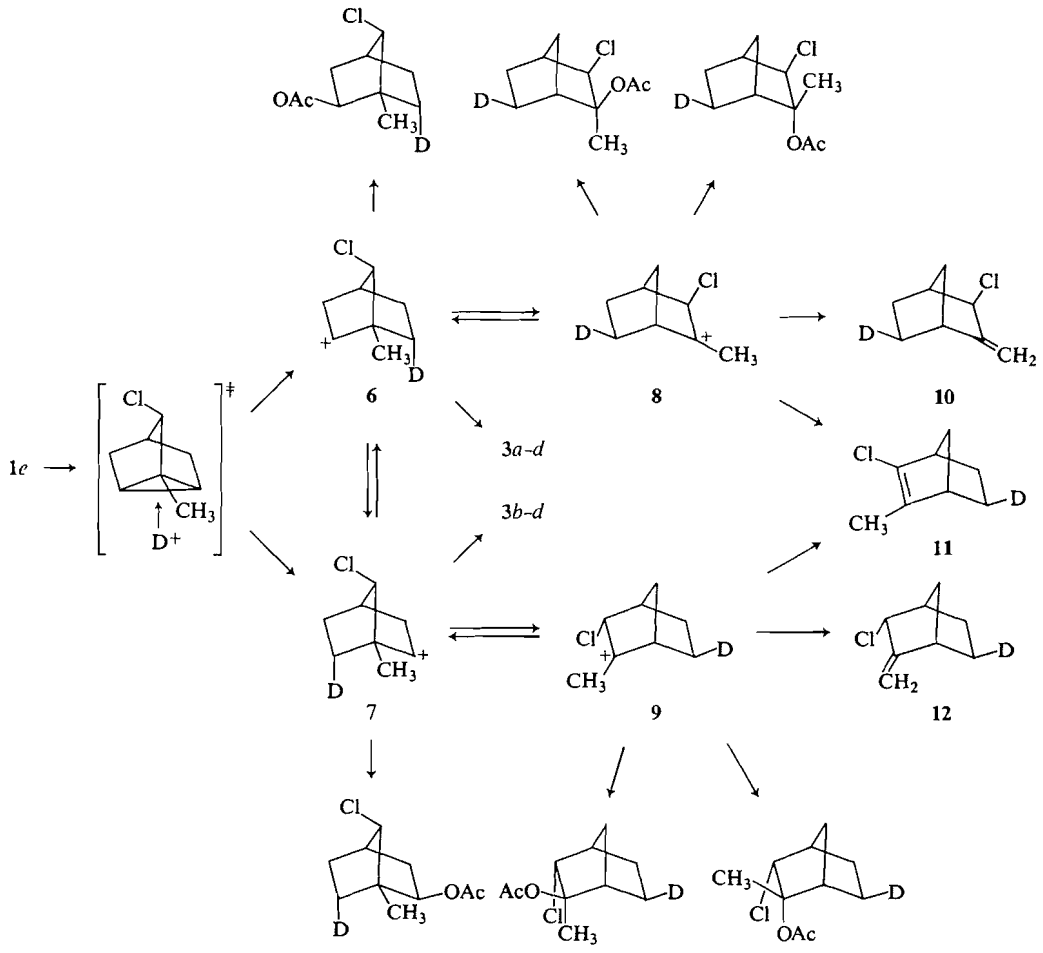

ported by an analysis based on the stereochemical purity of the deuterium at C-6 of the 7-chloroacetates. Since edge deuteronation of bonds **b** and **c** (Scheme 2) eventually leads to *syn*-7- and *anti*-7-chloroacetates with deuterium located *exo* at C-6, the amount of *exo* deuterium should be a measure of the extent of protonation of bonds **b** and **c**. From the ^1H nmr and ^2H nmr analyses it is clear that approximately 10–20% of the deuterium is *exo* at C-6 and this result supports our proposal.

That deuterium is located at C-2 of **3***d*-*d* indicates that bond **b** of **1***e* is edge deuteronated to yield cation **15** that in turn leads, via an alkyl shift and a hydride shift, to *anti*-7-chloro-1-methyl-*exo*-2-norbornylacetate-*endo*-2-*d* (Scheme 4). It is interesting to note that there is no deuterium at C-2 of the *syn*-7-chloroacetate, and we suggest two reasons for this result. If deuteronation of bond **c** occurs to yield cation **16** that rearranges via a 1,2-alkyl shift (Scheme 5), perhaps the 6,2-hydride shift

TABLE 2. Distribution of deuterium in 7-chloro-1-methyl-*exo*-2-norbornyl acetates

Substrate	Method	CH_3	H-2	*endo*-6-H	H-7	*d* by ^1H nmr

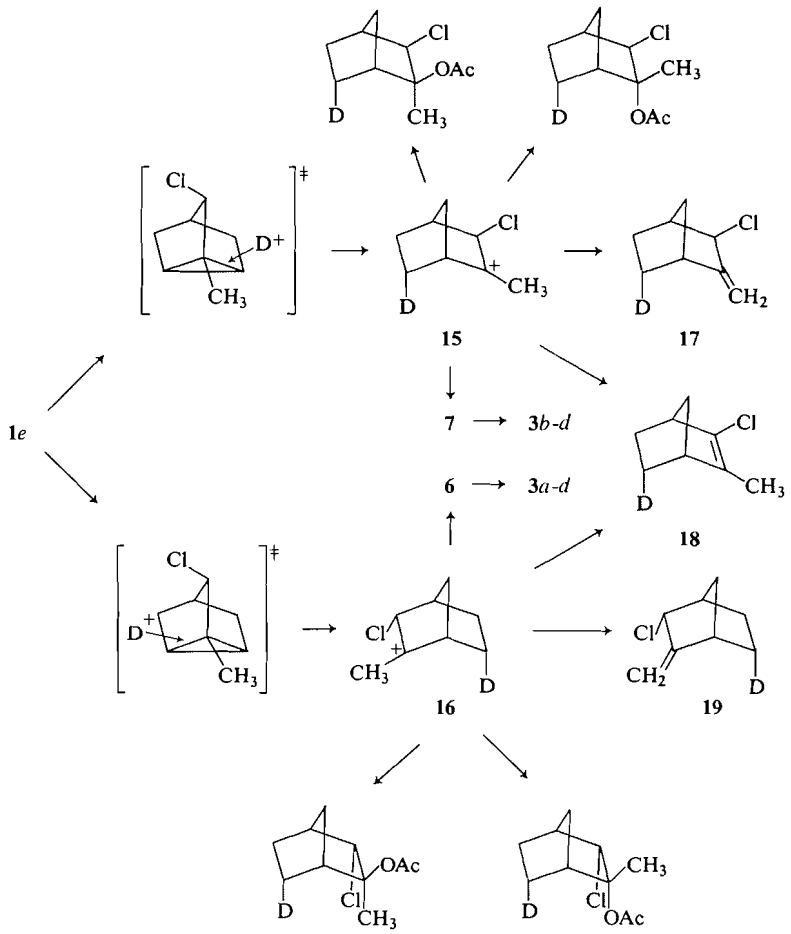
*The errors are the sum of errors (±5%) in the integral at the labelled site and in a standard one proton integral derived as an average of the H-4, *endo*-3-H, and *exo*-3-H integrals with an assumed error of ±5% in each.
†The peaks were traced, cut out, and weighed. An error of ±10% is assumed in this analysis and the deuterium content at each site is related to the total deuterium content determined by mass spectrometry.
‡These values correspond to *endo* and *exo* deuterium at C-6.

SCHEME 1



required to convert the *anti*-7-chlorocation to the *syn*-7-chlorocation does not compete with reaction with solvent. This, however, seems an unreasonable expectation because the *anti* to *syn* conversion via a hydride shift competes with solvent capture in the acetolysis of *anti*-7-chloro-*exo*-2-norbornyl tosylate (16). Perhaps bond **c** of **1***e* is sterically hindered by the chloro and methyl groups to the point where ring-opening occurs predominately by cleavage of bonds **a** and **b**.

As far as exchange of the methyl group is concerned, 3-chloro-2-methylenenorbornanes **12** and/or **19** must be involved as intermediates (Schemes 1 and 2).

It is interesting to note that in this case the secondary acetates are the kinetic products rather than the tertiary acetates which are the kinetic products of the ring-opening of 1-methylnortricyclene (**1***d*). This must be a consequence of the fact that the $-I$ effect of the chlorine outweighs the small $+I$ effect

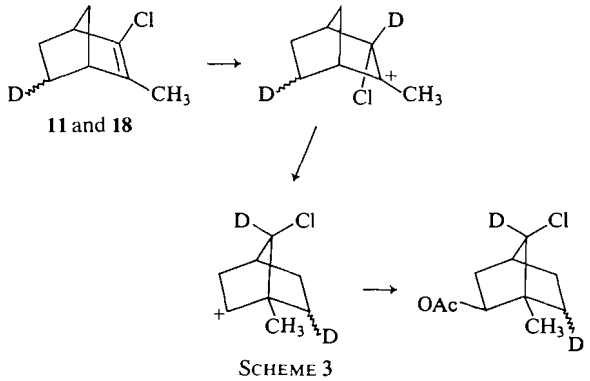
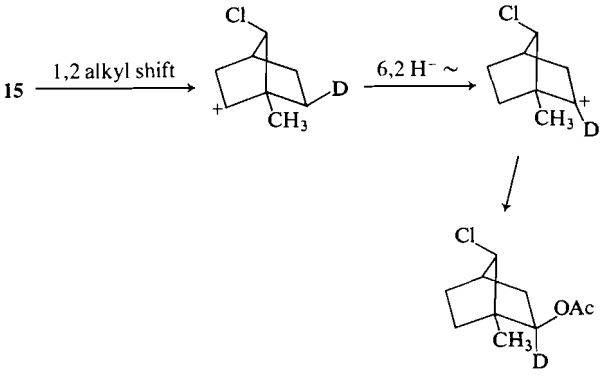
SCHEME 2



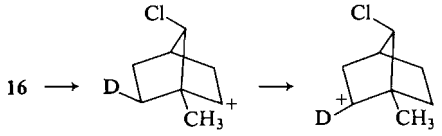
of the methyl group and thereby directs the ring-opening via bond *a*.

Experimental



General

Proton magnetic resonance (pmr) spectra were recorded on Varian T-60, A-60, and HA-100 spectrometers with tetramethylsilane (TMS) as the internal standard. Samples were dissolved in either carbon tetrachloride or carbon disulfide. Deuterium magnetic resonance (dmr) spectra were recorded on a Varian model XL-100 spectrometer. Chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Infrared spectra were recorded on Perkin Elmer 337 and Beckman IR-5 infrared spectrometers and the samples were dissolved in carbon tetrachloride or carbon disulfide. Absorption frequencies were calibrated with a polystyrene film and are expressed in reciprocal centimeters (cm^{-1}). For brevity, the notation cm^{-1} is excluded. Mass spectra were taken on a Hitachi Perkin Elmer RMU-6A spectrometer at 80 eV. Deuterium assay analyses were performed at 10 to 15 eV and are expressed as atoms of deuterium per molecule in excess of natural abundance deuterium. Analytical gas liquid partition chromatography was performed on a Varian Aerograph Model 204B dual column analytical gas chromatograph equipped with dual flame ionization detectors using helium as the carrier gas. The gas flow rate was usually 20–30 mL/min. Preparative gas liquid partition chromatography was carried out on a Varian Aerograph Model A-90-P gas chromatograph with a thermal conductivity detector and a helium flow rate of 50–60 mL/min. Spinning band distillations were performed on a Nester–Faust auto annular 30 in Teflon spinning band distillation column. Melting points were recorded on a Kofler hot-stage apparatus and are uncorrected. Boiling points are also uncorrected.



All organic solutions were dried with either anhydrous sodium sulfate or magnesium sulfate.

SCHEME 4

SCHEME 5

2-Methyl-2-norbornene

In a typical run, ethylene (800 psi) and methylcyclopentadiene dimer (125 g) were reacted at 200°C for 12 h in a Monel pressure apparatus (Parr Model 4914) fitted with a glass liner. The reaction vessel was cooled to room temperature and the excess ethylene was released. The reaction mixtures of eight runs were combined, filtered, and distilled through a 30 cm vacuum-jacketed Vigreux column. The fraction boiling between 110 and 120°C was collected and redistilled at atmospheric pressure through the Nester–Faust spinning-band column. After a forerun of 5 g was collected, the first fraction (100 g, head temperature 80–120°C), 1-methyl-2-norbornene was collected; ^{1}H nmr (CCl_4, 100 MHz) δ: 5.98 (quartet, 1H, J = 5.0 and 2.5 Hz, H-3), 5.75 (d, 1H, J = 5.0 Hz, H-2), 2.78 (broad s, 1H, H-4), 1.37 (s, 3H, —CH_3), 1.90–0.95 (m, 6H, norbornyl envelope). The second fraction (50 g, head temperature 105°C) was a mixture of 1- and 2-methyl-2-norbornenes; ir (neat): 3060 (olefinic C—H); ^{1}H nmr (CCl_4, 100 MHz) δ: 5.48 (broad s, 1H, H-3), 2.75, and 2.58 (broad s, each 1H, bridgeheads), 1.74 (d, 3H, J = 1.5 Hz, —CH_3), 1.74–0.85 (m, 6H, norbornyl envelope).

Chlorination of 2-Methyl-2-norbornene

2-Methyl-2-norbornene (110 g, 1.02 mol) was dissolved in methylene chloride (500 mL) and pyridine (105 mL) in a three-necked flask fitted with a mechanical stirrer and gas inlet and outlet tubes. The flask was cooled in an ice bath and chlorine gas that was first passed through concentrated sulfuric acid was bubbled into the stirred solution until the mixture turned yellow permanently. After the solution reached room temperature it was washed with water (150 mL), dilute hydrochloric acid (10%, 2 × 200 mL), saturated bicarbonate solution (2 × 200 mL), and water (2 × 200 mL). The organic layer was dried, concentrated, and the yellow oil (150 g) that remained was analyzed by analytical glpc on a 1/8 in. × 10 ft, 5% SE-30 column at 140°C. The major component (35%) of a total of at least seven products had the shortest retention time. Separation of the tricyclic compound was attempted by fractional distillation through a 30 cm glass column packed with glass helices and wrapped several times with aluminum foil. During the early stages of the distillation a white substance solidified in the column and caused the forerun to become cloudy. The first fraction consisted of 30.0 g of a colorless liquid, bp 35–40°C (20–25 Torr), which was shown by analytical glpc on a 1/8 in. × 10 ft, 10% Carbowax column (190°C) and nmr spectroscopy to be >96% pure. This compound was labile on a 5% SE-30 column at 100°C when the injector and detector block temperatures were high (>200°C). The second fraction was 47 g of a clear yellow liquid; bp 80–90°C (20–25 Torr); ^{1}H nmr (CCl_4, 60 MHz) δ: 4.1 and 3.3 (AB quartet, J = 11 Hz), 3.9 (m, 1H), 2.3–1.2 (m, 7H). After the second fraction was collected, a yellow solid collected in the condenser and the distillation was stopped. No further attempts were made to separate the compounds remaining in the pot.

The first fraction (30 g) was further purified by spinning-band distillation under reduced pressure (80 ± 2 Torr) with a head temperature of 51°C and a pot temperature of 56°C. After 2 mL of forerun, three separate fractions were collected and each was estimated by analytical glpc on a 1/8 in. × 10 ft, 5% SE-30 column at 100°C to be at least 97% pure. The fractions were combined to yield 18.0 g of 7-chloro-1-methylnortricyclene (**1***e*); ir (neat): 3075 and 3010 (cyclopropyl C—H), 1455, 1445, 1310, 1295, 1240, 925, 905, 850, 800, 775; ^{1}H nmr (CCl_4, 100 MHz) δ: 3.65 (d, 1H, J = 1.5 Hz, H—C—Cl), 2.12 and 1.4 (AB pattern, each 1H, J = 10.5 Hz, protons at C-7), 2.03 (broad s, 1H, H-4), 1.40 (m, 2H, protons at C-5), 1.23 (s, 3H, —CH_3), 1.04 (s, 2H, H-1 and H-6).

Cleavage of 7-Chloro-1-methylnortricyclene in Acid Medium

7-Chloro-1-methylnortricyclene (5.47 g, 39 mmol) was dissolved in 75 mL of 0.1 M H_2SO_4 – CH_3COOH and the mixture was heated to 62 ± 2°C under an atmosphere of nitrogen in an oil bath. The progress of the reaction was monitored by analytical glpc on a 1/8 in. × 10 ft, 15% Carbowax column at 180°C and was estimated to be >93% complete after 105 h. The excess acid was quenched with saturated sodium bicarbonate solution and the products were extracted into ether (3 × 350 mL). The combined extracts were washed with water (4 × 100 mL), dried, and concentrated to yield 7.7 g (97%) of chloroacetates. Analytical glpc on a 1/8 in. × 10 ft, 15% Carbowax column at 180°C showed two products in a ratio of 24:76 which did not change through the course of the reaction. To check for decomposition and/or rearrangement of the reaction products during analysis by gas chromatography, the injector and detector block temperatures were altered. There was no significant change of the product ratio as the injector (215 to 130°C), detector (225 to 140°C), and column temperatures (180 to 150°C) were varied.

The two products were isolated by preparative glpc on a 1/4 in. × 10 ft, 15% FFAP column at 150°C and the compound of shortest retention time (13 min) was identified as *anti*-7-chloro-1-methyl-*exo*-2-norbornyl acetate (**3***a*); ir (CS_2): 1740 (C=O), 1380, 1235(s), 1060, 1025, 860(s), 695; ^{1}H nmr (CS_2, 100 MHz) δ: 4.55 (d of d, 1H, J = 8.0 and 3.0, *endo*-2-H), 3.77 (broad s, 1H, *syn*-7-H), 1.89 (s, 3H, —OAc), 0.97 (s, 3H, —CH_3) 2.25–1.00 (m, 7H, norbornyl envelope); ms (70 eV) *m/e* (relative intensity): 202(2), 160(4), 142(11), 124(25), 109(22), 80(100). The compound of longest retention time (15 min) was *syn*-7-chloro-1-methyl-*exo*-2-norbornyl acetate; ir (CS_2): 1740 (C=O), 1375, 1240, 1065, 1030, 860, 695; ^{1}H nmr (CS_2, 100 MHz) δ: 4.51 (t with fine structure, 1H, J = 6 Hz, *endo*-2-H), 3.51 (broad s, 1H, *anti*-7-H), 2.22 (broad s, 1H, H-4), 1.87 (s, 3H, —OAc), 1.02 (s, 3H, —CH_3), 2.02–0.95 (m, 6H, norbornyl envelope); ms (79 eV) *m/e* (relative intensity): 142(10), 107(91), 81(75), 80(100). The molecular ion at *m/e* 202 was discernable only at an ionizing voltage of 10–15 eV.

LAH Reduction of Chloroacetates

To a slurry of lithium aluminum hydride (0.95 g, 25 mmol) and dry ether (50 mL) in a 125 mL flask fitted with a reflux condenser, a calcium chloride drying tube, and a magnetic stirrer, were slowly added 3.28 g (16 mmol) of the mixture of

chloroacetates dissolved in dry ether (20 mL). The mixture was refluxed for 3.0 h and cooled. The excess hydride was carefully destroyed with water (3 mL) and the products were extracted into ether (3 × 100 mL). After the ethereal extracts were washed with water (1 × 50 mL), dried, and concentrated, an oily residue (2.5 g, 97%) with a foul odour was obtained. Analytical glpc on a 1/8 in. × 10 ft, 15% Carbowax column at 180°C revealed two products in a ratio of 22:78 which were separable by preparative glpc on a 1/4 in. × 10 ft, 15% FFAP column at 170°C. The product of shortest retention time was collected as a white waxy solid and was identified as *syn*-7-chloro-1-methyl-*exo*-2-norbornanol; ir (CS_2): 3600(OH), 1305, 1265, 1210, 1145, 1095, 1080, 1030, 1015, 980, 940, 860, 830, 805, 770; ^1H nmr (CS_2, 100 MHz, Fig. 1*a*) δ: 3.62 (broad s with fine structure, 1H, *anti*-7-H), 3.35 (broad quintet, 1H, *endo*-2-H), 2.31 (broad s, 1H, H-4), 1.16 (s, 3H, $—CH_3$), 2.03–1.05 (m, 7H, norbornyl envelope and OH). *Anal.* calcd. for $C_8H_{13}OCl$: C 59.81, H 8.10, Cl 22.12; found: C 59.63, H 8.02, Cl 22.28.

The compound of longest retention time was collected as a white waxy solid and identified as *anti*-7-chloro-1-methyl-*exo*-2-norbornanol; ir (CS_2): 3625 (free OH), 3700–3250 (hydrogen bonded OH), 1340, 1310, 1290, 1270, 1235, 1195, 1075, 1005, 965, 905, 840, 740; ^1H nmr (CS_2, 100 MHz, Fig. 1*c*) δ: 3.81 (broad s, 1H, J = 8.0 and 3.0 Hz, *endo*-2-H), 1.05 (s, 3H, $—CH_3$), 2.25–0.75 (m, 7H, norbornyl envelope and OH). *Anal.* calcd. for $C_8H_{13}OCl$: C 59.81, H 8.10, Cl 22.12; found: C 59.68, H 8.13, Cl 21.96.

The *syn*-7-chlorohydrin (0.030 g) was complexed with 0.114 g of $Eu(fod)_3$ in carbon tetrachloride (0.5 mL); ^1H nmr (100 MHz, Fig. 2*a*) δ: 16.7 (broad s, 1H, *endo*-2H), 10.7 (d, 1H, J = 14 Hz, *exo*-3-H), 7.7 (s, 3H, $—CH_3$), 7.1 (s, 1H, *anti*-7-H), 6.1 (dd, 1H, J = 14 and 7 Hz, *endo*-3-H), 5.1 (broad s, 1H, H-4), 3.70 (m, 1H, *endo*-6-H), 3.30–2.80 (m, 3H, *exo*-5-H, *exo*-6-H, and *endo*-5-H).

Similarly, the *anti*-7-chlorohydrin (0.44 g) was complexed with 0.208 g of $Eu(fod)_3$ in carbon tetrachloride (0.5 mL); ^1H nmr (100 MHz, Fig. 2*c*) δ: 17.9 (d, 1H, J = 7 Hz, *endo*-2-H), 12.9 (d, 1H, J = 14 Hz, *exo*-3-H), 12.3 (s, 1H, *syn*-7-H), 7.4 (s, 3H, $—CH_3$), 7.0 (dd, 1H, J = 14 and 7 Hz, *endo*-3-H), 5.1 (broad s, 1H, H-4), 4.5 (t with fine structure, 1H, J = 8 Hz, *endo*-6-H), 4.10–3.25 (m, 3H, *exo*-5-H, *exo*-6-H, and *endo*-5-H).

Oxidation of Chlorohydrins

A mixture (3.0 g) of the chlorohydrins was oxidized by Brown's reagent (21) to a mixture of chloroketones in 95% yield. Analytical glpc on 1/8 in. × 10 ft, 15% Carbowax column at 165°C showed two products in a ratio of 23:77 that were separated by preparative glpc on a 1/4 in. × 10 ft, 15% FFAP column at 140°C. The product of shortest retention time was identified as *anti*-7-chloro-1-methyl-2-norbornanone; ir (CS_2): 1760 (C=O), 1305, 1280, 1090, 1055(s), 1005, 975, 905, 855(s), 800, 740, 615; ^1H nmr (CS_2, 100 MHz) δ: 3.75 (s with fine structure, 1H, *syn*-7-H), 2.58 (m, 1H, H-4), 1.04 (s, 3H, $—CH_3$), 2.35–1.15 (m, 6H, norbornyl envelope); ms (70 eV) *m/e* (relative intensity): M^+ 158(6), 114(12), 81(100). The product of longest retention time was *syn*-7-chloro-1-methyl-2-norbornanone; ir (CS_2): 1760 (C=O), 1340, 1315, 1300, 1265, 1240, 1165, 1130, 1065, 1030, 965, 950, 930, 895, 875, 865, 835, 790, 760; ^1H nmr (CS_2, 100 MHz) δ: 3.98 (m, 1H, *anti*-7-H), 1.06 (s, 3H, $—CH_3$), 2.65–1.45 (m, 7H, norbornyl evelope); ms (70 eV) *m/e*: M^+ 158.

Reduction of Chloroacetates by Sodium in 2-Propanol

The mixture of chloroacetates (0.5 g) was reduced by sodium in 2-propanol as described in the preceding paper (11). Analytical glpc on a 1/8 in. × 10 ft, Carbowax column at 150°C revealed one major product (>95%) that was isolated by preparative glpc on a 1/4 in. × 10 ft, 15% FFAP column at 130°C. It was shown to be 1-methyl-*exo*-2-norbornanol by comparison of its pmr and ir spectra to those of an authentic sample.

Cleavage of 7-Chloro-1-methylnortricyclene in D_2SO_4–CD_3COOD

Into a three-necked flask fitted with a condenser and a calcium chloride drying tube were placed 50 mL of acetic acid-d_4 (Merck, Sharp and Dohme of Canada Ltd., 99.5 at.% *d*) and sulfuric acid-d_2 (0.516 g). Nitrogen gas was slowly bubbled through the solution that was heated to 65 ± 2°C in an oil bath. 7-Chloro-1-methylnortricyclene (2.99 g, 21 mmol) was added to the flask, the mixture was magnetically stirred, and the progress of the reaction was monitored by analytical glpc on a 1/8 in. × 10 ft, 15% Carbowax column at 175°C. After 60 h, the reaction was neutralized with saturated aqueous sodium bicarbonate and the products were extracted into ether. The extracts were washed with water, dried, and concentrated to yield 7.1 g (91%) of deuterated chloroacetates.

LAH Reduction of Deuterated Chloroacetates

The deuterated chloroacetate mixture (4.0 g, 19 mmol) was reduced with lithium aluminum hydride (0.84 g, 22 mmol), as previously described, to 3.0 g (97%) of a mixture of *anti*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* and *syn*-7-chloro-1-methyl-*exo*-2-norbornanol-*d*. The deuterated chlorohydrins were separated by preparative glpc on a 1/4 in. × 10 ft, 25% GE XF-1150 column at 170°C, *syn*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* (0.045 g) was complexed with $Eu(fod)_3$ (0.215 g) in carbon tetrachloride (0.5 mL) and its spectrum recorded. Analysis of the integrals (average of 5) established that deuterium was located in the methyl group (0.05 ± 0.17) and *endo* at C-6 (0.89 ± 0.06). Analysis of this sample by ^2H nmr (Fig. 3*a*) showed that deuterium was located in the methyl group (0.09 ± 0.01) and at C-6 (0.96 ± 0.04).

From the ^1H nmr spectrum of *anti*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* (0.034 g) complexed with 0.192 g of $Eu(fod)_3$ in carbon tetrachloride (0.5 mL) (Fig. 2*d*) the following deuterium distribution was determined: CH_3, 0.10 ± 0.07; *endo*-2-H, 0.15 ± 0.10; *endo*-6-H, 0.94 ± 0.07; H-7, 0.13 ± 0.09. Analysis by ^2H nmr (Fig. 3*b*) gave the following results: CH_3, 0.22 ± 0.02; *endo*-2-H, 0.05 ± 0.01; H-6, 0.88 ± 0.09; H-7, 0.14 ± 0.02.

Oxidation of Deuterated Chlorohydrins

A mixture of *anti*-7-chloro-1-methyl-*exo*-2-norbornanol-*d* and 1-methyl-*syn*-7-chloro-*exo*-2-norbornanol-*d* was oxidized to a mixture of the corresponding chloroketones. After work-up, each ketone was isolated by preparative glpc on a 1/4 in. × 10 ft, 25% GE XF-1150 column at 157°C and assayed for deuterium mass spectrometrically. The deuterated *syn*-7-chloroketone was a composite of 4% d_0, 87% d_1, 9% d_2 species (1.05 excess *d* per molecule) and the *anti*-7-chloroketone was a composite of 5% d_0, 67% d_1, 22% d_2, 6% d_3 species (1.29 excess *d* per molecule).

Kinetic Measurements

In a typical run 0.16 mmol of each nortricyclene and *cis*-decalin, which was used as the internal standard, were dissolved in 0.1 *M* H_2SO_4 – CH_3COOD (10 mL) in a 25 mL round-bottom flask sealed with a serum cap. The mixture was placed in a Haake constant temperature bath maintained at 70.0 ± 0.1°C and after a 15 min equilibration period aliquots (0.4 mL) were withdrawn two at a time at approximately 1.5 h intervals over a period of 25 h. When the aliquots were withdrawn, ether (2 mL) was added and the acid was neutralized by $NaHCO_3$.

Each aliquot was analyzed three times by analytical glpc using a 4 mm × 2 m 3% OV-1 column maintained initially at a temperature of 65°C. After the nortricyclenes and the *cis*-decalin exited, the oven temperature was increased rapidly to 200°C to remove the higher boiling acetates. Peak areas were determined with a Varian Aerograph Model 485 electronic integrator. The pseudo-first-order rate constants were calculated by a least-squares evaluation of a plot of log (peak area nortricyclene/peak

area *cis*-decalin) vs. time. The correlation coefficients were greater than 0.996 and the average error was ±10%. The second order rate constants are 1.96×10^{-4} and 7.59×10^{-4} M^{-1} s^{-1} for **1***b and* **1***e*, respectively.

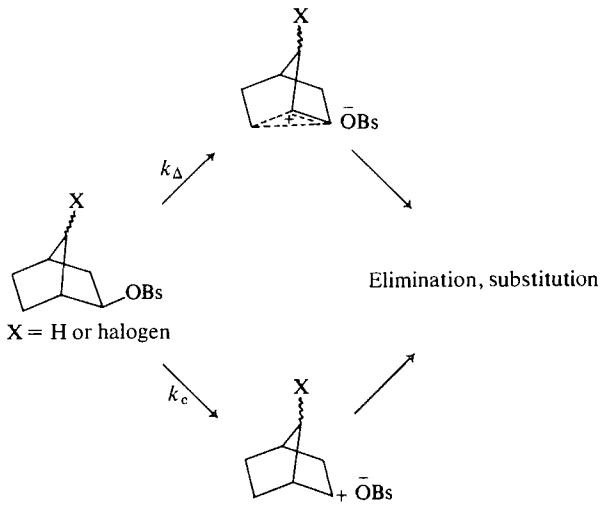
Solvolysis of specifically deuterated 7-chloro- and 7-bromo-*exo*-2-norbornyl brosylates; unusually large γ-kinetic isotope effects in the absence of σ-participation

NICK HENRY WERSTIUK, GEORGE TIMMINS, AND FRANK PETER CAPPELLI
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 5, 1979

NICK HENRY WERSTIUK, GEORGE TIMMINS, and FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1738 (1980).

A series of specifically deuterated *syn*-7-chloro-, *anti*-7-chloro-, *syn*-7-bromo-, and *anti*-7-bromo-*exo*-2-norbornyl brosylates have been prepared and solvolyzed in NaOAc-buffered 80:20 EtOH–H_2O. For solvolysis at 25°C the γ-kinetic isotope effects (KIE's) for *syn*-7-chloro-*exo*-2-norbornyl brosylate-*endo*-6-*d* (**1***e*), *anti*-7-chloro-*exo*-2-norbornyl brosylate-*endo*-6-*d* (**2***c*), *syn*-7-bromo-*exo*-2-norbornyl brosylate-*endo*-6-*d* (**1***f*), *anti*-7-bromo-*exo*-2-norbornyl brosylate-*endo*-6-*d* (**2***d*), *syn*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**1***g*), *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**2***e*) are 1.125 ± 0.007, 1.128 ± 0.005, 1.063 ± 0.008, 1.149 ± 0.020, 1.119 ± 0.011, and 1.115 ± 0.013, respectively. There is no detectable γ-kinetic isotope effect for solvolysis of *anti*-7-chloro-*endo*-2-norbornyl brosylate-*endo*-6-*d* (**3***a*) and the β-KIE for *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*-3-*d* (**4***a*) is 1.111 ± 0.011. From a consideration of the possible sources of the unusually large secondary KIE's, we conclude that the *exo*-6-*d* and *endo*-6-*d* γ-KIE's likely are derived from a combination of effects rather than from participation of the C1—C6 bond in the ionization step.



NICK HENRY WERSTIUK, GEORGE TIMMINS et FRANK PETER CAPPELLI. Can. J. Chem. **58**, 1738 (1980).

On a préparé et solvolysé, dans une solution tampon de AcONa 80:20 EtOH–H_2O, les brosylates norbornyl-2-*exo* deutérés de façon spécifique des chloro-7 *syn*, chloro-7 *anti*, bromo-7 *syn* et bromo-7 *anti*. Les effets isotopiques cinétiques γ (EIC) de la solvolyse à 25°C sont respectivement de: 1,125 ± 0,007, 1,128 ± 0,005, 1,063 ± 0,008, 1,149 ± 0,020, 1,119 ± 0,011 et 1,115 ± 0,013 pour les brosylates des chloro-7 *syn* norbornyl-2-*exo* *d*-6-*endo* (**1***e*), chloro-7 *anti* *d*-6-*endo* (**2***c*), bromo-7 *syn* *d*-6-*endo* (**1***f*), bromo-7 *anti* *d*-6-*endo* (**2***d*), chloro-7 *syn* d_2-5,6-*exo*,*exo* (**1***g*) norbornyl-2 *exo*, chloro-7 *anti* d_2-5,6-*exo*,*exo* (**2***e*) norbornyl-2 *exo*. Il n'y a pas d'effet isotopique cinétique γ apparent pour la solvolyse du brosylate du chloro-7 *anti* *d*-6-*endo* norbornyl-2 *endo* (**3***a*) et l'effet isotopique cinétique β du brosylate de chloro-7 *anti* *d*-3-*exo* norbornyl-2 *exo* (**4***a*) est égale à 1,111 ± 0,011. A partir d'une considération des sources probables des effets isotopiques cinétiques secondaires anormalement élevés, nous concluons que les EIC-γ des brosylates *d*-6 *exo* et *d*-6 *endo* proviennent probablement d'une combinaison d'effets plutôt que d'une participation de la liaison C1—C6 à l'étape d'ionisation.

[Traduit par le journal]

Introduction

γ-Kinetic hydrogen isotope effects (KIE's) have been used to probe the nature of transition states and intermediates generated solvolytically (1). Murr and Jerkunica and their co-workers (2, 3) observed unusually large γ-KIE's for solvolysis of *exo*-2-norbornyl brosylate-*exo*-6-*d* (**1***a*) and *exo*-2-norbornyl brosylate-*endo*-6-*d* (**1***b*), and interpreted the results on the basis of an assisted ionization. Our interest in detailing the mechanisms of acid-catalyzed ring opening of nortricyclenes (4) and in the non-classical ion problem (5), led us to determine the γ-KIE's for norbornyl substrates bearing an electron withdrawing group at C-7 to establish more accurately the source of the γ-KIE's. Since the large γ-KIE's are supposedly derived from participation of the C1—C6 bond (2, 3) we reasoned that introduction of a strongly electron withdrawing group at C-7 should reduce the contribution of the k_Δ process (Scheme 1) and thereby reduce the γ-KIE. Since our studies (4, 6) of the ring-opening of 3-halonortricyclenes provided us with ample stocks of *syn*-7-chloro-*exo*-2-norbornanol-*endo*-6-*d* (**1***c*), *syn*-7-bromo-*exo*-2-norbornanol-*endo*-6-*d* (**1***d*), *anti*-7-chloro-*exo*-2-norbornanol-*endo*-6-*d* (**2***a*), and *anti*-7-bromo-*exo*-2-norbornanol-*endo*-6-*d* (**2***b*), it was a simple matter to prepare the corresponding brosylates **1***e*, **1***f*, **2***c*, and **2***d* and determine the solvolytic γ-KIE's.

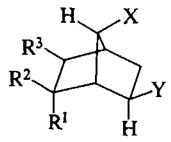
Exo-2-*endo*-6-*d* (**1***b*)		1.11 ±0.01[i]	
Endo-2-*exo*-6-*d*		1.00 ±0.02[i]	
Endo-2-*endo*-6-*d*		0.97 ±0.01[i]	

[a]Determined mass spectrometrically at low voltage (10–15 eV). Average of five determinations. Deviations are the standard deviations.
[b]Obtained by analysis of the corresponding ketones.
[c]Obtained by analysis of *anti*-7-chloronorbornene-*exo*,*exo*-5,6-d_2.
[d]The halobrosylates were solvolyzed in 80:20 volume percent ethanol–water buffered by 0.040 *M* sodium acetate.
[e]Average of at least three runs. Deviations are the standard deviations.
[f]Corrected for incomplete deuteration according to the method of Schepple *et al.* (51).
[g]For a discussion of the temperatures at which the solvolyses were carried out see the Experimental. The cell compartment temperatures were 50°, 60.0°, 60.0°, 60.0°, 57.8°, 51.1°, and 57.8°C for **1***e*, **2***c*, **1***f*, **1***g*, **2***e* and **4***a*, respectively. The external bath temperature for **3***a* was 80.0°C.
[h]Isotope effect at 25°C evaluated using the equation $RT/n \ln (k_H/k_D) = \Delta(\Delta F)$ (ref. 12).
[i]See ref. 2.

To complete the study and to establish a point of comparison with the parent *exo*-brosylates, **1***a* and **1***b*, we prepared *syn*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**1***g*), *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**2***e*), *anti*-7-chloro-*endo*-2-norbornyl brosylate-*endo*-6-*d* (**3***a*), *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*-3-*d* (**4***a*), and determined the KIE's in buffered (0.04 *M* NaOAc) 80:20 EtOH–H_2O.

Surprisingly, we find the γ-KIE's for 7-halo-*exo*-brosylates **1***e*, **1***g*, **2***c*, **2***d*, and **2***e* to be slightly larger than the γ-KIE's for the parent *exo* substrates and the γ-KIE for *syn*-7-bromo-*exo*-brosylate **1***f* is less than the KIE for brosylate **1***b* (Table 1). Also, as in the case of *endo*-2-norbornyl tosylate, the γ-KIE for *anti*-7-chloro-*endo*-2-brosylate **3***a* is negligibly small. In this paper we expand on a preliminary account of our work (7) and give a detailed interpretation of the results.

Results



Preparation of Substrates

The chloro and bromobrosylates **1***e*, **1***f*, **2***c*, and **2***d* were prepared from the corresponding deuterated chlorohydrins and bromohydrins **1***c*, **1***d*, **2***a*, and **2***b* that were obtained via acid-catalyzed ring-opening of 3-chloro- and 3-bromonortricyclene (6). That the deuterium in **1***c*, **1***d*, **2***a*, and **2***b* was at least 90% stereochemically pure *endo* at C-6 was established by nmr and ir spectroscopy. The non-deuterated chlorohydrins were synthesized by the method of Roberts *et al.* (8) and the bromohydrins were prepared from bromoacetates obtained by the acid-catalyzed ring opening of 3-bromonortricyclene (6). To prepare *syn*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**1***g*), we converted norbornene-*endo*,*endo*-5,6-d_2 (9) into deuterated chlorohydrin **1***h* and brosylated the chlorohydrin. The synthesis of *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 (**2***e*) began with a $LiAlD_4$ reduction of acetoxynorbornadiene (10) that yielded *anti*-7-norbornenol-*exo*,*exo*-5,6-d_2 (**5***a*). Conversion of the dideuterated norbornenol to *anti*-7-chloronorbornene-*exo*,*exo*-5,6-d_2 (**5***b*) (11), followed by hydroboration and brosylation, gave **2***e*. That the deuterium was at least 90% stereochemically pure *exo* was established by ^1H nmr. To prepare the chlorohydrins **3***b* and **3***d*, the precursors of the deuterated and nondeuterated *endo*-2-brosylates **3***a* and **3***c*, chloroketones **6***a* and **6***b* were reduced by lithium tri-*tert*-butoxyaluminum hydride to a 92:8 mixture of the *endo*- and *exo*-chlorohydrins, and the *endo*-chlorohydrin was isolated by preparative glpc. *Anti*-7-chloro-*exo*-2-norbornanol-*exo*-3-*d* (**4***b*), the precursor of brosylate **4***a*, was prepared by deuteroboration of *anti*-7-norbornenyl chloride. To insure that the deuterium was located specifically *exo* at C-3, a ^1H nmr study using $Eu(fod)_3$ was carried out as described in the Experimental. The deuterium content of each brosylate, based on the analysis of the corresponding ketone, is listed in Table 1.

deuterated brosylates were carried out in 80:20 (volume percent) EtOH–H_2O buffered by 0.04 *M* sodium acetate in a temperature-controlled cell compartment of a Cary Model 14 ultraviolet spectrophotometer. First-order rate constants and the standard deviations for the *exo*-brosylate solvolyses were calculated from sets of $-\ln(A_t - A_\infty)$ and time data by means of a linear least-squares analysis. Since A_∞ for *endo*-brosylates **3***a* and **3***c* could not be determined because of long half-lives, first-order rate constants were determined by computer-fitting the absorbance and time data to an exponential curve of the form $A_t = Be^{-kt} + C$. To check the accuracy of the curve fitting procedure the experimental values of A_t for solvolysis of the *exo*-brosylates were similarly fitted to the exponential curve. Since the A_∞'s and the rate constants obtained by curve-fitting the data for *exo* solvolyses were in excellent agreement with those obtained directly, we are confident that the *endo* rate constants obtained by the curve-fitting method are also accurate. Representative first-order plots for the simultaneous solvolysis of the pairs of brosylates **1***i* and **1***i*, **1***e* and **1***i*, and **2***d* and **2***h* are given in Figs. 1(*a*), 1(*b*), and 1(*c*), respectively. The isotope effects are listed in Table 1 and Table 2 lists the relative percent yields of the products of solvolysis of the 7-chloro- and 7-bromo-*exo*-2-brosylates. Because the extended reaction time led to decomposition of products we were unable to obtain an accurate product analysis for the *endo*-brosylates **3***a* and **3***c*.[1]

Discussion

Solvolysis of a norbornyl sulfonate ester is describable by a modified Winstein ion pair scheme (Scheme 2) which includes the possibility for a 1,2-alkyl shift ((k_R^I) or hydride shift (k_{HS}^I) at the intimate ion pair (IIP) stage. If nonclassical rather than classical ions are intermediates the scheme is simplified somewhat because species IV and VI generated by a 1,2-alkyl shift need not be considered. While internal return ($k_{-1} \neq 0$) occurs when *exo*-norbornyl substrates are solvolyzed, external return does not occur ($k_{-2} = 0$) and substitution takes place at the solvent separated ion pair (SSIP) stage

[1]Gassman and Hornback (13) found that 3-chloronortricyclene (7%), *syn*-7-chloro-*exo*-2-norbornyl acetate (11%), *anti*-7-chloro-*exo*-2-norbornyl acetate (69%), and *exo*-5-chloro-*exo*-2-norbornyl acetate (8%) are the major products of acetolysis of *anti*-7-chloro-*endo*-2-norbornyl tosylate after 10% reaction.

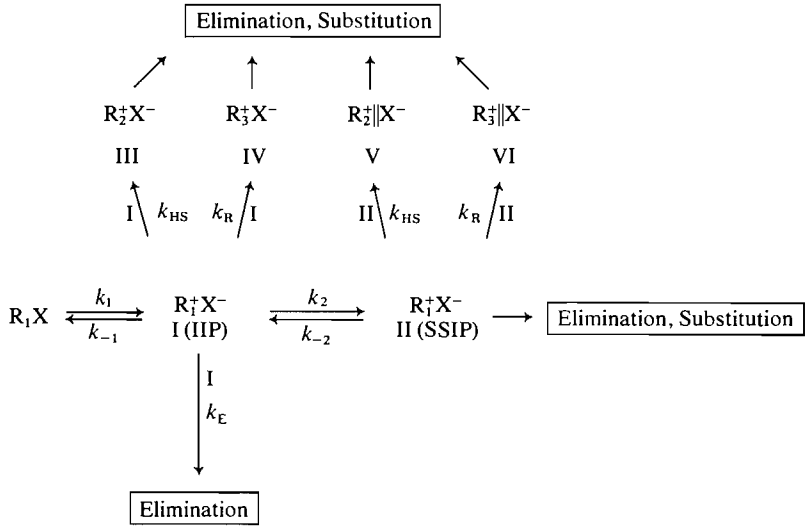
(14). External return does not occur when *endo* substrates are solvolyzed, and, since racemic *exo* products are formed (15), substitution also occurs predominately at the SSIP stage. It is clear then that the destruction of IIP's is rate determining in norbornyl solvolyses and in order to interpret the unusually large γ-deuterium isotope effects observed for the solvolysis of *exo*-norbornyl and 7-halo-*exo*-norbornyl brosylates it is imperative to establish which processes contribute to the rate-determining destruction of IIP's and to establish whether or not hydrogen isotope effects on the processes contribute to the observed KIE's. To that end, the following questions must be addressed. Since halonortricyclenes are significant products (Table 2) of the solvolysis of 7-halonorbornyl substrates, is elimination (k_E^1) from the IIP rate determining? Does participation of the *endo* hydrogen at C-6 occur during ionization? Does a rate determining hydride shift (k_{HS}^1) occur at the IIP stage to form a separated ion pair which is instantaneously scavenged by solvent? And, finally, if the γ-KIE is solely due to a change in C—H force constants as a result of participation of the C1—C6 bond, is the partition isotope effect (PIE), $(k_{1H}/k_{-1D})/(k_{2H}/k_{-2D})$ significant (16)?

Elimination

While a number of recent reports have documented the correlation between rate-determining 1,2-elimination and β-KIE's (17–24), up to the present there have been no reports of comparable studies involving bicyclic systems which yield cyclopropanes by 1,3-elimination. Where 1,2-elimination at the IIP stage is considered to be one of the rate-controlling steps, unusually large β-KIE's are associated with substantial yields of alkene. Also the variation of the β-KIE correlates with the amount of elimination which is usually controlled by solvent nucleophilicity (22). In general, elimination occurs at the IIP stage when a proton is abstracted by an adjacent fairly basic leaving group in non-nucleophilic polar solvents (24). On the other hand, when elimination occurs from SSIP's there is no correlation between the β-KIE's and the extent of elimination. Such is the case when 7-methyl-7-norbornyl tosylate[2] (22) and *tert*-butyl chloride[3] (18, 25, 26) are solvolyzed. In the former case (22) the authors suggested that

[2]Isotope effects (k_H/k_{D_3}) of 1.94, 1.84, 2.10, and 2.00 were observed in HOAc (78% elim), 80% EtOH–H_2O (65%), 97% TFE–H_2O (62%), and 80% TFE–H_2O (51%) respectively.



[3]Isotope effects $(k_H/k_{D_3})^{\frac{1}{3}}$ of 1.378, 1.356, 1.33, 1.34, 1.34, 1.35, and 1.32 were observed in 70% TFE–H_2O (17%) and 54% EtOH–H_2O (8.3%), 63% HOAc–H_2O (13.2%), 48% 2-propanol–H_2O (8.1%), 51% pyridine–H_2O (12.8%), and 29% HOAc–HCOOH (11.8%), respectively.

Syn-7-bromo-*exo*-2-*endo*-6-*d* (**1***f*)	18	39	10	28	2	4
Anti-7-bromo-*exo*-2- (**2***h*)	10	9	48	5	20	8
Anti-7-bromo-*exo*-2-*endo*-6-*d* (**2***d*)	7	8	56	5	16	7
Syn-7-chloro-*exo*-2- (**1***i*)[b]	35	21	11	19	11	3
Syn-7-chloro-*exo*-2-*exo*,*exo*-5,6-d_2 (**1***g*)	20	27	11	25	17	0
Anti-7-chloro-*exo*-2- (**2***g*)[b]	20	7	39	5	23	6
Anti-7-chloro-*exo*-2-*exo*,*exo*-5,6-d_2 (**2***e*)	22	6	38	4	23	7
Anti-7-chloro-*exo*-2- (**2***g*)[b]	19	7	40	5	22	7
Anti-7-chloro-*exo*-2-*exo*-3-*d* (**4***a*)	28	7	36	5	18	6

[a]The relative percent yields were determined by electronic integration of peak areas and are averages of at least four determinations. The average error was ±10%.
[b]Since the product ratios were determined for different runs, the results give an indication of the reproducibility of the experiments.

SCHEME 2

elimination from the IIP was not significant because the tosylate anion is a weak base.

Since solvolysis of a 7-halonorbornyl brosylate yields a weakly basic anion remote from the *exo* and *endo* hydrogens at C-6, the proximity effect that facilitates 1,2-elimination at the IIP stage is not important in norbornyl solvolyses unless there is movement of the anion at the IIP stage. That *syn*-7-chloro-*exo*-2-norbornyl tosylate isomerizes appreciably to the *anti*-tosylate during acetolysis (27) shows that the tosylate anion is mobile at the IIP stage in acetic acid. In our case, however, that there is no detectable curvature of the *syn*-halobrosylate rate plots (Figs. 1(*a*) and (*b*)) establishes that there is no build-up of the least reactive *anti*-halobrosylates during solvolysis. Hence, movement of the brosylate anion does not occur in 80:20 EtOH–H_2O that is more nucleophilic than HOAc.

It may be argued that acetate ion, present at a concentration of 0.04 *M*, acts as a base. However, since Winstein *et al.* (28) determined that nortricyclene is only a minor product (5%) of solvolysis of *exo*-norbornyl tosylate in acetic acid containing 0.1 *M* KOAc, 0.04 *M* acetate is not expected to promote elimination at the IIP stage in a nucleophilic solvent such as 80:20 EtOH–H_2O.

That there is no correlation between the γ-KIE's and the extent of 1,3-elimination from the *syn*- and *anti*-halobrosylates (Table 3) is characteristic of the tertiary systems (*vide supra*) where elimination oc-

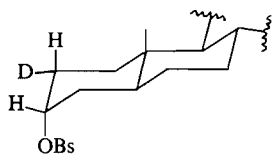
TABLE 3. γ-KIE's and relative percent yields of halonortricyclenes

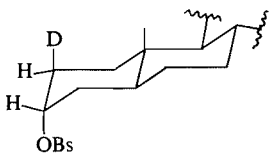
Brosylates	γ-KIE	Relative % yield of halonortricyclenes: Non-deuterated brosylate	Relative % yield of halonortricyclenes: Deuterated brosylate
1*i*, **1***e*	1.115±0.007	35	20
2*g*, **2***c*	1.114±0.005	21	13
1*j*, **2***f*	1.055±0.008	25	18
2*h*, **2***d*	1.132±0.020	10	7

curs predominantly at the SSIP stage. That 1,3-elimination of a proton occurs at the SSIP stage and therefore is not rate determining is also supported by the fact that the γ-KIE's for *exo* and *endo* deuterium at C-6 are identical. If, in fact, rate determining elimination was the major source of the γ-KIE's, since the *endo* hydrogen (deuterium) is lost preferentially (Table 4) with an isotope effect of 1.5–1.8,[4,5] the γ-KIE's for the *endo* deuterated 7-halo-*exo*-brosylates **1***e*, **1***f*, **2***c*, and **2***d* should be greater than KIE's of **1***g* and **2***e* because the latter effects would only be related to an α-effect of less than 1.2. Furthermore, acetolysis of *anti*-7-chloro-*endo*-2-norbornyl tosylate (13), for which we expect the γ-KIE to be negligibly small based on our results for **3***a*, yields 3-chloronortricyclene (7%) as a major product (13).



Hydrogen Participation

Participation of the *endo* hydrogen at C-6 in the ionization step is also a possibility because the edge-protonated nortricyclene may approach the classical or bridged ions in stability.[6] Although there are no documented examples of 1,3-hydrogen participation, 1,2-participation seems well established and manifests unusually large solvolytic β-KIE's (32–35) which are considered to be small primary KIE's. The β-KIE's are small primary KIE's for two reasons. The transition states are not linear and bond cleavage at the migration origin is compensated by bond formation at the migration terminus. According to O'Ferrall's (36) model for 1,2-hydrogen participation, both the symmetric *I*($v_R^{\ddagger}$) and asymmetric *II* ($v_L^{\ddagger}$) modes are sensitive to the isotopic mass of the migrating group but quite insensitive to transition state asymmetry, unlike $v_R^{\ddagger}$ and $v_L^{\ddagger}$ for linear transition states. Since the isotope effects for E-1 1,2-elimination, 1,2-hydride shifts, and 1,2-hydrogen participation all fall in the same range (1), the transition states for these processes must be similar in structure. That the isotope effects for E-1 1,3-elimination (29, 32) fall in



I($v_R^{\ddagger}$) II($v_L^{\ddagger}$) III

the range of the isotope effects for 1,2-elimination strongly indicates that 1,3-processes involving transition states or intermediates of the type III are describable on the same basis as 1,2-processes.[7] Therefore, we expect an isotope effect of 1.5–2 for 1,3 (6,2)-hydrogen participation. As in the case of rate-determining 1,3-elimination (*vide supra*) if there is no 1,3-hyperconjugative stabilization of the developing norbornyl cation by the *exo*-C—H bond at C-6, the solvolytic *endo* γ-KIE should be larger than the *exo* γ-KIE because the latter effect would be related only to an α-effect of less than 1.2. That 1,2-elimination and 1,2-hydrogen participation exhibit β-KIE's which are of the α-type has been established by Tarle *et al.* (33) who determined the solvolytic β-KIE's for the 3-α-cholestanyl brosylates **13** and **14**. The large β-KIE exhibited by **14** is due to 1,2-hydrogen participation and rate determining 1,2-elimination. The KIE observed for **13** results from an α-type effect on the two processes and a hyperconjugative component.

k_H/k_D = 1.130±0.019

13

k_H/k_D = 1.599±0.013

14

[4]We assume here that there is no selective homohyperconjugative stabilization of the *exo*-transition state by the *exo*-C—H bond at C-6.

[5]Since the elimination isotope effect (k_H/k_D) is defined by the ratio

$$\left(\frac{\%\Delta}{\%\text{ other products}}\right)_H \Big/ \left(\frac{\%\Delta}{\%\text{ other products}}\right)_D$$

(29) the elimination KIE's are 1.78, 1.71, 1.58, and 1.52 for the *syn*-7-chloro, *anti*-7-chloro, *syn*-7-bromo, and *anti*-7-bromo-*exo*-2-brosylates, respectively.

[6]It has been established that the activation energy for 6,2-hydride shift in the norbornyl system is 5.9 kcal per mole (31). Thus for the edge protonated species to be a significant intermediate, a stabilization of approximately 6 kcal must result from C—H participation in the 7-halo systems.

[7]It is also possible that 1,3 (6,2)-elimination and 6,2-shifts occur basically from a classical ion via very similar transition states. That 1,3 (6,2)-elimination occurs in preference to 1,2 (3,2)-elimination, that 6,2-hydride shifts occur more readily than 3,2-shifts, that loss of an *endo* hydrogen is preferred, and that the stereochemistry of the 6,2-shift is *endo–endo*, provide support for such a hypothesis in the case of the norbornyl system.

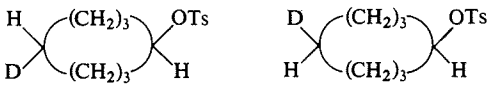
TABLE 4. Deuterium content of halonortricyclenes and fractional percent deuterium losses



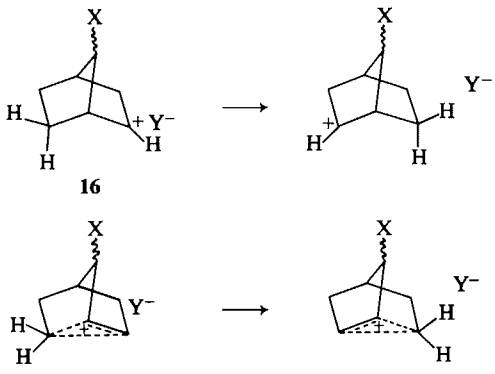
Halobrosylate (excess d per molecule)	Halonortricyclene[a] $\%d_0$	$\%d_1$	$\%d_2$	Excess d per molecule	Fractional % deuterium loss
1*e* (0.98)	78[c]	22	0	0.22	77.6
2*c* (0.97)	77	23	0	0.23	76.3
1*f* (0.97)	62	38	0	0.38	59.8
2*d* (0.97)	68	31	1	0.33	64.8
1*g* (1.85)	7	9	84	1.77	3.9
2*e* (1.82)	7	4	89	1.81	0.5

[a]The halonortricyclenes were isolated from large scale solvolyses (0.2–1 g) in 35–50 mL of solvent.
[b]Rounded to the nearest 0.01 d.
[c]Rounded to the nearest unit.

Since the γ-KIE's for the 7-chlorobrosylates **1***e*, **1***g*, **2***c*, and **2***e* are much less than 1.5 and they are identical within experimental error, a k_Δ process involving the *endo* hydrogen at C-6 cannot be the sole source of the solvolytic γ-KIE's. In this respect it is interesting to note that Parker and Watt (38) have established that the KIE's for solvolysis of 5-deuterated cyclooctyl tosylates **15** and **16** depend on the orientation of the deuterium relative to the leaving group (see also ref. 37). A 1,5-hydride shift occurs during solvolysis and a *trans*-1,5-shift is preferred over a *cis*-1,5-shift by 10:1. Based on the assumption that the participation isotope effect should be in the range of 1.5–3.0 they interpreted the results on the basis of a 50–20% fractional involvement of a k_Δ process involving the *trans* hydrogen.[8] It is conceivable that a fraction of the solvolysis of the 7-halo-*exo*-2-brosylates **1***e*, **1***f*, **1***g*, **2***c*, **2***e*, and **2***d* also occurs by participation of the *endo* hydrogen at C-6. It is interesting to note that the isotope effect for **16**, related to an α-effect, is less than the primary KIE for hydrogen participation in the case of **15**.

6,2-Hydride Shifts

As is shown in Table 2 the halohydrins and ethers formed via a 6,2-hydride shift constitute 10–20% of the solvolysis products. This result indicates that 6,2-shifts occur to the same extent as in the solvolysis of other *exo*-norbornyl substrates (29, 30, 39–41). If classical (**16**) or non-classical (**17**) intermediates are involved and a 6,2-hydride shift occurs at the IIP stage to yield an ion pair which reacts at a diffusion controlled rate with solvent, a primary KIE, estimated to be around 1.5, could contribute to the observed KIE (Scheme 3). As in the case of 1,3 (6,2)-elimination and 1,3 (6,2)-hydrogen participation (*vide supra*) it is difficult to account for the *exo* isotope effect on that basis unless selective homohyperconjugative stabilization of the *exo* transition state by the *exo*-C—H bond also occurs during ionization.

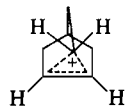


$k_H/k_D = 1.124 \pm 0.008$ **15**

$k_H/k_D = 1.044 \pm 0.010$ **16**

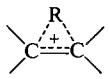
Ionization Isotope Effect

That *exo*-2-norbornyl brosylates and tosylates solvolyses are characterized by unusually large γ-KIE's[9] has been taken as evidence that solvolysis is assisted (2, 3). If solvolysis of an *exo* substrate indeed leads to a non-classical cation, then alkyl migration isotope effects should serve as good models for the solvolytic γ-KIE because the bonding in the non-classical ion (**20**) and the transition



SCHEME 3

[8]An attractive alternative source of the KIE's not discussed by Parker (38) involves a rate determining 1,5-hydride shift at the IIP stage to form a separated ion pair that reacts at a diffusion controlled rate with solvent. The KIE's for the 1,5-shift would be similar to the KIE's for the k_Δ process.



[9]While Murr *et al.* (2) have reported that the KIE's for solvolysis of the 6-*exo*-*d* and 6-*endo*-*d*-*exo*-brosylates are identical within experimental error in 80:20 ethanol–water (1.09 ± 0.03 and 1.11 ± 0.01) and in acetic acid (1.09 ± 0.01 and 1.11 ± 0.01), Jerkunica *et al.* (3) have reported that the *exo* KIE (1.149 ± 0.016) is somewhat larger than the *endo* KIE in acetic acid (1.097 ± 0.011). The source of this difference is not obvious.

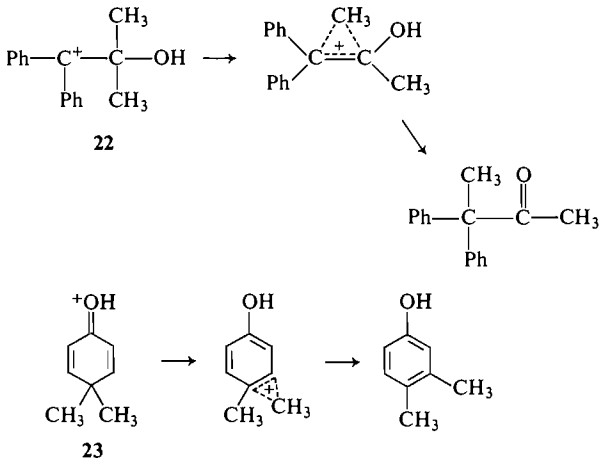
For personal use only.

states for alkyl migration (**21**) should be similar. The results of several important studies which bear on this point have been published recently. Shubert and LeFevre (42) established that the migrational isotope effect for acid-catalyzed rearrangement of 1,1-diphenyl-2-methyl-1,2-propanediol (**22**) is 1.064 per deuterium and Vitullo and Logue (43) reported that the migrational KIE for acid-catalyzed rearrangement of 4,4-dimethylcyclohexadiene (**23**) is 1.077 per deuterium. Also, Winnik *et al.* (44) showed that the KIE for benzyl migration in the Baeyer–Villiger oxidation of 1-phenyl-2-propanone is 1.034 per deuteron and suggested that the transition state for migration was product-like. In our view it is reasonable to assume that the average



20

21

of the methyl migrational KIE's (1.07) is a good measure of the maximum KIE because the methyl group should be approximately half-transferred in both transition states. Since maximum change of C—H force constants at C-6 of the norbornonium ion is achieved when the ion is fully formed and the transition state of its formation lies approximately midway between substrate and the ion, a γ-KIE much less than 1.07 of perhaps 1.02–1.04 per deuterium would be expected for assisted solvolysis. Clearly, the γ-KIE's observed for **1***e*, **1***f*, **1***g*, **2***c*, **2***d*, and **2***e* are not in accord with this ex-

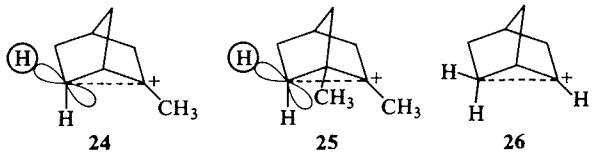
22

23

pectation. Furthermore, the halogen at C-7 would reduce the contribution of a k_Δ pathway (Scheme 1), should such a process be involved in *exo* solvolysis, because charge would develop at C-1. Although Goering and Degani (27) suggest that nonclassical ions are involved as intermediates in the acetolysis of 7-chloro-*exo*-2-norbornyl tosylates, they state that the low yield (~2%) of 3-chloro-2-norbornyl acetates is probably due to the low cationic character at C-1 because of the inductive effect of the adjacent chlorine atom. Consequently, if the γ-KIE's are derived from γ-participation, the KIE's for **1***e*, **1***f*, **1***g*, **2***c*, and **2***e* should be smaller than the KIE's for **1***a* and **1***b*. Again, this expectation is not borne out by our experiments. That charge development at C-1 would result in a destabilization of the 7-halocations is supported by the work of Goering and Degani (27) who showed that the 7-chloronorbornyl tosylates are 250 times more reactive solvolytically than *exo*-3-chloro-*exo*-2-norbornyl tosylate.

It is interesting to note that the β-KIE for solvolysis of *anti*-7-chloro-*exo*-2-norbornyl brosylate-*exo*-3-*d* (**4***e*), within experimental error, is identical to the β-KIE for solvolysis of *exo*-2-norbornyl brosylate-*exo*-3-*d* (KIE = 1.11 ± 0.01) in 80:20 EtOH–H_2O (45). This provides support for our view that the 7-halo-*exo*-2- and *exo*-2-norbornyl brosylates solvolyse by similar mechanisms.

Conclusions



It appears from our analysis, that 1,3 (6,2)-elimination and/or 6,2-hydride shifts at the IIP stage and *endo*-hydrogen participation individually or in combination, cannot account for the large γ-KIE's observed for the solvolysis of 7-halo-*exo*-2-norbornyl brosylates. From an analysis based on methyl migrational KIE's and the fact that the halogen at C-7 should reduce the contribution of a k_Δ process, it is clear also that the unusually large γ-KIE's observed for **1***e*, **1***f*, **1***g*, **2***c*, **2***d*, and **2***e* cannot be derived from participation of the C1—C6 bond.

In our view there are two possible sources of the large γ-KIE's. It is conceivable that the isotope effects are equal within experimental error because of a fortuitous combination of isotope effects derived from several sources. While the *exo* isotope effect may be a combination of a primary isotope effect due to 1,3 (6,2)-participation of the *exo*-C—H bond and an α-effect derived from 1,3 (6,2)-elimination and/or a 6,2-hydride shift at the IIP stage, the *endo* KIE can result from 1,3 (6,2)-elimination and/or a 6,2-shift at the IIP stage. With respect to 1,3-participation of the *exo*-C—H bond, Olah and co-workers (31, 46) found that the *exo* proton at C-6 of the norbornyl cations **25** and **26** is deshielded and stated that a 1,3 (6,2)-interaction was responsible for the effect. Since participation of the *exo*-C—H bond in the ionization step and 1,3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(6,2)-elimination and/or 6,2-shifts at the IIP stage can occur only when *exo* substrates are solvolyzed, our hypothesis is consistent with the γ-KIE's observed for the *exo*- and *endo*-brosylates.

A 1,3 carbon interaction, as described recently by Bauld *et al.* (47), is a possible alternative source of the unusually large γ-KIE's. Such an interaction between C-2 and C-6 in the norbornyl cation, as represented by **26**, would very nicely account for

24 **25** **26**

the observed KIE's because the *exo-d* and *endo-d* effects would be expected to be identical and independent of the substituent at C-7. That the 1,3 (6,2)-carbon interaction is predicted to be most pronounced for ionization of an *exo* substrate (47) is in keeping with the fact that the *exo* KIE's are larger than the *endo* KIE's. It is possible that the interaction between the *syn* groups in the bromobrosylate 1*f* distorts the 2.2.1-system, reduces the degree of 6,2-carbon interaction in the transition state, and thereby lowers the γ-KIE.

Experimental

General

Nuclear magnetic resonance spectra were recorded on Varian T-60, A-60, and HA-100 spectrometers with tetramethylsilane (TMS) as the internal standard. Samples were dissolved in either carbon tetrachloride or carbon disulfide and chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Infrared spectra were recorded on Perkin Elmer 337 and Beckman IR-5 infrared spectrometers and the samples were dissolved in carbon tetrachloride or carbon disulfide. Spectra were calibrated with a polystyrene thin film and peak positions are expressed in cm^{-1}. Ultraviolet spectra were recorded on a Cary spectrophotometer Model 14. Mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6A spectrometer at 80 eV and deuterium assays were performed at 10–15 eV. Analytical gas liquid partition chromatograms (glpc's) were obtained on a Varian Aerograph Model 204B dual column analytical gas chromatograph equipped with dual flame ionization detectors using helium as the carrier gas. The helium flow rate was usually 20–30 mL/min. Product ratios were determined by an Aerograph Model 485 electronic digital integrator. Preparative gas liquid partition chromatography was carried out on a Varian Aerograph Model A-90-P gas chromatograph equipped with a thermal conductivity detector at a helium flow rate of 50–60 mL/min. Melting points were recorded on a Kofler hot-stage apparatus and are uncorrected. Boiling points are also uncorrected. Pentane was stirred vigorously over fuming sulfuric acid, washed with sodium bicarbonate solution, dried, and distilled. Dry ether refers to ether that was distilled from lithium aluminum hydride. Pyridine was refluxed over barium oxide for 48 h and distilled. All solutions were dried with either anhydrous sodium sulfate or magnesium sulfate. Microanalyses were performed by Galbraith Laboratories, Inc., Knoxville, TN.

Preparation of Brosylates

In a typical brosylation reaction, the chlorohydrin or bromohydrin was dissolved in dry pyridine and the solution was cooled in an ice bath. A 10–20% mole excess of freshly recrystallized brosyl chloride (mp 73–74°C), recrystallized from petroleum ether (30–60°C), was slowly added to the ice-cold solution of chlorohydrin which was placed in the refrigerator at 0°C for at least one week. The brosylation of the *syn*-bromohydrin required two weeks. The product was isolated in the following manner. Several small pieces of ice were added to the solution and the reaction vessel was allowed to warm to room temperature. After the ice had melted, the solution was diluted with water and extracted with chloroform. The combined extracts were washed successively with cold water, cold dilute hydrochloric acid, saturated bicarbonate solution, cold water, and dried. After the solvent was removed under reduced pressure, the solid or oil which remained was decolorized with carbon and then recrystallized from a suitable solvent system. Crude yields of 80–95% were usually obtained.

Deuterium Assay

Since both the deuterated halohydrins and their corresponding halobrosylates gave weak parent ions when analyzed by mass spectrometry, the determination of deuterium content of these compounds by this method was not reliable. Therefore, we determined the deuterium content mass spectrometrically by analyzing the corresponding deuterated haloketones which were obtained by oxidation of the deuterated halohydrins.

Syn-*7-chloro*-exo-*2-norbornyl Brosylate (1i)*

The brosylate was recrystallized from pentane–ether and had the following characteristics: mp 112–113°C; ir (CS_2): 1375, 1350, 1315, 1190, 1100, 1075, 1040, 1020, 970, 940, 895, 875, 825, 775, 750, 640, 620, 600, 550; nmr (CS_2, 100 MHz) δ: 7.63 (m, 4H, arom), 4.50 (m, 1H, *endo*-2-H), 3.76 (broad s with fine structure, 1H, *anti*-7-H), 2.43 and 2.28 (broad s, each 1H, bridgeheads), 2.20–1.10 (m, 6H, norbornyl envelope). *Anal.* calcd. for $C_{13}H_{14}SO_3Br$: C 42.69, H 3.83; found: C 42.57, H 3.84.

Syn-*7-chloro*-exo-*2-norbornanol*-endo-6-d *(1c)*

The deuterated chlorohydrin was prepared by LAH reduction of *syn*-7-chloro-*exo*-2-norbornyl trideuteroacetate-*endo*-6-*d* that was obtained from the electrophilic cleavage of 3-chloronortricyclene in deuterated medium (6). A small sample of the chlorohydrin was oxidized to **6***c* and deuterium was assayed mass spectrometrically: 3.33 ± 0.02% d_0, 95.01 ± 0.21% d_1, 1.67 ± 0.24% d_2; 0.985 ± 0.002 excess deuterium atoms per molecule.

