One may, however, argue that the methyls do not deform enough to go into the conformation implied above because of angle strain. In this alternative scenario the near-zero values of Δ presumably arise from nearly equal contributions from **2** and **3**, but with opposite signs. A variation on this hypothesis arises if one considers the possibility that perturbations in $\pi^{R'}$ and $\pi^{R''}$ may be quite small. Under such circumstances, with equal contributions from **2** and **3** and R = *tert*-butyl, the value of Δ may reflect a relatively large contribution from the Δ_{ID} term rather than a conformational effect.

Given that the isopropyl methyl carbon resonance in 4-methyl-1,2-pentadiene, **32**, is $\delta = 22.9$, we observe a diamagnetic ε-substituent effect of approximately 0.3 ppm for both methyl carbons (entry 1) and a ζ-substituent effect of approximately 0.2 ppm, also to higher field (entries 2–4). Of note here is the observation that δ_a and δ_b in species **3** and **4** show the two extremes as represented in entries **1** and **2**. Unfortunately we were not able at this time to obtain definitive conformational data based upon existing correlations between stereo-

32

chemical factors in the allenes and ^{13}C nmr chemical shifts. Studies related to this problem are, however, in progress.

In summary these data reflect the probable conformational origin of axial dissymmetry induced chemical shift nonequivalence of isopropyl methyl carbons in allenic systems.

On the nature of the radical pairs involved in the Grignard reaction

BAREND JOHANNES SCHAART, CORNELIS BLOMBERG, OTTO SJOUKE AKKERMAN, AND FRIEDRICH BICKELHAUPT

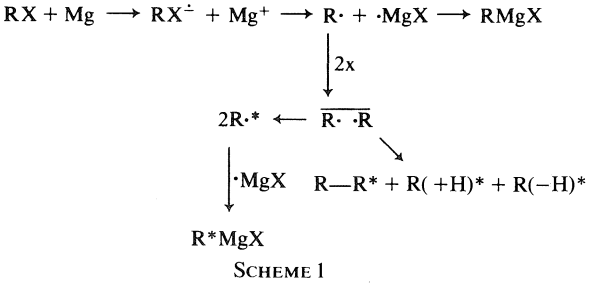
Scheikundig Laboratorium der Vrije Universiteit, De Boelelaan 1083, 1081 HV Amsterdam–Buitenveldert, The Netherlands

Received November 13, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

BAREND JOHANNES SCHAART, CORNELIS BLOMBERG, OTTO SJOUKE AKKERMAN, and FRIEDRICH BICKELHAUPT. Can. J. Chem. **58**, 932 (1980).

During the simultaneous reaction of alkyl bromides and of *p*-halosubstituted benzyl bromides with magnesium in THF/C_6D_6 (1:4), CIDNP net effects (emission) are observed in the ^1H nmr spectrum. The effects are opposite to those occurring during the reaction of preformed ethylmagnesium bromide and the benzyl bromides. These results constitute firm evidence that only alkyl radical pairs $\overline{R{\cdot\cdot}R}$ are responsible for the CIDNP effects, and that the radicals R· are generated in the Grignard reaction proper, rather than in unrelated side reactions such as Wurtz coupling or metal halogen exchange.



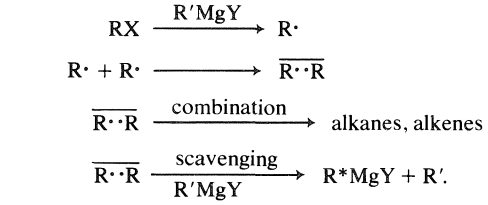
BAREND JOHANNES SCHAART, CORNELIS BLOMBERG, OTTO SJOUKE AKKERMAN et FRIEDRICH BICKELHAUPT. Can. J. Chem. **58**, 932 (1980).

On a observé dans le spectre rmn du ^1H des effets globaux de polarisation nucléaire dynamique induite chimiquement (PNDIC) qui apparaissent pendant la réaction silmultanée entre le magnésium dans un mélange THF/C_6H_6 (1:4) et des bromures d'alkyles et des bromures de benzyles substitués en position *para* par un halogène. Les effets sont en opposition à ceux observés lors de la réaction des bromures d'éthylmagnésium et des bromures de benzyles préformés. Ces résultats constituent une preuve tangible du fait que seuls les paires de radicaux alkyles $\overline{R{\cdot\cdot}R}$ sont responsables des effets PNDIC et du fait que les radicaux R· sont générés par la réaction de Grignard proprement dite plutôt que par des réactions secondaires indépendantes telles qu'un couplage de Wurtz ou une réaction d'échange métal–halogène.

[Traduit par le journal]

Introduction

In recent years strong support has been obtained (1–3) for the mechanism of formation of Grignard compounds in the reaction of alkyl halides with magnesium metal (henceforth called the Grignard reaction) as presented in Scheme 1.



SCHEME 1

The evidence was based on product analysis and on a study of the influence of the solvent (2, 3*a*), on kinetic studies (3*b–d*), and in particular on the observation of CIDNP effects in the ^1H nmr spectrum (2). However, some problems remained.

In the first place, two radical pairs were originally considered as plausible precursors of the polarized products in the reaction, i.e., $\overline{R{\cdot\cdot}MgX}$ (**1**) and $\overline{R{\cdot\cdot}R}$ (**2**). Unfortunately, the *g*-factor of MgX· is not known, but it is likely to be different from the *g*-factor of R·. With $\Delta g \neq 0$, the occurrence of **1** as polarizing radical pair should have given rise to net effects (4). This was not the case; only multiplet effects were observed in the Grignard reagent. Consequently **1** was considered to be unlikely, but additional evidence was clearly desirable.

In the second place, Lawler and Livant (5) have shown that the polarization in the Grignard compound could in principle also arise from a catalyzed halogen–metal exchange reaction of the newly formed Grignard reagent with the alkyl halide (Scheme 2). Although evidence has been presented that this latter reaction was not responsible for the major part of the polarization observed in the Grignard reaction (1), an unequivocal confirmation of the proposed scheme was deemed necessary.

In the present investigation conclusive evidence on these problems is presented. The novel approach applied involved the study of the Grignard reaction using mixtures of halides which produce radicals with different *g*-factors.

Results and Discussion

The Unique Involvement of Radical Pairs of Type $\overline{R\cdot\cdot R}$ *(2)*

The ^{1}H nmr spectrum was recorded on a Varian A56/60 D spectrometer during the reaction of ethyl bromide and *p*-chlorobenzyl bromide with magnesium in a mixture of tetrahydrofuran and perdeuterobenzene (1:4), eq. [1]; this spectrum is shown in Fig. 1.

[1] $CH_3CH_2Br + p\text{-}ClC_6H_4CH_2Br + Mg \xrightarrow[C_6D_6]{THF} CH_3CH_2MgBr + p\text{-}ClC_6H_4CH_2MgBr + \text{other products}$

Besides the formation of small amounts of *p*-$ClC_6H_4CH_2MgBr$ (CH, δ = 1.78 ppm), a clear net emission (E) superimposed on a multiplet effect E/A for the CH_2-group of CH_3CH_2MgBr (δ = −0.03 ppm) is observed. This can be explained by invoking the radical pairs

$\overline{p\text{-}ClC_6H_4CH_2\cdot\cdot CH_2CH_3}$ and $\overline{CH_3CH_2\cdot\cdot CH_2CH_3}$

as precursors of polarized CH_3CH_2MgBr. With $g_{CH_3CH_2\cdot}$ = 2.0025 (6) and $g_{p\text{-}ClC_6H_4CH_2\cdot}$ = 2.0027 (4*a*), application of Kaptein's sign rules (7) predicts the polarization observed for the CH_2 group of CH_3CH_2MgBr; in particular a net emission (E) and an E/A multiplet are expected ($\Gamma = \mu\cdot\varepsilon\cdot A_i\cdot\Delta g$ = +·−·−·−=−: E since μ = + (F-pair), ε = − (escape reaction), A_i = −22.4 (6), and $\Delta g = g_{CH_3CH_2\cdot} - g_{p\text{-}ClC_6H_4CH_2\cdot}$ = −; $\Gamma = \mu\cdot\varepsilon\cdot A_iA_j\cdot J_{ij}\cdot\delta_{ij}$ = +·−·−·+·+·+=+: E/A since μ = + (F-pair), ε = − (escape reaction), A_j = + 26.9 (6), J_{ij} = +, δ_{ij} = + (both nuclei *i* and *j* reside on the same radical).

Even more clearly, the net effect is demonstrated in the analogous reaction of CH_3I and *p*-$ClC_6H_4CH_2Br$ with magnesium in THF-d_8/C_6D_6 (Fig. 2). In this case a multiplet effect is not possible and a pure net emission is observed for CH_3MgI and for ethane (δ = −1.0 ppm and δ = 0.8 ppm respectively; $g_{CH_3\cdot}$ = 2.0025 (6)). Methane could not be detected in this reaction.

The cage product *p*-$ClC_6H_4CH_2CH_3$, however, is observed with a net polarization in agreement with Kaptein's sign rule (δ = 1 ppm, triplet, A, CH_3; δ = 2.3 ppm, quartet, E, CH_2). No net polarization was observed when either CH_3I or *p*-$ClC_6H_4CH_2Br$ were separately reacted with magnesium under identical conditions. It is obvious that ·MgBr cannot have the same *g*-factor as both $CH_3\cdot$ and *p*-$ClC_6H_4CH_2\cdot$; therefore, radical pairs

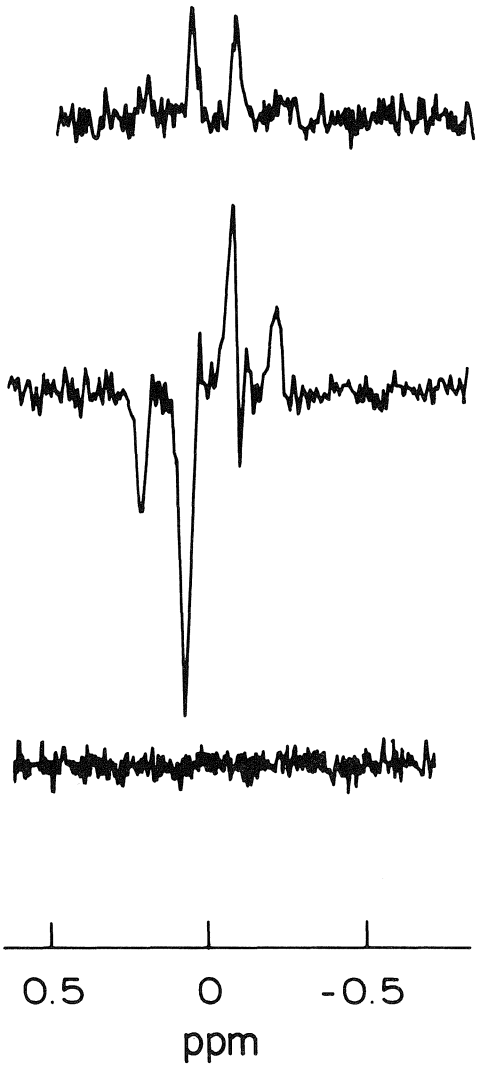

FIG. 1. Part of the 60 MHz ^{1}H nmr spectrum recorded during the reaction of C_2H_5Br and *p*-$ClC_6H_4CH_2Br$, with Mg in THF/C_6D_6 (1:4). (*a*) *t* = 0; (*b*) *t* = 0.5 min; (*c*) *t* = 4 min.

$\overline{R\cdot\cdot MgX}$ (type **1**) cannot be the source of the observed net effect.

So the CIDNP effects in the simultaneous reaction of CH_3I (or CH_3CH_2X, X = Br, I) and *p*-$ClC_6H_4CH_2Br$ with magnesium not only constitute the first example of net polarization observed in a Grignard reagent, but, by exclusion, also provide conclusive evidence that radical pairs originating from the alkyl groups of the alkyl halides (type **2**) are directly and exclusively involved as intermediates in the process leading to polarization in the Grignard reaction.

As stated earlier (2*b*), it is surprising that radical

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

FIG. 2. Part of the 60 MHz ^{1}H nmr spectrum recorded during the reaction of CH_3I and p-$ClC_6H_4CH_2Br$ with Mg in THF-d_8/C_6D_6 (1:4). (*a*) $t = 0$; (*b*) $t = 2$ min; (*c*) $t = 3$ min; (*d*) $t = 7$ min.

pairs of type **1**, although they must necessarily be postulated in the mechanism of Scheme 1, do not give rise to observable polarization. Several possible explanations can be advanced. According to the diffusional model of Adrian (8), the maximum net effect in a given magnetic field is reduced if large differences in the g-factor occur (less than 20% of the maximum enhancement may be found for $[\Delta g] > 20.10^{-3}$). Determination of the g-factor of ·MgBr is necessary to decide if this explanation is appropriate. Alternatively, rapid electron spin relaxation could be responsible for the absence of nuclear polarization (9) from the type **1** radical pairs.

The Origin of Polarizing Radical Pairs of Type 2

It has been shown in the previous section that in the simultaneous reaction of CH_3CH_2Br and p-$ClC_6H_4CH_2Br$ with magnesium, the CIDNP may be explained by invoking a diffusive encounter alkyl radical pair, e.g. $\overline{R \cdot\cdot R}$. With respect to the origin of such a radical pair, it has been pointed out in the introduction that the source of the radicals involved is to a certain extent subject to controversy (1, 5). These radicals might in principle be produced either by electron transfer from the metal to the alkyl halide (Scheme 1), in which case the polarization would reveal information on the Grig-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nard process proper (1, 2), or the radicals might be produced in a secondary reaction between the Grignard compound and the alkyl halide (Scheme 2), in which case polarization is irrelevant with regard to the principal steps of the Grignard reaction (5).

However, it has now been unequivocally shown that in the present case Scheme 2 is not to any observable extent responsible for the polarization effects occurring during the Grignard reaction, by performing the reaction of Scheme 2 separately, i.e., by adding p-$ClC_6H_4CH_2Br$ to a solution of preformed CH_3CH_2MgBr in THF/C_6D_6 at 40°C (Fig. 3). In this reaction, an absorption effect (A) is recognized in the CH_2-group of the Grignard reagent, which is opposite to the emission observed in the Grignard reaction!

The same effect is observed when the reaction is performed with p-$BrC_6H_4CH_2Br$ ($g_{p\text{-}BrC_6H_4CH_2\cdot} = 2.0047$) (4*a*), although in this case the effect is less obvious. This is completely in agreement with the prediction of the relative intensities of the lines in the multiplet by the method of Müller (10) (Fig. 4).

By the same arguments as given in the previous section, net polarization again implies that $\overline{p\text{-}ClC_6H_4CH_2\cdot\cdot CH_2CH_3}$ must be the polarizing radical pair. Moreover, as can be seen in Fig. 5, CH_3CH_2Br is produced simultaneously, and it also shows net absorption (CH_2, $\delta = 2.92$ ppm; A). Application of Kaptein's sign rule (7) for net effects (CH_3CH_2MgBr and CH_3CH_2Br, quartet, A, $\Gamma = \mu\cdot\varepsilon\cdot A_i\cdot\Delta g = \mu\cdot-\cdot-\cdot-$, so $\mu = -$; singlet precursor) indicates that both CH_3CH_2MgBr and CH_3CH_2Br are escape products from radical pairs from *singlet precursors*.[1]

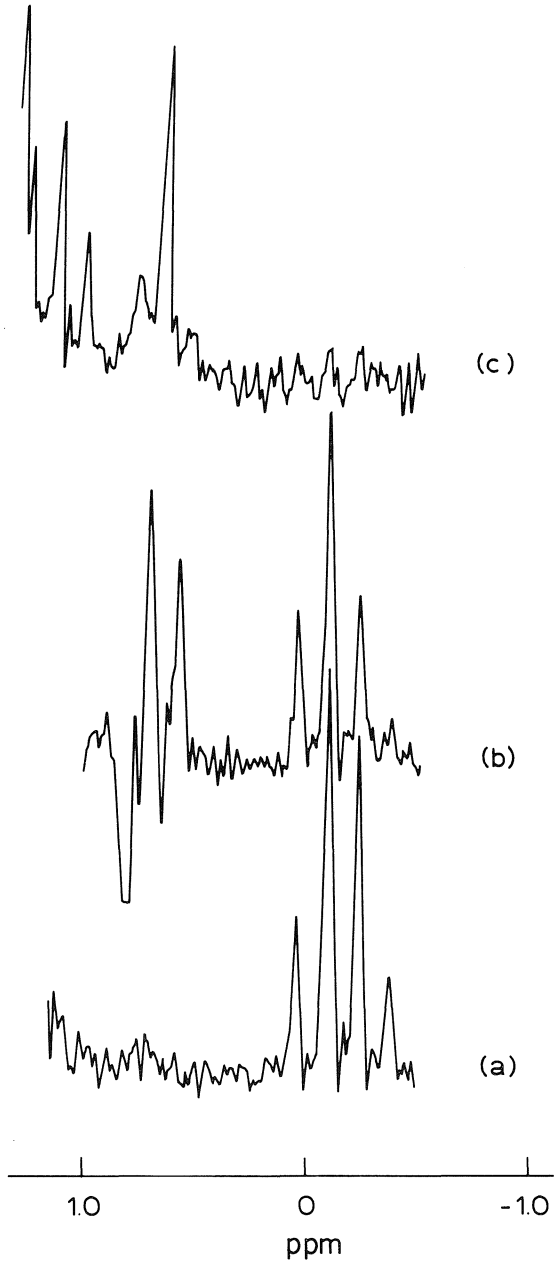
Evidently, the following reactions occur (Scheme 3):

$$CH_3CH_2MgBr + p\text{-}ClC_6H_4CH_2Br \xrightarrow{S} \overline{p\text{-}ClC_6H_4CH_2\cdot\cdot CH_2CH_3}$$

$$\overline{p\text{-}ClC_6H_4CH_2\cdot\cdot CH_2CH_3} \longrightarrow CH_3CH_2Br\ (A) + CH_3CH_2MgBr\ (A)$$

SCHEME 3

The mechanism of incorporation of the polarized ethyl radicals into CH_3CH_2MgBr and CH_3CH_2Br is uncertain at the moment. However, the observed effects may be of great importance for a better understanding of metal–halogen exchange and Wurtz-type reactions. The occurrence of singlet precursors during the reaction of alkyl halides (11) and benzyl halides (12) with organolithium compounds has been reported, but CIDNP was observed in the side products only and not in the organolithium reagent. The CIDNP observed in our Grignard compound confirms the occurrence of radicals during the metal halogen exchange reaction.



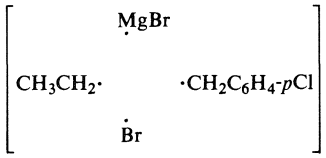


FIG. 3. Part of the 60 MHz ^1H nmr spectrum recorded during the reaction of C_2H_5MgBr with p-$ClC_6H_4CH_2Br$ in THF/C_6D_6 (1:4). (*a*) Before, (*b*) during, (*c*) after the reaction.

[1]If catalytic impurities are responsible for CIDNP during the Grignard reaction, they should give the same polarization in the reaction of the benzyl halide with a preformed Grignard reagent since these impurities are still present in the latter.

FIG. 4. The 60 MHz ^{1}H nmr spectrum of the methylene protons of C_2H_5MgBr recorded during the reaction with p-$BrC_6H_4CH_2Br$ in THF/C_6D_6 (1:4).

Both the product formation and the polarization effects described in this reaction are consistent with the occurrence of a caged system in the reaction of Scheme 3:

An extensive discussion of this aspect is beyond the scope of the present investigation. However, whatever the details of the mechanism of the metal–halogen exchange reaction may be, it does not significantly contribute to the polarization; Scheme 1 represents the only mechanism of the Grignard reaction compatible with the experimental results.

It should finally be pointed out that while opposite CIDNP net effects are observed in the Grignard reaction and in the metal–halogen exchange reaction in the case of added benzyl halide, Lawler and Livant have shown that if the halide and the Grignard reagent both carry alkyl groups, the Grignard and the exchange reaction exhibit CIDNP multiplet effects of the same sign (5). This inconsistency may be related to the catalyzed character of Lawler and Livant's reaction; moreover, there still exists some controversy on the mechanism of the Wurtz reaction (13), and also in this respect the observed phenomena deserve further investigation.

Thermochemistry of the lower bromides of tantalum

ALAN D. WESTLAND

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 23, 1979

ALAN D. WESTLAND. Can. J. Chem. **58**, 938 (1980).

The standard enthalpy of formation of tantalum(IV) bromide has been determined by solution calorimetry: $\Delta H_f^0(TaBr_4(c)\ 298\ K) = -125.6 \pm 0.5$ kcal mol^{-1}. Experimental estimates of the enthalpies of formation of tantalum(III) bromide and tantalum(II,III) bromide were also obtained. Estimates of the entropies and heat capacities of the compounds are also given.

ALAN D. WESTLAND. Can. J. Chem. **58**, 938 (1980).

On a déterminé, par calorimétrie en solution, l'enthalpie standard de formation du bromure de tantale(IV); $\Delta H_f^0(TaBr_4(c)\ 298\ K) = -125.6 \pm 0.5$ kcal mol^{-1}. On a également obtenu des évaluations expérimentales des enthalpies de formation des bromures de tantale(III) et de tantale(II,III). On donne également des évaluations des entropies et des capacités calorifiques de ces composés.

Thermochemical data are lacking for the lower bromides of tantalum. The present work reports a solution calorimetric determination of the standard enthalpy of formation of tantalum(IV) bromide. Measurement of the enthalpies of solution of $TaBr_4$ and $TaBr_5$ in aqueous hydrofluoric acid enables one to relate the enthalpy of formation of one compound to that of the other. An estimate of the enthalpy of formation of the lower bromides can be based on the equilibria

$$2TaBr_4(c) \rightleftharpoons TaBr_3(c) + TaBr_5(g)$$

and

$$5TaBr_3(c) \rightleftharpoons 4TaBr_{2.5}(c) + TaBr_5(g)$$

(A) Calorimetric Determination of the Standard Enthalpy of Formation of Tantalum(IV) Bromide

Schäfer and Kahlenberg have shown that Ta(IV) chloride reacts quantitatively with hydrofluoric acid to form Ta(V) solution and hydrogen (1). Those authors incorporated H_2PtCl_6 into the solution to serve as a catalyst and cautioned that the reaction should be carried out in an argon atmosphere in order to prevent catalyzed oxidation of the hydrogen by air. The present author found that $TaBr_4$ reacted completely in the absence of catalyst within approximately 10 min. Reactions were carried out in the calorimeter both with and without added platinum and no difference in the time of reaction was observed. The presence of platinum was therefore deemed not to be necessary but outgassing of the acid with argon for 1–2 h was essential.

Experimental Section

Tantalum Bromides

These were prepared from tantalum sheet (Fansteel Metals 99.95%) and purified bromine. The pentabromide was prepared from the elements at 450°C in a previously evacuated and sealed system. Bromine in the samples was determined by totally hydrolyzing the compound in a closed container with aqueous hydroxide and completing the determination by the Volhard method. *Anal.* calcd. for $TaBr_5$: Br 68.83; found: Preparation 1, 68.81; Preparation 2, 68.79. The tetrabromide was prepared by reduction of $TaBr_5$ with aluminium foil (Ventron, 99.997%) at 250°C (2). Many attempts to prepare the compound led to material which, while exhibiting acceptable analytical purity, failed to dissolve completely and reproducibly in the calorimeter. It was found that in the final step of the synthesis, which consisted of subliming away excess $TaBr_5$, surface decomposition of the product occurred and this led to the production of sparingly soluble lower bromide. The best procedure consisted in carrying out the reduction of $TaBr_5$ with slightly less than the stoichiometric quantity of aluminium at 250°C for 7 days and then subliming away the unwanted bromides at 180°C over a period of several days. Two preparations dissolved with the required rapidity. *Anal.* calcd. for $TaBr_4$: Br 63.86; found: Preparation 1, 63.23; Preparation 2, 63.41. The tetrabromide appeared to be much more hygroscopic than the corresponding chloride.

Hydrofluoric Acid

Two solutions were prepared from 48% acid (Baker). The concentrations were determined by alkalimetric titration of weighed portions. (*a*) Hydrofluoric acid containing 7.80 ± 0.02% w/w HF. The 350 g portions used in the calorimeter contained 1.364 mol of HF and 17.91 mol of H_2O. (*b*) Hydrofluoric acid containing 8.98 ± 0.02% w/w HF. The 261.8 g portions used in partial processes [3*b*] and [3*c*] below contained 1.175 mol HF and 13.23 mol H_2O.

Hydrobromic Acid

A 0.697 ± 0.002% w/w HBr solution was prepared from the concentrated acid. The 40.00 g portions of this solution used in partial process [3*b*] contained 0.00345 mol HBr and 2.204 mol H_2O.

Calorimeter

The apparatus was identical to that described previously (3) except that the calibration heater had been replaced with a carbon resistor having a resistance of 112.1 ± 0.05 ohm. This was enclosed in a gold-plated copper sheath which was attached to a polyethylene tube in such a manner that it could be completely immersed in the calorimeter acid. A trial measurement of the heat of solution of tris(hydroxymethylamino)methane (THAM) in 0.1 *N* HCl gave $\Delta H_{solution} = -58.7$ cal g^{-1}.

Montgomery *et al.* report a weighted mean value of -58.685 ± 0.01 cal g^{-1} (4). The THAM used in the present work was Fisher Brand Certified Primary Standard (99.9%) which was heated in air prior to use.

The solid samples were sealed in thin-walled quartz bulbs which could be crushed under the calorimeter acid. The bulbs were coated with wax. The dissolving of $TaBr_4$ was complete in about 10 min; $TaBr_5$ dissolved more quickly. The temperature readings were corrected for heat loss or gain by the method of Kubaschewski *et al.* (5). The measurement of enthalpies of mixing was carried out by means of an adaptation described previously (3).

The Partial Processes

The method involves relating $TaBr_4$ to $TaBr_5$ for which the standard enthalpy of formation is known accurately (3, 6). The various partial processes used in the Hess's Law treatment are described by the equations which follow. The relative quantities shown refer to the typical case in which 2.0 g of $TaBr_4$ are dissolved in 350 g of 7.80% HF solution but the reactions are written for 1 mol tantalum. Braces enclose solution compositions expressed in moles. The concentrations were chosen rather arbitrarily and the weights of solute and solvent used were governed by the capacity and range of the calorimeter.

[1] $\{TaF_5; 336.5HF; 5HBr; 4483.6H_2O\} \overset{\Delta H_1}{\rightleftharpoons} TaBr_5(c) + \{341.5HF; 4483.6H_2O\}$

[2] $TaBr_4(c) + \{341.5HF; HBr; 4483.6H_2O\} \overset{\Delta H_2}{\rightleftharpoons} \{TaF_5; 336.5HF; 5HBr; 4483.6H_2O\} + \frac{1}{2}H_2$

[3] $\frac{1}{2}H_2 + \frac{1}{2}Br_2 + \{341.5HF; 4483.6H_2O\} \overset{\Delta H_3}{\rightleftharpoons} \{341.5HF; HBr; 4483.6H_2O\}$

These reactions sum to give

$$TaBr_4(c) + \tfrac{1}{2}Br_2 \overset{\Delta H_4}{\rightleftharpoons} TaBr_5(c)$$

where $\Delta H_4 = \Delta H_1 + \Delta H_2 + \Delta H_3$.

Results

Process 1. The Dissolving of $TaBr_5$(c) in 7.80% Hydrofluoric Acid

In a previous study (3) it was shown that the enthalpy of dissolving $TaBr_5$ in hydrofluoric acid was essentially independent of sample size at the low concentrations of interest here (ca. 1.5 g $TaBr_5$ in 350 g solvent). The values of ΔH_1 obtained were 93.0_1, 93.0_5, 92.8_7, 93.2_1, and 92.9_0 kcal mol^{-1}. The mean value is $\Delta H_1 = 93.0 \pm 0.14$ kcal mol^{-1}. The uncertainty range here as elsewhere below indicates the standard deviation of the individual values from the mean value.

Process 2. The Dissolving of $TaBr_4$(c) in 7.80% Hydrofluoric Acid

Process 2 requires that 2.0 g of $TaBr_4$ be dissolved in 350 g of 7.80% HF which also contains 1 mol HBr per mol of $TaBr_4$ employed. The requisite amount of HBr was added to the calorimeter acid in the form of an aqueous solution. The resulting slight change in the concentration of HF was compensated for in earlier runs by using slightly more concentrated HF solution but in the absence of such compensation the resulting error was shown to be <0.05 kcal mol^{-1}. It was not convenient to prepare exactly 2.0 g samples of $TaBr_4$ as indicated by the ideal partial process 2. Instead, various quantities were dissolved in 7.80% hydrofluoric acid and the mean value of the observed enthalpies was chosen. There was, as with $TaBr_5$, no indication that the enthalpy of solution was influenced by sample size. The values of ΔH_2 obtained were 83.0, 82.3, 81.9, 82.1, and 82.3 kcal mol^{-1}. The mean value is 82.3 ± 0.5 kcal mol^{-1}.

The reaction produced 0.5 mol H_2 per mol of $TaBr_4$ dissolved. The gas was evolved saturated with water vapour and HF. According to the vapour pressure data of Brosheer *et al.* (7), 0.014 mol water was thereby removed from the solution which therefore entailed a correction of -0.15 kcal mol^{-1} $TaBr_4$. The values of ΔH_2 given include the correction.

Process 3. The Enthalpy of Formation of Hydrogen Bromide in Solution

Reaction 3 refers to a process which cannot be measured readily. However, this reaction may be replaced by three others which when added together give reaction 3.

[3*a*] $\frac{1}{2}H_2 + \frac{1}{2}Br_2 + 640.7H_2O \overset{\Delta H_{3a}}{\rightleftharpoons} \{HBr; 640.7H_2O\}$

[3*b*] $\{HBr; 640.7H_2O\} + \{341.5HF; 3842.9H_2O\} \overset{\Delta H_{3b}}{\rightleftharpoons} \{341.5HF; HBr; 4483.6H_2O\}$

[3*c*] $\{341.5HF; 4483.6H_2O\} \overset{\Delta H_{3c}}{\rightleftharpoons} \{341.5HF; 3842.8H_2O\} + 640.7H_2O$

The enthalpy ΔH_{3a} (-28.94 ± 0.02 kcal) was obtained from a standard compilation (8). ΔH_{3b} and ΔH_{3c} were determined by mixing [3*b*]: 40.00 g 0.697% HBr solution and [3*c*]: 39.72 g H_2O with 261.8 g 8.98% HF solution in the calorimeter. The enthalpies obtained were as follows: ΔH_{3b}, -1.40, -1.48, and -1.47 kcal; mean $= -1.45 \pm 0.04$ kcal; ΔH_{3c}, $+2.42$, $+2.37$, $+2.38$, and $+2.40$ kcal. Mean $= +2.39 \pm 0.02$ kcal.

TABLE 1. Thermodynamic values for $TaBr_4$ at 298 K

State	ΔH_f^0 (kcal mol^{-1})	S^0 (cal K^{-1} mol^{-1})	ΔG_f^0 (kcal mol^{-1})	C_p
Solid	-125.6 ± 0.5	56 ± 2	-118 ± 2	$25 + 15 \times 10^{-3}T$
Gaseous	-95 ± 3	104 ± 5	-101 ± 3	$26 - 2 \times 10^{5}T^{-2}$

The Addition of the Partial Processes

The enthalpy of the process $TaBr_4(c) + \frac{1}{2}Br_2(l) \rightleftharpoons TaBr_5(c)$ is obtained from the individual enthalpies:

$$\Delta H_1 = +93.01 \pm 0.14 \text{ kcal}$$

$$\Delta H_2 = -82.3 \pm 0.5 \text{ kcal}$$

$$\Delta H_{3a} = -28.94 \pm 0.02 \text{ kcal}$$

$$\Delta H_{3b} = -1.45 \pm 0.04 \text{ kcal}$$

$$\Delta H_{3c} = +2.39 \pm 0.02 \text{ kcal}$$

whence $\Delta H_4 = -17.3 \pm 0.5$ kcal. The error limit on ΔH_4 is the root-mean-square of the values for the individual ΔH_i. The error limits on subsequent enthalpy values are similarly defined.

By combining this value with the standard enthalpy of formation of solid $TaBr_5$ (3, 6): $\Delta H_f^0(TaBr_5(c)) = -142.9$ kcal mol^{-1}, we obtain the enthalpy of formation of solid $TaBr_4$:

$$Ta(c) + 2Br_2(l) \rightleftharpoons TaBr_4(c)$$

$$\Delta H_f^0(TaBr_4(c)), 298 \text{ K} = -125.6 \pm 0.5 \text{ kcal mol}^{-1}$$

(B) Thermochemistry of $TaBr_4$, $TaBr_3$, and $TaBr_{2.5}$

Until now it has not been possible to survey the thermochemistry of the lower bromides of tantalum. A phase equilibrium study has revealed the temperature ranges for the existence of $TaBr_4$, $TaBr_{2.83}$, $TaBr_{2.5}$, and $TaBr_{2.33}$ (2). The thermochemistry of the last of these remains unexamined still but we are able to make estimates concerning the others.

The tribromide appears to possess a fairly broad homogeneity range, the lower limit of which has the composition $TaBr_{2.83}$ and which is obtained by equilibration with $TaBr_{2.5}$. When the phase is equilibrated with $TaBr_4$ it has a composition close to $TaBr_{3.16}$ (9).

(1) $TaBr_4$

The above reported enthalpy of formation of solid $TaBr_4$ may be combined with other estimated quantities to give the set of values in Table 1 which may be used in thermodynamic calculations of a somewhat approximate nature.

The estimates have been made by employing Kopp's Law and the established values of heat capacities of similar compounds as found in standard compilations (8, 10). It is a corollary of this principle that one may estimate entropies of solids by an additivity rule. A formula suggested by Geiseler provides estimates of entropies for vapours (11).

Unfortunately, vapour pressure data for $TaBr_4$ are not available, owing no doubt to the difficulty of measurement. We can therefore provide only a rough estimate of the enthalpy of sublimation. The following considerations are useful. The enthalpies of sublimation of $ZrBr_4$ and $HfBr_4$ are reported to be 25.5 and 24.1 kcal mol^{-1} (12, 13). Similarly the ΔH_{subl} values for $NbBr_5$ and $TaBr_5$ are 26.5 and 25.4 kcal mol^{-1} respectively (14). We assume that the ΔH_{subl} value for $TaBr_4$ is likewise about 1.3 kcal mol^{-1} less than that for $NbBr_4$. A previous estimate gives $\Delta H_{subl}(NbBr_4) = 30$–$35$ kcal mol^{-1} (15). We therefore obtain $\Delta H_f^0(TaBr_4(g))$ given in Table 1 with the same range of uncertainty as $\Delta H_{subl}(NbBr_4)$.

The heat capacities were derived from $ZrBr_4(c)$ and $TiBr_4(g)$ by subtracting the heat capacities of the metals at 298 K. The halogen contribution so obtained was then added to the heat capacity of tantalum metal. The related compounds UCl_4, UBr_4, and $ThBr_4$ enable us to infer the standard entropies of $TaBr_4$ by making use of the observation that if we have S_{298}^0 for a chloride, the increment in entropy which would result by replacing Cl by Br is the same in all analogous compounds, e.g. UCl_4 and UBr_4.

The empirical formula of Geiseler (11) gives the value for $S^0(TaBr_4(g)\ 298\ K) = 104.3$ cal K^{-1} mol^{-1}.

(2) $TaBr_{3.16}$

Tantalum tribromide possesses a fairly broad range of nonstoichiometry at ≥ 325°C which extends from $TaBr_{2.83}$ to $TaBr_{3.16}$ (2, 9). We consider first the upper range limit.

Recommended values are

$$\Delta H_f^0\ (TaBr_{3.16}(c)\ 298\ K) = -114.7 \pm 3 \text{ kcal mol}^{-1}$$

$$S^0\ (TaBr_{3.16}(c)\ 298\ K) = 45 \pm 3 \text{ cal K}^{-1} \text{ mol}^{-1}$$

$$C_p\ (TaBr_{3.16}(c)) = 21 + 12 \times 10^{-3}T$$

Schäfer *et al.* (9) have provided the information that at 625 ± 10 K, $TaBr_{3.16}$ was found to be in equilibrium with $TaBr_4(c)$ and $TaBr_5(g)$ at a pressure of 0.39 atm. The calculations were thus based upon

the equilibrium

$$1.19TaBr_{3.16}(c) + TaBr_5(g) \rightleftharpoons 2.19TaBr_4(c)$$

The estimated entropy utilized the reported values for UBr_3 and $TiBr_3$.

(3) $TaBr_{2.83}$

Recommended values are

$$\delta H_f^0\,(TaBr_{2.83}(c)\ 298\ K) = -103 \pm 4\ kcal\ mol^{-1}$$

$$S^0\,(TaBr_{2.83}(c)\ 298\ K) = 41 \pm 3\ cal\ K^{-1}\ mol^{-1}$$

$$C_p\,(TaBr_{2.83}(c)) = 19 + 10 \times 10^{-3}T$$

McCarley and Boatman (2) have shown that when the tribromide is equilibrated with $TaBr_{2.5}$, material with the lower composition limit, $TaBr_{2.83}$, is obtained. We may estimate the enthalpy of formation of this phase from the observation that the enthalpies of formation per equivalent of $NbCl_{2.67}$ and $NbCl_{3.13}$ are nearly equal, i.e. 47 and 46 kcal respectively. If we assume that the tantalum tribromide phase is similar in this respect we obtain

$$\Delta H_f^0(TaBr_{2.83}) = (2.83/3.16)\,\Delta H_f^0(TaBr_{3.16})$$

(4) $TaBr_{3.0}$

The stoichiometric tribromide is not distinguished by any particular stability. However, thermochemical calculations may be carried out with the following provisional values:

$$\Delta H_f^0\,(TaBr_3(c)\ 298\ K) = -109 \pm 4\ kcal\ mol^{-1}$$

$$S^0\,(TaBr_3(c)\ 298\ K) = 43 \pm 3\ cal\ K^{-1}\ mol^{-1}$$

$$C_p\,(TaBr_3(c)) = 20 + 11 \times 10^{-3}T$$

The enthalpy value was obtained by linear interpolation between the values for the upper and lower phase limits.

(5) $TaBr_{2.5}$

Recommended values are

$$\Delta H_f^0\,(TaBr_{2.5}(c)\ 298\ K) = -95 \pm 4\ kcal\ mol^{-1}$$

$$S^0\,(TaBr_{2.5}(c)\ 298\ K) = 38 \pm 3\ cal\ K^{-1}\ mol^{-1}$$

$$C_p\,(TaBr_{2.5}(c)) = 18 + 9 \times 10^{-3}T$$

Schäfer *et al.* (9) found that for the process

$$6.58TaBr_{2.5}(c) + TaBr_5(g) \rightleftharpoons 7.58TaBr_{2.83}(c)$$

the $TaBr_{2.5}$ phase was in equilibrium at 713 K with 0.83 atm of $TaBr_5$ vapour. The entropy estimate was based on the assumption that $TaBr_{2.5}$ could be regarded as equivalent to $TaBr_2$ plus $TaBr_3$ in the way that $S^0(Fe_3O_4)$ is nearly equal to $S^0(FeO) + S^0(Fe_2O_3)$. $PbBr_2$ and UBr_3 were used as the model compounds.

Thermodynamic and transport properties of binary liquid systems

SHEO PRAKASH, KANDIMALLA SIVANARAYANA, AND OM PRAKASH

Chemical laboratories, University of Allahabad, Allahabad, India

Received June 20, 1979[1]

SHEO PRAKASH, KANDIMALLA SIVANARAYANA, and OM PRAKASH. Can. J. Chem. **58**, 942 (1980).

Densities, viscosities, and sound velocities were determined for the system *o*-chlorophenol + acetone and *o*-chlorophenol + ethyl methyl ketone at 25°C. From the experimental results, the deviation in isentropic compressibility K_S, excess molar volume V^E, excess viscosity η^E, and excess molar free energy of activation of flow G^{*E} were calculated. The deviations from ideality of the thermodynamic and transport functions are explained on the basis of molecular interactions between the components of the mixture.

SHEO PRAKASH, KANDIMALLA SIVANARAYANA et OM PRAKASH. Can J. Chem. **58**, 942 (1980).

On a déterminé les densités, les viscosités et les vitesses du son dans les systèmes *o*-chlorophénol + acétone et *o*-chlorophénol + éthyl méthylcétone à 25°C. Utilisant les résultats expérimentaux, on a calculé la déviation de compressibilité isentropique, K_s, le volume molaire en excès, V^E, l'excès de viscosité, η^E et G^{*E} l'énergie d'activation molaire libre en excès de l'écoulement. On explique les déviations par rapport aux fonctions thermodynamique et de transport idéales en se basant sur les interactions moléculaires entre les composants du mélange.

[Traduit par le journal]

Introduction

The variation of ultrasound velocities, isentropic compressibilities, intermolecular free lengths, and free volumes of binary liquid mixtures of protic, aprotic, and associating liquids with changing mole fraction of one of the components has been investigated by some of the workers (1–5). The trends of changes have been interpreted by these workers in terms of difference in size of molecules and the strength of interaction taking place between the components of the mixtures. The measurement of the ultrasound velocity in mixtures formed by liquid components reveals the degree of deviations from ideality, eventual molecular associations, if any, as well as important correlations with various parameters. This paper deals with our investigations of the thermodynamic and transport properties of binary liquid mixtures and is in continuation of our previous studies (6–8). From the experimental results of densities, sound velocities, and viscosities for the systems *o*-chlorophenol + acetone and *o*-chlorophenol + ethyl methyl ketone at 25°C, the thermodynamic and transport functions: deviation in isentropic compressibility K_S, excess molar volume, V^E, excess viscosity η^E, and excess molar free energy of activation of flow G^{*E}, have been computed.

Experimental

Density

Densities of pure liquids and their mixtures were determined by using a double walled pyknometer having narrow bore and provided with ground glass stoppers. The pyknometer was calibrated against pure benzene and acetone. Densities are accurate to within ± 0.0001 g cm^{-3}.

Sound Velocity

The continuous wave interferometric technique was used for the measurement of ultrasonic velocity (9). The ultrasound waves of 2 MHz frequency produced by a gold plated quartz crystal fixed at the bottom of a cell are passed through the medium and are reflected by a moveable metallic plate kept parallel to the crystal. When the separation between the crystal and the plate is exactly a whole multiple of sound wave length, standing waves are produced. Acoustic resonance due to these standing waves gives rise to an electrical reaction to the generator driving the quartz plate and the anode current of the generator becomes maximum. The micrometer screw is raised slowly to note maximum anode current. The wave length was determined with the help of total distance moved by the micrometer for 20 maximum readings of the anode current. The product of wavelength and the frequency gives the ultrasound velocity. The accuracy in velocity measurements was ±0.18%.

Viscosity

Viscosities were determined with a viscometer similar to Cannon-Ubbehlohde viscometer calibrated against pure liquids (acetone and benzene) and the accuracy was found to be ±0.005 cP.

All the measurements were carried out at a constant temperature 25°C, and for that purpose a thermostatically controlled bath constant to ±0.01°C was used.

Materials and Solutions

o-Chlorophenol (RDSH, Germany) was fractionally distilled over Zn Powder, the middle fraction redistilled over BaO, and the middle colourless fraction collected. Acetone (SM) and ethyl methyl ketone (SM) were redistilled and further purified by standard methods described by Weissberger (10). The purities of the chemicals were checked by comparing the values of the density with those reported in the literature. *o*-Chlorophenol, $\rho(25°C) = 1.25854\,g\,cm^{-3}$ (lit. 1.25770 g cm^{-3} (11)), acetone, $\rho(25°C) = 0.78513\,g\,cm^{-3}$ (lit. 0.78502 g cm^{-3} (12), 0.7851 g cm^{-3}(2)), and ethyl methyl ketone, $\rho(30°C) = 0.79419\,g\,cm^{-3}$ (lit. 0.79452 g cm^{-3} (12)). At the time of preparing the mixtures care was taken to avoid loss of liquids by evaporation.

Results

The values of density ρ, sound velocity v, and

TABLE 2. Values of coefficients a_0, a_1, and a_2 determined by the method of least squares and the standard error of estimate (σ)

System	Function	a_0	a_1	a_2	σ
o-Chlorophenol + acetone	K_s	−66.29	28.56	−7.78	0.28
	V^E	−8.35	2.02	1.87	0.18
	η^E	−0.61	3.08	1.52	0.05
	G^{*E}	1115	529	−143	12.47
o-Chlorophenol + ethyl methyl ketone	K_s	−49.46	13.14	1.68	0.40
	V^E	−8.25	−0.19	1.06	0.22
	η^E	−0.49	3.11	1.24	0.04
	G^{*E}	912	675	−319	12.04

viscosity η for the two systems are listed in Table 1. Isentropic compressibility k_S, molar volume V, and deviation in isentropic compressibility K_S were obtained from the expressions

$$[1] \quad k_S = v^{-2}\rho^{-1}$$

$$[2] \quad V = (X_1M_1 + X_2M_2)/\rho$$

$$[3] \quad K_S = k_S - [X_1k_{S,1} + X_2k_{S,2}]$$

where M_1, M_2 are molecular weights of the components 1 and 2 and X_1 and X_2 are their mole fractions. k_S, $k_{S,1}$, and $k_{S,2}$ are the isentropic compressibilities of the mixtures and the pure components 1 and 2, respectively.

The excess viscosity η^E, excess molar volume V^E, and excess molar free energy of activation of flow G^{*E} were calculated from the following equations (13):

$$[4] \quad \eta^E = \eta - (X_1\eta_1 + X_2\eta_2)$$

$$[5] \quad V^E = V - (X_1V_1 + X_2V_2)$$

$$[6] \quad G^{*E} = RT[\ln \eta V - (X_1 \ln \eta_1V_1 + X_2 \ln \eta_2V_2)]$$

where η and V are the viscosity and molar volume respectively of the mixtures; η_1, η_2 and V_1, V_2 are the viscosities and molar volumes of the pure components 1 and 2, respectively; R is the gas constant; and T is the absolute temperature.

Each set of results was best fitted with an empirical equation of the form

$$[7] \quad A/X_1X_2 = a_0 + a_1(X_1 - X_2) + a_2(X_1 - X_2)^2$$

The method of least squares was used to determine the values of the coefficients a_0, a_1, and a_2 of the functions K_S, V^E, η^E and G^{*E}, represented by A in eq. [7]. The values of these coefficients along with the standard error of estimate (σ) have been given in Table 2.

Figures 1, 2, 3, and 4 show the values of K_S, V^E, η^E, and G^{*E} as a function of the mole fraction of *o*-chlorophenol. The continuous curves were obtained by substituting the coefficients a_0, a_1, and a_2 in eq. [7].

Discussion

The choice of *o*-chlorophenol has been based on its limited polymerization through intermolecular hydrogen bonding in the pure state. The addition of ketones causes the rupture of intramolecular and intermolecular hydrogen bonding in *o*-

chlorophenol and this will be followed by association of unlike molecules through intermolecular hydrogen bonding.

In most theories of the behaviour of non-electrolyte solutions the major contribution to the deviation from ideal mixing are attributed to the dispersion forces (14). In such theories the deviations are expected to be positive. Negative deviations from ideal behaviour in mixtures of molecules different in size can be accounted for by geometric considerations (15).

Attempts have been made to explain the behaviour of liquid mixtures on the basis of sign and magnitude of the excess volume V^E, and deviation in isentropic compressibility K_S. A negative value of K_S and V^E indicates strong interaction between the components of the mixtures while their positive values are indicative of weaker interaction. When the strength of interaction between the unlike molecules increases, K_S and V^E become increasingly negative.

Figures 1 and 2 show negative K_S and V^E with well marked maxima at 0.4 and 0.5 mole fractions of *o*-chlorophenol respectively. The negative values of V^E for the liquid systems are well explained by Prigogine (16) in terms of different size of the molecules or the dipole–dipole interaction between them. In the present case the observed values of V^E and K_S indicate that the association between unlike molecules predominates over dissociation of *o*-chlorophenol aggregates.

According to Fort and Moore (17) the values of η^E are negative for the systems in which dispersion forces are dominant, becoming less negative and then increasingly positive as the strength of interaction increases. Figure 3 shows that the values of η^E are negative at first but become positive when mixtures are rich in *o*-chlorophenol. The values of G^{*E} are positive over the entire range of composition with maxima at 0.6 mole fraction of *o*-chlorophenol (Fig. 4).

From these observations one can infer that the interactions in *o*-chlorophenol + acetone are stronger than that in *o*-chlorophenol + ethyl methyl ketone.

Etude par resonance magnétique multinucléaire d'intermédiaires réactionnels électrophiles. Partie 8. Action des acides de Lewis chlorés $COCl_2$, $POCl_3$, $(CH_3)_2N{=}CHCl^+Cl^-$ et Cl_2 sur l'hexaméthylphosphotriamide (HMPT)

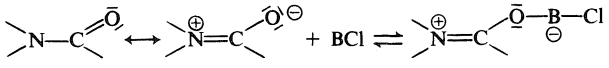
Reçu le 4 juillet 1979[1]



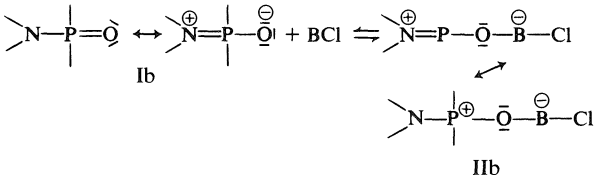
S. POIGNANT, J. R. GAUVREAU et G. J. MARTIN. Can. J. Chem. **58**, 946 (1980).

L'étude de la structure des intermédiaires électrophiles issus de carboxamides et d'acides de Lewis chlorés a été étendue au cas des amides phosphoriques. L'action de $COCl_2$ et $POCl_3$ sur l'hexaméthylphosphotriamide (HMPT) peut conduire à l'obtention d'un sel de chlorophosphonium (**3***a*) qui a été mis en évidence et caractérisé par rmn (^1H, ^{13}C, ^{31}P, ^{15}N). Un mécanisme de formation semblable à celui du chlorure de chloroiminium (réactif de Vilsmeier) obtenu avec les amides a été proposé. L'action du chlore sur le HMPT ne conduit pas à un sel stable du même type mais essentiellement au produit de substitution (**2**). Un nouveau composé biphosphoré (**6**) a pu être identifié dans le cas de l'action d'un excès de chlore.

S. POIGNANT, J. R. GAUVREAU, and G. J. MARTIN. Can. J. Chem. **58**, 946 (1980).

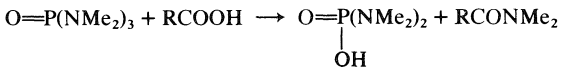
The structural study of the electrophilic intermediates obtained from carboxamides and chlorinated Lewis acids is extended to the phosphoric amides. The action of $COCl_2$ and $POCl_3$ on hexamethylphosphotriamide (HMPT) can lead to a chlorophosphonium salt (**3***a*) the structure of which is proved by nmr spectroscopy (^1H, ^{13}C, ^{31}P, ^{15}N). The mechanism of formation is comparable to that of the chloroiminium chloride (Vilsmeier reagent) from the corresponding amides. The action of chlorine on HMPT does not lead to a stable salt of the same kind but essentially to the substitution product (**2**). A new biphosphorylated compound (**6**) has been identified when an excess of chlorine is reacted with HMPT.

L'interaction entre des amides tertiaires et des acides de Lewis conduit à la formation de sels d'iminium, réactifs électrophiles, intermédiaires de réaction dans la formylation de Vilsmeier–Haack. Nous avons étudié la structure (1*a*), la cinétique de formation (1*b*, *c*) et les réactions d'échanges de nucléophiles (1*d*) des sels de chloroiminium obtenus à partir du *N,N*-diméthylformamide (DMF) et des oxychlorures minéraux. Ce travail a ensuite été étendu aux carboxamides *N,N*-bisubstitués (1*e*) et aux analogues sulfurés des amides (*N,N*-diméthylthioamides) et des acides de Lewis ($CSCl_2$, $PSCl_3$) (1*f*). Dans tous les cas, on obtient des composés salins qui présentent une activité électrophile importante et dont les applications synthétiques sont très nombreuses (2). La formation des sels d'iminium à partir des amides (ou des thioamides) s'explique par le caractère dipolaire de ces dernières qui leur permet de s'associer, dans un premier stade, aux acides de Lewis.

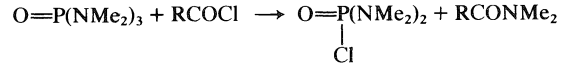


Ia IIa

Il est donc intéressant de considérer le cas d'autres bases oxygénées de grande polarité pour tenter de préparer de nouveaux types de réactifs électrophiles et d'en préciser la structure. A cet égard, les nitrosamines et les amides phosphoriques offrent des exemples intéressants:



Les nitrosamines (A≡N) sont effectivement alkylées aisément en sels de diazenium (3*a*) ou protonés par les acides forts (3*b*), et nous envisageons maintenant le cas de l'hexaméthylphosphoramide



Ib IIb

Les acides organiques (4*a*) conduisent au remplacement d'un ou plusieurs groupements N—Me_2 soit par un OH dans le cas d'un acide carboxylique:

soit par un chlore dans le cas d'un chlorure d'acide:

Les acides minéraux se complexent également avec le HMPT pour donner, soit des complexes stables comme HMPT, BF_3 (4*b*) soit une substitution

d'un ou plusieurs groupements NMe_2 (HMPT, oxychlorures). Comme avec le chloroforme (3,5) le HMPT conduit à des complexes 1–1 stables avec les phénols (4, 6):

$$Ar—O—H + O{=}P(NMe_2)_3 \rightleftharpoons Ar—O—H^{\delta-}\cdots O^{\delta+}{=}P(NMe_2)_3$$

Cependant, le HMPT peut subir, comme les carboxamides, des attaques nucléophiles d'organolithiens (7):

$$RLi + HCH_2N(CH_3O)P[N(CH_3)_2]_2 \rightarrow RH + LiCH_2N(CH_3O)P[N(CH_3)_2]_2$$

$$\downarrow$$

$$LiOP[N(CH_3)_2]_2 + CH_2{=}NCH_3$$

de même que l'interaction d'une base forte (6, 8):

$$B^{\ominus} + HCH_2N(CH_3O)P[N(CH_3)_2]_2 \rightleftharpoons BH + {}^{\ominus}CH_2N(CH_3O)P[N(CH_3)_2]_2$$

Nous nous sommes limités dans ce travail à l'action des oxychlorures d'acides minéraux, du chlore et du sel de chloroiminium sur le HMPT et nous avons pu préparer et caractériser de nouveaux sels de phosphonium halogénés. Ces résultats apportent des données structurales originales qui peuvent permettre de préciser le mécanisme d'action des acides de Lewis halogénés en milieu HMPT.

Action des oxychlorures minéraux sur le HMPT

Alors que l'oxychlorure de phosphore $POCl_3$ est connu pour provoquer le remplacement d'un ou plusieurs groupements diméthylamino (9) par des atomes de chlore, Normant et Deshayes (10) utilisent le chlorure de thionyle avec le HMPT pour chlorer des alcools mais n'observent en rmn aucune complexation du HMPT:

$$ROH + SOCl_2 \xrightarrow{HMPT} RCl + SO_2 + HCl$$

Nous n'avons effectivement pu mettre en évidence aucune entité comparable au sel d'iminium obtenu par action de $SOCl_2$ sur le diméthylformamide (DMF). Par contre avec le phosgène, $COCl_2$, et l'oxychlorure de phosphore, $POCl_3$, un sel de phosphonium a pu être caractérisé (Tableau 1).

Action du phosgène $COCl_2$

L'action du phosgène sur le HMPT conduit probablement à un intermédiaire électrophile **1***a* instable, qui évolue, suivant la température de réaction, vers deux composés phosphorés distincts (**2** et **3***a*) que la rmn nous a permis de mettre en évidence et de caractériser.

Les paramètres rmn figurent dans le Tableau 1. Le déplacement à champs faibles des protons NMe_2 du sel est tout à fait comparable à celui observé dans les sels d'iminium, de même que l'exaltation du couplage $^1J_{^{13}C—H}$ (1*e*) et ceci reflète la nature ionique du composé. Le couplage J_{PNCH} est également exalté par rapport à sa valeur dans le HMPT de départ.

L'évolution des composés **2** et **3***a* est différente et dépend de la température. Dans le premier cas (*A*), le chlorure de carbamoyle formé réagit extemporanément avec le phosgène pour donner le chlorure de phosgéniminium $>N^{+}{=}CCl_2Cl^-$ déjà étudié dans un autre contexte par Viehe (11). Le chlorure de chlorophosphonium **3***a* est stable et difficilement hydrolysable, cependant une hydrolyse basique conduit à la formation de HMPT et de HCl. A température ambiante, la réaction conduit à un mélange des composés **2** et **3***a* avec prédominance de **3***a* (voir Partie expérimentale).

Action de l'oxychlorure de phosphore $POCl_3$

L'action de $POCl_3$ sur le HMPT conduit également à un sel de phosphonium. Il se forme très probablement un intermédiaire instable (analogue à **1***a*) lequel évolue en fonction de la température soit vers le sel **3***b* soit vers le composé covalent **2** déjà évoqué.

Notons qu'en opérant à froid et à partir d'un mélange équimoléculaire HMPT/$POCl_3$, il est possible d'obtenir du sel de phosphonium **3***b* en quantité pratiquement stœchiométrique. Comme dans le cas de **3***a* l'hydrolyse basique de **3***b* conduit à la formation de HMPT, $OPOCl_2^-$ et Cl^-. Avec un excès de HMPT et en opérant à chaud le produit covalent **2** devient alors prépondérant.

Les spectres ^1H, ^{13}C et ^{31}P du composé **3***b* (Tableau 1) sont tout à fait cohérents avec la structure proposée et s'expliquent avec les mêmes arguments qui ont été évoqués dans le cas de l'action du phosgène. Notons que l'anion n'influe pas sur les valeurs de $\delta_{^1H}$ et $\delta_{^{31}P}$ du cation, contrairement au cas des sels de chloroiminium; l'encombrement stérique autour de l'atome de phosphore chargé positivement est probablement responsable de ce fait. En effet, même si nous sommes en présence de paires d'ions intimes, l'anion est probablement trop loin du centre positif pour que son effet se fasse sentir.

Les valeurs $\delta_{^{31}P}$ sont conformes aux données de la littérature (12) obtenues sur des composés similaires. La complexation provoque un déplacement à champ faible du phosphore de l'amide

SCHÉMA 2

TABLEAU 2. Variations comparatives des paramètres rmn du DMF, du HMPT et des chlorures correspondants

Groupement	Δδ ou ΔJ		DMF → $(CH_3)_2\overset{+}{N}CHCl\ Cl^-$	HMPT → $[(CH_3)_2N]_3\overset{+}{P}Cl\ Cl^-$
$N(CH_3)_2$	$\Delta(^1J_{^{13}C-H})$	Hz	+7	+5.5
	$\Delta\delta_{^{13}C}$	ppm	+12	+0.7
	$\Delta\delta_{^{15}N}$	ppm	+59.4	+11.3
CCl/C=O	$\Delta\delta_{^{13}C}$	ppm	+5	—
PCl/P=O	$\Delta\delta_{^{31}P}$	ppm	—	+29.3

engagé dans le carbocation (+53.8 ppm). L'existence de l'anion $OPOCl_2^-$ est confirmée par le signal à −8.5 ppm déjà attribué dans le sel de chloroiminium (1*e*). Les variations des divers déplacements chimiques et couplages, comparativement entre la complexation du DMF et celle de l'HMPT, sont rassemblées dans le tableau 2. Il est notamment intéressant de comparer les $\Delta\delta_{^{15}N}$ et $\Delta\delta_{^{13}C}$. On ne retrouve pas, en série phosphorée, l'important effet paramagnétique sur l'écran de l'azote lorsqu'on passe de l'amide au sel de Vilsmeier. Sur la base des relations entre $\delta_{^{15}N}$ et la barrière à la rotation autour des liaisons N—X que nous avons établies précédemment (3*c*, 3*b*), il est possible de supposer que la variation de la délocalisation N—P ne doit pas être très accentuée entre le

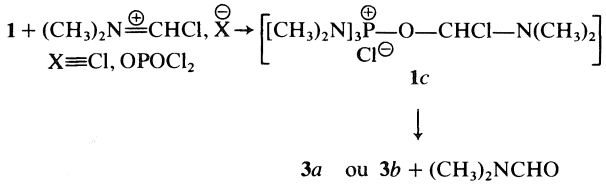

SCHÉMA 3

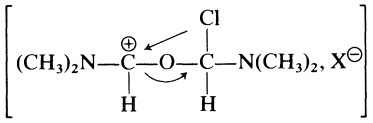
HMPT et les complexes **3**. L'effet paramagnétique observé en résonance du phosphore correspond au changement d'électronégativité des substituants et de la conjugaison p_π–d_π entre le substituant et l'atome de phosphore. Ce comportement traduit l'augmentation du caractère électrophile du phosphore dans **3**, qui reste cependant moins important que celui de l'atome de carbone dans le sel de chloroiminium.



Action du chlorure de chloroiminium (réactif de Vilsmeier) $(CH_3)_2\overset{+}{N}{=}CHCl,\ Cl^-$

Lors de nos travaux sur les phénomènes d'échange (1*d*) intervenant lors de la réaction de formation du complexe de Vilsmeier nous avons montré que ce complexe était lui-même un acide de Lewis plus fort que $SOCl_2$, $POCl_3$ ou $COCl_2$.

Cette remarque se vérifie ici car l'action de $(CH_3)_2\overset{+}{N}{=}CHCl\ Cl^-$ sur le HMPT est rapide et complète.

L'intermédiaire instable **1***c* conduit au sel de chlorophosphonium **3***a* ou **3***b* probablement par un mécanisme de prototropie du chlore identique à celui envisagé dans l'échange intermoléculaire DMF – sel d'iminium (1*d*, *e*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Dans ce cas l'équilibre est totalement déplacé vers la formation du sel de phosphonium beaucoup moins réactif que le complexe de Vilsmeier. Appel et Willms (13) ont d'ailleurs utilisé la forte réactivité du chlorure de chloroiminium dans le domaine de la synthèse peptidique, confirmant ce que nous avions prévu lors de nos précédents travaux.

Action du chlore Cl_2

Les halogènes (Cl_2, Br_2) peuvent être utilisés en milieu HMPT soit pour oxyder des alcools (14) en cétone soit pour les additionner sur des composés tels que les alcènes (15) et obtenir, par addition *trans*, des dibromoalcanes. Nous avons étudié l'action du chlore sur le HMPT en l'absence de tout autre réactif afin de tenter de caractériser un intermédiaire de réaction, comme dans le cas des oxychlorures minéraux. Le sel de chlorophosphonium du type **3** ne se forme pas mais un sel d'oxyphosphonium **5** a été caractérisé. Les intermédiaires **4***a* ou **4***b* expliqueraient parfaitement les phénomènes observés.

En l'absence d'autre réactif le complexe **4***a* évolue vers l'espèce **2** déjà caractérisée avec $POCl_3$.

De plus lorsque la réaction est effectuée en excès de chlore, nous pouvons mettre en évidence le caractère acide de Lewis du composé **2**. En effet au fur et à mesure de sa formation **2** réagit sur le HMPT pour former un intermédiaire instable **1***d* voisin de **1***b* envisagé avec $POCl_3$.

Aucun réarrangement ne conduit à un sel de phosphonium stable comme avec $POCl_3$; par contre un excès de chlore catalyse la formation d'un composé bi-phosphoré covalent très stable **6**. L'identification du composé **6** a été facilitée par l'utilisation de la rmn ^{31}P et des techniques d'irradiation sélective (cf. Tableau 1 et Fig. 1).

Enfin, il faut noter qu'à température plus élevée ou en présence d'un excès de HMPT, il se forme plusieurs produits difficilement identifiables qui sont probablement des composés de polymérisation.

Conclusion

La réaction entre un acide de Lewis et une amide tertiaire a pu être étendue avec succès au cas de l'hexaméthylphosphotriamide, à basse température. En effet les oxychlorures $COCl_2$ et $POCl_3$, de même que le complexe de Vilsmeier lui-même, se complexent toujours sur l'atome d'oxygène basique du HMPT. Un mécanisme général rend compte de l'évolution d'un premier intermédiaire du type "oxonium" vers un sel contenant l'atome de chlore.

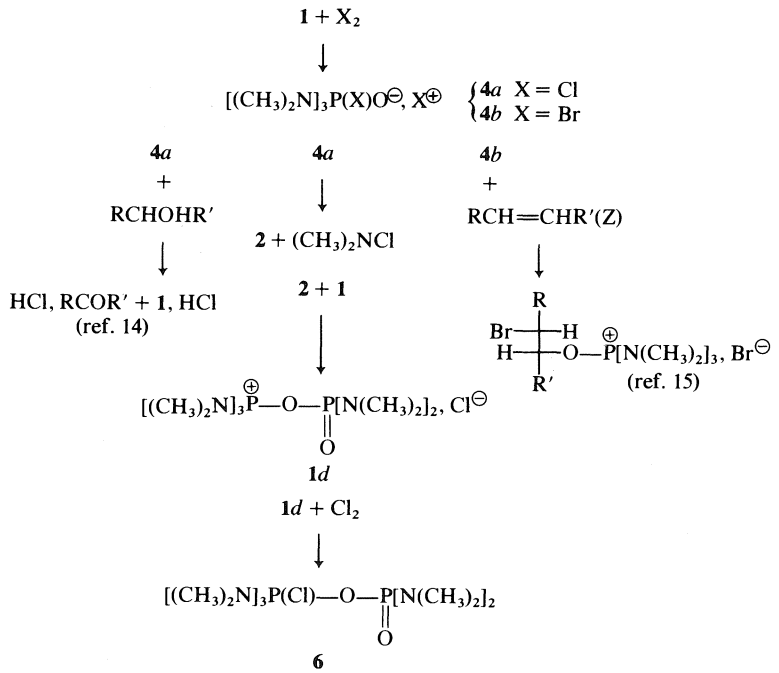


SCHÉMA 4

For personal use only.

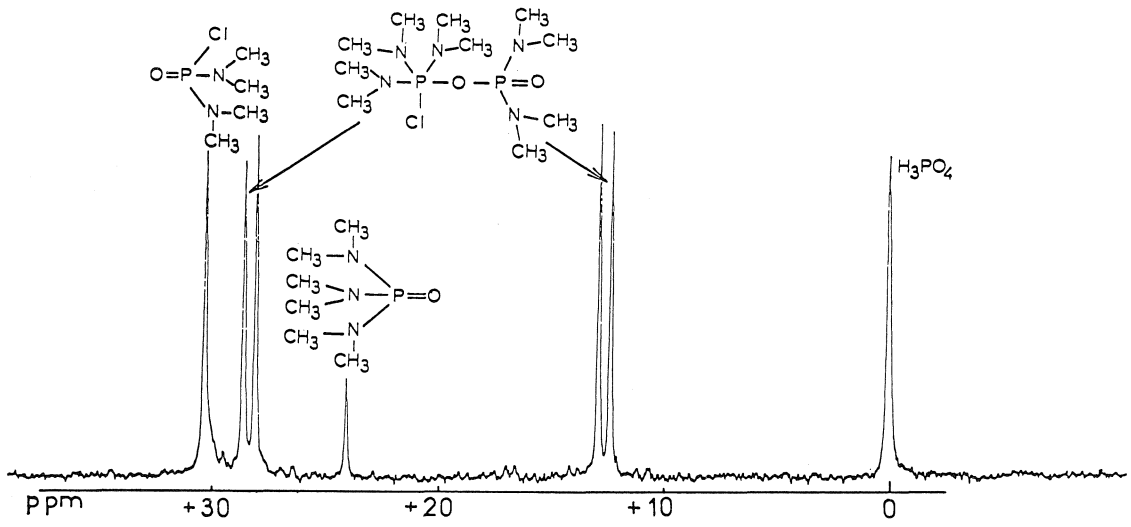

FIG. 1. Action du chlore sur le HMPT; spectre rmn ^{31}P (36.44 MHz); solvant: CH_2Cl_2; $T = 200$ K. La double irradiation sélective du composé **6** a été effectuée à 36.44 MHz tandis que la résonance du proton était observée à 90 MHz. L'irradiation des deux atomes de phosphore a ainsi permis l'identification des signaux de résonance protonique des groupes $(CH_3)_2N$.

Sel de chloroiminium avec le DMF : $\left[\begin{matrix}\diagdown\\ \diagup\end{matrix}N{=}C{-}Cl\right]^{\oplus}\ X^{\ominus}$

Sel de chlorophosphonium avec le HMPT : $\left[\begin{matrix}\diagdown\\ \diagup\end{matrix}N{=}P{-}Cl\right]^{\oplus}\ X^{\ominus}$

Le sel de phosphonium est nettement moins réactif que le sel d'iminium puisque la réaction de ce dernier avec la base de départ (le HMPT) est complète. Par ailleurs, ce sel de phosphonium présente un faible caractère électrophile car il n'attaque pas plus le DMF qu'il ne s'échange avec le HMPT lui-même. La présence d'un sel de chlorophosphonium similaire a été postulée comme intermédiaire réactionnel de la formation d'alkoxytrisdiméthylaminophosphonium (TDAP). (16). La variation des paramètres rmn (notamment δ_{15N}) est en accord avec les observations de réactivité chimique. Le chlore ne peut remplacer les acides de Lewis chlorés mentionnés précédemment car il ne conduit pas à un sel de phosphonium mais plutôt au produit monochloré de substitution par l'intermédiaire d'un complexe d'un autre type. Toutefois il faut noter que son utilisation en synthèse en qualité d'agent chlorant ou oxydant en milieu HMPT, peut s'accompagner de la formation de produits polyphosphorés qui résulte de son action directe sur la phosphoramide.

Partie expérimentale

Préparation des produits

Les réactifs et solvants ont été soigneusement séchés et distillés avant chaque manipulation. L'appareillage est purgé par un courant d'azote sec.

Sels de chlorophosphonium **3***a et* **3***b*

A 0°C une solution de 0.05 mol de phosgène ou d'oxychlorure de phosphore dans 30 cm³ de chlorure de méthylène est additionnée au moyen d'une ampoule de Mariotte à une solution de 0.05 mol (8.7 cm³) de HMPT dans 50 cm³ d'éther. Une agitation est maintenue tout au long de l'addition. Le sel de phosphonium cristallise. A la fin de la réaction le solvant est évaporé, les cristaux sont lavés plusieurs fois à l'éther puis séchés. On obtient ainsi avec un rendement de 100% 11.7 g de sel **3***a* et 16.6 g de sel **3***b*.

Les résultats de microanalyse[2] confirment les formules **3***a* et **3***b*. *Anal.* calc. (**3***a*): C 30.8, H 7.8, Cl 30.3, N 18.0, P 13.2; trouvée: C 30.4, H 8.1, Cl 29.9, N 17.9, P 13.2. *Anal.* calc. (**3***b*): C 21.7, H 5.5, Cl 32.0, N 12.6, O 9.6, P 18.6; trouvée: C 21.9, H 5.7, Cl 31.5, N 12.5, O 9.8, P 18.2.

Si la température de réaction est supérieure à 0°C, il se forme du composé **2**, la proportion de **2** augmentant avec la température. Dans ce cas le résidu liquide peut être distillé (point ébullition 112°C sous 12 Torr). Il est intéressant de noter que l'hexaéthylphosphoramide $((C_2H_5)N)_3P{=}O$ ne réagit pas sur $COCl_2$ ou $POCl_3$ dans les mêmes conditions que le HMPT.

Hydrolyse des sels de chlorophosphonium **3***a et* **3***b*

A 10 g de sel **3***a* ou **3***b* sont additionnés 50 cm³ d'une solution d'eau saturée en K_2CO_3. Après 24 heures d'agitation, on constate par rmn du ^{31}P que l'hydrolyse est totale et qu'il s'est formé du HMPT.

Réaction du réactif de Vilsmeier sur le HMPT

A partir de 5 g de diméthylformamide on prépare le réactif de Vilsmeier selon la méthode habituelle (1*a*). Puis on additionne la quantité stœchiométrique de HMPT en suivant le même mode opératoire que pour la préparation de **3***a* et **3***b*.

Réaction du chlore sur le HMPT

A −70°C, une solution de 0.01 mol (1.83 cm³) de HMPT dans 2 cm³ de $CDCl_3$ est additionnée goutte à goutte à 5 cm³ d'une solution de $CDCl_3$ contenant 0.02 mol de chlore. Une agitation

[2]Les analyses quantitatives élémentaires ont été réalisées par le centre de microanalyses du Centre National de la Recherche Scientifique à Caen.

est maintenue tout au long de l'addition. Des prélèvements sont effectués et étudiés en rmn à la même température.

Spectres de résonance magnétique nucléaire

Les spectres ^1H ont été réalisés à 60 MHz au moyen d'un spectromètre Varian A 60 A.

Les spectres ^{13}C ont été enregistrés à 25.18 MHz en utilisant un spectromètre Varian XL 100-12 (temps d'acquisition At = 2s, angle d'impulsion $\theta = 30°$). Les déplacements chimiques ^1H et ^{13}C ont été mesurés par rapport au tétraméthylsilane (TMS) utilisé en référence interne. Les spectres ^{31}P à 36.44 MHz (At = 1.365 s, $\theta = 25°$, référence interne H_3PO_4) et ^{15}N à 9.117 MHz (At = 0.683 s, $\theta = 45°$, référence interne CH_3NO_2) ont été réalisés au moyen d'un spectromètre Bruker WH 90 DS. Les spectres ont été réalisés pour le proton dans CH_2Cl_2 et pour les autres noyaux dans $CDCl_3$ avec des concentrations de l'ordre de 2 mol L^{-1}. Chaque spectromètre est en outre équipé d'une sonde à température variable qui a été utilisée pour étudier à basse température les intermédiaires instables.

Solvent effect on the protonation of some alkylamines[1]

ALFONSO MUCCI, ROBERT DOMAIN, AND ROBERT L. BENOIT
Département de Chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received August 31, 1979

ALFONSO MUCCI, ROBERT DOMAIN, and ROBERT L. BENOIT. Can. J. Chem. **58**, 953 (1980).

Thermodynamic data were obtained at 25°C for the solution and protonation of six bases B: ammonia, three methylamines, and monoethyl and *n*-propylamines in dimethylsulfoxide (Me_2SO) and propylene carbonate (PC). Vapour pressure, potentiometric, and calorimetric determinations were carried out. The solvent effect on the basicity order and protonation of the amines is analysed by using gas phase data and comparing the solution thermodynamics of gaseous B and BH^+. The heat of solution of B in both solvents is close to its heat of condensation. The solution data for BH^+ are discussed in terms of two recent hydration data interpretations.

ALFONSO MUCCI, ROBERT DOMAIN et ROBERT L. BENOIT. Can. J. Chem. **58**, 953 (1980).

On a obtenu des données thermodynamiques sur la dissolution et la protonation à 25°C de six bases B: l'ammoniac, les trois méthylamines et les monoéthyl et *n*-propylamines dans le diméthylsulfoxyde (Me_2SO) et le carbonate de propylène (PC). On a effectué des déterminations de pression de vapeur, potentiométrie et calorimétrie. L'effet de solvant sur l'ordre de basicité et la protonation des amines est analysé en utilisant des données en phase gazeuse et en comparant la thermodynamique de solution de B et BH^+ gazeux. La chaleur de solution de B dans les deux solvants est voisine de sa chaleur de condensation. Les données sur la solution de BH^+ sont examinées en relation avec deux interprétations récentes de données sur l'hydratation.

Trends in the reactivity of chemical species belonging to related series, when referred to condensed phases, may differ widely from the more regular trends observed in the gas phase. For instance, it is well known that the gas phase basicity of NH_3 and the methylamines B as deduced from proton affinities varies according to $NH_3 < MeNH_2 < Me_2NH < Me_3N$, while in aqueous solution the order based on enthalpy of protonation is $NH_3 < MeNH_2 > Me_2NH > Me_3N$ (1). The apparently anomalous order in water has been shown to result from two opposite trends, one for B where its solution exothermicity increases in the order $NH_3 < MeNH_2 < Me_2NH \sim Me_3N$, while for BH^+ the trend reverses with $-\Delta H^0_w$ (BH^+) decreasing according to $NH_4^+ > MeNH_3^+ > Me_2NH_2^+ > Me_3NH^+$.

Using relevant thermodynamic data and Born–Haber type cycles, several authors (refs. 1 and 2 and references cited therein) carried out detailed analyses of the relations between gas phase and aqueous basicity of related series of amines. The major factor responsible for the basicity sequence in aqueous solution was found to be the change in hydration enthalpy of the ammonium ions ΔH^0_w (BH^+) within a related series. For this, two explanations have been proposed. On the one hand, following an earlier qualitative proposal (3), Jones and Arnett (1) attributed the major part of this variation in ΔH^0_w (BH^+) to the change of the number of N^+—H hydrogen bonds available for solvation. On the other hand, Aue *et al.* (2), in their recent analysis, accounted for the changes in ΔH^0_w (BH^+) (after suitable corrections) in terms of the simple classical Born electrostatic theory.

Given the complex nature of the interactions between both solutes B and BH^+ and solvent water, a thermodynamic study of the protonation of a series of amines in selected non-aqueous solvents should be of interest since it might provide a test of the previously proposed models and should give further insight into the solvent effect on an important proton transfer reaction. We are presenting here the results of such a study in which the solvents dimethylsulfoxide (Me_2SO) and propylene carbonate (PC) were used. These solvents, which belong to the dipolar aprotic class, were selected for several reasons. First, solute–solvent interactions in these non-hydrogen-bonded media are likely to be simpler than in water. Then, the relevant bulk properties of the solvents, dielectric constant and basicity, are sufficiently different for a meaningful test of their effect on the protonation and solvation data. Finally, the same solvents were also used by Krishnan and Friedman (4) for a related study of the heats of solution of amine salts as well as of hydrocarbons and alcohols. The amines we studied include ammonia, the methylamines ($MeNH_2$, Me_2NH, Me_3N), monoethylamine ($EtNH_2$), and *n*-propylamine (*n*-$PrNH_2$).

Experimental

Materials

PC (Anachemia) was doubly distilled under vacuum and middle portions were collected. Me_2SO (BDH) was reagent grade. Both solvents were dried and stored over activated 4A molecu-

lar sieves. Trifluoromethanesulfonic acid from 3M Co. had a purity of 99.5%. The gaseous amines (Canadian Liquid Air) were the best grades available and their purity was NH_3 (99.9%), $MeNH_2$ (98.0%), Me_2NH, (99.0%), Me_3N (99.0%), $EtNH_2$ (98.5%). Liquid *n*-$PrNH_2$ was a white label product from Eastman Kodak. Tetraethylammonium iodide (NEt_4I) (Baker) was dried in a vacuum oven at 50°C for 24 h.

Calorimetry

The heat of solution of the gaseous amines in 200 mL Me_2SO was determined at 25°C. The gas calorimeter and procedure have been described in an earlier publication (5). The concentration of the amines dissolved after each calorimetric run was determined by addition of a known volume of solution to an excess of aqueous standard HCl solution and back titration with standard NaOH. From 3–7 determinations were carried out for each amine. The heat of protonation of the gaseous amines in Me_2SO was obtained similarly by dissolving the amines in an excess of 0.1 *M* solution of HCF_3SO_3, a strong acid in this solvent (6). The amount of amine reacted was deduced after titration of the remaining excess acid. The heats of solution and protonation of liquid *n*-$PrNH_2$ were measured with an LKB Model 8725-2 Isoperibol calorimeter previously described (7), the amount of amine dissolved or reacted being known from the weights of the glass ampoules. Some difficulties were met in the calorimetric work in PC since the primary and secondary amine solutions proved to be unstable at 25°C because of the formation of carbamates (8). For example, the least stable solution, that of $MeNH_2$, was 40% decomposed in 25 min at 25°C, but the decomposition was reduced to 7% for the same duration at 10°C. An ancillary study of the kinetics of amine decomposition showed that the ratio $(amine)_t/(amine)_0$, as measured by acid–base titration, decreased linearly with time, at least initially. This ratio was also proportional to the shift of the OH ⇌ NH proton nmr resonance signal. We found that the reaction rates for the different amines varied according to $MeNH_2 \sim Me_2NH \gg EtNH_2 \sim$ *n*-$PrNH_2$. On the basis of these results, the calorimetric measurements of the heats of solution in PC were carried out at 10°C for $MeNH_2$ and Me_2NH and at 25°C for $EtNH_2$ and *n*-$PrNH_2$ (9). Corrections were also used to determine the amount of amine dissolved in the calorimetric runs and to calculate the heat involved since the formation of carbamate is exothermic.

Vapour Pressure Measurements

Solution vapour pressures were measured with a precision quartz gauge (Texas Instruments) whose quartz spiral was kept at 60°C. The 60 mL cell containing the magnetically agitated solution was kept in a water bath regulated to ±0.005°C. The glass tubing connecting the cell with the gauge was thermally jacketed. The solutions were degassed by repeated freezing and evacuation. The concentration of the amines in solution was determined by acid–base titration after each measurement.

Potentiometry

Potentiometric titration of Me_2SO solutions of the amines with HCF_3SO_3 in Me_2SO were carried out at 25°C in a thermostated cell placed in a glovebox under a stream of dry nitrogen. An essentially constant ionic strength was maintained by making the solution initially 0.100 *M* in Et_4NI. The pair of electrodes used were a Radiometer G202 B glass electrode and an I^-/I_3^- reference electrode consisting of a platinum wire in a Me_2SO solution 10^{-2} *M* in I_2 and 2×10^{-2} *M* in I^- (10). The junction connecting the reference electrode to the cell was a 10^{-1} *M* Et_4NClO_4 solution in Me_2SO. The potential measurements were made with a Tacussel potentiometer. Stable readings were obtained within 1 min. The glass electrode was calibrated with a series of HCF_3SO_3 solutions in Me_2SO containing 0.100 *M* Et_4NI.

Results

Energetics of Solution of NH_3 and Amines

Enthalpy

The heats of solution, Q, of the bases in Me_2SO and PC were determined for varying quantities of each amine (1 to 5×10^{-2} mol for NH_3 and the gaseous amines and 2 to 8×10^{-3} mol in the case of liquid *n*-$PrNH_2$). The values of Q were plotted against the number of moles, and the slopes of the least-squares lines gave the molar enthalpy of solution. Since no concentration dependence was observed within the limits of error, these molar enthalpies of solution can be taken as the infinite dilution values ΔH_s^0 (B). In the case of liquid *n*-$PrNH_2$, ΔH_s^0 (B) was obtained by subtraction from the heat of solution, the heat of vaporization at 25°C, 7.44 kcal mol^{-1} (11). Our values of ΔH_s^0 (B) (kcal mol^{-1}) and the enthalpy of solution of B in Me_2SO and PC are given in Table 1. Also included in this table are literature values of ΔH_s^0 (B) in water.

Free Energy

The total vapour pressure of NH_3 and amine solutions in Me_2SO was measured at 25°C as a function of concentration, usually 0.1–2.0 *M*. In view of the very low vapour pressure of Me_2SO, 0.60 Torr, the vapour pressures of the solutes, 40–400 Torr, were calculated by subtracting from the total vapour pressure the solvent vapour pressure obtained from Raoult's law. The plots of P_B vs. the mole fraction X_B were linear and least-squares analyses gave values of Henry's constants, K_x, with their standard deviations (less than 2% of K_x). The free energies of solution were calculated from ΔG_s^0 (B) = RT ln K_c, where K_c, Henry's law constant, is in atm. mole L^{-1} so that comparisons could be made with water. Table 2 presents our values of ΔG_s^0 (B) (standard deviation less than 0.01) for Me_2SO as well as literature data for water as solvent. Because of complications arising from the reaction of some of the amines with PC, no measurements of vapour pressure were made in this solvent.

Energies of Protonation of NH_3 and Amines

Enthalpy

The heats of solution, Q, of the bases in Me_2SO containing an excess of HCF_3SO_3 were determined for varying amounts of the amines (1 to 12×10^{-3} mol). The plots of Q vs. the number of moles of base were linear and the least-squares slopes gave $\Delta H_{n,s}^0$, the heat of neutralization of gaseous B (liquid *n*-$PrNH_2$), according to reaction [1]:

[1] $B(g) + H^+(s) = BH^+(s)$ $\quad \Delta H_{n,s}^0$

Values of $\Delta H_{n,s}^0$ were combined with those of ΔH_s^0

[a]Reference 1.
[b]Standard state defined as: B (real gas, 1 atm) → B (hypothetical 1 *M*, s).

(B), the heat of solution of gaseous or liquid B, to yield $\Delta H^0_{p,s}$, the heat of protonation of B in Me_2SO:

[2] $B(s) + H^+(s) = BH^+(s)$ $\Delta H^0_{p,s}$

with $\Delta H^0_{p,s} = \Delta H^0_{n,s} - \Delta H^0_s$ (B). Our values of $\Delta H^0_{p,s}$, the enthalpy of protonation of the solute bases in Me_2SO, are given in Table 3 together with the corresponding literature values for these bases in water as solvent.

Because of the limited stability of HCF_3SO_3 and of some amines in PC, the values of $\Delta H^0_{p,s}$ in PC were obtained indirectly from published data by combining enthalpies for the following three reactions:

[3] $HCl(g) = H^+(s) + Cl^-(s)$

[4] $BH^+(s) + Cl^-(s) = BHCl(c)$

[5] $B(g) = B(s)$

Data for reactions [3] and [4] are taken from refs. 5 and 4, respectively. By combining these three reactions, we obtain enthalpy data for reaction [6]:

[6] $HCl(g) + B(g) + BH^+(s) = H^+(s) + B(s) + BHCl(c)$ $\sum \Delta H_s$

in both water and PC for each amine. Finally values of $\Delta H^0_{p,s}$ for reaction [2] in PC are deduced from:

[7] $\Delta H^0_{p,pc} = \Delta H^0_{p,w} - \sum \Delta H_{pc} + \sum \Delta H_w$

Using the values of $\Delta H^0_{p,w}$ from Table 3, the values of $\Delta H^0_{p,pc}$ thus computed are listed in Table 3.

Free Energy

The values of the equilibrium constant *K* for reaction [2] for NH_3 and the amines in Me_2SO were deduced from our potentiometric curves obtained from the neutralization of 10^{-2} *M* solutions of B by 0.1 *M* HCF_3SO_3. The solutions were also made 0.100 *M* in Et_4NI. The slopes of the least-squares plots of the potential of the glass electrode against log [BH^+]/[B] varied between 60.1 and 61.6 mV according to the nature of B. These values are in satisfactory agreement with the slope of 61.5 mV obtained when plotting ΔE vs. log [HCF_3SO_3] between 2×10^{-4} and 3×10^{-2} *M* acid in a 0.100 *M* Et_4NI Me_2SO solution. The p*K* values calculated from the half-neutralization potentials, and the corresponding free energies $\Delta G^0_{p,s}$ are listed in Table 4, together with the p*K* literature values given for water as solvent. No corrections were made for the effect of the ionic strength which would be small for this type of protonation reaction. The p*K* values obtained for NH_3 and $EtNH_2$ are within 0.1 unit of the values determined by Kolthoff *et al.* (12) using a glass electrode and a silver – 0.01*M* silver nitrate reference electrode calibrated with buffer solutions of known pH.

Discussion

Our data in Tables 3 and 4 for the enthalpy and free energy of protonation emphasize the fact that the basicity order of the substituted amines is solvent dependent. While the order based on $\Delta H^0_{p,s}$ is $NH_3 < MeNH_2 > Me_2NH > Me_3N$ and $NH_3 < MeNH_2 < EtNH_2 \sim$ *n*-$PrNH_2$ in water, the sequence found in Me_2SO or PC is $NH_3 \sim MeNH_2 \sim$ (or <) $EtNH_2 \sim$ *n*-$PrNH_2 > Me_2NH > Me_3N$. These trends are at variance with the gas phase order $NH_3 < MeNH_2 < EtNH_2 <$ *n*-$PrNH_2 < Me_2NH < Me_3N$ which corresponds to the proton affinities (13) listed in Table 3. If we now choose as basicity parameter the free energy or protonation $\Delta G^0_{p,s}$ (or p*K*) (Table 4) instead of $\Delta H^0_{p,s}$, the gas phase basicity order remains the same but the solution basicity order is modified. A complete analysis

of the complex solvent effect on the protonation thermodynamic functions $\Delta H^0_{p,s}$ and $\Delta G^0_{p,s}$ can best be carried out by using corresponding data for the gas phase and comparing the thermodynamics of solution of H^+, B, and BH^+. To broaden our discussion, we will also consider literature data for the same processes in water (1, 2).

If we look first at the solvent effect on the solution of the gaseous amines B, the enthalpy data in Table 1 show that for a given amine ΔH^0_s (B) varies little when passing from Me_2SO to PC, but much more when passing to H_2O. Furthermore, when considering the effect of the nature of B, ΔH^0_s (B) is much less exothermic and changes less for Me_2SO or PC than for H_2O. The free energies of solution ΔG^0_s (B) in Table 2 reflect the smaller solubilities of B in Me_2SO but show less difference between Me_2SO and H_2O than ΔH^0_s (B). The entropies of solution ΔS^0_s (B) in Table 2 are smaller for Me_2SO than for H_2O and vary little for Me_2SO with the nature of B, in contrast with the large variations for H_2O. A good Barclay–Butler (ΔH^0_s–ΔS^0_s) plot (14) with a 600 K slope is obtained for the solution of 5 amines in Me_2SO, *n*-$PrNH_2$ remaining off the line. Krishnan and Friedman (15) have shown that for many solvents the heat of solution of gaseous alkanes and aliphatic alcohols of increasing chain length could be explained in terms of group contributions. Our data for Me_2SO and our series of primary amines showed a smaller —CH_2— group contribution. These authors (15) have also proposed a general equation which we have used to calculate the heat of solution of the amines in Me_2SO with literature values for the solutes and solvent physical parameters. The values thus obtained for ΔH^0_s (B) were systematically 1–2 kcal mol^{-1} less exothermic than the experimental values. However, both observed trends, increasing exothermicity with increasing chain length for primary amines and decreasing exothermicity with increasing number of methyl substituents for the methylamines, were correctly predicted. The same calculations carried out for PC as solvent led to a poorer agreement with our experimental data for the primary amines. More valuable information can be obtained by comparing the heat of solution of the amines and their heat of condensation $-\Delta H^0_v$ (B). Table 1 shows very similar $-\Delta H^0_s$ and ΔH^0_v values for both Me_2SO and PC. Thus if we look at the solution process of the amines B as a two-step process, condensation of B followed by mixing of liquid B with Me_2SO or PC, the previous observation indicates a very small heat of mixing of liquid B with both solvents. Considering the polar nature of both solute and solvent molecules, this is somewhat unexpected, although we have obtained similar results in a recent study of the thermodynamics of solution of SO_2, a polar solute, in some polar aprotic solvents (16). Data in Table 1 show clearly that when water is the solvent the picture is entirely different, the much more exothermic heat of solution of the amines in H_2O reflecting in part the contribution from the hydrophobic-type interactions of the carbon chain of the alkylamines with water.

Turning now to the solvent effect on the solution of the gaseous ions BH^+, the values of the enthalpies of solution ΔH^0_s (BH^+) were calculated by means of a relation derived from the thermodynamic cycles relating protonation processes in the gas phase and in the solvents.

$$\Delta H^0_s(BH^+) = \Delta H^0_{p,s} - \Delta H^0_{p,g} + \Delta H^0_s(B) + \Delta H^0_s(H^+)$$

The value of the enthalpy of solvation of the gaseous proton $\Delta H^0_s(H^+)$ selected for water is −270.0 kcal mol^{-1} while the corresponding values for Me_2SO and PC are derived from the above and from the enthalpies of transfer of H^+ between H_2O and Me_2SO and PC. These latter values were in turn obtained from experimental values for reaction [3] and the enthalpies of transfer of Cl^- between H_2O and Me_2SO (5) and PC (14) based on

the tetraphenylborate–tetraphenylarsonium extrathermodynamic assumption. The values of $\Delta H_s^0(BH^+)$ thus calculated are listed in Table 5. Similar calculations were carried out for $\Delta G_s^0(BH^+)$ in H_2O and Me_2SO using data in Tables 2 and 4 and for $\Delta G_s^0(H^+)$, the values -261.0 kcal mol^{-1} in water and -265.5 kcal mol^{-1} in Me_2SO, the latter one calculated from the free energy of transfer between H_2O and Me_2SO obtained by Kolthoff (17). The values of $\Delta G_s^0(BH^+)$ as well as those of $\Delta S_s^0(BH^+)$ are given in Table 6.

Let us now consider the solvent effect on the energetics of solution of the gaseous ions BH^+ in relation to the bulk dielectric constant D of the solvents Me_2SO (46.6), PC (65.1), and H_2O (78.5). First, the values of $-\Delta G_s^0(BH^+)$ are consistently higher in Me_2SO than in H_2O. This is opposite to what would be qualitatively expected on the basis of the simple Born equation relating $-\Delta G_s^0$ and D. Second, if we calculate $-\Delta G_s^0$ for a given ion BH^+ such as NH_4^+, using the ionic radius $r_{NH_4^+} = 1.70$ Å and a previously established relation (18), we obtain for $-\Delta G_s^0(NH_4^+)$ in Me_2SO 95.6 kcal mol^{-1}, in contrast to our value 86.3 kcal mol^{-1}. The failure of the simple Born treatment to account for the effect of a change in the dielectric constant of the solvent on the free energy of solvation of BH^+ ions can also be shown to extend to the enthalpy of solvation $\Delta H_s^0(BH^+)$. However, Aue *et al.* (2) recently concluded that by modifying this electrostatic approach they could satisfactorily explain their thermodynamic results derived from gas phase and aqueous data for the protonation of a large series of nitrogen bases. Aue *et al.* essentially subtracted from the thermodynamic parameter for the solution in water of gaseous BH^+ ions a non-electrostatic contribution assumed to be equal to the corresponding parameter for the solution of B. The remaining electrostatic contributions ΔH^{el} and ΔG^{el} were said to follow the expected dependence on suitably calculated values of $1/r_{BH^+}$. In order to test this approach, using our data in Tables 5 and 6, we deduced values of $-\Delta H_s^0(BH^+)^{el}$ for Me_2SO and PC and compared these values with those calculated from the simple Born equation using the values of r_{BH^+} calculated by Aue *et al.* (2). Poor agreement was found, the calculated values being higher than the experimental ones for NH_4^+ but consistently lower by up to 25–35 kcal mol^{-1} (the difference increasing with r_{BH^+} for all other BH^+ ions. It therefore seems that this modified electrostatic approach fails to provide a quantitative picture of the solvent effect for the solution enthalpies of the BH^+ ions we have studied here.

TABLE 5. Enthalpies of solution of gaseous ammonium ions and proton (kcal mol^{-1}) at 25°C

	$-\Delta H_s^0(BH^+)$		
BH^+	H_2O	Me_2SO	PC
NH_4^+	88.6	98.4	93.7
$MeNH_3^+$	82.7	90.1	86.1

H^+	270.0	276.1	259.1

TABLE 6. Free energies (kcal mol^{-1}) and entropies (cal mol^{-1} deg^{-1}) of solution of gaseous ammonium ions and proton at 25°C

	$-\Delta G_s^0(BH^+)$		$-\Delta S_s^0(BH^+)$	
BH^+	H_2O	Me_2SO	H_2O	Me_2SO
NH_4^+	82.3	86.3	21.1	40.6
$MeNH_3^+$	75.3	78.4	24.8	39.3
$Me_2NH_2^+$	68.4	70.5	28.2	37.9
Me_3NH^+	61.4	62.6	26.5	35.2
$EtNH_3^+$	72.6	75.8	33.9	41.3
n-$PrNH_3^+$	70.8	74.6	36.6	40.3
H^+	261.0	265.5	30.2	35.6

The second approach we have considered to explain the solvent effect on our values of $\Delta G_s^0(BH^+)$ and $\Delta H_s^0(BH^+)$ is non-electrostatic and is an extension of the proposal of Trotman-Dickenson (3) developed by Jones and Arnett (1). These workers attributed the variation of free energy and enthalpy of hydration of $R_nNH_{4-n}^+$ ions essentially to the change in the number $(4-n)$ of H bound to N which can form H-bonds to water. Looking at our data for Me_2SO and PC in Tables 5 and 6, we first note a gradual decrease in the values of $-\Delta G_s^0(BH^+)$ and $-\Delta H_s^0(BH^+)$ when passing from NH_4^+ to $MeNH_3^+$, $Me_2NH_2^+$ and Me_3NH^+. There is an average decrease per H-bond of 7.9 kcal mol^{-1} and 8.4 kcal mol^{-1} in Me_2SO for ΔG^0 and ΔH^0, respectively, and 7.3 kcal mol^{-1} in PC for ΔH^0. However, when we consider the ions $MeNH_3^+$, $EtNH_3^+$, and n-$PrNH_3^+$, which could all form three H-bonds, both ΔG^0 and ΔH^0 values in Me_2SO and PC show some decrease with the size of the substituent. Thus, contributions from the carbon chain to the solvation process of BH^+ ions in Me_2SO and PC cannot be entirely neglected, making the H-bond picture a qualitative one. The values of the ionic entropies of solvation $\Delta S_s^0(BH^+)$ listed in Table 6 show only minor and regular variations for Me_2SO but large changes for water. Considering now the effect of the solvent on the solvation thermodynamics of each ion BH^+, our values for $-\Delta G_s^0(BH^+)$ in Table 6 are higher in Me_2SO than

in water by about 1.0 kcal mol^{-1} per possible H-bond. This is in line with the higher basicity of Me_2SO. When we include the data for PC in Table 5 we also find that BH^+ solvation enthalpy is more exothermic in Me_2SO than in PC, in accordance with the higher basicity of Me_2SO. However, the exothermicity is lower in water than in both Me_2SO and PC, although the basicity of water as defined by $\Delta H^0_s(H^+)$ is between that of Me_2SO and PC. The anomalous position of water and of other H-bonding solvents in such relationships between two basicity parameters has already been discussed (19).

In concluding this discussion, we can say that our analysis has brought into focus the complex interplay of the many factors which control the effect of a change of solvent on the basicity order and the protonation thermodynamic functions of a series of substituted bases. The complexity of the solvent effect is magnified when protonation data ($\Delta G^0_{p,s}$ and $\Delta H^0_{p,s}$) are compared for solvents belonging to different classes such as dimethylsulfoxide and water (12). Thus, the unexpectedly small and irregular pK ($\Delta G^0_{p,s}$) differences for the series of amines B in Me_2SO and H_2O (Table 4) result from irregular entropy compensations of nearly constant $\Delta H^0_{p,s}$ differences. Furthermore, the higher exothermicity of $\Delta H^0_{p,s}$ in Me_2SO (Table 3) is in turn due to both variable but more exothermic $\Delta H^0_s(BH^+)$ and less exothermic $\Delta H^0_s(B)$ values in Me_2SO, which are in part opposed by a more exothermic $\Delta H^0_s(H^+)$ in Me_2SO. Our analysis shows clearly that attempts to rationalize pK differences with such a pair of solvents in terms of one simple solvent parameter such as the proton transfer activity coefficient were bound to be unsuccessful.

NOTE ADDED IN PROOF: The pK values of the BH^+ ions in PC may be calculated from known values in acetonitrile since ΔpK for related BH^+ ions in both solvents appears to be constant (20). However, there are discrepancies in pK values in PC reported by two groups of workers (20, 21).

Volumetric and thermochemical properties of ionic surfactants: sodium decanoate and octylamine hydrobromide in water

ROSARIO DE LISI,[1] GÉRALD PERRON, AND JACQUES E. DESNOYERS[2]
Department of Chemistry, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1
Received November 20, 1979

ROSARIO DE LISI, GÉRALD PERRON, and JACQUES E. DESNOYERS. Can. J. Chem. **58**, 959 (1980).

The heat capacities per unit volume and the densities of sodium decanoate (NaDec) in water were measured as a function of concentration and temperature in the range 0.5 to 45°C. Similar data were obtained for octylamine hydrobromide at 5 and 15°C. Enthalpies of dilution of NaDec in water were measured at 25°C. From these and previously published data the apparent and partial molal heat capacities, expansibilities, volumes, and relative enthalpies were determined as a function of temperature and concentration. The concentration dependence of $\bar{V}_2$ and $\bar{L}_2$ is similar to that of other surfactants such as alkyltrimethylammonium bromides and sodium dodecyl sulfate, but in contrast with the other surfactants, $\bar{C}_{P,2}$ goes through a sharp maximum in the micellization region at the lower temperatures. These thermodynamic properties can be analysed with a phase-separation model to give the changes in volume, heat capacity, and enthalpy during micellization as a function of temperature. The limitations of this model are also discussed.

ROSARIO DE LISI, GÉRALD PERRON et JACQUES E. DESNOYERS. Can. J. Chem. **58**, 959 (1980).

Les capacités calorifiques par unité de volume et les masses volumiques du décanoate de sodium (NaDec) dans l'eau ont été mesurées en fonction de la concentration et de la température dans la région 0.5 à 45°C. Des données semblables ont été obtenues pour le bromhydrate d'octylamine à 5 et 15°C. Les enthalpies de dilution de NaDec ont été mesurées à 25°C. A partir de ces données et d'autres obtenues auparavant, les capacités calorifiques, les enthalpies, les expansibilités et les volumes molaires apparents et partiels ont été déterminés en fonction de la température et de la concentration. La dépendance de $\bar{V}_2$ et $\bar{L}_2$ sur la concentration est qualitativement semblable à d'autres surfactants, tels les bromures d'alkyltriméthylammonium et le dodécyl sulfate de sodium. Par contre, $\bar{C}_{P,2}$ passe par un maximum étroit dans la région de la micellisation aux basses températures, contrairement à d'autres surfactants. Ces fonctions thermodynamiques peuvent être analysées au moyen d'un modèle de changement de phase pour obtenir les changements de volume, de capacité calorifique et d'enthalpie durant la micellisation en fonction de la température. Les limites de ce modèle sont aussi discutées.

Introduction

In a continuing study on the thermodynamic properties of aqueous surfactants we have examined systematically the alkylamines hydrobromides (1, 2) and nonyl and decyltrimethylammonium bromides in water (3–5). With the former system the effect of chain length was investigated, mostly with the aim of understanding the properties of surfactants in the dispersed state, i.e. in the pre-micellar region. The two alkyltrimethylammonium bromides were investigated thoroughly in the micellar region. It was thus possible to examine the temperature dependence of the thermodynamic functions and in particular of the heats, entropies, volumes, and heat capacities of micellization. All these functions were shown to be self-consistent and should prove very useful in checking quantitatively various models and theories.

Anionic surfactants were also investigated. The volumes and heat capacities of some alkyl sulfates (6) and alkyl carboxylates (7) were reported at 25°C. Of these, the carboxylates seem most interesting since they show very sharp changes near the critical micelle concentration (CMC). We therefore felt that carboxylate surfactants might be promising as model systems to investigate microphase transitions in surfactant solutions.

The alkyl carboxylates have been extensively studied in the literature. The thermodynamic studies have been concerned with the determination of the CMC under various conditions (8, 9), the volumetric

properties (10, 11), the heat capacities (12), and the enthalpies (13). However, most of these studies were limited to the determination of the thermodynamic functions of micellization and a detailed study of the properties in the micellar region were usually not made. Since it is through a careful study of this region that models for the various equilibria in solution will eventually be established these systems need further investigation.

The useful working range of most of our thermodynamic techniques is above 0.01 mol kg^{-1}. The CMC must therefore be well above this concentration limit if the micellization region is to be studied thoroughly. Therefore the highest homolog that can be investigated conveniently is sodium decanoate (NaDec) which has a CMC above 0.08 mol kg^{-1} at 25°C. In this paper we will report heat capacities, enthalpies, volumes, and expansibilities of NaDec over a wide temperature range. In a following paper (14) the activities and entropies will be presented. Since the volumes and compressibilities have also been investigated thoroughly by Vikingstad *et al.* (10, 11), as in the case of the two alkyltrimethylammonium bromides, all the thermodynamic properties will be known with this system in water.

As it was mentioned above, the alkylamine hydrobromides were investigated primarily in the pre-micellar region and over the whole concentration range at 25°C only. Measurements were therefore repeated at 5 and 15°C for octylamine hydrobromide (OABr), mostly in the micellar region. It will thus be possible to investigate the temperature dependence of the thermodynamic functions with this system also.

Experimental

The purification procedure for OABr was reported previously (2). The NaDec was prepared by titrating decanoic acid (Aldrich, gold label), purified by fractional recrystallizations, with NaOH solution. Then water was removed with a flash evaporator. All solutions were prepared by weight with deionized (Continental Deionized Water System) distilled water. The solutions were titrated to a pH of 9.2 to suppress hydrolysis as much as possible (15). Still, a slight cloudiness appeared in the solutions below the CMC suggesting the existence of traces of free decanoic acid or high molecular weight alcohols, which were probably solubilized in the micelles above the CMC. Repeated purification did not eliminate this. Similar effects were observed by Høiland and Vikingstad (16). However, the high reproducibility of the data, the excellent group additivity between data for various carboxylates, and the excellent agreement between the present data on volumes and those of Vikingstad *et al.* (11) and Kale and Zana (17) suggest that these traces of impurities do not have a significant effect on the thermodynamic properties. Still, freshly prepared solutions were used whenever possible, and, if they had to be kept for an extended period, they were kept in a refrigerator in tightly closed bottles.

With the exception that the injection in the flow microcalorimeter was made with a Gilson peristaltic pump (Minipuls 2), the techniques used, the procedure and the precision of the measurements are the same as those reported in previous studies on surfactants (5) and do not require further discussion.

Results

The apparent molal volumes ϕ_V and heat capacities at constant pressure ϕ_C were calculated from the differences in densities and in heat capacities per unit volume. The temperature of measurement of ϕ_V is lower than that of ϕ_C by a constant amount (0.35 K) as a consequence of the two instruments being placed in series. However, the error introduced by this temperature difference in the calculation of ϕ_C is well within the experimental uncertainty. Measurements were made at 0.5 (a few data points), 2, 5, 10, 15, 25, 40 (a few data points), and 45°C for NaDec and at 5 and 15°C for OABr. Enthalpies of dilution of NaDec were obtained at 25°C only. The original data are given elsewhere[3] but the data at even molalities are given in Table 1.[4] The experimental ϕ_V and ϕ_C in the pre-micellar region can be fitted in molality m by the equation

$$[1] \quad \phi_Y = \phi_Y^0 + A_Y m^{1/2} + B_Y m$$

where Y stands for V or C and A_Y are the limiting slopes calculated from the Debye–Hückel theory. The parameters ϕ_Y^0 and B_Y, obtained from a least-squares fit, are given in Table 2.

The apparent molal relative enthalpies ϕ_L are derived from the enthalpies of dilution in the usual way (2) and can be expressed as a polynomial in $m^{1/2}$ in the pre-micellar region:

$$[2] \quad \phi_L = A_L m^{1/2} + B_L m + C_L m^{3/2} + \ldots$$

where again A_L is the limiting Debye–Hückel slope for relative enthalpies.

Volumes

The concentration dependence of ϕ_V (not shown) of NaDec and OABr is similar to that of other surfactants (3–7, 10, 11, 17); ϕ_V does not change much in the pre-micellar region, increases sharply at the CMC, and levels off slowly at higher concentration. The value at infinite dilution ϕ_V^0, which is equal to the standard partial molal volume $\bar{V}_2^0$, is shown as a function of temperature in Fig. 1 and compared

[a]From $\bar{V}$ data.
[b]Values in parentheses are extrapolated values.

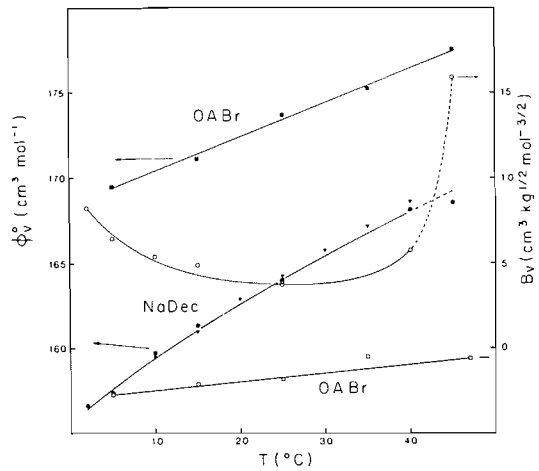

FIG. 1. Temperature dependence of the parameters ϕ_V^0 and B_V of eq. [1] for sodium decanoate and octylamine hydrobromide: ϕ_V^0, ● and ■, present results, ▽, Kale and Zana (17), ▼, Vikingstad *et al.* (11); B_V, ○ and □, present results.

with the data of Vikingstad *et al.* (11) on NaDec. The mean deviation between both sets of data is 0.2 cm^3 mol^{-1} up to 25°C, which is excellent agreement. On the other hand our ϕ_V^0 at 45°C is lower by 1.5 cm^3 mol^{-1} from the value extrapolated from Vikingstad. A close examination of our data and procedure leads us to suspect that the thermostat for our densimeter might not have been functioning properly at 45°C as a result of the instruments being placed in series. Consequently the actual temperature of measurement could have been lower by one or two degrees. Some data were measured at 40°C in the pre-micellar region checking the temperature in the densimeter and the agreement with Vikingstad was now excellent (see Fig. 1). This error at 45°C could have an important effect on the parameter B_V and on the CMC but should not affect the data at high concentration too much. Also an error of 1.5 cm^3 mol^{-1} could affect our ϕ_C data by about 6 J K^{-1} mol^{-1}, but fortunately the effect on the concentration dependence of ϕ_C will be much smaller.

Another indication of the accuracy of the present data comes from the group additivity of the homologous series RCOONa at 25°C. The difference in $\bar{V}_2^0$ of NaDec and Na octanoate (7) is 31.8 cm^3 mol^{-1} which is twice the average CH_2 contribution, 15.9 cm^3 mol^{-1}, of other similar homologous series (1, 18).

The increase of ϕ_V^0 with temperature is typical of hydrophobic solutes in water. This will be discussed further through expansibilities.

The parameter B_V, which is a measure of the deviation from the Debye–Hückel theory, is also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

shown in Fig. 1. The sign and temperature dependence of B_V of OABr are typical of surfactants and other hydrophobic solutes (4). On the other hand B_V of NaDec are positive like other carboxylates (7) suggesting that the carboxylate group plays an important role in the solute–solute interactions. If ${\phi_V}^0$ of NaDec was too negative at 45°C, B_V could then be too positive. It would therefore be dangerous to put too much weight on the large increase in B_V of NaDec at 45°C.

The partial molal volumes $\overline{V}_2$, obtained from a plot of $\Delta(\phi_V m)/\Delta m$ against the mean molality (3), are shown at three temperatures in Fig. 2. The initial break in the curves are taken as the CMC. This graph can be used to calculate the change in volume during micellization (4), ΔV_m. Essentially the linear part of $\overline{V}_2$ beyond the CMC is extrapolated to the CMC and the difference between this value of $\overline{V}_2$ and the value of $\overline{V}_2$ at the initial break is taken as ΔV_m. These values are given in Table 2. In general the values for NaDec are about 1 $cm^3\ mol^{-1}$ smaller than those of Vikingstad *et al.* (11). Vikingstad

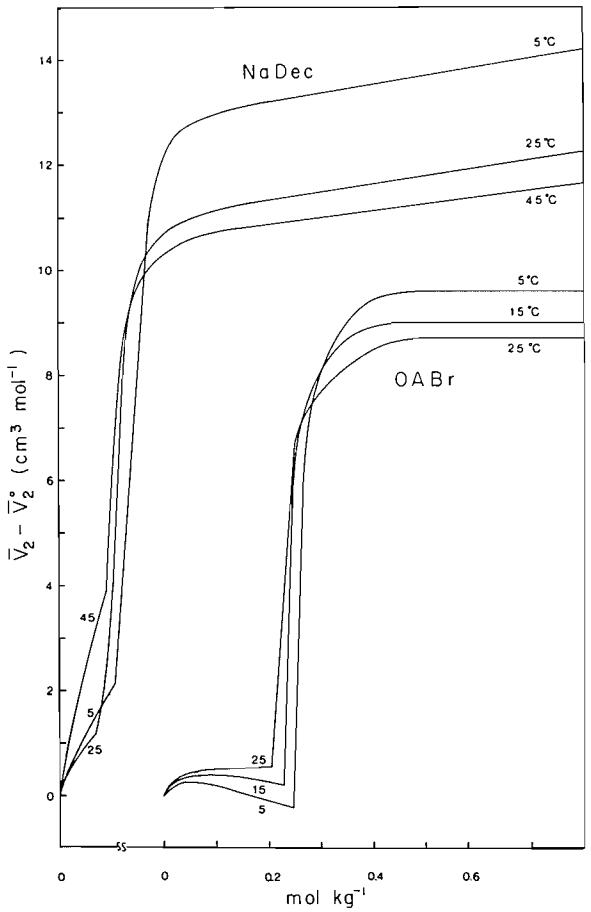

FIG. 2. Partial molal volumes of sodium decanoate and octylamine hydrobromide.

calculated the volume of the surfactant in the micellar state V_m directly from the apparent molal volumes, i.e.

$$[3] \quad \phi_V = \frac{\mathrm{CMC}}{m} V_s + \frac{m - \mathrm{CMC}}{m} V_m$$

where V_s is the molar volume of the surfactant in the dispersed state. It can readily be shown that this method is equivalent to the one used above. The total volume of the solutions above the CMC is given by

$$[4] \quad V = \sum_i n_i \overline{V}_i$$
$$= n_w \overline{V}_w + n_s \overline{V}_s + n_m \overline{V}_m$$
$$= 55.51 V_w + \mathrm{CMC}\,\overline{V}_s + (m - \mathrm{CMC})\,\overline{V}_m$$

where the subscript w refers to water. Equation [4] implies that the concentration of monomers remains constant beyond the CMC. The value of ${\overline{V}_2}^a$ above the CMC is then given by

$$[5] \quad {\overline{V}_2}^a = (\partial V/\partial m)_{T,P}$$
$$= \overline{V}_m + 55.51(\partial \overline{V}_w/\partial m) + \mathrm{CMC}(\partial \overline{V}_s/\partial m) + (m - \mathrm{CMC})(\partial \overline{V}_m/\partial m)$$

In the pre-micellar region the volumes of the solution is given by

$$[6] \quad V = 55.51 \overline{V}_w + m \overline{V}_s$$

and the value ${\overline{V}_2}^b$ below the CMC is given by

$$[7] \quad {\overline{V}_2}^b = \overline{V}_s + 55.51\partial(\overline{V}_w/\partial m) + m(\partial \overline{V}_s/\partial m)$$

Combining eq. [5] and eq. [7]

$$[8] \quad {\overline{V}_2}^a - {\overline{V}_2}^b = \overline{V}_m - \overline{V}_s + (m - \mathrm{CMC}) \times \partial(\overline{V}_m - \overline{V}_s)/\partial m$$
$$= \Delta V_m + (m - \mathrm{CMC})\partial \Delta V_m/\partial m$$

At the CMC it is therefore correct to identify ${\overline{V}_2}^a - {\overline{V}_2}^b$ with ΔV_m.

The partial molal volume $\overline{V}_2$ can also be calculated from ϕ_V, given by eq. [3],

$$[9] \quad {\overline{V}_2}^a = (\partial(\phi_V m)/\partial m)_{T,P}$$
$$= V_m + \mathrm{CMC}(\partial V_s/\partial m) + (m - \mathrm{CMC}) \times (\partial V_m/\partial m)$$

Similarly in the pre-micellar region

$$[10] \quad {\overline{V}_2}^b = V_s + m(\partial V_s/\partial m)$$

Again, combining eq. [9] and eq. [10],

$$[11] \quad {\overline{V}_2}^a - {\overline{V}_2}^b = V_m - V_s + (m - \mathrm{CMC}) \times \partial(\overline{V}_m - \overline{V}_s)/\partial m$$
$$= \Delta V_m + (m - \mathrm{CMC})(\partial \Delta V_m/\partial m)$$

Although the parameters V_m and V_s used by Vikingstad *et al.* (10) are apparent molal volumes, they lead to the same ΔV_m as in our procedure provided the data are extrapolated to the CMC. If the data are not extrapolated, then larger values for ΔV_m can result since $\bar{V}_2$ increases slightly with m above the CMC (Fig. 2). This difficulty would not arise with OABr since $\bar{V}_2$ is essentially constant beyond the CMC (Fig. 2).

As it had been observed with other surfactants (2, 3, 5) ΔV_m generally decreases as the temperature increases.

Heat Capacities

There are no data in the literature which can be used to compare with our ϕ_C data. On the other hand some idea of the accuracy of the present data can be obtained from group additivity. The difference in $\bar{C}_{P,2}{}^0$ between NaDec and sodium octanoate (7, 19) is 176 J K^{-1} mol^{-1}, in very close agreement with twice the accepted value for the methylene group, 88–90 J K^{-1} mol^{-1} (2, 18–20).

The apparent molal heat capacities of NaDec and OABr, contrary to those of alkyltrimethylammonium bromides (5), show a pronounced hump in ϕ_C in the micellization region at low temperatures. These humps disappear at 45°C for NaDec and at 25°C for OABr. In Fig. 3 the experimental ϕ_C values in the hump region are plotted against m for three temperatures. The magnitude of the hump as a function of the temperature does not change in a regular way. In order to fix this, some data points were measured in the hump region at 0.5°C. The humps at low temperatures were missed for OABr in our earlier work (2) since very few data points were obtained in the CMC region.

As in the case of volumes, $\bar{C}_{P,2}$ were calculated from ϕ_C and are shown for three temperatures in Fig. 4. Here the changes in $\bar{C}_{P,2}$ are very large near the CMC and are nearly discontinuous at low temperature.

The temperature dependence of $\phi_C{}^0$ and B_C, shown in Fig. 5, is similar to that of other hydrophobic electrolytes such as the larger tetraalkylammonium halides (21) and surfactants (4).

The concentration at the first break in $\bar{C}_{P,2}$ was taken as the CMC, which in general is slightly lower from those derived from $\bar{V}_2$. The CMC and the concentration at the maximum in $\bar{C}_{P,2}$ are plotted against temperature in Fig. 6. These critical concentrations tend to the same value at higher temperatures but diverge significantly at lower temperatures.

The ΔC_m was calculated from an extrapolation of the relatively linear regions below and above the CMC region, ignoring the hump for this purpose.

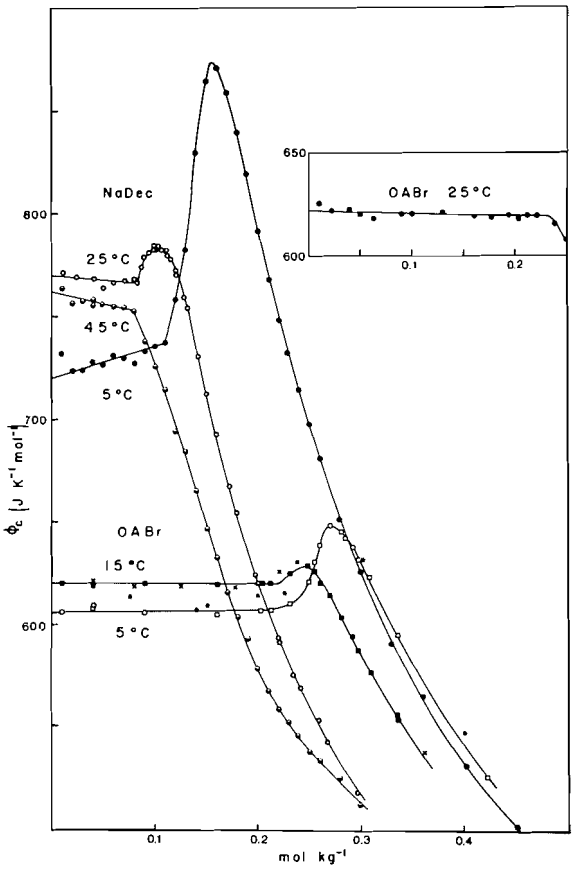

FIG. 3. Apparent molal heat capacities of sodium decanoate and octylamine hydrobromide.

These ΔC_m are given in Table 2, and, as in the case of ΔV_m, they decrease in magnitude as the temperature increases.

Enthalpies

The apparent molal relative enthalpies of NaDec were measured at 25°C and are shown in Fig. 7. The partial molal relative enthalpies $\bar{L}_2$ were then calculated at various temperatures from the heat capacities (4) and are also shown for 5, 25, and 45°C in Fig. 7. The enthalpies of OABr have been reported elsewhere at 25°C (2). Using the $\bar{C}_{P,2}$ data at 5, 15, and 25°C, $\bar{L}_2$ were also calculated at various temperatures and are shown in Fig. 8. As with alkyltrimethylammonium bromides (5) the relatively linear region of $\bar{L}_2$ below and above the CMC were extrapolated to the CMC and the differences were taken as ΔH_m; they are reported in Table 2. These ΔH_m obtained graphically at temperatures other than 25°C are compared in Table 2 with those calculated from

$$[12] \quad \Delta H_m{}^T = \Delta H_m{}^{298} + \int_{298}^{T} \Delta C_m \mathrm{d}T$$

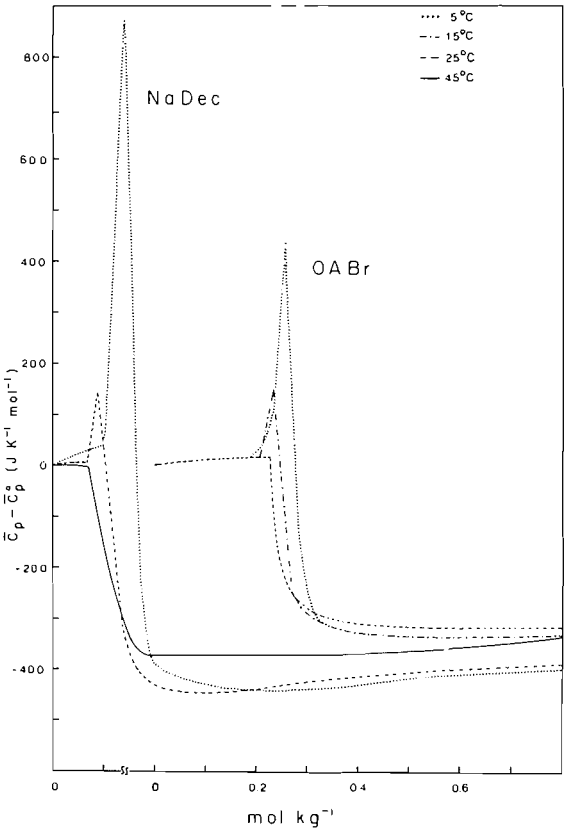

FIG. 4. Partial molal heat capacities of sodium decanoate and octylamine hydrobromide.

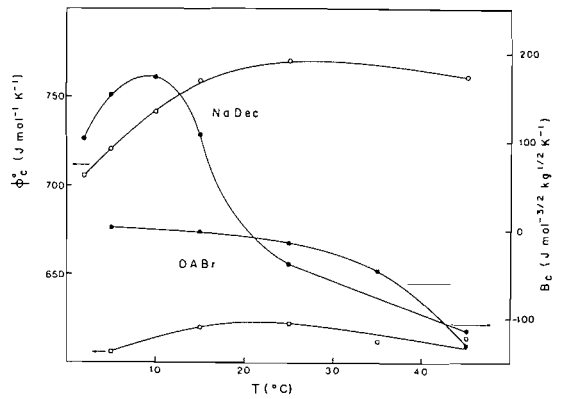

FIG. 5. Temperature dependence of the parameters ϕ_c^0 and B_c of eq. [1] for sodium decanoate and octylamine hydrobromide.

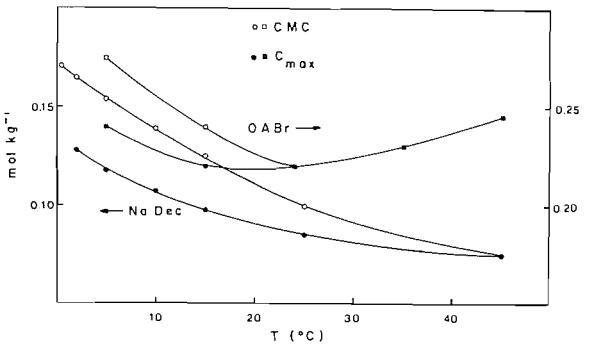

FIG. 6. Temperature dependence of the CMC and the concentration corresponding to the maximum heat capacity of sodium decanoate.

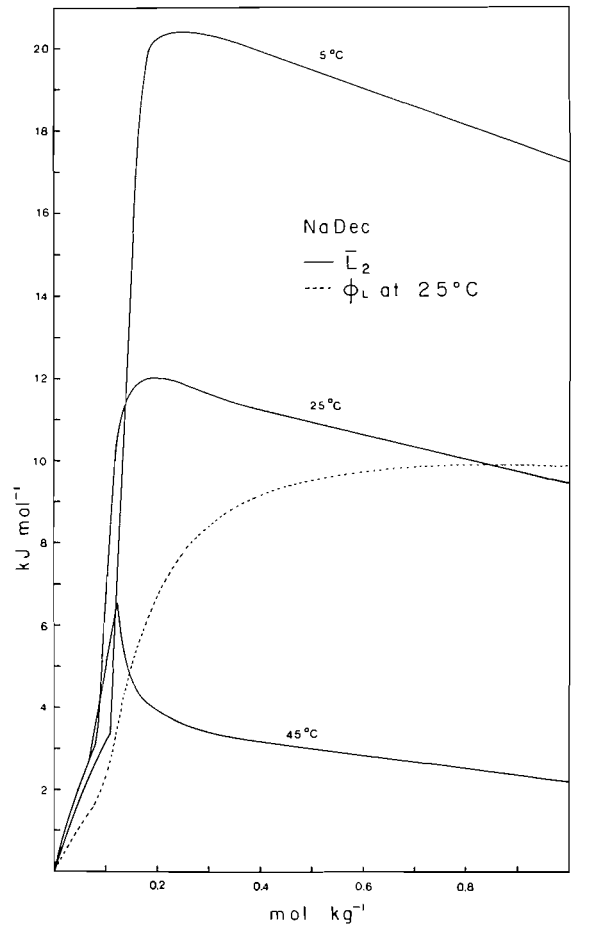

FIG. 7. Apparent and partial molal relative enthalpies of sodium decanoate.

The agreement is excellent, showing the self-consistency of the calculations.

As in the case of heat capacities no values of ΔH_m by calorimetric determination are reported in the literature, and consequently it is impossible to test the accuracy of these parameters. The concentration dependence of $\bar{L}_2$ of NaDec has the same general shape as K octanoate (13).

Discussion

The main objective in this work was to investigate the thermodynamic functions in the CMC region.

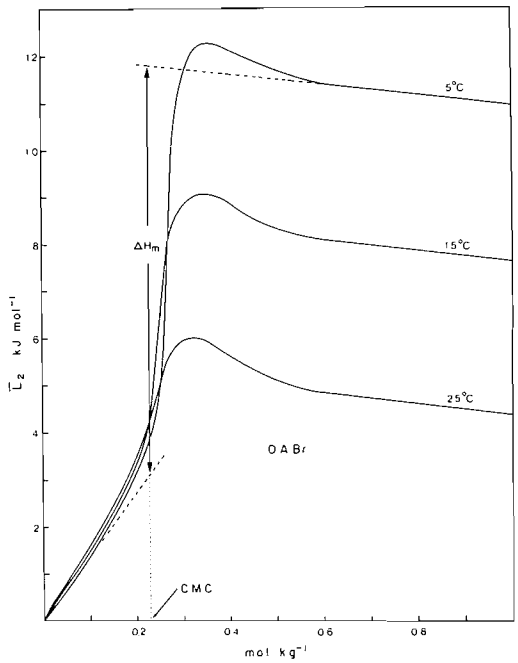

FIG. 8. Partial molal relative enthalpies of octylamine hydrobromide: ΔH_m, experimentally determined enthalpy of micellization at 5°C.

The parameter B_C of alkyltrimethylammonium bromides (3, 5) were positive, especially at low temperatures, but ϕ_C or $\bar{C}_{P,2}$ showed no hump near the CMC. The pronounced humps with NaDec and OABr at low temperatures were also observed with aqueous solutions of *tert*-butanol (22), *n*-butoxyethanol (23), diethylmethylamine and triethylamine (24), and tetrabutylammonium octanoate (7).

The method of measuring ΔV_m, described above, is based on a phase separation model. Essentially the CMC is considered equivalent to a solubility and the micelles to a reservoir of surfactant molecules or microphases. This is why the model predicts that at the CMC there will be a sudden change in $\bar{V}_2$, and any additional solute molecule will dissolve in the micelles. In actual fact $\bar{V}_2$ reaches the value of $\bar{V}_m$ at concentrations which are at 2 to 4 times the CMC. Obviously this means that phase transition models are only approximately valid for micellization, especially for shorter-chain surfactants, and micellization occurs over a range of concentration. Therefore, depending on the method of definition used, one or more CMC can be observed and different methods of extrapolating the data may lead to different values of the CMC (25). For example, Zimmels and Lin (9) identify up to three CMC's with NaDec and Markins *et al.* (26), two. The usually quoted CMC of NaDec is close to 0.10 mol kg^{-1} (8, 27) which fall in between the initial break and the leveling-off region. Obviously micellization is a complex phenomenon and more refined theoretical approaches, such as multiple equilibria, would be required to account for the change in thermodynamic functions in the CMC region. Still the phase transition approach is a convenient way of defining ΔV_m.

The treatment used for ϕ_V and $\bar{V}_2$ can readily be extended to enthalpies. Corresponding to eqs. [3] and [8] we now have

$$[13]\quad \phi_H = \frac{\text{CMC}}{m} H_s + \frac{m - \text{CMC}}{m} H_m$$

$$[14]\quad \phi_L = \frac{\text{CMC}}{m} L_s + \frac{m - \text{CMC}}{m} L_m$$

and

$$[15]\quad \bar{L}_2^a - \bar{L}_2^b = \Delta H_m + (m - \text{CMC})\partial\Delta H_m/\partial m$$

Therefore, the present method of measuring ΔH_m is consistent with the phase-separation approach. In view of the large concentration dependence of ϕ_L and $\bar{L}_2$ in the pre- and post-micellar regions, many of the calorimetric determinations of ΔH_m based on integral heats of dilution or of mixing are erroneous and may even lead to the wrong sign (25, 28, 29).

The interpretation of the concentration dependence of heat capacities does not seem as straightforward as $\bar{V}_2$ and $\bar{L}_2$ since, with NaDec and OABr at low temperatures, $\bar{C}_{P,2}$ goes through a large hump near the CMC. Some idea of the origin of this hump can be obtained from Fig. 9 where $\bar{C}_{P,2}$ is compared with $\bar{L}_2$ for NaDec at 10°C. The first break of the two curves coincide and both functions reach their micellar value at about the same concentration. The values of $\bar{L}_2$ at 5 and 15°C are also shown in Fig. 9. Since $\bar{C}_{P,2}$ is the temperature dependence of $\bar{L}_2$, it follows that the hump arises because both ΔH_m and the CMC decrease significantly with temperature.

Recently Benson (30) was able to account nearly quantitatively for the high heat capacity of water from a simple two-species model. Hvidt (31) also applied independently a similar model to the expansibility and compressibility of water. Jolicoeur *et al.* (32), through a similar approach, predicted quantitatively the shape and the maximum of ϕ_C accompanying the complexation of K^+ with a crown ether. Applying the same reasoning to the phase-transition model for micellization, it is possible to account for the hump in ϕ_C of some surfactants. Equation [13] can be derived with respect to T,

$$[16]\quad \phi_C = \frac{\text{CMC}}{m} C_{ps} + \frac{m - \text{CMC}}{m} C_{pm} - \frac{\Delta H_m}{m} \frac{\partial\,\text{CMC}}{\partial T}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

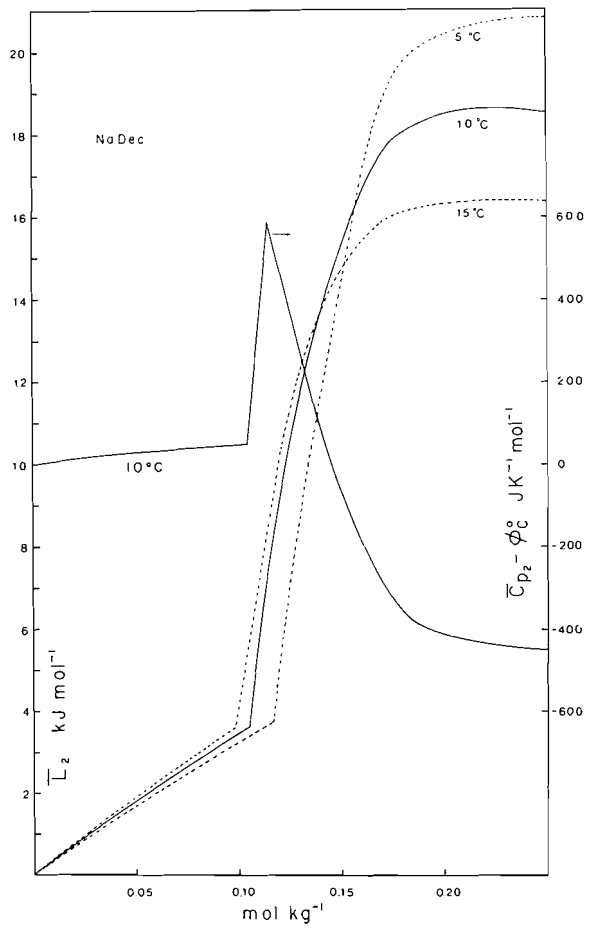

FIG. 9. Comparison of the partial molal heat capacities and relative enthalpies of sodium decanoate at 10°C.

If the CMC is considered the concentration of the monomers in equilibrium with micelles, then it is generally accepted that the standard free energy for micelle formation is proportional to $(1 + \beta)RT \times \ln \text{CMC}$, where β is the degree of dissociation. From the Gibbs–Helmholtz equation it then follows that

$$[17] \quad \Delta H_m = -(1 + \beta)RT^2 \frac{\partial \ln \text{CMC}}{\partial T}$$

if β does not vary with temperature. Replacing $\partial \text{CMC}/\partial T$ from eq. [17] into eq. [16], it follows that

$$[18] \quad \phi_C = \frac{\text{CMC}}{m} C_{ps} + \frac{m - \text{CMC}}{m} C_{pm} + \frac{\text{CMC}}{(1 + \beta)mRT^2} (\Delta H_m)^2$$

At $m = \text{CMC}$, the magnitude of the hump should then be $(\Delta H_m)^2/(1 + \beta)RT^2$.

Taking the data in Table 2 for NaDec at 5°C the predicted hump for full dissociation ($\beta = 1$) is 251 J K^{-1} mol^{-1} while the experimental value is 147 J K^{-1} mol^{-1}, which is of the same magnitude.

The value of $\bar{C}_{P,2}$ can be obtained from the differentiation of eq. [18] and the hump is now given by

$$[19] \quad \bar{C}_P(\text{relax}) = \frac{2\text{CMC}\,\Delta H_m(\partial \Delta H_m/\partial m)}{(1 + \beta)RT^2}$$

For an ideal micellar system ΔH_m should be constant and consequently no hump (but a discontinuity) should be observed with $\bar{C}_{P,2}$. Therefore this hump is a direct measurement of the deviation from the phase-transition model. It should therefore be possible from the shape of the concentration dependence of ϕ_C or $\bar{C}_{P,2}$ in the CMC region to obtain quantitative information on the various equilibria involved in the micellization process. Obviously alkyltrimethylammonium bromides do not micellize in the same way as sodium carboxylates or alkylamine hydrobromides since their ϕ_C go through a maximum at the CMC but show no hump.

The above simple model suggests that the hump should increase continuously as the temperature is lowered. In actual fact this is not so. The temperature dependence of the maximum ϕ_C of NaDec is shown in Fig. 10, and it can be seen that the hump goes through a maximum somewhere between 2 and 5°C. This temperature region also corresponds to the region where B_C goes through a maximum. It is also interesting to note that B_C of Pen_4NBr also goes through a maximum in D_2O at low temperature (21) and that the association constant of tetraalkylammonium halides obtained from conductivity also seem to pass through a maximum somewhere around the temperature of maximum density of water (33).

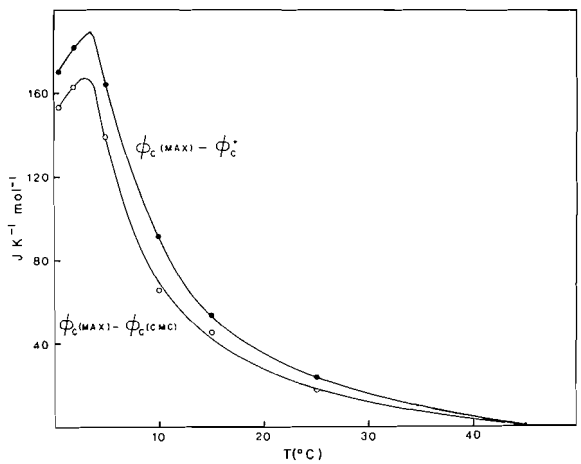

FIG. 10. Temperature dependence of the maximum value of ϕ_C of NaDec.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

The partial molal expansibilities $\bar{E}_2$ obtained from the temperature dependence of $\bar{V}_2$ are shown as a function of m and of T on Fig. 11. Despite the larger uncertainty with this function, definite trends are apparent. $\bar{E}_2$ of most organic solutes in water go through a maximum (23). However, at low temperatures this maximum becomes a well-defined hump. As with heat capacities the existence of this hump can be predicted with the phase-transition model. By analogy with eq. [18], the apparent molal expansibility after the CMC is given by

$$[20]\quad \phi_E = \frac{\mathrm{CMC}}{m} E_s + \frac{m - \mathrm{CMC}}{m} E_m + \frac{\mathrm{CMC}}{(1 + \beta)mRT^2} \Delta H_m \Delta V_m$$

The size of the hump in ϕ_E will therefore depend on the sign and magnitude of ΔH_m and ΔV_m. Since for most surfactants at low temperature both ΔH_m and ΔV_m are positive, a positive hump is predicted. Our data on $\bar{E}_2$ of NaDec are not precise enough to ascertain if the hump goes through a maximum, as in the case of $\bar{C}_{ps}$, or not. The sign of ΔE_m is negative for NaDec but it is difficult to say if ΔE_m changes with T or not in view of the experimental uncertainty.

Vikingstad *et al.* (11) have studied the adiabatic compressibility of NaDec; $\bar{K}_{S,2}{}^0$ is negative and increases with temperature, but $\Delta K_{S,m}$ is positive and decreases in magnitude with temperature. These trends are consistent with the other thermodynamic properties. Unfortunately the concentration dependence of ϕK_S or $\bar{K}_{S,2}$ are not given. It is therefore difficult to say if any maximum or hump is present or absent in the CMC region.

The temperature dependence of the CMC can in principle be predicted from ΔH_m and ΔC_m. If ΔC_m is assumed to vary linearly with temperature, $\partial \Delta C_m / \partial T = B$, it was shown then (3) that

$$[21]\quad (1 + \beta)R \ln \frac{\mathrm{CMC}}{(\mathrm{CMC})_0} = \left(\Delta H_m{}^0 - T_0 \Delta C_m{}^0 + \frac{BT_0{}^2}{2}\right)\left(\frac{1}{T} - \frac{1}{T_0}\right) - (\Delta C_m{}^0 - BT_0) \ln \frac{T}{T_0} - \frac{B}{2}(T - T_0)$$

where the reference state is taken as 298.15 K. Equation [21] can be solved for different values of β and it turns out that no single value of β can account for the experimental CMC given in Table 2 and in Fig. 6 (defined as the initial break). To fit the data, β has to be assumed to be around 0.2 at low temperatures and zero at high temperatures. A value for the CMC intermediate between the initial break and the final one is required to fit the data with a single β. Very good agreement with literature was obtained for the temperature dependence of the CMC of sodium dodecylsulfate (3) since in this case micellization is sharp. With NaDec or OABr the CMC is ill-defined and it is more difficult to apply eq. [21]. Again this stresses the importance of finding better quantitative models for micellization.

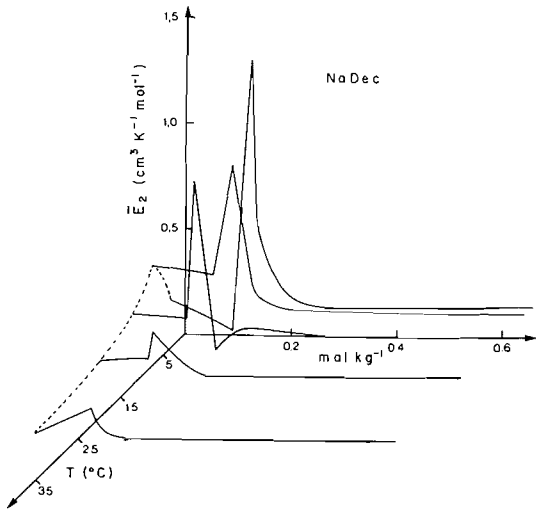

FIG. 11. Temperature and concentration dependence of the partial molal expansibilities of sodium decanoate.

Thermodynamics of ionization of 2,4- and 2,5-dinitrophenol in dimethylsulfoxide

KOK-SIONG SIOW AND KOK-PENG ANG[1]

Department of Chemistry, University of Singapore, Bukit Timah Road, Singapore 1025

Received October 2, 1979

KOK-SIONG SIOW and KOK-PENG ANG. Can. J. Chem. **58**, 970 (1980).

Ionization constants of 2,4- and 2,5-dinitrophenol in dimethylsulfoxide were measured by the conductance method at five temperatures ranging from 20 to 40°C. The ionization constants of 2,4-dinitrophenol are much larger than those of 2,5-dinitrophenol, and in both cases they increase with temperature. The thermodynamic functions of ionization are discussed in terms of Hepler's theory for substituent and solvent effects. The ionization of phenols in dimethylsulfoxide is controlled by the enthalpy factor, both internal and environmental, which is in contrast to the entropy-controlled process in water.

KOK-SIONG SIOW et KOK-PENG ANG. Can. J. Chem. **58**, 970 (1980).

On a mesuré les constantes d'ionisation des dinitrophénols-2,4 et -2,5 dans le diméthylsulfoxyde, par la méthode de la conductivité à 5 températures allant de 20 à 40°C. Les constantes d'ionisation du dinitro-2,4 phénol sont plus élevées que celles du dinitro-2,5 phénol et, dans les deux cas, elles augmentent avec la température. On discute des fonctions thermodynamiques de l'ionisation en fonction de la théorie de Hepler relative aux effets du substituant et du solvant. Le facteur d'enthalpie interne et externe contrôle l'ionisation des phénols dans le diméthylsulfoxyde ce qui est à l'opposé de la réaction en phase aqueuse dont le facteur déterminant est l'entropie.

[Traduit par le journal]

Introduction

Dimethylsulfoxide (DMSO) is a dipolar aprotic solvent with a high dielectric constant (46.4). Its large dipole moment (3.9 D) and polarizability (n_D^{20} is 1.478) enable it to stabilize molecules and ions through dipole and induced-dipole interactions. It solvates strongly protons and other cations, as it has a high electron density on the unscreened oxygen atom in its molecules. Thus as a solvent, the properties of DMSO complement those of water which is typically protic, and it has been suggested that "DMSO is destined to achieve an importance as a solvent for quantitative work in organic chemistry comparable to that of water in inorganic chemistry" (1).

Ionization constants in DMSO have been determined for a fairly large number of substances. Few studies, however, have been made on the thermodynamics of ionization of acids in this solvent. In view of the importance of DMSO as a solvent, it would be desirable to have more data of enthalpies and entropies of ionization so as to achieve a better understanding of the ionization process in this solvent. Thus, with this in mind, measurements were made of the ionization constants of two dinitrophenols in DMSO as a function of temperature to evaluate their ΔH and ΔS of ionization. The results are discussed in terms of Hepler's theory for substituent and solvent effects (2). Finally, a comparison between DMSO and water is also made with respect to their effects on the ionization process.

Experimental

Materials

2.4- and 2,5-Dinitrophenol (Merck Chemicals) were purified by repeated crystallization from ethanol until constant melting point (2,4-dinitrophenol, 113–114°C and 2,5-dinitrophenol 105–106°C).

AnalaR grade potassium chloride was recrystallized twice from conductance water and dried overnight at 180°C.

Dimethylsulfoxide (Aldrich Chemical Co.) was purified by passage through a column of activated alumina (Merck's chromatographic grade in basic form). The solvent from the column was collected into a distillation flask and vacuum fractionated at a pressure of a few Torr. A first fraction amounting to about 10% of the total was rejected and the second fraction of about 75% was collected. The purified DMSO had a specific conductance of less than 9×10^{-8} ohm^{-1} cm^{-1} at 25°C.

Conductance water for KCl solutions: deionised water was heated with alkaline permanganate and distilled into an all glass still for a further stage of distillation in an atmosphere of nitrogen. The specific conductance of the conductance water ranged from 6 to 8×10^{-7} ohm^{-1} cm^{-1}.

Apparatus

Conductances of solutions were measured with the Wayne Kerr B642 Autobalance Universal Bridge. For the conductance range studied, the instrument has an accuracy of 0.1%.

Two conductance cells of different dimensions were used. The electrodes of the cells were lightly platinized according to the technique of Jones and Bollinger (3). The cell constants were determined with standard KCl solutions (4) in the usual manner.

Temperature control was provided by a thermostatic water bath maintained to ±0.02°C.

Procedure

Solutions of dinitrophenols in DMSO were prepared in a nitrogen-filled dry box. All the solutions, including KCl solutions, were prepared by weight corrected to their vacuum values. Concentration in volume was then calculated from weight concentration and density. Solutions of different concentrations were prepared by successive dilution of a stock solution. Transfer

*The literature pK values for 2,4-dinitrophenol in DMSO are: 5.2, from ref. 7; 5.4, from ref. 8.

TABLE 4. Limiting molar conductance, ionization constant, and thermodynamic functions for 2,5-dinitrophenol in DMSO

Temperature (°C)	Λ_0	$K \times 10^7$	ΔG^0 (cal mol^{-1})	ΔH^0 (cal mol^{-1})	ΔS^0 (cal deg^{-1} mol^{-1})
20	19.0	1.21	9280		
25	22.2	1.33	9380	3560	−19.5
30	25.7	1.48	9480	3760	−18.9
35	29.9	1.64	9570	3970	−18.2
40	34.5	1.82	9660		

of DMSO solutions to the conductance cells was performed in the dry box; the cells were stoppered before being taken out of the dry box for immersion in the thermostatic bath. Conductance readings were recorded when they became invariant with time; this took about 1 h for each measurement.

Values of the viscosity, density, and dielectric constant of the solvent were interpolated from the data of Yao and Bennion (5).

Results

The molar conductance data for dinitrophenol solutions together with the specific conductances of solvent at different temperatures are shown in Tables 1 and 2.[2] The data were evaluated according to the method of Fuoss and Shedlovsky (6). The following equation was used

$$[1] \quad 1/\Lambda S(z) = 1/\Lambda_0 + c\Lambda S(z)f^2/K\Lambda_0^2$$

The plot of $1/\Lambda S(z)$ versus $c\Lambda S(z)f^2$ was linear; the limiting molar conductance, Λ_0, and the ionization constant, K, were obtained from the intercept and the slope. The values are summarized in Tables 3 and 4. The values of the ionization constant calculated directly from the equation at various concentrations also show satisfactory consistency.

For the purpose of calculating the thermodynamic functions, the experimental data at various temperatures were fitted to an equation of the following form

$$[2] \quad \ln K = a + bT + cT^2$$

by the method of least-squares to yield thermodynamic functions of ionization as shown in Tables 3 and 4. The values for ΔH are quoted only for 25, 30, and 35°C, since ΔH is derived from the temperature dependence of ln K and it is expected that there is more uncertainty at the extremes of the temperature range. As an independent check on these ΔH values, the experimental ln K values were plotted versus $1/T$ and the slopes of the curves were estimated graphically. The results so obtained agreed with those calculated to within 10 to 20 cal mol^{-1}.

Discussion

As we are more interested in the relative acidities of the two phenols, we may begin our discussion with the following equation

$$[3] \quad \text{2,4-D} + \text{2,5-D}^- \rightleftharpoons \text{2,4-D}^- + \text{2,5-D}$$

where 2,4-D$^-$ and 2,5-D$^-$ indicate the anions of the respective dinitrophenols. Following Hepler's method of separating the thermodynamic functions into the "internal" and "environmental" contributions, and making the assumption (9) that ΔS_{int} for a symmetrical reaction, such as the one above, is nearly zero and can be neglected, we obtain for the reaction

$$[4] \quad \delta\Delta G = (\Delta H_{2,4\text{-D,int}} - \Delta H_{2,5\text{-D,int}}) + (\Delta H_{2,4\text{-D,env}} - \Delta H_{2,5\text{-D,env}}) - T(\Delta S_{2,4\text{-D,env}} - \Delta S_{2,5\text{-D,env}}) = \delta\Delta H_{int} + \delta\Delta H_{env} - T\delta\Delta S_{env}$$

$$[5] \quad \delta\Delta G = \delta\Delta H_{int} \text{ (in the absence of solvent)}$$

[2]Complete set of data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, the National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

For personal use only.

where ΔH's and ΔS's refer to the enthalpies and entropies of ionization of the two phenols.

Values of ΔH_{int} at 25°C for *p*- and *m*-nitrophenol in relation to the unsubstituted phenol[3] have been found (11) to be -3690 and -2130 cal mol^{-1} respectively. If it is assumed that the additivity principle of substituent effects (12) applies here, the difference (-1560 cal mol^{-1}) between the above two ΔH_{int} values may then be taken as the value of $\delta\Delta H_{int}$ in our case. Comparing it with the experimental $\delta\Delta G$ value (-2550 cal mol^{-1}), this means that about 60% of the overall difference in acidity of the two dinitrophenols in DMSO is accounted for by the substituent effects.

The effects of solvent may be illustrated in a convenient way by referring to the following scheme

[6]

$$\begin{array}{ccc} \text{2,4-D (g)} + \text{2,5-D}^- \text{(g)} & \xrightarrow{\delta\Delta G_g} & \text{2,4-D}^- \text{(g)} + \text{2,5-D (g)} \\ \downarrow \Delta G_s(\text{2,4-D}) \quad \downarrow \Delta G_s(\text{2,5-D}^-) & & \downarrow \Delta G_s(\text{2,4-D}^-) \quad \downarrow \Delta G_s(\text{2,5-D}) \\ \text{2,4-D (DMSO)} + \text{2,5-D}^- \text{(DMSO)} & \xrightarrow{\delta\Delta G_s} & \text{2,4-D}^- \text{(DMSO)} + \text{2,5-D (DMSO)} \end{array}$$

At 25°C the values of ΔS of the two compounds are nearly equal, suggesting that $\delta\Delta S_{env} \approx 0$ and hence $[\Delta S_s(\text{2,4-D}^-) - \Delta S_s(\text{2,4-D})] \approx [\Delta S_s(\text{2,5-D}^-) - \Delta S_s(\text{2,5-D})]$ for the above scheme. This indicates that the relative entropy of solvation for 2,4-D$^-$ and that for 2,5-D$^-$ with reference to their respective parent compounds are about the same. The ΔH data, on the other hand, show that

$$\begin{aligned} \delta\Delta H_{env} &= \delta\Delta H - \delta\Delta H_{int} \\ &\approx -2750 - (-1560) \\ &\approx -1190 \text{ cal mol}^{-1} \end{aligned}$$

where

$$\begin{aligned} \delta\Delta H_{env} = {} & [\Delta H_s(\text{2,4-D}^-) - \Delta H_s(\text{2,4-D})] \\ & - [\Delta H_s(\text{2,5-D}^-) - \Delta H_s(\text{2,5-D})] \end{aligned}$$

Thus, in relation to their respective parent compounds the 2,4-D$^-$ anion is stabilized by solvation by DMSO to a greater extent than is the 2,5-D$^-$ anion. The effect of solvation accounts for the remaining 40% of the overall difference in acidity of the two phenols in DMSO. As mentioned earlier, DMSO solvates anions through dipole and induced-dipole interactions and its solvation power increases with the size and polarizability of the ions. The negative charge on the anion of 2,4-D is spread over the phenolic oxygen and the oxygen atoms of both the nitro groups and hence is more delocalized than is the case for the anion of 2,5-D. It is to be expected, therefore, that the former would be solvated by DMSO more strongly than the latter. That the delocalization of the anion confers enhanced acidity on the acid in DMSO has also been noted by Bordwell *et al.* (13).

It would be interesting to compare the results here with those in aqueous solutions. Hepler (11) has shown that the stronger acidity of *p*-nitrophenol over *m*-nitrophenol in water is due almost entirely to its favourable entropy of ionization. The ΔH ($= \Delta H_{int} + \Delta H_{env}$) values for these two phenols (in water) were about equal, although the ΔH_{int} of *p*-nitrophenol is expected to be less positive as its anion is stabilized by resonance to a greater extent. Thus, the two results in DMSO and in water are totally in contrast with each other, showing that the two solvents complement one another in their solvent capabilities. In water, the solvent will interact more strongly with the anion of *m*-nitrophenol which has a relatively concentrated negative charge compared with the more diffuse charge on the resonance stabilized anion of *p*-nitrophenol. This stronger interaction results in a more negative ΔH_{env} value for *m*-nitrophenol which almost completely off-sets the favourable ΔH_{int} of *p*-nitrophenol. At the same time, however, it makes the entropy of solvation for *m*-nitrophenol less favourable than for *p*-nitrophenol, owing to the loss in translational freedom of the water molecules bound to it.

It has also been noted (14) that for the series: phenol, 4-nitrophenol, 2,6-dinitrophenol, and 2,4,6-trinitrophenol, the acidity in DMSO increases along the series faster than in water. This is demonstrated by a progressive drop in ΔpK ($pK_{DMSO} - pK_{H_2O}$) for the series from 6.5 to 3.8 to 1.3 and to ca. -1.3. This fact can now be explained in terms of the differential properties of the two solvents. As the

[3]McMahon and Kebarle (10) have recently measured ΔG^0 (taken as $\approx \Delta H^0$ on the assumption that $\Delta S^0 \approx 0$) for the same reactions in gas phase. Their values were, however, obtained at 327°C.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

degree of delocalization in the anions increases along the series, their stabilization by induced-dipole interactions will become stronger and stronger in DMSO relative to that in water.

From the above argument it may be concluded that the ionization of phenols in DMSO is controlled by the enthalpy of ionization, both internal and environmental. This is in contrast to the entropy-controlled process for the ionization of phenols in water.

The solution conformation of prostacyclin as determined by high field proton magnetic resonance techniques[1]

GEORGE KOTOVYCH,[2] GERDY H. M. AARTS, TOM T. NAKASHIMA, AND GLEN BIGAM
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 12, 1979

GEORGE KOTOVYCH, GERDY H. M. AARTS, TOM T. NAKASHIMA, and GLEN BIGAM. Can. J. Chem. **58**, 974 (1980).

The proton magnetic resonance (^{1}H nmr) spectrum at 400 MHz of prostacyclin at pH 10.4 in glycine buffer has been completely analyzed utilizing homonuclear double resonance, inversion recovery, and difference nOe experiments. The spectral analysis shows that the two protons at C-4 are non-equivalent even though they are removed from the asymmetric centres at C-8 and C-9 by five bonds. The difference nOe measurements verify the configuration at C-5.

Proton longitudinal relaxation times (T_1) were measured at 400 and 200 MHz. From the T_1 frequency dependence, effective rotational correlation times ranging from 2.3×10^{-10} to 3.0×10^{-10} s were calculated for H-5, H-9, H-11, and H-15. This indicates that the portion of the molecule encompassed by these protons has a longer correlation time than is observed for the C-2 and the C-17 to C-19 protons, for which the average correlation time is 1.2×10^{-10} s. Hence the aliphatic side chains have more segmental motion.

GEORGE KOTOVYCH, GERDY H. M. AARTS, TOM T. NAKASHIMA et GLEN BIGAM. Can. J. Chem. **58**, 974 (1980).

On a analysé complètement le spectre de résonance magnétique du ^{1}H de la prostacycline à 400 MHz, à un pH de 10.4 dans un tampon de glycine, en utilisant la double résonance homonucléaire, l'inversion de récupération et des expériences de différences de enO. L'analyse spectrale révèle que les deux protons en position C-4 ne sont pas équivalents même s'ils sont éloignés des centres asymétriques C-8 et C-9 par 5 liaisons. Des mesures de différence enO permettent de vérifier la configuration au niveau du carbone en position 5.

On a mesuré les temps de relaxation longitudinale (T_1) à 400 et 200 MHz. En se basant sur l'effet de fréquence sur T_1, on a calculé les temps de corrélation rotationnelle efficace pour les protons H-5, H-9, H-11 et H-15 qui varient entre $2.3 - 10^{-10}$ et $3 - 10^{-10}$ s. Ceci indique que la portion de la molécule entourée par ces protons a un temps de corrélation plus grand que celui observé pour les protons portés par les carbones 2 et 17 à 19 pour lesquels le temps moyen de corrélation est de 1.2×10^{-10} s. En conséquence les chaînes latérales aliphatiques ont plus de mouvement segmentaire.

[Traduit par le journal]

Introduction

The metabolic pathway of arachidonic acid proceeds via the cyclic endoperoxides which are then rapidly converted into thromboxane, prostacyclin (PGI_2), and other prostaglandins. Prostacyclin (Fig. 1) was discovered by Moncada *et al.* (1). It inhibits platelet aggregation and relaxes vascular smooth muscle (2). (The structure of PGI_2 was first presented in 1976 (ref. 2, pp. 179–187).) On the other hand, thromboxane A_2 induces platelet aggregation and causes contraction of arteries (ref. 2, pp. 133–154). Hence there exists in blood vessels a delicate balance involving prostacyclin, which, in the circulatory system, is generated by the vessel walls (3) and thromboxane A_2, which is produced by the platelets (4). In fact, clinical studies have shown that low doses of aspirin (160 mg per day) present an effective, nontoxic, antithrombic regimen in man. These prevent pathologic thromboses by blocking platelet synthesis of thromboxane without affecting the synthesis of vascular prostacyclin (5).

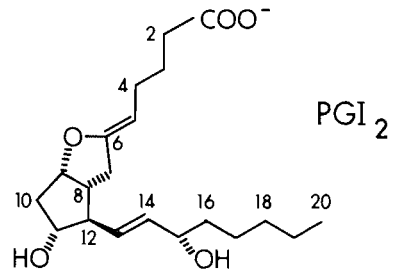

FIG. 1. Structure of prostacyclin (PGI_2).

Because of the diverse functions of these two compounds, we have studied the conformation of PGI_2 in solution using high-field ^{1}H nmr techniques. We have previously studied thromboxane B_2 in $CDCl_3$ and CD_3OD solutions (G. Kotovych and G. H. M. Aarts, Can. J. Chem. 1980, in press) as the biologically active thromboxane A_2 has a half-life of only about 32 s (ref. 2, pp. 133–154). In this way we hope to correlate the structure and activity of these compounds in solution.

Materials and Methods

The sodium salt of prostacyclin was a gift from Dr. John Pike of the Upjohn Co., Kalamazoo, MI. The present measurements were carried out in glycine-d_5 buffer (0.02 *M*) in D_2O and the pH of the buffer was adjusted to 10.4 (uncorrected meter reading)

[1]This is paper No. 3 in a series of high-field nmr studies on vitamins and prostaglandins. For paper No. 1 see ref. 16; paper No. 2 is in press.

using 40% (w/w) NaOD in D_2O. A high pH was used for these studies since even at a pH of 7.6, PGI_2 is rapidly hydrolyzed to 6-ketoprostaglandin $F_{1\alpha}$ (6). The buffer solution was vacuum degassed using the freeze–pump–thaw technique. The sodium salt of PGI_2 was weighed out into the nmr tube and the required volume of the buffer solution was added. With the exception of the pH adjustment, the complete preparation was carried out in a dry box under a nitrogen gas atmosphere. The final PGI_2 concentration was 0.02 *M*. The samples were then vacuum degassed and sealed. All glassware was cleaned extensively, including a nitric acid wash, to eliminate paramagnetic impurities. To check for the presence of these impurities, one sample was prepared with ~0.5 mol% EDTA and the measured relaxation times remained unchanged.

The nmr measurements were carried out in the Fourier transform mode using the Bruker WH-400/DS and the Bruker WH-200/DS nmr spectrometers and the Aspect 2000 Data System utilizing 16 or 32K of data memory. With the exception of the difference nOe measurements, all of the experiments were carried out at 277 K to maintain sample stability. The deuterium resonance of the solvent D_2O was used as the lock signal. The homonuclear decoupling experiments were also performed in the pulse mode. The chemical shifts, with respect to the methyl resonance of TSP, and coupling constants, were calculated to first order (with the exception of H-4 and 4*) at 400 MHz and are reported with an accuracy of about ±0.010 ppm and ±0.20 Hz, respectively. For maximum accuracy, spectra were expanded to a width of 2 Hz/cm.

The proton longitudinal relaxation rates were obtained using the 180°–τ–90° two pulse sequence. Usually 10 τ values were included in the analysis of the data, based on the initial slope of a plot of $\ln((M_\infty - M_\tau)/(M_\infty))$ vs. τ. These *M* values were obtained from the measurement of the sum of the peak heights of a multiplet corresponding to a given proton. Three M_∞ values were measured for maximum accuracy. Data are not reported where there was significant overlap of resonances due to different protons. The relaxation rates were obtained from a computer analysis of the data using a least-squares program. The T_1 values are reproducible from one sample to a second sample with an accuracy of ±5%. Consequently, the error limits on the $T_{1D}(400)/T_{1D}(200)$ quotient are ±10%. The difference nOe experiments were carried out in the standard manner (7) at both frequencies at 298 K since at the higher temperature the proton rotational correlation times are shorter and provide larger enhancements (7–9).

Results

Four different techniques were required to assign the proton resonances and to determine the proton chemical shifts. These are: characteristic proton chemical shifts, double resonance techniques, inversion recovery spectra, and difference nOe experiments. The resonances for H-2, H-13 and 14, H-17 to 19, and H-20 were assigned on the basis of their characteristic chemical shifts. Many of the other proton resonances, including H-9, H-5, H-15, and H-11, were assigned on the basis of homonuclear proton decoupling experiments. For example, irradiation of H-9 (Fig. 2B) simplifies the resonances due to H-10α, H-10β, and H-8. This experiment also shows that the coupling between H-7α and H-8β is nearly zero, which indicates a dihedral angle of almost 90°. Irradiation of the H-10α and the H-3 multiplet confirms the chemical shift of H-2 and H-10β as well as the coupling constants J(9-10α) and J(10α-11) (Fig. 2C). Finally, irradiation of H-4 and 4* confirms the chemical shift of H-5 and H-3 (Fig. 2D).

Assignments based on the difference nOe experiments are shown in Fig. 3. These experiments are based on the fact that protons in close proximity to the irradiated proton will be observed, even if these proton resonances are hidden by other resonances. As seen in Fig. 3B, upon saturating H-5, a large nOe is observed for H-7α and H-4 and 4*. This experiment allowed the assignment of H-7α, since from molecular models this proton is closest to H-5. It also appears that H-2 and H-3 are slightly enhanced, which is probably not surprising. Decoupling experiments carried out on H-5 showed that the low field H-7 resonance is due to the C-7 proton in the β position because of the allylic long-range coupling between H-7β and H-5 (10). In Fig. 3C, when H-11 is saturated, an nOe is observed for the other protons that are β to the ring, namely H-10β and H-8β, proving that the 10β proton resonance is to low field of the 10α proton resonance. In addition, an nOe is observed for H-13 and H-14. In an additional experiment, H-9 was saturated and an nOe was observed for H-10β and H-8, all of which are β to the ring. An enhancement was not observed for H-11. Finally, saturation of the overlapping H-8 and H-7α multiplets (Fig. 3D) yields an nOe for H-7β, H-12, H-11, and H-9, as expected. An nOe is also observed for H-13 and H-14. An nOe for H-13 and H-14 in these two experiments is consistent with freedom of rotation about the C12—C13 bond. This was confirmed by an nOe experiment in which H-13 and H-14 were saturated and ring protons H-8, H-11, and H-12 showed an nOe enhancement.

To confirm that H-10β does in fact resonate to low field of H-10α, further difference nOe experiments were carried out. These are shown in Fig. 4. In Fig. 4B, the H-10β multiplet is saturated and an nOe is observed for the nearest protons, namely H-10α and H-11. The nOe at H-9 cannot be confirmed due to the residual HDO signal. However, when the H-10α multiplet is saturated, a large nOe is observed for H-10β, as expected, but a very weak effect is now observed for H-11, which is β to the ring. These experiments confirm the H-10α and H-10β assignments.

Finally, chemical shifts were also obtained from the inversion recovery spectra by selective nulling of overlapping multiplets. As seen in Fig. 5, the

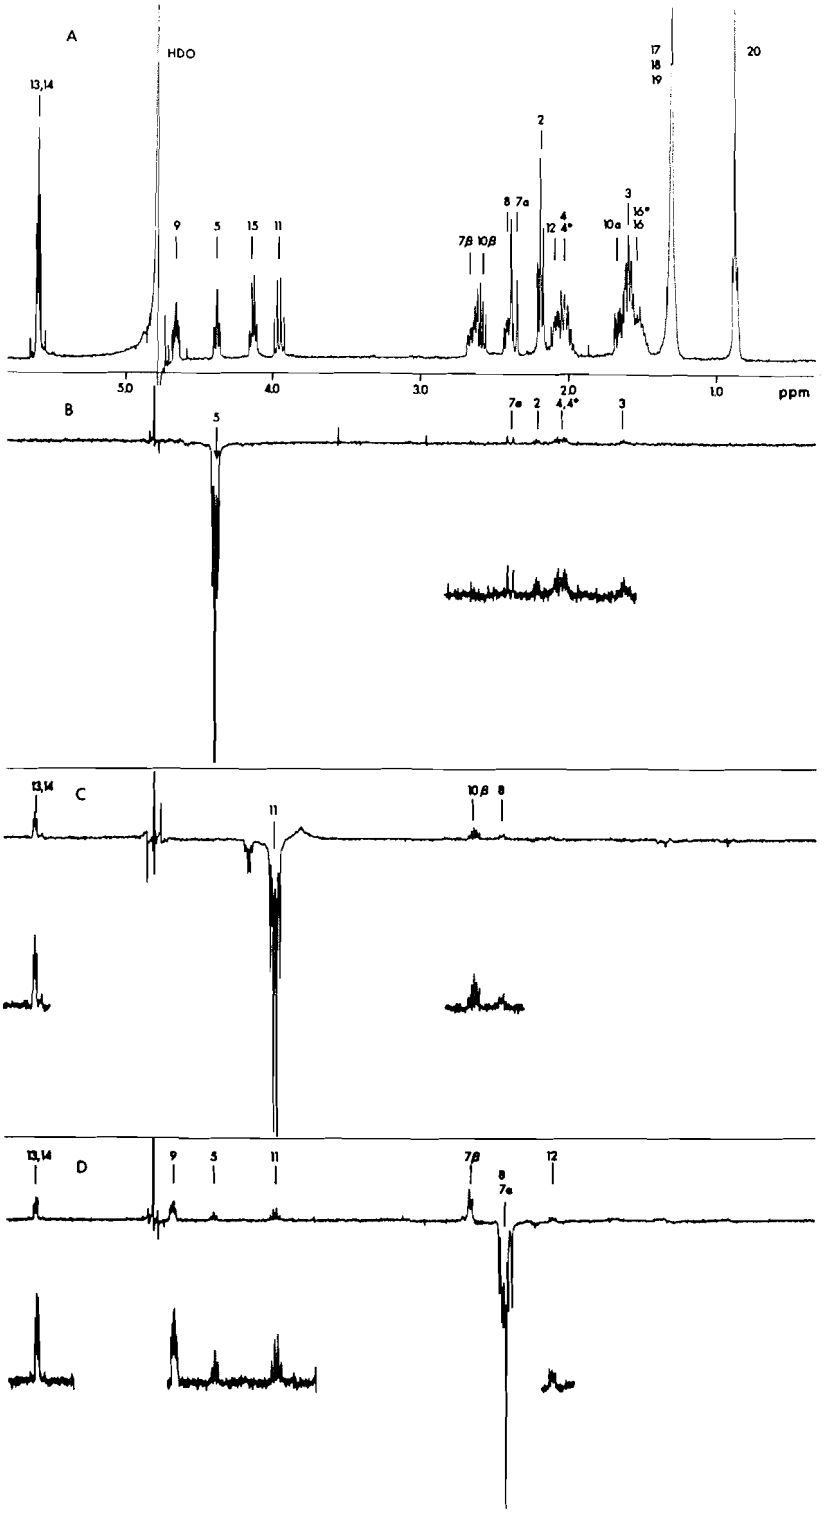

FIG. 3. Results of the difference nOe experiments performed at 400 MHz at 298 K. The normal spectrum is seen in A. In B, H-5 is saturated and an nOe is observed for H-7α, H-4,4* and a smaller nOe is observed for H-2 and H-3. In C, H-11 is saturated and an nOe is observed for H-13, H-14, H-10β, and H-8. In spectrum D, H-7α and H-8 are saturated and the protons experiencing the nOe are indicated. For these experiments, 16K data points were used together with 800 scans, a 90° pulse width of 10.7 μs and a delay time of 6 s.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

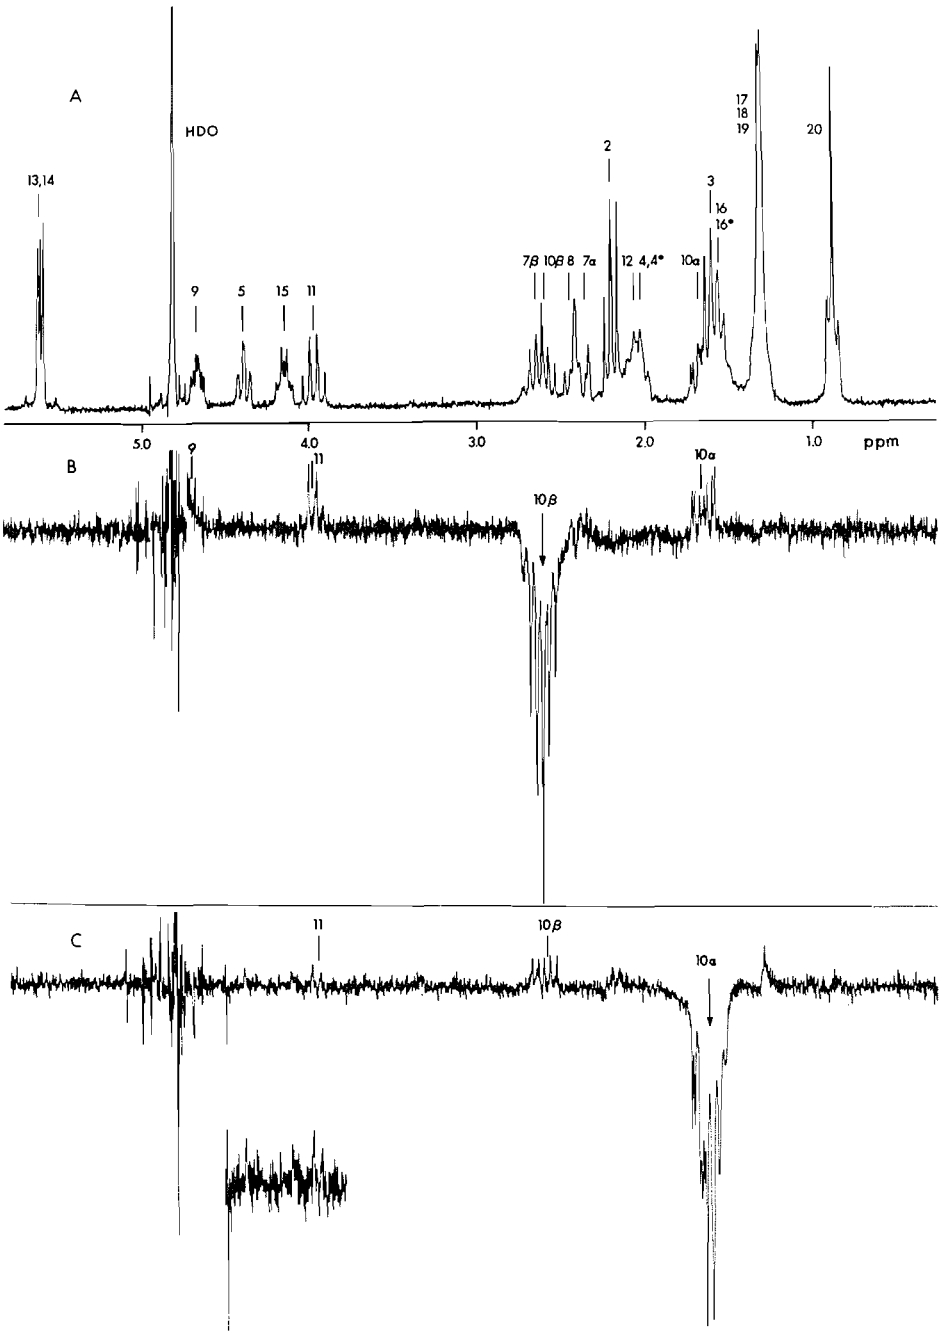

FIG. 4. The difference nOe experiments performed at 200 MHz at 298 K. The normal spectrum is seen in A, whereas in B H-10β was saturated. An nOe is observed for H-10α and H-11β. In C, H-10α is saturated and a large nOe is observed for H-10β and a small nOe for H-11. 16K data points were used together with 800 scans, a 90° pulse width of 5.2 μs and a delay time of 6 s.

multiplet corresponding to H-4 and 4* is readily visible when a τ value of 0.6 s is used in the 180°–τ–90° two-pulse sequence since H-12, having a longer T_1 value, is nulled. Similarly, the doublet corresponding to H-7α is clearly visible from the spectrum with a τ value of 0.4 s, since the resonances corresponding to H-8 are now nulled.

On the basis of the above experiments, the chemical shifts of all the protons were assigned and these are tabulated in Table 1, together with the

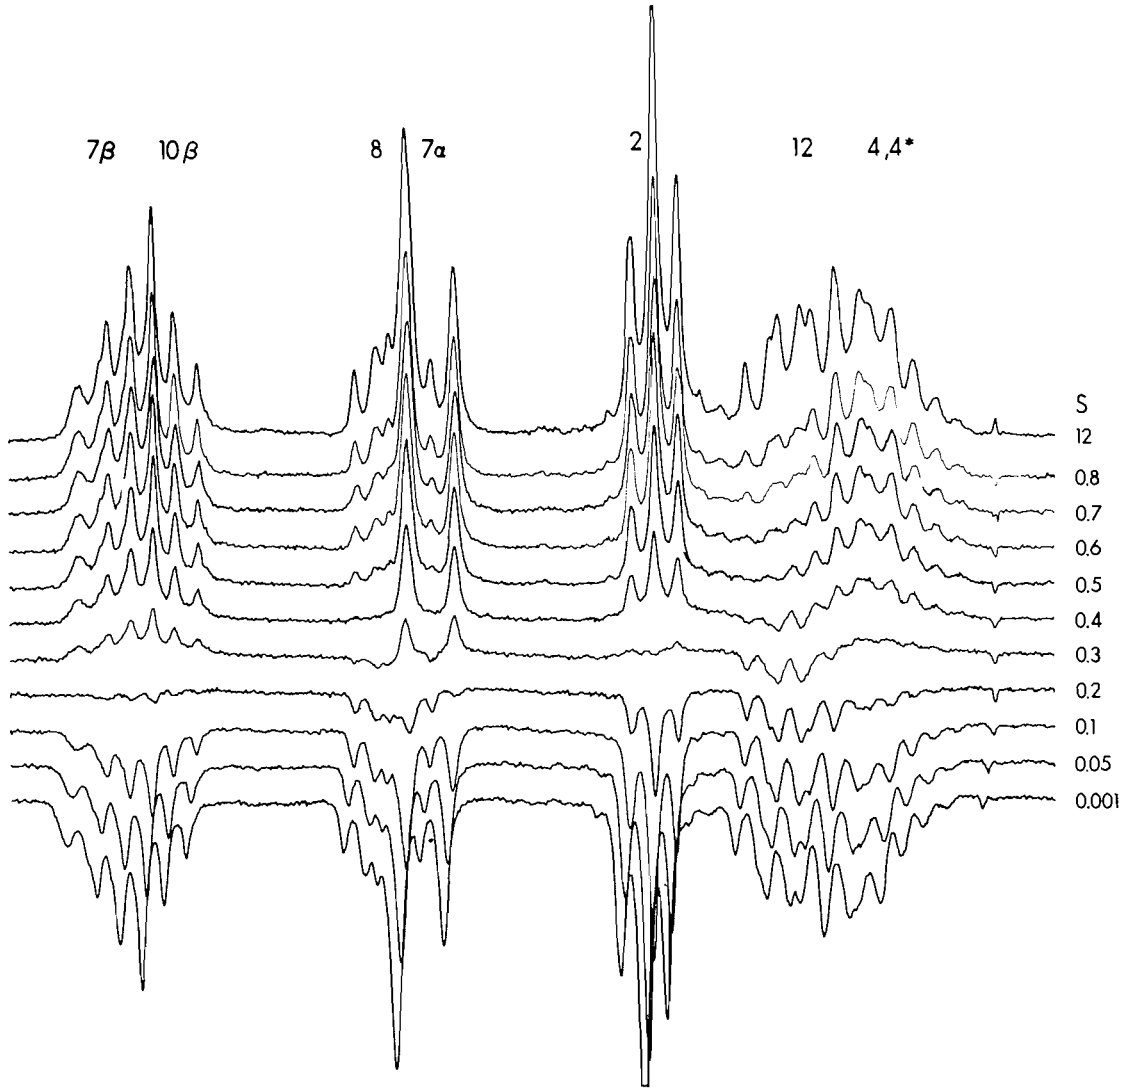

FIG. 5. The 180°–τ–90° inversion recovery spectra of prostacyclin in glycine buffer at 277 K obtained at 400 MHz; 48 scans were used to obtain each spectrum together with 32K data points.

coupling constants. A most interesting aspect of the analysis was the observation of the chemical nonequivalence of the two protons at C-4, even though they are removed by five bonds from two asymmetric centres at C-8 and C-9. The observed and calculated spectra are shown in Fig. 6 and the chemical shift difference between these two protons is 21 Hz at 400 MHz. The spectra represent the AB portion of an ABM_2X system, where the two C-3 protons are represented by M_2, and H-5 is represented by X. The agreement between the calculated and observed spectra is excellent, considering that the line width at half height of the C-4 protons is about 4 Hz, and the observed spectrum is obtained from an inversion recovery experiment.

The results of the proton longitudinal relaxation times, based on the initial slope approximation, are given in Table 2, at 200 and 400 MHz. Since the samples were degassed and prepared in a deuterated buffer, and one sample contained EDTA to check on the absence of paramagnetic impurities, the initial rates are very nearly equal to $1/T_{1D}$, where T_{1D} is the longitudinal relaxation time due to the dipolar interaction.

Discussion

The analysis of the 400 MHz spectrum of prostacyclin yields two important results. The first is the observation that the chemical shift of H-10β is to low field of the chemical shift for H-10α. Our

[a]The chemical shifts, with respect to TSP, and the coupling constants, are calculated to first order except for H-4 and 4* where these parameters were obtained from the simulated spectrum. The H-12 and H-15 multiplets cannot be analyzed to first order due to virtual coupling arising from the very small chemical shift between H-13 and H-14 as well as between H-16 and H-16*. Therefore measured splittings for the H-15 multiplet are reported (6.5 Hz).
[b]From the simulated spectrum carried out using the Bruker Software and Aspect 2000 Data System.
[c]Centre of multiplet.

assignment is based on the difference nOe experiments and is consistent with the torsion angle dependency of chemical shifts published previously (11). The torsion angle between C(H)—OH and C(10)—H-10α is ~0°, and hence the OH group is expected to shield H-10α by 0.25 ppm and to deshield H-10β by 0.25 ppm. The ether oxygen at C-9 is also *cis* to H-10α and hence a chemical shift difference of 0.95 ppm is observed between H-10α and H-10β. A shift difference of 0.90 ppm between similar protons has been observed in 1,3-disubstituted five-membered prostanoid precursors (11).

TABLE 2. Proton T_1 data and effective rotational correlation times for PGI_2 at 4°C[a]

Proton	$T_{1D}(200)$	$T_{1D}(400)$	τ_R (s)
2	0.41	0.48	1.1×10^{-10}
5	0.69	1.09	2.3×10^{-10}
9	0.57	0.96	2.5×10^{-10}
11	0.50	0.92	3.0×10^{-10}
15	0.49	0.83	2.6×10^{-10}
17, 18, 19	0.45	0.56	1.3×10^{-10}

[a]The average errors in τ_R are about $\pm 0.4 \times 10^{-10}$ s, based on the ±10% error in the $T_{1D}(400)/T_{1D}(200)$ quotient.

Secondly, protons 4 and 4* are chemically nonequivalent. The observed and calculated spectra which are shown in Fig. 6 are in excellent agreement and the chemical shift difference is 21 Hz. This non-equivalence is probably enhanced by the presence of the oxygen at C-9 and is due to the asymmetric centers at C-8 and C-9. Examples of long-range nonequivalence have been previously documented (ref. 10, p. 377).

The chemical shifts of H-9, H-5, H-15, and H-11 are in the same order as those observed for the PGI_2 methyl ester in $CDCl_3$ (12). In fact, the presence of the H-9 multiplet in the range of 4.45–4.55 ppm has been used (13) to assign compounds stereochemically related to (6*S*)-5,6-dihydroprostacyclin. However, in the present study, the chemical shifts are to lower field than those observed in $CDCl_3$ due to the solvent D_2O.

The results of the proton relaxation measurements are shown in Table 2. Due to multiplet overlap, correlation times could not be obtained for all protons. Typical spectra used for this analysis are shown in Fig. 7.

The frequency dependence for $1/T_{1D}$ has been worked out by Solomon (14) for two interacting spins and the equation for the general case may be written as (ref. 15, and references therein):

$$\frac{1}{T_{1D,j}} = \sum_{i \neq j} \frac{C^6}{r_{ij}^{\,6}} \left(\frac{\tau_R}{1 + \omega_I^{\,2}\tau_R^{\,2}} + \frac{4\tau_R}{1 + 4\omega_I^{\,2}\tau_R^{\,2}} \right)$$

In this equation, C is a product of physical constants, r_{ij} are the internuclear distances in Å, ω_I is the proton resonance frequency in rad/s, and τ_R represents the average rotational correlation time. This formula assumes dipole–dipole relaxation, isotropic motion, and no internal motion (15).

There are two unknowns in this equation, τ_R and r_{ij}. When relaxation rates at two frequencies are known, for example at 200 and 400 MHz, the correlation time, τ_R, for a given proton can be evaluated from a plot of τ_R vs. the $T_{1D}(400)/T_{1D}(200)$ quotient. This plot has previously been applied to the analysis of relaxation times of Vitamin D de-

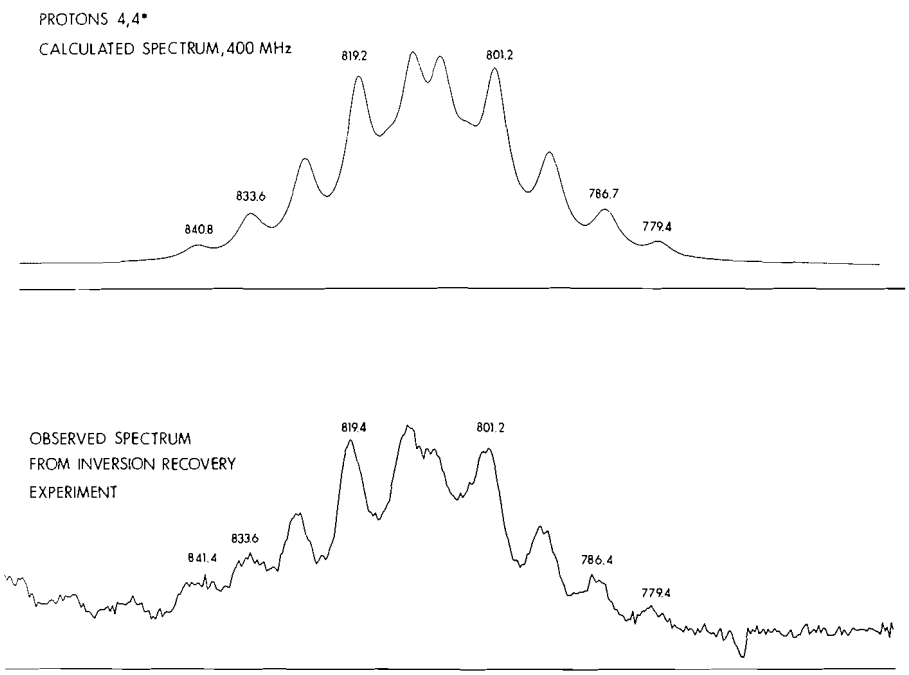

FIG. 6. The observed spectrum for H-4 and 4* obtained from the inversion recovery experiment shown in Fig. 5 ($\tau = 0.6$ s). The simulated spectrum is also shown and is in excellent agreement with the observed spectrum. The chemical shift difference between these two protons is 21 Hz. A line width at half height of 4 Hz was used in the calculation. Six representative observed and calculated frequencies are indicated. In the spectral simulation, $J(3–4) = J(3–4^*)$ was set at 7.20 Hz and $J(4–4^*)$ was set at 14.5 Hz.

rivatives (16) and thromboxane B_2 in $CDCl_3$ solution (G. Kotovych and G. H. M. Aarts, Can. J. Chem. 1980, in press). A similar approach, but at 220 and 100 MHz, has previously been applied in the measurement of the correlation times for the propionyl–CoA protons (17). In the present study, initial relaxation rates are obtained from coupled spectra. However, as first order spectra are observed for most of the multiplets, errors associated with interpreting initial relaxation rates due to cross relaxation are minimized (18, 19).

Using the calibration graph published previously (16), the effective rotational correlation times for the protons listed in Table 2 were evaluated. These range from 2.3×10^{-10} to 3.0×10^{-10} s for the rigid portion of the molecule encompassing protons 5–15. However, for H-2, H-17, H-18, and H-19 the frequency dependence is very small and the correlation times are shorter by a factor of two than for the other measured protons. The present results are in agreement with the ^{13}C relaxation measurements on prostaglandin $F_{2\alpha}$ (20) and its methyl ester (21). The ^{13}C results indicate that the prostaglandin molecule possesses rigidity encompassing carbon atoms 5–15, but carbon atoms 2–4 and 16–20 possess a greater flexibility, as would a butyric acid or an *n*-pentyl side-chain. The agreement between these studies and the present study is excellent, considering the fact that prostaglandin $F_{2\alpha}$ has only one five-membered ring.

The nOe is proportional to r^{-6}, where r is the distance between the irradiated and the observed protons. The present difference nOe data shows that saturation of H-5 causes an enhancement for H-7α (Fig. 3B). This confirms that H-5 is *cis* to C-7 and not *trans*. This configuration of H-5 was previously shown on the basis of chemical shift additivities (12), an empirical approach, whereas the nOe is quantitative in determining points of configuration. Finally, saturation of H-11 proves that H-12 is α to the ring, as expected, since an nOe is not observed for H-12 (Fig. 3C).

In conclusion, homonuclear decoupling experiments, inversion recovery experiments, as well as difference nOe measurements were required to completely assign the 400 MHz ^1H nmr spectrum of prostacyclin. The two protons at C-4 are nonequivalent even though they are removed by 5 bonds from the asymmetric centres at C-8 and C-9. The effective rotational correlation times indicate that the portion of the molecule from H-5 to H-15 possesses a greater rigidity than the side chain protons H-2 or H-17 to H-19. Finally, the difference nOe measurements verify the configuration at C-5.

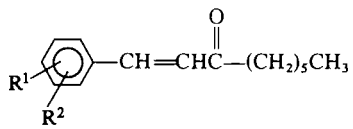
Received November 19, 1979

J. R. DIMMOCK, L. M. SMITH, and P. J. SMITH. Can. J. Chem. **58**, 984 (1980).

The second order rate constants for the reaction of ethanethiol with a number of conjugated nuclear-substituted styryl ketones and related Mannich bases in 50% aqueous acetonitrile was undertaken. Variation of the alkyl group adjacent to the carbonyl function was accompanied by altered avidity to ethanethiol which was explained as being due in part to the varying inductive effects of the alkyl groups which would, in turn, affect the stability of the reaction intermediates. The greatest disparity in reactivity between groups of compounds was between the ketones and analogous Mannich bases which was in accord with the marked difference in bioactivities between these two groups of compounds.



J. R. DIMMOCK, L. M. SMITH et P. J. SMITH. Can. J. Chem. 58, 984 (1980).

On a entrepris l'étude des constantes de vitesse de deuxième ordre de la réaction de l'éthanethiol avec un certain nombre de styrylcétones conjuguées ayant des substituants sur le noyau, et avec les bases de Mannich apparentées dans l'acétonitrile aqueux à 50%. Un changement du groupe alkyle adjacent au carbonyle s'accompagne d'une altération de l'avidité pour l'éthanethiol. Ce fait est attribué en partie au changement d'effets inductifs des groupes alkyles qui a leur tour affecte la stabilité des intermédiaires de la réaction. Du point de vue de la réactivité entre les groupes de composés, on observe la plus grande disparité entre les cétones et les bases de Mannich analogues ce qui est en accord avec la différence profonde de bioactivités entre ces groupes de composés.

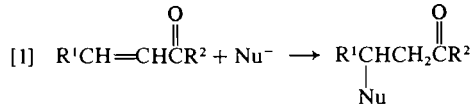
Introduction

A large number of α,β-unsaturated ketones have a wide spectrum of biological activities (1) including antitumour properties (2–4). Some of the enones prepared in our laboratories and evaluated as candidate anticancer drugs were the styryl ketones **1** and their corresponding Mannich bases **2**, which showed a marked disparity in biological properties (2). While the ketones were either inactive or possessed only marginal potencies versus a tumour cell line in mice and were bereft of murine toxicity, the Mannich bases **2** were active in an *in vitro* screen, showed pronounced toxicities to mice, and certain of the compounds displayed significant potencies against tumours in mice. The question was therefore raised as to the reason for this dramatic change in biological activities produced by molecular modification of **1** to the Mannich bases **2**.



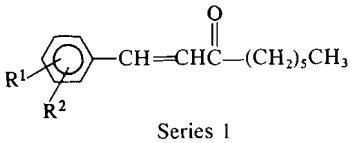
1 (R = H, Cl, $N(CH_3)_2$)

2 (R = H, Cl)

The biological activities of molecules containing the α,β-unsaturated carbonyl group have been attributed to reactivity towards cellular thiols (5–7). It was decided, therefore, to react certain members of series **1** and **2** with a model thiol, ethanethiol, under similar reaction conditions. A similar reactivity of **1** and **2** with the thiol would lead one to assume that other chemical or physicochemical parameters may be important in explaining the differences in bioactivities of **1** and **2**, while a marked increase in chemical reactivity of **2** would imply a greater reactivity for certain cellular nucleophiles.

Nucleophilic attack by anions on α,β-unsaturated carbonyl compounds, eq. [1], is known

[1] $R^1CH{=}CHCR^2 + Nu^- \longrightarrow R^1CHCH_2CR^2$ (Nu)



as the Michael reaction and has been extensively studied primarily because of its synthetic usefulness (8–12). To our knowledge there have been

very few kinetic studies on the reaction of a neutral nucleophile on an α,β-unsaturated ketone (13, 14). Accordingly, the present investigation involved firstly the reaction of ethanethiol with a series of ring-substituted hexyl styryl ketones, **3–11**, series 1, as well as several styryl ketones possessing varying alkyl groups **12–15**, series 2, and secondly the reaction of some of the corresponding Mannich bases **16–21**, series 3 and 4, in buffered solution at several pH values in order to evaluate the electronic and stereochemical factors which govern the rate of the addition reaction.

Results

A series of α,β-unsaturated ketones **3–15** were prepared and in all cases they were shown to be the *E*-isomer. The rate constants, k_2, for the reactions of these compounds with ethanethiol in a buffered 50% acetonitrile–water[2] solvent at 37°C at several pH values are shown in Table 1.

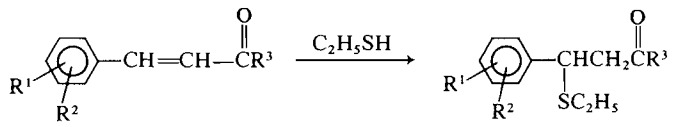
It was found in all cases that the substrates were stable under the conditions employed in the absence of thiol and, as well, the adducts **23** were formed quantitatively and did not undergo elimination under the reaction conditions. The reactions were studied under pseudo first order conditions with the thiol present in large excess.

23 $R^1 = R^2 = H$, Cl; $R^3 = H$, CH_3; $R^4 = H$, $(CH_2)_4CH_3$, $(CH_2)_3CH_3$

A Hammett plot of log k/k_0 versus σ was carried out for the reaction of the styryl ketones **3–11** from which a ρ value of $+1.59 \pm 0.07$ was obtained. It should be noted that compounds with *ortho* substituents are less reactive than the analogous *para*-substituted isomer. The Hammett ρ value for the reaction of ethanethiol with **12** and **13** was calculated to be +1.56 and with **14** and **15** it was found to be +1.16.

Several Mannich bases corresponding to the styryl ketones **3–15** were prepared and their rate constants determined under the same conditions as for the ketones except that the increased reactivity of the Mannich salts relative to the ketones necessitated the use of a lower concentration of the thiol. The Mannich bases, like the ketones, were shown to be the *E*-isomers. The rate constants, k_2, are shown in Table 2.

All of the Mannich salts **16–20** were stable in the solvent system employed in the absence of thiol. However, in the case of **21**, elimination occurred at a significant rate in the absence of ethanethiol to give the corresponding olefin, eq. [2].



The reaction of the Mannich salts with ethanethiol in buffered solution was not as straightforward as the reaction of the corresponding ketones. While the ketones reacted smoothly with thiol to completion and an excellent pseudo

[2]This solvent was necessary in order to permit solubility of the reactants and buffer salts.

value was found to be $+1.01 \pm 0.13$. The Hammett value for the reaction of compounds **19** and **20** with ethanethiol was calculated to be +1.06.

Discussion

As Table 1 indicates, the rate constants for the thiol addition increase as the alkyl moiety of the ketones is varied from 1-methylpentyl to *n*-hexyl to methyl; i.e., the k_2 values for **12**, **3**, and **14** are 0.814, 1.67, and 5.10, respectively. Since it has been established that all the ketones exist exclusively as the *E*-isomer, molecular models reveal that steric variation of the alkyl group would be unlikely to affect the rate of attack of the thiol at the olefinic carbon atom. It is noteworthy that for the reaction of the ring-substituted ketones in series 1, the only point which fell significantly from the Hammett plot was that of the 2,6-dichloro compound, **8**. Presumably a steric effect is involved for reaction of this substrate with thiol.

It is reasonable to suggest that the alkyl groups to some degree affect the rate of reaction by an inductive effect. A consideration of the Taft σ^* values indicates that the 1-methylpentyl side chain is a better electron donor than the *n*-hexyl and methyl groups. The possible intermediate, **26**, in the addition process will consequently be of higher energy when the electron donating power of R is increased and hence the rate of reaction will be decreased.

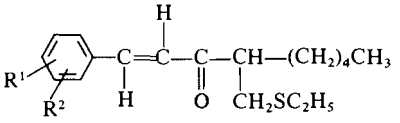
26

It is unlikely, however, that the alkyl side chain R affects the rate of formation of **26** purely by an inaffects the rat of formation of **26** purely by an inductive effect. Undoubtedly, to some degree, the change in the R group leads to a change in the rate by means of a solvation effect. The larger alkyl groups will cause a greater disruption of solvent structure than methyl and also a reduction in solvent stabilization of the developing negative charge at the transition state.

Examination of the ρ values obtained for the three series of ketones where the alkyl group was changed is consistent with the effect of the R groups on the rate of reaction. The 1-methylpentyl and hexyl groups confer lower reactivity on the conjugated α,β-unsaturated ketones than the methyl group and hence the reactivity of the two former series of compounds will be more dependent on nuclear substituents and a larger ρ value would be predicted. The observed ρ values for the ketones in which the alkyl group is 1-methylpentyl, *n*-hexyl, and methyl were found to be 1.56, 1.59, and 1.16, respectively, and the results obtained are therefore in accord with the reactivity–selectivity principle (15, 16).

In order to gain an insight into the nature of the attacking nucleophile onto the α,β-unsaturated ketones, the second order rate constant for the addition reaction of **3** and **9** was determined at pH values of 7.4,[3] 7.0, and 6.4 (Table 1). It was found that the k_2 values for **3** and **9** at pH 7.0 and 6.4 were approximately 40% and 10% of the value obtained at pH 7.4. This observation may be rationalized in that by lowering the pH the concentration of ethanethiol anion, $C_2H_5S^-$, is also lowered and hence attack at the olefinic carbon is retarded.

A comparison of the rate constants for addition to the ketones, Table 1, with the corresponding rate constants for addition to the Mannich salts, Table 2, shows that the Mannich bases are considerably more reactive to thiol addition than the related ketones. Since the nitrogen of the Mannich salt will be significantly protonated at the pH values of the present experiments, the protonated ammonium group will inductively stabilize the intermediate of addition **26** leading to a faster reaction. It should be noted that for the Mannich salts **16** and **19** where R^3 is changed from hydrogen to methyl, a rate decrease is observed, Table 2, in agreement with the observations noted for the corresponding ketones. It is reasonable to expect that solvation effects are important for the reaction of the Mannich bases, as for the ketones. Such effects probably account, to a significant extent, for the difference of reactivity noted for the ketones and their corresponding Mannich bases.



The ρ values for the two Mannich systems, namely series 3, compounds **16–18**, and series 4, compounds **19** and **20**, were found to be 1.01 and 1.06, respectively. The decrease in ρ value when the electron-withdrawing ammonium group is placed in the alkyl side chain compared to that for the analogous ketones is reasonable since this electron-withdrawing group increased the rate of reaction and hence the selectivity, as measured by ρ, is decreased.

The Mannich salts, like the ketones, were less reactive with ethanethiol when the pH of the buffered solution was lowered. As the results in Table 2 indicate, the reactivity of the thiol with two of the Mannich bases **16** and **18** at pH 7.0 and 6.4 was approximately 50% and 20%, respectively, of that of the rate at pH 7.4. This would support the view of

[3]Experiments were initially performed at pH 7.4 in order to simulate physiological conditions.

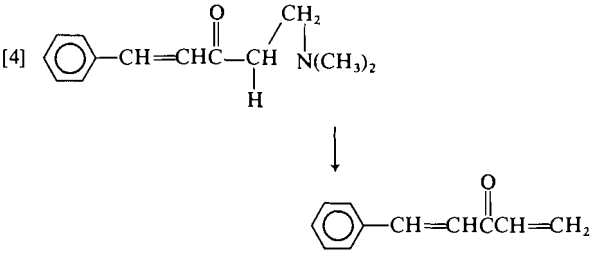
the ethylthio anion, $C_2H_5S^-$, being the nucleophile in the addition reaction of the styryl ketones as well as the related Mannich bases. The literature describes the reaction of thiolate ions with unactivated aryl halides in hexamethylphosphoramide (17) but no evidence of nucleophilic aromatic substitution by the $C_2H_5S^-$ anion in the case of the ring-chlorinated ketones or Mannich bases was found. In addition, while the possibility exists of the direct displacement of the onium group in the Mannich salts by thiol to produce **27** and **28**, this did not occur in the present study.

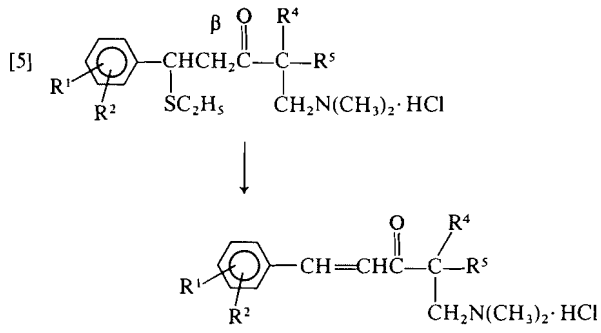
27 $R^1 = R^2 = H$
28 R^1 = 3-Cl; R^2 = 4-Cl

The possible role of the nitrogen atom of the Mannich bases acting as a nucleophile with intramolecular attack of the α,β-unsaturated group must be considered. This effect would be more pronounced at higher pH values and, indeed, the rate is greater for reactions carried out at pH 7.4 rather than at 6.4. That the amine nitrogen is not involved as a nucleophile, however, is shown by the fact that the quaternary ammonium analogue of Mannich salt **18**, prepared by quaternization of the Mannich base with methyl halide, was only slightly less reactive than **18**; i.e., $k_2 = 0.0801$ and 0.190 for the quaternary ammonium compound and **18**, respectively.



As indicated previously, the reaction of the Mannich salts with thiol is more complex than the corresponding reaction with the ketones. While the ketone reaction was straightforward and proceeded to completion, the reaction of the Mannich bases with thiol gave a linear kinetic plot to only 30% reaction and this process did not reach completion. A consideration of the possible elimination reaction of the Mannich salts when $R^4 = H$ to give the alkene

29



29 must be considered, eq. [3]. That this elimination process is not significant is shown by the fact that the Mannich salts, where $R^4 = H$ and CH_3, have similar reactivities and behave kinetically in an identical manner. When $R^4 = CH_3$, elimination to give **29** is not possible.

It has been proposed (18, 19) that elimination from Mannich salts proceeds intramolecularly with the free amine nitrogen acting as the abstracting base. Even though the amine nitrogen would be significantly protonated under the pH conditions of the current study, it was found that the Mannich salt **21**, where $R^4 = R^5 = H$, underwent elimination at a very fast rate in the absence of thiol, eq. [2], whereas **16** with $R^4 = H$ and R^5 = pentyl was stable under the same conditions. Presumably, the ability of the nitrogen base to remove the hydrogen would be more favoured sterically when $R^4 = R^5 = H$, eq. [4], if the reaction proceeds intramolecularly.

The addition of thiol to the Mannich salts did not proceed to completion but, in fact, equilibrium was attained. The addition product from the reaction of salt **16** with thiol eliminated to give the α,β-unsaturated carbonyl compound **16**, i.e., $k_r = 1.42 \times 10^{-4}$ s^{-1}. The equilibrium constant $K = k_2/k_r$ is therefore 3.2×10^2 M^{-1}. The reversal of the addition process is more favourable for the Mannich salts than for the ketone series possibly due to the increased acidity of the β-hydrogen when the strong electron-withdrawing ammonium group is incorporated into the molecule, eq. [5].

In conclusion, these studies indicate that dramatic differences in avidity of a model nucleophile, ethanethiol, exist between styryl ketones and the related Mannich bases. Thus the five Mannich bases **16–20** react on average approximately 240 times more quickly than the analogous ketones **3**, **8**, **9**, **12**, and **13**, respectively, and this differential in chemical reactivity may explain the marked difference in bioactivities between the two series of compounds. It should be noted, however, that the rate of attack of ethanethiol by the Mannich bases is appreciably slower than the rate of attack by an established SH-alkylator, *N*-ethylmaleimide.

Experimental

Nuclear magnetic resonance spectroscopy was carried out using a Varian T-60 spectrometer by running the spectrum of the compound in deuterochloroform, unless otherwise stated, at room temperature with tetramethylsilane as the internal standard. Infrared spectra were run as films using a Beckman AccuLab 4 machine. Ultraviolet spectroscopy was undertaken utilizing a Gilford 250 spectrophotometer. Mass spectra were determined with an MS-12 spectrometer by Christine Nicholaichuk, Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon. Melting points and boiling points are uncorrected. Elemental analyses were obtained by R. E. Teed, Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon. Organic extracts were washed with water, dried over anhydrous magnesium sulphate, and the solvent removed *in vacuo* with a rotary film evaporator. Fisher reagent grade acetonitrile was dried (anhydrous calcium chloride) and distilled prior to use while the *N*-ethylmaleimide employed in this study was the gold label variety purchased from Aldrich. Thin-layer chromatography was undertaken using Eastman chromatogram alumina sheets of 100 μm thickness.

Syntheses of Nuclear Substituted Styryl Ketones (3–15) and Related Mannich Bases (16–22)

Compounds **3**, **4**, **6–9**, and **11** were prepared by the literature procedure (20), compound **5** by the previously reported method (2), compounds **12** and **13** were obtained by the method described earlier (21), and compound **14** by the literature method (22). The Mannich bases **16–18** were prepared by the literature procedure (23), **19** and **20** by a previously described method (21), and **21** by the literature method (24). The quaternary ammonium compound derived from the free base of **18** was prepared according to the literature procedure (22). The remaining compounds were prepared as follows and the physical data are given in Table 3.

1-(*p*-Methylphenyl)-1-nonen-3-one, **10**, was prepared by the literature procedure (20), crystallizing from petroleum ether (bp 30–60°C), as shiny, colourless plates.

1-(3,4-Dichlorophenyl)-1-buten-3-one, **15**, was prepared as follows. A mixture of 3,4-dichlorobenzaldehyde (0.5 g, 0.003 mol) and 1-triphenylphosphoranylidene-2-propanone (1.0 g, 0.003 mol) in benzene (50 mL) was heated under reflux for 24 h. Evaporation of the solvent produced a semisolid which was triturated with ether. The solid was removed by filtration, and evaporation of the ether gave a yellow oil which solidified on cooling. Recrystallization of the solid from petroleum ether (bp 30–60°C) gave **15** as beige needles.

1-(3,4-Dichlorophenyl)-5-dimethylamino-1-penten-3-one hydrochloride **22** was prepared from **17** by the literature method (23) and crystallized from acetone as pale yellow granular crystals. No melting point was obtained as the compound decomposed on heating.

Preparation of the Thiol Adducts of Nuclear Substituted Styryl Ketones 23, and Related Mannich Bases 24, 25

Thiol adducts of the unsaturated ketones **3**, **4**, **6**, **7–9**, and **12–15** were prepared in quantitative yield and the structures verified by elemental analysis.[4] Details of the preparation of one of the compounds, **23** ($R^1 = R^2 = R^3 = H$; $R^4 = (CH_2)_5CH_3$), exemplifies the generality of this reaction.

A mixture of 1-phenyl-1-nonen-3-one, **3** (20 g, 0.09 mol) and ethanethiol (5.6 g, 0.09 mol) in benzene (75 mL) containing two to three drops of piperidine was heated under reflux for 24 h. Evaporation of the solvent gave a yellow oil, which on distillation produced 1-ethylthio-1-phenyl-nonan-3-one, as a pale yellow oil. Mass spectrum *m/e*: 278 (M^+), 218, 113.

The Mannich bases **16** and **18** were converted to the corresponding thiol adducts by the following general method. A mixture of the Mannich bases as the hydrochloride salts (0.01 mol) and ethanethiol (0.015 mol) in ethanol (50 mL) containing two to three drops of piperidine was heated at 40°C for 48 h. The solvent was removed and, on cooling, the resultant solid was triturated with petroleum ether (bp 30–60°C) to give waxy yellow solids which were recrystallized from acetone as fluffy colourless crystals producing **24** and **25**. The physical data for these two compounds is found in Table 3.

Syntheses of 4-Ethylthiomethyl-1-phenyl-1-nonen-3-ones 27, 28

The following general method was employed in preparing these thio derivatives from **16** and **18**, respectively. A mixture of the Mannich base (0.01 mol) and ethanethiol (0.015 mol) was heated under reflux in xylene (50 mL) for 5 h. The solvent was removed, giving a viscous oil which was distilled producing the desired products **27** and **28** as pale yellow oils. The physical data for these two compounds are found in Table 3.

Determination of the Rates of Reaction of Ethanethiol with the Nuclear Substituted Styryl Ketones 3–21

The ketones **3–15** were reacted with ethanethiol under the following conditions. The appropriate ketone (10^{-3} *M*) was dissolved in approximately 23 mL of the acetonitrile–phosphate buffer in a 25 mL volumetric flask heated in a water bath at 37 ± 0.1°C. At the commencement of the reaction ($T = 0$), ethanethiol (300 μL) was added and the volume of the reaction mixture adjusted to 25 mL. At regular time intervals, a 1.0 mL aliquot was diluted to 10.0 mL with 50% aqueous ethanol and 1.0 mL of this solution was further diluted to 25 mL. Absorbance readings of this solution were taken at the appropriate absorption maxima of the ketone.

In the case of the Mannich bases **16–20**, the appropriate compound as the hydrochloride salt (10^{-3} *M*) was dissolved in the acetonitrile–phosphate buffer mixture and the volume adjusted to 25.0 mL. In a separate flask, ethanethiol (100 μL) was dissolved in the same solvent and diluted to 25.0 mL. A portion of the Mannich base salt solution (1.0 mL) was placed in 25.0 mL volumetric flask heated at 37°C in a water bath. At the commencement of the reaction, ethanethiol solution (1.0 mL) was added to the heated solution and the volume adjusted to 25.0 mL. At regular time intervals, aliquot portions (1.0 mL) of the mixture were diluted to 10.0 mL with 50% aqueous ethanol and the absorbance recorded at the absorbance maxima of the

[4]Details of the boiling points and elemental analyses of these thiol adducts are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Mannich base hydrochlorides. The kinetic data were obtained during the early stages of the reaction and the optical density at infinity was taken as zero, assuming the reaction proceeded to completion. The rate constants obtained by this procedure agreed very well with the rate constants determined by the initial slope method and hence can be ascribed to the forward reaction.

The kinetic runs were carried out in triplicate under pseudo first order conditions. The best fit of the line to the points was obtained by a least-squares treatment of the data using an HP 2000 computer. The second order rate constants, k_2, were obtained by dividing the values of k_1 by the concentration of ethanethiol. The acetonitrile–phosphate buffer mixtures were prepared as follows. A solution of monobasic sodium phosphate monohydrate (9.30 g) in double distilled water was adjusted to 1000 mL (solution A) and a solution of dibasic sodium phosphate heptahydrate was prepared by dissolving the salt (17.88 g) in water and diluting to 1000 mL (solution B).

