A comparison of the stereochemistry and kinetics of thermolysis of *R*-(+)-laurolenic acid, *R*-(+)-laurolenal, and *R*-(+)-laurolenol

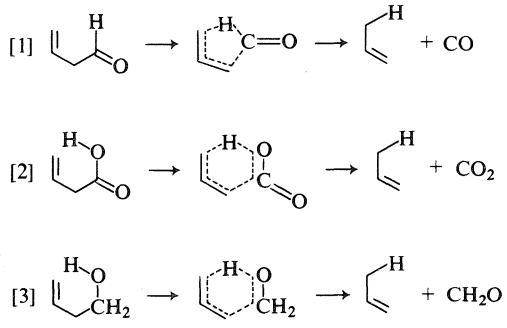
ROBERT J. CRAWFORD AND HIROKAZU TOKUNAGA

Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 12, 1979

ROBERT J. CRAWFORD and HIROKAZU TOKUNAGA. Can. J. Chem. **58**, 463 (1980).

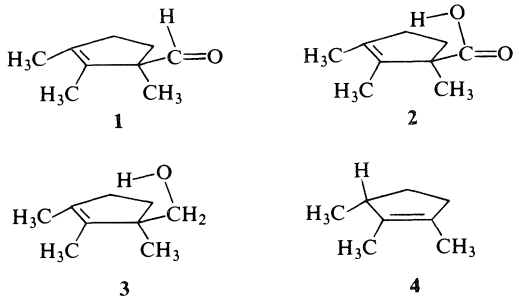
The thermolysis of *R*-(+)-laurolenal (**1**) produces *R*-(+)-1,2,3-trimethylcyclopentene in high optical purity. The alcohol **3**, at 297°C, similarly produces the alkene *R*-(+)-**4**, but with mechanistic complications in that the formaldehyde produced oxidizes the alcohol **3** to the corresponding aldehyde **1**. The alcohol **3**-d_2 was used to show the extent of aldehyde conversion by virtue of the formation of **4**-d_1. Comparison of the decarboxylation of the acid, decarbonylation of the aldehyde, and demethanalation of the alcohol gives relative rates of 9:2:1 at 297°C.



ROBERT J. CRAWFORD et HIROKAZU TOKUNAGA. Can. J. Chem. **58**, 463 (1980).

La thermolyse du *R*-(+) laurolenal (**1**) produit le *R*-(+) triméthyl-1,2,3 cyclopentène avec une grande pureté optique. De la même manière l'alcool **3** chauffé à 297°C produit l'alcène *R*-(+)-**4** mais selon un mécanisme compliqué car il implique que le formaldéhyde produit oxyde l'alcool **3** en l'aldéhyde correspondant **1**. On a utilisé l'alcool **3**-d_2 pour mettre en évidence l'importance de la transformation en aldéhyde au moyen de la formation de **4**-d_1. En comparant la cinétique de la thermolyse de l'acide, de l'aldéhyde et de l'alcool on obtient des vitesses relatives de 9:2:1 à 297°C.

[Traduit par le journal]



Introduction

Earlier we presented kinetic and isotope effect evidence that supported a cyclic transition state (as in eq. [1]) for the decarbonylation of β,γ-unsaturated aldehydes (**1**). We now wish to report that the implied stereochemistry for this process has been verified by using *R*-(+)-laurolenal (**1**). While examining the stereochemical implications of the aldehyde decarbonylation, we undertook a comparison of this process with the analogous decarboxylation of the β,γ-unsaturated acid (eq. [2]) and the thermolysis of γ,δ-unsaturated alcohols.

The kinetics of decarboxylation of β,γ-unsaturated acids have been examined in detail by Bigley and May, and by Smith and Blau (2) as have the kinetics for the γ,δ-alcohol thermolysis (3). A comparison of the stereochemistry and the ease of the reactions is made for the substrates **1**, **2**, and **3**.

The aldehyde (**1**), acid (**2**), and alcohol (**3**) can be prepared optically pure from (−) α-bromocamphoric anhydride (5) by the procedures of Meyer *et al.* (4) and Baggiolini *et al.* (6).

1 **2** **3** **4**

Results and Discussion

Samples of *R*-(+)-laurolenal (**1**), upon thermolysis in a static system at 297°C, gave rise to carbon monoxide and (*R*)-(+)-1,2,3-trimethylcyclopentene (**4**). Kinetically, the reaction is first order, the rate constant k_1 being (2.14 ± 0.04) × 10^{-5} s^{-1} at 297°C. The olefin **4** produced from **1**, $[\alpha]_D^{25}$ +630.7° (*c* 1.57, $CHCl_3$), lit. (5) value for optically pure aldehyde $[\alpha]_D^{23}$ +624.2 ± 4.7° (*c* 1.50, $CHCl_3$), was dextrorotatory implying the *R* configuration on the basis of the absolute configuration assigned by Baggiolini *et al.* (6). The magnitude of the olefin's rotation, $[\alpha]_D^{25}$ +64.5° (*c* 4.47, $CHCl_3$), lit. value $[\alpha]_D^{23}$ +63.4° (neat), allows one to conclude that the reaction is stereospecific and that the aldehydic hydrogen is delivered to the γ carbon on the same face as the carbon monoxide is expelled. Samples of the unreacted aldehyde recovered after one half-life showed no indication of any racemization and similarly samples of olefin taken at 50, 75, and 90% completion gave, within experimental error, the same rotational values.

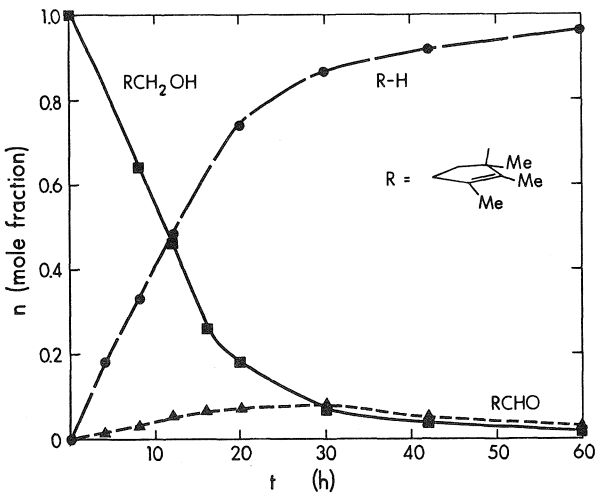
The aldehyde **1** has been shown to undergo photolysis to give *S*(−)**4**, and thus can be used as a source of either enantiomer.

The acid **2** decarboxylates readily at 297°C, $k_2 = (9.37 \pm 0.30) \times 10^{-5}\ s^{-1}$, to give cleanly the alkene **4**, $[\alpha]_D^{25}$ +65.5°. Studies at 1, 3, and 5 half-lives indicated that neither the reactant nor the product was undergoing any racemization.

The alcohol **3** was slower in thermolysis than **1** or **2**, and gave poor kinetic results, rate plots indicating that the reaction was going faster at higher conversion. A carefully degassed sample of **3** which had been purified by gas–liquid chromatography gave, after 20 h, 67% of **4**, 26% of **3**, and 7% of **1** along with methanol, formaldehyde, and carbon monoxide. Figure 1 shows the concentrations of **1**, **3**, and **4** at various times during the thermolysis of thoroughly degassed samples of **3**. In order to verify that a significant portion of the thermolysis of **3** was first undergoing oxidation to the aldehyde a sample of **3**-d_2 was studied. Table 1 gives the percentage of alkene containing deuterium upon thermolysis of **3**-d_2 under a variety of conditions. While 14% of the alkene contained deuterium when **3**-d_2 underwent thermolysis to 90% completion, the percentage alkene-d_1 rose to 51% when formaldehyde was added at the outset, demonstrating that formaldehyde acts as an oxidizing agent to transform the alcohol **3** into the aldehyde **1**. This also explains the appearance of carbon monoxide and methanol as thermolysis products.

We suggest that the thermolysis of **3**, and of **3**-d_2, occurs by two paths.

Initially the thermolysis of **3** is about half the rate of **1**, but as the concentration of formaldehyde builds up the rate of formation of **4** increases and detectable amounts of aldehyde **1**-d_1 are found to be present.



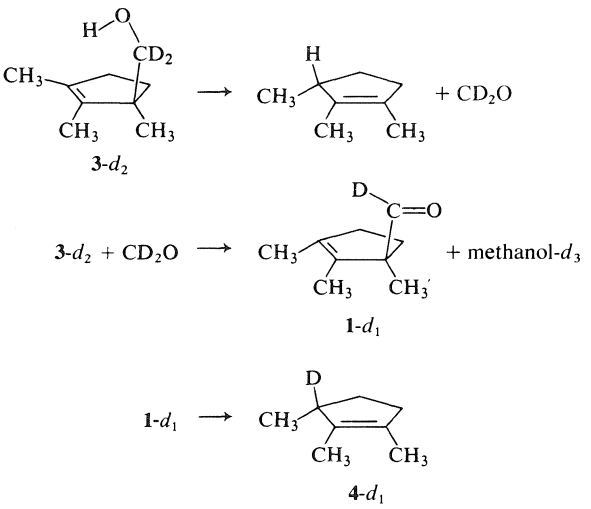


FIG. 1. Product composition for the thermolysis of laurolenol at 297°C.

TABLE 1. Percentage **4**-d_1 produced by the thermolysis of **3**-d_2 in the presence of formaldehyde, methanol, and carbon monoxide. Analysis by mass spectrometry

Conditions	Pressure (atm)*	(RD/RH + RD)100 at 25% conversion	75% conversion	90% conversion
3-d_2	3.2	3.4	11.4	26.5
	1.5	1.4	6.2	21.2
3-d_2 + CH_2O(11-fold)	3.2	13	40	51
3-d_2 + CH_3OH + (11-fold)	3.2	1.3	4.2	7.1

*Calculated pressure of **4**-d_2 at 297°C.

The presence of methanol suppresses the amount of deuterium incorporated, suggesting that the oxidation of **3**-d_2 by formaldehyde is reversible.

Conclusions

The thermolyses of **1**, **2**, and **3** all occur by the transfer of a hydrogen across the face of the cyclopentenyl ring to give **4** in high optical purity. The thermolysis of **2** is slightly faster than that of **1** and the thermolysis of **3** is complicated in that the formaldehyde produced acts as an oxidizing agent to convert some **3** into **1**, but this does not perturb the stereochemistry of the product.

Experimental

All boiling points are uncorrected. Samples were first purified by preparative gc using a Nester Faust model 350 "Prepkromatic". The rotations were measured on a Perkin Elmer Model 121 polarimeter. Mass spectral data were obtained on a Vickers MS-2 and an AEI-MS-50. The ^{1}Hmr spectra were obtained using a Varian A-56/60 spectrometer. The kinetic procedures were the same as those reported previously (1).

(R)-(+)-Laurolenic Acid (2)

The procedure used was essentially that of Meyer *et al.* (4)

starting from (−) α-bromocamphoric anhydride (5), $[\alpha]_{589}^{25}$ +172°, $[\alpha]_{365}^{25}$ +733° (*c* 2.70, $CHCl_3$) (lit. (6) $[\alpha]_D^{23}$ +155° (*c* 2.20, $CHCl_3$)).

(R)-(+)-Laurolenol (3)

The procedure used was that of Baggiolini *et al.* (6) and the sample was purified by gc using a 20 ft SF-96 column at 120°C; $[\alpha]_{589}^{25}$ +15.5°, $[\alpha]_{365}^{25}$ +52.7° (*c* 3.01, $CHCl_3$) (lit. (6) $[\alpha]_D^{23}$ +16° (*c* 3.2, $CHCl_3$)).

(R)-(+)-Laurolenol-d_2 *(3-*d_2*)*

The deuterated alcohol was prepared by reducing the acid **2** with $LiAlD_4$ by the aforementioned procedure (6). Mass spectrum $d_2 > 99\%$.

(R)-(+)-Laurolenal (1)

The procedure of Doering *et al.* (7) involving the use of sulfur trioxide – pyridine complex in dimethyl sulfoxide was used to oxidize the alcohol to the corresponding aldehyde. The aldehyde was purified by preparative gc using a 20 ft SF96 column at 120°C; $[\alpha]_{589}^{25}$ +630°, $[\alpha]_{365}^{25}$ +4960° (*c* 1.57, $CHCl_3$) (lit. (6) $[\alpha]_D^{23}$ +624° (*c* 1.5, $CHCl_3$)).

Etude par rmn du proton et du carbone-13 de pyrimidines substituées. IV.[1] Empêchement de rotation dans des *N*,*N*-diméthylamino-4 pyrimidines à l'état monoprotoné

JACQUES RIAND,[2] MARIE-THÉRÈSE CHENON ET NICOLE LUMBROSO-BADER

Université Paris VI, Laboratoire de Spectrochimie, Centre National de la Recherche Scientifique, 2, rue Henri Dunant, 94320 Thiais, France

Reçu le 6 septembre 1979

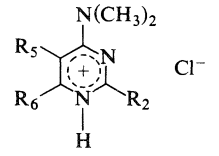
JACQUES RIAND, MARIE-THÉRÈSE CHENON et NICOLE LUMBROSO-BADER. Can. J. Chem. **58**, 466 (1980).

L'enthalpie libre d'activation pour le processus de rotation autour de la liaison C—N exocyclique dans divers chlorures de *N*,*N*-diméthylaminopyrimidinium a été déterminée par analyse de la forme des bandes observées en rmn du proton et du carbone-13.

La monoprotonation des *N*,*N*-diméthylaminopyrimidines entraîne une augmentation importante (de 14 à 24 kJ mol^{-1}) de l'enthalpie libre d'activation relative au groupe diméthylamino. Du fait de la prédominance de la forme monoprotonée (N-1 H) cet accroissement est plus grand quand le groupement diméthylamino est en position 4 que lorsqu'il est en position 2. Il en résulte que la différence de conjugaison des groupes diméthylamino en position 4 et 2 avec le cycle pyrimidique se trouve accentuée par la monoprotonation de ces composés.

JACQUES RIAND, MARIE-THÉRÈSE CHENON, and NICOLE LUMBROSO-BADER. Can. J. Chem. **58**, 466 (1980).

The free energy of activation for hindered rotation about the C—N exocyclic bond in some *N*,*N*-dimethylaminopyrimidine hydrochlorides has been determined by ^1H and ^{13}C nmr line-shape analysis.



Monoprotonation of *N*,*N*-dimethylaminopyrimidines induces a large increase of the free energy of activation (from 14 to 24 kJ mol^{-1}). This increase is larger for the 4-dimethylamino group than for the 2-dimethylamino group due to the predominance of the monoprotonated (N-1 H) form. Consequently, the difference of conjugation of the 4- and 2-dimethylamino groups with the pyrimidine ring is more pronounced in the monoprotonated species.

Introduction

Dans un précédent travail nous avions étudié par rmn le problème de la conjugaison du groupement diméthylamino avec le cycle pyrimidique dans une série de *N*,*N*-diméthylamino-4 pyrimidines (1). Nous avons poursuivi ce travail en examinant de façon quantitative l'influence de la protonation sur la conjugaison dans ces mêmes molécules. Cette étude devait permettre en outre une comparaison intéressante avec les résultats de calculs théoriques déjà effectués sur des composés voisins (2, 3).

Les enthalpies libres d'activation $\Delta G^{\neq}$ des groupes diméthylamino dans les processus de rotation empêchée autour de la liaison C—N exocyclique ont été déterminées par rmn du proton et du carbone-13.

Les composés étudiés sont le chlorure de *N*,*N*-diméthylaminopyrimidinium **1** et quelques uns de ses dérivés chlorés **2** et **4**, méthylé **3** et diméthylaminé **5**.

1 $R_2 = R_5 = R_6 = H$
2 $R_2 = Cl, R_5 = R_6 = H$
3 $R_2 = R_6 = CH_3, R_5 = H$
4 $R_2 = Cl, R_5 = CH_3, R_6 = H$
5 $R_2 = N(CH_3)_2, R_5 = R_6 = H$

Résultats

La méthode de détermination des paramètres thermodynamiques d'activation a déjà été décrite dans une précédente publication (1). L'analyse complète par forme de bande a été faite en rmn du carbone-13 pour les composés **1** à **5**. Elle permet d'obtenir les paramètres thermodynamiques $\Delta H^{\neq}$, $\Delta S^{\neq}$ et $\Delta G^{\neq}$ relatifs au processus de rotation. A titre de confirmation, l'enthalpie libre d'activation $\Delta G^{\neq}$ a été déterminée à la température de coalescence, pour l'ensemble des composés, en rmn du proton. Dans ce cas la constante de vitesse k_c a été calculée à l'aide de la relation (4) $k_c = \pi\Delta\nu_\infty/\sqrt{2}$ et l'équation d'Eyring (5) permet alors de déterminer $\Delta G^{\neq}$.

En ce qui concerne le choix du solvant, le méthanol ayant été utilisé pour les pyrimidines à l'état neutre (1), nous avons repris ce même solvant pour faciliter les comparaisons. Il était toutefois fondamental de vérifier que celui-ci n'entraînait pas de déprotonation des sels étudiés. Or le méthanol étant un peu plus acide que l'eau (6), les pK_a dans ce solvant sont voisins ou légèrement supérieurs à ceux obtenus dans l'eau. Ainsi la méthyl-4 pyridine a un pK_a de 6.02 ± 0.02 dans l'eau et de 6.09 ± 0.01 dans le méthanol (7). En ce qui concerne la *N*,*N*-diméthylamino-4 pyrimidine, **1**, son pK_a dans l'eau étant de 6.35 (8), on a calculé qu'aucune déprotonation n'intervient dans l'eau et

donc *a fortiori* dans le méthanol. Il en est de même pour les dérivés **3** et **5**, la substitution du noyau pyrimidique par un groupement méthyle ou diméthylamino ayant pour effet d'augmenter le pK_a. Le seul problème est relatif aux molécules substituées en position 2 par un chlore, c'est-à-dire les pyrimidines **2** et **4**. Ce substituant a pour effet de diminuer notablement leur basicité en raison de son caractère électroattracteur; ainsi la chloro-2 *N*-méthylamino-4 pyrimidine a un pK_a de 2.83 (9). Un groupe méthyle sur l'atome d'azote exocyclique a par contre pour effet d'augmenter la basicité de la pyrimidine; la différence de pK_a entre la *N*,*N*-diméthylamino-4 pyrimidine et l'amino-4 pyrimidine est en effet de 0.64 (8, 10). Le pK_a dans l'eau de la chloro-2 *N*,*N*-diméthylamino-4 pyrimidine peut, dans ces conditions, être évalué à environ 3.15. Il sera un peu plus élevé pour la chloro-2 *N*,*N*-diméthylamino-4 méthyl-5 pyrimidine du fait de la présence du groupe méthyle en position 5. En conséquence la déprotonation que pourrait éventuellement subir les chlorures **2** et **4** dans le méthanol n'excéderait pas 3.5%; elle peut être considérée comme négligeable.

Nous avons néanmoins tenu à corroborer les valeurs des enthalpies libres d'activation obtenues dans le méthanol avec celles obtenues dans un autre solvant. Nous avons choisi l'alcool benzylique dont l'acidité est sensiblement la même que celle du méthanol (11). Or il a été montré que, pour des solvants d'acidité voisine, le pK_a d'un soluté donné serait inversement proportionnel à la constante diélectrique du solvant (12, 13). Dans l'alcool benzylique ($\varepsilon = 13.1$) la déprotonation des chlorures étudiés serait donc encore plus faible que dans le méthanol ($\varepsilon = 32.6$).

Les paramètres thermodynamiques d'activation et certaines données relatifs à la rotation empêchée autour de la liaison C—N exocyclique dans les pyrimidines protonées sont donnés dans le tableau 1.

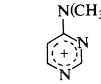
Les diagrammes d'Eyring $\log_{10} k/T$ en fonction de $1/T$ pour les pyrimidines **1** à **5** sont donnés sur la fig. 1.

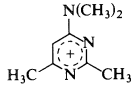
Discussion

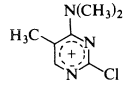
Nous discuterons nos résultats en considérant les valeurs de $\Delta G^{\neq}$ de préférence à celles de $\Delta H^{\neq}$, compte tenu de la meilleure précision obtenue sur la détermination de $\Delta G^{\neq}$ (14) et du fait que l'entropie d'activation $\Delta S^{\neq}$ doit être voisine de zéro dans les processus de rotation.

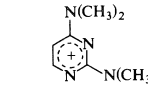
Effets de solvant

Bien que des travaux antérieurs aient montré une augmentation de la valeur de l'enthalpie libre d'activation $\Delta G^{\neq}$ avec la constante diélectrique du solvant (15, 16), nous avons observé ici un effet contraire en comparant les résultats obtenus dans le méthanol ($\varepsilon = 32.6$) et dans l'alcool benzylique ($\varepsilon = 13.1$). Or il ne peut s'agir d'une déprotonation des sels dans ces solvants, l'écart entre les valeurs de $\Delta G^{\neq}$ déterminées dans le méthanol et l'alcool benzylique étant le même (1.5 kJ mol^{-1}) pour les pyrimidines **1** et **2**, de pK_a très différents (voir plus haut).









L'augmentation (de 1.5 à 3.3 kJ mol^{-1}) de l'enthalpie libre d'activation déterminée dans l'alcool benzylique pourrait alors s'interpréter par l'existence d'interactions spécifiques entre le noyau pyrimidique et le solvant benzénique. Des interactions de ce type ont d'ailleurs déjà été mises en évidence pour de tels systèmes (17). La proximité des deux noyaux aromatiques entraînerait une gêne stérique pour le processus de rotation, ce qui conduirait à une élévation de la hauteur de la barrière de rotation. Pour confirmer cette hypothèse, nous avons étudié le chlorure de pyrimidinium **3** dans l'alcool butylique; le pK_a de la pyrimidine correspondante est suffisamment élevé pour qu'aucune déprotonation ne puisse intervenir. Aucun effet de solvant n'a été observé sur les valeurs des $\Delta G^{\neq}$ obtenues dans les deux solvants non aromatiques, alcool butylique ($\varepsilon = 17.1$) et méthanol ($\varepsilon = 32.6$). Aucune variation notable des valeurs de $\Delta G^{\neq}$ n'avait d'ailleurs été observée dans le cas des pyrimidines à l'état neutre (1) étudiées dans des solvants non aromatiques.

Effets de substituant

En ce qui concerne l'influence de la nature des substituants en position 2 sur la barrière de rotation du groupe diméthylamino en position 4, on ne retrouve pas une augmentation des valeurs de $\Delta G^{\neq}$ avec le caractère électroattracteur de ces substituants comme nous l'avions observé sur les molécules neutres. Une corrélation du même type avait cependant été obtenue pour des sels de *N*,*N*-diméthylaminopyrylium (18). Dans le cas des chlorures de pyrimidinium, la présence d'un proton très acide peut favoriser des interactions de type liaison hydrogène avec le milieu, interactions dont l'importance pourrait être liée non seulement à l'acidité du chlorure considéré mais encore à l'encombrement des substituants en position 2. Compte tenu de la gamme relativement restreinte des valeurs de $\Delta G^{\neq}$, ces phénomènes secondaires pourraient justifier l'absence de corrélation entre les enthalpies libres d'activation et les pouvoirs

[f]Paramètres relatifs au groupement diméthylamino en position 2.

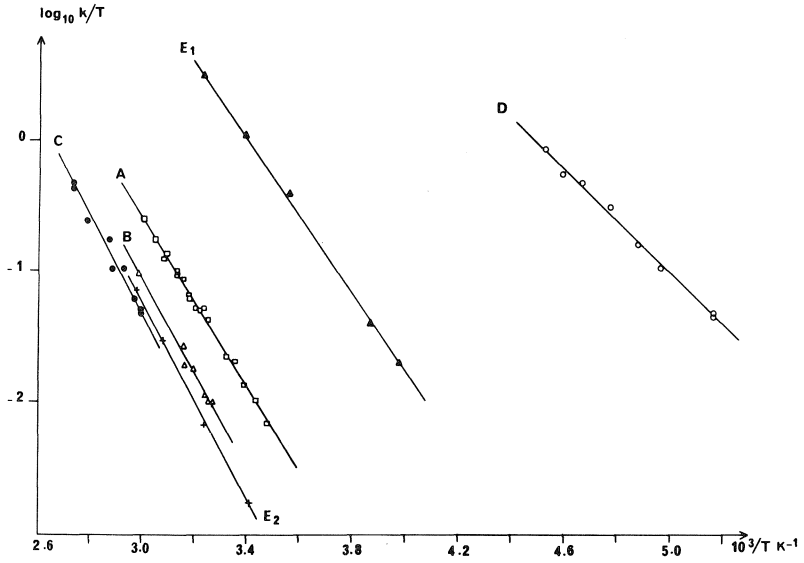

FIG. 1. Diagrammes d'Eyring relatifs à la rotation empêchée du groupement diméthylamino dans les chlorures de *N*,*N*-diméthylaminopyrimidinium (^{13}C rmn): (A) pyrimidine **1** en solution dans CD_3OD (R = 0.998) (R est le coefficient de corrélation); (B) pyrimidine **2** en solution dans CD_3OD (R = 0.990); (C) pyrimidine **3** en solution dans $C_6H_5CH_2OH$ (R = 0.985); (D) pyrimidine **4** en solution dans CD_3OD (R = 0.997); (E) pyrimidine **5** en solution dans CD_3OD (1) diméthylamino en position 2 (R = 0.9994) (2) diméthylamino en position 4 (R = 0.9996).

électroattracteurs des substituants considérés. Par contre, la corrélation entre ces pouvoirs électroattracteurs et les constantes de couplage $^1J(NMe_2\text{-}4)$ relatives au groupement diméthylamino en position 4 subsiste pour les molécules protonées.

La comparaison des résultats obtenus sur les composés **2** et **4** montre que l'introduction d'un groupement méthyle en position 5 abaisse, par effet stérique, la barrière de rotation d'environ 30 kJ mol^{-1}. Un résultat analogue avait été obtenu sur les mêmes molécules à l'état neutre (1).

Influence de la monoprotonation

Nos résultats montrent que la monoprotonation des *N*,*N*-diméthylaminopyrimidines entraîne une augmentation importante $\Delta(\Delta G^{\neq})$ de l'enthalpie libre d'activation relative à la rotation empêchée du groupe diméthylamino (voir tableau 2).

Cet accroissement de $\Delta G^{\neq}$ peut s'expliquer par la prédominance, parmi les formes de résonance, des structures limites quinoïdes favorisées par l'augmentation de la charge positive de l'atome d'azote exocyclique dans le cas des cations.

Des calculs sur l'amino-4 pyridine ont en effet montré que la contribution de telles formes limites est plus importante à l'état monoprotoné qu'à l'état neutre (3). Par ailleurs des travaux théoriques portant sur l'amino-4 diméthyl-2,5 pyrimidine (19) et sur des *N*,*N*-diméthylaminopyridines (2) indiquent une augmentation de l'indice de liaison pour la liaison C—N exocyclique lors de la protonation, augmentation en bon accord avec les résultats de notre étude.

Ces travaux théoriques prévoient également que l'accroissement de cet indice de liaison est plus

TABLEAU 3. Données expérimentales relatives aux chlorures de *N,N*-diméthylaminopyrimidinium

Composé	Solvant	Concentration mol L^{-1}	Rmn du carbone-13[a]	Rmn du proton[a]
 1	CD_3OD	0.55	$\Delta\nu_\infty = 13.70 - 0.011\,t$ $\Delta W_{diox}^{N(CH_3)_2} = 0.36 - 0.001\,t$	$\Delta\nu_\infty = 8.22 - 0.0005\,t$
	$C_6H_5CH_2OH$	0.28	$\Delta\nu_\infty = 11.10 - 0.031\,t$ $\Delta W_{diox}^{N(CH_3)_2} = 0.17\ (t = 7°C)^b$	$\Delta\nu_\infty = 2.80\ (t = 35°C)^c$
 2	CD_3OD	0.62	$\Delta\nu_\infty = 12.99 - 0.011\,t$ $\Delta W_{diox}^{N(CH_3)_2} = 0.30 - 0.006\,t$	$\Delta\nu_\infty = 6.51 - 0.004\,t$
	$C_6H_5CH_2OH$	0.6	—	$\Delta\nu_\infty = 11.55 + 0.023\,t$
 3	CD_3OD	0.44	$\Delta\nu_\infty = 14.90 - 0.018\,t$	$\Delta\nu_\infty = 11.0\ (t = 35°C)^b$
	$C_6H_5CH_2OH$	0.70	$\Delta\nu_\infty = 13.86 - 0.012\,t$ $\Delta W_{diox}^{N(CH_3)_2} = 0.58 - 0.003\,t$	$\Delta\nu_\infty = 22.5\ (t = 35°C)^b$
 4	CD_3OD	0.57	$\Delta\nu_\infty = 16.20 - 0.032\,t$ $\Delta W_{diox}^{N(CH_3)_2} = 0.27 - 0.013\,t$	—
 5	CD_3OD	1.7	$\Delta\nu_\infty(2) = 6.68 - 0.046\,t$ $\Delta\nu_\infty(4) = 16.04 - 0.031\,t$ $\Delta W_{diox}^{N(CH_3)_2(4)} = 0.5\ (t = 7 \text{ et } 20°C)^b$	—
	$C_6H_5CH_2OH$	1.0	$\Delta\nu_\infty(4) = 15.00 - 0.03\,t$ $\Delta W_{diox}^{N(CH_3)_2(4)} = 1.7 - 0.02\,t$	$\Delta\nu_\infty(4) = 7.55 + 0.065\,t$

[a]Les valeurs de $\Delta\nu_\infty$ et ΔW sont données en Hz et les températures en degré Celsius. Les chiffres entre parenthèses indiquent la position des groupements diméthylamino dans le composé **5**.
[b]Les valeurs de ΔW et $\Delta\nu_\infty$ déterminées aux températures indiquées ont été considérées constantes dans la gamme de température étudiée.

important lorsque le proton se fixe sur l'atome d'azote en *para* du groupement diméthylamino (2, 19). Or, notre étude de la monoprotonation des

Forme (N-1 H)

Forme (N-3 H)

amino-4 pyrimidines (20, 21) a montré que la forme prédominante est bien la forme (N-1 H). Dans ces conditions, on s'attend, pour ces composés, à un effet de la protonation sur la valeur de $\Delta G^{\neq}$ supérieur à celui observé lors de la protonation de l'adénine, par exemple, pour laquelle le site préférentiel de protonation est l'atome d'azote en *ortho* du groupe amino (22). C'est bien ce qui est observé, si l'on compare la valeur $\Delta(\Delta G^{\neq})$ pour la *N,N*-diméthylamino-4 pyrimidine (15 kJ mol^{-1}) à la valeur obtenue pour la *N,N*-diméthyladénine (9.7 kJ mol^{-1}) (23, 24). De même dans le cas de la bis *N,N*-diméthylamino-2,4 pyrimidine, l'augmentation de $\Delta G^{\neq}$ est de 24 kJ mol^{-1} pour le groupement diméthylamino en position 4 alors qu'elle n'est que de 14 kJ mol^{-1} lorsque ce groupement est en position 2 (cf. tableau 2). La différence entre les valeurs de $\Delta G^{\neq}$ pour ces deux groupements en position 4 et 2 est de 5.9 kJ mol^{-1} pour la molécule neutre alors qu'elle est de 15.9 kJ mol^{-1} pour la molécule protonée. La différence de conjugaison des groupes diméthylamino en position 4 et 2 avec le cycle pyrimidique se trouve donc accentuée par la monoprotonation du composé.

Conclusion

Cette étude a permis de montrer que la monoprotonation des *N,N*-diméthylaminopyrimidines entraîne une augmentation importante de l'enthalpie libre d'activation du groupe diméthylamino. Du fait de la prédominance de la forme monoprotonée (N-1 H), cet accroissement de $\Delta G^{\neq}$ est plus grand quand le groupement diméthylamino est en position 4 que lorsqu'il se trouve en position 2. Ceci met en évidence le fait que la différence de conjugaison des groupes diméthylamino en position 4 et 2 avec le cycle pyrimidique se trouve accentuée par la monoprotonation de ces composés.

Partie expérimentale

Les chlorures de pyrimidinium **1** à **5** ont été préparés par action de HCl sur les pyrimidines correspondantes et purifiés par sublimation sous vide poussé.

Les spectres rmn du proton et du carbone-13 ont été réalisés sur les appareils et selon les conditions opératoires déjà décrits dans la précédente étude (1). Il a été nécessaire d'utiliser un thermomètre à mercure pour les mesures des températures dans les expériences en rmn du carbone-13. Le mercure subissant un échauffement lié à la haute fréquence, les mesures ont été effectuées sans découplage des protons, une correction de température due à l'utilisation du découpleur étant faite ensuite.

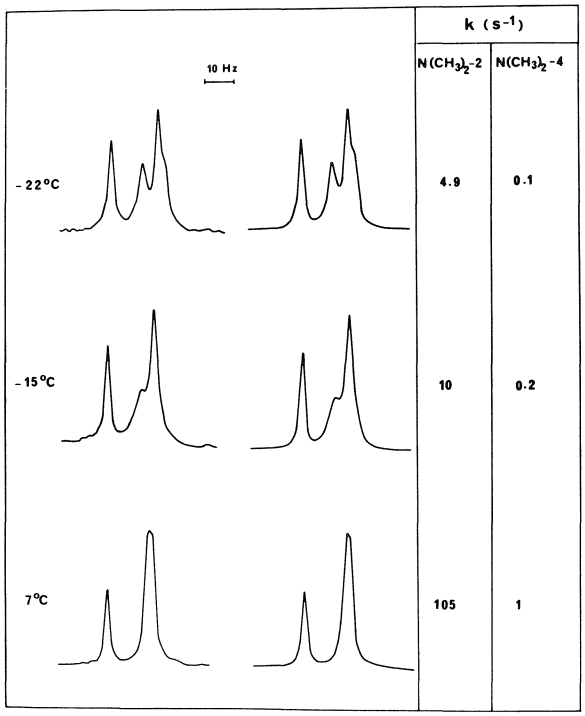

FIG. 2. Spectres rmn du carbone-13 relatifs aux groupements diméthylamino dans le chlorure de bis *N*,*N*-diméthylamino-2,4 pyrimidinium en solution dans CD_3OD. Spectres expérimentaux (à gauche) et simulés (à droite) à différentes températures.

Attribution des spectres rmn du carbone-13

Les déplacements chimiques des carbones et les constantes de couplage $J(^{13}C—^{1}H)$ ont été déterminés[3] pour les chlorures de *N*,*N*-diméthylaminopyrimidinium **1** à **5**. L'attribution des spectres résulte de la détermination de ces constantes de couplage et de l'application des différentes règles caractérisant ces constantes dans le noyau pyrimidique (25). Dans le cas du composé **5**, l'attribution des signaux relatifs aux deux groupements diméthylamino en position 2 et 4 a été établie sans équivoque. Elle résulte de l'attribution obtenue pour la molécule neutre (1) et de l'évolution des déplacements chimiques de ces groupes pour des mélanges de molécules neutre et monoprotonée en proportions variables.

Analyse de la forme des bandes

En absence d'échange, la largeur du signal relatif au groupe diméthylamino $W_{N(CH_3)_2}$ ainsi que la différence $\Delta\nu_\infty$ des déplacements chimiques entre les deux sites ont été déterminées par les mêmes méthodes que celles utilisées dans l'étude précédente (1). Les résultats concernant ce dernier paramètre $\Delta\nu_\infty$ ainsi que la différence ΔW entre les largeurs des raies relatives au groupe diméthylamino et à la référence utilisée (dioxanne) sont donnés dans le tableau 3 pour l'ensemble des produits étudiés par analyse de forme de bandes. Ces paramètres $\Delta\nu_\infty$ et ΔW varient peu avec la température mais il est cependant nécessaire de tenir compte de ces faibles variations dans le calcul pour affiner les résultats. On remarque que $\Delta\nu_\infty$ augmente en rmn du proton alors que ce paramètre diminue en rmn du carbone-13 quand le solvant utilisé est $C_6H_5CH_2OH$ au lieu de CD_3OD.

L'analyse totale par forme de bandes a été effectuée à l'aide du programme DNMR que nous avons modifié pour tenir compte du recouvrement des bandes relatives aux deux groupements diméthylamino en position 2 et 4 dans le cas du composé **5** à l'état neutre et à l'état monoprotoné (cf. fig. 2).

A ^{13}Cmr study of 2′-deoxynucleotides in the *syn* and *anti* conformation

WALTER P. NIEMCZURA[1] AND FRANK E. HRUSKA

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 29, 1979

WALTER P. NIEMCZURA and FRANK E. HRUSKA. Can. J. Chem. **58**, 472 (1980).

The geminal and vicinal ^{13}C—^{31}P coupling constants for the 3′- and 5′-monophosphates and 3′,5′-diphosphates of thymidine and its isomer 6-methyl-2′-deoxyuridine have been obtained for aqueous solutions at various pH values. Since the thymine base is *anti* and the 6-methyluracil base is *syn*, the data provide information about the influence of the orientation about the *N*-glycosyl linkage on the conformation about the C(5′)—O(5′)(ϕ) and C(3′)—O(3′)(ϕ′) bonds. The ^3J(C4′—P5′) couplings reveal a preference for the t(ϕ) conformer of the 5′-nucleotidyl units, in agreement with previous measurements of ^{1}H—^{31}P coupling constants. The ^3J(C4′—P3′) and ^3J(C2′—P3′) couplings are consistent with a preference for the t(ϕ′) conformer for both the *syn* and *anti* 3′-nucleotidyl units. The response of these couplings to secondary ionization of the phosphate is different for the thymine and 6-methyluracil derivatives and suggests a phosphate–phosphate interaction for the *syn*, but not the *anti*, 3′,5′-diphosphates. A correlation between the sugar-pucker and the ϕ′ orientation is revealed. The ^2J(C5′—P5′) and ^2J(C3′—P3′) are relatively insensitive to the ionization state of the phosphate as well as to other structural features of the deoxyribose phosphate backbone.

WALTER P. NIEMCZURA et FRANK E. HRUSKA. Can. J. Chem. **58**, 472 (1980).

On a obtenu les constantes de couplage géminal et vicinal du ^{13}C et du ^{31}P des monophosphates 3′ et 5′ et des diphosphates-3′-5′ de la thymidine et de son isomère méthyl-6 déoxy-2′ uridine en solutions aqueuses et à différents pH. Puisque la base thymine est *anti* et la base méthyl-6 uracile est *syn* les données fournissent des informations au sujet de l'influence de l'orientation autour du lien *N*-glycosyle sur la conformation autour des liaisons C(5′)—O(5′) (ϕ) et C(3′)—O(3′) (ϕ′). Les couplages ^3J(C4′—P5′) révèlent une préférence pour le conformère t(ϕ) du nucléotidyle-5′ en accord avec les mesures antérieures des constantes de couplage ^{1}H—^{31}P. Les couplages ^3J(C4′—P3′) et ^3J(C2′—P3′) sont conformes avec une préférence pour le conformère t(ϕ′) dans le cas des deux nucléotidyles-3′ *syn* et *anti*. La reponse de ces couplages à une ionisation secondaire du phosphate est différente pour les dérivés de la thymine et de la méthyl-6 uracyle, et suggère une interaction phosphate–phosphate dans les dérivés *syn*. Cette interaction n'existe pas dans les diphosphates-3′,5′ *anti*. On révèle une corrélation entre la molécule fléchie de sucre et l'orientation ϕ′. Les couplages ^2J(C5′—P5′) et ^2J(C3′—P3′) sont relativement indépendants de l'état d'ionisation du phosphate et des autres particularités structurales du squelette de déoxyribose phosphate.

[Traduit par le journal]

Introduction

An important conformational feature of nucleosides is the sugar-base torsion angle (χ) which defines the relative orientation of the base and sugar moieties (Fig. 1). Useful model compounds for evaluating the consequences (1) of the presence of a *syn* pyrimidine base are nucleosides possessing a 6-methyl substituent since it is certain that molecules so substituted are *syn* (2–6).[2] It has been demonstrated that ^{13}C nmr can provide for nucleotides structural information complementary to that derived from ^{1}H nmr (7–11).[3] In this work we report our determination of the pH dependence of the ^{13}C—^{31}P coupling constants of the 3′-, 5′-, and 3′,5′-phosphate derivatives of dT and dT* in aqueous solution. The data provide information about the influence of *syn* and *anti* bases on the orientation about the C(5′)—O(5′)(ϕ) and C(3′)—O(3′)(ϕ′) bonds.

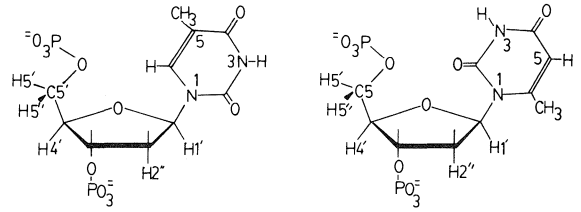

FIG. 1. Structural formulae of d(pTp) (left, *anti* conformation) and d(pT*p) (right, *syn* conformation), the 3′,5′-diphosphates of 2′-deoxythymidine (dT) and 6-methyl-2′-deoxyuridine (dT*).

Experimental

Materials

The dT, 3′dTMP, and 5′dTMP were purchased from the Sigma Chemical Co. The dT* was synthesized according to the Holy procedure (12). The 3′dT*MP and 5′dT*MP were prepared by direct phosphorylation of the appropriately blocked (5′-O-trityl or 3′-O-benzyl) derivative of dT*, according to published procedures (6). The 3′,5′-diphosphates were made by direct phosphorylation of unprotected dT and dT* using condi-

[1]Holder of a University of Manitoba Fellowship. This work represents for W. P. N. partial fulfillment of a doctoral degree.

[2]Dr. G. I. Birnbaum has informed us that crystalline dT* is *syn*.

[3]Abbreviations used: nmr, nuclear magnetic resonance. tions identical to those used to generate the monophosphates. Details of all syntheses may be found in the doctoral thesis of W. P. N.

Spectra

^{13}C spectra were obtained in the Fourier transform mode on a Bruker WH-90DS spectrometer (22.63 MHz), equipped with a Nicolet-1180 computer, the NTC-FT-1180 software package and quadrature phase detection. Spectral widths were typically 3800 Hz acquired into 16 K data points and zero-filled to 32 K. To apodize the free-induction decay (FID), exponential multiplication using a line broadening equal to the digital resolution (ca. 0.2 Hz) was applied. Normally spectra were recorded with complete proton noise decoupling, though some proton-coupled spectra were obtained to facilitate peak assignments.

All samples were examined in 10 mm outer diameter tubes, at concentrations of 80–100 mg/mL in D_2O, containing 1% dioxane as internal reference.[4] The probe temperature was regulated to 297 ± 1 K. Paramagnetic ions were removed by chromatography on Chelex-100 (Bio-Rad Laboratories) and treatment with dithizone (J. T. Baker Chemical Co.) in CCl_4, as suggested by Cozzone and Jardetzky (13). The 3′,5′-diphosphate solutions contained small amounts (~2 m*M*) of EDTA. The pH was adjusted by the addition of dilute NaOD or DCl and is given as the pH meter reading. (In Figs. 2, 4, and 5 (see below) 0.4 units should be added to this reading to correct for the deuterium isotope effect (14).)

Results and Discussion

Spectral Assignment

The assignment of the base and sugar carbon atoms was carried out by comparison of our ^{13}C spectra with published data (7–11, 15–18). The presence of splittings (1–8 Hz) attributable to ^{13}C—^{31}P couplings facilitated location of the C(2′), C(3′), and C(4′) atoms of the 3′-nucleotides and of the C(4′) and C(5′) atoms of the 5′-nucleotides. The influence of phosphorylation and phosphate ionization on the sugar carbon shifts also proved useful. Several proton-coupled spectra were also obtained for assigment purposes.

Geminal ^{13}C—^{31}P Coupling Constants

The following comments can be made about the geminal coupling constants, ^2J(C3′—P3′) and ^2J(C5′—P5′), of the 3′-, 5′-, and 3′,5′-phosphates of dT and dT* (see pH titration curves in Fig. 2). The magnitudes of ^2J(C3′—P3′) and ^2J(C5′—P5′) lie in the ranges 4.1–5.1 Hz and 4.2–5.3 Hz, respectively, and show little variation over the entire pH range. They are similar to the ^2J(C,P) couplings reported (9) as a function of pH, for 3′UMP, 3′AMP, 5′UMP, and 5′AMP (4.3–5.0 Hz). They are also similar to the ^2J(C,P) values of (*a*) the 2′-, 3′-, and 5′-AMP fragments of the ribodinucleoside monophosphates, 3′, 5′ApA, and 2′,5′ApA, (10), (*b*) the dTMP and dT*MP fragments of the 2′-deoxydinucleoside monophosphates d(TpT), d(T*pT), d(TpT*), and d(T*pT*),[5] and (*c*) the UMP fragments of the ribopolynucleotide, poly U (7). Thus, the ^2J(C,P) couplings appear to be relatively intensive to structural changes. It should be stressed, however, that certain modifications can lead to large changes in ^2J(C,P) couplings. Thus, in the strained 3′,5′-cyclic nucleotides ^2J(C5′—P5′) can be as large as 7.0 Hz (8, 19), reflecting perhaps changes in the P—O—C bond angle (20) and P—O torsion angle (20, 21).

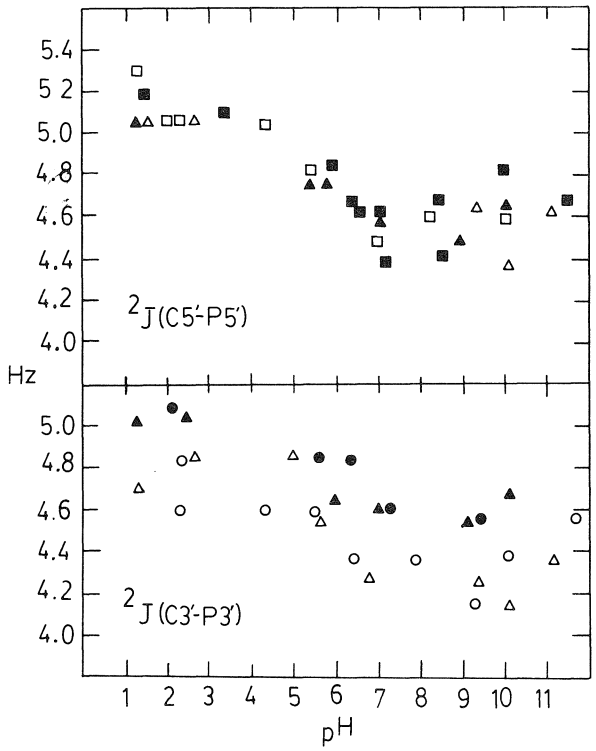

FIG. 2. Geminal ^2J(C3′—P3′) (*a*) and ^2J(C5′—P5′) (*b*) coupling constants in Hz versus pH of the solution (uncorrected for deuterium isotope effect). Solid symbols, T derivatives; open symbols, T* derivatives (see footnote 2). 3′dTMP (●), 3′dT*MP (○), 5′dTMP (■), 5′dT*MP (□), dpTp (▲), dpT*p (△).

Though the ^2J(C,P) couplings vary little, a weak, sigmoidal trend can be discerned in the pH titration curves (Fig. 2). For both couplings, decreases of a few tenths of a Hz occur for the T and T* derivatives in the pH range 5–7, due presumably to the phosphate ionization. The plots are in reasonable agreement with the pK_a values (~6.3) reported for secondary phosphate ionization of 3′- and 5′-nucleotides in the 2′-deoxyribose series (13, 22).

[4]No concentration dependence of the *J* values of 3′dT*MP was noted in the 30–100 mg/mL range.

[5]Unpublished data of the authors.

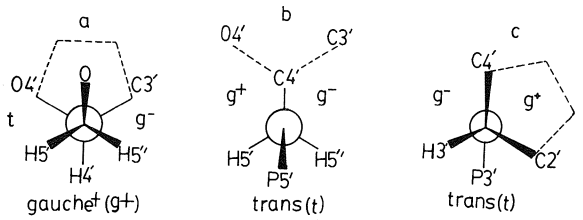

FIG. 3. Newman projections viewed along (*a*) C4′—C5′(ψ), (*b*) C5′—O5′(ϕ), and (*c*) C3′—O3′(ϕ′); g^+, t, and g^- refer respectively to the conformational domain containing the 60°, 180°, (−180°), and 300° (−60°) conformer defined according to ref. 24. (*a*) $g^+(\psi)$ conformer shown; t, g^- give location of O5′ in t(ψ) and $g^-(\psi)$ respectively. (*b*) t(ϕ) conformer shown; g^+, g^- give location of P5′ in $g^+(\phi)$ and $g^-(\phi)$ respectively. (*c*) t(ϕ′) conformer shown; g^+, g^- give location of P3′ in $g^+(\phi')$ and $g^-(\phi')$, respectively.

Conformation about the C(5′)—O(5′)(ϕ) Bond

The work of Mantsch and Smith on 5′-nucleotides (7) first showed that ^3J(C4′—P5′) coupling constants provide information about the ϕ bond orientation (Fig. 3). This vicinal coupling should, according to Govil and Smith (11), be large (~10 Hz) for the t(ϕ) conformer and small (~2 Hz) for the $g^+(\phi)$ and $g^-(\phi)$ conformers. Then, it is simple to derive:

$$[1] \quad n(t\phi) \approx [^3J(C4'—P5') - 2]/8$$

where $n(t\phi)$ is the fractional contribution from t(ϕ) to the conformer blend.[6]

The effect of pH on the vicinal ^3J(C4′—P5′) couplings of 5′dTMP, dpTp, 5′dT*MP, and d(pT*p) is shown in Fig. 4. The Alderfer–Ts'o data (9) for the ribose derivatives, 5′UMP and 5′AMP, are included. (Note that the ordinate of Fig. 4 is given in Hz and in %t(ϕ) obtained from eq. [1].) Overall, the ^3J(C,P) values span a range from 7.8–8.9 Hz. Weak sigmoidal behaviour can be discerned in the 5′dTMP data, with ^3J(C,P) at pH > 8, on the average, 0.3 Hz less than at pH < 6.0. (This behaviour cannot be discerned in the data for d(pTp), 5′UMP, and 5′AMP.) Similarly, the data for the T* derivatives define a sigmoidal curve, but here an increase of ~0.3 Hz is seen in ^3J(C,P) as the solution becomes basic. If the ionization of the phosphate exerted only a direct (through-bond) effect on ^3J(C,P), this difference in behaviour for the T and T* derivatives would not be expected. Therefore, it is reasonable to conclude that these variations in

[6]Also, $n(t\phi)$ has been related (6) to $\sum'(=^3J(H5'—P5') + ^3J(H5''—P5'))$ via $n(t\phi) \approx (25 - \sum')/20.8$ which provides an *independent* means of determining the population of t(ϕ) and the combined weighting of $g^+(\phi)$ and $g^-(\phi)$. This expression may be combined with eq. [1] to yield $^3J(C4'—P5') \approx 11.6 - 0.38\sum'$ which describes the expected correlation between the $^{13}C—^{31}P$ and $^1H—^{31}P$ coupling data. Similar, simple expressions have proven to be useful in correlating nmr data for nucleotides (23).

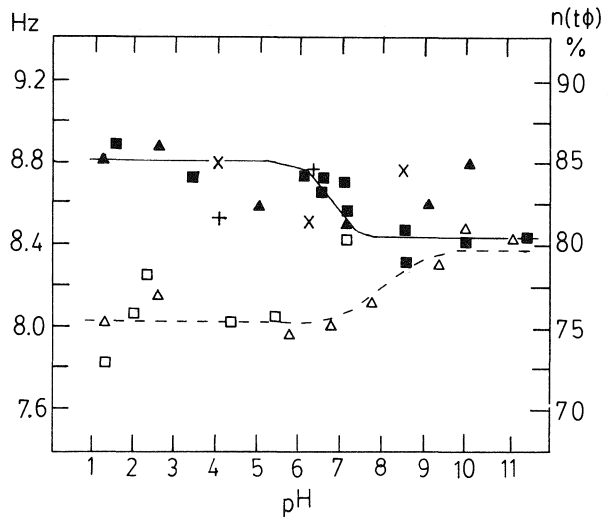

FIG. 4. Vicinal ^3J(C4′—P5′) coupling constants in Hz versus pH of the solution (uncorrected for deuterium isotope effect). Solid symbols, T derivatives; open symbols, T* derivatives. 5′dTMP (■), 5′dT*MP (□). dpTp (▲), dpT* (△), Alderfer–Ts'o data (9) for 5′UMP (×) and 5′AMP (+).

^3J(C,P), are in part due to the conformational effects.

In conformational terms, our ^3J(C,P) data (Fig. 4) are in general agreement with previous ^1H nmr and X-ray diffraction studies. Thus, a distinct preference for t(ϕ) is indicated, with $n(t\phi) > 71\%$ in all instances. In the crystal state all known 5′-nucleotidyl fragments are t(ϕ) (24). Furthermore, for 5′dTMP, d(pTp), 5′UMP, and 5′AMP, the ^3J(C4′—P5′) values are identical at all pH values to within 0.5 Hz, with $n(t\phi)$ in the range 78–87%. Thus, for this collection of molecules, neither the nature of the base (purine or pyrimidine) nor of the sugar (ribose or deoxyribose), nor the presence of a 3′-phosphate influences $n(t\phi)$, in agreement with the ^1H nmr work of Davies and Danyluk (25).

At acid pH the ^3J(C4′—P5′) values for the T* molecules are on the average 0.7 Hz smaller than those for the T derivatives. This apparent decrease in $n(t\phi)$ for the dT*MP and d(pT*p), relative to their T counterparts, is in line with previous findings, based on ^1H nmr (6), that *syn* pyrimidine bases lead to decreases in the population of the $g^+(\psi)$ conformer about the C(4′)—C(5′) bond, a consequence of which is a decrease in the t(ϕ) population for C(5′)—O(5′). This interdependence of the ϕ and ψ conformers has been discussed in detail (ref. 6 and references therein).

At basic pH, however, little difference is noted in the ^3J(C4′—P5′) values for the T and T* molecules. Apparently ionization of the phosphate has led to some ϕ bond changes in, particularly, the T* molecules.

Conformation about the C(3')—O(3') (φ') Bond

In principle three staggered conformers, $g^+(\phi')$, $t(\phi')$, and $g^-(\phi')$, are accessible to the C(3')—O(3') bond of a 3'-nucleotide (Fig. 3). However, steric considerations and energy calculations (26–28) have indicated that the $g^+(\phi')$ conformer can be excluded in any evaluation of the φ' conformer weightings. Thus, nmr spectroscopists have been led to interpreting their $^{13}C—^{31}P$ and $^1H—^{31}P$ coupling constant data in terms of a two-state $t(\phi') \rightleftarrows g^-)\phi')$ model (9, 25, 29, 30). However, because of a recent survey by Sundaralingam and co-workers[7] of the crystal structures of 3'-ribonucleotides, the appropriateness of the two-state model for interpretation of solution coupling data must itself remain open to question. They have found that, for these ribose derivatives (eight in total), the φ' values define a *single* broad range from −91.5° to −164.9°. This range comprises adjoining segments of the $g^-(\phi')$ domain (centered at −60°). In one instance, 3'AMP·2H_2O, φ' is −123°, which means that the H(3') and P(3') are but 3° from the eclipsed situation. Thus, it seems that this eclipsed conformer does not present a particularly large barrier to interconversion between $t(\phi')$ and $g^-(\phi')$. Energy calculations (31,32) also point to the absence of a major barrier to rotation about the C(3')—O(3') bond. Given these studies by Sundaralingam and co-workers, translation of nmr data into $t(\phi')$ and $g^-(\phi')$ populations in a two-state model may be unjustified since the coupling constants could equally well be a reflection of averaging within a single broad range of conformer angles approximating that observed in the crystal state.[8]

Because of this uncertainty, we shall interpret our coupling constants in a qualitative manner which does not imply a choice between a two-state or broad "single-state" model. We shall assume simply that the vicinal $^{13}C—^{31}P$ couplings in the C(2') or C(4')—C(3')—O(3')—P(3') fragments vary in a Karplus manner with the φ' torsion angle. Thus, ^3J(C2'—P3') and ^3J(C4'—P3') should be relatively large in the $g^-(\phi')$ and $t(\phi')$ *domains*, respectively, and relatively small in the $t(\phi')$ and $g^-(\phi')$ *domains* respectively (Fig. 3). If, in the future, evidence is provided for a two-state situation, then separate populations for $t(\phi')$ and $g^-(\phi')$ could be obtained quite simply from our data.

Figure 5 shows the pH dependence of the vicinal ^3J(C2'—P3') and ^3J(C4'—P3') couplings for 3'dTMP, d(pTp), 3'dT*MP, and d(pT*p); also included are the data for 3'UMP (indicated by ×) taken from Alderfer and Ts'o (9). For our 2'-deoxyribose derivatives, as well as for 3'UMP, the ^3J(C2'—P3') and ^3J(C4'—P3') couplings are confined to the ranges 0.5–3.9 Hz and 5.9–8.5 Hz, respectively. Thus, in all cases a preference is indicated for the $t(\phi')$ domain in which P(3') is *trans* to C(4') and *gauche* to C(2'). There are, however, some important differences in the trends for the T and T* molecules.

The ^3J(C2'—P3') couplings on the one hand and ^3J(C4'—P3') couplings on the other are similar for 3'dTMP and d(pTp) over the entire pH range. Thus, the presence of a 5'-phosphate, in either the monoanionic form (pH < 6.0) or dianionic form (pH

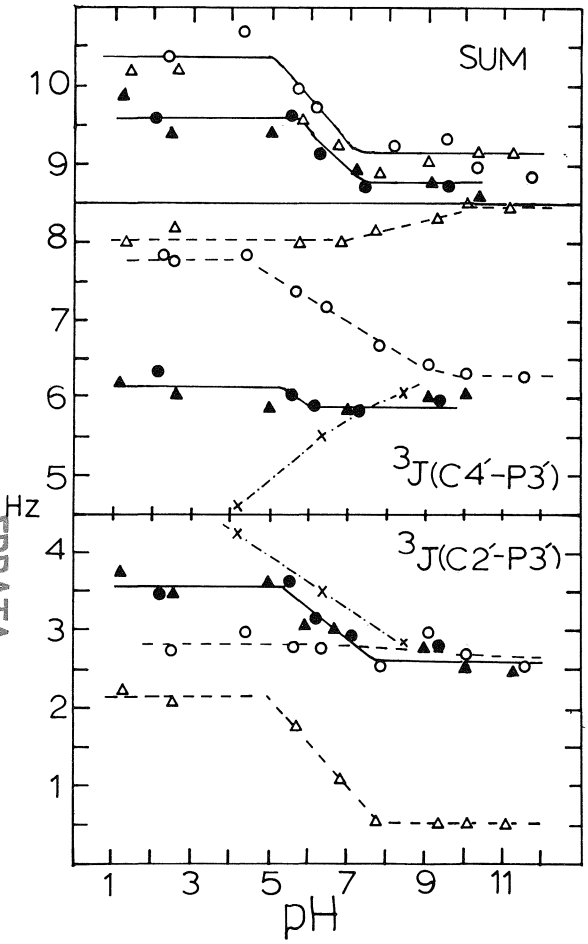

FIG. 5. Vicinal ^3J(C2'—P3') and ^3J(C4'—P3') coupling constants and the sum, ^3J(C2'—P3') + ^3J(C4'—P3'), for a 3'-nucleotidyl unit versus pH of the solution (uncorrected for the deuterium isotope effect). Solid symbols, T derivatives; open symbols, T* derivatives. 3'dTMP (●), 3'dT*MP (○), 5'dTMP(■), 5T*MP (□), d(pTp)(▲), d(pT*p) (△). 3'UMP (×) from Alderfer and Ts'o (9). The 0.5 Hz ^3J(C2'—P3') couplings for d(pT*p) in basic solution were estimated from the line width of the C(2') resonance since no splitting was observed.

[7]Private communication from M. Sundaralingam.

[8]More meaningful here would be a survey of crystal φ' data for 2'-*deoxy*-3'-nucleotides. Unfortunately, only the value for the internal C(3')—O(3') bond of d(pTpT) is available (33): φ' = −108°, 12° from the H(3')—P(3') eclipsed conformer.

> 8.0), appears to have little influence on the preferred orientation of the ϕ' bond. The ^3J(C4′—P3′) couplings are to within experimental error invariant over the pH range, while the ^3J(C2′—P3′) couplings decrease by about 0.5 Hz in basic solution, reflecting presumably the secondary ionization of the 3′-phosphate. It would, however, be difficult to disentangle the contributions of the through-bond and the conformational effects of this ionization, but overall it seems that ϕ' for the T derivatives is not affected by the changes in charge on the 3′- and 5′-phosphates.

It is interesting to note that in *basic* solution the corresponding couplings of 3′UMP and 3′dTMP are identical. In acid solution, however, ^3J(C4′—P3′) in 3′UMP is about 1.5 Hz smaller than its counterpart in 3′dTMP. Thus, in basic solution the 2′-hydroxyl has no influence on the ϕ' orientation which is apparent in the ^{13}C, ^{31}P couplings. However, in acid solution, when the phosphate groups are monoanionic, the 2′-hydroxyl appears to destabilize slightly the t(ϕ') domain. The near equality of the ^3J(C2′—P3′) (4.2 Hz) and ^3J(C4′—P3′) (4.6 Hz) couplings of 3′UMP in acid solution would indicate a near balance in time spent in the t(ϕ') and g$^-$(ϕ') domains.

For 3′dT*MP and d(pT*p) at *acid* pH the ^3J(C4′—P3′) couplings are about 1.5–2.0 Hz larger than those for the T molecules. On the other hand, the ^3J(C2′—P3′) couplings are smaller for the T* molecules, by ~0.5 Hz for 3′dT*MP and by ~1.5 for d(pT*p). Thus, the t(ϕ') domain appears to be stabilized by the *syn* T* base, the effect being noticeably larger at the 3′,5′-diphosphate level. This apparent dependence of the ϕ' orientation upon the conformation about the *N*-glycosyl link (χ) cannot be due to a direct effect since the base and 3′-phosphate lie on opposite sides of the sugar ring. It is more likely that this dependence of ϕ' on χ is mediated by the changes in the sugar ring conformation elicted by the *syn* base (see below).

Some interesting changes (Fig. 5) are seen in the T* data as the solution enters the *basic* range in which the phosphates bear two negative charges. Thus, while ^3J(C4′—P3′) for 3′dT*MP shows a decrease from ~7.8 Hz to 6.3 Hz, ^3J(C2′—P3′) shows little dependence on pH. In basic solution the couplings of 3′dT*MP are to within experimental error identical to their counterparts in 3′dTMP. This indicates that the *syn* base does not have large effects on the ϕ' torsion angle distribution of a 3′-nucleotide in basic solution.

More dramatic pH effects are noted for the 3′,5′diphosphate of T*. Thus, in basic solution ^3J(C2′—P3′) decreases by 1.5 Hz to 0.5 Hz[9] while ^3J(C4′—P3′) increases by ~0.5 Hz to 8.5 Hz. For 3′dT*MP and d(pT*p), the magnitudes of the corresponding couplings diverge as the phosphates undergo secondary ionization. And, in basic solution large differences (2 Hz) are evident in the couplings for the pair of T* derivatives. (In acid solution these differences are much smaller, about 0.7 Hz for ^3J(C2′—P3′) and 0.2 Hz for ^3J(C4′—P3′).) These 2 Hz differences indicate that, for a T* unit, the 5′-phosphate influences the conformation about the C(3′)—O(3′) bond, particularly when the 3′- and 5′-phosphates bear two negative charges. This contrasts with the situation for 3′dTMP and d(pTp) where no difference in the corresponding couplings is noted at any pH, no 5′-phosphate influence thus being apparent. The magnitudes of the couplings for d(pT*p) in basic solution, 0.5 Hz for ^3J(C2′—P3′) and ~8.5 Hz for ^3J(C4′—P3′), indicate a very strong preference for the t(ϕ') conformer. The diminutive value of ^3J(C2′—P3′) suggests further a strong tendency towards a 90° Karplus angle between the C(2′)—C(3′) and O(3′)—P(3′) bonds. The Govil–Smith equation (11) for ^{13}C, ^{31}P couplings predicts a 0.5 Hz coupling for an 86° Karplus angle. This Karplus angle corresponds to a ϕ' value of −154° which falls near to the t(ϕ') extreme of the broad range defined by the ϕ' values of crystalline 3′-ribonucleotides (see above).

Also, given the diminutive value of ^3J(C2′—P3′) (0.5 Hz) in d(pT*p) in basic solution, we may consider the magnitude of ^3J(C4′—P3′) (8.5 Hz) as a lower-limit estimate for a *trans* (180° Karplus angle) ^3J(C,P) coupling for the C(4′)—C(3′)—O(3′)—P(3′) and C(2′)—C(3′)—O(3′)—P(3′) fragments in basic solution.

Requiring some explanation are (*a*) the apparent stabilization of the t(ϕ') conformer by the *syn* T* base and (*b*) the apparent influence of the 5′-phosphate on the ϕ' orientation in the T*, but not the T, derivatives, and the strong, if not overwhelming, preference for t(ϕ') in d(pT*p). The apparent dependence of the ϕ' orientation upon the conformation about the *N*-glycosyl linkage cannot be due to a direct interaction since the base and the 3′-phosphate lie on opposite sides of the sugar ring. The results of X-ray crystallographic and theoretical studies (discussed below) suggest that this dependence of ϕ' on χ is mediated by changes in the sugar ring pucker elicited by the change from the *anti* T base to the *syn* T* base. More explicitly, this

[9]The 0.5 Hz couplings were estimated from the C(2′) bandwidth (0.7 Hz). No splitting was detected.

ϕ', χ dependence is probably a further manifestation of a sugar pucker – ϕ' correlation apparent for the nucleotide units of yeast tRNA(phe) (34) and 3′-nucleotides in solution (35), and predicted by energy calculations (36). The correlation is such that $g^-(\phi')$ is likely only for 2′ *endo* sugars and is destabilized by the 3′ *endo* pucker. This suggested correlation is consistent with the crystalline structure of d(pTpT) (33) and the 3′-ribonucleotide structures surveyed by Sundaralingam and coworkers (see above).

The trends in the ^3J(C,P) data of the T and T* derivatives can, for the most part, be understood in terms of this pucker – ϕ' correlation. Thus, 2′-deoxyribosides are known to favor the 2′*endo* pucker in solution and in the crystal state (23,24). However, the presence of the *syn* T* base leads to a partial shift towards the 3′*endo* conformation (4, 6). (In addition, the *syn* base leads to a flattening [10] of the sugar ring in solution (6) as well as the crystal state.[11]) The general shift towards $t(\phi')$ for the T* derivatives is reasonable now if the $g^-(\phi')$ conformer is in fact unstable in a 3′ *endo* unit. Furthermore, the pronounced shift towards $t(\phi')$ in d(pT*p) upon secondary phosphate ionization suggests that the destabilization of the 3′ *endo* – $g^-(\phi')$ combination is, at least in part, due to an electrostatic repulsion between the 3′- and 5′-phosphates. This repulsion would be particularly severe when the C(4′)—C(5′) bond is $g^-(\psi)$ and less important for the $g^+(\psi)$ and $t(\psi)$ conformers (Fig. 3).

Clearly then, rotation into $t(\phi')$ seems to be a mechanism to reduce the repulsion of the negatively charged phosphates. Apparently, when the 3′- and 5′-phosphates bear two negative charges (pH > 8.0) a preponderance of $t(\phi')$ obtains. However, no phosphate–phosphate interactions are apparent in d(pTp) since the $^{13}C,^{31}P$ couplings are identical, at all pH values, to the corresponding couplings in 5′dTMP. This suggests that phosphate–phosphate interactions are important only in 3′ *endo* sugars.

The Sum $^3J(C4'—P3') + {}^3J(C2'—P3')$

A useful quantity to consider is the sum ^3J(C4′—P3′) + ^3J(C2′—P3′). These sums for the 3′-, 5′-, and 3′,5′-phosphates of dT and dT* are plotted versus pH in Fig. 5. The sums lie for the most part within the broad range from 8.3 Hz to 10.5 Hz. The data for the T and T* derivatives show a sigmoidal pH dependence, with the sums decreasing by ~1 Hz as the solution becomes basic. That the inflection points occur in the pH 6–7 range suggests a dependence upon the ionization state of the phosphates. In both the acid and basic range the T* sums are typically larger than those of the T derivatives by, on the average, 0.5 Hz. The sum values are smaller for the ribose derivatives 3′UMP (8.8–9.0 Hz) and 3′AMP (8.3–9.0 Hz) (9).

The sums in Fig. 5 may serve to caution proponents of a two-state model who estimate $t(\phi')$ and $g^-(\phi')$ conformer populations from ^3J(C,P) couplings. In a two-state model with interconversion between "fixed" $t(\phi')$ and $g^-(\phi')$ conformers the sum values are expected to be constant (9). However, it is clear from Fig. 5 that the structure changes in the sugar and the phosphate ionization state have led to a spread of about 20% in the sum values. This variation may be due in part to alterations in the angular characteristics of the "fixed" conformers and, in the case of phosphate ionization, to direct effects on the individual ^3J(C,P) coupling. Some care must be taken then in comparisons of the measured data and calculated ϕ' populations.

Conclusions

The pH dependence of the $^{13}C—^{31}P$ couplings of the 3′-, 5′-, and 3′,5′-phosphates of the *syn* dT* and *anti* dT nucleosides has been provided. The ^2J(C,P) couplings are relatively insensitive to pH changes for the entire series of molecules, though a weak sigmoidal behavior was discerned. A preference for the $t(\phi)$ conformer is indicated by the ^3J(C4′—P5′) data, in line with previous $^1H—^{31}P$ data. A high degree of flexibility in the ϕ' bond is apparent in the ^3J(C4′—P3′) and ^3J(C2′—P3′) couplings. The preference for the $t(\phi')$ domain noted for the 3′-nucleotidyl units in the T series is enhanced upon replacement with the *syn* T* base. This indicates that the orientation of a pyrimidine base about the *N*-glycosyl linkage is reflected in the ϕ' orientation. The trends suggest a correlation between the 3′ *endo* pucker and the $t(\phi')$ conformation.

Hydrodesulphurization mechanism of thiophene and tetrahydrothiophene on a cobalt molybdenum catalyst

JOSÉ M. PAZOS AND PAULINO ANDRÉU

Centro de Petróleo y Química, Instituto Venezolano de Investigaciones Científicas, Caracas, Venezuela[1]

Received June 6, 1979

JOSÉ M. PAZOS and PAULINO ANDRÉU. Can. J. Chem. **58**, 479 (1980).

The hydrodesulphurization mechanism of thiophene and tetrahydrothiophene has been developed at high pressures and over a broad range of temperature and contact time on a commercial $CoMo-Al_2O_3$ catalyst. The influence of the pretreatment on the catalyst activity and stability was also studied. The pretreatment with a mixture of H_2 and H_2S was found to be the most convenient. It was found that the sulphur uptake of the fresh catalyst increases with temperature and that an excess of sulphur in the catalyst leads to an initial higher activity.

The thiophene reaction seems to occur simultaneously by two pathways: one consists of ring opening, and the second is yielding tetrahydrothiophene. The latter is the slowest step. The tetrahydrothiophene reacts faster than the thiophene and its reaction mechanism involves mainly the rupture of the C—S bond. However, thiophene was detected in small concentrations, showing the contribution of a second route for the tetrahydrothiophene hydrodesulphurization. Experiments carried out with benzene seem to indicate the existence of three different kinds of active sites in the catalyst: desulphurization, aromatics hydrogenation, and olefin saturation sites.

JOSÉ M. PAZOS et PAULINO ANDRÉU. Can. J. Chem. **58**, 479 (1980).

On a élaboré le mécanisme d'hydrodésulfurisation du thiophène et du tétrahydrothiophène à haute pression et sur une large échelle de température et de temps de contact avec une catalyseur commercial mixte: $CoMo-Al_2O_3$. On a également étudié la stabilité ainsi que l'influence d'un traitement préalable sur l'activité du catalyseur. On a trouvé que le traitement préalable, par un mélange de H_2 et de H_2S, est celui qui convient le mieux. On a constaté que la fixation de soufre sur le catalyseur frais augmente avec la température et que l'excès de soufre sur le catalyseur conduit à une activité initiale plus forte.

La réaction du thiophène semble se produire suivant deux voies: l'une consiste en une ouverture du cycle, et l'autre conduit au tétrahydrothiophène. La dernière voie est l'étape la plus lente. Le tétrahydrothiophène réagit plus vite que le thiophène et le mécanisme de sa réaction implique principalement la rupture de la liaison C—S. Cependant on a décelé de faibles concentrations de thiophène indiquant par là l'existence d'une deuxième façon d'hydrodésulfuriser le tétrahydrothiophène. Les expériences conduites dans le benzène semblent indiquer l'existence de trois différentes sortes de sites actifs sur le catalyseur: un site de désulfurisation un d'hydrogénation aromatique et un de saturation des oléfines.

Introduction

Numerous sulphur compounds have been used to study different aspects of the hydrodesulphurization of crude oil distillates. As the greater part of the sulphur in the crude is held in stable ring structures of the thiophene type, thiophene has often been chosen as a model compound. Since the pioneering work of Pease and Keighton (1), several papers have been published dealing mainly with the mechanism of thiophene hydrodesulphurization. The most accepted reaction models imply two separated mechanisms. Either the C—S bond is ruptured, a condition leading to such intermediates as mercaptanes and butadiene (2–4), or ring saturation occurs, which forms tetrahydrothiophene (5–7). In both proposed models, the final products are always a mixture of butanes, butenes, and hydrogen sulphide.

The authors consider that the thiophene reaction is worth a further study because there is no general consensus about its reaction mechanism. On the other hand, the mechanisms proposed are generally valid only at conditions far from those used industrially. Therefore, in this work we studied the mechanism of thiophene hydrodesulphurization over a wide range of pressures, temperatures, and contact times. The reaction of the intermediate tetrahydrothiophene and the influence of different pretreatments on the catalyst stability and activity were also studied in detail.

Experimental

Apparatus and Procedure

The experiments were carried out in a bench scale unit using a flow microreactor with a fixed bed of catalyst. The whole system was made of stainless steel. The reactor was 21 cm long and 1 cm id. The catalyst bed was always 3 cm^3 placed at the centre of the reactor. The top and the bottom of the reactor were filled with an inert ceramic material.

The reactant, thiophene or tetrahydrothiophene, was diluted in heptane and mixed with an excess of hydrogen (H_2/solvent = 2 mol/mol), just before the reactor. A gas-chromatograph was connected in series with the reactor, so that the reactor effluents could be analysed continuously. The extent of the reaction was followed by the weight conversion of the reactant.

Materials

A typical commercial $CoMo-Al_2O_3$ was used in all the ex-

periments. It was supplied by Akzo Chemie (Ketjenfine 124 – 1.5 E) as 1.5 mm diameter extrudates. The catalyst was used as particles of an equivalent diameter equal to 0.75 mm. The catalyst characteristics are 4% CoO, 12%, MoO_3, surface area = 250 $m^2 g^{-1}$, pore volume = 0.52 mL g^{-1}.

The chemicals used were hydrogen (99% purity), thiophene from Aldrich (99% purity), tetrahydrothiophene from Eastman Kodak, heptane from Fluka (99% purity), and benzene from Merck (99% purity).

Analysis

The reaction products were analysed as they left the reactor by a gas-chromatograph provided with a flame ionization detector. The chromatographic column was SE-30 over Varaport (400 × 0.318 cm od), which was used to obtain a preliminary group separation of C_4 gases, thiophene, tetrahydrothiophene, and heptane. The C_4 gases were resolved by using a 16% bis-2-methoxiethyladipate (730 × 0.318 cm od) plus 30% DC-200 (100 × 0.318 cm od) over Chromosorb column.

The products detected in the thiophene reaction were C_4 gases, tetrahydrothiophene, and unreacted thiophene. A typical gas distribution obtained at 290°C and 28 atm was isobutane (ca. 50 wt%), 1-butene (ca. 30 wt%), and *trans*-2-butene (ca. 20 wt%). A more exhaustive analysis of the liquid products was carried out by using a GC-MS system. In addition to tetrahydrothiophene, small amounts of 2-methyl-2-propanethiol and traces of di-*n*-butylsulphide, 2-*n*-butylthiophene, and 2-*n*-butyltetrahydrothiophene were also detected.

The products observed in the tetrahydrothiophene reaction were C_4 hydrocarbons, thiophene, and unreacted tetrahydrothiophene. The distribution of gases and liquids was found to be similar to that of thiophene, but no trace of 2-*n*-butyl thiophene and 2-*n*-butyl- tetrahydrothiophene was detected.

Results

Pretreatment of the Catalyst

A study of the influence of different pretreatments on the catalyst stability and activity was carried out initially. Fresh samples (A, B, C) of the same catalyst were submitted to different pretreatments in the reactor. Sample A was exposed directly to the feedstock at reaction conditions; sample B was initially reduced with hydrogen at 300°C for 1 h and finally 2 h at 350°C, and sample C was presulphided with a mixture of $H_2 + H_2S$ (3.5% volume of H_2S) for 1 h at 300°C and 2 h at 350°C. Figure 1 shows the activity of the three catalyst samples as a function of the hours on stream (HOS). It can be observed that catalyst A exibits the lowest initial activity due to the fact that it was present as an oxide. As HOS increases, the catalyst becomes sulphided with the H_2S formed under reaction conditions. It took about 20 h for the catalyst to become stable. The prereduced catalyst B shows a higher initial activity than catalyst A and required only 6 h to be sulphided. Finally it reaches the same level of activity of catalyst A. Catalyst C, previously sulphided, shows the highest initial activity, and thus indicating the importance of the sulphided form for the catalyst activity.

It follows from Fig. 1 that catalyst C shows also the highest activity, ca. 90%, while A and B give

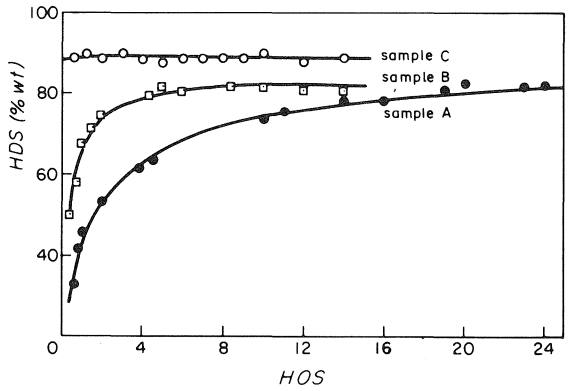

FIG. 1. Influence of the pretreatment in the catalyst activity and stability. Reaction conditions: P = 42 atm, T = 310°C, θ = 0.97 h, $p_H{}^0$ = 26.3 atm, $p_T{}^0$ = 2.5 atm. Sample A, catalyst without pretreatment. Sample B, catalyst prereduced with H_2. Sample C, catalyst presulphided with $H_2 + H_2S$.

80%. This is due to a higher sulphur content of catalyst C. The reasons for this higher sulphur concentration may be explained as follows: (*a*) The higher H_2S concentration in the reactor, since catalyst C was presulphided with $H_2 + H_2S$. (*b*) The higher sulphiding temperature of catalyst C. The dependence of sulphur uptake with temperature has been previously reported (8). (*c*) The reduction of catalysts A and B before their sulphidation. The reduced catalysts are more refractory to sulphidation than the corresponding oxides (9). Therefore, their sulphiding should be lower.

A used catalyst was regenerated by heating it up

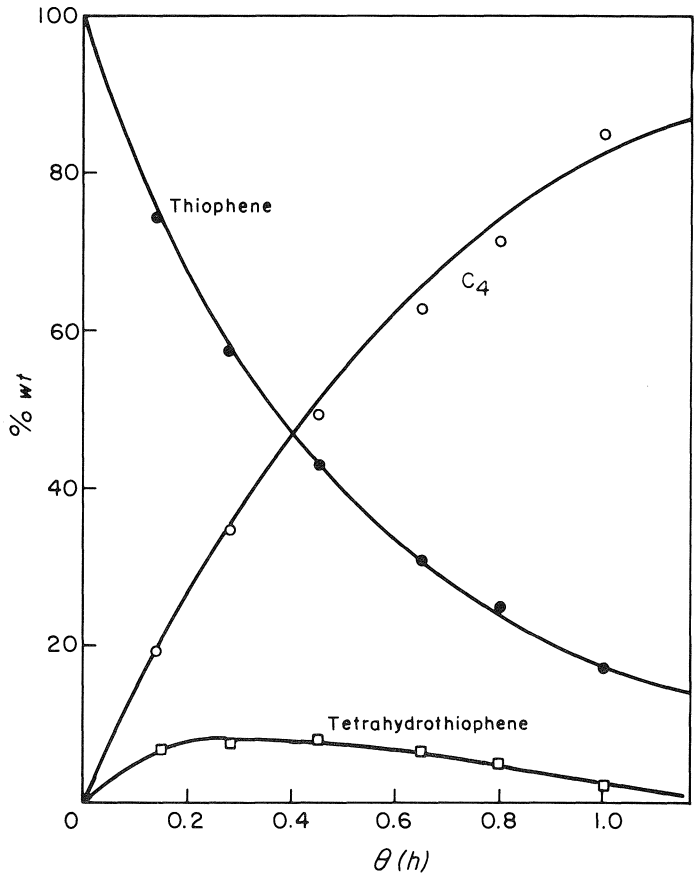

FIG. 3. Thiophene product distribution as a function of the contact time, θ. Reaction conditions: P = 28 atm, T = 290°C, p_H^0 = 17.6 atm, p_T^0 = 1.66 atm.

in air for 10 h and subsequently presulphided again under the same conditions with H_2 + H_2S (3.5% volume H_2S) for 1 h at 300°C and 2 h at 350°C. Its initial activity was surprisingly higher than that of the fresh catalyst, as can be observed in Fig. 2. We reasoned that the regenerated catalyst still had some remaining sulphur and consequently, it showed after sulphiding an excess of sulphur concentration, which is responsible for the initial higher activity. In order to confirm this, the fresh catalyst, already presulphided, was sulphided for 4 h more at 350°C with H_2 + H_2S (3.5% volume H_2S). This catalyst showed a behaviour similar to the regenerated catalyst, as can be observed in Fig. 2. This fact indicates again that the initial higher activity is probably due to an excess of sulphur in the catalyst.

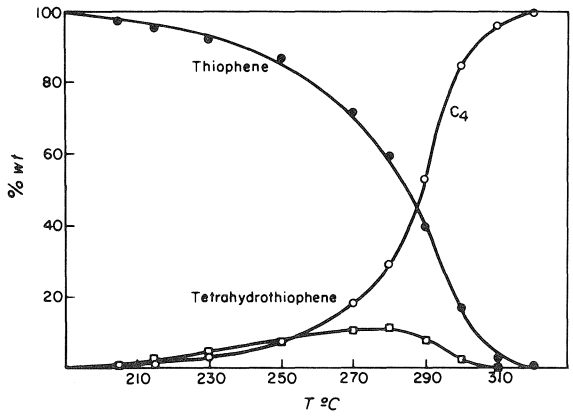

FIG. 4. Thiophene product distribution as a function of the temperature. Reaction conditions: P = 28 atm, θ = 0.56 h, p_H^0 = 17.6 atm, p_T^0 = 1.66 atm.

Product Distribution of Thiophene Hydrodesulphurization

The product distribution obtained in the thiophene reaction was studied over wide conversion ranges as a function of the contact time (θ) and temperature (Figs. 3 and 4, respectively). It can be observed in both figures that tetrahydrothiophene is the main intermediate detected. The low tetrahydrothiophene concentration, as shown in Fig. 3, indicates that the thiophene reaction occurs by a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

consecutive reaction, where the first step is the hydrogenation of the thiophenic ring to form tetrahydrothiophene. However, a deeper analysis of Fig. 3 shows that the thiophene hydrodesulphurization also takes place by rupturing of the C—S bond: the yield curve of the C_4 hydrocarbons formed do not exhibit the typical induction period characteristic of the consecutive reactions. These two facts clearly support that the thiophene hydrodesulphurization occurs by parallel reactions.

The thiophene product distribution as a function of the temperature, Fig. 4, indicates that at $T <$ 250°C, the conversion of thiophene is very small (less than 10 wt%) and that the predominant reaction is the hydrogenation of thiophene to tetrahydrothiophene. At $T >$ 250°C, the tetrahydrothiophene formation goes through a maximum and then decreases because the tetrahydrothiophene reacts very fast to give C_4 hydrocarbons. On the other hand, at $T >$ 250°C the contribution of the ring opening of the thiophene to give directly C_4 gases increases markedly.

The thiophene conversion data are consistent with the pseudo-first order reaction rate as can be observed in Fig. 5.

Product Distribution of Tetrahydrothiophene Hydrodesulphurization

For a better understanding of the thiophene hydrodesulphurization mechanism, a further study of the tetrahydrothiophene hydrodesulphurization has been carried out under similar experimental conditions. Figures 6 and 7 show the product distribution as a function of contact time and temperature respectively. These figures indicate the following facts: (*a*) Thiophene, product of the dehydrogenation of tetrahydrothiophene, is the main intermediate, although its concentration is very small (generally under 5 wt%). The presence of thiophene has been observed by other workers (10, 11). (*b*) Tetrahydrothiophene reacts faster than thiophene at similar operating conditions. This is in agreement with the fact that the hydrogenated compounds are more reactive than the corresponding aromatic compounds (12). (*c*) The mechanism of tetrahydrothiophene hydrodesulphurization is similar to the thiophene reaction and can be expressed by parallel reactions. One reaction yields thiophene, and the other one is the rupture of the C—S bond of the tetrahydrothiophene. This second reaction is the predominant one.

The tetrahydrothiophene reaction can be adjusted by the pseudo-first order kinetic equation as is shown in Fig. 5.

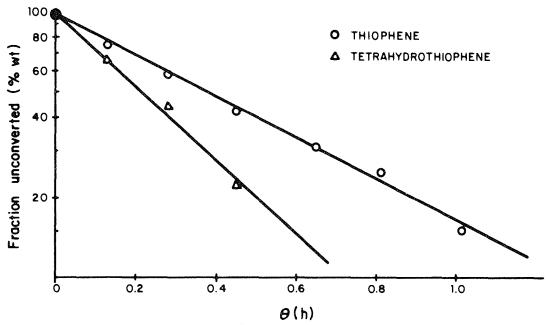

FIG. 5. Pseudo first-order kinetic equation for thiophene and tetrahydrothiophene conversion. Reaction conditions: P = 28 atm, T = 290°C, p_H^0 = 17.6 atm, p_s^0 = 1.66 atm (S is thiophene and tetrahydrothiophene, respectively).

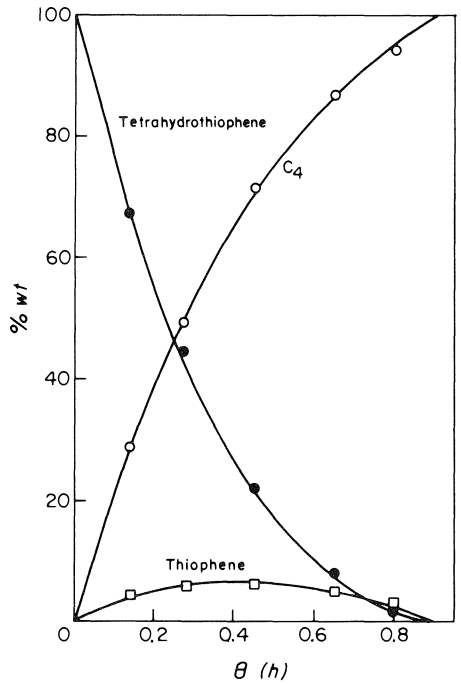

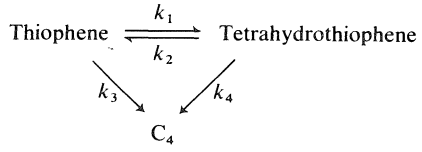

FIG. 6. Tetrahydrothiophene product distribution as a function of the contact time. Reaction conditions: P = 28 atm, T = 290°C, p_H^0 = 17.6 atm, p_{Th}^0 = 1.66 atm.

Discussion

The former results show that the thiophene hydrodesulphurization is a complex reaction, which can be expressed as follows:

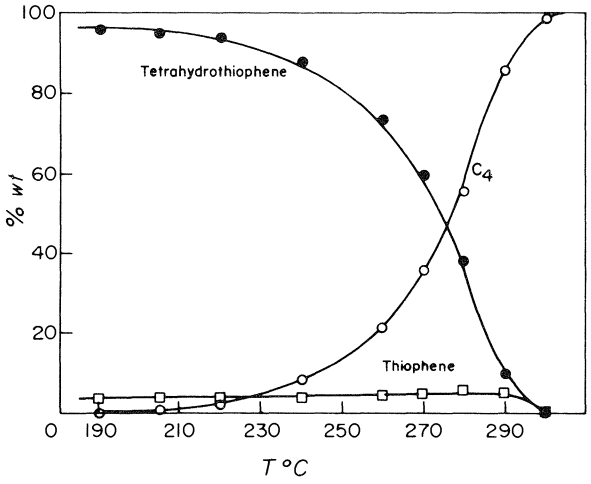

FIG. 7. Tetrahydrothiophene product distribution as a function of the temperature. Reaction conditions: P = 28 atm, θ = 0.56 h, p_H^0 = 17.6 atm, p_{Th}^0 = 1.66 atm.

Thus the thiophene reaction occurs simultaneously by hydrogenation to tetrahydrothiophene and by a straight ring opening, which involves the rupture of the C—S bond.

The concentration of thiophene (T), tetrahydrothiophene (Th), and C_4 hydrocarbons can be expressed by the following equations:

$$[1]\quad T(\theta) = A_1 \exp(\alpha_1\theta) + A_2 \exp(\alpha_2\theta)$$

$$[2]\quad Th(\theta) = A_1\alpha_3 \exp(\alpha_1\theta) + A_2\alpha_4 \exp(\alpha_2\theta)$$

$$[3]\quad C_4(\theta) = A_3 + A_1\alpha_5 \exp(\alpha_1\theta) + A_2\alpha_6 \exp(\alpha_2\theta)$$

where A_i (wt%) and α_i (h^{-1}) are empirical constants and θ is the contact time (h). These equations are the solutions of the rate expressions for the thiophene network. Each reaction was assumed to be first order.

To evaluate the contribution of the different reactions to the thiophene network, the individual rate constants k_i were estimated. Several methods are available to determine kinetic coefficients for complex reaction models (13). In the present work, the coefficients A_i and α_i were determined from the experimental points of Fig. 3 with a non-linear least-squares program. From α_i, the individual rate constants were estimated. The following values were obtained:

$$k_1 = 2.06 \times 10^{-4}\ s^{-1}$$

$$k_2 = 4.94 \times 10^{-4}\ s^{-1}$$

$$k_3 = 3.69 \times 10^{-4}\ s^{-1}$$

$$k_4 = 9.58 \times 10^{-4}\ s^{-1}$$

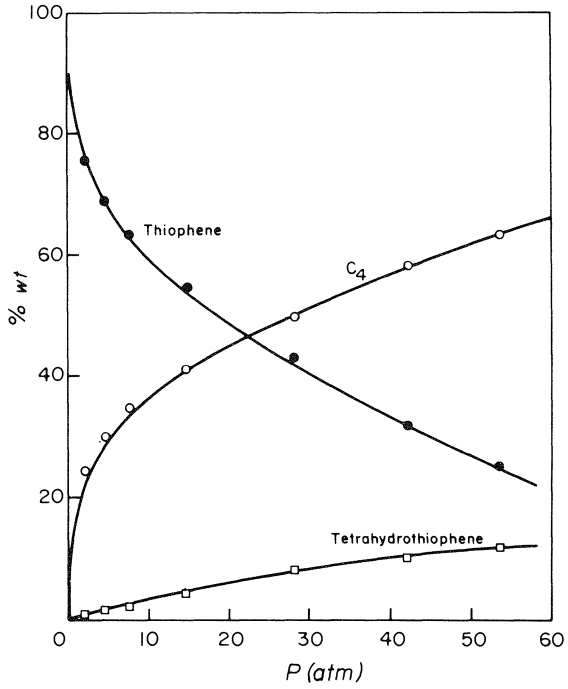

FIG. 8. Thiophene product distribution as a function of the total pressure. Reaction conditions: T = 290°C, θ = 0.45 h.

The lines of Fig. 3 show the concentration profile of thiophene, tetrahydrothiophene, and C_4 predicted by eqs. [1], [2], and [3]. There is a close agreement between these curves and the experimental points.

The values of the rate constants obtained indicate that the thiophene reaction occurs mainly through the rupture of the C—S bond. On the other hand, it is shown that tetrahydrothiophene has higher desulphurization activity than thiophene.

This mechanism has been proved to be valid over a broad range of pressures, as shown in Fig. 8. It can be observed that the tetrahydrothiophene concentration increases with the total pressure. This can be an explanation of why tetrahydrothiophene has not been proposed as an intermediate by several authors who usually worked at atmospheric pressure (2–4).

In Fig. 9, we present a more complete picture of the mechanism of the thiophene reaction, based on the products observed by mass spectrometry at typical reaction conditions. Not only tetrahydrothiophene and butenes, but also mercaptanes and sulphides have been detected as intermediates, which show the complexity of this reaction. However, they were found in small concentrations.

Finally, some experiments were carried out by substituting the solvent heptane by benzene in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

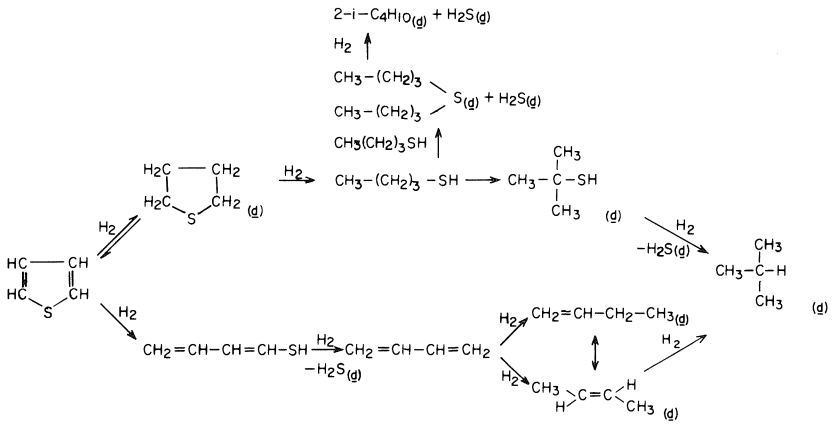

FIG. 9. Mechanism of thiophene HDS.

order to ellucidate the type of sites involved in the thiophene reaction. The effect of changing the solvent from pure heptane to pure benzene through various ratios was to decrease the C_4 from 5.7% to 4.5% and the tetrahydrothiophene from 6.6% to 5.4%, but the ratio tetrahydrothiophene/C_4 remained constant at 1.2. The benzene should adsorb on hydrogenation sites affecting the tetrahydrothiophene concentration but it should not be affected to the same extent as the C_4 concentration. The results obtained seem to indicate that benzene is adsorbed on both aromatic hydrogenation and desulphurization sites; therefore, it competes for the same adsorption sites of thiophene. Though there is need for further evidence, we could suggest the existence of three different types of active sites involved in hydrodesulphurization reactions: aromatics hydrogenation, olefines saturation, and desulphurization sites.

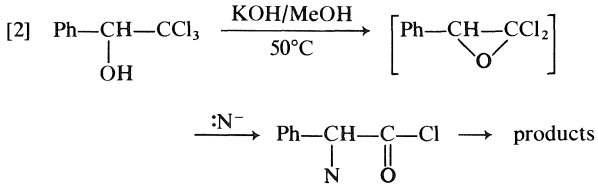
Phenyl(trichloromethyl)carbinol undergoes an unimolecular, predominantly intramolecular conversion into potassium α-chlorophenylacetate on stirring with 10% aqueous potassium hydroxide at 0°C for several days. Besides providing an interesting example of a 1–2 chlorine shift, the reaction is of potential importance for the synthesis of α-chloro acids. The study of a variety of (trichloromethyl)carbinols shows the reaction is general for secondary (trichloromethyl)carbinols as well as trichloroethanol. The mechanism of the reaction involves the preliminary formation of an epoxide. Several mechanisms are considered for the conversion of the epoxide to the α-chloroacetate anion, but none accounts for all of the experimental facts. Tertiary carbinols break down at the epoxide stage into a ketone and carbon monoxide.

WILKINS REEVE, JAMES R. MCKEE, ROBERT BROWN, SITARAMA LAKSHMANAN et GERTRUDE A. MCKEE. Can. J. Chem. **58**, 485 (1980).



Le phényl(trichlorométhyl)carbinol subit une transformation unimoléculaire (intramoléculaire de façon prédominante) en α-chlorophénylacétate de potassium par agitation avec de l'hydroxyde de potassium en solution 10% aqueuse à 0°C pendant plusieurs jours. En plus de fournir un exemple intéressant de glissement 2–1 du chlore, la réaction est d'une grande importance pour la synthèse des acides α-chlorés. L'étude de plusieurs types de (trichlorométhyl)carbinols montre que la réaction est générale pour les (trichlorométhyl)carbinols aussi bien que pour le trichloréthanol. Le mécanisme de cette réaction implique la formation préliminaire d'un époxyde. On a considéré plusieurs mécanismes dans le cas du passage de l'époxyde à l'anion α-chloroacétate mais aucun d'eux explique les faits expérimentaux. Les carbinols tertiaires au stade de l'époxyde se dégradent en cétone et en monoxyde de carbone.

Phenyl(trichloromethyl)carbinol was reported by Jocic in 1897 to react with ice-cold aqueous potassium hydroxide solution over a two or three day period to form α-chlorophenylacetic acid in 27% yield (1). This is a reaction without precedent and raises questions about the mechanism by which the new carbon–chlorine bond is formed. There has been no subsequent use of the reaction, and its scope and usefulness have never been studied.

[1] $\mathrm{Ph{-}CHOH{-}CCl_3} \xrightarrow[0°C]{\mathrm{KOH}} \mathrm{Ph{-}CHCl{-}COOH}$

Phenyl(trichloromethyl)carbinol reacts with a wide variety of nucleophiles in methanolic potassium hydroxide at 50°C to form α-substituted phenylacetic acids, or if structural features allow ring closure, heterocyclic compounds are formed (2). These reactions involve the preliminary formation *in situ* of a dichloro epoxide which undergoes ring opening by S_N2 attack of the nucleophile (3). Other reactions of phenyl(trichloromethyl)carbinol have also been studied (4).

[2] 

Unlike the reaction of (trichloromethyl)carbinols with nucleophiles, the reaction described by Jocic (1) is best carried out by stirring a suspension of phenyl(trichloromethyl)carbinol at 0°C for a few days in four equivalents of aqueous 10% potassium hydroxide solution. Our work shows that it is predominately an intramolecular, unimolecular reaction which differs from the bimolecular reaction in mechanism, optimum reaction conditions, and structural requirements of the carbinol.[2]

Scope of Reaction

The reaction works well with phenyl(trichloromethyl)carbinol, so this compound was chosen to

[1]Taken in part from the doctoral theses of J. R. McKee (1974) and R. Brown (1968).

[2]In our laboratories we refer to this intramolecular transformation carried out in a heterogeneous, aqueous reaction mixture at 0°C as the Jocic reaction to distinguish it from the bimolecular reactions with various nucleophiles carried out in alcoholic potassium hydroxide solution at 50°C. Ж. Іоцича (1870–1914) was a student of A. E. Favorskii at the University of St. Petersburg. His name has been transliterated into German as Jozitsch and Jocicz and into French as Iotsitch. Chemical Abstracts (J. T. Dickman) suggests Z. Jocic as the preferred Anglicized form.

determine the optimum reaction conditions. The optimum temperature is 0°C; at −5°C the reaction occurs too slowly with no gain in yield, and at 5°C the formation of mandelic acid becomes more important as a side reaction. Ten percent aqueous potassium hydroxide is the best reaction medium; 5% and 20% solutions give somewhat lower yields of products. With 10% sodium hydroxide solution a gel formed; the reaction occurred more slowly, and lower yields of product were obtained. Four molar equivalents of base are used. Surprisingly, the addition of methanol or other oganic solvents caused a drastic decrease in the rate of reaction; the use of 80% ethanol – 20% water slows down the reaction rate about 35-fold. Solvation of the leaving chloride ion may be important in the rate-determining step; as the media becomes more non-aqueous, this driving force decreases. The reaction in 10% aqueous potassium hydroxide is heterogeneous, and vigorous mechanical stirring speeds up the reaction. The use of oleic acid (5% of the weight of the carbinol) as a dispersing agent helps if less vigorous stirring is used (such as with the use of a magnetic stirring bar), but is without effect if a motor-driven paddle stirrer is used. The half life of the reaction is variable due to the heterogeneous nature of the reaction, but can be as low as 15 h with vigorous stirring. In a typical experiment of one half life duration at 0°C, the reaction mixture consisted of about 15% benzaldehyde, 51% unreacted phenyl(trichloromethyl)carbinol, and 30% α-chlorophenylacetic acid. After three half lives, 60–70% of α-chlorophenylacetic acid was formed.

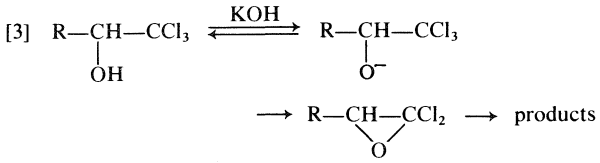
The reaction is successful with a wide variety of secondary carbinols as is shown in Table 1.

No measurable reaction occurs with 2,2,2-trichloroethanol at 0°C, but the reaction does occur slowly at 25°C. Tertiary (trichloromethyl)carbinols do not form α-chloro acids except in small amounts; these are presumably formed by the competing, slow bimolecular reaction (eq. [2]). Thus dimethyl(trichloromethyl)carbinol gives 3% of α-chloroisobutyric acid (5). The major products formed from the tertiary (trichloromethyl)carbinols are carbon monoxide and the ketone from which the starting carbinol could be prepared by the addition of chloroform.

Molecularity of Reaction

With phenyl(trichloromethyl)carbinol, the reaction was found to be 83% intramolecular by adding radioactive chloride ion to the initial aqueous potassium hydroxide solution and determining how much was incorporated into the final isolated chloro acid. In a similar manner, a displacement reaction by which chloride ion in solution might replace part of the covalently bound chlorine of the chloro acid was demonstrated to be too slow to account for more than 0.6% of the chlorine in the final chloro acid. Accordingly, approximately 17% of the chlorine in the final chloro acid is due to a mechanism in which chloride ion in solution is captured by some reactive intermediate, and 83% of the chlorine in the chloro acid comes from an intramolecular rearrangement.

A kinetic study of the reaction using phenyl(trichloromethyl)carbinol shows the reaction to be first order in carbinol and zero order in base (because the hydroxyl group is largely in the alkoxide form) with a half life of 15 to 30 h depending on how efficiently the mixture is stirred. It is difficult to draw mechanistic conclusions from the data because of the heterogeneous nature of the mixture. Fortunately, two (trichloromethyl)carbinols were found which are soluble under the reaction conditions. One is *p*-chlorophenyl(trichloromethyl)carbinol; this is somewhat more acidic than the parent phenyl(trichloromethyl)carbinol and dissolves in excess 10% potassium hydroxide solution.



Concerning the acidity of the carbinols, we could not determine the pK_a of the neutral (trichloromethyl)carbinols by electrometric titration since excess base had to be present before they would dissolve, but the potassium salt of *p*-carboxyphenyl(trichloromethyl) carbinol was soluble, and titration with aqueous potassium hydroxide indicated the pK_a of the carbinol function to be approximately 11.3. Trichloroethanol is known to have a pK_a in the 11.8 to 12.2 range (6), and presumably most of the (trichloromethyl)carbinols have similar pK_a values. *p*-Methoxyphenyl (trichloromethyl)carbinol should be a weaker acid due to the electron releasing *p*-methoxy group, and this probably accounts for the unreactivity of this carbinol.

The kinetics of the reaction of *p*-chlorophenyl(trichloromethyl)carbinol with 10% aqueous potassium hydroxide at 0°C was followed by titrating aliquots of the reaction mixture for unreacted base, and the reaction was found to follow first order kinetics to at least 50–70% of completion. An experiment in which the carbinol concentration was halved demonstrated the reaction was first order in carbinol. Another experiment at twice the concentration of base showed the reaction rate to be independent of increases in base concentration.

Similar kinetic data at 30°C were obtained with 2,2,2-trichloroethanol which is also soluble in 10% potassium hydroxide solution. Carbon monoxide

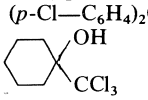
For personal use only.

was evolved during the course of the reaction. Its evolution also followed first order kinetics and the moles evolved were about 5% of the moles of starting alcohol. The major product of the reaction was chloroacetic acid, formed in 23% yield, but under the basic reaction conditions, some of the chloroacetate reacts with the trichloroethanol to form trichloroethoxyacetate in 15% yield, so the product isolated consisted of a mixture of these two acids.

The kinetic experiments clearly establish the rate determining step to be the formation of the intermediate dichloro epoxide. The rapid equilibration established between the carbinol and its anion cannot be rate determining, and a slow step subsequent to dichloro epoxide formation would involve a relatively rapid consumption of the first third of the base followed by a slower consumption of the remainder. No such behavior is observed and no evidence has been obtained for a build-up of the dichloro epoxide. Experimentally, the disappearance of total base was measured rather than the disappearance of alkoxide alone, but if a large fraction of the carbinol is in the alkoxide form, the two are proportional to each other.

Under the same experimental conditions, both the *p*-chloro ($t_{\frac{1}{2}}$ = 27 h) and the *p*-methyl ($t_{\frac{1}{2}}$ = 45 h) analogs react more slowly than phenyl(trichloromethyl)carbinol ($t_{\frac{1}{2}}$ = 16 h) but this is of limited mechanistic significance as far as the chlorine migration step is concerned since the rate controlling step is in the initial formation of epoxide.

Stereochemistry



The reaction of (*R*)-(−)-phenyl (trichloromethyl) carbinol with 10% aqueous potassium hydroxide at 0°C for eight hours gave α-chlorophenylacetic acid which was 91% racemized and 9% inverted. Control experiment with (*S*)-(+)-α- chlorophenylacetic acid showed 70% was racemized in eight hours under the same reaction conditions. This corresponds to 45% racemization during the four hour period that the average α-chlorophenylacetate molecule was exposed to the base in the initial reaction. Racemization occurs about eight times faster than the substitution of the chlorine by hydroxyl. Racemization involves the formation of an enolate anion whereas substitution proceeds unimolecularly via an α-lactone (3, 8). The relatively easy racemization of the α-chloroacetate anion makes it difficult to tell how much racemization occurs during the intramolecular migration of the chlorine. Seventeen percent of the reaction is intermolecular, and chloro acid formation by attack of chloride ion on an intermediate such as the epoxide shown in reaction sequence [2] should involve inversion. Accordingly, the observed results are consistent with complete racemization during the intramolecular chlorine migration to form chloro acetate, with the observed 9% of inverted chloro acid arising from the 17% of product not formed by the intramolecular pathway. It has previously been shown that the optical activity of the starting phenyl(trichloromethyl)carbinol is unchanged by treatment with methanolic potassium hydroxide at 40°C for 90 min (3).

Control experiments with (*R*)-(−)-α-chloro phenylacetyl chloride (71% optically pure) showed the reaction time for 50% reaction with excess 1 *M* potassium hydroxide solution at 0°C to be a maximum of seven minutes under heterogeneous reaction conditions. After eighty minutes, the potassium (*R*)-(−)-α-chlorophenylacetate formed was converted to the acid; no racemization could be detected.

By-products

The major by-products of the reaction, aside from unreacted starting carbinol, are carbon monoxide and a carbonyl compound. The (trichloromethyl)carbinols can be made by the base catalyzed condensation of chloroform with aldehydes and ketones, and Jocic postulated that the carbonyl by-product was formed by the reverse of this condensation reaction (1). With phenyl(trichloromethyl)carbinol, the benzaldehyde and the carbon monoxide are 10 to 20% of theory, and this is typical of the behavior of the secondary carbinols. With the tertiary (trichloromethyl)carbinols, the reaction proceeds almost exclusively to give the ketone and carbon monoxide, and little chloro acid is formed. With phenyl(trichloromethyl)carbinol the formation of carbon monoxide is first order in carbinol. That the source of the carbon monoxide is not chloroform (and therefore not trichloromethide anion (7)) is shown by: (*a*) chloroform is absent in the alkaline reaction mixture at the end of the reaction; (*b*) (trichloromethyl)carbanion, generated from 1,1,1-trichloropropanone, gives chloroform and little or no carbon monoxide under the reaction conditions; (*c*) extra chloroform added at the beginning of an otherwise normal reaction between phenyl(trichloromethyl)carbinol and aqueous potassium hydroxide solu-

tion at 0°C survives the reaction and can be measured by glc of a xylene extract of the reaction mixture. Since the formation of carbon monoxide involves fragmentation of the molecule and chloroform is not an intermediate, the most likely source is the dichloro epoxide slowly breaking down to the carbonyl component and dichlorocarbene which hydrolyzes to carbon monoxide.

Another side reaction that occurs is the hydrolysis of the chloro acid to the hydroxy acid under the alkaline reaction conditions. As shown in Table 1, all of the chloro acid is hydrolyzed when starting with *p*-tolyl(trichloromethyl)carbinol, but virtually no hydrolysis occurs with *p*-chlorophenyl(trichloromethyl) carbinol. This behavior is in accord with the σ values of the two *para* substituents. If one uses the ρ value of -2.66 found for the hydrolysis of α-bromophenylacetate anion (8), the Hammett equation predicts the α-chloro-*p*-tolylacetate anion would hydrolyze 10 or 13 times more rapidly than the α,*p*-dichlorophenylacetate anion, depending on whether the comparison is based on σ or σ^+ (used by Kemp and Metzger) substituent values respectively.