Syn-*7-chloro*-exo-*2-norbornyl Brosylate*-endo-6-d *(1e)*

The brosylate **1***e* had the following properties: mp 112–112.5°C; ir (CS_2): 1360, 1300, 1190(s), 1100, 1070, 1040, 1015, 970, 935, 890, 820, 775(s), 635, 610, 595, 550; nmr (CCl_4, 100 MHz) δ: 7.68 (m, 4H, arom), 4.60 (m, 1H, *endo*-2-H), 3.79 (broad s, 1H, *anti*-7-H), 2.50 and 2.30 (broad s, each 1H, bridgeheads), 2.20–1.05 (m, 5H, norbornyl envelope).

Norbornene-exo,exo-*5,5*-d_2

Norbornadiene (50.0 g, 0.54 mol) was dissolved in methanol (75 mL), 3 g of palladium on powdered charcoal (10% catalyst) were added and the mixture was treated with deuterium gas (13.2 L, 0.54 mol, 700 Torr) (48). A similar run was performed and the solutions were combined and filtered. Water (300 mL) was added and the products were extracted into pentane (3 × 300 mL). After the extracts were washed with water (2 × 50 mL) and dried, the organic solvent was removed by distillation through a 70 cm glass column filled with glass helices. Short path distillation of the products into a flask cooled by Dry Ice yielded 100 g of waxy solid. Analytical glpc on 1/8 in. × 10 ft 5% SE-30

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

column at 60°C showed that the reaction mixture consisted of 12% norbornadiene, 71% norbornene-*exo*,*exo*-5,6-d_2, and 17% norbornane-d_4.

Syn-7-exo-*2-dibromonorbornane*-endo,endo-*5,6*-d_2

To 100 g of the mixture, dissolved in methylene chloride (300 mL) and pyridine (70 mL) and cooled in an ice-water bath, was slowly added bromine (161 g, 1.0 mol) in methylene chloride (50 mL) over a period of three hours. After the addition was complete, the organic layer was washed with dilute sodium thiosulfate solution (2 × 100 mL), water (2 × 100 mL), dilute hydrochloric acid (10%, 2 × 70 mL), saturated sodium bicarbonate solution (100 mL), and water (2 × 100 mL). The organic layer was dried and methylene chloride was removed by distillation through a 30 cm glass column filled with glass helices. Distillation of the pot residue through a 30 cm vacuum jacketed Vigreux column afforded 24 g of deuterated 3-bromonortricyclene and 53.2 g of *syn*-7-*exo*-2-dibromonorbornane-*endo*,*endo*-5,6-d_2; bp 80–85°C/0.7 Torr (lit. (49) bp 70–74°C/0.25–0.30 Torr). Redistillation of the fraction afforded 42.0 g of dibromide of bp 80–83°C/0.7 Torr; nmr (CCl_4, 100 MHz) δ: 3.90 (m, 2H, *anti*-7-H and *endo*-2-H), 2.70–2.10 (m, 4H, *exo*-3-H, *endo*-3-H, H-1 and H-4), 1.65 (broad s, 2H, *exo*-5-H and *exo*-6-H). It was noted that isomerization of the dibromide occurred during analysis by glpc if the injector and detector block temperatures were kept above 160°C.

Syn-7-*bromonorbornene*-endo,endo-*5,6*-d_2

Syn-7-*exo*-2-dibromonorbornane-*endo*,*endo*-5,6-d_2 (35.6 g, 139 mmol) was dissolved in a saturated solution of potassium *tert*-butoxide in *tert*-butanol (1 *M*, 350 mL) and the mixture was refluxed for 33 h on a steam bath. The brown solution was poured into water (350 mL) and extracted with pentane (3 × 300 mL). After the extracts were washed with water (150 mL), dilute hydrochloric acid (10%, 100 mL), saturated sodium bicarbonate solution (100 mL), water (2 × 100 mL), and dried, pentane was removed by distillation through a 30 cm Vigreux column. The brown oily residue which remained was vacuum distilled to yield 17.0 g (70%) of *syn*-7-bromonorbornene-*endo*,*endo*-5,6-d_2 of bp 67–68°C/20 Torr; nmr (CCl_4, 100 MHz) δ: 5.95 (s with fine structure, 2H, H-2 and H-3), 3.79 (s, 1H, *anti*-7-H), 2.95 (m, 2H, H-1 and H-4), 1.72 (broad s, 2H, *exo*-5-H and *exo*-6-H), 1.10 (m, 0.08H, *endo*-5-H and *endo*-6-H). The integrals showed that the deuterium at C-5 and C-6 was at least 90% stereochemically pure *endo*.

Norbornene-endo,endo-*5,6*-d_2

Syn-7-bromonorbornene-*endo*,*endo*-5,6-d_2 (17.0 g, 97 mmol) and tri-*n*-butyl tin hydride (85.9 g, 0.30 mol) were sealed in a thick walled glass tube under vacuum. After being heated over a steam bath for 36 h, the tube was opened and its contents were poured into a 250 mL three necked flask which was connected to three gas dispersion bottles. The first bottle was empty, the second contained water, and the third contained sodium hydroxide pellets. The flask was heated gently with a heat gun and nitrogen gas was bubbled directly through the reaction mixture. At the outlet of the three gas dispersion bottles, 7.0 g (75%) of norbornene-*endo*,*endo*-5,6-d_2 were collected in a receiver cooled by Dry Ice. Its nmr spectrum was identical to the spectrum reported previously (9); nmr (CCl_4, 100 MHz) δ: 5.90 (t, 2H, H-2 and H-3), 2.80 (m, 2H, H-1, and H-4), 1.55 (broad s with fine structure, 2H, *exo*-5-H and *exo*-6-H), 1.31 and 1.04 (d with fine structure, 1H each, J = 8 Hz, *syn*-7-H and *anti*-7-H). Deuterium was assayed mass spectrometrically (1.90 excess deuterium atoms per molecule).

Syn-7-*chloro*-exo-*2-norbornanol*-exo,exo-*5,6*-d_2 *(1h)*

Hypochlorous acid prepared from hydrochloric acid (10%, 10 mL) and sodium hypochlorite (40 mL) was vigorously stirred with norbornene-*endo*, *endo*-5,6-d_2 (0.74 g, 8.0 mmol) at 0°C for 24 h. (8). Deuterated 3-chloronortricyclene and *syn*-7-chloro-*exo*-2-norbornanol-*exo*,*exo*-5,6-d_2 (**1***h*), the major products, were isolated by preparative glpc on a 1/4 in. × 10 ft 15% FAPP column at 150°C. Deuterium in 3-chloronortricyclene was assayed mass spectrometrically: 5% d_0, 35% d_1, 61% d_2 species; 1.57 excess *d* per molecule: **1***h*; nmr (CS_2, 100 MHz) δ: 3.85 (m, 1H, *anti*-7-H), 3.62 (broad m, 1H, *endo*-2-H), 2.30 (d, 1H, H-4), 2.25 (broad s, 1H, H-1), 2.00 (broad s, 1H, —OH), 1.90 (m, 2H, *exo*-3-H and *endo*-3-H), 1.11 (broad s with fine structure, 2H, *endo*-5-H and *endo*-6-H). The chloroketone **6***d* obtained from **1***h* by oxidation was assayed for deuterium mass spectrometrically; 4.67 ± 0.18% d_0, 5.99 ± 0.02% d_1, 89.40 ± 0.48% d_2 species, 1.847 ± 0.015 excess deuterium atoms per molecule.

Syn-7-*chloro*-exo-*2-norbornyl Brosylate*-exo,exo-*5,6*-d_2 *(1g)*

Syn-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 prepared from **1***h* had a mp 112–113°C; nmr (CCl_4, 100 MHz) δ: 7.64 (m, 4H, arom), 4.52 (m, 1H, *endo*-2-H), 3.75 (broad s with fine structure, 1H, *anti*-7-H), 2.43 and 2.26 (broad s, each 1H, bridgeheads), 2.15–1.70 (m, 2H, *exo*-3-H), 1.15 (s, 2H, *endo*-5-H and *endo*-6-H).

Anti-7-*chloro*-exo-*2-norbornanol*

Anti-7-chloro-*exo*-2-norbornanol was prepared by treatment of norbornene with hypochlorous acid as reported by Roberts *et al.* (8), by LAH reduction of *anti*-7-chloro-*exo*-2-norbornyl acetate that was obtained from electrophilic (CH_3CO_2H, H_2SO_4) cleavage of 3-chloronortricyclene (6), and by hydroboration of *anti*-7-chloronorbornene (11) that was prepared from *anti*-7-norbornenol.

Hydroboration of anti-7-*chloronorbornene*

Anti-7-chloronorbornene was hydroborated and the organoborane was treated with alkaline hydrogen peroxide according to the published procedure (27) to give a 95% yield of *anti*-7-chloro-*exo*-2-norbornanol. The product was shown to be homogeneous by analytical glpc on a 1/8 in. × 10 ft 3% GE-XF1150 column at 155°C.

Anti-7-*chloro*-exo-*2-norbornyl Brosylate (2g)*

Anti-7-chloro-*exo*-2-norbornyl brosylate recrystallized from 1:2 ether – petroleum ether (30–60°C) had a mp 69.5–71.0°C; ir (CS_2): 1375, 1190(s), 1180, 1100, 1075, 1065, 1015, 970, 940, 920, 890, 870, 825, 780, 605, 550; nmr (CCl_4, 11 MHz) δ: 7.75 (m, 4H, arom), 4.47 (m, 1H, *endo*-2-H), 4.16 (broad s, 1H, *syn*-7-H), 2.42 and 2.30 (broad s, each 1H, bridgeheads), 2.05–1.60 and 1.20 (m, 6H, norbornyl envelope). *Anal.* calcd. for $C_{13}H_{14}SO_3Br$: C 42.69, H 3.83; found: C 42.72, H 3.88.

Anti-7-*chloro*-exo-*2-norbornanol*-endo-*6*-d *(2a)*

Anti-7-chloro-*exo*-2-norbornyl trideuteroacetate-*endo*-6-*d* obtained by electrophilic cleavage of 3-chloronortricyclene in deuterated medium (6) was reduced by LAH in ether to *anti*-7-chloro-*exo*-2-norbornanol-*endo*-6-*d* (**2***a*); ir (CS_2): 3600, 1310, 1280, 1265, 1225, 1085, 1070, 1030, 995, 940, 910, 870, 850, 815, 805, 785, 700; nmr (CCl_4, 100 MHz) δ: 4.18 (s with fine structure, 1H, *syn*-7-H), 3.75 (dd, 1H, J = 7.5 and 2.5 Hz, *endo*-2-H), 2.23 and 2.11 (broad s, each 1H, bridgeheads), 2.00–1.00 (m, 6H, norbornyl envelope and —OH). A small sample of the chlorohydrin was oxidized to chloroketone **6***e* and deuterium was assayed mass spectrometrically; 3.81 ± 0.01% d_0, 95.04 ± 0.18% d_1, 1.15 ± 0.18% d_2 species; 0.976 ± 0.004 excess deuterium atoms per molecule.

Anti-7-*chloro*-exo-*2-norbornyl Brosylate*-endo-*6*-d *(2c)*

The deuterated chlorobrosylate had a mp 71–72°C; ir (CS_2): 1320, 1310, 1190(s), 1100, 1070, 1055, 1015, 980, 965, 935, 915, 890, 870(s), 825, 790, 740, 700, 640, 625, 605, 550; nmr (CCl_4, 100 MHz) δ: 7.76 (s, 4H, arom), 4.46 (m, 1H, *endo*-2-H), 4.15 (s,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

1H, *syn*-7-H), 2.40 and 2.30 (broad s, each 1H, bridgeheads), 2.00–1.79 and 1.15 (m, 5H, norbornyl envelope).

Anti-*7-norbornenol*-exo,exo-*5,6*-d_2 (*5a*)

7-Acetoxynorbornadiene (20 g, 0.13 mol) was reduced by LAD (6.0 g, 0.14 mol) in dry ether (125 mL) under an atmosphere of nitrogen. After 4.5 h at room temperature a paste of sodium sulfate (dried at 150°C for 3 days) and deuterium oxide was carefully added to the reaction mixture until gas was no longer evolved. The mixture was stirred overnight (13 h) and then the inorganic salts were filtered off. The ethereal layer was separated and the aqueous phase was extracted with ether (3 × 50 mL). After the combined organic layers were washed with water, solvent was removed by distillation through a 30 cm glass column filled with glass helices to yield *anti*-7-norbornenol-*exo*,*exo*-5,6-d_2 (48, 50).

Anti-*7-chloronorbornene*-exo,exo-*5,6*-d_2 (*5b*)

Anti-7-chloronorbornene-*exo*,*exo*-5,6-d_2 was prepared in 50% yield by treatment of *anti*-7-norbornenol-*exo*,*exo*-5,6-d_2 with thionyl chloride according to the literature method (11); nmr (CCl_4, 100 Mz) δ: 6.00 (t, 2H, J = 2 Hz, H-2 and H-3), 3.67 (s with fine structure, 1H, *syn*-7-H), 2.70 (m, 2H, H-1 and H-4), 2.00 (m, 0.12 H, *exo*-5-H and *exo*-6-H), 0.98 (s, 2H, *endo*-5-H and *endo*-6-H). Integration showed that deuterium at C5 and C6 was at least 90% stereochemically pure *exo*. Deuterium was assayed mass spectrometrically: 7.36 ± 0.02% d_0, 3.40 ± 0.33% d_1, 89.40 ± 0.43% d_2 species; 1.849 ± 0.002 excess deuterium atoms per molecule.

Anti-*7-chloro*-exo-*2-norbornanol*-exo,exo-*5,6*-d_2 (*2f*)

Hydroboration of *anti*-7-chloronorbornene-*exo*,*exo*-5,6-d_2 (*5b*) with subsequent oxidation by alkaline hydrogen peroxide (27) gave 90% of *anti*-7-chloro-*exo*-2-norbornanol-*exo*,*exo*-5,6-d_2 (*2f*) that was purified by preparative glpc on a 1/4 in. × 10 ft 25% GE XF-1150 column at 180°C; nmr (CCl_4, 100 MHz) δ: 4.16 (broad s with fine structure, 1H, *syn*-7-H), 3.75 (dd, 1H, J = 7 and 3 Hz, *endo*-2-H), 2.24 (d, 1H, J = 4 Hz, H-4), 2.11 (broad s, 1H, H-1), 2.06 (s, 1H, —OH), 1.75 (dd, 1H, J = 7 and 13 Hz, *endo*-3-H), 1.40 (d of d, 1H, J = 3 and 13 Hz, *exo*-3-H), 1.05 (broad s, 2H, *endo*-5-H and *endo*-6-H).

Anti-*7-chloro*-exo-*2-norbornyl Brosylate*-exo,exo-*5,6*-d_2 (*2e*)

Anti-7-chloro-*exo*-2-norbornyl brosylate-*exo*,*exo*-5,6-d_2 recrystallized from 1:2 ether – petroleum ether (30–60°C) had a mp 69–70°C; nmr (CCl_4, 100 MHz) δ: 7.65 (s, 4H, arom), 4.45 (dd, 1H, J = 4 and 6 Hz, *endo*-2-H), 4.10 (broad s with fine structure, 1H, *syn*-7-H), 2.39 (broad s, 1H, H-1), 2.27 (m, 1H, H-4), 1.75 (m, 2H, *exo*-3-H and *endo*-3-H), 1.11 (s, 2H, *endo*-5-H and *endo*-6-H).

Anti-*7-chloro*-exo-*2-norbornanol*-exo-*3*-d (*4b*)

Into a three necked flask fitted with a magnetic stirrer, condenser, addition funnel, drying tube, and nitrogen inlet were placed *anti*-7-chloronorbornene (3.0 g, 16 mmol), diglyme (7 mL, distilled from lithium aluminum hydride) and sodium borodeuteride (0.34 g, 8 mmol). Freshly distilled boron trifluoride etherate (1.4 g, 10 mmol) dissolved in diglyme (6 mL) was slowly added to the flask at room temperature and then the mixture was stirred for 3 h. Water (20 mL) was added to the reaction mixture followed by sodium hydroxide (3 *N*, 7 mL) and hydrogen peroxide (33%, 7 mL). After the solution was stirred for 14 h, it was extracted with ether (4 × 30 mL), the combined ether extracts were washed with water (3 × 20 mL), and dried. A 90% yield (2.1 g) of *anti*-7-chloro-*exo*-2-norbornanol-*exo*-3-*d* (*4b*) was obtained; nmr (CCl_4, 100 MHz) δ: 4.19 (broad s, 1H, *syn*-7-H), 3.77 (d, 1H, J = 7 Hz, *endo*-2-H), 2.60 (broad s, 1H, —OH), 2.26 and 2.14 (broad s, each 1H, bridgeheads), 2.05–1.70 and 1.10 (m, norbornyl envelope).

The position of deuterium was verified by complexation of non-deuterated and deuterated chlorohydrins with $Eu(fod)_3$. When 0.134 g of $Eu(fod)_3$ was complexed with 0.034 g of *anti*-7-chloro-*exo*-2-norbornanol in carbon tetrachloride (0.5 mL), most of the proton resonances were separated from each other: nmr (CCl_4, 100 MHz) δ: 16.90 (d, 1H, J = 7 Hz, *endo*-2-H), 12.40 (s, 1H, *syn*-7-H), 1084 (broad d with fine structure, 1H, J = 4 Hz, *exo*-3-H), 10.25 (broad s, 1H, H-1), 6.38 (dd, 1H, J = 7 and 14 Hz, *endo*-3-H), 5.10 (broad s, 1H, H-4), 3.80–3.00 (m, 4H, H-5 and H-6). Complexation of *anti*-7-chloro-*exo*-2-norbornanol-*exo*-3-*d* (0.037 g) with $Eu(fod)_3$ (0.160 g) in carbon tetrachloride (0.5 mL, mole ratio LSR/alcohol = 0.61) and subsequent analysis by nmr spectroscopy revealed that the *exo* proton (σ 11.20) at C-3 was absent; nmr (CCl_4, 100 MHz) δ: 17.90 (d, 1H, J = 7 Hz, *endo*-2-H), 12.90 (s, 1H, *syn*-7-H), 10.80 (broad s, 1H, H-1), 6.60 (d, 1H, J = 7 Hz, *endo*-3-H), 5.17 (broad s, 1H, H-4), 4.00–3.00 (m, 4H, H-5 and H-6). The resonance due to *endo*-3-H (δ: 6.60) appeared as a doublet due to loss of geminal coupling with *exo*-3-H.

A small sample of *4b* was oxidized to *anti*-7-chloro-2-norbornanone-*exo*-3-*d* and the deuterium was assayed mass spectrometrically: 6.58 ± 0.01% d_0, 93.52 ± 0.21% d_1, 0.10 ± 0.23% d_2 species; 0.936 ± 0.003 excess deuterium per molecule.

Anti-*7-chloro*-exo-*2-norbornyl Brosylate*-exo-*3*-d (*4a*)

The deuterated chlorobrosylate had the following properties: mp 70–71°C; nmr (CCl_4, 100 MHz) δ: 7.70 (s, 4H, arom), 4.45 (d, 1H, J = 7 Hz, *endo*-2-H), 4.13 (broad s, 1H, *syn*-7-H), 2.41 and 2.29 (broad s, each 1H, bridgeheads), 2.15–1.80 (m, 3H, *exo*-5-H, *exo*-6-H, and *endo*-3-H), 1.15 (m, 2H, *endo*-5-H, and *endo*-6-H).

Anti-*7-chloro-2-norbornanone* (*6f*)

The chloroketone *6a* was obtained via electrophilic (CH_3CO_2H, H_2SO_4) cleavage of 3-chloronortricyclene as previously reported (6).

Lithium Tri-tert-*butoxyaluminum Hydride Reduction of* Anti-*7-chloro-2-norbornanone*

Anti-7-chloro-2-norbornanone (0.61 g, 4 mmol) in tetrahydrofuran (20 mL) was added to a stirred solution of lithium tri-*tert*-butoxyaluminum hydride (1.3 g, 5 mmol) in tetrahydrofuran (15 mL). The yellow solution was refluxed and after 7.5 h it was estimated by analytical glpc that the reaction was >95% complete. Water (50 mL) and dilute hydrochloric acid (10%, 20 mL) were added to the reaction mixture and the products were extracted into ether (4 × 50 mL). The combined ethereal extracts were washed with water (50 mL), saturated bicarbonate solution (50 mL), water (50 mL), and dried. Evaporation of solvent under reduced pressure left a white solid (0.56 g). Analytical glpc analysis on a 1/8 in. × 10 ft 3% GE XF-1150 column at 155°C revealed that *anti*-7-chloro-*endo*-2-norbornanol (92%) and *anti*-7-chloro-*exo*-2-norbornanol (8%) were present. A pure sample of *anti*-7-chloro-*endo*-2-norbornanol (*3d*) had a mp 83–84°C (lit. (49) mp 84–86°C); nmr (CCl_4, 100 MHz) δ: 4.00 (quintet with fine structure, 1H, *exo*-2-H), 3.70 (broad s with fine structure, 1H, *syn*-7-H), 2.83 (s, 1H, —OH), 2.25–0.85 (m, 8H, norbornyl envelope).

Anti-*7-chloro*-endo-*2-norbornyl Brosylate* (*3c*)

The chlorobrosylate purified by recrystallization from ether – petroleum ether 30–60°C (1:2) had a mp 49–51°C; nmr (CCl_4, 100 MHz) δ: 7.70 (m, 4H, arom), 4.75 (quintet with fine structure, 1H, *exo*-2-H), 3.80 (broad s, 1H, *syn*-7-H), 2.50–1.20 (m, 8H, norbornyl envelope). *Anal.* calcd. for $C_{13}H_{14}SO_3Br$: C 42.69, H 3.83; found: C 42.83, H 3.79.

Anti-*7-chloro-2-norbornanone*-endo-*6*-d (*6g*)

The deuterated chloroketone *6g* was prepared from the corre-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

sponding acetate which was obtained via electrophilic (CD_3CO_2D–D_2SO_4) cleavage of 3-chloronortricyclene as previously reported (6). Mass spectrometric analysis established that the sample contained 0.976 ± 0.004 excess deuterium atoms per molecule.

Lithium Tri-tert-*butoxaluminum Hydride Reduction of* Anti-*7-chloro-2-norbornanone*-endo-*6*-d

The deuterated chloroketone (0.50 g) was reduced to the chlorohydrin by the method previously described. A pure sample of *anti*-7-chloro-*endo*-2-norbornanol-*endo*-6-d was isolated by preparative glpc on a 1/4 in. × 10 ft 25% GE XF-1150 column at 160°C; nmr (CCl_4, 100 MHz) δ: 4.00 (multiplet, 1H, *exo*-2-H), 3.70 (broad s with fine structure, 1H, *syn*-7-H), 2.52 (s, 1H, —OH), 2.20–0.85 (m, 7H, norbornyl envelope).

Anti-*7-chloro*-endo-*2-norbornyl Brosylate*-endo-*6*-d *(3a)*

The chlorobrosylate had a mp 48–50°C; nmr (CCl_4, 100 MHz) δ: 7.70 (m, 4H, arom), 4.75 (quintet with fine structure, 1H, *exo*-2-H), 3.80 (s, 1H, *syn*-7-H), 2.50–1.25 (m, 7H, norbornyl envelope).

Syn-*7-bromo*-exo-*2-norbornyl Brosylate (1j)*

Syn-7-bromohydrin (0.18 g, 90% pure) obtained via the acid-catalyzed ring-opening of 3-bromonortricyclene (6) was converted to 0.086 g of brosylate that exhibited a mp of 122–123°C after three recrystallizations from ether; nmr (CS_2, 100 MHz) δ: 7.63 (narrow m, 4H, arom), 4.48 (dd with fine structure, 1H, *endo*-2-H), 3.73 (narrow m, 1H, *anti*-7-H), 2.46 (broad m, 1H, H-1), 2.28 (broad m overlapped norbornyl envelope, H-4), 2.3–1.0 (norbornyl envelope).

Syn-*7-bromo*-exo-*2-norbornanol-6*-endo-d *(1d)*

The deuterated bromohydrin was prepared by LAH reduction of *syn*-7-bromo-*exo*-2-norbornyl acetate-6-*endo-d* that was obtained by electrophilic cleavage of 3-bromonortricyclene in deuterated medium (6). A small sample of the bromohydrin was oxidized to ***6h*** and deuterium was assayed mass spectrometrically: 4.27 ± 0.18% d_0, 94.03 ± 0.42% d_1, 1.71 ± 0.24% d_2 species; 0.967 ± 0.005 excess deuterium atoms per molecule.

Syn-*7-bromo*-exo-*2-norbornyl Brosylate-6*-endo-d *(1f)*

Deuterated *syn*-bromohydrin (0.90 g) (6) was converted into 0.096 g of brosylate of mp 123–124°C after three recrystallizations from pentane–ether. Its nmr (CS_2, 100 MHz) was similar to that of **1*j*** (*vide supra*), the only differences being a simplification of the norbornyl envelope from σ 2.3–0.10 and a significant decrease in intensity of the signal in the region of σ 1.1.

Anti-*7-bromo*-exo-*2-norbornyl Brosylate (2h)*

The bromohydrin (0.14 g) obtained via the acid catalyzed ring-opening of 3-bromonortricyclene (6) was converted into 0.076 g of brosylate that exhibited a mp of 76–77°C after three recrystallizations from pentane–ether; nmr (CS_2, 100 MHz) δ: 7.65 (sharp s, 4H, arom), 4.39 (dd, 1H, *endo*-2-H), 4.03 (sharp m, 1H, *syn*-7-H), 2.26 (broad m, 2H, H-1 and H-4), 3.1–0.9 (norbornyl envelope).

Anti-*7-bromo*-exo-*2-norbornanol-6*-endo-d *(2b)*

The deuterated bromohydrin was prepared by LAH reduction of *anti*-7-bromo-*exo*-2-norbornyl acetate-6-*endo-d* that was obtained by electrophilic cleavage of 3-bromonortricyclene in deuterated medium (6). A small sample was oxidized to ***6i*** and deuterium was assayed mass spectrometrically: 5.63 ± 0.12% d_0, 92.48–0.28% d_1, 1.90 ± 0.20% d_2 species; 0.977 ± 0.007 excess deuterium atoms per molecule.

Anti-*7-bromo*-exo-*2-norbornyl Brosylate-6*-endo-d *(2h)*

Anti-7-bromo-*exo*-2-norbornanol-*endo*-6-*d* (0.065 g) was converted into 0.057 g of brosylate that exhibited a mp of 75–76°C after three recrystallizations from pentane–ether; nmr (CS_2, 100 MHz) δ: 7.65 (sharp s, 4H, arom), 4.40 (dd, 1H, *endo*-2-H), 4.05 (sharp m, 1H, *syn*-7-H), 2.28 (broad m, 2H, H-1 and H-4), 2.1–1.0 (norbornyl envelope). Its nmr spectrum was similar to that of the non-deuterated brosylate, the major difference being a reduction of the signal at σ 1.1.

Kinetic Measurements

Solvolyses were carried out in 80:20 EtOH–H_2O containing 0.04 *M* sodium acetate. Water was refluxed in potassium permanganate for several hours and distilled five times and ethanol was purified by two distillations. An ultraviolet spectrum of the solvent mixture did not reveal any interfering absorptions. Solvolysis isotope effects were obtained by simultaneously observing the solvolysis of the non-deuterated and deuterated substrates spectrophotometrically in a Cary Model 14 spectrophotometer. By circulating water from a Haake Model NBe bath through the temperature controlled cell compartment, the desired temperature and temperature control were achieved during the kinetic runs. At the start of a kinetic run several Pasteur pipettes, each wrapped with aluminum foil, and three sample cells were placed in the cell compartment to equilibrate with the temperature of the cell compartment for at least 10 h. Before a solvolysis run was initiated, the appropriate brosylates were purified by recrystallization and kept under a vacuum at room temperature for 0.5 h. The brosylates (2–3 mg) were weighed into 2 mL volumetric flasks that were then equilibrated in the water bath for 0.5 h. Solvent (2 mL) that also was equilibrated to the bath temperature was rapidly transferred into two volumetric flasks containing the brosylates, the flasks were vigorously shaken in order to ensure complete solution, and allowed to equilibrate in the water bath for 5 min. Each solution was rapidly transferred, with insulated Pasteur pipettes, into a 1.00 cm cell in the compartment of the spectrophotometer. After 10 min, readings were taken at an absorbance maximum initially at 5 min intervals by running the pen and chart paper from 10 s before to 10 s after the minute. As the rate decreased readings were taken at 10 min intervals and then at 20 min intervals. The cells were switched simply by shutting off the recorder and manually manipulating the cell carriage. The slit controls were shut off during a run to avoid fluctuations. Absorbance readings were taken for at least three half-lives. A check of the zero reading on the instrument after the infinity reading (10 half-lives) generally revealed a negligible baseline drift of less than ±0.003 of an absorbance unit. The rate data which usually consisted of 20–30 sets of data points were subjected to a least-squares analysis to evaluate the slopes and standard deviation in the slopes. Changes in absorbance as a function of time were monitored for *anti*-7-chlorobrosylate at 276 nm and for *syn*-7-chlorobrosylate at 260 nm. The *syn*- and *anti*-7-bromobrosylates were monitored at 260 and 266 nm, respectively. Kinetic runs with deuterated material were performed only after control runs with two non-deuterated brosylates showed that a ratio of the rate constants between 0.99 ± 0.01 to 1.01 ± 0.01 was routinely obtainable. Corrections due to incomplete deuteration were usually small because of the high degree of deuterium incorporation in the compounds. The kinetic runs for non-deuterated and deuterated *syn*-7-chloro-*exo*-2-norbornyl brosylate were carried out at a cell temperature in the region of 50°C. Half-lives were generally in the order of 50–60 minutes. For *anti*-7-chloro-*exo*-2-norbornyl brosylates, the solvolyses were performed at 60°C and the half-lives were around 35–40 min. The kinetic procedure for *anti*-7-chloro- *endo*-2-norbornyl brosylate was slightly different from that described above. Water at 80°C was circulated through cell holders and the cell compartment was maintained at 71°C with water from a second Haake Model NBe circulating bath. Absorbance readings at 266 nm were taken as a function of time for about 36 h at approximately 4–6 h intervals and 9–10

points were used to determine the first-order rate constants. Since the half-life of the solvolytic reaction was about 12 h, A_∞ and the rate constant were calculated from the (A_t, t) readings by curve-fitting routine which fitted the data to an equation of the form $A_t = Be^{-k}$. To check the accuracy of this method, all the solvolytic data for *anti*- and *syn*-7-chloro-*exo*-2-norbornyl brosylates were analyzed by this method and A_∞ and k were calculated. Excellent agreement between fitted and experimental values and ratio constants was noted. The rate constants and standard deviations, for representative runs of *exo*-brosylate, along with the cell compartment temperatures, are as follows: **1***i*, $1.645 \pm 0.005 \times 10^{-4}$ s^{-1}; **1***e*, $1.498 \pm 0.005 \times 10^{-4}$ s^{-1} (50.0°C); **2***g*, $3.427 \pm 0.004 \times 10^{-4}$ s^{-1}; **2***c*, $3.077 \pm 0.005 \times 10^{-4}$ s^{-1} (60.0°C); **1***j*, $5.738 \pm 0.017 \times 10^{-4}$ s^{-1}; **1***f*, $5.452 \pm 0.016 \times 10^{-4}$ s^{-1} (60.0°C); **2***h*, $3.050 \pm 0.004 \times 10^{-4}$ s^{-1}; **2***d*, $2.733 \pm 0.003 \times 10^{-4}$ s^{-1} (60.0°C); **2***g*, $2.875 \pm 0.003 \times 10^{-4}$ s^{-1}; **4***a*, $2.627 \pm 0.004 \times 10^{-4}$ s^{-1} (57.8°C). Rate constants of $1.497 \pm 0.020 \times 10^{-5}$ s^{-1} and $1.567 \pm 0.020 \times 10^{-5}$ s^{-1} (80.0°C) were obtained for a typical simultaneous solvolysis of the *endo*-brosylates **3***a* and **3***c*, respectively. While the temperature of the bath was set in the range 50–60°C and controlled to better than ±0.05°C, the temperature within the cell compartment was several degrees lower than the bath. That the temperature control was adequate is seen from the quality of the rate data (Figs. 1(*a*), (*b*), and (*c*)).

Synthesis of 4-deoxydaunosamine and 4-deoxyristosamine[1]

HANS H. BAER AND HANNA R. HANNA
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received April 2, 1980

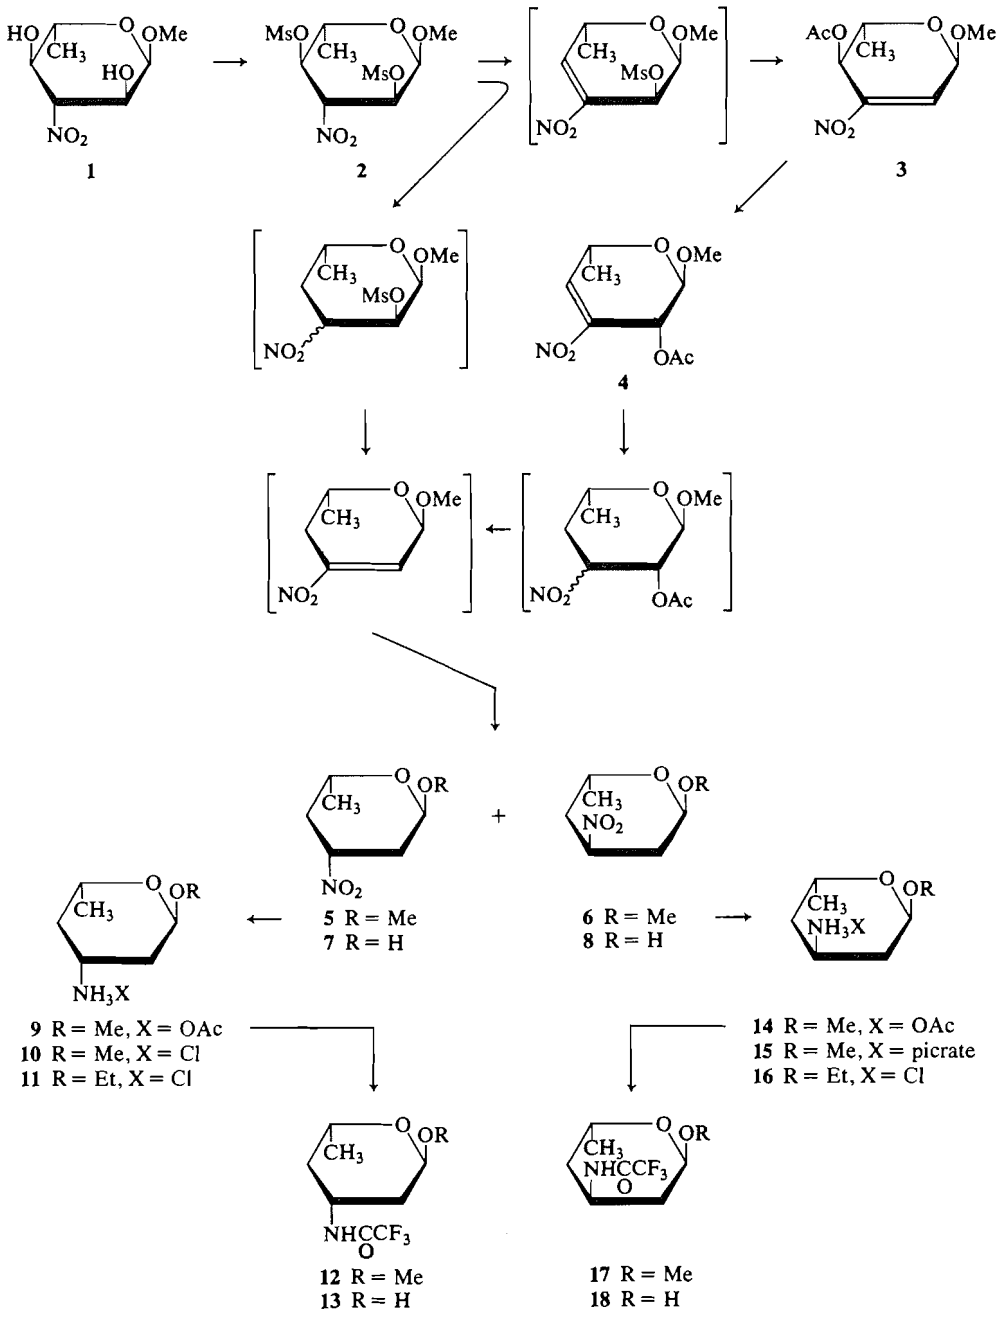
HANS H. BAER and HANNA R. HANNA. Can. J. Chem. **58**, 1751 (1980).

Treatment of methyl 3,6-dideoxy-2,4-di-*O*-methylsulfonyl-3-nitro-α-L-glucopyranoside (**2**) with sodium acetate and acetic acid in acetone gave methyl 4-*O*-acetyl-2,3,6-trideoxy-3-nitro-α-L-*erythro*-hex-2-enopyranoside (**3**) as a kinetic product, and the 2-*O*-acetyl-3,4,6-trideoxy-3-nitro-α-L-*threo*-hex-3-eno isomer **4** as the thermodynamically preferred product. Treatment of **2** or **4** with sodium borohydride produced a separable mixture of methyl 2,3,4,6-tetradeoxy-3-nitro-α-L-*threo*-hexopyranoside (**5**) and its α-L-*erythro* epimer (**6**), the latter being convertible into the former by base-catalyzed epimerization. Acid hydrolysis of **5** and **6** afforded the corresponding free nitro sugars **7** and **8**. Catalytic hydrogenation of **5** led to the corresponding amino glycoside, isolated as the acetate **9** or hydrochloride **10**; similarly, **6** gave the epimeric amine which was isolated as its acetate **14** or picrate **15**. *N*-Trifluoroacetylation of **9** provided the *N*-trifluoroacetyl glycoside **12** which was hydrolyzed to give a 49% yield (overall from **2**) of 2,3,4,6-tetradeoxy-3-trifluoroacetamido-L-*threo*-hexose (4-deoxy-*N*-trifluoroacetyldaunosamine, **13**). Analogously, **14** afforded the epimeric *N*-trifluoroacetyl glycoside **17** which was hydrolyzed to give a 28% overall yield of 2,3,4,6-tetradeoxy-3-trifluoroacetamido-L-*erythro*-hexose (4-deoxy-*N*-trifluoroacetylristosamine, **18**).

HANS H. BAER et HANNA R. HANNA. Can. J. Chem. **58**, 1751 (1980).

Le méthyl-3,6-didesoxy-2,4-di-*O*-méthylsulfonyl-3-nitro α-L-glucopyranoside (**2**) traité par l'acétate de sodium et l'acide acétique dans l'acétone donne le méthyl-4-*O*-acétyl-2,3,6-tridésoxy-3-nitro-α-L-*érythro* hex-2-ène pyrannoside (**3**) comme produit cinétique et l'isomère 2-*O*-acétyl-3,4,6-tridésoxy-3-nitro-α-L-*thréo*-hex-3-ène (**4**) comme produit thermodynamique. Les composés **2** ou **4**, traités par le borohydrure de sodium, conduisent à un mélange dont on peut séparer le méthyl-2,3,4,6-tétradésoxy-3-nitro-α-L-*thréo*-hexopyranoside (**5**) et son épimère α-L-*érythro* (**6**); ce dernier peut être transformé en composé *thréo* par épimérisation en présence d'une base. L'hydrolyse acide de **5** et de **6** conduit aux sucres nitro libres **7** et **8**. L'hydrogénation catalytique de **5** conduit à l'aminoglucoside correspondant que l'on a isolé sous forme d'acétate **9** ou de chlorhydrate **10**. D'une manière analogue, le composé **6** donne l'amine épimère que l'on a isolé sous forme d'acétate **14** ou de picrate **15**. La *N*-trifluoroacétylation du composé **9** fournit le *N*-trifluoroacétylglycoside **12** qui par hydrolyse donne avec un rendement de 49% (à partir de **2**) le 2,3,4,6-tétradésoxy-3-trifluoroacétamido-L-*thréo* hexose (4-désoxy-*N*-trifluoroacétylduanosamine, **13**). De la même manière, le composé **14** conduit au *N*-trifluoroacétylglycoside épimère **17** qui par hydrolyse conduit avec un rendement global de 28% au 2,3,4,6-tétradésoxy-3-trifluoroacétamido-L-*érythro* hexose (4-désoxy-*N*-trifluoroacétylristosamine, **18**).

[Traduit par le journal]



The amino sugars daunosamine (3-amino-2,3,6-trideoxy-L-*lyxo*-hexose) and ristosamine (its L-*ribo* isomer) are objects of much interest in medicinal chemistry. The former constitutes the sugar moiety of the anthracycline glycosides daunorubicin and adriamycin, which are effective therapeutic agents against a broad spectrum of human tumors (1), and the latter is a component of the antibiotic, ristomycin-A, isolated from *Proactinomyces fructiferi* (2). Intensive and promising efforts are currently directed in several laboratories towards the development of semisynthetic, modified analogs of daunorubicin and adriamycin which might display increased efficacy or lower cardiopathogenicity, a cumulative, dose-related side-effect (3) that curtails the administration of the natural drugs. To this end, a large variety of analogs modified in the sugar portion have been synthesized and, in part, evaluated pharmacologically (4–10). Among the substitutes for daunosamine whose attachment to the anthracyclinone aglycons showed promise in early screening were 4-deoxydaunosamine (6) and ristosamine (7); the D-enantiomer of ristosamine also gave an active glycoside (10). These developments motivated the search for new and convenient synthetic approaches to these and similar amino sugars. Of particular advantage are designs furnishing the desired amino sugars in a form suitable for subsequent linking to aglycons, e.g., as *N*-trifluoroacetyl derivatives. Continuing our program (11, 12) in the area of preparative chemistry of nitrogenous, polydeoxy sugars, we have recently announced (13) the synthesis of various derivatives of 3-amino-2,3,4,6-tetradeoxy-L-*threo*-hexose (4-deoxydaunosamine) and its L-*erythro* isomer (4-deoxyristosamine); the present article records full experimental details together with some additional, appertaining results.

4-Deoxy-*N*-trifluoroacetyldaunosamine (**13**) has been prepared previously in a four-step reaction sequence from methyl *N*-trifluoroacetyldaunosaminide which, in turn, had been elaborated from natural daunorubicin (5, 6). It would doubtless be possible to produce it similarly from synthetic

[1]The essential results of this work were first disclosed at the 62nd Canadian Chemical Conference, Vancouver, B.C., June, 1979. For a preliminary communication, see ref. 13.

daunosamine for which there is now available a practical method of preparation starting from methyl α-D-mannopyranoside and comprising 9 steps (14). A multistep, achiral synthesis of racemic, 4-deoxy-D,L-daunosamine has also been achieved (15). The main feature of our alternative approach is the use of nitro sugars as intermediates; it leads to **13** and, in parallel, to the isomer **18**, with six steps being required for each from readily available methyl α-L-rhamnopyranoside.

The starting point was methyl 3,6-dideoxy-3-nitro-α-L-glucopyranoside (**1**), a key intermediate used in previous amino sugar syntheses (11, 16, 17); it is conveniently prepared in crystalline form, in about 40% yield, from methyl α-L-rhamnopyranoside by the nitromethane cyclization method. The glycoside **1** was converted into its 2,4-dimesylate **2** (yield, 80%) as already described for the D-enantiomer (12*a*). Introduction of the required deoxy functions in the positions 2 and 4 was

then achieved, either in a stepwise sequence or in a single operation. For the former mode, **2** was treated with sodium acetate and acetic acid in acetone solution, in order to produce the 2-O-acetyl-3-enoside **4** according to the procedure first applied (12*d*) in the D-series. As expected, this was successful. However, it was discovered in the present work, through the use of a different solvent for monitoring the reaction by tlc, that under the conditions previously specified (namely, after 10 min of heating at reflux temperature), an additional product was actually present in the reaction mixture. It disappeared when the reaction time was extended to 1 h, and pure crystalline **4** was then isolated in 70% yield. To investigate the nature of the intermediary compound, the reaction was performed at room temperature, at which the rate was conveniently slow. The intermediary product was then seen to arise first, and it could be isolated in crystalline form upon work-up of the reaction mixture after 2 h, at the time of incipient appearance of **4**. It proved to be the known, isomeric 4-*O*-acetyl-2-enoside **3** by comparison of its nmr spectrum and optical rotation with reported data (11*b*). When crystalline **3** was resubjected to the aforementioned reaction conditions, it was completely converted into **4**.

The discovery of **3** as a kinetic intermediate between **2** and **4** provides an interesting supplement to our earlier discussion (12*d*) of the elimination–addition mechanism proposed for this reaction. We had considered two possible pathways without expressing a preference. One of them was assumed to lead, via a 4-*O*-mesyl-2-enoside, to **4** directly, while the other one was formulated to give, via the isomeric 2-*O*-mesyl-3-enoside, an intermediary 4-*O*-acetyl-2-enoside which would then rearrange to **4**. The actual occurrence of **3** as such an intermediate can now be taken as evidence for the second alternative.[2] It is thought that this pathway is favored for electronic reasons. An initial elimination of mesylate anion in **2** should preferentially occur from position 4, rather than from position 2 where the inductive effect of the neighboring anomeric center renders anion departure more difficult (11*b*).

Reduction of **4** with sodium borohydride followed by acidification gave, in up to 90% yield, a mixture of methyl 2,3,4,6-tetradeoxy-3-nitro-α-L-*threo*-hexopyranoside (**5**) and its α-L-*erythro* isomer (**6**). The ratio of **5** to **6**, visually estimated by tlc as approximately 1:2 or 2:3, did not appear to change materially with variations in reaction temperature (−30 to +25°C) or solvent (ethanol, methanol, or *tert*-butanol). A similar mixture was obtained, more conveniently and in nearly quantitative yield, by treatment of the dimesylate **2** with sodium borohydride in dichloromethane–ethanol (1.5 h at 25°C). Whereas part of the preponderant isomer **6** crystallized directly from the acidified reaction mixture, the bulk of the products had to be separated by column chromatography on silica gel, whereby it was essential to maintain the medium lightly acidic throughout the operation. Pure **5** and crystalline **6** were thus isolated in yields of 26 and 56%, respectively. Compound **6** was thermodynamically unstable and tended to epimerize to **5** in neutral to slightly basic medium. This conversion, occurring for example in methanolic solution in the presence of silica gel and a trace of triethylamine, could be readily monitored by tlc; after 6 h, only a trace of **6** was left. By making preparative use of this epimerization, pure **5** could be isolated, after chromatography, in a yield of 71% based on **2**.

The formation and interconversion of **5** and **6** must involve the nitronate anion common to the two epimers. Evidently, protonation leads to **6** as the kinetically favored product. The nmr spectrum of **6** is consistent with the normal chair conformation having an axial nitro group. Although a limited distortion cannot be ruled out, any significant deviation (e.g., adoption of a skew form) should have manifested itself clearly in the ring-proton coupling pattern. Since axial-nitro epimers are rarely encountered in sugar nitronate protonation (see refs. 18 for discussions), **6** provided a surprise, not so much in that it was formed in the present case but in that it was sufficiently stable for isolation.

Although not required for the planned amino sugar synthesis, the free nitro sugars **7** and **8** were prepared from their respective glycosides **5** and **6**. Whereas the hydrolysis of **5** was performed under customary conditions using hot, 0.5 *M* aqueous sulfuric acid (1.5 h), that of **6** was achieved best at room temperature by treating the compound for 2 h with moist chloroform saturated with hydrogen chloride. Hydrolyses with hot, aqueous sulfuric or acetic acids resulted in considerable degrees of decomposition and gave poor yields of **8**. The 2,3,4,6-tetradeoxy-3-nitro-L-hexoses crystallized in the form of upward-mutarotating α-anomers.

Apart from the fact that reduction of **5** followed by *N*-acylation and hydrolysis led to the known

[2]We had tentatively formulated (12*d*) as a then hypothetical intermediate, the 4-epimer of (D) **3**, for reasons of its advantage in conformational energy (absence of $A^{(1,2)}$ strain). However, the less-stable **3** which has now been found as a kinetic product makes the facile rearrangement to **4** an even more plausible event. Incidentally, **3** cannot have arisen from a 4-*O*-mesyl-2-enoside precursor by an S_N2 displacement, in view of the retention of the C-4 configuration. Had the 4-epimer been found, such a displacement might have been invoked as an alternative to the elimination–addition sequences which we advocate.

amino sugar **13** (see below), the configurational assignment of **5** and **6** was readily derived from nmr spectra (100 MHz in $CDCl_3$). Thus, the nitromethine proton (H-3) in the equatorial-nitro glycoside **5** gave a low-field, symmetrical triplet of triplets whose spacings of 12 and 4.5 Hz indicated diaxial relations with H-2a and H-4a and axial–equatorial relations with H-2e and H-4e. These splittings were mirrored in the well-separated, highfield signals of H-2a (a symmetrical triplet of doublets) and H-4a (a quartet) showing, respectively, additional coupling with H-1 (3.5 Hz) and H-5 (12 Hz) as well as geminal coupling (12–13 Hz). Spacings found in the well-separated multiplets for H-5 (a sextet of doublets) and H-2e and H-4e (partially overlapping) accorded therewith. The spectrum of the free sugar **7** showed almost the same features except for some reasonably expected differences in chemical shifts and, of course, for the absence of a methoxyl resonance. By contrast, the glycoside **6** displayed for its (equatorial) H-3 proton a narrow multiplet containing only small vicinal couplings. Deshielding of H-3 was somewhat weaker, and that of H-5 was slightly stronger, than in the epimer **5**. The clearly separated signals for H-2a (an octet) and H-4a (a septet) reflected the small vicinal couplings with H-3 (5.5 and 4.5 Hz) in addition to 14.5–15 Hz geminal couplings and 3.7 and 11.5 Hz couplings with H-1 and H-5, respectively. The free sugar **8** gave a less well resolved spectrum (taken in dimethyl sulfoxide-d_6 because of insufficient solubility in chloroform). However, the character of the clear signals for H-3 (a narrow multiplet) and H-4a (a septet as in **6**) corroborated the assignment.

Platinum-catalyzed hydrogenation of the nitro glycoside **5** furnished methyl 3-amino-2,3,4,6-tetradeoxy-α-L-*threo*-hexopyranoside, isolated in >90% yields either as the acetate salt **9** or the hydrochloride **10** (both crystalline). When **9** was treated for 5 min at room temperature, with chloroform saturated with hydrogen chloride and containing 0.75% of ethanol,[3] it was converted in high yield into the corresponding ethyl glycoside hydrochloride **11**. Next, the salt **9** was quantitatively *N*-trifluoroacetylated in the presence of triethylamine, to give crystalline methyl 4-deoxy-*N*-trifluoroacetyl-α-daunosaminide (**12**) which was hydrolyzed with 3.5 *M* acetic acid, affording in 94% yield the crystalline 2,3,4,6-tetradeoxy-3-trifluoroacetamindo-α-L-*threo*-hexose (**13**). The overall yield in the sequence **1** → **2** → **5** → **9** → **12** → **13** was 49%, based on isolated pure intermediates.

An analogous sequence of reactions was performed in the 3-epimeric, L-*erythro* series. Thus, catalytic hydrogenation of **6** in the presence of acetic acid gave methyl 3-amino-2,3,4,6-tetradeoxy-α-L-*erythro*-hexopyranoside acetate (**14**) in virtually quantitative yield. Although crystallizable, **14** was both hygroscopic and rather volatile, subliming *in vacuo*; it was characterized by its nmr spectrum but, for elemental analysis, it was first converted into the highly crystalline picrate **15**. The ethyl aminoglycoside hydrochloride **16** was obtained from **14** exactly like **11** from **9**. *N*-Trifluoroacetylation of **14** provided in 92% yield methyl 4-deoxy-*N*-trifluoroacetyl-α-ristosaminide (**17**) as a chromatographically pure, volatile syrup that was characterized spectroscopically and hydrolyzed with acetic acid to afford crystalline 2,3,4,6-tetradeoxy-3-trifluoroacetamido-α-L-*erythro*-hexose (**18**). The overall yield in the sequence **1** → **2** → **6** → **14** → **17** → **18** was 28%.

Experimental

For general procedures and instrumental techniques, see previous articles from this laboratory (18). The nmr data refer to 100-MHz spectra of solutions in chloroform-*d* (unless otherwise specified) containing tetramethylsilane as an internal standard. Splittings were measured in expanded spectra, usually of 250 Hz sweep width. All new compounds gave infrared spectra consistent with the assigned structures. Optical rotations were recorded at room temperature. The following solvent mixtures (v/v) were used for tlc: 1:2 ethyl acetate – chloroform (*A*); 1:2 methanol–chloroform (*B*); ethyl acetate – petroleum ether in the proportions 1:1 (*C*), 1:2 (*D*), 1:3 (*E*), and 1:4 (*F*); and 1:6 ethyl acetate – hexane (*G*). Petroleum ether refers to the fraction of bp 30–60°C.

Methyl 3,6-Dideoxy-3-nitro-α-L-glucopyranoside (1)

The preparation of **1** from methyl α-L-rhamnopyranoside as originally performed by us (17) yielded 26% of the product by direct crystallization plus ca. 14% by column chromatography of the mother liquor. A minor modification of the procedure, employed later on (12*c*) in the D-series, gave 35% of product by crystallization, processing of the mother liquor being dispensed with. For the present work, we routinely prepared the mixture of stereoisomeric nitro glycosides as previously described and applied the whole, crude mixture (from 25 g of methyl α-L-rhamnopyranoside) to a column containing 800 g of silica gel (packed by suspending the gel in chloroform). Elution with 4:1 chloroform – ethyl acetate produced syrupy L-*manno* isomer followed by a mixture of the L-*gluco* and L-*galacto* isomers. This mixture was passed through a second column of the same size, which was eluted with 1:1 ethyl acetate – hexane to give pure **1** (11.9 g, 41%) melting at 141–143°C as recorded (17), followed by a small amount of the L-*galacto* isomer, mp 155–156°C (lit. (17) mp 154–157°C). A procedural variant involved omission of the first-mentioned column. The slow-moving L-*galacto* isomer was separated, by one chromatography using 1:1 ethyl acetate – hexane, from jointly emerging L-*manno* isomer and **1**, and the latter was then obtained pure in good yield by crystallization from chloroform.

Methyl 3,6-Dideoxy-2,4-di-O-methylsulfonyl-3-nitro-α-L-glucopyranoside (2)

A solution of **1** (2.0 g) in dichloromethane (100 mL; dried over molecular sieve) containing freshly distilled methanesulfonyl chloride (2.6 mL) was cooled to −40°C, and a solution of

[3]Ordinary, ethanol-stabilized, chloroform was used.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

triethylamine (3.4 mL; dried over and distilled from CaH_2) in dry dichloromethane (20 mL) was then added dropwise over a period of 10 min. (Pilot experiments had shown that, at this point, all of **1** ($R_f \sim 0.2$) had disappeared and a strong spot of **2** ($R_f \sim 0.6$) was visible together with a weak, faster spot ($R_f \sim 0.8$; tlc with solvent *A*) which presumably represented an elimination product.) The reaction was immediately quenched by the addition of methanol (40 mL) at −40°C before the mixture was allowed to assume room temperature. Solvent evaporation gave a residue that was taken up in a small amount of ethyl acetate whereby the main part of crystalline triethylammonium chloride remained undissolved. The solution was filtered by suction through a 2-cm layer of silica gel (prewashed with ethyl acetate) which removed remnant salt; the filter cake was washed with ethyl acetate followed by petroleum ether. The filtrate was evaporated and coevaporated with several portions of added 1-propanol. Finally, the residue was dissolved in a minimal amount of hot 1-propanol from which **2** crystallized upon slow cooling to room temperature. The yield was 2.82 g (80%); mp 133–134°C, $[\alpha]_D$ −122.9° (*c* 1, chloroform). The ir and nmr spectra were identical with those of the D-enantiomer for which was found (12*a*) mp 132–132.5°C and $[\alpha]_D$ + 110.5°.

*Methyl 4-O-Acetyl-2,3,6-trideoxy-3-nitro-*α*-*L*-*erythro*-hex-2-enopyranoside (3) and Methyl 2-O-Acetyl-3,4,6-trideoxy-3-nitro-*α*-*L*-*threo*-hex-3-enopyranoside (4)*

The dimesylate **2** (1.0 g) and anydrous sodium acetate (0.5 g) were stirred at room temperature in acetone (25 mL) containing glacial acetic acid (0.5 mL). Monitoring by tlc (solvent *E*) revealed the concurrent consumption of **2** (R_f 0.15) and appearance of **3** (R_f 0.5) as a single product. After 2 h, traces of a second product, namely **4** (R_f 0.45) began to appear. (The spots of **3** and **4** were clearly separated provided the quantity of mixture applied to the plate was not too large.) The reaction was stopped at this point by the addition of ether (10 mL), which precipitated sodium acetate, and evaporation of the filtrate therefrom, followed by azeotropic removal of acetic acid with added toluene. The residue was extracted three times with boiling hexane. The extracts were evaporated giving a material that yielded nearly pure **3** (210 mg, 33%) by crystallization from absolute ethanol at −70°C. Recrystallized once from hot hexane (with slow cooling and storage of the solution at room tmperature), **3** formed long needles (180 mg), mp 87°C and $[\alpha]_D$ +97.3° (*c* 1.3, chloroform). The data recorded (11*b*) for **3** obtained in a different way were mp 81–81.5°C and $[\alpha]_D$ +99.3° (chloroform); the nmr spectrum of the present sample agreed with the published one (11*b*) in every detail.

For the preparation of **4**, a solution of **2** (1.0 g) and anhydrous sodium acetate (1.0 g) in acetone (25 mL) containing glacial acetic acid (1 mL) was boiled under reflux. Thin layer chromatography with solvent *E* indicated the disappearance of **2** and the occurrence of **3** and **4** early on; the intensity of **3** (R_f 0.5) subsequently diminished and, after 1 h, **4** (R_f 0.45) remained as the sole detectable product. The reaction mixture was processed as described above except that the residue obtained after removal of the acetic acid was passed through a small tube (disposable pipet) filled with silica gel, by means of solvent *C*. After solvent evaporation, **4** crystallized from a minimal amount of absolute ethanol on storage at −27°C; yield, 0.45 g (70%), mp 81–82°C, $[\alpha]_D$ −162.6° (*c* 1.5, chloroform). Literature (11*b*) mp 81–81.5°C and $[\alpha]_D$ −165°, and for the D-enantiomer, lit. (12*d*) mp 81–82°C and $[\alpha]_D$ +163°. The nmr spectrum was identical with the published (11*b*) spectrum of **4**.

*Methyl 2,3,4,6-Tetradeoxy-3-nitro-*α*-*L*-threo-hexopyranoside (5) and L-erythro Isomer 6*

Preparation from 4

Sodium borohydride (500 mg) was added to a solution of **4** (500 mg) in absolute ethanol (50 mL) which was stirred at +5°C. After 15 min methanol (15 mL) and an acidic cation exchange resin were added. The deionized solution was evaporated to give a residue from which several portions of methanol were evaporated to remove boric acid. The syrupy product was dissolved in ethyl acetate, treated with activated charcoal, and recovered after filtration through Celite and solvent removal. The dried syrup (350 mg, 92%) was a mixture of **5** (R_f 0.42) and **6** (R_f 0.28), with the latter predominating (tlc with solvent *F*; droplets of acetic acid were applied with the sample spots at the starting line of the plates).

Preparation from 2

Sodium borohydride (1.0 g) followed by absolute ethanol (30 mL) was added at room temperature to a stirred solution of **2** (1.0 g) in dichloromethane (100 mL). An exothermic reaction ensued, causing some refluxing of solvent. Monitoring by tlc as just described indicated complete consumption of **2** after 1–1.5 h and the formation of **5** and **6** in proportions similar to those above. The reaction mixture was then cooled (5–10°C), acidified to pH 4 by slow addition of glacial acetic acid, and filtered through a layer of Celite (prewashed with acetic acid followed by dichloromethane). Evaporation of the filtrate gave a white residue that was extracted several times with warm petroleum ether. The combined extracts were freed from acetic acid by coevaporation with toluene, and the remaining syrup was freed from residual toluene by short drying in an oil pump vacuum at room temperature. The product was then redissolved in petroleum ether, a small amount of insoluble material being filtered off. It was determined in one experiment that 470 mg (97.5%) of **5** + **6** was present at that stage.

Separation

The mixture of **5** and **6** (from 1.0 g of **2**) contained in a minimum volume of petroleum ether deposited long needles of **6** (153 mg) upon storage overnight at −27°C. The mother liquor was chromatographed on silica gel (20 g). The column was prepared by first soaking the gel in a mixture of acetic acid and dichloromethane for 2 h and then washing the packed column with hexane (50 mL). Irrigation with a mixture of petroleum ether (400 parts), benzene (100 parts), ethyl acetate (50 parts), and acetic acid (1.2 parts) gave homogeneous but syrupy **5** (126 mg, 26%) and crystalline **6** (115 mg, 56% when added to the previous crystals). The two isomers gave well-resolved ir spectra (ν_{max} 1550 cm^{-1}, strong, NO_2) which were very similar in character but showed significant differences in band positions and intensities in the fingerprint region.

Compound **5** showed $[\alpha]_D$ −139° (*c* 1.3, chloroform); nmr δ: 4.90 (dd, $J_{1,2e}$ = 2, $J_{1,2a}$ = 3.5 Hz, H-1), 4.84 (tt, partially overlapping H-1, $J_{2a,3} = J_{3,4a}$ = 12 Hz, $J_{2e,3} = J_{3,4e}$ = 4.5 Hz, H-3), 3.90 (12 lines, $J_{4e,5}$ = 2, $J_{4a,5}$ = 12, $J_{5,6}$ = 6.3 Hz, H-5), 3.34 (s, 3H, OMe), 2.43–2.18 (m, 2H, H-2e and H-4e), 2.01 (octet, $J_{1,2a}$ = 3.5, $J_{2a,3}$ = 12, $J_{2a,e}$ = 13 Hz, H-2a), 1.70 (q, $J_{3,4a} = J_{4a,5} = J_{4a,e}$ = 12 Hz, H-4a), 1.23 (d, 3H, *J* = 6.3 Hz, H-6).

Compound **6** showed mp 43°C, $[\alpha]_D$ −145° (*c* 1.1, chloroform); nmr δ: 4.73 (narrow m, $J_{1,2a}$ = 3.5, $J_{1,2e}$ = 2, $J_{1,4e}$ = 0.8 Hz, H-1), 4.49 (m, 16 lines; $J_{2e,3}$ = 2.7, $J_{2a,3}$ = 5.5, $J_{3,4e}$ = 3.3, $J_{3,4a}$ = 4.5 Hz, H-3), 4.19 (m, 12 lines; $J_{4e,5}$ = 2.5, $J_{4a,5}$ = 11.5, $J_{5,6}$ = 6.5 Hz, H-5), 3.27 (s, 3H, OMe), 2.72 (d sx, $J_{2a,e}$ = 15, $J_{1,2e}$ = 2, $J_{2e,3}$ = 2.7, $J_{2e,4e}$ = 1.2 Hz, H-2e), 2.52 (dm, with low-field m partially overlapping upfield sx of H-2e; $J_{4a,e}$ = 14.5, and *J* = 0.8, 1.2, 2.5, and 3.3 Hz, H-4e), 2.09 (dq, $J_{2a,e}$ = 15, $J_{1,2a}$ = 3.5, $J_{2a,3}$ = 5.5 Hz, H-2a), 1.61 (dq, $J_{4a,e}$ = 14.5, $J_{3,4a}$ = 4.5, $J_{4a,5}$ = 11.5, H-4a), 1.22 (d, 3H, *J* = 6.5 Hz, *C*—Me). *Anal.* calcd. for $C_7H_{13}NO_4$ (175.2): C 47.99, H 7.48, N 8.00; found: C 48.00, H 7.32, N 8.10. The crystals were volatile; they sublimed when being kept overnight in an oil-pump vacuum at room temperature.

Similar yields of **5** and **6** could be obtained by chromatography of their whole mixture (without prior partial crystallization of **6**), in which case a correspondingly larger proportion of silica gel

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(30–35 g) had to be used. However, when a mixture of **5** and **6** (350 mg) was chromatographed on silica gel (35 g) which had *not* been pretreated with acetic acid, and elution was performed with solvent *G* instead of the aforementioned slightly acidic solvent, there was obtained pure **5** (202 mg) followed by mixed fractions totalling 103 mg, and no pure **6** emerged. It appeared that the slower-moving **6** was continuously being isomerized on the way through the column. To verify this, a sample of such a mixture (from 50 mg of **2**) was dissolved in methanol (5 mL) and stirred with silica gel (1 g) in the presence of a few drops of triethylamine. The isomerization was monitored by tlc (solvent *F*). After 10 min, the spot intensities were reversed, and after 6 h, only a trace of **6** remained visible.

Accordingly, for the preparation of **5** in optimum yield, the dimesylate **2** (500 mg) was treated with sodium borohydride as described before. After acidification and filtration through Celite, the reaction mixture was evaporated and an ethereal solution (50 mL) of the crude product was washed with cold, saturated $NaHCO_3$ solution (3×) and water (2×), dried over $MgSO_4$, and evaporated to give a ~2:3 mixture of **5** and **6** (214 mg, 89%). This was stirred for 3 h at room temperature with silica gel (1 g) in methanol (5 mL) containing triethylamine (10 drops). Upon removal of the gel and solvent, the isomerized material was purified by passage through a column of silica gel (15 g) by means of solvent *G*. There was obtained 170 mg (70.5%) of pure **5** followed by a small fraction (27 mg) containing **5** and **6**.

*2,3,4,6-Tetradeoxy-3-nitro-α-*L*-*threo*-hexose (**7**)*

A solution of **5** (200 mg) in tetrahydrofuran (2 mL) and 0.5 *M* sulfuric acid (20 mL) were heated on a steam bath for 90 min. The tlc (solvent *E*) then indicated **5** to be absent and showed a single, mobile spot (R_f 0.2) together with an immobile spot. The cooled hydrolyzate was extracted several times with ethyl acetate, and the combined extracts were washed several times with small volumes of aqueous $NaHCO_3$ solution and once with water. Drying ($MgSO_4$) and evaporation of the organic solution gave a yellow syrup that was purified by redissolution in ethyl acetate and treatment with activated charcoal followed by filtration through a small quantity of silica gel. The product was then recovered as a chromatographically homogeneous solid (112 mg, 61%) that formed colorless crystals from ethyl acetate – petroleum ether; mp 117–118°C, $[\alpha]_D$ −96° (3 min) → −76.3° (21 h, final; *c* 1, chloroform) and −39.8° (8 min) → −36.0° (20 and 120 min; *c* 1, water). Nuclear magnetic resonance δ: 5.48 (narrow m; d after D_2O exchange; $J_{1,2e} = 2$, $J_{1,2a} = 3.5$ Hz, H-1), 4.94 (tt, $J_{2a,3} = J_{3,4a} = 12$, $J_{2e,3} = 4.5$, $J_{3,4e} = 4$ Hz, H-3), 4.19 (m, 16 lines; $J_{4a,5} = 11.5$, $J_{5,6} = 6.5$, $J_{4e,5} = 2$ Hz, H-5), 2.95 (t, $J \sim 2.7$ Hz, removable by D_2O exchange, OH), 2.42 (d sx, $J_{2a,e} = 13$, $J_{1,2e} = J_{2e,4e} = 2$, $J_{2e,3} = 4.5$ Hz, H-2e), 2.35 (d of quintets partially overlapping the H-2e multiplet, $J_{4a,e} = 13$, $J_{4e,5} = J_{2e,4e} = 2$, $J_{3,4e} = 4$ Hz, J-4e), 2.03 (o, $J_{2a,e} = 13$, $J_{2a,3} = 12$, $J_{1,2a} = 3.5$ Hz, H-2a), 1.74 (q, with center lines broadened; $J_{4a,5} = 11.5$, $J_{3,4a} = 12$, $J_{4a,e} = 13$ Hz, H-4a), 1.25 (d, 3H, $J = 6.5$ Hz, *C*—Me). *Anal.* calcd. for $C_6H_{11}NO_4$ (161.2): C 44.72, H 6.88, N 8.69; found : C 44.75, H 6.93, N 8.54.

*2,3,4,6-Tetradeoxy-3-nitro-α-*L*-erythro-*hexose (**8**)*

A mixture of glycoside **6** (100 mg) and ethanol-free chloroform (10 mL) saturated with gaseous hydrogen chloride was stirred at room temperature for 2 h, with the addition of a few drops of water. Evaporation then gave a solid (89 mg, 97%) that was recrystallized from hot ethanol with addition of ethyl acetate, to give colorless **8** (70 mg, 76%), mp 141.5–142°C; $[\alpha]_D$ −59.6° (5 min) → −46.2° (15 min) → −23.0° (45 min) → +3.2° (17 h, const; *c* 1, methanol). The sugar was sparingly soluble in cold water; nmr in $(CD_3)_2SO$ δ: 6.07 (m, removable with D_2O, OH), 5.06 (narrow m, H-1), 4.70 (narrow m, H-3), 4.27 (broad m, H-5), 2.5–1.9 (unresolved m, 3H), 1.55 (septet, $J = 4.5$, 11, and 15 Hz, H-4a), 1.12 (d, $J = 6.5$ Hz, *C*—Me). *Anal.* calcd. for $C_6H_{11}NO_4$ (161.2): C 44.72, H 6.88, N 8.69; found: C 44.49, H 7.01, N 8.55.

*Methyl 3-Amino-2,3,4,6-tetradeoxy-α-*L*-threo-*hexopyranoside Acetate (**9**)*

Platinum dioxide catalyst (500 mg) was prehydrogenated in glacial acetic acid (30 mL), and a solution of **5** (500 mg) in absolute ethanol (20 mL) was added. The hydrogenation was performed for 10 h at ambient temperature and pressure. Thereafter, tlc indicated complete reaction of **5** (R_f 0.5 in solvent *F* or ~ 0.8 in solvent *B*) and the presence of **9** (R_f 0 and ~ 0.2, respectively). The filtered solution was evaporated, with azeotropic removal of acetic acid by addition of toluene. The remaining syrup gave crystals, mp 108°C (with prior sintering), from dichloromethane – ethyl acetate – petroleum ether, but these were found to contain 5% of ash (by combustion analysis). An ethyl acetate solution of the product was treated with charcoal, filtered through a layer of Celite, and evaporated to give pure **9** (540 mg, 92%), mp 115–116°C, $[\alpha]_D$ −115° (*c* 1.3, chloroform); nmr δ: 8.20 (s, 3H, $\overset{+}{N}H_3$), 4.79 (narrow m, H-1), 3.85 (broad m, H-3), 3.45 (broad m, H-5), 3.31 (s, 3H, OCH_3), 1.95 (s, 3H, AcO^-, superposed on unresolved m for H-2e and H-4e in the 2.2–1.9 region), 1.61 (sx containing 1 small and 2 large splittings, H-2a), 1.31 (q, $J \approx 12$ Hz, H-4a), 1.20 (d, 3H, $J = 6.5$ Hz, *C*—Me). *Anal.* calcd. for $C_9H_{19}NO_4$ (205.3): C 52.66, H 9.33, N 6.82; found: C 52.81, H 9.28, N 6.76.