A mixture of acetonitrile (500.0 mL) and solution A (280.0 mL) was placed in a 1000 mL volumetric flask and solution B was added to 1000 mL. The pH of the resultant solution was 7.40. The acetonitrile buffer solutions of 7.00 and 6.40 were prepared in a similar manner, except that the amounts of solution A were 389.0 and 490.0 mL respectively. These buffer solutions were stable for a period of at least two months. No sodium chloride was added to these solutions due to its preventing complete solubility of the ketones.

The products obtained by reacting ethanethiol with the styryl ketones and Mannich bases were identified as follows. Reaction between 1-phenyl-1-nonen-3-one and ethanethiol occurred under identical conditions to that of the kinetic procedure. The mixture was extracted with chloroform and removal of the solvent produced an oil shown by infrared and nmr spectroscopy as well as mass spectrometry to be 1-ethylthio-1-phenyl-nonan-3-one.

Reaction of ethanethiol and 1-(3,4-dichlorophenyl)-4-dimethylaminomethyl-1-nonen-3-one hydrochloride, **18**, occurred as described previously whereby approximately 30% of the Mannich base had reacted. The reaction mixture was extracted with chloroform and evaporation of the solvent *in vacuo* produced an oil which was examined by thin-layer chromatography. Using petroleum ether (bp 60–80°C) as the developing solvent, four spots with R_f values of 0.41, 0.62, 0.68, and 0.80 were observed. Under these conditions, 1-(3,4-dichlorophenyl)-4-dimethylaminomethyl-1-ethylthio-1-nonane, **25**, gave an R_f value of 0.68 and the hydrochloride salt a value of 0.62. The unreacted Mannich free base had an R_f value of 0.80 and the hydrochloride salt one of 0.41 under these conditions, while both 1-(3,4-dichlorophenyl)-4-methylene-1-nonen-3-one, **29** (R^1 = 3-Cl; R^2 = 4-Cl, $R^5 = (CH_2)_4CH_3$), and 1-(3,4-dichlorophenyl)-4-ethylthiomethyl-1-nonen-3-one, **28**, move with the solvent front. In order to confirm the absence of these latter two compounds, thin-layer chromatography using petroleum ether (bp 30–60°C) of the reaction product was undertaken and four spots with R_f values of 0.26, 0.32, 0.38, and 0.47 were observed. Under these conditions, 1-(3,4-dichlorophenyl)-4-methylene-1-nonen-3-one and 1-(3,4-dichlorophenyl)-4-ethylthiomethyl-1-nonen-3-one had R_f values of 0.54 and 0.36, respectively, and the unreacted free Mannich base and hydrochloride salt had R_f values of 0.47 and 0.26, respectively, while the free Michael adduct and its hydrochloride salt had R_f values of 0.38 and 0.32, respectively.

An examination of the stability of the reactants and products was undertaken. The ketones **3**, **9**, **12–15**, as well as the Mannich base hydrochlorides **16–20**, were dissolved in the acetonitrile–phosphate buffer solution, pH 7.40, and heated at 37°C for the length of the period of the reaction. No change in absorbance was observed. In addition, the thiol adducts of the ketone, **23**, were found to be stable under the reaction conditions. The thiol adduct of the Mannich base, **25**, reverted slowly to the precursor Mannich base, **18**, under the same conditions as the reaction of the Mannich bases with ethanethiol. The k_1 value for this adduct was found to be $1.42 \times 10^{-4}\ s^{-1} \pm 5.78\%$ by following the increasing absorbance of the Mannich base.

The order of reaction between ethanethiol and these enones under the experimental conditions employed was investigated. Three different concentrations of the styryl ketone **3** (2.28, 3.87, and 5.75×10^{-3} *M*) were reacted with the same concentration of ethanethiol, namely 1.62×10^{-1} *M*, while three different concentrations of the Mannich base **16** (1.08, 1.85, and 2.63×10^{-4} *M*) were each reacted with ethanethiol (6.49×10^{-3} *M*). The order of reaction of both compounds with respect to ethanethiol was shown to be one. Similarly, three different concentrations of ethanethiol (1.62, 2.16, and 2.70×10^{-1} *M*) were reacted with **3** (5.55×10^{-3} *M*) and three different concentrations of ethanethiol (6.49, 7.57, and 8.65×10^{-4} *M*) were reacted with **18** (2.10×10^{-5} *M*) and the order of reaction was likewise shown to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

be one. In all of these experiments, the concentration of thiol was at least twentyfold in excess.

N-Ethylmaleimide was shown to be stable in the acetonitrile–phosphate buffer mixture, pH 7.40, over a 24-h period at 37°C. Reaction of *N*-ethylmaleimide with ethanethiol under the reaction conditions employed for thiol reaction with the ketones **3–15** showed that the reaction proceeded too fast to measure in the same manner as previously undertaken. However the reduction in the absorption maxima of *N*-ethylmaleimide at 300.5 nm was observed (25) and indicated that the reaction was at least 97% complete within 64 s.

Received September 13, 1979

UPENDRA NATH DASH and SURENDRA KUMAR NAYAK. Can. J. Chem. **58**, 992 (1980).

From the emf measurements of the buffered cell

$$Ag,AgCl/KCl(m_3),KOBz(m_2),HOBz(m_1),chloranil/Pt$$

the standard potentials of the chloranil electrode have been determined in formamide at 15, 25, 35, and 45°C. The standard molal potential of the chloranil electrode has been expressed through the equation

$$E_m^0 = (3.8042 \pm 0.0001) - (10.538 \pm 0.0003) \times 10^{-2}T + (183.455 \pm 0.001) \times 10^{-4}T \ln T - (61.049 \pm 0.006) \times 10^{-6}(T^2/2)$$

The standard thermodynamic quantities, ΔG^0, ΔH^0, ΔS^0, and ΔC_p^0 for the electrode reaction have been calculated from the standard molal potential, E_m^0 of the electrode at these temperatures.

UPENDRA NATH DASH et SURENDRA KUMAR NAYAK. Can. J. Chem. **58**, 992 (1980).

On a déterminé les potentiels normaux d'une électrode de chloranil dans le diméthylformamide à 15, 25, 35 et 45°C à partir des mesures de la fem d'une cellule tamponée de

$$Ag,AgCl/KCl(m_3),KOBz(m_2),HOBz(m_1),chloranil/Pt$$

Le potentiel molaire normal de l'électrode de chroranil peut être représenté par l'équation:

$$E_m^0 = (3.8042 \pm 0.0001) - (10.538 \pm 0.0003) \times 10^{-2}T + (183.455 \pm 0.001) \times 10^{-4}T \ln T - (61.049 \pm 0.006) \times 10^{-6}(T^2/2)$$

On a calculé les quantités thermodynamiques ΔG^0, ΔH^0, ΔS^0, et ΔC_p^0 pour la réaction à l'électrode à partir du potentiel molaire normal, E_m^0, de l'électrode à ces températures.

[Traduit par le journal]

Introduction

A survey of the literature (1, 2) shows that the chloranil electrode in conjunction with the hydrogen or the silver – silver chloride electrodes has been studied in aqueous, mixed aqueous, and non-aqueous media at 25°C, and the standard potential of this electrode was reported in water (0.664 V), 50% aqueous alcohol (0.664 V), glacial acetic acid (0.680 V), and 50% aqueous dioxane (0.715 V) at this temperature. But the original study of the chloranil electrode by Conant *et al.* (1) led to the assumption that the potential of the saturated chloranil electrode against the hydrogen electrode is independent of the solvent, and for some time this might be a plausible factor for its study in other solvents. However, later studies reporting different values for the potential of this electrode in glacial acetic acid and in 50% aqueous dioxane indicated invalidity of this assumption and inspired the present authors to study this electrode in formamide, a solvent closely resembling water from the point of dielectric constant and viscosity.

The cells without liquid junction involving silver – silver chloride and quinhydrone electrodes have been widely used in formamide (3) for the determination of ionization constants of various acids in this solvent. The acetic acid – acetate and benzoic acid – benzoate buffer cells have been successfully employed in this solvent for evaluation of the standard potentials of the silver – silver halides (4) and the silver – silver thiocyanate electrodes (3*e*) by using the quinhydrone electrode as the standard reference half-cell in these buffer cells.

In the present study, we have employed the benzoic acid – benzoate buffer cell involving the silver – silver chloride and chloranil electrodes, and accordingly the cell studied was

[A] $Ag,AgCl/KCl(m_3),KOBz(m_2),HOBz(m_1),chloranil/Pt$

Experimental

The preparation of silver – silver chloride electrode has been described earlier (5). Chloranil electrodes were prepared according to Hall *et al.* (6). Chloranil was a "Loba Chemie Wien – Fischamend Austranal-Praparate" sample. The cell vessels are of the type recommended by Harned and Wright (7).

Benzoic acid, potassium benzoate, and potassium chloride were the same samples as used in earlier studies (3*e*). Formamide (B.D.H., L.R.) was purified as described elsewhere (8).

Solutions for emf measurements were prepared by dissolving

the appropriate weighed amounts of salts and acid in known weights of formamide.

The setting up of the cell [A] was similar to that of the cell involving the quinhydrone and silver – silver chloride electrodes (*3a*) except that the saturated solution of chloranil – formamide salts and acid was warmed to 50°C in order to have an adequate saturation of chloranil and then cooled to room temperature (*6c*) and subsequently transferred to the chloranil compartment of the cell in which the platinized platinum electrode had previously been placed under a dry nitrogen atmosphere. The silver – silver chloride electrode was placed in the appropriate cell compartment which had first been thoroughly rinsed and then filled with formamide solution which was previously warmed to 50°C and cooled to room temperature with a view to having an identical experimental condition with that of the chloranil solution. After filling, the cell was kept in the thermostat at the required temperature with an accuracy of ±0.1°C.

Electromotive force measurements were made with a Bajaj (India) potentiometer in conjunction with a dc galvanometer (OSAW) and a Western standard cell (Muirhead and Co., England). The reproducibility was of the order of ±0.2 mV.

Results and Discussion

A summary of emf data of the buffered cell was presented in Table 1 along with other data at 15, 25, 35, and 45°C.

Standard potential of the chloranil electrode from the study of the buffered cell was found by almost an identical procedure as adopted in previous studies (*3e*, 4).

The auxiliary function, $E_m^{0\prime}$, was calculated with the help of the equation

$$[1]\quad E_m^{0\prime} = E_m^0(\mathrm{Ag/AgCl}) - E + 2.3026(RT/F) \times [\mathrm{p}K_a - \log(m_1 m_3/m_2)] = E_m^0 - 2.3026(RT/F)\log[\gamma(\mathrm{HOBz}) \times \gamma(\mathrm{Cl^-})/\gamma(\mathrm{OBz^-})] = E_m^0 + f(I)$$

and the standard molal potential, E_m^0, of the chloranil electrode was found by method of extrapolating (9–11) $E_m^{0\prime}$ (Fig. 1) to zero ionic strength, $I = 0$ (here, $I = m_2 + m_3$), as $\log[\gamma(\mathrm{HOBz})\gamma(\mathrm{Cl^-})/\gamma(\mathrm{OBz^-})]$ tends to zero. The symbols in eq. [1] have their usual significance. The values of E_m^0(Ag/AgCl) and that of pK_a for benzoic acid needed for calculation are known in formamide at the temperatures under investigation (*3b*, *3e*, 12).

The values of E_m^0 of the chloranil electrode, thus obtained are presented in Table 1. The values of the standard deviations calculated by the least-squares method are also included in Table 1. The values for the standard potential on the molar (E_c^0) and mole-fraction (E_N^0) scales have also been calculated at experimental temperatures by the usual equations (13)

$$[2]\quad E_N^0 = E_m^0 - 2(2.3026RT/F)\log(1000/M)$$

and

$$E_c^0 = E_m^0 + 2(2.3026RT/F)\log\rho$$

where M and ρ are the molecular weight and density, respectively, of formamide. The variation of the standard potential in molal (E_m^0), molar (E_c^0), and mole-fraction (E_N^0) scales with temperature has been expressed through the equations of the type,

$$[3]\quad E_x^0 = A + BT + CT\ln T + DT^2/2$$

where x is m, c, or N, and T is the temperature in K. The parameters A, B, C, and D in eq. [3] on different scales are presented in the following chart along with their standard deviations calculated by least-squares method.

x	A	-10^2B	10^4C	-10^6D
m	3.8042±0.0001	10.538±0.0003	183.455±0.001	61.049±0.006
c	12.0532±0.0003	41.932±0.002	733.944±0.014	244.738±0.707
N	3.8265±0.0001	10.608±0.001	183.486±0.002	60.559±0.828

A comparison of the standard potential of the chloranil electrode obtained in formamide at 25°C (0.8360 V) with those reported in water (0.664 V), 50% aqueous alcohol (0.664 V), glacial acetic acid (0.680 V), and 50% aqueous dioxane (0.715 V) at this temperature shows that the E_m^0 value is higher in formamide than in other solvents.

It is thus clear that these differences in the E_m^0 values obtained in different media are due to the fact that tetrachlorohydroquinone is solvated in certain solvents and any change in E_m^0 value on passing from water or other solvents to formamide will be due to variation of solvation. It is, however, known (2) that in glacial acetic acid tetrachlorohydroquinone forms the solid solvate $C_6Cl_4(OH)_2 \cdot 2CH_3COOH$, while in 50% aqueous dioxane it forms the solid solvate $C_6Cl_4(OH)_2 \cdot C_4H_8O_2$. Unfortunately, the present work does not provide a means of examining

the solid phase in equilibrium with the saturated solution in formamide, however, the ΔG^0 values computed at 25°C from the relation,

$$[4] \quad \Delta G^0 = -nFE_m^0$$

for the electrode reaction

$$\text{Tetrachlorobenzoquinone(s)} + H_2(g) + \text{solvent} \rightleftharpoons \text{tetrachlorohydroquinone(solvated)} + 2e$$

in water (-128.14 kJ mol^{-1}), glacial acetic acid (-131.23 kJ mol^{-1}), 50% aqueous dioxane (-137.98 kJ mol^{-1}), and formamide (-161.33 kJ mol^{-1}) show that any change in ΔG^0 on passing from water to formamide will be due to variation of free energy of solvation. The higher free energy due to solvation of tetrachlorohydroquinone in formamide in comparison with those in water, glacial acetic acid, or 50% aqueous dioxane may be due to the fact that tetrachlorohydroquinone is more solvated in formamide than in other media. This is consistent with the result obtained in the case of quinhydrone electrode in formamide (9).

The standard Gibbs energy change, ΔG^0, for the electrode reaction calculated on the molal scale by means of eq. [4] at different temperatures is expressed by the equation,

$$[5] \quad \Delta G^0 = -A' - B'T - C'T \ln T - D'T^2/2$$

in J mol^{-1}, where A', B', C', and D' are, respectively, nF times A, B, C, and D, the constants in eq. [3]. As usual, the values of the standard entropy change, ΔS^0, were evaluated from the relation

$$\Delta S^0 = -\partial(\Delta G^0)/\partial T$$

and are fitted to the equation,

$$[6] \quad \Delta S^0 = B' + C' + C' \ln T + D'T$$

in J mol^{-1} K^{-1}. Using the ΔG^0 and ΔS^0 values so obtained in the Gibbs–Helmholtz equation ($\Delta G^0 = \Delta H^0 - T\Delta S^0$), the values of ΔH^0 were calculated at different temperatures and have been expressed through the equation

$$[7] \quad \Delta H^0 = -A' + C'T + D'T^2/2$$

in J mol^{-1}. The ΔC_p^0 values were computed for the electrode reaction at different temperatures from

Reactions of bis(ditertiaryphosphine) complexes of rhodium(I) with carbon monoxide, dioxygen, dihydrogen, and hydrogen chloride[1]

BRIAN R. JAMES AND DEVINDER MAHAJAN

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received November 20, 1979

BRIAN R. JAMES and DEVINDER MAHAJAN. Can. J. Chem. **58**, 996 (1980).

The products, resulting from addition under mild conditions of the gaseous molecules CO, O_2, H_2, and HCl, to some rhodium(I)–bis(ditertiaryphosphine) complexes, are described; the P⌒P phosphines used were $Ph_2P(CH_2)_nPPh_2$, n = 1–4, and (+)-diop (diop = 2,3-*O*-isopropylidene 2,3-dihydroxy-1,4-bis(diphenylphosphino)butane). Monocarbonyls were isolated from addition of CO to $Rh(P⌒P)_2^+BF_4^-$ complexes (n = 1 and 3), the reactions being reversible; there was no reaction with the n = 2 system, while the n = 4 and diop systems absorbed > 1 mol of CO per Rh to give mixtures of products. The same cation precursors add O_2 to yield *cis*-$Rh(P⌒P)_2O_2^+BF_4^-$ adducts (n = 1–3), the binding being reversible for the n = 2 system; pure products were not isolated with the n = 4 cation which absorbs 3 mol O_2/Rh; the diop system was unreactive toward O_2. Reversible additions of 1 mol H_2 yield isolable *cis*-$H_2Rh(P⌒P)_2^+BF_4^-$ complexes with the n = 3 and diop systems; the n = 1 and 2 $Rh(P⌒P)_2^+$ cations are unreactive toward H_2, while a mixture of hydrides is formed from the n = 4 species. The chlorohydrido cations $HRh(P⌒P)_2Cl^+A^-$ (A = Cl, BF_4, PF_6, SbF_6), n = 1–3, were prepared via routes involving addition of gaseous HCl to precursor $Rh(P⌒P)_2Cl$ complexes; however, the reactions with the n = 4 and diop systems did not yield pure products.

The solution structures of all the isolated five- and six-coordinate addition products have been determined using ^1H and variable temperature ^{31}P nmr. The five-coordinate carbonyl with n = 1 shows equivalent phosphines from −50 to 25°C, while the n = 3 system shows inequivalent phosphines resulting from a trigonal bipyramidal structure with an equatorial carbonyl. The $HRh(P⌒P)_2Cl^+$ cation, n = 3, has *cis* geometry, while *trans*-structures are preferred for the n = 1 and 2 species.

BRIAN R. JAMES et DEVINDER MAHAJAN. Can. J. Chem. **58**, 996 (1980).

On décrit les produits résultant de l'addition, dans des conditions douces, de molécules de CO, O_2, H_2 et HCl à l'état gazeux sur quelques complexes de rhodium(I) bis(ditertiaryphosphines). On a utilisé les phosphines P⌒P suivantes: $Ph_2P(CH_2)_nPPh_2$, n = 1–4 et (+)-diop (diop = *O*-isopropylidène-2,3 dihydroxy-2,3 bis(diphénylphosphino)-1,4 butane). On a isolé des produits monocarbonylés résultant de l'addition réversible de CO sur les complexes $Rh(P⌒P)_2^+BF_4^-$ (n = 1 et 3). On n'obtient pas de réaction avec le système n = 2 tandis que dans les systèmes où n = 4 et où le groupe diop absorbé est > 1 mol de CO/Rh, on obtient un mélange de produits. Les mêmes précurseurs cationiques additionnent de l'oxygène pour conduire à l'adduit $Rh(P⌒P)_2O_2^+BF_4^-$ *cis* (n = 1–3); le mode de liaison est réversible dans le cas du système n = 2. On n'a pas isolé de produits purs dans le cas du cation n = 4 qui absorbe 3 mol de O_2/Rh. Le système diop ne réagit pas avec l'oxygène. Les additions réversibles de 1 mol de H_2 donnent les complexes $H_2Rh(P⌒P)_2^+BF_4^-$ *cis* que l'on peut isoler avec n = 3 et le système diop. Les cations $Rh(P⌒P)_2^+$ où n = 1 et 2 ne réagissent pas avec H_2 tandis qu'on obtient un mélange d'hydrures à partir des espèces où n = 4. On a préparé les cations chlorohydrido $HRh(P⌒P)_2Cl^+A^-$ (A = Cl, BF_4, PF_6, SbF_6), n = 1–3 en utilisant l'addition de HCl gazeux sur les complexes précurseurs $Rh(P⌒P)_2Cl$. Cependant les réactions avec les systèmes n = 4 et diop ne donnent pas des produits purs.

On a déterminé la structure des solutions de tous les produits d'addition penta et hexacoordonnés en utilisant la rmn du ^1H et celle du ^{31}P à température variable. Les composés carbonylés pentacoordonnés avec n = 1 présentent des phosphines équivalentes entre −50 et 25°C, tandis que les systèmes où n = 3 présentent des phosphines non équivalentes résultant d'une structure trigonale bipyramidale avec un carbonyle en position équatoriale. Le cation $HRh(P⌒P)Cl^+$, n = 3 a une géométrie *cis* tandis que la structure *trans* est privilégée pour les espèces où n = 1 et 2.

[Traduit par le journal]

Introduction

We are currently interested in the activation of small gas molecules by bis(tertiaryphosphine) $Ph_2P(CH_2)_nPPh_2$ complexes of rhodium(I), and reactivity patterns as a function of n, and have reported recently (1) on the synthesis of $Rh(P⌒P)_2X$ complexes,[2] where X is a coordinated or associated anionic moiety including H, Cl, BF_4, PF_6, SbF_6. The complexes effect catalytic hydrogenation of unsaturated carboxylic acids (1), and a report on catalytic decarbonylation of aldehydes using $Rh(P⌒P)_2^+$ cations (P⌒P = dpe and 1,3-bis(diphenylphosphino)propane) appeared (2) after completion of the CO work described in the present paper. The complex $HRh(dpe)_2Cl^+Cl^-$ was noted some years ago to be an extremely effective catalyst for hydrogenation of terminal olefins (3), while the crystal structure of *trans*-$HRh(dpm)_2Cl^+BPh_4^-$ was reported (4) during the preparation of this manuscript. $Rh(dpe)_2O_2^+PF_6^-$ was one of the first reported dioxygen adducts characterized by crystallography (5).

In this paper, we describe the synthesis and the

characterization of rhodium complexes obtained by addition of CO, O_2, H_2, and HCl to a range of $Rh(\widehat{P\ P})_2X$ complexes. The studies are pertinent to the known catalytic hydrogenation and decarbonylation properties and to any potential carbonylation and oxygenation properties. The general synthetic procedures described have been used earlier to synthesize especially a range of corresponding iridium complexes (5–12), while such studies on the rhodium systems have been more limited and less systematic (5, 9, 13–16). There has been particular interest in the solution structure of the five- and six-coordinate iridium complexes (8, 10–12), and we also report here the solution structure of some corresponding rhodium systems. The paper by Baird's group (16) appeared after submission of the present work.

Experimental

Most of the materials, apparatus, and experimental techniques used were described previously in conjunction with the synthesis of the precursor $Rh(\widehat{P\ P})_2X$ complexes, X = Cl, BF_4 (1 and references therein). The gases CO (C.P. grade), HCl (Technical), and H_2 (Prepurified), were Matheson products and were used as provided. O_2 was obtained as Extra Dry grade from Canadian Liquid Air. The stoichiometries of the gas/Rh solution reactions were measured using the constant pressure apparatus described previously (17).

PPh_3 in an appropriate solvent was used as a reference for the low temperature ^{31}P nmr, although all the ^{31}P shifts are reported in ppm (upfield positive) from 85% H_3PO_4.

Carbonyl Complexes

$Rh(\widehat{P\ P})_2CO^+BF_4^-$ ($\widehat{P\ P}$ = dpm, dpp)

CO was bubbled through a CH_2Cl_2 solution (5 mL) of $Rh(dpm)_2^+BF_4^-$ (0.28 g, 0.29 mmol) or $Rh(dpp)_2^+BF_4^-$ (0.30 g, 0.30 mmol). Addition of diethyl ether precipitated a yellow complex that was filtered at 0°C, washed with ether, dried, and stored under a CO atmosphere.

The $Rh(dpe)_2^+BF_4^-$ complex under the same conditions was unreactive toward CO. $Rh(dpb)_2^+BF_4^-$ yielded a yellow complex contaminated with a white powder, ν(CO) at 1962 and 2003 cm^{-1}. Attempts to synthesize $Rh(dpb)_2CO^+Cl^-$ via an exchange reaction using *trans*-$RhCl(CO)(PPh_3)_2$ with excess dpb, a method found successful for iridium analogues (11), also gave a mixture of products with ν(CO) at 1910 and 1941 cm^{-1}.

$Rh(diop)_2^+BF_4^-$ with CO in CH_2Cl_2 again yielded an inseparable mixture with ν(CO) bands at 1976 and 2015 cm^{-1}. Reaction of $Rh(diop)_2Cl$ with CO in benzene followed by addition of ether yielded a yellow complex, **A**, with CO bands at 1926 and 1974 cm^{-1} and a band at 308 cm^{-1} assignable to ν(Rh—Cl), different to that of the starting complex at 284 cm^{-1}; the same CO bands have been reported for the five-coordinate complex[3] $Rh(diop)(diop^*)(CO)_2^+Cl^-$, **B**, prepared by a different route (15). We repeated the literature preparation and obtained a complex with an ir identical to that of **A**. The analyses of the products obtained by either method were always 2–3% low in carbon to correspond to complex **B**.

[3]diop* represents the monodentate diphosphine.

Dioxygen Complexes

Slight modifications of a literature procedure (5) were used to prepare the dioxygen complexes.

$Rh(\widehat{P\ P})_2O_2^+BF_4^-$ ($\widehat{P\ P}$ = dpm, dpe, dpp)

O_2 was bubbled through an orange methanol solution (20 mL) of $Rh(dpm)_2^+BF_4^-$ (0.22 g, 0.23 mmol); the brown solid that separated after a few minutes was filtered, washed with methanol, and dried *in vacuo*. The dpe and dpp analogues at corresponding concentrations separated out on concentrating to a 5 mL volume at 0°C; the filtered solids were washed with diethyl ether and dried *in vacuo*.

A deep red methanol solution (20 mL) of $Rh(dpb)_2^+BF_4^-$ (0.25 g, 0.24 mmol) slowly became brown under O_2 over ~20 h; addition of diethyl ether yielded an impure brown solid with ir bands at 851 cm^{-1} and 1120 cm^{-1}, likely attributable to ν(O_2) and ν(P—O), respectively (18, 19). The $Rh(diop)_2^+BF_4^-$ complex was essentially unreactive toward O_2 under similar conditions.

Dihydride Complexes

$H_2Rh(\widehat{P\ P})_2^+BF_4^-$ ($\widehat{P\ P}$ = dpp and (+)-diop)

H_2 was bubbled for a few minutes through a red CH_2Cl_2 solution (10 mL) of $Rh((\widehat{P\ P})_2^+BF_4^-$ (0.35 mmol). Addition of diethyl ether to the pale yellow solution at 0°C induced crystallization of the white dihydrides. The crystals were filtered, washed with ether, dried, and stored under H_2.

The same procedure using dpb gave a mixture that almost certainly contained some of the $H_2Rh(dpb)_2^+BF_4^-$ complex (ν(Rh—H) 2072 cm^{-1}, τ20.3 (pair of multiplets in $CDCl_3$ at 25°C)). The $Rh(dpm)_2^+$ and $Rh(dpe)_2^+$ cations were unreactive toward H_2 under similar conditions.

Chlorohydrido Complexes

$HRh(\widehat{P\ P})_2Cl^+A^-$ ($\widehat{P\ P}$ = dpm, dpe, dpp; A = Cl, BF_4, PF_6, SbF_6)

The $HRh(dpm)_2Cl^+Cl^-$ complex was obtained as white crystals on bubbling HCl(g) through an orange solution of $Rh(dpm)_2Cl$ or $Rh(dpm)_2^+BF_4^-$ (0.33 mmol) in methanol (15 mL); the solid was filtered, washed with methanol, and dried *in vacuo*. The dpe and dpp analogues were similarly made using ethanol solutions (15 mL) of $Rh(\widehat{P\ P})_2Cl$ (0.40 mmol), but after stirring for a few minutes, excess HCl(g) was removed by a flow of Ar. Concentration to ~5 mL, followed by addition at 0°C of 20 mL diethyl ether, yielded light yellow crystals that were filtered, washed with ether, and dried *in vacuo*. The $HRh(dpe)_2Cl^+Cl^-$ complex has been prepared previously from a precursor Rh(III)–alkyl complex (3).

The $HRh(P\ P)_2Cl^+A^-$ (A = BF_4, PF_6, SbF_6) complexes with dpm, dpe, and dpp, were prepared from CH_2Cl_2 solutions (5 mL) of the chlorides (0.15 mmol) by addition of the AgA salt (0.15 mmol in 5 mL acetone); after filtering off the AgCl, the solution was concentrated to ~2 mL and 3 mL THF then added. Addition of diethyl ether gave products that were filtered, washed with ether, and dried *in vacuo*. Attempts to prepare the $HRh(\widehat{P\ P})_2Cl^+A^-$ complexes by treatment of the chlorides with aqueous HA solutions, a method successful for the iridium analogues (11, 12), were unsuccessful. Addition of 2 mol of AgA salt per $HRh(\widehat{P\ P})_2Cl^+Cl^-$ also yielded the $HRh(\widehat{P\ P})_2Cl^+A^-$ complexes, instead of the expected (12) dicationic species $HRh(\widehat{P\ P})_2^{2+}2A^-$.

Attempts to synthesize pure $HRh(\widehat{P\ P})_2Cl^+A^-$ (A = Cl, BF_4) complexes with dpb and diop proved unsuccessful. The reaction of HCl(g) with solutions of $Rh(dpb)_2Cl$ appeared to yield light yellow mixtures, although ir bands at 2150 cm^{-1}, assignable to ν(Rh—H), and 280 and 290(sh) cm^{-1}, assignable to ν(Rh—Cl), indicated the presence of $HRh(dpb)_2Cl^+Cl^-$, as did a high field broad multiplet at τ26.5 in the ^1H nmr in $CDCl_3$ at 25°C. Simi-

[a]In $CDCl_3$ at 25°C.
[b]Measured in ppm (downfield positive) from TMS in $CDCl_3$, unless stated otherwise; all multiplets unless designated s, singlet.
[c]ν(CO) for the carbonyls; ν(O_2) for the dioxygen complexes; ν(RhH) for the hydrido complexes; Nujol.
[d]Under CO; under Ar, the multiplets of $Rh(\widehat{P\ P})_2^+$ are seen also (1).
[e]In acetone-d_6.
[f]Under O_2; the dpe data refer to $Rh(dpe)_2^+$ due to loss of O_2.
[g]Reference 16 gives τ 18.6 for an *in situ* species.
[h]Pair of multiplets.
[i]Under H_2.
[j]Impure complex.
[k]Reference 13 gives τ 21.5 and ν(Rh—H) 2030 cm^{-1} for the PF_6^- salt.
[l]Data essentially identical for X = Cl or BF_4.
[m]J_{Rh-H} 18.0, J_{P-H} 13.0 Hz, agrees with literature data for the BPh_4^- salt (4); ref. 4 gives ν(Rh—H) = 2080 cm^{-1}.
[n]J_{Rh-H} 15.0, J_{P-H} 6.0 Hz, agrees with literature data (3); ref. 3 gives ν(Rh—H) = 2048 cm^{-1}.
[o]$J_{Rh-H} = J_{P-H}$ = 13.0 Hz agrees with literature data (16); ref. 16 gives ν(Rh—H) = 2090 cm^{-1}.

larly, the presence of $HRh(diop)_2Cl^+Cl^-$ in a mixture was indicated by spectral data: ir at 2130 cm^{-1}, ν(Rh—H); and 278, 290 cm^{-1}, ν(Rh—Cl); ^{1}H nmr ($CDCl_3$ at 25°C) at τ22.0, br multiplet.

Results and Discussion

Oxidative addition or just simple addition of the XY molecules (XY = CO, O_2, H_2, and HCl) to the four- or five-coordinate rhodium(I) complexes $Rh(\widehat{P\ P})_2A$, $\widehat{P\ P}$ = dpm, dpe, dpp, dpb, and diop; A = Cl, BF_4 (1), has been used to synthesize rhodium(I) and rhodium(III) complexes of the type $Rh(\widehat{P\ P})_2(XY)_m^+A^-$. Pure complexes were isolated when m = 1, and Tables 1–3 list analytical, conductivity, and spectroscopic data for these species. The gas:Rh stoichiometry was measured in several solvents for formation of the carbonyl, dioxygen, and dihydride complexes listed in Table 1, and was found to be ~1.0 under 1 atm gas at 25°C in all cases

[a]Measured in ppm (upfield positive) from 85% H_3PO_4. Shifts for the free ligands ($CDCl_3$ or CH_2Cl_2) occur at +22.25 (dpm), +12.52 (dpe), +17.25 (dpp), +15.95 (dpb), and +22.50 (diop).
[b]In CH_2Cl_2/acetone-d_6 (2:1 v/v).
[c]Under CO.
[d]Reference 15 gives δ −15.2, + 12.5; J_{Rh-P} 115, 86; J_{P-P} = 46 for an impure Cl^- salt in CD_2Cl_2.
[e]Data from ref. 11.
[f]Reference 16 gives essentially same data for the Cl^- salt formed *in situ* in CH_2Cl_2.
[g]Under H_2 ref. 16 gives δ −17.0, −6.3; J_{Rh-P} 99.80; J_{P-P} = 30 for the Cl^- salt formed *in situ* in $CDCl_3$.
[h]Under H_2. Slight changes in δ with temperature.
[i]Data essentially identical for X = Cl, or BF_4.
[j]Reference 4 gives δ 15.8 (J = 83) for the BPh_4^- salt.
[k]Doublet of doublet of triplets, not well resolved. Reference 16 gives δ −12.3, +8.9; J_{Rh-P} = 90, 93; J_{P-P} = 35 for the Cl^- salt at −70°C. At room temperature the doublet was at δ −1.9 (J = 90 Hz).

except the $Rh(dpe)_2^+/O_2$ system; the O_2-binding for this system was readily reversible under these conditions and the stoichiometry corresponded, for example, to an equilibrium constant of ~0.5 atm^{-1} (21).

Carbonyl Complexes

The nonreactivity of the $Rh(dpe)_2^+$ cation as a chloride salt toward 1 atm CO has been noted previously (15). The pure $Rh(\widehat{P\ P})_2CO^+$ cations ($\widehat{P\ P}$ = dpm, dpp) have been isolated for the first time as the BF_4^- salts, although the dpp complex has been made by Sanger via a different procedure (15) as the Cl^- salt in a mixture with the binuclear complex $[RhCl(CO)(dpp)_2]_2$. The $Rh(\widehat{P\ P})_2CO^+BF_4^-$ complexes are stable in the solid state, but in solution readily lose CO in a reversible manner to generate the $Rh(\widehat{P\ P})_2^+$ cations (1), as evidenced by loss of the terminal CO band in the ir, and by changes in the visible spectra from continua (increasing absorption on going from 450–350 nm) to λ_{max} at 385 and 446 nm for the dpm salt, and at 412 nm for the dpp salt (1). The $^{31}P\{^1H\}$ nmr data for $Rh(dpp)_2CO^+BF_4^-$ under Ar at 25°C correspondingly show the doublet of the $Rh(dpp)_2^+$ species (1). Under CO at 25°C, the spectrum is a doublet of doublet of triplets broadened at the base suggesting some fluxionality, but this sharpens at −50°C (Fig. 1) to the A_2B_2X pattern expected for a trigonal bipyramidal structure with an equatorial carbonyl ligand. Sanger (15) had reached a similar conclusion from ^{31}P data on his impure chloride product; the two sets of data are in good agreement.

The ^{31}P spectrum for the $Rh(dpm)_2CO^+BF_4^-$ complex under CO is a sharp doublet at 25°C and −50°C. The equivalent P atoms can result from a square pyramidal (with apical CO) or a fluxional bipyramidal (tbp) structure. The latter is favoured. The corresponding $Ir(dpm)_2CO^+Cl^-$ complex also exhibits a single ^{31}P resonance even at −92°C, while the dpe analogue is tbp at this temperature (and in the solid state (7)) but is fluxional at −21°C, and a decrease in rearrangement barrier between square pyramid and tbp structures in the order dpp > dpe > dpm has been suggested (11). Under Ar at 25°C, two overlapping ^{31}P doublets measured for $Rh(dpm)_2CO^+$ result from an equilibrium mixture with the decarbonylated product; at −50°C, two well defined doublets confirm the presence of both $Rh(dpm)_2^+$ (δ 20.83, J_{Rh-P} = 115 Hz, cf. ref. 1) and $Rh(dpm)_2CO^+$. The ^1H nmr for the methylene protons similarly shows the equilibrium mixture in the absence of the CO atmosphere.

The $Rh(\widehat{P\ P})_2^+BF_4^-$ ($\widehat{P\ P}$ = dpb, diop) complexes in solution absorbed 1.3–1.7 mol CO per Rh, and this, together with the ir data, is consistent with some dicarbonyl product in the isolated mixtures. Sanger was also unable to prepare a pure $Rh(dpb)_2CO^+Cl^-$ complex using a different route, and as reported (15), we also found the ^{31}P spectra of the mixtures too complicated to be of value. Complex **A** obtained from carbonylation of

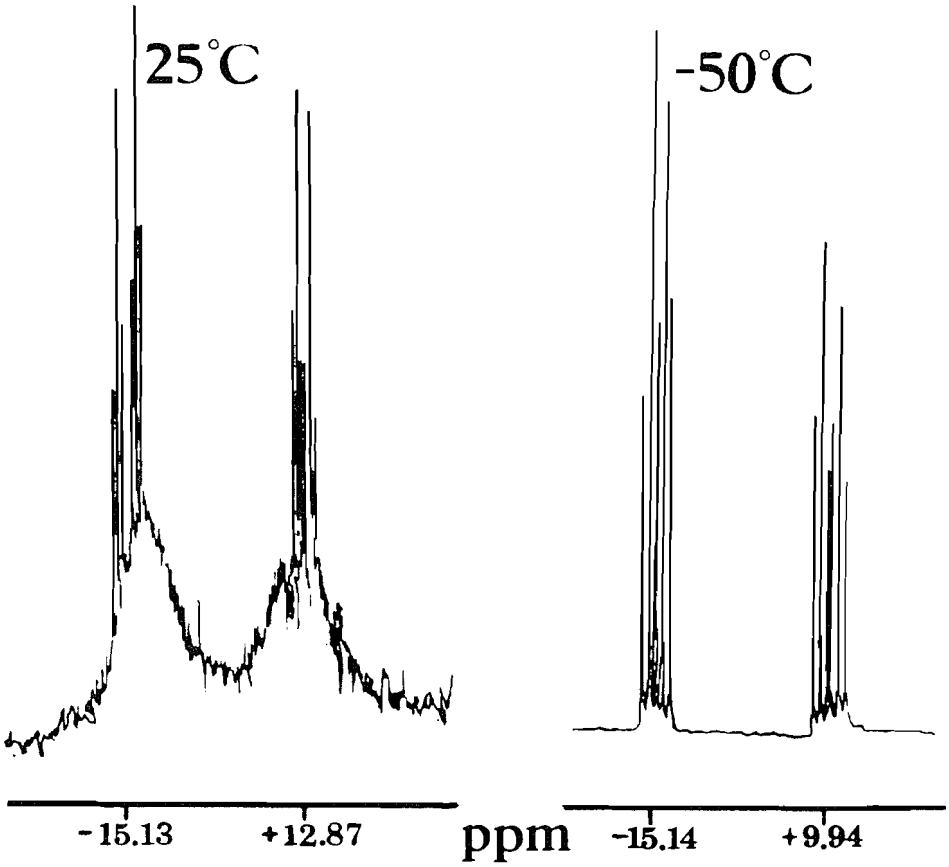

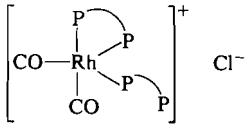

FIG. 1. ^{31}P nmr of $Rh(dpp)_2(CO)^+BF_4^-$ in CH_2Cl_2/acetone-d_6 under CO at 25 and −50°C.

$Rh(diop)_2Cl$ appears to be a mixture containing some $Rh(diop)(diop^*)(CO)_2^+Cl^-$, **B** (15), but the 308 cm^{-1} band, conductivity data (for formula **B**, Λ = 28 under Ar, and 37 ohm^{-1} cm^2 mol^{-1} under CO, at 25°C in nitromethane), the gas uptake stoichiometry, and carbon analysis, suggest contamination with neutral complexes such as $[RhCl(CO)(diop)]_2$ (15) or $RhCl(CO)(diop)(diop^*)$. Dimeric species such as $[(diop)(CO)_2Rh(\widehat{P\ P})Rh(CO)_2(diop)]^{2+}$ could also be present.

B

Dioxygen Complexes

The $Rh(\widehat{P\ P})_2O_2^+BF_4^-$ complexes are obtained analytically pure by oxygenation of the $Rh(\widehat{P\ P})_2^+$ cations with dpm, dpe, and dpp. The ir bands in the 880–900 cm^{-1} region are typical of side-on coordinated peroxide (19), and the complexes are formally six-coordinate rhodium(III) species. The anion of the previously characterized $Rh(dpe)_2O_2^+PF_6^-$ complex obscures the $\nu(O_2)$ region (5). In solution the $Rh(dpe)_2O_2^+$ cation readily loses O_2 (5), and this is readily monitored spectrophotometrically by a change from a continuum to an absorption maximum at 407 nm (1). The dpm and dpp systems show much stronger O_2-binding that is irreversible in solution at ambient temperatures.

The ^{31}P spectra (Fig. 2) show the expected doublet of doublet of triplets A_2B_2X pattern. The dpm and dpp complexes are nonfluxional at 25°C; the dpe system shows just the simple doublet of the $Rh(dpe)_2^+$ cation (1), due to loss of O_2, although ^{31}P nmr at −80°C has revealed previously (11) the expected pattern of a rigid $Rh(dpe)_2O_2^+$ species. The substantially larger downfield shifts noted for the dpe dioxygen complex (and the HCl adduct, see below) provide a further example of extra deshielding apparent in five-membered ring systems (16, 22). A recent report (16) notes ^{31}P nmr data for a $Rh(dpp)_2O_2^+Cl^-$ species formed *in situ*, initially inadvertently; agreement is excellent.

The $Rh(dpb)_2^+BF_4^-$ complex in dichloroethane

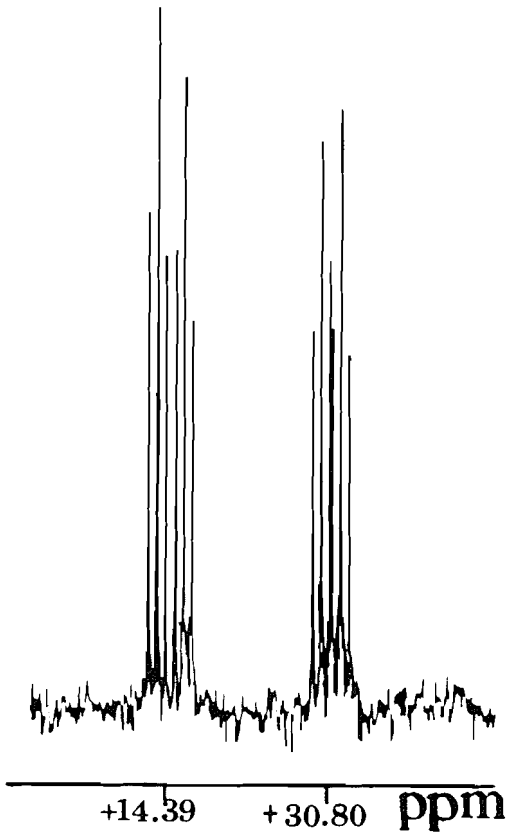

FIG. 2. ^{31}P nmr of $Rh(dpm)_2O_2^+ BF_4^-$ in CH_2Cl_2/acetone-d_6 at 25°C.

solution at 25°C absorbed ~2.8 mol O_2 per Rh and this, coupled with the ir of the product obtained from methanol solutions (see Experimental), would be consistent with the formulation $Rh(dpbO_2)_2O_2^+BF_4^-$ in which all the phosphines have been converted to the oxide, but the carbon analysis is ~6% too low. Such complexes containing coordinated phosphine oxides are known, for example $[RhCl(OPPh_3)_{0.67}O_2]_n$ (23) and *cis*-$Rh(PPh_3)_2[OPPh_2C(S)NPh]O_2$ (24), and a nonstoichiometric compound formed after some loss of the phosphine oxide into solution could be formulated for the dpb product. However, the complex ^{31}P nmr spectra are more consistent with an impure compound.

Dihydride Complexes

The well known nonreactivity of $Rh(dpe)_2^+$ toward 1 atm H_2 (25, 26) is obtained also for the dpm analogue. However, the dpp and diop analogues are readily isolated as the *cis*-$H_2Rh(\widehat{P\ P})_2^+BF_4^-$ complexes; both complexes on dissolving in solution under Ar readily lose H_2. The dihydrides are comparable to the known *cis*-$H_2Rh[P(CH_3)_3]_4^+$ complex (27), and show ν(Rh—H) in the ir, a pair of multiplets in the high-field ^1H nmr at 25°C, and two resonances in the $^{31}P\{^1H\}$ nmr; based on the literature data (27), the lower field resonance for each system is attributed to the mutually *trans* P atoms, and that at higher field to the P atoms *trans* to the hydrides. The presence of two P resonances at all temperatures rules out the *cis–trans* rearrangement that has been observed in complexes of the type H_2ML_4 (M = Fe, Ru; L = phosphine, phosphite (28, 29)). The ^{31}P data possibly suggest some temperature dependence in terms of line-width for the higher field resonance, although a relatively poor signal-to-noise ratio in the 25°C spectra clouds the issue somewhat; such broadening could result from mutual exchange of the two P atoms *trans* to hydrides; as judged by the inability of rhodium(I) mono(ditertiaryphosphine) complexes to add H_2, a P atom *trans* to hydride is not favoured, at least thermodynamically (14, 30).

The $H_2Rh(diop)_2^+$ cation has been characterized previously as the ClO_4^- and PF_6^- salts, although ^{31}P nmr data were not studied (13). The carbon analysis in our sample was slightly low due to the presence of some CH_2Cl_2 solvent in the crystals. A previous attempt to isolate $H_2Rh(dpp)_2^+$ as the chloride salt was unsuccessful (14, 16), but nmr data on a system formed *in situ* (16) agree well with ours.

The impure $H_2Rh(dpb)_2^+BF_4^-$ complex isolated is likely contaminated with the starting complex, since solution gas-uptake data showed a H_2:Rh stoichiometry of ~0.6.

Chlorohydrido Complexes

Oxidative addition of HCl(g) to $Rh(\widehat{P\ P})_2Cl$ leads to the formation of $HRh(\widehat{P\ P})_2Cl^+$ cations with $\widehat{P\ P}$ = dpm, dpe, and dpp. The isolated chloride salts give low analyses for carbon (Table 1), but pure salts with BF_4^-, PF_6^-, and SbF_6^- anions are readily made from the chloride using the appropriate silver salt. Analogous iridium(III) chloride complexes, prepared via the oxidative addition procedure, also show low carbon content due to contamination by HCl (6), and a somewhat high chloride analysis for the $HRh(dpe)_2Cl^+Cl^-$ complex (Table 1, footnote *f*) suggests a similar explanation for the rhodium systems, especially since the ^{31}P spectra were clean (see below). Further recrystallizations did not improve the elemental analyses.

The dpe and dpp chlorohydrido complexes lose HCl in *N*,*N*-dimethylacetamide (DMA), a relatively basic solvent, to generate the $Rh(\widehat{P\ P})_2^+$ cations (1), while the $HRh(dpm)_2Cl^+$ complex does not decompose. The hydride in the $HRh(\widehat{P\ P})_2Cl^+$ cations is readily detected in the ir, and ^1H nmr high field at 25°C (Table 2). The latter appears as a

For personal use only.

doublet of quintets for the dpm and dpe systems, and as a sextet for the dpp system that is explicable if $J_{P-H} \sim J_{Rh-H}$; these 25°C data reveal equivalent P atoms which can result from either a *trans* chlorohydrido structure or a fluxional *cis* structure.

The corresponding doublet of the $^{31}P\{^1H\}$ nmr at 25°C for the dpp cation broadens on cooling, and at −85°C approximates to two doublets of triplets, characteristic of a non-rigid structure with *cis*-geometry for the H and Cl atoms (11, 12, 16, 31). The ^{31}P spectra for the dpm and dpe cations showed a doublet that was unchanged from 25 to −60°C. The crystal structure of $HRh(dpm)_2Cl^+$-BPh_4^- (made inadvertently via a reaction in which ethanol is the hydride source) shows a *trans* geometry (4); the ^1H and ^{31}P nmr data reported are identical to ours, although the ν(Rh—H) band is observed at 2080 cm^{-1}, some 15 cm^{-1} higher than our value. A higher stretching frequency is expected for a hydride *trans* to chloride rather than phosphine, but usually the differences are much larger (32) and a difference in the associated anion is sufficient (33) to account for the ir discrepancy. A *trans*-geometry is considered more likely then for our $HRh(dpm)_2Cl^+$ salt, and the dpe analogue due to the similar ν(Rh—H) value. However, this remains somewhat equivocal since rearrangement barriers do decrease as *n* decreases (11, 12), and the ν(Rh—H) values for *trans* geometries, at least neglecting ring size effects, might be expected to be greater than that of 2100 cm^{-1} measured for *cis*-$HRh(dpp)_2Cl^+$.

Pure $HRh(\widehat{P\ P})_2Cl^+$ species with $\widehat{P\ P}$ = dpb and diop were not isolated, although their presence in mixtures is strongly indicated by spectroscopic data (see Experimental); a broad band around 3500 cm^{-1} in the solid isolated with the diop system could be a ν(OH) band resulting from acid cleavage of the ligand acetal group. Such a reaction has been observed in ruthenium systems containing a sulfoxide analogue of diop (—PPh_2 replaced by —$SOCH_3$ (34, 35)).

It should be noted that for the $HRuCl(diop)_2$ complex, ^{31}P and ^1H nmr data, which revealed inequivalent P atoms, were initially interpreted as usual in terms of a *cis* geometry; however, an X-ray analysis revealed a *trans* structure, the inequivalence being due to a distortion resulting from the presence of the dioxolane ring in the diop. The comparable $HRuCl(dpb)_2$ complex, and the dpp and dpe analogues, show C_{4v} symmetry down to −60°C as judged by the high-field ^1H nmr, and have been assumed to have *trans* structures (31, 35–37).

A claim that $HRh(dpe)_2Cl^+Cl^-$ is an extremely active catalyst for hydrogenation of terminal olefins (3) prompted us to test the potential activity of the $HRh(\widehat{P\ P})_2Cl^+A^-$ complexes ($\widehat{P\ P}$ = dpm, dpe, dpp; A = Cl, BF_4) described here. Under conditions comparable to those reported in the literature (3), we observed no hydrogenation of olefinic substances. However, addition of a base, or use of DMA as solvent, removes the HCl and generates the active $Rh(\widehat{P\ P})_2^+$ catalysts (1). The literature procedure use for isolation of the catalytic $HRh(dpe)_2Cl^+Cl^-$ involved separation from insoluble black residues (3); traces of contaminant metal could account for the observed catalytic hydrogenation.

General

Despite our systematic study of the reactions of small gas molecules with $Rh(\widehat{P\ P})_2^+$ cations as the length of the —$(CH_2)_n$— carbon chain increases between the ligating P atoms, it is difficult to discern any definite reactivity patterns, although the *n* = 4 and diop systems gave mixtures of products in every case except the diop/H_2 reaction. Ligands of the type $A(CH_2)_nA'$, where $n \geq 5$ and A and A′ are donor groups, tend to bridge metal atoms in preference to forming a chelate ring, but this depends very much on the bulk of the substituents on A and A′ (38, 39). In rhodium systems containing one diphosphine per Rh, the tendency to form diphosphine-bridged dimers is marked even with *n* = 1, 3, and 4; in fact, the *n* = 2 appears exceptional in giving a chelate ring, reflecting presumably the extra stability of the five-membered ring (4, 15). Thus, some dissociation of one diphosphine ligand from our $Rh(\widehat{P\ P})_2^+$ systems could lead to formation of a dimeric species, for example, $[RhCl(CO)(diop)]_2$ in the CO reaction. The bis(diop) complexes $HRh(diop)_2$ and $Rh(diop)_2^+$ yield active hydrogenation catalysts via processes that do involve dissociation of a phosphine moiety (1, 40, 41). Such dissociation can also lead to gas uptake: metal stoichiometries of >1.0, as exemplified by formation of the $Rh(diop)(diop^*)(CO)_2^+$ species. Our results then imply that the Ph_2P—C_4—PPh_2 ring systems dissociate more readily than the *n* = 1–3 systems. A recent study using platinum(II) diphosphine – $SnCl_2$ complexes as hydroformylation catalysts revealed maximum activity for the *n* = 4 system, and this was similarly attributed to a loose *cis*-coordination of the diphosphine in the strained seven-membered chelate ring (42).

Within the series $Rh(\widehat{P\ P})_2O_2^+$, ν(O—O) increases from 881–896 cm^{-1} as *n* goes from 1 to 3,

For personal use only.

while only the $n = 2$ system shows reversible O_2-uptake behaviour. This adds further indirect support (43) against a widely accepted correlation between O—O bond strength (and length) and O_2 lability (44), which would require reversible behaviour by the $n = 1$ system also.

The $n = 2$ cation also appears anomalous in the $n = 1$–3 series in not binding CO, especially since the iridium analogue does (26). Of the $n = 1$–3 cations, only the $n = 3$ forms a dihydride, although the $n = 1$ system with dimethyl- instead of diphenylphosphino moieties is known to add H_2 (45). We are currently studying the kinetics and the thermodynamics of the reactions described in this paper, and this should help in unravelling the subtleties involved. Otsuka and co-workers (46, 47) have been studying the structure and reactivity of the nickel subgroup *cis*-$M[PR_2(CH_2)_nPR_2]X_2$ complexes (X = O, H), and have suggested a possible correlation between lability of X_2 and the interligand angle PMP; the steric bulk of the R groups appears dominant.

The regular trend in decreasing ν(Rh—H) values with decreasing ring size within the $HRh(P\frown P)_2Cl^+$ cations could possibly be rationalized within a *cis*-series (H *trans* to P) by an increased *trans* influence as a result of a more easily attained linear H—Rh—P arrangement, at least as n decreases from 4–2 (cf. ref. 46). However, the situation must be much more complex considering the likely different *cis* and *trans* geometries within the series. Kinetic and thermodynamic details on the HCl binding would again be of value in explaining, for example, the respective irreversible and reversible character of the reaction in DMA for the apparently *trans* dpm and dpe systems.

In view of the proved or potential catalytic activity of the $Rh(P\frown P)_2^+$ species generally (see Introduction), a more systematic attempt to acquire crystallographic data is also being made.

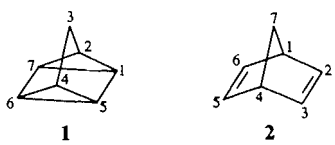
Electrophilic cleavage of cyclopropanes. The areneselenenylation of tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclene)[1,2]

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET, AND DENNIS G. GARRATT[3]

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received October 2, 1979

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET, and DENNIS G. GARRATT. Can. J. Chem. **58**, 1005 (1980).

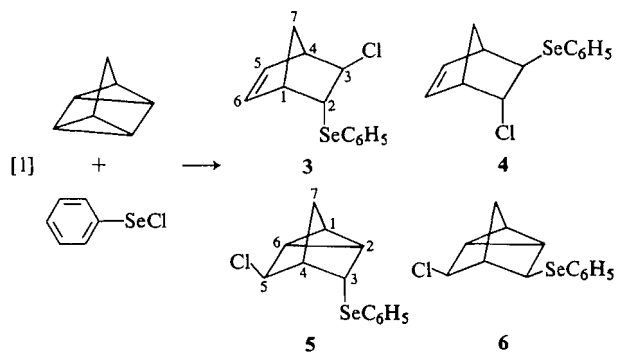


The reaction of benzeneselenenyl chloride with tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclene) yields, under conditions of kinetic control, adducts of both 1,3- and conjugative 1,6-addition, the latter being formed preferentially. Electrophilic cleavage of the cyclopropane ring occurs by both retention and inversion of configuration. In agreement with the known propensity for bond cleavage in this system only the C5—C6 and/or the C1—C7 bonds are broken. The rate of cyclopropane ring cleavage is found to follow second order kinetics, first order in quadricyclene and first order in selenenyl chloride; k_{obs} = 1850 vs. 12 300 dm^3 mol^{-1} s^{-1} for bicyclo[2.2.1]hepta-2,5- diene at 24.5°C in methylene chloride solvent. The use of nucleophilic solvents such as HOAc, CH_3OH, and CH_3CN gives products of solvent-incorporation, preferentially via 1,3-addition.

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET et DENNIS G. GARRATT. Can. J. Chem. **58**, 1005 (1980).

La réaction du chlorure de benzènesélénènyle avec le tétracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclène) donne, sous contrôle cinétique, les adduits résultants d'une addition-1,3 ainsi que d'une addition conjuguée-1,6. L'addition conjuguée-1,6 est préférentielle. Le clivage électrophile du cyclopropane se produit à la fois avec rétention et inversion de configuration. Conformément à la tendance connue pour ce système à rompre les liaisons, seules les liaisons C5—C6 et/ou C1—C7 se rompent. On a trouvé que la vitesse d'ouverture du cyclopropane a une cinétique de second ordre. Elle est d'ordre 1 dans le cas du quadricyclène et d'ordre 1 dans le cas du chlorure de sélénènyle; k_{obs} = 1850 vs. 12 300 dm^3 mol^{-1} s^{-1} dans le cas du bicyclo[2.2.1]heptane diène-2,5 à 24.5°C dans le chlorure de méthylène. L'utilisation de solvants nucléophiles, tels que AcOH, CH_3OH et CH_3CN donne de préférence des produits d'incorporation du solvant par l'intermédiaire d'une addition-1,3.

[Traduit par le journal]



Electrophilic additions of areneselenenyl halides (1) and pseudohalides (2) to carbon–carbon double and triple bonds have received considerable interest of late. No attention has, however, been devoted to the possible reaction of these electrophiles with carbon–carbon single bonds in, for example, cyclopropanes. In this article we wish to report the results of a detailed examination of the cyclopropane ring cleavage of tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane, **1**, using benzeneselenenyl chloride as the electrophilic reagent. The choice of **1** as substrate was made from a consideration of its anticipated high reactivity with selenium electrophiles. Both **1** and the isomeric olefin bicyclo[2.2.1]hepta-2,5-diene, **2**, normally display high reactivity (3), presumably as a result of their large strain energies, 78.7 and 25.6 kcal mol^{-1}, respectively (4). Earlier studies involving the reaction of benzeneselenenyl chloride with **2** substantiate these expectations (5); the specific rate constants for the reactions of **2** and the less strained olefin, cyclohexene, with benzeneselenenyl chloride in methylene chloride solution at 25°C being, respectively, 12 400 and 272 dm^3 mol^{-1} s^{-1}.

1 **2**

Results

The reaction of **1** with benzeneselenenyl chloride was initially studied in methylene chloride solution at 23–25°C. The reaction is essentially instantaneous, the deep red coloration of the selenenyl chloride solution disappearing immediately upon mixing. Immediate ^1H and ^{13}C nmr analysis of the crude product mixture, after work-up, shows the presence of four adducts **3–6** in the relative proportions 62:30:5:3. No evidence was found for prod-

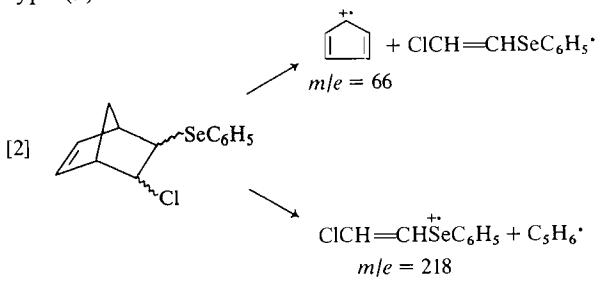
TABLE 1. Solvent dependence of the product ratio under conditions of kinetic control for the cyclopropane ring cleavage of tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane by benzeneselenenyl chloride at 23–25°C

Solvent	ε[a]	% Composition 3	4	5	6	7	8	Ratio A[b]	Ratio B[c]
n-C_5H_{12}	1.84 (20°C)	63	26	5	6	—	—	68:32	89:11
CCl_4	2.23	61	27	4	8	—	—	65:35	88:12
Et_2O	4.34 (20°C)	54	23	9	14	—	—	63:37	77:33
CH_2Cl_2	8.9	62	30	5	3	—	—	67:33	91:9
CH_3CN	36.2	15	6	11	9	54	5	80:20	21:79
HOAc	6.19	20	9	0	0	48	23	68:32	29:71
CH_3OH	32.6	0	0	0	0	74	26	74:26	0:100

[a]Dielectric constant at 25°C, except as indicated in parentheses, for the pure liquid.
[b]Ratio A: the ratio of edge-on attack to corner or end-on attack.
[c]Ratio B: the ratio of conjugative 1,6-addition to 1,3-addition.



ucts of Wagner–Meerwein type rearrangement or alternative configurations with respect to 1,3- or conjugative 1,6-addition.

Similar results are observed when the solvent is *n*-pentane, carbon tetrachloride, or diethyl ether, as is shown in Table 1. The effect of polar hydroxylic solvents such as alcohols and carboxylic acids, wherein substantial amounts of solvent-incorporated products may be formed, was also investigated. Results obtained using methanol, acetonitrile, and acetic acid as solvent are also given in Table 1.

Assignment of structures, as shown in eq. [1], follows from an analysis of their spectral properties and a comparison of these data (ir, ms, and ^{1}H, ^{13}C nmr) with those of the known sulphur analogues (6). For example, the two tricyclo[2.2.1.0^{2,6}]heptanes, **5** and **6**, each have seven aliphatic carbon resonances in their respective ^{13}C nmr spectra, three of which resonate at higher field than those normally associated with the bicyclo[2.2.1]heptane ring system (7). The presence of these high field carbons indicates that only one of the two cyclopropane rings in **1** has been cleaved during the formation of these species. Additional support for these assignments is found in the ir spectra in the form of weak–medium absorptions in the range 12.2–12.6 μm (8).

The structure of **5** is clearly the C3 epimer of **6** as determined by ^{13}C nmr analysis. The *endo* orientation of the phenylseleno moiety at C3 in **5** follows from the observed paramagnetic shift of C3 in **5** relative to **6** and a diamagnetic shift of C5, albeit a small one, in **5** relative to **6**. The small absolute value of this latter shift difference was unanticipated but presumably results from a combination of the expected γ-*gauche* interaction and an anisotropy effect from the phenyl ring operating in the opposite sense. A similar observation has been made with respect to the analogous sulphur compounds.

Compounds **3** and **4** both have five aliphatic carbons and two olefinic carbons as determined by ^{13}C nmr spectroscopy. Mass spectral analysis of samples of each species shows molecular ions at *m/e* 284 (calcd. 283.657). A major fragmentation path for each compound is the mass spectrometric equivalent of a "retro Diels–Alder reaction" giving rise to a very strong peak at *m/e* 66 which corresponds to a $C_5H_6^{+\cdot}$ fragment. The presence of an intense ion cluster at *m/e* 218 (calcd. 217.559 C_8H_7SeCl) indicates that either fragment may carry the positive charge. This observation is strong evidence for norbornenyl derivatives with only protons in positions C1, 4, 5, 6 and C7, thus ruling out skeletal rearrangements of the Wagner–Meerwein type (9).

[2] 

The ^{1}H nmr spectrum of **4** has two triplets situated at δ 4.30 and 3.05 ppm. Associating the low field triplet with a proton geminal to chlorine and the high field triplet with a proton geminal to the phenylseleno group allows one to tentatively assign the proton geminal to chlorine as *exo* and that geminal to the phenylseleno moiety as *endo* (10).[4] In contrast, **3** has apparent triplets at δ3.86 and 3.62 ppm. If one again associates the low field triplet with the proton geminal to chlorine and the high field triplet with the proton geminal to the

[4]This follows from a comparison of the spectral properties of the adduct derived from benzeneselenenyl chloride and bicyclo[2.2.1]hept-2-ene, the data for which are given in the Experimental.

phenylseleno group, and notes that the chemical shifts of *endo* protons are usually shifted upfield relative to *exo* protons, all else being equal, it is apparent that in this case the chlorine atom is oriented *exo* and the phenylseleno moiety is oriented *endo*, the opposite to **4**.

In view of the relatively large ratio of olefinic to cyclopropyl adducts ((**3** + **4**)/(**5** + **6**) = 91:9 in, for example, CH_2Cl_2) it is important to know the possibility regarding isomerization of **1** and **2** under our reaction conditions. Control experiments using an excess of **1** show only the presence of unreacted **1**, thereby suggesting that the products arise solely via ionic cleavage of the cyclopropane rings of **1**. As a further probe in this regard we have determined the rate of reaction of **1** with benzeneselenenyl chloride.

The rate of cyclopropane ring cleavage by benzeneselenenyl chloride in methylene chloride solution at 24.5°C was followed by the stopped-flow technique using a Durrum–Gibson stopped-flow spectrophotometer. The rate of disappearance of benzeneselenenyl chloride was followed by measuring the decrease in its absorption at 433 nm. The cyclopropane ring cleavage was found to exhibit second order kinetics, first order in quadricyclene **1**, and first order in selenenyl chloride, to at least 80% completion of the reaction. For comparison the specific rate constants for the addition to the isomeric olefin **2** and the analogous results for the reactions of benzenesulphenyl chloride are given in Table 2.

When hydroxylic solvents were used, the only products of solvent-incorporation isolated or observed were the C3 epimeric tricyclo[2.2.1.0^{2,6}]heptanes, **7** and **8**, formed with inversion

7 **8**

SO = CH_3O
CH_3CO_2

of configuration at C5, the site of nucleophilic attack by the solvent. No evidence was found for conjugative 1,6-addition or products of Wagner–Meerwein rearrangement.

In order to ascertain whether or not the electrophile was indeed still the selenenyl chloride,[5] a series of control experiments were carried out under equivalent conditions but in the absence of the substrate **1**. While both acetic acid and methanol will react with benzeneselenenyl chloride, the former albeit extremely slowly, we were able to determine that the substrate **1** reacts many orders of magnitude faster. To ensure that benzeneselenenyl chloride would be the predominant, if not the only, electrophilic species, we always added the powdered selenenyl chloride or a concentrated solution of it in methylene chloride

[5]Selenenyl halides are known to react with alcohols to give selenenic esters (11).

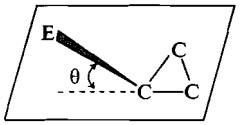
(the minimum volume possible was used), with vigorous stirring, to a solution of **1** in the appropriate solvent.

The use of acetonitrile, a more basic but somewhat less nucleophilic solvent, yields a mixture of all four chloro adducts plus two acetamides, resulting from nucleophilic attack by the nitrogen atom of the solvent followed by hydrolysis under conditions of an aqueous work-up.



Discussion

Conceptually there exist two distinct modes whereupon a strained carbon–carbon single bond might interact with an electrophile EN. For example, the electrophile and the strained bond may approach each other orthogonally, ie. edge-on attack. In the case of cyclopropane itself one would anticipate the maximum interaction of orbitals to occur when the electrophile approaches the single bond in the same plane as the three carbons which define the ring, as is shown in Scheme 1 for $\theta = 0°$. In the case of a substituted cyclopropane as is found in the substrate **1**, the best angle of approach with respect to this plane may be significantly different, although values of θ as large as 90° seem very unlikely if one accepts the Walsh model for the orbitals in cyclopropanes. The major point to be noted is that this type of interaction leads to retention of configuration at the carbon atom, wherein the new bond is formed with the electrophilic portion of the reagent (E of EN).

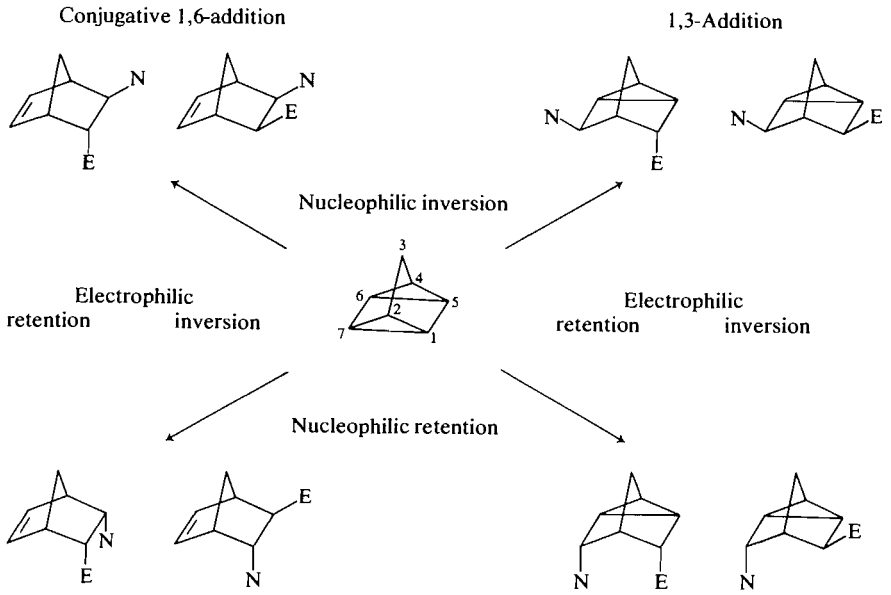
Alternatively, the electrophile may approach the corner of the strained bond along an extended axis joining the two carbon atoms, that is to say, collinearly or end-on, the interaction ultimately resulting in inversion of configuration at the carbon atom forming the new bond with E. Once again, we note that in the case of an unsymmetrically substituted cyclopropane, as in **1**, the preferred orbital interaction may lead to an angle of approach somewhat different from the idealized situation of collinearity. The possible product configurations resulting from these scenarios are shown in Scheme 2 using **1** as substrate.

Edge-on Attack
retention of configuration at carbon
in plane $\theta = 0°$

Corner or End-on Attack
inversion of configuration at carbon
in plane $\theta = 0°$, equivalent to collinear attack

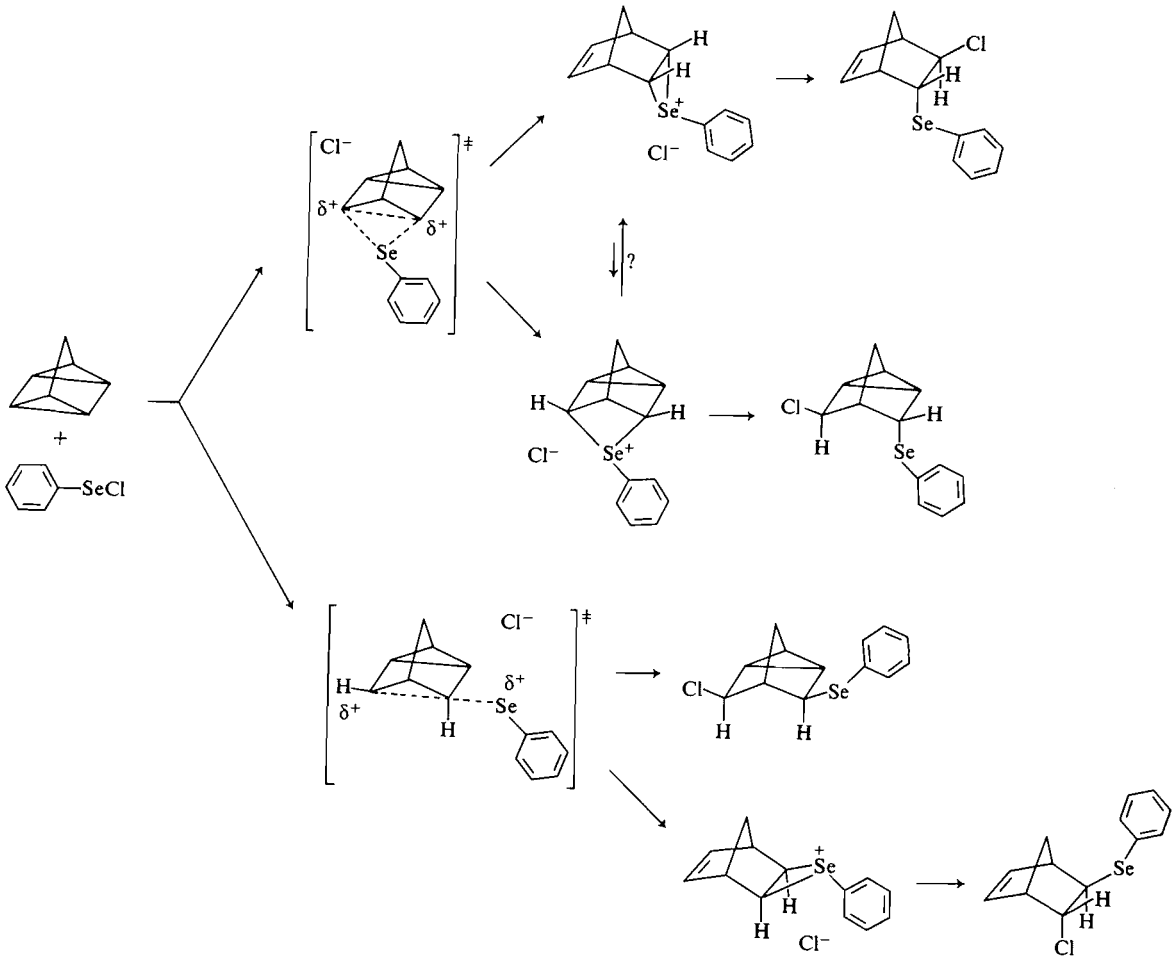
SCHEME 1

This classical approach may be unnecessarily restrictive as initial attack may in fact involve an *edge which does not finally suffer cleavage*, with subsequent cleavage occurring after edge-to-corner isomerization (3*c*). Such a scenario, however, exchanges one problem for another, that is, how does one distinguish whether or not attack occurs on a bond which *is not* subsequently cleaved or in some other way altered? Since no attempts in this laboratory or elsewhere, to our knowledge, have succeeded, we propose to consider our results in terms of the concepts just developed.



From a mechanistic viewpoint, the results given in Table 1 may be explained in terms of the two classical competitive pathways on the reaction hypersurface as shown in Scheme 3 for the specific case of areneselenenylation.

The reasonableness of this scheme is readily demonstrated by an examination of the available data. The observation of second order kinetics, first order in both selenenyl chloride and cyclopropane, **1**, serves to define the composition of the



$$[3] \quad -d[C_6H_5SeCl]/dt = k_{obs}[C_6H_5SeCl][\mathbf{1}]$$

rate determining transition state(s) as containing one molecule of each species. In accord with our previous discussion, the observation of products with both *exo* and *endo* phenylseleno groups implies two different modes of approach and interaction. In this respect it becomes clear that our rate constant k_{obs} may be partitioned into at least two terms, k_{edge} and k_{corner}. The values of these terms may be estimated from the observed product distributions under conditions of kinetic control. This necessitates that we make the assumption that the reverse reaction(s) are much slower than the primary interaction and that the activation energy for product formation is very small compared with the barrier height for interconversion among the intermediate ions, which seems reasonable. The ratio of the products is then equal to the ratio of the population of the starting states.

On this basis, since 67% of the attack is edge-on, and 33% of the attack is corner, we obtain $k_{edge} = 1239.5$, and $k_{corner} = 610.5\ dm^3\ mol^{-1}\ s^{-1}$, respectively. A similar partitioning of the k_{obs} for the reaction of benzeneselenenyl chloride with **2** and the corresponding data for benzenesulphenyl chloride are given in Table 2.

An analysis of these reactivity data is quite instructive. Bicyclo[2.2.1]hepta-2,5-diene, **2**, is known to be more stable than **1**. The strain inherent in these polycyclic systems results in a value of ΔH_f^0 for **1** which is larger than that for **2** by 8.98 kcal mol^{-1} in the condensed phase at 25°C and 9.95 kcal mol^{-1} in the gas phase (12). The strainless $\Delta\Delta H_f^0$ is calculated to be approximately 43.1 kcal mol^{-1} which leads to a calculated difference in strain energies of 52.1–53.1 kcal mol^{-1} (13). The question thus arises as to the extent to which this difference in enthalpies, or strain energies, is retained at the rate determining and product determining transition states.

If relief of all or some part of this ground state strain difference occurs, the difference in the free energy of activation, $\Delta\Delta G^{\ddagger}$ ($=\Delta G^{\ddagger}(\mathbf{2}) - \Delta G^{\ddagger}(\mathbf{1}) \equiv RT \ln[k_{obs}\mathbf{1}/k_{obs}\mathbf{2}]$), will be positive. On the other hand, an increase in the ground state strain difference will lead to a negative value for $\Delta\Delta G^{\ddagger}$. This latter scenario corresponds to a negative value of $\ln[k_{obs}\mathbf{1}/k_{obs}\mathbf{2}]$ or a value for $k_{obs}\mathbf{1}/k_{obs}\mathbf{2}$ of less than one. Such an observation would be indicative of an opening of the free energy gap between the initial isomer pair where ΔG_i, the free energy of isomerization for the process $\mathbf{1} \rightarrow \mathbf{2}$, is less than zero.

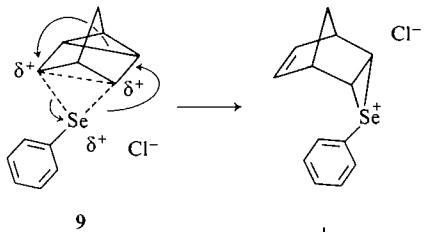
As can be seen from the analysis in Table 2, both benzeneselenenyl chloride and benzenesulphenyl chloride react with **1** and **2** in a similar fashion giving rise to values of $\Delta\Delta G^{\ddagger}$ of -1.12 and -1.05 kcal mol^{-1}, respectively. Values of $\Delta\Delta G^{\ddagger}$ based upon a partitioning of the data in terms of *edge-on* and *endo* attack or *corner* and *exo* attack are also negative, indicative therefore of rate determining transition states with apparently little or no release of the strain energy inherent in **1** relative to that of **2**. Phrased somewhat differently, the available data are indicative of a higher activation energy for the reaction of these electrophiles with **1**.

Mechanistically, we interpret these data as reflecting the expected much lower reactivity of a cyclopropyl single bond relative to an olefinic double bond. The difference in reactivity is apparently so large that even the possible release of 53 kcal mol^{-1} of strain energy is not able to force a reversal of the normal trend. Alternatively, if one views the electrophilic interaction of these reagents with **1** and **2** as examples of nucleophilic displacement at bivalent selenium or sulphur, it is possible to interpret our data in terms of the cyclopropane single bond reacting as a poorer nucleophile than the π orbital of the olefinic double bond.

Considering the observed product distributions, Table 1, we observe a number of trends. For example, in all solvent systems studied the proportion of edge-on attack is greater than that of corner or end-on attack. In particular, the percentage of edge-on attack is relatively constant, 66 ± 3%, for solvents with a dielectric constant, ε, less than 10, where the effect of the dielectric constant of the medium is approximately comparable to that of its specific solvating action (14). In the case of methanol, where the dielectric constant is 32.6, the effect of the dielectric constant appears to be of minor importance compared with the specific solvating action (14, 15). This latter point is perhaps best demonstrated by the greater proportion of edge-on attack, 74% vs. 66%, and the complete absence of products of conjugative 1,6-addition. We note that the latter are observed to predominate when non-nucleophilic solvents are used.

In acetonitrile, a solvent system which may be considered slightly more polar and more basic, but less nucleophilic, than either acetic acid or methanol, we observe an even larger ratio of edge-on attack to corner attack, 80:20. In contrast to methanol, we observe products of conjugative 1,6-addition in the product mixtures obtained from acetonitrile and acetic acid, plus the chloro adducts, **5** and **6**, in acetonitrile. These latter results are interpreted as reflecting the lower nucleophilicities of these solvents compared to methanol. Of particular note are the enhanced yields of tricyclo[2.2.1.0^{2,6}]heptanes in the nucleophilic solvents, and the observation that these tricyclic adducts are almost exclusively products of solvent-incorporation. The presence of solvent-incorporated products of 1,3-addition and the absence of the analogous species of conjugative 1,6-addition presumably reflects the ability of these solvents to effectively trap the first formed cationic intermediates before rearrangement is possible.

The predominance of edge-on attack during areneselenenyl chloride addition is interpreted as the result of a combination of the very good neighbouring group ability of bivalent selenium (16) and the high electron density along the edge of the cyclopropane defined by the C1—C7 and C5—C6 bonds of **1**.



The products of conjugative 1,6-addition are of some interest since they serve to establish the orientation of ring opening in the second cyclopropane system as occurring stereospecifically with *inversion* of configuration at C3 when the electrophilic portion, E = C_6H_5Se, attacks with *retention* of configuration at C2, but with *retention* of configuration at C3 when E(=C_6H_5Se) forms a new bond with *inversion* at C2. This stereospecificity may be explained by the isomerization of the initially formed selenonium ions, **9** (a selenetanium ion) and **10**, to *endo* and *exo* norbor-

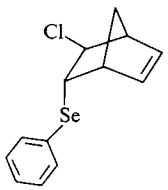
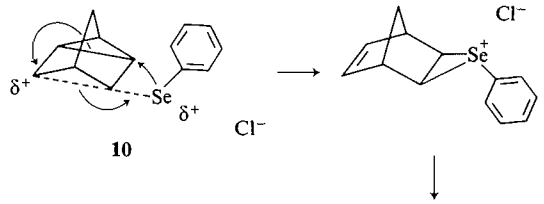
For personal use only.

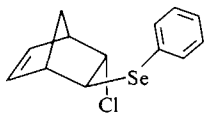


nenyl seleniranium ions (eqs. [4] and [5]) followed by nucleophilic attack by chloride ion. In this regard we note that the tricyclic adducts **5**–**8** are *exo* at C5, implying inversion of configuration at carbon, which is indicative, using Cristol *et al.*'s criteria of the absence of free carbonium ions on the reaction hypersurface (17).

The configurational results given above are similar to those obtained when one uses the analogous sulphenyl chloride as the electrophile (18, 19).



[4]



9

[5]

10

In comparing our data for areneselenenylation with that for arenesulphenylation a number of important differences are immediately obvious (19). Firstly the ratio of edge-on attack to corner attack favours corner attack, 42:58, these data contrasting with the 67:33 ratio found during this investigation. Secondly, 1,3-addition is favoured over conjugative 1,6-addition, 76:24, during arenesulphenylation compared to a value of 9:91 during areneselenenylation. Thirdly, no product of conjugative 1,6-addition resulting from edge-on attack is observed during the addition of arenesulphenyl chlorides to **1**, while the analogous species is the major adduct formed during the areneselenenyl chloride addition reaction! This result is very significant since it appears to indicate that the conjugative cyclopropyl group is unable to compete with neighbouring bivalent sulphur for stabilization of positive charge at C5 during edge-on attack, but does compete very effectively with bivalent selenium. This rationale, which suggests that bivalent sulphur is a better neighbouring group than bivalent selenium leads, however, to a contradiction, in that the preference for the selenenyl chloride to attack edge-on while sulphenyl chlorides prefer corner attack seems to be indicative of bivalent selenium being the more effective neighbouring group. We interpret this difference in product distributions in terms of isomerizations of the type shown in eq. [4]. The data given herein suggest that in nonpolar media the *endo* norbornenyl seleniranium ion is favored over the selenetanium ion, whereas during sulphenylation the analogous thietanium ion is the more stable species.

Experimental

General

^{1}H nuclear magnetic resonance spectra were recorded on Varian Associates T-60 and HA-100 spectrometers; ^{13}C nmr spectra were recorded on a Varian FT80-16K spectrometer using chloroform-*d* as an internal lock and reference. All spectral parameters are referenced to TMS as an internal standard and all spectra were run in sealed tubes. Infrared spectra were run in NaCl cavity cells as CCl_4 solutions using a Unicam 1100 spectrophotometer.

Benzeneselenenyl chloride was available commercially (Aldrich). This material contains a small amount of phenylselenium trichloride and must be recrystallized prior to use.

Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane, **1**, was purchased from Aldrich and used without further purification. The purity of **1** was established via nmr and glc. All analytical and preparative tlc separations were performed on Analtech or Macherery–Nagel precoated plates, silica gel GF, using CH_2Cl_2 as eluant. Spot visualization was accomplished using uv, iodine, and phosphomolbydic acid – EtOH.

Caution

Scrupulous avoidance of contact with the materials used during this study is essential. All reactions were carried out in an isolation glove box equipped with a filter system suitable for use with carcinogenic or radioactive material, with a reduced atmospheric pressure inside the box. This procedure was used because of medical problems which arose during the course of study of the analogous reaction with **2** *approximately four years previously. Within twelve hours of carrying out the areneselenenylation reaction with norbornadiene, the author suffered an acute attack of asthmatic bronchitis. This attack resulted in hospitalization of the experimenter. There had been no prior history of attacks of this nature. The medical diagnosis* suggests *that the attack may have resulted from a chemical irritant. Subsequent increased sensitivity towards lung problems has been noted by the author, particularly with respect to norbornenyl and nortricyclyl compounds. The physical and toxicological properties of these selenium compounds have not been fully investigated. Organoselenium compounds are, in general, somewhat malodorous and have in some cases been reported as carcinogenic.*

The Reaction of Benzeneselenenyl Chloride with Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane

A solution of C_6H_5SeCl (0.575 g, 3.00 mmol) in 20 mL anhydrous CH_2Cl_2 was added dropwise to a stirred solution containing **1** (0.276 g, 3.00 mmol) in 30 mL of anhydrous CH_2Cl_2 at room temperature. The red coloration of the selenenyl chloride disappeared immediately. The solvent was removed at room temperature and the crude yellow oil stored under nitrogen. This oil, which corresponded to a quantitative yield, was analyzed by nmr. A similar procedure was used in the cases involving *n*-pentane, diethyl ether, cyclohexane, and carbon tetrachloride. When acetonitrile or acetic acid was used as solvent the reaction mixture, including solvent, was extracted from aqueous medium and neutralized with sodium carbonate, using methylene chloride. Adduct mixtures were dried over magnesium sulphate and isolated as above. The solvent methanol was removed by evaporation at 45°C. Control experiments indicate that methanolysis of chloro adducts under these conditions is negligible.

Exo-*3-phenylseleno*-exo-*5-chlorotricyclo[2.2.1.0^{2,6}]heptane* **6** gave ir (CCl_4, NaCl): 12.35 μm (nortricyclene); ^{1}H nmr δ: 3.96 (bs, 2H, C3*H*, C5*H*); ^{13}C nmr δ: 14.8 (d, C1), 16.7 (d, C2), 49.8 (d, C3), 42.8 (d, C4), 64.8 (d, C5), 20.5 (d, C6), 34.2 (t, C7).

Endo-*3-phenylseleno*-exo-*5-chlorotricyclo[2.2.1.0^{2,6}]heptane* **5** gave ir (CCl_4, NaCl): 12.3 μm; ^{1}H nmr δ: 4.02 (m, 1H, C5*H*Cl), 3.82 (m, 1H, C3*H*Se); ^{13}C nmr δ: 12.2 (d, C1), 17.3 (d, C2), 50.2 (d, C3), 41.0 (d, C4), 62.4 (d, C5), 19.6 (d, C6), 30.2 (t, C7).

All samples gave satisfactory elemental analyses and mass spectra in addition to the ir and nmr data given above.

Kinetic Studies

All kinetic runs were carried out on a Durrum–Gibson stopped-flow spectrophotometer. Prior to any set of kinetic runs the instrument was allowed to stabilize for at least 2 h. A constant temperature bath was maintained at 24.50 ± 0.03 °C. The instrument was checked out and calibrated prior to each set of runs. Zero and 100% transmittance lines were determined by running pure solvent vs. the cyclopropane solution. Kinetic runs with each solution were carried out until a reproducible trace was stored on the oscilloscope. Measurements were carried out in the standard way. The specific rate constant for the reaction of benzeneselenenyl chloride with methanol in methylene chloride, under conditions equivalent to those used to determine k_{obs} for **1**, is 0.011 dm^3 mol^{-1} s^{-1}. Thus benzeneselenenyl chloride reacts with **1** approximately 1.7 × 10^5 times faster than it does with methanol. Since pure methanol is 24.7 mol dm^{-3}, the kinetic excess, or factor by which **1** will be preferred under our reaction conditions, [**1**] = 0.04 mol dm^{-3}, is approximately 274.

Electrophilic cleavage of cyclopropanes. II. Concerning the effect of increasing electron demand upon the product-determining transition state in the reaction of 4-substituted-2-nitrobenzenesulphenyl chlorides and benzenesulphenyl chlorides with tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclene)[1]

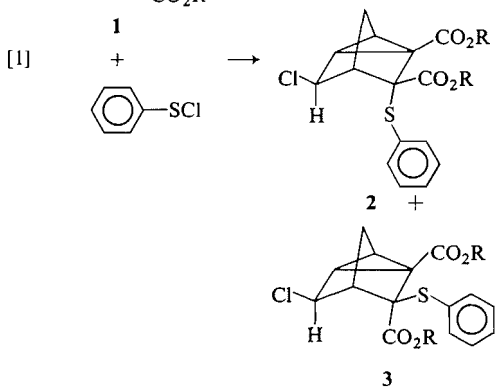
PIERRE L. BEAULIEU, ANN KABO, and DENNIS G. GARRATT. Can. J. Chem. **58**, 1014 (1980).

The effect of increasing electron demand upon the product-determining transition state in the reaction of arenesulphenyl chlorides with tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane has been investigated. As the electron donating ability of the remote substituents on the phenyl ring of the sulphenyl chloride is varied from nitro to methoxy the relative proportion of adducts derived from edge-on attack is found to increase relative to that of adducts derived from corner attack. An *ortho*-nitro group was found to lead to a stabilizing interaction only in the case of 2,4-dinitrobenzenesulphenyl chloride. A mechanism involving the competition between the two conceptual modes of approach is suggested.



PIERRE L. BEAULIEU, ANN KABO et DENNIS G. GARRATT. Can. J. Chem. **58**, 1014 (1980).

On a étudié l'effet d'une augmentation de l'affinité électronique sur l'état de transition conduisant au produit principal lors de la réaction des chlorures d'arènesulphényles avec le tétracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane. Comme la tendance à donner des électrons par des substituants dans des positions éloignées du cycle phényle du chlorure de sulphényle varie du groupe nitro au groupe méthoxy, on a trouvé que la proportion relative d'adduits résultant d'une attaque sur le côté augmente par rapport à celle des adduits résultant d'une attaque au sommet. On a trouvé qu'un groupe nitro en position *ortho* conduit à une interaction stabilisante uniquement dans le cas du chlorure de dinitro-2,4 benzènesulphényle. On suggère un mécanisme qui fait intervenir une compétition entre ces deux types d'approches.

[Traduit par le journal]

Considerable attention has been given to the mechanism of arenesulphenylation of carbon–carbon double and triple bonds (1). A survey of the literature, however, indicates a paucity of data with respect to the analogous electrophilic cleavage of carbon–carbon single bonds in strained systems such as cyclopropanes. The reaction of sulphenyl halides with simple alkyl- or aryl-substituted cyclopropanes is generally quite sluggish even in the presence of Lewis acids such as $AlCl_3$ and BF_3.[3] An apparent exception to these observations is the report of Morrill and co-workers (2) of the facile ionic cyclopropane ring cleavage in the highly strained quadricyclene systems tetracyclo[3.2.0.0^{2,7}.0^{4,6}]-heptane-1,5-dicarboxylic acid **1***a* and its dimethyl ester **1***b* by benzenesulphenyl chloride (eq. [1]) to give *exo*-5-chloro-*endo*-3-phenylthiotricyclo-[2.2.1.0^{2,6}]heptane-2-*exo*-3-dicarboxylic acid, **2***a*, the C3 epimer **3***a*, and the corresponding dimethyl esters, **2***b* and **3***b*, in approximately equal amounts, the addition of 4-toluenesulphenyl chloride, under

a R = H
b R = CH_3

equivalent conditions, giving analogous results (3).[4] These data were interpreted in terms of the

[4]We have extended the *endo–exo* terminology beyond its original usage in norbornane systems (3*a*) to nortricyclenes in accord with the suggestion of Cristol and Lalonde (3*b*), by referring configurations with respect to the unsubstituted methano bridge. We agree with Cristol and Lalonde that the use of the terms *endo* and *exo* in these connotations is better than coining new terms, even though the original derivations are not precisely applicable.

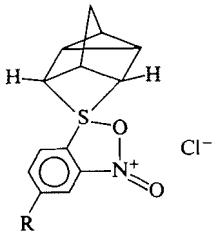
4

absence of a bridged sulphonium ion, **4**, as the sole intermediate prior to the product-determining transition state.



These results were very unexpected. Theoretical considerations based upon the Walsh model for cyclopropane (4) led one to predict that edge-on attack would be preferred over corner or end-on attack during electrophilic ring cleavage (5). The excellent neighbouring group ability (6) of bivalent sulphur, giving rise to species such as **4**, was expected to enhance this edge-on attack. These concepts have been discussed in detail in the preceding article.

The absence of epimers at C5 in Morrill *et al.*'s work is also of note since Cristol and co-workers have given evidence that the subsequent attack by the nucleophilic portion, N of EN, proceeds by inversion, unless a carbonium ion-like intermediate is formed on the reaction hypersurface prior to the product-determining transition state (7). Presumably both retention and inversion would have been observed if C5 obtained carbonium ion character, although the presence of ion-pairs, the importance of which has not been estimated, may lead to a situation favouring one epimeric form almost to the exclusion of the other.

A further intriguing aspect of Morrill *et al.*'s results with **1***a* and **1***b* is the absence of products derived from conjugative 1,6-addition. While such results appear common for the systems **1***a* and **1***b*, ionic cleavage of tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane, **5**, usually gives substantial amounts of 2,3-disubstituted bicyclo[2.2.1]hept-2-enes as well as 3,5-disubstituted tricyclo[2.2.1.$0^{2,6}$]heptanes and, in some cases, products of Wagner–Meerwein type rearrangement (8).

In this article we report our observations of cyclopropane ring cleavage in **5** using a series of arenesulphenyl chlorides. The substrate **5** was chosen to allow comparisons to be made with a previous study from this laboratory, which utilized the isomeric olefin bicyclo[2.2.1]hepta-2,5-diene (9). Our aim here and in the previous study (9) is to demonstrate the variable product ratios which result from making minor changes in the electrophilicity of the sulphenyl chloride while holding the steric factors in the product-determining transition state constant. In effect we use the tool of increasing electron demand (10). The relative proportions of the *endo*-2-arylthio-3-chlorobicyclo-[2.2.1]hept-5-enes, the adducts of conjugative 1,6-addition derived from edge-on attack, to the *endo*-3-arylthio-5-chlorotricyclo[2.2.1.$0^{2,6}$]-heptanes as a function of the substituents R^2 and R^4 (see Table 1) should give a measure of the electron demand on the sulphur atom towards stabilizing charge development on C3 and C5 of the system. A second measure of the electron demand on sulphur will be reflected in the ratio of *endo*-arylthio adducts to *exo*-arylthio adducts, i.e., products derived from edge-on attack versus those derived from corner attack, since only the stability of a bridging species such as **4** would be expected to be affected by a change in the electrophilicity of the sulphenyl halide. In this respect one expects to observe an increase in the proportion of *endo*-arylthio adducts as the electrophilicity of the sulphenyl chloride is increased through electron donating substituents.

The use of three subseries of arenesulphenyl chlorides, namely those possessing the *ortho*-nitro substituent and those with only a *para* substituent or an *ortho* substituent other than nitro, was the result of our interest in the possible bonding interaction of an oxygen atom from an *ortho*-nitro group with the adjacent sulphur atom leading to a spirosulphurane intermediate **6** instead of the commonly hypothesized sulphonium ion **4**.

6

Studies involving the reaction of arenesulphenyl halides with carbon–carbon double bonds, which correlate thiiranium ion structure with product geometry, have provided considerable insight into the nature of the ionic intermediates and have demonstrated that simple alkane- and arenesulphenyl halides often react in a manner quite different from that of *ortho*-nitro substituted arenesulphenyl halides (11). Thus of paramount importance, in addition to the effect of increasing electron demand, is the determination of what effect, if any, the *ortho*-

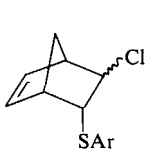
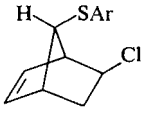
nitro substituent is really contributing to the reactions under consideration. For example, one can envision a destabilization through inductive electron withdrawal, and/or a steric interaction, instead of the aforementioned stabilization of positive charge on sulphur.



Results and Discussion

We have found that reaction of **5** with arenesulphenyl chlorides under ionic conditions gives two or all three of the adducts **7–9** (eq. [2]), when



[2] 

5 **7** **8** **9**

methylene chloride is used as solvent at ambient temperature. No evidence was found for products of edge-on conjugative 1,6-addition, **10**, or Wagner–Meerwein rearrangement, **11**. The very different product compositions and distributions obtained from **5** and its isomeric olefin bicyclo[2.2.1]hepta-2,5-diene, indicate the absence

10

11

of common intermediates and of thermal isomerization of the type **5** ⇌ diene.

Product analyses were based upon previously defined criteria utilizing ^1H and ^{13}C nmr spectroscopy (9, 12). All compounds in addition gave mass and infrared spectra in accord with their structures. The ^{13}C nmr data for species **7** and **8** indicated three cyclopropyl methine carbons with characteristic high-field chemical shifts (12) and high $^1J_{^{13}C-^1H}$ values (13). The remaining carbon resonances, methine *geminal* to chlorine or sulphur and the methylene bridge, were readily identified on the basis of their chemical shifts and multiplicities. The ^1H nmr spectra also exhibit shifts and coupling constants in accord with literature values for tricyclo[2.2.1.$0^{2,6}$]heptanes. In addition we were able to compare these spectral data for **8** and **9** with those of authentic samples prepared during the analogous investigation using bicyclo[2.2.1]-hepta-2,5-diene.

The structure of **7** is clearly the C3 epimer of **8** as determined by ^{13}C nmr analysis. The *endo* orientation of the arylthio moiety at C3 follows from the observed paramagnetic shift of C3 in **7** relative to **8**

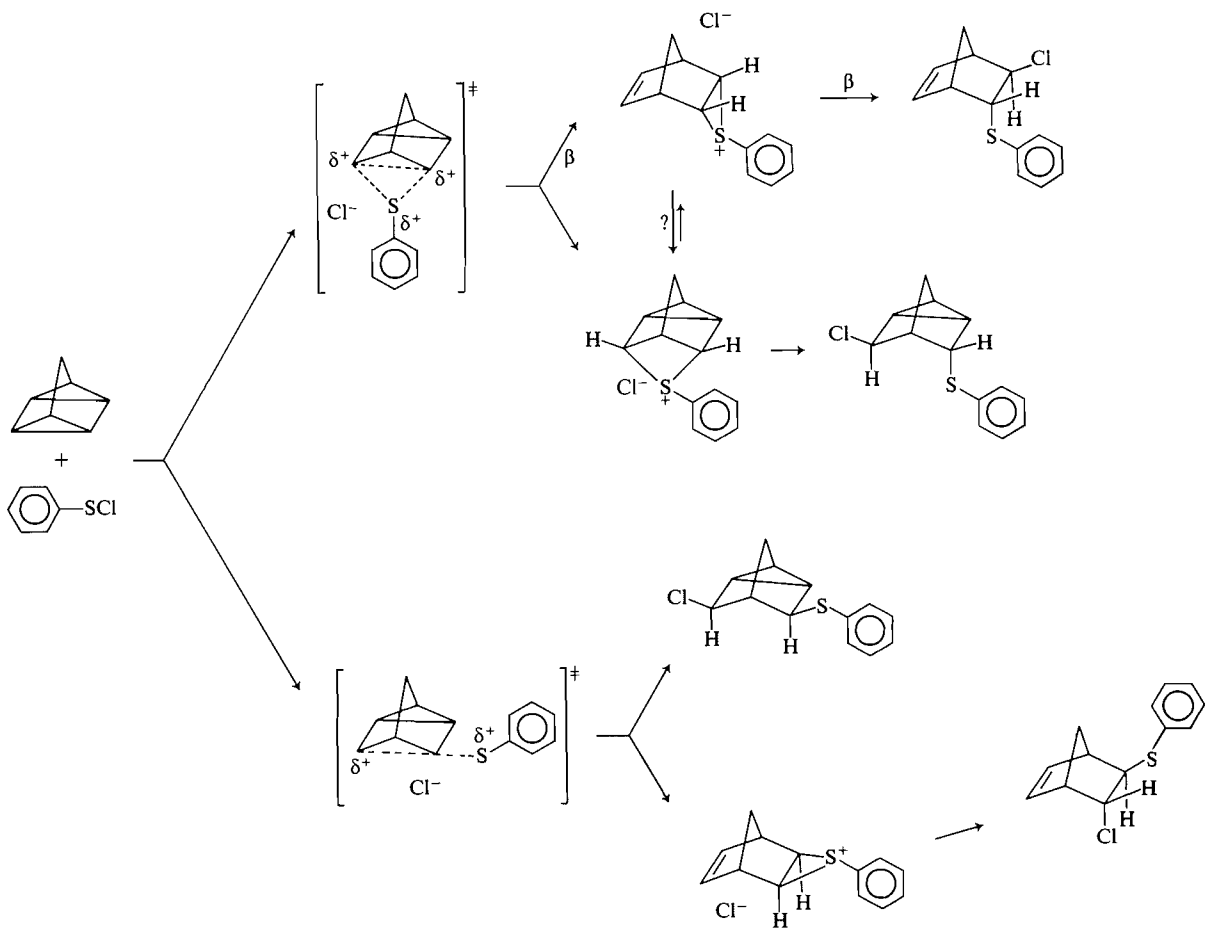
and a diamagnetic shift of C5, albeit a small one, in **7** relative to **8**. The small absolute value of this latter shift difference was unanticipated but presumably results from a combination of the expected γ-*gauche* interaction and an anisotropy effect from the phenyl ring operating in the opposite sense.

The kinetically controlled product distributions were determined by immediate ^{1}H and ^{13}C nmr analysis of the reaction mixtures (Table 1). In each case it was possible to observe and integrate non-overlapping resonances from each species, thereby allowing product ratios to be readily determined. Control experiments using individual samples of the respective adducts, obtained via preparative tlc and/or column chromatography on silica gel, indicate that subsequent isomerizations are much slower than the initial addition process. Product distributions, however, could not be determined from the isolated yields obtained via these separation procedures. The compounds are not entirely stable under our chromatography conditions. The isolation of up to four additional species, unidentified at present, in yields of less than 2–5% of the total reaction mixture employed for separations was observed. These species are believed to be artifacts of the chromatographic procedure and *not* true products of the initial additions.

An examination of the primary product distributions (Table 1) shows a number of trends. A very significant result is the absence of even traces of *endo*-2-arylthio-3-chlorobicyclo[2.2.1]hept-2-enes, **10**, since this indicates that the conjugative cyclopropyl group is unable to compete with neighbouring bivalent sulphur for stabilization of positive charge at C5, during edge-on attack. Our ascertainment of the absence of even traces of the olefins **10** is substantiated by a series of control analyses performed using independently synthesized samples of the olefins **10** (9). Secondly, the observation and isolation of only one olefinic product derived from corner attack is important since it establishes the orientation of ring opening in the second cyclopropane system as occurring stereospecifically with *retention* of configuration at C3. That the two tricyclic adducts, **7** and **8**, are *exo* at C5, implying inversion of configuration at carbon, is in accord with Morrill *et al.*'s results and is furthermore indicative, using Cristol and co-workers' criteria, of the absence of free carbonium ions on the reaction hypersurface.



Regarding the results from *ortho*-nitro substituted benzenesulphenyl chlorides (entries 1–5), one observes that the ratio of edge-on attack to end-on or corner attack, 7:(8 + 9), increases as the electron donating ability of the *para* substituent on the arenesulphenyl chloride is varied from nitro, a poor donor, to methoxy, a good donor. This type of variation is much more dramatic in the absence of the *ortho*-nitro substituents as is shown in entries 6–15, the change going from 0:100 to 57:43.

It is interesting to observe here that 2,4-dinitrobenzenesulphenyl chloride (entry 1) appears to be somewhat better at stabilizing charge development on sulphur, as reflected in the proportion of edge-on attack, than 4-nitrobenzenesulphenyl chloride (entry 6). We interpret this difference as a result of neighbouring group assistance for a weakly stabilized, or perhaps non-stabilized sulphonium ion of type **4**. A further examination of Table 1 indicates that little, if any, extra stabilization is obtained from an *ortho*-nitro group when the *para* substituent is more electron donating than nitro. Thus, comparing entries 2 and 9, 3 and 11, 4 and 12, or 5 and 15, we see significant increases in the percentage of edge-on attack in the absence of the *ortho*-nitro group. These data suggest that, if anything, in these cases the *ortho*-nitro substituent leads to a destabilization of charge development on sulphur in the product-determining transition state. This is of course reasonable since nitro groups are generally considered as electron withdrawing.

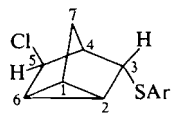
On the basis of the above it appears that only in the case of 2,4-dinitrobenzenesulphenyl chloride does the *ortho*-nitro substituent lead to a stabilizing interaction, possibly via formation of a spirosulphurane intermediate such as **6**. This neighbouring group assistance by the *ortho*-nitro substituent appears to occur as a result of the dual electron withdrawal of both nitro groups, since as we have noted above, in the presence of more electron donating substituents in the *para* position one observes only the electron withdrawing properties of the *ortho*-nitro group.

This scenario is further supported by a comparison of entries 4 and 16 where the relative orientation of methyl and nitro substituents is reversed. It is not clear at this time whether or not the small decrease in the percentage of edge-on attack on going from entry 4 to 16 results from a stronger destabilizing effect of a *para*-nitro group relative to an *ortho*-nitro group, from a stronger stabilizing effect of a *para*-methyl group relative to an *ortho*-methyl group, or from different steric interactions in the transition state for methyl and nitro. Comparing entries 12 and 17 one notes that a second methyl group leads to an increase in the amount of edge-on attack, but that this increase, 5%, is relatively small.

If one compares the ratio of edge-on attack to

SCHEME 1

corner attack for 1,3-addition the variations as a function of R^2, R^4 are much larger. The validity for such a partition of data is, however, questionable since, as an examination of the last column of Table 1 shows, the relative proportion of 1,3-addition to conjugative 1,6-addition during corner attack is not constant, and indeed does not appear to rigorously follow any set pattern. For example, regarding only entries 6, 9, 11, 12, and 15, we observe values of 60:40 ± 2 in every case but 12, which is 78:22. Looking only at column 6, which represents the proportion of species **9**, one observes that these values fall between 30 and 46% when there is a nitro group or another strong electron withdrawing group, e.g., CF_3, present. If the only substituents present are good donors such as methyl, ethyl, *tert*-butyl, and methoxy, the proportion of **9** drops to 10–18%. This also holds for +T substituents[5] such as the halogens F, Cl, and Br. In the case of fluorine the +T effect appears to override the −I or electron-withdrawing inductive effect as is seen in the small proportion, 18%, of olefinic product and the higher ratio of edge-on to corner attack (compare entries 10 and 11). Considering the data as a whole, we observe a general increase in the percentage of conjugative 1,6-addition resulting from corner attack as the ability of the substituents to stabilize charge development on sulphur is decreased.



Unfortunately our data base is too small to allow us to convincingly explain this observation.

The results reported herein may be explained in terms of the two classical competitive pathways on the reaction hypersurface as shown in Scheme 1. We have indicated two product types resulting from each hypothetical intermediate. Route β, which corresponds to the formation of an olefinic product from edge-on attack, was included despite the absence of such adducts in this solvent system. We note that related studies with the corresponding

[5] +T is Ingold's symbol for the effect wherein substituents like NH_2 and OCH_3 can supply electrons by resonance (14).

areneselenenyl chlorides have indicated that the product compositions in these ring cleavages are very sensitive to subtle changes in solvent properties. On this basis we anticipate the formation of such species with the proper choice of solvent.

Summary

Our studies show that the electrophilic cleavage of cyclopropane rings by arenesulphenyl chlorides in systems such as **5** can be accounted for in terms of two competing reaction orientations. Small variations in the molecular structure of the electrophile are seen to result in a change in neighbouring group participation, while retaining an essentially identical steric environment within the vicinity of the reaction site. The degree of neighbouring group participation is found to be a function of the electron demand of the incipient ionic species, the kinetically controlled product distributions reflecting the effect of this electron demand upon the product-determining transition state.

Experimental

General

All melting points were measured on a Fisher-Johns block and are reported uncorrected. The ^1H nmr spectra were recorded on Varian Associates T-60 and HA-100 spectrometers; ^{13}C nmr spectra were recorded on a Varian FT80-16K spectrometer, using chloroform-*d* as an internal lock and reference. All spectral parameters are referenced to TMS as an internal standard.

Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane was purchased from Aldrich and used without further purification. The purity was confirmed via nmr and glc; ^{13}C nmr ($CDCl_3$) δ: 32.0 (t(dd), C3, $^1J_{C,H}$ = 131.4 Hz, $^2J_{C,H} \simeq {}^3J_{C,H}$ = 4.0 Hz), 23.0 (d(tt), C2, C4, $^1J_{C,H}$ = 166.0 Hz, $^2J_{C,H}$ = 8.6, 3.3 Hz), 14.8 (d(ddt) C1, C5, C6, C7, $^1J_{C,H}$ = 184.7 Hz).

2,4-Dinitrobenzenesulphenyl chloride was prepared by the method of Lawson and Kharasch (15) from bis(2,4-dinitrophenyl) disulphide. Recrystallized from CCl_4, mp 96–96.5°C (lit. (15) mp 97–98°C).

2-Nitro-4-chlorobenzenesulphenyl chloride was prepared by the method of Turner and Conner (16) using 1,4-dichlorobenzene as starting material; mp 98°C (lit. (16) mp 97.5–98°C).

2-Nitrobenzenesulphenyl chloride was commercially available (Aldrich). Recrystallized from CCl_4, mp 76°C (lit. (16) mp 75.4–75°C).

2-Nitro-4-methylbenzenesulphenyl chloride was prepared from the analogous aniline by the procedure of Zincke and Rose (17). Recrystallized from CCl_4, mp 89–90°C.

2-Nitro-4-methoxybenzenesulphenyl chloride was prepared from the analogous aniline as above. Crystallized as brilliant orange needles from CCl_4, mp 106–107°C.

The remaining arenesulphenyl chlorides were prepared from the corresponding commercially available thiols or disulphides by chlorination with molecular chlorine in CCl_4 with cooling (0–4°C). All physical data were as expected (18).

General Reaction Procedure

Product studies were carried out as previously described (19). In the cases of 2-nitro-4-substituted benzenesulphenyl chlorides ^1H nmr analysis was carried out during the course of the reactions and thereafter to ensure the establishment of kinetically controlled product distributions. Because of the essentially instantaneous nature of the reactions of arenesulphenyl chlorides which lack the *ortho*-nitro substituent, only the slow isomerizations *post*-addition were observable by ^1H nmr. Samples of individual adducts were isolable via preparative tlc on silica gel

For personal use only.

using CH_2Cl_2 or 80:20 cyclohexane – ethyl acetate as eluant depending upon the substituents. ^{13}C nuclear magnetic resonance parameters for adducts of type **7** are listed in Table 2; ^{13}C nmr parameters for adducts of types **8** and **9** have been reported previously (9).

Addition of arenesulphenyl chlorides to 2-methylenebicyclo[2.2.1]hept-5-ene: effect of increasing electron demand upon the rate and product determining transition states[1]

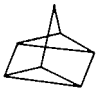
DENNIS G. GARRATT,[2] PIERRE L. BEAULIEU, AND VERONIQUE M. MORISSET
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received October 3, 1979

DENNIS G. GARRATT, PIERRE L. BEAULIEU, and VERONIQUE M. MORISSET. Can. J. Chem. **58**, 1021 (1980).

The rates and products of addition of a series of sixteen arenesulphenyl chlorides to 2-methylenebicyclo[2.2.1]hept-5-ene, **7**, and the *E*, *Z* isomeric 2-ethylidenebicyclo[2.2.1]hept-5-enes, **8** and **9**, have been determined in methylene chloride solution. The major species from attack on **7** is always *endo*-3-arylthio-1-chloromethyltricyclo[2.2.1.$0^{2,6}$]heptane, the product of *exo* attack upon the *endocyclic* double bond with homoallylic participation of the *exocyclic* π system. No evidence was found for initial electrophilic attack upon the *exocyclic* double bond.

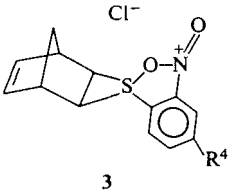
DENNIS G. GARRATT, PIERRE L. BEAULIEU et VERONIQUE M. MORISSET. Can. J. Chem. **58**, 1021 (1980).



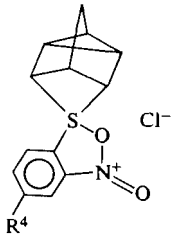
On a déterminé la vitesse de formation des produits d'addition d'une série de 16 chlorures d'arènesulphényles sur le méthylène-2 bicyclo[2.2.1]heptène-5 (**7**) et sur les isomères (*E*) et (*Z*) des éthylidènes-2 bicyclo[2.2.1]heptènes-5 **8** et **9** en solution dans le chlorure de méthylène. Le produit principal résultant de l'attaque du composé **7** est toujours l'arylthio-3 chlorométhyl-1 tricyclo[2.2.1.$0^{2,6}$]heptane *endo*, produit qui provient d'une attaque *exo* sur la double liaison *endocyclique* avec une participation homoallylique du système π *exocyclique*. On n'a pas trouvé de preuves d'une attaque électrophile initiale sur la double liaison *exocyclique*.

[Traduit par le journal]

In two previous articles (1, 2) we have discussed the effect of increasing electron demand (3) upon the product determining transition state in the reaction of arenesulphenyl chlorides with carbon–carbon double bonds and single bonds using respectively bicyclo[2.2.1]hepta-2,5-diene, **1**, and tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane, **2**, as substrates.

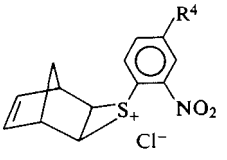


1



2

The aim of these studies was two-fold. Firstly, we desired to ascertain the effect of varying the electrophilicity of the sulphenyl halide while retaining an essentially constant steric environment in the product determining transition state. In this way we would obtain a measure of the degree of charge development on the substrate within this transition state as a function of two neighbouring group effects, the neighbouring groups being the arylthio moiety and the homoallylic double bond in **1** or the conjugative cyclopropyl moiety in **2**. Secondly, we wished to obtain information with respect to the possible bonding interaction of an oxygen atom from the *ortho* nitro group, in *ortho* nitro substituted arenesulphenyl chlorides, with the adjacent sulphur atom which could lead to spirosulphurane intermediates of type **3** and **4** instead of the commonly accepted sulphonium ions **5** and **6** (4).



In regard to this latter point, we observed a stabilizing interaction only in the case of 2,4-dinitrobenzenesulphenyl chloride, presumably as a result of the dual electron withdrawal of both nitro groups, since in the presence of more electron donating substituents in the *para* position one observes only the electron withdrawing properties of the *ortho* nitro group.

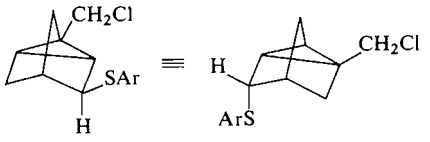
16	$2,5\text{-}(Cl)_2C_6H_3SCl$		98	2	0	98:2	98:2

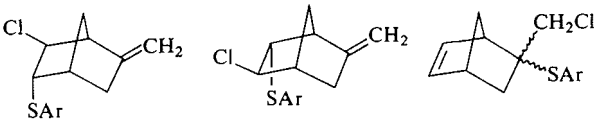
As an extension of these studies we report herein the analogous series of reactions using 2-methylenebicyclo[2.2.1]hept-5-ene, **7**, and the *E*,*Z* isomeric 2-ethylidenebicyclo[2.2.1]hept-5-enes, **8** and **9**, respectively. Our interest in this system stems from the possibility of determining the relative propensity for attack upon an *exocyclic* vs. an *endocyclic* double bond as a function of the electrophilicity of the sulphenyl halide while simultaneously obtaining a measure of the relative neighbouring group efficiency of the arylthio moiety and the homoallylic double bond. Furthermore, this system is of interest since it allows one to ascertain the regiochemistry of the reaction. The importance of this latter point has been discussed in a number of recent reviews (5, 6).

Results and Discussion

We have found that the reaction of **7** with arenesulphenyl chlorides under ionic conditions in methylene chloride solution gives one, two, or all three of the adducts **10–12** (eq. [1]). In all cases species **10**, *endo*-3-arylthio-1-chloromethyltricyclo[2.2.1.$0^{2,6}$]heptane, the product of *exo* attack upon the *endocyclic* double bond with homoallylic participation of the *exocyclic* π system, is the major adduct (see Table 1).[3] No evidence is found for the presence of products derived from *endo* attack upon the *endocyclic* double bond, **13–15**, or for

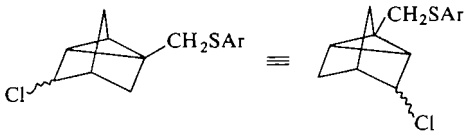


[3]We have extended the *exo–endo* terminology beyond its original usage in bicyclo[2.2.1]heptane systems (*7a*) to nortricyclenes in accord with the suggestion of Cristol and Lalonde (*7b*) by referring configuration with respect to the unsubstituted methano bridge at carbon 7.



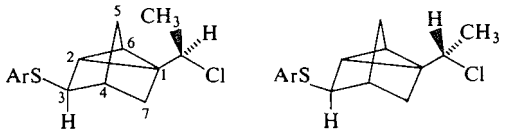
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

initial attack upon the *exocyclic* double bond, **16** and **17**. The absence of products of *endo* addition, possibly the result of a steric interaction with the C3 *endo* proton, is in contrast to our results and those of others with substrate **1**.



The reactions of arenesulphenyl chlorides with

13



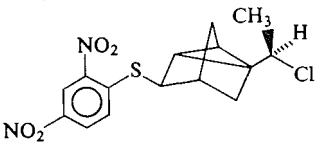
14 **15** **16**

17

the *E*,*Z* isomeric dienes **8** and **9** similarly give rise to products of *exo* attack upon the *endocyclic* double bond with homoallylic rearrangement. Of note is the observation that while the electrophilic attack is apparently stereospecific, subsequent nucleophilic attack by chloride ion is non-stereospecific, giving rise to essentially equal mixtures of the 3-*RS*,8-*RS* and 3-*RS*,8-*SR* diastereoisomeric nortricyclenes, **18** and **19**. This result is important since the only

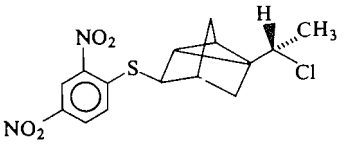
18 **19**

related case of homoallylic rearrangement during a sulphenyl chloride addition, which dealt with bicyclo[2.2.1]hepta-2,5-diene, **1**, gives a single adduct via an apparent "homo-S_N2'" attack by chloride ion on the intermediate thiiranium ion (1).



Product analyses are based upon previously defined criteria utilizing ^{1}H nmr and ^{13}C nmr spectroscopy (1, 2, 8). All compounds in addition give mass and infrared spectra in accord with their structures (9).

For example, the ^{1}H nmr spectrum of adduct **20**, derived from the addition of 2,4-dinitrobenzenesulphenyl chloride with **7**, has an AB quartet centered at δ 3.84 ($^2J_{AB}$ = 10 Hz), integrating as two protons, assigned to the —CH_2Cl moiety, and a broad singlet at δ 3.55 (1H, $W_{1/2}$ = 3.5 Hz) assigned to the proton geminal to the arylthio group. No evidence was found for olefinic protons.



The ^{13}C nmr data for **20** indicate two cyclopropyl methine carbons with the characteristic high-field chemical shifts (10), δ 19.7 and 22.5, and large $^1J_{C,H}$ values, 175.4 and 179.1 Hz, respectively.[4] An additional high-field quaternary carbon, δ 28.3, consistent with a cyclopropyl center is also observed. The remaining carbons (methine bridgehead, methylene bridges, and the methine carbon, which is bonded to the arylthio group) are readily assigned on the basis of their chemical shifts and multiplicities.

The electron-impact mass spectrum of **20** has a low intensity molecular ion cluster at *m*/*e* 340. Characteristic fragments include the loss of a chlorine atom ($M^+ - {}^{35}Cl$; *m*/*e* 305), loss of the arylthio group ($M^+ - 199$; *m*/*e* 141) followed by loss of CH_2Cl ((*m*/*e* 141) − 49; *m*/*e* 92) and a retro Diels–Alder fragmentation with loss of ethylene to give a C_6H_6Cl fragment ((*m*/*e* 141) − 28; *m*/*e* 113). The loss of an oxygen atom or a NO fragment from the molecular ion was also of note.

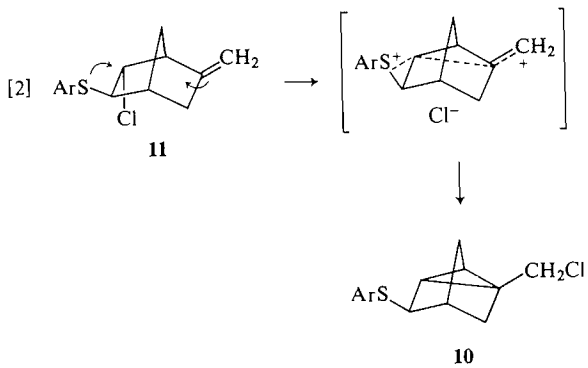
The regiochemistry of the addition was confirmed by an examination of the analogous products derived from dienes **8** and **9**. Thus in the ^{1}H nmr spectra, we observe quartets at δ 4.18 and 4.27 which are readily assigned to the methine protons geminal to the chlorine atoms in diastereomers **21** and **22**. The protons geminal to the arylthio group in the diastereomers have virtually magnetically equivalent environments, resonating at δ 3.53 and 3.55, respectively. We note that no attempt has been made on our part to rigorously assign the relative configuration of adducts **21** and **22** (**18** and **19**) at this time.

21

22

A comparison of the ^{13}C nmr spectra of **20**, **21**, and **22** is most instructive. The carbons directly bonded to chlorine resonate at δ 59.4 and 59.0 in **21** and **22**. This represents paramagnetic shifts of 12.8

[4]See ref. 10*a*, Chapt. 10.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

and 12.4 ppm, respectively, upon the substitution of a methyl group for a proton, in accord with the anticipated α effect.[5] In contrast, the methine carbons geminal to sulphur show essentially a constant magnetic environment, δ 51.2 in **20** vs. δ 50.9, 51.2 for **21**, **22**. These shift differences would be reversed if a regiochemistry such as is found in species **17** were present.

In accord with the above, the mass spectra of **21** and **22** have intense molecular ions at *m/e* 354. Characteristic fragmentations include the loss of HCl ($M^+ - 36$; *m/e* 318), the loss of C_2H_4Cl (α-cleavage, $M^+ - 63$; *m/e* 291), and the loss of ArS ($M^+ - 199$; *m/e* 155). This latter fragment further fragments via loss of ethylene (retro Diels–Alder, (*m/e* 155) − 28; *m/e* 127) followed by loss of HCl ((*m/e* 127) − 36; *m/e* 91) to give the very stable C_7H_7 cation-radical.

The presence of adducts of type **11** and **12** derived from *exo–anti* attack upon the *endocyclic* double bond is also quite instructive. The assignment of configuration in these cases is made by a comparison of the spectral parameters (^1H, ^{13}C nmr, ir, ms) of samples of the phenylthio and anisylthio forms of **11** and **12** with the analogous samples of *exo*-2-arylthio-*endo*-3-chlorobicyclo-[2.2.1]heptane prepared via the addition of benzenesulphenyl and 4-methoxybenzenesulphenyl chlorides to bicyclo[2.2.1]hept-2-ene, **23**. The spectral parameters of these compounds have been previously reported (11, 12). The assignment of the arylthio group in species **11** as *exo* is very important. This piece of data in conjuction with the observation that adducts of type **11** isomerize to the nortricyclene adducts **10** (presumably by way of a thiiranium ion-like intermediate resulting from neighbouring group assistance of carbon–chlorine bond cleavage by the arylthio group) allows one to assign the configuration in **10** as *endo*.[3]

An examination of the primary product distributions (Table 1) shows a number of trends. Regarding first of all the results from *ortho* nitro-substituted benzenesulphenyl chlorides (entries 1–5), one observes the formation of adducts of type **10** only. This is very important because it indicates that a homoallylic *exocyclic* double bond is more efficient at stabilizing charge development at C6 of **7** than is the neighbouring 2-nitroarylthio group. This is true even when that group has a methoxy substituent in the *para* position (entry 5)! These data contrast very strongly with our previous results with substrate **1** (1), wherein we observed that a homoallylic *endocyclic* double bond is in general less efficient than the neighbouring 2-nitroarylthio group at stabilizing charge development on carbon. In this study we find that even where very efficient electron donors are involved, as in entries 12–14, the homoallylic *exocyclic* double bond is more efficient than sulphur towards such stabilization. This is perhaps most dramatically demonstrated for the isomeric 2-ethylidenebicyclo[2.2.1]hept-5-enes, **8** and **9**, where only products of homoallylic rearrangement are isolable or observed spectroscopically.

Furthermore, in contrast to the reactions with substrates **1** and **2**, we do not observe any evidence for a stabilizing interaction from an *ortho* nitro substituent even in the case of 2,4-dinitrobenzenesulphenyl chloride (1, 2). A comparison of entries 1 and 6, 2 and 9, 3 and 11, 4 and 12, and 5 and 14 shows that in each case the *ortho* nitro substituent contributes a destabilizing effect upon the thiiranium ion-like intermediate as it approaches the product determining transition state.

In order to gain a more complete idea of the electronic factors affecting this reaction, we have carried out a series of kinetic studies using as substrates compounds **1**, **2**, **7**, **8**, and **23**. The rates of addition of the arenesulphenyl chlorides which lack the *ortho* nitro substituent were measured in methylene chloride solution at 24.5°C by means of the stopped-flow technique using a Durrum-Gibson stopped-flow spectrophotometer. The rate of disappearance of the sulphenyl chlorides was followed by measuring the decrease in their absorptions at 392.5 nm. All the rates (Table 2) were measured under pseudo first order conditions. The data from all runs gave linear first order plots. The second order rate constants were obtained by dividing the pseudo first order rate constants by the substrate concentrations.

On examination of Table 2 one recognizes immediately the rather unanticipated result, that for any given substrate the rate constants, k_2, are essentially constant. There is little, if any, correlation between the rates of addition and the electron

[5]See ref. 10*a*, Chapt. 2.

TABLE 2. Specific rate constants for the reaction of some ring-substituted arenesulphenyl chlorides with substrates **7**, **8**, **1**, **2**, and **23** in methylene chloride solution at 24.5°C

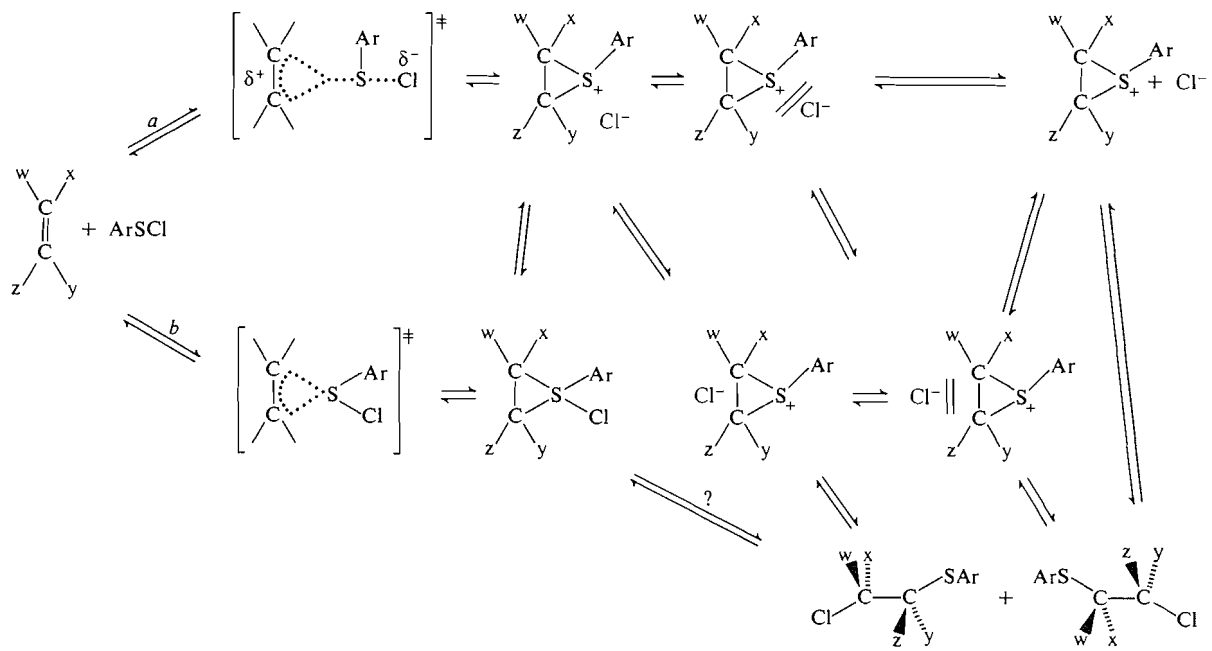
donating or electron withdrawing ability of the ring-substituents on the sulphenyl chloride. In terms of σ–ρ linear free energy relationships, one finds values of ρ which are essentially *zero*, perhaps slightly negative or slightly positive! These data must be interpreted in terms of the virtual absence of charge development upon sulphur in the rate determining transition state! In the cases of substrates **7** and **8** one might also state that there is apparently little, if any, charge development on sulphur in the product determining transition state. Yet our earlier investigations dealing with substrates **1** and **2** showed a very strong dependence in the product determining states for the electron donating or withdrawing abilities of the ring-substituents, an observation indicative, when coupled with the kinetic data, of different rate and product determining transition states.

It is, furthermore, very important that in the case of substrate **23**, only products of *exo–anti* addition have been isolated or observed, since this rules out σ participation as playing a significant role (11–13). One must not, however, rule out the significance of *anti* addition, particularly since electrophilic attack upon the bicyclo[2.2.1]heptyl system very frequently occurs *syn* (14)!

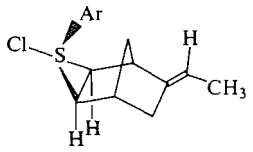
The available data suggest a bridged rate determining transition state. This transition state must, however, have little or no charge development on sulphur if our interpretation of the rate data (Table 2) is correct. The need for a bridged rate determining transition state follows from the absence of products of *exo–syn* or Wagner–Meerwein type rearrangement (σ participation) which would presumably result were an open carbonium ion (norbornyl carbonium ion, etc.) present on the reaction hypersurface. This argument is based on the concept that if the rate determining transition state is not bridged, the succeeding intermediate should lose its configurational integrity and thereby give rise to additional products. The absence of such products therefore indicates a bridged rate determining transition state.



On the basis of these data and the plethora of results previously published (5, 6, 15), a mechanism involving at least one intermédiate and two transition states is required. Although many variations on the following scenarios are conceptually possible, two mechanisms have received the most attention (see Scheme 1). Path *a* in Scheme 1 is the sulphur analogue of the S_N2 mechanism. Path *b* involves a different angle of approach between the substrate molecule and the sulphenyl chloride and leads to an episulphurane species which may ionize to the thiiranium ion or may proceed directly to products.

While the rate data in Table 2 readily rule out a mechanism involving initial dissociation of the sulphenyl halide to a sulphenium ion, ArS^+, followed by attack on the olefinic double bond,[6] to give a thiiranium ion (16), it is clear that both paths *a* and *b* can accommodate these results. In path *a* a rate determining transition state structure of the S_N2 sort is anticipated to have a charge distribution leading to a ρ value which is zero or slightly positive, in analogy to S_N2 displacement at carbon. In path *b* the formation of an episulphurane intermediate may occur in such a way that little or no charge develops on sulphur in the transition state, despite the obvious redox nature of the reaction. Although conclusive evidence is lacking, at this time, as to which path most correctly corresponds to the actual reaction hypersurface, it is clear that given the dissociation of the sulphur–chlorine bond in an episulphurane-like intermediate one arrives at the same series of thiiranium ion-pairs, which serve to define the probable product determining transition state structures (5, 6).

Of importance in regard to the nature of the product determining transition state is the observation of non-stereospecific attack by chloride ion on the intermediates derived from dienes **8** and **9**. From this result it would appear that a concerted rearrangement of episulphuranes such as **24** and **25** to product does not occur, or that **24** and **25** are not the sole precursors. One must, however, be careful. A consideration of the possible bonding modes for an episulphurane type species suggests a trigonal bipyramid configuration (17, 18). Thus even in the case of "stereospecific" *exo* attack upon the olefinic double bonds of, for example, **8**, two



[6]Rate limiting formation of a sulphenium ion, RS^+, from RSCl may be considered as the sulphur analogue of an S_N1 displacement at carbon.

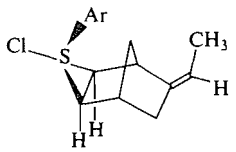
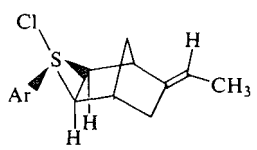


SCHEME 1

isomeric episulphuranes may be formed: **24** and **24'**. If both **24** and **24'** are formed in equivalent amounts, it would be possible for **18** and **19** to be formed via concerted rearrangements of the form



24

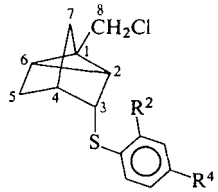
25

24 → **18**, **24'** → **19**, or vice versa. Such a scenario ([**24**] = [**24'**]), however, seems very unlikely to us on both electronic and steric grounds. Our own preference is for product formation at the intimate or solvent-separated ion-pair stage. Further studies, however, will be necessary to clearly define the reaction hypersurface.

In terms of comparing these results for 2-methylenebicyclo[2.2.1]hept-5-ene with those of others for different electrophiles, it is of note that Hassner and co-workers (19) have shown preferential iodination of the *endocyclic* double bond using IN_3 and INCO, whereas von Schleyer and O'Conner report (20) the preferential protonation of the *exocyclic* double bond, both series of reactions leading to nortricyclic products. The difference between von Schleyer's results and those of Hassner and of ourselves is readily interpreted in terms of ion stabilities.

24'

Protonation of the *exocyclic* double bond of **8** leads to a tertiary carbonium ion, whereas the analogous attack upon the *endocyclic* double bond would give only a secondary species, albeit one which could be stabilized by both σ and π participation. Alternatively one can view the differentiation between the two π systems in terms of kinetics. Protonation of a 1,1-disubstituted alkene is known to occur many orders of magnitude faster than attack upon a 1,2-disubstituted alkene (21). An extension of this scenario explains the preferential attack by electrophiles such as IN_3, INCO, and ArSCl on the *endocyclic* double bond. It is known that where bridged rate determining transition states are common, a *cis*-1,2-disubstituted double bond generally reacts faster than a similarly substituted 1,1-disubstituted alkene (22, 23).



Experimental

All melting points were measured on a Fisher-Johns block and are reported uncorrected. The ^1H nmr spectra were recorded on Varian Associates T-60 and HA-100 spectrometers in chloroform-*d*, the TMS resonance being used to provide the field-frequency lock; ^{13}C nmr spectra at 20.000 MHz were obtained on a Varian FT80-16K spectrometer. Samples (100–300 mg/1 mL) in chloroform-*d* were contained in 10 mm tubes. The deuterium resonance from the solvent was used for the field-frequency lock. A spectral width of 4000 Hz with an acquisition time of 1.023 s, using 2-40K transforms, was em-

ployed. Coupling constants ($J_{^{13}C-^1H}$) were measured from high resolution spectra enhanced by applying the noise modulated decoupling field between data acquisition periods to retain the nOe. Signal assignments were made with the assistance of off-resonance, single-frequency decoupled spectra. All chemical shifts are expressed (δ, ppm) from internal TMS. Representative parameters are given in Tables 3 and 4. Mass spectra were recorded using an MS-9. Infrared spectra were recorded using a Unicam 1100 spectrometer, with matched NaCl 0.1071 mm cavity cells as CCl_4 or $CHCl_3$ solutions. All analytical and preparative tlc separations were performed on Analtech or Macherey-Nagel precoated plates, silica gel GF. Visualization of the tlc spots was accomplished by I_2, uv (254 nm), and phosphomolybdic acid – EtOH.

2-Methylenebicyclo[2.2.1]hept-5-ene was purchased from Aldrich and used without further purification. The purity was confirmed via ir, nmr, and glc; ir (CCl_4) μm: 3.12(w), 3.21(m), 3.3–3.4(bs), 3.45(m), 5.65(bw), 5.98(m), 6.32(bw), 6.88(bm),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

7.4(m), 9.8(w), 10.0(w), 10.4(w), 10.6(m), 11.0(m), 11.2(s), 11.6(m); ^{1}H nmr ($CDCl_3$) δ: 5.22(m, 2H), 4.18(m, 1H), 3.02(m, 1H), 2.37(m, 1H), 0.93–2.2(m, 4H); ^{13}C nmr ($CDCl_3$) δ: 150.9(s, C2), 136.4(d, C6), 134.3(d, C5), 103.3(t, C8), 51.0(d, C1), 50.2(t, C7), 42.1(d, C4), 33.6(t, C3).

2-Ethylidenebicyclo[2.2.1]hept-5-ene was purchased from Aldrich. Analysis via nmr and glc indicated that this material was a 78:22 mixture of the *E* and *Z* isomers. Separation was accomplished on an analytical scale using glc/SE-30 column. Only exploratory product studies were carried out on isomerically pure samples, since reactivity studies indicated nonstereospecific addition. E *isomer*: ^{1}H nmr partial ($CDCl_3$) δ: 4.85(q, 1H, $=CHCH_3$); ^{13}C nmr ($CDCl_3$) δ: 50.5(d, C1), 142.0(s, C2), 31.1(t, C3), 41.8(d, C4), 134.4(d, C5), 135.9(d, C6), 50.3(t, C7), 112.7(d, C8), 14.8(q, d, C9). Z *isomer*: ^{1}H nmr partial ($CDCl_3$) δ: 4.48(q, 1H, $=CHCH_3$); ^{13}C nmr ($CDCl_3$) δ: 44.8(d, C1), 141.4(s, C2), 33.6(t, C3), 41.4(d, C4), 133.7(d, C5), 136.9(d, C6), 49.5(t, C7), 113.1(d, C8), 14.6(q, d, C9).

Arenesulphenyl chlorides were prepared as previously described (1, 2). Bicyclo[2.2.1]hept-2-ene, bicyclo[2.2.1]hepta-2,5-diene, and tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane were the commercial products. These materials were analyzed as previously described (1, 2) and used without further purification.

General Procedure was as previously described (1, 2). Kinetic studies were carried out as previously described (23). Melting points of crystalline *endo*-3-arylthio-1-chloromethyltricyclo[2.2.1.0^{2,6}]heptanes are Ar = 2,4-$(NO_2)_2$: 101–105°C; 2-NO_2, 4-Cl : 76–78°C; 2-NO_2 : 77–79°C; 2-NO_2, 4-CH_3 : 59–61°C; 2-NO_2, 4-CH_3O : 62–63°C.

Elemental analysis (C, H, S) was carried out on all new compounds and found to be within ± 0.35% of the theoretical values. Isomerization of species **11** and **12** to **10** was observed by recording the ^{1}H and ^{13}C nmr spectra of the crude reaction mixtures over a period of two months. While it was immediately clear that **11** isomerizes to **10**, the simultaneous isomerization of **12** to **11** made it difficult to determine at this time whether or not **12** is able to go to **10** directly.

Factors influencing the nature of seleniranium ions in selenenyl chloride additions to alkenes: the use of methanol as solvent[1]

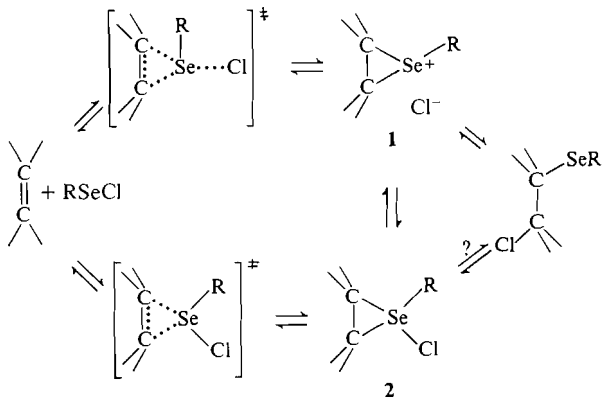
DENNIS G. GARRATT[2] AND ANN KABO

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received October 4, 1979

DENNIS G. GARRATT and ANN KABO. Can. J. Chem. **58**, 1030 (1980).

The reaction of benzeneselenenyl chloride with some simple alkylsubstituted acyclic and cyclic alkenes has been investigated using methanol as the solvent. Products of solvent-incorporation, β-methoxyalkyl phenyl selenides, are normally favoured over the analogous chloro species, but exceptions have been noted. The observation of products of solvent-incorporation, Wagner–Meerwein rearrangement, and homoallylic rearrangement is in accord with an Ad_E2 mechanism involving both intimate and solvent-separated ion-pairs prior to the product forming step.



DENNIS G. GARRATT et ANN KABO. Can. J. Chem. **58**, 1030 (1980).

On a étudié la réaction du chlorure de benzènesélènènyle avec quelques alcènes simples acycliques et cycliques ayant un substituant alkyle en utilisant le méthanol comme solvant. Les produits résultant de l'incorporation du solvant, les phénylsélénures de β méthoxyalkyles, sont normalement favorisés par rapport aux analogues chlorés, mais on a noté quelques exceptions. L'observation des produits résultant de l'incorporation du solvant, de transpositions de Wagner–Meerwein, de transpositions homoallyliques, est en accord avec un mécanisme Ad_E2 impliquant des paires d'ions liés et des paires d'ions séparés par le solvant avant l'étape de formation des produits.

[Traduit par le journal]

Considerable attention has been given to the reactions of areneselenenyl halides with carbon–carbon double bonds (1). The addition reaction has been found to be *anti*-stereospecific by numerous investigators (2). This observation in addition to supplementary kinetic evidence (3) has been used as the basis for postulating a mechanism (see Scheme 1) involving a seleniranium ion, [3] **1**, and/or an episelenurane, **2**, intermediate prior to the product forming step (4, 5). In a recent article (6), we reported that an open cationic species may exist prior to the product forming step in additions to vinyl ethers such as 3,4-dihydro-2*H*-pyran. The intermediacy of a bridged species was, however, evident from an analysis of kinetic data, suggesting therefore that a seleniranium ion-like species precedes any cation of the open structure.

Such data are generally interpreted in terms of an Ad_E2 mechanism (7). The usual criteria of such a two-step mechanism, solvent-incorporated or rearranged products, are, however, quite rare in selenenyl halide additions. For example, the reaction of 2,4-dinitrobenzeneselenenyl chloride with *E*- or *Z*-1-phenylpropene in acetic acid, which is albeit a poor or weak nucleophilic solvent, fails to give acetate products under conditions of kinetic control (2*a*). Similar results have been reported by others using the somewhat stronger electrophiles, benzeneselenenyl chloride and bromide (1*f*, 2*b*). Furthermore, bicyclo[2.2.1]hept-2-ene, an olefin prone to skeletal rearrangements during electrophilic attack, gives only the products of *exo–anti* addition when reacted with benzeneselenenyl chloride or thiocyanate in methylene chloride solution (8).

[3]We note that the use of the term *seleniranium ion*, particularly in Scheme 1, was not and is not intended to imply a dissociated ion. It has always been our belief that a series of ion-pairs is to be found on the reaction hypersurface. This statement is not, however, intended to suggest that a dissociated ion is not formed under some circumstances. The authors wish by this note to remove any possible confusion which might exist over the usage of such nomenclature in the future as apparently currently exists with respect to the use of thiiranium or episulphonium ion in the analogous reactions of sulphenyl chlorides (see for example ref. 1*a*, pp. 828–854, and ref. 10).

alcohols, has been ignored, primarily it would appear because of the leitmotif of organic chemistry that one can not, or at least should not, carry out reactions in a medium which itself readily reacts with one of the reagents.

In this case the reaction of selenenyl halides with alcohols to give selenenic esters (selenenyl alkoxides) has been known for over forty years (9). We observe the reaction of benzeneselenenyl chloride with methanol to be bimolecular, the rate of disappearance of selenenyl chloride following second order kinetics, first order in both selenenyl chloride and methanol in methylene chloride solution. Comparing k_2 for the reaction of benzeneselenenyl chloride with methanol to that of k_2' for the *analogous* reaction with ethylene (3), $k_2 = 0.011$ $dm^3\ mol^{-1}\ s^{-1}$ vs. $k_2' = 498$ $dm^3\ mol^{-1}\ s^{-1}$, CH_2Cl_2/25°C, indicates that the π orbital of a carbon–carbon double bond is a more effective nucleophile than the oxygen atom of an alcohol as far as nucleophilic displacement at bivalent selenium is concerned!!

If one makes the assumption, the validity of which is unfortunately not known, that the difference in relative reactivity of ethylene vs. methanol, $\simeq$ 45 250:1, is the same in methanol as in methylene chloride, and if one notes that the concentration of methanol in pure methanol is approximately 24.7 mol dm^{-3}, it becomes apparent that under normal reaction conditions, wherein the alkene concentration in the solvent is in the range of 0.04–0.12 mol dm^{-3}, the probability of the selenenyl chloride reacting preferentially with the alkene is at least 70–200:1. Such a scenario will be valid for any alkene which is more reactive than ethylene.

On the basis of these observations and calculations it became apparent that one should be able to carry out reactions between benzeneselenenyl chloride and simple alkenes in polar and nucleophilic solvents such as methanol.[4] It was anticipated that by virtue of the greater polarity and nucleophilic nature of methanol one would be able to draw further mechanistic conclusions with respect to the importance of ion-pairs during the reaction of selenenyl halides with alkenes.[3] Furthermore, it was felt that the use of methanol or other alcohols as solvents might open up a new series of potentially useful synthetic reagents for the introduction, both stereo- and regiospecifically, of an ether functionality into an organic substrate.

We wish to present experimental data which have a direct bearing upon this problem.

[4]Methanol has been used as a solvent for other nucleophilic substitutions at selenenyl selenium (11).

Results and Discussion

In the early stages of this investigation we examined the effect of increased solvent polarity and nucleophilicity using simple *E*- and *Z*-1,2-dialkylsubstituted ethylenes, such as the isomeric 3-hexenes, and 2,5-dimethyl-3-hexenes. In each case a mixture of methoxy- and chloro-adducts is isolable; the products being formed by net *anti*-stereospecific addition (see Table 1). Assignments are based upon both ^1H and ^{13}C nmr spectroscopy (Tables 2 and 3, and Experimental). The ratio of methoxy- to chloro-adducts, $[ROCH_3]/[RCl]$, is found to be generally greater than one, but some exceptions are apparent, as in, for example, the case of *Z*-2,5-dimethyl-3-hexene.

Control experiments demonstrate that the reaction of selenenyl chloride with methanol is much slower than the additions and that samples of chloroadducts are not solvolyzed under our reaction conditions. Supplementary data of this form are also available from the literature (12). McManus and Lam have determined that the methanolysis of 2-chloroethyl phenyl selenide follows first order kinetics, $k = 2.94 \times 10^{-4}\ s^{-1}$, which corresponds to $\tau_{1/2} = 39$ min. The essentially instantaneous nature of these additions, $\tau_{1/2}$ = a few milliseconds to seconds, dependent upon concentrations, thus rules out methanolysis of the chloroadducts as being significant.

When unsymmetrically substituted ethylenes, such as the 4,4-dimethyl-2-pentenes, are reacted under these conditions, attack by methanol is highly regioselective, occurring at the least sterically hindered position to give the *anti*-Markownikoff adducts.[5] These data are indicative of the importance of steric factors towards directing the approach of the solvent molecule, CH_3OH, to the least hindered secondary site of the initially formed intermediate, although the importance of nonrepulsive electronic effects can not be totally ruled out.

The use of *Z*- and *E*-1-phenylpropene as substrates is particularly instructive. The addition is *anti*-stereospecific and regiospecific in the Markownikoff sense in accord with earlier studies (2*a*,

[5]In the tables we use the designation Markownikoff, *M*, and *anti*-Markownikoff, *aM*, to distinguish between regioisomeric adducts. Since such nomenclature is confusing for adducts derived from 1,2-disubstituted or tetrasubstituted ethylenes, we have adopted the convention that when both olefinic carbon atoms contain the same number of *alkyl groups* the Markownikoff isomer is defined as that one in which the chloride or methoxide moiety is bonded to the carbon whose sum of Taft's inductive substituent constants, $\Sigma\sigma^*$, is the more negative. This method of nomenclature has been previously employed (19).

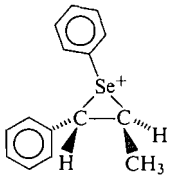
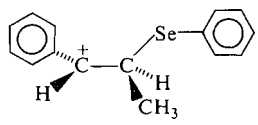
*(2-*RS*, 3-*RS*) and (2-*RS*, 3-*SR*) diastereoisomers.

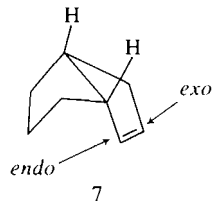


13). It is clear from these observations that the increased polarity of the medium is not able to shift the relative order of stabilities between isomeric β-phenylseleno benzylic carbonium ions, **3** and **4** (usually the less stable species), and seleniranium ions, **5** and **6**. Alternatively, we can make the hypothesis that if **3** and **4** are formed on the reaction hypersurface, they collapse to products faster than rotation about the C1—C2 single bond, i.e., faster than isomerization and equilibration of the form: **3**⇄**4**. The exclusive formation of products of *anti*-addition would then be, presumably, the result of retardation of *syn* attack because of the bulk of the β-phenylseleno group, as seems reasonable.



5

3

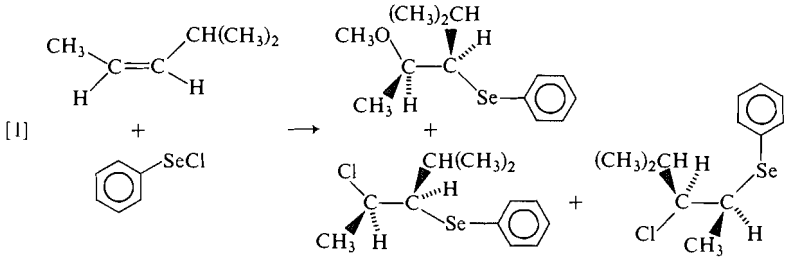


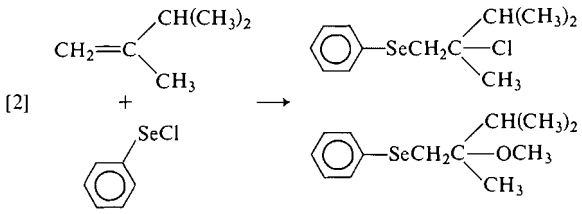
6

4

With 1,1-disubstituted and trisubstituted ethylenes, benzeneselenenyl chloride reacts regiospecifically in the Markownikoff sense, electronic factors apparently overriding steric hindrance to approach in contrast to our observations for 1,2-dialkylsubstituted ethylenes (eqs. [1] and [2], Table 1). In comparison, we note that areneselenenyl chlorides show an equivalent regiospecificity in methylene chloride solution, whereas arenesulphenyl chlorides add regioselectively in the opposite, i.e., *anti*-Markownikoff sense.

The configurational-selectivity,[6] ie, the ability of the selenenyl chloride to preferentially attack one face of the olefinic π system, is demonstrated by the reaction of benzeneselenenyl chloride with *cis*-bicyclo[3.3.0]oct-2-ene, **7**. The ratio of *exo* to *endo* attack is found to favour the sterically least hindered *exo* face in both methanol and methylene chloride solution (eq. [5]), $(exo/endo)_{CH_3OH}$ = 74:26, $(exo/endo)_{CH_2Cl_2}$ = 81:19. Of note, however, is the relative distribution of regioisomers. For example, the major species from the reaction of benzeneselenenyl chloride with **7** in methanol is the



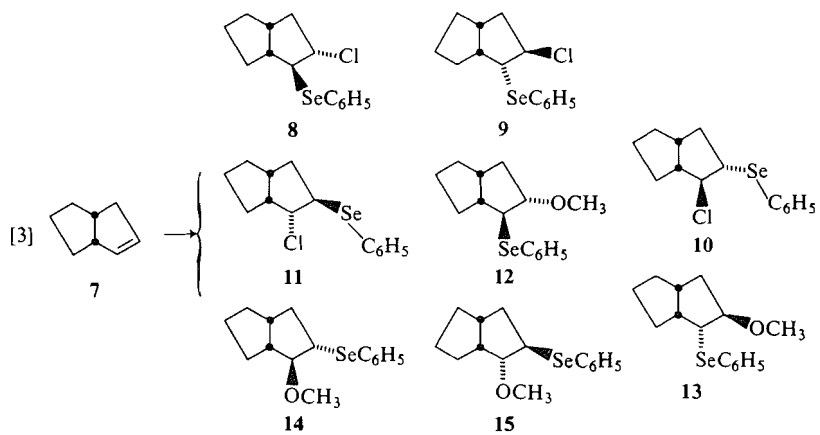


7

Markownikoff adduct of *exo* attack with solvent-incorporation, **15**. This compound plus its chloro analogue, **11**, account for 54% of the reaction mix-

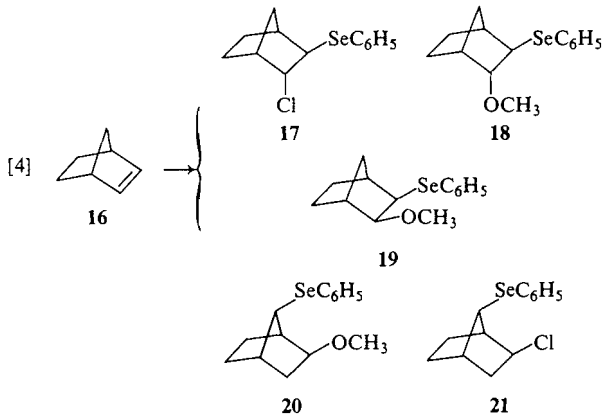
[6]The term configurational-selectivity was originally coined in reference to a problem in allene chemistry in which it became necessary to distinguish which face or faces of the orthogonal π systems was/were being attacked (20). The extension of the use of this term to problems such as *exo* and *endo* attack seems to us quite reasonable.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



ture, the *anti*-Markownikoff adducts of *exo* attack, **8** and **12**, accounting for another 20%. In methylene chloride solution, *anti*-Markownikoff attack, on the *exo* face, compound **8**, accounts for 57% compared to 24% Markownikoff, **11**, the reverse of the situation in methanol! These observations are more striking if one compares the product distribution from **7** with those from the acyclic alkene, *Z*-4-methyl-2-pentene (Table 1). In the latter case we observe only a marginal change in the ratio of Markownikoff to *anti*-Markownikoff adducts upon changing the solvent. Furthermore, attack by methanol is regiospecific in the *anti*-Markownikoff sense. Clearly there are no gross preferences involved, but rather some subtle admixture of factors, most likely involving series of ion-pairs.

The reaction of benzeneselenenyl chloride with bicyclo[2.2.1]hept-2-ene, **16**, is most instructive in this regard. In methylene chloride solution only the product of *exo–anti* addition, **17**, is isolable or observed. In contrast, we find five products, **17–21**, when methanol is the solvent (eq. [4]). In addition to the products of *exo–anti* addition, we observe minor amounts of *exo*-2-methoxy-*syn*-7-phenylselenobicyclo[2.2.1]heptane, **20**, and *exo*-2-chloro-*syn*-7-phenylselenobicyclo[2.2.1]heptane, **21**, the result of Wagner–Meerwein rearrangement, plus *exo*-2-phenylseleno-*exo*-3-methoxybicyclo[2.2.1]-heptane, **19**, a product of *exo–syn* addition! No evidence was found for products of elimination, such as nortricyclenes.

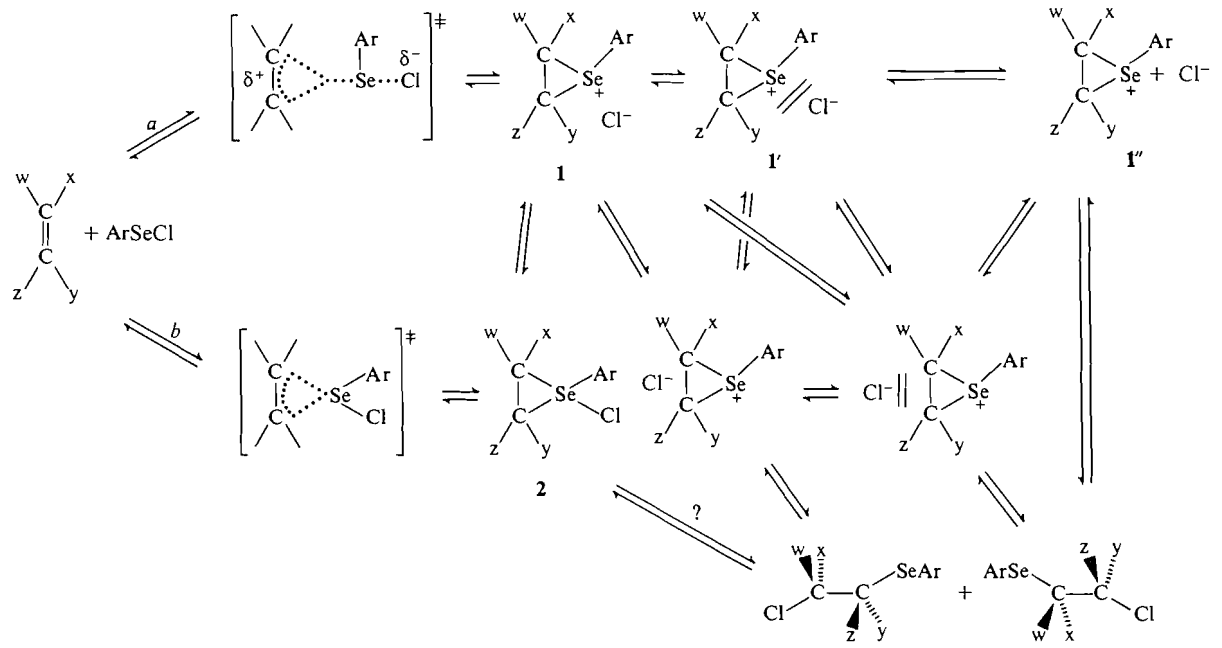


To account for the data discussed up to this point we require a more complex reaction hypersurface, such as is shown in Scheme 2. In terms of this scheme we interpret the results from **16** as reflecting competitive attack by chloride ion and methanol on a seleniranium ion species at the intimate ion-pair, **22**, and solvent-separated ion-pair, **23**, stage. The ratio of chloro adduct **17** to the methoxy adduct **18** ([**17**]/[**18**] = 72:28) presumably reflects a higher rate of collapse to product from the intimate ion-pair **22**, than is possible for the alternative species **23**.

The observation of Wagner–Meerwein rearrangement and *exo–syn* addition is indicative of the presence of a relatively low barrier towards interconversion of seleniranium ion **23** and solvent-separated norbornyl carbonium ions, such as **24** and **25** (eq. [5]).

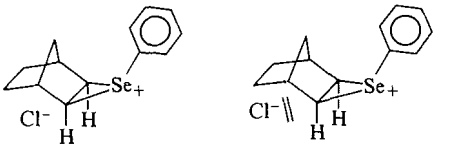
The reaction of benzeneselenenyl chloride with the analogous olefin, bicyclo[2.2.2]oct-2-ene,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



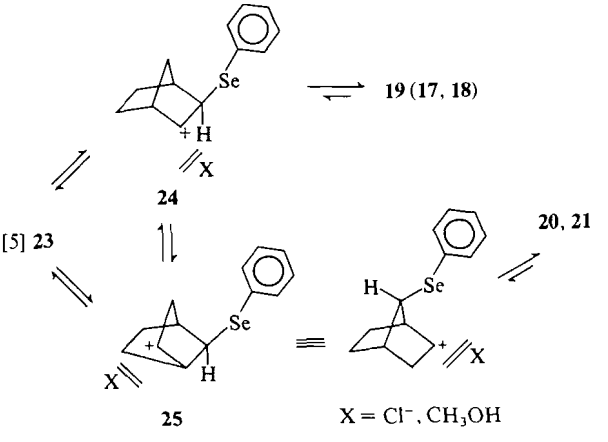
yields only products of simple 1,2-*anti* addition, as is shown in eq. [6]. Attempts to force a series of rearrangements by use of elevated temperatures were unsuccessful.

The reaction of benzeneselenenyl chloride with bicyclo[2.2.1]hepta-2,5-diene, **26**, shows a number of interesting trends which are quite distinct from those already discussed. Thus in methanol solution, four species, all the result of homoallylic attack, **27–30**, are isolable. Of primary importance is the observation of adducts arising from both *exo* and *endo* addition, and the predominance of *endo* attack: [**27** + **29**]/[**28** + **30**] = [*exo*]/[*endo*] = 21:79. These observations contrast with those described earlier for the reaction with **16** which proceeds exclusively with *exo*-configurational-specificity (eq. [7]).



In methylene chloride solution the reaction of **26** with benzeneselenenyl chloride also yields adducts of *exo* and *endo* attack, [*exo*]/[*endo*] = [**27** + **31**]/[**32**] = 39:61, but in this case products of simple 1,2-addition (*exo–anti* and *endo–anti*) are found to predominate. One interpretation of these solvent-oriented differences is collapse to products in methylene chloride solution from intimate ion-pairs, such as **33** and **34**, before π participation by the homoallylic double bond is able to become important. To explain the exclusive formation of nortricyclenes in methanol, it appears sufficient to infer that attack upon the homoallylic double bond of the first formed intimate ion-pairs **35** and **36** by methanol occurs preferentially. Such a scenario also accounts for the high ratio of methoxy to chloro adducts, [$ROCH_3$]/[RCl] = 95:5, since the solvent molecules do not have to enter the sterically hindered zone near selenium in order to react, and since the chloride ion does not have to migrate to the far side of the reacting system. The formation of *exo*-chloro nortricyclenes may be rationalized in the same way by assuming an intermolecular attack by chloride ion instead of rearrangement of the first formed ion-pair. This of course necessitates that the chloride ion which attacks the ion-pair originates from a different ion-pair.

The absence of *endo*-chloro and *endo*-methoxy nortricyclenes, and of products of Wagner–Meerwein rearrangement, is indicative, using Cristol's criteria, of the absence of free or dissociated carbonium ions on the reaction hypersurface (14). It is



SCHEME 2

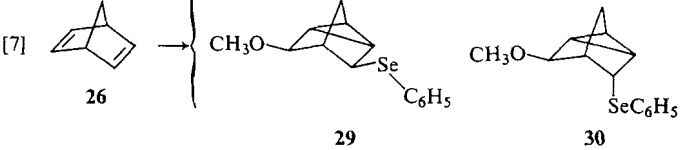
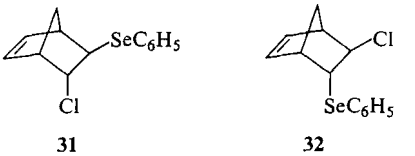
22 23



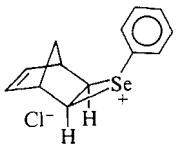
not immediately obvious, however, why species **28** is found in methanol but not in methylene chloride. Once again, very subtle factors appear to be responsible. We note that precedence for *endo* attack upon substrate **26** is to be found in the literature, although rarely is *endo* attack favoured over that of *exo* (15).



27 28

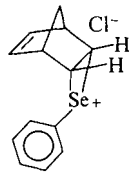
31 32

The high yields of products derived from homoallylic rearrangement in the latter example suggested to us that a more detailed investigation of dienes containing properly aligned double bonds might be most fruitful. We therefore studied the reactions of benzeneselenenyl chloride with 1,4-cyclohexadiene (eq. [12]), bicyclo[4.4.0]deca-1(6),3-diene (eq. [13]), bicyclo[4.3.0]nona-1(6),3-diene (eq. [14]), *Z,Z*-1,5-cyclooctadiene (eq. [15]), 2-methylenebicyclo[2.2.1]hept-5-ene, **37** (eq [16]), and the *E,Z* isomeric 2-ethylidenebicyclo-[2.2.1]hept-5-enes, **44** and **45** (eq. [17]).



As can be seen from eqs. [12]–[15], for the first four substrates only products of net 1,2-*anti* addition are observed or isolated in both methanol and methylene chloride solutions. Similar results have been reported for related electrophiles such as arenesulphenyl halides (16, 17). These results are significant inasmuch as they are indicative that an open carbonium ion is not involved at any stage in the reaction mechanism.

The reaction of benzeneselenenyl chloride with **37** (eq. [16]) is very interesting for we observe only marginal chemoselectivity in methylene chloride solution, attack upon the *endocyclic* double bond being preferred over attack upon the *exocyclic* double bond by a ratio of 60:40. In methanol, however, the reaction is chemospecific, attack occurring exclusively on the endocyclic double bond. This observation is indicative of a change in the relative reactivities of 1,2- and 1,1-disubstituted double bonds as the polarity and nucleophilicity of the solvent is varied.



Of further note is the observation that the homoallylic products, **38** and **39**, are the result of attack upon the *endocyclic* double bond. While species **40** readily isomerizes and solvolyzes to

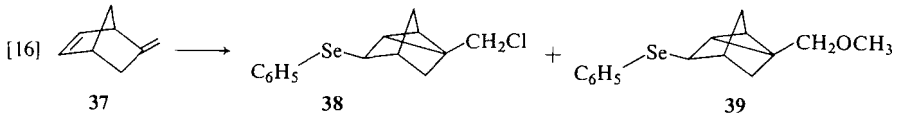
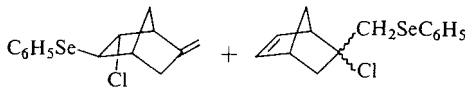
give **38** and **39** at elevated temperatures (refluxing methanol), attempts to convert **41** into nortricyclenes **42** and **43** failed. Only adducts **38** and **39** were isolated from an attempted methanolysis of **41**. We interpret this result in terms of a reversible addition sequence, in which **37** and benzeneselenenyl chloride are regenerated and then reacted, forming the thermodynamically preferred adducts **38** and **39**.

In the case of the isomeric 2-ethylidenebicyclo[2.2.1]hept-5-enes, **44** and **45** (eq. [17]), only products of *exo* attack upon the *endocyclic* double bond with homoallylic rearrangement are observed in both methanol and methylene chloride. Of note is the observation that while the electrophilic attack is configurationally specific-*exo*, subsequent nucleophilic attack by chloride ion or methanol is non-stereospecific, giving rise to essentially equal amounts of the 3-*RS*,8-*RS* and 3-*RS*,8-*SR* diastereoisomeric nortricyclenes, **46**, **48** and **47**, **49**, respectively.



While homoallylic carbonium ions, such as **50** and **51**, or equilibrating free carbonium ions, such as **52**, **53**, and **54**, may exist on the reaction hypersurface, the absence of further products, particularly those resulting from attack β to the phenylseleno moiety, **55** and **56**, and those arising from Wagner–Meerwein rearrangements, tends to rule out their importance. A more plausible scenario, from the point of view of the authors, is a *non*-configurationally-selective attack by chloride ion or methanol upon seleniranium ions such as **57** and **58**. A similar route presumably is required for diene **37** in methanol solution.

Conclusions



In summary, benzeneselenenyl chloride shows chemical behaviour in methanol which is similar in many cases to that found in less polar media, such as methylene chloride, but with a few marked differences. In particular, these results are indicative of the need for a relatively complex reaction mechanism such as Scheme 2. It should be noted that the main difference between Schemes 1 and 2 is the expansion of the concept of a seleniranium ion intermediate into three forms: the intimate ion-pair, **1**, solvent-separated ion-pairs, **1′**, and the free or dissociated ion, **1″**. The sum of the evidence for areneselenenylation of alkenes in methanol is most consistent with a mechanism wherein these intermediates are all rather close in energy. The need for two types of intimate and solvent-separated ion-pairs follows from the observation of *anti*-stereospecific addition since in the absence of a freely rotating carbonium ion the counter ion must migrate to the far side of the substrate ion. While all of these ion types may not exist for any given reaction, the results obtained during this study show the need for at least two of them.

The data presented in this study can not, however, be used at this time to specify a less ambiguous reaction hypersurface, particularly with re-

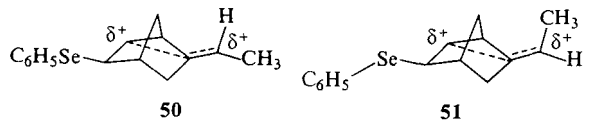
42 43

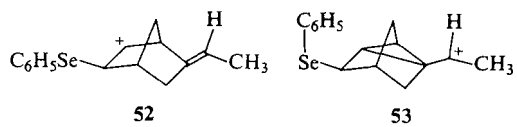
spect to the rate limiting step. This arises in part from the absence of kinetic data, particularly the kinetic order of the reaction. While we have determined that the reaction follows second order kinetics (first order in both benzeneselenenyl chloride and alkene, in methylene chloride, chloroform, acetic acid, and nitromethane), third order kinetics, second order in selenenyl chloride, have been observed in ethyl acetate (3, 18). Thus the nature of the solvent may affect the outcome of the addition more dramatically than is often anticipated. Kinetic studies in methanol solution are currently under active investigation in this laboratory.

Experimental



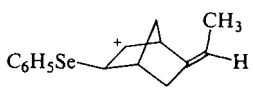
General

Proton and carbon-13 nmr spectra were run on Varian Associates HA-100, T-60, and FT80-16K spectrometers using chloroform-*d* as an internal standard and lock. All spectral parameters are referenced to TMS as an internal standard. Infrared spectra were run in matched NaCl cavity cells, 0.1071 mm, as $CHCl_3$ solutions using a Unicam 1100 spectrophotometer.

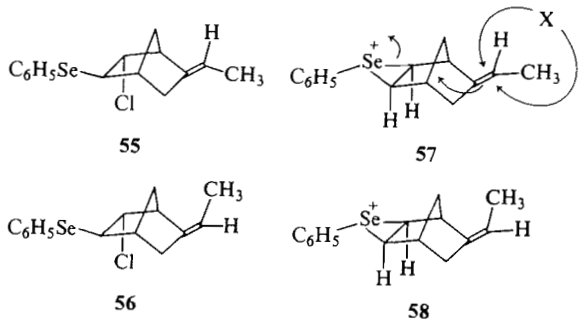


Benzeneselenenyl chloride was commercially available (Aldrich). This material contains a small amount of phenylselenium trichloride and must be recrystallized prior to use; mp 63–64.5°C. Olefins used during this study were commercially available from either Aldrich or Chemical Samples. Their purity in each case was determined by nmr, ir, and glc. All analytical and preparative tlc separations were performed on Analtech or Macherey–Nagel precoated plates, silica gel GF or alumina GF, using methylene chloride as eluant.

General Procedure



To a quantity (1.0–4.0 mmol) of alkene in 35–95 mL of absolute methanol (ACS) was added dropwise a solution of benzeneselenenyl chloride in methylene chloride which contained the minimum volume possible of solvent for the molar equiv-



50 51

52 53

54

55 57

56 58

X = Cl^-, CH_3OH

alent of electrophile. The reaction mixture was stirred until the bright red coloration of the reagent disappeared. General reaction times were less than 2 min. Immediate evaporation of the solvent (35–45°C) yielded colourless to pale yellow oils. All compounds were immediately analyzed by nmr, ir, glc, and ms. Isolated yields were essentially quantitative, the mixture of methoxy and chloro adducts accounting for 98%+ of the starting equivalents of alkene during preparative scale reactions.

Product Data for Cyclic and Polycyclic Adducts

Caution: Scrupulous avoidance of contact with the adducts of benzeneselenenyl chloride and bicyclo[2.2.1]hepta-2,5-diene, **26**, is essential! All reactions were carried out in an isolation glove-box equipped with a filter system suitable for use with carcinogenic or radioactive material, with a reduced atmospheric pressure inside the box. This procedure was used because of medical problems which arose during the preliminary study of this reaction during 1975. Within twelve hours of carrying out the areneselenenylation reaction, the author (DGG) suffered an acute attack of asthmatic bronchitis. This attack resulted in hospitalization of the experimenter. There had been no prior history of attacks of this nature. The medical diagnosis *suggests* that the attack may have resulted from a chemical irritant. Subsequent increased sensitivity towards lung problems has been noted by the author, particularly with respect to norbornenyl and nortricyclic compounds.

An air-stable, red, crystalline, N-bonded acetonitrile complex of Os(III), $OsCl_3(NCCH_3)(P(C_6H_5)_3)_2$, has been prepared and characterized by elemental analysis, magnetic susceptibility, and a single crystal X-ray structure determination. Crystals are monoclinic, space group $P2_1/c$, cell dimensions $a = 10.029(2)$, $b = 15.233(2)$, $c = 25.246(4)$ Å, $\beta = 113.65(1)°$, and $Z = 4$. Three dimensional X-ray diffraction intensity data were collected on an automatic four circle diffractometer using Cu radiation. Full-matrix least-squares refinement on F converged at $R = 0.038$ for 4384 unique observations. The Os atom has a slightly distorted octahedral coordination geometry, with *trans* phosphine ligands, mean Os—P 2.406(2) Å. The acetonitrile ligand is σ-bonded through the N atom, Os—N 2.038(6) Å. The bond *trans* to the acetonitrile ligand, Os—Cl(1) 2.364(2) Å, is not significantly different from the mean of the *cis* Os—Cl bonds, 2.361(2) Å.

R. L. PARKES, N. C. PAYNE et E. O. SHERMAN. Can. J. Chem. **58**, 1042 (1980).

On a préparé un complexe cristallin rouge, stable à l'air de Os(III)–acétonitrile lié par l'azote: $OsCl_3(NCCH_3)(P(C_6H_5)_3)_2$ et on l'a caractérisé par l'analyse élémentaire, la susceptibilité magnétique et par une détermination structurale par diffraction des rayons-X sur un monocristal. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ et les dimensions de la maille sont respectivement $a = 10.029(2)$, $b = 15.233(2)$, $c = 25.246(4)$ Å, $\beta = 113.65(1)°$ et $Z = 4$. Les intensités diffractées ont été mesurées à l'aide d'un diffractomètre automatique à 4 cercles en utilisant la radiation du cuivre. L'affinement, basé sur 4384 facteurs de structures,conduit par moindres carrés (matrice entière), a été conclu lorsque $R(F) = 0.038$. L'atome d'osmium a une coordination octaédrique légèrement déformée avec les ligands phosphines en position *trans*. La longueur moyenne de la liaison Os—P est de 2.406(2) Å. Le ligand acétonitrile est lié à l'osmium par une liaison σ, par l'atome d'azote; Os—N = 2.038(2) Å. La liaison en position *trans* par rapport au ligand acétonitrile Os—Cl(1) 2.364(2) Å ne diffère pas de façon significative de la valeur moyenne 2.361(2) Å de la liaison Os—Cl en position *cis*.

[Traduit par le journal]

Introduction

Although halide complexes of osmium(III) of general formula $OsX_3(R_3P)_3$ with monodentate alkyl, dialkylaryl, and alkyldiaryl tertiary phosphines are well known (1), the corresponding complexes with triaryl phosphines have not been reported. During the preparation of dichlorotris(triphenylphosphine)osmium(II) by the method of Oudeman, Van Rantwijk, and Van Bekkum (2), a red crystalline solid was isolated, which by elemental and spectroscopic analysis appeared to contain triphenylphosphine, acetonitrile, and chloride ligands in the ratio 2:1:3, respectively. Subsequent X-ray examination of this material has shown that this compound is *mer*-trichloro-(acetonitrile)bis(triphenylphosphine)osmium(III). The preparation and structure of this compound are described in this paper.

Experimental

All solvents were thoroughly deaerated with nitrogen by the freeze–pump–thaw method. Reactions were carried out under nitrogen in a closed apparatus or in a nitrogen filled dry box.

Disodium hexachloroosmate(IV) was prepared from osmium tetroxide (Fisher Chemical Co.) by the standard literature procedure (3). Triphenylphosphine (Eastman Chemicals Co.) was recrystallized twice from absolute ethanol before use.

Magnetic susceptibility measurements were made with a Cahn, Model 7600 Faraday balance at 23.0 ± 0.5°C. Melting points were determined under vacuum in sealed capillaries and are uncorrected. Infrared spectra were obtained on a Perkin Elmer, Model 621, Grating Spectrometer as Nujol mulls between KBr plates. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, TN, U.S.A. Mass spectra were obtained with a Varian MAT 311A Spectrometer directly on the solid sample in a heated probe.

Preparation of Trichloro(acetonitrile)bis-(triphenylphosphine)osmium(III)

A modification of the procedure reported by Oudeman *et al.* (2) was used. A solution of disodium hexachloroosmate(IV) (2.35 g, 4.85 mmol) in 95% ethanol (100 mL) was added dropwise to a refluxing, stirred solution of triphenylphosphine (11.45 g, 43.65 mmol) in 95% ethanol (100 mL). After heating for 1.5 h, dark green dichlorotris(triphenylphosphine)osmium(II) was deposited from the brown–green reaction mixture. The mixture was cooled and transferred to the dry box where the osmium(II) complex (2.71 g, 53.3%) was removed by filtration. The remaining filtrate was then refluxed for an additional 5 h under nitrogen and yielded a grey–green solid in a yellow–brown solution. The solid material was separated and treated with acetonitrile (5 mL) to produce a red slurry. This mixture was chromatographed in the dry box on a 2.5 × 30 cm alumina

column. Elution with methylene chloride yielded a mobile bright red fraction which was collected and an immobile yellow band which was discarded. Evaporation of the methylene chloride solvent produced 2.00 g (47.8%) of a red solid which was dried under vacuum (10^{-3} Torr) at 60°C. The material was recrystallized from methylene chloride/hexane (1:1 v/v) yielding bright red crystals mp 250°C (decomp.). *Anal.* calcd. for $Os(CH_3CN)[P(C_6H_5)_3]_2Cl_3$: C 52.93, H 3.87, Cl 12.33, N 1.62; found: C 52.40, H 3.53, Cl 12.70, N 1.54. Magnetic moment: 2.0 BM.

Collection and Reduction of X-ray Data

A photographic examination showed monoclinic symmetry and systematic absences of $h0l$ for l odd and $0k0$ for k odd, uniquely defining the space group as $P2_1/c$. Precise cell dimensions and an orientation matrix were determined at 22°C by a least-squares procedure, employing the diffractometer setting angles of 27 carefully centered reflections with $35° < 2\theta < 56°$. Crystal data for $OsCl_3(CH_3CN)(P(C_6H_5)_3)_2$ are as follows

$C_{38}H_{33}Cl_3NP_2Os$ fw = 862.2
a = 10.029(2) Å, b = 15.233(2) Å, c = 25.246 Å, Z = 4, β = 113.65(1)°, V = 3533 Å, μ = 93.9 cm^{-1}, $F(000)$ = 1685 e, D_{obsd} = 1.64(1) g cm^{-3} (by neutral buoyancy in CCl_4 and CH_2BrCH_2Br), D_{calcd} = 1.621 g cm^{-3}.

A total of 6506 observations was recorded by the θ–2θ scan technique at a scan rate of 2° per min out to a 2θ maximum of 130° on a Picker FACS-1 diffractometer operating under the Vanderbilt disc system (4). Prefiltered (Ni foil, 0.018 mm) Cu radiation was used ($\lambda(K\alpha_1)$ = 1.54056 Å). Stationary counts of 10 s were recorded at the scan limits. Crystal quality, as evidenced by ω scans of 0.10° width at half-height, and the regular recording of six standard reflections, 100, 110, 020, 0$\bar{2}$0, 012, and 006, remained unchanged during the 13 day period required to record the data. After corrections for background, Lorentz and polarization effects, $\sigma(I)$ values were assigned as described elsewhere (5). Since the approximate crystal dimensions were 0.20 × 0.06 × 0.06 mm^3 the data were corrected for absorption using the analytical method of de Meulenaer and Tompa in the program AGNOST (6). The crystal had 6 faces, the forms {100} and {001}, (0$\bar{1}$0) and a fractured face best described as (153). Transmission coefficients varied from 0.357 to 0.655. All computing was carried out on the CDC Cyber 73/14 at the University of Western Ontario, using the programs described in detail elsewhere (7).

Structure Solution and Refinement

The structure was solved by Patterson and Fourier techniques using 4384 unique observations with $I > 3\sigma(I)$ that were considered "observed". Refinement was by full-matrix least-squares techniques on F, minimizing $\Sigma\omega(|F_o| - |F_c|)^2$, where $\omega = 4F_o^2/\sigma^2(F_o)^2$. Scattering factors for Os, Cl, P, C, and N were taken from the International Tables (8), those for H from Stewart *et al.* (9), and anomalous contributions calculated by Cromer and Liberman (10) were included for the Os, Cl, and P atoms. Refinement proceeded smoothly, and in the final cycle the Os, Cl, P, N, and acetonitrile C atoms were assigned anisotropic thermal parameters, while the phenyl C atoms were refined isotropically. The contributions of the 33 H atoms, all located earlier in a difference Fourier synthesis, were included in idealised positions. Refinement converged (4384 observations, 226 variables, maximum coordinate shift 0.07 esd) with agreement factors $R_1 = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.038$ and $R_2 = (\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega F_o^2)^{1/2} = 0.042$. The error on an observation of unit weight was 1.34 electrons. Secondary extinction was not present, and a statistical study indicated a suitable weighting scheme. The highest peak in a total difference Fourier synthesis was 1.1(1) e $Å^{-3}$, at (0.448, 0.000, 0.346), and of no chemical significance. Of the 2122 unused data, none differed by more than 4σ from the calculated value.

Atomic coordinates are given in Table 1 for the non-hydrogen atoms. Thermal parameters for these atoms, hydrogen atom parameters, and observed and calculated structure amplitudes (in electrons, × 10), are available.[2]

Thus a satisfactory refinement was achieved assuming a N-bonded acetonitrile ligand. To confirm this assignment, an attempt was made to refine the three atom species as an isonitrile ligand, coordinated through a C atom. However non-positive definite thermal parameters were observed for the atom coordinated to Os, so the original formulation was retained.

Results and Discussion

The air stable red compound has not been previously reported. The presence of acetonitrile as suggested by elemental analysis was also apparent in the mass spectrum of the products of thermal decomposition of the complex at 250°C. In addition to the acetonitrile peak at mass 41, peaks due to triphenylphosphine and its fragmentation products were also observed. No parent peak or other osmium containing fragment was detected. The X-ray analysis (*vide infra*) unequivocally demonstrates that the compound is correctly formulated as *mer*-trichloro(acetonitrile)bis(triphenylphosphine)-osmium(III). The effective magnetic moment of 2.0 BM agrees well with the magnetic properties of similar low spin, d^5 osmium(III) compounds (1). The octahedral coordination observed in this compound parallels that reported for other osmium compounds (1) and for the mixed complex, $OsCl_3(NH_3)[P(C_6H_5)_3]_2$ (11). It should be noted that no infrared band attributable to the nitrile stretching vibration of acetonitrile coordinated to osmium is observed in the region 2500–1800 cm^{-1} in which such absorptions usually occur (12, 13). The absence of a nitrile stretching band has been reported for a Re analogue (14) and other species containing N-bonded acetonitrile ligands (15).

The crystals are built up from independent molecules of the acetonitrile complex depicted in Fig. 1. The shortest intermolecular non-bonding contact is 2.32 Å between H atoms attached to phenyl C atoms C(14) and C(46). Intramolecular dimensions are given in Table 2; in this and all other tables estimated standard deviations are given in parentheses.

The Os atom has a distorted, octahedral coordination geometry, with *trans* phosphine ligands,

[2]Lists of hydrogen atom parameters, anisotropic thermal parameters, and structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Cl(2)—Os—Cl(3)	171.04(7)	C(41)—P(2)—C(51)	104.4(3)
P(1)—Os—P(2)	177.83(6)	C(41)—P(2)—C(61)	103.1(3)
Os—N—C(1)	177.2(6)	C(51)—P(2)—C(61)	99.7(3)
N—C(1)—C(2)	179.6(9)		

Table 2. Bond distances and bond angles within the molecule are very similar to those observed in $OsCl_3(NH_3)(P(C_6H_5)_3)_2$ (11), *mer*-$OsCl_3(P(CH_3)_2(C_6H_5))_3$ (16), and the Re analogue, $ReCl_3(CH_3CN)(P(C_6H_5)_3)_2$ (14). The solid state deviations from octahedral geometry at the Os atom are most apparent in the displacement of Cl(2) and Cl(3) away from Cl(1) towards the CH_3CN ligand, Cl(2)—Os—Cl(3) 171.04(7)°. Furthermore, the angles at the two P atoms are significantly distorted to permit rings 3 and 4 (Fig. 1) to "sandwich" the CH_3CN ligand. This is particularly apparent in the Os—P(1)—αC angles of 108.3(2) and 111.2(2)° for rings 3 and 4, compared to values ranging from 117.8(2) to 120.1(2)° for the other four phenyl rings. Similar distortions have been attri-

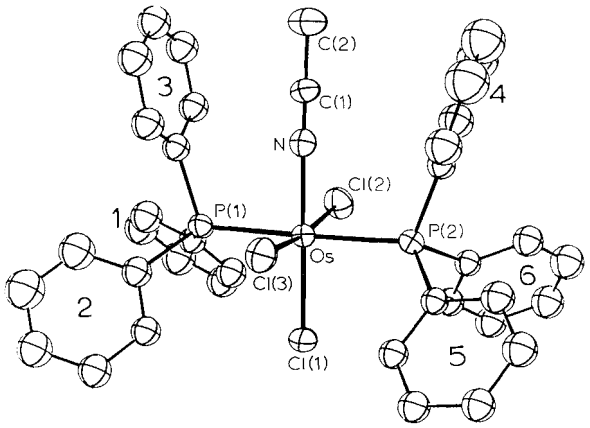

FIG. 1. An illustration of the molecule, drawn with thermal ellipsoids at the 50% probability level. H atoms have been omitted, and atoms C(11) through C(16) form ring 1, etc.

buted to steric crowding (11). Dimensions within the phenyl rings are unexceptional.

The acetonitrile ligand is σ-bonded to the Os atom, Os—N—C(1) 177.2(6)°, and remains linear, N—C(1)—C(2) 179.6(9)°. There is no significant lengthening of the C≡N bond, 1.121(9) Å, compared to that of free acetonitrile, 1.15(3) Å (17). The Os—Cl(1) bond length of 2.364(2) Å *trans* to the acetonitrile ligand is not significantly different from the mean of the *cis* Os—Cl bonds, 2.361(2) Å, indicating a *trans* influence for the acetonitrile ligand comparable to that of Cl. The Os—N bond, 2.038(6) Å, is significantly shorter (9σ) than that of 2.136(9) Å observed in $OsCl_3(NH_3)(P(C_6H_5)_3)_2$, much of which is presumably due to the different hybridizations at the N atom.

Substituent positional effect on radiative lifetimes of anthracene sulphonates

A. K. GUPTA, SEKHAR BASU, AND K. K. ROHATGI-MUKHERJEE
Physical Chemistry Section, Jadavpur University, Calcutta-700032, India

Received August 30, 1979

A. K. GUPTA, SEKHAR BASU, and K. K. ROHATGI-MUKHERJEE. Can. J. Chem. **58**, 1046 (1980).

Excited state lifetimes of anthracene-1-sulphonate, anthracene-2-sulphonate, anthracene-1,5-disulphonate, and anthracene-1,8-disulphonate have been studied by photoselection and single photon counting methods. Experimental lifetimes are compared with theoretical values. For anthracene- monosulphonates, exciplex formation with water is proposed. In the case of anthracene-1,8-disulphonate, distortion in molecular geometry is found responsible for the higher non-radiative decay constant. Summation of nonradiative decay constants, Σk_i, increase in the series 1-AS < 2-AS < 1,5-AS ≪ 1,8-AS. The sharp increase for 1,8-AS is perhaps due to distortion of the molecular geometry due to steric effect of two bulky and charged $-SO_3^-$ groups on the same side of the anthracene skeleton.

A. K. GUPTA, SEKHAR BASU et K. K. ROHATGI-MUKHERJEE. Can. J. Chem. **58**, 1046 (1980).

On a étudié par sélection photochimique et par les méthodes de dénombrement de photon unique, les durées de vie de l'état excité des sulfonate-1, sulfonate-2, disulfonate-1,5 et disulfonate-1,8 d'anthracène. On a comparé les durées de vie expérimentales aux valeurs théoriques. On propose la formation d'un exciplex avec l'eau dans le cas des monosulfates d'anthracène. Quant au disulfonate-1,8 d'anthracène, on a trouvé que la distorsion de la géométrie moléculaire est responsable de la forte constante de désintégration non radiative. La sommation des constantes de désintégration non radiative Σk_i, augmente dans la série S-1A < S-2A < S-1,5A ≪ S-1,8A. La forte augmentation dans le cas du disulfonate-1,8 d'anthracène est peut être due à la distorsion de la géométrie moléculaire provoquée par l'effet stérique des deux groupes chargés et volumineux SO_3^- du même côté du squelette anthracène.

[Traduit par le journal]

Introduction

Anthracene sulphonates exhibit interesting variations in their excited state properties depending upon the number and the position of sulphonate (SO_3^-) groups introduced in the anthracene moiety. In aqueous solution, anthracene-1-sulphonate (1-AS) gives structureless and anthracene-2-sulphonate (2-AS) gives nearly structureless fluorescence spectra. On the other hand, fluorescence spectra for anthracene-1,5-disulphonate (1,5-AS), and anthracene-1,8-disulphonate (1,8-AS) have vibrational features and the mirror-image symmetry relationship between absorption and emission spectra is preserved. In aprotic solvents the vibrational structures in the emission spectra of monosulphonates are restored and the spectrum shifts towards the blue (1). The quantum yields of fluorescence also depends strongly on the nature of solvent and 1-AS has been suggested as a suitable probe for polarity (2). These observations provide a necessary rationale for systematic investigations into the radiative and nonradiative processes in these interesting molecules.

A knowledge of natural radiative lifetime, actual radiative lifetime, and fluorescence quantum yields can throw some light on the photophysical behaviour of these molecules. The mean radiative lifetime τ^0 is defined as the time spent by the atom or the molecule in the excited state after electronic excitation if unperturbed by the environment. It is measured by the time required for the intensity of fluorescence to fall to 1/eth of its initial value and is given by

$$[1] \quad \tau^0 = 1/k_f$$

where k_f is the unimolecular rate constant for fluorescence emission. However, in a real system other competitive processes occur and the measured lifetime τ is much less than the mean radiative lifetime.

The observed lifetime is given by

$$[2] \quad \tau = \frac{1}{k_f + \sum k_i} = \frac{\tau^0 k_f}{k_f + \sum k_i}$$

and

$$[3] \quad \tau = \tau^0 \phi_f$$

where Σk_i is the summation of rate constants for all modes of deactivation of the excited state by nonradiative pathways and ϕ is the quantum yield of fluorescence.

Several formulae have been derived to relate the mean radiative lifetime τ^0 to the absorption and emission bands of large polyatomic molecules. A relationship given by Förster (3) assumes a mirror image symmetry between the absorption and emission bands. But the formula due to Strickler and Berg (4) avoids such assumption. Their expression is

$$[4] \quad \tau^0 = 2.88 \times 10^{-9} \frac{n_f^3}{n_a} \frac{\int F d\bar{\nu}}{\int (F/\bar{\nu}^3) d\bar{\nu}} \int (\varepsilon_{\bar{\nu}}/\bar{\nu}) d\bar{\nu}$$

where F is the relative fluorescence quantum intensity at wave number $\bar{\nu}$ cm^{-1}; n_f and n_a are refractive indices of the solvent over fluorescence and absorption bands. Therefore, if ϕ_f, the quantum yield of fluorescence, is known then eq. [4] together with eq. [3] can be used to determine the actual lifetimes of electronically excited molecules.

Another important method for the measurement of actual lifetimes is by the method of photoselection, that is, by the study of depolarization of fluorescence emission. An expression connecting the degree of polarization of fluorescence and excited state lifetime due to Perrin (5) is given by

$$[5] \quad 1/p = 1/p_0 + (1/p_0 - 1/3)(RT/\eta V)\tau$$

where p and p_0 are degrees of polarization at viscosities η and ∞ respectively; τ is the excited state lifetime; and V is the molar volumes of the fluorescing molecule; R and T have their usual significance. The degree of polarization, p_0, at infinite viscosity can be calculated from the intercept when $1/p$ is plotted against $1/\eta$ (Perrin's plot). This expression is based on Brownian movement of rotation in a solvent of viscosity η.

The most direct method of estimating τ is the time correlated single photon counting technique (6) in which every emitted photon is counted as a function of time. In this technique, the time of emission of individual photons is measured in terms of the amplitude of the pulse triggered by the photon. Photons of various heights are counted in a multichannel analyser. The plot of the number of pulses as a function of time gives the decay curve from which the lifetime or the decay constant can be computed.

Material and Methods

Anthracene 1-, 2-monosulphonates and 1,5-, 1,8-disulphonates abbreviated as 1-AS, 2-AS, 1,5-AS, and 1,8-AS were prepared from corresponding quinones. The method has been described earlier (7).

The absorption spectra were measured manually in a Beckmann Spectrophotometer Model DU4700. The same instrument with spectrofluorimetric attachment was used for fluorescence measurement. The excitation source was a 6-W Hg-vapour lamp with a filter (Beckmann 22630) to isolate 365 nm radiation.

Quantum efficiency and polarization measurements were made with a Brice Phoenix Universal Light Scattering Photometer Model 1000 series. For the measurement of quantum efficiency, the solution was purged with N_2. Measurements were repeated a number of times before the data were accepted. The set of polarizer and analyzer was supplied with the instrument. The exciting radiation of wave length 365 nm was isolated by inserting a Wood's glass filter in the incident beam. The detector unit was a 1P28 photomultiplier tube attached to a rotating shaft so that it could be positioned at any angle. The polarization was measured at 90° to the incidence direction. No correction as suggested by Azumi and McGlynn (8) was considered necessary since the intensity ratio with the polarizer oriented in vertical and horizontal directions was unity when a solution of anthracene sulphonate was taken in a low viscosity solvent such as water. Each polarization measurement was repeated five times and the average value was taken.

The measurement of actual lifetime, τ, by single photon counting technique were performed by Dr. G. Beddard and Dr. T. Harriman at the Royal Institution of Great Britain, London. The solutions were 10^{-5} M in water and not deaerated. Oxygen concentration in aerated solution is of the order of 10^{-4} M under the partial pressure of O_2 in the atmosphere and temperature of experiment. It can cause a change of about 2% in measured lifetime in the nanosecond range as can be shown from oxygen quenching data (9). The τ value was obtained by data-fitting technique assuming exponential decay curve.

Results

Determination of Mean Radiative Lifetime

The mirror image relationship between absorption and emission does not hold good for 1-AS and 2-AS although for disulphonates the relationship is applicable. For the former the emission spectra are structureless and red shifted in aqueous solution. Therefore for the determination of mean radiative lifetime τ^0, from integrated areas under the absorption and emission bands, the equation of Strickler and Berg was preferred. The integrals $\int F d\bar{\nu}$, $\int (F/\bar{\nu}^3) d\bar{\nu}$, and $\int (\varepsilon_{\bar{\nu}}/\bar{\nu}) d\bar{\nu}$ were calculated by measuring the areas under the respective curves (Figs. 1 and 2) using a planimeter. The natural

radiative lifetimes so computed are presented in Table 1. It is evident from Table 1 that anthracene, 1-AS, 2-AS, and 1,5-AS have very nearly the same values for mean natural radiative lifetime τ^0 with an average deviation of ± 0.9 in the nanosecond range. But the value differs largely for 1,8-AS.

The dilute solution values of quantum yield of fluorescence, ϕ_f^0, were determined by using anthracene in benzene as fluorescence standard ($\phi_f^0 = 0.29$) (10). All the solutions were of identical optical density at wave length 365 nm. The ϕ_f^0 values are almost equal for all the sulphonates and are also close to that for anthracene in benzene (Table 2). This is indicative of the fact that the SO_3^- groups do not have a large perturbation effect on the energy levels of anthracene. Knowing ϕ_f^0 and τ^0, the actual lifetime τ can be calculated from eq. [3].

Lifetime Measurements from Polarization Studies

The polarization of fluorescence was measured as a function of viscosity η. The viscosity was varied by adding different proportions of water to glycerol and the corresponding values obtained from the Handbook of Chemistry and Physics. The Perrin plot obtained by plotting $1/p$ vs. $1/\eta$ are given in Fig. 3. The values of p_0 calculated therefrom are tabulated in Table 3. Equation [5] was utilized to calculate τ, the actual lifetime, for the four anthracene sulphonates. The molar volumes of the compounds necessary for calculation of τ were obtained from their respective solid state density data (11). However, the correctness of using solid state molar volumes in the expression is questionable, since the volume together with its solvation envelop is involved in the Brownian movement of rotation. But, as anthracene is a big molecule with hydrophobic character even though the $-SO_3^-$ group is hydrophilic, the overall degree of solvation may be considered to be small as the charge density is low. The calculated values of τ from polarization studies have been tabulated in Table 3. The concentration of the fluorescer was such that concentration depolarization was avoided ($c = 10^{-5}$ *M*).

Table 4 compares the values of τ for various anthracene sulphonates determined by different methods. The τ values obtained by single-photon counting technique are included and are given in column 4. In the last column are given the ratios of τ_{cal} to τ_{photon}.

Discussion

Anthracene is an interesting molecule from the viewpoint of spectroscopy because a number of energy levels of different symmetry type and spin multiplicity are located near the first allowed absorption band (12). Slight variation in their posi-

tions, which may be brought about by physical parameters such as temperature and solvent or by substitution in different positions of the anthracene skeleton, can alter their photophysical properties by changing their oscillator strength, transition dipole directions, extent of vibronic mixing with the background levels or by switching over of energy levels etc. These changes will eventually be reflected in the lifetimes of the species.

It is interesting to note from Table 4 that the polarization method and the single photon counting technique yield τ values with similar trends. But calculated values differ widely for 1-AS, which is much less than the observed value, and for 1,8-AS, which is much greater than the observed value. For 1,8-AS, the molar extinction coefficient is considerably reduced which is apparent in large τ^0 (Table 1). Two bulky and similarly charged —SO_3^- groups on the same side of the ring may cause distortion of the planar hydrocarbon skeleton leading to reduced absorption probability and consequently enhanced calculated natural radiative lifetime. The ratio τ_{cal}/τ_{photon} (i.e. single photon value) as recorded in column 5 of Table 4 brings out the trend clearly. The Strickler–Berg (4) expression is not very suitable for molecules with weak transition ($\varepsilon < 8000\ cm^2\ mol^{-1}$) and if the geometry of the molecule changes on excitation. In the case of 1,8-AS, the extinction coefficient is low ($\varepsilon_{max} \simeq 3000\ cm^2\ mol^{-1}$) but there is no indication of any difference in geometry in the excited and the ground state energy levels from absorption and emission spectra.

From the lifetime data available, it is possible to calculate the radiative k_f and nonradiative (Σk_i) decay constants (Table 5) for these molecules from the following expression obtained by rearrangement of expression [2].

$$[6] \quad 1/\tau - 1/\tau^0 = \Sigma k_i$$

The single photon counting technique is one of the most reliable methods for measuring decay constants. The τ^0 values used were obtained from τ_{photon} and measured values of quantum yield ϕ_f according to eq. [3] and k_f from eq. [1].

A large increase in nonradiative decay constant for 1,8-AS suggests additional degradative path-

ways in this molecule. Distorsion may bring about the possibility of internal conversion $S_1 \rightsquigarrow S_0$ or enhancement of the intersystem crossing ($S_1 \rightsquigarrow T$) rate, k_{isc}. For 1,8-dimethylnaphthalene, the increase in k_{isc} has been attributed to distortion of the naphthalene planar configuration due to steric effect of adjacent methyl groups (13). On the other hand, reduction in fluorescence yield for 6-hydroxy-9-phenylfluoron (HPF) in 0.01 *M* KOH as compared to fluorescein has been explained by Lindquist and Lundeen (14) as due to the possibility of molecular distortion in HPF which increases internal conversion. In HPF, the —COOH group of fluorescein is replaced by H and absorption and emission spectra remain unchanged.

Such discrepancy between calculated and observed values may also arise if the $^1L_b \leftarrow A$ transition is hidden under the intense $^1L_a \leftarrow A$ transition and absorbing and emitting states are different. For example, for biphenyl in cyclohexane the experimental value is 89 ns, whereas the calculated value is only 2.9 ns (15); the discrepancy has been explained by assuming involvement of hidden transitions. However, this kind of situation would introduce negative polarization in the fluorescence emission. But p_0 values for all the four anthracene sulphonates under study are the same at infinite viscosity ($p_0 = 0.33$). This indicates that the emission dipole has the same direction for all these compounds. The deviation of p_0 from the ideal value (i.e. $p_0 = 0.5$) is yet to be explained. However, Perrin (16) obtained $p_0 \simeq 0.25$ for anthracene. Such a decrease from the ideal value could also be due to the involvement of some torsional vibrations or to exciplex formation as suggested by Valeur and Weber (17) for indole molecule.

The loss of structure in fluorescence spectra as well as the discrepancy between calculated and observed values of τ in the case of 1-AS clearly indicates that the emitting state is not the pure S_1 state of the compound. The possibility of emission from an exciplex between excited 1-AS and H_2O molecules may be considered. Since in non-aqueous media the emission band is quite structured and a mirror image of the absorption band, complexation in the excited state, is specific for H_2O only. The absence of a pH effect on fluorescence spectra does not support the possibility of internal or external proton transfer in the excited state. In the case of indole a similar exciplex between H_2O and the excited molecule was observed (18). Khalil *et al.* (19) have reported increase in fluorescence intensity of exciplex formed between polar molecules with an increase in solvent polarity. This further supports our conclusion that loss of structure in emission spectra in aqueous solution for monosulphonates is due to specific solute–solvent interactions in the excited state.

Oxidative cleavage of conformationally rigid vinyl orthoesters. Evidence for primary and secondary stereoelectronic control in the cleavage of tetrahedral intermediates

PIERRE DESLONGCHAMPS, NORMAND BEAULIEU,[1] ROBERT CHÊNEVERT, AND ROBERT A. DICKINSON[2]

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 10, 1979

PIERRE DESLONGCHAMPS, NORMAND BEAULIEU, ROBERT CHÊNEVERT, and ROBERT A. DICKINSON. Can. J. Chem. **58**, 1051 (1980).

Permanganate oxidation of either axial vinyl orthoester **1** or equatorial vinyl orthoester **7** yields essentially hydroxy ester **5** only. These results can be interpreted on the basis of stereoelectronic effects which control the cleavage of tetrahedral intermediates **2** and **8**.

PIERRE DESLONGCHAMPS, NORMAND BEAULIEU, ROBERT CHÊNEVERT et ROBERT A. DICKINSON. Can. J. Chem. **58**, 1051 (1980).

L'oxydation au permanganate de l'orthoester vinylique axial **1** ou équatorial **7** donne l'hydroxy ester **5** principalement. Ces résultats peuvent être expliqués en tenant compte des effets stéréoélectroniques qui contrôlent la fragmentation des intermédiaires tétraédriques **2** et **8**.

In 1972 we elaborated a new theory stating that the stereochemistry of the tetrahedral intermediate is a determining factor in the formation of products during the hydrolysis of esters and amides (1–3). We have postulated that the precise conformation of tetrahedral intermediates is very important because their specific decomposition is controlled by the orientation of the non-bonded electron pairs of the heteroatoms (stereoelectronic control).

We have since then obtained experimental evidence in favor of this principle from four different types of experiments: (*a*) the oxidation of acetals by ozone (4), (*b*) the acid hydrolysis of cyclic orthoesters (1, 5), (*c*) the hydrolysis of *syn* and *anti* *N,N*-dialkylated imidate salts (6), and (*d*) the concurrent carbonyl–oxygen exchange during the hydrolysis of esters and amides (7).

Each of these different types of experiments has furnished strong evidence, and taken together, they provide rather convincing arguments in favor of the principle of stereoelectronic control.[3] However, they cannot be considered absolute proof for this theory. This is because, in each of these experiments, the knowledge of the precise stereochemistry of the tetrahedral intermediate is gained by the application of the principle of stereoelectronic control which is then reused to predict the breakdown of that same tetrahedral intermediate. Consequently there is some ambiguity, as the theory is used to predict both the stereochemistry of the tetrahedral intermediate as well as its breakdown.

We therefore looked for an experiment in which the assignment of the stereochemistry of the tetrahedral intermediate would be independent of the stereoelectronic theory. Such an experiment, if successful, could confidently be considered as unambiguous proof.

We wish now to report a study on the oxidation of conformationally rigid bicyclic vinyl orthoesters **1** and **7** which appeared to fulfil these requirements.[4]

We chose the bicyclic axial vinyl orthoester **1** (Scheme 1) in the hope that we could find a reagent to transform **1** into the intermediate **2**. This intermediate **2** with the OH group in the axial position is equivalent to the intermediate which we have postulated in the ozonolysis of acetals **3** and in the hydrolysis of orthoester **4**, and should thus behave similarly during its cleavage, yielding only the hydroxy ester product **5**. The other possible product, the bicyclic lactone **6**, should again not be observed.

This new approach was also quite interesting because the isomeric bicyclic equatorial vinyl orthoester **7** could also presumably be prepared and it should give, with an appropriate reagent, the intermediate **8** having an equatorial OH group. This investigation of the cleavage of vinyl orthoesters could therefore not only confirm the fragmentation behavior of the intermediate **2** but it would also be valuable for the complementary experiment of observing the breakdown of intermediate **8** with the OH group in the equatorial position.

Results

Synthesis of Orthoesters 1 and 7

The syntheses of axial and equatorial vinyl orthoesters **1** and **7** are described in Scheme 2. Reaction of the known dioxenium salt **10** (5) in dichloromethane containing 2-chloroethanol and

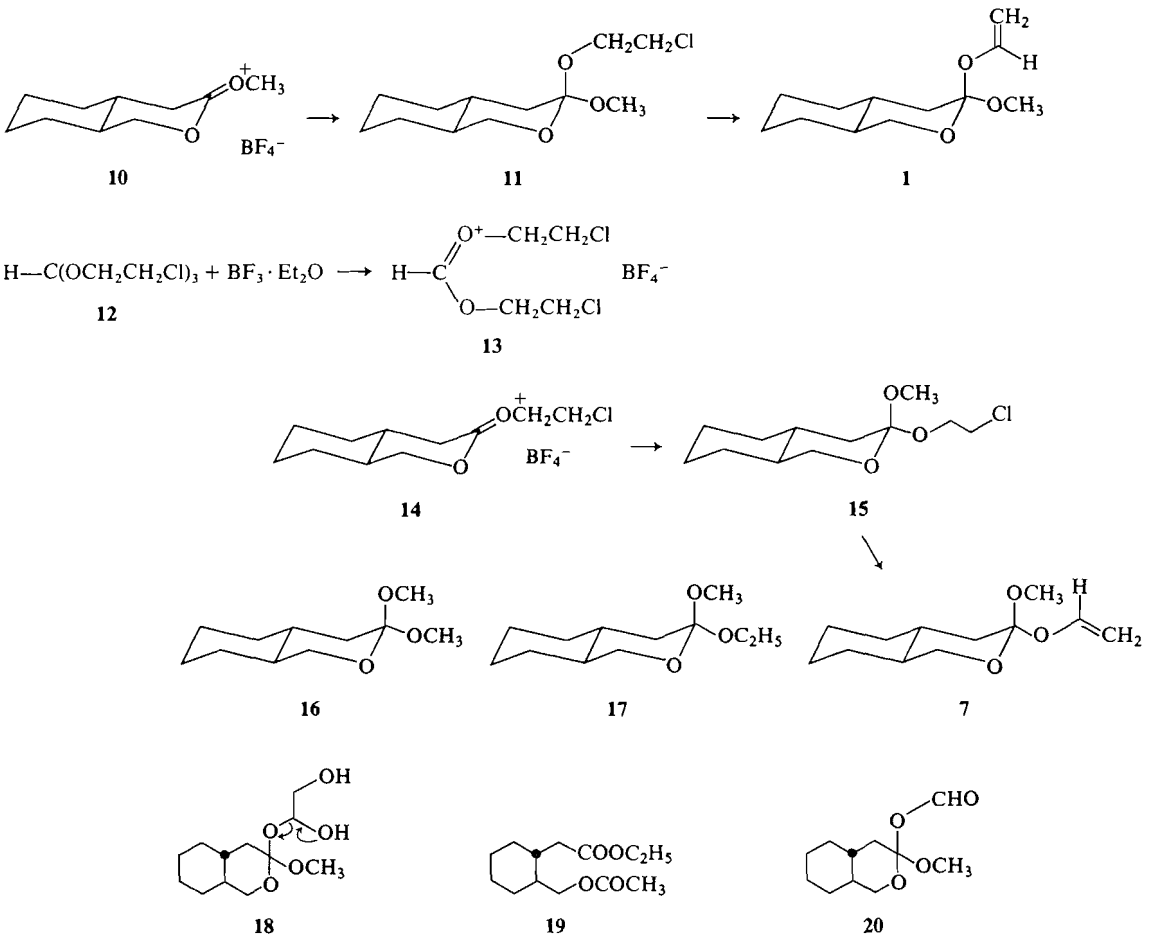
SCHEME 1

triethylamine at −78°C gave axial chloroethyl equatorial methyl orthoester **11**. Treatment of crude **11** with potassium *tert*-butoxide in tetrahydrofuran gave axial vinyl methyl orthoester **1**.