Reaction in Deuterium Oxide

Phenyl(trichloromethyl)carbinol, and its *p*-chloro and *p*-methyl analogues, were allowed to react with potassium hydroxide in deuterium oxide under the usual conditions; the unreacted carbinol was separated by ether extraction, and the reaction mixture was then acidified with aqueous hydrochloric acid to give the product acid. This was examined by ^{1}Hmr to determine the deuterium uptake.

The recovered phenyl(trichloromethyl)carbinol showed a phenyl to α-hydrogen ratio of 5:1; no deuterium exchange occurred prior to the reaction. The chloro acids produced showed considerable deuterium incorporation in the α-position but no more than was observed in control experiments in which the chloro acids were equilibrated with deuterium oxide under approximately the same reaction conditions. Accordingly, it appears the chloro acid with a proton in the α-position is initially formed and deuterium incorporation occurs subsequent to this. The results are in Table 2.

Mechanism of Reaction

The reaction occurs under conditions which suggest there are no radical intermediates. We have considered a number of ionic mechanisms; none is in complete accord with all the known facts. McDonald *et al.* have studied the rearrangement of 1-chloro-4-methylcyclohexene oxide to 2-chloro-4- methylcyclohexanone both thermally and catalyzed by zinc chloride, and postulated an α-ketocarbonium ion – chloride ion pair intermediate (9). Similar results were obtained with 2-chloronorbornene *exo*-oxide (10), and with 2-chlorobicyclo[2.2.2]oct-2-ene oxide (11). 2-Chloronorbornene *exo*-oxide on treatment with lithium diethylamide in refluxing bezene–ether forms mostly tricyclo[2.2.1.$O^{2,6}$] heptan-3-one, presumably by α-elimination, chloride ion loss, and transannular insertion of the α-keto carbene (12). McDonald has reviewed the literature covering reactions of this type (13). Unfortunately, these reactions in non-protic solvents seem to bear little relationship to the reaction we have studied in cold,

TABLE 2. Percent incorporation of deuterium in the Jocic reaction

Starting carbinol	Product acid (% D)	% Deuterium in control acid
Ph—CHOH—CCl_3	Ph—CHCl—COOH (47)	45
p-Cl—C_6H_4—CHOH—CCl_3	*p*-Cl—C_6H_4—CHCl—COOH (72)	82
p-Me—C_6H_4—CHOH—CCl_3	*p*-Me—C_6H_4—CHOH—COOH (12)	7

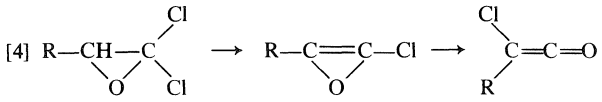
aqueous, basic solution. As stated before, the presence of organic solvent causes a drastic decrease in the rate of the Jocic reaction.

The experimental observations that a mechanism should account for include the following. (*a*) The apparent structural requirement for a proton on the α-carbon of the carbinol. (*b*) The intramolecular nature of the chlorine migration. (*c*) The requirement for aqueous, basic reaction conditions. 1,1,3,3,3-Pentachloropropylene oxide is a known stable dichloro expoxide (14) which undergoes no reaction with water or with potassium chloride solution, but in the presence of cold dilute base undergoes both chlorine and hydrogen migration; trichloroacrylic acid is the product formed by chlorine migration (15). (*d*) Extensive or complete racemization. (*e*) The failure of the α-hydrogen of the chloro acid to be replaced by deuterium during the conversion of the dichloro epoxide to the initially formed α-chloro acetate when the reaction is carried out in deuterium oxide.

Carbonium Ion Mechanism

A carbocation is formed either by chloride ionization, or by epoxide ring opening, or by a concerted mechanism involving both processes perhaps with an intermediate chloronium ion. These mechanisms fail to explain why base is necessary (see *c* preceding paragraph), how a neopentyl group can go through the reaction unrearranged, and why the reaction should fail with tertiary (trichloromethyl)carbinols.

Carbene Mechanism



The base removes a proton from the dichloro epoxide and the ring opens forming a carbene which abstracts the neighboring chlorine to form a carbanion of the chloro acid. This mechanism requires that the α-hydrogen of the chloro acid be replaced by deuterium if the reaction is carried out in deuterium oxide, and this did not occur. Otherwise, it is consistent with all the known facts.

Enol Hypochlorite Mechanism

The chlorine is assumed to migrate from carbon to oxygen to form an enol hypochlorite which then chlorinates the α-carbon via a quasi four-membered ring. This mechanism fails to explain why the reaction fails with tertiary (trichloromethyl)carbinols. The predicted intermediate hypochlorite should be capable of being trapped by a wide variety of general reducing agents whereas the following reducing agents were without effect: potassium stannite, potassium iodide, potassium arsenite, hydroquinone, and β-naphthol. Two reducing agents, potassium dithionite and sodium formaldehydesulfoxylate, did cause phenylacetic acid to be formed in 42 and 19% yields, respectively, from phenyl(trichloromethyl)carbinol. These are unusual reducing agents, and the mechanism by which they participate in the reaction is not clear.

Chlorooxirene Mechanism

Oxirenes have been postulated as intermediates in the oxidation of acetylenes (16, 17). They may have a transient existence in the Wolff rearrangement by photolysis (18, 19). They are highly strained unstable compounds, and chlorooxirenes are unknown. The strain energy of oxirene has been estimated to be 40 kcal/mol vs. 13 kcal/mol for oxirane (16).

The mechanism requires the α-hydrogen to be completely replaced by deuterium in a reaction carried out in deuterium oxide, and this did not occur. Unpublished evidence obtained by Tsuk (20) against the chlorooxirene mechanism follows. (Dibromochloromethyl)phenylcarbinol under the Jocic conditions yields mostly α-bromophenylacetic acid. If the oxirene mechanism were operating, the two bromines would be eliminated in the first two steps giving a chlorooxirene, and this would yield a chloro acid.

Of the above four mechanisms, the one involving a carbene (or carbenoid) accounts for all of the experimental evidence except the lack of deuterium exchange. The lack of exchange may be rationalized by assuming a carbenoid transition state. The α-proton is not completely abstracted by the base, the epoxide ring opens, and predominately intramolecular migration of the neighboring chlorine then occurs concurrent with the reformation of the carbon–hydrogen bond. This is speculation, and perhaps it is best to say that the true

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

mechanism by which the reaction occurs is still not established.

Experimental

Melting points and boiling points are corrected. The infrared spectra were recorded on a Perkin-Elmer Model 337 infrared grating spectrophotometer and the nmr spectra on either a Varian A-60D or a Perkin-Elmer R-12 spectrometer. Chemical shift values are expressed as δ values (ppm) downfield from tetramethylsilane as internal standard. Rotations were measured on a Franz, Schmidt, and Haensch (Berlin S) polarimeter with a sodium lamp as a light source. Polarimeter tubes of 2-dm length were used; concentration terms are grams of solute per 100 mL of solution. Elemental microanalyses were performed by Dr. Franz J. Kasler and Mrs. Shelesa L. A. Brew. Mass spectra were obtained by Dr. Martha Gay on a Du Pont mass spectrometer. Gas–liquid chromatographic analyses were performed on a Hewlett Packard 5750B research chromatograph. "Isooctane" used in recrystallization was 2,2,4-trimethylpentane.

Phenyl(trichloromethyl)carbinol

This is best prepared from benzene (30 mol), commercial anhydrous chloral (3 mol), and anhydrous aluminum chloride (0.75 mol) following the procedure of Dinesmann (21). The optimum amount of aluminum chloride was determined in a preliminary run. Too little caused incomplete reaction and too much causes large amounts of α,β,β,β- tetrachloroethylbenzene and high boiling materials to be formed. The reaction mixture was washed twice with 5% sodium carbonate solution to destroy chloral and chloral polymers. The carbinol, 500 g (63% of theory after allowing for 15% of α,β,β,β- tetrachloroethylbenzene impurity), was distilled rapidly to minimize decomposition and collected at 120–140°C (1 Torr). The completion of the distillation is marked by a sharp rise (ca. 40°C) in the temperature as 2,2-diphenyl-1,1,1-trichloroethane begins to distill. The composition of the distilled carbinol can be determined from its ^{1}Hmr spectrum: the α-hydrogens of the carbinol, the tetrachloroethylbenzene, and the diphenyltrichloroethane occur at δ 5.17, 5.37, and 5.0 respectively (CCl_4).

We have found that the best way to purify the distilled carbinol is to crystallize 500 g from 300 mL of "isooctane". After seeding the solution and cooling to 10°C for 30 min, 210 g of the pure crystalline carbinol was filtered off. An equal amount could be obtained by a similar treatment of the concentrated mother liquors. An equilibrium melting point obtained by immersing a thermometer in several grams of the material in a test tube was 32–34°C, and 34–35°C after a final recrystallization from ethanol. The capillary mp was 37°C (lit. (21) mp 37°C); ^{1}Hmr ($DCCl_3$) δ: 7.42 (broad s, 5, Ph), 5.12 (s, 1, CH), and 3.52 (s, 1, OH); in CCl_4, δ: 7.56 (m, 2, Ph), 7.3 (m, 3, Ph), 5.13 (s, 1, CH), and 4.67 (s, 1, OH).

The carbinol was converted to α-chlorophenylacetic acid by the general procedure given below. From 22.4 g of the carbinol there was obtained 11.6 g of α-chlorophenylacetic acid, mp 74–76°C (lit. (22) mp 78°C) after crystallization from hexane.

Conversion of p-*Chlorophenyl(trichloromethyl)carbinol to* p-*Chlorophenyl-α-chloroacetic Acid*

This illustrates the general procedure for the "Jocic reaction" (see footnote 2); this procedure was used with all of the (trichloromethyl)carbinols. The starting material was prepared as above from chlorobenzene and chloral and purified by conversion to the acetate by refluxing overnight with acetic anhydride and acetyl chloride. After recrystallization from ethanol, the acetate melted at 122–123°C (lit. (23) mp 120–121°C); ^{1}Hmr (CCl_4) δ: 7.86 (d, 2, J = 9 Hz, Ph), 7.63 (d, 2, J = 9 Hz, Ph), 6.53 (s, 1, CH), and 2.29 (s, 3, CH_3). The acetate was converted back to the carbinol by refluxing overnight with a solution composed of ten volumes each of isopropyl alcohol, concentrated hydrochloric acid, and water. The carbinol was recrystallized from "iso-octane" to give crystals (19% overall yield), mp 47–48°C (lit. (24) mp 47°C); ^{1}Hmr (CCl_4) δ: 7.90 (d, 2, J = 9 Hz, Ph), 7.61 (d, 2, J = 9 Hz, Ph), 5.33 (s, 1, CH), and 3.33 (s, 1, OH).

In a 250-mL, round-bottomed flask equipped with a magnetic stirrer and thermometer were placed 13 g (0.05 mol) of *p*-chlorophenyl(trichloromethyl)carbinol and 11.2 g (0.2 mol) of potassium hydroxide in 100 mL of water, all at 0°C. The solution was stirred for three days at 0°C. During this time a number of 2-mL aliquots were titrated with standard hydrochloric acid to obtain kinetic data. The alkaline reaction mixture was extracted with ether to obtain the neutral fraction (4.0 g), and the aqueous solution on acidification and extraction with ether yielded 4.5 g (44% of theory, 63% allowing for unreacted carbinol) of *p*-chlorophenyl-α-chloroacetic acid which had the following properties after recrystallization from "isooctane"; mp 75–77°C (lit. (25) mp 75–76°C); ir (KBr): 3300–2400, 1725, 1600, 1475, 1420, 1410, 1290, 1270, 1215, 1190, 1170, 1095, 1080, 1005, 960, 890, 855, 820, 790, 745, 660, 605, and 505 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 11.43 (s, 1, COOH), 7.51 (s, 4, Ph), and 5.40 (s, 1, CH).

The neutral fraction was shown by ^{1}Hmr to consist of 78% *p*-chlorophenyl (trichloromethyl)carbinol and 22% of *p*-chlorobenzaldehyde.

Radiochemistry

Ten grams of phenyl(trichloromethyl)carbinol (0.045 mol) was stirred for 69 h at 0°C with 105 mL of 1.5 *N* aqueous potassium hydroxide (0.158 mol), and 10 μCi of chloride-36 ion (1.02×10^7 counts/min measured with a methane-flow proportional counter with a counting efficiency of 46%). The concentration of ionic chloride in the reaction mixture varied from near zero initially to 0.9 *M* after 69 h, determined by titration. The 3.64 g of α-chlorophenylacetic acid (47% yield) obtained gave 196 counts/(mg min). Accordingly, 6.9% of the radioactive chloride and therefore a maximum of 6.9% of the chloride in solution was incorporated into the α-chlorophenylacetate. Since the average amount of chloride ion present during the reaction was 50 mequiv., 3.5 mequiv. of chloride ion is the maximum that could be incorporated into the 21.3 mequiv. of final α-chlorophenylacetic acid. From this it follows that at least 83% of the chlorine in the α-chlorophenylacetate comes from the original phenyl(trichloromethyl)carbinol by an intramolecular migration.

Unreacted carbinol recovered from the above reaction mixture had no radioactivity.

A possible S_N2 displacement reaction between radioactive ionic chloride and the α-chlorophenylacetate was shown to be too slow to have appreciable effect on the above results. Twenty milliequivalents of potassium α-chlorophenylacetate, 80 mequiv. of potassium chloride, 100 mequiv. of potassium hydroxide, and 20 μCi (2.04×10^7 counts/min) of chloride-36 ion were stirred in 100 mL of water at 0°C for 68 h as in the above experiment. α-Chlorophenylacetic acid was isolated quantitatively and found to have only 8 counts/(mg min). Accordingly less than 0.2% of the available radioactive chloride ion was incorporated into the α-chlorophenylacetate.

Kinetic Data

Seven 2-mL aliquots of the *p*-chlorophenyl(trichloromethyl)-carbinol reaction mixture were titrated with 0.1 *N* hydrochloric acid to a phenolphthalein end point. From the amount of base consumed, the percent of carbinol converted to the chloro acid was calculated. Plotting the log of the percent of carbinol reacted against the reaction time at 0°C gave a straight line with a first order rate constant of 4.2×10^{-4} min^{-1}. A second experiment identical to the first, except the amount of carbinol was halved, likewise followed first order kinetics with $k_1 = 4.2 \times 10^{-4}$ min^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

For personal use only.

A third experiment identical to the first, but with the potassium hydroxide doubled, likewise gave the same first order reaction rate constant. The calculation of the percent of carbinol converted to chloro acid from the base consumption is somewhat in error due to the by-product dichlorocarbene which also consumes base. Accordingly, the value of the above kinetic experiments is limited to establishing that the reaction is first order in *p*-chlorophenyl (trichloromethyl)carbinol and zero order with respect to base under these experimental conditions. No reaction occurs in the absence of base.

A similar study was carried out starting with trichloroethanol at 30°C, and the reaction was found to be first order in the trichloroethanol.

Kinetic data on trichloroethanol reaction

[Trichloroethanol] (mol/L)	[Base] (mol/L)	Calcd. k_1 ($min^{-1} \times 10^3$)
0.2	1.12	2.3
0.67	1.12	2.3

Stereochemistry

R-(−)-Phenyl(trichloromethyl)carbinol (1.1 g, 0.05 mol, $[\alpha]_D^{25}$ −15.8° (*c* 11.7, EtOH) (42% optically pure)) (3), 1.25 g (0.02 mol) of potassium hydroxide, 1 mL of 10% potassium oleate solution, and sufficient water to make 10 mL of final solution were stirred together for 8 h at 0°C. The crude acid fraction was sublimed (40–60°C for 1 week) and recrystallized from "isooctane" to give 0.044 g of *S*-(+)-α-chlorophenylacetic acid, $[\alpha]_D^{27}$ +7.3° (*c* 1.295, benzene) (3.8% optically pure). The literature $[\alpha]_D^{12}$ of *R*-(−)-α-chlorophenylacetic acid is −191° (*c* 3.35, benzene) (26).

For a control experiment, 1.15 g of *S*-(+)-α-chlorophenylacetic acid, $[\alpha]_D^{28}$ +53.2° (*c* 3.1, EtOH) was dissolved in 100 mL of 1.11 *N* potassium hydroxide and allowed to stand at 0°C for 8 h. The reaction mixture was poured into ice and dilute sulfuric acid, and extracted with ether. The *S*-(+)-α- chlorophenylacetic acid had a rotation of $[\alpha]_D^{25}$ +15.9° (*c* 31, benzene).

Deuterium Exchange

Phenyl(trichloromethyl)carbinol (2.2 g, 0.01 mol) and 2.5 g (0.045 mol) of potassium hydroxide, dissolved in sufficient deuterium oxide (99.8% pure) to make 20 mL of solution, were stirred at 0°C for 22 h. Aliquots were periodically withdrawn and titrated and the time for 50% reaction calculated to be 21 h. The reaction mixture was extracted with ether to recover the neutral fraction (0.8 g). This was washed with a saturated bisulfite solution to remove benzaldehyde and the residual oil shown to be unreacted phenyl(trichloromethyl)carbinol from its ^{1}Hmr spectra. The phenyl to α-hydrogen ratio was 5:1 showing that no deuterium exchange had occurred prior to the rearrangement to the chloro acid.

After removing the neutral fraction, the reaction mixture was acidified with ice and hydrochloric acid and the acid fraction extracted with ether to give 0.48 g of α-chlorophenylacetic acid, mp 76–79°C after crystallization from hexane. Its ^{1}Hmr spectra (CCl_4) showed a phenyl to α-hydrogen ratio of 5:0.53, showing that 47% deuterium incorporation occurred at the α-position. The results obtained with two other carbinols in similar experiments are given in Table 2.

Control experiments were carried out by dissolving the product acids in alkaline dueterium oxide under the same reaction conditions as above but for one-half the time of the main reaction. The results are in Table 2.

o-*Allylphenyl(trichloromethyl)carbinol Reactions*

o-Iodoallylbenzene was prepared in 18% yield from *o*-allylaniline (from zinc chloride catalyzed rearrangement of *N*-allylaniline at 140°C (27), by diazotization and reaction with potassium iodide, bp 131–137°C (40 Torr); ir (film): 3100, 3080, 3010, 2990, 2910, 1645, 1600, 1580, 1460, 1440, 1020, 990, 920, and 750 cm^{-1}; ^{1}Hmr (CCl_4) δ: 7.87 (m, 1, Ph), 7.21 (m, 2, Ph), 6.91 (m, 1, Ph), 6.0 (d of d of t, 1, J = 19, 11, and 6 Hz, —CH═), 5.16 (d of d, 1, J = 11 and 1.5 Hz, ═CH_2), 5.1 (d of d, 1, J = 19 and 1.5 Hz, ═CH_2), and 3.5 (d, 2, J = 6 Hz, —CH_2—). *Anal.* calcd. for C_9H_9I: 44.29, H 3.72, I 51.99; found: C 44.34, H 3.65, I 51.80.

The *o*-iodoallylbenzene was converted into its Grignard reagent and this was poured into an ether solution containing 90% of the theoretical amount of anhydrous chloral. Distillation gave a 48% yield of *o*-allylphenyl(trichloromethyl)carbinol, bp 124–135°C (0.4 Torr); ir (film): 3600–3300, 3100–2900, 1640, 1450, 1390, 1290, 1175, 1050, 990, 920, 820, 770, 730, 640, and 600 cm^{-1}; ^{1}Hmr (CCl_4) δ: 7.83 (m, 1, Ph), 7.3 (m, 3, Ph), 6.0 (m, 1, —CH═), 5.53 (s, 1, —C*H*OH—), 5.00 (m, 2, ═CH_2), 3.63 (d of d, 2, J = 6 and 8 Hz, —CH_2—), and 3.07 (s, 1, —OH). *Anal.* calcd. for $C_{11}H_{11}Cl_3O$: C 49.75, H 4.17, Cl 40.05; found: C 49.52, H 4.22, Cl 39.80.

A mixture of 9.3 g of the above carbinol and 7.9 g of potassium hydroxide in sufficient water to make 70 mL was stirred at 0°C for 72 h. The crude acid fraction (2.0 g) was converted to methyl *o*-allylphenyl-α-chloroacetate containing an estimated 15% methyl *o*-allylmandelate based on elemental analyses and the presence of a weak absorption peak at 3500 cm^{-1} in the ir spectrum. The distilled material had the following properties: bp 148–154°C (7 Torr); ir (film): 1760 (C═O); ^{1}Hmr (CCl_4) δ: 7.2 (m, 4, Ph), 6.25–5.5 (m, 1, allyl), 5.58 (s, 1, —CHCl—), 5.1 (s, 1, allyl), 5.0 (m, 1, allyl), 3.67 (s, 3, OCH_3), and 3.5 (m, 2, CH_2); high-resolution (ms) obsd./calcd. *Exact Mass* for $C_{12}H_{13}ClO_2$: 224.0604/224.0651. *Anal.* calcd. for $C_{12}H_{13}ClO_2$: C 64.29, H 5.79, Cl 15.8; found: C 65.20, H 5.88, Cl 12.80.

The neutral fraction amounted to 6.2 g and was shown (^{1}Hmr) to consist of 1.5 g of *o*-allylbenzyaldehyde and 4.7 g unreacted carbinol. The two were separated by column chromatography on neutral Brockman alumina using benzene and methanol successively as eluents.

p-*Bromophenyl(trichloromethyl)carbinol Reactions*

The crude carbinol was prepared as above from bromobenzene and chloral, purified by conversion to the acetate, mp 145–147°C; ir (KBr): 1750, 1230, 1065, 1045, 1020, 940, 880, 830, 780, 720, 675, 615, and 530 cm^{-1}. The acetate was hydrolyzed to the carbinol by the same procedure used with the *p*-chloro analog. The crystals were recrystallized from "isooctane", mp 55°C; ir (KBr): 3600–3400, 2940, 1600, 1500, 1400, 1320, 1285, 1240, 1185, 1110, 1065, 1005, 870, 825–810, 770, 710, 660, 630, and 615 cm^{-1}; ^{1}Hmr (CCl_4) δ: 7.42 (broad s, 4, Ph), 5.04 (s, 1, CH), and 3.3 (s, 1, OH).

A mixture of 15.2 g of the above carbinol and 11.2 g of potassium hydroxide in sufficient water to make 100 mL was stirred at 0°C for 48 h. The crude *p*-bromophenyl-α-chloroacetic acid (6.1 g) was recrystallized from "isooctane" and melted at 82–84°C (lit. (28) mp 82–83°C). The neutral fraction consisted of *p*-bromobenzaldehyde (0.34 g) and unreacted carbinol (7.5 g), bp 159–162°C (2 Torr).

tert-*Butyl(trichloromethyl)carbinol Reactions*

The carbinol was prepared in 17% yield from trichloromethylmagnesium chloride (29) (from *n*-butylmagnesium chloride and chloroform in THF at −78°C) and 2,2-dimethylpropanal at−70°C; bp 102–108°C (45 Torr), mp 47–48°C (lit. (30) mp 49°C); ir (film): 3500, 3000–2850, 1480, 1380, 1060, 1020, 810, 780, 710, and 630 cm^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A mixture of 4.1 g of the above carbinol and 4.5 g of potassium hydroxide in sufficient water to make 40 mL was stirred at 0°C for 24 h. The crude acid fraction amounted to 0.35 g; it was methylated with diazomethane. The ester mixture consisted (glc with a silicon gum rubber column at 100°C) of 22% methyl trimethyllactate (8 min retention time) and 78% methyl 2-chloro-3,3-dimethylbutyrate (10 min retention time). The methyl trimethyllactate was identified by comparison with an authentic sample (31, 32). The methyl 2-chloro-3,3-dimethylbutyrate was characterized as follows: ir (film): 2950, 1760, 1280, and 1160 cm^{-1}; ^{1}Hmr (CCl_4) δ: 4.14 (s, 1, —CHCl—), 3.85 (s, 3, —OCH_3), and 1.17 (s, 9, CH_3). *Anal.* calcd. for $C_7H_{13}ClO_2$: C 51.07, H 7.96, Cl 21.54; found: C 50.86, H 8.21, Cl 21.25.

Trichloroethanol Reactions

From 14.9 g of trichloroethanol and 22.4 g of potassium hydroxide in 200 mL of water at 30°C for 6 h there was obtained 3.7 g of a crude acid mixture consisting (^{1}Hmr analysis) of 2.1 g of chloroacetic acid and 1.6 g of trichloroethoxyacetic acid. One liter of carbon monoxide was evolved during the first 203 min of reaction. The gas was dried and characterized by the 2160 and 2110 cm^{-1} bands in its ir spectrum (33). The evolution was first order in trichloroethanol with $k_1 = 1.07 \times 10^{-4}$ min^{-1}. Chloroacetic acid was isolated by distillation and identified by its mp of 55–57°C, and its ir and ^{1}Hmr spectra. The residue was identified as trichloroethoxyacetic acid by its mp of 70°C (lit. (34) mp 69.5°C) and its ^{1}Hmr spectrum.

p-*Tolyl(trichloromethyl)carbinol Reactions*

The crude carbinol, bp 128–150°C (2 Torr), containing 25% of the *ortho* isomer and 8% tetrachlorotolylethanes (^{1}Hmr analysis) was prepared from toluene and chloral (21), and converted to the acetate by refluxing with a six-fold excess of acetic anhydride and acetyl chloride (2 to 1 ratio) for 8 h. Properties of *p*-tolyl(trichloromethyl)carbinol acetate after two recrystallizations from ethanol: mp 106–108°C (lit. (21) mp 107–108°C); ir (KBr): 3500–3300, 1620, 1510, 1400, 1330, 1300, 1250, 1200, 1180, 1065, 865, 825–780, 740, 720, 650, 620, and 510 cm^{-1}; ^{1}Hmr (CCl_4) δ: 7.04 (d, 2, J = 9 Hz, Ph), 6.74 (d, 2, J = 9 Hz, Ph), 5.88 (s, 1, —C*H*OH), 2.08 (s, 3, CH_3—), and 2.05 (s, 3, CH_3).

The above carbinol acetate was hydrolyzed to the carbinol by the same procedure used for the chloro analog. The crystals were recrystallized from "isooctane": mp 63–64°C (lit. (21) mp 63–64°C), ir (KBr): 3020–2900, 1730, 1360, 1220, 1170, 1050–1030, 925, 870, 785, 740, 710, 670, 615, 595, 550, and 510 cm^{-1}; ^{1}Hmr (CCl_4) δ: 7.38 (d, 2, J = 8.5 Hz, Ph), 6.71 (d, 2, J = 8.5 Hz, Ph), 4.93 (s, 1, CH), 3.43 (s, 1, OH), 2.32 (s, 3, CH_3).

A mixture of 11.9 g of the above carbinol and 11.2 g of potassium hydroxide in sufficient water to make 100 mL was stirred at 0°C for 48 h. The neutral fraction (8.9 g) consisted (^{1}Hmr analysis) of 0.7 g of *p*-tolualdehyde and 7.6 g of *p*-tolyl(trichloromethyl)carbinol. The compounds were separated by glc (silicon gum rubber at 200°C), and identified by comparison with authentic samples. The acid fraction (2.1 g) was *p*-tolylglycollic acid and was recrystallized from benzene: mp 145–147°C (lit. (35) mp 145–146°C); ir (KBr): 3450, 3350, 3100–2500, 1700, 1290, 1180, 1060, 935, 880, 820, 730, 705, and 580 cm^{-1}; ^{1}Hmr (DMSO-d_6) δ: 7.14 (d, 2, J = 8 Hz, Ph), 6.97 (d, 2, J = 8 Hz, Ph), 4.9 (s, 1, CH), and 2.2 (s, 3, CH_3).

A reference sample of *p*-tolylglycollic acid was prepared by the method outlined in Organic Syntheses (36).

1-(Trichloromethyl)-1-cyclohexanol Reactions

The carbinol, mp 57–59°C, was prepared from cyclohexanone and chloroform (37). A mixture of 10.6 g of the carbinol, 11.2 g of potassium hydroxide, and 90 mL of water was stirred at 0°C for 10 h. The neutral fraction (3.0 g) was cyclohexanone, identified by its ir and the mp of its dinitrophenylhydrazone. The acid fraction (0.85 g) could not be thoroughly characterized. Its ^{1}Hmr spectrum suggested that it was mostly 1-chlorocyclohexanecarboxylic acid with around 25% 1-cyclohexenecarboxylic acid. This corresponds to an 8% yield of the chloro acid.

*Di(*p*-Chlorophenyl)(trichloromethyl)carbinol Reactions*

A mixture of 18.5 g of di(*p*-chlorophenyl) (trichloromethyl) carbinol[3] and 12.5 g of potassium hydroxide in sufficient water to make 100 mL was stirred at 0°C for three days. The acid fraction was negligible. The crude neutral fraction appeared by nmr analysis to be substantially pure 4,4′-dichlorobenzophenone together with its isomeric impurity. After one recrystallization from 95% ethanol, it melted at 144–148°C (lit. (38) mp 145°C), and its ir spectrum was identical with that of an authentic sample.

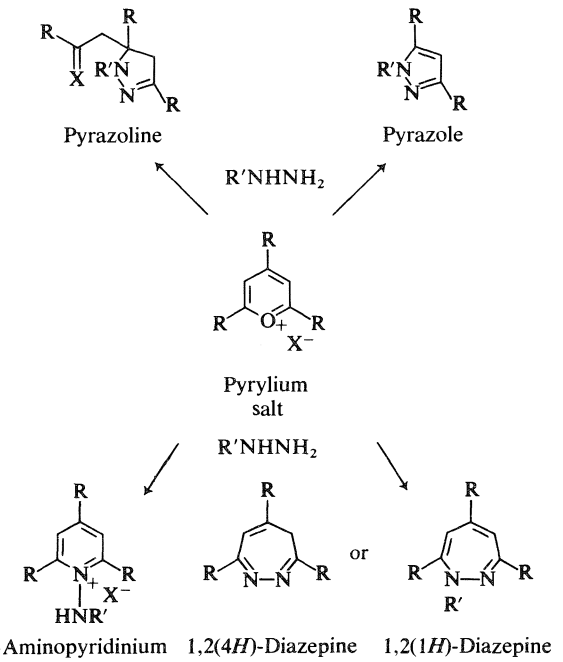
Reaction of pyrylium salts with hydrazine and methylhydrazine. Concerning the scope of the 1,2(4*H*)-diazepine synthesis[1,2]

D. J. HARRIS,[3] G.Y.-P. KAN, T. TSCHAMBER,[4] and V. SNIECKUS[5]

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received October 10, 1979

D. J. HARRIS, G.Y.-P. KAN, T. TSCHAMBER, and V. SNIECKUS. Can. J. Chem. **58**, 494 (1980).



The reaction of pyrylium salts **1***a*–e with methylhydrazine gives pyrazolines (**2**), pyrazoles (**3**), pyridines (**4**), 1,2-diazepine (**5**), and *N*-methylaminopyridinium salts (**6**). Product composition has been studied as a function of pyrylium salt counter anion, concentration of methylhydrazine, and conditions of the reaction (Table 1). Pyridines (**4**) and 1,2-diazepines (**5**) are minor components, the major products being the pyrazolines (**2**) and pyrazoles (**3**). The reactions of more unusual pyrylium salts (**1***f*–i, **8***a*, **9***a*, **9***c*, and **11***a*) with hydrazine have been shown to provide 1,2(4*H*)-diazepines (**10**, **12**–**15**) and *N*-aminopyridinium salts (**8***b*, **9***b*) (Table 2), the nature of the product apparently depending on the absence or presence of 2-methyl substitution respectively in the starting pyrylium salts.

D. J. HARRIS, G.Y.-P. KAN, T. TSCHAMBER et V. SNIECKUS. Can. J. Chem. **58**, 494 (1980).

La réaction des sels de pyrylium **1***a*–*e* avec la méthylhydrazine conduit aux pyrazolines (**2**), aux pyrazoles (**3**), aux pyridines (**4**), à la diazépine-1,2 (**5**) et aux sels de *N*-méthylaminopyridinium (**6**). On a étudié la composition des produits en fonction de l'anion des sels de pyrylium, de la concentration de la méthylhydrazine et des conditions de la réaction (Tableau 1). Les pyridines (**4**) et les diazépines-1,2 (**5**) sont des produits secondaires, les produits principaux de la réaciton étant les pyrazolines (**2**) et les pyrazoles (**3**). On a montré que les réactions des sels de pyrylium les moins usuels (**1***f*–*i*, **8***a*, **9***a*, **9***c* et **11***a*) avec l'hydrazine conduisent aux (4*H*)-diazépines-1,2 (**10**, **12**–**15**) et aux sels de *N*-aminopyridinium (**8***b*, **9***b*) (Tableau 2). La nature des produits dépend apparemment de l'absence ou de la présence d'un substituant méthyle en position 2 dans les sels de pyrylium de départ.

[Traduit par le journal]

Pyrylium salts undergo reaction with a host of nucleophiles to give a variety of heterocyclic, benzenoid, and open chain products (2–6). We initiated work on the reaction of highly, invariably aryl, substituted pyrylium and thiapyrylium salts with hydrazines in connection with our interest to prepare new 1,2-diazepine derivatives (1, 7). This reaction, first briefly described by Schneider and Seebach (8), well documented (5), and extensively studied more recently by several groups (7, 9–12), leads to pyrazolines (9), pyrazoles (10), *N*-aminopyridinium salts (9*a*, 9*c*, 10, 11), or 1,2-diazepines (9*e*, 9*f*, 9*g*, 12) (Scheme 1). The products obtained are dependent on the structures of the pyrylium salts and hydrazine derivatives and the reaction conditions. Balaban has isolated intermediates in some of these reactions (9*g*–*h*) and we have studied the interrelationships of these substances by thermal and acid-catalyzed reactions (13). Subsequent to our preliminary communication (1), we have studied the reaction of a number of diverse pyrylium salts with hydrazine in attempts to extend the scope and define the limitations of the 1,2-diazepine synthesis (12). The details of both studies (1, 6) constitute the current report.

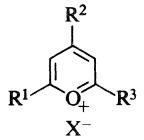
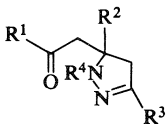
TABLE 1. Reaction of 2,4,6-triphenylpyrylium salts 1*a–e* with methylhydrazine



Compound	Ratio 1:$MeNHNH_2$	Reaction conditions	Products (% yield)[a]			
1*a*	1:2	PhH, 0°C → room temperature, 6 h		3*a*(50–68)	4*a*(5)	
1*a*	1:4	PhH, room temperature, 2 h	2*a*(33)	3*a*(38)	4*a*(1)	
1*a*	1:2	Et_2O, room temperature, 4 h		3*a*(64)	4*a*(5)	5(13)
1*a*	1:2.5	EtOH, room temperature, 4 h		3*a*(87)		
1*a*	1:60	Neat, room temperature, 5 h		3*a*(90)		5(1)
1*b*	1:2.5	EtOH, room temperature, 4 h		3*a*(81)		
1*c*	1:60	Neat, 0°C, 7 h		3*a*(92)		
1*d*	1:2.5	PhH, room temperature, 9 h	2*b*(15)	3*a*(8)		6(57)
1*e*	1:2.5	EtOH, room temperature, 4 h	2*b*(2)	3*a*(80)		
1*e*	1:60	Neat, 0°C, 16 h	2*b*(40)	3*a*(42)		

[a] 10–40% of acetophenone was isolated from all of the reactions listed.

Reaction of Pyrylium Salts 1a–e *with Methylhydrazine*



The results from the reaction of pyrylium salts 1*a–c* with methylhydrazine are summarized in Table 1. In the non-polar solvents benzene and ether as well as with neat methylhydrazine, the pyrylium iodide 1*a* gave the pyrazole 3*a* as the major product with minor amounts of pyrazoline (2*a*), pyridine (4*a*), and diazepine (5) derivatives. In addition, acetophenone was always detected by nmr in the crude reaction mixtures from 1*a* as well as from 1*b* and 1*c*. The yield of the diazepine 5 is not a maximum limit since it was shown that this compound partially decomposed in solution or on chromatography over silica gel into 2,4,6-triphenylpyridine (4*a*) and 1-methyl-3,5-diphenylpyrazole (3*a*) (see Experimental). Change of counter anion from iodide (1*a*) to fluoroborate (1*b*) or perchlorate (1*c*) had little effect on the distribution of products (compare 1*a* and 1*b* to EtOH, 1*a* and 1*c* in neat methylhydrazine). In contrast to the same reaction with the corresponding thiapyrylium salts which provided good yields of the diazepine 5 (7), the pyrylium salts 1*a–c* gave trace or minor amounts of this product (e.g., in Et_2O as solvent). Pyrazolines 2*a* and 2*b* were identified by their characteristic nmr spectra (7, 9*g*, 14) and their quantitative thermal fragmentation to the pyrazoles 3*a* and 3*b* and acetophenone. The structures of the other products 4*a* and 5 were confirmed by comparison with authentic samples.

Attempts to obtain diazepine products from the 2-methyl-4,6-diphenylpyrylium salts 1*d* and 1*e* were totally unsuccessful (Table 1). However, in comparison to the reaction of 1*a*, the product composition in benzene at room temperature changes to yield, besides minor amounts of the pyrazoline 2*b* and the pyrazole 3*a*, the *N*-aminopyridinium salt 6. Although 6 was first isolated in 1921 by Schneider and Seebach (8), its structure was not firmly established (15) but this is clear from its spectral and analytical data and its hydrogenolysis into 2-methyl-4,6-diphenylpyridine (4*b*) (see Experimental). The contrast in the reaction of 1*a* and 1*d* with methylhydrazine in benzene may be attributed to steric hindrance in cyclization of the respective open-chain methylhydrazone intermediates 7*a* and

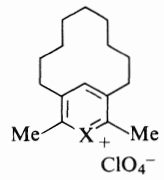
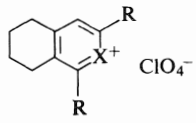
7*b* (7, 9*g–h*). In the case of **1***a*, cyclization of **7***a* to *N*-methylamino-2,4,6-triphenylpyridinium hydroiodide (path *a*) is presumably prevented by the steric congestion of the contiguous *N*-methylamino and 2,6-diphenyl substituents which would result upon final dehydration. A less stringent steric requirement is presented by the Michael reaction of **7***a* (path *b*), leading to the pyrazoline **2***a*. In fact, an open-chain hydrazone (**7***c*) may be isolated from the reaction of **1***a* with phenylhydrazine which requires forcing conditions (refluxing EtOH) for conversion into the corresponding pyrazoline **2***c* (9*h*). The duality of *N*-aminopyridinium salt or pyrazole formation from 2,6-dimethyl substituted pyrylium salts has been previously observed (10*b–d*). The production of similar amounts of **2***b* and **3***a* from the reaction of the unsymmetrical pyrylium salt **1***d* in benzene or without solvent suggests the lack of steric discrimination in the initial attack of methylhydrazine at the 2- and 6-positions.



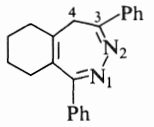
In marked contrast and contrary to expectation based on a steric argument, predominant formation of the pyrazole **3***a* results when the reaction is carried out in ethanol solution. Similar behaviour has been observed in the reaction of 2-methyl-4,6-diphenylpyrylium perchlorate with hydrazine (10*d*). On the other hand, Reissenweber and Sauer recently showed that 2-methyl-4,6-diphenylpyrylium salts with an additional methyl or phenyl substituent at the 3-position undergo reaction with hydrazine to give the corresponding 1,2(4*H*)-diazepines (12*a*). Undoubtedly complex equilibria are involved in these reactions, and a satisfactory mechanistic explanation is presently not available. However, we have observed similar behaviour in the reaction of unsymmetrical *N*-iminopyridinium ylides with peroxides (16).

Reactions of Pyrylium Salts **1**f–i, **8**a, **9**a, **9**c, *and* **11** *with Hydrazine*



As an extension of the reaction of pyrylium salts with hydrazine (12) and in the hope of preparing new diazepine derivatives, we tested a diverse group of substrates. The results (Table 2) are a continuation of the previously observed trend (see above), i.e., 2,6-dialkylpyrylium salts (**8***a*, **9***a*), excluding the 2,6-di-*tert*-butyl case (**1***i*), yield *N*-aminopyridinium derivatives (**8***b*, **9***b*), whereas 2,6-diaryl systems (**1***f–g*, **9***c*, **11**) containing 4-substituents provide 1,2(4*H*)-diazepines (**13**, **14**, **10**, **12**).

Treatment of the (9)-pyrylophanium perchlorate **8***a* with hydrazine in ethanol at room temperature afforded the *N*-aminopyridinium salt **8***b* in 75% yield. The physical and spectral data are identical to those reported by Balaban for **8***b* subsequent to the completion of our work (9*c*). We also prepared the acetylated product **8***c* which is a potential intermediate for a photochemical synthesis of the (9)-diazepinophanium system. Under the conditions used for **8***a*, the dimethyltetrahydro-2-benzopyrylium salt **9***a* also gave an *N*-aminopyridinium derivative **9***b* (60% yield). These products (**8***b*, **8***c*, **9***b*) all showed mass spectra characteristic of *N*-aminopyridinium salts (major fragmentation by loss of $HClO_4$ and NH_2 or NHAc) (17).



The effect of 2,6-dialkyl vs. -diaryl substituents may be gleaned from the comparison of the reaction of pyrylium salts **9***a* and **9***c* with hydrazine. Under identical conditions to those used for **9***a*, compound **9***c* gave the bicyclic 1,2(4*H*)-diazepine **10** in moder-

ate yield. The structure of **10** is fully consistent with the spectral data (see Experimental). An interesting feature of its nmr spectrum at ambient temperature is the sharp doublet at δ 3.45 (J = 12 Hz) assigned to half of the C-4 methylene AB pattern. This contrasts with simple 1,2(4*H*)-diazepines which show broadened AB systems near room temperature owing to the ring inversion phenomenon (6, 12*e*, 18). In **10**, such a process has a considerably higher activation energy as a result of the carbocyclic ring fusion. Evidence for this could not be obtained by temperature variable nmr studies due to decomposition of **10** above +50°C. Hungarian workers have recently shown that fully aromatic compounds corresponding to **9**, X = O, even with a 3-methyl substituent may be ring expanded to the 1,2(4*H*)-diazepines by reaction with hydrazine (12*d*). The ring-fused diphenylpyrylium salt **11** also furnished a diazepine derivative (**12**) in 85% yield. The nmr spectrum of compound **12** shows an interesting temperature dependence for the benzylic (H_A, H_B) and diazepine ring (H_C, H_D) protons. Envelope-like peaks are observed at δ 4.58 and 4.4 at ambient temperature which split into two AB spin systems at δ 4.85 (d, J = 20 Hz) and 4.46 (d, J = 20 Hz), and δ 5.33 (d, J = 12 Hz) and 3.51 (d, J = 12 Hz), respectively, at the lower temperature limit (−40°C). The latter AB pattern is characteristic both in the large chemical shift difference and coupling constant of the C-4 methylene absorptions of the 1,2(4*H*)-diazepine system (12*e*, 18) and can therefore be assigned to the H_C and H_D protons of **12**. The absorptions at δ 4.85 and 4.46 are thus assigned to the H_A and H_B protons. Since the low temperature limit spectrum shows no evidence for doubling of the two AB systems which would implicate four isomers, we conclude that the coalescence phenomenon is due to a single synchronous process involving five-membered ring and diazepine ring inversions. This is supported by the almost identical free energies of activation calculated for the H_A, H_B ($\Delta G_C^{\ddagger}$ = 13.1 kcal/mol, T_C = +2.5 ± 2°C) and the H_C, H_D ($\Delta G_C^{\ddagger}$ = 13.4 kcal/mol, T_C = +17 ± 2°C) systems at their respective coalescence temperatures. Compared to the 3,5,7-triaryl-1,2(4*H*)-diazepine ring system (Scheme 1), compound **12** is modified by a methylene bridge between C-6 and the *ortho* position of the C-7 phenyl group. The effect of this bridge is to pinch the diazepine at the C-6 to C-7 bond thereby inducing greater ring planarity which, in turn, is expected to facilitate the ring inversion process in **12** compared to the simple triaryl-1,2(4*H*)-diazepines. The higher activation energy observed for the latter systems, $\Delta G_C^{\ddagger}$ = 17–18 kcal/mol is in agreement with this view.

The unsymmetrical triaryl pyrylium perchlorate **1***f* and the 2-styrylpyrylium fluoroborate **1***g* afforded 1,2(4*H*)-diazepines **13** and **14** respectively in moderate yields. That **13** was a mixture of Δ^4- and Δ^5- double bond isomers was inferred from the nmr spectrum which showed two singlets for the methoxyl hydrogens at δ 3.9 and 3.75 in a ratio of 3:1 and a broadened ABX pattern for the methylene (δ 4.4, 2.65) and diazepine ring vinyl (δ 6.7) protons (12*e*, 18). That the appearance of two methoxyl singlets is not due to two diazepine conformational isomers undergoing slow ring inversion was established by variable temperature nmr studies (room temperature → 130°C) which showed the collapse of the methylene protons but no change in the methoxyl absorptions. Attempts to separate the two double bond isomers by thin-layer chromatography were not successful. Treatment of **13** with acid over a long period of time resulted only in equilibration to a 1:1 mixture (nmr analysis). The product **14**, on the other hand, appeared to be a single isomer on the basis of tlc and nmr spectral criteria. Aside from the ABX pattern for the methylene and vinyl hydrogens at δ 2.5, 4.2, and 6.22 respectively, the nmr spectrum showed a sharp singlet at δ 6.9 assigned to the coincidental absorption of the styryl hydrogens. The available evidence does not allow the definite assignment of the Δ^4- or Δ^5-isomer to product **14**.

Treatment of 2,6-diphenylpyrylium perchlorate **1***h* with hydrazine gave the unstable pyrazoline **2***d*. Its structure was supported by the characteristic nmr spectrum which could be compared with those of the previously obtained pyrazolines (**2***a–c*) (7, 9*g*, 14) (see Experimental) and by its thermal fragmentation into 3-phenylpyrazole (**3***d*) and acetophenone. From this and other (10*b*, 12*b–c*) observations, it appears that a 4-substituent in the pyrylium salt is essential for the formation of diazepine products.

Since methyl substituted pyrylium salts gave only *N*-aminopyridinium salts, pyrazoles, or pyrazolines, we wished to test the reaction of an alkyl substituted pyrylium salt lacking acidic hydrogens. Treatment of 2,4,6-tri-*tert*-butylpyrylium perchlorate **1***i* with hydrazine resulted in smooth conversion into the corresponding 1,2(4*H*)-diazepine **15** in 90% yield. The structure was consistent with the nmr spectrum which showed an ABX system at δ 2.25 (d, J = 13 Hz, C-4 H_A), δ 3.3 (d, J = 13 Hz, C-4 H_B), and δ 6.15 (br s, C-6 H) typical for the 3,5,7-triaryl-1,2(4*H*)-diazepines (12*e*, 18) but shifted to higher field on account of lack of the anisotropic effect of the aryl rings. Balaban has recently prepared the 5-methyl- and 5-

TABLE 2. Reaction of pyrylium salts **1***f–i*, **8***a*, **9***a*, **9***c*, and **11** with hydrazine

trideuteromethyl-3,7-di-*tert*-butyl-1,2(4*H*)-diazepines from the corresponding pyrylium salts (12*c*) demonstrating that 4-alkyl substituents (bearing acidic hydrogens) are compatible with the formation of diazepine products.

In summary, we have shown that the reaction of pyrylium salts with hydrazine, previously demonstrated to give 1,2(4*H*)-diazepines (7, 12), can be extended to provide some new monocyclic (**13–15**) and more highly condensed (**10**, **12**) diazepine derivatives. In contrast, the reaction of 2-methyl substituted pyrylium salts (**8***a*, **9***a*) with hydrazine leads to *N*-aminopyridinium salts (**8***b*, **9***b*) whereas the reactions of simple salts **1***a–e* with methylhydrazine leads mainly to ring contracted products (**2**, **3**).

Experimental

General Methods

Melting points were determined on a Mel-Temp or Fisher-Johns apparatus and are uncorrected. Analyses were performed by A. B. Gygli, Toronto, Ont., Micro-Tech Lab Inc., Skokie, IL., Galbraith Laboratories, Inc., Knoxville, TN., Enviro Analytical Laboratory, Knoxville, TN., and Heterocyclic Chemical Corporation, Harrisonville, MO. The infrared spectra were recorded on Beckman IR-5A, IR-10, and PE-180 instruments. Nuclear magnetic resonance spectra were recorded on Varian T-60, HA-100, and Perkin-Elmer R-12B spectrometers in deuteriochloroform solution using TMS as internal standard unless otherwise stated. Mass spectra were determined on AEI-MS 30, double beam, double-focussing spectrometer with perfluorokerosene mass marker. Thin layer and preparative chromatography were carried out with Merck silica gel GF-254 and column chromatography was performed using silica gel (0.05–0.20 mm), both obtained from Brinkman (Canada). Benzene and ether were dried over sodium using benzophenone as

indicator. Ethanol was dried over magnesium activated with iodine followed by distillation. Hydrazine hydrate (99–100%) and methylhydrazine (bp 87–89°C) were used directly without purification.

Preparation of Pyrylium Salts

All pyrylium salts are known compounds and were prepared according to literature procedures or slight variations thereof.

*2,4,6-Triphenylpyrylium Iodide (**1**a):* mp 220–222°C (lit. (19) mp 221°C).

*2,4,6-Triphenylpyrylium Fluoroborate (**1**b):* mp 214–215°C (lit. (19) mp 214–215°C).

*2,4,6-Triphenylpyrylium Perchlorate (**1**c):* mp 287–288°C (lit. (19, 20) mp 290°C).

*2-Methyl-4,6-diphenylpyrylium Iodide (**1**d):* mp 218–220°C (lit. (19) mp 222°C).

*2-Methyl-4,6-diphenylpyrylium Fluoroborate (**1**e):* mp 242–246°C (lit. (21) mp 247–249°C).

*2-(p-Methoxyphenyl)-4,6-diphenylpyrylium Perchlorate (**1**f):* mp 238–239°C (lit. (21) mp 236°C).

*2-Styryl-4,6-diphenylpyrylium Perchlorate (**1**g):* mp 230–232°C (lit. (22) mp 235°C).

*2,6-Diphenylpyrylium Perchlorate (**1**h):* mp 230–231°C (lit. (19) mp 220–225°C).

*2,4,6-Tri-*tert*-butylpyrylium Perchlorate (**1**i):* mp 254–255°C (lit. (23) mp 254–255°C).

*11,13-Dimethyl[9](2,6)-pyrylophanium Perchlorate (**8**a):* mp 170–171°C (lit. (24) mp 170°C).

*1,3-Dimethyl-5,6,7,8-tetrahydro-2-benzopyrylium Perchlorate (**9**a):* mp 80–82°C (lit. (25) mp 79–80.5°C).

*1,3-Diphenyl-5,6,7,8-tetrahydro-2-benzopyrylium Perchlorate (**9**c):* mp 222–226°C (lit. (26) mp 215°C).

*2,4-Diphenyl-5H-indeno[1,2-b]pyrylium Perchlorate (**11**):* mp 267–268.5°C (lit. (27) mp 269–270°C).

*Reaction of Pyrylium Salts **1**a–e with Methylhydrazine (Table 1)*

The following experiments represent typical conditions and isolation procedures for the reactions summarized in Table 1. Pyrazole (**3**)–pyrazoline (**2**) product composition varied somewhat as a function of the chromatographic procedure (size of column, rate of elution).

*Reaction of **1**a in Benzene at 0°C*

Methylhydrazine (0.92 g, 20 mmol) was added to a stirred suspension of **1***a* (4.36 g, 10 mmol) in dry benzene (150 mL) at 0°C. The mixture was stirred for 6 h during which time it was allowed to warm to room temperature. The orange-red solution was carefully concentrated *in vacuo* at room temperature to give a gum which was dissolved in ethanol (1 mL) to deposit overnight 120 mg (5%) of red crystals of *1-methyl-3,5,7-triphenyl-1,2(1H)-diazepine* (**5**), mp 116°C (lit. (7) mp 116.5–118°C) shown to be identical by mixture mp and nmr spectral comparison with an authentic sample (7).

Chromatography (CH_2Cl_2 eluent) of the mother liquor gave in order of elution acetophenone (90 mg, 7.5%), *2,4,6-triphenylpyridine* (**4***a*) (160 mg, 5%), and *1-methyl-3,5-diphenylpyrazole* (**3***a*) (1.67 g, 68%). Acetophenone was characterized by comparison of its phenylhydrazone with an authentic sample. Compounds **4***a*, mp 137°C (lit. (19) mp 137–138°C) and **3***a*, mp 52°C (lit. (28) mp 59–60°C) were shown to be identical by mixture mp and nmr spectral comparison with authentic samples prepared by literature methods.

*Reaction of **1**a in Benzene at Room Temperature*

Methylhydrazine (1.06 mL, 20 mmol) was added dropwise to a rapidly stirred suspension of **1***a* (2.13 g, 5 mmol) in benzene (60 mL) and the mixture was stirred for 2 h. The reaction mixture was evaporated to dryness *in vacuo* and the residue was chromatographed. Elution with methylene chloride – hexane (7:3) gave *2,4,6-triphenylpyridine* (**4***a*) (14 mg, 1%) and acetophenone (115 mg, 19%) characterized as described above. Further elution with methylene chloride gave in order *1-methyl-3,5-diphenylpyrazole* (**3***a*) (475 mg, 38%), identified as given above, and *1-methyl-3,5-diphenyl-5-phenacylpyrazoline* (**2***a*) (624 mg, 33%) as a viscous unstable oil, nmr δ:2.63 (s, 3H, NCH_3), 3.30 and 3.98 (AB q, 2H, J = 16 Hz, ring CH_2), 3.48 (s, 2H, CH_2CO), 6.95–7.75 (m, 15H, Ar H).

Thermolysis of **2***a* under nitrogen at 135°C (oil bath temperature) for 1 h gave, after chromatography (silica gel, CH_2Cl_2–hexane (7:3), then CH_2Cl_2 elution), quantitative yields of acetophenone and the pyrazole **3***a* which were characterized as described above.

*Reaction of **1**d in Benzene*

The reaction was carried out in benzene as described for **1***a* using **1***d* (1.84 g, 5 mmol) and hydrazine (0.53 mL, 10 mmol). After a few minutes, a yellow precipitate appeared. After stirring for 9 h, the precipitate was collected and recrystallized ($CHCl_3$–EtOH) to give 1.06 g (53%) of *1-methylamino-2-methyl-4,6-diphenylpyridinium iodide* (**6**), mp 179–180°C (lit. (15) mp 180°C); nmr δ:2.7 (d, 3H, J = 6 Hz, $NHCH_3$), 3.3 (s, 3H, CH_3), 7.05 (q, 1H, J = 6 Hz, NH), 7.5–7.95 (m, 10H, Ar H), 7.8 and 8.4 (2d, 2H, J = 2.5 Hz, pyridine β-H).

Hydrogenation (Pd/C, EtOH) of **6** (200 mg) as described previously (13) afforded, after chromatography (CH_2Cl_2 eluent), *2-methyl-4,6-diphenylpyridine* (**4***b*), 109 mg, 88%, mp 217–218°C (lit. (29) mp 218°C), which was shown to be identical with an authentic sample by mp, mixture mp, and nmr spectral comparison.

The filtrate obtained after separation of **6** was concentrated *in vacuo* and the residue was chromatographed (CH_2Cl_2–Et_2O eluent) to give *1-methyl-3,5-diphenylpyrazole* (**3***a*) (94 mg, 8%) followed by *1,3-dimethyl-5-phenyl-5-phenacylpyrazoline* (**2***b*) (210 mg, 15%) as a viscous, unstable oil, nmr δ:1.91 (s, 3H, CH_3), 2.53 (s, 3H, NCH_3), 3.20 (s, 2H, CH_2CO), 3.33 and 3.92 (AB q, 2H, J = 16 Hz, ring CH_2), 7.09–7.58, 7.76–8.05 (m, 10H, Ar H).

Thermolysis of **2***b* under the conditions described for **2***a* above gave, after chromatography (CH_2Cl_2–hexane (7:3), then CH_2Cl_2 elution), acetophenone and *1,3-dimethyl-5-phenylpyrazole* (**3***b*) in quantitative yields. Compound **3***b*, oil, lit. (30*a*) mp 21°C; nmr δ:2.25 (s, 3H, CH_3), 3.60 (s, 3H, NCH_3), 6.0 (s, 1H, C-4 H), 7.10–7.30 (m, 5H, Ar H) was shown to be identical by tlc and nmr spectral comparison with an authentic sample prepared by a literature method (30*b*).

*Rearrangement of 1-Methyl-3,5,7-triphenyl-1,2(1H)-diazepine (**5**) in the Presence of Silica Gel*

Compound **5** (104 mg, 0.31 mmol) and silica gel (2 g) in benzene (30 mL) suspension were stirred at room temperature for 72 h. The mixture was evaporated to dryness and chromatographed to give 6 mg (7%) of *2,4,6-triphenylpyridine* (**4***a*) and 63 mg (86%) of *1-methyl-3,5-diphenylpyrazole* (**3***a*) both of which were characterized by mp, mixture mp, and uv and nmr spectral comparisons with authentic samples.

*Reaction of Pyrylium Salts **1**f–i, **8**a, **9**a, **9**c, and **11** with Hydrazine*

These reactions were carried out according to the representative example (**8***a*) given below. All products were purified by direct crystallization with the exception of **10** which was chromatographed (silica gel, PhH eluent). The yields and physical and spectral data are summarized in Table 2.

N-*Amino-11,13-dimethyl-[9](2,6)-pyridophanium Perchlorate* (**8**b)

Hydrazine (0.16 mL, 3.2 mmol) was added to a slurry of the pyrylium salt **8***a* (530 mg, 1.55 mmol) in ethanol (14 mL) and the reaction mixture was stirred at room temperature for 0.5 h. The resulting solid was collected and recrystallized from ethanol to give 780 mg (75%) of **8***b* whose spectral data were identical with those reported by Balaban (9*c*).

N-*Acetamido-11,13-dimethyl-[9](2,6)-pyridophanium Perchlorate* (**8**c)

Compound **8***c* was obtained in 95% yield according to a literature method (31), mp 198–199°C; ir (KBr): 3200, 1720, 1600 cm^{-1}; nmr δ:8.3 (s, 1H, pyridine γ-H), 3.2–2.8 (t, 4H, 2β-CH_2 to pyridine ring), 2.75 (s, 6H, $2CH_3$), 2.4 (s, 3H, CH_3CO), 2.0–1.55 (br s, 4H, $2CH_2$), 1.4–0.9 (br s, 10H, CH_2); ms *m/e* (% relative intensity): 388 (M^+, nil), 289(14, $M^+ - ClO_4$), 273(96), 231(82), 134(54), 133(68), 122(46), 120(36), 106(78). *Anal.* calcd. for $C_{18}H_{29}N_2O_5Cl$: C 55.60, H 7.46, N 7.21; found: C 55.78, H 7.30, N 7.15.

Thermolysis of 3-Phenyl-5-phenacyl-2-pyrazoline (**2**d)

Compound **2***d* (400 mg, 1.51 mmol) was heated neat at 120°C (oil bath temperature) for 3 h. Chromatography (silica gel, benzene eluent) gave 54 mg (30%) of acetophenone and 90 mg (41%) of *3(5)-phenylpyrazole* (**3***c*), mp 76–77°C (lit. (32) mp 78°C), which was shown to be identical by mp, mixture mp, and nmr spectral comparison with an authentic sample prepared by a literature method (33).

The chemistry of aurodox and related antibiotics

HUBERT MAEHR, MICHAEL LEACH, THOMAS H. WILLIAMS, AND JOHN F. BLOUNT
Chemical Research Department, Hoffmann–La Roche Inc., Nutley, NJ 07110, U.S.A.
Received September 17, 1979

HUBERT MAEHR, MICHAEL LEACH, THOMAS H. WILLIAMS, and JOHN F. BLOUNT. Can. J. Chem. **58**, 501 (1980).

The studies which led to the complete structure elucidation of the antibiotic aurodox, including the chiralities of all eleven asymmetric centers and the *cis–trans* isomerism of all seven exocyclic double bonds, are summarized. Aurodox was correlated stereochemically with mocimycin. Thus, aurodox can be described as *N*-[7-[5(*R*)-[7-[1,2-dihydro-4-hydroxy-1-methyl-2-oxo-3-pyridinyl]-6-methyl-7-oxo-1(*E*),3(*E*),5(*E*)-heptatrienyl]tetrahydro-3(*S*),4(*R*)-dihydroxyfuran-2(*S*)-yl]-6(*S*)-methoxy-5,7(*R*)-dimethyl-2(*E*),4(*E*)-heptadienyl]-α(*S*)-ethyl-5,5-dimethyltetrahydro-2(*R*),3(*R*),4(*R*)-trihydroxy-6(*S*)-[1(*E*),3(*Z*)-pentadienyl]-2*H*-pyran-2-acetamide. Mocimycin, probably identical with kirromycin, is the corresponding *N*-desmethyl homolog.

HUBERT MAEHR, MICHAEL LEACH, THOMAS H. WILLIAMS et JOHN F. BLOUNT. Can. J. Chem. **58**, 501 (1980).

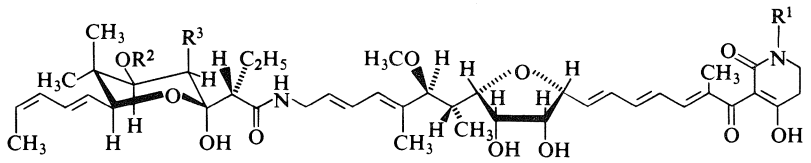
On résume les études qui ont conduit à la résolution complète de la structure de l'antibiotique aurodoxe incluant la chiralité des onze centres asymétriques et l'isomérie *cis–trans* des sept doubles liaisons exocycliques. On a relié stéréochimiquement l'aurodoxe à la mocimycine. Alors, on peut décrire l'aurodoxe comme étant: *N*-[[[[dihydro-1,2 hydroxy-4 méthyl-1 oxo-2 pyridinyl-3]-7 méthyl-6 oxo-7 heptatriényl-1(*E*),3(*E*),5(*E*)]-5(*R*) tétrahydrodihydroxy-3(*S*),4(*R*)furannyl-2(*S*)]-7 méthoxy-6(*S*) diméthyl-5,7 heptadiène-2(*E*),4(*E*)yl] α(*S*)-éthyl diméthyl-5,5 tétrahydro trihydroxy-2(*R*),3(*R*),4(*R*) [pentadiène-1(*E*),3(*Z*)yl]-6(*S*) 2*H* pyranne acétamide-2. La mocimycine probablement identique à la kirromycine est l'homologue *N*-desméthyle correspondant.
[Traduit par le journal]

Introduction

Within the past few years a chemically novel group of narrow-spectrum antibiotics has emerged and already comprises six members. Aurodox[1] (**1***b*) (1–3) and its *N*-desmethyl analog mocimycin (**1***a*) (4–6) were the first members discovered. Kirromycin (7) is most likely identical with mocimycin (8). Efrotomycin (**1***c*) (9, 10) is a glycoside consisting of a disaccharide and aurodox as the aglycone. Dihydromocimycin (**1***e*) (11) and kirrothricin (**1***f*) (12, 13) each contain a 4-hydroxy-5,6-dihydro-2-pyridone ring. Kirrothricin deviates further from the general theme of the other members as it lacks both the central tetrahydrofuran ring and the hydroxy group at position 3 on the terminal tetrahydropyran arrangement. That same 3-deoxy function differentiates heneicomycin (**1***d*) (14) from aurodox. From a biosynthetic viewpoint, therefore, dihydro-**1***d* would have represented a more likely structure for kirrothricin than the proposed structure **1***f*. The structure of azdimycin (15) is as yet unknown.

In addition to great chemical similarity, these antibiotics are all primarily active against a limited number of Gram-positive bacteria, notably bacilli (3, 7, 16, 17), the narrow antibacterial spectrum being ascribed to inefficient uptakes.

The mechanism of action was studied most intensively with kirromycin (18–26) and was found to involve inhibition of protein synthesis. In prokaryotic cells interaction with the elongation factor Tu was demonstrated. A similar mode of action is probable for all antibiotics of this group and for this reason the cumulative term elfamycins was proposed to emphasize elongation-factor involvement (27). The subsequent observation that elfamycins with EF-Tu specificity include labilomycin (pulvomycin) (26) as a remote structural relative suggests caution in the use of a cumulative term based on mechanism of action alone.



Aurodox (28, 29), mocimycin (30, 31), and efrotomycin (32, 33) are intended for veterinary use, especially as growth-promoting feed additives for farm animals and as chemotherapeutic agents in the control of dysentery caused by Treponema infections. Although mocimycin (**1***a*) and dihydromocimycin (**1***e*) have very similar chemical structures and antimicrobial *in vitro* spectra, only mocimycin promoted growth in animals (11, 34). However, both antibiotics were active against Treponema infections.

Production of these antibiotics appears to be afflicted by generally low fermentation yields; not surprisingly, therefore, aurodox biosynthesis was found to be regulated by feedback inhibition (35) so that production of the other members are likely to be subject to the same phenomenon. Increased yields of aurodox were achieved by aurodox-resistant mutants (36). In addition, a chemical conversion of mocimycin to aurodox was described (27).

[1]Aurodox is the designation of antibiotic X-5108 adopted by the USAN committee. The previously proposed name "goldinodox" has been withdrawn.

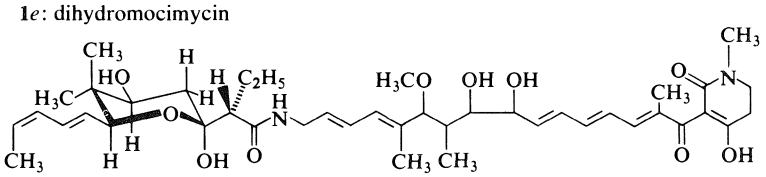
1*a*: $R^1 = R^2 = H$, $R^3 = OH$ (mocimycin, kirromycin)

1*b*: $R^1 = CH_3$, $R^2 = H$, $R^3 = OH$ (aurodox)



1*c*: $R^1 = CH_3$, $R^2 =$, $R^3 = OH$(efrotomycin)

1*d*: $R^1 = CH_3$, $R^2 = R^3 = H$ (antibiotic A21A, heneicomycin)

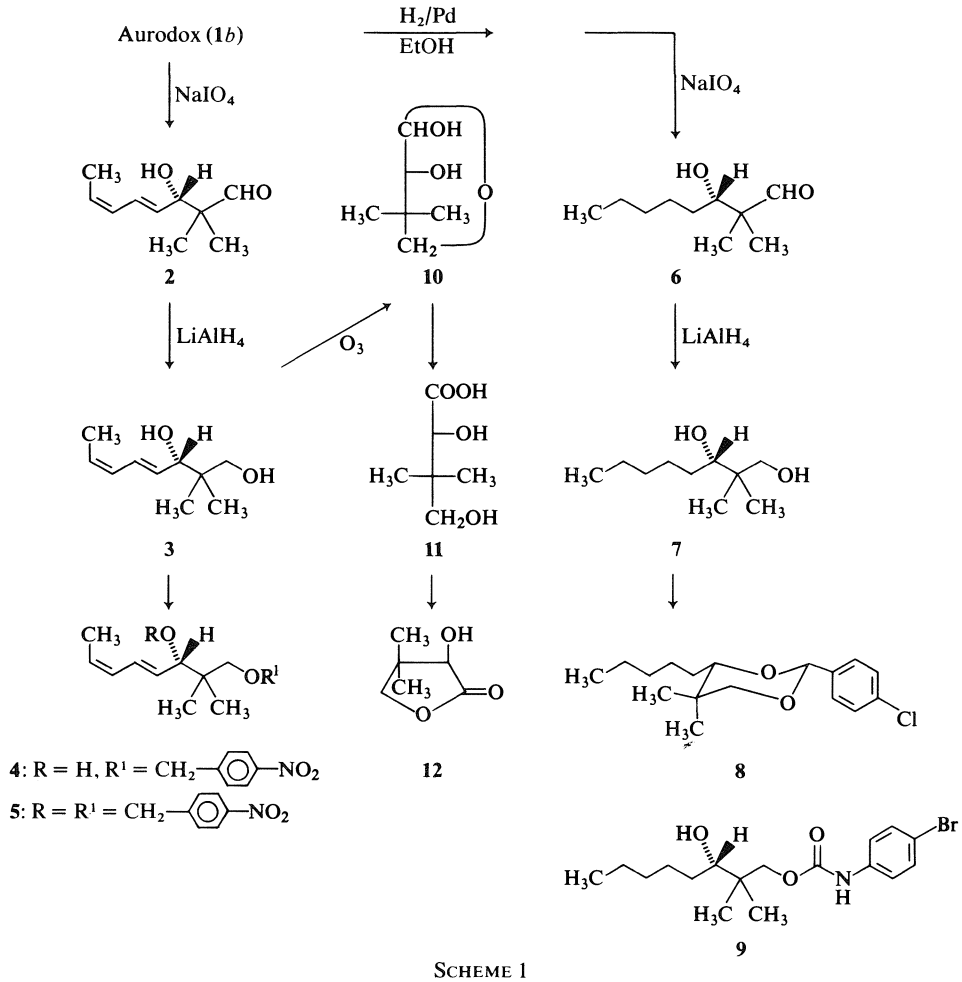
1*e*: dihydromocimycin

1*f*: kirrothricin

Aurodox was the first antibiotic of this group to receive a complete structural analysis. In view of the increasing interest in these antibiotics, both as potential commercial agents and biochemical tools, the chemical studies which led to the structure elucidation of aurodox and which were published only in part, are summarized in this paper.

Configuration of Aurodox

Aurodox was isolated from the fermentation broth of *Streptomyces goldiniensis* by extraction with organic solvents and was precipitated as the sodium salt (3). Although the antibiotic is a yellow, amorphous, monoprotic acid with $pK_a = 6.1$, salts of aurodox could be converted to the acid by extraction with an organic solvent such as dichloromethane even at pH 7. Further purification was achieved by Craig-distribution or chromatography (3).



The acid is soluble in solvents such as ethanol, acetone, chloroform, and ethyl acetate, but is insoluble in water. Alkali salts dissolve in water, pyridine, methanol, and ethanol but are insoluble in acetone and chloroform. Prolonged exposure to light or standing in acidic or basic solutions reduces the antibacterial activity of the antibiotic. Whereas antibiotic titers of the free acid dropped significantly upon storage at room temperature for six months in solid form, no decrease was observed when the sodium salt was stored in the refrigerator for several years.

Elemental analyses of aurodox and alkali salts thereof suggested an empirical formula of $C_{44}H_{62}N_2O_{12} \cdot H_2O$ with $[\alpha]_D$ −82.8° (*c* 0.52, ethanol). Thermoosmotic molecular-weight determination in methanol supported the calculated value of 810. The empirical formula requires 15 units of unsaturation, 7–8 of which were accounted for by rapid hydrogen uptake upon catalytic hydrogenation in ethanol over palladium-on-charcoal.

Aurodox exhibited a characteristic and unique uv spectrum (3) and the ir spectrum indicated polyhydroxy nature. Moreover, aurodox was rapidly oxidized by periodate. Extraction of the oxidation mixture afforded β-hydroxyaldehyde **2** as impure syrup which was reduced with metal hydride and characterized as the resulting diol **3** and its mono- and di-(4-nitrobenzoic) esters **4** and **5** (Scheme 1). The uv maximum at 235 nm observed in **2** prevailed in **3** suggesting the presence of a diene not in conjugation with the aldehyde carbonyl group.

The structure of **2**, including the configuration of the diene, was primarily deduced from the ^1H nmr spectrum of **3** and confirmed by those of **4** and **5** (Fig. 1) (37). Coupling constants of 15 and 11 Hz permitted the assignment of the 4*E* and 6*Z* configurations, respectively, in **2** and the diastereotopic

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

SCHEME 1

nature of the protons on C1 was evident from the resulting AB pattern in the spectra of **3** and **4**. Coincidentally, however, these protons became isochronous in the corresponding spectrum of the di-nitrobenzoic ester **5** (Fig. 1).

As expected, **1***b* yielded 2,2-dimethyl-3-hydroxyoctanal (**6**) after catalytic hydrogenation and oxidation by periodate. Reduction of **6** with lithium aluminum hydride gave the crystalline diol **7**, which was further characterized as the 2-(4-chlorophenyl)-4-pentyl-5,5-dimethyl-1,3-dioxane (**8**), a colorless liquid obtained by short-path distillation at 3 Torr (bath temperature 145°C), and as the 2,2-dimethyl-1,3-octanediol-1-(4-bromophenyl)carbamate (**9**), obtained as colorless plates with mp 124°C, $[\alpha]_D$ −19.9° (*c* 0.5, dioxane). Ozonolysis of **3** gave D-glycero-3,3-di-*C*-methyltetrose (**10**) which was oxidized to the known D-pantoic acid (**11**) and isolated as D-(−)-pantolactone (**12**) (38, 39) with the same $[\alpha]_D$, and hence with the same chirality, as natural pantothenic acid, thus establishing the chiral center in **2** as 3*S*.

Whereas catalytic hydrogenation of aurodox in ethanol yielded a homogeneous product, a similar reduction in acetic acid caused fragmentation (Scheme 2). One of these degradation products was obtained in crystalline form and ultimately identified as [1*R*-(1β,3α,5α,6α,9α)]-9-ethyl-1,5-dihydroxy-4,4-dimethyl-3-pentyl-2,7-dioxabicyclo[4.3.0]nonan-8-one (**14**) by single-crystal Roentgen-diffraction analysis of its 4-bromobenzoate **15** (Fig. 2) (37). Consonant with the isolation of **14** from aurodox by catalytic hydrogenation in acetic acid, mild treatment of aurodox with acetic acid gave diene **13**, termed goldinono-1,4-lactone-3,7-hemiacetal, derived from the hypothetical parent goldinonic acid **16**[2] and

[2]Trivial names of degradation products were derived from the name of the aurodox-producing Streptomyces goldiniensis.

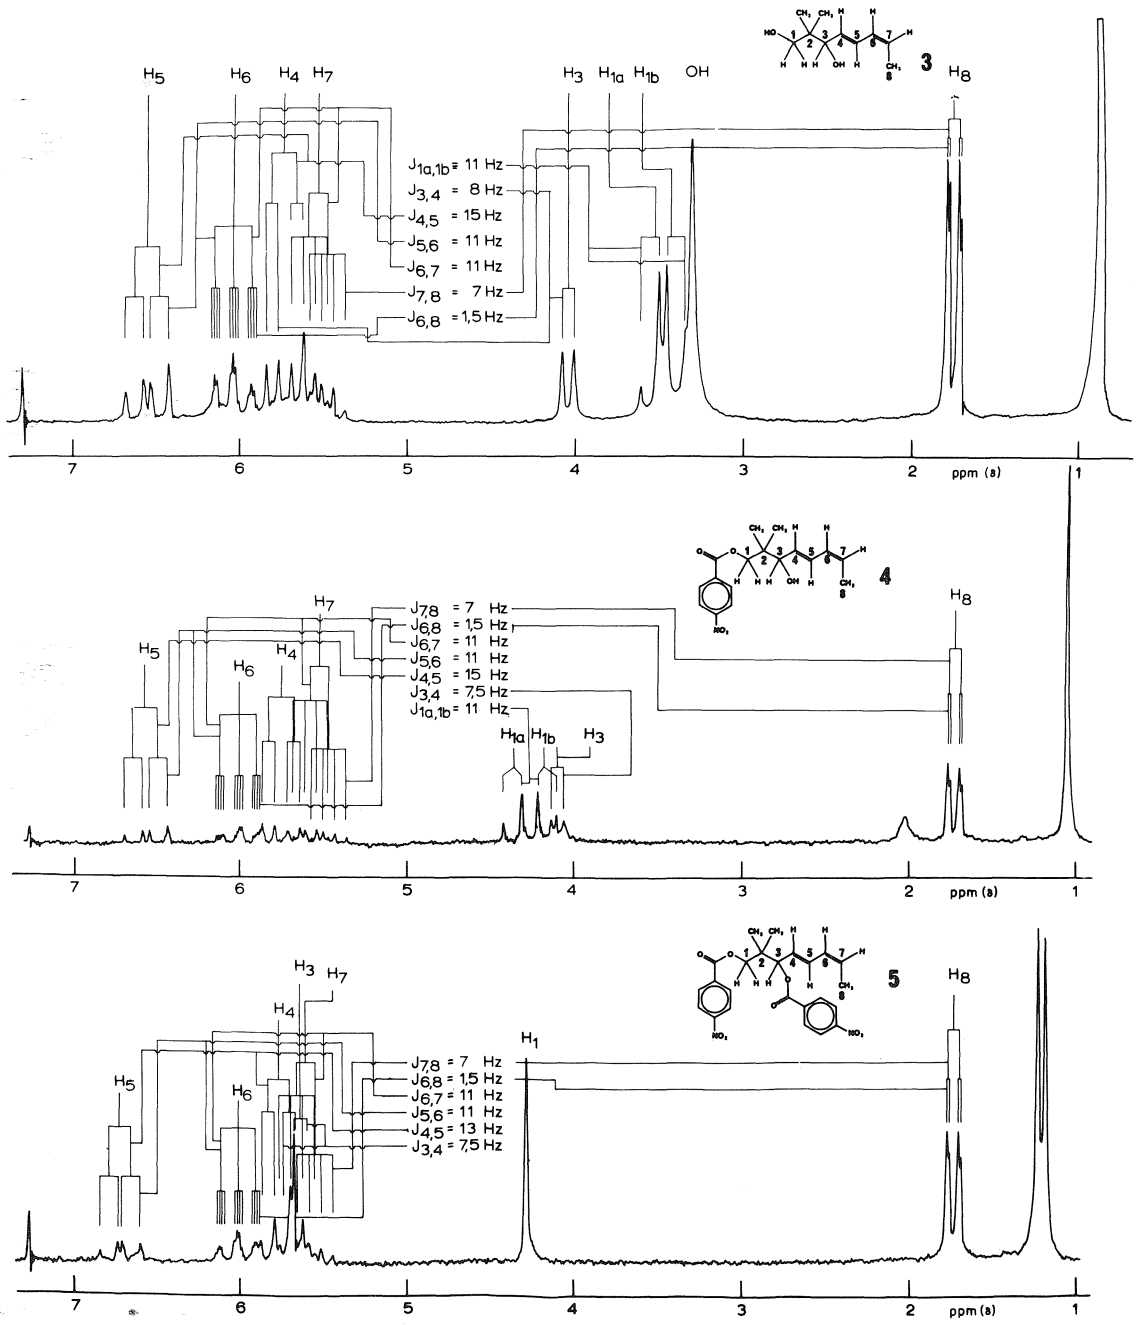

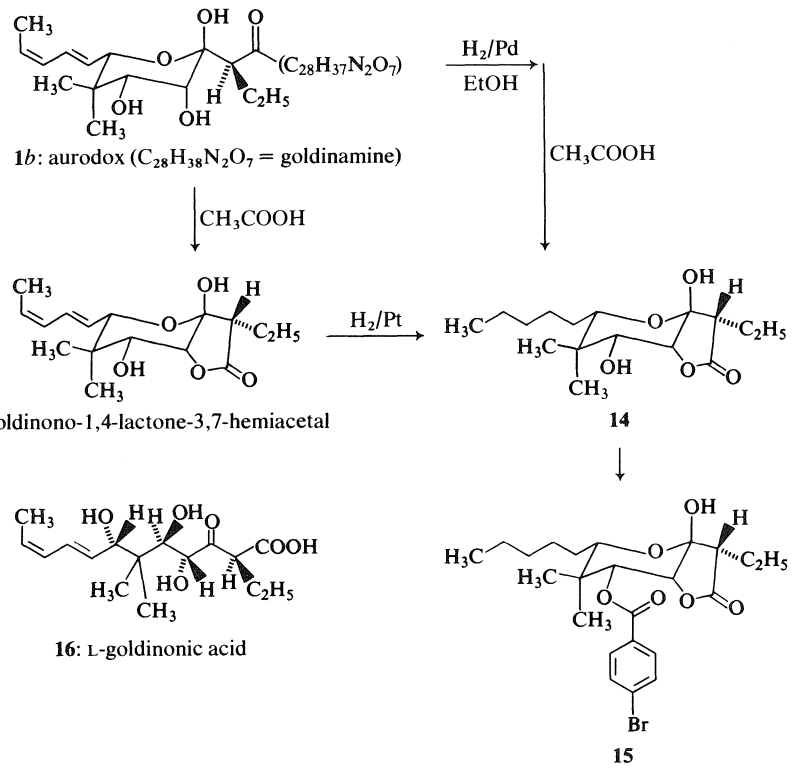

FIG. 1. ^{1}H nmr spectra of **3**, **4**, and **5**.

readily converted to the lactone **14** by catalytic hydrogenation.

Clearly, dienal **2**, obtained by oxidative fission of aurodox by periodate (Scheme 1), is derived from the goldinonic acid moiety, supplying evidence for the (1*E*,3*Z*)-configuration of the pentadienyl side chain in **13** and the presence of a vicinal diol function in aurodox shown in goldinonic acid **16** but absent in goldinono-1,4-lactone-3,7-hemiacetal **13** which is resistant to periodate. Further, the absence of carboxyl-, non-conjugated keto-, and δ-lactone-bands in the ir spectrum of aurodox suggested the goldinonic-acid portion to be arranged in aurodox as the goldinonyl-3,7-hemiacetal form shown in **1***b* (Scheme 2). The facile cleavage of the amide bond with concomitant formation of the δ-

SCHEME 2

lactone function in **13** is explained by anchimeric participation of the axial hydroxyl group of the tetrahydropyran ring resulting in lactone formation and expulsion of the remaining molecular portion $C_{28}H_{38}N_2O_7$.

As potential 1,3-dicarbonyl compounds, **1***b*, **13**, and **14** could conceivably be subject to racemization at the α-carbon center. The nearly quantitative isolation of **14** after hydrogenation and mild acetic acid treatment of **1***b*, however, was interpreted as a good indication that the α(*S*)-configuration is also present in **1***b*.

Catalytic hydrogenation of aurodox sodium salt over palladium-on-charcoal in ethanol followed by hydrolysis in hot water liberated 4-hydroxy-1-methyl-2(1*H*)-pyridone (**19**) (40), characterized as the formaldehyde condensation product **20** (Scheme 3), whereas unreduced aurodox was resistant to hydrolysis under the same conditions. With a pK_a of 6.67, **19** was suspected to be responsible for the acidic nature of the antibiotic and to be linked via C3 in the aurodox molecule, for the two protons at C5 and C6 in **19** were readily identified as a characteristic AB pattern in the ^1H nmr spectrum of **1***b*. Further, the liberation of **19** by hydrolysis after catalytic reduction of **1***b* suggested linkage to a carbonyl group; reduction of the carbonyl group generates an aldol-type arrangement severable by mild hydrolysis.

To exploit the mild fragmentation reaction by acetic acid, which had led to **13** as the only crystalline product together with numerous other components, aurodox sodium salt was reacted with 4-bromobenzyl bromide to yield aurodox(4-bromobenzyl) ether **18**. Subsequent acetic acid treatment of **18** and analysis of the reaction mixture were hoped to be facilitated by the bromobenzyl group providing ready recognizability, blockage of one reactive site, and a heavy atom for possible crystallographic analysis of **18** or appropriate fragments thereof. Aurodox derivative **18**, however, was an amorphous but homogeneous compound and the resulting reaction mixture with acetic acid fortunately contained only two major components, namely **13** and a new, larger fragment, termed goldinamine(4-bromobenzyl) ether (**22**), easily separated from each other by Craig-distribution or chromatography on silicic acid. Goldinamine(4-bromobenzyl) ether contained the uv-chromophore of aurodox with the characteristic maximum at 325 nm and proved to be an amorphous amine, generating salts with acids, a yellowish color with ninhydrin, and *N*-(2,4-dinitrophenyl) derivative **26** with 1-fluoro-2,4-dinitrobenzene.

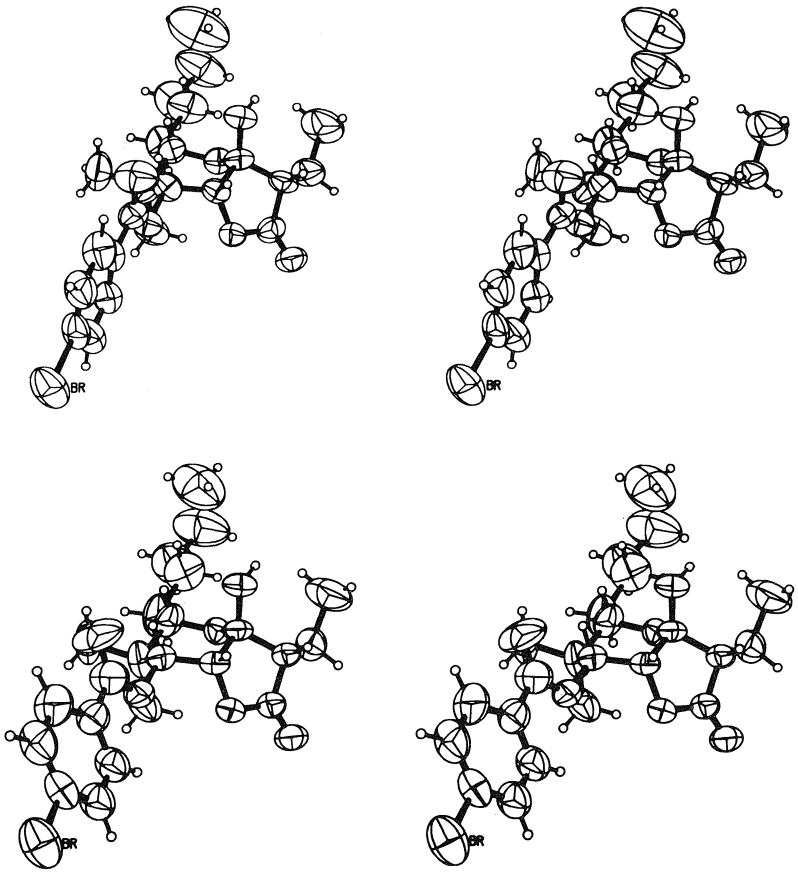

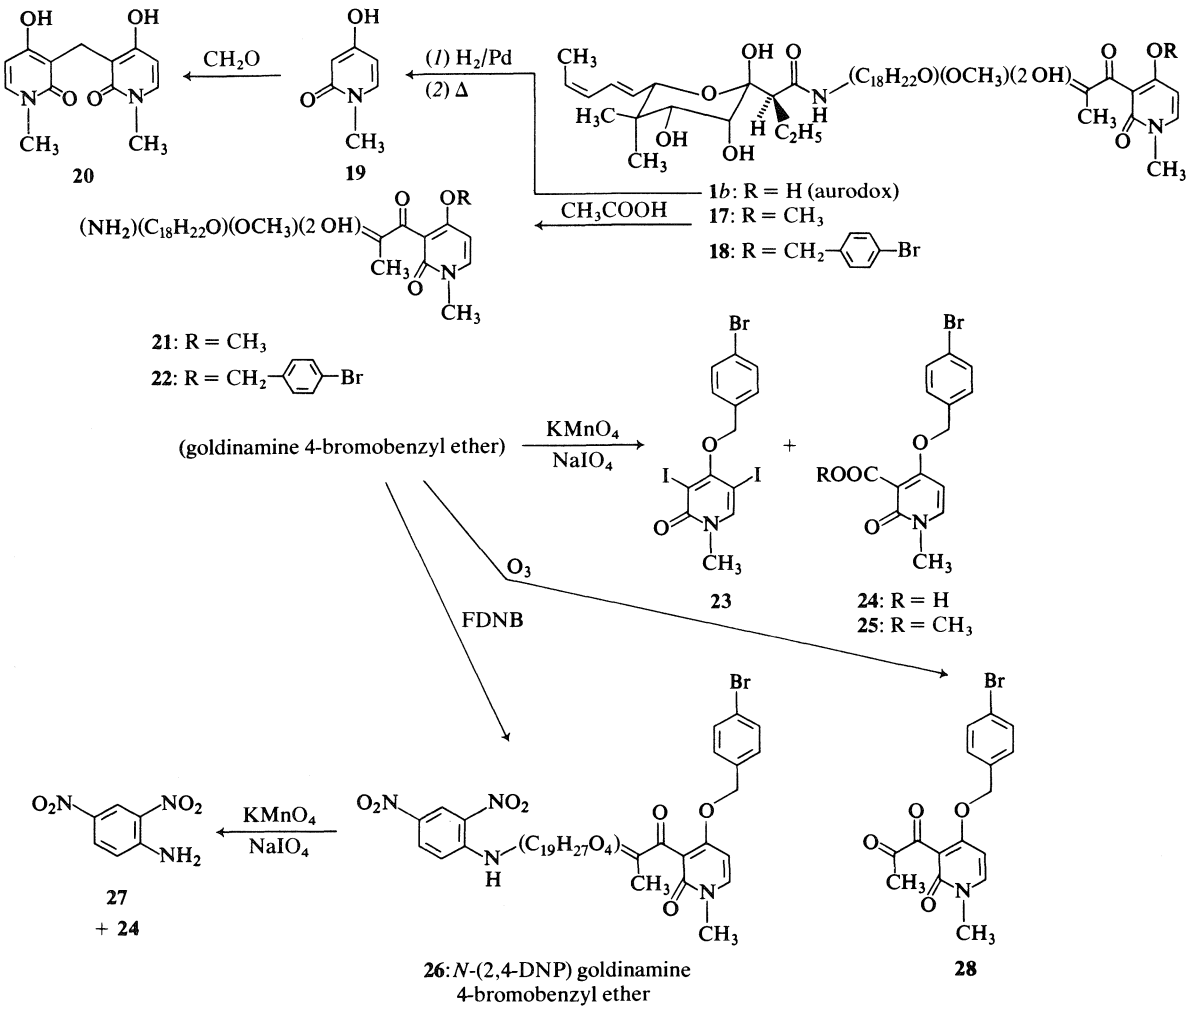

FIG. 2. Stereodrawing showing the absolute configuration of **15** (37) and the conformations of the two independent molecules found in the crystal. The thermal ellipsoids are scaled to the 50% probability level. The hydrogen atoms are shown as spheres of arbitrary size at their calculated positions; they were not included in the structure analysis.

The absence of an amino function in the intact antibiotic suggested goldinonic acid 3,7-hemiacetal to be linked to goldinamine through an amide bond as shown in Scheme 3.

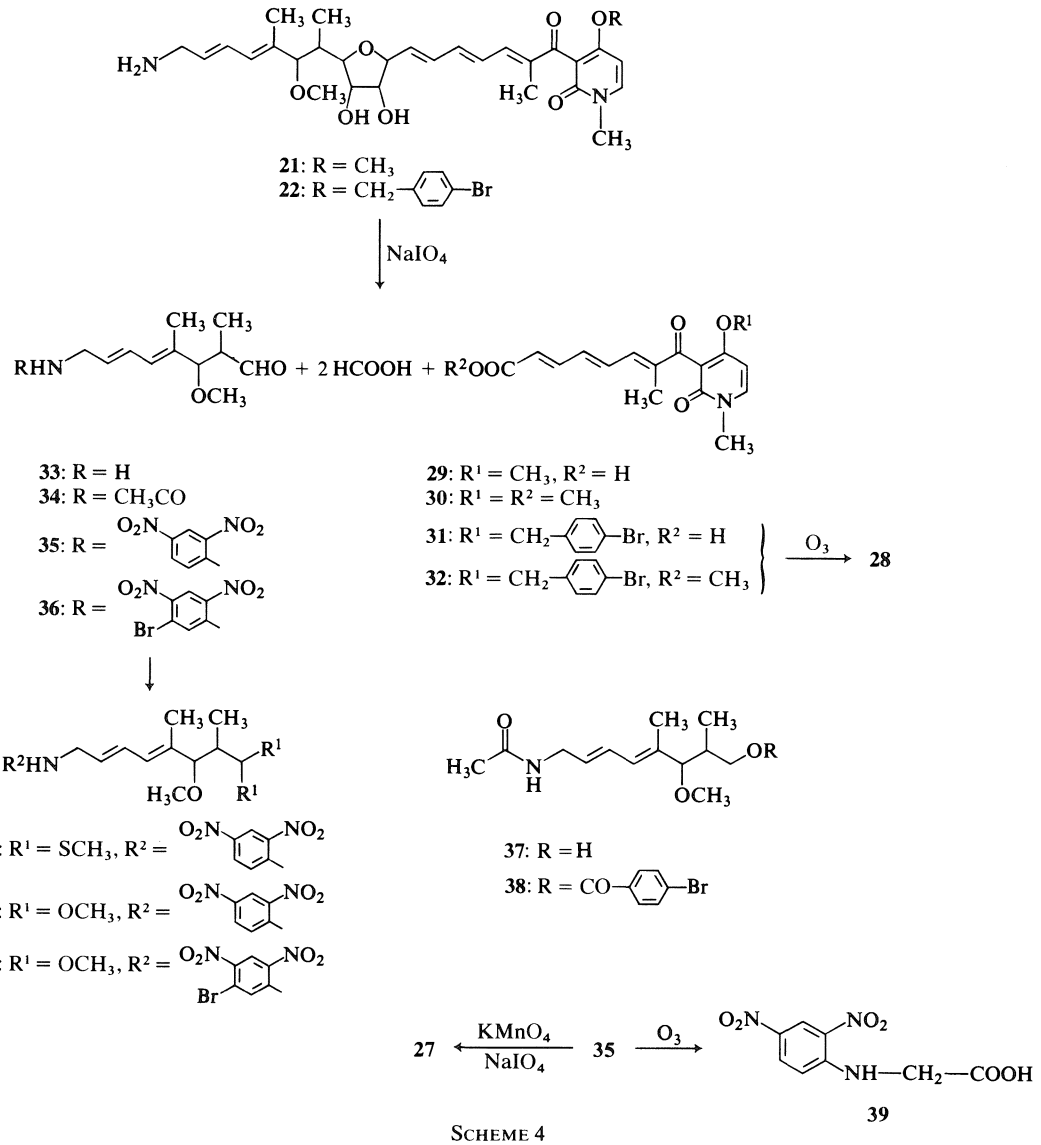
The elemental composition of goldinamine, $C_{28}H_{38}N_2O_7$, was originally estimated by analyses of a number of salts and amino derivatives of **22**, none of which were obtainable in crystalline form.

Oxidation of **22** with a mixture of potassium permanganate and sodium metaperiodate gave crystalline 4-(4-bromobenzyloxy)-1-methyl-1,2-dihydro-2-oxopyridine-3-carboxylic acid (**24**), further characterized as methyl ester **25**, and slightly yellow needles of an artifact, identified as 4-(4-bromobenzyloxy)-3,5-diiodo-1-methyl-2(1*H*)-pyridone (**23**). Ozonolysis of **22** in methanol deposited crystalline 4-(4-bromobenzyloxy)-1-methyl-3-pyruvoyl-2(1*H*)-pyridone (**28**), whereas oxidation of goldinamine derivative **26** with potassium permanganate and sodium metaperiodate afforded **24** as well as 2,4-dinitrobenzeneamine (**27**).

N-Acetylgoldinamine(4-bromobenzyl) ether (*N*-acetyl-**22**) formed a di-*O*-acetyl derivative with acetic anhydride and pyridine, a cyclic carbonate with ethyl chloroformate, an *O*-isopropylidene derivative with acetone and a dialkoxyphenylborane with benzeneboronic acid indicating two vicinal non-tertiary hydroxyl groups. A methoxy group evident from the ^{1}H nmr spectra of **1***b* and **22** led to **1***b* (Scheme 3) as partial structure for aurodox. Indeed, **22** reacted rapidly with sodium metaperiodate liberating 8-[4-(4-bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridyl]-7-methyl-8-oxo-2,4,6-octatrienoic acid (**31**), obtained in crystalline form, syrupy 8-amino-3-methoxy-2,4-dimethyl-4,6-octadienal (**33**), and two equivalents of formic acid (Scheme 4) (41). Both trienoic acids **29** and **31**, the former accessible by an analogous oxidation of goldinamine methyl ether (**21**), contained the long-wave uv maximum of aurodox and of goldinamine derivatives **21** and **22**, and were readily converted to methyl esters **30** and **32** with diazo-

SCHEME 3

methane. Both **31** and **32** were degraded by ozonolysis to **28** previously obtained from **22**.



With the exception of the double bond at position 6, the configuration of trienoic acid **31** could be deduced from the ^1H nmr spectrum as shown in Fig. 3.

The olefin protons exhibited a five-spin system consisting of one doublet at δ 5.98 ($J_{2,3}$ = 15 Hz) attributed to H2, one doublet of quartets at δ 6.81 ($J_{5,6}$ = 11 and $J_{6,Me}$ = 1 Hz) attributed to H6, and three doublets of doublets. The doublet of doublets at lowest field at δ 7.32 was assigned to H3, since it possesses the same splitting ($J_{2,3}$ = 15 Hz) present in the H2 doublet. Both H4 and H5 exhibited doublets of doublets with identical coupling constants, but the doublet of doublets at δ 7.13 was assigned to H5 on the basis of the distortion of the H6 signal. Thus, it was possible to assign the (2*E*,4*E*)-configuration on the basis of the two large coupling constants $J_{2,3}$ and $J_{4,5}$.

The (6*E*)-configuration was established by single-crystal Roentgen-diffraction analysis (41) of **31**. The crystal was obtained as a 1:1 adduct with chloroform. As seen in Fig. 4, the *xy*-plane bisecting the π-orbital at carbonyl carbon C8 is not parallel with the corresponding plane bisecting the π-orbital of the pyridone ring and renders the molecule dissymmetric. The crystal is centrosymmetric with both enantiomeric conformations present.

The dienal **33** (Scheme 4) was isolated as the syrupy *N*-acetyl and *N*-(2,4-dinitrophenyl) derivatives **34** and **35**, respectively, and yielded the elemental composition of the parent substance **33** as $C_{11}H_{19}NO_2$ by mass spectrometry. Oxidation of **35** with potassium permanganate and sodium metaperiodate gave 2,4-dinitrobenzeneamine. With

SCHEME 4

ozone, followed by oxidative work-up, *N*-(2,4-dinitrophenyl)-glycine (**39**) was obtained from **35** and indicated the presence of an allylic amine in **33**. Sodium borohydride reduced **34** to the dienol **37** with the unaltered uv maximum at 240 nm, originally observed in both **33** and its *N*-acetyl derivative **34**, implying the presence of a 2,4-pentadienylamine in **33** without conjugation of the diene with the aldehyde group. The structure of **35** as shown in Fig. 5, with the exception of the double-bond configuration at C4, was readily derived from the ^{1}H nmr spectrum.

The *threo*-configuration in **33** was originally deduced from the intensity ratio of free vs. bonded hydroxyl stretching-absorptions in the ir spectrum of alcohol **37** (42). The observed value of 0.26 was in good agreement with the reported value of 0.15 for *threo*-3-ethoxy-2,4-dimethyl-4-hexenol (43), permitting hydrogen bonding in a stereochemically less crowded conformation as compared to the less stable hydrogen-bonded arrangement of the *erythro* isomer with a reported value of 1.4 (Fig. 6). Further, inspection of the rather diagnostic ^{1}H nmr chemical shift of the methyl group at C2 in **37** (δ 0.66) was also in good agreement with that of *threo*-3-ethoxy-2,4-dimethyl-4-hexenol (δ 0.60), whereas two synaxial interactions between a methyl group and an unshared electron pair on oxygen cause a significant paramagnetic shift of the methyl group in the *erythro* isomer (δ 0.90) (43).

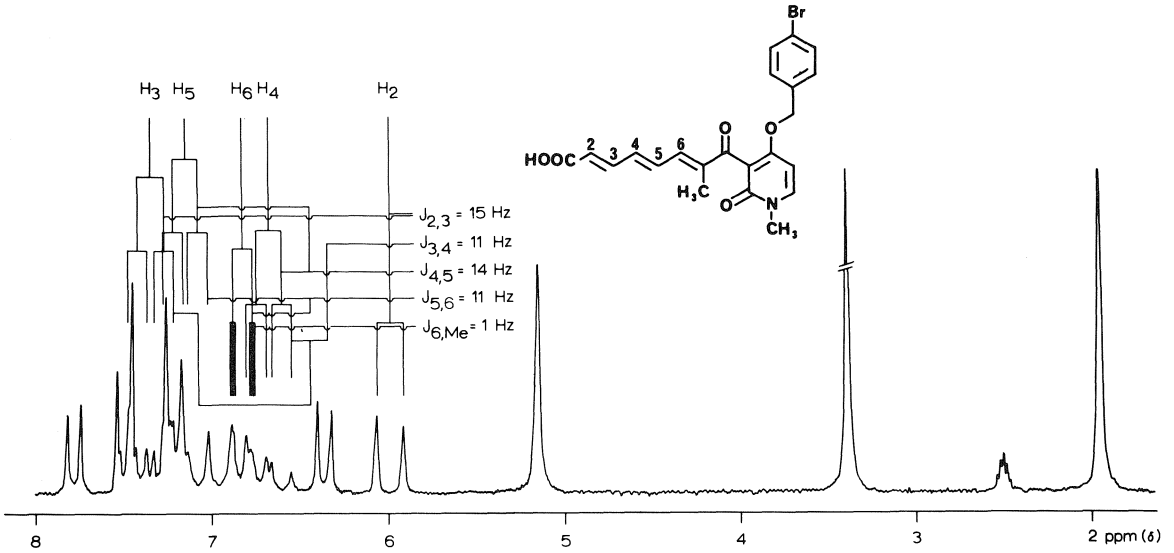

FIG. 3. ^{1}H nmr spectrum of **31**.

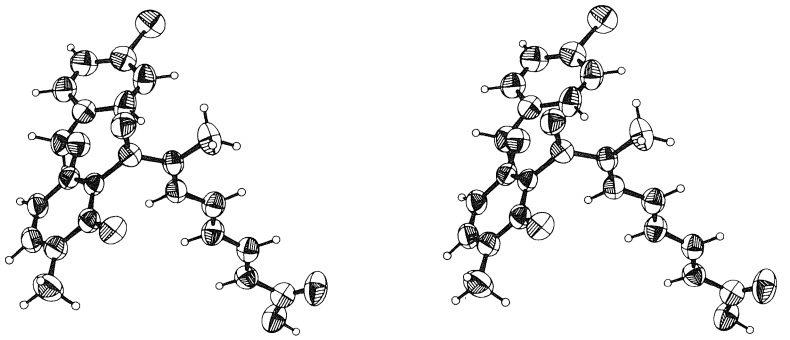

FIG. 4. Stereodrawing of one of the two enantiomeric conformations of **31** present in the crystal.

Attempts to crystallize **37** or esters such as **38** failed. Of a number of acetals prepared only **40** and **41** were crystalline. Of the two only **41** was suitable for a single-crystal Roentgen-diffraction analysis which confirmed the previously assigned *threo* configuration, established the all-*trans* isomerism, but, in the absence of a heavy atom, left the chirality undetermined. Introducing an anomalous scatterer while maintaining all other structural features of the one crystallographically suitable acetal **41** was accomplished with a new reagent, 1-bromo-5-fluoro-2,4-dinitrobenzene (42). Accordingly, [*threo*-(4*E*,6*E*)]-8-[(5-bromo-2,4-dinitrophenyl)-amino]-3-methoxy-2,4-dimethyl-4,6-octadienal (**36**) was prepared from **33** and converted to the crystalline acetal **42** which was indeed suitable for crystallographic analysis (42) establishing the absolute configuration shown in Fig. 7 (bottom). The crystal structure of **41** (41) is shown on top of Fig. 7 for comparison.

As illustrated in Scheme 4, periodate cleaves goldinamine derivatives **21** and **22** in the center, each liberating two moles of formic acid as well as dienal **33** and a trienoic acid as the two terminal fragments. The identification of this center as a 2,5-disubstituted 3,4-dihydroxytetrahydrofuran ring was first accomplished by analysis of the ^{1}H nmr spectra of goldinamine derivatives **26** and **43** (Fig. 8) (41). There were four methine protons, H2′–H5′, attached to sp^3-hybridized carbons in *N*-(2,4-dinitrophenyl) goldinamine (4-bromobenzyl) ether (**26**) which were not part of either degradation products **31** or **33**. Conversion of **26** to the di-*O*-acetyl derivative **43** shifted protons H2′–H5′ paramagnetically, rendering them recognizable as four dd sets and part of a multiple-spin system. Subjected to the more intensive paramagnetic shifts, protons H3′ and H4′ were assigned to carbons bearing acetoxy groups in vicinal relationship based on a common coupling constant

of 5 Hz. Coupling constants $J_{2',3'} = 7$ and $J_{4',5'} = 4$ Hz established the connection C2′—C3′—C4′—C5′. Irradiations indicated by bold arrows (Fig. 9), at the proton frequencies of H1 and H2′ in **43**, resulted in the expected multiplicity changes as depicted; the surviving coupling constants are also shown. The resulting side-chain assignments to positions 2′ and 5′ in **43** could be confirmed by analysis of the ^{1}H nmr spectrum of the *O*-isopropylidene-*N*-(2,4-dinitrophenyl)-goldinamine(4-bromobenzyl) ether (**44**) exhibiting a new set of coupling constants; concordantly, irradiations at the proton frequencies of H4′ and H6′ in **44** led to the spectral simplifications illustrated in Fig. 9 (8).

goldinamine, various derivatives were investigated by electron-impact mass spectrometry, but useful spectra were only obtained after replacement of the 4-bromobenzyl group in **22** by a methyl substituent. The resulting **21** was readily prepared by acetic acid treatment of aurodox methyl ether (**17**) (Scheme 3) and converted to goldinamine derivatives **47–50** whose mass spectra exhibited molecular ions, with the exception of **48** which gave *m/e* 588 ($M - CO_2 - H_2O$) as the highest observable mass peak. Molecular formulas of **21** and **47–50**, and hence that of goldinamine itself, could be deduced unequivocally on the basis of the low-resolution mass spectra of **47–50** and the known chemistry of the periodate-oxidation products derived from **22** (Scheme 4), but were further confirmed by high-resolution mass spectra of **49** and **50**.

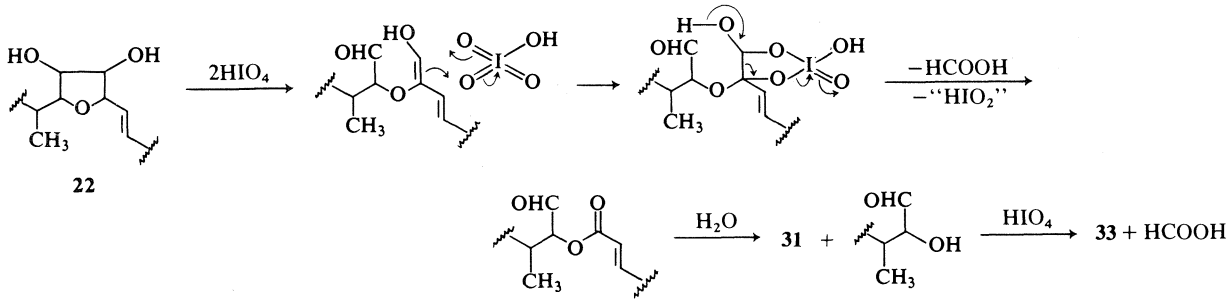
The tetrahydrofuran structure in goldinamine and aurodox does not remain unexplained by the surprising periodate-oxidation products shown in Scheme 4. Hesse and Mix had demonstrated that carbon–carbon double bonds are cleavable by periodate if at least one carbon is substituted by a free hydroxyl group and if the double bond is in conjugation with a carbonyl group (44). The oxidation of **22** by periodate could thus be postulated to proceed as depicted in Scheme 5 without intention to differentiate between homolytic and heterolytic processes or to show actual hydration states of the iodine compounds. After initial glycol cleavage one of the formyl groups enolizes to become part of a conjugated system; the new double bond conforms to the Hesse–Mix criteria of cleavability by periodate as it contains a hydroxyl group and is in conjugation with a carbonyl group, although only in a hexatrienylogous fashion. A molecule of periodate, it is now implied, adds across the enolic double bond, followed by decomposition of the resulting cyclic iodic ester to liberate formic acid, hypothetical iodous acid, and an ester which yields **31** as well as an α-hydroxyaldehyde upon hydrolysis, the latter being subject to further oxidation with periodate to afford a second mole of formic acid and dienal **33**. The possible intermediacy of iodous acid is supported by the transient appearance of free iodine by disproportionation (41).



To determine the stereochemistry of the tetrasubstituted tetrahydrofuran ring in goldinamine, the relative configuration was investigated initially (45). Assuming a *cis* relationship between the two vicinal hydroxyl groups, as suggested by the ease of *O*-isopropylidenation and cyclic borate-ester formation, there are only four possible arrangements as depicted in Fig. 10 (**51–54**).

In view of the great variability of the dihedral angles in five-membered rings, and hence of the corresponding coupling constants (46–48), the problem of stereochemical assignments was thought to be resolvable by comparison of coupling constants after increasing conformational rigidity of goldinamine by introduction of a 1,3-dioxolane ring and by selecting model tetrahydrofurans with substituents closely approximating those of *O*-isopropylidene-*N*-(2,4-dinitrophenyl)goldinamine(4-bromobenzyl) ether (**44**). Thus, four model substances **55–58** (Fig. 10) were synthesized by standard reactions from D-mannose (**55** and **57**) and D-glucose (**56** and **58**). Coupling constants for vicinal hydrogens ranged from 3–6 Hz for *cis* and were less than 1 Hz for *trans* relationships. The observed values of 3.5, 6, and 4 Hz in **44** were in agreement with the corresponding coupling constants 3, 6, and 4 Hz in **55** and **57** (Figs. 9 and 10), consistent with an all-*cis* configuration of the tetrahydrofuran moiety in **44** and hence in goldinamine (45).