*Methyl 3-Amino-2,3,4,6-tetradeoxy-α-*L*-threo-*hexopyranoside Hydrochloride (**10**)*

Compound **5** (100 mg, 0.57 mmol) in 95% ethanol (7 mL) was added to platinum dioxide catalyst (100 mg) that had been prehydrogenated in a mixture of ethanol (2 mL), water (0.4 mL), and *N* hydrochloric acid (0.6 mL). Complete hydrogenation at ambient temperature and pressure required 24 h. Removal of the catalyst and solvent gave a solid which was dried *in vacuo* and then washed with ethyl acetate, dissolved in ethanol, treated with charcoal, and recovered by evaporation of the solution. The colorless material then crystallized from ethanol – ethyl acetate and showed mp 175°C (dec.), raised to 182–183°C by recrystallization from methanol – ethyl acetate. The yield of pure **10** was 98 mg (94.5%), R_f 0.5 (tlc with solvent *B*), $[\alpha]_D$ −108.3° (*c* 1, water); nmr in $(CD_3)_2SO$ δ: 8.43 (s, 3H, $\overset{+}{N}H_3$), 4.79 (narrow m, H-1), 3.74 (broad m, H-3), ~3.4 (broad m, H-5), 3.24 (s, 3H, OCH_3), 2.2–1.9 (unresolved m, 2H, H-2e and H-4e), 1.63 (sx, $J = 3.5$ and 2 × 12.5 Hz, H-2a), 1.31 (q, $J = 3 \times 12$ Hz, H-4a), 1.13 (d, 3H, $J = 6.5$ Hz, *C*—Me). *Anal.* calcd. for $C_7H_{16}ClNO_2$ (181.7): C 46.28, H 8.88, N 7.71; found: C 46.36, H 9.06, N 7.53.

A sample of the acetate **9** (27 mg) was dissolved in 1% methanolic hydrogen chloride (10 mL). Evaporation gave crystalline **10** (23 mg, 96%), mp 182–183°C after recrystallization from methanol – ethyl acetate.

*Ethyl 3-Amino-2,3,4,6-tetradeoxy-α-*L*-threo-*hexopyranoside Hydrochloride (**11**)*

Compound **9** (100 mg) was dissolved in chloroform (10 mL) that contained 0.75% of ethanol as a stabilizer and that had been saturated with hydrogen chloride. After 5 min the solution was evaporated and the residue was recrystallized from chloroform and a few drops of ethanol by slow addition of ethyl acetate. The yield of **11** was 80 mg (84%); mp 190–192°C (dec.), $[\alpha]_D$ −94° (*c* 0.7, water). Nuclear magnetic resonance ($CDCl_3$ + CD_3OD) δ: 4.94 (narrow m, H-1), 4.0–3.4 (unresolved m, 4H, H-3, H-5, and ethyl CH_2), 2.35–2.0 (unresolved m, 2H, H-2e and H-4e), 1.80 (sx, $J = 3.5$ and 2 × 12 Hz, H-2a), 1.50 (q, $J = 3 \times 12$ Hz, H-4a), 1.21 (d, $J = 6.5$ Hz, *C*—Me), 1.18 (t, 3H, $J = 7$ Hz, ethyl CH_3).

Anal. calcd. for $C_8H_{18}ClNO_2$ (195.7): C 49.10, H 9.27, N 7.16; found: C 48.84, H 9.56, N 6.91.

*Methyl 2,3,4,6-Tetradeoxy-3-trifluoroacetamido-α-*L*-threo-hexopyranoside (12)*

To a cooled (−30°C) solution of **9** (300 mg) in spectroscopy-grade chloroform (14 mL) was added dry triethylamine (1 mL) followed by trifluoroacetic anhydride (1.5 mL) which was introduced dropwise while the temperature was allowed to rise to −20°C. Shortly thereafter, tlc (solvent *D*) indicated **12** (R_f 0.4) as the sole product. Water (10 mL) was added at −20°C and, after some stirring, the separated aqueous phase was extracted three times with chloroform. The combined organic phase and extract was washed with sodium bicarbonate solution followed by water, dried ($MgSO_4$), and evaporated to give a solid residue (365 mg). Recrystallization from ethyl acetate – petroleum ether gave long, colorless needles of **12** (350 mg, 99%), mp 123–123.5°C, $[\alpha]_D$ −128.8° (*c* 0.7, chloroform); nmr δ: 6.26 (broad signal, NH), 4.83 (narrow m, H-1), 4.37 (11 peaks, sx of overlapping t; $J_{2e,3} = J_{3,4e} = 4$, $J_{3,NH} = 8$, $J_{2a,3} = J_{3,4a} = 12$ Hz, H-3), 3.94 (16 lines, q of dd; $J_{4e,5} = 2$, $J_{4a,5} = 12$, $J_{5,6} = 6.3$ Hz, H-5), 3.34 (s, 3H, OCH_3), 2.2–1.9 (m, 2H, ill-resolved), 1.52 (sx with broadened center peaks; $J_{1,2a} = 3.5$, $J_{2a,3} = 12$, $J_{2a,e} = 13$ Hz, H-2a), 1.195 (d, 3H, $J = 6.3$ Hz for *C*—Me, superposed on q, 1H, $J = 3 \times 12$ Hz, H-4a). *Anal.* calcd. for $C_9H_{14}F_3NO_3$ (241.2): C 44.82, H 5.85, N 5.81; found: C 44.59, H 5.94, N 5.68.

*2,3,4,6-Tetradeoxy-3-trifluoroacetamido-*L*-threo-hexose (13)*

The glycoside **12** (160 mg) was hydrolyzed with 3.5 *M* acetic acid (16 mL) at 90°C for 2.5 h, after which tlc (solvent *D*) indicated complete conversion of **12** (R_f 0.4) into **13** (R_f 0.15). The hydrolyzate was diluted with water and extracted five times with chloroform. The extract was washed five times with small amounts of cold sodium bicarbonate solution and then once with water, dried ($MgSO_4$), and evaporated. The solid residue was crystallized from ethyl acetate – petroleum ether to give **13** (141 mg, 94%), mp 166–167°C; ms *m/e*: 227 (M^+), 210 (weak, $M^+ - OH$), and 209 (strong, $M^+ - H_2O$); $[\alpha]_D$ −85° (initial, extrapolated) → −80° (5 min) → −74° (15 min) → −57° (80 min) → −48° (4 h) → −47° (20 h, *c* 0.18, chloroform), and −26.4° (4 min) → −24.6° (2 h, final, *c* 0.5, water); lit. (6) mp 159–160°C, $[\alpha]_D$ −80° (*c* 0.1 in chloroform; no mutarotation recorded). Nuclear magnetic resonance in $(CD_3)_2SO$ δ: 9.2 (broad, NH), 6.49 (d, 0.15H, $J = 6.5$ Hz, OHβ), 6.12 (dd, 0.85H, $J = 1$ and 4 Hz, OHα), 5.18 (broad s, $W_H = 6$ Hz, H-1e; intensity slightly less than 1H but supplemented by a weak signal for H-1a at 4.60), 4.4–3.8 (m, 2H, H-3 and H-5), 1.9–1.4 (m, 3H, H-2e, H-4e, and H-2a), 1.20 (q, $J = 3 \times 12$ Hz, H-4a), 1.06 (d, 3H, $J = 6$ Hz, *C*—Me), in good agreement with the reported (6) data. Upon addition of D_2O, the NH and OH signals disappeared and, because of progressive mutarotation, the signal for H-1a (dd, $J = 2$ and 8.5 Hz) grew in intensity and a second *C*—Me doublet became visible at δ 1.12. *Anal.* calcd. for $C_8H_{12}F_3NO_3$ (227.2): C 42.29, H 5.32, N 6.17; found: C 42.42, H 5.17, N 5.97.

*Methyl 3-Amino-2,3,4,6-tetradeoxy-α-*L*-erythro-hexopyranoside Acetate (14) and Picrate (15)*

The nitro glycoside **6** (430 mg) was hydrogenated catalytically in acetic acid – ethanol as described for **5**. The reaction was complete after 6 h as indicated by tlc (solvents *F* and *B*), and processing was performed as for **9**. The crude product was briefly dried *in vacuo* at 25°C (prolonged drying results in losses owing to sublimation), then dissolved in ethyl acetate and filtered through Celite. Careful addition of petroleum ether to the concentrated solution followed by storage at −27°C produced colorless, hygroscopic crystals (**14**) which were rapidly dried *in vacuo* after decanting the mother liquor; yield, 500 mg (99%). Thorough drying for analysis was impractical because of the volatility of the compound; nmr δ: 7.28 (broad signal, $\overset{+}{N}H_3$, removable by D_2O exchange), 4.82 (narrow m, H-1), 4.06 (broad m, H-5), 3.52 (narrower m, H-3), 3.32 (s, 3H, OCH_3), 1.96 (s, 3H, AcO^-), 2.1–1.4 (unresolved m), 1.21 (d, 3H, $J = 6$ Hz, *C*—Me).

Concentrated solutions of **14** and picric acid, both in benzene, were mixed and cooled to ~+6°C. Yellow, crystalline **15** precipitated in nearly quantitative yield. Isolated and washed with ether, it had mp 163–164°C (dec.), raised to 164–165°C (dec.) by recrystallization from benzene–ether; $[\alpha]_D$ −59.2° (*c* 1.4, methanol); nmr in $(CD_3)_2CO$ δ: 8.67 (s, 2H, arom.), 4.89 (narrow m, H-1), 4.24 (broad m, 12 lines, H-5), 3.94 (narrow m, H-3), 3.35 (s, 3H, OCH_3), 1.75 (o, $J_{3,4a} = 4.5$, $J_{4a,5} = 12$, $J_{4a,e} = 15$ Hz, H-4a), 1.20 (d, 3H, $J = 6.3$ Hz, *C*—Me). The remaining ring proton signals were obscured by solvent signals. *Anal.* calcd. for $C_{13}H_{18}N_4O_9$ (374.3): C 41.71, H 4.85, N 14.97; found: C 41.74, H 4.75, N 14.86.

*Ethyl 3-Amino-2,3,4,6-tetradeoxy-α-*L*-erythro-hexopyranoside Hydrochloride (16)*

Obtained from the acetate **14** (150 mg) exactly as described for the preparation of **11** from **9**, compound **16** (122 mg, 86%) was recrystallized from chloroform – ethyl acetate; mp 141–142°C (dec.), $[\alpha]_D$ −84.6° (*c* 0.7, water); nmr δ: 8.47 (broad, removed by D_2O exchange, $\overset{+}{N}H_3$), 4.96 (narrow m, H-1), 4.11 (broad m, H-5), 3.85 (m, H-3), 3.5 (m, 2H, ethyl CH_2), 2.4–2.0 (m, 2H, unresolved, H-2e and H-4e), 1.86 (dt, $J = J' = 3.5$, $J_{gem} = 15$ Hz, H-2a), 1.63 (septet, $J = 4$, $J' = 12$, $J_{gem} = 15.5$ Hz, H-4a), 1.27 (t, 3H, $J = 7$ Hz, ethyl CH_3), 1.21 (d, 2H, $J = 6.3$ Hz, *C*—Me). *Anal.* calcd. for $C_8H_{18}ClNO_2$ (195.7): C 49.10, H 9.27, N 7.16; found: C 48.88, H 9.56, N 6.91.

*Methyl 2,3,4,6-Tetradeoxy-3-trifluoroacetamido-α-*L*-erythro-hexopyranoside (17)*

The glycoside acetate **14** (120 mg) in chloroform (7 mL) was treated with triethylamine (1 mL) and trifluoroacetic anhydride (0.5 mL) as described for the preparation of **12** from **9**, at an initial temperature of −30°C, rising to 0°C by the end of the addition. Completion of the reaction was verified by tlc (solvent *E*). The mixture was cooled again (−10°C) before the reaction was quenched by the addition of water (10 mL). Work-up as described for **12** gave **17** as a yellow syrup that was purified by passage through a small column of silica gel (8 g), with 1:5 ethyl acetate – petroleum ether as the eluent. There was obtained **17** (130 mg, 92%) as a colorless, chromatographically homogeneous syrup, R_f 0.3 (tlc with solvent *E*), $[\alpha]_D$ −4.3° (*c* 2.1, chloroform); nmr δ: 8.0 (broad, NH), 4.84 (broad s, $W_H = 6$ Hz, H-1), 4.29 (m, H-3), 3.94 (broad m, H-5), 3.40 (s, 3H, OCH_3), 2.1–1.8 (m, 3H, unresolved), 1.50 (septet, $J = 3.5$, $J' = 11.5$, $J_{gem} = 15$ Hz, H-4a), 1.19 (d, 3H, $J = 6.5$ Hz, *C*—Me). The compound was volatile *in vacuo* so as to render drying for analysis impractical.

*2,3,4,6-Tetradeoxy-3-trifluoroacetamido-*L*-erythro-hexose (18)*

Glycoside **17** (300 mg) was hydrolyzed for 2.5 h with 3.5 *M* acetic acid (40 mL) at 90°C. Complete hydrolysis of **17** (R_f 0.6) to **18** (R_f 0.5) was indicated by tlc (solvent *D*). Processing as described for **13** gave **18** (200 mg, 70%) as colorless crystals from ethyl acetate – petroleum ether; mp 112–113°C, $[\alpha]_D$ +28.9° (*c* 1.5, chloroform) and +10° (*c* 1.3, water); ms *m/e*: 227 (M^+), 210 (weak, $M^+ - OH$), and 209 (strong, $M^+ - H_2O$). Nuclear magnetic resonance δ: 8.3 (broad, removable by D_2O exchange, NH), 5.43 (narrow m, $W_H = 7$ Hz, contracting to t with $W_H = 5$ Hz after D_2O exchange, H-1), 4.3 (m, 2H, H-3 and -5), 3.82 (narrow t, $J = 2$ Hz, removable by D_2O exchange, OH), 2.1–1.7 (m, 3H, unresolved), 1.52 (septet, $J_{3,4a} = 3.5$, $J_{4a,5} = 11.5$, $J_{4a,e}$

= 14.5 Hz, H-4a), 1.20 (d, 3H, J = 6.5 Hz, C—Me). *Anal.* calcd. for $C_8H_{12}F_3NO_3$ (227.2): C 42.29, H 5.32, N 6.17; found: C 41.98, H 5.58, N 5.95.

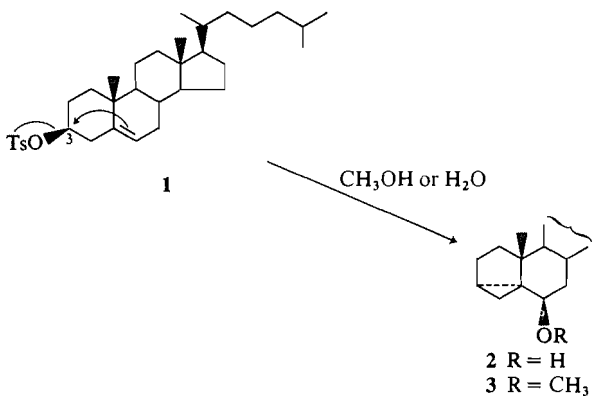
The solvolysis of the *p*-toluenesulphonate and methanesulphonate of cholesta-1,5-diene-3β-ol

PARIS E. GEORGHIOU[1] AND MARGARET A. MACDIARMID
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received August 20, 1979[2]



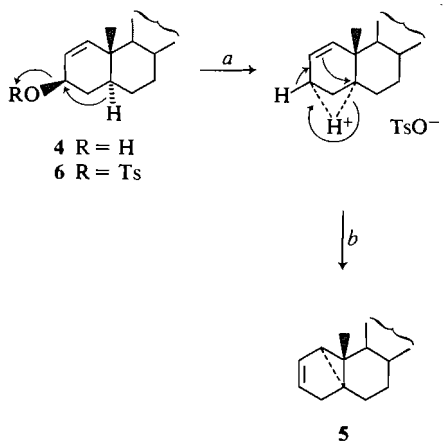
PARIS E. GEORGHIOU and MARGARET A. MACDIARMID. Can. J. Chem. **58**, 1759 (1980).

In situ preparations of 3β-tosyloxycholesta-1,5-diene and 3β-mesyloxycholesta-1,5-diene were subjected to methanolysis and hydrolysis. The products obtained were those of nucleophilic displacement with inversion at C3, as well as the epimers formed with retention of stereochemistry. No cyclized products could be isolated.

PARIS E. GEORGHIOU et MARGARET A. MACDIARMID. Can. J. Chem. **58**, 1759 (1980).

Nous décrivons la préparation *in situ* du tosylate et du mésylate de cholesta-1,5-diene-3β-ol. Le méthanolyse et l'hydrolyse en milieu acétonique aqueux de ces deux composés conduit à la formation aussi bien des produits avec inversion que des produits avec retention de configuration en position 3. On n'a pas observé expérimentalement la formation d'un produit de cyclisation.

Baldwin recently proposed a set of simple empirical rules (1) to predict the relative facility of different ring closures. According to the these rules, both 3-*exo*–*tet* and 3-*exo*–*trig* ring closures leading to the formation of three-membered rings are favoured processes. The well-known "*i*-cholesteryl" solvolytic rearrangement (2) of cholesteryl tosylate **1** to form the C3—C5 bicyclo ring A steroids **2** or **3** is an example of the former type. Here, the breaking of the C3–oxygen bond of the tosylate **1** is exocyclic to the 3-membered ring formed in the reaction and the geometry of C3 is tetrahedral (see Scheme 1):

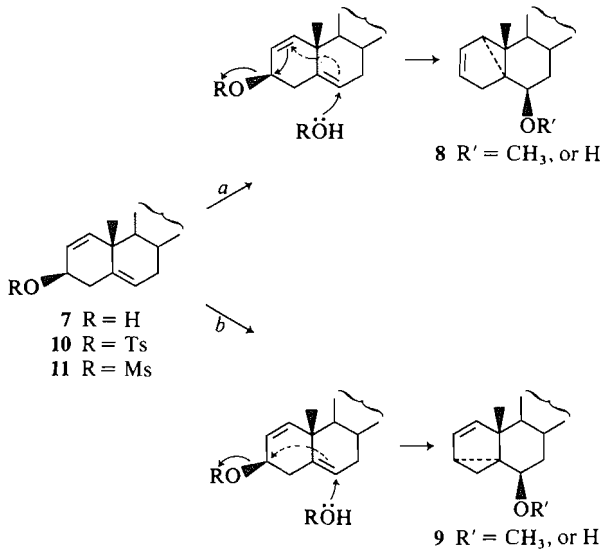


SCHEME 1

There are no simple examples of the 3-*exo*–*trig* ring closure resulting in the formation of a three-membered carbon ring in steroids.[3]

It appeared to us that cholesta-1,5-diene-3β-ol, **7** could serve to ascertain whether or not a preference is exhibited for one type of three-membered ring formation over the other. In principle, the C1—C5 bicyclo ring A-type compound[4] **8** could be formed via a 3-*exo*–*trig* ring closure with concommitant elimination. On the other hand, the *i*-cholesteryl-type product **9** could be formed via the 3-*exo*–*tet* mode (see Scheme 2):

formation of 1α,5-cyclo-5α-cholest-2-ene, **5**. A mechanism was proposed which involved a 1,3-transannular hydrogen shift in the tosylate **6** which is too unstable to be isolated. The second step in the rearrangement (step (*b*)) could be regarded as an example of a 3-*exo*–*trig* ring closure in which C5 is an incipient carbonium ion which could be considered to be approximately trigonal:



[1]Author to whom correspondence should be addressed.
[2]Revision received May 12, 1980.
[3]Laing and Sykes (3) however, have reported that the attempted tosylation of 5α-cholest-1-en-3β-ol, **4**, resulted in the

[4]The preparation of another C1—C5 bicyclo ring A steroid, 1α,5-cyclo-5α-cholestan-3β-ol-6-one in which ring B is functionalized has been reported by Laing and Sykes (4). These results, however, could not be duplicated (see ref. 5).

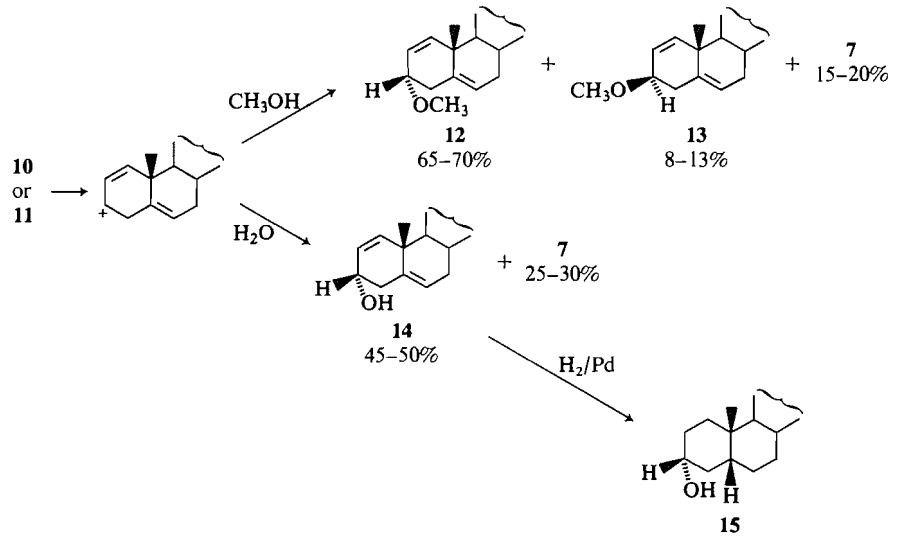
SCHEME 2

Thus, the preparation of the tosylate, **10**, or the mesylate, **11**, could provide the means for the solvolytic pathways envisioned by paths (*a*) or (*b*) depicted in Scheme 2. The dienol **7** was prepared by the method of Kaneko *et al.* (6). It was, however, unstable in pyridine, and underwent a rapid, irreversible rearrangement as evidenced by ^{1}Hmr spectroscopy. Thus, since the conventional method (7) could not be employed, the tosylate, **10**, and mesylate, **11**, were formed by using stoichiometric amounts of *n*-butyllithium as the base, hexamethylphosphoric triamide (HMPA), and an excess of the appropriate sulphonyl chloride at low temperatures. The resulting products, however, could not be isolated; upon concentration of the organic solutions used to extract the steroidal compounds from the reaction mixture the products decomposed spontaneously and rapidly. It was therefore necessary to use the preparations containing the sulphonates **10** or **11** *in situ*, without further attempts at their isolation. Thus, the crude reaction mixtures were quenched by their addition to the respective solvolytic media. Typically, one-half of a tosylation mixture was removed by use of a syringe and methanolysed in potassium acetate-buffered 80% methanol–chloroform; the second half and hydrolysed in potassium acetate–buffered 80% acetone–water (2). The products were monitored, isolated, and characterized in the usual manner.

Methanolysis



The products (and their yields) obtained by the methanolysis of the sulphates **10** and **11** were identical. A non-polar component (65–70%) and a second, more polar component (15–20%), were isolated by preparative layer chromatography (plc). The latter was shown to be identical to the starting dienol **7**. The balance of material consisted of several minor components (each < 1%) which could not be identified. Spectroscopy revealed that the non-polar component consisted of a mixture which was further separated by high pressure liquid chromatography (hplc). Two products were isolated in pure form. The major product had spectral characteristics consistent with the structure for 3α-methoxycholesta-1,5-diene, **12**. High resolution ^{1}Hmr and spin-decoupling experiments of the minor compound showed this to be the 3β-methoxy compound **13**. The latter was confirmed by its preparation directly from the dienol **7** under conditions which would ensure no epimerization of the C3 position, namely by using *n*-butyllithium, HMPA, and methyl iodide. The methyl ether thus produced was analysed by hplc and it consisted of a single component with no trace of the more strongly retained epimer. Thus, the formation of the β-methoxide **13** does not merely result from the presence of the corresponding amount of epimer as an impurity in the starting dienol **7**.

Hydrolysis

The hydrolyses of the two sulphonates **10** and **11** afforded identical products and yields, a similar observation to that made in the methanolyses described above. Again, two major components could be detected and isolated by plc. The less polar compound constituted only 45–50% of the total yield of recovered products and the second, more polar compound, which was identical with the starting material **7**, comprised 25–30%. These yields were obtained consistently. Thus, the methanolyses, which were conducted in parallel with one-half of the same tosylate and mesylate preparations afforded approximately 10% less of the dienol **7**. It can be concluded that approximately 10% of the *in situ*-formed tosylate or mesylate was hydrolysed by a pathway which leads to retention of configuration to produce **7**. In the methanolysis of course, the equivalent reaction leads to the formation of the 3β-methoxy compound **13**. Presumably, the tosylation or mesylation was only of the order of 80–85% complete, so that the plc work-up of crude typical sulphonation reaction mixtures affords approximately 20–15% of the unreacted dienol **7**.

The major product of the hydrolysis is the C3 epimer of **7**, namely cholesta-1,5-dien-3α-ol, **14**, which was confirmed by its hydrogenation to produce a compound which was identical in all respects to 5β-cholestan-3α-ol ("epicoprastanol"), **15**. Scheme 3 summarizes these results:

SCHEME 3

Discussion

We were unable to detect either the C3—C5, or the C1—C5 cyclized products **8** or **9**. Thus we cannot make any unambiguous conclusions on the question of the competitive modes of ring closure, on the basis of these experiments.

In order to establish whether or not the presence of HMPA in the crude tosylate (or mesylate) preparations affects the pathway of the subsequent solvolyses, the solvolytic procedure described above was repeated using cholesteryl tosylate **1** prepared in an identical manner. We observed results comparable to those of Kosower and Winstein (2), and obtained 3,5-cyclocholestan-6β-ol, **2**, and 3,5-cyclocholestan-6β-yl methyl ether, **3**, from the *in situ* preparations of **1**.

The products which we observed during this study can most easily be accounted for in terms of an S_N1-type substitution involving a carbocationic intermediate **18**. We were unable to isolate any of the allylic-rearrangement products but we cannot exclude the likely possibility that allylic stabilization of the C3 carbonium ion by the C1—C2 double bond does occur. The high inversion-to-retention product ratio can be accounted for by a shielding of the β-face of the steroid to the nucleophile by the leaving group, and by the steric effect due to the C19-methyl group.

Experimental

All reactions were carried out under argon. Melting points were determined on a Fisher–Johns melting point (hot stage) apparatus. Infrared spectra were recorded on a Perkin–Elmer 237B grating ir spectrophotometer, in carbon tetrachloride solutions. Proton magnetic resonance spectra were recorded with a Varian Model A-60 60 MHz, or a Bruker WP-80 80 MHz instrument in deuteriochloroform solutions. Ultraviolet spectra were recorded on a Perkin–Elmer 202 uv–vis spectrophotometer in hexane solutions. Baker silicic acid was used for column chromatography. Merck silica gel PF 254-366 was used for preparative layer chromatography (plc) using 20 × 20 cm plates of 1.0 mm thickness. High-pressure liquid chromatography (hplc) was performed on an Altex Model 312 liquid chromatographic system.

Cholesta-1,5-diene-3β-ol (7)

The dienol **7** was prepared by the method of Kaneko *et al.* (6). An improvement to this procedure was found to be one in which cholesta-1,5-diene-3-one was purified by chromatography on silicic acid prior to its reduction to **7**.

In situ *Preparations of Cholesta-1,5- diene-3β-tosylate (10)*

A solution of the dienol **7** (384 mg, 1 mmol) in freshly distilled tetrahydrofurane (4.0 mL) was prepared in a dry 10-mL reaction flask fitted with a rubber septum, a stirring bar, and an argon inlet needle. To this solution was added distilled hexamethylphosphoric triamide (0.35 mL) and a small amount (1–2 mg) of triphenylmethane. The solution was cooled to −40°C and treated with *n*-butyllithium (~0.25 mL of 2.2 *M* solution in hexane) added dropwise with the help of a syringe. The resulting pink solution was then warmed to 0°C and to this was added *p*-toluenesulphonyl chloride (380 mg, 2.0 mmol) which had been freshly purified by Pelletier's method (8). The pink colour immediately disappeared.

When this mixture was worked up in the usual manner by pouring into ice-cold water, extracting with ether, followed by washing the ether extracts with cold freshly prepared 5% aqueous sodium bicarbonate, the resultant colorless oil obtained upon concentration of the ether extract rapidly decolorized, indicating decomposition. The crude reaction mixtures were therefore used directly in the subsequent methanolysis and hydrolysis.

In situ *Preparations of Cholesta-1,5-diene-3β-mesylate (11)*

The crude mesylate preparations used in the methanolysis and hydrolysis of **11** were prepared exactly as described for **10** except that freshly distilled methanesulphonyl chloride was used.

Methanolysis of in situ *Preparations of (10) and (11)*

In a typical methanolysis, an aliquot estimated to contain approximately 1.0 mmol of **10** (or **11**) was removed from the crude tosylation (or mesylation) preparation described above. This was added directly with the help of a syringe into a mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

containing anhydrous potassium acetate (392 mg, 4 mmol), anhydrous methanol (4.0 mL), and chloroform (4.0 mL). After stirring for 10 min at room temperature, a precipitate formed. At this point tlc indicated that the reaction was complete but the mixtures were usually worked up after 1 h. The solvent was removed under vacuum. The residue was dissolved in ether (10 mL), washed with three portions (1.0 mL) of aqueous phosphate pH 7.0 buffer, dried over anhydrous magnesium sulphate, and concentrated to dryness. The residue (300 mg) was chromatographed on plc plates using a benzene 8 – ether 1 mixture as the solvent system. Ultraviolet light examination of the developed plates revealed several compounds which were separated and analysed spectroscopically. The total yield of material recovered from the plc plates was 297 mg. A band of R_f 0.9 consisted of 15 mg of a compound whose spectra are characteristic of *n*-butyltosylate. The band at R_f 0.75 consisted of 200 mg (75%) of a mixture of **12** containing approximately 10% of its epimer, **13**. The only other band containing a significant amount, 35 mg (13%), of product had R_f 0.25 and was identical in its spectral and chromatographic features to **5**.

The mixture consisting of **12** and **13** was separated on hplc using a Partisil-10 9 mm id column and 10% hexane – 90% dichloromethane as the solvent. Two major products were eluted and collected. The less polar compound was 3α-methoxycholesta-1,5-diene **12**, mp 81°C, from methanol; ir ν_{max}: 2950, 1080 cm^{-1}; uv λ_{max} (ε): 208 (32000) nm; ^{1}Hmr δ: 0.68 (s, methyl at C(18)), 0.83 (s, methyl at C(19)), 2.40 (m, two protons at C(4) spin-coupled to proton at C(3)), 3.34 (s, methyl of methoxy group at C(3)), 3.69 (m, proton at C(3) spin-coupled to protons at C(4) and C(2)), 5.40 (m, proton at C(6)), 5.73 (d of d, B portion of an AB-type system due to proton at C(2), which is spin-coupled (J = 10 Hz) to proton at C(1), also (J = 5 Hz) to proton at C(3) and by long-range coupling to a proton at C(4)), and 6.02 (d, A portion of an AB-type system due to proton at C(1), which shows only spin-coupling to proton at C(2)); ms *m/e*: 398 (M^+), 383 ($M^+ - CH_3$), 366 ($M^+ - CH_3OH$), 351 (383 – CH_3), 285 ($M^+ - C_8H_{17}$), 253 (285 – C_8H_{17}), 211 ($M^+ - C_{11}H_{22}$, CH_3OH). *Anal.* calcd. for $C_{28}H_{46}O$: C 84.36, H 11.63; found: C 84.10, H 11.42. The other compound was 3β- methoxycholesta-1,5-diene **13**, mp 65.5°C from methanol; ν_{max}: 2950, 1085 cm^{-1}; uv λ_{max}: 210 nm; ^{1}Hmr δ: 0.70 (s, methyl at C(18)), 0.83 (s, methyl at C(19)), 2.50 (m, two protons at C(4)), 3.38 (s, methyl of methoxy group at C(3)), 3.80 (m, proton at C(3) spin-coupled to protons at C(4), C(1), and C(2)), 5.43 (m, proton at C(6)), 5.58 (d of t, B portion of an AB-type system due to proton at C(2), which is spin-coupled (J = 10 Hz) to proton at C(1), also (J = 0.5 Hz) to protons at C(3) and a proton at C(4)), and 5.82 (d of d, A portion of the AB-type system due to proton at C(1) which is spin-coupled to C(2) and has long-range (J = 1.0 Hz) spin coupling with proton at C(3); ms *m/e*: 398 (M^+), 383 ($M^+ - CH_3$), 366 ($M^+ - CH_3OH$), 351 (383 – CH_3), 285 ($M^+ - C_8H_{17}$), 253 (285 – C_8H_{17}), 211 ($M^+ - C_{11}H_{22}$, CH_3OH). *Anal.* calcd. for $C_{28}H_{46}O$: C 84.36, H 11.63; found: C 84.18, H 11.52%.

Hydrolysis of in situ *Preparations of (10) and (11)*

In a typical hydrolysis, an aliquot estimated to contain approximately 1.0 mmol of **10** (or **11**) was removed from the crude tosylation (or mesylation) preparation described above. This was added directly with the help of a syringe into a solution containing potassium acetate (393 mg, 4 mmol), 2.0 mL water, and 8.0 mL acetone. The mixture was stirred overnight before work-up. The mixture was concentrated under vacuum. The residue was dissolved in ether (10 mL), washed with three portions (1.0 mL) of aqueous phosphate pH 7.0 buffer, dried over magnesium sulphate, and concentrated to dryness. The residue (360 mg) was chromatographed on plc plates using a benzene 8 – ether 1 mixture as the solvent system. Several compounds could be detected by ultraviolet light and these were separated and analysed spectroscopically. The total yield of material recovered from the plc plates was 290 mg. The major band R_f 0.40 consisted of 155 mg (54%) of cholesta-1,5-dien-3α-ol **14**, mp 51–52°C from aqueous acetone; ir ν_{max}: 3560, 3350, 2940, 1030 cm^{-1}; ^{1}Hmr δ: 0.75 (s, methyl at C(18)), 0.86 (s, methyl at C(19)), 2.70 (m, two protons at C(4) spin-coupled to proton at C(3)), 4.10 (m, proton at C(3) spin-coupled to protons at C(4) and C(2)), 5.53 (m, proton at C(6)), 5.76 (d of d, B portion of an AB-type system due to proton at C(2) which is spin-coupled (J = 10 Hz) to proton at C(1), also (J = 5 Hz) to proton at C(3) and by long-range coupling to a proton at C(4)), and 5.96 (d, A portion of an AB-type system due to proton at C(1), which shows only spin-coupling to proton at C(2)); ms *m/e*: 384 (M^+), 383, 369 ($M^+ - CH_3$), 366 ($M^+ - H_2O$), 355 ($M^+ - C_2H_5$), 351 ($M^+ - CH_3$, H_2O), 271 ($M^+ - C_8H_{17}$). *Anal.* calcd. for $C_{27}H_{44}O$: C 84.31, H 11.53; found: C 84.15, H 11.48%.

The other major band, R_f 0.25, consisted of 70 mg (24%) of **7**.

3β-Methoxycholesta-1,5-diene (13)

A solution of **7** (40 mg) in freshly distilled tetrahydrofurane (10 mL) was prepared in a 5-mL reaction flask fitted with a rubber septum and an argon inlet needle. To this solution was added distilled hexamethylphosphoric triamide (0.04 mL) and a small amount (< 1 mg) of triphenylmethane. The solution was cooled to −40°C and treated with a few drops of *n*-butyllithium (2.2 *M* solution in hexane) with the help of a syringe until a pink colour formed. After a few minutes' standing, a few drops of methyl idodide was added to the pink solution, again with the help of a syringe. The resultant light yellow solution was warmed to room temperature and then concentrated under vacuum. The plc purification of the crude residue obtained afforded **13** which was identical in all respects with **13** obtained in the methanolysis of **10** and **11**.

Hydrogenation of Cholesta-1,5-dien-3α-ol (14)

A mixture consisting of **14** (22 mg) glacial acetic acid (5 mL) and platinum oxide (3 mg) was hydrogenated at atmospheric pressure. Even though tlc indicated that starting material was still present, the reaction was worked up after 2 h. The catalyst was filtered off and the acetic acid removed under vacuum. The residue was chromatographed on plc using the benzene 8 – ether 1 solvent system. A band was isolated consisting of 9.3 mg (78% of reacted material) of a compound identical in all respects with 5β-cholestan- 3α-ol, **15**.

Kinetics of the magnetite–maghemite–hematite transformation, with special reference to hydrothermal systems

THOMAS WILSON SWADDLE[1] AND PHILLIP OLTMANN

THOMAS WILSON SWADDLE and PHILLIP OLTMANN. Can. J. Chem. **58**, 1763 (1980).

Maghemite, prepared in the usual way (but with exclusion of silica, e.g., from glassware) by precipitation of non-stoichiometric magnetite $Fe_{3-x}O_{4-x}$ in aqueous MOH (M = Na, K) followed by air oxidation, picks up moisture from the air to reach the limiting composition $M_\delta H_{1-\delta}Fe_5O_8$, where $\delta \sim 0.02$–0.03 for fresh material, but changes under hydrothermal conditions because of ion exchange. Despite the role of absorbed moisture in stabilizing maghemite, formation of the latter from $Fe_{3-x}O_{4-x}$ is markedly retarded, and its decomposition to α-Fe_2O_3 greatly accelerated, under hydrothermal conditions relative to the rates of the corresponding reactions of the dry solids. The rate of hydrothermal decomposition of maghemite is strongly retarded by silica. Over the range 160–187°C at least, silica-free maghemite decomposes in water according to the empirical equation $-\ln(1-\alpha) = (kt)^n$, where α is the fractional extent of decomposition, and $n \sim 2.5$ for neutral water (with $k = 1.3 \times 10^{-5}$ s^{-1} at 160°C and 3.1×10^{-5} s^{-1} at 175°C) but approaches unity, without major effects on the overall time-scale of reaction, at high [MOH]. The mechanistic significance of these and previous results are considered; the hydrothermal conversion of maghemite to hematite evidently proceeds by a dissolution–reprecipitation sequence.

THOMAS WILSON SWADDLE et PHILLIP OLTMANN. Can. J. Chem. **58**, 1763 (1980).

La maghémite, préparée de manière habituelle (mais avec élimination de la silice par exemple celle de la verrerie) par précipitation de la magnétite non stoechiométrique $Fe_{3-x}O_{4-x}$ dans du MOH aqueux (M = Na, K) suivie d'une oxydation à l'air, absorbe l'humidité de l'air pour atteindre une composition limite de $M_\delta H_{1-\delta}Fe_5O_8$ où $\delta \sim 0.02$–0.03 pour le produit frais, mais il se produit des changements dans des conditions hydrothermiques par suite de l'échange d'ions. En dépit du rôle de l'humidité absorbée en tant que stabilisatrice de la maghemite, la formation de cette dernière à partir de $Fe_{3-x}O_{4-x}$ est fortement retardée et sa décomposition en Fe_2O_3 α est grandement accélérée dans des conditions hydrothermiques s'apparentant aux vitesses des réactions correspondantes des solides secs. La vitesse de décomposition hydrothermique de la maghémite est fortement retardée par la silice. Au moins dans l'intervalle de 160–187°C, la maghémite dépourvue de silice se décompose dans l'eau selon l'équation empirique $\ln(1-\alpha) = (kt)^n$, où α est le degré fracitonnel de décomposition et $n \sim 2.5$ pour l'eau neutre (avec $k = 1.3 \times 10^{-5}$ s^{-1} à 160°C et 3.1×10^{-5} s^{-1} à 175°C) mais s'approche de l'unité sans effet appréciable sur le temps global de réaction à forte concentration de MOH. On considère la signification du point de vue du mécanisme de ces résultats et des résultats antérieures; la conversion hydrothermique de la maghémite en hématite se fait évidemment selon la séquence dissolution–reprécipitation.

[Traduit par le journal]

Introduction

The cubic iron(III) oxide maghemite ("γ-Fe_2O_3"), although thermodynamically unstable with respect to hematite (α-Fe_2O_3) and not usually considered a common mineral, does occur widely in terrestrial (notably highly-weathered tropical) soils (1, 2), has been reported to be an important secondary mineral in certain subvolcanic hydrothermal breccia bodies (3), appears to be a major constituent of the sands of Mars (4, 5), and has even been said to be the substance responsible for the visible absorption spectrum of interstellar matter (6), though the last seems improbable (7).

Maghemite forms in nature either through the oxidation of magnetite (Fe_3O_4) if this is sufficiently finely-divided (3, 8–15), through the oxidation at ambient temperatures of aqueous iron(II) via precipitated "green rusts" under conditions of limited O_2 supply (i.e., slow reaction) (16, 17), and possibly through dehydration of lepidocrocite (γ-FeO(OH)) (1, 18–20) although a redox cycle may be involved in this last case (1, 21). Whatever the mechanism, it appears that the presence of water is necessary for the formation of maghemite, natural or synthetic (7,

11, 22, 23), probably because the cation vacancies in the pseudo-spinel lattice can be stabilized by the occupation of some or all of the vacant octahedral cation sites by H^+ up to the limiting composition HFe_5O_8, i.e., $5Fe_2O_3 \cdot H_2O$ (24, 25), and indeed virtually all samples of maghemite seem to contain some bound water (11, 22–25). Yet, in spite of this, it has been shown (20, 26, 27) that water also facilitates the conversion of maghemite to α-Fe_2O_3.

A major objective of the present study was therefore to elucidate the kinetic factors governing the metastability of maghemite in aqueous (in effect, hydrothermal) environments. This has relevance to the understanding of the corrosion of ferrous metals in high-temperature aqueous environments; a film of maghemite is known to form in the anodic oxidation of iron in water at room temperature (28) and in the aqueous corrosion of pearlitic steel at pH 6.2–6.8 over the temperature range 20–287°C (29), as well as in the "dry" oxidation of iron by (moist) air near 20°C (30, 31). Maghemite may, in fact, be more common as a corrosion product than is generally appreciated, since the X-ray diffraction pattern of the poorly-crystalline material is difficult to distinguish from that of magnetite (30); this may have relevance, for example, to the characterization of the finely-divided corrosion products ("crud") formed in the heat-transfer systems of water-cooled nuclear power reactors, especially if there exists the possibility of an excursion to oxidizing conditions. In any event, we wish to stress once again (32) that the possible formation and persistence of metastable intermediates such as maghemite must be taken into account when making thermodynamically-based predictions about the outcome of hydrothermal reactions, since these substances could well be the actual reactive species governing the mechanism and course of reaction.

Experimental

Characterization of Materials

Solids in general were characterized by their powder X-ray diffraction (XRD) patterns in comparison with those in the JCPDS files. Elemental analyses, where required, were carried out on solutions of the solids in a small excess of 8–12 *M* HCl (*M* = mol dm^{-3} at 294 K and 89 kPa). Iron(II) was determined by titration with chromate(VI), and iron(III) both gravimetrically as tris(8-hydroxyquinolinato) iron(III) and volumetrically with chromate(VI) after $SnCl_2$ reduction, with good agreement (±0.2%) (33). The sodium and potassium contents of iron compounds were determined (±2%) by flame emission analysis, using a Varian Techtron Model 1200 spectrophotometer and KNO_3 and CsCl as the respective ionization suppressants.

Specific surface areas (SSA) were determined (±2 $m^2 g^{-1}$) by the BET(N_2) method with a Micromeritics Model 2200 High-Speed Surface Area Analyzer, degassing the samples for 40 min at 180 ± 10°C under dry N_2.

Preparation of Materials

Except where the use of glassware is specifically indicated, the maghemite samples and reaction media referred to below were "silica-free", i.e., they were prepared using polyethylene or other non-siliceous laboratory ware exclusively. Fresh Fisher Certified analytical grade reagents were used; KOH was supplied in plastic bottles, and was therefore preferred over NaOH, which came in glass jars. Distilled water was passed through Barnstead deionizer and organic removal cartridges before use.

Magnetite

Finely-particulate "magnetite", conveniently described as a non-stoichiometric solid solution, $x\gamma$-$Fe_2O_3 \cdot (1 - x)Fe_3O_4$ or $Fe_{3-x}O_{4-x}$ exclusive of absorbed water, was typically prepared by slowly adding 1500 cm^3 of a solution of iron(II) sulfate (0.14 *M*) and iron(III) ammonium sulfate (0.28 *M*) to 500 cm^3 fresh aqueous KOH (6.4 *M*), maintained at 90–95°C with vigorous stirring throughout the addition. The black precipitate was filtered, washed thoroughly with water until the filtrate was neutral and then with acetone, air-dried, and powdered. This material was typically found to contain 14.5% iron(II) (cf. 24.1% for stoichiometric Fe_3O_4), i.e., x in $Fe_{3-x}O_{4-x}$ was 0.49, ignoring the small absorbed water content. Removal of O_2 from the reaction mixture by purging with N_2 increased the iron(II) content only marginally (to 15.1%), since most of the loss of iron(II) probably resulted from the spontaneous decomposition of $Fe(OH)_2$ (34, 35). The XRD patterns contained no reflections other than those of $Fe_{3-x}O_{4-x}$; in particular, no iron silicates were detectable even when the preparation was done in glassware (contrast the formation of nickel talc in $Ni(OH)_2$ preparations (32)). The specific surface area (SSA) of samples so prepared was typically 75 $m^2 g^{-1}$; larger SSA's (to 120 $m^2 g^{-1}$) were obtainable by more rapid mixing of the reagents and allowing the temperature to fall accordingly, while very slow mixing produced an SSA of about 45 $m^2 g^{-1}$.

Well-crystallized (SSA < 0.1 $m^2 g^{-1}$), stoichiometric magnetite was made by hydrothermal decomposition of FeNTA·H_2O (36). Yields of some 90% were obtained in 50–80 h at 240°C with initial concentrations Fe(III) ~ 0.1 *M*, NaOH ~ 0.3 *M*. With [FeNTA] ~ 0.2 *M*, well-crystallized $FeCO_3$ was also precipitated, while at 185–190°C the product was α-Fe_2O_3.

Maghemite

Finely-particulate magnetite was completely converted to maghemite by heating in air for 15 min at 180°C. At room temperature, the product picked up moisture rapidly from the air until a constant weight was reached. No crystalline phases other than maghemite could be detected by XRD in this final product, even after heating for a further 72 h in air at 180°C. A sample (**A**) of specific surface 72 $m^2 g^{-1}$, used in most of the kinetic experiments described below, analyzed as follows: Fe^{3+}, 68.0 ± 0.2%; Fe^{2+}, < 0.005; H_2O (weight loss on heating to 800°C), 2.1 ± 0.1; K^+, 0.279 ± 0.005; Na^+, < 0.005; SO_4^{2-}, undetectable. *Anal.* calcd. for $(K_{0.029}H_{0.971})Fe_5O_8$: Fe^{3+} 68.2, H_2O 2.20, K^+ 0.277.

A sample (**B**) of maghemite (SSA 76 $m^2 g^{-1}$) prepared using NaOH in place of KOH analyzed similarly to **A** but with 0.103 ± 0.002% Na^+ and no detectable K^+; this corresponds to $(Na_{0.020}H_{0.980})Fe_5O_8$.

On going from $Fe_{3-x}O_{4-x}$ to maghemite, the attainable saturation magnetization (see below) increased by about 7%, but there was no significant change in the SSA.

In our hands, attempts to prepare maghemite by the method of Rao *et al.* (37) involving thermal decomposition of $FeC_2O_4 \cdot 2H_2O$ gave products which contained 50–80% α-Fe_2O_3 (XRD) and up to 1.7% iron(II), as well as maghemite.

Kinetics of the Hydrothermal Conversion of Maghemite to α-Fe_2O_3

Typically, 0.500 ± 0.003 g maghemite was mixed with water

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

or aqueous alkali[2] (usually 5.0 or 10.0 cm^3) in PTFE-lined autoclaves (small capacity of stainless steel (38), larger of titanium (35)), sealed under nitrogen or air as required, and thermostatted to ±0.2 K in a preheated forced-convection oven (38). The autoclaves were withdrawn and quenched in cold water after selected times t_{oven} in the furnace; the effective reaction time t_{corr} was taken to be $t_{oven} - 0.7$ h, as previously established and verified by extrapolation in those cases exhibiting "first order" kinetics (see below). The solid contents were filtered, washed with water and then acetone, then air-dried.

The percentage of maghemite in these products was estimated from the apparent percentage weight increase Δw experienced by small samples in a Faraday magnetic susceptibility apparatus (cf. ref. 39) under conditions of linear dependence of Δw on applied field, i.e., of saturation magnetization. Calibration with $HgCo(NCS)_4$ indicated the product of field and field gradient, held constant according to a gaussmeter for all samples in a given kinetic run, to be typically about 3×10^3 g cm^{-2} s^{-2}, giving Δw of about 26% for freshly-prepared maghemite, as against 0.03% for the feebly ferromagnetic product, α-Fe_2O_3. It was established, using prepared mixtures of maghemite and α-Fe_2O_3, that Δw was essentially proportional (±2%) to the percentage of maghemite, once this had been equilibrated with the hydrothermal medium (see below). The magnetization of hydrothermally-treated maghemite just before the onset of conversion to hematite in a kinetic run was taken to represent 100% maghemite; in most cases, the Δw value for $t_{oven} = 0.5$ h sufficed.

Results

(*i*) The aerial oxidation of magnetite to maghemite proceeded more rapidly in the "dry" state than under hydrothermal conditions. The oxidation of $Fe_{3-x}O_{4-x}$ (SSA ~ 75 m^2 g^{-1}) at 180°C was complete in 15 min without change in SSA (cf. refs. 14 and 40), and the product remained unchanged over a further 72 h at this temperature, whether prepared with exclusion of silica or not. By contrast, oxidation of $Fe_{3-x}O_{4-x}$ by excess air under hydrothermal conditions (1.0 *M* alkali or neutral) at 180°C was incomplete after several hours, in which time conversion of maghemite to α-Fe_2O_3 would have been important (e.g., 99% complete in 12 h in water, if silica-free).

(*ii*) Coarsely-crystalline, stoichiometric Fe_3O_4 underwent "dry" oxidation in (moist) air slowly and directly to α-Fe_2O_3, whereas finely-particulate $Fe_{3-x}O_{4-x}$ oxidized rapidly to maghemite first. Well-crystallized magnetite (SSA < 0.1 m^2 g^{-1}, particle size 10–100 μm (36)) gave only 2% α-Fe_2O_3 after 24 h at 260°C, according to chemical analysis and XRD; the small-angle reflections characteristic of maghemite were entirely absent. Under these conditions, a sample of genuine maghemite (SSA 72 m^2 g^{-1}) decomposed only to the extent of 5% α-Fe_2O_3; at 400°C, 50% α-Fe_2O_3 resulted after 24 h, and 95% after 4 days. Thus, had maghemite been the initial product of oxidation of the well-crystallized Fe_3O_4 at 260°C, it would surely have been detected.

(*iii*) Freshly-prepared silica-free maghemite picked up moisture from the air, reaching constant weight within a few hours. This material contained significant amounts of alkali metal ion M^+ from the MOH used in making $Fe_{3-x}O_{4-x}$, despite washing this last until the filtrate was neutral, and analyzed as $(H_{1-\delta}M_\delta)Fe_5O_8$, within experimental uncertainty, with δ typically 0.02 (material **B**, M = Na) to 0.03 (material **A**, M = K). Hydrothermal treatment at ~175°C in pure water decreased the M^+ content slightly, e.g., from 0.28 to 0.22% K in **A**, before decomposition to α-Fe_2O_3 was detectable, and this was accompanied by an increase of ~5% in the apparent SSA (measured *after drying* at 180°C; see Table 1) as well as an increase of 11–13% in the saturation magnetization attainable in the Faraday measurements. Samples of $Fe_{3-x}O_{4-x}$ also showed an augmentation in the attainable saturation magnetization on hydrothermal treatment, the increase being roughly proportional to x.

Treatment of $H_{1-\delta}M_\delta Fe_5O_8$ with aqueous MOH (0.1–1.0 *M*) at ~175°C, on the other hand, increased δ markedly (e.g., from 0.28 to 0.82% K^+ for **A** in 1.0 *M* KOH) before detectable α-Fe_2O_3 formation, and the attainable saturation magnetization *decreased* by 7% (0.1 *M* KOH) to 12% (1.0 *M* KOH) simultaneously. Treatment of $H_{1-\delta}M_\delta Fe_5O_8$ with aqueous M′OH at ~175°C led to the replacement of most of the M by M′, as well as an overall increase in the alkali metal ion content; thus, after $t_{oven} = 0.5$ h with the oven at 175°C, the K^+ content of substance **A** in 1 *M* NaOH fell from 0.28 to 0.047%, while the Na^+ content rose from < 0.005% to 0.32%.

The amount of moisture driven off from $H_{1-\delta}M_\delta Fe_5O_8$ at 180°C under dry nitrogen was close to that released on total decomposition to α-Fe_2O_3 in air at 800°C (2.1%), especially when δ was relatively large (Table 1), suggesting that small residual amounts of H^+ *or* M^+ are intricately involved in maintaining the spinel structure (cf. refs. 24, 25). Larger percentages of moisture (to ~5% for SSA ~ 120 m^2 g^{-1}) were recovered at 180°C from hydrothermally-treated maghemite which had been prepared using glassware; these percentages correlated roughly with surface area, and probably reflected contamination by silica.

(*iv*) The presence of silica retarded the hydrothermal decomposition of maghemite. Maghemite, made from $Fe_{3-x}O_{4-x}$ prepared with ~1.5 h exposure to boiling KOH in Pyrex glassware, was only 7% converted to α-Fe_2O_3 after 3 h in water at 187°C, whereas for silica-free maghemite the conversion to hematite was over 97% complete under

[2]Throughout this paper, concentration data refer to the original solutions at 294 K and 89 kPa, rather than hydrothermal conditions. Increases in concentration due to the generation of the saturated vapor pressure were in no case more than 0.3%.

the same conditions. Table 2 gives data which confirm this effect and show unambiguously that the deliberate introduction of reagent-grade SiO_2 into the maghemite–hematite reaction mixture had similar results.

(*v*) The *nature* of the hydrothermal decomposition products of maghemite, also, depended to some extent upon the presence or absence of silica and the composition and temperature of the reaction medium. Silica-free maghemite was converted exclusively to α-Fe_2O_3 in both plain water and 1.0 *M* KOH or NaOH at all temperatures (150–190°C). Hematite was again the sole product in plain water when maghemite prepared in glassware was used, but in strongly alkaline solutions α-FeO(OH) (goethite) was also formed, and was the exclusive product in 1 *M* NaOH at 150–166°C. The product distribution was then also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

sensitive to the cation present; after 116 h at 174.8°C in 1 *M* MOH, maghemite prepared in glassware decomposed to the extent of 59% giving α-Fe_2O_3 and a trace of α-FeO(OH) when M was Na, and 90% giving α-FeO(OH) and a trace of α-Fe_2O_3 when M was K (silica-free maghemite decomposed to α-Fe_2O_3 completely and exclusively in all control experiments).

(*vi*) Neither the original maghemite nor its decomposition product, hematite, showed any decreases in surface area on hydrothermal treatment in water or 1 *M* NaOH that could be attributed to a significant degree of Ostwald ripening (crystal growth by dissolution and reprecipitation of the same phase) on the time-scale of the hydrothermal kinetic experiments, according to BET–SSA measurements and the scanning electron microscope (SEM). Thus, the decline in SSA accompanying the disappearance of maghemite, exemplified in Table 1, was a direct consequence of reaction to form relatively large crystals of hematite, growth of which effectively ceased on depletion of the maghemite nutrient. The small *increase* noted above in the apparent SSA of maghemite on initial exposure to hydrothermal environments probably reflected surface roughening by hydration followed by drying at 180°C in the BET procedure.

The final product in plain water was red hematite of SSA about 2 $m^2 g^{-1}$ (cf. 40–120 $m^2 g^{-1}$ for the original maghemite); a sample of SSA 5 $m^2 g^{-1}$ in which 4% unreacted maghemite remained was seen under the SEM to consist mainly of α-Fe_2O_3 rhombohedra of size 0.3 μm in general and in no case greater than 1.0 μm. In 1.0 *M* KOH, the hematite product was purple–brown to metallic grey, the SSA was not measurable ($\lesssim$ 0.1 $m^2 g^{-1}$) with the apparatus available, and the SEM showed it to consist mainly of well-crystallized tables up to 5 μm across and about 1 μm thick, morphologically similar to the larger hematite crystals prepared hydrothermally by Laudise and co-workers (41).

Maghemite (substance **A**, 72 $m^2 g^{-1}$), heated for 1 h at 800°C in air, decomposed to hematite of SSA 5 $m^2 g^{-1}$.

(*vii*) The decay curves of maghemite, defined by Δw, were sigmoidal in plain water but approached exponential at high alkali concentrations (Table 1 and Fig. 1). These curves can be generally represented to within the experimental uncertainty by the equation

$$[1] \quad -\ln(1-\alpha) = (kt_{corr})^n$$

where α is the molar fractional extent of reaction at the effective reaction time t_{corr} (so that % maghemite = $100(1 - \alpha)$), n is a constant determining

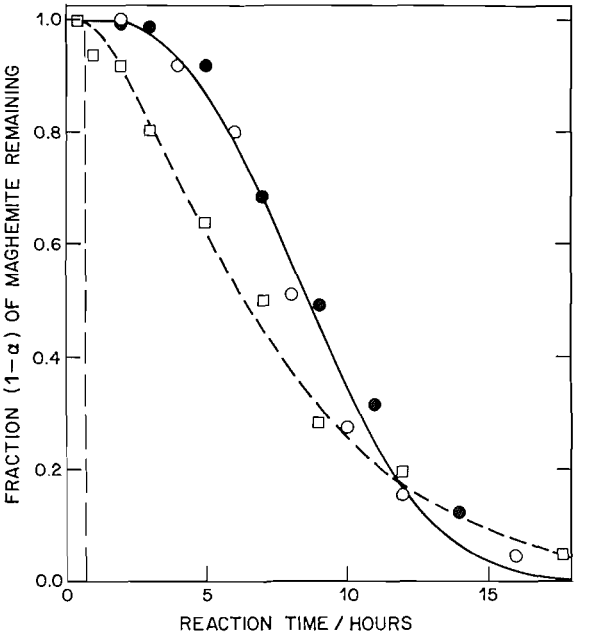

FIG. 1. Hydrothermal conversion of silica-free maghemite (preparation **A**) to hematite at 174.5 ± 0.3°C. Open circles: plain water. Filled circles: plain water, 20 mg α-Fe_2O_3 per g maghemite added. Squares: 1.05 *M* KOH. Vertical broken line: effective zero reaction time. Curves: fit of data to eq. [1].

curve shape (exponential if $n = 1$, sigmoidal if $n > 1$), and k is a time-scaling constant. Equation [1] resembles those developed by Avrami (42), Erofeyev (43), and others (44, 45) for phase transformations in homogeneous solids, but similar equations describe some chemical dissolution processes involving metal oxides (46) and, indeed, a variety of non-chemical phenomena (Weibull–Kao statistics) (47, 48). We emphasize that our choice of eq. [1] was made on purely empirical grounds, without reference to any mechanistic model, and accordingly no special interpretation should be attached to the shape and scaling parameters, n and k.

Table 3 summarizes the kinetics of the hydrothermal transformation of silica-free maghemite to hematite according to eq. [1], based on Δw measurements; SSA and moisture content data (Table 1) and estimates of the relative amounts of maghemite and hematite by XRD were less precise than Δw, but confirmed these results semi-quantitatively at least. These reaction rates were independent of the age of the maghemite sample (up to 1 year), the presence of O_2 or CO_2 in the autoclaves, the nature of M^+ in the MOH used in the preparation and in the reaction mixture, the relative amounts of the solid and liquid phases (the latter was always at least 10-fold greater by weight), and the dimensions and structural metal of the autoclaves. After comple-

[a]From magnetization (Δw) data; r is the coefficient of correlation, and $\pm$ indicates standard deviation. Specific surface of starting material 72 $m^2 g^{-1}$ in all cases.

tion of the reactions in plain water, the liquid phase was neutral or slightly alkaline.

Early experiments using maghemite prepared in glassware showed, in general, a similar conformity to eq. [1], e.g., at 178°C, $n = 1.8$ with $k = 4.3 \times 10^{-5}$ s^{-1} for 0.01 M NaOH, and $n = 1.0$ with $k = 2.7 \times 10^{-5}$ s^{-1} for 0.10 M NaOH, confirming the general effect of $[OH^-]$ upon n seen in Table 3; the possibility of silica contamination, however, excludes these data from the table.

(*viii*) "Seeding" the reaction mixture with α-Fe_2O_3 up to the same amount as maghemite did *not* accelerate the conversion of maghemite to hematite, regardless of the presence or absence of alkali or of silica (Table 2 and Fig. 1). An apparent slight *retarding* effect of added hematite is too small to be significant.

(*ix*) The rate of the hydrothermal conversion of maghemite to hematite was somewhat greater the larger the SSA of the starting material (A_0), as Table 4 shows for silica-free maghemite in water. These data, on fitting to eq. [1] with n fixed at 2.24, give $k = 1.7 \times 10^{-4}$ s^{-1} for $A_0 = 46$ $m^2 g^{-1}$ and $k = 2.0 \times 10^{-4}$ s^{-1} for $A_0 = 75$ $m^2 g^{-1}$. In an early experiment, good fits to eq. [1] were obtained with $n = 1.00$ (cf. "first order" homogeneous reaction kinetics) for maghemite samples of $A_0 = 85$ and 120 $m^2 g^{-1}$ in 0.1 M NaOH at 178°C, giving $k = 2.7 \times 10^{-5}$ and 6.4×10^{-5} s^{-1} respectively; these samples were, however, prepared using glassware. The important point is that the effect of SSA was quite small below, say, 80 $m^2 g^{-1}$, so that it was possible to obtain reproducible kinetics from one batch of maghemite to another so long as the SSA's were roughly similar.

(*x*) "Maghemite" made from ferrous oxalate (37) had a relatively low SSA (32 $m^2 g^{-1}$) yet showed a rapid decline in Δw on hydrothermal treatment, e.g., even at 95°C, $k \sim 4 \times 10^{-5}$ s^{-1} with $n \sim 1.0$ in eq. [1]. This material, however, contained 0.7% iron(II) in addition to some 50% α-Fe_2O_3; since the latter has been shown not to affect the hydrothermal conversion rate of pure maghemite to hematite, it appears that iron(II) may catalyze the reaction. For all other maghemite preparations used in these kinetic studies, however, the iron(II) content was known to be much less than 0.01% and was probably less than 0.001%.

TABLE 4. Effect of initial surface area A_0 on the kinetics of hydrothermal conversion of silica-free maghemite to hematite in water at 187.5°C

Discussion

The analytical data and the observations (*iii*) support the suggestion of Braun (24) that maghemite, as prepared and used in this study, is better represented as HFe_5O_8, rather than in the traditional way as "γ-Fe_2O_3", but they also show that the protons which fill the octahedral cation vacancies of the pseudo-spinel Fe_2O_3 structure (24, 25) are to some extent exchangeable with Na^+ and K^+. These respective ions will therefore be present in maghemite derived from magnetite prepared by precipitation of iron(II)–(III) mixtures with hot aqueous NaOH or KOH, since this magnetite is not stoichiometric Fe_3O_4 but rather a solid solution of Fe_3O_4 in maghemite, represented above as $Fe_{3-x}O_{4-x}$ but in fact containing moisture (and hence protons in cation sites) roughly in proportion to x. Alkali-metal ferrites with the spinel ($LiFe_5O_8$, $NaFe_5O_8$) (24, 49) or other (KFe_5O_8) (49, 50) structures, or of the "β-alumina" type $(1 + y)M_2O \cdot 11Fe_2O_3$ (M = Na, K) which retains some elements of the spinel structure (51–56), are well known, as are some mixed-alkali-metal analogues (51, 57). The maghemite samples $H_{1-\delta}M_\delta Fe_5O_8$ prepared in this study contained far less alkali metal ion than these ferrites, since δ was always less than 0.1, but we note that the saturation magnetization of maghemite decreased as δ increased, in accordance with the lack of ferromagnetism at room temperature in ferrites such as KFe_5O_8, KFe_7O_{11}, and $KFe_{11}O_{17}$ (50, 52).

The mechanism of oxidation of "dry" magnetite by air has been the subject of controversy (9–13), but it seems that the presence of water is necessary for maghemite production, otherwise hematite is formed (9, 11, 22–25). This applies whether or not α-Fe_2O_3 nuclei are present (13, 23). The present study (results (*iii*)) suggests that uptake of water from the gas phase by magnetite is associated with non-stoichiometry in the latter ($Fe_{3-x}O_{4-x}$, $0 < x \leq 1$), presumably because the protons of the water can be accommodated in the cation vacancies, concomitantly stabilizing the spinel structure (22–25, 58); thus, coarsely crystalline, *stoichiometric* Fe_3O_4 oxidizes to α-Fe_2O_3 even when prepared by a "wet" method (36) (results (*ii*)). Since the finely-particulate magnetite which results from conventional "wet" methods is invariably non-stoichiometric, and indeed since surface oxidation of any very finely powdered magnetite can lead to significant overall departures from stoichiometry, the well-established correlation (9–15) between magnetite particle size and oxidation product can be recast in terms of the capacity of the non-stoichiometric solid for water uptake.

The oxidation of magnetite evidently involves the migration of Fe^{3+} ions outwards toward newly-formed O^{2-} at the crystal surface (40). The oxidation should therefore proceed relatively quickly to maghemite if sufficient water protons are present to preserve the spinel structure during oxidation, but *not* so many as to *eliminate* the cation vacancies, through which the Fe^{3+} ions can diffuse with relative ease. If this picture is correct, the aerial oxidation of $Fe_{3-x}O_{4-x}$ in hydrothermal conditions should still yield maghemite, but at a much *slower rate* than in air alone, because cation vacancies will be almost immediately eliminated by the large excess of water. This is indeed the case (result (*i*)); thus, paradoxically, although water is necessary for the production of maghemite, a superabundance of water suppresses the rate of the process dramatically.

A further paradox is that the presence of liquid water accelerates the subsequent decomposition of maghemite to hematite, despite the importance of water in enabling maghemite to exist.

The hydrothermal decomposition of maghemite occurs in a temperature regime some 170°C cooler than does the "dry" transformation to hematite, as may be seen by comparing Tables 1 and 2 with Feitknecht and Mannweiler's Fig. 2 (59) (which refers to a maghemite preparation "1" closely similar in particle size to our preparations **A** and **B**). The SEM showed that the reaction in plain water gave nicely-formed rhombohedra of α-Fe_2O_3, much larger (~300 nm length) and better shaped than either the parent maghemite crystals or hematite formed by the decomposition of the dry solid in air at higher temperatures, as exemplified by Feitknecht and Mannweiler's Fig. 6 (59). Thus, although increases in crystallite size and decreases in SSA are observed in the conversion of "dry" maghemite to hematite as well as in the hydrothermal reaction, the mechanisms of reaction are evidently different, a topotactic particle-to-particle chain reaction being likely in the former (59) and a dissolution–reprecipitation process involving discrete particles in the latter. Alkaline hydrothermal media produced still larger, clean-facetted tables of hematite, characteristic of growth from hydrothermal solution (41).

The kinetics of the hydrothermal decomposition of maghemite in plain water (results (*vii*)) differed from those of the "dry" reaction in being much faster and in the sigmoidal, as opposed to roughly exponential, shape of the plots of extent of reaction vs. time (Fig. 1, compare refs. 58 and 59). Again, markedly different reaction mechanisms are indicated. The Avrami–Erofeyev type of relationship (eq. [1]), which describes the sigmoidal curves, empirically, is commonly associated with reactions occurring in initially homogeneous solid phases (42–45), although Kabai (46) applied it to the kinetics of dissolution of metal oxides in aqueous acids with the conclusion that values of n greater than unity were associated with physical disintegration of the solid oxide (increase in SSA); neither situation, however, seems relevant in the present context.

The observation (*viii*), that seeding with α-Fe_2O_3 does *not* accelerate the hydrothermal transformation of maghemite, eliminates hematite nucleation and the availability of hematite surfaces for growth as rate-determining factors. Furthermore, the absence of any evidence for hydrothermal ripening of either maghemite or hematite on the time-scale of these kinetic experiments (results (*vi*)) argues against any rapid dissolution–reprecipitation pre-equilibrium, or reversibility of the precipitation of α-Fe_2O_3, as mechanistically significant processes. The most feasible remaining mechanistic model, therefore, is one in which both the dissolution of maghemite and a subsequent solution-phase step leading to the precipitation of α-Fe_2O_3 are slow and irreversible. The latter process may require a pre-existing α-Fe_2O_3 surface or surrogate, but the *extent* of this may not be rate determining if the concentration of iron(III) in solution is very low (as seems likely). Reactions [2] and [3] seem reasonable models; the aqueous form of iron(III) is taken

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

to be the neutral hydroxo-species in accordance with the predominance of cation hydrolysis under hydrothermal conditions (35) and the absence of any significant effect of low concentrations of alkali.

[2] $2HFe_5O_8(s) + 14H_2O(l) \rightarrow 10Fe(OH)_3(aq)$

[3] $10Fe(OH)_3(aq) \rightarrow 5\alpha\text{-}Fe_2O_3(s) + 15H_2O(l)$

Taking reaction [3] to be first-order in iron(III) its rate will be limited at first by the slow build-up of $[Fe(OH)_3]$ from zero; then, after a relatively rapid main phase, the diminished surface of maghemite remaining will limit the dissolution rate (we note that SSA does affect the reaction rate somewhat — observation (*ix*)), leading to a sigmoidal plot of α against time. Assuming, by analogy with $Ni(OH)_3^-(aq)$ (32), that $Fe(OH)_4^-(aq)$ becomes the important iron(III) species in water at high pH and elevated temperatures, we can anticipate that high $[OH^-]$ will speed up the supply of iron(III) to the solution phase but, by the same token, slow the precipitation step by permitting higher [Fe(III)] to remain in solution. This will lead to an approach to exponential kinetics ($n = 1$ in eq. [1]) which are faster than the corresponding sigmoidal kinetics in the earlier stages but slower later; this is indeed observed (Fig. 1), and the larger, better-formed $\alpha\text{-}Fe_2O_3$ crystals obtained in 1 *M* alkali also suggest higher iron(III) levels in solution and slower precipitation.