Dichloroethyl dioxenium fluoroborate salt **13** was prepared *in situ* by the reaction of boron trifluoride etherate and trichloroethyl orthoformate (**12**) (9). The reaction of unpurified **13** with bicyclic lactone **6** gave the corresponding chloroethyllactonium salt **14** which was not purified. Treatment of crude **14** with methanol in dichloromethane containing triethylamine (5) gave crude equatorial chloroethyl axial methyl orthoester **15**. Treatment of crude **15** with potassium *tert*-butoxide in tetrahydrofuran gave equatorial vinyl methyl orthoester **7** contaminated with dimethyl orthoester **16** (4%) (5) and with axial methyl equatorial ethyl orthoester **17** (10%) (5).[5] Purification by low temperature vpc gave equatorial vinyl methyl orthoester **7** containing 8% of axial methyl equatorial ethyl orthoester **17**. Compound **7**[6] was not purified further and was used as such.



Oxidative Cleavage of Vinyl Orthoesters 1 and 7

The two vinyl orthoesters **1** and **7** were each treated during 3 min with potassium permanganate in a buffered solution containing ^{18}O-labelled water (≈32% ^{18}O) mixed with acetonitrile. Under these conditions, both vinyl orthoesters had reacted completely. This operation was then followed by the addition of a large excess of pyridine and acetic anhydride. It was anticipated that under those conditions potassium permanganate would react with vinyl orthoesters **1** and **7** to generate the tetrahedral intermediates **2** and **8** respectively (via an intermediate such as **18** (10)). The intermediates **2** and **8** would then break down to give either hydroxy ester **5** or bicyclic lactone **6**. The hydroxy ester **5**, if formed, would then be esterified and isolated as the acetate methyl ester **9**. The use of an ^{18}O-labelled solvent was to verify that the permanganate oxidation yielded the intermediates **2** and **8** via the expected intermediate **18** or its equivalent.

[5]The formation of **17** is presumably a result of an exchange between the dichloroethyl dioxenium fluoroborate **13** and diethyl ether which was present as a by-product. This exchange must have produced some of the corresponding diethyl dioxenium fluoroborate which in turn alkylated the lactone with an ethyl group instead of a chloroethyl group.

[6]The assignment of stereochemistry for the two vinyl orthoesters **1** and **7** is based on the method of synthesis (5), and on the proton nmr chemical shift of the OCH_3 group of orthoesters (5).

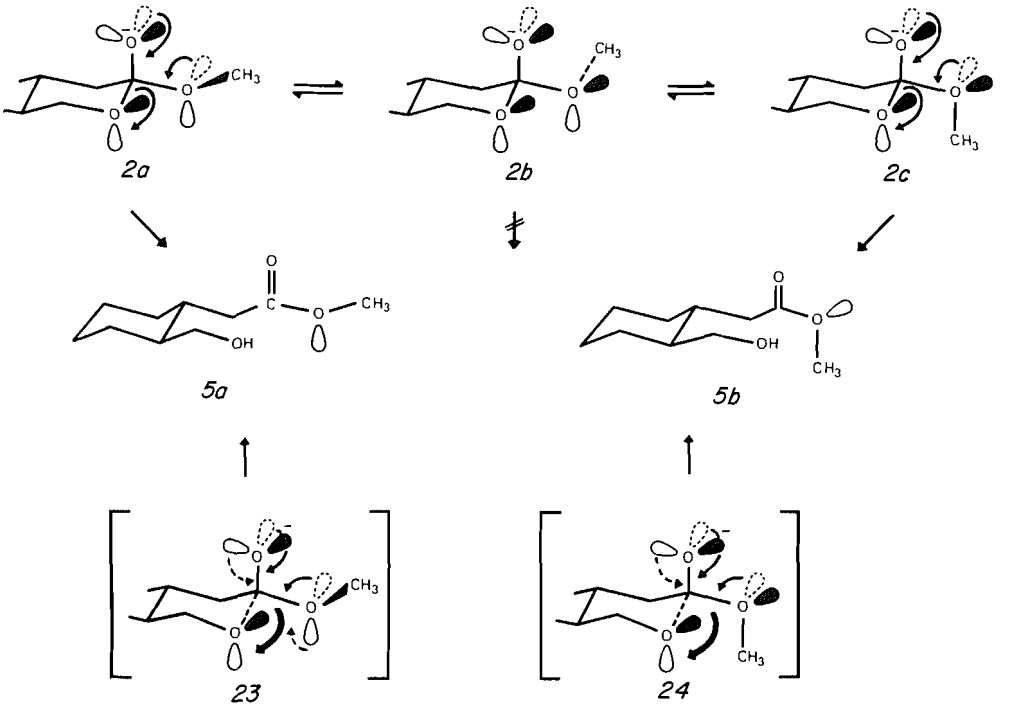
SCHEME 2

Under the above conditions (buffer pH = 13), axial vinyl orthoester **1** gave acetate methyl ester **9** (98%) and bicyclic lactone **6** (2%). Mass spectral analysis showed that acetate methyl ester **9** contained 9% of ^{18}O, which corresponds to a theoretical incorporation of 28%. Under similar conditions (buffer pH = 10), the equatorial vinyl orthoester **7** (containing 8% of **17**) gave acetate methyl ester **9** (88%), bicyclic lactone **6** (3%), and acetate ethyl ester **19** (9%). Mass spectral analysis showed that acetate methyl ester **9** contained 13% of ^{18}O which corresponds to a theoretical incorporation of 41%.



Pure orthoester **17** was found to be resistant to potassium permanganate under the above conditions, but it was transformed into acetate ethyl ester **19** by treatment with pyridine and acetic anhydride. It can therefore be concluded that both the axial and the equatorial vinyl orthoesters **1** and **7** gave essentially only hydroxy ester **5**.

The partial ^{18}O incorporation shows that there must be two pathways by which the vinyl orthoesters **1** and **7** give hydroxy ester **5**. In one pathway, the oxygen of the vinyl ether in **1** and **7** must be lost. One possibility is that **1** and **7** would form in part the ion **10** which would then react with the solvent to give labelled hydroxy ester **5** via the intermediate **2**[7] (5). In the other pathway, the vinyl orthoesters **1** and **7** must have formed the desired intermediates **2** and **8** respectively, with retention of the oxygen atom of the vinyl ether function.

The oxidation of equatorial vinyl orthoester **7** was repeated, except that the reaction time for the $KMnO_4$ oxidative reaction was changed from 3 to 35 min. Under those conditions, **7** gave a mixture of bicyclic lactone **6** (29%), acetate methyl ester **9** (63%), and acetate ethyl ester **19** (8%). The ^{18}O incorporation in **6** (55%) and **9** (53%) was essentially the same. This result shows that hydroxy

[7]For instance, it is conceivable that $KMnO_4$ would react with the vinyl ether function to yield in part the corresponding orthoester formates **20**. These formates (**20**) derived from **1** and **7** could then easily give the dioxenium salt **10**.

SCHEME 3

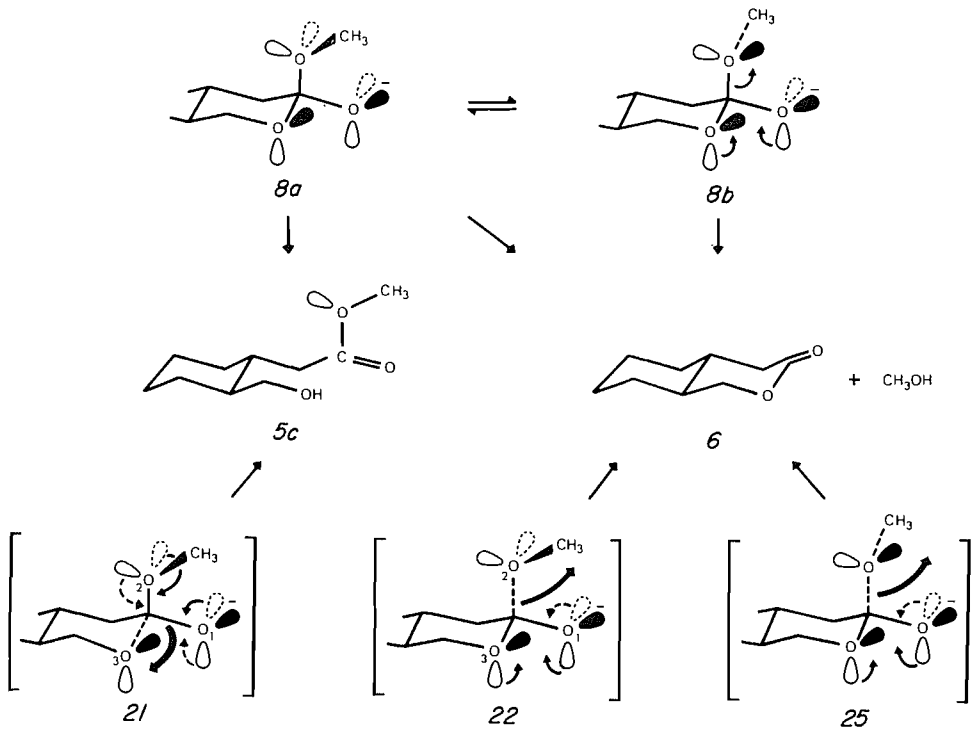
ester **5** was formed from intermediate **8**, and **5** was then partly transformed into bicyclic lactone **6** prior to the acetic anhydride – pyridine treatment.

We have concluded from this set of experiments that vinyl orthoesters **1** and **7** have yielded *in situ* the intermediates **2** and **8** respectively and that these two intermediates are cleaved to yield hydroxy methyl ester **5** only.

Discussion

Both tetrahedral intermediates **2** and **8** yield the hydroxy ester **5** in preference to the bicyclic lactone **6**. This result may appear to be unusual because the formation of the bicyclic lactone **6** should presumably be easier; indeed, in the formation of **6**, two molecules are formed (**6** and CH_3OH) and the ring is not broken, while in the formation of **5** only one molecule is formed and the ring is cleaved. It is therefore evident that there must be some parameters which lower specifically the energy of the transition state for the formation of hydroxy ester **5**.

We think that these parameters are of stereoelectronic nature. It is possible to explain the formation of hydroxy ester **5** from intermediate **2** by considering the principle of stereoelectronic control. However, the principle of stereoelectronic control cannot explain the exclusive formation of hydroxy ester **5** from intermediate **8** because it allows both processes. It is, however, possible to understand the preference for the formation of hydroxy ester **5** from intermediate **8** by considering the importance of another stereoelectronic effect which can be related to the anomeric effect (11).



Thus, two effects must now be considered in the stereoelectronic theory: primary stereoelectronic control as previously defined (two oxygens having each an electron pair oriented antiperiplanar to the leaving group) and secondary stereoelectronic control[8] as defined by the anomeric effect.

We will first consider the possible cleavages of the axial intermediate **2** which is derived from orthoester **1**. The intermediate **2** can exist in the three conformations **2***a*, **2***b*, and **2***c* (Scheme 3) and stereoelectronic control predicts the following results: **2***a* can only give the hydroxy ester in the Z conformation **5***a*, **2***b* cannot break down; whereas **2***c* can only produce the hydroxy ester in the *E* conformation **5***b*. Thus, stereoelectronic control predicts the formation of hydroxy ester **5** only, a result identical to the observed one.

It must be added at this stage, but for reasons to be discussed later, that it is very likely that if the

[8]This classification is justified by the fact that these two effects have their origin in the same chemical principle, orientation in space of non-bonded electron pairs. We also think that the primary stereoelectronic effect is a stronger effect than the secondary stereoelectronic effect (*vide infra*).

For personal use only.

SCHEME 4

three conformers **2***a*, **2***b*, and **2***c* are produced, they must be interconvertible[9] by rotation, and the formation of hydroxy ester **5** should occur from **2***a* only. Indeed, we will later argue that a transition state yielding an *E* ester (**2***c* → **5***b*) cannot compete with a transition state which yields a *Z* ester (**2***a* → **5***a*).

Examination of the possible stereoelectronically controlled cleavages of the equatorial intermediate **8** derived from orthoester **7** leads to the following conclusions. The equatorial intermediate **8** can take two different conformations, **8***a* and **8***b* (Scheme 4). The conformer **8***a* can cleave to yield either the hydroxy ester **5** or the lactone **6** and intermediate **8***b* can break down in only one direction to yield the lactone **6**. Thus stereoelectronic control allows the formation of both products, the hydroxy ester **5** and the lactone **6**, but only the former is observed experimentally. Consequently, this result indicates that the energy barrier for the formation of the hydroxy ester **5** is lower than that for the formation of the lactone **6**. Again, it is likely that if both conformers **8***a* and **8***b* are formed, they must be interconvertible by rotation, and the formation of hydroxy ester **5** should occur from the cleavage of **8***a*.

The next task is to rationalize the fact that the energy barrier for the formation of hydroxy ester **5** is lower than that for bicyclic lactone **6**. We think that it is due to an electronic effect which is similar to the anomeric effect observed in acetals (11).

For this analysis, it is necessary to consider the orientation of *all the electron pairs on the two oxygens which will eventually form the ester function* in **5** and in **6**. Formulas **21** and **22** describe the two transition states of conformer **8***a* which lead to the hydroxy ester **5***c* and to the bicyclic lactone **6** respectively. In both of them, there are two oxygens (O1 and O2 in **21**, and O1 and O3 in **22**) having each an electron pair antiperiplanar to the bond to be cleaved (C—O3 in **21**, and C—O2 in **22**). This is the stereoelectronic effect that we have previously discussed (1–3) which can now be defined as the primary stereoelectronic driving force for the cleavage reaction.

There are, however, other secondary stereoelectronic effects which are operating in both transition states **21** and **22**. In **21**, the axial oxygen (O2) has an electron pair antiperiplanar to the equatorial C—O1 bond, thus this electron pair can

[9]We have previously postulated the lack of conformational change prior to the breakdown of the tetrahedral intermediate (2). We no longer believe that it is necessary to invoke this postulate for hemiorthoesters. For a discussion see pp. 1303–1308 in ref. 3. For cases where this postulate applies see ref. 7.

be delocalized into the antibonding orbital (σ^*) of the C—O1 bond (12). This electronic delocalization confers a double bond character to the C—O2 bond, as is believed to be the case for acetals (11). Similarly, the equatorial oxygen (O1) also has an electron pair antiperiplanar to the axial C—O2 bond. In transition state **22**, the equatorial oxygen (O1) has an electron pair oriented antiperiplanar to the C—O3 bond, but in the ring oxygen (O3) one electron pair is not oriented antiperiplanar to a polar bond. Thus, in addition to the primary stereoelectronic effect (symbolized by ⌒) which occurs in both transition states, transition state **21** has two additional secondary electronic effects (symbolized by ⌒) whereas transition state **22** has only one. It is therefore reasonable to expect that the reaction via transition state **21** is a lower energy process than that via **22**.

It is also interesting to note that **21** leads to the stable *Z* form of an ester (**5***c*) while **22** leads to the less stable *E* form (**6**) (13). Therefore, a correlation seems possible between the energy of the transition state and the geometrical form of the ester produced. Indeed, it can be seen that a transition state leading to a *Z* ester will always have two secondary stereoelectronic effects and that leading to an *E* ester will always have only one. For instance, the conversion of **2***a* into **5***a* (a *Z* ester), will occur via transition state **23** (Scheme 3) which has, besides primary stereoelectronic control (⌒), two secondary electronic effects (⌒). On the other hand, the conversion of **2***c* to **5***b* (an *E* ester) will occur through transition state **24** which has only one secondary electronic effect (⌒). A similar situation is observed in the **8***b* → **6** transformation (cf. **25** in Scheme 4).[10]

We think that this type of secondary electronic delocalization is also operative in the two geometrical forms of the ester function. In the *Z* form of an ester, each oxygen has an electron pair involved in the π system (primary stereoelectronic control). There are two additional electron pairs (one on each oxygen) which are each antiperiplanar to a C—O bond, and can therefore be delocalized in the antibonding orbital (σ^*) of these two C—O σ bonds (secondary stereoelectronic control). In the *E* form of an ester, besides the two electron pairs which form the π system, there is only one electron pair (on the C=O oxygen) which can be delocalized.

SCHEME 5

Thus, in the *Z* form, there are two secondary electronic effects, illustrated in two dimensions by **26** and in three dimensions by **27** (Scheme 5). In the *E* form, there is only one secondary electronic effect, as shown in two dimensions by **28** and in three dimensions by **29**. The *Z* form is more stable than the *E* form in esters (13) and we think that this difference in stability is due mainly to the additional electronic delocalization present in the *Z* form only.

We have recently studied (14) the iodine ion displacement reaction on unsymmetrical cyclic dioxenium salts and the results obtained could be rationalized on the basis of secondary stereoelectronic effect. This secondary stereoelectronic effect in esters is similar to the anomeric effect observed in acetals (2). The only difference is that the central carbon is trigonal (sp^2 hybridized) in esters and tetrahedral (sp^3 hybridized) in acetals.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton nmr spectra were recorded on a Varian A-60 or a Bruker WP-60 instrument. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The following abbreviations have been used: s, singlet, m, multiplet. ^{13}C nmr spectra were obtained with a Bruker H-90 instrument. Vapor phase chromatographic (vpc) analyses were carried out on a Varian Aerograph instrument, model 920. (Column A: SE-30, 10% Chromosorb W, 60–80 mesh and column B: SE-30, 5% Chromosorb W, 100–120 mesh.) Mass spectral assays were obtained using a Hitachi-Perkin-Elmer RMU-6A instrument at 70 ev.

Bicyclic lactone **6** was obtained by Baeyer–Villiger oxidation of *trans*-hydrindanone-2 (15).

[10]It is interesting to note that secondary stereoelectronic effects can also influence the leaving group ability of an alkoxide group. For instance, in the competing transition states **21** and **22**, the ring oxygen in **21** which has only one anomeric effect should be a better leaving group than the OCH_3 group in **22** which has two anomeric effects. This effect lowers again the energy of transition state **21** by comparison with transition state **22**. In the other transition states **23**, **24**, and **25**, the leaving group oxygen has only one anomeric effect.

Axial Chloroethyl Equatorial Methyl Bicyclic Orthoester 11

Trimethyloxonium tetrafluoroborate (470 mg, 3.0 mmol) (16) was added to a solution of bicyclic lactone **6** (170 mg, 1.1 mmol) in anhydrous dichloromethane (10 mL). This mixture was magnetically stirred at room temperature for 15 h in a dry box containing an atmosphere of nitrogen and was then added to a cooled solution (−78°C) of 2-chloroethanol (2 mmol) and triethylamine (3 mmol) in dichloromethane (30 mL). The reaction mixture was left for 30 min at −78°C and left to warm up to room temperature. A saturated solution (20 mL) of sodium carbonate was added. The organic phase was separated and the aqueous phase was extracted with dichloromethane (2 × 25 mL). The combined organic extract was dried with potassium carbonate, filtered, and evaporated to yield crude orthoester **11** (206 mg, 75%); vpc (column A, temperature: injector, 170°C; detector, 100°C; column, 115°C): retention time, 7.0 min; ir (CCl_4): 1000–1200 cm^{-1}; nmr (CCl_4) δ: 1.0–1.2 (12H, m), 3.38 (3H, s, OCH_3), and 3.70 (6H, m, —OCH_2CH_2Cl and OCH_2); ms *m/e* (70 ev): 248, 250 (ratio 3:1, M^+), 217, 219 ($M^+ - OCH_3$), 169 ($M^+ - OC_2H_4Cl$).

Trichloroethyl Orthoformate (12)

Triethyl orthoformate (7.41 g, 50 mmol) was mixed with 2-chloroethanol (24.15 g, 300 mmol), benzene (200 mL), and a catalytic amount of *p*-toluenesulfonic acid. The mixture was refluxed overnight. The solution was then washed with a solution of sodium bicarbonate, dried over sodium carbonate, filtered, and evaporated to dryness. Distillation *in vacuo* gave pure trichloroethyl orthoformate (**12**) (7.75 g, 62%); bp 145°C/12 Torr, (lit. (17) bp 157°C/14 Torr); nmr ($CHCl_3$) δ: 5.48 (1H, s, CH) and 3.87 (12H, m, OCH_2CH_2Cl); ms *m/e* (70 ev): 250, 252 (M^+).

Equatorial Chloroethyl Axial Methyl Bicyclic Orthoester 15

Trichloroethyl orthoformate (**12**) (1.0 g, 4 mmol) was mixed with boron trifluoride etherate (5 mmol, 600 μL) in a dry box under an atmosphere of nitrogen. The mixture was magnetically stirred for 20 min, bicyclic lactone **6** (265 mg, 1.72 mmol) was added and the mixture was left for 90 min. Anhydrous ether (10 mL) was added and the mixture was stirred for 5 min. The mixture was left and then the ether was decanted to leave an insoluble residue. This residue was washed once more with ether. The reddish residue was dissolved in anhydrous dichloromethane (10 mL) and was added to a cooled solution (−78°C) of methanol (5 mmol), triethylamine (5 mmol), and dichloromethane (25 mL). After 30 min at −78°C, the reaction mixture was warmed up to room temperature and a saturated solution of sodium carbonate (20 mL) was added. The two phases were separated, the aqueous phase was extracted with dichloromethane (2 × 25 mL), and the combined organic phase was dried with potassium carbonate. Filtration and evaporation gave crude equatorial chloroethyl axial methyl bicyclic orthoester **15** which was distilled *in vacuo* (328 mg, 78%); bp 120°C/1 Torr; ir ($CHCl_3$): 1000–1200 cm^{-1}; nmr ($CDCl_3$) δ: 1.0–2.0 (12H, m), 3.30 (3H, s, OCH_3), and 3.80 (6H, m, —OCH_2CH_2Cl and OCH_2); ms *m/e* (70 ev): 248, 250 (ratio 3:1, M^+), 217–219 ($M^+ - OCH_3$).

Axial Vinyl Bicyclic Orthoester 1

A solution of freshly sublimed potassium *tert*-butoxide (225 mg, 2 mmol) in anhydrous tetrahydrofuran (10 mL) was slowly added to a solution of axial chloroethyl equatorial methyl bicyclic orthoester **11** (150 mg, 0.6 mmol) in tetrahydrofuran (5 mL). The mixture was then refluxed for 2 h. Most of the solvent was removed *in vacuo*, the residue was mixed with a solution (5 mL) of sodium bicarbonate (5%) and the aqueous mixture was extracted with ether (3 × 25 mL). The organic extract was dried on potassium carbonate, filtered, and evaporated to yield axial vinyl bicyclic orthoester **1** (110 mg, 88%); vpc (column B, temperature: injector, 118°C; detector, 112°C; column, 100°C): retention time, 28.5 min; ir (CCl_4): 1635 and 1000–1200 cm^{-1}; nmr (CCl_4) δ: 1.0–2.0 (12H, m), 3.29 (3H, s, OCH_3), 3.6 (2H, m, CH_2O), 4.13, 4.56, and 6.5 (1H, 1H, 1H, ABX system, $J_{AX(cis)}$ = 6.5 Hz, $J_{BX(trans)}$ = 15 Hz, and $J_{AB(gem)}$ = 1 Hz); ^{13}C nmr δ: 143.8 (C11), 112.6 (C1), 91.6 (C12), 68.4 (C5), 48.7 (C10), 40.7 (C4), 37.7 (C2), 36.5 (C3), 32.5 (C9), 27.0 (C6), and 25.9 (C7 and C8); ms *m/e* (70 ev): 212 (M^+, absent), 181 ($M^+ - OCH_3$), 169 ($M^+ - OC_2H_3$).

Equatorial Vinyl Bicyclic Orthoester 7

A solution of freshly sublimed potassium *tert*-butoxide (250 mg, 2.2 mmol) in anhydrous tetrahydrofuran (10 mL) was slowly added to a solution of equatorial chloroethyl axial methyl bicyclic orthoester **15** (339 mg, 1.37 mmol) in tetrahydrofuran (8 mL) and the mixture was refluxed for 1 h. The solvent was then removed *in vacuo* and a solution (5 mL) of sodium bicarbonate (5%) was added. The aqueous phase was extracted with ether (3 × 25 mL), the organic extract was dried with potassium carbonate, filtered, and evaporated. The residue was distilled *in vacuo* to yield a mixture (251 mg, 84%) of dimethyl bicyclic orthoester **16** (4%, retention time 20.3 min, (5)), equatorial vinyl orthoester **7** (86%, retention time 28.3 min, (5)), and equatorial methyl axial ethyl orthoester **17** (10%, retention time 29.2 min); vpc (column A, temperature: injector, 112°C; detector, 122°C; column, 105°C). Purification by vpc gave equatorial vinyl orthoester **7** containing 8% of equatorial methyl axial ethyl orthoester **17**; ir (CCl_4): 1640 and 1000–1200 cm^{-1}; nmr (CCl_4) δ: 1.0–2.1 (12H, m), 3.33 (3H, s, OCH_3), 3.6 (2H, m, CH_2O), 4.07, 4.47, and 6.50 (1H, 1H, 1H, ABX system, $J_{AX(trans)}$ = 15 Hz, $J_{BX(cis)}$ = 6.5 Hz, $J_{AB(gem)}$ = 1.5 Hz); ^{13}C nmr δ: 144.3 (C11), 112.6 (C1), 91.8 (C12), 68.3 (C5), 47.4 (C10), 40.8 (C4), 38.9 (C2), 37.2 (C3), 32.4 (C9), 27.1 (C6), and 25.2 (C7 and C8); ms *m/e* (70 ev): 212 (M^+, absent), 181 ($M^+ - OCH_3$), 169 ($M^+ - OC_2H_3$).

Oxidation of Axial Vinyl Bicyclic Orthoester 1

A. A solution of axial vinyl bicyclic orthoester **1** (80 mg, 0.37 mmol) in anhydrous acetonitrile (0.5 mL) was rapidly added to a mixture of potassium permanganate (1.0 mmol), acetonitrile (1 mL), buffer (60 μL, $NaHCO_3$–NaOH, pH = 13), and ^{18}O-labelled water (30 μL, 96.5% ^{18}O), and the mixture was magnetically stirred for 3 min. Pyridine (10 mL) and acetic anhydride (8 mL) were added and the mixture was left for 15 h. Ether (60 mL) was added and the organic phase was washed with hydrochloric acid (10%, 3 × 40 mL). The organic phase was dried with magnesium sulfate, filtered through Celite, and evaporated (64 mg, 74%). Analysis by vpc (column B, temperature 150°C) showed a mixture of bicyclic lactone **6** (2%, retention time, 9.5 min) and acetate methyl ester **9** (98%; retention time, 15.0 min) which were identified with authentic samples (5). Acetate methyl ester **9** was obtained pure by vpc and mass spectral analysis and showed an ^{18}O incorporation of 9.0% which corresponds to 28% theoretical incorporation.

B. Axial vinyl orthoester **1** (79 mg, 0.37 mmol) in acetonitrile (0.5 mL) was added to a mixture of potassium permanganate (3 mmol), buffer (0.1 mL), and acetonitrile (1 mL). The mixture was left for 3 min and a solution (50 mL) of potassium bicarbonate (5%) was added. The mixture was extracted with ether (3 × 50 mL), the organic extract was dried over potassium carbonate, filtered, and evaporated to dryness (46 mg). Analysis by ^1H nmr showed the absence of axial vinyl orthoester **1**.

Oxidation of Equatorial Vinyl Bicyclic Orthoester 7

A. Equatorial vinyl orthoester **7** (150 mg, 0.71 mmol) containing 8% of equatorial ethyl axial methyl orthoester **17** was oxidized by a procedure similar to that described for compound **1**, except that the buffer was at pH = 10. It yielded a mixture

(127 mg, 79%) of bicyclic lactone **6** (3%; retention time, 10 min), acetate methyl ester **9** (88%; retention time, 15 min), and acetate ethyl ester **19** (9%; retention time, 21 min) identified by comparison with authentic samples (5); vpc (column B, temperature: 152°C). Acetate methyl ester **9** was obtained pure by vpc and mass spectral analysis showed an ^{18}O incorporation of 13.2% which corresponds to 41% theoretical incorporation.

B. Equatorial vinyl orthoester **7** (81 mg, 0.38 mmol) containing 11% of equatorial ethyl axial methyl orthoester **17** was oxidized by a procedure similar to that described above except that the reaction time for the oxidation was 35 min. After acetylation with pyridine and acetic anhydride, it yielded after workup a mixture (57 mg) of bicyclic lactone **6** (29%), acetate methyl ester **9** (63%), and acetate ethyl ester **19** (8%). Bicyclic lactone **6** and acetate methyl ester **9** were obtained pure by vpc (column B) and mass spectral analysis showed a theoretical ^{18}O incorporation of 55% in bicyclic lactone **6** (^{18}O = 17.7%) and 53% in acetate methyl ester **9** (^{18}O = 17.1%).

Oxidation of Axial Methyl Equatorial Ethyl Orthoester 17

A solution of axial methyl equatorial ethyl orthoester **17** (110 mg, 0.5 mmol) in acetonitrile (3 mL) was added to a mixture of potassium permanganate (1.0 mmol) and buffer (pH = 10, 90 μL). The mixture was left for 3 min and a solution (30 mL) of sodium bicarbonate (5%) was added. The mixture was extracted with dichloromethane (3 × 25 mL), the organic extract was dried with potassium carbonate, filtered, and evaporated to dryness to give axial methyl equatorial ethyl orthoester **17** unchanged (103 mg).

Reaction of Axial Methyl Equatorial Ethyl Orthoester 17 with Pyridine and Acetic Anhydride

A solution of axial methyl equatorial ethyl orthoester **17** (90 mg, 0.42 mmol) in acetonitrile (3 mL) was mixed with buffer (pH = 10, 90 μL). Pyridine (10 mL) and acetic anhydride (5 mL) were added and the mixture was left for 15 h. The solvent was removed *in vacuo* and dichloromethane (50 mL) was added. The organic solution was washed with water (2 × 25 mL), dried with magnesium sulfate, filtered, and evaporated to yield a mixture (94 mg) of acetate ester **9** (93%, retention time: 27.5 min) and bicyclic lactone **6** (7%, retention time: 11.2 min); vpc (column B, 146°C).

Acknowledgements

We wish to thank Professor J. K. Saunders for the interpretation of ^{13}C nmr spectra.

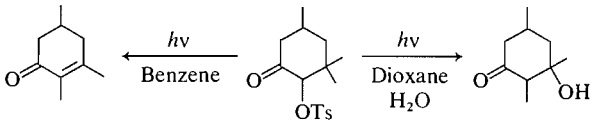
Photoelimination from a γ-substituted α,β-unsaturated ketone

JAMES L. CHARLTON AND GERALD N. LYPKA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received November 5, 1979

JAMES L. CHARLTON and GERALD N. LYPKA. Can. J. Chem. **58**, 1059 (1980).



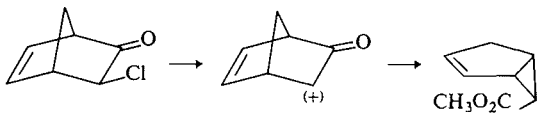
During a study of unsaturated six membered ring sultones (1), it was found that irradiation of the sultone **7** in methanol gave the esters **8** and **9** as primary photoproducts. These esters, on continued irradiation, led to a completely aromatic compound which has now been identified as 12-hydroxy-11-phenylbenzo(*j*)fluoranthene **10**.

JAMES L. CHARLTON et GERALD N. LYPKA. Can. J. Chem. **58**, 1059 (1980).

Lors de l'étude des sultones contenant un cycle à 6 non saturé (1), on a trouvé que l'irradiation de la sultone **7** dans le méthanol donne les esters **8** et **9** comme produits principaux. Ces esters sous irradiation continue se transforment en un composé complètement aromatique identifié comme étant l'hydroxy-12 phényl-11 benzo[*j*]fluoranthène (**10**).

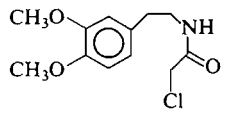
[Traduit par le journal]

The photoelimination of the substituents from ketones has been the subject of several recent investigations. α-Tosyloxyketones have been examined by Iwasaki and Schaffner (2) who reported that irradiation in the $n\pi^*$ absorption band of the 2,5-*cis*-tosyloxyketone **1** led to the cyclohexanone **2** in benzene solution and to ketol **3** in aqueous dioxane.



2 1 3

An α-keto carbonium ion was proposed as an intermediate. In later work Schaffner and co-workers extended the scope of this reaction to include electrophilic substitution on aromatic nuclei (3). Similarly Lai, in his study of tosyloxyketones, proposed an α-ketocarbonium ion pathway leading to a Favorski-type process (4).



The photolysis of α-chloroketones has been studied by a number of groups (5). As an example, Kaplan and Hartwig photolized the ketone **4**, in methanol, to give **5** in 95% yield (5*a*). As in tosyloxyketones, a carbonium ion was postulated as an intermediate.

Yonemitsu and co-workers have conducted several studies on the photochemistry of *N*-chloroacetamides (6). For instance, photolysis of 3,4-dimethoxy phenethylamide **6** caused expulsion of the chlorine to yield both radical and cationic intermediates (7).

4 5, 95%

A vinyl analogue of these α-photoelimination reactions is reported here. Extensive irradiation of the sultone **7** gave a compound which analysed for $C_{26}H_{16}O$ and exhibited a signal for only one non-

6

aromatic proton at δ 5.42 in the nuclear magnetic resonance spectrum. This signal disappeared on the addition of deuterium oxide. As well, the carbon-13 nuclear magnetic resonance spectrum exhibited only one carbon down-field at δ 148.6 with the rest all falling in the aromatic region between δ 119.1 and δ 137.8. The infrared spectrum showed hydroxyl absorption at 3530 cm^{-1} and the

mass spectrum gave a molecular ion peak at *m/e* 344.

Ozonolysis in ethyl acetate at −20°C and sublimation of the products, after oxidative workup, led to the isolation of benzoic acid and phthalic anhydride.

The most reasonable interpretation of these data is represented by the structure 12-hydroxy-11-phenylbenzo(*j*)fluoranthene, **10**, and the following mechanism is proposed:

7 8 9 10

SCHEME I

The intermediacy of the esters **8** and **9** was established by their isolation (1) and conversion, by photolysis, to the phenol **10**. While we have represented the intermediate in this reaction as cationic, we have no direct evidence for its existence and a radical mechanism cannot be excluded.

The structure of **10** was further substantiated by the similarity of its ultraviolet spectrum to that of benzo(*j*)fluoranthene (8) and by the expected bathochromic shift of the ultraviolet spectrum on going from neutral to basic medium.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. Infrared spectra were obtained with a Beckman IR-10 instrument and nuclear magnetic resonance spectra were recorded on a Varian EM-360 (^{1}Hmr) or a Bruker WH90-DS (^{13}Cmr) instrument. Chemical shifts are reported in ppm downfield from tetramethylsilane. Mass spectra were recorded on a Finnegan 1015 mass spectrometer.

Irradiation of Sultone 7

Sultone **7** (1) (198 mg) was dissolved in methanol (150 cm^3) and irradiated, under nitrogen, for 3 h with a 450 W medium pressure mercury lamp, using a pyrex filter. The reaction was followed by thin layer chromatography (Camag DSF-5 silica gel, eluent ethyl acetate – petroleum ether 1:4). The solvent was removed under vacuum and the residue chromatographed on silica gel (eluent ethyl acetate – petroleum ether, 1:4) to give yellow crystals (130 mg, 78% yield) which recrystallized from benzene, melting point 180–183°C; λ_{max} (CH_3OH) (ε): 432(3 000), 385 (6 500), 366 (4 950), 333 (27 200), 318 (30 400), 236 (50 000), and 224 (ε 47 000) nm; λ_{max} (0.7 *N* KOH/CH_3OH) (ε): 513 (5 000 nm; ν_{max}($CHCl_3$): 3530 and 1570 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 5.42(s), 7.5(m); ^{13}Cmr ($CDCl_3$) δ: 148.7, 137.8–119.1 (overlapping signals); *Anal.* calcd. for $C_{26}H_{16}O$: C 90.67, H 4.68; found: C 90.70, H 4.59.

Ozonolysis of 10

The photoproduct **10** (90 mg) was dissolved in ethyl acetate (30 cm^3) and treated at −20°C with ozone until the yellow colour disappeared. Hydrogen peroxide (5 cm^3; 30% solution) and sodium hydroxide (15 cm^3; 1 *N*) were added and the solution refluxed for 5 min. It was then acidified (1 *N* HCl) and extracted with ether. These extracts were dried ($MgSO_4$) and evaporated to leave a residue that could be partially separated by fractional sublimation, one compound subliming at 25–50°C (0.004 Torr) and the other at 50–130°C (0.004 Torr). Recrystallization of the former from chloroform – light petroleum gave a compound, mp 119–120°C. A mixture melting point with benzoic acid showed no depression. Recrystallization of the second compound from chloroform – light petroleum gave crystals, mp 128–130°C. A mixture melting point of this compound with phthalic anhydride showed no depression. Infrared spectra of the above compounds were identical to those of authentic samples.

Catalytic hydrogenations of 5α-cholestan-3-ones and related compounds with Urushibara nickel A catalyst in cyclohexane gave a distinct preponderance of unstable axial 3α-ols. Product ratios of axial alcohols decreased with increasing solvent polarity. For 3-oxo-5α-steroids, the cobalt catalyst was less selective for the axial alcohol formation. On the other hand, conversion of 5β-cholestan-3-one into the corresponding axial 3β-ol was most successfully attained by hydrogenation catalyzed by Urushibara cobalt A catalyst in methanol. For such a 5β-ketone, alcoholic media with higher polarities were more favorable for giving the product rich in axial alcohol. The stereochemistry of the products obtained from hydrogenations conducted in nonpolar solvents may be understood in terms of the steric congestion around the ketone carbonyl group. However, when alcohols were used as solvents, the product ratios obtained did not correlate well with the congestion ratios of substrates.

MASAYOSHI ISHIGE et MICHIO SHIOTA. Can. J. Chem. **58**, 1061 (1980).

L'hydrogénation catalytique des cholestane-5α ones-3 et de composés apparentés au moyen du catalyseur de nickel A de Urushibara dans le cyclohexane a conduit à la formation prépondérante des alcools-3α axiaux instables. La proportion d'alcool axial décroît quand on augmente la polarité du solvant. Dans le cas des oxo-3 stéroides-5α, le catalyseur au cobalt est moins sélectif quant à la formation d'alcool axial. D'autre part, la transformation de la cholestane-5β one-3 en l'alcool-3β axial correspondant se fait plus facilement par hydrogénation catalytique en présence du cobalt A de Urushibara dans le méthanol. Dans le cas de la cétone 5β, l'utilisation d'un milieu alcoolique à forte polarité favorise grandement la formation de l'alcool axial. On peut comprendre la stéréochimie des produits d'hydrogénation dans des solvants non polaires en fonction d'une compression stérique autour du groupe carbonyle de la cétone. Cependant, quand on utilise des alcools comme solvants, la proportion de produits obtenus ne correspond pas tout à fait aux taux de compression des substrats.

Introduction

With synthetic methods in hand for preparing steroid axial 3-alcohols from the corresponding ketones (1–8), we are interested in examining the stereoselectivity of catalytic hydrogenation of 3-oxo-steroids.

Compared with the syntheses of equatorial alcohols, the preparation of the axial isomers has generally been troublesome. It is well known that the catalytic hydrogenation of unhindered cyclic ketones in acidic media gives a preponderance of the axial alcohols (9–11). However, the method is limited in its application to various kinds of steroids, not only because the selectivity of the products is not always satisfactory, but also because the use of strong acids often leads to the formation of by-products. In neutral solvents, nearly equal amounts of isomeric alcohol are frequently obtained (11); the reason proposed is that the attack of hydrogen occurs equally from either side of the molecule in those compounds in which there is little difference in steric hindrance around the carbonyl group. However, the preponderance of steroid axial 3-alcohols obtained by catalytic hydrogenation using neutral solvents under mild conditions (1–6) suggests that this reductive technique will provide a convenient route for preparing axial 3-ols because of the ease of the procedure and the high selectivity for less stable axial alcohols. Furthermore, the data collected, which contravene the general tendency,[1] are helpful in understanding the stereochemistry of catalytic hydrogenation of unhindered alicyclic ketones.

The purpose of the present work is twofold: first, to investigate the finding that some 5α-cholestan-3-ones can be favorably hydrogenated to the 3α-ols using Urushibara nickel A catalyst in cyclohexane and to check the general applicability of this method to the preparation of steroid axial 3-alcohols; second, to compare the ratios of axial to equatorial alcohols obtained in order to find the controlling factors of stereoselectivity of the catalytic hydrogenation.

Results and Discussion

Hydrogenations of 5α- and 5β-Cholestan-3-ones (1 and 2)

In a previous publication (3), we have described in part the effects of solvents and catalysts on the product ratios in the hydrogenation of 5α-cholestan-3-one (**1**). Among the catalysts tested, Urushibara nickel A (abbreviated to U-Ni-A

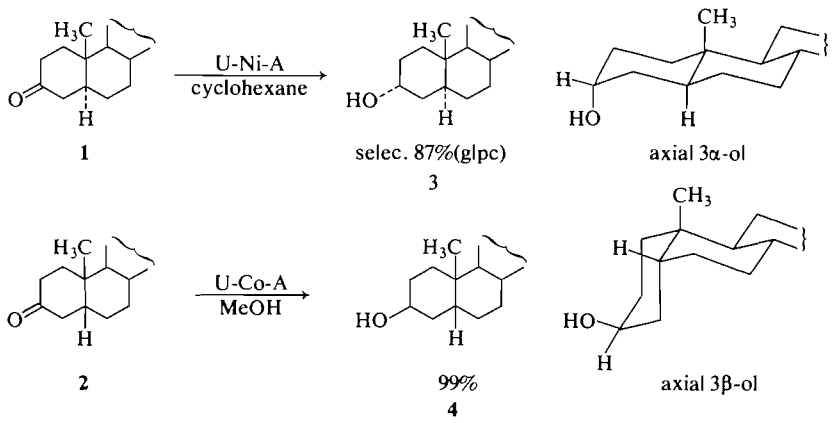
TABLE 1. Effect of solvents on the product ratios (axial alcohol %) in the hydrogenations of 5α- and 5β-cholestan-3-ones with Urushibara catalysts

Ketone	Catalyst	Axial alcohol %				
		MeOH	EtOH	*i*-PrOH	*t*-BuOH	Cyclohexane
5α-Cholestan-3-one	U-Ni-A	42	47	48	53	87
	U-Co-A	33	34	47	60	73
	U-Cu-A	—	—	—	11	26
5β-Cholestan-3-one	U-Ni-A	72	76	60	51	57
	U-Co-A	99	89	75	72	52
	U-Cu-A	—	—	—	65	47

hereafter), which was prepared by the acid treatment of precipitated nickel, appeared to be most promising for the preferential production of the axial 3α-ol when it was used in hydrocarbon solvents. By using some other Urushibara catalysts, we have now examined more extensively the effects of these reagents on the selectivity of reduction of 5α- and 5β-cholestan-3-ones (**1** and **2**). According to the procedure described previously, the reactions were carried out at 30–35°C under high pressure. The stereochemistry of hydrogenation in neutral media is very sensitive to contamination and to the catalyst. A trace of water in the reaction causes a great diminution of the proportion of axial alcohol. Thus the water in the reaction system must be carefully removed. The results are summarized in Table 1.

It can be recognized from the table that in the presence of U-Ni-A and U-Co-A, the change in the product ratio with solvent presents a striking contrast between the 5α- and 5β-ketones. The formation of axial 3α-ol (**3**) from the 5α-ketone **1** was not favorable in alcohol media with higher polarities, while the same ketone gave products predominant in axial alcohol when a nonpolar solvent such as cyclohexane was used. A tendency to increase the 3α-ol ratio with decrease of solvent polarity can be more clearly seen when the data for the reduction of the 5α-ketone in ether are considered (3). On the other hand, the 5β-ketone **2** was preferentially hydrogenated to the axial 3β-ol (**4**) in more polar media.

The catalysts play another important role for selectivity. Although the properties of the nickel and cobalt catalysts used appear similar, the difference in selectivity of the metals can be noticed when the product ratios are examined in detail. In the reactions of 5α-cholestan-3-one, nickel was more selective for the formation of axial 3α-ol than cobalt. With 5β-cholestan-3-one, on the contrary, cobalt more effectively favored the formation of the axial 3β-ol **4** than nickel. Therefore the best result for axial alcohol formation from 5α-cholestan-3-one was obtained under the conditions with U-Ni-A in cyclohexane, whereas the 5β-ketone **2** was most preferentially hydrogenated to the corresponding axial alcohol in the presence of U-Co-A in methanol.



These findings may imply that in the presence of the nickel and cobalt catalysts, 5α-cholestan-3-one is more likely to give the corresponding equatorial 3β-ol through the adsorbed transition complex which is stabilized in more polar solvents, whereas the reduction of the 5β-ketone to the axial 3β-ol proceeds through the species stabilized in similar polar media. If this is the case, it would mean that the adsorbed transition complexes of nickel are generally less polar than those of cobalt, although the polarities of the complexes vary with substrates and solvents.

More distinct examples of opposite stereoselectivities have been reported in the palladium or platinum catalyzed hydrogenation of 5α- and 5β-cholestan-3-ones (5). The reduction of 5α-cholestan-3-one with palladium in *t*-BuOH gives the equatorial 3β-ol in 98% selectivity, while the reduction of the 5β-ketone results in the formation of the axial 3β-ol in 95% selectivity under the same conditions. Similar results are also obtained with *i*-PrOH and tetrahydrofuran, but not with cyclohexane. Platinum catalysts have a similar selectivity, but are somewhat less selective than palladium.

Hydrogenations of 5-Cholesten-3-one (5) and 5α-Cholest-6- and -7-en-3-ones (6 and 7)

The hydrogenation with U-Ni-A in hydrocarbon solvents has proved most useful when the method is applied to 5-cholesten-3-one (**5**), since **5** is liable to isomerize to the conjugated ketone in the presence of acids. A unique characteristic of U-Ni-A reduction is that the yield of epicholesterol (5-cholesten-3α-ol) (**8**) is superior to those observed with most other methods of preparation (1, 12–21). The yield of the U-Ni-A reactions varies widely if contaminants, one of which is frequently water

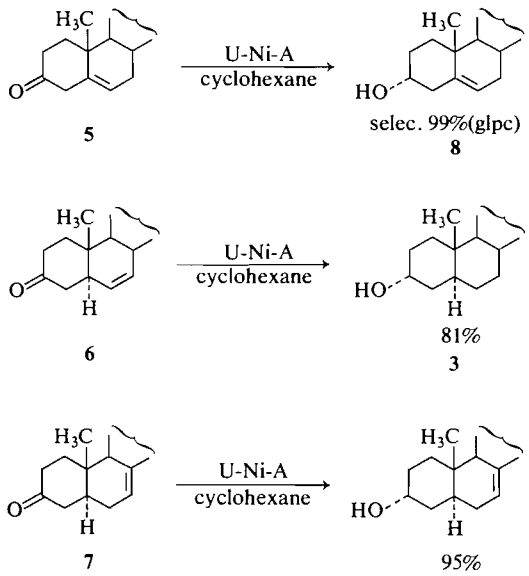


SCHEME 1

contained in the reaction system, are present. When water is thoroughly removed, the yield is found to be improved over that previously reported (94% (3) up to about 99%).

The hydrogenation of 5α-cholest-6-en-3-one (**6**) under the same conditions gave a mixture of saturated 3α-ol and 3β-ol in the ratio of 81:19. The C=C double bond of the ketone appeared more readily hydrogenated than the carbonyl group, and the reduction may proceed mainly through 5α-cholestan-3-one as an initial reduction product. The product ratio from this ketone is, in fact, analogous to that from 5α-cholestan-3-one.

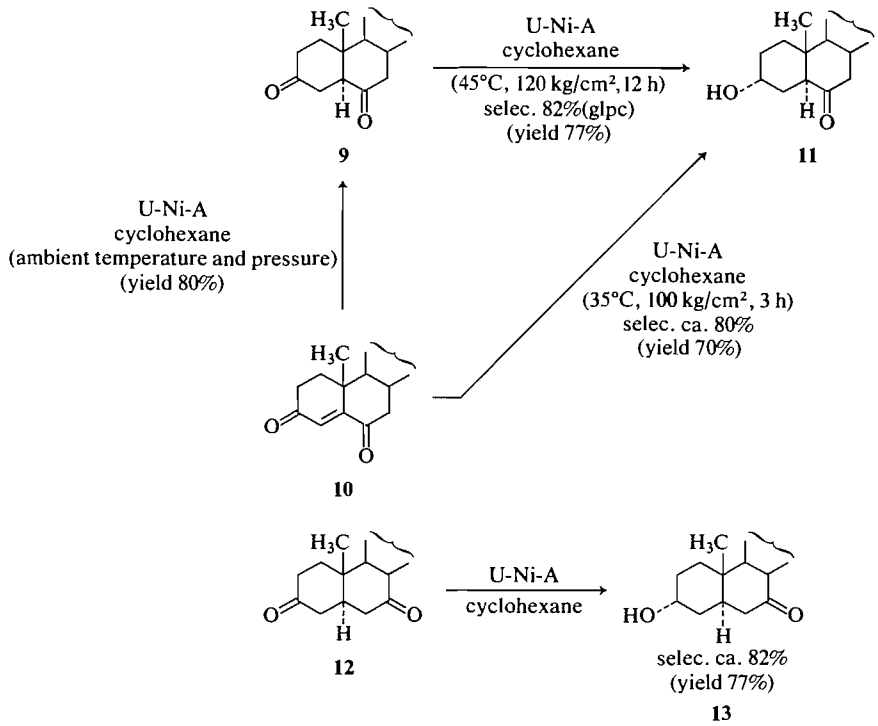
In the reaction of 5α-cholest-7-en-3-one (**7**), the ethylenic double bond remained unreacted and only the carbonyl group was selectively converted into the 3α-hydroxyl group.

Compared with the results of saturated ketones,

5 8 6 3 7

SCHEME 2

the higher selectivities of axial 3α-ol from the unsaturated ketones are related to the presence of C=C double bonds in the B-ring. The geometry of the unsaturated steroidal ketones might participate in the preponderance of the axial alcohols, but the pronounced preference for a 3α-hydroxyl group is difficult to explain on the basis of steric control alone.



Hydrogenations of 5α-Cholestan-1-one, -2-one, -4-one, and -6-one

In order to investigate the relationship between the positions of carbonyl groups and the selectivities, the hydrogenations of 5α-cholestan-1-one, -2-one, -4-one, and -6-one with U-Ni-A in cyclohexane were attempted. The 1-one, 4-one, and 6-one did not undergo hydrogenation after a long reaction time. Only the 2-one was readily hydrogenated to give the axial 2β-ol in a good yield (Table 2). In this case, the strong preference for axial alcohol formation seems to be caused by the exclusive α-face attack of hydrogen on the carbonyl group because the approach of catalyst from the β-side is hindered by the presence of a *syn*-axial angular methyl group. However, from the fact that the hydrogenation using *t*-butyl alcohol solvent showed the diminution of the 2β-ol ratio, it is rather questionable to consider that a strong preference is exclusively a consequence of steric hindrance to β-face attack upon the ketone.

TABLE 2. The product ratio in the hydrogenation of 5α-cholestan-2-one with U-Ni-A

Solvent	Product ratio (%)	
	2β (axial)	2α (equatorial)
Cyclohexane	98	2
t-BuOH	80	20
EtOH	80	20

SCHEME 3

Hydrogenations of 4-Cholestene-3,6-dione (10) and 5α-Cholestane-3,6- and -3,7-diones (9 and 12)

A previous paper has described the preparation of 3α-hydroxy-5α-cholestan-6-one (**11**) and -7-one (**13**) from the corresponding diones with U-Ni-A in cyclohexane (4). Striking features of the reactions are represented both by the exclusive reduction of the 3-carbonyl group and by the selective formation of the axial 3α-hydroxyl group. However, since the 3,6-dione **9** is intrinsically less reactive, the reaction must be effected for a long time under slightly more drastic conditions than usual. Inspection of a model of this dione shows that a conformational change of the A-ring caused by a change from sp^2 to sp^3 at C3 gives rise to a slight clockwise rotation of bonds attached to C5 relative to those at C10. This rotation tends to force a further decrease on the originally small torsion angle between C5—C6 and C9—C10 bonds. The distortions opposed to those stemming from C3 will retard the reduction of compound **9**. On the other hand, the 3,7-dione **12** will not be affected so greatly, as indicated in the experiments, by a geometry deformation involving the reaction, because the separation of the 7-carbonyl group from C5 by a methylene enables the B-ring to accommodate the small skeletal deformations around the C5—C10 bond.

The unreactivity of the carbonyl group at the 6- and 7-positions may be ascribed to steric hindrance. In this connection, 5α-cholestan-6-one and 3β-acetoxy- and 3β-hydroxy-5α-cholestan-6-ones were found to undergo no hydrogenation under the same conditions. However, when *t*-BuOH solvent was used instead of cyclohexane, 3β-hydroxy-5α-cholestan-6-one and -7-one were readily hydrogenated into the mixtures containing 5α-cholestane-3β,6β- and -3β,7β-diols respectively. Likewise each 3β-hydroxy ketone is known to be converted into the diols with U-Ni-B in EtOH (22).

These results suggest that steric hindrance will predominately control stereochemistry in nonpolar solvents whereas it will not always prevail in alcohol media.

The preparation of 3α-hydroxy-5α-cholestan-6-one (**11**) could be easily attained by the hydrogenation of 4-cholestene-3,6-dione (**10**) with U-Ni-A in cyclohexane under high pressure. Generally the use of alcohol solvent is undesirable as the yield of the product decreases. However, even at ambient temperature and pressure, it happened that Δ^4-3,6-dione **10** gave the desired product in *t*-BuOH in a good yield, but further examination to obtain reproducible results is needed. The reduction in cyclohexane at atmospheric pressure yielded 5α-cholestane-3,6-dione as a major product.

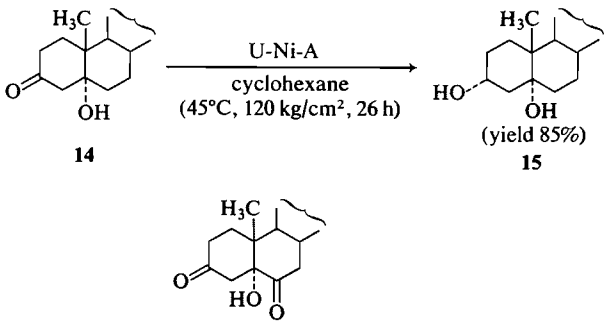
Although the analysis of the stereochemical results of the reduction of this conjugated ketone is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

not clear, it is evident that reaction to form 3α-hydroxy-6-one **11** does not proceed via the intermediate 5α-cholestane-3,6-dione **9** because the reaction of the dione **9** is very slow (see Scheme 3). The formation of the desired hydroxy ketone may be envisaged as resulting from either rapid isomerization of the 5β-isomer or partial reduction of a species of 3,5-diene-3,6-diolate coordinating with the metal.

Hydrogenation of 5-Hydroxy-5α-cholestan-3-one (14)

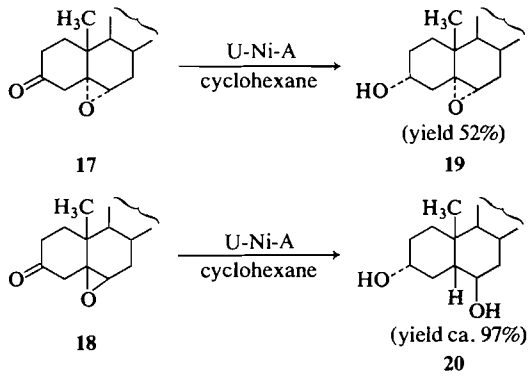


A unique character in the reduction of 5-hydroxy-5α-cholestan-3-one (**14**) is the highly selective conversion of the 3-carbonyl group into the axial 3α-hydroxyl group; 5α-cholestane-3α,5-diol (**15**) was thus obtained as the only product. However, as the hydroxy ketone **14** reacted very slowly, the reaction had to be carried out for a long time at a more elevated temperature under higher pressure. The situation was almost independent of solvents and catalysts. Therefore it is probable that the stereoselectivity is exclusively determined by steric factors.

In addition, we found that the hydrogenation of 5-hydroxy-5α-cholestane-3,6-dione (**16**) does not take place under these drastic conditions.

Hydrogenations of 5,6α-Epoxy-5α- and 5,6β-Epoxy-5β-cholestan-3-ones (17 and 18)

The examination of the behavior of epoxy ketones to catalytic hydrogenation under neutral conditions is of interest, and the reduction of some 5,6-epoxy ketones with U-Ni-A in cyclohexane were attempted.



In preliminary experiments, we found that 5,6α-epoxy-5α-cholestan-3-one (**17**) was characteristically converted into different products depending on the reaction conditions employed. For example, the epoxy ketone **17** gave 6α-hydroxy-4-cholesten-3-one as a major product when stirred in ethanol in the presence of alumina, whereas 5α-cholestane-3,6-dione was produced when cyclohexane was used instead of ethanol.

SCHEME 4

Under the conditions using cyclohexane solvent in the presence of U-Ni-A but without hydrogen gas, the α-epoxy ketone **17** changed into an oily mixture which appeared to contain mainly 4-cholestene-3α,6α-diol. On the other hand, under the hydrogen atmosphere, 5,6α-epoxy-5α-cholestan-3α-ol (**19**) was the main component obtained from a crude oily product, which was easily isolated as a crystalline solid (mp 120–121°C, 52% yield) by column chromatography on silica gel. Subsequent oily material eluted was composed of several minor compounds, which were produced through the cleavage of the epoxy ring. Since the epoxy alcohol obtained was stable as compared with the starting epoxy ketone, it is suggested that the rate of reduction of the carbonyl group is comparable to that of epoxide-ring cleavage.

The epoxide ring of 5,6β-epoxy-5β-cholestan-3-one (**18**) was more labile, opening under the influence of the metal. The hydrogenation of this β-epoxy ketone **18** under the same conditions as above afforded crude crystals, from which 5β-cholestane-3α,6β-diol (**20**) was obtained in a ca. 97% yield by recrystallization, mp 142–143.5°C. It is probable that the diol is the hydrogenation product of an intermediate 6β-hydroxy-4-cholesten-3-one.

SCHEME 5

Steric Control in the Reduction of Ketones

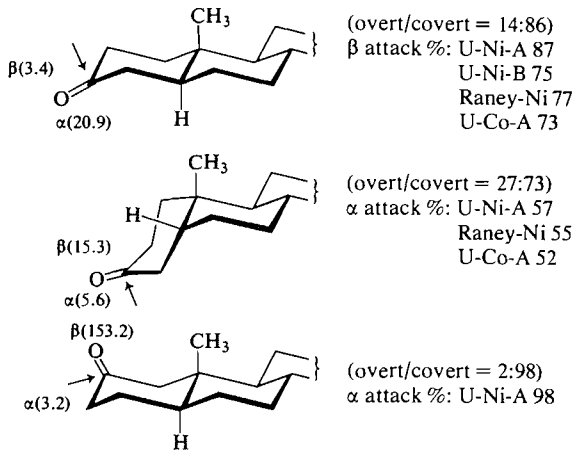
Although the interpretation of the stereochemistry of addition reactions of ketones in terms of steric factors has been the subject of some controversy,[2] the importance of this factor operating in the reduction of ketones has been well recognized since the 1950's.

The concept of steric approach control in the addition reactions of hindered cyclic ketones has

[2]For recent reviews concerning the stereochemical mechanism, see ref. 23.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

been well accepted since proposed by Dauben *et al.* (24), and additional explanations advanced for unhindered cyclic ketones have been offered by many workers (21–28).



Recently two types of approach to estimate the steric environment about a reaction center have been offered, based on the theoretical calculations.

Perlberger and Müller pointed out that the rates for the reduction of ketones are interpreted in terms of two parameters derived from force-field calculations (29). However, the parameters concerning steroid ketones are not available from the reported papers.

Wipke and Gund have shown that the steric congestions calculated with molecular mechanics correlate well with the stereoselectivity of ketone additions by large nucleophiles, or in highly congested substrates (30). For addition of small nucleophiles to uncongested ketones, the torsion-corrected functions are successfully used to reproduce the stereoselectivity of the reduction. The values of overt (β) and covert (α) congestions of 5α-cholestan-3-one are 3.4 and 20.9 respectively. The ratio of these congestions (14:86) is fairly close to the product ratios obtained in the nickel-catalyzed hydrogenation in cyclohexane (β attack %: U-Ni-A 87, U-Ni-B 75, Raney-Ni 77). In the case of 5α-cholestan-2-one, good correlation between the experimental product ratio (98% α attack) and the congestion functions (3.2α, 153.2β or 2:98) was also observed. These findings thus suggest that the selectivity in the reactions is dominated by steric control with reagents, meaning that the slow step is in an early (reactant-like) transition state. This consideration consistently explains the facts that highly congested ketones, such as 5α-cholestan-1-one, -4-one, and -6-one, resist reaction in a nonpolar solvent. However, neither the congestions (5.6α, 15.3β or 27:73) nor the torsion-corrected ones (ratio of overt/covert, 13:87) of 5β-cholestan-3-one seem to reflect as well the observed ratios (β attack %: U-Ni-A 57, Raney-Ni 55).

It is reasonably conceivable that the A-ring of a 5β-ketone, in which the C4—C5 bond is axial with regard to the B-ring, is in a somewhat higher energy level relative to that of a 5α-ketone, being torsionally strained to minimize the energy in the ground state. This torsion strain is probably less than the strain predicted from the Chérest and Felkin's concept (31). Therefore the discrepancy between the observed and calculated product ratios in the 5β-ketone might be diminished by correcting the congestion function by using parameters suitable for torsion in the ground state.

The cobalt-catalyzed reductions in a nonpolar solvent give similar results to those obtained with nickel. Thus, the preference for attacking direction of reagents is, to a large extent, predictable by the congestions of ketones.

NOTE: Arrow denotes the direction of preferable attack of hydrogen on carbonyl carbon. The figures in parentheses represent the congestion values.

SCHEME 6

The aspects of reactions in polar alcoholic solvents are more enigmatic. Considering that the congestion or corrected congestions do not correlate well with the product ratios, most stereochemical results do not obviously appear to reflect a steric or torsion effect. With the 5β-ketone, torsional effects involving solvation may not prevail, because the assignment of stereochemistry based on the torsional-corrected congestions is the reverse of the observed preferred direction of hydrogen addition to the carbonyl carbon. Additionally, from the viewpoint of steric hindrance, 5α-cholestan-2-one is of interest, in that the ratio of the equatorial 2α-ol tends to increase in alcohol media, though the attack from the β-side is strongly hindered. In such cases, it may be rather questionable that steric control is a principal factor in determining the stereochemistry. In addition, it is evident that a concept of "product development control" does not explain the predominant formation of the products. The alcoholic solvents can probably play various roles in the reaction processes, such as association with a substrate, adsorption on the catalyst metal, and proton donation.

Experimental

All the melting points were determined on a Yanagimoto hot-stage and are uncorrected. The nmr spectra were recorded with a JEOL C-60 HL nmr spectrometer using chloroform-*d* solvent containing TMS as an internal standard unless otherwise stated. The ir spectra were measured on a JASCO IR-G spectrometer using KBr discs. The product ratios were determined with a Shimadzu GC-4APF gas chromatograph by using either a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

3 m glass column packed with 1.5% Silicone OV-17 on silanized Shimalite (80–100 mesh) or a 50 m glass capillary column (0.3 mm id; Silicone OV-101; Scott-type).

Catalysts

The catalysts used were prepared according to the procedure described previously (3). In order to remove the water completely from the catalyst surface, the crystallites, which were thoroughly washed with water and then with *t*-BuOH, were suspended once in the solvent by means of an ultrasonic cleaner, then precipitated by centrifugation, and separated out from the liquid by decantation. The procedures were carried out repeatedly. The catalysts thus obtained were used immediately.

Hydrogenation

According to the procedure described in the previous paper (3), the hydrogenations were usually effected at 30–35°C under a high pressure of 70–100 kg/cm². For preparative purposes, the hydrogenations of 5α-steroids were usually carried out with U-Ni-A catalyst in cyclohexane, whereas the reactions of the 5β-series were performed with U-Co-A in methanol.

Hydrogenation of 5α-Cholestan-3-one (1)

A typical example of the hydrogenation of 5α-cholestan-3-one with U-Ni-A in cyclohexane was reported previously (3). The crude product was chromatographed on silica gel with hexane–ether (8:2) to give pure 5α-cholestan-3α-ol (**3**) in 72% yield; mp 188–189°C (lit. (32) mp 186–187°C). Successive elution with hexane–ether (1:1) afforded 5α-cholestan-3β-ol; mp 141–142°C (lit. (33) mp 142–143°C).

Hydrogenation of 5β-Cholestan-3-one (2)

A typical example will be described. 5β-Cholestan-3-one (100 mg) was hydrogenated with U-Co-A (freshly prepared from 1.5 g of precipitated cobalt) in methanol (3 mL) for 2.5 h in a similar manner to that with the 5α-ketone. The product was purified by column chromatography on silica gel with hexane–ether (19:1) to give 5β-cholestan-3β-ol (**4**) in 75% yield; mp 101–102°C (lit. (15) mp 106°C); ir: 3280 (strong) and 1030 (sharp, strong) cm⁻¹; nmr (δ): 4.03 (3α-H), 0.95 (19-H), and 0.65 (18-H).

Hydrogenations of 5-Cholesten-3-one (5) and 5α-Cholest-6-en- and -7-en-3-ones (6 and 7)

Preparation of 5-cholesten-3α-ol (epicholesterol) (**8**) from 5-cholesten-3-one using U-Ni-A in cyclohexane was presented in a previous report (3). The crude crystals gave 5-cholesten-3α-ol (**8**) (92% yield) when they were chromatographed on silica gel using hexane–ether (9:1); mp 139–140°C (lit. (1) mp 141°C).

5α-Cholest-6-en-3-one (**6**) (100 mg) was hydrogenated with U-Ni-A (from 1 g of precipitated nickel) in cyclohexane (3 mL) for 2.5 h at 35°C under the pressure of 90 kg/cm². After purification of the product by column chromatography on silica gel, the spectroscopic data and melting point revealed that 5α-cholestan-3α-ol (**3**) was the major component, which was found to be contained in the crude product in a proportion of 81% by means of gas chromatographic analysis.

The hydrogenation of 5α-cholest-7-en-3-one (**7**) was carried out for 5 h under the same conditions as above. Gas chromatographic analysis showed that the product consisted of two compounds in the ratio of 95:5. 5α-Cholest-7-en-3α-ol was isolated in 88% yield by column chromatography on silica gel with hexane–ether (9:1); mp 174–175°C (lit. (34) mp 175–176°C); ir: 3300 (strong), 1660 (weak), 1045, and 1005 (sharp, strong) cm⁻¹; nmr (δ): 5.10 (7-olefinic H) and 4.00 (3α-H).

Hydrogenations of 5α-Cholestane-3,6-dione (9) and 4-Cholestene-3,6-dione (10)

The preparative procedure of 3α-hydroxy-5α-cholestan-6-one (**11**) from these ketones was described previously (4). 5α-Cholestane-3,6-dione was hydrogenated under slightly more drastic conditions than usual. The crude product gave compound **11** in 77% yield after purification by column chromatography; mp 163–164°C (lit. (35) mp 159–160.5°C). The reduction of 4-cholestene-3,6-dione gave the same 3α-hydroxy ketone **11** in 70% yield.

Hydrogenation of 5α-Cholestane-3,7-dione (12)

The procedure to prepare 3α-hydroxy-5α-cholestan-7-one (**13**) is given in our previous paper (4). The desired 3α-hydroxy-7-one **13** was obtained from 5α-cholestane-3,7-dione (**12**) in 77% yield; mp 197–198°C.

Hydrogenation of 5-Hydroxy-5α-cholestan-3-one (14)

5-Hydroxy-5α-cholestan-3-one (**14**) (100 mg) was reduced in cyclohexane (3 mL) with U-Ni-A (from 3 g of precipitated nickel) at 45°C for 26 h under the pressure of 120 kg/cm². The product was recrystallized twice from ethanol to give 5α-cholestane-3α,5-diol (**15**) in 85% yield; mp 197–198°C (lit. (36) mp 199°C); ir: 3300 (strong), 1120 (sharp, strong), 1100 (shoulder), 1075, 1033 (sharp, strong), 1110 (sharp), and 1000 cm⁻¹; nmr (δ): 4.00 (3β-H).

Hydrogenations of 5,6α-Epoxy-5α- and 5,6β-Epoxy-5β-cholestan-3-ones (17 and 18)

5,6α-Epoxy-5α-cholestan-3-one (**17**) was prepared from 5,6α-epoxy-5α-cholestan-3β-ol by Pfitzner and Moffatt's oxidation method (37). To a solution of 5,6α-epoxy-5α-cholestan-3β-ol (1.209 g, 3 mmol), dimethyl sulfoxide (5 mL), benzene (10 mL), pyridine (0.24 mL), and dicyclohexylcarbodiimide (1.85 g) was added 0.12 mL of trifluoroacetic acid with swirling. The mixture was allowed to stand overnight at room temperature. Water (ca. 25 mL) was added to the yellowish mixture and the insoluble dicyclohexylurea was removed by filtration. The organic phase was then extracted with water (50 mL × 6), dried over sodium sulfate, and evaporated. The residue was dissolved in ether and a small amount of precipitate was filtered. After evaporation of the solvent, the crude product was twice recrystallized from ethanol to give 624 mg of 5,6α-epoxy-5α-cholestan-3-one **17** (first crop) (52%); mp 120–121.5°C (lit. (38) mp 122–123°C); ir: 1720 cm⁻¹; nmr (pyridine-d_5) δ: 3.24 (d, 1H, J = 15 Hz, 4α-H), 2.87 (d, 1H, J = 4 Hz, 6β-H), 1.28 (19-H), and 0.65 (18-H) (39).[3]

The hydrogenation of this ketone **11** (100 mg) was carried out with U-Ni-A (prepared from 1 g of precipitated nickel) in cyclohexane (3 mL) at 35°C for 3 h under a pressure of 100 kg/cm². The oily material formed was chromatographed on silica gel (15 g) with hexane–ether (9:1). The first fraction gave 5,6α-epoxy-5α-cholestan-3α-ol (**19**) in a yield of 53 mg (52%); mp 120–121°C (lit. (41) mp 122–123°C); ir: 3550, 1050, 1020, 1010, and 940 cm⁻¹; nmr (pyridine-d_5) δ: 3.95 (broad, 1H, $W_{1/2}$ ca. 8 Hz, 3β-H), 2.74 (d, 1H, J = 4 Hz, 6β-H), 1.01 (19-H), and 0.61 (18.H).[3] The subsequent fractions gave a yellow oil, which was found to be a mixture of several compounds by gas chromatography.

According to the same procedure as described above, 5,6β-epoxy-5β-cholestan-3-one (**18**)[4] was obtained by the oxidation of 5,6β-epoxy-5β-cholestan-3β-ol (605 mg, 1.5 mmol). The yield of first crop was 214 mg (36%); mp 128–129°C; ir: 1720 cm⁻¹;

[3]The calculated values of chemical shifts of 19-H for 5α,6α-epoxy ketone and 5α,6α-epoxy-3α-ol by Zürcher's method (ref. 40) are 1.267 and 1.025 ppm respectively. The parameters of 18-H for 5,6-epoxides are not given in the literature.

[4]Only a limited number of papers have reported that 5,6β-epoxy-5β-cholestan-3-one is detectable in the mixture resulting from the epoxidation of 5-cholesten-3-one with *m*-chloroperbenzoic acid. The practical preparation of this compound does not appear to have been described (ref. 42).

nmr[5] (pyridine-d_5) δ: 3.03 (d, 1H, J = 15 Hz, 4β-H), 2.90 (d, 1H, J = 2.5 Hz, 6α-H), 1.08 (19-H), and 0.62 (18-H). *Anal.* calcd. for $C_{27}H_{44}O_2$: C 80.94, H 11.07; found: C 80.97, H 10.95.

The hydrogenation of β-epoxy ketone **18** (100 mg) was performed under the same conditions as in the case of the α-epoxy ketone. The crude crystalline product with mp 127–128°C was recrystallized from acetone–methanol (1:1) to give 97.6 mg of 5β-cholestane-3α,6β-diol (**20**) (ca. 97%); mp 142–143.5°C (lit. (43) mp 134–136°C); ir: 3470, 1090, 1062, 1038, 1019, and 965 cm^{-1}; nmr[6] δ: 3.70 ($W_{1/2}$ ca. 8 Hz, 6α-H), 3.50 ($W_{1/2}$ ca. 15 Hz, 3β-H), 1.11 (19-H), and 0.68 (18-H).

Acknowledgments

We are grateful to Miss Akiko Kono for the syntheses of 5,6-epoxy ketones. Thanks are also due to Miss Ritsuko Omachi for the preparation of 5α-cholestan-2-one.

Received November 8, 1979

HAROLD J. JENNINGS, KARL-GUNNAR ROSELL, and DENNIS J. CARLO. Can. J. Chem. **58**, 1069 (1980).

The structure of the *Pneumococcus* type-19 (19F) capsular polysaccharide has been reinvestigated using nmr spectroscopy. It is composed of residues of 2-acetamido-2-deoxy-D-mannose, D-glucose, L-rhamnose, and phosphate in the molar ratio of 1:1:1:1. The polysaccharide is linear and is composed of the above components in a repeating unit of the following structure: →4)-β-D-ManNAc*p*-(1→4)-α-D-Glc*p*-(1→2)-α-L-Rha*p*-(1-PO_4^-)→.

HAROLD J. JENNINGS, KARL-GUNNAR ROSELL et DENNIS J. CARLO. Can. J. Chem. **58**, 1069 (1980).

On a étudié de nouveau la structure du polysaccharide capsulaire *Pneumococcus* type 19 (19F) en utilisant la rmn. Il est composé d'unités d'acétamido-2 déoxy-2 D-mannose, de D-glucose, de L-rhamnose et de phosphate dans un rapport molaire de 1:1:1:1. Le polysaccharide est linéaire et le monomère contient les constituants mentionnés ci-dessus dans la séquence suivante: →4)-β-D-ManNAc*p*-(1→4)-α-D-Glc*p*-(1→2)-α-L-Rha*p*-(1-PO_4^-)→.

[Traduit par le journal]

Introduction

The pneumococcal polysaccharides have recently assumed importance due to their use in a multivalent vaccine against pneumococcal infections (1, 2). Because of the diversity of pneumococcal types the choice of capsular polysaccharides used in the vaccine was based on serological surveys of the most prevalent types among pneumococcal isolates (2). However most of these surveys have been carried out using typing sera which do not differentiate between cross-reacting types (3). Types 19 (19F) and 57 (19A) are in this category, being highly cross-reactive and both being implicated in pneumococcal infections (3, 4). Component analysis has revealed that type 19 (19F) contains 2-acetamido-2-deoxy-D-mannose, D-glucose, L-rhamnose, and phosphate (4, 5), whereas type 57 (19A) contains the former plus 2-acetamido-2-deoxy-D-glucose and D-galactose as additional components (4). The structural basis for this cross-reaction is of special interest for vaccine production (3) and is probably based on a structural unit involving the components common to both types. We now report the complete structural elucidation of the type 19 (19F) polysaccharide which was accomplished using ^{13}C and ^{1}H nmr spectroscopic techniques. Some preliminary structural features of this polysaccharide have been previously published (5, 6).

Experimental

Materials

Pneumococcal capsular polysaccharide type 19 (19F) was prepared from pneumococcal strains obtained from Robert Austrian and the capsular type of the strain was confirmed by quellung reactions with factor antisera from the SSI by Robert Austrian, University of Pennsylvania. The organisms were grown in a fermenter and the polysaccharides were extracted and purified as previously described (4). Alkaline phosphatase (calf intestine, 2-8 unit/mg) was obtained from Schwarz/Mann, Orangeburg, NY.

General Methods

Solutions were concentrated under reduced pressure below 50°C. Optical rotations were determined on a Perkin-Elmer 141 instrument with 10 mm semi-micro cells at 23±1°C. Gas liquid chromatography (gc) was performed on a Hewlett-Packard 5830A instrument equipped with a flame ionization detector and a model 18850A electronic integrator. The glass columns (180 × 0.15 cm) used contained the following liquid phases on 100–200 mesh gas Chromosorb Q: (*i*) 3% ECNSS-M at 190°C for alditol acetates and at 170°C for partially methylated alditol acetates, (*ii*) 3% OV-17 at 190°C for amino-sugar derivatives, (*iii*) 3% OV-1 at 230°C for permethylated oligosaccharide derivatives, and (*iv*) 1% ECNNS-M from 160–220°C at 3°C per min for alditol acetates. Combined gas liquid chromatography – mass spectrometry (gc–ms) was carried out on a Finnigan 3100D instrument using the above columns and an ionization potential of 70 eV.

The ^{13}C nmr spectra were recorded in 10 mm tubes at 37°C on a Varian CFT20 spectrometer operating at 20 MHz in the pulsed Fourier transform mode with complete proton decoupling. Chemical shifts are reported in parts per million (ppm) downfield from external tetramethylsilane and the ^{2}H resonance of deuterium oxide was used as a field-frequency lock signal. The samples were run as deuterium oxide solutions at concentrations of approximately 50 mg per mL.

The ^{1}H nmr spectra were measured at 85°C on a Varian CFT 20 spectrometer operating in the pulsed Fourier transform mode. Samples were lyophylised (×2) from 99.7% D_2O and run

in the same solvent. The apparent first-order coupling constants (Hz) were measured directly and the chemical shifts (δ) are expressed relative to internal sodium 3-trimethylsilylpropionate-2,2,3,3-d_4.

Analytical Methods

Analyses for amino sugar were performed using a Technicon Autoanalyser in which the hydrolysates were first incubated with alkaline phosphatase. Acid hydrolysis of the polysaccharide was carried out using 4 *M* HCl at 100°C, at intervals between 4 and 24 h and the total 2-amino-2-deoxy-mannose content was determined by extrapolation to zero time. Phosphorus was determined by the method of Chen *et al.* (7).

Monosaccharide Composition

The polysaccharide (5 mg) was hydrolysed with 2 *N* HCl in a sealed ampoule for 4 h at 100°C. The HCl was removed by codistillation from water and the resultant residue was divided into two equal parts. One part was deaminated (8) with water (0.6 mL), acetic acid (1.0 mL), and 5% aqueous sodium nitrite (1.0 mL) for 1 h at room temperature. During these conditions the 2-amino-2-deoxy-D-mannose was converted to D-glucose (9). The solution was passed through a Dowex 50 (H+) ion-exchange column and lyophylised. The aldoses were then converted to alditol acetates (10) and analysed by gc–ms analysis using column (*i*). The remaining part of the residue was subjected to the same procedures as above, omitting the deamination step.

Some previous glycose analyses were also performed both with and without deamination as described above except for the use of milder acidic conditions (0.25 *M* H_2SO_4 at 100°C for 16 h).

Methylation Analysis

The polysaccharide (3 mg) was methylated with methyl iodide in the presence of methyl sulfinyl anion according to the method of Hakomori (11). The methylated product was recovered by partitioning the reaction mixture between water and chloroform and the chloroform phase was concentrated to dryness. The permethylated polysaccharide was treated with 90% formic acid at 100°C for 2 h and the hydrolysate was concentrated to dryness following which the residue was further hydrolysed with 0.25 *M* H_2SO_4 at 100°C for 16 h. Following neutralisation ($BaCO_3$) and filtration, the hydrolysate was concentrated to dryness. The residual partially methylated reducing sugars were converted into partially methylated alditol acetate derivatives which were analysed by gc–ms analysis (12,13) using columns (*i*) and (*ii*). An identical procedure was used for the methylation analysis of the trisaccharide alditol except that prior to acid hydrolysis some of the permethylated trisaccharide alditol was subjected directly to gc–ms analysis using column (*iii*).

Partial Hydrolysis of the Polysaccharide

The type 19 polysaccharide (80 mg) of $[\alpha]_D$ +41° (*c*, 0.5 in water) was treated with 0.1 *M* HCl (5 mL) at 100°C for 20 min. After neutralization with 1 *M* NaOH the solution was concentrated to small volume and applied to a Sephadex G-25 column (90 × 2 cm) and eluted with water. Monitoring of the eluate using a Waters Associates differential refractometer (model R 403) and by treating portions of the eluate with phenol–H_2SO_4 (14) yielded one single phosphorylated trisaccharide component of $[\alpha]_D$ +55° (*c*, 1.0 in water) which contained 5.2% P. The phosphorylated trisaccharide was treated with $NaBH_4$ (100 mg) and the solution was left for 3 h at room temperature. The solution was then neutralized with acetic acid and the resultant phosphorylated trisaccharide alditol was purified by the application of this concentrated solution to a Sephadex G-25 column as described above. The phosphorylated trisaccharide alditol was treated with alkaline phosphatase (5 mg) in 0.1 *M* $(NH_4)_2CO_3$ (3 mL) at pH 9.0 for 5 days at 37°C. The solution was extracted with 90% aqueous phenol at room temperature and following centrifugation to promote phase separation the aqueous layer was removed. A further aqueous layer was obtained using identical procedures following an additional aqueous washing of the phenol layer using an equal volume of water. The two aqueous layers were combined, concentrated to small volume and the resultant dephosphorylated trisaccharide alditol was purified by the application of this concentrated solution to a Sephadex G-25 column as previously described. The resultant lyophylised material contained only 0.1% P.

Configuration of Glycosidic Linkages

The trisaccharide alditol (10 mg) was acetylated with pyridine – acetic anhydride (1:1) (1 mL) for 4 h at 90°C. After evaporation to dryness the product was purified on a Sephadex LH 20 column (25 × 2 cm) using chloroform–acetone (2:1) as eluant. The eluate was monitored by using chloroform–methanol (6:1) as the irrigant.

The peracetylated trisaccharide alditol was then dissolved in acetic anhydride (1 mL) and oxidized with chromic acid (100 mg) essentially by previously described methods (15,16). After 1 h at 50°C in an ultrasonic bath, water (4 mL) was added to the cooled reaction mixture and the product was recovered by chloroform extraction (3 × 5 mL). The combined chloroform extracts were then concentrated to dryness and hydrolysed with 0.5 *M* trifluoroacetic acid (1 mL) for 16 h at 100°C. The resulting sugars were converted into alditol acetates and analysed by gc–ms using column (*iv*).

Results and Discussion

Analyses of the type 19 polysaccharide demonstrated that it contained 2-acetamido-2-deoxy-D-mannose, D-glucose, L-rhamnose, and phosphate in the molar ratio of 1:1:1:1 thus indicating that it is composed of a trisaccharide repeating unit. These sugar components have been previously identified in a type 19 pneumococcal polysaccharide (5, 6), although the particular strain of the type 19 organism used in these experiments was not mentioned. Hydrolyses performed using strongly acidic conditions (2 *N* HCl) with and without deamination yielded a glucose/rhamnose molar ratio of 2:1 and 1:1 respectively, the additional glucose in the former experiment originating from the deamination of the 2-amino-2-deoxy-D-mannose residue (9). All hydrolyses using milder acidic conditions gave lower glucose contents due to the acid-stability of the amino–sugar linkage and thus indicated that 2-acetamido-2-deoxy-D-mannose was probably linked glycosidically to the glucose residue.

Methylation of the type 19 polysaccharide and subsequent hydrolysis of the permethylated product yielded equal proportions of 2,3,6-tri-*O*-methyl-D-glucopyranose and 3,4-di-*O*-methyl-L-rhamnopyranose identified as their alditol acetate derivatives by gc–ms (12). This indicated the presence of both 2-linked rhamnopyranose and 4-linked glucopyranose residues in the polysaccharide. The methylated mannosamine derivative was not detected in this analysis due to the presence of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

retained phosphate substituent. However, this derivative was detected in the methylation analysis of the reduced dephosphorylated trisaccharide originally obtained by the partial acid hydrolysis of the polysaccharide.

Methylation of the trisaccharide alditol ($NaBD_4$ reduced) and subsequent gc–ms analysis of the permethylated produce indicated a single component which gave a fragmentation pattern in its mass spectrum consistent with the structure shown in Fig. 1. The following fragments with their relative intensities (in brackets) were obtained: *m/e* 45(61), 46(18), 59(100), 71(57), 48(43), 88(64), 101(48), 103(21), 111(23), 115(38), 129(59), 134(21), 142(39), 155(21), 174(4), 196(3), 206(32), 228(18), 260(3). The sequence of the sugars in the reduced trisaccharide was divulged by the masses 206 and 260 which are indicative of the rhamnopyranose and 2-acetamido-2-deoxy-D-mannopyranose being situated at the reducing and non-reducing end respectively of the original trisaccharide repeating unit of the polysaccharide. This structure was also confirmed by hydrolysis of the permethylated trisaccharide alditol which yielded 1,3,4,5-tetra-*O*-methyl-L-rhamnitol, 2,3,6-tri-*O*-methyl-D-glucose, and 2-deoxy-3,4,6-tri-*O*-methyl-2-(*N*-methylacetamido)-D-mannopyranose. The mode of linkage of the phosphate diester to the trisaccharide repeating unit and the configuration of the other linkages was determined by ^{13}C and ^{1}H nmr spectroscopy.

The ^{13}C nmr spectrum of the type 19 polysaccharide is shown in Fig. 2 and indicates that it is composed of a trisaccharide phosphate repeating unit depicted in Fig. 2. Some of the assigned chemical shifts for the polysaccharide and the reduced trisaccharide repeating units are listed in Table 1, together with $^{13}C—^{31}P$ coupling constants. The three anomeric signals of the polysaccharide at 95.1, 98.9, and 100.6 ppm were assigned to C-1″,

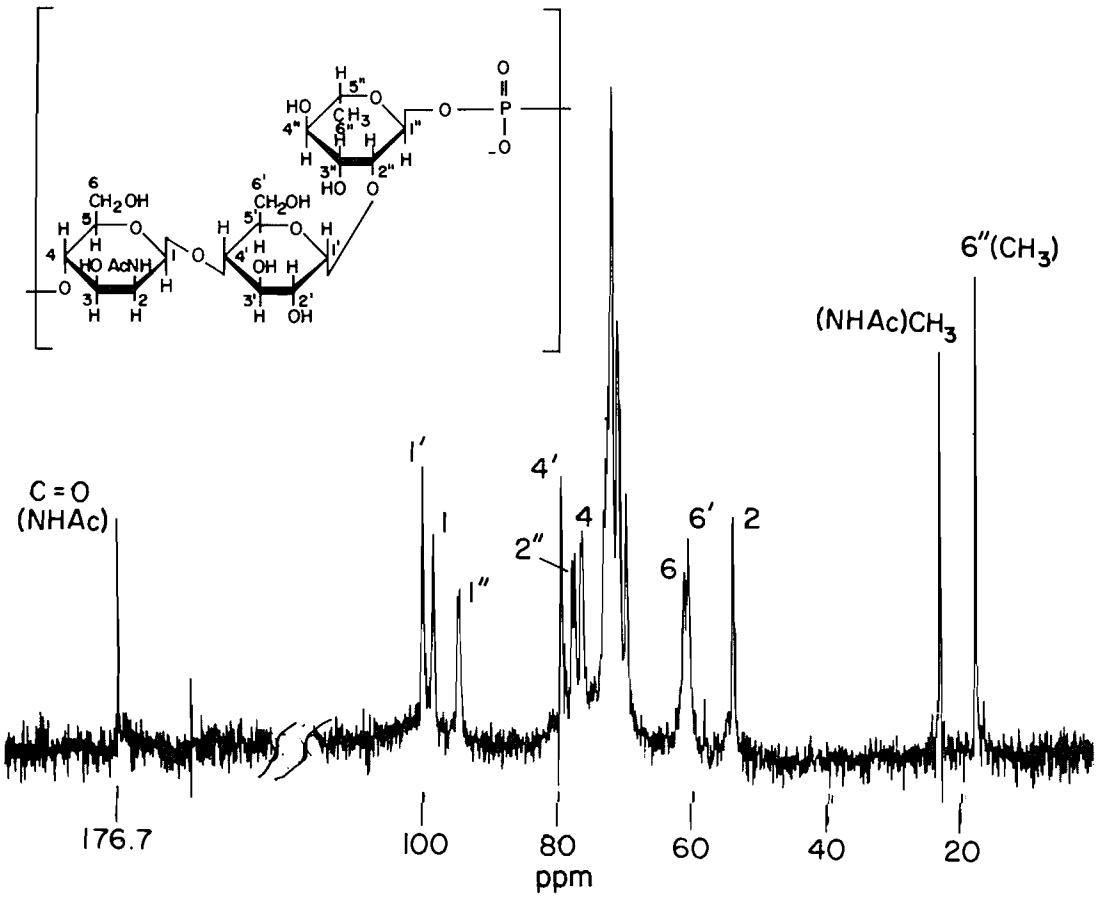

FIG. 2. Fourier-transformed ^{13}C nmr spectrum of the native type 19 pneumococcal polysaccharide taken with an aquisition time of 0.5 s and spectral width of 4 kHz. The number of free induction decays was 114 000. Inset: The repeating unit of the type 19 polysaccharide.

C-1, and C-1′ respectively on the following evidence. Because of $^{13}C—^{31}P$ coupling the signal at 95.1 ppm was assigned to C-1″ ($^2J_{C\text{-}1'',P} = 5.6$ Hz) of the rhamnopyranose residue and confirmation of this assignment was obtained when this C-1″ signal was changed from a doublet to an uncoupled singlet at 61.0 ppm in the ^{13}C nmr spectrum of the trisaccharide with the reduced rhamnopyranose endgroup. On the basis of the previous assignments (17) the signal at 100.6 ppm was assigned to C-1′ of the α-D-glucopyranose residue and by difference the remaining anomeric signal at 98.9 ppm could be assigned to C-1 of the 2-acetamido-2-deoxy-D-mannopyranose residue.

That the phosphate diester was linked to C-4 of the 2-acetamido-2-deoxy-D-mannopyranose residue could be deduced from the ^{13}C nmr spectrum of the polysaccharide. The presence of two exocyclic hydroxymethyl signals at 61.6 and 61.0 ppm indicated that C-6 is unsubstituted (18) and the fact that in comparison with monomer models (19) C-2 is not significantly shielded and is not involved in $^3J_{C\text{-}2,P}$ coupling eliminates the possibility of a 3-linkage. Of the two $^{13}C—^{31}P$ coupled signals in the linkage region of the ^{13}C nmr spectrum of the polysaccharide (Fig. 2) at 78.1 and 76.8 ppm, the former was assigned to C-2″ of the rhamnopyranose residue ($^3J_{C\text{-}2'',P} = 8.7$ Hz) because this doublet was shifted to an uncoupled singlet at 79.0 ppm in the ^{13}C nmr spectrum of the phosphorylated reduced trisaccharide (Table 1). In contrast the coupled signal at 76.8 ppm remained virtually unchanged in both the above ^{13}C nmr spectra and therefore it could be attributed to a $^{13}C—^{31}P$ coupled signal of one of the carbons of the 2-acetamido-2-deoxy-D-mannopyranose residue. Although this latter residue is known to be linked at C-4 it was deduced that the low-field signal at 76.8 ppm could not be attributed to C-4 but could be assigned to the unlinked C-5 of the same residue. This was because this signal which had remained virtually unchanged in the ^{13}C nmr spectra of both

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

polysaccharide and the phosphorylated reduced trisaccharide became an uncoupled singlet which had undergone a characteristic small downfield shift (1.1 ppm) in the ^{13}C nmr spectrum of the dephosphorylated reduced trisaccharide (Table 1). Had this signal been associated with the linkage carbon (C-4) one would have expected a substantial upfield shift (approximately 4 ppm) in this carbon on dephosphorylation based on chemical shift differences between the related 2-acetamido-2-deoxy-D-glucopyranose (19) and its 4-phosphate derivative (20). That this signal at 77.9 ppm in the ^{13}C nmr spectrum of the dephosphorylated reduced trisaccharide is due to C-5 of the non-reducing terminal 2-acetamido-2-deoxy-mannopyranose residue is only consistent with this residue being in the β-D-configuration because it has been established using monomer models (19) that C-5 of this residue in the α-D-configuration would be more shielded and thus would occur at a higher field position (73.2 ppm) in the ^{13}C nmr spectrum. The assignment of the β-D-configuration to the 2-acetamido-2-deoxy-mannopyranose residue is also consistent with the results of chromic acid oxidation of the peracetylated dephosphorylated reduced trisaccharide where the above residue was destroyed leaving only the glucose and rhamnitol residues in a 1:1 ratio as determined by gc analysis. It has been previously demonstrated that pyranose sugars in which the aglycone is in an equatorial position (β-D-configuration) are readily oxidized while those in an axial position (α-D-configuration) are not (16). This result also confirmed the assignment of the α-D-configuration to the glucopyranose residue. Yadomae *et al.* (6) using ^{13}C nmr spectroscopy have also recently established the β-D-configuration of the non-reducing terminal 2-acetamido-2-deoxy-mannopyranose residue of a disaccharide obtained from the type 19 polysaccharide. The remaining uncoupled signal in the linkage region of the ^{13}C nmr spectrum of the type 19 polysaccharide at 79.9 ppm could be assigned to C-4′ of the α-D-glucopyranose residue which is consistent with previous assignments on other 4-linked α-D-glucopyranose residues (17). In addition, because this residue is the middle residue of the trisaccharides obtained from the type 19 polysaccharide, the uncoupled signal at 79.9 ppm remains virtually unchanged in the ^{13}C nmr spectra of the polysaccharide and both the phosphorylated and dephosphorylated reduced trisaccharides (Table 1).

The remaining assignment of the anomeric configuration of the L-rhamnopyranose residues of the type 19 polysaccharide could not be deduced from chemical shift data because of the lack of sensitivity of the anomeric signals of glycopyranoses in the *manno*-configuration (21, 22). That these rhamnopyranose residues were in the α-L-configuration was indicated by an increase in specific rotation when the polysaccharide of $[\alpha]_D$ +41° was hydrolysed to the phosphorylated trisaccharide of $[\alpha]_D$ +55°. Such a positive increase is due to the newly formed β-L-rhamnopyranose residues in the resultant equilibrium mixture of trisaccharides with reducing rhamnose residues (23). Also the ^1H nmr spectrum of the polysaccharide gave an anomeric signal (doublet of doublets) at δ5.68 ($J_{H\text{-}1'',H\text{-}2''}$ = 1.3 Hz) which could be assigned to the L-rhamnopyranose residue due to the presence of 3-bond $^1H—^{31}P$ coupling ($^3J_{H\text{-}1'',P}$ = 6.7 Hz). Due to their relative insensitivity to changes in anomeric configuration these coupling constants were unsatisfactory for assigning the anomeric configuration of glycopyranoses in the *manno*-configuration (24). However on the basis of studies on mannopyranosyl phosphates (24) the low-field position (δ 5.68) of the doublet of doublets is indicative of the rhamnopyranose residue having the α-L-configuration. The ^1H nmr spectrum of the polysaccharide also has two other anomeric doublets at δ 5.18 ($J_{H\text{-}1',H\text{-}2'}$ = 3.8 Hz) and δ 5.04 ($J_{H\text{-}1,H\text{-}2}$ = 1.6 Hz), the coupling constants of which are consistent with those expected for α-D-glucopyranose and 2-acetamido-2-deoxy-β-D-mannopyranose residues respectively. Thus the type 19 polysaccharide is composed of the repeating unit depicted in Fig. 2. This structure is identical to one recently proposed for the pneumococcal type 19 polysaccharide in an independent study.[3]

Reactions of cyclopropylcarbinol in dilute hydrochloric acid

CHOI CHUCK LEE AND ALLAN J. CESSNA

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received December 5, 1979

CHOI CHUCK LEE and ALLAN J. CESSNA. Can. J. Chem. **58**, 1075 (1980).

The treatment of cyclopropylcarbinol (**1**-OH) with dilute HCl has been used as a method for the preparation of cyclobutanol (**2**-OH). While **2**-OH is the major product in this reaction, a careful investigation showed the presence of a total of 13 products, namely, the alcohols **1**-OH, **2**-OH, and allylcarbinol (**3**-OH), cyclopropylcarbinyl, cyclobutyl and allylcarbinyl chlorides (**1**-Cl, **2**-Cl and **3**-Cl, respectively), dicyclopropylcarbinyl, cyclobutyl cyclopropylcarbinyl, allylcarbinyl cyclopropylcarbinyl, dicyclobutyl and allylcarbinyl cyclobutyl ethers (**1**-O-**1**, **2**-O-**1**, **3**-O-**1**, **2**-O-**2**, and **3**-O-**2**, respectively), as well as butyraldehyde and isobutyraldehyde. The alcohols, chlorides, and ethers likely arose from reactions of the bicyclobutonium ion with available nucleophiles in the reaction mixture. The minor amounts of the two aldehydes may be due to a ring opening isomerization of 2-methylcyclopropanol, the latter in turn resulted from a net 1,3-hydride shift in the cyclopropylcarbinyl cation, probably via an edge-protonated cyclopropane-type of species. Treatment of [α-^{14}C]cyclopropylcarbinol (**1**-OH-α-^{14}C) with dilute HCl gave samples of **1**-OH-*x*-^{14}C,**2**-OH-*x*-^{14}C, and **3**-OH-*x*-^{14}C the degradation of which showed that all three methylene groups in these alcohols have become equivalent, indicating a complete equilibration between isotope-position labeled bicyclobutonium ions.

CHOI CHUCK LEE et ALLAN J. CESSNA. Can. J. Chem. **58**, 1075 (1980).

On a utilisé l'action de l'acide chlorhydrique dilué sur le cyclopropylcarbinol (OH-**1**) comme méthode de préparation du cyclobutanol (OH-**2**). Bien que l'alcool OH-**2** soit le produit majoritaire, une étude soignée indique la présence de 13 produits qui sont les alcools OH-**1**, OH-**2** et l'allylcarbinol (OH-**3**), les chlorures de cyclopropylcarbinyle, de cyclobutyle et d'allylcarbinyle (respectivement Cl-**1**, Cl-**2** et Cl-**3**), les éthers de dicyclopropylcarbinyle, de cyclobutyle et de cyclopropylcarbinyle, d'allylcarbinyle et de cyclopropylcarbinyl, de dicyclobutyle et finalement d'allylcarbinyle et de cyclobutyle (respectivement **1**-O-**1**, **2**-O-**1**, **3**-O-**1**, **2**-O-**2** et **3**-O-**2**) ainsi que le butyraldéhyde et l'isobutyraldéhyde. Les alcools, les chlorures et les éthers proviennent de la réaction entre l'ion bicyclobutonium avec les agents nucléophiles disponibles dans le mélange réactionnel. Les faibles quantités d'aldéhydes obtenues peuvent être dues à une isomérisation du produit résultant de l'ouverture du cycle du méthyl-2 cyclopropanol; ce dernier à son tour provient d'une transposition-1,3 d'hydrure dans le cation cyclopropylcarbinyle probablement par l'intermédiaire d'espèces du type cyclopropane protoné à la périphérie. L'action du HCl dilué sur le cyclopropylcarbinol[α ^{14}C] (OH-**1** α ^{14}C) donne des échantillons de OH-**1**-*x* ^{14}C, OH-**2**-*x* ^{14}C et OH-**3**-*x* ^{14}C); leur dégradation révèle que les trois groupes méthylènes de ces alcools deviennent équivalents et qu'il en résulte un équilibre complet entre les ions cyclobutonium margués par des isotopes dans certaines positions.

[Traduit par le journal]

It has been known since 1960 that the treatment of cyclopropylcarbinol (**1**-OH) with dilute HCl is a good method for the preparation of cyclobutanol (**2**-OH) (1). In our recent study on exchange reactions between cyclobutane and tritiated trifluoromethanesulfonic acid (2), we have used this method to prepare **2**-OH as a carrier to aid the identification of products after the mixture from the exchange reaction was quenched with H_2O. In the purification of **2**-OH prepared from **1**-OH (1), it was noted from vpc analysis that while **2**-OH was the main product, many other products were also present and this led us to undertake a further investigation of the reaction.

Roberts and co-workers (1) treated **1**-OH with about 1 *N* HCl to give a 72% yield of product which analyzed by vpc as 97% **2**-OH and 3% allylcarbinol (**3**-OH). In the present study, preliminary experiments were carried out to test the effect of HCl concentration on the relative compositions of **1**-OH, **2**-OH, and **3**-OH and the results are summarized in Table 1. In the subsequent work, either 1.4 or 2.0 *N* HCl was utilized.

Figure 1 shows the chromatogram from the vpc analysis of the products after **1**-OH was treated with 2.0 *N* HCl at 85°C for 1.5 h (Expt. 1). The identities of the various components and their relative yields for Expt. 1 and similar data from other experiments are given in Table 2. The identification of the various products was carried out by fractionation into broad fractions each containing several components and the individual compounds in each of these fractions were identified by nmr

TABLE 1. Relative amounts of cyclopropylcarbinol (**1**-OH), cyclobutanol (**2**-OH), and allylcarbinol (**3**-OH) from vpc analysis after treatment of **1**-OH with HCl at 85°C for 1.5 h

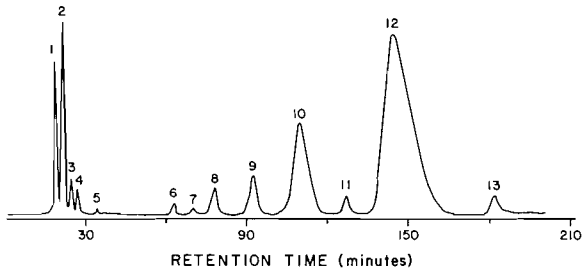

FIG. 1. Vapor phase chromatogram of products from the treatment of cyclopropylcarbinol (**1**-OH) with 2.0 *N* HCl at 85°C for 1.5 h.

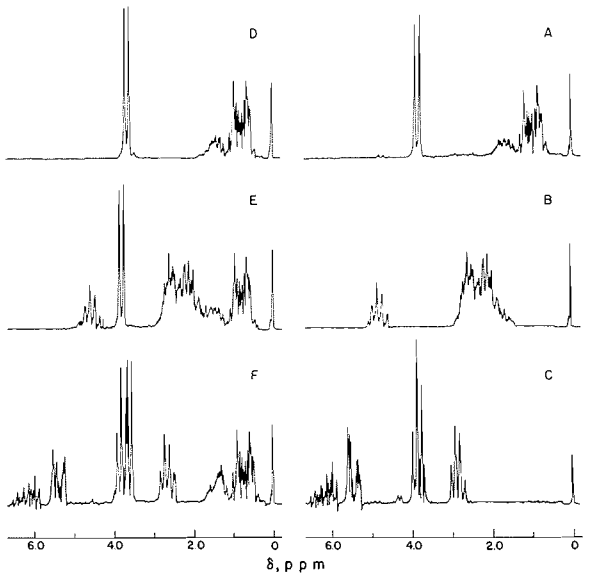
and by peak reenforcement with authentic samples. The authentic samples prepared for this purpose, besides **1**-OH, **2**-OH, and **3**-OH, were the cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl chlorides (**1**-Cl, **2**-Cl and **3**-Cl, respectively), dicyclopropylcarbinyl ether (**1**-O-**1**), cyclobutyl cyclopropylcarbinyl ether (**2**-O-**1**), and allylcarbinyl cyclopropylcarbinyl ether (**3**-O-**1**). Figure 2 gives the nmr spectra of these chlorides and ethers, showing the very characteristic absorptions of the cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl groups.

The facile interconversion between cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl cations was first reported by Roberts and Mazur (3), and these interconversions presumably proceed via the bicyclobutonium ion **4** (4). The early literature



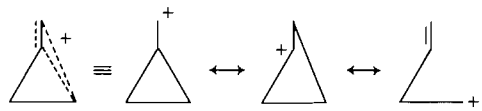


FIG. 2. ^{1}H nmr spectra, A, B, C, D, E, F, are, respectively, the spectra of cyclopropylcarbinyl chloride (**1**-Cl), cyclobutyl chloride (**2**-Cl), allylcarbinyl chloride (**3**-Cl), dicyclopropylcarbinyl ether (**1**-O-**1**), cyclobutyl cyclopropylcarbinyl ether (**2**-O-**1**), allylcarbinyl cyclopropylcarbinyl ether (**3**-O-**1**).

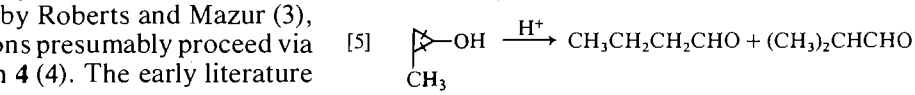
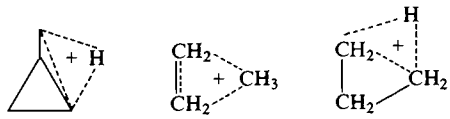
4

on these systems has been reviewed (5), and recent studies with low temperature ^{13}C nmr have been reported by Olah, Roberts, and their co-workers (6, 7). Most of the products given in Table 2 may be readily accounted for by reactions of **4** with available nucleophiles during the treatment of **1**-OH with dilute HCl.



[1] $\mathbf{4} + Cl^- \longrightarrow \mathbf{1}\text{-Cl} + \mathbf{2}\text{-Cl} + \mathbf{3}\text{-Cl}$

[2] $\mathbf{4} + H_2O \xrightarrow{(-H^+)} \mathbf{1}\text{-OH} + \mathbf{2}\text{-OH} + \mathbf{3}\text{-OH}$



[3] $\mathbf{4} + \mathbf{1}\text{-OH} \xrightarrow{(-H^+)} \mathbf{1}\text{-O-}\mathbf{1} + \mathbf{2}\text{-O-}\mathbf{1} + \mathbf{3}\text{-O-}\mathbf{1}$

[4] $\mathbf{4} + \mathbf{2}\text{-OH} \xrightarrow{(-H^+)} \mathbf{2}\text{-O-}\mathbf{1} + \mathbf{2}\text{-O-}\mathbf{2} + \mathbf{3}\text{-O-}\mathbf{2}$

Of interest is the origin of the two other minor products, butyraldehyde and isobutyraldehyde. Since cyclopropanol is known to isomerize to propionaldehyde under hydrolytic conditions (8, 9), it is likely that these two 4-carbon aldehydes arose from acid catalyzed isomerization of 2-methylcyclopropanol (eq. [5]). This conclusion is

[5] 

supported by the observation that when an attempt was made to prepare 2-methylcyclopropanol from the treatment of 2-methylcyclopropylmagnesium bromide with O_2 followed by decomposition of the resulting complex with 2% H_2SO_4, the major products were butyraldehyde and isobutyraldehyde. The formation of 2-methylcyclopropanol would involve an overall 1,3-hydride shift in the cyclopropylcarbinyl cation. Thus it may be speculated that this suggests a possible minor involvement of edge-protonated cyclopropane **5**, and in this context **4** and **5** may be regarded as analogous to corner- and edge-protonated cyclopropanes **6** and **7**, respectively (10).

5 **6** **7**

Using isotopic labeling, various degrees of equivalence among the three methylene groups in the cyclopropylcarbinyl, cyclobutyl, and allylcarbinyl products have been observed (1, 4, 5), and these findings have been attributed to equilibra-

tions between bicyclobutonium ions as illustrated in Scheme 1 (5). In the treatment of [α-$^2H_2$]cyclopropylcarbinol (**1**-OH-α-d_2) with dilute HCl (1), it was inferred from the nmr spectrum of the cyclobutanone obtained from oxidation of the **2**-OH-d_2 product that the D-labeled methylene group was statistically distributed among the C-2, -3, -4 positions of the cyclobutanol.

In an attempt to verify the nmr results observed by Roberts and co-workers, isotopic scrambling studies using the ^{14}C-tracer technique were carried out. After [α-^{14}C]cyclopropylcarbinol (**1**-OH-α-^{14}C) was treated with 1.4 *N* HCl at 85°C for 1.5 h (conditions used in Expt. 2, Table 2), degradation by known methods (see Experimental) of the recovered **1**-OH-*x*-^{14}C, **2**-OH-*x*-^{14}C, and **3**-OH-*x*-^{14}C gave the data summarized in Table 3. These results, showing $\frac{1}{3}$ of the ^{14}C-activity on each of the three methylene groups, unequivocally demonstrated the equivalence of these methylene groups

SCHEME 1

in all three alcoholic products, thus confirming the earlier observation of Roberts and co-workers and indicating that complete equilibration as shown in Scheme 1 had taken place.

Experimental

Treatment of 1-OH with Dilute HCl

As an illustration of the experimental procedure, Expt. 1 (Table 2) is described below.

A mixture of 15.0 g (0.21 mol) of **1**-OH and 85 mL of 2.0 *N* HCl was heated at 85°C for 1.5 h. The material was then neutralized with 2.0 *N* KOH and then continuously extracted with ether for 24 h. The extract was dried over $MgSO_4$ and the ether was removed to give a residue which on vpc analysis (25 ft, $\frac{1}{8}$-inch copper column packed with 25% β,β′-oxidipropionitrile on 60/80 mesh Chromosorb P-AW) gave the chromatogram shown in Fig. 1. Subsequently, the residue was fractionated to give 2.6 g of fraction 1, bp 72–88°C, containing peaks 1 to 5 (chlorides and aldehydes), 9.8 g of fraction 2, bp 118–128°C, containing peaks 10, 12, and 13 (alcohols), and 1.8 g of fraction 3, bp 140–148°C, containing peaks 6–9 and 11 (ethers). The presence of various components in each of the three fractions was indicated by their nmr spectra and individual components were identified by peak reenforcement with authentic samples on vpc analysis. In fraction 3, peaks 7, 9, and 11, respectively, were identified as the ethers **3**-O-**1**, **2**-O-**1** and **1**-O-**1**. Since authentic samples of other possible ethers were not prepared, tentative assignments for peaks 6 and 8 were based on nmr and vpc considerations. Integration of the nmr spectrum of fraction 3 showed the presence of relatively more cyclobutyl group than was suggested by the vpc peak area of **2**-O-**1** relative to that of **1**-O-**1**. Hence the other ethers present likely contained the cyclobutyl group, and peaks 6 and 8 were assigned to **3**-O-**2** and **2**-O-**2**, respectively.

Preparation of Authentic Compounds

The alcohols, **1**-OH, **2**-OH, and **3**-OH, were prepared by previously reported methods of Roberts and co-workers, **1**-OH from the $LiAlH_4$ reduction of cyclopropanecarboxylic acid (3), **2**-OH from the vpc purified major fraction in the present work (1), and **3**-OH from $LiAlH_4$ reduction of vinylacetic acid (11). The nmr spectra of these alcohols are essentially the same as those reported by Servis and Roberts (11).

Previous preparations of **1**-Cl, such as those from the chlorination of methylcyclopropane (3) and from the reaction of **1**-OH with $SOCl_2$ (1), generally gave various mixtures of **1**-Cl, **2**-Cl, and **3**-Cl. Pure **1**-Cl was prepared in the present work by the treatment of **1**-OH in CCl_4 with triphenylphosphine (12, 13).

Triphenylphosphine (14.7 g, 56 mmol) was added in one batch to a stirred solution of 4.0 g (56 mmol) of **1**-OH in 25 ml of CCl_4. The mixture was refluxed for 2 h, cooled, and 50 mL of ether was added. After filtration and thorough washing of the solid material with more ether, the filtrate was washed with H_2O, dried over $MgSO_4$, and then fractionally distilled to give 2.5 g (51%) of product, bp 79–83°C. Vapor phase chromatographic analysis using a 10 ft, $\frac{1}{8}$-inch stainless steel column packed with 25% FFAP on Chromosorb P showed the presence of about 5% CCl_4 as impurity. After purification by preparative vpc, the **1**-Cl obtained, bp 83°C, gave the nmr spectrum shown in Fig. 2A.

In a similar way, **2**-Cl was prepared from **2**-OH, triphenylphosphine, and CCl_4 in 32% yield, bp 81–82°C (lit. (3) bp 82–83°C). Using the method described by Roberts and Mazur (3), **3**-Cl was prepared from the reaction of **3**-OH with $SOCl_2$ in the presence of pyridine; it boiled at 75°C (lit. (3) bp 73–74°C). The nmr spectra of **2**-Cl and **3**-Cl are shown in Fig. 2, B and C.

The ethers, **1**-O-**1**, **2**-O-**1**, and **3**-O-**1**, were prepared by the reaction of the appropriate alkoxide with cyclopropylcarbinyl bromide (**1**-Br), the latter being prepared from the treatment of **1**-OH with triphenylphosphine in CBr_4 (12, 13) as in the analogous preparation of **1**-Cl.

Sodium cyclopropylmethoxide was prepared by the portionwise addition of 1.84 g (80 mmol) of Na to a stirred solution of 5.0 g (70 mmol) of **1**-OH in 100 mL of anhydrous ether. After stirring for an hour, the alkoxide solution was decanted into a flask containing 9.4 g (70 mmol) of **1**-Br and fitted with a reflux condenser and a drying tube. The mixture was heated under reflux for 5 h. At this point, vpc analysis of the reaction mixture showed the presence of a substantial amount of unreacted **1**-Br. In order to raise the reaction temperature, 50 mL of dry acetone was introduced, most of the diethyl ether was removed by fractional distillation, and the remaining material was refluxed for a further 5 h when vpc analysis showed that essentially all of the **1**-Br had disappeared. The reaction mixture was then diluted with 50 mL of ether and filtered. The filtrate was washed with H_2O, dried over $MgSO_4$, and fractionated to give 4.1 g of crude product which contained about 5% **1**-OH and about 15% mesityl oxide as impurities. After purification by preparative vpc, the desired product, **1**-O-**1**, bp 148–149°C, gave the nmr spectrum shown in Fig. 2D.

In the preparation of **2**-O-**1** and **3**-O-**1**, the reaction of sodium cyclobutoxide or sodium allylmethoxide with **1**-Br was again utilized. Both reactions were carried out at about the same time and in both cases acetone rather than ether was directly used as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

the initial solvent. After work-up as described in the preparation of **1**-O-**1**, it was found that the major product was mesityl oxide, derived from the condensation of acetone. Sufficient amounts of the desired products, **2**-O-**1** and **3**-O-**1**, however, were recovered from preparative vpc for subsequent peak reenforcement studies. Their nmr spectra are given in Fig. 2, E and F.

Attempted Synthesis of 2-Methylcyclopropanol (8)

By analogy with the synthesis of cyclopropanol from the reaction of the Grignard reagent with O_2 (14), an attempt was made to prepare **8** from the reaction of 2-methylcyclopropylmagnesium bromide with O_2. 2-Methylcyclopropyl bromide (8.2 g, 61 mmol), prepared as described by Kirmse and Wedel (15), was converted to the Grignard reagent in about 150 mL of anhydride ether. O_2 was then bubbled through the reaction mixture until precipitation of the white solid complex had apparently ceased. A 2% H_2SO_4 solution (75 mL) was added and the mixture was stirred overnight. Upon work-up, the major products as shown by vpc were butyraldehyde and isobutyraldehyde, presumably derived from ring opening isomerization of **8**. Unreacted 2-methylcyclopropyl bromide and some minor components were also present, but no attempt was made to identify the minor compounds.

Experiments with [α-^{14}C]cyclopropylcarbinol (1-OH-α-^{14}C)

The **1**-OH-α-^{14}C was prepared as previously described (4). To 40 mL of 1.4 *N* HCl was added 0.98 g (14 mmol) of **1**-OH-α-^{14}C and the mixture was heated at 85°C for 1.5 h. The resulting material was neutralized with dilute KOH and about 1.0 g each of ordinary **1**-OH, **2**-OH, and **3**-OH were added as carriers. After continuous extraction with ether and work-up as described earlier, the three alcohols, **1**-OH-*x*-^{14}C, **2**-OH-*x*-^{14}C, and **3**-OH-*x*-^{14}C, were recovered by preparative vpc and then degraded to give the isotopic scramblings recorded in Table 3.

The degradation of **1**-OH-*x*-^{14}C and **2**-OH-*x*^{14}C (4) were carried out via $KMnO_4$ oxidation to cyclopropanecarboxylic acid and succinic acid, respectively. Schmidt reactions on these two acids gave, respectively, cyclopropylamine and ethylenediamine which were converted to the corresponding benzamide and dibenzamide for activity determination. The procedures for these degradative reactions have been described previously (4).

Cleavage of the double bond in **3**-OH-*x*-^{14}C to give HCHO, recovered as the dimedon derivative, was effected by oxidation with performic acid followed by treatment with periodate, using the procedures previously described for similar reactions with allylcarbinyl chloride (4). The **3**-OH-*x*-^{14}C was also hydrogenated to give 1-butanol which was in turn oxidized to butyric acid and then degraded to propylamine, again using previously reported procedures (16, 17).

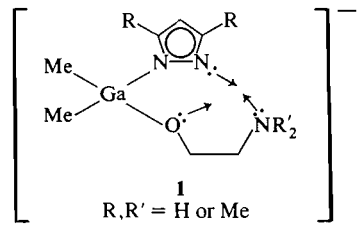
KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **58**, 1080 (1980).

Details of the synthesis and physical properties of novel molybdenum and tungsten carbonyl compounds containing the bidentate chelating thiomethoxymethyl group and tridentate chelating gallate ligands are described. Crystals of $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ are triclinic, $a = 8.144(1)$, $b = 9.150(1)$, $c = 13.731(1)$ Å, $\alpha = 96.155(6)$, $\beta = 98.83(1)$, $\gamma = 108.73(1)°$, $Z = 2$, space group $P\bar{1}$ and crystals of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ are monoclinic, $a = 8.1754(7)$, $b = 15.074(1)$, $c = 16.708(1)$ Å, $\beta = 94.365(6)°$, $Z = 4$, space group $P2_1/c$. The structures were solved by Patterson and Fourier syntheses and were refined by full-matrix least-squares procedures to final R values of 0.021 and 0.033 for 3679 and 4362 reflections with $I \geq 3\sigma(I)$ respectively. The Mo atoms in both structures are best described as heptacoordinate with bidentate η^2-CH_2SMe ligands. Important bond lengths (corrected for libration) are: Mo—S, 2.4750(6), Mo—C(S), 2.202(3), Mo—O, 2.248(2), Mo—N(pyrazolyl), 2.192(2), Mo—N(amino), 2.394(2), Mo—C(O), 1.903(3) and 1.957(3), Ga—O, 1.912(2), Ga—N, 2.020(2), and Ga—C, 1.962(4) and 1.969(4) Å for $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$; corresponding distances for $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ are 2.4906(8), 2.211(3), 2.263(2), 2.205(2), 2.403(3), 1.906(3), 1.958(3), 1.918(2), 2.014(3), 1.963(4), and 1.966(4) Å.



KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **58**, 1080 (1980).

On décrit la synthèse et les propriétés physiques des nouveaux composés carbonylés du molybdène et du tungstène contenant le groupe thiométhoxyméthyle comme agent chélatant bidentate et des ligands gallate chélatés de façon tridentate. Les cristaux de $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ sont triclinques $a = 8.144(1)$, $b = 9.150(1)$, $c = 13.731(1)$ Å, $\alpha = 96.155(6)$, $\beta = 98.83(1)$, $\gamma = 108.73(1)°$, $Z = 2$, groupe d'espace $P\bar{1}$ et les cristaux de $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ sont monocliniques $a = 8.1754(7)$, $b = 15.074(1)$, $c = 16.708(1)$ Å, $\beta = 94.365(6)°$, $Z = 4$, groupe d'espace $P2_1/c$. On a résolu les structures par les synthèses de Patterson et de Fourier et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs respectives R de 0.021 et de 0.033 pour 3679 et 4362 réflexions avec $I \geq 3\sigma(I)$. Les atomes de molybdène dans les deux structures sont heptacoordonnés avec les ligands bidentates η^2-CH_2SMe. Les longueurs importantes de liaisons (corrigées pour la libration) sont: Mo—S, 2.4750(6), Mo—C(S), 2.202(3), Mo—O, 2.248(2), Mo—N(pyrazolyl), 2.192(2), Mo—N(amino), 2.394(2), Mo—C(O), 1.903(3) et 1.957(3), Ga—O, 1.912(2), Ga—N, 2.020(2) et Ga—C, 1.962(4) et 1.969(4) Å pour $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$; les distances correspondantes pour $[MeGa(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ sont 2.4906(8), 2.211(3), 2.263(2), 2.205(2), 2.403(3), 1.906(3), 1.958(3), 1.918(2), 2.014(3), 1.963(4) et 1.966(4) Å.

[Traduit par le journal]

Introduction

Recently sulfur ligand transition metal complexes have attracted considerable attention (1–4). Those of molybdenum have merited special interest since there is evidence that redox reactions which are catalyzed by molybdoenzymes occur at sites where the molybdenum is coordinated by one or more sulfur atoms (5). Our continuing investigations into the coordinating properties of organogallate ligands of the type **1** (6–9), has resulted in a series of carbonyl complexes of molybdenum and tungsten containing both the ligand **1** and the organosulfur ligand "CH_2SMe". The complexes have been probed to determine the nature of the sulfur–metal bonding and definitive structural parameters, resulting from crystal structure determinations, are presented for the complexes $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$.

sodium hydride (Alfa Inorganic) were used as supplied. Ethanolamine and *N,N*-dimethylethanolamine were refluxed over anhydrous $CaSO_4$ and distilled prior to use. Thiomethoxymethyl chloride was prepared using a literature method (10) and gallium trimethyl was prepared as previously described (11). Molybdenum and tungsten hexacarbonyls were used as supplied (Strem) and $(MeCN)_3M(CO)_3$ (M = Mo or W) were prepared by a literature method (12).

Preparations

The ligands **1** were prepared as sodium salts in THF solution by the method already described (6–8). The tricarbonyl anions, $LM(CO)_3^-$ (M = Mo or W), incorporating these ligands were prepared, again as sodium salts in THF solution, by adding a THF solution of the ligand salt, NaL, to an equimolar amount of $(MeCN)_3M(CO)_3$ and refluxing for about 1 h. After cooling to −78°C a THF solution of $ClCH_2SMe$ was added dropwise with stirring to the air-sensitive yellow solution of the anion. The mixture was warmed to room temperature and the solvent removed under vacuum. The brown residue was extracted with benzene and the mixture filtered. Evaporation of the filtrate left an oily solid which was washed with methanol to produce a yellow powder. Recrystallization from benzene gave bright yellow crystals of the product. Yields of purified crystals were 15–25%. Analytical data, selected ir frequencies, and ^1H nmr data for the eight compounds are collected in Table 1. The compound $MeGa(N_2C_3H_3)_3Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ was prepared similarly from the ligand $Na^+MeGa(N_2C_3H_3)_3^-$ (13). *Anal.* calcd.: C 33.7, N 16.8, H 3.4; found: C 33.9, N 16.6, H 3.4. ν_{CO}: 1942, 1805 (CH_2Cl_2); 1924, 1776 (Nujol); 1955, 1948, 1835, 1822 (cyclohexane). ^1H nmr (C_6D_6): τ 9.99 s (GaMe); 8.61 s (SMe); 6.77 d, 6.07 d, relative intensity 1:1 (CH_2—S); 4.11, 4.01 relative intensity 1:2 (^4H); 2.97, 2.84 relative intensity 1:2 (^5H); 2.29, 2.10, 1.71 relative intensity 1:1:1 (^3H). Mass spectrum: parent ion (22%); P − CO (16%); P − 2CO (100%).

Spectra

Mass spectra were recorded on a Varian MAT CH4 mass spectrometer at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer and ^1H nmr spectra on a Varian XL-100 spectrometer using FT techniques.

X-ray Crystallographic Analyses

*[Dimethyl(*N,N*-dimethylethanolamino)(1-pyrazolyl)gallato-(*N(2),O,N(3)*)](*η²*-thiomethoxymethyl)dicarbonylmolybdenum*

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.425 × 0.138 × 0.226 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Mo K_α radiation (λ = 0.71073 Å). Crystal data (at 22°C) are:

$C_{13}H_{24}GaMoN_3O_3S$ fw = 468.08

Triclinic, a = 8.144(1), b = 9.150(1), c = 13.731(1) Å, α = 96.155(6), β = 98.83(1), γ = 108.73(1)°, V = 944.0(3) Å^3, Z = 2, ρ_c = 1.647 g cm^{-3}, $F(000)$ = 472, μ(Mo K_α) = 22.7 cm^{-1}. Absent reflections: none. Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

Intensities were measured with graphite monochromatized Mo K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω scan at 0.91–6.71° min^{-1} over a range of (0.55 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 2%. After data reduction, an absorption correction was applied using the Gaussian integration method (14, 15). Transmission factors ranged from 0.566 to 0.758. Of the 4315 independent reflections measured, 3679 (85%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The positions of the Mo, Ga, and S atoms were determined from the three-dimensional Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. After full-matrix least-squares refinement of all non-hydrogen atoms with anisotropic thermal parameters to R = 0.034, a difference map gave the positions of all 24 hydrogen atoms which were included in subsequent cycles of refinement with isotropic thermal parameters. The scattering factors of ref. 16 were used for non-hydrogen atoms and those of ref. 17 for hydrogen atoms. Anomalous scattering factors from ref. 18 were used for the Mo, Ga, and S atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$, is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (19–21). The final value of g was 1.97(11) × 10^4. Convergence was reached at R = 0.021 and R_w = 0.028 for 3679 reflections with $I \geq 3\sigma(I)$. For all 4315 reflections R = 0.030 and R_w = 0.029.

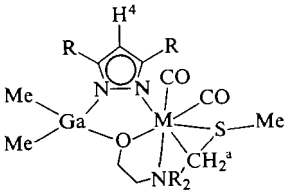
On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.11 and 0.79σ, respectively. The mean error in an observation of unit weight was 0.9165. A final difference map showed maximum fluctuations of ±0.4 e Å^{-3} near the heavy atoms and ±0.2 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 2 and 3 respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1]

*[Dimethyl(*N,N*-dimethylethanolamino)(3,5-dimethyl-1-pyrazolyl)gallato(*N(2),O,N(3)*)](*η²*-thiomethoxymethyl)-dicarbonylmolybdenum*

Details of the structure analysis are the same as for $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ except where noted. Crystal dimensions were 0.15 × 0.53 × 0.62 mm. Forty-seven reflections were used in the refinement of the unit-cell parameters. Crystal data are:

$C_{15}H_{28}GaMoN_3O_3S$ fw = 496.13

Monoclinic, a = 8.1754(7), b = 15.074(1), c = 16.708(1) Å, β = 94.365(6)°, V = 2053.0(3) Å^3, Z = 4, ρ_c = 1.605 g cm^{-3}, $F(000)$ = 1008, μ(Mo K_α) = 19.4 cm^{-1}. Absent reflections: $0k0$, $k \neq 2n$, and $h0l$, $l \neq 2n$ define uniquely the space group $P2_1/c$ (C_{2h}^5, No. 14).



An ω–2θ scan at 1.55–10.08° min^{-1} over a range of 0.70 + 0.35 tan θ° in ω was employed. Of 5927 independent reflections measured (to 2θ = 60°), 4362 (73.6%) had intensities greater than 3σ(I) above background. An absorption correction was applied, transmission factors ranging from 0.276 to 0.633.

The coordinates of the Mo, Ga, and S atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.042. All 28 hydrogen atoms were located from a difference map at this point and were included in subsequent

[1]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

cycles of refinement with isotropic thermal parameters. The final value of the extinction parameter g was 0.68(10) × 10^4. Convergence was reached at $R = 0.033$ and $R_w = 0.039$ for 4362 reflections with $I \geq 3\sigma(I)$. For all 5927 reflections $R = 0.054$ and $R_w = 0.042$. The mean and maximum parameter shifts on the final cycle of refinement corresponded to 0.12 and 1.5σ respectively and the mean error in an observation of unit weight was 1.1480.

The thermal motions of both molecules have been analysed in terms of rigid-body modes of translation, libration, and screw motion (22) using the computer program MGTLS. For $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$, **2** (rms σU_{ij} = 0.0016 Å^2), analysis of all non-hydrogen atoms except carbonyl oxygens and methyl carbons C(3), C(4), and C(6) gave physically reasonable rigid-body parameters and rms ΔU_{ij} = 0.0028 Å^2. For $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$, **3** (rms σU_{ij} = 0.0019 Å^2), three separate analyses were employed. All non-hydrogen atoms except carbonyl oxygen atoms and methyl carbons C(3), C(4), and C(12)–C(15) gave rms ΔU_{ij} = 0.0044 Å^2, but indicated significant independent motion of the Ga and N(3) tetrahedra, these being analysed separately giving rms ΔU_{ij} = 0.0019 and

$[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$	0.68–1.18(4–8)	0.97(11)

0.0021 Å^2 respectively. The appropriate bond distances have been corrected for libration (23), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths for both molecules appear in Table 4 along with the uncorrected values. Corrected bond angles do not differ from the uncorrected values listed in Table 5 by more than 1σ. Intra-annular torsion angles are given in Table 6 and possible weak hydrogen bonds are listed in Table 7.

Results and Discussion

The experimental evidence summarized in Table 1 together with mass spectral data (see below) suggests a monomeric pseudo-octahedral structure for the compounds studied, both in solution and in gas phase. As with previous carbonyl complexes utilizing these gallate ligands (8, 9) it is conjectured that the tridentate chelating ligands are *fac* ligands in all the complexes herein reported. The proposed monomeric pseudo-octahedral structure incorporating a *fac* gallate ligand has been proven conclusively for the $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ complexes in the solid state through crystal structure determinations (see below).

Infrared Spectra

The infrared spectra of the complexes in CH_2Cl_2 solutions and as Nujol mulls (Table 1) show two equally strong broad bands in the carbonyl stretching region of the spectrum indicating a *cis*

arrangement of the two CO ligands in the complexes. For those four complexes soluble in cyclohexane four sharp bands of roughly equal intensity were observed in this region of the spectrum. A similar phenomenon was evident in CS_2 solution ir measurements. These results suggest the presence of positional or orientational isomers in these two solvents. Positional isomers could arise if the "CH_2SMe" moiety were to be substituted for CO at different octahedral positions in the decarbonylation reaction in the final stage of the synthesis. However, molecular models indicate that the most favored position of substitution, sterically, should be the one opposite the pyrazolyl nitrogen atom, and this is indeed shown to be so in the two solid state structures described below. The second type of isomerism possible, orientational, would arise if the CH_2SMe ligand in a fixed octahedral position were oriented differently in the two isomers. Here there are two distinct possibilities, one involving a rotation of the sulfur ligand about the CH_2–S bond axis to place the S—Me group in different up or down positions in two isomers, the other, a rotation of the sulfur ligand about the midpoint of the CH_2—S bond which would give the ligand two different "bites" relative to the remainder of the unsymmetrical octahedral molecule. It is noteworthy that the ^1H nmr results (C_6D_6 solution) also indicate the presence of two isomers in solution but with a significantly different ratio than those indicated by the ir results for cyclohexane or CS_2 solutions. The synthesis and study of the molecule $MeGa(N_2C_3H_3)_3Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ was undertaken to help clarify the above observations. In this complex we have a symmetrical tridentate chelating ligand and positional isomerism is not possible. The ^1H nmr results for this compound (C_6D_6 solution) indicate the presence of one isomer, whereas the ir results (cyclohexane solution), with 4 ν_{CO} bands, indicate the presence of two isomers of approximately equal concentration. With this molecule a different "bite" for the sulfur ligand should not give rise to more than two ν_{CO} bands for a mixture of the two conformers. To explain the spectrum different orientations of the S—Me group towards and away from the gallate ligand in the two isomers is a distinct possibility. It is interesting to compare the above results with those reported for the analogous compound (η^5-C_5H_5)$Mo(CO)_2(\eta^2\text{-}CH_2SMe)$ (24–26). For this compound only two ν_{CO} bands are reported both for halocarbon oil mull (24) (1922, 1838 cm^{-1}) and cyclohexane solution (25) (1952, 1869 cm^{-1}) spectra, indicating just one isomer for this complex. Again in this molecule positional and "bite" isomerism are not possible and evidently the highly unfavorable arrangement with the SMe group oriented towards the η^5-C_5H_5 ring is not observed. The ir results for the complexes (Table 1) with unsymmetrical gallate ligands may equally satisfactorily be explained on the basis of two different isomers in solution with the S—Me group pointing away from the gallate ligand in one isomer and in the opposite direction in the other isomer.

The presence of isomers so clearly shown in cyclohexane and CS_2 solutions but not in CH_2Cl_2 may be due to a solvent effect or to the fact that the ν_{CO} bands in CH_2Cl_2 are broad and the bands for different isomers, if present, may be unresolvable. It is not uncommon, however, in this type of complex for the isomer ratio to be drastically altered by merely changing the solvent (27, 28). In C_6H_6 solvent the ν_{CO} bands are not well resolved, due to interference from solvent absorptions but in the spectrum of the complex where R = R′ = Me

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

(Table 1) it does appear that one isomer is greatly favored with two strong ν_{CO} bands detectable at 1914 and 1786 cm^{-1}, a result in keeping with the ^1H nmr results.

As with previous results (8, 13, 24, 25, 29, 30), ν_{CO} values for the tungsten complexes are 10–15 cm^{-1} lower than those for the corresponding molybdenum compounds. In the relevant complexes in the present series the ν_{NH} values show the same trend to lower values for the tungsten compounds.

^1H Nuclear Magnetic Resonance Spectra

These results, collected in Table 1, were obtained using C_6D_6 solutions. For all the complexes (excepting $MeGa(N_2C_3H_3)_3Mo(CO)_2(\eta^2\text{-}CH_2SMe)$) the spectra indicate the presence of two isomers in solution. Each isomer can be readily associated with a particular set of proton signals due to the quite different relative amounts of each isomer present in the solution. Table 1 lists approximate isomer ratios obtained from the relative integrations of the two sets of Ga—Me signals for each complex. It is evident that the fewer the methyl substituents on the gallate ligand (i.e. R = R′ = H) the closer the isomer distribution (4:1). With R = H, R′ = Me or R = Me, R′ = H, the effect is relatively the same, the isomer ratio now about 8:1. When R = R′ = Me the preference of one isomer over the other is much larger, about 20:1.

It is tempting to rationalize these results on the same basis as the ir results, viz. two orientational isomers in solution. It might be expected, however, that interconversion of such isomers would be influenced by temperature and that eventually at higher temperatures an "average" spectrum would be observed. The four Ga—*Me* signals displayed by the complexes at room temperature are very sharp and remain so at elevated temperatures (80°C) with no noticeable broadening. This result suggests that either the interconversion process for the rotational isomers is not very facile or that the ^1H nmr experiment is showing the presence of two positional isomers in C_6D_6 solution. Unfortunately the complexes which gave isomer ratios closest to unity in the ^1H nmr experiments were not soluble in cyclohexane or CS_2 to enable a search for an expected 8 ν_{CO} bands due to 4 orientational isomers (2 for each positional isomer). Those complexes which were soluble in these solvents would most probably have relatively too little of the less abundant isomer to show up in the ir spectrum.

The isomer distributions should be compared with those observed in the corresponding nitrosyl complexes (8). In the latter, the isomer ratio (necessarily positional isomers) depends greatly on the position of methyl substitution. Thus if R = H, R′ = Me the isomer ratio is 1:1, but if R = Me, R′ = H the ratio is 5:1. In the present series of complexes the corresponding ratios are much less variant (see Table 1). An argument in favor of the orientational isomer explanation is the fact that well formed crystalline samples of the pure complexes were easily obtained (compare the poor crystalline samples of the corresponding nitrosyl complexes) and even samples used in X-ray studies when examined in solution gave the above ir and ^1H nmr results.

The non-equivalence of the two CH_2 protons of the CH_2SMe moiety is clearly demonstrated in the AX patterns observed for these protons in all the complexes ($J \approx 6.0$ Hz). This is consistent with the mode of bonding of this ligand in the solid state structures (see below) in which the "CH_2SMe" group and the Mo atom are involved in a three-membered metallocyclic ring with a "tetrahedral" CH_2 grouping.

Mass Spectra

Although the fragmentation patterns were similar for all compounds, the relative intensities of the various signals within a particular fragmentation pattern differed markedly for analogous molybdenum and tungsten derivatives. For all the compounds the monomer parent ion signal was the highest *m/e* recorded. The four molybdenum compounds displayed as their strongest signals the ions corresponding to the parent minus two CO groups (P − 2CO) with P − 2CO − Me (90%) and P (40%) being quite strong. P − CO and P − Me were observed as weak signals. In contrast, for the four tungsten compounds the signal corresponding to the P − 2CO − Me was the strongest with P − CO (70%) and P (40%). P − 2CO and P − Me were observed but weak. Another noteworthy feature of the set of spectra was the strong signal corresponding to P − 2CO − Me_2S (60%) observed in all four compounds containing the "$OCH_2CH_2NMe_2$" moiety but the very weak signal due to this ion or its complete absence in the four compounds containing the "$OCH_2CH_2NH_2$" fragment.

In all eight spectra the intensity ratios of the individual peaks in multi-peak signals agree closely with theoretical predictions based on the percentage isotope composition of the contributing metal atoms.

X-ray Crystallographic Analyses of $[Me_2Ga(N_2C_2H_3)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$, 2, and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Mo(CO)_2(\eta^2\text{-}CH_2SMe)$, 3

With the exception of one weak intermolecular interaction for each structure (C—H···S for **2** and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

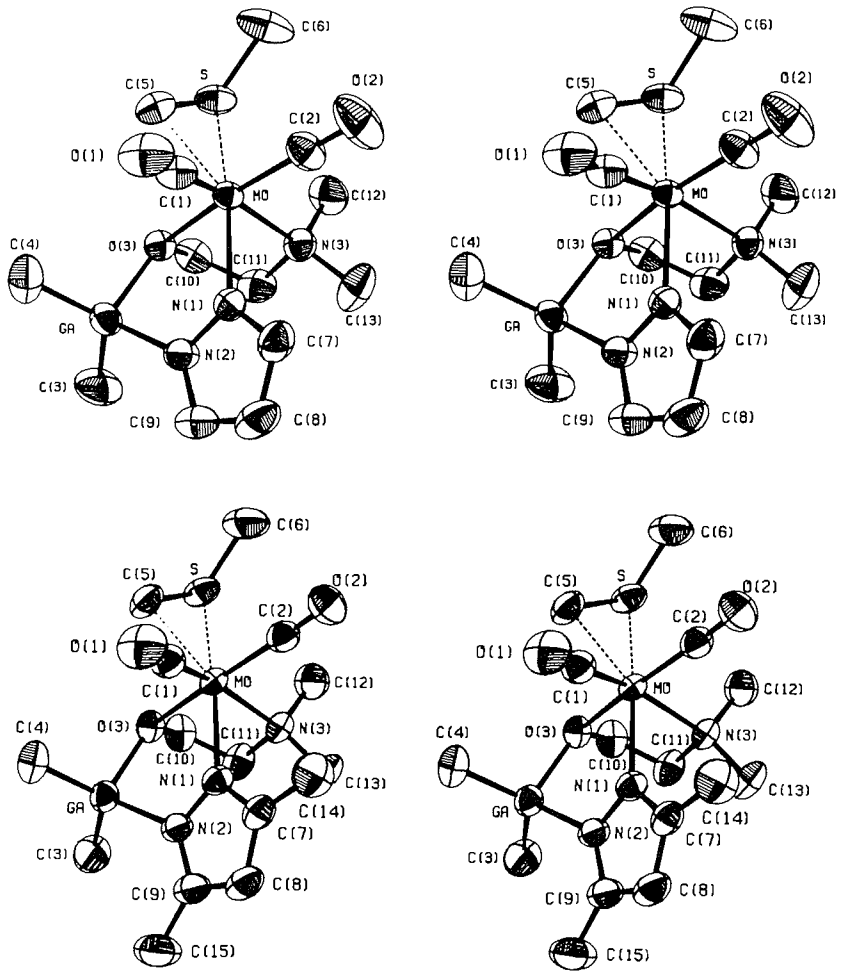

FIG. 1. Stereo views of the [dimethyl(*N*,*N*-dimethylethanolamino)(1-pyrazolyl)gallato(*N*(2),*O*,*N*(3))](η^2-thiomethoxymethyl)dicarbonylmolybdenum (top) and [dimethyl(*N*,*N*-dimethylethanolamino)(3,5-dimethyl-1-pyrazolyl)gallato(*N*(2),*O*,*N*(3))]-(η^2-thiomethoxymethyl)dicarbonylmolybdenum (bottom) molecules.

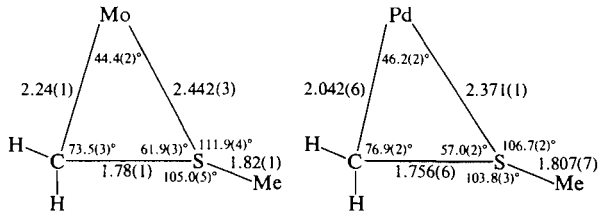
C—H···O for **3**, see Table 7), the solid state structures of both complexes consist of discrete molecular units separated by normal van der Waals distances.

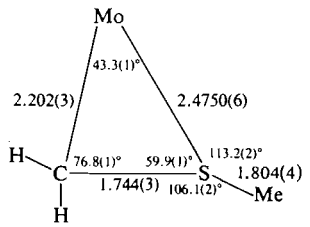
The coordination about molybdenum in both molecules may be regarded as distorted octahedral with the η^2-CH_2SMe ligand occupying one coordination site or as heptacoordinated with a bidentate η^2-CH_2SMe ligand (see Fig. 1). The latter description is consistent with the observed angles between the carbonyl groups (79.8(1)° for **2**, 79.2(1)° for **3**) (26 and references therein). The η^2-CH_2SMe ligand is situated opposite the pyrazolyl nitrogen atom as predicted from molecular model studies. Molecules **2** and **3** are stereochemically equivalent to the related allyl complex $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$, **4** (9). Bond lengths and angles in the $Mo(CO)_2$ moieties in **2**, **3**, and **4** are equal within experimental error and, as noted earlier (9), there are significant differences between the pairs of Mo—C(O) and C—O distances. The Mo—C(O) distances *trans* to oxygen are shorter than those *trans* to nitrogen by an average of 0.055 Å as a result of both steric and *trans* effects. The substituents of the gallate ligands, **1**, influence the bond lengths to the chelated metal. The Mo—N(amino) distance in **4** (R′ = H) is 2.285(2) Å and in the present structures (R′ = Me) the corresponding Mo—N distances increase to a mean value of 2.399(5) Å. When R changes from H to Me, the Mo—O distances increase slightly, but significantly, from 2.248(2) Å in **2** to a mean of 2.266(3) Å in **3** and **4**. The Mo—N(pyrazolyl) distances in **2** and **3** (2.192(2) and 2.205(2) Å) are slightly, but significantly, shorter than the corresponding distance of 2.222(2) Å in **4**, reflecting a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



small electronic difference between the η^3-C_4H_7 and η^2-CH_2SMe ligands.

The steric requirements of the asymmetric gallate ligand were found to force an unusual orientation of the 2-methylallyl ligand in **4** (9) in which the methyl group was oriented toward the carbonyl ligands. This also occurs in both **2** and **3** as well as in the related molecule (η^5-C_5H_5)Mo(CO)$_2$(η^2-CH_2SMe) (26), all of which have the SMe group directed toward the carbonyl ligands. Unlike in solution, where orientational isomerism involving the η^2-CH_2SMe ligand is indicated, only one such isomer is present in the solid state. Weak intramolecular C—H···S hydrogen bonds (see Table 7) may be responsible for the predominance of one of the isomers in solution (see Table 1) and in combination with intermolecular C—H···S interactions in **2** and C—H···O interactions in **3** are sufficient to completely eliminate the minor isomer in the solid.



The M(η^2-CH_2SMe) systems in **2** and **3** are compared with those in (η^5-C_5H_5)Mo(CO)$_2$(η^2-CH_2SMe) (26) and (Ph_3P)PdCl(η^2-CH_2SMe) (31) in Fig. 2. The Mo—S distances in **2** and **3** differ significantly and both are longer than the corresponding distance in (η^5-C_5H_5)Mo(CO)$_2$(η^2-CH_2SMe) (26) while the Mo—C distances in **2** and **3** are somewhat shorter than in the cyclopentadienyl complex although these differences are not significant. Steric effects are most likely responsible for these differences, the S atoms in **2** and **3** being separated by less than the sum of van der Waals radii from both C(10) and C(12) of the gallate ligand. The C—S distances of all four complexes shown in Fig. 2 are equal within experimental error, those in the MCS ring being significantly shorter than the S—Me distances by a weighted mean of 0.054 Å. This shortening of the CH_2—S bonds corresponds to only a minimal amount of double bond character. The bond angles at C(5) in both of the present structures are equal within experimental error to the corresponding values observed in the low-temperature structure of (Ph_3P)PdCl(η^2-CH_2SMe) (31), confirming tetrahedral coordination for this atom. The Mo—C(5) distances (2.202(3) and 2.211(3) Å) in the present structures are significantly shorter than the terminal Mo—C(allyl) distances of 2.324(3) and 2.335(3) Å in **4** (which are shorter than the central Mo—C(allyl) bond, 2.372(3) Å). The above evidence indicates that the best description of the MCS system involves the formation of a three-membered metallocyclic ring containing an M—C σ-bond and lone-pair donation by S to the metal as noted previously (31).

The gallium atoms have distorted tetrahedral coordination geometry with bond angles ranging

(C_5H_5)Mo(CO)$_2$(CH_2—S—Me) (Ph_3P)PdCl(CH_2—S—Me)

($Me_2Ga(N_2C_3H_3)OCH_2CH_2NMe_2$)Mo(CO)$_2$($CH_2$—S—Me)

($Me_2Ga(N_2C_5H_7)OCH_2CH_2NMe_2$)Mo(CO)$_2$($CH_2$—S—Me)

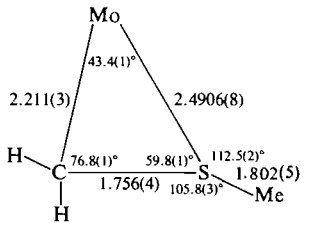


FIG. 2. Bond lengths (Å) and angles in the M(η^2-CH_2SMe) moiety.

from 92.24(7) to 125.0(2)°. All bond lengths and angles in the asymmetric gallate ligand are in good agreement with those observed in related structures (6, 7, 9, 32, 33) and the ligand conformation is similar to other structures in which the ligand is facially coordinated (7, 9, 32). The pyrazolyl groups in both structures are significantly nonplanar (χ^2 = 24.6 and 26.4 for **2** and **3** respectively) with the metal atoms considerably displaced from the N_2C_3 planes (Mo by −0.1336(2) and −0.2270(2), Ga by 0.2070(3) and 0.3722(4) Å for **2** and **3** respectively).

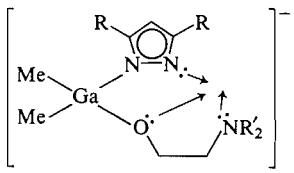
KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **58**, 1091 (1980).

The preparation and physical properties of octahedral and trigonal bipyramidal complexes incorporating the tris-chelating ligands $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NR'_2)]^-$ (R' = H or Me) are described. Crystals of [dimethylbis(3,5-dimethyl-1-pyrazolyl) gallato ($N(2)$, $N'(2)$)][dimethyl (3, 5 - dimethyl - 1 - pyrazolyl) (N, N - dimethylethanolamino(gallato ($N(2)$, O, $N(3)$)]nickel(II) are triclinic, $a = 20.8562(11)$, $b = 9.1536(4)$, $c = 8.2798(4)$ Å, $\alpha = 100.204(3)$, $\beta = 85.513(4)$, $\gamma = 101.989(3)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by Patterson and Fourier syntheses and was refined by full-matrix least-squares procedures to $R = 0.048$ and $R_w = 0.078$ for 5508 reflections with $I \geq 3\sigma(I)$. The coordination about the Ni atom is distorted trigonal bipyramidal with the two nitrogen atoms from the $Me_2Ga(N_2C_5H_7)_2$ ligand occupying equatorial positions. The tridentate $Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)$ ligand is meridionally coordinated with the oxygen in the equatorial and the two nitrogens in the axial positions. Important bond lengths (corrected for libration) are: Ni—N(eq), 2.005(3) and 2.006(3), Ni—O, 1.993(3), Ni—N(pz—ax), 2.072(3), Ni—N(amino), 2.229(3), Ga—O, 1.913(3), Ga—N, 1.971(3)–1.989(3), and Ga—C, 1.961(10)–1.986(6) Å.



KENNETH S. CHONG, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **58**, 1091 (1980).

On décrit la préparation et les propriétés physiques de complexes octaédriques et trigonaux bipyramidaux incorporant les ligands trichélatés $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NR'_2)]^-$ (R' = H ou Me). Les cristaux de [diméthylbis(diméthyl-3,5) pyrazolyl-1)-gallato($N(2)$,$N'(2)$)][diméthyl(diméthyl-3,5 pyrazolyl-1)(N,N-diméthyléthanolamino)gallato($N(2)$,O,$N(3)$)] nickel(II) sont triclinques avec $a = 20.8562(11)$, $b = 9.1536(4)$, $c = 8.2798(4)$ Å, $\alpha = 100.204(3)$, $\beta = 85.513(4)$, $\gamma = 101.989(3)°$, $Z = 2$ groupe d'espace $P\bar{1}$. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs conventionnelles $R = 0.048$ et $R_w = 0.078$ pour 5508 réflexions avec $I \geq 3\sigma(I)$. La coordination autour de l'atome de nickel est déformée de façon trigonale bipyramidale avec les deux atomes d'azote du ligand $Me_2Ga(N_2C_5H_7)_2$ en positions équatoriales. Le ligand tridentate $Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)$ est coordonné de façon méridionale avec l'oxygène équatorial et les deux atomes d'azote en positions axiales. Les longueurs importantes de liaison (corrigés pour la libration) sont: Ni—N(eq), 2.005(3) et 2.006(3), Ni—O, 1.993(3), Ni—N(pz—ax), 2.072(3), Ni—N(amino), 2.229(3), Ga—O, 1.913(3), Ga—N, 1.971(3)–1.989(3) et Ga—C, 1.961(10)–1.986(6) Å.

[Traduit par le journal]

Introduction

A series of four anionic tridentate chelating ligands of the type **1** has been synthesized. Previous reports dealt with octahedral complexes of the first row transition elements (Mn → Zn) incorporating the ligand **1** where R = H and R' = H (1), binuclear

1, R = H or Me; R' = H or Me

transition metal complexes (Co → Zn) using the ligand **1** where R = H and R' = Me (2), and carbonyl compounds of Mo, W, and Mn using all four ligands (3). The present account investigates the coordinating properties of the two ligands where R = R' = Me and where R = Me and R' = H towards divalent transition metal ions M^{2+} (where M = Fe, Co, Ni, Cu, and Zn). Depending on the ligand a series of trigonal bipyramidal five-coordinate transition metal complexes (R = R' = Me) or a series of six-coordinate octahedral transition metal complexes (R = Me and R' = H) were isolated. Steric factors, which in the main determine the geometry adopted about the transition metal ion, are discussed, and the crystal structure of the five-coordinate nickel(II) complex is presented.

Experimental

Starting Materials

Air-sensitive materials were handled in a glove box under an atmosphere of oxygen-free dry nitrogen or in a nitrogen-blanketed apparatus. Tetrahydrofuran (THF) was dried by refluxing over lithium aluminum hydride and was used immediately following distillation. Benzene was dried by refluxing over molten potassium followed by distillation. 3,5-Dimethylpyrazole (K and K laboratories) and sodium hydride (Alfa Inorganic) were used as supplied. Ethanolamine and N,N-dimethylethanolamine were refluxed over anhydrous $CaSO_4$ and distilled prior to use. Gallium trimethyl (4) and $FeCl_2 \cdot 1.5$ THF (5) were prepared as described previously.

Preparative Details

Ligand Synthesis

The two ligands employed in this study were synthesized by

the same general route described previously for 1 where R = R' = H (1) and where R = H and R' = Me (2). Thus, sodium 3,5-dimethylpyrazolide was prepared in THF by reacting sodium hydride with 3,5-dimethylpyrazole. One molar equivalent of trimethyl gallium was then added followed by either ethanolamine or *N*,*N*-dimethylethanolamine depending on which ligand 1 was required. Refluxing at this final stage produced a clear THF solution of the desired ligands. These solutions were used in the subsequent preparations of the transition metal complexes. The purity of the ligand solutions was evident from the high-yield syntheses of numerous complexes incorporating one ligand per metal centre (3).

Preparation of the Complexes

The preparations of the complexes listed in Table 1 were all very similar and can be summarized by the following procedure. The transition metal starting materials for all the preparations are given in Table 1, together with physical data for the isolated complexes.

To one equivalent of a stirred solution or suspension of the transition metal salt in THF was added two[1] equivalents of ligand in the same solvent. The resulting precipitate was allowed to settle and the clear solution isolated. The THF solvent was then removed *in vacuo* and the solid remaining recrystallized from xylene or bezene to yield well-formed crystals in each case.

Spectra

A Varian MAT CH4 spectrometer was used to record mass spectra at 70 eV with an ion source temperature of 100–180°C. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer as Nujol mulls and electronic absorption solution spectra on a Cary 14 spectrometer.

X-ray Crystallographic Analysis of [Dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato(N(2),N'(2))][dimethyl(3,5-dimethyl-1-pyrazolyl)(N,N-dimethylethanolamino)gallato-(N(2),O,N(3))]nickel(II)

The crystal chosen was mounted in a general orientation and had dimensions of ca. 0.70 × 0.48 × 0.42 mm. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections measured on a diffractometer with Cu K_α radiation (λ = 1.54184 Å). Crystal data (at 22°C) are:

$C_{23}H_{43}Ga_2N_7NiO$ fw = 631.80
Triclinic, a = 20.8562(11), b = 9.1536(4), c = 8.2798(4) Å, α = 100.204(3), β = 85.513(4), γ = 101.989(3)°, V = 1520.3(1) Å^3, Z = 2, ρ_c = 1.380 g cm^{-3}, $F(000)$ = 656, μ(Cu K_α) = 27.74 cm^{-1}. Absent reflections: none. Space group $P\bar{1}$ (C_i^1, No. 2) from structure analysis.

Intensities were measured with graphite monochromatized Cu K_α radiation on a Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.26–10.06° min^{-1} over a range of (0.70 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of 3 check reflections, measured every 3600 s throughout the data collection, remained constant to within ±2.5%.

After data reduction, an absorption correction was applied using the Gaussian integration method (6, 7). Transmission factors ranged from 0.224 to 0.449 for 480 sampling points. Of the 6233 independent reflections measured, 5508 (88.4%) had intensities greater than 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = background count.

Analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics. The coordinates of the gallium and nickel atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from subsequent Fourier syntheses. The "ethanolamine" carbon atoms C(17), C(22), and C(23) were found to be twofold disordered; site occupancies were estimated from relative peak heights on a Fourier map to be 0.70 for "a" sites and 0.30 for "b" sites. Isotropic refinement of the disordered carbon atoms with the occupancy factors fixed resulted in nearly equal thermal parameters for corresponding pairs, thus the site occupancies were kept fixed at these values throughout the refinement. All of the ordered non-hydrogen atoms and the three disordered carbon atoms with 0.70 occupancy were refined with anisotropic thermal parameters and the remaining disordered carbon atoms with isotropic thermal parameters to R = 0.058. A difference map gave positions for all ordered hydrogen atoms which were subsequently refined with isotropic thermal parameters. Ideal positions (C—H = 0.98 Å, $B_H = B_C + 1.1$) were calculated for the disordered hydrogen atoms which were included as fixed atoms in the final stages of the refinement.

The scattering factors of ref. 8 were used for non-hydrogen atoms and those of ref. 9 for hydrogen atoms. Anomalous scattering factors from ref. 10 were used for the Ga and Ni atoms. The weighting scheme, $w = 1/\sigma^2(F)$ where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of $|F_o|$ and was employed in the final stages of refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (11–13). The final value of g was 0.60(4) × 10^4. Convergence was reached at R = 0.048 and R_w = 0.078 for 5508 reflections with $I \geq 3\sigma(I)$. For all 6263 reflections R = 0.052 and R_w = 0.078. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.36 and 3.5σ (oscillating hydrogen thermal parameter) respectively. The mean error in an observation of unit weight was 2.89. A final difference map showed maximum fluctuations of ±1.0 e Å^{-3} near the gallium atoms and ±0.4 e Å^{-3} elsewhere. The final positional and thermal parameters appear in Tables 2 and 3[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (14) using the computer program MGTLS. The rms standard error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0033 Å^2. Analysis of all non-hydrogen atoms excluding methyl carbon atoms and C(16) gave rms U_{ij} = 0.0046 Å^2 and physically reasonable rigid-body parameters. The appropriate bond distances have been corrected for libration (15), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 4 along with the uncorrected values and corrected bond angles do not differ by more than 1σ from the uncorrected values listed in Table 5. Intra-annular torsion angles defining the conformations of the chelate rings are given in Table 6.

Results and Discussion

Mass Spectra

The mass spectra of the octahedral complexes,

[1]In the preparation of the five-coordinate copper complex it was necessary to use a 3:1 ligand to metal salt stoichiometry as a 2:1 ratio produced intractable oils only.

[2]The structure factor table and Table 3 (thermal parameters) are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

*Prime denotes occupancy 0.70, double primes denote occupancy 0.30.

$[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]_2M$, display signals due to the parent ions in addition to signals from ions arising from predictable fragmentation patterns. In each case the most intense signal was due to the ion $[MeGa(N_2C_5H_7)_2(OCH_2CH_2NH_2)M]^+$. No ions of higher mass than the octahedral parent ion were observed in the spectra, a result which substantiates the presence of monomeric species in the gas phase.

In the case of the five-coordinate complexes, the signal corresponding to the parent ion was either very weak or absent. The strongest signal in the majority of the spectra corresponded to the ion $[MeGa(N_2C_5H_7)_2(OCH_2CH_2NMe_2)M]^+$. The one exception was the Cu complex which gave as its strongest signal that corresponding to the ion $[MeGa(N_2C_5H_7)(OCH_2CH_2NMe_2)Cu]^+$. This ion was not present in the fragmentation patterns of the remaining five-coordinate complexes. As in the case of the octahedral complexes, no signals due to ions of higher mass than the monomeric five-coordinate species were observed.

In both sets of spectra the relative intensities of the individual peaks in multi-line signals agreed well with those predicted on the basis of the natural isotope compositions of the contributing metal atoms.

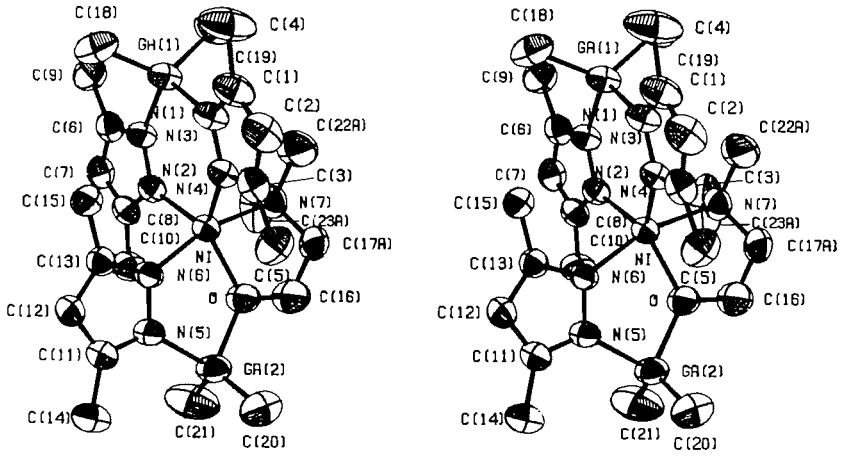

FIG. 1. Stereo view of the [dimethylbis(3,5-dimethyl-1-pyrazolyl)gallato(*N*(2),*N*′(2))][dimethyl(3,5-dimethyl-1-pyrazolyl)(*N*,*N*-dimethylethanolamino)gallato(*N*(2),*O*,*N*(3))]nickel](II) molecule, 50% thermal ellipsoids are shown for the non-hydrogen atoms.

Infrared Spectra

The infrared spectra of the octahedral complexes display N—H vibrations identical to the *meridional* octahedral complexes formed with the ligand **1** where R = R′ = H (1). It is therefore not unreasonable to assign this same arrangement to the gallate ligands in the present complexes. The visible spectrum (see below) of the Ni derivative provides further evidence for this assignment for this complex.

The infrared spectra of the five-coordinate complexes fell into two groups. The Fe, Ni, and Zn complexes formed one group with very similar spectra whilst the Co and Cu complexes formed the second group. These two groups displayed marked differences in their ir spectra in the region 1600–400 cm^{-1} (see Fig. 2). These differences between the spectra of the two groups of complexes probably arise from different molecular geometries. A trigonal bipyramidal geometry has been demonstrated for the Ni complex through an X-ray structure determination (see below) whereas a severely distorted trigonal bipyramidal geometry is suggested for the Co complex by its visible spectrum.

Electronic Spectra

The electronic spectra of the complexes were recorded in the range 300–1400 nm and are listed and assigned in Tables 7 and 8.

The spectra of the octahedral nickel and cobalt complexes are as expected for high-spin Ni(II) and Co(II) complexes, and have been analysed on the basis of the energy levels discussed in ref. 16. D_q and B values are listed in Table 7. The observed ν_2 and ν_3 bands of the nickel complexes were used in the calculation of these parameters. This leads to a calculated value of 10.4 kK for ν_1 for both nickel complexes. The expected $\rightarrow {}^1E_g$ transitions are 13.1 kK ($C/B = 4.5$ has been assumed for the calculation of the ${}^1E_g$ transition (16)) in close agreement with the 12.9 kK experimental values. Similarly ν_1 and ν_3 have been used to calculate D_q and B of the cobalt complex. This leads to a calculated value of 19.8 kK for ν_2 for the complex. Comparison of the D_q values of the present complexes with those for the octahedral complexes of Ni(II) and Co(II) using the ligand **1** where R = R′ = H (1) shows the present values to be slightly lower than the previous ones, suggesting a weaker crystal field in these new complexes. Comparison of the ε values of the absorptions for the new nickel complexes with those reported earlier for the *fac* and *mer* octahedral complexes where R = R′ = H (2) suggests a *meridional* arrangement of the ligand in the present complexes. This postulation is also supported by the Nujol ir spectrum which shows three distinct bands in the ν_{NH} region of the spectrum.

The spectra of the five-coordinate Ni, Co, and Cu complexes are presented in Fig. 3. The nickel spectrum has been assigned on the basis of the crystal field model discussed by Ciampolini (17). With the exception of the splitting of one band the spectrum can be interpreted in terms of a trigonal bipyramidal model. The splitting of the band around 11.5 kK into two components indicates a reduction of symmetry from the idealized D_{3h} on which the model is based. Reduction to C_{3v} symmetry would give two bands as transitions to $^3A_1(F)$ and $^3A_2(F)$ instead of degenerate transitions to $^3A_1'' + {}^3A_2''$ in D_{3h} symmetry. The spectrum of the present compound is almost identical to that of $[Ni(trenMe)Cl]^+$ where trenMe = tris(2-dimethylaminoethyl)amine (18), the bromo analog of which has been shown by X-ray crystallography to possess C_{3v} microsymmetry (19). The only notable difference in the present spectrum is the shift of all the bands to higher energy (NiN_4O chromophore vs. NiN_4Cl chromophore).

The overall shape of the cobalt spectrum did not fit ligand field models for either trigonal bipyramidal or square pyramidal geometries. This is no doubt due to severe distortions from these idealized geometries in the present complex. Indeed it is well

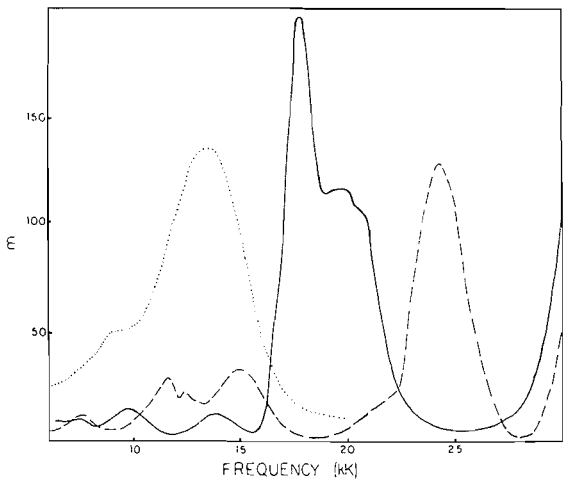

FIG. 3. Electronic spectra of the five-coordinate Ni, Co, and Cu complexes (- - - Ni, — Co, · · · Cu).

known that trigonal bipyramidal cobalt(II) complexes are commonly more distorted toward the tetrahedron than their Ni(II) analogs (20). The band positions for the present complex correlate closely with those of the complex $\{Co(NP_3)Br\}^+PF_6^-$, where NP_3 = tris(2-diphenylphosphinoethyl)-amine, which has been shown by X-ray crystallography to possess an extremely distorted trigonal bipyramidal geometry (21).

The assignment of the bands given in Table 8 is based on the ligand field model proposed by Wood (22) for idealized high-spin trigonal bipyramidal Co(II) complexes. The expected singlet band for the transition $4A_2' \rightarrow 4E''$ is replaced in the spectrum of the present compound by a complex band envelope, no doubt due to the aforementioned distortions from the idealized geometry.

The spectrum of the five-coordinate copper derivative shows essentially one band with a shoulder to lower energy. The spectrum does not in itself point to a particular geometry for the complex but it is not inconsistent with a highly distorted geometry similar to the one proposed for the cobalt compound. It has already been pointed out that the two complexes have identical ir spectra, suggestive of similar molecular geometries.

The mechanism of formation of the present five-coordinate complexes is not obvious. A previous study (2) using the $[Me_2Ga(N_2C_3H_3)(OCH_2CH_2NMe_2)]^-$ ligand demonstrated that bis-ligand octahedral complexes could not be formed. In that study binuclear five-coordinate metal complexes were produced and a plausible mechanism proposed. It was not surprising, therefore, that the more sterically demanding ligand $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]^-$ did not lead to octahedral complexes. Further, it is again

For personal use only.

thought that the five-coordinate complexes formed with this ligand must arise from a decomposition of the second (and subsequent) incoming ligands. The absence of the ligand $Me_2Ga(N_2C_5H_7)_2^-$ in the starting materials was evidenced by the complete lack of production of the previously characterized $\{Me_2Ga(N_2C_5H_7)_2\}_2Cu$ compound (23, 24).

X-ray Crystallographic Analysis of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]$-$Ni[(N_2C_5H_7)_2GaMe_2]$

The structure of $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Ni[(N_2C_5H_7)_2GaMe_2]$ consists of discrete molecular units separated by normal van der Waals distances. There are a number of short intramolecular C—H···O and C—H···N interactions which may correspond to weak hydrogen bonds present in the structure (O···H(5a) 2.57(8), N(2)···H(15b) 2.60(5), N(2)···H(22c) 2.47, N(2)···H(22e) 2.58, and N(4)···H(23e) 2.65 Å). In any case these interligand contacts are indicative of steric crowding about the central metal.

The coordination geometry about the nickel atom is distorted trigonal bipyramidal. The tridentate $Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)$ ligand is meridionally coordinated with the oxygen occupying an equatorial position and the two nitrogen atoms are in the axial sites. The two remaining equatorial positions are occupied by the two nitrogen donors of the $Me_2Ga(N_2C_5H_7)_2$ ligand. The angle between the axial groups is 164.8(1)°.

The nature of complexes formed by the reaction of the gallate ligands L, **1**, with divalent metals of the first transition series is determined by steric factors. When R′ = H and R = H (2) or Me (Table 1), octahedral complexes L_2M are formed. When R′ = Me and R = H binuclear five-coordinate complexes $(\mu\text{-}N_2C_3H_3)_2(LM)_2$ were isolated (1) and the present study shows that when R = R′ = Me mononuclear five-coordinate species $[Me_2Ga(N_2C_5H_7)_2]ML$ are obtained.

The complex (Fig. 1) contains two systems of three fused rings which have the Ni atom in common and are approximately at right angles to one another. The central six-membered $Ga(2)N_4Ni$ ring is significantly non-planar, the Ni atom being displaced from the plane defined by the other five atoms in the ring (see Table 6 for torsion angles). The $[Me_2Ga(N_2C_5H_7)_2]Ni$ system is slightly folded, the angle between normals to the two pyrazolyl mean planes being 9.1(1)°. This is intermediate between the markedly folded systems observed in the square planar complexes $[Me_2Ga(N_2C_3H_3)_2]_2M$, M = Cu (24) and Ni (25) and the nearly planar arrangement found in the tetrahedral complex $[Me_2Ga(N_2C_5H_7)_2]_2Cu$ (24). The ligand **1** has internal geometry and conformation similar to that observed for other "meridionally" coordinated ligands **1** (1, 2, 26). All three pyrazolyl rings are planar within experimental error ($\chi^2 = 1.9$, 5.5, and 0.6 for N_2C_3 rings containing N(1), N(3), and N(5) respectively) and in each case the metal atoms are displaced significantly from the mean planes (Ga(1) −0.1463(5), Ni 0.1297(6) from the N(1) ring; Ga(1) −0.1112(5), Ni 0.2284(6) from the N(3) ring and Ga(2) 0.1894(6), Ni −0.2581(6) Å from the N(5) ring).

The equatorial Ni—N bond distances (2.006(3) and 2.005(3) Å) are equal within experimental error and are both significantly longer than the mean Ni—N(pz) distance of 1.895(4) Å in the square planar complex $[Me_2Ga(N_2C_3H_3)_2]_2Ni$ (25). The Ni—O, Ni—N(pz), and Ni—N(amino) distances involving the $Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)$ ligand are 1.993(3), 2.072(3), and 2.229(3) Å. These values may be compared to corresponding distances of 2.037(3), 2.112(3), and 2.279(3) Å in trigonal bipyramidal $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NMe_2)]Fe(NO)_2$ (26); 1.981(3), 2.023(4), and 2.173(3) Å (all basal) in the binuclear square pyramidal complex $(\mu\text{-}N_2C_3H_3)_2(CuL)_2$ (1) and mean values of 2.047(2), 2.097(6), and 2.152(4) Å in octahedral *mer*-L_2Ni (2).

Electrochemical oxidation of carboxylic acid anions in the presence of some mono- and di-substituted olefins[1]

PHILIPPE J. CHAMPAGNE[2] AND ROGER N. RENAUD

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 12, 1979

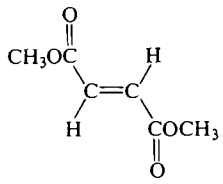
PHILIPPE J. CHAMPAGNE and ROGER N. RENAUD. Can. J. Chem. **58**, 1101 (1980).

The anodic oxidation of the sodium salts of acetic, propionic, and isovaleric acids was performed in the presence of a series of ethylenic compounds bearing electron-withdrawing substituents. The results showed that under certain experimental conditions the electrogenerated radicals added to the ethylenic double bond to give mainly 1,2-dialkylated products.

The stereoisomers obtained were separated and, whenever possible, identified. Their physical properties are reported.

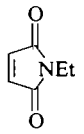
PHILIPPE J. CHAMPAGNE et ROGER N. RENAUD. Can. J. Chem. **58**, 1101 (1980).

Les sels sodés des acides acétique, propanoïque et méthyl-2 propanoïque ont été oxydés électrochimiquement en présence de composés éthyléniques ayant des substituents électroattracteurs. Les résultats ont démontrés que, sous certaines conditions expérimentales, les radicaux formés attaquent la double liaison pour donner principalement des composés dialkylés.



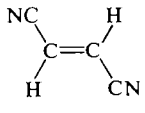
Les stéréoisomères obtenus ont été séparés et, dans certain cas, identifiés. Leurs propriétés physiques sont rapportées.

In the previous paper in this series (1) we reported the dimethylation of some symmetrical 1,2-disubstituted ethylenes via electrochemically generated methyl radicals.



$$ZCH{=}CHZ \xrightarrow[\text{electrolysis}]{CH_3CO_2Na} ZCH(CH_3){-}CH(CH_3)Z$$

This reaction proceeded cleanly in high yields (55–88%) and in each case gave a 1:1 mixture of *meso* and *racemic* stereoisomers. The purpose of the present study was to investigate the generality of this reaction both in terms of the nature of the alkyl radical and the nature of the electron-withdrawing substituents on the ethylene molecule. As well as for the symmetrically disubstituted ethylenes (**1–3**), we have investigated the reactivity of the radicals derived from acetic, propionic, and isovaleric acids in the presence of an unsymmetrical disubstituted ethylene (**4**) and a monosubstituted ethylene (**5**).



The only interesting 1,2-dialkylation of olefinic compounds reported in the literature is via the dialkyl copperlithium addition to α,β-ethylenic ketones (2). The electrochemical approach described in this paper is useful for alkylation of olefins substituted with a variety of electron-withdrawing groups.

Experimental

Starting materials **2**, **3**, and **4** and sodium benzenesulfinate were commercially available. The dimethylester **1** was readily synthesized from fumaric acid (3). The vinyl sulfone **5** was prepared by a method developed in this laboratory and detailed below. All melting points are uncorrected. The cell used in this study and the general procedure for electrolysis of the sodium carboxylate in the presence of ethylenic substrates have been reported earlier (1). Gas–liquid chromatographic analyses and separations were performed respectively on a Fisher/Victoreen Series 4400 with a 6% SE 30 on Anakrom ABS 90/30 column and an aerograph Autoprep model A-700 using a 20 ft × 3/8 in. column, 30% SE 30 on 45/60 chromosorb P. Proton magnetic resonance spectra were taken in deuteriochloroform on a Varian Associates spectrometer model EM 360 and are reported in the δ scale. The mass spectra were obtained from a Finnigan 4000 GC-MS mass spectrometer.

Phenyl Vinyl Sulfone (5)

A solution of benzenesulfinic acid, sodium salt (11.2 g, 63.4 mmol), and 1-bromo-2-chloroethane (38.0 g, 236 mmol) in absolute ethanol (500 mL) was refluxed for 3 days, cooled, and then filtered to remove most of the sodium bromide. The ethanol was removed on a rotary evaporator and the white solid residue was extracted with CH_2Cl_2. After filtering and evaporation of the solvent, a white solid was obtained (11.6 g) which, by ^1H nmr, contained a mixture of the expected β-chloroethyl phenyl sulfone and the disubstituted product 1,2-bis-(phenylsufonyl)ethane. This mixture was treated directly with

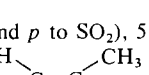
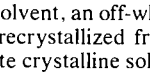
triethylamine (10 mL) in CH_2Cl_2 (100 mL) and successively refluxed overnight, washed with water, dried over $MgSO_4$, and filtered. On evaporation of the solvent, an off-white solid (9.6 g) was obtained. This solid was recrystallized from a minimum amount of ethanol to give a white crystalline solid (3.4 g) which proved to be the disubstitution product $C_6H_5SO_2CH_2CH_2SO_2C_6H_5$, mp 184–186°C (lit. (4) 183–184°C). *Anal.* calcd. for $C_{14}H_{14}S_2O_4$: C 54.19, H 4.52, S 20.64; found: C 54.03, H 4.75, S 20.36.

The filtrate, after evaporation of the ethanol, gave a sticky yellowish solid (6.2 g). This solid was recrystallized from benzene in a Craig tube and repeated cooling and centrifuging yielded pure phenyl vinyl sulfone (4.0 g, 34%), mp 69.5–70.5°C (lit. (5) 68.5°C); ^{1}H nmr: 7.85 (2 H, m, ArH *o* to SO_2), 7.55 (3 H, m, ArH *m* and *p* to SO_2), 5.87–7.00 (3 H, m, olefinic). *Anal.* calcd. for $C_8H_8SO_2$: C 57.10, H 4.76, S 19.05; found: C 57.30, H 4.93, S 18.94.

Anodic Oxidation of Acetic Acid Anion[3]

(*A*) In the presence of **4** (1.49 g, 0.03 *M*)





The extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatile matter, then at 100°C to give a viscous yellow oil (1.22 g) which by vpc showed two major peaks, the faster moving peak being slightly larger than the slower one and having the same retention time as the starting material **4**. However, ^{1}H nmr indicated the presence of only a very small amount of **4**. On the Autoprep this fraction gave three peaks, the smallest having the same retention time as **4**. The two slowest moving peaks, approximately equal in area, were separated on the Autoprep and shown to be *threo*- and *erythro*-2-phenyl-3-nitrobutane (**6**) in a total yield of 37%. First peak (*threo*- or *erythro*-**6**); ^{1}H nmr: 7.20 (5 H, broad s, Ph), 4.63 (1 H, m, methine α to NO_2), 3.20 (1 H, m, methine α to Ph), 1.30 (6 H, d, J = 7.0 Hz, methyls). *Anal.* calcd. for $C_{10}H_{13}NO_2$: C 67.05, H 7.28, N 7.82; found: C 67.17, H 7.65, N 7.56. Second peak (*threo*- or *erythro*-**6**); ^{1}H nmr: 7.2 (5 H, s, Ph), 4.72 (1 H, m, methine α to NO_2), 3.40 (1 H, m, methine α to Ph), 1.59 (3 H, d, J = 7.0 Hz, methyl), 1.33 (3 H, d, J = 7.0 Hz, methyl). *Anal.* found for $C_{10}H_{13}NO_2$: C 67.54, H 7.64, N 7.58.

After treatment with NaOMe in MeOD in an nmr tube each of the above isomers gave the same nmr spectrum with no apparent methine absorptions and two 3 proton methyl singlets at 1.32 and 1.45.

(*B*) In the presence of **5** (3.69 g, 0.066 *M*)[4]

The extracted oil (4.30 g) was vacuum distilled at 10^{-2} Torr and 25°C to remove traces of volatile material, then at 110°C to give a colourless viscous oil (3.80 g), and at 200°C to give a colourless oil (0.30 g) which formed white crystals on standing at room temperature.

Column chromatography of the 110°C fraction on silica gel using a mixture of hexane/ethyl acetate (4:1) as eluent gave, as a first fraction, 2-phenylsulfonylbutane (**7**) (2.95 g, 69%); ^{1}H nmr: 7.80 (2 H, m, ArH *o* to SO_2), 7.52 (3 H, m, ArH *m* and *p* to SO_2), 2.85 (1 H, m, methine α to SO_2), 1.82 (2 H, m, methylene), 1.19 (3 H, d, CH_3C—, J = 6.8 Hz), 0.88 (3 H, t, CH_3CH_2—, J = 6.8 Hz). *Anal.* calcd. for $C_{10}H_{14}SO_2$: C 60.60, H 7.05, S 16.16; found: C 60.83, H 7.20, S 16.28.

Further elution with the same solvent system gave phenyl 1-propenyl sulfone (**8**), mp 65.5–66.0°C (lit. (6) 67–68°C); ^{1}H nmr: 7.83 (2 H, m, ArH *o* to SO_2), 7.53 (3 H, broad s, ArH *m* and *p* to SO_2), 5.9–7.4 (2 H, m, ), 1.9 (3 H, d,  , J = 6.8 Hz).[5] *Anal.* calcd. for $C_9H_{10}SO_2$: C 59.34, H 5.49, S 17.58; found: C 59.55, H 5.63, S 17.70.

The white solid obtained from distillation was shown to be 3,4-bis(phenylsulfonyl)hexane (**9**) as a mixture of isomers resulting from dimerization of the β-methylated radical intermediate, mp 112–114°C; ^{1}H nmr: 7.78 (4 H, m, ArH *o* to SO_2), 7.50 (6 H, broad s, ArH *m* and *p* to SO_2), 3.58 (2 H, t, methines α to SO_2), 1.98 (4 H, m, methylene), 0.90 (6 H, 2t, methyls, J = 7.0 Hz). *Anal.* calcd. for $C_{18}H_{22}S_2O_4$: C 59.02, H 6.01, S 17.49; found: C 59.10, H 6.19, S 17.39.

Anodic Oxidation of Propionic Acid Anion[6]

(*C*) In the presence of **1** (1.49 g, 0.03 *M*)

The extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatile components and then at 80°C to give a colourless oil (2.20 g) which on vpc showed two major peaks equal in area and a few other minor peaks. The two major peaks were separated on the Autoprep and shown to be the *meso*- and *dl*-3,4-dicarbomethoxyhexane (**10**) (1.29 g, 64%). Both isomers were oils at ambient temperature. The ^{1}H nmr spectra of the two peaks collected together and collected separately were superimposable and all agreed well with the expected spectrum for **10**: (*meso*, *dl*, and *meso* + *dl*) 3.67 (6 H, s, methoxyls), 2.61 (2 H, m, methines), 1.60 (4 H, m, methylenes), 0.88 (6 H, t, methyls, J = 7.0 Hz). *Anal.* calcd. for $C_{10}H_{18}O_4$: C 59.50, H 8.90; found: (first peak) C 59.62, H 8.79; (second peak) C 60.02, H 8.62; (combined peaks) C 59.21, H 8.67.

(*D*) In the presence of **2** (1.25 g, 0.03 *M*)

The extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatiles, then at 100°C to give 1.34 g of a colourless oil. The vpc of this oil showed two major peaks equal in area, which were separated on the Autoprep and shown to be the *trans* and *cis* isomers[7] of 2,3-diethyl-*N*-ethylsuccinimide (**11**) (0.65 g, 36%). First peak (*trans*-**11**); ^{1}H nmr: 3.55 (4 H, q, N-CH_2CH_3, J = 7.0 Hz), 2.53 (2 H, m, methines), 1.79 (4 H, m, CH_3CH_2CH), 1.15 (3 H, t, NCH_2CH_3, J = 7.0 Hz), 1.00 (6 H, t, CH_3CH_2CH). *Anal.* calcd. for $C_{10}H_{17}NO_2$: C 65.60, H 9.28, N 7.66; found: C 65.53, H 9.30, N 7.82. Second peak (*cis*-**11**); ^{1}H nmr: 3.52 (4 H, q, NCH_2CH_3, J = 7.0 Hz), 2.75 (2 H, m, methines), 1.70 (4 H, m, CH_3CH_2CH), 1.15 (3 H, t, NCH_2CH_3, J = 7.0 Hz), 1.02 (6 H, t, CH_3CH_2CH, J = 7.0 Hz). *Anal.* found: C 65.32, H 9.16, N 7.90.

(*E*) In the presence of **3** (1.00 g, 0.0386 *M*)

The extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatile materials, then at 70°C to give 1.0 g of colourless oil which by vpc was shown to consist of > 90% of an approximately 1:1 mixture of *meso* and *dl* isomers of 2,3-diethylsuccinonitrile (**12**) (total yield 52%). These products could be separated either on the Autoprep or on a silica gel column (hexane/ethyl acetate 4:1). The stereoisomers were indistinguishable by ^{1}H nmr but could be identified tentatively by melting points (8). First peak

[3]The general procedure for the oxidation reaction and initial workup is given elsewhere (1) and includes, after the electrolysis, evaporation of solvents, extraction from water with CH_2Cl_2, and evaporation of CH_2Cl_2.

[4]The substrate concentration in this case was increased to allow separation of some dimer.

[5]The ^{1}H nmr spectrum of the olefinic region and that of the methyl doublet are essentially identical to those regions in the spectrum of crotonic acid.

[6]This run and all subsequent runs were prepared as described in ref. 1 with substitution of the relevant acid for acetic acid.

[7]As utilized previously (1), the *cis* and *trans* isomers can be assigned according to the nmr shifts of the methine protons. As for 2,3-dimethyl-*N*-phenylsuccinimide (7) the methine protons are shifted to lower field for the *cis* isomer and to higher field for the *trans* isomer.

(*meso*-**12**) mp 51–52°C after being treated with a 5% solution of NaOH and sublimed (lit. (8*a*) 45–50°C); ^{1}H nmr: 2.74 (2 H, m, methines), 1.90 (4 H, m, methylenes), 1.20 (6 H, t, methyls, J = 7.0 Hz). *Anal.* calcd. for $C_8H_{12}N_2$: C 70.59, H 8.82, N 20.59; found: C 70.29, H 8.70, N 20.29. Second peak (*dl*-**12**) mp 54–56°C (lit. (8*b*) 56–57°C); ^{1}H nmr: 2.74 (2 H, m, methines), 1.90 (4 H, m, methylenes), 1.20 (6 H, t, methyls, J = 7.0 Hz). *Anal.* found: C 70.28, H 8.72, N 20.36.

(*F*) In the presence of **4** (1.49 g, 0.03 *M*)

The yellow extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatile materials. Increasing the temperature to 100°C gave 1.74 g of viscous slightly yellow oil which showed several minor peaks on the vpc along with a peak having the same retention time as **4** (28%) and the expected doublet of peaks of nearly equal area. These two peaks were separated by preparative tlc (silica gel, hexane/ethyl acetate 4:1) and identified as the *threo* and *erythro* isomers of 3-nitro-4-phenylhexane (**13**) (0.85 g, 41%). First peak (*threo*- or *erythro*-**13**); ^{1}H nmr: 7.25 (5 H, m, Ph), 4.55 (1 H, m, methine α to NO_2), 2.90 (1 H, m, methine α to Ph), 1.60 (4 H, broad m, methylenes), 0.81 (3 H, t, methyl, J = 7.0 Hz), 0.70 (3 H, t, methyl, J = 7.0 Hz); ms *m/e*: 207 $(M)^+$. *Anal.* calcd. for $C_{12}H_{17}NO_2$: C 69.57, H 8.21, N 6.76; found: C 69.88, H 8.42, N 6.81. Second peak (*erythro*- or *threo*-**13**); ^{1}H nmr: 7.19 (5 H, m, Ph), 4.58 (1 H, m, methine α to NO_2), 2.95 (1 H, m, methine α to Ph), 1.82 (4 H, m, methylenes), 0.94 (3 H, t, methyl, 7.0 Hz), 0.74 (3 H, t, methyl, J = 7.0 Hz); ms *m/e*: 207 $(M)^+$. *Anal.* found: C 69.79, H 8.44, N 6.62.

(*G*) In the presence of **5** (1.68 g, 0.03 *M*)

The light yellow extracted oil was distilled at 10^{-2} Torr and 25°C to remove volatile materials (mostly propionic acid) and at 130°C to give 2.18 g of colourless viscous oil which showed three main peaks on the vpc. This oil was separated on a silica gel column (hexane/ethyl acetate 4:1) to give three fractions. The first fraction corresponded to 3-phenylsulfonylhexane (**14**) (1.03 g, 37%) as an oil; ^{1}H nmr: 7.87 (2 H, m, ArH *o* to SO_2), 7.59 (3 H, m, ArH *m* and *p* to SO_2), 2.89 (1 H, m, methine), 1.57 (6 H, m, methylene), 0.97 (6 H, t, methyls, J = 6.8 Hz). *Anal.* calcd. for $C_{12}H_{18}SO_2$: C 63.70, H 7.86, S 14.15; found: C 63.87, H 8.04, S 14.06. The second fraction corresponded to *trans*-1-phenylsulfonyl-1-butene (**15**) (0.566 g, 29%); ^{1}H nmr: 7.87 (2 H, m, ArH *o* to SO_2), 7.58 (3 H, m, ArH *m* and *p* to SO_2), 6.79[8] (2 H, m, ), 2.24 (2 H, m, methylene), 1.02 (3 H, t, methyl, J = 7.0 Hz). *Anal.* calcd. for $C_{10}H_{12}SO_2$: C 61.20, H 6.12, S 16.16; found: C 61.31, H 6.32, S 16.16. The third fraction was a white crystalline compound corresponding to the starting material **5** (0.057 g).

Anodic Oxidation of Isovaleric Acid Anion

(*H*) In the presence of **1** (1.44 g, 0.03 *M*)

The extracted oil was washed with a saturated $NaHCO_3$ solution, then distilled at 10^{-2} Torr and 35°C to remove volatiles and at 75°C to give 3.27 g of a colourless mixture of solid and oil which formed a gel on standing. The vpc of this fraction in ether showed several high vapour pressure peaks and a doublet of peaks of nearly equal area. The gel was repeatedly cooled in a Craig tube and centrifuged at 1500 rpm to give 0.48 g (19%) of a white solid which, after recrystallizing from ethanol, melted at 86.0–87.5°C and was shown to be one isomer of the dialkylation product, dimethyl 2,3-diisobutylsuccinate (**16**); ^{1}H nmr: 3.66 (6 H, s, methoxyls), 2.68 (2 H, m, methines α to carbonyl), 1.59 (6 H, m, methylenes and methines δ to carbonyl), 0.89 (12 H, d, $(CH_3)_2CH$—, J = 5.5 Hz). *Anal.* calcd. for $C_{14}H_{26}O_4$: C 65.08, H 10.14; found: C 64.92, H 10.13. The residual oil contained a trace of the solid by vpc and a second major peak with a longer retention time which was separated on the Autoprep as an oil. This oil was shown to be the other isomer of **16** (0.44 g, 17%); ^{1}H nmr: the same as for the first peak. *Anal.* found: C 64.91, H 10.13.

(*I*) In the presence of **2** (1.25 g, 0.03 *M*)

The extracted oil was washed with a saturated solution of $NaHCO_3$ to remove excess acid, then distilled at 10^{-2} Torr and 25°C to remove volatiles and at 60°C to give 4.65 g of a colourless oil which contained several low vapor pressure components by vpc analysis and a doublet of peaks of nearly equal area at longer retention time. The two slower moving components were separated on the Autoprep as oils and shown to be the *cis* and *trans* isomers of 2,3-diisobutyl-*N*-ethylsuccinimide (**17**) (1.58 g, 66%). First peak (*trans*-**17** (7)); ^{1}H nmr: 3.47 (2 H, q, NCH_2CH_3, J = 7.0 Hz), 2.48 (2 H, m, methines α to carbonyl), 1.70 (6 H, m, methylenes, and methines of isobutyl groups), 1.18 (3 H, t, NCH_2CH_3, J = 7.0 Hz), 0.98 (12 H, d, methyls of isobutyl groups, J = 6.0 Hz). *Anal.* calcd. for $C_{14}H_{25}NO_2$: C 70.40, H 10.45, N 5.86; found: C 70.06, H 10.34, N 5.76. Second peak (*cis*-**17**); ^{1}H nmr: 3.47 (2 H, q, NCH_2CH_3, J = 7.0 Hz), 2.87 (2 H, m, methines α to carbonyl), 1.70 (6 H, m, methylenes and methines of isobutyl groups), 1.18 (3 H, t, NCH_2CH_3, J = 7.0 Hz), 0.98 (12 H, m, methyls of isobutyl groups, J = 6.0 Hz). *Anal.* found: C 70.28, H 10.61, N 5.83.

(*J*) In the presence of **3** (1.0 g, 0.038 *M*)

The extracted oil was washed with a saturated solution of $NaHCO_3$, then distilled at 10^{-2} Torr and 25°C for 6 h to remove volatile materials. Increasing the temperature to 70°C gave a solid which was shown by vpc to be almost pure *meso*- and *dl*-2,3-diisobutylsuccinonitrile **18** in equal amounts (1.10 g, 45%); ^{1}H nmr: 2.70 (2 H, m, methines α to C≡N), 1.02 (6 H, m, methylenes and methines of isobutyl groups), 0.92 (12 H, d of d's, methyls, J = 6.0 Hz). *Anal.* calcd. for $C_{12}H_{20}N_2$: C 75.00, H 10.40, N 14.60; found: C 75.12, H 10.39, N 14.49.

The two components of the mixture were separated on the Autoprep and their ^{1}H nmr spectra were identical with that of the mixture. First peak (*meso*- or *dl*-**18**) mp 104.5–106°C. *Anal.* found: C 75.13, H 10.55, N 14.39. Second peak (*meso*- or *dl*-**18**) mp 94–95°C. *Anal.* found: C 74.80, H 10.37, N 14.71.

(*K*) In the presence of **4** (1.49 g, 0.03 *M*)

The extracted oil was washed with a saturated solution of $NaHCO_3$ to remove excess acid and distilled at 10^{-2} Torr and 25°C for 6 h to remove volatile materials. The viscous residue was distilled in a Späth bulb at 125°C to give 1.3 g of yellow oil which by vpc showed several minor peaks along with three peaks of nearly equal area. The slowest one could not be identified but the other two corresponded to *threo*- and *erythro*-2,7-dimethyl-4-nitro-5-phenyloctane (**19**). These stereoisomers were separated by preparative tlc to give a total yield of 0.60 g (23%) of products. First peak (*threo*- or *erythro*-**19**); ^{1}H nmr: 7.29 (5 H, m, Ph), 4.68 (1 H, m, methine α to NO_2), 3.07 (1 H, m, methine α to Ph), 1.49 (6 H, broad m, methylenes and methines of isobutyl groups), 0.81 (12 H, m, methyls); ms *m/e*: 263 $(M)^+$. *Anal.* calcd. for $C_{16}H_{25}NO_2$: C 73.00, H 9.51, N 5.32; found: C 73.16, H 9.71, N 5.22. Second peak; ^{1}H nmr: 7.20 (5 H, m, Ph), 4.70 (1 H, m, methine α to NO_2), 3.09 (1 H, m, methine α to Ph), 1.55 (6 H, broad m, methylenes and methines of isobutyl groups), 0.88 (12 H, m, methyls); ms *m/e* 263 $(M)^+$. *Anal.* found: C 73.18, H 9.75, N 5.12.

[8]This is assumed to be the *trans* isomer by analogy with **9** since both **9** and **15** are most likely formed by the same mechanism and their ^{1}H nmr spectra in the olefinic regions are nearly identical, being centered around 6.79 ppm.

TABLE 1. Electrochemical oxidation of carboxylic acid anions in the presence of substituted olefinic substrates

$$XCH{=}CHY \xrightarrow[\text{electrolysis}]{RCOO^-} XCH(R){-}CH(R)Y$$

Substrate	%[a] 1,2-dialkylated product[b]		
	R = CH_3	R = CH_2CH_3	R = $CH_2CH(CH_3)_2$

(*L*) In the presence of **5** (1.68 g, 0.03 *M*)

The extracted oil was washed with a saturated $NaHCO_3$ solution and distilled at 10^{-2} Torr and 75°C to remove volatile materials. Further distillation at 150°C gave 2.07 g of a crude viscous slightly yellow oil. This oil was fractionated on a silica gel column (hexane/ethyl acetate 4:1) to give as a first fraction 1.15 g (41%) of a colourless oil corresponding to 4-phenylsulfonyl-2,7-dimethyloctane (**20**); ^{1}H nmr: 7.85 (2 H, m, ArH *o* to SO_2), 7.56 (3 H, m, ArH *m* and *p* to SO_2), 2.90 (1 H, m, methine α to SO_2), 1.48 (8 H, m, methylenes and methines of alkyl chains), 0.85 (12 H, d of d's, unresolved methyls). *Anal.* calcd. for $C_{16}H_{26}SO_2$: C 68.10, H 9.22, S 11.34; found: C 68.26, H 9.40, S 11.50.

A second fraction was obtained in 24% yield (0.528 g) which was shown to be the monoalkylated elimination product, *trans*-1-phenylsulfonyl-4-methyl-pent-1-ene (**21**);[9] ^{1}H nmr: 7.81 (2 H, m, ArH *o* to SO_2), 7.51 (3 H, m, ArH *m* and *p* to SO_2), 6.1–7.3 (2 H, m, $\overset{H}{\diagdown}C{=}C\overset{}{\diagup}$), 1.69 (3 H, broad m, methylene and methine), 0.90 (6 H, d of d's, methyls, J = 6.0 Hz). *Anal.* calcd. for $C_{12}H_{16}SO_2$: C 64.30, H 7.14, S 14.30; found: C 64.45, H 7.32, S 14.24.

The third fraction obtained was identified as the starting material **5** (0.29 g).

Results and Discussion

The electrochemical oxidation of various carboxylic acid anions in the presence of olefinic substrates bearing electron-withdrawing substituents (Table 1) can be seen to give acceptable yields of dialkylated products. The reaction appears to be quite general to a large variety of acids and substrates. While there is a fairly wide variation in the yields obtained from different combinations of acid and substrate, it must be noted that all reactions were carried out under the same experimental conditions, including current and time of electrolysis. The yields obtained in each case are a function of the reactivity of the olefin, the reactivity of the radical, and the tendency for the reagents to undergo side reactions such as (*a*) dimerization by the radicals, (*b*) loss of a second electron by the radicals to form carbonium ions which can react with the solvent, and (*c*) loss of an H atom by the radical intermediate to form the monoalkylated olefin. The conversion of substrate to products was not always quantitative and the unconverted starting material was either recovered or detected in the reaction mixture. This means that the yields of dialkylated products could be increased substantially by the addition of more carboxylic acid and a longer reaction time.

It has been shown previously that for monosubstituted olefins bearing electron-withdrawing groups such as carboxylic esters (9) the initial radical attack occurs at the terminal carbon, β to the electronegative substituents. There has been considerable discussion as to whether this occurs because of stabilization of the resulting α radical by the substituent (product-like transition state) or because of a polar effect guiding the direction of initial attack (transition state similar to starting material) (10). The results obtained from the reaction of **5** with methyl radicals show that the initial radical attack occurs exclusively on the olefinic carbon atom β to the sulfone, since only the β-alkylated elimination (or abstraction) product **8** and the dimer **9**, resulting from combination of two α-sulfonyl radicals, are formed aside from the dialkylated product **7**. The

[9]As for compounds **9** and **15**, the olefinic region in the ^{1}H nmr spectrum of **21** is nearly identical to that of *trans*-crotonic acid.

relative instability of an α-sulfonyl radical is indicated by the large amount of olefinic product **8** formed. These results are an indication that for addition of alkyl radicals to α,β-unsaturated sulfones, the transition state for the first radical addition occurs quite early on the reaction coordinate.

The ratio of *cis* to *trans* addition resulting in *meso/dl* or *threo/erythro* mixtures was approximately 1:1 in all cases and no further effort was made to differentiate between the stereoisomers.

In summary, the electrochemical oxidation of carboxylic acid anions in the presence of olefins bearing electron-withdrawing groups appears to be a useful and unparalleled method of dialkylation of double bonds. Several aspects of this reaction are currently under study and will be reported later. One limitation of the dialkylation reaction appears to be the bulk of the attacking radicals. The formation of isopropyl radicals in the presence of **1** under the present reaction conditions resulted in a yield of < 10% of dialkylation product while *t*-butyl radicals gave very small yields of dimeric and polymeric products.

The structure of an unusual disulfide, formed from reaction between a sulfene–amine zwitterion and thionyl chloride

J. STUART GROSSERT,[1] MADAN M. BHARADWAJ, J. BRIAN FAUGHT, AND ARIS TERZIS[2]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 28, 1978[3]

J. STUART GROSSERT, MADAN M. BHARADWAJ, J. BRIAN FAUGHT, and ARIS TERZIS. Can. J. Chem. **58**, 1106 (1980).

Thionyl chloride has been shown to react with the zwitterion from dimeric sulfene and triethylamine to give bis(methylsulfonyl dichloromethyl) disulfide, **3**. The structure of **3** was determined from its spectral properties and was confirmed by an X-ray crystal structure analysis. Dechlorination of **3** gave bis(methylsulfonylmethyl) disulfide, **4**. Raman spectra of **3** and **4**, as well as of **5** and **6**, two related sulfones derived from 2,4,6-trithiaheptane, are reported.

J. STUART GROSSERT, MADAN M. BHARADWAJ, J. BRIAN FAUGHT et ARIS TERZIS. Can. J. Chem. **58**, 1106 (1980).

On a montré que le chlorure de thionyle réagit avec les paires d'ions du sulfène dimère et la triéthylamine pour conduire au bis(méthylsulfonyle dichlorométhyl) disulfure **3**. On a déterminé la structure du composé **3** à partir de ses propriétés spectrales et on l'a confirmée par une analyse de la structure du cristal à l'aide de rayon-X. La déchloration de **3** donne le bis(méthylsulfonylméthyl) disulfure **4**. On donne les spectres Raman des composés **3** et **4** aussi bien que ceux de **5** et **6** qui sont deux sulfones apparentées provenant du trithia-2,4,6 heptane.

[Traduit par le journal]

Thionyl chloride, **1**, has been shown to react with a wide variety of organic molecules (1, 2). We report here the formation of a novel disulfide, **3**, from the reaction between **1** and a solution of the zwitterion, **2**, formed *in situ* when sulfene dimerizes and complexes with triethylamine (3, 4).

Elemental analysis of **3** required that it be assigned the formula $C_4H_6Cl_4O_4S_4$, which indicates that a reduction at sulfur in the conversion **2** → **3** had occurred. The infrared spectrum showed characteristic sulfonyl stretching bands at 1160 and 1340 cm^{-1}. The presence of a methanesulfonyl group was confirmed by an ^1H nmr singlet at δ 3.30 and a quartet in the off-resonance ^{13}C nmr spectrum at δ 43.8. The latter spectrum showed also a quaternary carbon, bound to electronegative substituents, at δ 109.6. These chemical shifts compare with those of similar compounds (5), and the symmetry of the molecule is clearly shown by the simplicity of the nmr spectra.

The mass spectrum of **3** was in accord with the proposed structure, although no molecular ion could be observed (*vide infra*). The ions at *m/e* 161, 146, and 114 all clearly contained 2 chlorine atoms whereas the ion at *m/e* 79 contained only one chlorine atom. The ions at *m/e* 114 and 79 could reasonably be attributed to the species $CCl_2S^{+\cdot}$ and $CClS^+$ respectively. It is interesting to note that although the peak at *m/e* 79 ($CH_3SO_2^+$) is prevalent in the mass spectra of compounds containing methanesulfonyl groups (5), in this case the peak-height ratio of *m/e* 79:81 corresponds closely to that expected for an ion containing one chlorine atom, which suggests that formation of $CH_3SO_2^+$ is not an important fragmentation in the mass spectrum of **3**. The ions at *m/e* 161, 146, 114, and 79 provide good evidence for the presence of the $CH_3SO_2CCl_2SS$— fragment in **3**. Some similarities in fragmentation patterns have been observed in the mass spectra of bis(trichloromethyl) disulfide (6) and bis(chloromethyl) disulfide.[4]

The ultraviolet spectrum of **3** showed only end absorption. At first sight, this was surprising since most dialkyl disulfides exhibit uv absorption around 250 nm (7–10). However, it may be noted that di-*tert*-butyl disulfide shows only end absorption (8, 9), and that although changes in the torsion angle (ω) about the C—S—S—C bond have a major influence in the value of λ_{max} (9), it is not clear exactly what role the electronegativity of substituents will play. For instance, bis(trifluoromethyl) disulfide has λ_{max} = 237 nm, but this compound has only been studied by electron diffraction in the gas phase (10) and ω has not been determined.

Reductive removal of the chlorines from **3** with a classical HI/P procedure gave **4**. The structure of **4** was apparent from its elemental analysis and from simple ^1H and ^{13}C nmr spectra which required the presence of two $CH_3SO_2CH_2$— groups in a simple, symmetrical molecule. The sulfonyl groups in **4**

were clearly indicated by infrared absorptions at 1305 and 1110 cm^{-1}. The mass spectrum of **4** showed a molecular ion at *m/e* 250 and a base peak at *m/e* 45 (CHS^+). The ultraviolet spectrum of **4** showed a clean absorption maximum at 243 nm.

Although the foregoing evidence constituted reasonable proof for the structure of **3**, it was deemed advisable to undertake an X-ray crystal structure analysis, particularly given the rather novel reaction which led to its formation. The interatomic distances and bond angles in **3** are given in Fig. 1 (see Experimental for structure data). There is good agreement between the dimensions of the two halves of the molecule. Equivalent bond lengths differ by about 1 esd from their average values with the exception of the C—Cl distances which differ by as much as 2.5 esd's.

The C—S—S—C torsion angle in **3**, ω, was found to be 113.3°. Repulsion between the lone-pair electrons on the sulfur atoms in disulfides is expected to be a minimum when ω = 90° (7, 9), although values of ω outside the range of 80–100° are well documented (11, 12).

The S—S bond distance in **3** was found to be 2.018(2) Å which may be compared with the S—S bond distance of 2.060(3) Å in orthorhombic sulfur (13). The S—S bond distance in disulfides is known to depend both on the value of ω and on the electronegativity of the substituents attached to sulfur (12). As in the case of the ultraviolet spectra, it is not clear what role electronegativity of substituents on sulfur will play in affecting bond length of disulfides since, unlike the relation between ω and bond length (12), no systematic study of this relationship appears to have been reported. However, the S—S bond distance in **3** is quite reasonable when compared with values of 2.05 ± 0.019 Å

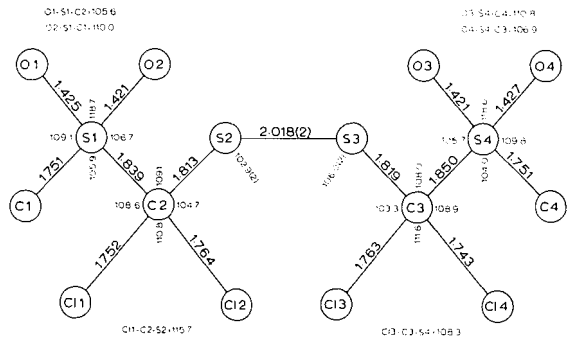

FIG. 1. Numbering and structural parameters for bis(methylsulfonyldichloromethyl) disulfide, **3**. Bond lengths (Å) and bond angles (°) of the non-hydrogen atoms are shown. The error in bond lengths and bond angles is 0.005 Å and 0.3° respectively, unless otherwise noted in parentheses.

found for bis(trifluoromethyl) disulfide (10) and 2.022(2) or 2.012(2) Å for bis(succinimidoyl) disulfide (14). These are examples of disulfides with substituents of greater electronegativity than alkyl groups.

It is noteworthy that three sets of C—S bond lengths were observed in **3** and that the differences between the sets are significant. The sum of the covalent radii of carbon and sulfur is 1.81 Å (15), and the average bond length of 1.816(2) Å observed for C(2)—S(2) and C(3)—S(3) is not significantly different. The longest C—S bond distance in **3** was observed for the equivalent C(2)—S(1) and C(3)—S(4) bonds which average 1.845(5) Å. This is consistent with the nonobservance of a molecular ion in the mass spectrum of **3**; in fact, the ion at highest *m/e* (307) corresponds to $M^{\ddagger} - CH_3SO_2$, i.e. to cleavage of the C(2)—S(1) or C(3)—S(4) bond.

In recent years, the value of the S—S stretching frequencies of disulfides, as observed in the Raman spectrum, has become increasingly important in correlations with the disulfide structure (7, 16). Most disulfides show the S—S stretching frequency as an intense band in the range of 510–540 cm^{-1}, and this value has been correlated with the magnitude of the C—S—S—C torsion angle, ω (16). Since compounds **3** and **4** represent disulfides with novel substituents, it was deemed worthwhile to examine their Raman spectra. It appeared that the appropriate bands were present, but since assignment of these bands is not always straightforward (17), the Raman spectra of the cor-

*Absorption maxima are reported in units of cm^{-1}; intensities (in parentheses) are given using standard abbreviations.
†Ms = $MeSO_2$.
‡Both these two bands were shown to be strongly polarized when the spectrum was studied using a benzene solution of **3**.

responding sulfones **5** and **6** derived from 2,4,6-trithiaheptane (5) were run also. The results are recorded in Table 1. From these it is apparent that a clear-cut assignment of the S—S stretching frequency in **3** and **4** is not a simple problem, and the obvious cautionary note about making untested assignments of such peaks in molecules with more complex functionalities should be made. Similar problems have been encountered previously, even with relatively simple dialkyl disulfides (18).

In conclusion, it is intriguing to speculate on the mechanism by which **3** may be formed. It is probable that initial reaction between **2** and **1** yields an intermediate,**7**, conversion of which into the sulfenyl chloride, **9**, can be postulated to proceed via **8**. The conversion **7** → **8** is supported by the work of Krubsack and co-workers (2),[5] whereas the desulfonylation **8** → **9** has a precedent in work by Fusco *et al.* (19). Reduction of sulfenyl chlorides to disulfides (**9** → **3**) is amply documented (8).

Experimental

General

Most details have been provided previously (5). The Raman spectra were run in the solid phase using an Argon ion laser at 4880 Å excitation in conjunction with a Spex 1401 double monochromator.

Preparation of Bis(methylsulfonyldichloromethyl) Disulfide, 3[6]

A solution of triethylamine (20.7 mL, 0.15 mol) in acetonitrile (100 mL) was cooled to −40°C. With continuous stirring, a solution of methanesulfonyl chloride (7.8 mL, 0.1 mol) in acetonitrile (15 mL) was added over a 30-min period, and the mixture was stirred for a further 2 h. The mixture was filtered rapidly, purified thionyl chloride, **1**, (20) (25 mL) was added to the filtrate, and the resulting solution was stirred at room temperature for 15 h. The solvent was rotary evaporated to give a yellow solid which was partitioned between $CHCl_3$ and water. The $CHCl_3$ extract (washed and dried) gave a yellow oil which crystallized from MeOH to give **3** as colorless plates,yield 4.6 g, 47%, mp 119–120°C; ir(KBr) ν_{max}: 3030 w, 2940 w, 2930 w, 1320 vs, 1145 vs, 955 m, 940 m, 780 m, 695 m cm^{-1}; for Raman spectrum see Table 1; uv showed only end absorption; for nmr see text; ms *m/e*: 313(2.2), 311(7.8), 309(13.3), 307(10.7), 163(5.6), 161(7.1),. 151(7.1), 149(8.9), 148(3.3), 147(6.7), 146(4.4), 116(6.6), 114(8.9), 111(22.2), 95(17.3), 81(33.2), 79(100), 63(28.0), 48(14.4), 47(26.6), 45(17.8), 44(13.7), 38(8.9), 36(26.6); *Anal.* calcd. for $C_4H_6Cl_4O_4S_4$: C 12.38, H 1.56, Cl 36.53, S 33.04%, M 388.13; found: C 12.28, H 1.46, Cl 37.06, S 33.08%, M (cryoscopic) 380.

Crystal Data of 3

$C_4H_6Cl_4O_4S_4$ fw = 388.14

Orthorhombic, a = 20.999(3), b = 12.347(2), c = 10.585(1) Å, V = 2744.4 Å^3, Z = 8, ρ_c = 1.878 g cm^{-3}, (18°C, CuK_α, λ = 1.54051 Å).

Preliminary photographic data showed the crystals to be orthorhombic, with the following systematic absences: *h*0*l*, $l = 2n + 1$; *hk*0, $h = 2n + 1$; 0*kl*, $k = 2n + 1$. These absences uniquely identify the space group as P_{bca} (No. 61).