Chirality of the Tetrahydrofuran Moiety: Absolute Configuration of Aurodox

We had established the geometry of all double bonds, the absolute configuration of the five chiral centers of the goldinonic acid 3,7-hemiacetal portion, the two in the exocyclic part of goldinamine, and the relative configuration of the central tetrahydrofuran ring in goldinamine. There were, therefore, only two structural possibilities for aurodox remaining, differing with respect to enantiomeric tetrahydrofuran rings, but identical otherwise.

A distinction was thought possible by fusing a 6-membered ring onto the 4′–5′ face of the tetrahydrofuran ring in **22** (Scheme 6) containing the two known chiral centers C1 and C2 derived from the exocyclic diene-chain of goldinamine. This approach would lead to a conformationally fixed carbon–carbon bond between two chiral centers. De-

SCHEME 5

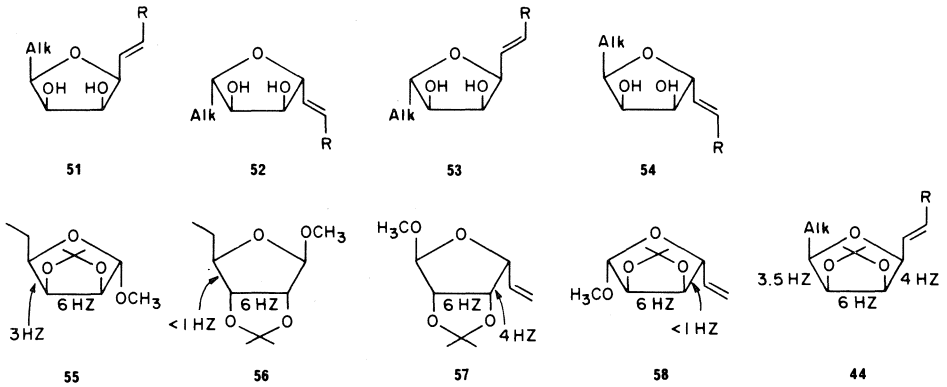


FIG. 10. Possible relative configurations of the tetrahydrofuran moiety in goldinamine (**51–54**) and selected model compounds (**55–58**).

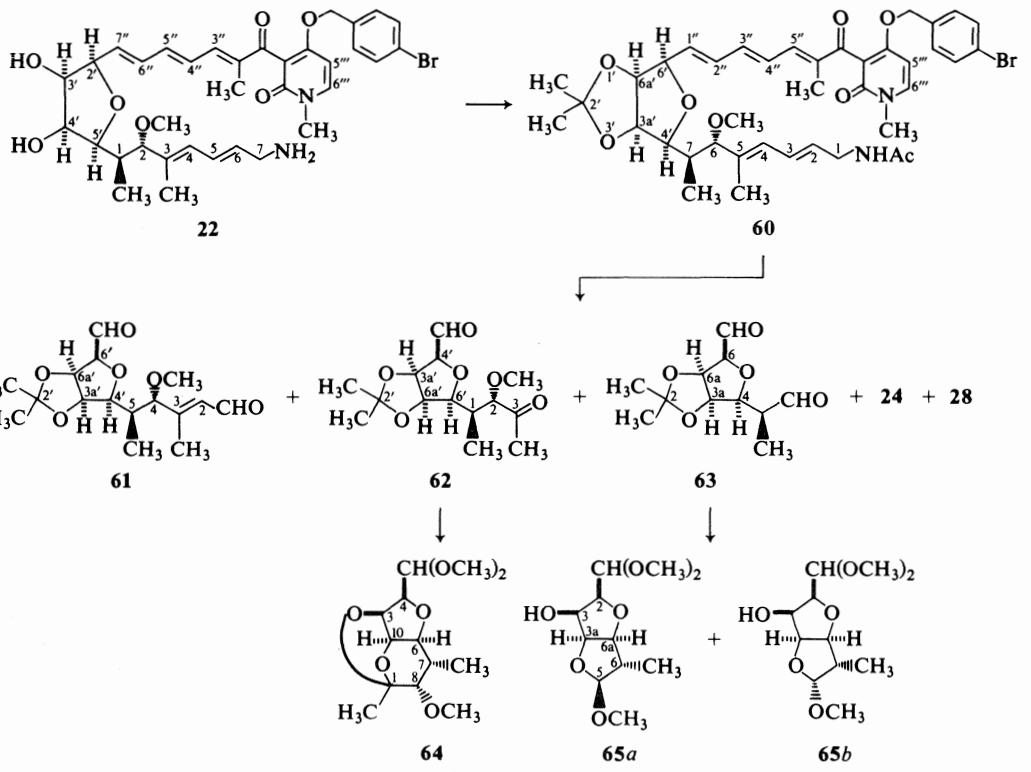
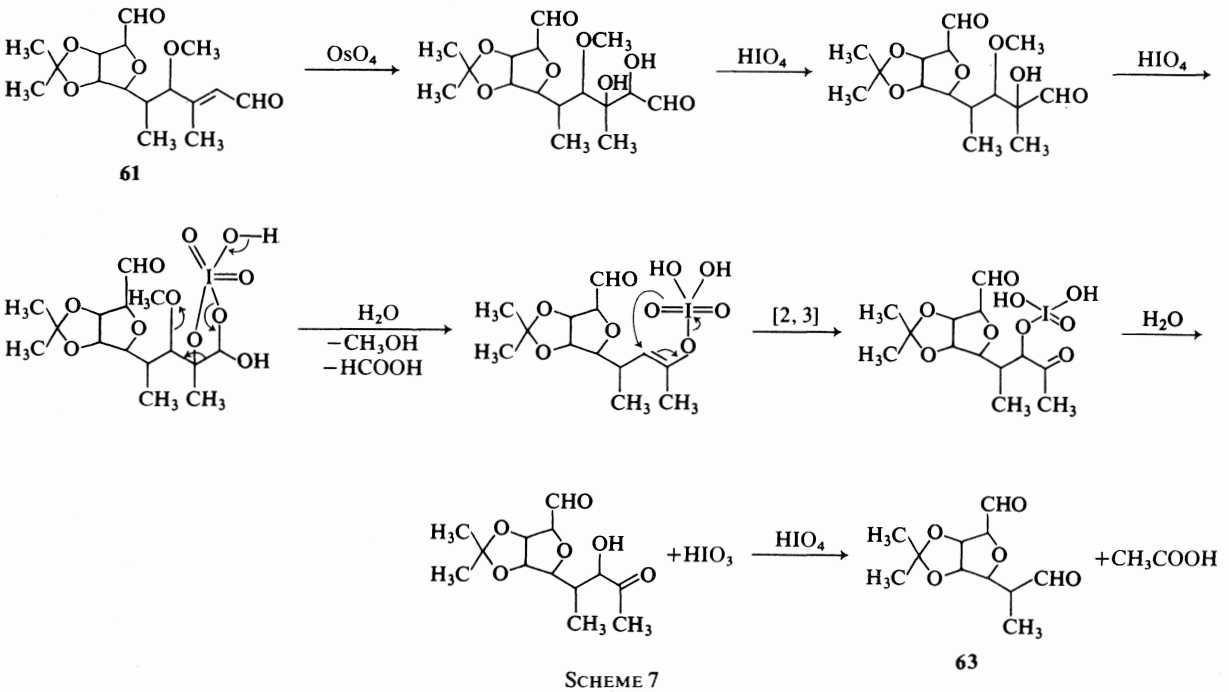


rived from the diene side-chain of goldinamine and designated C1, one of the two carbons possesses an established (*S*) configuration, the other being part of the tetrahydrofuran system. With the known relative configuration of the tetrahydrofuran ring, therefore, determination of the *threo*- or *erythro*-configuration of this bond, on the basis of its coupling constant, would obviously yield the chirality of C5′ in goldinamine and hence the absolute configuration of the entire tetrahydrofuran system. Thus, the *N*-acetyl derivative of **22** was converted to the *O*-isopropylidene compound **60** (Scheme 6)[3] and then oxidatively cleaved with osmium tetroxide and periodate yielding a mixture containing predominantly the α,β-unsaturated aldehyde **61**, smaller quantities of ketone **62** and other minor products, one of which presumably was the dialdehyde **63** as suggested by evidence presented later. The expected pyridones **24** and **28** were also isolated.

The most attractive starting material for the planned ring closure was the ketone **62**. Consequently, the oxidation mixture derived from **60** was chromatographed on a column of silica gel removing crystalline **24** and **28** and affording a fraction containing **61** as major and **62** as minor products but presumably still contaminated with small amounts of **63**. This mixture was treated with ozone, affording ketone **62** as major product, and subsequently with methanolic hydrogen chloride to effect acetalization of the aldehyde and transacetalization involving the 3-oxo position. This procedure led to a mixture of three products (Scheme 6). The major one was the expected (7*S*,8*S*) - 4 - (dimethoxymethyl) - 1,7 - dimethyl - 8-methoxy - 2,5,9 - trioxatricyclo [4.2.2.$0^{3,10}$] decane (**64**) derived from **62**, whereas the two minor components were identified as the two anomeric (6*S*)-hexahydro - 5 - methoxy - 2 - (dimethoxymethyl) - 6 - methylfuro[3,2-*b*]furan-3-ols (**65***a* and **65***b*) derived from **63**.



Both **62** and **63** contain a diastereotopic carbonyl group in their side chain and a protected chiral diol on their tetrahydrofuran rings. Involving these two groups, transacetalization of **62** occurs in stereorestricted fashion forming stereospecifically but one acetal **64**. Only one of the two potential hydroxyl groups in **63** participates in the transacetalization

[3]To differentiate graphically between relative and absolute configurations we chose bold (▼) and dashed (▽) wedges to indicate absolute stereochemistry, sets of bold lines (▮) and/or broken lines (≡) represent relative configuration.

For personal use only.

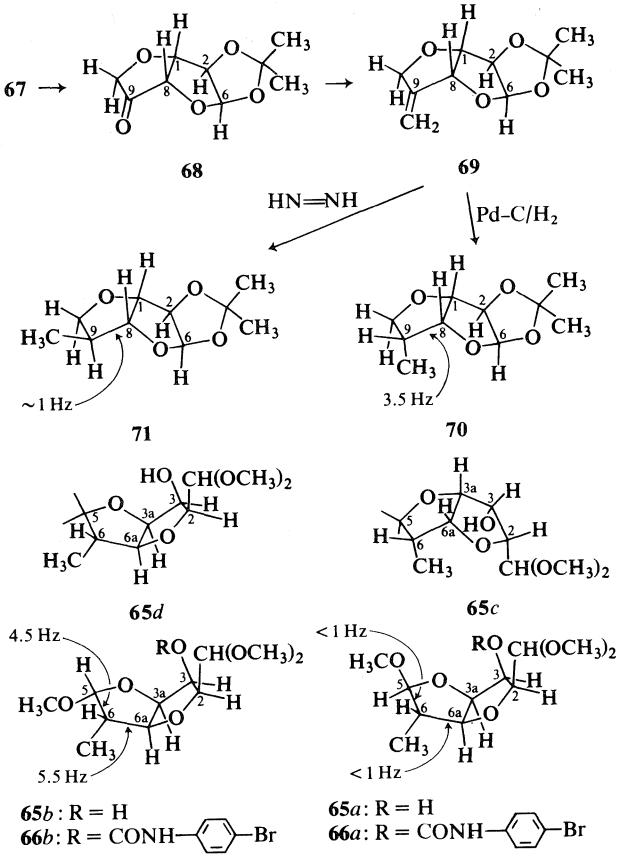
process; the second hydroxyl group is donated by the solvent affording two anomeric products **65***a* and **65***b*.

The generation of 2-[2,2-dimethyl-6-formyltetrahydrofuro[3,4-*d*]-1,3-dioxol-4-yl]-2-methylethanal (**63**) from **60** is entirely unexpected but could conceivably be explained as depicted in Scheme 7. Hydroxylation of dialdehyde **61** is followed by glycol cleavage to form a new dialdehyde which forms a cyclic periodic ester. This ester could either decompose to furnish oxoaldehyde **62**, which is actually observed, or the decomposition of the ester could occur with fragmentation as indicated. The resulting mono-coordinated periodic ester could then undergo a 2,3-sigmatropic rearrangement actually reoxygenating position 2 of the side chain and hence yielding an iodic ester which is hydrolyzable to a species cleavable by periodate to yield dialdehyde **63**.

Of the condensation products **64**, **65***a*, and **65***b* the tricyclic acetal **64** appeared most suitable for the ascertainment of chirality. Its existence confirmed the vicinal *cis*-orientation of 3′, 4′, and 5′ in goldinamine and since acetalization generated only one new chiral center in **64** there were only two diastereomeric alternatives **64***a* and **64***b* for consideration (Scheme 8). They are enantiomeric with respect to the acetal carbon 1, derived from the 3-oxo position of **62** and C3 of goldinamine, and the tetrahydrofuran ring, but are identical with respect to the chiral centers 7 and 8 derived from C1 and C2 of **62** and goldinamine. The bond C6—C7 in **64***a* is, therefore, of *threo*- and that in **64***b* of *erythro*-configuration with dihedral angles of ca. 45° and 75°,



SCHEME 8. Possible configurations of **64**. The numbers shown in parentheses refer to carbon designations of the original goldinamine derivative **60**.

respectively (Scheme 8). Using a $J^{\circ} = 12$ Hz the Karplus equation led to a prediction of $J_{6,7} = 6$ Hz for the *threo* configuration (**64***a*) and $J_{6,7} = 0.5$ Hz for the *erythro* configuration (**64***b*). In view of the observed coupling constant $J_{6,7} = 2$ Hz the *erythro* configuration and hence structure **64***b* appeared somewhat more likely than **64***a*, but no unequivocal assignment was possible by this analysis (49).

The search for an alternative to determine the chirality of C5′ in goldinamine by analysis of the C1—C5′ bond led to the study of the minor methanolysis products **65***a* and **65***b* derived from **60** (Scheme 7). Mass spectrometry established **65***a* and **65***b* as closely related isomers with elemental compositions of $C_{11}H_{20}O_6$, ir spectra suggested the absence of carbonyl groups, and ^1H nmr spectra were compatible with (6*S*)-hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-*b*]furan-3-ols obviously derived from dialdehyde **63**. Concerning their configuration, the chirality of C6 had previously been established by single-crystal analysis of **42** and the relative configuration of the tetrahydrofuran ring, derived from goldinamine, was considered to possess vicinal all-*cis* substituents. Disregarding the configuration at C5, only the two structures **65***c* and **65***d* (Scheme 9) had to be assessed; both are identical with respect to the chirality at C6 but are related enantiomerically with respect to the tetrahydrofuran rings located on the right-hand side. The crucial problem consisted of the differentiation of the two possible bonds between carbons 6 and 6a; a *cis* configuration would establish structure **65***c* and a *trans* relationship structure **65***d*.

To aid analysis, 3,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose (**67**) (58) was oxidized with osmium tetroxide – periodate to [1*R*-(1β,2α,6α,8β]-4,4-dimethyl-3,5,7,11-tetraoxatricyclo[6.3.0.0^{2,6}]undecan-9-one (**68**) which served as substrate in a Wittig reaction with triphenylmethylphosphorane leading to olefin **69**. Catalytic hydrogenation of **69** gave the expected [1*S*-(1β,2α,6α,8β,9α)]-4,4,9-trimethyl-3,5,7,11-tetraoxatricyclo[6.3.0.0^{2,6}]undecane (**70**) as major (88%) and the 9β isomer **71** as minor product (12%) by preferential hydrogen addition to the double bond from the least hindered side.

Stereoselective hydrogenation with diimide involving hydrogen addition from the more hindered side has been demonstrated, *inter alia*, with 7-oxynorbornadienes via *exo–cis* addition (51). To prepare the 9β-epimer **71** stereoselective hydrogen addition from the more hindered side was required. Accordingly, hydrogenation of olefin **69** was attempted with diimide. This reduction indeed pro-

SCHEME 9

ceeded stereoselectively yielding **71** as major (64%) and **70** (36%) as minor product.

The two model compounds **70** and **71** thus obtained possess identical central tetrahydrofuran rings but differ in the chirality of C9. As a result, **70** exhibits a *cis* and **71** a *trans* configuration between carbons 8 and 9. $J_{8,9} = 1$ Hz allowed unequivocal assignment of structure **71** to the major diimide hydrogenation product; the isomer with $J_{8,9} = 3.5$ Hz, therefore, had to be represented by structure **70**.

The availability of **70** and **71** was thought to enable identification of the methanolysis products derived from **63**, both possessing the same basic moiety of either structure **65***c* or **65***d*. The configurations at centers 8 and 9 of the tetrahydrofuran rings in **70** and **71** resemble the C6—C6a face of **65***c* and **65***d*, respectively, so that $J_{6,6a} \leqq 1$ Hz would point to structure **65***d* and $J_{6,6a} \gg 1$ Hz would favor **65***c*.

Spectral analysis of the two methanolysis products revealed that one of them had two coupling constants $J_{5,6}$ and $J_{6,6a}$ of < 1 Hz each, signifying two vicinal *trans* relationships and hence establishing **65***a* as shown in Scheme 9. The other isomer was most likely the 5-epimer demanding configuration **65***b*.

In view of the close relationship between the configurations represented by **65***a* and **65***b*, the two greatly different coupling constants $J_{6,6a}$ of < 1 Hz (**65***a*) and 5.5 Hz (**65***b*) did not appear to support a *trans* configuration between carbons 6 and 6a in structure **65***b*, a conclusion supported by the *trans* coupling constant $J_{8,9} = 1$ Hz in **70**. Hence, doubt was cast upon the chiral integrity of C6. Racemization at C6 was unlikely, however, in view of the reaction conditions employed and because only two methanolysis products derived from **63** were observed, both of which exhibited virtually identical chemical shifts of the 6-CH_3 groups but differed markedly in the chemical shifts of H5. With two oxygen substituents on the same ring side, moreover, H5 of **65***b* would be expected to absorb at lower field than H5 of **65***a*, and it is indeed observed that H5 of **65***b* absorbs at a field 0.29 ppm lower than H5 of **65***a*. C5 in **65***b* was thus certainly of the *R*-configuration shown. One of the two coupling constants $J_{5,6} = 4.5$ and $J_{6,6a} = 5.5$ Hz in **65***b* therefore had to be assigned to a *trans* configuration since one vicinal *cis* and one *trans* configuration between carbons 5, 6, and 6a must be involved regardless of the chirality of C6.

These results could be summarized as follows. The *R*-configuration of **63** is most probably preserved in the methanolysis products **65***a* and **65***b*. Structure **65***a* (Scheme 9) could then be assigned to one of the methanolysis products in view of $J_{5,6} = J_{6,6a} < 1$ Hz. The C6—C6a bond in **65***a* and **65***b*, and the C1—C5′ bond in goldinamine are of *erythro* configuration so that **64***b* is indeed the structure of the methanolysis product of **63** and C5′ of goldinamine has the *S*-configuration.

A single-crystal Roentgen analysis of **64** subsequently established **64***b* as the correct structure (49). It was also possible to prepare and analyze the crystalline hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-*b*]furan-3-ol(4-bromophenyl)carbamic acid esters **66***a* and **66***b* (Fig. 11) confirming the structures **65***a* and **65***b* as the methanolysis products derived from **63**.

The crystal structure analyses of **64***b* and **66***b* yielded the absolute configurations which, in turn, were in agreement with the previously determined chiral centers of **42**. Thus, the previously assigned all-*cis* configuration of the tetra-substituted tetrahydrofuran ring in goldinamine, the *erythro* configurations of C6—C6a, the chiral integrities of C6, and the epimeric relationship in **65***a* and **65***b* were confirmed.

These studies and others (52) demonstrated that

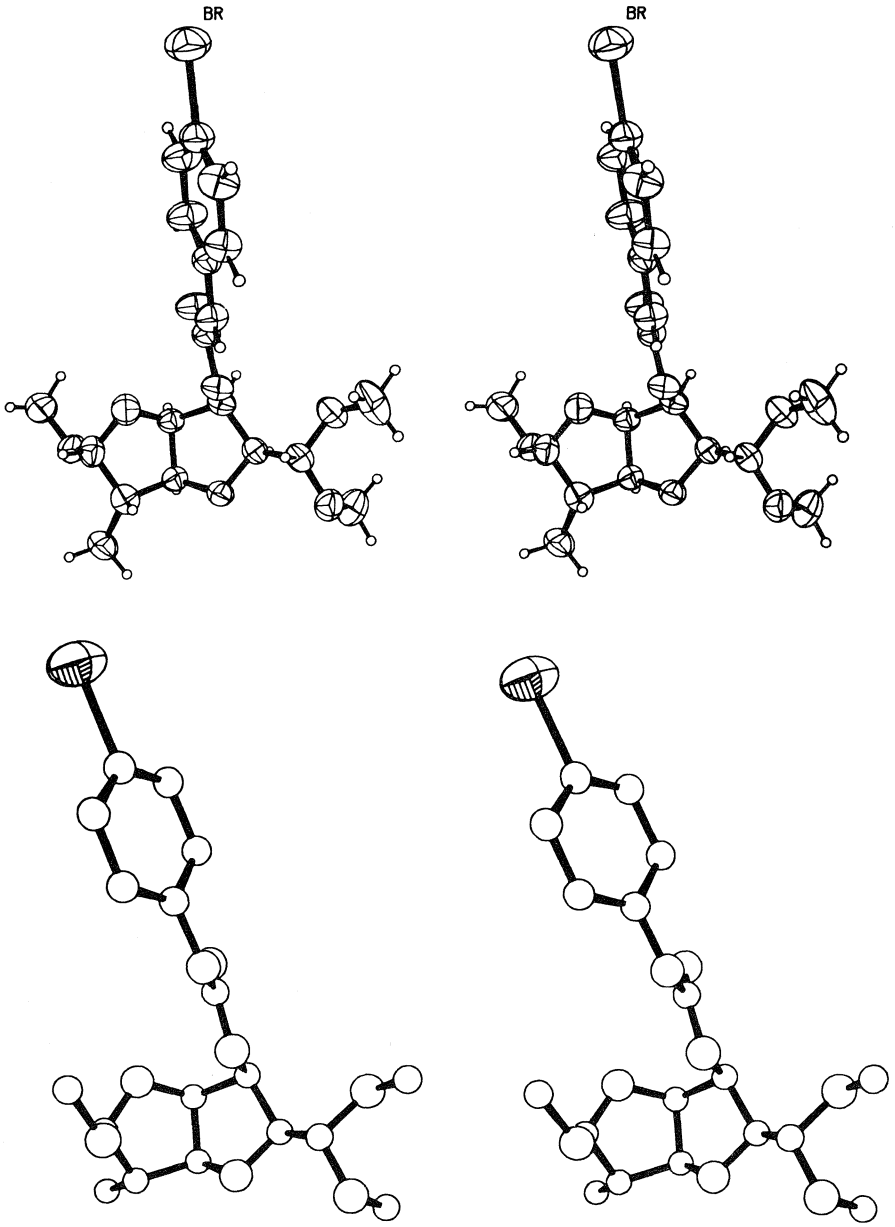

FIG. 11. Stereodrawings showing the conformations and absolute configurations of **66***b* (upper) and **66***a* (lower). The thermal ellipsoids of the anisotropic atoms are scaled to 50% probability level. The isotropic atoms are shown as spheres of arbitrary size.

vicinal coupling constants in the relatively rigid tetrahydrofuro[3,4-*d*]-1,3-dioxoles and tetrahydrofuro[2,3-*d*]-1,3-dioxoles can vary over a range of 0–6.5 Hz yielding very little configurational information. The only permissible conclusion appears to be based on $J \leqq 1$ Hz diagnostic for *trans* configurations. We seemed to have demonstrated convincingly the relative configuration of the tetrahydrofuran ring in goldinamine by ^{1}H nmr spectroscopy in conjunction with model compounds **55–58** and the resulting conclusions turned out to be correct. The study of the 5-epimers **65***a* and **65***b* as well as the 9-epimers **70** and **71** explicitly showed, however, that any extension of assignments due to coupling constants considerably larger than 1 Hz, although based on carefully chosen model systems, will remain problematic.

With the completed structure analyses of **64**, **65***a*,

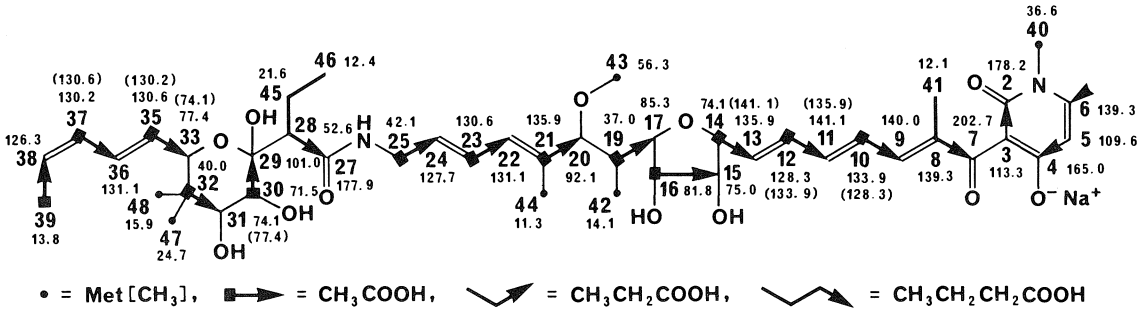

FIG. 12. Biosynthetic pattern and ^{13}C nmr chemical shifts of aurodox sodium salt.

and **65***b* the last stereochemical problems were resolved so that the structure of aurodox can be represented by **1***b*.

Configuration and Chirality of Mocimycin

Constitutional parity of des-*N*-methyl aurodox (**1***a*) with mocimycin (53, 54) was likely in view of very similar nmr spectra of aurodox (**1***b*) and mocimycin, differing only by the presence or absence, respectively, of an *N*-methyl signal. Proof for this assumption was furnished (8) by the demonstration that mocimycin gave mono- and dimethylated products identified as des-*N*-methyl **17** and **17**, the latter also prepared from **1***b* (Scheme 3). Both methylation products of **1***a*, upon treatment with acetic acid, yielded goldinono-1,4-lactone-3,7-hemiacetal (**13**) identical with authentic **13** as shown by spectral and chiroptical properties, and also afforded des-*N*-methyl **21** and **21**, respectively. The latter two goldinamine derivatives, both derived from mocimycin, were *N*-trifluoroacetylated furnishing **46** and **47**, respectively, whose elemental formulas were deduced by mass spectrometry. Further, **47** was also prepared from aurodox via **21** and exhibited a mass spectrometric fragmentation pattern identical to **47** from mocimycin (8). Configurational and chiral parity of the goldinamine moieties of mocimycin and goldinamine was conclusively demonstrated (8) by identical ord and cd spectra of **47** derived from **1***a* and **1***b*, by additional degradation and derivatization reactions of mocimycin yielding des-*N*-methyl-**29**, **29**, [4*E*, 6*E*, 2*R*, 3*S*]-8-acetylamino-3-methoxy-2,4-dimethyl-4,6-octadienal (**34**), and (1*R*,3*R*,4*S*,6*S*,7*S*,8*S*,10*R*)-4-(dimethoxymethyl)-1,7-dimethyl-8-methoxy-2,5,9-trioxatricyclo [4.2.2.$0^{3,10}$]decane (**64***b*), encompassing all remaining chiral centers.

Biosynthesis and ^{13}C nmr Spectrum of Aurodox

The availability of various degradation products of aurodox permitted the ^{13}C spectral assignments of aurodox with very few ambiguities remaining.[4] As expected, the 14 olefin methine carbons, especially C9–C13 of the trienone portion, posed problems in view of their similar chemical shifts. The incorporation of acetate, previously demonstrated (55, 56), was used to divide C9–C13 into two categories: C9, C11, and C13 derived from [1-^{13}C]-acetate, and C10 and C12 from [2-^{13}C]acetate. Assigning C9 by SFOR residual coupling led to the spectral results summarized in Fig. 12.

Biosynthetic studies with ^{14}C- and ^{13}C-labeled precursors (55, 56) showed the goldinonic acid portion derived from five acetate and one butyrate units with the geminal dimethyl group at C32 labeled by L-[Me-^{13}C]methionine. The goldinamine portion is derived from eight consecutive acetate units involving a sixteen-carbon polyketide chain methylated at C19 and C21, and a propionate unit. The origin of the pyridone moiety is somewhat obscure, in part due to general peak-broadness of C3 and C5 in [2-^{13}C]acetate labeled aurodox. The peak at 139.3, now assigned to C6, showed threefold enrichment in [1-^{13}C]acetate labeled aurodox while C2 and C4 were two and sevenfold enriched, respectively. It appears, therefore, that acetate is involved in the biosynthesis of the pyridone ring although a detailed proposal remains to be determined. The biosynthetic results are summarized in Fig. 12.

Experimental

All evaporations were carried out at reduced pressure. For chromatography we used silica gel (Woelm, <0.08 mm), silicic acid (Mallinckrodt, 100 mesh), and precoated tlc plates (Merck, silica gel F-254 for analytical and Merck, silica gel PF-254 for preparative plates). All solvent ratios are v/v. The following solvent systems were employed: chloroform–methanol – concentrated ammonium hydroxide, 40:10:1 (*A*); chloroform – ethyl acetate – methanol, 5:5:1, (*B*); chloroform – diethyl ether, 1:1 (*C*); chloroform – diethyl ether, 1:2 (*D*); chloroform – diethyl ether, 2:1 (*E*); chloroform–methanol, 4:1 (*F*); chloroform–methanol, 9:1 (*G*); cyclohexane – diethyl ether, 1:1 (*H*); cyclohexane–chloroform, 1:1 (*I*); and 1-butanol – acetic acid – water, 4:1:1 (*J*). Spots were visualized under uv light unless stated otherwise. Melting points were obtained on a hot stage (Reichert, Thermopan) and are uncorrected. ^1H and ^{13}C nmr spectra were obtained on a Varian XL-100 spectrometer in the

continuous-wave mode and Fourier-transform mode, respectively.

(3S, 4E, 6Z)-3-Hydroxy-2,2-dimethyl-4,6-octadienal (2)

Aurodox sodium salt (4.2 g, 5 mmol) was dissolved in water (200 mL) containing sodium hydrogen carbonate (4 g). The solution was diluted with dioxane (400 mL), cooled in an ice bath, and further diluted with an ice-cold solution of sodium metaperiodate (10.7 g, 50 mmol) in water (400 mL). The reaction mixture was stirred at ca. 4°C for 20 h, immersed in an ice bath, quenched by the addition of ethylene glycol (5.6 mL), stirred for 2 h, and extracted with diethyl ether (4 × 400 mL). The combined extracts were washed with water (2 × 150 mL) and dried. Evaporation of the solvent gave crude **2** as oil (830 mg), R_f 0.60 (*B*). A small sample was purified by preparative tlc; uv (dioxane) λ_{max}: 235(ε 18770, diene) nm; *Mol. Wt.* calcd. for $C_{10}H_{16}O_2$: 168.24; found (ms) *m/e* (%): 168 (38), 97 (100).

(3S, 4E, 6Z)-2,2-Dimethyl-4,6-octadiene-1,3-diol (3)

A solution of crude **2** (820 mg) in diethyl ether (75 mL) was added dropwise over a 30 min period to a stirred mixture of lithium aluminum hydride (2 g) in diethyl ether (300 mL). After stirring for 4 h at 5°C excess hydride was destroyed by dropwise addition of saturated sodium sulfate solution. The ether layer was removed by decantation, the white precipitate was washed with ether, and the ethereal solutions were combined, dried, and concentrated to a syrup of crude **3** (810 mg). A solution of this material in chloroform was chromatographed on a column of silica gel (25 g) with chloroform (200 mL) and system *E* as mobile phase affording pure **3** as a syrup, R_f 0.55 (*B*), 0.28 (*E*); uv (2-propanol) λ_{max}: 233 (ε 24700) nm. The ^{1}H nmr spectrum is shown in Fig. 1. *Mol. Wt.* calcd. for $C_{10}H_{18}O_2$: 170.25; found (ms) *m/e* (%): 170 (6), 97 (100).

Aurodox (4-Bromobenzyl) Ether (18)

4-Bromobenzyl bromide (3 g, 12 mmol) was added to a solution of **1***b* sodium salt (8.33 g, 10 mmol) in dimethylformamide (125 mL). The solution was kept for 3 days at room temperature in the dark, transferred to a separatory funnel with ethyl acetate (1 L) and saturated sodium hydrogen carbonate solution (350 mL). The organic phase was washed once with sodium hydrogen carbonate solution (350 mL), three times with water (100 mL each), and dried ($MgSO_4$). Concentration gave a thin, yellow syrup which was dissolved in acetone (20 mL) and chromatographed on a column of Sephadex LH-20 (9 cm × 47 cm) with acetone as mobile phase. Fractions containing pure **18** were combined (tlc), concentrated to a volume of 50 mL, and slowly added to ether (500 mL) under vigorous stirring. After further addition of petroleum ether (500 mL) the precipitate was collected by filtration, washed with ether and petroleum ether, and dried under reduced pressure, R_f 0.72 (*A*), 0.20 (*B*). *Anal.* calcd. for $C_{51}H_{67}BrN_2O_{12}\cdot H_2O$ (998.03): C 61.38, H 6.97, N 2.81, Br 8.01; found: C 61.37, H 7.14, N 2.71, Br 8.18.

[1R-(1β,3α,5α,6β,9α,E,Z)]-9-Ethyl-1,5-dihydroxy-4,4-dimethyl-3-(1,3-pentadienyl)-2,7-dioxabicyclo-[4.3.0]nonan-8-one (Goldinono-1,4-lactone-3,7-hemiacetal, 13) and [2R,3R,4S,5S,1(R),2(S*)]-4-(4-Bromobenzyloxy)-1-methyl-3-[7-[5-[7-amino-2-methoxy-1,3-dimethyl-3(E),5(E)-heptadienyl]-3,4-dihydroxytetrahydro-2-furyl]-2-methyl-1-oxo-2(E),-4(E),6(E)-heptatrienyl]-2(1H)-pyridinone (Goldinamine (4-Bromobenzyl) Ether, 22)*

A solution of **18** (400 mg) in acetic acid (10 mL) was kept at room temperature for three days in the dark or was heated on the steam bath for 20 min. The acetic acid was removed by distillation and codistillation with toluene. The residue was dissolved in chloroform and chromatographed on a column containing silicic acid (35 g). Elution started with chloroform (fractions 1–6, 12 mL each) and was followed by chloroform–methanol, 20:1 (7–20), chloroform–methanol, 4:1 (21–40), and chloroform–methanol – acetic acid, 16:4:1 (41–86). Fractions 14–17 contained crude **13** (111 mg, R_f 0.24, (*A*)) which were purified by rechromatography or preparative tlc (0.48 (*B*)) to give white crystals of **13**, mp 110°C; $[\alpha]_D$ −23° (*c* 1.0, $CHCl_3$) (37). *Anal.* calcd. for $C_{16}H_{24}O_5$ (296.35): C 64.84, H 8.16; found: C 64.56, H 8.29. Fractions 54–77 were pooled and concentrated to a syrup, redissolved in water and freeze-dried to yield amorphous **22** acetic acid salt hemihydrate (116 mg), R_f 0.6 (*A*); nmr (CD_3OD)[5] δ: 0.82 (d, 3, $J_{1,Me}$ = 7 Hz, 1-Me), 1.71 (s, 3, 3-Me), 1.89 (s, 3, *Me*COO^-), 1.94 (s, 3, 2″Me), 2.20 (m, 1, $J_{1,Me}$ = 7 Hz, H1), 3.15 (s, 3, OMe), 3.37 (d, 1, $J_{1,2}$ = 10 Hz, H2), 3.47 (s, 3, NMe), 3.57 (d, 2, $J_{6,7}$ = 6 Hz, H7), 3.71 (dd, 1, $J_{1,5'}$ = 7 and $J_{4',5'}$ = 4 Hz, H5′), 4.19 (dd, 1, $J_{3'4'}$ = 5 and $J_{4'5'}$ = 4 Hz, H4′), 4.32 (m, 2, H2′ and H3′), 5.11 (s, 2, CH_2—C_6H_5), 5.75 (dt, 1, $J_{5,6}$ = 15 and $J_{6,7}$ = 7 Hz, H6), 6.03 (d, 1, $J_{4,5}$ = 10 Hz, H4), 6.08 (dd, 1, $J_{2',7''}$ = 7 and $J_{6'',7''}$ = 14 Hz, H7″), 6.41 (dd, 1, $J_{5'',6''}$ = 11 and $J_{6'',7''}$ = 14 Hz, H6″), 6.43 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5‴), 6.48 (dd, 1, $J_{4''5''}$ = 14 and $J_{5''6''}$ = 11 Hz, H5″), 6.61 (dd, 1, $J_{4,5}$ = 10 and $J_{5,6}$ = 15 Hz, H5), 6.68 (dd, 1, $J_{3''4''}$ = 11 and $J_{4'',5''}$ = 14 Hz, H4″), 6.91 (d, $J_{3'',4''}$ = 11 Hz, H3″), 7.18, 7.43 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4), and 7.70 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6‴). *Anal.* calcd. for $C_{35}H_{43}BrN_2O_7\cdot CH_3COOH\cdot\frac{1}{2}H_2O$ (752.71): C 59.04, H 6.43, N 3.72, Br 10.62; found: C 59.01, H 6.33, N 3.77, Br 10.89.

The free base of **22** was prepared by dissolving **22** acetic acid salt (50 g) in water (5 mL) and adding 0.1 *N* sodium hydroxide solution to pH 9.2. The precipitate was collected, washed with water, and dried to yield a light tan, amorphous powder; nmr ($CDCl_3$) similar to **22** acetic acid salt but lacking a signal for acetate, and H7 shifted diamagnetically to δ 3.28.

[2S,3S,4R,5R,7(R),6(S*)]-N-[7-[5-[7-[(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridinyl]-6-methyl-7-oxo-1(E),3(E),5(E)-heptatrienyl]tetrahydro-3,4-dihydroxy-furan-2-yl]-6-methoxy-5,7-dimethyl-2(E),4(E)-heptadienyl]acetamide (N-Acetyl 22)*

Acetic anhydride (8 mL) was added to a solution of **22** acetic acid salt (2 g) in methanol (20 mL). After one hour the mixture was added dropwise to a rapidly stirred mixture of ether (700 mL) and petroleum ether (600 mL). The precipitate was collected, dried, redissolved in acetone (4 mL), and chromatographed on a column of Sephadex LH-20 (51 mm × 510 mm) with acetone as mobile phase. Pure fractions were pooled, evaporated, and redissolved in acetone. The resulting solution was added dropwise to rapidly stirred petroleum ether (400 mL). The precipitate was collected by filtration and dried to give an amorphous powder (1.65 g) (R_f 0.15 (*B*); 0.85 (*F*); 0.50 (*G*)); nmr (CD_3OD) similar to that of **22** acetic acid salt, but shows δ 1.94 (s, 3, N—Ac).

[2S,3R,4S,5R,7(R),6(S*)]-N-[7-[5-[7-[(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridinyl]-6-methyl-7-oxo-1(E),3(E),5(E)-heptatrienyl]tetrahydro-3,4-bis(acetyloxy)-furan-2-yl]-6-methoxy-5,7-dimethyl-2(E),4(E)-heptadienyl]acetamide (N,O,O-Triacetyl 22)*

A solution of **22** acetic acid salt (150 mg) was dissolved in anhydrous pyridine (4 mL) and acetic anhydride (2 mL) was added. The solution was kept in the dark overnight, evaporated to dryness, the residue dissolved in chloroform, and chromatographed on silica gel (8 g). With system *B* as mobile phase pure fractions were obtained which were pooled and evaporated. Dissolving the residue in chloroform and precipitating with petroleum ether gave amorphous *N,O,O*-triacetyl **22** (140 mg), R_f 0.25 (*B*); nmr (CD_3OD) δ: 0.85 (d, 3, $J_{7,Me}$ = 7 Hz, 7-Me), 1.63 (s, 3, 5-Me), 1.92, 1.95, 2.04 (3s, 9, CH_3CO), 1.98 (s, 3, 6″-Me), 2.21 (m, 1, H7), 3.03 (s, 3, CH_3O), 3.23 (d, 1, $J_{6,7}$ = 10 Hz, H6), 3.50 (s, 3, NMe), 3.86 (d, 2, $J_{1,2}$ = 6 Hz, H1), 3.92 (dd, 1, $J_{2',7'}$ = 7 and

[5]For proton designations see Scheme 6.

$J_{2',3'}$ = 3 Hz, H2'), 4.57 (dd, 1, $J_{4'5'}$ = 6 and $J_{1'',5'}$ = 7 Hz, H5'), 5.11 (s, 2, CH_2—C_6H_5), 5.41 (dd, 1, $J_{4',5'}$ = 6, $J_{3',4'}$ = 4.5 Hz, H4'), 5.46 (t, 1, $J_{3',4'} = J_{2',3'}$ = 4.5 Hz, H3'), 5.64 (dt, 1, $J_{2,3}$ = 15 and $J_{1,2}$ = 6 Hz, H2), 5.84 (dd, 1, $J_{1'',5'}$ = 7 and $J_{1'',2''}$ = 14.5 Hz, H1''), 5.94 (d, 1, $J_{4,5}$ = 11 Hz, H4), 6.38 (dd, 1, $J_{2'',3''}$ = 11 and $J_{1'',2''}$ = 14 Hz, H2''), 6.41 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5'''), 6.45 (dd, 1, $J_{3'',4''}$ = 14 and $J_{2'',3''}$ = 11 Hz, H3''), 6.50 (dd, 1, $J_{4,5}$ = 11 and $J_{5,6}$ = 15 Hz, H3), 6.69 (dd, 1, $J_{4'',5''}$ = 11 and $J_{3'',4''}$ = 14 Hz, H4''), 6.87 (d, 1, $J_{4'',5''}$ = 11 Hz, H5''), 7.17, 7.41 (AA'BB', 4, J_0 = 8.5 Hz, C_6H_5), and 7.67 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6''').

[2R,3R,4S,5S,1(R),2(S*)]-4-(4-Bromobenzyloxy)-1-methyl-3-[7-[5-[7-(2,4-dinitrophenylamino)-1,3-dimethyl-2-methoxy-3(E),5(E)-heptadienyl]-3,4-dihydroxytetrahydro-2-furyl]-2-methyl-1-oxo-2(E),4(E),6(E)-heptatrienyl]-2(1H)-pyridone (**26**)*

2,4-Dinitrofluorobenzene (0.35 mL) was added to a mixture of **22** acetic acid salt (0.5 g), potassium carbonate (1 g), and acetone (30 mL). After shaking for 20 h in the dark, the suspension was filtered, the filtrate evaporated, and the residue chromatographed on a column of Sephadex LH-20 (25 mm × 510 mm) with acetone as mobile phase to furnish **26** by precipitation with petroleum ether from concentrated solution (0.3 g), R_f 0.71 (*G*); nmr ($CDCl_3$)[6] δ: 0.87 (d, 3, $J_{1,Me}$ = 7 Hz, 1-Me), 1.70 (s, 3, 3-Me), 2.02 (s, 3, 2''-Me), 2.20 (m, 1, H1), 3.22 (s, 3, 2-OMe), 3.31 (d, 1, $J_{1,2}$ = 9.5 Hz, H2), 3.50 (s, 3, NMe), 3.56 (m, 1, H5'), 4.22 (m, 3, NCH_2 and H2'), 4.42 (m, 2, H3' and H4'), 5.03 (s, 2, OCH_2), 5.85 (dt, 1, $J_{5,6}$ = 15.5 and $J_{6,7}$ = 6 Hz, H6), 6.06 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5'''), 6.06 (m, 2, H4 and H7''), 6.30–6.80 (m, 4, H4'', H5, H5'', H6''), 6.90 (d, 1, $J_{3'',4''}$ = 10 Hz, H3''), 6.99 (d, 1, $J_{5,6}$ = 9 Hz, H6 of DNP), 7.17, 7.48 (AA'BB', 4, J_0 = 8.5 Hz, C_6H_4), 7.35 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6'''), 8.35 (dd, 1, $J_{3,5}$ = 3 and $J_{5,6}$ = 9 Hz, H3 of DNP), 8.72 (t, 1, $J_{7,NH}$ = 6 Hz, NH), 9.20 (d, 1, $J_{3,5}$ = 3 Hz, H5 of DNP). A 220 MHz spectrum is shown in Fig. 8.

[2R,3S,4R,5S,1(R),2(S*)]-4-(4-Bromobenzyloxy)-1-methyl-3-[7-[5-[7-(2,4-dinitrophenylamino)-2-methoxy-1,3-dimethyl-3(E),5(E)-heptadienyl]-3,4-bis(acetyloxy)tetrahydrofuran-2-yl]-2-methyl-1-oxo-2-methyl-2(E),4(E),6(E)-heptatrienyl]-2(1H)-pyridinone (**43**)*

A mixture of **26** (0.30 g), pyridine (3 mL), and acetic anhydride (1.5 mL) was stirred at 25°C for 26 h and then added dropwise to diethyl ether – petroleum ether (1:2, 200 mL). The resulting precipitate of crude **43** (0.29 g) was chromatographed on Sephadex LH-20 (acetone) yielding pure **43** (0.26 g), R_f 0.52 (*B*); nmr shown in Fig. 8.

[3aS,4R,6aR,6S,1(R),2(S*)]-4-(4-Bromobenzyloxy)-1-methyl-3-[7-[6-[7-(2,4-dinitrophenylamino)-2-methoxy-1,3-dimethyl-3(E),5(E)-heptadienyl]-tetrahydro-2,2-dimethyl-furo[3,4-d]-1,3-dioxol-4-yl]-2-methyl-1-oxo-2(E),4(E),6(E)-heptatrienyl]-2(1H)-pyridinone (**44**)*

2,2-Dimethoxypropane (0.5 mL) and bis(4-nitrophenyl) phosphate (75 mg) were added to a solution of **26** (100 mg) in acetone (5 mL). The mixture was neutralized with Dowex 1 (HCO_3^-) after 2 h, the resin filtrate and washings (methanol) were evaporated, and the residue chromatographed on Sephadex LH-20 (acetone) to yield pure **44** as yellow powder by precipitation with petroleum ether, R_f 0.52 (*B*); nmr ($CDCl_3$)[7] δ: 0.93 (d, 3, $J_{1,Me}$ = 6 Hz, 1-Me), 1.29, 1.43 (2s, 3 each, 2-Me_2), 1.70 (s, 3, 3-Me), 2.03 (s, 3, 2''-Me), 2.31 (m, 1, H1), 3.18 (s, 3, 2-OMe), 3.36 (d, 1, $J_{1,2}$ = 9.5 Hz, H2), 3.49 (s, 3, NMe), 3.57 (dd, 1, $J_{1',6}$ = 6 and $J_{6',6a'}$ = 3.5 Hz, H6'), 3.97 (dd, 1, $J_{3a',4'}$ = 4 and $J_{4',7''}$ = 8 Hz, H4'), 4.16 (t, 2, $J_{6,7} = J_{7,NH}$ = 6 Hz, NCH_2), 4.62 (dd, 1, $J_{3a',4'}$ = 4 and $J_{3a',6a'}$ = 6 Hz, H3a'), 4.71 (dd, 1, $J_{3a',6a'}$ = 6 Hz and $J_{6',6a'}$ = 3.5 Hz, H6a'), 5.03 (s, 2, OCH_2), 5.75 (dt, 1, $J_{5,6}$ = 15 and $J_{6,7}$ = 6 Hz, H6), 6.02 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5'''), 6.03 (m, 2, H4 and H7''), 6.30–6.80 (m, 4, H4'', H5, H5'', H6), 6.88 (d, 1, $J_{3'',4''}$ = 10 Hz, H3''), 6.95 (d, 1, $J_{5,6}$ = 9 Hz, H6 of DNP), 7.13, 7.45 (AA'BB', 4, J_0 = 8.5 Hz, C_6H_4), 7.37 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6'''), 8.28 (dd, 1, $J_{3,5}$ = 3 and $J_{5,6}$ = 9 Hz, H5 of DNP), 8.65 (t, 1, $J_{7,NH}$ = 6 Hz, NH), 9.15 (d, 1, $J_{3,5}$ = 3 Hz, H3 of DNP).

*[1R-(1β,3α,5α,6β,9α)]-9-Ethyl-1,5-dihydroxy-4,4-dimethyl-3-pentyl-2,7-dioxabicyclo[4.3.0]nonan-8-one (Tetrahydrogoldinono-1,4-lactone-3,7-hemiacetal, **14**)*

Crude **13** (2 g) in acetic acid (30 mL) was stirred with prehydrogenated platinum oxide (160 mg) for 8 h under hydrogen pressure of 2 atm. Removal of the catalyst and solvent gave a syrup which was dissolved in chloroform and chromatographed on alumina (40 g). Changing to chloroform – ethyl acetate (9:1) as the mobile phase eluted **14**. Final purification was achieved by chromatography on Sephadex LH-20 (50 mm × 570 mm) with acetone as mobile phase. Crystallization from ethanol–water gave white needles (1.2 g), R_f 0.60 (*B*) (37).

*4-Hydroxy-1-methyl-2(1H)-pyridone (**19**)*

A solution of **1***b* sodium salt (10 g) in ethanol (150 mL) was hydrogenated (3.5 atm) over 10% palladium-on-barium sulfate (2 g) for 6.5 h. The catalyst was filtered off, the filtrate was diluted with water (150 mL), refluxed for 5 h, and evaporated to dryness. The dry residue was extracted three times with chloroform, the remaining solids were dissolved in methanol–water, 2:1, and the solution passed through a column of Dowex 50 X-4 (200–400 mesh, H^+, 50 mL). The resin was rinsed with methanol–water (2:1, 100 mL) followed by methanol–water–pyridine (2:2:1) which eluted **19**. Pooling and concentration of the appropriate fractions gave a syrup which solidified on standing. Recrystallization from ethanol–diethyl ether gave large prisms of **19** (700 mg), R_f 0.19 (*A*), 0.25 (*B*); mp 168–170°C. *Anal.* calcd. for $C_6H_7NO_2$ (125.14): C 57.59, H 5.64, N 11.19; found: C 57.62, H 5.75, N 11.13; (40).

The acid was converted to the thallium salt with thallium ethoxide and recrystallized from methanol–ethanol–ether to afford colorless needles, mp 203–204°C. *Anal.* calcd. for $C_6H_6NO_2Tl$ (328.51): C 21.94, H 1.84, N 4.26; found: C 21.83, H 1.71, N 4.26.

*Methylenebis(4-hydroxy-1-methyl-2(1H)-pyridinone) (**20**)*

Formaldehyde solution (37%, 0.1 mL) and piperidine (one drop) were added to a solution of **19** (120 mg) in ethanol–water (1:1, 4 mL). The mixture was refluxed on the steam bath for 10 min and refrigerated. The precipitate was recrystallized from ethanol–chloroform (84 mg), R_f 0.80 (*A*); mp 300–305°C; uv λ_{max} (ε): 282 (11 580) in 0.1 *N* HCl, 281–282 (12 900) nm in 0.1 *N* KOH; nmr ($CDCl_3$) δ: 3.49 (s, 6, 2 NMe), 3.74 (s, 2, CH_2), 6.09 (d, 1, $J_{5,6}$ = 8 Hz, H5), 7.06 (d, 1, $J_{5,6}$ = 8 Hz, H6), and 13.01 (s, 2, 2 OH). *Anal.* calcd. for $C_{13}H_{14}N_2O_4$ (262.26): C 59.4, H 5.38, N 10.68; found: C 59.72, H 5.35, N 10.52.

*4-(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxopyridine-3-carboxylic Acid (**24**)*

A solution of potassium carbonate (4.14 g), sodium metaperiodate (8.5 g), and potassium permanganate (63 mg) in water (400 mL) was added to a solution of **22** acetic acid salt (500 mg) in 90% *tert*-butanol (500 mL). The mixture was stirred overnight at room temperature in the dark, acidified (pH 1.5, 6 *N* sulfuric acid), and extracted with diethyl ether (500 mL). The dried extract was evaporated and the residue triturated repeatedly with chloroform. The remaining solids were then extracted with chloroform–methanol (9:1, 50 mL). This extract was evaporated and the residue allowed to crystallize from hot methanol. Recrystallization from methanol–ethanol–water gave colorless

prisms of **24**, R_f 0.10 (*A*); mp 224°C. *Anal.* calcd. for $C_{14}H_{12}BrNO_4$ (338.16): C 49.73, H 3.58, N 4.14; found: C 49.68, H 3.58, N 4.23 (40).

*4-(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxopyridine-3-carboxylic Acid Methyl Ester (**25**)*

Diethyl ether (2 mL) containing an excess of diazomethane was added to a suspension of **24** (15 mg) in tetrahydrofuran (3 mL) and methanol (0.5 mL). After stirring for 45 min a clear solution resulted. The mixture was concentrated after 3 h and addition of ether and petroleum ether gave needles of **25**, R_f 0.45 (*B*), 0.88 (*F*); mp 180°C. *Anal.* calcd. for $C_{15}H_{14}BrNO_4$ (352.19): C 49.43, H 4.15, N 4.12; found: C 49.43, H 4.10, N 3.91.

*4-(4-Bromobenzyloxy)-3,5-diiodo-1-methyl-2(1H)-pyridone (**23**)*

The combined chloroform extracts of the residue, which were described in the preparation of **24** were concentrated and chromatographed on a column of silicic acid (8 g) with chloroform as mobile phase. Fractions containing the spot with R_f 0.45 (*C*) were pooled and evaporated. The residue was further purified by preparative tlc with the same solvent system. The silicic acid was extracted with system *G* and the product crystallized from diethyl ether – petroleum ether to give slightly yellow needles (29 mg), R_f 0.75 (*B*); mp 204–205°C; nmr ($CDCl_3$) δ: 3.58 (s, 3, NMe), 5.02 (s, 2, CH_2), 7.49, 7.53 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4), and 7.65 (s, 1, H6). *Mol. Wt.* calcd. for $C_{13}H_{10}BrI_2NO_2$: 544.7989; found (ms) *m/e*: 544.8033.

*(6S,7R,2E,4E)-N-(7-Formyl-6-methoxy-5-methyl-2,4-octadienyl)acetamide (**34**)*

A solution of sodium metaperiodate (1.9 g) in water (160 mL) was added to a solution of **22** acetate (1 g) in a mixture of dioxane (140 mL) and methanol (20 mL). A transient wine-red color developed immediately indicating the liberation of iodine. The mixture was stirred in the dark for 2.5 h and centrifuged after addition of barium hydroxide to pH 8.3. Acetic anhydride (15 mL) was added to the stirred supernatant and, after one hour, the pH was adjusted to 8.4 with 19 *M* sodium hydroxide solution and extracted with ether (400, 200, and 200 mL). The combined and dried extracts were evaporated to a syrup (350 mg) of nearly pure **34**. Preparative tlc (*B*) gave a straw-colored syrup with R_f 0.55 (*B*) and 0.68 (*G*); cd (*c* 0.012 *M*, dioxane): $[\theta]_{318}$ 0, $[\theta]_{290}$ + 3750, $[\theta]_{248}$ 0, $[\theta]_{220}$ + 8750, $[\theta]_{204}$ 0; nmr ($CDCl_3$) δ: 0.85 (d, 3, $J_{2,8}$ = 7 Hz, H8), 1.69 (s, 3, 5-Me), 2.00 (s, 3, CH_3CO), 2.59 (ddq, 1, $J_{7,CHO}$ = 3, $J_{6,7}$ = 10, and $J_{7,8}$ = 7 Hz, H7), 3.17 (s, 3, OCH_3), 3.63 (d, 1, $J_{6,7}$ = 10 Hz, H6), 3.95 (t, 2, $J_{1,2}$ = $J_{1,NH}$ = 6 Hz, NCH_2), 5.67 (dt, 1, $J_{2,3}$ = 15 and $J_{1,2}$ = 6 Hz, H2), 6.00 (d, 1, $J_{3,4}$ = 10 Hz, H4), 6.06 (broad, 1, NH), 6.48 (dd, 1, $J_{3,4}$ = 10 and $J_{2,3}$ = 15 Hz, H3), and 9.75 (d, 1, $J_{7,CHO}$ = 3 Hz, 7-CHO).

*(2E,4E,6E)-8-[4-(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridyl]-7-methyl-8-oxo-2,4,6-octatrienoic Acid (**31**)*

The aqueous phase obtained after extraction of **34** in the above procedure was adjusted to pH 3.0 with 18 *N* sulfuric acid and the solution repeatedly extracted with dichloromethane. The dried extract was evaporated and the residue redissolved in chloroform. Upon standing the concentrated chloroform solution deposited a monochloroform solvate of **31** as yellow needles. Drying at 75°C and 0.5 Torr gave the chloroform-free product, R_f 0.15 (*A*) and 0.58 (*J*). *Anal.* calcd. for $C_{22}H_{20}BrNO_5$ (458.31): C 57.66, H 4.40, N 3.06, Br 17.43; found: C 57.71, H 4.36, N 3.18, Br 17.47 (40).

The ^1H nmr spectrum of **31** and a stereoscopic view of the crystal structure are shown in Figs. 3 and 4, respectively.

*(2E,4E,6E)-8-[4-(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridyl]-7-methyl-8-oxo-2,4,6-octatrienoic Acid Methyl Ester (**32**)*

A suspension of **31** (350 mg) in tetrahydrofuran (30 mL) and methanol (2 mL) was mixed with diethyl ether (30 mL) containing an excess of diazomethane and stirred overnight. The resulting clear solution was evaporated. Crystallization from methanol–water gave **32** as yellow needles, R_f 0.62 (*J*) and 0.75 (*F*); mp 164°C; nmr (DMSO-d_6) δ: 1.98 (s, 3, 7-Me), 3.43 (s, 3, NMe), 3.73 (s, 3, OMe), 5.19 (s, 2, CH_2), 6.11 (d, 1, $J_{2,3}$ = 15 Hz, H2), 6.41 (d, 1, $J_{5',6'}$ = 7.5 Hz, H5′), 6.74 (dd, 1, $J_{3,4}$ = 11 and $J_{4,5}$ = 14.5 Hz, H4), 6.86 (d, 1, $J_{5,6}$ = 11 Hz, H6), 7.25 (dd, 1, $J_{4,5}$ = 14.5 and $J_{5,6}$ = 11 Hz, H5), 7.26, 7.54 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4), 7.47 (dd, 1, $J_{2,3}$ = 15 and $J_{3,4}$ = 11 Hz, H3), and 7.84 (d, 1, $J_{5',6'}$ = 7.5 Hz, H6′). *Anal.* calcd. for $C_{23}H_{22}BrNO_5$ (472.34): C 58.49, H 4.69, N 2.97; found: C 58.17, H 4.86, N 2.93.

*(6S,7S,2E,4E)-N-(8-Hydroxy-5,7-dimethyl-6-methoxy-2,4-octadienyl)acetamide (**37**)*

A solution of **34** (100 mg) in ethanol (10 mL) was cooled in an ice bath and treated with sodium borohydride (100 mg). After 20 min at 0°C water (20 mL) was added and the pH of the solution was adjusted to 3.1. The mixture was extracted with diethyl ether (3 × 25 mL). The dried extracts were evaporated and the residue purified by preparative tlc in system *B* to yield a colorless syrup of **37** (90 mg), R_f 0.48 (*B*) and 0.59 (*G*); uv (2-propanol) λ_{max}: 239 (ε 21 500) nm; nmr ($CDCl_3$) δ: 0.67 (d, 3, $J_{6,7}$, $J_{7,Me}$ = 6.5 Hz, 7-Me), 1.66 (s, 3, 5-Me), 1.94 (m, 1, H7), 1.98 (s, 3, CH_3CO), 3.16 (broad, 1, OH), 3.16 (s, 3, 6-OMe), 3.34 (d, 1, $J_{6,7}$ = 9 Hz, H6), 3.60 (d, 2, $J_{7,8}$ = 6 Hz, H8), 3.91 (t, 2, $J_{1,2}$ = $J_{1,NH}$ = 6 Hz, NCH_2), 5.67 (dt, 1, $J_{2,3}$ = 15 and $J_{1,2}$ = 6 Hz, H2), 5.96 (d, 1, $J_{3,4}$ = 11 Hz, H4), 6.37 (d, 1, $J_{1,NH}$ = 6 Hz, NH), and 6.42 (dd, 1, $J_{3,4}$ = 11 and $J_{2,3}$ = 15 Hz, H3).

*(2S,3S,4E,6E)-8-Acetylamino-3-methoxy-2,4-dimethyl-4,6-octadien-1-yl 4-Bromobenzoic Acid Ester (**38**)*

The ester was prepared with 4-bromobenzoyl chloride in pyridine in the usual fashion yielding **38** as a syrup, R_f 0.73 (2); nmr ($CDCl_3$) δ: 0.86 (d, 3, $J_{2,Me}$ = 7 Hz, 2-Me), 1.68 (s, 3, 4-Me), 2.00 (s, 3, CH_3CO), 2.09 (m, 1, H2), 3.14 (s, 3, 3-OMe), 3.31 (d, $J_{2,3}$ = 9 Hz, H3), 3.94 (t, 2, $J_{7,8}$ = $J_{8,NH}$ = 6 Hz), 4.30 (dd, 1, J_{gem} = 11 Hz, $J_{1a,2}$ = 6.5 Hz, H1a), 4.54 (dd, J_{gem} = 11 Hz, $J_{1b,2}$ = 4 Hz, H1b), 5.66 (dt, 1, $J_{6,7}$ = 15.5 and $J_{7,8}$ = 6 Hz, H7), 5.96 (d, 1, $J_{5,6}$ = 10.5 Hz, H5), 5.98 (broad, 1, NH), 6.44 (dd, 1, $J_{5,6}$ = 10.5 and $J_{6,7}$ = 15.5 Hz, H6), and 7.57, 7.92 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4).

*(2R,3S,4E,6E)-8-[(2,4-Dinitrophenyl)amino]-3-methoxy-2,4-dimethyl-4,6-octadienal (**35**)*

A solution of sodium metaperiodate (1.5 g) in water (160 mL) was added to a solution of **22** acetic acid salt (1 g) in dioxane (140 mL) and methanol (20 mL). After standing in the dark for 5 h the pH was adjusted to 8.4 (barium hydroxide) and the suspension was centrifuged. Sodium hydrogen carbonate (1.5 g) was added to the supernatant, followed by 2,4-dinitrofluorobenzene (1 g) in methanol (5 mL). After stirring in the dark for 16 h, the mixture was extracted with diethyl ether and the extracts were combined, dried, and evaporated. A chloroform solution of the residue was chromatographed on silicic acid (75 g) with chloroform as mobile phase. The major yellow band was isolated and gave **35** as a yellow syrup (270 mg), R_f 0.67 (*D*); ^1H nmr shown in Fig. 5. *Mol. Wt.* calcd. for $C_{17}H_{21}N_3O_6$: 363.14, found (ms) *m/e* (%): 363 (6), 196 (100).

*(2R,3S,4E,6E)-8-[(2,4-Dinitrophenyl)amino]-3-methoxy-2,4-dimethyl-4,6-octadienal Dimethyl Acetal (**41**)*

To a solution of **35** (110 mg) in methanol (5 mL) and 2,2-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

dimethoxypropane (1 mL) was added bis(4-nitrophenyl)phosphate (50 mg). After two h at room temperature, the solution was neutralized with Dowex 1 (HCO_3^-). The filtrate and resin washings (acetone) were concentrated, redissolved in chloroform, and chromatographed on a column of silicic acid (35 g) with chloroform as mobile phase. The major band was concentrated to a syrup which solidified on standing. Recrystallization from acetone–ethanol gave yellow prisms of **41**, R_f 0.78 (*D*); nmr ($CDCl_3$) δ: 0.71 (d, 3, $J_{2,Me}$ = 7 Hz, 2-Me), 1.68 (s, 3, 4-Me), 1.97 (m, 1, H2), 3.17 (s, 3, 3-OMe), 3.40 (d, $J_{2,3}$ = 9 Hz, H3), 3.43, 3.50 (2s, 3 each, 1-$(OMe)_2$), 4.17 (t, 2, $J_{7,8}$ = $J_{8,NH}$ = 6 Hz, NCH_2), 4.53 (d, 1, $J_{1,2}$ = 3 Hz, H1), 5.77 (dt, $J_{6,7}$ = 15 and $J_{7,8}$ = 6 Hz, H7), 6.04 (d, 1, $J_{5,6}$ = 10.5 Hz, H5), 6.60 (dd, 1, $J_{5,6}$ = 10.5 and $J_{6,7}$ = 15 Hz, H6), 6.95 (d, 1, $J_{5',6'}$ = 9.5 Hz, H6′), 8.30 (dd, 1, $J_{3',5'}$ = 2.5 and $J_{5',6'}$ = 9.5 Hz, H5′), 8.66 (broad, 1, NH), 9.16 (d, 1, $J_{3',5'}$ = 2.5 Hz, H3′).

*(2*R*,3*S*,4*E*,6*E*)-8-[(3-Bromo-4,6-dinitrophenyl)amino]-3-methoxy-2,4-dimethyl-4,6-octadienal Dimethyl Acetal (**42**)*

A solution of sodium metaperiodate (1.9 g) in water (70 mL) was added to a solution of **22** acetic acid salt (500 mg) in dioxane (70 mL) and methanol (10 mL). After standing for 4 h in the dark, the mixture was adjusted to pH 8.3 with barium hydroxide solution and centrifuged. Sodium hydrogen carbonate (1.5 g) and 1-bromo-5-fluoro-2,4-dinitrobenzene (42) (1 g) were added, the mixture stirred in the dark for 3 h and stored overnight at 4°C. The octadienal **36** was isolated and converted to the dimethyl acetal **42** as described (42), R_f 0.75 (*D*) and 0.24 (*H*); nmr ($CDCl_3$) δ: 0.71 (d, 3, $J_{2,Me}$ = 7 Hz), 1.68 (s, 3, 4-Me), 1.97 (m, 1, H2), 3.17 (s, 3, 3-OMe), 3.39 (d, 1, $J_{2,3}$ = 9 Hz, H3), 3.43, 3.49 (2s, 3 each, 1-$(OMe)_2$), 4.10 (t, 2, $J_{7,8}$ = $J_{8,NH}$ = 6 Hz, NCH_2), 4.50 (d, 1, $J_{1,2}$ = 3 Hz, H1), 5.71 (dt, $J_{6,7}$ = 15 and $J_{7,8}$ = 6 Hz, H7), 6.02 (d, 1, $J_{5,6}$ = 10.5 Hz, H5), 6.60 (dd, 1, $J_{5,6}$ = 10.5 and $J_{6,7}$ = 15 Hz, H6), 7.21 (s, 1, H2′), 8.43 (broad, 1, NH), and 8.98 (s, 1, H5′).

*[3a*R*,4*S*,6*R*,6a*S*,6(*S**),7(*R**)]-N[6-[7-[(4-Bromobenzyloxy)-1,2-dihydro-1-methyl-2-oxo-3-pyridinyl]-6-methyl-7-oxo-1(*E*),3(*E*),5(*E*)-heptatrienyl]tetrahydrofuro-[3,4-d]-2,2-dimethyl-1,3-dioxol-4-yl]-6-methoxy-5,7-dimethyl-2(*E*),4(*E*)-heptadienyl]acetamide (**60**)*

Bis(4-nitrophenyl)phosphate (0.5 g) was added to a solution of *N*-acetyl **22** (2 g) in acetone (40 mL) and 2,2-dimethoxypropane (15 mL). The solution was neutralized the next day with Dowex 1-X2 (HCO_3^-), filtered, and evaporated. The resulting syrup was chromatographed on a column of Sephadex LH-20 (51 mm × 510 mm) with acetone as mobile phase to yield homogeneous **60** as yellow powder upon concentration to dryness (1.47 g), R_f 0.35 (*B*) and 0.60 (*G*); nmr ($CDCl_3$)[5] δ: 0.90 (d, 3, $J_{7,Me}$ = 7 Hz, 7-Me), 1.28, 1.42 (2s, 3 each, 2′-Me_2), 1.66 (s, 3, 5-Me), 1.97 (s, 3, 6″-Me), 1.99 (s, 3, $COCH_3$), 2.29 (m, 1, H7), 3.13 (s, 3, 6-OMe), 3.29 (d, 1, $J_{6,7}$ = 9 Hz, H6), 3.45 (s, 3, NMe), 3.48 (broad, 1, H4′), 3.87 (t, 2, $J_{1,2}$ = $J_{1,NH}$ = 6 Hz, NCH_2), 3.90 (broad, 1, H6′), 4.62 (m, 2, H3a′ and H6a′), 5.04 (s, 1, OCH_2), 5.64 (dt, 1, $J_{2,3}$ = 15 and $J_{1,2}$ = 6 Hz, H2), 5.92 (m, 3, H4, H1″ and NH), 6.04 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5‴), 6.49 (m, 4, H3, H2″, H3″, H4″), 6.87 (d, 1, $J_{4'',5''}$ = 10 Hz, H5″), 7.30 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6‴), and 7.10, 7.43 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4).

*[3a*R*,4*S*,6*S*,6a*R*,4(*S**),5(*R**)]-5-[6-Formyltetrahydro-2,2-dimethylfuro[3,4-d]-1,3-dioxol-4-yl]-4-methoxy-3,5-dimethyl-2-pentenal (**61**), [3a*R*,4*S*,6*S*,6a*R*,1(*R**),2(*S**)]-Tetrahydro-6-(2-methoxy-1-methyl-3-oxobutyl)furo[3,4-d]-1,3-dioxole-4-carboxaldehyde (**62**), and 4-(4-Bromobenzyloxy)-1-methyl-3-pyruvoyl-2(1*H*)-pyridone (**28**)*

A solution of osmium tetroxide (102 mg) in dioxane–water (1:1, 160 mL) was combined with a solution of **60** (6.3 g, 8 mmol) in dioxane (160 mL). Sodium metaperiodate (71 g, 0.33 mol) was added in portions to the stirred solution over a one hour period. After three additional hours of stirring in the dark the mixture was filtered and the filtrate extracted continuously with diethyl ether for six hours. The dried extract was evaporated to a syrup (6.2 g) which was chromatographed on silicic acid (350 g) taking fractions of 15 mL and using chloroform (fractions 1–120), chloroform – 2-propanol (99:1, fractions 121–240), and chloroform–methanol (9:1, fractions 241–360) as mobile phases.

Fractions 206–216 contained a mixture of **61** as major and **62** as minor component and was obtained as a colorless syrup (1.5 g).

Fractions 218–236 gave a crystalline residue, which was recrystallized from methanol as colorless needles of **28** (0.68 g), R_f 0.06 (*C*) and 0.72 (*G*, blue tetrazoleum) (40).

Fractions 260–300 furnished **24** as white needles from aqueous ethanol, R_f 0.10 (*A*).

The mixture of **61** and **62** was partially resolved by chromatography on silicic acid (85 g) with chloroform as mobile phase taking 15 mL fractions. Fractions 36–48 gave a mixture of **61** and **62** in a ratio of 3:1 (0.60 g) and fractions 49–75 afforded pure **61** (0.57 g) as a colorless syrup, R_f 0.32 (*C*) and 0.86 (*G*, blue tetrazoleum); nmr ($CDCl_3$) δ: 1.09 (d, 3, $J_{5,Me}$ = 7 Hz, 5-Me), 1.27, 1.43 (2s, 3 each, 2′-Me_2), 2.15 (d, 3, $J_{2,Me}$ = 1.5 Hz, 3-Me), 2.47 (sextet, $J_{4,5}$ = $J_{4',5}$ = $J_{5,Me}$ = 7 Hz, H5), 3.26 (s, 3, 4-OMe), 3.49 (d, 1, $J_{4,5}$ = 7 Hz, H4), 3.62 (dd, 1, $J_{3a',4'}$ = 3.5 and $J_{4',5}$ = 7 Hz, H4′), 3.87 (dd, 1, $J_{6',6a'}$ = 4 and $J_{6',CHO}$ = 1.5 Hz, H6′), 4.68 (dd, 1, $J_{3a',4'}$ = 3.5 and $J_{3a',6a'}$ = 6 Hz, H3a′), 4.96 (ddt, 1, $J_{3a',6a'}$ = 6 and $J_{6',6a'}$ = 4 Hz, H6a′), 6.03 (d, 1, $J_{1,2}$ = 8 Hz, H2), 9.62 (d, 1, $J_{6',CHO}$ = 1.5 Hz, 6′-CHO), 10.08 (d, 1, $J_{1,2}$ = 8 Hz, H1).

The mixture of **61** and **62** (0.60 g) was dissolved in methanol (15 mL) and ozonized at −78°C for 30 min although ozone-uptake required only 5 min. Excess ozone was removed with nitrogen and dimethyl sulfide was added at room temperature until potassium iodide was no longer oxidized. The solution was concentrated to yield crude **62** without any remaining **61**. For further purification the residue was chromatographed on silicic acid (35 g) with chloroform as mobile phase yielding **62** (0.40 g) as the major detectable component with blue tetrazoleum, R_f 0.43 (*C*) and 0.90 (*G*); nmr ($CDCl_3$) δ: 1.11 (d, 3, $J_{1,Me}$ = 7 Hz, 1-Me), 1.25, 1.39 (2s, 3 each, 2-Me_2), 2.16 (s, 3, 3-Me), 2.56 (ddq, 1, $J_{1,2}$ = 9, $J_{1,6}$ = 5, and $J_{1,Me}$ = 7 Hz, H1), 3.35 (s, 3, 2-OMe), 3.44 (d, 1, $J_{1,2}$ = 5 Hz, H2), 3.58 (dd, 1, $J_{1,6}$ = 5 and $J_{6,6a}$ = 9 Hz, H6), 3.86 (dd, 1, $J_{3a,4}$ = 4.5 and $J_{4,CHO}$ = 1.5 Hz, H4), 4.22 (dd, 1, $J_{3a,6a}$ = 6 and $J_{6,6a}$ = 3.5 Hz, H6a), 4.46 (dd, 1, $J_{3a,4}$ = 4.5 and $J_{3a,6a}$ = 6 Hz, H3a), and 9.57 (d, 1, $J_{4,CHO}$ = 1.5 Hz, 4-CHO).

*[1*R*,3*R*,4*S*,6*S*,7*S*,8*S*,10*R*]-4-(Dimethoxymethyl)-1,7-dimethyl-8-methoxy-2,5,9-trioxatricyclo[4.2.2.0^{3,10}]decane(**64***b*), [2*S*-(2β,3β,3aα,5β,6α,6aα)]-Hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-b]furan-3-ol (**65***a*), and [2*S*-(2β,3β,3aα,5α,6α,6aα)]-Hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-b]furan-3-ol(**65***b*)*

A solution of crude **62** (560 mg) in methanol (10 mL) was cooled to −78°C and acetyl chloride (1 mL) was added. The mixture was allowed to warm to 23°C, kept for 3 h at 23°C, and then refrigerated overnight. After the solution was neutralized with 2.25 *N* methanolic sodium methoxide (6.3 mL), cyclohexane (50 mL) and water (30 mL) were added. The aqueous phase was extracted twice more with cyclohexane. From the combined, water-washed cyclohexane extracts, **64***b* was obtained as colorless prisms and recrystallized from petroleum ether (80 mg), mp 98°C (49). Additional **64***b* could be obtained by chromatography of the mother liquors on silicic acid with system *I* as mobile phase, R_f 0.67 (*C*) (sulfuric acid spray); nmr ($CDCl_3$) δ: 0.94 (d, 3, $J_{7,Me}$ = 7.5 Hz, 7-Me), 1.49 (s, 3, 1-Me), 2.40 (d quintet, 1, $J_{6,7}$ = 2 and $J_{7,8}$ = $J_{7,Me}$ = 7.5 Hz, H7), 3.36, 3.43, 3.48 (3s, 3 each, 3-OMe), 3.40 (d, 1, $J_{7,8}$ = 7.5 Hz, H8), 3.75

For personal use only.

(dd, 1, $J_{3,4}$ = 2 and $J_{4,CH}$ = 7.5 Hz, H4), 4.20 (dd, 1, $J_{6,7}$ = 2 and $J_{6,10}$ = 7.5 Hz, H6), 4.25 (dd, 1, $J_{3,4}$ = 2 and $J_{3,10}$ = 4 Hz, H3), 4.53 (d, 1, $J_{4,CH}$ = 7.5 Hz, 4-CH), 5.02 (dd, 1, $J_{3,10}$ = 4 and $J_{6,10}$ = 7.5 Hz, H10).

The aqueous phase remaining after the extraction with cyclohexane was extracted twice with chloroform to yield a residue which was chromatographed on silicic acid (10 g) collecting 10-mL fractions and using system *I* as mobile phase. Fractions 24–26 gave pure **65***b* as colorless syrup (30 mg), R_f 0.48 (*C*, sulfuric acid); nmr ($CDCl_3$) δ: 1.05 (d, 3, $J_{6,Me}$ = 7 Hz, 6-Me), 2.29 (ddq, $J_{5,6}$ = 4.5, $J_{6,6a}$ = 5.5 and $J_{6,Me}$ = 7 Hz, H6), 2.76 (broad, 1, OH), 3.35, 3.41, 3.47 (3s, 3 each, 3 OMe), 3.73 (dd, 1, $J_{2,3}$ = 3 and $J_{2,CH}$ = 7.5 Hz, H2), 4.10 (dd, 1, $J_{2,3}$ = 3 and $J_{3,3a}$ = 5.5 Hz, H3), 4.24 (dd, 1, $J_{3a,6a}$ = 6.5 and $J_{6,6a}$ = 5.5 Hz, H6a), 4.64 (d, $J_{2,CH}$ = 7.5 Hz, 2-CH), 4.64 (dd, 1, $J_{3,3a}$ = 5.5 and $J_{3a,6a}$ = 6.5 Hz, H3a), and 5.03 (d, $J_{5,6}$ = 4.5 Hz, H5).

Fractions 28–35 yielded pure **65***a* as colorless syrup (30 mg), R_f 0.43 (*C*, sulfuric acid); nmr ($CDCl_3$) δ: 1.03 (d, 3, $J_{6,Me}$ = 7.5 Hz, 6-Me), 2.48 (q, $J_{5,6}$ = $J_{6,6a}$ < 1 and $J_{6,Me}$ = 7.5 Hz, H6), 3.35 (m, 1, H2), 3.42, 3.46, 3.51 (3s, 3 each, 3 OMe, overlapping with OH), 4.06 (d, 1, $J_{3a,6a}$ = 6 Hz, H6a), 4.11 (dd, 1, $J_{2,3}$ = 3 and $J_{3,3a}$ = 6 Hz, H3), 4.66 (d, 1, $J_{2,CH}$ = $J_{2,CH}$ = 7.5 Hz, 2-CH), 4.77 (s, 1, H5), 4.92 (t, $J_{3a,5}$ = 6 Hz, H3a).

*[2S-(2β,3β,3aα,5β,6α,6aα)]-Hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-b]furan-3-ol 4-Bromophenylcarbamic Acid Ester (**66**a)*

A mixture of **65***a* (25 mg), pyridine (1.5 mL), benzene (1.5 mL), and 4-bromophenylisocyanate (35 mg) was allowed to react overnight, diluted with cyclohexane (3 mL), and filtered. The filtrate was evaporated and purified by preparative tlc, and the band with R_f 0.22 (*C*) was extracted with system *G* to afford a crystalline residue of **66***a* which was recrystallized from benzene–cyclohexane (21 mg), mp 165°C. $[\alpha]_D$ −50.5° (*c* 0.5, ethanol); nmr ($CDCl_3$) δ: 1.07 (d, 3, $J_{6,Me}$ = 7.5 Hz, 6-Me), 2.43 (tq, 1, $J_{5,6}$ = $J_{6,6a}$ = 3 and $J_{6,Me}$ = 7.5 Hz, H6), 3.28, 3.37, 3.43 (3s, 3 each, 3 OMe), 3.90 (dd, 1, $J_{2,3}$ = 4 and $J_{2,CH}$ = 7.5 Hz, H2), 4.17 (dd, 1, $J_{3a,6a}$ = 6 and $J_{6,6a}$ = 3 Hz, H6a), 4.66 (d, 1, $J_{2,CH}$ = 7.5 Hz, 2-CH), 4.72 (d, 1, $J_{5,6}$ = 3 Hz, H5), 4.88 (t, 1, $J_{3,3a}$ = 5.5 and $J_{3a,6a}$ = 6 Hz, H3a), 5.21 (dd, 1, $J_{2,3}$ = 4 and $J_{3,3a}$ = 5.5 Hz, H3), 6.89 (s, 1, NH), and 7.34, 7.40 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4). *Anal.* calcd. for $C_{18}H_{24}BrNO_7$ (446.30): C 48.44, H 5.42, N 3.14; found: C 48.56, H 5.52, N 3.21.

A crystal of **66***a* with the dimensions of 0.01 mm × 0.08 mm × 0.35 mm served for crystallographic analysis. It was of space group $P2_1$ with unit-cell dimensions a = 5.245(6), b = 13.981(10), c = 13.980(20) Å, β = 94.85(8)° and d calcd. = 1.449 g/cm³ for Z = 2. Of the 1020 reflections examined (2θ < 96.5°) only 520 were considered significant due to the small size of the crystal. The structure was solved by Patterson and Fourier methods with final refinement by full-matrix least squares. Anisotropic thermal parameters were used for the bromine atom and isotropic temperature factors were used for the lighter atoms; the hydrogen atoms were not included. The final discrepancy index is R = 0.082 (Fig. 11). Attempts to determine the absolute configuration of **66***a* on the basis of the available crystallographic data gave inconclusive results.

*[2S,(2β,3β,3aα,5α,6α,6aα)]-Hexahydro-5-methoxy-2-(dimethoxymethyl)-6-methylfuro[3,2-b]furan-3-ol 4-Bromophenylcarbamic Acid Ester (**66**b)*

The alcohol **65***b* was converted to the urethane **66***b*, purified by preparative tlc (R_f 0.53, *C*) as described for the anomer, and obtained as colorless needles from benzene–cyclohexane, mp 156°C; $[\alpha]_D$ −129.9° (*c* 0.5, ethanol); nmr ($CDCl_3$) δ: 1.07 (d, 3, $J_{6,Me}$ = 7.5 Hz, 6-Me), 2.32 (tq, 1, $J_{5,6}$ = $J_{6,6a}$ = 4.5 and $J_{6,Me}$ = 7.5 Hz, H6), 3.32, 3.37, 3.42 (3s, 3 each, 3 OMe), 4.00 (dd, 1, $J_{2,3}$ = 4.5 and $J_{2,CH}$ = 7.5 Hz, H2), 4.31 (dd, 1, $J_{3a,6a}$ = 6.5 and $J_{6,6a}$ = 4.5 Hz, H6a), 4.64 (d, 1, $J_{2,CH}$ = 7.5 Hz, 2-CH), 4.79 (dd, 1, $J_{3,3a}$ = 6 and $J_{3a,6a}$ = 6.5 Hz, H3a), 4.95 (d, 1, $J_{5,6}$ = 4.5 Hz, H5), 5.28 (dd, 1, $J_{2,3}$ = 4.5 and $J_{3,3a}$ = 6 Hz, H3), 6.70 (s, 1, NH), and 7.33, 7.41 (AA′BB′, 4, J_0 = 8.5 Hz, C_6H_4). *Anal.* calcd. for $C_{18}H_{24}BrNO_7$ (446.30): C 48.44, H 5.42, N 3.14; found: C 48.52, H 5.53, N 2.98.

Diffraction data of **66***b* were collected from a crystal with the dimensions of 0.15 mm × 0.30 mm × 0.45 mm, space group $P2_1$, and unit-cell dimensions of a = 11.371(5), b = 8.965(5), c = 10.116(5) Å, β = 94.66(4)° and d calcd. = 1.441 g/cm³ for Z = 2. Of the 2286 accessible reflections with 2θ < 152°, 2011 were considered significant. The structure was solved by the heavy atom method. Four Fouriers, based on successively more complete trial structures, were required to locate all non-hydrogen atoms. During the preliminary refinement of the structures the imaginary part of the anomalous dispersion correction ($\Delta f''$) was set to zero. At the conclusion of this refinement, in which all atoms were anisotropic, the positions of the hydrogen atoms were calculated. The hydrogen atoms were included in all subsequent calculations but their parameters were not refined. The final refinement of the structure was carried out by full-matrix least squares. In order to establish the absolute configuration, two separate refinements were made. In one the correct value of the imaginary part of the dispersion correction was used and in the other the sign of $\Delta f''$ was reversed (equivalent to refining the antipode of **66***b*). The absolute configuration was taken as the one which had the lower weighted R-value (0.0529 and 0.0572). The configuration corresponding to the higher R-value could be rejected (as being the correct absolute configuration) at a significance level substantially better than 0.005, according to the test described by Hamilton (57). The final unweighted discrepancy index is R = 0.037 for the 2011 observed reflections (Fig. 11).

*Mocimycin Methyl Ether (N-Desmethyl-**17**) and Aurodox Methyl Ether (**17**)*

Methyl iodide (2 mL) was added to a solution of mocimycin sodium salt (3 g) in dimethylformamide (15 mL) and the mixture kept in the dark for 4 days. The mixture was then equilibrated with ethyl acetate (250 mL) and water (50 mL). The ethyl acetate phase was washed with water (2 × 50 mL), 0.5 *M* trisodium phosphate solution (6 × 50 mL), water (5 × 50 mL), dried, and evaporated to afford an amorphous, yellow powder (1.7 g) which proved to be a mixture of two major components. Upon chromatography of this mixture on a column of Sephadex LH-20 (55 mm × 720 mm) with acetone as mobile phase, **17** (8) was eluted first (R_f 0.76, *A*) and obtained as yellow powder upon evaporation of the pooled fraction (0.4 g), rechromatography (Sephadex LH-20, 2-butanone) and precipitation from acetone – petroleum ether.

Continued elution furnished *N*-desmethyl-**17** (8), obtained as yellow powder (0.6 g) after rechromatography (Sephadex LH-20, 2-butanone) and precipitation from acetone – petroleum ether. Additional *N*-desmethyl-**17** (0.3 g) was obtained from aqueous extracts of the combined trisodium phosphate phases after chromatographic purification.

Compound **17** could also be prepared directly from **1***b*. A solution of **1***b* sodium salt in dimethylformamide and methyl iodide (10 mL) was shaken for 4 days in the dark and poured into a separatory funnel containing ethyl acetate (75 mL) and 5% aqueous sodium hydrogen carbonate solution (25 mL).

The organic phase was washed twice with sodium hydrogen carbonate solution, three times with brine, dried, filtered, and evaporated yielding crude **17** (4.59 g). A portion (1.5 g) was chromatographed on a column of Sephadex LH-20 (51 mm × 510 mm) with acetone as mobile phase. Homogeneous fractions (tlc) were pooled and evaporated to afford **17** as yellow, amorphous powder (1.0 g) (8).

[2R,3R,4S,5S,1(R),2(S*)]-4-Methoxy-1-methyl-3-[7-[5-[7-amino-2-methoxy-1,3-dimethyl-3(E),5(E)-heptadienyl]-3,4-dihydroxytetrahydro-2-furyl]-2-methyl-1-oxo-2(E),4(E),6(E)-heptatrienyl]-2(1H)-pyridone Acetic Acid Salt (**21** Acetic Acid Salt)*

A solution of **17** (2.35 g) in acetic acid (20 mL) was either allowed to stand at room temperature in the dark for 4.5 days or was heated on the steam bath for 20 min, the solvent was evaporated, and the residue subjected to Craig distribution in chloroform–methanol – acetic acid – water (5:1:1:4). After 199 transfers, tubes 145–177, which contained a homogeneous solute, were pooled, concentrated, and freeze-dried, yielding goldinamine methyl ether acetic acid salt (**21** acetic acid salt) as amorphous, yellow powder (0.97 g), R_f 0.64 (*A*); nmr ($CDCl_3$) δ: 0.84 (d, 3, $J_{1,Me}$ = 7 Hz, 1-Me), 1.67 (s, 3, 3-Me), 2.00 (s, 6, OAc and 2″-Me), 2.17 (m, 1, H1), 3.17 (s, 3, 2-OMe), 3.25 (d, 1, $J_{1,2}$ = 9.5 Hz, H2), 3.49 (s, 3, NMe), 3.49 (broad, 3, NCH_2 and H5′), 3.76 (s, 3, 4″-OMe), 4.17 (m, 1, H2′), 4.34 (m, 2, H3′ and H4′), 5.97 (m, 3, H4, H6, H7″), 6.10 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H5‴), 6.49 (m, 4, H4″, H5, H5″, H6″), 6.86 (d, 1, $J_{3'',4''}$ = 10 Hz, H3″), 7.38 (d, 1, $J_{5''',6'''}$ = 7.5 Hz, H6‴).

[8]Proton designations are those used in **22** (Scheme 6).

[2S,3S,4R,5R,6(S),7(R*)]-N-[7-[5-[7-(1,2-Dihydro-4-methoxy-1-methyl-2-oxo-3-pyridinyl)-6-methyl-7-oxo-1(E),3(E),5(E)-heptatrienyl]tetrahydro-3,4-dihydroxyfuran-2-yl]-6-methoxy-5,7-dimethyl-2(E),4(E)-heptadienyl]trifluoroacetamide (**47**)*

Goldinamine methyl ether acetic acid salt (**21** acetic acid salt, 105 mg) was converted to the *N*-trifluoroacetamide as described above in the preparation of **46**. The evaporated reaction product was chromatographed on a column of Sephadex LH-20 (acetone) to yield **47** as yellow powder (87 mg), R_f 0.23 (*B*). *Mol. Wt.* calcd. for $C_{31}H_{39}F_3N_2O_8$: 624.66; found (ms) *m/e* (%): 624 (0.4), 166 (1,2-dihydro-4-methoxy-1-methyl-2-oxo-3-carbonyl cation, 100).

[2S,3S,4R,5R,6(S),7(R*)]-N-[7-[5-[7-(1,2-Dihydro-4-methoxy-1-methyl-2-oxo-3-pyridinyl)-6-methyl-7-oxo-1(E),3(E),5(E)-heptatrienyl]tetrahydro-3,4-dihydroxyfuran-2-yl]-6-methoxy-5,7-dimethyl-2(E),4(E)-heptadienyl]acetamide (**49**)*

A solution of **21** acetic acid salt (200 mg) in methanol (1.5 mL) and acetic anhydride (0.7 mL) was kept overnight at 25°C and added to a mixture of ether (55 mL) and petroleum ether. The precipitate was collected by centrifugation, washed repeatedly, and chromatographed on a column of Sephadex LH-20 with 2-butanone as mobile phase. The *N*-acetyl compound, **49**, was obtained as amorphous, yellow powder (152 mg), R_f 0.53 (*A*). *Mol. Wt.* calcd. for $C_{31}H_{42}N_2O_8$: 570; found (ms) *m/e*: 570, 552 (M − H_2O), 538 (M − MeOH), 520 (M − H_2O − MeOH), and 506 (M − 2MeOH) as highest mass peaks. Calculated: 552.2840 ($C_{31}H_{40}N_2O_7$), 538.2683 ($C_{30}H_{38}N_2O_7$), 520.2577 ($C_{30}H_{36}N_2O_6$), 506.2420 ($C_{29}H_{34}N_2O_6$); found: 552.2844, 538.2701, 520.2566, 506.2429.

[2S,3R,4S,5R,6(S),7(R*)]-N-[7-[5-[7-(1,2-Dihydro-4-methoxy-1-methyl-2-oxo-3-pyridinyl)-6-methyl-7-oxo-1(E),3(E),5(E)-heptatrienyl]tetrahydro-3,4-dimethoxyfuran-2-yl]-6-methoxy-5,7-dimethyl-2(E),4(E)-heptadienyl]acetamide (**50**)*

To a solution of **49** (100 mg) in dimethylformamide (1 mL) was added barium oxide (100 mg) and barium hydroxide octahydrate (100 mg) followed by dimethylsulfate (0.2 mL) (58). After stirring for 24 h additional barium oxide (100 mg) and dimethylsulfate (0.1 mL) were added. After a total reaction time of 40 h concentrated ammonium hydroxide solution (0.2 mL) was added and stirring continued for 10 min. Addition of chloroform (10 mL) to the stirred mixture was followed by centrifugation. The chloroform solution was decanted and the syrupy solids were washed repeatedly with chloroform. The combined chloroform extracts were washed with brine (3 × 10 mL) and water (10 mL) and evaporated. The resulting solution of **50** in *N,N*-dimethylformamide was diluted with acetone and chromatographed on a column of Sephadex LH-20 (acetone). Pure **50** (30 mg) was isolated as usual, R_f 0.10 (*B*). *Mol. Wt.* calcd. for $C_{33}H_{46}N_2O_8$: 598.74; found (ms) *m/e*: 598, 566 (M − MeOH), and 534 (M − 2MeOH) as highest mass peaks. Calculated: 598.3259 ($C_{33}H_{46}N_2O_8$), 566.2996 ($C_{32}H_{42}N_2O_7$), 534.2734 ($C_{31}H_{38}N_2O_6$); found: 598.3326 (extrapolated over 30 mass units), 566.2979, 534.2728.

*(2E,4E,6E)-8-[4-Methoxy-1,2-dihydro-1-methyl-2-oxo-3-pyridinyl]-7-methyl-8-oxo-2,4,6-octatrienoic Acid (**29**)*

To a solution of **21** acetic acid salt (200 mg) in methanol (4 mL) and dioxane (16 mL) was added sodium metaperiodate (0.5 g) in water (20 mL). The mixture was stirred for 4 h at 25°C in the dark, the pH was adjusted to 8.4 with barium hydroxide and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

resulting suspension centrifuged. Acetic anhydride (1.5 mL) was added to the supernatant under stirring, followed by another 0.5 mL 30 min later. After one hour the mixture was adjusted to pH 8.4 with sodium hydroxide and repeatedly extracted with diethyl ether. Drying and evaporation of the combined ether phase gave **34** (50 mg). The aqueous phase was adjusted to pH 3 (sulfuric acid) and extracted with dichloromethane (2 × 40 mL). Evaporation gave a residue which crystallized from methanol–chloroform–ether to yield **29** as yellow prisms, R_f 0.13 (*A*), 0.52 (*J*); mp 220–222°C; uv λ_{max} (ε): 208–209 (32 500), inflection 232–233 (5 500), inflection 295 (16 000), 331–332 (41 200), and inflection 340 (39 900) nm in 0.1 *N* HCl, 208–209 (33 000), inflection 232 (8 000), inflection 295 (16 000), and 333–340 (39 600) nm in buffer (pH = 7), inflection 232 (7 800), inflection 295 (16 500), and 332–340 (40 000) nm in 0.1 *N* KOH; nmr (Me_2SO-d_6) δ: 1.91 (s, 3, 7-Me), 3.37 (s, 3, OMe), 3.72 (s, 3, NMe), 5.95 (d, 1, $J_{2,3}$ = 15 Hz, H2), 6.31 (d, 1, $J_{5',6'}$ = 7.5 Hz, H5′), 6.70 (dd, 1, $J_{3,4}$ = 11 and $J_{4,5}$ = 14.5 Hz, H4), 6.81 (d, 1, $J_{5,6}$ = 11 Hz, H6), 7.12 (dd, 1, $J_{4,5}$ = 14.5 and $J_{5,6}$ = 11 Hz, H5), 7.30 (dd, 1, $J_{2,3}$ = 15 and $J_{3,4}$ = 11 Hz, H3), and 7.79 (d, 1, $J_{5',6'}$ = 7.5 Hz, H6′). *Mol. Wt.* calcd. for $C_{16}H_{17}NO_5$: 303.33; found (ms) *m/e (%)*: 303 (17), 166 (100).

*[1R-(1β,2α,6α,8β)]-4,4-Dimethyl-3,5,7,11-tetraoxatricyclo-[6.3.0.0^{2,6}]undecan-9-one (**68**)*

To a vigorously stirred solution of 3,6-anhydro-1,2-*O*-isopropylidine-α-D-glucofuranose (**67**, 1.70 g, 8.41 mmol) (50) (R_f 0.07 (*H*), greenish color with anisaldehyde – sulfuric acid spray) in dichloromethane (50 mL) was added dropwise ca. 0.2 *M* sodium metaperiodate solution while keeping the pH at 6–7 with intermittent addition of sodium hydrogen carbonate solution (59). Addition was complete after 30 min as indicated by a permanent color change from dark to greenish yellow. Stirring was continued for 3 h, 1-propanol (0.5 mL) was added, and the mixture was filtered 15 min later. The dichloromethane phase was decanted, combined with two further extracts, washed twice with a little water, dried, and evaporated to yield **68** as a syrup. Short-path distillation (bath temperature 105°C, 0.5 Torr) gave a colorless syrup (1.45 g, 7.24 mmol, 86%) which crystallized very slowly on standing, R_f 0.06 (*H*), reddish color with anisaldehyde; ir (neat) ν: 1778 (ketone) cm^{-1}; nmr ($CDCl_3$) δ: 1.33, 1.48 (2s, 3 each, 4-Me_2), 3.90, 4.24 (AB, 2, $J_{10a,10b}$ = 17 Hz, H10), 4.40 (d, 1, $J_{1,8}$ = 3 Hz, H1), 4.71 (d, 1, $J_{1,8}$ = 3 Hz, H8), 4.75 (d, 1, $J_{1,2}$ = 0 and $J_{2,6}$ = 3.5 Hz, H2), 6.02 (d, 1, $J_{2,6}$ = 3.5 Hz, H6).

*[1S-(1β,2α,6α,8β)]-4,4-Dimethyl-9-methylene-3,5,7,11-tetraoxatricyclo[6.3.0.0^{2,6}]undecane (**69**)*

A hexane solution of *n*-butyllithium (3.75 mL, 1.6 *M*) was added to diethyl ether (15 mL) under argon followed by methyltriphenylphosphonium bromide (2.14 g, 6 mmol) in one portion under stirring. A solution was gradually obtained and after 4 h of continued stirring a solution of **68** (1 g, 5 mmol) in diethyl ether (15 mL) was added. The resulting suspension was refluxed under stirring for 3 h and stirred overnight at room temperature. The ethereal supernatant was combined with three additional ether extracts, washed with water, dried, and evaporated to a syrup. Dissolving the syrup in a little chloroform and adding petroleum ether deposited crystalline triphenylphosphine oxide. Evaporation of the mother liquor gave a syrup containing mostly **69** purified by chromatography on a column of silica gel with system *I* as mobile phase to give **69** as colorless syrup (0.249 g, 1.26 mmol), R_f 0.53 (*H*), brownish color with anisaldehyde – sulfuric acid spray; nmr ($CDCl_3$) δ: 1.34, 1.52 (2s, 3 each, 4-Me_2), 4.30, 4.54 (tAB, 2, $J_{6,7}$ = 2 and $J_{10a,10b}$ = 13 Hz, H10), 4.43 (d, 1, $J_{1,2}$ = 0 and $J_{1,8}$ = 3.5 Hz, H1), 4.67 (d, 1, $J_{1,2}$ = 0 and $J_{1,8}$ = 4 Hz, H2), 5.00 (d, 1, $J_{1,8}$ = 3.5 Hz, H8), 5.15, 5.40 (2t, 1 each, $J_{6,7}$ = 2 Hz, =CH_2), 5.93 (d, 1, $J_{2,6}$ = 4 Hz, H6).

*[1S-(1β,2α,6α,8β,9α)]-4,4,9-Trimethyl-3,5,7,11-tetraoxatricyclo[6.3.0.0^{2,6}]undecane (**70**)*

Catalytic hydrogenation of **69** (50 mg) over palladium-on-charcoal (10%, 50 mg) in ethanol (2.5 mL) for 2 h at 3.5 atm gave a mixture of **70** (88%) and **71** (12%) both with R_f 0.53 (*H*), olive-green color with anisaldehyde – sulfuric acid spray.

Nuclear magnetic resonance of **70** ($CDCl_3$) δ: 1.08 (d, 3, $J_{9,Me}$ = 7 Hz, 9-Me), 1.31, 1.47 (2s, 3 each 4-Me_2), 2.23 (m, 1, $J_{8,9}$ = 3.5, $J_{9,10a}$ = 7, and $J_{9,10b}$ = 10.5 Hz, H9), 3.35 (dd, 1, $J_{9,10b}$ = 10.5 and $J_{10a,10b}$ = 7.5 Hz, H10b), 3.90 (t, 1, *J* = 7.5 Hz, H10a), 4.43 (d, 1, $J_{1,2}$ = 0 and $J_{1,8}$ = 3.5 Hz, H1), 4.50 (d, 1, $J_{1,2}$ = 0 and $J_{2,6}$ = 3.5 Hz, H2), 4.68 (t, 1, $J_{1,8}$ = $J_{8,9}$ = 3.5 Hz, H8), 5.86 (d, 1, $J_{2,6}$ = 3.5 Hz, H6).

*[1S-(1β,2α,6α,8β,9β)]-4,4,9-Trimethyl-3,5,7,11-tetraoxatricyclo[6.3.0.0^{2,6}]undecane (**71**)*

Potassium azodicarboxylate (971 mg, 5 mmol) was added to a solution of **68** (198 mg, 1 mmol) in methanol (5 mL) and a solution of 2 *N* acetic acid in methanol (5 mL) was added to the yellow suspension at a rate of 1 mL/6 min under vigorous stirring. Stirring was continued for 1 h. Diethyl ether (10 mL) was added to the colorless mixture, the salts were filtered off, and the filtrate evaporated. The resulting residue was extracted with hot cyclohexane affording a mixture of **69** (35.9%), **70** (21.5%), and **71** (42.6%) as determined by glpc (column 3 m × 4 mm; OV-225, 10%, on GCQ 100/200; column temperature 80→190°C, 2°/min, retention times 54, 51.0, and 51.6 min, respectively).

Nuclear magnetic resonance of **71** ($CDCl_3$: 0.97 (d, 3, $J_{9,Me}$ = 7 Hz, 9-Me), 1.31, 1.47 (2s, 3 each, 4-Me_2), 2.42 (ddq, 1, $J_{9,10b}$ = $J_{9,Me}$ = 7 Hz and $J_{8,9}$ = 1 Hz, H9), 3.51 (dd, 1, $J_{9,10a}$ = 1.5 and $J_{10a,10b}$ = 8 Hz, H10a), 3.94 (dd, 1, $J_{9,10b}$ = 5.5 and $J_{10a,10b}$ = 8 Hz, H10b), 4.43 (d, 1, $J_{1,2}$ = 0 and $J_{1,8}$ = 3.5 Hz, H1), 4.54 (d, 1, $J_{1,2}$ = 0 and $J_{2,6}$ = 3.5 Hz, H2), 4.58 (dd, 1, $J_{1,8}$ = 3.5 and $J_{8,9}$ = 1 Hz, H8), 5.86 (d, 1, $J_{2,6}$ = 3.5 Hz, H6).

ALFIO CORSINI, HUSAIN MEHDI, and ALLEN CHAN. Can. J. Chem. **58**, 527 (1980).

When carbon monoxide gas is interacted with a methanolic reagent solution of hydrazine and K[Ru(III)OEP(CN)$_2$] (OEP = octaethylporphyrin), a carbonylated complex of Ru(II)OEP is formed and excess carbon monoxide is strongly adsorbed on the walls of the fused-quartz reaction cell. The adsorbed carbon monoxide is very difficult to remove and unless appropriate measures are taken, it remains on the cell walls to interact with the reagent solution in subsequent experiments, thus leading to the possibility of erroneous interpretation. The amount of adsorbed carbon monoxide, while less than a complete monolayer, is significant.

ALFIO CORSINI, HUSAIN MEHDI et ALLEN CHAN. Can. J. Chem. **58**, 527 (1980).

Quand le monoxyde de carbone gazeux réagi avec une solution méthanolique de réactif d'hydrazine et de K[(Ru(III)OEP(CN)$_2$], il se forme un complexe carbonylé de Ru(III)OEP et l'excès de monoxyde est fortement adsorbé par les parois de la cellule de la réaction en quartz fondu. Le monoxyde carbone adsorbé est très difficile à enlever et bien que des précautions soient prises, il demeure dans les parois de la cellule et réagi par la suite avec le réactif en solution dans d'autres expériences conduisant ainsi à des interprétations erronées. La quantité de monoxyde de carbone absorbée est significative bien qu'elle soit moindre qu'une monocouche complète.

There has been considerable interest in the study of dioxygen, dinitrogen, and carbonyl derivatives of synthetic metalloporphyrins with the view towards the development of simple models that mimic the behaviour of the more complex biological heme proteins (e.g., refs. 1–6).

Our interest in metalloporphyrins has been focused on their suitability as potential selective analytical reagents for the determination of carbon monoxide in polluted atmospheres. In an effort to improve upon the sensitivity of the Fe(II)TPP(pip)$_2$ system (TPP = *meso*-tetraphenylporphine, pip = piperidine) for CO (7), we have initiated a study of Ru(II) porphyrins as potential reagents. This study was stimulated by reports of the formation of stable carbonylated complexes of several Ru(II) porphyrins (6, 8–12).

We wish to report that in the course of investigations with the Ru(II)OEP complex (OEP = octaethylporphyrin), we found that the surface of the fused-quartz cells used in the work became grossly contaminated with strongly adsorbed CO, which subsequently interacted with the Ru(II)OEP reagent solution in later experiments. A purpose of this report is to caution other workers engaged in similar studies with metalloporphyrins to ensure that the surfaces of reaction vessels are free of adsorbed CO prior to experimentation.

Experimental

Spectrophotometric Measurements

Spectra of the ruthenium complexes of OEP in the visible range were recorded on a GCA McPherson double-beam spectrophotometer, Model EU-700, against methanol or distilled water references. Stoppered fused-quartz cells (1 cm) were used. Differential infrared measurements to identify CO adsorbed on the surface of a thin plate (1 mm) of fused quartz were made with a Nicolet 7199 FT-IR instrument. The quartz plate was clamped onto a cell holder and positioned in the same way each time a spectrum (100 scans) was taken.

Materials

All chemicals used were of sufficient purity for the purpose intended. CO gas was used directly from lecture bottles. $Ru_3(CO)_{12}$ and OEP were obtained from the Strem Chemical Co.

Syntheses

Ru(II)OEP(CO)(CH$_3$OH)

$Ru_3(CO)_{12}$ (250 mg) and OEP (250 mg) were refluxed in toluene (100 mL) for 24 h under nitrogen. Removal of unreacted solid and of the solvent yielded crude Ru(II)OEP(CO) which was chromatographed in benzene on Grade V alumina. The intense orange band was collected and the benzene removed to give the purified orange carbonyl complex (ν_{CO}^{KBr} = 1950 cm^{-1}). A dilute solution (~5×10^{-6} *M*) in methanol gave a spectrum in the visible range virtually identical to that for Ru(II)OEP(CO)-(C_2H_5OH) reported by Farrell *et al.* (6).

Ru(II)OEP(py)$_2$

The dipyridinate was prepared by modification of the procedure used by Hopf *et al.* (11). The solution of Ru(II)OEP(CO) (60 mg) in freshly distilled pyridine (10 mL) was placed in a thick-walled quartz tube and subjected to at least 5 freeze–pump–thaw cycles. The tube was sealed and irradiated at 300 nm (Rayonet apparatus) for 3 days. Ru(II)OEP(py)$_2$ formed as a dark precipitate. After removal of the excess pyridine, the solid was dissolved in benzene and chromatographed in 90% benzene – 10% pyridine on Grade 1 alumina. The major dark band was collected. If a band at 1950 cm^{-1} was observed in the infrared spectrum of the product, the latter was rechromatographed. The spectrum in the visible range has been previously reported (11).

K[Ru(III)OEP(CN)$_2$]

The procedure of Chow and Cohen (8) for K[Ru(III)-

$TPP(CN)_2$] was followed except that 50 mg of $Ru(II)OEP(py)_2$, 50 mL of THF (freshly distilled), and 1 mL of a saturated aqueous solution of KCN (freshly recrystallized) were interacted under reflux (using a double-condenser system) for 4 days, with a stream of filtered air gently bubbling through the mixture. Any THF lost by evaporation was replaced. Progress of the reaction was followed by periodic removal of an aliquot for spectral testing. The spectrum of $K[Ru(III)OEP(CN)_2]$ is quite distinct from that of $Ru(II)OEP(py)_2$. After complete reaction, the solvent was removed and the residue treated with a small volume of water to dissolve excess solid KCN. The product was collected on a fine frit, washed with water, dried at 80°C in a vacuum desiccator for 2 days, and recrystallized from methanol. The visible spectrum is given in Fig. 1.

Reagent Solution and Reaction with CO

A 5.0×10^{-5} *M* stock solution of $K[Ru(III)OEP(CN)_2]$ in methanol was prepared. Exactly 1.000 mL of this solution was placed in a 10-mL volumetric flask by means of a Gilmont micropipette, followed by about 5 mL of methanol, 100 μL (Eppendorf pipet) of fresh hydrazine, and then sufficient methanol to the mark. The final solution was about 0.3 *M* in hydrazine. A 1.00-cm fused quartz cell was filled with this solution and CO gas from a lecture bottle was gently bubbled through it for 2 to 10 min. The spectrum was then recorded and compared to that of the reagent solution through which no CO gas was passed (Fig. 1). The cell was cleaned, normally by rinsing twice with methanol which is sufficient to remove $Ru(II)OEP(CO)(CH_3OH)$ from the quartz walls, and fresh reagent solution was then introduced for additional experiments.

Results and Discussion

The experiments described in this work were qualitative in nature; quantitative experiments relating to the analytical determination of CO in atmospheres will be reported later.

The spectrum of $K[Ru(III)OEP(CN)_2]$ (curve 1, Fig. 1) is characteristic of Ru(III) porphyrins (Soret band at 390 nm and broad, less intense absorption at about 480–560 nm) and is very similar to that reported for $K[Ru(III)TPP(CN)_2]$ (8) and the $Ru(III)(OEP)(CH_3CN)_2^+$ cation (6). The addition of hydrazine results in a spectrum (curve 2, Fig. 1) resembling those (6, 11, 12) of non-carbonylated Ru(II) porphyrins (a broadened, less intense Soret band at 394 nm than exhibited by carbonylated Ru(II) porphyrins and maxima at 498 and 526 nm). We believe the spectrum corresponds to the complex $Ru(II)OEP(N_2H_4)_2$ for which the hydrazine (in large excess at 0.3 *M*) serves not only to reduce Ru(III) to Ru(II) but also to ligate the metal ion. We have not been able to isolate the complex in purity because of its decomposition in solution. At analytical concentrations of 4.98×10^{-6} and 2.49×10^{-6} *M*, a pseudo first-order rate constant of $1.50 \pm 0.01 \times 10^{-4}$ s^{-1} was calculated for the decomposition.