[4] $2HFe_5O_8(s) + 10OH^-(aq) + 14H_2O(l) \rightleftharpoons 10Fe(OH)_4^-(aq)$

[5] $10Fe(OH)_4^-(aq) \rightarrow 5\alpha\text{-}Fe_2O_3(s) + 10OH^-(aq) + 15H_2O(l)$

Since maghemite exhibits ion-exchanging properties, the solid that reacts in aqueous KOH is not, strictly speaking, chemically the same as that in aqueous NaOH or in plain water. Fortunately, the rate of formation of hematite from maghemite was found to be the same in 1 *M* NaOH as in 1 *M* KOH, so that it is permissible to write eqs. [4] and [5] simply in terms of HFe_5O_8 and OH^-.

The above facts and proposed mechanisms contrast with those for the superficially similar alkaline hydrothermal conversion of $Ni(OH)_2$ to NiO (32), in which the reaction corresponding to [4] is rapid and reversible (giving rise to Ostwald ripening of $Ni(OH)_2$), the rate of the step analogous to [5] is completely controlled by the available area of NiO (leading to a dependence of α on t_{corr}^3), and neutral-pH pathways analogous to [2] and [3] are undetectable.

The dramatic retardation of the hydrothermal decomposition of maghemite by silica (results (*iv*), (*v*)) has obvious implications relating to the survival of maghemite in nature, where it is usually accompanied by quartz (2), and to laboratory practice in investigating iron oxides. Any explanation of the effect needs to accommodate the facts that, when silica is present and the pH is high, goethite may form in place of hematite when the alkali cation present in solution is K^+ but is itself suppressed, leaving hematite as the major product in the long term, when the cation is Na^+. Four distinct modes of involvement of silica can readily be visualized, but each presents problems.

(*a*) Iron(III) becomes complexed by silicate species in solution, so retarding steps [3] and [5]. Thermodynamic data on the weak complexing of Fe^{3+} by $Si(OH)_4$ at 25°C and low pH are available (60) but are inapplicable to high temperatures and neutral or alkaline solutions because of hydrolysis and polymerization. Even if the complexing power of low levels of dissolved silicate could be shown to be sufficient to reduce the iron(III) concentration markedly, however, this alone would not explain why goethite may form instead of hematite in some circumstances but not in others. Many polybasic anions (61) including silicate (62, 63) are known to inhibit the somewhat analogous aqueous conversion of iron(III) hydroxide gels to α-FeO(OH), but there is no correlation of this effect with iron(III) complex stability constants, again suggesting that inhibition by such potential complexing agents occurs elsewhere than in the solution phase.

(*b*) Silica impregnates or coats the maghemite with a dissolution-resistant iron(III) silicate, so suppressing steps [2] and [4]. Chemisorption of this kind has been demonstrated for other iron(III) oxide – hydroxide materials by infrared spectroscopy, although, just as in the present study, XRD patterns gave no indication of this (17, 63). Highly resistant coatings of acmite, $NaFeSi_2O_6$, form readily in hydrothermal media containing NaOH, iron(III), and silica, but no potassium analogue is known (64); this suggests a connection with the fact that goethite formation, though favored by high concentrations of KOH (cf. decomposition of ferrihydrite (65)), is itself suppressed by NaOH. It is, however, difficult to see why the identity of the final product should be determined by suppression of step [4] rather than by influencing [5]; goethite was never obtained when silica was absent.

(*c*) Decomposition via dissolution is stopped by silica as in (*b*), but slow solid-phase reactions continue (cf. Schwertmann (61)). Neither direct measurement (results (*i*)) nor extrapolation of rate data (58, 59) indicate any significant solid-state decomposition of maghemite at ~180°C on the time-scale of our experiments, but it is conceded that "dry"

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

decompositions involve a different (partially dehydrated) kind of maghemite from that present in the hydrothermal systems.

(*d*) Silica eliminates the nuclei or coats the growth surfaces of the product, possibly by acmite formation. Such an interaction would presumably affect goethite differently from the less reactive hematite, and would also explain the cation effect as in (*b*). Unfortunately, the evidence of seeding experiments (results (*viii*), Fig. 1, and Table 2) indicated in every case that nucleation and product surface availability were *not* rate-controlling in hematite formation, although they might have been in the production of goethite (65, 66). The possibility remains that these factors may come to be rate-controlling if they are drastically reduced by interaction with silica; a small quantity of silica could conceivably deactivate large areas of product growth surface or large numbers of nuclei.

Some light may be shed on this mechanistic problem by comparing the characteristics of the hydrothermal transformation of maghemite ("γ-Fe_2O_3") with those reported by Schwertmann and Taylor (66) for the conversion of lepidocrocite (γ-FeO(OH)) to goethite in aqueous alkali at 20–80°C. In common with the Fe_2O_3 system, the FeO(OH) conversion occurs via solution rather than topotactically, is faster for smaller particles, follows various kinds of rate equations (including sigmoidal and quasi-exponential) depending on [KOH] and temperature, and is suppressed by silicate. On the other hand, the Ostwald ripening of FeO(OH) in the presence of silicate, the marked accelerating effect of KOH, and the facilitation of reaction by seeding differentiate the FeO(OH) system from the Fe_2O_3. Schwertmann and Taylor (66) argue persuasively that silicate affects the γ-FeO(OH) reaction by inhibiting nucleation of goethite. We therefore suggest that silica together with Na^+ affects the production of goethite from maghemite by suppressing its nucleation, but that silica affects the more important reaction, α-Fe_2O_3 formation, through some other process, probably similar to (*b*) above.

Finally, we note that agitation had no significant effect on the rate of reaction of γ-FeO(OH) (66). The same was taken to be true of the maghemite reaction, since diffusional processes are rapid in hydrothermal systems, but we were unable to check this assumption for lack of PTFE-lined, non-magnetic stirred autoclaves with precise temperature control.

The reaction of $(OHP)_3Fe(II)$ (OHP = 4,7-dihydroxy-1,10-phenanthroline) with oxygen in aqueous 0.1 *N* NaOH solution takes place according to the stoichiometry:

$$4\,(OHP)_3Fe(II) + 2H_2O + O_2 \rightarrow 4(OHP)_3Fe(III) + 4OH^-$$

This stoichiometry holds whether $(OHP)_3Fe(II)$ or O_2 is in excess. The rate law over a wide range of $(OHP)_3Fe(II)$ and O_2 concentrations at 0.1 *N* NaOH has the form:

$$-\tfrac{1}{4}[(OHP)_3Fe(II)]/dt = -d[O_2]/dt = k_2[(OHP)_3Fe(II)][O_2]$$

A notable feature of this oxidation is that *free* HO_2^- is not produced as an intermediate. A plausible mechanism involving *bound* superoxide or peroxide as intermediates is proposed. Due to the redox nature of the OHP ligand and the low potential of the $(OHP)_3Fe(II)$ complex, a 4 electron transfer from one $(OHP)_3Fe(II)$ to one O_2 to give a Fe(IV) species with an oxidized ligand is a distinct possibility. The rate–pH profile is consistent with the protonation of $(OHP)_3Fe(II)$ ($pK_a \approx 9.4$) to give a more reactive species.

FLORA T. T. NG et PATRICK M. HENRY. Can. J. Chem. **58**, 1773 (1980).

La réaction du $(OHP)_3Fe(II)$ (OHP = dihydroxy-4,7 phénanthroline-1,10) avec l'oxygène dans une solution aqueuse de NaOH 0,1 *N* se fait selon la stoechiométrie:

$$4\,(OHP)_3Fe(II) + 2H_2O + O_2 \rightarrow 4(OHP)_3Fe(III) + 4OH^-$$

Cette stoechiométrie est valable même lorsque $(OHP)_3Fe(II)$ et O_2 sont en excès. Sur une large échelle de concentration de $(OHP)_3Fe(II)$ et de O_2 dans le NaOH 0,1 *N*, la loi de la vitesse a la forme:

$$-\tfrac{1}{4}[(OHP)_3Fe(II)]/dt = -d[O_2]/dt = k_2[(OHP)_3Fe(II)][O_2]$$

Le fait important de cette oxydation est l'absence de l'intermédiaire HO_2^- libre. On propose un mécanisme plausible impliquant comme intermédiaire un superoxyde ou un peroxyde lié. Compte tenu de la nature redox du ligand OHP et du faible potentiel du complexe de $(OHP)_3Fe(II)$, on peut considérer une autre possibilité faisant intervenir un transfert de 4 électrons d'un $(OHP)_3Fe(II)$ à un O_2 conduisant à l'espèce Fe(IV) avec un ligand oxydé. Le profil de la vitesse vs. le pH est en accord avec la protonation de $(OHP)_3Fe(II)$, ($pK_a \approx 9.4$) qui conduit à des espèces plus réactives.

Introduction

The interaction of dioxygen with iron has aroused considerable interest in recent years both because of the importance of such interactions in biological systems such as hemoproteins and oxidases (1–5) as well as in the reduction of oxygen for fuel cell applications (6). A fundamental understanding of the reaction of dioxygen with iron complexes would help elucidate similar processses in biological systems.

A number of workers have reported the oxidation of Fe(II) species by O_2 in aqueous solution (7–14). In general two types of kinetic behaviour are observed: first order in [oxygen] and second order in [Fe(II)] or an anion promoted reaction which is first order in [oxygen] and first order in [Fe(II)]. The former must proceed by the interaction of two atoms of Fe^{2+} with O_2 [1]–[3],

[1] $Fe^{2+} + O_2 \rightleftharpoons Fe^{2+}O_2$

[2] $Fe^{2+}O_2 + Fe^{2+} \rightarrow Fe^{2+}O_2Fe^{2+}$

[3] $Fe^{2+}O_2Fe^{2+} + 2H^+ \rightarrow 2Fe^{3+} + H_2O_2$

while the second is postulated to involve formation of superoxide in the rate limiting step [4], [5]

[4] $Fe^{2+}O_2 + X^- \xrightarrow{\text{slow}} FeX^{2+} + O_2^-$

[5] $Fe^{2+} + O_2^- + 2H^+ \xrightarrow{\text{fast}} Fe^{3+} + H_2O_2$

although it has been pointed out that iron(IV) rather than O_2^- could be an intermediate in the second mechanism [6].

[6] $X^- + Fe^{2+}O_2 + 2H^+ \rightarrow FeX^{3+} + H_2O_2$

In all mechanisms it is assumed that the hydrogen peroxide formed reacts rapidly with more Fe^{2+} to complete the reduction to water.

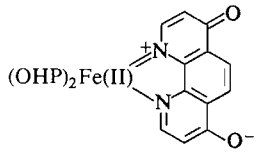
[7] $H_2O_2 + 2Fe^{2+} + 2H^+ \rightarrow 2Fe^{3+} + 2H_2O$

Of interest in regard to possible Fe(IV) intermediates is the work of Hammond and Wu (15) who studied the reaction of Fe(II) chloride species with O_2 in non-aqueous solvents. Their results were consistent with a $4e^-$ reduction of O_2 by $2Fe^{2+}$ [8].



[8] $2FeCl_2 + O_2 \rightarrow Cl_2FeOOFeCl_2 \rightarrow 2Cl_2FeO$

Collman and co-workers (6) have synthesized bridged porphyrin rings for the purpose of preparing binuclear iron(II) porphyrins which would cause a similar $4e^-$ reduction of O_2 by formation of two Fe(IV) species. Iron(IV) porphyrins have been characterized (16–18).

Tris(4,7-dihydroxy-1,10-phenanthroline)iron(II), $(OHP)_3Fe(II)$, reacts so rapidly with O_2 in alkaline aqueous solution that it has been used as a reagent for determination of dissolved oxygen (19). The mechanism of this oxidation is of interest for several reasons. First the oxidation very likely proceeds by a mechanism not involving direct interaction of O_2 with the Fe(II) atom since the Fe(II) is coordinately saturated. To our knowledge no reactions of Fe(II) with O_2 in which O_2 does not enter the primary Fe(II) coordination sphere have been reported. However, outersphere oxidations of ruthenium(II) amines (20, 21) and hexacyanochromium(II) have been reported (22). Secondly the reduction potential of this complex is so low (−0.06 V in basic media (23)) that Fe(IV) species become likely intermediates. Finally the ligand is formally analogous to hydroquinone and should itself be capable of donating two electrons to O_2:

[9] 

$(OHP)_3Fe(II)$

$\xrightarrow{-2H^+}$ 

+ $2e^-$

1

This paper describes a kinetic study of the reaction of $(OHP)_3Fe(II)$ with O_2 in aqueous basic medium.

Results

(a) Stoichiometry and Products

A solution of $(OHP)_3Fe(II)$ in 0.1 *N* NaOH is rose red with an absorption maximum at 520 nm ($\varepsilon = 1.48 \times 10^4$). As reported by Poe and Diehl (19) passage of air or oxygen through the solution resulted in a blackish grey solution with absorption maxima at 750 nm ($\varepsilon = 1.6 \times 10^3$), 650 nm (broad, $\varepsilon = 1.6 \times 10^3$), and 520 nm ($\varepsilon = 3.3 \times 10^3$). The colour of $(OHP)_3Fe(II)$ could not be restored by passage of argon or nitrogen through the solution but the addition of ascorbic acid or sodium dithionite as reducing agents under an O_2 free atmosphere did give a rose red solution with a spectrum quantitatively the same as the starting $(OHP)_3Fe(II)$ solution.

By adding O_2 gradually to a solution of $(OHP)_3Fe(II)$, Poe and Diehl (19) found that the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

overall stoichiometry of the reaction was 4-$(OHP)_3Fe(II)$'s per O_2 consumed. To determine if H_2O_2 is an intermediate in the reaction we have independently measured the stoichiometry when O_2 is in excess. For this purpose we used both a constant pressure gas uptake apparatus (24) and an oxygen electrode. The results are listed in Table 1. Within experimental error the data are consistent with the stoichiometry shown below:

$$[10] \quad 4(OHP)_3Fe(II) + O_2 + 2H_2O \rightarrow 4(OHP)_3Fe(III) + 4OH^-$$

Hydrogen peroxide was not detected by the standard KI /starch indicator method.

(b) Kinetics of Reaction of $(OHP)_3Fe(II)$ with Molecular Oxygen

The oxidation kinetics were measured under pseudo first order conditions using either O_2 or $(OHP)_3Fe(II)$ in excess. Most runs were followed spectrophotometrically using a stopped-flow reactor but a few with $(OHP)_3Fe(II)$ in excess were followed by metering the O_2 concentration with an oxygen electrode. All kinetic runs obeyed good pseudo first order kinetics. As expected from the stoichiometry given by [10] the values of the pseudo first order rate constant, k_{obs}, obtained when O_2 was in excess were about four times those when $(OHP)_3Fe(II)$ was in excess. The data, which are listed in Tables 2 and 3, are consistent only with the rate expression given by [11]

$$[11] \quad -\frac{1}{4}\frac{d[(OHP)_3Fe(II)]}{dt} = \frac{-d[O_2]}{dt} = k_2[(OHP)_3Fe(II)][O_2]$$

where k_2 has a value of $114 \pm 11\ M^{-1}\ s^{-1}$ at 25°C. Addition of excess OHP ligand did not affect the value of k_2.

Rates were measured over the temperature range of 25–45°C (Table 4). Values of $\Delta H^{\ddagger} = 14.8 \pm 0.6$ kcal/mol and $\Delta S^{\ddagger} = 0.8 \pm 2$ eu were calculated from the data.

To determine the effect of pH on rate the kinetics were studied over the pH range 8–13. Data could not be obtained at lower pH because of the instability of $(OHP)_3Fe(II)$ at pH $\leq$ 8 (25). A plot of k_2 versus pH is shown in Fig. 1. The value of k_2 is practically constant between the pH range of 10–13. The value of k_2 increases rapidly in the region 9.75–9.0 and levels off again. The midpoint of the curve is at about pH = 9.4.

(c) Reaction of $(OHP)_3Fe(II)$ with HO_2^-

The approximate rate of reaction of hydrogen peroxide in 0.1 *M* NaOH with $(OHP)_3Fe(II)$ at 25°C was determined using peroxide in excess. Since the K_a of H_2O_2 in H_2O at 25°C is 2.4×10^{-12} (26) the peroxide will exist as HO_2^- under these conditions. Pseudo first order kinetics were observed. At $[(OHP)_3Fe(II)] = 5 \times 10^{-5}\ M$ in 0.1 *M* NaOH the $t_{1/2}$ was 50 s at $5 \times 10^{-4}\ M$ $[HO_2^-]$ and 4 s at $5 \times 10^{-3}\ M$ $[HO_2^-]$. Thus the rate expression is of the form given by [12] with a value of approximately $14\ M^{-1}\ s^{-1}$ for k_2'.

TABLE 2. Kinetic data for the oxidation of $(OHP)_3Fe(II)$ by molecular oxygen at 25°C and 0.1 *N* NaOH obtained by spectrometric techniques[a]

$[(OHP)_3Fe(II)]$ ($M \times 10^6$)	$[O_2]$[b] ($M \times 10^4$)	k_{obs} ($s^{-1} \times 10^2$)	k_2 ($M^{-1}\ s^{-1}$)

Discussion

Oxidation of metal ions and complexes by molecular oxygen usually occurs through an inner-sphere pathway, namely, O_2 coordinates to the metal ion in the primary coordination sphere prior to the oxidation step (20). One special feature of the $(OHP)_3Fe(II)$ reductant is the fact that it is coordinately saturated and, unless it dissociates in the course of reaction, interaction of O_2 with the iron(II) during reduction is unlikely. Dissociation of OHP from $(OHP)_3Fe(II)$ is known to be slow at pH < 14 (23) and addition of free OHP did not inhibit the rate of reduction of O_2. Furthermore, $(OHP)_3Fe(III)$ was obtained quantitatively whereas dissociation of OHP ligand would produce Fe(III) hydroxyl species as final products (23). The value of $\Delta S^{\neq} = 0.8 \pm 2$ eu also suggests that no OHP dissociation occurs in the rate determining step. Thus oxidation of $(OHP)_3Fe(II)$ by O_2 very likely occurs via a path without direct coordination of O_2 to $(OHP)_3Fe(II)$ in the primary coordination sphere; however, a 7 coordinate intermediate could not be ruled out. A seven coordinate dioxygen adduct of Fe(II) with a binuclear structure bridged by a singlet dioxygen has been reported (27).

The exact state of $(OHP)_3Fe(II)$ in basic solution is not known for certain but all or most of the six protons must be removed by equilibria such as [13] where the deprotonated ligand can exist in either the **A** or **B** forms. Recent studies with a Ru(II)–OHP complex indicate that form **B** is important for the deprotonated ligand (28). The value of E_0 for $(OHP)_3Fe(II)$ does not change from pH 10 to 13 suggesting only one species is present in this range (23).

[13] 

Since the protonation of one or more of the oxygens in $(OHP)_3Fe(II)$ could profoundly affect the electron transfer capability of the ligand, a rate–pH study was undertaken. The rate–pH profile shown in Fig. 1 resembles a pH titration curve with a pK_a of ca. 9.4 strongly suggesting that one of the phenoxide anions is being protonated to give a species which is about 80 times more reactive. Of course as mentioned earlier, the state of protonation of the $(OHP)_3Fe(II)$ under the reaction conditions is not known but it is probably close to being completely deprotonated. The value of 9.4 for pK_a is reasonable for one of the six protonation equilibria; $Ru(II)(OHP)(2,2\text{-bipyridine})_2$ has a pK_a of 10.1 for the loss of both protons (28).

The proton acceleration could also result from stabilization of intermediate species by protonation. Kurimura and co-workers (14) found in the reduction of O_2 by iron(II) chelated with ligands such as EDTA the protonated chelate ring reacted about 30 times faster than the unprotonated chelate. This was attributed to stabilization of O_2^- by formation of O_2H. However, the acid dissociation constant of O_2H is 5×10^{-5} (29) so this stabilization would not occur under the basic conditions of the present study if O_2^- existed as a true intermediate. However, there would be no conflict with the experimental result if O_2^- is associated with the $(OHP)_3Fe(II)$ complex (see later discussion).

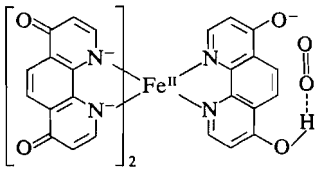
The rate expression given by [11] eliminates mechanisms such as given by [1]–[3] involving the interaction of $2(OHP)_3Fe(II)$ with one O_2 in the rate limiting step, but is consistent with an initial one electron transfer from one $(OHP)_3Fe(II)$ to one O_2 giving O_2^- [14].

$$[14] \quad (OHP)_3Fe(II) + O_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (OHP)_3Fe(III) + O_2^-$$

$$[15] \quad O_2^- + (OHP)_3Fe(II) \xrightarrow[k_3,\ H^+]{\text{fast}} (OHP)_3Fe(III) + HO_2^-$$

Thus using an E_0 value of 0.06 for $(OHP)_3Fe(II)$–$(OHP)_3Fe(III)$ potential and a value of -0.563 for the O_2–O_2^- potential (30) an equilibrium constant of 3×10^{-9} can be calculated for [14]. This value combined with an experimental k_2 value of 114 M^{-1} s^{-1} gives a value of 3.8×10^{10} M^{-1} s^{-1} for k_{-2} which is greater than or equal to the diffusion controlled rate constant. Since good first order kinetics were observed for over 90% of reaction, a k_3 value greater than k_{-2} is required. Thus on the basis of the k_{-2} and k_3 values as calculated from the literature values of redox potential, a mechanism involving production of *free* superoxide in a one electron transfer step does not appear likely. An alternative would involve a two electron transfer to produce Fe(IV) and peroxide intermediates [16].

$$[16] \quad (OHP)_3Fe(II) + O_2 \xrightarrow{H^+} (OHP)_3Fe(IV) + HO_2^-$$



However, there is a piece of experimental evidence which argues against the production of a free HO_2^- intermediate as written in [15] and [16]. In most studies on Fe(II) oxidation, the peroxide formed would react rapidly with more Fe(II) via [7] to give the observed stoichiometry of 4 Fe(II) per O_2. In the present system the rate of reaction of $(OHP)_3Fe(II)$ with O_2 is 8 times faster than its reaction with HO_2^-. Thus in the runs using excess O_2 the observed stoichiometry should be 2 rather than the 4 observed.[3] Furthermore, it is of interest to note the oxidation of bipyridyl and phenanthroline complexes of Fe(II) with H_2O_2 has been reported to occur via a ligand dissociation mechanism (31). The conclusion from our experimental result is that HO_2^- is not produced as a *free* intermediate, but rather is oxidized to OH^- before it escapes from the solvent cage. Two electron transfer within the solvent cage has been suggested in the oxidation of Fe(II) (EDTA) complex by H_2O_2 (32).

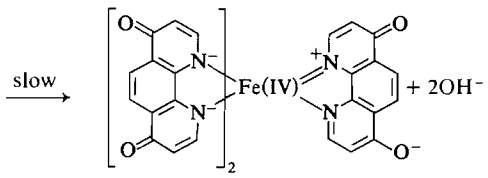
To account for the kinetic data and the fact that no free HO_2^- was produced, a mechanism involving bound superoxide [17] or peroxide intermediates [18] are proposed.

$$[17] \quad (OHP)_3Fe(II) + O_2 \rightleftharpoons (OHP)_3Fe(III)O_2^-$$

$$[18] \quad (OHP)_3Fe(II) + O_2 \rightleftharpoons (OHP)_3Fe(IV)O_2^{2-}$$

Formulations of bound superoxide or peroxide as $(OHP)_3Fe(III)O_2^-$ or $(OHP)_3Fe(IV)O_2^{2-}$ respectively do not necessarily imply direct bonding of O_2 to Fe(II). Furthermore, the $\Delta S^{\neq}$ value of 0.8 $\pm$ 2 eu suggests that a seven coordinate intermediate is not formed in the rate determining step. An attractive possiblity is the association of O_2 with $(OHP)_3Fe(II)$ via the π system of the phenanthroline ring. Donor and acceptor type interaction between O_2 and the porphyrin ring has been proposed in the O_2 binding to solid hemes (33). Thus, electron transfer could occur through the π-system of the phenanthroline ring in a manner analogous to that suggested for electron transfer through porphyrin or polypyridyl rings in several systems (18, 34–37). The effect of H^+ on rate could be interpreted as stabilization of bound O_2 and/or its reduction intermediates via possibly hydrogen bonding with the OH group on the phenanthroline ring as represented in **2**. Stabilization of O_2 via hydrogen bonding has been proposed by Pauling in oxyhaemoglobin (38)

2



If the rate determining step is as indicated in [17], an interesting possibility arises in that multielectron transfer from $Fe(III)(OHP)_3$ to bound O_2^- could occur within the solvent cage of the inter-

[3]Of course if $(OHP)_3Fe(II)$ is in excess the observed stoichiometry would be 4 since HO_2^- would eventually be able to react with the excess $(OHP)_3Fe(II)$.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

mediate $[(OHP)_3Fe(III)O_2^-]$ species. Enzymatic reduction of O_2 to H_2O is thought to take place by multielectron transfer steps (39). A simultaneous reversible 2 electron transfer at the same potential on a bis(1,3,5-triketonato) dicopper(II) has been reported (40). Multielectron transfer in the present system seems reasonable since OHP is an organic redox system (see [9]). Also Fe(IV) species could be involved since the negative charge of the OHP ligand would stabilize this oxidation state of iron. In the limit, a 4 electron reduction of O_2 would be accomplished within the lifetime of $[(OHP)_3Fe(III)O_2^-]$ to produce a highly oxidized Fe species, **3**, as shown in [19] and [20].

[19] $(OHP)_3Fe(II) + O_2$

3

[20] $\mathbf{3} + 3(OHP)_3Fe(II) \xrightarrow{fast} 4(OHP)_3Fe(III)$

The nature of **3** is speculative and an intermediate involving Fe(II) and 2 oxidized ligands is also feasible. In **3**, the high positive charge at the metal center is largely neutralized by **B** forms of the other anionic ligands. As mentioned earlier for a Ru(II) complex of OHP the **B** forms are of considerable importance in deprotonated ligands (28). One might argue that **3** is produced from four 1 electron transfer steps, a sequence of two 2 electron transfer steps or a direct 4 electron step. On the basis of the results presently available, one cannot distinguish between these possibilities. However, a four electron reduction of O_2 by one metal center within the lifetime of the solvent cage (regardless of the detailed electron transfer step) is a distinct possibility.

Experimental

Materials

4,7-Dihydroxy-1,10-phenanthroline and ferrous sulfate were purchased from G. Frederick Smith. Oxygen and argon were obtained from Canadian Oxygen Limited. All other chemicals were of reagent grade.

Tris(4,7-dihydroxy-1,10-phenanthroline)iron(II) was prepared *in situ* by adding a 1:3 molar ratio of $FeSO_4 \cdot 7H_2O$ in H_2O to 4,7-dihydroxy-1,10-phenanthroline dissolved in NaOH in the absence of oxygen. Such solutions were prepared as needed since air had to be rigorously excluded.

Kinetic Studies

Kinetic studies were carried out on a Durrum stopped-flow spectrophotometer with gas-tight syringes or a Cary 118 spectrophotometer. Standard gas-tight syringe techniques were used to transfer air sensitive solutions which were degassed with argon. The reactions were carried out under pseudo first order conditions with either O_2 or $(OHP)_3Fe(II)$ in excess. The rates were followed by measuring either the decrease of the iron(II) species at 510 nm or the increase of the iron(III) species at 750 nm. Good pseudo first order kinetics were observed for most runs and the pseudo first order rate constants were obtained from a plot of $\log (OD_\infty - OD_t)$ against time.

A few experiments were performed by monitoring the O_2 concentration using a Beckman oxygen meter equipped with an oxygen electrode. A thermostated cell with an air tight stopper was used to house the electrode system. The oxygen meter was connected to a strip chart recorder. A measured amount of $(OHP)_3Fe(II)$ was added to a solution of known $[O_2]$ in the cell and the kinetics followed by decrease in $[O_2]$ with time.

The study of the variation of rate with pH was carried out using the Durrum stopped-flow spectrophotometer. At pH's of 12 or above the $(OHP)_3Fe(II)$ in solutions of the desired hydroxide concentration was mixed with solutions of the same hydroxide concentration saturated with O_2. Most of the runs at lower pH were made using buffer solutions. Stock solutions of 5×10^{-3} *M* $(OHP)_3Fe(II)$ were made up in 0.1 *M* NaOH and aliquots of the stock solution were added to an argon degassed buffer solution (ca. 0.4 mL of stock $(OHP)_3Fe(II)$ solution to ca. 10 mL of buffer solution). The rates of oxidation were obtained from the increase in OD at 750 nm with time. In all runs the ionic strength was maintained at 0.1 *M* by addition of $NaClO_4$.

Buffers used were NH_4Cl/NH_4OH, glycine/NaOH (41*a*) and tris(hydroxymethyl)aminoethane hydrochloride (tris)/$HClO_4$ (41*b*). The concentration of glycine and tris were kept at 0.01 *M*.

Stoichiometry

The stoichiometry of the oxidation was obtained using a Beckman oxygen meter and electrode or a constant pressure gas uptake apparatus described in ref. 24.

The H_2O_2 analysis in oxidized solutions of $(OHP)_3Fe(II)$ was carried out by the KI/starch procedure (42). Since $(OHP)_3Fe(III)$ would interfere with the determination, sulfuric acid was first added to the reaction mixture until the pH was less than 5. This precipitated the $(OHP)_3Fe(III)$ as a purplish black solid. After filtration the filtrate was treated with a 10% KI solution in 2 *N* H_2SO_4. After standing for a few minutes the solution was titrated with a standard $K_2S_2O_3$ solution (Fisher Scientific) using ca. 0.5 mL of a starch indicator solution to detect the endpoint. There was always a small amount of I_2 produced, but much less than that expected from the stoichiometry of [3] or [5] $(2(OHP)_3Fe(II)/H_2O_2)$. The small amount of oxidant present is very likely Fe(III) (aq) formed from dissociation of $(OHP)_3Fe(III)$ upon addition of H_2SO_4. A typical analysis is given below:

Oxidized $(OHP)_3Fe(II)$ solution (5 mL, 6×10^{-4} *M*) required 2.0 mL of 2.0×10^{-4} *M* $Na_2S_2O_3$ solution to discharge the blue colour. Since 1 mL of 1*M* $Na_2S_2O_3$ is equivalent to 0.017 g of H_2O_2, if I_2 is formed from peroxide, its concentration is given by the following calculation.

$$[H_2O_2] = \frac{2.0 \times (2.0 \times 10^{-4}) \times 0.017}{34 \times 5.0} \times 1000\ M = 4.0 \times 10^{-5}\ M$$

If one H_2O_2 were formed from two $(OHP)_3Fe(II)$ the peroxide concentration would be 3×10^{-4} *M*.

Théorie de l'absorption ultrasonore des solutions micellaires d'amphiphiles. Application à l'effet de la force ionique sur la dynamique d'échange d'amphiphiles entre micelles et solution environnante

R. ZANA ET S. YIV

Reçu le 27 février 1980

R. ZANA et S. YIV. Can. J. Chem. **58**, 1780 (1980).

L'expression de l'absorption ultrasonore associée au processus d'échange d'ions amphiphiles entre micelles et solution environnante a pu être établie par un calcul simple basé sur des hypothèses identiques à celles ayant permis à Aniansson et Wall d'obtenir l'expression du temps de relaxation associé à ce processus. L'expression obtenue étend les possibilités d'études de systèmes micellaires au moyen des méthodes de relaxation ultrasonore. Elle a été utilisée pour l'interprétation quantitative de mesures d'absorption ultrasonore relatives à l'effet de la force ionique sur la dynamique du processus d'échange dans les solutions micellaires de décanoate de potassium.

R. ZANA and S. YIV. Can. J. Chem. **58**, 1780 (1980).

An expression for the amplitude of the ultrasonic relaxation arising from the exchange of amphiphiles between micelles and surrounding solution has been derived on the basis of the same assumptions as used by Aniansson and Wall to obtain the expression of the relaxation time for this process. The derived expression somewhat extends the range of investigation of micellar systems which can be performed by means of the ultrasonic relaxation method. It has been used for the quantitative interpretation of ultrasonic absorption measurements concerning the effect of ionic strength on the dynamics of the exchange process in micellar solutions of potassium decanoate.

I. Introduction

Les solutions micellaires de détergents à chaîne alkyle comportant jusqu'à 12 carbones ont fait l'objet de nombreuses études par absorption ultrasonore (1–15). La plupart d'entre elles (1–10) sont antérieures à la publication de la théorie d'Aniansson et Wall (16) de la dynamique des solutions micellaires et une controverse était apparue en ce qui concerne la nature du processus de relaxation détecté par mesure de l'absorption ultrasonore: équilibre d'ionisation des contreions (1–3, 13) ou équilibre d'échange d'ions amphiphiles entre micelles et solution environnante (4, 5). Il est maintenant généralement accepté, depuis les travaux de Graber et coll. (4, 5) que la seconde attribution est la bonne. On peut donc dire que la méthode de relaxation ultrasonore a la première permis la mise en évidence et l'étude qualitative de la cinétique de l'échange des ions amphiphiles entre micelles et solution (4, 5). Toutefois, aucune interprétation quantitative basée sur le modèle d'Aniansson et Wall (16) n'a été donnée, à ce jour, aux nombreux résultats d'amplitudes de relaxation ultrasonore rapportés dans la littérature. La seule raison en est que le calcul de l'expression de l'absorption ultrasonore d'une solution d'amphiphile due au processus d'échange, basé que un modèle semblable à celui utilisé par Aniansson et Wall (16) pour établir l'expression du temps de relaxation τ_1 associé au processus d'échange, n'avait pas encore été effectué (17)[1]. Cette situation nous semblait d'autant plus regrettable que l'amplitude d'une relaxation ultrasonore ne nécessite pas pour son interprétation de mesures additionnelles, à la différence des amplitudes de relaxation déterminées au moyen des méthodes transitoires de relaxation chimique. Comme nous le verrons plus loin, l'amplitude R d'une relaxation ultrasonore contient des quantités cinétiques (constantes de vitesse) et thermodynamiques (changements de volume et d'enthalpie associé au processus). L'étude de R permet donc de compléter et/ou confirmer les informations obtenues à partir du temps de relaxation.

Ceci nous a conduit à établir l'expression de l'absorption ultrasonore due au processus d'échange d'ions amphiphiles entre micelles et solution environnante, sur la base du mécanisme utilisé par Aniansson et Wall (16) pour établir l'expression du temps de relaxation de ce processus et avec les mêmes hypothèses.

Dans une deuxième étape nous avons étudié l'effet de la force ionique sur la cinétique du processus d'échange par relaxation ultrasonore et interprété les résultats obtenus au moyen des expressions établies

[1]Durant la preparation de ce manuscrit est paru un article de Teubner (17) dans lequel cet auteur calcule l'expression de l'absorption ultrasonore associée au processus d'echange par une methode matricielle. Le résultat obtenu est comme nous le verrons plus loin identique au nôtre.

pour l'absorption ultrasonore. En effet, en dépit des nombreuses études de solutions micellaires par absorption ultrasonore et plus généralement au moyen des méthodes de relaxation chimique, aucune étude systématique de l'effet de la force ionique sur la cinétique du processus d'échange n'avait été effectuée. On trouve dans la littérature seulement quelques résultats très fragmentaires qui indiquent que, à une concentration en détergent donnée, le temps de relaxation associé au processus d'échange est peu affecté par l'addition de sel (2, 12).

Des considérations expérimentales nous ont guidé dans le choix de l'amphiphile ionique étudié. Rappelons que l'absorption ultrasonore ne permet pas d'étudier les amphiphiles dont la chaîne alkyle comporte plus de 12 atomes de carbone (4). L'équipement disponible au laboratoire qui permet d'explorer les fréquences comprises entre 0,8 et 300 MHz nous a fait choisir le décanoate de potassium pour lequel les temps de relaxation correspondent à des fréquences situées dans ce domaine. Un autre avantage du décanoate de potassium est qu'il a été étudié par Graber et coll. (4) et Yasunaga et coll. (2) en solution aqueuse, en l'absence de sel.

Nous présentons successivement le calcul de l'absorption ultrasonore, la partie expérimentale et la discussion des résultats.

II. Expression de l'absorption ultrasonore associée au processus d'échange d'ions amphiphiles entre micelles et solution environnante

(1) Les hypothèses

On suppose que la formation des micelles est régie par la loi d'action de masse et fait intervenir une série de réactions bimoléculaires:

$$A_1 + A_1 \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} A_2$$

$$[1] \qquad A_2 + A_1 \underset{k_3^-}{\overset{k_3^+}{\rightleftharpoons}} A_3$$

$$\text{----------}$$

$$A_{s-1} + A_1 \underset{k_s^-}{\overset{k_s^+}{\rightleftharpoons}} A_s$$

$$\text{----------}$$

où A_1 représente un amphiphile isolé et A_s une espèce associée comportant s amphiphiles (le caractère ionique des amphiphiles et la présence des contreions ne sont pas explicitement pris en considération).

Comme Aniansson et Wall, on fait l'hypothèse que la courbe de distribution des espèces associées, en fonction du nombre d'association s peut être divisée en 3 parties: une région 1 ($s < s_1$) qui correspond aux monomères et oligomères, une région 2 ($s_1 < s < s_2$) qui est celle des espèces associées présentes dans la solution micellaire à des concentrations extrêmement faibles, et une région 3 ($s > s_2$) qui correspond aux micelles proprement dites.

L'existence de la région 2 impose au système micellaire soumis à une perturbation très rapide de répondre dans un premier temps par un rééquilibrage rapide entre les micelles de la région 3 par des réactions du type [1]. Ces réactions d'échange d'ions amphiphiles entre micelles et solution environnante laissent le nombre de micelles de la région 3 inchangé, c'est-à-dire

$$[2] \qquad \sum A_s = \text{constante} \qquad \text{d'où} \sum \mathrm{d}A_s = 0$$

où les sommes sont prises sur toutes les espèces de la région 3, A_s est la concentration de l'espèces associée A_s.

De plus, on suppose que la distribution des micelles dans la région 3 obéit à une statistique gaussienne (16):

$$[3] \qquad A_s = A_0 \exp - \frac{(s-n)^2}{2\sigma^2}$$

où σ caractérise la largeur de la courbe de distribution, c'est-à-dire la polydispersité des micelles, n étant le nombre d'agrégation moyen des micelles.

Enfin, on suppose que les constantes de vitesse d'association k_s^+ et de dissociation k_s^- constantes et égales à k^+ et k^- dans la région 3. Cette hypothèse réduit le spectre de temps de relaxation relatif au système de réactions [1] à un seul temps de relaxation τ_1 dont l'expression a été donnée par Aniansson et Wall et que nous retrouvons dans le calcul qui suit.

(2) Le calcul

Il s'agit donc de calculer l'absorption ultrasonore associée à toutes les réactions couplées [1] se produisant dans la région 3. L'équation de vitesse relative au monomère s'écrit:

$$[4] \qquad \mathrm{d}A_1/\mathrm{d}t = \sum k^- A_s - \sum k^+ A_{s-1} A_1$$

où les A représentent des concentrations instantanées. Les ondes ultrasonores apportent une perturbation périodique aux valeurs des concentrations et des constantes de vitesse. Pour des ondes de fréquence angulaire $\omega = 2\pi f$ on peut écrire:

$$k^- = \bar{k}^- + \Delta k^- \, \mathrm{e}^{i\omega t}$$

$$k^+ = \bar{k}^+ + \Delta k^+ \, \mathrm{e}^{i\omega t}$$

$$[5] \qquad A_s = \bar{A}_s + \Delta A_s \, \mathrm{e}^{i\omega t} = \bar{A}_s + \xi_s \bar{A}_s \, \mathrm{e}^{i\omega t}$$

$$A_{s-1} = \bar{A}_{s-1} + \Delta A_{s-1} \, \mathrm{e}^{i\omega t}$$

$$= A_{s-1} + \xi_{s-1} \bar{A}_{s-1} \, \mathrm{e}^{i\omega t}$$

$$A_1 = \bar{A}_1 + \Delta A_1 \, \mathrm{e}^{i\omega t} = \bar{A}_1 + \xi_1 \bar{A}_1 \, \mathrm{e}^{i\omega t}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

La barre sur un symbole donné indique la valeur à l'équilibre de la quantité correspondante. Les Δ représentent les amplitudes des perturbations. Pour les concentrations nous avons fait usage des quantités ξ_s introduites par Aniansson et données par

[6] $\xi_s = (A_s - \bar{A}_s)/\bar{A}_s$

Si l'on remplace dans [4] les différentes quantités par leurs expressions [5] et que l'on tient compte de la condition d'équilibre

[7] $\bar{k}^+\bar{A}_1\bar{A}_{s-1} = \bar{k}^-\bar{A}_s$

de l'éq. [2] qui devient

[8] $\sum \Delta A_s = \sum \xi_s \bar{A}_s = 0$

et de la définition

[9] $K = k^-/k^+ = A_1A_{s-1}/A_s$

qui conduit à:

[10] $\Delta k^- = K\Delta k^+ + k^+\Delta K$

on obtient l'équation:

[11] $i\omega\xi_1\bar{A}_1 = -\bar{k}^-[\sum \bar{A}_s\xi_{s-1} + \xi_1\sum \bar{A}_s] + \bar{k}^+\Delta K \sum \bar{A}_s$

On transforme le terme entre crochets dans [11] en écrivant (18):

[12] $\bar{A}_s = \bar{A}_{s-1} + \frac{\partial \bar{A}_{s-1}}{\partial s}[s - (s-1)]$

$= \bar{A}_{s-1} + \frac{\partial \bar{A}_{s-1}}{\partial s}$

Pour calculer la dérivée de $\bar{A}_{s-1}$ par rapport à s on utilise l'éq. [3] d'où:

[13] $\sum \frac{\partial \bar{A}_s}{\partial s}\xi_s = -\frac{1}{\sigma^2}\sum s\bar{A}_s\xi_s = \frac{1}{\sigma^2}\xi_1\bar{A}_1$

La dernière égalité dans [13] représente la loi de conservation de la masse. Le terme entre crochets dans [11] s'écrit donc:

[14] $\xi_1\bar{A}_1\left[\frac{\bar{k}^-}{\sigma^2} + \bar{k}^-\frac{\sum \bar{A}_s}{\bar{A}_1}\right] = \xi_1\bar{A}_1/\tau_1$

En effet, la quantité entre crochets dans l'éq. [14] est identique à l'expression donnée par Aniansson et Wall (16) pour l'inverse du temps de relaxation associé au processus d'échange. L'équation [11] devient donc:

[15] $\xi_1\bar{A}_1 = \Delta\bar{A}_1 = \bar{k}^+\Delta K\tau_1 \sum \bar{A}_s/(1 + i\omega\tau_1)$

En outre on sait que:

[16] $\frac{\mathrm{d}\log K}{\mathrm{d}P} = -\frac{\Delta V_0}{\underline{R}T}$

d'où:

$$\Delta K \cong -\frac{\Delta V_0}{\underline{R}T}\bar{K}\Delta P$$

où ΔV_0 est le changement de volume associé à la réaction d'échange d'un ion amphiphile.

La combinaison des eqs [15] et [16] conduit à:

[17] $\frac{\Delta\bar{A}_1}{\Delta P}(1 + i\omega\tau_1) = -\frac{\bar{k}^-\Delta V_0\tau_1\sum\bar{A}_s}{\underline{R}T}$

La partie relaxationnelle (chimique) β_R de la compressibilité du système étudié s'exprime en fonction de $\Delta\bar{A}_1/\Delta P$ (qui est en fait la dérivée du degré d'avancement de la réaction par rapport à la pression) et est de plus reliée à l'absorption par longueur d'onde μ_M à la fréquence angulaire $\omega = 1/\tau_1$ par les relations (19):

[18] $\beta_R = -\Delta V_0\frac{\Delta\bar{A}_1}{\Delta P}(1 + i\omega\tau_1) = \frac{2\mu_M}{\pi d v^2}$

où d est la densité de la solution et v la vitesse de propagation des ondes ultrasonores.

D'autre part, l'équation qui relie μ_M à l'amplitude R de la relaxation ultrasonore s'écrit:

[19] $R = 4\pi\tau_1\mu_M/10^3 v$

où le facteur 10^3 a été introduit parce que les concentrations sont exprimées en mol/L.

L'équation qui donne l'absorption ultrasonore α/f^2 (α = coefficient d'absorption ultrasonore à la fréquence f) s'écrit:

[20] $\frac{\alpha}{f^2} = \frac{R}{1 + 4\pi^2 f^2\tau_1^2}$

où l'expression de R obtenue par combinaison des éqs [17] à [19] s'écrit:

[21] $R = \frac{2\pi^2}{10^3}\frac{dv}{\underline{R}T}\Delta V_0^2\tau_1^2\bar{k}^-\sum\bar{A}_s$

soit, en tenant compte de:

[22] $\sum \bar{A}_s = (C - \bar{A}_1)/n \cong (C - \mathrm{cmc})/n$

et en posant

[23] $a = (C - \bar{A}_1)/\bar{A}_1 \cong (C - \mathrm{cmc})/\mathrm{cmc}$

où C est la concentration de l'amphiphile en mol/L et où la concentration $\bar{A}_1$ du monomère est supposée égale à la concentration micellaire critique dénotée cmc,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

$$[24] \quad R = \frac{2\pi^2}{10^3}\frac{dv}{RT}\Delta V_0{}^2 \text{ cmc } \left(\frac{k^-}{n}\right) a\tau_1{}^2$$

avec

$$[25] \quad \frac{1}{\tau_1} = \frac{k^-}{\sigma^2}\left(1 + \frac{\sigma^2}{n}a\right)$$

L'expression [24] de R est identique à un facteur 2 près, à celle donnée par Teubner (17)[1]. Cet auteur a en fait établi l'expression du coefficient d'absorption de l'énergie transportée par l'onde ultrasonore, qui est deux fois plus grand que le coefficient d'absorption de l'amplitude de l'onde ultrasonore. Les appareillage utilisés en laboratoire mesurent ce dernier coefficient et il convient donc d'utiliser l'expression [24] dans les calculs relatifs à l'interprétation de ces mesures.

On peut facilement montrer par manipulation des éqs [20] et [24] que

(*1*) α/f^2 et R passent par un maximum pour des valeurs a_M et $a_{M,0}$ de a respectivement données par:

$$[26] \quad a_M = \left[\frac{\omega^2 + (\bar{k}^-/\sigma^2)^2}{(\bar{k}/n)^2}\right]^{1/2}$$

et

$$a_{M,0} = \frac{n}{\sigma^2}$$

(*2*) Les variations de α/f^2 et R au voisinage de la cmc ($a = 0$) sont linéaires avec C avec des pentes p et p_0 à la cmc, respectivement données par:

$$[27a] \quad p = 2\pi^2 dv\Delta V_0{}^2(\bar{k}^-/n)/10^3\underline{R}T[(\bar{k}^-/\sigma^2)^2 + \omega^2]$$

$$[27b] \quad p_0 = 2\pi^2 dv\Delta V_0{}^2(\bar{k}^-/n)/10^3\underline{R}T(\bar{k}^-/\sigma^2)^2$$

L'équation [27*a*] donne la possibilité d'obtenir $\bar{k}^-/n$ à partir de la courbe $\alpha/f^2 = f(C)$ à une fréquence donnée lorsque ΔV_0 a été préalablement déterminé. En fait, cette relation permet d'élargir les possibilités d'étude des amphiphiles par absorption ultrasonore, jusqu'ici restreintes aux amphiphiles comportant *moins* de 12 atomes de carbone, à des amphiphiles comportant jusqu'à 13 atomes de carbone dans leur chaîne alkyle. En effet, pour ces derniers on ne peut, avec les appareillages existant au laboratoire, mesurer l'absorption ultrasonore à des fréquences suffisamment basses pour la détermination de τ_1 et ainsi de $\bar{k}^-/n$, à partir des spectres ultrasonores (courbes α/f^2 en fonction de f). Il est par contre possible de déterminer les courbes $\alpha/f^2 = f(C)$ à une fréquence donnée. La pente de cette courbe à C = cmc permet alors d'obtenir $\bar{k}^-/n$, connaissant ΔV_0 et en supposant $(\bar{k}^-/\sigma^2)^2 \ll \omega^2$. La validité de cette approximation peut être contrôlée a posteriori, une fois $\bar{k}^-/n$ calculé. En effet, en prenant $\sigma^2/n = 2$ (ce qui correspond à une valeur maximum de n/σ^2) on peut alors vérifier que

$$(\bar{k}^-/n)^2(n/\sigma^2)^2 \ll \omega^2$$

Si celà n'est pas le cas, il suffit de refaire les mesures en fonction de la concentration à une fréquence plus élevée, de sorte que l'inégalité ci-dessus soit satisfaite.

Dans la suite, $\bar{k}^-$ est écrit k^-, par souci de simplification.

III. Partie expérimentale

(1) Méthodes

Le décanoate de potassium a été préparé par neutralisation stoechiométrique d'acide décanoique (Fluka purissinum) par de la potasse 1 *M* (Titrisol Merck).

Les absorptions ultrasonores ont été mesurées en utilisant un dispositif interferométrique aux fréquences inférieures à 5 MHz et un dispositif impulsionnel aux fréquences plus élevées (4).

Les nombres d'agrégation des micelles de décanoate de potassium en présence de KCl n'étant pas connus nous les avons déterminés en utilisant à cet effet la méthode récemment proposée par Turro et Yekta (20). Cette méthode repose sur la mesure de l'intensité de fluorescence d'une solution micellaire dans laquelle on introduit de faibles quantités d'une sonde de fluorescence et d'un inhibiteur. Ces deux types de molécules se distribuent parmi les micelles selon une statistique de Poisson. On peut alors montrer (20) que la relation suivante existe entre les concentrations c_Q et C_M de l'inhibiteur et des micelles et les intensités de fluorescence I et I_0 en présence et en l'absence d'inhibiteur:

$$[28] \quad I/I_0 = \exp(-c_Q/C_M)$$

avec

$$[29] \quad C_M = \frac{C - \text{cmc}}{n}$$

Comme Turro et Yekta (20) nous avons utilisé le 9-méthylanthracène comme inhibiteur et le [ruthénium tris(bipyridine)]$^{2+}$ comme sonde de fluorescence. Le 9-méthylanthracène utilisé (Aldrich 99%) contenait en fait près de 30% d'impuretés insolubles dans les solutions micellaires. Nous l'avons purifié par recristallisation fractionnée dans l'éthanol. Le [ruthénium tris(bipyridine)]$^{2+}$ était sous forme de sulfate. Nous avons vérifié la bonne marche de l'équipement utilisé et la bonne qualité des produits en reproduisant les expériences de Turro et Yekta sur le dodecylsulfate de sodium dans l'eau (20). Le nombre d'agrégation obtenu dans ces expériences: 62, était égal à celui donné par ces auteurs.

Les mesures ont été effectuées en gardant constantes les concentrations en inhibiteur (10^{-4} *M*) et en sonde de luminescence (2×10^{-4} *M*) et en faisant varier la concentration C en décanoate de potassium. Dans la pratique, ceci est obtenu en mélangeant deux solutions de décanoate de potassium de concentrations différentes mais de même teneur en inhibiteur et en sonde et en mesurant l'intensité de fluorescence à 600 nm. Le tracé de $(\log_e I_0/I)^{-1}$ en fonction de C donne une droite dont la pente fournit le nombre d'agrégation n des micelles. La cmc est la concentration pour laquelle $(\log_e I_0/I)^{-1}$ s'annule. Notons que si cette méthode fournit des valeurs relativement

0,1	0,075
0,25	0,058
0,5	0,040

[a]Valeur déterminée dans la réf. 4.

précises de *n*, les valeurs de cmc sont beaucoup moins précises que celles déterminées par d'autres méthodes, telles la conductivité ou l'absorption ultrasonore.

Nous avons ainsi obtenu en l'absence de KCl, et en présence de 0,1 *M* et 0,5 *M* de KCl les valeurs 32, 38 et 66 pour *n* et les valeurs 0,105 *M*, 0,085 *M* et 0,035 *M* pour la cmc, respectivement.

La valeur $n = 32$ obtenue en l'absence de KCl est en excellent accord avec les valeurs données par Tartar (21) pour des amphiphiles ayant la même chaîne alkyle. Cette valeur est également en bon accord avec celle que l'on peut calculer en supposant une micelle sphérique de rayon égal à celui de la chaîne étirée et ayant une densité égale à celle de la paraffine correspondante (21).

(2) Résultats ultrasonores

Les mesures d'absorption ultrasonore à une fréquence donnée (2,8 MHz) ont été utilisées pour obtenir les valeurs des cmc du décanoate de potassium en présence de KCl (voir fig. 1 et tableau 1). On sait en effet que les courbes $\alpha/f^2 = f$(concentration) présentent une augmentation de pente importante au-delà de la cmc, ce qui permet une détermination précise de cette concentration (4, 5). Les valeurs des cmc obtenues par absorption ultrasonore confirment la validité de la méthode

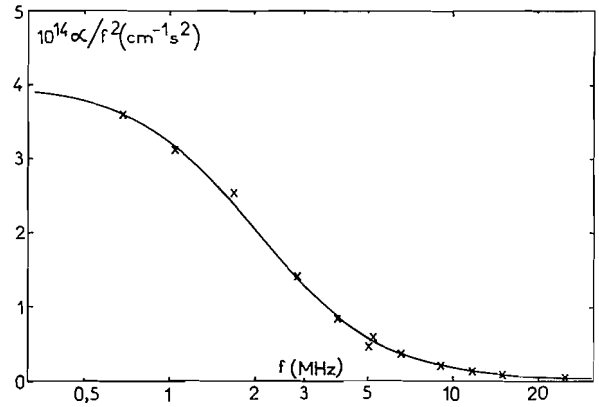

FIG. 2. Spectre ultrasonore d'une solution de décanoate de potassium $C = 0{,}28$ *M*, dans $H_2O - 0{,}1$ *M* KCl.

d'inhibition de fluorescence utilisée dans ce travail pour la détermination des nombres micellaires.

Comme le prévoient les calculs de Shinoda (22), la variation de log cmc en fonction de log (cmc + c_{KCl}) est une droite dont la pente (−0,56) se situe dans le domaine prévu par la théorie (−0,4 à −0,6).

L'absorption ultrasonore de solutions de décanoate de potassium en présence de KCl a été mesurée en fonction de la fréquence. L'équation:

$$[30] \quad \frac{\alpha}{f^2} = \frac{R}{1 + 4\pi^2 f^2 \tau_1^2} + B$$

a été utilisée pour rendre compte des résultats expérimentaux, *B* étant une constante ajustable généralement peu différente de l'absorption du solvant. A cet effet, nous avons adopté une méthode de moindres carrés pondérés, à deux paramètres *R* et τ_1, qui minimise la quantité

$$[31] \quad Q = \sum \left[\left[\left(\frac{\alpha}{f^2}\right)_{exp} - \left(\frac{\alpha}{f^2}\right)_{cal} \right] \Big/ \left(\frac{\alpha}{f^2}\right)_{exp} \right]^2$$

le paramètre *B* ayant été pris égal à 22×10^{-17} cm^{-1} s^2, valeur de α/f^2 pour l'eau et les solutions de KCl utilisées dans ce travail. Dans *Q* la somme est prise sur un nombre de termes égal au nombre de résultats expérimentaux pour chaque solution étudiée. La fig. 2 montre un exemple de spectre ultrasonore: la courbe en trait plein qui obéit à l'éq. [30] est celle qui rend le mieux compte des résultats expérimentaux. Le tableau 2 donne les valeurs de *R* et τ_1 ainsi obtenues pour chaque solution étudiée. Nous avons également fait figurer les valeurs obtenues à partir des résultats de Graber et coll. (4) pour le décanoate de potassium dans l'eau. Ces valeurs diffèrent légèrement de celles publiées (4), ces dernières n'ayant pas été obtenues par une méthode de moindres carrés pondérés mais par une méthode qui minimise la sommes des numérateurs dans l'éq. [31] et met ainsi un poids très grand sur les résultats à basse fréquence qui sont les moins précis.

Dans une deuxième étape l'éq. [25] a été utilisée pour rendre compte des résultats relatifs à τ_1, avec k^-/n et k^-/σ^2 comme paramètres ajustables (voir fig. 3). La méthode de moindres carrés pondérés conduit à des valeurs relativement précises de k^-/n qui représente la pente des droites $1/\tau_1 = f(a)$. Par contre les valeurs obtenues pour k^-/σ^2 (ordonnée à l'origine dans la représentation précédente) peuvent être très imprécises et il convient donc de déterminer cette quantité ou tout autre quantité permettant d'accéder à σ par une autre méthode.

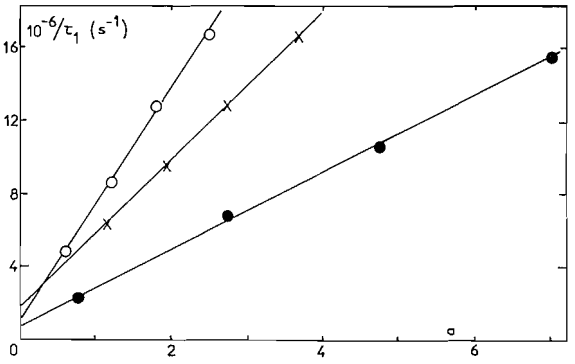

FIG. 3. Solutions de décanoate de potassium à 25°C. Variation de $1/\tau_1$ en fonction de a, en l'absence de KCl (○) et avec 0,1 M KCl (×) et 0,5 M KCl (●). Les droites obéissent l'éq. [25] et ont été obtenues comme indiqué dans le texte.

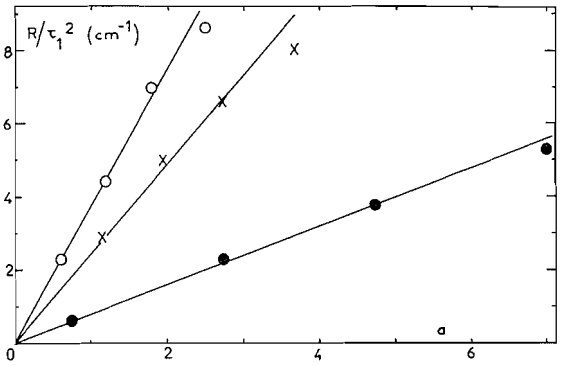

FIG. 4. Solutions de décanoate de potassium à 25°C. Variation de R/τ_1^2 en fonction de a sans KCl (○), avec 0,1 M KCl (×) et 0,5 M KCl (●). Les droites obéissent l'éq. [24] et ont été obtenues comme indiqué dans le texte.

Les valeurs de k^-/n et l'éq. [24] ont ensuite été utilisées pour rendre compte des valeurs de R/τ_1^2 en fonction de a, avec ΔV_0^2 comme seul paramètre ajustable (voir fig. 4).

Dans une dernière étape, les valeurs de ΔV_0 et k^-/n obtenues comme on vient de le dire ont été insérées dans l'éq. [24] où τ_1 a été remplacé par son expression [25] pour rendre compte des valeurs de R, avec σ^2/n comme seul paramètre ajustable (voir fig. 5). Les valeurs de σ^2/n ainsi obtenues sont en excellent accord avec celles calculées en formant le rapport $(k^-/n)/(k^-/\sigma^2)$ à partir des valeurs obtenues plus haut.

Les valeurs de k^-/n, ΔV_0 et σ^2/n obtenues comme on vient de le décrire sont données dans le tableau 3.

Nous avons également fait usage des courbes $\alpha/f^2 = f$(concentration) à fréquence fixe utilisées pour obtenir les cmc. Ces courbes obéissent à l'équation résultant de la combinaison des éqs [20] et [24] et la pente de ces courbes au voisinage de la cmc est donnée par l'éq. [27a]. Nous avons calculé à partir des valeurs de ces pentes, k^-/n en prenant les ΔV_0 de la colonne (d) du tableau 3 et inversement les ΔV_0, en prenant les valeurs de k^-/n de la colonne (a) du tableau 3. On voit que les valeurs de k^-/n obtenues à partir des droites $1/\tau_1 = f(C)$ sont en bon accord avec celles calculées comme il vient d'être décrit. De même les deux séries de valeurs de ΔV_0 sont en bon accord. Notons qu'à la fréquence 2,82 MHz à laquelle ont été réalisées les mesures de $\alpha/f^2 = f(C)$ en présence de KCl, l'éq. [27a] se simplifie car $(k^-/\sigma^2)^2 \ll \omega^2$. En l'absence de KCl, nous avons fait usage des valeurs de $\alpha/f^2 = f(C)$ rapportées par Graber et coll. (4) à 3,37 MHz pour calculer ΔV_0 et k^-/n comme nous venons de le dire.

Les trois dernières colonnes du tableau 3 donnent les valeurs de k^- calculées à partir de k^-/n (colonne (a)) et n, de σ

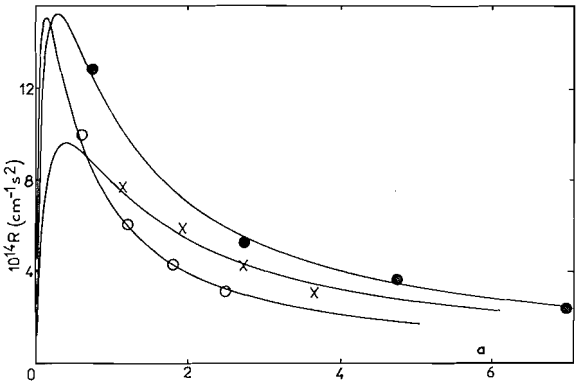

FIG. 5. Solutions de décanoate de potassium à 25°C. Variation de R en fonction de a sans KCl (○), avec 0,1 M KCl (×) et 0,5 M KCl (●). Les courbes obéissent l'éq. [24] et ont été obtenues comme indiqué dans le texte.

calculées à partir de σ^2/n (colonne (a)) et n et k^+, constante de vitesse de la réaction d'association d'un ion amphiphile à une micelle, calculée à partir de la relation (23)

[32] $k^+ = k^-/\text{cmc}$

IV. Discussion des résultats

La variation de k^+ avec la force ionique est dans le sens attendu. En effet, l'addition de sel apporte une

réduction des répulsions électrostatiques entre ions détergents libres et micelles, d'où une association plus facile de ces ions aux micelles, et des valeurs plus élevées de k^+. Il est intéressant de comparer les valeurs de k^+ du tableau 3 à la valeur $k_d{}^+$ calculée pour une réaction d'association complètement contrôlée par la diffusion, entre deux espèces non chargées, en utilisant à cet effet la relation de Smoluchowski:

$$[33] \quad k_d{}^+ = 4\pi r(D_{mic} + D_{mon})N_A/1000$$

Dans cette équation r représente la distance minimum d'approche ou distance de réaction, N_A est le nombre d'Avogadro, et D_{mic} et D_{mon} les coefficients de diffusion de translation des micelles et des ions détergents libres, respectivement. On prend pour r la longueur de la chaîne alkyle de l'ion décanoate soit 13×10^{-8} cm. En effet, on peut considérer que la collision entre une micelle et un ion détergent libre a lieu lorsque la distance entre la surface micellaire et le groupe chargé de l'ion détergent devient égale à la longueur de la chaîne alkyle. D'autre part, en première approximation D_{mic} peut être négligé devant D_{mon}. Cette dernière quantité a été calculée à partir de la conductivité équivalente limite de l'ion décanoate, en utilisant la relation donnée par Robinson et Stokes (24). On trouve ainsi $D_{mon} = 5,3 \times 10^{-6}$ cm^2 s^{-1}. L'insertion des valeurs de r et D_{mon} dans l'éq. [33] donne:

$$k_d{}^+ = 5,2 \times 10^9 \, M^{-1} \, s^{-1}$$

Cette valeur est proche de celle obtenue pour k^+ à forte force ionique. Elle diffère de la valeur obtenue à faible force ionique par un facteur 2,6, qui semble donc essentiellement dû aux répulsions électrostatiques.

Aniansson et coll. (25) ont donné l'équation suivante:

$$[34] \quad \frac{k^-}{n} = \frac{D_{mon}}{l_b{}^2} \exp(-\varepsilon/kT)$$

l_b est une longueur voisine de 1,265 Å indépendamment de la force ionique et ε représente la variation d'énergie libre associée au transfert d'un amphiphile d'une position dans laquelle sa chaîne alkyle est complètement à l'intérieur de la micelle, à une position où le groupe méthyl terminal est en contact avec la surface de la micelle. Cette expression ne permet pas de prévoir facilement le sens de la variation de cette quantité et donc de k^- avec la force ionique. En effet, à la variation de n se superpose celle de ε qui est la somme de deux contributions de signes opposés: l'une, ε_E d'origine électrostatique et l'autre, ε_H, d'origine hydrophobe. L'augmentation de force ionique se traduit par une diminution de ε_E mais également de ε_H. Le fait que k^- ne diminue que légèrement sous l'effet de la force ionique alors que n est doublé, indique que $e^{-\varepsilon/kT}$ diminue donc que ε augmente. Le terme ε_E diminue donc plus que ε_H en présence de 0,5 M KCl, par rapport à la situation qui prévaut en l'absence de force ionique.

Considérons maintenant les valeurs de ΔV_0 qui est le changement de volume associé au transfert d'un ion amphiphile de la phase aqueuse à la phase micellaire. En l'absence de force ionique le ΔV_0 du décanoate de potassium a été obtenu par mesure des densités (26, 27). La valeur moyenne est 9,5 cm^3/mol. Cette valeur est environ 35% plus grande que celle calculée à partir des résultats de Graber et coll. (4). L'amplitude R de la relaxation ultrasonore étant proportionnelle à $\Delta V_0{}^2$, la différence entre les valeurs obtenues par densité (26, 27) et par absorption ultrasonore correspond à une erreur par un facteur 1,84 sur R. On doit donc conclure que la valeur obtenue à partir des résultats de Graber et coll. (4) est trop faible, en partie peut être en raison d'erreurs dans

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

l'étalonnage des appareils ultrasonores utilisés à l'époque. Les résultats obtenus dans notre travail, c'est-à-dire en présence de force ionique semblent raisonnables sur la base de la différence entre les ΔV_0 pour le décanoate et le nonanoate de sodium (26, 27) et de la variation du ΔV_0 du nonanoate de sodium avec la force ionique (28). Ainsi ce ΔV_0 passe de 9,2 à 7,8 cm^3/mol lorsque la concentration en NaCl passe de 0 à 0,4 M (l'effet de la nature du contreion sur ΔV_0 est très faible). Notons toutefois que les calculs de ΔV_0 ont été faits sur la base d'équations dans lesquelles les activités des solutés ont été remplacées par les concentrations. Cette approximation, valable pour les solutions diluées, ne s'applique plus pour les concentrations auxquelles ont été réalisées les expériences discutées ici et peut donner lieu à d'importantes erreurs, particulièrement dans le cas des résultats relatifs aux mesures effectuées en l'absence de force ionique (29).

Nous terminons cette discussion par les valeurs de σ^2/n. En présence de force ionique, les valeurs obtenues pour cette quantité sont très proches de celles trouvées pour de nombreux autres détergents, les alkylsulfates de sodium 23 par exemple et correspondent à des indices de polydispersité de 1,05 environ. Au contraire, la valeur $\sigma^2/n = 6$ obtenue à partir des résultats de Graber et coll. (4) semble trop élevée. A ce point il convient à nouveau de rappeler que l'erreur sur les valeurs de σ^2/n (et donc sur σ) est importante. Néanmoins, la concordance entre les valeurs de σ^2/n dans les colonnes (*a*) et (*c*) tout comme celles de k^-/n dans les colonnes (*a*) et (*b*) et de ΔV_0 dans les colonnes (*d*) et (*e*) souligne la cohérence des différentes équations utilisées et également des résultats dérivés à partir des valeurs des temps de relaxation et des amplitudes de relaxation qui sont des quantités de nature différente.

Cette conclusion donne une base solide à l'utilisation des équations établies dans ce travail pour l'interprétation des résultats ultrasonores relatifs à d'autres systèmes (30).

Photo- and thermal isomerization of some 1-methoxyallyl cations

RONALD F. CHILDS[1] AND MARK E. HAGAR

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 19, 1980

RONALD F. CHILDS and MARK E. HAGAR. Can. J. Chem. **58**, 1788 (1980).

The 1-methoxy-, 1-methoxy-3-methyl-, and 1-methoxy-2,3-dimethylallyl cations, **2**, **5**, and **9**, were prepared by treatment of the dimethyl acetals of acrolein, crotonaldehyde, and tiglaldehyde, respectively, with FSO_3H. Each of these ions was capable of existing in various stereoisomeric forms. The thermodynamically preferred conformation of **2**, **5**, and **9** all had a C1—O, *E* configuration and **5** and **9** an *E* configuration about the C2—C3 bonds. Irradiation of FSO_3H solutions of these ions at −70°C using 254 nm light caused them to be converted to the other stereoisomers. Relatively efficient photoisomerism about both the C1—O and C2—C3 bonds was observed. The rates of the reverse thermal conversion of the photoproducts to **2**, **5**, and **9** were measured and on the basis of medium and substituent effects it was concluded that thermal isomerism about the C1—O bond takes place by an inversion process while stereomutation about the C2—C3 bond involves the addition of base to C3.

RONALD F. CHILDS et MARK E. HAGAR. Can. J. Chem. **58**, 1788 (1980).

On a préparé les cations allyliques: méthoxy-1, méthoxy-1 méthyl-3 et méthoxy-1 diméthyl-2,3 (**2**, **5** et **9**) en traitant respectivement les acétals diméthylés de l'acroléine, de la crotonaldéhyde et de la tiglaldéhyde par du FSO_3H. Chacun de ces isomères peut exister sous différentes formes stéréoisomères. La conformation thermodynamique préférée par **2**, **5** et **9** est celle où tous les trois ont une configuration *E* en C1—O et dans le cas de **5** et de **9** une configuration *E* autour des liaisons C2—C3. Par irradiation à 254 nm ces ions et solution dans le FSO_3H se transforment en d'autres stéréoisomères. On a observé une isomérisation photochimique relativement efficace autour des deux liaisons C1—O et C2—C3. On a mesuré les vitesses de transformation thermique inverse de ces produits photochimiques en **2**, **5** et **9** en fonction du milieu et des effets de substituants et on a conclu que l'isomérisation thermique autour de la liaison C1—O se fait par inversion tandis que la stéréomutation autour de C2—C3 implique l'addition d'une base à C3.