Data were collected from a crystal (0.13 × 0.11 × 0.18 mm) mounted with the *c* axis nearly parallel to the ϕ axis of a Picker FACS-1 automatic diffractometer, fitted with a graphite monochromator. The reflections were measured using the θ–2θ scan technique from a point 0.95° below the calculated 2θ position for $CuK_{\alpha 1}$ to 0.95° above the position calculated for $CuK_{\alpha 2}$ at the rate of 1° min^{-1}. Stationary-crystal, stationary-counter background counts of 20 s were recorded at each limit of the scan range. During the data collection, three standard reflections were measured at a period of 30 reflections. The intensity of 2 1 7 decreased by 32%, 8 7 3 by 40%, and 12 4 0 by 21%. A linear correction factor was applied to the data. A total of 2378 intensity measurements were recorded in the form *hkl* with $2\theta < 120°$ and reduced to a set of 2041 independent reflections. The integrated intensity was calculated as

$$I_{(net)} = I_{(scan)} - 0.5(t_T/t_B)(B_1 + B_2)$$

where $I_{(scan)}$ is the number of counts over the scan range, t_T is the scan time, t_B is the time for each background count B_1 and B_2. The standard deviations $\sigma(I)$ were calculated according to the expression

[5]We thank a referee for pointing out that although the conversion $R.SO_2\overset{+}{N}R_3' \rightarrow R.SO_2Cl$ has apparently not been reported on, it has been observed in the referee's laboratory.

[6]This compound may be named as 3,3,5,5-tetrachloro-2,4,5,7-tetrathiaoctane-2,2,7,7-tetraoxide also. Naming it as a disulfide has merit in that it draws attention to the dominant functional group.

*The form of the anisotropic vibration is $\exp[-2\pi^2(a^{*2}h^2U_{11} + \ldots + a^*b^*hkU_{12} + \ldots)]$.

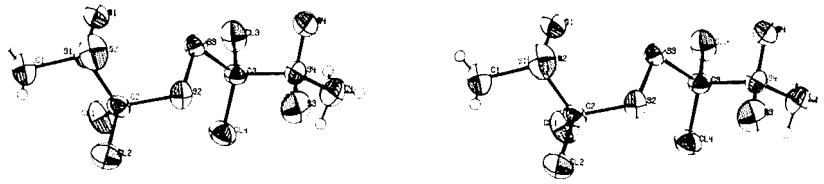

FIG. 2. A stereoscopic view of bis(methylsulfonyldichloromethyl) disulfide, **3**, showing ORTEP-generated 50% probability ellipsoids.

$$\sigma(I) = [N_T + 0.25\, t_T/t_B\,(B_1 + B_2) + C(I)^2 + 0.01^2\,(I - I_c)^2]^{1/2}$$

where N_T is the total net integrated scan count obtained in the time t_T, C is a factor to account for, among other things, instrument stability during data collection (for this structure C was 0.035), I is the net intensity, and I_c is I corrected for absorption. The last term in the expression is a factor accounting for errors in the absorption correction.

An absorption correction[7] was applied and the calculated transmission coefficients based on a linear absorption coefficient of 132.7 cm^{-1} for CuK_α radiation ranged from 0.210 to 0.346. Lorentz and polarization corrections were applied; 1522 reflections with $I > 2\sigma(I)$ were used in the refinement of the structure.

Solution and Refinement of the Structure of 3

The structure was determined using the direct-phasing program MULTAN (22). Two solutions were attempted from seven starting phases and the correct solution was chosen from the lowest Karle R factor. From the E-map all but two non-hydrogen atoms were located. These two atoms were found from the subsequent Fourier map, phased on the trial structure. A structure factor calculation based on this model gave a conventional R factor of 0.21 where

$$R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$$

Temperature and scale factors were taken from the Wilson plot. Block-diagonal, (9 × 9) least-squares refinement with unit weights and isotropic thermal parameters for all non-hydrogen atoms converged at $R = 0.124$. Refinement, minimizing $\Sigma(w|F_o| - |F_c|)^2$, was continued with anisotropic thermal parameters for the chlorine and sulfur atoms, and isotropic thermal parameters for the oxygen and carbon atoms. A weighting scheme was introduced ($w = 1/[\sigma^2(F_o)]$) as well as a secondary extinction correction (26). The R factor at convergence was 0.065. The inclusion of anisotropic thermal parameters for all atoms except the two methyl carbon atoms reduced R to 0.057. After final refinement, positional and anisotropic thermal parameters for all non-hydrogen atoms, and positional and isotropic thermal parameters for the six hydrogen atoms were calculated when $R = 0.057$. The six hydrogen atoms were located by a difference Fourier synthesis. The final R index on data with $I > 2\sigma(I)$ was 0.037; R_2, defined as $([\Sigma(w|F_o| - |F_c|)^2]/[\Sigma w|F_o|^2])^{1/2}$ was 0.048. The final "goodness of fit", $\{[\Sigma(w|F_o| - |F_c|)^2]/(m - n)\}^{1/2}$ was 0.83, where m is the number of observations and n is the number of refined parameters. The scattering factors for all atoms were taken from Cromer and Mann (27). Sulfur and chlorine were corrected for the real part of the anomalous dispersion (28).

Atomic positions and thermal parameters for the non-hydrogen atoms of **3** are presented in Table 2. Table 3, containing the hydrogen atom positional and thermal parameters, as well as bond lengths and angles involving hydrogen, Table 4, the structure factor table, and Table 5, the correct starting set of reflections with their phases, are in the Depository of Unpublished Data.[8] The bond lengths and angles for non-hydrogen atoms in **3** are detailed in Fig. 1. Figure 2 shows a stereoscopic view of **3**, and Fig. 3 gives a stereoscopic view of the molecular packing.

[7]The computer programs used were locally modified versions of the following: NRC-2 (data reduction) (21); NRC-3 (absorption correction) (21); MULTAN (22); FORDAP (23); NUCLS (24); ORTEP (25).

A high field proton magnetic resonance study of the solution conformation of thromboxane B_2[1]

GEORGE KOTOVYCH[2] AND GERDY H. M. AARTS
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 12, 1979

GEORGE KOTOVYCH and GERDY H. M. AARTS. Can. J. Chem. **58**, 1111 (1980).

The solution conformation of thromboxane B_2 (TXB_2) has been studied using high-field nuclear magnetic resonance techniques. In $CDCl_3$, both anomers are present in solution with 76% 11α-OH TXB_2 and 24% 11β-OH TXB_2. In CD_3OD, the predominant anomer is 11β-OH TXB_2 (80%) while the concentration of 11α-OH TXB_2 is 20%. The proton resonances were assigned at 400 MHz using double resonance techniques. The analysis of the vicinal coupling constants indicates that the six-membered ring is present in solution in a chair conformation with both of the aliphatic side chains equatorial. Proton longitudinal relaxation times were measured at 25°C in $CDCl_3$ for H-2, H-11β, H-12, H-13, H-14, and H-17 to H-19, both at 200 MHz and at 400 MHz. From the frequency dependence of these dipolar relaxation times, the rotational correlation times were evaluated. Within experimental error, all of the values are similar in magnitude ($\sim 2.0 \times 10^{-10}$ s) indicating that this is the molecular rotational correlation time.

GEORGE KOTOVYCH et GERDY H. M. AARTS. Can. J. Chem. **58**, 1111 (1980).

On a étudié la conformation du thromboxane B_2 (TXB_2) en solution, en utilisant les techniques de rmn à haut champ. Les deux anomères sont présents en solution dans le $CDCl_3$ dans la proportion de 76% de OH-11α TXB_2 et 24% OH-11β TXB_2. Dans le CD_3OD, l'anomère prédominant est le OH-11β TXB_2 (80%), le OH-11α TXB_2 est à une concentration de 20%. On a attribué les résonances du proton à 400 MHz en utilisant les techniques de double résonance. L'analyse des constantes de couplage vicinal indique que le cycle à 6 chaînons est présent en solution sous une conformation chaise avec les deux chaînes latérales aliphatiques en position équatoriale. On a mesuré les temps de relaxation longitudinale du proton à 25°C dans le $CDCl_3$ pour H-2, H11β, H-12, H-13, H-14 et de H-17 à H-19 à 200 et à 400 MHz. A partir de l'effet de la fréquence sur les temps de relaxation dipolaire, on a évalué le temps de corrélation rotationnelle. A l'intérieur des erreurs expérimentales, toute les valeurs sont du même ordre de grandeur ($\sim 2 \times 10^{-10}$ s) indiquant ainsi qu'il s'agit du temps de corrélation rotationnelle moléculaire.

[Traduit par le journal]

Introduction

The metabolic pathway of arachidonic acid involves the formation of cyclic endoperoxides which are rapidly converted into thromboxane A_2 (TXA_2), prostacyclin, and other prostaglandins (1, 2). TXA_2 was identified by Samuelsson and coworkers (2) (Fig. 1) and is a highly unstable compound. It has a half life of about 30–40 s before its conversion to thromboxane B_2 (TXB_2). TXA_2 possesses pronounced biological activity, and thromboxanes have been identified in many tissues including platelets, leucocytes, spleen, inflammatory granuloma, brain, and kidney (3). They are of considerable pathophysiological interest in thromboembolic diseases, anaphylactic reactions, and have a physiological role in normal hemostatis. TXA_2 is a strong platelet aggregating factor (3). In contrast, prostacyclin, which has been isolated and its structure has been determined (4, 5), is able to disaggregate platelets after the induction of platelet aggregation by ADP or arachidonic acid (5).

Because of the diverse functions of these prostaglandins, we have carried out a study of the conformation of TXB_2 using high field nuclear magne-

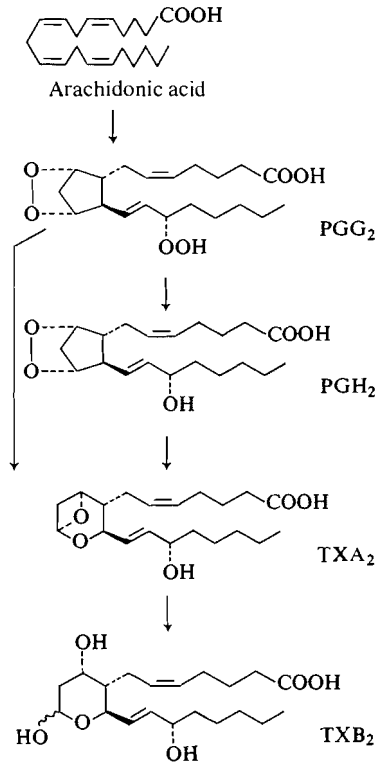

FIG. 1. The conversion of arachidonic acid to TXB_2.

tic resonance (nmr) techniques. As the lifetime of TXA_2 is too short for these studies, the present studies have centred on TXB_2. The detailed solution conformation may serve as an aid in the understanding of the action of TXA_2. In a related study, the conformation of prostacyclin has also been reported (6). In the solid state, diffraction experiments have shown that for TXB_2 there are two crystallographically independent molecules in the unit cell (7). The α chains (at C-8) are bent sharply in the middle and the carboxyl group is positioned either above or below the mean plane of the rest of the molecule.

In a recent review article (8), nmr data on thromboxanes were not mentioned. In the discussion of the synthesis of TXB_2 (ref. 5, pp. 103–113), Nelson *et al.* discussed the equilibrium of the α- and β-hydroxy forms that lead to a mixture of C-11 epimers in solution. From ^{13}C nmr data for TXB_2 in $CDCl_3$ (with a few percent of CD_3OD), about 35% of the α-hydroxy anomer and 65% of the β-hydroxy anomer were found. But detailed nmr studies of the proton chemical shifts, coupling constants, and proton longitudinal relaxation rates have not been carried out. However, Conover and Fried (9) have measured the proton chemical shifts for $PGF_{2\alpha}$ in phosphate buffer together with the proton–proton coupling constants for the cyclopentane ring. The magnitudes of the coupling constants were analyzed using the Karplus equation, and a half-chair conformation was proposed for this prostaglandin with only the hydroxyl group at C-9 in the pseudo-axial orientation.

In the present study, the conformation of the sugar-like TXB_2 six-membered ring is analyzed on the basis of the vicinal proton–proton coupling constants. Both 11α-OH TXB_2 and 11β-OH TXB_2 are present in solution and the concentrations of the two anomeric forms are determined from the spectra, both in CD_3OD and $CHCl_3$. The individual protons are assigned using double resonance techniques. As well, correlation times of individual protons in the molecule are determined from the measurement of the frequency dependence of the proton relaxation rates.

Materals and Methods

Thromboxane B_2 was a gift from Dr. John Pike, the Upjohn Co., Kalamazoo, MI. The thromboxane B_2 solutions were prepared in $CDCl_3$, 99.8% deuterated (from SCI-Graphics) at a concentration of approximately 2 mg per 0.35 mL $CDCl_3$. For the relaxation time measurements two concentrations, 4 mg and 2 mg per 0.35 mL of $CDCl_3$ were used. All materials were handled in a dry box in a nitrogen gas atmosphere. The $CDCl_3$ was purified by treating it with Al_2O_3 (B.D.H. Chemicals) and then vacuum degassing it several times (freeze–pump–thaw technique). The thromboxane was dried *in vacuo* overnight at a temperature of 60°C. The purified solvent was added to the dried thromboxane, the solution was then transferred to an nmr tube, and was vacuum degassed several times using the freeze–pump–thaw technique. Subsequently, the nmr tube was sealed. For all of the above experiments, the glassware was cleaned extensively to eliminate paramagnetic impurities. The same procedure was used in preparing the CD_3OD (from SCI-Graphics) solutions, except the treatment with Al_2O_3 was omitted.

The nmr measurements were carried out at 298 K using the Bruker WH-400/DS and the Bruker WH-200/DS nmr spectrometers operating at proton frequencies of 400 and 200 MHz, respectively. The experiments were carried out in the pulsed Fourier transform mode using the Bruker Aspect 2000 computer, 16K data points, and a pulse width of 5 μs (pulse angle = 42°) for the determination of the chemical shifts and coupling constants at 400 MHz. The repetition time of the pulse cycle was 2.0 s. The deuterium resonance of the solvents was used as the lock signal. The homonuclear decoupling experiments were performed in the pulsed mode using the same pulse width. The chemical shifts and coupling constants were calculated to first order and are reported with an accuracy of about 0.010 ppm (±4 Hz at 400 MHz) and about 0.20 Hz, respectively. For maximum accuracy, spectra were expanded to a width of 2 Hz/cm, the peaks were then bisected by vertical lines and from these spectra average values of chemical shifts and coupling constants were determined.

The proton longitudinal relaxation rates were obtained at both frequencies using the 180°–τ–90° inversion recovery sequence (10). Delay times of 12 s at 400 MHz and 10 s at 200 MHz were used. Usually 10 τ values were included in the analysis of the data, based on the initial slope of a plot of $\ln((M_\infty - M_\tau)/(M_\infty))$ vs. τ. In this plot, M_∞ is the equilibrium value of the magnetization and M_τ is the value of the magnetization at time τ between the 180° and 90° pulse sequence. These M values were obtained from the measurement of the sum of the peak heights of a multiplet corresponding to a given proton. Three M_∞ values were always measured for maximum accuracy and 30–50 scans were used for these measurements. The relaxation rates were obtained from a computer analysis of the data using a least-squares program. The T_1 values are reproducible from one sample to a second sample with an accuracy of ±5% at 400 MHz and ±10% at 200 MHz. Some overlap of multiplets corresponding to different protons was observed, mainly at 200 MHz, and hence the larger error limits at this frequency. Data are not reported where there was significant overlap of resonances corresponding to different protons. The one exception is for protons 17–19, which have identical chemical shifts. The relaxation rate for these protons is reported as it provides a probe of the mobility of this side chain.

Results

The complete 400 MHz proton magnetic resonance spectra of TXB_2 in $CDCl_3$ and CD_3OD are shown in Fig. 2. From the spectra (Figs. 2 and 3), it can be seen that both the α- and β-anomers are present in solution. In $CDCl_3$, the predominant anomer has the OH group at C-11 in the α configuration, hence H-11 is β to the ring (Fig. 4). In CD_3OD, the OH group at C-11 in the predominant anomer has the β configuration. The proton resonances were assigned on the basis of homonuclear proton decoupling experiments. Proton resonances corresponding to the minor anomers in $CDCl_3$ are

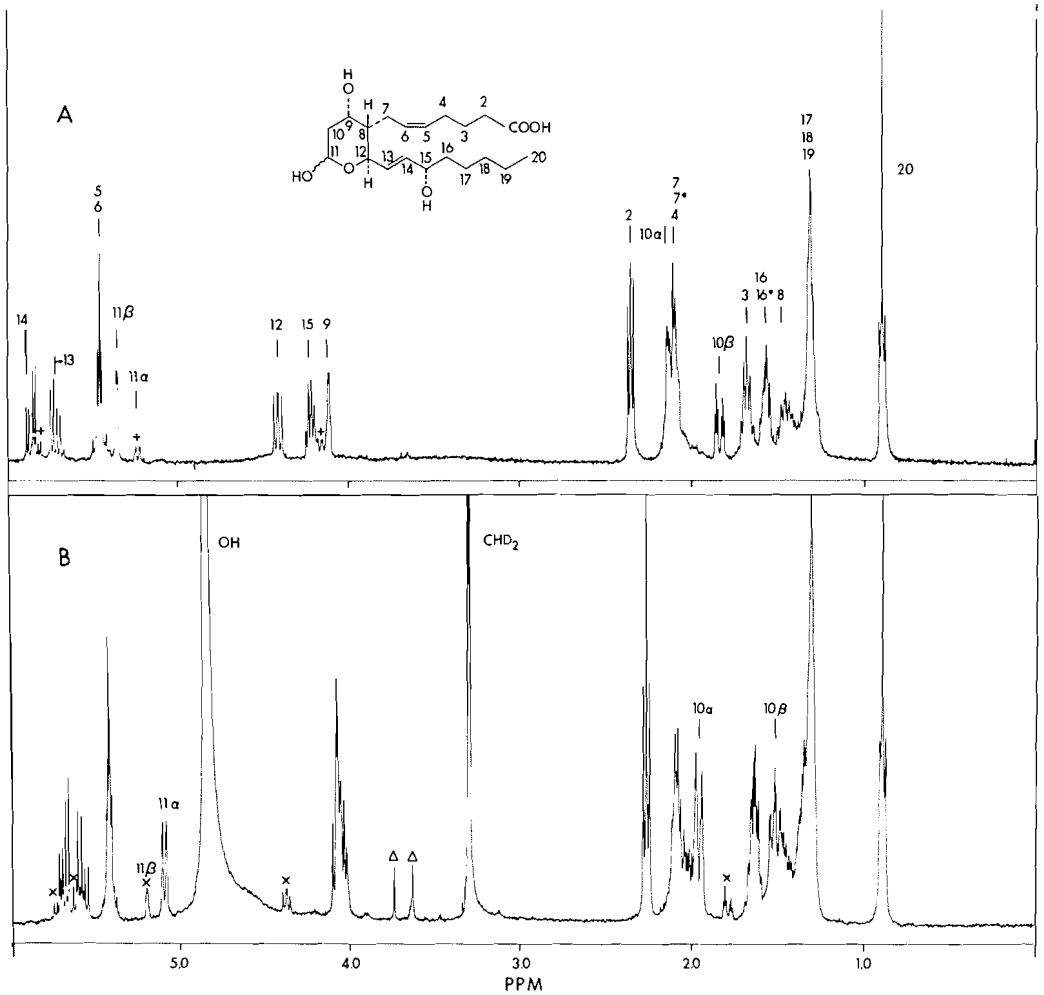

FIG. 2. A. The 400 MHz proton magnetic resonance spectrum of TXB_2 in $CDCl_3$. The assignment of the proton resonances is shown in the figure. Peaks indicated by a + are from the minor anomer. B. The 400 MHz proton magnetic resonance spectrum of TXB_2 in CD_3OD. Peaks indicated by an × are due to the minor anomer. The Δ represents artifacts.

indicated by a (+) in Fig. 2A and in CD_3OD by a (×) in Fig. 2B.

The chemical shifts and coupling constants for TXB_2 in $CDCl_3$ are listed in Table 1. TXB_2 is present in $CDCl_3$ solutions mainly as the 11α-OH TXB_2 anomer. Integration of the 11α and 11β proton resonances (Fig. 2A) indicates that the major anomer is present at a concentration of 76% while the minor anomer is present at a concentration of 24%. On the other hand, when CD_3OD is used as the solvent (Fig. 2B), the concentration of the 11α-OH anomer drops to 20% while the predominant anomer is now 11β-OH at a concentration of 80%.

A wide range of decoupling experiments were performed but only several representative experiments will be described. Decoupling of H-15 (4.22 ppm) in $CDCl_3$ solution yields a quartet for H-14 (5.86 ppm) due to the couplings J(13—14) and J(12—14). This experiment (Fig. 3B) also allows the assignment of the protons at C-16 (1.56 ppm) and establishes the chemical shift of H-14 for the minor anomer. Irradiation of H-11β allows the assignment of H-10α at 2.11 ppm and H-10β at 1.84 ppm. Then irradiation of H-12 (4.41 ppm) results in a doublet for H-13 and a change in the H-8 multiplet. The exact chemical shift of H-8 (1.48 ppm) was established by irradiating this multiplet over a range of frequencies until maximum decoupling for H-9 and H-12 was observed. Irradiation of H-2 (2.35 ppm) results in the assignment of H-3 at 1.68 ppm.

Upon irradiating the region between 2.1 and 2.2 ppm, the following changes in the spectrum were observed (Fig. 3C): a singlet for H-5 and H-6;

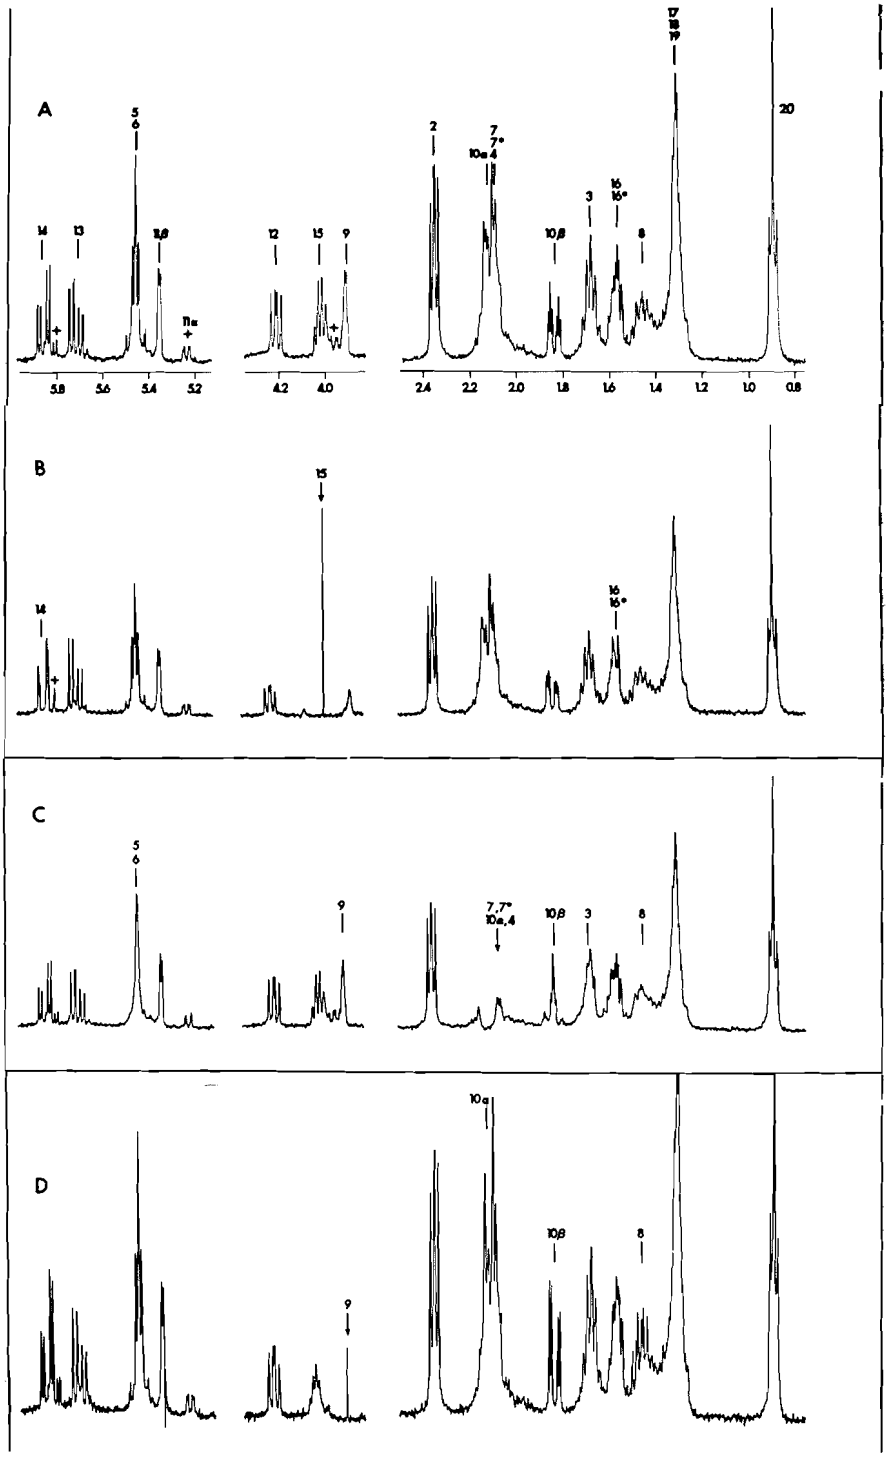

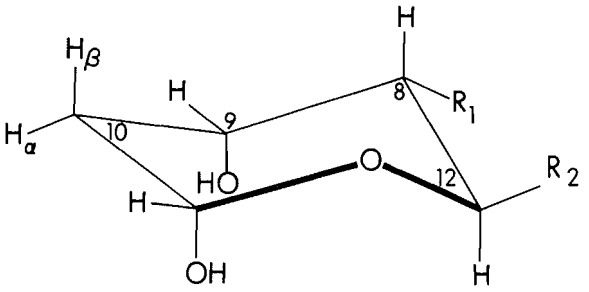

FIG. 3. Results of the proton homonuclear decoupling experiments on TXB_2 in $CDCl_3$ at 400 MHz. Spectrum A is the normal spectrum. In spectrum B, the H-15 multiplet is decoupled; in spectrum C, the region between 2.1 and 2.2 ppm is decoupled; whereas in spectrum D, the H-9 multiplet is irradiated.

11α-OH TXB_2

FIG. 4. The conformation of the predominant anomer of TXB_2 in $CDCl_3$, 11α-OH TXB_2. This is the conformation of the minor anomer in CD_3OD. The symbols R_1 and R_2 are: R_1 = —CH_2CH=$CHCH_2CH_2CH_2COOH$; R_2 = —CH=CH—$HC(OH)CH_2$-$CH_2CH_2CH_2CH_3$.

a sharpening of the resonances assigned to H-11β and H-11α, a singlet for H-9 (4.11 ppm), and a simplification of the H-10β, the H-3, and the H-8 multiplets. This arises since 5 protons are in this region. Finally, irradiation of H-9 (Fig. 3D) affects the H-8, H-10α, and the H-10β resonances and confirms their assignment.

Decoupling experiments were also performed on TXB_2 in CD_3OD and several of these will be summarized. When H-11α is irradiated, then H-10α and H-10β are identified for the 11β-OH anomer. This allows the measurement of J(10α—10β) and J(9—10α) and J(9—10β). When H-10α is irradiated, then H-11α collapses to a doublet, corresponding to J(10β—11α). The H-10β resonance also changes, giving a doublet of doublets, thus confirming the coupling J(9—10β) and J(10β—11α). Detailed measurements in CD_3OD were carried out only on the protons affected by the change of configuration at the anomeric center, and these data on the chemical shifts and coupling constants are presented in Table 2.

The results of the proton longitudinal relaxation time measurements, both at 200 MHz and at 400 MHz, are given in Table 3. The experiments were carried out on TXB_2 solutions in $CDCl_3$ at two concentrations, namely 2 mg and 4 mg per 0.35 mL of $CDCl_3$. The lowest possible concentrations were used so that only intramolecular dipolar interactions would be important. Relaxation mechanisms due to paramagnetic impurities have been minimized by careful cleaning of all glassware and the degassing of all samples. The deuterated solvent was used to eliminate solute–solvent dipolar interactions. The initial slope approximation was used in the analysis of the data. The sum of all the

[a]The chemical shifts and coupling constants are obtained from a first order analysis of the spectra. Internal TMS was used as the reference compound.
[b]Could not be measured due to multiplet overlap.

lines of a multiplet corresponding to a given proton was used to obtain the total intensity at a given τ value (11), as required for a coupled system. Consequently, the initial rates are very nearly equal to $1/T_{1D}$, where T_{1D} is the longitudinal relaxation time due to the intramolecular dipolar interaction. As the spin rotation mechanism must be considered in the relaxation of the methyl protons, the relaxation of these protons is not considered in the present study.

The frequency dependence for $1/T_{1D}$ has been worked out by Solomon (12) for two interacting spins, and equations for $1/T_{1D}$ relaxation in the general case have also been worked out (13, and references therein). When relaxation rates at two frequencies are known, for example at 200 MHz and at 400 MHz, the rotational correlation time τ_R for a given proton can be evaluated from a plot of τ_R vs the $T_{1D}(400)/T_{1D}(200)$ quotient. This plot has previously been applied to the analysis of relaxation times of Vitamin D derivatives (14). Using the calibration graph published previously (14), the correlation times for the protons listed in Table 3 were evaluated. These range from 1.7 to 2.2 × 10^{-10} s for all protons listed in the table at both TXB_2 concentrations. The one exception is for protons 17–19 at the lower TXB_2 concentration, where only a small frequency dependence for T_{1D} was observed, and a correlation time of ~1 × 10^{-10} s is calculated. In addition, these protons have the same chemical shift and this may affect the relaxation times. Hence, within experimental error, the correlation times for the measured protons are all equal. The error limits for the correlation times were obtained by taking the $T_{1D}(400)/T_{1D}(200)$ quotient ±15%, and evaluating the upper and lower limit values for the correlation times. These are given in Table 3. The value of ±15% was chosen, since the uncertainty in the T_1 data at 200 MHz is about 10%, and at 400 MHz it is about 5%.

Discussion

The H-11α multiplet is to high field of the H-11β multiplet in both solvents (Fig. 2). As well, H-10α resonates to low field of the H-10β. These results are consistent with the observation for carbohydrates that equatorially oriented protons resonate at lower field than chemically similar but axially oriented protons (15). As well, when a proton under consideration is axial, a shift of 0.30 ppm to low field is observed for each neighboring axial hydroxyl group in D_2O. In the present study, the 10β proton in CD_3OD resonates at 1.80 ppm for the 11α-OH TXB_2 anomer (11α-OH is axial) but shifts

to 1.52 ppm in the 11β-OH TXB_2 anomer (shift difference = 0.28 ppm). This is in excellent agreement with the predicted chemical shift difference.

Coupling constants for vicinal hydrogens are related to the torsion angle and Karplus (16, 17) has proposed a relationship of the form $^3J(H1, H2) = a \cos^2 \phi + b$ for saturated systems (H1—C1—C2—H2), where ϕ is the angle between the H1—C1—C2 and the H2—C2—C1 planes, and a and b are constants for the particular system under study. Other forms of this equation have been proposed but in all cases these equations must be used with care in determining torsion angles from coupling constants due to the difficulties in determining values for the constants for any one specific kind of structure (17, 18). Observed values of vicinal coupling constants for chair forms of a variety of carbohydrates have been tabulated (19). Coupling constants between vicinal diaxial protons have a mean value of 9.63 Hz and a range from 8.6–11.5 Hz, between diequatorial protons the mean value is 1.54 Hz (the range is 0.6–3.5 Hz) while the coupling constants between an axial proton and an equatorial proton fall in the range 1.5–5.8 Hz with a mean value of 3.66 Hz.

The vicinal coupling constants presented in Tables 1 and 2 indicate that TXB_2 is present in solution with the six-membered ring in a chair conformation and with both side chains equatorial. For 11α-OH TXB_2 (Tables 1*A* and 2*A*), the large values of 10.5 Hz for $^3J(8—12\alpha)$ in $CDCl_3$ and 9.8 Hz in CD_3OD indicate that these protons are diaxial and the dihedral angle involving these protons is close to 180°. Similarly, for 11β-OH TXB_2 the $^3J(10\beta—11\alpha)$ coupling constant is 9.4 Hz in $CDCl_3$ and 9.7 Hz in CD_3OD (Tables 1*B* and 2*B*). The magnitudes of J(axial–equatorial) and J(equatorial–equatorial) are as expected for both anomers in both solvents.

The results of the proton longitudinal relaxation time measurements are presented in Table 3. As expected, when the concentration of TXB_2 is doubled, the T_{1D} values decrease uniformly. This is due to intermolecular association which has been previously observed (9) for ^{13}C T_1 data on $PGF_{2\alpha}$. From the frequency dependence of the data, correlation times ranging from 1.7×10^{-10} to 2.2×10^{-10} s were evaluated for the protons listed in the table. These correlation times are similar in magnitude, within experimental error, at both TXB_2 concentrations. These data indicate that the molecular rotational correlation time is $\sim 2.0 \times 10^{-10}$ s.

Finally, the conformation of 11α-OH TXB_2 (Fig. 4) as determined in this study should be similar to that expected for TXA_2 since both bonds in the latter compound (Fig. 1) from the C-9 and C-11 carbon atoms to the bridging oxygen atom are α to the ring. The major anomer in $CDCl_3$ also has both of the C-9 and C-11 OH groups α to the ring.

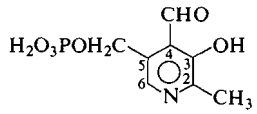
The binding of Co(II) to pyridoxal phosphate (PLP) at neutral pH was investigated with ^{31}P, ^{1}H, and ^{13}C nmr spectroscopy. The proton and phosphorus spin–lattice relaxation times of PLP were measured in the absence of Co(II) and with increasing amounts of the metal ion. The shifting and the relaxation enhancement of the phosphorus resonance in the presence of Co(II) have indicated the binding of the metal ion to the phosphate of PLP. The addition of metal ion also shifted and broadened the proton and carbon resonances. The shifting and broadening was the largest for the 4-CHO proton with other protons following the order 4-CHO ≫ 2-methyl > 5-methylene > 6-H. At neutral pH Co(II) shifted only the 5-methylene proton resonance of pyridoxamine phosphate (PMP) indicating binding of Co(II) only to the 5′-phosphate of PMP at this pH. Comparison of the shifting and broadening of the proton resonances of PLP with similar shifts in model compounds has indicated a structure for the 1:1 PLP:Co(II) complex in which the metal ion is simultaneously bound to the phosphate and the aldehyde oxygen. The proton spin–lattice relaxation times and the isotropic shifts of the ^{13}C resonances in the 1:1 PLP:Co(II) complex support this conclusion.



TENKASI S. VISWANATHAN et TERRENCE J. SWIFT. Can. J. Chem. **58**, 1118 (1980).

On a étudié le mode de liaison du Co(II) avec le phosphate de pyridoxale (PPL) à pH neutre en utilisant la spectroscopie de rmn du ^{31}P, du ^{1}H et du ^{13}C. On a mesuré les temps de relaxation spin–réseau du proton et du phosphore du PPL en l'absence de Co(II) et avec les quantités croissantes d'ion métallique. Le déplacement chimique et l'accroissement de relaxation de la résonance du phosphore en présence du Co(II) indiquent que l'ion métallique se lie au phosphate de PPL. L'addition de l'ion métallique provoque également un déplacement et transforme en massif la résonance du proton et du carbone. Cet effet de déplacement et d'élargissement est maximal dans le cas du proton du CHO en position 4 et décroît dans l'ordre CHO ≫ méthyl-2 > méthylène-5 > H-6. A pH neutre, le Co(II) ne déplace que la résonance du proton du méthylène en position 5 du phosphate de pyridoxamine indiquant ainsi que le Co(II) n'est lié qu'au phosphate-5′ de pyridoxamine (PPM) à ce pH. La comparaison du déplacement chimique et de l'élargissement de résonance du proton du PPL avec d'autres déplacements chimiques dans des composés types indique que le complexe PPL:Co(II) a une structure 1:1 dans laquelle l'ion métallique est lié simultanément au phosphate et à l'oxygène de l'aldéhyde. Le temps de relaxation spin–réseau du proton et les déplacements chimiques isotopiques du ^{13}C dans le complexe PPL:Co(II) 1:1 confirment cette conclusion.

[Traduit par le journal]

Introduction

Pyridoxal phosphate containing enzymes catalyze many biological reactions of amino acids. These include transamination, decarboxylation, deamination, and racemization. Most of the enzymatic reactions of PLP (**1**) have been duplicated by nonenzymatic model reactions in which pyridoxal or other appropriate hydroxyaldehydes and a divalent or trivalent metal ion serve as catalysts.

1 Pyridoxal phosphate

A general mechanism for PLP-catalyzed reactions proposed by Metzler and Snell (1) implies the formation of a Schiff base from PLP and an amino acid. In the nonenzymatic model systems the metal ion stabilizes the Schiff bases by chelation. In the ternary model systems involving PLP, an amino acid and a divalent metal ion, binary amino acid – metal ion and PLP – metal ion complexes are formed under certain conditions. The metal ion complexes of amino acids have been extensively studied. On the other hand, not much is known about the PLP – metal ion complexes. A recent attempt (2) to isolate and characterize these complexes yielded an insoluble polymeric solid. In a previous communication (3) we described a nuclear magnetic resonance spectroscopic method of studying these complexes at low concentrations with the aid of paramagnetic metal ions.

Paramagnetic complexes derived from biological ligands with multiple binding sites and metal ions such as Co(II), Ni(II), Cu(II), and Mn(II) lend themselves to detailed investigation of their structure by nmr spectroscopy. The effect of a paramagnetic metal ion on the chemical shifts and the rates of relaxation of the neighboring nuclei is so large that the ion is an exceptionally good probe of its surroundings. This paper describes the results of our studies on the binding of Co(II) to PLP and related compounds by ^{31}P, ^{1}H, and ^{13}C nmr spectroscopy. This metal ion forms well defined com-

plexes with PLP in aqueous solutions and the complexes are sufficiently labile to investigate their structure by nmr spectroscopy at high ligand-to-metal ratios.

Experimental

PLP, PMP, and AMP were purchased from Sigma Chemical company. The transition metal impurities in the commercial AMP sample were removed by passage of a solution of this sample through a cation exchange (chelex-100, Na form) column. Constancy of ^{31}P linewidth over a wide temperature range was taken as the criterion for the absence of transition metal ion contamination. The concentration of AMP employed for the ^{31}P nmr work was 0.21 *M*. The concentration of PLP and PMP for the ^{31}P nmr studies was about 0.25 *M* and it was about 0.5 *M* for ^{13}C nmr determinations. Stock solutions of Co(II) in deuterium oxide were prepared from reagent grade $Co(NO_3)_2 \cdot 6H_2O$ purchased from J. T. Baker Chemicals.

Most of the proton nmr studies described here were done at the ambient probe temperature of 37°C on a Varian A60A NMR spectrometer. Some proton studies were done at 100 MHz on a Varian HA-100 NMR spectrometer and proton T_1 measurements were done at 60 MHz on a TT-14 NMR spectrometer equipped with a Nicolet 1080 computer. All the ^{13}C and ^{31}P nmr work was done on a Varian XL-100 NMR spectrometer in the pulsed FT/proton noise decoupled mode. The temperature of the XL-100 probe was determined by inserting a calibrated thermometer inside the spectrometer probe. Internal tetramethylammonium (TMA) chloride was used as the reference for proton and carbon nmr studies. The reference used for ^{31}P nmr was hexamethylphosphoramide (HMPA) contained in a coaxial 4 mm tube. The susceptibility corrections to the chemical shift were negligible at the maximum concentration ($< 2 \times 10^{-3}$ *M*) of Co(II) used in this experiment. All resonances with frequency greater than the resonance frequency of the chosen reference material were given a positive sign for the chemical shift.

Theory

The actual nmr spectrum of ligands bound to a paramagnetic metal ion is often unobservable because of the large linewidths associated with such species. In general, the spectrum of the paramagnetic complex is obtained by the addition of small amounts of the paramagnetic metal ion to a solution containing the ligand molecules. The resultant shifting and broadening are extrapolated to obtain the spectrum for the pure complex.

Paramagnetic Relaxation by Cobalt(II)

The contribution T_{2p}^{-1} of the paramagnetic metal ion to the observed transverse relaxation rate T_2^{-1} of a ligand nucleus is given by

$$[1] \quad T_{2p}^{-1} = T_2^{-1} - T_{2o}^{-1}$$

where T_{2o}^{-1} is the contribution of other mechanisms. The equations for T_{2p}^{-1} for ligand nuclei in a solution containing only a fraction of coordinated ligand molecules have been derived by Swift and Connick (4). The longitudinal relaxation rate for ligand resonances in such systems is given by the equations of Bloembergen and Morgan (5) and Luz and Meiboom (6).

$$[2] \quad T_{1p}^{-1} = T_1^{-1} - T_{1o}^{-1} = f/(T_{1M} + \tau_M)$$

where f is the ratio [Co(II)]/[ligand], T_{1M} is the longitudinal relaxation rate of ligand nuclei in the complex and τ_M is the average residence time of the ligands in the bound form. The quantities T_{1p}^{-1}, T_1^{-1}, and T_{1o}^{-1} are defined as for T_2.

The relaxation rates T_{1M}^{-1} and T_{2M}^{-1} for ligand nuclei in the coordination sphere of Co(II) can be calculated theoretically from the Solomon–Bloembergen equation (7, 8).

$$[3] \quad T_{1M}^{-1} = T_{2M}^{-1} = \left[\frac{4}{3}\frac{s(s+1)g^2\beta^2\gamma_I^2}{r^6} + \frac{2}{3}\frac{s(s+1)A^2}{\hbar^2}\right]\tau_s$$

where τ_s is the electron spin relaxation time, A is the coupling constant for the electron–nucleus scalar interaction, and r is the electron–nuclear distance. For values of A/h, g, S, and r derived from X-ray crystallographic studies Shulman *et al.* (10) calculated a value of $T_{1M}^{-1} = T_{2M}^{-1} = 5.7 \times 10^2\ s^{-1}$ for the phosphorus nuclei in the Co(II)-bound phosphates. Comparing the experimentally determined T_{1M}^{-1}, T_{2M}^{-1} and the shifting values in PLP–Co(II) system with the theoretical values would indicate whether the complexation involves direct binding of the metal ion to the phosphate.

Paramagnetic Shifting by Cobalt(II)

Paramagnetic shifting by Co(II) may take place either by a dipolar mechanism or Fermi contact mechanism. A detailed discussion of these shift mechanisms may be found elsewhere (9). Contact shifts arise only if there is a significant amount of unpaired spin density at the resonating nucleus and the observation of contact shifts for ligand nuclei provides evidence for metal–ligand covalency. The dipolar shifts occur only in complexes in which the electronic magnetic moment is anisotropic. An accurate knowledge of the geometry of the complex is important to the quantitative separation of contact and dipolar contributions to the isotropic shift.

Results and Discussion

1. ^{31}P Nuclear Magnetic Resonance Studies of PLP–Co(II) System

The addition of cobalt nitrate solution to a 0.25 *M* solution of PLP at pD 6.2 results in considerable shifting and broadening of the phosphorus resonance of PLP. The temperature dependence of the

shifting and broadening for a [Co(II)]/[PLP] ratio of 2.4×10^{-3} is shown in Fig. 1. The curves are typical of diamagnetic $\rightleftharpoons$ paramagnetic exchange systems (4, 11) and indicate complexation between PLP and Co(II). Whether this complexation involves the phosphate group or not could be decided by comparing the shifting and broadening of PLP–Co(II) system with the corresponding data for an authentic phosphate–Co(II) complex such as AMP–Co(II). Shulman *et al.* (10) have studied the AMP–Co(II) system by continuous wave ^{31}P nmr at 24.31 MHz and concluded that the metal ion binds to the phosphate of AMP. We have reproduced their results under the conditions (pulse nmr at 40.5 MHz) employed in our studies.

Comparison of the data for AMP–Co(II) and PLP–Co(II) showed that the limit of very fast exchange does not exist for both systems simultaneously in the available temperature range, making accurate comparison of the shift $\Delta\omega$ difficult. However, the shift $\Delta\omega/f$ at the point of maximum shift in the curves should be comparable if the Co(II) binds directly to the phosphate of PLP as in AMP–Co(II). The value of $\Delta\omega$ was taken as the difference between the shift of the metal complex solution of known f at the point of maximum shift and the shift of the metal-free solution at the temperature of the maximum shift in the metal-containing solutions. Both shifts were referenced to an external HMPA contained in a coaxial capillary tube. The values of $\Delta\omega/f$ calculated by this method for AMP–Co(II) and PLP–Co(II) are 3.8×10^4 Hz and 3.3×10^4 Hz respectively. The good agreement indicates that Co(II) binds directly to the phosphate. The value of $\Delta\omega/f$ for PMP–Co(II) is slightly less than for PLP–Co(II). Potentiometric studies have indicated that the logarithm of the stability constants for 1:1 complexes of cobalt(II) with ribose phosphate (12), AMP (13), and PLP (12) are 2.08, 2.19, and 2.39 respectively. The close values also indicate that the primary mode of binding of Co(II) in these complexes is through the phosphate.

Since the PLP–Co(II) system does not enter the very fast exchange region in the temperature range studied, the line broadening data do not provide any structural information. However, they shed some light on the kinetics of the exchange of free and bound PLP molecules. The temperature dependence of T_{2p}^{-1} at temperatures 10° below the temperature of T_2^{-1} maximum (50°C) derives mainly from the temperature dependence of the term τ_M. In the slow exchange region Swift–Connick equation for T_{2p}^{-1} reduces to $T_{2p}^{-1} = f\tau_M^{-1}$. From the full linewidth at half height of 36.5 and 62.0 Hz at 278.2 and 288.6 K respectively an activation energy of 8 kcal can be calculated for the ligand exchange in the PLP–Co(II) system. The residence time τ_M at 5°C is 2.4×10^{-5} s.

The direct binding of Co(II) to the phosphate of PLP was also established from the measurement of the T_1 relaxation time of phosphorus in the complex. The point of maximum signal broadening for the PLP–Co(II) system occurs at 50°C. At temperatures 70°C and above $\tau_M \ll T_{2M}$, $\Delta\omega_M$ leading to the fast exchange limit. Since $T_{1M} = T_{2M}$ for the coordinated phosphate $\tau_M \ll T_{1M}$. Under these conditions eq. [2] reduces to $T_{1p}^{-1} = fT_{1M}^{-1}$. Figure 2 shows the linear dependence of T_{1p}^{-1}, T_{2p}^{-1}, and $\Delta\omega_p$ on f at 70°C. The value of T_{1M}^{-1} obtained by

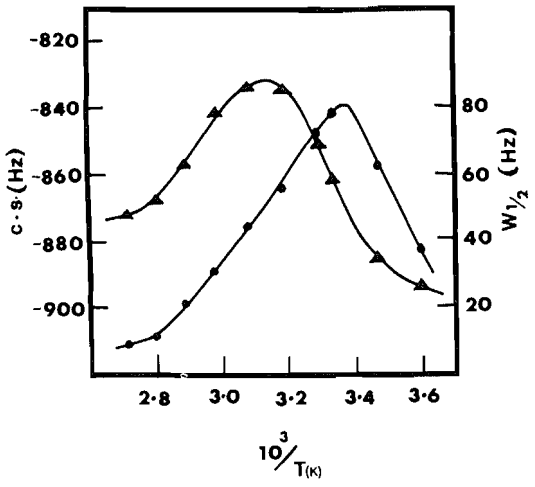

FIG. 1. Plot of the full linewidth at half maximum intensity (●) and the shift (▲) in Hz from hexamethylphosphoramide (HMPA) of the ^{31}P resonance of PLP–Co(II) at 40.5 MHz versus reciprocal temperature (K); $f = 2.4 \times 10^{-3}$.

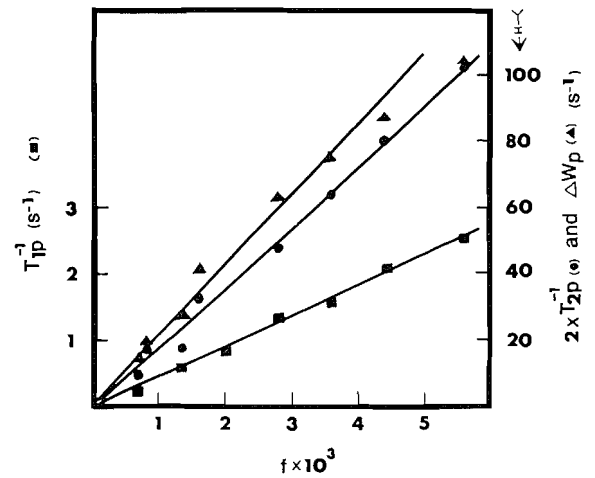

FIG. 2. The dependence of T_{1p}^{-1}, T_{2p}^{-1}, and the shift $\Delta\omega_p$ of the ^{31}P resonance of PLP–Co(II) on the concentration of Co(II) at 70°C.

extrapolation from this plot is $4.5 \times 10^2\ s^{-1}$, which is in good agreement with the value of $5.7 \times 10^2\ s^{-1}$ calculated for a Co(II)-bound phosphate from eq. [3]. Thus, the shift and T_1 data indicate that Co(II) binds directly to the phosphate of PLP. It also indicates that there is only one bound phosphate per Co(II) in the PLP–Co(II) complex. The phosphorus nmr study does not, however, indicate whether the metal binds to other sites in PLP. This question is answered by our proton and carbon nmr studies of this system.

2. Proton Nuclear Magnetic Resonance Studies

The proton nmr spectrum of PLP has been well studied. At pD 6.2 a cobalt-free solution gives sharp peaks for all the protons of PLP at 37°C. Progressive addition of Co(II) solution to PLP solution results in selective shifting and broadening of the resonances. The shifting and broadening increase linearly with the concentration of the metal ion. From the slope of the linear plots (not shown) values for $\Delta\omega_p$ and T_{2p}^{-1} were calculated for each of the proton resonances in a 1:1 PLP:Co(II) complex and they are shown in Table 1.

Table 1 shows that the extent of broadening and shifting is largest for the aldehyde proton and follows the order 4-CHO $\gg$ 2-CH_3 > 5-CH_2 $\approx$ 6-H. The 5-methylene protons are split by the phosphorus (J = 6 Hz) and the addition of metal ion collapses this coupling in addition to the broadening of this signal. In such cases it is difficult to be sure how to measure the linewidth and it was not measured. For calculation of the shift, the center of the doublet was used as the position of this resonance for small values of f. In PMP only the 5-methylene protons show considerable shifting at pD 6.2 and other protons exhibit negligible shift. At this pD the 4′-amino group of PMP remains protonated and chelation of the metal ion by the 3-O^- and the amino moieties is not likely to take place. Under these conditions the primary binding site for Co(II) in PMP would be the phosphate and the selective shifting of the 5-methylene manifests this interaction. The shift of 5-methylene in PMP–Co(II) and PLP–Co(II) are comparable. The large shifts of the 4-CHO and 2-methyl protons observed in PLP–Co(II) probably indicates a definite interaction of the Co(II) with the ring in PLP.

TABLE 1. Proton shift and broadening data at 60 MHz of 1:1 complexes of Co^{2+} and some phosphate-containing vitamins

Compound	Nucleus	Shift (Hz)	Full linewidth at half height (Hz)

	2′-CH_3	−13	—

[a]The shifting and the broadening of other protons are negligible.
[b]Reference 14.

The temperature dependence of the shifting and broadening of the PLP proton resonances by Co(II) was also studied to ascertain the contribution of rate effects to the observed linewidths. The 2-methyl and 6-H resonances are well into the fast exchange region at 37°C and the shifting has reached the weighted average value. The net shifting $\Delta\omega_p$ caused by the metal ion is nearly temperature independent for these resonances. The logarithm of the shifting and broadening of the 4-CHO resonance by Co(II) alone as a function of the inverse temperature is shown in Fig. 3. The figure shows that at 37°C the linewidth of this resonance has considerable contribution from the diamagnetic $\rightleftharpoons$ paramagnetic exchange rate term. No attempt was made to obtain structural information from proton linewidths because of this uncertainty and the lack of detailed knowledge about the

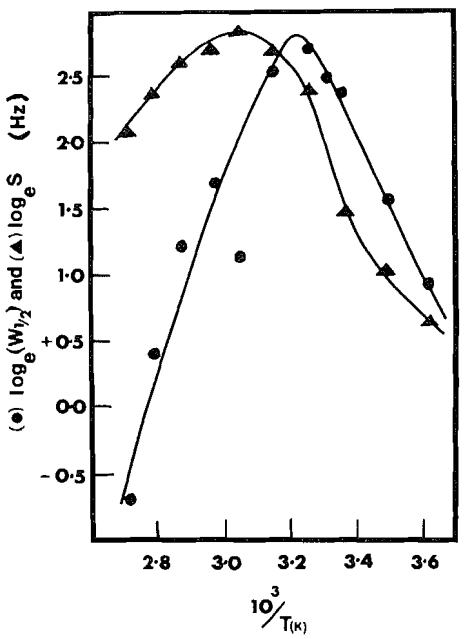

FIG. 3. The full linewidth at half height (●) and the shift (▲) of the CHO proton of PLP–Co(II) ($f = 1.2 \times 10^{-3}$) after correcting for the CHO $\rightleftharpoons$ $CH(OH)_2$ exchange.

mechanism for the proton transverse relaxation enhancement in this system.

The shifting of 6-H and 2-methyl protons in PLP–Co(II) are quite different from the shifts of 6-H and 2-methyl protons of α-picoline (15) in α-picoline complexes of cobalt(II) acetylacetonates indicating that Co(II) does not bind to the heterocyclic nitrogen of PLP at pD 6.2. It is not surprising since the nitrogen remains protonated at pD 6.2. But, raising the pD to 10 does not change the relative values of the shifting and broadening of the PLP resonances. Briggs (12) has observed that the metal ion was not competing with the final dissociating proton for a binding site in potentiometric titrations of 1:1 PLP:Co(II) solutions. An examination of space filling molecular models shows that the phosphate-bound metal cannot form a direct σ-bond with the heterocyclic nitrogen in a 1:1 PLP:Co(II) complex since it requires the metal ion to lie along the C_4—N axis in the plane of the ring. The sign and the relative shifts of the 6-H and 2-methyl protons in PLP–Co(II) are also not in accordance with the formation of an outersphere complex (11, 14) consisting of a trapped water molecule hydrogen bonded to the nitrogen and simultaneously coordinated to the metal ion. On the contrary, the large shifting and broadening of the formyl proton suggests that the interaction of the metal ion with the ring is through the CHO or 3-O^- or both.

The aldehyde group of PLP can exist in two forms, the free form, —CHO, and the hydrated form, —$CH(OH)_2$. The exchange rate for the CHO $\rightleftharpoons$ $CH(OH)_2$ equilibrium is very low at the pD and the temperature employed in our measurements. The free form is the dominant form and the hydrated form constitutes about 5% of the total PLP. Sharp resonances are obtained for both species. The 2-methyl signal of the two forms are superimposed on each other at 60 MHz in metal-free solutions but the addition of cobalt solution to PLP selectively shifts the 2-methyl resonance of the free aldehyde form downfield. The 2-methyl resonance of the hydrated form is also shifted downfield and broadened but the shifting is only 1/7-th of the shift of the 2-methyl in the free aldehyde form. The smaller shifting of the 2-methyl of the hydrated PLP by Co(II) is still about ten times the shift of the methyl resonance of PMP. The observed shifting of the 2-methyl resonance could not have been derived from the

$$\text{PLP–Co(II)} \rightleftharpoons \text{PLP} \rightleftharpoons \text{PLP}(H_2O)$$

exchange since the latter is extremely slow at the pD and the temperature employed in these studies.

TABLE 2. The observed proton spin–lattice relaxation times (60 MHz) and metal–proton distances in 1:1 PLP:Co(II) solutions (0.05 *M*) at 22°C

Nuclei	T_{1p}^{-1}	r (Å)
4-CHO	346.1	3.89
5-CH_2	108.0	4.73
6-H	25.4	6.02
2-CH_3 (free)	26.4	5.98
2-CH_3 (hydr)	21.8	6.17

Thus, the methyl shift data indicate that the phosphate-bound metal ion interacts to varying degrees with the ring in PLP, hydrated PLP, and in PMP. This conclusion is reinforced by a kinetic study (12) of the PLP–Ni(II) system. The study revealed the presence of both PLP(H_2O)–Ni(II) and PLP–Ni(II) complexes. The author has shown that the Ni(II) binds more strongly to the unhydrated form than to the hydrated species and the hydration of the free PLP is more favorable than the hydration of the metal complex. Thus, both the kinetic and nmr evidence indicate a specific interaction of the metal ion with the carbonyl functional group of the free PLP.

There are two possibilities for the phosphate-bound Co(II) to form a direct bond with the ring in the PLP:Co(II) complex: (*1*) The metal may bind to both 4-CHO and 3-O^- functional groups of another PLP molecule in a 2:1 PLP:Co(II) complex. (*2*) The metal could form a direct bond with the aldehyde oxygen in a 1:1 complex. The first possibility was ruled out by comparing the shift of the aldehyde proton of PLP and salicylaldehyde. Fritz *et al.* (16) studied the isotropic shifts of the proton resonances in a series of compounds of the type (X-salad)$_2$$CoB_2$ where X-salad is a substituted salicylaldehyde and B is a pyridine base. They observed that the CHO proton is shifted approximately 2.1×10^4 Hz downfield at 60 MHz compared to the shift in salicylaldehyde. These studies were repeated by Croasmun (17) in our laboratories and from his results an identical value was calculated for the shift of the CHO protons of salicylaldehyde in the coordination sphere of Co(II).

The shift of 0.86×10^4 Hz observed for the CHO proton in a 1:1 PLP:Co(II) complex is only 40% of the shift in a 1:1 salad:Co(II) complex. The smaller shift of CHO suggests that it is unlikely that Co(II) binds to the hydroxyaldehyde in PLP and salicylaldehyde in the same way. However, the shift of CHO is too large to be accounted for by a weak interaction with these groups. The smaller shift for the CHO of PLP as compared with the shift in salicylaldehyde may arise if the phosphate-bound

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

metal binds only to the aldehyde oxygen of PLP in a 1:1 complex. A covalent binding of the metal to the carbonyl group of free PLP will provide a mechanism for spin delocalization, which in turn will lead to large contact shifts. This model is consistent with the observation of small dipolar shifts due to the phosphate-bound metal in PLP(H_2O):Co(II) and PMP:Co(II) and large contact shifts in PLP:Co(II).

The spin–lattice relaxation times of the protons of PLP were also measured at 60 MHz and 22°C in the absence of any metal ion and with various concentrations of cobalt. The addition of cobalt(II) results in the selective enhancement of the T_1^{-1} of the PLP protons and the enhancement is linear with the concentration of cobalt(II). The values of T_{1P}^{-1} extrapolated for a 1:1 PLP:Co(II) complex are shown in Table 2. Since $\tau_M \ll T_{1M}$ at this temperature, the T_{1P}^{-1} values actually represent T_{1M}^{-1} values.

The cobalt(II) induced proton shifts shown in Table 1 are all to lower fields and they are all small. Therefore, the scalar term in eq. [3] would be much too small to account for the observed T_{1M} values. Hence, T_{1M} for PLP:Co(II) is dipolar determined and can be used to determine "r" the metal–nuclear distance. In Table 2 we list the value of r derived from the proton T_{1M} values assuming $S = 3/2$, $g = 2.8$, and a τ_s of 5×10^{-13} s, the same value used to interpret the phosphorus data and used by Shulman *et al.* (10) in Co–AMP and Co–ATP studies. The close r values for the 2-methyl protons in the PLP–Co(II) and PLP(H_2O)–Co(II) confirms that the T_1 relaxation of the protons is dipolar determined since the distance between the 2-methyl protons and the phosphate-bound metal ion should be nearly equal in both complexes. The differential shift of the 2-methyl protons in these two complexes should originate from a Fermi contact mechanism since the dipolar shift term should be nearly equal for both complexes. Thus, the shift and relaxation data collectively imply a covalent interaction of the metal ion with the ring in PLP–Co(II). The relative distances of the 5-methylene, 6-H, and 4-CHO from the metal ion indicate that the metal is probably forming a bond with the oxygen of the carbonyl group.

3. Carbon Nuclear Magnetic Resonance Studies

The ^{13}C nmr spectrum of PLP has been well studied (18). The shifting of the carbon resonances upon addition of Co(II) solution to a 0.5 *M* PLP solution at pD 6.2 was studied at 35°C. The results are shown in Table 3. The temperature dependence of these shifts was not studied and nothing is known about the mechanism of these carbon shifts. The cobalt(II) induced shifts are difficult to interpret since a combination of σ- and π-delocalisation of the unpaired electron coupled with the correlation effects and dipolar shifts would result in a complex shift pattern for large systems such as PLP–Co(II). Table 3 shows that the shifting of all the carbon resonances except the C-5 are downfield. The upfield shifting of the C-5 resonance might be the result of binding to the phosphate. The predominantly lowfield shift of the ^{31}P, ^{1}H, and ^{13}C resonances indicates that the delocalization of the odd electron takes place through σ-bonds. Examination of the molecular models shows that when Co(II) is bound to the phosphate and the aldehyde oxygen, the favored conformation would be one in which the CHO oxygen is directed away from the 3-O^-. This model allows enough mobility about the C4—C4′ bond to keep the CHO group in the plane of the pyridine ring. The odd electron could be transported to the ring through π-electrons and through a σ–π configuration interaction mechanism, but the lack of detailed knowledge about mechanism of ^{13}C isotropic shifts allows only speculations of possible mechanisms of spin transport.

TABLE 3. The isotropic shift of the carbon-13 resonances in the 1:1 PLP:Co^{2+} complex in aqueous solution at 35°C

Nucleus	Shift (ppm)	Shift (Hz) at 25.16 MHz	Relative shift

In conclusion, the present nmr study of the PLP–Co(II) system indicates that Co(II) binds to PLP through the phosphate and it also indicates the presence of an additional interaction with the ring. The interaction with the ring does not appear to be a chelate formation with the 3-hydroxy-4-aldehyde moiety. The proposed structure for the PLP–Co(II) complex is similar to the structure proposed for the PLP–Mn(II) complex (3) and both structures are in good agreement with the structure proposed for these complexes from a potentiometric study (12) of pyridoxal phosphate – divalent metal ion solutions.

Ruthenium(II) phthalocyanine complexes of the type $RuPcL_2$ (Pc = the phthalocyaninato dianion, L = various pyridines, imidazole, dimethylformamide, dimethylsulfoxide, and acetonitrile) may be prepared generally in solution by photolysis of RuPc(CO)L′ complexes in the presence of excess L (L′ may be the same as L or may be a different ligand), and in some cases as solids by extraction of crude RuPc with L. The solid RuPc(CO)L monocarbonyls can be formed from reaction of the $RuPcL_2$ complexes with carbon monoxide, as well as via an extraction procedure using L with crude RuPc(CO) formed from $Ru_3(CO)_{12}$ and phthalocyanine.

Chemical or electrochemical oxidation of the $RuPcL_2$ or monocarbonyl complexes generates a cationic ruthenium(II) phthalocyanine radical species and not ruthenium(III), as evidenced by esr and visible spectroscopy.

DAVID DOLPHIN, BRIAN R. JAMES, ALAN J. MURRAY et JOHN R. THORNBACK. Can. J. Chem. **58**, 1125 (1980).

Les complexes phthalocyanine de ruthénium(II) du type $RuPcL_2$ (Pc = dianions phthalocyaninato, L = différentes pyridines, imidazole, diméthylformamide, diméthylsulfoxyde et acétonitrile) peuvent généralement être préparés en solution par photolyse des complexes de RuPc(CO)L′ en présence d'un excès de L (L′ peut être identique à L ou peut être un ligand différent) et dans certains cas ils peuvent être préparés sous forme solide par extraction du RuPc brut avec L. Le solide monocarbonylé RuPc(CO)L peut être formé par la réaction des complexes $RuPcL_2$ avec le monoxyde de carbone aussi bien que par le procédé d'extraction utilisant L avec le RuPc(CO) brut formé à partir de $Ru_3(CO)_{12}$ et la phthalocyanine.

L'oxydation chimique ou électrochimique de $RuPcL_2$ ou des complexes monocarbonylés génère un radical cationique de phthalocyanine de ruthénium(II) et non de ruthénium(III) tel que mis en évidence par la rpe et la spectroscopie visible.

[Traduit par le journal]

Introduction

Continuing our interests in models for biological oxygenation and their potential for catalysis via O_2 activation (1–4), we are studying the chemistry of ruthenium(II) complexes with macrocyclic N_4 ligand systems. This paper reports studies on phthalocyanine complexes; the phthalocyaninato dianion (Pc) is a tetraazoporphyrinato ligand, the bridging methine positions and pyrrole rings of the porphyrin skeleton having been replaced by nitrogen, and benzpyrrole groups, respectively.

Although there have been several literature reports on the synthesis of ruthenium phthalocyanines, most of the complexes were not well-characterized. The reaction of *o*-cyanobenzamide with $RuCl_3 \cdot 3H_2O$ is reported to give "RuPc", which on extraction with aniline gives a crystalline solid, $RuPc \cdot 6C_6H_5NH_2$ (5, 6). Corresponding complexes were isolated with other amines such as *n*-butylamine and pyridines (7).[2] Extraction of the same crude "RuPc" with dmso and dmf also gives complexes of the same RuPc·6L stoichiometry (8). The dmso complex has been used as an nmr shift reagent (8). With concentrated H_2SO_4, "RuPc" is said to give $[RuPcH]^+$, protonation occurring on a non-coordinating nitrogen atom (9).

Ruthenium(III) species formulated ClRuPc and ClRu(PcCl) are said to be formed via reaction of $RuCl_3 \cdot 3H_2O$ with *o*-dicyanobenzene (10) or phthalocyanine, H_2Pc (11), respectively. Species formulated ClRuPc(L), where L = *o*-dicyanobenzene, *o*-cyanobenzamide, or py, have also been described (10). A recent report (12), which appeared after the completion of our studies, questions the existence of the ruthenium(III) phthalocyanines and describes the characterization of a diamagnetic ruthenium(II) species $Ru(ClPc) \cdot py_2 \cdot 4py$, which was previously formulated (10) as the ruthenium(III) species ClRuPc(py)·5py, as well as a $Ru(ClPc)(PPh_3)_2$ complex. Part of the work described in this paper has been reported briefly elsewhere (13).

Experimental

All synthetic reactions were carried out under an atmosphere of argon using standard vacuum line and Schlenk tube techniques. The ^1H nmr spectra were measured on a Varian XL-100 operating in the Fourier transform mode. The esr spectra were recorded at 77 K on a Varian E-3, no signals being observed at room temperature. Infrared spectra were measured on a Perkin Elmer 457, and electronic spectra on a Cary 17D.

Cyclic voltammograms were obtained using an H-cell with the three compartments separated by sintered glass frits. Potentials were measured at a platinum electrode against a Ag/AgCl reference electrode at 25 ± 2°C. The $^nBu_4N^+PF_6^-$ electrolyte (TBAH) was synthesized (14), recrystallized from ethanol, and dried under vacuo at 70°C. A polarographic analyzer (M.I. As-

sociates) in conjunction with an oscilloscope (Tektronix Inc.) measured the voltammograms at a scan speed of 250 mV/s. Coulometric experiments were carried out in a flow cell which enabled continuous monitoring of the visible spectrum of the solution during electrolysis. The coulometry was carried out in solution identical to those used for cyclic voltammetry, using a PAR-173 module with an HDC-371 integrator attachment.

Dmf, dmso, py, CH_3CN, and CH_2Cl_2 were freshly distilled, the CH_2Cl_2 being distilled from CaH_2. Other solvents and chemicals were used as reagent grade. *Ortho*-cyanobenzamide was synthesized using a literature procedure (15). Ruthenium trichloride trihydrate was obtained from Johnson Matthey Ltd. $Ru_3(CO)_{12}$ was a Strem Chemicals product.

Chemical oxidations for dilute solutions were carried out by a spectrophotometric titration procedure using Br_2 solutions.

Photolysis experiments were carried out under vacuum using a 650 W visible photo-flood lamp.

All the complexes synthesized gave satisfactory microanalytical data (P. Borda, this department). Reference 13 lists typical data for the $RuPcL_2$ and RuPc(CO)L complexes.

Preparation of Complexes

The details for the synthesis of crude "RuPc" from $RuCl_3 \cdot 3H_2O$ and *o*-cyanobenzamide, and the subsequent extraction procedure with pyridines to give well-characterized crystalline $RuPcL_2$ complexes, were given in our earlier report (13). The procedure for their carbonylation using 1 atm CO to give RuPc(CO)L, and isolation of the same carbonyls via an extraction procedure on crude RuPc(CO) made from $Ru_3(CO)_{12}$ and H_2Pc were also described (13).

*Carbonyl(*N,N'*-dimethylformamide)phthalocyaninatoruthenium(II)*

"RuPc" (1 g) was refluxed in dmf for 5 h and the resulting solution filtered. The resulting deep blue solution was then added to an alumina column containing hexane and the column eluted with hexane until all the dmf had been removed. Elution with diethyl ether and evaporation to a low volume yielded red-purple crystals of the complex (v(CO) = 1943 cm^{-1}, Nujol). Yield ca. 20%.

Bis(dimethylsulfoxide)- and Carbonyl(dimethylsulfoxide)-phthalocyaninatoruthenium(II)

"RuPc" (1 g) was refluxed in dmso for 3 h and the mixture filtered. Evaporation of the solution to low volume yielded purple crystals. Washing with hexane removes the excess dmso of crystallization, giving $RuPc(dmso)_2$. Yield ca. 40%. Carbonylation using 1 atm CO in dmso at 100°C (5 h) gives solutions that yield, after chromatography, RuPc(CO)(dmso) (v(CO) = 1955 cm^{-1}, Nujol).

*Bis(acetonitrile)-, Bis(imidazole)-, and Bis(*N,N'*-dimethylformamide)phthalocyaninatoruthenium(II) Species*

The bis(acetonitrile) species was readily formed *in situ* in dilute solution (10^{-4} *M*) by degassing an acetonitrile solution of $RuPc(dmso)_2$ and irradiating *in vacuo* with a 650 W tungsten lamp for ~15 min; other precursor complexes such as $RuPc(py)_2$, RuPc(CO)(py), or crude RuPc(CO) could be used with somewhat longer reaction times. Solutions of $RuPc(dmf)_2$ were prepared similarly from $RuPc(dmso)_2$ or RuPc(CO)(dmf). The bis(imidazole) species is readily formed via photolysis of $RuPc(dmso)_2$ in CH_2Cl_2 containing excess Im.

Results and Discussion

Synthetic Studies

An efficient route to the solid diamagnetic $RuPcL_2$ complexes involves Soxhlet extraction into L of crude "RuPc" formed from $RuCl_3 \cdot 3H_2O$ and *o*-cyanobenzamide. The method has been used with L = py, 4-Mepy, and 4-^{t}Bupy. The useful $RuPc(dmso)_2$ precursor complex can be obtained after a procedure involving refluxing "RuPc" in dmso; a similar procedure using dmf yields the monocarbonyl RuPc(CO)(dmf) formed presumably by decarbonylation of the amide, a process not uncommon for ruthenium (16, 17).

The RuPc(CO)L monocarbonyls are more generally prepared by treatment of $RuPcL_2$ solutions with 1 atm CO over prolonged periods at ≥ 100°C. The corresponding reactions for iron(II) systems are very fast even at room temperature (18). A less reliable method for making RuPc(CO)L complexes involves reaction of L with a crude RuPc(CO) product (13); this latter species is formed by refluxing $Ru_3(CO)_{12}$ with the neutral H_2Pc ligand in toluene under N_2, a procedure that has proved successful for synthesizing corresponding solvated Ru(porphyrin)(CO) complexes (19, 20). The phthalocyanine reaction probably gives RuPc(CO) (v(CO) = 1945 cm^{-1}, Nujol), but the method was somewhat irreproducible, and sometimes gave additional weak ir bands in the carbonyl region; chemical analyses were also variable.

Several other methods were tried in attempts to incorporate Ru(II) directly into the Pc ligand. These involved the reaction of chlororuthenate(II) solutions (21, 22), and more well-characterized precursors such as *cis*-$RuCl_2(dmso)_4$ (23), $Ru(dmso)_6^{2+}$ (24), $RuCl_2(PPh_3)_3$ (25), and $Ru(acac)_3$ (26), with M_2Pc (M = H, Na, Li), but only a small amount of metallation was apparent.

Photolysis of either RuPc(CO)L or $RuPcL_2$ in a solution of the appropriate ligand L′ leads to ready *in situ* formation of $RuPcL_2'$ species. The $RuPc(dmso)_2$ is a particularly useful precursor since the dmso ligands are readily photolabile, although the quantum yield of the process is low (< 0.01). Although a photo-flood lamp was used in these reactions, some experiments employing laser radiation have shown that only radiation < 400 nm is effective for the photochemical reactions (27). Stynes (28) has synthesized $RuPc(CH_3CN)_2$ via photolysis in CH_3CN of a species formed by reaction of $Ru_3(CO)_{12}$ with *o*-dicyanobenzene; the intermediate is again likely to be RuPc(CO), and it is of interest that Calderazzo's group has recently synthesized an iron analogue, FePc(CO)(dmf), by reaction of $Fe(CO)_5$ or $Fe(CO)_9$ with *o*-dicyanobenzene in dmf solution (29, 30).

Figure 1 summarizes the various reactions that we have studied. The species show characteristic visible spectra (Table 1) and the solution reactions are readily monitored spectrophotometrically.

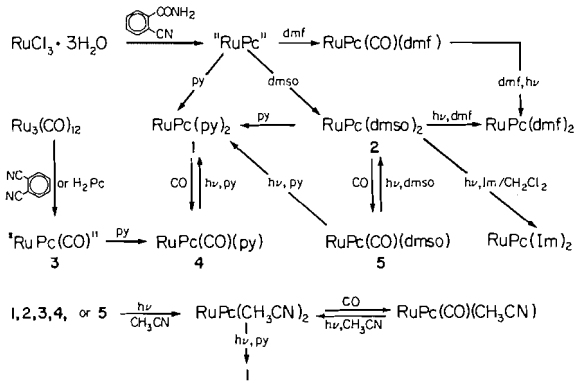

FIG. 1. Synthesis of Ru(II) phthalocyanine complexes; py here stands for pyridine, 4-methyl- and 4-tertiarybutylpyridine. The $Ru_3(CO)_{12}$/*o*-dicyanobenzene reaction is the work of Stynes (28).

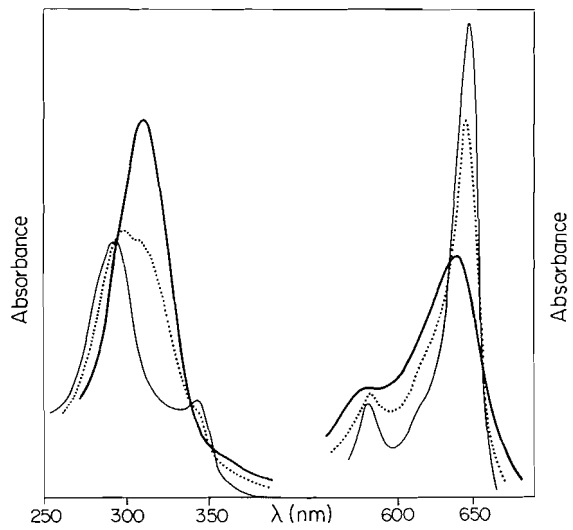

FIG. 2. Visible spectral changes during photolysis of RuPc(CO)(4-Mepy) (—) in CH_3CN giving $RuPc(CH_3CN)_2$ (—).

Photolysis in the coordinating solvents (pyridines, dmso, dmf, CH_3CN), or in CH_2Cl_2 with added ligand, always gave clean visible spectral changes with several isosbestic points; examples are shown in Figs. 2 and 3, as well as in the figure in ref. 13. In non-coordinating solvents in the absence of added ligand, the photolysis decolourized the solutions irreversibly due to decomposition of the Pc ligand, possibly to phthalimide.

The displacement of the dmso ligands in $RuPc(dmso)_2$ by pyridines to give $RuPc(py)_2$ occurred readily, in the absence of irradiation, by simply warming for a few minutes a pyridine solution of the bis(dmso) complex.

The complexes (Table 1) all show an intense absorption in the visible region (620–645 nm) together with a weaker band(s) at slightly higher energy (560–585 nm), and this is characteristic of metal phthalocyanine complexes (31, 32). Absorp-

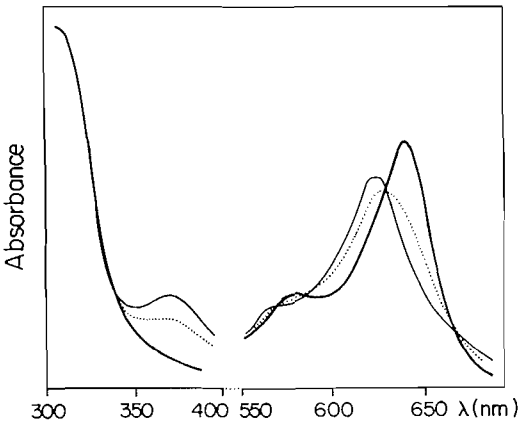

FIG. 3. Visible spectral changes during photolysis of $RuPc(CH_3CN)_2$ (—) in pyridine giving $RuPc(py)_2$ (—).

tion bands are also generally observed in the Soret region (340–380 nm) together with more intense ones around 290–315 nm. The RuPc(CO)L species, in the systems that we have studied, always have their intense visible absorption band at ca. 10–20 nm higher than, and with an extinction coefficient at least twice as large as, that of the corresponding $RuPcL_2$ species. The Soret band of the monocarbonyls studied appears at 30–40 nm below that of the corresponding bis(L) species. The bis(imidazole) and bis(acetonitrile) complexes appear exceptional in apparently not showing a Soret band, although this is probably masked by the more intense 312 nm band. In the related Ru(porphyrin)L_2 systems, replacement of one L by CO again gives a marked red-shift in the visible region, but the blue-shift in the Soret region is small (1, 33).

The ir spectrum of $RuPc(dmso)_2$ showed bands in the 1100 cm^{-1} region, possibly indicative of *S*-bonded dmso (24), although there are also Pc bands in this region; some weaker bands at 920–930 cm^{-1} could be due to *O*-bonded dmso, but this region is complicated by the presence of methyl rocking modes (34), and we have not synthesized the d_6-dmso analogue which would help to eliminate this ambiguity. A recent structure determination of the iron(II) analogue, $FePc(dmso)_2$, shows a somewhat unexpected and interesting result in that both dmso ligands are *S*-bonded (35); both Fe(II) and Ru(II) are considered to be border-line cases in the hard–soft acid classification (36) but, based on the iron data, the $RuPc(dmso)_2$ will almost certainly contain just *S*-bonded sulfoxide (see below). The ^1H nmr spectrum in $CDCl_3$ was not very satisfactory for this complex because of a solubility limitation, but the other complexes showed two pairs of doublets centered in the τ regions 0.6–0.9 and 1.8–2.1 (13), a typical pattern assigned to the α and β benz-protons of diamagnetic metallophthalocyanines (37). The absence of paramagnetic shifts in the ^1H nmr of $CHCl_3$ present in the solutions also shows the complexes to be diamagnetic (38).

A Faraday balance measurement on the $RuPc(4\text{-}^tBupy)_2$ complex confirmed the diamagnetism in this one case ($\chi_m = -860 \times 10^{-6}$ cgs at 20°C, the diamagnetic correction being about $+550 \times 10^{-6}$ cgs).

Oxidation Studies

Cyclic voltammograms were measured for a number of the ruthenium(II) complexes in 0.05 *M* TBAH–CH_2Cl_2 solution. The bis(pyridine) species show two chemically reversible one-electron oxidations (Fig. 4, Table 1), while the other species reveal just a single reversible one-electron oxidation (Table 1). Visible and esr spectral data (Table 1) demonstrate that the first oxidation occurs at the porphyrin ring, and the half-wave potentials (0.70–0.91 V) are formal reduction potentials for reaction [1]:

[1] $Ru^{II}[Pc(1-)]L_2^+ + e \rightarrow Ru^{II}(Pc)L_2$

(Pc itself refers to the dianion)

Solutions of the ruthenium phthalocyanine cations were prepared by exhaustive electrolysis in the TBAH–CH_2Cl_2 solution. The one-electron oxidations (±10%) proceed cleanly and reversibly over many cycles provided the potential is not significantly increased above the first oxidation potential; the solutions change from blue to red-purple and the visible spectral changes reveal several isosbestic points (Figs. 5, 6). All the oxidized species have two broad absorptions in the (510–535) and 700 nm regions, although the band at ~700 nm is less evident for the bis(pyridine) cations (Figs. 5, 6). The spectral changes are very similar to those observed for the one-electron oxidation of copper(II) phthalocyanine species to the $Cu[Pc(-1)]^+$ cation (39), and the general broadening of spectra with decreased intensity of the visible

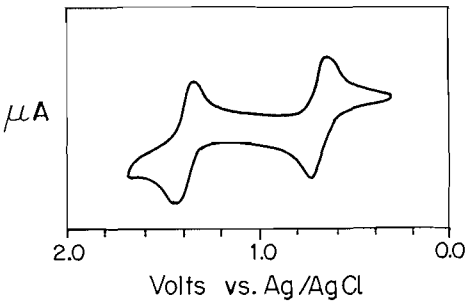

FIG. 4. Cyclic voltammogram for $RuPc(4\text{-}Mepy)_2$ in 0.05 *M* TBAH-CH_2Cl_2 vs. Ag/AgCl.

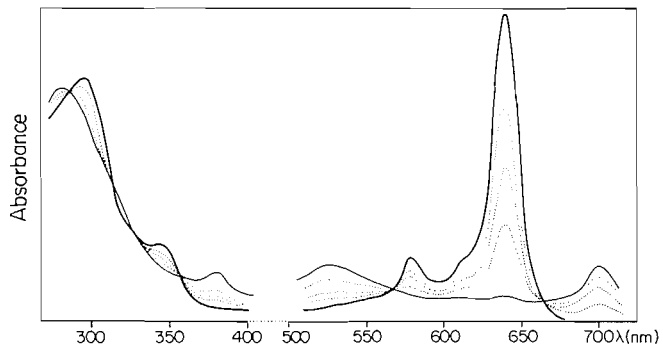

FIG. 5. Visible spectral changes during the one-electron oxidation (at 0.92 V with respect to a sce) of RuPc(CO)(py) (—) to cation (—) in 0.05 *M* TBAH–CH_2Cl_2.

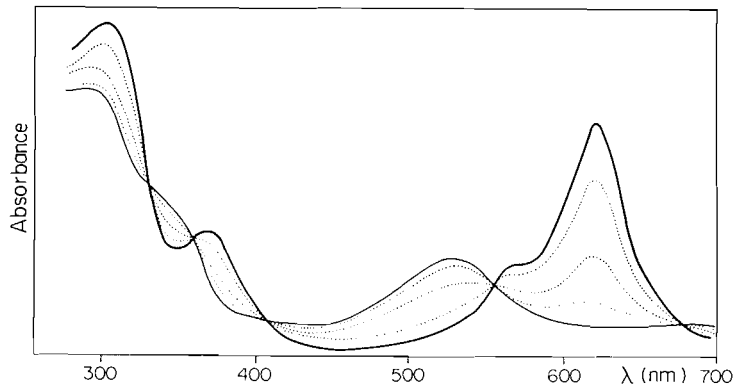

FIG. 6. Visible spectral changes during the one-electron oxidation (at 0.72 V with respect to a sce) of RuPc(4-^{t}Bupy)$_2$ (—) to cation (—) in 0.05 *M* TBAH–CH_2Cl_2.

bands is typical of that found for ligand oxidation in metallo-phthalocyanines and -porphyrins (40–42).

The esr spectra obtained for frozen solutions of the monocations at 77 K (Table 1) confirm that an electron has been removed from the phthalocyanine π-system to give the radical [Pc(1−)] ligand. The isotropic g values are close to the free electron value of 2.0 and are characteristic of oxidation at the phthalocyanine ring (40). Oxidation at the metal center to give $Ru^{III}Pc^+$ d^5 monocations would likely not give esr signals. Relatively few Ru^{III} complexes have been subjected to esr studies (44–47); there are difficulties in observing the signals due to fast relaxation times (48), and signals were not observed with $Ru^{III}(porp)(py)_2^+$ systems (43). The band-width of the $g = 2.0$ signal for a $Ru^{II}[Pc(-1)](CO)L^+$ monocarbonyl is invariably smaller than that of the corresponding bis(L) species (Table 1), and this can be used as a diagnostic tool, particularly for the pyridine systems where the effect is quite marked (e.g. for pyridine itself, 7.1 vs. 25 G). The differing degrees of line-broadening may result from interaction with the pyridine-nitrogen(s); no hyperfine splitting is observed in the signals.

The nature of the dication product from the second oxidation observed with the bis(pyridine) systems (1.32–1.40 V) has not been elucidated. Although stable on the cyclic voltammetric time scale, the dications could not be generated by electrolysis since decomposition occurred. The second oxidation could occur at the metal giving $Ru^{III}[Pc(-1)]L_2^{2+}$, or at the Pc giving $Ru^{II}[Pc(-2)]L_2^{2+}$.

A similar difficulty in elucidation of the dicationic species was encountered in a study of $Ru^{II}(porp)(CO)(py)$ complexes, where again the first oxidation pertained to formation of a porphyrin radical species $Ru^{II}[porp(-1)](CO)(py)^+$ (43, 49). A major difference in the porphyrin systems, however, is that a one-electron oxidation of carbonyl-free $Ru^{II}(porp)(py)_2$ species occurs *at the metal* to give $Ru^{III}(porp)L_2^+$ cations (43, 49). The introduction of CO in the porphyrins causes large anodic shifts for the first oxidation, e.g., $E_{1/2}[Ru(TPP)(CO)(py)] - E_{1/2}[Ru(TPP)(py)_2] =$

TABLE 2. Redox couples for some metallo-phthalocyanine and -porphyrin complexes[a]

Complex	M(III)/M(II)	M(II)L$^+$/M(II)[b]	Reference[c]
RuPc(CO)(py)	—	0.91	tw
$RuPc(py)_2$	—	0.77	tw
Ru(TPP)(CO)(py)	—	0.81	43
$Ru(TPP)(py)_2$	0.21	—	43
Ru(TPP)(CO)	0.93[d]	0.82	43, 53
Ru(OEP)(CO)(thf)	—	0.61	43, 49
$Ru(OEP)(py)_2$	0.08	—	49
$Ru(OEP)(CH_3CN)_2$	0.28	—	1
$Ru(TPP)(PEt_3)_2$	0.36	—	53
$Ru(TPP)(PPh_3)_2$	0.50	—	53
$Ru(TPP)(P(OMe)_3)_2$	0.59	—	53
$Ru(TPP)(^tBuNC)_2$	0.65	—	53
$FePc(py)_2$	—	0.70	50
CrPc/py	0.52	—	50
ZnPc/py	—	0.68	50
CoPc/py	0.22	—	50
MnPc/py	0.01	—	50

[a]All potentials in V vs. a sce at 25°C.
[b]Redox process involves Pc or porphyrin ligand.
[c]tw = this work; refs. 43, 49; data in 0.1 *M* TBAH–CH_2Cl_2; ref. 53, 0.1 *M* TBAH–CH_3CN/benzene; ref. 1, 0.1 *M* TBAH–CH_3CN; ref. 49, ClO_4^-–py.
[d]This assignment (ref. 53) seems incorrect.

0.60 V (Table 2), making the carbonyl complexes harder to oxidize and, indeed, this results in the change in oxidation site. The $\Delta E_{1/2}$ value for the Pc systems, $E_{1/2}$[RuPc(CO)(py)] − $E_{1/2}$[$RuPc(py)_2$], is only 0.14 V (0.10 V for the dmf system), and is more consistent with oxidation at the same site, namely, the phthalocyanine ligand. The level of the Pc π_{mo} must be higher than the metal *d* orbital in both monocarbonyl and bis(L) species; unlike in the porphyrin systems (43, 49), difference in π-back bonding ability between CO and, for example, pyridine is not sufficient to invert the relative positions of metal *d* and Pc π_{mo} levels, and this is possibly consistent with evidence that phthalocyanine ligands compared to porphyrins are exceptionally good π-acceptors (ref. 50). This also accounts for a general finding of metal phthalocyanine complexes being more stable towards oxidation than corresponding porphyrins (ref. 50, Table 2). The oxidation of the various bis(pyridine)ruthenium(II) phthalocyanines to species containing the [Pc(−1)] radical cation at 0.7–0.8 V (Table 1) is consistent with data (Table 2) showing oxidation of the Pc ligand in ZnPc solutions at 0.68 V (50, 51) and in FePc in py/ClO_4^- solutions at 0.7 V (50). Oxidation at 0.52 V in a CrPc/py system was assigned as a Cr(III)/Cr(II) couple (50). Compared to porphyrin systems, considerable stabilization of the low-spin Fe(II) and Cr(II) was attributed to π-back donation into the Pc ring (50). For low-spin Ru(II) such an effect would be even more marked, and reduction potentials are higher than for corresponding iron–Pc and –porphyrin systems (49, 52). Consistent with this is that the reported oxidation of $FePc(dmso)_2$ at 0.47 V occurs at the metal and not at the ligand (50). With MnPc– and CoPc–pyridine systems, the oxidation at much lower potentials (0.01 and 0.22 V, respectively) is again consistent with oxidation at the metal (50). The data indicate that ligand oxidation will occur in Pc systems at ≥0.60 V. With porphyrin systems, the presence of an axial CO ligand may raise the potential into the region of porphyrin ligand oxidation and again, at least with TPP and OEP, this could be in the same 0.6 V range (43, 49). Orbital descriptions on replacement of an axial amine ligand by CO in porphyrins of the Fe subgroup, and the implications for heme-based redox processes, have been presented (49, 52).

The limited data in Table 1 show the expected stabilization of the lower valency state by incorporation of a CO ligand (see also Table 2), and stabilization of the higher valency state by electron-donor substituents within pyridines (^{t}Bu > Me > H). The somewhat higher potential of the bis(dmso) complex, compared to the bis(dmf) *O*-bonded and the bis(CH_3CN) *N*-bonded systems could be consistent with stabilization of Ru(II) via π-backbonding through *S*-bonded sulfoxides. Other recent data on ruthenium porphyrins (Table 2) show similar trends: lower potentials with more basic phosphines, higher potentials with π-acceptor ligands (phosphites, isocyanides). Some of the higher potentials of the TPP derivatives reported by Boschi *et al.* (Table 2, ref. 53) are in the range where ligand oxidation could occur, although a different solvent

system was employed; the evidence for metal oxidation was lack of an esr signal, but the measurements appear to have been done at room temperature where the signal of the porphyrin radical is not detected (ref. 43 and this work). Visible spectra were not presented, and thus the site of oxidation is not well established. The suggested metal oxidation at 0.93 V for the Ru(TPP)(CO) complex (53) is almost certainly incorrect (43).

The one-electron oxidation products in our Pc systems could be formed in solution by chemical oxidation with bromine solutions. The esr spectra (including bandwidths) of the products were identical to those of the electrochemically generated species, indicating that the products are $Ru[Pc-(1-)]L_2^+$ with no incorporation of bromide. Dithionite readily reduced the oxidized species to the starting materials. Iodine, and also Ce^{4+} and $Fe(phen)_3^{3+}$, were ineffective oxidants, while chlorine gave irreversible oxidation beyond the first oxidation as evidenced via detection of the purple radical cation intermediates. Attempts to isolate the product of the Br_2 oxidation gave only mixtures which included the starting material.

The lack of reactivity of the Ru(II) phthalocyanine complexes toward O_2 in CH_2Cl_2 is consistent with the relatively high potentials listed in Table 1. The Fe(III)/Fe(II)–Pc couples have been shown to vary considerably with solvent and counter ion (50) and, although we do not yet have any corresponding data, this may well be true for the Ru couples. The $RuPc(dmf)_2$ in dmf, for example, does react with O_2 with loss of the visible absorption bands and a decrease in intensity of the Soret band; no esr signal is detected and irreversible oxidation of the Pc ligand is indicated. Since the ability to form a dioxygen complex is governed to some extent by the reduction potential of the metal system (2, 4, 54), we are hoping to "tune" the Ru(III)/Ru(II)–Pc couple for such reactivity (cf. ref. 50). Reversible O_2-binding by iron(II) phthalocyanine systems, after some controversial claims (55), has been accomplished recently (56–60), including a dmso system (58–60).

Our limited studies on cathodic reduction of the Ru(II) phthalocyanines were not successful, the systems showing somewhat irreversible and irreproducible behaviour. Some potentials in the range -1.7 to -1.9 V have been reported recently for $Ru(TPP)L_2$ systems (L = tertiary-phosphines, -phosphites, ^{t}BuNC) and attributed to the Ru(II)/Ru(I) couple, although the lower valent species were unstable chemically (53). Studies on the electrochemical reduction of Fe(II)Pc systems have been reported recently (61, 62).

Received November 19, 1979

DAVID P. RAINVILLE, RALPH A. ZINGARO, and JOHN P. FERRARIS. Can. J. Chem. **58**, 1133 (1980).

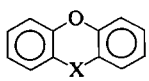
The phenoxachalcogenines have been studied as donors towards 7,7,8,8-tetracyanoquinodimethane. For the 1:1 complexes studied, the equilibrium constants, K, vary over the range 4–16; the enthalpy, ΔH^0, is about -2.0 kcal/mol; the free energy, ΔG^0, is -1.4 to -1.0 kcal/mol, and the entropy change, ΔS^0, is -7.3 to -3.5 eu. The entropy change is greatest in the case of the dibenzo-1,4-dioxane – 7,7,8,8-tetracyanoquinodimethane charge-transfer complex. This is attributed to the planarity of the dibenzo-1,4-dioxane molecule. The extinction coefficient, ε_c, for the series studied varies from 115 to 230, and no regularity in the trend has been noted.

The lack of any significant changes (with change in the chalcogen atom) in the thermodynamic values for the phenoxachalcogenine – 7,7,8,8-tetracyanoquinodimethane charge-transfer complexes is interpreted in terms of a similar π to π type interaction involving a delocalized π orbital of the phenoxachalcogenine rather than a localized n orbital of the hetero atom.

The room temperature four-probe dc conductivities of single crystals of PSe–TCNQ and PS–TCNQ were found to be 4×10^{-8} and 3×10^{-7} ohm^{-1} cm^{-1}, respectively.

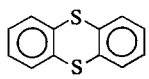
DAVID P. RAINVILLE, RALPH A. ZINGARO et JOHN P. FERRARIS. Can. J. Chem. **58**, 1133 (1980).

On a étudié les phénoxachalogénines en tant que donneurs vis-à-vis des tétracyano-7,7,8,8 quinodiméthanes. Dans le cas des complexes du type 1:1 étudiés, la constante d'équilibre K varie de 4 à 16, l'enthalpie ΔH^0 est d'environ -2.0 kcal/mol, l'énergie libre, ΔG^0 est de -1.4 à 1.0 kcal/mol et la variation d'entropie ΔS^0 est de -7.3 à 3.5 ue. La variation d'entropie est maximale dans le cas du complexe de transfert de charge entre le dibenzodioxanne-1,4 et le tétracyano-7,7,8,8 quinodiméthane. On attribue ce fait à la planéarité de la molécule de dibenzodioxanne-1,4. Dans les séries étudiées, le coefficient d'extinction ε_c varie de 115 à 230 et on n'a noté aucune régularité.



On interprète l'absence de tout changement significatif (avec le changement dans l'atome de chalcogène) dans les valeurs thermodynamiques du complexe de transfert de charge du phénoxachalcogénine tétracyano-7,7,8,8 quinodiméthane, en fonction d'une interaction de type $\pi \rightarrow \pi$ impliquant une orbitale π délocalisée de la phénoxachalcogénine plutôt qu'une orbitale localisée n l'hétéroatome.

Sur la base de quatre essais de conductivité dc à température ambiante sur un mono cristal de PSe–TCNQ et PS–TCNQ, on a trouvé les valeurs suivantes 4×10^{-8} et 3×10^{-7} ohm^{-1} cm^{-1} respectivement.



[Traduit par le journal]

Introduction

The phenoxachalcogenines (**1**) and related compounds such as thianthrene (**2**) have been studied with respect to their donor properties towards various acceptor molecules. A review of these studies can be found in a previous paper (1) in which the donor properties of the phenoxachalcogenines towards tetracyanoethylene and chloranil were reported.

X = Te	phenoxatellurine	PTe		

In the present study, the preparation of crystalline compounds with tellurium and selenium heterocyclic compounds using the well-known acceptor molecule 7,7,8,8-tetracyanoquinodimethane (TCNQ) (2) was sought. The choice of TCNQ as an acceptor molecule was made because of the high electron affinity of the polyene system conferred by the powerful electron withdrawing effect of the four cyano groups and because of the report of a 1:1 complex formed between TCNQ and tetrathiafulvalene (TTF) (3). This complex possesses one of the largest reported electrical conductivities of any known organic compound (3).

During the course of our investigations the donor properties of the phenoxachalcogenines (**1**) towards TCNQ were studied. The results of this study as well as the electrical conductivity measurements of several crystalline complexes formed between the phenoxachalcogenines and TCNQ are reported.

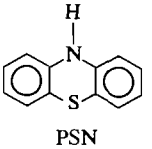
[a]By the method of Rose and Drago, see ref. 5.

Results and Discussion



Job's plots were prepared for each of the phenoxachalcogenine–TCNQ systems. In each case, a fairly broad maximum was observed at a mole fraction of 0.5 suggesting the formation of a weak 1:1 complex. The plots were symmetrical on either side of the maxima indicating the absence of higher complexes at the temperatures and concentrations used in these studies (4). These observations, however, do not preclude the possibility of the formation of higher complexes at different temperatures and concentrations.

The stoichiometry of the charge-transfer complex which forms between phenoxazine (PON) and TCNQ was also found to be 1:1 by Job's method. The maximum in the Job's plot of the PON–TCNQ system is not as broad as that observed in the phenoxachalcogenine–TCNQ systems, indicating that the PON–TCNQ complex has a somewhat larger equilibrium constant and is therefore less dissociated than the phenoxachalcogenine–TCNQ complexes.

Solid complexes were isolated for the four phenoxachalcogenine–TCNQ systems. In addition, solid complexes were also obtained from the phenoxazine (PON)- and phenothiazine (PSN)–TCNQ systems. The stoichiometry of these complexes was determined by chemical analysis of the isolated complex, and was found to be 1:1 in all cases.

PON

PSN

The equilibrium constants, K, and the extinction coefficients for the four phenoxachalcogenine–TCNQ complexes were calculated using the method of Rose and Drago (5). Examinations of the values for the equilibrium constants and the extinction coefficients for these systems show that they are relatively small. This indicates that the complexes formed in dichloromethane solution are relatively weak, probably of the $\pi-\pi$ charge-transfer type (4). We cannot exclude, however, the occurrence of a stronger charge-transfer band at higher frequencies arising from the large absorbances of both TCNQ and the phenoxachalcogenine in this region.

Table 2 shows the calculated values of the standard enthalpy changes for the four phenoxachalcogenine–TCNQ systems obtained by plotting log K vs. $1/T$ and determining the best fit for each line by the linear least squares method. The standard free entropy changes of formation for the four phenoxachalcogenine–TCNQ complexes were also determined using basic thermodynamic relationships and are reported in Table 2.

An examination of the data in Tables 1 and 2 for the values of K, ε_c, ΔH^0, and ΔS^0 leads to several conclusions. Among the four phenoxachalcogenines studied the entropy loss which accompanies the formation of the DBDO–TCNQ charge-transfer complex is greater than values measured for the other three complexes. Dibenzo-1,4-dioxane has been shown to possess an almost

TABLE 2. Calculated values for the standard enthalpy and entropy changes for the formation of the four phenoxachalcogenine–TCNQ charge transfer complexes

Donor	ΔH^0 kcal/mol	ΔS^0 eu (20°C)
Phenoxatellurine	−4.93	−3.49
Phenoxaselenine	−1.36	−1.02
Phenoxathiin	−2.41	−5.58
Dibenzo-1,4-dioxane	−3.12	−7.35

planar structure with the oxygen atoms displaced 0.16 to 0.17 Å from the plane (this would correspond to an angle of 164° about the O—O axis) (6), which would classify it as possessing D_{2h} symmetry if it were totally planar and C_{2v} symmetry if it were folded about the oxygen–oxygen axis. Furthermore, the DBDO–TCNQ complex has been studied in the solid state by X-ray diffraction analysis, which indicates that the DBDO molecules are essentially planar (7). In this study, it was shown that a relatively large separation of 3.46 Å exists between the planes of adjacent stacked TCNQ and DBDO molecules. This suggests that any charge-transfer interaction present in the solid state is weak. While DBDO has been shown to be almost planar, phenoxathiin (8) and phenoxatellurine (9) are folded along the O—S and O—Te axes at an angle of 138°. Phenoxaselenine probably has a similar angle about the O—Se axis due to its isomorphism (10) with phenoxatellurine and phenoxathiin. In view of these observations, the greater loss in entropy observed for formation of the DBDO–TCNQ complex compared with the phenoxachalcogenine–TCNQ complexes is expected. However, it should be noted that the geometry of dibenzo-1,4-dioxane in solution may differ from that in the solid state. If this is true, the greater entropy loss for the formation of the DBDO–TCNQ complex cannot be explained by the geometry of the DBDO molecule. No meaningful trend is observed for the entropies of formation among the other phenoxachalcogenine–TCNQ complexes. The value for the standard entropy of formation for the PTe–TCNQ charge-transfer complex exhibits a greater magnitude of change in comparison with the values for the PS–TCNQ and PSe–TCNQ complexes. This is expected because of the larger equilibrium constant for the PTe–TCNQ complex.

When the values of K, ε_c, ΔH^0, and related quantities are examined, it is apparent that no correlation can be made with the electronegativities of the chalcogen atom in the series O > S > Se > Te. Since oxygen is the most electronegative, the magnitude of ΔH for the DBDO–TCNQ complex should be less than that observed for the other complexes. This is not observed, indicating that the electronegativity of the chalcogen heteroatom is not the primary factor which determines the magnitude of the charge-transfer interaction. This suggests that the type of interaction for the phenoxachalcogenine series toward TCNQ is basically of the same type, involving a delocalized π orbital of the phenoxachalcogenine rather than a localized n-orbital of the chalcogen atom. This is corroborated by the observed mixed-stack arrangement of the DBDO–TCNQ complex (7) which is typical for donor–acceptor π to π type complexes (11). This conclusion is in agreement with that reached by Heller *et al.* (1), but differs from that reached by Hetnarski and Grabowska (12).

Hillebrand *et al.* (13) postulated in their study of the interaction of PS with TCNE that the absorption band at 6700–6800 Å is due to the transition from the highest occupied molecular orbital (HOMO) on the donor to the lowest unoccupied molecular orbital (LUMO) on the acceptor. The absorption peak at 4300–4500 Å was assigned to a somewhat higher energy transition from the second highest filled molecular orbital on the donor to the lowest unfilled orbital on the acceptor.

The phenoxachalcogenine–TCNQ complexes in dichloromethane exhibit absorption maxima from 6500–7550 Å. The observation of an absorption band below 4500 Å is precluded by the fact that TCNQ itself possesses strong absorption at wavelengths shorter than about 4500 Å. It is, however, reasonable to assume that the absorption bands at the wavelengths 6500–7350 Å are due to a HOMO–LUMO transition (13).

An examination of the work of Hetnarski and co-workers (12, 14), Hillebrand and co-workers (13, 15), Heller *et al.* (1), and this study, indicates that the type of donor interactions of the phenoxachalcogenines in charge-transfer systems involving TCNQ as the acceptor are of the π to π type.

Voltammetry (vs. SCE; 0.1 *M* Et_4NClO_4; MeCN; Pt electrode; 25°C) yields the following one electron oxidation potentials ($E_{\frac{1}{2}}$): PTe, +0.76 V; PSe, +1.10 V; PS, +1.18 V. The large differences between the first oxidation potentials of the phenoxachalcogenine donors and the first reduction potential of the acceptor (TCNQ, +0.14 V) suggests the complexes will possess a non-ionic ground state[1] and hence be insulating. Not surprisingly, the room temperature four-probe dc conductivities of single crystals of PSe–TCNQ and PS–TCNQ are 4×10^{-8} and 3×10^{-7} ohm^{-1} cm^{-1}, respectively. The use of a stronger, but related acceptor (FTCNQ) (16) whose first reduction potential is +0.26 V also affords insulating complexes with PTe, PSe, and PS ($\sigma < 6 \times 10^{-7}$ ohm^{-1} cm^{-1}, 300 K). Even the very strong acceptor DDQ ($E_{\frac{1}{2}} =$ 0.51 V) only raises the conductivity to ca. 10^{-6} ohm^{-1} cm^{-1}.

Other charge transfer complexes with donor

atoms towards TCNQ were isolated in the solid state. Phenoxazine–TCNQ with a λ_{max} at 7500 Å probably is similar to the phenoxachalcogenine–TCNQ complexes with π to π type charge transfer. As previously pointed out this is a 1:1 complex in dichloromethane solution. The analogous phenothiazine molecule readily forms a charge transfer complex with TCNQ. When solutions of TCNQ and phenothiazine are mixed together, the phenothiazine–TCNQ precipitates out of solution in the form of black needles. Because the complex precipitates so readily, solution studies were not performed. The solid complex has been shown to be a 1:1 complex by chemical analysis. In addition, the phenothiazine–TCNQ complex is also an insulator. Since phenoxazine is isomorphous with phenothiazine, the PON–TCNQ complex probably exhibits electrical properties similar to those of the phenothiazine–TCNQ complex.

Experimental

General Methods

All reactions of organometallic compounds were carried out in flame-dried glassware under pre-purified nitrogen using standard techniques (17). The ^{1}H nmr spectra were recorded on a Varian T-60 NMR spectrometer. The ^{13}C nmr were recorded on a JEOL Model JNM-PS-100 high resolution nmr spectrometer equipped with a Nicolet 1080 E data processing system in the T-1 mode. A sweep width of 5617.977 Hz (224.4 ppm), a sweep frequency of 25.0344 MHz (obsd), and an irradiating frequency of 99.5388 MHz at 10 W power were used. $CDCl_3$ was the source of an internal deuterium lock. Routine infrared spectra were recorded on a Beckman IR-8 spectrophotometer. Visible spectra were recorded on a Cary 14 spectrophotometer. Three electrode voltammetry measurements were conducted in an acid-washed all-glass cell equipped with O-ring seals and inert atmosphere purge. The potentiostat was an MPI System 1000 and I-V curves were displayed on an Omniscribe XY recorder. Electrical conductivity measurements were made on single crystals attached to four 25 μm gold wires with conducting silver paint. Ten microamps from a constant current source were passed through the sample and the voltage drop measured with a Keithley digital electrometer. Melting points were taken on a Büchi SMP-20 melting point apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, TN.

Reagents

Dichloromethane was purchased from Fisher Scientific Company and purified by distillation from P_2O_5 under nitrogen prior to use. Phenoxathiin was purchased from Eastman Organic Chemicals and recrystallized from methanol. It had a melting point of 56–57°C (lit. (10) mp 58°C); ir(KBr): 3075(w), 1540(m), 1400, 1280(w), 1270, 1200, 920, 855, 805, and 740 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ(ppm): 6.97(m); ^{13}C nmr ($CDCl_3$) δ(ppm): 155.685(s), 134.921(s), 129.085(s), 125.497(s), 119.580(s), 101.528(s). Phenoxazine was purchased from Aldrich Chemical Company and recrystallized from diphenyl ether. It had a melting point of 154–156°C (lit. (18) mp 156°C). Phenothiazine was purchased from Aldrich Chemical Company and recrystallized from ethanol to a melting point of 186°C (lit. (19) mp 186–187°C). 7,7,8,8-Tetracyanoquinodimethane was purchased from Aldrich Chemical Company. It was recrystallized twice from spectral grade acetonitrile and sublimed to a melting point of 294–296°C (lit. (2) mp 293.5–296°C). Other solvents and reagents (reagent grade) were purchased from commercial sources.

Phenoxatellurine was prepared by the method of Drew (20) in 34.1% yield; mp 76–77°C (lit. (20) mp 77°C); ^{1}H nmr ($CDCl_3$) δ(ppm): 7.5(d, 2H), 7.3(m 6H); ^{13}C nmr ($CDCl_3$) δ(ppm): 151.96(s), 127.47(s), 126.59(s), 124.29(s), 119.96(s), 117.61(s); ir (KBr): 1422, 1280(s), 1252(m), 1200, 1105(m), 930(s), 856, 790, 748(s), 709 cm^{-1}.

Phenoxaselenine was prepared by the method of Drew (21) in 72% yield; mp 86–87°C (lit. (21) mp 87–88°C); ^{1}H nmr ($CDCl_3$) δ(ppm): 7.1(m); ^{13}C nmr ($CDCl_3$) δ(ppm): 152.836(s), 129.223(s), 128.072(s), 124.839(s), 118.539(s), 116.128(s); ir (KBr): 3075(w), 1432(d, m), 1280(w), 1260, 1220, 1110(w), 930(w), 860(6), 800, and 750 cm^{-1}.

Dibenzo-1,4-dioxane was prepared by the method of Gilman and Dietrich (22) in 7% yield; mp 119–120°C (lit. (22) mp 119°C); ^{1}H nmr ($CDCl_3$) δ(ppm): 6.85(s); ^{13}C nmr ($CDCl_3$) δ(ppm): 141.998(s), 123.579(s), 116.128(s).

1:1 Donor Acceptor (TCNQ) Complexes

A typical procedure for the formation of TCNQ charge-transfer complexes is illustrated by the following procedure for the preparation of the phenoxatellurine – 7,7,8,8-tetracyanoquinodimethane complex.

In a 100 mL round bottomed flask were placed 0.7238 g (2.4486 mmol) of phenoxatellurine and 0.5000 g (2.4486 mmol) of 7,7,8,8-tetracyanoquinodimethane. To the flask was added 60 mL of spectral grade acetonitrile. The resulting solution was refluxed, with stirring, for 0.5 h. After the reflux period, the solution was cooled and the acetonitrile was evaporated *in vacuo* to leave 1.2238 g (2.4486 mmol, 100%) of PTe–TCNQ. *Anal.* calcd. for $C_{24}H_{12}N_4OTe$: C 57.62, H 2.40, N 11.21; found: C 57.44, H 2.34, N 11.46.

Charge-transfer complexes were also formed between TCNQ and the phenoxachalcogenines: phenoxaselenine, phenoxathiin, dibenzo-1,4-dioxane, as well as between TCNQ and the phenochalcogenazines: phenoxazine and phenothiazine. The yields for all of these preparations were quantitative. The crystalline products were all analytically pure.[2]

Solutions

Solutions of phenoxatellurine, phenoxaselenine, phenoxathiin, dibenzo-1,4-dioxane, phenoxazine, and 7,7,8,8-tetracyanoquinodimethane in dichloromethane were prepared by weighing the required amounts of the respective solids into clean weighing bottles. The solids were then transferred quantitatively into clean, dry volumetric flasks and diluted with the required amount of dry dichloromethane.

Solutions were prepared which yielded data amenable to the Rose–Drago method (5) for the calculation of equilibrium constants and extinction coefficients. The solutions were prepared by adding the required amount of the donor stock solution with a buret to a 10.0 mL volumetric flask and then evaporating the solvent. Ten milliliters of the TCNQ solution was then added to produce the required concentration of both components. A combined volume of 10.0 mL was generally used for Job's method studies. The visible spectra were obtained using cells thermostated at 10, 20, and 30°C.

All stock solutions were prepared using a water bath at 20°C. The change in volume of dichloromethane with temperature was calculated using the data of Heller (23) who determined that 1.000 mL of dichloromethane at 20°C occupies a volume of 1.014 mL at 30°C and 0.987 mL at 10°C.

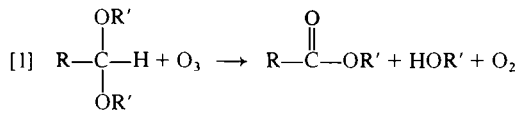
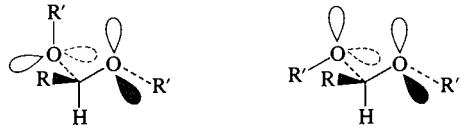
ROLAND J. TAILLEFER, SHIRLEY E. THOMAS, YVES NADEAU, S. FLISZÁR, and HERVÉ HENRY. Can. J. Chem. **58**, 1138 (1980).



A systematic investigation of the reaction between ozone and acetals to form acetal hydrotrioxides **A** has been undertaken. The stoichiometry of the reaction has been shown to be 1:1 in each reactant and the order of the reaction was also one in each reactant. Substituent effects measured in a variety of systems and under several conditions of temperature and solvent were found to be small ($\rho = -1.10$ to -1.58). Solvent polarity was also found to have little effect on the rate of the reaction. Mechanistically, these facts are interpreted in terms of a 1,3-dipolar insertion of ozone into the C—H bond of the acetal function.

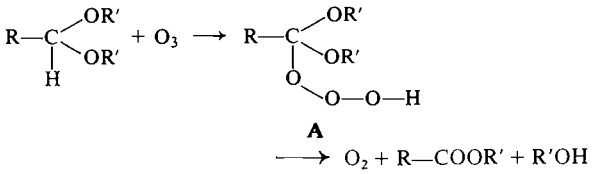
ROLAND J. TAILLEFER, SHIRLEY E. THOMAS, YVES NADEAU, S. FLISZÁR et HERVÉ HENRY. Can. J. Chem. **58**, 1138 (1980).

Une étude systématique de la réaction de l'ozone avec les acétals pour former les acétals hydrotrioxides **A** a été entreprise. On a trouvé que la stoechiométrie et l'ordre de la réaction étaient de un dans chacun des réactifs. L'effet des substituents sur la vitesse de réaction, mesuré dans plusieurs systèmes et sous différentes conditions de températures et de solvants est faible ($\rho = -1.10$ à -1.58) de même que l'effet de la polarité des solvants. Ces faits sont interprétés en invoquant un mécanisme d'addition 1,3-dipolaire de l'ozone dans le lien C—H de la fonction acétale.



Introduction

In 1971, it was first reported (1) that aldehyde acetals reacted with ozone to give esters in high yield (reaction [1]).



Experimental evidence was also provided (2–4) to suggest that for oxidation to proceed, it is required that one non-bonded electron pair on each oxygen of the acetal function lies antiperiplanar to the C—H bond of the acetal function (Scheme 1). Recently, it was shown (5) that an acetal hydrotrioxide (**A**, Scheme 2) is an intermediate in the reaction, and that singlet oxygen is produced during its unimolecular decomposition (5).

What is known now about the mechanism of the reaction can then be written as described in Scheme

Unreactive conformation Reactive conformation

SCHEME 1

SCHEME 2

2. This paper presents the results of a systematic investigation of the first step of this reaction, the oxidation step.

Experimental

The acetals used in this study were prepared by standard procedures or were commercial products. Their physical properties corresponded to literature values and their spectral properties were in accord with their structure. Vapor phase chromatographic analyses were carried out on a Hewlett-Packard F and M 5750 instrument with flame ionization detection, or Varian Aerograph instruments: model 2800 with thermal conductivity detector and temperature programming, or model 600 D with flame detector. Columns of various loadings (5%, 10%, 15%) and dimensions (6 ft × $\frac{1}{8}$ in., 5 ft × $\frac{1}{8}$ in., 10 ft × $\frac{1}{4}$ in., 15 ft × $\frac{1}{4}$ in.) were employed with the liquid phases XE-60, UCW-98, SE-30, carbowax-20 M, and PPE (OS-138). Peak intensities were measured either with a planimeter or by triangulation. Ozone was produced from a Welsbach Ozonator model T-816. Low temperature baths were either an acetone – dry ice mixture (−78°C) or a Neslab low temperature bath, model LTE-9 (−70°C – 0°C). Solvents used were spectrograde carbon tetrachloride, methylene chloride, or hexane previously treated with ozone, or spectrograde ethyl acetate.

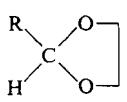
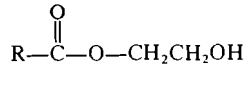
Stoichiometry and Order of the Reaction



The fast reacting dioxolane acetals (**1**) were used for these experiments. The rate of ozone production was measured iodometrically by absorbing the ozone–oxygen flow in an aqueous solution of potassium iodide (4%) during 300 s. The ozone–oxygen stream was passed through 10 mL of solvent (CCl_4 or CH_2Cl_2) before the KI solution to reproduce the reaction conditions. A solution of acetal in CCl_4 or CH_2Cl_2 (ca. 0.1 *M*) at 0°C was then introduced in place of the solvent above and the same procedure was repeated. The absorbed ozone can then be obtained by difference. A dry ice – acetone trap was placed between the reaction vessel and the KI vessel to remove any solvent losses. Acetal concentrations were assayed by vpc.

Kinetics



The kinetic method used to measure slow rates at low temperatures in ethyl acetate as solvent has been described previously (4). Rapid rates (solvent CCl_4; 0–35°C, dioxolane acetals **1**) were measured by stop-flow techniques using a Durrum-Gibson D-130 instrument, equipped with a reaction cuvette of 20 mm, a Jarrel-Ash 0.25 m monochromator with deuterium lamp. Optical densities were recorded on a Techtronic 535 oscilloscope equipped with a Polaroïd C-12 camera. Rates were measured by following the disappearance of ozone at 280 or 290 nm, where the extinction coefficients in carbon tetrachloride are 670 and 789 M^{-1} respectively (6). The competition method used to obtain relative rates for the dioxolane acetals **1** was that described by Hammett (7).

Results

The stoichiometry of the reaction of oxidation of 2-phenyl-1,3-dioxolane (**1**, R = C_6H_5) by ozone was first studied by Deslongchamps *et al.* (2) at −78°C in ethyl acetate as solvent. They found that in excess acetal, ozone oxidized 1 mol acetal to produce 1 mol oxygen and 1 mol hydroxy ester **2** (R = C_6H_5). The stoichiometry was further verified by the following experiments. A solution of acetal in excess concentration was reacted in an ozone–oxygen stream at 0°C. The acetals were assayed by vpc, and the absorbed ozone by iodometric titrations. The results are shown in Table 1. Similarly, a solution of acetal was reacted with excess ozone in carbon tetrachloride at 25°C under the conditions of a kinetic experiment. Ozone concentrations were measured spectrophotometrically. The results are shown in Table 2.

1

2

The results therefore show that under conditions where either ozone or acetal is in excess concentration, the stoichiometry of the reaction is clearly 1:1.

Order of the Reaction

The stoichiometry of the reaction, now being clearly established, suggests a second order reaction. Under the conditions where ozone is in slight excess, eq. [2] should apply (8)

$$[2]\quad \frac{1}{[O_3]_0 - [A]_0} \ln \frac{[O_3][A]_0}{[O_3]_0[A]} = kt$$

where $[O_3]$ is the concentration of ozone as determined spectrophotometrically, [A] the concentration of acetal deduced from the stoichiometry, and the subscript 0 refers to initial concentrations. Typical results are shown in Fig. 1 for the reaction of 2-methyl-1,3-dioxolane (**1**, R = CH_3) in carbon tetrachloride at 25°C. Other results obtained at different concentrations of ozone and acetal are shown in Table 3. These data suggest that the reaction is first order in both ozone and acetal.

Under the conditions where the acetal is in large excess, the reaction should become pseudo-first order in ozone. Again, for the case of the reaction of 2-methyl-1,3-dioxolane (**1**, R = CH_3) with ozone in carbon tetrachloride at 25°C, good linearity was observed as illustrated in Fig. 2. Table 4 shows the results obtained for different initial concentrations of ozone and acetal. The consistency of the second order rate constant and the identity of this rate with that obtained from second order kinetics clearly demonstrate that the reaction order is one in ozone and one in acetal.

Activation Parameters

The effect of temperature on the rate of oxidation of different acetals under various conditions is shown in Table 5. The activation parameters, found by plotting ln (k/T) vs. $1/T$, for these and other acetals are listed in Table 6.

Substituent Effects

The influence of substituents on the reactivity of various types of acetals was also investigated. Relative rate of oxidation of 2-alkyl substituted- and

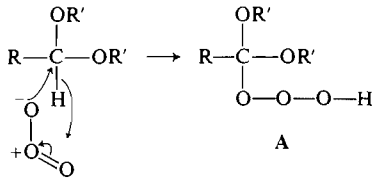
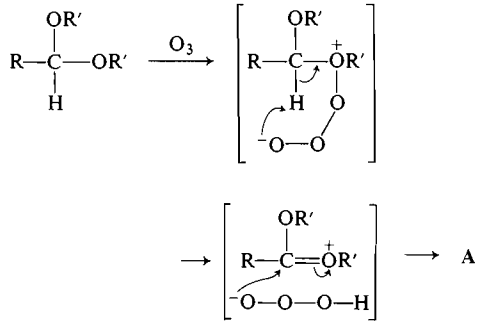
oxidation of ozone of 2-hexyl-5,5-dimethyl-1,3-dioxane was investigated at two temperatures. The results are shown in Table 10. The concentration of ozone in the different solvents was determined as previously published (4).

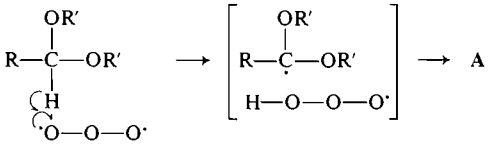


Discussion

Several mechanisms can be envisaged for the oxidation of the C—H bond of the acetal function by ozone to form the acetal hydrotrioxide **A**. These are depicted in Scheme 3. The possibility that the hydride transfer mechanism (Scheme 3*a*) might be operative arises from the strong conformational effects observed in these reactions (2–4). Antiperiplanar lone pairs will elongate the C—H bond as well as stabilize the incipient dioxonium ion. The 1,3-diplolar insertion mechanism (Scheme 3*b*) has been postulated for the ozonation of ethers (10–12), aldehydes (13, 14), and hydrocarbons (15, 16). Ozone attack on oxygen (Scheme 3*c*) is similar to that proposed for the ozonation of certain amines



(*a*) Hydride transfer mechanism



(*b*) 1,3-Dipolar insertion mechanism

(*c*) Attack on an ether oxygen

(*d*) Radical mechanism

SCHEME 3

(17), sulfides (18), and ethers (12). Finally, radical mechanisms (Scheme 3*d*) have been proposed for the ozonation of certain hydrocarbons (19–21) and alcohols (21) as well as ethers at high temperatures (11).

The highly negative entropies of activation found

for these reactions (Table 6) suggest a highly ordered transition state. Further, electron donation in the substituent accelerates the rates (Tables 7 to 9). These facts are compatible with all the mechanisms proposed in Scheme 3, except perhaps the radical mechanism (Scheme 3*d*) where one would expect a less negative entropy of activation (22). Although this criterion is not convincing by itself the fact that compound **3**, which would produce the stabilized radical **4**, did not react at all with ozone at room temperature for 3 h in ethyl acetate (2), strongly militates against a radical pair mechanism.

3

4

All ρ values (Table 9) are small in magnitude no matter what the experimental conditions (temperature and solvent). This can be interpreted by invoking either the argument that the charge created in the transition state is mainly stabilized by the oxygen atoms of the acetal function and to a much lower extent by the substituent, or else little charge is created in the transition state. This latter reason would be in accord with the observed solvent effects (Table 10). At −50°C for example, the observed acceleration is only a factor of 2 in going from the non-polar hexane solvent to the very polar acetic anhydride solvent. The same is true at −78°C (hexane to ethyl acetate). These facts would tend to eliminate highly polar transition states and/or intermediates described in Scheme 3*a* and 3*c*.

The most likely mechanism would then be the insertion mechanism (Scheme 3*b*).[3] Further evidence for this mechanism will be provided from a study of primary and secondary isotope effects presently underway.

Acknowledgments

Regioselectivity in cycloaddition reactions on solid phases[1]

VARDA YEDIDIA AND CLIFFORD C. LEZNOFF
Department of Chemistry, York University, Downsview, Ont., Canada M3J 1P3

Received November 23, 1979

VARDA YEDIDIA and CLIFFORD C. LEZNOFF. Can. J. Chem. **58**, 1144 (1980).

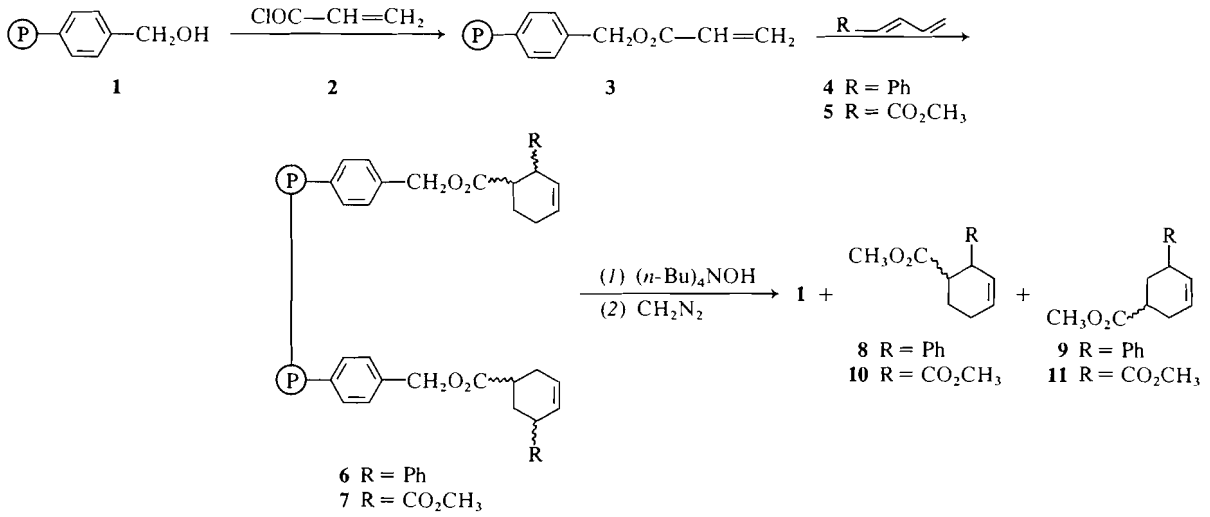
A 1% crosslinked divinylbenzene–styrene copolymer, incorporating benzyl acrylate groups, reacted in normal Diels–Alder reactions with *E*-1-phenyl-1,3-butadiene or methyl *E*-2,4-pentadienoate to give their respective polymer-bound benzyl cyclohexenecarboxylates. Polymer-bound benzyl propiolate and polymer-bound benzyl phenylpropiolate reacted with benzonitrile oxide in a typical 1,3-dipolar addition reaction to give their respective polymer-bound isoxazoles. Cleavage of the polymer-bound Diels–Alder adducts and the polymer-bound 1,3-dipolar addition adduct derived from polymer-bound benzyl propiolate gave mixtures of *ortho* and *meta* regiomers similar to those produced in analogous reactions in solution. Cleavage of the polymer-bound 1,3-dipolar addition adduct, derived from polymer-bound benzyl phenylpropiolate, followed by esterification, gave a solitary adduct, 4-carbomethoxy-3,5-diphenylisoxazole, but an analogous solution 1,3-dipolar addition yielded a 1:1 ratio of the two possible regiomers.

VARDA YEDIDIA et CLIFFORD C. LEZNOFF. Can. J. Chem. **58**, 1144 (1980).

Un copolymère styrène–divinylbenzène réticulé à 1% incorporant des groupes acrylate de benzyle réagit selon une réaction normale de Diels–Alder avec le phényl-1-*E* butadiène-1,3 ou le pentadièn-2,4 oate de méthyle pour donner leurs cyclohexènecarboxylates de benzyle respectifs liés aux polymère. Le propiolate de benzyle et phénylpropiolate de benzyle liés au polymère réagissent avec l'oxyde de benzonitrile selon une addition dipolaire-1,3 typique pour conduire à leurs isoxazoles respectifs liés au polymère. Le clivage des adduits de Diels–Alder du polymère auxquels ils sont liés ainsi que des adduits dipolaires-1,3 provenant du propiolate de benzyle liés au polymère conduit à des mélanges de régioisomères *ortho* et *méta* semblables à ceux obtenus lors des réactions analogues en solution. Le clivage du polymère de l'adduit dipolaire-1,3 qui provient du phénylpropiolate de benzyle lié au polymère suivi d'une estérification conduit à un seul produit, le carbométhoxy-4 diphényl-3,5 isoxazole; toutefois une réaction analogue en solution fournit les deux régioisomères possibles dans un rapport 1:1.

[Traduit par le journal]

Introduction



Cycloaddition reactions involving preformed insoluble polymer supports are rare. Blazka and Harwood (3) reacted a polymer-bound maleamide with cyclopentadiene to give a polymer-bound Diels–Alder adduct for possible use as a handle in enzymatic studies. Nieuwstad *et al.* (4) used a series of polymer-bound dienes in cyclo addition reactions with sulfur dioxide for the purpose of removing sulfur dioxide from waste and flue gases. In both of these cases the cycloaddition adducts were not liberated from the polymer support. In some mechanistic studies, Rebek and Gaviña and Gaviña *et al.* (5) have achieved the trapping of reactive intermediates with polymer-bound substrates and the Diels–Alder-like adducts were cleaved from the polymer and isolated.

Our interest in studying cycloaddition reactions on insoluble polymer supports results from the fact that we have achieved the synthesis of several types of *alicyclic* compounds in multistep syntheses on solid phases including chalcones (6), carotenoids (7), and insect pheromones (8) and wish to extend the synthetic possibilities to include the vast array of natural products containing cyclic systems. Only a few cyclization reactions have been accomplished on solid phases (9, 10). In addition, we felt that cycloaddition reactions performed on solid phases could result in cycloadducts having an altered ratio of regiomers compared to their solution phase analogs. It is well known that 1-substituted-1,3-butadienes react with 1-substituted alkenes containing an electron withdrawing group to give a great predominance of the *ortho* adduct over the *meta* adduct (11–13), often to the exclusion of the *meta* adduct entirely (14). In fact the problem of obtaining the disfavoured *meta* adducts has recently been addressed by Danishefsky *et al.* (15). We felt that the attachment of the dienophile or diene to an insoluble polymer support, necessarily through the substituent group, would increase the steric bulk of the substituent so that the *meta* adduct would become favoured over the *ortho* adduct. We also hoped that the yields of Diels–Alder reactions on insoluble polymer supports would increase compared to their analogous reactions in solution phase due to the decreased probability of intraresin reactions leading to polymeric products (10, 16). Furthermore, the Diels–Alder adducts could be efficiently isolated from the reaction mixture by simple filtration leaving excess reactants and by products in the solution phase (17). To ensure that formation of a *meta* adduct was not fun-

SCHEME 1.

damentally electronically disfavoured we selected known examples of Diels–Alder reactions in solution which gave at least some, however small, *meta* adduct and adapted those reactions to the solid phase conditions.

It was envisioned that altered regioselectivity of polymer-bound Diels–Alder reactions (compared to similar reactions in the solution phase) due to the steric bulk of the polymer may be difficult to achieve as most suitable Diels–Alder reactions are performed at moderately high temperatures where polymer mobility is high. For this reason we also wished to examine cycloaddition reactions at room temperature or lower. The 1,3-dipolar additions of nitrile oxides with alkenes or alkynes (18, 19) is carried out below room temperature and examples exist in which mixtures of regiomers are obtained. Furthermore, 1,3-dipolar additions are more sensitive to the polarity of the solvent in which the reaction occurs and it is possible that local solvent effects of the insoluble polymer at the reaction site could influence the regioselectivity of the 1,3-dipolar cycloadditions.

Results and Discussion

Diels–Alder Cycloadditions

A suspension of a 1% crosslinked divinylbenzene–styrene copolymer, containing benzyl alcohol functional groups, (**1**) (20), in tetrahydrofuran (THF) was treated with an excess of acryloyl chloride (**2**) and stirred for 18 h under argon at room temperature. Filtration of the mixture yielded the polymer-bound benzyl acrylate (**3**), suitable as a polymer-bound dienophile in Diels–Alder reactions (3). Treatment of a suspension of **3** with *E*-1-phenyl-1,3-butadiene (**4**) in hot xylene or methyl *E*-2,4-pentadienoate (**5**) in hot toluene gave the polymer-bound Diels–Alder cyclohexene adducts (**6**) and (**7**) respectively. Cleavage of **6** with tetra-*n*-butylammonium hydroxide in THF and subsequent esterification of the crude products yielded a mixture of *cis* and *trans* isomers of methyl 2-phenyl-3-cyclohexenecarboxylates (**8**) and *cis* and *trans* isomers of methyl 5-phenyl-3-cyclohexenecarboxylates (**9**) (21, 22). Similar treatment of **7** gave a mixture of *cis* and *trans* isomers of dimethyl 3-cyclohexene-1,2-dicarboxylates (**10**) and *cis* and *trans* isomers of dimethyl 3-cyclohexene-1,3-dicarboxylates (**11**) (14) (Scheme 1). Polymer **1** was recovered from both cleavage reactions and was capable of being recycled with little loss of capacity. The quantity of **2** bound to **1** was determined by cleavage of **3** with K_2CO_3 in methanol (23) to give solely 3-methoxypropanoic acid (**12**), the cleaved addition product. The amount of **12** recovered from **3** is consistent with the capacity of similar polymers (23), even though it is possible that some acrylic acid itself was formed and lost in the work-up through polymerization or evaporation. Thus the determined capacity of **3** for **2** represents a minimum value.

We have generally cleaved polymer-bound esters under basic conditions using initially (24) tetra-*n*-butylammonium hydroxide or K_2CO_3 in methanol but latterly exclusively the K_2CO_3 method (23) as it is simple and results in fewer by-products. Unfortunately attempted cleavage of **6** with K_2CO_3 in methanol gave some of **8** and **9** but even after 48 h, an infrared spectrum of the resulting polymer exhibited an absorption band at 1725

cm^{-1} indicating that complete cleavage had not occurred. Cleavage of **6** with tetra-*n*-butylammonium hydroxide in THF resulted in complete removal of the ester functionality.

Although we had successfully prepared cyclohexenes on solid phases by two Diels–Alder reactions we were interested in knowing whether we had changed the ratio of regiomers **8** to **9** and **10** to **11** compared to similar reactions not involving the polymer. Although Nazarov *et al.* (22) had previously reacted *methyl* acrylate (**13**) with **4** to give **8** and **9** in a 97:3 ratio and Overman *et al.* (14) reacted **13** with **5** to give **10** and **11** in an 82:18 ratio, we felt that even better control solution reactions would be the Diels–Alder reactions of *benzyl* acrylate (**14**) with **4** and **5** respectively. Thus **14** reacted with **4** to give a crude mixture of benzyl 2-phenyl-3-cyclohexenecarboxylates and benzyl 5-phenyl-3-cyclohexenecarboxylates which were cleaved and esterified in a manner identical to that of the polymer-bound adduct **6**. Isolation and purification of the products by preparative thin-layer chromatography (tlc) gave a mixture of **8** and **9**. The mixture of **8** and **9** could be readily analyzed by its nuclear magnetic resonance (nmr) spectrum which exhibited distinct $-OCH_3$ resonances for the two diastereomers of **8** and the two of **9**. Gas chromatography (gc) of the mixture exhibited four peaks of which the two fast moving ones of **8** were distinctly separated from the slower moving peaks of **9**. In addition the mixture of **8** and **9** was dehydrogenated as before (22) to give methyl 2-phenylbenzoate (**15**) and methyl 3-phenylbenzoate (**16**), which were compared by nmr and gc to authentic **15** and **16**, prepared by esterification of commercially available 2-phenylbenzoic acid and 3-phenylbenzoic acid. In a similar manner **14** reacted with **5** in a solution phase Diels–Alder reaction to give a mixture of the two diastereomers of **10** and the two of **11**, as shown by gc and nmr analysis. Hydrogenation of the mixture of **10** and **11** yielded a mixture of the saturated *cis*- and *trans*-dimethyl cyclohexane-1,2-dicarboxylates (**17**) and *cis*- and *trans*-dimethyl cyclohexane-1,3-dicarboxylates (**18**). Authentic *cis*-**17** and *trans*-**17** were prepared from the commercially available diacids. An authentic mixture of *cis*- and *trans*-**18** was readily prepared by oxidation of the commercially available mixture of cyclohexane-1,3-dimethanols by the method of Corey and Schmidt (25). The mixture of Diels–Alder adducts, **10** and **11**, obtained for the polymer-bound acrylate **3** and **5** was also hydrogenated to give a mixture of *cis*- and *trans*-**17** and *cis*- and *trans*-**18** which were compared to authentic **17** and **18** prepared above. The gc data of the *cis* and *trans* isomers of **8**, **9**, **17**, and **18** show the ratios of **8**:**9** and **17**:**18** for both the solid phase and solution Diels–Alder reactions (Table 1).

TABLE 1. Comparisons of the regioselectivity and yields in Diels–Alder reactions on solid phases and in solution

[e]From ref. 14.

As we can see from the data in Table 1, the Diels–Alder reactions performed herein on solid phases are similar to those done in a homogeneous phase with respect to distribution of regiomers and absolute yields of products.[2]

1,3-Dipolar Cycloadditions

Since it was felt that the lack of extensive alterations in regioselectivity in the Diels–Alder reactions on solid phases compared to their solution analogs (Table 1) was a result of the high temperatures of the Diels–Alder reactions, we decided to examine a cycloaddition reaction that occurs readily at lower temperatures but still gives a mixture of regiomers. Thus polymer **1** reacted with propiolic acid (**19**) or phenylpropiolic acid (**20**) to give the polymer-bound benzyl propiolate (**21**) and polymer-bound benzyl phenylpropiolate (**22**). Treatment of **21** and **22** with benzonitrile oxide, generated *in situ* from α-chlorobenzaldoxime, at 0°C in THF yielded the polymer-bound benzyl isoxazoles (**23**) and (**24**) respectively. Base cleavage of **23** and **24** as before, followed by esterification with CH_2N_2, gave *solely* methyl 3-phenylisoxazole-5-carboxylate (**25**) and *only* methyl 3,5-diphenylisoxazole-4-carboxylate (**26**) respectively in reasonable yield (Scheme 2). Although Huisgen *et al.* (26, 27) have shown that *methyl* propiolate and *methyl* phenylpropiolate reacted in a 1,3-dipolar addition addition reaction to give a *72:28 mixture* of **25** and methyl 3-phenyl-

[2]In this paper we were particularly interested in the possible change in *regioselectivity* of adducts in going to solid phase Deils–Alder reactions from their solution analogs and were less interested in changes in enantioselectivity. In addition, our base cleavage method is likely to cause *cis–trans* isomerization of the cycloadducts (22) and hence the *original* ratio of *cis* to *trans* isomers obtained in the solid phase reactions could not be accurately determined.

SCHEME 2.

isoxazole-4-carboxylate (**27**) and a *99:1 mixture* of **26** and methyl 3,4-diphenylisoxazole-5-carboxylate (**28**) respectively under almost identical conditions we believed that model reactions more similar to the polymer would use *benzyl* propiolate (**29**) and *benzyl* phenylpropiolate (**30**). Thus treatment of **29** and **30** with benzonitrile oxide as before yielded mixtures of crude benzyl isoxazoles. Base cleavage of the crude mixtures, derived from **29** and **30**, under conditions identical to those under which **23** and **24** were cleaved, followed, as before, by treatment with CH_2N_2 and purification by preparative tlc yielded pure **25** and 1:1 mixture of **26** and **28** respectively. The products were analyzed by nmr and gc and the results are summarized in Table 2. It is interesting to note that the regioselectivity of the 1,3-dipolar addition of **21** and **29** with benzonitrile oxide is identical and completely regioselective to give, after hydrolysis and reesterification, solely **25** while the reported addition of benzonitrile oxide to methyl propiolate gave a 3:1 *mixture* of regiomers **25** and **27**. We originally proposed that a bulky ester functionality on the alkyne would disfavour the normal "*ortho*" adduct compared to the "*meta*" adduct in cycloaddition reactions. The above experiments justified this hypothesis but showed that a polymer-bound benzyl ester group does *not* necessarily make the dienophile bulkier than a *simple* benzyl ester. On this basis we were very surprised to find that the 1,3-dipolar cycloaddition of polymer **22** with benzonitrile oxide proceeded to give *exclusively* the more hindered "*ortho*" adduct **26**, while the simple benzyl analog **30** yielded an expected mixture of **26** and **28**. Thus the bulky benzyl ester **30** yielded more of the "*meta*" isomer than the reported use of methyl propiolate which gave almost no "*meta*" adduct. Thus the course of the 1,3-dipolar cycloaddition of **30** proceeded in the right direction, but the reaction of polymer **22** with benzonitrile oxide proceeded in the opposite direction on the basis of the steric effect. It is known that reactions occurring on insoluble polymer supports

TABLE 2. Comparisons of the regioselectivity in benzonitrile oxide reactions with alkynoic esters on solid phases and in solution

Alkynoic ester	Products	Yield (%)	Regioselectivity[a] ratio
21	**25**[b]	80	100:0
29	**25**[b]	30	100:0
Methyl propiolate	**25**+**27**	98	72:28[c]
22	**26**[b]	81	0:100
30	**26**+**28**[b,d]	66	55:45
30	**26**+**28**[b,e]	54	72:28
Methyl phenylpropiolate	**26**+**28**	94	1:99

[a]This value represents the ratio of isoxazole 5-carboxylates compared to isoxazole 4-carboxylates.

[c]See ref. 27.
[d]In THF.
[e]In toluene.

can proceed in a solvent environment quite different than that of the bulk of solution (28) and that 1,3-dipolar cycloadditions are solvent dependent (13). It is thus possible that in the reactions of **22** with benzonitrile oxide the solvent at the reaction site is not THF, the bulk solvent, but the polymer itself which is toluene-like. To test this hypothesis we conducted the solution analog reaction of **30** with benzonitrile oxide in *toluene* to more closely simulate the possible solvent environment at the reactive site of the polymer. Cleavage of the crude product as above and treatment with CH_2N_2 actually afforded a mixture of **26** and **28** in a *decreased* ratio (1:2.5). Thus the local environment at the reaction site is *not* toluene-like and the true reason for the exclusive formation of **26** in the polymer-supported 1,3-dipolar addition remains conjecture at this time.

Conclusions

Our idea that a polymer-bound benzyl group is so bulky compared to a simple benzyl group that the regioselectivity of polymer-bound cycloaddition reactions can be altered compared to its solution analog is not valid and it appears that the polymer-

bound benzyl group is no more bulky than a simple benzyl group, at least, for Diels–Alder reactions at high temperatures. We have shown, however, that a benzyl ester group itself can alter the regioselectivity of cycloaddition reactions compared to simple methyl esters. We have demonstrated that the polymer can alter the regioselectivity of 1,3-dipolar cycloaddition reactions compared to its solution analog. Finally, we have demonstrated that cycloaddition reactions can be routinely performed on solid phases in yields comparable to or better than those in solution.

Experimental

A chloromethylated 1% divinylbenzene (DVB) – styrene copolymer, containing 1.09 mequiv. Cl/g of resin, obtained from Sigma Chemical Company was used as the starting resin in all resin transformations. Filtration was done under vacuum using sintered glass Büchner funnels. Suspensions and solutions were stirred using magnetic stirrers. Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra were recorded on a Varian LM 360 spectrometer using deuterochloroform as solvent and tetramethylsilane as the internal standard. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).) Mass spectra (ms) were recorded at 70 eV on a Hitachi Perkin Elmer RMU 6E mass spectrometer, attached to a Perkin Elmer 902 gas chromatograph (gc) fitted with a Scot 50-ft stainless steel OV 225 column. The number in parentheses after the indicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Other gas chromatography (gc) was recorded on a Varian aerograph (series 1700) gas chromatograph with a Varian aerograph (model 20) recorder. The column was a 7-ft column, 6% SE 30, 4% QF 1 on acid washed HMDS. Helium was used as the gas carrier with a 1 mL/s flow rate. The chart speed was 1.7 cm/s. The retention times are given in cm.

Preparation of Polymer-bound Acrylate (3)

A suspension of 5 g of 1% crosslinked divinylbenzene–styrene copolymer containing benzyl alcohol groups (**1**) in 100 mL of dry THF was stirred with 4.0 mL (49.3 mmol) of acryloyl chloride (**2**) under an argon atmosphere at room temperature for 18 h. The polymer was filtered, washed twice with THF, twice with methanol, twice with THF, twice with ether, and air dried to yield the polymer-bound acrylate (**3**); ir (KBr): 1725 (CO_2R), 1635, and 1415 cm^{-1} ($RCH{=}CH_2$).

The quantity of acryloyl chloride bound to polymer **1** was determined by cleavage of polymer **3** with K_2CO_3 in methanol (23) to yield 3-methoxypropionic acid from which the loading capacity of **3** was calculated. Thus polymer **3** contained 0.58 mmol of acrylate per gram of polymer.

Preparation of Polymers 6 and 7

A suspension of 3.5 g of polymer-bound acrylate (**3**) and 2.7 g (20.8 mmol) of *E*-1-phenyl-1,3-butadiene (**4**) (29) in 40 mL of xylene was refluxed for 18 h at 140°C in the presence of 0.05 g of phenyl-β-naphthylamine. The solution was cooled and the polymer was filtered and washed three times with benzene and twice with ether to give polymer **6**; ir (KBr): 1730 cm^{-1} (CO_2R).

In a similar manner polymer **3** was allowed to react with methyl *E*-2,4-pentadienoate (**5**)[3] in toluene at 110°C for 24 h in the presence of 4-*tert*-butylcatechol (14) to yield polymer **7**; ir (KBr): 1720–1740 cm^{-1} (CO_2R).

Preparation of the Cyclohexene Diels–Alder Adducts 8 and 9 from Polymers 6 and 10, and 11 from Polymer 7

A suspension of 0.4 g of polymer **6** was cleaved with 8.5 mmol of tetra-*n*-butylammonium hydroxide in 10 mL THF (30), and the crude product was esterified with CH_2N_2. The product was purified by preparative tlc using hexane–benzene (1:1) as the eluant to give 40 mg (80%) of a mixture of compounds consisting of **8** and **9** as an oil; ir (neat): 1710–1745 (CO_2R), 1655 (C=C), 1600 (ArC=C), and 1170 cm^{-1} (C—O); nmr δ: 7.18 (m, aromatic), 5.6–5.85 (m, vinylic), 3.85 (m, PhC*H*C=C), 3.65, 3.52, and 3.47 (s, OCH_3), 1.8–2.8 (m, allylic CH_2 and CH_2).

Gas chromatography (gc) (column temperature 180°C) indicated the presence of four isomers with the following retention times: $t_1 = 8.7$, $t_2 = 9.6$, $t_3 = 11.1$, $t_4 = 12.1$.

The mass spectrum (ms) of all the four isomers, obtained directly from gc–ms, showed molecular ions at *m/e* 216 and fragment ions at 156, 115, and 91.

Using a mixture of the *cis* and *trans* isomers of **8** and also a total mixture of the four isomers of **8** and **9** obtained as reported (22), it was established (using the peak enhancement method) that the first two peaks in the gc are due to the *cis* and *trans* isomers of **8** while the latter two minor peaks are due to the *cis* and *trans* isomers of **9** (Table 1).

The mixture of **8** and **9** liberated from polymer **6** was dehydrogenated as before (22) to give a mixture containing methyl 2-phenylbenzoate (**15**) and methyl 3-phenylbenzoate (**16**). Authentic **15** and **16** were obtained by esterification with CH_2N_2 of commercially available (K & K Fine Chemicals) 2-phenyl- and 3-phenylbenzoic acids respectively. Comparison of **15** and **16** obtained via **8** and **9** with authentic **17** and **18** by gc showed the compounds to have identical retention times, t(**15**) = 9.0, t(**16**) = 16.2.

Similarly (except that the purification was done using ether–hexane (1:1) as the eluant) 1 g of polymer **7** gave 60 mg (52%) of a mixture of **10** and **11** as an oil; ir (neat): 1710–1750 (3 shoulders, CO_2R); 1660 (C=O), and 1170 cm^{-1} (C—O); nmr δ: 5.8 (m, vinylic), 3.71 and 3.69 (s, OCH_3), 1.95–2.5 (m, CH_2).

The mixture was converted to the corresponding dimethyl cyclohexanedicarboxylates using 20 mg of 10% palladium on charcoal in 3 mL ethanol under 1 atm of hydrogen. The completion of the reaction was indicated by the disappearance of the vinylic protons in the nmr spectrum.

Authentic *cis*- and *trans*-dimethyl cyclohexane-1,2-dicarboxylates (**17**) were prepared from the commercially available (Aldrich) diacids by esterification with CH_2N_2, while a mixture of *cis*- and *trans*-dimethyl cyclohexane-1,3-dicarboxylates (**18**) was obtained by oxidation (25).

The gc analysis (column temperature 150°C) indicated the presence of 3 peaks. The peak enhancement method established that the first peak (t = 7.6) is due to the *cis* and *trans* isomers of (**17**) (76.5%) and the other two peaks ($t_1 = 8.6$, $t_2 = 10.0$) are due to the *cis* and *trans* isomers of (**18**) (23.5%).

The Use of Benzyl Acrylate (14) in the Preparation of the Diels–Alder Adducts 8 and 9 from 4 and the Adducts 10 and 11 from 5

To 2 g (12.3 mmol) or benzyl acrylate (**14**), prepared by the method of Banks *et al.* (31), in 5 mL of xylene was added 2.0 g

[3]Obtained from Tridom Chemicals and redistilled before use.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

(15.4 mmol) of *E*-1-phenyl-1,3-butadiene (**4**) (29) and the mixture reacted under conditions similar to those used in the preparation of polymer **6**. Xylene and the unreacted starting materials were distilled under reduced pressure. A portion of 0.3 g of the crude residue was stirred with 5 mmol of tetra-*n*-butylammonium hydroxide in 10 mL of THF for 48 h. The THF was then evaporated and the residue was diluted with 20 mL of water and washed four times with 20 mL of ether. The ether was dried over $MgSO_4$ and evaporated. No unhydrolyzed material was detected by nmr.

The water layer was acidified with HCl and extracted three times with ether. The ether was dried over $MgSO_4$ and evaporated. The product was then esterified and purified as before to yield 215 mg of the cyclohexene diesters. Analysis by gc indicated the presence of 94.4% of a mixture of *cis* and *trans* **8** and 5.6% of a mixture of *cis* and *trans* **9** (Table 1).

Similarly, 1 g (6.2 mmol) of **14** and 0.7 g (6.2 mmol) of methyl *E*-2,4-pentadienoate (**5**) were refluxed in 4 mL of toluene at 110°C for 24 h in the presence of 0.05 g of 4-*tert*-butylcatechol (14) to give a crude mixture of **10** and **11**.

Hydrolysis, hydrogenation, and esterification with CH_2N_2 of a portion of the product as before yielded a mixture containing 88.2% of a *cis* and *trans* mixture of **17** and 11.8% of a *cis* and *trans* mixture of **18**.

Preparation of Polymer-bound Propiolate 21 and Phenyl Propiolate 22

In a typical experiment, 3.5 g of **1**, 2.2 mL (35 mmol) of propiolic acid (**19**), and ~0.2 g of *p*-toluenesulfonic acid (32) in 150 mL benzene were placed in a round-bottomed flask of a Soxhlet extractor in which molecular sieves (3 Å) had been placed in a thimble. The suspension was refluxed for 24 h. The polymer was then filtered and washed twice with benzene, twice with methanol, once with water, once with methanol, once with dioxane, and twice with ether to give the polymer-bound propiolate (**21**); ir (KBr): 3280 (C≡C—H), 2140(C≡C), and 1715 cm^{-1} (CO_2R).

Similarly, **1** reacted with phenyl propiolic acid (**20**) to give the polymer-bound phenyl propiolate (**22**); ir (KBr): 2240 (C≡C—Ph) and 1710–1730 cm^{-1} (CO_2R).

Base hydrolysis of polymers **21** and **22** with tetra-*n*-butylammonium hydroxide in THF yielded regenerated polymer **1** and the respective propiolic acid from which the loading capacities of **21** and **22** were determined. Thus polymers **21** and **22** contained 0.43 mmol/g of **19** and 0.48 mmol/g of **20** respectively.

Preparation of the Polymer-bound 1,3-Dipolar Adducts 23 and 24

A suspension of 2.5 g polymer-bound propiolate (**19**) and 2.7 g (17.5 mmol) of benzohydroximoyl chloride (33) in 75 mL of dry THF was cooled in an ice bath under an argon atmosphere. To this mixture, 2.8 mL (20 mmol) of freshly distilled triethylamine in 15 mL of dry THF was added dropwise while stirring during a 20 min period. After the addition the reaction mixture was cooled for another hour and then allowed to warm to room temperature and stirred for 20 h. The polymer was filtered and washed twice with THF, twice with methanol, once with water, twice with dioxane, and twice with ether. The ir spectrum of **23** exhibited a band at 1740 cm^{-1} (CO_2R) and no absorptions at 3280 and 2140 cm^{-1} due to residual propiolate.

Similarly, polymer **22** was allowed to react with benzonitrile oxide, prepared *in situ* as above. After the reaction mixture was stirred for 20 h at room temperature a second equivalent amount of benzohydroximoyl chloride was added to the solution. The addition of the triethylamine was repeated as before and the reaction mixture was stirred at room temperature for another 20 h. The ir spectrum of 24 exhibited a band at 1730 cm^{-1} and no band at 2240 cm^{-1} (C≡C—Ph).

Preparation of Methyl 3-Phenylisoxazole-5-carboxylate 25 and Methyl 3,5-Diphenylisoxazole-4-carboxylate (26)

A suspension of 2.5 g of polymer **23** was cleaved with tetra-*n*-butylammonium hydroxide in THF and the product was esterified with CH_2N_2 as before to yield 256 mg of crude methyl 3-phenylisoxazole-5-carboxylate (**25**) as a solid. The solid was recrystallized from methanol to give 175 mg of pure **25**, mp 108–109°C (lit. (27) mp 109–110°C); ir (KBr): 1730(CO_2R), 1602, 1592, 1577 (phenyl and isoxazole ring), and 1150 cm^{-1} (C—O); nmr δ: 7.37–7.9 (m, 5, aromatic *H*), 7.25 (s, 1, *H*C=C), 4.0 (s, 3, OCH_3); ms *m/e*: 203(88) (M^+), 116(72) 104(100), 77(83).

Similarly, **24** yielded methyl 3,5-diphenylisoxazole-4-carboxylate (**26**) (27), mp 97–98°C (lit. (27) mp 98–99°C); ir (KBr): 1725 (CO_2R), 1610, 1595, 1570 (phenyl and isoxazole ring), and 1130 (C—O); nmr δ: 7.25–7.98 (m, 10, aromatic *H*), 3.67 (s, 3, OCH_3): ms *m/e*: 279(18) (M^+), 142(100), 115(95), 77(78).

Preparation of Isoxazoles 25, 26, and 28 from the Solution 1,3-Dipolar Addition to Benzyl Propiolate (29) and Benzyl Phenylpropiolate (30)

A solution of 1 g (6.25 mmol) of benzyl propiolate (**29**) (34), prepared in the same manner as **21**, was treated with the equivalent amount of benzonitrile oxide using the same procedure as used for the preparation of polymer **23**. After the reaction was completed the THF or toluene was evaporated and the crude residue was dissolved in 20 mL of ether. The ether layer was washed three times with water, dried over $MgSO_4$ and the ether evaporated. A portion of 0.32 g of the crude product was then hydrolyzed with tetra-*n*-butylammonium hydroxide in THF and esterified with CH_2N_2 as before to yield 165 mg of crude **25** as the sole product, which was then purified on preparative tlc using benzene–hexane (6:4) as the eluant to give 100 mg of pure **25**.

Benzyl phenylpropiolate (**30**) was prepared by a described method for related compounds (32). The product was distilled at 160°C at 0.03 Torr to give **30** in 50% yield; ir (neat): 2200 (C≡C), 1700–1730 (CO_2R), and 1590–1610 cm^{-1} (phenyl); nmr δ: 7.32 (m, 10, aromatic *H*) and 5.17 (s, 2H, PhCH_2O_2C); ms *m/e*: 236(10) (M^+), 129(98), 102(100), 91(99), 77(40). *Anal.* calcd. for $C_{16}H_{12}O_2$: C 81.34, H 5.12; found: C 81.19, H 5.10.

In a manner similar to that described for **29**, **30** was allowed to react twice with equivalent amounts of benzonitrile oxide using the procedure used for the preparation of polymer **24**. Base hydrolysis and an identical work-up as above gave a mixture of products. The composition of the mixture was determined by the O—CH_3 singlets absorption in the nmr spectrum and was found to consist of 41% of **26**, 51% of **28**, and 8% of methyl phenylpropiolate; ir (KBr): 1705–1725 (CO_2R), 1610, 1590, 1570, and 1490 (phenyl and isoxazole ring), and 1120 cm^{-1} (C—O); nmr δ: 7.75–8.05 (m, *ortho*-aromatic *H*), 7.3–7.57 (m, aromatic *H*), 3.88, 3.8, and 3.67 (s, OCH_3). In one experiment toluene was used as solvent instead of THF to give a mixture consisting of **26** and **28** in a 28:72 ratio.

Dissociation kinetics of potassium anion in methylamine

Y. HARIMA, H. KURIHARA, AND S. AOYAGUI[1]

Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, 152 Tokyo, Japan

Received January 2, 1980

Y. HARIMA, H. KURIHARA, and S. AOYAGUI. Can. J. Chem. **58**, 1151 (1980).

The potential-sweep voltammograms of solvated electrons in methylamine containing KI as the supporting electrolyte demonstrate the coexistence of one- and two-electron species in equilibrium. The $it^{1/2}$ vs. log t curve obtained with potential-step chronoamperometry exhibits a transient part between two plateaux. The analysis of this curve yields the approximate value of 10^2 s^{-1} for the first-order rate constant of the dissociation of the two-electron species, K^-.

Y. HARIMA, H. KURIHARA et S. AOYAGUI. Can. J. Chem. **58**, 1151 (1980).

On a mesuré les voltammogrammes à variation linéaire de potentiel des électrons solvatisées dans la méthylamine qui contient le KI comme l'électrolyte. Ils démontrent la coexistence des espèces à un- et deux-électrons en équilibre. La courbe $it^{1/2}$ vs. log t qui a été tracée à l'aide de la chronoampèrométrie exhibe une région de passage entre deux plateaux. Faisant l'analyse de cette courbe, on a obtenu ainsi la valeur approximative de 10^2 s^{-1} pour la constante du premier ordre de la dissociation des espèces à deux-électrons, K^-.

Dissolution of alkali metals, M, into certain amines, amides or ethers and pulse radiolysis of alkali amides in these solvents yield various chemical species that may be called alkali metal species or solvated electron species. They may be any of the one-electron species, e.g. e_s^- and $(M^+ \cdot e_s^-)$, and the two-electron species, e.g. $(M^+ \cdot e_s^-)_2$ and M^-, where e_s^- is the free solvated electron and the parentheses mean the ion-pair. Kinetic studies on the formation of these species in amines and ethers have recently been developed extensively by means of pulse radiolysis in conjunction with optical detection of the reactants or products (1). This technique, however, has no potentiality in the direct measurement of dissociation rates. It has been obtained only indirectly by using the dissociation constant. When the optical distinction of alkali metal species is hardly possible, as is the case with liquid ammonia solutions (2), the formation rate constant cannot be obtained even with the pulse radiolysis technique. An attempt was made to measure the dissociation rate constant in this solvent by an electrochemical method, but it was beyond the accessible limit of this technique (3).

This note deals with the potential-step chronoamperograms and potential-sweep voltammograms of solvated electrons in methylamine containing KI. They indicate the electron-transfer process coupled with a chemical reaction, consequently promising the electrochemical elucidation of the dissociation kinetics of the two-electron species, possibly K^-. In this solvent the formation process of K^- from e_s^- and K^+ is too slow to be followed by pulse radiolysis (4).

Methylamine was prepared and purified according to the method of Yamamoto *et al.* (5). The procedures of handling the solvent and preparing KI solutions were the same as described elsewhere (3). An air-tight electrolysis cell was used. Solvated electrons were generated by electrolysis. Potential-sweep voltammetric and potential-step chronoamperometric experiments were carried out in the way described previously (3). In all chronoamperometric experiments the electrode potential was stepped by 100 mV towards the anodic direction from the equilibrium potential. Measurements were made at -50 ± 1°C.

Figure 1 shows log i vs. E plots in potential-sweep voltammetry of the cathodic generation of solvated electrons in a 0.5 M KI solution of methylamine, where i and E are respectively the current density and the electrode potential. The experimental points in region I lie on a straight line whose slope is equal to that of the diffusion-controlled electron-transfer process with $n = 1$, n being the number of electrons transferred. In region II, they come to deviate from it and tend to lie on a straight line with $n = 2$. These curves have the same characteristics as those obtained with liquid ammonia solutions (3), except that the current density at which the straight lines of $n = 1$ and 2 cross is two orders of magnitude lower than the corresponding one in the latter curves. In liquid ammonia it has been concluded that a two-electron species is

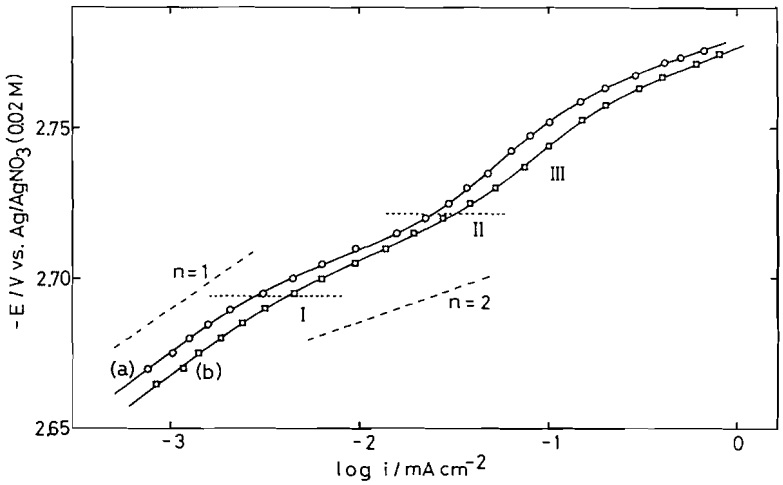

FIG. 1. Plots of log i vs. E in potential-sweep voltammetry for the cathodic generation of solvated electrons in 0.5 M KI solutions of methylamine at −50°C. Sweep rate: (*a*) 12.5 and (*b*) 25.0 mV s^{-1}. Broken lines show the theoretical slopes for the n-electron transfer reactions.

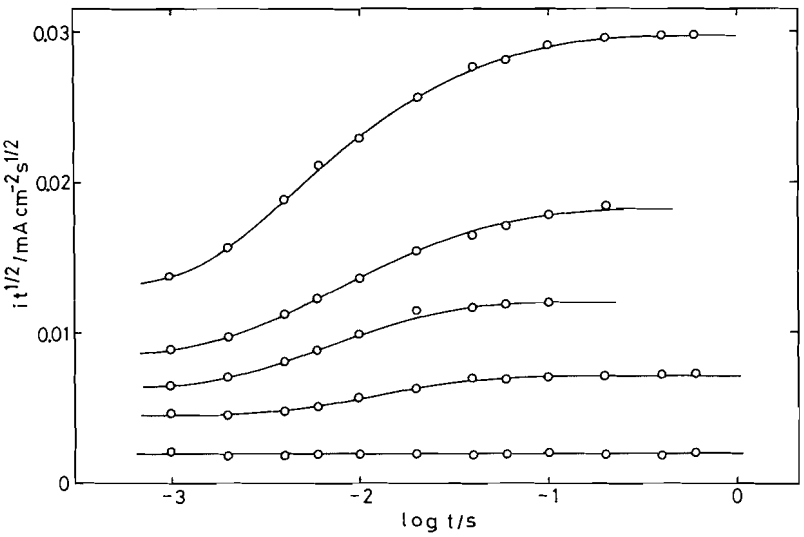

FIG. 2. Plots of $it^{1/2}$ vs. log t in potential-step chronoamperometry for the oxidation of 0.005 (lowermost)–0.1 (uppermost) mM solvated electrons in 0.5 M KI solutions of methylamine at −50°C. Potential-step height: +100 mV.

formed at potentials of region II, on the basis of such log i vs. E curves and also some other findings (3). From its analogy, it is very likely that the region II reaction in methylamine is also the formation of certain two-electron species.

Although region III is beyond the scope of this work, the concomitance of the potassium deposition may be strongly suggested by the poor reproducibility of the curves in this region and the poor solubility of this metal (6). It will be discussed in a separate paper on the basis of cyclic voltammetry.

Since it prevails to consider that the most probable two-electron species in alkylamines is M^- (7), the following reaction schemes can be written for regions I and II.

Region I:

$$[1]\qquad \begin{aligned} e_M^- &\rightleftharpoons e_s^- \\ e_s^- + K^+ &\underset{k_1}{\rightleftharpoons} (K^+ \cdot e_s^-) \end{aligned}$$

Region II:

$$[2]\qquad \begin{aligned} 2e_M^- &\rightleftharpoons 2e_s^- \\ 2e_s^- + 2K^+ &\rightleftharpoons 2(K^+ \cdot e_s^-) \underset{k_2}{\rightleftharpoons} K^- + K^+ \end{aligned}$$

where e_M^- is the electron in electrode metal and k's are the rate constants.

Figure 2 shows $it^{1/2}$ vs. log t plots in potential-step chronoamperometry obtained with 0.5 M KI solutions whose total solvated electron concentra-

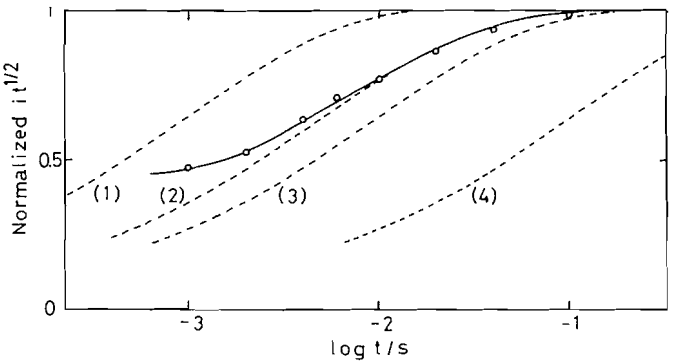

FIG. 3. Normalized $it^{1/2}$ vs. log t curves in potential-step chronoamperometry calculated with various α values. The circles reproduce the uppermost plot in Fig. 2. α = (*1*) 100, (*2*) 20, (*3*) 10, and (*4*) 1 s^{-1}.

tion, c_t, ranges from ca. 0.005 to 0.1 m*M*. In the lowermost curve corresponding to region I, the $it^{1/2}$ values are independent of time, as in liquid ammonia. This fact suggests that the electrode reaction in the solution containing only one-electron species is seemingly a simple diffusion-controlled process and the lower limit of the dissociation rate constant of $(K^+ \cdot e_s^-)$ is thus around 10^3 s^{-1} which is the reciprocal of the time-window of the technique employed. In solutions of higher c_t where K^- coexists with the one-electron species, e_s^- and $(K^+ \cdot e_s^-)$, each $it^{1/2}$ vs. log t curve has two plateaux and a transient region between them. At the first plateau the current density is considered to be controlled by the diffusuion of the one-electron species. The increase in $it^{1/2}$ with time in the transient region may be attributed to the kinetic current due to the formation of $(K^+ \cdot e_s^-)$ from K^-. For the sake of convenience in analysis, eq. [2] is rewritten in the following schematic form:

$$[3] \quad \begin{matrix} B \overset{k}{\rightleftharpoons} 2A \\ A \pm e_M^- \rightarrow C \end{matrix}$$

where k is the rate constant and B and A correspond respectively to K^- and the composite species whose concentration and diffusion coefficient are $[e_s^-] + [(K^+ \cdot e_s^-)]$ and D_{av}, respectively. Here the brackets mean the concentration and D_{av} the weighted mean of the diffusion coefficients of e_s^- and $(K^+ \cdot e_s^-)$. Figure 3 shows a comparison between the normalized experimental plot of $it^{1/2}$ vs. log t reproduced from the uppermost curve in Fig. 2 and the theoretical curve calculated from the analytical equation given by Tokuda and Matsuda (8) with various values for the parameter α defined by

$$[4] \quad \alpha = (1/3\pi)(D_A/D_B)([A]/[B])k$$

or in terms of $[e_s^-]$ and $[(K^+ \cdot e_s^-)]$, by

$$[5] \quad \alpha = (1/3\pi)(D_{av}/D_{K^-})k_2[K^+]([e_s^-] + [(K^+ \cdot e_s^-)])/[K^-]$$

where D's are the diffusion coefficients of the species subscript. The experimental curve was fitted best with the theoretical one of $\alpha = 20$ s^{-1}. The pseudo-first-order rate constant for the dissociation of K^-, $k = k_2[K^+]$, thus obtained was around 10^2 s^{-1}. The disagreement at low $it^{1/2}$ values may arise because the analytical equation was derived under the condition $[A]/[B] \ll 1$ which was not realized in the test solutions employed.

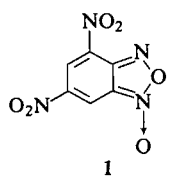
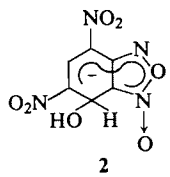
FRANÇOIS TERRIER, HABIB ACHASSI SORKHABI, FRANÇOIS MILLOT, JEAN-CLAUDE HALLE, and ROBERT SCHAAL. Can. J. Chem. **58**, 1155 (1980).



The kinetics of formation and decomposition of the hydroxyl-σ adduct **2** derived from 4,6-dinitrobenzofuroxan **1** have been studied in various water – dimethylsulphoxide (DMSO) – tetramethylammonium chloride ($I = 0.5\ M$) mixtures. At pH < 7, the formation of **2** occurs exclusively from water attack at the 7-carbon of **1**. This process is strongly favored by DMSO: the first-order rate constant $k_1^{H_2O}$ changes from $1.9 \times 10^{-2}\ s^{-1}$ in water to $1.33\ s^{-1}$ in 90% DMSO. Taking into account the decrease in the water content of the solutions, and assuming that only one water molecule participates in the reaction, this increase in $k_1^{H_2O}$ reflects a 10^3-fold increase in the ability of a water molecule to act as a nucleophile. This interesting result compares well with previous data reported by Murto for the solvolysis of 2,4-dinitrofluorobenzene in the same solvent mixtures.

FRANÇOIS TERRIER, HABIB ACHASSI SORKHABI, FRANÇOIS MILLOT, JEAN-CLAUDE HALLE et ROBERT SCHAAL. Can. J. Chem. **58**, 1155 (1980).



La formation et la décomposition du complexe hydroxylé **2** dérivé du dinitro-4,6 benzofuroxanne **1** ont été étudiées cinétiquement dans divers mélanges eau – diméthylsulfoxide – chlorure de tétraméthylammonium ($I = 0.5\ M$). Aux pH < 7, la formation de **2** résulte exclusivement de l'attaque de l'eau sur le carbone-7 de **1**. Cette réaction est très accélérée par le DMSO: la constante du premier ordre $k_1^{H_2O}$ est égale à $1.9 \times 10^{-2}\ s^{-1}$ dans l'eau et $1.33\ s^{-1}$ dans 90% DMSO. En tenant compte de la diminution de la concentration de l'eau des solutions et en supposant qu'une seule molécule d'eau participe à la réaction, on constate que cette augmentation de $k_1^{H_2O}$ reflète en réalité une augmentation de l'ordre de 1000 de la nucléophilie de l'eau. Ce résultat est en bon accord avec les données précédemment publiées par Murto pour la solvolyse du dinitro-2,4 fluorobenzène dans les mêmes mélanges.

Introduction

In aqueous solution, 4,6-dinitrobenzofuroxan **1** gives a very stable Meisenheimer-type complex which was previously identified by nmr and visible spectroscopy and which is completely formed at pH 5.5 (1). The kinetics of formation and decomposition of **2** have been thoroughly investigated between pH 1 and 13 ($I = 0.2\ M$) in pure water (1). The results showed that the formation of **2** arises exclusively from the attack of water molecules on the parent substrate **1** at pH < 7. Since there is no other report of this kind in the field of Meisenheimer complexes, it was of interest to study this reaction in water–DMSO mixtures. Such a study should provide information on the extent to which DMSO may affect the ability of water to act as a nucleophile in a nucleophilic aromatic substitution reaction. The results are compared with the data obtained for the solvolysis of 2,4-dinitrofluorobenzene in the same solvent mixtures (2).

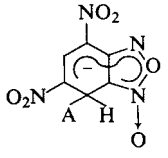
Results

4,6-Dinitrobenzofuroxan **1** ($\lambda_{max}^{water} = 415$ nm, $\varepsilon = 7050\ M^{-1}\ cm^{-1}$) behaves similarly in water and water–DMSO–NMe_4Cl 0.5 *M* mixtures and gives rapidly the very stable yellow-colored complex **2** ($\lambda_{max}^{water} = 462.5$ nm, $\varepsilon = 24\,400\ M^{-1}\ cm^{-1}$) according to Scheme 1.

$$[1]\quad \mathbf{1} + H_2O \underset{k_{-1}}{\overset{k_1^{H_2O}}{\rightleftharpoons}} \mathbf{2} + H^+ \qquad K_a = [\mathbf{2}][H^+]/[\mathbf{1}]$$

$$[2]\quad \mathbf{1} + OH^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{2} \qquad k_2 = [\mathbf{2}]/[\mathbf{1}][OH^-]$$



SCHEME 1

The thermodynamics and kinetics of formation and decomposition of **2** have been investigated in mixtures containing 30, 50, 70, 80, and 90% DMSO (by volume). Dilute hydrochloric acid solutions, various buffer solutions, and dilute tetramethylammonium hydroxide solutions were used. The ionic strength *I* was always kept constant at 0.5 *M* by adding tetramethylammonium chloride as needed. The solutions were the same as those recently used to build an acidity scale in water–DMSO–NMe_4Cl mixtures ($I = 0.5\ M$) (3). The pH values are relative to the standard state in this ternary solvent.

The pH values corresponding to the half-formation of **2** in every solvent mixture have been determined by plotting the variations at 465 nm of the optical density obtained at equilibrium as a function of pH. These $pH_{1/2}$ values, which denote the pH at which the parent molecule **1** and the complex **2** are present at equal concentrations, correspond to the pK_a values for the reversible formation of **2** (reaction [1]). The K_a values are summarized in Table 2 together with the values of the equilibrium constant K_2 calculated from eq. [3]; K_S^I is the autoprotolysis constant of water–DMSO mixtures containing Me_4NCl at the ionic strength 0.5 *M* (3*a*).

$$[3]\quad K_a = K_2 K_S^I$$

Kinetic determinations were carried out over a large pH range of 1–13 in 30 and 50% DMSO. The logarithmic values of the observed first-order rate constant k_{obsd} for the combined formation and decomposition of **2** in these solvent mixtures are plotted in Fig. 1 as a function of pH. Also presented are the k_{obsd} values measured in water at the same ionic strength ($I = 0.5\ M$). At the low buffer concentrations used in this study ($[A^-] + [AH] \leq 4 \times 10^{-2}$), no appreciable catalysis of the reactions was observed for the most acidic buffers (chloroacetate, 2-chlorobenzoate, benzoate, acetate). In contrast, we could detect some catalysis by the basic species A^- of the phosphate, 2-cyano, and 4-cyano phenoxide buffers in the three solvents. The k_{obsd} values used between pH 6 and 8.5 in the pH-rate profiles of Fig. 1 were therefore those extrapolated to zero buffer concentrations, but we did not further investigate this catalysis. The influence of the phenol buffers used above pH 8.5 (2-bromo phenol, 4-chloro phenol, and phenol) was different. The oscilloscope pictures taken in a stopped-flow apparatus revealed that the appearance of **2** is preceded by the very fast formation of short-lived species which are presumably the Meisenheimer-type adducts **3** arising from nucleophilic attack of the phenoxide anions A^- at the 7-carbon of **1** (1, 4–6). Because of these reactions, we were not able to perform measurements of k_{obsd} in these buffers. The k_{obsd} values at pH > 11 were measured in tetramethylammonium hydroxide solutions.

3

In 70, 80, and 90% DMSO, all the organic buffers, including carboxylate buffers, appeared to react with **1**. As a consequence, our kinetic determinations were confined to the hydrochloric acid solutions. The corresponding k_{obsd} values are summarized in Table 1.

The rate constant k_{obsd} reflects the rate of approach to equilibrium between **1** and **2** and is the sum of the individual pseudo-first-order rate constants k_f and k_d for the formation and decomposition of **2** respectively. As shown previously (1) k_f and k_d may be calculated from eqs. [4] and [5]. Figures 2 and 3 show the pH–rate profiles of k_f and k_d in various water–DMSO mixtures.

$$[4]\quad k_f = \frac{k_{obsd}}{1 + 10^{-pH}/10^{-pH_{1/2}}}$$

$$[5]\quad k_d = \frac{k_{obsd}}{1 + 10^{-pH_{1/2}}/10^{-pH}}$$

These pH–rate profiles are consistent with eqs. [6] and [7]:

$$[6]\quad k_f = k_1^{H_2O} + k_2[OH^-] = k_1^{H_2O} + k_2 K_S^I/[H^+]$$

$$[7]\quad k_d = k_{-1}[H^+] + k_{-2}$$

Scheme 1 shows the reactions to which the various constants, viz. k_2 and $k_1^{H_2O}$, refer to hydroxide ion and water attack of **1**, respectively, while k_{-2} and k_{-1} refer to non-catalyzed and H^+-catalyzed

decomposition of **2**, respectively. In water, 30 and 50% DMSO, the various rate coefficients were easily determined from the linear portions of each of k_f and k_d pH–rate profiles (high and low pH regions of each, respectively). In 70, 80, and 90% DMSO where our measurements were limited to the acidic region, the k_f and k_d pH–rate profiles are identical to a plateau and a straight line of slope −1 which give the $k_1^{H_2O}$ and k_{-1} values respectively. The various rate coefficients are summarized in Table 2. Also given are the K_a values calculated from the ratio $k_1^{H_2O}/k_{-1}$; as can be seen, they are in good agreement with those thermodynamically determined.

Discussion

The pK_a for formation of the adduct **2** changes from 3.62 in water to 1.5 in 90% DMSO. This 130-fold increase in K_a is due to the well-known tendency of DMSO to stabilize large polarizable anions such as **2** (7–12). Because of the strong dependence of the ionic product K_S^I upon the DMSO concentration (3*a*), the increased stabilization of **2** is, however, best measured by looking at the changes in the equilibrium constant K_2. As can be seen in Table 2, K_2 increases by a factor of 10^8 when going from water to 80% DMSO. This is the consequence of an increase in the rate constant k_2 for hydroxide ion attack on **1** and a concomitant de-

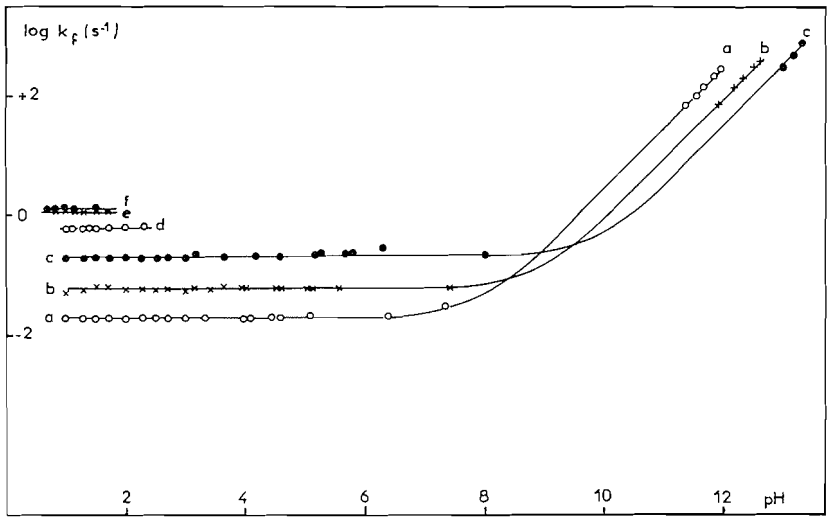

FIG. 2. pH dependence of k_f (s^{-1}) for the formation of the adduct **2** at 20°C. The plots *a, b, c, d, e, f* refer to water, and the mixtures containing 30, 50, 70, 80, and 90% DMSO by volume, respectively.

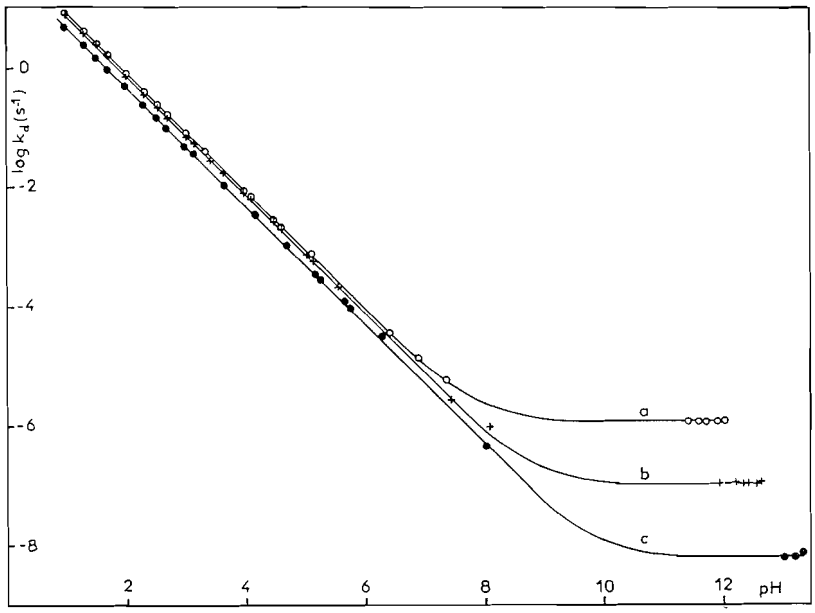

FIG. 3. pH dependence of k_d (s^{-1}) for the decomposition of the adduct **2** at 20°C. The plots *a, b, c* refer to water, 30% DMSO – 70% water, and 50% DMSO – 50% water (v/v), respectively.

crease in the rate constant k_{-2} for the spontaneous decomposition of **2**. DMSO has been found to affect similarly the rate and equilibrium constants for formation and decomposition of the hydroxyl σ-adducts derived from substituted 1-X-3,5-dinitro benzenes (13) and the reasons for this behaviour have been extensively discussed (9, 10, 14).

Comparison of the k_{obsd} pH–rate profiles with the k_f and k_d pH–rate profiles clearly shows that the formation of the adduct **2** arises exclusively from the attack of water molecules on **1** at the lower pH in water–DMSO mixtures. This result is largely the consequence of the very strong electron-withdrawing character of the furoxan ring (1, 15, 16) which is demonstrated by the very high thermodynamic stability of the adduct **2**. We note in particular that **2** is almost completely formed in a hydrochloric acid solution 0.001 *M* in 70, 80, and 90% DMSO.

As previously pointed out (1), the fact that water reacts so efficiently with 4,6-dinitrobenzofuroxan to give the anionic σ-complex **2** is the only report of

[d]Calculated from the ratio $k_1^{H_2O}/k_{-1}$.

this sort in the field of Meisenheimer complexes. Of particular interest therefore is the effect of DMSO on the rate of water attack on **1**. As can be seen in Table 2, there is an approximate 67-fold increase in the observed first-order rate constant $k_1^{H_2O}$ when going from water to 90% DMSO – 10% water. However, this increase in $k_1^{H_2O}$ does not give a right evaluation of the effect of DMSO since one must take into account the decrease in the water content as well as the number of water molecules participating in the reaction. Assuming that only one water molecule is involved in the transition state for complex formation on the whole range of the DMSO–water mixtures studied, calculation of the ratio $k_1^{H_2O}/[H_2O]$ gives the values of the second-order rate constant $k_1'^{H_2O}$ indicated in Table 2. One thus see that $k_1'^{H_2O}$, and consequently the nucleophilic power of a water molecule, increases about thousandfold when the solvent changes from water to 90% DMSO. DMSO would have a still more important effect on the rate of water attack if two or more water molecules are present in the transition state.

4 **5** **6**

From buffer catalysis and isotope effects (1), it has been shown that the reaction of water with **1** in aqueous solution proceeds via a transition state such as **4** which represents general base catalyzed water attack with a second water molecule acting as a base catalyst. DMSO has a well-known high tendency to associate with water to form hydrogen-bonded structures such as **5** in which the basic character of the water molecules is strongly enhanced (5, 17). On this basis, one can reasonably expect the reaction in water–DMSO mixtures to proceed faster via a transition state such as **6** where the DMSO molecule would be the base catalyst. Also noteworthy is the fact that the DMSO influence on the rate constant $k_1^{H_2O}$ for water attack on **1** is very close to the one observed by Murto on the rate constant for the water hydrolysis of 2,4-dinitrofluorobenzene **7** in the same experimental conditions (2). This similarity suggests that the rate-determining step of this latter reaction is, indeed, the formation of the corresponding intermediate σ-complex **8**, and not the expulsion of the fluoride ion, over the whole range of water–DMSO mixtures. Such a conclusion is in agreement with the fact that fluoride ion is a much better leaving group than hydroxide ion (18).

7 **8**

Experimental Section

Materials

4,6-Dinitrobenzofuroxan was prepared by the procedure of Drost (19); mp 172°C (lit. (19) 172°C). Buffer solutions were made up from the best available commercial grades of reagents. HCl solutions were made from Titrisol, tetramethylammonium hydroxide solutions from commercial (Eastman) 25% aqueous solutions.

Rate and pH Measurements

Stopped-flow determinations were performed on a Durrum

For personal use only.

stopped-flow spectrophotometer, the cell compartment of which was maintained to ±0.5°C. All kinetic runs were carried out under pseudo-first-order conditions with substrate concentrations of about 3×10^{-5} *M*. Rate constants are accurate to ±3%.

The pH was measured with a Tacussel Model Isis 20000 pH meter by using a cell involving a hydrogen electrode, as previously described (3). The pH values are relative to the standard state in the water–DMSO–NMe_4Cl 0.5 *M* mixtures.

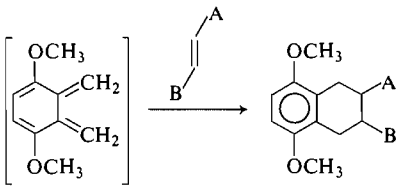
Capture du paradiméthoxyorthoquinodiméthane: synthèses de quinones et d'un intermédiaire de la daunomycinone

JOËLLE LADURANTY, LUCETTE LEPAGE ET YVES LEPAGE
Laboratoire de chimie organique A, 123, rue A. Thomas, 87060 Limoges, France

Reçu le 12 décembre 1979

JOËLLE LADURANTY, LUCETTE LEPAGE et YVES LEPAGE. Can. J. Chem. **58**, 1161 (1980).



Les auteurs décrivent de nouveaux dérivés *para*-diméthoxylés et acétoxylés des séries naphtalénique, anthracénique, naphtacénique, naphto(2,3-*c*) thiophénique et benzo(*c*) thiophénique par capture d'*ortho*-quinodiméthanes à l'aide de philodiènes variés. Parmi eux, un intermédiaire dans la synthèse de la daunomycinone a été préparé et a pu être oxydé en une benzoquinone qui permettrait l'accès à de nouveaux composés du même type que cet important produit "antileucémique".

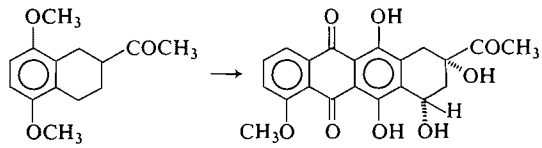
JOËLLE LADURANTY, LUCETTE LEPAGE, and YVES LEPAGE. Can. J. Chem. **58**, 1161 (1980).

New *para*-dimethoxyl and *para*-diacetoxy derivatives in the naphthalene, anthracene, naphthacene, naphtho (2,3-*c*) thiophene and benzo-*c*-thiophene series are synthesized via the trapping of *o*-quinodimethanes by various dienophiles. Among these compounds, an intermediate for the synthesis of daunomycinone has been prepared and can be oxidized to a benzoquinone which provides access to new analogues of this important antileukemic agent.

[Journal translation]

La capture, par des philodiènes, des *ortho*-quinodiméthanes préconisée par Cava *et al.* (1) devient de plus en plus utilisée en synthèse (2–4). Nous nous sommes proposés de synthétiser un certain nombre de composés *para*-diméthoxylés à l'aide de l'*o*-xylylène correspondant **1**, en particulier des quinones pouvant autoriser l'accès aux acènes diméthoxylés en 1,4, composés aux multiples usages potentiels: notamment le diméthoxy-1,4 anthracène (5*a*, *b*) a été utilisé comme capteur de benzyne (6) et a fait l'objet de mesures d'électroluminescence (7).

1



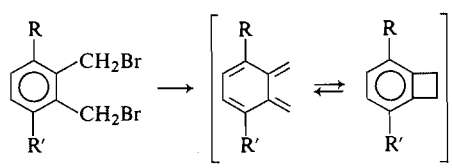
D'autre part, les groupements "méthoxy" sur ces positions permettent un accès facile aux quinones et hydroquinones correspondantes.

Nous avons effectué la synthèse de nouveaux dérivés *para*-diméthoxylés des séries naphtalénique, anthracénique, naphtacénique, naphto-(2,3-*c*) thiophénique et benzo(*c*) thiophénique par capture d'orthoquinodiméthanes à l'aide de philodiènes variés.

Nous donnons, d'autre part, une nouvelle préparation d'un intermédiaire **2** (8*a*, *b*, *c*) de la synthèse de la daunomycinone **3** (9) aglycone d'un composé antitumoral très étudié actuellement (10–16).

Il faut remarquer que cette cétone **2**, isolée par Wong et coll. (8*a*, *b*), a été aussi préparée récemment par une autre voie rapide par Blade et Hodge (8*c*).

A notre connaissance, lorsque nous avons débuté ce travail, aucune étape de la synthèse de la daunomycinone et des composés du même type ne



2 **3**

comprenait cette réaction de capture. Depuis, quelques synthèses différentes très récentes (17–19) utilisent des dienes instables.

Les *ortho*-quinodiméthanes ont le plus souvent été préparés par pyrolyse des sulfones (20), par pyrolyse des tétrahydrophtalazines (21) et par action de l'iodure de sodium sur les dérivés dibromés ou tétrabromés (1, 3, 4).

C'est cette dernière méthode que nous avons choisie; nous avons fait la réduction des composés monométhoxylé **4***c*, diacétoxylé **4***b* et diméthoxylé en 3,6 **4***a*.

Notons que seul le dérivé monométhoxylé **4***c*

4

a R = R′ = OCH_3; *b* R = R′ = $OCOCH_3$; *c* R = OCH_3, R′ = H

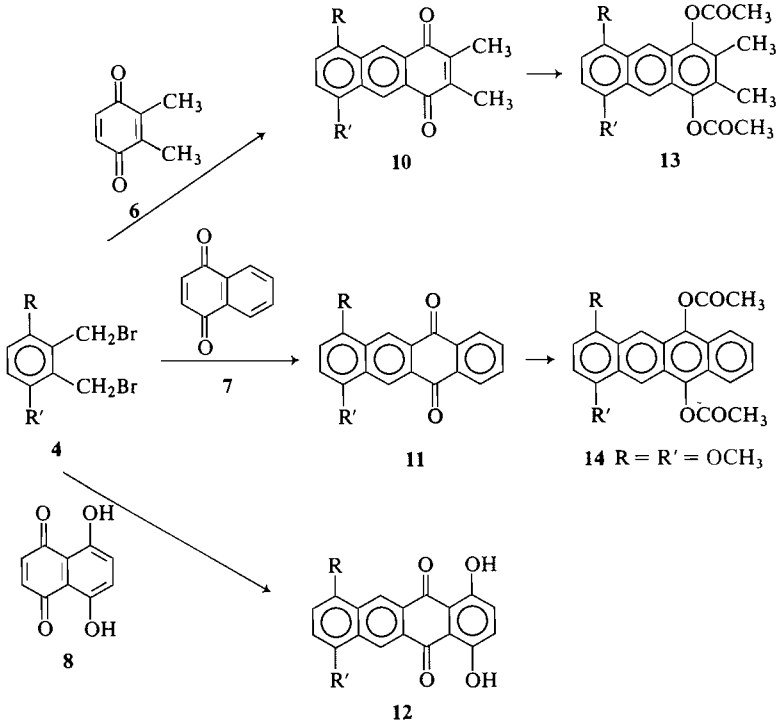
n'était pas connu; il a été préparé par action du *N*-bromosuccinimide sur le méthoxy-3 *ortho*-xylène.

La capture de ces dienes instables par la méthylvinylcetone **5***d* et par le *trans*-dibenzoyléthylène **5***e* nous a permis d'obtenir les produits d'addition attendus **2**, **9***a* et **9***b*.

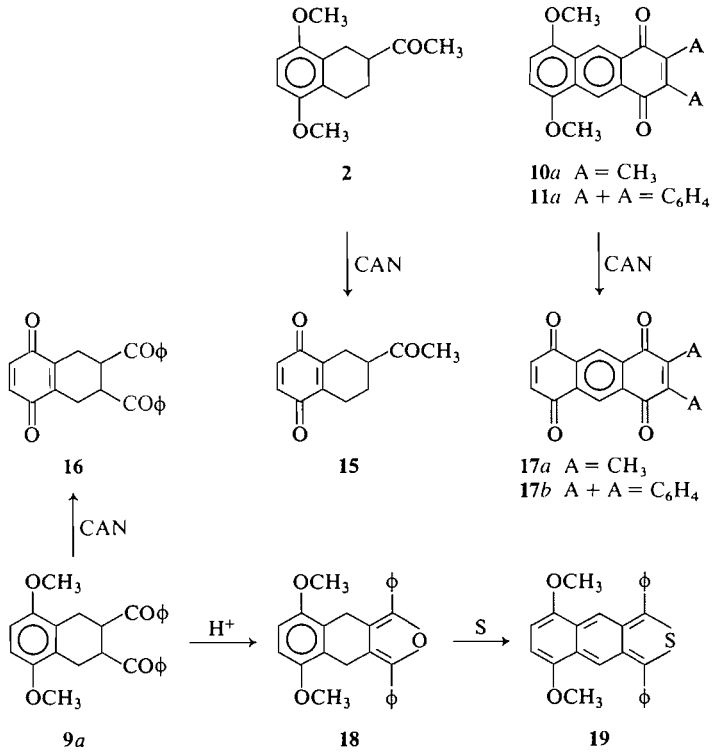


a R = R′ = OCH_3; *b* R = R′ = $OCOCH_3$; *c* R = OCH_3, R′ = H

Par contre ces *o*-xylylènes piégés par la diméthyl-2,3 benzoquinone **6** (22), la naphtoquinone **7** et la naphtazarone **8**[1] (23) ne nous ont pas donné les produits d'addition mais les quinones anthracéniques **10***a*, **10***b* et **10***c* ainsi que les quinones naphtacéniques **11***a*, **11***b*, **12***a* et **12***b* par suite d'une déshydrogénation dans le milieu réactionnel et aromatisation du noyau formé.

Les quinones **10***a*, **10***b*, **10***c* et **11***a* ont été réduites (en milieu acétylant) en les diesters phénoliques **13***a*, **13***b*, **13***c* et **14**. Les esters phénoliques **13** présentent une structure fine dans la zone 400–350 nm ainsi qu'une forte fluorescence bleu-turquoise au jour, caractéristiques des dérivés anthracéniques diméthoxylés. Quant au naphtacène **14**, la structure fine vers 450–500 nm très caractéristique de ce type de composés a pu être observée ainsi qu'une forte fluorescence orange au jour.

Nous avons soumis les composés *para*-diméthoxylés, **2**, **9**, **10***a* et **11***a* à une oxydation déméthylante à l'aide du nitrate d'ammonium et de cérium (CAN) (réactif préconisé par P. Jacob et coll. (24)); nous avons ainsi obtenu les quinones cétoniques **15** et **16** ainsi que les diquinones **17***a* et **17***b*. La quinone **15** devrait permettre un accès facile à des dérivés de la daunomycinone.

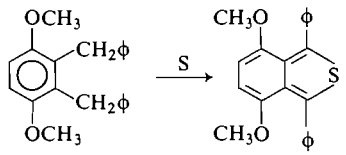


Le composé dibenzoylé **9***a* se cyclise facilement sous l'action des acides pour conduire au dihydronaphto(2,3-*c*) furanne **18** qui permet, par

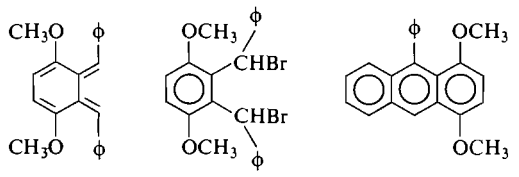
a R = R′ = OCH_3; *b* R = R′ = $OCOCH_3$; *c* R = OCH_3 R′ = H

[1]Nous adressons nos bien vifs remerciements à Monsieur le Professeur Otto Bayer et à Monsieur Gangneux, Directeur de la Société Ugine-Kuhlmann qui nous ont fourni gracieusement la naphtazarone et la naphtoquinone-1,4.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.



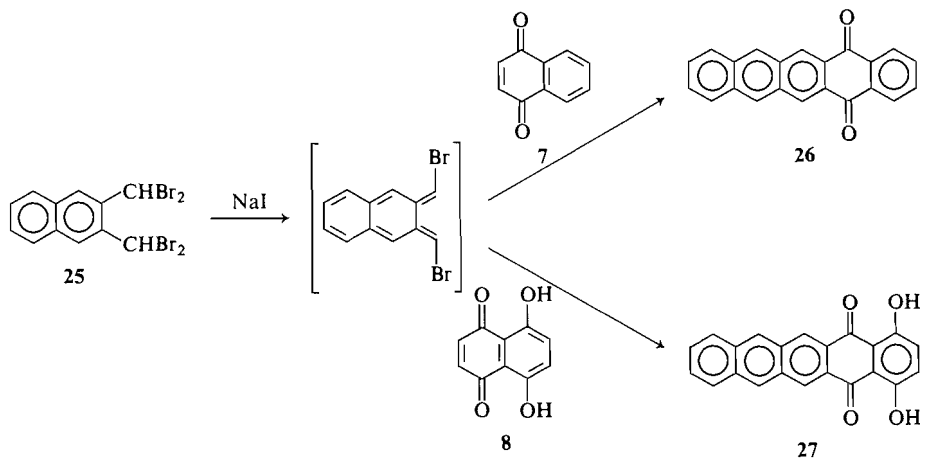
action du soufre, l'obtention du naphto(2,3-*c*) thiophène diméthoxylé **19** dont la réactivité et les caractéristiques spectrales sont voisines des autres composés, peu nombreux, de cette série (25, 26).



Nous avons voulu voir s'il nous était possible de piéger un *ortho*-quinodiméthane encombré, en l'occurence le diène **20**. A cet effet, nous avons isolé un nouveau composé dibenzylé, le dibenzyl-2,3 diméthoxy-1,4 benzène **21** obtenu par action du bromure de phénylmagnesium sur le composé dibromé **4***a*. Malheureusement, l'action du *N*-bromosuccinimide sur ce dérivé **21** n'a pas conduit au dérivé halogéné **22** attendu, mais à un composé bromé anthracénique dont la réduction a abouti au produit **23**, isolé il y a longtemps, par l'un de nous (*5b*).

Nous avons profité de ce résultat pour voir si l'action du soufre sur ce composé **21** conduisait préférentiellement à une carbocyclisation comme cela avait déjà été remarqué dans le cas du dibenzyl-2,3 *para*-terphényle (27), ou à une hétérocyclisation comme dans les cas d'encombrement stérique faible (27). En fait, nous n'obtenons pratiquement que le benzo(*c*) thiophène **24**.

Enfin, nous avons examiné si cette réaction de



capture à partir de dérivés di- ou tétrahalogénés pouvait s'étendre aux benzologues supérieurs, en particulier aux dérivés tétrabromés du diméthyl-2,3 naphtalène **25**. Cette réaction avait toutes les chances de réussir, car Cava et Shirley (28) avaient bien obtenu un adduit en traitant la sulfone naphtalénique en présence de *N*-phénylmaléimide. Nous avons donc traité le bis(dibromométhyl)-2,3 naphtalène **25** par l'iodure de sodium en présence de naphtoquinone **7** ou de naphtazarone **8** et nous avons ainsi obtenu les deux pentacènequinones **26** ou **27** correspondantes, décrites récemment (29).

Conclusion

Parmi les composés *para*-diméthoxylés décrits se trouve un intermédiaire important de la synthèse de la daunomycinone. Ce dernier composé a été transformé en une quinone nouvelle qui pourrait permettre un accès facile à de nombreux pro-

duits du même type que celui de cette très intéressante quinone cétonique.

Partie expérimentale

Les points de fusion instantanés ont été déterminés au bloc chauffant de Kofler ou de Maquenne. Les identifications de produits ont toujours été faites par trois méthodes différentes: épreuve du point de fusion du mélange, spectres infrarouge et ultraviolet–visible identiques. Les spectres infrarouge ont été enregistrés avec un spectrographe Perkin Elmer 297. Les spectres d'absorption uv–visible ont été enregistrés avec un spectrographe Beckman Acta M VI.

Nous sommes heureux d'exprimer notre gratitude à M. le Professeur Penicaut de l'U.E.R. des Sciences Médicales et Pharmaceutiques de Limoges qui vient de mettre à notre disposition un spectrographe Varian E.M. 360. Ces spectres sont pris dans $CDCl_3$ avec le tétraméthylsilane comme référence interne; les δ sont exprimés en ppm.

Les analyses élémentaires ont été effectuées par M. Leger (Laboratoire R. Bellon) ou par le service de Microanalyse du C.N.R.S. que nous remercions bien vivement.

Derives dibromométhylés **4**a *(30),* **4**b *(30) et* **4**c

Les dérivés dibromés **4***a* (30), **4***b* (30) et **4***c* ont été obtenus de façon classique par action du *N*-bromosuccinimide en présence de peroxyde de benzoyle sur les composés diméthylés correspondants.

*Méthoxy-1 bis(bromométhyl)-2,3 benzene (***4**c*)*

Un mélange de 10 g de diméthyl-2,3 anisole (10.4 cm^3), 300 cm^3 de tétrachlorure de carbone anhydre, 26.10 g de *N*-bromosuccinimide et 100 mg de peroxyde de benzoyle est porté à ébullition jusqu'à ce que le succinimide surnage (24 h). Après filtration à chaud, la solution est lavée à l'eau chaude jusqu'à ce que la phase aqueuse soit limpide. La phase organique est séchée sur sulfate de sodium, évaporée. D'une huile dense reprise par l'éther de pétrole (40–65°C) cristallisent 17.3 g de cristaux incolores, rdt 80%, pf inst 80°C (éther de pétrole). *Anal.* calc. pour $C_9H_{10}Br_2O$: C 36.77, H 3.43, Br 54.36; trouvée: C 36.84, H 3.56, Br 54.35.

Technique générale de capture de diènes (1)

Un gramme de dérivé dibromé, une quantité équimoléculaire de quinone ou autres philodiènes, 2 g d'iodure de sodium mis en présence dans 10 cm^3 de diméthylformamide anhydre sont maintenus à 90°C pendant 24 h. La solution brune obtenue est précipitée par l'eau contenant du bisulfite de sodium. Le produit est essoré, séché puis extrait au chloroforme (Soxhlet). Après évaporation, les cristaux sont lavés soit à l'éther soit à l'acétone.

*Dibenzoyl-2,3 diméthoxy-5,8 tétrahydro-1,2,3,4 naphtalène (*9a)

Dix grammes de dérivé dibromé **4***a* et 7.40 g de *trans*-dibenzoyl éthylène **5***e* traités par la méthode précédente pendant 6 h à 70°C permettent d'obtenir 5.64 g de cristaux, rdt 68%, pf inst 219–220°C (*n*-propanol); uv (CH_2Cl_2) λ_{max} en nm (log ε): 285 (3.83), 244 (4.56); ir (KBr) ν(C=O): 1685 cm^{-1}; rmn ^1H: δ en ppm: 7.3–8.2 (l, 10H, φC=O), 6.68 (s, 2H, aromatiques, H-6, H-7), 2.36–4.36 (l, 6H, CH_2 et CH), 3.73 (s, 6H, OCH_3). *Anal.* calc. pour $C_{26}H_{24}O_4$: C 77.98, H 6.14; trouvée: C 77.90, H 6.18.

*Diacétoxy-5,8 dibenzoyl-2,3 tétrahydro-1,2,3,4 naphtalène (*9b)

Deux grammes de dérivé dibromé **4***b* et 1.24 g de *trans*-dibenzoyléthylène **5***e* sont traités pendant 6 h à 70°C suivant la technique générale décrite plus haut; 1.3 g de cristaux incolores précipitent par addition d'éther, rdt 54%, pf inst 208–209°C (benzène); ir (KBr) ν(C=O): 1760 et 1680 cm^{-1}; rmn ^1H δ: 7.72 (l, 10H, φC=O), 6.97 (s, 2H, aromatiques, H-6, H-7), 4.17 (l, 2H, CHCO), 2.84 (l, 2H, CH_2), 2.20 (s, 6H, $OCOCH_3$). *Anal.* calc. pour $C_{28}H_{24}O_6$: C 73.67, H 5.30; trouvée: C 73.82, H 5.42.

*Dihydro-4,9 diméthoxy-5,8 diphenyl-1,3 naphto(2,3-*c*) furanne (***18***)*

Dans un litre d'un mélange acide acétique – acide chlorhydrique (4:1) sont dissous à chaud 5 g de composé dibenzoylé **9***a*. Après un reflux d'une heure, le furanne **18** précipite par refroidissement du milieu et 4.05 g de cristaux incolores sont filtrés, rdt 84%, pf inst 242°C (chloroforme à froid). Les cristaux fondent en rougissant. Ultraviolet ($CH_3C{\equiv}N$) λ_{max} (log ε): 350 inf, 332 (4.51), 318 inf, 297 (4.24), 240 inf; rmn ^1H δ: 7.60 (m, 10H, aromatiques, φ), 6.73 (s, 2H, aromatiques, H-6, H-7), 4.07 (s, 2H, CH_2), 3.87 (s, 6H, OCH_3). *Anal.* calc. pour $C_{26}H_{22}O_3$: C 81.65, H 5.80; trouvée: C 81.74, H 5.81.

*Diméthoxy-5,8 diphenyl-1,3 naphto(2,3-*c*) thiophene (***19***)*

Un mélange intime de 1 g de naphto(2,3-*c*) furanne **18** et de 0.280 g de soufre est chauffé pendant 25 min à 270°C. Après extraction au chloroforme R.P. et évaporation, le produit dissous dans le benzène est purifié par filtration sur colonne de silice. La solution rouge foncé à forte fluorescence orange est évaporée. Après lavage à l'éther, on recueille 0.640 g de cristaux rouges, rdt 62%, pf inst 223–224°C (benzène); uv et visible ($CH_3C{\equiv}N$) λ_{max} (log ε): 522 (3.86), 510 inf (3.85), 352 (3.75), 290 (4.46), 278 inf, 265 (4.52); rmn ^1H δ: 8.80 (s, 2H, aromatiques, H-4, H-9), 7.70 (l, 10H, aromatiques, φ), 6.28 (s, 2H, aromatiques, H-6, H-7), 3.96 (s, 6H, OCH_3). *Anal.* calc. pour $C_{26}H_{20}O_2S$: C 78.77, H 5.09, S 8.07; trouvée: C 78.55, H 5.20, S 8.20.

*Dibenzoyl-6,7 tétrahydro-5,6,7,8 naphtoquinone-1,4 (***16***)*

A 0.100 g de dibenzoyl-2,3 diméthoxy-5,8 tétrahydro-1,2,3,4

naphtalène **9***a* dissous dans 100 cm³ d'acétonitrile est ajouté 0.411 g de nitrate de cérium et d'ammonium en solution dans 6 cm³ d'eau. Après agitation de 30 min, extraction au chloroforme, lavage à l'eau, la phase organique est séchée sur sulfate de sodium, évaporée; 0.93 g de cristaux "jaune pâle" sont essorés après addition d'éther, rdt 86%, pf inst 233–234°C (diméthylformamide). Ultraviolet (CH_2Cl_2) λ_{max} (log ε): 330 (faible), 259 (4.05); ir ν(C=O): 1670 et 1650 cm^{-1}; rmn ^1H δ: 7.33–8.13 (l, 10H, φCO), 6.79 (s, 2H, C=C), 2.03–4.30 (l, 6H, $2CH_2$ et 2H en α du CO). *Anal.* calc. pour $C_{24}H_{18}O_4$: C 77.82, H 4.90; trouvée: C 77.50, H 5.06.

*Dibenzyl-2,3 diméthoxy-1,4 benzene (**21**)*

Trente grammes de diméthoxy-1,4 bis(bromométhyl)-2,3 benzène **4***a* dissous dans 500 cm³ de benzène anhydre sont ajoutés goutte à goutte à la solution benzénique bouillante de bromure de phenylmagnésium (préparée préalablement à partir de 96 cm³ de bromobenzène, 24 g de magnésium, 230 cm³ d'éther anhydre. Ce dernier a été remplacé en fin de réaction par un volume équivalent de benzène sec, puis distillé). Le reflux est maintenu pendant 15 h. Après traitement habituel et entraînement à la vapeur d'eau, des cristaux incolores sont isolés par addition de méthanol (16.5 g), rdt 56%, pf inst 111°C (méthanol); uv (CH_2Cl_2) λ_{max} (log ε): 296 inf, 291 (3.68), 269; rmn ^1H δ: 7.12 (l, 10H, φ), 6.80 (s, 2H, aromatiques, H-5, H-6), 3.97 (s, 4H, CH_2), 3.73 (s, 6H, OCH_3). *Anal.* calc. pour $C_{22}H_{22}O_2$: C 82.96, H 6.96; trouvée: C 82.90, H 6.88.