When CO gas is passed through a freshly prepared reagent solution, a spectrum (curve 3, Fig. 1) typical of those (6, 11, 12) for carbonyl derivatives of 6-coordinate Ru(II) complexes is obtained, with

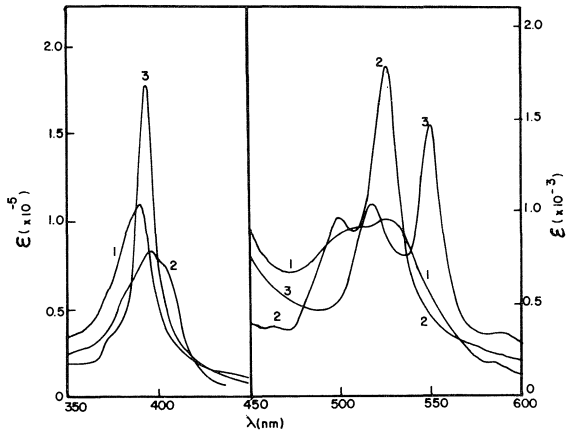

FIG. 1. Spectra of 5.0×10^{-6} *M* $K[Ru(III)OEP(CN)_2]$ in methanol, curve 1; with N_2H_4 (0.3 *M*) added, curve 2; and with CO gas subsequently passed through the solution for 2 min, curve 3.

a sharp intense Soret band at 394 nm ($\varepsilon = 1.75 \times 10^5$ M^{-1} cm^{-1}) and maxima at 518 nm ($\varepsilon = 10.3 \times 10^3$) and 550 nm ($\varepsilon = 14.8 \times 10^3$). Maximum absorbance was attained after 2 min of gentle bubbling. A FTIR spectrum (250 scans) in which the solvent absorption was subtracted showed the ν_{CO} bands at 1939 cm^{-1}, indicating the formation of a monocarbonyl rather than a dicarbonyl Ru(II) porphyrin, the latter being characterized by appreciably higher stretching frequencies (8, 10). Unlike the reagent solution, the CO complex is stable and is, presumably, $Ru(II)OEP(CO)(N_2H_4)$. As indirect evidence supporting this formulation, it was observed that the 391 and 548 nm bands of Ru(II)-OEP(CO)MeOH were shifted precisely to 394 and 550 nm on addition of N_2H_4 to a solution of the methanol complex. Also, the addition of N_2H_4 to a solution of Ru(II)OEP(CO) in CCl_4 caused shifts of the 395, 517, and 549 nm bands of the 5-coordinate complex to 398, 520, and 551 nm, respectively. In the infrared region, ν_{CO} shifted from 1955 to 1960 cm^{-1}. These shifts strongly indicate coordination of N_2H_4. (The NH_2 stretching frequencies in the region 3300–3100 cm^{-1} were due in part to excess N_2H_4.)

We noted that, curiously, when fresh reagent solution was placed and allowed to stand in a previously used fused-quartz cell cleansed in the normal manner, the characteristic maxima of the CO complex at 394, 518, and 550 nm "grew" into the spectrum with time. Typically, after 2.5 h, the absorbance of the Soret band at 394 nm was nearly 0.5 units. As the quartz cell was tightly sealed to eliminate the atmosphere as a source of CO, it was deemed that the CO was adsorbed on the inside surface of the cell from previous experiments. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

source was confirmed by the following observations: (*a*) when an identical cell not exposed to CO was used, the spectrum was that of the reagent with no appearance of the bands at 394, 518, and 550 nm, but when the interior surface of the cell was exposed beforehand to a stream of CO, the bands reappeared and grew with time; (*b*) a FTIR difference spectrum between two plates of a disassembled quartz cell, one exposed to CO and the other not, revealed a band at 2068 cm^{-1} due to adsorbed CO. This band was greatly diminished in intensity after the contaminated plate was submerged in reagent solution for several hours and the 394, 518, and 550 nm bands were clearly evident in the visible spectrum of the resulting solution.

The binding of CO to surfaces of silica, silicates, metal oxides, and transition metals to form an adsorbed phase is well documented (13–19). In fact, CO is one of the most strongly chemisorbed of the simple gases. Often, both vacuum pumping and baking are not sufficient to entirely remove the adsorbed CO from the surface. This observation was confirmed in the present study. Thus, when cells contaminated with CO were rinsed 6 times with methanol and subsequently either heated in a vacuum desiccator at 120°C for 0.5 h or soaked in an ammoniacal cuprous chloride solution for 1 day and then filled with the reagent solution, the bands of the CO complex were still observed, although with a reduction in intensity of about 75%. The most effective cleaning agent proved to be the reagent solution itself. The bands were not observed after the cells had been twice soaked in the reagent solution for 3.5 h and then refilled. This strong affinity of the Ru(II)OEP complex for CO is consistent with that observed for $Ru(II)TPP(aniline)_2$, which is reported to decarbonylate acetic anhydride (8). The tenacity with which the CO is bound to the fused-quartz surface suggests that it is chemisorbed rather than physically entrained.

From Beer's law and the volume of the cell, the amount of CO adsorbed on the cell walls was calculated to be 2.2×10^{-7} g. If the surface is assumed to be smooth, the number of CO molecules adsorbed per cm^2 is $\sim 10^{14}$; however, because the surface of fused quartz is very flawed and irregular, the actual value will be considerably lower and certainly much lower than that required for a complete monolayer ($\sim 10^{15}/cm^2$).

Our suspicions regarding surface contamination by CO were initially aroused in experiments to determine whether dinitrogen would bind to the Ru(II) porphyrin, as had been observed with Ru(II)mesoporphyrinIX(py) in monolayer assemblies (12) and, apparently, with $Ru(II)OEP(DMF)_2$ (6). The bubbling of N_2 gas through the reagent solution sometimes produced spectral changes (i.e., the growth of maxima at 394, 518, and 550 nm) and sometimes yielded only the spectrum of the decomposing reagent. These observations can now be understood in terms of CO contamination of some of the cells. (Under the solution conditions reported above and with clean cells, formation of the dinitrogen complex was not observed. Chow and Cohen (8) also observed no reaction between molecular nitrogen and Ru(II) porphyrins.) It is our hope that this report will provide a note of caution to other investigators involved in work related to the binding of gaseous species to metalloporphyrins.

Carbocyclic phenylaminephosphonate stereochemistry as probed via ^{13}C nmr chemical shifts and nuclear spin couplings from ^{13}C to ^{31}P and ^{15}N

GERALD W. BUCHANAN AND FREDERICK G. MORIN

Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received July 16, 1979

GERALD W. BUCHANAN and FREDERICK G. MORIN. Can. J. Chem. **58**, 530 (1980).

^{13}C nmr chemical shifts and ^{13}C—^{31}P couplings through one, two, and three bonds are reported for eleven carbocyclic phenylaminephosphonates with ring sizes from four to seven. On the basis of these data, inferences regarding preferred conformations are drawn. Low temperature spectra of the 4-methylcyclohexyl derivative show the existence of two conformers, populated in the ratio of approximately 2:1 at 183 K.

GERALD W. BUCHANAN et FREDERICK G. MORIN. Can. J. Chem. **58**, 530 (1980).

On rapporte les déplacements chimiques en rmn du ^{13}C et les constantes de couplage ^{13}C—^{31}P à travers un, deux et trois liens pour onze phenylaminophosphonates carbocycliques avec les grandeurs des cycles allant de quatre à sept chaînons. Sur la base de ces données, on tire des conclusions concernant les conformations privilegiées. Les spectres, obtenus à la basse temperature montrent l'existence de deux conformations peuplées dans la proportion approximative de 2:1 à 183 K, pour le dérivé 4-méthylcyclohéxyle.

Introduction

Recent publications from this laboratory (1, 2) have dealt with the application of ^{13}C nmr (chemical shifts and ^{13}C—^{31}P couplings) to the stereochemistry of carbocyclic hydroxyphosphono compounds. Some evidence for increased $^1J_{CP}$ and attenuated $^3J_{CP}$ values due to the presence of the electronegative OH function has been presented. We have now synthesized a series of carbocyclic phenylaminephosphonates to examine the influence of the less electronegative, but sterically more bulky NH—ϕ group on the nmr parameters. Some inferences regarding the preferred conformations of these molecules can be made, and the configurational effects on $^1J_{^{13}C^{31}P}$ and $^1J_{^{13}C^{15}N}$ are discussed.

Results and Discussion

The structures and numbering schemes for the materials examined are presented in Fig. 1. Table 1 contains the ^{13}C chemical shift data while Tables 2, 3, and 4 contain one, two, and three bond ^{13}C—^{31}P coupling constants respectively. Compounds **4** and **5** were also synthesized using ^{15}N enriched aniline and the ^{13}C—^{15}N couplings are recorded in Table 5.

Spectral Assignments

The carbon spectra were routinely recorded using complete ^1H noise decoupling. Subsequently the single frequency off-resonance decoupling method (SFORD) was employed to differentiate between CH_3, CH_2, CH, and quaternary carbons. Selective ^1H decoupling was used occasionally, and model compounds studied previously (1, 3) were valuable in many instances.

Conformational Implications

Before discussing the geometries of the

"mobile" systems **1–3**, it is instructive to look at data for the model compounds **4** and **5**. Generally, the ^{13}C shifts and vicinal CP couplings seem to be the most useful for obtaining insight into conformational preferences.

In **4**, the large $^3J_{CP}$ of 12.1 Hz to C-3,5 is indicative of an equatorial phosphorus atom with a dihedral angle of near 180° to C-3,5 (1, 2, 4). Compound **5** shows a non-resolvable $^3J_{CP}$ to C-3,5 indicative of an axial phosphorus atom (1, 2). It is important to note, however, that introduction of the axial phenylamino group in **4** causes a *reduction* of ca. 4 Hz in the $^3J_{CP}$ value to C-3,5, compared to compound **12**.

Another indicator of the configuration at C-1 in these materials is the chemical shift at C-3,5, and in this context it is useful to compare data for **4** and **5** with those reported earlier (3) for **12** and **13**.

12 $^3J_{3,5CCCP} = 16.2$ Hz

13 $^3J_{3,5CCCP} < 0.6$ Hz

The C-3,5 shift for **4** is 20.9 ppm, manifesting a *gauche*-"γ" (5) upfield steric shift of 5.6 ppm due to the introduction of the axial NH—ϕ group. By contrast the C-3,5 shift of **5** is essentially identical to that of **13** above, showing no chemical shift perturbation due to the equatorial phenylamino function.

Another interesting difference, although its origin is less clear, is the upfield "β" shift of 4.0 ppm found at C-2,6 of **4** vs. **5**.

With these data for "model" compounds in hand, we can now turn our attention to the conformationally less well-defined systems, starting with the cyclobutyl derivative **1**. In a puckered 1,1-disubstituted cyclobutane (6), one of the substituents will be axial and the other equatorial. The C-3 ring carbon experiences two *gauche*-butane type interactions with the axial substituent and should therefore experience an upfield shift at C-3 when an axial substituent is present at C-1. Our previous work (1, 3) demonstrated that an axial dimethylphosphono group induces an upfield shift of ca. 2.5 ppm at C-3,5 of a cyclohexane ring. The present results (above) for **4** vs. **12** indicate a much larger *gauche*-γ shielding (5.6 ppm) at C-3,5 due to an axial phenylamino function.

We now can consider the influence of introduc-

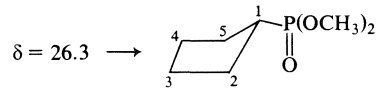
tion of the NH—ϕ group at C-1 in **1**, relative to **14** below, in which the dimethylphosphono group is deemed to be almost exclusively equatorial (7). The C-3 shift of **1** is 4.8 ppm upfield from that of **14**,



14

indicative of a preponderance of an axial phenylamino group. This finding is reasonable in view of the recent results (8) which show that $-\Delta G^0$ for the dimethylphosphono group is 2.0 kcal/mol in cyclohexane, while the $-\Delta G^0$ for the phenylamino group, although not known precisely, is likely to be somewhat smaller, ca. 1.0 kcal/mol (9) and *vide infra*.

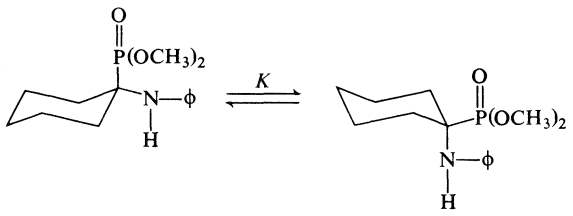
The vicinal coupling from ^{31}P to C-3 of **1** is 6.1 Hz, nearly identical to that (6.5 Hz) of the corresponding hydroxyphosphonate (2), and much smaller than the 18.7 Hz value found in **14** (7). As was demonstrated in **4** vs. **12**, the introduction of the phenylamino group reduces $^3J_{CP}$ by ca. 4 Hz for a constant dihedral angle. Thus the further reduction observed relative to **14** must be due to changes in the average $^3C—C—C—P$ torsional angle to a value closer to 90°. A combination of ring flattening in **1** as well as some contribution from the conformer with an axial phosphorus is probably present.

For the cyclopentyl derivative **2**, the C-3,4 shift is upfield by 2.0 ppm relative to the model compound **15** (below), consistent with the presence of a sec-

15

$^3J_{3,4CCCP}$ = 12.6 Hz

ond substituent at C-1. The vicinal $^{13}C—^{31}P$ coupling of 10.6 Hz in **2** indicates a preference for the equatorial dimethylphosphono group. The axial phenylamino function of **2** induces a much smaller upfield "γ" shift at C-3,4 than in the 6-membered ring model **4**. This appears to be a general phenomenon in the ^{13}C spectra of cyclopentyl compounds (10) and has been attributed to a lesser amount of ring puckering in a cyclopentane than in a cyclohexane ring system.



For the simple cyclohexyl derivative **3**, the nmr parameters indicate a strong preference for the conformer in which the dimethylphosphono group is equatorial. Using the isomeric 4-*tert*-butyl cyclo-

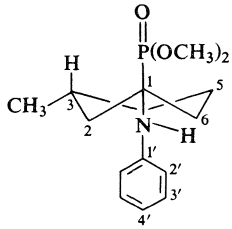
hexyl compounds **4** and **5** as models, one can calculate an equilibrium constant K for the process:

from the Eliel equation below (11) and the values for $^1J_{CP}$, i.e.,

$$K = \frac{J_{ax} - J_{mix}}{J_{mix} - J_{eq}}$$



where J_{ax} is the $^1J_{CP}$ value for the model compound **5**, J_{eq} is the $^1J_{CP}$ value for **4**, and J_{mix} represents $^1J_{CP}$ for **3**.

On this basis K is found to be 7.0 at 303 K. Low temperature experiments on **3** verify the large value of K, since the amount of the conformer with an axial phosphorus atom is insufficient for detection at 183 K. The ^{13}C spectrum of **3** at 183 K shows a $^1J_{CP}$ value of 161.0 Hz and $^3J_{CCCP}$ of 12.0 Hz, indicating that **4** is indeed a reasonable "model" for the conformer with an equatorial dimethylphosphono group.

These results for **3** reflect the published value for the conformational free energy of the dimethylphosphono group (2.0 kcal/mol) (8) which is sterically much larger than the NH—ϕ function. No data for this latter group itself are available, but the value for the $NHCH_3$ group is 1.0 kcal/mol (9).

For the 3-CH_3 compound **6**, the large $^3J_{CP}$ values to C-3 and C-5 are consistent with the presence of an equatorial phosphorus atom. The slightly smaller ^3J to the C-3 position may be due to some minor ring flattening due to the presence of the methyl function. In the case of **7**, the non-resolvable vicinal $^{13}C—^{31}P$ coupling to C-3 and C-5 suggests axial phosphorus by analogy with **5**. It is interesting to note for **5** and **7**, which are the only materials having a purely equatorial phenylamino group, that a substantial ^3J is found between the C-1′ position of the aromatic ring and the phosphorus atom.

In the isomers **5** and **7**, which possess an equatorial phenylamino group, the conformation below in which the ^{31}P and the C-1′ carbon are *trans*-coplanar, is relatively free of repulsive van der Waals forces. By contrast, in isomers having an axial phenylamino function, a *trans*-coplanar disposition of the ^{31}P and the C-1′ carbon produces conformations in which severe van der Waals repulsion is present between the aryl ring and the axial cyclohexane hydrogens at C-3 and C-5. Since it is well-documented (1, 2, 4) that *trans*-coplanar geometries produce maximal $^3J_{CP}$ values, this argument satisfactorily accounts for the observation of substantial ^3J values only when the phenylamino moiety is equatorial.

Chemical shift trends in **6** vs. **7** support the assignment of stereochemistry based on the vicinal C—P coupling. For example in **6**, the axial NH—ϕ group induces upfield "β" shifts of ca. 4 ppm at C-2 and C-6 relative to **7**, consistent with the trend noted earlier for **4** vs. **5**. Also, the larger *gauche*-"γ" shielding effect arising from the axial NH—ϕ is manifest in the C-3,5 shifts of **6** vs. **7**. The methyl group appears to be predominantly equatorial in both **6** and **7**, since its shift in both isomers is near that (23.3) found in methylcyclohexane itself (12, 13) where the strong preference for the equatorial position is well known.

A further point of interest regarding the chemical shifts as a function of configuration, is that the aromatic *ortho* and *para* resonances are consistently deshielded in isomers having the phenylamine group equatorial, i.e., **5** and **7**, compared to their respective counterparts **4** and **6**.

For the 4-methyl cyclohexyl compound **8**, the $^1J_{CP}$ and $^3J_{CCCP}$ values lie nearly mid-way between those of the "model" compounds **4** and **5**. Also, the

rather highly shielded 4-methyl group (δ = 19.1) suggests an appreciable contribution from a conformation having an axial CH_3 (14).

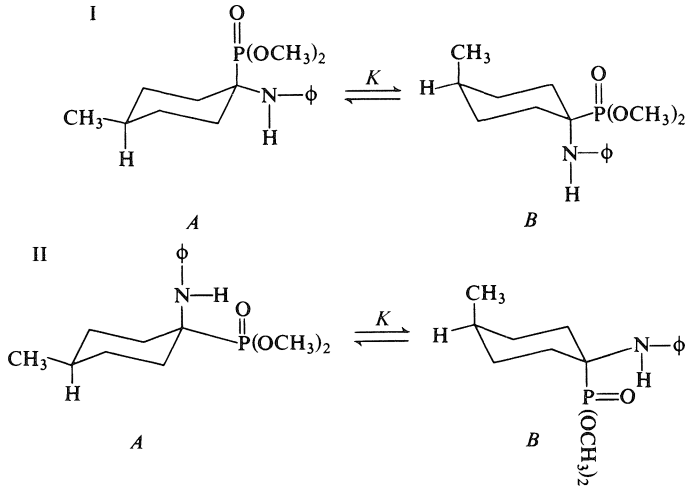
Low temperature spectra of **8** (in CD_2Cl_2 at 183 K) indeed showed the presence of two conformers. Although the spectrum was complicated by peak overlap, the CH_3 resonance of **8**, occurring at 19.1 ppm at 303 K, split into two resonances below 203 K. At 183 K, which represents the slow exchange limit, the chemical shifts of the axial and equatorial 4-CH_3 group are 17.0 and 23.4 ppm respectively. This 6.4 ppm chemical shift difference is comparable to that found in methylcyclohexane itself at 163 K (13).

At 183 K, the aromatic carbon resonances of **8** also split into two, but the chemical shift differences are only ca. 0.3 ppm. Extensive overlap in the cyclohexyl carbon resonance region of the spectrum prevents extraction of the full details of the spectra of the separate conformers of **8**.

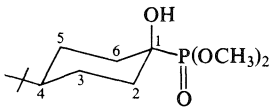
Nevertheless, one can discuss the conformations of **8** in terms of the two situations I and II depicted below.

From the low temperature spectra of **3** discussed earlier, we know that the steric size of the dimethylphosphono group must be considerably larger than that of the phenylamino function. Also, the conformational free energy of the CH_3 group is known to be ca. 1.7 kcal/mol (15). Thus, one can conclude that in scheme II above, conformer *A* would be expected to dominate to a very large extent over conformer *B*, and at low temperature, the spectrum would be essentially that of *A*.

By contrast, in scheme I, more equal populations of conformers *A* and *B* are expected. Examining the 4-CH_3 chemical shift of **8** at room temperature (δ = 19.1), in relation to the low temperature values (23.4 and 17.0), it is evident that the preferred conformation of **8** is in fact *B* of scheme I.



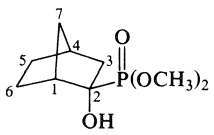
The equilibrium constant *K* calculated from the Eliel equation (11), is approximately 2.0, which translates into a free energy difference (at 183 K), of 0.25 ± 0.03 kcal/mol, between *A* and *B*, calculated from $-\Delta G^0 = RT \ln K$, using the chemical shift data of the preceding paragraph.



If one assumes additivity of conformational free energies, this result is surprising, in view of the published conformational free energy of the CH_3 group (1.7 kcal/mol) (15) and that for the dimethylphosphono group (2.0 kcal/mol) (8). It has been shown, however (16), that additivity of $-\Delta G^0$ values breaks down in 1,1-disubstituted cyclohexanes, especially when hydrogen bonding can occur between the substituents, as is the case in **8**.

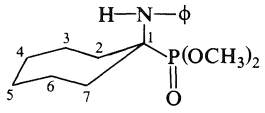
Of course, it would have been preferable to obtain *K* for **8** directly from the peak areas at 183 K, but spectral overlap ruled out such an approach. Also, ^1J's and ^3J's for the separate conformers of **8** could not be extracted from the spectrum at 183 K due to spectral complexity. High field spectrometers could solve this problem.

For the adamantyl compound **9**, the vicinal $^{13}C—^{31}P$ couplings are nearly identical to those reported (1) for the corresponding hydroxyphosphonate. The same holds true for the stereochemically "anchored" systems **4** vs. **16** (below) (1) and **10** vs. **17** (below). It appears therefore, that the electronic effects of OH vs. NH—ϕ substitution on $^3J_{CP}$ are comparable.



The cycloheptyl compound **11** shows a $^3J_{CP}$ value of 10.7 Hz, again nearly identical to that in the

16



$^3J_{PCC^{3,5}C} = 12.6$

17

$^3J_{PCC^7C} < 0.6$
$^3J_{PCC^4C} = 4.7$
$^3J_{PCC^6C} = 9.1$

corresponding hydroxyphosphonate (2). This large value for ^3J precludes the dominance of a twist chair conformation with isoclinal substituents, as has been discussed by us in detail earlier (2) for the hydroxyphosphonate. Indeed, X-ray crystallography (17) of 1-dimethylphosphono-1-hydroxycycloheptane has shown the presence of a substantial amount of the chair conformation in the solid. In this conformation, the dihedral angles P—C1—C2—C3 and P—C1—C7—C6 are 168.7 and 173.0° respectively. We suggest therefore that **11** is predominantly in the chair form below, with an equatorial phosphorus atom, leading to the large observed $^3J_{CP}$.

11

One-bond Couplings

The sign of $^1J_{CP}$ in pentavalent organophosphorus compounds is likely to be positive (18). For $^{13}C—^{31}P$ coupling in phosphonates (3) and hydroxyphosphonates (2), it has been shown that $^1J_{CP}$ becomes less positive as the number of *gauche* interactions experienced by the C—P bond increases. This trend is again apparent in these phenylaminophosphonates for cyclohexyl derivatives (Table 2).

Comparing the isomeric pair **4** and **5**, $^1J_{CP}$ is 9.7 Hz smaller in **5**, having the axial C—P bond, than in **4**. In the simple cyclohexyl compound **3** which lacks the *tert*-butyl group, $^1J_{CP}$ lies between the values for the "models" **4** and **5**, but much closer to the value for **4**, as discussed earlier.

In the case of the isomeric 3-CH_3 compounds **6** and **7**, the $^1J_{CP}$ for **7**, having the axial C—P bond, is 9.2 Hz less than for **6**. In the adamantyl derivative **9**, $^1J_{CP}$ is very close in value to results for **5** and **7**, which is reasonable, since in **9**, the C—P bond experiences the same number of *gauche* interactions as does the C—P bond of **5** and **7**.

For the 4-CH_3 compound **8**, the $^1J_{CP}$ value is approximately mid-way between results for the "model" compounds **4** and **5**, indicating two appreciably populated conformers, a finding borne out by the low temperature spectra of **8** discussed previously.

With respect to the configurational dependence of the one-bond $^{13}C—^{15}N$ couplings (Table 5), it is important to note that the sign of this interaction is probably negative (19). Thus, a trend consistent with $^1J_{CP}$ is evident in **4** and **5**. Specifically, in **4**, where the $^1C—N$ bond has two more *gauche* interactions than in **5**, the one bond coupling again becomes less positive, *i.e.*, *more negative* in **4** than **5**.

Experimental

Spectra

^{13}C nmr spectra were obtained using techniques described previously (1–3) on a Varian XL-100-12 spectrometer equipped with a Nicolet TT-100 Fourier Transform data system. For measurement of $^{13}C—^{31}P$ and $^{13}C—^{15}N$ couplings, normal sweep widths were 500 Hz and 8K data points were employed.

Materials

The following general procedure (20) was used for synthesis of the amine phosphonates from the appropriate carbocyclic ketone.

A mixture of 1.0 mmol ketone, 1.0 mmol aniline, and 1.0 mmol dimethyl phosphite in 1.0 mL benzene was stirred with 0.4 g 5 Å molecular sieves in a stoppered flask for 3 days. A further 20.0 mL benzene was added and the sieves and undissolved solids were filtered by gravity. The solvent was removed by rotary-evaporator and the crude product recrystallized from hexanes or hexanes/ethyl acetate. No attempt was made to maximize yields which were generally 30–40%.

All compounds displayed a 6 proton $CH_3O—P$ doublet at 3.8 ppm in ^1H nmr and the ^1H spectra integrated correctly. Melting points were obtained on a Buchi SMP-20 melting range apparatus and are uncorrected.

The following compounds were obtained in this fashion.

1-Dimethylphosphono-1-phenylaminocyclobutane (**1**): mp 121–122°C. *Anal.* calcd.: C 56.47, H 7.11, N 5.49, P 12.13; found: C 56.47, H 7.00, N 5.35, P 12.16.

1-Dimethylphosphono-1-phenylaminocyclopentane (**2**): mp 120–121°C. *Anal.* calcd.: C 57.99, H 7.49, N 5.20, P 11.50; found: C 57.81, H 7.27, N 5.29, P 11.58.

1-Dimethylphosphono-1-phenylaminocyclohexane (**3**): mp 110–111°C (lit. (21) mp 110–112°C).

1-Dimethylphosphono-1-phenylamino-4-*tert*-butylcyclohexanes (**4** and **5**): a first crop from recrystallization gave the pure isomer with axial phosphorus group (**5**), mp 139–140°C. ^1H nuclear magnetic resonance shows one $CH_3O—P$ doublet at 3.8 ppm and one *tert*-butyl singlet at 0.85 ppm. *Anal.* calcd.: C 63.70, H 8.91, N 4.13, P 9.13; found: C 63.83, H 8.80, N 4.02, P 9.02. A second crop furnished a sample of approximately a 1:1 mixture of **4**:**5**, mp 123–125°C; ^1H nmr shows two $CH_3O—P$ doublets at 3.8 ppm and two *tert*-butyl singlets at 0.85 and 0.87 ppm. *Anal.* calcd.: C 63.70, H 8.91, N 4.13, P 9.13; found: C 63.60, H 8.80, N 4.03, P 8.99. The procedure was repeated using ^{15}N-enriched aniline (99%, Stohler Isotope Company) to provide ^{15}N-enriched samples of **4** and **5**.

1-Dimethylphosphono-1-phenylamino-3-methylcyclohexanes (**6** and **7**): mp 109–115°C obtained as two isomers ratio **6**:**7** = 1:5; ^1H nmr shows two $CH_3O—P$ doublets at 3.8 ppm

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12

and two CH_3—CH doublets at 0.9 ppm. *Anal.* calcd.: C 60.59, H 8.14, N 4.71, P 10.42; found: C 59.71, H 7.90, N 4.76, P 10.14.

1-Dimethylphosphono-1-phenylamino-4-methylcyclohexane (**8**): mp 84–86°C. *Anal.* calcd.: C 60.59, H 8.14, N 4.71, P 10.42; found: C 60.64, H 8.15, N 4.83, P 10.33.

2-Dimethylphosphono-2-phenylaminoadamantane (**9**): mp 126–126.5°C. *Anal.* calcd.: C 64.45, H 7.81, N 4.18, P 9.24; found: C 64.42, H 7.68, N 4.25, P 9.34.

2-Dimethylphosphono-2-phenylaminobicyclo[2,2,1]heptane (**10**): mp 163.5–164.5°C. *Anal.* calcd.: C 61.43, H 6.87, N 4.78, P 10.56; found: C 61.31, H 7.00, N 4.64, P 10.45.

1-Dimethylphosphono-1-phenylaminocycloheptane (**11**): mp 105.5–106.5°C. *Anal.* calcd.: C 60.59, H 8.14, N 4.71, P 10.42; found: C 60.47, H 8.14, N 4.88, P 10.45.

Microanalyses were carried out by Spang Microanalytical Laboratory, Eagle Harbor, Michigan.

Quantitative determination of tantalum in niobium by neutron activation analysis

DONALD R. SADOWAY[1] AND S. N. FLENGAS
Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4
AND
R. G. V. HANCOCK
SLOWPOKE Nuclear Reactor Facility, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received August 1, 1979

DONALD R. SADOWAY, S. N. FLENGAS, and R. G. V. HANCOCK. Can. J. Chem. **58**, 537 (1980).

A method was devised for the determination of Ta both in mixtures of $NbCl_5$–$TaCl_5$ and in mixtures of $ANbCl_6$–$ATaCl_6$, where A = Na, K, Rb, or Cs. The method involves neutron activation analysis of Nb_2O_5–Ta_2O_5 samples prepared by conversion of the chlorocompounds.

DONALD R. SADOWAY, S. N. FLENGAS et R. G. V. HANCOCK. Can. J. Chem. **58**, 537 (1980).

On a conçu une méthode de détermination du tantale dans les deux mélanges suivants: $NbCl_5$–$TaCl_5$ et $ANbCl_6$–$ATaCl_6$ où A = Na, K, Rb ou Cs. La méthode implique l'analyse pour l'activation de neutrons des échantillons du Nb_2O_5–Ta_2O_5 préparés par la transformation des composés chlorés.

For personal use only.

During the course of an investigation to test the proposition that it is possible to separate Ta from Nb by the reaction of vapour mixtures of $NbCl_5$–$TaCl_5$ with either solid or molten ACl, where A = Na, K, Rb, or Cs, it became necessary to devise a technique for determining the concentration of Ta both in mixtures of $NbCl_5$–$TaCl_5$ and in mixtures of $ANbCl_6$–$ATaCl_6$, where the Ta concentration ranged from 0.5 to 10 wt.% on a metal–metal basis with Nb (1). Quantitative analysis of tantalum–niobium systems is difficult by standard chemical methods. X-ray fluorescence has been used successfully under carefully controlled conditions (2–6). To avoid potential problems such as matrix effects and the high dependence on the method of sample preparation inherent in this technique neutron activation analysis was chosen for the present work.

Sample Preparation

Since the chlorocompounds of niobium and tantalum hydrolyse readily, it was necessary to convert them to a stable form, in this case their pentoxides, by adding the salt mixtures to water, boiling for 5 min, and then evaporating to dryness. The cake which formed was ground to a powder which was then added to water, boiled for 5 min, and evaporated to dryness. Prior to this second evaporation, in the analysis of $ANbCl_6$–$ATaCl_6$ mixtures only, filtration was performed to separate the alkali-metal chloride presumed to have dissolved in the water. The dried cake was ground to a powder, added to concentrated NH_4OH, and evaporated to dryness. After grinding, the product was ignited in a platinum crucible at 900°C.

X-ray powder diffraction patterns verified that the hydrolysis of the pentachlorides to the pentoxides was complete, i.e. that Nb_2O_5 and Ta_2O_5 were formed. Furthermore, to prove that the hydrolysis of $AMCl_6$ proceeded according to the reaction

$$[1] \quad 2AMCl_6 + 5H_2O \rightarrow M_2O_5 + 10HCl + 2ACl$$

the filtrate, which was assumed to contain dissolved ACl, was evaporated to dryness. The X-ray powder pattern of the dried filtrate was identified as that of ACl in each case.

A reliable procedure for sample preparation having been established, a set of standards spanning the range 0.1 < wt.% Ta < 10 was made. First, large quantities of $NbCl_5$ and $TaCl_5$ were hydrolysed separately to make Nb_2O_5 and Ta_2O_5. The materials were screened through a 200 mesh sieve, and the appropriate amounts were mixed by a novel technique. Campbell and Carl (3) and Mitchell (4) have reported that mixed Ta_2O_5–Nb_2O_5 samples can be prepared by co-precipitation from hydrofluoric acid solutions. In this laboratory the oxides were found to be extremely difficult to dissolve, an observation made also by Campbell and Carl (3). A different method was used to mix the oxides.

The two powders were put into a 600 mL beaker containing approximately 300 mL of water. The water was heated to a violent boil and for about 10 min was stirred with a glass rod. The water was evaporated, and the powder was passed again through a 200 mesh sieve. Samples of the same nominal composition, some having been prepared by co-precipitation and others "wet mixed", were compared by neutron activation analysis. Results were within limits of statistical error of one another. As well, several samples from the same batch of wet-mixed material were analyzed to determine if the particle distribution was random. Again, the results agreed within statistical limits of error.

Results

The powdered samples weighed approximately 300 mg and were contained in polyethylene vials. They were irradiated in the SLOWPOKE nuclear reactor at this university in a neutron flux of 1.0×10^{11} n/cm^2 s for 60 s. After a decay time of 60 s the irradiated samples were counted for 300 s. Thus, the total time to analyze a sample was 7 min. Mea-

surements of γ-ray activities were made with a Canberra Ge(Li) detector coupled through a 452 Ortec spectroscopy amplifier to an 8100 series, 4096 channel Canberra analyzer. The detector has a nominal relative counting efficiency of 6.7% and a FWHM resolution of 1.9 keV for the 1332 keV γ-ray of ^{60}Co. γ-Ray peak intensities were evaluated by automatic analyzer integration of suitable manually selected spectral regions of interest at and near each peak.

Every time a set of samples was measured, the entire set of standards was also irradiated. While both Nb and Ta were counted, the Nb results were not found to be useful. Below about 3 wt.% Ta there was no discernible trend in the Nb results. Although self absorption effects in samples high in Ta give rise to curvature in the calibration curve, the measurements of the standards were best represented for our purposes by two least-squares lines, one for Ta concentrations less than 4 wt.% and one for Ta concentrations between 4 wt.% and 10 wt.%. The elemental Ta content of a sample was determined by comparison with the standard line recorded on the same day.

Typical results are the following. In the range, $0 < \text{wt.\% Ta} < 4$,

$$[2] \quad \text{wt.\% Ta} = -(0.20 \pm 0.07) + (117 \pm 3) \times 10^{-6} n$$

where n represents the number of counts $s^{-1}\,g^{-1}$ of oxide sample. The correlation coefficient[2] was $r = 0.9986$, and standard error of estimate was $\hat{S}_{y,x} = 0.08$. In the range $4 < \text{wt.\% Ta} < 10$,

$$[3] \quad \text{wt.\% Ta} = -1.07 \pm 0.24 + (142 \pm 4) \times 10^{-6} n$$

The correlation coefficient was $r = 0.9996$, and the standard error of estimate was $\hat{S}_{y,x} = 0.12$.

The corresponding amount of Ta_2O_5 present in the sample was then calculated, and the difference between this and the total mass of the sample was presumed to be the mass of Nb_2O_5. From the latter figure the mass of elemental Nb was calculated. Finally, the Ta concentration was reported as wt.% Ta in Ta–Nb metal. It has an absolute error of estimate of less than 0.1 wt.% over the range of interest. The lower limit of detection for this method using samples such as these described herein was determined to be 330 ppm Ta in Nb on a metal–metal basis (8).

This method is accurate provided that the sample consists of only Nb_2O_5–Ta_2O_5. As a precaution, then, the entire γ spectrum of each sample was scanned to detect the presence of any other metals. In samples prepared from the pentachloride mixtures of $NbCl_5$–$TaCl_5$ only Ta and Nb were found. However, samples prepared from $ANbCl_6$–$ATaCl_6$ mixtures contained small but measurable amounts of alkali metal representing less than 5% of the total mass of the sample. Since the chlorine content was below the lower limit of detection which was approximately 100 μg in those samples, it was concluded that the alkali metal was not present in the form of its chloride. So, it was assumed that the alkali metal was present as oxide or, more likely, niobate or tantalate, and the appropriate correction was made to the Ta concentration reported. Table 1 shows the isotope which was measured for each element. For tantalum both the tabulated γ-ray peaks were routinely counted. With the spectrometer employed, the 172 keV peak was approximately 25% greater than that at 147 keV, and the bremsstrahlung in the region of the former is approximately 30% weaker. Indeed, the results for the peak at 172 keV proved to be more reproducible and, thus, were favoured in the quantitative determination of tantalum.

TABLE 1. Nuclear data for sample analysis (7)

Element	Isotope measured	Half-life	γ-ray (keV)
Nb	^{94m}Nb	6.6 min	871.1
Ta	^{182m}Ta	16.2 min	146.7, 171.7
Na	^{24}Na	15 h	1368.4
K	^{42}K	12.52 h	1524.7
Rb	^{86m}Rb	1.02 min	555.8
Cs	^{131m}Cs	3.15 h	127.4
Cl	^{38}Cl	37.29 min	1642.0

The phase diagrams of the chlorides of the metals of Groups IIa and IIb with indium trichloride and water at 24°C

ELINOR M. KARTZMARK

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 12, 1979

ELINOR M. KARTZMARK. Can. J. Chem. **58**, 539 (1980).

The double salt formation between indium chloride and the chlorides of Groups IIa and IIb has been investigated, and a comparison is made with the double salts of the Group I chlorides and indium trichloride. Three double salts of formula $2BeCl_2 \cdot InCl_3 \cdot (4–5)H_2O$, $MgCl_2 \cdot InCl_3 \cdot (6–8)H_2O$, and $CaCl_2 \cdot InCl_3 \cdot 7H_2O$ were found. The phase diagrams of the chlorides of Groups IIa and IIb with indium trichloride and water prove that the double salts $MgCl_2 \cdot 2InCl_3 \cdot 10H_2O$, $2MgCl_2 \cdot InCl_3 \cdot 12H_2O$, $CaCl_2 \cdot 2InCl_3 \cdot 12H_2O$, $3CaCl_2 \cdot 4InCl_3 \cdot 30H_2O$, $SrCl_2 \cdot 2InCl_3 \cdot 8H_2O$, $SrCl_2 \cdot InCl_3 \cdot 8H_2O$, $ZnCl_2 \cdot 2InCl_3 \cdot 8H_2O$, and $2ZnCl_2 \cdot InCl_3 \cdot 5H_2O$ reported by Ensslin *et al.* (1) and recorded in Solubility of inorganic and metal organic compounds by Linke and Seidell (2) do not exist.

ELINOR M. KARTZMARK. Can. J. Chem. **58**, 539 (1980).

On a étudie la formation des sels doubles entre le chlorure d'indium et les chlorures des groupes IIa et IIb et on les a comparé aux chlorures doubles d'indium et des éléments du groupe I. On a trouvé trois sels doubles de formule $2BeCl_2 \cdot InCl_3 \cdot (4–5)H_2O$, $MgCl_2 \cdot InCl_3 \cdot (6–8)H_2O$ et $CaCl_2 \cdot InCl_3 \cdot 7H_2O$. Quant aux sels suivants $MgCl_2 \cdot 2InCl_3 \cdot 10H_2O$, $2MgCl_2 \cdot InCl_3 \cdot 12H_2O$, $CaCl_2 \cdot 2InCl_3 \cdot 12H_2O$, $3CaCl_2 \cdot 4InCl_3 \cdot 30H_2O$, $SrCl_2 \cdot 2InCl_3 \cdot 8H_2O$, $SrCl_2 \cdot InCl_3 \cdot 8H_2O$, $ZnCl_2 \cdot 2InCl_3 \cdot 8H_2O$ et $2ZnCl_2 \cdot InCl_3 \cdot 5H_2O$ rapportés par Ensslin *et al.* (1) et répertorés dans "Solubilité des composés inorganiques et organométalliques" de Linke et Seidell (2), les diagrammes de phase des chlorures doubles hydratés d'indium et des éléments du groupe IIa et IIB prouvent qu'ils n'existent pas.

[Traduit par le journal]

Introduction

In this paper the solubilities of indium trichloride together with the chlorides of the Group II metals in water were studied, with a view to determining the formulae of any double salts. In a previous paper (3) it was reported that all of the Group Ia metal chlorides, except sodium chloride, form one or more double salts with indium trichloride. Most of the studies in this area were done by Ensslin *et al.* (1) who reported many double salts with the general formula: $xMeCl_2 \cdot yInCl_3 \cdot zH_2O$ where x, y, z have values shown in Table 1.

The experimental technique of these studies was not such as would guarantee equilibrium; it was merely to analyse the wet residue, without reference to the solution, and did not ensure the nature of the solid phase. It seemed of interest to determine the complete phase diagrams and to compare double salt formation of the Group II chlorides with that of the chlorides of Group I. The phase diagram for the system hydrogen chloride – indium chloride – water, was also determined as completely as possible to round out the Group I series.

TABLE 1. Formulas of double salts of indium trichloride reported by Ensslin *et al.* (1) ($xMeCl_2 \cdot yInCl_3 \cdot zH_2O$)

Me	x	y	z	Me	x	y	z
Mg	1	2	10*	Sr	1	2	8*
	1	1	7		1	1	8*
	2	1	12*	Zn	1	2	8*
Ca	1	2	12*		2	1	5*
	3	4	30*				
	1	1	8				

*As shown in text, these double salts do not exist.

Experimental Method

All chemicals were of "Reagent" grade and were used without further purification. The closed solubility system was stirred for 2 or 3 days with a magnetic stirrer and separation of the solid phase was done with a centrifuge. (The saturated solutions in all of these systems were very viscous, making ordinary filtration impossible.) The saturated mother liquors and the wet solids were analysed and plotted. Ideally, tie-lines drawn through a series of such points intersect at a point corresponding to the pure solid phase. If, however, the wet solid has much mother liquor adhering its composition lies on the tie-line very close to the saturated solution end, and errors in extrapolation to the point of intersection result. For this reason, the wet residue was placed between pads of filter paper and subjected to hydraulic pressure (2000 psi) so as to remove as much mother liquor as possible without evaporation of water. The solids so obtained had compositions which plotted on tie-lines very close to the pure solid phase, thus minimizing error.

Methods of Analysis

The System $HCl–InCl_3–H_2O$

Anhydrous indium chloride was added to concentrated hydrochloric acid and the system stirred for 48 h. A white crystalline solid separated. To obtain a solution as high in hydrogen chloride as possible, dry hydrogen chloride gas was bubbled through the solution; the system was then closed and stirred overnight. The phases were separated by centrifuging and analysed gravimetrically for chloride as silver chloride and for indium as indium oxide, by precipitating with ammonia.

The System $BeCl_2$–$InCl_3$–H_2O

Attempts to determine the solubility of beryllium chloride were complicated by its reactivity with water according to a reaction proposed by Sidgwick and Lewis (4):

$$BeCl_2 + H_2O \rightleftharpoons Be(OH)Cl + HCl$$

Because of the evolution of HCl, estimation of beryllium chloride by chloride determination gave a low result of 42.9%, which is comparable with that of Blidin (5), 41.72%. Precipitation of Be^{2+} as beryllium oxide gave a value of 51.7% but, since the solid with which the saturated solution was in equilibrium is undoubtedly a mixture of $BeCl_2 \cdot xH_2O$ and BeO, neither of these values can be considered to be the true solubility. The formula of the hydrate is undefined: Everest (6) states that evaporation of a saturated aqueous beryllium chloride solution gives a hygroscopic solid, usually formulated as the tetrahydrate but the actual composition approaches $BeCl_2 \cdot 4.5H_2O$. It is a complex structure of close-packed layers of dihydrate with interstitial water between the layers.

Because of these difficulties which persist in systems containing low concentrations of indium chloride it was decided to work with larger proportions of indium chloride with a view to obtaining double salts. The method of analysis consisted in determining total oxide, i.e. BeO + In_2O_3, by addition of ammonia. In^{3+} was estimated by precipitation as In_2S_3, using gaseous H_2S. The Be^{2+} was obtained by difference. A great many systems were prepared yielding intersecting tie-lines, which established the salt ratio in the double salt, and the hydration with an uncertainty of one water molecule.

The System $MgCl_2$–$InCl_3$–H_2O

In^{3+} was estimated as In_2O_3 (by addition of ammonia and ammonium chloride); under these conditions Mg^{2+} remains in solution. To remove adsorbed Mg^{2+}, the gelatinous $In(OH)_3$ was dissolved in hydrochloric acid, reprecipitated, filtered, washed, and ignited to In_2O_3. Chloride was estimated as silver chloride and Mg^{2+} was calculated by difference. The same method of analysis was followed in the systems $SrCl_2$–$InCl_3$–H_2O, $BaCl_2$–$InCl_3$–H_2O, and $ZnCl_2$–$InCl_3$–H_2O.

The System $CaCl_2$–$InCl_3$–H_2O

In an earlier paper (7), a double salt with salt ratio of 6:5 was reported. In view of the simple formula of all other double salts in Groups I and II, as given in Table 2, it seemed appropriate to examine this system again, specifically to subject the solid phase to pressure removal of mother liquor.

TABLE 2. Double salts of indium trichloride with the chlorides of Groups Ia, IIa, and IIb

Ion	Formula of double salt
H^+	$HCl \cdot InCl_3 \cdot 3H_2O$
NH_4^+	$2NH_4Cl \cdot InCl_3 \cdot H_2O$
Li^+	$3\,LiCl \cdot InCl_3 \cdot 8H_2O$
Na^+	—
K^+	$3\,KCl \cdot InCl_3 \cdot H_2O$ $2\,KCl \cdot InCl_3 \cdot H_2O$
Rb^+	$2\,RbCl \cdot InCl_3 \cdot H_2O$
Cs^+	$2\,CsCl \cdot InCl_3 \cdot H_2O$
Be^{2+}	$2\,BeCl_2 \cdot InCl_3 \cdot (4\text{ to }5)H_2O$
Mg^{2+}	$MgCl_2 \cdot InCl_3 \cdot (6\text{ to }8)H_2O$
Ca^{2+}	$CaCl_2 \cdot InCl_3 \cdot 7H_2O$
Sr^{2+}	—
Ba^{2+}	—
Zn^{2+}	—
Cd^{2+}	—
Hg^{2+}	—

The System $CdCl_2$–$InCl_3$–H_2O

The analysis of this system follows the method of Dennis and Bridgman (8), in which Cd^{2+} is held in solution by the presence of ammonium chloride and the maintenance of very high pH using 25% sodium hydroxide solution as precipitant of the In^{3+}.

The System $HgCl_2$–$InCl_3$–H_2O

Hg^{2+} was precipitated as mercuric sulphide in the presence of sulphuric acid. The solid was filtered through a sintered glass crucible, washed with water, and dried at low temperature. To remove sulphur, it was refluxed with freshly distilled carbon disulphide and dried at 120°C. The filtrate was analysed for chloride as silver chloride. Mercuric ion must be removed before the precipitation of silver chloride, because of complex formation, as is well known. In^{3+} was obtained by difference except in systems low in In^{3+}, where it was determined directly as In_2O_3.

Discussion

The phase diagrams resulting from the solubility data[1] and analyses of wet solids are given in Figs. 1 to 8. The compositions of wet solids have been plotted as open squares on the tie-lines and are found to lie very close to the compositions of the pure solid phase in most of the diagrams. Where they do not, there is some question as to the degree of hydration of the double salt (Figs. 2 and 3) and this has been indicated by a solid bar on the diagram.

In the system HCl–$InCl_3$–H_2O, only three solubility systems were studied but these were sufficient to prove the existence of the double salt, $HCl \cdot InCl_3 \cdot 3H_2O$, as shown in Fig. 1. The compositions of two of the wet solids are so close to that of the double salt that they do not show on the diagram. No attempt was made to obtain the invariant system with $InCl_3 \cdot 4H_2O$ and double salt as solid phases. The rest of the solubility curve of the double salt is unobtainable at ordinary pressures.

As with Fig. 1, Fig. 2 is a partial phase diagram for the system $BeCl_2$–$InCl_3$–H_2O, the beryllium chloride side being unattainable because of hydrolysis. The ternary solubility point with 42% beryllium chloride is probably in error for the same reason. The remaining five systems "intersect" the line joining H_2O to $2BeCl_2 \cdot InCl_3$, over a range of hydration corresponding to from 4 to 5 mol of water. The double salt, then, has formula $2BeCl_2 \cdot InCl_3 \cdot (4\text{ to }5)H_2O$.

Figure 3 shows a double salt in the system $MgCl_2$–$InCl_3$–H_2O with a 1:1 salt ratio and a range of hydration of from 6 to 8 mol of water. The wet solid point containing 34.3% $MgCl_2$ and 33.2% $InCl_3$ which is in equilibrium with the invariant

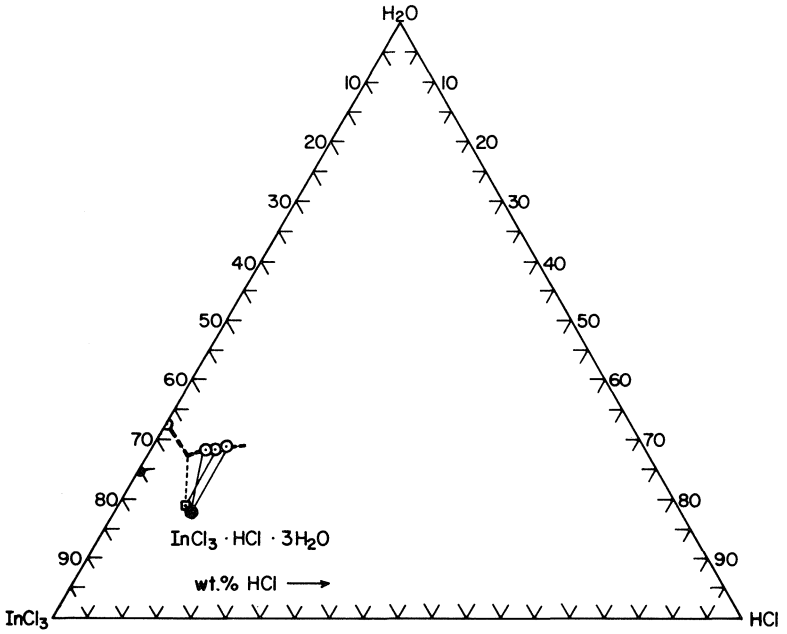

FIG. 1. The system $InCl_3$–H_2O at 24°C.

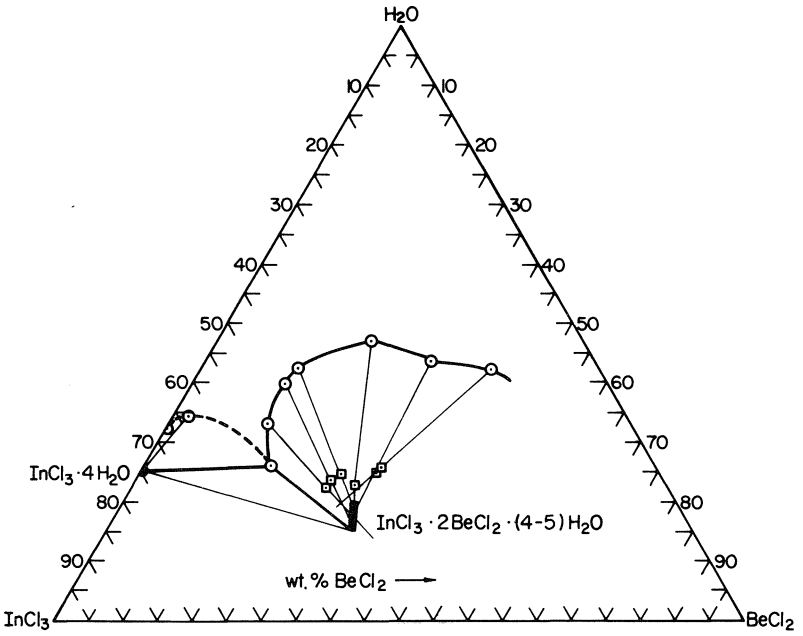

FIG. 2. The system $InCl_3$–$BeCl_2$–H_2O at 24°C.

solution 26.3% $MgCl_2$ and 28.8% $InCl_3$ lies outside of the invariant triangle for double salt and $MgCl_2 \cdot 6H_2O$ and is therefore in error: probably the result of loss of water.

The phase diagram for the system $CaCl_2$–$InCl_3$–H_2O has not been included in this paper; it is identical with that given in a former paper (7) except that the more accurate analysis of the wet solid yielded tie-lines intersecting at $CaCl_2 \cdot InCl_3 \cdot 7H_2O$.

There is no double salt in the system $SrCl_2$–$InCl_3$–H_2O, as shown in Fig. 4. The third field in the phase diagram results from the partial dehydration of $SrCl_2 \cdot 6H_2O$ to the dihydrate. This reaction occurs at 61.4°C in the absence of indium chloride, as reported in the $SrCl_2$–H_2O system by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

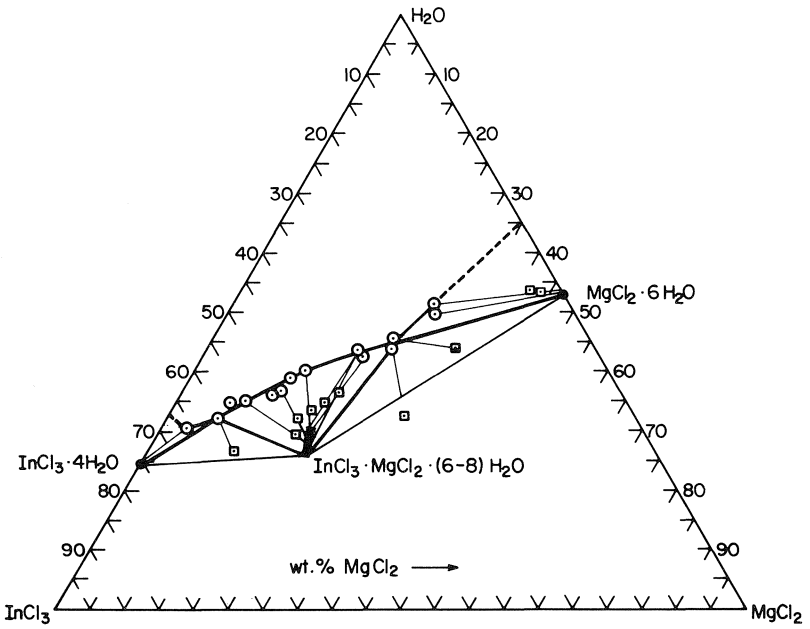

FIG. 3. The system $InCl_3$–$MgCl_2$–H_2O at 24°C.

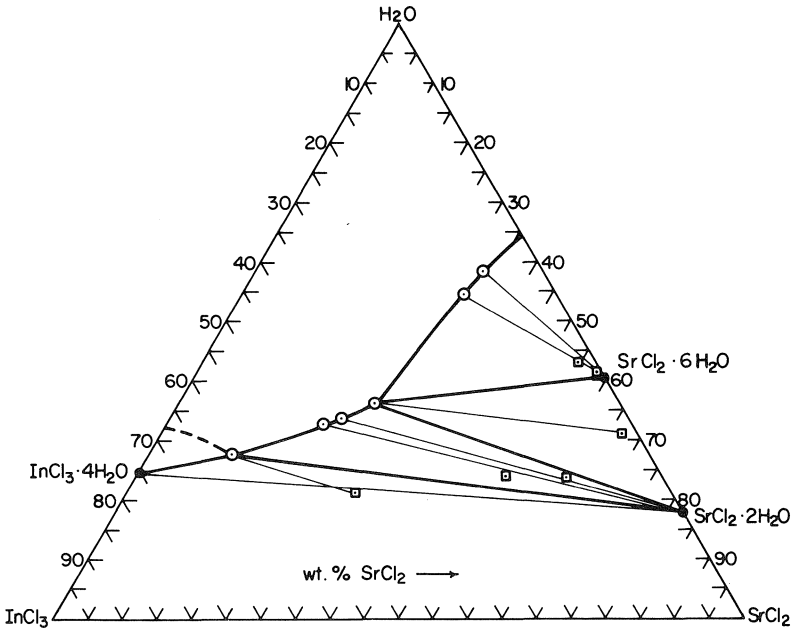

FIG. 4. The system $InCl_3$–$SrCl_2$–H_2O at 24°C.

Menzies (9). Further dehydration to the anhydrous salt occurs at a much higher temperature and thus does not take place at 24°C under the influence of indium trichloride.

In the phase diagram for the system $BaCl_2$–$InCl_3$–H_2O, shown in Fig. 5, it is proven that no double salt exists. The major field of the diagram is occupied by $BaCl_2 \cdot 2H_2O$, which is not dehydrated by indium chloride at 24°C.

The systems involving Group IIb metal chlorides do not produce double salts with indium trichloride, as is shown in Figs. 6, 7, and 8. The notable feature of the $ZnCl_2$–$InCl_3$–H_2O diagram, Fig. 6, is the fact that the invariant solution contains more than 50% zinc chloride. This is very unusual as is attested to by all of the other figures, where the invariant solution associated with $InCl_3 \cdot 4H_2O$ rarely contains more than 10% of the second com-

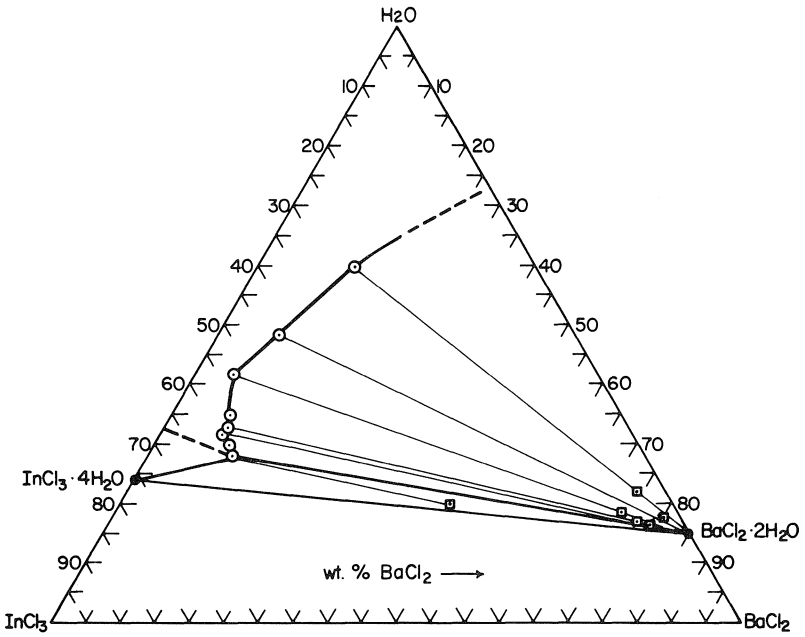

FIG. 5. The system $InCl_3$–$BaCl_2$–H_2O at 24°C.

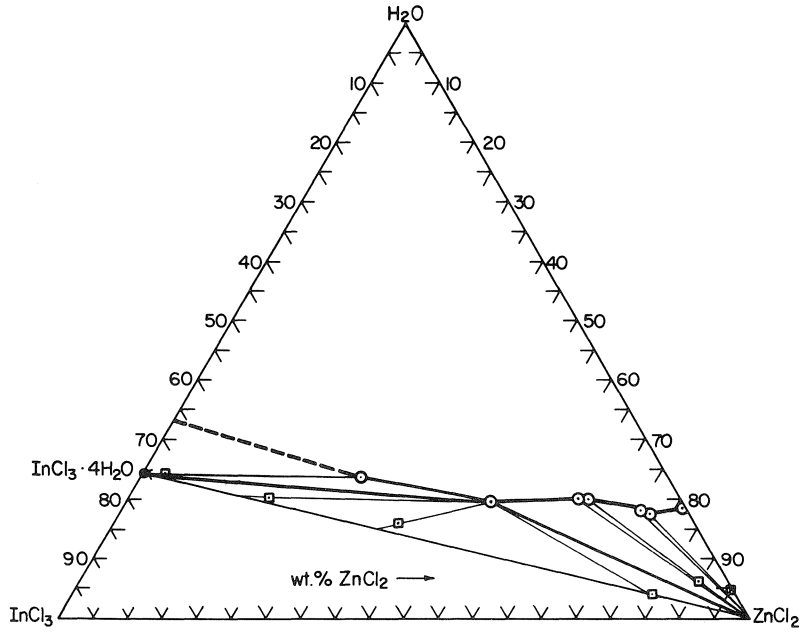

FIG. 6. The system $InCl_3$–$ZnCl_2$–H_2O at 24°C.

ponent. The behaviour in the $ZnCl_2$ system is possibly owing to the extremely high solubility of zinc chloride.

The solubility of cadmium chloride in water is reported in Linke's book Solubility of inorganic and metal organic compounds (2) as 54.65% at 25°C, the solid phase being $CdCl_2 \cdot 2\frac{1}{2}H_2O$. At 33.8°C the transition to the monohydrate occurs. The dehydration of $CdCl_2 \cdot 2\frac{1}{2}H_2O$ takes place at a lower temperature in the presence of indium trichloride; a large field of stability of the monohydrate occurs in the phase diagram at 24°C, as shown in Fig. 7. Finally, the system $HgCl_2$–$InCl_3$–H_2O, while it has no double salt, as proven in Fig. 8, is very interesting because it shows a sevenfold increase in the solubility of mercuric chloride, owing to the presence of 20% $InCl_3$. The $HgCl_2$ (s) field occupies the major portion of the diagram. This

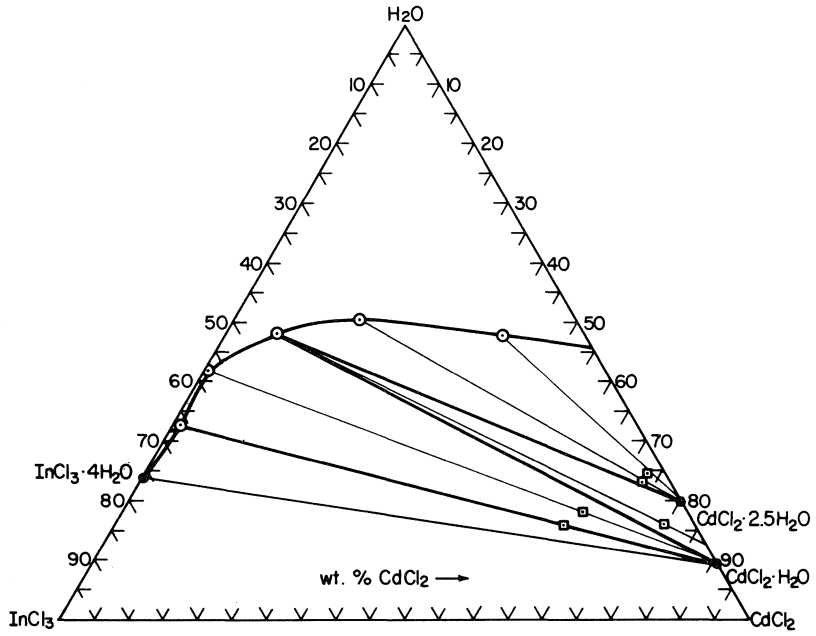

FIG. 7. The system $InCl_3$–$CdCl_2$–H_2O at 24°C.

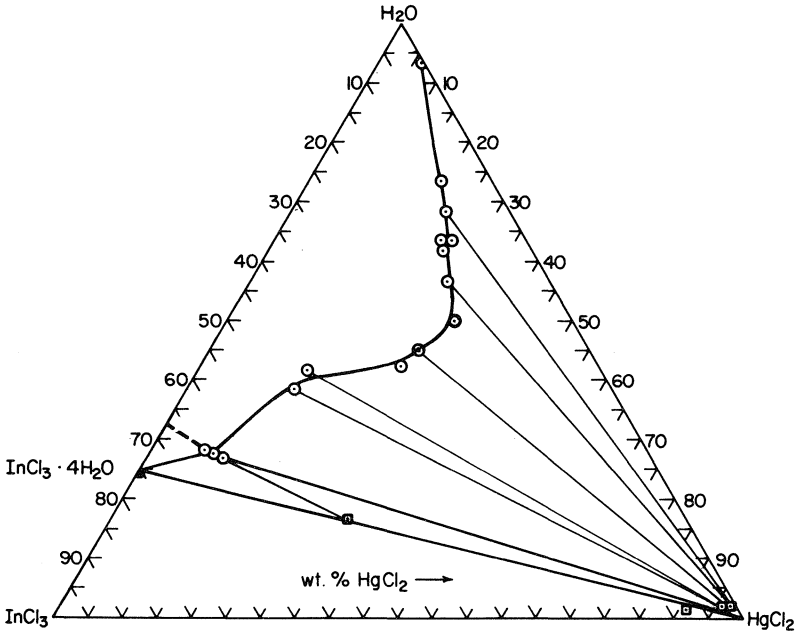

FIG. 8. The system $InCl_3$–$HgCl_2$–H_2O at 24°C.

increase in the solubility of mercuric chloride, which occurs also in the system HCl–$HgCl_2$–H_2O investigated by Thomas (10), may be due to complex ion formation in the solution. Nevertheless, the solid phase is anhydrous $HgCl_2$.

In conclusion, a summary of double salt formation between indium chloride and the chlorides of hydrogen, ammonium, and the metals of Groups Ia, IIa, and IIb are given in Table 2. All the double salts are congruently saturating.

The compositions of these ternary compounds have been reported in the usual way as double salts. Some, or all of them, may be salts containing the chloroindate anion. However, a phase rule study cannot decide this point.

Of immediate note in Table 2 is the absence of

eight double salts claimed by Ensslin *et al.* (2), viz. those marked * in Table 1. These systems are reported in Linke along with similar work on indium fluoride, indium iodide, and indium iodate, by the same author. It is questionable whether the several double salts reported in the latter systems have any validity either.

Among the chlorides of Group I, sodium chloride is the only one which does not form a double salt with indium trichloride. Indeed, sodium chloride forms few double salts with other chlorides. Exceptions reported in Linke are $Na_2PtCl_6 \cdot 5H_2O$ and $HgCl_2 \cdot NaCl \cdot 2H_2O$. Salt deposits formed by the evaporation of sea water (containing the ions Na^+, K^+, Mg^{2+}, Cl^-, and SO_4^{2-}) contain sodium chloride as the simple salt, while potassium chloride and magnesium chloride exist as double salts.

It is interesting to compare aluminum chloride, ferric chloride, and indium chloride with regard to double salt formation with other chlorides, as far as these are known. In the case of aluminum chloride, the only system reported by Linke is that with potassium chloride and in this case there is no double salt. On the other hand, however, ferric chloride shows a close correspondence with indium chloride, in that there is no double salt with sodium chloride, but one, and in the case of cesium chloride, two, double salts with the other Group I type ions.

The chlorides of Be, Mg, and Ca each form a double salt with indium trichloride. Strontium chloride and barium chloride do not form double salts with indium trichloride and neither do the chlorides of Group IIb. That mercuric chloride does not form a double salt with indium chloride is surprising, since it forms many double salts with the chlorides of Group I and Group II. Ferric chloride has not been studied as to its behaviour with the chlorides of Group II, so no comparison is possible.

Organocation speciation. I. A comparison of the interactions of methylene blue and paraquat with bentonite and humic acid

R. D. GUY,[1] D. R. NARINE, AND S. DESILVA
Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received July 27, 1979

R. D. GUY, D. R. NARINE, and S. DESILVA. Can. J. Chem. **58**, 547 (1980).

A model system composed of bentonite, humic acid (HA), polystyrene sulphonic acid (PSSA), methylene blue (MB), and paraquat was used to characterize the possible interactions of organocations in natural waters. The adsorption and desorption studies with bentonite indicated that the clay had a strong preference for the organocations over alkali and alkaline earth cations. Paraquat saturated the bentonite up to the cation exchange capacity whereas methylene blue did not completely saturate the clay but did form methylene blue aggregates on the clay surface. The aggregates could be readily removed by washing with distilled water. The organocation interactions with the anionic polyelectrolytes were more susceptible to changes in pH or ionic strength. Paraquat could be completely desorbed from HA and PSSA by raising the solution ionic strength to 0.1. Methylene blue could not be completely removed from the humic acid but could be removed from PSSA by raising the ionic strength to 0.1. The studies indicate that a combination of dialysis separations, variation of ionic strength, and spectrophotometric analysis could be used to determine the free paraquat and the bound paraquat susceptible to changes in environmental levels of pH and ionic strength.

R. D. GUY, D. R. NARINE et S. DESILVA. Can. J. Chem. **58**, 547 (1980).

Nous avons utilisé un système composé de bentonite, d'acide humique (AH), d'acide polystyrène sulfonique (APSS), de bleu de méthylène (BM) et de paraquat afin de caractériser les interactions possibles des organocations dans les eaux naturelles. Les études d'adsorption et de désorption avec la bentonite indiquent que l'argile préfère de beaucoup les organocations aux cations des terres alcalines. Le paraquat sature la bentonite jusqu'à la capacité d'échange des cations alors que le bleu de méthylène ne le sature pas complètement mais forme des agrégats de bleu de méthylène à la surface de l'argile. Les agrégats peuvent être facilement enlevés par lavage à l'eau distillée. Les interactions entre les organocations et les polyélectrolytes anioniques sont plus susceptibles de varier selon la force ionique ou le pH. Le paraquat peut être complètement désorbé du AH ou du APSS en augmentant la force ionique de la solution à 0.1. Le bleu de méthylène ne peut être enlevé complètement de l'acide humique; dans le cas du APSS on peut toutefois l'enlever en augmentant la force ionique à 0.1. Les études indiquent qu'on peut utiliser une combinaison de séparation par dialyse, de variation de la force ionique et d'analyse spectrophotométrique, pour déterminer le paraquat sous forme libre ou combinée susceptible de changer dans des milieux de différents pH ou de force ionique.

Introduction

The chemical interactions of organic compounds in the environment play an important role in the transport and persistence of the chemicals. The interactions also determine the ultimate biological activity of the toxic compounds. The concentration of a compound in an aquatic system will be determined by the rate of addition from the external environment, the rates of chemical, photochemical, and microbial decomposition, and the adsorption of the compound onto sedimentary and colloidal material. The partition of a chemical among soluble, colloidal, and particulate species plays a vital role in the toxicity of organic herbicides. Gillott *et al.* (1) have shown that the presence of sediment in test systems significantly reduces the toxicity of carbaryl and abate to algae. Guy and Narine (2) have shown that clay and colloidal humic substances reduce the toxicity of paraquat to algae. Other workers have indicated that herbicides in aquatic systems are associated with inorganic colloids (3), associated with dissolved and particulate humic substances (4), and dissolved in lipid coatings on particulates (5) and in biotic material. Since the role of adsorption reactions in environmental systems is so important it is necessary to develop

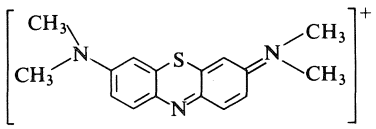
analytical methods for the speciation of organics in water systems.



Most work reported in the literature (6–8) has been concerned with the speciation of metal ions. One problem illustrated by the metal speciation studies is that the interpretation of the analytical response is often difficult. To overcome this problem Guy *et al.* (9, 10) have proposed that metal speciation schemes be developed using a chemical model approach. The first step in a model study is to characterize the physicochemical properties of cations in clay and humic colloid systems. The second step in this approach is to use the model system to test methods of speciation and correlate the analytical response with the physicochemical properties of the system. The purpose of this paper is to describe a model system suitable for testing the speciation of organic cations in fresh and marine waters.

Model Background

A viable model system should include organocations, dissolved inorganic salts, particulate matter, and dissolved organic material. Two organic cations are included in the model: 1,1′-dimethyl-4,4′-bipyridinium dichloride (**1**) (methyl viologen or paraquat), and methylene blue (MB, **2**).

1

2

Paraquat is included in the model because of its use as a herbicide. Methylene blue is included in the model to illustrate the relationships between the interaction of the cation with particulates and the charge and hydrophobic character of the organocation. Other reasons for the inclusion of methylene blue in the study are the demonstrated toxicity of the dye to algae (2), the extensive use of the dye as a method of evaluating cation exchange capacities of clays (11), and the significant body of literature describing the dye interactions with anionic polyelectrolytes (12–14).

Bentonite and humic acid (HA) are included in the model to represent suspended particulates and dissolved organic matter, respectively. The literature available describing the interactions between paraquat and soil colloids is voluminous (15–23). The principal conclusions reported in the literature are:

(*i*) The paraquat interaction with clay is an ion exchange reaction. Montmorillonite has a strong preference for paraquat and little paraquat (< 10%) is desorbed in the presence of a 1000-fold excess of Ba^{2+} (18).

(*ii*) Paraquat interacts with humic colloids using an ion exchange reaction. Calderbank and Tomlinson (24) have shown that the amount of paraquat adsorbed is inversely proportional to the stability of the metal cation – humic acid complex in the presence of a number of metal cations. Khan (16) has suggested that charge transfer may also be involved in the interaction between paraquat and humic acid.

A number of workers (25–28) have studied the interactions of methylene blue with clays. The results of these studies can be summarized as follows: the adsorption consists of two interactions, an ion exchange reaction and a physical adsorption reaction (25), and the methylene blue can be readily exchanged using alkaline earth cations.

Little work has been published on the interactions of methylene blue with humic substances. A number of papers (12–14) have been published on the interactions between dyes and synthetic polyelectrolytes. These investigations indicate that the interactions are very dependent on ionic strength and at high coverages adsorbed dye – soluble dye interactions are present. Polystyrene sulphonic acid (PSSA) has been included in the model studies so that a comparison can be made between cation interactions with HA and a well-characterized polyelectrolyte.

This paper describes the characterization of the organocations, bentonite, and humic acid model system at different values of pH (varied from pH 1 to pH 9) and ionic strength (over the range 10^{-4} to 0.6). This characterization had to be repeated, despite the large body of literature, for a number of reasons. Paraquat is applied as an aquatic herbicide at levels of 0.8–2.0 μg/mL (29). Water samples collected near the surface typically contain suspended solid loads of 1 mg to 100 mg/mL and dissolved organic carbon levels of 0–10 μg/mL. The pH values of natural waters are most commonly in the range 5.0 to 8.0. The studies reported in the literature are for soil systems using clay levels of 1.25–25 g/L and humic acid levels of 0.50–50 mg/mL. Few, if any, studies report the pH of the clay systems, and the humic acid studies were usually done at pH 4.0 in unbuffered systems. The paraquat concentrations used in the literature (at equilibrium) were at the 1–10 m*M* level. This study reports adsorption and desorption experiments using systems containing paraquat at the μg/mL level and colloid levels of 10 μg/mL to better

For personal use only.

reflect environmental levels. A second departure from previous studies is the use of dissolved humic acid (i.e., filterable through a 0.2 μm Nuclepore filter) instead of slurry techniques. The results reported in this study are closer to natural water systems than earlier reports.

Experimental

Chemicals

Bentonite (Fisher) was converted to the potassium form by an equilibration with 1 *M* KNO_3. The potassium form of the clay was placed in 300 mL of distilled water, blended at high speed for five minutes in a Waring blender, transferred to a one litre graduated cylinder, and made up to volume with distilled water. A 48 h settling period was used to remove the more dense particles and the upper 900 mL of the suspension was transferred into a second container. The clay content was determined by filtering through a 0.2 μm Nuclepore membrane filter. A typical suspension contained 3.21 ± 0.15 mg clay/mL. The cation exchange capacity was determined using both an ammonium acetate exchange method and a calcium exchange. The ammonium acetate method gave a cation exchange of 62 mmol K/100 g and the calcium uptake also gave a value of 62 mequiv./100 g (i.e., 31 mmol Ca/100 g).

Humic acid (Aldrich) was acid-washed with 3 *M* HNO_3 to remove heavy metals and to convert the humic acid to the fully protonated form. Solutions of humic acid were prepared by dissolving 300 mg of dried acid in one litre of distilled water to which five pellets of KOH were added. The concentration of humic acid was determined by allowing the undissolved entities to settle for seven days and filtering the solution. The undissolved matter was dried, weighed, and the concentration calculated by difference. A typical solution contained 187 μg HA/mL. The total acidity of the humic acid and the carboxyl content were found to be 6.7 mequiv./g and 2.4 mequiv./g, respectively.

Methylene blue was obtained as the hydrated chloride salt (Matheson). The dye content of the salt was obtained by drying under vacuum with anhydrone as the drying agent. The moisture content was found to be 19.0 ± 0.2%. All solutions were prepared using the dried solid. The purity of the methylene blue was checked by thin layer chromatography on a silica gel developed with 1:9 glacial acetic acid – methanol. A comparison of the developed chromatograms with possible contaminants (thionine, Azures, A, B, and C) indicated only methylene blue was present. Methyl viologen hydrate (Aldrich) was standardized by passing a 25.00 mL aliquot of the stock solution through a Rexyn 100 cation exchange resin in the hydrogen form. The protons released were titrated with standard base to a phenolpthalein endpoint.

Methods

The distribution of methylene blue and paraquat between solution and clay particulates was determined by two methods. The first was a bulk adsorption experiment in which known amounts of organocation were equilibrated with 40 mL of 5 ppm bentonite in polyethylene centrifuge tubes. After a 12 h equilibration the suspensions were centrifuged, decanted onto 0.20 μm Nuclepore membrane filters, and the residue washed with distilled water. Preliminary studies indicated that the adsorption of methylene blue and paraquat onto the bentonite was complete after 3 h. Controls indicated that no MB and paraquat were adsorbed onto the centrifuge tubes, filter, and associated glassware. The washings and the decantate were analyzed using visible spectrometry at 667 nm for MB. Paraquat was determined using the procedure of Calderbank and Yuen (30). The amount of cation adsorbed was determined by difference.

The second method for organocation–bentonite adsorption studies used a dialysis bag (Fisher, pore size 4.8 nm) to contain the clay suspension. The clay/dialysis bag was equilibrated with a solution containing known amounts of organocation. A 72 h equilibration was found to be sufficient. The suspension inside the dialysis bag was filtered and washed, as above, and the filtrate and outer solution analyzed for organocation. The amount of cation adsorbed by the dialysis bag was determined from controls (always less than 1% of the total) and the amount adsorbed onto the clay calculated by difference. The adsorption studies were done at different values of ionic strength (set by KNO_3) and pH.

Desorption experiments were done by equilibrating bentonite (saturated with organocation) and solutions containing monovalent, divalent, and trivalent cations at concentrations of 0.1 *M* and 0.5 *M* in centrifuge tubes. The amount of organocation released was determined at 24, 168, and 720 h. No difference was noted between the three measurements.

The distribution of MB and paraquat between solution and HA or PSSA was studied using the dialysis bag method. Solutions containing known amounts of organocation and HA or PSSA were shaken for 18 h with a dialysis bag containing distilled water. Preliminary studies indicated that dialysis equilibrium (organocation only) was attained in 3 h and in the presence of the polyelectrolytes within 6 h. An uv scan of the dialyzate of HA and PSSA indicated that no HA and PSSA diffused through the membrane or adsorbed onto the membrane. The concentration of organocation inside the dialysis bag was taken as the concentration of the free organocation. The amount adsorbed was calculated from the difference between total and free cation concentrations. Studies were done as a function of pH and ionic strength.

A study of the paraquat exchange reaction between solution and Dowex 50 × 8 (100–200 mesh) was initiated to determine the possibility of using a preconcentration step in a speciation procedure. One hundred millilitre aliquots of solutions containing paraquat, humic acid, and NaCl were passed through a column of 6 cm × 0.38 cm^2 of Dowex 50 × 8 in the H^+ form. The column was washed with 25 mL of 1 *M* NaCl and the paraquat eluted with 25 mL of saturated NH_4Cl. The paraquat concentrate was analyzed in the usual manner using an NH_4Cl (saturated) reference in the spectrophotometer.

Results and Discussion

Adsorption isotherms for paraquat and methylene blue onto clay are given in Fig. 1. The adsorption maxima for the two organocations at different values of ionic strength are given in Table 1. A preliminary set of experiments indicated that the same value of adsorption maxima was obtained whether the organocation was adsorbed onto the bentonite and then exposed to KNO_3 solutions (i.e., a desorption study) or the organocation was added to a KNO_3/bentonite suspension (i.e., adsorption experiment). The bulk adsorption and dialysis equilibration methods gave the same adsorption maxima. Table 2 presents the amount of organocation released from bentonite after equilibration with 0.1 *M* solutions of metal ions. Within experimental error the results indicate that the exchange reaction is reversible and little organocation is released in the presence of 10 000-fold excess of metal ion.

The results of the adsorption-desorption studies

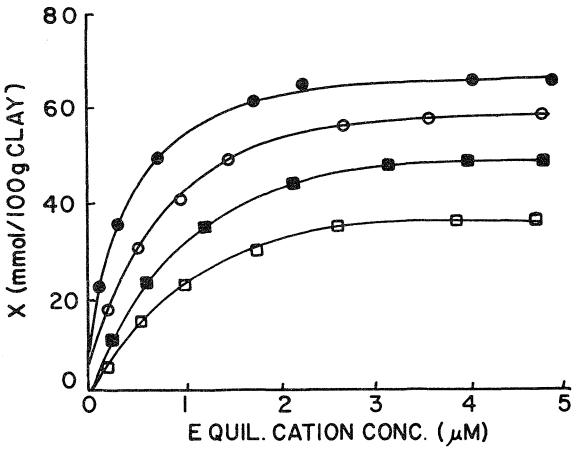

FIG. 1. Adsorption isotherms for paraquat and methylene blue onto bentonite. The solution pH was 6.1 and the free cation concentration was determined by dialysis. Point size reflects experimental uncertainty: ● MB, 0 *M* KNO_3; ○ MB, 0.1 *M* KNO_3; ■ paraquat, 0 *M* KNO_3; □ paraquat, 0.1 *M* KNO_3.

TABLE 1. Adsorption maxima* for bentonite–organocation systems

KNO_3 (*M*)	Paraquat (mequiv./100 g)	MB (mequiv./100 g)
0	90.2	64.0
0.01	80.2	61.0
0.05	76.6	59.2
0.10	74.0	57.0
0.50	66.2	52.0

*Experimental uncertainties in the adsorption maxima were ±3 mequiv./100 g.

TABLE 2. Desorption results* in the presence of 0.1 *M* cations

Cation	Paraquat released (%)	MB released (%)
Ca	9.4	0.6
Mg	8.0	0.7
Ba	9.4	0.7
Zn	8.7	—
Al	14.8	1.1
Li	4.1	0.4

*Organocation initially adsorbed at 0.01 *M* KNO_3 and then exposed to metal cation solutions. Uncertainties in amount released were ±1% for paraquat and ±0.2% for methylene blue.

indicate that the clay has a strong preference for methylene blue and paraquat over metal cations. The amount of methylene blue adsorbed was equal to the measured cation exchange capacity. Paraquat, however, was adsorbed in excess of the cation exchange capacity. This is in agreement with the work of Weber and Weed (18) done at higher clay and paraquat levels. Two possible reasons for the excess adsorption of paraquat are either a low measured cation exchange capacity or the presence of a second interaction other than cation exchange. A low cation exchange capacity can result when a clay suspension hydrolyzes and aluminum or iron replaces K^+ at the exchange sites. A sodium bentonite specially prepared to overcome hydrolysis[2] had a cation exchange capacity of 93.0 mequiv./100 g but when suspended in water the capacity decreased to 80 mequiv./100 g. An adsorption experiment found that the sodium bentonite adsorbed 93 mequiv./100 g of paraquat. This is strong evidence that the paraquat cation can displace adsorbed hydrolysis products. Methylene blue, however, could not displace the cations resulting from hydrolysis because of the lower charge of the dye cation and only 80 mequiv. MB/100 g were absorbed onto the sodium bentonite.

The bulk adsorption and dialysis equilibration methods used in this study included a washing of the filtered clay with distilled H_2O before analysis. Other workers who have used MB to determine the cation exchange capacity (CEC) of particulates centrifuge the equilibrated sample and determine the MB content of the centrifugate. A comparison of the two procedures indicated that high CEC results were obtained without washing. Methylene blue in solution at high concentrations can form dimers and tetramers (31) and Bergman and O'konski (25) noted that dimer formation on the clay surface occurred in the presence of montmorillonite.

[1] $MB^+ + K—Mont. \rightleftharpoons MB—Mont. + K^+$(ion exchange)

[2] $MB^+ + MB—Mont. \rightleftharpoons MB...MB—Mont.$ (aggregation)

Our studies showed that at MB/bentonite ratios below the clay CEC all of the MB was adsorbed and none could be removed by water washing. Above the CEC, however, the aggregated MB at the bentonite surface could be removed by washing with distilled water. Similar experiments with paraquat indicated no aggregation at the clay surface. The different aggregation behaviour of paraquat and methylene blue is probably a result of stronger repulsions between two divalent cations of paraquat whereas the lower, more delocalized, charge of a MB cation will tend to decrease the repulsions between ions.

Two exchange isotherms were done at pH 8 and 3 in 0.01 *M* KNO_3 to determine the competition between organocations and protons. The adsorption maxima at pH 8 were 65.0 ± 3 mequiv. MB/100 g and 88.0 ± 3 mequiv. paraquat/100 g whereas at pH 3 the values were 57.0 ± 3 mequiv. MB/100 g and 81.4 ± 3 mequiv. paraquat/100 g. The proton ap-

pears to compete more favourably with the organocations than the alkali earth cations.

The adsorption and desorption behaviour of methylene blue and paraquat in the presence of bentonite has a number of important consequences with respect to analytical speciation methods. If one wishes to estimate the application rate of paraquat to aquatic systems necessary to maintain a toxic dose of free paraquat, then a preliminary adsorption capacity of the particulates should be made. Some workers have suggested (11) that a CEC measurement with MB as the exchanger would be useful for both inorganic and organic ions. This work suggests, however, that the paraquat cation can displace hydrolysis products adsorbed on the bentonite particulates. The preliminary CEC measurement for paraquat should be made with paraquat and not extrapolated from regular CEC measurements using NH_4^+ or Ca^{2+} exchange. The strong adsorption of both methylene blue and paraquat onto the bentonite indicates that less than 10% of the bound cation is released under normal environmental conditions. In the environment a pH drop from 8 to 4 (caused by acid rain, for example) or an increase in ionic strength from 0.010 to 0.5 in the estuaries would cause only a slight shift in the adsorption equilibria from bentonite clays.

The dialysis of methylene blue and paraquat as a function of concentration in 0.01 *M* KNO_3 and 0.01 *M* KNO_3/7.8 μg HA/mL is shown in Fig. 2. It is evident that the interaction between organocation and humic acid is more favourable for MB than paraquat. Figures 3 and 4 present the adsorption isotherms at different values of ionic strength for paraquat and methylene blue, respectively. Both sets of isotherms fail to attain a plateau and the paraquat interaction is more susceptible to ionic strength variations. The isotherms for methylene blue and paraquat adsorption onto humic acid at different solution pH values are given in Figs. 5 and

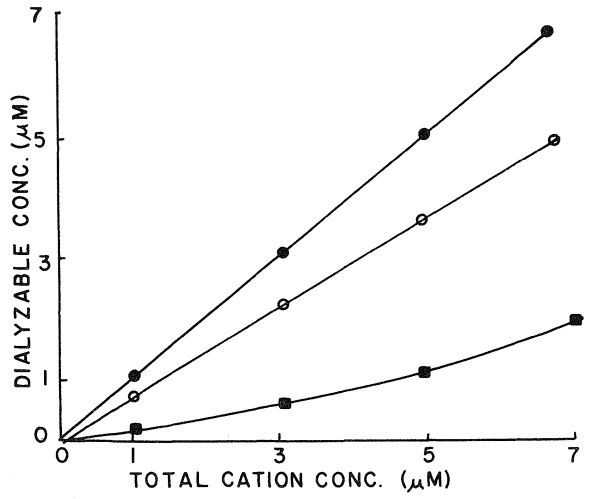

FIG. 2. A comparison of dialysis results for paraquat and methylene blue in the presence of humic acid. The separation was done at pH 6.5 and in 0.01 *M* KNO_3: ● MB, paraquat with no humic acid; ○ paraquat in 7.8 ppm HA; ■ MB in 7.8 ppm HA.

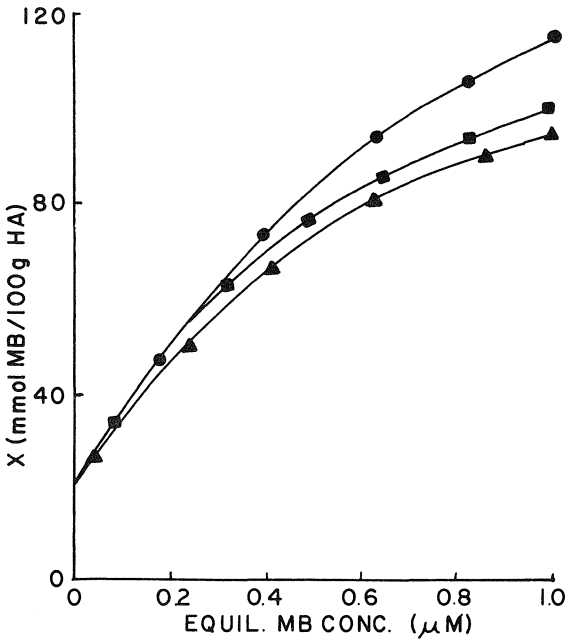

FIG. 5. Adsorption isotherms for methylene blue onto humic acid at different values of solution pH. All isotherms were done in the presence of 0.01 *M* KNO_3: ● pH 8.1; ■ pH 6.3; ▼ pH 1.0.

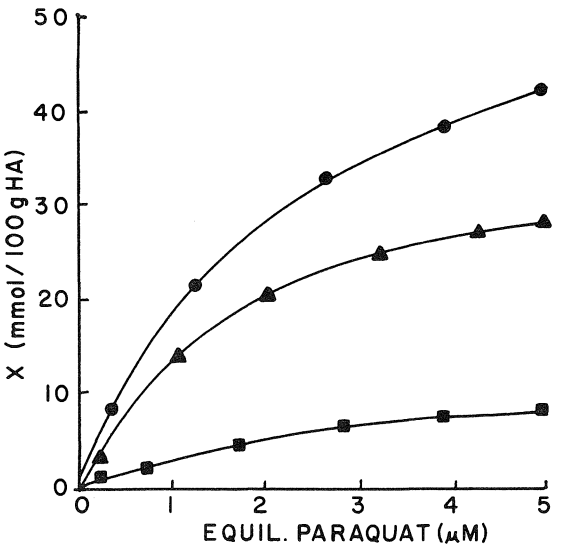

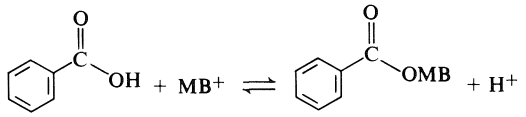

FIG. 6. Adsorption isotherms for paraquat and humic acid at different values of solution pH. All isotherms were done in the presence of 0.005*M* KNO_3: ● pH 8.2; ▼ pH 6.2; ■ pH 2.5.

6, respectively. Again, pH is more important for paraquat than MB. Desorption experiments indicate that 0.1 *M* KNO_3 and pH 1 solutions are capable of completely removing paraquat from humic acid. Similar experiments with methylene blue indicate that at pH 1 approximately 65% of the MB remains bound to humic acid and in 0.5 *M* KNO_3 50% of the MB remains bound to HA. Under similar conditions the copper – humic acid complex is completely dissociated at pH 1.0 (10).

The humic acid functional group responsible for exchange properties is a carboxylic acid:

The pH and ionic strength variations of paraquat indicate that the ion exchange reaction is the predominant interaction with humic acid. Methylene blue must have a secondary interaction with the humic colloid to account for the unusual pH dependence of the MB–HA system. It is possible that interactions between the more hydrophobic MB cation and aromatic backbone of humic acid may be present.

The isotherms for organocation interactions with HA can be compared to the interactions with PSSA shown in Fig. 7. The paraquat interacts with PSSA and HA in a similar fashion, that is, both isotherms are very dependent on ionic strength. The MB interaction with PSSA differs from the HA system in two respects. First the MB–PSSA system is very dependent on ionic strength. Secondly the MB–PSSA isotherm indicates that adsorbed molecules enhance the adsorption of additional molecules. Other workers (12–14) have interpreted this type of isotherm as indicative of dye–dye interactions on the polyelectrolyte.

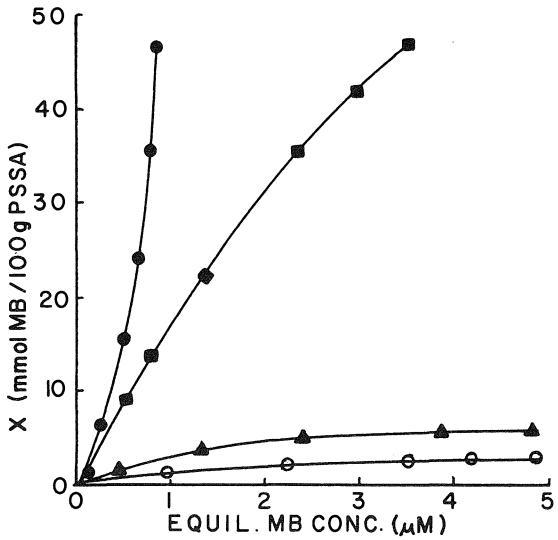

FIG. 7. Adsorption isotherms for methylene blue and paraquat onto PSSA. All isotherms were done at pH 6.0 and point size reflects experimental uncertainty of three samples: ● MB, 0 *M* KNO_3; ▼ paraquat, 0.01 *M* KNO_3; ■ MB, 0.05 *M* KNO_3; ○ paraquat, 0.1 *M* KNO_3.

The isotherms for the organocations with HA and PSSA have some importance with respect to speciation of aquatic systems. The paraquat–HA system is more susceptible to variations in pH and ionic strength than clay–paraquat systems. In transitions from fresh to salt water one can expect a significant release of paraquat from the humic substances; if the inorganic particulates are already saturated with paraquat then one can expect an increase in the concentration of free paraquat in the estuaries and in acidic waters. The interactions of MB with humic acid suggest that hydrophobic organic pollutants may be less susceptible to changes in pH and ionic strength.

The studies of bentonite/HA/organocation systems suggest the speciation scheme illustrated in Fig. 8. Table 3 presents the results obtained when the scheme is applied to a paraquat/bentonite/HA system and to paraquat/bentonite and paraquat/HA systems. The data summarized in Table 3 indicate that the humic acid and clay systems are additive. This probably is a result of the saturation of the clay with organocation and followed by a free paraquat/paraquat bound to humic acid equilibrium. As the ionic strength is increased the paraquat is completely released from the humic acid and partially released from the bentonite. Similar systems using humic acid at different levels indicate that the bentonite is always saturated before paraquat is bound to the humic acid.

The competition between clay and humic acid for paraquat suggests that an ion exchange resin should be able to remove bound paraquat from humic acid. Table 4 presents the results of column studies for humic acid and paraquat systems. The results indicate that a significant difference exists between dialyzable paraquat and total paraquat values but no significant difference between ion exchangeable and total paraquat results. This suggests that an ion exchange preconcentration step may be used to estimate the paraquat concentration in solutions after filtration to remove particulates.

The results of this study indicate that clay particulates will control the organocation concentration at levels of paraquat that do not exceed the clay cation exchange capacity. At paraquat levels above the exchange capacity of the clay humic acid will bind cations. The humic acid – paraquat interaction is very susceptible to changes in ionic strength and significant amounts will be released in the estuaries.

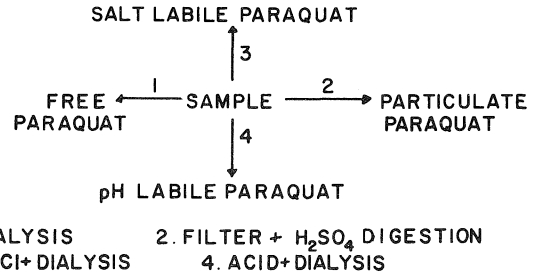

FIG. 8. Suggested speciation scheme for paraquat in natural waters.

TABLE 3. Paraquat* speciation in model systems

Added NaCl (*M*)	HA/clay	Free paraquat (μg/mL) Clay	HA
0	0	0.61	0.43
0.01	0.19	0.63	0.70
0.05	0.44	0.71	0.1
0.10	0.59	0.73	1.0
0.30	0.66	0.76	1.0
0.50	0.71	0.77	1.0
Organic bound paraquat	0.42	—	0.57

*Uncertainties in paraquat concentrations for runs done in triplicate were: HA/clay ±0.05 μg/mL; clay ±0.02 μg/mL; HA ±0.02 μg/mL. Initial concentration of paraquat was 1.0 ppm and clay and humic acid concentrations were 5 and 10 ppm, respectively. The organic bound paraquat was determined from: amt. bound (0 *M* NaCl) − amt. bound (0.1 *M* NaCl) − amt. released from clay.

TABLE 4. Ion exchange preconcentration recoveries*

Total paraquat (ppm)	HA (ppm)	NaCl (M)	Paraquat dialysis (ppm)	Paraquat (ppm) ion exchange
1.0	0	0	1.0	1.00
1.0	0	0.01	1.0	0.99
1.0	0	0.1	1.0	1.00
1.0	0	0.5	1.0	0.98
1.0	1	0	0.95	1.00
1.0	2	0	0.90	0.97

Organocation speciation. II. Methylene blue photosensitization as a model for speciation and toxicity of herbicides

ROBERT D. GUY[1] AND DEORAJ R. NARINE

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J1

Received July 27, 1979

ROBERT D. GUY and DEORAJ R. NARINE. Can. J. Chem. **58**, 555 (1980).

A chemical model that employs the photosensitization properties of methylene blue to mimic herbicide toxicity is used to test size separation as a method of chemical speciation. A spectrophotometric study of the dye interactions with the humic colloid indicated that the dye – humic acid complex has a weaker absorption spectrum than the free dye. The absorption spectra suggested that the binding sites on the humic acid are sufficiently isolated to prevent dye–dye interactions on the colloid surface. The dye photosensitization of tryptophan degradation indicated that only the free methylene blue was active in the presence of humic acid, clay, and polystyrene sulphonic acid. The model suggests that if the pollutant must be in true solution to be biologically active then a size separation by dialysis would be a satisfactory speciation procedure.

ROBERT D. GUY et DEORAJ R. NARINE. Can. J. Chem. **58**, 555 (1980).

On a utilisé un modèle chimique qui fait appel aux propriétés photosensibilisatrices du bleu de méthylène dans la toxicité de l'herbicide mimique, pour vérifier la séparation dimensionnelle comme une méthode de détermination de l'espèces chimique. Une étude spectrophotométrique des interactions entre le colorant et le colloide humique indique que le complexe colorant – acide humique a un spectre d'absorption plus faible que le colorant à l'état libre. Les spectres d'absorption suggèrent que les sites de liaison dans l'acide humique sont suffisamment isolés pour prévenir les interactions colorant–colorant à la surface du colloide. La dégradation du tryptophane photosensibilisée par le colorant indique que seul le bleu de méthylène est actif en présence d'acide humique, d'argile et de l'acide polystyrène sulfonique. Le modèle suggère que si le polluant doit se trouver réellement en solution pour être biologiquement actif la séparation par dialyse peut être satisfaisante comme méthode de détermination de l'espèce.

Introduction

Chemical speciation of toxic substances in the aquatic environment plays an important role in biological toxicity. Previous studies (1) have shown that paraquat, a cationic herbicide, was less toxic to an unicellular alga in the presence of bentonite and humic acid. Two mechanisms of pollutant toxicity to algae have been reported in the literature. The first mechanism is an interaction between the cell wall and pollutant that changes the wall's permeability. Cupric and mercuric ions have been found (2, 3) to interact with cell walls and cause a leakage of potassium ions out of the cell. The second mechanism is an interaction between a pollutant and cellular components that interferes with metabolism. Methyl viologen (paraquat) acts as a herbicide because the cation interferes in the electron transport chain in photosynthesis (4). In photosystem I the excited chlorophyll complex reduces paraquat instead of ferredoxin. The paraquat radical is rapidly oxidized by O_2 to form H_2O_2 and paraquat. It is the H_2O_2 produced that is the toxic substance. Paraquat, therefore, can be thought of as a photochemical herbicide; the chlorophyll absorbs light and reduces the paraquat which acts as a catalyst in the production of the toxic substance, H_2O_2.

Methylene blue (MB), a cationic dye, was found (1) to be toxic to algae at the 10^{-8} *M* concentration level. A preliminary study indicated that light was a prerequisite for toxicity. If the algae were grown in the presence of methylene blue but with an outer filter designed to reduce the incident light level at 665 nm (λ_{max} for MB) to 0.1% of its initial level the effect of the dye was algistatic. Algal flasks surrounded by the filter were found to exhibit normal growth and flasks containing MB but no outer filter were algicidal. Heitz and Wilson (5) have found similar insecticidal activity for the xanthene dyes; when insects fed xanthene dyes were exposed to visible light the dye was toxic.

The prerequisite of light for the toxicity of the dye indicates that the toxic effect is probably the result of a photosensitization reaction. Methylene blue absorbs light at 665 nm to form a singlet excited state which can cross over to yield a triplet excited state:

The photosensitization reaction has been reported in the literature (6–8) for the decomposition of nucleotides, aminoacids, and enzymes. The result of the dye attack on algal cell components would be algal death.[2]

The similarity in toxic mechanisms, a photochemical step and a catalytic production of the toxic substance, for methylene blue and paraquat allows one to design a chemical model to study organocation speciation. If one uses methylene blue as the organocation then one can substitute an amino acid as the speciation monitor instead of an algae. The advantages of a chemical model over the biological model is the ability to vary ionic strength and pH over larger ranges in a chemical system. This paper describes a study of the degradation of tryptophan in methylene blue, humic acid, and bentonite model systems.

Experimental

The clay, humic acid, polystyrene sulphonic acid (PSSA), and methylene blue preparations were described in Part I of this series (9). The tryptophan (Eastman Kodak) was dissolved in NaOH and stored in the dark.

The degradation studies were done in a light box composed of four cool-white, 35 W fluorescent lamps (13 cm apart). The temperature inside the light box was 27°C, and a flow rate of 350 mL air per min through the flasks was maintained using aquarium pumps. Solutions or suspensions containing humic acid or bentonite, methylene blue, and tryptophan ($1.0 \times 10^{-4}M$) in 250 mL Erlenmeyer flasks were irradiated in the light box. Tryptophan was monitored using uv spectrometry at 280 nm, MB and humic acid were found not to interfere, and the bentonite was removed by centrifugation before analysis. Dialysis separations were used to determine the free concentration of methylene blue in the suspensions.

Results and Discussion

Figure 1 presents the tryptophan degradation as a function of time for different levels of methylene blue at pH 7.8 in $1 \times 10^{-3}M$ $NaHCO_3$. A similar set of curves was generated for methylene blue in the presence of 0.5 ppm humic acid (also at pH 7.8 and $1.0 \times 10^{-3}M$ $NaHCO_3$). Figure 2 shows the amount of tryptophan degraded after eight hours as a function of total methylene blue concentration. The presence of the humic acid (curve *B*) significantly reduces the amount of tryptophan degraded. When the degradation results are replotted as a function of dialyzable methylene blue, curves *A* and *B* coincide (the triangles in curve *A* are for the dialyzable methylene blue in the presence of humic acid). A similar study of tryptophan/bentonite/methylene blue and tryptophan/PSSA/methylene blue systems showed that only the free or dialyzable methylene blue was responsible for tryptophan degradation.

One of the principal conclusions of the model studies reported in Part I (9) was that as the ionic strength increases significant desorption would occur for MB/HA systems but no desorption for MB/bentonite systems. Figure 3 presents the re-

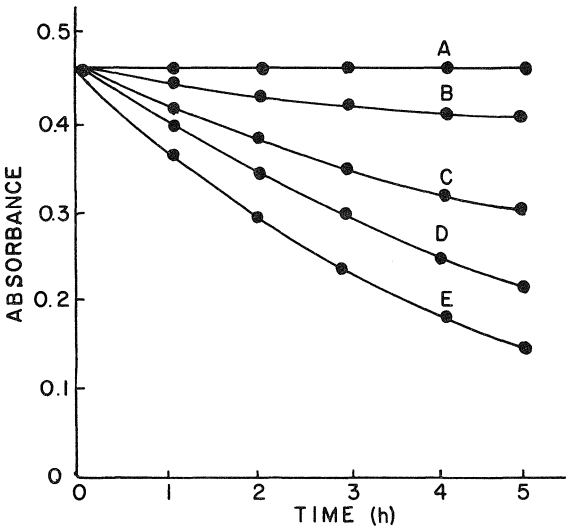

FIG. 1. Free methylene blue and tryptophan degradation in the presence of 100 ppb MB and 0.5 ppm humic acid at different NaCl concentrations. ● Free MB. ■ Tryptophan degradation.

[2]The algistatic effect observed in the flask surrounded by the filter is probably the result of the reduction of methylene blue by photosystem I. This will deprive the cell of a source of energy and over the long term will result in death. At the methylene blue levels used in these experiments, however, the principal short-term toxic effect is the photosensitization reaction.

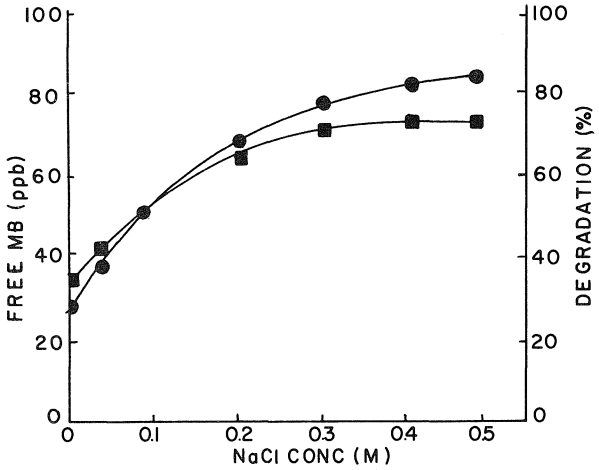

FIG. 3. Absorption spectra of MB and PSSA solutions: (*A*). MB control, (*B*). 5 ppm PSSA and 2 ppm MB, (*C*). 5 ppm PSSA and 1.2 ppm MB, (*D*). 5 ppm PSSA and 0.4 ppm MB. (*B*, *C*, and *D* are against the dialysate as reference.)

sults of a degradation study as a function of NaCl concentration. As the concentration of NaCl increases the dialyzable MB and the tryptophan degradation increase. For a 100 ppb MB/1 ppm bentonite system no release of MB and no degradation of tryptophan was observed over the same range of NaCl concentrations.

The results reported in Figures 1, 2, and 3 indicate that methylene blue in homogeneous solutions was a good photosensitizer for tryptophan degradation whereas in colloidal systems the degradation was proportional to the dialyzable methylene blue. Studies of methylene blue/colloid/algae systems (1) indicated that toxicity was related to the free MB. Within experimental error (±5%) there was no evidence that the bound dye was toxic to algae (1) or that the bound MB could act as a photosensitizer for tryptophan degradation. There are a number of possible reasons for the decrease in MB toxicity or the ability of MB to act as a photosensitizer. The colloidal polyelectrolytes (HA and PSSA) and bentonite may quench the $^1O_2$ produced by the bound MB. Silical gel, for example, quenches the production of $^1O_2$ in the silica gel/adsorbed MB systems (10). In algal systems the bound MB may be less toxic to algae because the MB is unavailable to the algae either for adsorption onto cell walls or for transfer across the cell membrane. In the MB/colloid/tryptophan systems, however, the tryptophan molecule should be able to interact either with $^1O_2$ or ^{3}MB at the colloid surface. A third possibility for the unreactive nature of bound MB is different light absorption and emission properties of MB bound to the colloid. A spectroscopic study of MB/HA and MB/PSSA systems was undertaken to investigate this possibility.

Figure 4 presents the visible absorption spectra of methylene blue in the presence of humic acid. Curves *A*, *B*, and *C* in Fig. 4 are for the total solutions against a water reference. The spectra are indistinguishable from the spectrum of free methylene blue. Curves *C* and *D* in Fig. 1 are for a solution of 2 ppm MB and 4 ppm humic acid. Spectrum *D* was recorded using the dialyzable methylene blue as a reference and hence is a difference spectrum representing the MB – humic acid complex (humic acid had no absorption in this region). A comparison of spectra for a constant humic acid concentration and varying methylene blue concentration indicated that the two new absorptions at 618 nm and 688 nm increased in height linearly as the concentration of MB increased. An increase in the MB – humic acid ratio did not cause a shift in absorption maxima (at 618 and 688 nm).

The solutions employed for spectra *C* and *D* in Fig. 4 contained 50% of the methylene blue in a dialyzable form. The decrease in absorption intensity of the bound methylene blue may result in a decrease in the number of MB molecules available for sensitization reactions. In solutions containing high humic acid to dye ratios, such that all of the methylene blue is bound to the colloid, no fluorescence below 800 nm is observed. It appears that the low photosensitization efficiency of bound methylene blue is a result either of poor light absorption properties or of quenching properties of the humic colloid.