[Traduit par le journal]

There have been several reports over the past few years on the photoreactions of protonated unsaturated carbonyl compounds (1, 2).[2] Frequently these cationic systems have been found to undergo photoisomerizations which are very similar to those encountered with the corresponding neutral compounds. A case in point, which forms the substance of this present paper, concerns the α,β-unsaturated carbonyl compounds. These, when irradiated in conventional solvents (3) or as protonated species in super acid media (2), undergo stereomutation about the carbon–carbon double bond. Protonated carbonyl compounds, however, have an additional mode of photoisomerization available which is not open to the neutral compounds, namely isomerization about the carbon–oxygen double bond. This potential photoreaction has not been detected with any of the protonated carbonyl compounds so far investigated.

Stereoisomerism about the carbon–oxygen bond of protonated carbonyl compounds is well established (4). In general, protonation of a carbonyl compound leads to a thermodynamic equilibrium mixture of the two possible stereoisomers. Interconversion of the two stereoisomers is facile and a variety of mechanisms have been suggested to account for this stereomutation. Exchange of the proton on oxygen with the acid pool is one of the more frequently encountered pathways for these isomerizations (5).

In order to eliminate the possibility of exchange reactions taking place with the acid medium and thus rendering potential photoisomerizations about the carbon–oxygen bond undetectable, it was decided to work with the corresponding *O*-methyl derivatives. We report here the preparation, photoisomerism, and thermal rearrangements of several 1-methoxyallyl cations. A preliminary account of part of this work has appeared (6).

Results

Preparation of Cations

1-Methoxyallyl cations were prepared by the protonation and cleavage in FSO_3H of the dimethyl acetals of several unsaturated aldehydes. In order to get clean solutions of these ions, it was found best to extract the acetal from Freon 11 into the acid at −78°C. The pale yellow solutions prepared by this route were stable for long periods and showed no discoloration when left at room temperature for several hours. Indeed a convenient way of removing the Freon was to purge the solutions with an

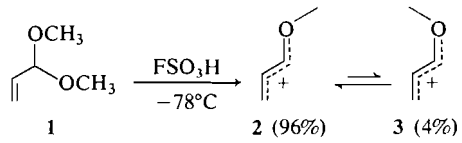
argon stream at room temperature. Protonated methanol (7), exhibiting a methyl resonance at ca. δ 4.25, was also present in the solutions. This did not interfere with any of the subsequent studies, although it was noted that thermally induced reactions of $CH_3OH_2^+$ occurred when the samples were kept at high temperatures.

Solution of acrolein dimethyl acetal, **1**, in FSO_3H gave **2**. The identity of this ion was evident from its ^{1}H nmr spectrum (Fig. 1A, Table 1) which was very similar to that of protonated acrolein (8). Neglecting stereoisomerism about the C1—C2 bond of **2**, which is expected to have a very low barrier to rotation (9), there are two possible isomers of the 1-methoxyallyl cation. It was clear from the nmr spectrum of the cation derived from **1** that one of the two possible isomers predominated. On the basis of the known steric preferences for protonated enals (4), the C1—O, *E* configuration was assigned to **2**.



As will be shown later, the C1—O, *Z* isomer **3** can be prepared and knowing its nmr spectrum it

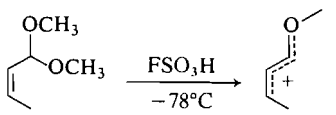
1 **2** (96%) **3** (4%)

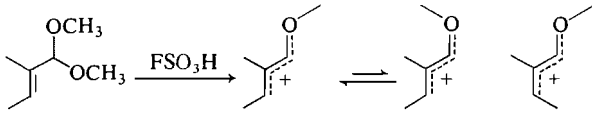


was possible to detect a small amount (4%) of **3** in equilibrium with **2**. This low concentration of **3** was observed in all samples of **2** that were prepared, even when the acid solutions were kept at temperatures well above those required for the thermal interconversion of **2** and **3**.

Extraction of **4** into FSO_3H led to the formation of predominantly one cation which was identified as **5**. The ^{1}H nmr spectrum of **5** (Fig. 2A) was very similar to that of the corresponding protonated aldehyde (2). It was clear that low concentrations of additional cations were present. Warming the solution to room temperature for several hours caused one of the minor cations to isomerize to **5**. This ion, which is characterized by a doublet resonance at δ 9.50 (Fig. 2A), was identified as **6**. (Evidence to support this will be presented later.) It would appear that **6** arises from protonation of small amounts of the dimethyl acetal of *cis*-crotonaldehyde formed during the synthesis of **1**.

The other minor isomer present was identified as

4 **5** (87%) **7** (13%)



6

7, the C1—O bond isomer of **5**, *vide infra*. The ratio of **5** to **7** was found to be 87 to 13 at −20°C.

Treatment of tiglaldehyde acetal **8** with FSO_3H gave very largely **9** together with a small amount of **10** (ca. 10%). Again it would seem that this minor isomer results from a *cis* impurity in the starting acetal. When the acid samples were held at 50°C the minor isomer reverted to **9**. No evidence for the presence of **11**, the C1—O *Z* isomer of **9**, could be detected either on the initial protonation or after the sample had stood at room temperature for a while.

The uv spectra of the cations **2**, **5**, and **9** were obtained at room temperature in concentrated H_2SO_4 and are summarized in Table 2. In each case the ions exhibited an intense absorption in the neighbourhood of 250 nm.

8 **9** **11** **10**

Photoisomerizations of the cations were carried out at low temperature (−70°C) using 254 nm light. Reactions were followed by low temperature ^{1}H nmr assay directly on the irradiated acid solutions. Degassing the samples prior to irradiation appeared to make no difference to the products observed.

Irradiation of a FSO_3H solution of **2** led to the formation of a new cation. The nmr spectrum of the resulting mixture (Fig. 1B) clearly showed that the product was closely related to **2**. Three vinyl resonances were present which had a very similar coupling pattern to that of **2**. In addition the new cation had an *O*-methyl group resonance at δ 4.87. On this basis the photoproduct was assigned the structure **3**. A similar photoisomerization was observed when **2** was irradiated in FSO_3H/SbF_5 (3:1) at low temperatures.

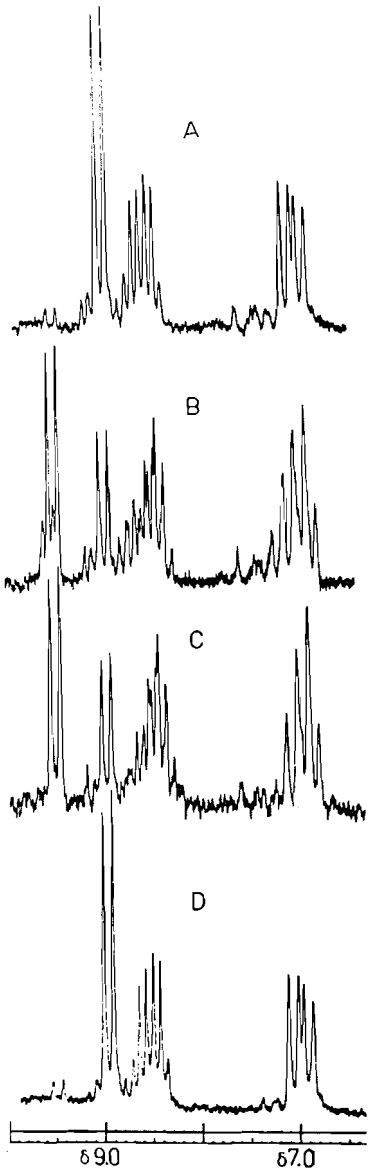

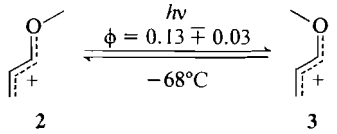

FIG. 2. Part of the ^{1}H nmr spectrum of **5**. A, prior to irradiation; B, after irradiation, sample kept at −50°C; C, after warming sample to −20°C; D, after warming to 38°C.

A photostationary state was set up between **2** and **3** consisting of 73% **2** and 27% **3** at −70°C. The quantum efficiency of the conversion of **2** to **3** was measured at −68°C using a relative method. A quantum yield of 0.13 ∓ 0.03 was found with FSO_3H as the acid medium. It was not possible to measure the quantum efficiency of the reverse reaction as we have been unable to generate a mixture of **2** and **3** which contained an excess of the latter ion.

On warming the acid solutions containing **2** and **3** to −20°C, a clean rearrangement of the latter ion to **2** was observed. The rate constants for this first order reaction were measured in FSO_3H and FSO_3H/SbF_5 media and are given in Table 3.

2 **3**

Irradiation of a cation mixture containing mostly **5**, as illustrated in Fig. 2A, or a mixture consisting of only **5** and **7**, led to the formation of a complex mixture of ions, Fig. 2B. On the basis of the results obtained with **2** above and protonated crotonaldehyde previously (2), it was expected that photoisomerization about both the C,C and C,O double bonds of **5** could take place to give a mixture of four isomers. Examination of the downfield region of the ^{1}H nmr spectrum of the mixture showed four doublets to be present. These doublet resonances were in a typical position for the C1-proton signals of the 1-methoxyallyl cations (Fig. 2B).

The system could be partially simplified by warming the FSO_3H solution to −20°C when two of the cations largely reverted to the other two (Fig. 2C). One of the two remaining ions was the starting cation **5**, while the other appeared to be **6**. Evidence for this latter assignment comes from the magnitude of the coupling constant between the two protons on the C2—C3 bond, J = 10.5 Hz. This coupling constant is very similar to that found for protonated *cis*-crotonaldehyde and is indicative of the C2—C3 bond of **6** having a *Z* configuration. When the acid solutions were warmed above room temperature, **6** was found to isomerize back to **5** (Fig. 2D).

With isomerism about the C2—C3 bond of **6** occurring at room temperature and above, then the reactions taking place at −20°C must have been stereomutations about the C1—O bonds. This means that **6** would be expected to have the more stable *E*-conformation about the C1—O bond and that the other two isomers seen initially at low temperatures would correspond to the C1—O *Z* isomers of **5** and **6**. One of these isomers is in thermal equilibrium with **5** in the final solution and

After heating to 38°C	87	0	13	0

5 **6** **7** **12**

was given the structure **7**. The other, by process of elimination, must be **12**. A summary of the composition changes as a function of irradiation and heating cycles is given in Table 4. The rate constants for the isomerizations are given in Table 3.

Measurement of the quantum yields associated with the various reactions taking place on irradiation of **5** was complicated by our inability to obtain pure samples of all the possible isomers. The only value obtained with any degree of confidence was that of the conversion of **5** to **6**, $\Phi = 0.24 \mp 0.05$ at −68°C in FSO_3H.

In contrast to the complex situation encountered with **5**, irradiation of **9** led to the production of only one new cation. The photoproduct was stable at room temperature and only underwent a slow isomerization to **9** when heated to 50°C. The high temperature required for this rearrangement indicated that the photoproduct was **10**, the C2—C3 isomer of **9**. No evidence for the presence of any additional isomers of **9** and **10** could be detected even when the ^1H nmr spectra of the solutions were recorded at −70°C immediately after irradiation.

Discussion

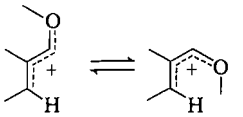
The results described above for **2**, **5**, and **9** clearly indicate that photoinduced stereomutations can occur about both the C1—O and C2—C3 partial bonds of these cations. Both of these processes have relatively high quantum yields suggesting that twisting about these bonds constitutes the major relaxation pathway for the excited states involved. In this regard the photochemical behaviour of these cations is more similar to that of a diene than that of the corresponding neutral carbonyl compounds (10).

One of the issues that has been investigated with the photoisomerizations of dienes is whether rotation about both double bonds can take place on a single excitation. A similar question can be raised with the 1-methoxyallyl cations. In this present work, however, it has not been possible to obtain sufficient quantum yield data or relative rates of initial isomerizations to answer this point.

Two-bond isomerizations would be expected only if triplet states of the 1-methoxyallyl cations were involved in these photoisomerizations. This would seem unlikely under the conditions used and most probably singlet π,π^* states are involved. Certainly such singlet states would be the lowest energy states available under the direct irradiation conditions used in this work (11). Intersystem crossing to the triplet manifold would be expected to be relatively inefficient, just as has been found for the simple dienes (10). Further evidence to support the suggestion that singlet states are involved in these reactions comes from the absence of any effect when oxygen is present. Assuming a singlet state to be involved, then perhaps the best way of viewing the reactions of these cations is for the initial excitation to give a planar diradical cation which can undergo rotation about either the C1—O or C2—C3 bonds. For isomerization about the C,C bond, the best representation of the structure when the C2—C3 bond is twisted through 90° would be one with the positive charge very largely localized on C3 (12).

Thermal Isomerizations

As can be seen from the data in Table 3, there is a marked contrast in the effect of medium change (FSO_3H, FSO_3H/SbF_5) on the rate of



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

stereoisomerism about the C2—C3 and C1—O bonds of the various cations. The large decrease in rate constant observed on addition of SbF_5 to the FSO_3H in the case of the conversion of **6** to **5** parallels that found for the corresponding protonated aldehyde isomerization (2) and indicates that this particular reaction proceeds by the specific interaction of base (FSO_3^-) with C3 during the isomerization (13).

On the other hand, stereomutation about the C1—O bond cannot involve such a base addition pathway. As can be seen by the data in Table 3, the rate constants for these reactions are almost medium independent. Moreover, the effect of introduction of a methyl group at C3 (cf. **3** → **2** with **7** → **5**) is also very small, indicating that there is no major change in charge distribution during the isomerization about the C1—O bond. Rather it would seem that this stereomutation involves an inversion at oxygen (14, 15, 16). The isoelectronic aldimines and ketimines undergo a similar inversion at nitrogen (15, 17).

The situation of the *O*-methyl cations derived from tiglaldehyde merit special mention in that no evidence was found for isomerism about the C1—O bond of these cations. The difference between the tiglaldehyde based systems and the other 1-methoxyallyl cations is the presence of the methyl group on C2. This will result in substantially increased steric interactions when the C1—O bond is in the *Z* configuration. If cation **11** were to adopt what seems to be the usually preferred C1—C2, *E* conformation, then a severe steric interaction between the methyl groups on C2 and the oxygen would result. The magnitude of this steric strain in the directly comparable allyl cations has been found to be of the order of 6 kcal/mol (18). On the other hand, if **11** were to adopt the C1—C2, *Z* configuration, then a severe interaction between the methyl group on oxygen and the C3 proton would result.

This steric strain associated with the *O*-methyl group interactions will have the effect of raising the ground state energy of the C1—O, *Z* isomers in the tiglaldehyde based systems. Consequently, in the equilibrium studies, it is not surprising that **11** was not detected in the presence of **9**. Moreover, this steric strain would also be reflected in a reduced barrier to the thermal isomerization of **11** to **9**. It would appear in the case of the photoisomerization of **9** that the reverse thermal isomerization of **11** to **9** could be considerably faster than the rate of its formation in the photochemical step and as a consequence, even if formed photochemically, remain undetected.

11 **11**

Experimental

General

The ^1H nmr spectra were recorded on Varian HA 100 and EM 390 spectrometers. All rate measurements were carried out on the former instrument with the probe temperatures being measured with an iron–constantan thermocouple. The uv spectra were obtained on a Cary 14 spectrometer. Preparative gas chromatography was performed on an Aerograph A-90-P3 instrument using a 10 ft × 1/4 in. column packed with 15% SE30 on Chromosorb W. FSO_3H was purified by distillation, purging the distillate with dry nitrogen and a further distillation. The acid so obtained had no absorption in the uv region at wavelengths greater than 235 mm.

Acetals

A procedure similar to that described by Van Allen (18) was used in all cases. The aldehyde (3.6×10^{-2} mol), trimethyl orthoformate (4.0 mL), anhydrous methanol (1.6 mL), and NH_4NO_3 (0.14 g) were stirred at room temperature for 5 h. The reaction mixture was filtered, treated with Na_2CO_3 (0.18 g) and distilled from bulb to bulb. Final purification of the acetals was carried out by preparative gas chromatography using a column temperature of 110°C. Acrolein dimethylacetal, **1** (19), retention time 2 min; crotonaldehyde dimethyl acetal, **4**, (20), retention time 2.3 min; tiglaldehyde acetal, **8** (21), retention time 3.5 min. With the latter two compounds no evidence of the presence of small amounts of the corresponding *cis*-isomers could be detected in their ^1H nmr spectra (Table 1).

Protonations

The acetal (10–20 mg) was weighed into a nmr tube and Freon 11 (0.25 mL) added in such a way that all the acetal was washed to the bottom of the tube. The tube was cooled in Dry Ice/acetone and cold FSO_3H (0.5 mL) added. Mixing of the two layers was carried out with a glass rod. For recording the ^1H nmr spectra at low temperature, it was not necessary to remove the Freon 11. For the photochemical experiments the Freon 11 was removed by purging the solution with argon at room temperature.

Irradiations

All photoisomerizations were carried out using 10 low pressure mercury lamps (Southern New England Ultraviolet Co. RPR 2537A) arranged in a circle around a partially silvered quartz Dewar. The Dewar was cooled to −70°C with a FTS FC2084P1 refrigeration unit. The samples were contained in 5 mm quartz nmr tubes which were sealed with regular plastic caps. In most cases the samples were not degassed. Reactions were monitored by low temperature ^1H nmr. Quantum yield measurements were carried out using a relative method with the photoinduced conversion of protonated *trans*-pent-3-en-2-one to the *cis*-isomer serving as the reference actinometer. The apparatus and techniques used have been reported separately (22).

Rate Measurements

These were carried out by monitoring the change in relative concentration of the various cationic species present in a given solution by ^1H nmr as a function of time. The temperature of the probe was measured before and after each kinetic run. The

relative concentrations were estimated by using peak heights of appropriate resonance of the cations.

The partial molal volume of two nickel chelate complexes

Y. K. SZE
Whiteshell Nuclear Research Establishment, Atomic Energy of Canada Ltd., Pinawa, Man., Canada R0E 1L0

AND

W. A. E. MCBRYDE
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received September 5, 1979[1]

Y. K. SZE and W. A. E. MCBRYDE. Can. J. Chem. **58**, 1795 (1980).

Partial molal volumes have been determined for the nickel(II) complexes of ethylenediaminetetraacetic acid (*mono* complex) and methyliminodiacetic acid (*bis* complex). The formation of these is accompanied by appreciable increases in volume, greater in the case of the second ligand. The observations are discussed in terms of reduced electrostriction of water by the complexes, and the different volume increases are accounted for by structural features of the complexes which are partially confirmed by spectral measurements.

Y. K. SZE et W. A. E. MCBRYDE. Can. J. Chem. **58**, 1795 (1980).

On a déterminé les volumes molaires partiels des complexes entre le nickel(II) et les acides éthylènediaminetétraacétique (complexe simple) et méthyliminodiacétique (complexe double). La formation de ces composés s'accompagne d'une augmentation importante de volume et elle est plus élevée dans le cas du deuxième ligand. On discute de ces observations en fonction d'un électrostriction réduite de l'eau par ces complexes et on attribue les différentes augmentations de volume à des caractéristiques structurales des complexes que les mesures spectrales confirment.

[Traduit par le journal]

Introduction

This investigation was prompted by the idea that volume changes which occur during formation of metal complexes might provide some evidence concerning the accompanying uptake or exclusion of solvent molecules. The concept of solvent exclusion has proved to be of some value in accounting for changes in stability constants observed as a result of changes in solvent composition (1, 2). The apparent molal volume of a solute at infinite dilution, obtained from measurements of the densities of solutions of graded concentrations, can be conventionally divided into partial molal volumes of ions, and from the latter, volume changes that accompany formation of a given complex may be derived. However, the interpretation of such volume changes appears to be limited to systems where the formation of complex from the reactants appears to be essentially complete.

We have selected for initial study the complexes of nickel(II) formed by ethylenediaminetetraacetic acid (EDTA) and methyliminodiacetic acid (MIDA), the molecule of the latter being very close to half that of the former. These ligands yield very stable complexes with nickel(II), the *bis* complex of the latter being of the same charge as the *mono* complex of the former. The essential difference between the two complexes is the absence of one chelate ring in the methyliminodiacetate case.

Experimental

Preparation of Solutions

Five series of solutions were studied, the preparation of which is described as follows.

Series 1. $Na_2NiEDTA \cdot 2NaClO_4$

A stock solution was prepared by refluxing NiO (Baker Analyzed) with $HClO_4$ (Baker Analyzed) for 24 h. Disodium EDTA dihydrate (Baker Analyzed) and NaOH (Baker analytical concentrate) in amounts slightly less than stoichiometric for $Na_2NiEDTA \cdot 2NaClO_4$ were added and refluxing continued. A small amount of NiO remaining undissolved was removed by filtration through a tared sintered-glass crucible. Its mass was determined to be about 0.5% of the NiO taken, and the concentration of the solution calculated from the mass of NiO actually dissolved. More Na_2EDTA, NaOH, and $HClO_4$ were added to provide the exact stoichiometry represented by the above formula. When cooled, the solution was transferred to a volumetric flask, diluted to the mark, and stored at a temperature close to 25°C. More dilute solutions were prepared by weighing portions of the stock solution and mixing with water in a volumetric flask.

Series 2. $K_2NiEDTA \cdot 2KNO_3$

This solution was prepared by direct weighing from $Ni(NO_3)_2 \cdot 6H_2O$ (BDH Analar, dried over anhydrous $CaSO_4$), EDTA (Baker Analyzed), and KOH (BDH concentrated volumetric solution).

Series 3. $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$

Prepared from stoichiometric proportions of $Ni(NO_3)_2 \cdot 6H_2O$, methyliminodiacetic acid (Aldrich Analyzed 99%), and NaOH.

Series 4. $Na_4EDTA \cdot 2NaOH$

Prepared from stoichiometric proportions of $Na_2EDTA \cdot 2H_2O$ and NaOH.

Series 5. $Na_2MIDA \cdot NaOH$

Prepared from stoichiometric proportions of methyliminodiacetic acid and NaOH.

Density Measurements

Densities of the solutions were measured by a vibration-tube flow densimeter (Sodev Model 0.1 D) under flow conditions (0.1 cm^3 min^{-1} for liquid and ca. 3 cm^3 min^{-1} for nitrogen). The resonance period of the vibrating tube was measured with a Hewlett Packard digital electronic counter (Model 5245 L). The densimeter was calibrated several times during each run with dried, filtered nitrogen gas, preheated to 25 ± 0.01°C, and with filtered, deionized, distilled, and degassed water (3). The consistency of the densimeter was checked with absolute methanol (Baker Photrex Reagent).

The temperature of the vibrating tube in the densimeter was maintained by water pumped through insulated tubing from a precision thermostat. The temperature of the water in the latter was controlled by a precision controller (Tronac Inc., Model PTC-1000) equipped with anticipating and proportioning devices and an integrator circuit to minimize temperature fluctuation. Cooling water for the precision thermostat was supplied from an auxiliary thermostat maintained at 24.5 ± 0.05°C through brass coils immersed in the former.

The temperature of the precision thermostat was set at 25°C by means of a thermometer with 0.1°C subdivisions and calibrated against an NBS-certified master. A Beckmann differential thermometer (0.01°C subdivisions) was used to note variation in temperature of the bath (to 0.0002°C). The latter was also monitored with a probe consisting of a thermistor in series with a metal-film resistor forming one arm of a Wheatstone bridge circuit. Alternatively the ratio of the resistances of the thermistor and the metal-film resistor was measured with a Hewlett Packard ratiometer. In either arrangement the output of the circuit was connected to a recorder the signal of which indicated that the temperature was contolled to within 0.0001°C during each day and rarely varied by more than 0.0002°C between days.

Densities (ρ) are related to the resonance period (τ) of the vibrating tube by the equation

$$\rho = A + B\tau^2$$

in which A and B are constants found by measuring the densities of two pure fluids, nitrogen gas and water.

Apparent molal volume, ϕ_v, was calculated by the equation

$$\phi_v = 1000(\rho^0 - \rho)/C\rho^0 + M_2/\rho^0$$

in which ρ is the density of the solution/g cm^{-3}, ρ^0 is the density of pure water/g cm^{-3}, C is the concentration of the solution/mmol cm^{-3} or mol dm^{-3}, and M_2 is the molar mass of the solute.

Spectroscopic Measurements

Visible spectra were recorded with a Cary 118 spectrophotometer at 25°C and in 1-cm cells.

Results and Discussion

Molar Volumes

Values found for ϕ_v are shown plotted against $C^{1/2}$ for the five series of solutions in Figs. 1 and 2. The plots in general support Redlich and Rosenfeld's equation (4). Only in the $Na_2NiEDTA \cdot 2NaClO_4$ series is some curvature apparent. By extrapolation to infinite dilution the partial molal volumes, $\bar{V}_2^0$, of the solute are obtained. The $\bar{V}_2^0$ values for $K_2NiEDTA \cdot 2KNO_3$ and $Na_2NiEDTA \cdot 2NaClO_4$ are (258.8 ± 0.5) cm^3 mol^{-1} and (242.9 ± 0.7) cm^3 mol^{-1} respectively. These two systems have $NiEDTA^{2-}$ as a common constituent. The difference in the $\bar{V}_2^0$ values for the two systems, namely 15.9 cm^3 mol^{-1}, can be accounted for in terms of the other constituents in the solutions. From the literature, $\bar{V}_2^0(KNO_3)$ = 38.0 cm^3 mol^{-1} (5), $\bar{V}_2^0(NaClO_4)$ = 42.9 cm^3 mol^{-1} (6), $\bar{V}_2^0(KClO_4)$ = 55.2 cm^3 mol^{-1} (7). Hence

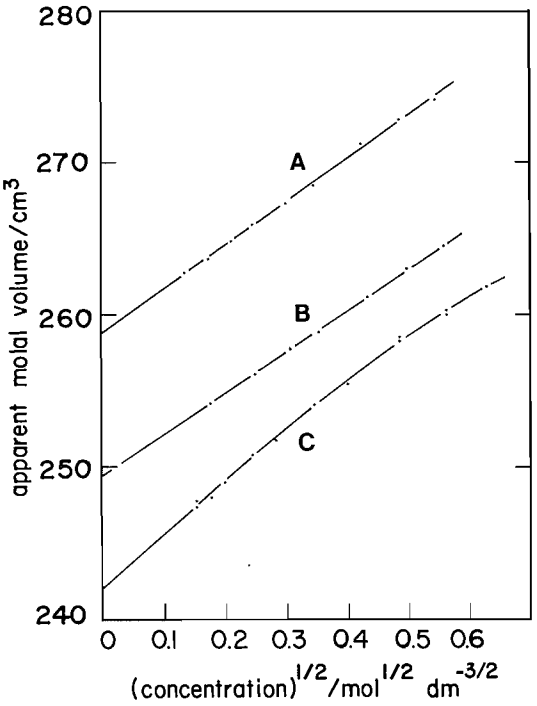

FIG. 1. Apparent molal volumes in aqueous solution. *A*, $K_2NiEDTA \cdot 2KNO_3$; *B*, $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$; *C*, $Na_2NiEDTA \cdot 2NaClO_4$.

[1] $$\bar{V}_2^0(K^+) - \bar{V}_2^0(Na^+) = \bar{V}_2^0(KClO_4) - \bar{V}_2^0(NaClO_4) = 55.2 - 42.9 = 12.3 \text{ cm}^3 \text{ mol}^{-1}$$

[2] $$\bar{V}_2^0(KNO_3) - \bar{V}_2^0(NaClO_4) = 38.0 - 42.9 = -4.9 \text{ cm}^3 \text{ mol}^{-1}$$

From [1] and [2]

$$\bar{V}_2^0(K_2NiEDTA \cdot 2KNO_3) - \bar{V}_2^0(Na_2NiEDTA \cdot 2NaClO_4) = 2 \times (12.3 - 4.9) = 14.8 \text{ cm}^3 \text{ mol}^{-1}$$

This value is sufficiently close to the experimentally measured value, 15.9 cm^3 mol^{-1}, to support the supposition that the partial molal volume of the constituent, $NiEDTA^{2-}$, is independent of background ions in the solution.

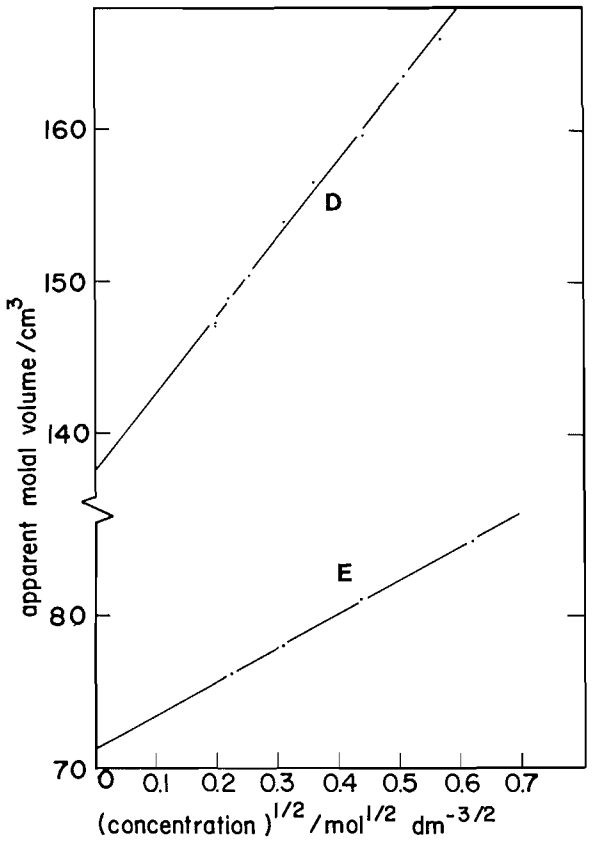

FIG. 2. Apparent molal volumes in aqueous solution. *D*, $Na_4EDTA \cdot 2NaOH$; *E*, $Na_2MIDA \cdot NaOH$.

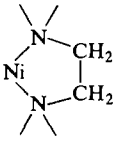
TABLE 1. Apparent and partial molal volumes

Solution	$\bar{V}_2^0$/cm³
$Na_2NiEDTA \cdot 2NaClO_4$	242.9±0.7
$NiEDTA^{2-}$	170.3±0.7[a]
$Na_2Ni(MIDA)_2 \cdot 2NaClO_4$	249.2±0.3
$Ni(MIDA)_2^{2-}$	176.6±0.3[a]
$Na_4EDTA \cdot 2NaOH$	137.6±0.9
$EDTA^{4-}$	174.4±0.9[a]
$Na_2MIDA \cdot NaOH$	71.1±0.2
$MIDA^{2-}$	89.5±0.2[a]
Ni^{2+}	−29.4[a]

[a]The partial molal volumes of ions were calculated using the results of this study and values of conventional partial molal volume of ions at 25°C (ref. 9*b*) corrected using Zana and Yeager's value for H^+, $\bar{V}^0(H^+) = -5.4$ at 25°C (ref. 9*b*, p. 542 and ref. 8).

In Table 1 are summarized the $\bar{V}_2^0$ values for $Na_2NiEDTA \cdot 2NaClO_4$, $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$, $Na_4EDTA \cdot 2NaOH$, and $Na_2MIDA \cdot NaOH$ together with those of some other ions of interest. These latter values were calculated with the aid of $\bar{V}_2^0$(ion) values based on Zana and Yeager's method for $\bar{V}_2^0(H^+)$ (8); this method is regarded as more reliable than others because it leads to better internal consistency among derived values of $\bar{V}_2^0$(ion) (9–12).



The following can be obtained from Table 1:

1. Reactions represented by

Ni^{2+}	+ $EDTA^{4-}$	→ $NiEDTA^{2-}$	$\Delta\bar{V}^0$
−29.4	174.2	170.3	+25.5 cm³ mol⁻¹
Ni^{2+}	+ $2MIDA^{2-}$	→ $Ni(MIDA)_2^{2-}$	
−29.4	2 × 89.6	176.6	+26.8 cm³ mol⁻¹

show considerable increase in volume. This may be attributed in part to a neutralization effect, and also to the fact that in the product the charge is distributed inside the complex entity with little interaction with water. These two factors lead to a significant decrease in electrostriction, with a consequent increase in volume (9).

2. The partial molal volume of $Ni(MIDA)_2^{2-}$ (176.6 cm³ mol⁻¹) is larger than that of $NiEDTA^{2-}$ (170.3 cm³ mol⁻¹). This difference in volume is believed to be statistically significant, and may be interpreted as follows: (*a*) The packing in the five-membered ring in $NiEDTA^{2-}$ should require less space than that required for $Ni(MIDA)_2^{2-}$ where

this ring is lacking. (*b*) In $NiEDTA^{2-}$ the nitrogen donor atoms are *cis* to one another, whereas in $Ni(MIDA)_2^{2-}$ the *trans* isomers are the likely configurations (see discussion of spectral observations). The consequent larger over-all dipole moment in the case of $NiEDTA^{2-}$ would cause a larger electrostriction of solvent, and may be responsible for its smaller volume. (*c*) The additional chelate effect (13) in $NiEDTA^{2-}$ results in stronger metal–ligand interactions with shorter Ni—O and Ni—N distances compared to those in $Ni(MIDA)_2^{2-}$.

Spectroscopy

In both $NiEDTA^{2-}$ and $Ni(MIDA)_2^{2-}$ there are two N and four O donor atoms, and therefore the complexes must be of lower symmetry than octahedral. These two elements are, however, close to one another in the spectrochemical series, and so to a good approximation the complexes can be treated as having a pseudo-octahedral geometry to which the rule of average environment can be applied (ref. 14, pp. 98, 103, 104). This is especially true for spectra of solutions at room temperature which is the case in the present study.

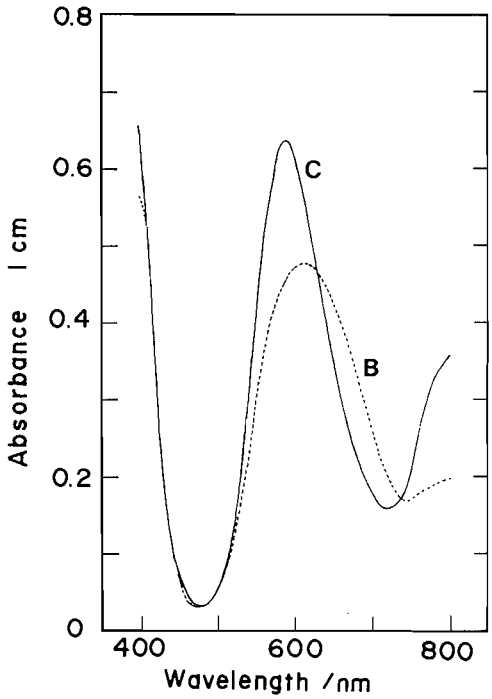

FIG. 3. Visible spectra of complexes in aqueous solution. *C*, $Na_2NiEDTA \cdot 2NaClO_4$, 0.080 mol dm^{-3}; *B*, $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$, 0.094 mol dm^{-3}.

Our results show that within the range studied (up to 0.16 mol dm^{-3} $Na_2NiEDTA \cdot 2NaClO_4$ and 0.125 mol dm^{-3} $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$) the absorbance, integrated from 730 nm to 470 nm (Fig. 3), is directly proportional to concentration for both systems. Also there is no change in band shape with concentration. These findings suggest that there are no shifts in equilibrium as concentration changes. In Fig. 3 the actual spectra for representative solutions of the two systems are shown. The absorbances and band positions are typical for a nickel complex with an octahedral field (15). The peaks at 588 nm and 610 nm for the $Na_2NiEDTA \cdot 2NaClO_4$ and $Na_2Ni(MIDA)_2 \cdot 2NaClO_4$ solutions respectively can be attributed to the $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transition of $NiEDTA^{2-}$ and $Ni(MIDA)_2^{2-}$. These positions lie between those for nickel complexes with six O donors (e.g., ca. 700 nm for $Ni(H_2O)_6^{2+}$) and those with six N donors (e.g., ca. 550 nm for $Ni(en)_3^{2+}$) (16). The solutions containing $NiEDTA^{2-}$ have higher molar peak absorbance (see Fig. 3) as well as greater integrated molar absorbance (1010 vs. 820 in units of absorbance × nm). This observation can be attributed (ref. 14. pp. 105, 106) to the lower symmetry for the $NiEDTA^{2-}$ complex as discussed previously.

The shorter wavelength for the peak observed for solutions containing $NiEDTA^{2-}$ compared to those containing $Ni(MIDA)_2^{2-}$ confirms that EDTA interacts more strongly with Ni than MIDA does. Such a shift can also be caused by ligands lying toward the stronger end of the spectrochemical series (15), but since the donor atoms are the same in the two systems, we attribute the shift to the additional chelate effect in EDTA. This interpretation is in accord with conclusions reached from a study of a large number of complexes of nickel with multidentate amines (ref. 14, pp. 105, 106, ref. 16).

Conclusions

(*1*) Complex formation in the two examples studied was accompanied by a considerable increase in molar volume which has been attributed to diminished electrostriction of solvent.

(*2*) The chelate effect, which has been established from stability constants of complexes, is also evident in the present study of partial molar volumes and spectra of $NiEDTA^{2-}$ and $Ni(MIDA)_2^{2-}$. The generality of these conclusions will require examination of other appropriate systems of complexes.

Oxidation products of arachidonic acid II. The synthesis of methyl 8*R*,9*S*,11*R*-trihydroxy-5*Z*,12*E*,14*Z*-eicosatrienoate

GEORGE JUST AND CORINNE LUTHE[1]

Department of Chemistry, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

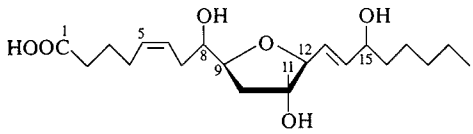
Received December 17, 1979

This paper is dedicated to the memory of Dr. Leo Marion

GEORGE JUST and CORINNE LUTHE. Can. J. Chem. **58**, 1799 (1980).

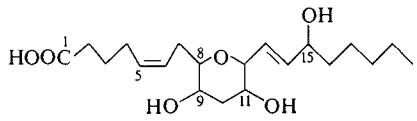
A stereospecific total synthesis of the title compound, **37**, starting from diacetone glucose (**9**), is described. Key intermediates in the synthesis are 3-deoxy-5,6-anhydro-1,2-*O*-isopropylidene-glucofuranose (**15**), obtained in 55% yield from **9**, and methyl 8-*tert*-butyldiphenylsilyl-9,11-*O*-isopropylidene-8*R*,9*S*,11*R*-trihydroxy-12-oxo-dodeca-5*Z*-enoate (**33**), an important intermediate in the synthesis of other oxidation products of arachidonic acid.

GEORGE JUST et CORINNE LUTHE. Can. J. Chem. **58**, 1799 (1980).



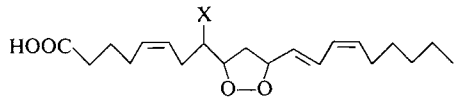
On décrit une synthèse totale stéréospécifique du composé mentionné dans le titre en partant du glucose diacétone (**9**). Les intermédiaires principaux de la synthèse sont: le déoxy-3 anhydro-5,6 *O*-isopropylidène-1,2 glucofurannose (**15**) obtenu avec un rendement de 55% à partir de **9** et le *tert*-butyldiphénylsilyl-8 *O*-isopropylidène-9,11 trihydroxy-8*R*,9*S*,11*R* oxo-12 dodécène-5*Z* oate de méthyle (**33**) un intermédiaire important dans la synthèse d'autres produits d'oxydation de l'acide arachidonique.

[Traduit par le journal]



A few years ago, Pace-Asciak and Wolfe (1) reported the isolation of compounds **1** and **2** and of 5,6-dihydro-**1** from the enzymatic conversion of tritiated arachidonic acid by sheep seminal vesicles. An apparently identical tetrahydrofuran of type **1** was recently isolated by Axelrod and co-workers from incubation of the same substrate with soy-bean lipoxygenase II (2). The structure of these compounds was determined from gc–ms data and a limited number of degradation studies. Their stereochemistry is at present unknown.

Pace-Asciak and Wolfe reported that **1** and **2** were synthesized along with prostaglandins (PGE_2). Axelrod and co-workers demonstrated that prostaglandin-like material was synthesized along with **1** (2*b*), and that two molecules of O_2 were incorporated per molecule of arachidonic acid during its soy-bean lipoxygenase II induced oxidation. These results have to be treated with some caution, since **1** made up only 10% of total oxidation product of arachidonic acid.



Based on these data, the biosynthetic pathway postulated by Pace-Asciak and Wolfe (1*b*), and the assumption that a stereochemically similar enzyme-site is responsible for both the formation of prostaglandin and **1** or **2**, the following biosynthetic pathway may be postulated. Removal of the 13-pro-*S* hydrogen of arachidonic acid (**6**) and reaction of the radical thus formed with O_2 leads to the formation of hypothetical intermediate **7**, either directly or via a hydroperoxide, which either cyclizes to form PGG_2 (3) (conventional PG-synthesis), or, due to some change of the enzyme-cavity, traps oxygen to give hydroperoxy-peroxide **3**. This or a related product may be envisaged to cyclize in a free radical manner (with further uptake of a molecule of O_2), or, if the oxygenation data are correct, in an ionic manner as depicted in Scheme 1. The polarization of the O—O bond into O^+ and

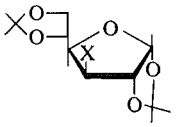
SCHEME 1

O^- is, of course, only a formalism not implying a free cationic species.

Nucleophilic attack (arrows labelled 2) of the olefinic linkage on the hydroperoxy oxygen, followed by hydration of the intermediate allylic carbonium ion, results in the formation of **2** after reduction of the peroxide. For the formation of **1**, a polarization of the peroxy linkage (see arrows labelled 1), followed by a 120° rotation of the C(10)—C(11) bond, leads to intermediate **3*** similar to the one postulated in the conversion of PGH_2 to PGI_2. Cyclization, hydration, and reduction of the hydroperoxide to an alcohol group then gives tetrahydrofuran **1**.

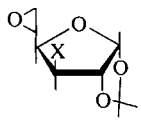
Whatever the mechanism of these rearrangements, this hypothesis predicts that the absolute stereochemistry of the oxygen atoms attached to C(9) and C(11) in **1** and **2** would be the same as those of the 4 and 2 positions of glucose.

On the other hand, one may envisage that the C(1)—C(9) chain of arachidonic acid (**6**) folds in the opposite manner, giving **1** and **2** in which the stereochemistry at C(9) and C(11) would be identical to those of the 4 and 2 positions of galactose. The double bond at C(5) and C(13) may be assumed to be identical to that of arachidonate derived prostaglandins, ie 5-*Z* and 13-*E*.



The peroxyhydroperoxide **3**, and its corresponding reduction products **4** and **5** have never been isolated. We hypothesize that this may be due to their instability, and propose to synthesize compounds **1**–**5** in a stereospecific manner, making use of the biosynthetic hypothesis described above to guide us in the selection of the most likely target molecules.

Since **1** and **2** contain five chiral centers (32 stereoisomers), and **3**, **4**, and **5** only three (8 stereoisomers), we propose to synthesize in the first instance triol **5** and attempt to detect its presence in the soy-bean lipoxygenase or sheep seminal vesicle induced oxidation of arachidonic acid. Positive identification of triol **5** would ascertain the stereochemistry of three of the five chiral centers in **1** and **2**.



As our first synthetic goal, we chose to prepare from the readily available diacetone glucose **9** compounds of the type **33**, convenient precursors to metabolites **1**–**5**.

The key steps in its synthesis from diacetone glucose **9** are its efficient transformation to the known epoxide **15** (4), previously obtained by a somewhat cumbersome procedure, attachment of the side-chain and transformation of the 1,2-acetonide into a free aldehyde. An important

further consideration is that the hydroxy groups at C(8) and C(9) of **33** be clearly differentiated, since tetrahydrofuran **1** and -pyran **2** differ only in the attachment of these two hydroxyl groups to C(12) of **33**.

In the first series of experiments, xanthate **10** (11) was submitted to the action of tributyltin hydride (5) according to the procedure of Barton and McCombie (6). The 3-deoxyglucose **11** (7) thus obtained could not be separated cleanly from tributyltin derivatives by distillation. However, when triphenyltin hydride (8), obtained by $LiAlH_4$ reduction of triphenyltin chloride (5), was used instead of tributyltin hydride, the deoxysugar **11**, bp 74–75°C, 0.3 Torr, could be prepared and isolated in large quantities without chromatography. Whereas the partial hydrolysis of the 5,6-acetonide poses no problems in diacetone glucose derivatives functionalized at C(3), a clean partial hydrolysis of **11** could not be effected.

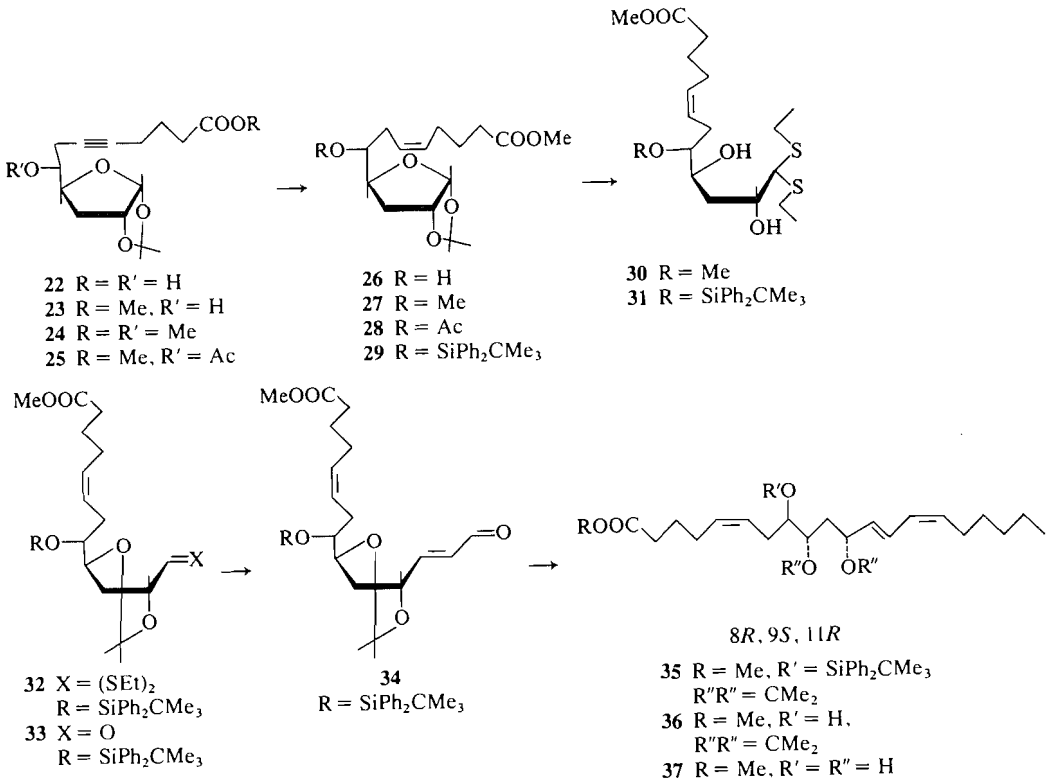
We next prepared xanthate **13** from the readily available epoxyalcohol **12** (9) and treated it with triphenyltin hydride. Comparison of the reaction product with authentic deoxyepoxide **15** indicated that less than 20% of **15** had been formed.

Epoxide **15** was obtained in good yield upon photolysis of acetate **14** of alcohol **12** (9) in aqueous HMPA using the method of Pete and Portella (10), but scaling up of the reaction gave very erratic results.

Deoxyepoxide **15** was eventually obtained in 55% yield, based on diacetone glucose, when the following procedure was used.

Xanthate **10** (11), made by an adaptation of a procedure described by Barton and McCombie (6), was hydrolysed to diol xanthate **16** with methanolic sulphuric acid, being careful to avoid any base in the workup as it resulted in the formation of poorly defined mixtures. Acetylation gave **17**, which was reduced with tributyltin hydride (6) in toluene. Evaporation gave semi-crystalline deoxydiacetate **18**, which was hydrolyzed with methanolic sodium methoxide to the deoxydiol **19**. Tosylation of crude **19** with one equivalent of *p*-toluenesulphonyl chloride – pyridine in chloroform gave monotosylate **20**, contaminated with 10–15% each of ditosylate **21** and diol **19**. Treatment with aqueous methanolic potassium hydroxide, followed by distillation, gave deoxyepoxide **15**. Treatment of **15** with the dilithium salt of 5-hexynoic acid (12) in HMPA gave in 57% yield acetylenic acid **22**, which was isolated either as its crystalline methyl ester **23**, mp 41–42°C, after treatment with diazomethane, or as its methyl ester methyl ether **24** by direct alkylation of the reaction mixture with excess methyl iodide. Hydroxy ester **23** was further characterized as its acetate **25**.

Alcohol **23**, methyl ether **24**, and acetate **25** were all three cleanly hydrogenated to the corresponding *Z*-olefins **26**, **27**, and **28**, using Brown's P-2 nickel-boride catalyst (13). Only one isomer was formed, as established by gc–ms and ^{13}C nmr. The geometry of the double-bond generated was assigned the *Z*-configuration, based mainly on analogy (13).



Alcohol **26** was transformed to its *tert*-butyldiphenylsilyl ether **29** (14), which is relatively acid- and base-stable, and can be removed in the presence of most other protecting groups.

Treatment of methyl ether **27** or silyl ether **29** with ethanethiol–$ZnCl_2$ at −10°C gave directly diol thioacetals **30** and **31**. The latter was transformed to its stable oily isopropylidene derivative **32**. Hydrolysis transformed the thioacetal to the corresponding unstable aldehyde **33**, which was converted to the unstable *E*-α,β-unsaturated aldehyde **34** by means of formylmethylenetriphenylphosphorane (15). Its ^1H nmr and ^{13}C nmr spectra clearly indicated the *E*-configuration of the newly established double-bond and attested to its purity (>95%). Reaction of **34** with triphenylhexylphosphorane gave two isomeric olefins in a ratio of approximately 9:1, as established by gc–ms, hplc, and ^{13}C nmr.

The major isomer was assigned structure **35**, based on the knowledge that unstabilized phosphoranes give *Z*-olefins as a major product. The minor component is therefore the 14-*E* isomer of **35** (14-*E*-**35**).

Reaction of **35** contaminated with 14-*E*-**35** with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

tetra-*n*-butylammonium fluoride in boiling tetrahydrofuran gave **36** contaminated with 10–15% of its 14-*E* isomer. Mild acid hydrolysis of crude **36** gave triol ester **37**, which would be cleanly separated from its 14-*E* isomer by flash-chromatography (16).

Experimental

General

Melting points were determined on a Gallenkamp block and are uncorrected. Mass spectra (ms) were obtained on a HP 5984 mass spectrometer or on a LKB-9000 mass spectrometer at 70 eV. Infrared (ir) spectra were obtained on a Perkin Elmer 297 spectrophotometer. Proton and carbon-13 magnetic resonance spectra were recorded on Varian T-60, T-60A, and on Brucker FT 90 spectrometers.

Xanthate of 1,2:5,6-Di-O-isopropylidene-α-D-glucofuranose (10)

The xanthate was prepared according to a slight modification of a procedure outlined by Barton and McCombie (6). To a stirred suspension of sodium hydride (8 g (50% oil dispersion), 0.17 mol) in 500 mL dry tetrahydrofuran (10°C, N_2) was added carbon disulfide (22.8 g, 0.30 mol), methyl iodide (28.4 g, 0.20 mol), imidazole (20 mg), and diacetone glucose (**9**) (26 g, 0.10 mol). The reaction was complete instantaneously; the excess sodium hydride was destroyed with glacial acetic acid. The solvents were removed *in vacuo*, and the residue extracted with ether (3 × 500 mL), washed with aqueous $NaHCO_3$ (2 × 50 mL) and water (3 × 50 mL), and dried over $MgSO_4$. Removal of the ether *in vacuo* yielded the pure xanthate **10**, mp 58–59°C (lit. (11) mp 60°C), quantitatively; nmr ($CDCl_3$) δ: 1.35 (s, 6H, CMe_2), 1.43 (s, 3H, CH_3), 1.55 (s, 3H, CH_3), 2.60 (s, 3H, S—CH_3), 3.93–4.40 (m, 4H, C(4)H, C(5)H, C(6)H), 4.66 (d, 1H, J = 4 Hz, C(2)H), 5.85–5.97 (m, 2H, C(1)H, C(3)H).

Xanthate of 1,2-O-isopropylidene-α-D-glucofuranose (16)

Xanthate **10** (35 g, 0.1 mol) was dissolved in a mixture of MeOH (575 mL), concentrated H_2SO_4 (14 mL), and H_2O (75 mL) and stirred at room temperature for 5 h to effect complete hydrolysis. Aqueous saturated sodium chloride solution was then added and the methanol was evaporated at 40°C *in vacuo*; the residue was extracted with CH_2Cl_2 (2 × 500 mL), washed with saturated salt solution until the aqueous layer was no longer acidic, and dried over $MgSO_4$. Evaporation of the solvent gave quantitatively oily xanthate **16**, which was used without purification in the next step. Nuclear magnetic resonance ($CDCl_3$) δ: 1.33 (s, 3H, CH_3), 1.53 (s, 3H, CH_3), 2.60 (s, 3H, S—CH_3), 2.75–3.25 (m, 2H, C(6)H), 3.60–4.15 (m, 3H, C(5)H, $(OH)_2$), 4.20–4.45 (m, 1H, C(4)H), 4.66 (d, 1H, $J_{1,2}$ = 4Hz, C(2)H), 5.93 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H), 6.03 (d, 1H, $J_{3,4}$ = 3 Hz, C(3)H).

Xanthate of 1,2-O-isopropylidene-5,6-di-O-acetyl-α-D-glucofuranose (17)

A solution of crude diol **16** (31 g, 0.1 mol) in anhydrous ether (800 mL) containing dry acetic anhydride (38 mL, 0.4 mol) and 4-dimethylaminopyridine (1.22 g) was stirred at room temperature for 1.5 h. The ether was then evaporated *in vacuo* and excess reagents were removed by azeotroping with toluene. The residue was extracted with ether (3 × 500 mL), washed with 1% HCl (2 × 50 mL), H_2O (3 × 50 mL), and dried over $MgSO_4$. Removal of the solvent yielded the xanthate diacetate quantitatively, which was used without purification in the next step; nmr ($CDCl_3$) δ: 1.34 (s, 3H, CH_3), 1.57 (s, 3H, CH_3), 2.00 (s, 3H, $COCH_3$), 2.08 (s, 3H, $COCH_3$), 2.60 (s, 3H, SCH_3), 3.97–4.80

(m, 3H, C(4)H, C(6)H), 4.64 (d, 1H, $J_{1,2}$ = 4 Hz, C(2)H), 5.10–5.43 (m, 1H, C(5)H), 5.97 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H), 6.08 (d, 1H, $J_{3,4}$ = 3 Hz, C(3)H).

1,2-O-isopropylidene-3-deoxy-5,6-di-O-acetyl-α-D-ribohexofuranose (18)

To tributyltin hydride (48 mL) in dry refluxing toluene (800 mL), under a N_2 atmosphere, was added over 1 h the crude diacetate xanthate **17** (35 g, 0.1 mol) in toluene (800 mL). The solution was refluxed for 16 h to effect complete reduction of the xanthate functionality. The toluene was then removed at reduced pressure. The deoxyfuranose **18** either crystallized out spontaneously, or had to be heated with ether–hexane to induce crystallization. Filtration gave **18**, contaminated with tributyltin by-products, which was used as such in the subsequent hydrolysis; nmr ($CDCl_3$) δ: 1.30 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 1.57–2.33 (m, 2H, C(3)H), 2.03 (s, 3H, $COCH_3$), 2.07 (s, 3H, $COCH_3$), 3.88–4.55 (m, 3H, C(4)H, C(6)H), 4.72 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.00–5.26 (m, 1H, C(5)H), 5.76 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H); $[\alpha]_D^{23}$ +18.4° (*c* 5.75 in $CHCl_3$).

1,2-O-isopropylidene-3-deoxy-α-D-ribohexofuranose (19)

Crude deoxy-diacetate **18** (25 g) in 280 mL dry 0.02 *M* methanolic sodium methoxide was maintained at room temperature for 2 h and then neutralized with acidic resin (AM-120 H^+). Removal of the resin, followed by evaporation of the methanol, gave the diol **19**, mp 81–82°C, (lit. (4) mp 80–81°C) in quantitative yield. It was used as such in the next step; nmr ($CDCl_3$, D_2O) δ: 1.32 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 1.60–2.30 (m, 2H, C(3)H), 3.40–4.40 (m, 4H, C(4)H, C(5)H, C(6)H), 4.70–4.83 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.81 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H).

1,2-O-isopropylidene-3-deoxy-6-O-p-toluenesulfonyl-α-D-ribohexofuranose (20) (4)

To the deoxy-diol **19** (17.4 g, 86 mmol, crude from previous reaction) and *p*-toluenesulfonyl chloride (16.40 g, 86 mmol) in 225 mL $CHCl_3$ (freshly distilled from P_2O_5) at −50°C under N_2 was added dropwise dry pyridine (19 mL) in 20 mL $CHCl_3$; the solution was maintained at −50°C for 3 h, and at room temperature for 20 h. The product was extracted with CH_2Cl_2 (2 × 700 mL), washed with cold 1% HCl till the washings were acidic, and then with H_2O (4 × 100 mL). The CH_2Cl_2 extracts were dried over $MgSO_4$, and evaporation of the solvent yielded a mixture of mono- and di-tosylate **20** and **21** (~9:1), which was used without purification in the subsequent epoxidation step. A sample of pure **20** was obtained by chromatography; nmr ($CDCl_3$, D_2O) δ: 1.27 (s, 3H, CH_3), 1.46 (s, 3H, CH_3), 1.65–2.28 (m, 2H, C(3)H), 2.42 (s, 3H, C_6H_4—CH_3), 3.82–4.30 (m, 4H, C(4)H, C(5)H, C(6)H), 4.69 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.71 (d, 1H, *J* = 4 Hz, C(1)H), 7.55 (4H, AB_q, δ_{AB} = 0.45, *J* = 8 Hz).

5,6-Anhydro-3-deoxy-1,2-isopropylidene-α-D-ribohexofuranose (15) (5)

The mixture of mono- and di-tosylates (25.9 g, crude from previous reaction) in MeOH (300 mL)/H_2O (60 mL) was cooled in an ice bath; the ice bath was then removed and approximately 1 equiv. aqueous KOH (1.17 *N*) was added dropwise till the pH of the solution remained basic; the reaction mixture was neutralized with acidic resin (AM-120 H^+) and the MeOH was evaporated at reduced pressure (<40°C). The residue was extracted with ether (3 × 750 mL); the ether fractions were washed with saturated salt solution (3 × 50 mL), dried over $MgSO_4$, and evaporated to give an oil which was distilled (110°C/0.3 Torr; Kugelrohr) to give the 5,6-anhydro-sugar (10.2 g, 55% yield from diacetone glucose), slightly contaminated with tri-butyltin by-products. The epoxide was used without further purification in the subsequent step; nmr ($CDCl_3$) δ: 1.33 (s, 3H, CH_3), 1.44–2.30 (m, 2H, C(3)H), 1.50 (s, 3H, CH_3), 2.53–2.89 (m, 2H, C(6)H), 3.05–3.23 (m, 1H, C(5)H), 4.05–4.36 (m, 1H, C(4)H), 4.75 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.81 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H).

Acid 22 and Methyl Ester 23

To 5-hexynoic acid (12) (1.9 g, 17 mmol) in 20 mL dry HMPA in an argon atmosphere at 5°C was added dropwise *n*-BuLi (21.1 mL, 33.8 mmol). The colorless solution became bright orange. The epoxide **15** (1.57 g, 8.45 mmol) in 10 mL HMPA was added dropwise, the ice bath removed (precipitation of the dianion may otherwise occur), and the reaction mixture was stirred at room temperature for 20 h. Acetic acid (0.97 mL, 17 mmol) was then added and the solvents were removed by Kugelrohr distillation (110°C/0.1 Torr). The residue was stirred and shaken in 1 *N* aqueous HCl – ether, and was then extracted with ether (3 × 400 mL); the ether extracts were washed with saturated salt solution (10 × 30 mL), dried over $MgSO_4$, and evaporated to yield oily **22** which was methylated with ethereal diazomethane; excess methyl hexynoate was removed at 60°C/0.1 Torr, and the residual oil was purified by flash chromatography (petroleum ether (30–60°C) – ethyl acetate, 4.6:4.0) to yield 1.5 g (57% yield) of crystalline **23**, mp 41–42°C. Infrared ($CHCl_3$): 1735 (C=O), 3480 (OH) cm^{-1}; nmr ($CDCl_3$) δ (glucose numbering): 1.31 (s, 3H, CH_3), 1.48 (s, 3H, CH_3), 1.54–2.58 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 3.08 (br s, 1H, OH, exchangeable with D_2O), 3.66 (s, 3H, CO_2CH_3), 3.68–4.47 (m, 2H, C(4)H, C(5)H), 4.74 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.78 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H). ms (70 eV) *m/e*: 297 (*M* − 15), 173 (*M* − (CH_2—C≡C—$(CH_2)_3$—CO_2Me)), 169 (HO—CH—CH_2C≡C—$(CH_2)_3$—CO_2Me), 143 (*M* − 169); $[\alpha]_D^{23}$ −16.5° (*c* 2.75 in $CHCl_3$); *Anal.* calcd. for $C_{16}H_{24}O_6$: C 61.54, H 7.69; found: C 61.77, H 7.50.

When the reaction was scaled up by a factor of two, problems with precipitation of reactants were encountered.

Methyl Ether 24

The reaction conditions were identical to those used for the formation of the alcohol methyl ester **23**, except that excess methyl iodide was used to quench the reaction instead of acetic acid. The reaction mixture was then stirred at 65°C for 2 h, and after the addition of 300 mL H_2O, it was extracted with ether (3 × 500 mL); the extracts were washed with H_2O (4 × 50 mL), dried over $MgSO_4$, and evaporated to give methyl ether **24** contaminated with 10% alcohol **23** and methyl 5-heptynoate. The latter was removed at 60°C/0.2 Torr and the product was then further purified by flash chromatography (petroleum ether (30–60°C) – ethyl acetate, 3:2) to give pure **24** (1.6 g, 58% yield). The proportions of **23** and **24** tended to fluctuate, depending on humidity and other variables which are not understood. Infrared ($CHCl_3$): 1737 (C=O), absence of OH at 3480 cm^{-1}; nmr ($CDCl_3$) δ (glucose numbering): 1.32 (s, 3H, CH_3), 1.49 (s, 3H, CH_3), 1.50–2.60 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 3.30–3.70 (m, 1H, C(5)H), 3.44 (s, 3H, OCH_3), 3.65 (s, 3H, CO_2CH_3), 4.16–4.48 (m, 1H, C(4)H), 4.71 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.77 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H): ms *m/e*: 326 (M^+), 311 (*M* − CH_3), 143 (*M* − MeOCHCH$_2$—CH≡CH$(CH_2)_3$COOMe); $[\alpha]_D^{23}$ −26.2° (*c* 2.55 in $CHCl_3$).

Acetate 25

A solution of **23** (0.93 g, 3 mmol), 4-dimethylaminopyridine (0.036 g, 0.3 mmol), and acetic anhydride (0.56 mL, 6 mmol) in anhydrous ether (25 mL) was stirred at room temperature for 1.5 h. The excess reagents were azeotroped off with toluene at 40°C, and the residue was extracted with ether (3 × 350 mL); the extracts were washed with cold 1% HCl (3 × 20 mL), H_2O (5 × 20 mL), dried over $MgSO_4$, and evaporated *in vacuo* to give the

For personal use only.

acetate **25** in quantitative yield; nmr ($CDCl_3$) δ (glucose numbering): 1.23–2.61 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 1.32 (s, 3H, CH_3), 1.50 (s, 3H, CH_3), 2.07 (s, 3H, $COCH_3$), 3.64 (s, 3H, CO_2CH_3), 4.15–4.53 (m, 1H, C(4)H), 4.70 (dd, 1H, $J_{1,2} \sim J_{2,3}$ = 4 Hz, C(2)H), 5.01 (dt, 1H, $J_{5,6} \sim J_{5,4}$ = 6 Hz, C(5)H), 5.76 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H).

Reduction of 23, 24, and 25 to Z-olefins 26, 27, and 28

To nickel acetate (0.76 g, 3 mmol) in a three-neck flask equipped with a septum was added 5 mL of 95% ethanol. The flask was connected to the hydrogenation apparatus and was flushed with hydrogen. The catalyst was produced by injecting 4.5 mL of a 0.5 *M* solution of sodium borohydride in 95% ethanol to the rapidly stirred solution of nickel acetate. The reaction vessel was reflushed with hydrogen and ethylene diamine (0.3 mL) was added. Hydrogenation was then initiated by introducing the acetylenic alcohol **23** (3.29 g, 10.5 mmol), in 15 mL ethanol, via the septum. Hydrogen uptake was quantitative within an hour and then virtually ceased. The reaction mixture was filtered through Celite, the ethanol was removed under reduced pressure, and the residue was extracted with ether (2 × 350 mL). The combined ether extracts were washed with H_2O (3 × 40 mL), dried over $MgSO_4$, and evaporated *in vacuo* to give the olefinic alcohol **26** in quantitative yield. Nuclear magnetic resonance ($CDCl_3$) δ (glucose numbering): 1.24–2.47 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 1.30 (s, 3H, CH_3), 1.49 (s, 3H, CH_3), ~3.6–4.2 (br s, 1H, OH, exchangeable with D_2O), 3.60–4.36 (m, 2H, C(4)H, C(5)H), 3.63 (s, 3H, CO_2CH_3), 4.60–4.80 (m, 1H, C(2)H), 5.33–5.56 (m, 2H, *Z*—CH=CH), 5.75 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H). The ^{13}C nmr spectrum indicated the presence of one major isomer; ^{13}C nmr ($CDCl_3$) δ: 173.93 (CO_2Me), 131.48 (C=C), 125.76 (C=C), 111.15, 105.27, 80.50, 70.58, 66.32, 51.38, 33.31, 31.90, 30.83, 26.73, 26.62, 26.08, 24.62. This was confirmed by gc–ms of **26**-*O*-trimethylsilyl ether, which indicated the presence of <3% of a minor impurity, possibly the *trans*-isomer, having approximately the same retention time; ms *m/e*: 371 ($M - CH_3$), 245 ($M - CH_2CH{=}CH(CH_2)_3COOCH_3$), 243 ($Me_3SiOCHCH_2CH{=}CH(CH_2)_3COOCH_3$), 143 ($M - 243$); $[\alpha]_D^{23}$ − 5.51 (*c* 4.05 in $CHCl_3$).

Acetate 28 was obtained from **25** using the same conditions. Its spectral data were similar to those of **25** except for the presence of the olefinic protons at 5.23–5.48 (m, 2H); ms *m/e*: 356 (M^+).

Methyl ether 27 was obtained from **24**, using ~35% of the catalyst used in the reduction of **23**. Its ^1H nmr spectrum was similar to that of **24** except for the olefinic protons at 5.47 ppm (m, 2H).

tert-*Butyldiphenylsilyl Ether 29*

To the alcohol **26** (3 g, 9.5 mmol) in dry dimethylformamide (6 mL) under N_2 was added *tert*-butylchlorodiphenylsilane (2.87 g, 10.5 mmol) and imidazole (1.42 g, 20.9 mmol); the reaction mixture was then stirred at 78°C for 17 h to effect complete silylation. Water (100 mL) was added and the product was extracted with ether (3 × 350 mL); the combined ether extracts were washed with H_2O (3 × 40 mL), dried over $MgSO_4$, and evaporated to afford the silylated alcohol, as a pale yellow oil, in quantitative yield. Infrared 1740 (COOMe) cm^{-1}; nmr (glucose numbering) ($CDCl_3$) δ: 1.07 (s, 9H, $SiCMe_3$), 1.24–2.40 (m, 10H, C(3)H, C(6)H, $CH_2CH_2CH_2$), 1.27 (s, 3H, CH_3), 1.44 (s, 3H, CH_3), 3.59 (s, 3H, CO_2CH_3), 3.87–4.36 (m, 2H, C(4)H, C(5)H), 4.54–4.73 (m, 1H, C(2)H), 5.13–5.37 (m, 2H, HC=CH), 5.56 (d, 1H, $J_{1,2}$ = 4 Hz, C(1)H), 7.13–7.80 (m, 10H, $SiPh_2$). The ^{13}C nmr spectrum was consistent with the structure proposed; $[\alpha]_D^{23}$ −25.1° (*c* 5.25 in $CHCl_3$).

*Methyl 8*R-tert-*butyldiphenylsilyloxy-9*S,*11*R-*dihydroxy-9,11-O-isopropylidene-12,12-di(ethylthio)dodeca-5*Z-*enoate (32) from 29 and 30 from 27*

To the silylated alcohol **29** (1.5 g, 2.7 mmol) in ethanethiol (3 mL) at −10°C was added anhydrous zinc chloride (1.4 g, 10.3 mmol). After one hour at −10°C, the excess ethanethiol was removed at −10°C *in vacuo*. The foamy residue was dissolved in ethyl acetate (50 mL) and aqueous $NaHCO_3$ (10 mL) was added; the precipitate which formed was filtered off and the filtrate was extracted with ethyl acetate (3 × 400 mL); the ethyl acetate extracts were washed with saturated salt solution (3 × 50 mL), dried over $MgSO_4$, and evaporated to give the thioacetal **31** in quantitative yield. Its nmr spectrum was consistent with the structure proposed; **30** was obtained from **27** in the same way.