*Diméthoxy-1,4 phenyl-9 anthracène (**23**) (réf. 5*b*)*

A 2 g de dibenzyl-2,3 diméthoxy-1,4 benzène **21** dissous dans 250 cm³ de tétrachlorure de carbone anhydre sont ajoutés 3.4 g de *N*-bromosuccinimide et 0.100 g de peroxyde de benzoyle. Après un reflux de 2.5 h, le succinimide surnageant est filtré à chaud. La phase organique est lavée à l'eau chaude, séchée sur sulfate de sodium et évaporée; une huile orange cristallise par addition d'éther (1.1 g de cristaux jaunes). Le spectre uv–visible de ces cristaux présente une structure fine vers 400 nm, caractéristique de la structure anthracénique. Ce composé n'a pas été étudié plus précisément. Il a été réduit par la technique suivante.

A 0.300 g d'hydrure de lithium et d'aluminium en suspension dans l'éther anhydre est ajouté 0.250 g du composé précédent. Après agitation de 2 h, apparition d'une fluorescence bleu-turquoise (uv), hydrolyse sur glace, extraction à l'éther, la phase organique est séchée sur sulfate de sodium et évaporée. Les cristaux "jaune vert" (140 mg) sont lavés avec du méthanol, pf inst 159°C (litt. (*5b*) pf 158–159°C (acétone)); uv et visible (CH_2Cl_2) λ_{max} (log ε): 394 (3.80), 368 (3.86), 350 (3.58), 272 (4.63).

*Diméthoxy-4,7 diphenyl-1,3 benzo(*c*) thiophène (**24**)*

Un mélange de 0.500 g de dibenzyl-2,3 diméthoxy-1,4 benzène **21** (15.7×10^{-4} mol) et de 0.170 g de soufre (53.1×10^{-4} mol) est chauffé à 270°C pendant une heure. Après extraction au chloroforme et évaporation du solvant, le produit est purifié par élution d'une solution cyclohexanique sur une colonne d'alumine neutre. La solution jaune orange à forte fluorescence verte est évaporée; 0.120 g de cristaux jaunes sont filtrés après lavage à l'éther de pétrole (40–65°C); pf inst. 161°C (xylène), rdt 22%; uv et visible (CH_2Cl_2) λ_{max} (log ε): 397 (4.11), 335 (3.50), 257 (4.36); rmn ^1H δ: 7.52 (l, 10H, φ), 6.20 (s, 2H, aromatiques, H-6, H-5), 3.68 (s, 6H, OCH_3). *Anal.* calc. pour $C_{22}H_{18}O_2S$: C 76.28, H 5.24, S 9.24; trouvée: C 76.08, H 5.16, S 9.36.

*Acétyl-2 diméthoxy-5,8 tétrahydro-1,2,3,4 naphtalène (**2**)*

A 5 g de dérivé dibromé **4***a* dissous dans 50 cm³ de diméthylformamide anhydre sont ajoutés 15 cm³ de méthylvinylcétone **5***d* (en excès) et 10 g de iodure de sodium et ce mélange est laissé à 60°C pendant 5 jours.

La résidu huileux obtenu par précipitation du milieu réactionnel dans l'eau "bisulfitique" est extrait à l'acétate d'éthyle. Après traitement classique, une solution benzénique est éluée sur colonne de silice et évaporée; 1.63 g est recueilli après lavage à l'éther de pétrole, rdt 45%, pf inst 81°C (éther de pétrole), (litt. (8) pf 81–82°C).

*Acétyl-7 tétrahydro-5,6,7,8 naphtoquinone-1,4 (**15**)*

A 0.800 g de composé diméthoxylé **2** dissous dans 15 cm³ d'acétonitrile sont ajoutés par petites fractions 5.7 g de nitrate d'ammonium et de cerium en solution dans 15 cm³ d'eau. Après 30 min d'agitation, le milieu réactionnel est extrait au chloroforme, le traitement habituel nous permet d'isoler 0.600 g de cristaux, rdt 80%, pf inst 76°C (cyclohexane–benzène 3:1). Ultraviolet–visible (EtOH) λ_{max} (log ε): 336 (faible), 257 (3.81); ir (KBr) ν(C=O): 1705–1650 cm^{-1}; rmn ^1H δ: 6.76 (s, 2H, C=C), 2.30 (s, 3H, $COCH_3$), 2.37 (m, 7H, CH_2 et CH). *Anal.* calc. pour $C_{12}H_{12}O_3$: C 70.57, H 5.92; trouvée: C 70.44, H 5.97.

*Diméthoxy-5,8 diméthyl-2,3 anthraquinone-1,4 (**10**a)*

Un mélange de 2 g de dérivé dibromé **4***a* et 0.84 g de diméthyl-2,3 benzoquinone **6** est traité suivant la technique générale: 0.75 g de cristaux rouges sont essorés, rdt 41%, pf inst 277–278°C (xylène); uv et visible (CH_2Cl_2) λ_{max} (log ε): 473 (3.73), 355 (3.34), 256 (4.81); ir (KBr) ν(C=O): 1670 cm^{-1}; rmn ^1H δ: 8.95 (s, 2H, aromatiques, H-9, H-10), 6.82 (s, 2H, aromatiques, H-6, H-7), 3.95 (s, 6H, OCH_3), 2.20 (s, 6H, CH_3). *Anal.* calc. pour $C_{18}H_{16}O_4$: C 72.96, H 5.44; trouvée: C 73.13, H 5.24.

*Diacétoxy-1,4 diméthoxy-5,8 diméthyl-2,3 anthracène (**13**a)*

A 1.5 g de zinc en poudre préalablement activé est ajouté 1.5 g de quinone **10***a* en solution dans 10 cm³ d'un mélange d'anhydride acétique – pyridine (5:1) puis laissé à reflux pendant 5 min. On verse sur glace et on reprend le zinc par 2-fois 5 cm³ d'acide acétique et on extrait au chloroforme. Après traitement habituel, on récupère 1.80 g de cristaux jaunes, rdt 96%, pf inst 232°C (benzène); uv et visible: ($CH_3C{\equiv}N$) λ_{max} (log ε): 394 (3.65), 369 (3.68), 264 (4.71), 248 (4.81); ir (KBr) ν(C=O): 1765 cm^{-1}; rmn ^1H δ: 8.62 (s, 2H, aromatiques, H-9, H-10), 6.60 (s, 2H aromatiques, H-6, H-7), 4.00 (s, 6H, OCH_3), 2.57 (s, 6H, $OCOCH_3$), 2.30 (s, 6H, CH_3). *Anal.* calc. pour $C_{22}H_{22}O_6$: C 69.10, H 5.80; trouvée: C 69.19, H 5.99.

*Diméthoxy-7,10 naphtacènequinone-5,12 (**11**a)*

On traite selon la technique générale 2 g de dérivé dibromé **4***a* et 0.975 g de naphtoquinone **7** (purifiée par sublimation). On obtient 0.73 g de cristaux oranges qu'on lave à l'acétone, rdt 37%, pf inst 279–280°C. Ultraviolet et visible ($CH_3C{\equiv}N$) λ_{max} (log ε): 458 (3.85), 300 (3.98), 259 (4.94); ir (KBr) ν(C=O): 1680 cm^{-1}; rmn ^1H δ: 9.17 (s, 2H, aromatiques, H-6, H-11), 8.33 (m, 2H, aromatiques, H-1, H-4), 7.74 (m, 2H, aromatiques, H-2, H-3), 6.82 (s, 2H, aromatiques, H-8, H-9), 3.98 (s, 6H, OCH_3). *Anal.* calc. pour $C_{20}H_{14}O_4$: C 75.46, H 4.43; trouvée: C 75.57, H 4.22.

*Diacétoxy-6,11 diméthoxy-1,4 naphtacène (**14**)*

Une solution de 0.710 g de quinone **11***a* dans 10 cm³ de mélange anhydride acétique – pyridine (5:1) est portée à reflux 5 min en présence de poudre de zinc préalablement activée. Après filtration du zinc, la liqueur rouge est versée sur de la glace pilée; le zinc est lavé par 2-fois 3 cm³ d'acide acétique chaud. Après extraction à l'acétate d'éthyle, lavage de la phase organique au bicarbonate de sodium et à l'eau, évaporation du solvant, on obtient 0.72 g de cristaux rouges, rdt = 80%, pf inst 229–230°C (benzène). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 510 (3.64), 480 (3.70), 460 inf (3.52), 430 inf, 401 (3.90), 379 (3.36), 368 (3.34), 295 (5.04), 285 (4.89), 272 (4.90); ir (KBr) ν(C=O): 1765 cm^{-1}; rmn ^1H δ: 8.95 (s, 2H, aromatiques, H-5, H-12), 7.7 (l, 4H, aromatiques, H-7, H-8, H-9, H-10), 6.55 (s,

For personal use only.

2H, aromatiques, H-2, H-3), 4.03 (s, 6H, OCH_3), 2.72 (s, 6H, $OCOCH_3$). *Anal.* calc. pour $C_{24}H_{20}O_6$: C 71.28, H 4.99; trouvée: C 71.04, H 5.08.

*Dihydroxy-1,4 diméthoxy-7,10 naphtacènequinone-5,12 (12*a)

Un mélange de 2 g de dérivé dibromé **4***a* et de 1.29 g de naphtazarone **8** (fraichement purifiée) est traité suivant la technique générale; 0.9 g de cristaux rouges sont recueillis, rdt 41%, pf inst 353°C (diméthylformamide et subl.). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 505 inf (3.84), 498 (3.84), 285 inf, 267 (4.61); ir (KBr) ν(C=O): 1635 cm^{-1}. *Anal.* calc. pour $C_{20}H_{14}O_6$: C 68.57, H 4.03; trouvée: C 68.58, H 4.26.

*Diacétoxy-5,8 diméthyl-2,3 anthraquinone-1,4 (10*b)

A partir de 2 g de dérivé dibromé **4***b* et de 0.72 g de quinone **6**, on peut obtenir par la méthode précédente 0.67 g de cristaux jaunes, rdt 36%, pf inst 278°C (diméthyl formamide). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 405 (3.67), 310 inf (3.75), 297 (4.93), 284 (5.06), 273 (5.11); ir (KBr) ν(C=O): 1785, 1775–1665 cm^{-1}; rmn ^1H δ: 8.69 (s, 2H, aromatiques, H-9, H-10), 7.43 (s, 2H, aromatiques, H-6, H-7), 2.53 (s, 6H, $OCOCH_3$), 2.19 (s, 6H, CH_3). *Anal.* calc. pour $C_{20}H_{16}O_6$: C 68.18, H 4.58; trouvée: C 67.92, H 4.58.

*Diméthyl-2,3 tétraacétoxy-1,4,5,8 anthracène (13*b)

La solution de 0.92 g de quinone **10***b* dans 10 cm^3 d'un mélange anhydride acétique – pyridine (5:1) est chauffée à reflux pendant 5 min en présence de poudre de zinc préalablement activée. Le milieu réactionnel se décolore et présente en fin de réaction une fluorescence bleue. Après traitement classique des réductions acétylantes, on essore 0.960 g de cristaux jaunes, rdt 84%, pf inst 290°C (diméthylformamide). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 396 (3.76), 375 (3.86), 357 (3.72), 339 (3.48), 325 inf, 262 (4.72); ir (KBr) ν(C=O): 1760 cm^{-1}; rmn ^1H δ: 8.23 (s, 2H, aromatiques, H-9, H-10), 7.30 (s, 2H, aromatiques, H-6, H-7), 2.48 (s, 6H, $OCOCH_3$ en 5.8), 2.43 (s, 6H, $OCOCH_3$ en 1.4), 2.27 (s, 6H, CH_3). *Anal.* calc. pour $C_{24}H_{22}O_8$: C 65.74, H 5.06; trouvée: C 65.80, H 5.06.

*Diacétoxy-7,10 naphtacènequinone-5,12 (11*b)

A partir de 4.21 g de dérivé dibromé **4***b* et de 1.75 g de naphtoquinone **7** (purifié par sublimation sous vide à 120°C), la méthode précédente nous permet d'isoler 1.71 g de cristaux jaunes, rdt 41%, pf inst 277–278°C (diméthylformamide). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 398 (3.70), 316 inf (3.84), 295 (4.53), 283 (4.55), 272 (4.54), 265 (4.53); ir (KBr) ν(C=O): 1770–1680 cm^{-1}; rmn ^1H δ: 8.93 (s, 2H, aromatiques, H-6, H-11), 8.39 (m, 2H, aromatiques, H-1, H-4), 7.81 (m, 2H, aromatiques, H-2, H-3), 7.50 (s, 2H, aromatiques, H-8, H-9), 2.56 (s, 6H, $OCOCH_3$). *Anal.* calc. pour $C_{22}H_{14}O_6$: C 70.58, H 3.77; trouvée: C 70.33, H 3.87.

*Diacétoxy-7,10 dihydroxy-1,4 naphtacènequinone-5,12 (12*b)

Le dérivé dibromé **4***b* (3 g) et la naphtazarone **8** (1.5 g) purifiée par extraction au Soxhlet conduisent par la méthode de capture de diène à 1.25 g de cristaux rouges, rdt 39%, pf inst 309°C (diméthylformamide et subl.). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 512 inf (3.98), 498 inf (4.14), 480 inf (4.24), 470 (4.25), 301 (4.46), 290 (4.53), 280 (4.58), 265 inf (4.47); ir (KBr) ν(C=O): 1775, 1645, 1620 cm^{-1}; rmn ^1H δ: 13 (s, 2H, OH), 8.97 (s, 2H, aromatiques, H-6, H-11), 7.53 (s, 2H, aromatiques, H-8, H-9), 7.37 (s, 2H, aromatiques, H-2, H-3), 2.57 (s, 6H, $OCOCH_3$). *Anal.* calc. pour $C_{22}H_{14}O_8$: C 65.05, H 3.47; trouvée: C 65.30, H 3.70.

*Diméthyl-2,3 méthoxy-5 anthraquinone-1,4 (10*c)

On chauffe 3 g de dérivé dibromé **4***c* et 1.39 g de quinone **6** dans les conditions précédentes et on traite suivant la même méthode; on essore 1.40 g de cristaux jaunes, rdt 52%, pf inst 219–220°C (diméthylformamide). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 433 (3.75), 324 (3.56), 297 (4.13), 281 (4.34), 261 (4.41); ir (KBr) ν(C=O): 1660 cm^{-1}; rmn ^1H δ: 9.03 (s, 1H, aromatique, H-10), 8.53 (s, 1H, aromatique, H-9), 7.55 (d, 2H, aromatiques, H-5, H-6), 6.93 (t, 1H, aromatique, H-7), 4.06 (s, 3H, OCH_3), 2.26 (s, 6H, CH_3). *Anal.* calc. pour $C_{17}H_{14}O_3$: C 76.67, H 5.30; trouvée: 76.56, H 5.39.

*Diacétoxy-1,4 diméthyl-2,3 méthoxy-5 anthracène (13*c)

On fait bouillir pendant deux minutes 0.290 g de quinone **10***c*, 0.3 g de zinc en poudre activé dans 4 cm^3 d'un mélange anhydride acétique – pyridine (5:1). La liqueur présente une fluorescence bleu. Après précipitation par l'eau, extraction, lavage au carbonate de sodium, la phase organique est séchée et évaporée. On isole 0.370 g de cristaux "jaune pâle", rdt 96%, pf inst 201–202°C (benzène). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 396 (3.68), 376 (3.81), 364 (3.69), 357 (3.71), 266 (4.68), 264 (4.67); ir (KBr) ν(C=O): 1760 cm^{-1}; rmn ^1H δ: 8.66 (s, 1H, aromatique, H-9), 8.16 (s, 1H, aromatique, H-10), 7.46 (d, 2H, aromatiques, H-7, H-8), 6.70 (m, 1H, aromatique, H-6), 4.30 (s, 3H, OCH_3), 2.56 (s, 6H, $OCOCH_3$), 2.30 (s, 6H, CH_3). *Anal.* calc. pour $C_{21}H_{20}O_5$: C 71.58, H 5.72; trouvée: C 71.50, H 5.88.

Pentacènequinone-5,14 (26) (réf. 29)

Un gramme de bis(dibromométhyl)-2,3 naphtalène **25** (31) est traité (48 h) en présence de naphtoquinone **7**. Nous avons obtenu 0.2 g de cristaux jaunes, rdt 36%, pf inst 374°C (diméthylformamide) (litt. (29) pf 375°C (subl.)).

Dihydroxy-1,4 pentacènequinone-5,14 (27) (réf. 29)

On traite 1 g de dérivé tétrabromé du diméthylnaphtalène **25** (31) en présence de 0.400 g naphtazarone **8** et d'iodure de sodium pendant 48 h. On isole 0.16 g de cristaux rouges, rdt 20%, pf inst 384°C (subl.) (litt. (29) pf 385°C (subl.)).

*Anthracènetétrone-1,4,5,8 (17*a)

A 0.600 g de quinone diméthoxylée **10***a* dissous dans 210 cm^3 d'un mélange acétonitrile–acétone (1:5) sont ajoutés goutte à goutte 3.40 g de nitrate d'ammonium et de cérium en solution dans 10 cm^3 d'eau. Après extraction au chloroforme, lavage à l'eau, la phase organique est séchée sur sulfate de sodium puis évaporée. On isole 0.31 g de cristaux "jaune pâle", rdt 58%, pf inst 224°C (acétonitrile). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 360 inf. (3.65), 355 (3.67), 304 inf (3.56), 252 (4.65); ir (KBr) ν(C=O): 1660 cm^{-1}; rmn ^1H δ: 8.86 (s, 2H, aromatiques, H-9, H-10), 7.13 (s, 2H, aromatiques, H-2, H-3), 2.26 (s, 6H, CH_3). *Anal.* calc. pour $C_{16}H_{10}O_4$: C 72.18, H 3.79; trouvée: C 71.70, H 3.90.

*Naphtacènetétrone-1,4,6,11 (17*b)

Une solution de 2.58 g de nitrate de cérium et d'ammonium dans 6 cm^3 d'eau est versée lentement sur 0.4 g de quinone diméthoxylée **11***a* dissous dans 360 cm^3 d'un mélange acétone–acétonitrile (5:1). Après une demi-heure d'agitation, extraction au chloroforme et traitement habituel, on essore 0.19 g de cristaux, rdt 52%, pf inst 262°C (diméthylformamide). Ultraviolet et visible (CH_2Cl_2) λ_{max} (log ε): 357 inf (3.79), 348 (3.84), 300 (3.74), 259 (4.75); ir (KBr) ν(C=O): 1670 cm^{-1}; rmn ^1H δ: 9.04 (s, 2H, aromatiques, H-5, H-12), 7.73–8.56 (m, 4H, aromatiques, H-7, H-8, H-9, H-10), 7.17 (s, 2H, aromatiques, H-2, H-3). *Anal.* calc. pour $C_{18}H_8O_4$: C 75.00, H 2.80; trouvée: C 74.45, H 3.01.

Remerciements

Les auteurs expriment leur gratitude à la Délégation Générale à la Recherche Scientifique et Technique pour la bourse accordée à l'un d'entre eux.

Réactions d'addition nucleophiles sur les cétones. Une méthode directe, simple, rapide et précise de mesure de vitesse de formation et de décomposition des combinaisons bisulfitiques

BERNARD BOYER, GÉRARD LAMATY ET JEAN PIERRE ROQUE

Laboratoire de Chimie Organique Physique, Université des Sciences et Techniques du Languedoc, Place Eugène Bataillon, 34060 Montpellier, France

Reçu le 21 février 1980

BERNARD BOYER, GÉRARD LAMATY et JEAN PIERRE ROQUE. Can. J. Chem. **58**, 1168 (1980).

Description d'une méthode qui permet, en une seule expérience, de mesurer directement la constante de vitesse d'addition de l'ion sulfite sur les carbonyles et la constante de vitesse de décomposition des combinaisons bisulfitiques.

BERNARD BOYER, GÉRARD LAMATY, and JEAN PIERRE ROQUE. Can. J. Chem. **58**, 1168 (1980).

A method is described which allows, with a single experiment, the determination of the rate constants of formation and decomposition of bisulfite addition compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Les travaux entrepris depuis plusieurs années au laboratoire nous ont conduit à proposer que la position de l'état de transition le long du chemin réactionnel dépendait de la nature du nucléophile (1). Certains, tels les ions BH_4^- et CN^-, donnent un état de transition plutôt tardif, d'autres comme le mercaptoéthanol ou l'hydroxylamine un état de transition plutôt précoce. L'ion sulfite est un autre exemple de nucléophile à état de transition précoce et il a été plusieurs fois utilisé tant par nous (2) que par d'autres auteurs (3).

Cependant, nous étant intéressé récemment à sa réactivité vis-à-vis de cétones encombrées, nous nous sommes heurtés à des difficultés expérimentales qui ne nous ont pas permis d'utiliser la technique cinétique volumétrique mise au point par l'un de nous (2); cette technique, outre le fait qu'elle est grosse consommatrice de produit, n'est pas applicable aux composés dont la combinaison bisulfitique est trop instable.

L'examen de la littérature, même la plus récente (3*d*, 3*e*) nous a montré qu'il n'existait aucune méthode de *mesure directe* de la constant de vitesse d'addition, k_a, de l'ion sulfite sur les carbonyles; toutes les méthodes décrites à ce jour consistent à mesurer la constante d'équilibre, K, et la constante de vitesse, k_d, de décomposition des combinaisons bisulfitiques et à égaler k_a au rapport k_d/K. Si la précision sur k_d est généralement bonne, celle sur K est beaucoup plus modeste ($\pm 5\%$ dans le meilleur des cas) et l'incertitude sur K se répercute sur k_a, ce qui rend cette technique indirecte impropre à l'un des usages que nous voulions en faire: mesurer les effets isotopiques cinétiques secondaires du deutérium, qui sont généralement faibles, sur des cétones encombrées pour lesquelles k_a est forcément petit.

Nous avons donc été amenés à essayer de mettre au point une méthode *directe*, et *précise* de mesure de k_a; au cours du déroulement de nos essais, nous nous sommes aperçus qu'il était possible de mesurer directement, sur le *même échantillon*, *et* k_a *et* k_d avec une précision tout à fait satisfaisante. C'est cette technique que nous décrivons dans ce mémoire; elle a l'avantage d'être simple à mettre en oeuvre, de consommer peu de produit et nous pensons qu'elle peut être utile aux autres groupes de chercheurs intéressés par l'étude de ce type de réaction.

Principe de la méthode

Elle consiste à étudier *directement* la réaction d'addition en ajoutant une quantité adéquate de cétone à une solution concentrée de bisulfite de Na et en suivant, par spectrophotométrie uv, la disparition de la cétone. Lorsque l'équilibre est atteint, on détruit le bisulfite restant par un réactif approprié que l'on ajoute en léger excès; la combinaison bisulfitique se décompose alors, libérant la cétone dont on suit l'apparition par uv et du bisulfite de Na qui est aussitôt neutralisé par l'excès de réactif.

Une telle méthode, pour pouvoir être appliquée, doit satisfaire aux conditions suivantes.

(1) Il faut que les solutions de sulfite soient stables au moins pendant la durée de la mesure. Nous avons constaté, par dosages iodométriques (4) répétés, qu'une solution de SO_3HNa, environ 0.5 *M*, à pH 5.41 dans un tampon acétique, perdait 3% de son titre environ en 10 jours; on peut donc raisonnablement admettre qu'elle évoluera très peu au cours d'une expérience qui dure au maximum quelques heures.

(2) Il faut que l'on puisse trouver une longueur d'onde adéquate. Les solution de bisulfite absorbent légèrement ($\varepsilon = 11$ à 256 nm) dans la région du

spectre (bande $n \rightarrow \pi^*$) du carbonyle. Il est toutefois possible, dans le domaine de concentrations utilisées, de trouver une longueur d'onde permettant d'observer la disparition et la réapparition de la cétone; nous avons constaté qu'à la longueur d'ordre de 295 nm les variations de densité optique ($\simeq 0.2$) étaient suffisantes pour suivre correctement l'évolution de la concentration en cétone.

(3) Il faut que l'on trouve un réactif qui consomme instantanément et totalement l'excès de sulfite. L'addition de l'ion sulfite étant réalisée, il fallait trouver un réactif qui éliminerait tout le sulfite libre, déplaçant ainsi l'équilibre vers la cétone. Notre choix s'est porté sur le formol 35%, neutralisé au préalable par une solution de soude 1 *N*; il est très réactif vis-à-vis du sulfite et donne instantanément un produit d'addition très stable. De plus, en solution aqueuse, il est présent sous forme d'hydrate et n'absorbe pas dans la région considérée ($\lambda = 295$ nm).

(4) Il faut qu'il existe un pH auquel les réactions d'addition et de décomposition aient approximativement la même vitesse. Afin de réaliser consécutivement, *sur le même échantillon et* l'addition de l'ion sulfite *et* la décomposition de la combinaison bisulfitique, il était nécessaire que les deux constantes de vitesse expérimentales soient à peu près du même ordre de grandeur.

Notre expérience antérieure nous a montré que dans le domaine de pH 5–6, cette dernière condition était remplie. Les composés carbonylés étant peu solubles dans l'eau, nous avons utilisé comme solvant un mélange H_2O/EtOH 60:40 en volume dans un tampon acétique, [AcOH] = 0.05 *M*, de pH égal à 5.41 (5).

Description de la méthode

Nous représenterons sur le schéma ci-dessous (fig. 1) un exemple de cinétique réunissant à la fois les variations de densité optique de la réaction d'addition de l'ion sulfite et celles de la réaction de décomposition des combinaisons bisulfitiques.

Réaction d'addition (partie (a) de la courbe enregistrée)

Nous nous sommes placés dans des conditions cinétiques du pseudopremier ordre; la concentration en sulfite est au moins 10 à 15 fois supérieure à la concentration en cétone ($[SO_3HNa]_0 \simeq 0.25\ M$; $[C{=}O]_0 \simeq 1.5 \times 10^{-2} M$).

L'avancement de la réaction se traduit par une décroissance de l'absorption du groupe carbonyle. On suit la disparition de la cétone jusqu'à ce que la courbe D = f(t) tende vers une valeur constante; l'équilibre est alors atteint.

La partie (a) de cette cinétique nous donne une constante de vitesse expérimentale du pseudo-

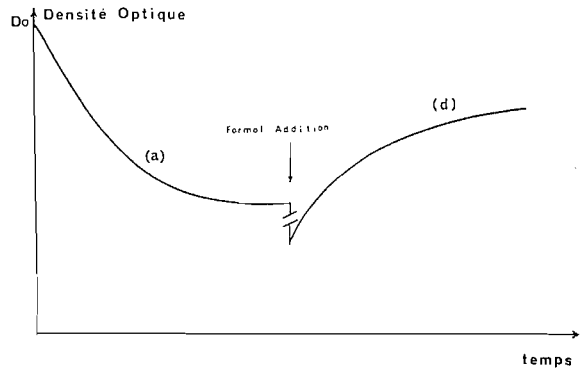

FIG. 1. Variation de la densité optique en function du temps.

premier ordre, k_f qui représente en fait la somme des constantes d'addition k_a, et de décomposition, k_d, puisque la réaction est équilibrée.

Réaction de décomposition (partie (d) de la courbe envisagée)

Lorsque l'équilibre est atteint, nous ajoutons dans la cuve 100 µL de formol neutre à 35% qui réagit avec le sulfite en excès et le fixe ensuite irréversiblement au fur et à mesure de sa formation, déplaçant ainsi l'équilibre vers la cétone.

Nous observons d'abord une chute brutale de la densité optique, résultant de la disparition de l'excès de SO_3HNa, puis une augmentation lente de la densité optique due à l'apparition de la cétone. On enregistre la courbe D = f(t).

Nous avons vérifié que la vitesse de la réaction de décomposition était indépendante de la quantité de formol ajouté, à condition qu'il soit en excès par rapport au sulfite total. Les constantes de vitesse de formation et de décomposition dépendant du pH utilisé, nous avons vérifié également qu'il n'y avait pas de variation de pH au cours de la réaction et en particulier lors de la fixation, par le formol, du sulfite en excès.

Nous mesurons alors la vitesse de disparition du composé d'addition, cette réaction est du premier ordre par rapport au substrat.

Détermination des constantes de vitesse de formation et de décomposition

Le mécanisme détaillé de la réaction correspond au schéma suivant (6):

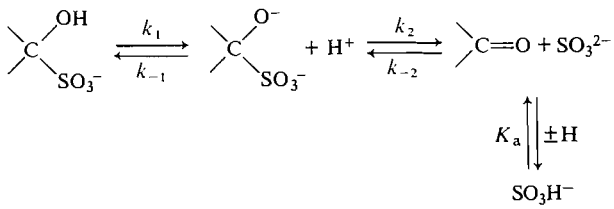

SCHÉMA I

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

On démontre (8) que les constantes de vitesse de formation, k_f, et de décomposition, k_d, mesurées *expérimentalement*, sont reliées à la constante d'addition réelle k_a par l'expression:

$$k_f = k_a[SO_3H^-] + k_d \text{ avec:}$$
$$k_d = k_1k_2/k_{-1}[H^+] \text{ et } k_a = k_{-2}K_a/[H^+]$$

La lissage, par la méthode des moindres carrés (7), des exponentielles obtenues sur les parties (a) et (d) des courbes (fig. 1) conduit aux valeurs k_f et k_d.

Connaissant la concentration exacte en SO_3HNa, obtenue par dosage iodométrique, k_f et k_d, nous pouvons alors déduire la constante de vitesse d'addition k_a, ainsi que la constante d'équilibre $K = k_d/k_a$ de décomposition de la combinaison bisulfitique.

Résultats

A titre d'exemple, nous donnons ci-dessous les résultats obtenus avec trois cétones encombrées, une cétone non encombrée et son homologue deutérié.

Pour chaque cétone, nous indiquons la concentration en ion sulfite, la constante de formation k_f, celle de décomposition k_d, celle d'addition k_a et enfin la constante d'équilibre de décomposition $K = k_d/k_a$. Toutes les valeurs des constantes de vitesse sont multipliées par 10^3 et sont exprimées en s^{-1} (k_f et k_d) ou $M^{-1}s^{-1}$ (k_a)

Norbornanone-2 $[HSO_3Na] = 0.223\ M$
k_f : 4.92, 4.94, 4.83, 4.88, 4.88, 4.92
k_d : 2.56, 2.55, 2.64, 2.62, 2.58, 2.61 $\quad \bar{k}_d = 2.593 \pm 0.036$
k_a : 10.58, 10.72, 9.82, 10.13, 10.31, 10.36 $\quad \bar{k}_a = 10.32 \pm 0.32$
$K = 0.25\ M^{-1}$

Méthyl-1 norbornanone-2 $[HSO_3Na] = 0.231\ M$
k_f : 3.63, 3.67, 3.68, 3.62
k_d : 3.35, 3.40, 3.40, 3.36 $\quad \bar{k}_d = 3.378 \pm 0.026$
k_a : 1.21, 1.17, 1.21, 1.13 $\quad \bar{k}_a = 1.18 \pm 0.04$
$K = 2.86\ M^{-1}$

Triméthyl-3,3,5 cyclohexanone $[HSO_3Na] = 0.249\ M$
k_f : 11.5, 11.6, 11.1, 11.2, 11.2, 11.1
k_d : 2.37, 2.36, 2.43, 2.37, 2.45, 2.42 $\quad \bar{k}_d = 2.400 \pm 0.038$
k_a : 36.66, 37.10, 34.82, 35.46, 35.14, 34.86 $\quad \bar{k}_a = 35.68 \pm 0.97$
$K = 0.067\ M^{-1}$

Cyclohexanone $[HSO_3Na] = 0.223\ M$
k_f : 41.9, 41.6, 41.7, 41.9, 41.5
k_d : 0.528, 0.525, 0.530, 0.523, 0.523 $\quad \bar{k}_d = 0.526 \pm 0.003$
k_a : 185.5, 184.2, 184.6, 185.5, 183.8 $\quad \bar{k}_a = 184.7 \pm 0.80$
$K = 2.80 \times 10^{-3}\ M^{-1}$

Cyclohexanone-2,2,6,6-d_4 $[HSO_3Na] = 0.223\ M$
k_f = 45.7, 45.6, 45.3, 45.8, 45.7, 45.6
k_d : 0.482, 0.482, 0.483, 0.487, 0.483, 0.485 $\quad \bar{k}_d = 0.484 \pm 0.002$
k_a : 202.8, 202.3, 201.0, 203.2, 202.8, 202.3 $\quad \bar{k}_a = 202.40 \pm 0.76$

Effets isotopiques:
$k_a^H/k_a^D = 0.913 \pm 0.008$ $\quad k_d^H/k_d^D = 1.087 \pm 0.010$

Partie expérimentale

Toutes les mesures ont été effectuées à 25.0 ± 0.1°C sur un spectrophotomètre uv Gilford-250. Les différentes solutions ont été préparées somme suit.

Solution A $[SO_3HNa] \simeq 0.5\ M$

Dans un ballon de 100 mL, on introduit 9.5055 g de pyrosulfite de sodium anhydre RP et on ajuste le volume par le tampon acétique. Cette solution est étalonnée au moment de l'utilisation.

Solution B $[C{=}O] \simeq 3 \times 10^{-2}\ M$

On pèse la quantité nécessaire de cétone pour préparer dans le même tampon 20 mL d'une solution dont la concentration initiale est voisine de $3 \times 10^{-2}\ M^{-1}$. Les solutions A et B sont plongées dans un bain thermostaté à 25.0 ± 0.1°C. Après l'équilibre thermique on met (*a*) dans la cuve de référence: 2 mL tampon; (*b*) dans la cuve de mesure: 1 mL solution A + 1 mL solution B.

Discussion

Les résultats présentés ci-dessus montrent qu'il

est possible de mesurer directement la constante de vitesse d'addition de l'ion sulfite sur un carbonyle avec une précision généralement très bonne; les déviations standards vont de 0.3% dans le meilleur des cas à 3.5% dans le plus mauvais. Contrairement à ce que l'on pourrait craindre les solutions concentrées de sulfite sont stables et l'absorption de l'ion SO_3^{2-} ne masque pas totalement celle du carbonyle. La méthode décrite ci-dessus est donc utilisable pour toutes les cétones, mêmes celles qui donnent une combinaison bisulfitique très instable (méthyl-1 norbornanone-2) dès lors que l'on ne se propose que d'étudier l'influence de la structure de la cétone sur k_a donc qu'une précision de l'ordre de 5% est suffisante.

En revanche si on est intéressé par le mesure des effets isotopiques secondaires, le plus souvent faibles, cette technique ne peut être utilisée qu'avec les cétones assez réactives, donnant une combinaison bisulfitique stable et pour lesquelles k_f et k_d sont très différentes l'une de l'autre. Pour cette raison, nous n'avons même pas essayé de mesuré les constantes de vitesse de la méthyl-1 norbornanone-2 deutériée, car les effets isotopiques que nous aurions pu calculer auraient été dépourvus de toute signification.

The development of simple synthetic routes from camphor to a variety of monoterpenoids and sesquiterpenoids has been the subject of recent investigations in our laboratory (1–3). One objective of our general synthetic scheme (1) was the conversion of camphor to longicamphor (**6***b*) (4) and the subsequent use of this compound as an intermediate in the synthesis of related sesquiterpenoids. Our initial synthetic approach to longicamphor (**6***b*) depended on the successful cyclisation of an intermediate enedione (**5**) to diketone (**6***a*) followed by selective reduction of the more accessible carbonyl group in this compound. A simple synthesis of enedione (**5**) from 8-bromocamphor (**1**) was subsequently achieved (cf. Scheme 1) but our preliminary attempts to cyclise this compound were unsuccessful. During investigations of an alternative synthetic route to enedione (**5**), however, an interesting new reaction occurred. In this alternative route, treatment of 8-iodocamphor ethylene acetal (**7**) (1, 2) with lithium acetylide provided an 8-ethynyl derivative

(**8**) whose lithium salt condensed with acetone to give acetylenic alcohol (**9**). It was expected that this compound would undergo Meyer–Schuster rearrangement (5) to the enedione (**5**). In the event, treatment of acetylenic alcohol (**9**) with 98% formic acid led to the formation of a crystalline product (mp 49–51°C (sealed tube); $[\alpha]_D$ +32.5 (c. 1.19, abs. EtOH); 50% yield (glc yield ~68–80%)) whose spectroscopic properties (λ_{max} end absorption, ν_{max} 1701, 1745 cm^{-1}; $\delta(CCl_4)$ 0.98 (6H, s), 1.05 (6H, s), 2.84 (1H, septet); *m/e* (relative intensity), 234 (M^+) (42), 191 (100), 163 (51) were inconsistent with the expected enedione structure (**5**). The absence of a 1415 cm^{-1} band in the ir spectrum and vinyl hydrogen signals in the nmr spectrum led us to consider that cyclisation had occurred during the formic acid treatment. Of three possible tricyclic diketone structures for this compound **12** was rejected by independent synthesis (cf. Scheme 2) and structure **14** was inconsistent with the presence of

12 **13** **14**

an $M - C_3H_7$ (isopropyl) peak in the mass spectrum and the septet at 2.84 δ in the nmr spectrum. Structure **13** was difficult to rationalise on mechanistic grounds and was also inconsistent with the presence of an $M - C_3H_7CO$ peak in the mass spectrum. A final solution to this structural problem was provided by X-ray crystallographic analysis which demonstrated that the diketone was a tricyclo[4.2.1.$0^{3,7}$]nonane derivative (**11**).

The bond lengths and a perspective view of **11** are shown in Fig. 1 and the bond angles are listed in Table 1. Atoms C(1), C(2), C(4), and C(5) (cf. Fig. 1) are co-planar, as are C(1), C(5), C(6), and C(7), and the cycloheptane skeleton C(1)—C(7) has the chair conformation. The [4.2.1.$0^{3,7}$]nonane system deviates considerably from idealized $m(C_s)$ symmetry as a result of ring substitution and the strain is reflected mainly in the small bond angles involving the bridge atoms C(3), C(8), and C(9). The crystal structure consists of well-separated molecules with the shortest intermolecular contacts corresponding to normal van der Waals' interactions.

3 **15** **16** **12**

SCHEME 2. *i*, $Me_2CHCH{=}PPh_3$; *ii*, Me_2CO/6 *N* HCl; *iii*, MCPBA/C_6H_6; *iv*, Me_3COH/Me_3COK; *v*, $CrO_3/H_2SO_4/H_2O/Me_2CO$.

Thus treatment of acetylenic alcohol (**9**) with formic acid results in cyclisation as well as rearrangement of the original bicyclo[2.2.1]heptane framework. A possible mechanism for this novel transformation[2] is shown in Scheme 1.

Experimental

Unless otherwise stated the following are implied. Melting points (mp) were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Gas chromatography was carried out on a Hewlett-Packard Model 5831-A gas chromatograph using 6 ft × 1/8 in. columns and nitrogen as carrier gas. The following columns were employed:

Column	Dimensions	Stationary phase	Support	Mesh
A	6 ft × 1/8 in.	3% OV-17	Chromosorb W (HP)	80/100
B	6 ft × 1/8 in.	3% OV-101	Chromosorb W(HP)	80/100

The carrier gas flow rate was about 35 mL/min. The 60 MHz nmr spectra were recorded on a Varian Associates Model T-60. The 100 MHz spectra were recorded on a Varian Associates Model HA-100 or Model XL-100 and the 270 MHz spectra were recorded on a 270 MHz instrument (7) constructed from a Bruker console, a Nicolet computer Model 293A with a Diablo disk, and a 270 MHz super conducting magnet supplied by Oxford Instruments. Signal positions are given in delta (δ) with tetramethyl silane (TMS) as an internal reference. Signal multiplicity and integrated area are indicated in parentheses. Infrared spectra were recorded on a Perkin-Elmer 137 spec-

[2]In terms of Baldwin's Rules (6), this transformation, in the initial stage, could be described as a 5-*exo*-dig cyclisation.

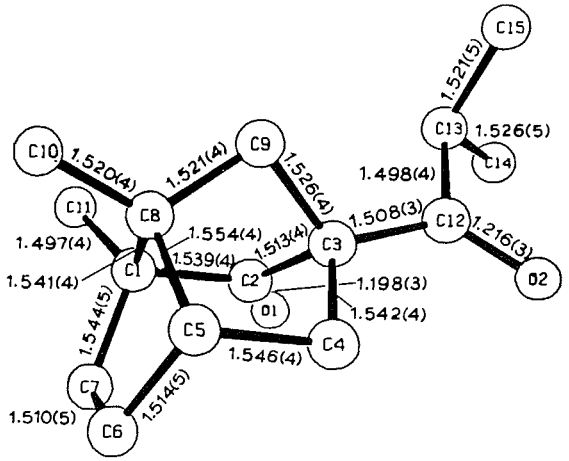

FIG. 1. Perspective view of **11** (crystallographic numbering) showing bond distances (Å) with their estimated standard deviations in parentheses. The atom numbering corresponds to those of Table 1.

trophotometer and optical rotations were measured with either a Perkin-Elmer Model 141 polarimeter or a Perkin-Elmer Model 241 MC polarimeter. Low resolution mass spectra were recorded on a Varian/Mat Model CH4B mass spectrometer and high resolution mass spectra were determined on the AEI Model MS902 or Model MS550 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver. All the solvents used for nmr, ir, and optical rotations were of spectral grade. Dry solvents were obtained in the following way: ether by distillation from sodium; hexamethylphosphoramide (HMPA), benzene, *t*-butanol, and hexanes by distillation from CaH_2; acetone by distillation from 4A molecular sieves; tetrahydrofuran (THF) by distillation from $LiAlH_4$.

(+)-8-Cyanocamphor Ethylene Acetal (2)

(+)-8-Bromocamphor ethylene acetal (10.0 g, 36.4 mmol) and sodium cyanide (10.70 g, 0.218 mol) were dissolved in dry hexamethylphosphoramide (HMPA) (100 mL) and the reaction mixture heated at 100°C for 4 days under a nitrogen atmosphere. Addition of water (200 mL) followed by extraction with petroleum ether (30–60) (5 × 50 mL) and workup in the usual way provided (+)-8-cyanocamphor ketal (**2**) (7.0 g, 88% yield) as a colourless oil; bp 85–87°C/10^{-2} mm; $[\alpha]_D^{26} = +5.06$ (c 2.35, 95% EtOH): $\delta(CCl_4)$ 0.76 (s, 3H), 1.05 (s, 3H), 2.13 (d, 1H, J = 17 Hz), 2.86 (d, 1H, J = 17 Hz), 3.79 (m, 4H) $\nu_{max}(CCl_4)$ 2247 and 1420 cm^{-1}; *m/e* 221 (M^+), 181, 113, 95 (base peak) M.W. calcd. for $C_{13}H_{19}NO_2$: 221.1415. Found (high resolution mass spectrometry): 221.1422. *Anal.* calcd. for $C_{13}H_{19}NO_2$: C 70.54, H 8.66, N 6.33; found: C 70.44, H 8.50, N 6.20.

8-Formylcamphor Ethylene Acetal (3)

8-Cyanocamphor ethylene acetal (**2**) (2.33 g, 10.6 mmol) was dissolved in dry hexane (30 mL) and the solution cooled (dry ice – acetone) to −50°C. Diisobutylaluminum hydride (DIBAL) (Alfa, 20% in hexane, 1 molar solution, 13.2 mL, 13.2 mmol) was added via syringe under a nitrogen atmosphere and the reaction was warmed to room temperature over 2 h.

The reaction mixture was carefully added to a mixture of saturated Rochelle salt and water (1:1; 150 mL). Hydrochloric acid (6 *N*) was added (5 mL) and this mixture was stirred vigorously for 2 h. Finally, saturated sodium bicarbonate (6 mL) was added and the solution separated into two distinct layers. The organic layer was separated and washed with saturated sodium chloride (50 mL), dried (sodium sulphate), and the solvent was evaporated to yield 8-formylcamphor ketal (**3**) as a clear colourless oil. The oil was chromatographed on alumina (Alumina Woelm Neutral; activity grade III) (50 g) and 8-formylcamphor ethylene acetal (**3**) was eluted from the column using 10% ether – 90% petroleum ether (30–60) as eluant (200 mL), (2.07 g, 88% yield). Removal of solvent provided **3** as a clear colourless oil which was used immediately without further purification; $\delta(CCl_4)$ 0.74 (s, 3H), 0.90 (s, 3H), 3.76 (m, 4H), 9.74 (t, 1H); $\nu_{max}(CCl_4)$ 2717, 1721, and 1404 cm^{-1}.

8-(3-Methyl-1-oxo-3-butenyl)camphor (4)

8-Formylcamphor ketal (**3**) (765 mg, 3.42 mmol) in ether (10 mL) was added to a 1 *M* ether solution of 2-methyl-2-propenyl magnesium chloride (15 mL; 15 molar equivalents) at 4°C (ice–water bath). The reaction was stirred for 20 min at 4°C and then for 45 min at room temperature. Careful hydrolysis was accomplished by dropwise addition of saturated ammonium chloride solution (50 mL) and the aqueous mixture was extrac-

For personal use only.

ted with ether (2 × 25 mL). The organic layers were combined and washed with saturated sodium chloride (1 × 10 mL) and dried over magnesium sulphate. Evaporation of the solvent gave 8-(1-hydroxy-3-methyl-3-butenyl)camphor ethylene acetal as a colourless oil (630 mg, 66% yield) after chromatography on silica gel (Silica Gel Woelm 100–200; activity grade III; 20% ether:80% petroleum ether (30–60) as eluant); δ(CCl_4) 3.78 (m, 4H), 4.80 (bm, 2H); ν_{max}(film) 3472, 1645, and 893 cm^{-1}.

8-(1-Hydroxy-3-methyl-3-butenyl)camphor ethylene acetal was deketalized in dioxane (15 mL) and 1 *N* hydrochloric acid (1.5 mL) for 17 h at room temperature. Workup provided a colourless oil (515 mg, 97% yield); δ(CCl_4) 0.87 (s, 3H), 1.10 (s, 3H), 3.53 (bs, 1H), 3.75 (bm, 1H), 4.82 (d, 2H, J = 7 Hz); ν_{max}(CCl_4) 3448, 1645, 1740, 1410, and 890 cm^{-1} which was oxidized immediately by dissolving in acetone (50 mL) and treatment with Jones reagent until a permanent orange colour remained in the solution. Workup in the usual manner gave 8-(3-methyl-1-oxo-3-butenyl)camphor (**4**) as a colourless oil (500 mg, 98% yield); ν_{max}(film) 1740, 1725, 1650, 1408, and 895 cm^{-1}.

8-(3-Methyl-1-oxo-2-butenyl)camphor (5)

A solution of 8-(3-methyl-1-oxo-3-butenyl)camphor (**4**) (50 mg, 0.21 mmol) in petroleum ether (30–60) (6 mL) containing wet ether (10 drops) was treated with alumina (Alumina Woelm Basic; activity grade one) (150 mg) for 19 h at room temperature.

The alumina was filtered, washed carefully with ether, and the total filtrate evaporated to yield 8-(3-methyl-1-oxo-2-butenyl)-camphor (**5**) (45 mg, 90% yield) as a colourless oil which crystallized on standing. This material was purified by sublimation (90°C/10 mm) to yield colourless crystals (mp 43–55°C); δ(CCl_4) 0.83 (s, 3H), 1.02 (s, 3H), 1.87 (d, 3H, J = 2 Hz), 2.12 (d, 3H, J = 2 Hz), 2.70 (dd, 1H), 5.93 (m, 1H); ν_{max}(CCl_4) 1739, 1692, 1618, and 1408 cm^{-1}; λ_{max}(MeOH) 238 (ε = 12 800); *m/e* 234 (M^+), 218, 206, 153, 136 (base peak), 95. *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.88, H 9.46; found: C 76.66, H 9.53.

8-Ethynylcamphor Ethylene Acetal (8)

A solution of 8-iodocamphor ethylene acetal (**7**) (1) (3.36 g, 10.4 mmol) in dry ether:HMPA (1:1) (20 mL) was added under nitrogen to a suspension of lithium acetylide ethylenediamine complex (Foote Mineral Company: 1.30 g, 14.1 mmol) in dry ether:HMPA (1:1) (40 mL). The reaction mixture was stirred at room temperature for 24 h and then added to saturated ammonium chloride (100 mL). Extraction with petroleum ether (30–60) (5 × 25 mL) and workup in the usual way yielded 8-ethynylcamphor ethylene acetal (**8**) (2.45 g) as an orange oil which was purified by vacuum distillation (bp, 68°C/5 × 10^{-3} mm) (1.24 g, 54% yield); δ(CCl_4) 0.78 (s, 3H), 1.02 (s, 3H), 2.62 (bm, 1H), 2.90 (bm, 1H), 3.77 (bm, 4H); ν_{max}(CCl_4) 3279 and 2128 cm^{-1}; *m/e* 220 (M^+), 205, 195, 181, 126, 113, 95 (base peak). M.W. calcd. for $C_{14}H_{20}O_2$: 220.1463. Found (high resolution mass spectrometry): 220.1459.

8-(3-Hydroxy-3-methyl-1-butynyl)camphor Ethylene Acetal (9)

A solution of 8-ethynylcamphor ethylene acetal (**8**) (1.77 g, 8.05 mmol) in dry ether (25 mL) was cooled at 4°C (ice–water) and then treated with *n*-butyllithium (3.94 mL; Alfa, 2.45 molar in hexanes; 1.2 equivalents) over 5 min. The reaction mixture was stirred at 4°C for 45 min, dry acetone (0.70 g, 12 mmol) was added, and the solution stirred at room temperature for 2.5 h.

The reaction mixture was poured into saturated ammonium chloride (100 mL), extracted with ether (2 × 25 mL) and the combined extracts washed with water (1 × 25 mL) and saturated sodium chloride (1 × 25 mL). Drying (magnesium sulphate) and evaporation yielded 8-(3-hydroxy-3-methyl-1-butynyl)-camphor ethylene acetal (**9**) (2.29 g) as a yellow oil. The crude product (Alumina Woelm Neutral; activity grade III) was applied to an alumina column in 5% ether – 95% petroleum ether (30–60). Elution with 50% ether – petroleum ether yielded 8-(3-hydroxy-3-methyl-1-butynyl)camphor ethylene acetal (**9**) (1.42 g, 63.4% yield) as a pale yellow oil; δ(CCl_4) 0.77 (s, 3H), 0.98 (s, 3H), 1.43 (s, 6H), 3.82 (bm, 4H); ν_{max}(CCl_4) 3448 and 2232 cm^{-1}; *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.33, H 9.42; found: C 73.04, H 9.52.

(+)3,7-Dimethyl-1-1-(2-methyl-1-oxopropyl)-tricyclo-[4.2.1.$0^{3,7}$]nonan-2-one (11)

A solution of 8-(3-hydroxy-3-methyl-1-butynyl)camphor ethylene acetal (**9**) (1.70 g, 6.12 mmol) in 98% formic acid (15 mL) was refluxed for 21 h. The reaction mixture was poured into water (50 mL), extracted with ether (3 × 20 mL) and the combined extracts washed with water (2 × 20 mL), saturated sodium bicarbonate (3 × 20 mL), water (1 × 20 mL), and saturated sodium chloride (2 × 20 mL). Drying (magnesium sulphate) and evaporation of the solvent yielded an orange oil (1.24 g, 79% pure by glc on column A at 150°C) which was purified by column chromatography on alumina (Alumina Woelm Neutral; activity grade III). Elution with petroleum ether (30–60) (400 mL) yielded **11** (1.0 g, 70% yield) as a pale yellow oil which crystallized on standing overnight. Recrystallization from petroleum ether (30–60) at −20°C gave **11** as colourless rods, mp 51–52°C. (sealed tube): δ($CDCl_3$) 1.09 (d, 3H, J = 7 Hz), 1.13 (s, 3H), 1.14 (d, 3H, J = 7 Hz), 1.40 (s, 3H), 2.89 (septet, 1H, J = 7 Hz); ν_{max}(CCl_4) 1745, and 1701 cm^{-1}; *m/e* 234 (M^+), 191, 163, 145, 135, 107, 95 (base peak); M.W. calcd. for $C_{15}H_{22}O_2$: 234.1620. Found (high resolution mass spectrometry): 234.1625. *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.88, H 9.46; found: C 77.09, H 9.48.

8-(3-Methyl-1-butenyl)camphor (15)

8-Formylcamphor ketal (**3**) (2.07 g, 9.24 mmol) in dry THF (40 mL) was added over 10 min to a clear orange solution containing isobutylphosphonium bromide (5.26 g, 13.2 mmol, 1.25 equivalents) and *n*-butyllithium (5.17 mL; Alfa, 2.25 molar in hexanes) in dry THF (40 mL). The reaction was stirred at room temperature for 8 h and excess ylide was destroyed with methanol (0.5 mL). The reaction mixture, preadsorbed on silica gel (Silica Gel Woelm, 100–200; activity grade III) (25 g), was then chromatographed on silica gel of the same activity (50 g). Elution with 20% ether – 80% petroleum ether (30–60) provided 8-(3-methyl-1-butenyl)camphor ethylene acetal as a colourless oil (1.94 g, 80% yield) (bp 82–83°C/2 × 10^{-3} mm); δ(CCl_4) 0.76 (s, 3H), 0.80 (s, 3H) 0.93 (d, 6H, J = 7 Hz), 3.80 (m, 4H), 5.23 (m, 2H); *Anal.* calcd. for $C_{17}H_{28}O_2$: C 77.21, H 10.68; found: C 76.93, H 10.53.

Deketalization was accomplished by dissolving the ketal olefin in a mixture of acetone (25 mL) and 6 *N* hydrochloric acid (10 drops) and stirring at room temperature for 8 h. Extraction of the diluted reaction product with ether and workup in the usual way provided 8-(3-methyl-1-butenyl)camphor (**15**) as a colourless oil (1.08 g, quantitative) (bp 75°C/10^{-3} mm); δ(CCl_4) 0.90 (s, 6H), 0.94 (s, 3H), 0.97 (s, 3H), 5.30 (m, 2H): ν_{max}(CCl_4) 1739, 1408, and 1370 cm^{-1}; *m/e* 220 (M^+), 138, 137, 136, 135, 125, 124, 122, 109 (base peak). M.W. calcd. for $C_{15}H_{24}O$: 220.1827. Found (high resolution mass spectrometry): 220.1811.

8-(1,2-Epoxy-3-methylbutyl)camphor (16)

A solution of *meta*-chloroperbenzoic acid (1.12 g, 6.5 mmol, 1.1 equivalents, 85% pure) in benzene (30 mL) was added over 30 min to a solution of 8-(3-methyl-1-butenyl)camphor (**15**) (1.3 g, 5.9 mmol) in dry benzene (30 mL) at 4°C (ice–water). The reaction was stirred at 4°C for an additional 0.5 h and then allowed to warm to room temperature over 2 h. Extraction of the benzene solution with small portions of saturated sodium bisulphite (5 mL portions) was continued until a negative starch–iodide test was obtained. Evaporation of the washed solvent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

yielded 8-(1,2-epoxy-3-methylbutyl)camphor (**16**) as a clear colourless oil (1.4 g, quantitative) (bp 84°C/10^{-3} mm); $\delta(CCl_4)$ 0.83 (s, 3H), 0.90 (d, 3H, J = 6 Hz) 1.04 (d, 3H, J = 6 Hz), 1.05 (s, 3H), 2.88 (m, 2H); $\nu_{max}(CCl_4)$ 1739, 1408, 1255, 948, and 881 cm^{-1}; *m/e* 236 (M^+), 193, 153 (base peak), 137, 136, 135, 123, 121, 109, 108, 107, 95, 94, 93; M.W. calcd. for $C_{15}H_{24}O_2$: 236.1775. Found (high resolution mass spectrometry): 236.1786.

1,6-Dimethyl-2-oxo-4-(1-oxo-2-methylpropyl)-tricyclo-[4.3.0^{1,6}.0^{3,7}]nonane (12)

8-(1,2-Epoxy-3-methylbutyl)camphor (**16**) (1.09 g, 4.24 mmol) was treated with dry *tert*-butanol (100 mL) containing potassium *tert*-butoxide (6.70 g, 59.8 mmol, 14 equivalents) at reflux under nitrogen for 8 h.

The reaction mixture was poured into water (200 mL) and extracted with petroleum ether (30–60) (4 × 25 mL). The organic layers were combined and washed with water (2 × 25 mL) and saturated sodium chloride (1 × 25 mL). Drying (sodium sulphate) and evaporation of the solvent yielded 1,6-dimethyl-2-oxo-4-(1-hydroxy-2-methylpropyl)tricyclo[4.3.0.^{1,6}0^{3,7}]nonane which was purified by chromatography on silicic acid (Malinckrodt Silicic Acid, 100 mesh) (40 g) using, at first, chloroform (100 mL) and then 1.5% ethanol (95%) – 98.5% chloroform (130 mL) as eluants. This yielded a mixture of diastereomeric alcohols (986 mg); $\delta(CCl_4)$ 0.82 (d, 3H, J = 7 Hz), 0.88 (s, 3H), 0.96 (s, 3H), 0.97 (d, 3H, J = 7 Hz), 2.24 (m, 1H), 2.68 (bs, 1H), 3.07 (bm, 2H); $\nu_{max}(CCl_4)$ 3413 and 1739 cm^{-1} which was oxidized in acetone using Jones reagent until a permanent orange colour remained in solution. Excess reagent was destroyed with a few drops of methanol and the reaction mixture was poured into water (100 mL). The product was isolated by extraction with diethyl ether (3 × 25 mL). The organic layers were combined and washed with saturated sodium bicarbonate (1 × 25 mL) and saturated sodium chloride (1 × 25 mL). Drying (magnesium sulphate) and evaporation of the solvent yielded 1,6-dimethyl-2-oxo-4-(1-oxo-2-methylpropyl)tricyclo[4.3.0^{1,6}.0^{3,7}]nonane (**12**) as a mixture of two diastereomers; $\delta(CCl_4)$ 0.89 (s, 3H), 0.98 (s, 3H), 1.06 (d, 6H, J = 7 Hz), 2.14 (bm, 1H), 2.50 (bs, 1H), 2.76 (m, 2H); $\nu_{max}(CCl_4)$ 1739 and 1710 cm^{-1}; *m/e* 234 (M^+), 163, 153 (base peak), 135, 107, 93, 79; M.W. calcd. for $C_{15}H_{22}O_2$: 284.1619. Found (high resolution mass spectrometry): 234.1612.

X-ray Crystallographic Analysis of 11

Upon exposure to air at ambient temperatures, a freshly prepared crystalline sample of **11** gradually turned into an amorphous solid in the course of 3–4 days. Several crystals were used in taking preliminary X-ray photographs and in the collection of intensity data. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 high-angle reflections measured on a diffractometer with MoK_α radiation (λ = 0.71069 Å). The crystal data at 22°C are:

Orthorhombic, a = 19.521(2), b = 10.238(2), c = 6.881(2) Å, V = 1375.2 Å^3, Z = 4, ρ_c = 1.132 g cm^{-3}, $\mu(MoK_\alpha)$ = 0.79 cm^{-1}. Systematic absences: $h00$ with h odd, $0k0$ with k odd, and $00l$ with l odd determine the space group uniquely as $P2_12_12_1$ (D_2^4, No. 19).

Intensities were recorded to 2θ = 53° with graphite monochromatized MoK_α radiation on an Enraf-Nonius CAD-4 diffractometer. A variable speed ω scan over a range of r = (0.85 + 0.35 tan θ) degrees in ω was employed. The scan was extended at both ends by r/4 for background measurement. Crystal orientation was monitored every 100 reflections and the intensities of three standard reflections checked hourly throughout the data collection. Of the 1662 independent reflections measured, 1015 (61%) had intensities greater than 3.5σ(I) above background where $\sigma^2(I) = S + B + (0.04S)^2$, with S = scan count and B = normalized background count. The data were corrected for Lorentz and polarization factors but absorption correction was considered unnecessary.

TABLE 2. Final positional parameters (fractional × 10^4) with estimated standard deviations in parentheses, and mean U_{ii} (Å^2 × 10^2)

Atom	x	y	z	Mean U_{ii}
C(1)	852(1)	2914(3)	269(4)	6.3

C(4)	1851(1)	4828(3)	−792(5)	7.3
C(5)	1076(1)	4953(3)	−1210(5)	7.4
C(6)	638(2)	5272(3)	542(6)	9.0
C(7)	561(1)	3991(4)	1606(4)	9.0
C(8)	877(1)	3533(3)	−1771(4)	6.2
C(9)	1529(1)	2999(3)	−2680(4)	6.8
C(10)	220(1)	3432(4)	−2948(5)	9.7
C(11)	503(2)	1618(4)	445(8)	12.0
C(12)	2746(1)	2948(3)	−1055(4)	5.9
C(13)	2909(1)	1557(3)	−1548(5)	7.3
C(14)	3445(2)	1012(4)	−153(7)	11.6
C(15)	3141(2)	1457(4)	−3653(6)	10.2
O(1)	1862(1)	2257(3)	2107(3)	9.1
O(2)	3197(1)	3735(2)	−726(4)	8.6

The structure was solved by direct methods using MULTAN (8). After full-matrix anisotropic refinement (local adaptations of ORFLS and FORDAP) of all 17 non-hydrogen atoms to R = 0.091, a difference map revealed the positions of all 22 hydrogen atoms, which were included in subsequent least-squares cycles with isotropic thermal parameters (B = 8.5 Å^2 for methyl H, 7.0 Å^2 for methylene and methine H).

Literature scattering factors of non-hydrogen atoms (9) and hydrogen atoms (10) were used and the function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with $w = 1/\sigma^2(F)$. Convergence was reached at R = 0.042 for 1015 observed reflections.

The final positional parameters of C and O atoms are given in Table 2. Lists of hydrogen atomic coordinates, thermal parameters, and structure factors have been placed in the Depository of Unpublished Data.[3]

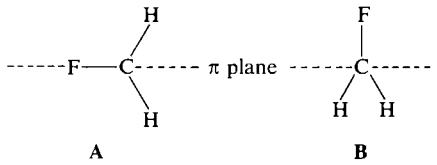
Received December 13, 1979

TED SCHAEFER, WALTER P. NIEMCZURA, RUDY SEBASTIAN, LEONARD J. KRUCZYNSKI, and WERNER DANCHURA. Can. J. Chem. **58**, 1178 (1980).

The coupling over seven bonds between ^{19}F nuclei and protons in *p*-methylbenzyl fluoride and a series of ring-substituted derivatives is used to estimate the value for a conformation in which the C—F bond lies in a plane perpendicular to the benzene ring. The *J* method is then used to show that in CS_2 solution, the conformational preference of the fluoromethyl group is very weak in 3,5-dichloro-4-methylbenzyl fluoride and in 3,5-dibromo-4-methylbenzyl fluoride. The barrier to rotation about the exocyclic carbon–carbon bond is perhaps as large as 0.2 kcal/mol. In *p*-methylbenzyl fluoride, the C—F bond prefers a plane perpendicular to the benzene plane by ca. 0.9 kcal/mol. Good agreement is found with the conformational preferences based on couplings over six or seven bonds between the methylene protons and the *para* ring or methyl protons. The deductions are compared with calculations at various levels of molecular orbital theory.



TED SCHAEFER, WALTER P. NIEMCZURA, RUDY SEBASTIAN, LEONARD J. KRUCZYNSKI et WERNER DANCHURA. Can. J. Chem. **58**, 1178 (1980).

On a utilisé les couplages à travers sept liaisons, entre le ^{19}F et les protons du fluorure de *p*-méthylbenzyle et d'une série de dérivés cycliques substitués dans le but de déterminer cette valeur pour une conformation de la liaison C—F qui se situe dans le plan perpendiculaire au noyau benzénique. On a alors utilisé la méthode *J* pour montrer qu'en solution dans le CS_2, la préférence conformationnelle du groupe fluorométhyle est très faible dans le cas du fluorure des dichloro-3,5, et dibromo-3,5 méthyl-4 benzyles. La barrière à la rotation autour de la liaison exocyclique carbone–carbone est peut être de 0.2 kcal/mol. Dans le cas du fluorure de *p*-méthylbenzyle, la liaison C—F se situe de préférence dans le plan perpendiculaire à celui du benzène avec une barrière à la rotation de 0.9 kcal/mol. On a trouvé que ces résultats s'accordent parfaitement avec les préférences conformationnelles évaluées sur la base des couplages à travers 6 ou 7 liaisons entre les protons méthyléniques et les protons situés en position *para* sur le cycle ou les protons du groupe méthyle. On a comparé les déductions ainsi faites avec des calculs d'orbitales moléculaires effectués à divers niveaux.

[Traduit par le journal]

Introduction

The internal barrier to rotation in toluene is only 0.014 kcal/mol (1) and, at 0.010 kcal/mol, is even lower in benzotrifluoride (2). Substitution in the methyl group to give a CH_2X or a CHX_2 sidechain changes the sixfold barrier for a CH_3 group to one of a predominantly twofold nature. These twofold barriers have been investigated in solution for X = F, Cl, Br, I, CH_3 (3–5) and a variety of other X substituents (6, 7). The investigations are mainly based on the $\sin^2\theta$ dependence of $^6J_p^{H,CH}$, the coupling constant over six bonds between protons in the sidechain and a *para* ring proton; θ is the angle by which the C—H bond twists out of the benzene plane (the *J* method). For 3,5-dichlorobenzyl fluoride, on the other hand, the determination of the twofold internal barrier was based on an assumed $\sin^2\theta$ dependence of $^6J_p^{H,CF}$ and yielded 0.26 kcal/mol (3). Conformations **A** and **B** were of low and high energy, respectively. These results

A **B**

were in satisfactory agreement with *ab initio* STO 3G calculations (3, 8) as well as with computations (3) based on MINDO MO methods. On the other hand, CNDO/2 and INDO MO calculations gave barriers an order of magnitude larger than these (3, 9), although they found **A** as the stable conformer.

Subsequent vibrational spectra (10) in solution were interpreted as arising from a large number of conformers, a result of free or nearly free internal rotation. The photoelectron spectra of benzyl halides have been interpreted in terms of a *gauche* conformation in which an α C—H bond prefers the benzene plane (11).

Whereas there exists satisfactory evidence for a sole $\sigma-\pi$ mechanism for $^6J_p^{H,CH}$ and hence for its $\sin^2\theta$ dependence (12), it was pointed out by Dr. R. Wasylishen that the $\sin^2\theta$ dependence of $^6J_p^{F,CH}$ in benzyl fluoride is not firmly established. While it is

true that INDO MO FPT calculations yield such a dependence (and also agree quantitatively with observed $^6J_p^{H,CH}$ values), a non σ–π component in $^6J_p^{F,CH}$ may exist. This component would then introduce an error into the barrier determination.

In view of the disagreement among the experimental and theoretical results above and of some recent evidence (13, 14) for small σ contributions to ^1H, ^{19}F couplings over six bonds, further work is in order. In addition, if the conformational preferences of the fluoromethyl group are indeed weak and are influenced by hyperconjugative interactions of the C—F bond with the aromatic π system (9, 15), then substituents may alter these preferences. The previous conclusions from the J method are related to 3,5-dichlorobenzyl fluoride and therefore need not hold for benzyl fluoride. Unfortunately, the ^1H nmr spectrum of benzyl fluoride would be intractable even at 400 MHz. Accordingly, we now examine *p*-methylbenzyl fluoride and a series of its derivatives. These compounds are amenable to spectral analysis and have the advantage that the $^7J_p^{CH_2,CH_3}$ and $^7J_p^{F,CH_3}$ can be treated as σ–π couplings.

Experimental

The fluoromethyl group was produced from the bromomethyl or chloromethyl groups by treatment with KF in the presence of 18-crown-6 ether (Aldrich) (16). The benzyl fluoride derivatives, the physical properties of some of which have been given by Béguin and Meary-Tertian (17) and by Schaefer and co-workers (3), were easily identified from their ^1H nmr spectra. In particular, the characteristic $^2J^{H,F}$ of 47 to 48 Hz in the methylene proton spectra confirmed the presence of the fluoromethyl group. Because of polymerization problems, the pure derivatives were not isolated.

A typical procedure went as follows. To 20 mL of acetonitrile (dried over Type 5A sieve, from Fisher) were added 1.55 g (9.2 m*M*) of 2,4,6-trimethylbenzyl chloride (Aldrich), 1.07 g (1.8 m*M*) of KF (dried at 250°C for 24 h), and 0.24 g (0.9 m*M*) of 18-crown-6 ether. The mixture was gently refluxed at 80°C with *vigorous* stirring for 90 h. The solution was decanted from KF and KCl and evaporated to a viscous mass. Extraction with petroleum ether left most of the crown ether behind. Subsequent removal of the petroleum ether resulted in a colorless solid which polymerized in about 5 min. A small portion was retrieved before polymerization and was dissolved in CS_2 in a 5 mm od nmr tube. The sample was degassed and flame-sealed. Under these conditions, the benzyl fluoride derivative was indefinitely stable.

The ^1H nmr spectra of all benzyl fluoride derivatives in degassed CS_2 solutions were recorded on an HA100 spectrometer at a probe temperature of 305 K. They were calibrated in the frequency sweep mode by placing markers at 2 to 5 Hz intervals. The frequencies of the markers relative to the TMS lock frequency were obtained by reading sweep and lock oscillator frequencies. Sweep rates were 0.01 or 0.02 Hz/s at a spectral dispersion of 1 Hz/cm. In this way peak frequencies could be found with a rms error of 0.02 Hz or better. Strong and weak multiple irradiation experiments (18) gave the signs of the long-range couplings to ^{19}F relative to $^2J^{H,F}$, known to be positive.

STO 3G MO calculations were performed as previously described (3).

Results and Discussion

Spectral Analyses

These were done in the usual manner with the computer program LAME (19, 20). The spectra of 2,4,6-trimethylbenzyl fluoride and of *p*-methylbenzyl fluoride could not be completely analyzed. For the latter, the ring protons are almost isochronous in CS_2 solution, so that while an analysis was problematical, decoupling of the ring protons yielded good values of $^7J_p^{CH_2,CH_3}$. In benzene-d_6 solution, the magnitude of $^7J_p^{F,CH_3}$ was the same as in CS_2 solution.

Figure 1 displays half of the methylene proton resonance of *p*-methylbenzyl fluoride under conditions where the ring protons are decoupled.

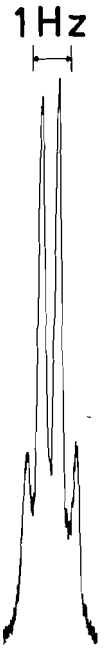
In Table 1 some spectral parameters are given for compounds **1** to **4** and **6** to **10**.

The Value of $^7J_{90}^{F,CH_3}$ and the Internal Barrier

If $^7J_{90}$ in eq. [1] can be found

$$[1] \quad {}^7J_p^{F,CH_3} = {}^7J_{90}\langle \sin^2\theta \rangle$$

then, as discussed for a similar situation previously (3), the observed value of $^7J^{F,CH_3}$ yields $\langle \sin^2\theta \rangle$,



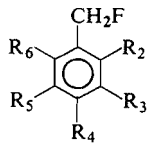


FIG. 1. This quartet is half the methylene proton resonance at 100 MHz and 305 K, obtained by decoupling the ring protons, of a ca. 10 mol% solution of *p*-methylbenzyl fluoride in CS_2. The quartet itself is centered at $\delta = 5.382_6$ ppm (TMS), $^2J^{H,F}$ is $48.1_2 \pm 0.05$ Hz and $\delta(CH_2)$ is 5.142_0 ppm.

relatable to V_2 for the fluoromethyl group. Various lines of evidence suggest that conformation **B** is the preferred conformer for **1** to **4** and that V_2 is greater than 4 kcal/mol. The nmr spectrum of 2,6-dichlorobenzyl fluoride in a nematic solvent suggests a V_2 of 4 to 5 kcal/mol (21). *Ab initio* calculations on this compound involve optimization of the C—C—F bond angle and find a V_2 of 6.8 kcal/mol (3). Dynamic nmr data (22) on **5** for X = Cl, Br, I (mean $\Delta G^{\ddagger}$ of 8.8, 10.7, and 12.1 kcal/mol, respectively, for reorientation of the CH_2X groups) can be plotted versus Van der Waals volumes (23) of the halogens and hydrogen (essentially a zero, sixfold, barrier for a methyl group). The smooth curve suggests a V_2 of ca. 5 kcal/mol for **1**.

The values of $^7J_p^{F,CH_3}$, in conjunction with calculations of $\langle \sin^2 \theta \rangle$, can now be used to place limits on $^7J_{90}$. If V_2 is infinite, $\langle \sin^2 \theta \rangle$ is unity for **1** and $^7J_{90}$ is 2.81 Hz. If V_2 is 4 kcal/mol, $\langle \sin^2 \theta \rangle$ is 0.91 and $^7J_{90}$ is 3.10 Hz. Actually, the $^7J^{F,CH_3}$ values for **3** and **4** suggest somewhat higher barriers than in **1** (there is some evidence (24) that *ortho* substituents in benzene derivatives hinder internal rotation as $CH_3 > Br > Cl$). In that event[3] the minimum value of $^7J_{90}$ is 3.15 Hz (V_2 is infinite) and the maximum is 3.43 Hz (if V_2 is 5 kcal/mol in **4**). If V_2 were 10 kcal/mol, $^7J_{90}$ would be 3.25 Hz. It seems reasonable, therefore, that $^7J_{90}$ is 3.34 ± 0.09 Hz.

In **6** and **7**, $^7J^{F,CH_3}$ is $1.63_5 \pm 0.02$ Hz. It follows that $\langle \sin^2 \theta \rangle$ is $1.63_5 \pm 0.02/3.34 \pm 0.09$ or 0.49 ± 0.02. Therefore V_2 is essentially zero, with the faint possibility that conformation **A** is favored by as much as 0.1_5 kcal/mol. Formally, V_2 is 0.06 kcal/mol, **A** favored.

5

$^7J^{CH_2,CH_3}$ *and the Internal Barrier in* **6** *and* **7**

In **6**, $^7J^{CH_2,CH_3}$ is 0.52 ± 0.01 Hz. For a vanishing V_2, $^7J_{90}$ would be 1.04 ± 0.02 Hz. As discussed in detail previously (3), $^7J_{90}$ is expected to be smaller than in *p*-xylene, where it is 1.24 Hz. INDO MO FPT calculations on benzyl fluoride suggest $^7J_{90}$ as 1.09 Hz. If true, then $\langle \sin^2 \theta \rangle$ is 0.48 and V_2 is 0.2 kcal/mol, **B** favored. If $^7J_{90}$ is 1.02 Hz, as previously assumed (3), V_2 becomes 0.1 kcal/mol, **A** favored. To within experimental error, then, $^7J^{CH_2,CH_3}$ is in agreement with the conclusions above, i.e., that the CH_2F group is nearly a free rotor in **6**.

A check on $^7J_{90}^{CH_2,CH_3}$ is available from the value

[3]It is interesting that INDO MO FPT calculations (3) find $^6J_{90}^{F,CH}$ as −3.18 Hz in conformation **B** of benzyl fluoride. This value should be equal in magnitude to $^7J_{90}^{F,CH_3}$ (12).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

of $^7J_p^{*F,CH_2}$ in **8** and **9**, being 2.55 ± 0.04 and 2.60 ± 0.02 Hz, respectively. Assuming that V_2 of the "free" CH_2F group is the same as in **6** and **7**, i.e., essentially zero, the presence of the fluorine substituent in this group has decreased the seven-bond ^1H, ^{19}F couplings by factors of $2.55/2.81_5$ or 0.91 and 2.60/2.96 or 0.88. The mean reduction of 0.89_5 is then presumably caused by the polarization of the C—H bonds, leading to decreased overlap with the π orbitals in the $\sigma-\pi$ mechanism (reductions by a factor of 0.9 occurs in analogous β-fluoroethyl radicals (25)). In other words, one might expect $^7J_{90}^{CH_2,CH_3}$ in **6** and **7** to be smaller than $^7J_{90}^{CH_3,CH_3}$ in *p*-xylene by a factor of 0.89, close to the values discussed at the beginning of this section.

In summary, $^7J^{F,CH_3}$ and $^7J^{CH_2,CH_3}$ agree that V_2 in **6** and **7** is 0 to 0.2 kcal/mol. The conformational preference of the CH_2F group is smaller than RT.

Conformational Preference in p-*Methylbenzyl Fluoride*

$^7J_p^{F,CH_3}$ is $2.1_5 \pm 0.1$ Hz, corresponding to a $\langle \sin^2\theta \rangle$ of 0.64 ± 0.04. Therefore **B** is preferred and V_2 is 0.9 ± 0.3 kcal/mol. $^7J_p^{CH_2,CH_3}$ is 0.42 ± 0.02 Hz and $\langle \sin^2\theta \rangle$ is 0.40 ± 0.03 corresponding to **B** stable and V_2 of 0.9 ± 0.3 kcal/mol. It seems certain that the conformational preference is much more marked in this compound than in **6** and **7**.

In 3,5-dichlorobenzyl fluoride and its 4-methyl derivative, the magnitudes of $^6J_p^{H,CH_2}$ and $^7J_p^{CH_2,CH_3}$ are identical, showing that V_2 is the same in these compounds. Because $^6J_p^{H,CH_2}$ in benzyl fluoride is not available, a similar comparison with its 4-methyl derivative cannot be made. Measurements of $^5J^{F,C}$ in benzyl fluoride and some model compounds (26) *could* be interpreted as indicating a preferred conformation **B** and a V_2 of between 0.1 to 0.8 kcal/mol (depending on how much of the five-bond coupling arises from a pure $\sigma-\pi$ mechanism).

Comparison with Molecular Orbital Calculations

Semiempirical calculations at the CNDO/2 level of MO theory (9) suggest **A** as more stable than **B** by 2.95 kcal/mol for benzyl fluoride and that a *p*-methyl substituent drops this preference to 2.75 kcal/mol. An earlier INDO result gave 2.4 kcal/mol for benzyl fluoride (3). In our opinion, the absolute values represent a gross overestimate (these methods tend to find "closely-connected" conformations for groups containing polar bonds). Nevertheless, it is interesting that a *p*-methyl substituent apparently lowers the energy of a **B** conformation by 0.2 kcal/mol.

The original STO-3G computations for a standard geometry found **A** to be more stable by 0.25 kcal/mol in benzyl fluoride (8). Optimization of the C—C—F angle (111.5°) gives **A** more stable than **B** by 0.34 kcal/mol. A similar procedure (C—C—F angle of 111.2°) finds **A** more stable by 0.55 kcal/mol in 3,5-dichlorobenzyl chloride. Again, optimization of the C—C—F angle (111.5°) gave **A** more stable by 0.23 kcal/mol in *p*-methylbenzyl fluoride. Comparison of all the MO data with the *J* method suggests that the STO-3G results are to be preferred over the semiempirical results for these compounds.

Conclusions

The conformational preference of the CH_2F group in 3,5-dichlorobenzyl fluoride, in 3,5-dichloro- and 3,5-dibromo-4-methylbenzyl fluoride, is very weak in solution and the twofold barrier to internal rotation about the exocyclic carbon–carbon bond is perhaps as large as 0.2 kcal/mol. In contrast, in *p*-methylbenzyl fluoride the conformer in which the C—F bond lies in a plane perpendicular to the benzene ring is preferred by ca. 0.9 kcal/mol. Spectral difficulties disallow an estimate for benzyl fluoride. STO 3G MO calculations are more reliable than CNDO/2 or PCILO approaches in assessing the conformational preferences.

Acknowledgments

We thank Ms. Priscilla Wang for assistance with the synthesis of the bromine derivatives, Dr. Rod Wasylishen and Dr. W. Adcock for helpful comments, and the Natural Sciences and Engineering Council of Canada for financial aid.

The activity coefficients of some polar solutes in benzene

A. V. ANANTARAMAN AND SAUL GOLDMAN

Guelph–Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 5, 1979

A. V. ANANTARAMAN and SAUL GOLDMAN. Can. J. Chem. 58, 1183 (1980).

Cryoscopy was used to determine the low concentration (< 1 molal) stoichiometric molal activity coefficients of: chlorobenzene, *m*-dichlorobenzene, *o*-dichlorobenzene, and nitromethane in benzene. The data were corrected to a fixed temperature (10°C) by using pre-existing heat of mixing data. The activity coefficients all showed negative deviations from Henry's law ideality, and some of the factors that contribute to this non-ideality were discussed.

A. V. ANANTARAMAN et SAUL GOLDMAN. Can. J. Chem. 58, 1183 (1980).

On a utilisé la cryoscopie pour déterminer les coefficients d'activité molaire stoechiométrique à faible concentration (1 molal) des *o*- et *m*-dichlorobenzènes et du nitrobenzène en solution dans le benzène. On a corrigé les données pour une température déterminée (10°C) en utilisant les données connues de chaleur de mélange. Tous les coefficients d'activité montrent des déviations négatives par rapport à la loi de Henry et on discute des facteurs qui contribuent au fait que les systèmes étudiés ne sont pas idéals.

[Traduit par le journal]

Introduction

Over the past half a century a large body of systematic data has been accumulated on the dilute solution activity coefficients of electrolytes in water. Since these data are sensitive to solute–solute and solute–solvent interactions at a molecular level, they have greatly contributed to our fundamental understanding of these interactions. In contrast to this, almost no systematic data on the low concentration activity coefficients of polar solutes in non-aqueous solvents exist. It is the purpose of this work to contribute data for these latter systems. The cryoscopic method is well-suited to the dilute solution regime, and so it was chosen in this investigation.

Experimental

Materials

The benzene (Fisher, B-245 reagent grade) was purified and dried as described elsewhere (1), and stored over molecular sieves (Fisher, 4 Å) for at least 10 days prior to use. Monochlorobenzene (Fisher, B-255 reagent grade) was purified by repetitively shaking with concentrated sulfuric acid until no colour appeared in the acid phase. It was then washed sequentially with water, aqueous potassium bicarbonate, and water. The product was dried with Drierite and then fractionally distilled; the middle half fraction was retained. *Ortho-* and *meta*-dichlorobenzene (Baker analyzed and BDH reagent grades respectively) were purified by repetitively shaking with concentrated sulfuric acid, water, 10% aqueous sodium hydroxide, and water. They were then dried with Drierite and fractionally distilled with the middle half fraction retained. Nitromethane (Fisher, N-98 reagent grade) was dried with Drierite and then fractionally distilled from Drierite with the middle half fraction retained. All the solutes were stored over Drierite for at least 10 days prior to use.

The densities of the materials used were determined at 25°C with a 25-mL long-stemmed pycnometer. The values found were as follows. Benzene 0.87362 (lit. 0.87368); nitromethane 1.13134 (lit. 1.13128); chlorobenzene 1.10082 (lit. 1.10098); *o*-dichlorobenzene 1.30042 (lit. 1.30033); *m*-dichlorobenzene 1.28305 (lit. 1.28280). The literature values were taken from a standard reference (2). The agreement with the literature values was considered to be satisfactory.

Freezing Point Apparatus

An adiabatic solution calorimeter, similar in design to one described elsewhere (3), was used. The principle features included a matched pair of thermistors immersed in oil in a U-shaped tube to determine temperature changes, an unsilvered glass Dewar flask, whose outer annular space could be readily evacuated or refilled with air, a stirrer shaft, a port consisting of a glass capillary tube for sampling and sample introduction, and a copper mesh tube which was used to contain molecular sieves. This tube was re-charged with fresh molecular sieves prior to each experimental run. The Dewar was surrounded by a transparent plexiglas can, and the entire apparatus was used in a constant temperature bath. The thermistors and accompanying circuitry (3) were sensitive to changes of 10^{-5}°C. They were calibrated with a standard platinum resistance thermometer (Rosemount Engineering Co., Model 162D).

Techniques

Dried solid benzene crystals were prepared by freezing benzene in the presence of molecular sieves. The solid was mixed with dried cold liquid benzene in the Dewar, and the apparatus was assembled and placed in a constant temperature bath set at about 5°C. The stirrer was started and the system (with air in the outer annular space of the Dewar) was allowed to approach equilibrium. After thermal drifting had slowed down, the annular space was evacuated and the final equilibrium state was approached. This procedure shortened the time required to reach equilibrium. Equilibrium was taken to exist when thermal drifting was reduced to 10^{-5}°C over a period of at least 10 min.

In preliminary experiments it was found that the temperature continuously drifted downward, and this was subsequently determined to be due to the gradual uptake of water by the system from the atmosphere. The use of molecular sieves contained in the copper mesh tube (which was immersed in the liquid phase) eliminated this drift (see below).

After equilibrium was established, liquid solute was added by means of a syringe fitted with a long needle through the glass capillary port. After the initial rapid temperature drop, a new

*θ = freezing point depression of solution relative to pure benzene.

temperature plateau was re-established and a sample of the solution was immediately extracted with a syringe for analysis of its solute concentration. During sampling, the stirrer was momentarily stopped so as to reduce the likelihood of crystal intake by the sampling syringe. It was easy to avoid crystals (and to check on the adequacy of the stirring and the quantity of residual solid phase) because the entire apparatus was transparent so that the experimentor was always able to see the system. After a new temperature plateau was established additional solute was added, the system was sampled, etc. In all cases the freezing mixture concentrations were determined by comparison of the solution densities with those of a set of previously prepared standards. The densities were all determined with a Picker densimeter (Sodev, Model 02D). During the course of a run, as the system temperature dropped, the bath temperature was periodically re-adjusted downward so as to maintain, as nearly as possible, adiabatic conditions. The flatness of the temperature–time plateaus provided an index of this.

Because of the water absorption problem, the dissolved water concentration before and after a typical run was determined with an aquatest Karl Fischer Titrimeter (Photovolt, model 702). The molecular sieves were incapable, during the pre-equilibration period, of totally drying the system, but they did maintain a fairly constant water content. Typically, we found the water concentrations before and after a run (about 4 h) to be ~0.0017 and ~0.0019 molar respectively. Since this represents a change of only ~0.0002 molar in dissolved total water concentration, we believe that the freezing point depressions reported here were only slightly, if at all, affected by the presence of dissolved water.

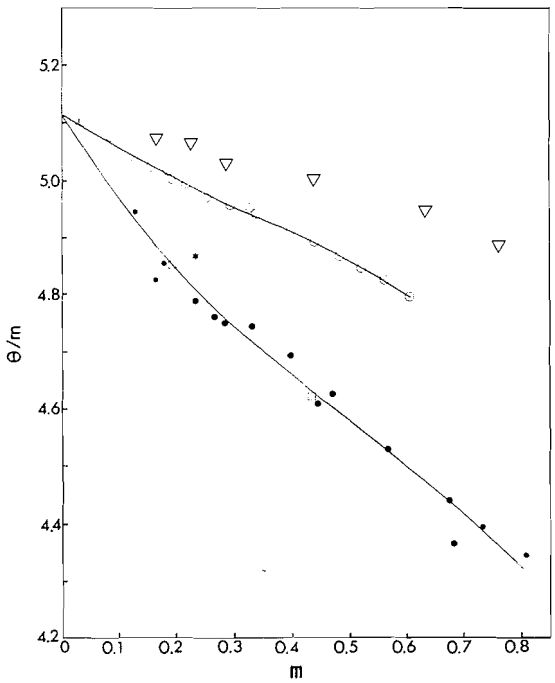

FIG. 1. Comparison with other data of the molal freezing point depression (θ/*m*) against molality (*m*). (●) This work, nitromethane; (□) ref. 4, nitromethane; (○) this work, chlorobenzene; (▽) ref. 5, chlorobenzene. The solid lines were calculated by eq. [1] and the least-squares constants in Table 2.

Results

The results obtained are entered in Table 1. For each system at least three independent runs were carried out. All these data can be smoothly extrapolated to $(\theta/m) = 5.113$ as $m \rightarrow 0$ (e.g. see Fig. 1). This is an indication that solid solutions of solute in benzene did not form. Comparisons with other data, for the two systems in which comparisons are possible, are shown in Fig. 1. In this figure we plot the molar freezing point depression (θ/*m*) rather than θ, against concentration, since the former plot

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

is much more sensitive to error than the latter. It is seen from Fig. 1 that for nitromethane our results agree very well indeed with those of Kraus *et al.* (4), but our chlorobenzene points fall significantly and consistently below those obtained by Bury and Jenkins for this system (5). The co-author of this article who did the experimental work (A.V.A.) was aware of this discrepancy and therefore repeated some of the chlorobenzene points several times, and under somewhat different conditions, to try to determine if some systematic error on his part was responsible for the discrepancy. The different conditions included: doing the experiments on different days, re-calibrating the densimeter frequently, arranging for the experimental runs to be of different lengths and injecting different quantities of solute during the run. No significant systematic error was found. We believe Bury and Jenkins' data on this system are in error, and that a likely source of this error was the way in which they tried to eliminate the effect of dissolved moisture. These authors used solid P_2O_5 immersed in their solutions to remove water. We feel that this is a poor method, since the H_3PO_4 formed from the reaction of water with P_2O_5 will dissolve in benzene and consequently influence the results.

Treatment of the Data

The freezing point data are treated in a conventional way (6, 7). It was found that the data in Table 1 could be represented by a Lewis and Randall j-function of the form

$$[1] \quad j = am + bm^2 + cm^3$$

where a, b, and c are constants, m is the solute molality,

$$j \equiv 1 - \theta/m\lambda$$

and θ is the freezing point depression corresponding to molality m.

$$\lambda = \frac{RT_0^2}{\bar{L}_0} \cdot \frac{W}{1000}$$

where T_0 = the freezing point of pure benzene, $\bar{L}_0$ = the latent heat of fusion of benzene at T_0, W = the molecular weight of benzene, and R is the gas constant. From a published study on the properties of benzene (8) we obtain the values $T_0 = 278.69$ K, $\bar{L}_0 = 2358$ cal/mol, and hence $\lambda = 5.113$ deg/molal.

The values of a, b, and c were found by fitting eq. [1] to the data in Table 1 by least-squares (9). The values thus found are entered in Table 2.

The connection between the j-function and the activity coefficient is (7):

TABLE 2. Least-squares estimates of constants in eq. [1]

Solute	a (molal)$^{-1}$	b (molal)$^{-2}$	c (molal)$^{-3}$
Chlorobenzene	0.125	−0.108	0.115
o-Dichlorobenzene	0.624	−2.651	3.560
m-Dichlorobenzene	0.258	−0.595	0.507
Nitromethane	0.319	−0.325	0.211

$$[2] \quad -\ln \gamma_{T_F} = j + \int_0^{[m]} j\,\mathrm{d} \ln [m] - \xi_1 \lambda I_1 - \xi_2 \lambda I_2$$

where γ_{T_F} = stoichiometric molal activity coefficient of the solute at the freezing point of the solution.

$$I_1 = \int_0^{\theta} (1 - j)\,\mathrm{d}\theta$$

$$I_2 = \int_0^{\theta} \theta(1 - j)\,\mathrm{d}\theta$$

$$\xi_1 = \left(\frac{2000}{WRT_0^2}\right)\left(\frac{\bar{L}_0}{T_0} - \frac{\bar{J}}{2}\right)$$

$$\xi_2 = \left(\frac{3000}{WRT_0^3}\right)\left(\frac{\bar{L}_0}{T_0} - \frac{2\bar{J}}{3}\right)$$

$\bar{J}$ is the difference between the molal heat capacities of liquid and solid benzene. It will be assumed to be invariant with temperature. This assumption is based on the dilute concentrations used and consequently on the small temperature range spanned by the experiments. From $J = 0.76$ cal/mol deg (8), and the previously given values of $\bar{L}_0$ and T_0 we find: $\xi_1 = 13.4 \times 10^{-4}$ molal/K^2; $\xi_2 = 7.103 \times 10^{-6}$ molal/K^3. Substituting eq. [1] into eq. [2] and doing the integrations provides a closed form expression for $\ln \gamma_{T_F}$ that is lengthy but straightforward enough to use (7). This expression, together with the entries in Table 2, provides the smoothed values of γ_{T_F} given at rounded molalities in Table 3.

Since the freezing temperatures of the solutions are composition-dependent the values of γ_{T_F} at different molalities refer to different temperatures. We now correct these γ_{T_F}'s to a fixed temperature by means of the thermodynamic relation (6):

$$[3] \quad \log_{10} \gamma_{T_S} = \log_{10} \gamma_{T_F} - \bar{L}_2 Y + \bar{J}_2 Z$$

where

$$Y = \frac{T_S - T_F}{2.303RT_ST_F}$$

and

$$Z = T_S Y - \frac{1}{R} \log_{10} \frac{T_S}{T_F}$$

TABLE 3. Activity coefficients at rounded molalities

[a] m is the solute molality.
[b] γ_{T_F} is the molal activity coefficient of the solute at the freezing point of the solution; it was obtained by eq. [2].
[c] γ_{10} is the molal activity coefficient of the solute at 10°C; it was obtained by eqs. [3] and [5].
[d] These values are given in parentheses because they were obtained by assuming the same correction as was used for the C_6H_6–o-$C_6H_4Cl_2$ system.

In eq. [3] T_F is the freezing point of the solution, T_S is some fixed temperature, and $\bar{L}_2$ and $\bar{J}_2$ are the relative partial molal enthalpy and heat capacity, respectively, of the solute. In this work we can only do this correction approximately, because values of $\bar{J}_2$ are unavailable, and because $\bar{L}_2$ is known (in effect) by extrapolation from concentrated solution data. Fortunately however, if T_S is selected so as to be fairly close to T_F (in this case T_S will be 283.15 K so that $T_S - T_F$ will be between ~4 to 9 K) then the correction is very small, so that our approximation of it should be adequate.

We approximate $\bar{J}_2$ by zero. The only support we have for this approximation comes from heat of mixing work on the benzene–chlorobenzene system (10) in which it was found that no temperature-dependence could be detected for the heat of mixing curve over the range 30–60°C. Since $\bar{J}_2$ comes from the temperature derivative of $\bar{L}_2$, and $\bar{L}_2$'s can be obtained from the heat of mixing curve (below) this indicates that $\bar{J}_2$ is, within experimental error, zero for this system.

We found that for the systems for which heat of mixing data were available: C_6H_6–C_6H_5Cl, C_6H_6–o-$C_6H_4Cl_2$, C_6H_6–CH_3NO_2, the heat of mixing data, in the dilute solute region, could be approximated by the quadratic formula:

$$[4] \quad \Delta H^m = KX_1X_2$$

In eq. [4] ΔH^m is the enthalpy of mixing per mol of mixture, K is a constant, and X_1, X_2 are the mole fractions of solvent and solute respectively. By applying the usual thermodynamic relations (11) to eq. [4] it is easily shown that:

$$[5] \quad \bar{L}_2 = K(X_1^2 - 1)$$

The values of K (in cal/mol) that were selected for use were: −6.7, +210, +720 for the systems C_6H_6–C_6H_5Cl (10, 12), C_6H_6–o-$C_6H_4Cl_2$ (13), C_6H_6–CH_3NO_2 (14), respectively. These values of K, together with eqs. [3] and [5], were used to obtain the values for γ_{10} given in Table 3. The correction for the C_6H_6–m-$C_6H_4Cl_2$ system was obtained by using the same K value as was used for the C_6H_6–o-$C_6H_4Cl_2$ system (+210 cal/mol).

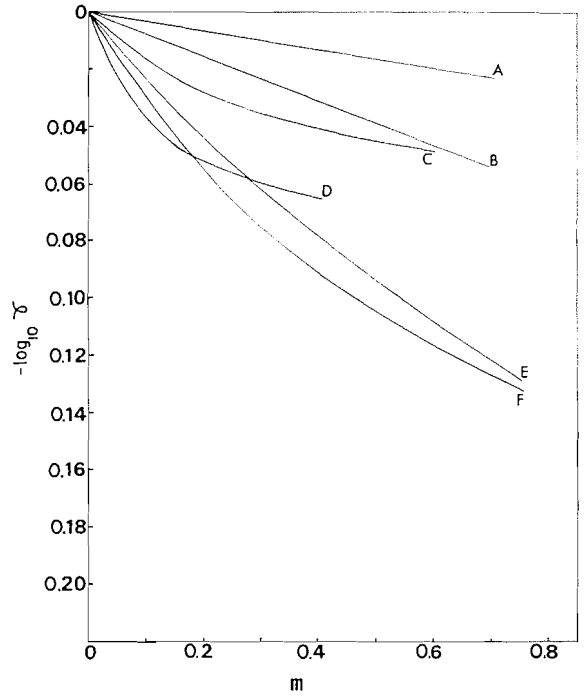

FIG. 2. Concentration-dependence of $\log_{10}\gamma$. The γ's are all corrected to 10°C. *A*, ideal solute behaviour;[2] *B*, chlorobenzene (this work); *C*, *m*-dichlorobenzene (this work); *D*, *o*-dichlorobenzene (this work); *E*, nitromethane (this work); *F*, nitrobenzene (7).

It is seen from Table 3 that the correction of the γ's from the freezing points of the solution temperatures to 10°C is an extremely small one, and in fact does not even effect the third decimal place for most of the entries in this table. Indeed, this correction is much smaller than the uncertainty in the γ's caused by the uncertainty in the value of λ (15).[1] Therefore for these systems, if one's purpose is merely to correct the γ's to a constant temperature that is close to the freezing point of the solvent, more elaborate efforts to get $\bar{L}_2$ and $\bar{J}_2$ accurately, are unjustified.

Discussion

The entries in Table 3 are displayed in log form in Fig. 2. For purposes of comparison we also include in this plot the function for an ideal solute,[2] and previous results for the system nitrobenzene in benzene (7), now corrected to 10°C.

Several principal features are apparent. (*1*) All the solutes show negative deviations from ideality in the low concentration region investigated. (*2*) In this concentration range, all the solutes, except chlorobenzene, show some upward curvature as the concentration rises. This behaviour (i.e. upward curvature with rising concentration) is reminiscent of electrolyte solution behaviour where it is caused by the increasing importance of repulsive forces between solute molecules. (*3*) The *o*- and *m*-dichlorobenzene systems seem to be part of a family of curves. The fact that the *ortho* curve is under the *meta* curve is consistent with their relative dipole moments (2.52 and 1.72 D for *o*-$C_6H_4Cl_2$ and *m*-$C_6H_4Cl_2$, respectively (16)).

The result that the activity coefficients of *o*-$C_6H_4Cl_2$ fall below those of $C_6H_5NO_2$ at low concentrations, despite the fact that $C_6H_5NO_2$ has a higher dipole moment than *o*-$C_6H_4Cl_2$ (4.27 vs. 2.52 D) and both molecules are similar in size and shape seems odd at first sight. We speculate that this *may* be a result of the effect of higher multiple moments (e.g. quadrupole, octupole, etc.) which at present are not known for these species. It is conceivable, for example, that dipole–quadrupole interactions between *o*-$C_6H_4Cl_2$ molecules are sufficiently more stabilizing (in a free energy sense) than the corresponding interactions between $C_6H_5NO_2$ molecules, to produce the results that were found (i.e., curves *D* and *F* under 0.2 molal). Unfortunately, since these higher multipole moments are not known, this must remain speculation.

We plan to extend these measurements to the solvent 1,4-dioxane, which is a slightly polar solvent (~0.50 D), in order to see how these activity coefficients are influenced by the nature of the solvent. This work will be reported as a separate communication.

[1]The uncertainty in the λ value of benzene is about 0.025 deg/molal (7). In the C_6H_6–*o*-$C_6H_4Cl_2$ system for example this uncertainty produces an uncertainty of about 0.020 units in γ when the concentration is 0.50 molal. At this concentration ($\gamma_{283} - \gamma_{T_c}$) = 0.0006 or ~30 times less than the uncertainty due to the uncertainty in λ. Similar results are obtained for the other systems.

[2]A solute that is ideal in the Henry's law sense has a *rational* activity coefficient of unity at all concentrations. From this, and the fact that the chemical potential is invariant with the concentration scale selected, one finds that: $\gamma = 1000/(1000 + Wm)$ where W is the molecular weight of the solvent. This equation (with $W = 78.114$) was used to obtain curve *A* in Fig. 2.

Synthesis of sugar-organometallic conjugates: ferrocenyl monosaccharide derivatives[1]

MICHAEL J. ADAM AND LAURANCE D. HALL

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received November 13, 1979

MICHAEL J. ADAM and LAURANCE D. HALL. Can. J. Chem. **58**, 1188 (1980).

Suitably blocked carbohydrates containing free thio **4**, amino **5**, and hydroxyl **10**, **19** nucleophilic functionalities have been treated with (*a*) ferrocenecarbonyl chlorides **2** and **3**, (*b*) *N*,*N*-dimethylaminomethylferrocene methiodide **12**, and (*c*) ferrocenyl tosylate **16** to form the ferrocenyl sugar derivatives **6**, **7**, **8**, **9**, **11**, **13**, **14**, **15**, and **20**. Direct conjugation of a free, water-soluble sugar to ferrocene was achieved by the formation of a Schiff's base between glucosamine hydrochloride **25** and ferrocene carboxaldehyde **24**. The synthesis of ferrocenyl sugars using bridging group technology is exemplified by the conjugation of the thio sugar **4** to ferrocene via the versatile coupling reagent cyanuric chloride **21** to form the *s*-triazine compound **23**. These products have been studied by ^{1}H nmr spectroscopy: chemical shifts, coupling constants, and proton spin–lattice relaxation measurements.

MICHAEL J. ADAM et LAURANCE D. HALL. Can. J. Chem. **58**, 1188 (1980).

On a traité des carbohydrates convenablement protégés contenant des fonctions nucléophiles libres (thio **4**, amino **5** et hydroxyle **10**, **19**) avec (*a*) les chlorures de ferrocènecarbonyle **2** et **3**, (*b*) avec l'iodométhylate de *N*,*N*-diméthylaminométhylferrocène **12** et (*c*) avec le tosylate de ferrocènyle **16** pour former les dérivés ferrocéniques **6**, **7**, **8**, **9**, **11**, **13**, **14**, **15** et **20** du sucre. On a réalisé la conjugaison directe d'un sucre libre soluble dans l'eau avec le ferrocène, par la formation d'une base de Schiff entre le chlorhydrate de glucosamine **25** et le carboxaldéhyde de ferrocène **24**. La synthèse de ferrocényles de sucres basée sur la technique de groupes servant de pont est démontrée par la conjugaison du thiosucre **4** avec le ferrocène par l'intermédiaire du chlorure cyanurique **21** un agent de couplage polyvalent qui conduit à la formation du composé *s*-triazine **23**. On a étudié ces produits par rmn ^{1}H: les déplacements chimiques, les constantes de couplage et les mesures de relaxation spin–réseau du proton.

[Traduit par le journal]

Introduction

Ferrocene **1** and its derivatives are finding (2) an ever-increasingly wide range of industrial and biochemical applications in areas ranging from the development of new iron-containing drugs (3) to the formation of ferrocene-modified polymers (4). Such derivatives are also of interest for a number of other reasons including the development of optically active catalysts (5), of metal compounds for new immunoassay techniques (6), of heavy metal probes for electron microscopy (7), of the synthesis of radiopharmaceuticals (8), and the modification of electrode surfaces (9). It might therefore be anticipated that these, and other, areas would be advanced in a variety of ways by the development of general routes to the synthesis of ferrocenyl sugar derivatives. And it might also be anticipated that the combined presence of the sugar and metal moieties would give these compounds interesting biological properties. Prompted by this, and by the fact that carbohydrates can be either water soluble, or when suitably substituted, soluble in organic media, we have investigated the synthesis of sugar–ferrocene conjugates in which the sugar moiety is covalently attached to the cyclopentadienyl ligand of the ferrocene complex.

We also document here the use of ^{1}H nmr spectroscopy to evaluate the primary structure of these compounds, and the effect that a proximal chiral sugar group has on the proton resonances of the cyclopentadienyl ring. Attention is also drawn to the use of proton spin–lattice relaxation measurements for the assignment of the proton resonances of substituted cyclopentadienyl rings.

Results and Discussion

Synthesis

A wide variety of ferrocene derivatives are susceptible to nucleophilic attack by the amino, hydroxyl, or thiol functional groups of suitably blocked carbohydrate derivatives. All of the reactions used here to form ferrocenyl sugar conjugates are of this type. The compounds formed were all crystalline (with exception of **20**) and were usually orange or red in color. This greatly facilitated their detection during thin layer chromatography (tlc) and as a result that technique provided a convenient method for following reactions; for the same reason it proved convenient to purify several compounds by silica-gel chromatography (see Experimental).

It was already known that the ferrocenoyl chlorides **2** and **3** (10) react readily with a variety of nucleophilic reagents, including thiols, amines, and alcohols, in dry organic solvents with a suitable base acceptor and it was a simple matter to treat **2** and **3** with a variety of blocked sugars, each containing one of these three functional groups. Reac-

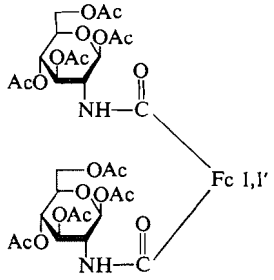
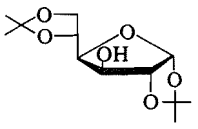
7

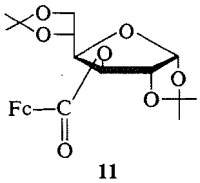


tion with 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranose **4** (11), and 1,3,4,6-tetra-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranose **5** (12) occurred readily at room temperature in dry chloroform with either pyridine or triethylamine, as the base acceptor, to form the mono- and 1,1′-dithioesters **6**, **7** and amides **8**, **9**. In like fashion, reaction of the mono-ferrocenoyl chloride with 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose **10** in dry pyridine overnight afforded the monosubstituted ester **11**.

N,N-Dimethylaminomethylferrocene methiodide **12** (13) also reacts with a variety of nucleophilic reagents by virtue of its benzyl-like structure and having the trimethylamine moiety as a gaseous leaving group. These reactions, however, require more vigorous conditions that those involving the acid chlorides, Thus, reaction with the 1-thio sugar **4** in boiling acetonitrile with anhydrous sodium carbonate was successful but a mixture of α and β anomers (40:60) was isolated (as determined by ^{1}H nmr), probably because of mutarotation of the 1-thio sugar under the basic reaction conditions. Fortunately, several recrystallizations from ethanol afforded the pure β compound **13**. Reaction of the 2-amino sugar **5** with two equivalents of the methiodide reagent **12** under the same conditions yielded the *N,N*-bis amine compound **14**. However this was not a good route to the secondary amine compound **15** since mixtures (as determined by tlc) of both **14** and **15** were always obtained even when a large excess of **5** was employed. All attempts to condense reagent **12** with sugar hydroxyl groups failed.

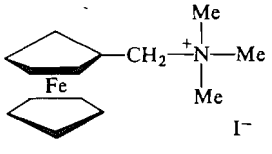


The ferrocenyl tosylate **16** was next evaluated as an alternative alkylating reagent to **12**. This compound does not appear to have been synthesized previously although its intermediacy was postulated in the formation of the ether **17** during reaction of the alcohol **18** with tosyl chloride in diethyl ether solution (14). This tosylate **16** proved to have the same high reactivity as other "benzylic" tosylates and as a result could not be prepared by the

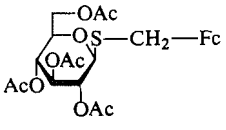


8

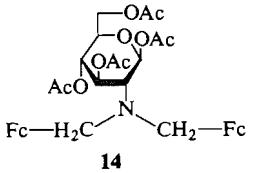
9



10



11



reaction of **18** with tosyl chloride in pyridine at ambient temperature. Instead it was prepared by the method of Kochi and Hammond (15) and used *in situ* (see Experimental) without isolation.

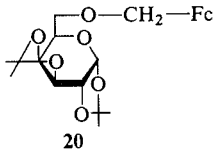
15

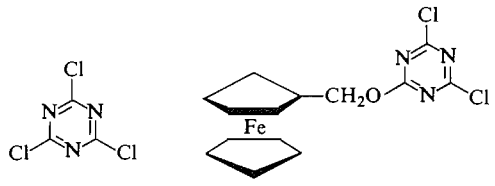


16 18

17

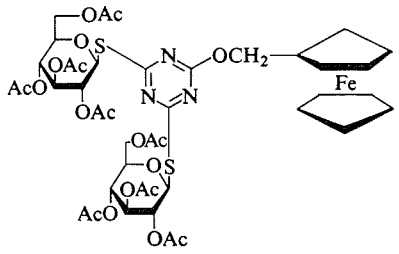
19

20



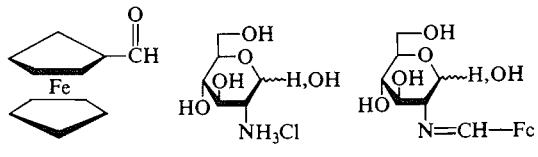
Reaction of **16** with the 1-thio sugar **4** at ambient temperature for 2 days gave **13** which was easily isolated since it crystallized readily from ethanol. The yield of **13** was much higher than that for the reaction between **4** and **12** and no evidence was found for the formation of the α anomer. With 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose **19** reaction of **16** in an ether solution for two days at room temperature was also successful but the yield was much lower than that found for the thio sugar reaction. Since this product **20** was an oil, workup was more difficult and purification was performed on column chromatography. Reaction of the tosylate with the 2-amino sugar **5** was also low-yielding and the solution had to be heated under reflux for 2 days in a chloroform–ether solution. The product **15** was, however, easily isolated since it could be extracted into dilute acid and then extracted back into ether upon neutralization; the starting 2-amino sugar was separated from the product since it was not soluble in ether.

Impressed by the ease with which *s*-triazine derivatives react with carbohydrate derivatives (16) we also evaluated this approach to the synthesis of ferrocenyl–sugar conjugates. Reaction of hydroxymethylferrocene **18** (17) with cyanuric chloride **21** in basic aqueous acetone afforded the ferrocenyl triazine dichloride **22**: although **17** was also formed as a byproduct it could be readily removed by filtration prior to crystallization of **22**. The dichloride **22** was somewhat unstable but could be stored for several weeks in an evacuated desiccator and was suitable for further reactions without purification. Reaction of **22** with two equivalents of the 1-thio glucose sugar **4** occurred readily in acetonitrile with triethylamine to yield the ferrocenyl sugar compound **23**.

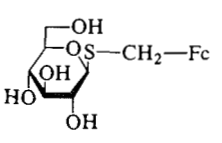


Two approaches were considered for the formation of water-soluble ferrocene–sugar conjugates: selective reaction of an unblocked sugar and deblocking of the above-described, blocked derivatives.

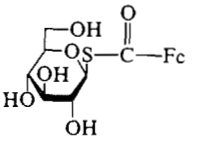
It is well known that amino sugars form Schiff's bases with aromatic aldehydes (18), and reaction of ferrocene carboxaldehyde **24** in ethanol with glucosamine hydrochloride **25** in the presence of triethylamine gave, as expected, the Schiff's base **26** in 70% yield. This reaction should find substantial generality. Unfortunately an initial attempt to stabilize the Schiff's base by reductive amination with sodium cyanoborohydride was unsuccessful; tlc of the reaction mixture indicated the formation of a mixture of compounds.



Attempts to deblock the substituted sugar conjugates were very disappointing since only two reactions gave acceptable yields. Thus de-*O*-acetylation of compounds **6** and **13** was successfully accomplished using sodium methoxide in methanol (19). Compound **13** was cleanly deacetylated and the product **27** crystallized readily from water as the monohydrate. Compound **6**, as expected under these conditions, was partially cleaved at the thio–ester linkage but the main prod-



21 22



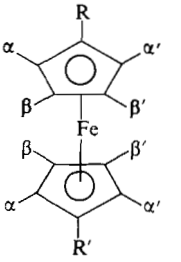
23

24 25 26

27

28

uct was the unblocked ferrocenyl derivative **28**; the product was easily purified by column chromatography and the methyl ferrocenecarboxylate was also isolated, and subsequently identified by ^{1}H nmr. Deacetylation of the 1,1′di-thio ester **7** proved to be very complex (tlc) and was not pursued further. More surprisingly, deacetylation of both the amides **8** and **9** with sodium methoxide in methanol was complex and no pure product could be isolated. Deacetylation of the amines **14** and **15** also proved disappointing; in each case two compounds which had very similar R_f values were detected by tlc and attempts to purify these compounds by preparative tlc or by column chromatography failed. The *s*-triazine derivative **23** was also exposed to these deacetylation conditions but again tlc showed the major product to be colorless (detection by H_2SO_4 charring), which suggests cleavage of either the thio sugar or ferrocene moieties from the triazine ring.



Removal of the isopropylidene blocking groups from **20** was also unsuccessful. The standard procedure of heating in dilute sulfuric acid could not be used since ferrocene compounds are readily oxidized under these conditions. Heating under reflux in aqueous methanol using IR 120 H^+ resin was tried but after 1 h the solution turned colorless and a colorless product having the same R_f value as the diacetone galactose precursor **19** was detected on tlc, suggesting that cleavage of the ether linkage was taking place. The resin had also turned green and it was thought that oxidation was occurring under these conditions as well.

Nuclear Magnetic Resonance Spectra

Proton Data

The ^{1}H chemical shifts and coupling constants for the ferrocenyl sugar derivatives **6**, **7**, **8**, **9**, **11**, **13**, **14**, **15**, **20**, **23**, **26**, **27**, and **28** are summarized in Table 1.

It is interesting to observe that a proximal chiral group renders all four protons of the substituted cyclopentadienyl ring inequivalent, as previously observed by Kursanov *et al.* (20) for cymantrene systems. The chiral group, in our case the sugar, renders the α,α′ and β,β′ protons diastereotopic and potentially four separate resonances can be observed. This turned out to be the case in the spectrum of compound **7**, but more usually only the

α protons are separated and the β protons remain overlapping as in the spectrum of compound **8**, Fig. 1. It should be noted that ^{13}C chemical shifts are more sensitive to this effect (21).

Assignment of the individual proton resonances of the substituted cyclopentadienyl rings of these chiral derivatives presents a problem. As we have reported elsewhere (22), a combination of ^{1}H—^{1}H spin-decoupling and ^{1}H spin–lattice relaxation measurements can give unequivocal results, and the assignments given in Table 1 are based on comparison with those given[2] previously (22).

From the ^{1}H chemical shifts and coupling constants of all the compounds synthesized, it seems probable that the sugar units have the same conformations as the sugar precursor. However compound **23** has a very interesting ^{1}H nmr spectrum indeed, Fig. 1(C), which merits separate discussion. The proton resonances of the two sugar rings in this compound are non equivalent in the ^{1}H nmr spectrum which implies that the molecule must favour a preferred set of conformations. Although there exist no formal symmetry elements in this molecule, it was argued initially that a pseudo-C_2 rotation axis, as shown, could be generated if there were free rotation (fast on the nmr time scale) about the bonds joining the substituents to the central triazine ring. However, the observed nonequivalences imply that steric hindrance prevents complete rotation about some of these bonds. In the insert Figure 1(E), of the acetate region, all eight acetate groups are resolved. Since the separation between two acetate resonances, common to both sugar rings, could not be more than 15 Hz, it would therefore be necessary for the bonds to rotate more slowly than $2\pi \times 15$ revolutions per second in order for separate resonances to be observed. This, however, would correspond to an unrealistically high barrier to rotation; it follows that our original argument is untenable. The following explanation appears to be preferable. It seems likely that the molecule favours a conformation in which the ferrocene moiety is oriented on

[2]Briefly it was shown that the β,β′-protons, each of which has two vicinal neighbours, relax at approximately twice the rate of the α,α′-protons which have only one neighbour.

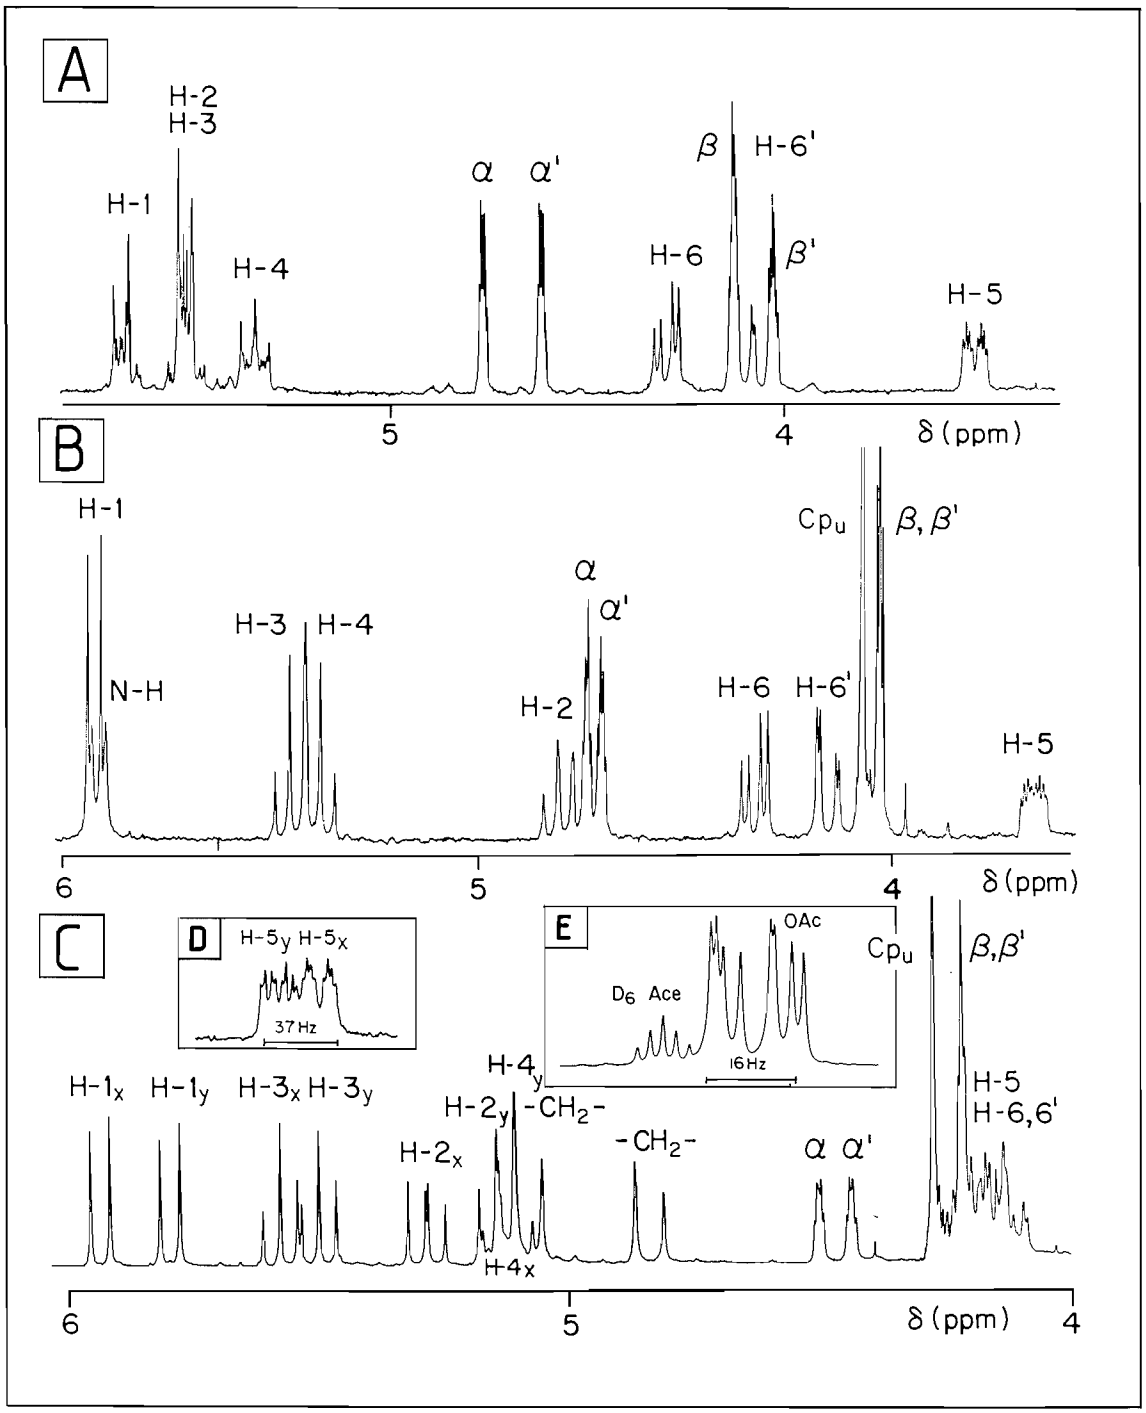

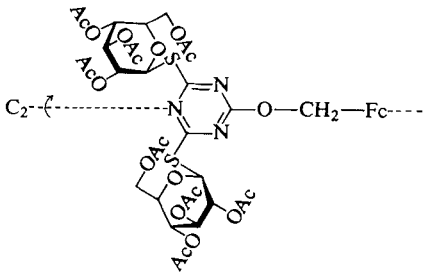

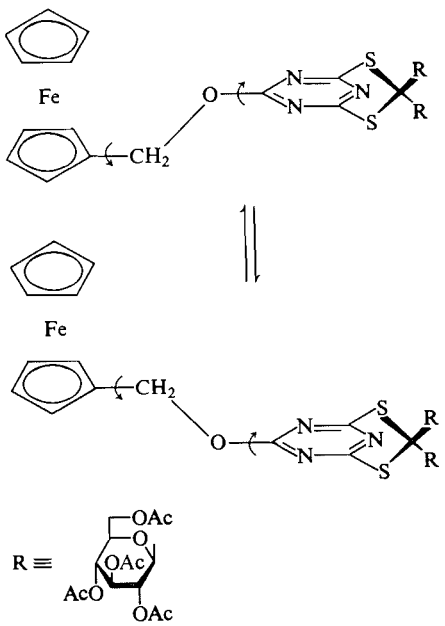

FIG. 1. Partial ^1H nmr spectra (270 MHz) of the sugar and cyclopentadienyl ring proton resonances of (A) compound **7** in deuteriobenzene (NA = 100), (B) compound **8** in deuteriobenzene (NA = 500), (C) compound **23** in deuterioacetone (NA = 50). The insert (D) shows the two H-5 resonances of compound **23** in deuteriobenzene (NA = 20) centered at 3.30 ppm and insert (E) shows the eight acetate resonances of compound **23** in deuterioacetone centered at 2.00 ppm. All spectra were accumulated at 32K data points with a sweep width of 3000 Hz and an acquisition time of 5.439 s at a temperature of 20°C. Cp_u refers to the singlet arising from the five protons of the unsubstituted cyclopentadienyl ring.

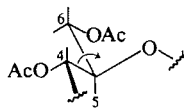

one side of the triazine ring as shown in the diagram. This would allow a rapid "cranking" motion about the bonds joining the ferrocene group to the triazine moiety which would be reasonable since this motion sweeps out only a small volume. It is then assumed that the bond rotations which would allow the ferrocene unit to tip over to the underside of the ring must be very slow. This seems also to be reasonable since a large inertial moment must be overcome in order for the bulky ferrocene group to make a 360° sweep through solvent molecules. It can then be seen from molecular models that the preferred conformation for the sugar units places one sugar unit above and one below the plane of the triazine ring as shown in the diagram. These two effects combined would then bring one sugar group much closer to the aromatic ring current of the ferrocene system than the other sugar group and result in a chemical shift difference between resonances of the two sugar moieties. This argument is supported by the spectrum in Fig. 1(C), since the sugar ring resonances $H_1 \rightarrow H_4$ for one

sugar group are all shifted in one direction with respect to the equivalent resonances of the other sugar group. That is, H_{1x} is to low field of H_{1y}, H_{2x} is to low field of H_{2y}, etc.

An interesting feature of the deuteriobenzene spectrum of **23** is that the H_5 resonances of the two sugar rings, shown in the insert Fig. 1(D), exhibit quite different coupling patterns. The H_{5y} resonance has a much larger $J_{5y,6y} = 5.2$ Hz than does the more usual value for H_{5x} of $J_{5x,6x} = 4.2$ Hz. This suggests that the bond joining C_{5y} and C_{6y}, as shown, is favouring preferred conformations, which reinforces the previous suggestion that this molecule is sterically crowded.

Experimental

All solutions were concentrated using a Buchi rotary evaporator. All melting points were determined using a Thomas Hoover Unimelt instrument (Model 6406-K) and are corrected. All optical rotations were determined using a Perkin-Elmer Polarimeter (model 241-MC).

Thin layer chromatography (tlc) was performed on silica gel plates (Baker-flex Silica gel 1B2-F) using the following solvents: (*A*) 1:1, toluene – ethyl acetate, (*B*) 4:1 toluene – ethyl acetate, (*C*) 1:5 methanol–chloroform. All blocked sugar ferrocenyl derivatives were checked for purity by tlc in solvents *A* or *B* and the unblocked compound in solvent *C*. Column chromatography was performed using 100–200 ASTM mesh silica (Fisher) packed in columns approximately 2.5 × 50 cm, and eluted with solvents *A*, *B*, or *C*. For reactions requiring anhydrous (dry) solvents the solvents were dried by standard methods, distilled, and stored under a nitrogen atmosphere.

Ferrocene was obtained from Sigma Chemical Company, Saint Louis, MO. All the ferrocene-derived starting materials were synthesized from known methods (see text) except for 1,1′-ferrocene dicarboxylic acid which was purchased from Strem Chemicals, Inc., Newburyport, MA. Sodium hydride was purchased from Alfa Products, Danvers, MA, as 50% dispersion in oil. *p*-Toluenesulfonyl chloride was purchased from Eastman Organic Chemicals, Rochester, NY, and purified by the method of Pelletier (23). Cyanuric chloride (97%) was purchased from Aldrich Chemical Co., Milwaukee, WI. All microanalyses were performed by Mr. P. Borda, of this Department. The mass spectra were obtained using an Atlas CH-4B mass spectrometer and high resolution determinations were obtained using an AEI MS-9 or an MS-50 mass spectrometer.

Proton nmr spectra were measured at 270 MHz with the prototype of a homebuilt spectrometer based on a Bruker WP-60 console, a Nicolet 1180 computer (32K), a Nicolet 293A pulse controller unit, a Diablo Disk, and an Oxford Instruments Superconducting solenoid. Concentrations of normal samples ranged from 0.01 to 0.10 *M* and T_1 measurements were performed in concentrations of < 0.05 *M*, with degassing achieved by 5 freeze–pump–thaw cycles. All deuterated solvents were obtained from Merck Sharp and Dohme, Montreal, Canada, and tetramethylsilane was used as a standard.

Reactions of 1-Ferrocenecarbonyl Chloride 2 and of 1,1'-Ferrocene Dicarbonyl Chloride 3 with Sugars 4, 5, and 10

Either 1 or 2 equivalents of the thio **4** or amino **5** sugars were added to a stirred solution of **2** or **3** (0.25 g) in dry chloroform (15 mL). Then 1 or 2 equivalents of either pyridine or triethylamine were added and the reaction allowed to stir for 15 min at room temperature. The mixture was then extracted twice with each of water, 5% sodium carbonate, and water again. The chloroform layer was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The 1,2,5,6-di-*O*-isopropylidene-α-D-glucofuranose sugar **10** was treated with **2** in dry pyridine overnight and after concentration, chromatographed on a silica gel column using solvent *B*.

2,3,4,6-Tetra-O-*acetyl-1-deoxy-1*-S-*(1-ferrocenecarboxylate)*-β-D-*glucopyranose* **6** was obtained in 60% yield from ethanol, mp 186–187°C, $[\alpha]_D^{22}$ +35.0°(*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{25}H_{28}FeO_{10}S$: C 52.11, H 4.86, S 5.56; found: C 52.02, H 4.92, S 5.80.

*1,1'-Bis-(*S-*(2,3,4,6-tetra*-O-*acetyl-1-deoxy-1-thio*-β-D-*glucopyranose)) ferrocenecarboxylate* **7** was obtained in 56% yield from ethanol, mp 213–214°C, $[\alpha]_D^{22}$ −36.0° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{40}H_{46}FeO_{10}S$: C 49.71, H 4.76, S 6.64; found: C 49.56, H 4.76, S 6.55.

*(2-*N-*(1,3,4,6-tetra*-O-*acetyl-2-amino-2-deoxy*-β-D-*glucopyranose))-1-ferrocenecarboxamide* **8** was obtained in 50% yield from ethanol, mp 182–183°C, $[\alpha]_D^{22}$ −2.5° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{25}H_{29}FeNO_{10}$: C 53.70, H 5.19, N 2.50; found: C 54.00, H 5.23, N 2.51.

*Bis-(2-*N-*(1,3,4,6-tetra*-O-*acetyl-2-amino-2-deoxy*-β-D-*glucopyranose))- 1,1- ferrocenecarboxamide* **9** was obtained in 60% yield from ethanol, mp 110–111°C, $[\alpha]_D^{22}$ +20.0° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{40}H_{48}FeN_2O_{20}$: C 51.53, H 5.15, N 3.00; found: C 51.29, H 5.25, N 2.98.

*(3-*O-*(1,2:5,6-di*-O-*isopropylidene*-α-D-*glucofuranose))-1-ferrocene carboxylate* **11** was prepared in 50% yield from column chromatography using solvent *B* and crystallization from ethanol–H_2O, mp 110–111°C, $[\alpha]_D^{22}$ −55.5° (*c* 0.64, $CHCl_3$). *Anal.* calcd. for $C_{22}H_{28}FeO_6$: C 59.50, H 6.31; found: C 59.27, H 6.07.

Preparation of 1,3,4,6-Tetra-O-*acetyl-2*-N,N-*bis-(1-aminomethylferrocene)-2-deoxy*-β-D-*glucopyranose* **14**

A mixture of *N,N*-dimethylaminomethylferrocene methiodide (2.5 g, 6.5×10^{-3} mol), the 2-amino sugar **5** (0.9 g, 2.6×10^{-3} mol), and sodium carbonate (0.8 g, 7.5×10^{-3} mol) in acetonitrile (40 mL) was heated to reflux for 12 h. The mixture was then evaporated to dryness, dissolved in chloroform, and extracted five times with water. The chloroform layer was dried over anhydrous sodium sulfate, filtered, evaporated to dryness and after trituration with hexane, filtered to give 1.28 g (66%). The compound was recrystallized by dissolution in a minimum of benzene, followed by addition of a small amount of hexane and subsequent addition of petroleum ether (bp 30–60°C) until a slightly cloudy solution was obtained, and then cooling; mp 97–98°C, $[\alpha]_D^{22}$ +77.0° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{36}H_{41}Fe_2NO_9$: C 58.19, H 5.52, N 1.88; found: C 57.88, H 5.56, N 1.93.

Preparation of 2,3,4,6-Tetra-O-*acetyl-1*-S-*(1-thiomethylferrocene)*-β-D-*glucopyranose 13 from 12*

A mixture of 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranose (2 g, 5.5×10^{-3} mol) the methiodide **12** (2 g, 5.2×10^{-3} mol), and anhydrous sodium carbonate (0.6 g, 5.6×10^{-3} mol) in acetonitrile (50 mL) was refluxed for 12 h. The mixture was evaporated to dryness, dissolved in chloroform, and extracted five times with water. The chloroform layer was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. The product was then column chromatographed on silica gel using solvent *A* and crystallized from ethanol to give 0.5 g (17%) of **13**, mp 129–130°C, $[\alpha]_D^{22}$ +32.0° (*c* 0.85, $CHCl_3$). This product however was found by ^1H nmr to be a mixture of α- and β-anomers (40:60). Five repeated recrystallizations from ethanol gave the pure β anomer, mp 139–140°C, $[\alpha]_D^{22}$ −39.0° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{25}H_{30}FeO_{10}S$: C 53.41, H 5.34, S 5.70; found: C 53.21, H 5.34, S 5.93.

Preparation of (1-Hydroxymethylferrocene)-p-*toluenesulphonyl Chloride* **16**

Sodium hydride (0.12 g, 2.5×10^{-3} mol) was placed in a 50 mL, two-necked flask and washed twice with anhydrous ether. Then dry ether was added (15 mL) along with dry 1-hydroxymethylferrocene (0.5 g, 2.3×10^{-3} mol). The mixture was then heated under reflux overnight under nitrogen. The stirred suspension of the alcoholate was cooled to −23°C and to this was added dropwise, over a period of 0.5 h, a solution of *p*-toluenesulphonyl chloride (0.44 g, 2.3×10^{-3} mol) in anhydrous ether (15 mL). The mixture was stirred at −10°C for two more hours and allowed to warm to room temperature for another hour. The mixture was then filtered under nitrogen through sintered glass and the resulting solution of the tosylate **16** used directly in subsequent reactions.

Preparation of 2,3,4,6-Tetra-O-*acetyl-1*-S-*(1-thiomethylferrocene)*-β-D-*glucopyranose 13 using the Tosylate 16*

1-Hydroxymethylferrocene (0.5 g, 2.3×10^{-3} mol) was converted into the tosylate **16**, to an ether solution of which was added a solution of the 1-thio sugar **4** (0.5 g, 1.4×10^{-3} mol) in dry chloroform (10 mL). The mixture was kept for 40 h at ambient temperature and was then filtered and evaporated to dryness. Upon addition of ethanol the product crystallized to give 0.67 g (87%) of **13**. One recrystallization from ethanol gave orange plates in 79% yield, mp 139–140°C. For further analytical data see the preparation via the methiodide **12**.

Preparation of 1,3,4,6-Tetra-O-*acetyl-2*-N-*(1-aminomethylferrocene)*-β-D-*glucopyranose* **15**

1-Hydroxymethylferrocene (0.5 g, 2.3×10^{-3} mol) was converted into the tosylate; to an ether solution of the tosylate was added a solution of the 2-amino sugar **5** in dry chloroform (20 mL). The mixture was heated under reflux for two days and was then filtered, evaporated to dryness, dissolved in ether, and extracted into 5% aqueous HCl. The aqueous layer was then neutralized with sodium bicarbonate and extracted with ether. The ether layer was dried over anhydrous sodium sulfate, evaporated to a small volume, and cooled. The compound **15** crystallized as fine needles in 30% yield, mp 126–127°C, $[\alpha]_D^{22}$ +8.0° (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{25}H_{31}FeNO_9$: C 55.08, H 5.69, N 2.57; found: C 54.79, H 5.54, N 2.69.

Preparation of 1,2:3,4-Di-O-*isopropylidene-3*-O-*(1-hydroxymethylferrocene)*-α-D-*galactopyranose* **20**

1-Hydroxymethylferrocene (0.5 g, 2.3×10^{-3} mol) was converted into the tosylate and to the ether solution was added the 6-hydroxy sugar **19** (0.45 g, 1.7×10^{-3} mol) in anhydrous ether (5 mL). The mixture was kept for two days and was then filtered, evaporated to dryness, and purified on silica gel column chromatography using solvent *A*, to give the compound as an oil in 20% yield, $[\alpha]_D^{22}$ −58.7° (*c* 0.8, $CHCl_3$). *Anal.* calcd. for $C_{23}H_{30}FeO_6$: C 60.30, H 6.55; found: C 60.16, H 6.59.

Preparation of 2-Deoxy-2-N-*(1-ferrocenecarboxaldehydeimine)*-α,β-D-*glucopyranose* **26**

A mixture of 1-ferrocenecarboxaldehyde (0.5 g, 2.3×10^{-3} mol), 2-amino-2-deoxy-α,β-D-glucopyranose hydrochloride (0.5 g, 2.3×10^{-3} mol), and triethylamine (0.24 g, 0.24×10^{-3} mol) in absolute ethanol (15 mL) was stirred vigorously for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

15 h. The mixture was then evaporated to a small volume and an equal amount of acetone added. The mixture was cooled and filtered to give 0.68 g (71%) product which was recrystallized by dissolving in a minimum of ethanol, evaporating to about half its volume, adding hexane, and refrigeration; mp 161–162°C, $[\alpha]_D^{22}$ +66.7° (*c* 0.33, MeOH). *Anal.* calcd. for $C_{17}H_{21}FeNO_5$: C 54.39, H 5.64, N 3.73; found: C 54.09, H 5.90, N 3.90.

Preparation of 2,4-Dichloro-6-(1-hydroxymethylferrocene)-s-triazine **22**

To an ice cold stirred solution of cyanuric chloride (0.86 g, 4.6×10^{-3} mol) in acetone (20 mL), over a period of 45 min was added, simultaneously, a mixture of hydroxymethylferrocene (1 g, 4.6×10^{-3} mol) in acetone (40 mL) and a solution of sodium hydroxide (5 mL of 4%) in water (55 mL). The solution was then filtered to yield a compound which was identified as the ferrocene ether dimer. The filtrate was allowed to become acidic upon standing at 0°C and the resulting orange precipitate filtered after 2 h to give the compound in 50% yield. This product is sufficiently pure for further reactions and should be stored in an evacuated desiccator. Purification was achieved by column chromatography on silica gel using solvent *A* and crystallized from ether–hexane, mp 120°C (dec.). *Anal.* calcd. for $C_{14}H_{11}N_3OCl_2Fe$: C 46.21, H 3.02, N 11.54; found: C 46.68, H 3.18, N 11.24; ms (high resolution) calcd. for $C_{14}H_{11}N_3OCl_2Fe$: 362.9615 amu; found: 362.9265 amu. Bis-(1-hydroxymethylferrocene)-ether was obtained in 15% yield, mp 113–114°C. *Anal.* calcd. for $C_{22}H_{22}Fe_2O$: C 63.83, H 5.32; found: C 63.84, H 5.45; ms (low resolution) calcd. for $C_{22}H_{22}Fe_2O$: 414 amu; found: 414 amu.

Preparation of 2-(1-Hydroxymethylferrocene)-4,6-bis-S-(2,3,4,6-tetra-O-acetyl-1-deoxy-1-thio-β-D-glucopyranose)-s-triazine **23**

Triethylamine (0.2 g, 2.0×10^{-3} mol) in acetonitrile (2 mL) was added to a stirred solution of compound **22** (0.3 g, 8.3×10^{-3} mol) and 1-thio glucose **4** (0.6 g, 1.65×10^{-3} mol) in acetonitrile (25 mL). After 10 min the mixture was poured into ice water (100 mL) and extracted with chloroform. The chloroform layer was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness. One recrystallization from isopropanol gave 0.6 g (74%), mp 120–121°C, $[\alpha]_D^{22}$ +25.4 (*c* 1, $CHCl_3$). *Anal.* calcd. for $C_{42}H_{49}FeN_3O_{19}S_2$: C 49.48, H 4.81, N 4.12; found: C 49.51, H 4.72, N 4.12; ms (high resolution) calcd. for $C_{42}H_{49}FeN_3O_{19}S_2$: 1019.1749 amu; found: 1019.1769 amu.

Preparation of 1-Deoxy-1-S-(1-thiomethylferrocene)-β-D-glucopyranose **27**

To a stirred solution of compound **13** (0.1 g) in methanol–chloroform (4 mL, 1:1) was added dry 0.2 *N* sodium methoxide (0.3 mL). After 30 min under nitrogen, the solution was neutralized with IR 120 H^+ ion exchange resin, filtered, evaporated to dryness, and crystallized from H_2O to give 52 mg (75%). Recrystallization from H_2O gave orange plates of the monohydrate, mp 145–146°C, $[\alpha]_D^{22}$ −43.2° (*c* 0.44, MeOH). *Anal.* calcd. for $C_{17}H_{22}FeO_5S$: C 49.55, H 5.82, S 7.78; found: C 49.84, H 5.65, S 7.70.

Preparation of 1-Deoxy-1-S-(1-ferrocenecarboxylate)-β-D-glucopyranose **28**

To a stirred solution of the thio ester **6** (0.1 g) in methanol–chloroform (4 ml, 1:1) was added 0.2 *N* sodium methoxide (0.7 mL) and the solution was stirred for 45 min under nitrogen. The solution was then neutralized with IR 120 H^+ resin and the mixture filtered, evaporated to dryness, and the compound chromatographed on a silica gel column using solvent *C* to give 35 mg (50%) from ethanol, mp 145–146°C, $[\alpha]_D^{22}$ −3.3° (*c* 0.3, $CHCl_3$). *Anal.* calcd. for $C_{17}H_{20}FeO_6S$: C 50.03, H 4.90; found: C 49.75, H 5.08.

Acknowledgments

It is a pleasure to thank the National Research Council of Canada for their support of this work via operating grants to L.D.H. (A-1905) and a Postgraduate Scholarship to M.A. (1977–1979). The authors would also like to thank Dr. Brian Kolthammer of this Department for helpful discussions relating to organometallic chemistry and to Dr. Jeremy Sanders, visiting here from Cambridge University, for assistance in the interpretation of the nmr spectrum of compound **23**.

Acylation of aromatic substrates with ketenes. An example of vinyl oxocation reactivity

K. R. FOUNTAIN,[1] PAMELA HEINZE,[2] MARK SHERWOOD,[3] DAVE MADDEX,[4] AND GREG GERHARDT[5]

Northeast Missouri State University, Kirksville, MO 63501, U.S.A.

Received December 14, 1979

K. R. FOUNTAIN, PAMELA HEINZE, MARK SHERWOOD, DAVE MADDEX, and GREG GERHARDT. Can. J. Chem. **58**, 1198 (1980).

Acylations of aromatic substrates with ketenes involve the reactivity of species similar to vinyl cations. Resonance stabilization of ketene – aluminum chloride complexes seems to make these complexes less reactive than corresponding vinyl cations.

The kinetic isotope effect of the reaction with dimethylketene and benzene is 1.06, compatible with vinylcation cases, but not with acylation with CH_3COBF_4 types of electrophiles.

Substrate specificity was determined from k (toluene)/k (benzene) values. It was 47.2 for dimethylketene and 173.7 for diphenylketene. The diphenylketene – aluminum chloride complex could be isolated.

K. R. FOUNTAIN, PAMELA HEINZE, MARK SHERWOOD, DAVE MADDEX et GREG GERHARDT. Can. J. Chem. **58**, 1198 (1980).

L'acylation de substrats aromatiques au moyen de cétènes fait intervenir la réactivité d'espèces semblables aux cations vinyliques. La stabilisation par résonance des complexes cétène – chlorure d'aluminium semble rendre ces complexes moins réactifs que les cations vinyliques correspondants.

L'effet isotopique cinétique de la réaction entre le diméthylcétène et le benzène est de 1.06. Il est compatible avec l'existence de cations vinyliques, mais il n'est pas compatible avec une acylation au moyen d'agents électrophiles du type CH_3COBF_4.

La spécifité du substrat est déterminée à partir des valeurs de k toluène/k benzène. Elle est de 47.2 pour le diméthylcétène et de 173.7 pour le diphénylcétène. On a pu isoler le complexe cétène – chlorure d'aluminium.

[Traduit par le journal]

Although acylations of aromatic rings with ketene have been known (1–4) for over forty years, no serious mechanistic study of this reaction has been undertaken. We report in this paper the results of experiments showing positional selectivity, the substrate selectivity, the intermolecularity of the transfer of the proton from the site of attack to the α position of the ketone, and the kinetic isotope effect. Experiments with both dimethyl and diphenyl ketenes were explored.

We used dimethylketene (DMK) prepared by Staudinger's method, pyrolysis of dimethylmalonic anhydride (5); it was redistilled before use. Diphenylketene (DPK) was prepared by the triphenylphosphine catalysed dehalogenation of 2-bromo-2,2-diphenylacetylbromide (6), and distilled before use. The yields from dimethylketene acylation with a variety of substrates are summarized in Table 1. (The low yields with benzene, in neat hydrocarbon, are in contrast to the modest yields of up to 45.0% reported by earlier workers for ketene (4).) The reaction mixtures for the reaction with benzene, by gas chromatography, revealed seven compounds besides the authentic ketone. These compounds were due to the reaction of dimethylketene with itself in the presence of aluminum chloride to give dimers, as was shown by comparing the nmr spectrum of the reaction mixture with a sample of dimethylketene which had been allowed to dimerize at room temperature. Other ill-defined materials which were nonaromatic (nmr) were not further examined. The low yields of isobutyrophenone obtained with benzene as a substrate are due to the faster rate of these side reactions compared to the rate of acylation of the aromatic nucleus. These side products were a constant feature of the reactions with less active aromatic substrates. They completely vanished in the cases of more active substrates such as toluene, which were exceptionally clean, giving only one ketone in most cases.

TABLE 1. Yields of ketones from acylation with dimethylketene at 25°C in neat hydrocarbon

Position Selectivity

The dimethylketene – aluminum chloride complex is highly positionally selective even though one might suspect that it should be highly reactive.

The position selectivity of dimethylketene was contrasted to that of isobutyryl chloride by analyzing the isomer distribution of reactions of the

TABLE 2. Comparison of *o/p* ratios for acylations with isobutyryl chloride and dimethylketene

Substrate	*ortho/para* × 10^2	
	Isobutyryl chloride	Dimethylketene
1. Toluene	4.33	0.00
2. Anisole	1.30	0.447
3. Ethylbenzene	0.0734	0.000
4. Cumene	0.000	0.000

acid chloride with aromatic substrates at 25°C. The results are shown in Table 2 in which *ortho/para* (*o/p*) ratios are given. No *meta* isomers were observed. Control experiments showed that no isomerization of products occurred under the reaction conditions, and as little as 0.1% of the isomers could be detected.

The nmr spin patterns of the *ortho* isomers, collected by preparative scale gc, displayed ABCD patterns similar to that of *o*-methylacetophenone (7) and had carbonyl bands at 1680 cm^{-1}. With dimethylketene only *para* isomers in yields of 15–50% were observed except with anisole and *o*-methylanisole. With anisole the *o/p* ratio was 4.47×10^{-3}. With *o*-methylanisole a mixture of the 4-isomer and 5-isomer in the ratio of 29:5 was obtained. It was observed that allowing pure samples of these ketones to stand in contact with aluminum chloride caused no changes to include *ortho* or *meta* isomers. Hence, it is likely that these mixtures represent the products of kinetic control and are not thermodynamically controlled mixtures. Since the selectivity of a reagent in discriminating between *ortho*- and *para*-positions depends not only on polar but also on steric interactions (8), one may thus infer that the reagents involved in acylation with $AlCl_3$ (dimethyl or diphenylketene) have a larger steric requirement than for an ordinary acid chloride acylation.

In no case of acylation with ketene did we find any *meta* isomers. This is unexpected because an acylating agent consisting of an oxovinyl cation should be a reactive species similar to an acylium ion. Such selectivity from reagents thought to be highly reactive has recently been reported by Stang and Anderson from alkylations with the stereoelectronically similar vinyl cations (9). Their product distributions are given in Table 3.

Except for toluene no *meta* isomer was observed. The *ortho*, *para* selectivity was lower for these vinyl cations than for the ketenes of this study. Both vinyl cation selectivity and ketene selectivity are higher than for acylations in general.

Cl	29.7	0.0	70.3

Substrate Selectivity

An indication of the substrate specificity of dimethylketene was obtained by competition experiments with benzene and toluene. In this case it was necessary to use an excess of benzene in the substrate mixture to ensure adequate detection of the isobutyrophenone in the rather complex gas chromatogram which arose due to the side products. The data on these experiments are summarized in Table 4. In each experiment a ratio of moles $AlCl_3$/moles dimethylketene of 2.5:1 was used.

The substrate specificity of 47.2[6] for dimethylketene found in this work contrasts with that found by Olah *et al.* (10) for acylation with $CH_3CO^+SbF_6^-$ or $CH_3CO^+SbCl_6^-$ which had toluene/benzene ratios of 125 and 121, respectively, for acylation in nitromethane at 25°C, and with acetyl chloride in nitromethane (11) which had a toluene/benzene ratio of 134. The dimethylketene – aluminum chloride reagent is thus actually more reactive than the other acylating agents cited in spite of the low yields with benzene and other moderately activated aromatic substrates. This finding supports the idea that the dimethylketene reacts more rapidly with itself in the presence of aluminum chloride than with a nonactivated or only moderately activated aromatic ring.

Our relative rates for toluene–benzene competitions compared with the value of 6.76 for vinyl cation alkylations (9) indicate that the substituted ketene – aluminum chloride complex is a great deal more substrate selective than the stereoelectronically similar vinyl cations. One might rationalize this greater substrate selectivity on the basis of structure **1** in which a mode of delocalization of charge is shown for the substituted ketene –

[a]In this experiment an aliquot showed that only a 64% yield of the diphenylketene was obtained.

aluminum chloride complex which is not available for the analogous vinyl cation. Analogous "resonance" arguments are advanced for the known stability of carbocations from α-haloethers (12).

Diphenylketene Studies

Our study of acylation of various aromatic substrates with diphenylketene supports the picture of a ketene – aluminum chloride complex as a site selective reagent prone to react with other ketene molecules rather than aromatic rings. Table 5 shows the yield data. All of these reactions were found to produce polymeric tar from which the ketones had to be removed.

We examined the nature of the ketene–$AlCl_3$ complex as follows. To a 2.4 g solution of diphenylketene in 300 mL of ligroin was added one equivalent of aluminum chloride plus 10% excess, assuming reaction [1]. The mixture became cloudy and a ring of brown precipitate formed on the bottom. An additional 10% excess of $AlCl_3$ was added and a white solid was noted. A small aliquot of this solid was removed, rapidly filtered, and an ir spectrum taken (Nujol). The absence of ketene was noted by the lack of absorption at 2100 cm^{-1}. Instead, a medium band at 1620^{-1} appeared. The solution above this precipitate contained diphenylketene as shown by the yellow color and ir spectrum. To this mixture was then added 50 mL of anisole and the solution allowed to stand overnight. Decantation of the ligroin from the resultant brown complex was followed by dissolving the complex in CH_2Cl_2 and treatment with ice–HCl. Solvent removal yielded 2.16 g (58.3%) of the anisyl ketone. This compares very well with 59.1% of this ketone obtained by slowly adding an excess of aluminum chloride to anisole and diphenylketene.

These data are consistent with formulation of the $AlCl_3$–diphenylketene adduct **2** as in [1].

[1] $(C_6H_5)_2C{=}C{=}O + AlCl_3 \rightarrow (C_6H_5)_2C{=}C{-}O{-}AlCl_3$
2

The lack of any ketene bands in the precipitate and the appearance of a band at 1620 cm^{-1} would indicate that coordination to the O atom does indeed occur. These results parallel those reported by Hurd, who isolated a similar $AlCl_3$–ketene complex in CS_2 which also gave acylations with benzene and anisole (1).

The substrate specificity of the diphenylketene – aluminum chloride complex differs from that of dimethylketene as seen by comparing the data in Table 4 with those in Table 6. We regard the value from the 10:1 experiment as more valid because of difficulties in comparing greatly different areas with our integrator.

The value of 173.7 for the relative rate of toluene to benzene indicates the greater kinetic stability of the diphenylketene – aluminum chloride complex over that of the dimethylketene – aluminum chloride complex, as we observed in the isolation of the DPK complex. No isolation of the dimethylketene – aluminum chloride complex was possible. When we attempted to assay its relative stability by first adding $AlCl_3$ to a solution of dimethylketene in carbon disulfide, then adding anisole, no acylated anisole was found (96% recovery of starting anisole).

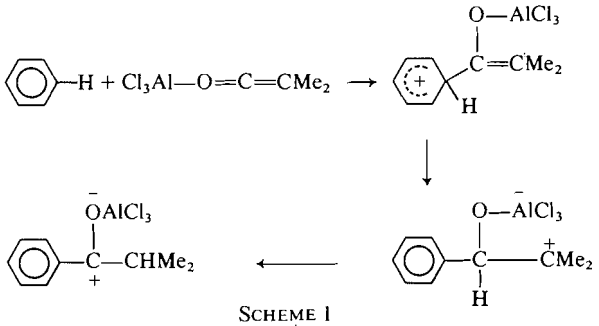
If one takes the relative rates of a toluene–benzene competition experiment as a measure of the kinetic stability of a species, one can order the vinyl type cations in the sequence below. This order allows one to think about structural variations

$$C_6H_5{-}\overset{+}{C}{=}CMe_2 < Cl_3\bar{A}l{-}O{-}\overset{+}{C}{=}CMe_2$$

$$< Cl_3\bar{A}l{-}O{-}\overset{+}{C}{=}C(C_6H_5)_2$$

TABLE 6. Substrate specificity for diphenylketene

Benzene/toluene	Substrate moles/ketene moles	Area ratio (mols/mol)	k(toluene)/k(benzene)
1:1	25	18.9	189
10:1	110	17.37	173.7



within the series in a consistent way. One can say that the phenyl ring attached directly to the charged carbon atom in the vinyl cation is less able to stabilize the charge than is the oxygen atom in the ketene complexes. This is certainly the order one would expect from consideration of the constants, say using σ^+ for OCH_3 as a model for —O—$AlCl_3$, and the σ^+ for C_6H_5(−0.78 vs. −0.18) (10).

The Intermolecularity of Proton Transfer

The unique stereoelectronic requirements of the dimethylketene – aluminum chloride complex, (if one accepts that coordination occurs at the oxygen as in **3**) allow intramolecular transfer of the proton on the benzene ring to the α-position in the final

$$(CH_3)_2C{=}C{=}\overset{+}{O}{-}\bar{A}lCl_3$$

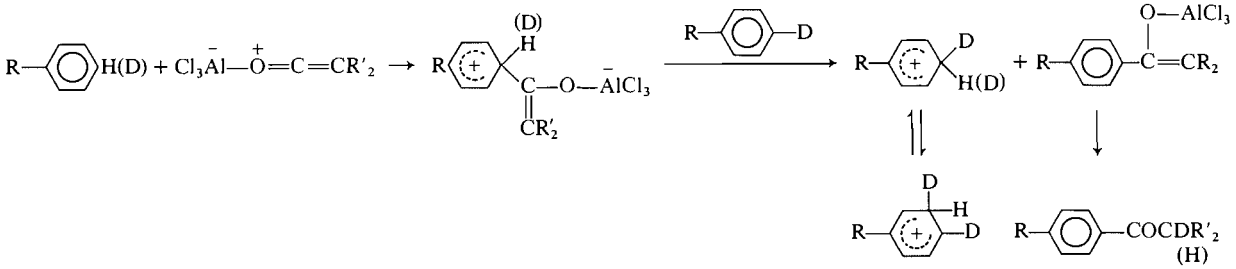
ketone as in Scheme 1 to be formally considered. The driving force could be a combination of formation of a stable carbocation and rearomatization. Such 1,2 shifts are well known in carbonium ion chemistry. Despite early workers' claims (1–4) that evolution of HCl occurred with ketene, the present reactions with dimethylketene or diphenylketene showed no tendency to evolve HCl although a careful check was made to observe it. The question of how the ketone arises via proton transfer is thus an important one if one is to determine a kinetic isotope effect. When toluene-d_8 was acylated with dimethylketene, the label was retained to the extent of 98 ± 2% (by nmr integration) indicating that the α-proton in the final product ketone does not enter the molecule in the work-up step as would be necessary if aluminum chloride formed a complex like **4** as suggested by early workers for the case of ketene (2). Likewise acylating benzene-d_6 with

SCHEME 1

diphenylketene gave 97 ± 1% retention of deuterium.

$$Cl_2Al{-}CH_2{-}COCl$$

Control experiments using ketones labeled in the α-position showed that exchange under work-up conditions could have been 7 ± 5%.



It was desirable to perform a crossover experiment in which one aromatic substrate was deuterated and the other was nondeuterated because the substrate itself in the foregoing experiments was the only source of deuterium (protium), hence allowing the probability that the result was predetermined. Accordingly, a 50:50 molar mixture of anisole and toluene-d_8 was acylated with dimethylketene with the result that each ketone was found to have deuterium at the α-position. The *p*-tolylketone was found to have ca. 70% protium at the α position. When *p*-toluene-*d* alone was acylated, label retention (D) occurred only to about 80% by nmr integration. These results clearly eliminate the formally possible Scheme 1 and point to a transfer of the proton via excess aromatic substrate as in Scheme 2.

When diphenylketene was used to acylate *p*-deuteriotoluene, the resulting ketone had a value of 72% protium at the α-position. This enhances the conclusions found for dimethylketene acylation in that extensive scrambling of the label occurs as in Scheme 2.

This mechanism is interesting because it allows the possibility of the observation of a large kinetic isotope effect. It is well documented that the absence of a base of sufficient strength to remove a proton easily leads to high kinetic isotope effects (13). One expects a high kinetic isotope effect in the present work due to the low basicity of the aromatic substrates (14, 15), i.e., more S_E3 character.

Following the method of Olah *et al.* (10), we determined the k_H/k_D for benzene acylation by comparing ratios of products from competition reactions with toluene–benzene and toluene – benzene-d_6. The reactions were run on mixtures having molar ratios of 5 mols of benzene-d_6 to one mol of toluene and 5 mols of benzene to one mol of toluene to circumvent difficulties in the analysis (see Experimental). The results are given in Table 7. The low value of 1.06 is contrasted with Olah's

SCHEME 2

value of 2.27 for acetylation with $CH_3CO^+SbF_6^-$ and CH_3COBF_4 complexes. This value is consistent with the great selectivity shown by the acylating agents from ketenes and is entirely consistent with the value of 0.98 ± 0.026 found by Stang and Anderson (9) for alkylation with vinyl cations.

A second paper reporting on Hammett–Brown (16) treatments of dimethylketene and diphenylketene acylations is in preparation.

Experimental

General

Infrared spectra were neat or Nujol mulls except where noted, and were run on a Beckman IR4. The nmr measurements were run in the solvents noted with TMS or DSS as internal standards. All chemicals were reagent grade Eastman or Aldrich products.

Preparation of Ketenes

Dimethylketene was prepared by the pyrolysis of dimethylmalonic anhydride as per Staudinger *et al.* (5). The material thus obtained was distilled twice before use and opened only to a dry nitrogen atmosphere.

Diphenylketene was made by debromination of α-bromodiphenylacetylbromide (7) with triphenyl phosphine in ligroin. The dibromotriphenyl phosphorane was filtered through a sintered glass funnel and hydroquinone (0.1 g) was added. The ligroin was removed by distillation under reduced pressure and the residue distilled to give yields of 60–85% of diphenylketene.

Preparation of Authentic Aryl Isopropyl Ketones

All authentic ketones were made by acylation with isobutyryl chloride and $AlCl_3$ in the aromatic substrate in excess as the solvent. The reactions were all at 25°C, and were catalysed by the addition of 2.5 equivalents of aluminum chloride per equivalent of acid chloride (4). The known isobutyrophenones were made into appropriate derivatives which were recrystallized to constant melting points. These compounds are summarized with their references in Table 8. The new isobutyrophenones synthesized in this work were also made into derivatives, and their analytical data appear below.

4-Methoxy-3-bromophenyl Isopropyl Ketone

This material was a solid and was analyzed as obtained (mp 66.5–68.8°C). *Anal.* calcd. for $C_{11}H_{13}BrO_2$: C 51.38, H 5.10; found: C 51.37, H 5.12.

Procedure for Acylation with Dimethylketene

Typically the reaction was run at 25°C in a flask fitted for mechanical stirring with excess hydrocarbon as the substrate. The best results were obtained when, following Williams and Osborne (4), aluminum chloride was added portionwise to a mixture of hydrocarbon and dimethylketene under an N_2 atmosphere. Accordingly, in each case the pure dimethylketene was mixed with a 20-fold excess of hydrocarbon and a 2.5 molar excess of $AlCl_3$ added slowly. The reactions were stirred for an hour after the addition was completed, then the reaction mixtures were poured onto ice and 6 *M* HCl. Extracting with equal volumes of dichloromethane, water washing, 5% sodium bicarbonate washing, water washing, then drying over magnesium sulfate, gave oils in each case after solvent removal. When distilled, these oils gave derivatives which were identical to those from the known ketones from acid chloride preparations.

Spectral data include ir at 1680–1690 cm^{-1}, ν (C=O) for all ketones (neat), and nmr signals at δ ($CDCl_3$): 3.6–3.8 (broad heptet 1H), and 1.13–1.25 (doublet, 6H).

Deuterium Labelling Experiments

A 1.5 g (0.021 mol) sample of doubly distilled dimethylketene was treated with 10 g (0.075 mol) of anhydrous aluminum chloride from a fresh bottle and 10 g (0.1 mol) of toluene-d_8 (99+% isotopically pure). After the reaction had subsided, it was stirred for an additional hour and worked up by pouring onto H_2O–HCl (6 *M*) in ice and extracting with dichloromethane. Washing with water twice and drying over $MgSO_4$ gave the ketone, after solvent removal. The ketone was purified by preparative scale gc (Varian 920 Autoprep) using a 20 ft × ⅜ in. 15% SE 30 on 30/60 Chromosorb W column. The nmr showed only a singlet at 1.2 ppm with a trace of heptet at 3.40 ppm which corresponded to an exchange of 4.5% (ratio of 3.4 to 1.2 was 3/66). The amount of exchange during workup was determined as follows. The parent unlabelled ketone was treated with a 2.5 molar excess of aluminum chloride (4.0 g of ketone + 10.0 g of aluminum chloride) in toluene, and stirred for one hour. It was then poured into 25 mL of D_2O–DCl (from $SOCl_2$ and D_2O). The workup then proceeded as for the other experiments. The nmr integration gave for the parent compound, before exchange, the ratios 88:66.5 for the signals at 1.1–1.25 and 7.0 ppm for a ratio of 1.32 (theory 1.2). After the exchange, the ratio was 84:63.5 = 1.32. Taking the signal at 1.1–1.25 as worth 6H, one obtains a

TABLE 7. k_H/k_D Values for benzene

Experiment	Area ratio = (tolyl ketone / benzene ketone)	k_H/k_D
Benzene–toluene 5:1	10.371	1.06
Benzene-d_6 – toluene 5:1	11.051	

TABLE 8. Derivatives of ketones

Ketone	Derivative	Melting point (°C) Found	Lit.	Reference
Isobutyrophenone	2,4 DNP	162–163	163	Ref. 17
4-Methoxyisobutyrophenone	Semicarbazone	211–212	212–213	Ref. 18; II, **8**, 118
4-Methylisobutyrophenone	Oxime	90–91	90–91	Ref. 18; II, **7**, 254
3,4-Dimethylisobutyrophenone	Oxime	67–68	68	Ref. 18; **7**, 335

ratio of 14.0 units/proton. In the parent compound before the exchange the signal at 3.4 due to α-C—H was 14.5 ± 0.5 units. After the exchange, experimental ratios for three experiments gave an average of 0 ± 3% exchange. The worst case gave 9% exchange with two experiments giving no exchange. (Ratios of 3.4 signal were 14.6, 14.5, and 13.2.)

When 4.11 g (0.021 mol) of diphenylketene was treated with aluminum chloride in 20 mL of benzene-d_6 (99.9% isotopically pure), and the reaction worked up by washing only with water, the nmr showed the ratio of the signal at 5.95 ppm to the aromatic signal to be 1:35 (1:10 theory). One can say that exchange to the extent of ~3% occurred in workup. This was entirely consistent with our results from dimethylketene.

Reactions with p-*Deuteriotoluene*

With Dimethylketene

A 2.0 g (0.0280 mol) sample of dimethylketene was treated with 22 g (0.233 mol) of *p*-deuteriotoluene (see below) and 5.7 g (4.29×10^{-2} mol) of aluminum chloride. The workup was as described above. After separation via preparative scale gc the nmr of the ketone showed 20% protium signal at 3.4 ppm (compared to the signals at 1.2). The signal at 1.25 had three components corresponding to the methyl groups of the deuterated and undeuterated ketones. The yield of ketone was 25%.

With Diphenylketene

A 1.78 g (9.18×10^{-3} mol) sample of diphenylketene was dissolved in 25 mL of *p*-deuteriotoluene with mechanical stirring. A sample of 3.33 g ($2.5 \times 9.18 \times 10^{-3}$ mol) of anhydrous aluminum chloride was added portionwise through the reflux condenser. The workup was as recorded above, omitting the base wash. The nmr spectrum showed 20 integral units for the signal at 2.32 ppm and 5 units for the proton at 6.0 ppm (the α-proton). This corresponds to ~72% protium content at the α position. The yield was ca. 10%.

Preparation of p-*Deuteriotoluene*

A 1 mol sample of *p*-bromotoluene was dropped onto 1.5 g-atoms of magnesium in ether. After the reaction had subsided, the mixture was stirred 24 h, then quenched by addition of 99+% deuterium oxide. Distillation gave 80 g of hydrocarbon. The nmr consisted of an A_2B_2 signal at 7.38 (4H) and a singlet at 2.38 (3H) (in $CDCl_3$ and neat). The ratios of integration were 130:96 (4.06 protons). This corresponds to ~94% deuteration.

Competition Experiments with Dimethylketene

General Procedure

Dimethylketene generated and purified as reported above was added to a 20-fold excess of a 50 mol% mixture of each substrate. Aluminum chloride was added portionwise with stirring of the reaction, and the reactions were stirred one hour after the addition was completed. Workup was as recorded above.

Gas chromatographic analysis was done on a Perkin-Elmer 3920 instrument (TC Bridge) with a 6 ft 10% Carbowax 20 m on 80/100 Chromosorb W column at a temperature of 190°C, He flow rate of 30 mL/min.

Relative response factors (RRF) were determined by mixing known concentrations of ketones (in g/100 mL) and determining the ratios of areas. This procedure gives a relative response factor (RRF) of area per g of ketone I/area per g of ketone II. The RRF for tolyl ketone/phenyl ketone was 1.3250. All competitions were done by comparing the rates of reaction with toluene for experimental convenience (12). The rate constant ratios were determined by the formula

$$\frac{k_a}{k_b} = \frac{[AX]}{[BX]} \Big/ \frac{[A_0]}{[B_0]}$$

In all cases the substrate ratios to ketene were large enough to ensure small errors in the rate ratios. Integration was performed by a Spectra Physics electronic integrator.

Authentic samples of ketones were used in artificial mixtures as a check on the accuracy of the integration technique. It was found that at very high ratios the integrator consistently overestimated the amount of the smaller component. Corrections were applied where appropriate or the reaction run was redone using a larger amount of less active substrate.

The benzene/toluene ratios were determined in this way using ratios of benzene/toluene of 1:1, 3:1, and 5:1. These results are summarized in Table 4.

Reactions of Diphenylketene with Aromatic Substrates

A typical procedure is given using ethyl benzene as a substrate at 25°C. A 9.7 g (0.05 mol) sample of distilled diphenylketene was dissolved in 50 mL of pure ethyl benzene. While this solution was magnetically stirred, a 2.5-fold excess of aluminum chloride (16.6 g) was added portionwise through the reflux condenser. The reaction mixture was stirred overnight, then poured into HCl – ice water and washed with water repeatedly until the

α,α-Diphenylchloroacetophenone	140–145	78.30	4.93	78.49	5.18	1.07

[a]Literature (ref. 18, vol. 7, p. 522) mp 135–136°C.
[b]In this experiment an aliquot showed that only a 64% yield of the ketene was obtained.

washings gave a pH of six by pHydrion paper. The excess ethyl benzene was removed by distillation. The residual brown tar was extracted repeatedly with hot pentane. The combined extracts were concentrated to ~50% of their volume and allowed to stand. Crystals of the product formed slowly and were collected. They showed ν(Nujol): 1675 (C=O) cm^{-1}. This procedure was used for all the ketones. The effectiveness of this technique for recovery was tested by dissolving a known amount of a ketone in pentane at the boiling point, concentrating it, and collecting crystals.

In the case of more active substrates very little polymerization occurred and recovery with pentane (subsequent to distillation of most of the substrate–solvent) was simple, since the polar ketone is not very soluble in the cold pentane solvent. Recovery of pure anisyl ketone from hot pentane was 98.3%. In the case of cumenyl ketone, however, which turned out to be soluble in pentane, the solid was recovered by triturating it out of the polymer with pentane, and recrystallizing the crude solid which was contaminated with cumene, from ethanol. As a check on the recovery method some pure cumenyl ketone was dissolved in cumene and as much of the cumene was distilled off as possible. Subsequently recrystallization from ethanol was effected. Recovery of the pure ketone was 80%.

The yields, melting points, and microanalytical data are recorded in Table 9.

Competition of Toluene and Benzene for Diphenylketene

These experiments were performed in an analogous manner to those for dimethylketene except that the analysis of the reaction mixtures was done using a Waters high performance liquid chromatography apparatus consisting of two Model 6000 pumps, a U6K loop injector, a Model 440 Absorbance Detector connected to a Soltec Model 252A recorder, and a Model 660 Solvent programmer. Integrations were performed as with the dimethylketene experiments. The column was a Whatman ODS – Magnum 9 C_{18} reverse phase column. Flow rate was 2.5 mL/min of 25% water – methanol.

The relative response factor for the tolyl ketone relative to the phenylketone was 1.296 as determined by artificial mixtures. The values corrected by the relative response factor appear in Table 6 along with the relative rates.

Crossover Experiment with Anisole and Toluene-d_8

A mixture of 15 g (0.14 mol) of anisole and 15 g (0.15 mol) of toluene-d_8 was treated with 1.56 g of clean, triple distilled dimethylketene (0.022 mol) and 10 g (0.075 mol) of anhydrous aluminum chloride in a three-necked flask equipped with a drying tube, mechanical stirrer, and addition funnel. After the reaction had subsided the mixture was poured onto 300 g of 6 *M* HCl – ice water and extracted with three 100-mL portions of dichloromethane. After drying over magnesium sulfate the solvent was removed and the higher boiling excess organic substrates were removed under reduced pressure. The residue was fractionally distilled through a 3 in. Vigreux column to give ketone materials in fractions two and three (bp 98–140°C; 10.5 Torr). These ketones were separated by preparative scale gc and analyzed by mass spectra (Varian EM 600 calibrated by perfluorokerosine-H) and nmr.

The nmr spectrum of the anisyl isopropyl ketone showed considerable incorporation of D at the isopropyl group. The mass spectrum had (average of 5 scans) a ratio of M to $M + 1$ of $0.380 \pm 5.53 \times 10^{-2}$ (standard deviation). The expected M to $M + 1$ ratio was 0.122. These figures indicate a protium/deuterium value of 3.83 in the anisyl ketone.

The nmr spectrum of the tolyl ketone showed retention of only about 70% of the deuterium label at the position as indicated by a septet at $\delta = 3.4$ (compared to the methyl signal at 1.1–1.25). These data indicated that proton transfer from the aromatic ring to the α-position was intermolecular.

GEORGE KOTOVYCH, GERDY H. M. AARTS, and KLAUS BOCK. Can. J. Chem. **58**, 1206 (1980).

Nuclear Overhauser effect difference experiments on vitamins D_2 and D_3 at 400 MHz allow an unambiguous assignment to be made for the H_E and H_Z protons bonded to the C-19 carbon. This assignment is especially important since the A ring, and hence the C-19 atom, undergoes a conformational interconversion. The results indicate the importance of proton nOe difference experiments in determining points of configuration and they indicate that the assignment of resonances based on allylic coupling constants in a molecule undergoing a conformational equilibrium can be incorrect.

GEORGE KOTOVYCH, GERDY H. M. AARTS et KLAUS BOCK. Can. J. Chem. **58**, 1206 (1980).

Des expériences de différence d'effet Overhauser nucléaire (eOn) effectuées sur des vitamines D_2 et D_3 à 400 MHz permettent d'identifier sans ambiguité les protons H_E et H_Z liés au carbone en position 19. Cette identification est spécialement importante puisque le cycle A, et par conséquent le carbone en position 19, subit une interconversion conformationnelle. Ces résultats témoignent de l'importance des expériences de différence de eOn sur les protons dans la détermination des sites de configuration et ils indiquent que les attributions de résonance basées sur les constantes de couplage allylique dans une molécule en équilibre conformationnelle peuvent être incorrectes.

[Traduit par le journal]

Introduction

Vitamin D compounds, which are extremely important for calcium and phosphorus metabolism (1), have been studied by nmr, especially to obtain information regarding the conformational equilibria of these molecules. Line assignments are extremely important, particularly if nOe measurements (2, and references therein) are to be used to obtain the conformation of these molecules in solution. For vitamin D_2, in CCl_4 solution, proton 19, with a chemical shift δ equal to 4.97 ppm, was assigned as the proton *cis* to the 5,6 double bond (3). This assignment was based on the predicted angular dependence of allylic coupling constants. Experimentally, however, the observed allylic coupling constant between this proton and the two protons at C-1 was about 1.0 Hz. The identical coupling constant is an average value and the averaging arises from the chair–chair interconversion of the A ring. The chemical shift for the second C-19 proton is 4.73 ppm. For vitamin D_3 (4), the same assignments for the multiplets corresponding to the two non-equivalent H-19 protons were made. These were also based on the coupling constant information. In addition, the H-19 resonance at low field was expected to be at lower field because of the possibility of mutual deshielding by the proximal 7-proton. The two H-19 resonances could not be assigned strictly on the basis of an $Eu(dpm)_3$ titration study of vitamin D_3 (4). The same assignments have been applied to a variety of vitamin D_3 derivatives (5, 6).

We have applied nOe difference spectroscopy to the study of vitamins D_2 and D_3 with the intention of obtaining information concerning distances in solution between individual protons (7). This technique was previously applied to gain information concerning the spatial structures of protein molecules, namely the basic pancreatic trypsin inhibitor (8) and for spectral assignments in lysozyme (9). The dependence of the homonuclear nOe, at two frequencies, on the correlation time has been elegantly discussed by Glickson *et al.* (10). While carrying out the present nOe difference experiments, an unambiguous assignment of the H_E and the H_Z protons at C-19 could be made. This is especially important in view of the fact that the C-19 carbon, bonded to the A ring, undergoes a conformational change due to the chair–chair interconversion of this ring.

Experimental

The nOe experiments were carried out at 400 MHz in the standard manner (8) using a Bruker WH-400/DS NMR spectrometer. The experimental procedure will be described briefly.

The gated decoupler was set on resonance for a minimum time of greater than 4 times the longest T_1 value for the molecule (7) to effectively saturate the resonance of the irradiated nucleus. Four free induction decay signals were accumulated. The memory was then negated and the experiment was repeated with the gated decoupler off-resonance (control spectrum). The off-resonance frequency was chosen following the procedure described previously (2), namely by placing it exactly equidistant in the spectrum from the resonance frequency of the observed nucleus but in the opposite direction from the on-resonance irradiating frequency (2). These four free induction decay signals were thus compared with the original four. The total number of sequences was determined by the required signal-to-noise ratio. After collecting the FID's the signal was Fourier transformed. A 90° pulse was used in order to obtain the best S/N ratio and the pulse width was 10.7 μs. A total of 16K data points were used. The sample preparation, including purification of the solvent ($CDCl_3$) and degassing were discussed previously (7).

Results and Discussion

The results of the nOe measurements are given in Table 1. The % nOe was calculated using the irradiated inverted peak as the reference. All nOe values were evaluated by integration. The results for both vitamins are the same within experimental error (±10%). The most important conclusion obtained from these experiments concerns the assignment of the C-19 protons. When proton 7 is irradiated, the high-field C-19 proton experiences an nOe. It is closest to proton 7 (11) and is therefore labelled C-19 H_Z following standard rules of nomenclature (12) (Figs. 1 and 2). The multiplet at δ = 1.47 ppm also exhibits an nOe. As this multiplet could not be definitively assigned, from the structure it must correspond to protons 14 and/or 15. The assignment of the upfield C-19 proton as C-19 H_Z is confirmed by irradiating it. As expected, a large nOe is observed not only for the low-field C-19

TABLE 1. Selective nOe enhancements observed for vitamins D_2 and D_3 at 400 MHz

Proton		% nOe	
Irradiated	Observed	D_2	D_3
19Z	19E	27	26
	7	6	6
19E	19Z	29	28
7	19Z	8	6
	6	6[a]	6[a]
	Multiplet at δ = 1.47 ppm[b]	11	13
6	4α	8	7
	4β	7	6
	7	6[a]	4[a]
	9β	12	10

[a]A distorted signal is observed for these protons since they are tightly coupled to the protons being irradiated.
[b]This multiplet corresponds to protons 14 and possibly 15. A definite assignment could not be made.

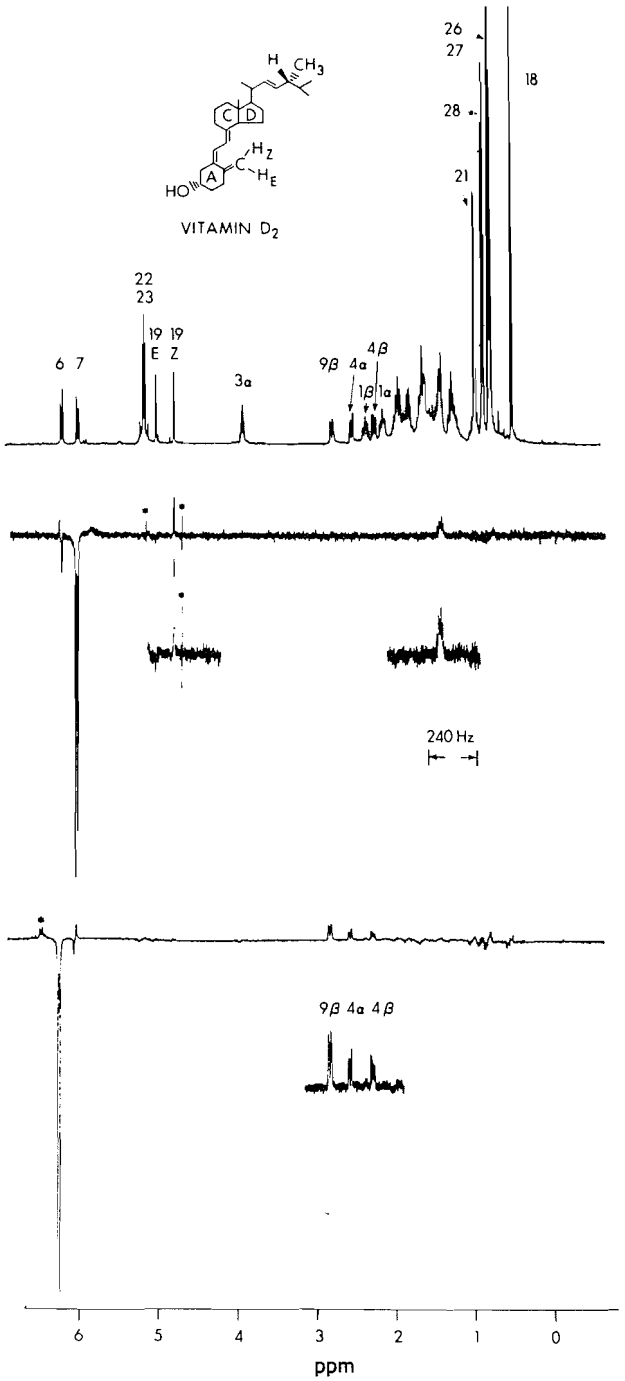

FIG. 1. The 400 MHz Fourier transform nmr spectrum for vitamin D_2 is seen at the top. The middle spectrum corresponds to the experiment where proton 7 is irradiated. An nOe is observed for the high-field proton at C-19, the doublet for proton 6 and the multiplet at δ = 1.47 ppm. The bottom spectrum corresponds to the experiment where proton 6 is irradiated. An nOe is observed for protons 4α, 4β, 7, and 9β. The * indicates instrumental artifacts.

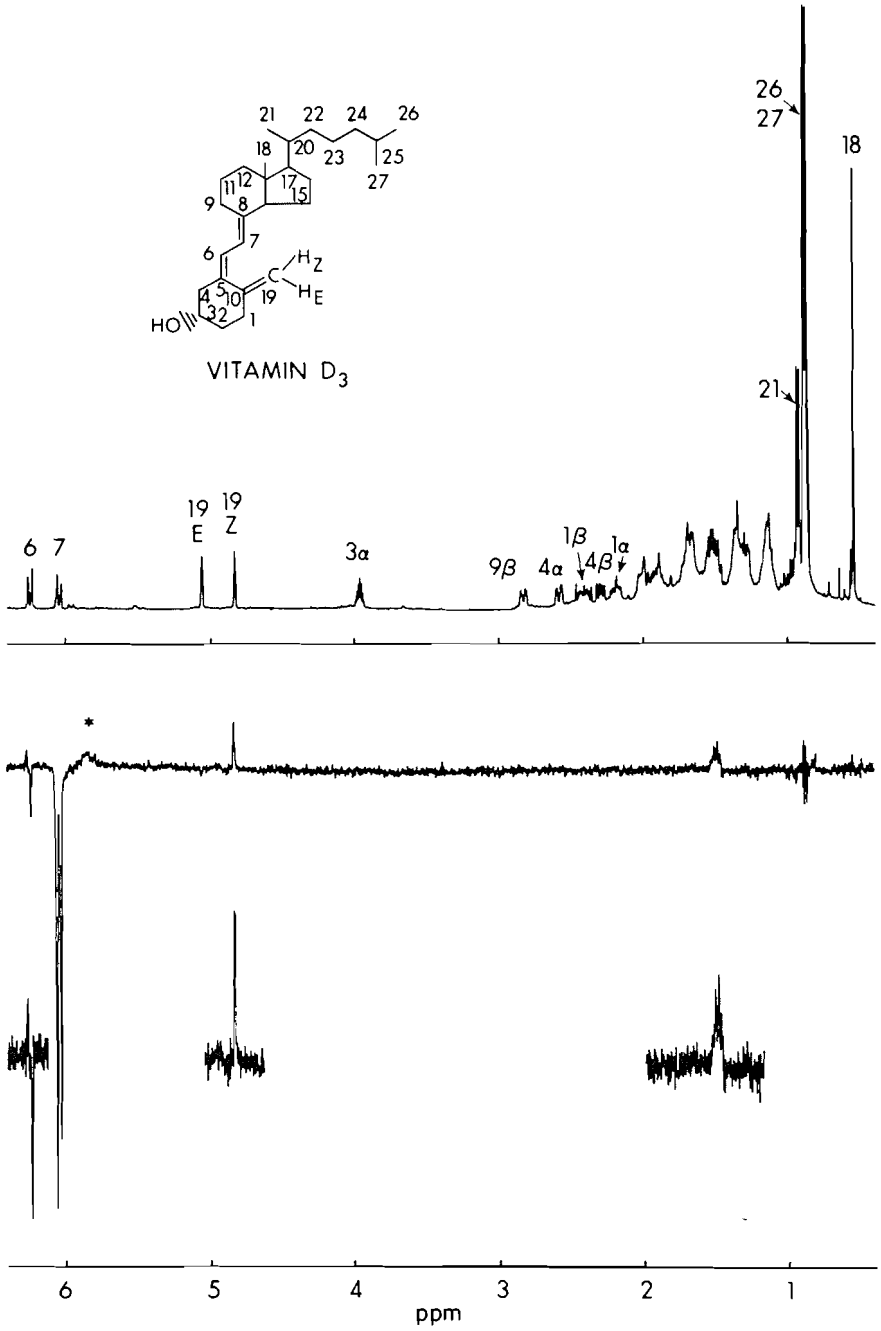

FIG. 2. The 400 MHz Fourier transform nmr spectrum for vitamin D_3 is seen at the top. The bottom spectrum corresponds to the experiment where proton 7 is irradiated. An nOe is observed for the high-field proton at C-19, the multiplet at $\delta = 1.47$ ppm and the doublet for proton 6. The * indicates experimental artifacts.

proton but also for proton 7 (Fig. 3). However, upon irradiation of the low-field C-19 proton, only the C-19 H_Z proton is observed to exhibit an nOe. This low-field proton is therefore labelled C-19 H_E. Finally, irradiation of proton 6 causes an nOe for protons 4α, 4β, and 9β. These protons are the closest to proton 6 and an nOe is expected (11). From the spectra (Figs. 1–3), it can be seen that small baseline effects can be observed in the high field region. At present these cannot be explained.

Irradiation of the H-6 proton doublet which forms an AB system with the H-7 proton produces a distorted resonance for the H-7 proton. A distorted signal for H-6 is also observed upon irradiation of

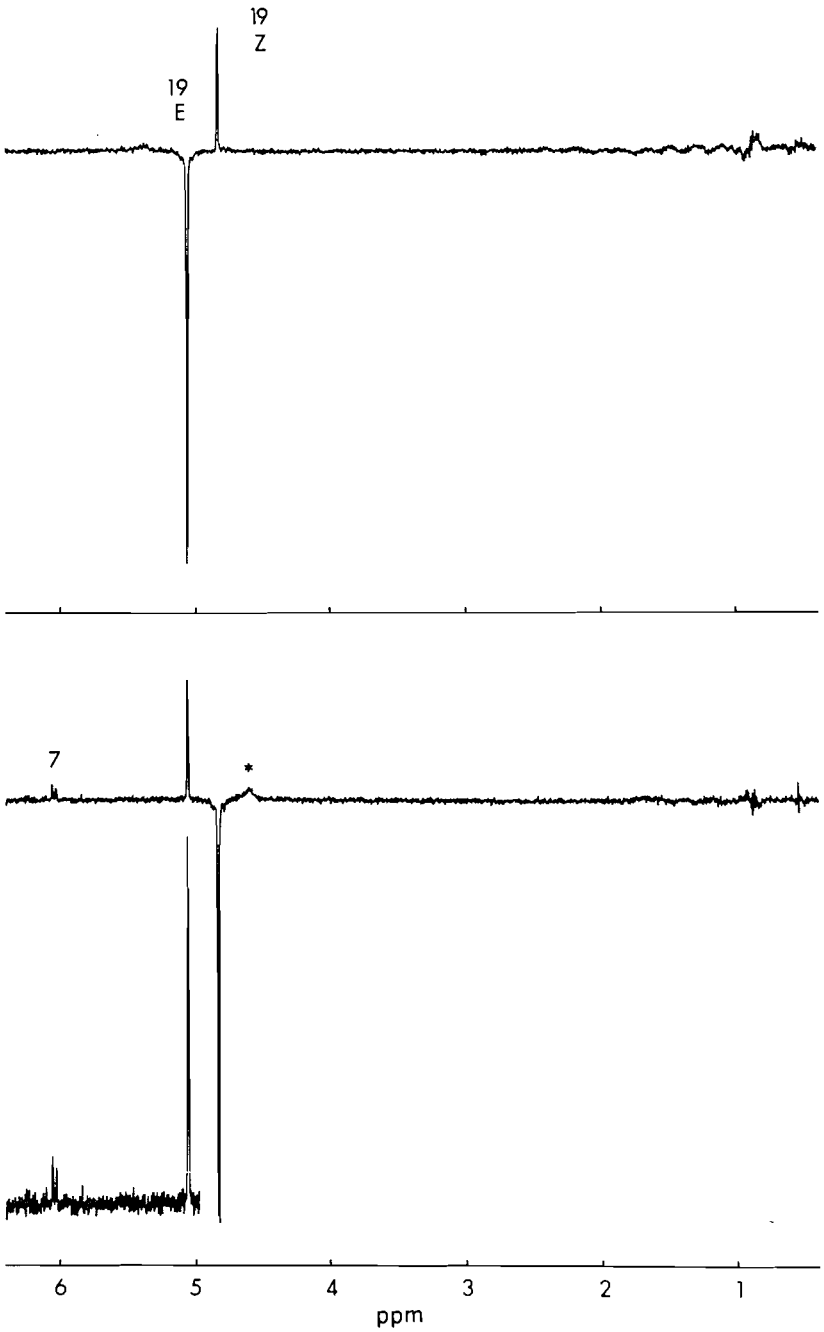

FIG. 3. NOe spectra for vitamin D_3. In the top spectrum, the low-field C-19 proton is irradiated and an nOe is observed for the high-field C-19 proton. In the bottom spectrum, the high-field C-19 proton is irradiated and proton 7 and the low field C-19 proton experience the nOe. The * indicates experimental artifacts.

the H-7 doublet. Similar effects were observed by carrying out the experiments with a small pulse angle of 10° (1.13 μs pulse width). As these two protons are tightly coupled, the observed nOe is smaller than expected (ref. 11, pp. 226–232). In addition, the power levels necessary for on-resonance saturation may affect the magnetization of both nuclei simultaneously and cause a distortion of the nucleus experiencing the nOe, especially if the lines irradiated are not subjected to the same saturation field. The latter condition may be difficult to obtain if the coupling constant between the two nuclei is large ($\geq$8 Hz) and at the same time the chemical shift difference is small.

In conclusion, we have shown the importance of the proton nuclear Overhauser effect difference experiment in determining points of configuration. This method has the distinct advantage that one experiment picks out all of the protons that are in close proximity to the irradiated proton even if these protons are hidden by some other resonances. Finally, the assignment of resonances based on allylic coupling constants in a molecule undergoing a conformational equilibrium, as does the A ring of vitamin D, can be incorrect.

Carbon-13 chemical shift assignments of chromones and isoflavones

HEM CHANDRA JHA AND FRITZ ZILLIKEN

Institute of Physiological Chemistry, University of Bonn, Nußallee 11, D-5300 Bonn 1, West Germany

AND

EBERHARD BREITMAIER

Institute of Organic Chemistry and Biochemistry, University of Bonn, Gerhard-Domagk-Straße 1, D-5300 Bonn 1, West Germany

Received January 28, 1980

HEM CHANDRA JHA, FRITZ ZILLIKEN, and EBERHARD BREITMAIER. Can. J. Chem. **58**, 1211 (1980).

Carbon-13 chemical shifts of 8 chromones and 35 isoflavones variously substituted by hydroxy-, acetoxy-, and methoxy-groups are assigned. The applicability of chemical shift increments reflecting inductive and resonance effects is discussed. Some general relations between substitution patterns and carbon shielding useful for the identification of naturally occurring isoflavones are outlined. Typical C—H couplings of chromone and phenyl carbons are analyzed for a 4′,6,7-trisubstituted derivative.

HEM CHANDRA JHA, FRITZ ZILLIKEN et EBERHARD BREITMAIER. Can. J. Chem. **58**, 1211 (1980).

On a attribué les déplacements chimiques en rmn ^{13}C de 8 chromones et de 35 isoflavones substituées de manière diverse par des groupes hydroxy, acétoxy et méthoxy. On discute de la possibilité d'appliquer des incréments de déplacement chimique comme méthode d'évaluer des effets inducteurs de résonance. On souligne quelques relations générales entre les schémas de substitutions et de blindage du carbone qui sont utiles pour l'identification des isoflavones naturelles. On analyse des couplages typiques C—H des carbones de la chromone et du phényle dans un dérivé trisubstitué en position 4′, 6 et 7.

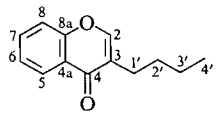
[Traduit par le journal]

Isoflavonoids are gaining considerable importance due to having potential contraceptive (1), antioxidative (2), and antifungal (3) properties. Their chief source of occurrence is in the leguminous plants, some of which are very much in use as food materials. Moreover, leguminous plants sometimes exhibit remarkable physiological activities attributable to their isoflavone contents. György and co-workers (2) found 4′,6,7-trihydroxyisoflavone to be the antioxidative substance of fermented soyabeans. A recent work ascribes hypolipidemic activity of Bengal gram (cicer arietinum) to the presence of biochanin A (4′-methoxy-5,7-dihydroxyisoflavone) and formononetin (4) (4′-methoxy-7-hydroxyisoflavone).

Structurally, isoflavonoids furnish a great variety in as much as natural products like isoflavanones, isoflavones, rotenoids, pterocarpans, coumestanes, 3-aryl-4-hydroxycoumarins, and coumaronochromones are all included in this group. The discovery and the structure elucidation of these substances have been to a large extent made possible due to application of spectroscopic methods. Among these, ^{13}C nmr has not yet been fully applied to study the isoflavone structure although the flavones as sister compounds have been subjected to much detailed investigations (5–8). Some of these works make only cursory reference to the spectra of specific isolated isoflavones. Recent papers (9, 10) describe the ^{13}C nmr spectra of selected isoflavones substituted in 4′,5,7-positions.

The present study concerns ^{13}C shifts of 43 chromones and isoflavones variously substituted in the rings A and B by methoxy-, hydroxy-, and acetoxy-groups (Table 1). As these substituents often occur in isoflavones and chromones isolated from plant material, the shift assignments outlined in Tables 2–6 may facilitate future work of determining the positions of oxygen functional groups in naturally occurring isoflavones and chromones.

Signals were assigned by comparing the ^{13}C shifts with literature data available for chromone (11), isoflavone (12), and its seven substituted derivatives (9, 10). In the aromatic carbon shift range, quaternary carbons were localized as sharp singlets by low power noise proton decoupling. Further straightforward assignment aids are the enhanced intensities observed for the C-2′,6′ and C-3′,5′ carbon pairs of the 4′-substituted derivatives and the inductive and mesomeric effects of hydroxy-, acetoxy-, and methoxy-groups (13).



A coupled spectrum of 6-acetoxy-4′,7-dimethoxyisoflavone, **47**, was taken in order to support the assignments made for the 4′,6,7-trisubstituted representatives **34–50**. The largest C—H coupling (196.5 Hz) was measured for C-2 (153.3 ppm) which experiences a considerable positive polarization not only by the α-inductive effect of the oxygen but also due to a mesomeric electron withdrawing of the β carbonyl group. These data have diagnostic value when isoflavones (unsubstituted in the 2-position) have to be distin-

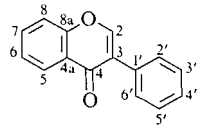
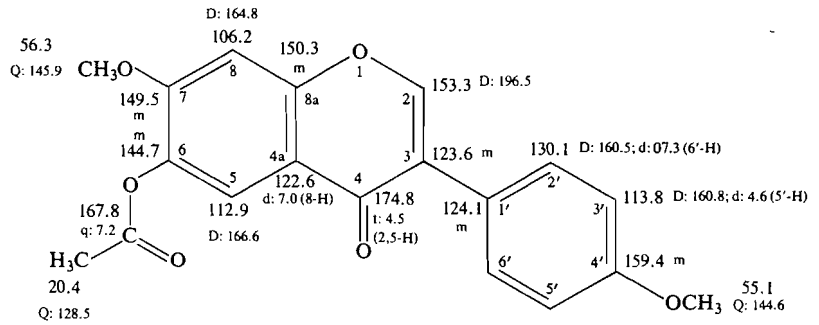
guished from flavones. (*i*) No long-range couplings were resolved for the protonated chromone ring carbons as no three-bond interactions ($^3J_{CH}$) are possible within a 3,6,7-trisubstituted chromone ring present in 6,7-disubstituted isoflavones. The one-bond C—H couplings are 166.6 Hz for C-5 (112.9 ppm) and 164.8 Hz for C-8 (106.2 ppm). These couplings are larger than the values observed for the protonated phenyl carbons (C-2′,6′ at 130.1 ppm: J_{CH} = 160.5 Hz; C-3′,5′ at 113.8 ppm: J_{CH} = 160.8 Hz). The corresponding doublet signals are additionally split by three-bond couplings with *meta*-protons (7.3 and 4.6 Hz). (*ii*) A typical quartet due to two-bond coupling ($^2J_{CO—CH_3}$ = 7.2 Hz) localizes the carbonyl carbon of the acetoxy group at 167.8 ppm. (*iii*) The assignment given for C-1′ and C-3 is based on the larger nuclear Overhauser enhancement experienced by C-1′ (124.1 ppm) on proton broad-band decoupling due to two *ortho*-protons.



The assignments of the following carbon pairs in Tables 2 and 3 are interchangeable due to signal crowding: C-5 and C-6, in **1** and **10**; C-3 and C-4a, in **8**, **9**, **47**, and **48**; C-7 and C-8a, in **15–17**, **25**, **27**, **34–47**; C-2′(6′) and C-3′(5′), in **10–19** and **28**; C-3′ and C-4′, in **54**.

In order to derive the substitution pattern of an unknown isoflavone it is useful to check the additivity of the empirical substituent increments. Substituent increments have therefore been deduced for the chromone and phenyl ring carbons in Tables 7 and 8 on the basis of as much data as available from Tables 2 and 3.



It turns out that electron releasing of a methoxy

TABLE 1 (*Concluded*)

group at position 6 of the chromone ring is weakened at C-7 ($z_o = -5.9$ ppm) due to $-m$-electron withdrawing of the *para* carbonyl group while electron releasing of a methoxy- or hydroxy-group at C-7 is increased at C-8 ($z_o = -17.9$ and -16.1 ppm) due to the $+m$-effect of the *ortho* chromone oxygen. The average $(z_o + z_{o'})/2$ of both *o*-effects in each case corresponds approximately to the OH and OCH_3 increments known for the benzene shifts (Table 8).

The shieldings of 6,7-dimethoxy- and 7-hydroxy-6-methoxyisoflavones (Tables 2 and 7) show that deviations from increment additivity of up to 4 ppm have to be expected for *o*-disubstituted chromone rings in isoflavones, particularly for the substituted carbons themselves. To conclude, benzene shift increments cannot be used to predict accurately the shieldings of benzenoid carbons in multisubstituted chromone rings since cooperative effects occur with the carbonyl carbon, the ring

oxygen, and between the substituents. In 4′-substituted isoflavones the effects of hydroxy-, methoxy-, and acetoxy-groups on 3-phenyl carbon shifts are essentially those reported for benzene (Table 8). In the 2′-substituted derivatives (**12–14**), however, the *ortho*- and *meta*-effects z_o, $z_{o'}$, and z_m, $z_{m'}$, differ among each other (Table 8), while the average values $(z_o + z_{o'})/2$ and $(z_m + z_{m'})/2$ again approximately correspond to the benzenoid shift increments. Considerable deviations from increment additivity are observed for polysubstituted 3-phenyl rings of isoflavones, particularly at the centers of substitution, as is shown for the phenyl carbons of 3′,4′,6,7-tetramethoxy- and 5,7-dihydroxy-3′,4′,5′-trimethoxyisoflavone **54** and **33** (italic values for increment values and Roman values for experimental values).

54

33

Definitive assignment of the phenyl carbons C-2′ and C-5′ of the tetramethoxy derivative **54** follows from a long-range coupling of $^3J_{CH} = 6.7$ Hz due to a *meta* proton only observed for the signal at 112.9 ppm which, therefore, belongs to C-2′.

Thus, although giving good shift predictions for carbons apart from substitution centers, carbon shift increments in general rather permit the prediction of the signal sequence than of accurate shielding values for higher substituted derivatives. Despite these restrictions concerning increment additivity, some specific shift values found in Tables 2–6 are very characteristic of certain substitution patterns.

A carbonyl shift of 181 ± 1 ppm clearly identifies a 5-hydroxy-group, the deshielding of about 6 ppm relative to all other substituted isoflavones arising from intramolecular hydrogen bonding between C-5-hydroxy and C-4-carbonyl.

Two NOE enhanced signals (off-resonance doublets) at 98 ± 2 ppm and 93 ± 2 ppm are characteristic of C-6 and C-8 in a 5,7-di-*O*-substituted chromone ring, while C-5 and C-8 of 6,7-disubstituted derivatives will appear as strong signals at 106 ± 2 ppm and 101 ± 2 ppm.

A 4′-substituted isoflavone (OH, OCH_3, but not $OCOCH_3$) is well characterized by the signal sequence 123 ± 2 ppm, 130 ± 1 ppm (strong), 114 ± 1 ppm (strong), and 158 ± 2 ppm.

An off-resonance quartet at 55.1 ± 0.1 ppm is very likely due to a 4′-methoxy group while all other methoxy groups of isoflavones and chromones resonate near 56 ppm (Table 4). In the case of 6,7-dimethoxy derivatives two closely spaced methoxy signals at 55.9 (C-6-OCH_3) and 56.2 ppm (C-7-OCH_3) will be observed most likely. For the substitution pattern 6-OCH_3-7-OH, a methoxy shielding of 55.85 ± 0.1 ppm can be expected, while 56.1 ± 0.1 ppm appears to characterize 6-OH-7-OCH_3 (Table 4).

As can be seen in Table 5, the carbonyl carbon of the acetyl group also seems to reflect the acetoxy position (4′-$OCOCH_3$: 169.5; 2′-$OCOCH_3$: 169.0; 6-$OCOCH_3$: 167.8; 7-$OCOCH_3$: 168.5 ppm), but the number of data available is too small for establishing a general rule.

As chromone and phenyl ring are isolated from each other in terms of carbon shielding (8, 9), equally substituted benzene rings in chromones and isoflavones exhibit almost identical ^{13}C shifts (Table 2) independent of the group at positions 3 (alkyl or phenyl) and substituents thereon.

Experimental Section

All ^{13}C nmr spectra were taken in a 50:50 (v/v) mixture of $CDCl_3$ and $(CD_3)_2SO$ in order to exclude solvent effects as much as possible. Internal tetramethylsilane (2 vol.%) was used as reference. Solutions (1 mL) were prepared from 10–40 mg chromone and isoflavone samples. A Bruker WP-60-FT instrument operating at 15.08 MHz for ^{13}C and 60 MHz in the proton decoupling channel was used (except for the spectrum of **47** which was taken at 20.115 MHz). The deuterium signal of $(CD_3)_2SO$ served for field/frequency stabilization at 8.67 MHz. A total of 20 000 accumulated 45° pulse interferograms were exponentially multiplied for a line broadening of 0.4 Hz, zero-filled to 16 K, Fourier-transformed and phase-corrected by a BNC-128 computer (20 Bit) to the real parts of the ^{13}C nmr spectra. For a spectral width of 3.75 kHz distributed among 8 K data points, the digital resolution was 0.45 Hz or 0.03 ppm. Chemical shifts were calculated from the digitized spectra by the computer. The values given in Tables 2–6 can be rounded to the nearest 10th of a ppm.

Preparation of the Isoflavones

The isoflavones and chromones have been prepared via the deoxybenzoins obtained by condensation of required phenols with derivatives of arylacetic acids or appropriate aliphatic acids (14–17). The methods had to be selected from among the Friedel–Crafts reaction, Fries rearrangement, or Hoesch condensations, depending on the nature of phenols used. Formylation of the deoxybenzoins and the ring closure were achieved by ethylformate/sodium (18) or ethyloxalylchloride/pyridin (19) or ethylorthoformate/piperidine–pyridine (20) or borontrifluoride etherate/methylsulfonyl chloride (21). The identity of the substances, so far as known, has been ascertained by mp comparisons. The genuineness of the new compounds was verified by elemental analysis and by application of uv-, ir-, nmr-, and mass-spectrometry.

Demethylations, methylations, and acetylations of the isoflavones were performed according to conventional methods.

The full characterization and preparation procedures for new isoflavone derivatives will be published separately.

Application de la spectrométrie infrarouge et Raman à l'étude des complexes en solution aqueuse: Fe^{3+}–$H_2C_2O_4$

MOHSEN JABER,[1] FRANÇOIS BERTIN ET GERMAINE THOMAS-DAVID

Laboratoire de Chimie Analytique II, Université Claude Bernard, Lyon I, 43 boulevard du 11 Novembre 1918, 69622 Villeurbanne, France

Reçu le 23 novembre 1979

MOHSEN JABER, FRANÇOIS BERTIN et GERMAINE THOMAS-DAVID. Can. J. Chem. **58**, 1220 (1980).

L'étude par spectrométrie Raman du système Fe^{3+}–$H_2C_2O_4$ en solution aqueuse montre très nettement la formation successive de trois complexes: $Fe(C_2O_4)^+$, $Fe(C_2O_4)_2^-$, $Fe(C_2O_4)_3^{3-}$, chaque espèce est caractérisée par un spectre Raman spécifique.

L'évolution de l'intensité des bandes Raman des trois complexes en fonction de la longueur d'onde de la raie excitatrice et la comparaison entre les spectres ir et Raman des trioxalates de fer(III) et d'aluminium montrent pour les oxalatoferrates un effet de pré-résonance Raman.

MOHSEN JABER, FRANÇOIS BERTIN, and GERMAINE THOMAS-DAVID. Can. J. Chem. **58**, 1220 (1980).

A study by Raman spectrometry of the system Fe^{3+}–$H_2C_2O_4$ in aqueous solution shows very clearly the successive formation of the three complexes: $Fe(C_2O_4)^+$, $Fe(C_2O_4)_2^-$, $Fe(C_2O_4)_3^{3-}$. Each species is characterised by a specific Raman spectrum.

The evolution of Raman band intensities with the range of exciting line, and the comparison between ir and Raman spectra of Fe(III) and Al(III) complexes, show for Fe(III) species a pre-resonance Raman effect.

La formation des oxalates complexes de fer(III) en solution aqueuse a fait l'objet de plusieurs investigations utilisant des techniques telles que la potentiométrie, la spectrophotométrie uv–visible, la polarographie ... (1–18). L'interprétation des résultats obtenus conduit la plupart des auteurs à proposer la formation de trois complexes mononucléaires $Fe(C_2O_4)^+$, $Fe(C_2O_4)_2^-$ et $Fe(C_2O_4)_3^{3-}$ (34). Toutefois Fronaeus (19), après examen des spectres infrarouges des solutions aqueuses d'oxalatoferrates, admet dans certains cas la formation de complexes polynucléaires; d'un autre côté Moorhead (20) et Bauer (21) par étude spectrophotométrique uv concluent à l'existence d'une espèce protonée $FeHC_2O_4^{2+}$. Il est possible que les divergences ainsi observées résultent de l'incertitude concernant le nombre de protons libérés par la formation des oxalates de Fe(III), surtout en milieu très acide.

Aucune étude complète n'a été effectuée par spectrométrie infrarouge et Raman sur ce système. D'une façon générale les oxalates complexes des métaux de transition sont des composés colorés qui absorbent fortement le rayonnement visible ou proche uv; ils n'ont pratiquement pas été étudiés par Raman à l'inverse de nombreux autres oxalates complexes incolores (22–28). Notons cependant les travaux de Vaisserman (27) et Gouteron (28) qui ont récemment publié les spectres de diffusion des oxalates de rhodium et d'iridium en utilisant une raie laser exitatrice dont la longueur d'onde est située en dehors de la région d'abosrption des composés; ces auteurs ne sont pas parvenus à obtenir le spectre Raman du trioxalate de Fe(III) et l'un d'eux (28) note une altération très rapide du composé lorsqu'il est soumis au rayonnement laser.

Dans le cadre d'un travail concernant l'application de la spectrométrie infrarouge et Raman à l'étude des équilibres complexes en solution aqueuse (29–33), nous présentons ici les résultats obtenus au cours de l'étude de la formation des différents complexes pour le système Fe^{3+}–$H_2C_2O_4$, en fonction de l'acidité des solutions et du rapport des concentrations analytiques en métal/coordinat. L'évolution des spectres met en évidence trois étapes successives qui présentent un léger phénomène de résonance Raman.

Conditions expérimentales

Solutions

Les solutions mères d'oxalate de fer(III) sont obtenues par dissolution, dans l'eau distillée, d'acide oxalique $H_2C_2O_4 \cdot 2H_2O$ et de chlorure ferrique $FeCl_3 \cdot 6H_2O$ dans des proportions adéquates; les réactifs utilisés sont des produits Merck pour analyses; on prépare des solutions de concentration 0.5 *M* en coordinat, avec un rapport métal/coordinat $t = 0$, 1, 1/2 et 1/3. Le degré d'acidité des échantillons examinés est fixé par addition d'acide chlorhydrique concentré Prolabo R. P. ou par neutralisation par de la soude concentrée (~10 *N*) et titrée; pour mesurer l'acidité de nos solutions nous avons utilisé la chaîne de mesures potentiométriques décrite précédemment (30–32).

Parallèlement aux solutions dans l'eau légère, on réalise des solutions deutériées de même concentration analytique (0.5 *M*) en coordinat par addition progressive de DCl 7.8 *N* à des échantillons obtenus par dissolution d'oxalate de sodium et de chlorure ferrique dans l'eau lourde, en quantités adéquates; tous ces réactifs sont des produits Merck pour analyses.

Pour chaque rapport $t = 0$, $t = 1$, 1/2 et 1/3, le domaine d'étude est limité par la précipitation de l'hydroxyde ferrique, soit pH ≤

3.5 pour $t = 1/3$, pH $\leq 2.\overline{5}$ pour $t = 1/2$, pH ≤ 2.0 pour $t = 1$ et pH ≤ 1.5 pour $t = 0$, rapport qui correspond aux solutions de chlorure ferrique dépourvues d'ions oxalates.

Spectres

On a enregistré une soixantaine de spectres ir et Raman de solutions ainsi préparées.

Les conditions d'obtention des spectres ir et Raman sont identiques à celles décrites précédemment (30–33). Toutefois, compte tenu de la coloration jaune–vert des solutions, l'enregistrement des spectres Raman et l'exploitation des résultats obtenus nécessitent ici quelques précautions particulières. Pour éviter l'échauffement et l'altération des solutions par suite d'une absorption trop importante du rayonnement laser au cours de l'enregistrement, nous avons réalisé un dispositif de circulation continue de la solution dans un tube capillaire en quartz, disposé verticalement et perpendiculaire au faisceau; la circulation est assurée par une pompe péristaltique; un tel dispositif exige un assez grand volume de solution: 50 mL environ. La puissance du laser a été limitée à 200 mW. Afin de mettre en évidence le phénomène de résonance Raman, on utilise quatre fréquences excitatrices à 514.5; 488.0; 476.5 et 457.9 nm.

Nous mesurons les intensités des raies de diffusion des complexes avec une grande précision en utilisant comme étalons internes les ions ClO_4^- et NO_3^- en concentration 0.04 *M* dont les raies caractéristiques sont situées respectivement à 936 et à 1050 cm^{-1}. De plus, pour chaque échantillon, nous procédons à deux enregistrements successifs; nous pouvons ainsi vérifier qu'il n'y a pas eu d'évolution notable ni dans la physionomie du spectre, ni dans les intensités des bandes pendant l'éclairement de la solution. Les intensités mesurées sont corrigées de la réponse spectrale du détecteur et de l'absorption des faisceaux diffusés par l'échantillon (29, 39, 40).

Les spectres d'absorption uv–visible de l'échantillon sont obtenus au moyen d'un spectromètre-enregistreur BECKMAN DK 2 A, double faisceau en cuves parallèlépipédiques de quartz, d'épaisseur 0.1 et 0.5 cm, à la température ambiante; l'eau distillée est utilisée comme solution de référence. Ces enregistrements sont complétés par des mesure effectuées à l'aide d'un spectromètre OPTICA monofaisceau, ce qui permet d'obtenir une valeur précise de l'absorbance des solutions pour des longueurs d'onde bien définies.

Résultats expérimentaux

Spectres infrarouges des oxalates de fer(III) en solution

Quel que soit le rapport t étudié, les spectres ir présentent les mêmes bandes; la neutralisation des solutions entraîne une diminution des bandes du coordinat $H_2C_2O_4$ ou de ses formes dissociées; simultanément d'autres bandes, dues aux complexes oxalatoferrates apparaissent, situées à 1710, 1680, 1460(?), 1395, 1255, 930, 890 et 800 cm^{-1}, et augmentent d'intensité avec le pH. Aux pH limites avant la précipitation de l'hydroxyde ferrique, les spectres ont sensiblement la même allure quel que soit le rapport t, à l'exception de la bande à 1710 cm^{-1} qui semble plus intense pour le rapport $t = 1/3$. On ne peut donc pas utiliser les spectres ir pour suivre de façon significative l'évolution des équilibres dans cet exemple.