Figure 5 presents the spectra of methylene blue in the presence of PSSA. Spectra *B*, *C*, and *D* were

recorded with the dialyzable methylene blue as the reference. As the dye–polyelectrolyte ratio increases the absorption maximum shifts to a lower wavelength. The difference in spectra between humic acid and PSSA can be interpreted as the sites in humic acid being farther apart than in PSSA. A number of workers (11–13) have suggested that the shift in absorption maxima is a result of the interaction of adjacent dye molecules when adsorbed onto polyelectrolytes. Bound methylene blue in the presence of PSSA does not fluoresce below 800 nm. It appears that the PSSA polyelectrolyte also quenches the bound methylene blue photosensitization reaction.

The model system described in this study indicates that only free methylene blue is capable of a photosensitization reaction. The dialysis separation procedure was able to determine the active methylene blue in clay and polyelectrolyte systems. This suggests that a dialysis separation could be used to determine the toxic components in natural waters if the toxic component had to be in a free form to interact with the algae cell.

A non-empirical SCF-MO study on the conformational properties and asymmetric deformations of dimethyl sulfoxide

PAUL G. MEZEY[1] AND ANIL KAPUR

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received August 21, 1979

PAUL G. MEZEY and ANIL KAPUR. Can. J. Chem. **58**, 559 (1980).

Conformational properties of dimethyl sulfoxide (DMSO) have been studied by *ab initio* molecular orbital method, using various gaussian basis sets. Polarization *d* functions are essential in reproducing the correct experimental geometry. Barriers to pyramidal inversion on sulfur and Me—S bond rotation have been calculated. The calculated asymmetric S—Me stretching potential indicates that minor intermolecular interactions may cause considerable geometric distortions in the DMSO molecule. These distortions are likely to contribute to the versatile biochemical effects of DMSO.

PAUL G. MEZEY et ANIL KAPUR. Can. J. Chem. **58**, 559 (1980).

On a étudié les propriétés conformationnelles du diméthylsulfoxyde (DMSO) par la méthode *ab initio* des orbitales moléculaires, en utilisant différents ensembles de base de gauss. Les fonctions de polarisation *d* sont essentielles pour reproduire la géométrie expérimentale convenable. On a calculé les barrières d'inversion pyramidale du soufre et de la rotation de la liaison Me—S. Le potentiel d'élongation asymétrique de la liaison S—Me calculé indique que des interactions intermoléculaires faibles peuvent causer des distorsions géométriques considérables dans la molécule de DMSO. Ces distorsions sont susceptibles de contribuer aux multiples effets biochimiques du DMSO.

[Traduit par le journal]

Introduction

A common feature appears to dominate the general conformational behaviour of most organosulfur compounds: along some internal coordinates the molecule shows very little resistance against deformations (1–10). By using a macroscopic analogy, along some coordinates these compounds show an "elasticity" similar to that of rubber, where, incidentally, sulfur bridges are largely responsible for the elastic properties. This "conformational elasticity" is by no means general for all internal coordinates. In fact, force constants for most normal modes of sulfur compounds fall in the usual range of stretching, bending etc. force constants of organic compounds. What appears characteristic, however, is the readiness of organosulfur molecules to undergo large deformations along one or some of the internal coordinates. The same trend is apparent for most organic molecules containing second row elements. However, the rich variety of organosulfur compounds, where this feature is present, suggests that sulfur moieties are particularly prone to deformations. The general "looseness" of the valence shell electron distribution in sulfur and also the near equivalence of carbon and sulfur electronegativities are factors that may facilitate such geometrical deformations.

The easy deformability of organosulfur compounds is unusual when compared to the deformability of molecules containing no second row elements. However, when comparing the relative ease of deformations for a given molecule along various internal coordinates, sulfur compounds appear even more peculiar. The deformability varies to a large extent from coordinate to coordinate for a given sulfur-containing molecule, and usually there is one coordinate direction along which the deformability far exceeds that in other coordinate directions.

Organic sulfur compounds frequently exhibit unusual conformational properties, that correspond to characteristic features on the conformational potential energy hypersurface of the molecule. Certain cross sections of the energy hypersurface are clearly distinguished by their flatness, giving rise to shallow minima or flat maxima. Earlier theoretical studies on various sulfilimines (7–10) indicated that potential curves corresponding to N—S bond rotations are extremely flat in rather wide angle intervals, although a complete 360° rotation is hindered. These studies indicated the presence of an unexpected low energy reaction path for the interconversion of enantiomeric forms (7, 8). Studies on the conformational energy hypersurface of the $H_2S{=}NH$ model molecule revealed segments along the S—N bond rotation coordinate, where the total energy E_t showed only negligible variations (10). The calculated transition states for various conformational processes were also unusual, showing very large variations of the curvature at the saddle point with the coordinate direction (Don Quixote type saddle surface (11, 12)).

The presence of extensive flat regions is not restricted to ground state energy hypersurfaces; *ab initio* studies of the first triplet state hypersurfaces of various thiocarbonyls showed similar features (13–16).

Of particular interest are those domains along a flat conformational path of sulfur compounds, which do not lie in the immediate neighbourhood of any of the energy minima, and, hence, the harmonic potential approach is no longer applicable there. In such cases the evaluation of the potential function from spectroscopic information is not always a trivial task. Similarly, the harmonic potential approach is inadequate in those regions, usually around points of inflection about halfway between a minimum and a maximum, where the slope is approximately constant. The more extensive this domain is and the closer it lies to the minimum, the narrower is the interval where the harmonic approximation can be applied. In the case of a symmetric potential, the curve is V shaped with a narrow harmonic region at the rounded off bottom of the V. In the linear regions Hooke's law is clearly inapplicable since there the restoring force is independent of the displacement, and a given force may result in unusually large deformations.

Dimethyl sulfoxide (DMSO) is an excellent model for a study of the above conformational problems. DMSO forms a wide variety of molecular complexes and many of its biochemical effects are believed to be related to the formation of such complexes (17). Experimental evidence indicates that the formation of a molecular complex may be accompanied by extensive geometric distortions of the DMSO structure (6). Interactions between two or more DMSO molecules are also thought to cause large geometric deformations. An X-ray analysis of DMSO crystals at 5°C showed a puzzling asymmetry of the molecule: the two chemically equivalent S—C bonds were found to differ by 0.05 Å (1), and refinement of the structure determination resulted in an even slightly larger difference. Although the reported large extent of discrepancy between the two bond lengths could possibly be an artefact of data processing, the authors of the study found no straightforward explanation. At a much lower temperature (−60°C), however, an independent X-ray study showed only minor differences between the two S—C bonds (18). While the experimental information appears somewhat contradictory, it is likely that the two C—S bonds in DMSO may undergo large deformations due to crystal forces without a large increase in the molecular total energy.

Method

The above findings motivated our present *ab initio* study on the conformational properties and asymmetric deformations of DMSO. Several points in various domains and along various cross sections of the conformational energy hypersurface of DMSO were calculated using the Hartree–Fock–Roothaan LCAO-MO-SCF technique. In order to maintain comparability with the results of earlier *ab initio* studies on sulfilimines (10) most calculations were carried out employing a 4-31 G (44-31 G for sulfur) gaussian basis set (Basis III). For preliminary surface scanning and geometry optimization, however, minimum 3G basis sets (Basis I), and for correct reproduction of the S=O stretching potential, 3 G basis sets augmented with *d* polarization functions (Basis II) have also been employed (19–22).

Deformations along four internal coordinates, corresponding to four characteristic conformation or geometry changes of DMSO were considered in some detail: (*i*) the C—S bond rotation, $\alpha_{S—Me}$; (*ii*) out-of-plane bending angle of S=O bond (pyramidal inversion on sulfur), $\theta_{S=O}$; (*iii*) S=O bond stretching, $r_{S=O}$; (*iv*) asymmetric S—Me stretching, represented by stretching of *one* of the S—C bonds, $r_{S—Me}$. All geometric parameters were optimized for a large number of DMSO structures, including pyramidal and planar forms, in two cycles of sequential approximations, using the minimum 3G basis set (Basis I). Points along cross sections (*ii*)–(*iv*) were reoptimized using the 4-31 G (44-31 G) basis sets (Basis III). The lowest energy pyramidal and planar DMSO structures that were obtained in the 3 G basis (Basis I) calculations, as well as points along crossections (*ii*)–(*iv*), were also reoptimized using the basis sets including polarization *d* functions on sulfur (Basis II).

As pointed out in detailed studies by Collins, v. R. Schleyer, Binkley, and Pople, small constrained gaussian basis sets without polarization *d* functions on sulfur are inadequate to give even qualitatively correct S=O bond lengths (22). This finding is rather intriguing as the same authors have also found that in spite of this inadequacy all other geometrical parameters of a representative set of sulfur compounds are considerably better reproduced than the S=O bond length, with the same gaussian basis sets, which do not include polarization *d* functions (22). Using model potentials for the atomic cores in SO_2, and representing the valence region with gaussian functions, both with and without polarization *d* functions, a detailed study by Huzinaga and Yoshimine (23) has indicated a simi-

[a] The S=O bond length was kept fixed at the X-ray experimental value of 1.47 Å (1).
[b] Geometric parameters correspond to optimized S=O bond length.

lar discrepancy in reproducing geometric parameters. The exclusion of polarization *d* functions caused a much larger relative error in the calculated S=O bond length than in the O—S—O bond angle. Apparently, predictions on bond angles in these molecules are much less sensitive to the presence of polarization *d* functions in the basis set than are predictions on S=O bond lengths, in spite of the directional properties of *d* functions. Similarly, calculated S—C and S—H bond lengths are also less sensitive to the inclusion of sulfur *d* functions in the basis set. The above findings suggest that cross sections (*i*), (*ii*), and (*iv*) of the DMSO energy hypersurface are likely to be adequately represented by employing *s* and *p* type basis functions only. By contrast, for calculation of the S=O stretching potential (*iii*) of DMSO, *d* functions appeared to be essential. For comparison, however, all three crossections, (*ii*), (*iii*), and (*iv*), have been recalculated using the Basis II that includes polarization *d* functions.

Results and Discussion

The optimized values of various geometric parameters of pyramidal and planar DMSO structures, and also the corresponding values of nuclear repulsion energies E_n and total energies E_t, as calculated with basis sets I, II, and III, are listed in Table 1. Experimental geometry data, taken from a recent compilation (24), are also included in the table. Using Bases I and III, two separate sets of optimizations were carried out. The parameters listed in the columns marked with an A were obtained by keeping the r_{SO} bond length constant at 1.47 Å, the value taken from the X-ray study of ref. 1. In the columns marked with a B the optimized value of the S=O bond length and the reoptimized values of the rest of the parameters are listed.

It is remarkable that the optimized values of the S=O bond length, calculated with the three bases, are extremely sensitive to variations in the bases, particularly to the inclusion of polarization *d* functions. This sensitivity exceeds even those of the set of simple sulfur compounds studied in ref. 22, and for Basis I the error (as measured from the experimental S=O bond length value of 1.48 Å, ref. 24) was as large as 0.34 Å. The calculated 1.82 Å S=O bond length is much larger than the Schomaker–Stevenson S—O single bond length of 1.69 Å (25). In fact, in the first optimization cycle with Basis I the S=O bond distance appeared divergent indicating the possibility of dissociation, and several optimization cycles were required to locate a real minimum at 1.82 Å. In spite of the qualitatively correct result of a stable S=O bond, Basis I fails to give even a qualitatively correct S=O bond length. By contrast, it is remarkable that the optimized values for the rest of the geometric parameters are markedly more accurate, although the error for the out-of-plane angle θ_{SO} is also rather large (6°). When restricting the S=O bond length to 1.47 Å (X-ray result, ref. 1) the corresponding optimum value of θ_{SO} (given in column A, Basis I) improves markedly (64.6°, in error by only 0.1°). However,

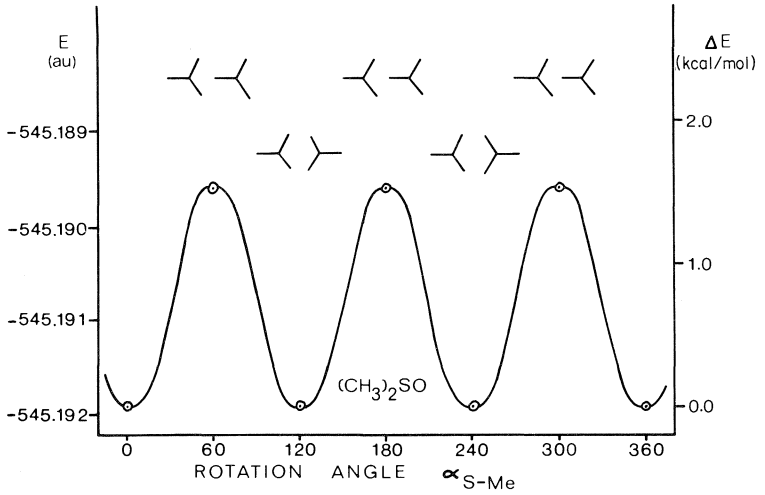

FIG. 1. Rotation potential curve along the α_{S-Me} coordinate of DMSO, calculated with basis I. Relative positions of the hydrogen atoms are shown above the extrema of the curve.

the optimized C—S bond length becomes much too long (1.86 Å as opposed to 1.81 Å). Nevertheless, the restriction on the S=O bond length brings about an overall improvement of the geometrical parameters.

Basis III gives a slightly better prediction for the S=O bond length, however, the 1.73 Å optimized value is still longer than the single bond value of 1.69 Å and much longer than the experimental value of 1.48 Å. The optimum out-of-plane angle 69.7° (θ_{SO} in column B) is somewhat better than the corresponding 70.6° result with Basis I (column B). In general, geometry predictions are reasonable for all but the SO bond length.

The inclusion of polarization *d* functions on sulfur (Basis II) gives rather accurate optimum values for all geometric parameters, in spite of the fact that in terms of total molecular energy this basis is inferior to Basis III. Bond lengths are accurate to 0.01 Å and bond angles to 2°. This finding is in excellent agreement with the results of Collins, Schleyer, Binkley and Pople on a set of simple sulfur compounds (22).

All three basis sets give consistently longer S=O bond predictions for planar DMSO than for the pyramidal optimum structure although both Bases I and III predict unreasonably long bond distances. By contrast, the 1.55 Å SO bond length predicted for the planar DMSO form by Basis II appears reasonable. The slight shortening of the S—C bonds may also be expected on a qualitative basis.

The periodic potential curve for the S—Me rotation (*i*), as calculated with Basis I is shown in Fig. 1. The relative positions of the hydrogen atoms in the two methyl groups are shown schematically above the extrema of the curve. This cross section does not show unusual flat regions or other unexpected features, and the calculated rotation barrier of 1.5 kcal/mol is close to the average value of barriers to Me group rotations.

In Fig. 2 the pyramidal inversion potentials (as a function of the out of plane angle θ_{SO}) are compared for basis sets I, II, and III. For Bases I and II the fully optimized total energy values are plotted, while for Basis III three different potential curves were calculated. Curve III A was obtained by constraining the S=O bond length to the X-ray experimental value of $r_{S=O}$ = 1.47 Å, curve III B was calculated with the S=O bond length reoptimized along the pyramidal inversion path (relaxed potential curve), while curve III C was obtained by recalculating the Basis II optimum structures with the larger Basis III. The calculated value for the inversion barrier is apparently very sensitive to the basis set, as well as to the constraints on the S=O bond length. Basis II predicts the largest inversion barrier, 59 kcal/mol, and the shortest optimum S=O bond length. For all other calculations, the shorter the S=O bond length, the larger the inversion barrier.

Polarization *d* functions appear to be essential in predicting correct geometry, particularly in predicting the correct value for the S=O bond length. For the calculation of the barrier height, however, the direct contribution of *d* functions to the calculated energy values appears to be less significant. Rather, the overall size of the basis set and the assumed geometry are of greater importance. The effect of geometry is clearly shown by the three curves III A, III B, and III C. Potential curve III A,

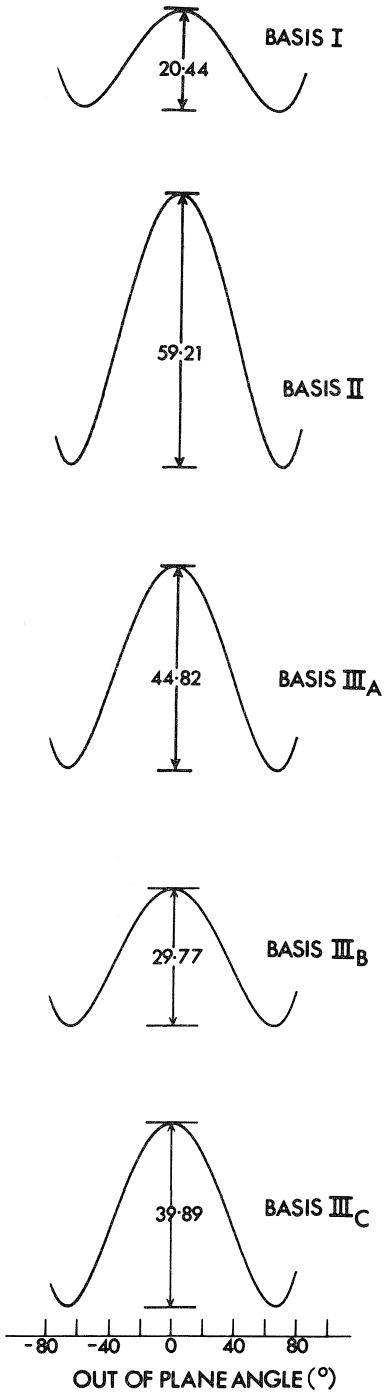

FIG. 2. Pyramidal inversion potentials and inversion barriers of DMSO as calculated with various gaussian basis sets. All barrier heights in kcal/mol.

calculated with a fixed $r_{S=O} = 1.47$ Å bond length, gives a barrier of 44.8 kcal/mol. This may be considered as an upper bound for the barrier of the true process that is likely to involve bond length variations. Curve III B, on the other hand, is likely to represent a lower bound (29.8 kcal/mol) for the true barrier, since the corresponding S=O bond lengths in the pyramidal and planar DMSO structures are far too large. The extreme case of infinite S=O bond length would certainly correspond to a lower bound for "pyramidal inversion", with no barrier at all. The 39.9 kcal/mol barrier of curve III C, that is, the energy difference between optimum pyramidal and planar Basis II structures recalculated with the large basis set III, falls in between these two bounds. This value is indeed a reasonable estimate for the inversion barrier on qualitative grounds (26). This barrier is about 16 kcal/mol higher than the calculated barrier to pyramidal inversion of the sulfilimine model $H_2S{=}NH$ (10), in qualitative agreement with available experimental information (26). The potential curve for the inversion process does not show unusual flat regions nor pathological V-type potentials.

In Fig. 3 the S=O stretching potentials are shown as calculated with basis sets I, II, and III. It is remarkable, that these curves are very different not only in terms of the position of their minima, but also in their shape. While curve II predicts the optimum S=O distance rather accurately, it shows

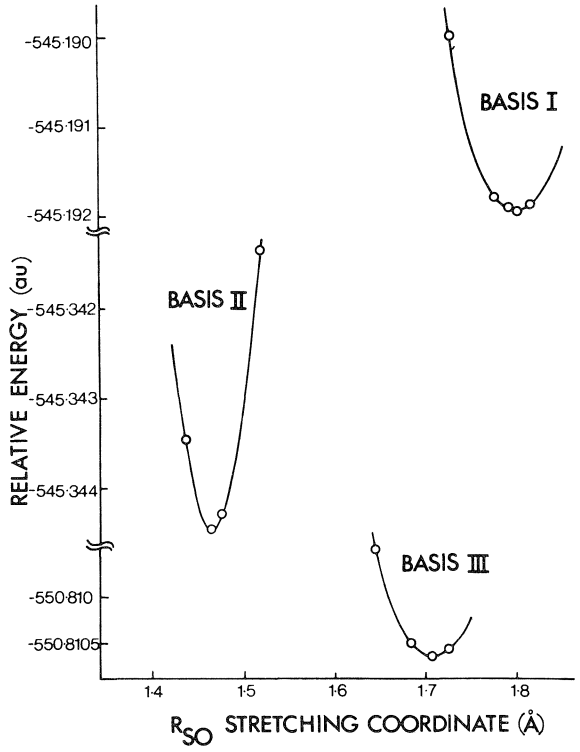

FIG. 3. Sulfur–oxygen bond stretching potentials of DMSO as calculated with various basis sets.

a much steeper potential than the other two curves. This feature is related to the shorter bond length and the implied steeper change in the nuclear repulsion energy, that, in general, is accompanied by a similarly steep change in the total electronic energy (12). While a perfectly parallel change in the slopes of the above two contributions would result in no net change in the slope of the total energy curve, the very fact that the slope of the total energy is the difference of two larger components, gives rise to a less-than-perfect cancellation, and leads to a steeper potential curve. The presence of diffuse polarization *d* functions for any *fixed* minimum position is likely to cause the potential curve to become shallower; thus the calculated steep potential is *not* a direct result of *d* function participation. The effect of *d* functions is indirect; they cause a shift of the calculated potential minimum from the unrealistic large values to the shorter $r_{S=O}$ = 1.49 Å value, accurate to 0.01 Å. The shorter bond length, in turn, gives rise to a steeper potential curve.

One of the characteristic features of the DMSO conformational hypersurface is the cross section along the plane defined by pyramidal inversion coordinate $\theta_{S=O}$ and asymmetric S—Me stretching coordinate $r_{S—Me}$. The energy surface associated with this cross section is shown in Fig. 4. It is remarkable, that in a 0.16 Å interval along the $r_{S—Me}$ coordinate, the calculated total energy E_t shows very small changes only, as compared to the variations along inversion coordinate $\theta_{S=O}$. In the two narrow valleys, along the $r_{S—Me}$ stretching coordinate containing the two symmetrically equivalent minima M_1 and M_2, the surface shows two extended flat regions. Bases I and II result in very similar flat regions, although the optimum stretching potentials along the bottom of the valley differ slightly, as it is shown in Fig. 5. The addition of polarization *d* functions to the basis set results in a more anharmonic stretching potential, that is, the curve becomes steeper for shorter bond lengths and less steep for longer distances. This result is in agreement with a general observation that polarization *d* functions lower the potential of distorted structures if the molecular distortion is associated with an increase in the atom–atom distances.

The calculated optimum S—C bond distances (1.81 Å and 1.82 Å with Bases I and II, respectively) fall in the range of the two asymmetric bond length values (1.775 and 1.821) found in the X-ray study of ref. 1. For such an asymmetric displacement of the two Me groups the calculated theoretical total energy increase is less than 0.4 kcal/mol. Consequently, our results indicate that as little as 0.4 kcal/mol may distort the DMSO ground state structure to the extent reported in the quoted X-ray study (1). Apparently, the looseness of the valence shell gaussian functions on sulfur and the relatively long equilibrium C—S bond length are responsible for the flatness of the stretching potential.

The $r_{S—Me}$ stretching potential is certainly flat in

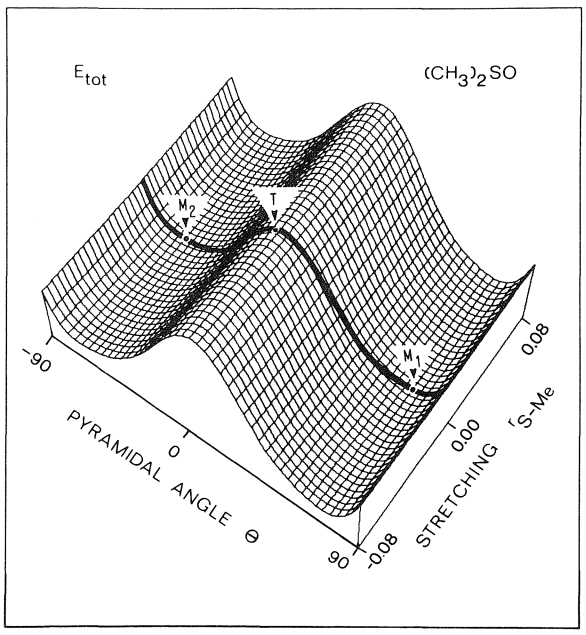

FIG. 4. Cross section of the DMSO conformational hypersurface along the plane of pyramidal inversion and S—Me asymmetric stretching coordinates.

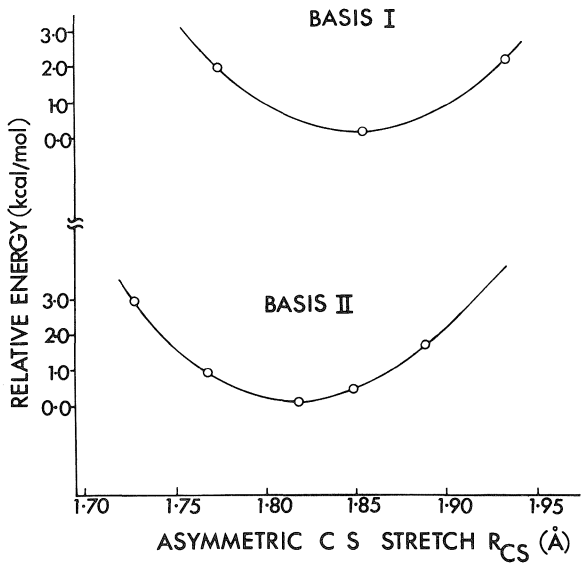

FIG. 5. Asymmetric S—Me stretching potentials of DMSO as calculated with Bases I and II.

an absolute sense: the variation of total energy is small in the given interval. The flatness of an energy surface, however, is also a relative characterization. A given cross section of the surface may appear flat as compared to another cross section, as is the case in our example for cross sections along coordinates $r_{S—Me}$ and $\theta_{S=O}$, respectively. Alternatively, one may consider a relative measure of variations of the total energy, relevant to the given molecule. Formally, one could assume that molecules composed from atoms of larger nuclear charge would show larger variations in total energy upon changes in geometry, simply as a result of larger variations in the nuclear repulsion terms. However, most often this is not the case: when comparing various conformational processes the total energy changes are not proportional to the accompanying changes in the nuclear repulsion terms. By generalizing this observation, one may consider the partitioning of the molecular total energy E_t into nuclear and electronic terms, E_n and E_e, respectively:

$$[1] \quad E_t = E_n + E_e$$

The repulsive nuclear term,

$$[2] \quad E_n = \sum_{i<j} Z_i Z_j / R_{ij}$$

certainly shows much larger variations in a given type of conformational process, if the nuclear charges Z_i are larger. It is the variation of E_n that must be compensated by opposite variations in the electronic term E_e, to approximately maintain the total energy of the molecular system. Consequently, a relative scale for the variations in total energy, E_t, relevant to a given molecular system may be obtained by comparing the variations of E_t to that of E_n, that is, ΔE_t to ΔE_n. The relative variation,

$$[3] \quad \Delta E_{rel} = \Delta E_t / \Delta E_n$$

is a relative measure of energy change along a potential curve. ΔE_{rel} is measured on an internal energy scale of the molecule, relative to ΔE_n, and is characteristic of the conformational change of the given molecule. As an example, one may consider molecules H_2 and F_2. While the force constants for these two molecules are of the same order of magnitude,[2] the nuclear repulsion term for F_2 is nearly two orders of magnitude larger than that of H_2. The similarity of the two force constants implies that a given elongation of the H—H and F—F bonds causes approximately equivalent ΔE_t changes in both molecules, in spite of the fact that the corresponding ΔE_n change in the nuclear repulsion term is nearly two orders of magnitude larger for F_2 than for H_2. This implies that in a relative sense the ΔE_n changes are far better compensated by opposite ΔE_e electronic energy changes in the case of F_2 than in the case of H_2. For F_2 the net energy change $\Delta E_t = \Delta E_n + \Delta E_e$ is a much smaller fraction of the underlying ΔE_n change than it is for H_2, and this difference is properly reflected in the corresponding relative variations, ΔE_{rel}.

The internal energy scale concept may be generalized to an entire conformational domain of an energy hypersurface; it is convenient to choose an internal energy scale on which the maximum variation of E_n (in the given domain) is unity. In the classical mechanical sense the flatness of a total energy surface, given in some absolute energy units, indicates the deformability of the molecular structure. The flatness of the scaled energy surface, on the other hand, is a relative measure of the degree of compensation between the ΔE_n and ΔE_e components.

Such a rescaling of the DMSO $E_t(r_{S—Me}, \theta_{SO})$ energy surface to the internal energy scale is shown in Fig. 6, together with component surfaces $E_n(r_{S—Me}, \theta_{SO})$ and $E_e(r_{S—Me}, \theta_{S=O})$. The two highest points in the given domain of the E_n surface ($r_{S—Me} = -0.08, \theta_{SO} = 90°$, and $r_{S—Me} = -0.08, \theta_{SO} = -90°$) correspond to 1.0 on the internal energy scale (equivalent to ~4.0 au on the absolute energy scale).

It is striking that the variations in E_t are almost unnoticeable on the internal energy scale, and the E_t surface appears almost perfectly flat. Apparently, the cancellation in the variations of E_n and E_e is close to 100%.

In most conformational processes there is a certain degree of cancellation between variations of E_n and E_e. By using the formal analogy of the le Chatelier principle, a partial cancellation between E_n and E_e may be interpreted as a tendency to approximately conserve the total energy E_t (12). A conformational change, that is, a rearrangement of the nuclei causes a change in the nuclear repulsion term E_n. This change may be regarded as a "perturbation" of the molecular system. Apparently, the electron distribution (and E_e) then readjusts in such a way as to counterbalance this perturbation by reducing the change in the molecular total energy, E_t. The loose valence orbitals of second row elements appear to facilitate this process. The appearance of flat regions on the E_t surface of DMSO, particularly, when represented on the internal energy scale, shows that this compensation process is extremely efficient for this molecule.

[2]The force constants are 5.2×10^{-5} and 4.5×10^{-5} dyn/cm for H_2 and F_2, respectively (27).

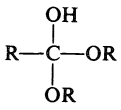
Received August 2, 1979

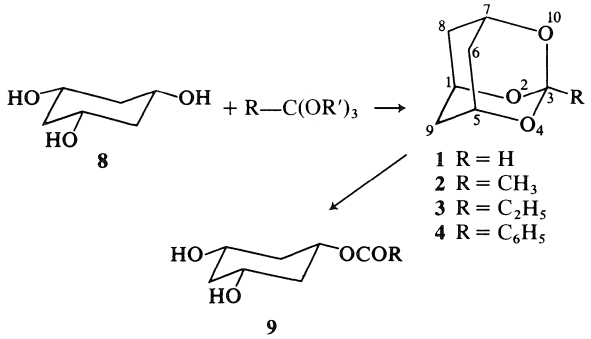
OTMANE BOUAB, GÉRARD LAMATY, CLAUDE MOREAU, ODILE POMARES, PIERRE DESLONGCHAMPS, and LUC RUEST. Can. J. Chem. **58**, 567 (1980).

The rates of hydrolysis of orthoesters, 2,4,10-trioxaadamantanes, substituted in position 3 (R = H, CH_3, C_2H_5, C_6H_5) have been determined at 25 and 40°C in dioxane/water (60:40 by volume). Substitution of hydrogen by the groups CH_3, C_2H_5, and C_6H_5 shows clearly a decrease in rate: 0.018 (CH_3), 0.014 (C_2H_5), and 0.003 (C_6H_5). This decrease, in accord with substituent effects, plus the strongly negative entropies of activation observed, suggests that the rate-determining step is the addition of water to the carboxonium ion intermediate.



OTMANE BOUAB, GÉRARD LAMATY, CLAUDE MOREAU, ODILE POMARES, PIERRE DESLONGCHAMPS et LUC RUEST. Can. J.Chem. **58**, 567 (1980).

Les vitesses d'hydrolyse des orthoesters trioxa-2,4,10-adamantanes substitués en position 3 (R = H, CH_3, C_2H_5, C_6H_5) ont été déterminées à 25 et 40°C dans un mélange eau/dioxanne 40/60 en volume. La substitution de H par les groupes CH_3, C_2H_5 et C_6H_5 entraîne un très net ralentissement: 0.018 (CH_3), 0.014 (C_2H_5) et 0.003 (C_6H_5). Ce ralentissement, en accord avec les effets de substituants et les entropies d'activation fortement négatives observées, suggère que l'étape déterminant la vitesse de réaction est l'addition de l'eau sur l'ion carboxonium intermédiare.



Introduction

In many hydrolysis reactions, a reactive intermediate is formed in which an atom of carbon is bonded to three electronegative atoms. The study of the reactivity of such intermediates is therefore a necessary and essential step in the elucidation of the mechanism of these reactions which have biological importance.

We believe that an important step has been realised lately by the work resulting in the elaboration of the stereoelectronic theory which demonstrates the significance of conformation in these intermediates, and in particular, intermediates of the type hemiorthoester which are formed in ester hydrolyses (2).

We wish to report on our study of the influence of the stereoelectronic effect on the hydrolysis rates of the system 2,4,10-trioxaadamantane substituted in position 3 (compounds **1**, **2**, **3**, and **4** in Scheme 1). These orthoesters possess the features of being rigid and favorable to stereoelectronic control as they contain two oxygen atoms (O_2 and O_4 each possessing a non-bonded electron pair antiperiplanar to the bond (C3—O10) susceptible to cleavage. The 2,4,10-trioxaadamantanes were prepared by the reaction of the appropriate aliphatic orthoester and *cis*-cyclohexane-1,3,5-triol (**8**) and on acid hydrolysis they yield the corresponding monoester **9** of *cis*-cyclohexane-1,3,5 triol (**8**).

SCHEME 1

Results

to 2 *M*) of hydrochloric acid in order to obtain reasonable rates. The solvent dioxane/water 60:40 by volume was chosen for solubility reasons and also because comparison of the results could be made with literature values; the Hammett H_0 acidity functions are known for this medium (3). The experimental results are given in Table 1.

By plotting the observed rate constants k_{obs} against proton concentration $[H^+]$, there is a linear relationship up to acid concentrations of 0.5 *M*, which gives directly the catalytic constant k_{H^+}. Above 0.5 *M* , the relationship is no longer linear, nor is it when k_{obs} is plotted against H_0, the Hammett acidity function.

In Table 2 are the catalytic constants k_{H^+} obtained for the different products studied as well as activation energies calculated from k_{H^+}. These activation energies are identical within experimental error with those calculated from k_{obs} at different acid concentrations. The results of De Wolfe and Jensen (4) on the corresponding aliphatic orthoesters, ethylorthoformate (**5**), ethylorthoacetate (**6**), and ethylorthobenzoate (**7**) are given for comparison in Table 3.

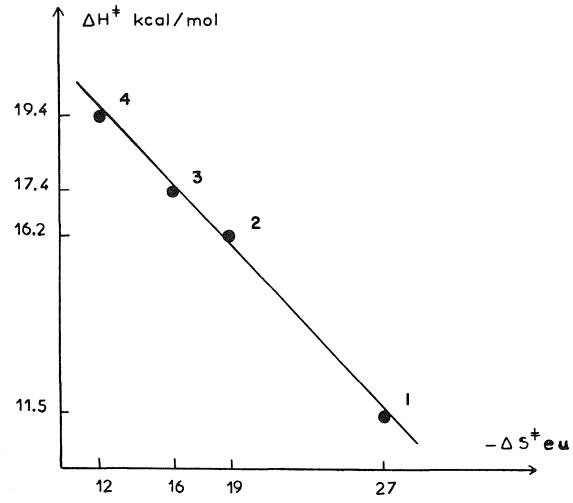
*20.5% dioxane.

Interpretation of Results

Comparison of our experimental results (Table 2) with those reported in the literature on the corresponding aliphatic orthoesters (Table 3) shows three fundamental differences. (*1*) The activation entropies are strongly negative for the 2,4,10-trioxaadamantanes, whereas they are slightly positive for the aliphatic orthoesters. (*2*) Substitution of H by CH_3, C_2H_5, or C_6H_5 decreases the hydrolysis rate in the trioxaadamantanes. Substitution of H by CH_3 in the aliphatic orthoesters augments the rate of hydrolysis. Substitution of H by C_6H_5 decreases the rate in the aliphatic orthoesters which is a particular case to be discussed later. (*3*) The rates of hydrolysis for the 2,4,10-trioxaadamantanes are considerably lower (10^{-6} to 10^{-9}) than those of the aliphatic orthoesters.

This behavior suggests that the mechanism of hydrolysis in the trioxaadamantanes is different from that in aliphatic orthoesters. A plot of $\Delta H^{\neq}$ against $\Delta S^{\neq}$ for the trioxaadamantanes shows a linear relationship (Fig. 1). The slope of the line β, isokinetic temperature, is 525 K which means that the hydrolysis of the 2,4,10-trioxaadamantanes is enthalpy controlled. The linear correlation also indicates that these products are all hydrolysed by the same mechanism (5).

The generally accepted mechanism for acid-catalysed hydrolysis of orthoesters involves 3 steps (6, 7), (*1*) formation of a carboxonium ion (eq. [1], Scheme 2), (*2*) formation of a hemiorthoester (eq. [2]), and (*3*) decomposition of hemiorthoester (eq. [3]). Hemiorthoester formation could equally result



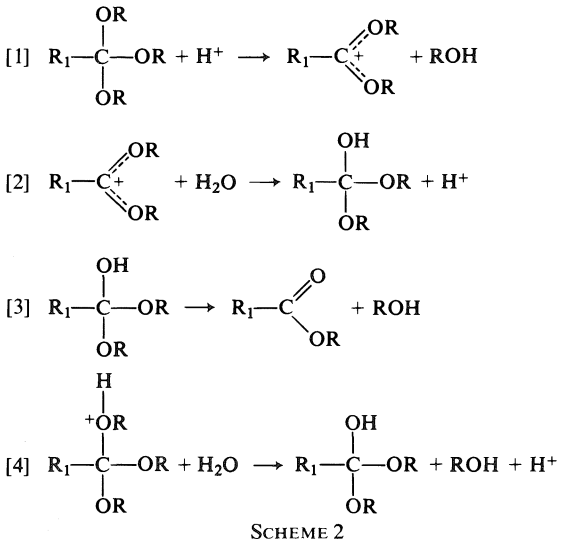


FIG. 1. Plot of $\Delta H^{\ddagger}$ against $\Delta S^{\ddagger}$ for the trioxaadamantanes ($\Delta H^{\ddagger} = -\beta\Delta S^{\ddagger}$).

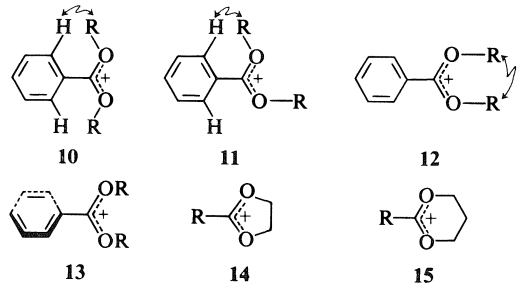
from attack by water on the conjugate acid of the orthoester (eq. [4]).



In most of the orthoester hydrolysis studied so far, the slow step is the carboxonium ion formation (eq. [1]); there is, however, a recent example implicating the decomposition of the hemiorthoester (eq. [3]) as being the critical process (8). A mechanism in which the rate-determining step is the carboxonium ion formation (eq. [1]) must be eliminated for the 2,4,10-trioxaadamantanes.

Examination of Table 3 (aliphatic orthoesters) gives the following conclusions: (*a*) the activation entropies of the processes for the catalytic constant k_{H^+} are low and positive (unimolecular reaction, mechanism A1); (*b*) the substituent effects go in the direction of increased resonance stabilisation of the

SCHEME 2

transition state when H is substituted by CH_3 and the rate is augmented in the substituted derivative. Following the same reasoning, substitution of H by C_6H_5 should further augment this stabilisation giving $k_{C_6H_5} > k_H$. In fact there is a rate decrease which could suggest a mechanistic change (9), but recent work serves to explain this rate decrease on the basis of steric factors (10). Four possible structures (**10**, **11**, **12**, and **13**) can be written for the carboxonium ion of ethylorthobenzoate (Scheme 3).

SCHEME 3

In the carboxonium ions **10**, **11**, and **12**, steric interactions (between the ortho hydrogens and the R groups in **10** and **11**, between the two R groups in **12**) make these structures unfavorable. In order to avoid these strong steric interactions, the benzene ring tends to lie perpendicular to the plane of the carboxonium ion (structure **13**), preventing at the same time conjugation between these two functions. It is therefore normal to observe a decrease in rate when H is substituted by C_6H_5. On the other hand, in the 1,3-dioxolenium ion **14** and in the 1,3-dioxenium ion **15**, (R = C_6H_5), conjugation is favored. Consequently, it is not surprising to observe an increase in rate when H is substituted by C_6H_5 in the hydrolysis of 2-methoxy-1,3-dioxolanes (10) and 2-methoxy-1,3-dioxanes (Table 4).[3]

Thus, whatever evidence is compared, activation entropies[4] or substituent effects, the reactivity of 2,4,10-trioxaadamantanes is incompatible with a mechanism involving carboxonium ion formation as the rate-determining step.

The decomposition of the hemiorthoester can equally be excluded as the rate-determining step as

[3]O. Pomares. Unpublished results.

[4]One referee has suggested that the negative entropy of activation could result from the fact that there could be a concerted process in eq. [1]. This is effectively what does occur when the hydrolysis of orthoesters is subjected to general acid catalysis: the $\Delta S^{\ddagger}$ values calculated from the catalytic constants of weak acids are strongly negative (−20 to −30 eu); however, the $\Delta S^{\ddagger}$ values calculated from the proton catalytic constants are near zero. In the present work, the discussion concerns only the rate constants k_{H^+}. The concerted process can therefore be safely eliminated from the $\Delta S^{\ddagger}$ values as well as from the substituent effects.

it is a unimolecular reaction which would give imperceptible or weakly positive activation entropies. There remains only the formation of the hemiorthoester to represent the rate-determining step in the hydrolysis of the 2,4,10-trioxaadamantanes.

The hemiorthoester can be formed in two ways: (*a*) by nucleophilic attack of water on the conjugate acid of the orthoester, an A2 mechanism (eq. [4]; (*b*) by addition of water to the carboxonium ion intermediate (eq. [2]). In both cases, water is implicated in the slow step which is in accord with the strongly negative activation entropies observed (5).

The A2 mechanism which involves the addition of water to the conjugate acid of the orthoester (Scheme 4, **16** → **17** must, however, be ruled out. By analogy with the S_N2 mechanism, the rate decrease on substituting H with CH_3 and C_2H_5 would be compatible with steric interactions but not when H is replaced by C_6H_5 as the resonance effect should give a rate increase ($k_{C_6H_5} > k_H$ (11)). Furthermore, if the hydrolysis of the 2,4,10-trioxaadamantanes involved an A2 mechanism, the 2,8,9-trioxabicyclo[3.3.1]nonane (**18**) which has a similar structure as well as electron pair orientation, should have a similar rate to **1**. However, it reacts much faster ($k_{18}/k_1 \simeq 4 \times 10^4$), at a rate comparable to that of the aliphatic orthoesters ($k_{18}/k_5 = 0.3$) (12) and probably according to the same mechanism. The addition of water to the conjugate acid of the orthoester as the slow step is therefore not the interpretation of the experimental results.

The addition of water to a carboxonium ion intermediate as the slow step in the hydrolysis of 2,4,6-trioxaadamantanes must therefore be examined. Table 2 indicates a rate decrease on substituting H by CH_3, C_2H_5, and C_6H_5. This can be interpreted on the basis of either steric and/or electronic factors. The steric interaction increases in the direction H, CH_3, C_2H_5, C_6H_5. It is therefore conceivable that the addition of water becomes more difficult in the same sense, which is in agreement with the experimental results. The carboxonium ion is increasingly stabilized on going from H to CH_3, C_2H_5, and C_6H_5. This stabilization of the ion increases the difficulty of water addition in the same sense, $k_H > k_{CH_3} > k_{C_2H_5} > k_{C_6H_5}$, which is again supported by the experimental results. Also, as the carboxonium ion becomes more highly stabilized, the charge on the reactive carbon will be increasingly dispersed; solvation would diminish, giving less and less negative activation entropies on going from H, CH_3, C_2H_5, and C_6H_5, which is in fact observed experimentally.[5]

TABLE 4. Relative rate constants (k_{H^+}) for the hydrolysis of aliphatic orthoesters, 1,3-dioxolanes, and 1,3-dioxanes

Orthoesters	k_{R^+} R = H	R = C_6H_5	References

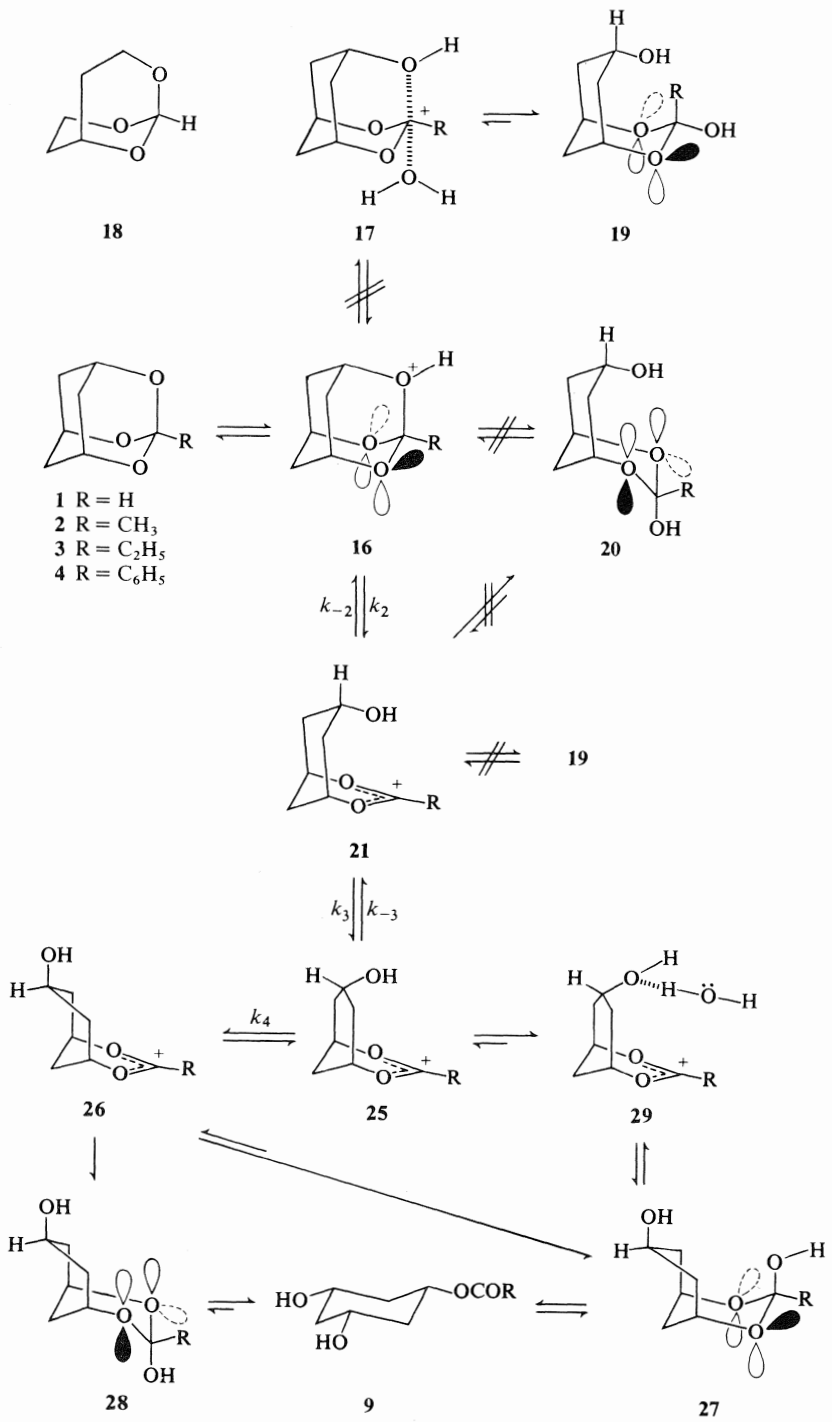
The experimental results are therefore compatible with the addition of water to a carboxonium ion as the slow step. This is the first time that such a hypothesis is envisaged in the hydrolysis of orthoesters. A reaction sequence is proposed in accord with the above requirements.

Two hypotheses can be theoretically considered depending on whether the carboxonium ions are planar or non-planar.[6] It is well established (X-rays supported by calculation), that 1,3-dioxolenium and 1,3-dioxenium ions (**14** and **15**) are planar (13, 14).[7] Consequently, we will consider only the planar carboxonium ions.

In the hydrolysis of the 2,4,10-trioxaadamantanes, the conjugate acid **16** of the orthoester would first give, with stereoelectronic control, the planar carboxonium ion **21**.[8] However, in the ion **21**, the most likely reaction is the internal return (k_{-2}): the hydroxyl group is close to the charged carbon and stereoelectronic control favors the attack on the carboxonium ion (15). The stereoelectronically controlled addition of water on the ion **21** to give **20** is therefore not likely, the return reaction (internal nucleophilic addition) being favored. The addition of water without stereoelectronic control to give **19** is equally excluded for the same reason. Furthermore that last sequence is equivalent to the A2 mechanism **16** → **17** → **19** previously eliminated.



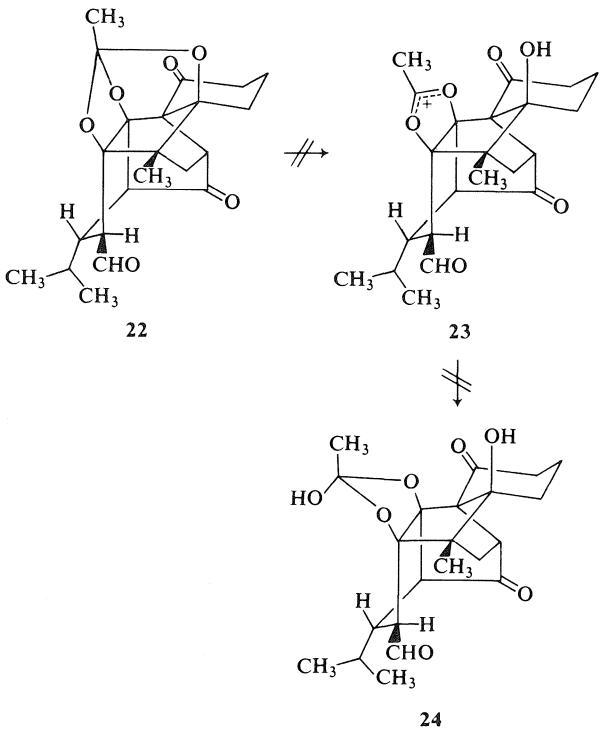
Conformational change on the ion **21** is therefore necessary prior to the addition of water to the carboxonium ion. Consequently, higher energy is needed, unlike the case of the aliphatic orthoesters where addition of water is rapid. This explains the much slower rate observed in the 2,4,10-trioxaadamantanes; a ring inversion is necessary

[5]Further work is in progress to determine if the electronic factors have the dominant influence.

[6] These two hypotheses were considered in the preliminary communication (1).

[7]Also H. Paulsen. Personal communication.

[8]The planar carboxonium ion implies that the atoms C1, O2, C3, O4, and C5 are in the same plane. The non-planar carboxonium ion would have the classical chair conformation.



SCHEME 4

($\Delta G^{\ddagger}$ inversion $\simeq$ 10 kcal/mol) and there is loss of translational entropy of one water molecule (4 to 5 kcal/mol). The 2,4,10-trioxaadamantanes therefore need 10 to 15 kcal/mol more than the aliphatic orthoesters for hydrolysis. Experimentally, the energy differences between the aliphatic series and the trioxaadamantanes is between 7 and 12 kcal/mol ($\Delta G^{\ddagger}_1 - \Delta G^{\ddagger}_5 \simeq 7$ kcal/mol; $\Delta G^{\ddagger}_2 - \Delta G^{\ddagger}_6 \simeq 12$ kcal/mol; $\Delta G^{\ddagger}_4 - \Delta G^{\ddagger}_7 \simeq 10$ kcal/mol).

An experimental result obtained independently

SCHEME 5

from this work indicates that the ring containing the hydroxyl group must undergo conformational changes prior to the attack of water on the carboxonium ion. In the orthoester **22** which is an intermediate product in the synthesis of ryanodine (16) (Scheme 5), such conformational change is impossible and the product was found to be completely resistant to hydrolysis (HCl, 1 *N*, dioxane (1:4), 25°C, 8 days). This result also excludes the possibility of a non-planar carboxonium ion or a hemiorthoester intermediate containing a boat form dioxane ring. The carboxonium ion **23** does not appear to be able to hydrate to give the equivalent of the boat form dioxane, i.e., the envelope 1,3-dioxolane **24**.

The first conformational change that can take place in ion **21** is its transformation into ion **25**. This ion could then be further transformed into the boat form **26**. Hydration of **26** with stereoelectronic control could then take place from the top or the bottom face of the ion to give respectively the hemiorthoesters **27** and **28** which can then break down to the reaction product **9** with stereoelectronic control.

This sequence of events must, however, be eliminated because the hydration of ion **26**, which would be a fast process, would occur after the slow step, the conformational change **21** → **25** → **26**. The large negative entropy of activation which has been experimentally observed could not be accounted for. In fact, ion **25** should behave similarly to ion **21**, in the sense that the internal return (k_{-3}) must be a more favorable process than the boat formation (k_4) because there must be some electrostatic attraction between the OH group and the positively charged carbon in **25**.

Ion **25**, however, can attract a molecule of water to form a species such as **29**. Examination of molecular models indicates that there is indeed room for the association of a molecule of water to **25** to give **29**. The species **29** would then undergo a conformational change to the boat form which would be synchronous with the attack of the associated water molecule on the carboxonium ion to give the hemiorthoester **27** which would then break down to the reaction product **9**.

There is also the possibility of a stereoelectronically controlled hydration on the α face of ion **25**, being concerted with a conformational change to a boat form cyclohexane ring (→ **25** → **28**). This would lead however, to the high energy, double boat conformer, **28**. The process **21** → **25** → **28** might therefore be incapable of competing with the preceding sequence **21** → **25** → **29** → **27**.

Conclusion

Hydrolysis of the 2,4,10-trioxaadamantanes reveals a comportment peculiar to these orthoesters. The substituent effects, the activation entropies, and the slow rates of hydrolysis led to the proposal of synchronous water addition to the carboxonium ion and conformational change (→ **21** → **25** → **29** →) as being the rate determining step of these hydrolysis reactions.

Experimental

Products

The 2,4,10-trioxaadamantanes substituted in position 3 were prepared by the transesterification of the corresponding methyl or ethyl orthoesters and from *cis*-cyclohexane-1,3,5 triol (**8**) (17–19). The products obtained show physical properties in accord with literature values. The nmr spectra were recorded on a Varian EM 390 in deuterochloroform with tetramethylsilane as internal reference and agree with the structure of the products.

Compound 1

Nuclear magnetic resonance δ: 1.79 (3H, doublet, $J \simeq 14$ Hz, H6a, H8a, and H9a), 2.76 (3H, doublet, $J \simeq 14$ Hz, H6e, H8e, and H9e), 4.36 (3H, wide singlet, H1, H5, and H7), and 5.80 (1H, singlet, H3).

Compound 2

Nuclear magnetic resonance δ: 1.40 (3H, singlet, CH_3), 1.67 (3H, doublet, $J \simeq 14$ Hz, H6a, H8a, and H9a), 2.58 (3H, doublet, $J \simeq 14$ Hz, H6e, H8e, and H9e), and 4.36 (3H, wide singlet, H1, H5, and H7).

Compound 3

Nuclear magnetic resonance δ: 0.94 (3H, triplet, $J \simeq 7$ Hz,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

CH_3), 1.65 (2H, quadruplet, $J = 7$ Hz, CH_2—CH_3), 1.69 (3H, doublet, $J \simeq 14$ Hz, H6a, H8a, and H9a), 2.60 (3H, doublet, $J \simeq 14$ Hz, H6e, H8e, and H9e), and 4.38 (3H, wide singlet, H1, H5, and H7).

Compound 4

Nuclear magnetic resonance δ: 1.78 (3H, doublet, $J \simeq 14$ Hz, H6a, H8a, and H9a), 2.78 (3H, doublet, $J \simeq 14$ Hz, H6e, H8e, and H9e), 4.53 (3H, wide singlet, H1, H5, and H7), and 7.2–7.9 (5H, two multiplets, C_6H_5).

Acidic Solutions

Acidic solutions were prepared from analytical material; the solvent dioxane/water 60:40 by volume includes the water in concentrated hydrochloric acid; dioxane from Merck Uvasol, spectrophotometric grade, was used. The acid concentrations were determined by pH measurements ($[H^+] = 10^{-pH}$) or by volumetric measurements.

Kinetics

The hydrolysis reactions were followed by uv spectrophotometry (Gilford 250 equipped with a thermostated compartment and automatic cell) measuring the increase in optical density due to appearance of products. The wavelengths used were 225 nm (**1**, **2**, **3**) and 239 nm (**4**). The quartz cells contained 2 mL of solution at the required temperature and a few μL of orthoester solution in pure dioxane were added (20 μL of 1 *M* solution (**1**, **2**, **3**); 5 μL of solution of 0.06 *M* (**4**)).

After shaking, the optical density was recorded as a function of time. Rate constants were obtained either on finding the exponential $D = D_\infty + (D_\infty - D_0)e^{-kt}$ by least squares (20) or by plotting ln $(D_\infty - D)$ with time. The orthoester concentrations were chosen for convenient variation of optical density of 0.3 to 0.4 (**1**, **2**, **3**), and 1.4 (**4**). Temperatures were read directly in the cells and the maximum error was ±0.05°C at 25°C and ±0.1°C at 40°C. Average reproducibility of rate constants was ±2%.

Product Analysis

After hydrolysis of a sample of orthoester under kinetic conditions, the solution was evaporated to dryness, and the hydrolysis product acetylated with pyridine and acetic anhydride. Nuclear magnetic resonance analysis confirmed the structures of the products.

In the hydrolysis of **4**, the nmr spectrum of the product obtained was found identical with that described in the literature (19). An indirect structural proof was obtained for the hydrolysis product of **2**. Acetylation of **8** gave *cis*-1,3,5-triacetatecyclohexane which was found identical to the product obtained from compound **2**.

Cis-*1,3,5-triacetoxycyclohexane*

Nuclear magnetic resonance (90 MHz) δ: 1.40 (3H, quadruplet, $J \simeq 12$ Hz, H2a, H4a, and H6a), 2.02 (9H, singlet, CH_3CO), 2.40 (3H, broad singlet, H2e, H4e, and H6e), and 4.83 (3H, multiplet, H1, H3, and H5).

Calculation of Activation Energies

The activation energies were calculated on the basis of the Arrhenius equation $k = A \exp(-E_a/RT)$ (21); error calculations were done by the method described in Wiberg (22).

Aspects of organocadmium chemistry. II.[1] Crystal and molecular structure of a complex between bis(trimethylsilylmethyl)cadmium and 2,2′-bipyridyl

GORDON W. BUSHNELL AND STEPHEN R. STOBART
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 21, 1979

GORDON W. BUSHNELL and STEPHEN R. STOBART. Can. J. Chem. **58**, 574 (1980).

The crystal structure of bipyridylbis(trimethylsilylmethyl)cadmium(II) hemibipyridyl, $[Cd(C_{10}H_8N_2)((CH_3)_3SiCH_2)_2]\cdot\frac{1}{2}(C_{10}H_8N_2)$ has been solved and refined to an *R*-value of 0.140 using 1230 reflections. The space group is $P2_1/c$ and the cell dimensions are a = 887.4(4), b = 947.0(5), c = 3245.(1) pm, β = 92.01(4)°, with four Cd-containing molecules and two bipyridyl molecules of crystallisation per cell. The 4-coordinate geometry at cadmium is most closely related to that of a linear cadmium dialkyl since the angle C—Cd—C = 156(2)°, and the bipyridyl ligand is weakly bound (Cd—N = 252, 253 pm) in a symmetrical manner with the angle N—Cd—N = 65(1)°. The distortion from linearity is away from the bipyridyl. The trimethylsilyl groups are also bent back from the heterocyclic ligand and are slightly staggered. The line between the methylene carbon atoms is approximately perpendicular to the mean plane of the bipyridyl molecule.

GORDON W. BUSHNELL et STEPHEN R. STOBART. Can. J. Chem. **58**, 574 (1980).

On a résolu la structure du cristal de bipyridilbis(triméthylsilylméthyl)cadmium(II) hemibipyridyle $[(Cd(C_{10}H_8N_2)-((CH_3)_3SiCH_2)_2]\cdot\frac{1}{2}(C_{10}H_8N_2)$ et on l'a affinée jusqu'à une valeur conventionnelle R de 0.140 pour 1230 réflexions. Le groupe d'espace est $P2_1/c$ et les dimensions de la maille sont a = 887.4(4), b = 947.0(5), c = 3245.(1) pm, β = 92.01(4)° pour 4 molécules contenant du Cd et deux molécules bipyridyle de cristallisation par maille. La géométrie tétracoordonnée du cadmium est reliée de plus près à celle d'un cadmium dialkyle linéaire puisque l'angle C—Cd—C = 156(2)° et le ligand bipyridyle est faiblement lié (Cd—N 252, 253 pm) d'une manière symétrique à l'angle N—Cd—N = 65(1)°. La distorsion par rapport à la linéarité est à l'opposé du bipyridyle. Les groupes triméthylsilyles sont aussi courbés le ligand hétérocyclique et sont légèrement décalés. La ligne entre les atomes de carbone du méthylène est approximativement perpendiculaire au plan moyen de la molécule bipyridyle.

[Traduit par le journal]

Introduction

Structural data for organocadmium derivatives are extremely limited. Dimethylcadmium in the gas phase has a linear configuration with a Cd—C bond length of 211.2(4) pm, as shown by an analysis of the pure rotational lines of the high resolution Raman spectrum (1). Recently we encountered (2) formation of thermally stable crystalline adducts between bis(trimethylsilylmethyl) cadmium (**1**) and the chelating donor molecules 1,10-phenanthroline or 2,2′-bipyridyl. Such behaviour contrasts markedly with that of dimethylcadmium, corresponding adducts of which dissociate completely at ambient temperature (3). While the adduct (**2**) of **1** with bipyridyl is very volatile, subliming easily *in vacuo* at 20°C and suggesting dissociation in the vapour phase, it is stable as a solid in the absence of air over many months. Microanalytical results were consistent with the formulation $Cd(CH_2SiMe_3)_2\cdot 1.5bpy$ and the availability of crystals led us to investigate the nature of complex **2** using X-ray crystallography, with a view to rationalising the unusual stoichiometry as well as achieving structural characterisation of the dialkylcadmium residue. Substantial difficulties associated with the volatility, air-sensitivity, and instability of the material to X-rays led to several repetitions of the crystal growth experiment and the mounting of more than ten crystals for the diffractometer. The structure of complex **2** has been solved from measurements which were evidently limited in precision. We now report the results which, despite their low accuracy, help to fill a sizeable gap in the literature.

Experimental

Preparation of the compound has already been described (2). Clear yellow crystals were grown *in vacuo* by vapour diffusion across a small temperature gradient. The material was sensitive to air and moisture, tended to volatilise in the Lindemann tube, and decomposed under X-radiation to an ochre solid. The crystal data are as follows:

$C_{23}H_{34}CdN_3Si_2$ fw = 521.1
Monoclinic, space group $P2_1/c$ (No. 14), unit cell a = 887.4(4), b = 947.0(5), c = 3245(1) pm, β = 92.01(4)°, cell volume 2.725(2) nm^3, density 1.27 g cm^{-3} (calcd), Z = 4, T = 23°C, λ = 71.069 pm ($MoK_{\bar{\alpha}}$), μ = 8.96 cm^{-1}.

The crystals were mounted on the a axis. Weissenberg and precession photography using $CuK_{\bar{\alpha}}$ radiation gave the symmetry and approximate cell dimensions. Fifteen pairs of reflections were centered at $\pm 2\theta$ (range 17–39°) on a Picker 4-circle diffractometer controlled by a PDP-11/10 minicomputer. Zr filtered $MoK_{\bar{\alpha}}$ radiation was used. The cell and orientation matrix were refined by least squares. Intensity measurements were done with $\omega = 0$ in the bisecting position using 50 steps of 0.04° in 2θ, counting for 1 s per step, with a 10 s background count at each end of the scan. Standards 0,0,14 and 0,5,2 were measured after each batch of 50 reflections and used to correct for instrument instability and crystal decomposition. Reflections were

scaled using the preceding set of standards. When the sum of the standards fell below 50% of its original value the crystal was replaced. Measurements were completed to $2\theta = 40°$, but were not punched unless $I > 3\sigma(I)$. Lorentz and polarisation factors were applied. Corrections for absorption were not possible since the shapes of the crystals, initially blocks elongated in the *a* direction, were soon ill defined.

Structure Determination

The Patterson function was used to solve the phase problem. The programs used were supplied by Penfold (4) and are based upon FORDAP, ORFLS, ORFFE, and ORTEP. The atomic scattering factors (5) were for unchanged atoms. The refinement was by minimisation of $\sum w(|F_o| - |F_c|)^2$ with the final weights derived from a weighting scheme: $w = 1/(A + Bx + Cx^2 + Dx^3)$ where $x = |F_o|$ and $A = 58.220$, $B = 0.29927$, $C = 1.4601 \times 10^{-2}$, $D = -0.31296 \times 10^{-4}$. Systematic variations in $w\Delta^2$ were thus largely eliminated. Only the cadmium and silicon atoms were given anisotropic vibration parameters. The final agreement factors were $R = 0.140$ and $R_w = 0.196$. The numbers of observations and variables are 1230 and 132 respectively. The final difference map had a maximum of 1.74×10^{-6} e pm^{-3} and a minimum of -1.05×10^{-6} e pm^{-3}. The hydrogen atoms were not located. The structure factor table, and atomic vibration parameters are available from the Depository of Unpublished Data.[2]

Results

Figure 1 shows the molecular structures and the atom labelling scheme. The fractional atomic coordinates are given in Table 1. Figure 2 gives the packing of the molecules in the unit cell. There are two uncoordinated bipyridyl molecules per cell. A crystallographic centre of symmetry is located in these molecules at the midpoint of the bond joining the two rings. The four cadmium-containing molecules and the two uncoordinated bipyridyl molecules account for the stoichiometry of the compound. The conformation of the free bipyridyl mole-

cules in **2** is probably *trans*, as in bipyridyl itself (6), and opposite to the approximate *cis* conformation found in many complexes. However, a disordered structure with *cis* bipyridyl molecules cannot be excluded on the basis of the available measurements.

The bond lengths are given in Table 2. The Cd—C distances (mean 214 pm) agree with those determined for $CdMe_2$ in the gas phase (1). The Cd—N bond lengths (252, 253 pm) are considerably greater than the sum of the covalent radii (148 + 70 pm) indicating weak bonding. The Si—C lengths are normal, as are the bond lengths of the bipyridyl molecules, to the accuracy of the determination.

The bond angles are presented in Table 3. The coordinated bipyridyl molecule and the two alkyl groups complete the four coordination at the cadmium centre. The most striking feature of the latter is the very wide angle of 156(2)° made by the methylene groups at the metal. The bulky trimethylsilylmethyl groups are bent back from the coordinated base and staggered to minimise steric repulsions. This is clearly consistent with complexation of a linear dialkyl skeleton as was suggested (2) on the basis of vibrational spectroscopy. The three pyridyl rings are planar with $\chi^2 = 0.16, 0.58, 18.7$ respectively, where $\chi^2 = \sum P_i^2/\sigma^2(P_i)$ and P_i is the perpendicular distance of atom i from the mean plane. The angle between planes 1 and 2 is 9.3°.

Table 4 contains selected non-bonding interatomic distances and is complete to 380 pm. The first four entries are the intramolecular distances which may explain sterically the departure of the

*Symmetry positions of the second atom relative to Table 1 coordinates. *1*, x, y, z; *2*, $-x, -y, -z$; *3*, $1-x, -y, -z$; *4*, $-x, \frac{1}{2}+y, \frac{1}{2}-z$; *5*, $x, 1+y, z$; *6*, $1-x; y-\frac{1}{2}, \frac{1}{2}-z$; *7*, $x, -\frac{1}{2}-y, \frac{1}{2}+z$; *8*, $1-x, \frac{1}{2}+y, \frac{1}{2}-z$; *9*, $-x, y-\frac{1}{2}, \frac{1}{2}-z$.

cadmium dialkyl from linearity. The next four entries and the last in the table are for the methylene and methyl carbon atoms, and show that the more important contacts are intermolecular. The coordinated bipyridyl shows fourteen intermolecular distances in the range 350–380 pm. The remainder of the table is concerned with intermolecular distances for the uncoordinated bipyridyl.

The most suitable comparison in relation to nitrogen coordination is that with the structure (7) of 2,2-bipyridylbis[pentacarbonylmanganese] cadmium(II). However, in this complex the mean Cd—N bond length of 235 pm may be contracted by enhanced acceptor ability at the cadmium centre through π back donation to the manganese atoms. This multiple bond character is held to account for the significantly shortened metal–metal distance. In octahedral $[Cd(N_3)_2(py)_2]$ (8), all of the Cd—N

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

distances are 234–235 pm, but a longer bond (mean 246 pm) is present (9) in [$CdBr_2 \cdot N,N,N',N'$- tetramethylethylenediamine]. The present value (mean 253 pm) and the narrow angle of 65° for N—Cd—N are complementary to one another and suggest a rather weak bond resulting from steric interaction with the bulky alkyl substituents, or electronic effects. On the basis of the latter, however, it is not clear why complex **2** should be more stable than its dimethyl cadmium analogue since Me_3SiCH_2— is more electron releasing than Me— (10).

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

JOHN A. FINDLAY and LAJOS RADICS. Can. J. Chem. **58**, 579 (1980).

Base catalysed hydrolysis of rapamycin ($C_{51}H_{79}NO_{13}$) affords six neutral compounds identified by chemical and spectroscopic means as **2***a*, **3***b*, **3***d*, **5**, 2,4-dimethylphenol, and L(−)-piperidine-2-carboxylic acid **6**, and whose generation has been plausibly rationalized. These findings as well as detailed analyses of ^{13}C nmr and ^{1}H nmr spectra provide independent corroboration of the X-ray derived rapamycin crystal structure **1**. Structurally homogeneous in the solid state, rapamycin is found to occur in solutions as a mixture of two conformational isomers (approximately 4:1). Through nearly complete assignment of the high field ^{1}H (400 MHz) and ^{13}C (100.6 MHz) nmr spectra, the isomerism is shown to be associated with *trans–cis* rotation of an amidic bond within the 31-membered macrolide ring. The predominant form corresponds to the conformer portrayed by X-ray analysis.

JOHN A. FINDLAY et LAJOS RADICS. Can. J. Chem. **58**, 579 (1980).

L'hydrolyse basique de la rapamycine ($C_{51}H_{79}NO_{13}$) fournit six composés neutres que l'on a identifiés par des méthodes chimiques et spectroscopiques comme étant les composés **2***a*, **3***b*, **3***d*, **5** ainsi que le diméthyl-2,4 phénol et l'acide L-pipéridinecarboxylique-2 **6** dont on a expliqué l'origine de façon plausible. Ces résultats aussi bien que les analyses complètes obtenues par la rmn du ^{13}C et du ^{1}H corroborent indépendamment la structure cristalline obtenue par rayon-X. On a trouvé que la rapamycine qui du point de vue structural est homogène en phase solide devient en solution, un mélange de deux conformères (approx. 4:1). En se basant sur une identification presque complète à partir des spectres de rmn du ^{13}C (100.6 MHz) et du ^{1}H (400 MHz), on a trouvé que l'isomérie est associée à une rotation *trans–cis* du lien amide du cycle macrolide à 31 atomes. La forme prédominante correspond au conformère révélé par analyse aux rayons-X.

[Traduit par le journal]

Recently we initiated concerted efforts towards the elucidation of the structure of the antifungal antibiotic rapamycin, isolated from cultures of *Streptomyces hygroscopicus* and originally believed to be $C_{56}H_{89}NO_{14}$ (1). While at the outset crystals of rapamycin were prepared for X-ray diffraction work, we also began chemical and nuclear magnetic resonance studies with the expectation that the structural question could be solved by studying various less complex degradation fragments in the event that the direct X-ray analysis of rapamycin proved unmanageable.

As we have already reported (2) our successful X-ray study has revealed the complete structure and relative stereochemistry of crystalline rapamycin **1**. The solution of the X-ray problem was assisted by information on structural moieties gleaned by preliminary scrutiny of ^{13}C nmr data providing such important details as the number, hydridization, degree, and nature of substitution of carbon atoms in the molecule. In addition, as the X-ray structural picture began to develop, information obtained from the ongoing chemical and spectroscopic studies proved helpful in confirming certain skeletal carbon sequences and functional features prior to the ultimate refinements. Of particular importance was the finding that the analysis of ^{13}C nmr data (see Table 3) confirmed independently that rapamycin has only 51 carbons and not 56 as initially reported (1). Early (25.16 MHz) carbon-13 nmr spectra also revealed that in solutions of various organic solvents rapamycin, structurally homogeneous in the solid state, occurs as a mixture of two non-separable isomers. The isomeric ratio of approximately 4:1 was found to be practically independent of the solvent and temperature (between 30 to 70°C). Attempts to remove the minor component either by chromatography or repeated crystallizations proved unsuccessful. The occurrence of two forms of rapamycin in solutions raised the obvious question as to which, if any, of these isomeric forms corresponds to the X-ray portrayed structure and geometry of the macrolide molecule. To answer this question and to obtain a detailed insight into the structural and conformational features of rapamycin in solutions, we carried out a high-field ^{1}H and ^{13}C nmr study of the antibiotic. (The complexity of the molecular structure and the presence of two isomers have rendered the proton and carbon-13 nmr spectra

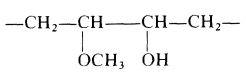
unmanageable for purposes of detailed spectral assignments when these were recorded at the frequencies of our iron magnet instrument.) As shown in the sequel, the results of the nmr analysis have afforded an independent and detailed corroboration for the X-ray derived molecular structure **1** and also disclosed that the two solution forms of rapamycin are interrelated by hindered rotation about a formal single bond within the 31-membered macrolide ring.

We now report details of these complementary chemical and spectroscopic studies.

Much of our chemical effort has been focussed on the base catalysed hydrolysis of rapamycin since this was known[1] to yield neutral and acidic fragments. Our attention was first devoted to the hydrolysis at room temperature using 1 *N* methanolic NaOH. While several neutral products could be noted by tlc they proved to be relatively unstable. Basic hydrolysis at reflux temperature gave, in ~ 20% yield, a mixture of five neutral products designated A, B, C. D, and E. The major acidic fraction proved to be a complex and intractable mixture and was not pursued.

Separation of the neutral compounds was achieved on silica gel columns. Compound A, the least abundant product, can be eluted with CH_2Cl_2, has a distinct phenolic odour, and is quite volatile. Spectroscopic data showed this compound to be 2,4-dimethylphenol and this was confirmed by comparison with an authentic sample.



Compound C, the major neutral product, displays a base peak *m/e* 304 in its mass spectrum corresponding to $C_{19}H_{28}O_3$. Structure **2***a* is assigned to C on the basis of the following data. The diol nature was established by facile and reversible conversion to a diacetate **2***b* which displays in its 100 MHz ^{1}H nmr spectrum (see Table 1) a downfield multiplet at δ 4.71 assigned to a secondary acetate and two acetoxy methyl signals (δ 2.04 and δ 2.22). The presence of a double bond was confirmed by hydrogenation of C-diol, **2***a*, and C-diacetate, **2***b*, to the corresponding dihydroderivatives **3***a* and **3***b*, respectively. The additional hydrogen deficiencies in C-diol are accounted for by a 2,4,6-trisubstituted phenol moiety and a six-membered ring containing two secondary vicinal oxygen-substituted carbons for which ample support exists in the ^{1}H nmr and ^{13}C nmr spectra of C-diol and its derivatives (see Tables 1 and 2). In particular the *meta* relationship of the aromatic protons follows from their mutual coupling (J = 2.3 Hz) while their *meta* relationship to the phenolic group follows from the relatively small acetylation shifts observed for the aromatic protons in both C-diol, **2***a* (+ δ 0.04 and δ 0.17), and dihydro-C-diol, **3***a* (δ 0.10 for both). Anticipated acetylation shifts for *ortho* and *para* protons are + δ 0.25 to 0.40 (3).

That the double bond is conjugated follows from consideration of uv spectra of C-diol and dihydro-C-diol, while the placement of a trisubstituted double bond *ortho* to the phenolic group is confirmed by the facile conversion of C-diol to an isomeric ether **4** (1:1 mixture of C8 diastereomers) whose ^{1}H nmr spectrum features two downfield methyl singlets (δ 2.1 and δ 2.2), a 3H singlet at δ 1.4 assigned to the C8 methyl, and a 2H singlet at δ 2.95 assigned to the allylic C7 protons. All other spectral data are in accord with the assigned structure **4**.

Careful analysis of the 100 MHz ^{1}H nmr data of C-diol, **2***a*, and C-diacetate, **2***b*, reveals the existence of a mixture of isomers (~ 7:1) in each case, no doubt due to geometrical isomerism at the double bond. From ^{13}C nmr chemical shift information on these compounds and comparison with literature data (4), we conclude that the major component has the *Z* configuration in each case.

The major mass spectral fragments of C-diol are at *m/e* 161 (52%) and 175 (41%) corresponding to fission between C8/C9 and C9/C10, respectively, while the dihydro-C-diol **3***a* shows major fragments at *m/e* 121 (33%), 135 (94%), and 162 (16%) attesting to the C6 to C9 sequence in **3***a* (see Scheme 1).

The existence, substitution pattern, and stereochemistry of a cyclohexane ring in C-diol and related compounds was established by 100 MHz ^{1}H nmr studies. Thus the sequence

as a part of a six-membered ring in a highly preferred chair conformation was determined by standard decoupling techniques. Furthermore, the two oxygen substituents were found to be *trans* diequatorial since the respective C12H and C13H show the large coupling (J = 9.0–9.2 Hz) associated with α-diaxial protons in a cyclohexane chair conformation. It follows that the C10 substituent should also be equatorial in view of the high conformational preference.

C-diol, **2***a*, and its diacetate, **3***b*, fail to undergo elimination when treated with paratoluenesulfonic acid in boiling benzene indicating that the C13 oxygen substituent does not readily achieve an axial conformation favourable for 1,2-*trans* elimination in agreement with a 1,2,4-triequatorial configuration for the ring substituents.

SCHEME 1. Mass spectral fragmentation of dihydro C-diol, **3***a*.

Compound D ($C_{19}H_{30}O_4$) is assigned structure **3***c* since its ^1H nmr spectrum shows a doublet for the C8 methyl at δ 0.8 (J = 7 Hz) and a doublet at δ 4.3 (J = 7 Hz) for the C7H. Compound D is quantitatively dehydrated to C-diol, **2***a* upon treatment with paratoluenesulfonic acid in benzene at room temperature. This assignment is fully supported by other spectroscopic data.

Compound B ($C_{19}H_{32}O_4$) proved to be a 1:1 diastereomeric mixture of methyl ethers, **3***d*, since the novel features of its ^1H nmr spectrum are a pair of methyl doublets at δ 0.95 (J = 6 Hz) and δ 0.7 (J

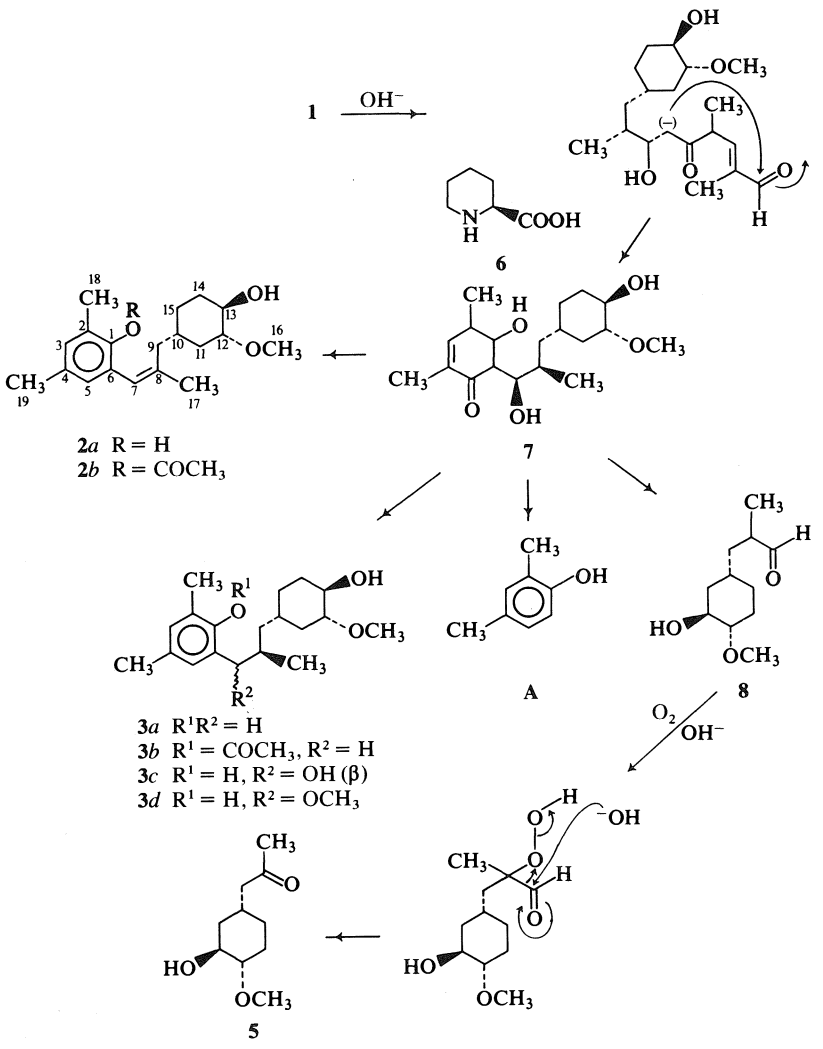
= 6 Hz) each integrating for ~ 1.5 H, and at δ 7.75 (0.5 H) and δ 7.8 (0.5 H), a pair of singlets assigned to the phenolic hydrogen of each isomer.

While the structures of compounds B, C, and D are fully supported by additional spectral data, chemical corroboration of their relationships comes from their individual conversions to the common product **4** by paratoluenesulfonic acid in refluxing benzene.

The neutral compound E ($C_{10}H_{18}O_2$) is assigned structure **5**. Its mass spectrum displays a strong molecular ion at *m/e* 186 (62%) and a base peak at *m/e* 129 ($M - CH_2COCH_3$) while less intense ions at *m/e* 111 and 97 correspond to 129 − H_2O and − CH_3OH, respectively. The infrared spectrum of E shows bands at 3450 cm^{-1} and 1700 cm^{-1} in accord with hydroxyl and ketone features. Assuming that E arises from the same moiety of rapamycin that affords B, C. and D, the stereochemistry should be as in structure **5**.

Thus the hydrolysis products A, B, C, D, and E all appear to be derived from the same portion of rapamycin. Since the latter was believed to feature a triene system but no aromatic moiety, we originally speculated that the aromatic ring might arise by condensation/cyclization of some suitably substituted trienone system. In support of this hypothesis was the observation that perhydrorapamycin, prepared by catalytic (Pt) hydrogenation, did not yield any A, B, C, or D. An equally attractive theory was that the neutral phenolic products are formed by condensation/cyclization/elimination of some suitably substituted 2,6-dicarbonyl system or equivalent.

The need to pursue these hypotheses further chemically was made unnecessary by the appearance of the preliminary and incomplete X-ray structural portrayals of rapamycin which featured a 1,2,4-trisubstituted six-membered ring remote from the triene system allowing us to abandon the trienone hypothesis. At this stage it was possible to confirm the sequence C22 to C30 (see structure **1**), establish the oxygen and methyl placements, and confirm the segment C38 to C47 and substituents in the developing rapamycin X-ray structural picture from our conclusions about compounds A, B, C, and D and their generation.



With the fully refined X-ray derived rapamycin structure **1** at hand (2), it is appropriate to account in detail for the formation of compounds A, B, C, D, and E. Plausible mechanistic rationalizations are given in Scheme 2 in which rapamycin **1** is first dissected via a β-hydroxyketone cleavage and a base catalysed ester hydrolysis. The resulting δ keto unsaturated aldehyde can then undergo self condensation and elimination of water to produce the aromatic fragments B, C, and D, while compound A is accounted for via a β-hydroxyketone cleavage of **7** which also supplies the aldehyde **8**. The latter is perceived as undergoing base catalysed oxidation at the position α to the aldehyde followed by oxidative decarboxylation to give compound E, **5**. It is worthy to note that the mass spectrum of rapamycin shows a remarkable similarity to those of compounds C, **2***a*, and D, **3***c*. Thus, the base peak of the rapamycin spectrum is at *m/e* 175 while the ion of next greatest intensity corresponds to the mass of C at *m/e* 304 (28%). Other prominent ions common to all three mass spectra are at *m/e* 161 and 135. Thus the major ion fragments from C and D at *m/e* 175 (C10/C9 cleavage), 161 (C9/C8), and 135 (C8/C7) are major features of the rapamycin mass spectrum indicating that electron impact on rapamycin results in cleavages leading to some fragments similar or identical to those obtained from the hydrolysis derived compounds C, **2***a*, and D, **3***c*.

Since D, unlike the oil B, is a sharp melting (63–65°C) crystalline compound, it is likely that its benzylic oxygen is derived directly from the rapamycin C22 ester ether by hydrolytic ester cleavage.

Not unexpectedly, we have isolated pipecolic acid **6** (piperidine-2-carboxylic acid) among the base catalysed hydrolysis products of rapamycin. This, together with the compounds cited above, accounts for the carbon sequence and substitution pattern C16 through C31 and constitutes an independent corroboration of more than half of the rapamycin structure as learned by X-ray.

More detailed information about the structural moieties and conformational features of rapamycin in solution is afforded by the analysis of the high-field ^1H and ^{13}C nmr spectra. Summarized in Tables 3 and 4, respectively, are the carbon-13 and proton nmr parameters of *both* isomeric species of the macrolide molecule as derived from the 100.6 MHz ^{13}C and 400 MHz ^1H nmr spectra of the $CDCl_3$ solution of rapamycin. The increased spectral dispersion, illustrated on Fig. 1, has made it possible to identify and, accordingly, characterize in terms of chemical shifts and ^1H — ^1H coupling constants 65 of the 79 protons and assign unambiguously *each* of the 51 carbon-13 resonances to the respective carbon atoms in both isomeric forms. Evaluation of the chemical shift differentials for the two isomers has led to elucidation of the nature and site of the isomerization. The differential shieldings of the carbon atoms in the two solution forms are also reported in Table 3.

SCHEME 2

The assignment of the resonances to the individual atoms in the molecule is based on standard FT nmr procedures. First, through a series of $^1H—\{^1H\}$ double resonance experiments, partial structures involving sequentially spin-coupled protons and terminated by proton-non-bearing carbon atoms were identified. Previous chemical information about the presence in rapamycin of a pipecolic acid unit and a trisubstituted cyclohexane moiety made it unnecessary to fully characterize five of the methylene groups (i.e., C-17, C-18, C-39, C-44, and C-45) giving rise to extensively coupled and strongly overlapping multiplets the analysis of which would have required a special experimental approach. Although their resonances were unambiguously located by simple double resonance methods, the pertinent ^1H nmr parameters, owing to the insufficient precision, are either omitted from Table 4 or reported indirectly through the couplings determined for contiguous protons. The partial structures thus derived are displayed in Fig. 2.

Subsequently, broad-band decoupled and a series of single frequency off-resonance decoupled $^{13}C—\{^1H\}$ spectra were recorded to yield off-resonance multiplicities, variable-frequency residual $^{13}C—^1H$ couplings, and off-resonance band shape informations which were then matched to the ^1H nmr-derived partial structures. Experimental verification of the assignments thus deduced was attained through an extensive series of single-frequency selective $^{13}C—\{^1H\}$ decoupling experiments. The assignment of resonances due to some of the methylene carbons with overlapping

complex ^1H resonance pattern was aided by ^{13}C chemical shift information gleaned by preceding studies of base-catalysed hydrolysis products (see Table 2). Low-power selective irradiation of resonances due to the terminal proton(s) in the partial structures of Fig. 2 gave rise to signal enhancement of neighbouring quaternary carbon resonance, a method that was fully exploited in establishing the missing links between the ^1H nmr-based structural units. The only carbon-13 resonances where the above experimental approach failed to yield connectivity information were those due to the α,β-diketo fragment (C-14 and C-15). In principle, in the event of lack of X-ray structure determination, chemical shift arguments and the variations of the isomerization-induced chemical shift changes (*vide infra*) would have been sufficient to define the placement of the latter unit in the macrolide ring and establish thereby the chemical structure of rapamycin in a one-to-one correspondence with the X-ray analysis.

Thanks to the greatly enhanced spectral dispersion used (and duly appreciated) in the present study, the above experimental assignment techniques could be applied with practically no added difficulties for the resonances due to the minor component of the rapamycin solution as well. Carbon-13 nmr spectra recorded at 100.6 MHz disclosed that each resonance of the major component has its own exact counterpart in the spectrum of the minor isomer, a finding that strongly suggested the occurrence of conformational differences, rather than structural changes between the two forms. Another remarkable fact about the isomerism is that it causes sizable differential shieldings of carbon atoms and protons practically throughout the entire molecule (see Tables 3 and 4) which can only be expected to occur when the isomerism is associated with an alteration of the overall geometry of the macrolide system. In principle, two alternative explanations may be considered that can account for such effects, (*1*) epimerization of the hemiacetal carbon atom (C-13), or (*2*) *trans* to *cis* amide isomerization via hindered rotation about the pipecolic acid N—CO bond. Closer examination of the chemical shift data for two isomers in Tables 3 and 4, however, reveals that the first alternative must be discarded. The differential shieldings observed for the hemiacetal ring atoms are less than or equal to the values noted in the other part of the molecule not involved directly in the isomerism, whereas epimerization of C-13 should

[a]Chemical shifts ($CDCl_3$) in ppm, relative to internal TMS, coupling constants in Hz. All parameter values were obtained by first-order approximation at 400 MHz.
[b]Near-coincidence with the lines of the major isomer.
[c]In the minor isomer: $J(22, 23A) + J(22, 23B) = 10$; $J(22, 38) = 6.5$.
[d]The identity (within experimental errors) of most of the ^{1}H—^{1}H coupling constants in the two conformers indicates that, presumably due to the size of the macro ring, the isomerism-induced changes in the overall molecular geometry (mirrored by the chemical shift differentials, see also Table 3) may occur without affecting significantly most of the H—C—C—H dihedral angles.

cause, through differences in the 1,3 steric interactions of the C-13 (OH) group and the C-13 (CO—CO..) side chain (3), considerable shielding variations at C-1 and C-11. The most significant isomerization shifts, both for protons and carbon atoms, are seen to appear in the immediate vicinity of the amide nitrogen, in particular, at C-16 and C-20. The alternating signs and the magnitude of these differential shieldings are fully consistent with the effects well known for hindered amide rotation (5, 3). If, on the other hand, it is assumed that the conjugation of the amide carbonyl with the C-14 oxo group does not reverse the sign of anisotropy and steric effects for the N—CO group, from the observed ^{1}H and ^{13}C shielding differentials it can be concluded that the configuration of the

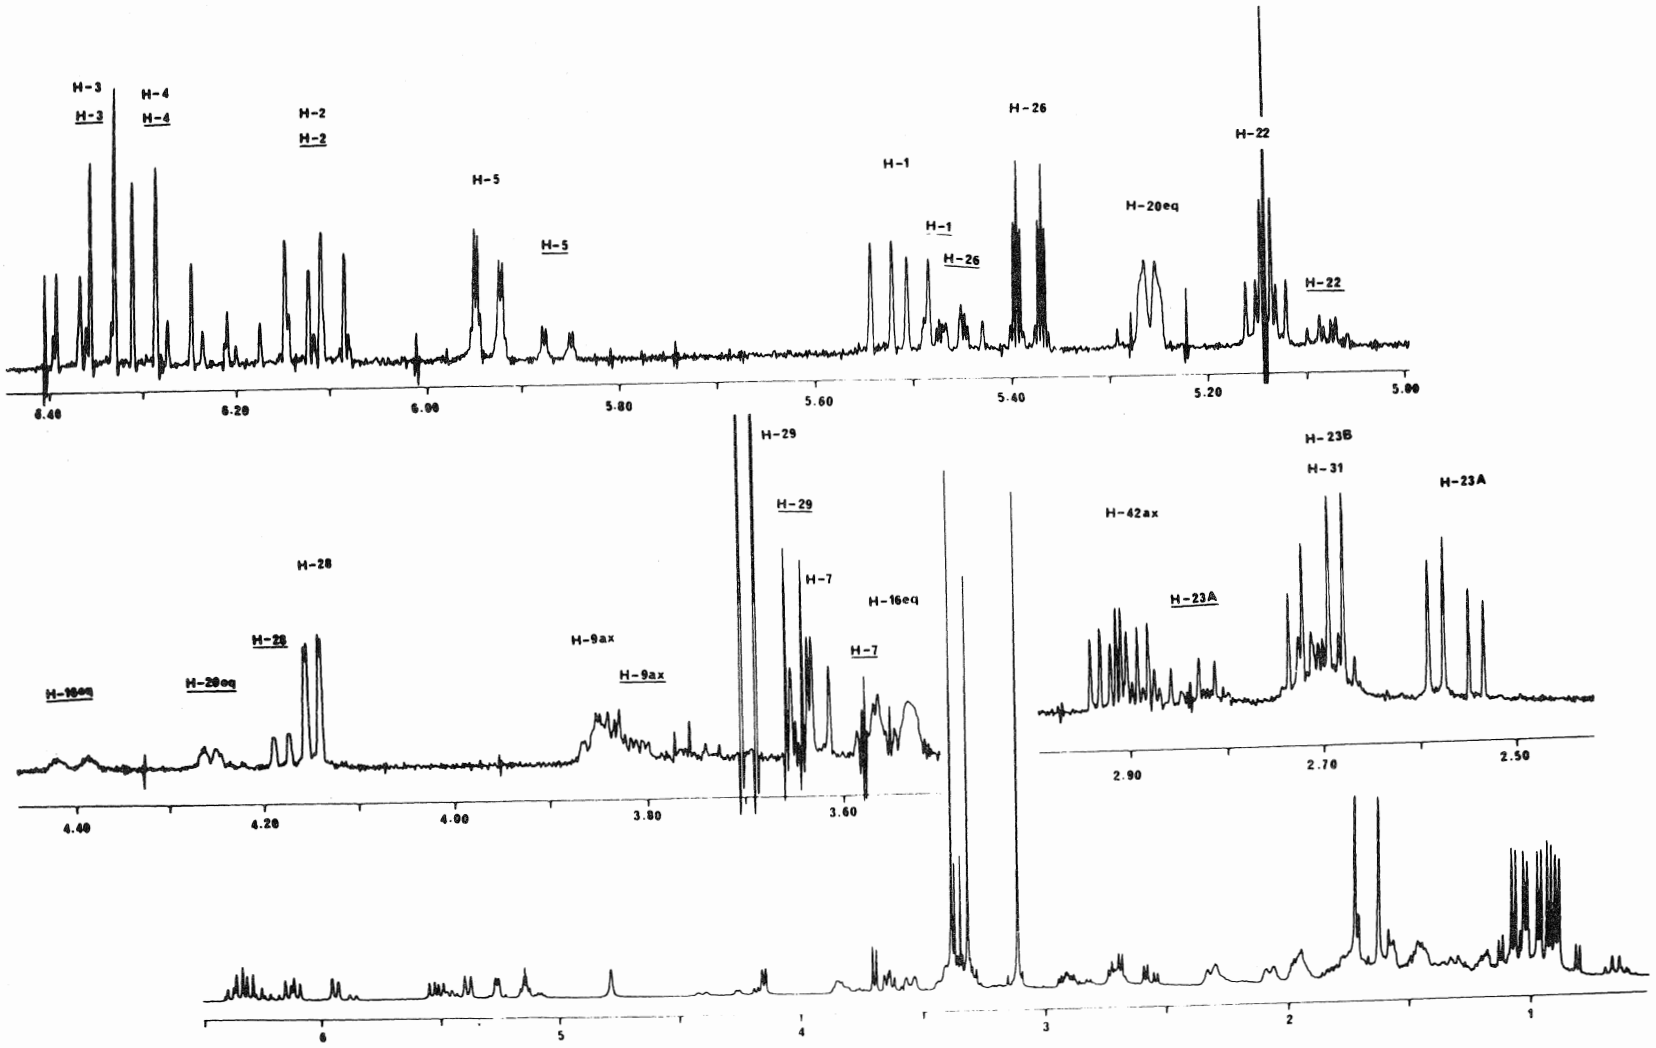

FIG. 1. 400 MHz ^{1}H nmr spectrum of rapamycin in $CDCl_3$. Underlined denotations refer to the minor isomer.

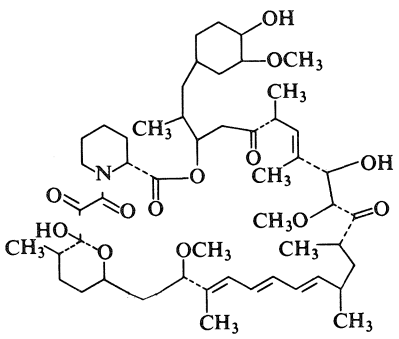

FIG. 2. Partial structures of rapamycin as obtained from the 400 MHz spectra. Dashed lines represent connections established by single frequency selective $^{13}C—\{^1H\}$ decouplings.

amide group (following the peptide denotation) is *trans* in the major isomer, i.e., identical with the X-ray portrayed stereochemistry, and *cis* in the minor component of rapamycin. Molecular models furthermore show that, in order to avoid excessive steric crowding, the *trans* to *cis* isomerization should cause the C-14 oxo group to change its orientation such that the two carbonyls maintain their *s-trans* arrangement. Support for this contention seems to be available from the observed significant downfield shift of the C-14 resonance in the minor isomer relative to this value in the major form and a simultaneous upfield shift of the C-37 methyl proton resonance.

Further important stereochemical details of the solution forms of rapamycin emerge from the analysis of the 400 MHz ^1H nmr data. The observed $^1H—^1H$ coupling constants afford a fairly comprehensive description of the relative steric orientations of substituent groups attached to the macrocycle in full agreement with the results of X-ray analysis and, in a similar way, confirm the all-*trans* geometry of the triene moiety. According to the X-ray structure, the side chain comprising the substituted cyclohexane is bent over the 31-membered macro ring such that the cyclohexane ring itself assumes a position above the sequence C-25, C-26, C-27 with its C-41 methylene group closer to the $\Delta^{26,27}$ double bond. As attested by the ^1H nmr observations, this particular conformational feature seems to be retained in the solution forms as well; due to the proximity of anisotropic environment, the *axial* C-41 methylene proton resonance appears at 0.64 ppm as the most shielded one in the entire molecule, while its *equatorial* partner resonates by 1.4 ppm to lower fields (at 2.08 ppm).

It has been assumed (6) that, by virtue of considerable intramolecular interactions characteristic of sterically crowded systems, the carbon-13 chemical shifts in macrolides may exhibit sizable deviations from the values generally encountered in "ordinary" molecules. This has been clearly borne out by the present study. Chemical shift calculations providing an accuracy of 2 to 3 ppm for open chain systems were found to be in error by typically 5 to 8 ppm in the rapamycin case. Most certainly, intramolecular interactions are to be invoked not only to explain the failure of empirical shift calculations in this and similar systems but also to account for the differential shieldings encountered with carbon atoms a great many bonds away from the site of the amide isomerization.

We have also ascertained that the absolute configuration of rapamycin is as portrayed in structure **1** by isolating L(−)-pipecolic acid **6** from its 6 *N* HCl hydrolysis products.

Experimental

Low field nmr spectra were recorded on Varian EM 360 (^1H, 60 MHz) and Varian XL-100-15 FT (^1H, 100.1 MHz and ^{13}C, 25.16 MHz) instruments. The high field nmr spectra were obtained with a Bruker WH 400E spectrometer operating at 400 MHz for protons and 100.62 MHz for carbon-13. Some of the $^1H—\{^1H\}$ double resonance experiments were carried out at 250 MHz using a Bruker WH 250 instrument, whereas many of the time consuming single frequency selective $^{13}C—\{^1H\}$ decouplings were made at 25.16 MHz using the large data table facilities of the Varian Disk FT accessory. The ir spectra were recorded with a Perkin-Elmer 247 spectrophotometer and uv spectra were measured with a Beckman Acta CIII instrument. Mass spectra were recorded with an Hitachi Perkin-Elmer RMU-6D instrument.

Basic Hydrolysis of Rapamycin

Rapamycin (2.15 g) in methanol (80 mL) was treated with aqueous NaOH (1 *N*, 80 mL) at reflux temperature for 1 h and then evaporated to remove the bulk of the methanol leaving a cloudy yellow-brown solution which was diluted to 700 mL and extracted continuously for 11 h. Evaporation of the ether extract after drying (anhydrous Na_2SO_4), gave a neutral oil (0.396 g). Acidification of the aqueous portion to pH 2 with HCl and continuous ether extraction afforded, after drying (anhydrous Na_2SO_4), an acidic oily mixture (1.46 g). A portion (64 mg) of neutral oil in ether (50 mL) was extracted twice with HCl (1 *N*, aqueous) washed with water, and evaporated, yielding a mixture indistinguishable from non acid extracted material on tlc basis. Neutralization of the aqueous HCl extract and extraction with ether afforded no basic product.

Chromatography of Neutral Hydrolysis Products

Neutral material (0.33 g) from the base hydrolysis of rapamycin was chromatographed on a column of silica gel (33 g). Eluting with $CHCl_3$ – ethyl acetate (9:1) gave compounds A (6 mg), B (4 mg), mixtures of B + C (195 mg), mixtures of C + E (71 mg), and compound D (28 mg). Rechromatography of the mixed fractions on silica gel (200 ×) using CH_2Cl_2 – ethyl acetate (100:15) gave further separation of B from C and with CH_2Cl_2 – ethyl acetate (7:3) C from E (C preceding). Fractions were examined by tlc using Merck silica gel 60F precoated plates (0.25 mm thick). Visualization was done with H_2SO_4/CH_2O spray followed by heating. The R_f factors were as follows: A (0.85), B (0.45), C and E (0.35), D (0.2). Initial coloration of B, C, and D was purple, while A was grey and all four were detectable by uv light prior to spraying. Compound E was not detectable by uv

and gave a yellow colour on spraying with H_2SO_4/CH_2O. All compounds except D were oils.

Compound A

The uv spectrum (95% ethanol) λ_{max} (ε): 232 (1320), 281 1830); 95% ethanol + OH^-) λ_{max} (ε): 244 (3170), 287 (2075), 297 (1585) (s). The ir spectrum (neat) ν_{max}: 3400 (hydroxyl), 1650–1605 (weak, aromatic) cm^{-1}. The mass spectrum *m/e*:122 (100, M^+), 121 (29, *M* – H), 107 (71, *M* – CH_3), 94 (24, *M* – CO), 78 (24).

Compound B, **3**d

The uv spectrum (95% ethanol) λ_{max} (ε) : 231 (2150), 281 (2350); (95% ethanol + OH^-) λ_{max} (ε) : 231 (2285), 245 (1545) (s), 281 (2350), 305 (670) (s). The ir spectrum (neat) ν_{max}: 3450 (hydroxyl), 1660–1610 (weak, aromatic) cm^{-1}. The ^1H nmr spectrum ($CDCl_3$) : δ_{TMS} : 0.7 (d, 1.5 H, *J* = 6 Hz, CH_3CH), 0.95 (d, 1.5 H, *J* = 6 Hz, CH_3CH), 1–2.1 (m, 11H), 2.2 (s, 6H, CH_3 aromatic), 2.5–3.2 (m, 2H, —CHO—), 3.3 (3H, s, CH_3O), 3.8 (m, 1H, benzylic $CHOCH_3$, 6.5 (s, 1H, $W_{1/2}$ = 4 Hz), 6.8 (s, 1H, $W_{1/2}$ = 4 Hz), 7.75 (s, 0.5 H, phenolic H), 7.8 (s, 0.5 H, phenolic H). *Exact Mass* calcd. for $C_{20}H_{32}O_4$: 336.2300; found (ms): 336.2299; ms (*m/e*): 306 (44, M^+), 304 (100, *M* – CH_3OH), 272 (16, *M* – CH_3OH – H_2O), 254 (16), 175 (66), 162 (44), 161 (88), 137 (50), 136 (95), 110 (44), 91 (44).

Compound C, **2**a

The uv spectrum (95% ethanol) λ_{max} (ε): 249 (5625), 293 (2675); (95% ethanol + OH^-) λ_{max} (ε): 243 (7905), 327 (3150). The ir spectrum (neat) λ_{max}: 3400 (hydroxyl), 1620, 1595 (aromatic) cm^{-1}. The mass spectrum *m/e*:304 (100, M^+), 272 (12, *M* – CH_3OH), 176 (11), 175 (41), 173 (12), 162 (16), 161 (52), 160 (16), 137 (12), 136 (12), 135 (24), 111 (12), 110 (32), 109 (12).

Compound D, **3**c

Melting point 63–65°C. The uv spectrum (95% ethanol) λ_{max} (ε): 230 (2265), 282 (2230); (95% ethanol + OH^-) λ_{max} (ε): 250 (3455), 302 (3380). The ir spectrum ($CHCl_3$) ν_{max}: 3450 (hydroxyl), 1650 – 1610 (aromatic) cm^{-1}. The ^1H nmr spectrum ($CDCl_3$) δ_{TMS}: 0.8 (d, 3H, *J* = 7 Hz, CH_3CH), 1 – 2 (complex m, 10H), 2.2 (s, 6H, aromatic CH_3), 2.3 – 2.6 (complex m, ~ 4H, O*H*, C*HOH*, $CHOCH_3$), 3.3 (s, 3H, CH_3O), 4.3 (d, 1H, *J* = 7 Hz, benzylic C*H*OH), 6.5 (bs, 1H, $W_{1/2}$ = 5 Hz, aromatic), 6.8 (bs, 1H, $W_{1/2}$ = 5 Hz, aromatic), 7.9 (bs, 1H, phenolic H). *Exact mass* calcd. for $C_{19}H_{30}O_4$: 322.2144; found: 322.2153. The mass spectrum *m/e*: 322 (10, M^+), 304 (38, *M* – H_2O), 175 (32), 161 (36), 151 (100), 135 (35), 123 (31), 110 (30), 97 (35).

Compound E, **5**

The ir spectrum (neat) ν_{max}:3450 (hydroxyl), 1700 (ketone) cm^{-1}. The ^1H nmr spectrum ($CDCl_3$) δ_{TMS} : 1 – 2.2 (m, 8H), 2.2 (s, 3H, CH_3CO), 2.4 (d, 2H, *J* = 6 Hz, $COCH_2$—CH), 2.7 – 3.5 (m, 2H, —CHO), 3.4 (s, 3H, CH_3O). Mass spectrum *m/e* : 186 (62, M^+), 129 (100, *M* – CH_3COCH_2), 110 (12, 129 – H_3O), 97 (12, 129 – CH_3OH), 32 (24, CH_3OH^+).

Dihydro-C-diol, **3**a

Compound C (12 mg) in ethanol (2 mL) was hydrogenated over prehydrogenated Adams' catalyst (10 mg) overnight at atmospheric pressure and room temperature. Filtration of the catalyst and evaporation of solvent gave oily dihydro-C-diol **3***a* (12 mg). The uv spectrum (95% ethanol) λ_{max} (ε): 230 (2860), 281 (2200); (95% ethanol + OH^-) λ_{max} (ε) : 230 (3165), 247 (s) (1585), 280 (2175), 304 (1265). The ir spectrum (neat) ν_{max} : 3400 (hydroxyl), 1650 – 1665 (aromatic) cm^{-1}. Mass spectrum *m/e* : 306 (45, M^+), 274 (48, *M* – CH_3OH), 256 (48), 176 (6), 175 (6), 162 (16), 136 (48), 135 (94), 122 (16), 121 (33), 120 (12).

C-diacetate, **2**b

Compound C (1.5 g) was treated with NaOAc (0.33 g) and Ac_2o (10 mL) at 90°C for 2 h after which time tlc indicated complete reaction. Water was added and extraction with CH_2Cl_2 was made. After washing the CH_2Cl_2 layer with dilute cold $NaHCO_3$ solution, drying (Na_2SO_4), and evaporating, an oil (1.76 g) was obtained. A partial purification was effected by chromatographing (1.6 g) on a silica gel (100 g) column using $CHCl_3$/EtOH (100:0.75). Rechromatography of the best fractions (0.25 g) on a silica gel column (75 g) using benzene/ether (19:1) gave the oily C-diacetate, **2***b* (0.198 g). The uv spectrum (95% ethanol) λ_{max} (ε) : 247 (5660); (95% ethanol + OH^-) λ_{max}: unchanged. The ir spectrum (neat) ν: 1760, 1740 (acetates), 1605 (aromatic) cm^{-1}. Mass spectrum *m/e*: 388 (40, M^+), 347 (21), 346 (80, *M* – CH_2CO), 286 (12), 272 (14), 255 (12), 254 (38), 176 (17), 175 (31), 161 (29), 111 (31), 110 (100).

Hydrolysis of C-diacetate, **2**b

C-diacetate (30 mg) in CH_3OH (4 mL) and NaOH solution (4 mL, 2 *N*) was stirred at room temperature for 12 h. (After 5 min tlc indicated complete hydrolysis.) Evaporation of CH_3OH and addition of H_2O and extraction with CH_2Cl_2 gave, after drying (Na_2SO_4), compound C, **2***a* (12 mg), clear oil.