To an acetone (100 mL) solution of thioacetal **31** (2.5 g, 4 mmol) obtained in this manner was added dimethoxypropane (5 mL) and *p*-toluenesulfonic acid (catalytic). After 1 h at room temperature the acetone was removed at reduced pressure and the residue extracted with ethyl acetate (3 × 400 mL); the ethyl acetate extracts were washed with aqueous $NaHCO_3$ (3 × 30 mL), saturated salt solution (3 × 30 mL), dried over $MgSO_4$, and evaporated to give the isopropylidene thioacetal **32** as a pale yellow oil, in quantitative yield. Infrared: 1737 (COOMe) cm^{-1}; nmr ($CDCl_3$) δ: 1.08 (s, 9H, Si—CMe_3), 1.10–2.92 (m, 16H, $5CH_2$, $2CH_3$), 1.34 (s, 6H, CMe_2), 2.70 (q, 4H, *J* = 7 Hz, $2SCH_2CH_3$), 3.60 (s, 3H, CO_2CH_3), 3.60–4.20 (m, 4H, H—CS, H—C—O), 5.19–5.44 (m, 2H, *Z*-HC=CH), 7.17–7.84 (m, 10H, $SiPh_2$); ms *m/e* (70 eV): 584 ($M^+ - CH_2C(OMe)OH$), 135 ($CH(SEt)_2$, 100%); *Anal.* calcd. for $C_{36}H_{54}O_5S_2Si$: C 65.65, H 8.21, S 9.73; found: C 65.69, H 7.96, S 9.49; $[\alpha]_D^{23}$ −29.4° (*c* 2.85 in $CHCl_3$).

*Methyl 8*R-tert-*butyldiphenylsilyloxy-9*S,*11*R-*dihydroxy-9,11-O-isopropylidene-12-oxo-dodeca-5*Z-*enoate (33)*

To the dithioacetal **32** (5.5 g, 8.4 mmol) in acetone–water (300 mL/30 mL) was added mercuric oxide (15 g, 69 mmol), and mercuric chloride (6.22 g, 23 mmol); the heterogeneous reaction mixture was stirred at room temperature for 8 h, and was then filtered into aqueous $NaHCO_3$ (100 mL); the filtrate was refiltered, the acetone removed *in vacuo*, and the residue extracted with CH_2Cl_2 (2 × 300 mL); the extracts were washed with aqueous KI (2 × 50 mL), saturated salt solution (3 × 50 mL), dried with $MgSO_4$, and evaporated to give in quantitative yield the oily, somewhat unstable aldehyde, in part as a hydrate; nmr ($CDCl_3$) δ: 0.90–2.40 (m, 10H, $5CH_2$), 1.07 (s, 9H, $SiCMe_3$), 1.37 (s, 3H, CH_3), 1.41 (s, 3H, CH_3), 3.60 (s, 3H, CO_2CH_3), 3.60–4.00 (m, 2H, C(8)H, C(9)H), 4.04–4.36 (m, 1H, C(11)H, 5.17–5.40 (m, 2H, HC=CH), 7.09–7.80 (m, 10H, $SiPh_2$), 9.53 (s, 0.8H, CHO).

*Methyl 8*R-tert-*butyldiphenylsilyloxy-9*S,*11*R-*dihydroxy-9,11-O-isopropylidene-14-oxo-tetradeca-5*Z,*12*E-*dienoate (34)*

To aldehyde **33** (4.34 g, 7.86 mmol) in 25 mL dry dimethylformamide under N_2, was added formylmethylenetriphenylphosphorane (2.4 g, 7.86 mmol) (15). After 20 h stirring at room temperature, water (300 mL) was added to the reaction mixture which was then extracted with ether (3 × 600 mL); the ether extracts were then washed with H_2O (3 × 50 mL), dried over $MgSO_4$, and evaporated to give the α,β unsaturated aldehyde in 90% yield; nmr ($CDCl_3$) δ: 0.96–2.43 (m, 10H, $5CH_2$), 1.09 (s, 9H, $SiCMe_3$), 1.39 (s, 6H, CMe_2), 3.60 (s, 3H, CH_3), 3.60–4.00 (m, 2H, C(8)H, C(9)H), 4.33–4.72 (m, 1H, C(11)H),

For personal use only.

5.20–5.44 (m, 2H, *Z*-CH=CH), 6.42 (AB q, 2H, $J_{12,13}$ = 16 Hz, $J_{13,14}$ = 6.5 Hz, $J_{11,13}$ = 1 Hz, $J_{11,12}$ = 4 Hz, OCH(11)—*CH*(12)=*CH*(13)—CH(14)O), 7.15–7.77 (m, 10H, $SiPh_2$), 9.47 (d, 1H, $J_{13,14}$ = 6.5 Hz, CHO).

*Methyl 8*R-tert-*butyldiphenylsilyloxy-9*S,*11*R-*dihydroxy-9,11*-O-*isopropylidene-eicosa-5*Z,*12*E,*14*Z-*trienoate (35)*

To *n*-hexyltriphenylphosphonium bromide (2.8 g, 6.6 mmol) in dry THF (15 mL) under argon at room temperature was rapidly added *n*-BuLi (5.1 mmol). The reaction mixture turned red immediately; it was stirred for 10 min, cooled to −78°C, and then aldehyde **34** (2.7 g, 4.7 mmol, in 10 mL THF) was added slowly via syringe. The reaction was over immediately and was warmed up rapidly by immersion into a room temperature water bath. The reaction mixture was quenched with H_2O, the THF removed *in vacuo*, and the residue extracted with hexanes (3 × 350 mL); the extracts were washed with H_2O (4 × 50 mL), dried over $MgSO_4$, and evaporated to give the desired 14-*Z* olefin **35**, as an oil, in 80% yield. A separation of the minor 14-*E* impurity was not carried out at this stage of the synthesis, since the peaks overlapped in hplc; nmr ($CDCl_3$) δ: 0.68–2.48 (m, 21H, $9CH_2$, $1CH_3$), 1.09 (s, 9H, $SiCMe_3$), 1.38 (s, 6H, CMe_2), 3.60 (s, 3H, $COOCH_3$), 3.60–3.93 (m, 2H, C(8)H, C(9)H), 4.13–4.53 (m, 1H, C(11)H), 5.17–6.70 (m, 6H, olefinic H's), 7.17–7.82 (m, 10H, $SiPh_2$); $[\alpha]_D^{23}$ −10.9° (*c* 3.60 in $CHCl_3$); *Anal.* calcd. for $C_{40}H_{58}SiO_5$: C 74.30, H 8.98; found: C 73.99, H 9.01.

*Methyl 8*R,9S,*11*R-*trihydroxy-9,11*-O-*isopropylidene-eicosa-5*Z,*12*E,*14*Z-*trienoate (36)*

A mixture of **35** (0.67 g, 1.04 mmol) and tetra-*n*-butyl ammonium fluoride (1.9 mmol) was stirred in dry tetrahydrofuran (11 mL) at 60°C under a nitrogen atmosphere for 4 h; the tetrahydrofuran was removed *in vacuo* and the residue was extracted with ether (3 × 350 mL), washed with H_2O (3 × 30 mL), and dried over $MgSO_4$ to give a quantitative yield of **36**, contaminated with diphenyl-*tert*-butyl silanol; the latter was removed by flash chromatography (petroleum ether – ethyl acetate, 4.3:1.0); nmr ($CDCl_3/D_2O$) δ: 0.68–2.46 (m, 21H, $9CH_2$, $1CH_3$), 1.42 (s, 3H, CH_3), 1.46 (s, 3H, CH_3), 3.39–3.98 (m, 2H, C(8)H, C(9)H), 3.63 (s, 3H, CO_2CH_3), 4.15–4.55 (m, 1H, C(11)H), 5.13–6.69 (6H, olefinic H's). The gc–ms analysis of a trimethyl silylated sample showed the presence of a minor component (~10–15%) with slightly longer retention time (14*E* isomer of **36**), and **36**. Both spectra were nearly superimposable; ms *m/e*: 480 (M^+), 243 ($Me_3SiOCH—CH_2CH=CH(CH_2)_3COOMe$). Its ^{13}C nmr confirmed the presence of a minor isomer; $[\alpha]_D^{23}$ +7.19° (*c* 2.60 in $CHCl_3$). The isomer could be cleanly separated by hplc (petroleum ether (30–60°C) – ethyl acetate, 8.5:1).

*Methyl 8*R,9S,*11*R-*trihydroxy-5*Z,*12*E,*14*Z-*eicosatrienoate (37)*

Alcohol **36** (0.41 g, 1 mmol) in 8 mL methanol and 2 mL 0.1 *N* aqueous HCl was stirred at room temperature for 1 h to effect complete hydrolysis. The solution was neutralized with basic resin (IR-45 OH), and the solvents removed *in vacuo*; the residue was redissolved in ether and dried over $MgSO_4$. Evaporation of the solvent gave triol **37**, as a mixture of 14*E* and *Z* isomers, in quantitative yield. The two olefins were separated by flash chromatography (petroleum ether – ethyl acetate, 3:4). Infrared (neat) 1735 (C=O), 3400 (OH) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.67–2.50 (m, 21H, $9CH_2$, $1CH_3$), 3.17–4.00 (m, 4H, C(8)H, C(9)H, two OH (exchangeable with D_2O)), 3.63 (s, 3H, CO_2CH_3), 4.20–4.60 (m, 1H, C(11)H), 5.18–6.68 (m, 6H, olefinic H's); ^{13}C nmr (acetone-d_6) δ: 174.10 (CO_2Me), 137.69, (C=C), 132.41 (C=C), 130.79 (C=C), 129.17 (C=C), 128.47 (C=C), 125.29 (C=C), 75.28, 74.74, 72.31, 51.49, 40.10, 33.74, 32.12, 31.53, 30.07, 28.24, 27.27, 25.54, 23.11, 14.26; ms *m/e* of tristrimethylsilyl ether: 584 (M), 243 ($Me_3SiOCHCH_2CH=CH(CH_2)_3COOCH_3$), $[\alpha]_D^{23}$ +5.81° (*c* 3.10 in $CHCl_3$); *Anal.* calcd. for $C_{21}H_{36}O_5$: C 68.48, H 9.78; found: C 68.39, H 9.77.

The ^{13}C-spectrum showed 6 olefinic C's, indicating the presence of one isomer only.

Mechanism of the formation of quinoline from *N*-methylacetanilide studied using ^{13}C-labeled substrates[1]

EDWARD LEETE

Natural Products Laboratory,[1] School of Chemistry, University of Minnesota, Minneapolis, MN 55455, U.S.A.

Received February 8, 1980

This paper is dedicated to the memory of Dr. Léo Marion[2]

EDWARD LEETE. Can. J. Chem. **58**, 1806 (1980).

Pictet discovered 90 years ago that quinoline and *p*-toluidine were formed on heating *N*-methylacetanilide with zinc chloride. It has now been shown that 6-methylquinoline is also produced in this reaction. It was established by means of ^{13}C nmr that [1-^{13}C-*acetyl*]-*N*-methylacetanilide affords quinoline and its 6-methyl derivative enriched at C-4. [*N*-*methyl*-^{13}C]-*N*-Methylacetanilide yielded [2-^{13}C]quinoline and [2,6-*methyl*-$^{13}C_2$]-6-methylquinoline. *N*-Methylpropionanilide afforded 3-methylquinoline. These results are in accord with a new mechanism for the formation of quinoline, different from the one previously proposed.

EDWARD LEETE. Can. J. Chem. **58**, 1806 (1980).

Il y a de cela 90 ans Pictet a découvert que le chauffage du *N*-méthylacétanilide en présence de chlorure de zinc produisait la quinoléine et la *p*-toluidine. Il est maintenant prouvé qu'il se forme également de la méthyl-6 quinoléine au cours de cette réaction. On a établi, au moyen, de la rmn du ^{13}C, que le [^{13}C-1 *acétyle*]-*N*-méthylacétanilide produit la quinoléine et ses dérivés substitués en position 6 enrichis au niveau du carbone en position 4. Le [*N*-*méthyl*-^{13}C]-*N*-méthylacétanilide produit la [^{13}C-2] quinoléine et la [2,*méthyl*-6 $^{13}C_2$] méthyl-6 quinoléine. Le *N*-méthylpropionanilide conduit à la méthyl-3 quinoléine. Ces résultats sont en accord avec un nouveau mécanisme de formation de la quinoléine, différent de celui proposé antérieurement.

[Traduit par le journal]

Introduction

In 1889 Pictet and Bunzl (1) discovered that *N*-ethylacetanilide (**1**) on heating with zinc chloride yielded a mixture of *p*-ethylaniline and 2-methylquinoline (**3**). Later it was found that *N*-methylacetanilide (**4**) afforded a mixture of *p*-toluidine (**7**) and quinoline (**8**) (2). These reactions have received no further study; indeed a recent review of synthetic methods for preparing quinolines (3) failed to even mention these publications of Pictet. Elderfield (4) discussed these reactions and rationalized them as illustrated in Fig. 1. It was proposed that the ethyl group of **1** migrated to the *ortho*-position under the influence of the zinc chloride to yield *o*-ethylacetanilide (**2**) which then cyclized to 2-methylquinoline. The formation of quinoline from **4** was considered to proceed via *N*-acetyl-*o*-toluidine (**5**) and 2-methylindole (**6**). 2-Methylindole can certainly be formed from **5** (Madelung synthesis) and a small amount of quinoline was obtained by heating 2-methylindole with zinc chloride (5). These obscure reactions of Pictet came to my attention serendipitously when checking the melting point of *N*-methylacetanilide (6). [1-^{13}C]Acetaldehyde was being prepared by the reduction of [1-^{13}C-*acetyl*]-*N*-methylacetanilide with lithium aluminum hydride (7), and the mechanism of the formation of quinoline from **4** seemed worthy of investigation using the ^{13}C-labeled **4**. The location of the excess ^{13}C in the ultimate quinoline could be readily determined by ^{13}C nmr spectroscopy.

Results and Discussion

[1-^{13}C-*acetyl*]-*N*-Methylacetanilide was prepared from *N*-methylaniline hydrochloride and sodium [1-^{13}C]acetate, condensing in aqueous solution in the presence of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (8). This amide was heated with zinc chloride at 290°C for 6 h in the presence of air. We confirmed the results of Pictet and obtained a small yield of *p*-toluidine (17%) and quinoline (6.5%) along with some *N*-methylaniline (28%). In addition 6-methylquinoline (4%) was isolated, identical with an authentic specimen (9), and readily separated from quinoline by gas chromatography. The ^{13}C nmr spectra of quinoline and 6-methylquinoline have been previously determined (10–12). An examination of the ^{13}C nmr spectra of the quinoline and 6-methylquinoline derived from [1-^{13}C-*acetyl*]-*N*-methylacetanilide revealed that they

[1]Contribution No. 173 from this laboratory.

[2]I worked with Dr. Marion as a postdoctoral fellow (1951–1954) at the National Research Council of Canada Laboratories, Ottawa. He introduced me to alkaloid chemistry and we collaborated in some of the first investigations on the biosynthesis of hordenine, gramine, and the tropane alkaloids. The present publication is relevant to his scientific accomplishments, since one of his earlier papers was a definitive study of the monomethyl and dimethylquinolines (ref. 17).

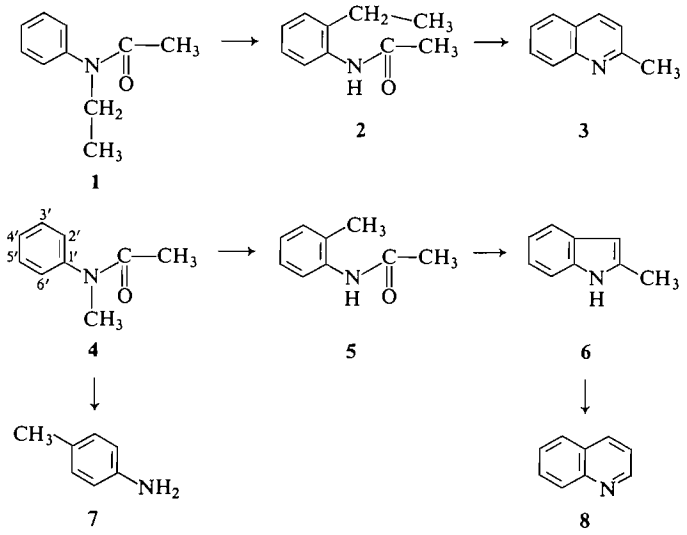

FIG. 1. Reactions discovered by Pictet and their previous rationalization.

were enriched only at C-4. This result is not consistent with the previous rationalization for the formation of quinoline. We thus suggest that quinoline and 6-methylquinoline are formed by the scheme illustrated in Fig. 2. It is proposed that the zinc chloride complex of *N*-methylacetanilide (**9**) serves as a source of acetylium and methyl carbonium ions. Electrophilic attack of *N*-methylaniline with the acetylium ion could yield *o*-acetyl-*N*-methylaniline (**11**) which would yield the imine **13** on dehydrogenation. An aldol condensation then affords 2,3-dihydro-4-quinolone (**15**), a compound having the same oxidation state as quinoline. The latter could thus be formed by enolization, double bond migration, and dehydration. 6-Methylquinoline (**14**) would be formed by an analogous series of reactions from 2-acetyl-4-methyl-*N*-methylaniline (**10**). It seems unlikely that **14** would be formed by reaction of quinoline with methyl carbonium ions, since electrophilic attack of quinoline occurs mainly at the 3, 5, and 8 positions. In a reaction which is considered to involve attack of quinoline with methyl carbonium ions, the main alkylated product was 3-methylquinoline (13). *p*-Toluidine results from electrophilic attack of acetanilide with methyl carbonium ions followed by deacetylation. In this hypothesis the *N*-methyl group of **4** becomes C-2 of quinoline. This was confirmed by carrying out the reaction with [N-*methyl*-^{13}C]-*N*-methylacetanilide. This labeled compound was obtained by reaction of acetanilide with sodium hydride in tetrahydrofuran, followed by addition of [^{13}C]methyl iodide. In a preliminary experiment acetanilide was reacted with butyl lithium followed by [^{13}C]methyl iodide. A mixture of the desired compound and [*N-methyl*-^{13}C, 3-^{13}C-*propionyl*]-*N*-methylpropionanilide (**15**) was obtained, the latter compound being the result of both *N*- and *C*-methylation. The ^{13}C nmr spectrum of this doubly labeled compound was of interest in that a four bond coupling (3.5 Hz) was observed between the highly enriched carbons. Our first thought that this splitting of the enriched positions was due to restricted rotation about the amide bond was rejected when it was found that no such splitting was observed in **15** of natural abundance. The quinoline and 6-methylquinoline derived from [*N-methyl*-^{13}C]-**4** were enriched at C-2, and the latter compound was also enriched at its C-methyl group. Further support for the scheme in Fig. 2 was obtained by heating **15** with zinc chloride. 3-Methylquinoline (**16**) was obtained as expected, together with a small amount of a dimethylquinoline which is probably the 3,6-dimethyl derivative.

Experimental

General

Melting points were determined in glass capillaries and are corrected. The ^{13}C nmr spectra were determined on a Varian XL-100-15 instrument operating at 25.16 MHz interfaced with a VFT-100 Fourier transform system. Chemical shifts are expressed in parts per million from tetramethylsilane (internal reference). Mass spectra were determined on an AEI-MS-30 double beam, double focusing spectrometer.

[*1*-^{13}*C*-acetyl]-N-*Methylacetanilide*, *4*

Sodium [1-^{13}C]acetate (91% ^{13}C, prepared from methyl magnesium iodide and $^{13}CO_2$ (14) (0.83 g, 0.01 mol), *N*-methylaniline

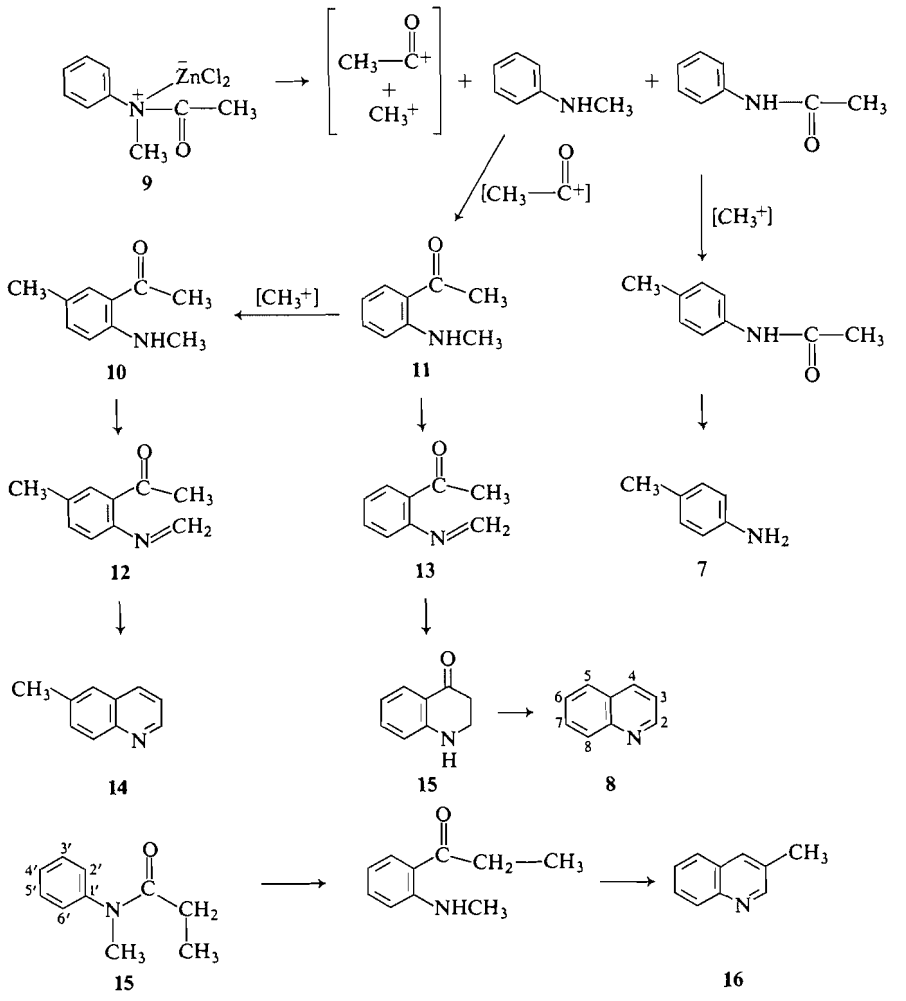

FIG. 2. Proposed mechanism for the formation of quinolines from *N*-acyl-*N*-methylanilines.

hydrochloride (1.6 g, 0.011 mol), and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (4 g) were dissolved in water (5 mL). After stirring for a few minutes a white solid separated which was crystallized from hot water affording **4** as colorless plates (1.31 g, 87% yield) mp 101–102°C; ^{13}C nmr ($CDCl_3$) δ: 170.1 (C=O), 146.4 (1'), 129.5 (3',5'), 127.5 (4'), 126.9 (2',6'), 37.0 (NMe), 22.2 (t, $'J$ = 53.3 Hz, CMe). Assignments were made by comparison with the spectrum of acetanilide (15).

[N-methyl-^{13}C]-N-*Methylacetanilide*

A solution of acetanilide (0.675 g, 0.005 mol) in tetrahydrofuran (5 mL) was added to a suspension of sodium hydride (0.26 g, 0.0054 mol, of a 50% suspension in mineral oil which had been washed with benzene by decantation) in tetrahydrofuran (10 mL) at 0°C in an N_2 atmosphere. After stirring for 10 min [^{13}C]methyl iodide (0.31 mL, 0.005 mol, 91% ^{13}C) dissolved in tetrahydrofuran (2 mL) was added during 20 min. The solution was stirred at 20°C for 1 h and then evaporated. The residue was suspended in water and extracted with ether. The residue obtained on evaporation of the dried (Na_2SO_4) extract was subjected to preparative tlc on Silica Gel 60 PF254 (Merck) developing with a mixture of chloroform, ethanol, and concentrated ammonia (100: 5: 0.5). Two main zones corresponding to *N*-methylacetanilide and acetanilide were obtained. Extraction of the upper zone with methanol afforded [*N-methyl*-^{13}C]-*N*-methylacetanilide which was purified by sublimation (90°C, 0.001 Torr) and crystallization from hexane (0.45 g, 60% yield). Its mass spectrum, run along with natural abundance material, indicated ^{13}C enrichment of 90.7%. Two prominent peaks at 106, 107 due to C_6H_5N-CH_3 and $C_6H_5NHCH_3$, respectively, in the unenriched material, were shifted to 107 and 108 in the ^{13}C-labeled compound. Its ^{13}C nmr spectrum was identical with unenriched material except that the signal due to the *N*-methyl group was greatly enhanced. No splitting of the other resonances were observed due to two or three bond couplings.

[N-methyl-^{13}C, 3-^{13}C-propionyl]-N-*Methylpropionanilide*, *15*

Butyllithium (3.0 mL of a 2.34 *M* solution in hexane = 0.0070 mol) was added at 0°C to a solution of acetanilide (0.78 g, 0.0058 mol) in tetrahydrofuran (10 mL) stirred in an N_2 atmosphere. After 5 min [^{13}C]methyl iodide (0.31 mL, 0.005 mol, 91% ^{13}C) was added and the mixture stirred for 3 h at 0°C. The reaction was worked up as described for [*N-methyl*-^{13}C]-*N*-methylacetanilide, and tlc yielded 3 components: *N*-methylpropionanilide (0.27 g) colorless plates from hexane, mp 58–59°C (lit. (16) mp 58.5°C), *N*-methylacetanilide (0.21 g), and acetanilide (0.25 g); ^{13}C nmr ($CDCl_3$) δ: 173.3 (C=O), 144.2 (1'),

129.2 (3′, 5′), 127.4 (4′), 127.1 (2′, 6′), 37.1 (d, ^4J = 3.5 Hz, NMe), 27.3 (t, ^1J = 35 Hz, CH_2), 9.7 (d, ^4J = 3.5 Hz, CMe).

Reaction of N-*Methylacetanilide with Zinc Chloride*

N-Methylacetanilide (0.5 g) was added to anhydrous zinc chloride (4 g) in a 50 mL round bottom flask and the mixture heated with an air condensor in a metal bath at 290°C for 6 h. The dark brown reaction mixture was then cooled, dissolved in 2 *N* hydrochloric acid, and then made strongly basic with NaOH. The mixture was extracted with ether and the dried (Na_2SO_4) extract evaporated to yield a brown oil which was distilled (160°C, 0.001 Torr).[3] The pale yellow oil (0.242 g) was subjected to tlc in Silica Gel 60 PF254. Many discrete zones were observed (by uv light). The compound with the highest R_f was *N*-methylaniline (102 mg), followed by *p*-toluidine (63 mg), and then a zone which had the same R_f as quinoline (47 mg). This material, dissolved in benzene was subjected to glc on an 8 ft × $^1/_4$ in. column of 5% Carbowax 20 M on Chromosorb W (60–80 mesh) at 160°C. With a He flow rate of 60 mL/min, the retention times of benzene, quinoline, and 6-methylquinoline were 4, 25, and 37 min, respectively. The ratio of quinoline to 6-methylquinoline in the reaction mixture was 3:2. The ^{13}C nmr spectra of the quinoline and 6-methylquinoline were essentially the same (± 0.2 ppm) from the previously published and assigned spectra (10–12). The *N*-methylacetanilide labeled with ^{13}C on the carbonyl or *N*-methyl group was reacted in the same way with zinc chloride. However, unenriched quinoline and 6-methylquinoline were added to the "quinoline" fraction from the tlc in order to facilitate their isolation and purification prior to ^{13}C nmr spectroscopy.

Reaction of N-*Methylpropionanilide with Zinc Chloride*

N-Methylpropionanilide (1.0 g) was heated with zinc chloride (8 g) at 290°C for 6 h and the reaction mixture worked up as described in the previous section. The "quinoline" fraction after distillation (160°, 0.001 Torr) yielded a picrate (25 mg), mp 188–189°C identical (mixture mp, ms, ir) with 3-methylquinoline picrate (lit. (17) mp 190°C). The mass spectra of the crude quinoline fraction indicated the presence of a small amount of a dimethylquinoline which was not isolated in a pure state.

Synthesis and stereochemistry of hydrogenated 1,1,4,4,7a-pentamethylindenes

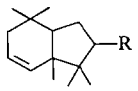
ALAN FRANCIS THOMAS, MICHEL OZAINNE, AND RENÉE GUNTZ-DUBINI

Research Laboratories, Firmenich SA, Geneva, Switzerland

Received January 29, 1980

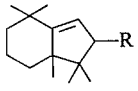
Dédié à la mémoire de Dr. Léo Marion

ALAN FRANCIS THOMAS, MICHEL OZAINNE, and RENÉE GUNTZ-DUBINI. Can. J. Chem. **58**, 1810 (1980).



Ease of methylation of hydrogenated 2*H*-inden-2-ones depends on the presence of a double bond in the cyclohexane ring, and occurs readily with compound **20** but not with **10**. Differences of reactivity are also noted in Wittig reactions. Most reactions of the system are highly stereoselective, and the stereochemistry of hydrogenated indenes is discussed.

ALAN FRANCIS THOMAS, MICHEL OZAINNE et RENÉE GUNTZ-DUBINI. Can. J. Chem. **58**, 1810 (1980).



La facilité avec laquelle les indène-2*H* ones-2 hydrogénées sont méthylées dépend de la présence d'une double liaison dans le cycle à six chaînons; ainsi, la méthylation du composé **20** est beaucoup plus facile que celle du composé **10**. On constate également des différences de réactivité lors de la réaction de Wittig. La plupart des réactions de ce système sont hautement stéréosélectives, ce qui nous a permis d'ailleurs d'approfondir notre connaissance de la stéréochimie des indènes hydrogénés.

Introduction

In the course of other work, we had occasion to investigate the stereochemistry of highly substituted hydroindanes. These substances are little known, and in particular, we chose to synthesize the crowded molecules **1** and **2** (where R contains a carbonyl or hydroxyl function to permit complexation with a lanthanide shift reagent), because in such cases, each atom should be readily identifiable by nmr methods.

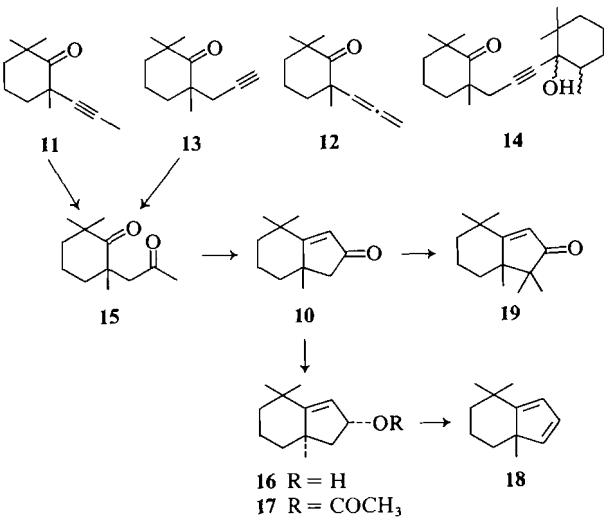
2

Syntheses

Initially, it appeared that the most rapid approach to the pentamethylated structures we had in mind would be by addition of a second methyl group in the β-position of the αβ-unsaturated cyclic ketone **3** obtained (1) from damascenone **4**, using lithium dimethylcuprate. The reaction was very slow, and only the 1,2-Grignard addition product **5** was isolated, together with the two hydrocarbons, **6**, **7**, from the dehydration of **5**. The normal Grignard reaction also works badly with ketone **3**; after 12 h at room temperature in the presence of excess methylmagnesium iodide, 60% of the starting material is recovered unchanged and about 30% is reduced (to the saturated ketone, **8**) without addition. To find out whether a compound with one or both of the double bonds reduced would perform better in organometallic addition reactions, catalytic reduction of **3** was undertaken, but a complex mixture of products was obtained, from which only the dihydroketone **9** could be identified.

We then investigated the methylation of 4,4,7a-trimethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-one **10**. This appears to be a new compound, and is readily made by a modification of the cyclization originally described by Islam and Raphael (2). Various conditions were tried for the introduction of a C_3 chain into 2,2,6-trimethylcyclohexanone at C(6). Using sodium hydride in dimethylformamide and 2,3-dichloropropene, 23% of the methylacetylene **11** was formed, together with a trace of the corresponding allene **12** and the terminal acetylene **13**. The latter was the major product (60%) using sodium amide in toluene and either propargyl chloride (the bromide is much less satisfactory[1]) or 2,3-dichloropropene. One of the reasons for the lower yield in this step is the formation of considerable amounts of a heavier compound, $C_{21}H_{34}O_2$, to which we ascribe the structure **14**, and which would arise from the addition of the terminal acetylene **13** to a second molecule of trimethylcyclohexanone. Using the usual conditions

4 **3** **5** **8** **9** **6** **7**



[1]Miller (3) obtained 26% yield in a similar reaction with 2-methylcyclohexanone and propargyl bromide. Certainly the yield would have been much improved if he had used the chloride.

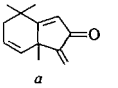
(acid + Hg^{2+}, see below), we were unable to hydrate the triple bond assumed to be present in **14**, so this was not usable for subsequent steps of the reaction sequence.

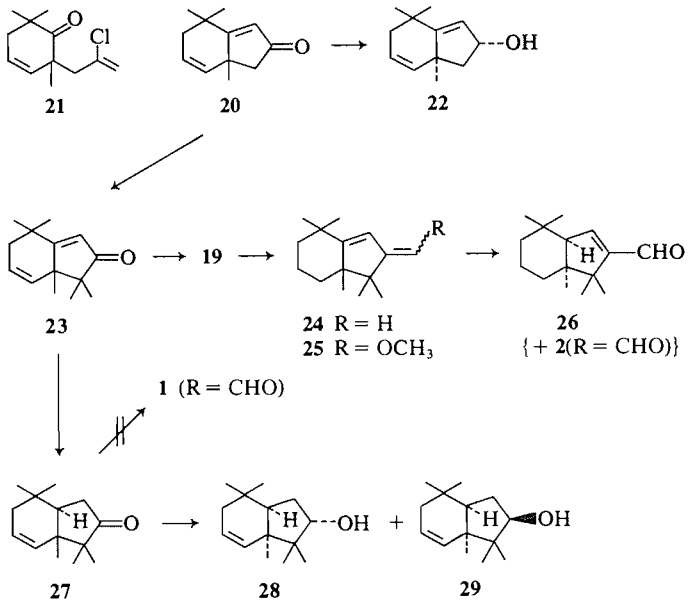
Hydration of the acetylenes **11** or **13** using Hg-impregnated Dowex 50 resin gave the diketone **15** in over 80% yield. Many variations for cyclizing conditions of this type of diketone have been described (2, 4), usually with yields of 60–75%, although Yoshikoshi and co-workers have reported higher yields (5). Using catalytic amounts of dry, powdered potassium hydroxide in boiling xylene, the bicyclic ketone **10** was obtained in one hour in 96% yield. Lithium aluminum hydride reduction of **10** gave an alcohol that was > 90% sterically homogeneous. This alcohol is presumably *cis* **16**, assuming approach of the reagent from the side of the molecule opposite to the angular methyl group (for spectral evidence see below). There is little information published about the metal hydride reduction of 7a-methylhexahydro-2-indenones of this type, although Furth *et al.* prepared both isomers of unsubstituted hexahydro-2*H*-inden-2-ol by a different route (6). Such alcohols are very easily dehydrated (cf. (7)) and both **16** and its acetate **17** could not be gas chromatographed, only the diene **18** being recovered.

Methylation of the ketone **10** proceeded very poorly, but a 20% yield of the ketone **19** was obtained, together with a certain amount of *O*-methylated products. Subsequently we were able to prepare **19** more efficiently, although it turned out to be of only limited use.



By a similar route to that just described, but starting from 2,6,6-trimethylcyclohex-2-enone (8), we prepared 4,4,7a-trimethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one **20** in acceptable yield. In this connection, we also prepared the chloroketone **21** in poor yield from 2,6,6-trimethylcyclohex-2-enone and 2,3-dichloroprop-1-ene in the presence of sodium amide in toluene. Lithium aluminum hydride reduction of **21** yielded a mixture of the corresponding stereoisomeric alcohols which should be cyclizable with formic acid according to Lansbury *et al.* (9). We were unable to confirm this, and indeed, it should be noted that Lansbury's cyclization is an unfavored "5-endo-trig" type following Baldwin's postulate (10).

The metal hydride reduction of the ketone **20** proceeded in the same way as for the more saturated ketone **10** (the alcohol **22** and its acetate were again unstable to gas chromatography), but methylation was much easier, 86% of 1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one **23** being isolated.[2] This fact illustrates how reactivity in the cyclopentane part of the molecule can be strongly influenced by unsaturation in the cyclohexane part, hindrance when this is saturated being the cause of the extensive *O*-alkylation of **10**. Catalytic hydrogenation of **23** gave the ketone **19** almost quantitatively by a much more convenient route than the earlier one.



The ketone **19** readily underwent Wittig reactions. After a small-scale reaction with methylenetriphenylphosphorane had been shown to give **24**, a similar reaction using methoxymethyltriphenyl phosphonium chloride in tetrahydrofuran with butyllithium yielded two isomers of the enol ether **25**. Without separating them, these were refluxed with oxalic acid for 2 h, when they were converted to the conjugated aldehyde **26**. No conditions were found to yield more than impure traces of the unconjugated aldehyde **2** (R = CHO). This behavior again contrasts with that of the analog unsaturated in the cyclohexane ring (see below). We believed that it would be difficult to convert **26** to our target molecules **2**, and impossible to convert it to **1**, and so the following approach was adopted.

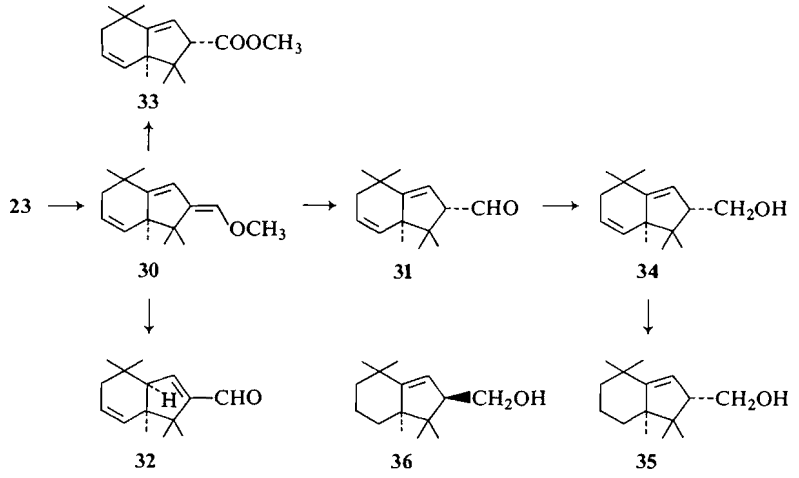
The conjugated double bond of the unsaturated ketone **23** was readily reduced by lithium in liquid ammonia, yielding a single substance **27**, to which a *cis* configuration was attributed, based on spectral

[2]An attempt to introduce a substituent at C(1) of **20** via the C(1)-methylene compound *a* gave such poor yields that it was abandoned (see Experimental).

a

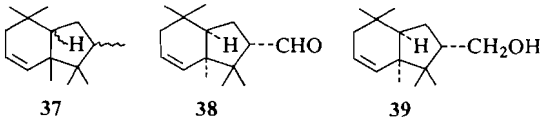
data (below) of both it and the two alcohols **28**, **29** (and their acetates) obtained from it by lithium aluminum hydride reduction. Furthermore, models show clearly that the 1,3-diaxial interaction between the angular methyl group and one of the methyl groups at C(4) would cause considerable strain in a *trans*-fused system. Compound **27** has a very unreactive carbonyl group. Although we could prepare **28** and **29** and their acetates, we were unable to carry out any form of Wittig reaction, and even methylmagnesium iodide and methyllithium were without action. Sowerby and Coates's method (11) for placing a methylene group at the position of a hindered carbonyl group by addition of the lithium salt of thioanisole followed by benzoylation yielded only the enol benzoate of **27**.

The more unsaturated ketone **23** reacted readily with the ylide from methoxymethyltriphenylphosphonium chloride. Probably two isomers were formed, but after chromatography on silica gel, only the *Z*-isomer **30** was characterized. Hydrolysis of the latter was very slow, 25% of the starting material being recovered after reflux for 30 h with oxalic acid (this recovered material was now a mixture of two isomers visible by gc), but it was also possible to isolate the unconjugated aldehyde **31** in ca. 50% yield, together with a small amount of the conjugated aldehyde **32**. In an attempt to improve the yield from the hydrolysis of the enol ether **30**, aqueous/ethereal perchloric acid was tried, but the only substances isolated from the reaction were the *E*-isomer of **30** (apparently less readily hydrolyzed than the *Z*-isomer[3]) and the ester **33**, easily recognizable from its nmr spectrum, and confirmed by the mass spectrum. This ester presumably arises by oxidation of the aldehyde **31** by the perchloric acid, and esterification by the methanol present. The conjugated aldehyde **32** could be obtained from the unconjugated one **31** by treatment with methanolic potassium hydroxide, and the two aldehydes are readily separable by gc, when **31** has a much shorter retention time on most columns than **32**.



Lithium aluminum hydride reduction of the unconjugated aldehyde **31** gave an alcohol **34**, catalytic hydrogenation of which yielded the alcohol **35**, both **34** and **35** being almost (>98%) stereochemically homogeneous. Metal hydride reduction of the aldehyde **26**, however, yielded the corresponding alcohol together with ca. 12% of a mixture (3:2) of the alcohol **35** and its stereoisomer **36**. This mixture proved to be inseparable on packed gc columns, and even on the capillary column at our disposal, only a single peak was observed.[4]

In order to make compounds of the type **1**, it is necessary to reduce the double bond of the cy-



[3]The fact that we isolated the *E*-enol ether after acid hydrolysis of the *Z*-enol ether suggests that protonation is reversible, and the rate-determining step in this case is hydration, unlike certain other examples of enol ether hydrolysis (12).

[4]A referee has pointed out that $LiAlH_4$ in ether is not a normal medium for $\alpha, \beta \leftrightarrows \beta, \gamma$ interconversion of the double bond. We suggest one possible explanation: formation of the enolate with $LiAlH_4$, which undergoes decomposition and reduction on addition of water, leading to both alcohols **35** and **36**.

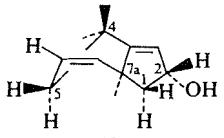
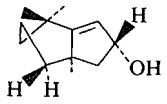
For personal use only.



clopentene ring of **31**. Treatment of **31** with lithium in liquid ammonia (in the hope that the double bond would be first displaced, then hydrogenated) left the material unchanged, while similar treatment of the conjugated aldehyde **32** yielded practically exclusively hydrocarbons (apparently the major product was a single isomer of **37**). Catalytic reduction of a mixture of the aldehydes **31** and **32** in ethanolic potassium hydroxide proceeded rapidly until about 0.6 equivalents of hydrogen had been absorbed, at which point unchanged unconjugated aldehyde **31** was recovered from the mixture, together with the aldehyde **38**. Reduction of **38** with lithium aluminum hydride yielded the single, crystalline alcohol **39**.



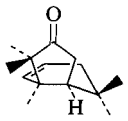
37 **38** **39**

Stereochemistry

The first stereochemical problem concerns the orientation of metal hydride reduction of the indenones **10** and **20**, in which the product is stereochemically almost homogeneous. Models suggest a boat-shaped cyclohexene ring for the ketone **20**, and possibly even for **10**, which avoids a 1,3-diaxial methyl group interaction. Approach from above would thus appear preferred, leading to configuration (and conformation) **22***a* for alcohol **22**. We have been unable to locate any earlier work on the stereochemistry of metal hydride reduction of this kind of system, but it is known that attack on the carbonyl group of 3-substituted cyclopentanones by metal hydrides (13) and Grignard reagents (14) occurs with slight preference from the opposite side of the ring to the substituent. Presumably this tendency will be augmented by the rigidity of the system, and the raising of the "flap" C(1) above the plane of the other four atoms of the cyclopentene ring. After reduction, this C(1) flap will be below the plane of the ring to ease the strain of the new hydroxyl group. This structure **22***a* is

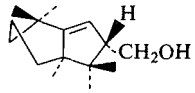
22*a*

16*a*



supported by the following spectral evidence. Of the protons at C(1), the ^{1}H nmr spectrum shows for one a signal at 1.49 ppm, and for the other at 2.24. The one at higher field is *cis* to the OH group (because of the much greater shift induced by Eu(fod)$_3$) and is "axial-like", so shifted upfield from what one might normally expect.[5] The protons at C(5) exhibit signals at about 1.96 ppm. They are indistinguishable until Eu(fod)$_3$ is added, when one shifts with $\Delta(\delta) = 0.16$ ppm (arbitrary concentration) at the same time as the other shifts with 0.32 ppm. The former is presumably *trans* to the OH group, and has $J_{5,6} = 6$ Hz, while the other proton at C(5) has $J_{5,6} = 2$ Hz (the geminal coupling, $J_{5,5'}$ is 17 Hz). We must thus place the *cis* C(5) proton nearly at right angles to the vinyl proton at C(6), the other C(5) proton being nearly parallel to C(6)—H. The ^{1}H nmr spectrum of the indenol saturated in the cyclohexane ring **16***a* is so similar to that of **22***a* that the stereochemistry of the cyclopentene ring must be the same. Using the

[5]We have recently reported a similar case of a high upfield shift of a C(4) proton in a cyclopentene (15).



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

$Eu(fod)_3$ shift reagent, it was possible to see that one of the protons at C(7) was responsible for a signal at 1.28 and the other at 1.73 ppm (found by extrapolating back to zero $Eu(fod)_3$ from the methylene group which shifted the most after $C(1)H_2$). Generally, axial protons are at higher field than equatorial protons, and the proton at 1.28 had J = 15, 12, and 4 Hz, consistent with a geminal, a *trans*-diaxial, and an equatorial coupling respectively, while the other proton had J = 15 and about 2 Hz. The axial proton was more strongly shifted by $Eu(fod)_3$ than the equatorial proton ($\Delta(\delta)$ = 0.62 and 0.38), so either the OH group is on the side of the axial proton, or the ring approaches a boat shape. We prefer the latter explanation, as this will relieve the strain of the 1,3-diaxial methyl groups at C(4) and C(7). In **16***a*, $J_{1,2}$ = 6.5 Hz for both the *cis* and *trans* couplings, but in **22***a*, $J_{1\text{-}cis,2}$ = 6 Hz, while $J_{1\text{-}trans,2}$ = 8 Hz, demonstrating again the fact that coupling constants around 5-membered rings are "notoriously uncertain" (16).

27*a*

35*a*

It has been mentioned in the literature without experimental evidence that lithium in liquid ammonia reduction of 7a-methyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-one gives 70% of the *cis* ring fused product (17). We ascribe a *cis* ring junction to the product **27***a* of the lithium in liquid ammonia reduction on the unsaturated ketone **23**. Models show this to be the more stable configuration, and some support is provided by the ^{13}C nmr spectra. On comparing the ^{13}C nmr spectrum of the relatively flat **20** and **23** (Table 1), for which there is no ambiguity, with the compounds having a reduced C(3)—C(3a) bond, we find that the signal for C(5) is always lower by about 6 Hz in the latter. These figures can only be accounted for by the presence in the reduced compounds of a nearly axial substituent at C(3a). A consequence of this *cis* configuration for **27***a* is the inaccessibility of the carbonyl group.[6] Metal hydride reduction of this ketone is much less stereoselective than with the others we have mentioned, but there is some preference for approach of the reagent from the *exo* side. Both the ^1H and the ^{13}C nmr spectra of the two alcohols **28** and **29** produced in this reaction lead to the assignment of the *endo* configuration, **29**, to the major product. In this case there is a marked downfield shift of especially C(7)H caused by the proximity of the oxygen atom. In the *exo* alcohol, **28**, the carbinol proton C(2)H is nearly parallel to the C(3a)—C(4) bond, causing a shielding of C(2) in this isomer, and there is also a small γ-effect of the hydroxyl group on C(3a) comparable with the effect in *cis* and *trans* 3-methylcyclopropanol (18).

The single alcohol, **35**, obtained after the Wittig reaction from ketone **23** had a signal (360 MHz ^1H nmr) corresponding to C(2)—H at 2.55 ppm, similar in appearance to the C(2)—H signal of **34**, with coupling constants of 6 and 9 Hz with the two dissimilar protons of the carbinol group; $J_{2,3}$ is very small (about 1 Hz). During the reduction of the conjugated aldehyde **26**, however, the allyl rearrangement that occurs is not stereospecific, and the mixture of **35** and **36** obtained exhibited all the signals of the alcohol **35** obtained by the other route, together with additional ones, notably a signal at 2.21 ppm which, in addition to the couplings of 6 and 9 Hz, had another ($J_{2,3}$) of 2.5 Hz. We assign the compound with the higher field signal for C(2)—H the stereochemistry with C(7a)—methyl and C(2)—H *cis*, the other (major) product being as shown in **35***a*. The lower $J_{2,3}$ coupling constant of the latter reflects the greater deformation of the cyclopentene ring in this case, increasing the dihedral angle between C(2)—H and C(3)—H.

If the deductions about the alcohols **34** and **35** are correct, it follows that the aldehyde **31** must also be *cis*, and probably the ester **33** too.

Experimental

The ^1H and ^{13}C nmr spectra were recorded on a Bruker 90 or a Bruker VH-360 instrument for higher resolution spectra. The 60 MHz ^1H nmr spectra were recorded on a Hitachi-Perkin Elmer R20B instrument. The solvent was always deuterochloroform, and chemical shifts (δ) were measured downfield from tetramethylsilane. Singlets, doublets, etc. are identified by their initial letters; $w_{\frac{1}{2}}$ = width in Hz of signal at half height. Mass spectra (ms) were measured on an Atlas CH 4 mass spectrometer using an inlet temperature of about 150°C, or on a MAT 110 instrument coupled with a capillary column gas chromatograph, both spectrometers using electrons of 70 eV. Results are quoted in *m/e* (% most important fragment) and generally the ten most important fragments are given. The uv spectra were measured on a Unicam SP 700A spectrometer in ethanol, with λ_{max} (ε) in nm. Infrared spectra were obtained on a Perkin Elmer type 125 spectrophotometer. Gas chromatography (gc) was carried out on a Carlo-Erba type GT chromatograph with He as carrier gas.

All compounds are characterized by nmr and ms; elemental analyses were also carried out when it was felt they could contribute useful information.

[6]It should be noted that another conformation besides **27***a* (or a more skewed version of **27***a*) is possible for this compound having the "flap" of the cyclohexene ring that carries the *gem*-dimethyl group (C(4)) upwards, but this would give severe strain between one of the methyl groups at C(1) and the axial methyl group at C(4); furthermore, it is difficult to account for the ^{13}C nmr spectra with this model.

*Alternative assignments.
†Doubtful assignment because signal is coincident with C(7a).

Dry, powdered potassium hydroxide is supplied by SUGRO, Basle, Switzerland, and the suspension of sodium amide in toluene is a product of DEGUSSA, Germany.

*1,3,3a,7,7-Pentamethyl-3a,6,7,7a-tetrahydro-1*H*-inden-1-ol, 5*

Into a suspension of cuprous iodide (4.3 g) in dry ether (80 mL) at −10°C was introduced a solution of methyllithium (prepared from 0.7 g Li and 7.1 g methyl iodide). The mixture was cooled to −60°C and 3,3a,7,7-tetramethyl-3a,6,7,7a-tetrahydro-1*H*-inden-1-one (**3**, 0.9 g) in absolute ether (5 mL) was added. After 5 h at 0°C, 55% of the starting material was unchanged (workup by quenching in NH_4Cl solution and ether extraction). The products were purified by gc (SP 1000 column), when the alcohol **5** was separated from the hydrocarbons **6** and **7**. Spectra of the title alcohol, **5**: ^1H nmr (60 MHz) δ: 1.05, 1.18, 1.28, 1.42, 1.69 (each s, CH_3); 5.17 (1H, $w_{\frac{1}{2}}$ = 4 Hz); 5.60 (2H, s + narrow d); ms: 173 (100), 188 ($M-18^{+\cdot}$, 55), 131 (31), 145 (22), 91 and 43 (16), 174, 158, and 41 (12), 132 (11), 191 ($M-15^{+}$, 6).

*3,3a,7,7-Tetramethyl-1-methylene-3a,6,7,7a-tetrahydro-1*H*-indene, 6*

^1H nmr (60 MHz) δ: 0.60 (s), 1.01 (6H, s), 1.75 (3H, d, J = 2 Hz, CH_3), 4.71 (1H) and 4.89 (1H) (each s, C=CH_2), 5.65 and 5.69 (each apparent s, 3H in all); ms: 173 (100), 131 (37), 188 ($M^{+\cdot}$, 26), 174, 145, and 91 (13), 158 and 132 (11).

*3,4,4,7a-Tetramethyl-1-methylene-3a,4,5,7a-tetrahydro-1*H*-indene, 7*

^1H nmr (60 MHz) δ: 0.62 (s), 1.08 (6H, s), 1.92 (3H, broad s) (CH_3); 4.50 and 4.68 (each s, C=CH_2), 5.50–6.0 (3H, m); ms: 173 (100), 188 ($M^{+\cdot}$, 61), 145 (56), 131 (54), 132 (35), 91 (27), 119 (22), 117 (21), 105 (19). This compound (**7**) has a slightly longer retention time on an SP 1000 column than **6**. The distinction between them is based on the shielding of the =CH_2 group by the adjacent methyl group in **7**, and the fact that this methyl group should be lost more easily in the ms of **6** (i.e. *m/e* 173 is a larger proportion of the total ionization in **6** than in **7**).

*3,3a,7,7-Tetramethyl-2,3,3a,6,7,7a-hexahydro-1*H*-inden-1-one, 8.*

3,a,7,7-Tetramethyl-3a,6,7,7a-tetrahydro-1*H*-inden-1-one, **3** (1.9 g, 0.5 equiv.) was added to a Grignard reagent prepared from magnesium (0.48 g) and methyl iodide (2.9 g) in ether. After 12 h at room temperature, the mixture was decomposed with saturated aqueous NH_4Cl solution. The product was extracted in ether and purified by chromatography on silica gel. There were isolated ca. 10% of the hydrocarbons **6** and **7** (but no alcohol **5**, which probably decomposed during chromatography), unchanged starting material (ca. 60%), and the title product. This was purified by gc on SP 1000; ^1H nmr (60 MHz) δ: 1.00 (9H, narrow m), 1.12 (3H, s) (CH_3), 5.67 (s) superimposed on a d (2H); ms: 107 (100), 192 ($M^{+\cdot}$, 43), 122 (42), 177 (19), 91 (15), 41 (14), 83 (13), 123 (11).

*3,3a,7,7-Tetramethyl-3a,4,5,6,7,7a-hexahydro-1*H*-inden-1-one, 9*

A solution of 3,3a,7,7-tetramethyl-3a,6,7,7a-tetrahydro-1*H*-inden-1-one, **3** (1.9 g) in ethanol (190 mL) was shaken in H_2 over a Pd–C (10% Pd) catalyst. The theoretical amount of H_2 was absorbed in 1 h. The mixture was filtered and from the residue, after concentration of the solvent, only the compound with the longest retention time (gc on SP 1000) was isolated from the complex mixture; ^1H nmr (60 MHz) δ: 0.90 (3H, s), 1.18 (6H, s), 1.99 (3H, d, J = 1.5 Hz, CH_3), 5.75 (1H, q, J = 1.5 Hz); ms: 110 (100), 123 (61), 177 (56), 192 ($M^{+\cdot}$, 24), 109 (21), 121 (20), 41 (19), 95 (16), 55 (13), 82 and 111 (11).

2,6,6-Trimethyl-2-(prop-1-ynyl)-cyclohexanone, 11

A suspension of sodium hydride (55% in oil, 33 g) was washed once with hexane, then dimethylformamide (1000 mL) was added. With efficient stirring, 2,2,6-trimethylcyclohexanone[7] (100 g) was added, and the mixture heated at 45–55°C for ca. 20 h, then cooled to 20°C. 2,3-Dichloropropene (95 g) was added over 45 min, during which the temperature rose to 30°C where it was maintained for a further 4.5 h. The mixture was then continuously extracted with pentane, and the pentane solution washed (water, 10% HCl, water, $NaHCO_3$, water), dried, and distilled. After 2,2,6-trimethylcyclohexanone (35 g, bp 40°C/10 Torr), the title product distilled (15 g, bp 100°C/10 Torr). For analysis, 2 g of this fraction was chromatographed on silica gel in hexane–ether (9:1), when 1.5 g was recovered (98% pure by gc on Apiezon). After gc, the substance had the following spectra: ^1H nmr (60 MHz) δ: 1.01, 1.22, 1.35, 1.73 (CH_3); ms: 80 (100), 79 (91), 135 (79), 107 (76), 91 (69), 93 (67), 106 (58), 41 (54), 39 (35)...178 ($M^{+\cdot}$, 8.5). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 81.10, H 10.00. The remaining 2% of this fraction, collected from the Apiezon column just after **11**, was *2,6,6,-trimethyl-2-(propa-1,2-dienyl)-cyclohexanone*, **12**. ^1H nmr (60 MHz) δ: 1.04 (3H), 1.12 (6H, s, CH_3), 4.80 (2H, d, J = 6–7 Hz), 5.20 (1H, d of d, J = 6 and 7 Hz, presumably negative (19)); ms: 122 (100), 109 (80), 108 (61), 121 (40), 79 (36), 41 and 43 (35), 178 ($M^{+\cdot}$, 32), 135 (27), 91 and 107 (26). A much heavier fraction, bp 120–125°C/0.001 Torr, was obtained at the end of the distillation. It was never completely pure but appeared to be mainly 2-(1-(1-hydroxy-2,6,6-trimethylcyclohexyl)-prop-1-yn-3-yl)-2,6,6-trimethylcyclohexanone, **14**. Infrared: 1690, 3550 cm^{-1} (C=O and OH); ^1H nmr (90 MHz)

[7]Prepared by catalytic reduction of 2,6,6-trimethylcyclohex-2-enone (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

On p. 1816, the preparation by method A of 2,6,6-trimethyl-2-(prop-2-ynyl)-cyclohexanone, 13, is incorrect. Method B is correct, and leads to 13, which has the spectral properties and microanalysis ascribed to it under method A.

δ: 0.95–1.25 (ca. 18H, m), 2.43 and 2.52 (ca. 2H, each s), no vinyl signals; ms: 82 (100), 55 (98), 69 (97), 41 (90), 42 (75), 83 (63), 57 (56), 75, 95, and 109 (42)...179 (33)...318 ($M^{+\cdot}$, 5). *Anal.* calcd. for $C_{21}H_{34}O_2$: C 79.19, H 10.76; found: C 80.51, H 11.03.

2,6,6-Trimethyl-2-(2-chloroprop-2-enyl)-cyclohex-3-enone, 21

2,6,6-Trimethylcyclohex-2-enone (138 g) and sodium amide (70% in toluene, 55 mL) were heated in toluene (1300 mL) at 85°C for 3.5 h, then for 2 h at reflux. The mixture was cooled to 10°C, and 2,3-dichloroprop-1-ene (114 g) added. After 17 h, the mixture was poured onto ice and extracted with pentane. Distillation of the products after concentration gave a fraction (16%) with bp 50–52°C/0.1 Torr which was practically pure **21**; ^{1}H nmr (60 MHz) δ: 1.12 (3H), 1.28, (6H, CH_3), 2.30 (d, J = 13 Hz, superimposed on another signal), 3.10 (1H, d, J = 13 Hz), 5.08 and 5.20 (each 1H, s), 5.72 (s, superimposed on d, 2H in all); ms: 70 and 109 (100), 93 and 107 (75), 41 (61), 177 (60), 137 (52), 68 (46), 91 (44)...212/214 ($M^{+\cdot}$, 4.5). *Anal.* calcd. for $C_{12}H_{17}ClO$: C 67.75, H 8.05; found: C 67.89, H 8.06. *2,6,6-Trimethyl-2-(prop-1-ynyl)-cyclohex-3-enone* was made either as for compound **11**, or by treatment of the chloro-compound **21** with sodium amide in dimethylformamide at 80°C for 6 h. The product had bp 40–45°C/0.1 Torr; ^{1}H nmr (60 MHz) δ: 1.10, 1.31, 1.35, 1.75 (s, CH_3), 2.30 (2H, apparent d, 2 Hz between signals), 5.71 (2H, s); ms: 91 (100), 133 (55), 106 (53), 105 (49), 41 (27), 39 (22), 70 (14), 77 (13), 161 (12)...176 ($M^{+\cdot}$, 2).

2,6,6-Trimethyl-2-(2-chloroprop-2-enyl)-cyclohex-3-enol

The ketone **21** was reduced with excess lithium aluminum hydride in dry ether. The excess reagent was decomposed with water, the mixture was filtered and concentrated, and the product was not purified further; ^{1}H nmr (60 MHz) δ: 0.96, 1.00, 1.01, 1.08, 1.20 (9H in all, CH_3), 1.91 (2H, d, J = 2.5 Hz), 2.46 and 2.66 (each 1H), 3.40 and 3.62 (1H together, broad s, carbinol H, ratio 6:4 corresponding to two isomers), 5.15 and 5.29 (each 1H, s), 5.53–5.55 (2H); ms: 43 (100), 139 (41), 95 (35), 41 (34), 81, 72, and 55 (21), 57 (19), 39, 59, and 121 (18), 178 (M − $HCl^{+\cdot}$, trace).

2,6,6-Trimethyl-2-(prop-2-ynyl)-cyclohexanone, 13

Method A ERRATA

2,2,6-Trimethylcyclohexanone (7 g) was added during 15 min to a suspension of sodium amide (70% in toluene, 3.2 mL) in toluene (70 mL). The mixture was heated 1.25 h at reflux, then cooled at 20°C while 2,3-dichloropropene (7.8 g) was added over 15 min, maintaining the temperature at 18–20°C. The mixture was kept overnight at 20°C, washed with water, dried, and concentrated. Distillation yielded 3.9 g of **13**, bp 95°C/10 Torr (60%, taking account of 1.8 g of starting material recovered in the top fraction). For analysis, it was purified by gc on OV 17; ^{1}H nmr (60 MHz) δ: 1.10, 1.15, 1.20 (each 3H, s, CH_3), 2.40 (2H, t, J = 2 Hz); ms: 82 (100), 55 (85), 41 (74), 79 (70), 107 (58), 69 and 72 (55), 39 (30), 93 (29)...178 ($M^{+\cdot}$, 24). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.80, H 10.27.

Method B

The 2,2,6-trimethylcyclohexanone enolate was prepared as in method A. Propargyl chloride (7.8 g) was added at 20°C. After 18 h stirring at this temperature, the mixture was washed with water, dried, and concentrated. Distillation of the residue yielded 3.8 g of **13**. Use of propargyl bromide gave only 23% yield of **13**.

2,6,6-Trimethyl-2-(prop-2-ynyl)-cyclohex-3-enone was made in the same way as that described for **13** (previous experiment), but starting from 2,6,6-trimethylcyclohex-2-enone (8). It was obtained in 57% yield, bp 47–58°C/0.1 Torr, sufficiently pure for subsequent experiments. For analysis it was purified by gc on OV 17; ^{1}H nmr (60 MHz) δ: 1.12, 1.28, 1.30 (each 3H, s, CH_3), 1.92 (1H, t, J = 3 Hz), 2.20–2.55 (4H, m), 5.6–6.0 with sharp s at 5.83 (2H); ms: 91 (100), 70 (80), 109 (70), 105 (69), 41 and 106 (45), 39, 67, and 92 (33), 161 (31)...176 ($M^{+\cdot}$, 2).

FOR ERRATA SEE at the top of this page, V59 #3 1981 p. 590

2,6,6-Trimethyl-2-(2-oxopropyl)-cyclohexanone, 15

2,6,6-Trimethyl-2-(prop-1-ynyl)-cyclohexanone (10 g) and Hg-impregnated Dowex 50 resin (20) in water (4 mL) and methanol (10 mL) were stirred for 1.3 h. The temperature rose to 32°C, and when it fell again, the mixture was filtered, concentrated, and distilled, bp 50°C/0.001 Torr, to yield 8.1 g (80%) of **15**; ^{1}H nmr (60 MHz) δ: 1.08 (6H, s), 1.14, 2.02 (each 3H, s, CH_3); AB system with A 2.27, B 3.25, $J_{A,B}$ = 18 Hz; ms: 43 (100), 114 (66), 69 (34), 41 (24), 95 (18), 55 (17), 82 (16), 81 (12), 139 (11)...196 ($M^{+\cdot}$, 2.4). *Anal.* calcd. for $C_{12}H_{20}O_2$: C 73.43, H 10.27; found: C 73.54, H 10.40.

2,6,6-Trimethyl-2-(2-oxopropyl)-cyclohex-3-enone was made in the same way from either 2,6,6-trimethyl-2-(prop-1-ynyl)-cyclohex-3-enone or 2,6,6-trimethyl-2-(prop-2-ynyl)-cyclohex-3-enone. The crude product could be distilled, bp 66°C/10 Torr, but generally it was cyclized directly; ^{1}H nmr (60 MHz) δ: 1.15 (6H, s), 1.20, 2.02 (each 3H, s, CH_3), ABX system with A 2.08, B 2.73, X 5.80, $J_{A,B}$ = 17, $J_{A,X}$ = 6, $J_{B,X}$ = 2 Hz; AB system with A 2.53, B 3.28, $J_{A,B}$ = 17 Hz. The vinyl proton (X) of the ABX system is coupled to another vinyl proton at 5.41 (J = 10 Hz); ms: 43 (100), 70 (29), 81 (27), 123 (25), 109 (23), 124 (15), 41 (14), 82 (13), 95 (12)...194 ($M^{+\cdot}$, 7.2).

4,4,7a-Trimethyl-1,4,5,6,7,7a-hexahydro-2H-inden-2-one, 10

A suspension of dry powdered potassium hydroxide (0.5 g) in xylene (40 mL) was heated at reflux with a water separator while 2-(2-oxopropyl)-2,6,6-trimethylcyclohexanone (4 g) was added. After a few minutes, water began to separate, and when this was finished (ca. 1 h), the xylene was washed (water) and concentrated. The residue was distilled, bp 40–45°C/0.01 Torr, to yield 3.5 g (96%) of **10**. Infrared: 1600, 1700 cm^{-1}; ^{1}H nmr (60 MHz) δ: 1.16, 1.21, 1.31 (each 3H, s, CH_3), 2.26 (2H, s), 5.80 (1H, s); ms: 136 (100), 121 (61), 108 (59), 178 ($M^{+\cdot}$, 56), 135 (54), 107 (51), 109 and 122 (44), 163 (43), 41 (41). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 81.01, H 10.15.

4,4,7a-Trimethyl-1,4,5,7a-tetrahydro-2H-inden-2-one, 20 was prepared similarly to **10** from 2-(2-oxopropyl)-2,6,6-trimethylcyclohex-3-enone (72 g) and anhydrous potassium hydroxide (1.1 g, then after 45 min, a further 0.5 g) in xylene (800 mL). After distillation, bp 65–70°C/0.01 Torr, 59.8 g (91%) of **20** was obtained which crystallized on cooling, mp 43–44.5°C; uv λ_{max}: 234 (ε_{max} 14 370); ^{1}H nmr (60 MHz) δ: 1.25, 1.31, 1.39 (CH_3), 2.15 (2H, d, J = 2.5 Hz), 2.38 (2H, s), 5.68 (t, J = 2.5 Hz) and 5.70 (2H together), 5.85 (1 H, s); ms: 133 (100), 161 (99), 176 ($M^{+\cdot}$, 91), 105 (53), 91 (46), 41 (39), 119 and 134 (33), 67 (31), 39 (28). *Anal.* calcd. for $C_{12}H_{16}O$: C 81.77, H 9.15; found: C 81.71, H 9.17.

4,4,7a-Trimethyl-1-methylene-1,2,4,5-tetrahydroinden-2-one, compound *a* in footnote 2. A solution of lithium amide in liquid ammonia (made from 6 g Li in 400 mL ammonia containing 0.3 g of ferric nitrate) was stirred while 4,4,7a-trimethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one (**20**, 143 g) in dry ether (300 mL) was added. The ammonia was allowed to evaporate overnight, and dry ether (100 mL) was added, then formaldehyde (25 g, made by heating paraformaldehyde, dried over P_2O_5, to 150°C) was passed into the solution in a current of dry nitrogen. The addition lasted 3 h, and the mixture was allowed to stand overnight before pouring onto ice and 10% hydrochloric acid. The products were extracted into pentane, and the organic layers were washed ($NaHCO_3$, water), dried, and concentrated. A sample (1 g) was distilled in a bulb apparatus, bp ≃ 100°C (oven temperature)/0.01 Torr, and gc then indicated ca. 70% unchanged starting material together with ca. 10% of a new substance of longer retention time, which was collected as the

product. Larger scale distillation resulted in polymerization; uv λ_{max}: 252 (ε_{max} 3 130); ^{1}H nmr (60 MHz) δ: 1.29, 1.35, 1.46 (CH_3), 2.15 (2H, broad s, C(5)H_2), 5.28 (1H, s), 5.8 (2H, m), 5.93 and 6.11 (each 1H, s); ms: 173 (100), 145 (60), 188 ($M^{+\cdot}$, 55), 130 and 105 (20), 91 (16), 115 and 77 (13), 117 (12). *Anal.* calcd. for $C_{13}H_{16}O$: C 82.93, H 8.56; found: C 83.13, H 8.52.

*1,1,4,4,7a-Pentamethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one, 23*

A suspension of sodium amide (12 mL, 70% in toluene) in toluene (700 mL) was stirred at reflux while 4,4,7a-trimethyl-1,4,5,7a-tetra hydro-2*H*-inden-2-one (**20**, 35 g) was added dropwise during 0.5 h. After a further 1.5 h at reflux, the mixture was cooled to 12°C and methyl iodide (25 mL) was added rapidly. The temperature rose to 26°C. After stirring for 2 h, the mixture was poured onto ice and the organic layer was washed, dried, and concentrated, yielding 42.4 g of material which appeared (gc) to be nearly homogeneous. The nmr spectrum indicated the presence of 4 CH_3 groups, one of which had δ 0.95 (d, J = 7 Hz) corresponding to a single C(1)—CH_3 group. The whole of this material was then treated again as before (with sodium amide and methyl iodide), and after concentration of the toluene, the residue was distilled to yield 38.4 g (86%) of practically pure **23**, bp 62–65°C/0.001 Torr. For analysis this was purified by gc on SP 1000; ^{1}H nmr (60 MHz) δ: 0.90, 1.05, 1.20, 1.25, 1.31 (CH_3), 2.11 (2H, d, J = 3 Hz, C(5)H_2), 5.61 (1H, s), 5.20 (1H, t, J = 3 Hz), 5.80 (1H, s); ms: 189 (100), 204 ($M^{+\cdot}$, 39), 190 (15), 41 (13), 119 (12), 161 (10). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 81.91, H 9.86.