Evolution des spectres Raman en fonction du rapport t *et de l'acidité des solutions*

(a) Spectres du chlorure ferrique en l'absence du coordinat

A pH = 1, il apparaît une bande très intense à 317 cm^{-1} et quatre bandes de faible intensité à 173, 423, 493 et 601 cm^{-1}, signalées par Sharma et Harston (35–38), et qui peuvent être attribuées aux complexes chlorés du type $|Fe(H_2O)_xCl_y|^{(3-y)}$. Par acidification, les bandes 173 et 317 cm^{-1} gardent la même fréquence, les bandes 423, 493 et 601 cm^{-1} diminuent d'intensité et il apparait simultanément une bande large vers 433 cm^{-1}, également notée par Sharma.

(b) Spectres des complexes pour le rapport t = *1/3 (fig. 1)*

(*i*) Domaine d'acidité $|HCl_{eq}| > 7\ N$; le spectre comporte les bandes de diffusion de $H_2C_2O_4$ ainsi que celles qui caractérisent les complexes chlorés du fer(III) citées ci-dessus.

(*ii*) Domaine $7\ N > |HCl_{eq}| > 3.1\ N$; l'intensité des bandes du coordinat libre et des complexes chlorés diminue; tandis qu'il apparait des bandes à 270, 548, 795, 900, 1258, 1395, 1693 et 1713 cm^{-1}, dont l'intensité augmente quand l'acidité de la solution diminue. Ces bandes sont certainement dues aux complexes oxalatoferrates. Dans ce domaine on constate un déplacement progressif de la fréquence de la bande à 317 cm^{-1} vers 307 cm^{-1}, résultant sans doute de l'interférence entre deux bandes provenant l'une de l'ion $FeCl_4^-$ (37), l'autre des complexes oxalatoferrates. La fig. 1 présente l'évolution des spectres dans la région de fréquences la plus caractéristique. Lorsque $|HCl_{eq}| = 3.1\ N$ il apparait une bande à 260 cm^{-1} tandis que disparait celle à 307 cm^{-1} citée plus haut, révélant ainsi la présence d'une bande intense à 297 cm^{-1}.

(*iii*) Domaine $3.1\ N \geq |HCl_{eq}| \geq 1.3\ N$: on observe un déplacement progressif des bandes des complexes oxalatoferrates accompagné d'importantes modifications d'intensité. Lorsque $|HCl_{eq}| = 1.3\ N$, les bandes observées se trouvent ainsi à 260, 297, 363, 533, 555, 796, 900, 1256, 1394, 1698 et 1720 cm^{-1}. Parallèlement les bandes du coordinat non engagé dans les complexes diminuent régulièrement d'intensité mais restent encore visibles même pour $|HCl_{eq}| = 1.3\ N$.

(*iv*) Domaine d'acidité allant de $|HCl_{eq}| \leq 1.3\ N$ à pH ≤ 3: les bandes du coordinat finissent par disparaître complètement; la disparition de la raie située à 848 cm^{-1} permet de repérer une raie à 855 cm^{-1} due aux complexes. Cette évolution s'accompagne (fig. 1) d'une diminution d'intensité puis

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

d'une disparition de la bande à 297 cm^{-1} qui était apparue dans une région intermédiaire, ainsi que d'un élargissement et d'un déplacement progressif de la bande à 260 cm^{-1} qui s'achève par l'apparition d'une bande étroite, très intense située à 249 cm^{-1}. Parallèlement, d'autres bandes se déplacent en fréquence d'une façon continue pour atteindre à pH = 2.8: 358, 508, 535, 560, 795, 855, 903, 1257, 1399, 1705 et 1729 cm^{-1}. L'intensité des bandes à 249, 560 et 1729 cm^{-1} subit une augmentation considérable par rapport à celle des autres bandes du spectre. Il semble que les complexes possèdent aussi une bande proche de 1640 cm^{-1} dans le domaine de la bande de déformation de l'eau.

L'examen des différents spectres pour le rapport $t = 1/3$ nous permet donc de distinguer quatre domaines dont trois correspondent à la formation de différents complexes oxalatoferrates.

(c) Spectres pour le rapport t = *1/2*

(*i*) Pour $|HCl_{eq}| > 3.1\ N$, on observe les bandes des oxalatoferrates repérées pour le rapport $t = 1/3$ en milieu fortement acide, ainsi que celles du coordinat et des chlorures de Fe(III). Le même phénomène d'interférence entre les bandes à 307 et à 317 cm^{-1} apparaît ici.

(*ii*) Domaine d'acidité $|HCl_{eq}| < 3.1\ N$: les spectres présentent des bandes déjà observées pour $t = 1/3$ dans l'intervalle $3.1\ N > |HCl_{eq}| > 1.3\ N$: la bande à 307 cm^{-1} disparait, tandis que celle à 297 cm^{-1} apparait. On constate une disparition complète des fréquences imputables à l'acide oxalique; à pH ~ 2 les bandes situées à 260, 297, 363, 490(?), 533, 555, 796, 855, 900, 1256, 1394, 1698 et 1720 cm^{-1} passent par un maximum d'intensité, particulièrement accentué pour les bandes à 260, 297, 555 et 1720 cm^{-1}.

(d) Spectres pour le rapport t = *1*

Les spectres obtenus sur toute la gamme d'acidité comprise entre $|HCl_{eq}| = 7.5\ N$ et pH = 1.4 présentent les mêmes caractéristiques. Au fur et à mesure de la neutralisation, les bandes de l'acide oxalique et celle des chlorures de fer(III) diminuent puis disparaissent tandis qu'il apparait des bandes situées à 270, 307, 548, 795, 853, 900, 1258, 1395, 1693 et 1713 cm^{-1} qui augmentent continuellement d'intensité sans changer de fréquence. Ces bandes correspondent à celles observées pour les rapports $t = 1/3$ et $t = 1/2$ lorsque $|HCl_{eq}| > 3.1\ N$. Elles atteignent un maximum d'intensité pour $|HCl_{eq}| = 1.3\ N$.

La bande à 307 cm^{-1} est bien due aux complexes oxalates et non à l'ion $FeCl_4^-$. On le vérifie en enregistrant le spectre d'une solution, à pH = 1, de nitrate ferrique qui présente les mêmes bandes que celles citées ci-dessus, à l'exception des raies de NO_3^-.

Discussion

Identification des différents complexes

L'observation globale des spectres Raman pour les trois rapports t, fait nettement apparaître trois étapes sur la complexation de Fe(III) par les ions oxalates. Celles-ci sont caractérisées par trois spectres nettement différents surtout dans la région de basse fréquence (fig. 2). En effet, l'espèce présente à pH 2.8 pour le rapport $t = 1/3$, n'apparait jamais pour les rapports $t = 1$ et $t = 1/2$. Pour $t = 1/3$, la précipitation de $Fe(OH)_3$ n'a lieu qu'à pH élevé, ce qui signifie que la quasi-totalité des ions Fe(III) sont complexés par l'oxalate; comme les bandes du coordinat libre sont absentes, on en déduit que l'espèce qui se forme à ce moment renferme trois groupements oxalate par métal: il s'agit très probablement de $Fe(C_2O_4)_3^{3-}$.

En milieu très acide: $|HCl_{eq}| > 3.1\ N$, on observe la formation d'un complexe qui possède les mêmes fréquences de vibration quel que soit le rapport t. Comme ces fréquences sont présentes pour le rapport $t = 1/1$ juste avant la précipitation de $Fe(OH)_3$ et qu'à ce moment les bandes du coor-

dinat ont disparu, on peut en conclure que ce complexe renferme un coordinat par métal: il s'agirait donc de $Fe(C_2O_4)^+$. La continuité qui existe entre les spectres de vibration des trois espèces semble exclure l'hypothèse de la formation d'une espèce protonée $FeHC_2O_4^{2+}$; de plus, dans ce complexe, les deux groupes carboxylates devraient être différents, ce qui est contraire aux observations spectrales.

Dans un domaine intermédiaire entre la formation de $Fe(C_2O_4)^+$ et celle de $Fe(C_2O_4)_3^{3-}$ il apparait un complexe dont les bandes ont été répertoriées. La fig. 1 montre que pour $t = 1/3$, ce complexe est prépondérant dans l'intervalle $3.1\ N \geq |HCl_{eq}| \geq 1.3\ N$; pour $t = 1/2$ ce complexe est pratiquement seul à pH ~ 0.5. Il est vraisemblable qu'il s'agit de l'espèce $Fe(C_2O_4)_2^-$.

La fig. 2 présente les spectres Raman de ces trois complexes dans le domaine 380–200 cm^{-1}; leurs fréquences de vibration ir et Raman sont rassemblées dans le tableau 1.

Il ne semble pas que les complexes polynucléaires du Fe(III) proposés par Fronaeus (19), se forment, du moins en quantité appréciable, car on devrait constater pour les pH élevés, surtout dans les rapports $t = 1/1$ et $t = 1/2$, une modification spectrale importante, comme cela se produit avec le système Be^{2+}–$H_2C_2O_4$ (31).

Remarques concernant le spectre Raman du complexe trioxalate

Nous indiquons, tableau 2, les fréquences ir et Raman des espèces $Fe(C_2O_4)_3^{3-}$ en solution et $Na_3Fe(C_2O_4)_3 \cdot 3H_2O$ cristallisé. Ce dernier composé a été préparé par évaporation très lente d'une solution d'oxalatoferrate dans un rapport $t = 1/3$ (pH = 2.8); son spectre Raman, enregistré pour plusieurs échantillons, est obtenu en utilisant le dispositif rétro-Raman et la raie excitatrice à 514.5 nm. Ce tableau donne par comparaison les fréquences ir du complexe $K_3Al(C_2O_4)_3 \cdot 3H_2O$ à l'état cristallisé et celles du spectre Raman du même complexe en solution. Les attributions sont celles données par Gouteron (28) et Vaisserman

249	A_1	2.26	2.88	3.24	3.93	0.10

(27) dans l'hypothèse d'une symétrie D_3; on admet que ces attributions sont également valables pour les vibrations du trioxalate d'aluminium. Pour le groupe D_3 les vibrations de types A_1 et E sont actives en absorption.

En comparant le spectre Raman du complexe $Fe(C_2O_4)_3^{3-}$ en solution au spectre ir de $K_3Fe(C_2O_4)_3 \cdot 3H_2O$ et aux spectres du trioxalate d'aluminium que nous avons enregistré aussi, on remarque l'absence d'une bande de type A_1 correspondant à ν(C—O) qui devrait apparaître vers 1430 cm^{-1} (par comparaison avec $Al(C_2O_4)_3^{3-}$), alors qu'à l'état solide on aperçoit une bande intense à 1463 cm^{-1}; deux bandes dépolarisées apparaissent à 1257 et 795 cm^{-1} qui pourraient être attribuées aux modes ν_a(C—O) et δ(O—C=O) de type A_2 normalement interdites en Raman classique. Le fait le plus remarquable est une augmentation considérable d'intensité des bandes de type A_1 situées à 1729, 560 et 249 cm^{-1}. Par contre la bande à 358 cm^{-1} de type E subit le phénomène inverse. Il en est de même pour la bande moyenne à 1399 cm^{-1} pour laquelle la valeur de rapport de dépolarisation (0.55) laisse quelques doutes quant à la symétrie du mode mis en jeu attribuée à un mode E.

Ces observations sont compatibles avec l'existence d'un phénomène de résonance Raman pour le complexe $Fe(C_2O_4)_3^{3-}$.

Spectres d'absorption électronique du complexe trioxalate

Le spectre d'absorption électronique d'une solution de chlorure ferrique de concentration CM = 10^{-3} *M* à pH ~ 3 présente une bande large avec un maximum pour λ_A = 280 nm. Au même pH et pour une même concentration en Fe(III), la formation du trioxalate entraîne un déplacement du maximum vers 260 nm dont le cœfficient d'absorption molaire est de 2600 $mol^{-1}\,cm^{-1}$. Ceci est en bon accord avec les résultats donnés dans la littérature (3–5, 12). L'absorbance devient nulle pour $\lambda > 350$ nm. Par contre pour la solution concentrée étudiée (CM = 0.167 *M*) par spectrométrie Raman et ir l'absorption n'est pas nulle dans le domaine des fréquences excitatrices utilisées. Les valeurs des cœfficients d'absorption molaire k (en supposant que la loi de Beer–Lambert est toujours applicable dans nos conditions de concentration) aux fréquences de diffusion Raman $\bar{\nu}_0 - \bar{\nu}$ du complexe sont:

(*i*) Pour λ_0 = 514.5 nm, k = 0 pour toutes les raies Raman.

(*ii*) Pour λ_0 = 488.0 nm, k atteint la valeur 0.7 $mol^{-1}\,cm^{-1}$ pour la raie $\bar{\nu}_0 - \bar{\nu}$ = 249 cm^{-1}.

(*iii*) Pour λ_0 = 476.5 nm, k varie de 0.00 pour 1729 cm^{-1} à 1.52 $mol^{-1}\,cm^{-1}$ pour 249 cm^{-1}.

(*iv*) Pour λ_0 = 457.9 nm, k varie de 0.55 pour 1729 cm^{-1} à 6.84 $mol^{-1}\,cm^{-1}$ pour 249 cm^{-1}.

On note que la fréquence $\bar{\nu}$ d'une raie du spectre Raman est toujours inférieure à la fréquence $\bar{\nu}_A$ du maximum d'absorption du spectre électronique.

Mise en évidence d'un effet de résonance Raman des complexes oxalatoferrates

(a) Evolution de l'intensité des bandes Raman du complexe $Fe(C_2O_4)_3^{3-}$ en fonction de la fréquence de la raie excitatrice

Les intensités relatives I_A/I_e, mesurées par rapport à l'intensité I_e de la raie étalon de l'ion ClO_4^- située à 936 cm^{-1} et corrigées de la réponse spectrale et de l'absorption du faisceau laser, sont reportées au tableau 3 en fonction des différentes raies excitatrices utilisées. La dernière colonne du tableau donne le rapport de dépolarisation ρ de chaque bande; celui-ci est pratiquement constant, quelle que soit la fréquence du laser. Nous avons enregistré les spectres plusieurs fois sur différentes solutions de même composition (rapport t = 1/3;

TABLEAU 4. Variation de l'intensité I_A/I_e des bandes de diffusion du complexe $Fe(C_2O_4)^+$ en solution en fonction de la longueur d'onde λ_0 de la raie excitatrice

Bandes de diffusion $\bar{\nu}_0 - \bar{\nu}$ (cm^{-1})	I_A/I_e à raie excitatrice λ_0 (nm)				
	514.5	488.0	476.5	457.9	$\rho = I_{vH}/I_{vv}$
1713	2.88	2.75	2.46	1.82	0.10
1395	0.86	1.94	2.38	3.34	0.28
1258	0.51	0.60	0.59	0.51	0.65
900	0.44	0.57	0.71	0.96	0.25
795	0.20	0.21	0.35	0.83	0.52
548	3.36	4.01	4.52	5.53	0.05
307	4.38	5.87	7.51	13.54	0.10
270	1.67	2.24	2.95	6.35	0.07

CM = 0.167 *M*; pH = 2.8); les intensités des bandes sont constantes.

On constate que l'intensité de la plupart des bandes augmente quand la fréquence de la raie excitatrice $\bar{\nu}_0$ s'approche du maximum $\bar{\nu}_A$ de la bande d'absorption électronique de l'échantillon. Cette variation observée apparait plus nettement sur la fig. 3 qui présente les spectres d'une solution de $Fe(C_2O_4)_3^{3-}$ obtenus en utilisant les raies extrêmes 514.5 et 457.9 nm.

L'intensité des bandes de type A_1 situées à 1729, 560 et 249 cm^{-1} est exaltée par rapport à celles des autres raies du même spectre et des bandes de $Al(C_2O_4)_3^{3-}$. Ces trois bandes subissent une augmentation importante quand $\bar{\nu}_0$ tend vers $\bar{\nu}_A$; le domaine de fréquences du laser dont nous disposions est trop éloignée de $\bar{\nu}_A$ pour nous permettre de tracer le profil d'excitation. L'intensité de la bande dépolarisée de type *E* à 358 cm^{-1} est très faible, elle augmente aussi quand $\bar{\nu}_0$ s'approche de $\bar{\nu}_A$. La même variation est observée pour la bande à 1399 cm^{-1}. Enfin l'intensité de deux bandes dépolarisées situées à 1257 et 795 cm^{-1} attribuables à des modes de type A_2 augmente légèrement.

Ainsi pour le spectre du trioxalate ferrique, la variation de l'intensité des bandes et l'apparition de raies interdites sont certainement la traduction d'un phénomène de Raman de résonance. Cependant la fréquence excitatrice étant toujours très éloignée de la fréquence $\bar{\nu}_A$ du maximum d'absorption électronique, l'absorption n'a lieu que pour des concentrations élevées et nous pensons plutôt qu'il s'agit d'une pré-résonance.

(b) Evolution de l'intensité des bandes Raman des complexes $Fe(C_2O_4)^+$ et $Fe(C_2O_4)_2^-$ en fonction de la longueur d'onde de la raie excitatrice

Les spectres de diffusion de ces deux espèces montrent comme pour le trioxalate des intensités relatives de raies très différentes.

A pH ~ 3 les solutions de $Fe(C_2O_4)^+$ et $Fe(C_2O_4)_2^-$ (10^{-3} *M* en Fe^{3+}) présentent des maximums vers 270 et 265 nm respectivement. Les cœfficients d'absorption molaire sont plus élevés que ceux de $Fe(C_2O_4)_3^{3-}$ mais pas suffisamment pour nous permettre de travailler en solutions diluées. A ces concentrations les complexes sont transparents dans le domaine visible; par contre les valeurs des cœfficients d'absorption molaire *k* aux fréquences de diffusion Raman des solutions plus concentrées étudiées sont:

(*i*) Pour $Fe(C_2O_4)^+$, $1.10 < k < 45.03$ mol^{-1} cm^{-1}.

(*ii*) Pour $Fe(C_2O_4)_2^-$, $0.80 < k < 26.59$ mol^{-1} cm^{-1}.

Nous donnons dans les tableaux 4 et 5 les intensités relatives corrigées I_A/I_e des bandes de diffusion Raman (par rapport à la bande référence de ClO_4^-) pour les différentes longueurs d'onde du laser utilisé. La dernière colonne présente les rapports de dépolarisation des bandes. Les intensités ont été mesurées pour plusieurs solutions, les résultats étant reproductibles. Lorsque la fré-

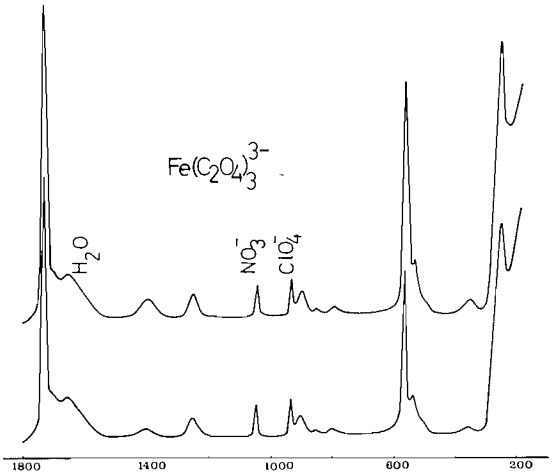

FIG. 3. Spectres Raman du complexe $Fe(C_2O_4)_3^{3-}$ enregistrés avec deux fréquences excitatrices: (*a*) raie 457.9 nm; (*b*) raie 514.5 nm.

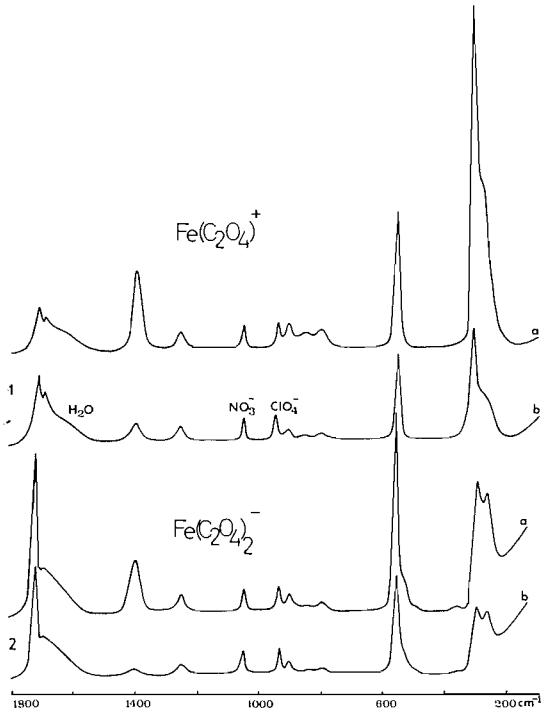

FIG. 4. Spectres Raman: (*1*) $Fe(C_2O_4)^+$; (*2*) $Fe(C_2O_4)_2^-$ enregistrés avec deux fréquences excitatrices ν_0: (*a*) raie 457.9 nm; (*b*) raie 514.5 nm.

quence $\bar{\nu}_0$ s'approche du maximum d'absorption $\bar{\nu}_A$:

(*iii*) Pour le complexe $Fe(C_2O_4)^+$, l'intensité des bandes situées à 1395, 900, 795, 548, 307 et 270 cm^{-1} augmente considérablement, tandis que celle de la bande à 1713 cm^{-1} diminue légèrement. L'intensité de la bande à 1258 cm^{-1} n'est pratiquement pas affectée.

(*iv*) Pour $Fe(C_2O_4)_2^-$ toutes les bandes augmentent d'intensité d'une manière significative, surtout celles à 1394, 555, 297 et 260 cm^{-1}.

Les phénomènes observés pour les deux composés sont dûs aussi à un effet de pré-résonance qui est plus important que dans le cas du trioxalate de fer(III). On présente fig. 4, les spectres Raman de pré-résonance de chaque espèce, enregistrés avec les raies extrêmes 514.5 et 457.9 nm et rapportés à une même intensité des bandes étalons. On voit nettement que par exemple pour $Fe(C_2O_4)^+$ l'intensité de deux bandes 1395 et 270 cm^{-1} est multipliée par 4 environ et celle à 1394 cm^{-1} du complexe $Fe(C_2O_4)_2^-$ est multipliée par 7.

Conclusion

L'étude systématique des solutions colorées d'acide oxalique et de chlorure de fer(III) par spectrométrie Raman, a permis de confirmer sans ambiguité la formation des trois complexes successifs: $Fe(C_2O_4)^+$, $Fe(C_2O_4)_2^-$, $Fe(C_2O_4)_3^{3-}$ et de rejeter l'existence d'une espèce protonée et celle d'une espèce polynucléaire, proposées antérieurement. L'enregistrement des spectres qui n'avait pu avoir lieu jusqu'à présent a été réalisé grâce à un dispositif particulier.

Chacune des espèces mises en évidence est caractérisée par un spectre Raman spécifique. Cependant, compte tenu de la nécessité de travailler à forte concentration et de la très grande stabilité des complexes qui se forment en milieu très acide, il n'a pas été possible de déterminer avec précision la concentration des espèces et d'en proposer une répartition en fonction du pH.

La comparaison entre les spectres ir et Raman des trioxalates de fer(III) et d'aluminium et l'évolution de l'intensité des bandes Raman des trois complexes en fonction de la longueur d'onde de la raie excitatrice du laser ont permis de montrer que les spectres de diffusion des oxalatoferrates présentent un effet de pré-résonance Raman.

Molecular rearrangements.[1] Part XVI. Thermolysis and photolysis of *N*-benzyldiphenylamine and *N*-phenylacetyldiphenylamine

M. Z. A. Badr, M. M. Aly, and A. M. Fahmy

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt, A.R.E.

Received October 25, 1979

M. Z. A. Badr, M. M. Aly, and A. M. Fahmy. Can. J. Chem. **58**, 1229 (1980).

Heating *N*-phenylacetyldiphenylamine in a sealed tube at 360°C gave rise to carbon monoxide, bibenzyl, toluene, stilbene, diphenylmethane, aniline, carbazole, *N*-benzylcarbazole, acridine, 9-phenylacridine, 4-aminotriphenylmethane, diphenylamine, *p*-benzyldiphenylamine, and *o*-aminodiphenylmethane. A similar result was also obtained on heating *N*-benzyldiphenylamine, with the exception of carbon monoxide. Such results in addition to those obtained from photolysis of *N*-phenylacetyldiphenylamine are interpreted in terms of a free-radical mechanism.

M. Z. A. Badr, M. M. Aly et A. M. Fahmy. Can. J. Chem. **58**, 1229 (1980).

Le chauffage de la *N*-phénylacétyldiphénylamine dans un tube scellé à 360°C conduit à la formation des produits suivants: monoxyde de carbone, bibenzyle, toluène, stilbène, diphénylméthane, aniline, carbazole, *N*-benzylcarbazole, acridine, phényl-9 acridine, amino-4 triphénylméthane, diphénylamine, *p*-benzyldiphénylamine et *o*-aminodiphénylméthane. On obtient les mêmes résultats en chauffant la *N*-benzyldiphénylamine à l'exception de la formation du monoxyde de carbone.On interprète ces résultats en plus de ceux obtenus par la photolyse de la *N*-phénylacétyldiphénylamine en fonction d'un mécanisme faisant intervenir un radical libre.

[Traduit par le journal]

The pyrolysis of diphenylamine by passing through a red-hot tube was reported in 1916 (1) to lead to the formation of carbazole. The photoconversion of diphenylamines to carbazoles has been subjected to extensive investigation by many workers (2–4).

The present work throws light on the mechanistic behaviour of *N*-phenylacetyldiphenylamine and *N*-benzyldiphenylamine on their thermolysis and photolysis.

Thermolysis of *N*-phenylacetyldiphenylamine by heating in a sealed tube under nitrogen atmosphere at ca. 360°C for 7 days gives rise to the products shown in Table 1.

The nature of the products suggests the preliminary homolysis of the acyl—N bond giving phenylacetyl and diphenylaminyl radicals. The phenylacetyl radicals decarbonylate (5) forming benzyl radicals which subsequently contribute to the formation of toluene, bibenzyl, and *trans*-stilbene as discussed in a previous work (6) or substitute on diphenylamine (formed through H-abstraction by diphenylaminyl radicals) in the *ortho*- and *para*-positions giving *o*-benzyldiphenylamine and its *p*-isomer (Scheme 1).

9-Phenylacridine is supposed to be formed from its precursor *o*-benzyldiphenylamine through consecutive cyclization and dehydrogenation processes (Scheme 2).

Furthermore, the benzyl radicals may undergo a reversible C—N coupling with diphenylaminyl radicals forming *N*-benzyldiphenylamine that subsequently rearranges into α-anilinodiphenylmethane through N—C phenyl migration from the free radical (I) into (II), probably through a bridged radical intermediate. The rearranged product, α-anilinodiphenylmethane, in turn undergoes pyrolysis forming ultimately aniline, diphenylmethane, and 4-aminotriphenylmethane. This hypothesis was further confirmed by the similar results which were obtained on heating *N*-benzyldiphenylamine under the same conditions (cf. Table 1). Moreover, thermolysis of α-anilinodiphenylmethane affords the formation of aniline, 4-aminotriphenylmethane, and diphenylmethane through homolysis of the C—N bond into anilino and diphenylmethyl free radicals that selectively abstract H, forming aniline and diphenylmethane, respectively, and/or undergo C—C coupling in the *para*-position of aniline, forming 4-aminotriphenylmethane together with a resinous polymeric material of unidentified structure.

The *o*- and *p*-semidine derivatives obtained by Welzel *et al.* (7), due to C—N dimerization of diphenylaminyl radicals generated through thermolysis of tetraphenylhydrazine, were not detected by us, due to the presence of the relatively more reactive benzyl radicals that ultimately change the fate of diphenylaminyl radicals through coupling at the *ortho*- and *para*-positions, forming the benzyldiphenylamines identified among the products. On the other hand, the instability of the

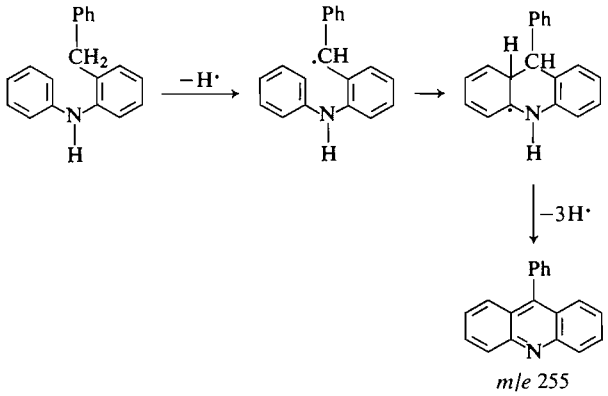
Residue	Non-volatile	1.80	(6.20)	1.25	(4.80)

[a] n_D^{20}: 1.4970; 2,4-dinitro derivative mixture mp 72°C.
[b] n_D^{27}: 1.5788; on oxidation with $K_2Cr_2O_7/H_2SO_4$ gave benzophenone; dinitrophenylhydrazone derivative mp, and mixture mp 237–238°C.
[c] Mixture mp 52°C; 4,4′-dinitro derivative mixture mp, 179–180°C.
[d] Mixture mp 124°C.
[e] n_D^{20}: 1.5836; acetyl derivative mp and mixture mp 113–114°C.
[f] Melting point and mixture mp 54°C, picrate mixture mp 182°C.
[h] Separated by column chromatography on silica gel (100–150 mesh) using benzene as eluent into *o*-isomer 0.15 g, acetyl derivative mixture mp 135°C and *p*-isomer 1.50 g, picrate mixture mp 179°C.
[i] 9-Phenyl acridine mixture mp 182–183°C, picrate mixture mp 185–186°C, and a trace amount of acridine as found by tlc, R_f values 0.54 and 0.65, respectively.
[j] Mixture mp 197–199°C.
[k] Mixture mp 199–200°C.
[l] Identified by preparative tlc using ether – petroleum ether (40–60°), 1:7 v/v, as eluent; carbazole R_f 0.35, picrate mp 185°C and *N*-benzylcarbazole R_f 0.27, picrate mp 104–105°C.
[m] Present as trace amount not more than 0.1% in diphenylamine fraction as found by preparative tlc; $R_{f(aniline)}$ 0.76, acetyl derivative mixture mp 113–114°C.
[n] Present as trace amount not more than 0.1% in acridine fraction as found by preparative tlc; $R_{f(ortho)}$ 0.72 and $R_{f(para)}$ 0.69 and their ir spectra are coincident with authentic samples.
[o] Present as trace amount not more than 0.1% in carbazole fraction as found by preparative tlc; R_f 0.46, and was further identified by coincidence of its ir spectrum with that of an authentic sample.



expected N—N coupling product tetraphenylhydrazine (7) under the conditions used must be responsible for its absence among the products.

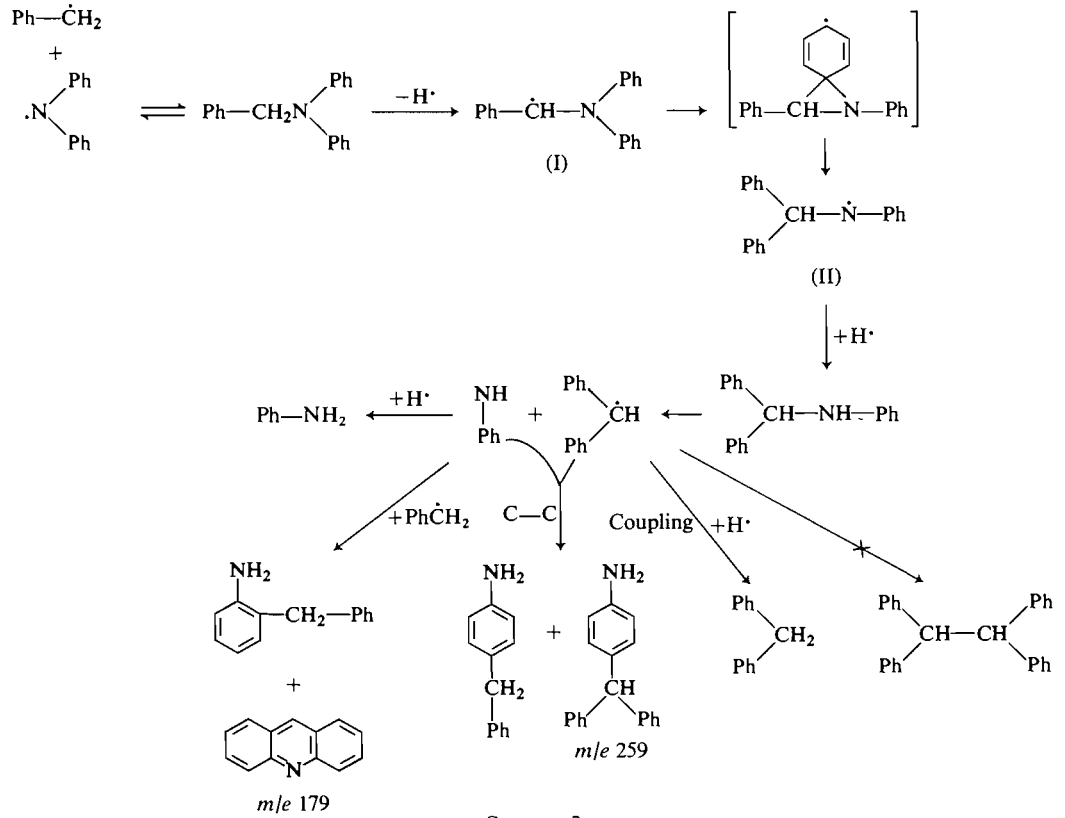
The plausible explanation for carbazole formation is through cyclization of diphenylaminyl radicals (Scheme 4) and not from diphenylamine, since prolonged heating of diphenylamine under the same conditions does not afford carbazole.

The *o*- and *p*-aminodiphenylmethanes can reasonably be assumed to form through coupling of

SCHEME 1

SCHEME 2

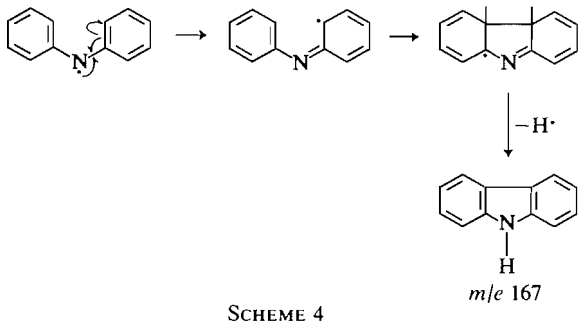
benzyl and phenylaminyl radicals. The *o*-isomer undergoes cyclization into acridine as described in a previous work (8) whereas the *p*-isomer remains unattacked.



Thermolysis of *N*-benzyldiphenylamine by heating in a sealed tube at ca. 360°C for 7 days gives rise to the same products as those obtained from thermolysis of *N*-phenylacetyldiphenylamine with the exception of carbon monoxide. Although some of the products are present in trace amounts due to the variable rate of decay of the free radical intermediates, yet their presence is of great importance for mechanistic interpretation. Such results can be explained by homolysis of the benzyl—N bond, furnishing benzyl and diphenylaminyl radicals that follow the previously mentioned chain sequence.

Irradiation of *N*-phenylacetyldiphenylamine in carbon tetrachloride as an aprotic solvent for 60 h leads to the formation of diphenylamine, *N*-benzyldiphenylamine, carbazole, 9-phenylacridine, *N*-benzylcarbazole, and *p*-benzyldiphenylamine as the only amine products. It is noteworthy that aniline, 4-aminotriphenylmethane, *o*- and *p*-aminodiphenylmethanes are absent among the products as detected by tlc.

Such main differences between thermolysis and photolysis indicate that the benzyl and diphenylaminyl radicals are held together within the solvent cage following a route analogous to Schemes 1, 2, and 4 rather than forming α-anilinodiphenylmethane as a preliminary product.



Experimental

All melting points are uncorrected. The ir spectroscopic analyses were carried out on a Pye-Unicam ir spectrophotometer, model SP 200G. The uv absorptions were carried out on a Pye-Unicam uv spectrophotometer, model SP 8000 using 95% ethanol as solvent. Gas–liquid chromatographic analysis was carried out on a Pye-Unicam gas chromatograph, "Series 104",

SCHEME 3

SCHEME 4

dual flame ionization detector, model 24, and the columns used were 4 ft × 5 mm packed with 20% SE30 on Chromosorb W (35–80 mesh) at 180°C and/or 10% SE30 on Celite (60–80 mesh). Thin-layer chromatography was carried out on plates covered with silica gel (25–40 mesh) and eluted with benzene–cyclohexane (3:1 v/v) or ether – petroleum ether (40–60°C) (1:7 v/v). Ultraviolet irradiation was carried out using a Mallinkrodt 150 W mercury discharge lamp.

Solvents used were of AnalaR grade and were used without further purification.

Molecular weight determinations of some reaction products were carried out by mass spectrophotometer, model A.E.I.M.S. 902.

Thermolysis of N-*Phenylacetyldiphenylamine and* N-*Benzyldiphenylamine*

N-Phenylacetyldiphenylamine (29 g, 0.1 mol) or *N*-benzyldiphenylamine (26 g, 0.1 mol) was heated in a sealed tube under nitrogen at about 360°C for 7 days. The tube was chilled in ice, opened, and the carbon monoxide formed in the case of *N*-phenylacetyldiphenylamine was detected by platinum chloride test paper and by absorption in a trap containing ammoniacal cuprous chloride (6). The products were separated as indicated in a previous work (6) and identified by elemental analysis, ir spectroscopy, and mixture mp determination with authentic samples and their derivatives, whenever possible, as summarized in Table 1.

Thermolysis of α-*Anilinodiphenylmethane*

α-Anilinodiphenylmethane (10 g) was heated in a sealed tube under nitrogen for 3 days and was worked up as mentioned previously to afford 4-aminotriphenylmethane (3.6 g, 36%), aniline (1.2 g, 12%), diphenylmethane (2.3 g, 23%), and a resinous polymeric material (2.4 g).

Photolysis of N-*Phenylacetyldiphenylamine*

N-Phenylacetyldiphenylamine (1 g) in carbon tetrachloride (100 mL) was irradiated at room temperature (25°C) for 60 h. The photolysate was separated into neutral and amine products. The neutral products were identified by glc as bibenzyl and stilbene in the ratio 1:2.5. The amine products were identified by tlc and their R_f values are indicated using ether – petroleum ether (40–60°C) (1:7, v/v) as eluent: diphenylamine (0.81), *p*-benzyldiphenylamine (0.76), *N*-benzyldiphenylamine (0.64), carbazole (0.35), *N*-benzylcarbazole (0.27), and 9-phenylacridine (0.21).

Preparation of Reference Compounds

N-*Benzyldiphenylamine* (ref. 9): needles from ethanol, mp 85–86°C.

N-*Phenylacetyldiphenylamine* (ref. 10): crystallized from ether, mp 73–74°C.

Bibenzyl (ref. 11): crystallized from ethanol, mp 52°C; 4,4′-dinitro derivative, mp 180°C.

trans-*Stilbene* (ref. 12): crystallized from ethanol, mp 123–124°C.

Diphenylmethane (ref. 13): crystallized from petroleum ether (40–60°C), mp 26°C, n_D^{27}: 1.5788.

9-Phenylacridine (ref. 14): yellow prisms from ethanol, mp 182–183°C; picrate, mp 185–186°C.

o-*Aminodiphenylmethane* (ref. 15): crystallized from petroleum ether (40–60°C), mp 51–52°C, acetyl derivative, 135°C.

p-*Aminodiphenylmethane* (ref. 16): crystallized from petroleum ether (40–60°C), mp 34–35°C; picrate, mp 179°C.

α-*Anilinodiphenylmethane* (ref. 17): prisms from ethanol, mp 58°C; bp 224°C/12 Torr; HCl salt, mp 202–203°C.

4-Aminotriphenylmethane (ref. 18): crystallized from ethanol, mp 199–201°C.

N-*Benzylcarbazole* (ref. 19): crystallized from ethanol, mp 114–116°C, picrate, mp 105°C.

p-*Benzyldiphenylamine* (ref. 20): crystallized from ethanol, mp 199°C.

The reaction of malondiamides with disulfur dichloride: a reinvestigation

GERALD W. KUTNEY AND IAN W. J. STILL
Erindale College, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received August 22, 1979

GERALD W. KUTNEY and IAN W. J. STILL. Can. J. Chem. **58**, 1233 (1980).

The reactions of a series of *N, N'*-dialkyl and *N,N'*-diaryl malondiamides with disulfur dichloride have been reinvestigated. The claim, made almost 60 years ago, that the products of this reaction are dithioketones R_2CS_2, is shown to be unfounded. The structures of these products are shown to be the symmetrically substituted 1,2,4,5-tetrathianes, **8***a–e*.

GERALD W. KUTNEY et IAN W. J. STILL. Can. J. Chem. **58**, 1233 (1980).

On a de nouveau étudié les réactions d'une série de *N,N'*-dialkyle et de *N,N'*-diaryle malonediamides avec le disulfure de chlore. Contrairement à ce qu'on pensait il y a de cela près de 60 ans, les produits de la réaction ne sont pas les dithiocétones R_2CS_2. On démontre que les produits sont les tétrathianes (**8***a–e*) substituées d'une façon symétrique en positions 1,2,4,5.

[Traduit par le journal]

Introduction

Although the first literature reports of the reaction of sulfur chlorides (S_2Cl_2 and SCl_2) with active methylene compounds are now almost 100 years old (1, 2), the apparent complexity of these reactions and the unusual nature of some of the products claimed have ensured a continuing, albeit sporadic, interest in the topic which has manifested itself in a number of recent publications (3–6). A closely related topic, which has also generated a good deal of recent interest, is the reaction of similar active methylene compounds with thionyl chloride (7–9).

The impetus for our present study, involving mainly the reactions of disulfur dichloride (sometimes referred to as sulfur monochloride) with active methylene compounds, was the intriguing, but so far unverified, report by Naik (10) that *N,N'*-diphenylmalondiamide **1***d* and related malondiamide derivatives afforded the "dithioketone" (thiosulfine) products **2**, formulated also by Naik as the dithiirane species **3**. The evidence for the "dithioketone" rested largely on the results of further chemical transformations of **2** and on the elemental analysis data. The fact that, almost 60 years later, no compound possessing the structural features of either **2** or **3** has been isolated [1] indicated to us that Naik's proposed structures were probably incorrect. In addition, the work of Hope and Wiles (4), which claimed that *N,N'*-diphenylmalondiamide and disulfur dichloride, when refluxed in benzene (the solvent used by Naik) in a 1:1 molar ratio, produced the tetrasulfide **4** ($n = 4$, $R = C_6H_5$) in 86% yield, appeared to be at variance not only with the results claimed by Naik but also with the behavior of another simple β-dicarbonyl compound, ethyl acetoacetate. Gompper *et al.* (3) had shown one year previously that ethyl acetoacetate on treatment with disulfur dichloride in a 2:1 molar ratio at 25°C in petroleum ether produced the simple symmetrical sulfide derivative **5**. Hope and Wiles (4) also demonstrated an apparent sensitivity of the reaction with disulfur dichloride to solvent effects by showing that malondiamide itself reacted only in refluxing dioxane, and not in refluxing benzene, to produce the trisulfide **4** ($n = 3$, $R = H$). Pizey and Symeonides (12) have very recently claimed the formation of di- or trisulfide type products on treatment of 2,4-pentanedione with disulfur dichloride, depending on the reaction conditions. Thus, all types of S_n-linked β-dicarbonyl compound from $n = 1$ to $n = 4$ have been reported. It seems clear, however, that a number of questions remain to be answered in this area and we have attempted to address these in the present paper.

[1]Several authors have claimed the intermediacy of such species in certain reactions. See, for example, one very recent report by Senning (11).

Results and Discussion

In order to investigate the reaction of β-dicarbonyl compounds of the *N,N'*-diphenylmalondiamide type with disulfur dichloride a series of *N,N'*-disubstituted malondiamides **1***a–h* was prepared by a standard literature route (13) by refluxing diethyl malonate with the appropriate primary amine. The products obtained, with the yields and some physical properties, appear in Table 1. Attempts to prepare the di-*tert*-butyl and di-4-nitrophenyl analogues by this route, or from malonyl dichloride, were unsuccessful. It will be noted from Table 1 that yields of the *N,N'*-dialkylmalondiamides were generally much higher than for their diaryl counterparts.

[a]Isolated yields of the diamides, recrystallized at least twice from ethanol.
[b]Spectra of compounds **1***a, b, c, g* were recorded in $CHCl_3$-*d*; those for entries **1***d, e, f, h* in DMSO-d_6.
[c]^{13}C nmr data showed δ for the C=O carbon consistently at 165–166 ppm.

the reaction of *N,N'*-disubstituted malondiamides with S_2Cl_2 in refluxing benzene (the conditions used by Naik (10)) indicated that these easily isolated, white crystalline solids were fully substituted on the central methylene carbon atoms, since no ^{1}H nmr signals attributable to —CO*CH*CO— or —COCH_2CO— groupings, or to enolic protons (17), were present (cf. Table 1 for nmr data of starting compounds). This seemed to indicate that the type of product **4**, reported by Hope and Wiles (4), was not formed under our conditions and we were thus left to conclude that (*a*) one of Naik's suggested structures **2** or **3** for these products was correct or (*b*) that some other structural feature which explained the ^{1}H nmr results must be present. In the latter case, we felt that the most reasonable structures to be considered were the 1,3-dithietane **6**, the 1,2,4-trithiolane **7**, or the 1,2,4,5-tetrathiane **8**. Around this time we were interested to discover a recent correction to a literature report of some 50 years earlier proposing the intriguing structure **9** for a reaction product. Berry *et al.* (18) have shown, using mass spectral and ^{125}Te Mössbauer studies, that **9** should in fact be formulated as the dimeric compound **10**. The obvious analogy between this situation and the one which we were investigating encouraged us to explore this possibility further. It is interesting to note in passing that the reaction of ethylamine with S_2Cl_2 has been reported to give the tetrathiane derivative **11***a* (19), while, more recently, Appel and Montenach (20) have reported the isolation of the analogue **11***b*, by the reaction of *N*-trimethylsilylbenzenesulfonamide with S_2Cl_2.

The results of the reactions of several malondiamide derivatives with S_2Cl_2 in a 1:2 molar ratio are summarized in Table 2, along with the major ^{1}H and ^{13}C nmr features of the products (*N,N'*-di-2,4-dichlorophenylmalondiamide gave a complex mixture of products in addition to a 36% recovery of the starting material). Elemental analysis data confirmed the empirical formulas to be as reported by Naik (10), which eliminates structures **6** and **7** from consideration. In the ^{1}H nmr spectra the main feature of interest concerns the chemical shift of the NH protons which appeared at around 7 ppm in the *N,N'*-dialkyl examples, as they had in the starting malondiamides, but at around 9 ppm in the diaryl examples. The apparent upfield shift (compared to

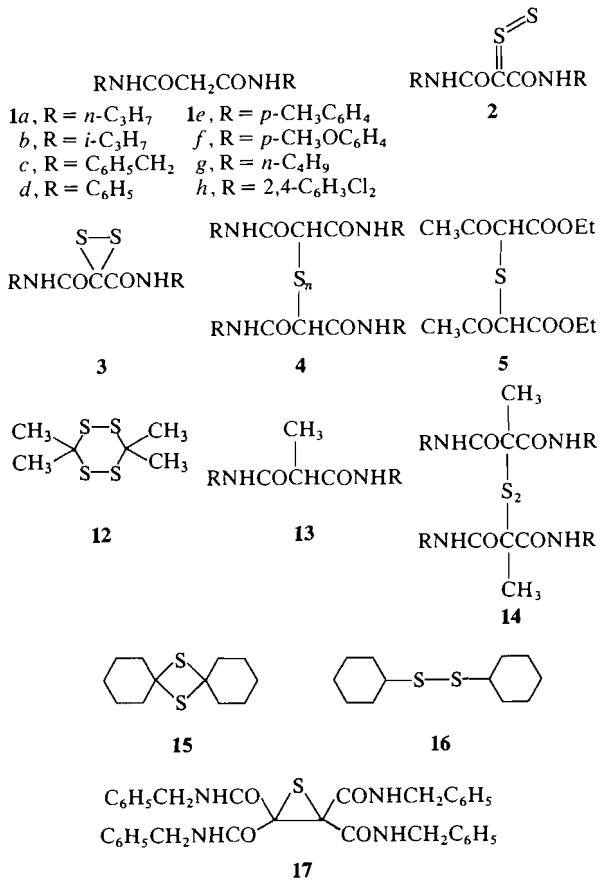

TABLE 2. Tetrathianes (**8***a–f*) from reactions of malondiamides (**1***a–f*) with S_2Cl_2

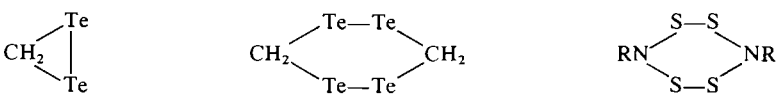
[f]This product appeared to be present from the ^{1}H nmr spectrum but decomposed upon (repeated) attempts at purification.

the starting compounds **1**) in the latter cases is almost certainly the result of a solvent change from DMSO-d_6 to $CHCl_3$-d_1. Not unexpectedly, we have also found the NH proton chemical shifts to vary significantly with concentration. The ^{13}C nmr chemical shifts for the fully-substituted central carbon atoms (former methylene group) and the carbonyl carbons also appear in Table 2. It should be noted that, although no data exist in the literature for direct comparison, the relatively high-field location of the former set of signals at ca. 73–75 ppm is much more in accord with the presence of an sp^3-hybridized carbon, such as is present in **8***a–e*, than the sp^2-hybridized carbon required by Naik's proposed structure **2**. Data have appeared in the literature for the ^{13}C nmr chemical shifts for a series of 2,2-disubstituted 1,3-dithianes (21), which appear in the range 45–54 ppm, and some ketone dithioacetals (22), with δ values even closer to those in Table 2, in the range 55–65 ppm. The model compound, 3,3,6,6-tetramethyl-1,2,4,5-tetrathiane **12**, was synthesized by a known procedure (23) and found to show a chemical shift of δ 59.1 for the quaternary carbons. In the series of tetrathianes **8***a–e* one would expect this value to be shifted to lower field by the presence of two carbonyl-bearing groups at each quaternary position.



Clearly, the most effective method to distinguish the possible structure type **8** from the "monomeric" structures such as **2**, **3** proposed by Naik, is to determine the molecular weights of the products in Table 2. Mass spectral evidence for a molecular ion peak was obtained only in the case of the *N,N'*-diisopropyl analogue. Significantly, however, fragment ions at *m/e* values substantially greater than called for by molecular formulas of type **2** or **3** were found in all cases. We then turned to other methods of molecular weight determination and the results of some Rast camphor melting point depression measurements and osmometric determinations are collected in Table 3. The results are in very good agreement with the 1,2,4,5-tetrathiane structure **8** for the products in Table 2. Determinations were not made in all cases, given the already demonstrated similarities in the nmr spectra of these compounds (Table 2).

The remaining points of interest in this investigation concern a possible mechanism for the conversion of **1** by S_2Cl_2 into **8** and an explanation for the formation of the acyclic tetrasulfide products in the work of Hope and Wiles (4). We have carried

out a number of experiments using *N,N'*-dibenzylmalondiamide and S_2Cl_2, varying factors such as number of equivalents of S_2Cl_2, temperature, and reaction time. In no case was any product other than the tetrathiane **8***c* isolated, although lowering the reaction temperature and reducing the amount of disulfur dichloride present from 2 to 0.5 equivalents sharply reduced the yields obtained.[2] There was no evidence for the formation of any disulfide **4** ($n = 2$, R = $C_6H_5CH_2$), in accordance with Naik's results (10), nor could we detect any evidence for an intermediate monosubstituted malondiamide of this general type when the reaction was monitored throughout by nmr. It seems to us that those findings, and other features such as the lack of formation of tetrathianes with tertiary malondiamides and also the much greater reactivity (towards S_2Cl_2) of all the malondiamides studied than simple β-diketones such as 2,4-pentanedione,[3] can be accounted for by an initial *N*-sulfenylation step and the possible, although not essential, intermediacy of a 1,2,3-dithiazolidine, as shown in Scheme 1. *N*-Sulfenylation with S_2Cl_2 is well precedented, not only for amides (4) but also for aromatic amines (24) and, very recently, for ketone hydrazones (25) where, interestingly, the authors also propose a dithioketone intermediate. It is of interest to note that the methylmalondiamides **13** were reported to readily form disulfides **14** with disulfur dichloride, possibly via a similar pathway (10, 26).

One interesting observation which may explain the isolation of the acyclic tetrasulfide **4** ($n = 4$) by Hope and Wiles was our finding that increasing the reflux time employed in the reaction of *N,N'*-diphenylmalondiamide with S_2Cl_2 from 3 to 6 h (in benzene) produced a product which was clearly not the 1,2,4,5-tetrathiane **8***d* produced earlier, but a buff solid which was almost insoluble in all the common organic solvents and may be the tetrasulfide reported by Hope and Wiles. It was also found that a sample of the tetrathiane **8***d* when left exposed to air and light for several days appeared to give the same type of highly insoluble product. A mechanistic proposal for the apparent rearrangement at this stage would be conjectural but apparently involves a C—S bond cleavage of some sort

and has analogy in the interesting photochemical rearrangement of **15** to the disulfide **16** (27).

Attempts to study the chemical behavior of the tetrathianes **8***a–e* have been made, but with little success. For example, these compounds did not react with hydrogen peroxide in acetone after six days at 25°C, or on refluxing for several hours, and also showed no reaction with H_2O_2-acetic acid at room temperature for several days. In contrast, refluxing for relatively short periods of time under the latter set of conditions led to extensive decomposition. Attempted ring cleavage of the tetrathianes with 2-methyl-2-propanethiolate ion also led to extensive decomposition. Photochemical cleavage/rearrangement was not attempted on compounds **8***a–e* directly, but the irradiation of the model tetrathiane **12** with a 400-W medium pres-

[2]One of the referees has suggested that the molar ratio of the reactants may be critical in determining the products formed (cf. refs. 3 and 4). Our results do not support this view, although it is clear that the reactions appear to be sensitive to other changes in the reaction conditions, such as temperature, reaction time, solvent polarity, etc.

sure mercury lamp, for 25 h in acetonitrile led to recovery of the starting material. More promisingly, the reaction of the *N,N'*-dibenzyl analogue **8***c* with triphenylphosphine in benzene led to the formation of the thiirane **17** in very good yield.[4] Further studies on this reaction of the tetrathiane derivatives are continuing.

Experimental

Infrared spectra were recorded with a Pye-Unicam SP1000 spectrometer and mass spectra on the Bell and Howell 21-490 instrument. The ^{1}H nmr spectra were recorded on a Varian EM-360 spectrometer and the ^{13}C nmr spectra on a Varian XL-100-15(FT) instrument at 25.16 MHz, operating at 32 ± 3°C, with acquisition times of 0.666 s and pulse widths of 12 μs (90° "flip angle" ≡ 55 μs). Melting points were determined using an Electrothermal Mark II apparatus and osmometric measurements on the Hewlett-Packard 302 Vapor Pressure Osmometer.

Synthesis of N,N'-*Disubstituted Malondiamides* **1**a–h

These were synthesized from diethyl malonate (see Table 1) by the general procedure of Whiteley and co-workers (13). Attempts to synthesize the *N,N'*-di-*tert*-butyl and *N,N'*-di-4-nitrophenyl analogs by this route, and others, were unsuccessful.

Reaction of Malondiamides with S_2Cl_2

(**8***a*): *N,N'*-Di-*n*-propylmalondiamide **1***a* (1.00 g, 5.38 mmol) and disulfur dichloride (1.50 g, 11.11 mmol) in 25 mL benzene were refluxed for 3 h. Evaporation of the solvent yielded the tetrathiane **8***a* (1.07 g, 80%). Recrystallization from hot absolute ethanol yielded white crystals: mp 195–195.5°C; ir ($CHCl_3$) ν: 3440 (NH), 1685 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.70–1.02 (t, 3), 1.18–1.86 (m, 2), 3.00–3.40 (q, 2), 6.98–7.30 (t, 1); ^{13}C nmr ($CDCl_3$) δ: 11.2 (CH_3), 22.5 (CH_2), 42.4 (CH_2NH), 73.9 (>C<), 162.2 (CO). *Anal.* calcd. for $C_{18}H_{32}N_4O_4S_4$: C 43.53, H 6.49, N 11.28, S 25.82; found: C 43.43, H 6.38, N 11.22, S 26.07.

(**8***b*): Prepared as **8***a* above. Infrared ($CHCl_3$) ν: 3420 (NH), 1680 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.08–1.40 (d, 6), 3.67–4.39 (q, 1), 6.80–7.06 (d, 1); ^{13}C nmr ($CDCl_3$) δ: 22.1 (CH_3), 43.2 (CH), 74.0 (>C<), 165.4 (CO). *Anal.* calcd. for $C_{18}H_{32}N_4O_4S_4$: C 43.53, H 6.49, N 11.28; found: C 42.91, H 6.44, N 11.19.

(**8***c*): Prepared as **8***a* above. Infrared ($CHCl_3$) ν: 3430 (NH), 1685 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.34–4.55 (d, 2), 7.08–7.63 (m, 6); ^{13}C nmr (DMSO-d_6) δ: 44.7 (CH_2), 73.9 (>C<), 127.5–136.7 (aromatic), 166.1 (CO). *Anal.* calcd. for $C_{34}H_{32}N_4O_4S_4$: C 59.28, H 4.68, N 8.13; found: C 58.85, H 5.24, N 7.76.

N,N'-Dibenzylmalondiamide **1***c* (0.11 g, 0.39 mmol) and disulfur dichloride (0.11 g, 0.81 mmol) in 2 mL $CDCl_3$ were placed in an nmr tube. The nmr spectrum was taken at approximately 5-min intervals. By monitoring the disappearance of the active methylene protons, it was determined that the reaction was over in 55 min at 25°C.

(**8***d*): Prepared as **8***a* above. Infrared (Nujol) ν: 3380, 3300 (NH), 1685, 1670 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.80–7.58 (m, 5), 8.92 (s, 1). *Anal.* calcd. for $C_{30}H_{24}N_4O_4S_4$: C 56.94, H 3.82, N 8.85; found: C 56.88, H 3.79, N 8.87.

N,N'-Diphenylmalondiamide (2.10 g, 8.33 mmol) and disulfur dichloride (1.13 g, 8.37 mmol) in 17 mL benzene were refluxed in an additional experiment for 6 h (4). Filtration yielded a buff colored solid (2.20 g). This compound was insoluble in all the common organic solvents. A sample of tetrathiane (prepared above) which had been left open to the air for several days changed dramatically in solubility characteristics and appeared finally to be identical with the insoluble product above.

(**8***e*): Prepared as **8***a* above. Infrared ($CHCl_3$) ν: 3430 (NH), 1685 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.29 (s, 3), 6.92–7.50 (m, 4), 8.88 (s, 1); ^{13}C nmr ($CDCl_3$) δ: 21.0 (CH_3), 75.3 (>C<), 120.5–135.6 (aromatic), 164.1 (CO). *Anal.* calcd. for $C_{34}H_{32}N_4O_4S_4$: C 59.28, H 4.68, N 8.13, S 18.62; found: C 58.72, H 4.79, N 8.09, S 18.61.

(**8***f*): *N,N'*-Di-4-methoxyphenylmalondiamide **1***f* (1.00 g, 3.18 mmol) and disulfur dichloride (0.89 g, 6.59 mmol) in 25 mL benzene were refluxed for 3 h. Removal of the solvent yielded a brown solid (1.18 g). Attempted purification by thick layer chromatography led to extensive decomposition upon addition of methanol.

3,3,6,6-Tetramethyl-1,2,4,5-tetrathiane **12**

This compound was prepared in 14% yield by the procedure of Magnusson (23); mp 92–95°C (lit. (28) mp 98°C).

Preparation of 2,2,3,3-Tetrabenzylcarbamoylthiirane **17**

The tetrathiane **8***c* (0.69 g, 1.00 mmol) and triphenylphosphine (0.52 g, 2.00 mmol) were stirred in benzene (20 mL) for 16 h at 25°C. Filtration yielded a white solid. Evaporation of the solvent yielded triphenylphosphine sulfide (0.35 g, 58%), mp 160–161°C (lit. (29) mp 157.5°C). Recrystallization of the white solid from 95% ethanol yielded the thiirane **17**, (0.32 g, 82% based on triphenylphosphine), mp 196–198°C. Infrared (Nujol) ν: 3315 (NH), 1680 (CO) cm^{-1}; ^{1}H nmr (DMSO) δ: 4.15–4.35 (d, 2), 7.20 (5H, s) 8.40 (1H, m). *Anal.* calcd. for $C_{34}H_{32}N_4O_4S$: C 68.88, H 5.44, N 9.46, S 5.41; found: C 68.21, H 5.92, N 9.18, S 5.28.

Air oxidation of Reissert compounds

MARIA D. ROZWADOWSKA AND DANUTA BRÓZDA

Institute of Chemistry, Adam Mickiewicz University, Grunwaldzka 6, 60-780 Poznań, Poland

Received December 10, 1979

MARIA D. ROZWADOWSKA and DANUTA BRÓZDA. Can. J. Chem. **58**, 1239 (1980).

Reissert compounds undergo autoxidation in basic solution giving rise to isoquinaldo- or quinaldonitriles. Under the same reaction conditions, dihydroisoquinoline Reissert compounds undergo oxidative decyanation to dihydroisocarbostirils. The intermediacy of α-peroxycyanides is proposed in this transformation.

MARIA D. ROZWADOWSKA et DANUTA BRÓZDA. Can. J. Chem. **58**, 1239 (1980).

Les composés de Reissert subissent une autoxydation en solution basique pour conduire aux isoquinaldo- ou aux quinaldonitriles. Dans les mêmes conditions les composés de Reissert du type dihydroisoquinoléine subissent une décyanation oxydative conduisant aux dihydroisocarbostiriles. On propose des α-péroxycyanures comme intermédiaires dans cette transposition.

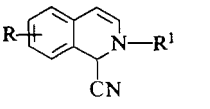
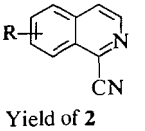
In a previous paper (1) we described the tendency of various Reissert compounds to undergo autoxidation in basic solution and reported that the course of the reaction is dependent on the oxygenation state of the compound. This has also been confirmed by other authors (2).

In this paper we wish to report the results of our further study in this area, particularly concerning the formation of intermediates in the oxidation of Reissert compounds containing the *N*-benzoyl group. We have measured the amount of oxygen used as well as established the form in which the cyano substitutent is eliminated from dihydro derivatives.

From the experimental point of view the phase-transfer conditions (3), or rather the two-phase catalytic system (4), used for the generation of carbanions proved to be the most convenient method for the measurements. The oxygen was taken from the air, the consumed amount being determined from the difference in volume before and after the reaction. The experiments were carried out under atmospheric pressure and at room temperature. Only derivatives with the *N*-benzoyl group could be used, because *N*-alkoxycarbonyl derivatives appeared to release volatile components in the course of oxidation; similarly, the dimethylformamide – sodium hydride procedure, used for the generation of carbanions, had to be dismissed.



We have found that isoquinoline derived Reissert compounds **1***a* and **5***a* need only a half-molar equivalent of oxygen to be oxidized to isoquinaldonitrile and dihydroisocarbostiril, respectively. In the product mixtures benzoic acid (90% of theory) and hydrogen cyanide (determined as AgCN, 80% of theory) could be found.



Oxidation of Reissert Compounds

It is well established that Reissert compounds **1**, **3** are readily converted into the corresponding heteroaromatic nitriles **2**, **4** in alkaline solutions (5–10). No mechanistic interpretation of this process has been given, although it has been suggested occasionally (9, 10) that the nitriles could have resulted from an interaction of Reissert anions with oxygen.

As can be seen from Schemes 1 and 2, Reissert compounds derived from isoquinolines **1** and quinolines **3** are oxidized to isoquinaldonitriles **2** and quinaldonitriles **4**, respectively, independently of the nature of the *N*-substituent. The yields are usually high, except for quinoline derivatives, where large amounts of insoluble polymers are formed.

In the case of *N*-sulfonyl derivatives **1***e*, *f*, these compounds could be transformed into isoquinaldonitriles even without the presence of oxygen. Among the products of this reaction corresponding sulfinic acid was found (5), which indicates that an internal red.–ox. process takes place.

SCHEME 2. Oxidation of quinoline Reissert compounds in the two-phase catalytic system.

The base-catalysed autoxidation of nitriles is well known (11–16). α-Alkylated arylacetonitriles or α-amino arylacetonitriles (to which belong Reissert compounds) undergo oxidative decyanation giving rise to ketones and isocyanates. However, only dihydro Reissert compounds behave in this way, being oxidized to carbonyl derivatives, whereas "normal" ones give the corresponding heteroaromatic nitriles. This difference can be explained if one considers that an alternative pathway of oxidizing a dihydro system versus an aromatic system exists.

A 2:1 molar ratio of Reissert compound to oxygen agrees well with the formation of 1 mol of benzoic acid and 1 mol of nitrile. We now would like to propose a plausible mechanism suggesting that the initially formed Reissert anion combines with molecular oxygen leading to a peroxy intermediate. In the two-phase catalytic system, the peroxy species decomposes immediately and oxidizes a second molecule of Reissert compound.

Although we were not able to perform a positive iodine–starch test at various stages of this reaction, we succeeded in oxidizing 2-benzoyl-1,2-dihydroisoquinaldonitrile **1***a* into isoquinaldonitrile **2***a* both by *m*-chlorperbenzoic acid and by hydrogen peroxide in the two-phase system and under an argon atmosphere. Benzoyl peroxide in catalytic amounts did not affect the rate of the autoxidation, but gave the same result when used in stoichiometric amounts.

Oxidation of Dihydro Reissert Compounds

The oxidation of *N*-benzoyl and *N*-alkoxycarbonyl dihydroisoquinoline Reissert derivatives **5***a–e* gave dihydroisocarbostiriles **6***a–e* or their *N*-acyl derivatives **8** (Scheme 3).

Hydrastinine pseudo-cyanide **5***h* was converted into oxyhydrastinine **6***h*, (NCH_3) in high yield.

N-benzenesulfonyl- and *N*-*p*-toluenesulfonyl-1-cyano-1,2,3,4-tetrahydroisoquinolines **5***f*, *g* as well as dihydroquinoline Reissert compounds **7** do not enter into the reaction with oxygen even at −76°C and with butyl lithium as the base.

In several experiments, in which the autoxidation of **5***a* and **5***d* was stopped immediately after the uptake of oxygen ceased, we were able to isolate the *N*-benzoyldihydroisocarbostiril **8**. This indicates that the initial oxidation is followed by hydrolysis.

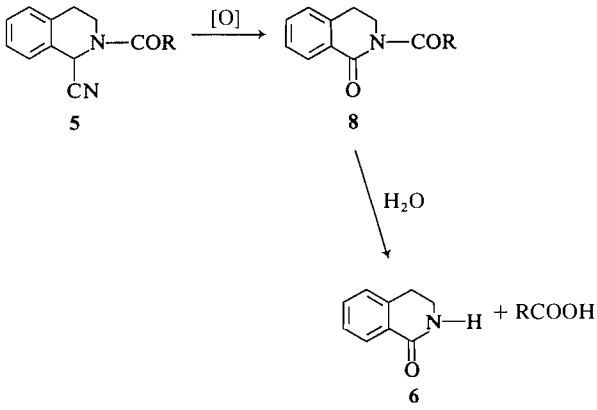
SCHEME 3. Oxidation of dihydroisoquinoline Reissert compounds in the two-phase catalytic system.

As has been mentioned before, the action of molecular oxygen on dihydro Reissert compounds yields carbonyl derivatives in a way similar to that in which aryl acetonitriles or α-amino arylacetonitriles are oxidized to ketones (11–16). In the latter case the cyano group is oxidized as well and eliminated as an isocyanate. Intermediate α-hydroperoxy nitriles have been isolated (14, 16, 17) in reactions carried out at low temperatures, in anhydrous solvents, and in the presence of such bases as potassium *tert*-butoxide or lithium diisopropylamide. A detailed kinetic study (16) revealed that a further decomposition of the peroxy nitriles to the carbonyl derivatives and isocyanates proceeds via a four-membered dioxetane as an intermediate.

In the case of oxidation of dihydro Reissert compounds in the two-phase system, where only a



7
a R = C_6H_5
b R = OC_2H_5

9
a R = H
b R = $COCH_3$

half-molar equivalent of oxygen is consumed, one would expect the elimination of the cyanide rather than the isocyanate ion. Indeed, this was the case. We were able to precipitate silver cyanide in 80% yield from the reaction in which 2-benzoyl-1,2,3,4-tetrahydroisoquinaldonitrile **5***a* was oxidized. We also got a positive cyanide test simply by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

treating the alkaline water layer, which was left after the separation of the organic phase, with ferrous sulfate and hydrochloric acid. At the same time the pyridine – cupric sulfate test (18) for the detection of isocyanates was negative.

Taking these facts into consideration, one could propose the following mechanism for the autoxidation of dihydro Reissert compounds in the two-phase system. The initial step also involves the formation of α-hydroperoxy cyanide, which then oxidizes a second molecule of the Reissert compound. In this way either a dimeric peroxide or two molecules of cyanohydrin are formed. The latter is known to readily undergo base-catalysed decomposition. However, we have not done any kinetic studies in order to confirm any of these suggestions.

In an experiment in which 2-benzoyl-1,2,3,4-tetrahydroisoquinaldonitrile **5***b* was oxidized at −76°C in tetrahydrofuran in the presence of butyl lithium, we observed the uptake of 1 mol of oxygen for oxidation of 1 mol of this compound. When this reaction was quenched with hydrochloric acid we isolated 1-hydroperoxy-2-benzoyl-1,2,3,4-tetrahydroisoquinaldonitrile **9***a* in good yield, whereas the addition of acetyl chloride, instead of hydrochloric acid, resulted in *O*-acetyl derivative **9***b*. Both crystalline peroxides were satisfactorily characterized by spectroscopic methods as well as by elemental analysis (see Experimental). Hydroperoxide **9***a* appeared to be unstable at temperatures above 0°C. When left overnight in acetone solution at room temperature it was converted into dihydroisocarbostiril **6***a* in 57% yield.

From these facts, one can come to the conclusion that the autoxidation of Reissert compounds may proceed via different mechanisms which are dependent on the reaction conditions. In the two-phase catalytic system, in which the reaction is run at room temperature and in the presence of aqueous sodium hydroxide and quaternary ammonium salts, the *in statu nascendi* formed hydroperoxide may serve as an oxidizing agent for the oxidation of a second molecule of Reissert compound. At low temperature and in anhydrous solvents the peroxy intermediate may be stable enough to be isolated and characterized.

Experimental

Melting points were determined on a Kofler block. Infrared spectra were measured in chloroform solution using 0.1 mm cells and approximately 0.2 *M* sample concentration on a Unicam SP 200G spectrometer and in KBr discs on a Beckman IR 4230 instrument. Chemical ionisation mass spectra (ci ms) were obtained using a Finnigan 1015D spectrometer with a model 6000 data collection system and electron ionization mass spectra (ei ms) were obtained with a JEOL MS 100-D instrument. Thin-layer chromatography (tlc) was run on precoated plates (Merck, silica gel 60 F 254).

The starting Reissert compounds were prepared according to the known procedure. Compounds **1**, **3** and dihydro analogs **5***a*, *d*, *e* were prepared from appropriate isoquinoline or quinoline derivatives by the modified procedure (20); dihydro Reissert compounds **5***b*, *c*, *f*, *g* by ionic hydrogenation of appropriate Reissert compounds (21); and derivatives **7** by a catalytic hydrogenation of quinoline Reissert compounds (23). Hydrastinine pseudocyanide **5***h* was prepared from hydrastinine and potassium cyanide according to ref. 22, yield 83%, mp 83–84.5°C (lit. (22) oil); ir: 2220 cm^{-1} (CN); ei ms *m/e*: 216(M^+), 215(M − 1), 190(M − CN), 188(M − CN − 2H), 173(M − CN − CH_3 − 2H) (base). *Anal.* calcd. for $C_{12}H_{12}N_2O_2$: C 66.67, H 5.56, N 12.97; found: C 66.83, H 5.81, N 12.83.

The following general procedure for air oxidation of Reissert compounds in the two-phase catalytic system was used. Air was bubbled into a well stirred two-phase system consisting of the Reissert derivative (1 mmol) in benzene (6–12 mL), 50% aqueous sodium hydroxide (1–2 mL), and 30 mg triethylbenzylammonium chloride (TEBA). After 1.5 h (or 20 h in the case of the dihydro Reissert compounds), the organic phase was separated and washed with water, dilute hydrochloric acid, and water. The solvent was evaporated and the residue was crystallized: isoquinaldonitrile from xylene, quinaldonitrile from ether – petroleum ether, and dihydroisocarbostiril from *n*-hexane. Products were characterized by their melting points, ir, and mass spectra, as well as by thin-layer chromatography, and compared with data published in the original literature.

Benzoic acid was determined in the following way. The aqueous phase that remained after the separation of the organic layer from the two-phase oxidation of **1***a* or **3***a* was rendered acidic and extracted with ether. After work-up, benzoic acid was obtained in 90 and 65% yield, respectively.

Silver cyanide was precipitated in the case of oxidation of compound **5***a*, when the aqueous layer was treated with silver nitrate, yield 80%.

Reactions in which the uptake of oxygen was measured were run in a closed system consisting of a 150 mL round-bottom flask connected to a gas buret.

Peroxides 9 from Dihydroisoquinoline Reissert Compound 5a

A solution consisting of 252 mg (1 mmol) of 2-benzoyl-1,2,3,4-tetrahydroisoquinaldonitrile **5***a* in tetrahydrofuran (5 mL) was placed in a 150 mL two-necked flask connected to a gas buret, which permitted the measurement of the volume of consumed oxygen. It was cooled to −76°C and 1 mmol of butyl lithium in hexane solution was added through a serum cup with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

vigorous stirring. After 1 mmol of oxygen was used (ca. 1.5 h) the temperature was allowed to rise to ca. 0°C and dilute hydrochloric acid was added. This then was extracted with ether, etheral extracts dried, and solvent evaporated at room temperature to give 147 mg (52%) of crystalline **9***a*. It was recrystallized from tetrahydrofuran, mp 114–115.5°C; ir (KBr): 3180 (OOH), 2175 (CN), 1630 cm^{-1} (CO); ci ms (NH_3) *m/e*: 295($M^+ + 1$), 279($M - O + 1$), 252 (base) ($M - HNCO + 1$), 157($M - OOH - COC_6H_5 + 1$); ei ms *m/e*: 277($M - OH$), 262($M - O_2$), 156($M - O_2 - C_6H_5CHO$), 105 (base) ($C_6H_5CO^+$). *Anal.* calcd. for $C_{17}H_{14}N_2O_3$: C 69.39, H 4.76, N 9.53; found: C 69.51, H 4.81, N 9.41.

When the reaction was quenched with acetyl chloride, **9***b* was obtained after the usual work-up, yield 135 mg (40%); mp 134–135°C, after recrystallization from methylene chloride – hexane (1:1); ir (KBr): 1790 (CO), 1670 cm^{-1} (CO); ci ms (NH_3) *m/e*: 337($M^+ + 1$), 279($M - OCOCH_2 + 1$), 261($M - OOCOCH_3$), 252 (base) ($M - CN - OCOCH_3 + 1$). *Anal.* calcd. for $C_{19}H_{16}N_2O_4$: C 67.86, H 4.76, N 8.33; found: C 67.70, H 5.03, N 8.44.

2-Benzoyl-3,4-dihydroisocarbostiril (8, R = C_6H_5)

2-Benzoyl-1,2,3,4-tetrahydroisoquinaldonitrile **5***a* (1 mmol) was oxidized with air oxygen in the two-phase catalytic system in the manner described in the general procedure.

The reaction was stopped after 50 min and worked up in the usual way. 2-Benzoyl-3,4-dihydroisocarbostiril (**8**, R = C_6H_5) (180 mg, 72%) was obtained, mp 132°C (lit. (24) mp 132°C) after crystallization from ethanol; ir, ms, and tlc were identical with an authentic sample.

Hydrolysis of 2-Benzoyl-3,4-dihydroisocarbostiril (8, R = C_6H_5)

A two-phase system consisting of compound **8** (R = C_6H_5), (125.5 mg, 0.5 mmol) in benzene (4 mL), 50% aqueous sodium hydroxide (0.5 mL), and TEBA (20 mg) was stirred at room temperature for 24 h under an argon atmosphere. The standard work-up resulted in 40 mg (55%) of dihydroisocarbostiril (**6**, R = H).

Oxidation of 2-Benzoyl-1,2-dihydroisoquinaldonitrile **1***a in the Two-phase Catalytic System, under Argon*

(A) With m*-Chlorperbenzoic Acid*

A two-phase catalytic system was prepared from compound **1***a* (260 mg, 1 mmol), benzene (6 mL), TEBA (30 mg), and 50% aqueous sodium hydroxide (1 mL). A rapid stream of argon was introduced and 250 mg of 84% *m*-chlorperbenzoic acid in benzene (3 mL) was added. After 24 h this mixture was worked up giving 150 mg (97%) of isoquinaldonitrile (**2**, R = H).

(B) With Hydrogen Peroxide

The two-phase system containing 1 mmol of compound **1***a* was prepared in the way described above. Then 0.5 mL of 31% hydrogen peroxide was added dropwise, the interval between two successive drops being 0.5 h. A vigorous stream of argon was passed through and the reaction carried out for 24 h. Then it was worked up in the usual way, to yield quantitative amounts of isoquinaldonitrile (**2**, R = H).

(C) With Benzoyl Peroxide

When 75% benzoyl peroxide was used as the oxidizing agent using the same reaction conditions as well as the same amounts of reactants, isoquinaldonitrile (**2**, R = H) was obtained in quantitative yield after 24 h.

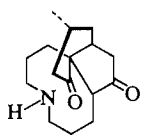
Synthesis of substituted hydrindanes. Part II. Approaches to the synthesis of fawcettimine

ROBERT H. BURNELL, ALAIN HUMBLET, JACQUES PELLETIER, AND SANTYNAND BADRIPERSAUD
Département de Chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received November 2, 1979

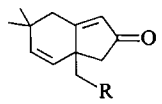
ROBERT H. BURNELL, ALAIN HUMBLET, JACQUES PELLETIER, and SANTYNAND BADRIPERSAUD. Can. J. Chem. **58**, 1243 (1980).

Several unsaturated hydrindanones have been prepared to assess various synthetic routes which could lead to the Lycopodium alkaloid fawcettimine. Comparison with an earlier model series starting from dimedone shows that this dihydroorcinol based sequence must be modified considerably.



ROBERT H. BURNELL, ALAIN HUMBLET, JACQUES PELLETIER et SANTYNAND BADRIPERSAUD. Can. J. Chem. **58**, 1243 (1980).

On a préparé plusieurs hydrindanones non saturées dans le but d'évaluer les différentes sortes de synthèse pouvant conduire à l'alcaloide lycopodium fawcettimine. La comparaison avec des séries de modèles antérieurs provenant de la dimédone montre que la séquence basée sur le dihydroorcinol doit être modifiée considérablement.



[Traduit par le journal]

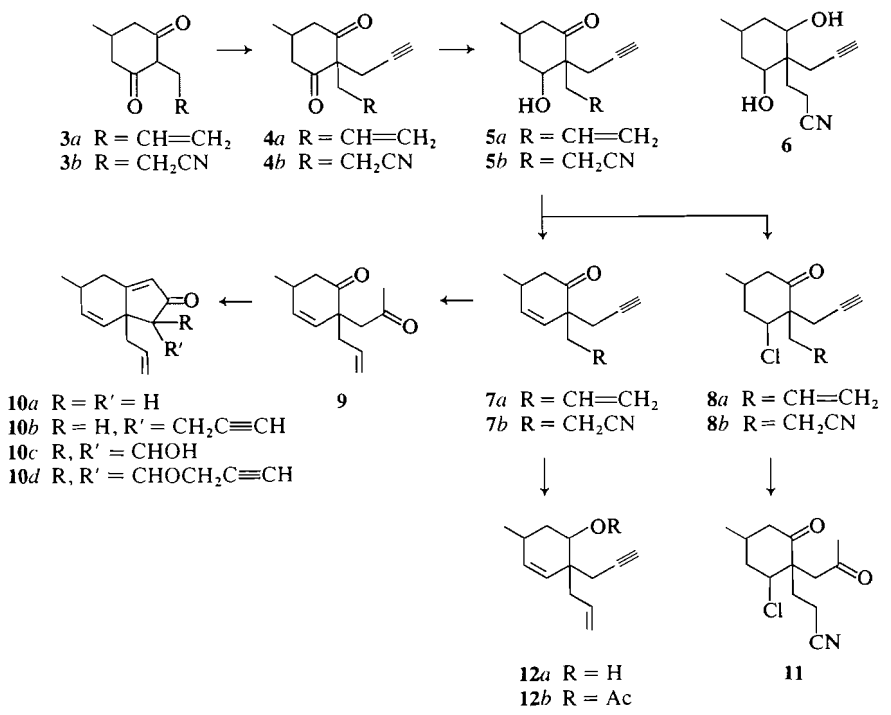
For personal use only.

In Part I of this series (1) we described the preparation of hydrindenones **2***a* and **2***b* as models for the synthesis of Lycopodium alkaloids such as fawcettimine **1**. Structural studies on the latter (2) show the more stable form of the alkaloid to be a hemi-aminal arising from transannular reaction of the six-membered ring carbonyl with the secondary amino residue. This equilibration would be inevitable if structure **1** were synthesised or of course impossible if the amino residue is *N*-acetylated. Our first synthetic models contained *gem*-dimethyl groups (**2***a* and **2***b*) while fawcettimine has but one methyl residue at this position, so we have examined the analogous syntheses starting from dihydroorcinol rather than dimedone, only to find that this trivial difference in starting material considerably changes the outcome.

1



2*a* R = CH_2COOH
2*b* R = $CH{=}CH_2$

As shown in Scheme 1, allyl and cyanoethyl dihydroorcinols (**3***a* and **3***b*) were both readily alkylated with propargyl bromide to give the 2,2-disubstituted 1,3-cyclohexadiones (**4***a* and **4***b*). As in the earlier models the diones were partially reduced to the ketols **5***a* and **5***b* although the conditions found necessary to avoid complete reduction to the diols such as **6** not only differed from each other (**5***a*: lithium tri-*tert*-butoxy aluminium hydride at 0°C; **5***b*: sodium borohydride at 0°C) but also from previous models with the *gem*-dimethyl groups, where even above room temperature for 2 days only one of the carbonyl groups was reduced in the presence of sodium borohydride. While varying the conditions did enable us to obtain the ketols in good yield, dehydration of **5***a* and **5***b* only grudgingly afforded the olefins **7***a* and **7***b* which were in both cases extremely difficult to separate from, what we learned later to be, the chlorine-containing substitution products **8***a* and **8***b*. The 2-cyanoethyl-2-propargylcyclohexenone **7***b* was never obtained pure enough for satisfactory elemental analysis but careful distillation of the allyl analogue **7***a* afforded material which we were able to carry through to the hydrindenone **10***a*. Thus hydration of the propargyl triple bond to give the diketone **9** and cyclisation in degassed aqueous potassium hydroxide afforded **10***a*. Other methods for eliminating the oxygen functions in **5***a* and **5***b*, via the mesylates, the tosylates, or the chloro compounds (**8***a* and **8***b*) were met with no greater success. Thinking that elimination might be more readily achieved later in the synthesis, the chloroketone **8***b* was converted to the dione **11** but cyclisations attempted in aqueous or anhydrous bases lead to alternate cyclisation products.

The discouraging failure of the dihydroorcinol series to imitate the sequence from dimedone did provide us with a limited quantity of material (**10***a*) which we could use to test the behaviour of the hydrindenone system to alkylation, which would be the next step in the overall synthesis. The structures of the products were secured only by mass spectrometric and other spectral evidence but alkylation under kinetically controlled conditions (3) with propargyl bromide was found to be exclusively at the methylene carbon to yield **10***b*. The latter was also obtained via the hydroxymethylene derivative **10***c*, but in this case the *O*-alkylated product **10***d* was also isolated. Since **10***b* contains the complete fawcettimine carbon skeleton this approach offered a reasonable chance of success if the

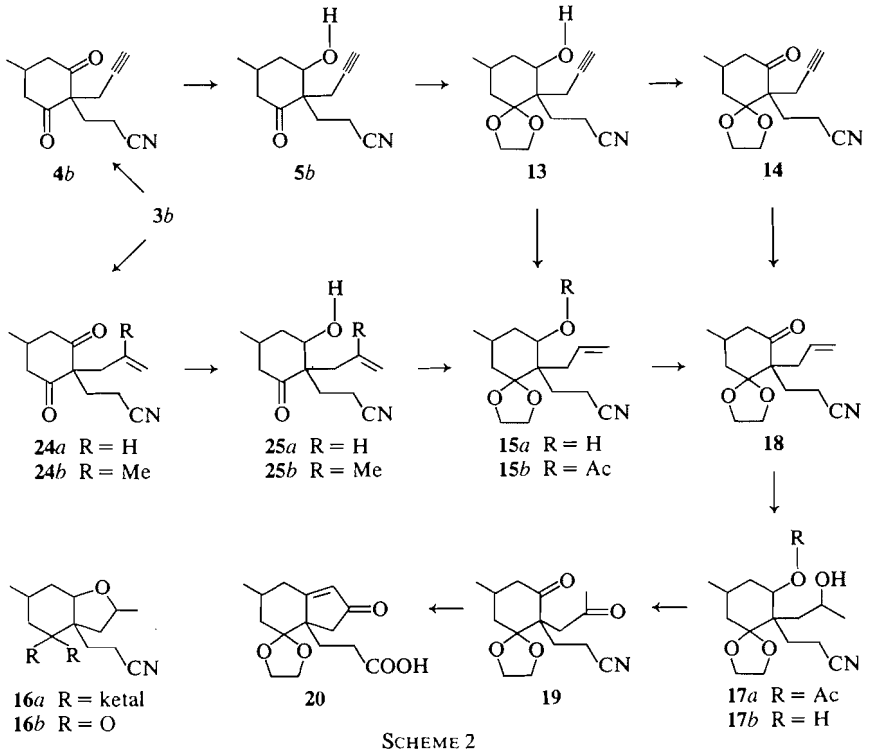
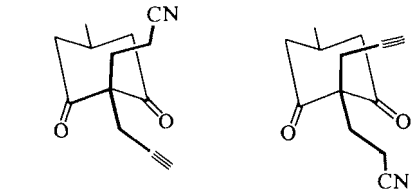


SCHEME 1

disastrous dehydration step could be avoided permitting an improvement in the overall yield (**3***a* → **10***a*; 11% overall). An alternate pathway involving the acetate **12***b* and the alcohol **12***a* was investigated but offered no advantage.

On eight previous occasions we had found that attempted ketalisation of 2,2-disubstituted cyclohexa-1,3-diones or 2,2-disubstituted 3-hydroxycyclohexanones under a variety of conditions lead only to the decomposition of the starting material, presumably by β-ketone fission or by retro-aldolisation. The hydroxy-ketone **5***b* proved to be an exception and the ketal-alcohol **13** was obtained in good yield by the classical method (Scheme 2). This not only renders the dehydration redundant but also preserves the potential carbonyl group necessary for fawcettimine. The hydroxyl group in **13** was oxidised affording the ketone **14** but attempted hydration of the triple bond also hydrolysed the ketal moiety which provoked cleavage of the ring. The hydroxy-ketal was hydrogenated over Lindlar catalyst to give the allyl derivative **15***a* but acetoxymercuration (4) of the latter gave the tetrahydrofuran **16***a* (characterised as the ketone **16***b*) whereas the acetyl derivative of **13** took 6 days to decolorise the reagent (normally less than 5 min suffices) and the yield of hydroxy-acetate **17***a* was poor. However, the ketone **18**, obtained by oxidation of alcohol **15***a* or by Lindlar-catalysed reduction of ketone **14**, reacted rapidly on acetoxymercuration and since sodium borohydride in sodium hydroxide was used to precipitate the mercury during the work-up, the intermediate diol **17***b* was oxidised by the Ratcliffe–Rodehorst method (5) to afford diketone **19**. The latter cyclised in aqueous potassium hydroxide to afford the hydrindenone **20** with concomitant hydrolysis of the nitrile.



During the course of these syntheses certain stereochemical preferences had become evident while all compounds are necessarily racemic. For instance, the alkylation of **3***b* establishes the quaternary centre in **4***b* producing the geometrical isomers **4***bZ* and **4***bE* and the relationship of the cyanoethyl and methyl substituents is not changed during subsequent transformations. The nmr spectrum of the product shows two methyl doublets at 1.15 and 1.08 δ in the ratio of 2:1 respectively but in our hands these isomers were inseparable. Most peaks in the nmr spectra of many of the products were broad. We had hoped to separate the mixtures to continue the synthesis with that isomeric racemate which could lead to fawcettimine but the first product where this was possible was the ketal-ketone **18**. Lengthy chromatography of the latter did provide one pure racemate (mp 94–95°C) and the other somewhat less pure (mp 56–60°C) which still contained about 10% of the

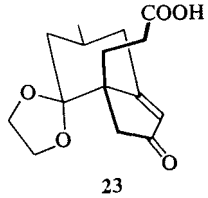

SCHEME 2

higher melting isomer. Before separation the nmr spectrum of the mixture showed two peaks for the methylene protons of the dioxolane ring at 3.98 and 3.93 δ in an approximate ratio of 2:1. The higher melting isomer showed only the 3.93 peak while the lower melting mixture showed mostly the 3.98 peak. The regions between 2.0 and 3.0 δ in the spectra were complex but distinctly different. It seemed hazardous to say which racemate corresponded to which of the structures **21***a* or **21***b*.

The diketone **19** proved easier to separate and the two racemates **22***a* and **22***b* could also be prepared from the purified samples of **21***a* and **21***b*. The main differences in properties were the melting points and the nmr signals for the methylene adjacent to the aliphatic ketone. In the spectrum of the higher melting diketone (mp 166–167°C) (obtained from the lower melting alkene) this methylene appeared as a singlet at 3.15 δ while in the other isomer (mp 113–115°C) this signal was lost in the complex system between 2.4 and 2.8 δ. The lower melting isomer decomposed on standing at room temperature. Examination of models suggests that the higher melting, more stable, and more abundant compound contains the stereochemistry required for (±)fawcettimine. Cyclisation of the diketone **19** before separation gave variable results but the pure racemic **22***a* afforded the cyclised acid without difficulty. This acid must have the structure shown in **23**. The overall yield from **3***b* to **23** was ca. 20% and this includes the loss incurred separating the diketone racemates.

Although fewer steps are involved Scheme 2 shows an alternate route to the hydrindenone acid

20 from the allyl-cyanoethylcyclohexa-1,3-dione **24***a* via the ketol **25***a* and the ketal **17** (mentioned earlier) but this offered no advantage in time or yield. A similar shorter synthesis involving the methallyl analog **24***b*, from which the methyl ketone can be readily obtained by ozonolysis, was abandoned when the hydroxy-ketone **25***b* failed to ketalise even under forcing conditions. This is hard to explain since the allyl compound **24***a* gave the corresponding ketal in 80% yield. After considerable experimentation we have found that the route can be shortened by partial ketalisation of the diketone **4***b* to the ketal **14** in 63% yield. Surprisingly neither of the similar diones **4***a* nor **24***b* afforded the ketal under the same or more vigorous conditions.

Recently, Inubushi and co-workers (6) have published a total synthesis of (±)fawcettimine.

Experimental

Unless otherwise stated the conditions and instruments for the spectra quoted are: uv, ethanol solutions, Beckman DK-1A; ir, Perkin–Elmer 457 and Beckman IR 12; nmr, Bruker HX 90, internal TMS standard, coupling constants in parentheses; ms, Varian M 66. Elemental analyses by the Pascher Laboratory, Bonn and Chemalytics, Arizona, U.S.A.

*2-Allyl-2-propargyl-5-methylcyclohexa-1,3-dione (**4**a)*

2-Allyl-5-methylcyclohexa-1,3-dione (**3***a*) (30 g) prepared by the method of Stetter and Dierichs (7) was added to a refluxing solution of potassium (7.5 g) in *t*-BuOH (500 mL) under nitrogen. After 5 h of reflux, propargyl bromide (18 mL) was added slowly to the cooled solution and the mixture was heated at 90°C for 10 h. After cooling, a crude oily product (containing some *O*-alkylated product) was obtained by adding dilute HCl and extracting with ether. To exclude the *O*-alkylated product, the oil was taken up in MeOH (200 mL) and treated with 10% HCl (300 mL) at reflux for 2 h. The neutral product obtained by extraction was distilled (84–86°C at 0.02 Torr) affording the diketone **4***a* (27 g, 74%); ν (film): 3280, 3080, 2120, 1730, 1700, and 1640 cm^{-1}; nmr (C_6D_6) δ: $CH_3C(H)$ d(6.5) 0.81, $HC{\equiv}C{-}CH_2$ t(3.0) 1.96 and d(3.0) 2.46, $CH_2{=}CH{-}$ m 5.0 and m 5.3; ms *m/e*: 204(M^+, weak), 134, 133, 91, and 69(base). *Anal.* calcd. for $C_{13}H_{16}O_2$: C 76.5, H 7.8; found: C 76.4, H 7.6.

*2-Allyl-2-propargyl-3-hydroxy-5-methylcyclohexanone (**5**a)*

To the diketone **4***a* (11 g) vigorously stirred in THF (300 mL) under nitrogen at 0°C was added very slowly a solution of lithium tri-*tert*-butoxy aluminium hydride (13 g) in THF (200 mL). After 5 h at 0°C saturated sodium sulfate solution (400 mL) was added and the resulting precipitate filtered (Celite). Evaporation afforded the hydroxy-ketone **5***a* (10.3 g, 94%). The minor product crystallised from CCl_4, mp 89–90°C; ν (KBr): 3550, 3300, 3110, 2130, 1715, and 1660 cm^{-1}; nmr ($CDCl_3$) δ: $CH_3C(H)$ d(6.0) 1.25, $HC{\equiv}C{-}CH_2$ t(3.0) 2.05, HOCH s 3.1 and dd(5.0 and 3.0) 4.2; ms *m/e*: 206(M^+), 165, 161, 121, 105, 91 and 78(base). *Anal.* calcd. for $C_{13}H_{18}O_2$: C 75.6, H 8.7; found: C 75.5, H 8.6.

The *major* product never crystallised but showed very similar spectral properties to those above except in the nmr where the C*H*—O(H) appears as dd(11.0 and 5.0) 4.15.

The *mesylate* prepared from the minor product, mp 98–99°C (from hexane). *Anal.* calcd. for $C_{14}H_{20}O_4S$: C 59.1, H 7.1, O 22.5; found: C 59.1, H 6.9, O 22.6.

The *tosylate* prepared from the minor product, mp 104–105°C (from EtOH). *Anal.* calcd. for $C_{26}H_{24}O_4S$: C 66.6, H 6.7, S 8.9; found: C 66.8, H 6.7, S 9.0.

*2-Allyl-2-propargyl-5-methylcyclohex-3-enone (7*a)*

The hydroxy-ketone **5***a* (20 g) in pyridine (500 mL) was cooled to 0°C. Phosphorus oxychloride (55 mL) was added dropwise and the temperature then kept at 70°C for 20 h. The cooled mixture was cautiously poured into stirred ice water and the crude product (17.5 g) obtained by $CHCl_3$ extraction. Vacuum distillation (Hempel column, 39°C at 0.02 Torr) afforded the cyclohexenone **7***a* (4.8 g, 28%) as a colourless oil, n_D^{25} 1.4955; ν (film): 3300, 3105, 3050, 2125, 1720, and 1650 cm^{-1}; nmr ($CDCl_3$) δ: $CH_3C(H)$ d(7.0) 1.05, $HC{\equiv}C{-}CH_2{-}$ t(3.0) 2.03 and d(3.0) 2.30, $-CH{=}CH-$ AB part of an ABX system ν_A 5.63 and ν_B 5.77 (10.0, 3.5, and 1.5); ms *m/e*: 188(M^+), 173, 147, 145(base), 131, 109, 107, 105, and 91. *Anal.* calcd. for $C_{13}H_{16}O$: C 82.9, H 8.6; found: C 83.0, H 8.5.

The residue from the first distillation was distilled with a shorter column (Vigreux) to give the chloroketone **8***a* (84°C at 0.02 Torr, 3 g), n_D^{25} 1.5053; ν (film): 3295, 3095, 2105, 1710, 1645, and 850 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(6.0) 1.05, $HC{\equiv}C{-}CH_2{-}$ t(2.0) 2.03 and d(2.0) 2.63, CH—Cl t(3.0) 4.63 (chloro substituent must be axial). *Anal.* calcd. for $C_{13}H_{17}OCl$: C 69.5, H 7.6, Cl 15.8; found: C 69.6, H 7.7, Cl 15.4.

The cyclohexenone **7***a* was also obtained from the chloroketone **8***a* (in 1,5-diazabicyclo[4.3.0]non-5-ene, 90°C, 2 h), from the mesylate (lithium bromide in DMF, this also gave the corresponding bromoketone), and from the tosylate (CCl_4, neutral alumina, reflux 4 h) but the best yields were 25, 30, and 45% respectively.

*2-Allyl-2-acetonyl-5-methylcyclohex-3-enone (**9**)*

The propargyl residue in **7***a* (6.6 g) was hydrated as described previously (1) (BF_3-etherate, trichloroacetic acid, MeOH, 20 h) and the crude oily product afforded the acetonyl compound **9** (73–74°C at 0.04 Torr, 5.1 g, 70%), n_D^{25} 1.4915; ν (film): 3075, 3020, 1720, 1715, and 1645 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(6.5), 1.10, CH_3CO s 2.02, $CH_2{=}CH{-}$ m 5.05 and m 5.66, $-CH{=}CH-$ AB part of ABX system ν_A 5.40 and ν_B 5.47 (9.5, 3.0, and 1.5); ms *m/e*: 206(M^+, weak), 164, 150, 149, 148, 124 (base), 122, 119, and 106. *Anal.* calcd. for $C_{13}H_{18}O_2$: C 75.6, H 8.7; found: C 75.4, H 8.8.

*8-Allyl-5-methylhydrinda-3,6-dien-2-one (**10**a)*

The diketone **9** (6.8 g) was cyclised using degassed aqueous KOH. Benzene–ether (5:2) elution of a neutral alumina column (activity III) afforded the liquid conjugated enone **10***a* (5.3 g, 85%), bp 80–82°C at 0.02 Torr, n_D^{25} 1.5249; λ_{max}: 234 (6500) nm; ν (film): 3100, 3040, 1715, 1650, and 1637 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(6.5) 1.15, CH_2CO ABq(18.0) centred at 2.28 (ν_A 2.14, ν_B 2.44), $CH_2{=}CH-$ m 5.02, $-CH{=}CH-$ AB part of ABX system ν_A 5.48 and ν_B 5.66 (9.0, 2.5, and 1.0), $=CHCO$ s 5.86 (broadened by allylic protons); ms *m/e*: 188(M^+), 147(base, $M-41$), 119, 117, 105, 91, 86, and 84.

2,4-Dinitrophenylhydrazone, mp 122–123°C. *Anal.* calcd. for $C_{19}H_{20}N_4O_4$: C 61.9, H 5.5, N 15.2; found: C 61.7, H 5.4, N 14.9.

*1-Propargyl-8-allyl-5-methylhydrinda-3,6-dien-2-one (**10**b)*

(*a*) Kinetically controlled alkylation of the hydrindadienone **10***a* (0.5 g) using essentially House *et al.*'s[3] method (lithium diisopropylamide, 1,2-dimethoxyethane, −20°C, rapid addition of propargyl bromide) afforded a coloured oil from which the propargyl-ketone **10***b* (0.235 g, 40%) was obtained by chromatography; λ_{max}: 234 (7150) nm; ν (film): 3300, 3080, 3020, 1705, 1645 (sh), and 1630 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(7.0) 1.16, $HC{\equiv}C{-}$ t(2.5) 2.05; ms *m/e*: 226(M^+), 185(base, $M-41$), 157, 147, 142, 119, and 115.

(*b*) The *hydroxymethylene derivative* **10***c* prepared using dry sodium methoxide in benzene, methyl formate and then adding **10***a*, solidified after evaporative distillation (yield 76%), mp 94–95°C (from petroleum ether); λ_{max}: 247 (9950) and 287 (7100) nm, λ_{max} (NaOH): 337 (10 450) nm; ν (KBr): 2800–2600, 1710,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

1635, and 1580 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(6.5) 1.14, =CHCO s 6.0, =CH—OH s 7.11 and s 10.9; ms *m/e*: 216(M^+), 195, 175(base, $M-41$), 163, and 147.

Alkylation of the hydroxymethylene **10***c* (potassium *tert*-butoxide, benzene) afforded the same *C*-alkylated product **10***b* (0.060 g) which was separated by column chromatography from the *O-alkylated product* **10***d* (0.060 g): λ_{max}: 247 (6600) and 283 (sh, 4600) nm; ν(CCl_4): 3300, 3100, 3040, 2120, 1720, 1650, 1275–1200, and 1100 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(7.0) 1.15, $HC\equiv C-CH_2-$ t(2.0) 2.60 and d(2.0) 4.60, =CHCO s 6.10, —C=CH—O—R s 7.20.

2-Allyl-2-propargyl-5-methylcyclohex-3-enol (12a)

The cyclohexenone **7***a* (4.0 g) was reduced as described above for **5***a* but at room temperature affording the low melting alcohol **12***a* (3.6 g, 81%), mp ca. 40°C (from petroleum ether by cooling in dry ice); ν (film): 3500(broad), 3300, 3080, 3020, 2100, and 1640 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(7.0) 1.00, $-CH_2-CH(OH)-$ m 1.44 and dd(12.0 and 4.0) 3.83, $HC\equiv C-CH_2-$ t(3.0) 2.03 and d(3.0) 2.40, $CH_2=CH-$ m 5.11 and m 5.72, $-CH\equiv CH-$ s 5.50 (!).

Converted to the *O-acetyl derivative* **12***b* in the usual manner but this was also liquid (bp 60°C at 0.01 mm), n_D^{25} 1.4848. Spectral changes as expected ($\nu_{C=O}$ 1735 and 1250 cm^{-1} and nmr ($CDCl_3$) δ: CH_3CO s 2.02). *Anal.* calcd. for $C_{15}H_{20}O_2$: C 77.6, H 8.7; found: C 77.6, H 8.8.

2(β-Cyanoethyl)-5-methylcyclohexa-1,3-dione (3b)

Dihydroorcinol (34 g), EtOH (81 mL) triethylamine (54 mL), water (81 mL), and freshly distilled acrylonitrile (24.2 mL, 35% excess) were heated to reflux for 3.5 h. After cooling in ice, the mixture was acidified with 50% HCl and the precipitated cyanoethyl product **3***b* (28.7 g, 60%) was filtered and washed with water, mp 161–162°C (from acetone, lit. (8) mp 159–163°C): λ_{max}: 261 (14 500) nm; ν (KBr): 3250–2100, 2245, 1635, and 1570 cm^{-1}; nmr (acetone-d_6) δ: CH_3—CH d(4.5) 1.06. *Anal.* calcd. for $C_{10}H_{13}O_2N$: C 67.0, H 7.3, N 7.8; found: C 67.1, H 7.3, N 7.7.

2(β-Cyanoethyl)-2-propargyl-5-methylcyclohexa-1,3-dione (4b)

To the cooled solution of potassium (15.5 g) dissolved in anhydrous *t*-BuOH (1 L) was added 2-cyanoethylcyclohexa-1,3-dione **3***b* (64.6 g) and the mixture refluxed for 4 h. To the cooled solution was then added propargyl bromide (4 equiv., drop by drop) and the refluxing continued for 40 h. The cooled reaction mixture was poured into dilute HCl and the product obtained by $CHCl_3$ extraction. The oil was purified by chromatography over neutral alumina (III) and the diketone **4***b* obtained as a low melting solid (64.2 g, 82%), mp 51–52°C (from EtOH – water): ν (KBr): 3270, 2250, 2120, 1730, and 1700 cm^{-1}; nmr ($CDCl_3$) δ: CH_3—CH two d(7.0) 1.08 and 1.15 relative intensities 2:1 respectively and m 2.14, CH_2CO s 2.25. *Anal.* calcd. for $C_{13}H_{15}NO_2$: C 71.9, H 7.0, N 6.4; found: C 71.9, H 7.0, N 6.3.

2(β-Cyanoethyl)-2-propargyl-3-hydroxy-5-methylcyclohexanone 5b

The diketone **4***b* (39.8 g) was dissolved in MeOH (800 mL) and cooled to 0°C. Sodium borohydride (1.89 g) in water (35 mL) was added with rapid stirring during 15 min and agitation continued for a further 15 min after which the mixture was poured into water (2 L) containing acetic acid (10 mL). Methylene chloride extraction gave an oil which crystallised after neutral alumina (III) chromatography. The partially reduced product **5***b* (38.9 g, 96%) being eluted with benzene – 2% ethyl acetate, mp 117–118°C (from acetone–hexane): ν (KBr): 3420 and 3380 (two OH bands), 3305 and 3265 (two ≡CH bands), 2255 and 2245 (two C≡N bands), 2115, 1700, 1050, and 1020 cm^{-1}; nmr ($CDCl_3$) δ: CH_3—C two d(5.0) 0.98 and 1.06, CH_2—C≡C d(2.5) 2.56, OH s 2.86. The *CH*OH of the minor product (25% from integration) showed dd(11.0 and 3.5) 3.73 and the major product (75%) dd(11.0 and 4.5) 4.12. *Anal.* calcd. for $C_{13}H_{17}NO_2$: C 71.2, H 7.8, N 6.4, O 14.6; found: C 71.4, H 7.8, N 6.2, O 14.5.

The *mesylate* was prepared in quantitative yield in the normal manner, mp 111–112°C (from acetone–hexane): ν (KBr): 3290, 2260, 1710, 1350, 1170, 950–935 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.09, CH_3 (in mesylate) s 3.08, C*H*—OMs dd(10.0 and 5.0) 4.76. *Anal.* calcd. for $C_{14}H_{19}NO_4S$: C 56.6, H 6.4, N 4.7, O 21.6; found: C 56.5, H 6.3, N 4.6, O 21.5.

The *tosylate*, mp 181–182°C (from acetone): ν(KBr): 3300, 3100, 1710, 1605, and 1370 cm^{-1}; nmr ($CDCl_3$) δ: CH_3—C d(5.5) 1.04, CH_3 (tosylate) s 2.42, aromatic protons d(8.0) 7.35 and d(8.0) 7.83. *Anal.* calcd. for $C_{20}H_{23}NO_4S$: C 64.3, H 6.2, N 3.8; found: C 64.3, H 6.1, N 4.0.

2(β-Cyanoethyl)-2-propargyl-5-methylcyclohexa-1,3-diol 6

This was the only reduced product when the reaction described above (**5***b*) was performed at room temperature, mp 160–161°C: ν (KBr): 3420, 3320, 2255, 2115, and 1000 cm^{-1}; nmr (acetone-d_6) δ: CH_3 d(5.0) 0.97, $HC\equiv C-CH_2-$ t(2.5) 2.32 and d(2.5) 2.58, CHOH m 3.90 and s 2.94 (D_2O). *Anal.* calcd. for $C_{13}H_{19}NO_2$: C 70.6, H 8.7, N 6.3; found: C 70.4, H 8.7, N 6.4.

The *diacetate*, mp 154–156°C (from hexane–acetone): ν (KBr): 3300, 2235, 2115, 1740, 1725, 1260, and 1240 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.00, CH_3CO s 2.07 and CH—OR dd(11.0 and 3.5) 4.92. *Anal.* calcd. for $C_{17}H_{23}NO_4$: C 66.9, H 7.6, N 4.6; found: C 67.0, H 7.7, N 4.5.

Dehydration of Ketol 5b (Affording 7b and 8b)

To ketol **5***b* (3.54 g) in anhydrous pyridine (80 mL), cooled in ice, was slowly added phosphorus oxychloride (10 equiv.). The mixture was then heated at 64°C for 21 h, cooled, and cautiously poured into ice water (500 mL). Methylene chloride extraction afforded an oil (3 g) from which on trituration with a small volume of hexane precipitated the *chloro compound* **8***b* (2.58 g, 67%), mp 94–95°C (from acetone–hexane): ν (KBr): 3300, 2240, 2105, 1715, and 760 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.08, C*H*—Cl t(3.5) 4.56. *Anal.* calcd. for $C_{13}H_{16}NOCl$: C 65.7, H 6.8, N 5.9, Cl 14.9; found: C 65.4, H 6.8, N 5.8, Cl 14.8.

The *semicarbazone*, mp 205–206°C (from EtOH–water). *Anal.* calcd. for $C_{14}H_{19}N_4OCl$: C 57.0, H 6.5, N 19.0, Cl 12.0; found: C 56.8, H 6.4, N 19.3, Cl 11.8.

The mother liquors from above were evaporated and the oil purified by preparative tlc (silica gel) to give the dehydration product **7***b* (0.400 g), bp 80°C at 0.04 Torr: ν (film): 3300, 3030, 2270, 2140, and 1720 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.5) 1.09, —CH=CH— dd(10.0 and 1.5) 5.42 and dd(10.0 and 1.5) 5.42 and dd(10.0 and 3.0) 5.89.

This same olefin (**7***b*) was obtained in low yield by heating the mesylate with lithium chloride in DMF, by refluxing the tosylate in pyridine for 4 days (40% yield after difficult purification), and by heating the tosylate with neutral alumina (activity I) in CCl_4 (yield 25%, the remainder being the alcohol **5***b*).

2(β-Cyanoethyl)-2-propargyl-3-ethylenedioxy-5-methylcyclohexanol 13

The ketol **5***b* (27.5 g), *p*-toluene sulfonic acid (1.0 g), and ethylene glycol (38.6 g) were refluxed in benzene (300 mL) for 48 h (Dean–Stark separator). After cooling the excess glycol was decanted and the ketal (80%) obtained by normal manipulation. To remove a small quantity of unreacted ketone **5***b*, the product was chromatographed over neutral alumina affording the ketal **13**, mp 113–114°C (acetone–hexane): ν (KBr): 3530, 3290, 2245, 2110, 1095, and 1025 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 0.92, HO—CH s 2.64 (D_2O) and dd(10.0 and 4.0) 3.67, $-OCH_2CH_2O-$ s 3.95. *Anal.* calcd. for $C_{15}H_{21}NO_3$: C 68.4, H 8.0, N 5.3, O 18.2; found: C 68.1, H 8.0, N 5.2, O 18.5.

The *tosylate*, mp 128–129°C (from ether–hexane): ν (KBr):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

3285, 2245, 2120, 1605, 1340, 1185, 1170, and 1120–1050 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.5) 0.91, aromatic CH_3 s 2.46, $—OCH_2CH_2O—$ s 3.97, $CH_{(ax)}$ OTs dd(11.5 and 4.5) 4.68, aromatic protons d(8.5) 7.38 and d(8.0) 7.83. *Anal.* calcd. for $C_{22}H_{17}NO_5S$: C 63.3, H 6.5, N 3.4, S 7.7; found: C 63.0, H 6.6, N 3.2, S 8.0.

2(β-Cyanoethyl)-2-propargyl-3-ethylenedioxy-5-methylcyclohexanone ***14***

(a) Ratcliffe–Rodehorst (5) Oxidation of Alcohol ***13***

Chromium trioxide (82.2 g) was added to a solution of pyridine (123 g) in methylene chloride (2 L). Stirring was continued for 10 min and then the alcohol **13** (36 g) in a minimum of methylene chloride was added all at once. After stirring for 1 h, the solution was decanted and the residue well washed with more methylene chloride. The combined organic solutions were washed and evaporation afforded the ketone **14** (36 g, quantitative), mp 101–102°C (softening at 91–92°C, from acetone–hexane): ν (KBr): 3280, 2250, 2120, 1710, and 1130–1040 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.04, $—OCH_2CH_2O—$ s 3.98. *Anal.* calcd. for $C_{15}H_{19}NO_3$: C 68.9, H 7.3, N 5.4; found: C 68.7, H 7.1, N 5.3.

(b) By Partial Ketalisation of ***4***b

To the diketone ***4b*** (10 g) in benzene (200 mL) was added ethylene glycol (18 mL) and *p*-toluene sulfonic acid (0.20 g). After 26 h of reflux in a Dean–Stark separator, the mixture was well washed, evaporated, and the ketal **14** (7.56 g; 63%) obtained by crystallisation from methanol–water.

2(β-Cyanoethyl)-2-allyl-3-ethylenedioxy-5-methylcyclohexanol ***15***a

(a) By Hydrogenation of ***13***

Lindlar catalyst (0.400 g) was hydrogenated in acetone (25 mL) containing quinoline (3 drops). The propargyl compound **13** (1.27 g) was added in a minimum of acetone and hydrogenation continued (uptake 1 mol). After filtering and washing the catalyst, evaporation afforded the crude product from which minor impurities were removed by chromatography over neutral alumina (activity III). The allyl compound ***15a*** (1.25 g, 97%) crystallised slowly from hexane–ether, mp 81–82°C: ν (KBr): 3460, 3080, 2250, 2240, 1645, and 1110–1025 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 0.94, HO—CH d(10.0) 3.28 and broad s 3.58 (D_2O), $—OCH_2CH_2O—$ s 3.90, $—CH=CH—$ m 5.1 and m 5.9. *Anal.* calcd. for $C_{15}H_{23}NO_3$: C 67.9, H 8.7, N 5.3; found: C 67.9, H 8.9, N 5.2.

The *acetate* ***15b*** crystallised from hexane, mp 77–78°C: ν (KBr): 3085, 2240, 1730, 1640, 1240, and 1090–1030 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.04, CH_3CO s 1.98, $—OCH_2CH_2O—$ two s 3.86 and 3.91. *Anal.* calcd. for $C_{17}H_{26}NO_4$: C 66.4, H 8.2, N 4.6; found: C 66.3, H 8.1, N 4.6.

The *3,5-dinitrobenzoate*, mp 140–141°C (from EtOH). *Anal.* calcd. for $C_{22}H_{25}N_3O_8$: C 57.5, H 5.5, N 9.2; found: C 57.6, H 5.6, N 9.4.

(b) By Ketalisation of ***25***a

Following the procedure described above for **13**, the ketol ***25a*** (see later) was converted to the allyl-ketal ***15a*** in 80% yield.

2,6-Dimethyl-4-ethylenedioxy-9-(β-cyanoethyl)-perhydrobenzofuran ***16***a

Mercuric acetate (1.45 g) was dissolved in water (5 mL) to which was added THF (5 mL). To this yellow solution was added the allyl derivative ***15a*** (1.2 g) in a minimum of THF (4). The color disappeared in 10–15 s and stirring was continued for 5 min. NaOH solution (5 mL of 3 *M*) followed by sodium borohydride (5 mL of a 0.5 *M* solution in aqueous sodium hydroxide 3 *M*) was added to precipitate the mercury. After decanting, the solution was saturated with NaCl and extraction afforded the liquid product ***16a*** (1.16 g, 97%): ν (film): 2240 and 1120–1040 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.0) 0.92, $CH_3—CH—O$ d(6.5) 1.32, $—OCH_2CH_2O—$ s 3.97. For characterisation the ketal moiety in tetrahydrofuran ***16a*** was hydrolysed (MeOH, water, HCl, room temperature, 16 h) to the *ketone* ***16b*** (ν (film): 2250, 1710, and 1140–1050 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.0) 1.04, $CH_3—CH—O$ d(6.0) 1.23 and m 4.0) which afforded a crystalline *semicarbazone*, mp 205–206°C (from ethanol). *Anal.* calcd. for $C_{14}H_{22}N_4O_2$: C 60.4, H 8.0, N 20.1; found: C 60.5, H 7.9, N 20.5.

2(β-Cyanoethyl)-2-allyl-5-methylcyclohexa-1,3-dione ***24***a

The nitrile ***3b*** (89.5 g) was alkylated with allyl bromide (4 equiv.) in the presence of potassium *tert*-butoxide (from potassium (21 g) in 1 L of *t*-BuOH) following the procedure outlined for ***4b***. The product ***24a*** (78%) showed bp 130–132°C at 0.04 Torr, n_D^{25} 1.4980; ν (film): 3095, 2245, 1728, 1700, 1650, and 937 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 two d(6.0) 0.96 and (5.5) 1.14, allyl residue m 4.98–5.75 (3H). *Anal.* calcd. for $C_{13}H_{17}NO_2$: C 71.2, H 7.8, N 6.4; found: C 71.2, H 7.7, N 6.3.

2(β-Cyanoethyl)-2-allyl-3-hydroxy-5-methylcyclohexanone ***25***a

The diketone ***24a*** (71.2 g) was reduced by the method described for ***5b*** affording the ketol ***25a*** (70 g, 97%), bp 132–135°C at 0.05 Torr, n_D^{25} 1.5003; ν (film): 3480, 3050, 2250, 1705, 1648, and 925 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.5) 1.06, HO—CH broad s 3.11 (D_2O) and for the minor product (ca. 25%) showed m 4.0 and the major product (ca. 75%), dd(11.0 and 5.0) 3.79, allyl residue m 4.96–6.0 (3H). *Anal.* calcd. for $C_{13}H_{19}NO_2$: C 70.6, H 8.7, N 6.3; found: C 70.3, H 8.7, N 6.3.

The *acetate*, mp 128–129°C (from MeOH); ν (KBr): 3090, 2245, 1730, 1705, 1645, and 1240 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.02, CH_3CO s 2.02, $—CH_2—CH=CH_2$ dt(5.5 and 1.5) 2.50, dt(5.5 and 1.5) 2.66, m 5.48–5.83 and m 5.0 (also contains $CH—OAc$). *Anal.* calcd. for $C_{15}H_{21}NO_3$: C 68.4, H 8.0, N 5.3; found: C 68.5, H 8.1, N 5.1.

The Hydroxy-acetate ***17***a

The acetyl derivative ***15b*** (1.20 g) was dissolved in a small volume of THF and added to a solution of mercuric acetate (1.245 g) in water (4 mL) and THF (4 mL). Decoloration of the mixture at room temperature took 6 days when the reaction was stopped by adding 3 *M* NaOH (4 mL) and sodium borohydride (4 mL of 0.5 *M* in aqueous NaOH). After decanting from the mercury, the solution was saturated with NaCl and methylene chloride extraction gave a mixture affording ***17a*** (9%) by chromatography (alumina activity IV), mp 135°C: ν (KBr): 3500, 2250, 1725, 1275, and 1100–1030 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.0) 0.94, $CH_3—CHOH$ d(6.5) 1.34, CH_3CO s 2.05, $—OCH_2CH_2O—$ d(6.5) 3.87.

2(β-Cyanoethyl)-2-allyl-3-ethylenedioxy-5-methylcyclohexanone ***18***

The alcohol ***15a*** (1.5 g) was oxidised with chromium trioxide (3.4 g) in pyridine (5.4 mL) and methylene chloride (85 mL) as described for **14**. The product **18** (1.4 g, 95%) crystallised with difficulty so the analytical sample was sublimed, mp 84–85°C: ν (KBr): 3090, 2245, 1705, 1645, and 1135–1005 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(6.5) 1.03, $—OCH_2CH_2O—$ s 3.93 and s 3.98 relative intensities 1:2, allyl residue 4.95–6.15 (3H). *Anal.* calcd. for $C_{15}H_{21}NO_3$: C 68.4, H 8.0, N 5.3; found: C 68.6, H 8.1, N 5.1.

This same product (**18**) was also prepared in quantitative yield by hydrogenating the corresponding propargyl compound **14** over Lindlar catalyst, as described for ***15a***.

Chromatography of **18** over silica gel gave, by slow elution with benzene – ethyl acetate 2%, fractions containing mostly the isomer ***21a*** in about 60% yield. The purest sample obtained showed mp 56–60°C (from ether–hexane), nmr ($CDCl_3$) δ: $—OCH_2CH_2O—$ s 3.98.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Further elution afforded pure **21***b* which crystallised from ether–hexane, mp 94–95°C, nmr ($CDCl_3$) δ: —OCH_2CH_2O— s 3.93.

In later experiments simply seeding a solution of the mixed racemates **18** with pure **21***b* provoked the crystallisation of the latter and the mother liquors were thus enriched in **21***a*. At best about 10% of **21***b* remained in the sample.

*2(β-Cyanoethyl)-2-acetonyl-3-ethylenedioxy-5-methylcyclohexanone **19** (via **17**b)*

The allyl ketone **18** (1.03 g) was hydrated as described for **17***a*, except that decoloration took only 8–10 s and stirring was continued for only 5 min. The usual work-up (borohydride–NaOH) only partially reduced the carbonyl functions and gave 0.897 g of a mixture of the diol **17***b* and the corresponding keto-alcohol which not even careful chromatography could separate. The diol mixture was oxidised as described in the preparation of **14**. The product (**19**, quantitative) crystallised but repeated recrystallisation from acetone–hexane effected the separation of the pure racemate **22***a*, mp 166–167°C: ν (KBr): 2240, 1720, 1700, and 1170–1040 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.5) 1.02, CH_3COCH_2— s 2.21 and s 3.15 (2H), —OCH_2CH_2O— s 3.95 (4H). *Anal.* calcd. for $C_{15}H_{21}NO_4$: C 64.5, H 7.6, N 5.0; found: C 64.4, H 7.8, N 4.7.

Silica gel chromatography of the mother liquors gave the lower melting isomer **22***b*, mp 113–115°C. The spectral data were virtually identical with those for **22***a* except for the absence of the nmr singlet at 3.15 δ (2H) which now complicated the multiplet in the 2.4–2.8 δ region.

In separate experiments, pure **21***a* was found to lead to **22***a* and the **21***b* samples afforded **22***b*. Yields were comparable in all cases.

*3[9(2-Oxo-4-ethylenedioxy-6-methylhydrind-1(8)-en)yl] Propionic Acid **20** (**23**)*

Under nitrogen, potassium hydroxide (1.32 g) was dissolved in degassed water (25 mL) and the diketone **19** (0.540 g of **22***a*) was added. The mixture was gently refluxed (under nitrogen) for 24 h and the crude product obtained by methylene chloride extraction. Preparative tlc over silica gel (ethyl acetate) afforded the cyclised acid **20** (0.300 g, 56%), mp 137–138°C: λ_{max}: 238 (12 300) nm; ν (KBr): 3600–2400, 3040, 1715(broad), and 1630 cm^{-1}; nmr ($CDCl_3$) δ: CH_3CH d(6.0) 0.98, —OCH_2CH_2—O s 3.92 (4H), =CH— s 5.93, —COOH br s 9.30 (D_2O). *Anal.* calcd. for $C_{15}H_{20}O_5$: C 64.3, H 7.2; found: C 64.2, H 7.2.

The *methyl ester* was prepared with excess ethereal diazomethane or better with methyl iodide and potassium carbonate, mp 101–103°C (from methanol): nmr ($CDCl_3$) δ: CH_3 d(6.0) 1.0, $COOCH_3$ s (3H) 3.63, —OCH_2CH_2O— s (4H) 3.92 and =CH—CO s 5.92.

When the mixture of isomeric racemates of **19** was used as starting material, the crude product was difficult to purify and was normally converted to the methyl ester and chromatographed. Yields varied from 15–40%.

*2(β-Cyanoethyl)-2-acetonyl-3-chloro-5-methylcyclohexanone **11***

The chloro-containing propargyl derivative **8***b* (2.3 g) was hydrated as described above, mercuric oxide (0.140 g), BF_3–etherate (0.1 mL), trichloroacetic acid (0.010 g), and MeOH (2 mL). After 2.5 h, H_2SO_4 (250 mL of 2%) was added to hydrolyse the intermediates and the diketone **11** then isolated by extraction (2.1 g, 85%), mp 126–127°C (from acetone–hexane): ν (KBr): 2240, 1712, 1705, and 760 cm^{-1}; nmr ($CDCl_3$) δ: CH_3 d(5.5) 1.07, CH_3COCH_2— s 2.21 and ABq (20) ν_A 3.11 and ν_B 2.83, CH—Cl t(3.5) 4.88. *Anal.* calcd. for $C_{13}H_{18}NO_2Cl$: C 61.1, H 7.1, N 5.5, Cl 13.9; found: C 60.9, H 7.3, N 5.2, Cl 13.6.

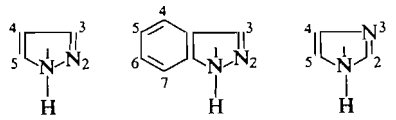
Indirect determination of the protonation constants $pK_a(B/BH^+)$ of substituted pyrazoles and indazoles from electrochemical results on the corresponding pentacyanoferrates complexes

JEAN-LOUIS BRISSET AND VICTOR ILIMBI

Laboratoire de Physicochimie des Solutions, LA CNRS 161, E.N.S.C.P. 11 rue Pierre et Marie Curie, 75231 Paris, France

Received December 18, 1979



JEAN-LOUIS BRISSET and VICTOR ILIMBI. Can. J. Chem. **58**, 1250 (1980).

A linear correlation is found between the oxidation potentials of the pentacyano (L) ferrates(II) complexes, where L refers to various substituted pyrazoles and indazoles, and the protonation constants of the heterocyclic base L. This correlation allows the $pK_a(L/LH^+)$ of very weak bases in these series be estimated.

JEAN-LOUIS BRISSET et VICTOR ILIMBI. Can. J. Chem. **58**, 1250 (1980).

Une corrélation linéaire entre le potentiel d'oxydation des complexes de type $Fe^{II}(CN)_5L$ (L: pyrazole ou indazole substitué) et la constante de protonation de la base L a été établie. Cette corrélation permet d'estimer le $pK_a(L/LH^+)$ de bases très faibles choisies dans ces séries.

The association between the pentacyanoferrate (II) or (III) moiety $Fe(CN)_5$ and various nucleophilic reagents R, such as organic bases involving one nitrogen atom, has been examined in numerous papers. The complexes $Fe(CN)_5R$ in which R refers to an amine or a pyridine molecule have been carefully investigated, but the literature is rather scanty on the pentacyanoferrates coordinated to a heterocyclic molecule involving several nitrogen atoms. The *N*-methylpyrazinium complex has been investigated through kinetic studies, but the 5-membered heterocyclic molecules have received little attention. When two nitrogen atoms are involved, the corresponding parent molecules are the pyrazole (PZ) or the imidazole (IM), according to the position of the N atoms in the ring.

PZ Indazole IM

Some kinetic and electrochemical results referring to the imidazole ferrate can be found in a few papers (1–5), but a more general study shows that this family of complexes has a very particular behaviour. Spectrophotometric data relevant to some pyrazole complexes are available in a work by Larue (6) (see Table 1).

A previous study (7–9) of the electrochemical behaviour of a number of pyridine complexes showed that the oxidation potential was pH-independent in the range $3 < pH < 12$ for a given complex, which could be therefore characterized by means of the relevant value of the half-wave oxidation potential $E_{1/2}$*. In addition, it was also shown that the $E_{1/2}$* values were linearly correlated to the acidity constants $pK_a(Py/PyH^+)$ of the pyridine ligands.

In this paper we are concerned with the substituted pyrazoles and indazoles complexes, and we attempt to discover whether a similar correlation occurs between the protonation constants $pK_a(B/BH^+)$ and the electrochemical data (viz. the values of the redox potentials) in a similar way as for the pyridine ferrates.

Experimental

The complexes were prepared *in situ* by dissolving solid $Na_3Fe(CN)_5(NH_3)$ and the appropriate ligand in a ratio close to 1:5 in a 0.5 *M* electrolytic solution of KCl or $NaClO_4$. The pH was varied by small additions of strong acid or base and measured immediately after recording the voltammetric curves. The device used for the electrochemical study (dc polarography on a platinum rotating electrode) has been described (8). The ligands were commercially available chemicals purchased from Ega, Fluka, or Aldrich, except for 4-chloropyrazole, 1-methylpyrazole, and 1-acetylpyrazole which were prepared according to known methods (10–12).

The acidity constants pK_a of the ligands were determined potentiometrically in 0.5 *M* KCl solutions.

Results and Discussion

The current–voltage curves recorded for the oxidation of the complexes verify the usual criteria for reversibility:

One monoelectronic wave is observed and the difference $E_{3/4} - E_{1/4}$ is found to be 0.06 V according to the usual value at 20°C.

As a side phenomenon, a second wave is observed for some indazole ferrates (compounds **8–11**) at less positive potentials; this wave is not identified presently, since it is not observed for the pure ligand, or for the pure aquoferrate.

[d]Calculated from eq. [1] (ionic strength 0.5).
[e]Thermodynamic data taken from ref. 14.
[f]Thermodynamic, calculated from values in ref. 14 by correcting with 0.17.
[g]Wavelength (nm) of the absorption peaks of the complexes on the 1st plateau. A linear correlation can be found between $E_{1/2}$ and λ^{-1}, as previously found for the pyridine complexes (9). For the ligands considered, the equations are respectively: $E(V) = 127.5\lambda^{-1} - 0.111$ for PZ, with $r^2 = 0.72$. $E(V) = 51.2\lambda^{-1} + 0.176$ for indazole, with $r^2 = 0.87$. Complex **11** was not considered because of its particular behaviour as an acido-basic indicator.

The plot: $\log (i/i_{lim} - i) = f(E)$, is linear and the slope confirms that one electron is involved in the redox process.

Levich's law is obeyed, and this gives evidence that the electrochemical process is diffusion-controlled.

For each compound, the values of the half-wave potentials $E_{1/2}$ in oxidation are plotted against the corresponding pH values (Fig. 1). The general outline of these diagrams consists of two plateaus for which $E_{1/2}$ is pH-independent joined by a straight line of slope − 0.06 V per pH unit. This is consistent with the following predominance area diagram, where LH refers to the heterocyclic ligand and L to the relevant deprotonated molecule (charges are omitted for the sake of clearness).[1]

However, the second plateau is not observed for some particular ligands, probably because it is located in the high pH range (pH > 12) which has not been investigated (e.g. pH > 12.5 for the indazole complexes). In addition, one can verify that for the 1-substituted ligands for which no proton loss can be considered (e.g. 1-methylpyrazole), the half-wave oxidation potential is not pH-independent in the range 2–12 as expected. The acido-basic properties of the complexes might then be attributed to the OH^- ions which attack at the ligand LH in a similar way as suggested by Gillard (13). The predominance area diagram should then be modified by replacing $Fe(CN)_5L$ by $Fe(CN)_5(LHOH)$. Experiments are under way to get further informations.

In addition, the values of $E_{1/2}$ for the first plateau are linearly correlated to the protonation constants $pK_a(LH/LH_2^+)$ of the ligands. It is noticeable that the results for the substituted pyrazole and indazole complexes fit very well on the same plot. This indicates that the acidity of the sp^2 nitrogen atom is concerned, as has already been found for the pentacyano (pyridine) ferrates(II) for which such an experimental correlation was verified for more than 20 ligands (9). The equation:

[1] $E_{1/2}\,(mV/sce) = -41.65pK_a + 309.43$

can be suggested as the general relationship relevant to the pyrazole and indazole ferrates, with a correlation coefficient of 0.99. It is worthwhile to

[1]Except for acidic media (pH < 2) where protonation occurs on the cyanide groups, the various redox systems considered are, with increasing pH:

$Fe^{II}(CN)_5(LH) \rightleftharpoons Fe^{III}(CN)_5(LH) + e^-$

corresponding to the first plateau of the plot $E_{1/2}$* vs. pH.

$Fe^{II}(CN)_5(LH) \rightleftharpoons Fe^{III}(CN)_5L + H^+ + e^-$

corresponding to the slope of 0.06 V per pH unit.

$Fe^{II}(CN)_5L \rightleftharpoons Fe^{III}(CN)_5L + e^-$

corresponding to the second plateau.

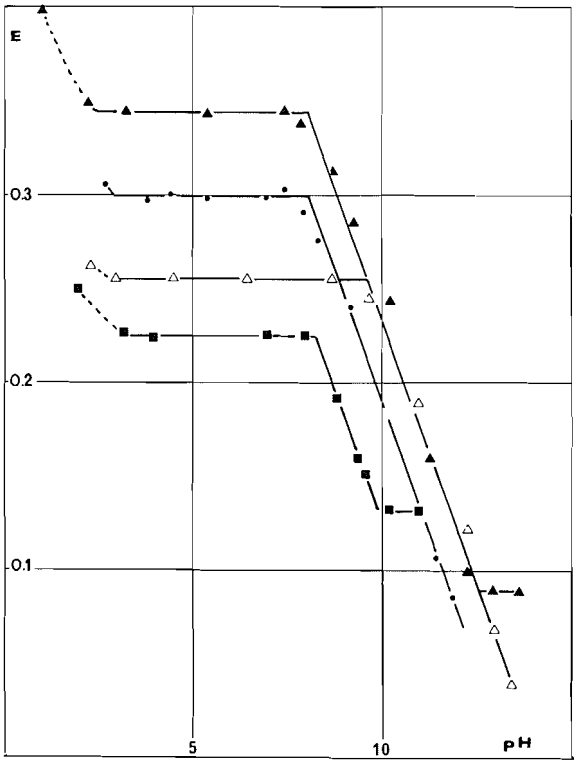

FIG. 1. Typical plots of the half-wave potentials vs. pH for the pentacyanoferrate complexes of 5-nitroindazole (●), 7-nitroindazole (▲), indazole (△), 4-chloropyrazole (■). E (V) is referred to the sce electrode.

mention that the slope of eq. [1] is about two times that of the pyridine correlation. As an immediate consequence, the protonation constants $pK_a(LH/LH_2^+)$ or very "acid" ligands taken in these series can be determined by means of eq. [1], provided one knows the $E_{1/2}$ vs. pH plots. We report in Table 1 the protonation constants pK_a of nitroindazoles and various substituted pyrazoles, which are otherwise too low to be determined potentiometrically.

The so-determined constants are not thermodynamic values since they are obtained from measurements performed at ionic strength 0.5 instead of zero. Assuming then that the ionic strength affects the constants $pK_a(LH/LH_2^+)$ in the same manner, one can estimate the thermodynamic values by calibrating against a given reference (e.g. unsubstituted indazole or pyrazole) or correcting the interpolated value by 0.17 according to ref. 14 (Table 1). The precision on the calculated values depends on the accuracy admitted for the polarographic measurements. Considering that $E_{1/2}$ is known with an accuracy of ±8 mV, then the pK_a values are determined within ± 0.2 pK units.

Activity corrections for ionic equilibria in aqueous solutions

MIAN S. SUN, DONALD K. HARRISS, AND VINCENT R. MAGNUSON

Department of Chemistry, University of Minnesota, Duluth, MN 55812, U.S.A.

Received July 30, 1979

MIAN S. SUN, DONALD K. HARRISS, and VINCENT R. MAGNUSON. Can. J. Chem. **58**, 1253 (1980).

Activity corrections for ionic equilibria in aqueous solutions at 25°C and ionic strengths up to 0.5 have been investigated. An empirical formula for activity corrections was generated by statistically fitting stability constant data for approximately 540 complexes, for which both thermodynamic and concentration stability constants were known, to a modified Debye–Hückel relationship. The general formula is

$$\Delta \log K = 0.51[\sqrt{I}/(1 + 1.50\sqrt{I}) - 0.09I]\chi - 0.09I$$

$\chi > 0$, where $\Delta \log K$ is the difference in the logarithms of the stability constants at infinite dilution and finite I ($I \leq 0.5$), and χ is an even integer dependent only on the stoichiometry and charge of the ions involved. Activity correction formulae for ionic equilibria involving classes of ligands (amino acid, inorganic, amine, and organic acid) also were developed. The general formula predicts stability constant corrections within 0.1 log unit for 87% of the data used at ionic strength 0.1 and 64% of the data at ionic strength 0.5. In addition, single ion activity coefficients as a function of ionic strength, $0 < I \leq 0.5$, are presented.

MIAN S. SUN, DONALD K. HARRISS et VINCENT R. MAGNUSON. Can. J. Chem. **58**, 1253 (1980).

On a étudié les corrections d'activité pour l'équilibre ionique en solution aqueuse à 25°C et à des forces ioniques allant jusqu'à 0.5. Les données relatives aux constantes de stabilité de 540 complexes pour lesquelles on connaît les constantes de stabilité thermodynamique et concentration, ajustées d'un point de vue statistique ont permis de produire une formule empirique du type Debye–Hückel de correction des activités. Cette formule générale est la suivante:

$$\Delta \log K = 0.51[\sqrt{I}/(1 + 1.50\sqrt{I}) - 0.09I]\chi - 0.09I$$

$\chi > 0$ dans cette formule $\Delta \log K$ est la différence des logarithmes des constantes de stabilité à dilution infinie et finie I ($I \leq 0.5$) et χ est un nombre entier pair qui dépend seulement de la stoechiométrie et de la charge des ions impliqués. On a également développé des formules de correction d'activité des équilibres ioniques qui font intervenir les classes de ligands (acide aminé, inorganique, amine et acide organique). La formule générale permet de prédire à 0.1 unité logarithmique près pour 87% des données utilisées les corrections de constantes de stabilité à une force ionique de 0.1 et pour 64% des données à une force ionique de 0.5. On présente de plus des coefficients d'activité d'un ion unique comme étant une fonction de la force ionique comprise entre $0 < I \leq 0.5$.

[Traduit par le journal]

Introduction

Utilization of literature data for aqueous ionic equilibria is hampered by the lack of ionic activity correction formulae of demonstrated validity for solutions of medium to high ionic strength. Recent data compilations (1, 2) provide a valuable resource with which to test the validity of existing formulae, and a means to develop an empirical formula applicable over a wide range of ionic strengths.

Correction to infinite dilution requires the knowledge of activity coefficients. The most commonly used formulae are the Debye–Hückel (3–5) and Davies (6, 7) equations. The former is said to be applicable at ionic strengths less than 0.1 (3) while the latter are said to be useful up to 0.5 (8). The reliability of these formulae for general application at higher ionic strengths remains questionable due to the lack of large-scale testing with experimental data.

Although the Debye–Hückel and Davies equations have been used extensively, many researchers have used a general equation of the same form to estimate single-ion activity coefficients at 25°C, e.g.,

$$[1] \quad \log \gamma = -0.51z^2\left(\frac{\sqrt{I}}{1 + A\sqrt{I}} + BI\right)$$

When $A = 1.0$ and $B = -0.2$ this equation is referred to as the Davies equation (6), although a value of -0.3 for B has been used in recent works (7). Equation [1] is referred to as the Debye–Hückel equation (3) when $A = 0.33a_0$ and $B = 0$ where a_0 is the effective ion diameter in Å; values of a_0 have been reported for a number of ions (9). Other values for these parameters have been suggested by Scatchard (5) ($A = 1.5$ and $B = 0$) and Güntelberg (4) ($A = 1.0$ and $B = 0$) with a suggested ionic strength less than 0.1.

In the compilation of Smith and Martell (1, 2), a great many stability constants are reported at $I = 0.1$ or 0.5, and for some, corresponding values at infinite dilution also are available. These data will be used to re-examine the parameters in eq. [1] and to establish guidelines for extrapolating the stability constant data at $0 < I \leq 0.5$ to infinite dilution.

Considering a reaction at equilibrium

$$a\mathrm{A} + b\mathrm{B} + \ldots . \rightleftharpoons p\mathrm{P} + q\mathrm{Q} + \ldots .$$

where all charges are omitted for simplicity, the thermodynamic equilibrium constant can be written

[a]This work, eq. [9].
[b]Davies, $B = -0.3$.
[c]Applicable to ML only.
[d]Applicable to ML_2 only.

$$k = \frac{[P]^p[Q]^q \cdots}{[A]^a[B]^b \cdots} \cdot \frac{\gamma_P{}^p\gamma_Q{}^q \cdots}{\gamma_A{}^a\gamma_B{}^b \cdots} = K_c K_\gamma$$

where K_c is the concentration equilibrium constant and K_γ the activity correction. The difference between logarithms of the thermodynamic equilibrium constant and the concentration equilibrium constant will be referred to as $\Delta \log K$,

$$[2] \quad \Delta \log K = (p \log \gamma_P + q \log \gamma_Q + \ldots) - (a \log \gamma_A + b \log \gamma_B + \ldots)$$

Assuming A and B in eq. [1] to be constants, independent of the nature of the ions, combination of eqs. [1] and [2] at 25°C yields

$$[3] \quad \Delta \log K = 0.51\left(\frac{\sqrt{I}}{1 + A\sqrt{I}} + BI\right)\chi$$

where

$$[4] \quad \chi = (az_A{}^2 + bz_B{}^2 + \ldots) - (pz_P{}^2 + qz_Q{}^2 + \ldots)$$

and the z's are charges for the ionic species. The χ values, as can be shown, take on only even integer values.

Using experimental data for $\Delta \log K$ at various values of χ and I, appropriate statistical treatments can be applied to eq. [3] to determine best values for A and B.

Treatment of Data

Stability constants, which were reported at both infinite dilution and $I = 0.1$ or 0.5, at 25°C for metal complexes over a wide range of metal ions and ligand types (amino acids, inorganic, organic acids, and amines), were selected from Smith and Martell. Approximately 850 $\Delta \log K$ values for metal complexes with $-6 \leq \chi \leq +18$ were collected. Average values of $\Delta \log K$ along with standard deviations at each χ value at 25°C for $I = 0.1$ and 0.5 are presented in Tables 1 and 2, respectively. A total of 47 different metals, including hydrogen, ranging in oxidation state from +1 to +4 and approximately 140 ligands were considered in this study. Data were not included for cases for which tetraalkylammonium salts were used as background electrolytes as use of these salts results in larger $\log K_c$ values than if salts such as $NaClO_4$ or KNO_3 are used (1, 2); also, approximately 15% of the possible data were rejected because of unreasonably high deviations from the means given in Tables 1 and 2.

With the exception of inorganic ligands, data at $\chi = 2$ are dominated by HL and H_2L. For $\chi \geq 4$ a variety of complexes with metal ions and/or protons are involved, except in the case of organic acids where the HL^- species yield the majority of values at $\chi = 4$. Negative values of χ were observed only for the amines due to positively charged ligands in reaction such as

$$M^{2+} + HL^+ \rightleftharpoons MHL^{3+}$$

Much of the data at $\chi = 0$ involves complex formation with neutral ligands. Data at $\chi = 0$ for other ligand categories either are lacking or highly uncertain (see Tables 1 and 2). The uncertainties in $\Delta \log K$, as indicated by the standard deviations, generally increase with χ and I.

TABLE 2. Average Δ log K values with standard deviations, numbers in parentheses are sample size, I = 0.5, 25°C

[a]This work, eq. [9].
[b]Davies, B = −0.3.
[c]Applicable to ML only.
[d]Applicable to ML_2 only.
[e]Applicable to ML_3 only.

At constant ionic strength all Δ log K values at a given value of χ as calculated by eq. [3] should be the same; a plot of Δ log K versus χ should give a straight line through the origin. Weighted linear regressions were performed on Δ log $K = m\chi + b$ and Δ log $K = m\chi$ for the raw data ($\chi \neq 0$) at constant ionic strength, I = 0.1 or 0.5, with weighting factors based on the uncertainties shown in Tables 1 and 2. In all cases linearity between Δ log K and χ is indicated by Pearson correlation coefficients greater than 0.96. The best fits do not pass through the origin for the amines, the organic acids, and the general case.

The B values calculated from the slopes for the Davies equation are dependent upon ionic strength, decreasing in magnitude with the ionic strength. Thus, assuming that the intercept is a function of I, $Cf(I)$, eq. [3] can be replaced with

$$[5] \quad \Delta \log K = 0.51\left(\frac{\sqrt{I}}{1 + A\sqrt{I}} + BI\right)\chi + Cf(I)$$

For eq. [1] with A = 1, it has been shown that B is a function of I as given below, applicable up to I = 3.0 (10):

$$[6] \quad B = \alpha + \beta F(I)$$

and

$$[7] \quad F(I) = [1 - (1 + 2\sqrt{I} - 2I)\exp(-2\sqrt{I})]/4I$$

where α and β are constants (10). Thus, with A = 1 eq. [5] becomes

$$[8] \quad \Delta \log K = 0.51\left[\frac{\sqrt{I}}{1 + \sqrt{I}} + \alpha I + \beta I F(I)\right]\chi + Cf(I)$$

A weighted least-squares procedure (11) was applied to eqs. [5] and [8] to evaluate the parameters α, β, A, B, and C. The weighting factors included the variances in I, as well as the variances in Δ log K. In view of the low precision of the reported ionic strengths (one significant figure), the uncertainties in I were assumed to be ±10%. The statistically best fit was found for $f(I) = I$.

Results and Discussion

The calculated parameters for eqs. [5] and [8] are tabulated in Table 3. The C values are identical for both equations within the precision shown in Table 3 and eq. [5] is as reliable as eq. [8] in predicting Δ log K.

For the amino acid and inorganic ligand cases, there was no statistical difference whether the term $f(I)$ was included or not. Thus, for these two ligand types we report C to be equal to zero.

All complexes used in this study other than those containing amines involve negatively charged ligands and exhibit χ values greater than zero. For $\chi > 0$ the observed Δ log K values of all complexes including amines fall within a narrow range. Using values of A, B, and C from Table 3 in eq. [5], the general expression for calculation of Δ log K is

$$[9] \quad \Delta \log K = 0.51\left(\frac{\sqrt{I}}{1 + 1.50\sqrt{I}} - 0.09I\right)\chi - 0.09I \qquad \chi > 0$$

In Fig. 1, calculated Δ log K values at I = 0.1 vs. χ are shown along with the average observed data classified by ligand type. Also shown for comparison

[b] SEE = standard error of estimate.

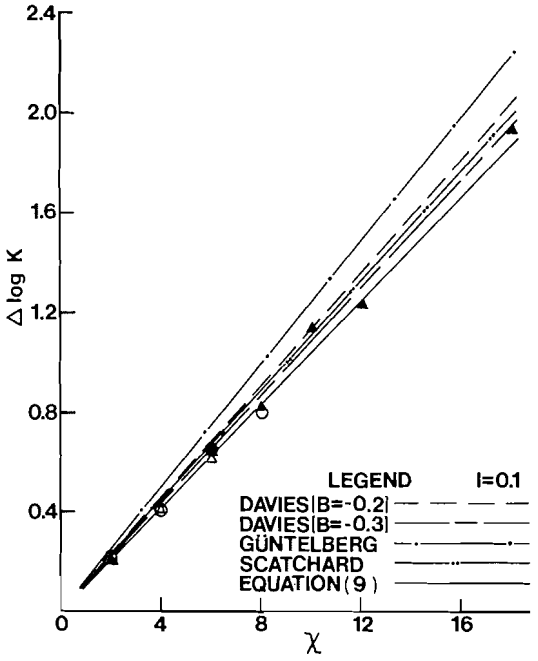

FIG. 1. Observed average $\Delta \log K$ values, $\chi > 0$, for metals complexing with organic acids (▲), inorganic (●), amino acids (△), and amines (○) at $I = 0.1$ and 25°C. The solid line is eq. [9] with $\Delta \log K$ plotted as a function of χ. Also shown for comparison is $\Delta \log K$ versus χ based on the Davies, Güntelberg, and Scatchard equations.

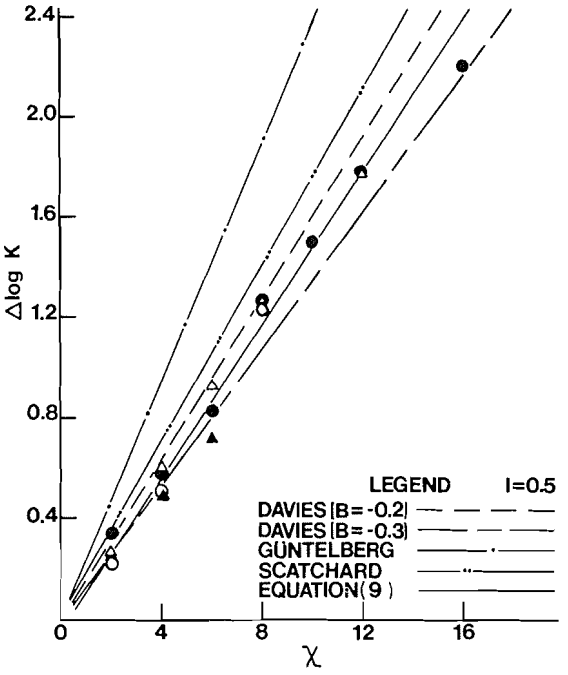

FIG. 2. Observed average $\Delta \log K$ values, $\chi > 0$, for metals complexing with organic acids (△), inorganic (●), amino acids (▲), and amines (○) at $I = 0.5$ and 25°C. The solid line is eq. [9] with $\Delta \log K$ plotted as a function of χ. Also shown for comparison is $\Delta \log K$ versus χ based on the Davies, Güntelberg, and Scatchard equations.

are the predicted $\Delta \log K$ values based on the Davies equations, both with $B = -0.2$ and -0.3, the Güntelberg equation, and the Scatchard equation. Similar plots are shown in Fig. 2 for the case $I = 0.5$. As can be seen from Fig. 1, both eq. [9] and the Davies equation with $B = -0.3$ successfully predict the observed values of $\Delta \log K$. However, at higher ionic strength (see Fig. 2, $I = 0.5$) eq. [9] clearly is superior in fitting the data.

A measure of the accuracy of eq. [9] can be obtained by noting that 87% of the $\Delta \log K$ values are predicted within ± 0.1 at $I = 0.1$ and 64% within these limits at $I = 0.5$. In terms of percentage errors in $\Delta \log K$, 89% and 74% are predicted within $\pm 20\%$ at $I = 0.1$ and $I = 0.5$, respectively.

The results for the amine complexes, as shown in Tables 1 and 2, appear to be unique. Metal amine complexes with values of $\chi > 0$, $\chi = 0$, and $\chi < 0$ correspond to complexes in which the ligands are negatively charged, neutral, and positive, respectively. The $\Delta \log K$ values at $\chi = 0$ divide into groups depending on the number of neutral ligands involved, and the $\Delta \log K$ ratios $-0.05 : -0.11 :: 1 : 2.2$ (Table 1, $I = 0.1$) and $-0.14 : -0.27 : -0.44 :: 1 : 1.9 : 3.1$ (Table 2, $I = 0.5$) indeed correspond to the number of ligands in ML, ML_2, and ML_3, respectively. The $\Delta \log K$ values are in fact the negative values of $\log \gamma_L$, $2 \log \gamma_L$, or $3 \log \gamma_L$ for the neutral ligands in these complexes. The logarithm of the activity coefficient for the neutral species should be proportional to the ionic strength (12), i.e.,

$$\log \gamma_L = cI$$

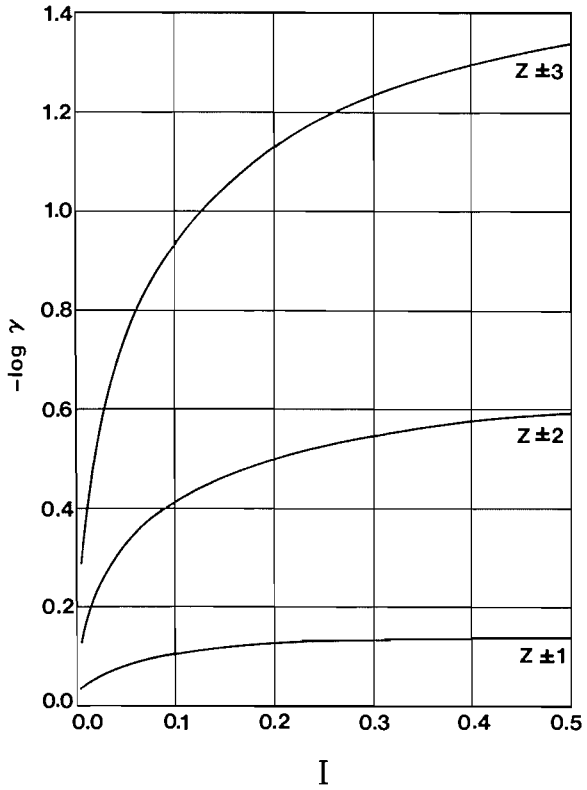

FIG. 3. Single ion activity coefficients predicted with smoothed $\Delta \log K$ values from eq. [9].

thus,

$$[10] \quad (\Delta \log K)_{\chi=0} = -ncI$$

where n is the number of neutral ligands in the complex and c is a constant. Using the data in Tables 1 and 2 for amines, the computed value of c is about 0.3. The reported values of $\Delta \log K$ at $\chi = 0$ for the silver(I) amine complexes, showing no discernible pattern, do not agree with the calculated values from eq. [10]. Using the parameters in Table 3, the equation for the amine complexes is

$$[11] \quad \log K = 0.51\left(\frac{\sqrt{I}}{1 + 1.42\sqrt{I}} - 0.41I\right)\chi - 0.30I \qquad \chi \neq 0$$

The activity coefficients for single ions can be estimated at a given ionic strength by fitting eq. [2] with smoothed $\Delta \log K$ values from eq. [9] using suitable linear combination of the logarithms of γ_1, γ_2, and γ_3 which are, respectively, the activity coefficients of singly, doubly, and triply charged ions. The results are shown in Fig. 3. Alternately, using the smoothed $\Delta \log K$ values from eq. [9] to fit eq. [3] with $I \leq 0.5$ and $\chi \leq 18$ leads to

$$[12] \quad \log \gamma = -0.51z^2\left(\frac{\sqrt{I}}{1 + 1.50\sqrt{I}} - 0.11I\right)$$

which reproduces the curves in Fig. 3 to the nearest 0.02 log unit. For singly and doubly charged ions these results differ slightly from those of Ringbom (13); however, the difference is much larger for the triply charged ions. For example, the activity coefficients (as $-\log\gamma$) for single ions with $z = \pm 3$ at ionic strengths 0.1, 0.3, and 0.5 are found to be 0.93, 1.23, and 1.34 in this work compared to 0.74, 0.96, and 1.03 in Ringbom's work.

Equations [9], [10], and [11] represent the best empirical choices to date for activity corrections in aqueous solutions for $I > 0.1$. They are recommended for use for the general case, neutral ligands ($\chi = 0$), and amines, respectively.

Analysis of ^{13}C nuclear magnetic resonance chemical shifts of acyclic hydrocarbons

HELMUT BEIERBECK AND JOHN K. SAUNDERS

Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 27, 1979

HELMUT BEIERBECK and JOHN K. SAUNDERS. Can. J. Chem. **58**, 1258 (1980).

The ^{13}C nmr chemical shifts of aliphatic hydrocarbons were derived from chemical shifts and probabilities of individual chain conformations. Conformer resonances were calculated with parameters developed for conformationally homogeneous cyclic molecules. Conformer populations were derived from bond rotation potentials and steric energy contributions, available from independent sources. This analysis contains non adjustable parameters. It represents a unified treatment of cyclic and acyclic hydrocarbon resonances, which is capable of dealing with molecular asymmetry and thus permits the determination of configuration in aliphatic hydrocarbons.

HELMUT BEIERBECK et JOHN K. SAUNDERS. Can. J. Chem. **58**, 1258 (1980).

Les déplacements chimiques en rmn de ^{13}C des hydrocarbures aliphatiques fûrent obtenus en combinant le déplacement chimique et la probabilité des conformations de la chaîne. Les résonances des conformères ont été calculés avec les paramètres utilisés pour les molécules cycliques conformationnellement homogènes. La population des conformères est obtenue des potentiels de rotation des liaisons et des contributions de l'énergie stérique; disponibles de source indépendante. Cette analyse ne contient pas de paramètre variable. Elle représente un traitement unique des résonances des hydrocarbures cycliques et acycliques, capable de s'ajuster à l'assymétrie moléculaire et ainsi permet la détermination de la configuration des hydrocarbures aliphatiques.

The early work by Grant and Paul (1) on aliphatic hydrocarbons provided one of the first demonstrations of the additivity of substituent effects on ^{13}C nmr chemical shifts. Unfortunately, their analysis was based on a topological, rather than geometric, description of molecular structure, and conformational interconversions were not explicitly taken into consideration. Consequently their substituent parameters could neither deal with molecular asymmetry, nor could they be applied to conformationally homogeneous cyclic substrates. Lindeman and Adams (2) later proposed an expanded and modified parameter set, but it too was topological and therefore incapable of dealing with molecular chirality.

Structure elucidation obviously includes the determination of configuration at asymmetric centers, and chemical shift parameters must be able to reproduce magnetic nonequivalence. Since chemical shift nonequivalence in asymmetric chains is the result of geometric nonequivalence in individual conformations, it cannot be understood without a knowledge of the physical properties of these conformations. In other words, the observed chemical shifts are conformational averages, and therefore have to be compared to conformational averages, calculated from conformer resonances and populations.

We have used such an approach to analyse the carbon chemical shifts of a series of saturated aliphatic hydrocarbons (3). The conformer resonances were calculated with a parametrization scheme developed for rigid cyclic substrates (4). The conformer populations were taken to be products of rotamer populations, and the rotational states of adjacent bonds were assumed to be independent. Steric contributions to conformer energies, although considered important (5), were ignored in order to simplify the analysis. Numerical values for the chemical shift and rotamer population parameters were derived by a least-squares fit of calculated to observed conformationally averaged resonances. The chemical shifts calculated from these conformer resonances and probabilities agreed reasonably well with the experimental values. However, magnetic nonequivalence in asymmetric molecules was greatly underestimated, and the rotamer populations derived by optimization did not agree too well with experimental values (6, 7).

The insensitivity of the calculated chemical shifts to molecular asymmetry turned out to be due to the neglect of steric contributions to the conformer energies, and these are now incorporated into the analysis. Secondly, it was decided to use experimentally determined rotational energies (6) and previously derived substituent parameter values for rigid cyclic systems (4) in place of parameter optimization.

The modified analysis of the ^{13}C nmr chemical shifts of saturated aliphatic hydrocarbons presented here contains no more adjustable parameters. It represents a unified treatment of cyclic and acyclic hydrocarbon resonances, which is capable

of dealing effectively with molecular chirality, and thus permits the determination of configuration in aliphatic hydrocarbons.

Results and Discussion

The conformer resonances are calculated with a parameter set developed for rigid, conformationally homogeneous substrates (4). The chemical shifts for primary, secondary, tertiary, and quaternary carbons are based on four separate reference parameters P, S, T, and Q. An increment HC is added for every 1,3-diaxial hydrogen–hydrogen alignment, a parameter CC for every carbon–carbon *gauche* arrangement, and an increment δ for every *syn*-axial δ interaction. In the previous analysis (3) the numerical parameter values were obtained by a least-squares fit to a set of aliphatic hydrocarbon data. In the present version the numerical values from ref. 4 are used (Table 1).

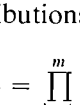
In the previous analysis (3) the conformational energies were simply considered to be the sums of the rotational energies of the constituent bonds of the chain, and steric energy contributions were ignored. Now the conformer energies are taken to be the sums of rotational and steric energy contributions E_{ij} with associated statistical weights u_{ij}.

$$u_{ij} = \exp(-E_{ij}/RT)$$

The conformer statistical weights Ω_j are the products of m statistical weights u_{ij}, corresponding to m contributions E_{ij} to the energy of conformer j.

$$\Omega_j = \prod_{i=1}^{m} u_{ij}$$

Division of the n conformer statistical weights Ω_j by their sum, the conformational partition function Z, then gives the conformer populations p_j



$$Z = \sum_{j=1}^{n} \Omega_j$$

$$p_j = \Omega_j/Z$$

There is rotational isomerism about four types of bonds. The three rotational states of bonds involving quaternary carbons are taken to be equally probable, with zero rotational energies and statistical weights of 1.0. The remaining three bond types correspond to butane, 2-methylbutane, and 2,3-dimethylbutane, whose rotational energy differences are available from Raman spectroscopic studies (6). The rotation potential for 2,3-dimethylbutane has been confirmed by low temperature ^{13}C nmr spectroscopy (7). The energies of the degenerate rotational states are set equal to zero, with statistical weights of 1.0, and the relative energies and corresponding statistical weights for the unique rotational states are given in Table 1.

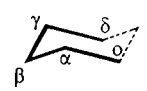


TABLE 1. Parameter definitions and numerical values[a]

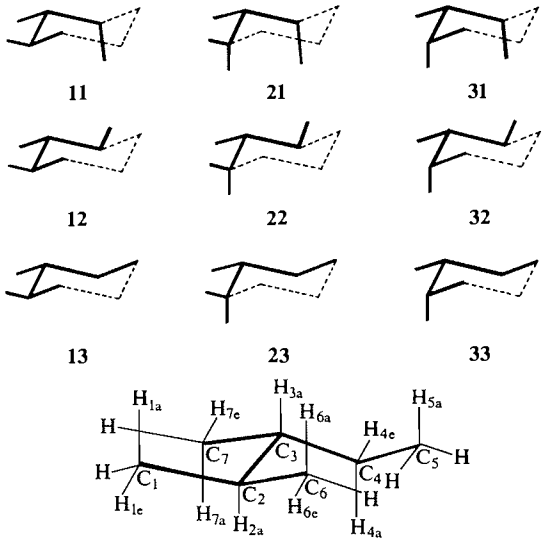
Chemical shift parameters		Value (ppm)
P		7.44
S		17.62
T		24.17
Q		26.53
HC		4.55
CC		1.85
δ		2.56

Population parameters	Energy (kJ/mol)	Statistical weight u_{ij}
	−4.042	5.055
	3.385	0.257
	−0.226	1.095
	8.368	0.035

[a]The chemical shift parameters are taken from ref. 4. The rotation potentials, taken from ref. 6, are the energies of the unique, relative to the degenerate, rotational state. The δ energy contribution is taken from ref. 5. The statistical weights are calculated for 300 K.

Two types of steric effects are considered, namely δ and ε interactions. The statistical weights of conformations, which would contain ε interac-



δ ε

tions, are set equal to zero. Each *syn*-axial δ interaction is taken to contribute 2.0 kcal/mol to the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

conformational energy (5). The δ energy term and its corresponding statistical weight are included in Table 1. If there are neither δ nor ε interactions, the "steric" statistical weight is 1.0.

The derivation of the C_1 and C_6 resonances of 2,3-dimethylpentane may serve as numerical illustration. Rotation about bonds C_2—C_3 and C_3—C_4 gives rise to nine molecular conformations, denoted **11** to **33**.

In conformer **13**, for example, bond C_2—C_3 is in the unique rotational state of 2,3-dimethylbutane, bond C_3—C_4 in a degenerate rotational state of 2-methylbutane, and there is one δ interaction between C_5 and C_6. The statistical weight Ω_{13} for conformation **13** of 2,3-dimethylpentane is therefore

$$\Omega_{13} = 1.095 \times 1.000 \times 0.035 = 0.038$$

This value and the remaining conformer statistical weights are listed in Table 2. The sum of the conformer statistical weights Ω_j, the partition function Z, is equal to 4.468 in this case, and division of the Ω_j by that value gives the conformer populations p_j in the last column of Table 2.

The chemical shifts of C_1 and C_6 in conformation **13** of 2,3-dimethylpentane are determined by the following interactions:

C_1	P300			
	HC	H_{1a}–H_{3a}	H_{1e}–H_{6e}	H_{1a}–H_{6a}
	CC	—		
	δ	—		
C_6	P301			
	HC	H_{6e}–H_{1e}	H_{6a}–H_{1a}	H_{6a}–H_{3a}
	CC	—		
	δ	C_6—C_5		

The primary carbon C_1 is involved in three HC, zero CC, and zero δ interactions (abbreviated P300), and its chemical shift in that conformation is

$$7.44 + 3 \times 4.55 = 21.09 \text{ ppm}$$

The primary carbon C_6 is engaged in three HC, zero CC, and one δ interaction (abbreviated P301), and its chemical shift is

$$7.44 + 3 \times 4.55 + 2.56 = 23.65 \text{ ppm}$$

The nine sets of conformer resonances for C_1 and C_6 are given in Table 3. Multiplication of these conformer resonances by the conformer populations of Table 2 gives the conformer contributions shown in the last two columns of Table 3. Their sums are the conformationally averaged chemical shifts.

The procedure was again tested with the hydrocarbon data of Lindeman and Adams (2), and was able to reproduce the complete set of chemical shifts with a standard deviation of 1.59 ppm (Table 4). The experimental data of ref. 2 were found to require a few corrections. Firstly, calculations suggested a reversal of the assignments for C_2 and C_3 of

TABLE 2. Derivation of conformer populations for 2,3-dimethylpentane

For personal use only.

2,3,3,4-tetramethylpentane, and this interchange was confirmed by off-resonance decoupling.[1] Secondly, the 2,4-dimethyl-3-ethylpentane data required two changes. With a 0.2 *m* $CDCl_3$ solution[1] at 30°C a chemical shift of 52.1 ppm was obtained for C_3, in place of 56.8 ppm (2). Furthermore, we found a pair of two carbon peaks at 19.4 and 21.5 ppm, and a one carbon signal at 20.2. Therefore the 20.0 ppm resonance of ref. 2 is assigned to C_7 and the 19.0 and 21.1 ppm peaks to C_1 and C_6.

Table 4 contains several examples of hydrocarbons with one or two asymmetric centers, and the presence of the chiral centers is clearly reflected in the calculated chemical shifts. Although magnetic nonequivalence is a consequence of chemical shift differences in individual chain conformations, it is essentially carried by population, rather than by chemical shift parameters. Consider the case of a chiral molecule with two magnetically nonequivalent carbons C_i and $C_{i'}$. Whatever the geometric relation of C_i to any other group R in any given molecular conformation *a*, i.e. whatever the contribution of R to the C_i resonance, another conformer *b* can always be found where $C_{i'}$ takes the place of C_i, i.e. where R makes the same chemical shift contribution to $C_{i'}$. The interactions of C_i and $C_{i'}$ with R may nevertheless lead to unequal contributions to the C_i and $C_{i'}$ resonances, since conformers *a* and *b* will generally occur with unequal probability. The analysis of the C_1 and C_6 resonances of 2,3-dimethylpentane, the simplest asymmetric aliphatic hydrocarbon, may serve as illustration. Clockwise 120° rotation about bond C_2—C_3 brings C_6 into a position previously occupied by C_1, relative to the rest of the molecule. Since this does not change the geometric relation between C_1 and C_6, the conformer shift of C_6 after rotation always equals the C_1 resonance before rotation. This is clearly seen in Table 3, where the C_6 conformer resonances repeat the C_1 values with a delay of three rows. That C_1 and C_6 are nevertheless nonequivalent is simply due to the fact that bond rotation changes the conformer populations. For example, the C_1 conformer shift in **13**, 21.09 ppm, equals the C_6 conformer shift in **23**, but the conformer contributions, 0.18 and 4.72 ppm, are quite different (Table 3).

The conformer populations are functions of rotation potentials as well as steric energy contributions, but it is the steric effects which transmit molecular asymmetry. The chiral center is always at least two bonds from C_i and $C_{i'}$, as in 2,3-dimethylpentane, and therefore the partial structure up to and including at least the γ carbons remains symmetric. It is of course precisely this molecular segment which makes the principal shift contributions, HC and CC, to the conformer resonances. Only the δ shift parameter originates outside this range. Now if $E_\delta = 0$, nothing perturbs the symmetry of this segment, and HC and CC interactions make equal contributions to C_i and $C_{i'}$. Magnetic nonequivalence is exclusively due to unequal probabilities of occurrence of δ shift contributions in this case. If $E_\delta \neq 0$, on the other hand, steric interactions will make some rotational states less probable, and thus destroy the symmetry of the rotamer populations. Now C_i and $C_{i'}$ are nonequivalent, because the much more important HC and CC interactions are no longer equally probable.

Consider again the case of 2,3-dimethylpentane.

$E_\delta = 0$. If the p_j are rederived by setting all $u_\delta = 1.0$ in Table 2, and the new conformer populations are used to weigh the conformer resonances in Table 3, a C_6–C_1 shift difference of only 20.12 – 20.08 = 0.04 ppm is obtained (Table 5). This difference is exclusively due to unequal δ shift contributions

$$(p_{13} + p_{31}) - (p_{21} + p_{33}) = 0.014$$

and 0.014 × 2.56 = 0.04 ppm. The case $E_\delta = 0$ corresponds to the previous version of the analysis (3). However, the chemical shifts have changed somewhat, since the parameters have changed.

$E_\delta = 8.368$ kJ/mol. *Syn*-axial δ interactions of C_1 and C_6 with C_5 destroy the symmetry of the rotational states of the C_2—C_3 bond.

State 1 $p_{11} + p_{12} + p_{13} = 0.317$

State 2 $p_{21} + p_{22} + p_{23} = 0.450$

State 3 $p_{31} + p_{32} + p_{33} = 0.234$

Bond C_2—C_3 is now more likely to be in rotational state 2, since this state is only once contained in a δ conformation, and state 3 twice. It is this population difference between rotational states 2 and 3 which is responsible for the nonequivalence of C_1 and C_6, since it leads to unequal HC interactions with C_3—H. In rotational state 1 both C_1 and C_6 are engaged in this HC interaction, in state 2 it is only C_6 and in state 3 only C_1. The resulting difference in HC contributions

$$(0.450 - 0.234) \times 4.55 = 0.98 \text{ ppm}$$

is precisely the difference between 20.05 ppm and 19.07 ppm (Table 5). It is clear from Table 5 that an underestimation of the value of E_δ should have no serious consequences for the derivation of chemical shifts, since the populations of conformations

[1]Samples of 2,3,3,4-tetramethylpentane and 2,4-dimethyl-3-ethylpentane were purchased from Chemical Samples Company.

15.0	0.001	19.01	20.05
20.0	0.000	19.01	20.05

with δ interactions rapidly reach their limiting value of zero.

2,3-Dimethylpentane was discussed in detail, since it is the simplest asymmetric hydrocarbon chain, and the effect of asymmetry on chemical shifts is most clearly seen in this system. The procedure is of course equally applicable to the derivation of chemical shifts of carbons further from the site of asymmetry, or in chains with more than one chiral center. The principal cause of magnetic nonequivalence, intra- or intermolecular, remains unchanged. Steric interactions perturb the rotational states of the individual bonds in the chain, and these changes in rotamer populations are a function of chirality. The changes in rotamer populations in turn determine the signs and magnitudes of the chemical shift differences. The conformational transmission over several bonds is illustrated by the dimethylheptanes.

Compound		Chemical shift C_1	C_8
2,3-Dimethylheptane	Obsd	17.9	20.1
	Calcd	19.1	20.0
2,4-Dimethylheptane	Obsd	22.1	23.1
	Calcd	22.8	24.0
2,5-Dimethylheptane	Obsd	22.3	22.5
	Calcd	23.1	23.2

The assignment of configuration in chains with more than one chiral center is demonstrated for the diastereomeric 3,4-dimethylhexanes.

3,4-Dimethylhexanes		Chemical shift C_1	C_2	C_3	C_7
meso	Obsd	11.8	25.8	39.5	15.8
	Calcd	11.8	27.0	40.3	15.9
d,l	Obsd	11.8	27.6	38.5	13.8
	Calcd	11.8	27.8	39.7	15.3

The calculations predict that in the *meso* isomer one primary and the tertiary carbon signal are shifted upfield, and the secondary carbon signal downfield relative to the *d,l* isomer. This is indeed found to be the case (8).[2] It should be emphasized

[2]The signal assignments for the diastereometric 3,4-dimethylhexanes in this article are based on the spectrum of the stereospecifically synthesized *meso* isomer (9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

that spectra for both isomers are required for an assignment of configuration.

To conclude, the analysis presented here is based on the accepted model for the conformational behaviour of chain molecules (5). Aliphatic hydrocarbons adopt a variety of rapidly interconverting conformations, each with distinct physical properties, and their behaviour cannot be understood without a knowledge of conformer properties and probabilities. There are no fundamental structural differences between cyclic molecules and individual conformations of acyclic substrates, and methods for the derivation of chemical shifts for rigid systems are equally applicable to the derivation of chain conformer resonances. The conformer probabilities are functions of the conformer energies, and the conformer energies are the sums of rotation potentials and steric energy contributions, which are available from independent sources. No additional assumptions or adjustable parameters are required. The analysis of the ^{13}C nmr chemical shifts of aliphatic hydrocarbons, based on this model, automatically predicts magnetic nonequivalence in chiral molecules, and represents a unified treatment of cyclic and acyclic hydrocarbons.

Beckmann rearrangement of cyclohexanone oxime has been carried out in vapor phase by means of a pulse reactor unit directly coupled to a gas chromatograph. The catalysts chosen gave good yields of ε-caprolactam. Apparent rate constants and activation energies were calculated in terms of the kinetic model of Bassett and Habgood. Selectivity studies, using pulse experiments interpreted by OPE curves, led to the conclusion that ε-caprolactam and 5-cyanopent-1-ene were competitive products. A reaction pathway is proposed which is in agreement with both the observed rates and selectivities.

A. COSTA, P. M. DEYÁ, J. V. SINISTERRA et J. M. MARINAS. Can. J. Chem. **58**, 1266 (1980).

On a effectué une transposition de Beckmann sur l'oxime de la cyclohexanone en phase gazeuse à l'aide d'un réacteur à impulsion relié directement à un appareil à chromatographie en phase gazeuse. Les catalyseurs choisis conduisent à l'ε-caprolactame avec de bons rendements. On a calculé les constantes de vitesse apparentes et les énergies d'activation en fonction du modèle cinétique de Bassett et Habgood. Des études de sélectivité, utilisant les expériences à impulsion interprétées par les courbes EPO, permettent de conclure qu'il y a formation compétitive de l'ε-caprolactame et du cyano-5 pentène-1. On propose un système de réaction qui est en accord avec les vitesses et les sélectivités observées.

[Traduit par le journal]

Introduction

The Beckmann rearrangement is a typical aniontropic rearrangement catalyzed by Brönsted and Lewis acids. It is of industrial importance in the conversion of cyclohexanone oxime to ε-caprolactam and catalysts for this application have often been described. However, only a few studies of the mechanism and kinetics in the vapor phase reaction have appeared in the literature (1, 2).

For years, we have used aluminium orthophosphates of the Kearby type (3) and other related systems as Friedel–Crafts type catalysts in different cationic organic processes with reagents in vapor phase (4–6). Among these is to be found the Beckmann rearrangement (7–9). For this paper we have chosen different bicomponent catalysts synthetized in a propylene oxide medium and described by us in a previous work (10), composed of aluminium orthophosphate and γ-alumina (75:25% by weight). These catalysts offer a greater surface acidity than other similar catalysts such as pure aluminium orthophosphate (11) or aluminium orthophosphate – silica systems (12). Furthermore, kinetics of the Beckmann rearrangement of cyclohexanone oxime on $AlPO_4$–γAl_2O_3 systems has been determined by using the Bassett and Habgood model (13). This model is applied to the first order processes in which the surface reaction is the controlling step and the partial pressure of the reactant is low.

Experimental

Synthesis of the Catalysts

(CBP)

A solution of 14.8 g of $Al(NO_3)_3 \cdot 9H_2O$ in 58 mL of doubly distilled water was cooled to 0°C and stirred mechanically while aqueous ammonia was added until complete precipitation of the aluminium hydroxide had occurred. At the same time a solution of 18.4 g of $AlCl_3 \cdot 6H_2O$ in 25 mL of doubly distilled water and 4.4 mL of H_3PO_4 (85% by weight) was cooled to 0°C and stirred mechanically while 26.5 mL of propylene oxide were added, causing an increase of the solution's viscosity. The last solution was added to the former precipitate and the resulting mixture was homogenized. Complete precipitation of the hydroxide and phosphate of aluminium was attained by the addition of aqueous ammonia until a gel was formed, which was left for 24 h at room temperature. After washing several times with isopropanol, the solid was collected by suction filtration and subsequently dried for 24 h at 100–110°C. Finally the catalyst was obtained by calcination for 3 h at 650 ± 10°C at 1 atm. The resulting catalyst can be stored indefinitely if reasonable precautions against basic vapors and moisture are observed.

(CBPU10), (CBPU20), (CBPO10), (CBPO20)

These systems were prepared in the same way as that of (CBP), except that, to the initial solution of $AlCl_3 \cdot 6H_2O$, 0.37 g of urea were added for (CBPU10), 0.74 g of urea for (CBPU20), 0.55 g of oxalic acid for (CBPO10), and 1.10 g of oxalic acid for (CBPO20).

Apparatus

The equipment was similar to that described by Choudary (14). A gas chromatograph, Hewlett-Packard 5834A, was modified by introduction of a microreactor between the sample inlet and the chromatographic column. The fixed bed vertical reactor was made of 2.5 mm id and 45 mm long stainless steel and heated by an electrical microfurnace. The catalyst particles (0.125–0.250 mm) were held in place by two plugs of glass wool. The reaction temperature was measured with a NiCr–Ni Din thermocouple connected to a Getrosist 96 Phillips controller. Pulses of a solution (1.5 *M*) of cyclohexanone oxime in benzene were introduced in a nitrogen carrier stream (flow rate 30 mL/min) by means of a standard 10 μL syringe, and the chromatographic separation of reactants and products was then carried out by using a 2 m by 6 mm column, packed with 10% Ucon on Chromosorb W 60–80, heated from 150 to 200°C with a rate of 10°C/min.

Procedure

(a) Operation of the Microreactor Unit

Catalyst charges of 6.0 and 14.0 mg were used. The catalyst was stabilized by heating to 200°C for 12 h in flowing nitrogen. Experiments were carried out at temperatures ranging from 200 to 320°C by inserting several pulses of 6 μL at each temperature and charge of catalyst.

(b) Identification of the Reaction Products

Identification of the reaction products was performed under testing conditions that led to a maximum yield in ε-caprolactam for the maximum total conversion. In these conditions the chromatograms showed the presence of eleven different signals. Those showing a major entity were analyzed by gc-ms (HP 5992A). The definitive assignation was achieved by preparing different solutions of cyclohexanone oxime in benzene and adding to each of them a small amount (5% by weight), with regard to the cyclohexanone oxime, of each of the previously identified products. These solutions were injected into reactor at reacting temperatures where the total conversion of the oxime was small, and the increase of the corresponding signal was checked.

(c) Determination of the Textural and Acidity Properties of the Catalysts

From the adsorption–desorption nitrogen isothermes at liquid nitrogen temperature, the surface area (S_{BET}) and accumulated pore volume (ΣV_p) were determined by the B.E.T. method (15). The total acidity of the catalysts and the density of acid centers were measured by titration in a non-aqueous medium by applying the alterations to the original method (16) proposed by Benesi (17) and Balikova (18), using *p*-dimethylaminoazobenzene as Hammett indicator.

Results and Discussion

(a) General

The addition of oxalic acid and urea brings about an alteration of the textural and acidic properties of the systems used without varying their chemical composition. However this addition does not produce any improvement in the characteristics of the catalysts, and the original catalyst (CBP) is the one that offers the best overall properties. The total conversion of cyclohexanone oxime increases with both temperature and catalyst charges, ε-caprolactam being the main reaction product as shown in Table 1. The thermal process without catalyst never surpasses 2% of the oxime input, thereby showing the effectiveness of the catalyst in the process. Once its activity is stabilized deactivation of the catalyst is minimal, since at insertion of one hundred pulses at regular time intervals, an activity decrease of only 5% is produced, in the experimental conditions described below.

TABLE 1. Typical distribution of reaction products[a]

Product	Yield (%)
Cyclohexanone oxime	5.8
ε-Caprolactam	73.1
Cyclohexanone	3.6
5-Cyanopent-1-ene	5.4
2-Methylpyridine	2.8
2-Cyclohexenone	1.2
6-Methyl-δ-valerolactam, propylene, and polymeric products[b]	3.8

[a]Reaction temperature 320°C; charge of catalyst (CBP), 10 mg.
[b]Arising from ε-caprolactam.

(b) Apparent Rate Constants and Activation Energies

From the Bassett and Habgood equation [1] (13):

$$[1] \quad \ln \frac{1}{1-X} = RTkK\frac{W}{Q}$$

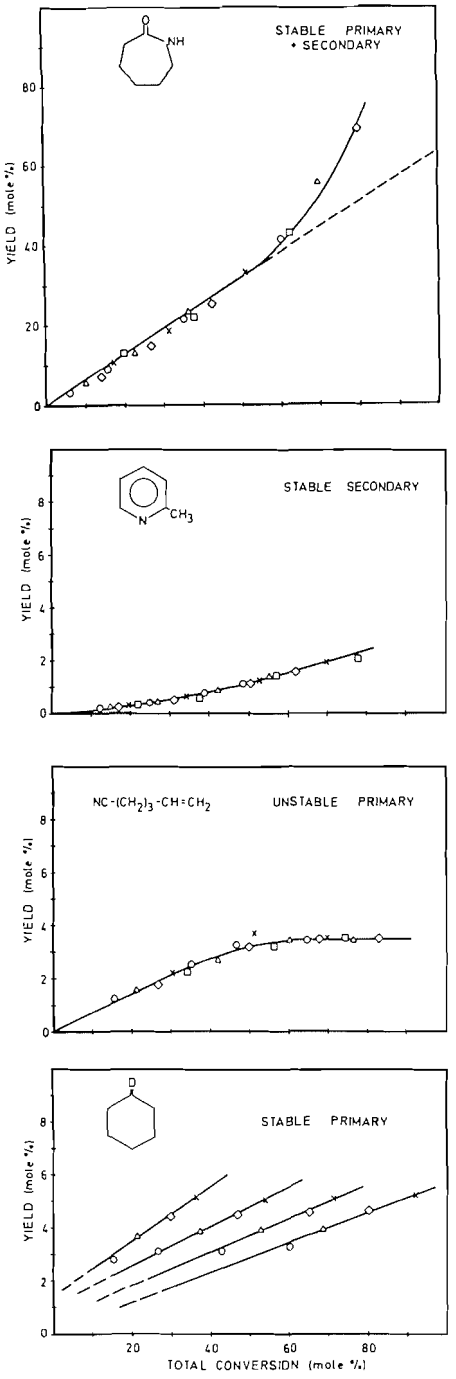
where X = molar fractionary conversion; R = gas constant (atm mL^{-1} mol^{-1}); T = reaction temperature (K); K = adsorption constant of the cyclohexanone oxime on the catalyst (mol atm^{-1} g^{-1}); k = rate constant of the surface process (s^{-1}); W = weight of catalyst (g); Q = flow rate of carrier gas (mL s^{-1}). It is possible to obtain the apparent rate constant (kK) at a fixed temperature by plotting $\ln [1/(1 - X)]$ vs. W, while the activation energy (E_a) of each catalyst was plotted representing $\ln \{\ln[1/(1 - X)]\}$ vs. W. The results are summarized in Table 2.

These results underscore the direct connection between the apparent rate constants and the total acidity of the catalysts, as indicated in Fig. 2, thereby verifying that other similar catalysts less acidic, i.e. pure aluminium orthophosphate (8), provide poorer results than the ones achieved with $AlPO_4$–γAl_2O_3 systems.

(c) Analysis of the OPE Selectivity Curves

The OPE selectivity curves were obtained by plotting the fractional conversion of a particular product against the total conversion, for different weight ratios of catalyst to introduced oxime (CAT/OX), such as has recently been described by Wojciechowski *et al.* (19). In this aspect the microcatalytic pulse technique is more advantageous than the conventional continuous flow technique in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



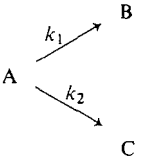


FIG. 1. OPE selectivity curves. The symbols represent the following CAT/OX ratios: 7.86 (○), 8.84 (△), 9.82 (◇), 11.79 (×), 12.85 (□).

several ways. The ratio (CAT/OX) is high whereas the duration of the reactant in the catalytic bed is very short. Consequently, the activity loss of the catalyst can be considered non-existant for any particular pulse. Thereby, as shown in Fig. 1, by applying this method to the main reaction products, it can be inferred that ε-caprolactam, 5-cyanopent-1-ene, and cyclohexanone are primary reaction products coming from cyclohexanone oxime. ε-Caprolactam and 5-cyanopent-1-ene adopt the behavior of stable and unstable primary products, respectively, at temperatures higher than 280°C. Cyclohexanone acts as a primary product although it has an unspecified catalytic effect, as the conversion of the cyclohexanone increases with the (CAT/OX) ratio but not with temperature.

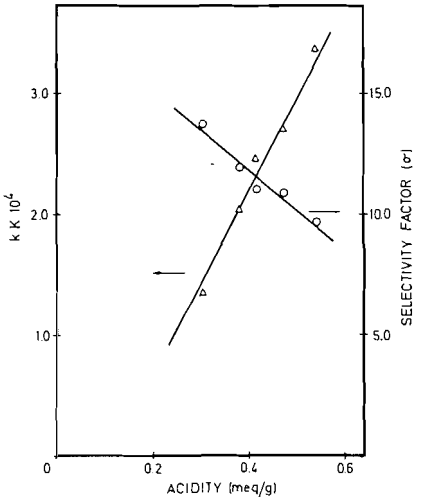
To determine which of the above mentioned products are really competitors, we used the kinetic selectivity criterion of Wheeler (20), viz., that for a process such as is outlined, and the follows a first order kinetic,

can be written as:

$$\sigma = k_1/k_2 = X_B/X_C$$

where k_1 and k_2 = rate constants; X_B and X_C = fractional conversions in B and C respectively; σ = kinetic selectivity factor.

The application of this criterion allows us to draw the conclusion that ε-caprolactam and 5-cyanopent-1-ene are competitive products, a conclusion in agreement with the mechanism proposed by Grob (21) for the Beckmann rearrangement of cyclohexanone oxime in homogeneous phase. Furthermore, by plotting the selectivity factors vs. the total acidity of the catalysts, Fig. 2, it can be



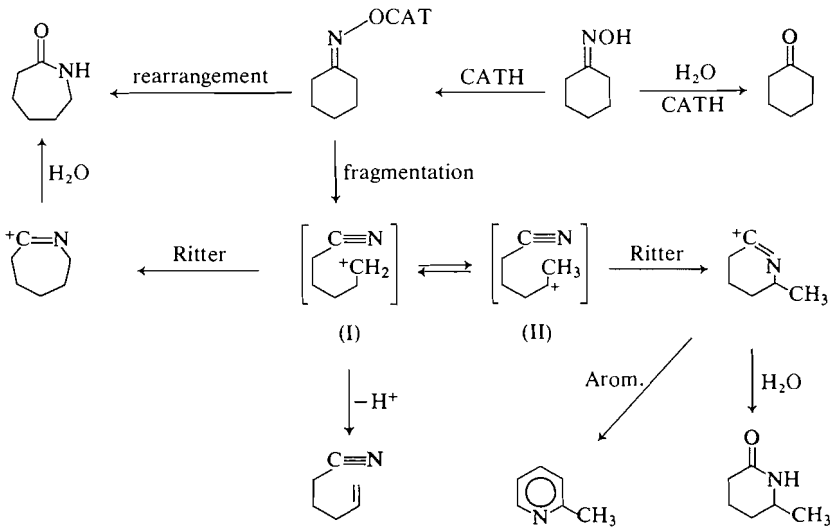


FIG. 2. Relationship between the total acidity of the catalyst, apparent kinetics constants, and selectivity factors.

TABLE 2. Summary of the most significant experimental variables for each catalyst

Catalyst	$kK\ 10^4$ (mol atm^{-1} g^{-1} s^{-1})	E_A (kcal mol^{-1})	σ	Acidity (mequiv. g^{-1})
CBP	3.37	20.19	9.65	0.55
CBPU10	2.73	21.56	10.91	0.48
CBPU20	2.06	15.77	11.61	0.38
CBPO10	2.44	19.26	10.97	0.42
CBPO20	1.31	17.35	13.63	0.31

seen that the catalytic activity increases as the process selectivity of ε-caprolactam diminishes, with an increase of the catalyst's acidity.

(d) Discussion of a Possible Reaction Pathway

The mechanism proposed below agrees with the experimental results and is an attempt to explain how each of the reaction products could be formed. The first step would imply the chemisorption of the cyclohexanone oxime on the catalyst, and then, either a rearrangement reaction could take place or a fragmentation process which would lead to the intermediate **I** being unstable. This in its turn could evolve to a more stable structure such as **II**.

The intermediate **II** would provide an explanation for the appearance of 2-methylpyridine, 6-methyl-δ-valerolactam as well as the existence of an alternative pathway for the formation of ε-caprolactam, according to its OPE curve. The appearance of 2-methylpyridine, through a way similar to that proposed by us, has been described (22) for this process in homogeneous phase using HMPT. Finally, 5-cyanopent-1-ene and cyclohexanone could be obtained, by proton loss from **I** and **II** and hydrolysis of the initial oxime, respectively.

Conclusion

The $AlPO_4$–γAl_2O_3 systems used in this study show promising catalytic activity for this process. The acidity of the catalyst is the main variable to be considered, but at the same time such an increase in acidity adds to the secondary process of fragmentation that disagrees with the proposal of rearrangement.

The photochemistry of 4-phenyl-1-iodobutane and 4-phenyl-2-iodomethyl-1-butene

JAMES LESLIE CHARLTON,[1] GAYNOR JANE WILLIAMS, AND GERALD NICHOLAS LYPKA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received November 5, 1979

JAMES LESLIE CHARLTON, GAYNOR JANE WILLIAMS, and GERALD NICHOLAS LYPKA. Can. J. Chem. **58**, 1271 (1980).

The photochemistry of 4-phenyl-1-iodobutane **3** and 4-phenyl-2-iodomethyl-1-butene **4** has been studied to investigate the effect of structure on the character of the intermediates generated on photolysis. The irradiation of the simple primary iodide **3** appears to yield only radical intermediates. By contrast the photolysis of the allylic iodide **4** yields products that are more consistent with cationic intermediates.

JAMES LESLIE CHARLTON, GAYNOR JANE WILLIAMS et GERALD NICHOLAS LYPKA. Can. J. Chem. **58**, 1271 (1980).

On a étudié la photochimie du phényl-4 iodo-1 butane (**3**) et du phényl-4 iodométhyl-2 butène-1 (**4**) dans le but d'examiner l'effet de la structure sur le caractère des intermédiaires engendrés par la photolyse. L'irradiation de l'iodure primaire **3** semble conduire uniquement à des intermédiaires radicalaires. La photolyse de l'iodure allylique **4** au contraire donne des produits qui sont compatibles avec des intermédiaires cationiques.

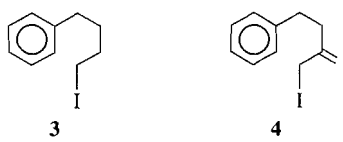
Introduction

Recent work by Kropp has shown that the photolysis of alkyl iodides can lead sequentially from free radical to ionic intermediates and that reaction products resulting from the ionic intermediates are often dominant (1).

$$RI \xrightarrow{h\nu} R\cdot \cdot I \rightarrow R(+)(-)I \rightarrow \text{products}$$



While Kropp has made use of this reaction to prepare unusual cations, others have used the photolysis of alkyl iodides to generate intermediates that have potential in organic synthesis. For instance, Gokhale has found that the irradiation of citronellyl iodide **1** yields *trans-p*-menth-8-ene **2** as illustrated in Scheme 1 (2).

SCHEME 1

This reaction may involve either radical or cationic cyclization with analogies existing for both modes, although in this case the orientation of the double bond in the product and the use of a nonpolar solvent would indicate a radical process is more likely (3). More extensive polyene cyclizations have been carried out using both radicals and cations as intermediates (3, 4) and it seems that alkyl iodides would make good starting materials for such processes.

In order to lay the ground work for such a project we have carried out an investigation of the photochemistry of 4-phenyl-1-iodobutane **3** and 4-phenyl-2-iodomethyl-1-butene **4**.

3 **4**

The 4-phenyl-1-iodo-butane **3** was chosen for study as extensive studies have been made on both the 4-phenylbutyl radical and cation generated by alternate methods. Iodide **4** was chosen as a model since the allylic radical is incapable of simple disproportionation by hydrogen atom transfer, a reaction which dominated the chemistry of the 4-phenylbutyl radical generated from **3** (*vide infra*).

Results and Discussion

The title compounds were irradiated in acetonitrile and/or benzene as outlined in Table 1 (for a preliminary report on this work see ref. 5).

Finely divided, anhydrous potassium carbonate was used as a scavenger for hydrogen iodide in acetonitrile whereas a separate aqueous phase was used to scavenge hydrogen iodide from benzene. Scheme 2 represents a general reaction mechanism for the photochemistry of **3**.

In the absence of HI and O_2 the major reaction of the initially formed radicals is the formation of the alkene **5**, both in benzene and in acetonitrile.

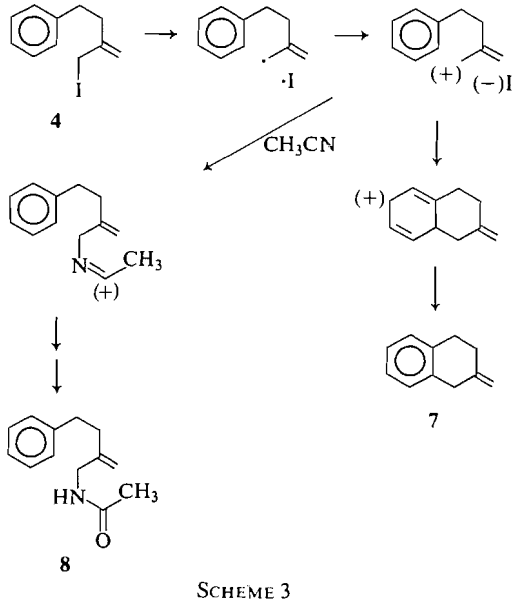
TABLE 1. Products and conditions of irradiation

Compound	Solvent	HI Scavenger	N_2/O_2	Products	% Yield
3	CH_3CN	K_2CO_3	N_2	**5**	99
	CH_3CN	K_2CO_3	O_2	**5**	52
	Benzene	H_2O	N_2	**5**	88
	Benzene	None	O_2	**5**	51
	Benzene	None	N_2	**5**	61
				6	27
4	CH_3CN	K_2CO_3	N_2	**7**	28
				8	37



SCHEME 2

In the presence of oxygen the yield of alkene is reduced from 100% in acetonitrile and 88% in benzene to 52 and 51% respectively. A possible interpretation is that 50% of the initially formed radical pairs give alkene while the remainder dissociate and can be trapped by oxygen and hydrogen iodide. Since there is a small effect of changing solvent on the process leading to alkene, there may be some justification to invoke a disproportionation to ions before collapse to the alkene. In benzene, the presence of hydrogen iodide causes many of the 4-phenylbutyl radicals to be reduced to the alkane **6**.

The yield of tetralin from the photolysis of **3** in either benzene or acetonitrile at 25°C was determined to be less than 2%. The absence of tetralin in this experiment contrasts with the work of De Tar who prepared the 4-phenylbutyl radical from di-δ-phenylvaleryl peroxide and obtained a 28% yield of tetralin in refluxing benzene (6). Kochi obtained an 11% yield of tetralin in a similar experiment (80°C in benzene) (7). Since we are able to confirm the presence of the 4-phenylbutyl radical by trapping with oxygen, and reduction with hydrogen iodide, we can only conclude that the intramolecular addition to the phenyl ring is an activated process and does not compete with alternate processes at 25°C.

In contrast to iodide **3**, iodide **4** gives mainly ionic products as illustrated in Scheme 3.

The presence of a carbonium ion is proved by the formation of amide **8**, a reaction analogous to the Ritter reaction (1, 8). It seems reasonable to conclude that product **7** also arises from the carbonium ion and it seems less likely that it arises from the

SCHEME 3

radical since the 4-phenylbutyl radical did not cyclize under the same conditions. It seems that the addition of the allylic cation to the phenyl ring is reasonably slow and that nucleophilic trapping by acetonitrile competes effectively. It is hoped that more reactive aromatic or alkene substituents will increase the tendency towards intramolecular addition and provide a route to polycyclic organic compounds.

Experimental

Nuclear magnetic resonance (nmr) spectra were recorded on a Varian EM360 or A 56-60 spectrometer using tetramethylsilane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

as internal standard and infrared (ir) spectra were recorded on a Unican SP1000. Mass spectra were recorded on a Finnigan 1015 mass spectrometer. All chromatography was carried out using the method described by Still *et al.* (9).

4-Phenyl-1-butanol

4-Phenyl butanoic acid (18 g, Aldrich) was reduced with lithium aluminum hydride (4.5 g) in ether (100 mL) in the usual way. Work up yielded 13.2 g of alcohol (91%).

4-Phenyl-1-iodobutane ***3***

4-Phenylbutanol (5.75 g), red phosphorous (0.5 g) and iodine (4.84 g) were refluxed in benzene to produce the iodide as outlined by Vogel (10). Work up yielded 6.7 g (67%) which could be further purified by chromatography (eluant, hexane): nmr (CCl_4) δ 1.53–2.0 (m, 4H), 2.45–2.83 (m, 2H), 2.96–3.3 (m, 2H), 7.15 (s, 5H); mass spectrum *m/e* (relative intensity) 260 (1), 133 (100), 91 (>100). *Anal.* calcd. for $C_{10}H_{13}I$: C 46.17, H 5.04; found: C 46.58, H 5.00.

4-Phenyl-2-methyl-1-butene

3-Chloro-2-methylpropene (35.5 g, 0.39 mol) in ether (50 mL) was added to benzyl magnesium chloride (from 49.1 g benzylchloride and 9.4 g magnesium, 0.39 mol) at room temperature. The mixture was refluxed 2 h, and worked up in the usual way by ether extraction to yield 54 g of crude product. Distillation under reduced pressure (130–135°C at 15 mm Hg) gave 37.7 g (66%) of a colourless oil: nmr (CCl_4) δ 1.72 (s, 3H) 2.0–2.9 (m, 4H), 4.61 (s, 2H), 7.05 (s, 5); mass spectrum *m/e* (relative intensity) 146 (5), 91 (100), 77 (7), 65 (20).

4-Phenyl-2-methyl-1-butene Oxide

m-Chloroperbenzoic acid (30 g, 0.17 mol) in methylene chloride (500 mL) was added to the alkene (20.5 g, 0.14 mol) in 100 mL of methylene chloride at a rate to maintain reflux. After addition of the peracid the solution was refluxed an additional 1/2 h, cooled to room temperature, filtered, and washed with 10% sodium bisulfite, then aqueous sodium bicarbonate. Drying ($MgSO_4$) and evaporation (*in vacuo*) yielded a colourless oil (21.8 g). Attempted distillation resulted in polymerization. Nmr (neat) δ 1.22 (s, 3H), 1.50–1.95 and 2.2–2.9 (m, 4H), 2.37 (s, 2H), 7.15 (s, 5H); mass spectrum *m/e* (relative intensity) 144 (32), 129 (100), 128 (65), 104 (35), 91 (88).

4-Phenyl-2-hydroxymethyl-1-butene

The alcohol was prepared from the epoxide (*vide supra*, 21.8 g, 0.135 mol) using lithium diethylamide (0.44 mol) according to the method of Crandall and Chang (11). The crude product (14 g) was chromatographed on silica gel (eluant benzene, benzene/ether 1:1) to give 5.0 g of a yellow oil (24%): nmr (CCl_4) δ 2.10–2.95 (m, 4H), 4.03 (broad s, 3H), 4.97 (d, 2H), 7.22 (s, 5H); mass spectrum *m/e* (relative intensity) 162 (2), 144 (2), 129 (6), 103 (100), 91 (75), 65 (31). *Anal.* calcd. for $C_{11}H_{14}O$: C 81.44, H 8.70; found: C 81.45, H 8.82.

4-Phenyl-2-tosyloxymethyl-1-butene

Toluenesulfonyl chloride (5.72 g, 0.03 mol) was added to a cooled solution of the alcohol (2.44 g, 0.015 mol) and pyridine (5.93 g, 0.075 mol) in methylene chloride (50 mL). After stirring 2 h and work up by extraction with ice water and aqueous bicarbonate, the dried ($MgSO_4$) organic layer was evaporated and the residue chromatographed on silica gel (eluant, hexane/benzene 1:1 then benzene) to yield the tosylate (1.23 g, 32%) as a colourless oil. Some alcohol (0.49 g) was also recovered. Nmr ($CDCl_3$) δ 1.95–2.77 (m, 4H), 2.32 (s, 3H), 2.32 (s, 2H), 4.95 (d, 2H), 7.12 (s, 5H), 7.47 (q, 4H): mass spectrum *m/e* (relative intensity) 190 (23), 155 (100), 144 (89), 129 (>100), 104 (45), 91 (>100). *Anal.* calcd. for $C_{18}H_{20}O_3S$: C 68.32, H 6.37; found: C 67.96, H 6.44.

4-Phenyl-2-iodomethyl-1-butene, ***4***

The iodide was prepared from the tosylate using a modification of the procedure of Tipson, Clapp, and Cretcher (12). NaI (0.9 g, 0.006 mol) was added to a solution of the tosylate (0.914 g, 0.003 mol) in acetone (20 mL) and stirred at room temperature for 1/2 h followed by filtration and evaporation of the acetone *in vacuo*. Chromatography on silica gel (eluant hexane/benzene 1:1) gave a pale violet oil (iodine contaminated, 0.6 g, 76%): nmr (CCl_4) δ 2.35–2.95 (m, 4H), 3.85 (s, 2H), 5.07 (d, 2H), 7.15 (s, 5H); mass spectrum *m/e* (relative intensity) 245 (1), 145 (53), 117 (16), 91 (100), 65 (24). *Anal.* calcd. for $C_{11}H_{13}I$: C 48.55, H 4.82; found: C 48.88, H 4.76.

Irradiations

Irradiations were carried out at 20–25°C in vycor or quartz vessels using either a low pressure mercury lamp (Ultraviolet Products PCQX1) or a medium pressure mercury lamp Hanovia, 450 W).

Photolysis of 4-Phenyl-1-iodobutane ***3***

In Acetonitrile

Anhydrous, powdered potassium carbonate was added to a solution of the iodide (0.185 g) in acetonitrile (15 mL), the system was flushed with dry nitrogen or oxygen and then irradiated with the Hanovia lamp at 20°C. Samples of the solution were analysed by a tandem gas chromatograph – mass spectrometer (10 ft × 1/8 in. SE30, 10% on chromosorb P, 160–220°C) and products were identified by comparison to authentic samples of 4-phenyl-1-butene and 1-phenylbutane (*vide infra*). Quantitative analysis was carried out by gas chromatography using naphthalene as internal standard. Yields were determined at 50–90% conversion and back corrected for unreacted iodide.

In Benzene

The iodide (200 mg) was dissolved in benzene (50 mL) and flushed with nitrogen or oxygen. In some samples, water was added (~20% the volume of benzene) to scavenge hydrogen iodide. Analysis was carried out as described above.

4-Phenyl-1-butene

Allyl bromide (47.8 g, 0.4 mol) was added to benzyl magnesium chloride (prepared from benzyl chloride, 50 g, and magnesium, 9.5 g) in ether at a rate to maintain reflux. After refluxing a further 45 min the reaction mixture was poured into 10% aqueous hydrochloric acid and the ether extract separated, dried, and evaporated. Distillation yielded a colourless oil 28.9 g (55%) (6).

4-Phenylbutane

Reduction of the alkene with hydrogen over palladium on charcoal (5%) gave the alkane in quantitative yield.

Photolysis of 4-Phenyl-2-iodomethyl-1-butene

Anhydrous, powdered potassium carbonate (1 g) was added to a solution of the iodide (0.438 g) in dry acetonitrile (100 mL). The solution was flushed with dry nitrogen and irradiated for 20 h using the Hanovia lamp. After filtration, and evaporation, chromatography on silica gel (eluant, hexane then acetone) yielded a colourless oil (51 mg), the iodide (94 mg) and with acetone, a yellow oil (194 mg). The yellow oil was further purified by silica gel chromatography (eluant, ether/acetone 49:1). The colourless oil eluted with hexane: nmr (CCl_4) δ 2.10–3.00 (m, 4H), 3.42 (s, 2H), 4.77 (s, 2H), 6.96 (s, 4H); mass spectrum *m/e* (relative intensity) 144 (96), 129 (>100), 115 (100), 91 (31), 77 (40), 63 (55), *Anal.* calcd. for $C_{11}H_{12}$: C 91.67, H 8.33; found: 91.18, H 8.72.

The oil eluted with acetone: nmr ($CDCl_3$), δ 2.00 (s, 3H), 2.15–3.03 (m, 5H), 3.90 (d, 2H), 4.96 (s, 2H), 7.27 (s, 5H); ir (neat 3300, 1645–1670 cm^{-1}; mass spectrum *m/e* (relative intensity) 203 (3), 144 (22), 129 (34), 122 (73), 91 (66), 70 (100).

4-Phenyl-3-aminomethyl-1-butene

The tosylate (300 mg) was stirred for 2 h at room temperature in a solution of acetonitrile – ammonium hydroxide (20 mL, 1:1). This was evaporated then taken up in ether and extracted with 3 *N* HCl. The HCl extract was made basic with aqueous bicarbonate and extracted with ether. Drying ($MgSO_4$) and evaporation yielded a colourless oil (62 mg): nmr (CCl_4) δ 2.13 (m, 6H), 3.0–3.3 (m, 2H), 4.90 (d, 2H), 7.17 (s, 5H); ir (neat) 3260–3440 cm^{-1}; mass spectrum *m/e* (relative intensity) 161 (2), 129 (31), 104 (21), 91 (100), 70 (> 100).

Synthesis of 4-Phenyl-2-acetamidomethyl-1-butene

The amine (*vide supra*, 62 mg) was dissolved in acetic anhydride (20 mL) and pyridine (2 mL), warmed on a steam bath for 1 h, and then evaporated to near dryness *in vacuo*. The residue was dissolved in ether, washed with 3 *N* HCl and aqueous bicarbonate, dried ($MgSO_4$), and evaporated to yield a colourless oil (68 mg). Chromatography on silica gel (eluant ether/acetone 49:1) yielded the amide, identical in every respect to that obtained from the photolysis of iodide **4** in acetonitrile (*vide supra*).

Electrophilic additions to allenes. IV. Concerning the nature of the *ortho*-nitro group effect in the reaction of arenesulphenyl chlorides with allenes[1,2]

DENNIS G. GARRATT[3] AND PIERRE L. BEAULIEU[4]

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received November 23, 1979

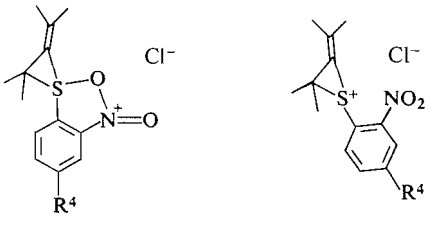
DENNIS G. GARRATT and PIERRE L. BEAULIEU. Can. J. Chem. **58**, 1275 (1980).

The reactions of twelve arenesulphenyl chlorides, five of which contained an *ortho*-nitro substituent, with ten 1,3-disubstituted allenes, using methylene chloride as solvent, are described. No evidence for a special *ortho*-nitro group effect involving a spirosulphurane type intermediate is observed. Variations in the chemoselectivity and configurational-selectivity of the additions are interpreted in terms of steric interactions in the product determining transition state.

DENNIS G. GARRATT et PIERRE L. BEAULIEU. Can. J. Chem. **58**, 1275 (1980).

On décrit les réactions, dans le chlorure de méthylène comme solvant, de 12 chlorures d'arènes-sulphényles, dont 5 contiennent un substituant nitro en position *ortho*, avec 10 allènes disubstitués en position 1,3. On n'a pas obtenu de preuve à l'effet que les groupes nitro en position *ortho* font intervenir un intermédiaire du type spirosulphurane. On interprète les variations de la chimiosélectivité et la sélectivité configurationnelle des additions en fonction d'interactions stériques dans l'état de transition déterminant la nature du produit.

[Traduit par le journal]



Introduction

Arenesulphenyl chlorides react with alkylsubstituted allenes to form products derived from exclusive attack by sulphur on the central allenic carbon. Rearranged or solvent-incorporated products have not been described, but sometimes products resulting from the loss of HCl are observed (2). The formation of 2:1 adducts, as a result of competitive addition of the sulphenyl halide to the first formed adduct, is normally not observed.

The rate law in polar solvents has been reported to be overall second order, first order in allene and first order in sulphenyl chloride (3). An Ad_E2 mechanism has been postulated in accord with that previously described for simple alkenes (4).

In the first article of this series we reported the observation that 2,4-dinitrobenzenesulphenyl chloride reacts with 1,3-disubstituted allenes, preferentially forming the *E* alkene (5). The ratio of *E* to *Z* alkene was found to increase as the bulk of the substituent group *cis* to the arylthio group increased. These results were interpreted in terms of steric approach control (6) leading to the formation of a series of alkylidenethiiranium ions or alkylideneepisulphuranes (3*b*, 7), in accord with the stereoselectivity previously reported by Jacobs and co-workers (2*e*).

Concern has been raised in a number of quarters (8) over the possible bonding interaction of an oxygen atom from the *ortho*-nitro group, in *ortho*-nitrobenzenesulphenyl halides, with the adjacent sulphur atom leading to a spirosulphurane intermediate **1** instead of the commonly accepted thiiranium ion **2**. Studies correlating thiiranium ion

1 **2**

structure with product geometry have provided considerable insight into the nature of thiiranium ions and have demonstrated that simple alkane- and arenesulphenyl halides often react in a manner quite different from that of *ortho*-nitro-substituted arenesulphenyl halides (8*e*, *f*, 9). However, while these sulphenyl chlorides may be considered atypical (8*h*, 10), the results previously obtained permit a reasonable starting point for the study of the ionic sulphenylation of allenes.

Of paramount importance is to determine what effect, if any, the *ortho*-nitro substituent is really contributing to the reactions under consideration. For example, in addition to the above mentioned *possible* stabilization of a positive charge on sulphur by delocalization into the adjacent nitro group, one can envision a destabilization through

inductive electron withdrawal, and/or a steric effect. It is the purpose of this investigation to elucidate those factors which influence the nature of the product determining step in the reaction of arenesulphenyl chlorides with allenes.

Results and Discussion

In order to ascertain the degree and type of involvement of the *ortho*-nitro substituent, we have investigated the reactions of allenes **3–12** with a series of six *para*-substituted arenesulphenyl chlorides, χC_6H_4SCl (χ = NO_2, CF_3, Cl, H, CH_3, CH_3O) I–VI, the corresponding *ortho*-nitro, *para*-substituted arenesulphenyl chlorides, VII–XI, and one further *ortho*-substituted arenesulphenyl chloride, XII, lacking the *ortho*-nitro substituent and thus serving to demonstrate specific steric and electronic effects.