Dihydro-C-diacetate, **3**b

C-diacetate (62 mg) in ethanol (3 mL) was hydrogenated over prehydrogenated Adams' catalyst (25 mg) for 23 h. Filtration and evaporation gave the oily dihydro-C-diacetate, **3***b* (60 mg). The uv spectrum (95% ethanol) λ_{max} (ε): 266 (14 700), 274 (s) (13 500); λ_{max} (OH^-): no change. The ir spectrum ν_{max}: 1750, 1730 (acetates), 1600 (aromatic) cm^{-1}. The mass spectrum *m/e*: 390 (13, M^+), 348 (28, *M* – CH_2CO), 316 (13), 288 (19), 274 (44), 256 (47), 136 (19), 135 (22), 122 (16), 121 (100).

Hydrolysis of Dihydro-C-diacetate, **3**b

Dihydro-C-diacetate (20 mg) in C_2H_5OH (2 mL) was treated with NaOH solution (1 *N*, 3 mL) at room temperature. After 15 min tlc showed complete hydrolysis. Evaporation and extraction with CH_2Cl_2 yielded an oil (12 mg) identical with dihydro-C-diol, **3***a*, obtained by catalytic reduction of C-diol, **2***a*.

Transformation of Compound D, **3**c, *to Compound C*, **2**a

Compound D (20 mg) in benzene (10 mL) was stirred with paratoluenesulfonic acid (5 mg) for 48 h at room temperature. Examination by tlc indicated conversion to compound C which was verified by extraction and purification giving an oil (11 mg) identical with C-diol, **2***a*.

Transformation of Compound C, **2**a, *to* **4**

Compound C (42 mg) in benzene (15 mL) was stirred with paratoluenesulfonic acid at room temperature for 3 days (tlc showed no change) and then heated at reflux for 8 h. After washing with water and evaporation, an oil (30 mg) was obtained which after chromatography on a silica gel (75 g) column eluted with $CH_2Cl_2/CH_3COOC_2H_5$ (7:3) gave **4**, an oil (20 mg), followed by recovered C (8 mg). The ir spectrum (neat) ν_{max}: 3430 (hydroxyl), 1600 (aromatic) cm^{-1}. The ^1H nmr spectrum ($CDCl_3$) δ_{TMS}: ~ 1–2 (m, 9H), 1.4 (s, 3H, CH_3C — O, (2.1 (s, 3H, CH_3), 2.2 (s, 3H, CH_3), 2.3–3.2 (m, 2H, —CH — O), 2.95 (s, 2H, benzylic), 3.3 (s, 1.5H, CH_3O), 3.35 (s, 1.5H, CH_3O), 6.75 (bs, 2H, aromatic) ppm. The mass spectrum of **4** *m/e*: 304 (100, M^+), 272 (11), 175 (50), 161 (81), 141 (16), 137 (22), 136 (24), 135 (36), 110 (36), 109 (20).

Transformation of Compound B, **3**d, *to* **4**

Compound B (60 mg) in benzene (20 mL) was treated with paratoluenesulfonic acid (20 mg) and stirred at room temperature for 3 days. Examination by tlc indicated no substantial change. After heating to reflux for ½ h, tlc revealed the presence of B, **3***d*, C, **2***a*, and **4**. After heating 5 h the mixture was worked up as above and yielded an oil (41 mg) identical with **4** obtained by dehydration of C, **2***a*, above.

Isolation of Piperidine-2-carboxylic Acid **6**

Rapamycin (1 g) in methanol (30 mL) was treated with 2 *N* NaOH (30 mL) under reflux for 1 h, then acidified to pH 2 and continuously extracted with ether for 48 h. Drying (anhydrous Na_2SO_4) and evaporation of the ether extract gave an oil (0.92 g) which was dissolved in $CHCl_3$ and extracted with water. Evap-

oration of the water afforded an oily product (55 mg) which when dissolved in 95% ethanol and applied to the several tlc systems below proved homogeneous and indistinguishable from an authentic sample of piperidine-2-carboxylic acid both in R_f and colour reactions. On cellulose plates (Merck 0.1 mm) (*a*) 2-propanol – 2-butanone – 1 *N* HCl (60:15:25 v/v), $R_f = 0.75$; (*b*) *n*-propanol – 25% NH_3 aqueous (7:3, v/v), $R_f = 0.70$. On silica gel plates (Merck 60F, 0.25 mm), *n*-propanol – 25% NH_3 aqueous (7:3, v/v), $R_f = 0.26$. Visualization employed ninhydrin in chloroform solution containing collidine applied by spraying. Subsequent heating (100°C, ~ 5 min) caused development of blue spot changing to reddish purple on exposure to air.

Rapamycin Mass Spectrum

Rapamycin (mp 183–185°C) was introduced via direct inlet system at 150–190°C and 70 ev. Mass spectrum *m/e*: 305 (8), 304 (28), 229 (5), 197 (8), 193 (5), 176 (15), 175 (100), 162 (5), 161 (6), 160 (7), 147 (13), 145 (8), 141 (5), 135 (11), 133 (7), 122 (6), 119 (8), 109 (9), 107 (6), 105 (11), 98 (7), 97 (7), 95 (8), 93 (7), 91 (12), 69 (10), 67 (9), 57 (8), 55 (18).

L(−)-Piperidine-2-carboxylic Acid (Pipecolic Acid) from Rapamycin

Rapamycin (5.0 g) in methanol (70 mL) was treated with 6 *N* HCl (200 mL) under reflux for 32 h. The reaction mixture was extracted with $CHCl_3$ and the aqueous layer was evaporated to dryness *in vacuo* yielding a yellow non-crystalline solid (0.33 g) which was purified by preparative tlc and proved to be identical with an authentic sample of pipecolic acid. Measurement of the ORD curve ($c = 0.1068$, 80% ethanol) showed it to be L(−)-piperidine-2-carboxylic acid by comparison with literature data (7).

Acknowledgements

Financial assistance from the Consiglio Nazionale delle Ricerche, Italy, the National Research Council of Canada, and the Department of External Affairs, Ottawa, is gratefully acknowledged. One of us (J.A.F.) is grateful to Professor G. B. Marini-Bettolo, Istituto di Chimica, Università Cattolica, Rome, for accommodation in his laboratory and for providing financial assistance during tenure of a Visiting Professorship. Thanks are due to Professor L. Boniforti, Laboratori di Chimica, Istituto Superiore di Sanità, Rome, for assistance in obtaining mass spectra. The authors are grateful to Ayerst Research Laboratories for providing a generous supply of rapamycin and for helpful discussions. The authors are indebted to Dr. H. Schneiders of Bruker-Physik AG, Karlsruhe, W. Germany, for making the company's high field nmr facilities available for the present study and to Dr. W. E. Hull for his assistance in recording the WH 400E spectra. Thanks are due to Dr. E. Baitz-Gács (Central Research Institute of Chemistry, Budapest) for her skillful assistance in the evaluation and compilation of the nmr data. Thanks are due to Johanne Rommens for assistance in isolating and identifying L(−)-pipecolic acid from rapamycin and to A. Taylor (Atlantic Regional Laboratory, Halifax) and J. A. Verpoorte (Department of Biochemistry, Dalhousie University) for providing its ORD curve.

Photochemical reactions of fluoro-substituted ketones with amines, tetraphenylborates, and organometals: an electron spin resonance study

KUANG S. CHEN, TERRY FOSTER, AND JEFFREY K. S. WAN
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

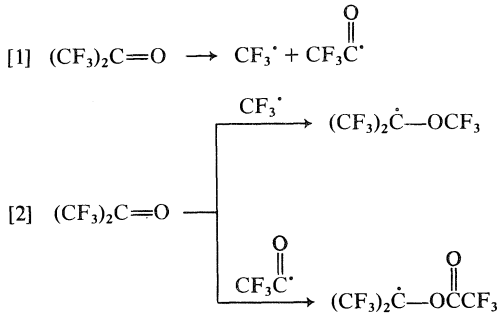
Received August 24, 1979

KUANG S. CHEN, TERRY FOSTER, and JEFFREY K. S. WAN. Can. J. Chem. **58**, 591 (1980).

Ammonium ion-pairs, solvent-separated alkali-metal ion-pairs, and Group IVB organometallic adducts of fluoro-substituted ketones were generated photochemically. The structure and the controlling factors for the formation of contact ammonium ion-pair were deduced from the effects of solvent, amine, and fluorine substitution. The effect of fluorine on the formation of the alkali-metal ion-pairs and organometallic adducts was discussed.

KUANG S. CHEN, TERRY FOSTER et JEFFREY K. S. WAN. Can. J. Chem. **58**, 591 (1980).

On a produit photochimiquement des paires d'ions ammonium, des paires d'ions de métaux alcalins séparés par un solvant et des adduits organométalliques du groupe IVB de fluorocétones. On a déduit la structure et les facteurs contrôlant la formation de la paire d'ions ammonium de contact, à partir des effets de solvant et de la substitution par une amine ou un fluor. On discute de l'effet du fluor sur la formation des paires d'ions de métaux alcalins et des adduits organométalliques.



[Traduit par le journal]

Introduction

The primary process in the quenching of triplet state carbonyl compounds with amines has remained controversial (1–3). The extent of charge transfer in the triplet exciplex seems to depend on the chemical system involved. Laser photolysis (4–6), CIDEP (7, 8), and CIDNP (9) are currently employed to clarify these mechanisms. The CIDEP and CIDNP applications to photochemistry have been reviewed recently (10).

While the successful esr observations of contact ammonium ion-pairs in the ketone–amine photochemical systems will shed some light on the controversial mechanism (11), the understanding of the structures and the controlling factors for the formation of contact ion-pairs may provide further insight into the fate of the counter amine radical cation. The photochemical reactions of various fluoro-substituted ketones with different amines in a wide range of solvents were studied, and the results will be presented and discussed.

The formation of contact ion-pairs has been partially ascribed to the exceptionally electron-deficient carbonyl group in the fluoro-substituted ketones (11), and this feature also dominates the chemistry of these compounds (12–14). Previous esr studies (15) have surmised that photolysis of perfluoroketones is similar to that of their hydrocarbon analogs with several outstanding exceptions. Among them, the radical addition to perfluoroketone is a significantly more facile process than it is with alkyl ketones as evidenced by the observations of products of Norrish type 1 reactions, reactions [1] and [2], on photolysing hexafluoroacetone in an inert fluorocarbon solvent,

We will utilize this kind of electron-deficient carbonyl and various fluoro-substituted ketones to trap the Group 1VB organometallic-centered radicals. The effect of fluorine on the adduct formation will be discussed.

The failure of resolving esr signal by the reaction of hexafluoroacetone with alkali metal in tetrahydrofuran (16) prompts us to investigate the alternative, by photolysing the tetrahydrofuran solution of fluoroketones in the presence of alkali-metal tetraphenylborates. This method has been proved useful in the preparation of ion-pairs and triple-ions of various carbonyl compounds (17). The results together with the effect of crown ethers will be described.

Experimental

Hexafluoroacetone was prepared from the dehydration of hexafluoroacetone sesquihydrate (Aldrich) in the presence of phosphorus pentoxide and was vacuum distilled at low temperature prior to use. 1,1,1-Trifluoroacetone, α,α,α-trifluoroacetophenone and decafluorobenzophenone from Aldrich and organometals from Alfa were used as received. Amines and organic solvents were further purified by the appropriate method prior to use (18). The gaseous chemicals were used as

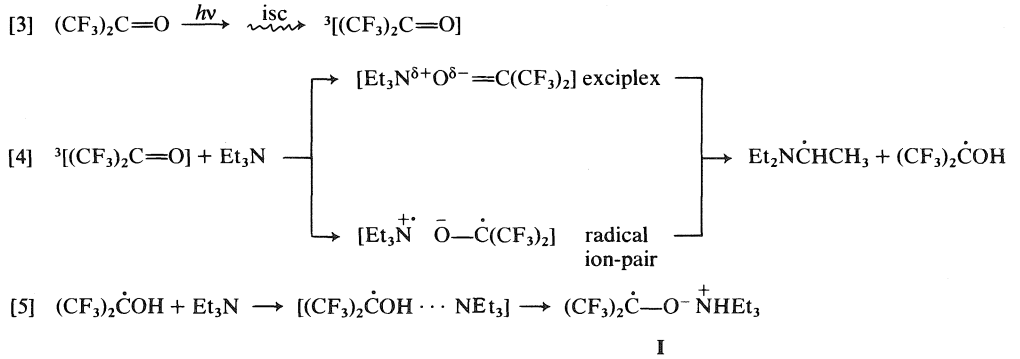
obtained from Matheson. Crown ethers and sodium tetraphenylborate were received from Aldrich. Other salts of tetraphenylboron were prepared by the method of Coplan and Fuoss (19).



The preparations of samples and the measurements of electron spin resonance and CIDEP by rotating sector were accomplished according to the previously described procedures (17, 20).

Results and Discussion

Photolysis of Fluoroketone Solutions in the Presence of Amines

When a degassed cyclopropane solution of hexafluoroacetone (HFA) and triethylamine (Et_3N) was uv irradiated in cavity at −78°C, a well resolved esr spectrum shown in Fig. 1*a* was recorded. No decay of signal on rotating sector was observed (20). The septet splitting can be unambiguously assigned to the six fluorines, since the hexafluoroacetone ketyl generated electrochemically in acetonitrile (16) gives the comparable fluorine splittings (see Table 1). The inserts on an expanded scale in Fig. 1*b* show that the additional triplet splitting with the correct theoretical intensity ratio is due to a nitrogen nucleus (^{14}N, $I = 1$). The partially resolved second order hyperfine splittings from six equivalent fluorine nuclei are in accordance with Fessenden's prediction (21). The spectrum is therefore assigned to the contact ammonium ion-pair of HFA.

The contact ammonium ion-pair is probably produced via the following scheme:

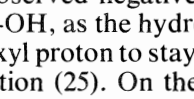
The structure of ion-pair **I** will be discussed later. The intermediate step in reaction [4] has remained controversial and seems to depend on the chemical systems studied (4–9). Reaction [5] has been postulated for other ketone–amine systems (7, 22). Although photoexcited HFA in its triplet state is a powerful hydrogen abstracting agent as evidenced by its photoreduction in the presence of even poor hydrogen donors such as cyclopropane (15), the efficient quenching of triethylamine on the excited state of HFA can neglect the contribution of $(CF_3)_2\dot{C}$—OH via reaction [6].

$$[6]\quad {}^3[(CF_3)_2C{=}O] \xrightarrow{c\text{-}C_3H_6} (CF_3)_2\dot{C}{-}OH$$

The ion-pair **I** can be either a contact ion-pair or solvent-separated ion-pair (23) depending on the solvent used. For example, while a contact ion-pair was observed in a non-polar solvent cyclopropane, a solvent-separated ion-pair resulted when THF was employed as the solvent (Fig. 1*c*). The modification of esr parameters from those of anion radical were used as the criteria to assign the formation of ion-pair since the additional hyperfine structure (hfs) from the counter cation is not resolved. This argument was used to propose the observation of ammonium ion-pairs of ninhydrin (24) even though the additional nitrogen hfs was not observed.

Surprisingly, no solvent-effect on the ammonium ion-pairs of α,α,α-trifluoroacetophenone (TFA) was noticed. A contact ion-pair was always observed when TFA and Et_3N were photolyzed in the following solvents, toluene, 2-propanol, tetrahydrofuran (THF), acetonitrile, and *N*,*N*-dimethylformamide (DMF). The esr parameters are given in Table 2. This result is in contrast with the usual observation in the alkali-metal ion-pairs of carbonyl compounds. For example, contact alkali-metal ion-pairs of xanthone were observed in THF but they would dissociate in a polar solvent such as DMF (25). On the other hand, the amine seems to play a very important role in determining the types of ion-pairs of TFA observed. While Et_3N, Bu_3N, and Am_3N gave the contact ion-pairs, NH_3, Me_3N, $(C_4F_9)_3N$, Et_2NH, $(Me_3Si)_2NH$, Me_3SiNMe_2, and Me_3SiNEt_2 produced the solvent-separated ion-pairs. It seems only tertiary amines will produce the contact ion-pairs but not all of the tertiary amines will work. The right basicity is a key factor too, the stronger Et_2NH or weaker Et_2NSiMe_3 than that of Et_3N only gave the solvent-separated ion-pairs. The effects of solvent and amine on the type of ion-pair formation clearly depend on the individual fluoroketone studied.



Furthermore, if a THF solution of the unsubstituted acetophenone, benzophenone, or 1,1,1-trifluoroacetone and Et_3N was irradiated, no esr signal or only protonated ketyl (22) was observed. However, when decafluorobenzophenone was employed, a contact ion-pair was observed (see Table 3). It appears that in order for the ketone to form a stable contact ammonium ion-pair as depicted in structure **II**, it is essential to have a fluoro-substituted alkyl group to serve as a powerful hydrogen-bonding source and an additional strong electron-withdrawing group to render the carbonyl exceptionally electron-deficient.

R = CF_3, C_6H_5, and C_6F_5

II

Evidence of fluorine hydrogen bonding was suggested by the observed negative hydroxyl proton hfs in $(CF_3)_2\dot{C}$—OH, as the hydrogen-bonding will cause the hydroxyl proton to stay more likely in the "in-plane" position (25). On the other hand, one can expect that without the influence of hydrogen-bonding, the hydroxyl proton hfs in the $(CH_3)_2\dot{C}$—OH radical would now be positive with the hydroxyl proton being in the most probable "out-of-plane" position. This is indeed the observed result (15).

III

Another possible structure, **III**, has been proposed in other ketone–amine systems (22). In the case of a contact ion-pair such as that found in our system, structure **III** should have led to the observation of the hfs from the proton in the ammonium cation. The hydrogen atom in the ammonium cation probably as an important "bridge" to bring the nitrogen closer to the fluoroketone radical anion, as represented in structure **II**. This can also account for the fact that a solvent-separated ion-pair was observed when tetra-*n*-butylammonium tetraphenylborate was used instead of tri-*n*-butylamine. The formation of solvent-separated ion-pairs in the photolyses of fluoroketones in THF in the presence of various tetraphenylborates will be described in the next section.

Photolysis of THF Solutions containing Fluoroketones and Tetraphenylborates

The standard alkali-metal reduction in an

ethereal solvent (26) has failed to produce the esr signal of ion-pair of HFA, TFA, or decafluorobenzophenone, but a solid precipitate, presumable salts of of pinacol (12*a*), was observed. However, when a THF solution of TFA and 18-crown-6 was brought to contact briefly with the potassium mirror, a well resolved esr signal of crown ether complexed potassium ion-pair of TFA was observed. The esr parameters are given in Table 2. This simple method of producing benzene radical anion (27) and sodium ion-pair of 2,6-di-*tert*-butylbenzoquinone (28) in non-polar solvent has been recently reported.

Another method, by irradiating a THF solution of carbonyl compounds in the presence of tetraphenylborates, has been successful in generating a variety of ion-pairs and triple-ions (17). We have employed this method to the following three fluoro-substituted ketones, HFA, TFA, and decafluorobenzophenone and the results are quite surprising.

When a THF solution of HFA and various tetraphenylborates was irradiated, an esr signal of two species was always observed. One of them can be generated in the absence of tetraphenylborate and was assigned as the protonated species. Although the counter solvent radical was not observed in THF or cyclopropane, they can be observed when propionic acid or 2-propanol was used as solvent. The other one has the similar esr parameters as those of solvent-separated ammonium ion-pair of HFA formed by photolysing a THF solution of HFA and Et_3N (see Table 1). It was assigned as solvent-separated ion-pairs of HFA. They were formed presumably via the following mechanism:

$$[7]\quad {}^3[(CF_3)_2C{=}O] \xrightarrow{\text{O-H}} (CF_3)_2\dot{C}{-}OH$$

$$[8]\quad (CF_3)_2\dot{C}{-}OH \rightleftharpoons (CF_3)_2\dot{C}{-}O^- + H^+$$

$$[9]\quad (CF_3)_2\dot{C}{-}O^- + M^+BPh_4^- \longrightarrow (CF_3)_2\dot{C}{-}O^-/M^+BPh_4^-$$

$$M = Li, Na, K, Bu_4^n \qquad \textbf{IV}$$

The photoreduction of the triplet HFA by a hydrogen donor has been described in the previous section. Reactions similar to [7] and [8] have been proposed in the photochemical generation of ion-pairs and triple ions (17). The solidus in **IV** was used to distinguish the solvent-separated ion-pair from the contact ion-pair.

Whether one can observe the protonated species or the ion-pair or both species depends on the dissociation process [8] as well as the driving force by the formation of ion-pairs, reaction [9]. When TFA was exposed to the similar condition, only solvent-separated ion-pairs were observed (Table 2). In the absence of tetraphenylborates, a weak esr signal of protonated species was detected. This signal can be enhanced by photolysis of a slowly flowing 2-propanol solution (0.5 mL/min). No counter solvent radical was observed in THF or 2-propanol. No polarization was detected for the protonated species. However, when a 2-propanol solution of TFA containing phenol with high concentration (>1 *M*) was irradiated, both protonated TFA and phenoxy radical were observed. Emissive CIDEP was observed in the phenoxy radical (20), again no polarization was observed in protonated TFA. If the phenol was replaced by hydroquinone or 2,6-di-*tert*-butylphenol, the emissive counter phenoxy radical was observed but no esr signal of protonated TFA was detected. The effect of fluorine anisotropic tensor on shortening the T_1 of protonated TFA is not clear yet. The short T_1 could be one of the possible reasons for not observing the polarization of protonated fluoroketones, although CIDNP has been observed in many fluoroketones (9).

The dissociation process, similar to reaction [8], must be very inefficient in the system of decafluorobenzophenone. The protonated species was the sole esr signal observed when THF solutions of decafluorobenzophenone and various tetraphenylborates, even in the presence of crown ethers, was irradiated. The esr parameters are given in Table 3. Reaction [8] also depends on the

solvent, when cyclopropane, instead of THF, was used, only the protonated species of HFA observed, no alkali-metal solvent-separated ion-pair was detected. This is inconsistent with the observations in ammonium ion-pairs, namely contact ion-pair was observed on cyclopropane while solvent-separated ion-pair was observed in THF.

A competitive reaction was also carried out by photolysing a THF solution of TFA in the presence of both Et_3N and tetraphenylborates. Only the contact ammonium ion-pair was observed. This indicates that the following exchange reaction is not important in this case,

[10] $TFA^{-\cdot}\overset{+}{N}HEt_3 + M^+BPh_4^- \xrightarrow{THF} TFA^{-\cdot}/M^+ + \overset{+}{Et_3N}HBPh_4^-$

Group IVB Organometallic Adducts of Fluoroketones

A complete series of Group IVB organometallic adducts of HFA was observed by photolysing cyclopropane solution of HFA in the presence of organometals and di-*tert*-butylperoxide. Under the similar conditions, 1,1,1-trifluoroacetone, TFA, decafluorobenzophenone, and benzophenone were studied. The observed esr parameters are given in Tables 1, 2, and 3, respectively.

The exceptionally electron-deficient carbonyl group of HFA results in several unusual features which merit further considerations. Although thioketones have trapped various carbon-centered radicals (29), benzil (30) and 2,6-di-*tert*-butylbenzoquinone (31) are the only two compounds that can utilize their "modified" carbonyl groups to trap alkyl radicals. HFA is the sole ketone, so far, that has successfully trapped carbon-centered radicals probably including triphenylmethyl radical. There are two reasons to believe that the observed esr signal during the photolysis of cyclopropane solution of HFA in the presence of triphenylmethane and di-*tert*-butylperoxide is due to the HFA adduct of triphenylmethyl radical: (*1*) There is no esr signal of triphenylmethyl radical which can always be observed under similar conditions except in the absence of HFA. (*2*) There is no additional hfs from hydroxyl proton of protonated species which can be resolved in the absence of triphenylmethane. TFA which can also form the contact ammonium ion-pair did not give any esr signal of alkyl radical adduct. This may imply that the exceptionally electron-deficient carbonyl group is not the only requirement for the formation of the adduct, some unknown fluorine effect may be involved. The weakness of lead–oxygen bond (32) may be the major reason for not observing esr signal of organolead adduct of acetone (33) or 1,1,1-trifluoroacetone. The observation of both trimethyl and triphenylplumbyl adducts of HFA may be partially ascribed to the two extremely electron-withdrawing CF_3 groups which tend to stabilize the negative charge on the organic molecule in the transition state through the polar effect.

[11] $(CF_3)_2C{=}O + {}^{\cdot}PbR_3 \rightarrow (CF_3)_2C{=}O{}^{\cdot}PbR_3 \longleftrightarrow (CF_3)_2\dot{C}{-}O{-}PbR_3 \rightarrow (CF_3)_2\dot{C}{-}\overset{-}{O}\overset{+}{P}bR_3$

The effect of fluorine on the stability of adducts also reflected in the reactions of benzophenone and perfluorobenzophenone with various phenylsilanes. Under similar conditions, while decafluorobenzophenone can give very good signals of all three triphenyl, diphenyl, and phenylsilyl adducts, benzophenone can only give a very good esr signal of triphenylsilyl adduct (34) and no signal of phenylsilyl adduct was observed.

The excellent esr signal of HFA adducts gives some hfs of carbon-13 and metals which may provide additional information on the structure of the adducts (35). For example, in the following three organosilyl adducts, the unusual small ^{29}Si splitting may be due to the highly pyramidal radical center or an expanded C_α—O—Si angle (15). The effect of β-fluorine on the radical configuration is minimum since the α-^{13}C splitting is not too far away from that of simple alkyl radicals (35). The big difference in α-^{13}C splittings between adducts **V** and **VI** is in accordance with an approximate molecular orbital theory calculation which predicted a decrease of more than 6 G in α-^{13}C splitting by going from ethyl to benzyl radicals (36). This in turn implies that the adduct **V** is planar at the radical site.

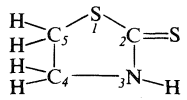
Received August 1, 1978[1]

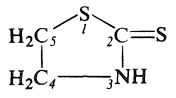
F. CHANON, M. RAJZMANN, M. CHANON, J. METZGER, and G. POUZARD. Can. J. Chem. **58**, 599 (1980).



^{1}H nmr ($^3J_{HH}$ values) and ^{13}C nmr results (shielding effect of *vicinal* methyl ^{13}C signals in *cis*-4,5-dimethylthiazolidine-2-thione) allows an estimation of the puckering in the five-membered monounsaturated heterocycle, thiazolidine-2-thione:

Application of Lambert's *R*-value equation provides a value of 41° for the torsional angle between C4 and C5, in contrast to an upper limit value of 25°, deduced from consideration of ^{13}C γ-effects; this disparity is discussed and compared with finite perturbation treatment of $^3J_{HH}$ values.

F. CHANON, M. RAJZMANN, M. CHANON, J. METZGER et G. POUZARD. Can. J. Chem. **58**, 599 (1980).



Les résultats fournis par la rmn du proton ($^3J_{HH}$) et par la rmn du carbone-13 (effets de masquage des ^{13}C des méthyles *vicinaux* dans la *cis*-diméthyl-4,5 thiazolidinethione-2) permettent d'évaluer le taux de plissement de l'hétérocycle pentagonal à une insaturation, la thiazolidinethione-2:

L'utilisation des valeurs *R* de Lambert fournit comme valeur du plissement 41°, alors que l'étude conduite à partir du masquage du carbone-13 des méthyles à partir de l'effet γ donne une limite supérieure de 25°. Cette différence d'évaluation est discutée et confrontée au calcul par les perturbations finies des $^3J_{HH}$.

Introduction

Conformational analysis of heterocyclic systems did not begin (1, 2) until well after the birth of classical conformational analysis (3). The uncertainty associated with the extension of well accepted tools of analysis for classical conformational systems, to unknown systems, is the main cause of this late development. For any new heterocyclic system under study, the obtained informations must be cross-checked by the use of different methods. The following reports illustrate this approach. The purpose of this paper is to define the conformational properties of the nonsymmetric monounsaturated heterocyclic system, namely thiazolidine-2-thione (TH-2-TH) **1**.

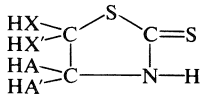
1

[1]Revision received November 12, 1979.

In this report, we will study the unsubstituted ring and in the next report (4), we will consider the effect of perturbations in this system due to the presence of substituents at positions 3, 4, and 5. This first paper tentatively answers the questions: is the heterocycle planar or puckered? If indeed the ring is puckered, to what extent is it, compared with its alicyclic homologs? Do the experimental results allow us to affirm that a pseudo-rotation process exists in this ring system?

Results and Discussion

Observation and Evaluation of the Degree of Puckering of the Thiazolidine-2-thione Ring



^{1}H Nuclear Magnetic Resonance — J_{vic} — Application of the Simplified Karplus Equation

The analysis of the ^{1}H nmr spectra (Table 1) gives nearly alike $^3J_{cis}$ and $^3J_{trans}$ values for the C4–C5 fragment in TH-2-TH. It had been pointed out (5) that similar J_{cis} and J_{trans} values in a five-membered ring suggest a highly flexible system. Following Karplus (6) $^3J_{HH}$ values can be described as functions of the

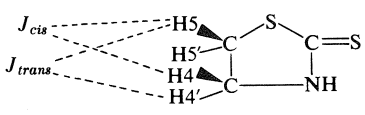
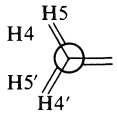
TABLE 1. ^{1}H nmr parameters for thiazolidine-2-thione heterocyclic protons*

$\delta_A = \delta_{A'}$	$\delta_X = \delta_{X'}$	J_{AX}	$J_{AX'}$
4.01	3.58	8.75	7.35



*Shifts in ppm; coupling constant in Hz; in ($^2H_6$)–acetone with TMS as internal reference; assignment of the heterocyclic proton signals deposited in the Journal archives.



torsional angle φ between the two corresponding *vicinal* carbon atoms.

[1] $^3J_{HH} = J_{0°} \cos^2 \varphi \qquad 0° \leq \varphi \leq 90°$

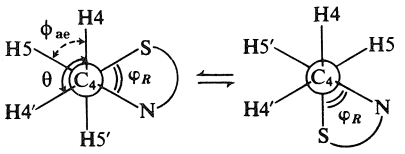
[2] $^3J_{HH} = J_{180°} \cos^2 \varphi \qquad 90° \leq \varphi \leq 180°$

In the case of a planar ring in TH-2-TH:

[3] $J_{cis}^{exp} = J_{45} = J_{4'5'} = J_{0°} = 8.75$ Hz

[4] $J_{trans}^{exp} = J_{45'} = J_{4'5} = J_{120°} = 7.35$ Hz

$= J_{180°} \cos^2 120°$ according to [2]



So

$J_{180°} = 29.4$ Hz with $J_{180°}/J_{0°} = 3.4$

The abnormally large value for 180° (6–8) rules out the possibility of a planar conformation for the TH-2-TH ring.

^1H Nuclear Magnetic Resonance — J_{vic} — The Use of Lambert's R*-value Method*

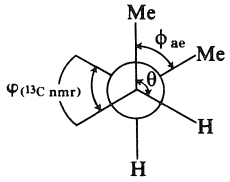
Assuming a puckered ring, thiazolidine-2-thione exists in a rapidly interconverting equilibrium mainly between two energetically equivalent conformations:

The N—C4—C5—S torsional angle φ_R can be evaluated (Lambert's *R*-value method (9)) using the ratio of the experimental *vicinal* coupling constant values in the CH_2—CH_2 fragment: i.e.

[5] $R = J_{trans}^{exp}/J_{cis}^{exp}$

and

[6] $\cos \varphi_R = [3/(2 + 4R)]^{1/2} \qquad$ for $\theta = 120°$



This type of calculation can be used for most of the six-membered rings and according to Lambert "there appears to be no theoretical reason to preclude applications to all common and medium rings" (9). In the TH-2-TH case, $R = 0.84$, i.e. $\varphi_R = 41°$; therefore Lambert's *R*-value implies a significant puckering of the ring as in the cyclopentane (10) and dioxolane cases (11).

^1H Nuclear Magnetic Resonance — $^2J_{H5H5'}$ and $^2J_{H4H4'}$ Values

In the series of 4- and 5-alkyl-substituted (Me, Et, *i*Pr, *t*Bu) TH-2-TH derivatives, the $^2J_{H4H4'}$ or $^2J_{H5H5'}$ values vary in a continuous and coherent way (4). However, substituent electronegativities vary only slightly along the series; thus the main factor which induces deviations in the J_{gem} values in the $\ddot{X} - CH_2$ fragment is the variation of the dihedral angle between the *C*—H bonds and the "lone-pairs orbitals" of the heteroatom Ẍ (12). The observed change in the J_{gem} values in the alkylated series was therefore assigned to conformational modifications of the ring (4): that establishes the mobility of the thiazolidine-2-thione ring.

^{13}C Nuclear Magnetic Resonance — $^{13}CH_3$ Signal in the cis*-Dimethylated Derivatives of TH-2-TH and in some* Vicinal *Dimethylated Models*

Stothers and co-workers (13, 14) showed the relationship between the spatial proximity and the observed shielding effects of the $^{13}CH_3$ signal in *vicinal* methyl groups. Inspections of the computed electron density distributions and details of the geometrical dependences lead to the suggestion that the mecanism of γ-effect may be considerably more complex than the commonly accepted C—H bond polarisation by nonbonded H · · · H interaction (15). However,[2] a graph of the shielding effect by a *vicinal* methyl group versus the estimated dihedral angle $\phi_{ae} = \varphi_{^{13}C\ nmr}$ in some model compounds

(14, 16–18) gives nearly a straight line (Fig. 1). To a large extent, this quasi-linearity agrees with the result of Seidman and Maciel (15); they performed a set of "computer experiments" using the modified-INDO finite perturbation theory of ^{13}C chemical shifts to explore the geometrical dependence of the shielding of methyl groups in systems presenting

[2]Recently Beierbeck and Saunders (19) have proposed a re-interpretation of the γ-effect. But they estimate that "their re-interpretation is of little consequence for the phenomenological use of ^{13}C chemical shifts as a tool in structure elucidation work" (private communication).

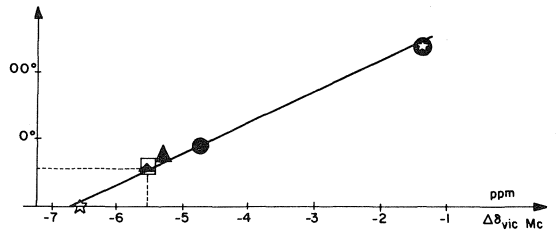

FIG. 1. ^{13}C nmr. Effects on $^{13}CH_3$ chemical shift by the introduction of a *vicinal* methyl ($\Delta\delta_{vic\ Me}$ in ppm). The dimethylated derivatives are: ✡, 2-*exo*-3-*exo*-dimethylnorbornane (14); ▲, *cis*-3,4-dimethylcyclopentanone (16); ●, *endo*-2-methylnorbornane (towards C6 γ-carbon) (14); ✪, 2-*endo*-3-*exo*-dimethylnorbornane (14); ○, *cis*-4,5-dimethylthiazolidine-2-thione (Table 2); □, *cis*-1,2-dimethylcyclopentane (18).

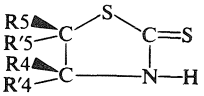

steric γ-effects. The γ-effects observed (Table 2) for the alkylthiazolidine-2-thiones suggest a Φ value of 25° (Fig. 1). This implies that the TH-2-TH ring can exist in a puckered conformation in solution. Moreover, in the case of the unsubstituted TH-2-TH, the torsional angle between C4 and C5 could even be smaller than 25°, when no steric interactions between adjacent methyls occur: i.e.

$$0° \leq \varphi_{(^{13}C\ nmr)} < 25°$$

Lambert's method gives a φ_R value of 41°. The same difference is observed in the cyclopentane case where $R = 0.80$ (10), indicating an average dihedral angle of 41° in contrast to the experimental value (10) or the calculated value (10*b*) of 27°. The $\Delta\delta_{vic\ Me}$ method in ^{13}C nmr gives a value of about 27° in *cis*-1,2-dimethylcyclopentane (18). Wilson and Bazzone (11*a*) found a φ_R value of 41° for dioxolane while $\varphi_{X\ ray}$ is found to be 21° (11*b*). These discrepancies can be explained in several ways. Fuchs (9*c*) had attributed them to appreciable deviation of θ from 120°. We took θ = 126° in eq. [7] (9*c*)

$$[7] \quad \varphi_R = \arccos\left[\frac{1 - \cos 2\theta}{2(R - \cos 2\theta)}\right]^{1/2}$$

TABLE 2. ^{13}C nmr. *Vicinal* methyl chemical shift in alkylthiazolidine-2-thiones

Substituents				Chemical shifts (ppm)		
R4	R'4	R5	R'5	$\delta_{^{13}CH_3-C4}$	$\delta_{^{13}CH_3-C5}$	$\Delta\delta_{vic\ Me}$ (γ-effect)
Me	H	Me	H	13.83	15.10	
Me	H	H	H	19.56		−6.73
H	H	Me	H		20.54	−5.44

and as Wilson and Bazzone (11*a*) we have noticed that this change in θ produces only a slight displacement of the rotational angle. On the other hand, Buys (20) has calculated that the rate of change of φ_R as a function of R is described by eq. [8]:

$$[8] \quad \partial\varphi_R/\partial R = 120 \cos^3 \varphi_R/\sin \varphi_R \qquad (\varphi_R \text{ in deg})$$

This rate is maximum near 45°. However, in this area, a change in R of 0.05 induces a variation of 1° in φ_R, and therefore the experimental error on R (0.03) cannot be the main cause of the elevated φ_R values. Furthermore, Lambert (9*a*) used the simplified Karplus equation [9]:

$$[9] \quad {}^3J_{HH} = A \cos^2 \varphi_R$$

neglecting the small second and third order terms B and C. Also, despite Lambert's assertion, one can wonder whether the presence of heteroatoms (nitrogen and sulfur) introduces errors that are not entirely compensated for in the R-value method. For example, the electronegativities of the S (χ_S) and N (χ_N) atoms linked to the CH_2—CH_2 fragment have additive influences on the ^3J values (6, 8); the influence of the difference in electronegativities ($\Delta\chi = \chi_X - \chi_H$ with X = S or N) may give rise to disparate contributions to J_{cis} and J_{trans}. Lambert's equation does not take this into account. In order to study the influence of this approximation on φ_R, we have treated the TH-2-TH ring within the finite perturbation approximation (21), using the CNDO-2 method. We obtain the values of the *cis* and *trans* coupling constants (21*a*). Table 3 lists these calculated ^3J values together with the corresponding $\varphi_{R(CNDO)}$ torsional angles of the C4—C5 bond, calculated by eq. [6] using R(CNDO) obtained from:

$$R\,(\text{CNDO}) = \langle J_{trans}{}^{calcd}\rangle / \langle J_{cis}{}^{calcd}\rangle$$

where $\langle J^{calcd}\rangle$ are CNDO-2 results.[3] Examination of Table 3 indicates that for the whole simulation, $\varphi_{R(CNDO)}$ is larger than $\varphi_{(geometry)}$, the real dihedral angle deduced from cartesian coordinates. This disparity could partly originate from an electronegativity effect. But, as the same type of discrepancy exists for dioxolane and cyclopentane rings, it seems that other factors could contribute to the overestimation of φ by the R-method.

Attempts to Determine the Existence of a Pseudorotational Process in the TH-2-TH Ring

In cyclopentane (22) the ring puckering rotates

[3]For a given geometry: $\langle J_{cis}{}^{calcd}\rangle = 1/2\ (J_{H4aH5e}{}^{calcd} + J_{H4eH5a}{}^{calcd})$, $\langle J_{trans}{}^{calcd}\rangle = 1/2\ (J_{H4aH5a}{}^{calcd} + J_{H4eH5e}{}^{calcd})$.

§No. 1 and No. 2 correspond respectively to weak and higher puckering (see $\varphi_{(geometry)}$).

around the carbocyclic skeleton without forcing the ring to pass over high potential energy barriers: this is pseudo-rotation. Among all the possible conformations for the cyclopentane ring, two possess elements of symmetry: the half-chair (C_2) and the envelope (C_s) arrangements. Calculations (22*a*, *c*, *d*) accounting for pseudo-rotation in cyclopentane, and accurate spectroscopic (10*a*, 22*h*, *i*) and thermodynamic (22*j*) evidences for such a phenomenon have been reported. Substitution of CH_2 groups in cyclopentane, by functions such as heteroatoms or sp_2 hybridized carbon atoms alters the course and the ability of the pseudo-rotation process (22). Significantly, X-ray analysis established (23) the planarity of the X—C (=Y)—Z portion in heterocycles of type **2**:

2

By analogy we can assume that the TH-2-TH ring is planar in the S—C(=S)—NH region. This reduces the number of degrees of freedom of the C4C5 fragment. That is to say, the low energy TH-2-TH conformations are those of equilibrium [*a*]:

a1 C5 out-of-plane envelope

a2 C4C5 out-of-plane half-chair

a3 C4 out-of-plane envelope

Interestingly, interactions due to Pitzer strain are weaker in methanethiol than in methylamine (24). For this reason, saturated heterocycles having at least two heteroatoms (of which one is sulfur (25)) preferentially adopt conformations in which the atom adjacent to the sulfur and the sulfur atom itself lie in the same plane. We deduce from this that the C5 atom in TH-2-TH would have a smaller tendency to leave the plane of the S—C (=S)—N fragment than the C4 atom. Such a discussion indicates that the order of the preferred conformations of TH-2-TH would be:

a3 > a2 > a1

However no experimental evidence exists for such an order of conformational stability. But the results of substituent effects introduced in 4- and 5-position agree with this order (4).

Conclusion

It would appear that, in solution, the TH-2-TH ring exists in a puckered form in which the C4—C5 dihedral angle is estimated to be smaller than 25°.

Discussion of the possible sources of error in Lambert's R value method indicates that results obtained by this approach for five-membered heterocycles must be treated with utmost caution. The results from nmr studies of 4-hydroxy-thiazolidine-2-thiones (4) confirm these suspicions. Although it is difficult to provide experimental evidence for a pseudo-rotation phenomenon in TH-2-TH, considerations of data on related heterocyclic systems

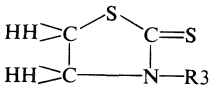
that it does occur and that the order of preference of the conformations of this molecule would be in the order:

C4 out-of-plane envelope > C4C5 out-of-plane half-chair > C5 out-of-plane envelope



Experimental

^1H Nuclear Magnetic Resonance — Spectra Analysis

Spectra were recorded at ambient temperature on Varian A60 (60 MHz) and HA 100 (100 MHz) spectrometers as ca. 0.1 *M* solutions in acetone-d_6–TMS was used as internal reference. The spectra of protons at C4 and C5 in the system:

in compound such as

are interpreted in terms of a "deceptively simple" AA′XX′ spin-system (26, 27). Since the 60 MHz spectrum exhibits more "visible" lines than that of the 100 MHz spectrum, an interpretation of the former is first carried out from which we estimate an average value of -12 Hz for the $J_{AA'}$ and $J_{XX'}$ coupling constants (as a matter of fact, calculated spectra do not depend on $J_{AA'}$ and $J_{BB'}$ values). Then, the series of parameters which gives the most satisfactory calculated spectrum (MLACO program) is refined (LAOCON program). Using refined parameters obtained at 60 MHz, we calculate (MLACO) the 100 MHz spectrum and find a good agreement between calculated and experimental spectra. Results are listed in Table 1.

The assignment of the proton chemical shifts is available in the Depository of Unpublished Data.[4]

^{13}C Nuclear Magnetic Resonance Spectra

The apparatus and conditions are described in the following paper (4).

Acknowledgements

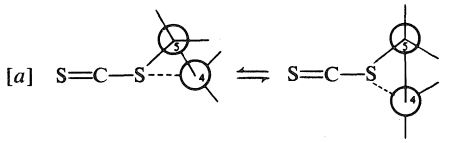
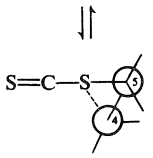
F. CHANON, M. RAJZMANN, M. CHANON, J. METZGER, G. POUZARD, and T. DRAKENBERG. Can. J. Chem. **58**, 604 (1980).



Variation of the conformational properties in a series of 4-R-thiazolidine-2-thiones (4-R = Me, Et, *i*Pr, *t*Bu, OH) and 5-R-thiazolidine-2-thiones (5-R = Me, Et, *i*Pr, *t*Bu) is deduced from ^{1}H nmr (Karplus ^3J, chemical shifts, $^2J_{44'}$, $^2J_{55'}$) ^{13}C nmr data and CNDO-2 calculations. In the absence of any transannular interaction, *vicinal* constraints and van der Waals requirements of the substituents control the conformational equilibrium. The pseudo-axial arrangement is favoured when 4-R = Me, while the substituent presents no preferential orientation when 5-R = Me. As the size of the 5-alkyl and the 4-alkyl substituent increases, its pseudo-equatorial orientation and the predominance of the C4C5 out-of-plane half-chair conformation are favoured. This does not lead to conformational exclusivity even when 4-R or 5-R is *t*Bu. When 4-R is hydroxy, there is a definite pseudo-axial conformation (anomeric effect) and the ring preference is of the C4 out-of-plane type.

F. CHANON, M. RAJZMANN, M. CHANON, J. METZGER, G. POUZARD et T. DRAKENBERG. Can. J. Chem. **58**, 604 (1980).

Les évolutions conformationnelles dans les R-4 thiazolidinethiones-2 (R-4 = Me, Et, *i*Pr, *t*Bu, OH) et les R-5 thiazolidinethiones-2 (R-5 = Me, Et, *i*Pr, *t*Bu) sont déduites de l'ensemble des résultats rmn ^{1}H (^3J-Karplus, δ_H, $^2J_{55'}$, $^2J_{44'}$), rmn ^{13}C et calculs CNDO-2. En l'absence d'interactions transannulaires, les contraintes *vicinales* et de van der Waals des substituants contrôlent l'équilibre conformationnel. Lorsque R-4 = Me, sa préférence est légèrement pseudo-axiale tandis que le substituant R-5 = Me n'a pas d'orientation spécifique. On observe, simultanément à une augmentation de la taille du substituant alkyle, une orientation de plus en plus équatoriale de ce dernier et une prédominance accrue de la conformation demi-chaise avec C4C5 hors plan. Ceci ne conduit pas toutefois à un blocage conformationnel même pour le *t*Bu. Pour R-4 = OH, une nette préférence pseudo-axiale se manifeste (effet d'anomérie) et le plissement du cycle est du type enveloppe avec C4 hors du plan du thiocarbonyle.

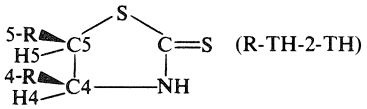


Introduction

In the preceding paper (1) we have shown for thiazolidine-2-thione (**1***a*) the existence of equilibrium [*a*]:

C5 out-of-plane envelope **a1**

C4C5 out-of-plane half-chair **a2**



C4 out-of-plane envelope **a3**

The conformer stability increases from left to right and the C4C5 torsional angle was evaluated to be ca. 25°.

[1]Revision received November 12, 1979.

Having introduced substitution at C4 (**1***b*, **1***c*, **1***d*, **1***e*, **1***f*) and C5 (**2***b*, **2***c*, **2***d*, **2***e*), i.e.

(R-TH-2-TH)

1*a*: 4-R = H; 5-R = H
1*b*: 4-R = Me; 5-R = H
1*c*: 4-R = Et; 5-R = H
1*d*: 4-R = *i*Pr; 5-R = H
1*e*: 4-R = *t*Bu; 5-R = H
1*f*: 4-R = OH; 5-R = H

2*b*: 4-R = H; 5-R = Me
2*c*: 4-R = H; 5-R = Et
2*d*: 4-R = H; 5-R = *i*Pr
2*e*: 4-R = H; 5-R = *t*Bu

we must answer the following questions: (*1*) What are the orientations of the (4-R)—C4 and (5-R)—C5 bonds? (*2*) How is equilibrium [*a*] modified? (*3*) What are the conformations resulting from rotation around the C—C4 and C—C5 bonds? (*4*) What origin can have these conformational effects?

The starting point is the application of the method of ratios (ref. 2, ref. 31, Annexe V, p. 111) to ^3J

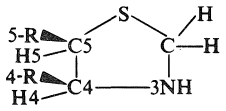
values of the ethanic fragment using the Karplus equation. CNDO-2 simulation results are compared with those from ^{13}C (Table 2) and ^{1}H nmr experimental data (Table 1).



Part A. 4-Alkyl and 5-Alkylthiazolidine-2-thiones

Results and Discussion

Pseudo-axial or Pseudo-equatorial Substituent Orientation

The $^{3}J_{cis}^{exp}$ and $^{3}J_{trans}^{exp}$ values of the ethanic fragment are used in the calculations based on the Karplus equation to obtain the C4C5 torsional angle φ_{calcd} and the proportion of the pseudo-axial conformer x (ref. 2, ref. 31, Annexe V, p. 111). The results are listed in Table 3. They reveal a slight pseudo-equatorial preference exhibited by the 4-methyl derivative **1***b* and a slight pseudo-axial one for the 5-methyl derivative **2***b*. The orientation of R is increasingly equatorial with increasing substituent size, particularly so for 4-R or 5-R = Et and *i*Pr. A pseudo-equatorial preference close to 100% is not observed. The effective orientation of the methyl substituent is supported by substituent effects on ^{13}C chemical shifts due to the introduction of methyl group (Table 4). α- and β-effects are both deshielding. The α4- and β5-effects are produced by introducing a methyl group at C4, while the α5- and β4-effects are produced by introducing a methyl group at C5.

First, we notice that the α4- and β5-effects are of the same order of magnitude as in thiazolidine derivatives (R-TH) **3** (5).

3*a*: 4-R = H; 5-R = H
3*b*: 4-R = Me; 5-R = H
3*c*: 4-R = H; 5-R = Me

Whestheimer calculations (6) and ir–Raman study (7) have shown a pseudo-axial preference for the methyl group in 4-methyl thiazolidine **3***b*; this similarity may provide an axial orientation of methyl group in both 4-methyl-TH-2 (**1***b*) and 4-methyl-Th (**3***b*). This is confirmed by examining α′4- and β′5-effects when introducing a second methyl group at C4 in **1***b*. Usually, the introduction of a *gem* methyl group on $C—CH_3$ induces weaker α′- and β′-effects, particularly when the second methyl group is "introduced" in a pseudo-axial position as in cyclopentane series (3, 4, 8). The larger the $\Delta\alpha_{Me}$ ($\Delta\alpha_{Me} = \alpha - \alpha'$) and $\Delta\beta_{Me}$ ($\Delta\beta_{Me} = \beta - \beta'$) differences, the more important is the proportion of equatorial methyl group in the monosubstituted derivative and vice-versa. By comparing the cyclopentane series (8) ($\Delta\alpha_{Me} = +5$ ppm, $\Delta\beta_{Me} = +2.8$ ppm) and the 4-R-THTH-2 series ($\Delta\alpha 4_{Me} = +1.12$ ppm, $\Delta\beta 5_{Me} = +1.38$ ppm), it appears that the proportion of equatorial methyl group is larger in methyl cyclopentane than in 4-methyl-2-TH (**1***b*); this is consistent with the predominance of the pseudo-axial position of the 4-methyl group, as in 4-Me-TH (**3***b*). Then for 4-methyl-TH-2-TH **1***b* the equilibrium [*b*]

$$[b] \qquad \underset{\mathbf{b1}}{\text{axial R}} \rightleftharpoons \underset{\mathbf{b2}}{\text{equatorial R}}$$

is slightly shifted to the left.

This result differs somewhat from the one obtained by the method of ratios which gave a slight pseudo-equatorial preference. Many authors (9) have emphasized that it is dangerous to calculate torsional angles from *vicinal* coupling constants in 5-membered rings. The coupling constant must be integrated on the basis of a pseudo-rotational circuit rather than from an ideal situation with an equilibrium between two conformations only. Furthermore, in our calculations, the C4 and C5 carbons were considered as perfectly tetrahedral, which is not the case in a 5-membered heterocycle with a sp^2 carbon atom (10). The use of a 126° value (instead of 120°) for the H4C4C5H4′ dihedral angle in 4-Me-TH-2-TH **1***b* gives a 52% value for x showing a slight pseudo-axial preference for the 4-methyl group. The ratio method, therefore, underestimates the pseudo-axial preference in **1***b*.

With respect to 5-methyl-TH-2-TH **2***b*, we note the important α5-value (already observed on the chemical shifts of carbons next to the sulfur atoms (5, 11)). Qualitative considerations (11*b*) on the charge distribution in $R—C_{sp^3}—X$ (X = S, N, O) imply that α-effects would be larger for X = S, due to the presence of vacant 3*d* orbitals on the sulfur. Thus, it is unwise to employ here α5- and α′5-effects as indices of conformational variation. Moreover, in none of the compounds discussed in the literature (5, 11) is the deshielding effect as large as the α5-effect noted here. Its value (+12 ppm) suggests that the methyl group in **2***b* cannot exist in a pseudo-axial conformation (4). By contrast, it is possible to use the β4- and β′4-values (the deshielding effects on the $^{13}C4$ chemical shift by introducing successive methyl groups at C5 on TH-2-TH **1***a*) which have mostly a steric origin. We note that

$$[1] \quad \Delta\beta 5_{(\text{Me at C4 in TH-2-TH})} < \Delta\beta 4_{(\text{Me at C5 in TH-2-TH})} < \Delta\beta_{(\text{Me in cyclopentane})}$$

H	*t*Bu	**2***e*	6.2	8.8	0.70	35.5	49

*φ_{calcd} is such that $J_{\varphi_{calcd}} = 4.22 - 0.5 \cos \varphi_{calcd} + 4.5 \cos 2\varphi_{calcd}$ with $J_{\varphi_{calcd}} = J_{cis}^{exp}/1.83$ (2).
†$x = 100 \times (R_{exp} J_{\varphi_{calcd}} - J_{120°} + \varphi_{calcd})/(J_{120°} - \varphi_{calcd} - J_{120°} + \varphi_{calcd})$ (2).

This intermediate value for $\Delta\beta 4_{(Me\ at\ C5\ on\ TH—TH)}$ implies that the proportion of equatorial methyl in 5-methyl-TH-2-TH (**2***b*) is included between the one existing in methylcyclopentane (a bit more than 50%) and the one in 4-methyl-TH-2-TH (**1***b*) (a bit less than 50%); then the proportion of equatorial methyl in 5-methyl-TH-2-TH (**2***b*) should be about 50%, as in the 5-methyl-TH (**3***c*) case (6, 7). This result disagrees with the one previously found by the Karplus method ($x_{2b} = 57\%$). We have seen that x is underestimated by 5% (which gives $x_{2b} = 62\%$) if C4 and C5 are perfectly tetrahedral. The discrepancy between the two methods probably comes from the fact that we considered only two preferred conformations in the Karplus method.

Assuming the presence of equilibria [*a*] and [*b*], we would have to sum $^3J_{cis}$ and $^3J_{trans}$ over at least six conformational arrangements (3 × 2), where the concentrations of **a1**, **a2**, **a3** are not negligible.

In the 4-methyl **1***b* case, we gave evidence of **a3** predominance, with probably weak concentrations of **a1** and **a2**. Thus, the conformational equilibrium would limit itself to:

C4 (out-of-plane envelope with axial methyl)

$\leftrightharpoons$ C4 (out-of-plane envelope with equatorial methyl)

Thus the 4-Me-TH-2-TH **1***b* case is situated nearly within the domain of application of the ratio method and the results are in better agreement with those of the ^{13}C nmr data than in the 5-Me-TH-2-TH **2***b* case.

The H5,H4 chemical shift variations between **1***b* and **1***e*, **2***b* and **2***e* are reported in Table 5. In the absence of data for 5-membered rings, we chose the *cis*-6-alkyl-4-methyl dioxanes **4***b* and **4***e* (12), and the *trans*-6-alkyl-4-methyl dioxanes **5***b* and **5***e* (12) for comparison purposes. We notice that for both the dioxane and the TH-2-TH series, the chemical shift

*In acetone-d_6.
†In CCl_4.

variations follow the same trend: a shielding effect on the *transoid* proton and a deshielding effect on the *cisoid* proton.

4
4*b*: 6-R = Me
4*e*: 6-R = *t*Bu

5
5*b*: 6-R = Me
5*e*: 6-R = *t*Bu

In series **4**, where both the methyl and 6-R substituents are equatorial (fixed ring geometry and substituent orientation), these effects are very small. In series **5**, assuming a constant ring geometry, the proportion of conformer with 6-R axial should decrease as the size of 6-R increases. Then, the observed variation of the chemical shift of the *transoid* and *cisoid* protons in compounds **1**, **2**, and **5** must have the same origin: the increasing tendency of the bulkier substituent to adopt a pseudo-equatorial orientation.

A circular dichroism study (ref. 31, p. 56) of **1***b*, **1***c*, and **1***d*, which are endowed with rotatory power, confirms the fact that a larger substituent shifts equilibrium [*b*] to the right.

Ring Geometry

Inspection of Table 3 shows that: (*i*) introduction of a methyl group at C4 or C5 in TH-2-TH brings in a slight increase of the dihedral angle φ_{calcd}, the effect being larger for the 4-position; (*ii*) an increase of the substituent size results in a decrease of φ_{calcd}, particularly so between 5-R = *i*Pr and *t*Bu, and 4-R = Et and *i*Pr.

The observed discontinuity in the variation of φ_{calcd} can originate either from two types of conformational change or from an artefact due to the method. In order to eliminate the possibility of such an artefact, we corroborated the φ_{calcd} variation by comparing the experimental proton chemical shifts and the $^2J_{55'}$ and $^2J_{44'}$ values with those calculated by the CNDO-2 method (14).

First, let us examine the variation of the experimental chemical shifts with substituents by comparing TH-2-TH **1**, **2**, and TH **3** series. As ^{13}C nmr conclusions, we have seen that equilibrium [*b*] is comparable in the 4-methyl derivatives **1***b* and **3***b* (light preference of axial methyl), and in the 5-methyl derivatives **2***b* and **3***c* (no preference of the substituent). We shall consider that H4 and H5 are far away from the anisotropic zone of thiocarbonyl group. As a second approximation, we shall admit that for the same H4 orientation, the anisotropic effect of the lone pair on the nitrogen is alike in TH-2-TH and in TH rings. An equatorial proton usually gives a signal at a lower field than an axial proton (16). Then, the difference in the intensity of the methyl substituent effects will originate from difference in the proton orientation, thus in ring geometries. First, the introduction of a methyl group at C4 or C5 deshields both the *geminal* and *transoid* protons while the *cisoid* proton is shielded (Table 6). In the 4-methyl derivatives **1***b* and **3***b*, the deshielding $\Delta\delta_{H4}$ effect is negligible in the case of thiazolidine **3***b*. It follows that H4 in **1***b* takes up a more equatorial orientation than in **3***b*, whose preferential ring conformation had been found (6, 7) as a half-chair geometry with C4N3 out-of-plane. Molecular models show that an equatorial H4 proton is closer to the ring plane, for a C4 out-of-plane envelope than for a C4N3 out-of-plane half-chair.

Therefore, the preferred ring geometry of **1***b* would be the C4 out-of-plane envelope **a3**. This corresponds to a shift of [*a*] to the right in going from **1***a* to **1***b*. Such a displacement would manifest itself in decreasing the C4C5 torsional value (17).

In the case of the 5-methyl derivatives **2***b* and **3***c*, the $\Delta\delta_{H5}$ deshielding value for the TH-2-TH ring **2***b* is smaller than for the TH ring **3***c*; it follows that H5 in **2***b* takes a more axial orientation than in **3***c*, where a C4 out-of-plane envelope and a C4N3 out-of-plane

TABLE 6. ^{1}H nuclear magnetic resonance: effects on the chemical shifts of heterocyclic protons by the introduction of a methyl group at position 4 and 5 of TH-2-TH and TH (ppm; + is deshielding; − is shielding)

Introduction of a methyl group in position	$\Delta\delta_{H4'}$	$\Delta\delta_{H4}$	$\Delta\delta_{H5}$	$\Delta\delta_{H5'}$
4 of TH-2-TH		+0.41 (*gem*)	+0.10 (*transoid*)	−0.38 (*cisoid*)
4 of TH (ref. 6, p. 62)		+0.02 (*gem*)	+0.18 (*transoid*)	−0.50 (*cisoid*)
5 of TH-2-TH	−0.43 (*cisoid*)	+0.07 (*transoid*)	+0.46 (*gem*)	
5 of TH (ref. 6, p. 110)	−0.50 (*cisoid*)	+0.02 (*transoid*)	+0.64 (*gem*)	

half-chair are found preferential (6, 7). In molecular models, it appears that H5 becomes more axial when C5 leaves the plane of the thiocarbonyl group. Thus the above weak $\Delta\delta_{H5}$ in **2***b* originates from an increase in the half-chair population **a2**: going from **1***a* to **2***b* displaces [*a*] to the left and brings about an increase of the C4C5 torsional angle (17).

Another conclusion can be drawn from Table 6. The large shielding effect on the H_{gem}/6-R proton (−0.50 ppm, Table 5) in the dioxanes **4**, in going from R = Me to R = *t*Bu, arises from spatial substituent interactions (12). The shielding effects, $\Delta\delta_{H_{gem}/R}$, in thiazolidine-2-thiones **1** and **2**, when R = Me to *t*Bu, being somewhat smaller (−0.35 ppm for **1** and −0.12 ppm for **2**, Table 5), something must exist which induces an incremental deshielding effect as H4 and H5 become more and more axial. If we neglect the anisotropic effect of the thiocarbonyl group, the deshielding increment can be assigned to a modification of the ring geometry in **1** and **2** as the substituent becomes larger. Simulation of such changes in 4-methyl-TH-2-TH and 5-methyl-TH-2-TH by the CNDO-2 method (Fig. 1) shows that:
(*i*) For **1***b*, the shift

[*c*] C4 out-of-plane envelope ⇋ C4C5 out-of-plane half-chair
(axial methyl) (equatorial methyl)

indeed results in the following simultaneous effects: deshielding of *cisoid* H5′ and particularly of H4; shielding of *transoid* H5.
(*ii*) For **2***b*, the change

[*d*] C5 out-of-plane envelope ⇋ C4C5 out-of-plane half-chair
(axial methyl) (equatorial methyl)

gives rise to the following simultaneous effects: deshielding of *cisoid* H′4 and, particularly, of H5; shielding of *transoid* H4.

The observed deshielding increment on H_{gem}/R, in going from R = Me to R = *t*Bu, can therefore originate from such conformational modifications

FIG. 1. ^{1}H nmr/CNDO-2 calculations. *One must not attach too much importance to the intrinsic value of an isolated result (ref. 13, ref. 31, Annexe 2, p. 36). Only the variation in a series of homologous compounds can have a real significance.
†No. 1 = slight puckering of the ring (1), No. 2 = important puckering of the ring (1) (see Table 2).

an heteroatom. An increase in χ or/and in orbital overlapping has positive contribution to ^2J (as ^2J is normally negative, a positive contribution implies a diminution of the absolute value). In series **1** and **2** we observe a diminution of $^2J_{55'}^{exp}$, and $^2J_{44'}^{exp}$ (Table 1, parts *a* and *b*), and particularly so between **1***c* and **1***d*, and **2***d* and **2***e*. Molecular orbital calculations performed by Bothner-By and Pople (19) for ^2J values account for most of the experimental trends. Accordingly, simulation by Pople and Santry CNDO-2 method (14*b*) (Table 7) shows that a diminution of $J_{55'}$ in 4-methyl-TH-2-TH **1***b* can have several conformational origins: (*i*) an increase in the proportion of axial conformer, the ring geometry remaining fixed; (*ii*) an increase of the half-chair (**a2**) proportion with 4-R being axial.

In this series (from **1***b* to **1***c*), we saw an increase of the proportion of the equatorial orientation of R. Then only factor (*ii*) can be considered responsible for the diminution of $J_{55'}^{exp}$.

In 5-methyl-TH-2-TH calculation, a diminution in $J_{44'}$ can be manifested in the following ring phenomena: (*i*) increase in ring puckering; (*ii*) increasing population of the axial conformation while the ring geometry remains fixed; (*iii*) passage from the **a3** to the **a1** conformation while the orientation of the substituent remains constant (5-R axial or equatorial); and (*iv*) increasing the population of the equatorial conformer with a passage from the **a3** to the **a2** conformation.

We previously demonstrated the increasing equatorial tendency of the substituent from **2***b* to **2***c* and no indication of an increase in the ring puckering has been experimentally noticed. Thus we can retain factor (*iv*), i.e., the diminution of $J_{44'}^{exp}$ value comes principally from the equilibria [*a*] and [*b*] being shifted to the right.

Spatial Orientation of the Substituents

The population of each rotamer about the C—C4 or C—C5 bonds follows from the application of the simplified Karplus equation (20) $J_\varphi = A^0 \cos^2 \varphi$ to the *vicinal* coupling constants in the

CH—C4 or CH—C5
| |
H H

fragment (see Experimental section).

For 4-R-TH-2-TH (4-R = Et, *i*Pr), the conformations with a methyl *gauche* to N are particularly energetic, while for 5-R-TH-2-TH (5-R = Et, *i*Pr) the conformations with a methyl group *gauche* to C4 are less stable. It then appears that the steric interactions are important: between a methyl group and N for the series **1***b* to **1***d*, between a methyl group and C4 for the series **2***b* to **2***d*.

Factors Influencing the Conformational Equilibria

We have summarized all the above conclusions, by schematically representing the observed conformational trends respectively in series **1** and **2** respectively in Tables 8 and 9.

By analogy with molecules of the type

(X, Y, Z = S, N)

the S—C—NH fragment is considered as planar (21).

S

We noted that the TH-2-TH ring singularity lies in the absence of any transannular interaction (1). The minimization of angle and Pitzer strains controls the ring conformation with equilibrium

a1 ⇋ **a2** ⇋ **a3**

being shifted to the right.

We are going to examine successively the conformational effects related to the introduction of heavier substituent on C4 and C5.

Introducing a 4-methyl group involves CH_3/C5H and CH_3/NH van der Waals interactions. To minimize them, the C4 atom moves off the thiocarbonyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

For personal use only.

plane, increasing the proportion of **a3** with a preferential axial substituent (Fig. 2). The steric origin of this last conformational change is corroborated in that it is accentuated by the presence of a *N*-methyl group (ref. 31, p. 124). Part of the effect could also lie in an attractive nonbonded interaction between the methyl carbon and the ring sulfur (23).

Introducing successive methyl groups on the *C*—C4 atom leads to a simultaneous introduction of other van der Waals interactions ($CH_3/C5H_2$ and CH_3/N), inducing the recorded modification (Table 8) in the conformational properties. Such changes are connected with the presence of a methyl group *gauche* to nitrogen. For the 4-ethyl substituent, we have seen that the methyl group lies preferentially *anti* to N; now the $CH_3/C5H_2$ interaction seems to be weak; so that 4-ethyl-TH-2-TH **1***c* has conformational properties comparable to that of the methyl derivative **1***b* (Fig. 3).

In 4-isopropyl-TH-2-TH **1***d*, the presence of a methyl group *gauche* to N results in a CH_3/N *gauche* interaction (Fig. 3) which is reduced in an equatorial substituent orientation. However, such an orientation corresponds to a maximum N—H/CH_3 *vicinal* interaction (Fig. 2), opening the H—N—C4—R4 dihedral angle, by forcing C4 back into the thiocarbonyl plane it results in a shift of equilibrium [*a*] to the left with an increasing proportion of **a2** (C4C5 out-of-plane half-chair form) and equilibrium [*b*] towards **b2** (pseudo-equatorial 4-R). The presence of an additional methyl group on the *C*—C4 atom in 4-*tert*-isobutyl-TH-2-TH (**1***e*), increases the former trends.

The 5-methyl group in 5-methyl-TH-2-TH **2***b* induces the C5 atom to leave the ring plane (24) due to an increase in C5—Me/C4—H Pitzer strain. This is necessarily accompanied by the re-entry of the C4 atom into the thiocarbonyl plane and an increase of the population of the half-chair **a2** form (displacement of the equilibrium [*a*] towards the left). Since the Pitzer interactions about a sulfur atom are weak, and in the absence of transannular interactions, no particular methyl orientation is preferred ($x = 50\%$).

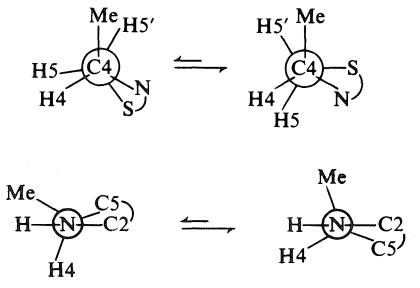

FIG. 2. *Vicinal* interactions in 4-methylthiazolidine **1***b*.

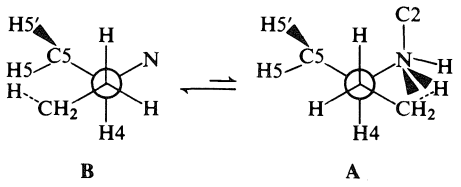

FIG. 3. Rotamers **B** and **A** for a pseudo-axial ethyl orientation in 5-ethylthiazolidine-2-thione **1***c*.

On introducing successive methyl groups on *C*—C5 (R5 = Et, *i*Pr, *t*Bu), there is a simultaneous setting up of van der Waals interactions, which explains the observed conformational changes (Table 9). These interactions are particularly important when a methyl group is *gauche* to C4. For the 5-ethyl derivative **2***c*, there is no such interaction in the preferred rotamer and the substituent orientation and ring geometry are comparable to those adopted by the 5-Me-Th-2-TH (**2***b*). By contrast with the 5-isopropyl derivative, **2***d*, one of the methyl groups is *gauche* to C4. The $CH_3/C4H_2$ interaction is minimized in an equatorial substituent orientation, which promotes a diminution in x without inducing a large change in ring geometry. In the 5-*t*Bu derivative **2***e*, two methyl groups are *gauche* to C4 (Fig. 4). The $CH_3(a)$/C4H′4 interaction forces the substituent to adopt an equatorial position which simultaneously gives rise to a $CH_3(b)$/C4H′4 repulsion. The latter is minimized by C4 going out of the thiocarbonyl plane: displacement of equilibrium [*a*] to the right.

Part B. 4-Hydroxy-thiazolidine-2-thione

The application of the method of ratios suggests (Table 3) a TH-2-TH ring modification by introducing an hydroxyl group on C4 (increase φ_{calcd}). The value of x for 4-hydroxy-TH-2-TH **1***f* is the same at ambient temperature and at −60°C (88–90%). Therefore, at ambient temperature **1***f* exists in a nearly totally biased equilibrium (x is underestimated as in the case of **1***b*).

The replacement of a methyl by an hydroxyl group exerts a negative effect on $^2J_{55'}{}^{exp}$ ($\Delta^2J_{55'}{}^{exp} = -1.56$ Hz). Such an effect is, however, reversed in the acyclic series (i.e. a positive effect ca. +2 Hz (24)). This behaviour is related to what has been observed

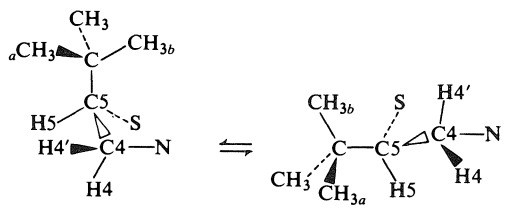

FIG. 4. Equilibrium [*b*] in 5-tertiobutylthiazolidine-2-thione **2***e*.

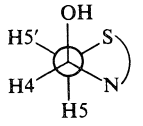
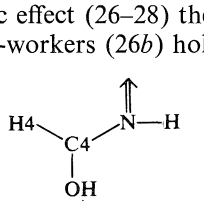


(25) in pyranose rings which exists in the forms **p1** and **p2**.



p1 **p2**

In agreement with the LCAO treatment described by Pople and Bothner-By (14*a*), the CH_2 protons occupying the *trans–gauche* position to an electronegative substituent as in **p1** have a smaller J_{gem} value (therefore a greater absolute value) than the *gauche–gauche* arrangement in **p2**.

Therefore the notable decrease in J_{gem}^{exp}, when a methyl group is replaced by an hydroxyl at C4 in TH-2-TH, is compatible with an orientation of **p1** type; thus the hydroxyl group occupies a pseudo-axial orientation.

Such an orientation of an electronegative atom bearing lone pairs is encountered in many heterocycles where the phenomenon is referred to as the anomeric effect (26). Among various factors invoked to account for the anomeric effect (26–28) the interpretation of Havinga and co-workers (26*b*) holds the attention:

the non-bonding N electrons (*p* orbital of a sp^2 atom) are delocalized into the conveniently oriented C4—O antibonding σ orbital. This satisfactorily explains the preferred pseudo-axial orientation of the C4—OH bond. The overlapping is thus maximum in a C4 out-of-plane envelope.

Experimental

Obtention of the Substituted Thiazolidine-2-thiones

The alkyl-TH-2-TH **1***a*, **1***b*, **1***c*, **2***b*, **2***c*, **2***d*, and **2***e* were obtained by reacting an aminoalkyl hydrogenosulfate with CS_2 in presence of NaOH (29, 30). The **1***d* and **1***e* compounds result from the action of CS_2 on appropriate aziridines (22, 29).

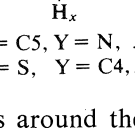
The 4-hydroxy-TH-2-TH **1***f* was obtained by the reaction of bromacetaldehyde with ammonium dithiocarbamate (15, 29).

(a) ^1H Nuclear Magnetic Resonance

The 60 MHz spectra were recorded on Varian A60 and HA100 Spectrometers. Approximatively 0.1 *M* solutions in acetone-d_6 were used with TMS as internal reference. The ^1H nmr spectra of the 5-alkyl-TH-2-TH (**2**) were considered to originate from ABC, ABCX, $ABCX_2$, $ABCX_3$ spin systems, while the 4-alkyl-TH-2-TH (**1**) one originates from ABX, ABXY, $ABXY_2$, and $ABXY_3$ spin systems. The methods of analysis has been reviewed (ref. 31, Annexe III, p. 69). The spectral parameters are given in Table 1.

(b) ^{13}C Nuclear Magnetic Resonance

The ^{13}C nmr spectra were recorded from natural abundance signals at a frequency of 25.16 MHz on a Fourier Transform Varian XL100/15 spectrometer. Solutions (1 *M* or 2 *M*) were used in chloroform-*d* which also served as internal reference. The spectral parameters are listed in Table 2.



Spectra Interpretation

^1H Nuclear Magnetic Resonance — ^5J values in the Ethanic Fragment: an Application of the Karplus Equation to Calculate the C4C5 Torsional Angles and Conformer Populations

The two classical methods of conformational analysis (ratios and differences) based on Karplus equation have been compared (2*k*) using *cis* and *trans vicinal* coupling constants of the C4C5 fragment. We chose, as did Elguero and Fruchier (2*j*), the ratio method, which gave the most coherent results for the variously substituted TH-2-TH; these results are listed in Table 3. The values of J_φ, $J_{120°-\varphi}$, $J_{120°+\varphi}$, ΔJ_φ, $R(J_\varphi)$, ΔJ_K, and $R(J_K)$ for values of φ_{calcd} between 0° and 360° were kindly provided by Elguero.

Spatial Orientation of the Substituent. Calculations

(i) Methyl Derivatives **1**b *and* **2**b

1*b*: X = C5, Y = N, $x = 4$
2*b*: X = S, Y = C4, $x = 5$

The three rotamers around the C—H_x bond are energetically equivalent; if we suppose only one *gauche J* value, we can write (1):

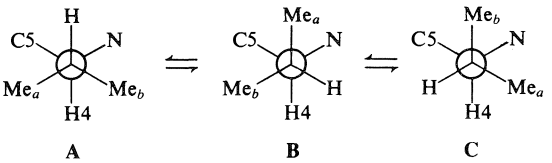
[3] $J_{HH_x} = \frac{1}{3}(2J_{gauche} + J_{anti})$

Applying the simplified Karplus relationship (20)

[4] $J_\varphi = A^0 \cos^2 \varphi$

and supposing that $\varphi_{gauche} = 60°$ and $\varphi_{anti} = 180°$, we obtain

$$J_{gauche} = (A^0/4) \quad \text{and} \quad J_{anti} = A^0$$



Therefore by applying [3] to the experimental value we obtain:

$$A^0_{(1b)} = 12.7 \text{ Hz} \quad \text{and} \quad A^0_{(2b)} = 12.76 \text{ Hz}$$

(ii) 4-Isopropyl-TH-2-TH **1**d

The **A**, **B**, and **C** conformations being not energetically equivalent, the corresponding populations

For personal use only.

A B C

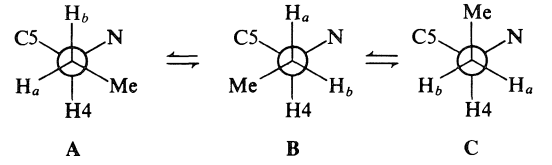
P_A, P_B, and P_C are such that

[5] $J_{HH4} = P_A J_A + (P_B + P_C)J_{gauche}$

We equate J_{HH4} with J_{exp} value to obtain

$J_{HH4} = 6.4$ Hz (Table 1)

It follows



$P_A = 0.34$ and $(P_C + P_B) = 0.66$

In the absence of a third equation for resolving the system, a consideration of the ^{13}C nmr data (Table 4) is helpful. The successive introduction of methyl groups on the *C*—C4 atom of **1***b* induces γ5-, γ′5-, and γ″5-effects, respectively (Table 4). The weakest γ″5-effect is associated to the introduction of a methyl *anti* to C5. This implies that conformation **B** is favoured. Therefore

$P_B > (P_A = 0.34) > P_C$

(iii) 4-Ethyl-TH-2-TH **1**c

By analogy with the preceding paragraph we

A B C

write:

[6] $J_{H_aH4} = (P_A + P_C)J_{gauche} + P_B J_{anti}$

[7] $J_{H_bH4} = (P_B + P_C)J_{gauche} + P_A J_{anti}$

We identify these average values with the experimental values. There are two possibilities. The first estimation

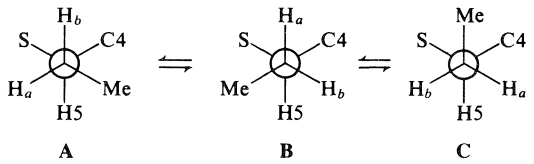
[I] $J_{H_aH4} = 5.97$ Hz and $J_{H_bH4} = 7.1$ Hz

leads to the following result

[I′] $P_C = P_B = 0.29$, $P_A = 0.41$

The second estimation

[II] $J_{H_aH4} = 7.1$ Hz and $J_{H_bH4} = 5.97$ Hz



gives

$P_A = P_C = 0.29$, $P_B = 0.41$

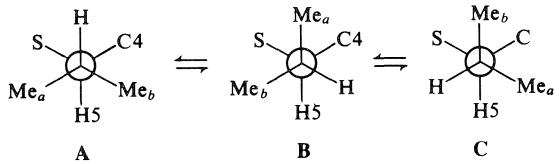
The two methyl groups in **1***d* being *gauche* to C5 in the preferential conformation, the ethyl substituent must adopt a conformation presenting a methyl *gauche* to C5. **C** is sterically disfavoured; then **B** is the preferred arrangement. This corresponds to hypothesis [II]; the H_a and H_b chemical shifts (Table 1) confirm this choice, since in conformation **B**, H_a, *gauche* to both C5 and N, is more shielded than H_b *gauche* to N but *anti* to C5.

(iv) 5-Ethylthiazolidine-2-thione **2**c

By analogy with the 4-ethyl-TH-2-TH (**1***c*) case, the two experimental values ($J_1^{exp} = 7.5$ Hz and

A B C

$J_2^{exp} = 6.4$ Hz) lead to two solutions for the set of population:



[i] $P_A = 0.33$; $P_B = 0.45$; $P_C = 0.22$

[ii] $P_A = 0.45$; $P_B = 0.33$; $P_C = 0.22$

Inspection of the ^{13}C nmr γ-effects (Table 4) helps for the choice of the correct solution. Let the γ4-, γ′4-, and γ″4-effects be experienced by the $^{13}C4$ chemical shift on introducing successive methyl groups on the *C*-C4 atom. The smallest γ4-effect must be assigned to the methyl group situated *anti* to C4. Therefore in **2***c*, the preferential rotamer has its methyl group *anti* to C4, i.e. rotamer **B** is favoured (solution *i*). This result is corroborated by ^1H nmr: proton H_a is more shielded ($\delta_{H_a} = 1.74$ ppm) than H_b ($\delta_{H_b} = 1.84$ ppm).

(v) 5-Isopropyl-TH-2-TH **2**d

The only values that can be evaluated are: $P_A = 0.40$ and $P_B + P_C = 0.60$. In **2***c* the methyl

A B C

group is preferentially *anti* to C4. Similarly in **2***d*, one of the methyl group must be *anti* to C4 (**C** is eliminated) while the other one must be *gauche* to C4 (γ′4 = −2.53 ppm). In our evaluation, we have seen that groups *gauche* to both endocyclic bonds are particularly disfavoured. This leads us to conclude

$P_A = 0.40 > P_B > 0.30 > P_C$

Synthesis and carbon-13 nuclear magnetic resonance spectra of monoethyl 4-nitro and 4-amino phthalates

KALKUNTE S. SESHADRI AND JOHN D. BACHA

Gulf Research & Development Company, P.O. Box 2038, Pittsburgh, PA 15230, U.S.A.

Received March 23, 1979[1]

KALKUNTE S. SESHADRI and JOHN D. BACHA. Can. J. Chem. **58**, 617 (1980).

Carbon-13 nmr has been found to be an effective spectroscopic method for measuring the ratio of isomeric monoethyl esters resulting from the esterification of 4-nitrophthalic acid, the alcoholysis of 4-nitrophthalic anhydride, and the catalytic reduction of monoethyl 4-nitrophthalates. Precise values of the ^{13}C chemical shifts for 1-ethyl and 2-ethyl 4-nitrophthalate and the corresponding 4-aminophthalates were determined; the shielding parameters are explained in terms of known structural effects. Details of the esterification, alcoholysis, reduction reactions, and the isolation of 1-ethyl 4-nitrophthalate are described.

KALKUNTE S. SESHADRI et JOHN D. BACHA. Can. J. Chem. **58**, 617 (1980).

On a trouvé que la spectroscopie de la rmn du ^{13}C est une méthode efficace de mesure du rapport des isomères des esters monoéthyliques provenant de l'estérification de l'acide nitro-4 phtalique, de l'alcoolyse de l'anhydride nitro-4 phtalique et de la réduction catalytique des nitro-4 phtalates d'éthyle. On a déterminé les valeurs exactes des déplacements chimiques du ^{13}C pour les nitro-4 phtalates d'éthyle-1 et d'éthyle-2 et les amino-4 phtalates correspondants. On explique les paramètres de blindage en fonction d'effets structuraux connus. On décrit en détail l'estérification, l'alcoolyse, les réactions de réduction et la séparation du nitro-4 phtalate d'éthyle.

[Traduit par le journal]

Introduction

Polyimide resins, for industrial high-temperature applications, are usually prepared by copolymerization of aromatic acid anhydrides or their monoalkyl esters and aromatic diamines. Thermally stable polyimides can also be prepared by homopolymerization of suitable multi-functional monomers, e.g., monoethyl 4-aminophthalates.

Monoethyl 4-aminophthalates can exist in two isomeric forms which are obtained by the catalytic reduction of the corresponding 4-nitrophthalates. The monoethyl 4-nitrophthalates are prepared by treating 4-nitrophthalic acid or its anhydride with excess ethanol. In both of these reactions, one of the monoesters might be formed at the exclusion of the other or a mixture of both isomers could be formed. ^{13}C nmr spectroscopy was selected as an analytical tool to determine the structure and the distribution of the products formed. This report describes the following: (*1*) the synthesis of 4-nitrophthalic anhydride (4NPAN) from 4-nitrophthalic acid (4NPAC), (*2*) esterification of 4NPAC, (*3*) alcoholysis of 4NPAN, (*4*) isolation of 1-ethyl 4-nitrophthalate, (*5*) the catalytic hydrogenation of monoethyl 4-nitrophthalates, and (*6*) the ^{13}C spectra of model compounds and reaction products.

Results and Discussion

The compounds pertinent to this work and their carbon-13 shielding data are presented in Fig. 1 and Table 1, respectively. The assignment of resonance positions in the carbon-13 spectra depends on several factors: (*1*) observation of proton-induced splitting patterns in the off-resonance decoupling experiments, (*2*) reduced nuclear Overhauser enhancement for quaternary centers, (*3*) available data on model compounds, and (*4*) empirical schemes for predicting the ^{13}C chemical shifts for a proposed structure.

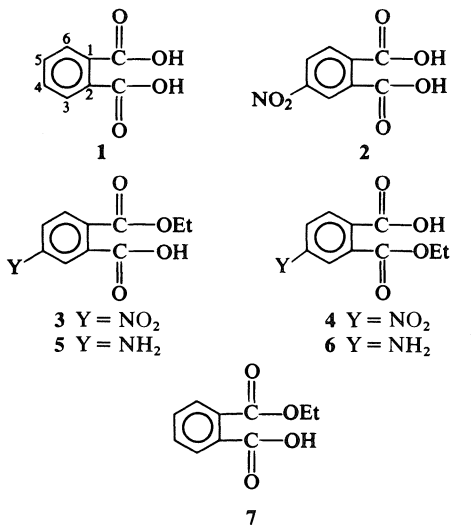

FIG. 1. Identification of compounds whose ^{13}C shieldings are given in Table 1.

The spectra of the esterification and the reduction reaction product mixtures are complex with closely spaced resonance positions. The fortuitous

*Spectra of all samples were obtained in acetone – acetone-d_6 solution.

isolation of 1-ethyl 4-nitrophthalate, its complete reduction to the amino derivative, and the spectra of the nitro and the amino derivatives, however, greatly aided the spectral analysis.

The spectrum of **2** can be readily interpreted. Since the effect of the nitro group on the shielding of aromatic ring carbons is known (1), ring carbon shifts for **2** could be calculated from the data for phthalic acid. The calculated values are in good agreement with the experimental results. The doublet at the lowest field in the spectrum is assigned to the two carbonyl carbons.

Published chemical shift data for carbonyl compounds that are pertinent to the present work are the results on acetophenones (2), in which the shielding of carbonyl carbon is practically insensitive to the substituents in the *para* and *meta* positions. In general, our results concur with this observation. In the present case, however, the shielding of carbonyl carbons is shifted more, due to the nitro group, than in the *para* and the *meta* nitroacetophenones.

The assignments of a particular shielding to a specific ring nucleus in **3** is straightforward by comparison with 4NPAC. However, an interesting aspect of the spectrum is the near equality of the shieldings of carbonyl carbons in the acid and the ester function in acetone. This equality is probably due to the solute–solvent interactions. Normally, the shieldings of ester and acid carbonyl carbons are separated by about 7 ppm (3, 4). To understand this feature, we prepared (5) and examined the spectrum of monoethyl phthalate. This ethyl phthalate is soluble both in chloroform and acetone, whereas the nitro derivative is sparingly soluble in $CHCl_3$.

The carbon-13 spectrum of monoethyl phthalate in $CDCl_3$ has been reported (6) and the chemical shifts for the acid and the ester carbonyl carbons are 172.3 and 168.2 ppm, respectively. This is in agreement with our results. In acetone, the shielding of the acid carbonyl carbon is shifted upfield to 169.3 ppm; however, the carbonyl carbon of the ester group is practically unchanged. The shielding of the carbonyl carbon of an acid is shifted upfield as it is diluted in an aprotic or protic solvent. This is due to the disruption of the dimeric species of the acid by the rupture of hydrogen bonds. The upfield shift is substantial in an aprotic solvent and marginal in a protic solvent since, in the latter medium, the ruptured hydrogen bonds are replaced by weaker hydrogen bonds via interaction with the solvent molecules (7). Based on this analysis, it is expected that the shielding of the acid carbonyl carbon of ethyl nitrophthalate in acetone will be at a higher field than in hydrogen bonded acids. Therefore, the resonances of the acid and the ester carbonyl carbons are close to each other. The elimination of hydrogen bonding, in addition to the shielding effect, narrows the resonance absorption. Therefore, specific assignment of chemical shifts to individual carbonyl carbons has not been possible.

The partial ^{13}C spectrum of the reaction products of esterification of 4NPAC is shown in Fig. 2. The spectrum has extraneous peaks due to unconverted 4NPAC which are disregarded. The remaining spectrum suggests that the reaction product is a mixture of two structurally similar ethyl esters. Due to the strategic location of the nitro group, it is expected that the esterification should result in the two isomeric half-esters (8). This is substantiated by the ^{13}C spectrum. As a first step in the analysis of the spectrum, protonated ring carbon resonances of equal intensity were grouped together. By comparison with the spectrum of **3**, one group (peaks at 125.0, 127.1, and 130.7 ppm) is due to the presence of the 1-ethyl isomer. It is natural to expect that the other group (peaks at 124.4, 126.6, and 131.2) is due to the presence of the 2-ethyl isomer. The diester is a possibility. However, the sum of the integrated intensity of a peak from each group is equal to the integrated intensity of the methylene resonance at

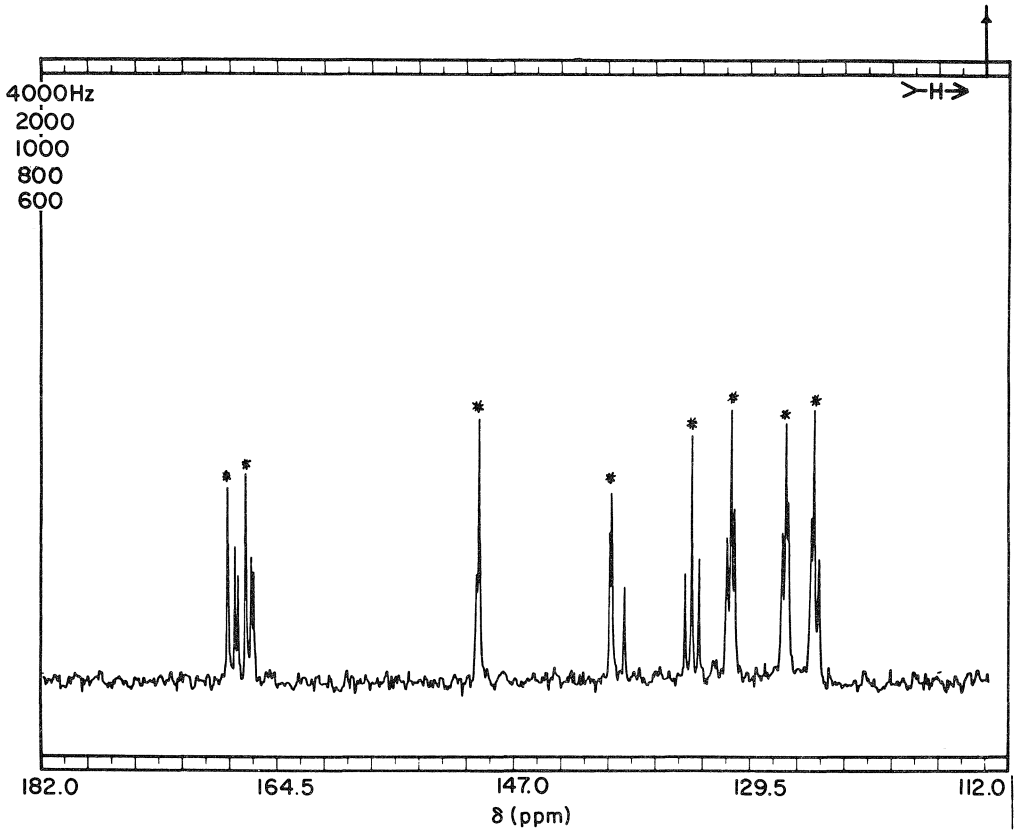

FIG. 2. Proton decoupled ^{13}C spectrum of reaction products of 4NPAC with EtOH. Asterisks indicate absorptions due to the unconverted 4NPAC.

62.7 ppm. Therefore, the reaction product is a mixture of 1-ethyl and 2-ethyl isomers. Their relative concentration is given in Table 2 (entry 2). The shielding of ring carbons in the two isomers differs enough to give well separated peaks, whereas the shielding of the methyl and methylene carbons are identical.

Regarding the quantification of results, all the spectra in this study were obtained with a tip angle of 42°, acquisition time of 1.024 s, and a pulse delay of 10 s. These conditions are adequate for quantitative analysis (9), provided the resonances due to the quaternary centers are neglected. The accuracy of intensity measurement is ±5.0%, with a precision within 1%.

TABLE 2. Percent composition of isomers

Method*	1-Ethyl isomer	2-Ethyl isomer
1	61.5	38.5
2	56.3	43.7
3	55.0	45.0
4	50.0	50.0
5	57.8	42.2

*(1) Alcoholysis of 4-nitrophthalic anhydride (reflux method), (2) esterification of 4-nitrophthalic acid, (3) alcoholysis of 4-nitrophthalic anhydride (room temperature method), (4) Pd/C catalyzed reduction of monoethyl 4-nitrophthalates, (5) Pt_2O catalyzed reduction of monoethyl 4-nitrophthalates.

The alcoholysis of 4NPAN at room temperature and at the boiling point of ethyl alcohol also results in a mixture of half-esters with a slight variation in the product distribution (cf. Table 2, entries 3 and 1).

The catalytic reduction of 4-nitrophthalic anhydride in ethanol could eventually result in the two isomers of monoethyl 4-aminophthalates. The carbon spectrum supports this thesis. The partial spectrum, with Pd/C as the catalyst, is shown in Fig. 3.

Three regions of the spectrum are relevant to the discussion. The resonances around 61 and 14 ppm prove that the esterification has taken place, while the absence of resonance absorptions between 124–127 ppm and the appearance of new signals at a higher field, 113–118 ppm, establishes that the reduction is complete. The reduction of a nitro group to an amino group results in the upfield shift of the three ring carbons, *ortho* and *para* to the amino group.

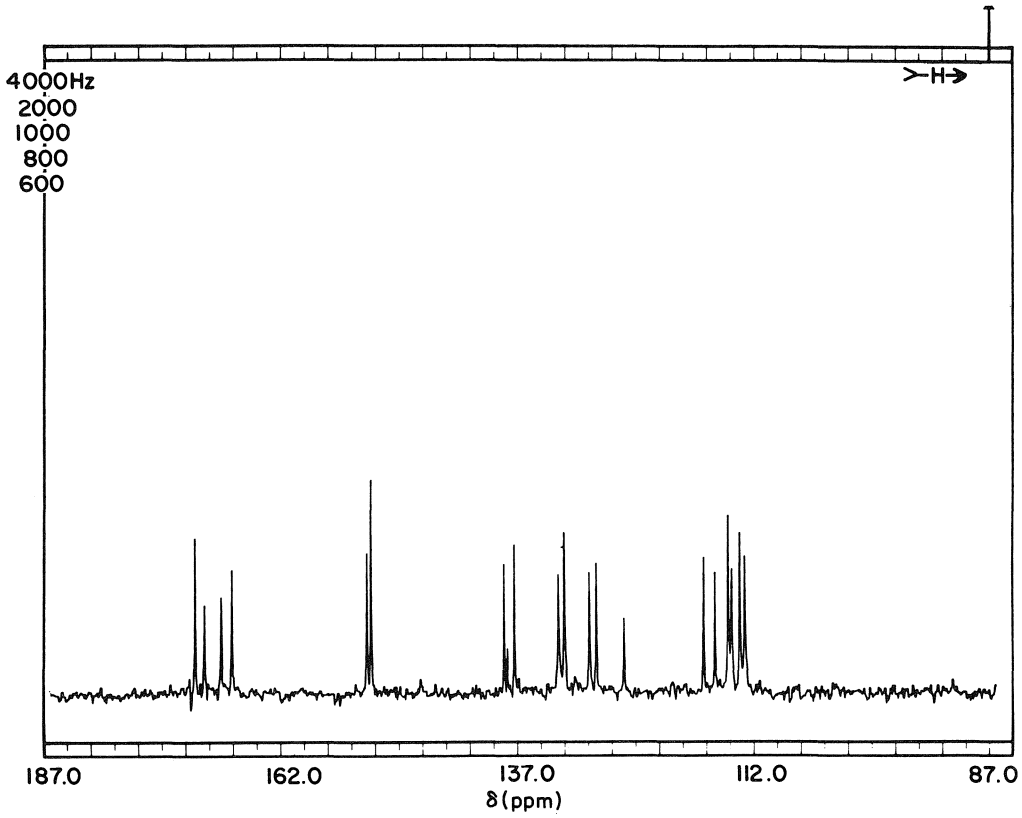

FIG. 3. Proton decoupled ^{13}C spectrum of products from reduction reaction: hydrogen reduction (Pd/C catalyst) of 4NPAN in EtOH.

The spectrum has ten pairs of closely spaced peaks, suggesting that the reaction product is a mixture of two similar compounds. The pair around 61 ppm is due to the methylene carbons. The pair at 132.3 and 132.9 ppm is due to a protonated ring carbon from each structure in the mixture. As before, the sum of the intensities of the pair at 61 ppm is equal to that of the pair around 132 ppm, proving that the two isomers of the half-esters are the products of reduction reaction. Here they are formed in equal amounts (Table 2, entry 4). Pt_2O also catalyses this reaction to give identical products. However, the isomers are formed in a different ratio (Table 2, entry 5).

To assign resonance positions in the spectrum of the reduction reaction product to individual isomers of the aminophthalate, we obtained the 1-ethyl isomer from 1-ethyl 4-nitrophthalate. The reduction of the nitro group to the amino group was accomplished by a process known as *catalytic transfer hydrogenation*, instead of by the conventional method in which hydrogen gas and a metal catalyst are used. Many commonly encountered functional groups, including the nitro group, can be reduced with cyclohexene as the hydrogen donor and Pd/C as the catalyst (10).[2] The spectrum of **5**, thus prepared, was obtained with the same instrumental parameters as the other spectra in this study. It has resonance positions in the expected positions and no extraneous signals are observed. Also, the signals due to the protonated ring carbons, the methylene, and the methyl carbons are of equal intensity. These observations clearly prove that the reduction has proceeded to completion without any side reactions. Since the shielding data are now available for **5**, the data for **6** were obtained from the spectrum of the reduction product mixture.

The unusual shieldings of C-1 and of carbonyl carbons in **5** and **6** prompt the following comments. The electron donating group shields the *para* carbon nuclei in an aromatic structure and the extent of the upfield shift varies with the *para* substituent. For example, in aniline (1), *p*-toluidine (11) and methyl *p*-dimethylaminobenzoate (12), the shifts in

[2]The catalytic transfer hydrogenation procedure described in the literature has been modified by Dr. D. M. Jewell of our laboratory and has been tested using several nitro compounds with complete success. We are extremely grateful to Dr. Jewell for preparing for us the amino isomer from the nitro isomer.

the shielding of *para* carbon by the NH_2 group are −10.3, −9.5, and −13.6, respectively. In **5** and **6** compared to **7** the shifts are −16.4 and −17.5, respectively. The larger shifts observed may be due to the electronic interaction of the carbonyl group bound to C-1 with the lone pair of electrons of the *para* NH_2. Such interaction is supported by the significant differences in the shielding of the two carbonyl carbons in **5** or **6** when compared with **3** or **4**.

Experimental

Isolation of 1-Ethyl Hydrogen 4-Nitrophthalate

Five grams of the mixture of isomeric monoethyl 4-nitrophthalates (mp 95–105°C), prepared from 4-nitrophthalic anhydride at room temperature, and water (100 mL), were heated with stirring in a 50°C water bath for 1 h. The resulting mixture was vacuum filtered without cooling to separate 3.45 g of insoluble material, mp 104–109°C (after vacuum oven drying at 50°C). Upon cooling to room temperature over 1 h, the filtrate yielded fine, needlelike crystals which were separated and dried. The melting point of the isolated crystals (0.3 g, 126–129°C) was in good agreement with the literature value (8) (127–128°C) for 1-ethyl 4-nitrophthalate. After standing for several days at room temperature, the filtrate yielded a second crop of less well-formed crystals which were separated and dried (0.4 g, mp 104–125°C). The 2-ethyl isomer has a melting point of 137°C (8), which further substantiates that this procedure isolates the 1-ethyl isomer.

Synthesis of 4-Nitrophthalic Anhydride

This compound was prepared from 4-nitrophthalic acid (Eastman Kodak Co., No. 3112) via azeotropic dehydration (13). The quality of the product, a very pale yellow powder, mp 118–119°C (lit. (14) mp 117–119°C), was established by titration with 0.10 *N* aqueous NaOH.

Esterification of 4-Nitrophthalic Acid

4-Nitrophthalic acid (21.1 g, 0.1 mol) and anhydrous ethanol were refluxed with stirring under nitrogen for 30 h. The solvent was then removed on a Rotavap and the solid yellow residue (22.7 g) dissolved in 10% aqueous sodium carbonate (100 mL). This solution was extracted with diethyl ether and then reacidified with 3 *N* aqueous HCl. This resulted in an insoluble oil which solidified upon chilling. The solid was then separated by vacuum filtration, washed with cold water, and dried in an unheated vacuum oven, giving 21.8 g of yellow solid, mp 144–149°C.

Alcoholysis of 4-Nitrophthalic Anhydride at Reflux

4-Nitrophthalic anhydride (19.3 g, 0.1 mol) and absolute ethanol (300 mL) were refluxed with stirring under nitrogen for 24 h. After evaporation on a Rotavap, a granular yellow solid (23.9 g) resulted. The solid was slurry washed twice with 100 mL portions of hexane and thoroughly evaporated in an unheated vacuum oven, giving 23.3 g (97.5%) of monoethyl 4-nitrophthalates, a very pale yellow powder, mp 95–110°C.

Alcoholysis of 4-Nitrophthalic Anhydride at Room Temperature

4-Nitrophthalic anhydride (19.3 g, 0.1 mol) was dissolved in absolute ethanol (300 mL) by stirring at room temperature for about 1 h. This solution was then evaporated on a Rotavap for several hours; the resulting crystalline residue was treated as above. This resulted in 22.8 g (95%) of monoethyl 4-nitrophthalate, mp 95–105°C. The material was characterized by titration (0.5 g sample dissolved in a mixture of water–ethanol: 100:50 mL) with 0.2 *N* aqueous NaOH (*Equiv. Wt.* calcd.: 239.2; found: 237.2).

Pd/C Catalyzed Reduction of Monoethyl 4-Nitrophthalates

4-Nitrophthalic anhydride (1.93 g, 0.1 mol) was dissolved in absolute ethanol (100 mL) in a 300 mL heavy walled glass vessel. 5% Pd/C (0.015 g) was added and hydrogen pressure (80 psig) was applied to the magnetically stirred mixture. After 0.5 h at 24–26°C, pressure had fallen to 50 psig. The system was repressured with hydrogen, and after 5 h the pressure had fallen to 70 psig. The system was again repressured and the reduction allowed to run overnight. During the 18 h period, an additional 8 psig of hydrogen was absorbed. The catalyst was separated by vacuum filtration, and the product solution stripped of solvent on a Rotavap. Ethanol was completely removed by slurrying the residue twice with toluene and reevaporating and then holding the final residue overnight in an unheated vacuum oven under a slight nitrogen stream. This resulted in 1.8 g (86% yield) of monoethyl 4-aminophthalates (yellow powder), mp 114–123°C.

PtO_2 Catalyzed Reduction of Monoethyl 4-Nitrophthalates

4-Nitrophthalic anhydride (2.42 g, 0.0125 mol) was dissolved in absolute ethanol (100 mL) in a 300 mL heavy walled glass vessel. Platinum oxide (0.2 g) was added and a hydrogen pressure (60 psig) applied to the magnetically stirred mixture. Hydrogen absorption was rapid. The temperature rose from 27 to 40°C despite air cooling of the reaction vessel. After about 3 min, pressure stabilized at 41 psig. The system was repressured with hydrogen. After about 4 h at 26°C, only 6 psig of additional hydrogen was absorbed.

The product mixture was worked up as in the previous example. This resulted in 2.3 g (88% yield) of monoethyl 4-aminophthalates (yellow powder), mp 107–120°C.

Spectra

Carbon-13 nuclear magnetic resonance spectra, were obtained by the pulsed Fourier transform technique at 20.0 MHz on a Varian CFT-20 spectrometer.

Samples were studied in acetone – acetone-d_6 solutions containing a few drops of TMS and all chemical shifts are expressed in ppm downfield from TMS.

Photoelectron spectra of substituted acetophenones. Correlations with reactivity

E. J. McAlduff

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received September 6, 1979

E. J. McAlduff. Can. J. Chem. **58**, 622 (1980).

Ultraviolet photoelectron spectra of 4-R-acetophenones (R = $N(CH_3)_2$, *t*-Bu, Cl) have been determined and the three lowest ionization potentials assigned. Combination of these data with literature data on other 4-R-acetophenone allows correlations of n_O IP with redox potentials, nmr chemical shifts of acetyl protons, and chemical reactivity data. Both Ph_S and n_O IP's correlate with Hammett σ_P constants of the substituent and Ph_S IP's are found to be linearly related to the first IP's of the analogous monosubstituted benzenes.

E. J. McAlduff. Can. J. Chem. **58**, 622 (1980).

On a déterminé les spectres photoélectroniques ultraviolets de R-4 acétophénones (R = $N(CH_3)_2$, *t*-Bu, Cl) et on a attribué les trois potentiels d'ionisation les plus faibles. Ces données combinées à celles de la littérature relatives à d'autres R-4 acétophénones permettent des corrélations de n_OPI avec les potentiels rédox, les déplacements chimiques en rmn des protons du groupe acétyle et avec les données de réactivité chimique. Il existe une corrélation entre les Ph_S ainsi que les PI_s avec les constantes σ_P de Hammett des substituants et on a trouvé qu'il existe une relation linéaire entre les Ph_S ainsi que les premiers PI's des benzènes monosubstitués analogues.

[Traduit par le journal]

Introduction

Ultraviolet photoelectron spectroscopy provides a method of monitoring the effects of substituents on valence orbital ionization potentials. One of the main empirical approaches to the problem of the effects of substituents on reactivity has been the use of linear free energy correlations. Since substituted benzene systems are prime examples of cases where linear free energy relationships are demonstrated, the photoelectron spectra of substituted benzenes have been extensively studied (1–8). The first ionization energy might be expected to correlate directly with reactivity when electron transfer is involved. Thus satisfactory correlations have been obtained using polarographic oxidation potentials and optical charge transfer absorption bands (9). Correlations have also been observed between rate and ionization potential for H–D exchange in hydrocarbons catalysed by Pt(π) chloro complexes (10).

The photochemical, electrochemical, and chemical reactivity of acetophenones has been thoroughly investigated. Consequently this class of disubstituted benzenes should be a fruitful area for correlations of PES data with chemical reactivity. The three highest occupied molecular orbitals of acetophenone are designated n_O, Ph_S, and Ph_A. n_O is the non-bonding oxygen lone pair orbital. Ph_S is the component of the doubly degnerate e_{1g} of benzene which has maximum electron density at the position of substitution and *para* to it. This orbital is the one whose IP should be most influenced by *para* substituents. The Ph_A orbital is the component of e_{1g} which has a node at the position of substitution and *para* to it and high electron density at the *ortho* and *meta* positions. In theory it should be possible to distinguish between acetophenone reactions occurring at the carbonyl oxygen and those occurring at the phenyl ring in that the former rates should correlate better with n_O IP and the latter with phenyl-type IP's.

The PE spectra of a wide variety of substituted acetophenones have been previously published (3–5). In this investigation the PE spectra of 4-dimethylamino-, 4-*t*-butyl, and 4-chloro acetophenone have been determined in order to complete the series of acetophenones and to make more extensive correlations possible.

Results and Discussion

The PE spectra are shown in Fig. 1 and the vertical IP's and assignments are listed in Table 1.

Electron releasing substituents interact conjugatively with the phenyl e_{1g} orbital via a high lying lone pair orbital to produce an antibonding combination (Ph_S) which is shifted to lower IP and a stabilized level (Ph) which results from the bonding combination of phenyl and lone pair orbital. Generally this Ph level is of sufficiently high IP that it is obscured by the σ bands. When a strong electron releasing group is substituted on benzene as in *N*,*N*-dimethylaniline, the lone pair is sufficiently high lying that the Ph level is well separated from the σ bands. The Ph level is also raised by interaction with a lower lying phenyl orbital (11.5 eV in benzene) and as a consequence the destabilization of Ph_S is not matched by the stabilization of Ph. Thus in *N*,*N*-dimethylaniline the Ph_S and Ph IP's

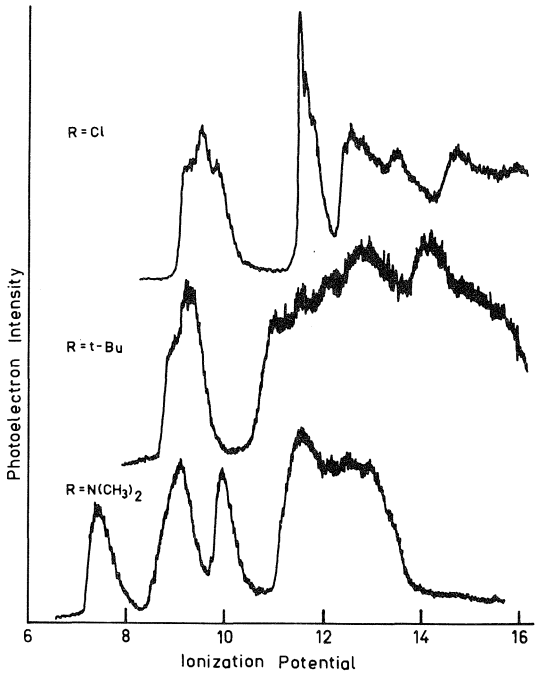

FIG. 1. Photoelectron spectra of 4-R-acetophenones.