*1,1,4,4,7a-Pentamethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-one, 19*

A. The foregoing experiment (for **23**) was carried out with ketone **10** (1.5 g), repeating the process as described. The residue was distilled, bp 58–60°C/0.1 Torr, to yield 0.3 g of material containing a number of products. The main one was isolated by gc on silicone oil, and proved to be the title product, mp. 36–36.2°C; uv λ_{max}: 237 (ε_{max} 12 300); ^{1}H nmr (90 MHz) δ: 1.02 (6H), 1.22 (6H), 1.28 (3H, CH_3), 5.82 (1H, s); ms: 191 (100), 137 (64), 136 (60), 206 ($M^{+\cdot}$, 45), 41 (38), 163 (34), 123 (33), 121 and 69 (28), 43 and 149 (24). *Anal.* calcd. for $C_{14}H_{22}O$: C 81.50, H 10.75; found: C 81.72, H 10.70.

Immediately preceding this compound in the gc (silicone oil) was a peak with spectra consistent with *1,4,4,7a-tetramethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-one*: ^{1}H nmr (90 MHz) δ: 1.05 (3H, d, J = 7 Hz), 1.15, 1.21, 1.27 (CH_3), 5.88 (1H, s); ms: 122 (100), 177 (90), 136 (89), 192 ($M^{+\cdot}$, 80), 41 (78), 173 (72), 149 (66), 121 (64), 69 (58), 107 (53). Other by-products were not fully characterized, but often exhibited a signal in the ^{1}H nmr spectrum at δ ≈ 3.8 (OCH_3).

B. The ketone **23** was hydrogenated in ethanol over a palladium on charcoal catalyst (10% Pd). There was quantitative absorption of 1 equivalent of H_2 to give the title compound, **19**, identical with the material described above.

1,1,4,4,7a-Pentamethyl-cis-*1,3,3a,4,5,7a-hexahydro-2*H*-inden-2-one, 27*

Small pieces of lithium (containing 1% of sodium, 4.2 g in all) were dissolved in ammonia (1000 mL). During 40 min, solution of 1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one (**23**, 28 g, 0.14 mol) in *tert*-butanol (12.6 g, 0.17 mol) and dry ether (250 mL) was added. After further stirring for 10 min, solid ammonium chloride (30 g) was added over 10 min, then the ammonia was allowed to evaporate while ether (250 mL) was added. The resulting ethereal solution was poured into water, washed, and concentrated. Distillation of the residue yielded 39.7 g (98%) of practically pure title product; ir: 1735 cm^{-1}; ^{1}H nmr (60 MHz) δ: 0.94, 0.97 (each s, 9H altogether), 1.20, 1.28 (CH_3), 5.52 (2H, s); ms: 121 (100), 206 ($M^{+\cdot}$, 15), 105 (14), 41 and 122 (10).

This compound was recovered unchanged from the following reactions: CH_3MgI in ether, CH_3Li in ether, $(C_6H_5)_3P{=}CHOCH_3$ in toluene or tetrahydrofuran, $(C_6H_5)_3P{=}CH_2$ in toluene or tetrahydrofuran, prepared using either sodium hydride or butyllithium.

Lithium aluminum hydride reductions of 2H*-inden-2-ones* were carried out by adding the ketone (1 g) dropwise to a suspension of lithium aluminum hydride (0.2 g) in dry ether (50 mL). Excess reagent was decomposed by addition of water, and the solution was filtered and concentrated. Acetates were made by acetylation of the crude alcohol in pyridine with acetic anhydride. The following were thus obtained.

*4,4,7a-Trimethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-*cis*-ol, 16*

Spectra were measured on the crude material which decomposed on gc; ^{1}H nmr (360 MHz) δ: 1.05, 1.12, 1.17 (CH_3), ABX system with A 1.45, B 2.24, X 4.89, $J_{A,B}$ = 12, $J_{A,X}$ = 8, $J_{B,X}$ = 6.5 Hz; X is also coupled with C(3)H at 5.35 (J = 1.5 Hz). A weak signal at 5.50 (d, J = 2 Hz, C(3)H) was consistent with the presence of < 10% of the *trans* alcohol; ms: 147 (100), 97 (78), 123 (56), 107 (49), 109 (48), 41 (43), 96 (39), 91 (38), 43 and 119 (37)...180 ($M^{+\cdot}$, 12).

The *acetate* was purified by distillation, bp 58–59°C/0.01 Torr; ^{1}H nmr (60 MHz) δ: 1.09, 1.10, 1.20, 2.03 (CH_3), 2.30 (1H, d of d, J = 6.5 and 12 Hz), 5.38 (1H, d, J = 1.5 Hz), 5.73 (1H, t, J = 6.5 + ca. 1.5 Hz); ms: 147 (100), 43 and 119 (35), 91 (28), 105 (26), 93 (23), 162 (22), 41 (21), 107 and 123 (14)...222 ($M^{+\cdot}$, 2).

*4,4,7a-Trimethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-*cis*-ol, 22*

The crude material was distilled, bp 57–60°C/0.001 Torr, and was then practically pure (thin-layer chromatography) but decomposed on gc; ^{1}H nmr (360 MHz) δ: 1.12, 1.17, 1.20 (CH_3), ABX system with A 1.49, B 2.24, X 4.97, $J_{A,B}$ = 12.5, $J_{A,X}$ = 8, $J_{B,X}$ = 6 Hz, 1.96 (2H, m, see theoretical part), 5.38 (1H, s, C(3)H), 5.47 (1H, d of q, J = 10, 6, and 2.5 Hz, C(6)H), 5.59 (1H, d + further coupling, J = 10 Hz, C(7)H); ms: 145 (100), 163 (97), 121 (63), 105 (50), 122 (46), 41 and 43 (41), 91 (37), 107 (35)...178 ($M^{+\cdot}$, 25). A very weak signal was just visible at δ 5.73 (d, J = 10 Hz) consistent with C(7)H of the *trans* alcohol.

The *acetate* distilled at bp 41°C/0.001 Torr and decomposed on gc; ^{1}H nmr (60 MHz) δ: 1.11, 1.15, 1.22, 2.01 (CH_3), 5.38 (1H, broad s), 5.52 (t, J = 3 Hz) overlapping 5.55 (s, together 2H), 5.80 (1H, t, J = 7 Hz); ms: 145 (100), 43 (23), 105 and 160 (16), 130 and 146 (13), 91 (10)...205 (2.5), 220 ($M^{+\cdot}$, 0.5).

*1,1,4,4,7a-Pentamethyl-2,3,3a,4,5,7a-hexahydro-1*H*-inden-2-ols, 28 and 29*

The crude material from the $LiAlH_4$ reduction exhibited two peaks (gc on Carbowax). Separated by preparative gc, the alcohol with the shorter retention time (55% of the mixture) was the *endo* alcohol **29**, and was liquid at 20°C: ^{1}H nmr (360 MHz) δ: 0.79, 0.93, 0.98, 0.99, 1.02 (CH_3), 1.48 (1H, d of d, J = 7 and 16 Hz, C(3)—*exo*-H), 2.32 (1H, d of d of d, J = 7, 11, and 16 Hz, C(3)—*endo*-H), ABX system with A 1.65, B 2.01, X 5.66, $J_{A,B}$ = 17, $J_{A,X}$ = 6, $J_{B,X}$ = 2 Hz, C(5)CH_2—C(6)H, 1.75 (1H, m, J = 1, 7, and 11 Hz, C(3a)H, 3.50 (1H, d of d, J = 7 and 11 Hz, C(2)H), 5.76 (1H, d of d, J = 1 and 10 Hz, C(7)H); ms: 107 (100), 122 (56), 121 (42), 41 (24), 43, 69, 93 and 105 (15), 91 and 175 (13)...190 (9), ...208 ($M^{+\cdot}$, trace).

The endo-*acetate* was distilled (bulb, bp ≈ 60°C/0.001 Torr); ^{1}H nmr (60 MHz) δ: 0.85, 0.88 (2), 0.99, 1.00, 1.95 (CH_3), 4.71 (1H, d of d, J = 4 and 6.5 Hz), 5.51 (2H, d, J = 2 Hz); ms: 107 (100), 122 (96), 43 (39), 121 (31), 119 (23), 175 and 41 (22), 105 (20), 69 (18)...250 ($M^{+\cdot}$, 4.5).

The alcohol with the longer retention time (45% of the mix-

ture) was the *exo* alcohol, **28**, and crystallized, mp 77–78°C; ^{1}H nmr (360 MHz) δ: 0.80, 0.86, 0.91, 0.96, 1.01 (CH_3), 1.49 (d of d of d, J = 9, 12, and 13 Hz, C(3)—*endo*-H), 1.86 (d of d of d, J = 5, 9, and 13 Hz, C(3)—*exo*-H), 1.77 (d of d, J = 5 and 12 Hz, C(3a)H, ABX system with A 1.53, B 1.95, X 5.55, $J_{A,B}$ = 17, $J_{A,X}$ = 2, $J_{B,X}$ = 6 Hz, C(5)H_2—C(6)H, 5.44 (d of d, J = 2 and 10 Hz, C(7)H); ms: 107 (100), 122 (54), 121 (43), 41 (29), 43 and 69 (19), 91, 93, and 105 (17), 123 and 128 ($M^{+\cdot}$, 14)...190 (3).

The exo-*acetate* was distilled (bulb, bp ≃ 60°C/0.001 Torr); ^{1}H nmr (60 MHz) δ: 0.83, 0.86, 0.89, 0.98, 1.03, 2.01 (CH_3), 4.70 (1H, m, C(2)H), 5.52 (2H, broad s + m); ms: 122 (100), 107 (99), 43 (40), 121 (28), 41 (25), 119 and 69 (20), 123 (16), 134 (15), 175 and 105 (13)...250 ($M^{+\cdot}$, 4.3).

*3a,7,7-Trimethyl-4,5,6,7-tetrahydro-3a-*H*-indene,* ***18***

Either 4,4,7a-trimethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-*cis*-2-ol, **16**, or its acetate, **17**, was injected into a gas chromatograph and the single product collected; uv λ_{max}: 256 (ε_{max} 10 500); ^{1}H nmr (60 MHz) δ: 1.08 (6H, s), 1.21 (3H, s, CH_3), 5.90 (1H, t, J = 1 Hz), 6.22 (2H, apparent d, J = 1 Hz); ms: 147 (100), 119 (37), 91 (27), 162 ($M^{+\cdot}$) and 105 (25), 93 (20), 41 and 148 (11), 77 and 133 (10).

*1,1,4,4,7a-Pentamethyl-2-methylene-1,4,5,6,7,7a-hexahydro-*2H*-indene,* ***24*** *(R = H)*

A solution of methyltriphenylphosphonium bromide (1 g) in absolute tetrahydrofuran (10 mL) was treated with butyllithium (1.1 equiv.) in hexane. When solution was complete, the pentamethylindenone (**19**, 0.1 g) was added at 0°C. The mixture was refluxed for 1 h, then poured into water, and the product was isolated in pentane. For analysis it was purified by gc on silicone oil; ^{1}H nmr (90 MHz) δ: 0.97, 1.03, 1.04, 1.16, 1.18 (CH_3), 4.58, 4.77, 5.88 (each 1H, s); ms: 189 (100), 133 (65), 119 (63), 204 ($M^{+\cdot}$, 55), 147 (42), 134 (42), 135 (41), 41 (39).

Attempted Coates Reaction of ***27****: 1,1,4,4,7a-Pentamethyl-3a,4,5,7a-tetrahydro-1*H*-inden-2-yl Benzoate,* ***11***

To a solution of thioanisole (2.8 g) and 1,4-diazabicyclo[2.2.2]octane (2.5 g) in dry tetrahydrofuran (30 mL) at 0°C was added butyllithium (1 equivalent) in hexane during 12 min. The precipitate said to occur here was not observed. A solution of the ketone **27** (4 g) in dry tetrahydrofuran (10 mL) was added at 0°C, the temperature was allowed to rise to 30°C, and the mixture allowed to stand overnight at room temperature. It was then cooled to 0°C and benzoic anhydride (9.9 g) in tetrahydrofuran (20 mL) was added. After standing for 3 h at room temperature, the mixture was stirred with 100 mL of pentane and filtered, the filtrate being directly chromatographed on silica gel in hexane. From the first fractions about 2.3 g of thiosanisole was recovered, then 4.5 g of a mixture which, after rechromatography on silica gel, gave 4 g of material which was distilled (bp ca. 180°C, (oven temperature)/0.001 Torr) and consisted of nearly pure title product. ^{1}H nmr (60 MHz) δ: 1.05, 1.10 (15H, CH_3), 5.50 (2H, broad s), 5.75 (1H, d, J ≃ 1 Hz), 7.2–7.6 (3H, m), 7.95–8.2 (2H, m); ms: 105 (100), 123 (47), 77 (42), 41 (24), 56 (22), 55 (14), 43, 51, and 122 (13)...205 and 220 (1).....234 (trace), 310 ($M^{+\cdot}$, 0). *Anal.* calcd. for $C_{21}H_{26}O_2$: C 81.25, H 8.44; found: C 80.98, H 8.17.

*2(Z)-Methoxymethylene-1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-indene,* ***30***

Butyllithium (8% in hexane, 15 mL) was added to methoxymethyltriphenylphosphonium chloride (7 g) in dry tetrahydrofuran (50 mL) at 0°C. After 30 min, 1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-inden-2-one (**23**, 2 g) was added at −80°C over 10 min. The temperature was allowed to rise to 25°C, then stirring was continued overnight. The mixture was poured into water, and the product isolated in ether. The residue after concentration was chromatographed in hexane over a small column of silica gel (25 g). Concentration of the eluate yielded a single substance (gc on SP 1000) which was purified for analysis by preparative gc; ^{1}H nmr (60 MHz) δ: 0.87, 1.03, 1.15 (2), 1.28, 3.52 (CH_3), 1.91 (2H,d, J = 3 Hz), 5.55 (d, J = 3 Hz) superimposed on 5.58 (s) (together 3H), 5.97 (1H, s). The stereochemistry is attributed on account of the chemical shifts of the C(3)H and CH_3O protons, compared with the other isomer (following experiment). Mass spectra: 217 (100), 107 (45), 232 ($M^{+\cdot}$, 33), 106 (25), 79 (20), 39 and 185 (17), 41 and 218 (16), 43 and 187 (15).

*2(E)-Methoxymethylene-1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-indene and Methyl 1,1,4,4,7a-Pentamethyl-1,4,5,7a-tetrahydro-2*H*-indene-2-carboxylate (*cis*?),* ***33***

A solution of perchloric acid in ether was prepared by shaking aqueous perchloric acid (70%) with ether. To this solution (50 mL of the upper layer) 1,1,4,4,7a-pentamethyl-2(*Z*)-methoxymethylene-1,4,5,7a-tetrahydro-2*H*-indene, (**30**, 1 g), was added. After 15 min, the mixture was washed to neutrality, dried, and concentrated. Purified by gc (SP 1000), the first peak consisted mainly of the *E*-isomer of the starting material with the following spectra; ^{1}H nmr (60 MHz) δ: 0.88, 1.01, 1.03, 1.19, 1.20, 3.61 (CH_3), 1.95 (2H, d, J = 3 Hz), 5.57 (d, J = 3 Hz) superimposed on 5.63 (s, 3H together), 6.01 (1H, s). The main product, purified by gc (Apiezon) from a small amount of the corresponding aldehyde (**31**, described below), was the ester **33**; ^{1}H nmr (60 MHz) δ: 0.66, 1.05, 1.11, 1.16, 1.20, 3.68 (CH_3), 1.93 (2H, d, J = 3 Hz), 3.45 (1H, d, J = Hz, C(2)H), 5.43 (broad s overlapping a multiplet, total 3H); ms: 173 (100), 233 (89), 189 (71), 119 (65), 201 (42), 248 ($M^{+\cdot}$) and 147 (36), 41 (33),133 (32), 159 (29).

*2-Methoxymethylene-1,1,4,4,7a-pentamethyl-1,4,5,6,7,7a-hexahydro-2*H*-indene, 25*

Following the procedure just described (for **30**), the title product was prepared from 1,1,4,4,7a-pentamethyl-1,4,5,6,7,7a-hexahydro-2*H*-inden-2-one (**19**, 3.3 g), methoxymethyltriphenylphosphonium chloride (25.5 g), and butyllithium (9.16% in hexane, 46 mL) in tetrahydrofuran (70 mL), leaving the mixture for 21 h at room temperature. The product was purified by chromatography on silica gel. A sample collected from gc on SP 1000 had ^{1}H nmr (60 MHz) δ: 0.99, 1.02, 1.09, 1.14, 1.20, 3.52 (CH_3, signals from another isomer visible), 5.58 and 5.92. The crude material was used in the next experiment.

*1,1,4,4,7a-Pentamethyl-*cis*-3a,4,5,6,7,7a-hexahydro-1*H*-indene-2-carbaldehyde,* ***26***

The material from the previous experiment (ca. 3g) was heated at reflux for 2 h in dioxan (30 mL), water (30 mL), and oxalic acid (5 g). Gas chromatography showed the reaction to be complete, and the product was then isolated in pentane. Over 90% was the title material, and it was purified by gc (SP 1000); ^{1}H nmr (60 MHz) δ: 0.95 (3H), 1.06 (12H, CH_3), 2.35 (1H, d, J = 2 Hz), 6.81 (1H, d, J = 2 Hz), 9.73 (1H, s); ms: 220 ($M^{+\cdot}$), 123 and 121 (100), 137 and 41 (92), 205 (71), 135 (70), 107 (67), 109 (64), 69 (59). *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found: C 80.88, H 10.86. These figures reflect the ready oxidation of the substance in air. Immediately before the gc peak corresponding to this aldehyde, there was a small region from which a mixture of two unconjugated aldehydes was identified. Too little was available for full spectral analysis, but the following were observed: ^{1}H nmr (90 MHz) δ: 2.75 (t, J = 4 Hz) and 3.18 (t, J = 2 Hz), 5.33 (d, J = 4 Hz) and 5.54 (d, J = 2 Hz), 9.70 (d, J = 4 Hz) and 9.80 (d, J = 2 Hz); ms: 191 (100), 69 (46), 135 (43), 121 and 109 (41), 41 (38), 123 (26), 43 (25), 107 (23)...220 ($M^{+\cdot}$, 2); small fragments at *m/e* 235 and 250 indicated the presence of the corresponding methyl ester.

1,1,2,4,4,7a-Hexamethyl-2,3,3a,4,5,7a-hexahydro-1H-indene, 37

Lithium (0.2 g) in small pieces was added to liquid ammonia (50 mL). After 30 min, 1,1,4,4,7a-pentamethyl-3a,4,5,7a-tetrahydro-1*H*-indene-2-carbaldehyde (**32**, 0.5 g) in *n*-butanol (0.25 mL) and dry ether (10 mL) was added over 10 min. The mixture was stirred for a further 10 min, the solid ammonium chloride was added, followed by ether (20 mL). The ammonia was allowed to evaporate, ice and a little HCl were added, and the mixture was washed to neutrality. Concentration of the solvents left a nearly homogeneous substance (by capillary column on UCON) which had the following spectra: ^{1}H nmr (90 MHz) δ: 0.94, 0.95, 0.98, 1.09, 1.18 (in all 18H, CH_3), 4.51 (s superimposed on d, 2H together); ms: 121 (100), 41 and 105 (20), 206 ($M^{+\cdot}$, 20), 43, 57, 91, 93 (9).

*1,1,4,4,7a-Pentamethyl-1,4,5,7a-tetrahydro-2H-indene-2-*cis*-carbaldehyde, 31, and 1,1,4,4,7a-Pentamethyl-*cis*-3a,4,5,7a-tetrahydro-1H-indene-2-carbaldehyde, 32*

1,1,4,4,7a-Pentamethyl-2(*Z*)-methoxymethylene-1,4,5,7a-tetrahydro-2*H*-indene (**30**, 4.7 g) was heated in dioxan (30 mL) and saturated aqueous oxalic acid (50 mL) in an apparatus fitted with a water separator. After 3 h the dioxan in the separator was removed, then again after 7 h. Refluxing was continued for a total of 30 h, then the mixture was extracted with pentane and the organic phase washed with water to neutrality, dried, and concentrated to yield a residue that consisted of about 25% starting material, now two peaks on gc (1:1, SP 1000 column). The remainder was a mixture of the two title aldehydes which were separated by gc (SP 1000). The spectral properties were, for aldehyde **31**: ^{1}H nmr (60 MHz) δ: 0.79, 1.08, 1.14, 1.20 (2) (CH_3), 1.95 (2H, m, C(5)H_2), 3.32 (1H, t, J = 1.5 Hz, C(2)H), ca. 5.5 (3H, m), 9.81 (1H, d, J = 1.5 Hz); ms: 189 (100), 133 (38), 119 (35), 69 and 41 (28), 190 (24), 147 (23), 105 (20), 175 and 91 (18)...218 ($M^{+\cdot}$, 16).

For aldehyde **32**: ^{1}H nmr (60 MHz) δ: 1.04, 1.06, 1.10, 1.15, 1.21 (CH_3), 1.75 (2H, m), 2.47 (1H, broad s), 6.77 (1H, d, J = 2.5 Hz), 9.70 (1H, s); ms: 121 (100), 41 (50), 203 (42), 147 (39), 107 (36), 105 (35), 119 and 91 (34), 189 and 218 ($M^{+\cdot}$, 31).

Treatment of **31** with methanolic potassium hydroxide at 60°C for 2 h yielded almost exclusively **32**.

*(1,1,4,4,7a-Pentamethyl-1,4,5,7a-tetrahydro-2H-inden-*cis*-2-yl)-methanol, 34*

1,1,4,4,7a-Pentamethyl-1,4,5,7a-tetrahydro-2*H*-indene-2-*cis*-carbaldehyde (**31**, 0.1 g) was reduced as usual with excess lithium aluminum hydride in dry ether. After the usual workup, a small amount was isolated by gc (SP 1000) for analysis, the remainder being reduced catalytically directly (next experiment); ^{1}H nmr (360 MHz) δ: 0.63, 1.04, 1.06, 1.11, 1.15 (CH_3), 1.86 (2H, m, C(5)H) displaced by Eu(fod)$_3$ to respectively, 2.17 (d of d, J = 5 and 17 Hz) and 2.29 (J = 2.5 and 17), 2.73 (1H, d of d of d, J = 6, 9, and 1.5 Hz, C(2)H), 3.56 (d of d, J = 9 and 10.5 Hz), and 3.71 (d of d, J = 6 and 10.5 Hz, carbinol CH_2), 5.27 (s, C(3)H), 5.37 (1H, d of t, J = 10 and 1 Hz, C(7)H), 5.60 (1H, d of t, J = 4, 4, and 10 Hz); ms: 189 (100), 119 (50), 220 ($M^{+\cdot}$, 46), 133 (44), 205 and 55 (41), 41 (38), 145 (35), 187 and 69 (29). *Anal.* calcd. for $C_{15}H_{24}O$: C 81.76, H 10.98; found C 81.76, H 10.80.

*(1,1,4,4,7a-Pentamethyl-1,4,5,6,7,7a-hexahydro-2H-inden-*cis*-2-yl)-methanol, 35*

The crude material (0.09 g) from the previous experiment was shaken in hydrogen over platinum on charcoal (10% Pt) in ethanol (5 mL). Absorption ceased after 35 min, when 90% of the theoretical volume of H_2 was absorbed. Filtration and concentration yielded practically pure **35**, which was purified by gc (on SP 1000). The ^{1}H nmr spectrum showed it to contain < 10% of the *trans* isomer; ^{1}H nmr (360 MHz) δ: 0.70, 0.98, 1.04, 1.09 (2) (CH_3), 1.69 (1H, m, C(6)H), 2.55 (1H, m, J = 1.5, 6, and 8 Hz, C(2)H, 3.56 and 3.69 (each 1H, m, carbinol CH_2), 5.29 (broad s, $w_{\frac{1}{2}}$ = 2.5 Hz, C(3)H); ms: 191 (100), 69 (37), 109 (35), 135 (32), 41 (31), 121 (27), 107 and 55 (49), 43 (21), 207 (18)...222 ($M^{+\cdot}$, 6.5). See also the following experiment.

*(1,1,4,4,7a-Pentamethyl-3a,4,5,6,7,7a-hexahydro-1H-inden-*cis*-2-yl)-methanol*

The aldehyde **26** was reduced as usual with excess lithium aluminum hydride in dry ether. The product consisted of about 88% of the title product (by gc on SP 1000) which was purified by gc from ca. 12% of a peak with shorter retention time. The main product had ^{1}H nmr (60 MHz) δ: 0.79, 0.87, 1.00 (3) (CH_3), 2.18 (1H, $w_{\frac{1}{2}}$ ≃ 5 Hz, C(3a)H), 4.15 (2H, apparent q, w ≃ 5 Hz, carbinol CH_2), 5.61 (1H, d, J = 1 Hz); ms: 109 (100), 207 (82), 191 (78), 121 (71), 41 (66), 69 (48), 189 (42), 135 and 107 (39), 55 (38)....222 ($M^{+\cdot}$, 22). The smaller peak with shorter retention time was repurified by gc on OV 17, and consisted of a mixture (3:2) of the alcohol **35**, described in the foregoing experiment, and what was apparently the *trans* isomer, **36**, identified by the presence of the following signals (360 MHz) δ: 0.92, 0.94, 1.08, 1.12, 1.13 (CH_3), 2.21 (d of d of d, J = 3, 6, and 8 Hz, C(2)H), 5.36 (d, J = 3 Hz, C(3)H).

*1,1,4,4,7a-Pentamethyl-*cis*-2,3,3a,4,5,7a-hexahydro-1H-indene-2-*exo*-carbaldehyde, 38*

A solution of a 6:4 mixture of 1,1,4,4,7a-pentamethyl-1,4,5,7a-tetrahydro-2*H*-indene-2-*cis*-carbaldehyde, **31**, and 1,1,4,4,7a-pentamethyl-*cis*-3a,4,5,7a-tetrahydro-1*H*-indene-2-carbaldehyde, **32** (0.22 g, obtained directly from hydrolysis of the enol ether **30**) in ethanolic potassium hydroxide (20 mL 5% KOH) was hydrogenated over a palladium on charcoal catalyst (10% Pd). After 0.6 equivalents of H_2 were absorbed, the rate of uptake slowed to nearly zero, and the mixture was diluted with water and extracted with pentane. Concentration of the pentane yielded the title product, **38**, together with unchanged **31**. The former was purified by gc on SP 1000, but only a mass spectrum was recorded, the remainder being converted directly to the alcohol (see next experiment); ms: 107 (100), 121 (76), 134 (67), 123 (62), 41 and 122 (55), 93 and 119 (40), 69 (38)...220 ($M^{+\cdot}$, 20).

*(1,1,4,4,7a-Pentamethyl-*cis*-2,3,3a,4,5,7a-hexahydro-1H-inden-2-*exo*-yl)-methanol 39*

The mixture obtained in the foregoing experiment was reduced directly with excess lithium aluminum hydride in dry ether. After workup, the mixture of **34** and **39** was separated by either chromatography on silica gel, or by preparative gc on SP 1000, the title product **39** having the shorter retention time in both cases, and crystallizing on elution, mp 100–102°C; ^{1}H nmr (360 MHz) δ: 0.71, 0.89, 0.92, 0.98, 1.00 (CH_3), 1.52 (d of d, J = 5 and 17 Hz) and 2.01 (broad d, J = 2 and 17 Hz, C(5)H_2), 3.46 (d of d, J = 8.5 and 10.5 Hz) and 3.69 (d of d, J = 5 and 10.5 Hz, carbinol CH_2), 5.46 (d of d, J = 3 and 10 Hz, C(7)H), 5.57 (d of d of d, J = 2, 6, and 10 Hz, C(6)H; ms: 107 (100), 122 (95), 121 and 41 (35), 123 (28), 136 (25), 93 (22), 119 and 69 (15)...189 (3)...222 ($M^{+\cdot}$, 5). *Anal.* calcd. for $C_{15}H_{26}O$: C 81.02, H 11.79; found: C 80.75, H 11.56.

Acknowledgements

We are indebted to Dr. K. H. Schulte-Elte for useful discussions and a sample of compound **3**. Useful suggestions from Dr. G. Ohloff are also gratefully acknowledged. Mr. René Menghetti is thanked for assistance in the preparation of com-

pound *a*. We are grateful to Dr. W. Hoffmann, BASF, Ludwigshafen, for a supply of 2,6,6-trimethylcyclohex-2-enone. Mr. W. Thommen is thanked for meticulous nmr measurements.

Received December 31, 1979

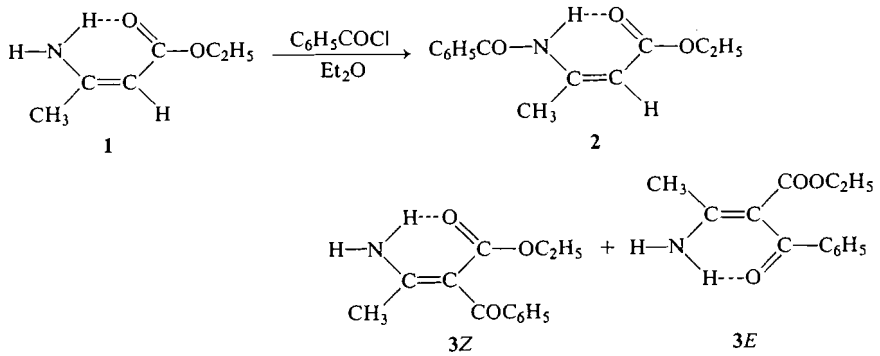
This paper is dedicated to the memory of Dr. Léo Marion

GARY D. FALLON, BRYAN M. GATEHOUSE, ALLAN PRING, IAN D. RAE, and JOSEPHINE A. WEIGOLD. Can. J. Chem. **58**, 1821 (1980).

Ethyl-3-amino-2-benzoyl-2-butenoate crystallizes from pentane as either the *E* (mp 82–84°C) or the *Z*-isomer (mp 95.5–96.5°C). The *E* isomer is less stable, and changes spontaneously into the *Z*, which has been identified by X-ray crystallography. The structure is characterised by an N–H/ester CO hydrogen bond and a very long C2—C3 bond (1.39 Å). Nuclear magnetic resonance methods have been used to measure the rate of $Z \rightleftharpoons E$ isomerization at several temperatures, leading to the estimate that the free energy of activation at 268 K is 56 ± 8 kJ.

GARY D. FALLON, BRYAN M. GATEHOUSE, ALLAN PRING, IAN D. RAE et JOSEPHINE A. WEIGOLD. Can. J. Chem. **58**, 1821 (1980).

L'amino-3 benzoyl-2 butène-2 oate d'éthyle cristallise dans le pentane sous la forme *E* (pf 82–84°C) ou sous la forme *Z* (pf 95,5–96,5°C). L'isomère *E* est moins stable et se transforme spontanément en la forme *Z* que l'on a identifiée par cristallographie de rayons-X. La structure est caractérisée par une liaison hydrogène N—H/ester-CO et une liaison C2—C3 (1,39 Å) très longue. On a utilisé la rmn pour mesurer la vitesse d'isomérisation $Z \rightleftharpoons E$ à différentes températures; on évalue l'énergie libre d'activation à 56 ± 8 kJ à 268 K.



[Traduit par le journal]

Introduction

The benzoylation of ethyl 3-amino-2-butenoate **1** gives approximately equal quantities of *N*- and *C*-acylated products, **2** and **3** respectively, as reported by Buckler *et al.* (1). These authors gave no physical data for their products, but did convert ester **2** to the corresponding carboxylic acid, the melting temperature of which was comparable to that reported by Barker (2). Barker prepared the acid from an ester, mp 95°C, which had been reported much earlier by Benary (3).

Benary, in his work, had isolated *two* benzoyl derivatives from benzoylation of ester **1**, each of which upon mild acid-catalysed hydrolysis yielded a neutral substance which was identified as benzamide (although just how, Benary does not say). Each of the benzoyl compounds was thus classified as an *N*-benzoyl compound. The melting temperatures were 95–96°C and 46–48°C with the latter compound being much the more soluble in organic solvents.

We report here that benzoylation of ester **1** gives *three* products, the *N*-benzoyl **2** with melting temperature 48–48.5°C, and the *C*-benzoyl compounds **3***Z* melting at 95.5–96.5°C and **3***E* at 82–84°C. This last melting temperature is recorded with rapid heating, for with slower heating the crystals of this isomer melt in the range 76–83°C, resolidify, and then melt again at 96–97°C. The infrared spectra of the two isomers are quite different, and our structural assignments are supported by ^1H and ^{13}C nmr spectra at several temperatures, and by X-ray diffraction studies with the **3***Z* isomer. We have also determined the average energy of activation and other thermodynamic parameters for the isomerization $3Z \rightleftharpoons 3E$.

Results

X-Ray Crystallography

The crystal structure is shown in Fig. 1 and consists of the packing of discrete molecules which, besides the normal van der Waals interactions, are held together by an intermolecular hydrogen bond between H(2N) and the ether oxygen, O(3); H(2N)···O(3), 1.88 Å; N···O(3) 2.90 Å. There is also an intramolecular hydrogen bond between H(1N) and the ester carbonyl oxygen, H(1N)···O(1), 1.82 Å; N···O(1)2.66 Å. There are no other unusual intermolecular contacts. (The data are summarized in Tables 1–4.) Fig. 2 indicates the intermolecular hydrogen bond and the labelling scheme of the atoms.

Due to the presence of the intramolecular hydrogen bond between H(1N) and O(1) the atoms C(1)—C(5), N, O(1), O(2) form a nearly coplanar arrangement (Table 4), the maximum deviation being 0.085(3) Å by O(2). The structure is also highly polarized, as depicted in structure **4***Z*, resulting in short C(3)—N and C(2)—C(5) ester distances and a long C(2)—C(3) bond. For comparison, C(2)—C(3) is 1.390(5) Å whereas the "double" bond length in several α,β-unsaturated carbonyl compounds is 1.36(1) Å(4), and C(3)—N is 1.320(4) Å, even shorter than the C—N distance in most amides, 1.333(5) Å(4).

On the other side of the double bond, however, the C(2)—C(5) benzoyl distance is greater than the C(2)—C(1) ester distance, 1.480(4) vs. 1.444(5) Å, and thus more normal (4), and the benzoyl carbonyl is twisted out of the plane of the molecular backbone by 48.5°, with O(3) 0.758(3) Å above the plane (Table 4). There is also a twist of 31.0°, in the opposite sense, about the C_6H_5—CO bond, as is commonly observed in the benzoyl moiety e.g. 26° in benzamide (5).

Nuclear Magnetic Resonance Spectra

The ^{1}H nmr spectrum of the *N*-benzoyl compound **2** shows the expected multiplets for the ethoxy group and the benzoyl moiety, slightly broadened singlets for the methyl (2.55) and vinyl hydrogens (5.05 ppm) and a broad signal for the amide hydrogen.

The spectra of the isomers **3***E* and **3***Z* (Table 5) are quite distinct but it was not possible to deduce structures by consideration of these spectra alone. The hydrogens of the ethoxy groups are shielded in both isomers, but more so in the *Z*-isomer. If we take as standards the values for ethyl acetate (6), then the CH_2 and CH_3 of **3***Z* are shielded by 0.63 and 0.45 ppm respectively, and those of **3***E* by 0.50 and 0.20 ppm.

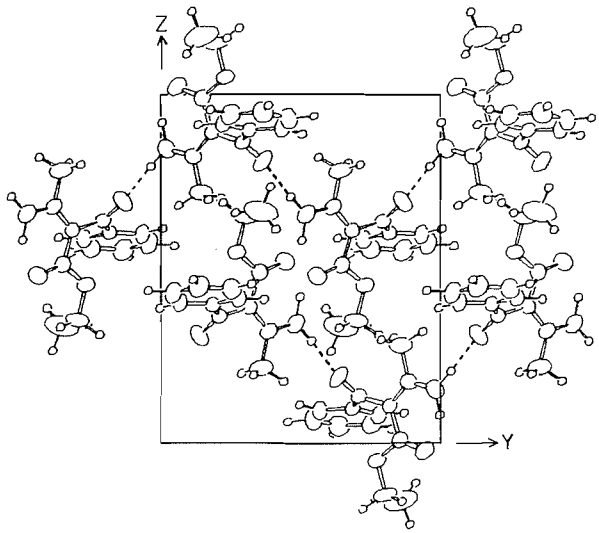

FIG. 1. Unit cell contents projected down a^*. The intermolecular hydrogen bonds are shown with dotted lines. Hydrogen thermal parameters were reduced for clarity.

The NH_2 resonances are the only ones to show appreciable changes with temperature. At low temperatures, they are unusually sharp (width at half-height about 5 Hz) and ^2J is evident as a splitting in each of the NH signals. The observed value, 6 Hz, is comparable to the 4.9 Hz observed for $^2J_{HNH}$ in 2-aminoacetophenone-^{15}N by Wasylishen and Schaefer (7), but approximately twice as large as those for NH_2 in amides (examples and references collected by Wasylishen and Schaefer (7)). The splitting is lost at temperatures above 233 K, and those which are not intramolecularly hydrogen-bonded move upfield at temperatures above 250 K. The assignment of these two types of NH is made on the basis of their chemical shifts i.e., intramolecularly hydrogen-bonded NH resonances at lower field.

In DMSO-d_6 solution, only a single set of signals is observed and it was not possible to cool the solution far enough before crystallization intervened to observe separation of resonances for the individual isomers or even substantial line-broadening.

The ^{13}C nmr assignments (Table 6) have been made by comparison with literature values, including those for 3-amino-2-enones (8) which confirmed the values for C2 and C3. The C2 and ester CO resonances were assigned on the basis that the latter would have the longer relaxation time, being further from any hydrogen atoms, and therefore give a less intense peak in the normal spectrum.

Thermodynamic Parameters

When an isomer mixture can be enriched in one isomer, or a single isomer can be generated in solution, and then the system be observed during the approach to equilibrium, it is possible to evaluate a rate constant k, which is the average for the forward and reverse reactions (9, 10). In our case, the equilibrium ratio **3***Z*:**3***E* is 1.1 : 1 and almost invariant with temperature. Thus the forward and reverse rates must be almost equal, so k is a very good approximation to the separate rates and ΔG for the isomerization is calculated to be 0.23 kJ mol^{-1}. The values of k, derived by Gutowsky *et al.*'s method (9) are given in the Experimental for temperatures in the range 243 K to 268 K. The values were used in a graphical solution of the Arrhenius equation (11*a*) which yielded a value of 56 ± 2 kJ mol^{-1} for the activation energy. A similar treatment using the Eyring equation (11*b*, 12) gave $\Delta H^{\ddagger}$ = 61 ± 15 kJ mol^{-1} and $\Delta S^{\ddagger}$ = 17 J deg^{-1} mol^{-1} with a large uncertainty. The calculated value for the free energy of activation, $\Delta G^{\ddagger}$, at 268 K is 56 ± 8 kJ mol^{-1}.

Discussion

The X-ray diffraction results reveal a molecule (**3***Z*) in which the amino group is hydrogen-bonded to, and coplanar with, the ester group while the benzoyl group is twisted out of the plane. There was some expectation that the benzoyl group might be held closer to the plane by conjugation with the amino group i.e., a contribution from canonical structure **4***Z*. The two bases for this expectation are that, first, methyl 3-dimethylamino-2-propenoate is found (13) only in the *E* form **5**, and attempts to prepare the *Z* isomer have been unsuccessful (14). Second, the crystal structure of dimethyl (dimethylaminomethylene)-malonate **6** shows (14) that the dimethylamino group and the *trans* ester group are coplanar. In our case, the hydrogen-bonding interaction in **3***Z* is sufficient to reverse this preference for *trans* over *cis* conjugation.

Two other enamine crystal structures, of compounds **7** and **8**, are relevant to our discussion. In compound **7**, there is *trans* conjugation of nitrogen and carbonyl but also a 25° twist about the tetrasubstituted double bond (15). In compound **8**, the intramolecular hydrogen bonding stabilizes the planar *Z* geometry (16). The critical bond lengths for the conjugated path in these four compounds

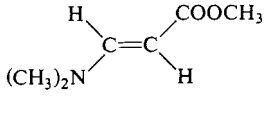
		O(6) 0.992(4)

are collected in Table 7, from which it can be seen that crowding in compound **7** has reduced significantly the extent of conjugation. In our compound **3***Z*, the non-conjugated carbonyl is twisted out of the general plane by 49° whereas, in compound **6**, the non-conjugated *cis* carbonyl is twisted through 54°.



The barrier to rotation about the formal carbon–carbon double bond in compound **3** may also be compared to those observed for other 3-amino-2-enoates, but only values for tertiary amines are available for comparison. Thus, for compound **6**

$\Delta G^{\ddagger}$ is 65.3 kJ mol^{-1} (at 291–295 K for solution in CH_2Cl_2) (17) but the extra methyl substituent in the amino-ethylidine compound **9** decreases this barrier to ca. 26 kJ mol^{-1}, presumably by destabilizing the planar ground state of the conjugated system (17). The value for **3** is higher than might be expected from these comparisons, and from consideration of the values collected by Jackman (18) for similar systems, and we attribute this to the stabilizing influence of the intramolecular hydrogen bond in **3***E* and **3***Z*.

The shielding of the ethyl group by the benzene ring which is so evident in the ^{1}H nmr spectra of both isomers, but particularly in **3***E*, is not evident in the corresponding ^{13}C nmr spectra and probably arises from rotations about the O—CH_2 and CH_2—CH_3 bonds which bring the hydrogens close to the face of the ring. The relatively large value for $^2J_{HNH}$, for a molecule in which the configuration about nitrogen is planar and in which the nitrogen lone pair is extensively delocalized, is in accord with the predictions, based on MO calculation, of Wasylishen and Schaefer (7). The apparent lowering of the barrier to rotation about C2—C3 for solutions in DMSO-d_6 is to be expected if the transition state is highly polarized and thus better stabilized in the polar solvent than in $CDCl_3$. Similar reductions have been noted for ketene mercaptals which are essentially planar in the ground state (19).

In the ^{13}C spectra, the non-conjugated carbonyl substituent has only a small effect on the chemical shift of C3 for which the observed values are much like those reported (20) for ethyl-*E*-3-dimethylamino-2-butenoate (C2 84.0, C3 160.6 ppm) and *E*-4-dimethylamino-3-penten-2-one (C3 93.7, C4 160.3 ppm). The chemical shifts of the olefinic carbons C2 and C3 in compound **3***Z* also attest to the extensive polarization of the system depicted in structure **4***Z* and discussed above in connection with the bond length and barrier to rotation. The accumulation of positive charge in the C3—N region, and of negative charge at the C2—CO, would result in deshielding of C3 and shielding of C2 as observed. More extreme examples of this kind are described by W. A. Thomas (private communication) including compound **10** for which the C3 resonance is found at 166.1 ppm and C2 at 31.9 ppm, reflecting considerable charge accumulation at C2 as well as the normal shielding effect of the nitrile group on an adjacent carbon (21).

In isomer **3***Z* the angle between the ring and carbonyl planes is at 31° only slightly larger than that observed in other compounds in which a C_6H_5—CO—C=C group is present (22). A Dreiding model of isomer **3***E*, however, suggests that the steric pressures on the benzoyl group are somewhat larger when the ester group is not constrained by an intramolecular hydrogen bond, and it is reasonable to suppose that the benzene ring will adopt a conformation in which it is roughly orthogonal to the plane of the conjugated and hydrogen-bonded system. Such a configuration would be consistent with our observation that the hydrogens of this ring all have approximately the same chemical shift, since deshielding of the *ortho* hydrogens by the carbonyl would not be significant.

There remains the question of how selective crystallization of one or other isomer may be brought about from a solution containing both **3***E* and **3***Z*. The material obtained from the crude products of benzoylation of enamine **1** was isomer **3***E* which was used successfully to seed the chromatographic column fractions. This material shows the double melting point which signifies its thermal transition to isomer **3***Z*. This crystalline isomer **3***E* spontaneously changes to isomer **3***Z* when left at room temperature, and subsequent recrystallization from pentane always gave **3***Z*. On only one occasion has our subsequent work produced the single isomer **3***E*, and then as a crystalline mass obtained from evaporation of a $CDCl_3$ solution (not strictly a recrystallization). We did commence a crystal structure determination with isomer **3***E* but the crystal changed before the measurements could be completed, and subsequent measurements on some unaltered crystals, which had constituted only a very small fraction of the original material, revealed the *Z*-isomeric structure discussed above. Infrared spectra confirmed that these small crystals were not the same as those which initially constituted the bulk of the material but that, after a time, the crystals were homogeneous in an infrared, but not a morphological sense.

Experimental

General

Infrared spectra were recorded for paraffin mulls on a Jasco IRA-1 grating infrared spectrophotometer. ^1H and ^{13}C nuclear magnetic resonance spectra were recorded on a Bruker WH90 spectrometer operating at 90 and 22.62 MHz respectively. The $CDCl_3$ was shaken with solid Na_2CO_3 immediately prior to use to remove traces of acid which catalysed the isomerization. The probe temperature of the spectrometer was adjusted with a stream of cold nitrogen gas and controlled with a Bruker temperature control unit.

Suitable single crystals for X-ray investigation were obtained by recrystallizing the compound from pentane. A crystal of dimensions 0.08 × 0.10 × 0.07 mm was selected for the study. Unit cell parameters were refined by least-squares refinement of 2θ values ($24 < 2\theta < 60$) for 32 reflections measured on a Philips PW1100 automatic diffractometer with graphite monochromated CuKα_1 radiation (λ = 1.54051 Å). Crystal data (at 18°C) are:

$C_{13}H_{15}NO_3$ fw = 233.26
Monoclinic, a = 7.983(4), b = 11.234(7), c = 14.873(8) Å, β = 108.08(9)°, V = 1268.0 Å^3, ρ_o = 1.21(2), Z = 4, ρ_c = 1.22 g·cm^{-3} (20°C, by flotation), $F(000)$ = 496, μ(CuKα_1) = 6.33 cm^{-1}. Space group $P2_1/c$ (No. 14).

A unique data set was collected out to 2θ = 130° by the ω-scan technique. 2153 unique reflections were measured; of those 1314 obeyed the condition $F_o^2 \geq 3\sigma(F_o)^2$ and were used in the subsequent calculations. Three strong reflections, monitored every 2 h, showed no significant variation in intensity over the data collection period.

The data were processed with a program written for the PW1100 diffractometer (23). A value of 0.04 was used for p in the estimation of $\sigma(F_o^2)$. All reflections were corrected for Lorentz polarization and absorption effects, (transmission factors ranged between 0.959 to 0.940), but not extinction. Scattering factors for C°, H°, N°, and O° were corrected for anomalous dispersion (24).

The structure was solved by direct methods. Phases for 241 terms with $|E|$ values greater than 1.20 were determined by application of the tangent formula (25). The best E map gave sites for 16 of the 17 non-hydrogen atoms. A Fourier synthesis revealed the position of the remaining non-hydrogen atom. Full-matrix least-squares refinement in which the non-hydrogen atoms were given anisotropic temperature factors yielded an R index of 0.106. Calculated coordinates for those H atoms bonded to carbon, assuming a C—H bond length of 1.08 Å, were included in the refinement, and the sites of the hydrogens on nitrogen were located by difference Fourier. The H atom positional parameters were not refined; the refined isotropic thermal parameter for the H atoms grouped as alkyl, aryl, and nitrogen hydrogen atoms are listed in Table 2. Refinement converged to give R = 0.067 and $R_w = (\Sigma w||F_o| - |F_c||^2/\Sigma w|F_o|^2)^{1/2}$ = 0.060. The reflections 121, 202, and 104 were considered to be extinction affected and were omitted from the final cycles of the refinement, which converged to give R = 0.060 and R_w = 0.056 for the 1311 observed terms. (R = 0.107 for the total data.)

The direct-method calculations and least-squares refinements were made with the SHELX76 program (26). In the latter, the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with the terms being weighted according to $w = 1/\sigma^2|F_o|$. Final atomic coordinates and thermal parameters are listed in Table 2. The program ORTEP (27) was used to produce the diagrams. Details of intramolecular distances and angles, and least squares planes are given in Tables 3 and 4. Standard errors are enclosed in parentheses and are in units of the last place of decimals. Structure factors are deposited.[1]

Benzoylation of Ethyl 3-Amino-2-butenoate

The amino ester (12.9 g, 0.10 mol) and triethylamine (10.0 g, 0.10 mol) were boiled under reflux in tetrahydrofuran (200 mL) while benzoyl chloride (14.57 g, 0.105 mol) was added dropwise over 1 h. The solution was boiled for a further 2 h and then cooled and filtered to remove triethylamine hydrochloride. The filtrate was evaporated and the oily residue was recrystallized from pentane (500 mL) to give white crystals, mp 82–84°C (2.92 g). This material dissolved in $CDCl_3$ to give a 1:1 mixture of isomers **3***Z* and **3***E*, but was subsequently shown to be crystalline **3***E*. The mother liquor from the crystallization was evaporated and the remaining oil was dissolved in benzene and chromatographed over alumina. The first fraction (3.07 g) was recrystallized from pentane to give the *N*-benzoyl compound **2**, mp 48–48.5°C. Infrared spectrum ν_{max}: 3200, 1700, 1665 and 1630 cm^{-1}; ^{1}H nmr spectrum: 1.30 (t, J = 8 Hz, 3H), 2.55 (s, 3H), 4.23 (q, J = 8 Hz, 2H), 5.05 (s, 1H), 7.55 (m, 3H), 8.0 (m, 2H), 7.9 (bs, 1H). Subsequent fractions gave an oil (2.80 g) which could be seeded to yield crystalline **3***E*, followed by mixtures eluted with benzene – 5% ethyl acetate and containing ethyl acetoacetate.

Kinetics

The isomer **3***Z* (5.5 mg) was dissolved in $CDCl_3$ (0.50 mL) at 195 K (acetone – solid CO_2) in the nmr tube, which was then inserted into the precooled probe and warmed to the operating temperature for each run. Following Gutowsky (11) the average rate constant, k, was calculated by integration of several pairs of signals, but the best results were obtained with the singlet methyl resonances and these were used in the calculations. The values of k (s^{-1}) at the various temperatures were:
1.25×10^{-4} at 243 K; 2.26×10^{-4} at 248 K; 4.90×10^{-4} at 253 K; 6.08×10^{-4} at 258 K; 5.75×10^{-4} at 263 K; 1.88×10^{-3} at 268 K.

Studies on the total synthesis of bisindole alkaloids within the voacamine family

JAMES P. KUTNEY,[1] AKIO HORINAKA, ROBERT S. WARD, AND BRIAN R. WORTH

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

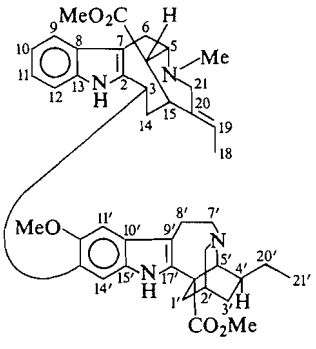
Received February 11, 1980

This paper is dedicated to the memory of Dr. Léo Marion

JAMES P. KUTNEY, AKIO HORINAKA, ROBERT S. WARD, and BRIAN R. WORTH. Can. J. Chem. **58**, 1829 (1980).

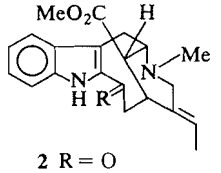
The reactions of perivinol (**27**) with voacangine (**3**), and of perivinol with catharanthine (**29**), yield in each case two bisindole alkaloids of the voacamine type. ^1H and ^{13}C nmr data are used to assign structures to these compounds and the general utility of these techniques for determining the position of attachment of the 2-acylindole unit to the Iboga unit in such compounds is discussed. The reaction of dregaminol (**28**) with catharanthine is also reported.

JAMES P. KUTNEY, AKIO HORINAKA, ROBERT S. WARD et BRIAN R. WORTH. Can. J. Chem. **58**, 1829 (1980).



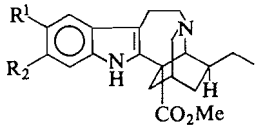
Les réactions du périvinol (**27**) avec la voacangine (**3**) et du périvinol avec la catharanthine (**29**) donnent dans chaque cas deux alcaloides bisindoles du type voacamine. On a utilisé les données de la rmn du ^1H et du ^{13}C pour attribuer les structures de ces composés et on discute de l'utilité générale de ces techniques dans la détermination du point d'attache de l'unité acyl-2 indole à l'unité Iboga dans ces composés. On décrit également la réaction du drégaminol (**28**) avec la catharanthine.

[Traduit par le journal]



Introduction

The bisindole alkaloids of the voacamine type represent a large family of natural products which has received considerable attention in numerous laboratories (1). The majority of these investigations have concentrated on the isolation and structure elucidation of these systems and on the development of some chemistry concerned with the structural relationships between the various members. Our own recent interests have been concerned with the development of a totally synthetic approach which we hope could be sufficiently versatile to encompass the preparation of a substantial number of alkaloids within this family.



Structural analysis of voacamine (**1**) as the parent member of this series, as well as the more recently isolated alkaloids reveals that they all possess an indole part plausibly derived from a 2-acyl indole unit, for example vobasine (**2**), and an Iboga system, for example voacangine (**3**). Indeed a partial synthesis of voacamine (**1**) and its natural isomer voacamidine (**4**) was first achieved by Büchi and co-workers (2) by heating vobasinol (**5**) and voacangine (**3**) in dilute methanolic hydrogen chloride.

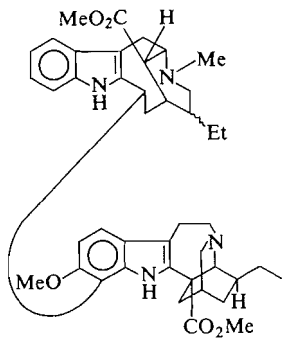
The bisindole alkaloids conodurine (**6**) and conoduramine (**7**) (3) represent examples where the Iboga unit is isovoacangine (**8**) while tabernamine (**9**) (4) represents the first example in which the aromatic ring of the Iboga unit lacks an oxygen substituent.

The recently isolated tabernaelegantines (5), for example, tabernaelegantines A and C (**10**), contain the dihydrovobasine type unit while the alkaloid accedinisine (**11**) (6) reveals a dimeric structure in which the Iboga unit has been replaced by a normacusine B type skeleton, the latter having been interrelated chemically with the 2-acylindole family (7).

On the basis of these examples it is clear that any versatile synthetic approach to this family of alkaloids must allow the functional variations inherent in these units.

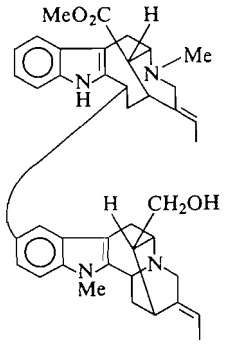
The synthesis of the Iboga unit, as portrayed in tabernamine, has been completed in these and other laboratories (8) so that the introduction of the methoxyl group into the aromatic ring remains as the only synthetic step to be achieved. This problem is presently under study in these laboratories.

A synthetic sequence to the 2-acylindole unit has been recently completed in our laboratories (9) and the approach is sufficiently versatile to allow the extension to the various types of systems noted above.



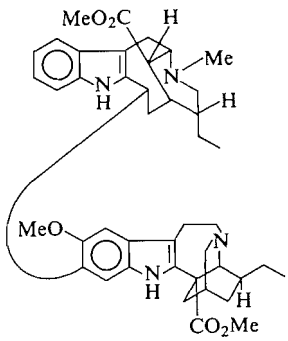
The third phase of our program concerns the further development of a versatile coupling process which would allow the required bisindole system to be derived from the appropriate monomeric units. We wish to report here some of our initial observations concerned with this aspect of the overall study.

As noted above, the coupling of vobasinol (**5**) with voacangine (**3**) does provide an entry into the voacamine family. However, in this instance the methoxyl activation within the voacangine system allows a specific reaction of carbon atoms 11 and 13 generating **1** and **4**. The situation is less clear with indole units lacking such functionality, as would be required in the synthesis of **9** and **11**. Although there are now a number of reported instances in which this type of reaction has been employed (4–7, 10–12), the position of attachment of the 2-acylindole unit to the Iboga system has not in all cases been unequivocally established. It became necessary to provide a more detailed study of this reaction and to determine its general utility with various indole systems.



At the outset it was clear that an unambiguous spectroscopic method for direct assignment of the mode of coupling would be highly desirable and we selected ^{1}Hmr and ^{13}Cmr spectroscopy for this purpose. The results presented below amplify the utility of this method.

^{1}H Nuclear Magnetic Resonance Spectra



When the aromatic ring of the Iboga unit carries a methoxyl substituent, as in voacamine, the position of attachment of the 2-acyl indole moiety can be readily established on the basis of the ^{1}H nmr spectrum. Thus, the spectrum of voacamine (**1**) contains two one-proton singlets at 6.76 and 6.92 ppm

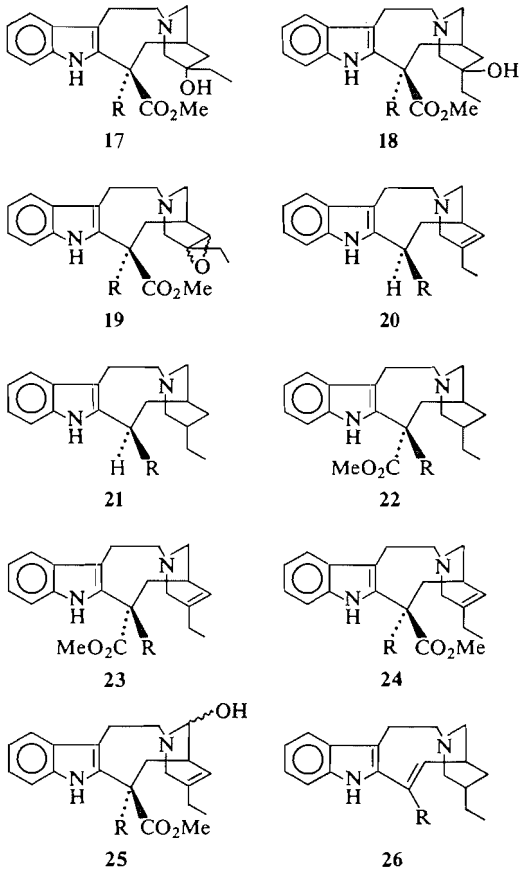
[b]References 3 and 6.
[c]Numbers in parentheses are J values (Hz).



(2, 6), which can be assigned to H-11′ and H-14′. Voacamidine (**4**) on the other hand gives rise to two one-proton doublets (J = 8.5 Hz) at 6.70 and 7.05 ppm (3, 6), which can be assigned to the *ortho* related protons H-13′ and H-14′. Similarly, the spectrum of conodurine (**6**) contains two one-proton doublets (J = 8 Hz) at 7.26 and 6.82 ppm, while the spectrum of conoduramine (**7**) contains two one proton singlets at 6.91 and 6.79 ppm. Other relevant examples are shown in Tables 1 and 2.

If we next consider compounds in which the Iboga unit carries no other substituents on the aromatic ring, as in tabernamine (**9**), then the problem of assigning the correct structures becomes more difficult since the aromatic region of the ^{1}H nmr spectrum is more complex. Tabernamine is in fact the only compound of this type so far reported, although accedinisine (**11**) and accedinine (**15**) (6) are also useful for comparison purposes (cf. capuvosine and capuvosidine (12)). On the basis that, in the unsubstituted monomeric alkaloids, e.g. ibogamine (**16**), H-11 appears well downfield from the other aromatic protons (13, 14) the presence of a low-field doublet at 7.28 ppm in the spectrum of tabernamine (**9**) (4) is taken as evidence that the 2-acyl indole unit is bonded to C-13′ (see Table 3). By the same token, in accedinisine (**11**) the 2-acyl indole unit is assumed to be attached to C-12′ since a low-field singlet is observed at 7.20 ppm which can be assigned to H-11′ (6).

^{13}C *Nuclear Magnetic Resonance Spectra*

Examination of the ^{13}C nmr spectra of alkaloids of the vinblastine type (Table 4) reveals that the carbon atom of the vindoline unit which is directly bonded to the cleavamine unit is shifted downfield by ca. 16.4 ppm relative to its position in the spectrum of vindoline itself (see Fig. 1). Neighbouring carbon atoms are also affected in a reproducible manner by attachment of the cleavamine moiety.

Of more relevance to the present study is the observation of similar shifts in the spectra of tabernaelegantines A–D (5) when compared with the spectrum of isovoacangine (**8**) (Table 5). The ^{13}C nmr spectra therefore provide another approach to the problem of identifying the point of attachment in voacamine type alkaloids, and could be particularly useful in cases where the aromatic ring of the

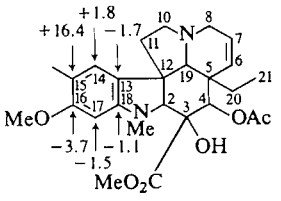
Iboga unit is unsubstituted as for example in tabernamine (**9**).

Chemical Experiments

We have studied the reactions of perivinol (**27**) and dregaminol (**28**) with voacangine (**3**) and catharanthine (**29**), using the HCl/MeOH coupling procedure developed by Büchi *et al.* (2). The reaction of dregaminol with voacangine has been previously shown to yield two products, dihydrovoacamine (**12**) and dihydrovoacamidine (**13**) (2). The reaction of perivinol (**27**) with voacangine (**3**) also gave two products which were separated in small amounts by hplc and which both gave a molecular ion at m/e 690 in their mass spectra (for details see Experimental). The two compounds were identified as *N*-demethylvoacamine (**30**) and *N*-demethylvoacamidine (**31**) on the basis of their 270 MHz ^{1}H nmr spectra (Table 6). Thus, *N*-demethylvoacamine (**30**) exhibits two singlets in the aromatic region of its spectrum at 6.79 and 6.92 ppm which can be assigned to H-11′ and H-14′, whereas *N*-demethylvoacamidine exhibits two doublets (J = 8 Hz) at 6.77 and 7.09 ppm, which can similarly be assigned to H-13′ and H-14′. *N*-Demethylvoacamine has been reported as a natural product, occurring along with voacamine and voacamidine in *Tabernaemontana accedens* (6).



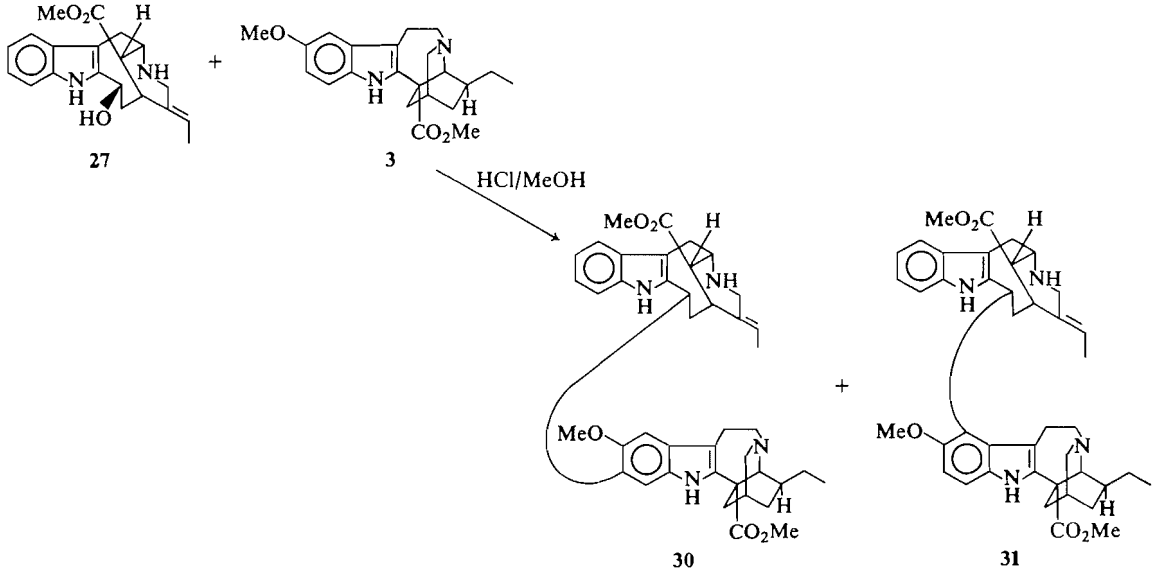


FIG. 1

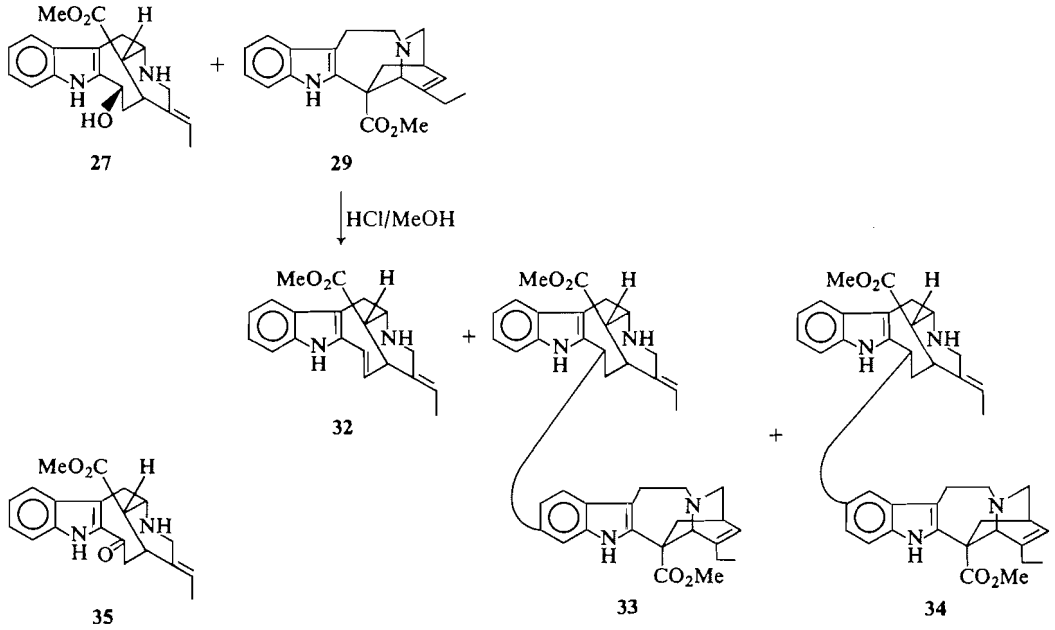

The reaction of perivinol (**27**) with catharanthine (**29**) afforded three products along with large amounts of unreacted catharanthine. The major product (34% yield) was readily identified as the alkene (**32**) formed by dehydration of perivinol (7). The two minor products (7% each) both showed a molecular ion at m/e 658 in their mass spectra and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

exhibited uv spectra similar to that of tabernamine (**9**) (4). Although the ^{1}H nmr spectra of these products were, as expected, more complex than those of the methoxy substituted compounds, their structures could be tentatively assigned on the basis of their aromatic proton signals. Thus the presence of a doublet (J = 8 Hz) at 7.39 ppm in the spectrum of the less polar compound (Table 7), which can be assigned to H-11′ , indicates that both the 11′ and 12′ positions are unsubstituted in this compound. Furthermore, the presence of a singlet at 6.95 ppm indicates that the acyl–indole unit must be attached to C-13′ and the compound is therefore assigned structure **33**. In contrast, the ^{1}H nmr spectrum of the more polar compound showed a low-field singlet at 7.31 ppm, which can be assigned to H-11′, and which therefore indicates that in this case the acyl–indole unit is attached to C-12′. This compound is therefore assigned structure **34**.

These tentative conclusions are supported by an analysis of the ^{13}C nmr spectra of both compounds (Tables 8 and 9). The signal at 139.9 ppm in the spectrum of **33** can be assigned to C-13′ and is therefore shifted downfield by 18.6 ppm relative to its position in the spectrum of catharanthine itself (18). Similarly the signal at 137.6 ppm in the spec-

trum of **34** can be assigned to C-12′ and is shifted downfield by 18.7 ppm relative to its position in the spectrum of catharanthine (**29**).

The reaction of dregaminol (**28**) with catharanthine (**29**) also gave two dimeric products (M^+ 674) which by analogy with the perivinol–catharanthine reaction are assumed to have structures **36** and **37**. The two compounds were separated by thick layer chromatography but due to the very small amounts of material available were not fully characterized.

Although these preliminary efforts did show the feasibility of coupling various indole units to the voacamine type dimers, the method was obviously not satisfactory for the efficient production of compounds for biological testing. In this light, alternative methods of accomplishing the coupling in-

cluding the further use of the alkenes such as **32** have come under active investigation. Products derivable by these means will be reported elsewhere.

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer. Low resolution mass spectra were recorded on either an Atlas CH-4B or an AEI MS-902 spectrometer. High resolution mass measurements were made on an AEI MS-50 spectrometer. THe ^{1}H nmr spectra were recorded on Varian XL-100 and Nicolet Oxford H-270 instruments; ^{13}C nmr spectra were recorded on a Bruker WP-80 instrument. Chemical shifts are reported as ppm from tetramethylsilane which was used as internal standard. Nuclear magnetic resonance data for compounds **30**–**34** are given in Tables 6–9.

Perivinol (**27**) and dregaminol (**28**) were prepared by sodium borohydride reduction of the corresponding 2-acyl indole alkaloids (2). Dihydrovoacamine (**12**) and dihydrovoacamidine (**13**) were prepared by the method previously described by Büchi *et al.* (2).

Reaction of Voacangine with Perivinol

A mixture of voacangine (20 mg) and perivinol (20 mg) in 1% methanolic hydrogen chloride (4 mL) was heated under reflux for 1½ h in an atmosphere of nitrogen. The reaction mixture was then diluted with water (8 mL) and neutralized with sodium carbonate giving a heavy white precipitate which was extracted with dichloromethane. The residue obtained on evaporation (40 mg) was separated by column chromatography on silica gel to give the two bisindole alkaloids (total yield 26 mg) which were further purified by reverse phase hplc (70% CH_3CN – 30% H_2O) to give N-*demethylvoacamine* (**30**); uv (EtOH) λ_{max}: 220 (27, 922), 284 (10, 578), 292 (10, 488) nm; *m/e*: 704(*M* + 14, 1%), 690(M^+, 1.7%), 538(1), 524(1), 511(1.3), 491(0.7), 463(0.7), 446(0.7), 435(0.7), 429(1.5), 421(1), 407(1), 393(1.5), 379(1), 368(2.5), 355(2.5), 341(1.5), 323(2), 309(2), 295(2), 281(7), 207(7), 149(80), 121(35), 119(94), 117(100%); *Exact Mass* calcd. for $C_{42}H_{50}N_4O_5$: 690.3780; found (ms): 690.3791); and N-*demethylvoacamidine* (**31**); uv(EtOH) λ_{max}: 228 (24, 840), 284 (11, 040), 292 (10, 488) nm; *m/e*: 704(*M* + 14, 2%), 690(M^+, 1.7%), 538(3.5), 524(1.5), 511(0.5), 509(1), 409(1), 393(1), 368(1), 355(1), 350(1.5), 295(1.7), 281(2.5), 207(7), 149(100), 121(25), 119(50), 117(60%); *Exact Mass* calcd. for $C_{42}H_{50}N_4O_5$: 690.3780; found (ms): 690.3784.