			XI	NO_2	CH_3O
			XII	CH_3	H

All reactions were carried out at ambient temperature except as noted (see Table 1) using methylene chloride as solvent. The kinetically controlled product distributions, Table 1, were determined by immediate ^1H nmr analysis of the reaction mixture. Reaction end-points were determined by the disappearance of the S—Cl chromophore ($\lambda_{max} \simeq 392$ nm) and/or a negative starch–iodide test (11) Analysis of the respective ^1H, ^{13}C nmr spectra and the mass spectral fragmentation patterns, using the criteria previously established (1, 5), indicates that the 1:1 adducts are formed via regiospecific attack of the arylthio moieties on the central allenic carbon (eq. [1]).

[1] $ArSCl + RCH{=}C{=}CHR' \rightarrow RCH{=}C(CHClR')(SAr) + R'CH{=}C(CHClR)(SAr)$

Qualitatively one observes that the 4-substituted 2-nitrobenzenesulphenyl chlorides, VII–XI, react many orders of magnitude slower than the analogous 4-substituted arenesulphenyl chlorides ($\tau_{\frac{1}{2}}$ 1–4 days at 0.05 *M* vs. a few milliseconds). Furthermore, the relative reactivity of the 4-substituted 2-nitrobenzenesulphenyl chlorides is observed to follow the order XI > X > IX > VIII > VII, in accord with the rate measurements of Brown and Hogg (12), using cyclohexene as substrate, and in accord with the predicted relative electrophilicities based upon the known charge stabilization characteristics of the 4-substituents. The much greater reactivity of those sulphenyl chlorides which lack the *ortho*-nitro functionality precluded any similar observations at this time.

Considering only the data applicable to the symmetrically substituted allenes, one observes the previously described increase in the *E*:*Z* ratios (5) as R and R′ are varied from methyl to ethyl ... isopropyl ... *tert*-butyl. In the absence of an *ortho*-nitro substituent (entries I–VI, XII) the *E*:*Z* ratios are fairly constant: R = CH_3, 50–55:50–45; R = C_2H_5, 69–72:31–28; R = iC_3H_7, 79–82:21–18; R = tC_4H_9, 97–100:3–0. When an *ortho* nitro substituent is present (entires VII–XI) these values are in general 5% to 10% larger: R = CH_3, 59–64:41–36; R = C_2H_5, 72–80:28–20; R = iC_3H_7, 92–100:8–0; R = tC_4H_9, 100:0.

While the above data suggest the possible interplay of a steric effect on the part of the *ortho* nitro group, no definitive indication of a specialized electronic stabilizing interaction is apparent. The available data for unsymmetrically 1,3-disubstituted allenes is, however, more instructive.

Firstly, let us consider the chemoselectivity of the reaction. By use of the term *chemoselective* we mean the proportion of attack upon one of the mutually perpendicular π bonds relative to the other. In Table 1 this is given as the ratio α:β. When R = CH_3 and R′ = C_2H_5 the value of α:β is relatively constant 53–55:47–45 (entries I–XII). However, when R = CH_3 and R′ = iC_3H_7, the proportion of attack next to R′ is found to be 5 to 10% less when an *ortho* nitro group is present, irrespective of the nature of the *para* substituent. This is more pronounced where R = CH_3 and R′ = tC_4H_9, the difference being 20-40%. Little variation is, however, observed within a given series. Compare, for example, entries I–VI or VII–XI. A possible set of anomalous data exists for ratios given under entry VI, the *para* methoxy species. We believe that these ratios may reflect thermodynamic control rather than kinetic control as a result of very fast isomerizations, most likely via allylic inter-

mediates. Attempts to unambiguously prove this ascertainment have not thus far been successful.

The observed variations in the ratio α:β are quite important. In the first paper of this series (5) we noted that very little chemoselectivity, with respect to which of the mutually perpendicular π bonds of the allene system is attacked, was observed. We hypothesized, on this basis, the presence of an effective mechanism for the transmission of the inductive electron donation of the alkyl groups to the remote double bond. Using the more extensive basis set now available we can see that this interpretation was too limited in scope and that other factors must be interacting during the product determining transition state.

No systematic variations, as a function of the *para* substituents, are apparent from an examination of the α:β ratios. What is observed, is a decrease in the percentage of α attack, as reflected in a low value of α:β when R′ is bulky, particularly when R′ = *tert*-butyl, and when there is an *ortho* substituent on the arenesulphenyl chloride, be that substituent *nitro* or *methyl*! The observation of a similar effect for an *ortho* methyl substituent would appear to rule out the need to invoke a specialized spirosulphurane intermediate of type **1**. The somewhat larger effect of an *ortho* nitro group relative to methyl may result from its larger steric bulk. Minor variations as in the case of allene **12**, entries VII–XII are then interpreted in terms of conformational effects on the part of the planar nitro group. The α:β values are therefore also in accord with a steric interaction mechanism during "steric approach control".

The configurational selectivity, i.e. the *E*:*Z* ratio, for the α and β double bonds, shows trends very similar to those found for the symmetrically substituted allenes. The ratio of *E* to *Z* alkene is found to increase as the bulk of the substituent groups *cis* to the arylthio group increases. Furthermore, the *E*:*Z* ratio for 2-methyl- and 2-nitrobenzenesulphenyl chlorides are remarkably similar as is seen on comparing entries IX and XII. These effects are taken as indicative of a long-range steric interaction between the remote substituent, be it R or R′, and the approaching reagent in accord with steric approach control as previously described (5). These data therefore give additional support to our hypothesis of the predominance of a steric effect for the *ortho* nitro group. It is thus our ascertainment that on the basis of the 120 reactions studied and reported herein, there is no evidence to require a novel intermediate of the spirosulphurane variety on the reaction hypersurface for the arenesulphenylation of 1,3-disubstituted allenes. We also note that while there exists a great rate decrease upon substituting an *ortho* nitro group for an *ortho* hydrogen, there is little evidence for a similar dramatic change with respect to the product determining transition states! Of importance in this regard is the observation that 2-methylbenzenesulphenyl chloride reacts many orders of magnitude faster than 2-nitrobenzenesulphenyl chloride, yet shows similar configurational-selectivity!

Experimental

General

All melting points were recorded on a Fisher–Johns block and are uncorrected. The ^{1}H nmr spectra were run on Varian Associates T-60 and HA-100 spectrometers; ^{13}C nmr spectra were run on a Varian Associates FT-80 spectrometer using a 16K memory. Chloroform-*d* was used as an internal lock and reference. All spectral parameters are referenced to TMS as an internal standard. Tables of spectra data are available upon request from the authors.

Allenes

2,3-Pentadiene was commercially available. 2,3-Hexadiene, 5-methyl-2,3-hexadiene, 5,5-dimethyl-2,3-hexadiene, 3,4-heptadiene, and 2,6-dimethyl-3,4-heptadiene were prepared by standard literature procedures from the commercially available alkenes (Chemical Samples) (13). 2,2,6,6,-Tetramethyl-3,4-heptadiene, 2,2,6-trimethyl-3,4-heptadiene, 2,2-dimethyl-3,4-heptadiene, and 2-methyl-3,4-heptadiene were prepared by the method of Vermeer and co-workers (14).

2,4-Dinitrobenzenesulphenyl chloride was prepared by the method of Lawson and Kharasch (15) from bis(2,4-dinitrophenyl)disulphide. Recrystallized from CCl_4, mp 96–96.5°C (lit. (15) mp 97–98°C).

2-Nitro-4-chlorobenzenesulphenyl chloride was prepared by the method of Turner and Conner (16) using *p*-dichlorobenzene (Aldrich) as starting material; mp 98°C (lit. (16) mp 97.5–98°C).

2-Nitrobenzenesulphenyl chloride was commercially available (Aldrich). Recrystallized from CCl_4, mp 76°C (lit. (15) mp 74.5–75°C).

2-Nitro-4-methylbenzenesulphenyl chloride was prepared from the analogous aniline by the procedure of Zincke and Rose (17). Recrystallized from CCl_4, mp 89–90°C (lit. (17) mp 90°C).

2-Nitro-4-methoxybenzenesulphenyl chloride was prepared from the analogous aniline as above. Crystallized as brilliant orange needles from CCl_4, mp 106–107°C. The remaining *arenesulphenyl chlorides* were prepared from the corresponding thiol or disulphide by chlorination with molecular chlorine in CCl_4 with cooling (0–4°C). Physical properties were as previously reported (18).

Product Studies

These were carried out as previously described (1, 5). In the cases of 2-nitroarenesulphenyl chlorides, ^{1}H nmr analysis was carried out during the course of the reactions and thereafter to ensure the establishment of kinetically controlled product distributions. Because of the essentially instantaneous nature of the reactions of arenesulphenyl chlorides lacking the *ortho*-nitro group, only the slow isomerizations, post-addition, were observable by ^{1}H nmr.

Effect of the acyl substituent on the equilibrium constant for hydration of esters

J. PETER GUTHRIE[1] AND PATRICIA A. CULLIMORE

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 10, 1979

J. PETER GUTHRIE and PATRICIA A. CULLIMORE. Can. J. Chem. **58**, 1281 (1980).

Heats of hydrolysis have been measured for the trimethyl orthoesters of isobutyric, propionic, benzoic, methoxyacetic, chloroacetic, and cyanoacetic acids using aqueous acid with an organic cosolvent where necessary, and of the corresponding esters in alkaline solution. Solubilities or free energies of transfer from gas to aqueous solution have been measured, permitting calculation of the free energies of formation of the aqueous orthoesters, and by methods which we have published previously, calculation of the free energies of formation of the covalent hydrates of the esters, and the free energy changes for hydration of these esters.

Using estimated pK_a values equilibrium constants were calculated for the addition of hydroxide to the esters. The data are in good agreement with the appropriate Marcus equation relating rate and equilibrium constants with a value for b of 8.99 ± 0.17. This line was used to estimate the equilibrium constant for addition of hydroxide, and thence of water, to some additional esters where only the rate constant was available. Rate constants for hydrolysis of methyl esters in aqueous solution at 25°C were calculated from literature data, correcting for the effect of other conditions as necessary. From the equilibrium constants for addition of water we could estimate the rate constants for uncatalyzed hydrolysis; for the cases where this rate constant has been measured, the agreement was satisfactory. For acid catalyzed hydrolysis the data permit a test of the two alternative mechanisms considered previously, namely specific acid catalysis and general acid catalysis with hydronium ion acting as a general acid. For esters the mechanism is clearly specific acid catalysis, but for aldehydes and ketones it appears very likely that the mechanism is general acid catalysis.

J. PETER GUTHRIE et PATRICIA A. CULLIMORE. Can. J. Chem. **58**, 1281 (1980).

On a mesuré les chaleurs d'hydrolyse des orthoesters triméthyliques des acides isobutyrique, propionique, benzoique, méthoxyacétique, chloroacétique et cyanacétique en utilisant une solution aqueuse acide avec un cosolvant organique lorsque cela s'avère nécessaire; on a aussi mesuré les chaleurs d'hydrolyse des esters correspondants en solution basique. On a mesuré les solubilités ou les énergies libres de transfert de la phase gazeuse à la solution aqueuse ce qui a permis de calculer les énergies libres de formation des orthoesters aqueux et de calculer, au moyen de méthodes publiées antérieurement, les énergies libres de formation des hydrates covalents des esters et les changements d'énergie libre d'hydratation de ces esters.

On a calculé les constantes d'équilibre de la réaction d'addition de l'hydroxyde sur les esters en utilisant les valeurs approximatives du pK_a. Les données sont en parfait accord avec l'équation appropriée de Marcus reliant la vitesse et les constantes d'équilibre avec une valeur de $b = 8.99 \pm 0.17$. Cette donnée est utilisée pour évaluer la constante d'équilibre de la réaction d'addition d'hydroxyde et par conséquent, celle de l'eau sur les quelques esters additionnels lorsque la constante de vitesse est la seule donnée disponible. On a calculé les constantes de vitesse d'hydrolyse des esters méthyliques en solution aqueuse à 25°C à partir des données de la littérature en corrigeant s'il y a lieu, pour tenir compte de l'effet des autres conditions. On peut évaluer les constantes de vitesse d'hydrolyse non catalysée à partir des constantes d'équilibre de la réaction d'addition de l'eau. Dans les cas où l'on a mesuré la constante de vitesse, l'accord est satisfaisant. En ce qui a trait à l'hydrolyse acide, les données permettent de vérifier les deux mécanismes alternatifs considérés antérieurement en particulier la catalyse acide spécifique et la catalyse acide générale à l'aide d'ion hydronium agissant comme un acide général. Dans le cas des esters, le mécanisme est nettement une catalyse acide spécifique mais pour les aldéhydes et les cétones il semble être plus communément du type catalyse acide générale.

[Traduit par le journal]

Introduction

We have previously reported potentially useful relations between rate and equilibrium constants for carbonyl reactions (1). In that work it was suggested that equilibrium constants for the addition of hydroxide to esters (or other carbonyl compounds) could be estimated from the Marcus (2–4) equation relating rate to equilibrium constant; it seemed important to increase the number of esters used to establish this relationship from the three which

were then available. Accordingly we have prepared a series of orthoesters and measured their heats of hydrolysis as well as the heats of hydrolysis of the corresponding esters. Where necessary we have also measured the quantities necessary to calculate the free energies of transfer from gas to 1 *M* aqueous solution. Then, by methods which we have developed (5–8) it is possible to calculate the free energy of formation of the ester hydrate and thus the equilibrium constant for hydration of the ester. These new data confirm and extend our previous (1) findings, and now permit a definite answer to the question of the mechanism of acid catalyzed ester hydrolysis.

We have also been able to predict rate constants for various hydrolytic processes which have not yet been measured.

Results and Discussion

The calorimetric results obtained in this work are gathered in Table 1. The ideal heat of hydrolysis for an ester refers to the process:

[1] $RCOOCH_3(l) + H_2O(l) = RCOOH(l) + CH_3OH(l)$

The actual process measured calorimetrically is:

[2] $RCOOCH_3(l) + HO^-(aq) = RCOO^-(aq) + CH_3OH(aq)$

To transform eq. [2] into the form of eq. [1] requires that the enthalpy change for the reaction of acid (liquid or solid) with hydroxide ion, as well as the heats of solution of methanol and water be known. By combining these values we can calculate the overall enthalpy change for eq. [1], and then, if the standard heats of formation for the acid, methanol, and water are available, $\Delta H^0_f(l)$ for the ester can be calculated. For this work the standard enthalpies for formation of isobutyric, chloroacetic, cyanoacetic, and methoxyacetic acids were either of inadequate precision or unavailable, so that the standard enthalpies of formation (and subsequently calculated values for $\Delta H^0_f(g)$, $\Delta G^0_f(g)$, and $\Delta G^0_f(aq)$) for the corresponding esters and orthoesters, were reported as a sum with an unknown.

Similarly, the ideal heat of hydrolysis for the

[l]Solvent was pH 7 phosphate buffer.

orthoester refers to the process:

[3] $$RC(OCH_3)_3(l) + H_2O(l) = RCOOCH_3(l) + 2CH_3OH(l)$$

when the actual process measured was:

[4] $$RC(OCH_3)_3(l) + H_2O(aq) = RCOOCH_3(aq) + 2CH_3OH(aq)$$

To convert eq. [4] into the form of eq. [3] we must know the heats of solution of the ordinary ester, methanol, and water. The overall enthalpy change for eq. [3] and a value for $\Delta H^0_f(l)$ for the orthoester (pending a known value for ΔH^0_f for the corresponding acid) can be calculated as previously described.

Whenever possible aqueous solvents were used for calorimetric measurements. The usual solvents are aqueous 0.1 N HCl or 0.1 N NaOH; aqueous 1 N NaOH would be used if the rate of hydrolysis was slow in tenth normal base, or 0.001 N HCl would be used if acid catalyzed decomposition occurred too rapidly in tenth normal acid. Solubility problems sometimes necessitated the use of mixed solvent systems: 50 or 70% methanol in water, or 90% dimethyl sulfoxide in water. Methanolic solvents were often unsatisfactory for alkaline hydrolysis because although solubility was improved, the rate of reaction was markedly slower than in water.

Entropies of the gaseous compounds were estimated as described in the Calculations. Free energies of transfer were determined for all esters and orthoesters as described in the Experimental. The data and results from these experiments are summarized in Table 2. With these data in hand the free energies of formation could be derived; thermodynamic quantities used in this paper are collected in Table 3. In some cases the heat of formation of the parent carboxylic acid is unknown or only approximately known. In such a case the heats and free energies of formation of the ester and orthoester are unspecified by a constant unknown quantity, but values based on the difference be-

tween two such numbers as, for instance, the free energy change upon covalent hydration of an ester, are fully specified.

From the free energies of formation of the ester hydrates and the esters, we could calculate the free energy changes, and hence the equilibrium constants for the addition of water to the esters. Using the linear free energy relationships which we reported earlier (1) the pK_a for ionization of the ester hydrate to give the anionic tetrahedral intermediate could be readily calculated. Then, by means of the cycle shown in Scheme 1, the equilibrium constants for the addition of hydroxide to the esters may be calculated. Similarly, by estimating the appropriate pK_a values using the relations developed previously (1) we may derive the equilibrium constants for the addition of water to give the zwitterionic intermediate and for the reaction of ester with hydronium ion to give the cationic tetrahedral intermediate. The reaction of protonated ester with water to give this same cationic species is more of a problem because of the need to know the pK_{BH^+} value for the ester itself. Ester pK_{BH^+} values are often not yet available; we have used the available data and estimated further values from the appropriate linear free energy relations (see the Calculations).

All of the equilibrium constants so calculated are found in Table 4. For comparison with these equilibrium constants we required rate constants for the acid, base, and uncatalyzed hydrolysis of methyl esters in aqueous solution at 25°C. Although a vast amount of effort has been expended in the study of ester hydrolyses, many of the investigations have been in mixed solvents, or have involved other esters or other temperatures. For some esters only the esterification rate and not the hydrolysis rate has been measured. In order to obtain a set of rate constants for the same conditions as the equilibrium constants, we have made extensive use of linear free energy relationships to correct the rate constants from the literature to standard conditions. We have found that many of the linear free energy relationships have slopes differing from unity, so that it would not be correct to use rate ratios to correct from one set of conditions to another. All of the data upon which our final set of rate constants is based are to be found in the Supplementary Tables.[2] The rate constants for aqueous solution are found in Table 4, which also contains estimated values for those rate constants which have not yet been reported. The estimation procedures are described below.

SCHEME 1

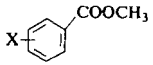
Marcus and Cohen (2–4) derived an expression for the rate of reaction within an encounter complex which is equivalent to:

$$[5] \quad \log k = \log (k_B T/h) - b(1 - (\log K)/4b)^2$$

Following Hine (9), we have translated the original expression derived by Marcus, which was expressed in terms of free energies of activation and reaction into a form expressed in terms of rate and equilibrium constants. The dimensionless parameter b is a measure of the "intrinsic barrier", i.e. the kinetic barrier to reaction when the equilibrium constant is 1.0. This expression holds only for log K between $-4b$ and $+4b$; for very favorable reactions, $\log k = \log (k_B T/h)$, i.e. $d \log k/d \log K = 0.0$; and for very unfavorable reactions $\log k = \log (k_B T/h) + \log K$, i.e. $d \log k/d \log K = 1.0$. The expression describes a smooth curve between these two limiting lines, and has only one adjustable parameter. It should be stressed that the equation must be applied to a single reaction step, occurring within an encounter complex. An encounter complex will be assumed to mean two or more molecules confined within the same solvation cage, but not necessarily interacting either favorably or unfavorably.

Since most reactions involve diffusion steps either before or after the chemical reaction step, it is necessary to use somewhat more complicated expressions to describe the reactions in terms of the observable rate and equilibrium constants. We will now derive the appropriate expressions for those cases relevant to the present discussion. We will take explicit account of the possibility of changes in rate determining step as the chemical steps become fast enough to compete with diffusion steps: as Murdoch (14) has pointed out, this can lead to additional curvature in rate equilibrium correlations beyond that implied by eq. [5]. The theory has generally been discussed in terms of the rather

$$[6] \quad A + B \rightleftharpoons C + D$$



symmetrical type of reaction shown in [6], where

diffusion processes can become rate limiting for either forward or reverse reactions. Two other reaction types, which will be more useful for the present paper will be discussed below; for all three models we will consider the three cases: equilibrium constant very favorable in the forward direction, about unity, and very unfavorable in the forward direction. The full model for process [6] involves diffusion together of the reactants, reaction within the encounter complex, and diffusion apart of the products. It is necessary to make some allowance for the rate and equilibrium constant for the encounter complex formation and dissociation processes. Hine (9) has made the very reasonable proposal that the equilibrium constant for encounter complex formation should be about $0.017\ M^{-1}$; this was calculated assuming that the nucleophile could encounter the carbonyl group from either side, but had to be in a sphere of radius 1.5 Å (the van der Waal's radius of oxygen) touching the carbon, and that there was no special attraction or repulsion. We have employed this value for the equilibrium constant for the formation of all encounter complexes involving two solutes. If Hine's suggested value is adopted, then certain consequences follow; in particular, the rate of diffusion together of reactants must be less than the value for simple spherical reagents in order to cause the equilibrium constant to have the value required. We have endeavored to assign reasonable values to these rate constants in the following way. The encounter distance was taken as 3 Å and the rate constant for diffusional separation was calculated from the Eigen eq. [7] (10)

$$[7] \qquad k_{-1} = (3/R_{ij}^2)(D_i + D_j)$$

using a value of 1.5×10^{-5} cm^2 s^{-1} for the diffusion constants of both species.[3] The rate constant so calculated was 1.0×10^{11} s^{-1}. From this rate constant and the equilibrium constant we may calculate that k_1, the rate constant for diffusion together to form the complex, is 1.7×10^9 s^{-1}.[4] Although there are certainly objections possible to the way in which these values were estimated, they are logically consistent and there is no obvious way to derive more exact expressions. It seems preferable to us to use rather approximate values and accept a certain crudeness in the theory and degree of fit to experimental data in order to have only one adjustable parameter and no more.

[3]Values of about this magnitude are found for various small molecular species, and are not strongly sensitive to size of molecules; see ref. 11.

[4]This may be shown, by expressing the rate constant in terms of the Smoluchowski equation (12), to correspond to a solid angle for approach of the nucleophile of 3.14 rather than 4π.

With these considerations in mind we may then consider the three cases of interest. First, for reactions with two reactants and two products eq. [6] can be elaborated as eq. [8]. Reaction coordinate

[8] $A + B \rightleftharpoons A,B \rightleftharpoons C,D \rightleftharpoons C + D$

diagrams for each of the three cases for this model are illustrated in Fig. 1; the three cases shown are (*a*) reaction rate is diffusion controlled in the forward direction; (*b*) reaction rate is controlled by the rate of the chemical transformation, with ΔG related to ΔG^0; (*c*) reaction rate is diffusion controlled in the reverse direction. The figure helps make it clear that the equilibrium constant to be used in the Marcus expression for this process is the overall equilibrium constant for eq. [8] since in our approximation the equilibrium constants for the formation of the encounter complexes from starting materials and products are the same. This will not always be the case, but unless there are clear theoretical grounds for assuming that they are unequal (as when there is an electrostatic interaction) or there is convincing experimental evidence demanding such a conclusion it seems to us preferable to use an inexact expression in place of one which gives a better fit but uses numerous parameters not well determined by the data. This seems particularly important in the situation of interest for this paper where the data span wide ranges of rate and equilibrium constants, but in the latter case are of limited precision.

If the equilibrium constants for the diffusion together of substrates or diffusion apart of products, for the process in eq. [8], were markedly different, the equilibrium constant for the chemical step would no longer be that for the overall process. If the encounter process had a large barrier (a high "work term" to bring reactants together) then the limiting rate constant at very favorable equilibrium constant would be much less than the diffusion limit. There are numerous cases where sizeable "work terms" have been invoked (13) but this is always to explain one or two divergent points.

When the equation for the overall process is derived, making the steady state assumption for encounter complex, rather more complex equations than those previously employed are obtained. That one must consider changes from rate limited transport to rate limiting reaction, and that this can be an additional source of curvature in rate equilibrium correlations has been shown by Murdoch (14).

A somewhat different formulation is necessary for the case of carbonyl addition processes, where we wish to consider reactions such as [9], of the

[9] $A + B \rightleftharpoons C$

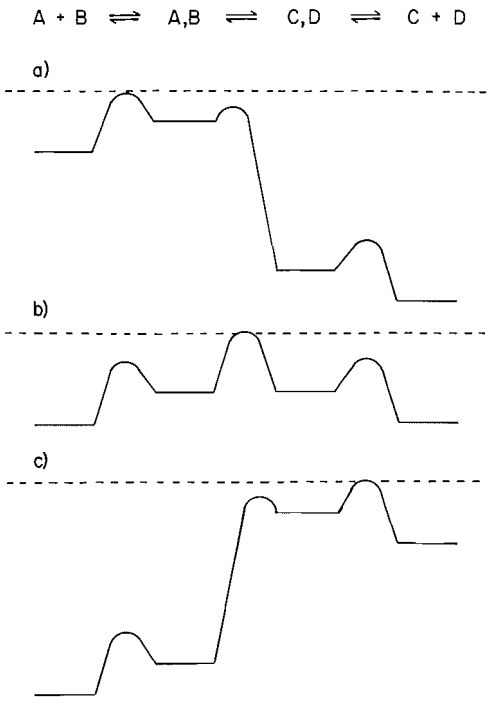

FIG. 1. Reaction coordinate diagrams for the case of two reactants and two products. (*a*) Equilibrium constant very favorable for product formation, diffusion together of reactions is rate limiting. (*b*) Equilibrium constant is of intermediate magnitude, chemical reaction step is rate limiting. (*c*) Equilibrium constant is very unfavorable for product formation, diffusion apart of products is rate limiting.

type where the forward reaction can be limited by the rates of diffusion together of A and B, as the equilibrium constant becomes very large in the direction favoring C, but the reverse reaction can in principle become as fast as a molecular vibration, 10^{13} s^{-1}, as the equilibrium constant for formation of C becomes very unfavorable. Equation [9] should be expanded to eq. [10].

[10] $A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A,B \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C$

Figure 2 makes clear that our assumptions require the use of a different value for the equilibrium constant, reduced from the overall equilibrium constant by the equilibrium constant for encounter complex formation. This model leads to the overall eq. [11] which we have used in this paper for hydroxide addition to carbonyl compounds. This leads to slightly different numerical results from those previously reported, but does not change the qualitative conclusions.

[11] $k_{obs} = k_1/(1 + k_{-1}/k_2)$

$\log k_2 = 13 - b(1 - \log K/4b)^2$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

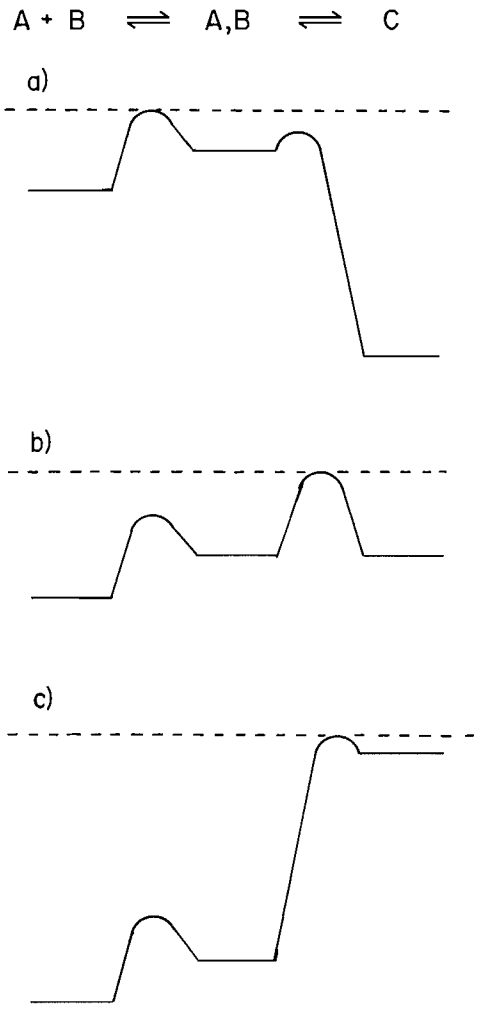

FIG. 2. Reaction coordinate diagrams for the case of two reactants and only one product. (*a*) Equilibrium constant very favorable for product formation, diffusion together of reactants is rate limiting. (*b*) Equilibrium constant is of intermediate magnitude, chemical reaction step is rate limiting. (*c*) Equilibrium constant is very unfavorable for product formation, rate constant for breakdown of the product is approaching the vibration limit.

There are additional problems when the nucleophile is water, since the solvent does not need to diffuse into contact with the carbonyl compound. However there is probably a need for a water molecule to reorient itself so that it is able to react; we indicate such a reoriented water as H_2O^* in [12].

[12] $A + H_2O \rightleftharpoons A, H_2O^* \rightleftharpoons C$

The only limitation on the forward rate as the equilibrium constant becomes very large in the direction favoring products is then the relaxational time of water molecules, which corresponds to a

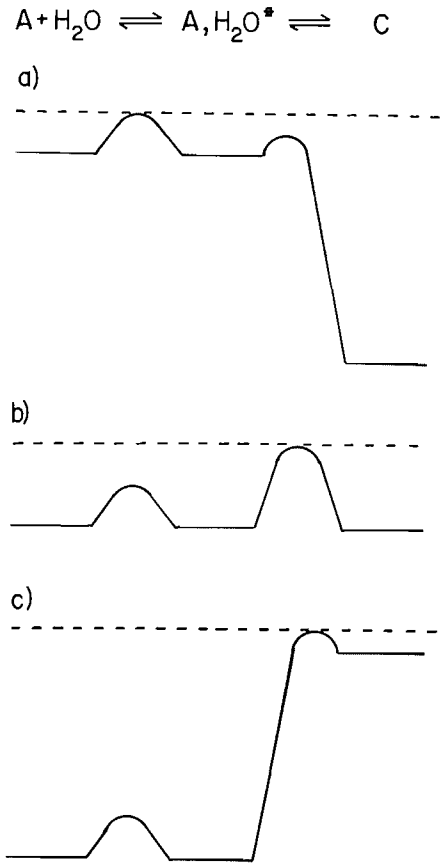

FIG. 3. Reaction coordinate diagrams for the case of two reactants, one of which is water, and only one product. (*a*) Equilibrium constant very favorable for product formation, relaxation of water to give a molecule of water in a reactive orientation is rate limiting. (*b*) Equilibrium constant is of intermediate magnitude, chemical reaction step is rate limiting. (*c*) Equilibrium constant is very unfavorable for product formation, rate constant for breakdown of product is approaching the vibration limit.

rate constant of about 10^{11} s^{-1}.[5] In the absence of any further information we have set the equilibrium constant for reorganization to 1.0 and applied eq. [11] to this case as well. Since the data do not fall in regions where solvent reorganization is likely to be rate limiting, this uncertainty should have little qualitative effect, although it does mean that the equilibrium constant will be in error by some unknown offset.

Figure 3 illustrates this case; there are several points which require discussion; first it is quite possible if not certain that a similar solvent reorganization step should be included in the cases

[5]This value is derived from various relaxation times reported for water molecules in liquid water, which seem to be in approximate agreement at about 3×10^{-12} s (ref. 15), implying a rate constant of about 10^{11} s^{-1} or a little larger.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

discussed earlier. What is not certain is what the equilibrium constant for the reorganization process should be or what would constitute unambiguous evidence for such a process becoming an important contribution to the overall rate equation.

The effect of using these various forms of the Marcus equation upon the actual shape of the curves is relatively small for b values significantly greater than 1 if the equilibrium constants are neither very small nor very large. If the equilibrium constants are such that the curve begins to approach one of the asymptotes, then it clearly makes a very considerable difference which form of the equation is used.

The new thermochemical data reported in this paper permit the calculation of equilibrium constants for the addition of water or hydroxide to six additional esters, supplementing the three for which this was possible from our previous work (1). We may test these new equilibrium constants several ways. First we may show that the equilibrium constants for addition of hydroxide lead to a good correlation with the rate constants for attack of hydroxide and that the points fall on a line consistent with the Marcus eq. [11]. Figure 4 shows that this is indeed the case and that the points fall on a line within experimental error; the b value calculated by the method of least squares for the 9 points is 8.99 ± 0.17. This value differs from that reported earlier (1) because we are now fitting to a different equation. If the equation used in ref. 1 is used for the 9 esters for which data are now available, the b value obtained by least squares is very similar to that obtained for three esters (1). Secondly we may show that the rates of uncatalyzed attack of water on the esters are consistent with the equilibrium constants calculated for the addition of water to give the zwitterion, as was done previously (1). Unfortunately only one of the esters studied in the present work has had its water rate measured; Fig. 5, which includes other points obtained as described below, shows that for the esters for which data are available the agreement with eq. [11] is poorer if the reaction is assumed to proceed directly to the neutral tetrahedral species. Since we are using a different equation, the details of the fit are slightly changed, from that described in ref. 1, but the qualitative conclusion is unchanged, that only addition to give the zwitterion provides a satisfactory description of the data. Thirdly, we may plot the equilibrium constants for hydration against the Taft σ^* values for the acyl substituent; this plot, shown in Fig. 6, shows a reasonably good linear free energy relationship, with a reasonable ρ^* value of 3.02 with the correlation coefficient, $r = 0.944$ for 8 points.

Since the equilibrium constants derived from our thermochemical data seem to be in satisfactory agreement with the kinetic behavior of the esters,

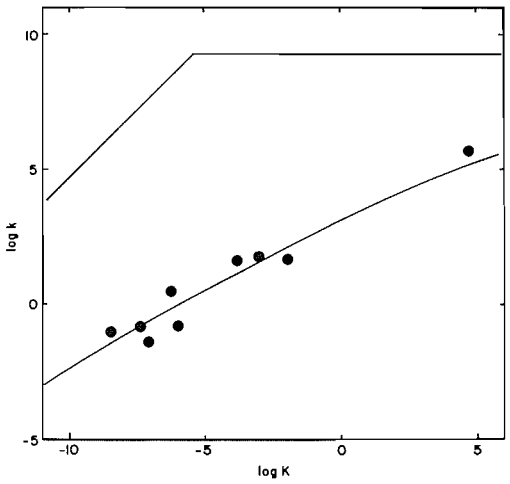

FIG. 4. Marcus curve for hydroxide attack on esters. The line through the points is drawn using the value of b determined by least squares, 8.99 ± 0.17. The limiting line corresponding to $b = 0$ is also shown.

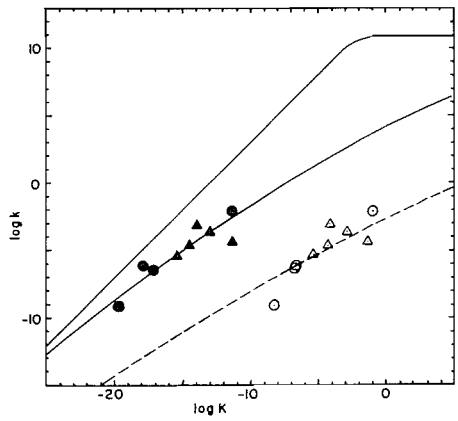

FIG. 5. Marcus curve for uncatalyzed hydrolysis of esters. (——) and open points, calculated assuming that the attack of water leads directly to the neutral tetrahedral intermediates, i.e. concerted proton transfer. (○) points where K^- was determined from thermochemical data; (△) points where K^- was determined from the curve relating rate and equilibrium constants for hydroxide attack. The line was determined by least squares, $b = 15.74 \pm 0.32$; the weighted sum of the squares of the deviations was 15.2 (points based on thermochemistry were given double weight). Note that two of the points derived from thermochemistry deviate badly. (—) and closed points, calculated assuming that the attack of water leads to the zwitterion, with fast subsequent proton transfer. The line was determined by least squares, $b = 8.81 \pm 0.28$; the weighted sum of the squares of the deviations was 7.81. Note that in this case the most serious deviation was for dimethyl oxalate, where the equilibrium constant was determined from the correlation for hydroxide reactions. The limiting line corresponding to $b = 0$ is also shown.

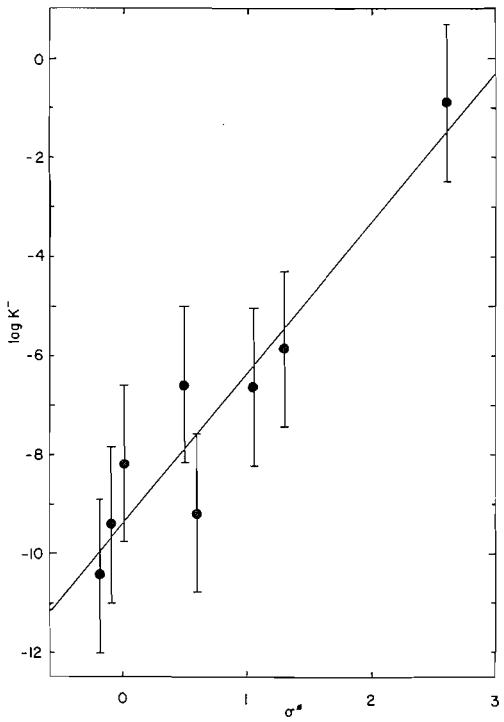

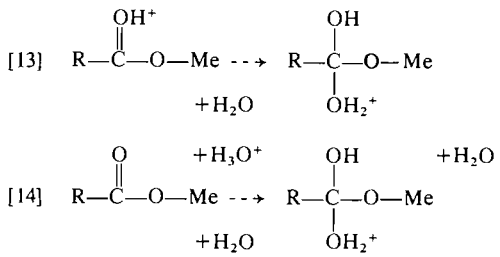

FIG. 6. Relationship between log K^0 and σ^* for aliphatic esters. The best line (least squares) is $\log K^0 = -9.336 + 3.02\sigma^*$.

we are emboldened to try using the Marcus relationship to derive further equilibrium constants from literature values of rate constants for the hydroxide ion catalyzed hydrolysis of esters. As we have previously pointed out (1) this reaction is mechanistically unambiguous (provided, as is generally the case, that the leaving group is as good a leaving group as hydroxide or better) and therefore is likely to be very satisfactory for this purpose. Equilibrium constants so estimated are found in Table 4, along with values derived more directly from experiment. This procedure allows us to obtain many more equilibrium constants. The derived data can be tested by looking at the correlation between rate and equilibrium constants for the water reaction, for which we now have five additional points; the agreement is seen from Fig. 5 to be satisfactory. Since no water rates are available for the aromatic esters, the equilibrium constants estimated for them cannot be tested in this way.

With significantly less confidence we can use these new equilibrium constants for addition to esters, derived from the rate constants for hydroxide attack, to estimate rate constants for the water reaction, where they have not been reported. These estimated rate constants are given in Table 4. Some at least are experimentally accessible, without requiring unreasonably prolonged reaction times.

Acid catalyzed hydrolysis of esters poses a problem, since there are two mechanisms which both lead to plausible fits of data to the Marcus equation with the limited set of data initially available (1), namely specific acid catalyzed[6] addition of water in which water adds to the protonated ester to give the protonated form of the tetrahedral intermediate, process [13], or general acid catalyzed[6] addition of water, with hydronium ion acting as general acid, so that water plus hydronium ion combines with the ester to give the protonated tetrahedral intermediate, process [14].

The difficulty with process [13] was that the best available values for the pK_{BH^+} values of carbonyl compounds led to some points falling in impossible regions, corresponding to rate constants exceeding the relaxation rate for water (1); this was not compelling because there is considerable uncertainty concerning the true pK_{BH^+} values for simple carbonyl compounds, and recent values for acetone have varied from −2.72 (16) to −5.37 (17). Only for the more negative values of the pK_{BH^+} for acetone and other simple carbonyl compounds do the points fall in forbidden regions. We have a strong preference for these more negative values since an analysis[7] of the published data for protonation of acetone showed that there was a two step protonation process, as proposed by Palm *et al.* (18). This analysis was used as a starting point for the pK_{BH^+} assignment of Cox *et al.* (17). For acetaldehyde and formaldehyde, the two compounds which could give a clear answer to the question, there are no accepted values for pK_{BH^+}, although several attempts have been made to measure them (19–21). From the data in ref. 21 a pK_{BH^+} value of −8.1 can be deduced for formaldehyde.[7]

With a larger set of equilibrium constants for hydration in hand we can endeavor to give a clearer

[6]Specific acid catalyzed and general acid catalyzed are used in the strict mechanistic (as opposed to kinetic) sense to mean that the proton is fully (specific) or partially (general) transferred at the transition state.

answer to the question. It must be borne in mind that in this attempt the only solidly established facts are the observed rate constants. The equilibrium constants for hydration are, we believe, reliable although imprecise, but most have not been tested. The pK_{BH^+} values for the esters, although various attempts have been made to measure them (22–24), are still plagued by the uncertainties which beset all measurements of ionization constants for very weak bases. We have extended the set of esters for which pK_{BH^+} values are available by the use of linear free energy relationships; see the Calculations. The pK_{BH^+} values for the tetrahedral intermediates are necessarily (since one cannot prepare a solution of these metastable species for titration) based upon extrapolation from simpler compounds using linear free energy relations which are bound to be imperfect. In the case of the protonated alcohol species, there are so few direct measurements that it was necessary to base the linear free energy relation (1) on indirectly measured basicities (25). Nevertheless, the values for pK_{BH^+} of the intermediate are probably fairly reliable since they were used in deriving the zwitterion content for the neutral intermediate in the successful correlation for uncatalyzed hydrolysis.

If we plot the observed rate constants for acid catalyzed reaction vs. the equilibrium constants calculated for process [14] we find a rather implausible looking graph, Fig. 7, with severe scatter of the data about the best line. A more detailed examination of structure reactivity relationships for esters makes this mechanism look very unsatisfactory. The well known fact that the rate constants for the acid catalyzed reactions of *meta*- and *para*-substituted benzoate esters are almost independent of substituent means, in terms of mechanism [14], that the effects of substituents on hydration and upon protonation of the neutral hydrate must almost cancel, since in terms of the Marcus equation, if the rate constants are independent of structure while falling short of diffusion controlled values, then the equilibrium constants must also be independent of structure. This leads to an unreasonable requirement that the ρ value for pK_{BH^+} of the tetrahedral intermediate be of the same magnitude as the ρ value for the hydration. Although the ρ value of 2.9 which we observe for hydration of aromatic esters appears quite reasonable for this process, which occurs at the carbon directly bonded to the benzene ring, it is far too large for an ionization at an atom separated from the ring by one carbon atom; for anilines ρ for pK_a is −2.81 (26) while for benzylamines it is −1.05 (27). Similarly for the aliphatic esters the ρ^* value for the acid catalyzed hydrolysis is ~0, so that ρ^* for ionization of the tetrahedral intermediate must have a magnitude of 2.4, which is again too large for a substituent effect with an intervening carbon atom; ρ^* for $R—NH_3^+$ is −3.15 (26) while for $R—CH_2—NH_3^+$ it is −1.75 (7). These arguments suggest that the general acid catalyzed mechanism is probably not correct, and force us to the specific acid catalyzed path.

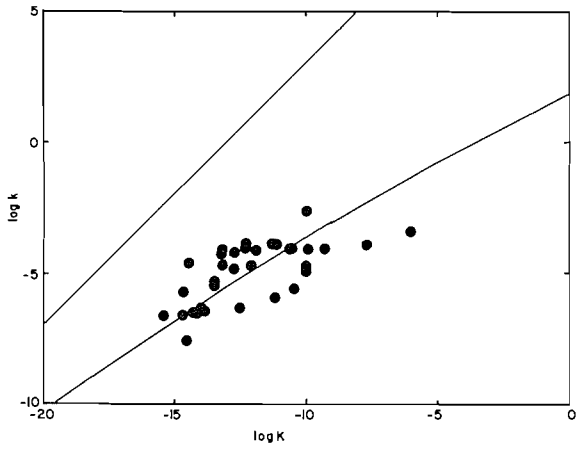

FIG. 7. Marcus curve for acid catalyzed ester hydrolysis assuming that this follows mechanism [14], with general acid catalysis by hydronium ion. The line is the best fit by least squares, but is not satisfactory, $b = 11.12 \pm 0.19$, sum of squares of deviations = 33.91. The limiting line corresponding to $b = 0$ is also shown.

Alternatively we may use the best available pK_{BH^+} values for the esters (see Calculations) and see how well the data obey the Marcus equation for mechanism [13]. When the data are plotted in this way, the points fall in reasonable accord with eq. [11] for $b = 8.45 \pm 0.10$. This supports the assumption of a simple specific acid catalyzed path for acidic hydrolysis of esters, but there remain the problems with the simple carbonyl compounds. These problems exist only if the assumption is made that these compounds should also fall on the same line as the esters, but this assumption seemed reasonable in view of the behavior seen for uncatalyzed and base catalyzed addition of water. Since the pK_{BH^+} values for all of acetone, acetaldehyde, and formaldehyde would have to be very close to 0.0 for these compounds to fall on the same line as the esters for the simple specific acid mechanism, this seems unlikely to be the correct description for them. Alternatively there may be a change in mechanism between the esters and the simple carbonyl compounds, with the former showing specific acid catalysis, and the latter showing general acid catalysis with hydronium ion acting as general acid.

Other investigations, to be reported separately,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

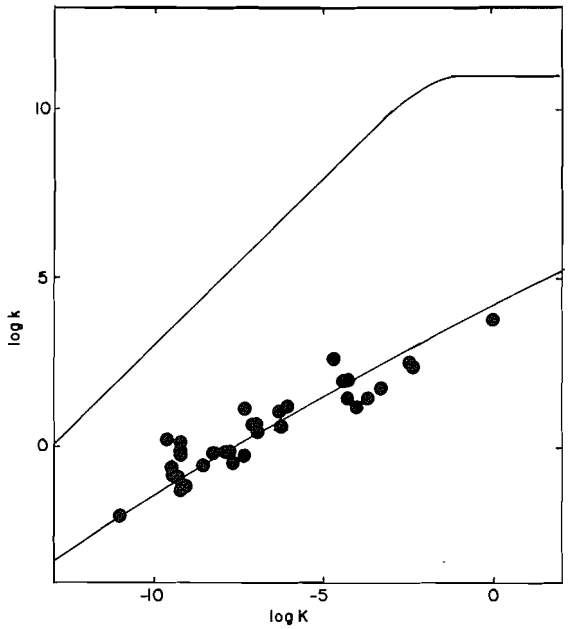

FIG. 8. Marcus curve for acid catalyzed ester hydrolysis assuming that this follows mechanism [13], with specific acid catalysis. The line is the best fit by least squares, and looks much better than for mechanism [14]. The b value is 8.76 ± 0.10, sum of squares of deviations = 9.09. The limiting line corresponding to $b = 0$ is also shown.

have independently led us to the conclusion that the acid catalyzed reactions of simple aldehydes and ketones are actually general acid catalyzed, while the analogous reactions of esters are specific acid catalyzed.

Assuming that the specific acid catalyzed path is indeed followed, we have estimated rate constants for these esters for which no values have been reported. These rate constants are found in Table 4.

Experimental

Materials

Trimethyl orthobenzoate (Aldrich, bp 87–88°C/7 Torr) was used as received. The trimethyl orthoesters of propionic, isobutyric, chloroacetic, and methoxyacetic acids were prepared by the method of McElvain and Nelson (28). The corresponding acids and esters were commercially available. Purity was evaluated by nmr spectroscopy, and compounds were distilled where necessary. The nmr spectra were recorded on a Varian T-60 spectrometer.

Methods

Heats of solution and reaction were measured using a simple calorimeter as previously described (29). Solubilities of organic liquids were measured as previously described (30) for concentrations $>0.03\,M$. For the less soluble compound, trimethylorthobenzoate, 200 mL of 0.001 N HCl were saturated with the orthoester and allowed to equilibrate with stirring at 25 ± 1°C. A 100 mL aliquot of the aqueous layer was drawn and shaken continuously for two minutes with each of five consecutive 4 mL portions of $CHCl_3$. After each extraction the chloroform layer was transferred to a 25 mL volumetric flask by syringe. A suitable reference standard was added and the solution was made up to the mark with $CHCl_3$. Concentrations were evaluated by electronic integration of their nmr spectra.

Free energies of transfer (ideal gas at 1 atm to 1 M aqueous solution with an infinitely dilute reference state) were calculated from solubilities and vapour pressures where possible. For the purpose of these calculations $< 1\,M$ compound will be assumed to behave ideally. For compounds with a solubility exceeding 1 M (i.e. trimethyl orthomethoxyacetate, methyl methoxyacetate, methyl cyanoacetate), a method was devised whereby the vapour pressure above a solution of known concentration at 25°C could be measured, thus giving the free energy of transfer directly. N_2 gas was passed into dilute aqueous solution of known concentration of compound through sintered glass, at a rate which would allow sufficient time for the gas to come to equilibrium with water and the compound (ca. 30 mL min^{-1}). The saturated N_2 gas was then passed through a trap which prevented direct transfer of entrained droplets, and then into a dry ice – acetone cooled condenser where water and compound were condensed. The flow rate was established using a gas flow meter at the end of the train. The water to compound mole ratio in the condensate was determined using nmr. At a gas flow rate of ca. 30 mL min^{-1}, it took ca. 19 h to collect 1 mL of condensate. It was assumed that the vapour pressure of water above the dilute solution was that of pure water.

Calculations

The standard entropy in the gas phase was estimated by the group contributions method of Benson (31). Following Benson we use C for tetrahedral carbon, C_B for aromatic carbon, and C_d for doubly bonded (alkene) carbon. If the desired group contribution was not available, a value was approximated by using one for a similar group. The effects of sp^3 oxygen and carbon on the S^0 for a group were regarded as being equal, so that the contribution for the group, [C $(O)_3$ (C)], could be substituted by the value for [C $(C)_4$]. For trimethyl orthobenzoate, where the group required [C $(O)_3$ (C_B)], the known value for [C $(C)_3$ (C_B)] was used. For methyl benzoate, S^0 values for the groups, [C_B (C_d)] and [CO (C) (O)], were used for the groups, [C_B (CO)] and [CO (C_B) (O)], respectively. It was also necessary to substitute the value of the group, [C (Cl) (C) $(H)_2$], for that of [C (Cl) (CO) $(H)_2$], for methyl chloroacetate.

Steric effects on the free energy change for the reaction:

[15] $\quad C—OCH_3 + H_2O = C—OH + CH_3OH$

were determined as previously described (32). For trimethyl orthoisobutyrate, it was also necessary to consider a sixth neighbour H—H interaction worth 2.00 kcal mol^{-1} (33), in addition to the usual interactions. For trimethyl orthobenzoate, we needed an approximate energy for the coaxial interaction of the π cloud with two hydrogens. Space filling models of trimethyl orthobenzoate show that phenyl cyclohexane (34) is not a good model to give us this energy. The maximum value for each interaction of this type would be that for a fifth neighbour hydrogen – lone pair interaction worth 0.15 kcal mol^{-1} (35). As the π cloud would be less "directed" than a lone pair, one would expect the energy for the former type of interaction to be smaller. Therefore, zero should be an acceptable value for the energy of this interaction.

Very few values for pK_{BH^+} values of esters have been reported. For aliphatic esters we have earlier reviewed the literature and selected values (1); from these data eq. [16] relating pK_{BH^+} to the Taft ρ^* value for the acyl substituent could be derived.

[16] $\quad pK_{BH^+} = -4.17 - 1.71\rho^*$

For aromatic esters, Edward and Wong have recently published

what should be a reliable value for ethyl benzoate, using characteristic vector analysis to correct for solvent effects (24); their value is −6.16. We assume that the ρ value for esters will be approximately equal to that reported for benzoic acids (using pK_{BH^+} values determined assuming that the acids were Hammett bases) namely −1.09 (36). This assumption can be tested by considering the ρ values for acetophenones using pK_{BH^+} values based upon the assumption of Hammett base behavior (37) ρ = −2.22, and using pK_{BH^+} values derived by characteristic vector analysis, $\rho^* = -1.69$ (17). The assumption is clearly only appproximately valid. Another estimate can be made assuming that ρ is the same as for benzamides, for which pK_{BH^+} values are available for the unsubstituted and *p*-nitro substituted derivatives (24). Both ρ values were used and the average was calculated, with the difference between the two estimates taken as the uncertainty in pK_{BH^+}. All of the data on which our estimated pK_{BH^+} values are based may be found in Supplementary Tables S16 and S17.[2]

Etude par la résonance de l'azote 15 et du phosphore 31 de la liaison P—N dans des dérivés du phosphore trivalent; analyse statistique des données expérimentales

JEAN-PAUL GOUESNARD, JEAN DORIE et GÉRARD J. MARTIN

Laboratoire de Chimie Organique Physique, ERA CNRS 315, Faculté des Sciences, 44072 Nantes, France

Reçu le 10 juillet 1979[1]

JEAN-PAUL GOUESNARD, JEAN DORIE et GÉRARD J. MARTIN. Can J. Chem. **58**, 1295 (1980).

L'étude par rmn de l'azote 15 et du phosphore 31 et par rmn dynamique du carbone 13 d'une cinquantaine d'amino-phosphines a permis de systématiser le rôle des facteurs physico-chimiques qui gouvernent la distribution électronique de la liaison azote–phosphore(III). Une analyse factorielle et régressionnelle des paramètres rmn $\delta^{15}N$, $\delta^{31}P$ et $^1J_{P—N}$ appartenant à plusieurs séries d'amino-phosphines a permis de mettre en évidence l'existence de facteurs communs et de différentes corrélations dans les familles de composés et entre les variables rmn. Ces résultats statistiques ont été discutés en termes d'effets topologiques, électroniques et stériques des substituants. Le rôle des substituants de l'atome d'azote et de l'atome de phosphore sur les paramètres rmn ainsi que sur la barrière à la rotation autour de la liaison P—N, $\Delta G_T^{\neq}$, est interprété sur la base de considérations relatives à l'hybridation des atomes d'azote et de phosphore, à la conjugaison p_π–d_π et à la nature des états électroniques (terme ΔE^{-1}) du fragment P—N.

JEAN-PAUL GOUESNARD, JEAN DORIE, and GÉRARD J. MARTIN. Can. J. Chem. **58**, 1295 (1980).

Natural abundance ^{15}N and ^{31}P nmr and dynamic ^{13}C nmr have been applied to the study of about fifty aminophosphines, in order to generalize the influence of the chemical factors which govern the electronic distribution of the nitrogen–phosphorus III bond. Factor and regression analyses of $\delta^{15}N$, $\delta^{31}P$, and $^1J_{P—N}$ values performed on different series of aminophosphines have shown that common factors and various correlations exist between the nmr parameters in the different kinds of derivatives. The statistical results are discussed in terms of topologic, electronic, and steric contributions. The nature of the different substituents of the nitrogen or phosphorus atoms governs the observed changes in screening, coupling constants, and the rotational barriers $\Delta G^{\neq}$ around the P—N bond, which are explained in considering the type of nitrogen and phosphorus hybridization, the p_π–d_π donation and the electronic states (ΔE^{-1} approximation) of the P—N fragment.

Introduction

Les aminophosphines dérivant du phosphore trivalent présentent une grande activité chimique et biologique. Leur structure et leur comportement stéréochimique dynamique ont abondamment été étudiés en résonance magnétique nucléaire (rmn) du proton, du carbone et notamment du phosphore (1). Par contre, il existe très peu de résultats de mesures effectuées en résonance de l'azote 14 (2*a*) ou 15 (2*b*–*e*). Nous avons montré que le déplacement chimique $\delta^{15}N$ pouvait être, dans certaines conditions, une bonne sonde pour évaluer le degré de délocalisation électronique autour des liaisons N—X (3*a*) et nous avons appliqué cette méthode au cas des liaisons N—C (3*b*), N—Si (4), et N—N (5). Nous nous proposons ici d'analyser statistiquement les valeurs de $\delta^{15}N$, $\delta^{31}P$ et $^1J_{(^{31}P—^{15}N)}$ de plusieurs familles d'aminophosphines P(III) et de tenter d'interpréter les correspondances observées en termes d'effets électroniques (délocalisation) et stériques.

Résultats

A. Déterminations expérimentales

Les aminophosphines étudiées correspondent à la formule $X(Y)P—N(R)_2$ et sont définies dans le Tableau 1. La différence de nature des substituants R de l'atome d'azote définit 10 séries de composés numérotées de I à X, et dans chaque série, la nature des substituants X et Y du phosphore caractérise le composé. Ainsi l'aminophosphine IV **14** aura la formule $(iC_3H_7)_2N—P(Cl)C_6H_5$. Dans le Tableau 2, nous avons indiqué les valeurs des paramètres physico-chimiques représentant les effets électroniques et stériques des substituants X, Y et R du système P—N. Ces valeurs ont été extraites des mises au point récentes les plus fiables. Les paramètres σ_I et σ_{R^0} de Taft *et al.* (6*a*) compilés par Exner (6*b*), ont été préférés à ceux de Swain et Lupton car la séparation des effets de champ et de résonance est illusoire dans cette systématique (7). Le terme $R_{P—X}$ représente la polarisabilité électronique d'une liaison P—X (9) supposée être une mesure de la contribution du terme d'énergie d'excitation moyenne (ΔE^{-1}) à $\delta^{31}P$ pour différentes liaisons P—X. L'effet stérique, caractérisé par le paramètre E_S proportionnel au rayon de van der Waals a été introduit par Taft (8*b*) et compilé par Unger et Hansch (8*a*). Les paramètres rmn δ et J sont rassemblés dans les Tableaux 3 et 4. Le Tableau 3 regroupe les données relatives à toutes les séries de fragment aminé, pour deux types de substituants du phosphore **14** et **17**, et permet ainsi de comparer l'influence des substituants de l'atome d'azote sur les paramètres rmn. Le Tableau 4 offre au contraire la possibilité d'examiner le rôle joué

par les substituants du phosphore dans trois séries de référence I, II et IV. Le Tableau 5 rassemble les données accessibles de rmn dynamique relatives au processus de rotation restreinte autour de la liaison P—N. Les données de la littérature ont été complétées par des mesures que nous avons effectuées par rmn dynamique du carbone.

B. Calculs statistiques

(*a*) L'analyse factorielle des valeurs $\delta^{15}N$, $\delta^{31}P$ et $^1J_{P—N}$ a été effectuée sur 24 observations différentes correspondant à chacun des trois paramètres rmn associés aux composés **14**, **17**, **22**, **24**, **25**, **28**, **29** et **31** des séries I, II et IV. Dans ce type d'approche statistique (10*a*), utilisée initialement en rmn pour étudier les effets de solvant (10*b*–*e*) et les effets de substituants halogénés (10) sur δ, nous avons pu mettre en évidence le nombre et l'influence relative des facteurs liés au type de la substitution sur l'atome d'azote, qui gouvernent les paramètres $\delta^{15}N$, $\delta^{31}P$ et $^1J_{P—N}$. De plus, l'analyse factorielle nous a permis d'obtenir le degré d'autocorrélation

TABLEAU 2. Effets électroniques et stériques des substituants X ou Y du système $(R)_2N—P(X)Y$. Les valeurs de σ_I et σ_R ont été extraites de la compilation des effets de substituants réalisée par Exner (6*b*); elles correspondent aux déterminations effectuées par Taft *et al.* en rmn de ^{19}F (6*a*). $R_{P-X,Y}$ représente la réfraction de la liaison P—X ou P—Y; les valeurs de *R* ont été extraites de la mise au point de Le Fevre (9). Les valeurs du paramètre stérique de Taft (8*b*), E_S, sont issues du travail de Unger et Hansch (8*a*)

des variables rmn: $\delta^{15}N(I) = f[\delta^{15}N(II)]$, etc. Les résultats sont indiqués dans le Tableau 6.

(*b*) L'analyse régressionnelle des variables rmn entre elles $\delta^{15}N = f(\delta^{31}P)$, $\delta^{15}N = f(^1J_{P-N})$ et $\delta^{31}P = f(^1J_{P-N})$ (Tableau 7) nous a permis de mettre en évidence les analogies et les différences de comportement. Il est intéressant de noter à ce sujet que le nombre d'observations ne doit pas être nécessairement le même pour les trois séries, contrairement au cas de l'analyse factorielle décrite ci-dessus.

(*c*) Nous avons finalement essayé d'approfondir les interprétations structurales des analyses statistiques précédentes, en tentant d'obtenir des corrélations significatives entre les variables rmn et des paramètres structuraux traduisant le nombre des substituants de l'atome d'azote. En second lieu, nous avons essayé de mettre en évidence des corrélations entre les variables rmn et les paramètres de substituants σ_I, σ_R et E_S.

Discussion des résultats

A. Etude statistique de l'intercorrélation des paramètres rmn

(a) Analyse factorielle des données rmn relatives aux séries I, II et IV

L'analyse permet de mettre en évidence le degré de corrélation des variables entre elles et le nombre minimum de facteurs dont dépendent les variables. Les résultats du Tableau 6 montrent qu'un seul facteur suffit pratiquement pour exprimer $\delta^{15}N$ et $\delta^{31}P$ dans les trois familles étudiées. La matrice des données originales peut être reproduite avec une erreur moyenne sur chaque point inférieure à 0.3 ppm. La série IV se comporte d'une façon très légèrement différente des deux séries I et II. L'autocorrélation de $\delta^{15}N$ ou de $\delta^{31}P$ dans les trois séries considérées est en général très satisfaisante. Il est ainsi possible de prévoir le comportement de $\delta^{15}N$ et de $\delta^{31}P$ dans une série de référence. Ce résultat peut présenter un intérêt structural notable. Par contre, deux facteurs sont nécessaires pour rendre compte des valeurs de $^1J_{P-N}$ à ± 0.3 Hz et si les variables I et II se comportent d'une façon analogue, la série IV se différencie très nettement ici. Le degré de corrélation de $^1J_{P-N}$ dans les séries I et II est bon, mais est médiocre dans les deux autres cas, I et IV ou II et IV. Cette méthode n'est entachée d'aucun arbitraire, mais n'apporte cependant aucune explication physico-chimique sur la nature et l'origine des facteurs. Celle-ci sera réalisée dans le paragraphe B sur la base d'analyses régressionnelles de chaque paramètre rmn en termes d'effets de structure et de substituants.

(b) Analyse de l'interdépendance des paramètres rmn entre eux (Tableau 7)

$\delta^{15}N$ et $\delta^{31}P$

Il est intéressant de noter que les valeurs $\delta^{15}N$ sont bien corrélées au déplacement chimique du phosphore pour les trois séries considérées (Fig. 1). Les valeurs des pentes *b* des droites de régression indiquent que $\delta^{15}N$ varie environ deux fois moins que $\delta^{31}P$ et l'erreur moyenne sur l'estimation de $\delta^{15}N$ à partir de $\delta^{31}P$ est de 3 ppm. Ainsi, l'influence des effets électroniques des substituants X et Y du phosphore se traduit dans le même sens, sur $\delta^{15}N$ et

[a–d]Voir la légende du Tableau 3.
[f]Valeurs obtenues par spectroscopie ^{14}N et extraites de la réf. 2*a*.
[g]La valeur $\delta^{31}P$ du composé I 22 est de 160.0 Hz, réf. 1*a*.

sur $\delta^{31}P$ mais d'une façon atténuée dans le premier cas. Dans la série IV, la plus encombrée, l'atténuation des effets de X, Y sur $\delta^{15}N$ atteint presque 60%. Enfin, la croissance algébrique, des ordonnées à l'origine *a*, en fonction de la substitution alkyle sur l'atome d'azote est à mettre en relation avec l'effet β (cf. B).

$\delta^{15}N$ *et* $^1J_{P-N}$

Les corrélations sont très bonnes dans les deux séries (I, II) où ne se manifeste pas d'encombrement stérique, et les pentes ont des valeurs très voisines (Fig. 1). On constate que les points correspondant à la série IV ont une dispersion statistique importante, mais si on les répartit en deux familles, contenant les composés chlorés ou non chlorés, on obtient alors une bonne corrélation pour les deux types de molécule ($R = 0.95$) et des ordonnées à l'origine et pentes voisines ($a = -361.5$ et -370.0, $b = 0.91$ et 0.87 respectivement). Les composés I-**1**, **2** et **21** se comportent d'une façon anormale par rapport à la série considérée. En effet, dans les cas considerés, les substituants de l'atome de phosphore présentent soit un encombrement stérique notable, soit une faible electronegativité. Cet aspect est developpé par ailleurs (32).

[a]Avec correction β pour les séries II ou IV.
[b]Résultat non significatif.

$\delta^{31}P$ et $^1J_{P-N}$

L'allure des droites de régression est comparable pour les deux séries I et II, et aucune corrélation significative ne peut être obtenue pour la série IV.

Ainsi le comportement de $\delta^{15}N$ et $\delta^{31}P$ vis à vis de $^1J_{P-N}$ est tout à fait semblable: $\delta^{15}N$ et $\delta^{31}P$ varient dans le même sens et une augmentation du déplacement chimique (effet paramagnétique) entraine une augmentation du couplage. Cependant $^1J_{P-N}$ ressent différemment les interactions électroniques et stériques des substituants R, X et Y.

B. Interprétation des variations des paramètres rmn en fonction de la structure moléculaire

(a) Influence des substituants de l'atome d'azote (R) sur $\delta^{15}N$ et $^1J_{P-N}$

Les résultats discutés précédemment peuvent s'expliciter en tenant compte de la substitution α, β et γ de l'atome d'azote. Les composés **14** des séries I à X ont été choisis comme molécules de référence et la matrice utilisée pour le calcul régressionnel a été construite sur la base des valeurs du Tableau 3 et du nombre n de substituants en α, β et γ.

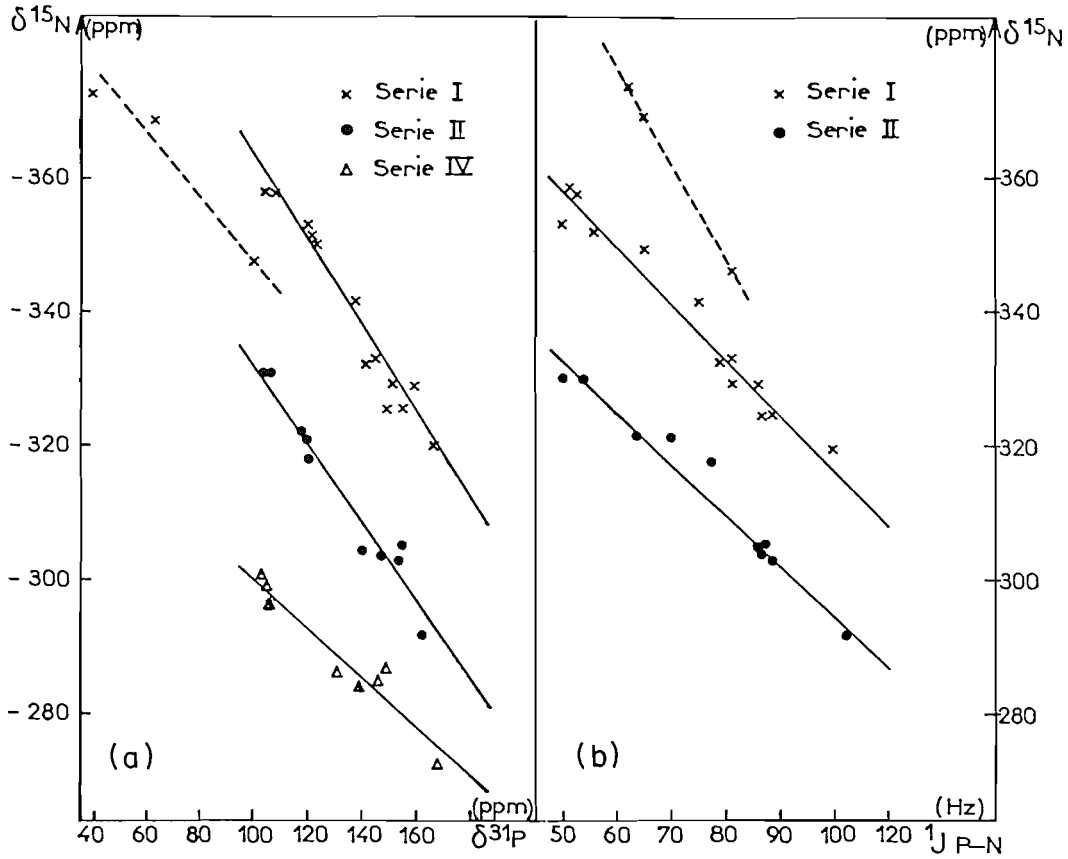

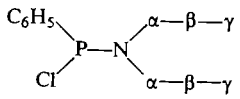

FIG. 1. (*a*) Variation du déplacement chimique de l'azote (en ppm/NO_3^-) par rapport à celui du phosphore (en ppm/H_3PO_4 85%) pour différentes séries $(CH_3)_2N$(I), $(C_2H_5)_2N$(II) et $(iC_3H_7)_2N$(IV) d'amino-phosphines; (*b*) variation du déplacement chimique de l'azote (en ppm/NO_3^-) en fonction de la constante de couplage phosphore–azote (en Hz). Une augmentation algébrique de δ correspond à une diminution de l'écran.

Les valeurs de $\delta^{15}N$ rapportées à la série $(CH_3)_2N—P<$ origine de la corrélation, sont convenablement exprimées au moyen du seul paramètre β. On calcule aussi un effet γ diamagnétique (−0.6 ppm) mais cet incrément n'est pas statistiquement significatif.

$$[1]\quad \delta^{15}N(\pm 1.7)\ \text{ppm} = -331.7(\pm 1.4) + 11.6(\pm 0.5)n(\beta)$$

$$R = 0.996 \quad t_b = 23 \quad N = 8$$

Ce résultat est en accord avec la valeur de l'incrément β_t déterminé pour des amines tertiaires (24*c*). Lorsque le calcul régressionnel est effectué sur une série plus variée de composés et en distinguant les différents types d'amines, la valeur de l'incrément β varie de 12 à 22 ppm. L'effet β n'est pas constant d'une série de composés à l'autre et dépend de la nature du groupe X (C(β)—C(α)—*N*—X ou C(β)—C(α)—*C*—X) directement lié à l'atome *N* (ou *C*) considéré (24*a*, *b*). Un comportement analogue a été souligné en résonance du carbone (25*a*) et il a été suggéré (25*b*) que la variation de l'effet β pouvait être relié à l'ordre de liaison π du fragment *C*···X. Cette observation est à rapprocher des corrélations que nous avons étudiées entre $\delta^{15}N$ et les valeurs de l'enthalpie libre d'activation du processus de rotation autour de la liaison N—X (3). La relation [1] permet d'expliquer les résultats de l'analyse factorielle au moyen d'un facteur topologique caractérisant un seul type de substituant β. On peut cependant affiner les prédictions de $\delta^{15}N$ dans toutes les séries de composés aminophosphorés dans lesquels les substituants X et Y du phosphore varient, en décomposant cet effet en deux incréments β′ et β″

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

représentant respectivement la première et la seconde substitution alkyle $\beta' = 13.6$ ppm et $\beta'' = 10.0$ ppm avec $\beta = \frac{1}{2}(\beta' + \beta'')$.

En ce qui concerne $^1J_{P—N}$, deux facteurs ont été mis en évidence par l'analyse factorielle et, en effet, cette constante de couplage ne peut s'exprimer correctement qu'en fonction de deux paramètres de substitution, β et γ ($R = 0.95$, $N = 8$).

$$[2] \quad {}^1J_{P—N}(\pm 0.8)\ \text{Hz} = 76.6 + 1.3(\pm 0.2)n(\beta) + 0.7(\pm 0.3)n(\gamma)$$

La constante $^1J_{P—N}$ augmente donc avec le nombre et la grosseur des substituants alkyles de l'atome d'azote.

Il faut noter que les valeurs de $\delta^{31}P$ ne changent pas en fonction de la substitution alkyle de l'atome d'azote ($\delta^{31}P = 140.4 \pm 0.5$ ppm pour les composés **14** des différentes séries) sauf lorsqu'il y a une double substitution $\beta\beta$ et dans ce cas $\delta^{31}P = 131 \pm 1$ ppm (effet diamagnétique).

(b) Influence des substituants X, Y de l'atome de phosphore sur les paramètres rmn

Tous les substituants X et Y, que nous avons considérés, à l'exception du groupe CH_3 (I.1) sont capables de se conjuguer par un mécanisme p_π–p_π ou p_π–d_π avec l'atome de phosphore. Il a été montré que l'environnement électronique de l'atome de phosphore III dépend étroitement de l'état d'hybridation de la paire libre d'électrons (26) et de la conjugaison p_π–d_π. Une augmentation du transfert $p_\pi \rightarrow d_\pi$ vers l'atome de phosphore se traduit par un effet diamagnétique notable sur $\delta^{31}P$ (28). Or, les modifications de la structure électronique de P se répercutent d'une façon analogue sur l'azote, car $\delta^{15}N$, $^1J_{P—N}$ et $\delta^{31}P$ varient dans le même sens (cf. A-b). Nous avons étudié les trois types d'effets décrits dans le paragraphe A: σ_I et σ_{R^0}, E_S et $R_{P—X}$.

Il est intéressant de constater que les valeurs de $\delta^{31}P$, $\delta^{15}N$ et $^1J_{P—N}$ sont corrélées d'une façon significative à σ_I, mais non à σ_{R^0} (13 points série I)

$$[3] \quad \delta^{31}P(\pm 10) = 102(\pm 6) + 103(\pm 16)\sigma_I(X, Y) \qquad R = 0.88 \quad t_b = 6.1$$

$$[4] \quad \delta^{15}N(\pm 6) = -327(\pm 4) + 69.5(\pm 10)\sigma_I(X, Y) \qquad R = 0.90 \quad t_b = 6.9$$

$$[5] \quad {}^1J_{P—N}(\pm 5) = 44(\pm 3) + 71(\pm 8)\sigma_I(X, Y) \qquad R = 0.93 \quad t_b = 8.3$$

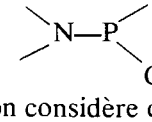
Ces corrélations traduisent l'existence d'un effet paramagnétique sur le déplacement chimique et d'une augmentation du couplage avec l'accroissement des effets inducteurs attracteur des substituants X et Y. L'adjonction de σ_{R^0} à σ_I, n'augmente pas d'une façon statistiquement significative les corrélations avec $\delta^{15}N$, $\delta^{31}P$ et $^1J_{P—N}$ car le test F de Snedecor (31) reste inférieur à sa valeur théorique bien que la valeur du coefficient de corrélation R augmente sensiblement.

Les corrélations des variables rmn $\delta^{15}N$, $\delta^{31}P$ et $^1J_{P—N}$ avec le terme stérique E_S ne sont pas significatives si on considère les séries I, II ou IV dans leur ensemble. Cependant les valeurs de $\delta^{31}P$ peuvent se grouper en deux familles importantes correspondant à des molécules chlorées ou non chlorées, respectivement. La liaison P—Cl étant beaucoup plus polarisable que les autres, on doit attendre une influence paramagnétique du terme

ΔE^{-1} plus grande sur $\delta^{31}P$(Cl, X) que sur $\delta^{31}P$(X, Y)

(26). On peut alors calculer deux droites de régression pour ces deux familles de composés.

Composés chlorés:



$$[6] \quad \delta^{31}P(\pm 2.6) = 258 + 32E_S \qquad R = 0.96 \quad 9\ \text{pts} \quad t_b = 8.4$$

Composés non chlorés:

$$[7] \quad \delta^{31}P(\pm 4.8) = 206 + 26E_S \qquad R = 0.95 \quad 9\ \text{pts} \quad t_b = 7.7$$

L'influence de l'encombrement stérique et de la polarisabilité de la liaison P—Cl se retrouve dans le comportement de $\delta^{15}N$ et $^1J_{P—N}$, car, à l'exception des composés chlorés, on observe une diminution de $\delta^{15}N$ (effet diamagnétique) et de $^1J_{P—N}$ avec la grosseur des substituants, liée aux modifications d'hybridation du fragment phosphore–azote par variation de l'encombrement stérique. Des substituants encombrants sur le phosphore tendent à rendre l'azote pyramidal et provoquent un effet diamagnétique sur $\delta^{15}N$ et une diminution de $^1J_{P—N}$. Au contraire, une augmentation de la grosseur des substituants de l'azote confère à celui-ci une hybridation à tendance sp^2 qui augmente $^1J_{P—N}$ et $\delta^{15}N$.

Les anomalies observées dans la série IV peuvent s'expliquer par l'existence d'une structure pyramidale privilégiée (27), conforme aux résultats d'une étude effectuée par RX sur la trimorpholinophosphine (30). Le cas des composés aromatiques

peut s'expliquer aisément si on considère que la valeur $E_S = -1.01$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

utilisée (Tableau 2), correspond à une conformation d'encombrement minimum du cycle aromatique. En fait, comme le noyau phényle se conjugue partiellement avec P, son encombrement réel doit être plus important. Dans ce cas, le transfert p_π–d_π du cycle phényle vers le phosphore l'emporte sur celui du group $N(R)_2$ qui tend à adopter une disposition sp^3 (effet diamagnétique).

C. Relation entre les paramètres rmn et la barrière à la rotation autour de la liaison P—N

De nombreux auteurs (ref. du tableau 5) ont déterminé les valeurs $\Delta G^{\neq}$ et la référence (23) contient une discussion générale du phénomène de topoisomérisation. L'examen des valeurs d'enthalpie libre d'activation permet de mettre en évidence plusieurs traits caractéristiques du comportement des amino-phosphines. On constate notamment que la barrière augmente avec l'accroissement de la taille des substituants R sur l'atome d'azote et lorsque les substituants X et Y présentent des inerties différentes et des encombrements voisins, mais la grosseur intrinsèque de X, Y n'entraine qu'une faible diminution de $\Delta G_T^{\neq}$. Dans l'hypothèse de l'existence d'une géométrie trigonale de l'azote à l'état fondamental et tétraédrique dans l'état de transition, l'accroissement de la taille des substituants R de l'azote rend moins probable une géométrie non plane de l'azote, et entraine une augmentation de la barrière. Par contre l'augmentation de la taille des substituants X ou Y du phosphore favorise un azote pyramidal et entraine une faible diminution de la barrière, d'autre part lorsque les substituants X et Y ont des encombrements stériques sensiblement identiques on peut observer une dépendance de $\Delta G_T^{\neq}$ avec les effets électroniques des substituants ($\Delta G_T^{\neq}$ **I 1** < $\Delta G_T^{\neq}$ **I 17** par exemple).

Contrairement à ce que nous avons observé dans les séries N—X où X est un atome ne possédant pas d'orbitale *d* (e.g., X = C, N) (3), aucune corrélation simple n'apparaît entre $\delta^{15}N$ (ou $^1J_{P—N}$) et $\Delta G^{\neq}$. Cette absence de corrélation confirme aussi le rôle prépondérant de l'encombrement stérique dans l'état de transition sur le mécanisme de rotation autour de la liaison P—N. On peut cependant mettre en évidence une tendance de variation de la barrière avec $\delta^{31}P$; $\Delta G_T^{\neq}$ diminue avec l'écran du phosphore.

Série	$\Delta G_T^{\neq}$ (kJ mol^{-1})	$\delta^{31}P$ (ppm)
I, II, III, V, X	44 à 46	140 à 142.5
IV, VI	55 à 56	131

Cependant, le petit nombre de points correspondant à des valeurs différentes de $\Delta G^{\neq}$ et $\delta^{31}P$ ne permet pas de calculer une corrélation très significative.

L'effet diamagnétique observé sur $\delta^{31}P$ est en accord avec l'augmentation de la conjugaison p_π–d_π de l'azote vers le phosphore.

Partie expérimentale

Préparation des aminophosphines

Les aminophosphines sont obtenues par action de l'amine secondaire sur les chlorophosphines selon la réf. 29*a*. Le composé **I 1** a été synthétisé en faisant réagir le bromométhyl magnésium sur l'amino dichlorophosphine (29*a*). Les aminophosphines oxygénées **I 27** et **I 35** résultent de la réaction de l'éthanol sur la tris(diméthylamino) phosphine (29*b*). Certains composés triaminés ne se forment pas dans de bonnes conditions car de nombreuses réactions d'échange interviennent. Les structures des produits préparés ont été vérifiées par rmn ^1H, ^{13}C ou ^{31}P.

Résonance magnétique nucléaire

Les spectres ^{15}N ont été obtenus au moyen d'un spectromètre Bruker WH 90-DS, en abondance naturelle dans des liquides purs à 301 K après addition de 0.08 *M* de $Cr(AcAc)_3$ dissous dans 10% de $CHCl_3$; SW = 6000 Hz, At = 0.68 s, PW = 12 × 10^{-6} s, ν_0 = 9.117 MHz. Découplage large bande (2 W), nombre d'accumulation: 2 × 10^4 à 2 × 10^5 suivant la masse moléculaire. Les composés chlorés donnent des rapports signal-sur-bruit meilleurs que les autres composés. Les déplacements chimiques ont été repérés par rapport à une solution dans D_2O, H^+ de $^{15}NO_3$ Na enrichi à 30% contenue dans un tube coaxial de 4 mm centré dans un tube échantillon de 15 mm ($\delta(Ni/CH_3NO_2)$ = $\delta(Ni/NO_3^-)$ − 1.5 ppm). Les spectres ^{31}P ont été enregistrés sur un appareil Bruker WH 90-DS pour des produits purs ou en solution à 30% dans un mélange 50:50 $CS_2/CO(CD_3)_2$ (cas IV **17**) ou en solution à 30% dans $CHCl_3$ (cas IV **31** et IX **14**); SW = 12000 Hz, At = 0.34 s, PW = 7 × 10^{-6} s, ν_0 = 36.447 MHz, découplage large bande, nombre d'accumulations: 100. Les valeurs de $\delta^{31}P$ sont indiquées en ppm par rapport à H_3PO_4. Les expériences de rmn dynamique ont été réalisées au moyen du spectrographe Bruker WH 90-DS en résonance de ^{13}C (SW = 3000 Hz, At = 1.34 s, PW = 3 × 10^{-6} s, ν_0 = 22.635 MHz, découplage large bande, nombre d'accumulations = 10^3).

Calculs statistiques

Les analyses factorielles ont été effectuées au moyen des sous-programmes CORRE: matrice de corrélation, EIGEN et TRACE: valeurs propres et vecteurs propres, LOAD: matrice factorielle, sur calculatrice IBM 1130. Les régressions linéaires ont été effectuées au moyen d'un calculateur de bureau. Les paramètres statistiques ont les significations habituelles: $R_{x,y}$ coefficient de corrélation, *S* écart-type sur les coefficients de la régression, et $tb_x = b_x/Sb_x$. La valeur calculée tb_x doit être supérieure à la valeur t_F trouvée dans la table de Fischer en fonction de *N* et de la probabilité *P* d'existence dérivée pour la corrélation. Ainsi pour *P* = 99% et N = 8, 10, 13, 23 et 31 on trouve t_F = 3.3, 3.2, 3.0, 2.8 et 2.7. Le test *F* permet de vérifier si l'adjonction d'une seconde variable indépendante x_2 à la régression conduit à une amélioration significative de la corrélation. Si la valeur $F = S_y^2/S_y'^2$ (où S_y et S_y' représentent les écarts-types sur l'estimation par la corrélation à 1 et 2 variables respectivement) est plus grande que F_S, la corrélation bilinéaire est significative. F_S se trouve dans les tables de Snedecor en fonction de *N* et *N'* (31).

Cinétique d'oxydation des oximes du benzaldéhyde et de l'acétophénone par l'ion thallique

ROBERT LORTIE ET MIKLOS ZADOR

Département de Chimie, Université de Montréal, C.P. 6210, Succursale A, Montréal (Qué.), Canada H3C 3V1

Reçu le 19 décembre 1979

ROBERT LORTIE et MIKLOS ZADOR. Can. J. Chem. **58**, 1305 (1980).

La cinétique d'oxydation des oximes du benzaldéhyde et de l'acétophénone par le Tl(III) a été étudiée en milieu aqueux. La réaction s'effectue par deux étapes consécutives: formation d'un intermédiaire nitroso et sa décomposition ultérieure. L'oxime forme un complexe interne avec le Tl(III), ce qui conduit à l'équation de vitesse: $-d[\text{oxime}]/dt = K_1k_2[\text{oxime}][\text{Tl(III)}]/(1 + K_1[\text{Tl(III)}])$. La formation du produit final carbonylé est inhibée par le Tl(III), dû à la formation d'un complexe résistant à la décomposition. La coordination du Tl(III) par les ions chlorure affecte de façon différente la vitesse des deux étapes. Le mécanisme de la réaction est discuté.

ROBERT LORTIE and MIKLOS ZADOR. Can. J. Chem. **58**, 1305 (1980).

The kinetics of oxidation of benzaldehyde and acetophenone oximes by Tl(III) in aqueous medium has been studied. The reaction occurs in two consecutive steps: formation of a nitroso intermediate and its decomposition. The oxime forms a complex with Tl(III) leading to the rate equation: $-d[\text{oxime}]/dt = K_1k_2[\text{oxime}][\text{Tl(III)}]/(1 + K_1[\text{Tl(III)}])$. The formation of the final carbonyl product is inhibited by Tl(III), a result of the formation of a complex resistant to decomposition. Coordination of Tl(III) by chloride ions affects the rate of the above two steps. The reaction mechanism is discussed.

L'utilisation de sels thalliques pour régénérer les dérivés carbonylés par oxydation des oximes, phenylhydrazones et semicarbazones constitue une méthode intéressante en synthèse (1). L'oxydation des oximes s'effectue d'après l'éq. [1].

$$[1]\quad R_1R_2C{=}NOH + Tl^{3+} + \tfrac{1}{2}H_2O \rightarrow R_1R_2CO + Tl^{+} + 2H^{+} + \tfrac{1}{2}N_2O$$

McKillop et ses collaborateurs ont montré qu'elle est rapide et sélective dans le cas d'un grand nombre d'oximes (1).

Le travail présent est consacré à l'étude de la cinétique et du mécanisme d'oxydation des oximes du benzaldéhyde et de l'acétophénone en milieu aqueux par le perchlorate thallique.

Partie expérimentale

Les solutions de perchlorate thallique ont été obtenues par dissolution du Tl_2O_3 (B.D.H.) dans l'acide perchlorique. La concentration en Tl(III) a été déterminée par iodométrie. L'oxime du benzaldéhyde est un produit commercial (Eastman), contenant les isomères *syn* et *anti* à l'équilibre. L'oxime du cyclohexanone et l'oxime *anti* de l'acétophénone ont été synthétisés et caractérisés par des méthodes standards (2).

L'acétoxy-1 nitroso-1 cyclohexane a été synthétisé comme suit: 1.45 g (~ 1.3 mmol) d'oxime du cyclohexanone sont dissous dans 10 mL de CCl_4 ajouté de quelques gouttes d'anhydride acétique. On y ajoute 5 g (~ 13 mmol) de $Tl(OAc)_3$ que l'on maintient en suspension en agitant à l'aide d'une barre magnétique. Après 15 min à reflux on obtient une solution verte qui ne contient plus du Tl(III). La solution est lavée par de l'eau, contenant du bicarbonate de sodium, filtrée et séchée sur du sulphate de magnésium.

A cause de son instabilité, le produit, l'acétoxy-1 nitroso-1 cyclohexane, est caractérisé directement en solution dans le CCl_4 par rmn, rpe et le spectre visible (rmn: multiplet du cycle δ = 1.7 ppm et δ = 2.3 ppm, singulet de l'acétoxy δ = 2.4 ppm; rpe: triplet I:1:1, a_n = 12.6 Oe, comparé à a_n = 13.2 Oe obtenu dans le CH_2Cl_2 (3); spectre visible λ_{max} = 667 nm, comparé à λ_{max} = 665 nm dans le CH_2Cl_2 (3)).

La cinétique d'oxydation a été suivie par spectrophotométrie soit en enregistrant les spectres à intervalles réguliers (Pye-Unicam model 1700), soit en enregistrant la variation d'absorbance à longueur d'onde constante (Zeiss PMQ II). Un grand excès de Tl(III) par rapport à l'oxime a été utilisé. Les constantes de vitesse d'ordre un ont été obtenues à partir de la relation $kt = \ln[(A_0 - A_\infty)/(A_t - A_\infty)]$, où A_0, A_t et A_∞ représentent les absorbances aux temps 0, t et infini respectivement. Les conditions expérimentales choisies sont discutées dans le chapitre Résultats.

La température de réaction a été maintenue constante à ± 0.1°C. La force ionique du milieu a été ajustée à 1 *M* à l'aide de perchlorate de sodium.

Lors de l'étude de l'influence d'ions chlorure, il a fallu procéder, dans certains cas, par addition de solution de chlorure de sodium pendant le déroulement de la réaction pour pouvoir étudier les deux étapes (voir plus loin).

Résultats

Les spectres uv du mélange réactionnel enregistrés à intervalles réguliers, révèlent clairement que l'on est en présence de deux réactions consécutives. Les spectres initial et final correspondent bien aux réactifs et aux produits carbonylés; cependant, comme l'indique la fig. 1, une bande plus intense apparait entre 240–250 nm en cours de réaction.

La fig. 2 montre un résultat typique obtenu en enregistrant la variation d'absorbance à longueur d'onde constante en fonction du temps. On observe d'abord une augmentation d'absorbance ce qui est suivie d'une diminution plus lente pour arriver à l'absorbance du produit carbonylé. Ces résultats indiquent la formation d'un intermédiaire réactionnel ce qui impose des précautions particulières

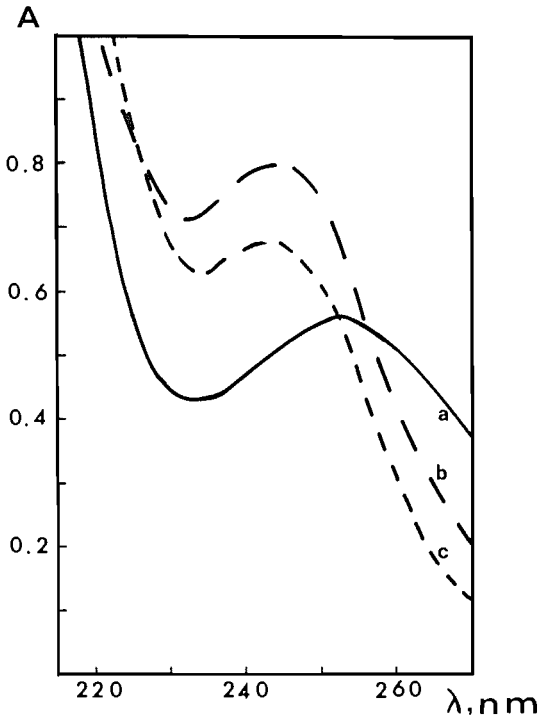

FIG. 1. Spectres d'absorption de la solution réactionnelle aux temps correspondant à la prédominance de (a) oxime du benzaldéhyde, (b) intermédiaire, (c) benzaldéhyde.

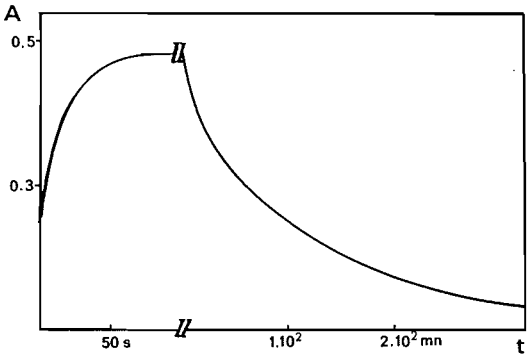

FIG. 2. Variation d'absorbance lors de l'oxydation de l'oxime du benzaldéhyde. T = 45°C; $[H^+]$ = 1 M; [Tl(III)] = 1.25 × 10^{-2} M; [oxime] = 5 × 10^{-4} M; λ = 290 nm.

pour l'étude cinétique d'autant plus que la vitesse relative des deux phénomènes varie, d'après les résultats préliminaires, de façon significative avec la concentration en Tl(III) et de ses ligands dans le milieu réactionnel.

Cinétique de la première étape

Pour l'étude de cette étape on a choisi une longueur d'onde où l'absorbance de l'intermédiaire et du produit final sont identiques (un point isobestique de la fig. 1). Ceci permet d'éliminer entièrement l'interférence de la deuxième étape. En présence d'un grand excès de Tl(III) ([Tl(III)] ≫ [oxime]) des cinétiques d'ordre un ont été observées.

La constante de vitesse expérimentale, k_{exp}, augmente d'abord avec la concentration en Tl(III) (Fig. 3); il y a ensuite une courbure conduisant vers un plateau. Ce comportement est caractéristique d'un mécanisme impliquant la formation d'un complexe entre les deux réactifs:

$$\text{Tl(III)} + \text{oxime} \rightleftharpoons \text{Tl(III)}\cdot\text{oxime} \qquad K_1, \text{ rapide}$$

$$\text{Tl(III)}\cdot\text{oxime} \rightarrow \text{intermédiaire} \qquad k_2, \text{ lent}$$

$$[2] \quad -\mathrm{d[oxime]}/\mathrm{d}t = k_2K_1[\text{oxime}][\text{Tl(III)}]/(1+K_1[\text{Tl(III)}])$$

Les résultats sont en accord avec l'éq. [3], qui représente l'expression habituelle de la constante de vitesse expérimentale d'un mécanisme à deux étapes dont le premier implique la formation rapide et réversible d'un complexe entre les deux réactifs.

$$[3] \quad k_{exp} = k_2K_1[\text{Tl(III)}]/(1 + K_1[\text{Tl(III)}])$$

L'ensemble des paramètres cinétiques est résumé au tableau 1, qui indique également l'accord obtenu entre k_{exp} et k_{calc} obtenu à l'aide de l'éq. [3]. La variation de la concentration en acide perchlorique de 0.25 à 1 M, à force ionique constante n'affecte pas de façon significative les constantes de vitesse.

Le complexe Tl(III)·oxime a été mis en évidence par spectrophotométrie; sa formation conduit à une augmentation appréciable d'absorbance par rapport à la somme de celle du Tl(III) et l'oxime entre 250 et 310 nm. Cependant, dû à sa nature peu stable et, en partie, à l'absorbance élevée du Tl(III) aux hautes concentrations, des bonnes valeurs de K_1 n'ont pas pu être obtenues par cette méthode.

Cinétique de la deuxième étape

L'intermédiaire formé se décompose avec diminution d'absorbance à 260–290 nm pour l'oxime

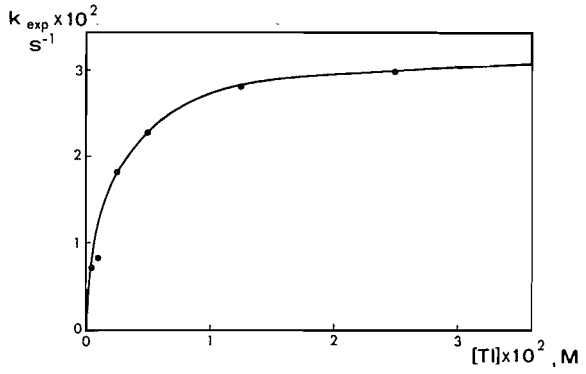

FIG. 3. Variation de k_{exp} avec la concentration en Tl(III). T = 45°C; $[H^+]$ = 0.5 M; [oxime du benzaldéhyde] = 5 × 10^{-5} M.

2.5	1.20	1.5	1.8
5.0	0.55	2.5	1.4
12.5	0.23	5.0	1.0
25.0	0.12	7.5	0.70
		10.0	0.54
$k_4/K_3 = (3.0 \pm 0.3)10^{-6}\ M\ s^{-1}$		$k_4/K_3 = (5.9 \pm 1)10^{-7}\ M\ s^{-1}$	

*T = 45°C; [$HClO_4$] = 1.0 M; [oxime] = 5×10^{-5} à 5×10^{-4} M; solvant = H_2O.

du benzaldéhyde et à 230–270 nm pour l'oxime de l'acétophénone.

La constante de vitesse d'ordre un de cette étape k'_{exp} diminue avec l'augmentation de la concentration du Tl(III) en excès (voir tableau 2). De plus, l'addition du Tl(III) au mélange réactionnel pendant le déroulement de cette étape est suivie d'une diminution instantanée de la pente de la courbe absorbance vs. temps. La réaction est donc inhibée par le Tl(III). Par conséquent, à haute concentration en Tl(III) la formation de l'intermédiaire est beaucoup plus rapide que sa disparition, donc cette dernière étape a pu être étudiée facilement. A basse concentration en Tl(III) la nature consécutive de la réaction est apparente, les deux réactions ont alors des vitesses comparables. Comme même une contribution faible d'absorbance de la première étape influe significativement sur l'allure des courbes, de bonnes valeurs des constantes n'ont pas pu être obtenues à des concentrations en Tl(III) inférieures à celles du tableau 2. L'augmentation de l'acidité de 0.25 à 1.0M conduit à une diminution de 35% de k'_{exp}.

L'effet inhibiteur du Tl(III) a été interprété en admettant la formation d'un complexe de celui-ci avec l'intermédiaire (I) formé d'après le schéma suivant:

$$Tl(III) + I \rightleftharpoons Tl(III)\cdot I \qquad K_3, \text{ rapide}$$

$$I \rightarrow \text{produit carbonylé} \qquad k_4, \text{ lent}$$

Ceci conduit, en présence d'un excès de Tl(III) aux équations

$$[4] \quad d[\text{carbonyle}]/dt = k_4[I]_{total}/(1 + K_3[Tl(III)])$$

$$[5] \quad k'_{exp} = k_4/(1 + K_3[Tl(III)])$$

Le graphe de $1/k'_{exp}$ vs. [Tl(III)] donne une droite en accord avec l'éq. [5], permettant à déterminer la valeur de k_4/K_3. L'ordonnée à l'origine est très faible; par conséquent k_4 n'a pas pu être obtenu. Ceci implique que K_3[Tl(III)] > 1, donc l'intermédiaire est fortement complexé, beaucoup plus fortement que l'oxime ($K_3 \gg K_1$).

Influence des ions chlorure

L'influence des ions hydroxyles n'a pas pu être étudiée en détail, dû aux effets multiples (catalytiques et hydrolytiques) d'une variation de la concentration en H^+, et la faible solubilité du Tl(III) à pH élevé. L'influence de la coordination du Tl(III) a donc été étudiée au moyen d'ions chlorure dont l'affinité pour l'ion Tl^{3+} est bien connue (4).

Les ions chlorures influencent les deux étapes de l'oxydation de l'oxime du benzaldéhyde. Seul un domaine de concentration assez restreint a pu être étudié, dû à l'effet différent sur les deux étapes et l'absorbance élevée des complexes Tl(III)—Cl.

Les résultats présentés au tableau 3 montrent l'effet inhibiteur des ions chlorure sur k_{exp}. Les valeurs de k_{exp} ont pu être interprétés par l'éq. [6] analogue à l'éq. [3] contenant un terme dû à $TlCl^{2+}$.

$$[6] \quad k_{exp} = \frac{k_2K_1[Tl(III)] + k_{2,TlCl}K_{1,TlCl}[TlCl^{2+}]}{1 + K_1[Tl(III)] + K_{1,TlCl}[TlCl^{2+}]}$$

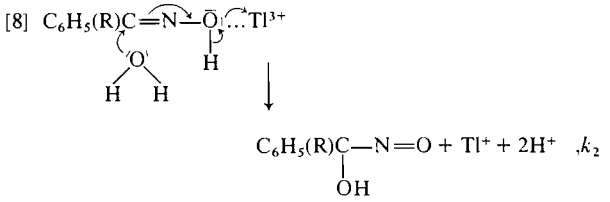
†Constantes de vitesse de décomposition de l'intermédiaire en présence d'ions chlorure (k'_{Cl}) par rapport à celle obtenue en l'absence d'ions chlorure (k'_0).

La régression pondérée, basée sur la distribution des espèces Tl—Cl obtenue en utilisant les constantes de stabilité de la littérature (4), a permis de déterminer les constantes: $K_{1,TlCl} = 200\,M^{-1}$ et $k_{2,TlCl} = 3.4 \times 10^{-2}\,s^{-1}$. Il est à noter, que les espèces $TlCl_2^+$ et $TlCl_3$ n'ont pas de contribution significative à l'éq. [6] ce qui cause la diminution importante de vitesse pour $Cl/Tl > 1$.

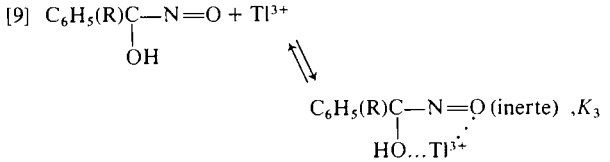
La constante de vitesse de décomposition de l'intermédiaire augmente avec la concentration d'ion Cl^- ajouté jusqu'à un rapport $Cl/Tl = 1$. Ceci s'explique en admettant que $TlCl^{2+}$ complexe moins fortement l'intermédiaire que Tl^{3+}, entraînant l'augmentation de la concentration de l'intermédiaire libre de l'éq. [4] et, par conséquent, l'augmentation de k'_{exp}. La diminution subséquente de la vitesse est assez difficile à expliquer sans des données sur la stabilité du complexe mixte de type $TlCl_2 \cdot L$. Ceci signifierait que $TlCl_2^+$ complexe plus fortement l'intermédiaire que $TlCl^{2+}$.

Il est très significatif cependant qu'en présence d'un excès de chlorure ($Cl/Tl \geq 4$), où $TlCl_3$ et $TlCl_4^-$ prédominent, la vitesse devient beaucoup plus grande en accord avec l'éq. [4], dû à l'impossibilité de former des complexes avec l'intermédiaire.

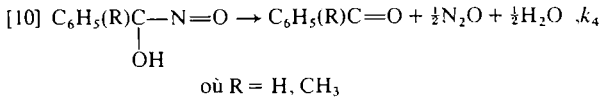


Discussion

Les résultats obtenus sont en accord avec le mécanisme postulé par McKillop *et al.*, qui ont montré pour la première fois, l'utilité de l'oxydation thallique des oximes en synthèse (1). Nos résultats ont apporté les preuves de ce mécanisme ainsi que les données sur la vitesse des différentes étapes. Le mécanisme proposé est le suivant:



[7] $C_6H_5(R)C{=}NOH + Tl^{3+} \rightleftarrows C_6H_5(R)C{=}NO(H)Tl^{3+}$,K_1



1

La formation du complexe Tl(III)· oxime (1) a été

[8] 

2

[9] 

[10] 

où R = H, CH_3

clairement démontrée et les constantes de formation K_1, déterminées. L'intervention de complexes internes avec le Tl(III) a été proposée, lors de l'oxydation d'autres substrats hydroxylés, tels l'acide formique (5) et de divers benzènediols (6), et récemment dans l'oxydation de l'acide mercapto-2 succinique (7).

L'absence d'inhibition par H^+ implique que le complexe est de type $> C{=}NO(H)Tl^{3+}$, donc il n'y a pas de départ de protons lors de la coordination, celle-ci mettant en jeu un doublet libre de l'oxygène. Ceci a été suggéré dans le cas de l'acide formique (5). Toutefois, l'équilibre:

$$Tl^{3+} + H_2O \rightleftarrows TlOH^{2+} + H^+$$

est déplacé vers la gauche avec l'augmentation de l'acidité, ce qui peut entraîner une variation de réactivité du Tl(III).

L'influence des ions chlorure montre que l'introduction du premier ligand ne réduit que peu la réactivité de l'espèce formée, $TlCl^{2+}$, envers l'oxime. Il est probable que ce soit similaire pour $TlOH^{2+}$, ce qui serait en accord avec l'influence négligeable de l'acidité.

Le remplacement de H par CH_3 en position α affecte de façon différente K_1 et k_2. Pour R = H on a $K_1 = 5.2 \times 10^2\,M^{-1}$ à comparer avec $K_1 = 2 \times 10^3\,M^{-1}$ pour R = CH_3. Cette augmentation est attendue, compte tenu de l'effet électron-donneur du CH_3, plus élevé que celui de H, et du caractère électrophile du Tl^{3+}. Il est cependant plus difficile à expliquer la diminution de k_2; $k_2 = 3.2 \times 10^{-2}\,s^{-1}$ (R = H) comparée à $6.3 \times 10^{-3}\,s^{-1}$ (R = CH_3). Il y a probablement un empêchement stérique du CH_3 lors de l'attaque de la molécule d'eau dans l'éq. [8]. De plus, cette attaque nucléophile nécessite une charge positive partielle sur ce carbone, qui est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

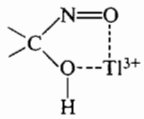
surement plus faible en présence du groupe CH_3, ce qui peut contribuer également à la diminution de k_2.

Une réactivité similaire ou supérieure de TlX^{2+} (X = OH, Cl) par rapport à Tl^{3+} trouvé dans ce cas se retrouve dans l'oxydation d'autres substrats hydroxylés: dans le cas de benzènediols, ($k_{TlOH} > k_{Tl}$ (6)) et de la forme énolique du cyclohexanedione-1,2 ($k_{TlOH} > k_{Tl}$, $k_{TlCl} > k_{Tl}$ (8)). Ce comportement contraste avec celui observé lors de l'oxydation des oléfines ($k_{Tl} \gg k_{TlX}$ (9, 10)).

Cette différence s'explique par la possibilité de formation d'un complexe interne du thallium impliquant les doublets libres des oxygènes des hydroxyles et, dans le cas de l'oxime, la facilité de délocalisation des électrons du système $\diagdown C{=}N{-}O{-}Tl$, sous l'influence du thallium électrophile, nécessaire à l'étape 8. Dans le cas des oléfines, la formation du lien C—Tl nécessite la destruction du système π de l'oléfine; la réactivité du Tl^{3+}, plus électrophile, est donc largement supérieure à celle de TlX^{2+}.

La décomposition oxydative du produit d'oxythallation, qui présente certaines analogies avec l'étape 8, nécessite aussi le développement d'une charge positive sur l'atome de carbone en β, mais celui-ci est séparé du thallium par un lien σ (carbone–carbone) et la délocalisation des électrons est beaucoup moins aisée. Pour cette raison, la réduction de charge et du caractère électrophile, lors de la coordination du thallium, entraînent une diminution très importante de la réactivité (10). La réactivité négligeable de $TlCl_2^+$ est une caractéristique générale de l'oxydation de substrats organiques.

Le complexe Tl(III)·oxime n'a pas été observé dans une étude cinétique effectuée dans un mélange acide acétique – eau (11). Ceci est attribuable à la prédominance des complexes $Tl(OAc)_n^{3-n}$ qui présentent moins d'affinité pour les oximes. La différence importante de réactivité observée pour l'oxime de l'acétophénone ($k = 0.18 M^{-1}\,s^{-1}$ calculée pour 45°C dans l'acide acétique aqueux (11) à comparer à notre valeur de $k_2K_1 = 12 M^{-1}\,s^{-1}$) montre aussi que la coordination par les ions acétate diminue fortement la réactivité du Tl(III); il n'est cependant pas possible de dire si k_2 ou K_1 est la plus affectée.



Les spectres rpe, pris sur le mélange réactionnel lors du déroulement de la réaction, n'ont pas permis la détection de radicaux iminoxy, $C_6H_5(R)C{=}NO^{\cdot}$ suggérés comme intermédiaires dans l'oxydation d'oximes par divers oxydants à un électron (3), et aussi dans le cas du Tl(III) en milieu acide acétique – eau (12).

L'intermédiaire nitroso (**2**) n'a pas pu être isolé dans les conditions expérimentales dû à son instabilité, causé par le groupe OH en position α.[1]

Nous avons pu isoler un intermédiaire nitroso en oxydant l'oxime du cyclohexanone par le $Tl(OAc)_3$, en utilisant le tétrachlorure de carbone comme solvant, ce qui empêche la solvolyse ultérieure et permet la caractérisation *in situ*. L'ion acétate participe à la réaction comme nucléophile et le produit obtenu est l'acétoxy-1 nitroso-1 cyclohexane, présentant le spectre rpe caractéristique en accord avec les données de la littérature (3).

Dû à la réactivité très faible de $Tl(OAc)_3$, l'oxydation d'oximes du benzaldéhyde et de l'acétophénone n'a lieu qu'à température élevée dans ce solvant où les dérivés nitroso correspondants, peu stables (13), se décomposent.

L'aspect le plus important de l'étape de décomposition de l'intermédiaire nitroso (**2**) dans cette séquence de réactions consécutives est l'inhibition par l'ion thallique. Elle s'explique en admettant la formation d'un complexe avec l'intermédiaire nitroso dont la vitesse de décomposition est négligeable. Dans ce cas il y a possibilité de formation d'un chélate à cinq atomes du type:

ce qui explique la stabilité accrue par rapport à l'oxime monodentate ($K_3 \gg K_1$).

La faible diminution de k'_{exp} avec l'augmentation de l'acidité s'explique qualitativement par le déplacement de l'équilibre d'hydrolyse:

$$Tl^{3+} + H_2O \rightleftarrows TlOH^{2+} + H^+$$

vers la formation de Tl^{3+} et son effet subséquent sur l'éq. [5]. Comme $TlCl^{2+}$ inhibe moins que Tl^{3+}, il est probable que ce soit similaire pour $TlOH^{2+}$.

Enfin, le schéma réactionnel implique que le rapport k_{exp}/k'_{exp} est fortement dépendant de la présence de ligands du Tl(III). En absence d'ions chlorure (à $[Tl(III)] \geq 5 \times 10^{-3} M$) on a un rapport $k_{exp}/k'_{exp} \geq 50$, ce qui se traduit par une accumulation de l'intermédiaire nitroso dont la cinétique de décomposition peut être étudiée. Par contre, en présence d'un excès d'ions chlorure (Cl/Tl ≥ 3) on

[1]L'absence de signal rpe aux faibles concentrations utilisées n'exclut pas la présence du dérivé nitroso. En effet, son spectre rpe est dû au radical-anion $N{-}O^{\cdot -}$, présent à très faible proportion (3, 13). Ce dernier est favorisé en présence de bases et un spectre rpe est alors obtenu. Ce spectre est cependant très compliqué dû à la formation de complexes avec le Tl(III) et dû aux couplages avec son spin nucléaire.

a l'inverse, $k_{exp}/k'_{exp} \ll 1$, et la formation de l'intermédiaire devient l'étape lente de la réaction.

Ces conclusions montrent encore une fois la nécessité de milieux non-complexants pour l'obtention du mécanisme détaillé de l'oxydation thallique.

Magnitudes of ^{18}O isotope shifts in ^{13}C nuclear magnetic resonance spectra of ketones and alcohols

JAMES DIAKUR, THOMAS T. NAKASHIMA, AND JOHN C. VEDERAS[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 18, 1980

JAMES DIAKUR, THOMAS T. NAKASHIMA, and JOHN C. VEDERAS. Can. J. Chem. **58**, 1311 (1980).

The magnitudes of ^{18}O-induced isotope shifts in ^{13}C nmr spectra of ketones and aldehydes are dependent on structure and range from about 0.05 ppm to 0.03 ppm for the carbon attached to ^{18}O. An increase in negative charge density on the carbonyl oxygen or conjugation to an aromatic ring reduces the size of the upfield shift. The shifts in [^{18}O]alcohols are solvent-dependent, range from 0.03 ppm to 0.01 ppm, and tend to decrease in the order tertiary ≥ secondary ≥ primary ≥ phenols.

JAMES DIAKUR, THOMAS T. NAKASHIMA et JOHN C. VEDERAS. Can. J. Chem. **58**, 1311 (1980).

L'intensité des déplacements isotopiques induits par l'^{18}O dans les spectres rmn du ^{13}C des cétones et des aldéhydes dépend de la structure et se situe entre 0.05 et 0.03 ppm pour le carbone lié à l'^{18}O. Une augmentation de la densité de la charge négative de l'oxygène du carbonyle ou la conjugaison avec le noyau aromatique réduit l'ampleur du déplacement vers les champs forts. Les déplacements dans les alcools marqués à l'[^{18}O] dépendent du solvant et se situent entre 0.03 et 0.01 ppm et tendent à diminuer dans l'ordre tertiaire ≥ secondaire ≥ primaire ≥ phénols.

[Traduit par le journal]

Introduction

Isotopic substitution frequently causes a measurable change in the nmr chemical shifts of neighboring nuclei. Although the best-studied examples are the isotopic shifts induced by ^{2}H in ^{13}C nmr (1), a number of other systems are known, including ^{2}H and ^{13}C effects in ^{19}F nmr spectra (2), ^{13}C and ^{15}N in ^{59}Co nmr (3), ^{15}N in ^{1}H nmr and ^{13}C nmr (4), and ^{34}S in ^{13}C nmr (5). Oxygen-18 has been shown to produce such isotopic shifts in ^{55}Mn and ^{95}Mo nmr spectra (6) as well as the very useful effect in ^{31}P nmr (7). Recently we (8) and the research groups of Van Etten (9) and Darensbourg (10) independently confirmed theoretical predictions (11, 12) of ^{18}O-induced upfield shifts in ^{13}C nmr spectra.[2] The detection of such shifts using high field nmr permits direct observation of the position and extent of ^{18}O labeling in organic molecules. This methodology is especially useful with polyoxygenated substances where the usual mass spectrometric analysis (13) would require extensive degradations or preliminary specific labeling to ascertain the exact structures of the fragments. We recently applied the technique to a biosynthetic study of averufin, a precursor of aflatoxins (14).

The present study attempts to empirically explore some of the steric and electronic factors which determine the magnitude of the ^{18}O-induced isotope shifts in ^{13}C nmr in ketones and alcohols. Since changes in chemical shielding due to isotopic substitution are controlled by the dynamic state of the molecule (2, 12, 15), calculation of the magnitude of this effect requires exact knowledge of changes in molecular geometry and electron density. Nevertheless, general trends with predictive value are accessible by experimental methods. We have included some results from previous work (8) for comparison.

Experimental

^{13}C nmr Spectra

All ^{13}C nmr spectra were measured at 100.6 MHz on a Bruker WH 400 spectrometer in the Fourier Transform mode. In a typical experiment, 0.25 to 1.0 mmol of sample (30–50% ^{18}O, natural abundance ^{13}C) was dissolved in 2.5 mL of $CDCl_3$ containing tetramethylsilane, and the full proton-decoupled spectrum was obtained using a 10 mm probe. The normal conditions employed a 32K data block, 500 to 1000 scans, 25 000 Hz sweep width, 0.65 s acquisition time, and 45° pulse angle. Signals for carbons bearing oxygen were subsequently expanded using a 32K data block, 500 to 100 scans, 1000 Hz sweep width, 16.3 s acquisition time, and 45° pulse angle. A number of experiments were repeated at higher resolution to ensure reliable isotope shift values. Since all samples contained at least 50% unlabeled compound, the peaks due to carbons bearing ^{16}O provided an internal reference for measurement of the chemical shift change upon ^{18}O substitution.

Oxygen-18 Compounds

Unlabeled commercially-available ketones and aldehydes were purified as necessary by distillation or recrystallization prior to exchange with [^{18}O] water. The method of Radlick was used to prepare tropone (16). Dihydrodibenzo[*a*,*d*]cyclooctene-12(5*H*) one was synthesized according to Stewart and coworkers (17) from 2-(γ-phenylpropyl)benzoyl chloride. The latter compound was made by a modification of literature procedures (18); the keto group of the chalcone intermediate was reduced with sodium borohydride in methanol and the resulting lactone was hydrogenated with palladium on charcoal in acetic acid – ethanol to produce 2-(γ-phenylpropyl)benzoic acid.

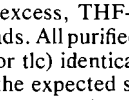
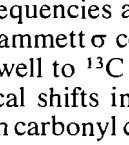
The carbonyl compounds were labeled by reflux (3-96h) in a 1:1 mixture of [^{18}O]water[3] (30–60% isotopic purity) and dioxane or THF (19). Alcohols labeled with oxygen-18 were prepared by sodium borohydride reduction (4-fold excess, THF-methanol, 3h, 25°C) of the [^{18}O] carbonyl compounds. All purified products had chromatographic properties (vpc or tlc) identical with authentic unlabeled materials, and gave the expected spectra (ir, ^{1}H nmr, ^{13}C nmr, uv, and mass spectra). Isotopic content was mass spectrometrically determined for every sample on an AEI MS2 instrument.



Results and Discussion

In a preliminary communication (8) we suggested that the magnitude of the isotope shift for carbonyl carbons attached to ^{18}O tends to decrease in the order: ketones ≥ aldehydes ≥ esters ≥ amides. Conjugation of the carbonyl to an aromatic system also appeared to decrease the shift size. The *para*-substituted acetophenones seemed suited for examination of electronic influences on isotope shift since their basicities had already been compared to carbonyl stretching frequencies and thermodynamic parameters (20). Hammett σ constants of *para*-substituents correlate well to ^{13}C and ^{15}N coupling constants and chemical shifts in several aromatic systems (21). Although carbonyl chemical shifts of *para*-substituted acetophenones (22) and benzaldehydes (23) do not show such a correlation with σ, the formyl proton chemical shifts of the benzaldehydes do. Mathias has suggested the *para*-substituent changes the electron density at the oxygen but not at the carbonyl carbon. The differences in isotope shift values for the acetophenones (Table 1) are too small to allow quantitative correlation with σ constants, but increasing electron donation by the *para* group coincides with decreasing isotope shift. This decrease in shift magnitude due to electron donation is illustrated by the two carbonyl groups of averufin (Fig. 1) (14). A shift of 4.17 Hz is observed in the 100.6 MHz ^{13}C nmr for C-10 of ^{18}O-labeled averufin; fluorenone and anthrone have similar shift sizes. However, the carbonyl at C-9 which has donation through the π system from the oxygens at C-1, C-3, C-6, and C-8 shows a shift of only 2.95 Hz, the smallest we have yet measured for a carbonyl group. As expected, this trend is not evident in the corresponding benzylic alcohols (Table 2) since the oxygen is not conjugated to the aromatic system. The low shift value of 1-(*p*-aminophenyl) ethanol may be due to hydrogen bonding or solvent effects.[4]



[3]The [^{18}O]water was generously donated by the Stable Isotopes Resource of Los Alamos National Laboratory, Los Alamos, NM, U.S.A.

[4]Although solvent has little effect on isotope shift magnitude in carbonyl groups, the effects on alcohols can be substantial (8); *vide infra*.

Comparison of the *ortho*, *meta*, and *para* methylacetophenones suggests some rotation of the carbonyl out of conjugation with the ring in the *ortho* isomer. Though complicated by other electronic factors, such steric inhibition of resonance can be observed in infrared (24), ultraviolet (25), and ^{13}C nmr spectra (22) of *ortho*-substituted acetophenones. Stewart and co-workers have shown that the *ortho–ortho* bridged diaryl ketones (Table 1) are useful for studying the effects of deconjugation on basicities and ultraviolet spectra

(17). Kazakova *et al.* (26) have also investigated their reduction potentials and the esr spectra of their anion radicals as a function of ring size.[5] As the number of methylene groups in the bridge increases, at least one of the aromatic rings is forced out of conjugation with the carbonyl and the solution basicity decreases. Since isotope shift is dependent on molecular dynamics,[6] in particular anharmonic vibration and rotation (12, 15), it is not surprising that its correspondence to ultraviolet spectra, basicities, or reduction potentials is poor. The general trend, however, is a decrease in the magnitude of the isotope shift due to conjugation. Not only do saturated ketones display larger shifts than unsaturated ketones, but the planar fluorenone and nearly planar anthrone have similarly small shifts despite very different electronic properties. Benzophenone is less planar than anthrone (17) and shows a larger isotope shift as do the other bridged diaryl ketones. The reason for the

[5]The esr spectrum of the radical derived from 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-one indicates a carbonyl–phenyl angle of 18–26° (27).

[6]The conformational behavior of 6,7-dihydro-5*H*-dibenzo-[*a*,*d*]cycloocten-12-one has been examined by nmr; see experimental part of ref. 28.

relative shift sizes of 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-one ($n = 2$) and 6,7-dihydro-5*H*-dibenzo[*a*,*d*]cycloocten-12-one ($n = 3$) remains unestablished. Molecular models suggest that the preferred conformation of the latter compound may have one of the aromatic rings in conjugation with the carbonyl whereas that of the former does not, but this view is not supported by the studies described above (17,26). As expected, the highly basic planar tropone (29) has a much smaller shift than its folded derivative (30), 5*H*-dibenzo[*a*,*d*]cyclohepten-5-one.

Ring size effects were tested in the cyclic aliphatic ketone series since their ^{13}C nmr chemical shifts (31), ionization potentials (32), vibrational–rotational spectra, and geometries (33) had already been examined. The ^{18}O-induced isotope shifts in this group are very similar, although a slight decrease can be observed for cyclobutanone. Interestingly, the relative shift magnitudes vary considerably in the corresponding cyclic alcohols. This may be due to relative degrees of freedom and to changes in hybridization of the carbon–oxygen bond. Based on analogy with hydrocarbons (34), as the internal bond angle decreases, the carbon–carbon bonds acquire more *p* character while the carbon–oxygen bonds assume more *s* character. An increase in *s* character of a single bond holding an isotope is predicted to produce a decrease in nmr isotope shift (2, 15), and cyclobutanol does indeed show the smallest shift of the cyclic alcohols.[7] Conformational effects probably contribute to the irregular variation observed in this series.

In contrast to carbonyl compounds, alcohols show considerable solvent influence on ^{18}O isotope shift magnitude. Hydroxylic solvents such as D_2O, methanol-d_4, or *tert*-butanol-d_{10} frequently (but not always) broaden the signals for the ^{18}O-labeled and unlabeled species to a single peak encompassing the whole region. So far this phenomenon has not appeared with labeled tertiary alcohols, suggesting that the existence of multiple hydrogen-bonded forms in solution may be responsible for the effect. The magnitude of the shift decreases in the order: tertiary alcohols $\geq$ secondary alcohols $\geq$ primary alcohols $\geq$ phenols. Although the only phenols examined have been the hydroxyl groups of averufin (Fig. 1), we expect further work will show this order to be generally valid. It is interesting to note that as the number of alkyl groups on the carbon bearing the hydroxyl increases, the hardness of the oxygen as a base increases and the ionization potential decreases (36). Currently it is not possible to separate the through-bond electronic influences from steric bulk effects on isotope shift.

The present work establishes that the ^{18}O isotope shift is generally observable in high field (100.6 MHz) ^{13}C nmr, and that its magnitude depends on structure. These shifts on the carbons attached to oxygen in ketones and aldehydes range from approximately 0.05 ppm to 0.03 ppm, whereas those of alcohols span about 0.03 ppm to 0.01 ppm. Donation of negative charge to the labeled carbonyl oxygen or conjugation to an aromatic ring decreases the size of the effect. Saturated alcohols exhibit a substantial trend for an increasing isotope shift as the substitution at the carbinol carbon increases. Although the solvent has little influence on shift magnitude in ^{18}O carbonyls, this is not true for alcohols, presumably because of hydrogen bonding. In our preliminary communication (8) we also detected shifts at carbons β to the site of isotopic substitution in two esters, but those ketones and alcohols which were examined showed at best slight broadening due to the presence of both ^{18}O and ^{16}O species. Possibly spectrometers operating at even higher field may be able to resolve these signals.

[7]The geometry of cyclobutanol has been studied by microwave spectroscopy (35).

1,2-Diphenyl-3,5-dimethyl-4-oxo-6,7-diazabicyclo[3.2.0]hept-2-ene, a nitrogen unsubstituted diazetidine with an unusually unreactive nitrogen

DEANE D. MCINTYRE, DONALD MACKAY, AND LICHIN L. WONG[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received December 28, 1979

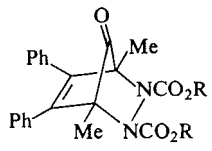
DEANE D. MCINTYRE, DONALD MACKAY, and LICHIN L. WONG. Can. J. Chem. **58**, 1316 (1980).

In the title ring system, the benzylic nitrogen (N_7), whether substituted or not, is abnormally unreactive. Hydrolysis of the di-urethanes **3***a* or *b* occurs readily at N_6 to give **10***a* or *b*, but not at all at N_7. In **3***d* Pd—H_2 removes very rapidly the benzyloxycarbonyl group at N_6 but only very slowly the one at N_7. The product **7** is the first example of a diazetidine unsubstituted on nitrogen which has been fully characterized.

N_6 in **7** or in **10***a* or *b* can be readily acylated (products **24**, **13**, **14**), acyloxylated (**23***a–c*, **3***a*, **3***b*, **11**, **12**), or methylated (**25**). All efforts to induce similar reactions at N_7 in **7** or in its monosubstituted derivatives **23** or **24** failed.

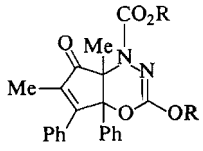
Diazetidine **7** is thermally very stable, but it is rapidly oxidized by a wide variety of reagents to 2,5-diphenyl-3,4-dimethylcyclopentadienone and nitrogen. There is no evidence for the intermediacy of the cyclic azo compound **19**, even when the oxidation is carried out at −50°C.

DEANE D. MCINTYRE, DONALD MACKAY et LICHIN L. WONG. Can. J. Chem. **58**, 1316 (1980).



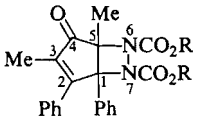
Dans le système cyclique mentionné dans le titre, l'azote benzylique (N_7) qu'il soit substitué ou non est anormalement peu réactif. L'hydrolyse des di-uréthanes **3***a* ou *b* se produit facilement au niveau de l'azote N_6 pour conduire à **10***a* ou *b*, mais pas du tout au niveau N_7. L'hydrogénation en présence de palladium du composé **3***d* enlève rapidement le groupe benzyloxycarbonyle en N_6 mais n'enlève que très lentement celui en N_7. Le produit **7** est le premier exemple d'une diazétidine non substituée sur l'azote qui soit entièrement caractérisée.

L'azote en position 6 du composé **7** ou des composés **10***a* ou *b* peut facilement subir une réaction d'acylation (produits **24**, **13**, **14**), d'acyloxylation (**23***a–c*, **3***a*, **3***b*, **11**, **12**) ou de méthylation (**25**). Tous les efforts en vue d'induire des réactions semblables sur l'azote en position 7 ou dans ses dérivés monosubstitués **23** ou **24** ont échoué. La diazétidine **7** est très stable thermiquement, mais elle est rapidement oxydée par un très grand nombre de réactifs en diphényl-2,5 diméthyl-3,4 cyclopentadiénone et en azote. Il n'y a pas de preuve de l'existence du composé azocyclique intermédiaire (**19**) même quand l'oxydation est réalisée à −50°C.



[Traduit par le journal]

We have previously shown that the cyclone 2,5-dimethyl-3,4-diphenylcyclopentadienone reacted with azo esters to give the bridged adducts **1**, which isomerized readily and reversibly to the 1,3,4-oxadiazines **2**, and more slowly but quantitatively to the 1,2-diazetidines **3** (1). The four-membered ring system is thus thermodynamically the most stable of the three isomers.



A quite different behaviour was observed when the cyclone reacted with azodiacyls. With azodibenzoyl, *p,p'*-dinitroazodibenzoyl (1), or azodiacetyl only the oxadiazines **5***a–c* were isolated, the yields being quantitative. If the reaction was monitored by ^{1}Hmr spectroscopy at 35°C, a slow process due to the low concentration of the cyclone monomer, the methyl singlets of the intermediates **4** were detectable to a maximum concentration of about 13% in the case of **4***a* in carbon tetrachloride, and 10% in the case of **4***b* in benzene. The oxadiazines were thermally very stable, **5***a* being unaffected when heated up to 170°C. Above 200°C complete decomposition occurred, there being no evidence of the diazetidines.

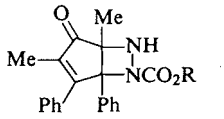
of **6** was due to a relative thermal instability of **6** (by contrast with **3**), or to the existence of too high a barrier to **6** from either of the isomers **4** or **5**.

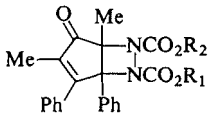
An answer to this could be provided by an independent synthesis of a diazetidine such as **6**, to which one logical precursor would be the parent diazetidine **7**.

We report here on several synthetic approaches to the diacyldiazetidine containing ring system **6**. We also describe an efficient synthesis of the cyclic hydrazine **7**, the first example of a diazetidine unsubstituted on nitrogen which has been fully characterized.

That a 1,2-diacyldiazetidine is capable of independent existence was established in a recent report of the formation of **8** from azodibenzoyl and quadricyclane (2). Its structure was inferred from its ir peak at 1680 cm^{-1} and the symmetry in its ^{1}Hmr spectrum. To check the possibility that the oxadiazine **9** might account for these spectra, with fortuitous shift equivalence of stereochemically unrelated protons, the synthesis was repeated.[2] The uv spectrum of the product with a broad shoulder centred around 275 nm rigorously excluded structure **9** in which a strong band at 290–300 nm would be required (7). The ^{13}Cmr spectrum also confirmed the equivalence of all the expected carbons in **8**.

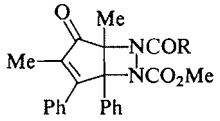


7 **8** **9**



A notable feature in the ^{1}Hmr spectra of the series of urethanes **3***a–c* was the extraordinary shielding and broadening effects observed for the protons next to the acyloxy oxygen at the benzylic nitrogen (N_7).[3,4] We have attributed this (1) to the closeness of these groups to the face of the benzene ring at C_2. In the crystal of the *p,p'*-dibromo derivative of **3***a* the methyl carbon is, at the nearest point, less than 3.5 Å above the plane of the benzene ring (8); the methyl protons must rotate within 1 Å closer, thus accounting for the shielding effect. It is also evident that the ester group is somewhat embedded in a cavity created by the two benzene rings and the other ester group. As the present work will show, the protection afforded the environment round N_7 leads to greatly diminished reactivity at it or its substituents.[5]

An example of this effect already described is the alkaline hydrolysis of **3***a* and *b* which occurred easily at N_6 to give the basic esters **10***a* and *b*, but not at all at N_7 (9). Under more vigorous conditions the diazetidine ring was destroyed, giving the cyclone (with acid quite different reactions were observed both with **3***a* (10) and with **10***a* (9)).



The NH group in **10***a* and *b* was normal in every way. Methyl chloroformate in pyridine regenerated **3***a* from **10***a*. The mixed isomeric diazetidines **11** and **12** were made by respective treatment of **10***a* and **10***b* with ethyl and methyl chloroformate. The ester methyl group in **11** and the methylene group in **12** showed the expected anomaly in the ^{1}Hmr spectrum.

10*a*, R = Me
b, R = Et
c, R = CH_2Ph

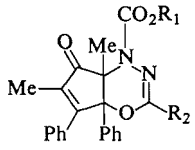
11, R_1 = Me, R_2 = Et
12, R_1 = Et, R_2 = Me

13, R = Me
14, R = Ph

Treatment of **10***a* with acetyl or benzoyl chloride gave **13** or **14**. These appeared to be potential precursors to a diacyldiazetidine like **6**, by a sequence of preferential urethane hydrolysis followed by acylation. In the event the urethane group was again the more resistant to hydrolysis, 1 *N* KOH in methanol giving an almost quantitative yield of **10***a* from **14**.

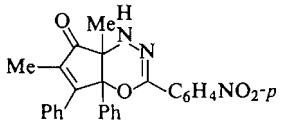
A compound like **13** or **14** is one of two possible isomeric diazetidines which could be formed in principle as thermal end products of the reaction of the cyclone with an acylazo ester. In view, how-

[2]Cases are known in which originally proposed 1,2-diacyl-1,2-diazetidine structures have been revised to 1,3,4-oxadiazines (3–5). The adduct of furan and azodibenzoyl has been assigned a diazetidine structure (6), but this is incorrect: we have shown (unpublished work) it to be an oxadiazine.



[3]In **3***a* the methyl group was shielded (ca. 0.9 ppm from the other methyl group) and slightly broadened. In each of **3***b* and *c* one of the methylene protons was normal and the other was shielded (Δδ0.9 and 2.2 ppm, respectively) and broadened.

[4]The Chemical Abstracts numbering system is used (see structure **3**). Earlier papers used a different system (1, 9). The numbering system for the 1,3,4-oxadiazines described here, **5** and **15–17**, is also amended (see structure **5**).



[5]Since the ring system is very stable these proximity effects cannot be destabilizing to the molecule. N_7 is not so much crowded as inaccessible.

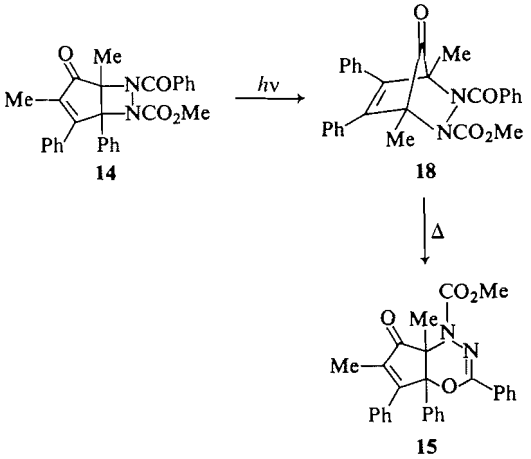
ever, of the exclusive formation of oxadiazines **5***a–c* from azodiacyls the result when the cyclone was heated with methyl benzoylazocarboxylate or ethyl *p*-nitrobenzoylazocarboxylate was entirely predictable. Only **15** or **16** was isolated, the mode of regioisomeric fusion being confirmed for the latter. Its uv absorption at 338 nm, like that of **5***c* at 335 nm, is diagnostic of the *p*-$NO_2C_6H_4\overset{|}{C}{=}N$ chromophore (7). Hydrolysis with 1*N* alkali gave the base **17** which was converted into **5***c* with *p*-nitrobenzoyl chloride in pyridine.



15, R_1 = Me, R_2 = Ph
16, R_1 = Et, R_2 = $C_6H_4NO_2$-*p*

17

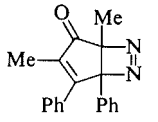
The oxadiazine **15** could also be prepared by photolysis of the diazetidine **14** in benzene at 10°C, conditions known to convert **3** into the bridged adduct **1** (1). The bridged adduct **18** was in fact observable by ^{1}Hmr spectroscopy. After 1 h the solution contained about 30% **18**, 50% **15**, and 20% starting material; after 3.5 h the yield of **15** was quantitative. At no stage was there any indication of the presence of the regioisomer of either **15** or **14**. Presumably the only processes involved are the photoisomerization of **14** to **18**, followed by the thermal isomerization of the very labile **18** to **15** (Scheme 1).

SCHEME 1

Another potential route to **7**, and thence to **6**, might be by reductive cleavage of the trichloroethyl groups in **3***c*. This technique usually employs an acidic medium (Zn dust, acetic acid) (11), and since compounds **3** were unstable to acid (10) we elected instead to make the dibenzyl ester **3***d*, on which hydrogenolysis could be carried out under neutral conditions.

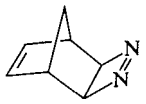
Good yields of **3***d* were obtained directly by refluxing the cyclone with dibenzyl azodicarboxylate in bromobenzene. It showed the expected ^{1}Hmr features in its methylene protons ($CDCl_3$), a normal position for the AB quartet of the N_6 ester group (5.23δ), and for the A doublet of the N_7 ester (4.99δ), but a broadened shielded X doublet (3.79δ) for the other proton.

Treatment of **3***d* with hydrogen over Pd–charcoal caused the rapid removal of the group at N_6, followed by the much slower (about 50-fold) removal of the group at N_7. The intermediate **10***c* was readily identified in the spectrum of the semihydrogenated material, by its methylene AX quartet (5.03, 3.81δ), but no effort was made to isolate it. Hydrogenolysis was complete in 16–20 h, furnishing the free 1,2-diazetidine **7**. The crude hydrazine could be purified by allowing a solution of it in ethyl acetate – hexane to evaporate slowly under nitrogen giving faintly yellow-green crystals, which decomposed between 110 and 115°C without a well defined mp. Its identity as **7** followed from its mass spectrum (M^+ = 290 and 292 for the normal and deuterated compound), its (weak) NH and single C=O absorption in the ir spectrum, the enone chromophore at 280 nm (1) and its ^{1}H and ^{13}Cmr spectra.



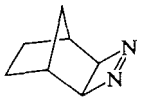
Earlier examples of 1,2-unsubstituted diazetidines have been prepared as precursors to cyclic azo compounds, and have either been oxidized without isolation (12), or isolated but not further characterized due to their instability (13). There have been passing references to 3,3,4,4-tetrafluorodiazetidine, but without any details regarding its properties (14).

Though impure **7** decomposed rather rapidly to the cyclone, purified samples kept well at room temperature. In the absence of oxidizing agents it is in fact a remarkably stable substance, having a half-life of 2.5 days in refluxing benzene, the cyclone being the only non-volatile product formed. Whether di-imide is also produced is not certain, since thermolysis in the presence of cyclohexene gave no detectable amounts of cyclohexane.

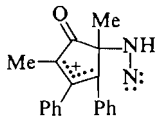


Oxidation of **7** to the cyclone occurred with great ease with a range of reagents: mercuric oxide in ether, ethereal hydrogen peroxide, and cupric chloride in buffered acid were used at room temperature. In an attempt to detect or intercept the intermediate diazetine **19** homogeneous oxidations were followed by low temperature ^{1}Hmr spectroscopy in $CDCl_3$. Benzoyl peroxide, diethyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



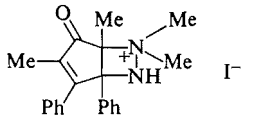
azodicarboxylate, and *p*-benzoquinone all smoothly oxidized **7**, but even at −50°C the only new peaks observed were those of the monomer and dimer of the cyclone.



19

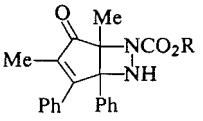
20

21



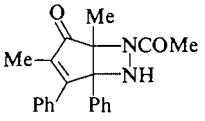
22

If oxidation does proceed through **19** its decomposition even at −50°C must be very rapid. This is in vivid contrast with the stability of the diazetines **20** and **21** whose half-lives are of the order of 10^5 and 10^6 days respectively at room temperature (12). Most of this stabilization has been attributed to the forbiddenness of the reaction (a retro 2+2 cycloaddition). Major differences here are the creation of a resonance stabilized (enone) group and the unsymmetrical nature of **7**. The latter may permit a polar, non-concerted, and low energy pathway for loss of nitrogen. For example, removal of hydride in a first oxidation step could produce the allylically stabilized nitrene **22**. In that case **19** would not be an intermediate at all.

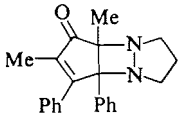


All other reactions of **7** support completely the view that it has a normal, reactive N atom and a very unreactive one.

A range of acyloxy and acyl groups could be introduced on N_6 using the appropriate chloride and pyridine. The methyl and ethyl esters **23***a* and *b* are the regioisomers of the hydrolysis products **10***a* and *b*. The benzyl ester **23***c* was prepared and hydrogenolyzed back to **7**, confirming the preservation of the diazetidine ring in the acylation reactions. The acetyl derivative **24**, along with **13** and **14**, shows that the diazetidine system is stable with at least one acyl group on nitrogen.



Even the use of an excess of methyl chloroformate in pyridine at room temperature or at 100°C failed to convert **23***a* into **3***a*. Similarly attempts to acetylate **24** to **6***a* were abortive. The reactions were monitored by ^{1}Hmr spectroscopy, with no evidence of any methyl peaks other than those due to **23***a* (an anomalous shift was of course expected for the N_7 acetyl group in **6***a*). Bases used without success were triethylamine, 1,5-diazabicyclo-[3.4.0] non-5-ene, potassium carbonate, sodium hydride, lithium di-isopropylamide, and *n*- and *tert*-butyllithium. Decomposition of the substrate occurred, especially with the inorganic bases. Phthaloyl chloride gave a complex reaction with **7**, but certainly none of the desired cyclic hydrazide derivative.



25

23*a*, R = Me
b, R = Et
c, R = CH_2Ph

24

26

Reaction of **7** with methyl iodide and potassium carbonate gave a dimethylation product, the stable quaternary iodide **25**, but no *N*,*N*′-dimethyl derivative. The use of 1,3-ditosyloxypropane led to recovery of **7**, and 1,3-dibromo and di-iodopropane caused oxidation to the cyclone; there was no evidence for the formation of compound **26**. Triethyloxonium fluoborate likewise gave the cyclone from **7**. Attempts to methylate the amide **24** with methyl iodide in the presence of either potassium carbonate or diazabicyclononene were also unsuccessful.

We have thus failed to replace the hydrogen on N_7 in any of the diazetidines **7**, **23**, or **24** with any substituent, other than deuterium in the case of **7**. In the failure specifically to replace it with an acyl group our original question of whether such a diazetidine is inherently unstable with respect to the isomeric oxadiazine is still unanswered.

Experimental

The following spectrometers were used: for ir, a Beckman IR10; for uv, a Unicam SP.800B; for ^{1}Hmr, a Varian T-60 or Perkin-Elmer R12B; for ^{13}Cmr, a Bruker WP-80; for ms, a Varian MAT CH-7. Melting points are uncorrected.

Ultraviolet and ^{13}Cmr Spectra of 3,4-Dibenzoyl-3,4-diazatricyclo[4.2.1.0^{2,5}]non-7-ene (8)

Compound **8** was prepared from quadricyclane and azodibenzoyl as described by Landis and Mitchell (2). It had: λ_{max}(EtOH) sh 275 nm (−NCOPh) (ε 6000); δ(^{13}C)($CDCl_3$): 40.6, 45.2 (C_1,C_6 or C_2,C_5), 67.1 (C_9), 128.5, 128.9, 132.2, 132.6 (Ph), 136.0 (C_7,C_8), 178.8 (C=O) ppm.

cis-*1-Acetyl-3,6,7a-trimethyl-4a,5-diphenyl-7-oxo-1,4a,7,7a-tetrahydrocyclopent[e][1,3,4]-oxadiazine (5a)*

The cyclone (1.30 g, 5 mmol) was refluxed for 12 h in a freshly prepared solution of azodiacetyl (7) (5.7 mmol) in tetrachloro-

For personal use only.

ethylene (20 mL). The solvent was evaporated and the residue crystallized on addition of pentane. Filtration gave **5***a* (94%) which was twice crystallized from cyclohexane as prisms, mp 168–169°C; ν(CCl_4): 1736 (keto C=O), 1690 (amide C=O), 1677 (C=N) cm^{-1}; λ_{max}(EtOH): 242 (ε 15 600) (MeC=N), 283 (ε 12 600) (β-enone) nm; δ(CCl_4–$CDCl_3$): 7.5–6.9 (10H, Ph, m), 2.13 (6H, COMe and C_3—Me, fortuitous s), 1.77 (3H, C_6—Me, s), 0.97 (3H, C_{7a}—Me, s) ppm. *Anal.* calcd. for $C_{23}H_{22}N_2O_3$: C 73.78, H 5.92, N 7.48; found: C 73.55, H 5.90, N 7.69.

The reaction was also monitored by ^{1}Hmr spectroscopy in carbon tetrachloride at 35°C. After 90 h the methyl singlet due to the intermediate **4***a* accounted for about 13% of the total methyl absorption. Compound **4***a* had δ 2.22 (6H, OMe, s), 2.01 (6H, C—Me, s) ppm.

Samples of **5***a* (30 mg) were heated for 4 h in an evacuated sealed tube (*a*) *at 170°C*: the slightly discolored product was completely unreacted **5***a*; (*b*) *at 210°C*: the ^{1}Hmr spectrum of the black tarry product showed that profound degradation had occurred.

1,2-Diphenyl-3,5-dimethyl-6-ethoxycarbonyl-7-methoxycarbonyl-4-oxo-6,7-diazabicyclo[3.2.0]hept-2-ene (11)

The basic ester **10***a* (100 mg, 0.29 mmol) was kept at room temperature for 3 days in pyridine (1 mL) containing ethyl chloroformate (50 mg, 0.46 mmol). The solution was blown to dryness, and water was added giving the colorless diester (87 mg, 71%) (see Table 1 for further details).

6-Methoxycarbonyl-7-ethoxycarbonyl Compound 12 (Isomer of 11)

The basic ester **10***b* (157 mg, 0.43 mmol) and methyl chloroformate (200 mg, 2.1 mmol) in pyridine (1.5 mL) reacted to the extent of about 50% after 3 days at room temperature (work-up as for **11**). The half reacted material was treated with fresh chloroformate (2 mmol) in pyridine (2 mL) and left for 7 more days. Work-up gave the diester (148 mg, 80%) (Table 1).

1,2-Diphenyl-3,5-dimethyl-6-acyl-7-methoxycarbonyl-4-oxo-6,7-diazabicyclo[3.2.0]hept-2-ene (Table 1)

The 6-Acetyl Compound 13

Acetic anhydride (95 μL, 0.95 mmol) and **10***a* (9) (300 mg, 0.86 mmol) were refluxed for 1 h in pyridine (3 mL). Evaporation and addition of water gave crystalline **13** (294 mg, 88%).

The 6-Benzoyl Compound 14

A solution of benzoyl chloride (50 mg, 0.36 mmol) and **10***a* (116 mg, 0.33 mmol) in pyridine (2.5 mL) was kept at room temperature for 2 days. It was then worked up as for **13** giving a 90% yield of **14**.

Hydrolysis of 14

A solution of **14** (200 mg, 0.39 mmol) was dissolved in 1*N* potassium hydroxide in methanol (10 mL), kept for 12 h, and extracted with an ether–water mixture. The ether layer was washed repeatedly with water, to remove the methanol, and then dried and evaporated to give nearly pure **10***a*.

cis-*1-Methoxycarbonyl-3-phenyl-6,7a-dimethyl-7-oxo-1,4a,7,7a-tetrahydrocyclopent[e][1,3,4]-oxadiazine (15)*

(a) From Methyl Benzoylazocarboxylate

1-Methoxycarbonyl-2-benzoylhydrazine, mp 139–142°C, was synthesized from methyl chloroformate and benzhydrazide in pyridine, and was crystallized from dilute methanol. The hydrazine (1.0 g, 5.2 mmol), *N*-bromosuccinimide (0.93 g, 5.2 mmol), and pyridine (0.41 g, 5.2 mmol) were allowed to react in chloroform (10 mL). The clear orange solution which was immediately formed was allowed to stand for 15 min and was then shaken out thoroughly with water and dried. It was then evaporated in a stream of dry nitrogen to give the orange oily azo compound (0.86 g, 87%): δ($CDCl_3$): 8.1–7.8 (2H, *o*-Ph, m), 7.8–7.3 (3H, *m* + *p*-Ph, m), 4.08 (3H, OMe, s) ppm.

The azo compound (0.84 g, 4.4 mmol) and the cyclone (1.0 g, 3.9 mmol) were refluxed in benzene (100 mL) for 12 h. The almost colorless solution was evaporated to a residue which crystallized on addition of hexane containing a small amount of ether. The precipitate (1.7 g, 98%) had the ^{1}Hmr spectrum of analytically pure **15**, obtained by recrystallization as prisms, mp 150.5–152°C, from methanol; ν(CCl_4): 1745 (ester C=O), 1717 (keto C=O), 1656 (C=N) cm^{-1}; δ($CDCl_3$): 8.2–7.0 (15H, Ph, m, including 2 sharp s at 7.40 and 7.18), 3.87 (3H, OMe, s), 2.17 (3H, C_6—Me, s) 1.20 (3H, C_{7a}—Me, s) ppm. *Anal.* calcd for C_6—Me, s), 1.20 (3H, C_{7a}—Me, s) ppm. *Anal.* calcd. for $C_{28}H_{24}N_2O_4$: C 74.32, H 5.35, N 6.19; found: C 74.26, H 5.40, N 6.18.

(b) From Diazetidine 14

A solution of **14** (0.45 g, 1.0 mmol) in dry benzene (150 mL) was irradiated at 10°C through Pyrex with a 125-W Hanovia uv immersion lamp. Work-up of a portion after 1 h showed the presence of the intermediate **18**, as well as unreacted **14** and the final product **15**. The proportions of these as determined by ^{1}Hmr spectroscopy were **14**:**18**:**15** = 20:30:50%; after 2.5 h they were 10:30:60%. The reaction was complete in 3.5 h (compound **18** had Me absorptions at δ(CCl_4): 3.26 (3H, OMe, s), 1.87, 1.68 (each 3H, C—Me, s) ppm). Evaporation gave a crystalline residue of **15** in essentially quantitative yield. Recrystallization gave material identical with the product from (*a*).

cis-*1-Ethoxycarbonyl-3-*p*-nitrophenyl-6,7a-dimethyl-7-oxo-1,4a,7,7a-tetrahydrocyclopent[e][1,3,4]-oxadiazine (16)*

1-Ethoxycarbonyl-2-*p*-nitrobenzoylhydrazine, mp 196–196.5°C (lit. (15) mp 185–187°C), was converted into its mercuric salt (7). The salt (12 g, 26 mmol) in carbon tetrachloride (100 mL) was stirred while bromine (4.2 g, 26 mmol) was added. After 0.5 h, the whole was filtered and evaporated to give the azo compound (6.2 g, 95%) as an orange oil; δ(CCl_4): 8.42, 8.27, 8.13, 7.98 (4H, $NO_2C_6H_4$, q), 4.52 (2H, —OCH_2, q, J = 7 Hz), 1.49 (3H, CH_3, t) ppm.

A solution of the cyclone (1.48 g, 5.7 mmol) and the azo compound (1.43 mmol, 5.7 mmol) was refluxed in benzene (30 mL) for 3 h and evaporated. Addition of hexane caused formation of a pale yellow solid (2.48 g, 85%) which was crystallized from ethanol as pale yellow needles, mp 228.5–230°C; ν(CCl_4): 1746 (ester C=O), 1718 sh (keto C=O), 1646 (C=N) cm^{-1}; λ_{max}(EtOH): 287 (enone) (ε 21 000), 338 (*p*-$NO_2C_6H_4$C=N) (ε 10 000) nm; δ($CDCl_3$): 8.2–7.1 (14H, arom., m), 4.36 (2H, —OCH_2, q, J = 7 Hz), 2.17 (3H, C_6—Me, s), 1.40 (3H, ester Me, t), 1.23 (3H, C_{7a}—Me, s) ppm. *Anal.* calcd. for $C_{29}H_{25}N_3O_6$: C 68.09, H 4.93, N 8.21; found: C 68.43, H 5.07, N 8.14.

*Conversion of Oxadiazine 16 into Oxadiazine 5*c

A solution of **16** (256 mg, 0.50 mmol) in 1*N* potassium hydroxide in aqueous methanol (1:1, 60 mL) was kept for 1 day at room temperature, and then made just neutral to litmus. Extraction with methylene chloride gave a yellow solution which on evaporation afforded the base **17** (79 mg, 36%) as a yellow solid, used in the next step without further purification; ν(Nujol): 3270 (NH), 1700 (C=O) cm^{-1}; δ($CDCl_3$): 8.2–6.9 (14H, arom., m), 5.62 (1H, N—H, b), 2.13 (3H, C_6—Me, s), 0.96 (3H, C_{7a}—Me, s) ppm.

The base **16** (110 mg, 0.25 mmol) and *p*-nitrobenzoyl chloride (62 mg, 0.33 mmol) were allowed to react in pyridine (1.5 mL) at room temperature for 1 week. The solvent was evaporated and the residue crystallized by adding water. Recrystallization from benzene–pentane gave **5***c*, identical by mp and mixed mp with authentic **5***c* (1).

*1,2-Diphenyl-3,5-dimethyl-6,7-dibenzyloxycarbonyl-4-oxo-6,7-diazabicyclo[3.2.0]hept-2-ene (3*d)

We thank the Lucidol Division of Pennwalt Chemical Co., Buffalo, NY, for a generous gift of dibenzyl azodicarboxylate. It was recrystallized from ether – petroleum ether (bp 30–60°C) before use.

The azo compound (6.0 g, 20 mmol) and the cyclone 5.2 g (20 mmol) were refluxed together in bromobenzene (100 mL) for 16 h. The residue left on evaporation crystallized on addition of ether–isooctane. The crystals were washed with cold methanol and recrystallized from chloroform–methanol as colorless prisms (50%) (Table 1).

1,2-Diphenyl-3,5-dimethyl-4-oxo-6,7-diazabicyclo-[3.2.0]hept-2-ene (7)

A solution of **3***d* (2.0 g, 3.6 mmol) in ethyl acetate (30 mL) containing 5% Pd on charcoal (200 mg) was treated with hydrogen at room temperature for 16 h. Filtration and evaporation gave a light green oil which slowly crystallized on addition of hexane. The solid (0.75 g, 72%) was crystallized by allowing a solution of it in ethyl acetate – hexane to evaporate under nitrogen. The yellow-green prisms decomposed with melting between 110 and 115°C; $\nu(CCl_4)$: 3272 (NH), 1710 (C=O) cm^{-1}; λ_{max}(EtOH): 280 nm (enone) (13 400); *m/e* 290 (M^+), 260 (M—N_2H_2) (deuterated **7** had: *m/e* 292 (M^+)); $\delta(^1H)$ ($CDCl_3$): 7.4–6.8 (10H, Ph, m), 4.18 (2H, NH, b), 2.15 (3H, C_3—Me, s), 1.07 (3H, C_5—Me, s) ppm; $\delta(^{13}C)(CDCl_3)$: 206.8 (C_4), 137.5–126.5 (C_2, C_3, and Ph), 79.7 (C_1), 69.5 (C_5), 16.2 (C_3—Me), 10.8 (C_5—Me) ppm. *Anal.* calcd. for $C_{19}H_{18}N_2O$: C 78.59, H 6.25, N 9.65; found: C 78.84, H 6.57, N 9.45.

In the above hydrogenation, consumption of the first equivalent of hydrogen was rapid (ca. 20 min). In one run the reaction was interrupted at this stage and worked up as above. The residue consisted mainly of **10***c* (>80%) which was not further purified; $\delta(CDCl_3)$: 7.5–6.9 (15H, Ph, m), 5.03 (1H, A portion of CH_2 AX, d, J = 13 Hz), 3.81 (1H, X portion of CH_2 AX, broadened d) ppm.

Thermal Reactions of 7

(a) Half-life Measurement

A solution of **7** (60 mg, 0.4 *M*) in benzene was heated in refluxing benzene and its ^{1}Hmr spectrum periodically monitored. Decomposition to the cyclone, the only detectable product, was 50% complete in 2.5 days.

(b) Attempt to Detect Di-imide

A solution of **7** (60 mg) was refluxed in cyclohexene (1 mL) for one day by which time decomposition to cyclone was complete. Gas–liquid chromatographic analysis (6 ft × 1/8 in. column, 10% XE-60) failed to detect any cyclohexane in the cyclohexene.

Oxidation of 7

(a) Room Temperature

After completion of the reaction with the chosen oxidizing agent, in general using 60 mg (0.21 mmol) in 10 mL of solvent, the organic solution was filtered, if necessary, and then evaporated to dryness. The residue was examined by ^{1}Hmr spectroscopy and found to consist only of cyclone in each case. (*i*) Mercuric oxide (1 g) in ether. (*ii*) Ethereal hydrogen peroxide obtained by shaking the ether several times with 50% aq. hydrogen peroxide. (*iii*) Cupric chloride (50%) in a sodium acetate – acetic acid buffer at pH 5, and ether.

(b) Low Temperature ^{1}Hmr Experiments

In each case 60 mg of **7** and an equivalent of oxidizing agent were dissolved in $CDCl_3$ (0.5 mL) cooled down to at least −50°C. The solution was transferred rapidly to the chilled nmr tube which was immediately placed in the probe, previously cooled to the lowest temperature to be studied in the run. The temperature was raised as needed to a level at which reaction occurred at a convenient rate. In each case **7** gave only the monomer and dimer of the cyclone (at higher temperatures only the dimer). Any other new peaks were attributable to the reduced form of the oxidizing agent except in the case of (*iii*) when small amounts of the adduct of the cyclone and the quinone were detectable. (*i*) Benzoyl peroxide, −10°C. (*ii*) Diethyl azodicarboxylate, −50°C. Diethyl hydrazodicarboxylate was isolated at the end of the run. (*iii*) *p*-Benzoquinone, −10°C. The formation of the Diels–Alder adduct of the quinone and cyclone was confirmed by synthesis of a reference sample.

1,2-Diphenyl-3,5-dimethyl-6-acyl or acyloxy-4-oxo-6,7-diazabicyclo[3.2.0]hept-2-ene (Table 1)

*The 6-Methoxycarbonyl-, 6-Ethoxycarbonyl-, 6-Benzyloxycarbonyl Compounds (**23**a, **23**b, **23**c), and the 6-Acetyl Compound (**24**)*

To a solution of **7** (0.50 g, 1.72 mmol) in dry ether (40 mL) containing pyridine (2 mL) was added 5 equivalent of the appropriate acyl chloride. The whole was stirred for 30 min, the ether was evaporated, and water was added to the semi-solid residue to induce crystallization. The products were recrystallized from aqueous methanol and then from ether–hexane: **23***a*, 60%; **23***b*, 50%; **23***c*, 60%; **24**, 70%.

The use of 1 equivalent of acyl chloride led to rather slow formation of the above products.

*Hydrogenolysis of **23**c*

A solution of **23***c* (100 mg, 0.24 mmol) in ethyl acetate (10 mL) containing 5% Pd on charcoal (20 mg) was stirred with hydrogen for 1 h. Filtration and evaporation gave the diazetidine **7**.

Attempted Phthaloylation of 7

Phthaloyl chloride (42 mg, 0.21 mmol) and **7** (60 mg, 0.21 mmol) were kept in pyridine (1 mL) for 12 h. Evaporation, addition of water, and ether extraction led to an ether soluble fraction whose ^{1}Hmr spectrum was extremely complex.

*Attempted Acylation of **23**a and **24** with Pyridine as Base*

A solution of **23***a* (39 mg, 0.11 mmol) and methyl chloroformate (26 mg, 2.8 mmol) in pyridine (0.4 mL) was heated at 100°C in an nmr tube. There was no change in the spectrum over a period of 12 h. Work-up gave pure unreacted **23***a*.

Compound **24** was similarly treated with acetyl chloride, again without any change.

*Attempted Acetylation of **24** with Other Bases*

In general **24** (100 mg, 0.30 mmol), dissolved in a suitable solvent (5 mL), was treated with 1.2 equivalent of the base and then 1 equivalent of acetyl chloride. Work-up consisted of addition of ether and water, aqueous extraction, and evaporation of the ethereal solution. In all cases the ^{1}Hmr spectrum of the residues was very complex. (*i*) Sodium hydride, ether. (*ii*) Lithium di-isopropylamide, benzene. (*iii*) *n*-Butyllithium, benzene. (*iv*) *tert*-Butyllithium, benzene. All these reaction mixtures darkened badly within 0.5 h, except for reaction (*ii*). (*v*) Triethylamine, neat. (*vi*) 1,5-Diazabicyclo[3.4.0]non-5-ene, benzene. (*vii*) Potassium carbonate (2 g), methylene chloride. These reaction mixtures were stirred for 12 h.

N,N-*Dimethyldiazetidinium Iodide **25***

A solution of **7** (430 mg, 1.48 mmol) in methyl iodide (5 mL) was stirred with potassium carbonate (2 g) under nitrogen for 3 h, and ether (10 mL) was added. The heavy potassium salts settled to the bottom leaving a milky suspension of the organic iodide which was carefully decanted and filtered. The precipitate was washed with ether (460 mg, 70%). Compound **25** was a colorless solid, decomposing >160°C, freely soluble in water

and sparingly in $CDCl_3$; ν(Nujol): 3350 (NH), 1703 (C=O) cm^{-1}; λ_{max}(EtOH): 300 nm (enone) (8200); *m/e*: 319 ($C_{21}H_{23}N_2O^+$), 127 (I^+); δ($CDCl_3$): 7.5–7.2 (10H, Ph, broad s), 3.73 (3H, $\overset{+}{N}$—Me, s), 3.55 (3H, $\overset{+}{N}$—Me, s), 2.30 (3H, C_3—Me, s), 1.37 (3H, C_6—Me, s) ppm. *Anal.* calcd. for $C_{21}H_{23}IN_2O$: I 28.43; found: I 28.33.

Attempted Alkylations

(a) On 7

In each case **7** (60 mg, 0.21 mmol) was treated with the alkylating agent (1 equivalent) in a suitable solvent under nitrogen, and after 12 h the solution was filtered, if necessary, and evaporated.

(*i*) 1,3-Propaneditosylate, potassium carbonate (1 g), in methylene chloride: **7** was recovered there being no evidence of the formation of **26**. (*ii*) 1,3-Dibromopropane, potassium carbonate (1 g), in benzene, reflux: cyclone was formed; 1,2-diiodopropane, neat, behaved similarly. (*iii*) Triethyloxonium fluoborate, in methylene chloride: cyclone was formed.

(b) On 24

The *N*-acetyl compound (60 mg, 0.18 mmol) in methyl iodide (2 mL) was stirred under nitrogen for 12 h with potassium carbonate (1 g). Filtration and evaporation gave unreacted **24**. The same result was obtained when diazabicyclononene was used as base.

The reaction of potassium iodide in polyhydrogen fluoride – pyridine with two cage diols. A simple synthesis of tetracyclo[6.3.0.0^{4,11}.0^{5,9}]undeca-2,6-diene ("homohypostrophene")

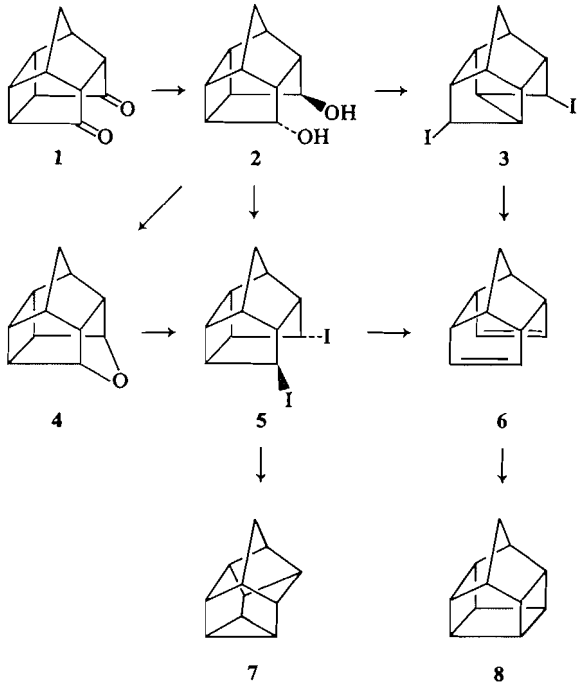
DAO CONG DONG AND JOHN T. EDWARD

Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal, P.Q., Canada H3A 2K6

Received January 14, 1980

DAO CONG DONG and JOHN T. EDWARD. Can. J. Chem. **58**, 1324 (1980).

The diol **2** was converted by treatment with potassium iodide in polyhydrogen fluoride – pyridine into a mixture of the diiodide **5** and homohypostrophene **6**. The diol **10** under the same conditions gave the ether **14**. Treatment of the mixture of **5** and **6** with sodium in boiling tetrahydrofuran gave an easily-separable mixture of **6** and **7**.



DAO CONG DONG et JOHN T. EDWARD. Can. J. Chem. **58**, 1324 (1980).

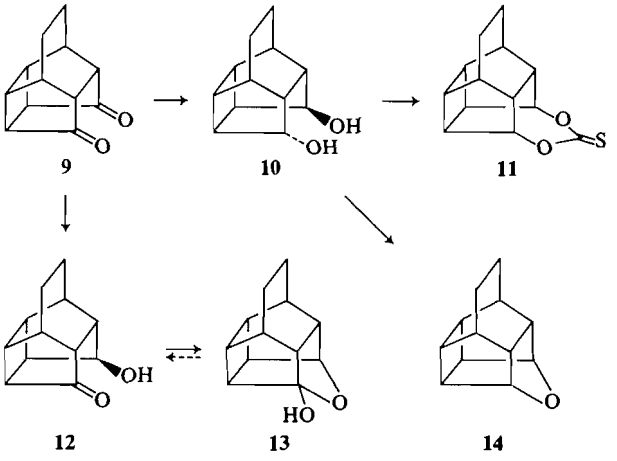
Le diol **2** traité par l'iodure de potassium dans une combinaison de polyfluorure d'hydrogène – pyridine est transformé en un mélange de diiodure **5** et d'homohypostrophène **6**. Le diol **10** dans les mêmes conditions donne l'éther **14**. Le mélange de **5** et **6** traité par le sodium dans le tétrahydrofuranne à l'ébullition fournit un mélange de **6** et de **7** que l'on peut facilement séparér.

[Traduit par le journal]

Introduction

Recently three groups (1–3) simultaneously described routes from the diketone **1** (4) to homohypostrophene **6** whence homopentaprismane **8** may be prepared by photocyclization (2, 3). Perhaps the simplest of these routes was the three-step procedure (Scheme 1: **1** → **2** → **3** → **6**) of Smith and Barborak (1). We now describe a variant of this procedure even simpler in practice. As before (1), the diketone was reduced to the *endo,endo*-diol **2** (1, 5). The latter was treated with potassium iodide in polyhydrogen fluoride – pyridine, a reagent recently developed by Olah and Welch (6), and the reaction was monitored by ^{1}H nmr. The diol **2** disappeared from the reaction mixture within 7 hours, and three products appeared: first the ether **4** ("oxabirdcage" (5, 7)) formed rapidly and then disappeared (20% after 2 h, 7% after 7 h, 0% after 24 h); then more slowly, the diiodide **5** and homohypostrophene **6**. After 24 h the mixture of **5** and **6** was isolated and, without separation, treated with sodium in boiling tetrahydrofuran, a reagent known to convert **5** to a mixture of **6** and **7** (2). In the event, final overall yields of 55% of **6** and 31% of **7** were obtained. These two products were easily separable by chromatography on silica impregnated with silver nitrate.

SCHEME 1



The attempt to obtain bishomohypostrophene from the homologous diketone **9** (4, 8, 9) by a similar series of reactions failed. Lithium aluminum hydride reduction of **9** gave a diol (10, 11) for which Dekker *et al.* (10) have established the *endo,endo* configuration (10) by reaction with thionyl chloride to form a cyclic sulfite; we have confirmed this by formation of the cyclic thiocarbonate **11**. Reaction of the diol **10** with potassium iodide in polyhydrogen fluoride – pyridine at room temperature gave the ether **14** as the only product, even after prolonged standing. Recently Nakazaki *et al.* (11) converted **10** into **14** by treatment with sulfuric acid in acetic acid at 120°C for 42 h. Evidently polyhydrogen fluoride – pyridine may prove advantageous in the conversion of some diols into ethers under mild conditions.

Dekker *et al.* (10) obtained **13** by treatment of **9** with sodium borohydride, or by formation of the monoethylene ketal of **9**, borohydride reduction,

SCHEME 2

and acid hydrolysis, a sequence which obviously involved the hydroxy ketone **12** as an intermediate. We have confirmed these results, obtaining **13** by reduction of **9** with one equivalent or with a large excess of borohydride. The equilibrium **12** ⇄ **13** evidently lies far to the right (no C=O bond in ir spectrum). By contrast, Cookson *et al.* (4) found that treatment of **1** with one mol (4 equivalents) of sodium borohydride gave a mixture of mono- and di-reduction products, and that the former existed mainly as uncyclized hydroxy ketone (C=O in ir). Treatment of **1** with a large excess of borohydride gave a mixture of isomeric diols. These and other results (4, 10) indicate a considerably greater propensity for the formation of an ether bridge in the polycyclic compounds related to **9** than in their lower homologues related to **1**, a result in keeping with simple considerations based on ring strain (4, 12).

Experimental

Melting points were taken in capillary tubes using a Gallenkamp apparatus and are uncorrected. The nmr spectra were recorded on a Varian T-60A spectrometer in $CDCl_3$ containing tetramethylsilane (TMS) as internal standard. Infrared spectra were recorded in KBr pellets on a Perkin-Elmer 297 spectrophotometer. Mass spectra were recorded at 70 eV on a LKB 9000 or a Hewlett-Packard mass spectrometer. Elemental analyses were performed by Dr. C. Daessle of Montreal and Galbraith Laboratories, Inc., Knoxville, TN, U.S.A. Tetrahydrofuran was dried by refluxing over lithium aluminum hydride, followed by distillation.

Hexacyclo[5.4.0.0^{3,6}.0^{4,11}.0^{5,9}.0^{8,10}]undecane (7) and Tetracyclo[6.3.0.0^{4,11}.0^{5,9}]undeca-2,6-diene (6)

Diol **2** (4.0 g, 22.5 mmol) was added to a magnetically stirred solution of polyhydrogen fluoride – pyridine (75 g) containing potassium iodide (20.0 g, 120 mmol) in a polyethylene bottle. The reaction mixture was stirred for 24 h, quenched by pouring on to ice-water (200 g), and extracted with ether (3 × 100 mL). The ether layer was washed with aqueous sodium thiosulfate, dried (Na_2SO_4), and passed quickly through a short column of neutral alumina (30 g). Solvent was removed and the oily residue (8.5 g) was found by nmr to be a mixture of diolefin **6** (from singlet at δ 5.90; olefinic protons (2)) and diodide **5** (from AB pattern at δ 1.37, 1.78; methylene protons (1, 2)).

The oily mixture, dissolved in dry THF (30 mL) was added dropwise to a stirred suspension of sodium (4.0 g) in dry THF (40 mL) under nitrogen. The reaction mixture was then refluxed for 1.5 h, filtered, and the filtrate poured into ice-water. The aqueous layer was extracted with pentane, and the combined extracts were dried (Na_2SO_4). Careful removal of solvent gave 3.44 g of a colorless oil shown by nmr to be made up of **6** and **7** in the ratio 2:1. The mixture was separated by chromatography on 30% $AgNO_3$ – silica gel. Elution with pentane gave 1.0 g (31% from diol **2**) of hexacyclo[5.4.0.0^{3,6}.0^{4,11}.0^{5,9}.0^{8,10}]undecane **7**, mp 127–129°C (lit. (2) mp 132–134°C; nmr ($CDCl_3$) δ:1.42 (d, $J \simeq$ 1 Hz, 2H), 1.6–2.4 (complex m, 4H), 1.6–3.1 (complex m, 6H); mass spectrum *m/e*: 144(34) (molecular ion), 129(29), 116(12), 115(15), 80(22), 79(100), 78(55), 77(33), 66(51), 40(25). Elution with 20% Et_2O – pentane gave 1.8 g (55% from diol **2**) of **6**, mp 145–146°C (sublimed) lit. (1) mp 143–145°C, (ref. 2) mp 141.5–142.5°C, (ref. 3) mp 139–140°C, (ref. 7) mp 143.5–144.5°C); nmr ($CDCl_3$) δ:5.90 (s, $w_{\frac{1}{2}} \simeq$ 3 Hz, 4H, olefinic H), 3.20 (m, 2H, bridge head H), 2.37 (broad s, $w_{\frac{1}{2}} \simeq$ 5 Hz, 4H, 1, 4, 5, and 8 methine protons), 1.70 (broad s, $w_{\frac{1}{2}} \simeq$ 3 Hz, methylene protons); mass spectrum *m/e*:144(34) (molecular ion), 129(24), 128(16), 115(14), 91(4), 79(100), 78(30), 77(42).

When diol **2** was treated with polyhydrogen fluoride – pyridine containing potassium iodide for only 7 h under the conditions described above, and the reaction product then submitted to reduction by sodium in THF, the ether **4** (7%; characterized by ir, nmr, and mass spectrum) was isolated in addition to **6** and **7**.

Pentacyclo[6.4.0.0^{2,7}.0^{3,11}.0^{6,10}]dodecane-9,12-diol (10)

To a solution of **9** (11.52 g, 0.06 mol) in dry THF (350 mL) was added dropwise a suspension of lithium aluminum hydride (6.1 g, 0.16 mol) in dry THF (200 mL). The mixture was refluxed for 30 h. Dilute HCl (6%) was added to the cooled reaction mixture and an inorganic solid was filtered off. The organic layer was separated from the aqueous layer and the latter extracted with chloroform (6 × 100 mL). The extracts and organic layer were combined, dried (Na_2SO_4), and concentrated to afford **10** as a colorless solid (8.0 g, 70%) mp 149–153°C. Recrystallization from ethyl acetate raised the mp to 170–172°C (lit. (11) mp 168–170°C); nmr ($CDCl_3$) δ:5.45 (s, 2H, OH), 3.70 (br s, $w_{\frac{1}{2}} \simeq$ 6 hz, H9–H12), 2.4–3.0 (m, 6H), 1.3–1.9 (m, 6H); ir (KBr):3140 (br), 1510 (br), 1255 (s), 1150 (s), 1090 (s), 1063 (m) cm^{-1}; mass spectrum *m/e*: 192(4) (molecular ion), 174(68), 156(12), 146(58), 145(40), 118(31), 107(27), 104(40), 95(32), 91(100), 80(94), 79(81), 77(52). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 75.11, H 8.56.

Pentacyclo[6.4.0.0^{2,7}.0^{3,11}.0^{6,10}]dodecane-9,12-thiocarbonate (11)

A solution of **10** (0.96 g, 5 mmol) and *N,N'*-thiocarbonyldiimidazole (1.00 g, 5 mmol) in dry toluene (40 mL) was refluxed with stirring under nitrogen for 1.5 h. The solvent was removed *in vacuo* and the residue was taken up in chloroform (150 mL). The resulting solution was washed successively with 5% HCl, water, saturated $NaHCO_3$ solution, and water. The organic layer was dried (Na_2SO_4) and concentrated *in vacuo*. A colorless solid was removed by filtration (1.00 g, 90%), mp 320–322°C; nmr ($CDCl_3$) δ:4.30 (broad s, $w_{\frac{1}{2}} \simeq$ 12 Hz, 2H, H9–H12), 3.27 (broad s, $w_{\frac{1}{2}} \simeq$ 18 Hz, 2H), 2.93 (broad s, $w_{\frac{1}{2}} \simeq$ 7 Hz, 2H), 2.70 (poorly resolved m, 2H), 1.60 (m, 6H); ir (KBr):2955 (m), 2915 (m), 2860 (m), 1425 (s), 1310 (s), 1250 (s), 1000 (s) cm^{-1}; mass spectrum *m/e*:234(m, 100), 174(24), 146(21),

130(15), 117(41), 118(20), 115(26), 79(91), 78(41), 77(44). *Anal.* calcd. for $C_{13}H_{14}O_2S$: C 66.63, H 6.02, S 13.68; found: C 66.91, H 6.11, S 13.69.

Reaction of Diol 10 with Potassium Iodide in Polyhydrogen Fluoride – Pyridine

Diol **10** (1.0 g, 5.3 mmol) was added to a stirred solution of polyhydrogen fluoride – pyridine (20 g) containing potassium iodide (7.5 g, 11.5 mmol) in a polyethylene bottle. The reaction mixture was stirred at room temperature for 24 h, quenched by pouring onto ice-water (100 g), and extracted with ether (3 × 50 mL). The ether extract was washed with aqueous sodium thiosulfate, dried (Na_2SO_4), and poured quickly through a short column of neutral alumina. The solvent was removed and the residue (0.90 g) was sublimed (100°C/8 Torr) to give 4-oxahexacyclo[5.4.2.$0^{2,6}$.$0^{3,10}$.$0^{5,9}$.$0^{8,11}$]tridecane **14** as a colorless solid (0.70 g, 76%), mp 178–179°C (lit. (11) mp 182–184°C); nmr ($CDCl_3$) δ:4.77 (m, 2H), 2.68 (m, 2H), 2.43 (m, 2H), 2.23 (m, 2H), 1.70 (m, 2H), 1.50 (broad s, 4H); ir (KBr):2950 (m), 2940 (m), 2860 (m), 1465 (w), 1335 (m), 1507 (m), 1255 (m), 1033 (s), 962 (s), 855 (s) cm^{-1}; mass spectrum *m/e*: 174(100) (molecular ion), 173(11), 146(34), 130(19), 131(23), 117(5), 104(34), 91(64), 79(78), 78(63), 77(40), 65(19). *Anal.* calcd. for $C_{12}H_{14}O$: C 82.72, H 8.10; found: C 82.55, H 8.28.

4-Oxahexacyclo[5.4.2.$0^{2,6}$.$0^{3,10}$.$0^{5,9}$.$0^{8,11}$]tridecane-3-ol (13)

Sodium borohydride (0.76 g, 20 mmol) was added to a stirred solution of the diketone **9** (1.88 g, 10 mmol) in 95% EtOH (20 mL). The solution was stirred at room temperature for 10 h, then water (15 mL) was added and the solution refluxed gently for 10 min on a steam bath. Thirty-five milliliters of water was added and the solution extracted with chloroform (4 × 50 mL). The combined organic extracts were dried (Na_2SO_4) and concentrated *in vacuo* to give the alcohol **13** as a colorless solid (1.46 g, 77%) mp 181–183°C. Sublimation at 130°C (8 Torr) gave material with mp 191–192°C; nmr ($CDCl_3$) δ:4.65 (t, $J \simeq$ 5 Hz, 1H, —CHO—), 4.45 (br band 1H, O*H*), 1.50 (br s, $w_{\frac{1}{2}} \simeq$ 5 Hz, 4H, methylene protons), 1.6–3.0 (complex m, 8H, methine protons); ir (KBr):3220 (broad s), 2915 (s), 2900 (s), 2865 (m), 1350 (2), 1325 (s), 1153 (s), 1120 (s), 1010 (s), 906 (s) cm^{-1}; mass spectrum *m/e*:190(22) (molecular ion), 172(8), 145(81), 144(19), 131(24), 130(24), 129(27), 118(46), 117(72), 107(23), 105(47), 99(29), 92(100), 91(99.8), 77(40.) *Anal.* calcd. for $C_{12}H_{14}O_2$: C 75.76, H 7.42; found: C 75.54, H 7.62.

With one equivalent of $NaBH_4$, the same reaction gave **13** in 80% yield.

Electrophilic cleavage of cyclopropanes. III. The reaction of molecular bromine with tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane[1,2]

DENNIS G. GARRATT[3]

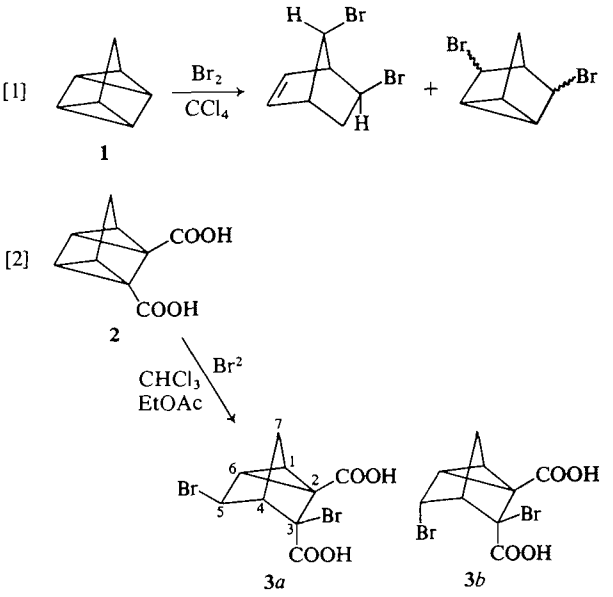
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received October 19, 1979

DENNIS G. GARRATT. Can. J. Chem. **58**, 1327 (1980).

The ionic addition of molecular bromine to tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclene) has been investigated in a variety of solvent systems. Depending upon the nature of the solvent, three or more of six dibromo and five solvent-incorporated adducts are isolable. A mechanism involving a series of ion-pairs and competitive edge-on vs. corner (end-on) attack is proposed.

DENNIS G. GARRATT. Can. J. Chem. **58**, 1327 (1980).



On a étudié l'addition ionique du brome moléculaire sur le tétracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane (quadricyclène) dans plusieurs systèmes de solvants. Dépendant de la nature du solvant, on a pu isoler un minimum de 3 de 6 adduits dibromés et de 5 adduits incorporant le solvant. On propose un mécanisme impliquant une série de paires d'ions et des attaques compétitives par le côté ou par le sommet (end-on).

The reaction of tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane, **1**, with bromine in carbon tetrachloride solution has been reported by Dauben and Cargill (1) to yield a mixture of 3,5-dibromotricyclo[2.2.1.0^{2,6}]-heptanes and *exo*-2-*syn*-7-dibromobicyclo[2.2.1]-hept-5-ene. The relative proportions were, however, not reported not were data of unambiguous mechanistic utility forthcoming. A related study involving the bromination of tetracyclo-[3.2.0.0^{2,7}.0^{2,6}]heptane-1,5-dicarboxylic acid, **2**, has been reported (2) to give a nortricyclic dibromide, **3**, of indeterminate configuration at C5. Cristol and co-workers (3) subsequently provided evidence that in the absence of carbonium ion-like intermediates, nucleophilic attack during the second step of the reaction occurs with inversion of configuration at carbon. These data would then support the assignment of configuration at C5 in terms of an *exo* bromine atom, **3***a* (2, 4).

The results, while indicative of apparently stereospecific inversion of configuration at carbon during both electrophilic cleavage and subsequent nucleophilic attack, contrast with other reports (5) of more varied stereochemical pathways. For example, Skell and co-workers (6) have reported the ionic bromination of dehydroadamantane, **4**, in the presence of isoamyl nitrite to give a 59:41 mixture of the isomeric 2,6-dibromoadamantanes, **5** and **6**. They argued that since all aspects of ionic brominations of cyclopropanes point to formation

of a 1-bromo-3-carbonium ion, it is reasonable to attribute to the second step, the reaction with bromide ion, the proportioning between axial and equatorial approach.

An alternative rationalization of their data, however, would be a competitive attack by bromine, both from the edge and the corner, followed by stereospecific attack by bromide ion with inversion of configuration at carbon.

In their detailed mechanism, Skell and co-workers propose the ionic reaction of bromine with alkylcyclopropanes to occur at the least substituted position, with inversion, to produce a bromocarbonium ion – bromide ion-pair which undergoes

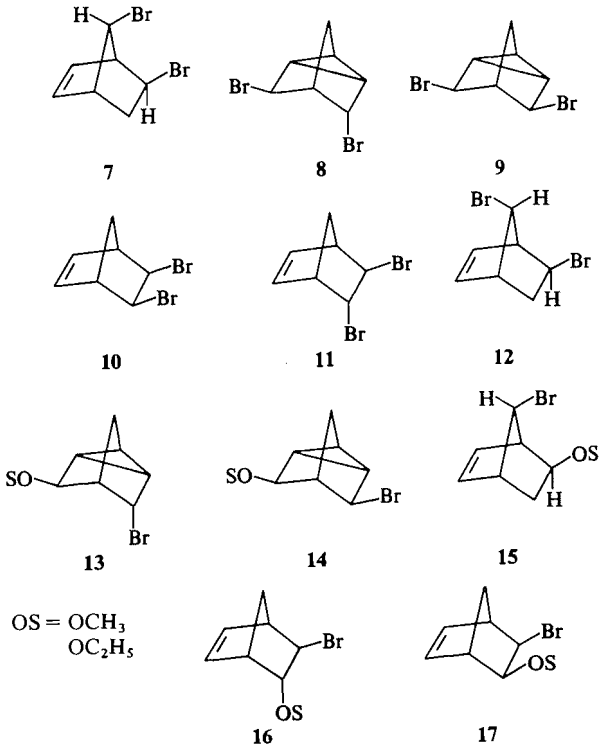
extensive sequential rearrangements, uncharacteristic of solvolysis-type intermediates (i.e. intimate or solvent-separated ion-pairs), but characteristic of the nonrelaxed or free carbonium ion-anion pairs (6). The question remains, however, as to how general this scheme is. For example, the known propensity for C5—C6 (C1—C7) bond cleavage in **1**, and the relatively good neighbouring group ability of bromine, suggests a driving force for edge-on attack and thus retention of configuration at carbon instead of inversion during the first step.



Our interest in the stereochemistries of arene-selenenylations and arenesulphenylations of cyclopropanes, in particular the tetracyclo-[3.2.0.0.^{2,7}.0^{4,6}]heptane system led us to re-examine the initial work of Dauben and Cargill and to extend the mechanistic probe to include an investigation of the effect of solvent upon the product determining step. In analogy with earlier work on alkenes and alkynes (7), the effect of protic solvents on the product composition and stereochemistry is anticipated to give important data with respect to the number and types of intermediates involved.

Results and Discussion

The reaction of equimolar quantities of bromine and **1** in methylene chloride solution at ambient temperature, 23–25°C, in the presence or absence of isoamyl nitrite, but in the dark, results in an essentially quantitative yield of crude dibromides, **7–9**. The reaction is exothermic and appears to occur essentially instantaneously, the red-brown coloration of bromine disappearing immediately to give a clear colorless solution. Characterization of the crude dibromides (isolated via evaporation of the solvent under nitrogen) by means of ^{1}H and ^{13}C nmr analysis confirms the initial assignments of Dauben and Cargill. It may be noted that these previous assignments were made in accord with the observations of Winstein and co-workers (8), which were based on the analogous bromination of bicyclo[2.2.1]hepta-2,5-diene.

One olefinic product is observed when the solvent is methylene chloride or carbon tetrachloride (see Table 1). This species is identified as *exo*-2-*syn*-7-dibromobicyclo[2.2.1]hept-5-ene, **7**, on the basis of its ^{13}C nmr spectrum and by comparison with an authentic sample prepared by the analogous bromination of bicyclo[2.2.1]hepta-2,5-diene in accord with the procedure of Winstein and co-workers (8).

The remaining two species, **8** and **9**, isolable from these solvents are isomeric nortricyclenes. Compound **8** exhibits seven aliphatic carbon resonances

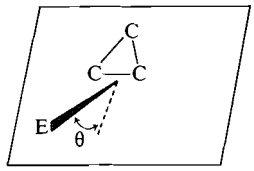
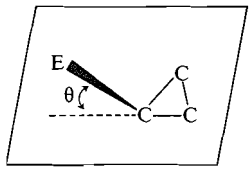
in its ^{13}C nmr spectrum, three of which resonate at higher field than that normally observed for norbornyl carbons and are thus readily assigned as the cyclopropyl carbon resonances. The absence of symmetry allows one to immediately assign **8** as *exo,endo*-3,5-dibromotricyclo[2.2.1.0^{2,6}]heptane. In contrast to **8**, compound **9** exhibits only five aliphatic resonances and therefore has a plane of symmetry which passes through C1, C4, and C7. Assignment of **9** as *exo,exo*-3,5-dibromotricyclo-[2.2.1.0^{2,6}]heptane follows from a comparison of this species' spectral properties, ^{1}H, ^{13}C nmr, and ir, with those of an authentic sample prepared from bicyclo[2.2.1]hepta-2,5-diene. The symmetric dibromide prepared in this way has been shown elsewhere (8), by means of dipole moment studies, to be di-*exo*.



An examination of the ^{13}C nmr resonances at this point (see Experimental) leads to a rather surprising observation. If one considers the relative chemical shifts of C7 in **8** and **9**, one would expect C7 in **9** to resonate at higher field than the analogous methylene carbon in **8** because of the double γ *gauche* effect of two *exo* bromines in the case of **9** vs. only one *exo* bromine in **8** (9, 10, 11). We observe, however, C7 resonances at δ 30.1 and 33.2 for **8** and **9** respectively, the opposite of our initial expectations! A reexamination of our data for the analogous 3-arylthio, 5-chloro and 3-phenylseleno, 5-chloro nortricyclenes (12, 13, 14) also shows this trend. While a rationalization for this apparent reversal in the normal γ *gauche* effect is not immediately obvious, we note that some care must be exercised in making assignments in this ring system.

If cyclohexane is used as solvent, two further dibromo adducts, **10** and **11**, are observed. Both **10** and **11** are norbornenyl derivatives as is demonstrated by olefinic protons in the ^{1}H nmr spectra and olefinic carbon resonances at δ 137.4 and 137.2, 135.2, respectively. Compound **10** has only four resonances in its ^{13}C nmr spectrum and is thus assigned on the basis of its symmetry as *exo,exo*-2,3-dibromobicyclo[2.2.1]hept-5-ene. The presence of seven resonances in the analogous spectrum of **11** defines it as *exo,endo*-2,3-dibromobicyclo[2.2.1]hept-5-ene.



The use of hydroxylic solvents, such as methanol and ethanol, leads to products of solvent-incorporation, **13–15**, in addition to the normal dibromides, **7–9**. In both of these solvents, products of solvent-incorporation are found to predominate by a factor of 8 or 9 to 1 for a bromine concentration of 0.01–0.06 mol dm^{-3}.

In order to acquire further data with respect to the effect of changing the polarity and nucleophilicity of the solvent system, we carried out a number of reactions in mixtures of methanol and methylene chloride. As can be seen from an examination of Table 1, the percentage of dibromo adducts relative to the percentage of solvent-incorporated adducts decreases as one progresses from neat methylene chloride to neat methanol, as would be expected. Of particular interest, however, is the product distribution obtained in 0.5:99.5 methanol – methylene chloride. Under these reaction conditions the molar concentration of methanol was equivalent to that of molecular bromine. Our results indicate that, on a competitive basis, bromide ion is a more effective nucleophile

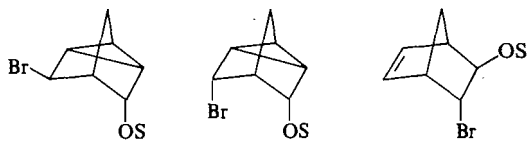
than methanol by a factor of at least 13 to 1. Also of note is the observation of a further, previously unknown, dibromo adduct **12**. On the basis of its ^{13}C nmr spectrum and its mass spectrum which exhibits a retro-Diels–Alder fragmentation to yield a C_5H_5Br cation-radical, we are able to assign the configuration as *exo,anti*-2,7-dibromobicyclo-[2.2.1]hept-5-ene.



In order to elaborate on the importance of these observations, we note that conceptually there exist two distinct modes whereupon a strained carbon–carbon single bond might interact with an electrophile, EN. For example, the electrophile and the strained bond may approach each other orthogonally, i.e. edge-on attack. In the case of cyclopropane itself, one would anticipate the maximum interaction of orbitals to occur when the electrophile approaches the front lobe of the single bond in the same plane as the three carbons which define the ring, as is shown in Scheme 1 for $\theta = 0°$. In the case of a substituted cyclopropane, as is found in substrate **1**, the best angle of approach with respect to this plane may be significantly different, although values of θ as large as 90° seem very unlikely if one accepts the Walsh model for the orbitals in cyclopropanes. The major point to be noted is that this type of interaction leads to *retention* of configuration at the carbon atom, wherein the new bond is formed with the electrophilic portion of the reagent (E of EN).

Alternatively, the electrophile may approach the corner of the strained bond along an extended axis joining the two carbon atoms, that is to say, collinearly or end-on, the interaction between the rear lobe of the bond undergoing cleavage and the electrophile ultimately resulting in inversion of configuration at the carbon atom forming the new bond with E. Once again we note that in the case of an unsymmetrically substituted cyclopropane as in **1**, the preferred orbital interaction may lead to an angle of approach which is different from the idealized situation of collinearity.

This classical approach may be unnecessarily restrictive as initial attack may in fact involve an *edge which does not finally suffer cleavage*, with subsequent cleavage occurring after edge-to-corner isomerization (15). Such a scenario, however, exchanges one problem for another, that is, how does one distinguish whether or not attack occurs on a bond which *is not* subsequently cleaved or in some other way altered?

Such a classical approach is not without controversy. One referee, for example, has pointed out that LCAO SCF MO calculations of the electrostatic potential energy experienced by a unit positive charge as it interacts with the electrons and nuclei of cyclopropane (16) establish clearly, at least to his satisfaction, that an electrophile attacks a three-membered ring in an edge-wise fashion. It was further pointed out that this is not surprising because the electron density is concentrated in that region and that steric hindrance to approach of the electrophile towards corner attack must exist. In direct contrast are the results and interpretations of Skell and co-workers (6), who, as we have previously noted, prefer the alternate scenario of stereospecific corner attack.

It is our contention that the classical two-competitive-pathways approach best explains the data given in Table 1. Thus, species **12** and **13** are the result of edge-on attack, while **7**, **9**, **10**, and **14–17** result from corner attack. Compounds **8** and **11** are assigned as the products of edge-on and corner attack, respectively, in accord with the assignments of the solvent-incorporated species, **13** and **16**. In this respect we note the absence of such species as **18–20**.

18 **19** **20**

Considering the observed product distributions in Table 1, we observe a number of trends. For example, the ratio of edge-on attack to corner attack (ratio A) shows a smooth variation from neat methylene chloride, 50:50, to neat methanol, 54:46, passing through a minimum for the 5:95 methanol – methylene chloride solvent system. The overall effect of changing the polarity of the solvent system

either by using mixed solvents or neat solvents appears, however, to be minimal as judged by ratio A. This point is further demonstrated by comparing the relative nucleophilicities, N_{rel}, of bromide ion to methanol (column 16, Table 1) as the solvent polarity is varied. Although the values of N_{rel} vary from 13- to 25-fold preferences in favour of bromide ion over that of methanol, an error of 3 or 4% in the product distributions, which is quite reasonable for the nmr and glc techniques used, would be sufficient to average out these differences. To show this effect we have calculated the possible error in N_{rel} based upon an error of ±4% in the ratio B. These values are shown in Fig. 1. The mean values of N_{rel}, based upon these high–lows, are given in Table 1, column 16, in parentheses. The average of these values is 20.2 in very good agreement with the value of 19.5 calculated on the basis of our primary N_{rel} values. We therefore conclude that solvent polarity has little effect upon the relative nucleophilicities of bromide ion and methanol for attack on the intermediate species during the bromination of tetracyclo[3.2.0.$0^{2,7}$.$0^{4,6}$]heptane.

The relatively high percentage of nortricyclenes compared to olefinic products, in all solvent systems, presumably reflects the ability of bromide ion, and the alcohols, to effectively trap the first formed cationic intermediates before rearrangement is possible. These intermediates are in all likelihood intimate ion-pairs, **21** and **22**, or solvent-separated ion-pairs, **23** and **24**, as are shown in Scheme 2. The absence of *endo* methoxy and ethoxy nortricyclenes lends support to this scenario, in accord with Cristol *et al.*'s criteria (3). This observation also serves to rule out a stereochemical interpretation such as Skell's, at least in so far as solvent-incorporated products are concerned, unless one is willing to propose that the active electrophile is CH_3O^+, which seems very unlikely under our reaction conditions. Furthermore, it would appear even less likely that **8** is formed according to Skell's hypothesis when **18** is not observed or isolated.

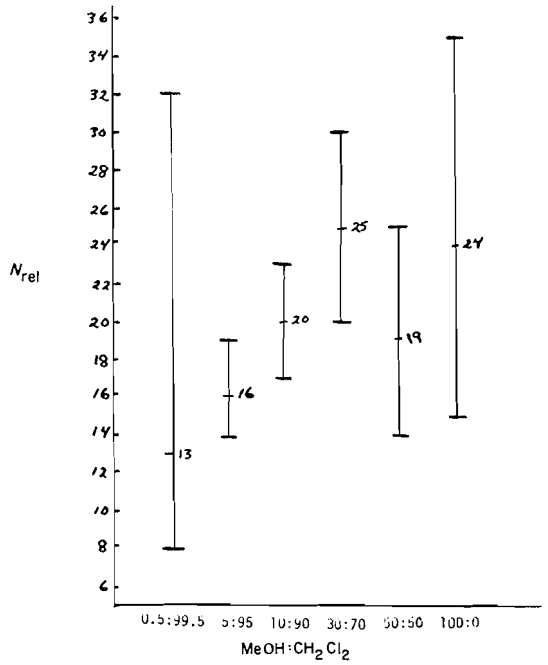

FIG. 1. Plot of N_{rel} as a function of mixed solvent ratio assuming an error of ±4% in the measurement of ratio B.

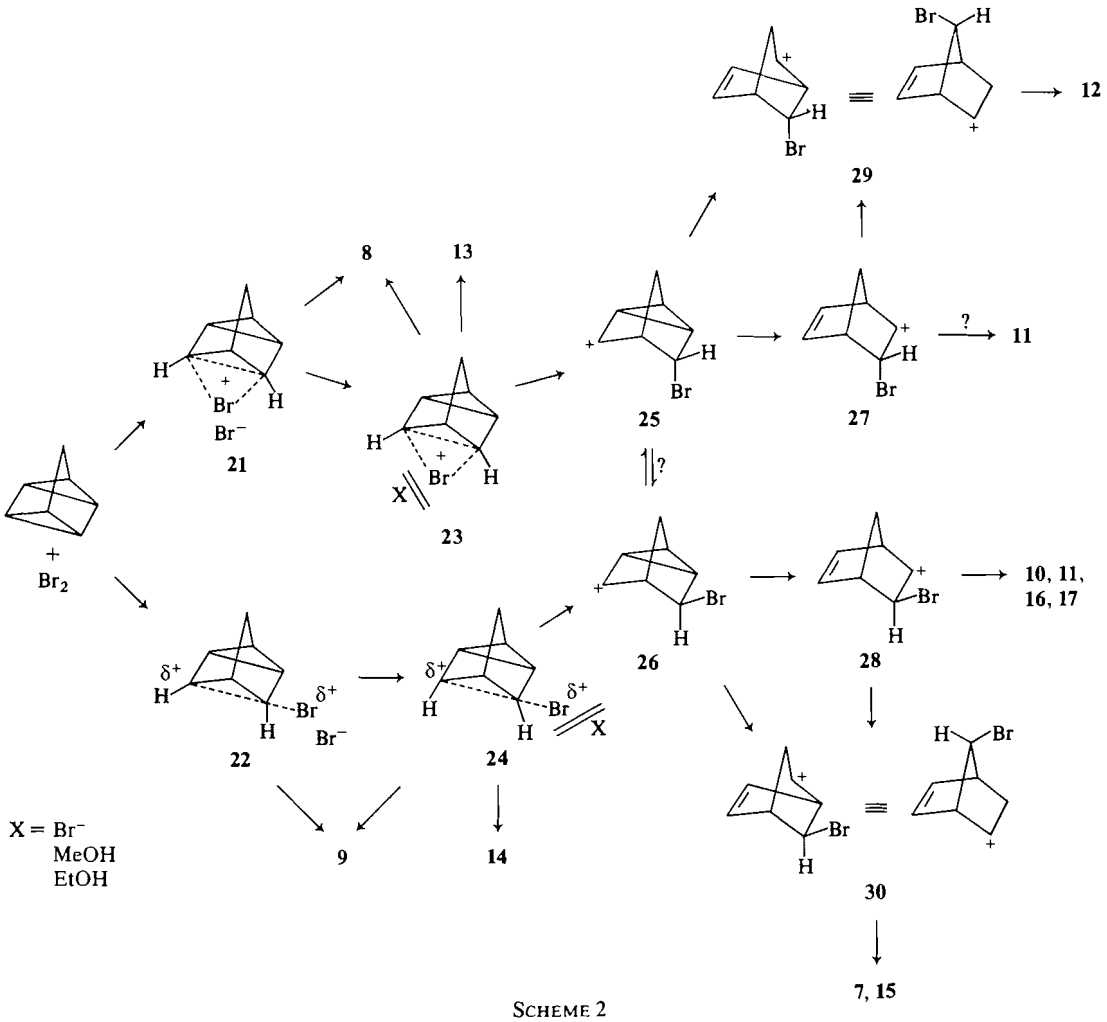
The further dissociation of ion-pairs **21–24** to free carbonium ions **25** and **26** is presumably followed by a fast isomerization to the isomeric unsaturated ions **27–30**. Species **28** appears to have a long enough life-time in some solvent systems to collapse to products **10**, **11**, **16**, and **17** while ion **27**, when it exists, seems to immediately undergo Wagner–Meerwein rearrangement to ion **29**.

The exact nature of the ionic species and their relationship to each other on the reaction hypersurface is not yet unambiguous. For example, it is conceivable that **25** and **26** might interconvert by a 6,2-hydrogen shift. If such an isomerization occurs the true origin of compounds **7**, **10–12**, and **15–17** must be considered in doubt. We stress however that the absence of adducts **18** and **19** rules out **25** and **26** as long-lived intermediates. This latter interpretation rests very strongly on the validity of Cristol's hypothesis (see ref. 3). If Cristol's hypothesis is true, our data require a mechanism involving both corner and edge-wise attack. A mechanism based upon only edge-wise attack may be ruled out!



The interpretation suggested above, while quite different from that of Skell and co-workers, may only reflect the perhaps anomalous behaviour of this very novel and reactive ring system. We acknowledge that the mechanism of Skell and coworkers accounts very well for a plethora of data. In view of the results presented above we suggest, however, that their stereochemical interpretation may be incorrect.

Experimental

General

The ^{1}H nmr spectra were recorded on Varian Associates T-60 and HA-100 spectrometers. The ^{13}C nmr spectra were recorded on a Varian FT-80-16K spectrometer with a broad band probe, operating at 20 000 MHz, using chloroform-*d* as an internal lock and reference. All spectra were run in sealed tubes. Infrared spectra were run in NaCl cavity cells as $CHCl_3$ solutions, using a Unicam 1100 spectrometer. All analytical and preparative tlc separations were performed on Analtech precoated plates.

SCHEME 2

Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]heptane, **1**, was available commercially from Aldrich. It was used without further purification. The purity of **1** was established by nmr and glc (SE-30 column).

Caution: Scrupulous avoidance of contact with the materials prepared during this investigation is essential! *At least two deaths of laboratory workers in Winstein's laboratory have been attributed to these compounds.* All samples were handled in this laboratory under conditions of continuous isolation, using a glove box equipped with a filter system suitable for use with carcinogenic and radioactive material!

The Reaction of Bromine with Tetracyclo[3.2.0.0^{2,7}.0^{4,6}]-heptane

A solution of bromine (1–3 mmol) in 20–30 mL of the appropriate solvent is added dropwise to a stirred solution containing a molar equivalent of **1** in 30–50 mL of the same solvent. The solvent is removed at room temperature by rotary evaporation (a temperature of 45°C was used with both MeOH and EtOH), and the crude yellow oils stored under nitrogen. These oils which corresponded to an essentially quantitative yield were analyzed by nmr and mass spectroscopy. Chromatographic separation of the various isomers was accomplished on silica gel. Product distributions could *not* be determined from these isolated yields, however, because of isomerization problems on the plates. The glc yields (SE-30) were, however, in agreement, ±2–3%, with the values calculated from both ^{1}H and ^{13}C nmr spectra. Because of the toxicity factors and handling difficulties associated with these compounds no attempt was made to obtain physical properties such as melting points, or elemental analysis.

Spectroscopic Properties

Values of ^{13}C nmr ($CDCl_3$) δ: *exo*-2-*syn*-7-dibromobicyclo-[2.2.1]hept-5-ene: 48.7 (d, C1), 54.1 (d, C2), 29.1 (t, C3), 44.0 (d, C4), 135.8 (d, C5), 137.8 (d, C6), 56.4 (d, C7). *Exo*-2-*anti*-7-dibromobicyclo[2.2.1]hept-5-ene: 51.4 (d, C1), 56.0 (d, C2), 33.0 (t, C3), 44.4 (d, C4), 133.0 (d, C5), 134.5 (d, C6), 59.2 (d, C7). *Exo,exo*-2,3-dibromobicyclo[2.2.1]hept-5-ene: 44.5 (d, C1, C4), 52.4 (d, C2, C3), 137.4 (d, C5, C6), 30.2 (t, C7). *Exo,endo*-2,3-dibromobicyclo[2.2.1]hept-5-ene: 44.5 (d, C1), 52.8 (d, C2(C3)), 52.6 (d, C3(C2)), 45.6 (d, C4), 135.2 (d, C5), 137.2 (d, C6), 30.2 (t, C7). *Exo,exo*-3,5-dibromotricyclo[2.2.1.0^{2,6}]-heptane: 13.5 (d, C1), 22.3 (d, C2, C6), 51.0 (d, C3, C5), 43.9 (d, C4), 33.2 (t, C7). *Exo,endo*-3,5-dibromotricyclo[2.2.1.0^{2,6}]-heptane: 15.5 (d, C1), 19.4 (d, C2), 53.7 (d, C3), 43.9 (d, C4), 54.3 (d, C5), 22.1 (d, C6), 30.1 (t, C7). *Exo*-2-methoxy-*syn*-7-bromobicyclo[2.2.1]hept-5-ene: 46.9 (d, C1), 82.2 (d, C2), 29.4 (t, C3), 43.9 (d, C4), 134.6 (d, C5), 139.0 (d, C6), 56.7 (d, C7), 56.8 (q,

A tunable pulsed Raman spectrometer capable of probing picosecond processes[1]

D. NICOLLIN, P. BERTELS, AND J. A. KONINGSTEIN
Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received January 16, 1980

D. NICOLLIN, P. BERTELS, and J. A. KONINGSTEIN. Can. J. Chem. **58**, 1334 (1980).

A pulsed tunable laser Raman spectrometer is described. The relevant characteristics are: tunability in the range of 355–755 nm, peak power of > 100 kW, pulse duration 3.2 ns, spectral line width < 0.1 cm^{-1}. Raman pulses can be studied in real time with a resolution > 10 ns while Raman spectra can be recorded with an experimental slit width > 0.5 cm^{-1}. The overall performance of the instrument may be compared to that of a conventional cw laser Raman spectrometer having typical power levels of 100 mW. Spectroscopic measurements are discussed which demonstrate the capability of the apparatus to probe Raman processes which occur at the pico and microsecond time scale.

D. NICOLLIN, P. BERTELS et J. A. KONINGSTEIN. Can. J. Chem. **58**, 1334 (1980).

On décrit un spectromètre Raman au laser à impulsions que l'on peut ajuster. Les principales caractéristiques sont: la synthonisation dans l'intervalle de 355–755 nm, une puissance maximale > 100 kW, durée d'impulsion de 3.2 ns, la largeur de la ligne spectrale > 0.1 cm^{-1}. Les impulsions Raman peuvent être étudiées en temps réel avec une résolution > 10 ns tandis que les spectres Raman peuvent être enregistrés avec une largeur de pente > 0.5 cm^{-1}. La performance totale de l'instrument peut être comparée à celle d'un spectromètre Raman conventionnel au laser o.c. ayant un niveau typique de puissance de 100 mW. On discute des mesures spectroscopiques qui démontrent la capacité de l'appareil d'explorer les effets Raman qui se produisent dans des intervalles de temps de l'ordre de la pico et de la microseconde.

[Traduit par le journal]

I. Introduction

For all practical purposes it appears that pulsed laser Raman spectroscopy is apt to have a great impact in the study of short-lived intermediates, properties of electronic excited states including their lifetime (1–3). In order to explore these properties one has to make use of the frequency tunability of the pulsed laser radiation, its very high peak power combined with short duration, and narrow spectra line width. However, the above properties can only be fully evaluated if the scattered light can be monitored with a system having a detection capability including real time resolution, high spectral resolution, high sensitivity, and low noise. Although several reports have appeared in the literature dealing with pulsed Raman spectrometers, none of the systems described therein met all the above required characteristics simultaneously (4–7). In the present work we described a Raman spectrometer in which level of operation combines high performance in all mentioned characteristics. The organization of this paper is as follows. In section II the instrument is described in full detail and in section III a short discussion is presented of some relevant results unique to pulsed light scattering spectroscopy as obtained with the instrument.

II. Description of the Experimental Set-up

In this section the various components of the tunable pulsed laser Raman spectrometer are described.

A. The Laser Light Source and Optical Arrangement

The unit used in the present set-up (see Fig. 1) is composed of a N_2 laser which pumps a dye laser. The N_2 laser, model M2000 from Lambda Physik, generates light pulses having ~1 mW peak power with a duration of 4 ns and a variable repetition rate up to 50 Hz. This laser is used to pump a Lambda Physik FL 2000 dye laser which includes one amplifier stage. Relevant characteristics of the laser system are a high conversion efficiency (~10%) for dyes which produce stimulated emission in the spectral range of 355–755 nm. This can be extended to 217 nm with frequency doubling, with a spectral band width of ~1 cm^{-1} and this value can be reduced to a factor 10 by installing an etalon in the laser cavity while maintaining ~80% of the energy. Associated with the laser peak is a broad band emission spectrum due to superradiance of the dye laser oscillator stage, which is usually of such high intensity that it prevents the recording of weak Raman spectra. In order to overcome the effect of superradiance, a tunable grating filter (PTR optics model F 100 with variable slits) was placed between the sample and dye laser. This filter reduces the effective laser light level to an approximate average power level of 2.5 mW with the laser operating at a 25 pulses/s repetition rate (0.1 mJ/pulse). We found however that for certain samples, like transparent liquids or properly polished transparent single

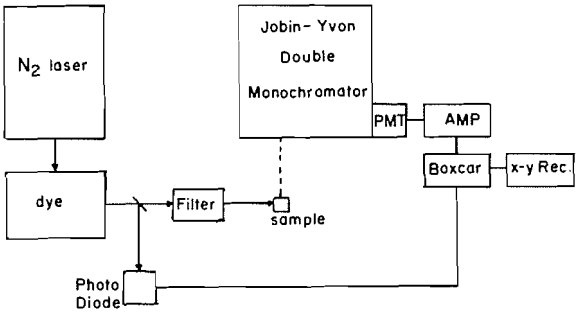

FIG. 1. Schematics of the pulsed laser Raman spectrometer. The tunable dye laser is built following a modular concept, that is, oscillator, amplifier cells, and dye reservoir are interchangeable. Not shown is the optical system for the collection of the scattered light.

crystals, spectra could be recorded some 10 nm away from the peaking frequency of the superradiance emission without the use of the filter. This is specially true if the laser emission occurred away from the center frequency of the superradiance band and towards longer wavelength.

The light from the laser was focussed into the sample. This caused some problems in that without the tunable grating filter in place and in employing a spherical lens with $f < 25$ cm the quartz cells containing liquid samples were damaged and cracks developed in even such hard crystals like rare earth garnets or ruby, causing a larger increase in the scattered light level. Damage to the sample was, however, eliminated if the spherical lens was used in combination with the filter or the lens itself replaced with a cylindrical one. This would, at the same time, prevent the possible occurrence of non linear effects (8). It is thus important to measure from time to time the light level of the laser pulses and this was achieved by using a GEN-TEC ED 100 Joule meter, or a GCO holographic radiometer to determine the average power of the pulses (the two instruments were in agreement to within 10%). Neutral density screens of pure nickel were employed in combination with the GCO radiometer to prevent saturation of the probe. Glass neutral density filters are of no use because they are immediately damaged by the powerful laser pulses. In our experiments the scattered light pulses were dispersed with a Jobin Yvon double monochromator equipped with curved holographic gratings. The stray light rejection rate of this instrument amounts to 10^{-14} if measured at 20 cm^{-1} away from a Rayleigh line and spectra were recorded in the 90° geometry.