TABLE 1. Substituted acetophenone IP's in eV (±0.05) and assignments

	Ph_S	Ph_A	n_O	Other
4-$N(Me)_2$	7.57	9.13	8.85	9.99 Ph
4-*t*-Bu	9.01	9.51	9.25	
4-Cl	9.60	9.90	9.38	11.52 *n*Cl

are located at 7.37 and 9.80 eV respectively (3). An analogous result is observed for 4-$N(Me)_2$-acetophenone in that Ph_S is observed at 7.57 eV and Ph at 9.99 eV which is clearly separated from the σ bands. The broad band at 9.13 eV in 4-$N(CH_3)_2$ acetophenone is assumed to contain ionizations from two levels. The main band at 9.13 eV is assigned to Ph_A which has been destabilized from 9.77 eV in acetophenone (3) whereas the shoulder at 8.85 eV is assigned to the n_O orbital which has decreased from 9.37 eV in acetophenone (3). The change in IP from acetophenone to 4-$N(Me)_2$-acetophenone of 0.64 eV for Ph_A and 0.42 eV for n_O is significantly less than that observed for Ph_S (1.98 eV).

The three bands are no longer resolved in 4-*t*-Bu-acetophenone and the result is a band at 9.25 eV with shoulders on both sides at 9.01 and 9.51 eV. The Ph IP is no longer identifiable since it is masked by the broad σ envelope which begins at 10.6 eV. The central band is assigned to ionization from the n_O orbital and the shoulders at 9.01 and 9.51 are assigned to Ph_S and Ph_A. All three IP's are about 0.1 eV lower than those observed for 4-Me acetophenone (3). This is analogous to the effect observed when the IP's of toluene (3) and *t*-butylbenzene are compared (6).

For 4-Cl acetophenone the PE spectrum shows a broad band centred at 9.60 eV with shoulders on both sides at 9.38 and 9.90 eV. If the previous order of energy levels were maintained in 4-Cl acetophenone the IP at 9.38 eV would be assigned to Ph_S and that at 9.60 eV to n_O. This assignment does not seem reasonable in that it predicts a change in n_O IP upon Cl substitution of acetophenone to be ~0.2 eV and essentially no change in Ph_S as a result of Cl substitution. In general one would expect Cl substitution on the phenyl ring to produce a larger change in Ph_S IP than in n_O. Furthermore, if this assignment is used, it predicts a destabilizing of Ph_S upon Cl substitution from 9.55 in acetophenone to 9.38 which is opposite to the Cl substituent effect observed from benzene to chlorobenzene (9.24 to 9.31 eV) (2). For these reasons a reversal in the order of energy levels is assumed for 4-Cl-acetophenone and the IP at 9.38 eV is assigned to n_O and the main band at 9.60 eV to Ph_S. This assignment is then consistent with the direction and magnitude of substituent effects anticipated if one considers 4-Cl-acetophenone to be formed either by Cl substitution of acetophenone or $COCH_3$ substitution of chlorobenzene. The IP at 9.90 eV in 4-Cl-acetophenone is assigned to Ph_A which represents a stabilization by ~0.2 eV from chlorobenzene or 0.1 eV from acetophenone.

The correlation diagram in Fig. 2 shows the three highest levels of 4-substituted acetophenones using literature data (3, 4) for those acetophenone IP's previously determined. The inversion of levels is assumed to occur at the parent acetophenone and is maintained for Cl and NO_2. If this assignment is correct, it would mean that Br and Cl produce opposite effects on the Ph_S IP of acetophenone with Br destabilizing Ph_S to 9.23 eV and Cl stabilizing Ph_S to 9.60 eV. This phenomenon is not confined to acetophenones, however, and is also present in substituted toluenes (6) where Br destabilizes the toluene IP from 8.85 to 8.71 eV and Cl stabilizes it to 8.90 eV. The correlation diagram in Fig. 2 also suggests that an error has been made in the assignment of 4-Br-acetophenone and the IP at 9.53 eV should be assigned to n_O and the one at 9.8 should be assigned to Ph_A rather than vice versa (4). This is

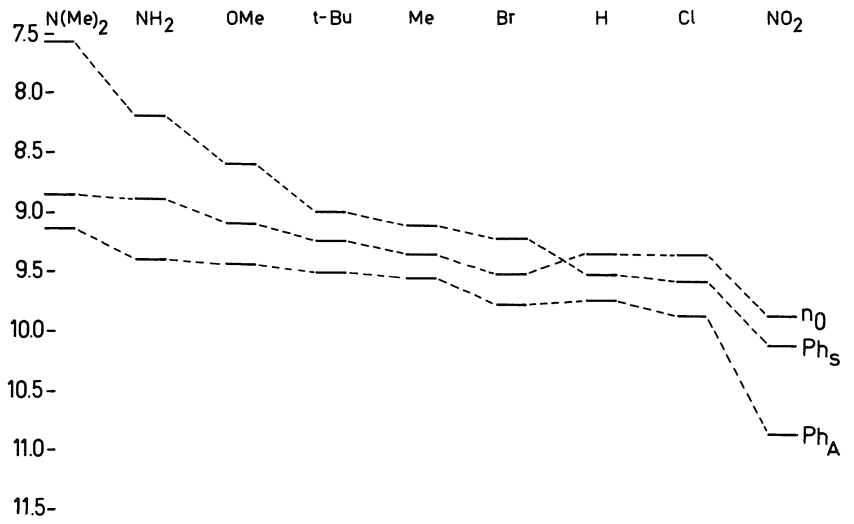

FIG. 2. Correlation diagram of three highest occupied molecular orbitals of 4-R-acetophenones. IP's for R = NH_2, OMe, Br, NO_2 from ref. 4, R = Me, H from ref. 3, R = $N(CH_3)_2$, *t*-Bu, Cl, this work.

the only change made from the literature data in Fig. 2.

Linear relationships, whose slopes are related to electron donor ability of the substituent, have been shown to exist between the first phenyl IP of disubstituted and monosubstituted benzenes (6, 7). A similar relationship, in basic agreement with that of Koenig *et al.* (11), has been shown to exist for substituted acetophenones. Least-squares analysis of this relationship results in the equation

$$IP(Ph_SX\text{-}C_6H_4\text{-}COCH_3) = -0.26 + 1.06\,IP(Ph_SX\text{-}C_6H_4)$$

with a correlation coefficient of 0.988.

Reactivity Correlations

Substituent Constants

Correlations of substituted benzene IP's with substituent constants have frequently been attempted (5, 7, 12). Figure 3 shows a correlation of Ph_S and n_O IP as a function of substituent constant σ_P. (For a comprehensive discussion of Hammett constants see Johnson (13).) σ_P contains a contribution from both inductive and resonance effects and thus should correlate with both Ph_S and n_O IP's. For both n_O and Ph_S, as the electron-withdrawing strength of the substituent increases, the IP increases. Least-squares analysis of the data in Fig. 3 yields the equations

$$Ph_S = 9.15 + 1.53\sigma_P$$

and

$$n_O = 9.36 + 0.65\sigma_P$$

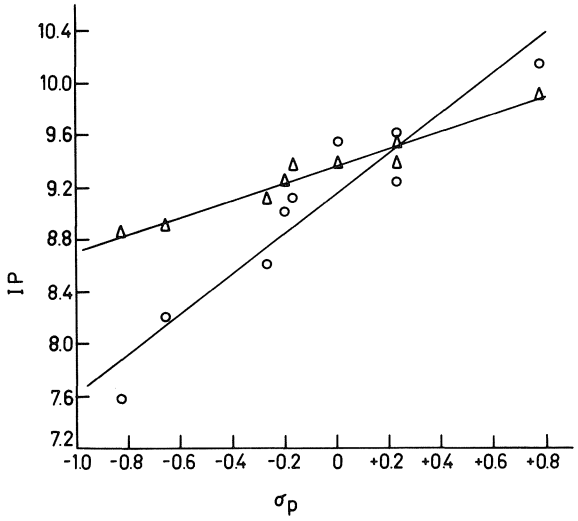

FIG. 3. IP vs. σ_P for 4-R-acetophenones ○ Ph_S, △ n_O.

with correlation coefficients of 0.95 and 0.975 respectively.

Correlations with Redox Potentials

The single configuration formulas for singlet and triplet excitation energies are given by the following equations

$$E_S = E_{HO} - E_{LU} - J_{12} + 2K_{12}$$

$$E_T = E_{HO} - E_{LU} - J_{12}$$

where E_{HO} and E_{LU} are the energies of the highest occupied and lowest vacant orbitals and J_{12} and K_{12} are Coulomb and exchange integrals (14). The lowest gas phase ionization potential gives a measure

For personal use only.

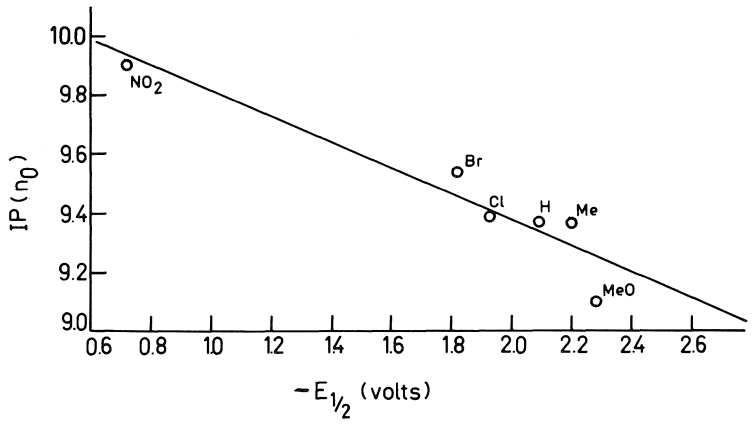

FIG. 4. IP(n_0) vs. $-E_{1/2}$ (reduction potential) for acetophenones.

of the HOMO energy whereas electron affinity data provide information on LUMO energies. In solution, polarographic half-wave reduction potentials ($E_{1/2}^{red}$) and oxidation potentials ($E_{1/2}^{oxid}$) are assumed to be linearly related to the LUMO and HOMO energies respectively. Loutfy and Loutfy (15–18) have obtained linear correlations between the $n \rightarrow \pi^*$ triplet energy and the reduction poential for a wide variety of aromatic ketones. An implicit assumption in these correlations was that the HOMO energy and the Coulomb integral, J_{12}, remained constant throughout the series. Figure 4 shows the results of a correlation between n_0 IP and the negative of the electroreduction potential (15) for a variety of acetophenones. Least-squares analysis of the results leads to the equation

$$IP(n_0) = 10.24 - 0.435(-E_{1/2})$$

with a correlation coefficient of 0.945. The result points out the fact that as the substituent changes both the n orbital energy and the π^* orbital energy, as indicated by the reduction potential, are changing. Thus the linear correlation between the $n \rightarrow \pi^*$ triplet energy and E_{LUMO} or reduction potential must result from changes in E_{HOMO} and J_{12} cancelling each other rather than from constancy in these parameters. The result also suggests that care must be exercised in correlating data from one medium or type of experiment to another since these correlations contain ambiguities which are difficult to quantify.

Chemical Reactivity

Young and Jencks have studied the reversible reaction of bisulfite with substituted acetophenones (19). In that investigation a modified Yukawa–Tsuno equation (20) was used to separate substituent effects into polar and resonance components. When the logarithms of the second order rate constant for attack of sulfite dianion on the carbonyl compound is plotted against the n_0(IP) a linear relationship is obtained for six acetophenones. Least-squares treatment of the data resulted in the equation

$$\log k = -20.96 + 2.45IP$$

with correlation coefficient of 0.96. The stronger electron-withdrawing substituents (high n_0 IP) are observed to produce a faster reaction rate with the anionic species which can be explained in terms of stabilization of the transition state by electron withdrawal.

Similar behavior is observed when one plots the logarithm of the detritiation rate constant (21) for substituted acetophenones vs. n_0(IP). Least-squares analysis of the log k vs. IP(n_0) data yields the equation

$$\log k = -17.60 + 1.64IP(n_0)$$

with a correlation coefficient of 0.95. In the interest of brevity the graphs of log k vs. IP for the rate correlations are not presented.

Correlations with Nuclear Magnetic Resonance Data

Correlations of photoelectron spectra with nmr data have been attempted previously for substituted benzamides (6). If the n_0(IP) of substituted acetophenones is plotted against the chemical shift of acetyl protons in CCl_4 (22) a linear relationship is observed. This is expected since the extent of chemical shift is proportional to the electron density in the region of the acetyl protons and the n_0(IP) is also a function of the acetyl group electron density. It is observed that substituents which act to remove electron density from the acetyl group

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

produce both a higher n_O(IP) and a larger acetyl proton chemical shift. Least-squares analysis of the correlation between n_O(IP) and chemical shift yields the equation

$$IP(n_O) = -2.45 + 4.71\delta$$

with a correlation coefficient of 0.97 for seven *para*-substituted acetophenones.

Experimental

Photoelectron spectra were determined on a Perkin-Elmer PS-18 photoelectron spectrometer with heated probe. Xenon and argon were used as internal calibrants and the resolution as measured on the 15.76 eV peak of Ar was 25–30 meV. Peak positions (band maxima) listed in Table 1 represent the average of at least five determinations. The acetophenones were commercial samples and were used without further purification.

Erratum: A reformulation of the theory of unimolecular reactions

Andrew W. Yau and Huw O. Pritchard
Centre for Research in Experimental Space Science, York University, Downsview, Ont., Canada M3J 1P3

Received January 10, 1980
(Ref: Can. J. Chem. **56**, 1389 (1978))

Five small but substantive errors in this paper have come to our attention:

(*i*) In [14], γ_i should read λ_i.

(*ii*) In eq. [26], κ_{rr} and κ_{ss} should be interchanged in the numerator.

(*iii*) In eq. [42], $\tilde{n}_j$ should read $\tilde{n}_i$.

(*iv*) In Table 2, the value of B_r for C_2H_5NC should be 33.26 cm^{-1}.

(*v*) Dr. J. M. Simmie (Galway) has found that the deposited algorithm yields slightly different answers on different computing machines: the trouble is caused by a ubiquitous mixed-mode FORTRAN operation in the 59th instruction of the program which should read NMAX(I) = 0.5E0*(1.E0/XE(I)−1.E0) + 1.E−4; adding 1×10^{-4} at this point causes all machines to give the correct answers, or subtracting 1×10^{-4} causes all machines to give the answers deposited as a test case with the algorithm.

Determination of oxalate by gas chromatographic measurement of carbon dioxide evolved from the photochemical decomposition of iron(III) oxalate

JEAN M. COOLEY[1] AND B. KRATOCHVIL[2]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 25, 1979

JEAN M. COOLEY and B. KRATOCHVIL. Can. J. Chem. **58**, 627 (1980).

Oxalate over the range of 0.4 *M* to 1×10^{-5} *M* can be determined with an accuracy of about 2% by injection of sample solutions into a photolytic cell containing an acidic solution of iron(III). Ultraviolet irradiation decomposes the iron(III) oxalate complex to iron(II) and carbon dioxide. The carbon dioxide then is purged from the cell in a stream of helium, dried, separated from other gases on a column of silica gel, and measured with a thermal conductivity detector. Interference from calcium, magnesium, thorium, aluminum, and several carboxylic acids is slight, while that from malonic, citric, formic, and tartaric acids is moderate. Strong ultraviolet absorbing species affect results by reducing the efficiency of photolysis.

JEAN M. COOLEY et B. KRATOCHVIL. Can. J. Chem. **58**, 627 (1980).

On peut déterminer l'oxalate sur une échelle de concentration allant de 0.4 *M* à 1×10^{-5} *M* avec une précision de 2% en injectant des échantillons de solution dans une cellule photolytique contenant une solution acide de fer(III). L'irradiation ultraviolette décompose le complexe oxalate de fer(III) en fer(II) et en bioxyde de carbone. Le bioxyde de carbone est retiré de la cellule en faisant passer un courant d'hélium, puis après séchage, on le sépare des autres gaz sur une colonne de silica gel et on en détermine la quantité à l'aide d'un détecteur à conductivité thermique. Le calcium, le magnésium, le thorium, l'aluminium et plusieurs acides carboxyliques interfèrent faiblement tandis que l'interférence due aux acides malonique, citrique, formique et tartrique est modérée. Les espèces absorbant fortement dans l'ultraviolet affectent les résultats en réduisant l'efficacité de la photolyse.

[Traduit par le journal]

Introduction

The photochemical oxidation–reduction reaction of the iron(III) monooxalate complex,

$$2FeC_2O_4^+ \xrightarrow{h\nu} 2Fe^{2+} + 2CO_2 + C_2O_4^{2-}$$

has been used for the determination of both iron(III) and oxalate. Rao and Aravamudan (1) applied it to the measurement of oxalate by titrating the resultant iron(II) with sodium vanadate. Later, Riggs and Bricker (2) measured the iron(II) by titration with sodium dichromate or, for smaller amounts of oxalate, by spectrophotometric determination with 1,10-phenanthroline. Cooley and Kratochvil (3) determined the carbon dioxide formed by using a CO_2 electrode in a continuous flow system. The advantage of analysis of carbon dioxide is that interferences from substances that reduce iron(III) but do not produce carbon dioxide are avoided. Although the CO_2 electrode has several merits, it is subject to interference from aromatic and low molecular weight carboxylic acids.

Accordingly, a gas chromatographic detector system for carbon dioxide similar to that employed by Swinnerton, Linnenbom, and Cheek (4) was investigated. In the procedure developed the iron(III) monooxalate complex is decomposed photochemically to carbon dioxide in a reaction cell. The carbon dioxide is purged from the cell with a stream of helium and separated from other volatiles on a column of silica gel prior to measurement with a thermal conductivity detector. The method is simple, more sensitive to small amounts of oxalate than the CO_2 electrode method, and relatively insensitive to the sample matrix.

Experimental

Apparatus

As shown in Fig. 1, helium carrier gas flowed through one side of the thermal conductivity cell (GOW-MAC Instrument Co., Model TR 11B), through a four-way stopcock, and into the 2.3- × 8-cm irradiation compartment via a 10- to 20-μm glass frit. For ease of disassembly, polypropylene fittings (Cheminert, Chromatronix, Inc.) were used on the capillary tubing that connected the compartment to the stopcock. A low pressure mercury lamp (Pen Ray, Model 11SC-1, Ultra Violet Products, Inc.) placed in a quartz finger (o.d. 1.5 cm) in the compartment lid provided the necessary ultraviolet radiation. An O-ring joint and No. 35 clamp held the finger assembly in place. In the assembled cell the bottom of the finger nearly touched the frit. In this way the sample solution occupied an annular space around the lamp and thereby was efficiently exposed to radiation. Reagent solutions and samples were introduced and removed with a syringe through a septum near the bottom of the compartment. During use the cell was wrapped in aluminum foil to shield the operator from ultraviolet radiation and to increase the efficiency of the irradiation step.

The gases purged from the cell after radiation passed through the stopcock via 1.6-mm (1/16-in.) stainless steel tubing to a 1- × 30-cm column of 8-mesh calcium sulfate desiccant (Drierite, W. A. Hammond Co.). (A ground-glass joint near one end of the column facilitated replacement of spent drying agent.) The gases were separated on a U-shaped 0.6- × 90-cm column of 40- to

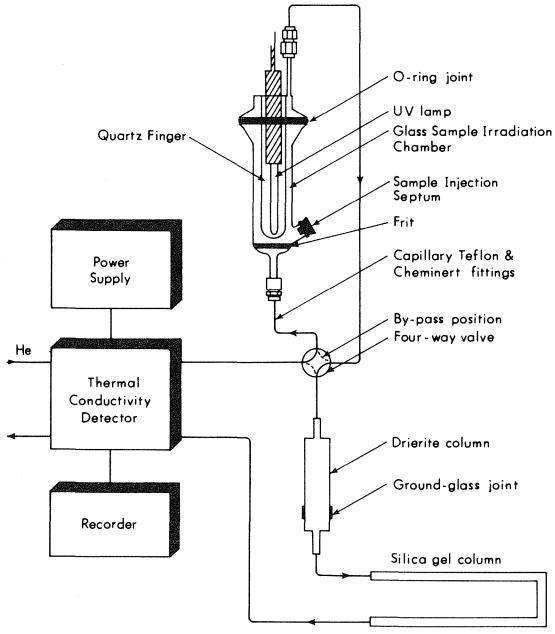

FIG. 1. Apparatus for the determination of oxalate by gas chromatographic measurement of carbon dioxide generated by photolytic decomposition of iron(III) oxalate.

60-mesh silica gel (Fisher) thermostated at 40°C. Connections were Swagelok fittings, 8-mm one-hole silicone rubber stoppers, or Kovar seals. The output of the thermal conductivity detector was monitored with a Hewlett Packard 7101 BM strip chart recorder.

Procedure

A 1-mL portion of a mixture of iron(III) in sulfuric or hydrochloric acid was injected into the assembled compartment. The optimum concentrations depend on the amount of oxalate in the sample (see later discussions). Next, a 5-mL portion of the oxalate sample was injected. A Chaney adaptor on the syringe aided in reproducing sample volumes. The stopcock was then turned so that a stream of helium passed through the frit and purged volatile components, particularly residual carbon dioxide, from the compartment. Purging was continued until the air peak appeared on the recorder. The compartment was then isolated from the helium flow and the sample exposed to ultraviolet light for 5 min; during this time a stream of air was directed over the surface of the uv lamp to provide cooling.

At the end of the irradiation period the stopcock was turned to purge the solution with helium. The gas was directed through the Drierite column, where water vapour was removed, and then through the silica gel column and the detector. Upon completion of each run the solution in the cell was removed through the septum using a needle attached to a length of tubing. Helium pressure from within forced the contents to waste.

Calibration curves were prepared by measurement of solutions of known oxalate concentration. As the peaks were very narrow, peak heights rather than areas were recorded.

Chemicals

Potassium oxalate solutions were prepared in a 0.5 M NaCl – 0.1 M H_2SO_4 matrix. Iron(III) solutions were prepared from sulfate or chloride salts in sulfuric or hydrochloric acid. All chemicals were reagent grade or better and were used as received.

Results and Discussion

Examination of a number of variables in the system was carried out to optimize operating conditions.

Stripping Efficiency

The efficiency of the helium purge for removal of carbon dioxide from the reaction cell was ascertained by comparison of the peak heights obtained from (*1*) injection of sodium bicarbonate solutions into sulfuric acid and (*2*) decomposition of sodium bicarbonate solutions by direct injection into an Aerograph heated inlet (220°C) ahead of the silica gel column. The two procedures gave similar results, showing the helium purge to be a suitable method for removal of carbon dioxide from solutions in the cell.

Helium Flow Rate

For the injection of 5 mL of 1.0×10^{-4} M potassium oxalate into 1 mL of 3.1×10^{-3} M iron(III) ammonium sulfate in 4 M H_2SO_4, the relative standard deviation for four determinations was 5.11% at a flow rate of 143 mL/min, 2.80% at 115 mL/min and 0.87% at 86 mL/min. Although slower flow rates gave improved precision, the time required per determination also increased. Carrier flow rates of about 100 mL/min were generally chosen, allowing a determination to be completed in about 15 min.

Irradiation Time

To determine the optimum irradiation time, a series of measurements was made in which 5-mL portions of a 1.0×10^{-4} M potassium oxalate solution were irradiated in the presence of 1 mL of 1.1×10^{-3} M iron(III) ammonium sulfate in 0.6 M HCl for varying times. Table 1 lists the extent of reaction, assuming a 20-min irradiation time gave 100% conversion of oxalate to carbon dioxide. Since the rate of carbon dioxide evolution is rapid initially, and

then falls off, 5 min was selected as a compromise between excessive time per determination and sufficient reaction to obtain satisfactory results. A disadvantage of lengthy irradiation is that expansion of the cell contents by warming from the lamp causes a small portion of the solution to be forced through the frit. This problem is minimized by keeping irradiation times short, cooling the lamp and compartment with a stream of air, keeping the volume below the frit to a minimum and placing the stopcock higher than the frit so that the connecting tubing slopes upward.

Effect of Wavelength of Irradiation

In previous work (3) the sample was irradiated by a medium pressure 140-W Hanovia lamp (λ_{max} 366 nm). To assess the effect of radiation wavelength on the reaction, investigation of different low pressure 5.5-W Pen Ray lamps was carried out. The Model 11SC-1 lamp emits most of its radiation at 254 nm, while the Model 11SC-1L contains a fluorescent sleeve and filter that converts the 254 nm radiation to a band peaking at 366 nm. Little difference was observed between the two. The Model 11SC-1 was used for subsequent work because of its greater availability.

Effect of Acid Concentration

The previous studies (3) with a continuous flow system showed that the extent of carbon dioxide production from oxalate increases with increasing pH. These results were confirmed with this system. Examples of the effect of two different concentrations of H_2SO_4 and HCl are shown in Fig. 2. A final acidity of 0.5 *M* or lower appears optimum.

Effect of Iron(III) Concentration

To measure the effect of varying iron(III) concentration, a set of seven solutions 0.6 *M* in HCl and ranging between 0.53 and 5.3×10^{-4} *M* in $FeCl_3$ was prepared. Acidified iron(III) chloride solution (1 mL) and 5 mL of 1.0×10^{-4} *M* potassium oxalate solution were injected into the compartment, and the carbon dioxide production was measured. The optimum ratio of iron(III) to oxalate was found to be between 2:1 and 20:1. A low (2:1) ratio is best for higher oxalate concentrations because high concentrations of iron(III)–chloro species block ultraviolet radiation from reaching the oxalate complex. These optimum iron to oxalate ratios are higher than those measured in the earlier system (3) because the initial purging removes oxygen and prevents in situ oxidation of iron(II) to iron(III).

Similar results were obtained when $FeNH_4(SO_4)_2$ and H_2SO_4 were substituted for the chloride species. The iron(III)–sulfate complexes absorb in the ultraviolet region as strongly as the corresponding iron(III)–chloride species.

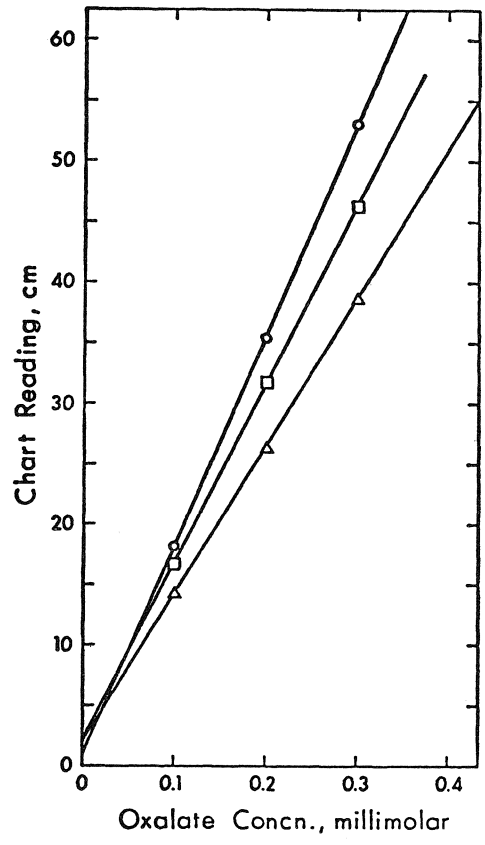

FIG. 2. Effect of concentration of hydrochloric and sulfuric acid on the iron(III)–oxalate reaction: ○, 0.10 *M* H_2SO_4 and HCl; □, 0.70 *M* HCl; △, 0.70 *M* H_2SO_4.

Effect of Metal Ions

A number of ions in addition to iron(III) react with oxalate. To evaluate the level of their interference, solutions of calcium chloride, magnesium chloride, thorium chloride, and potassium aluminum sulfate were added in varying amounts to oxalate samples. Table 2 shows that calcium and magnesium interfere little over the concentration range studied, whereas thorium and aluminum begin to interfere significantly only at concentrations 50 times that of oxalate. Addition of selected chelating agents to samples containing these metals would likely decrease this interference even further.

Effect of Other Carboxylic Acids

Since iron(III) forms complexes with a number of carboxylate anions, their effect on the determination was investigated, with the results shown in Table 3. In general, the absolute error was 10% or less when the ratio of interfering salt to oxalate was

[a]Oxalate added as 2.5 mL of a 2.0×10^{-4} *M* potassium oxalate solution to a reagent solution of 1 mL of 2.1×10^{-3} *M* iron(III) ammonium sulfate in 0.6 *M* H_2SO_4. Each carboxylate species added in 2.5-mL volume.

10 or less. Malonate, citrate, formate, and tartrate interfered more seriously than the other acids. The amount of carbon dioxide produced can be related in a general way to the magnitude of the conditional formation constant between the carboxylic acid and iron(III) (3).

Applicability to the Determination of Oxalate in Urine

Preliminary experiments were performed to assess the possibility of applying the method to the determination of oxalate in urine. Because urine samples absorb strongly in the ultraviolet region, it was found necessary to increase the amount of iron(III) added. Aliquots of individual urine samples spiked with varying amounts of oxalate gave straight-line calibration plots, indicating that the method merits further study.

In summary, the photochemical oxidation of oxalate to carbon dioxide provides a useful method for the determination of oxalate. The system described here has several advantages over the continuous flow system using the CO_2 electrode. It is relatively rapid, does not require expensive equipment, and is subject to fewer interferences than most other methods. Replicate 5-mL portions of solutions containing from 1×10^{-4} *M* to 4×10^{-5} *M* oxalate were analyzed with an accuracy of about 2% and a relative standard deviation of about 0.9%. By use of appropriate concentrations of iron(III), linear calibration curves can be obtained for oxalate concentrations over the range of 0.4 *M* to 1×10^{-5} *M*.

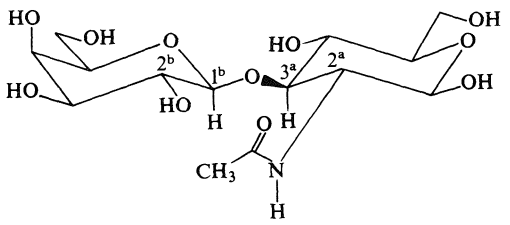
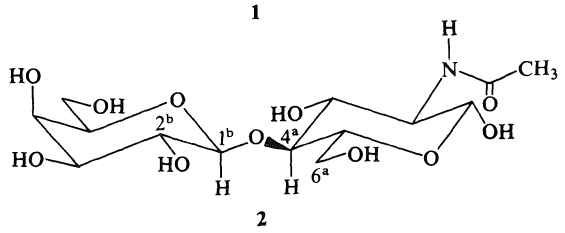
Nuclear magnetic resonance properties are shown to be in good accord with those that are expected for synthetic oligosaccharides in the conformations which are predicted by hard-sphere molecular modelling and taking into consideration the important contribution by the *exo*-anomeric effect. The studies involve first a comparison of the βDGal(1→3)βDGlcNAc (Type 1) and βDGal-(1→4)βDGlcNAc (Type 2) disaccharide structures based mainly on ^{13}Cmr and then an examination of the relationships between the calculated conformations and ^{1}Hmr and ^{13}Cmr parameters for human blood group determinants which are derived from the Type 1 core disaccharide. Among the structures examined are the di-, tri-, and tetrasaccharides for the ABH and Lewis antigenic determinants. Certain immunological–conformational relationships are noted.

R. U. LEMIEUX, K. BOCK, L. T. J. DELBAERE, S. KOTO et V. S. RAO. Can. J. Chem. **58**, 631 (1980).



On montre que les propriétés de rmn sont en accord avec celles attendues pour les oligosaccharides synthétiques selon les conformations prévues par les modèles sphériques rigides et en tenant compte de la contribution importante de l'effet anomérique *exo*. Les études impliquent en premier lieu une comparaison des structures des disaccharides βDGal(1→3)βDGlcNAc (type 1) et βDGal(1→4)βDGlcNAc (type 2) basée principalement sur les données de la rmn du ^{13}C et en second lieu l'étude des relations existant entre les conformations calculées et les paramètres de la rmn du ^{1}H et du ^{13}C des déterminants du groupe sanguin humain qui dérivent du noyau disaccharide de type 1. Parmi les structures examinées on trouve le di, tri et tétrasaccharides pour le ABH et les déterminants antigéniques de Lewis. On note certaines relations immunologiques–conformationnelles.

[Traduit par le journal]



Introduction

Oligosaccharidic structures are present in a variety of natural products and are implicated in a wide range of biological phenomena. An appreciation of the conformational properties of these substances is basic to progress toward a proper understanding of their biological activities especially in terms of their interactions with a wide range of receptor sites. This paper first considers the conformational properties of two disaccharides which serve as building units of a variety of human blood group determinants found at cell surfaces and in body fluids either as glycosphingolipids (1) or blood-group specific glycoproteins (2). The further glycosidation of these structures yields more complete determinants related to the ABH and Lewis blood group systems and the conformational analyses of these structures is then considered.

The Lewis-a (Le^{a}) and -b (Le^{b}) antigenic determinants are derived from the disaccharide *N*-acetyllacto-*N*-biose I (βDGal(1→3)βDGlcNAc) (**1**). The human A and B blood group determinants are

1

2

derived from either this disaccharide or *N*-acetyllactosamine (βDGal(1→4)βDGlcNAc) (**2**). These structures are said to be of Type 1 and Type 2, respectively. The human O blood group is characterized by the H determinant (αLFuc(1→2)-βDGal(1→4)βDGlcNAc) which is the precursor to the Type 2 A and B determinants and which is bound by the lectin *Ulex europaeus* (3). The H (Type 1) determinant (αLFuc(1→2)βDGal(1→3)βDGlcNAc) was recently (4) associated with the Lewis-d activity and will be referred to herein as the Le^{d} determinant. This determinant is not bound by *Ulex europaeus* which agglutinates human H red

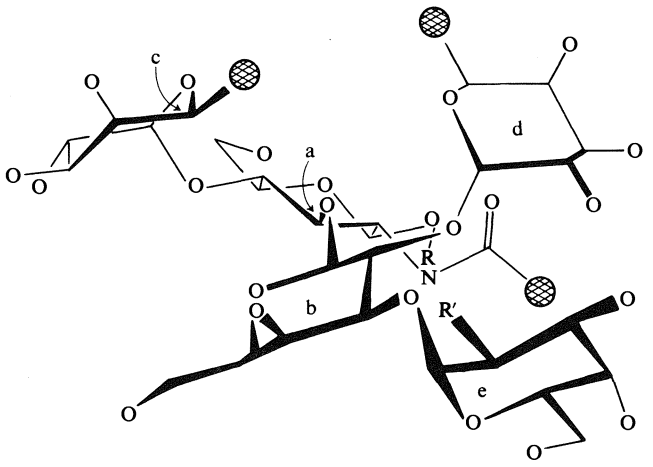
cells.[5] The Le^d determinant is the immediate biosynthetic precursor of the Le^b determinant. The ABH (Type 2) determinants are related to glycosphingolipids present at the surface of human red blood cells whereas the Type 1 antigens are basically related to epithelial cells but are transported by the serum to red cells (5).

It has become increasingly evident that the receptor sites of antibodies, lectins, and enzymes are not necessarily specific for that sugar unit of an oligosaccharide upon which these act but, instead, may require that structure as substrate which is provided by a substantially larger unit of the oligosaccharide. Paulson and co-workers (6) have recently detected interesting examples. Thus, although a β-D-galactopyranosidase efficiently catalyzed the hydrolysis of the terminal β-D-galactopyranosyl unit of βDGal(1→4)βDGlcNAc-(1→3)βDGal(1→4)βDGlc (lacto-*N*-neotetraose), the enzyme was ineffective for the hydrolysis of βDGal(1→3)-βDGlcNAc(1→3)βDGal(1→4)βDGlc (lacto-*N*-tetraose). Also, whereas the terminal galactosyl unit of lacto-*N*-neotetraose was sialylated by a βDGal-α-(2→6)-sialyl transferase, the isomer was inert. This is not surprising from a chemical structure point of view since the attachment of a glycosyl group to another sugar provides a structure with the atoms in substantially different environments than were present in the individual sugars. Even for a small receptor site, only the very terminal grouping atoms remain in a constant environment. Therefore, an understanding of antibody and enzyme specificities, for example, will require precise information on the preferred conformations for oligosaccharide chains. In general, the conformations of the pyranose rings in the sugar unit can be expected to be those preferred for the sugar as a simple glycoside and this can usually be readily ascertained by nuclear magnetic resonance spectroscopy. Therefore, the conformations of oligosaccharide chains are expected to depend mainly on conformational preferences involving the glycosidic bonds.



Lemieux and Koto (7) reviewed the earlier literature concerned with the conformational properties of glycosidic linkages including molecular modelling through hard-sphere calculations and the role of the *exo*-anomeric effect (8). At that time, there existed no basis for anticipating the magnitude of the dependence of the *exo*-anomeric effect on torsion angle. Therefore, it was assumed that the torsion angles defined by the aglyconic carbon and the anomeric hydrogen (termed the ϕ^H angle), because of the *exo*-anomeric effect, would be near ±55° and ±50° for α- and β-glycopyranosides (the sign depending on the absolute configuration of the glycoside and with the aglyconic carbon in *syn*-clinal orientation with both the anomeric hydrogen (H-1) and the ring-oxygen (O-5) of the glycosyl group). Their considerations of the preferred conformations for the cyclohexyl α- and β-D-glucopyranosides and derivatives of these compounds by way of substitutions at the 2 and 6 positions of the cyclohexyl ring appeared to substantiate this proposal (7). Furthermore, it became apparent that the "virtual" torsion angle defined by the anomeric and aglyconic hydrogen atoms (by projection through the anomeric and aglyconic carbons) would normally be less than |30°|. Therefore, oligosaccharide structures may be usefully represented by approximate conformational formulas such as those presented above for the βDGal(1→3)βDGlcNAcOR (**1**) and βDGal(1→4)βDGlcNAcOR (**2**) glycosides. Thus presented, the formulas imply that, whereas $O\text{-}2^b$ is in close proximity to $N\text{-}2^a$ in the Type-1 linkage of **1**, this atom ($O\text{-}2^b$) is remote from $N\text{-}2^a$ but near $C\text{-}6^a$ in the Type-2 structure (**2**). An appreciation of both the conformational preferences of such glycosidic linkages and how strongly these are held is the purpose of this communication. The approach in this regard which is used herein is first to estimate the preferred conformations by way of molecular model considerations and then to test the conclusions thereby reached by nuclear magnetic resonance studies. These studies were made possible by the chemical syntheses of the ABH and Lewis related compounds listed in Scheme 1. These syntheses were outlined in a preliminary communication (9) wherein some of the conclusions reached in this paper were briefly presented. The projection formulas in Scheme 1 display the general conclusions reached regarding the Type 1 determinants. The conclusions reached regarding the conformations of the A and B trisaccharides are expected to apply as well to the Type 2 determinants.

It is to be noted that throughout this presentation the various monosaccharide units are specified as units a to e as shown in the formula of Scheme 1. Furthermore, these ring designations will be used to specify φ and ψ torsion angles for the glycosidic bonds and, also, to specify atoms within each unit.

Discussion

The designations for the various torsion angles

[5]Since the submission of this manuscript, it was found (R. U. Lémieux, J. Le Pendu, and O. Hindsgaul. J. Antibiot. In press) that, as expected from considerations of structural analogies, the de-*N*-acetylated form of the Le^d determinant is strongly bound by this lectin.

defined by neighboring atoms about a glycosidic linkage in terms of ϕ and ψ angles used herein are those proposed by Lemieux and Koto (7), except that in this communication the use of ϕ and ψ will infer ϕ^H and ψ^H, respectively. Also, the same general procedure was used for the hardsphere calculations; namely, that recommended by Venkatachalam and Ramachandran (10).

In order to program the hard-sphere calculations, it was necessary to prepare the three-dimensional models for the individual sugar units by using atomic parameters provided by X-ray crystallographic structures. Since neither the crystal structure for compound **1** nor that for **2** was available, the parameters used were derived from those reported for 4-*N*-(2-acetamido-2-deoxy-β-D-glucopyranosyl)-L-aspargine trihydrate (11) and lactose hydrate (12). The coordinates for the β-D-galactopyranosyl group were taken from this latter structure rather than those reported for methyl 6-*O*-acetyl-β-D-galactopyranoside (13) because the group, as in structures **1** and **2**, is the non-reducing unit of a disaccharide and, also, the crystal structure was more highly resolved. In these and all other calculations involving the acetamido group, the group was placed in that orientation wherein the vicinal C═O and C—N bonds are eclipsed. As previously done by Rees and Skerrett (14), all the calculations reported herein were simplified by treating the hexose units as 6-deoxyhexose structures.

This paper also deals with a variety of structures related to the AB and Lewis human blood group determinants which contain αDGalNAc, αDGal, and αLFuc residues. The atomic parameters for these units were derived from those reported for 2-acetamido-2-deoxy-α-D-galactopyranose (15) and methyl α-D-galactopyranoside (16). The atomic parameters for the α-L-fucopyranoside units were synthesized by inversion of those reported for methyl α-D-galactopyranoside rather than using the less precise data reported for α-L-fucopyranose (17, 18).

It is expected that crystal field forces can

influence bond lengths and valence angles so that appreciable changes may occur when the compound leaves the crystal to enter into aqueous solution. Such effects are assumed to be negligible except for atoms which interact about the glycosidic bond. Bond lengths are expected to remain essentially constant except as influenced by changes in the ϕ angle as a consequence of the *exo*-anomeric effect (8, 19). Substantial changes in bond angles appeared more likely. Therefore, tests were made in an attempt to gauge the influence such changes have on the interaction energies provided by the hard-sphere calculations. The tests indicated that $\pm 2\%$ changes in bond lengths have negligible influence. However, $\pm 2\%$ changes in valence bond angles had appreciable effects on the calculated total interaction energy. In extreme cases the effect was up to near 0.8 kcal/mol. However, the influence on torsion angles appeared negligible within the range ($\pm 5°$) which was arbitrarily set for this study. As a consequence of these tests, it was decided to attach significance to energy calculations that differed by more than ± 0.5 kcal/mol. However, it must be stressed that these assumptions are made solely to provide a basis for the hard-sphere calculations that is sufficiently rigid to be tested for utility. The goal was to determine whether or not such analyses provided conformations in good general accord with assessments made by other physical methods, especially nuclear magnetic resonance spectroscopy. If so, then justification would be gained for using the method to anticipate conformational preferences for structures in aqueous solution when other methods of analysis are not applicable and thereby assist in studies of structure – biological activity relationships.

A choice of a general value for the valence angle defined by the atoms (C-1^b)—(O-1^b)—(C^a) of the glycosidic bond which is termed the τ angle was made, since this procedure greatly simplified the calculations while appearing to not adversely affect the conclusions reached. The effect of the value of this angle on energy content can be judged from the data plotted in Fig. 1. It is seen that, as previously noted by Sundaralingam (20), changes of τ in the range 113° to 119° with $\psi = 50°$ have little influence on the value of the ψ angle predicted for the lowest energy conformer. This was also the case at other values for ϕ. Since the net attractive interactions remain nearly constant, evidently, the net repulsive interactions diminish with increasing τ angle with the energy contents of more conformers becoming nearly equal. It is apparent from Fig. 1 that any τ value in the range 113° to 119° could serve our

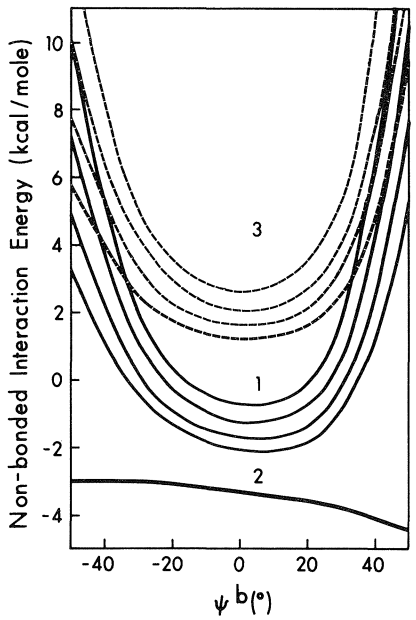

FIG. 1. Changes in non-bonded interaction energies which arise from rotation about the aglyconic bond (change in ψ^b torsion angle) of the βDGal(1→3)βDGlcNAc disaccharide (**1**) with the ϕ^b torsion angle set at 50°. The calculations are reported for τ valence angle values of 113°, 115°, 117°, and 119°. Plots 1 show that the non-bonded interaction energies decrease with increasing τ angle. Plot 2 is a composite curve and shows that the attractive interactions did not change with change in τ angle. Plots 3 display how the repulsive interactions decreased with increasing τ angle.

present purposes. Nevertheless, the specific value of 117° was adopted for all our calculations involving intersugar glycosidic bonds, primarily since this higher value would tend to minimize "hard" repulsive interactions. This is considered desirable since, in a real situation, a "hard" interaction could be effectively avoided by a slight change in the valence angle and the computer program used did not allow for such an adjustment. It may be noted in this regard that the τ values for both α- and β-linked disaccharides in the crystalline state are somewhat larger than 116° (19, 21).

The energy profiles for compounds **1** and **2** obtained by plotting the energy of the most stable conformer (that is, that with the most favorable ψ angle for the given ϕ angle) against the ϕ angle are presented in plots 2 of Fig. 2. It is seen that the minimum energy conformer in both cases is predicted to be that with a ϕ value near 50°. Since the conformations in the range $0 \leq \phi \leq 70°$ all differ in energy by less than one kcal/mol, this approach to the gaining of information on conformational preferences, on its own, would therefore predict a large range of energetically near-equivalent con-

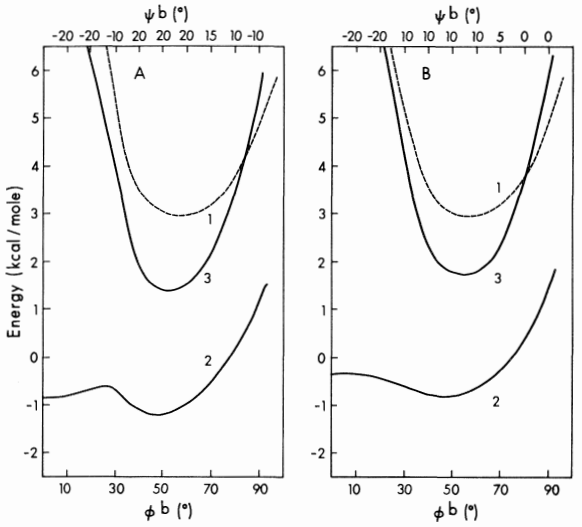

FIG. 2. The changes in energy estimated to occur with changes in the ϕ^b torsion angles; *A*: for the βDGal(1→3)βDGlcNAc disaccharide (**1**); *B*: the βDGal(1→4)βDGlcNAc disaccharide (**2**). Plots 1 display the change in bonding energy attributed to the *exo*-anomeric effect (Table 1). Plots 2 show the change in non-bonded interaction energy, and plots 3 provide the changes in energy content obtained by addition of plots 1 and 2. The ψ^b torsion angles calculated to be the energetically most favorable are provided at 10° intervals of the ϕ^b torsion angle.

formers; that is, conformationally highly flexible structures for these disaccharides. However, the range of energetically near-equivalent conformers was expected (7) to be very substantially restricted for reasons of the *exo*-anomeric effect.

Lemieux *et al.* (8) recently provided further experimental evidence in the support of the *exo*-anomeric effect having a strong influence on the conformational preference for a glycosidic linkage. Furthermore, Jeffrey *et al.* (21) have recently published the potential energy surfaces for internal rotation in dimethoxymethane as derived by *ab initio* molecular orbital calculations and thereby provided an estimate of the change in potential energy that should occur with change in the ϕ torsion angle. As previously expected on theoretical grounds (19), the most favorable value for ϕ is near 60° and the energy rises (because of weakening of the glycosidic bond) as this torsion angle is either increased or decreased from this favorable orientation for the *exo*-anomeric effect. Our procedure then is to add changes in energy expected to arise from changes in the *exo*-anomeric effect to the changes estimated by hard-sphere calculations. It must be stressed at this point that Jeffrey *et al.* (21) did not calculate the shapes for these curves but, instead, only presented possible trends. As presented, the trends provide little energy change in the

[a]Estimated from the plots presented by Jeffrey and co-workers (21).

range 60 ± 15° and, therefore, minimize the influence of the *exo*-anomeric effect in this important region. Nevertheless, we felt that there was no alternative, at this time, than to accept the plots as provided in order to construct our approach for estimating conformational preferences about glycosidic linkages by way of a combination of hard-sphere calculations and values for the *exo*-anomeric effect. These latter values are presented in Table 1 and are taken from the plots provided by Jeffrey *et al.* (21)[6].

For convenience, we propose to designate this approach for the calculation of conformational preferences about glycosidic linkages as the HSEA (hard-sphere, *exo*-anomeric) method.

As seen in Fig. 2, the coupling of the hard-sphere calculations with the *exo*-anomeric effect provides potential energy curves (plots 3) for the disaccharides **1** and **2** which indicate that the glycosidic linkages possess ϕ angles in the range 40° to 60°. We conclude, therefore, that the glycosidic linkages for these compounds in aqueous solution largely adopt conformations in this range and that the weighted average of this conformer population will be well represented by the mid-way conformer with ϕ = 50°. It must be noted in this regard that the procedure involves no effort to judge the influence of either dipole–dipole interactions or of the solvent water. Kitaygorodsky, whose expressions (22) for the calculation of the non-bonded interactions are used in the hard-sphere calculations, has recently reviewed (23) these limitations. We entertain the primitive approach used herein because, as will be seen, the procedure provided conformations for the

structures examined in this investigation that proved well substantiated by their nuclear magnetic resonance properties. In other words, we expect that more sophisticated approaches such as force-field calculations (24) will be developed but that such developments will require theoretical insights on such matters as dipole–dipole interactions, possible intramolecular hydrogen bonding effects, and solvation which are not, to our knowledge, presently available. Under such circumstances, we see little alternative than to use the simplest possible approach and to be ready to adjust this approach as likely will be required by future experimental findings. The pertinent question at this point is to ask why do the simple HSEA calculations used herein appear to provide useful approximations to the conformational properties of these oligosaccharides in aqueous solution. That is, it may prove, in fact, that the *exo*-anomeric effect and non-bonded interactions about the glycosidic bond dominate over other possible effects on conformational preference to such an extent that other influences are, to a useful first approximation, negligible. As will be seen, the agreement between the calculated structures and those inferred by the nuclear magnetic resonance studies appear too good in too many circumstances to be merely fortuitous and the communication of these findings is the main purpose of this paper.

In the following discussions, the conformational preference for a glycosidic linkage is expressed in terms of a single conformer. It must be understood in this regard that the intention is simply to indicate what may comprise the most highly populated conformer within a range of conformers in the well of the potential energy surface. The nuclear magnetic resonance parameters reflect a weighted average of these conformers and it is this conformer which is expected to coincide with that anticipated by the HSEA method.

The most favorable ψ angles provided in Fig. 2 were obtained from ψ energy profiles such as those plotted in Fig. 3 for the $\phi = 50°$ conformers for **1** and **2**. It is seen that rather broad energy wells are obtained so considerable conformational flexibility may also be expressed by rotation about the aglyconic bonds. These curves, as was discussed above with regard to Fig. 1 can be somewhat "sharpened" by decreasing the τ angle in order to "harden" the interactions. However, this did not alter the conclusion reached that the "best" conformations for the disaccharides **1** and **2** appear to be those with $\phi = 50°, \psi = 20°$ and $\phi = 50°, \psi = 10°$, respectively. These conformations display that, although the constituent sugars are the same, the

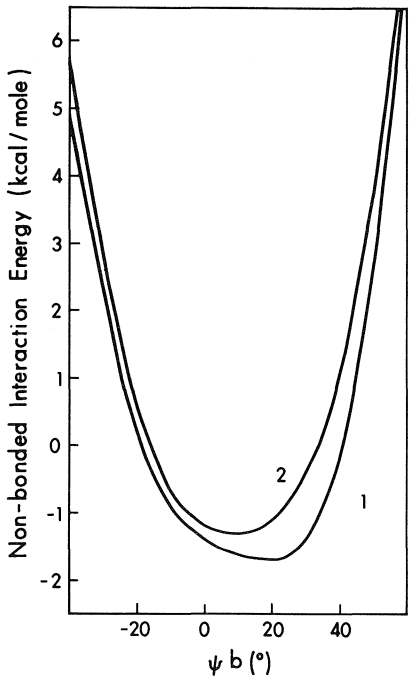

FIG. 3. Changes in non-bonded interaction energy which result from changes in the ψ^b torsion angles and keeping the ϕ^b torsion angles at the values (50° in each case; see Fig. 2) which are expected to be energetically most favorable. Plot 1 is for the βDGal(1→3)βDGlcNAc disaccharide (**1**) and plot 2 is for the βDGal(1→4)βDGlcNAc isomer (**2**).

two structures are stereochemically very different except in the immediate environment of C-4′ of the β-D-galactopyranosyl groups and, therefore, must be expected to possess significantly different immunological properties. Also, the near environments of the O-2′ atoms of the βDGal residues of **1** and **2** are sufficiently different that it seems improbable (9) that, as is commonly assumed, it is the same α-L-fucosyl transferase that converts **1** and **2** to the Le^d and H determinants, respectively. Furthermore, the αLFuc residues in these determinants are in such substantially different environments that anti-Le^d antibodies may react only very weakly if at all with the H-determinant and vice versa. As was noted above, the lectin *Ulex europaeus* combines with the H (Type 2) determinant, but is not appreciably bound by the Le^d (Type 1) determinant (3).

In order to gain experimental evidence for the conformations of the disaccharides **1** and **2** that are indicated by the plots 1 of Fig. 2, the ^1H- and ^{13}Cmr spectra of these compounds were examined as glycosides of 8-methoxycarbonyloctanol. All of the complex glycosides that were examined have this aglycon since the synthesis of such structures provides a linking arm for the preparation of artificial

[a]Measured under the conditions reported for the ^{1}Hmr spectra in the Experimental and are expected to be within 0.1 Hz. The vicinal coupling constants observed for the oligosaccharides listed in Tables 6–10, when the chemical shift could be determined directly, were in good accord with those listed above for the corresponding glycosyl group.

antigens and immunoadsorbents (9). Inspection of the data presented and referred to in Tables 2 and 6 shows a close correspondence between the ^{13}C- and ^{1}H-chemical shifts found for the βDGal groups of the disaccharides **1** and **2**. Furthermore, these shifts differ little from those found for methyl β-D-galactopyranoside (**9**). The vicinal coupling constants listed in Table 3 require the $^4C_1$ conformation and it is concluded that this conformation is maintained in the oligosaccharides. Because of substitutional effects, the chemical shifts listed in Table 2 for the βDGlcNAc residues of **1** and **2** are not expected to correlate directly with those found for the simple βDGlcNAc glycoside **8**. However, the patterns of the shifts observed are in general accord with expectation and there can be no doubt that these residues are in the $^4C_1$ conformation.

It is seen that the introduction of the βDGal group at C-3 of **8** to form **1** caused an 8.7 ppm deshielding of this atom. This deshielding was also observed at C-4 in the formation of **2**. As will be seen later on, these deshielding effects appear highly sensitive to changes in the hybridization of the atoms about the glycosidic linkage. It is perhaps noteworthy in this regard that the energy calculations presented in Figs. 2 and 3 indicate that the preferred conformations for these two disaccharides possess about the same conformational energy minima and that no

For personal use only.

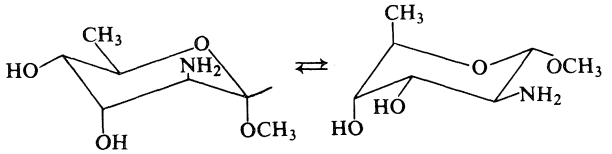
important non-bonded interactions are present in these conformations which could cause appreciable distortion of the glycoside valence angles. The close correspondence of the chemical shifts for H-1^b and C-1^b of the β-D-Gal residues of **1** and **2**, namely 4.69 and 104.33, and 4.74 and 103.78 ppm, respectively, lend support to this contention. These data do not provide evidence in support of the conformational preferences provided by the HSEA calculations. However, these calculations require conformations for **1** and **2** which bring the anomeric and aglyconic hydrogens in near van der Waals contact and, therefore, the selective irradiation of the signal for one of these hydrogens could be expected to cause nuclear Overhauser enhancement of the intensity of the signal for the other hydrogen. With the advent of FT high-field spectrometers, measurements of nuclear Overhauser enhancements can be detected with confidence to within ±2%. Indeed, meaningful enhancement of the signal for H-3^a by 14% was observed on irradiating H-1^b of **1**. Similarly the signal for H-4^a of **2** was enhanced by 12% on irradiation of H-1^b, therefore requiring that the "virtual" torsion angle for these hydrogen atoms be so small as to bring them into contact. On the basis of the HSEA calculations the H-1^b to H-3^a and H-1^b to H-4^a internuclear distances for **1** and **2** are expected to be 2.36 and 2.44 Å, respectively. The internuclear distances for *syn*-axial hydrogens on a β-galacto pyranose ring are 2.53 (H-1 to H-3) and 2.36 Å (H-1 to H-5) and their signals were enhanced by 12–15%.

It seemed possible that further evidence in support of the conformations assigned to **1** and **2** (Fig. 3) could be gained by an nmr study of the disaccharides **3***a* and **4**. That is, it was expected that changes in the substituents at C-2^a from acetamido to amine and at C-2^b from hydroxyl to amine would cause changes in conformational preference of little if any consequence to this work. Also, it was expected that the *gluco* configuration for the nonreducing sugar unit in **3***a* and **4** is conformationally equivalent to the *galacto* configuration present in **1** and **2**. These expectations were supported by hard-sphere calculations.

As would be anticipated, since the acetamido group of **2** is remote from the galactosyl group, hard-sphere calculations showed no influence on conformational preference to result from changing this substituent to an amino group. In the case of compound **1**, with φ set at 50°, the lowest energy conformer for the corresponding amine was estimated to have a ψ angle of 10° rather than the 20° calculated for **1**. Essentially the same results were found for compounds **3***a* and **4**. In this regard, it



3*a*

4

may be noted that, whereas the β-shift (25) of C-1^b of **4** caused by di-*N*-acetylation was the same (1.4 ppm) as that found on *N*-acetylation of 2,2,2-trichloroethyl 2-amino-deoxy-β-D-glucopyranoside, the β-shift obtained on di-*N*-acetylation of **3***a* was slightly greater (1.0 ppm). As will be seen below, this difference is not necessarily related to more than a very slight change in conformation to result from changing the C-2^b substituent in **1** from $NHCOCH_3$ to NH_2.

Lemieux *et al.* (26) obtained direct evidence for a change in the steric requirement for a free amino group as compared to the protonated form. Thus, for example, whereas the equilibrium constant estimated for the $^4C_1$ (**5***a*) and $^1C_4$ (**5***b*) forms by

5*a* **5***b*

analysis of the ^{1}Hmr spectra of methyl 2-amino-2,6-dideoxy-α-D-altropyranoside was 0.33, in acid media, where the amino groups were protonated, the equilibrium favored the $^1C_4$ conformer (K_e = 4.00). This result can be attributed to the positively charged ammonium group which, because of stronger solvation by water, is more space-demanding than is the neutral amino group. These authors (26) also examined the effect of protonation of the amino groups in compounds **3***a* and **4** on the chemical shifts of the ^{13}C-atoms. As seen in Table 2, the β-shifts (25) observed for **4** are near the 4.5 ± 0.5 ppm values normally observed (27). However, for compound **3***a*, although the shifts observed for C-1^a and C-3^b are in the normal range, the shifts for C-3^a and C-1^b (those carbon atoms involved in the intersugar glycosidic bond) are exceptionally high. This effect must arise in part from the normal β shifts but also as a result of a conformational change. The conformation anticipated for **3***a* by hard-sphere calculation (φ = 50°, ψ = 10°, τ = 117°) has an internuclear distance for N-2^a and N-2^b of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

3.80 Å. Since the N to N distance for solid ammonia is 3.38 Å, then the amino groups in **3***a* may be expected to be separated, on the average, by only about 0.4 Å. Consequently, should protonation of these groups lead to the more space-demanding ammonium groups, then some alteration in conformation should result both for this reason and because an electrostatic repulsion is created between the two positively charged ammonium groups. In these regards, it is to be noted that protonation of the free amino form of **6** (Table 2) caused substantially smaller upfield shifts for C-3^a and C-1^b than those observed for **3***a*. This is as expected since the O-2^b of **6** was not protonated as a result of the change in pH. The shift of 5.6 ppm observed for C-3^a in the case of **6** is large enough to be taken as an indication that the nitrogen atom is in close proximity to an atom (considered to be O-2) in the β-D-galactopyranosyl group. The situation is also seen in the shift of 5.2 ppm observed for C-1^b of the lactosamine analog **4**. In this case, the prognosis is that N-2^b is in close proximity to C-6^a. The chemical shifts for C-2^a, C-4^a, C-5^a, and C-2^b are included in Table 2 to indicate that the protonations did not cause substantial change in the conformations of the pyranose ring since, if so, these atoms would be expected (28), along with C-3^a and C-1^b, to show appreciable shift differences between the free amine and protonated form. This matter has an important bearing on the discussions that follow.

The interaction of the ammonium groups in the protonated form of **3***a* could effect a conformational change either by changes in the ϕ and ψ torsion angles and/or by a change in the τ angle. On the basis of the $\phi = 50°$, $\psi = 10°$, and $\tau = 117°$ model for compound **3***a*, the internuclear H-3^a to H-1^b distance is 2.31 Å. A change of the τ angle to 113° reduces this distance to 2.21 Å whereas a change to 121° increases the distance to 2.41 Å. These changes have, however, little effect on the N-2^a to N-2^b distance which remains within 3.80 ± 0.03 Å. Therefore, an alternate explanation for the abnormally high β-shifts for both C-3^a and C-1^b of **3***a* was sought. The calculations suggested that the energetically most favorable way to achieve a substantial change in the N-2^a and N-2^b distance was by increasing the ϕ angle from 50° to 70°. The changes in non-bonded interactions and the *exo*-anomeric effect that would result would involve a conformational energy gain estimated to be about 0.7 kcal/mol and provide H-3^a to H-1^b and N-2^a to N-2^b distances of 2.51 and 4.39 Å, respectively. Nuclear magnetic resonance evidence in support of this postulate was sought on the basis that accurate measurement of the relaxation contributions between individual protons via the intramolecular dipole–dipole mechanism can be made (29) and can be used to estimate interproton distances within ±0.1 Å.

The T_1-values that could be determined for the ^{1}H and ^{13}C atoms of **3***b* both as the diamine and as the dihydrochloride salt are listed in Table 4. It is seen that the T_1-values for hydrogen atoms at the extremities of the molecules, namely H-1^a, H-6^a, and H-6^b are, within experimental error, the same for the compound in both forms. Therefore it can be assumed that the transformation and the change in medium have not altered appreciably the rates at which the molecules tumble. The ^{13}C-data also support this conclusion. On the basis of the assumption that the *N*-deuteration has not altered the rates of tumbling, the rather considerable changes in T_1 values observed for the more internal H-1^b and H-3^a atoms can be assigned to a change in the conformational preference about the intersugar glycosidic bond. That is, since the measurements were made at high dilution (0.05 *M*) in deuterium oxide and the solutions were free of paramagnetic contributions to the relaxations, it can be expected that these changes are largely the result of changes in the distances of these hydrogen atoms to other hydrogens in the same molecule. In other words, the rate of relaxation ($1/T_1$) may be considered as directly proportional to the sum of the inverse ratios of the various distances between the given hydrogen and all the other hydrogen atoms in the molecule; that is,

$$1/T_1 = C \sum_{i \neq j} r_{ij}^{-6}$$

where *C* is a proportionality constant (30). Using appropriate X-ray crystallographic data to locate the positions of the various hydrogen atoms relative to both H-1^b and H-3^a in compound **3***b* in various conformations, values for these sums can be estimated. The O-6 atoms were placed in *anti*-periplanar orientation to the C-4 atoms in each of the sugar units since this orientation appears preferred in the case of glucopyranosyl groups (31, 32). The values for the sums calculated for H-1^b and H-3^a of compound **3***b* in the conformations $\phi = 50°$, $\psi = 10°$ and $\phi = 70°$, $\psi = 10°$ (the conformations expected for the compound as the free diamine and dihydrochloride salt, respectively) are presented in Table 5. This table also presents the values for the constant *C* that are inferred by these values and the T_1 values for these hydrogen atoms which are given in Table 4. The T_1 value for H-3^a of the diamine could not be measured with good precision and may be neglected for these purposes. However, the val-

[a]The ^{1}Hmr data were obtained at 270 MHz, the ^{13}Cmr data 67.89 MHz and the ^{13}C-T_1 values at 22.63 MHz. The solutions for the ^{1}Hmr were 0.05 *M* in D_2O (1% dioxane as internal reference, δ = 3.64 ppm) and for the ^{13}Cmr 0.3 *M* in D_2O (5% dioxane as internal reference, δ = 67.40 ppm) and all the experiments were performed at 300 K. The assignments for H-6[a]; H-6′[a]; H-6[b], H-6′[b]; and C-6[a], C-6[b] may be reversed. Also, the assignments for C-2, C-2[b] and C-6[a], C-6[b] of the dihydrochloride.
[b]Determined from the zero crossover.

TABLE 5. The relationship between T_1 values for H-1[b] and H-3[a] of the disaccharide **3** and the intramolecular interproton distances

		$\sum_{i \neq j} r_{ij}^{-6} \times 10^3$ (Å^{-6})		T_1 (s)		*C*

50	10	17.2	17.3	0.495	0.491	117	118
70	10	14.6	14.7	0.631	0.687	109	99

ues for *C* obtained for the other three are seen to all be within 114 ± 5. This finding is considered to offer important circumstantial evidence in support of the general conclusions reached regarding the slight conformational change expected to result on the basis of HSEA calculations. That is, the method would have been expected to detect a major change in the distance between H-1[b] and H-3[a]. It may be noted in this regard that the protonation of **3***b* caused a change in molecular rotation of 31.4° which is near that observed on protonation of methyl 2-amino-2-deoxy-β-D-glucopyranoside; namely 25.8°. These observations can be taken as further indication that the protonation of **3***b* caused little change in the torsion angles about the inter-sugar glycosidic bond (7).

In view of the generally good agreement between the conformations expected for **3***b* on the basis of HSEA calculations and the physical properties expressed by **3***b*, the conformation φ = 50°, ψ = 20°, τ = 117° inferred for **1** by HSEA calculation is taken as well representative of its actual conformation. As will be seen below, the conformation for **1** found further support in terms of the conformation required for the Lewis-a trisaccharide (**15**). The conformation of the Type 2 disaccharide (**2**) predicted by HSEA calculation (Figs. 2 and 3); namely, φ = 50°, ψ = 10°, τ = 117°, places the C-6[a] to O-2[b] and H-4[a] to H-1[b] internuclear distances at 3.96 and 2.44 Å respectively. Rees and Skerrett (14) have proposed the conformation φ = 42°, ψ = −18° for cellobiose in aqueous solution. It may be expected that cellobiose would have conformational properties about the glycosidic bond which are closely similar to that proposed above for *N*-acetyllactosamine (**2**).

The above conclusion that the unexpectedly large chemical shifts for C-1[b] and C-3[a] which occur

on protonation of **3***b* are caused not by a substantial change in conformation but, instead, largely by changes in valence angle (because of a change in the *exo*-anomeric effect with the change in ϕ) appears confirmed by the changes in chemical shift observed for aglyconic carbons as the result of a glycosidation at a neighboring position.

Examination of the ^{1}Hmr data for the Lewis-a trisaccharide (**15**) and related structures, which are presented in Table 6, shows that the spectrum for **15** is closely approximated by the addition of the appropriate chemical shifts for the disaccharides **1** and **14**. The main apparent discrepancies are with H-3^a and H-5^c. Relative to the chemical shift of H-5 in methyl α-L-fucopyranoside (**10**), H-5^c is deshielded by 0.32 ppm in the case of the disaccharide **14** and by 0.83 ppm in the case of the trisaccharide **15**. Lemieux *et al.* (33) assigned these strong specific deshielding effects to electrostatic interaction of H-5^c with O-3^a and O-5^b in the case of **15**. This indication that the αLFuc residues of **14** and **15** are similarly oriented relative to the βDGlcNAc residue is further supported by the values for $\delta_{15} - (\delta_1 + \delta_{14})$ found for the other hydrogens in these αLFuc groups. Similarly, these values for the βDGal units of **1** and **15** require that the orientation of the βDGal group for **1** is only slightly altered by the introduction of the αLFuc group to form **15**. That is, it is concluded on the basis of this ^{1}Hmr data that the preferred conformations about the glycosidic bonds in the disaccharides **1** and **14** are closely maintained in the composite trisaccharide **15**. As will be seen later on with reference to Table 11, nuclear Overhauser enhancement measurements are in accord with this conclusion. On this basis, a consideration of the ^{13}Cmr data presented in Table 6 leads to the conclusion that the formation of **15** from either **1** or **14** must have caused changes in hybridization about the already formed glycosidic bonds without causing substantial change in overall conformation. This conclusion is indicated by the pronounced shielding of the intersugar aglyconic carbons of **1** and **14** on glycosidation of the neighboring position. As seen from Table 6, the galactosylation of **8** to form **1** caused a deshielding of C-3^a by 8.70 ppm and the fucosylation of **8** to form **14** caused a deshielding of C-4^a by 7.63 ppm. These effects are those normally found in linear oligosaccharide structures (34). However, the glycosidation of the position vicinal to the existing glycosidic linkage of either **1** or **14** to form **15** causes strong shielding of the neighboring aglyconic carbon; that is C-3^a of **1** is shielded by 6.36 ppm and C-4^a of **14** is shielded by 5.08 ppm. Furthermore, the deshielding of C-4^a of **1** on fucosylation to form **15** is 3.77 ppm and that of C-3^a of **14** on galactosylation to form **15** is 3.60 ppm, substitutional effects on chemical shifts that are only about half those normally observed. In view of the shielding effects discussed above in relation to the protonation of **3** and the conclusion that these arose as a consequence of changes in hybridization and, consequently, screening of the carbon atoms with only slight changes in the overall conformation of the molecule, it is proposed that the ^{13}C-shifts observed for C-3^a and C-4^a of **15** mainly arise from non-bonded interactions between the vicinal glycosyl groups which in turn lead to changes in the geometries of the glycosidic bonds, mainly in terms of valence angles, away from the less constrained situation and that these changes result in changes in the screening of the nuclei from the magnetic field while causing only a slight change in the overall conformation of the molecule. These effects on chemical shift would be in line with the conclusions reached by Gorenstein (28) on influence of valence angle change on ^{13}C-chemical shifts.

The hypothesis presented above for the rationalization of the ^{13}C-chemical shifts is supported by the data presented in Tables 7 and 8 for the A and B trisaccharide determinants. The fucosylation of the galactoside **11** to form **18** deshielded C-2^b by 5.72 ppm. Introduction of the αDGalNAc or αDGal group at C-3^b of **11** deshielded this carbon by 4.17 and 4.58 ppm, respectively. These latter substitutional effects are seen to be considerably smaller than those observed in the formation of the disaccharides **1**, **14**, and **18** and this matter will be considered later on in connection with HSEA calculations, nuclear Overhauser enhancements, and $^3J_{C,H}$ coupling constants. Completion of the trisaccharides **21** and **22** from **18** caused shieldings of C-2^b by 4.45 and 4.12 ppm, respectively. On the other hand, completion of **21** and **22** from **19** and **20**, respectively, caused shieldings of C-3^b by only 1.03 and 0.73 ppm, respectively. It is apparent that these glycosidations cannot strongly shield a vicinal carbon (C-3^b) which was already strongly shielded relative to other aglyconic carbons in disaccharide structures. Examination of the ^{1}Hmr data in Tables 7 and 8 as was done above for that in Table 6 again leads to the conclusion that the conformations of the glycosidic linkages in the disaccharide structures are well maintained in the composite trisaccharide. The only substantial differences in chemical shift are for H-2^b and H-3^b where, as for H-3^a and H-4^a of **15** (Table 6), appreciable (>0.2 ppm) shifts to lower field were observed between the actual spectrum

and that anticipated by choosing appropriate signals from the spectra for the disaccharides. These deshielding effects are in all likelihood related to the shielding of the corresponding carbon atoms caused by the glycosidations and attributed to changes in hybridization to accommodate the neighboring glycosyl groups.

The basic objective of this investigation was to examine whether or not the conformations for oligosaccharides predicted by the simple HSEA calculations are in acceptable agreement with the nuclear magnetic resonance properties found for these compounds. If so, then sufficient confidence would be gained in the results of the HSEA calculations to warrant their consideration in studies of structure–activity relationships in, for example, antibody–antigenic determinant binding. The remainder of this presentation is concerned with the finding that the conformations implied by HSEA calculation do indeed allow acceptable rationalization of the ^{1}Hmr spectral data.

The disaccharide (**14**), 4-*O*-(α-L-fucopyranosyl)-2-acetamido-2-deoxy-β-D-glucopyranoside, is a building unit for the Lewis-a and -b antigenic determinants. Plot 2 of Fig. 4 shows that the changes in non-bonded interactions, which result from changes in the φ torsion angle of the glycosidic linkages and estimating the most favorable ψ torsion angle by hard-sphere calculations only, describe a broad and shallow trough within the range

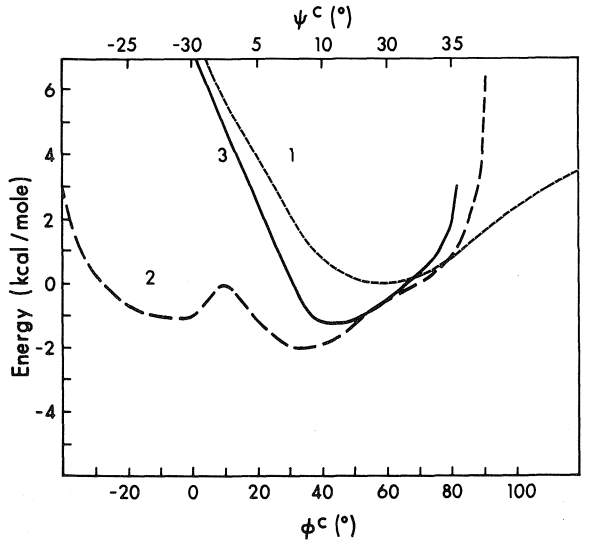

FIG. 4. Change in energy estimated to occur with changes in the ϕ^c and ψ^c torsion angles for the αLFuc(1→4)βDGlcNAc disaccharide (**14**). Plot 1 displays the change in bonding energy attributed to the *exo*-anomeric effect (Table 1), plot 2 shows the change in non-bonded interaction energy, and plot 3 indicates the change in energy content obtained by addition of plots 1 and 2. The ψ^c torsion angles calculated to be the energetically most favorable for the various ϕ^c angles are presented above.

(−40° to 120°) plotted. Within the *arbitrary* level of confidence of ± 0.5 kcal/mol which is placed on this method of calculation, plot 2 would allow conformations within very broad ranges for both the ϕ (−10° to 60°) and the ψ (−30° to 30°) torsion angles. However, addition of the contributions expected for the *exo*-anomeric effect (plot 1) provides plot 3 which strongly restricts the allowed conformations. Plot 3 indicates that the glycosidic linkage should tend to adopt ϕ angle values in the range 35° to 60° and ψ angle values in the range 5° to 30°. As seen in Table 6, H-5^c of the α-L-fucosyl group is deshielded by 0.32 ppm relative to the position of the signal for this hydrogen in methyl α-L-fucopyranoside. Inspection of a molecular model for the disaccharide shows that the above-mentioned range of ϕ and ψ torsion angles places H-5^c in close proximity to O-3^a (2.30 Å) and this interaction was expected to be the origin of the intramolecular deshielding of H-5^c.

As can be appreciated by consideration of molecular models, variation of the ϕ and ψ angles for this compound within the ranges 35° to 60° and 5° to 30°, respectively, should mainly influence the interactions between H-4^a and H-1^c and O-3^a and H-5^c. An examination of these changes showed that the changes in the H-4^a to H-1^c distances caused little change (<0.1 kcal/mol) in the non-bonded interactions between these atoms. However, the range of conformations involves a substantial change in the O-3^a to H-5^c interactions. These changes are plotted against the ϕ torsion angles in Fig. 5. It is seen that as the angle is increased, the internuclear distance decreases, and that, whereas the interaction is near zero for ϕ = 40°, ψ = 10°, the interaction increases to near 0.7 kcal/mol at ϕ = 55°, ψ = 25°. It is further seen in Fig. 5 that this increase in energy is paralleled by the total energy calculated (plot 2) for the molecule as ϕ is increased from 35° to 55°. As seen from Table 6, H-5^c is substantially (0.32 ppm) deshielded relative to the position of the signal for this atom in methyl α-L-fucopyranoside. This deshielding suggests considerable compression between H-5^c and O-3^a in this disaccharide and, consequently, a value of ϕ for the energetically most favorable conformer that is greater than 40°. The influence of the *exo*-anomeric effect is expected to be only 0.2 kcal/mol for a change in ϕ angle from 45° to 60°. That the orientation of the fucosyl group in this disaccharide (**14**) is nearly the same as in the Lewis-a trisaccharide (**15**) is inferred by the small difference (0.05 ppm) in the chemical shifts for H-1^c. It seems probable that the conformation of **14** is nearly the same as that for this unit in **15** both for this reason and, as will be considered below, the more pronounced deshielding of H-5^c in **15**.

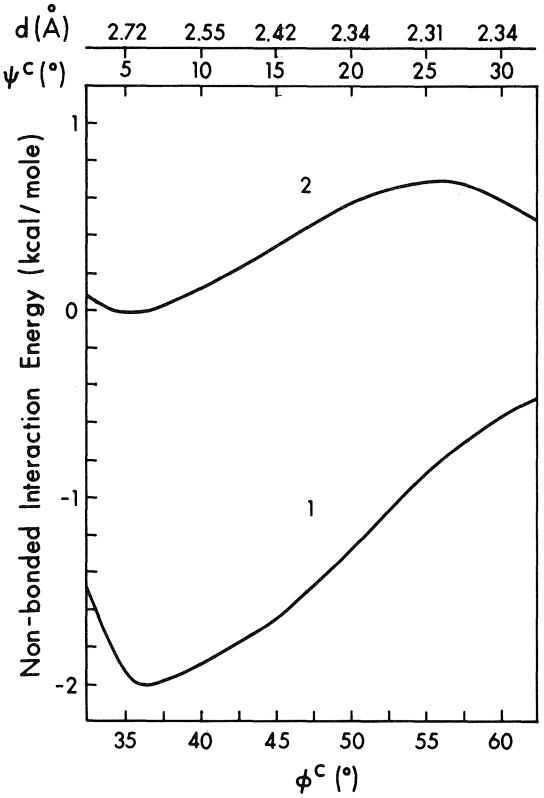

FIG. 5. Changes in non-bonded interaction energy with changes in the ϕ^c and ψ^c torsion angles for the αLFuc(1→4)-βDGlcNAc disaccharide (**14**). Plot 1 indicates the change in total non-bonded interaction energy and plot 2 shows the contribution to the total change in non-bonded interaction energy made by the interaction between O-3^a and H-5^c. The internuclear distances (d) between these atoms are presented above with the ψ^c torsion angles calculated to be the energetically most favorable at the various ϕ^c torsion angles.

In order to estimate by HSEA calculations which conformation appears most favorable for the Lewis-a trisaccharide (**15**), it was assumed that the fucosyl group would have an orientation within the above-set range for the disaccharide (**14**). The energetically most favorable conformation that was obtained had ϕ^b = 50°, ψ^b = 20° and ϕ^c = 55°, ψ^c = 25° (see Fig. 6). It seemed remarkable that the values for ϕ^b and ψ^b are those which appeared most favorable for the component βDGal(1→3)-βDGlcNAc disaccharide (**1**) (see Fig. 2).

Judging from Fig. 5, values of ϕ^c = 40°, ψ^c = 10° would be expected to be favorable for the trisaccharide (**15**) since these parameters seemed favorable for the parent disaccharide (**14**). However, on

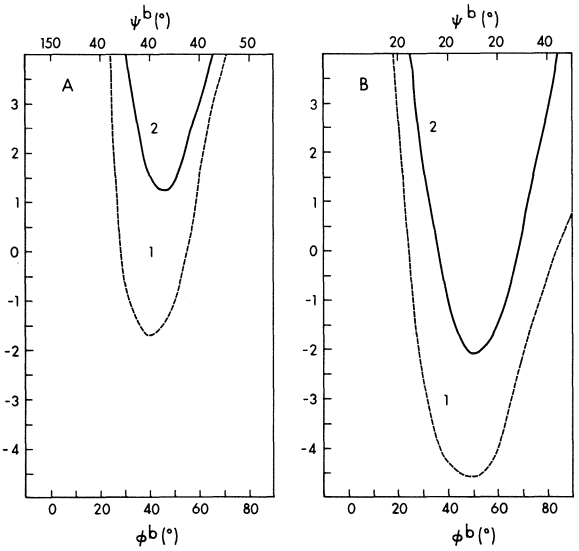

FIG. 6. Changes in energy with changes in ϕ^b and ψ^b torsion angle for the βDGal(1→3)[αLFuc(1→4)]βDGlcNAc (Lewis-a) trisaccharide (**15**) with ϕ^c and ψ^c set in *A* at 40° and 10° (*A*) and in *B* at 55° and 25°. Plots 1 indicate the calculated non-bonded interaction energies and plots 2 indicate the energy contents obtained by addition of the influence of the *exo*-anomeric effect (Table 1). The ψ^b values are those calculated to be the energetically most favorable at the various ϕ^b values.

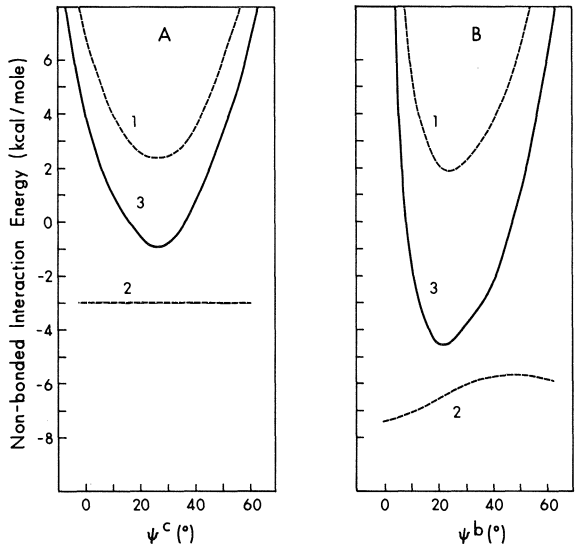

FIG. 7. Changes in non-bonded interaction energies; *A*: with changes in ψ^c for the αLFuc(1→4)βDGlcNAc disaccharide (**14**) with ϕ^c set at 55°, and *B*: with changes in ψ^b for the βDGal(1→3)[αLFuc(1→4)]βDGlcNAc (Lewis-a) trisaccharide (**15**) with ϕ^b, ϕ^c, and ψ^c set at 50°, 55°, and 25°, respectively. Plots 1 show the changes in repulsive interactions, plots 2 indicate the changes in attractive interactions, and plots 3 are the sums of plots 1 and 2.

using these values to calculate the most favorable conformation for **15**, the conformation (see Fig. 6*A*) with $\phi^b = 50°$ and $\psi^b = 40°$ has an energy content 3.5 kcal/mol greater than the above-mentioned $\phi^b = 50°$, $\psi^b = 20°$, $\phi^c = 55°$, $\psi^c = 25°$ conformer (see Fig. 6*B*). This significant difference in energy arose from a net decrease (0.5 kcal/mol) in attractive interactions and a net increase (3 kcal/mol) in repulsive interactions. These calculations form an interesting example of how the branching of an oligosaccharide chain from vicinal positions of the branching sugar unit can result in substantial interaction between the two branched sugar units and likely has a bearing, as mentioned above, on the chemical shifts of the aglyconic carbon atoms.

The plots in Fig. 7 provide an indication of how attractive forces can influence conformational preference. Plot 7*A* shows that for the disaccharide (**14**) with $\phi^c = 55°$, changes in the ψ^c angle had little influence on the attractive interactions. However, as seen in plot *B*, with ϕ^c, ψ^c, and ϕ^b set at 55°, 25°, and 50°, respectively, the branched trisaccharide **15** shows a change in net attractive forces of nearly 1 kcal/mol for a change in ψ^b from 20° to 40°. Thus, as will be seen below, although repulsive interactions between H-5^c and both O-3^a and O-5^b are expected to exist, adoption of the $\psi^b = 20°$ orientation appears to set up attractive interactions between the α-fucosyl and β-galactosyl residues that can effectively compensate for the additional repulsive interactions.

In view of the foregoing, the conformation $\phi^b = 50°$, $\psi^b = 20°$, $\phi^c = 55°$, $\psi^c = 25°$ (Fig. 7*B*) is taken as well representative of that most favorable for the Lewis-a trisaccharide (**15**). In this conformation, both O-3^a and O-5^b are expected to have internuclear distances with H-5^c calculated to be in the range 2.3 to 2.5 Å. The resulting interaction of H-5^c with the lone-pair electrons of O-3^a and O-5^b would be near one kcal/mol. This presumably accounts for the strong deshielding (0.83 ppm) observed for H-5^c relative to H-5 of methyl α-L-fucopyranoside (**10**) and why this atom is more deshielded than it is in the related disaccharide (**14**) where the chemical shift would be influenced intramolecularly by O-3^a only.

It is seen from Table 9 that the chemical shifts for H-1^c and H-5^c are, within experimental error, the same for the Lewis-a (**15**) and Lewis-b (**17**) determinants. Therefore, it could be concluded that the conformation of the Lewis-a trisaccharide is maintained in the Lewis-b determinant which contains an additional α-fucosyl group. It may be noted in this regard that the heterogeneous population of

antibodies raised against an artificial antigen formed from the Lewis-b tetrasaccharide determinant (3) cross-reacted extensively with the Lewis-a trisaccharide determinant. This observation requires similarities in the conformations of the Lewis-a and -b determinants as is indicated by the nmr data (Table 9).

Since the chemical shifts for H-1^c and H-5^c are very nearly the same for the Lewis-a (**15**) and Lewis-b (**17**) oligosaccharides (see Table 9) and $\phi^b = 50°, \psi^b = 20°, \phi^c = 55°, \psi^c = 25°$ were expected to well represent the conformation for the Lewis-a portion of **17**, the orientation of the second α-fucosyl group (ring d) in **17** was calculated using these conformational parameters. The results of these HSEA calculations are plotted in Fig. 8*A*. It is seen that the most favorable conformation is predicted to have $\phi^d = 40°$ and $\psi^d = 20°$. The plot shows that a ϕ^d torsion angle of 55° is strongly prohibited. As already discussed, the core disaccharide, βDGal(1→3)βDGlcNAc (**1**) has the acetamido group in very close proximity to O-2^b of the βDGal unit. Therefore, it was to be expected that the energy barrier in the range of φ angles of 40° to 60° in the case of the Lewis-b tetrasaccharide (**17**) arose mainly because of non-bonded interactions between the acetamido group and the α-L-fucosyl group which is attached to O-2^b. Indeed, as seen from Fig. 8*B*, this barrier was not present when HSEA calculations were made for the simple H-disaccharide (**18**). However, as for the Lewis-b tetrasaccharide, the most favorable value for ϕ^d remained in the region of 40°. This low value as compared to $\phi^c = 55°$ for the other α-L-fucosyl group in **17**, appears to arise because of interaction between H-1^d and O-3^b. That is, with $\phi^d = 40°$, the H-1^d to O-3^b interaction was calculated to be 0.3 kcal/mol as compared to 3 kcal/mol with $\phi^d = 55°$. It is noteworthy at this point that the orientation of this α-L-fucosyl group is influenced by interactions between both H-1^d and O-3^b and H-5^d and O-3^a. Movement to reduce the H-1^d to O-3^b interaction increases the other. Thus, the Le^d determinant (**16**) may be expected to have a particularly well defined conformation. As a consequence of these interactions with oxygen atoms, H-1^d and H-5^d would be expected to be deshielded. Certainly, as seen from Table 9, H-5^d in both the Lewis-d (**16**) and Lewis-b determinants (**17**) is significantly deshielded (0.3 ppm) as compared to the chemical shift of H-5 in methyl α-L-fucopyranoside (**10**). The occurrence in **17** of H-1^d at 5.39 ppm as compared to 5.25 ppm for H-1^c is more difficult to appreciate but is in line with extra deshielding of H-1^d by O-3^b. However, in this case, the difference in non-bonded interactions about the anomeric center is expected to be

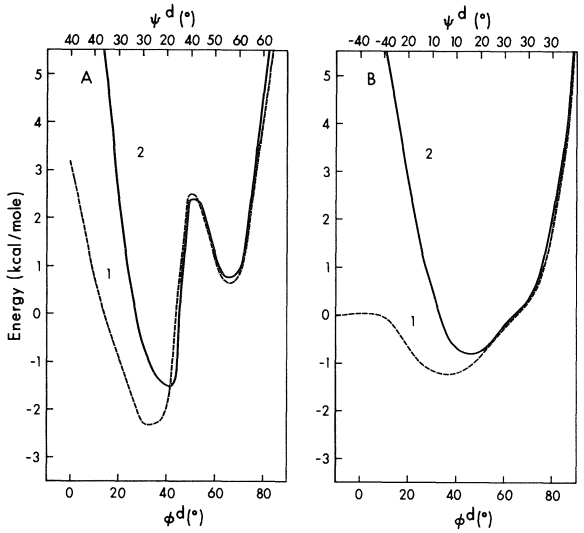

FIG. 8. Changes in energy with changes in ϕ^d and ψ^d; *A*: for the αLFuc(1→2)βDGal(1→3)[αLFuc(1→4)]βDGlcNAc (Lewis-b) tetrasaccharide (**17**) and setting ϕ^b, ψ^b, ϕ^c, and ψ^c at 50°, 20°, 55°, and 25°, respectively; and *B*: for the αLFuc(1→2)βDGal disaccharide (**18**). Plots 1 provide the changes in non-bonded interaction energy and plots 2 provide in each case the changes in energy obtained by adding the contribution expected to be made by the *exo*-anomeric effect (Table 1) to plots 1.

significant and may have an appreciable effect. It is remarkable in this regard that both C-1^d and H-1^d produce their signals at lower field than C-1^c and H-1^c, respectively.

In view of the above-noted expectation that the orientation of the αLFuc residue of the H-disaccharide (**18**) is well buttressed into position, it was of interest to compare the results of HSEA calculations for the Le^d-trisaccharide (**16**) obtained on setting $\phi^d = 40°$ and $\psi^d = 20°$ (the favorable orientation (Fig. 8) for the fucosyl group of **18**) with the results obtained on setting $\phi^b = 50°$ and $\psi^b = 20°$ (the favorable orientation (Fig. 2*A*) for the galactosyl group of **1**). The results of these calculations are presented in Fig. 9. A comparison of the plots shows that for $\phi^d = 40°, \psi^d = 20°$, the conformation with $\phi^b = 60°, \psi^b = 20°$ (see Fig. 9*B*) appears very considerably more favorable than that for $\phi^b = 50°, \psi^b = 20°$ (see Fig. 9*A*). Returning to Fig. 6*B*, it is seen that the choice of $\phi^b = 50°, \psi^b = 20°$ instead of $\phi^b = 60°, \psi^b = 20°$ as representing the most favorable conformation for the Lewis-a trisaccharide (**15**) rested on a difference of only about 0.5 kcal/mol. Since a difference of this magnitude in the present context must be considered as insignificant, there can be no basis for revising the conformation of the Lewis-a trisaccharide on this account. However, the influence of the values for ϕ^b and ψ^b on the Lewis-d trisaccharide (a matter of 2 kcal/mol, see Fig. 9*B*), made interesting a comparison of the total

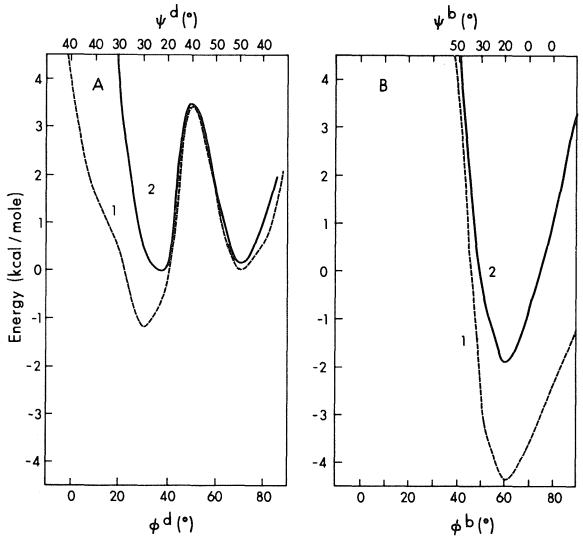

FIG. 9. Changes in energy with changes in values for ϕ^b, ψ^b, ϕ^d, and ψ^d for the αLFuc(1→2)βDGal(1→3)βDGlcNAc (H-Type 1 or Lewis-d) trisaccharide (**16**); *A*: for changes in ϕ^d and ψ^d with ϕ^b and ψ^b set at 50° and 20°, respectively; and *B*: for changes in ϕ^b and ψ^b with ϕ^d and ψ^d set at 40° and 20°, respectively. Plots 1 provide the changes in the non-bonded interaction energies and plots 2 provide the changes in energy obtained on adding to plots 1 the contribution expected to be made by the *exo*-anomeric effect (Table 1).

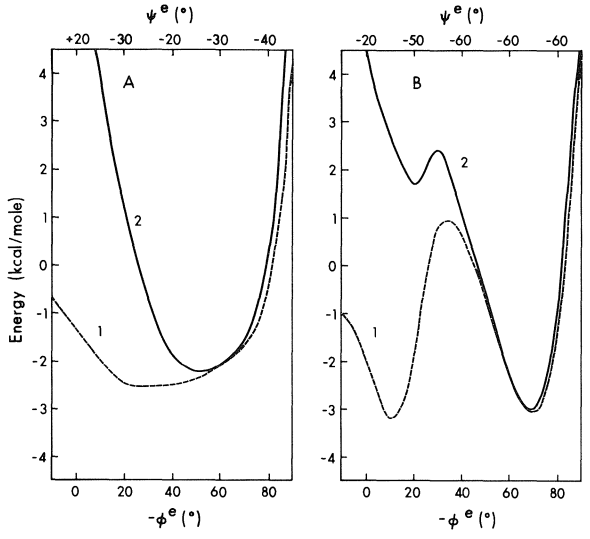

FIG. 10. Changes in energy with changes in values for ϕ^e while keeping ϕ^d = 40° and ψ^d = 20°; *A*: for the αDGalNAc(1→3)-βDGal (**19**) and αDGal(1→3)βDGal (**20**) disaccharides (the A(B) disaccharides); and *B*: for the αLFuc(1→2)[αDGalNAc-(1→3)]βDGal (**21**) and αLFuc(1→2)[αDGal(1→3)]βDGal (**22**) trisaccharides (the A(B) trisaccharides). Plots 1 and 2 are the results of the hard-sphere and HSEA calculations, respectively.

energy contents for the Lewis-b tetrasaccharide in the two conformations. These were found to be −8.6 kcal/mol for $\phi^b = 50°$, $\psi^b = 20°$, $\phi^c = 55°$, $\psi^c = 25°$, $\phi^d = 40°$, $\psi^d = 20°$, and −9.9 kcal/mol for $\phi^b = 60°$, $\psi^b = 20°$, $\phi^c = 55°$, $\psi^c = 25°$, $\phi^d = 40°$, $\psi^d = 20°$. This difference in energy could be traced to interactions between the α-L-fucosyl (d) group and the acetamido group of the a-unit, mainly interactions involving H-3^d. Since the orientation of the acetamido group was arbitrarily set, no significance is attached to this difference. The change of ϕ^b from 50° to 60° would provide an increase of the H-5^c to O-5^b distance by 0.17 Å. This matter was not investigated further since the difference in conformation is considered to be too slight to be of consequence to this present work.

The conformation of the Lewis-b tetrasaccharide is illustrated by the projection formula presented in Scheme 1 (units a, b, c, d). It is seen that the two fucosyl residues are expected both to extend above the β-sides of the βDGal(1 → 3)βDGlcNAc core chain and in near van der Waals contact since the internuclear distances between H_3C-6^c and H_3C-6^d and between H_3C-6^c and O-5^d are expected to be near 4.3 and 3.9 Å respectively. This latter interaction and that between H_3C-6^d and O-3^a (which are separated by nearly 4.1 Å) are likely responsible for the signals for C-6 methyl groups of the fucosyl groups in the Lewis-b tetrasaccharide (**17**) being slightly but significantly to lower field (see Table 9) than the signals for these groups in the Lewis-a (**15**) and Lewis-d (**16**) trisaccharides. Examination of the $\delta_{17} - (\delta_{15} - \delta_{16})$ values presented in Table 9 shows that the ^{1}Hmr spectrum for the Lewis-b tetrasaccharide (**17**) is in good accord with that which would be anticipated ($\delta_{15} + \delta_{16}$) from the spectra of the related trisaccharides. The agreement is not as good in the case of the ^{13}Cmr spectra. This is not surprising in view of the evidence presented above that these chemical shifts are highly sensitive to even slight changes in the valence angles.

The energies calculated for conformations for the A and B disaccharides with the same φ and ψ angles were essentially identical. This is understandable since, as can be appreciated from the conformational formulas shown in Scheme 1, all energetically plausible conformations have the 2-substituent (R′) of the α-D-*galacto* (e) residue directed away from the other sugar units. Therefore, to simplify the presentation, these structures will be considered together and termed the A(B) oligosaccharides.

As seen from Fig. 10*A*, hard-sphere calculation would allow a broad range of ϕ^e and ψ^e angles (plot 1) for the A(B) disaccharide. The range is reduced to −40 to −70° (plot 2) by introducing the *exo*-anomeric effect. Therefore, unless the *exo*-anomeric effect has a much stronger influence in the range 60° ± 15° than that provided in Table 1,

substantial conformational flexibility about the glycosidic linkage can be expected.

It was concluded above that the Le^d-trisaccharide (**16**) has the α-L-fucosyl group in the orientation $\phi^d = 40°$ and $\psi^d = 20°$. These values were used to calculate the ϕ^e energy profile plotted in Fig. 10*B* for the A(B) trisaccharides (**21** and **22**). Comparison of plots 1 in Fig. 10 shows that the introduction of the α-L-fucosyl group to form the trisaccharide introduced an important barrier to rotation with the maximum at near $\phi^e = -40°$. In the absence of an influence by the *exo*-anomeric effect, energy minima at both $\phi = -10°$ and $-70°$ would be expected. However, on completing the HSEA calculation to provide plot 2 of Fig. 10*B*, it is seen that the conformation $\phi^d = 40°$, $\psi^d = 20°$, $\phi^e = -70°$, $\psi^e = -60°$ is expected to be strongly favorable for the trisaccharides **21** and **22**. Fig. 10*B* is an interesting example of how the *exo*-anomeric effect can seriously influence a decision based on hard-sphere calculations only.

Furthermore, it appears useful (see Table 10) to compare the ^{1}Hmr parameters for the B-tetrasaccharide (**24**) with those of the two component trisaccharides; namely, the Le^d-trisaccharide (**16**) and the B-trisaccharide (**22**). It is at once seen that the spectrum for **24** can be anticipated quite well from those observed for **16** and **22**. As mentioned above with regard to the Le^b determinant (Table 9), ^{13}Cmr chemical shifts are not expected to be well anticipated by this procedure. Nevertheless, the agreement between the anticipated spectrum ($\delta_{16} + \delta_{22}$) and that found for **24** is noteworthy.

The results achieved in terms of nuclear Overhauser enhancements (nOe) and the coupling of ^{13}C to ^{1}H atoms over three bonds and involving the anomeric hydrogen of the α-linked residues c, d, and e of Scheme 1 lend strong support to the conclusions reached above regarding the conformation of the structures listed in Scheme 1. These experiments could be conducted since the H-1 signals are well separated from the other signals in the spectra and these equatorial hydrogens are essentially free of interactions with other intraunit hydrogens except for the neighboring H-2 atoms. Furthermore, the availability of FT high field nmr spectrometers renders routine the reliable detection of nOe's of as little as 2% of the normal intensity of the signal under the conditions of the measurement.

Measured nOe effects are highly sensitive to a number of experimental factors including concentration, the presence of paramagnetic substances, the complexity and nature of the molecule under investigation, and the measurement itself. Therefore, the absolute value of a nOe is not in itself significant except in the sense that a strong observed nOe requires a close proximity of the two hydrogen atoms. However, the relative values of nOe's for two or more hydrogens within the same molecule and obtained at the same time through the irradiation of a specific hydrogen atom are significant in the sense that hydrogen which has the greatest nOe must, on the average, be closer to the hydrogen that was irradiated. Thus, although the absolute value is only of qualitative value, the ratios of nOe's measured at the same time are of at least semiquantitative value.

As seen from Table 11, significant enhancements of the H-2 atoms were observed on irradiation of the neighboring H-1 atoms. This is in keeping with the fact that these two atoms are separated by only 2.36 Å. These enhancements therefore can serve as an internal standard for interpreting the nOe's observed for other hydrogens which showed enhancement. As seen from Table 11, the ratios of the nOe's observed for H-2^c and H-4^a (the hydrogen at the aglyconic carbon (termed H-A) of the αL-Fuc(c) units of the Lewis-related oligosaccharides, **14**, **15**, and **17**) are nearly the same as those found for H-3^a of **1**. These results require that these H-A hydrogen atoms are nearly the same distance from H-1 and, in view of the constancy of the chemical shifts observed for both H-1 and C-1 for these compounds, the indication is clear that the orientation of this unit (c) is the same for the Le-disaccharide (**14**), the Le^a trisaccharide (**15**), and the Le^b tetrasaccharide (**17**). Furthermore, the HSEA calculations place H-1^c and H-4^a at an internuclear distance of 2.68 Å in accord with the general trend of the relative nOe's. Also, the HSEA calculations place H-1^c at a distance of 2.69 Å from C-6^a, a distance which would require strong interaction between H-1^c and the H-6^a and H-$6'^a$ atoms. The observation of a readily measurable nOe for the H-$6'^a$ atom (that which is strongly coupled to H-5^a) supports this conclusion. Furthermore, the relaxation time of H-1^c is 0.41 s as compared to that (0.60 s) for H-1^d which requires a greater proton density about H-1^c, namely, the proximity of the H-6^a atoms. Finally, it was noted from the HSEA molecular model that H-5^c should be only 2.40 Å from H-2^b. Therefore, selective irradiation of H-5^c (which was readily possible because of its deshielding by O-3^a and O-5^b) could be expected to provide an nOe for H-2^b of nearly the same magnitude as that expected for the *syn*-clinal H-4^c which is separated from H-5^c by 2.45 Å. In fact, irradiation of H-5^c caused enhancements of 6% for H-2^b and 5% for H-4^c. The *syn*-axial H-3^c which is estimated to be 2.67 Å from H-5^c was enhanced by 4%.

The HSEA calculations indicate internuclear

24				4	4	4				5	3(4)[c]	—[d]

[a]The term H-A is used for the proton at the aglyconic carbon. The relevant interatomic distances estimated by HSEA calculations are provided in the text.
[b]Nuclear Overhauser enhancements of 2 and 5% were observed for H-6[a] and H-6'[a], respectively.
[c]Nuclear Overhauser enhancements presented in parentheses are those for H-4[b].
[d]Coupling was not detectable (< 1.5 Hz).
[e]An nOe of 4% was observed for H-3[e].

distances for H-1[d] and H-2[b] of 2.44 Å and, therefore, the nOe for H-2[b] would be expected to be about the same as that for H-2[d] on irradiation of H-1[d]. It is seen from Table 11 that this was indeed the case for all the compounds which contain the αLFuc(d) unit. Furthermore, the ψ^c angles for the αLFuc(c) units was estimated to be 25° and somewhat greater than the ψ^d torsion angle of 20° estimated for the compounds with αLFuc(d) units. Therefore, it could be expected (7, 8) that these latter compounds would possess somewhat greater values for the anomeric carbon to aglyconic hydrogen coupling constants than for the former αLFuc(c) units. It is seen from Table 11 that the general trend of coupling constants is in accord with this expectation.

The HSEA calculations predict the rather remarkable $\phi = -70°$, $\psi = -60°$ for the e-units (βDGalNAc or βDGal). On the basis of the general trends observed for $^3J_{C,H}$ coupling constants, the $^3J_{C\text{-}1^e,H\text{-}3^b}$ values would be expected to be small in comparison to either the $J_{C\text{-}1^c,H\text{-}4^a}$ or $J_{C\text{-}1^d,H\text{-}2^b}$ values. As seen from Table 11, this was the case. Furthermore, the ratios of the nOe's for the H-2[e] to H-3[b] atoms on irradiation of H-1[e] appear definitely greater than for the similar situations involving the αLFuc(d) units. This is in accord with the calculated greater separation of the H-1[e] to H-3[b] atoms (3.19 Å) than the H-1[d] to H-2[b] atoms (2.44 Å). Furthermore the HSEA molecular models place the H-1[e] atom 2.17 Å from the H-4[b] atom. Thus, the very significant nOe's observed for the H-4[b] atoms noted in Table 11 are in further accord with the calculated structure. Also, in the case of the A trisaccharide (**21**) a significant nOe of H-3[e] was observed on irradiation of H-1[d]. In accord with this, the molecular model predicts an internuclear distance of 2.47 Å for these two atoms. Finally, in this regard, it is of interest to examine the effects on the internuclear distances for the anomeric and aglyconic hydrogens of changing the ϕ and ψ torsion angles presented in Scheme 1 by ±5° since these torsion angles cannot be expected to have been estimated more accurately than within this range. For ϕ^c and ψ^c in the ranges 55 ± 5° and 25 ± 5°, the H-1[c] to H-4[a] distance is in the range 2.68 ± 0.11 Å. Similarly for the ϕ^d,ψ^d and ϕ^e,ψ^e torsion angles, variations of ±5° provided internuclear distances of 2.48 ± 0.10 Å and 3.19 ± 0.11 Å. These relative distances are in accord with the relative nOe's observed and these considerations stress that the torsion angles presented in Scheme 1 must be interpreted with considerable latitude.

In summary, the above-noted correlations based on ^{13}C- and ^1H-chemical shifts, $^3J_{H,H}$ and $^3J_{C,H}$ coupling constants, T_1 and nOe measurements appear to well justify the conformations for the various oligosaccharides presented in Scheme 1. Therefore, it is concluded that the simple HSEA approach to the anticipation of the preferred conformation of oligosaccharide structures may find a useful role in the conformational analyses of these biologically important structures. In contrast to the approaches based on *ab initio* force field calculations (24, 32), the computing costs are readily met. Also, the HSEA calculations are conceptually simple and manageable by most practising chemists and offer the important advantage of bringing to the experimentalist an appreciation in semiquantitative fashion of the specific non-bonded interactions which dominate the situation. Furthermore, once

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

the coordinates for the various atoms are placed in the computer memory, the approach provides a simple access to spatial characteristics of the model which may be of interest to structure – biological activity correlations which is much superior to consideration of space-filling molecular models only. On the other hand, it must be kept well in mind that the approach at this time is not rigorous in many regards and conclusions drawn from such calculations must be treated accordingly.

Experimental

^{1}Hmr spectra were obtained at 310 K in D_2O unless otherwise stated, on a Bruker HX-270 instrument operating at 270 MHz. The use of a spectral width of 3 kHz, with a data memory of 64 K gave a digital resolution of ±0.1 Hz. The pulse width used was 15μs (90°). Acetone 1% was used as internal reference (δ = 2.480). Assignments were done using (*a*) double resonance experiments in connection with partial relaxed spectra (35), (*b*) observing carbon spectra with selective proton irradiation (^{1}H chemical shifts determined by this method are given in italics), and (*c*) nuclear Overhauser enhancement experiments (36).

Relaxation data were obtained by the inversion recovery method using the initial slope approximation, and the T_1-values determined from a semilogarithmic fit and from an exponential fit to all the relaxation data using the expression given by Saas and Ziessow (37). The agreement between these two was in general within 5% which was also considered the experimental error. This indicates that it is reasonable to assign a single exponential behavior to the relaxation of a given proton.

^{13}Cmr spectra were obtained at 310 K in D_2O on the same instrument operating at 67.89 MHz. The use of a spectral width of 10 kHz with a memory of 32 K gave a digital resolution of ±0.6 Hz. The pulse width used was 12 μs (90°). Dioxane 1% was used as internal reference (67.40 ppm). Assignments were done using (*a*) selective proton irradiation, (*b*) coupled carbon spectra, and (*c*) isotope effects (38).

The T_1 values were obtained at 22.63 MHz on a Bruker WH-90 instrument using the inversion recovery method. This field was used in order to avoid heating of the ionic samples which occur at the high field (39).

*Methyl 2-Amino-2-deoxy-3-O-(2-amino-2-deoxy-β-D-glucopyranosyl)-β-D-glucopyranoside (***3b***)*

The compound was prepared following the procedure described (25) for the preparation of the corresponding 2,2,2-trichloroethyl glycoside (**3a**). The only appreciable difference was in the separation of the diphthalimido derivative of **3** from inorganic salts. Since this intermediate was soluble in water, the neutralized aqueous solution was taken to dryness and the diphthalimido compound was extracted from the residue using boiling acetone. The crude product resisted crystallization and was converted directly to **3** by treatment with hydrazine in the usual manner. Pure amorphous **3**, $[\alpha]_D^{25}$ −25.8° (water) as the diamine was obtained by chromatography on a column of Dowex 1 × 8 resin (hydroxide form). *Anal.* calcd. for $C_{13}H_{26}N_2O_9$: C 44.04, H 7.40, N 7.91; found: C 43.51, H 7.30, N 8.18.

The ^{13}Cmr spectrum (Tables 2 and 4) required a high state of purity. The ^{1}Hmr spectrum (Table 4) measured at 270 MHz was virtually first-order and in complete accord with the assigned structure.

In order to prepare the dihydrochloride salt of **3**, an aqueous solution was taken to pH 1 with hydrochloric acid and the resulting solution was freeze-dried to a highly deliquescent amorphous powder; $[\alpha]_D$ −16.9° (water).