Reaction of Catharanthine with Perivinol

A mixture of catharanthine (250 mg) and perivinol (250 mg) in 1% methanolic hydrogen chloride (25 mL) was heated under reflux for 1½ h in an atmosphere of nitrogen. Work-up as described in the previous experiment gave a residue (ca. 500 mg) which was separated by preparative hplc using a stainless steel column (12 in. × 1 in.) packed with Porasil A. Elution with dichloromethane – 2% methanol containing 0.1% triethylamine at a flow-rate of ca. 18 mL/min afforded unreacted catharanthine (210 mg), *3,14-dehydrodeoxoperivine* (**32**) (86 mg); uv(EtOH) λ_{max}: 227 (19, 588), 296 (9, 258) nm; *m/e*: 322.1681(M^+, $C_{20}H_{22}N_2O_2$, 55%), 263.1546(*M* − 59, $C_{18}H_{19}N_2$, 12%), 222.1269 ($C_{16}H_{16}N$, 15%), 221.1202 ($C_{16}H_{15}N$, 23%), 220.1128 ($C_{16}H_{14}N$, 20%), 206.0959 ($C_{15}H_{12}N$, 23%), 194.0956 ($C_{14}H_{12}N$, 11%), 180.0816 ($C_{13}H_{10}H$, 12%), 168.0799 ($C_{12}H_{10}N$, 18%), 167.0729 ($C_{12}H_9N$, 36%), 149.0244 ($C_{11}H_3N$, 15%), 130.0653 ($C_9H_{10}N$, 11%); *3-(13′-catharanthinyl)deoxoperivine* (**33**) (34 mg); uv(EtOH) λ_{max}: 228 (45, 786), 285 (16, 724), 293 (16, 450) nm; *m/e*: 672(*M* + 14, 0.2%), 658(M^+, 0.5%), 644(0.2), 551(1),

Reaction of Catharanthine with Dregaminol

A mixture of catharanthine (30 mg) and dregaminol (35 mg) in 1% methanolic hydrogen chloride (5 mL) was heated under reflux for 1½ h in an atmosphere of argon. Work-up as described above gave a yellow oil which was separated by preparative tlc to give catharanthine (17 mg) and the two bisindole alkaloids which were further purified by preparative tlc to give *3-(13′-catharanthinyl)deoxodregamine* (**36**) (26 mg); uv(MeOH) λ_{max}: 227 (47, 813), 286 (15, 554), 293 (16, 702) nm; ν_{max}($CHCl_3$): 3465, 3360, 2940, 1720, 1465, 1450, 1440, 1340, 1326, 1290, 1155, 1080, 1050, 985, 900, 880 cm^{-1}; δ ($CDCl_3$): 8.14 (br s, 2H, NH), 7.1–7.6 (m, 7H), 5.00 (dd, 4, 11), 3.38 (s, 3H), 2.77 (s, 3H), 2.48 (s, 3H); *m/e*: 688(*M* + 14, 0.5%), 674(M^+, 2.7%), 565(0.8), 547(0.8), 533(0.8), 492(1), 479(0.8), 387(4), 385(5), 370(18), 354(32), 352(30), 338(100), 323(90%); and *3-(12′-catharanthinyl)deoxodregamine* (**37**) (6 mg); uv(MeOH) λ_{max}: 227(41, 442), 287 (14, 118), 293 (14, 573) nm; *m/e*: 688(*M* + 14, 0.2%), 674(M^+, 3.3%), 493(0.8), 480(1), 383(13), 370(65), 369(85), 367(55), 353(70), 351(55), 339(74), 338(84), 337(88), 336(75), 323(75), 322(84), 321(76), 308(68), 307(63), 306(79), 305(78), 304(74), 293(65), 292(76), 291(62), 290(80), 280(78), 279(80), 278(90), 276(80), 264(65), 252(82), 251(68), 250(65), 248(68), 238(80), 237(75), 235(75), 224(85), 223(85), 222(80), 221(80), 220(70), 219(70), 210(80), 209(90), 208(80), 207(85), 206(80), 205(80), 187(100), 181(100%).

Received February 12, 1980

This paper is dedicated to the memory of Dr. Léo Marion

GERARDO BURTON, ROBERT L. BAXTER, J. MARTYN GUNN, PHILIP J. SIDEBOTTOM, PAUL E. FAGERNESS, KOZO SHISHIDO, JOHN Y. LEE, and A. IAN SCOTT. Can. J. Chem. **58**, 1839 (1980).

Applications of ^{13}C nmr in following the metabolism and fate of ^{13}C enriched substrates in whole cells are described. Studies on the elaboration of coproporphyrinogens I (**2***a*) and III (**2***b*) from [5-^{13}C]-δ-aminolevulinic acid (**1**) and [11-^{13}C]-porphobilinogen (PBG, **3**), in *Rhodopseudomonas spheroides* and *Propionibacterium shermanii*, respectively, the randomization of ^{13}C from [3-^{13}C]-propionate by *P. shermanii*, the biosynthesis of citrate, gentisalcohol (**4**), and patulin (**5**) from [2-^{13}C]-acetate by *Penicillium urticae*, and the anaerobic metabolism of [1-^{13}C]-glucose in rabbit erythrocytes are reported.

GERARDO BURTON, ROBERT L. BAXTER, J. MARTYN GUNN, PHILIP J. SIDEBOTTOM, PAUL E. FAGERNESS, KOZO SHISHIDO, JOHN Y. LEE et A. IAN SCOTT. Can. J. Chem. **58**, 1839 (1980).

On décrit les applications de la rmn du ^{13}C à l'étude du métabolisme et de l'évolution des substrats enrichis en ^{13}C dans les cellules entières. On décrit les études réalisées (*a*) sur l'élaboration des coproporphyrinogènes I (**2***a*) et III (**2***b*) à partir de l'acide [^{13}C-5]-δ-aminolévulinique (**1**) et du [^{13}C-11]porphobilinogène (PBG, **3**) dans le *Rhodopseudomonas sphéroides* et le *Propionibactérium shermanii* respectivement, (*b*) sur la distribution au hasard du ^{13}C du [^{13}C-3]propionate par le *P. shermanii*, (*c*) sur la biosynthèse du citrate, du gentisalcool (**4**) et de la patuline (**5**) à partir de l'acétate [^{13}C-2] par le *Penicillium urticae* et (*d*) sur le métabolisme anaérobique du [^{13}C-1] glucose dans les érythrocytes du lapin.

[Traduit par le journal]

In the last decade nmr spectroscopy has been developed as an elegant method of studying metabolic processes *in vivo*. The pioneering studies of Moon and Richards in 1973 set the stage for numerous studies using ^{31}P nmr as a non-invasive technique for metabolic studies (1–4 and references cited therein). Although ^{13}C nmr was first used in 1972 (5) as a probe for yeast metabolism, the inherent difficulties of sensitivity and decoupling with ^{13}C delayed the development of the method until quite recently when it was shown independently by Shulman and co-workers (6, 8) and by our group (7) that Cmr spectroscopy is a powerful tool for viewing the metabolic flux of ^{13}C-enriched substrates *in vivo*. In this paper we describe the further development of this technique to study metabolic processes in four organisms, *Rhodopseudomonas spheroides, Propionibacterium shermanii, Penicillium urticae,* and red blood cells (rabbit erythrocytes). The technique has the great advantage of viewing intracellular and extracellular metabolites as they are formed, since the simple experiment of washing the cells and resuspension can be used to check location of the signals. The main problem is that of maintaining field homogeneity, but the examples which follow have all been studied at low field (20 MHz in ^{13}C) in a Varian FT-80 instrument using conventional programming and standard 10 mm tubes. Under these conditions excellent spectra can be recorded. These studies should also be regarded as a preliminary test of a method which will gain its full power at superconducting fields in wide tubes where other problems such as dissipation of heat generated by decoupling have to be solved.

δ-*Aminolevulinic Acid Metabolism in* Rhodopseudomonas spheroides

The ^{13}C nmr spectra of cells of *R. spheroides* immediately following addition of [5-^{13}C]-aminolevulinic acid (**1**) and after a 16 h incubation are shown in Fig. 1. Multiplets observed at 21.9 and 125.0 ppm ($^1J_{^{13}C-^{13}C}$ = 51.5 Hz) are assigned to the *meso* methylene and α-pyrrolic carbons of coproporphyrinogens (copro'gen) I (**2***a*) and III (**2***b*) (1:3), respectively. While the type I isomer presents only two doublets at 125.0 and 21.9 ppm corresponding to the α-pyrrolic and *meso* carbons, copro'gen III has a doublet at 125 ppm for the α-pyrrolic carbons, a doublet at 22.0 ppm corresponding to the α and β *meso* carbons, a triplet at 22.0 ppm for the γ *meso* carbon, and a singlet at 21.9 ppm for the δ *meso* carbon.

Due to the superposition of copro'gen I and III

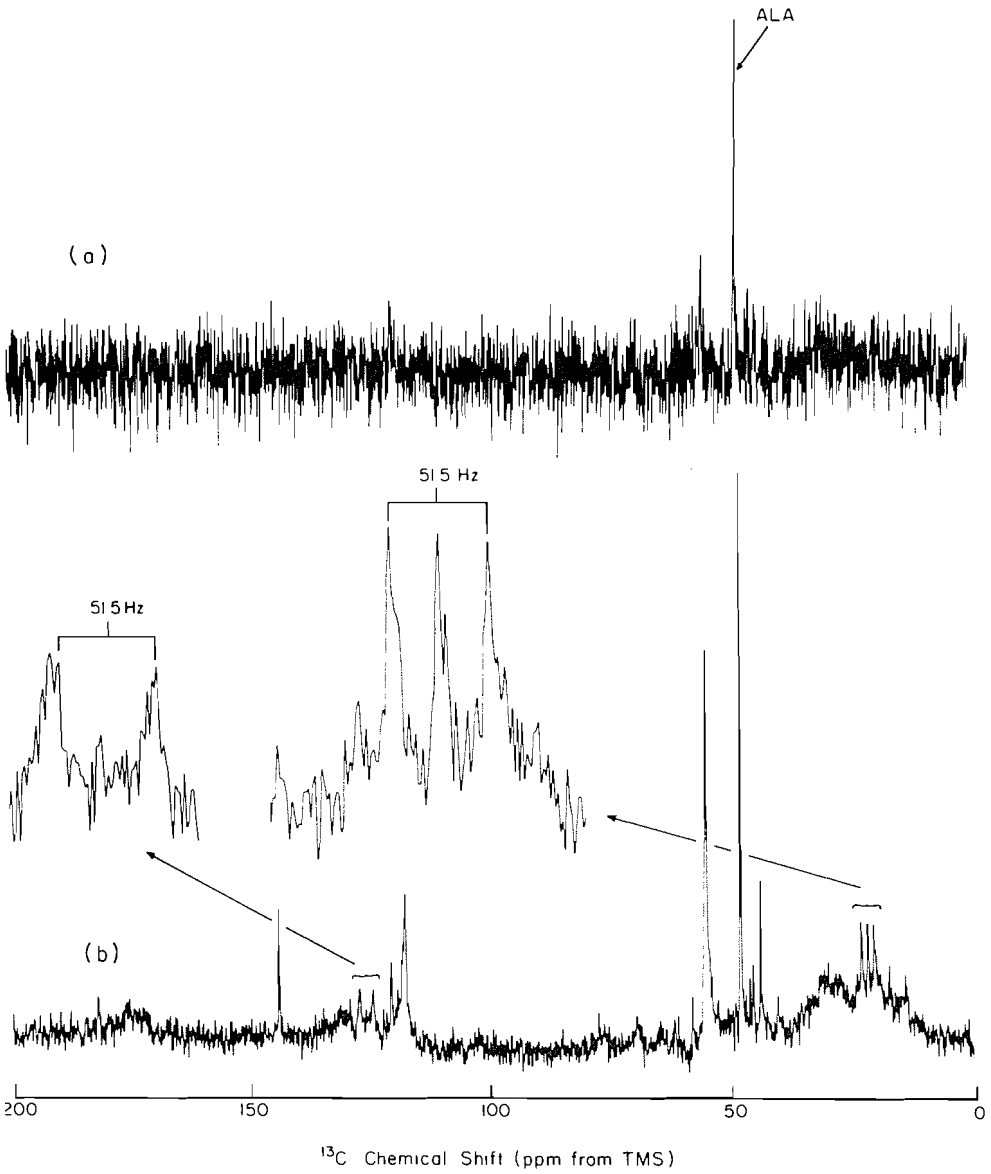

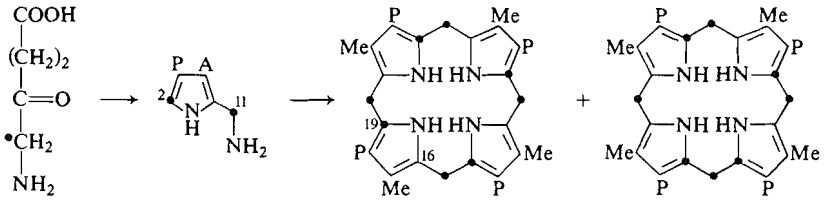

FIG. 1. Spectra of cells of *R. spheroides* (ATCC 17023) fed with [5-^{13}C]-aminolevulinic acid (ALA, 12 μmol). Cells were grown anaerobically under illumination for 17 days in ATCC medium 550, harvested by centrifugation at 13 700 g, washed and suspended in phosphate buffer (100 μ*M*, pH 7.6, ca. 10^9 cells/mL); (*a*) spectrum at 0 h (900 pulses), (*b*) spectrum at 16 h (70 713 pulses).

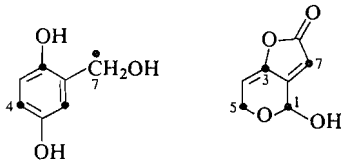
resonances and the non-quantitative instrumental conditions (dictated by signal-to-noise considerations), it is not possible to determine accurately the relative incorporation of [5-^{13}C]-ALA into each of the *meso* and α-pyrrolic positions by analysis of line intensities (9). However, the close similarity of the observed *meso* carbon multiplet to the intensity pattern calculated for a 1:3 mixture of **2***a* and **2***b* uniformly enriched in the positions shown indicates that the labelled precursors are not significantly diluted by endogenous substrates. Similar spectra were obtained for the supernatant and for washed packed cells showing that isomers were observed both intra- and extra-cellularly.



Porphobilinogen and Glucose Metabolism in Propionibacterium shermanii

In a similar experiment, [11-^{13}C]-PBG (**3**) was added to *P. shermanii* cells in a glucose-supplemented phosphate buffer, thus producing copro'gen I (**2***a*) and III (**2***b*) labelled exclusively in the *meso* methylene groups. Porphyrinogen biosynthesis was monitored over a period of 82 h in the nmr tube by observing the decrease in intensity

1 3 (A = CH_2CO_2H) (P = $CH_2CH_2CO_2H$) 2a 2b

•denotes ^{13}C

4 5

of the PBG signal at 35.5 ppm and the complementary increase of the broad signal of copro'gen I and III (δ 22.0 ppm). Representative spectra obtained at 4, 31, and 82 h are shown in Fig. 2. Simultaneously, since non-enriched glucose was periodically added to the medium during the first 24 h, the formation of propionate (CH_3, 10.9; CH_2, 31.2 ppm[2]), acetate (CH_3, 24.0 ppm), and succinate (CH_2, 34.8 ppm) was observed at natural abundance as the glucose concentration decreased. A disaccharide, identified as αα'-trehalose, can be discerned (C-1, 93.9 ppm) as it initially accumulates in the glucose-rich medium and is slowly consumed later by the starved cells. The fact that some trehalose but no propionate, succinate, or acetate is present in the spectrum of the washed cells indicates that the disaccharide is an intracellular component.

A further extension of this experiment was to incubate washed *P. shermanii* cells with [3-^{13}C]-sodium propionate; in this case (Fig. 3) a rapid randomization of the ^{13}C label between positions 2 and 3 of the substrate (31.2 and 10.9 ppm) and C-2 of succinate (34.8 ppm) was observed, indicative of equilibrium in the methylmalonyl pathway.

Polyketide Biosynthesis in Penicillium urticae

An illustration of acetate metabolism was provided by a time course experiment on the mould *P. urticae*. After 30 h of growth [2-^{13}C]-sodium acetate (10 μmol/mL) was added to the medium and a further aliquot was added after an additional 12 h. Spectra obtained on samples of aliquots of the culture at 0, 12, 24, and 36 h after the initial feeding are shown in Fig. 4. After 12 h all of the added [2-^{13}C]-acetate had been metabolized primarily to citrate (46.1 ppm) while within 24 h resonances at 116.7, 116.5, and 60.3 ppm, corresponding to the C-4, C-6, and hydroxymethyl carbon of gentisalcohol (**4**), were in evidence. Following the appearance of these signals, peaks at 111.4, 89.2, and 60.4 ppm assignable to the C-7, C-1, and C-5 of patulin (**5**) were observed (11). Accumulation of intracellular saturated fatty acids was evident from the gradual increase in the characteristic "even carbon" signals at 14.7, 27.9, 30.5, and 32.5 ppm. Concomitant with the decrease of citrate concentration, an increase of the succinate (C-2) signal at 34.2 ppm was observed. In an analogous experiment using [1-^{13}C]-acetate over a shorter time course (48 h), peaks at 117.6 and 177.1 ppm corresponding to C-6 of gentisalcohol and the carbonyl of citric acid were observed, together with a peak at 63.5 ppm which could not be assigned.

Glycolysis in Erythrocytes

Time-elapsed spectra of rabbit erythrocytes fed with [1-^{13}C]-D-glucose under essentially anaerobic conditions are shown in Fig. 5. A gradual increase in intensity of the signal at 20.7 ppm corresponds to accumulation of [3-^{13}C]-lactic acid as the principal end product of anaerobic glycolysis. In a similar experiment with [6-^{13}C]-D-glucose the 20.7 ppm signal was also observed. In both cases a broad peak (A, Fig. 5) is evident at 67.2 ppm. A signal close to this frequency has previously been assigned to C-1 of fructose-1,6-diphosphate (FDP) in *E. coli* cells (6) and to C-3 of 2,3-diphosphoglycerate (DPG) in erythrocytes (12). However, at physiological pH, FDP exhibits resonances at 66.9 and 65.4 ppm for C-1 and C-6, respectively,

[2]Chemical shifts of α and β carbons or carboxylic acids are pH dependent (10). Assignments of such signals are based on identical chemical shifts at the pH of the media and spiking of cell homogenates with authentic compounds.

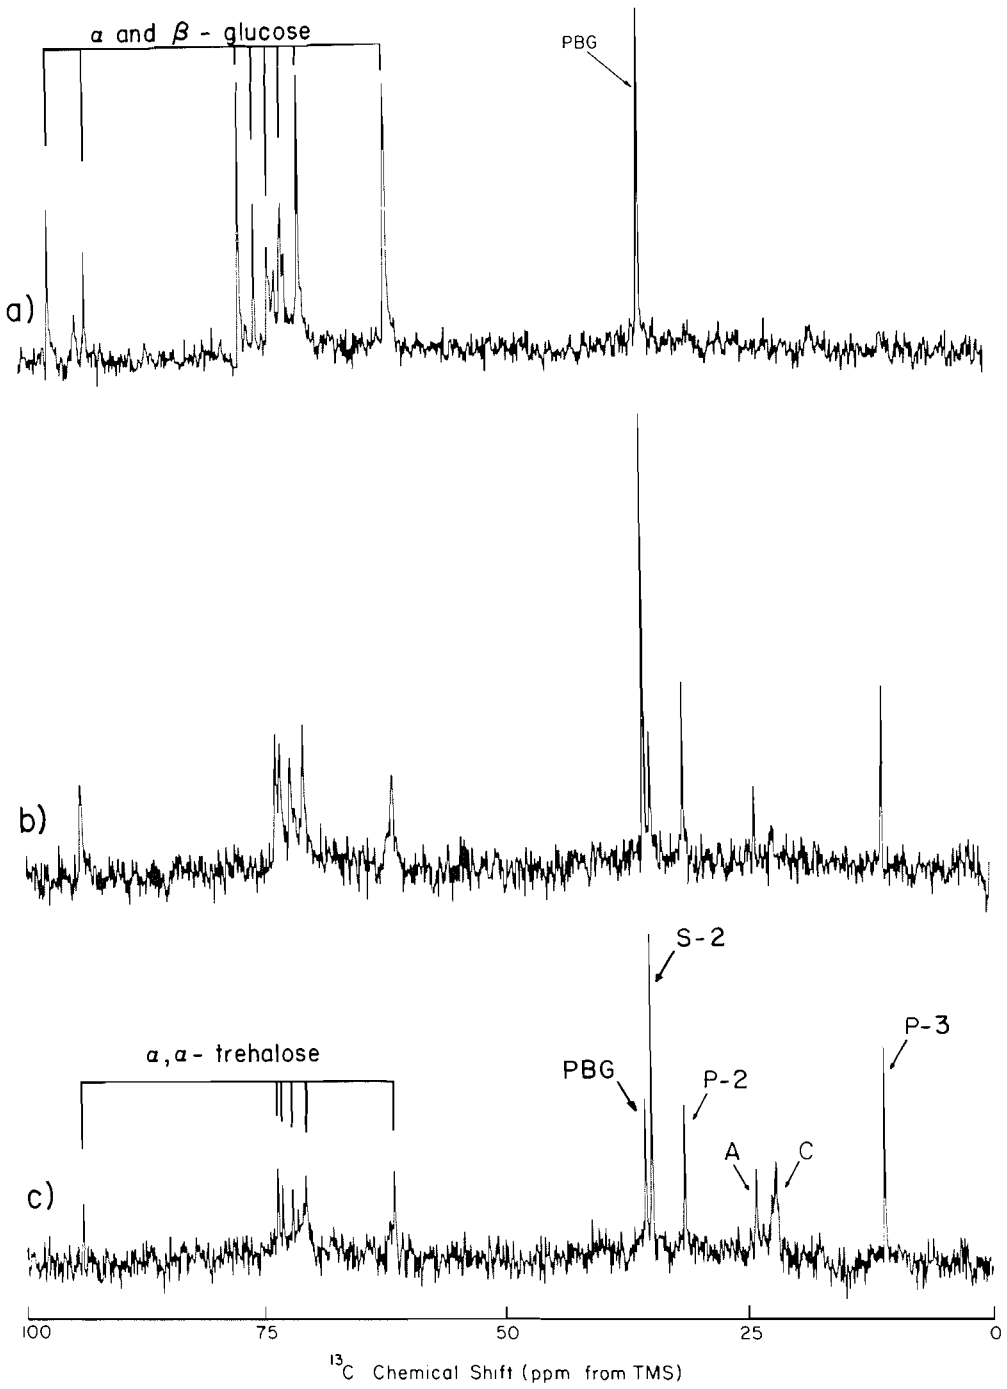

FIG. 2. Metabolism of [11-^{13}C]-porphobilinogen (PBG) by cells of *Propionibacterium shermanii* (ATCC 9614). Cells were grown anaerobically for 17 days, harvested by centrifugation, and incubated at 28°C in phosphate buffer – glucose (pH 7.6). Spectra (15 000 pulses) recorded at (*a*) 4 h, (*b*) 31 h, and (*c*) 82 h after addition of PBG. P-2 and P-3 (C-2 and C-3 of propionate); A (C-2 of acetate); S-2 (C-2 of succinate); C (*meso*-C of coproporphyrinogen I and III).

while the C-3 signal of DPG is an apparent triplet (J_{COP} = 4.5 Hz, J_{CCOP} = 4.5 Hz) at 67.2 ppm. In view of the high concentration of the latter compound in erythrocytes under anaerobic conditions (13), the 67.2 ppm resonance can be assigned to C-3 of DPG. Broadening of the C-3 signal may reflect an increase in reorientational correlation time for DPG due to binding with intracellular deoxyhemoglobin

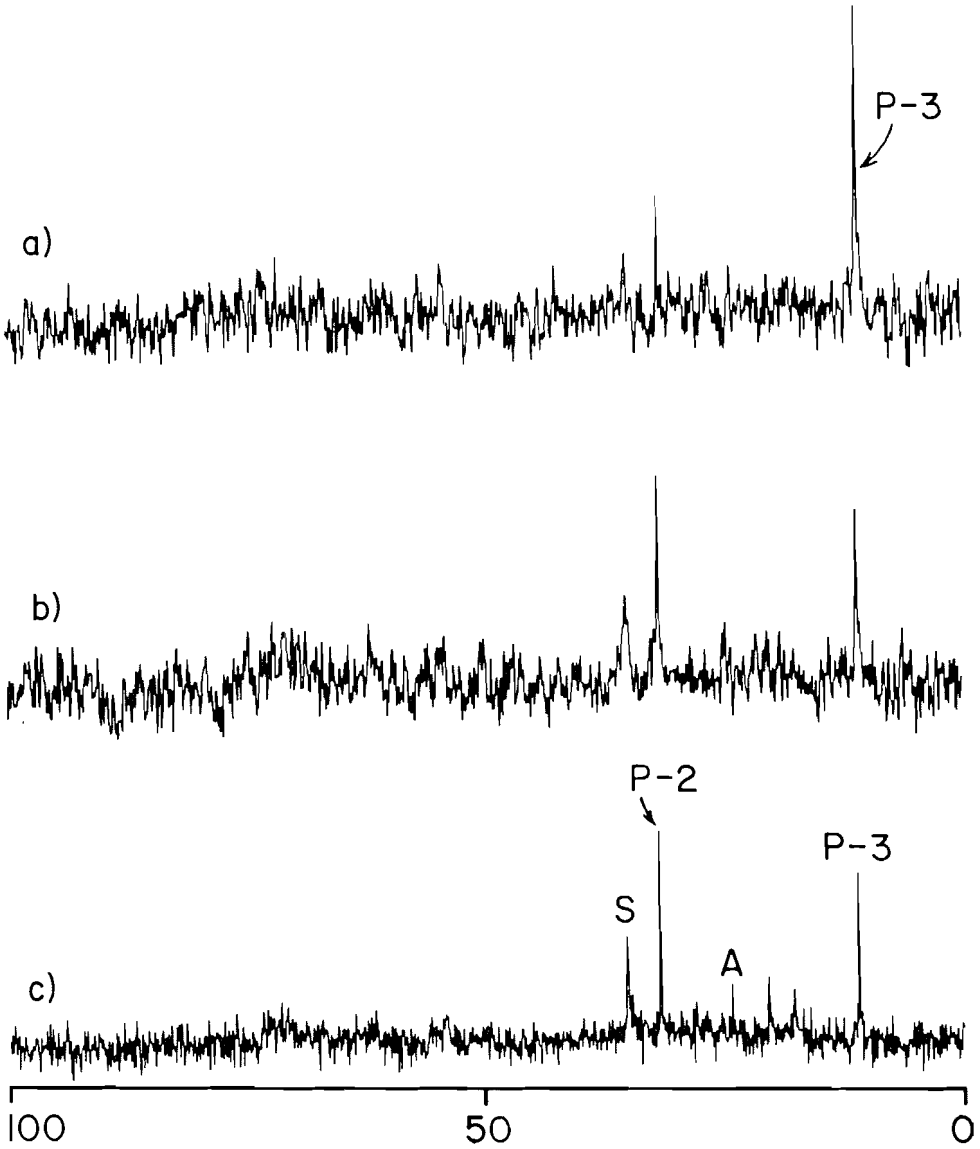

FIG. 3. Metabolism of [3-^{13}C]-propionate by *P. shermanii*. Washed cells suspended in phosphate buffer (100 μ*M*, pH 7.6) containing [3-^{13}C]-propionate (26 μmol). Spectra were recorded at (*a*) 10 min (2 200 pulses), (*b*) 70 min (2 200 pulses), and (*c*) 9 h (9 000 pulses). A (C-2 of acetate); S (C-2 of succinate); P-2, P-3 (C-2, C-3 of propionate).

(13). However, interaction of the 2 and 3 phosphate groups with metal ions may also be responsible for broadening of the resonance. Binding of DPG to deoxyhemoglobin has recently been studied by ^{31}P nmr (14).

The above examples are illustrative of a powerful non-invasive method applicable to detection of metabolic intermediates at concentrations down to approximately 1 μmol/mL of packed cells (10^8–10^{10} cells). It should be emphasized that this technique can provide information which is frequently lost during chemical analysis of disrupted cells. The assignment of chemical shifts in ^{13}C nmr spectroscopy is obviously of paramount importance in this field and the present studies are now being extended to multiply-labelled substrates, e.g., uniformly enriched ^{13}C-glucose, where appropriate homo- and heteronuclear couplings will provide diagnostic evidence for the structures of the intermediates detected.

Experimental

[5-^{13}C]-δ-Aminolevulinic acid (ALA, 86 atom% ^{13}C) was synthesized from K^{13}CN (90 atom% ^{13}C) and ethyl 3-formyl

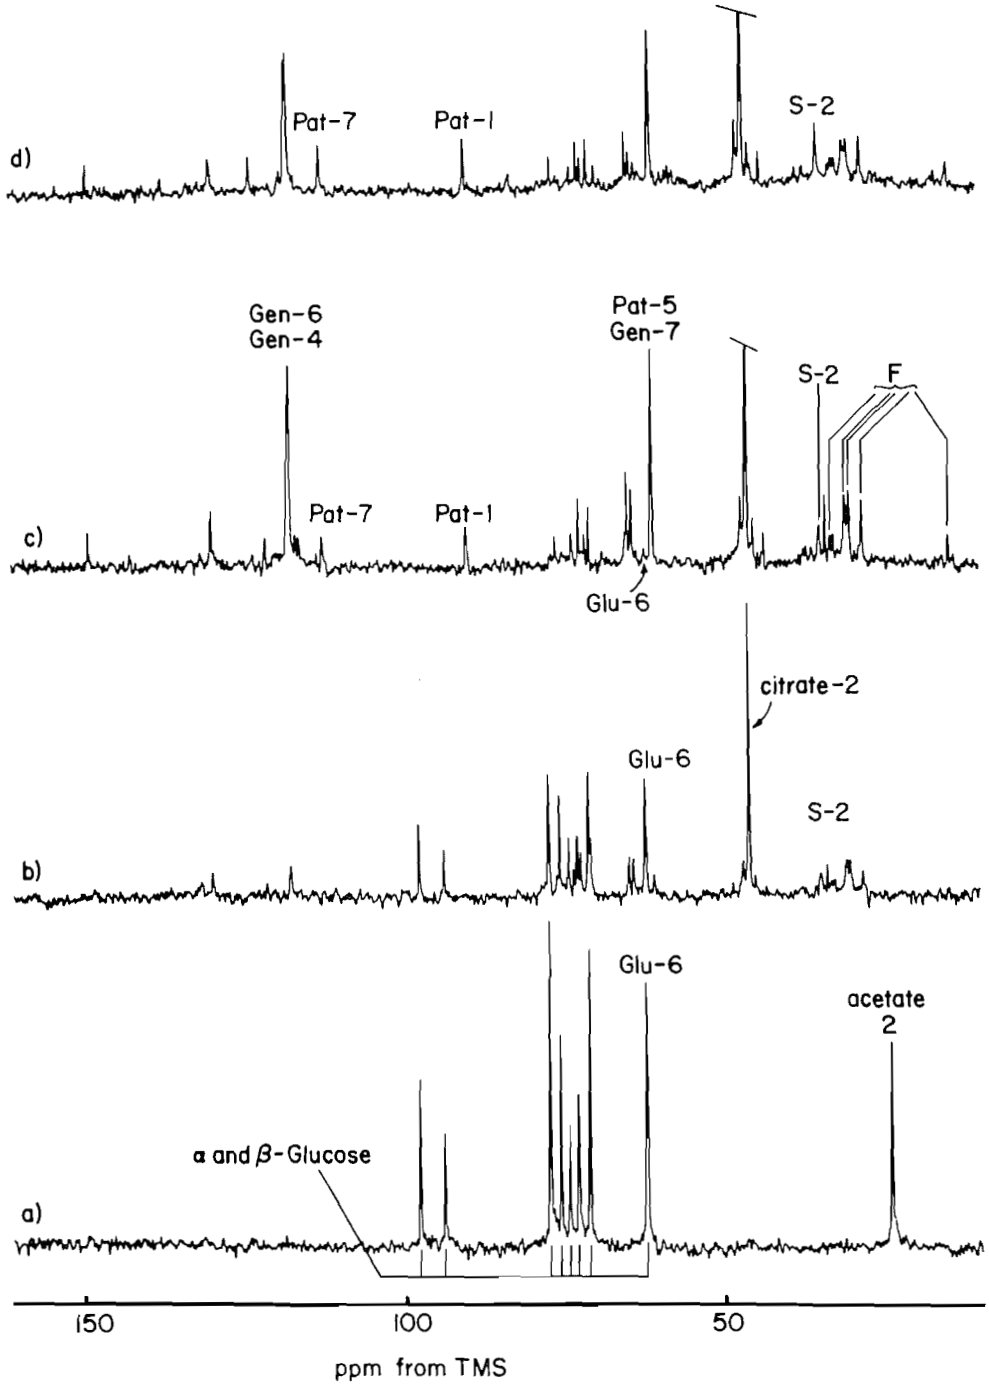

FIG. 4. Metabolism of [2-^{13}C]-acetate by *P. urticae* (NRRL 2159A). Cells were grown aerobically under previously described conditions (13) (pH 4.6) for 30 h and transferred to shake flasks containing medium supplemented with [2-^{13}C]-acetate (10 μ*M*, 90 atom%); additional [2-^{13}C]-acetate added after a further 12 h. Spectra (2 000 pulses) were recorded on aliquots of packed cells at (*a*) 0, (*b*) 12, (*c*) 24, and (*d*) 36 h after feeding. Pat-1, 5, and 7, Gen-4, 6, and 7 and S-2 denote the labelled carbons of patulin (**5**), gentisalcohol (**4**), and succinate, respectively. F denotes the signals assigned to the (even) carbons of cellular fatty acids.

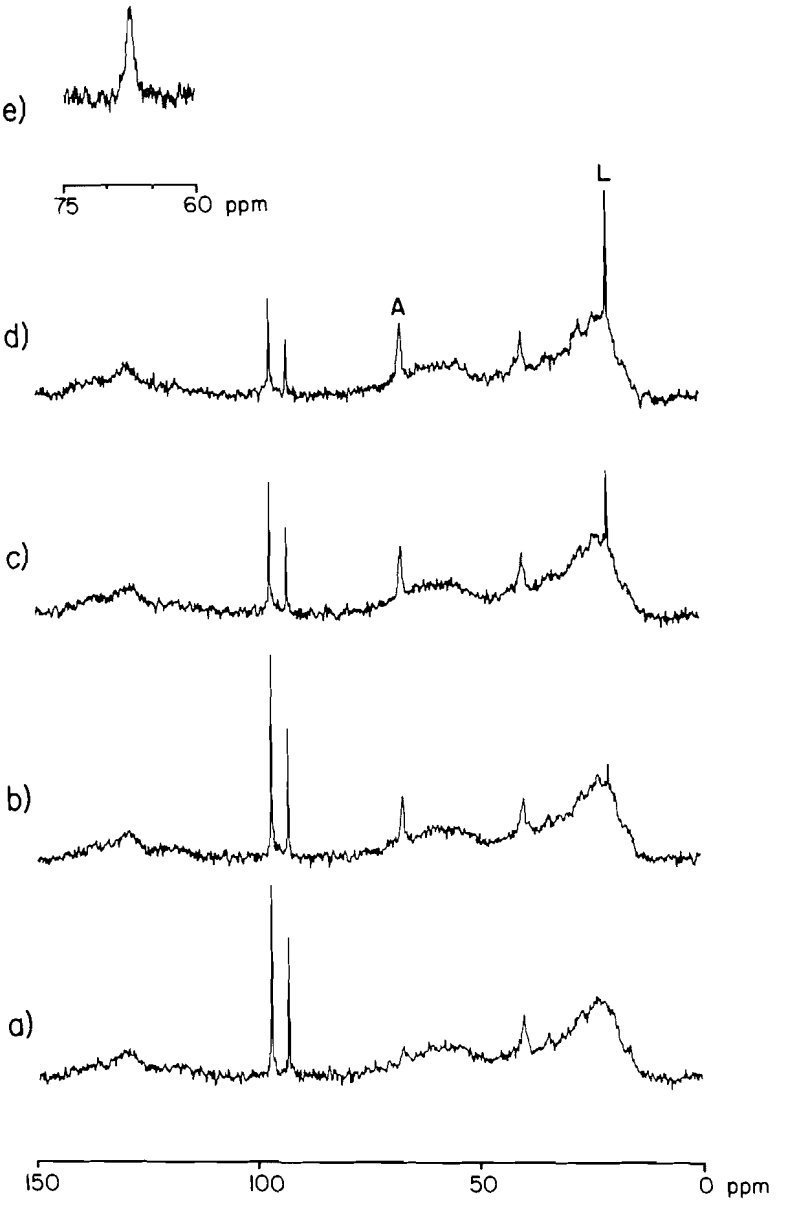

FIG. 5. Time course of [1-^{13}C]-glucose metabolism by rabbit erythrocytes. Cells were separated from whole blood, obtained by heart puncture, by centrifugation at 1 000 g, washed, and suspended in 20 m*M* phosphate – 150 m*M* NaCl buffer, (pH 7.4, ca. 10^8 cells/mL). [1-^{13}C]-Glucose (5 μ*M*) was added as an unequilibrated mixture containing principally the β anomer. Spectra (3 750 pulses, 0.5 s acquisition time, and 1.6 Hz line broadening) at (*a*) 0, (*b*) 4, (*c*) 8, and (*d*) 12 h after feeding, (*e*) higher resolution spectrum of 67.2 ppm peak (10^5 pulses, 0.8 s acquisition time, 0.7 Hz line broadening); A, C-3 of DPG; L, C-3 of lactate.

propionate (15); [11-^{13}C]-porphobilinogen (PBG, 87 atom% ^{13}C) was prepared by a modification of the synthesis of Fuhrhop and Smith (16); [3-^{13}C]-sodium propionate (87 atom% ^{13}C) was prepared from $^{13}CH_3I$ (90 atom% ^{13}C) and diethyl malonate (17); [1-^{13}C]- and [2-^{13}C]-sodium acetate (90 atom% ^{13}C) were purchased from Stohler Isotope Chemicals, Waltham, MA; [1-^{13}C]- and [6-^{13}C]-D-glucose (90 atom% ^{13}C) were kindly provided by Los Alamos Scientific Laboratory. Where appropriate, ^{13}C enrichments of precursors were measured by ^{1}H nmr.

The ^{13}C nmr spectra were obtained at 20 MHz on a Varian FT-80 spectrometer in 10 mm tubes using approximately 1.1 mL of cell suspension containing 10% D_2O as an internal lock. Typically, spectra were run at 28–30°C using 90° pulses, a spectral width of 5 000 Hz, an 8K data table, a 0.8 s pulse repetition rate and ca. 0.7 Hz of line broadening due to exponential weighting of the free induction decay (F.I.D.).

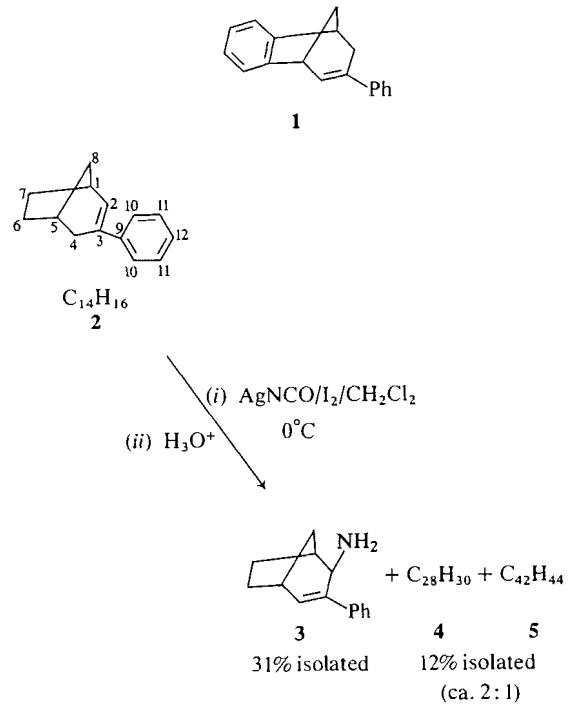
Received February 21, 1980

This paper is dedicated to the memory of Dr. Léo Marion

ALAN RICHARD HARRIS, KEITH MILLS, MICHAEL MARTIN-SMITH, PETER MURRAY-RUST, and JUDITH MURRAY-RUST. Can. J. Chem. **58**, 1847 (1980).

The novel hexacyclic title hydrocarbon, formed by an unusual oxidative dimerization of 3-phenylbicyclo[3.2.1]oct-2-ene, has been isolated and its structure elucidated by means of X-ray crystallography. The trivial name 4b-phenylmariontetraene is proposed for the hydrocarbon. Crystals are orthorhombic, *Pbca*; $a = 21.87(2)$, $b = 10.57(2)$, $c = 17.41(2)$ Å from diffractometer measurements (Mo $K\bar{\alpha}$ radiation). $V = 4024.2$ Å^3, $Z = 8$, $D_c = 1.21$ Mg m^{-3}, $F(000) = 1584$, $\mu = 0.34$ cm^{-1}. The structure was solved by direct phasing methods with MULTAN 78 and was refined by weighted full-matrix least-squares procedures to $R = 0.046$ for 2287 observed reflexions.



ALAN RICHARD HARRIS, KEITH MILLS, MICHAEL MARTIN-SMITH, PETER MURRAY-RUST et JUDITH MURRAY-RUST. Can. J. Chem. **58**, 1847 (1980).

On a isolé le nouvel hydrocarbure hexacyclique mentionné dans le titre qui se forme par une dimérisation oxydante inhabituelle du phényl-3 bicyclo[3.2.1]octène-2, et on a déterminé sa structure par diffraction de rayons-X. Pour cet hydrocarbure, on propose le nom vulgaire suivant phényl-4b mariontétraène.

A partir des mesures de diffraction (radiation Mo $K\bar{\alpha}$), on a trouvé que les cristaux sont orthorhombiques *Pbca*; $a = 21,87(2)$, $b = 10,57(2)$, $c = 17,41(2)$ Å. $V = 4024,2$ Å^3, $Z = 8$, $D_c = 1,21$ Mg m^{-3}, $F(000) = 1584$, $\mu = 0,34$ cm^{-1}. On a résolu la structure par la méthode des moindres carrés (matrice entière) et on l'a affinée jusqu'à une valeur de $R = 0,046$ pour 2287 réflexions observées.

[Traduit par le journal]

The last twenty-five years have witnessed a fine honing of X-ray crystallographic technique to provide an extremely sharp tool capable of giving rapid elucidation of the full molecular constitutions of crystalline organic compounds of high structural complexity. The economy of time inherent in the method is reflected in the present structural elucidation of an unexpected by-product, a report offered in tribute to Léo Marion's early appreciation (1–5) of the potential of the X-ray method. Reaction of the alkene **2** (6) with a mixture of silver cyanate and iodine, applying the conditions employed by Stoll *et al.* (7) on the related alkene **1**, gave not only the expected allylamine **3** but also two hydrocarbons **4** and **5** shown by mass spectrometry and microanalysis to have the empirical formulae $C_{28}H_{30}$ and $C_{42}H_{44}$ respectively. Application of ^{13}C and ^1H nmr spectroscopy to the lower molecular weight hydrocarbon **4** (isolated in 12% yield) did not permit unequivocal structural assignment. Accordingly an X-ray crystallographic analysis was undertaken on the hydrocarbon **4**, which can be formally viewed as representing a dimerization of **2** with concurrent loss of two hydrogen atoms. The

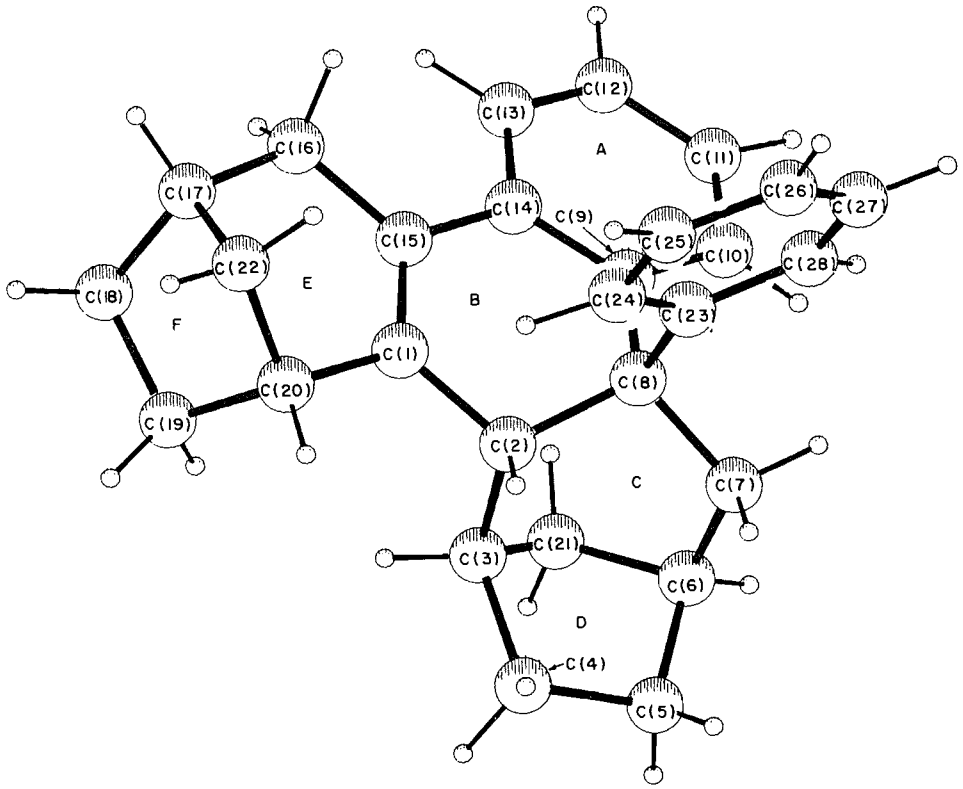

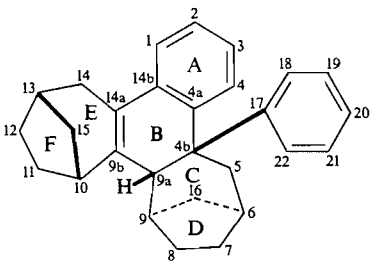

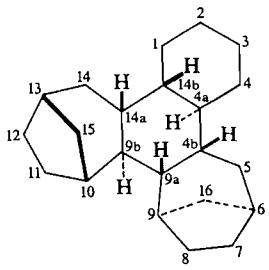

FIG. 1. View of the molecule of the hydrocarbon $C_{28}H_{30}$, **4**, employing the arbitrarily assigned crystallographic numbering. Tables of fractional atomic co-ordinates, bond distances, bond angles, and torsion angles employing this crystallographic numbering system together with lists of structure factors and thermal parameters have been deposited with the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2 and with the Crystallographic Data Centre, Cambridge, England.

result, portrayed in accordance with the initially assigned (arbitrary) X-ray numbering, is shown in Fig. 1, permitting representation of the compound in accordance with Chemical Abstracts convention as **6**, namely

6

(4bα,6β,9β,9aα,10α,13α)-4b,5,6,7,8,9,9a,10,11,12,13,14-dodecahydro-4b-phenyl-6,9:10,13-dimethanodicyclohepta[*a,c*]naphthalene. It is proposed that the trivial name, marionane, be given to the saturated hexacyclic ring system **7** in the stereochemistry shown, thus permitting **6** to be termed 4b-phenylmarion-1,3,4a(14b),9b(14a)-tetraene. The highly bridged ring system present in **6** has not been studied structurally before. The X-ray results as shown in Fig. 1 reveal the conformation of the rings in terms of the crystallographic numbering to be as follows. Rings D and F are both envelopes with flaps at C(21) and C(22) respectively. Ring C is a boat with prows at C(8) and C(21) but flattened and twisted at C(2), C(8). Ring B is an irregular half chair. Ring E is a sofa with almost perfect mirror symmetry and the E/F system has almost perfect local mirror symmetry, the plane

passing through C(15), C(22) and the mid-point of C(18)—C(19). Work directed towards the purification and structural elucidation of the second hydrocarbon by-product, $C_{42}H_{44}$ (corresponding to an oxidized trimer of **2**) and on the mechanism of formation of both the hydrocarbons is in progress and will be reported elsewhere.

Experimental

X-ray Crystallographic Data

On crystallization from toluene–ethanol the hydrocarbon **4** afforded large rhombs. A crystal with dimensions 0.5 × 0.65 × 0.65 mm was used for the study. Systematic absences (from Weissenberg photographs) *hk*0 *h* odd, *h*0*l* *l* odd and 0*kl* *k* odd indicated space group *Pbca*. Crystal data:

$C_{28}H_{30}$ fw = 366

a = 21.87(2), b = 10.57(2), c = 17.41(2) Å, from diffractometer measurements (Mo $K\bar{\alpha}$ radiation) V = 4024.2 Å^3, Z = 8, D_c = 1.21 Mg m^{-3}, F(000) = 1584, μ = 0.34 cm^{-1}.

Data were collected for *h*0-11*l* with θ_{max} = 25° on a Stoe STADI-2 2-circle diffractometer (graphite monochromated Mo $K\bar{\alpha}$ radiation). This gave 3348 data of which 2287 unique reflexions with $I > 3\sigma(I)$ were used in subsequent calculations. Lorentz and polarization corrections (but none for extinction or absorption) were applied and the data scaled by a Wilson plot. The structure was solved by direct phasing methods with MULTAN 78 (8) and the SHELX-76 system of programs (9) was used for refinement calculations. Complex neutral atomic scattering factors were taken from International Tables for X-ray Crystallography (10). Weighted full-matrix least-squares refinement (including isotropic hydrogen atoms) converged at R = 0.046 for 2287 observed reflexions ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$); R_w = 0.047 ($R_w = \Sigma(||F_o| - |F_c||\cdot w^{1/2})/\Sigma(|F_o|\cdot w^{1/2})$, $w = 3.81/(\sigma^2(F_o) + 4.6 \times 10^{-4}F_o^2)$. (The weighting scheme parameters were adjusted by the SHELX program (9).) In the final cycle all shifts in parameters were less than their standard deviations.

Preparation of Compounds

Melting points were determined on a Townson and Mercer melting point apparatus and are uncorrected. Proton magnetic resonance spectra were recorded on a Varian Associates EM390 90 MHz spectrometer and ^{13}C spectra were recorded on a Varian Associates XL100 spectrometer. Signal positions are quoted in δ units with TMS or DSS as the internal standard. Gas–liquid chromatography was carried out on a Perkin-Elmer F30 machine. Mass spectra were recorded on a Kratos-AEI MS30 spectrometer. Ultraviolet spectra were recorded on a Perkin-Elmer 402 spectrometer and infrared spectra were recorded on a Perkin-Elmer 357 grating spectrometer.

3-Phenylbicyclo[3,2,1]oct-2-ene **2**

This compound was prepared by a nickel(II) acetylacetonate catalysed coupling reaction (11) between phenyl magnesium bromide and 3-bromo- or 3-chlorobicyclo[3,2,1]oct-2-ene. This method gives a 6–8-fold increase in yield over the literature procedure (6). A solution of phenyl magnesium bromide (prepared from magnesium (9.6 g; 0.4 mol) and bromobenzene (42 mL; 62 g; 0.4 mol)) in ether (150 mL) was added dropwise, with cooling (0°C) under nitrogen, to a stirred mixture of nickel acetylacetonate (0.3 g) and 3-bromobicyclo[3,2,1]oct-2-ene (50 g, 0.267 mol) (12). The mixture was stirred at room temperature for 20 h and then hydrochloric acid (200 mL; 2 *M*) was added dropwise at 0°C. The organic phase was separated and the aqueous phase was extracted with ether (2 × 200 mL). The combined organic solutions were dried ($MgSO_4$) and evaporated *in vacuo*. The residual yellow oil (50 g) was distilled to give the title compound as a colourless oil (45 g; 91%), bp 109–113°C/1.5 Torr (lit. (6) bp 80°C/0.5 Torr); uv λ_{max} (EtOH): 220 (ε 9 200), 253 (12 000), 292 (sh, 500) nm; ir ν_{max} ($CHBr_3$): 1630 cm^{-1} (m, C=C); ^{1}H nmr ($CDCl_3$): 7.70–7.00 (5H, m, aromatic), 6.40 (1H, d, J = 7Hz, —*CH*=CPh—), 2.80–1.00 (10H, m, aliphatic); ^{13}C nmr δ (ppm): 141.3, s(C3); 133.1, s(C9); 131.1, d(C2); 128.1, d and 124.6, d(C10 and C11); 126.5, d(C12); 38.9, t(C4); 35.7, d(C1); 35.3, t(C7 and C8); 33.5, d(C5); 30.5, t(C6).

Reaction of Alkene 2 with a Mixture of Iodine and Silver Cyanate

A solution of the alkene **2** (43 g; 0.23 mol) in dichloromethane (400 mL) at 0°C under nitrogen atmosphere was treated with silver cyanate (13) (43 g; 0.22 mol) and then with iodine (57 g; 0.22 mol) in portions (~5 g) over 1 h. The mixture was stirred at 0°C for 4 h and kept at 0–5°C overnight, filtered, and the filtrate washed with aqueous sodium thiosulphate solution (8%; 250 mL). The solution was dried ($MgSO_4$) and evaporated *in vacuo*. The residual pale yellow oil (45 g) was dissolved in a mixture of acetone (600 mL) and concentrated hydrochloric acid (100 mL), kept at room temperature overnight, and then evaporated *in vacuo*. The residue was partitioned between water (300 mL) and ethyl acetate (400 mL) and some insoluble material (A) was filtered off (see below). The aqueous layer was separated, washed with ethyl acetate (300 mL), and then basified with aqueous sodium hydroxide (2 *M*). The crude basic material was extracted into ethyl acetate (3 × 200 mL). The combined extracts were dried ($MgSO_4$) and evaporated to ca. 200 mL *in vacuo*. The solution was treated with ethereal hydrogen chloride (8%) until no more precipitate formed and the salt was filtered off and crystallized from a mixture of methanol and ethyl acetate to give 3-phenylbicyclo[3,2,1]oct-3-en-*exo*-2-amine, hydrochloride,[1] **3** (14.4 g; 31%) as a white powder mp 249–251°C (dec). Ultraviolet (EtOH) λ_{max}: 244 nm (ε 11 100); ^{1}H nmr (D_2O): 7.65 (5H, br s, aromatic), 6.60 (1H, d, J = 7 Hz, —CH=CPh—), 4.32 (1H, d, J = 3.5 Hz, $>CH—NH_2$), 2.90–1.40 (8H, m, remaining aliphatic). *Anal.* calcd. for $C_{14}H_{17}N{\cdot}HCl$: C 71.33, H 7.69, N 5.95, Cl 15.04; found: C 71.41, H 7.78, N 6.19, Cl 15.23%.

The insoluble material (A) described above was filtered off and crystallized from a mixture of toluene and ethanol to give the hydrocarbon **4** (5 g; 12%) as off-white crystals mp 167–170°C (X-ray sample had mp 167.5–170°C); glc 4 *M* 2% OV-17 column at 280°C, retention time 11.4 min, 98.8% purity. Ultraviolet (cyclohexane) λ_{max}: 221 (ε 21 000), 227 (21 000), 233 (17 500), 283 (9 100) nm; ^{1}H nmr ($CDCl_3$): 7.30–6.80 (9H, m, aromatic), 2.87–0.88 (21H, m, aliphatic); ^{13}C nmr δ(ppm): 150.6, s(C14a); 143.2, s and 142.2, s(C14b and C9b); 134.8, s(C4a); 127.3, d and 126.9, d, (C18, C19, C21, and C22); 126.3, d, 125.9, d, 125.6, d, 125.2, d, and 122.4, d(C1, C2, C3, C4, and C20); 121.8, s(C17); 58.1, d(C9a); 42.7, d and 42.1, d(C9 and C10); 42.4, s(C4b); 39.2, d(C6); 36.7, t, 35.9, t, 35.5, t, 34.1, t, 33.6, t, and 32.6, t(C5, C7, C8, C11, C14, C15, and C16); 32.4, d(C13); 31.3, t(C12) (numbering as in **6**); ms *m/e*: 366 (100%; M^+), 297 (28%; $M - C_5H_9$), 286 (91%; $M - C_6H_8$), 217 (33%; $M - C_{11}H_{17}$). *Anal.* calcd. for $C_{28}H_{30}$: C 91.80, H 8.20; found: C 91.79, H 8.32%.

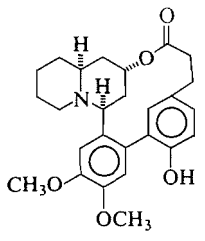
Mercuric acetate assisted methoxylations and hydroxylations of lythrine resulted in a regio and stereoselective introduction of the substituent at the benzylic position with *S*-stereochemistry. The compounds obtained are thus epimeric at C13 with the naturally hydroxylated alkaloid lythridine and its derivatives. The implications of the results in planning the total synthesis of lythrine is discussed.

I. LANTOS, C. RAZGAITIS, B. LOEV et B. DOUGLAS. Can. J. Chem. **58**, 1851 (1980).



Les méthoxylations et hydroxylations de la lythrine assistées par l'acétate mercurique conduisent à une introduction régiosélective et stéréosélective d'un substituant en position benzylique avec une stéréochimie *S*. Les composés obtenus sont donc épimères au niveau du carbone en position 13 de l'alcaloïde naturel lythridine hydroxylé et de ses dérivés. On discute des implications de ces résultats dans la planification de la synthèse totale de la lythrine.

Since their initial isolation (1) alkaloids of the Lythracea plant family have provided a wealth of research opportunities for workers primarily interested in their structural elucidation (2) or total synthesis (3). Structurally, they are classified into five distinct classes (4*a*) depending on the presence of a quinolizidine ring in either the *cis*- or *trans*-configuration or of a piperidinyl moiety and whether these are associated with a biphenyl or diphenyl ether aromatic fragment.

Previous work within our laboratories described the isolation (1*b*), structure elucidation (2*b*), and total synthesis of decinine (**1**) (3*a*), and decamine (**2**) (3*b*), compounds with *trans* and *cis*-quinolizidine configuration respectively, linked to biphenyl moieties. That report, as well as those of others (3*c*), which describe the total synthesis of the analogous diphenyl ether, utilizes methodology appropriate for the synthesis of alkaloids containing a fully saturated methylene chain in the macrocyclic lactone portion. Extension of this basic synthetic scheme to the biosynthetically related lythrine[2] (**3**) and lythridine (**5**), necessitated an investigation into some of the reactions and potential interconversions of these species, and these results are disclosed herein. We anticipated that the previously known conformation of the macrocyclic lactone ring in **3** and **5** (2*b*, *c*) would facilitate the interpretation of the stereochemical course of the reaction.

Mercuric acetate assisted methoxylation (5) of methyl lythrine (**6**) over a period of 48 h resulted in the formation of a single methoxy derivative **7** (Scheme 1). The proton nmr of this newly formed compound suggested that the methoxy substituent entered at the benzylic position. Spectral comparison of **7** with the dimethyl derivative of lythridine (**8**), prepared by MeI/NaH treatment of the natural product **5**, revealed that both compounds exhibited methine proton signals of the ABX spectral pattern, centered within the same range of the spectra at 4.50 ppm (however, while the Hx quartet in the spectrum of **7** derived from splitting by coupling constants of 2 and 6 cps, the corresponding signals

SCHEME 1

in the nmr of **8** had splittings of 3 and 10 cps and were thus a much broader pattern). Since no other change could be detected from a spectral comparison of **7** and **8**, the two compounds were assigned epimeric structures at C13. This assignment was unequivocally proven by the series of conversions shown in Scheme 1.

Conversion of lythridine to the *epi*- series took advantage of the solvolytic lability of the secondary benzylic hydroxyl group in its molecule. We had expected that treatment with methanol under strongly acidic conditions would lead to unimolecular displacement resulting in at least partial inversion of this asymmetric centre. We were quite surprised, however, to find that stirring **5** in MeOH·BF_3 at room temperature for 0.5 h resulted in the formation of a single methoxy derivative **4**, in better than 80% yield, which was identical to the methoxy compound obtained from lythrine (**3**) with $Hg(OAc)_2$/MeOH.

The methine proton signals in the spectrum of **4** displayed a pattern typical of **7** with splitting constants of 2 and 5 cps, and the structural relationship with **7** was fully established by methylation with MeI/K_2CO_3. The ease with which transformation 5 → 4 occurred excludes the probability of structural changes taking place other than epimerization at C13 and thus unambiguously supports our structural assignments for **4** and **7**. It is noteworthy that in the above methoxylation no methoxy compound with the natural C13-*R*-stereochemistry was formed.

Hydroxylation of **6** with mercuric acetate in aqueous THF followed the same stereochemical course. A single hydroxy compound (**9**) was isolated which proved to be epimeric with lythridine at C13 through its conversion to the *epi*-dimethyl compound **7**, by MeI/NaH or $CH(OCH_3)_3$·BF_3 (7).

The foregoing results indicate that mercury assisted additions to the α,β-unsaturated lactone of lythrine take place in a fully regio and stereoselective manner. The newly formed substitutent always

enters at the benzylic β-position and obtains the *S*-stereochemistry, epimeric to the naturally hydroxylated alkaloids. Furthermore, it is also seen that the benzylic substituent readily undergoes ionization under the influence of Lewis acids, and trapping of the carbonium ion by the solvent always affords the thermodynamically more stable *epi*-substituted products. Our experimental finding that hydroxy compound **9** afforded dimethyl *epi*-lythridine (**7**) via both basic methylation and acid assisted methoxylation further supports this unimolecular methoxylation mechanism.

Oxymercuration studies in the literature (8, 9) suggest a mechanistic course highly dependent on the substitution pattern about the olefin and its geometry. Both *syn* and *anti* additions of the mercurial and nucleophile have been observed. An examination of the molecular geometry of lythrine, based on the X-ray model (2*b*), indicates a rather rigid framework with substantial steric crowding from the pro-*R* face of the double bond. As a stereochemical consequence *direction of mercurial approach* (8) governs the product configuration in analogy with strained ring oxymercuration reactions. The nature of the intermediate seems to be a highly stabilized mercury substituted carbonium ion as previously suggested by Brown and Kawakami (10).

Our results are relevant in the design of a synthetic scheme toward the total synthesis of lythrine and lythridine. We have previously attempted to prepare lythrine (**3**) from the open *cis*-α,β-unsaturated hydroxy acid precursor but this was unsuccessful. Our present work suggests a more accessible intermediate, *epi*-lythridine (**9**), whose preparation requires no stereochemical control at the dihydroxy acid stage because of its much preferred formation in the ring closed macrocycle. We are currently working on methods to transform the *epi*-hydroxy group to the *cis* olefinic linkage of the natural product. The total synthesis of lythridine (**5**), on the other hand, will require a dihydroxy acid precursor with defined stereochemistry together with mild conditions for the cyclization to avoid epimerization of the C13 asymmetric centre.

Experimental

Melting points were determined on a Thomas–Hoover melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer Infracord spectrophotometer and ^{1}H nmr spectra were obtained on a Varian Associates model T-60 spectrometer. Signal positions are given in δ units with tetramethylsilane as internal standard.

Preparation of 17-Methyllythrine (17,22,23-Trimethoxylythran-11-one, 6)

To a stirred solution of lythrine (47.0 g, 0.108 mol) in 1.4 L of 10% sodium hydroxide and 800 mL of dioxane was added dropwise 140 mL dimethyl sulfate. The reaction was allowed to stir overnight at ambient temperature and the precipitated product was filtered and crystallized from chloroform – petroleum ether (1:1) mixture to afford 34.0 g (72%) of **6**, mp 236–237°C; ir (Nujol): 1694, 1257, 1123, 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.13 (s, 1H, aromatic), 6.95 (m, 5H, aromatic), 6.84 and 5.82 (AB system, 2H, J = 13 Hz, CH=CH), 5.26 (m, 1H, C*H*—OCO), 3.90, 3.84, and 3.76 (s, 3 × 3H, 3 × CH_3O), 2.8 to 1.3 (m, 14H). *Anal.* calcd. for $C_{17}H_{31}NO_5$: C 72.14, H 6.95, N 3.12; found: C 72.34, H 7.24, N 3.02.

Preparation of 13,17-Dimethyl-13-epilythridine (12,13-Dihydro-13(S),17,22,23-tetramethoxylythran-11-one, 7)

Method A: To a solution of **6** (2.0 g, 4.5 mmol) in 50 mL of methanol was added 4.3 g of mercuric acetate and the solution was stirred at room temperature for 96 h. After cooling the reaction mixture in an icebath, sodium borohydride (0.8 g, 21 mmol) was slowly added and the resulting dark grey suspension was diluted with water to 120 mL. The solution was extracted with chloroform, the organic extract was dried over anhydrous magnesium sulfate, and after filtration was evaporated to an oil which was crystallized by trituration with ether. A yield of 1.2 g (54%) of **7** was obtained by this method, mp 222–223.5°C, ir (Nujol): 1709, 1250, 1197, 1123 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.1 (s, 1H, aromatic), 7.0 (m, 3H, aromatic), 6.9 (s, 1H, aromatic), 5.1 (br s, 1H, CHOCO), 4.52 (q, 1H, X part of ABX system, J_{AX} = 2 Hz, J_{BX} = 6 Hz, C*H*OCH_3), 3.92, 3.86, 3.76, and 3.35 (s, 4 × 3H, 4 × OCH_3), 3.2–1.1 (m). *Anal.* calcd. for $C_{28}H_{35}NO_6$: C 69.83, H 7.33, N 2.91; found: C 70.02, H 7.24, N 2.92.

Method B: 13-Methyl-*epi*-lythridine (**4**, 1.67 g, 3.5 mmol) was dissolved in a mixture of 50 mL dioxane and 50 mL 10% sodium hydroxide, and dimethyl sulfate (4.5 mL) was added over the period of 15 min. The mixture was allowed to stir overnight and was evaporated at reduced pressure to almost dryness, yielding a glassy residue which was diluted with 50 mL of water and was extracted with methylene chloride (150 mL). The organic extract was dried over anhydrous magnesium sulfate, was filtered, and the filtrate was evaporated to a glass which was triturated with ether and crystallized; 1.15 g of **7** was obtained (67%).

Method C: 17-Methyl-13-*epi*-lythridine (**9**, 2.0 g, 4.3 mmol) was dissolved in 30 mL of dimethylformamide, and sodium hydride (50% oil, 0.2 g, 4.5 mmol) was added. The anion was generated with stirring at room temperature for 0.5 h and methyl iodide (0.7 g, 5 mmol) was added to the suspension. Stirring was continued overnight and the reaction was diluted with water to 100 mL. The product was extracted with ether, the ethereal solution was dried over anhydrous magnesium sulfate, and after filtration the filtrate was evaporated at reduced pressure to a glass. The product (1.8 g, 88%) was obtained crystalline by trituration with ether.

Preparation of 13-Methyl-epi-lythridine (12,13-Dihydro-17-hydroxy-13(S),22,23-trimethoxylythran-11-one, 4)

Method A: To a solution of 2.0 g (4.75 mmol) of lythrine in 50 mL of methanol was added mercuric acetate (4.3 g) and the mixture was stirred at ambient temperaturs for 3 days. The solution was cooled in an ice bath and 1.0 g (26 mmol) of sodium borohydride was slowly added, resulting in a darkly colored mixture which was diluted with water to 120 mL and was extracted with chloroform. Evaporation of the chloroform extract at reduced pressure resulted in a glassy solid which was dissolved in 50 mL of methanol and was saturated with hydrogen sulfide gas. The alcoholic solution was filtered over a Celite bed and was evaporated to yield 2.07 g (98%) of **4**, which was recrystallized from methylene chloride – ether, mp 160–165°C; ir (Nujol): 3448, 1694, 1204, 1123, 1052 cm^{-1}; ^{1}H nmr ($CHCl_3$):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

7.3–7.0 (m, 3H, aromatic), 6.85 (s, 1H, aromatic), 5.05 (br s, 1H, C*H*OCO), 4.45 (q, X part of AB system, 1H, $J_{AX} = 2$ Hz, $J_{BX} = 5$ Hz, $CHOCH_3$), 3.90, 3.82, and 3.30 (s, 3 × 3H, 3 × OCH_3), 3.30–1.2 (m).

Method B: Boron trifluoride etherate (1.35 mL, 11 mmol) was added in one portion to a cooled solution of lythridine (1.3 g, 3 mmol) in 40 mL of methylene chloride followed by the dropwise addition of trimethylorthoformate (0.76 g, 7.2 mmol) over the period of 20 min. Stirring was maintained for an additional 0.5 h and the solution was diluted to 150 mL with methylene chloride. After washing the solution with 2 *N* hydrochloric acid (3 × 50 mL) and 5% sodium carbonate (2 × 50 mL), it was dried over anhydrous sodium sulfate, filtered, and evaporated to an oil at reduced pressure. Trituration of the oily residue with methylene chloride – ether mixture resulted in 0.9 g of the crystalline **4**.

Method C: Lythridine **5** (0.10 g, 0.2 mmol) was added to 2 mL of $BF_3 \cdot 2CH_3OH$ complex and the reaction was allowed to stand at room temperature for 0.5 h. Chloroform (30 mL) was added, and the resultant solution was washed with 5% sodium carbonate (2 × 30 mL) and saturated brine. After drying the solution over anhydrous magnesium sulfate it was filtered and the filtrate was evaporated to a glass at reduced pressure. Trituration with methylene chloride – ether obtained 0.07 g of solid product **4**.

*13,17-Dimethyllythridine (12,13-Dihydro-13(*R*),17,22,23-tetramethoxylythran-11-one, 8)*