B. The Detection System

It has previously been remarked that the recording of nanosecond signals requires constant advances in the state of the art (9, 10). In our system where the nanosecond signals are due to Raman scattering rather than fluorescence or phosphorescence processes, use was made of the following components: (*i*) a cooled photomultiplier, (*ii*) suitable amplification stages for the signals emerging from the photomultiplier, and (*iii*) a boxcar integrator. Among those the photomultiplier tube is by far the corner stone of the system. This tube should have a rise time faster than that of the signal pulses in order not to distort them. Also, the photocathode should have a high sensitivity in the spectral range of interest and in addition the PMT should also have a high gain. Several considerations made us choose the RCA C31034 photomultiplier tube. The small size of its cathode, rather broad spectral response, fast rise time (2.3 ns at 2000 V), high gain ($\sim 10^7$ at 2000 V), reasonable price, and availability made this tube a prime candidate for pulsed work. The popular and commonly used ITT FW 130 PM tube in cw experiments cannot be used in the present experimental arrangements (11) because of its slow rise time while other phototubes having a less than 1 ns rise time are considerably more expensive.

In Fig. 2 we display the time response behaviour of the RCA C31034 PMT due to a single photoelectron leaving the cathode. We note that the pulse shape of the signal due to the event has a fwhm of 3.2 ns which happens, in a fortuitous way, to be equal to the width of the light pulses coming from the dye laser system (these pulses are, according to the manufacturer, 20% shorter than the 4 ns pulses of the N_2 laser). There is a great deal of information available in the literature regarding the detection of fluorescence spectra excited with pulsed lasers (12–16). They and Raman signals from strongly scattering systems like CCl_4 etc. can be detected directly by feeding the signal of the PMT in a boxcar integrator. For example, we obtained a full scale output signal of the boxcar, without amplification of the Raman signal pulses, for the 996 cm^{-1} band of benzene excited by radiation of 0.3 mJ/pulse ($\lambda = 457.9$ nm) at 20 μm spectrometer slit widths (spectral slit width 0.5 cm^{-1}). However, in order to detect weaker Raman signals it is necessary to amplify first the anode pulses and then feed them into a boxcar integrator.

The amplification of the weak Raman signals was achieved by cascading fast pulsed amplifiers (LeCroy W 101 A). Two stages were incorporated in the system which resulted in an overall gain of 100, a total rise time of ~ 1 ns, and a noise output of 5 mV

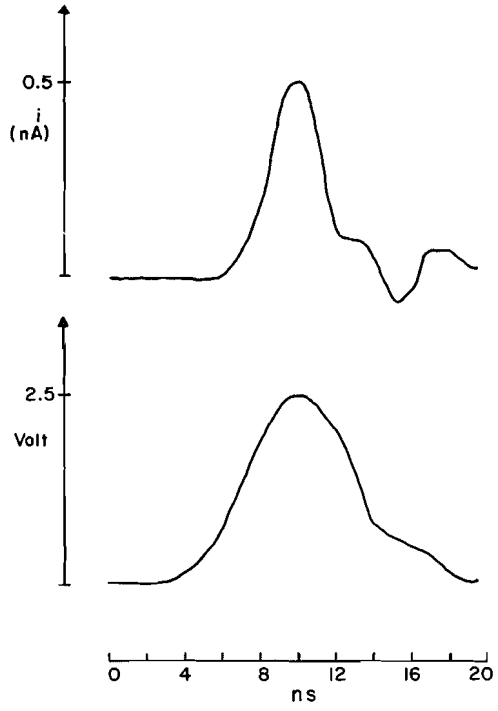

FIG. 2. Top: trace due to a single photoelectron response of the RCA C31034 PMT (HV = 2000 V) recorded with a A 7633 Textronix scope. The anode rise time is 2.3 ns and the fwhm is 3.2 ns. The behaviour of the tailing end of the pulse is due to ringing effects of the amplification system. Bottom: pulse due to Rayleigh-scattered light signals which were amplified by the cascading preamplifiers. The increase in fwhm is due to instrumental limitations of the boxcar integrator.

(10). Great care was taken in order to reduce, as much as possible, pickup of rf noise, generated by the N_2 laser placed only 2 m away from the detection system (12). Turning to the boxcar integrator EGG PAR model 162 (main frame) with gated integrator (model 164) we found that it was necessary to equip the main frame with a digital storage option to handle the low repetition rate of the light pulses so that the smallest aperture duration setting of ~10 ns could be used to obtain the best matching of the anode pulse. At this point it seems worthwhile to emphasize that this gate width determines the lowest time resolution capability of the system. A typical resulting shape of a light pulse due to Raman scattering is displayed in Fig. 2 and the fwhm amounts to ~6 ns. We feel this value to be of some importance because it permits real time studies of Raman signals, employing the 100 ns to 50 ms ranges of the boxcar integrator. The triggering of the model 162 was achieved in the following way. Although the power supply of the N_2 laser provides an electronic signal pulse which could be used for triggering purposes, we found that using these pulses did not result in real advantages. First of all the time delay between this pulse and the light pulse is ~500 ns which prevents one from using the highest time resolution scale of 100 ns (aperture delay range) of the boxcar if additional delay lines are to be eliminated. Secondly, due to changing characteristics of the thyratron of the N_2 laser, the time delay of ~500 ns is apt to change. These problems were circumvented by allowing part of the beam of the N_2 laser itself to fall on a EGG FND 100 ultra fast silicon photodiode (rise time < 1 ns), and by using the output signals for triggering purposes. The time required for the laser light pulses to reach the sample and then the photocathode of the PMT and from there via the amplification stages of the boxcar amounts to a total of ~75 ns. This delay is about equal to the dead time of the boxcar after the triggering signal from the photodiode has entered this instrument and therefore allows us to use all the aperture delay ranges (100 ns – 50 ms for lifetime measurement purposes). A Raman spectrum can now be recorded selecting the aperture duration of ~10 ns fixed in time and by letting the monochromator scan over a required spectra range. On the other hand, the signal can also be displayed in real time by setting the monochromator at a fixed wavelength and in letting the aperture duration scan within any of the ranges available on the model 162. The reproducibility of the instrument with regard to the latter option lifetime measurements can be seen in Fig. 3 where decay curves of the R_1 fluorescence line of ruby are shown.

III. Light Levels, Noise Characteristics, and Performance

It is clear from Fig. 3 that sensitivity problems do not interfere with a determination of the lifetime of strong signals like that due to phosphorescence but such can be quite different if a similar determination has to be carried out of a weaker (Raman) signal. Thus it seems worthwhile to present an evaluation of the performance of the system in comparison with that of the well known cw laser Raman systems.

A. Light Levels

The characteristics of the RCA c31034 PMT as given by the manufacturer are a typical 10% quantum efficiency in the green, a fwhm of 3.2 ns for the anode pulse, and a current gain G of 4×10^5 at 1520 V.

A quantum efficiency of 10% means that some 10 incoming photons are required to cause the ejection of 1 photoelectron from the photocathode. Given

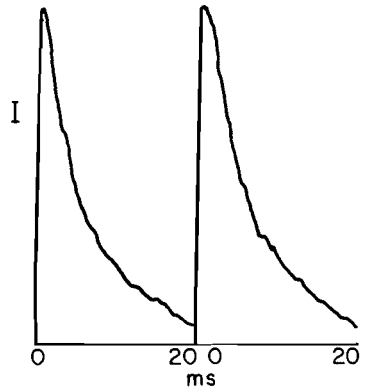

FIG. 3. Repetitive scans of pulses due to phosphorescence radiation at the frequency of the R_1 line of ruby. Phosphorescence was induced by the pulsed laser operating at $\lambda = 514.5$ nm. The long decay as compared to that of the laser light pulse (see Fig. 2) is due to the rather long lifetime of the excited state in which the phosphorescence transition originates.

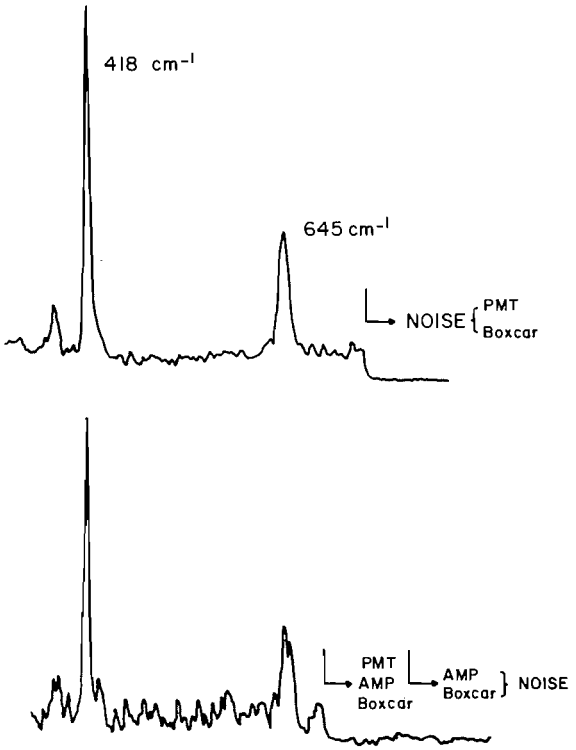

FIG. 4. Top: part of the Raman spectrum of ruby excited with the 514.5 nm radiation of the pulsed dye laser. The pulses due to Raman scattered light were fed directly from the PMT into the boxcar integrator. Also shown is the noise level due to PMT and boxcar only. Bottom: same part of the Raman spectrum with the laser intensity attenuated by a factor of 100 but now recorded with cascading amplifier *and* boxcar. Also shown is the noise level due to the various electronic components of the overall system.

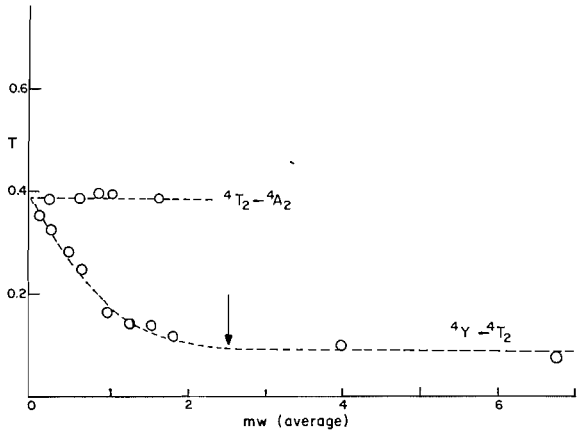

FIG. 5. Transmission at 457.9 nm of a 3.2×10^{-3} *M* solution of the complex $Cr(bpy)_3(ClO_4)_3$ in water as a function of the power of the pulsed laser. The horizontal line represents transmission characteristics due to the $^4T_2 \leftarrow {}^4A_2$ transition of $Cr(bpy)_3^{3+}$ with a cross section $\sigma = 8.89 \times 10^{-19}$ cm^2. Upon an increase of the power density (relative to the number of molecules in the irradiated area), achieved by focussing the laser light into the sample, the ground state $^4A_2$ becomes depopulated and the occurrence of excited state transitions of the type $^4Y \leftarrow {}^4T_2$ (with a cross section $\sigma = 2.56 \times 10^{-18}$ cm^2) causes the transmission to decrease and approach a constant value for I_L(average) > 2.5 mW. This behaviour is in the present analysis not interpreted in terms of bleaching of the $^4A_2$ ground state but rather, within the time frame of the duration of the pulse (~4 ns) the majority of the $Cr(bpy)_3^{3+}$ molecules are considered to be in the $^4T_2$ excited state (with an experimentally estimated lifetime of ~10 ps) and spectroscopic processes (like Raman or other optical transitions) associated with the $^4A_2$ ground state cannot be detected anymore.

the fwhm and gain G, we compute an output anode pulse current of 2×10^{-5} A, employing the relation $i = eg/\text{fwhm}$ (which assumes a triangular pulse shape) (9). This current being led across a 50 Ω load resistor generates a pulse of 1.0 mV at the input of the first amplification stage. The overall gain of the stages is 100, which means that an input voltage of 100 mV is applied to the gated integrator which, together with the main frame, produces an output voltage of 10 V. Hence the original 10 incoming photons give rise to a total signal of 10 V on a recorder if every single photon produces one volt! To check the validity of the above we carried out the following series of measurements. The output of the pulsed dye laser tuned to 514.5 nm was set at an average power of 10 mW (0.4 mJ energy per pulse at 25 Hz or 1.25×10^5 W peak power in 3.2 ns) which corresponds to 10^{15} photons. A Raman signal of CCl_4 was then generated by arbitrarily adjusting the slits of the J.Y. monochromator to yield 10 V (one photoelectron/pulse full scale recorder) signal. We compute a light scattering efficiency

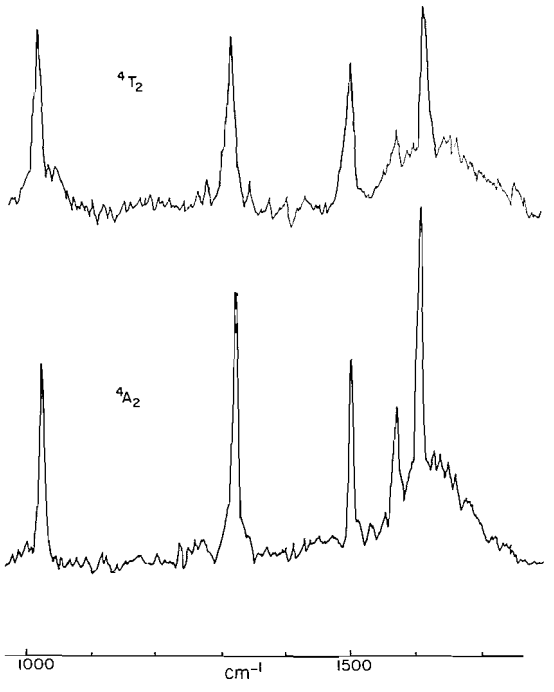

FIG. 6. Part of the Raman spectrum of $Cr(bpy)_3^{3+}$ recorded with the pulsed laser apparatus. The Raman shifts are due to normal modes involving motions of the atoms of the bipyridine rings. The top spectrum is that with the laser radiation >2.5 mV (average) focussed into the cell and consequently (see Fig. 5) Raman spectra are induced from $^4T_2$ only. The lower spectrum is that with the beam unfocussed (horizontal line in Fig. 5) and represents light scattering from $^4A_2$ only.

factor of 10^{-14}. Next, all parameters and, in particular, the geometrical arrangement were kept the same and the pulsed laser was replaced by a cw argon ion laser also operating at 514.5 nm with an average power of 400 mW corresponding to 10^{18} photons/s. Given the reduction factor of 10^{14} we now compute that 10^4 photons/s reach the photocathode and 1000 photoelectron/s are ejected. The calculated value for the current i follows from $i = NeG$ which in our example amounts to an average value of $i = 6.4 \times 10^{-11}$ A. By replacing the pulsed amplifiers and boxcar by a pico ammeter we measured a current precisely equal to the calculated value.

B. Noise Characteristics and Performance

Using the data sheet supplied by the manufacturer, that is 50_{cps} at $T = -30°C$ for the PMT, a typical number for the noise would be $1.6 = 10^{-7}$ counts/pulse as obtained by multiplying the dark count by the anode pulse width (5–7, 17). To evaluate the overall performance of the instrument versus the conventional cw systems we made use of the numbers given in the preceding section, hence:

$$[1]\quad \frac{(S/N)_{cw}}{(S/N)_{pulsed}} = \frac{\dfrac{1000_{cps}}{50_{cps}}}{\dfrac{1_{c/pulse}}{1.6 \times 10^{-7}{}_{c/pulse}}} = 3.2 \times 10^{-6}$$

This number for the ratios of the signal-to-noise in both systems appears to be precisely equal to the experiment ratio of the average power of the cw laser versus the pulsed laser peak power (6) (0.4 W vs. 25×10^5 W). However, this calculation really refers to an ideal case in the sense that, in our system, the computed noise would amount to 1/1000th of the width of the trace on the recorder paper. Furthermore eq. [1] overestimates the actual performance of the present system in that contrary to a cw system (in which the PMT noise is always larger than the noise of photon counting unit), the opposite holds for a pulsed amplified

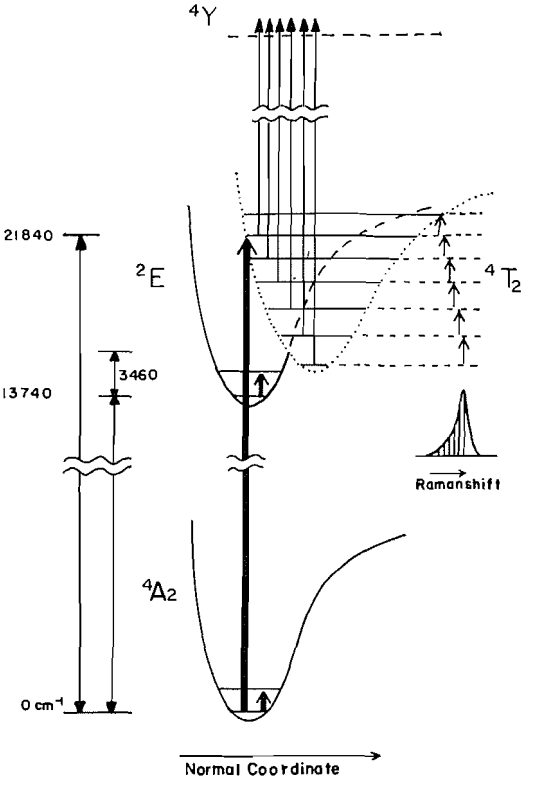

FIG. 7. Part of the energy level diagram of (2,2′-bipyridine)Cr(III) relevant to the present experiments. The energy of the pump (λ = 457.9 nm) reaches vibrational levels in the upper part of the $^4T_2$ electronic surface. Due to the larger number of photons delivered by the pulsed laser during the lifetime of these levels (and those in the bottom of the well) in comparison to the number of molecules in the irradiated area, population of these levels takes place and absorption transitions (at 457.9 nm) of the type ^4Y–$^4T_2$ takes place (see also Fig. 5). In addition Raman transitions are induced and due to the anharmonicity effect the band is expected to be broadened towards smaller shifts (see Fig. 8).

system. This is clearly demonstrated by the results displayed in Fig. 4, where spectra are shown recorded with and without the cascaded amplifiers. The upper trace (Fig. 4) shows a near flat response if the slits are closed, representing, in fact, boxcar ouput noise only. On the other hand the lower trace of Fig. 4 shows the effect of boxcar + amplifier

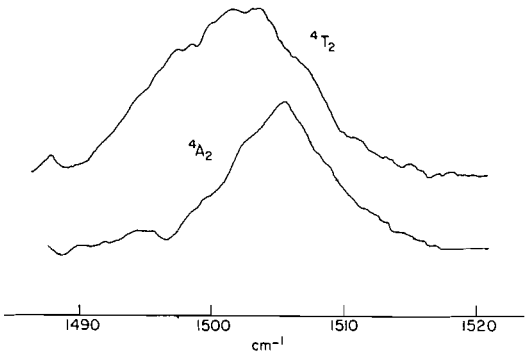

FIG. 8. A comparison of the band contours of a Raman effect of $^4T_2$ and $^4A_2$: $Cr(bpy)_3(ClO_4)$ in H_2O.

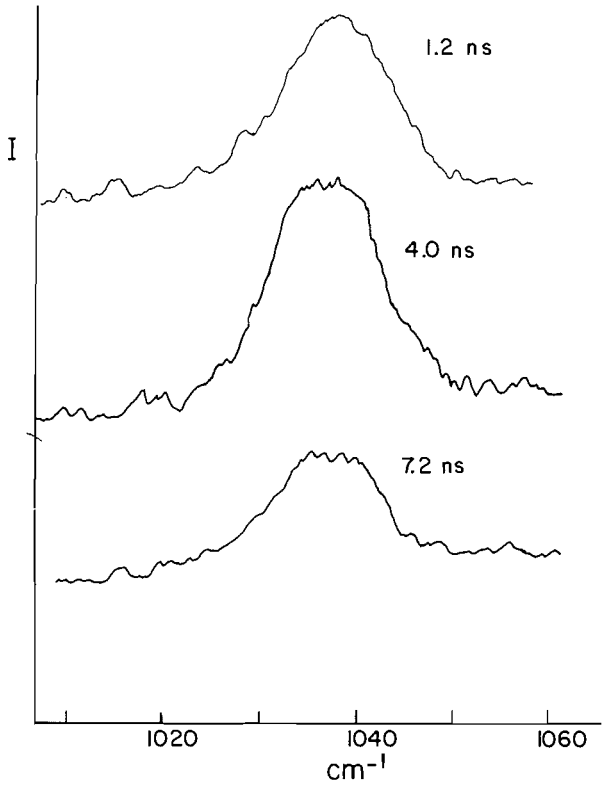

FIG. 9. Recordings of the Raman band at ~1040 cm^{-1} for different positions of the aperture duration (gate) of the boxcar integrator (at the 50 ns time scale). The recording shown in the middle is that where the center of the aperture duration (gate) coincides with the center (peak) of the pulse due to scattered light (see Fig. 8).

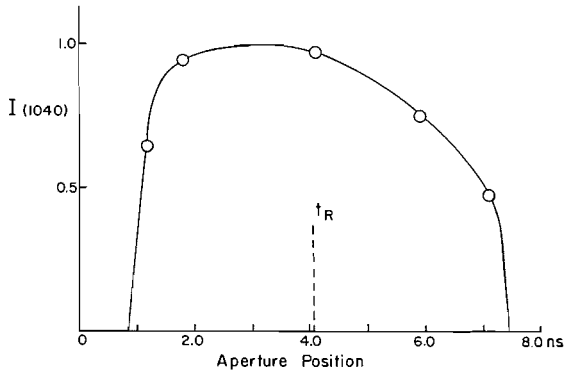

FIG. 10. The integrated intensity of the Raman band at ~1040 cm^{-1} of $Cr(bpy)_3^{3+}$ as a function of the position of the aperture of the boxcar in real time. Based on the real shape of the pulse of the dye laser (Fig. 2, bottom) one predicts an intensity distribution for the Raman signal which would favour that part of the curve with the position of the aperture $> t_R$. The experimental results represented by open circles indicate the opposite and the intensity distribution is due to the fact that during the rise time of the pulse ($t_R \approx 2.3$ ns), the time evolution of the population characteristics of the vibrational levels in the top part of the electronic surface of $^4T_2$ is favoured over those in the bottom and hence vibrational light scattering of those levels contribute to the overall intensity. The situation is reversed for $t > t_R$.

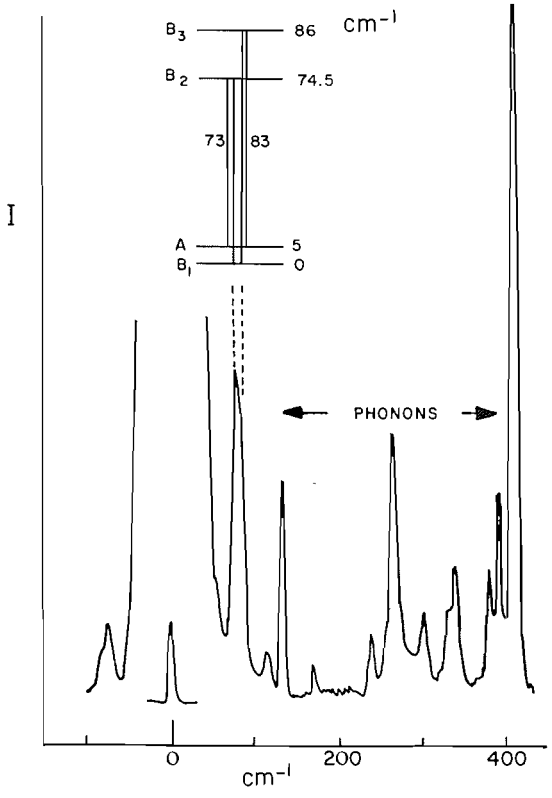

FIG. 11. Part of the Raman spectrum of terbium aluminum garnet ($TbAl_5O_{12}$) at 77 K recorded with the pulsed system (λ = 496.0 nm). Phonons and electronic Raman effects are indicated including the assignment of the electronic transitions.

noise. As anticipated, changes are not detectable if the high voltage of the PMT is switched off.

Taking advantage of the fact that the actual level due to PMT noise always remains below that of boxcar + cascaded amplifiers we increased the high voltage of the PMT to its maximum rating. By using the data of Fig. 4 we actually estimated an overall decrease of the (S/N) ratio by more than three orders of magnitude for the pulsed system (including amplification), with respect to the value used for $(S/N)_{pulsed}$ of eq. [1]. Taking into account also the fact that the availability of light levels for the pulsed system is always a thousand times smaller than that of a cw laser (operating at the ~1 W power range) we finally conclude that the effective performance (of the pulsed light scattering apparatus discussed here) is comparable to that of a conventional ~100 mW cw laser Raman system.

IV. Some Spectroscopic Results

As already indicated above, the present experimental arrangement has features which are not present in cw laser Raman spectrometers and in this section we present some typical results. The large peak power in combination with the short pulse duration of the pulsed laser for instance can be used to populate short-lived excited states of molecules or complexes, and that part of the pulse not used for optical pumping can, within the same pulse duration, serve as the Raman probe.

The degree of population of such an excited state can be determined from a measurement of the transmission of the sample as a function of the intensity of the laser tuned to the frequency of an absorption band of the molecule. For small values of I_L Beer's law is applicable and the transmission remains constant as a function of I_L. If, however,

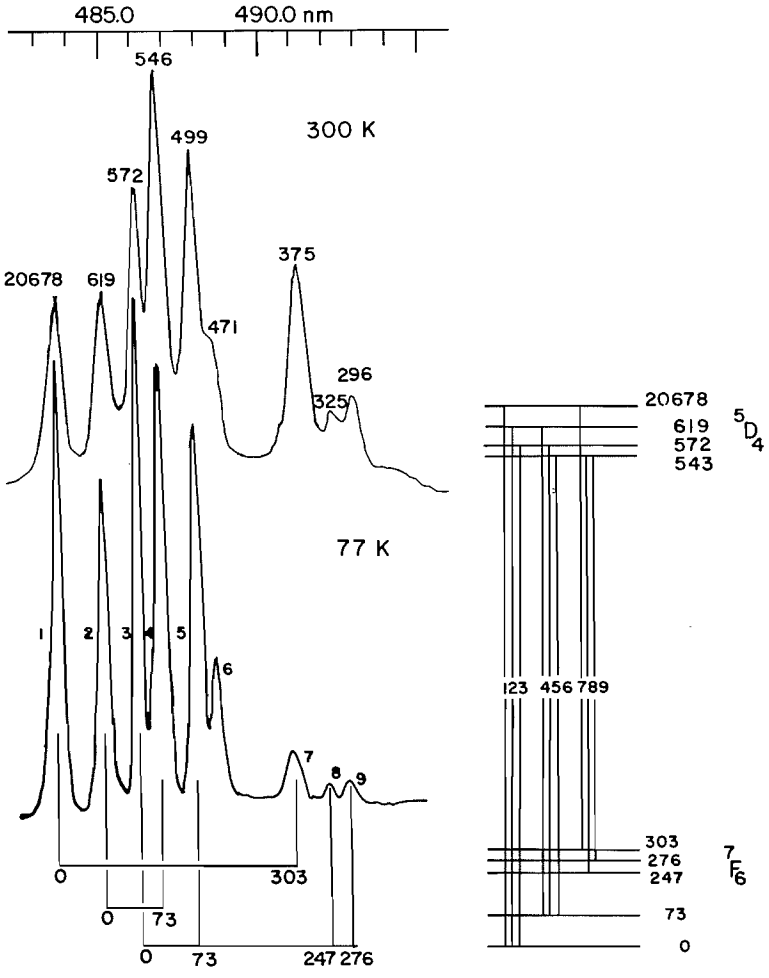

FIG. 12. The absorption spectrum of $TbAl_5O_{12}$ (single crystal) at 300 K and 77 K showing the $^5D_4 \leftarrow {}^7F_6$ transition. The energy level diagram for $^5D_4$ and $^7F_6$ is deduced from the frequency and intensity spectrum.

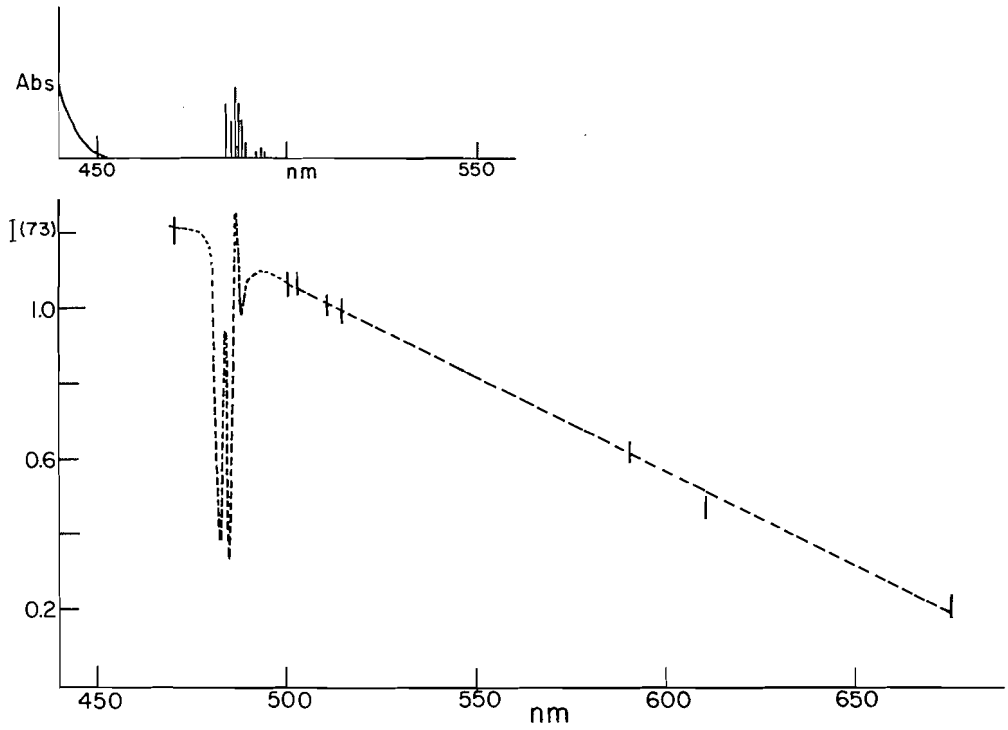

FIG. 13. Resonance enhancement/reduction profile of the intensity for the electronic Raman shift at 73 cm^{-1} of $TbAl_5O_{12}$. Measurements in the range of 483.0–490.0 nm were carried out with an interval of 0.2 nm. The reduction of the Raman intensity is due to interference effects arising from contributions of electric dipole matrix elements of opposite sign in the expression for an element of the electronic Raman scattering tensor.

some population occurs of an excited state then the value of the transmission changes because of depopulation of the ground state. Also, the possibility should not be excluded that another transition originates in the populated excited state and, depending on the cross section of this transition, we find that the value of the transmission increases or decreases if compared to that for low I_L. If conditions of population saturation of the excited state are approached for increasing values of I_L then T too approaches a constant value and such a behaviour was observed for the complex $Cr(byp)_3(ClO_4)_3$ in H_2O (see Fig. 5). A detailed analysis of the absorption process reveals that the $^4T_2$ state of $[Cr(bpy)_3]^{3+}$ is populated and not ^2E (which is at $\sim 13\,400\ cm^{-1}$ and $E_{^4T_2} > E_{^2E}$). The estimated lifetime of the $^4T_2$ state is ~ 10 ps and thus cannot be Raman probed with cw lasers due to power limitations (20). Part of the Raman spectrum $^4T_2$: $Cr(bpy)_3{}^{3+}$ and that of $^4A_2$: $Cr(bpy)_3{}^{3+}$ is shown in Fig. 6. We note a marked increase in the width of the Raman bands of $^4T_2$: $Cr(byp)_3{}^{3+}$ versus those of $^4A_2$: $Cr(bpy)_3{}^{3+}$. The energy of the optical pump at 457.9 nm, which produces population of $^4T_2$, is not in resonance with the 0–0 electronic transition, nor with that of the first vibronic side band of a normal mode. The actual experimental situation is that where the energy of the pump is in resonance with vibrational states having at least $v = 6$ for some of the normal modes in $^4T_2$ and population of the vibrational levels with $v < 0$ of $^4T_2$ is achieved (Fig. 7) via vibration relaxation. Due to the rapid rise time of ~ 2.3 ns (leading edge) of the laser pulse, it could be possible to detect Raman scattering from the excited vibrational levels even if the relaxation time of the cascading process is in the picosecond region. In that case some population would occur of the excited vibrational levels and of relevance here too, from the point of view of experimental observation of Raman scattering from levels with $v \neq 0$, is the fact that the intensity of $I_v(Q)$ of a vibrational Raman process originating in a level labelled with the quantum number v is related to the intensity of a similar process $I_0(Q)$ originating in the level with $v = 0$ by

$$I_v(Q) = (v + 1)I_0(Q)$$

In addition, as a result of the effect of anharmonicity we find that the shift of the Raman band due to the transition originating in higher v levels is smaller than that of the transition originating in $v = 0$. Many of the observed bands of $^4T_2$: $Cr(bpy)_3{}^{3+}$ show a

For personal use only.

broadening but (see Fig. 8) not a well resolved spectrum towards lower shift values. In Fig. 9 we show recordings of the Raman band centered at $\sim 1040\ cm^{-1}$ of $^4T_2$: $Cr(bpy)_3^{3+}$ under different conditions of the position of the center of the aperture of the boxcar in real time so that in effect the edge, center, and tailing edge of the 3.2 ns long pulse were isolated. In the situation where the aperture is fixed to isolate the leading edge, the overall intensity of the Raman band could contain contributions of transitions originating in the top of the well. On the other hand, contribution to the intensity from transitions in the bottom of the well should occur if the aperture is adjusted to isolate the tailing end of the pulse. Assuming a symmetrical shape for the laser pulse we anticipate for reasons given above that the overall intensity of the Raman band for the former should be stronger than for the latter if the cascading process takes place. The results displayed in Fig. 10 reveal the presence of an intensity enhancing process during the rise time of the laser pulse and are taken as evidence that the band contour of the Raman shifts for $^4T_2$: $Cr(bpy)_3^{3+}$ is mainly due to the cascading (vibrational relaxation) process at the picosecond time scale, the details of which shall be published elsewhere.

We now turn our attention to some other results where advantage has been taken of real time resolution and tunability of the pulsed laser. The Raman spectrum shown in Fig. 11 is that of a single crystal of terbium aluminum garnet and the shift at $\sim 80\ cm^{-1}$ is due to an electronic Raman effect of the crystal field components of the split $^7F_6$ ground manifold (21). It is noted that the $80\ cm^{-1}$ shift is well isolated from the Rayleigh time.

Using the tunability of the system, spectra were also recorded with $481.0 < \lambda_L < 495.0$. Absorptions due to $^5D_4 \leftarrow {}^7F_6$ transitions of Tb^{3+} are shown in Fig. 12 and the exciting radiation is seen to cover the regions where absorption takes place. Conditions are met for the occurrence of either pre or resonance electronic Raman scattering and the results shown in Fig. 13 demonstrate their effects on the intensity enhancements or reduction of the electronics Raman shift. The intensity behaviour can be traced back to the occurrence of electric dipole matrix elements of opposite signs in the well known expression from element $\alpha_{\rho\sigma}$ of the scattering tensor. It is also seen that under rigorous resonance conditions the intensity enhancements or reductions are small on account of the weak ocillator strength of the Laporte forbidden $^5D_4$–$^7F_6$ transitions shown in Fig. 12.

Probably the most interesting aspect of a resonance Raman process is its time dependent behaviour with respect to the non resonance case.

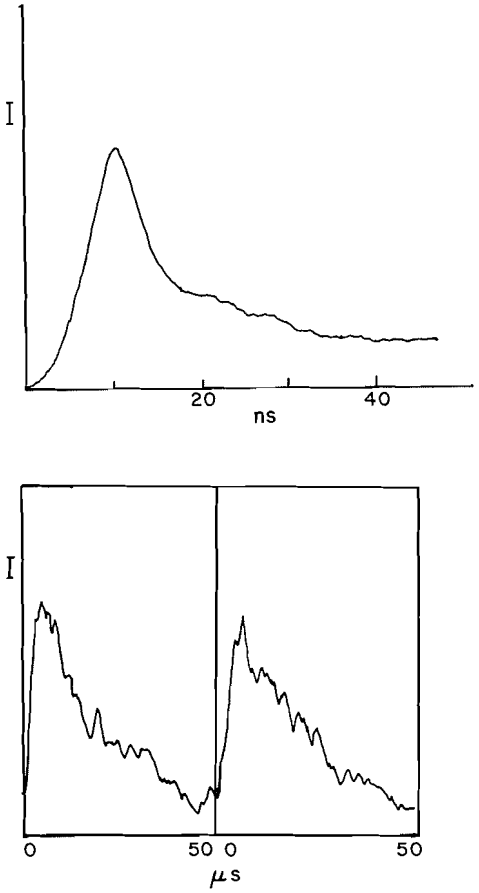

FIG. 14. Raman pulse in real time due to a resonance enhanced electronic light scattering effect with a shift of 73 cm^{-1} of $TbAl_5O_{12}$. The exciting wavelength $\lambda_L = 494.9$ nm is 0.1 nm removed from the position of an absorption band of $TbAl_5O_{12}$ (see Fig. 11). Clearly visible at the 50 ns scale of the boxcar (top) is the tailing end of the Raman pulse, while the decay itself becomes fully visible at the 50 μs scale. A lifetime of $\tau = 31.5\ \mu s$ is determined from the decay which value is in good agreement with the lifetime $\tau = 33.5 \pm 0.1\ \mu s$ (determined from fluorescence transitions) of the resonating excited state at 20 619 cm^{-1} (see Fig. 11) of $TbAl_5O_{12}$.

From the data shown in Fig. 13, it can be seen that for $\lambda_L = 485.0$ nm the maximum contribution due to resonance scattering to the overall intensity is $\sim 50\%$. Given a lifetime of the resonating electronic state longer than the duration of the laser pulse, the effect of such a lifetime on the pulse due to resonance Raman scattering would be visible if this pulse is displayed in real time. In this particular case the Raman pulse displayed in real time should show a decay pattern having its origin located at half the peak height of the pulse (22, 23). The results for the 73 cm^{-1} electronic Raman shift given in Fig. 14 are in good agreement with the predicted pulse shape. Like the results of $Cr(bpy)_3^{3+}$, those of TbA1G shall also be discussed in greater detail

elsewhere, they are used in the present work to demonstrate the capability of the present system to probe effects which occur at the pico and microsecond time scale.

Tricyclic aromatic ketones by cycliacylation of carboxylic acid derivatives of indan, tetralin, and benzosuberane

M. ELAINE ISABELLE, ROBERT H. WIGHTMAN,[1] HAJRO W. AVDOVICH,[2] AND DAVID E. LAYCOCK[2]

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

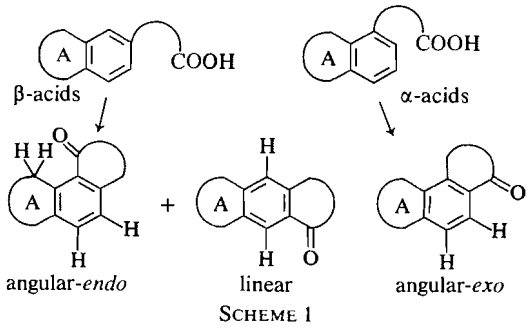
Received April 1, 1980

M. ELAINE ISABELLE, ROBERT H. WIGHTMAN, HAJRO W. AVDOVICH, and DAVID E. LAYCOCK. Can. J. Chem. **58**, 1344 (1980).

The synthesis of a homologous series of new carboxylic acids substituted in the α-position of indan, tetralin, and benzosuberane is accomplished using an efficient general procedure. Cycliacylation of these acids and their corresponding β-isomers produces a complete series of tricyclic aromatic ketones.

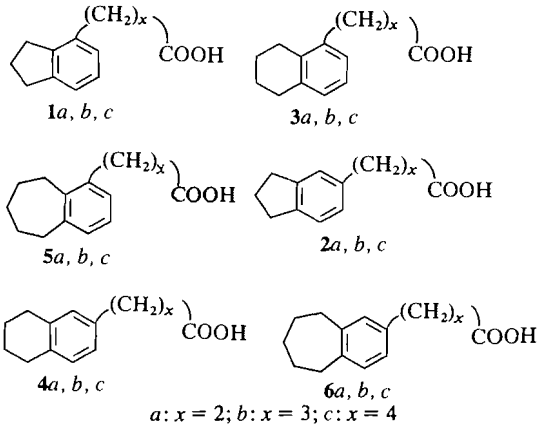
M. ELAINE ISABELLE, ROBERT H. WIGHTMAN, HAJRO W. AVDOVICH et DAVID E. LAYCOCK. Can. J. Chem. **58**, 1344 (1980).

Faisant appel à une méthode générale efficace, on a synthétisé une série homologue de nouveaux acides carboxyliques substitués en position α de l'indane, de la tétraline et du benzosubérane. La cycloacylation de ces acides et de leurs isomères β correspondants produit une série complète de cétones tricycliques aromatiques.



[Traduit par le journal]

Introduction



The intramolecular cycliacylation of certain bicyclic acids is a general route for the preparation of a variety of tricyclic ketones with varying acyclic ring sizes and positioning of the carbonyl group as outlined in Scheme 1.

Such tricyclic ketones are potential precursors of the corresponding tricyclic aromatic hydrocarbons (1) or of other more unsaturated species (2). Such compounds could also be useful models for probing conformational effects on the central aromatic ring or anisotropic effects of the carbonyl group.

Intramolecular acylations have been regularly reported in the literature for various simple (3) or substituted carbocyclic (4) and heterocyclic (5) ring systems. Although the β-substituted acids can, in principle, cyclize in two directions to produce a linear[3] or angular-*endo*[3] ketone (6), the predominant linear isomer was often the only product reported (7). Preference for linear formation has been ascribed to "steric effects" (8) despite the fact that in one case complete angular formation has been noted (9).

SCHEME 1

Previous syntheses of the β-substituted acids have exploited the fact that *ortho*-disubstituted benzenes acylate predominantly in the β-position. Thus a propanoylation/Willgerodt sequence (10) or malonic ester condensation on the chloromethyl derivative (9) have been employed for syntheses of propanoic acids of the type **2***a*, **4***a*, **6***a* while acylation with succinic (11) or glutaric (3) anhydride followed by reduction of the keto-acids has been the method of choice for butanoic acids of the type **2***b*, **4***b*, **6***b* or pentanoic acids of the type **2***c*, **4***c*, **6***c*. Only two α-substituted acids have been reported using rather fortuitous **3***a* (12) or lengthy **1***a* (13) sequences.

In this paper we wish to report a short general sequence for preparing the nine pairs of isomeric acids, **1***a*–*c* – **6***a*–*c*, formally derivable from indan,

tetralin, and benzosuberane. The synthesis follows from our recently developed preparative methods (14) for α-substituted (as well as β-substituted) derivatives of these bicyclic hydrocarbons. We also report the cyclization products, the tricyclic ketones **7***a–c* – **15***a–c* which represent all variations of 5, 6, and 7 membered acyclic rings outlined in Scheme 1 and permit, for the first time, direct spectral comparison of these compounds.

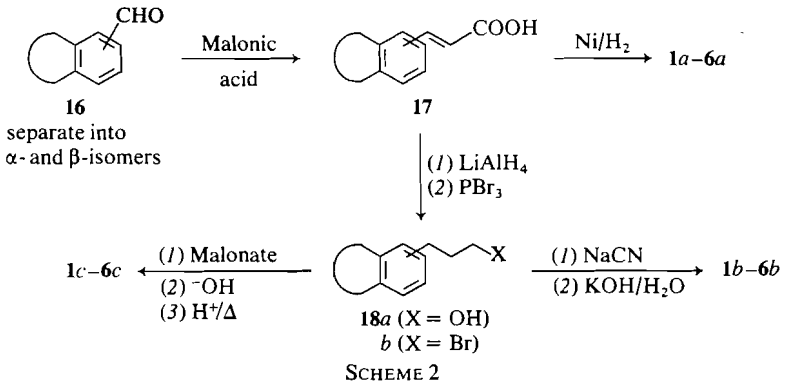
Results and Discussion

*The Bicyclic Acids, 1*a–c – *6*a–c



The sequence is outlined in Scheme 2. All acids were synthesized from the corresponding acrylic acids, **17**, which are directly available from the aldehydes, **16**. The aldehydes are quite amenable to separation of α- and β-isomers and readily derivable from the corresponding hydrocarbons. The acrylic acids could then be converted by rather conventional procedures to acids with any desired length of side chain. We have found all steps in the sequence to be clean and of high yield (80–90%) except the final decarboxylation (40–70%). All intermediates were nicely characterizable by ir and ^{1}H nmr.

*The Tricyclic Ketones, 7*a–c – *15*a–c

Scattered reports in the literature propose a variety of conditions which effect such cycliacylations (15) to the tricyclic ketones. The sole variation to this approach involves β-acylation with 3-chloropropanoyl chloride followed by cyclialkylation to produce angular-*exo*[3] ketones **9***a* (10, 16) and **12***a* (17).

Treatment of the acid chloride with $SnCl_4$ apparently maximizes formation of the angular-*endo* isomer from the β-acids (9). By using these conditions, which do not permit equilibration of the two isomers, and glc analytical techniques we were able to complete a comprehensive study of the formation of tricyclic ketones of the type **7***a–c* – **15***a–c*. In general the crude cyclization products were quite clean, any impurities being minor ones as judged by glc. Reaction mixtures could be resolved by preparative layer or short column (18) chromatography. The products from cyclizations of **6***b* and **6***c* were completely resolved by hplc but none of the minor components exhibited spectral characteristics (ir, nmr) expected for the angular-*endo* isomers, **13***b* or **13***c*, respectively. In most cases, the linear isomer predominated and overall yields were lower for cyclization products from the pentanoic acids. These results are summarized in Table 1 together with the ^{1}H nmr pattern for the aromatic protons of the ketones, the most diagnostic structural information.

The lack of detection of the benzosuberane-derived ketones **13***b*, **13***c* together with the rather dramatic differences in linear/angular-*endo* ratios

induced by merely changing the cyclization conditions would indicate that simple steric arguments are not adequate to explain direction of cyclization. Perhaps the size of ring A has a varying effect on the electron densities of the benzene ring carbons or previous conditions may have permitted linear/angular equilibration (19). As intimated previously (8), an interesting ^{1}H nmr anisotropic effect of the carbonyl group on the nearest benzylic protons of ring A allows differentiation of linear and angular-*endo* isomers. We have found this trend to be less distinguishable as the size of the acyclic rings increases. From such a comprehensive series of ketones we find the *J* values and chemical shifts for the aromatic protons to be more diagnostic.

We hope to be able to prepare the missing ketones by a totally different route (20) and investigate in more detail (*i*) possible factors in the cyclization process and (*ii*) the conformational implications of more detailed spectral analyses of effects of the carbonyl group or its derivatives.

Experimental

General Details

Melting points were obtained on a Buchi SMP-20 melting range apparatus. Infrared spectra in CS_2 (ν_{max} in cm^{-1}) were recorded on a Perkin Elmer 237B spectrophotometer. Ultraviolet spectra [λ_{max} in nm (ε)] were obtained in 95% EtOH on a Perkin Elmer-Coleman-124 spectrophotometer. Proton magnetic resonance (^{1}H nmr) spectra were recorded on a Varian T-60 (60 MHz) instrument; all values are recorded in ppm (δ) with reference to TMS. All ^{1}H nmr were taken in $CDCl_3$ with 1% TMS. Band shape is indicated by s(singlet), d(doublet), t(triplet), m(multiplet), b(broad). Thin or preparative layer chromatography was performed using silica gel G (0.25 mm layers or 2.0 mm respectively) on glass plates (Merck). Analytical glc data were obtained on: (*i*) a Hewlett Packard F&M 402 instrument using a ¼ in. × 6 ft column, oven temperatures of 150–200°C, and flow rate of nitrogen at 70 mL/min or (*ii*) a Perkin Elmer 990 using a ⅛ in. × 12 ft column, temperatures of 160–180°C, and argon flow rate 25 mL/min. Columns were packed with 3% OV210 on Chromosorb W, 100–120 mesh. Microanalyses were obtained from Spang Microanalytical Laboratory, MI, U.S.A.

*Preparation of the Bicyclic Acids, 1*a–c – *6*a–c

All of these compounds exhibited ir bands at 3300–2700 (—OH), 1720 (C=O) typical of carboxylic acids. Additionally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

their ^{1}H nmr spectra displayed a typical pattern consisting of absorptions centred at 11.5–9.0 (disappears with D_2O, —COO*H*), ~7.0 (aromatic *H*), 2.7(benzylic —CH_2— plus —CH_2—COOH) and ~1.8 (other —CH_2—).

Analytical samples could be obtained by crystallization from petroleum ether, sublimation at 0.01 Torr, or isolation from preparative layer plates.

*The Propanoic Acids, 1*a–*6*a

The corresponding acrylic acid **17**(14) was reduced using Raney nickel alloy (Al:Ni = 1:1) in hot aqueous NaOH as outlined by Cook *et al.* (21). Yield of crude product, of sufficient purity for further reaction, was always 85–90%.

1*a*, mp 113–114°C (lit. (13) mp 113–114°C); ^{1}H nmr: 10.7 (1H, bs), 7.1 (3H, m), 2.8 (8H, m), 2.0 (2H, m). **2***a*, mp 84–85°C (lit. (8) mp 85–86°C, lit. (10) mp 83°C); ^{1}H nmr: 8.8 (1H, bs), 7.1 (3H, m), 2.8 (8H, m), 2.1 (2H, m). **3***a*, mp 135–136°C (lit. (12) mp 136–137°C); ^{1}H nmr: 9.9 (1H, bs), 7.0 (3H, s), 2.7 (8H, m), 1.7 (4H, m). **4***a*, mp 82–83°C (lit. (22) mp 81–82°C, lit. (8) mp 78°C, lit. (23) mp 82°C, lit. (24) mp 70–71°C); ^{1}H nmr: 11.1 (1H, bs), 7.0 (3H, s), 2.7 (8H, m), 1.8 (4H, m). **5***a*, mp 84–85°C; ^{1}H nmr: 11.4 (1H, bs), 7.0 (3H, s), 2.8 (8H, m), 1.7 (6H, m); *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found: C 76.77, H 8.12. **6***a*, mp 99–100°C (lit. (25) mp 102–103°C); ^{1}H nmr: 11.4 (1H, bs), 7.0 (3H, s), 2.8 (8H, m), 1.7 (6H, m).

The acrylic acid **17**(X mol) could be reduced to the corresponding saturated alcohol **18***a* by reduction with $LiAlH_4$(X mol) in anhydrous ether (26). We have found it most convenient to introduce the acid gradually via a Soxhlet extractor and to continue reflux of the ether for 20–24 h. A normal workup would produce 80–90% yields of neutral material, which proved to be the alcohol, in sufficient purity to continue. These compounds were nicely characterized by certain spectral data, notably ir (hydroxyl at 3500, no carbonyl at ~1720) and ^{1}H nmr (3 aromatic *H* at ~7.0, —CH_2—CH_2—OH as a 2H, t centred at ~3.7, and 1 O*H* exchanging with D_2O at ~2.3).

The alcohol **18***a* (X mol) was readily converted to the bromide **18***b* using PBr_3 (0.5 X mol) in benzene (8). After workup the bromide was obtained in 80–90% yield and of sufficient purity to continue. Again the intermediates were easily characterized by selected absorptions in the ir (no hydroxyl bands) with ^{1}H nmr (3 aromatic protons, ~7.1 and —CH_2—CH_2—Br, 2H, t, ~3.4).

*The Butanoic Acids, 1*b–*6*b

The approach outlined by Patwardhan (8) was employed (see also ref. 4). The bromide **18***b* was converted to the corresponding nitrile using KCN in refluxing methanol. Yields were routinely ≥90% of a product judged sufficiently clean by spectral data, e.g. ir ~2250(—CN) and ^{1}H nmr: ~3.0 (2H, t, —CH_2—CH_2—CN), to proceed. Hydrolysis using KOH in refluxing aqueous ethylene glycol produced an acidic product in ≥85% yield.

1*b*, mp 81–83°C; ^{1}H nmr: 10.7 (1H, bs), 7.1 (3H, m), 2.5 (8H, m), 1.9 (4H, m). *Anal.* calcd. for $C_{13}H_{16}O_2$: C 76.44, H 7.89; found: C 76.78, H 7.78. **2***b*, mp 54–55°C (lit. (27) mp 55°C, lit. (28) mp 56°C); ^{1}H nmr: 9.6 (1H, bs), 7.2 (3H, m), 2.9 (8H, m), 2.0 (4H, m). **3***b*, mp 94–95°C; ^{1}H nmr: 9.5 (1H, bs), 7.0 (3H, bs), 2.7 (8H, m), 1.8 (6H, m). *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.02, H 8.25; found: C 77.25, H 8.29. **4***b*, mp 47–49°C (lit. (23) mp 47–49°C, lit. (8) mp 44–45°C); ^{1}H nmr: 10.9 (1H, bs), 7.0 (3H, m), 2.6 (8H, m), 1.8 (6H, m). **5***b*, mp 55°C; ^{1}H nmr: 10.9 (1H, bs), 7.0 (3H, s), 2.6 (8H, m), 1.7 (8H, m). *Anal.* calcd. for $C_{15}H_{20}O_2$: C 77.55, H 8.68; found: C 77.67, H 8.66. **6***b*, mp 88°C; ^{1}H nmr: 8.5 (1H, bs), 7.0 (3H, m), 2.6 (8H, m), 1.6 (8H, m). *Anal.* calcd. for $C_{15}H_{20}O_2$: C 77.55, H 8.68; found: C 77.90, H 8.40.

*The Pentanoic Acids, 1*c–*6*c

Sodium hydride (X mol, as a 55% mineral dispersion) was freed of mineral oil by rinsing with petroleum ether and decanting (2×), then suspended in dry benzene–DMF (4:1 v/v). Diethyl malonate (X mol) in anhydrous benzene was added dropwise at room temperature, then stirred until evolution of hydrogen was complete (~30 min). This solution was cooled in an ice-bath and the appropriate bromide **18***b* (1.05 X mol) in dry DMF was added dropwise so that the temperature of the reaction mixture never exceeded 15°C. This mixture was stirred at room temperature overnight by which time an aliquot in water gave a neutral pH and the condensation was considered complete. Workup yielded a viscous oil constituting 80–90% mass recovery. Hydrolysis and decarboxylation using a variety of conditions (4, 8, 29) produced an acidic product in yields of 25–60% based on starting bromide.

1*c*, mp 59°C; ^{1}H nmr: 10.7 (1H, bs), 7.1 (3H, m), 3.1–1.4 (14H, m). *Anal.* calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found: C 76.57, H 8.08. **2***c*, mp 64–65°C (lit. (7) mp 70–71°C), ^{1}H nmr: 10.6 (1H, bs), 7.0 (3H, m), 3.1–1.5 (14H, m). **3***c*, mp 91°C; ^{1}H nmr: 10.8 (1H, bs), 7.0 (3H, m), 2.7 (8H, m), 1.8 (8H, m). *Anal.* calcd. for $C_{15}H_{20}O_2$: C 77.70, H 8.25; found: C 77.62, H 8.44. **4***c*, mp 54–55°C (lit. (11) mp 57–58°C, lit. (8) mp 54–55°C); ^{1}H nmr: 10.9 (1H, bs), 7.0 (3H, m), 2.6 (8H, m), 1.8 (8H, m). **5***c*, amorphous solid, ^{1}H nmr: 10.8 (1H, bs), 7.0 (3H, m), 2.6 (8H, m), 1.6 (10H, m). *Anal.* calcd. for $C_{16}H_{22}O_2$: C 78.01, H 9.00; found: C 78.01, H 9.12. **6***c*, mp 62–64°C (lit. (3) mp 63°C); ^{1}H nmr: 11.5 (1H, bs), 7.0 (3H, m), 2.6 (8H, m), 1.7 (10H, m).

*Preparation of the Tricyclic Ketones, 7*a–c – *15*a–c

The following general procedure, modified from that reported by Arnold and Rondestvedt (9), was employed for all cyclizations. The acid (2.0 mmol) was dissolved in dry benzene (5–10 mL) and to this solution was added PCl_5 (2.2 mmol). The flask was stoppered and the contents magnetically stirred at room temperature until the PCl_5 had dissolved (~30 min). This was taken as indication that the acid chloride was now formed *in situ*. The flask was immersed in an ice-bath and the contents chilled to 0°C at which time $SnCl_4$ (4.0 mmol) was added. The dark coloured reaction mixture was stirred for a further 30 min at 0°C, then for 90 min at room temperature. Yields of cyclized material could be increased if necessary by extending the reaction period at room temperature with no change in the linear/angular ratio, see Table 1 for several examples. The reaction mixture was poured onto ice, rendered acidic, extracted with ether (3×), and the combined organics washed with 5% aqueous NaOH (2×) to remove any unreacted acid (could be recovered). After drying and removing solvent the neutral products could be analyzed by tlc (petroleum ether – benzene 1:1 v/v) or glc. Purification was achieved by silica-gel column chromatography, crystallization (petroleum ether), sublimation, or preparative layer chromatography for separation of linear and angular isomers.

Solvent Variation

Cyclization of the β-acids, **2***a–c*, **4***a–c*, **6***a–c* usually resulted in formation of both linear **8***a–c*, **11***a–c*, **14***a–c* or angular-*endo* compounds **7***a–c*, **10***a–c*, **13***a–c* as easily determined by glc. We have found no difference in linear/angular ratios from **4***a* and **4***b* when the cyclizing medium was nitrobenzene (9) or benzene and therefore have used the latter solvent exclusively. All ratios summarized in Table 1 represent our standard conditions (*vide supra*) and are obviously quite different from other reports, e.g. ref. 8.

Equilibration Studies

No equilibration rearrangements between linear and angular isomer pairs, e.g. **7***b*/**8***b* or **10***b*/**11***b* could be detected by glc using standard cyclization conditions; i.e. $SnCl_4$ (2 equiv.) in benzene for 5 h at room temperature.

Characterization of Ketones

Isolated yields, linear/angular isomer ratios, and selected ^{1}H nmr data are available in Table 1. Additional, unavailable data

The page numbers for these two papers were interchanged in the Contents of the May 1, 1980 issue. The page number should be 928 for the article by Pierre L. Beaulieu, Veronique M. Morisset, and Dennis G. Garratt and 875 for the article by Normand Beaulieu and Pierre Deslongchamps.

As well, the page number in the Author Index should be 928 for Beaulieu, P. L., Morisset, V. M., and Garratt, D. G. and 875 for Beaulieu, N. and Deslongchamps, P.

Reactions of thiyl radicals. XIII. Photochemically induced exchange reactions of liquid alkyl disulfides

DINESH GUPTA AND ARTHUR R. KNIGHT[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received January 3, 1980

DINESH GUPTA and ARTHUR R. KNIGHT. Can. J. Chem. **58**, 1350 (1980).

The liquid phase photolysis of some 35 liquid alkyl disulfide mixtures has been studied. The corresponding unsymmetrical disulfide is the only significant product of the reaction and the system attains a photo-equilibrium state at longer exposure times. Product formation is completely eliminated by the addition of nitric oxide.

Quantum yields have been redetermined for the methyl disulfide – ethyl disulfide system using four different light sources. Initial rates have been measured for each of the 35 combinations and have been shown to be a function of total molecular weight of the disulfide mixture and to be strongly influenced by steric factors. These effects are most pronounced for mixtures wherein the exchange reaction between thiyl radical and a symmetrical disulfide is important as indicated by quantum yields above unity. Combinations of isodisulfides give rise to anomalously high rates.

DINESH GUPTA et ARTHUR R. KNIGHT. Can. J. Chem. **58**, 1350 (1980).

On a étudié la photolyse en phase liquide de 35 mélanges de disulfures d'alkyles à l'état liquide. Le disulfure asymétrique correspondant est le seul produit important de la réaction et le système atteint un état d'équilibre photochimique à des temps d'exposition plus longs. L'addition d'oxyde nitrique élimine complètement la formation des produits.

On a déterminé de nouveau les rendements quantiques du système disulfure de méthyle – disulfure d'éthyle en utilisant quatre sources différentes de lumière. On a mesuré les vitesses initiales pour chacune des 35 combinaisons; on a montré qu'elles dépendent du poids moléculaire total du mélange de disulfure et que des facteurs stériques les influencent fortement. Ces effets sont plus prononcés dans les cas de mélanges où la réaction d'échange entre le radical thiyle et le disulfure symétrique est importante tel qu'indiqué par les rendements quantiques du système déjà mentionné. Les combinaisons d'isodisulfures conduisent à des vitesses anormalement grandes.

[Traduit par le journal]

Introduction

The liquid phase photolysis of mixtures of disulfides and of disulfide–thiol mixtures have been investigated previously by several workers (1–6) and in this laboratory (7, 8).

When mixtures of alkyl disulfides are photolysed in the 250–300 nm region, the corresponding unsymmetrical disulfide is formed rapidly with high quantum yield. On prolonged irradiation the system generally attains a photo-equilibrium with the equilibrium constant for the process

[1] $RSSR + R'SSR' \rightleftharpoons 2\,RSSR'$

having a value of 4.

As a continuation of our investigations in this area we have studied and report here on the photolysis of mixtures of C_2 through C_{10} alkyl disulfides in condensed phase to determine the influence of molecular weight and structure on the initial rate of the exchange reaction. Some additional measurements of quantum yields have been made and the effect of added nitric oxide has been examined.

Experimental

All photolyses were carried out at room temperature with degassed samples. For most initial rate studies the light source was a Vycor 7910 filtered Hanovia 306-20 medium pressure mercury lamp. The combination of cut-off filter, lamp output, and disulfide absorption confined significant absorption to the 230–360 nm region, with the predominant absorption being the strong self-reversed emission around 250 nm. When a low pressure Hanovia 68745 Hg-lamp was used, the absorption was confined essentially to the 253.7 nm line. In the actinometric experiments, the low pressure Hg-lamp, a Zeiss LX501 high pressure xenon lamp and Zeiss M401 1d or Bausch and Lomb 780 TD monochromator combination, or a Spectra-Physics Model 185 He–Cd laser with output at 325 nm were also employed. Quantum yield measurements were carried out with the lamp–cell assembly mounted on a optical bench with a quartz lens system which provided an essentially uniform parallel incident light beam.

Disulfide samples were obtained commercially and purified where required by low pressure distillation or prep-scale gc. Purities were verified by gc or mass spectrometric analysis. Product analysis was by thermal conductivity or flame ionization gc using tricresylphosphate or Apiezon-M columns.

Light intensities were determined using a modified potassium ferrioxalate method (9–11).

For initial rate studies 200 nm^3 samples were irradiated in a 6 mm od quartz tube. For actinometric experiments, the cell was a 1.0 cm square quartz tube with a 2.0 μm^3 sample size.

Results

The attainment of photochemical equilibrium in three representative disulfide mixtures of different proportions was followed using both the medium and low pressure Hg-lamp light sources. The results are summarized in Table 1.

TABLE 1. Equilibrium constants for photolysed disulfide mixtures

Reactants	Mol% composition	Equilibrium constant K^a	Equilibrium constant K^b
$CH_3SSCH_3/C_2H_5SSC_2H_5$	50/50	4.0 ± 0.2	3.7 ± 0.2
	20/80	4.0 ± 0.2	—
	80/20	4.1 ± 0.2	—
$CH_3SSCH_3/n\text{-}C_3H_7SSC_3H_7$	50/50	4.3 ± 0.3	4.2 ± 0.1
	80/20	3.9 ± 0.3	—
$C_2H_5SSC_2H_5/n\text{-}C_3H_7SSC_3H_7$	50/50	4.0 ± 0.4	3.7 ± 0.2
	20/80	2.8 ± 0.5	—
	80/20	3.6 ± 0.7	—

[a]Medium pressure Hg-lamp.
[b]Low pressure Hg-lamp.

With one exception the values observed are close to the statistically expected value of 4.0. Although the 20% ethyl disulfide/80% *n*-propyl disulfide system was carried to what appeared to be a constant composition, it may be that prolonged irradiation is required to attain the equilibrium concentration of the $C_2H_5SSC_3H_7$ product. For these systems the equilibrium state is approached with a rate that varies considerably from mixture to mixture, with the equilibrium state being attained after a period of 1 to 3 h.

The main body of experiments involved the determination of the initial rates in disulfide combinations, photolysed as equimolar pure liquid mixtures by the medium pressure Hg-lamp. In all systems examined the mol% of the unsymmetrical disulfide formed generally increased linearly with exposure time up to ca. 10–15% product.

The initial rate data for straight chain disulfide mixtures from methyl disulfide to pentyl disulfide are shown in Table 2. Here, as with other initial rate data to be tabulated below, the rates were obtained from a least-squares treatment of mol% vs. exposure time. Standard deviations were between 4 and 6%. The initial rate of mixed disulfide formation is lowest for the dibutyl disulfide – dipentyl disulfide systems. The only significant product of these systems is the mixed disulfide. For longer irradiation times with the higher molecular weight mixtures small amounts of other products (<5%) were observed, but were not identified.

Ten additional combinations were studied to compare initial rates in $n\text{-}C_3H_7SSC_3H_7$–RSSR and $i\text{-}C_3H_7SSC_3H_7$–RSSR mixtures. The data are presented, along with the appropriate rates from Table 2 for comparison, in Table 3.

The change from *n*-propyl disulfide to isopropyl disulfide as the second component of the mixture results in a significant decrease in the rate of product formation. The remarkable exception to this trend is the ten-fold increase for the iso–iso combination.

TABLE 2. Initial rates of mixed disulfide formation for straight chain dialkyl disulfides

(RSSR + R'SSR')	Initial mixed disulfide yields, μmol min^{-1} R' = C_2H_5	*n*-C_3H_7	*n*-C_4H_9	*n*-C_5H_{11}
R = CH_3	14.8	13.9	1.44	0.58

iso-C_4H_9	0.85	8.3
sec-C_4H_9	11.9	4.7
n-C_5H_{11}	0.37[a]	0.14
iso-C_5H_{11}	0.57	5.9

[a]Data from Table 2.

The butyl disulfide – RSSR systems provide an opportunity to examine steric effects over a potentially broader range. Table 4 lists the initial rates for 15 such combinations, again along with 7 rates from Tables 2 and 3 for convenience in comparing values. Two systems could not be studied because of the difficulties in separating reactant and product disulfides.

The additional iso–iso combination included here, 1-$C_5H_{11}SSC_5H_{11}$ – 1-$C_4H_9SSC_4H_9$, shows the even more pronounced rate in rate compared to the analogous *n*–iso system. The trend to lower

n-C_5H_{11}	0.23[a]	0.23	0.13	0.04
iso-C_5H_{11}	0.29	20.6	0.18	0.05

[a]Data from Table 2.
[b]Data from Table 3.

rates with higher molecular weight is again a general characteristic. The lowest rates are observed for the mixtures containing *tert*-butyl disulfide.

In addition to the rates listed in the tables, two other combination were studied, methyl disulfide – isopentyl disulfide and ethyl disulfide – isopentyl disulfide for which the initial rates, in μmol min^{-1}, were 0.71 and 0.61 respectively.

Equimolar mixtures of methyl disulfide and ethyl disulfide were photolysed with three different light sources and apparent initial quantum yield of methylethyl disulfide formation determined as follows: $\phi' = 21.4 \pm 1.9$ (low pressure Hg-lamp, $I_a = 1.28 \pm 0.1$ μEinstein min^{-1}), 20.7 ± 1.8 (medium pressure Hg-lamp, $I_a = 0.81 \pm 0.5$ μEinstein min^{-1} and 24.4 ± 2.2 (325 nm laser, $I_a = 0.16 \pm 0.01$ μEinstein min^{-1}). The values obtained, however, are only apparent quantum yields because of the lack of identity of reactant and actinometer absorption characteristics.

One of the difference factors that can be accommodated, however, is that of concentration. Using 0.762 *M* solution of methyl disulfide – ethyl disulfide in cyclohexane which has the same absorption at 254 nm as the ferrioxalate actinometer, an apparent quantum yield of 15.8 ± 1.0 was found using the low pressure Hg-lamp.

Thus, despite the various uncertainties associated with these data, the quantum yield is evidently on the order of magnitude of 20. On that basis, and if the methyl disulfide – ethyl disulfide system is used as an internal actinometer in this system, disulfide mixtures irradiated with the low pressure lamp and which have initial rates less than 0.75 μmol min^{-1} represent systems with quantum yields less than unity.

The apparent initial quantum yields are evidently independent of both wavelength and, over the very limited range examined, intensity. All wavelengths studied involve excitation in the same absorption band of the disulfides centered at ca. 250 nm and extending to ca. 350 nm. This is consistent with the expectation that in condensed phase the net result of the primary process occurring in this absorption envelope is the production of thermalized RS species.

In previous investigation in this laboratory (7), appreciably higher quantum yields were found. We believe that some of this difference is due to the incorporation into the present experiments of the recently identified (10, 11) modifications and precautions required for accurate light intensity determinations. A more significant factor, however, may be that very small disulfide sample volumes were used in the previous work and the thermal blanks, which in the present systems are insignificant compared to the photochemical reaction in the much larger sample sizes used, may in those experiments, have made a much larger contribution to the total observed yields than was allowed for.

Finally, to establish definitively that the exchange reaction is exclusively free radical in nature, several experiments were conducted in which methyl disulfide – ethyl disulfide mixtures that had been saturated with nitric oxide were photolysed. No mixed disulfide products could be detected in any of these experiments.

Discussion

The general mechanistic features of these disulfide systems are well established. Photolysis leads to S—S bond rupture and the RS radicals formed either recombine, or participate in the exchange reaction with parent disulfide molecules. If a single disulfide is formed, recombination is the only significant reaction and no products can be observed at moderate exposure times.[2]

The overall mechanism which is consistent with the gross features of the photoreaction is as follows:

$$[2a] \quad RSSR + h\nu \leftrightarrows 2\,RS$$

$$[2b] \quad R'SSR' + h\nu \leftrightarrows 2\,R'S$$

$$[3a] \quad R'S + RSSR \rightarrow RSSR' + RS$$

$$[3b] \quad RS + R'SSR' \rightarrow RSSR' + R'S$$

$$[4] \quad RS + R'S \rightarrow RSSR'$$

When the concentration of RSSR′ attains significant levels, its photolysis leads to the observed photo-equilibrium.

$$[2c] \quad RSSR' + h\nu \leftrightarrows RS + R'S$$

The absence of any non-disulfide products and the attainment of the same equilibrium distribution,

[2]Some product formation has been noted (12) for very long exposures in similar systems, but none can be detected from C_2 to C_{10} disulfide mixtures at the exposure times studied here.

independent of proportion of starting material, along with the previously reported (7) attainment of an equilibrium with $K = 4.0$ beginning with 98% $CH_3SSC_2H_5$, all attest to the validity of this representation of the system.

If k_t represents the average value of k_4 and the rate constants for the reverse of reactions [2*a*] and [2*b*]; k_p, the average of k_{3a} and k_{3b}; and [D], the total disulfide concentration in an equimolar mixture, the mechanism predicts the following expression for the quantum yield of methylethyl disulfide formation

$$[5] \quad \phi_{RSSR'} = [D]k_p(1/I_a k_t)^{1/2}$$

The relative contributions of reactions [3] and [4] to RSSR′ formation will be reflected in quantum yields in the following way. To the extent that reaction [3] is the principal source of RSSR′, the observed quantum yields will be in excess of unity. On the other hand, the more important is reaction [4], and the reverse of [2*a*] and [2*b*] taking place in the bulk of the reaction mixture, the lower will be observed ϕ values. Superimposed on this effect will be the influence of cage recombination of the initially formed thiyl radicals in process [2]. The effective value of k_t will thus be influenced by two different types of RS combinations.

Thus in systems with small quantum yields, the observed variations in rates must be due primarily to alterations in the contributions of reactions [2] and [4].

The observed initial rates listed in Table 2 show that for the straight chain disulfide mixtures yields are in approximately inverse proportion of total molecular weight. The one remarkable exception to this trend is the ethyl disulfide – *n*-propyl disulfide mixture. There is no obvious explanation for this observation.[3]

Three other sets of data for comparison can be extracted from the Tables 2–4, to examine the effect of total molecular weight of the mixture of RSSR′ rates; namely *sec*-butyl disulfide – RSSR, *n*-butyl disulfide – RSSR, and *tert*-butyl disulfide – RSSR, where RSSR represents the various straight chain disulfides whose indicated mixtures could be studied. With again one exception, the CS_3SSCH_3 – *sec*-butyl disulfide mixture, the rates are approximately linearly dependent on total molecular weight. The variation observed, however, is much smaller when the RSSR component is changed from CH_3SSCH_3 to *n*-$C_5H_{11}SSC_5H_{11}$ in the *tert*-butyl disulfide – RSSR mixtures (Table 4). In all of those mixtures, the quantum yields of mixed disulfide formation would be less than ca. 0.2. It would appear therefore that in a system where the exchange reaction [3] is not significant, the effect of molecular weight, essentially thiyl radical size, is relatively minor.

The effect of branching can be illustrated by a comparison of the *n*-propyl disulfide vs. isopropyl disulfide mixtures rates reported in Table 3. Excluding the iso–iso combinations to be discussed below, the observed initial rates are always lower for the mixture containing the isodisulfide. The effect appears to be a general one in that it is observed in mixtures with quantum yields both above and below unity. By contrast, in the butyl systems, the data in Table 4 show relatively little diminuition of rate in changing from an *n*-butyl to an isobutyl disulfide mixture component, although again the iso–iso combinations show much higher yields. The reduced sensitivity of rate of radical reactions for butyl disulfide systems compared to their propyl analogues is consistent with the observations of Pryor and Platt (13) in a study of the reactions of phenyl radicals with propyl and butyl disulfides. As observed here, the sensitivity to steric factors was significantly diminished in the isobutyl systems.

Comparing the rates for the *n*-pentyl disulfide – RSSR and isopenyl disulfide mixtures shows that the latter are slightly higher, iso–iso combinations excepted, and the general trend to lower rates with higher total molecular weight is also apparent. The quantum yields here, however, are mostly less than unity. Thus the steric effect related factors which give rise to a decrease in rate in going from *n*- to isodisulfides are more significant when quantum yields exceed unity (propyl systems) or are near unity (butyl systems) and are evidently counterbalanced by other effects when exchange reactions is diminished in importance as evidenced by quantum yields of less than unity.

The systems containing *tert*-butyl disulfide all exhibit very low rates with quantum yields less than ca. 0.2. Here evidently steric effects are the determining factor. They would presumably both militate against radical diffusion, increasing the probability of cage recombination, and render the RS–disulfide exchange less facile.

Finally, the perplexing behaviour of the iso–iso combinations requires comment. Without exception the observed rate for every iso–iso mixture studied is anomalously high both in terms of its value relative to the appropriate *n*-isomers but absolutely in comparison to all systems studied. The iso–iso combinations for C_3- and C_4-disulfides are

[3]To ensure that the inordinately high rate was not the result of an experimental artifact, the rates for these mixtures were redetermined using American Petroleum Institute Standard samples, confirming the initially observed very large values.

about 10 times larger than the corresponding *n*–iso systems; for C_4–C_5 the factor is about 70. Indeed the isobutyl disulfide – isopentyl disulfide combination shows an initial rate greater than that of the reference methyl disulfide ethyl disulfide system. Since the exchange reaction [3] is almost certainly more efficient when CH_3S radicals attack RSSR than the analogous process with iso-C_5H_9S and iso-C_4H_9S the effect must have its origin in reactions [2] and [4].

Further investigation is evidently required to elucidate this aspect of the system. A study is now being initiated in which the photochemical systems studied here will be used to prepare various unsymmetrical disulfides, such as, for example, iso-C_3H_7SS (*n*-C_3H_7), which can be co-photolysed with symmetrical and other unsymmetrical disulfides, so that the precise effect of these steric factors can be elucidated in the greater amount of detail that will evidently be necessary to understand fully the evident complexities in these systems.

WOLFGANG J. WESTERHAUS, OSVALD KNOP, and MICHAEL FALK. Can. J. Chem. **58**, 1355 (1980).

A determination of the crystal structure of ammonium tetraphenylborate (ATPB) at 120 K shows that the ammonium ion in this crystal, at a site of symmetry D_{2d}, is oriented in a way consistent with the expectation from a simple model based on Coulombic interaction. Infrared spectra of the isotopic ammonium ions obtained between 10 K and room temperature indicate that the effect of the tetraphenylborate anion on the strength of the N—H bond (as measured by the stretching frequency) is small and independent of temperature, and that the distortion of the ammonium ion from T_d symmetry is slight. From the combined evidence it is concluded that the ammonium ion in ATPB must be regarded as hydrogen-bonded, but the potential field due to the four phenyl rings surrounding the ammonium ion offers little resistance to the bending (and probably also to the librational) motion of the ion.

WOLFGANG J. WESTERHAUS, OSVALD KNOP et MICHAEL FALK. Can. J. Chem. **58**, 1355 (1980).

Une détermination de la structure cristalline de tétraphénylborate d'ammonium (ATPB) à 120 K montre que l'ion ammonium dans ce cristal, au site de symétrie D_{2d}, est orienté d'une manière conforme à celle prévue à partir d'un modèle simple basé sur une interaction coulombienne. Les spectres infrarouge des ions ammonium isotopiques obtenus entre 10 K et la température ambiante indiquent que l'effet de l'anion tétraphénylborate sur la force de la liaison N—H (telle que mesurée par la fréquence de valence) est faible et indépendant de la température et que la distorsion de l'ion ammonium par rapport à la symétrie T_d est faible. L'ensemble de ces preuves permet la conclusion que l'ion ammonium dans l'ATPB doit être considéré comme lié par des liaisons hydrogène, mais le potentiel dû aux quatre cycles phényl entourant l'ion ammonium offre peu de résistance au mouvement de déformation de l'ion (et probablement aussi au mouvement de libration).

[Traduit par le journal]

Introduction

The recent renewal of interest (2, 3) in the title compound (ATPB) has been prompted by the remarks of Nakamoto *et al.* (4) in a paper dealing with stretching frequencies as a function of distance in hydrogen bonds. These authors quote the results of Bonham, who found the ir "non-hydrogen-bonded" NH stretching frequencies for various salts of the $(NEt_nH_{4-n})B(C_6H_5)_4$ type to lie near 3100 cm^{-1}, and they compare these frequencies to the corresponding frequencies in other ammonium salts (e.g. in NH_4Cl, 3110 cm^{-1}) "where hydrogen bonding is probably not an important factor". They note that these frequencies are rather low for hydrogen-bonding interactions as weak as those in N^+—H···Cl^- bonds and suggest that the low frequencies found in such bonds "arise only partly from hydrogen bonding". Consequently charge and coordination effects must be taken into account. The implication for ATPB thus appears to be that (*i*) the hydrogen bonding in this crystal is very weak and (*ii*) the NH stretching frequency is unexpectedly low (i.e. it appears to correspond to a stronger hydrogen bond than the trends observed in other crystals containing N—H···X bonds would warrant), and that for reasons other than hydrogen-bonding interactions. In the present paper we examine new evidence bearing on these two points. Here, as elsewhere in this series, the term "hydrogen bonding" shall include all factors which restrict rotation of the ammonium ion to torsional oscillations.

In Parts IV and VI (2, 3) we reported the isolated ND stretching and bending frequencies of the NH_3D^+ probe ion in ATPB at 90 K. The stretching frequency $\nu_1(NH_3D^+)$, 2364 cm^{-1}, is significantly above the corresponding frequency in NH_4Cl, 2289 cm^{-1}, but similar to the isolated ND stretching frequencies in $(NH_4)_2PbCl_6$ and $(NH_4)_2TeCl_6$, in which crystals hydrogen bonding is judged to be weak but not absent. The position of ATPB in a $\nu_1(NH_3D^+)$ vs. N···X distance plot (X = F, Cl, Br, I; Fig. 1 of ref. 3) is uncertain, for we do not know what constitutes the appropriate N···X distance in this crystal, but in the $\nu_{4bc}(NH_3D^+)$ vs. $\nu_1(NH_3D^+)$

plot (Fig. 3 of ref. 3) the ATPB point falls in a region characteristic of weak hydrogen bonding and high C.N. The ν_{4bc} frequency of ATPB at 90 K is in fact lower than any ν_{4bc} (90 K) frequency observed in an ammonium halide to date. The ν_1 frequency is higher than our estimate of the 'free-ion' ν_1 frequency in simple and complex ammonium halides.[3] This we have ascribed (3) to a state of compression of the ammonium ion in the structure, which is dominated by electrostatic forces; this explanation in a way implies the suggestion of Nakamoto *et al.* that coordination effects are important. The K (5, 6) and Rb (7, 8) tetraphenylborates have been reported to be isostructural with ATPB (disregarding the ammonium hydrogens), and the unit-cell dimensions of the Rb salt (7–9) are practically indistinguishable from those of ATPB. From this it is evident that the non-uniform charge distribution on the ammonium ion and the hydrogen-bonding ability of NH_4^+ do not play a structure-determining role in this crystal at room temperature, which supports the above implication (*i*).

Clearly the increase in ν_1 from the 'free-ion' value[3] due to the compression ('volume') effect could overwhelm any ν_1 lowering that might result from a vestigial hydrogen-bonding interaction. This raises the interesting question of the whereabouts of the ammonium hydrogens in the crystal and the nature of the hydrogen-bonding interaction in a situation where a single ionic charge is spread over an assembly of a number of atoms. Considering the spatial dilution of the anionic charge, there seems to be *a priori* no reason why reorientation of the ammonium ion should not approximate to a very weakly hindered 'free' rotation, unless interaction between the ammonium hydrogen and the charge in the π systems of the benzene rings is significant. If it is, there ought to be a reasonable chance of finding the ammonium hydrogens localized in regions of space corresponding to the hydrogen-bonding geometry between reorientations.

A determination of the room-temperature crystal structure of ATPB by photographic methods (7) did not provide any indication of where the ammonium hydrogens might be located. We therefore set out to redetermine the room-temperature structure from diffractometer intensities and supplement it by a companion determination at low temperature, in the hope that the information so obtained would go some way toward resolving the problem. At the same time we extended the ir study of the NH_3D^+ probe ion in ATPB to include the effect of temperature between 10 and 293 K on the spectrum of this ion as well as on certain bands of the NH_4^+ and ND_4^+ spectra.

[3]We do not know to what extent the 'free-ion' ν_1 frequency estimated for ammonium halides (3) is applicable to ATPB, ammonium halides being so far the only group of ammonium compounds for which such a frequency is available, but it is our present belief that the use of this estimate represents the situation in ATPB essentially correctly.

Structure Determination

Needle-shaped crystals of ATPB (fw = 337.28) precipitated on mixing aqueous solutions of equimolar amounts of the commercial Na salt and NH_4Cl at room temperature. Recrystallization from a 1:1 mixture of water and acetone yielded small stout prisms well suited for diffraction experiments.

Weissenberg photographs at room temperature indicated a body-centred tetragonal unit cell. This is consistent with the space groups $I\bar{4}m\underline{2}$ and $I\bar{4}2m$ considered as likely in ref. 9 and with $I\bar{4}2m$ resulting from the structure determination of ref. 7. The crystallographic data are presented in Table 1. No evidence of crystallographic transition between 10 K and room temperature was found in the ir spectra of ATPB, deuterated or undeuterated, in accord with the unchanged crystallographic symmetry observed at 120 K (see below) and with the heat capacity measurements between 20 and 298 K (Staveley and Davies, cited in ref. 7).

Crystal Structure at Room Temperature

Intensities from a 0.2 × 0.2 × 0.36 mm³ crystal were measured on a Picker FACS-1 diffractometer with an ω–2θ scan ($4° \leq 2\theta \leq 120°$; minimum base width, 2.0°) using Cu Kα radiation. Of the 245 independent reflections 198 had $I > 3\sigma(I)$; these were used in the structure determination. The data were reduced to a standard scale by a routine procedure and corrected for Lorentz and polarization factors but not for absorption ($\mu_{Cu} = 4.05\ cm^{-1}$). Four reflections (110, 002, 004, 006) which were obvi-

*Numbering of atoms as in ref. 6; associated C and H atoms bear the same number. *S*, site symmetry. Upper line, room temperature; lower line, 120 K. The positional parameters have been multiplied by 10^4 and the thermal parameters by 10^3. The anisotropic temperature factor is defined as $T = u_{11}a^{*2}h^2 + 2u_{12}a^*b^*hk + \ldots$.
†Isotropic temperature factor.
‡At 120 K, see text.

ously affected by extinction were omitted from the calculations. Scattering factors for neutral atoms were taken from ref. 10.

The positional parameters of the non-hydrogen atoms in the K salt (6), with N replacing K, were used as starting parameters for a full-matrix least-squares refinement in $I\bar{4}2m$, initially with isotropic temperature factors. The phenyl hydrogens (but not the ammonium hydrogens) were located on a difference Fourier map when the conventional *R* was 0.11. With anisotropic temperature factors for all non-hydrogen atoms *R* converged to 0.047. A difference Fourier map at this stage showed four symmetry-related regions of higher density at approximately 1 Å from the N atom. Fixing the ammonium hydrogens in these positions and taking 0.08 Å^2 as their isotropic temperature factors resulted in $R = 0.040$ and $R_w = 0.041$.[4] A refinement of the positional parameters of all the atoms, including the ammonium hydrogens, converged but yielded very short N—H distances (0.63 Å) and large esd's.

The final values of the positional and thermal parameters are listed in Table 2. The positional parameters differ only slightly from those obtained by Webster (7) using an overall isotropic temperature factor. The geometry of the tetraphenylborate ion is practically indistinguishable from the geometry of the ion in the K salt (6), the differences between the interatomic distances being within one or at most two standard deviations, and similarly for the bond angles.

Crystal Structure at Low Temperature

For the structure determination from low-temperature intensities a larger crystal (0.25 × 0.25 × 0.7 mm^3) and an Enraf-Nonius CAD-4 diffractometer fitted with a cold-gas-flow cryogenic device were used. The crystal was enclosed in a glass capillary. The unit-cell dimensions at 120(10) K are shown in Table 1. The intensity collection at this temperature using Mo Kα radiation (μ_{Mo} = 0.32 cm^{-1}) gave 293 independent reflections with $I > 2\sigma(I)$. All but two were used in the refinement; the 110 and 002 reflections suffered from extinction and were omitted.

A refinement starting from the room-temperature parameter values (excluding the ammonium hydrogens) brought the *R* value down to 0.052. A difference Fourier map at this stage showed four symmetry-related peaks at 0.97 Å from the N atom. Including hydrogens with positional parameters corresponding to these maxima reduced *R* to 0.044 and R_w to 0.041 and gave reasonable esd's for both the positional and thermal parameters of these

[4]Weighting schemes of the type $w^{-1} = \sigma^2|F_o| + k|F_o|^2$ (σ = individual esd calculated from diffractometer counting statistics) were used in all refinements.

atoms, comparable to those of the phenyl hydrogens. The final parameter values are compared in Table 2 with those from the room-temperature determination. Interatomic distances and bond angles in the tetraphenylborate anion calculated from these values are listed in Table 3.

Discussion

A projection of the contents of a unit cell of ATPB on (001) is practically identical with the projection for the K salt in Fig. 1 of ref. 6. The ammonium ion, at a site of symmetry D_{2d}, is inside a cage formed by two pairs of phenyl rings, each pair belonging to a different anion; the two pairs are rotated by 90° relative to each other into a tetrahedral configuration. The electron density distribution corresponding to the ammonium hydrogens is illustrated in Fig. 1. The difference Fourier map obtained with the 120 K data shows clearly the regions of excess electron density associated tetrahedrally with the N atom. The local maxima (labelled H(5) in Table 2) are at 0.98 Å from N and their radius vectors from N point into the phenyl rings, the nearest carbon being C(4) at 2.44 Å and the farthest C(1) at 2.78 Å. The maxima form with the N atom an angle of 152° with the S_4 axis as bisector, and 93° with a twofold axis parallel to (001) as bisector.

The nearest N—H vector of an undistorted NH_4^+ tetrahedron in this orientation would form an angle of ~80° with the C(1)—C(4) line, whilst the radius vector corresponding to H(5) forms an angle of ~60°, i.e. H(5) is closer to C(4) and so presumably closer to the effective location of one-quarter of the anionic charge. It thus appears that the location of the maxima, which does not coincide with the positions of the ammonium hydrogens required by undistorted tetrahedral geometry, is determined by the dynamic behaviour of the ammonium ion.

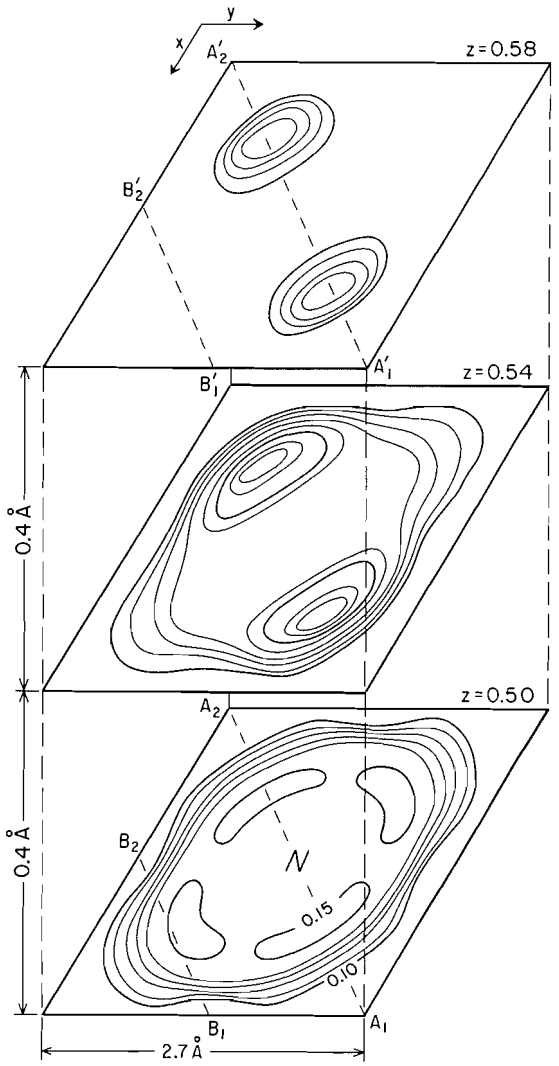

FIG. 1. Difference Fourier map of ATPB at 120 K. Axonometric presentation of sections parallel to (001) showing the 0.01 e/Å^3 contours around the B atom at $(0, 0, \frac{1}{2})$. The $z = 0.46$ and 0.42 sections (not shown) are obtained from the $z = 0.54$ and 0.58 sections respectively through operations of D_{2d} at the $(0, 0, \frac{1}{2})$ site. The outermost contour in each section corresponds to 0.10 e/Å^3.

At room temperature maxima attributable to the ammonium hydrogens are much more diffuse and no meaningful statement can be made about the most probable positions of these atoms.

The question of what constitutes hydrogen bonding apart, the observed orientation of the NH_4^+ ion in ATPB may be viewed simply as a consequence of the nonuniform charge distribution

on both ions. Webster (7), without specifying details of the calculation, makes the following statement: "It is calculated that the electrostatic potential energy is lowest when the H atoms of the ammonium ion point towards the centres of the benzene rings. After rotation of the ion through 90° about the *c*-axis, the potential energy is considerably greater and likely to prevent free rotation. When rotated in a direction perpendicular to the *c*-axis, the ion passes through several positions of varying maximum and minimum energy, so that the true nature of the oscillation of the ion is probably complicated." Limited point-charge calculations, with charges of equal magnitude and having the appropriate signs placed on the ammonium hydrogens and the C(4) atoms, confirm Webster's finding (Fig. 2); results of the same type are obtained when the negative charges are on the C(1) instead of the C(4) carbons. It may be significant that rotation about the S_4 axis of the ammonium ion (Fig. 2*A*) is more restrictive than the rotations about axes perpendicular to S_4 (Figs. 2*B*, *C*), for this difference is consistent with what is seen in the Fourier map.

Calculation of the corresponding variation of the Coulombic energy with angle of rotation for other types of reorientation of a rigid NH_4^+ ion, e.g. rotation about a threefold axis, was not attempted. Whilst calculation of the potential energy variation over the entire sphere of rotation would admittedly be instructive, the model underlying the results shown in Fig. 2 is too simplistic to warrant a more extensive effort in that direction. It seems unlikely that a potential minimum lower than that for $\alpha = 45°$ would be found, and the latter should be considered to be the global minimum in the absence of a proof to the contrary.

Infrared Spectroscopy

Partially deuterated ATPB samples were prepared by recrystallization from H_2O–D_2O–acetone mixtures of the appropriate D content. The sample crystals were finely ground and mulled with hydrocarbon or fluorocarbon oil. The mulls were sandwiched between KBr or CaF_2 plates. Details of the ir spectrometer will be found in ref. 11.

The NH_3D^+ probe ion spectrum was studied with samples containing 0.5% D, effectively corresponding to infinite dilution. The highest deuteration obtained, ca. 95% D, was adequate for a study of ND_4^+ and NHD_3^+ bands. However, as the concentration of the latter ion in this sample was not sufficiently low to qualify as isotopic isolation, only the NH stretching frequency of NHD_3^+ is reported. The principal bands of the isotopic ammonium ions observed between 4000 and 1000 cm^{-1} are listed in Table 4.

NH_3D^+ Absorptions

At 10 K the ND stretching fundamental ν_1 and the ND bending fundamental ν_{4bc} (for notation, see ref. 3 and preceding papers in this series) give rise to sharp single bands with halfwidths (= full width at half height) of only 3–4 cm^{-1} (Fig. 3). At higher temperatures both bands broaden and the integrated intensity of ν_1 diminishes, whilst that of ν_{4bc} remains nearly constant. The frequencies shift very little: between 10 K and room temperature ν_1 has shifted by only $-1.6(6)$ cm^{-1} and ν_{4bc} by only $+1.5(6)$ cm^{-1}, while their halfwidths have increased to 11–14 cm^{-1}. The changes of the observed band parameters are gradual (Fig. 4).

NH_4^+ and ND_4^+ Absorptions

A consequence of the large separation of the ammonium ions in the crystal, $d(N\cdots N) \sim 8$ Å, is a relatively weak vibrational coupling between neighbouring ions, with the result that the features observed in the NH_3D^+ probe spectrum are replicated with considerable fidelity in the NH_4^+ and ND_4^+ spectra.

The ir-active fundamental $\nu_3(NH_4^+)$ gives rise, at 10 K, to one main absorption peak and three smaller peaks (Fig. 5); corresponding four maxima appear in the ND_4^+ spectrum. The H/D frequency ratios are about 1.33. This precludes the possibility that some of the bands are due to combinations of ν_3 or ν_1 with translational or collective lattice modes, as such combinations would be expected to yield lower ratios. At higher temperatures the three smaller peaks rapidly lose intensity, and above about 100 K only one symmetric $\nu_3(NH_4^+)$, or $\nu_3(ND_4^+)$, fundamental is observed (Fig. 5). The ir-active bending fundamentals $\nu_4(NH_4^+)$ and $\nu_4(ND_4^+)$, as well as the corresponding overtones $2\nu_4(NH_4^+)$ and $2\nu_4(ND_4^+)$, give rise to only one band each, even at 10 K.

We have examined with special interest the 1600–1700 cm^{-1} region in the spectrum of undeuterated ATPB, where the combination mode $\nu_4 + \nu_6$ involving the librational mode $\nu_6(NH_4^+)$ may occur. At 10 K three sharp bands were observed, at 1712.6, 1686.3, and 1608.5 cm^{-1}. Their intensities diminished rapidly with increasing temperature and the bands were no longer evident above 100 K (Fig. 6). On deuteration the bands disappeared but similar bands emerged in the ND_4^+ spectrum between 1200 and 1250 cm^{-1}. Whilst the exact correspondence of the NH_4^+ and ND_4^+ features is uncertain (the H/D frquency ratios vary from 1.33 to 1.38

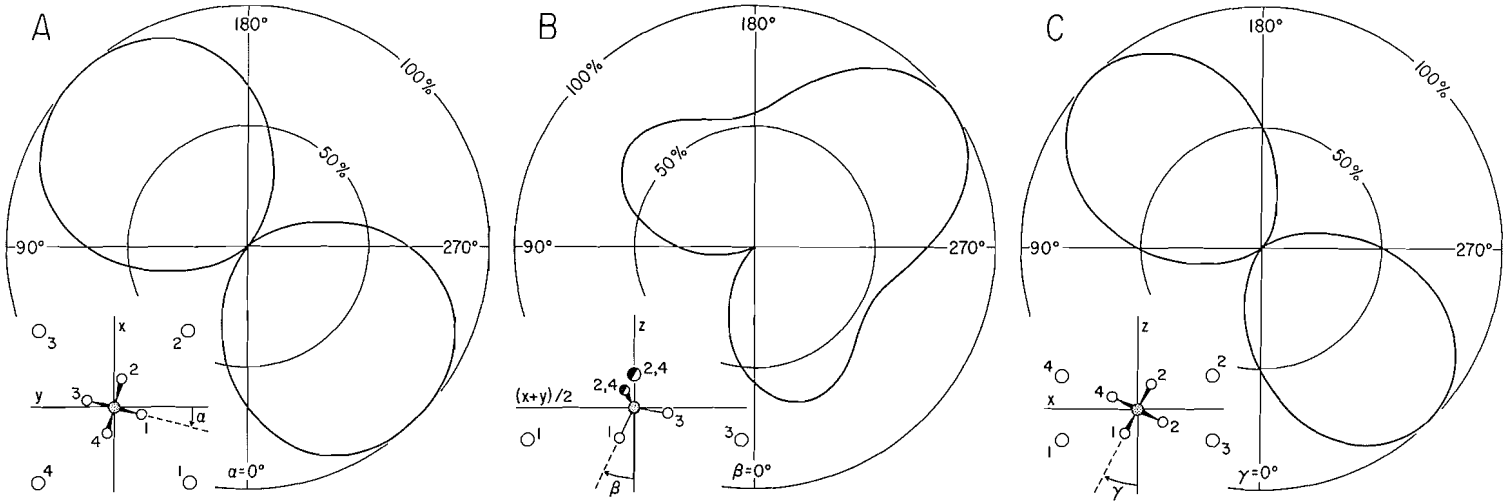

FIG. 2. Variation of the Coulombic interaction energy with the angle of rotation of a rigid NH_4^+ tetrahedron in ATPB. Point charges of equal magnitude are placed on the ammonium hydrogens (positive) and on the C(4) atoms of the anion (negative). (*A*) Rotation about the S_4 axis of the ammonium ion (coincident with *z*). (*B*) Rotation about a line bisecting *x* and *y*. (*C*) Rotation about a C_2 axis of the ammonium ion (coincident with *y*). The values plotted as functions of the angle of rotation represent percentages of the difference between the maximum and the minimum value of the Coulombic energy resulting from the calculation. The minimum value, which corresponds to the most symmetric static orientation of the ammonium ion ($\alpha = 45°$, as found by experiment), is believed to be the global minimum for this model.

*The precision of the peak-frequency determination (in parentheses) depends on band shape and intensity. The accuracy of the frequency scale is about ±1 cm^{-1}.
†Intensity rapidly decreases with increasing temperature. Band not observable above about 100 K.
‡This is the ν_{4bc} frequency.

(Table 3)) a strong argument in support of the assignment of these bands to $\nu_4 + \nu_6$ is that no other NH_4^+ absorption occurs in this region except for the bending fundamental $\nu_2(NH_4^+)$. That fundamental, however, is ir-inactive under the D_{2d} site symmetry and has been observed only in a few cases of extreme distortion of the ammonium tetrahedron (cf. ref. 11).

Deductions from the Spectra

(*a*) For $\nu_{4bc}(NH_3D^+)$ the D_{2d} site symmetry of the ammonium ion requires a 1:1 doublet (12). Only a single sharp band is observed down to 10 K, which implies that the symmetry of the ion is effectively T_d, as concluded previously (2). For $\nu_4(NH_4^+)$, $\nu_4(ND_4^+)$, $2\nu_4(NH_4^+)$, and $2\nu_4(ND_4^+)$ two ir-active components are expected under D_{2d}, but only a single band is observed in each case, again implying that the symmetry of the ion is effectively T_d.[5] One may conclude that hydrogen bonding is either very weak or absent; more correctly, there is no indication of hydrogen-bonding interactions that would exert an appreciable distorting force on the ion.

(*b*) For $\nu_1(NH_3D^+)$ a single band is expected for both T_d and D_{2d} symmetry (12). The observed singlet therefore provides no information as to whether or not the ammonium ion is distorted. For $\nu_3(NH_4^+)$ and $\nu_3(ND_4^+)$ a doublet is expected under the D_{2d} site group as opposed to a singlet under T_d. The single band observed above 100 K is consistent with the absence of appreciable distortion from T_d, but the emergence of additional bands on further cooling appears to indicate that some distortion may be present. However, the number of the observed features is larger than expected for a simple distortion. The origin of the small additional bands thus remains uncertain and no firm deduction can be made.

(*c*) As pointed out above, the frequency of the $\nu_{4bc}(NH_3D^+)$ absorption, 1234 cm^{-1}, is the lowest on record. The 293 K frequency of $\nu_4(NH_4^+)$, 1391 cm^{-1}, is lower than all but one of the 35 $\nu_4(NH_4^+)$ frequencies reported for an assortment of ammonium salts at room temperature by Waddington (13) and by Dunsmuir and Lane (14); the only lower frequency is that of $(NH_4)_2ReI_6$, 1388 cm^{-1}. The $2\nu_4(NH_4^+)$ frequency, 2774 cm^{-1}, again is the lowest of the 29 $2\nu_4$ values reported in refs. 13 and 14. These very low frequency values indicate that the potential field due to the four phenyl rings offers little resistance to the bending motion of the ammonium ion, hence hydrogen bonding must be very weak or absent.

(*d*) In contrast, the value of the $\nu_3(NH_4^+)$ frequency is not exceptional. The reported values vary from 3100 to 3300 cm^{-1}, with 14 values higher and 20 values lower than the frequency for ATPB,

[5]The $2\nu_4/\nu_4$ frequency ratio is independent of temperature and isotopic substitution: the average for the values listed in Table 4 is 1.9940(2).

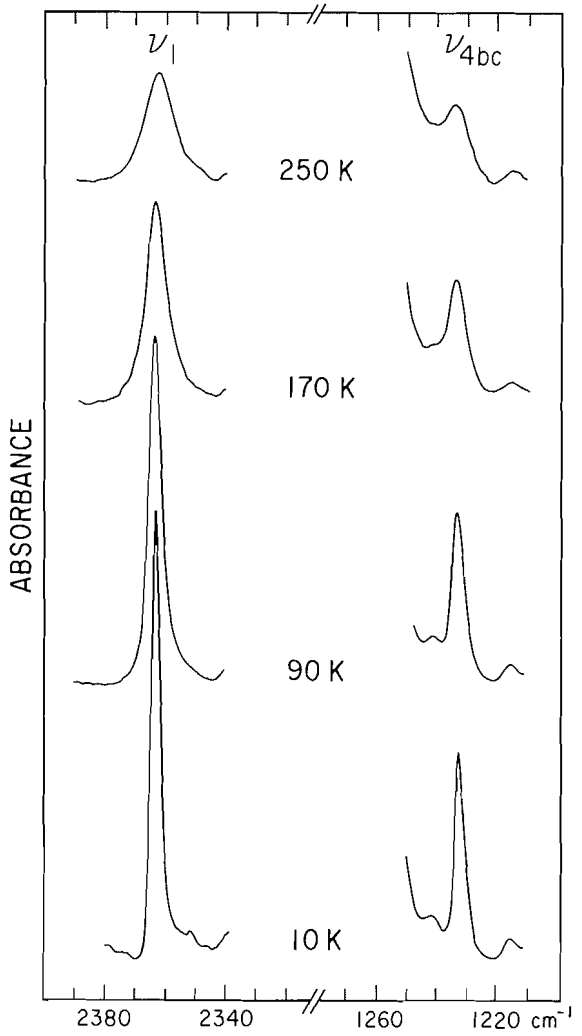

FIG. 3. The regions of the ND stretching fundamental $\nu_1(NH_3D^+)$ and the ND bending fundamental $\nu_{4bc}(NH_3D^+)$ in the ir spectrum of ATPB (0.5% D) at different temperatures.

3216 cm^{-1}. Likewise, the $\nu_1(NH_3D^+)$ frequency is not exceptional for an ammonium ion involved in weak hydrogen bonding. In the plot of $\nu_1(NH_3D^+)$ vs. $\nu_{4bc}(NH_3D^+)$ (Fig. 3 of ref. 3), the point for ATPB falls below the points for cubic $(NH_4)_2MCl_6$ and $(NH_4)_2MBr_6$. This indicates that, by comparison, the hydrogen-bonding interaction in ATPB, as measured by the ν_1 frequency, is very weak but still evident.

(*e*) The bending and stretching frequencies of ATPB remain nearly stationary with temperature between 10 and 293 K. This is a situation analogous to that in $(NH_4)_2SnCl_6$ and $(NH_4)_2PtBr_6$ (11) and is a manifestation of the weakness of hydrogen bonding.

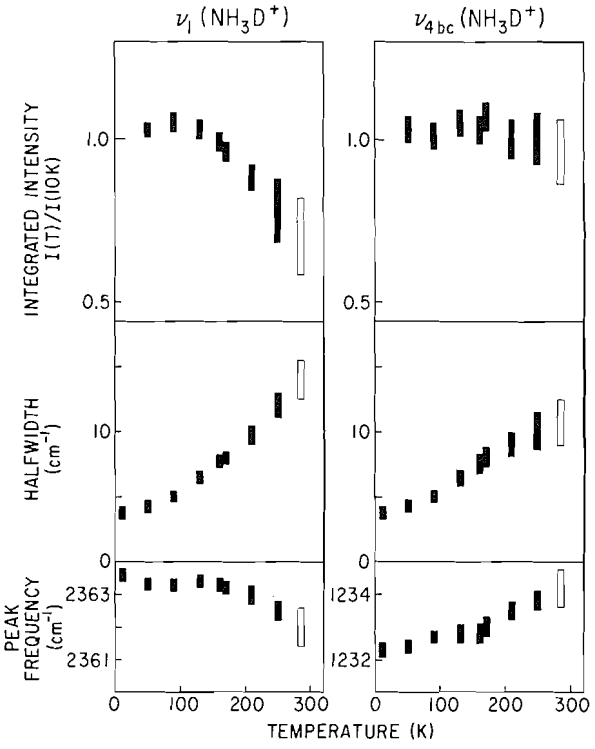

FIG. 4. Effect of temperature on band parameters of $\nu_1(NH_3D^+)$ and $\nu_{4bc}(NH_3D^+)$ of ATPB (0.5% D). The open rectangles denote values at 293 K obtained by extrapolation. The integrated intensities are normalized to the respective 10 K values.

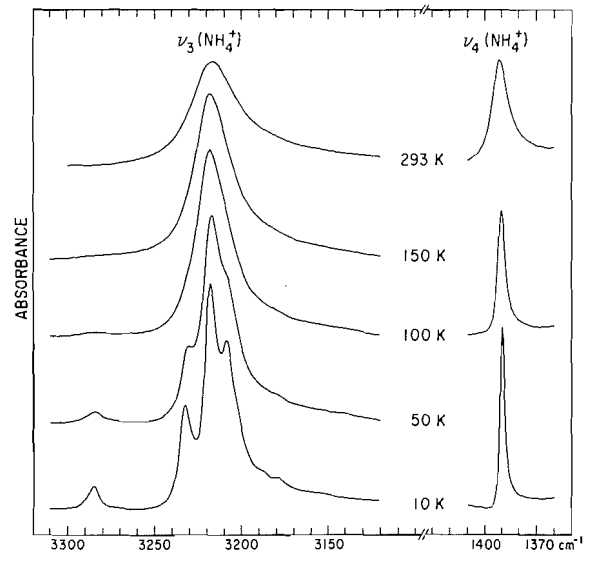

FIG. 5. The regions of the stretching fundamental $\nu_3(NH_4^+)$ and the bending fundamental $\nu_4(NH_4^+)$ in the spectrum of undeuterated ATPB at different temperatures.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

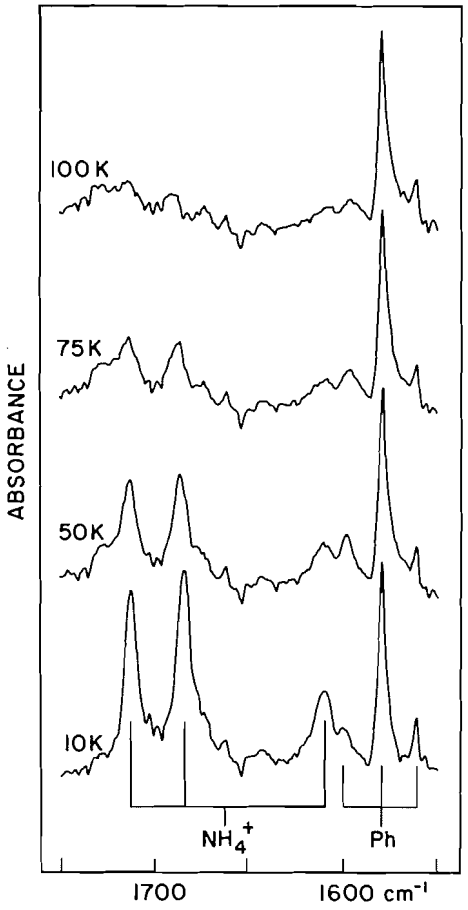

FIG. 6. The region of the combination mode $\nu_4 + \nu_6$ of NH_4^+ in the spectrum of undeuterated ATPB at different temperatures. The bands marked Ph are due to vibrations of the phenyl groups of the anions.

(*f*) In contrast to the band frequencies, which remain almost unchanged, the integrated intensity of the stretching vibrations is appreciably lowered when the temperature is increased above 150 K. The bending vibrations do not undergo such weakening. These observations indicate that the stretching modes have an increased intensity at low temperatures, implying the presence of at least some weak hydrogen bonding.

(*g*) The absorptions due to both the stretching and bending modes of NH_3D^+, NH_4^+, and ND_4^+ gradually broaden as the temperature increases. Studies of other ammonium salts (refs. 1 and 11 and results to be published) seem to indicate that such broadening occurs independently of the strength of hydrogen bonding and cannot serve as its indicator.

(*h*) Some of the evidence under *a* to *g* supports the existence of weak but significant hydrogen bonding (*d*, *f*), some of it indicates the absence of hydrogen bonding (*a*, *c*, *e*), and some of it is indeterminate (*b*, *g*). However, the occurrence of the bands clearly due to the combination $\nu_4 + \nu_6$ (involving the librational mode ν_6) in the low-temperature spectra of both NH_4^+ and ND_4^+ can be taken, following Waddington (13), as unequivocal evidence of the presence of weak hydrogen bonding at least at low temperatures. From the fact that these bands diminish rapidly with increasing temperature and are not observable above 100 K we may estimate the strength of the hydrogen bonding in ATPB relative to that in other ammonium compounds. In the spectrum of $(NH_4)_2SnCl_6$ the $\nu_4 + \nu_6$ bands disappear somewhere between 22 and 80 K (3), whilst those in the spectrum of NH_4ClO_4 disappear at about 150 K (results to be published). The strength of the hydrogen bonding in ATPB is thus intermediate between these two cases.

Conclusions

The picture that emerges on combining the crystallographic and spectroscopic evidence is then as follows. The ammonium ion in ATPB is at a site of symmetry D_{2d} from 10 K to room temperature, but its distortion from T_d symmetry is slight, in fact insufficient to produce an observable splitting of the ν_4, $2\nu_4$, and ν_{4bc} absorptions. The interaction which exists between the charges on the ammonium hydrogens and those residing in the π systems of the anion is strong enough to prevent the ammonium ion from rotating freely, but as the very low value of the $\nu_{4bc}(NH_3D^+)$ frequency indicates, the shape and magnitude of the potential barrier permit rotational displacements of the N—H bonds of appreciable amplitude even at 120 K, at least in some directions. The effect of the anion on the strength of the N—H bond, as measured by the values of the $\nu_1(NH_3D^+)$ and $\nu_3(NH_4^+)$ stretching frequencies, is small, comparable to that in the weakly hydrogen-bonded ammonium ions in $(NH_4)_2MCl_6$ and $(NH_4)_2MBr_6$, and practically unaffected by changes of temperature. We conclude that hydrogen-bonding interactions (i.e. the totality of factors which reduce free rotation of the ammonium ion to torsional oscillations) are present in ATPB, certainly at 120 K and below, and that the ir–spectroscopic manifestations of these interactions are consistent with their weakness.

Revision of the structures of partially acylated derivatives of aldose diethyl dithioacetals

T. Bruce Grindley[1] and Rathy Ponnampalam

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 28, 1979

T. Bruce Grindley and Rathy Ponnampalam. Can. J. Chem. **58**, 1365 (1980).

^{1}H nuclear magnetic resonance spectroscopy is used to correct the structures of most of the known partially acylated derivatives of aldose diethyl dithioacetals which contain more than one acyl group. Previous work had suggested that the hydroxyl group on carbon-2 was the least readily acylated secondary hydroxyl group; current work indicates that it is among the most readily acylated. Evidence is presented which shows that the preferential methylation of aldose diethyl dithioacetals at O-2 is caused by the presence of the sulfur atoms.

T. Bruce Grindley et Rathy Ponnampalam. Can. J. Chem. **58**, 1365 (1980).

La spectroscopie de rmn ^{1}H est utilisée pour corriger la structure de la plupart des dérivés connus, partiellement acylés, des diéthyl dithioacétals d'aldose contenant plus d'un groupe acyle. Des travaux antérieurs ont suggéré que le groupe hydroxyle sur le carbone 2 était le groupe secondaire le moins facilement acylé. Le présent travail indique que ce groupe est un des plus facilement acylés et on y démontre aussi que la méthylation préférentielle des diéthyl dithioacétals d'aldose à la position O-2 est due à la présence d'atomes de soufre.

There has been considerable interest in the selective acylation of carbohydrates in the last few years (1). This activity has been directed at evaluating the relative reactivities of the various hydroxyl groups and also at generating useful synthetic intermediates. Although little systematic attention has been given to the partial acylation of aldose diethyl dithioacetals, a number of partially acylated derivatives have been synthesized (2–7). It is well established that acylation can be performed selectively at the terminal primary hydroxyl position (2). In addition, a number of derivatives which are more fully substituted have been prepared in fair to good yields (3–7). With one exception (7), the structures of these derivatives were considered to have the acyl groups on the terminal hydroxyl group and then progressively up the carbon skeleton. For instance, the tri-*O*-benzoyl derivative of D-galactose diethyl dithioacetal was considered to be the 4,5,6-tri-*O*-benzoyl derivative (6). One of these derivatives, the tetrabenzoyl derivative of D-glucose diethyl dithioacetal, has been the subject of a number of reports (9–11) and it has been considered an important enough intermediate for its preparation to be included in *Methods in Carbohydrate Chemistry* (12). The structures of these derivatives were established by chemical methods of which the most important involved initially treating the partially acylated derivative with silver oxide and methyl iodide. Since migration of acyl groups is known to occur under these conditions (1), we considered the structures of the derivatives established in this way to be uncertain. In this publication, we revise the structures of four of the five known derivatives of this type.

Results

Structural Assignment

Structural assignments for this series of compounds were made from the ^{1}H nmr spectra by using the well-known observation (13) that conversion of an hydroxyl group to an acetate causes the signal for a geminal secondary proton to appear 1.0–1.2 ppm downfield from its position in the unsubstituted derivative. The effect of a benzoate group is similar. Since the number of acyl groups present in each derivative was already known, the above observation allowed totally unambiguous structural determination after the individual signals in the ^{1}H nmr spectra had been assigned to specific protons.

2,4,5,6-Tetra-O-benzoyl-D-glucose Diethyl Dithioacetal (1) and its Derivatives

A single tetrabenzoyl derivative (**1**) of D-glucose diethyl dithioacetal had been previously prepared both under Schotten–Baumann conditions (3, 12) (51% yield) and with benzoyl chloride in pyridine (9) (20% yield). To assign its structure, compound **1** had been methylated (14) with silver oxide and methyl iodide to give a monomethyl derivative, which, after debenzoylation and treatment with phenylhydrazine and acid, gave a methoxyl-free osazone. On this basis, compound **1** was assumed to be 3,4,5,6-tetra-*O*-benzoyl-D-glucose diethyl dithioacetal. The tetrabenzoyl derivative synthesized in the current work has nearly identical physical constants as the derivative obtained ear-

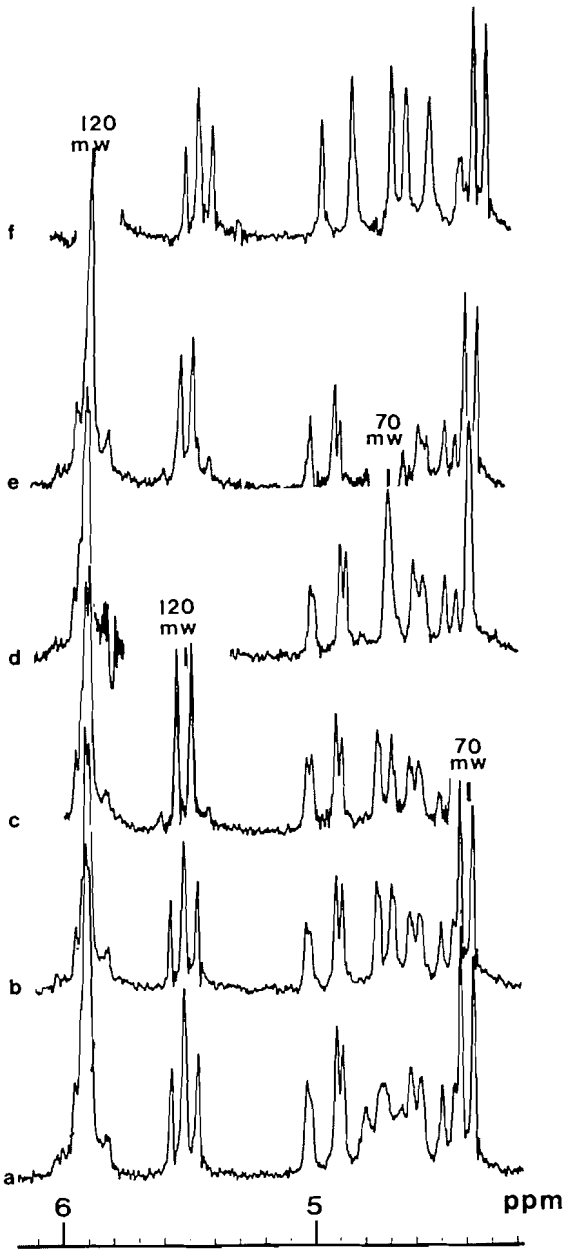

FIG. 1. Partial ^1H nmr spectra at 100 MHz of 2,4,5,6-tetra-*O*-benzoyl-D-glucose diethyl dithioacetal (**1**) in chloroform-*d* under various conditions: (*a*) normal spectrum; (*b*) after exchange with water-d_2; (*c*)–(*f*) decoupling experiments on the exchanged sample using the power indicated.

lier (3, 9, 12). In the nmr spectrum of **1** at 100 MHz in chloroform-*d*, the signals for the individual skeletal protons could be assigned easily by exchange with water-d_2 and by a series of selective homonuclear decoupling experiments. The definitive experiments are shown in Fig. 1. The chemical shifts and coupling constants were obtained by iterative fitting of the signals for H-2, H-3, H-4, H-5, H-6, and H-6′ in the spectra after exchange using a locally modified version of the computer program LAOCN-4A (15). The ^1H nmr spectral parameters are reported in Tables 1 and 2. The signals for H-2, H-4, and H-5 are distinctly further downfield ($\geq$ 0.8 ppm) than that of H-3. In addition, the signal for H-3 shows coupling to a proton which is removed by exchange with water-d_2. Thus, this compound must be 2,4,5,6-tetra-*O*-benzoyl-D-glucose diethyl dithioacetal.

Methylation of **1** with silver oxide and methyl iodide in dioxane gave a monomethyl derivative (**2**), in 58% yield, with identical physical properties to that obtained earlier (14). In the nmr spectrum at 100 MHz of **2** in chloroform-*d*, all signals could be assigned unambiguously by means of a series of decoupling experiments starting with the distinctive doublet for H-1. The signal for H-2 was a quartet at δ 3.83, more than 1.97 ppm upfield of any of the signals for the secondary protons (see Table 1). Thus, this compound was 3,4,5,6-tetra-*O*-benzoyl-2-*O*-methyl-D-glucose diethyl dithioacetal and a benzoyl group had migrated during the methylation step.

Treatment of 2,4,5,6-tetra-*O*-benzoyl-D-glucose diethyl dithioacetal (**1**) with mercuric chloride in absolute methanol in the presence of cadmium carbonate gave the dimethyl acetal (**3**) in 39% yield. All signals in the ^1H nmr spectrum of **3** in

[a]Downfield from internal TMS in chloroform-*d*.
[b]From spectra at 100 MHz.
[c]From spectra at 250 MHz.
[d]H-5 and H-5′
[e]From spectra at 79.6 MHz.

chloroform-*d* at 250 MHz were assigned to specific protons using decoupling and exchange with water-d_2. Examination of the chemical shifts of the proton signals (see Table 1) showed that the product **3** was 2,4,5,6-tetra-*O*-benzoyl-D-glucose dimethyl acetal. Methylation of **3** under the same conditions as **1** yielded a mixture which was shown by high pressure liquid chromatography to consist of one major component plus a number (>4) of minor components. The major product was separated (48% yield) by preparative high pressure liquid chromatography and was shown by ^{1}H nmr spectroscopy as previously (see Tables 1 and 2) to be 2,4,5,6-tetra-*O*-benzoyl-3-*O*-methyl-D-glucose dimethyl acetal (**4**).

2,4,5-Tri-O-benzoyl-D-xylose Diethyl Dithioacetal (5)

A tribenzoyl derivative (**5**) of D-xylose diethyl dithioacetal had been previously prepared in 29% yield under Schotten–Baumann conditions (4). The same compound was prepared here under both Schotten–Baumann conditions and in better yield (52%) with benzoyl chloride in pyridine. As previously, the ^{1}H nmr spectrum of this compound could be used for structural assignment. The signals for two secondary protons, H-2 and H-4, were considerably downfield of that of the third (H-3). The signal for H-3 also showed coupling to an OH proton. Thus this derivative is 2,4,5-tri-*O*-benzoyl-D-xylose diethyl dithioacetal. The structure of this compound had previously been considered to be 3,4,5-tri-*O*-benzoyl-D-xylose diethyl dithioacetal by analogy with the structure of the glucose derivative (**1**) and by its conversion to crystalline 3,4,5-tri-*O*-benzoyl-D-xylose phenylosazone in 1% yield. This latter process was performed in three steps: conversion to the dimethyl acetal, hydrolysis of this acetal with acid, then conversion to the osazone in a refluxing mixture of acetic acid and phenylhydrazine. The rearrangement may have occurred in either of the last two steps since migrations of benzoyl groups in acid (1) or in the presence of amine bases (16) are well established.

2,5,6-Tri-O-benzoyl-D-galactose Diethyl Dithioacetal (6)

A tribenzoyl derivative (**6**) of D-galactose diethyl dithioacetal had been prepared (5) in 30% yield under Schotten–Baumann conditions and in 52% yield with benzoyl chloride in pyridine. In the present work, a single compound was also prepared in similar yields under these conditions but the compound prepared had a slightly lower mp (153–154°C vs. 160–163°C (5)) and a more negative rotation ($[\alpha]_D^{24.5}$ −10.3° vs. +1.7° (5)). Some difficulty was experienced in recrystallizing this compound since it slowly decomposed in ethanol to a dibenzoyl derivative (**7**) which was separately synthesized from galactose diethyl dithioacetal (see later). It seems unlikely that the sample prepared here is different from that prepared earlier (5) since similar yields were obtained under both sets of reaction conditions. The nmr spectrum of **6** in chloroform-*d* at 80 MHz (see Fig. 2) was analyzed as previously. The low-field chemical shifts of the signals for the secondary protons H-2 and H-5 (see Table 1) indicated that the compound was 2,5,6-tri-*O*-benzoyl-D-galactose diethyl dithioacetal (**6**).

The previous method of structural assignment for compound **6** involved conversion of **6** successively to the dimethylacetal and its di-*O*-methyl

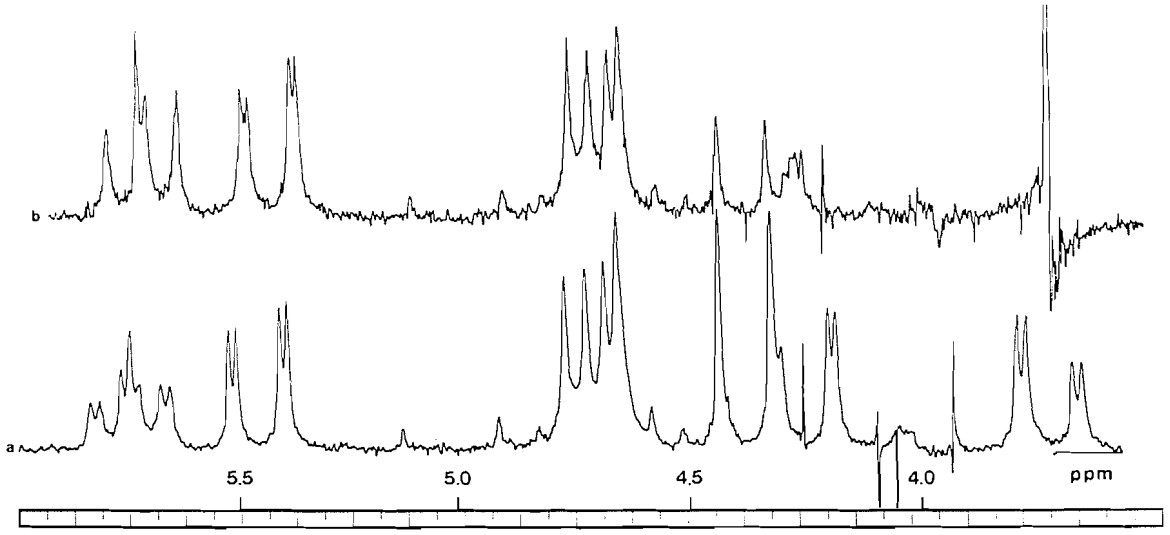

FIG. 2. Partial ^{1}H nmr spectra at 80 MHz of 2,5,6-tri-*O*-benzoyl-D-galactose diethyl dithioacetal (**6**) in chloroform-*d* after exchange with water-d_2 under the following conditions: (*a*) no decoupling; (*b*) decoupling at position indicated by the line which has been cut off.

derivative. Then two hydrolysis steps gave a dimethylgalactose derivative whose rotation was compared with that of authentic 2,3-di-*O*-methyl-D-galactose. All of these compounds derived from **6** were syrups. In addition, the di-*O*-methyl galactose derivative was converted to a mono-*O*-methyl phenylosazone which was shown to be 3-*O*-methyl-D-galactose phenylosazone by comparison of melting points and by a mixed melting point experiment. Unlike the structural proofs used for the earlier compounds, there is no obvious flaw in this method. However, since the nmr evidence presented here is absolutely unambiguous, at some point the previous method of structural proof must have gone astray.

Treatment of D-galactose diethyl dithioacetal with benzoyl chloride (2.2 equiv.) in pyridine yielded 5,6-di-*O*-benzoyl-D-galactose diethyl dithioacetal (**7**) in 77% yield. The structure of this compound was established by ^{1}H nmr spectroscopy as previously (see Tables 1 and 2).

2,3,5,6-Tetra-O-acetyl-D-glucose Diethyl Dithioacetal (8)

A tetra-*O*-acetyl derivative (**8**) of D-glucose diethyl dithioacetal had been prepared from D-glucose diethyl dithioacetal by treatment with acetic anhydride and sodium acetate (6). The same compound was also produced by detritylation of 2,3,4,5-tetra-*O*-acetyl-6-*O*-triphenylmethyl-D-glucose diethyl dithioacetal (**9**) and by mercaptalation of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose with ethanethiol and zinc chloride (17). The sample studied in the current work was initially obtained from chromatography of the mixture resulting from detritylation of **9**. Once seed crystals were obtained, the product from the acetylation of D-glucose diethyl dithioacetal also crystallized.

For personal use only.

Examination of the products obtained from both reactions by tlc showed a very complex mixture in which the crystalline product obtained was the most prominent. In contrast, the products of partial benzoylations were relatively simple with the single product obtained being predominant in all cases. It had previously been shown (6) that this compound (**8**), on methylation with silver oxide and methyl iodide, gave 2-*O*-methyl-3,4,5,6-tetra-*O*-acetyl-D-glucose diethyl dithioacetal. It was recognized at that time (6) that this evidence did not constitute proof of structure. However, it was later considered (8, 18) that the most likely structure was 3,4,5,6-tetra-*O*-acetyl-D-glucose diethyl dithioacetal. Analysis of the ^{1}H nmr spectrum at 100 Hz of **8** in chloroform-*d* as previously with the aid of decoupling experiments unambiguously showed that this product was 2,3,5,6-tetra-*O*-acetyl-D-glucose diethyl dithioacetal (**8**).

Discussion

From the above structural assignments, it is apparent that the 2-hydroxyl group of aldose diethyl dithioacetals is one of the most likely secondary hydroxyl groups to be acylated. Under Schotten–Baumann conditions (i.e. in $CHCl_3$ and NaOH), pure 5,6-di-*O*-benzoyl-D-galactose diethyl dithioacetal (**7**) quickly rearranged to a mixture in which the starting material is most prominent as monitored by tlc. When compound **7** was placed in dry pyridine containing pyridine hydrochloride, compound **7** was stable as indicated by tlc although the reaction mixture from which **7** had been isolated had contained small amounts of other products. Thus reaction under Schotten–Baumann conditions is probably under thermodynamic control whereas that with benzoyl chloride in pyridine is under kinetic control. Since the same major products are produced under both types of reaction conditions, it would appear that the factors which determine the stability of the products are similar to those which determine the rates of reaction and vice versa. However, the factors determining these stabilities are obviously complex and further discussion of selective acylation at this time would be premature.

It is well known that the predominant product of monomethylation of aldose diethyl dithioacetals is the 2-*O*-methyl ether (1, 19). In the current work it has been shown that partially acylated aldose diethyl dithioacetals rearrange on methylation under Purdie's conditions to give the 2-*O*-methyl ether as the predominant product. However, methylation of 2,4,5,6-tetra-*O*-benzoyl-D-glucose dimethyl acetal yields the product of direct methylation at O-3. Hence, it is probably the sulfur atoms of the diethyl dithioacetal group which cause selective methylation at O-2.

The actual role that sulfur plays is somewhat uncertain. Wander and Horton (8) have suggested sulfur participation during the methylation step. Haines (1) has suggested methylation on sulfur followed by an intramolecular nucleophilic displacement. These mechanisms are similar and both involve an intramolecular nucleophilic displacement at a tetrahedral carbon atom in a five-membered ring, a process which has been described as 5-Endo-Tet by Baldwin (20). Because of the geometric requirements of the transition state, such processes are very unfavourable (20). Lemieux (18) has suggested that the solid silver oxide in the methylation reaction mixture adsorbs the sulfur atoms of the diethyl dithioacetal and hence brings the adjacent 2-OH group in close contact with adsorbed methyl iodide. This suggestion seems most reasonable at this time.

Experimental

Melting points were determined by using a Reichert melting point apparatus and are uncorrected. Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter at 23 ± 3°. The ^{1}H nmr spectra were recorded at 79.6, 100, or 250 MHz on Varian CFT-20, Varian HA-100, or Bruker WM-250 nmr spectrometers in chloroform-*d* with tetramethylsilane as an internal standard. Selective homonuclear decoupling on the CFT-20 and HA-100 spectrometers was performed using Wavetek Model 171 frequency synthesizers. Coupling constants and chemical shifts were determined by using the computer program LAOCN-4A (15) to iteratively simulate those parts of the spectrum which were second order for the spectra of all compounds except **3**. The signals for at least five of the protons were simulated in each case. The 7 spin system of the skeletal protons of **3** was iteratively simulated using the program resident in the WM-250 spectrometer. Thin layer chromatography was performed on 0.25-mm thick Brinkmann silica gel G/uv-254 glass plates cut to be approximately 7 cm long. Plates were developed by spraying with 2% ceric sulfate solution in *M* sulfuric acid and then heating the plates for a few min at 150°C. Eluent systems used were: *A*, 2:1 (v/v) petroleum ether (30–80°C) – ethyl acetate; *B*, 3:1 (v/v) petroleum ether (30–80°C) – ethyl acetate; *C*, 1:1 (v/v) petroleum ether (30–80°C) – ethyl acetate; *D*, 5:1 (v/v) petroleum ether (65–110°C) – ethyl acetate; and *E*, 19:1 (v/v), chloroform–methanol. High pressure liquid chromatography was performed on a Waters analytical liquid chromatograph. Physical constants of compounds prepared by literature methods are listed in Table 3. Elemental analyses were determined by the Microanalysis Laboratory, Toronto and by the Canadian Microanalytical Service, Vancouver, B.C.

2,4,5,6-Tetra-O-benzoyl-D-glucose Dimethyl Acetal (3)

Dried 2,4,5,6-tetra-*O*-benzoyl-D-glucose diethyl dithioacetal (1.0 g, 1.4 m*M*) was dissolved in absolute methanol (15 mL) in which dry cadmium carbonate (1.32 g, 7.7 m*M*) was suspended and the mixture was refluxed at an oil bath temperature of 72°C. A solution of mercuric chloride (2.09 g, 7.7 m*M*) in absolute methanol (10 mL) was added in portions with vigorous mechanical stirring. The mixture was refluxed for 4 h with occasional

TABLE 3. Physical properties of compounds prepared by literature methods

Compound	Melting points (°C) Present work	Melting points (°C) Lit.	Optical rotations Present work	Optical rotations Lit.	Reference
1	165–167	166–168	+22.8	+23.5	12
2	87–88	88–89	+64.6	+64.5	10
5	137.5–139	138–140	−2.5	+6.0	4
6	153–154	161–162	−10.3	+1.7	5
8	117–118	117–118	−24.6	−25	18

addition of small amounts of cadmium carbonate. The mixture was filtered into a flask containing cadmium carbonate (0.5 g) and the filtrate was evaporated to dryness under reduced pressure. The residue was extracted several times with chloroform (4 × 25 mL). The combined chloroform extracts were washed with saturated potassium iodide solution (3 × 25 mL), then with water (3 × 50 mL), and dried over anhydrous magnesium sulfate. The chloroform solution was filtered and the filtrate was evaporated under reduced pressure to a white solid which was recrystallized from methanol; yield 0.35 g (38.5%); mp 139–141°C; R_f 0.44 (solvent *A*); $[\alpha]_D^{25.0}$ +48.9 (*c* 0.55, in chloroform); ^{1}H nmr (HA-100) δ: 7.24–7.44, 7.82–8.00 (m, Ph protons). *Anal.* calcd. for $C_{36}H_{34}O_{11}$: C 67.28, H 5.33; found: C 67.17, H 5.21.

2,4,5,6-Tetra-O-benzoyl-3-O-methyl-D-glucose Dimethyl Acetal (4)

Dried compound **3** (0.266 g, 0.4 m*M*) was stirred at room temperature in dry dioxane (1.4 mL). Methyl iodide (2.6 mL), freshly prepared silver oxide (0.26 g), and Drierite (0.3 g) were added and the stirring was continued for 24 h. The silver salts were collected and washed with methanol. The filtrate was evaporated to a syrup which was purified by high pressure liquid chromatography using a Vydac 10 μm silica gel column (24 cm × 0.76 cm) using solvent *D* as eluant. The syrupy product was homogeneous on hplc, yield 0.13 g (48%); $[\alpha]_D^{22}$ −7.4 (*c* 0.7, in chloroform); ^{1}H nmr (HA-100) δ: 7.26–7.50, 7.88–8.02 (2m, Ph protons). *Anal.* calcd. for $C_{37}H_{36}O_{11}$: C 67.67, H 5.53; found: C 67.97, H 5.48.

2,4,5-Tri-O-benzoyl-D-xylose Diethyl Dithioacetal (5)

A solution of dried D-xylose diethyl dithioacetal (2 g, 7.8 m*M*) in dry pyridine (10 mL) was cooled to 0°C. Benzoyl chloride (2.9 mL, 3.5 g, 3.2 equiv.) was added in 3 equal portions at 5 min intervals. The reaction mixture was stirred at 0°C for 1 h, then overnight at room temperature. The reaction mixture was taken up in methylene chloride (30 mL), and the resulting solution was washed with 1 *N* hydrochloric acid (0°C, 2 × 30 mL), water (30 mL), a saturated sodium bicarbonate solution (30 mL) and water (30 mL), and then dried over anhydrous magnesium sulfate. The solution was concentrated to a yellow syrup which solidified on standing. Recrystallization from ethanol–water gave 2.3 g (52%) of compound **5** with physical constants as in Table 3. The crystals were homogeneous on tlc in solvent *A* (R_f 0.71).

5,6-Di-O-benzoyl-D-galactose Diethyl Dithioacetal (7)

A solution of dried D-galactose diethyl dithioacetal (3.0 g, 10 m*M*) in pyridine (15 mL) was stirred for 15 min at 0°C. Benzoyl chloride (2.68 mL, 2.2 equiv.) was added to the solution in small portions over 15 min. The solution was stirred 1 h at 0°C, then a further 12 h at room temperature. The reaction mixture was taken up in methylene chloride (50 mL) and the resulting solution was washed with ice cold 1 *N* hydrochloric acid solutions (3 × 35 mL), water (40 mL), saturated sodium bicarbonate (30 mL) and water (50 mL), dried over magnesium sulfate, and concentrated to dryness. The resulting amorphous solid was recrystallized twice from chloroform – petroleum ether 1:1, yield 3.72 g (77.5%); R_f 0.70 (solvent *C*); mp 148–149°C; $[\alpha]_D^{24.5}$ +55.8° (*c* 1.15, in chloroform); ^{1}H nmr (HA-100) δ: 1.18, 1.22 (2t, J = 7.5 Hz, 6H, 2-SCH$_2$CH_3); 2.64 (q, J = 7.5 Hz, 4H, 2-SCH_2CH$_3$); 7.34–7.54, 7.92–8.14 (m, 10H, 2-OBz). *Anal.* calcd. for $C_{24}H_{30}S_2O_7$: C 58.28, H 6.11, S 12.96; found: C 58.18, H 6.13, S 13.15.

Equilibration Experiments

Compound **7** (200 mg) in chloroform (2 mL) was mechanically stirred at 0°C. A 2 *N* sodium hydroxide solution (5 mL) was added and the reaction followed by tlc with solvent *E* as eluant. Compound **7** had R_f 0.44 and components with R_f's 0.38, 0.35, and 0.33 had appeared after 5 min. Of these, the component with R_f 0.35 gave the most intense spot. The intensities of these spots varied with time but the one from **7** was always the most intense. Equilibrium was reached at ~30 to 45 min. At this time, of the minor components, the one with R_f 0.38 was most intense but that at R_f 0.33 had disappeared.

Compound **7** (200 mg, 0.4 m*M*) in pyridine (5 mL) containing pyridine hydrochloride (100 mg, 0.87 m*M*) was stirred for 2 days. Thin layer chromatography (solvent *E*) indicated that only the starting material was present.

Amide hydrogen bonding in organic medium

J. N. SPENCER,[1] ROBERT C. GARRETT, FRED J. MAYER, JOHANNA E. MERKLE, CARLA R. POWELL, MAI T. TRAN, AND SCOTT K. BERGER

Lebanon Valley College, Annville, PA 17003, U.S.A.

Received February 12, 1980

J. N. SPENCER, ROBERT C. GARRETT, FRED J. MAYER, JOHANNA E. MERKLE, CARLA R. POWELL, MAI T. TRAN, and SCOTT K. BERGER. Can. J. Chem. **58**, 1372 (1980).

Thermodynamic parameters for the self-association of *N*-methylformamide and *N*-methylacetamide in CCl_4 solvent have been determined by infrared spectroscopy. The pure base calorimetric method was used to determine the enthalpy of hydrogen bond complex formation of *N*-methylformamide and *N*-methylacetamide with *N*,*N*-dimethylformamide, *N*,*N*-dimethylacetamide, ethyl acetate, and dioxane. Comparison of the calorimetric and spectroscopic results show that the dimers of *N*-methylformamide and *N*-methylacetamide are linear with hydrogen bond enthalpies of -2.9 and -3.9 kcal mol^{-1} respectively. The carbonyl group of *N*-methylacetamide was found to be a better proton acceptor than the carbonyl of *N*-methylformamide in agreement with theoretical predictions. *N*-methylacetamide was found to be a better proton donor than *N*-methylformamide in disagreement with theoretical predictions. The dimer self-association constants appear to be larger than previously reported.

J. N. SPENCER, ROBERT C. GARRETT, FRED J. MAYER, JOHANNA E. MERKLE, CARLA R. POWELL, MAI T. TRAN et SCOTT K. BERGER. Can. J. Chem. **58**, 1372 (1980).

On a déterminé, par spectroscopie infrarouge, les paramètres thermodynamiques de l'auto-association du *N*-méthylformamide et du *N*-méthylacétamide dans le CCl_4 comme solvant. On a utilisé la méthode rigoureuse de base de la calorimétrie pour déterminer l'enthalpie de la liaison hydrogène lors de la formation des complexes du *N*-méthylformamide et du *N*-méthylacétamide avec le *N*,*N*-diméthylformamide, *N*,*N*-diméthylacétamide, l'acétate d'éthyle et le dioxanne. La comparaison des résultats calorimétriques et spectroscopiques montre que les dimères du *N*-méthylformamide et du *N*-méthylacétamide sont linéaires avec des enthalpies respectives pour la liaison hydrogène de -2.9 et -3.9 kcal mol^{-1}. On a trouvé que le groupe carbonyle du *N*-méthylacétamide est un meilleur accepteur de proton que le groupe carbonyle du *N*-méthylformamide ce qui est en accord avec les prévisions théoriques. On a trouvé contrairement aux prévisions théoriques que le *N*-méthylacétamide est un meilleur donneur de proton que le *N*-méthylformamide. Les constantes d'auto-association du dimère semblent être plus grandes que celles indiquées antérieurements.

[Traduit par le journal]

Introduction

The interpeptide hydrogen bond linkage, N—H···O=C, found in the interior of proteins is generally considered to be in an "organic like" environment. Thus measurements of the enthalpy of formation of analog amide compounds in organic medium have been used to provide estimates of the stability of the interpeptide hydrogen bond in proteins. *N*-methylacetamide (NMA) is the most frequently used analog compound for the peptide unit in proteins. The self-association of NMA in CCl_4 solvent has been studied by various means but considerable disagreement still exists concerning the thermodynamic parameters for this hydrogen bond. Reported equilibrium constants for the dimer of NMA in CCl_4 range from 1 to about 50 (1–7). The hydrogen bond enthalpy has been variously given as -3.7 to -5.4 kcal mol^{-1} (1–7).

Several theoretical studies of the amide group (8–12) have been carried out on the analog compounds, formamide, *N*-methylformamide (NMF), acetamide, and *N*-methylacetamide (NMA). The effect of methyl substitution on the stabilization energies of complexes involving these analog compounds has been of considerable concern (8, 12). Experimental enthalpies of dimerization of NMF and NMA are needed to provide further insight into the relative hydrogen bonding ability of these amides. This paper reports on spectroscopic and calorimetric studies of the hydrogen bonding of NMF and NMA with various proton acceptors. Because of the uncertainty about the degree of polymerization and the importance of linear and cyclic structures, previous results for the thermodynamic parameters for self-association of these amides show considerable differences. The combination of the spectroscopic and calorimetric studies of this work, used independently of each other, remove some of these uncertainties and should provide more reliable estimates of the difference in hydrogen bonding ability of NMF and NMA and of the magnitude of the thermodynamic functions for the N—H···O=C hydrogen bond in organic medium.

Experimental

The calculation of thermodynamic data from spectroscopic data has previously been described (13). Equilibrium constants were determined at 15 and 30°C in CCl_4 for the self-association of NMF and NMA by the method of Liddel and Becker (14). The free N—H stretching frequency at 3475 cm^{-1} for NMA and

TABLE 1. Enthalpies of solution (kcal mol^{-1})

Solute	Solvent				
	CCl_4	DMA	DMF	EtOAc	Dioxane
NMF	+3.89±0.13	−0.25±0.03	−0.02±0.02	+1.11±0.06	
DMF	+0.85±0.04	−0.10±0.04	+0.00	+0.32±0.02	
NMA[a]	+4.48±0.08	+0.04±0.04	+0.32±0.03	+1.47±0.15	+1.64±0.02
DMA[a]	+0.40±0.09	+0.00	+0.01±0.01	+0.27±0.03	+0.44±0.02

[a]Enthalpies of solution in all solvents determined at 30°C. For NMF and DMF the solution enthalpies were determined at 25°C. Error reported is the standard deviation of a single measurement for those systems showing no concentration dependence; for those systems exhibiting a concentration dependence the uncertainty is the error in the least squares extrapolation to infinite dilution.

3467 cm^{-1} for NMF was monitored and a plot of absorbance divided by initial concentration vs. initial concentration was made to find the limiting slope and intercept from which the equilibrium constants were calculated. The Beckman Acta M IV spectrophotometer with a NIR sensitivity setting of 10× was used to record spectra of the amides down to concentrations of less than 10^{-3} M. The limiting slope was found over the concentration range of about 8×10^{-3} M − 1×10^{-3} M. Overlap of the free and complex band was observed for both self-associated complexes. A correction for the overlap was made by symmetric reflection of the bands. Frequency shifts were determined by extrapolation of a plot of frequency shift vs. concentration to infinite dilution.

The calorimetric method of analysis and the calorimeter have been previously described (15, 16). The pure base calorimetric method was used for all calorimetrically determined enthalpies reported in this work. This method was developed for systems of the type studied here, i.e., systems with low formation constants and small enthalpy changes (17). According to the pure base method, if a small quantity of hydrogen bonding acid is injected into the pure base as solvent, two contributions to the heat observed are involved, the heat due to hydrogen bonding and that heat term which might occur if there were no hydrogen bonding. If a proper model compound is chosen the hydrogen bonding heat term can be isolated. A reference solvent is chosen to correct for enthalpies of solution of the acid and model compound. The enthalpy of hydrogen bond formation, ΔH^{f}_{HB}, can then be calculated from

$$[1] \quad \Delta H^{f}_{HB} = (\Delta H^{A}_{S} - \Delta H^{M}_{S})_{base} - (\Delta H^{A}_{S} - \Delta H^{M}_{S})_{ref}$$

where ΔH_S is the enthalpy of solution and A and M refer to acid and model compound respectively. Thus if the enthalpy of hydrogen bond formation between NMA and DMF is desired, it is only necessary to determine the enthalpy of solution of NMA and its model compound, DMA, in DMF and in the reference solvent which was CCl_4 for all systems in this study. Equation [1] is then used to calculate ΔH^{f}_{HB} and the resulting ΔH^{f}_{HB} is corrected according to procedures already given (16). Millimole quantities of acid were injected in 200 mL of solvent for all systems. In those cases where a concentration dependence of ΔH_S was observed, extrapolation to infinite dilution was made. All enthalpies of solution of NMA and DMA were made at 30°C so that the more easily handled liquid NMA could be injected into the solvent. All other enthalpies of solution were determined at 25°C.

Aldrich 99% NMA and NMF were distilled under nitrogen atmosphere. Aldrich Gold Label DMA was stored over molecular sieves and distilled under nitrogen. The purifications of other reagents have been previously given (15). All sample preparation was carried out in a dry box.

Results and Discussion

The enthalpies of solution at infinite dilution for NMF and NMA in the various solvents of this study are given in Table 1. These enthalpies and eq. [1] were used to calculate the uncorrected pure base enthalpies of hydrogen bond formation given in Table 2. The pure base enthalpies corrected for differences in enthalpies of solution between acid and model compound as outlined previously (16) are also given in Table 2.

The equilibrium constants, frequency shifts, enthalpy, and entropy changes calculated from the spectroscopic data are given in Table 3. The agreement between the spectroscopically determined enthalpy changes for the self-association of NMF and NMA and the calorimetrically determined enthalpy changes for NMF–DMF and NMA–DMA complexes is quite good considering the difficulty of making spectral measurements on such weak complexes. The Liddel–Becker method (14) of calculation of equilibrium constants from spectral data is sensitive to scatter in data points. The estimated uncertainty in the enthalpy change calculated from spectral data for the NMF and NMA dimer formation is about 1 kcal mol^{-1} and the equilibrium constants are uncertain to about 10%.

The calorimetrically determined enthalpy

changes for the NMF–DMF and NMA–DMA complexes clearly refer to the formation of a single N—H···O=C hydrogen bond. Because of the agreement between the calorimetric enthalpies and the self-association enthalpies for NMF and NMA determined spectroscopically it seems most reasonable to infer that the NMA and NMF dimers are linear and not cyclic.

Several investigators have reported self-association constants of less than 10 for NMA in CCl_4. However, a self-associated complex band is clearly defined at concentrations below 3×10^{-3} *M*. For self-association constants much less than about 20, the molar absorptivity of the complex would have to be quite large to permit observation of this band. From the self-association constants reported in this work the molar absorptivity of the NMA self-associated complex can be calculated to be about 140 which is reasonable compared to the monomer molar absorptivity of about 100. If the self-association constant were 10 the complex absorptivity would have to be greater than 300 for the complex band to be observed at concentrations as low as those used in this work.

The difference between the NMF dimer enthalpy and the NMA dimer enthalpy determined spectroscopically and the difference determined calorimetrically for the NMF–DMF and NMA–DMA complexes are approximately the same and show that NMA forms a stronger hydrogen bonded dimer than NMF. The frequency shifts also support this contention.

Theoretical studies by Johansson *et al.* (9) predict that the amide resonance form

should cause the amide C=O to be a 2.9 kcal mol^{-1} better proton acceptor than an aldehyde C=O. Similar resonance structures can be drawn for ethyl acetate but because the nitrogen is less electronegative than oxygen, the nitrogen of the amide linkage can better accommodate the positive charge than the ester oxygen. The corrected data in Table 2 show that the amide carbonyl is a better proton acceptor than the ethyl acetate carbonyl and illustrate the importance of the amide resonance effect.

Johansson *et al.* (9) predict the amide N—H to be a 2.8 kcal mol^{-1} better proton donor than the amine N—H. No consistent data are available for a non-aromatic amine but comparison with *N*-methylaniline can be made. Previously reported pure base enthalpies (15) for the hydrogen bonded complexes of *N*-methylaniline with ethyl acetate and DMF corrected according to ref. 16 are −1.6 and −2.3 kcal mol^{-1} respectively. The NMF complexes with ethyl acetate and DMF have hydrogen bond enthalpies of −2.3 and −2.9 kcal mol^{-1} respectively, which indicates that the NMF N—H is a 0.6–0.7 kcal mol^{-1} better proton donor than the amine N—H. The NMA complexes with DMF and ethyl acetate show that the N—H of NMA is a 1.3 kcal mol^{-1} better proton donor than the amine N—H.

Del Bene's (12) *ab initio* SCF calculations on the effects of methyl substituents on amide hydrogen bonding predict that NMF should be a better proton donor than NMA and that the carbonyl of NMA should be a better proton acceptor than the carbonyl of NMF. If the hydrogen bond enthalpies of the complexes of NMA and NMF with the same proton acceptor are compared it may be seen from Table 2 that NMA is a stronger proton donor and that the difference in enthalpy between the NMF and NMA complexes is approximately constant at 0.7 kcal mol^{-1} with NMA being the better proton donor in all cases. The enthalpy of complex formation of NMF with DMA is 0.2 kcal mol^{-1} larger than with DMF. Similarly the NMA complex enthalpy with DMA is 0.3 kcal mol^{-1} stronger than with the DMF complex. Del Bene's calculations (12) show that methyl substitution at the nitrogen does not alter electron density at the oxygen of amides so that if DMA and DMF can be taken as representative of the carbonyl in NMF and DMF, the predictions that the NMA carbonyl should be a better proton acceptor than the NMF carbonyl are borne out.

The enthalpy change for the DMA–dioxane complex is included in Table 2 to provide an estimate of the differences in proton accepting ability

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

of a carbonyl oxygen and an oxygen in an ether like linkage. The amide carbonyl is a considerably better proton acceptor but the ethyl acetate carbonyl is approximately the same in proton accepting ability as the dioxane oxygen.

The calculations of Del Bene (12) and Johansson *et al.* (9) predict that methyl substitution can cause an increase in electron density about the N—H and carbonyl groups. Del Bene's results show that methyl substitution affects the electron density at the N—H proton substantially the same whether the methyl substituent is bonded to the carbon or nitrogen. Thus methyl substitution at the carbon is primarily responsible for the increased basicity of the amide carbonyl but should have little effect on the N—H proton donating ability. The results of this study are in agreement with the predicted increase in carbonyl basicity due to carbon methyl substitution but disagree with the predictions concerning the proton donating ability of the N—H. Because the experimental work was carried out in condensed medium solvation effects may be important. Unpublished data from this laboratory show that specific solvation interactions may occur at the nitrogen of amides. Methyl substitution at the carbon of an amide may provide steric hindrance to the approach of a solvent molecule and thus account for the increased donating ability of NMA over NMF.

The best enthalpy changes for the self-association of the dimers of NMF and NMA are -2.9 and -3.9 kcal mol^{-1} respectively. Of the 1 kcal mol^{-1} difference in enthalpy of formation between these two dimers about 0.7 kcal mol^{-1} can be attributed to the better proton donating ability of NMA and about 0.3 kcal mol^{-1} to the better proton accepting ability of the NMA carbonyl.

VICTOR M. S. GIL

Centro de Química de Coimbra and Department of Chemistry, University of Aveiro, Portugal

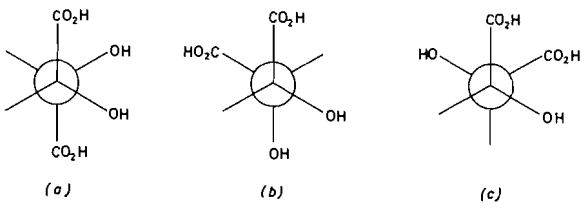
Received October 24, 1979

JOSÉ ASCENSO and VICTOR M. S. GIL. Can. J. Chem. **58**, 1376 (1980).

Vicinal H—H and C—H coupling constants are reported for (+)-tartaric acid and *meso*-tartaric acid at various pH values and used in a discussion of the conformation of these molecules. This is found not to change much with pH. For the *meso* form, in particular, the most favoured conformer is determined not so much by the possibility of internal OH···OOC hydrogen bonding but, at least in part, by stabilization of polar conformations in a solvent (H_2O) of high dielectric constant.

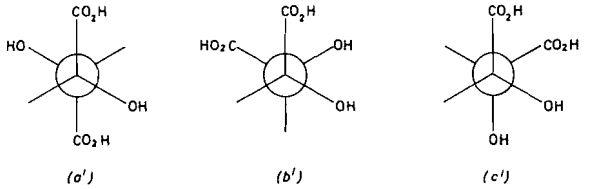
JOSÉ ASCENSO et VICTOR M. S. GIL. Can. J. Chem. **58**, 1376 (1980).

On rapporte les constantes de couplage vicinal H—H et C—H des acides (+)-tartarique et *méso*-tartarique à différents pH; on les utilise pour discuter de la conformation de ces molécules et on a trouvé que celles-ci ne varient pas appréciablement avec le pH. Dans le cas de la forme *méso* en particulier, le conformère le plus favorisé est déterminé non pas tant par la possibilité d'une liaison hydrogène intramoléculaire OH....OOC mais du moins en partie par la stabilisation des conformations polaires par H_2O un solvant de forte constante diélectrique.



[Traduit par le journal]

Introduction



During an nmr study of rotational isomerism and metal complexation of simple carboxylic acids in aqueous solutions, the need was felt to know the conformations of active and *meso*-tartaric acids as free ligands at various pH values.

Such conformations are known for the solid state (1, 2). Regarding solutions, the work of Hargreaves and Richardson (3) on the changes of the rotatory power of (+)-tartaric acid presents an interpretation partly based on conformational changes with temperature, solvent, and concentration, it being assumed that the most stable conformation in solution is essentially the same as that of the crystal. For the optically inactive *meso*-tartaric acid in solution, no report of any conformation study was found.

In solution and at room temperature, there is rapid internal rotation of the molecules around the HC—CH bond. An approximate way of approaching rotational isomerism often used is to regard the mean molecular conformation as an weighted average of the conformations of the three staggered rotational isomers. For (+)-tartaric acid, these are as follows:

whereas for meso-tartaric acid they are:

(*b'*) and (*c'*) being enantiomers.

Since vicinal $^1H—^1H$ ($^3J_{HH}$) and $^{13}C—^1H$ ($^3J_{CH}$) spin coupling constants depend on the dihedral angles, we have obtained those coupling constants for various pH values and related them to the conformation of the tartaric acids in a manner similar to that previously used in related systems.

Experimental

The spectra were run on JEOL PS-100, Varian XL-100, and Varian HA-100 spectrometers, at the temperature of the probes (~30°C) except when otherwise specified. D_2O solutions were used throughout; for ^1H and ^{13}C studies the concentration was, respectively, 0.5 *M* and 2 *M*. The pH was adjusted with NaOD and $(CH_3)_4NOH$. The pH* values quoted are the direct pH-meter readings. Gated irradiation of protons was used to observe nOe in ^{13}C spectra without decoupling.

Results and Discussion

Since, because of symmetry, the normal (C)—^1H spectra of both tartaric and *meso*-tartaric acids consist of just one line, use had to be made of the (^{13}C)—^1H satellites to get $^3J_{HH}$. The values are shown in Table 1.

TABLE 1. $^3J_{HH}$ values (Hz) for tartaric acids

L(+) Tartaric		*Meso*-Tartaric	
pH*	*J*	pH*	*J*
1.6	2.30±0.05	1.4	2.6
2.5	2.25	2.4	2.6
3.5	2.15	3.7	2.6
4.5	1.80	4.5	2.7
5.5	1.75	5.5	3.0
6.5	1.70	6.5	3.1
7.2	1.70	7.5	3.0
8.4	1.65	9.3	3.0
9.6	1.85	12.6	3.1
10.5	1.80		
11.5	1.75		
12.5	1.80		

Irrespective of the degree of ionization, the *J* values for tartaric acid are typical of an essentially *gauche* coupling constant. This is in accordance with the reasonable assumption that (*a*), which is approximately the conformation in the solid state (1), is the most stable conformer in solution; this arrangement provides, simultaneously, the least repulsion of the carboxylic groups and a possibility of intramolecular OH···CO_2H hydrogen bonds (3). However, a possible contribution of (*c*) cannot be ruled out. The weight of (*a*) is expected to increase upon ionization of the CO_2H groups (due to stronger repulsion of the CO_2^- groups). The observed decrease of J_{HH} is consistent with the expectation; in fact, due to the orientation dependence of substituent effects on $^3J_{HH}$, the OH and CO_2H (or CO_2^-) groups should make $^3J_{HH}$ less for (*a*) than for (*c*) (ref. 4, see also below).

The arguments of least repulsion of carboxylic groups and establishment of intramolecular hydrogen bonds would lead one to expect (*a'*) to be the most favoured conformation for *meso*-tartaric acid in solution. However, the $^3J_{HH}$ values presented in Table 1 are again typical of *gauche* coupling. This shows that the conformations are essentially (*b'*) and (*c'*). It is noted that these are the conformations in any of the crystal forms of *meso*-tartaric acid, stabilized by intermolecular rather than intramolecular hydrogen bonds (2). The ionization of the acid should increase the weight of (*a'*) leading now to an increase of $^3J_{HH}$; this is observed but the effect is small. It is clear that even when the CO_2H groups are fully (and the OH partially) ionized, (*b'*) and (*c'*) are much more stable than (*a'*).

The ^{13}C nmr signal for the carboxylic groups of both acids is the X part of an AA'X spectrum, where A and A' are the CH hydrogen atoms. Figure 1 shows such signals for tartaric acid (pH* = 0.9) and *meso*-tartaric acid (pH* = 0.9).

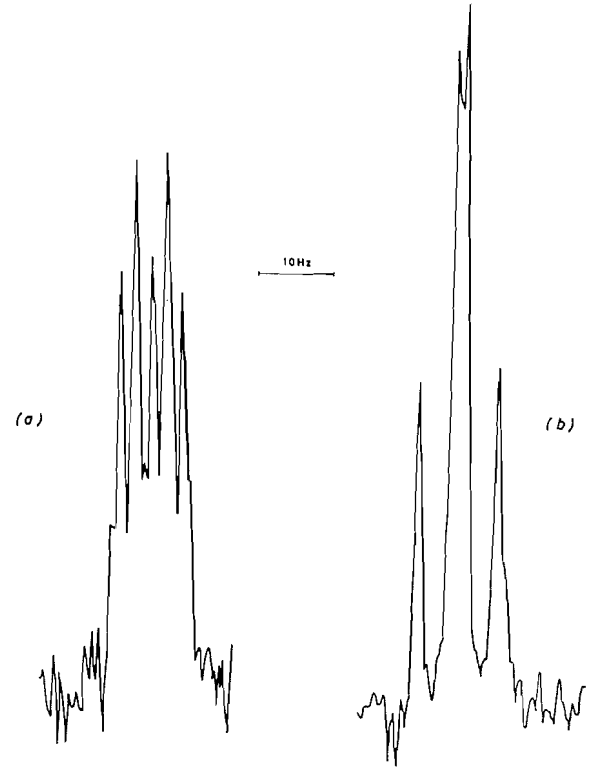

FIG. 1. Carboxylic ^{13}C signal for (*a*) *L*(+) tartaric acid and (*b*) *meso*-tartaric acid (2 *M* solutions in D_2O, pH* = 0.9).

As the X-combination lines are clearly detected and easily assigned on intensity grounds, the analysis of the X spectra gives the values of the vicinal and geminal $^{13}CO_2H—^1H$ coupling constants as pairs (it is not possible to distinguish between J_{AX} and $J_{A'X}$). The analysis immediately shows that these coupling constants have opposite signs, the geminal being almost certainly the negative one. Whenever the magnitudes of $^2J_{^{13}CO_2H—H}$ and $^3J_{^{13}CO_2H—H}$ are appreciably different, the assignments are made by comparison with similar related systems (5) as far as ^2J is concerned, and by recognizing that ^2J for tartaric and *meso*-tartaric acids should be about the same. The various coupling constants are shown in Table 2.

It is thus found that the vicinal $^{13}CO_2H—^1H$ coupling constant in (+)-tartaric acid, for any pH, is typical of a *gauche* orientation of the coupled nuclei (5). This shows that between conformations (*a*) and (*c*), (*a*) is by far the more stable; if it were (*c*) where such orientation is *trans*, the ^3J value should be of the order of 7 Hz (ref. 5, see also below).

TABLE 2. $^3J_{^{13}CO_2H-^1H}$ and $^2J_{^{13}CO_2H-^1H}$ values (Hz) for tartaric acids

L(+) Tartaric			*Meso*-Tartaric		
pH*	^3J	^2J	pH*	^3J	^2J
0.9	1.0	−5.2	0.9	3.7	−5.1
1.4	1.0	−5.0	3.8	3.9	−4.4
3.5	1.1	−4.8		4.4	or −3.9
5.1	1.3	−4.5	6.9	3.6	−4.3
8.0	1.3	−4.4		4.3	or −3.6
11.4	0.7	−3.9	12.3	3.6	−4.6
				4.6	or −3.6

The vicinal $^{13}CO_2H-^1H$ coupling constant in *meso*-tartaric acid, for any pH, is intermediate between *gauche* and *trans* values, in accordance with the dominant contributions of conformations (*b'*) and (*c'*).

In Table 3 the magnitudes of the geminal $^{13}CH-C^1H$ coupling constant are also recorded. The difference observed for both acids is noteworthy. This must be attributed mainly to the dependence of the $^{13}CH-C^1H$ coupling constant on the orientation of the substituent OH group bonded to ^{13}C, with respect to ^1H. It is expected that $^2J_{CH}$ should increase if the substituent is *trans* to ^1H and decrease if it is *gauche* (6). Accordingly, $^2J_{CH}$ should be larger in tartaric acid (mainly conformation (*a*), *trans* situation) than in *meso*-tartaric acid (mainly conformations (*b'*) and (*c'*), an equal mixture of *trans* and *gauche* arrangements). This is observed if, as is likely, the values for *meso*-tartaric acid are negative.

If, and in spite of the limitations of the method, we attribute reasonable values to the vicinal H—H and C—H coupling constants of the staggered conformers, we can obtain the approximate weight of the conformations (*a*), (*b*), (*c*) and (*a'*), (*b'*), (*c'*).

As far as the $^3J_{HH}$ values are concerned, we take essentially the approach previously used for malic acid (7), coupled with the assumption that, since the effect of an individual substituent is reduced when another similar substituent is present, the total effect of the 4 substituents is in between $\frac{1}{2}$ and $\frac{3}{4}$ of the sum of the individual effects. The various *J*-values would then be as follows: $^3J_{HH}^{(a)} = 1.9 \pm 0.9$, $^3J_{HH}^{(b)} = 13.3 \pm 1.5$, $^3J_{HH}^{(c)} = 3.6 \pm 0.6$, $^3J_{HH}^{(a')} = 13.3 \pm 1.5$, $^3J_{HH}^{(b')} = 2.7 \pm 0.7$, $^3J_{HH}^{(c')} = 2.7 \pm 0.7$.

Regarding the vicinal C—H coupling constants, we base our estimates on the work of Feeney and co-workers (5) on the conformation of amino acids and allowing for the replacement of NH_2 by OH, the presence of a second CO_2H group and the dependence of $^3J_{CH}$ on the orientation of the substituents (6). We thus have the following tentative values: $^3J_{CH}^{(a)} = 1.0 \pm 0.5$, $^3J_{CH}^{(b)} = 1.5 \pm 0.5$, $^3J_{CH}^{(c)} = 6.5 \pm 1.0$, $^3J_{CH}^{(a')} = 2.5 \pm 0.5$, $^3J_{CH}^{(b')}$; $^3J_{CH}^{(c')}$ *gauche* $= 0.5 \pm 0.5$, *trans* $= 6.5 \pm 1.0$.

It is clear that in view of the values shown in Tables 1 and 2, the uncertainties quoted above can lead to appreciable errors. However, we will proceed with the following calculations.

If it is assumed that the tartrate ion exists almost exclusively in conformation (*a*), then, from Table 1, $^3J_{HH}^{(a)} \simeq 1.7$ and from Table 2, $^3J_{CH}^{(a)} \simeq 0.7$. By using $^3J_{HH}^{(b)} = 13.3$, $^3J_{HH}^{(c)} = 3.6$ and $^3J_{CH}^{(b)} = 1.5$, $^3J_{CH}^{(c)} = 6.5$ we obtain the following weights for tartaric acid at pH* = 1.6: $a = 0.91$, $b = 0.04$, $c = 0.05$.

For *meso*-tartaric acid, because of degeneracy of (*b'*) and (*c'*), the J_{HH} or the J_{CH} values alone enable the calculation of the various weights. According to the values above for the three rotamers and those in Tables 1 and 2, we have $2.0 \leq {}^3J_{HH}^{(b')} = {}^3J_{HH}^{(c')} \leq 2.6$ and $2 \times 3.7 \leq J_{CH}^{(b')}(gauche) + {}^3J_{CH}^{(b')}(trans) \leq 8.5$. By then using $^3J_{HH}^{(a')} = 13.3$ and $^3J_{CH}^{(a')} = 2.5$ we obtain, separately (for pH* = 0.9): $a' = 0.03 \mp 0.03$, $b' = c' = 0.48 \pm 0.02$, and $a' = 0.16 \mp 0.16$, $b' = c' = 0.42 \pm 0.08$.

As already mentioned, the finding that conformation (*b'*) (or (*c'*)) is much more stable than (*a'*) is somewhat surprising, although this is the molecular conformation of *meso*-tartaric acid in the solid state (2). To find out whether self-association through intermolecular hydrogen bonding is sufficiently important in aqueous solution to explain the preference for conformation (*b'*) instead of (*a'*), we have obtained the J_{HH} values for 5 *M* and 0.1 *M* solutions of tartaric and *meso*-tartaric acids as well as for solutions at 80°C. Within experimental error (less than ±0.1 Hz) no changes were detected.

An important difference between (*a'*) and (*b'*) is that the former has no electric dipole moment whereas (*b'*) and (*c'*) will have an appreciable di-

pole moment. In a solvent of high dielectric constant such as water, these latter conformations will therefore be more stabilized. In tartaric acid the lowest energy conformation (*a*) is also that corresponding most likely to a higher dipole moment. However, in order to assess the importance of this effect as well as specific hydrogen bonding to the H_2O molecules, studies in other solvents are needed. These will be the object of a future paper.

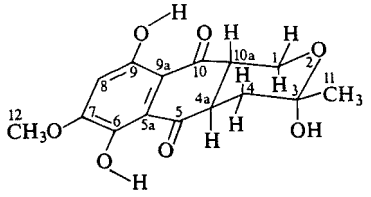
ITSUO KUROBANE, LEO C. VINING, A. GAVIN MCINNES, and JOHN A. WALTER. Can. J. Chem. **58**, 1380 (1980).

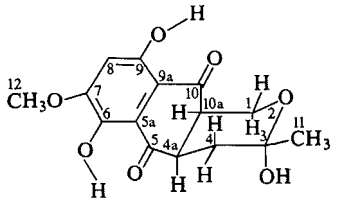
The pattern of ^{13}C and ^{2}H incorporation from [1-^{13}C]-, [2-^{13}C]-, [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]-, and [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate into dihydrofusarubin **1**, produced by cultures of *Fusarium solani*, has been determined by ^{13}C and ^{2}H nmr of the derivatives anhydrofusarubin **3** and anhydrofusarubin diacetate **4**. The results show that **1** is biosynthesized from seven uniformly-incorporated acetate units with C-3, C-11 originating from the "starter" unit. They strongly suggest that linear head-to-tail condensation of an acetate and six malonate units forms a single-chain heptaketide intermediate. The evidence also suggests that, during conversion of [^{13}C, ^{2}H]-labeled acetyl-CoA to malonyl-CoA, ^{2}H is transferred to biotin carboxyl carrier protein where it does not exchange rapidly with the medium and is available for conversion of endogenous malonyl-CoA to [^{2}H]-enriched acetyl-CoA.

ITSUO KUROBANE, LEO C. VINING, A. GAVIN MCINNES et JOHN A. WALTER. Can. J. Chem. **58**, 1380 (1980).



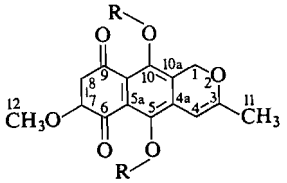
Faisant appel à la rmn du ^{13}C et du ^{2}H des dérivés de l'anhydrofusarubine **3** et du diacétate d'anhydrofusarubine **4**, on a déterminé le schéma d'incorporation du ^{13}C et du ^{2}H présents dans des acétates [^{13}C-1]-, [^{13}C-2]-, [^{13}C-$1_{0;1;1}$,^{13}C-$2_{1;0;1}$] et [^{13}C-$2_{0;1}$,^{2}H-$2_{3;3}$]- dans le dihydrofusarubine **1** qui est produit par des cultures de *Fusarium solani*. Les résultats indiquent que la biosynthèse du composé **1** se fait à partir de sept unités acétate incorporées uniformément avec les C-3, C-11 provenant de l'unité de départ. Ils suggèrent fortement que la condensation linéaire tête-queue d'un acétate et de 6 unités de malonate forme un intermédiaire heptacéture à chaîne droite. Les preuves suggèrent également que pendant la transformation du CoA-acétyle marqué au [^{13}C,^{2}H] en CoA-malonyle, le ^{2}H est transféré au carbonyle de la biotine de la protéine porteuse où il ne s'échange pas rapidement avec le milieu et où il est disponible pour la transformation du CoA-malonyle endogène en CoA-acétyle enrichi en [^{2}H].

[Traduit par le journal]



Introduction

We have shown recently (1) that *Fusarium solani* produces two diastereoisomeric 4a, 10a-dihydrofusarubins **1***a* and **1***b* which are non-enzymically oxidized by air to fusarubin (oxyjavanicin) **2** (2–6) when the culture medium becomes alkaline. Javanicin (3), norjavanicin (6), bostrycoidin (7), and (+)-solaniol (8) have also been isolated from this *Fusarium* species.



Biosynthetic studies of javanicin (3-acetonyl-5,8 - dihydroxy-6-methoxy-2-methyl-1,4-naphthoquinone) using [1-^{14}C]acetate, [2-^{14}C]malonate, and [Me-^{14}C]methionine (9) suggested that the methoxyl group is formed exclusively from methionine and the remaining carbons from acetate and malonate. The methyl group attached to the napthoquinone ring is derived from C-1 of acetate by reduction. Because of the similarity of their structures, a common progenitor has been considered for **2**, bostrycoidin, (+)-solaniol, and javanicin (8, 10). We have found that javanicin and the dihydrofusarubins are produced by *F. solani* early in the fermentation, norjavanicin appearing as a minor product at a later stage along with **2** during

the alkaline oxidation of **1**. Full details of these experiments will be published elsewhere (11).

We report here a possible biosynthetic pathway for **1**, established by ^{13}C and ^{2}H nmr spectroscopy of anhydrofusarubin **3** and its acetate derivative **4** enriched with [1-^{13}C]-, [2-^{13}C]-, and [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate, and of **4** enriched with [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate.

Materials and Methods

Production and Isolation of Fusarubin (2)

Fusarium solani f. sp. *cucurbitae* race 2 S-199, obtained from Professor P. E. Nelson, Department of Plant Pathology, Fusarium Research Center, College of Agriculture, Pennsylvania State University, was maintained on potato-dextrose agar slants. A spore suspension (2.5 mL), adjusted in concentration to OD 0.25 at 640 nm, was used to inoculate each 50 mL of fermentation medium. The medium consisted of maltose (20 g), ammonium tartrate (4.6 g), KH_2PO_4 (1 g), $MgSO_4 \cdot 7H_2O$ (0.5 g), $FeSO_4 \cdot 7H_2O$ (0.01 g), salt solution (10 mL), and mineral solution (10 mL) per liter. The salt solution contained 1% (w/v) each of NaCl and $CaCl_2$; the mineral solution contained (mg L^{-1}) $ZnSO_4 \cdot 7H_2O$ (880), $CuSO_4 \cdot 5H_2O$ (40), $MnSO_4$ (6), H_3BO_3 (6), and $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (4). Fermentation was carried out in 250 mL Erlenmeyer flasks for 6 days at 25°C with shaking at 220 rpm. The mycelium was removed by filtration, and fusarubin was extracted with ethyl acetate at pH 3 from the filtrate. After ethyl acetate was removed by evaporation *in vacuo*, the residue was washed with petroleum ether (bp 30–60°C), then crystallized once from ethyl acetate – ethanol (2:1). The average yield was 180 mg per liter.

Fusarubin (**2**): mp 184–185°C, red needles from ethyl acetate – ethanol (2:1); λ_{max} (95% ethanol): 225, 302, 470, 495, and 532 nm (log ε 4.49, 3.94, 3.82, 3.88, and 3.70); ν_{max} (KBr): 3460 (m, free OH), 3405 (m, H-bonded OH), 1595 (s, H-bonded C=O) cm^{-1}; ^{1}H nmr (pyridine-d_5) δ: 1.78 (s, 3H, H-11), 2.82 and 3.26 (AB, 2H, ^{2}J = 18 Hz, H-4), 3.75 (s, 3H, H-12), 5.11 and 5.22 (AB, 2H, ^{2}J = 18 Hz, H-1), 6.38 (s, 1H, H-8), and 13.3–13.5 (bs, 5, 10-OH); ms *m/e*: 306, 288, 273, 259, 245, 217.

Formation and Purification of Anhydrofusarubin (3)

A glacial acetic acid solution of once-crystallized fusarubin was kept for 2 days at 45°C. Cold water was added to the solution and the resultant precipitate of anhydrofusarubin was collected by filtration, washed with water, dissolved in $CHCl_3$, and purified by column chromatography on silicic acid using a mixture of benzene – ethyl acetate (12:1) for elution. The product was dissolved in $CHCl_3$ and washed twice with a 1 m*M* aqueous solution of ethylene diamine tetraacetic acid (EDTA) for ^{13}C nmr analysis.

Anhydrofusarubin (**3**): mp 190–191°C, violet prisms from $CHCl_3$; λ_{max} (95% ethanol): 236.5, 290, 348, and 540 nm (log ε 4.25, 4.22, 3.56, and 3.84); ν_{max} (KBr): 3430 (m, H-bonded OH), 1595 (s, H-bonded C=O) cm^{-1}; ^{1}H nmr ($C^{2}HCl_3$) δ: 2.01 (d, 3H, ^{4}J = 1.0 Hz, H-11), 3.91 (s, 3H, H-12), 5.19 (s, 2H, H-1), 5.96 (q, 1H, ^{4}J = 1.0 Hz, H-4), 6.15 (s, 1H, H-8), 12.57 and 12.97 (s, 5, 10-OH); ms *m/e*: 288, 273, 245, 217.

Acetylation of Anhydrofusarubin

Purified anhydrofusarubin was dissolved in 2 mL of pyridine and 2 mL of acetic anhydride, then kept for 8 h at 45°C. Cold water was added to the reaction mixture and the precipitate of anhydrofusarubin diacetate **4** was collected by filtration, washed with water, dissolved in $CHCl_3$, and washed twice with 1 m*M* EDTA solution for ^{13}C nmr analysis.

Anhydrofusarubin Diacetate (**4**): mp 186–187°C, orange needles from $CHCl_3$; λ_{max} (95% ethanol): 217, 285, and 455 nm (log ε 4.33, 4.20, and 3.59); ν_{max} (KBr): 1755 (s, aliphatic C=O), 1575 (s, H-bonded C=O) cm^{-1}; ^{1}H nmr ($C^{2}HCl_3$) δ: 1.96 (d, 3H, ^{4}J = 1.0 Hz, H-11), 2.43 (s, 3H) and 2.46 (s, 6H), (14, 16-CH_3), 3.81 (s, 3H, H-12), 5.11 (s, 2H, H-1); 5.68 (q, 1H, ^{4}J = 1.0 Hz, H-4), and 5.91 (s, 1H, H-8); ms *m/e*: 372, 330, 288, 273, 245, 217.

Labeled Precursors

Sodium [1-^{14}C]acetate was obtained from New England Nuclear Corporation, Boston, MA. Sodium [1-^{13}C]-, [2-^{13}C]-, and [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate (all 90% ^{13}C) were supplied by Merck Sharp and Dohme Canada Ltd., Pointe Claire, P.Q. Sodium [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate (90% ^{13}C; >95% ^{2}H) was prepared by dissolving sodium [2-^{13}C]acetate (90% ^{13}C; 37.1 mmol) in sodium deuteroxide solution (7.42 mmol sodium in 22.5 mL $^{2}H_2O$ (99.7% ^{2}H)) and heating in a sealed stainless steel tube for 20 h at 137°C to exchange protons for deuterons (12). This exchange process was repeated four times, resulting in a high deuterium content (>95%) as determined by ^{1}H and ^{13}C nmr analyses. Note that [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate has been called [1,2-^{13}C]acetate in our previous publications e.g. ref. 13.

Feeding with [1-^{14}C]Acetate

Each 500 mL volume of *F. solani* culture received a supplement of 205 mg of sodium acetate containing 10 μCi of [1-^{14}C]acetate at 1, 1.5, 1.75, 2, 2.5, or 3 days after inoculation. The cultures were harvested at 6 days, and the ^{14}C-labeled fusarubin was isolated, converted to anhydrofusarubin, and purified as described above.

Feeding with [1-^{13}C]-, [2-^{13}C]-, [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]-, and [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]Acetate

Each 1-litre volume of *F. solani* culture was supplemented with 510 mg of precursor, 40 to 42 h after inoculation. The cultures were harvested at 6 days and the ^{13}C-enriched fusarubin was isolated and converted to anhydrofusarubin diacetate.

Analytical Instruments

Mass spectra were obtained with a Dupont/CEC 21-491 mass spectrometer, uv spectra with a Unicam SP 8000 recording spectrophotometer, and infrared spectra with a Perkin-Elmer 521 grating infrared spectrometer, using samples compressed in KBr pellets. Radioactivity was measured with a Nuclear Chicago ISOCAP/300 scintillation counter. Proton nmr spectra were recorded with a Varian HA-100 continuous-wave spectrometer; conditions were: frequency 100 MHz, sweep rate 2 Hz s^{-1}, radiofrequency field 0.5 mG, filter bandwidth 2 Hz, temperature 30°C, internal lock to $(CH_3)_4$ Si, 5 mm sample tubes. The 25.16 MHz ^{13}C and 15.36 MHz ^{2}H nmr spectra were obtained with a Varian XL-100/15 Fourier-transform nmr spectrometer, at 29°C and using 5 mm diameter sample tubes. For decoupling ^{1}H at 100 MHz, $\gamma H_2/2\pi$ was ca. 3500 Hz with broadband irradiation by 0° to 180° phase modulation at 150 MHz; for decoupling ^{2}H at 15.36 MHz, $\gamma H_2/2\pi$ was ca. 310 Hz, phase modulation frequency 40 Hz. The other conditions for each experiment follow in the sequence: nucleus observed, spectral width, acquisition time, number of data points, flip angle, time constant for weighting free induction decay, amount of sample, solvent, nucleus used for lock, nuclei decoupled: **4** at natural abundance, ^{13}C, 5120 Hz, 1.6 s, 16384, 19° or 30° if high-resolution (hr) spectrum with 1.6 s delay between data acquisition periods, −1.6 s, 83 mg in 0.5 mL $C^{2}HCl_3$, ^{2}H, ^{1}H (switched off during acquisition time for hr spectrum); **3** at natural abundance, ex [1-^{13}C]acetate and ex [2-^{13}C]acetate, ^{13}C, 5120 Hz, 0.8 s (1.6 s for hr with 1.6 s delay between acquisitions), 8192 (16384 for hr), 18° (30° for hr), −0.4 s, ca. 100 mg washed with EDTA, ca.

3.5 mL C^2HCl_3, ^2H, ^1H; **3** and **4** ex [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate, ^{13}C, 5120 Hz, 3.2 s, 32768, 40°, −1.6 s, 56 mg in 0.6 mL C^2HCl_3 (**3**) or 120 mg in ca. 1.0 mL $C^2H_2Cl_2$ (**4**), ^2H, ^1H (switched off during acquisition for hr); **4** ex [2-$^{13}C_{0;1}$,2-$^2H_{3;3}$]acetate, ^{13}C, 5120 Hz, 3.2 s, 32768, 25°, −1.6 s, 87 mg in 0.5 mL C^2HCl_3/C_6F_6 4:1, ^{19}F, ^1H, and ^2H, also with relaxation reagent $Cr(acac)_3$ (1.5 mg) added to 0.3 mL solvent (C^2HCl_3/C_6F_6 = 5:1), same conditions except flip angle 54°, delay between data acquisition periods 7 s with ^1H decoupling field off during delay, time constant for weighting −0.4 s; **4** ex [2-$^{13}C_{0;1}$,2-$^2H_{3;3}$]acetate, ^2H, 500 Hz, 2.0 s, 2000, 90°, −0.8 s, 87 mg in 0.5 mL C^2HCl_3/C_6F_6 4:1, ^{19}F, ^1H.

Results

Incorporation of [1-^{14}C]Acetate

A preliminary experiment showed a much higher specific incorporation of ^{14}C into anhydrofusarubin when [1-^{14}C]acetate was fed on the second day of fermentation at a concentration in the culture of 5 m*M* rather than 2 m*M*. Subsequently the same precursor, at 5 m*M* concentration, was fed at times varying between 1 and 3 days from inoculation. After 6 days [^{14}C]-labeled **2** was isolated and converted to **3**. The specific incorporation of radioactivity (Fig. 1) was highest when the precursor was added 40 to 42 h after incoulation, when the pH of the culture was at a minimum.

Since **1** is converted non-enzymically to **2** in the cultures of *F. solani* under alkaline oxidative conditions, the incorporation of acetate should correlate with the production of **1** rather than **2**. Production of **1** could be detected after 12 h of fermentation and increased rapidly up to 2 days, after which its concentration decreased and **2** began to accumulate in the culture (Fig. 2). This evidence indicates clearly that **1** is being converted to **2** after 2 days when the pH of the culture rises, and is consistent with acetate being initially incorporated into **1**.

Assignment of ^{13}C Resonances

The assignment of ^{13}C resonances in the spectra of **3** and **4** was based on chemical shift trends, multiplicities, and J_{CH} values from high resolution (hr) spectra, and ^{13}C—^{13}C coupling information from spectra of **3** and **4** labeled from [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate. Resonances of carbons bonded to hydrogen were easily recognized through their distinctive multiplicities and long-range ^{13}C—^1H couplings (Table 1): C-1 a triplet ($^1J_{CH}$ to 1-H_2), C-4 a doublet of quartets ($^1J_{CH}$ to 4-H, $^3J_{CH}$ to 11-H_3), C-8 a doublet ($^1J_{CH}$ to 8-H), C-11 a quartet of doublets ($^1J_{CH}$ to 11-H_3, $^3J_{CH}$ to 4-H), and C-12 a quartet ($^1J_{CH}$ to 12-H_3), the latter resonance being at lower field than that of C-11. Matching of ^{13}C—^{13}C coupling constants (Table 1) enabled identification of the resonances of C-10a, C-3, and C-4a. Carbon-8 is ^{13}C—^{13}C coupled to the carbon resonating at lowest field, which must be C-9, since this carbon and C-6 are expected to be the most deshielded.

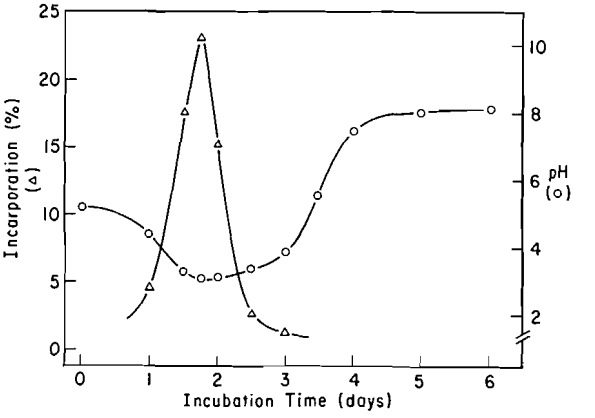

FIG. 1. Incorporation (%) of [1-^{14}C]acetate into dihydrofusarubins (△) and culture pH during fermentation (○).

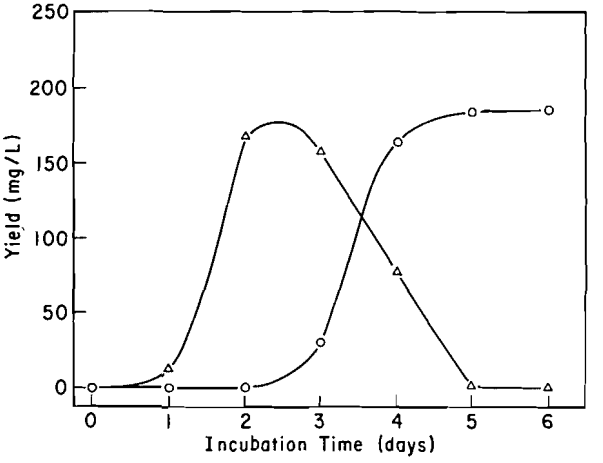

FIG. 2. Production of dihydrofusarubins (△) and fusarubin (○).

Carbon-6 is thereby identified, and the carbon to which it is ^{13}C—^{13}C coupled must be C-7 as its resonance in the hr spectrum shows a quartet characteristic of a carbon bearing a methoxyl group. Of the four remaining carbons, those bonded to oxygen will be less shielded than C-5a and C-9a, and the last is identifiable since its resonance is a doublet in the hr spectrum of **4** ($^3J_{CH}$ to 8-H) while that of C-5a is a singlet (both these resonances, and those of C-6 and C-9, show a small ^{13}C—^1H coupling to the hydroxyl hydrogens in the hr spectrum of **3**). Although the resonance for C-5 of **3** is chemically shifted upfield from that of C-10 by only 1.2 Hz, the two signals were easily distinguished because the former was a doublet ($^3J_{CH}$ to 4-H) in the hr spectrum whereas the other was a triplet ($^3J_{CH}$ to 1-H_2).

Enrichment with [1-^{13}C]- and [2-^{13}C]Acetate

The most favourable conditions determined from feeding experiments with radioactive acetate were used to incorporate [1-^{13}C]- and [2-^{13}C]acetate.

*In ppm (±0.05) referred to $(CH_3)_4Si$. Resonances of acetyl carbons of 4 are: δ_c 20.87, q, $^{1}J_{CH}$ 130.3 Hz (both methyl carbons); δ_c 168.85, 168.95, q, $^{2}J_{CH}$ 7.1 Hz (carbonyl carbons).
†Abbreviations: s = singlet, d = doublet, t = triplet, q = quartet, m = broad multiplet.
‡Calculated from integrated resonance intensities (see text and ref. 13).
§Calculated from I_c, I_d, and I_m of resonance of other carbon in ^{13}C—^{13}C pair (see text and ref. 13). Multiplets were simulated and the total intensity estimated from components that were resolved.
‖I_m could not be accurately measured for these carbons which may be adjacent to three (or fewer) ^{13}C atoms. If the level of incorporation is uniform, $I_m/(I_{d_1} + I_m)$ for these carbons should be ca. $2p/(p + 1) = 0.58$ where p is the average $I_m/(I_{d_1} + I_m)$ for all other labeled carbons shown at foot of column.
¶Satellites of the C-8 resonance showed an additional splitting due to a coupling ($^{2}J_{CC}$ = 13.5 Hz) to C-9a, for which $I_m/(I_d + I_m) = 0.40 \pm 0.04$.
**Not measurable due to overlap of resonances or poor signal/noise.

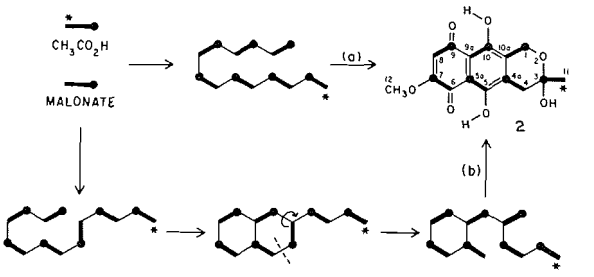
Carbon-13 enriched **2** was isolated and converted to **3**. The distribution of ^{13}C label was calculated, as described previously (13), by comparing integrated resonance intensities in ^{13}C nmr spectra of natural-abundance and enriched samples of **3**, using identical experimental conditions. Samples were washed with EDTA in order to remove residual paramagnetic impurities which might affect resonance intensities. The results (Table 1) show ca. 2.0% enrichment from [1-^{13}C]acetate at C-1, C-3, C-4a, C-5a, C-7, C-9, and C-10, and ca. 1.8% enrichment from [2-^{13}C]acetate at C-4, C-5, C-6, C-8, C-9a, C-10a, and C-11.



Enrichment with [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]Acetate

Using the same enrichment methods, **2** was labeled from 90% ^{13}C-enriched [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate and converted to **3** and **4**. The ^{13}C nmr spectra of these samples showed, in addition to the singlet resonances (integrated intenseity I_c), satellite doublet signals (integrated intensity I_{d_1}) due to ^{13}C—^{13}C spin–spin coupling where intact doubly ^{13}C-labeled units had been incorporated. Seven pairs of covalently-bonded ^{13}C—^{13}C atoms were identified by matching coupling constants (Table 1). This information, together with the enrichment pattern from [1-^{13}C]- and [2-^{13}C]acetate, established the biosynthetic origin of **1** from seven acetate units arranged as in Scheme 1. The presence of multiplets (integrated intensity I_m), arising from the incorporation of more than one ^{13}C atom adjacent to a particular ^{13}C atom, established that the labeled precursor had been incorporated at high concentration (average $I_m/(I_m + I_{d_1})$ = probability of ^{13}C adjacent to a ^{13}C—^{13}C unit = 0.40 ± 0.03) with subsequent dilution by material at natural ^{13}C abundance to an average ^{13}C enrichment $E = 6.5 \pm 0.7\%$ (Table 1). The latter figure was calculated from I_{d_1}, I_m, and I_c for the resonance of the ^{13}C—^{13}C coupled partner of the carbon under consideration, using formula [3] of ref. 13 and solving for $E(\%) = 100\,px\,C^{P}_{13,13}$ since the approximation $px \ll 1$ does not apply in this case. Symbols are defined in ref. 13.

Enrichment with [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]Acetate

The most favourable conditions for incorporating ^{14}C-labeled acetate into **2** were used once again for trideuteroacetate (90% ^{13}C, >95% ^{2}H at C-2). The isotopically enriched **2** was converted to **4** for ^{2}H and ^{13}C nmr analysis.

The only signals observed in the ^{2}H nmr spectrum of ^{13}C,^{2}H-enriched **4** were those at $\delta_{^2H}$ 1.93, which arise from a deuteromethyl group. These consisted of a singlet resonance due to ^{2}H bonded to ^{12}C and a doublet ($^{1}J_{^{13}C^{2}H}$ = 20.5 Hz) for ^{2}H attached to ^{13}C. The singlet–doublet ratio I_c/I_d was

SCHEME 1

ca. 1/4.5 and this unexpected result requires that ^{2}H from the precursor (I_c/I_d = 1/9) has exchanged with ^{1}H bonded to ^{12}C in the endogenous acetate pool before incorporation into the metabolite (see Discussion for possible explanation).

Three isotopically chemically shifted resonances upfield of the C-11 $^{13}C^{1}H_3$ signal were also present in the ^{13}C nmr spectrum obtained with simultaneous [^{1}H,^{2}H]-broadband decoupling. Signal collapse, due to an increase in multiplicity when the ^{2}H-decoupling field was removed, confirmed that these resonances arose from $^{13}C^{1}H_2{}^{2}H$, $^{13}C^{1}H^{2}H_2$, and $^{13}C^{2}H_3$ species. After the ^{13}C natural abundance contribution to the $^{13}C^{1}H_3$ resonance had been subtracted, their distribution was found to be: $^{13}C^{1}H_3$, 8 ± 5%; $^{13}C^{1}H_2{}^{2}H$, 33 ± 5% at $\Delta\delta_c$ 0.24 ppm; $^{13}C^{1}H^{2}H_2$, 39 ± 5% at $\Delta\delta_c$ 0.49 ppm; $^{13}C^{2}H_3$, 20 ± 5% at $\Delta\delta_c$ 0.73 ppm. The estimated error in measuring the isotope chemical shift $\Delta\delta_c$ was ±0.02 ppm. No other resonances due to carbon bearing deuterium were observed. Resonances for C-4, C-11 ($^{2}J_{CC}$ = 6.3 ± 0.5 Hz) and C-8, C-9a ($^{2}J_{CC}$ = 13.5 + 1.0 Hz) were accompanied by satellites arising from two-bond ^{13}C—^{13}C coupling, and the average intensity ratio $I_d/(I_d + I_c)$ = 53 ± 3% for these signals indicated once again that the labeled precursor was incorporated at a high concentration, the enriched metabolite being diluted subsequently with natural abundance material. Some of the resonances for the other enriched carbons had similar satellites but their intensities were not measurable because the $^{2}J_{CC}$'s were small.

Discussion

The results of the enrichment experiments with [1-^{13}C]-, [2-^{13}C]-, and [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate show that **1** is biosynthesized from seven acetate units, although they do not establish which of several possible biosynthetic routes leads to the final arrangement. Scheme 1 shows two examples. Nevertheless it is noteworthy that overall ^{13}C enrichments in all experiments were uniform within error, favouring a single heptaketide intermediate for **1** since two ketide intermediates (14) would probably be diluted to different extents with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

natural-abundance material. Formation from one polyketide molecule (15), followed by ring scission, is also possible (Scheme 1, route (b)).

The study with [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate established the presence of $^{13}C^{1}H_3$, $^{13}C^{1}H_2{}^{2}H$, $^{13}C^{1}H^{2}H_2$, and $^{13}C^{2}H_3$ species in the ratio 8% : 33% : 39% : 20% (±5%) at position-11. This represents a 57 ± 5% ^{2}H content at this site, which is considerably less than the >95% ^{2}H of the precursor methyl group. In the latter > 86% of the ^{13}C-labeled methyl groups will have been present as $^{13}C^{2}H_3$. Considerable exchange between ^{1}H and ^{2}H must have occurred during incorporation of the precursor, probably as a result of equilibration between acetate and malonate (16). We have suggested above that ^{2}H is transferred from [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate to ^{12}C in the endogenous acetate pool. This would require that ^{2}H transferred to biotin carboxyl carrier protein (17) during conversion of isotopically labeled acetyl-CoA to malonyl-CoA not exchange rapidly with the hydrogens in water but be available to form ^{2}H-enriched acetyl-CoA from endogenous malonyl-CoA. This being so, the reaction in *F. solani* takes place in a hydrophobic environment. The presence of residual $^{13}C^{2}H_3$ in the metabolite, together with the observation that C-3 is derived from the carboxyl group of acetate, demonstrates that C-11 and C-3 originate from the "starter" acetate unit which initiates formation of the polyketide chain. However, our experiments did not show the increased ^{13}C-enrichment at C-11 that has been associated with "starter" groups in some previous studies (15). Lack of ^{2}H at other sites, and particularly at C-4, is noteworthy. It seems unlikely that this can be accounted for by exchange of methylene protons in malonyl thioesters. This, under physiological conditions, is slow on the time-scale of fatty acid (18, 19), and probably also of polyketide, biosynthesis. A more likely reason for the absence of ^{2}H in ring carbons of **1** is that the hydrogens of water exchange with those in the activated methylene groups of a growing poly-β-ketomethylene chain. This type of exchange occurs rapidly with β-ketoacyl thioesters (19). In concluding that the dihydrofusarubins are probably formed by linear head-to-tail condensation of an acetate and six malonate units to form a single-chain heptaketide intermediate, we are influenced primarily by other examples of polyketide-derived metabolites where there is stronger evidence for biosynthesis via a single chain.

Measurements of $I_m/(I_{d_1} + I_m)$ for resonances in the spectra of **3** and **4** (Table 1) indicate that the ^{13}C-enrichment at the time of incorporation of [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate is ca. 40%. Intensities of satellites arising from two-bond ^{13}C—^{13}C coupling in the spectrum of **4** enriched with [2-$^{13}C_{0;1}$,2-$^{2}H_{3;3}$]acetate permitted comparable ^{13}C-enrichments to be calculated from $I_d/(I_d + I_c)$ for C-4 and C-9a. Since these enrichments were relatively uniform, it follows that the heptaketide precursor of **1** is formed within a short time, during which the precursor is not heavily diluted by unlabeled molecules arising from metabolism of the main carbon source. The low overall ^{13}C enrichment in these experiments is readily explained. Before the feeding with [1-$^{13}C_{0;1;1}$,2-$^{13}C_{1;0;1}$]acetate, 70% of the normal total yield of **1** had been produced (Fig. 2) and supplementation with acetate reduced production to about 80% of the normal yield. Consequently only 1/8th of the total sample is produced after feeding. Since 40% of that is formed from [^{13}C]acetate, the final ^{13}C enrichment is ca. 1/8 × 40% = 5%, in reasonable agreement with the measured average (6.5%, Table 1).

Osmotic and activity coefficients in dilute potassium chloride solutions at 25°C

CHAI-FU PAN

Department of Chemistry, Alabama State University, Montgomery, AL 36101, U.S.A.

Received January 28, 1980

CHAI-FU PAN. Can. J. Chem. **58**, 1386 (1980).

Osmotic and activity coefficients of dilute aqueous potassium chloride solutions are calculated from the simplified forms of the Stokes and Robinson equation. The hydration parameters in these equations are obtained from the vapor pressure data measured at higher concentration regions and the ion-size parameter is chosen as the sum of the crystallographic radii of the cation and anion of the electrolyte. The results are very satisfactory in comparison with existing data.

CHAI-FU PAN. Can. J. Chem. **58**, 1386 (1980).

A partir de la forme simplifié de l'équation de Stokes et Robinson, on a calculé les coefficients osmotiques et ceux d'activité de solutions aqueuses diluées de chlorure de potassium. On a obtenu les paramètres d'hydradation de ces équations à partir des données de pression de vapeur mesurée à plus forte concentration et on a choisi comme paramètre de dimension de l'ion la somme des rayons cristallographiques du cation et de l'anion de l'électrolyte. Les résultats sont très satisfaisants si on les compare aux données existantes.

The osmotic and activity coefficients in dilute electrolyte solutions may be calculated from the simplified forms of the Stokes–Robinson equation when the required parameters in these equations are available (1, 2). The ion-size parameter $\mathring{a}$ may be chosen as the sum of the crystallographic radii of the cation and anion of the electrolyte, and the corresponding value for the hydration number h is obtained from vapor pressure data (3). For example, for potassium chloride solutions, $\mathring{a} = 3.14$ Å and $h = 6.5$. The calculated values of h in dilute regions decrease with increasing concentration. This is attributed to the factors other than hydration to cause the deviations from the Debye–Hückel law (4, 5). Osmotic and activity coefficients in the regions are thus obtained when the values of h are available. The application of the method is demonstrated in this short article.

Calculations and Results

By assuming a linear relationship in the plot of h vs. m (3), where $h = 5.548$ when $m = 0.1$ and $h = 6.500$ when m approaches zero, an equation is obtained, i.e., $h = -9.520m + 6.500$. Values of h at different concentrations are calculated from the equation. They are shown in Table 1.

The mean molal activity coefficients of KCl in the concentration range up to 0.1 m are calculated from the following equation (2)

$$[1] \quad \ln \gamma_{\pm} = \frac{K_1 m^{1/2}}{1 + K_2 m^{1/2}} + 0.036(h - 1)m$$

in which $K_1 = -1.17604$ and $K_2 = 0.328618\mathring{a}$.

The molal osmotic coefficients are related to the activity coefficients by the Gibbs–Duhem equation. One convenient form is

$$[2] \quad \phi = 1 + \frac{1}{m}\int_0^m m \, \mathrm{d} \ln \gamma_{\pm}$$

Recall that h is a linear function of m in the regions, it takes the form

$$[3] \quad h = \alpha m + \beta$$

where $\alpha = -9.520$ and $\beta = 6.500$.

By substituting [1] and [3] into [2], we obtain

TABLE 1. Osmotic and activity coefficients in dilute aqueous potassium chloride solutions at 25°C

			$\gamma_{\pm}$

$$[4]\quad \phi = 1 + \frac{K_1}{K_2{}^3 m}[(1 + K_2 m^{1/2}) - 2\ln(1 + K_2 m^{1/2}) - (1 + K_2 m^{1/2})^{-1}] + 0.018(\beta - 1)m + 0.024\alpha m^2$$

Values of ϕ at different concentrations are calculated from the above equation. The calculated values of $\gamma_\pm$ and ϕ are collected in Table 1. In comparison with the existing data compiled by Hamer and Wu (6) and Lewis and Randall (7), the results are very satisfactory (see Table 1).

Discussion

The hydration number of an electrolyte ought to be independent of concentration in dilute solutions for which there are a lot of water molecules present for every ion in solution. The value of h in Table 1 decreases with increasing concentration; this is due to factors other than hydration. If all other factors are negligible, the value of h at 0.1 m should be nearly 6.5, for there are still more than 250 water molecules per ion; where $h = 5.548$ at 0.1 m may be considered as an "adjusted value" of the hydration number; it is a parameter only. Consequently, the net effect of all other factors put together lowers the value of h about 15% at 0.1 m. They have greater effects in more concentrated regions.

Received December 28, 1979

KELVIN K. OGILVIE and MONA J. NEMER. Can. J. Chem. **58**, 1389 (1980).

The synthesis of the 5′-monomethoxytrityl-2′-*tert*-butyldimethylsilyl-3′-levulinylribonucleosides **4** of the four major bases involved in the phosphite procedure for the synthesis of oligoribonucleotides is described along with the 2′,3′-isomeric derivatives **6**. This report describes a total protection system for nucleotide units which allows for the block condensation procedure to be used for the synthesis of long chains. The procedure is illustrated by the synthesis of a hexadecauridylic acid.

KELVIN K. OGILVIE et MONA J. NEMER. Can. J. Chem. **58**, 1389 (1980).

On décrit la synthèse des monométhoxy-5′ *tert*-butyldiméthylsilyl-2′ lévulinyl-3′ ribonucléosides **4** des quatre bases principales impliquées dans le procédé du phosphite pour la synthèse des oligoribonucléotides ainsi que les dérivés isomères 2′,3′ **6**. Cette publication décrit un système de protection totale des unités nucléotides qui permet la synthèse de longues chaînes. On illustre la méthode en synthétisant l'acide hexadécauridylique.

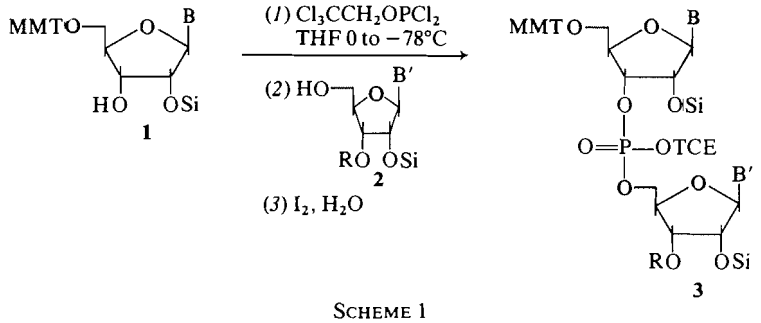
Introduction

Our current research program is directed toward the development of a practical method for the synthesis of oligoribonucleotides. We have been presenting (1–5) the major aspects of our method which involves two important features: (*1*) the use of the *tert*-butyldimethylsilyl (TBDMS) group to protect the 2′-position of ribonucleosides, and (*2*) the use of the phosphite coupling reagents to join the nucleoside units together. The overall approach is outlined schematically in Scheme 1. The major advantages of our method include speed and efficiency. The silylated nucleoside units **1** and **2** can be obtained rapidly and in large quantity. The phosphite procedure allows units **1** and **2** to be coupled together in 30–90 min using very simple techniques.



We have previously described in detail the synthesis of all levels of silylated ribonucleosides and the general procedures for the synthesis of nucleotides up to the tetranucleotide stage (2, 3, 5). We have also described (4) the synthesis, by single unit addition, of the heptanucleotide GCAACCA corresponding to the 3′-terminus of the $tRNA^{fMet}$ from *E. coli*. This latter sequence represents the longest ribonucleotide chain assembled by a stepwise route and yields at each stage ranged from 87 to 50% and total condensation times never exceeded 2 h 45 min.

In the present manuscript we wish to describe the extension of our procedures to include block condensations. Such a development is necessary in order to attempt the synthesis of very long chains such as the sequence of nucleotides in a transfer RNA. Others have succeeded in coupling ribonucleotide blocks using different procedures. For example, Ikehara and co-workers have recently (6) coupled a trimer and a tetramer using triisopropylbenzenesulfonyl chloride (TPS) to give a 30% yield (spectrophotometrically determined) after a reaction process that involved 72 h. Werstiuk and Neilson (7) have succeeded in coupling a tetramer and a pentamer to give a nonamer in 50% yield. The condensing agent was mesitylenesulfonyl triazolide (MS-TRI) and a total of 16 days was

[1]This article also constitutes Part XI in a series on silyl protecting groups in nucleoside and nucleotide chemistry. For the previous article in both series see ref. 4.

SCHEME 1

required to couple the two units together. van Boom and Burgers added a tetramer to a decamer (4:1 ratio) using triisopropylbenzenesulfonyl-4-nitroimidazolide (TPS-NI) and a 3.5 day reaction (8). The yield was 58%. Wiewiorowski and co-workers (9) combined a trimer and a tetramer in a 58% yield using triisopropylbenzenesulfonyl tetrazolide (TPS-TET) as condensing agent in a 3 h reaction (preceded by a 6–8 h requirement for preparation of the reagents in a form suitable for coupling).

The current article describes the synthesis of the key molecules **2** (R = $CH_3COCH_2CH_2CO$— = Lv) for all the common ribonucleosides and the synthesis of the di, tetra, octa, and hexadecauridylic acids via a block condensation procedure. We believe the hexadecauridylic acid represents the longest reported ribonucleotide synthesized by purely chemical means. As a result, this synthesis clearly demonstrates the success of the methods used. Furthermore, no condensation required more than 90 min to join two blocks together and the ratio of the blocks being coupled was 1 to 0.8 even at the hexadeca stage. Yields ranged from 85% for the synthesis of the dimer **3** (B = Ur, R = Lv), 76% for the tetramer **10***a*, 76% for the octamer **12***a* to 51% for the hexadecamer **13***a*. These yields and times compare favorably with other reported block condensation procedures as discussed above.

Discussion

The general procedure for the synthesis of any ribonucleotide by the phosphite procedure is outlined in Scheme 1 for the synthesis of the dinucleotide **3**. Compound **3** is the smallest nucleotide unit to serve for block condensations. In order to be able to couple preformed blocks together any unit such as **3** must be capable of being extended from either the 3′- or 5′-ends. Thus the choice of the group R is critical to this procedure and we have found the levulinyl group (Lv) to be completely compatible with our system. This group was introduced to carbohydrates by Guthrie and Lucas (10) and extended to nucleosides by Hassner *et al.* (11). van Boom and Burgers (8, 12) have shown the utility of the levulinyl group for 5′-protection in conjunction with the procedures their group has developed for the synthesis of oligoribonucleotides.