Acknowledgements

The nmr studies reported herein were made possible by the availability of the required oligosaccharides by chemical syntheses. Dr. D. A. Baker, Dr. Y. Fouron, and Dr. Z. Abbas synthesized the B di- and trisaccharides. Dr. Z. Abbas and Dr. Y. Fouron accomplished the synthesis of the B-tetrasaccharide. Dr. R. M. Ratcliffe synthesized the A blood-group related structures as well as the derivative of lactosamine. The details of these fine synthetic accomplishments will be reported separately. Mr. P. Senn and Mr. K. Kong provided valuable assistance in terms of programming and computer services.

The authors are extremely grateful and wish to thank all of the above-mentioned colleagues for very special cooperation in these matters.

The financial support of the National Research Council of Canada (A172) and the Medical Research Council of Canada (SP-3) through grants to R. U. Lemieux and valuable cooperation provided by Chembiomed Ltd. are gratefully acknowledged.

The microanalyses and 100 MHz nmr spectra were carried out by the analytical and spectral service laboratories of this department.

The high field Bruker HX-270 NMR instrument was provided by the Danish Natural Science Research Council.

^{13}C and ^{2}H spin–lattice relaxation in solid adamantane

RODERICK E. WASYLISHEN AND BRIAN A. PETTITT

Department of Chemistry, University of Winnipeg, Winnipeg, Man., Canada R3B 2E9

Received October 25, 1979

RODERICK E. WASYLISHEN and BRIAN A. PETTITT. Can. J. Chem. **58**, 655 (1980).

Spin–lattice relaxation times for the ^{13}C nuclei of adamantane and the ^{2}H nuclei of adamantane-d_{16} are reported for most of the temperature range of the solid I (plastic) phase, and for the solid II phase just below the transition point. Angular correlation times are shown to be in good agreement with those previously obtained from proton nmr data by Resing.

RODERICK E. WASYLISHEN et BRIAN A. PETTITT. Can. J. Chem. **58**, 655 (1980).

On rapporte les temps de relaxation spin–réseau du noyau ^{13}C de l'adamantane et du noyau ^{2}H de l'adamantane-d_{16} pour la plupart des intervalles de température de la phase solide I (plastique) et de la phase solide II juste en dessous du point de transition. On montre que les temps de corrélation angulaire sont en parfait accord avec ceux obtenus antérieurement par Resing à partir de données de la rmn du proton.

Introduction

Adamantane (tricyclo[3,3,1,1,^{3,7}]decane, $C_{10}H_{16}$) figures centrally in the experimental and theoretical investigation of orientational disorder in crystals (1,2). The solid II → solid I phase transition at 208.6 K (ΔS = 1.95 R) (3) is complicated by hysteresis but can be grossly characterized as a tetragonal → face-centred cubic transformation accompanied by a 9% increase in volume and substantial thawing of rotational modes (4). The molecules in phase I are thought to be randomly distributed between two distinguishable orientations connected by rotations through $\pi/2$ about the cubic four-fold axes (Fig. 1), and a study of the neutron incoherent elastic structure factor (5) concluded that the dynamics of the disorder are probably dominated by jumps about these axes. A recent study of coherent inelastic neutron scattering from a single crystal of $C_{10}D_{16}$ at 293 K (6) revealed that heavily damped collective librations are also present on the scale of 25 times the jump frequency.

Rotational and translational jump times for phases I and II were measured by Resing (7) via a thorough investigation of proton nmr relaxation rates. In a previous article (8) on another disordered crystal (succinonitrile), we showed that the conventional proton-decoupled ^{13}C inversion–recovery experiment (and, to a lesser extent, ^{14}N linewidths) can be an efficacious means of determining jump times. In this article, we report correlation times for the solid I states of $C_{10}H_{16}$ and $C_{10}D_{16}$ determined by an investigation of the ^{13}C and ^{2}H resonances.

Experimental

Adamantane (99+%, Gold Label) was obtained from the Aldrich Chemical Company and adamantane-d_{16} (98 at% D) from Merck, Sharp, and Dohme.

^{13}C nmr spectra were measured at 20 MHz on a Varian CFT-20 spectrometer equipped with an 8 mm variable temperature probe, using polycrystalline samples and a coaxial tube for the acetone-d_6, D_2O, or methyl sulphoxide-d_6 deuterium lock material. Typically, 30 to 60 scans were accumulated using acquisition times of 0.5 s to 1.0 s, sweep widths of 2 kHz, and an rf decoupling field ($\gamma B_2/2\pi$) of about 4.5 kHz. ^{2}H spectra of adamantane-d_{16} were measured at 13.81 MHz on a Bruker SXP pulsed spectrometer. All T_1's were obtained by a nonlinear least squares analysis (9) of the standard inversion–recovery pulse sequence. The $\pi/2$ pulse was 16 μs for the ^{13}C measurements and 6 μs for the ^{2}H measurements. The temperature was maintained with an accuracy of ±2 K by a nitrogen gas flow.

Results and Discussion

The methine (CH) ^{13}C resonance is 184 Hz to high field of the methlyene (CH_2) ^{13}C at 20 MHz and proton-decoupling reduces the linewidths from

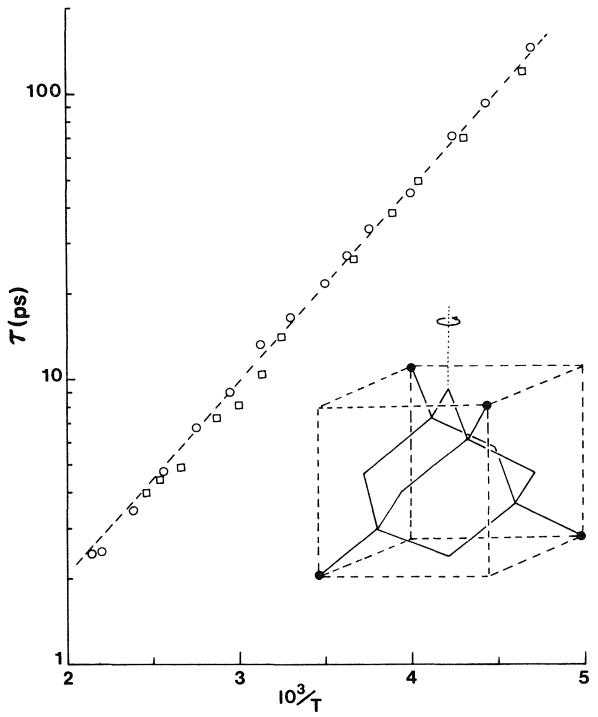

FIG. 1. Temperature dependence of angular correlation times in the solid I phase of adamantane: squares, ^{13}C data for $C_{10}H_{16}$; circles, ^{2}H data for $C_{10}D_{16}$; broken line, representation of the ^{1}H data of ref. 7. The inset shows one of the two distinguishable orientations of adamantane and one of the cubic four-fold axes.

1.1 kHz to approximately 40 Hz in the solid I phase, thus producing a well-resolved pair of lines throughout this phase. T_1's for the naturally abundant ^{13}C's of polycrystalline $C_{10}H_{16}$ are listed in Table 1 along with methine–methylene T_1 ratios and effective angular correlation times. The τ's were calculated from the $T_1(CH_2)$'s under the assumption that dipolar coupling with the bonded (1.09 Å) and nearest neighbour (2.16 Å) protons, modulated by isotropic rotation, dominates the relaxation (10), a procedure that is supported by an observation of full nuclear Overhauser enhancement factors (11) and satisfactory agreement between the average $T_1(CH)/T_1(CH_2)$ ratio (1.72) and the theoretical value (1.85). The temperature dependence of both T_1's is characterized by an activation energy, E_a, of 3.2 kcal/mol, and the τ's are shown in Fig. 1 to be in good agreement with those determined by proton nmr (7). The two values of τ for the solid II phase are also in agreement with the proton data, but at lower temperatures resolution of the lines is precluded by broadening characteristic of the "non-extreme narrowing" region.

Deuterium quadrupolar T_1's for the solid phase of $C_{10}D_{16}$ are listed in Table 2 along with angular correlation times derived from them assuming that the quadrupolar coupling constant, e^2qQ/h, is 174 kHz (the value in cyclohexane) and that the assymmetry parameter is negligible (10). Good agreement of these τ's with the ^{13}C and ^{1}H data is illustrated in Fig. 1. The τ's of $C_{10}D_{16}$ are systematically a little longer than those of $C_{10}H_{16}$, as the larger moment of inertia (24%) would lead one to expect, but the observed differences are within the uncertainties in the experimental data and e^2qQ/h.

It is worth noting that if the high symmetry of the adamantane system is broken by substituents, orientational disorder persists. Differential scanning calorimetry experiments (12) have indicated the existence of disordered phases in the 1-haloadamantanes and molecules with from one to four methyl groups. We have examined the ^{13}C nmr spectra of several 1-substituted adamantanes, showing that the 1-amino species is disordered at room temperature, and that 1-hydroxyadamantane

undergoes an order ↔ disorder phase transition at 366 ± 2 K. ^{13}C relaxation times in the disordered phases of these molecules reflect a high degree of anisotropy, but we were unable to obtain a consistent account of the T_1 ratios in terms of Woessner's two-parameter rotational diffusion model (13). Perhaps anisotropic jump models along the lines of those used by Brot and co-workers (14) in the analysis of neutron scattering and nmr data for disordered quinuclidine, $HC(CH_2CH_2)_3N$, will prove to be useful in this regard, but many more experiments are needed.

Conformations of bridged diphenyls. XV. Crystal structure of (4′-carbomethoxy-2′-nitrophenoxy)benzene and the effect of intramolecular interactions in nitro substituents

RAMANATHAN GOPAL, W. DAVID CHANDLER, AND BEVERLY E. ROBERTSON[1]

Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received November 2, 1978[2]

RAMANATHAN GOPAL, W. DAVID CHANDLER, and BEVERLY E. ROBERTSON. Can. J. Chem. **58**, 658 (1980).

The structure of (4′-carbomethoxy-2′-nitrophenoxy)benzene, $C_{14}H_{11}NO_5$, has been determined by X-ray diffraction. The crystals are monoclinic, $a = 8.880(7)$, $b = 9.792(4)$, $c = 14.820(5)$, $\beta = 90.07(5)$, $P2_1/c$ with $Z = 4$. The integrated intensities of 2966 independent reflections were measured on a four-circle diffractometer, 2072 of which were used in the refinement to give a final least-squares weighted residual of 0.062 and a conventional R factor of 0.086. The absence of *ortho* substituents on one ring of the molecule allows it to adopt the twist-nitro-*distal* conformation. The lengths of the bonds from the unsubstituted ring and the substituted ring to the bridging oxygen atom are 1.409(3) and 1.353(3) Å respectively. The torsional angles about those bonds are 54.6° and 16.5°. The angle subtended at the bridging oxygen atom is 120.0(3)°.

The unusual thermal ellipsoids associated with one of the nitro oxygen atoms of this structure and with a nitro oxygen atom of three related structures occur when the nitro substituent is nearly coplanar with the phenyl ring on which it is substituted and also has a neighbouring substituent or bridging group. The unusual thermal ellipsoids then result from repulsive exchange forces.

RAMANATHAN GOPAL, W. DAVID CHANDLER et BEVERLY E. ROBERTSON. Can. J. Chem. **58**, 658 (1980).

On a déterminé par diffraction de rayons-X la structure du (carbométhoxy-4′ nitrophénoxy-2′) benzène $C_{14}H_{11}NO_5$. Les cristaux sont monocliniques $a = 8.880(7)$, $b = 9.792(4)$, $c = 14.820(5)$, $\beta = 90.07(5)$, $P2_1/c$ avec $Z = 4$. On a mesuré les intensités intégrées de 2966 réflexions indépendantes à l'aide d'un diffractomètre à 4 cycles. De ces réflexions 2072 sont affinées pour avoir une moyenne résiduelle finale des moindres carrés de 0.062 et une valeur conventionnelle R de 0.086. L'absence de substituants en position *ortho* sur un cycle de la molécule lui permet d'adopter une conformation croisée du groupe nitro le plus éloigné. Les longueurs de liaison entre les cycles substitué et non substitué et l'atome d'oxygène sont respectivement de 1.409(3) et 1.353(3) Å. Les angles de torsion autour de ces liaisons sont de 54.6° et 16.5°. L'angle sous tendu à l'atome d'oxygène en position de pont est de 120.0(3)°.

L'ellipsoide thermique peu usuel associé à l'un des atomes d'oxygène du groupe nitro de cette structure et à l'atome d'oxygène du groupe nitro de trois structures apparentées se produit quand le substituant nitro est quasi coplanaire avec le cycle phényle sur lequel il est substitué et qui a également un substituant voisin ou un groupe en position de pont. L'ellipsoide thermique peu usuel résulte alors des forces de répulsion.

[Traduit par le journal]

Introduction

We have established the important role of the *ortho* substituents of di-*ortho*-substituted phenyl rings of bridged diphenyl compounds in determining the conformation of such compounds (1–5). In particular, the steric requirements of the *ortho* substituents outweigh competing conjugative effects (6). In tri-*ortho*-substituted bridged diphenyls with bridging groups which contain more than one atom and which are strongly electronegative (SO, SO_2, CO) the conformation is twist with the mono-*ortho*-substituent *proximal*.[3] If the bridging group is weakly electron donating (CH_2) or less bulky (O and S) the conformation is skew with the mono-*ortho*-substituent *distal*. It has recently been demonstrated by Paulus that intramolecular hydrogen bonding involving the bridging group and *ortho* substituents can also fix the orientation of one of the rings (7).

In di- or tri-*ortho*-substituted bridged diphenyls which do not contain large electronegative bridging groups the main steric interactions are between *ortho* substituents on one ring and the *ortho* substituents or π-electrons on the other ring. These interactions do not necessarily exist in a mono-*ortho*-substituted bridged diphenyl and other effects such as conjugation and interaction between the single *ortho* substituent and the bridge become important. We have therefore chosen to determine the structure of the mono-*ortho*-substituted bridged diphenyl, (4′-carbomethoxy-2′-nitrophenoxy)benzene.

A number of bridged diphenyl compounds whose structure we have reported previously have contained a nitro substituent with one oxygen atom showing an unusual thermal ellipsoid. The phenomenon occurs again in (4′-carbomethoxy-2′-nitrophenoxy)benzene. We shall therefore attempt to shed some light on the origin of this phenomenon.

Experimental

(4′-Carbomethoxy-2′-nitrophenoxy)benzene was formed by

the reaction of phenol, NaOH, and methyl 4-chloro-3-nitrobenzoate. They were reacted for 20 h according to the method of Wright and Jorgenson (8) as generalized by Chandler *et al.* (9). The mp after four recrystallizations from absolute ethanol was 103.5–105.0°C. The crystals are translucent with a slight yellowish colour and have well defined faces. A sample with dimensions 0.65 mm on a side was used for data collection. The systematic absences ($h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$) and the Laue symmetry gave the space group $P2_1/c$.

The integrated intensities of 2966 independent reflections with 2θ values between 2° and 55° were measured on a Picker FACS-1 automated diffractometer using MoKα radiation with a graphite monochromator. The θ–2θ scan mode was used with a scan rate of 2° min^{-1} and a minimum base width of 2.95° in 2θ. The background was counted for 40 s at each limit of the scan. The intensities of three standard reflections were monitored after the intensities of each 100 reflections were measured and were not observed to change significantly. The centered positions of 21 reflections with 2θ values between 40° and 45° (MoKα_1) were used to calculate the cell parameters by least-squares. The estimated standard deviations given below for the lattice constants were taken directly from the least-squares calculations.

Crystal data are as follows:

$C_{14}H_{11}NO_5$ fw = 273.6
Monoclinic, $P2_1/c$; $a = 8.880(7)$, $b = 9.792(4)$, $c = 14.820(5)$ Å, $\beta = 90.07(5)°$, $\rho_o = 1.40(1)$ g cm^{-3} (flotation)$_3$, $\rho_c = 1.408$ g cm^{-3}, $Z = 4$, $F(000) = 568$ e, λ(MoKα_1) = 0.70926 Å, μ(MoKα) = 1.13 cm^{-1}, $T = 22(1)$°C.

The intensity data were reduced to observed structure factors using standard procedures. No corrections were made for the effects of absorption or extinction. The scattering factors for the carbon, oxygen, and nitrogen atoms were taken from Cromer and Mann (10). The scattering factor for the hydrogen atoms was taken from Stewart *et al.* (11). The 374 reflections with $|E| > 1.40$ were used to solve the structure using the logical symbolic addition method.[4] An E-map calculated with the non-trivial solution with the highest figures of merit yielded all carbon, nitrogen, and oxygen atoms. The structure was refined anisotropically and the hydrogen atoms were found from a difference Fourier calculation. The structure was refined further treating the hydrogen atoms isotropically. The final cycles of refinement used the 2072 reflections for which $|F_o| > \sigma(F_o)$, where $\sigma(F_o) = 1.0 + 0.01(F_o) + \sigma'(F_o)$ and where $\sigma'(F_o)$ is an estimated standard deviation based entirely on counting statistics. At this point the final value of the weighted residual R_w and the conventional R factor were 0.067 and 0.086 respectively.

It was apparent that the thermal ellipsoid for the atom O(5) was elongated normal to the plane of the nitro group which is itself nearly coplanar with the phenyl ring to which it is bonded. It was decided that an attempt should be made to examine the electron density associated with this atom in more detail. The atom O(5) was removed from the refinement and a difference Fourier map was prepared. The electron density associated with the atom O(5) showed as a ridge of electron density with a saddle point slightly lower in electron density (~10%) than the two peaks at the end of the ridge.

The electron density associated with O(5) was then represented by two half atoms, O(51) and O(52), initially positioned at the two peaks in the ridge. Refinement was continued using isotropic temperature factors for these half atoms. The final values of R_w and R were 0.062 and 0.086 respectively. The final positional and thermal parameters are given in Table 1 with estimated standard deviations. The observed and calculated structure factors have been placed in the Depository of Unpublished Data.[5] The bond lengths and angles and the atomic numbering are given in Fig. 1.

Discussion

In the closely related compound 2-(4′-carbomethoxy-2′-nitrophenoxy)-1,3,5-trimethylbenzene, the mesityl ring deviates 11.0° from being orthogonal to the plane of the central C—O—C plane and the conformation is skew-nitro-*distal* (3). In the present compound, (4′-carbomethoxy-2′-nitrophenoxy)benzene, the absence of the di-*ortho* substituents allows the equivalent ring to rotate further and the conformation is twist-nitro-*distal*. The angles between the planes of the molecule, as labelled in Fig. 2 are given in Table 2. The torsional angles [C(4)—O(1)—C(7)—C(8)] and [C(7)—O(1)—C(4)—C(5)], which correspond to the dihedral angles *2,3* and *1,2*, are ±16.5° and ±54.6° respectively. The plus and minus signs refer to the two enantiomers which must be present because the space group of the structure is centrosymmetric.

The bonds to the bridging oxygen atom differ by 0.056(5) Å which compares with 0.053(3) Å in the similar trimethyl substituted compound (3). In a previous paper (2) we have discussed the relationship between these bond length differences and the electronic properties of the substituents on the rings.

The use of two half atoms to represent the electron density at the atom O(5) decreased R_w by 0.005. Similar anomalous thermal ellipsoids have been observed previously for nitro oxygen atoms in this series of structures; in the two independent molecules of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene (1), in 2-(4′-carbomethoxy-2′-nitrothiophenyl)-1,3,5-trimethylbenzene (4), and in 2-(4′-carbomethoxy-2′-nitrobenzyl)-1,3,5-trimethylbenzene. In these four cases the refinement with half atoms replacing a single atom to represent the anomalous thermal ellipsoid was not attempted.

It has been observed previously that the O—N—O angle of *ortho*-nitro substituents in these compounds tends to increase as the dihedral angle between the NO_2 group and the phenyl ring to which it is bonded increases (16). Figure 3 shows

[4]The structure was solved using the Germain and Woolfson program LSAM (12). All Fourier calculations were carried out using the Zalkin program FORDAP (13). The Busing *et al.* program ORFLS (14) was used for least-squares refinement. Stereograms were prepared with the aid of the Johnson program ORTEP (15).

TABLE 1 (*Concluded*)

the O—N—O angle plotted against the dihedral angle for all of the compounds reported in this series.[6] The correlation between O—N—O angle and dihedral angle seems to be followed for all cases where the nitro group is *ortho* to any substituent, including the bridging group of a bridged diphenyl compound. It is not followed when there are not restrictions to the nitro group being coplanar with the phenyl ring, as in the case of the *ortho*-nitro-substituents in the two independent molecules of 2-(2′-carbomethoxy-4′-nitrophenoxy)-1,3,5-trichlorobenzene and the *para*-nitro-substituent of 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*tert*-butylbenzene (2).

The anomalous thermal ellipsoids occur in these compounds when the nitro-substituents form lower dihedral angles with the phenyl ring in spite of the presence of a neighbouring substituent or bridging group. The apparent exception is the *ortho*-nitro substituent in 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*tert*-butylbenzene. In this substituent both oxygen atoms show highly anisotropic thermal ellipsoids extended normal to the plane of the nitro group, although not as severe as in the five cases where only one oxygen atom is unusual.

The appearance of the anomalous thermal ellipsoids only in those cases where steric effects decrease the O—N—O angle suggests that repulsive exchange forces arising from contact with neighbouring substituents or bridging groups are involved in the creation of the anomalous thermal ellipsoids. In terms of potential energy maps, these forces together with the effect of conjugation between the nitro group and the ring (which restricts the rotation of the substituent) lead to a potential well, which when traversed normal to the plane of the phenyl ring, shows a broad minimum or perhaps double minima. If the barrier between those minima are large with respect to kT, then the anomalous thermal ellipsoids would represent static disorder.

In other cases it is clearly possible for the nitro

[6]For the purpose of calculating the dihedral angle between the NO_2 group and the phenyl ring and the O—N—O angle in the case of the compound reported here, the position of the single atom of unit weight representing the electron density of O(5) was used.

group to be rotated adequately out of the plane of the phenyl ring in order to avoid close contact with neighbouring groups, as, for instance, in bridged diphenyls with proximal conformations or in 2-(4′-carbomethoxy-2′-nitrophenoxy)-1,3,5-trimethylbenzene (3). Therefore, other factors must be present in those compounds in which the substituent is not rotated. The nature of the packing of the molecules might be expected to be an important factor in restricting the rotation of the substituent.

In the present structure, (4′-carbomethoxy-2′-

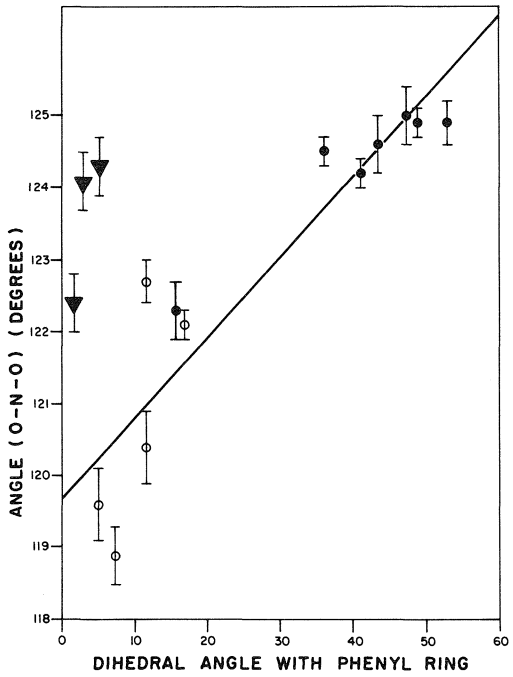

FIG. 3. O—N—O angle (deg) for nitro groups versus dihedral angle between the nitro substituent and the phenyl ring to which it is bonded. All circles represent nitro groups with neighbouring substituents or bridging groups. Open circles represent groups with an unusual thermal ellipsoid representing one of the oxygen atoms. The least-squares line is fitted to all circles. The triangles represent nitro groups with no neighbouring substituent or bridging group. The correlation coefficient is 0.92.

nitrophenoxy)benzene, the reason that the nitro group is constrained from rotation is apparent from the packing diagram as shown in Fig. 4. The nitro groups are sandwiched between the parts of two neighbouring molecules which are approximately coplanar with the nitro substituent and its phenyl ring. In other cases where the nitro substituent is nearly coplanar with its phenyl ring, in spite of the crowding from neighbouring groups, the reason is not clear. In the two independent molecules of 2-(3′-methyl-4′-nitrophenoxy)-1,3-diisopropylbenzene (1) and in 2-(4′-carbomethoxy-2′-nitrobenzyl)-1,3,5-trimethylbenzene (5) the oxygen atoms showing the anomalous thermal ellipsoids share the common feature that they face two hydrogen atoms of a neighbouring methyl group or bridging CH_2 group which straddle the plane of the phenyl ring on which the nitro group is substituted, and therefore also straddle the oxygen atom in question. It is our opinion that in all of these cases, adequate information is not available for us to predict the nature of the motion, or lack thereof, of the anomalous oxygen atom.

The possibility must be considered that the unusual behavior of the oxygen atom leads to an artificially low value for the O—N—O angle, and the true value of the angle, after corrections, is therefore relatively constant. However, in order to generate the single anomalous oxygen thermal ellipsoid, we must assume either a rotation of the NO_2 group about the N—O bond to the normal oxygen atom or a "riding motion" of the anomalous oxygen atom about the N atom which maintains a constant N—O distance to that atom (18). In both cases, the O—N—O angle is not artificially reduced by the thermal motion. In the event that the anomalous thermal ellipsoids represent static disorder, the O(51)—N(1)—O(4) and O(52)—N(1)—O(4) angles (117.4(4) and 113.7(4)° respectively) must be taken as a measure of the O—N—O angle in these circumstances, and they are lower than those used in Fig. 3, which are based on single atoms.[7]

In the compound reported here the nitro-substituents occur in pairs related by centers of symmetry. The O(5)···O(5) distance of 3.46 Å is shorter than the O···O distances involving any of the other oxygen atoms showing anomalous thermal ellipsoids, but it is greater than the van der Waals contact distance. However, the separation between the position of two symmetry-related O(51) half atoms is shorter than ver der Waals contacts at 2.52 Å. Therefore, the two O(51) positions cannot be occupied simultaneously. The two O(5) atoms related by the center of symmetry must either move concertedly or be disordered so as to violate the local center of symmetry between them.[8]

The reason for the existence of the anomalous thermal ellipsoids seems to be related to repulsive exchange forces. However, we would expect the entire nitro group to be affected, as in the case of the *ortho*-nitro-substituent in 2-(2′,4′-dinitrophenoxy)-1,3,5-tri-*tert*-butylbenzene (2) because of the rigidity of the NO_2 group. This implies a weakening (and thus a lengthening) of the bond to the anomalous oxygen atom, and a strengthening (and thus a shortening) of the bond to the normal oxygen atom.

[7]The errors quoted for bond lengths and angles were calculated with the program ORFFE (17). The true errors in the bond lengths and angles which involve the half atoms O(51) and O(52) representing the thermal ellipsoid of atom O(5) suffer from additional effects involving the inadequacies of the model and are, therefore, larger than those quoted, but by an indeterminate amount.

[8]If both atoms resided simultaneously in the position O(52), the temperature factor for O(52) should be smaller than that of O(51), which it is not.

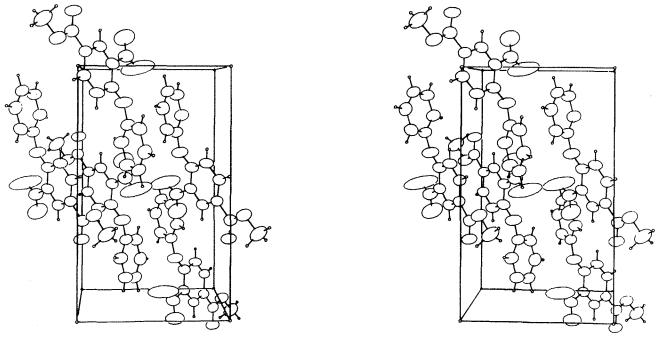

FIG. 4. Stereoscopic view of the molecular packing. The ***a*** axis points to the right, the ***b*** axis is into the paper, and the ***c*** axis points up.

In order to test this hypothesis it is necessary to use accurate bond lengths and therefore the effects of thermal motion on the bond lengths should be removed. It is difficult to make accurate corrections for thermal motion for all of the bonds involved because of the large values of the anisotropic temperature factors and because of the uncertainty as to what they really represent. The results obtained are not conclusive. Nevertheless, we suspect that the close contact between the nitro substituent and a neighbouring group cause additional changes within the molecule.

ROSEMARY C. E. DURLEY, WILLIAM L. WALTZ, and BEVERLY E. ROBERTSON. Can. J. Chem. **58**, 664 (1980).

Crystals of [Pt(Et_4dien)I]I, where Et_4dien = $(C_2H_5)_2NC_2H_4NHC_2H_4N(C_2H_5)_2$, have been prepared. A three dimensional crystal structure analysis has been carried out in a monoclinic unit cell having $a = 12.565(8)$, $b = 7.576(6)$, $c = 21.040(15)$ Å, $\beta = 91.12(2)°$ and space group $P2_1/c$, $Z = 4$. Full-matrix least-squares using 1982 independent, observed reflections converged at $R = 0.067$. The platinum atom has square-planar co-ordination. The orientation of the four ethyl groups with respect to the plane of the ligand is similar to that observed in related molecules, in spite of a lack of similarity of the molecular packing. The iodide ion appears to be hydrogen bonded to the ligand.

ROSEMARY C. E. DURLEY, WILLIAM L. WALTZ et BEVERLY E. ROBERTSON. Can. J. Chem. **58**, 664 (1980).

On a préparé des cristaux de [Pt(Et_4dien)I]I où Et_4dien = $(C_2H_5)_2NC_2H_4NHC_2H_4N(C_2H_5)_2$. On a effectué une analyse tridimensionnelle de la structure du cristal pour une maille monoclinique ayant $a = 12.565(8)$, $b = 7.576(6)$, $c = 21.040(15)$ Å, $\beta = 91.12(2)°$ et un groupe d'espace $P2_1/c$, $Z = 4$. Une analyse par la méthode des moindres carrés (matrice complète) de 1982 réflexions indépendantes observées conduit à une valeur de $R = 0.067$. L'atome de platine a une coordination plan-carrée. L'orientation des 4 groupes éthyles par rapport au plan du ligand est semblable à celle observée dans les molécules apparentées en dépit d'un manque de similitude de l'entassement moléculaire. Les ions iodures semblent être liés au ligand au moyen de l'hydrogène.

[Traduit par le journal]

Introduction

Studies of the substitution reactions of palladium(II) and platinum(II) complex ions of the type $[M(dien)X]^+$ and $[M(Et_4dien)X]^+$, where dien and Et_4dien represent the tridentate ligands diethylenetriamine and *N,N,N′,N′*-tetraethyldiethylenetriamine respectively and X is a replacable ligand such as a halogen or pseudohalogen, have played a prominent role in the elucidation of the substitution mechanisms of square-planar metal complexes (1, 2). This prominence is due in part to the marked difference in kinetic behavior between these two types of systems. For the dien compounds, their substitutional processes involve an associative mechanism of the type commonly encountered with many square-planar complex ions containing palladium or platinum centers. In contrast, the Et_4dien species are remarkably less reactive and the mechanism now shows signs of having considerable dissociative character. The origin of these features has been attributed to the fact that the ethyl groups may severely limit access to the metal center owing to their possible occupancy of positions above and below the molecular plane (1). In a limiting sense, the Et_4dien ligand would then give rise to a *pseudo-octahedral* geometry about the metal center. In keeping with this view, molecular models suggest the possibility of considerable steric hindrance arising from the presence of the ethyl moieties. However, recent reports by Bresciani and co-workers (3) on the crystal structure analysis of $[Pd(Et_4dien)NO_2]^+$ and $[Pd(dien)N_3)^+$ indicate a more open structure. In order to discern if these structures may be representative of a more general situation, we have undertaken a crystal structure investigation of the Et_4dien compound, [Pt(Et_4dien)I]I, where the metal center is now platinum(II) and the X group is iodine. Crystals of this compound were found to be more suitable for X-ray studies than the analogous chlorine material. While this platinum–iodide compound exhibits a different space group and packing factors from those of the palladium systems, the relative positions of the ethyl groups are very similar in all three cases. Furthermore, our results suggest the possibility of hydrogen bonding between the complex cation and the iodide anion. The pattern of this interaction appears to differ from that reported for [Pt(dien)Br]Br (4).

Experimental

Preparation of [Pt(Et_4dien)I]I

[Pt(Et_4dien)I]I refers to iodo-*N,N,N′,N′*-tetraethyldiethylenetriamineplatinum(II) iodide. The compound was prepared by a procedure similar to that used by Watt and Cude to prepare iodo(diethylenetriamine)platinum(II) iodide (5). $PtI_2 \cdot H_2O$ was mixed with Et_4dien and baked to dryness. The solid was extracted with water at 90°C, and the unreacted $PtI_2 \cdot H_2O$ was separated by filtration. The latter was again treated with Et_4dien as before. The various filtrate fractions

were combined and the pH was adjusted to ca. 6–7 by the addition of HI. The solution volume was reduced by use of a rotoevaporator until crystallization occurred. The crystals were collected, washed with ice-cold water, and then recrystallized from hot water (80°C). The solution was allowed to stand overnight in a refrigerator. After collection, the pale yellow crystals were washed with icy water and then dried under vacuum. The yield was 65% and aqueous solutions exhibited a peak at 313 nm ($\varepsilon = 54.7\,m^2/mol$). *Anal.* calcd. for [Pt(Et_4dien)I]I: Pt 29.37, C 21.70, H 4.40, I(total) 38.21; found: Pt 29.15 ± 0.8, C 21.87 ± 0.2, H 4.32 ± 0.2, I 38.35 ± 0.5.

Crystal Data

$PtI_2C_{12}H_{29}N_3$ fw = 664.26

Monoclinic $P2_1/c$, $a = 12.565(8)$, $b = 7.576(6)$, $c = 21.040(15)$ Å, $\beta = 91.12°(2)$, $V = 2002.5Å^3$, $\rho_c = 2.204\,g/cm^3$, $\rho_o = 2.26(4)\,g/cm^3$ (flotation), $Z = 4$, $\mu(MoK\alpha) = 104.8\,cm^{-1}$.

The pale yellow crystals were predominately plates and all were of relatively poor crystalline quality. Several crystals of this form were examined but all were found to be twinned. A needle shaped crystal was then selected (dimensions 0.12 × 0.08 × 0.40 mm³). Systematic absences ($h0l$, $l = 2n + 1$; $0k0$, $k = 2n + 1$) indicated the space group $P2_1/c$. The cell parameters were calculated by least-squares refinement of 27 manually centred reflections on a Picker four-circle diffractometer using MoKα radiation.

Crystal Structure Determination

Intensity data were collected on an automated Picker diffractometer in the θ/2θ scan mode using MoKα radiation. A scan rate of 1°/min was used with a minimum scan width of 2° and a 40 s background count at each limit of the scan. Three reflections were monitored after every 50 reflections and their intensities did not change significantly. The intensity of 2731 independent reflections was measured below $2\theta = 46°$. The quality of the crystal did not warrant any further data collection. Only the 1982 independent reflections with intensity greater than $1.75\sigma(I)$ were used in the least-squares refinement. Full anisotropic absorption corrections were applied and the data were corrected for Lorentz and polarization factors. The scattering factors were taken from Cromer and Mann (6).

A Patterson synthesis was computed and possible platinum and iodine positions were postulated and used to calculate phases for a Fourier analysis. Successive Fourier synthesis gave positions for all 18 non-hydrogen atoms in the asymmetric unit. Refinement was carried out by use of full-matrix least-squares. A difference synthesis suggested anisotropy in thermal parameters. For the latter cycles of least-squares the platinum, iodine, nitrogen, and ring carbon atoms were refined with anisotropic temperature factors. Refinement converged with R equal to 0.067. Hydrogen atoms were not observed in the difference Fourier synthesis and therefore were not included in any model of the structure. The largest peaks observed in the difference Fourier (1.8 e A^{-3}) were associated with the platinum atom. Final observed and calculated structure factors have been placed in the Depository of Unpublished Data.[1] The square root of the standard deviation of an observation of unit weight is 1.266. The weights were calculated from $w^{-1/2} = 3.93 + 0.270|F_o| + 0.000048|F_o|^2$. This function was found to give constant distribution of $w|\Delta F|^2$ with respect to $|F_o|$. The final weighted residual was 0.105. The large weighted residual reflects the fact that it was not possible to obtain good quality crystals of this compound and the weighting scheme emphasizes the contribution of the many weak reflections which were recorded. Final atomic positional parameters together with their estimated standard deviations are listed in Table 1.

[1]Complete set of tabular data is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and Discussions

The numbering scheme for [Pt(Et_4dien)I]I is shown in Fig. 1 together with co-ordination bond lengths. A stereoscopic view of the cation is shown in Fig. 2. Selected angles are given in Table 2.

Structure of Cation

The complex cation is found to have square-planar co-ordination with the platinum bonded to one iodine and three nitrogen atoms. A pseudo-mirror plane normal to the plane of the ligand is evident in Fig. 2. The differences in some of the bond lengths given in Fig. 1 and the bond angles in Table 2 for bonds and angles related by this local mirror plane exceed the sum of the related standard deviations. We suspect that this implies that the true standard deviations are larger than those given by the least squares.

The Pt atom is slightly removed from the plane of its four ligands and that plane shows some tetrahedral distortion. The following are the distances of the four ligands from least-squares plane parallel to the four ligands but which passes through the position of the Pt atom: I(1), 0.027; N(1), 0.073; N(2), 0.016; N(3), 0.074 Å. The angles around the Pt atom deviate from 90° reflecting the fact that the *bite* of the tridentate ligand is slightly smaller than ideal for bonding to a Pt atom. This is shown by the large N(1)—Pt—I(1) and N(3)—Pt—I(1) angles of 96° whereas the N(1)—Pt—N(2) and N(2)—Pt—N(3) angles are contracted to 85° and 83° respectively. The platinum bond lengths are all within the normal range (4, 7, 8). The central nitrogen bond length [Pt—N(2)] is 1.98(2) Å and is significantly shorter than the other two dentate bonds (2.10(2) and 2.09(2) Å). Such contractions of the central bond and angles were observed in [Pd(Et_4dien)X]$^+$ where X is NO_2 or N_3 (3). The complex ion, [Pt(dien)Br]$^+$, shows similar angular geometry but the central Pt—N bond is no longer the shortest co-ordination bond (4). The average bond distances in the [Pt(Et_4dien)I]$^+$ cation are [C—N], 1.49(3) Å and [C—C], 1.57(3) Å. These are within the expected range (3, 4, 9).

The orientation of the ethyl groups with respect to the ligand plane is shown in Fig. 2. The ethyl groups are spread away from the ligand plane although the extent of this differs above and below the plane. It is noteworthy that the conformation of the Et_4dien ligand, in particular the ethyl positions

and distribution of the metal–nitrogen bonds, are very similar in the palladium and platinum complexes in spite of the differing substituents (NO_2, N_3, I), differing space groups and different molecular packing. It appears that these structures have less congestion in the axial positions above and below the coordination plane than is implied by molecular models (1). Thus we would suggest that the conformation of the ethyl groups may reflect the inherent properties of the Et_4dien ligand system in a square-planar environment rather than constraints imposed by the X group or by packing factors such as hydrogen bonding.

Packing in the Crystal

Figure 3 illustrates the packing in the [Pt(Et_4-dien)I] crystal. Layers of cations alternate with iodide ions. Contacts of less than 4 Å were examined for possible hydrogen bonding. The iodide ion sits between the cation nitrogen atom N(2) of one molecule and the C(2) and C(3) atoms of a neighboring molecule. The close contacts and related angles are given in Table 3. The I(2)—N(2) distance of 3.48 Å is 0.17 Å smaller than the sum of the van der Waal's radii of the two elements (7). Since the angles about N(2) are also favourable (10), it may be postulated that there is hydrogen bonding between the iodide ion I(2) and the acidic proton attached to N(2). This hydrogen bonding would be consistent with the kinetic data (1); the effect of the hydroxyl ion in promoting substituents is believed to involve loss of a proton from this

TABLE 3. Close contacts to iodide ion and related angles

Bond	Distance (Å)	Bonds	Angle (deg)
N(2)—I(2)	3.48(2)	C(2)—N(2)—I(2)	99(2)
		C(3)—N(2)—I(2)	101(2)
		Pt—N(2)—I(2)	114(1)

central nitrogen atom. Hydrogen bonding of a less specific nature was postulated for the bromide ion in [Pt(dien)Br]Br (4). The different possible hydrogen bonding patterns of [Pt(dien)Br]Br and [Pt(Et_4dien)I]I may explain the differences observed between the Pt—N bond lengths of the two complexes as mentioned in the previous section.

Autohydrolysis of aspen milled wood lignin

JAIRO H. LORA AND MORRIS WAYMAN

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A4

Received August 3, 1979

JAIRO H. LORA and MORRIS WAYMAN. Can. J. Chem. **58**, 669 (1980).

In order to obtain further understanding of the nature of lignin reactions during autocatalysed hydrolysis (autohydrolysis) of wood, milled wood lignin (MWL) was isolated from aspen (*Populus tremuloides*) and treated under autohydrolysis conditions. By this means reactions of the lignin itself could be distinguished from those taking place between lignin and the carbohydrate or other components of the wood. The material after the reaction was separated into a dioxane insoluble fraction (DI), a dioxane soluble but ether insoluble fraction (DSEI), and an ether soluble fraction (ES). Studies were carried out on the DI and DSEI fractions; no direct study was made of the small ES fraction.

The formation of DI material increased linearly during the first 7.5 min at 170°C and then levelled off. At the same time DSEI decreased and then levelled off. Gel permeation chromatography of the DSEI fraction suggested that during autohydrolysis there is an initial generation of low molecular weight fragments which recombine to form first a high molecular weight soluble fraction and from this the insoluble product. The DSEI fraction contained increased conjugated and unconjugated keto groups. Carboxylic acids were also detected; they have been attributed to the reincorporation of low molecular weight aromatic acids generated by the hydrolysis of the corresponding esters. The dioxane insoluble (DI) fraction had fewer unconjugated keto groups than the DSEI fraction, indicating that these groups participated in the condensation reactions leading to the formation of insoluble material. These probably involve position 6 of the aromatic ring.

JAIRO H. LORA et MORRIS WAYMAN. Can. J. Chem. **58**, 669 (1980).

Dans le but d'obtenir de plus amples informations sur la nature des réactions de la lignine lors de l'hydrolyse autocatalysée (autohydrolyse) du bois, on a isolé du peuplier (*Populus tremuloides*) la lignine de bois moulu (LBM) et on l'a soumise à une autohydrolyse. Par ces réactions de la lignine on peut distinguer celles qui ont lieu entre la lignine et les carbohydrates ou d'autres dérivés du bois. Les produits de la réaction sont séparés en fraction insoluble dans le dioxanne (ID), fraction soluble dans le dioxanne mais insoluble dans l'éther (SDIE) et en une fraction soluble dans l'éther (SE). On a étudié les fractions ID et SDIE mais on n'a pas fait d'études directes sur la petite fraction SE.

La formation de produits ID augmente linéairement durant les 7.5 premières minutes puis se stabilise. En même temps la fraction SDIE diminue puis se stabilise. La chromatographie sur gel de la fraction SDIE suggère que lors de l'autohydrolyse il y a formation initiale de fragments de faibles poids moléculaires qui se recombinent d'abord pour donner la fraction soluble de poids moléculaire élevé et à partir duquel se forme le produit insoluble. La fraction SDIE contient des groupes cétoniques conjugués et non conjugués. On a également décelé des acides carboxyliques et on les attribue à la réincorporation d'acides aromatiques de faibles poids moléculaires issus de l'hydrolyse d'esters correspondants. La fraction insoluble dans le dioxanne (ID) a moins de groupes cétoniques conjugués que la fraction SDIE. Ceci indique que ces groupes participent aux réactions de condensation qui conduisent à la formation de produits insolubles. Ces derniers font probablement intervenir la position 6 du cycle aromatique.

[Traduit par le journal]

Introduction

It has been reported by several authors (1–6) that by autocatalysed hydrolysis (autohydrolysis) of wood, the lignin is modified in such a way that it can be partially extracted in a second stage at low temperatures using certain organic solvents or dilute aqueous alkalies. Earlier work at this laboratory (7–10) has shown that at any given temperature there is a characteristic autohydrolysis time for maximum lignin extractability. This has been explained in simple terms as the result of reactions of two different types, in one of which extractable lignin is formed, while in the other, insoluble structures are generated.

Previous studies of the reactions affecting lignin during autohydrolysis (7–20) have used wood, and thereby the wood carbohydrates or their derivatives were present to react with the lignin. In order to avoid such reactions, it was decided to study the effects of autohydrolysis on isolated lignin. By this means, reactions of the lignin itself could be characterized and distinguished from those taking place between lignin and other wood components. The findings of these studies are presented and discussed here.

Aspen milled wood lignin (MWL) was used as a model for lignin and treated under conditions similar to those prevailing during autohydrolysis. After the treatment the products were separated into three fractions: (*i*) material insoluble in dioxane–water (9:1) (DI), (*ii*) material soluble in dioxane–water (9:1) but insoluble in ether (DSEI), and (*iii*) material soluble in ether (ES).

This paper discusses the yields and chemical structures of the DI and DSEI fractions, and the changes in molecular weight distribution of the DSEI material. The DI and DSEI fractions were characterized by elemental and methoxyl analysis, and by spectroscopic methods. The ES fraction, which contained low molecular weight aromatic

compounds, and was a minor proportion of the total, was not studied further.

Results

Yields

Figure 1 shows the yields of DI and DSEI fractions as a function of autohydrolysis time at 170°C. After 2 min the formation of DI lignin began; between 2 and 7.5 min the amount of DI lignin increased linearly with a slope equal to 10.1% min^{-1} and then tended to level off. The DSEI fraction showed an opposite trend, decreasing initially very quickly, and then at a slower rate. An estimate of ES may be obtained as ES = 100 − (DI + DSEI). This amounted to about 10% during the first 5 min of heating, then fell rapidly to zero. Between 10 and 30 min ES was formed to about 5% of the total.

Molecular Weight Distribution of DSEI Fractions

Figure 2 presents gel permeation chromatograms (GPC) for representative DSEI samples as well as for the MWL used as starting material. Most chromatograms took the form of a bimodal curve. The first peak was eluted at the exclusion volume, determined by running blue dextran (mw ≃ 2×10^6) through the column, and may thus represent the accumulation of molecules of hydrodynamic volume greater than that separable by Sephadex G100 (21). The sequence of chromatograms is rather similar to that obtained with wood autohydrolysis lignin (10), except that the sharp peak of high molecular weight soluble lignin was obtained in 40 min at 195°C with wood, and in 2 min at 170°C with the isolated lignin. The high molecular weight peak almost disappeared by 30 min at 170°C with MWL, whereas its disappearance required 120 min at 195°C on autohydrolysis of wood. Each chromatogram was divided into two fractions: (*i*) a high molecular weight lignin (HML) including material eluted up to fraction number 30 (elution volume less than 77 mL), (*ii*) a low molecular weight lignin (LML) including material eluted after fraction number 30 (elution volume more than 77 mL).

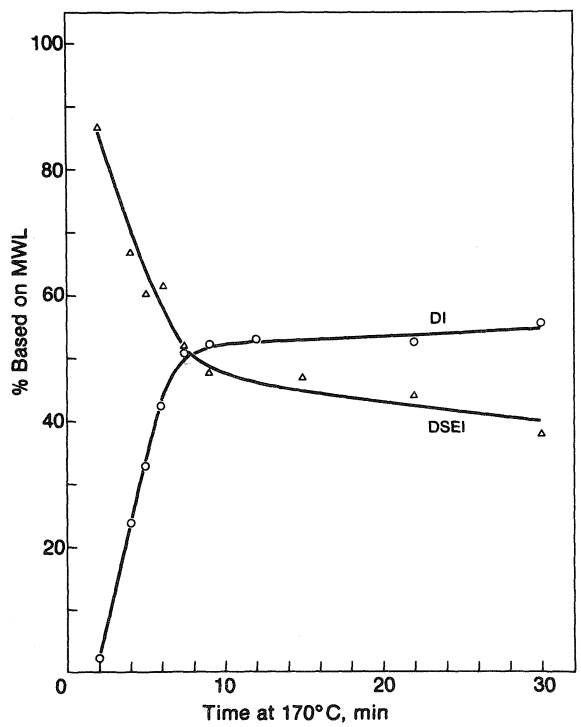

FIG. 1. Yield of DI and DSEI fractions after simulated autohydrolysis of aspen MWL at 170°C.

The relative amounts of HML and LML in the DSEI samples were estimated as the ratio between the area under either the HML or the LML fractions and the total area under the chromatograph. The figures obtained in this way should be taken only as approximations since the absorptivity at 280 nm (wavelength used in the detector of the gpc system) may be somewhat different for the HML and LML fractions due to chemical differences. With the information generated in this way, estimated yields of HML and LML were obtained (Fig. 3).

Figures 2 and 3 indicate that at the beginning of the treatment there was an increase in the yield of HML and a reduction in the yield of LML indicating that the former was being obtained from the latter. The yield of HML was highest for the sample obtained after 2 min of autohydrolysis, that is, when formation of DI material was just beginning (Fig. 1). As time progressed the yield of HML decreased due to the increasing formation of DI material and to depolymerization. The decrease in the yield of HML for times above 6 min (when little DI lignin was being formed) was mostly due to depolymerization resulting in the formation of LML. The linearity of the curve of log of yield of HML vs. time for times above 6 min (Fig. 3) suggests first order kinetics for the depolymerization reaction with a rate constant $k_1 = 0.084\,min^{-1}$, as a first approximation.

In the case of LML, after the initial very fast decrease, the yield levelled off. Thus, during the first minutes condensation of LML producing HML prevailed while in the latter stages of the reaction little HML formed and there was a balance between the depolymerization of HML with formation of LML and the depolymerization of LML with formation of ES materials.

Elemental Analysis

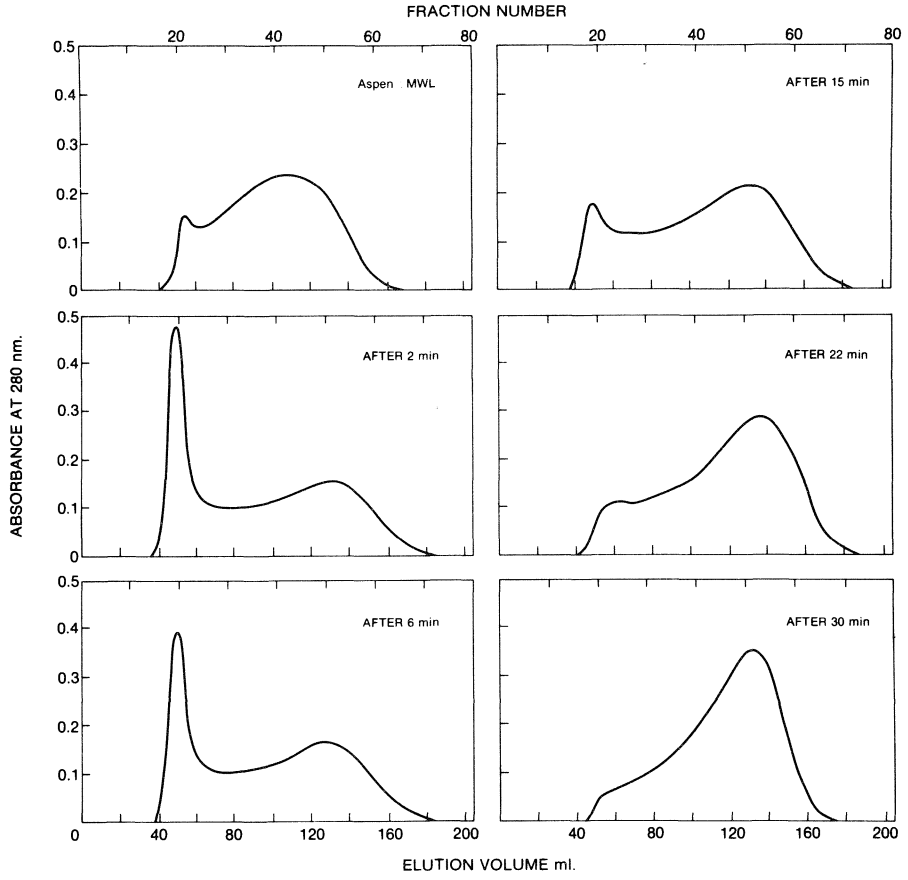

FIG. 2. Molecular weight distributions of DSEI samples obtained after simulated autohydrolysis of aspen MWL at 170°C.

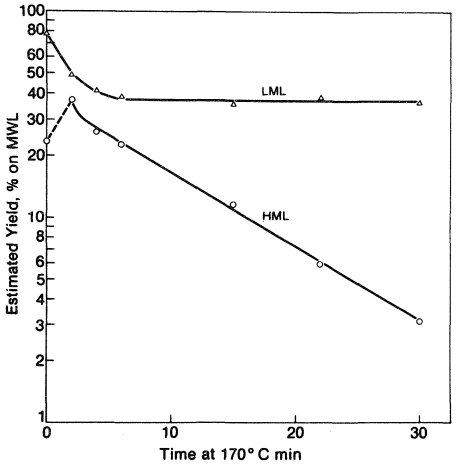

FIG. 3. Effect of time on the yield of LML and HML after simulated autohydrolysis of aspen MWL.

for aspen MWL and for the DSEI and DI samples obtained after autohydrolysis for 30 min at 170°C. Based on these data C_9 formulae were calculated and have been included in Table 1. The values obtained for MWL are within accepted ranges for hardwoods. A value of O/C_9 higher than 3 has been observed in other lignins of the genus *Populus* (22), and is consistent with the presence of aromatic esters, which has been shown by ir spectroscopy. As observed, the DI sample showed higher carbon content and lower oxygen content than MWL, while the DSEI material exhibited lower carbon and higher oxygen content than the starting material. Little variation was observed in methoxyl content, the DI sample exhibiting a slightly lower OCH_3/C_9 than MWL.

Infrared Spectroscopy

Figure 4 shows the infrared spectra obtained for aspen MWL and for representative DSEI and DI samples. The clearest differences occurred in the 1650–1800 cm^{-1} and the 700–930 cm^{-1} regions, the remainder being typical of aspen MWL and hardwood lignins in general. In the 1000–1400 cm^{-1} region, the absorption due to the aromatic methoxyl groups is strongly affected by the presence of carbonyl groups, rendering interpretation of changes difficult.

TABLE 1. Chemical analysis and C_9 formulae of lignins after autohydrolysis of aspen MWL at 170°C

Type of material	Time at 170°C (min)	Analysis (%) C	H	O	OCH_3	C_9 formula	Molcular weight C_9 unit
MWL		59.2	5.92	34.9	20.1	$C_9H_{8.27}O_{3.23}(OCH_3)_{1.36}$	210.20
		60.0	6.19	33.9	20.4	$C_9H_{8.65}O_{3.03}(OCH_3)_{1.37}$	207.53
DSEI	30	58.6	5.51	35.9	20.0	$C_9H_{7.50}O_{3.39}(OCH_3)_{1.37}$	212.13
DI	30	61.0	6.14	32.8	20.2	$C_9H_{8.41}O_{2.85}(OCH_3)_{1.32}$	202.86

The 1650–1800 cm^{-1} Region

In addition to the 1670 cm^{-1} band characteristic of conjugated carbonyl groups, MWL exhibited a shoulder at 1700–1720 cm^{-1} which disappeared upon saponification. Reduction of MWL with alkaline $NaBH_4$ caused a general decrease in the absorption between 1650 cm^{-1} and 1800 cm^{-1} and uncovered a broad maximum between 1700 and 1715 cm^{-1}. Based on the results of these tests and in agreement with other authors (23–25), the 1700–1720 cm^{-1} absorption was assigned to conjugated ester groups.

In the DSEI fractions the 1700–1720 cm^{-1} band was very prominent and increased with time of autohydrolysis. Reduction with $NaBH_4$ caused a partial decrease in the intensity of the band, which indicated the presence of unconjugated β-keto groups (26). Upon saponification it was not possible to reprecipitate the lignin at pH 6–7, which suggested the presence of carboxylic acids. A fraction precipitated at pH 4 showed also a lower absorption at 1700–1720 cm^{-1} interpreted as due to the presence of β-keto as well as carboxylic acid groups. For the DI samples the absorption at 1700–1720 cm^{-1} was comparatively small and diminished with increasing time.

The 700–930 cm^{-1} Region

Bands appearing in this region are attributed to aromatic C—H out-of-plane in-phase (umbrella) deformations which are strongly affected by proximity among hydrogen atoms. As a general rule, proximity to other hydrogens will decrease the frequency of the absorption. Thus, from the ir spectra in this region, the substitution pattern may be inferred (27).

As illustrated in Fig. 4, the DI samples exhibited clear signs of modification of the substitution pattern as evidenced by the lowering of intensity in the syringyl band at 922 cm^{-1} and by the appearance of a strong band at 872 cm^{-1} and a weaker one at 890 cm^{-1}. The bands at 872 and 890 cm^{-1} are attributed to isolated aromatic C—H vibrations, that is, they indicate condensation. On the basis of wide evidence from the literature (28–31), the 872 cm^{-1} band can be assigned to a 1,3,4,6 tetra substitution pattern (1,2,4,5, in IUPAC nomenclature[1]) or to penta substitution. Thus penta substitution (in the case of syringyl units) and 1,3,4,6 tetra substitution (in the case of guaiacyl units) appear to be the prevailing structures in the insoluble lignins. These results agree with the work of others (32–36), who have found that, under acid conditions, condensation preferentially occurs in position 6 through an electrophilic substitution reaction. Proof of structure would require a wet chemistry procedure such as neutral permanganate oxidation and identification of the carboxylic acids so produced.

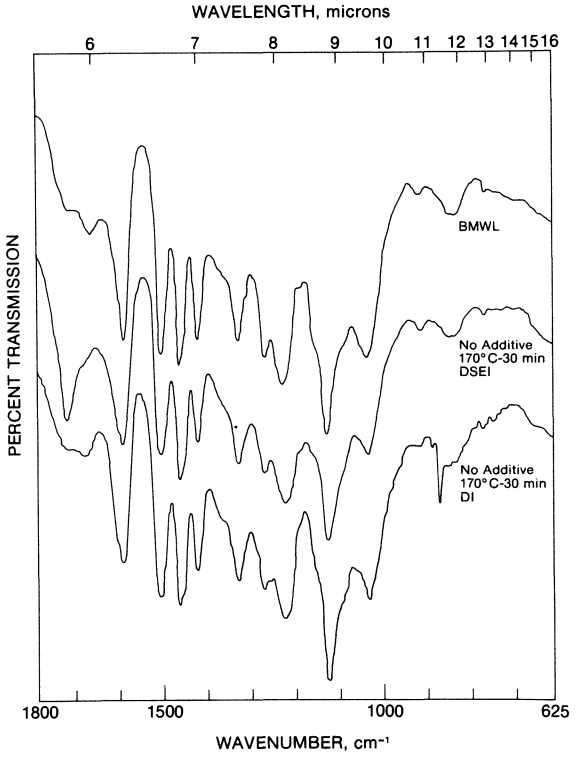

FIG. 4. Infrared spectrum of DSEI and DI lignins obtained after simulated autohydrolysis of aspen MWL at 170°C.

[1]IUPAC nomenclature names the phenolic position as 1, whereas in the lignin literature, position 1 is the point of attachment of the aliphatic side chain. In this paper we shall use the lignin nomenclature.

The DSEI samples showed the same bands as MWL but some differences in shape indicates that the substitution pattern had been modified. With increase in reaction time, the absorption above 860 cm^{-1} progressively increased, thus affecting the shape of the 830–860 cm^{-1} band; the absorption between 700 and 800 cm^{-1} decreased as indicated by the change of slope of the base line in that region. Since absorption above 860 cm^{-1} is characteristic of isolated aromatic C—H bands and absorption below 800 cm^{-1} is typical of more than one adjacent aromatic C—H bond, the trends observed here indicate increasing condensation, that is, a decrease in the number of adjacent aromatic C—H bonds and increase in the number of isolated aromatic C—H bonds. This modification of the substitution pattern, however, did not reach the same extent as in the DI samples.

Ultraviolet Spectroscopy

Two maxima (296 and 366 nm) appeared in the alkali–acid difference spectrum for a DSEI sample obtained after autohydrolysis at 170°C for 30 min. The absorption at 366 nm corresponds to ionized phenolic hydroxyl groups conjugated with carbonyl groups, carbon–carbon double bonds, or biphenyl groups; the 296 nm band corresponds to any other ionized phenolic hydroxyl groups (37). Sodium borohydride reduction caused a considerable decrease in the absorption at 366 nm and an increase in the intensity of the 296 nm band, suggesting that the higher wavelength absorption must be mainly due to the presence of conjugated carbonyl groups. The lack of significant absorption above 320 nm in the difference spectrum of the reduced sample indicated the absence of high amounts of stilbene and phenyl coumarone structures conjugated with ionized phenolic hydroxyl groups.

Discussion

The decrease in the yield of DSEI lignin, accompanied by the increase in the formation of DI materials, indicates that the latter are being obtained from the former. The initial linearity of the curve relating yield of DI lignin to autohydrolysis time suggests that the formation of insoluble material proceeds through a zero order reaction. This can be understood as a result of the reaction taking place in a medium in which lignin is not soluble and thereby the formation of DI material depends on the physical proximity of the sites involved, rather than on concentration. That proximity is largely predetermined by the structure of lignin.

From molecular weight distribution studies, a scheme for the depolymerization and repolymerization reactions can be postulated. MWL is a polydispersed material composed of high and low molecular weight fractions, HML and LML. By depolymerization HML produces low molecular weight DSEI materials similar to LML as well as a small amount of ES. By repolymerization, the LML produces high molecular weight DSEI materials similar to HML, as well as a small amount of ES. Insoluble DI is formed from the soluble HML as the reaction continues.

The postulated overall mechanism indicates that lignin repolymerization under autohydrolysis conditions does not necessarily result in the immediate formation of insoluble materials. It is only after condensation has proceeded to a certain extent that the molecule becomes insoluble. The findings reported here give support to the conclusion that the HML fraction reported by Chua and Wayman (10) in their study of lignins obtained by autohydrolysis of aspen wood, instead of being a relatively unchanged fragment of the original lignin of the wood, is the result of recondensation reactions involving the low molecular weight fragments generated at the onset of autohydrolysis. These reactions take place much more rapidly upon autohydrolysis of the isolated lignin than they do in the wood. While physical (diffusional) effects may account for part of this rate difference, the major rate-retarding effect in the wood may be attributable to the participation of hemicellulose degradation products in the reactions, which become incorporated into the products (10). However, from a molecular point of view, the course of the reaction appears to be much the same, that is, depolymerization to low molecular weight fragments followed by repolymerization to soluble higher molecular weight condensation products, which, as the condensation proceeds, become insoluble.

The presence of conjugated and unconjugated carbonyl groups in the products can be attributed to the splitting of ether linkages resulting in the formation of structures with side chains analogous to the side chains of Hibbert's ketones. This agrees with what has been reported for other acid degradation processes of lignin, such as acidolysis or ethanolysis (38–50). The increase of absorption with increasing time agrees with the predominance of lower molecular weight materials at longer times in agreement with the gpc studies. The carboxylic acid groups are attributed to the incorporation into the lignin of low molecular weight carboxylic acids generated by the hydrolysis of the corresponding esters; this has also been proposed in the studies of autohydrolysis wood lignins (18). These low

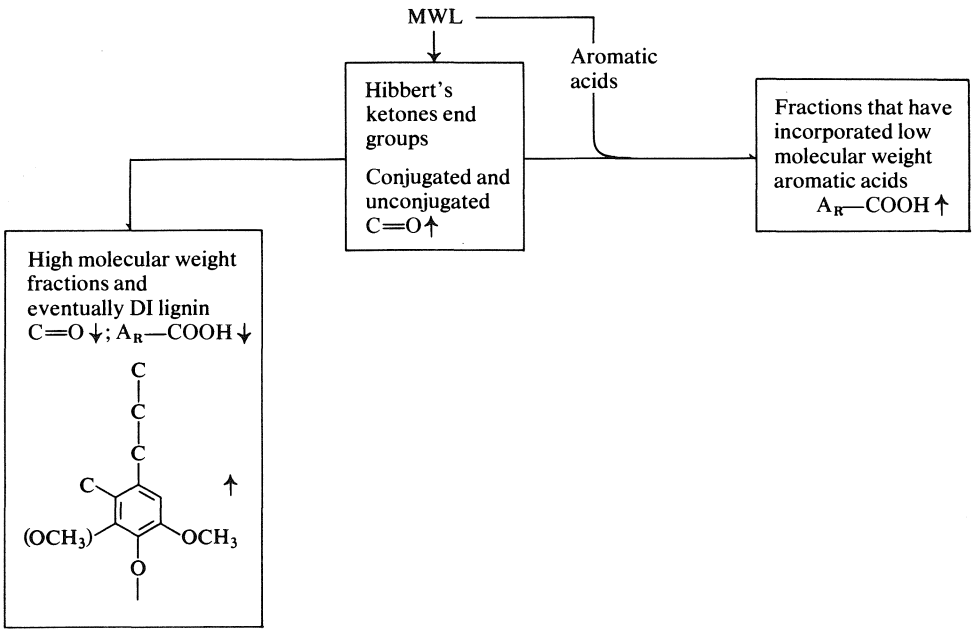

FIG. 5. Structural changes during simulated autohydrolysis of aspen MWL as revealed by spectral studies.

molecular weight compounds can act as blocking agents for lignin repolymerization, in the same way as the aromatic additives reported by Wayman and Lora (51).

The low absorption at 1700–1720 cm^{-1} shown by the DI samples suggests that the β-keto groups appearing in the DSEI fraction participated in condensation reactions leading to the formation of DI materials. The absence of keto groups in the DI samples agrees with the low values of O/C_9 exhibited by the insoluble materials. The participation of ketols in acid condensation reactions has been proposed by Marton (52). The weak absorption at these frequencies also indicates that the aromatic carboxylic acids are present only in relatively small amounts in the DI samples, in agreement with their proposed role as preventives of lignin repolymerization.

The appearance in the DI samples of a new bond at position 6 of the aromatic ring indicates its involvement in the condensation reactions leading to the formation of insoluble materials. In contrast, Wayman and Chua (20), in their ir studies of lignins unextractable after aspen wood autohydrolysis, did not observe substantial modifications of the substitution pattern of the ring. This suggests that in the case of wood the formation of insoluble lignin is mainly the result of condensation with the carbohydrates or their derivatives, rather than the result of lignin self-condensation. The incorporation into the lignin of non-lignin substances during wood autohydrolysis is also supported by the fact that the values for OCH_3/C_9 for the DSEI and DI samples obtained from aspen MWL are very similar to those of the starting material, and considerably higher than those reported for autohydrolysis lignins obtained from wood (10, 16, 20). The slightly lower value of OCH_3/C_9 for the DI sample reported here is attributed to the predominance of guaiacyl type lignin in the insoluble materials, in agreement with the findings of Wayman and Chua (19).

Figure 5 gives a summary of the structural changes occurring as a result of autohydrolysis of aspen MWL.

Experimental

*Preparation of Aspen MWL (*Populus tremuloides*)*

Extractive-free wood meal (prepared according to TAPPI Standard T12m59) (100 g) was ground in a ball mill under CO_2. After 18 days the material was extracted with dioxane–water (9:1) and the extract concentrated to dryness under vacuum and purified according to the method of Lundquist *et al.* (53).

Autohydrolysis of Aspen MWL

Aspen MWL (100 mg) was placed in a small glass beaker specially designed to fit 25-mL stainless steel pressure vessels. After the addition of 0.6 mL of water (pH 3.5, adjusted with acetic acid) the pressure vessel was put in a desiccator under vacuum in order to remove trapped air and then was closed in a glove box under a nitrogen atmosphere. The moisture was distributed by immersing in an oil bath at 105°C; after 10 min of immersion with constant shaking provided by a wrist action machine, the pressure vessel was taken out and immersed with

constant shaking in an oil bath at 170°C. It was found that after 2.5–3 min, the temperature inside the vessel was within 0.5°C of the bath temperature. After the reaction time was completed, the vessel was taken out of the oil bath and immersed in an ice water bath, opened, and the contents transferred quantitatively to 20-mL vials using dioxane and water in such amounts that at the end 15 mL of dioxane–water (9:1) was in the vial. Then, three 6-h extractions were carried out using 15 mL of dioxane–water (9:1), centrifuging after each extraction. The material remaining insoluble in the solvent, DI, was filtered into a preweighed C porosity sintered glass crucible, washed, first with dioxane, then with anhydrous ether, and finally with petroleum ether, dried under vacuum at room temperature, and weighed. The material soluble in dioxane–water (9:1) was concentrated to about 1 mL at 30°C under vacuum, dissolved in 1.5 mL of dichloroethane–ethanol (2:1) and precipitated into 45 mL of anhydrous ether. The material insoluble in ether but soluble in dioxane–water (9:1), DSEI, was washed 3 times with anhydrous ether and twice with petroleum ether; each washing was done by adding 15 mL of the corresponding solvent, shaking overnight with a wrist action machine and centrifuging. At the end, the DSEI product was transferred with petroleum ether to a preweighed M or F porosity sintered glass crucible, dried under vacuum, and weighed.

Molecular Weight Distributions

The procedure described by Chua and Wayman (10) was followed. The chromatograms in Fig. 2 were obtained on 2 mg samples.

Elemental Analysis

C, H, and methoxyl were determined by Schwarzkopf Microanalytical Laboratory, New York.

Infrared Spectroscopy

Pellets were prepared using 1 mg of sample and 300 mg of KBr; spectra referred to 300 mg pure KBr pellets obtained with a Beckman IR-9 spectrophotometer operated in a double beam mode.

Difference Ultraviolet Spectroscopy

Solution A was obtained by dissolving 5 mg of lignin in dioxane (9 mL), methanol (25 mL), and 1 *N* HCl (1 mL). The acid solution was prepared by mixing 5 mL of solution A with water (5 mL) and dioxane (2.5 mL). The alkali sample was prepared analogously but using 0.5 *N* NaOH instead of water. The difference spectrum was obtained by running the alkali solution against the acid solution in a Unicam SP 1700 spectrophotometer.

Derivatization

Borohydride reduced samples and saponified samples were prepared according to the procedure of Sarkanen *et al.* (23).

Absolute rate constants for hydrocarbon autoxidation. 28. A low temperature kinetic electron spin resonance study of the self-reactions of isopropylperoxy and related secondary alkylperoxy radicals in solution[1]

EDWARD FURIMSKY,[2] JAMES A. HOWARD, AND JENNIFER SELWYN[3]

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

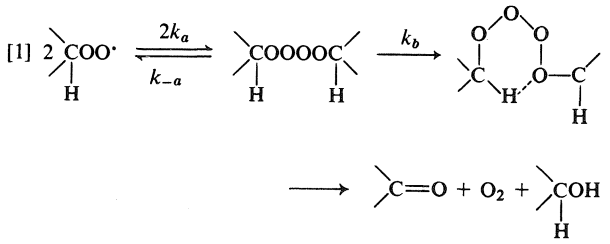
Received November 7, 1979

EDWARD FURIMSKY, JAMES A. HOWARD, and JENNIFER SELWYN. Can. J. Chem. **58**, 677 (1980).

Isopropylperoxy radicals at low temperatures exist in equilibrium with di-isopropyl tetroxide. The thermodynamic parameters for this equilibrium are very similar to the values of ΔH^0 and ΔS^0 for the *tert*-butylperoxy radical – di-*tert*-butyl tetroxide equilibrium. Differences in second-order rate constants for mutual destruction of secondary and tertiary alkylperoxy radical appear to result from differences in rate constants for unimolecular decomposition of secondary and tertiary alkyl tetroxides.

Isopropylperoxy radicals have the same termination rate constant in the gas phase and in solution.

EDWARD FURIMSKY, JAMES A. HOWARD et JENNIFER SELWYN. Can. J. Chem. **58**, 677 (1980).



A basse température, les radicaux isopropylperoxy existent en équilibre avec le tétroxyde de di-isopropyle. Les paramètres thermodynamiques de cet équilibre ressemblent beaucoup aux valeurs de ΔH^0 et ΔS^0 de l'équilibre entre le radical *tert*-butylperoxy et le tétroxyde de di-*tert*-butyle. Les différences dans les constantes de vitesse d'ordre 2 pour la destruction mutuelle du radical alkylperoxy secondaire et tertiaire semblent résulter des différences entre les constantes de vitesse de la décomposition unimoléculaire des tétroxydes d'alkyles secondaires et tertiaires.

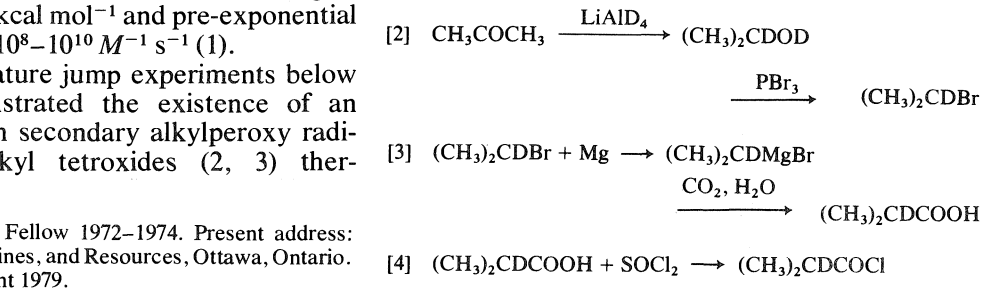
Les radicaux isopropylperoxy ont la même constante de vitesse de rupture en phase gazeuse et en solution.

[Traduit par le journal]

Introduction

The self-reaction of secondary alkylperoxy radicals at ambient temperatures and below in solution is generally believed to proceed through a cyclic transition state (the Russell mechanism) although kinetic and product studies are not entirely consistent with this mechanism.[4]

At temperatures above about 193 K irreversible decays of s-$RO_2^{\bullet}$ are second-order with respect to the radical concentration and activation energies fall in the range 1–5 kcal mol^{-1} and pre-exponential factors in the range 10^8–10^{10} M^{-1} s^{-1} (1).



Although temperature jump experiments below 193 K have demonstrated the existence of an equilibrium between secondary alkylperoxy radicals and di-*sec*-alkyl tetroxides (2, 3) thermodynamic parameters for this equilibrium (ΔH_a^0 and ΔS_a^0) have not been determined because irreversible radical decays have been too fast.

In this article we present the results of a low temperature kinetic electron spin resonance spectroscopic study of the self-reaction of the isopropylperoxy radical which enables us to report the approximate values of ΔS_a^0 and ΔH_a^0 for this radical and also to demonstrate that some secondary alkylperoxy radicals can decay with first-order kinetics below 173 K.

Experimental

Materials

Acyl peroxides were synthesized from the appropriate acid chloride and sodium peroxide (4). Isobutyryl chloride (Eastman) and 2-methylbutyryl chloride (Eastman) were used without further purification. Cyclopentanecarbonyl chloride was prepared from cyclopentane carboxylic acid (Aldrich) by the method of Brown (5). Isobutyryl chloride-α-d_1 was synthesized by the reaction sequence,

Radical Production

The radicals were produced directly in the cavity of a Varian

E-4 EPR spectrometer equipped with a variable temperature accessory by photolysis of the alkylformyl peroxide in oxygen-saturated dichlorodifluoromethane.

$$[5]\quad \mathrm{RC(O)OC(O)R} \longrightarrow 2\mathrm{R}^{\cdot} + 2\mathrm{CO_2}$$

$$[6]\quad \mathrm{R}^{\cdot} + \mathrm{O_2} \longrightarrow \mathrm{RO_2}^{\cdot}$$

Radical concentrations were measured and decays followed by standard kinetic electron spin resonance spectroscopic techniques (2, 6).

Results and Discussion

Above 173 K isopropylperoxy, isopropyl-α-d_1-peroxy, cyclopentylperoxy, and *sec*-butylperoxy decayed with clean second-order kinetics, i.e., $-\mathrm{d}[s\text{-ROO}^{\cdot}]/\mathrm{d}t = 2k_t[s\text{-RO}_2^{\cdot}]^2$, where $2k_t$ is the second-order rate constant for mutual radical destruction. Values of $2k_t$ and Arrhenius parameters for these radicals are listed in Table 1. Included in this table are kinetic parameters for the s-$\mathrm{RO_2}^{\cdot}$ prepared by photolysis of di-*tert*-butyl peroxide in the oxygenated hydrocarbon (RH) (3). Agreement between kinetic data for secondary alkylperoxy radicals prepared by the two methods is satisfactory.

Below 173 K temperature jump experiments indicated that cyclopentylperoxy and *sec*-butylperoxy radicals exist in equilibrium with their tetroxide. Values of ΔH_a^0 and ΔS_a^0 could, however, not be estimated because irreversible radical decay was too fast.

The isopropylperoxy radical decays irreversibly more slowly than either cyclopentylperoxy or *sec*-butylperoxy and below 173 K the radical concentration could be reversibly increased and decreased by raising and lowering the temperature with no significant loss in radical concentration. Equilibrium constants for this process were estimated using the procedure of Scaiano and Ingold (7). Thus a sample of isobutyryl peroxide in oxygen-saturated CF_2Cl_2 was photolysed continuously at 143 K. The initial rate of production of i-$\mathrm{PrO_2}^{\cdot}$, $(\mathrm{d}[i\text{-PrO}_2^{\cdot}]/\mathrm{d}t)_0$, was measured and the steady-state radical concentration $[i\text{-PrO}_2^{\cdot}]_{ss}$ was determined at the end of the period of photolysis, t. If it is assumed that i-$\mathrm{PrO_2}^{\cdot}$ at low temperatures only disappear by combination to give tetroxide the total number of i-$\mathrm{PrO_2}^{\cdot}$ produced, $[i\text{-PrO}_2^{\cdot}]_{tot} = (\mathrm{d}[i\text{-PrO}_2^{\cdot}]/\mathrm{d}t)_0 t$ and the equilibrium constant can be calculated from

$$[7]\quad K_a = \frac{[i\text{-PrO}_2^{\cdot}]_{tot} - [i\text{-PrO}_2^{\cdot}]_{ss}}{2[i\text{-PrO}_2^{\cdot}]_{ss}^2}$$

Values of $[i\text{-PrO}_2^{\cdot}]_{ss}$ were measured at each temperature and K_a calculated from [7]. The plot of $\ln (K_a/M^{-1})$ against the reciprocal of the absolute temperature yielded the thermodynamic parameters $\Delta H_a^0 = -8.0$ kcal mol^{-1} and $\Delta S_a^0 = -25$ cal deg^{-1} mol^{-1}.

TABLE 1. Absolute rate constants and Arrhenius parameters for self-reaction of some *sec*-alkylperoxy radicals*

E_p/(kcal mol^{-1})	—	2.6(3.1)	1.1(2.7)

*The data shown in parentheses are from ref. 3 for cyclopentylperoxy and *sec*-butylperoxy and ref. 14 for isopropylperoxy.

Isopropyl-α-d_1-peroxy radicals decay irreversibly somewhat more slowly than isopropylperoxy because of a lower rate constant for termination (8). Below 173 K this radical exists in equilibrium with its tetroxide and $\Delta H_a^0 = -8.0 \pm 0.4$ kcal mol^{-1} and $\Delta S_a^0 < -33 \pm 3$ cal deg^{-1} mol^{-1}.

The thermodynamic parameters for the equilibrium between i-$\mathrm{PrO_2}^{\cdot}$ and its tetroxide are very similar to the values of ΔH_a^0 and ΔS_a^0 for *tert*-butylperoxy and related tertiary alkylperoxy radicals (2, 6). We are, therefore, tempted to conclude that thermodynamic parameters for the alkylperoxy radical – tetroxide equilibrium are not influenced to any great extent by the nature of the alkyl moiety.

Mill and Stringham (9), a number of years ago, failed to prepare diisopropyl tetroxide by photolysis of 2,2′-azoisopropane in oxygenated $CFCl_3$–CF_2Cl_2 while Adamic, Howard, and Ingold (6) did not observe the esr spectrum of the isopropylperoxy radical in this system. Our success with isobutyryl peroxide as a source for the isopropylperoxy radical implies that acyl peroxides are better photochemical sources of alkyl radicals at low temperatures than azo compounds.

It has been reported that secondary alkylperoxy radicals prepared by photolysis of di-*tert*-butyl peroxide in oxygen-saturated alkane decay with second-order kinetics below 193 K (3). Rates of radical decay in this system would, however, appear to have been influenced by the presence of an unstable mixed *tert*-alkyl *sec*-alkyl trioxide (10).

We find that plots of $[s\text{-RO}_2^{\cdot}]^{-1}$ against time for radicals prepared from the acyl peroxide at temperatures around 173 K showed pronounced upward curvature and below this temperature decayed with

TABLE 2. Rate constants for first-order decay of some *sec*-alkylperoxy radicals

Temperature (K)	$10^3 k_{epr}^1/s^{-1}$		
	Isopropyl-peroxy	Cyclopentyl-peroxy	*sec*-Butyl-peroxy
148	—	2.6	—
152	—	6.7	4
157.5	0.6	21.5	—
163	—	80	24
167	5.3	100	—

"clean" first-order kinetics. In this respect secondary alkylperoxy radicals behave like other radicals which exist in equilibrium with an excess of a diamagnetic dimer (11).

Values of the first-order rate constant k_{epr}^1 for isopropylperoxy, cyclopentylperoxy, and *sec*-butylperoxy were measured (Table 2) and found to increase in the order isopropylperoxy < *sec*-butyl peroxy < cyclopentylperoxy, i.e., k_{epr}^1 depends on the nature of the secondary alkyl group attached to oxygen.

Unfortunately, k_{epr}^1 could not be measured over a wide temperature range because above 173 K radical decays were not first-order while below 143 K radical concentrations were very small because of the high ratio of tetroxide to free radical. A plot of log (k_{epr}^1/s^{-1}) against K^{-1} for cyclopentylperoxy did, however, yield log $(A_{epr}^1/s^{-1}) = 12 \pm 1$ and $E_{epr}^1 = 10 \pm 0.6$ kcal mol^{-1}.

If reaction [1] describes the overall self-reaction of *sec*-alkylperoxy radicals, the rate of radical decay is given by

$$\frac{-d[s\text{-}RO_2^{\cdot}]}{dt} = \frac{2k_bK_a[s\text{-}RO_2^{\cdot}]^2}{1 + 4K_a[s\text{-}RO_2^{\cdot}]}$$

where $K_a = k_a/k_{-a}$ and when $K_a[s\text{-}RO_2^{\cdot}] > 1$ radical decays will be first-order. If this is the case $k_{epr}^1 = 0.5k_b$, where k_b is the unimolecular rate constant for tetroxide decomposition. This suggests that for cyclopentylperoxy $k_b/s^{-1} \sim 2 \times 10^{12} \exp(-10$ kcal mol$^{-1})/RT$.

Analogous first-order decays at low temperatures have not been observed for tertiary alkylperoxy radicals because these radicals are very persistent in the presence of significant concentrations of tetroxide.

Activation parameters for unimolecular decomposition of tertiary alkyl tetroxides = 10^{15}–10^{17} s^{-1} and 16–18 kcal mol^{-1} have, however, been calculated from kinetic and thermodynamic parameters for irreversible and reversible decays at temperatures where $4K_a[t\text{-}RO_2^{\cdot}] < 1$ and $2k_t = 2k_bK_a$ (2, 6).

Calculation of the activation parameters for unimolecular decomposition of dicyclopentyl tetroxide by this method gives $A_b = 10^{15}$–$10^{15.5}$ s^{-1} and $E_b = 10.6$–11.1 kcal mol^{-1}. Clearly there is poor agreement between pre-exponential factors estimated from k_{epr}^1 and $2k_t/K_a$ while activation energies calculated by the two methods are in good agreement.

A similar situation also exists for di-*tert*-butyl tetroxide because Mill and Stringham (9) and Bartlett and Guaraldi (12) have estimated $A_b = 10^{9.3}$–10^{12} s^{-1} and $E_b = 11$–12 kcal mol^{-1} from rates of oxygen evolution from solutions containing the tetroxide.

It has been suggested by Bowman, Gillan, and Ingold (13) that an additional 14.4 cal deg^{-1} mol^{-1} of entropy are lost in the formation of a cyclic rather than a linear transition state from two peroxy radicals, i.e., $A_b(s\text{-}RO_2^{\cdot})$ should be $\sim 10^{-3}A_b(t\text{-}RO_2^{\cdot})$. The value of A_b for cyclopentylperoxy radicals determined from k_{esr}^1 is consistent with this proposal whereas the more accurate value of A_b estimated from $2k_t/K_a$ is not consistent with this proposal. Clearly kinetic data for tetroxide decompositions are not accurate enough to provide information regarding the geometry of the transition state.

It would, however, appear that $E_b(s\text{-}RO_2^{\cdot}) < E_b(t\text{-}RO_2^{\cdot})$ suggesting that $A_b(s\text{-}RO_2^{\cdot})$ is almost certainly $< A_b(t\text{-}RO_2^{\cdot})$.

Conclusions

Secondary alkylperoxy radicals exist in equilibrium with di-*sec*-alkyl tetroxides with thermodynamic parameters which appear to be similar to the corresponding parameters for tertiary alkylperoxy radicals. At temperatures below 173 K radical decays follow first-order kinetics which is consistent with the influence of a radical-diamagnetic dimer equilibrium on rates of radical decay. Bimolecular rate constants for self-reaction of *sec*-alkylperoxy radicals depend on the nature of the alkyl moiety almost certainly because of differences in the rates of irreversible tetroxide decomposition.

Kinetic and thermodynamic parameters for irreversible and reversible decay of these radicals are not entirely self consistent and cannot be used with any certainty as evidence for or against the Russell mechanism for self-reaction of secondary alkylperoxy radicals (1).

Values of $2k_t$ for isopropylperoxy at 229 K and below are in excellent agreement with rate constants calculated using the Arrhenius parameters reported by Kirsch, Parkes, Waddington, and Woolley (14) obtained at higher temperatures in the gas phase. The similarity between these two sets of

data substantiates the conclusion that an alkylperoxy radical has the same termination rate constant in the gas and liquid phases (14).

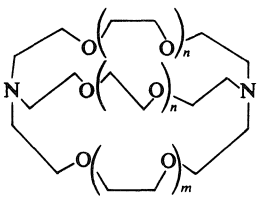
Received September 11, 1979

GORDON WALTER WOOD, MEI-KUEN AU, NING MAK, and PUI-YAN LAU. Can. J. Chem. **58**, 681 (1980).

Field desorption mass spectra have been recorded for most of the 45 cryptates which may be formed from complexation of [2.2.2]-, [2.2.1]-, and [2.1.1]-cryptand with Li^+, Na^+, and K^+ ions in combination with the anions Cl^-, Br^-, I^-, OTs^-, and BPh_4^-. The cryptate cation predominated in almost all of the spectra. The stability of the complexes was found not to be simply related to goodness of fit of the cation in the cryptand cavity, but a significant trend in stability in the order $BPh_4 > I > Br > Cl$ was found. This order of complex stability was shown to be consistent with known thermodynamic parameters. These results are discussed briefly in terms of applications to analysis of alkali metal cations.

GORDON WALTER WOOD, MEI-KUEN AU, NING MAK et PUI-YAN LAU. Can. J. Chem. **58**, 681 (1980).

On a enregistré les spectres de masse à ionisation par désorption de champ pour la plupart des 45 cryptates qui peuvent se former par suite de la complexation des cryptands [2.2.2]-, [2.2.1]-, et [2.1.1] avec les ions Li^+, Na^+, K^+ dont les anions sont Cl^-, Br^-, I^-, OTs^- et BPh_4^-. Le cryptate de cation prédomine dans presque tous les spectres. On a trouvé que la stabilité des complexes n'est pas simplement reliée à la façon parfaite avec la quelle le cation se glisse dans la cavité du cryptand mais qu'il existe une tendance significative de stabilité dans l'ordre: $BPh_4 > I > Br > Cl$. On montre que cet ordre de stabilité du complexe est en accord avec des paramètres thermodynamiques connus. On discute brièvement des résultats en fonction des applications à l'analyse des cations de métaux alcalins.



[Traduit par le journal]

Introduction

Although field desorption mass spectrometry (FDMS) has now become established among the standard methods for analysis and structure determination (1), the technique continues to be plagued by unwanted side-effects from the presence of alkali metal ions in samples. For those samples which contain these ions only as impurities, various clean-up procedures have been used with mixed results. In addition, a significant proportion of the non-volatile samples for which FDMS is in principle applicable are presented as salts with Na^+ or other cation as an integral part of the species. Examples of the latter are barbiturates, nucleotides, and carboxylates.

One of our early attempts to improve FD spectra of alkali metal containing samples involved the addition of macrocyclic ligands to complex the metal ion and thus remove its deleterious effect (2, 3). During that work we noted a number of interesting trends in behavior, particularly for the class of macrobicyclic ligands now called cryptands (4). The ready formation of alkali metal ion complexes with these ligands and the widespread study of their kinetic and thermodynamic properties in other connections (5–9) led us to examine an extended set of these complexes by FDMS. The results obtained provide some insights on management of alkali metal ion impurities in FDMS, on the potential of these complexes for analysis of metal ions, and on the nature of the FD process.

Spectra of complexes of cryptands **I–III** with a variety of Li^+, Na^+, K^+ salts are compared for ease of ionization, stability, and other features.

I, [2.2.2]-cryptand; $n = m = 1$
II, [2.2.1]-cryptand; $n = 1, m = 0$
III, [2.1.1]-cryptand; $n = 0, m = 1$

Results and Discussion

The complexes studied comprise a 3 × 3 × 5 matrix as follows. Cryptands **I–III** were combined with Li^+, Na^+, K^+ salts of the following anions: Cl^-, Br^-, I^-, OTs^-, BPh_4^-. Of the 45 potential complexes in this set, 39 were attempted; 3 failed to give a spectrum: **I**·LiCl, **I**·KCl, and **II**·KCl. Tables 1–3 report results on the 36 complexes successfully desorbed. Trials were not made of the remaining 6 combinations with ligand **III**.

Field desorption mass spectra of the 13 complexes with [2.2.2]-cryptand, **I**, are presented in Table 1. The base peak for these complexes is generally the cryptate cation ($L + C$). Considera-

[f]m/z 837(6); not reproducible; assigned to $(2L + 2C + \mathbf{I})^+$.
[g]At 20 mA and above salt clusters Na_3OTs_2 and Na_2OTs dominate the spectrum.

tion of the exception, **I** · NaBr, along with the fact that **I** · KCl and **I** · LiCl failed to give a spectrum, is the first suggestion of an important anion effect that will be discussed later. Minor peaks are recorded at $L + C \pm 1$ and $L + C \pm 2$ for most of these complexes. Each of these may represent gain or loss of the corresponding number of H atoms from the complex, but allowance must first be made for the contribution to these peaks of isotopes. Thus, in addition to the usual contributions from ^{13}C and ^{18}O, we have ^{41}K and ^{6}Li in the appropriate complexes. With these corrections made, the only peak that remains with significant intensity is $L + C - 2$. Further support for apparent loss of 2H from the ligand is seen in the $L - 2$ peaks of two of the spectra.

Complexation of two Li^+ ions with the oversized ligand **I** was found only for **I** · LiI. This doubly charged ion appeared throughout the series of scans with appropriate isotope peaks at half-integral mass values, but was unexplainedly absent from complexes containing anions other than I^-.

The **I** · NaOTs complex shows a minor peak at m/z 523, apparently containing the anion. Stronger peaks of this kind are seen in Table 2.

Since FDMS is frequently limited in reproduci-

[a]L = ligand, [2.1.1]-cryptand; M = metal cation.
[b]Anode heating current.
[c]TI = total ion intensity in arbitrary units.
[d]Above 20 mA several ions corresponding to portions of the salt are found: $NaBPh_4^{+\cdot}$, $(Na_2BPh_4)^+$, $BPh_3^{+\cdot}$, BPh_2^+, $(NaBPh_3)^+$.

bility by ion statistics, we have reported for each of the spectra in this paper a measure of the total ion intensity, TI. The units of TI are arbitrary but previous experience indicates that on average each unit represents 10^2–10^3 ions at the detector. It is thus expected that scan-to-scan reproducibility will deteriorate rapidly for low values of TI (<1), and also where individual peak intensities fall below this threshold.

A number of features already discussed may be seen in the spectra of cryptates in Table 2. Once again, the complex with KCl failed to give a reproducible spectrum. Of the remaining 14 members of this set, only II·KBr and II·KI failed to give spectra in which $L + C$ was the dominant single peak. The apparent excess abundance of some isotope peaks may simply reflect poor ion statistics, but it appears that both II·KOTs and II·$KBPh_4$ may contain one extra H ($L + C + 1 = 25, 34, L + C + 2 = 15, 20$ respectively). Likewise, $L + C - 2$ is fairly consistent in Li complexes and the more intense spectra of Na complexes.

Both II·KOTs and II·LiOTs exhibit some unusual ions. The peaks in the former at m/z 505, 506, 507 are the most clear-cut example in this study of protonation of the macrobicyclic ligands, a reaction which is well-known in solution (8). The ions m/z 557, 536 from the same complex appear to reflect some decomposition of the ligand. The doubly-charged $L + 1$ ion from II·LiOTs may be rationalized as arising from protonation and ionization of the same ligand, presumably at the two nitrogens.

Results for cryptand III complexed with all 5 Li salts and representative Na and K examples are shown in Table 3. Although all spectra contain $L + C$ as base peak, only III·LiI, III·$LiBPh_4$, and perhaps III·$NaBPh_4$, III·LiBr give reasonably intense peaks for this dominant ion. As before, there is some loss of 2H ($L + C - 2$). Although the large K^+ ion is accommodated surprisingly well by this small ligand ($L + C = 100$), there is a significant ion corresponding to complexation of two ligands by one cation. This process may occur even where sizes are matched, as in I·KBr where $2L + C$ is found above 18 mA.

There is some judgement involved in the selection of one scan from a sequence at increasing anode temperatures, and thus an uncertainty in the "best" anode temperature. In spite of this fact, two generalizations seem to be fairly safe. First, the anode temperature reported for the "best fit" complex is higher than for the "misfits". Thus the average anode current for [$K^+ \subset$ 2.2.2] is 19 mA, compared to 16 mA for both Na^+ and Li^+ complexes with this cryptand. Desorption of [$Na^+ \subset$ 2.2.1] complexes was only 1–2 mA higher than for the other cations, but [$Li^+ \subset$ 2.1.1] complexes desorbed at 20 mA compared to 17 mA for [$Na^+ \subset$ 2.1.1] complexes and 14 mA for the one [$K^+ \subset$ 2.1.1].

The average anode temperature for the various halide salts also appeared to increase from Cl^- to Br^- to I^- (14 to 16 to 19 mA). This trend may be related to the lattice energy of the alkali metal halides as presented subsequently.

Perhaps the most striking general conclusion that can be drawn from these spectral data is the lack of correlation between apparent complex stability in FDMS and the well-known solution measurements of thermodynamic stability in which each cryptand complexes selectively with the alkali metal ion which most nearly fits its cavity. Thus [2.2.1]-cryptand accommodates Na^+ well (log K_s = 5.3 in H_2O); K^+ to a lesser extent (log K_s = 3.9); and even less, Li^+ (log K_s = 2.5). These stability constants reflect free energy changes upon exchange of the cation between cryptand cavity and the solvent.

TABLE 4. Enthalpy and entropy of ligation of alkali metal ions[a]

Cryptand	Transfer function	Alkali metal ion Li	Na	K
[2.2.2] (I)	H_l	—	113	97
	S_l	—	33	31
[2.2.1] (II)	H_l	132	111	93
	S_l	22	20	22
[2.1.1](III)	H_l	137	111	—
	S_l	25	29	—

[a]$M^+_{gas} + L_{aq} \rightarrow [M^+ \subset L]_{aq}$ as reported in ref. 7.

The most obvious difference between this process and decomposition of a cryptate complex on the FD anode is the lack of solvation for the cation released. As a first approximation to the FD situation, we may compare the free energies of transfer of the cations in question from a cryptand cavity to the gas phase (free energy of ligation, ΔG_l). Such numbers have recently been determined where the cryptand is in aqueous solution and further dissected into enthalpies and entropies of ligation, Table 4 (7).

Clearly, selectivity of cryptand for different cations cannot be found in the entropy of ligation terms, which are essentially constant for each ligand regardless of the cation. The enthalpy terms increase for the smaller cations *irrespective of the goodness of fit*. Thus transfer of Li^+ from [$Li^+ \subset$ 2.2.1] hydrate to the gas phase costs 20 kcal/mol more than the same change for Na^+, in spite of the log K_s difference of ca. 3 (5.3 − 2.5) in the other direction. Likewise, the enthalpy of the hydrated [$Na^+ \subset$ 2.2.2] is 16 kcal/mol more favorable with respect to the gas phase ion than is [$K^+ \subset$ 2.2.2], whereas stabilities of the cryptates in H_2O differ by 1.4 log units in the other sense.

This analysis allows one to attribute the usual selectivity of these cryptands to solvation of the uncomplexed cation (7) and thus justify the absence of selectivity in FD. However, some further rationale for the marked anion effect would be desirable. Among the several gross approximations[2] in equating the transfer process above with the FD situation is the assumption that the released cation enters the gas phase. Indeed, other experience indicates that at the moderate anode temperatures employed here, the cation will simply join the waiting external anion. If the free energy gain of that recombination may be approximated by

$$M^+_{gas} + X^-_{gas} \rightarrow MX_{solid}$$

a likely source of the large anion effect on stability in FDMS becomes evident. Thus for the alkali halides, X = Cl, Br, I; M = Li, Na, K; chlorides are ca. 9 kcal/mol more stable in terms of ionic lattice energy than bromides which in turn are ca. 11 kcal/mol more stable than iodides. Although the thermodynamic data for tetraphenylborates are less complete, combination of available experimental (10) and theoretical (11) values enables one to estimate the corresponding change from I to BPh_4 at 65 kcal/mol. According to this interpretation, the variation of cryptate stability as measured by FDMS abundance of the $L + C$ ion is at least partly a function of the ionic lattice energy of the ion pair formed when the cryptate cation is released. The general trend of increased stability I > Br > Cl may be seen in Tables 1–3 with a few apparent exceptions. The much smaller ionic interaction in tetraphenylborate salts is accompanied by an additional improvement in stability of cryptates of these compounds.

Several procedures for analysis of alkali metal ions by FDMS have been reported (12). For trace amounts of alkali metal ions, cryptate formation would no doubt improve sensitivity and reproducibility of desorption in FDMS. The present results suggest that a single cryptand large enough to accommodate the largest ion to be analyzed should be just as satisfactory as a series of ligands selected to match the size of each cation. Further, conversion of the analyte to BPh_4^- or other suitable low lattice energy form should give improved results.[3]

Experimental

Mass spectra were recorded on a Varian MAT CH5 DF mass spectrometer operating under the control of an INCOS 2000 data system as previously described (13).

Cryptates were prepared by the addition of an equimolar amount of salt to a solution of 50 mg of cryptand in 5 mL $CHCl_3$. The mixture was stirred at room temperature overnight, and the solvent evaporated. The residue was redissolved in 1 mL of $CHCl_3$ for FDMS analysis.

Reactions of some substituted phenols with chromyl and vanadyl chlorides

JOHN F. HARROD AND ASHA PATHAK
Chemistry Department, McGill University, 801 Sherbrooke Street West, Montreal, P.Q., Canada H3A 2K6

Received August 22, 1979

JOHN F. HARROD and ASHA PATHAK. Can. J. Chem. **58**, 686 (1980).

The oxidation of 2,4,6-tritertbutylphenol and several other alkyl and halophenols by CrO_2Cl_2 and $VOCl_3$ was studied. The products of CrO_2Cl_2 oxidation are mostly quinones and diphenoquinones, whilst those of $VOCL_3$ oxidation also include major amounts of dealkylated phenols and C—C coupled dimers. The product distributions are interpreted in terms of a mechanism involving phenoxyl radicals, ligand transfer from metal to radical, and either phenoxonium ions or metallate esters where there is sufficient electron withdrawal from the organic group for it to exhibit carbenium ion properties. The differences in behaviour between CrO_2Cl_2, $VOCl_3$, and $CuCl_2$ are attributed to different balances between the oxidation potential and Lewis acidity of the metal complexes. It is concluded that CrO_2Cl_2 is not a good model for proposed ferryl intermediate in heme oxidase systems since it induces 1 → 3 rather than 1 → 2 halogen shifts and an NIH shift that is best explained by carbenium ion-like intermediates.

JOHN F. HARROD et ASHA PATHAK. Can. J. Chem. **58**, 686 (1980).

On a étudié l'oxydation du tritert-butyl-2,4,6 phénol et de plusieurs autres phénols alkylés et halogénés par CrO_2Cl_2 et $VOCl_3$. Les produits de l'oxydation par CrO_2Cl_2 sont principalement des quinones et des diphénoquinones alors que ceux résultant de l'oxydation par $VOCl_3$ comprennent également des quantités appréciables de phénols désalkylés et des dimères liés par une liaison C—C. On interprète la répartition des produits en fonction d'un mécanisme qui fait intervenir des radicaux phénoxyles, des transferts de ligands du métal au radical et soit des ions phénoxonium ou des esters de type métallique dans lequel le groupe organique est suffisamment polarisé pour exhiber les propriétés d'un ion carbénium. On attribue les différences de comportement entre le CrO_2Cl_2, le $VOCl_3$ et le $CuCl_2$ aux différents équilibres entre les potentiels d'oxydation et l'acidité de Lewis des complexes métalliques. On a conclu que le CrO_2Cl_2 n'est pas un bon modèle pour l'intermédiaire ferryle proposé dans les systèmes hème oxydase puisqu'il induit un glissement 1→3 d'halogène plutôt que 1→2 et un glissement NIH qui s'explique mieux par un intermédiaire de type carbénium.

[Traduit par le journal]

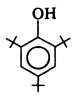
Introduction

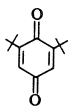
Oxochromium(VI) compounds have been cited as models for the reactive intermediates in oxygenases such as cytochromes P-450 (1, 2). Both the experimentally observed NIH shift in chromate oxidations of aromatic nuclei (1) and theoretical calculations on orbital populations in the chromate ion (2) have been adduced as evidence for a similarity between the oxygen transfer in Cr(VI) oxidations and in oxygenations catalysed by cytochrome P-450. As part of a wider investigation of the mechanisms whereby metal ions oxidize phenols (3), or catalyse their oxidation by dioxygen, we have studied the oxidation of tritertbutylphenol by chromyl chloride. The choice of this reaction was based on the usefulness of tritertbutylphenol in detecting radical, as opposed to other mechanistic pathways in phenol oxidation (3, 4). An earlier study of the oxidation of phenols by chromyl chloride showed the reaction to be quite selective for the production of 1,4-quinones (5).

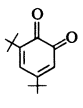
The scope of the present investigation was broadened to include the reaction of tritertbutylphenol with vanadyl trichloride. Besides the chemical similarity of vanadyl chloride to chromyl chloride and to the supposed "ferryl" species that have been suggested as intermediates in the active cycles of a number of heme-containing oxidative enzymes (6), the reagent is of interest in view of its exceptional selectivity in certain phenol-coupling reactions (7).

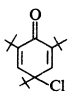
Results

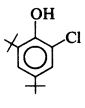
Reaction of 2,4,6-Tritertbutylphenol with Chromyl Chloride

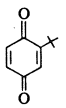


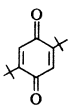


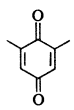


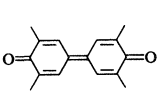












The title reaction occurred extremely rapidly in hexane at −65°C with the precipitation of a buff coloured, apparently amorphous solid. This solid was extremely moisture sensitive and all attempts to isolate products directly from it resulted in intractable, tarry material. Most of the organic material was bound up in this solid and could most easily be recovered by hydrolysis and extraction with organic solvents. Much of the organic material could also be released under anhydrous conditions by treatment of the solid with pyridine. Such treatment led to the formation of an insoluble, apparently polymeric, pyridine–chromium(III) compound and released most of the organic reaction products into solution.[1] This technique was less convenient to use than aqueous hydrolysis, but it served to show that most of the products released on hydrolysis did not depend on externally supplied water for their production. It should be stressed,

[1]Similar observations were made by Leigh and Strickson (5*c*).

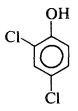
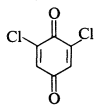
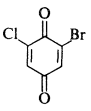
however, that the infrared spectrum of the buff coloured precipitate, even when samples were prepared under scrupulously anhydrous conditions, was dominated by bands due to water. This water was probably a reaction product and most likely ligated to the Cr(III) in the product.

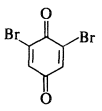
The major products from oxidation of 2,4,6-tritertbutylphenol **1** with CrO_2Cl_2 are shown in Table 1. The most significant difference between the cases with 1:1 and 2:1 mole ratio of oxidant to substrate was the production of a substantial amount of the 2-electron oxidation product **4** under oxidant-deficient conditions.

In order to establish whether or not the formation of the orthoquinone **3** involved prior dealkylation of **1** to 2,4-ditertbutylphenol, **6**, a reaction of the latter with excess CrO_2Cl_2 was studied. The results for this reaction are also shown in Table 1.









Reactions of 2,4,6-Tritertbutylphenol and Some of its Derivatives with $VOCl_3$

Addition of $VOCl_3$ to a solution of **1** in hexane resulted in the immediate formation of a dark blue precipitate and a dark blue supernatant liquor. Attempts to isolate a crystallizable product from the dark blue solid were not successful, probably because it was a fairly complicated mixture. These attempts to characterize the solid were complicated by its extremely deliquescent nature. It was therefore decided to use a hydrolytic workup similar to that used with the product of the chromyl chloride reaction.

From the results depicted in Table 2, it is evident that the $VOCl_3$ reaction is much more complicated than that of CrO_2Cl_2, at least in terms of the reaction products. The products of the $VOCl_3$ reaction may be classified in terms of their oxidation level,

2,4,6-Tribromo-		59	17	9

namely, (*i*) dealkylated phenol (no oxidation), (*ii*) C—C coupled dimers (one-electron oxidation), (*iii*) chlorophenol and cyclohexadienones (two-electron oxidation), and (*iv*) quinones (four-electron oxidation). A particularly striking feature of the reactions listed in Table 2 is the apparent insensitivity of the total organic product oxidation level to reaction conditions. The average number of electrons lost per molecule of reactant **1** ranged from 1.3 to 1.9 even though the minimum available oxidizing equivalents (assuming V^V to be a one-electron oxidant) ranged from two to eight. Although little change occurred in the average oxidation level of the organic product, there was an appreciable increase in the amounts of C—C dimers and 1,4-quinone relative to other products.

The distribution of products was quite insensitive to temperature from ambient down to −60°C, but at higher temperature the chlorodealkylation product **5** increased at the expense of C—C coupled dimers.

A single test reaction was run using the tritertbutylphenoxyl radical instead of **1**. The product distribution obtained was essentially the same as that for **1** under the same conditions.

The reactions of the chlorocyclohexadienone **4**, and the phenols **5**, **6**, and 2,6-ditertbutylphenol, **9**, were studied to establish their possible roles as intermediates in the tritertbutylphenol reaction. Neither **5** nor **6** reacted rapidly enough to be implicated as essential intermediates, although **6** did give the same C—C coupled dimers and quinones as did **1**. The product of the latter reaction at a $VOCl_3$ to phenol ratio of two was notable for the absence of the chlorophenol **5**, even though the chlorodealkylated dimer, **11**, was the major product. At a $VOCl_3$ to phenol ratio of four, a considerable amount of **5** was produced but the yields of the C—C coupled dimers and quinones were not appreciably altered.

The products of the reaction of **9** with $VOCl_3$, in addition to excluding **9** as an intermediate in the tritertbutylphenol reaction, underline the curious regioselectivities which must be operative to give rise to the products observed in the reactions of **1**. Thus, **9** yields the diphenoquinone **14** as the major product and only a trace of the quinone **2**. Although a considerable amount of alkyl migration occurred, as indicated by the production of an appreciable amount of **6**, no *ortho*-coupled oxidation products were detected.

Oxidation of 2,6-Dimethyl-4-deuteriophenol by CrO_2Cl_2

Oxidation of the title phenol by chromyl chloride yielded 2,6-dimethylbenzo-1,4-quinone, **16**, (55% based on phenol) and 3,3′,5,5′-tetramethyldiphenoquinone, **17**, (30%), as expected from the results of Strickson and Leigh (*5b*). Mass spectrometric analysis showed that ca. 30% of **16** had retained a single deuterium and that ca. 10% of **2** contained a single deuterium.

Oxidation of the title phenol by ferricyanide gave **17** in almost quantitative yield, but with zero retention of deuterium.

Oxidation of Polyhalophenols by CrO_2Cl_2

Since the oxidation of 2,6-dichlorophenol, **18**, was known to give 2,6-dichloro-1,4-benzoquinone, **19**, quite selectively on oxidation with CrO_2Cl_2 (*5a*) (see Table 3), an attempt to synthesize the corresponding orthoquinone, **20**, by oxidation of 2,4-dichlorophenol was made. Instead of **20**, the product proved to be almost entirely **19** (Table 3). To determine whether **19** resulted from intramolecular halogen shift, or from oxidative dehalogenation accompanied by chlorination with CrO_2Cl_2, a number of oxidations of bromo- and chlorobromophenols by CrO_2Cl_2 were investigated. The results of some of these reactions are shown in Table 3.

Discussion

Reactions of Phenols with Chromyl Chloride

The general features of the chromyl chloride oxidation of alkyl and halophenols have been outlined in a series of papers by Strickson *et al.* (5). Contrary to the report of Leigh and Strickson (*5c*), who detected only the orthoquinone as a product of tritertbutylphenol oxidation, the ortho- and paraquinones **2** and **3** were isolated in roughly equal

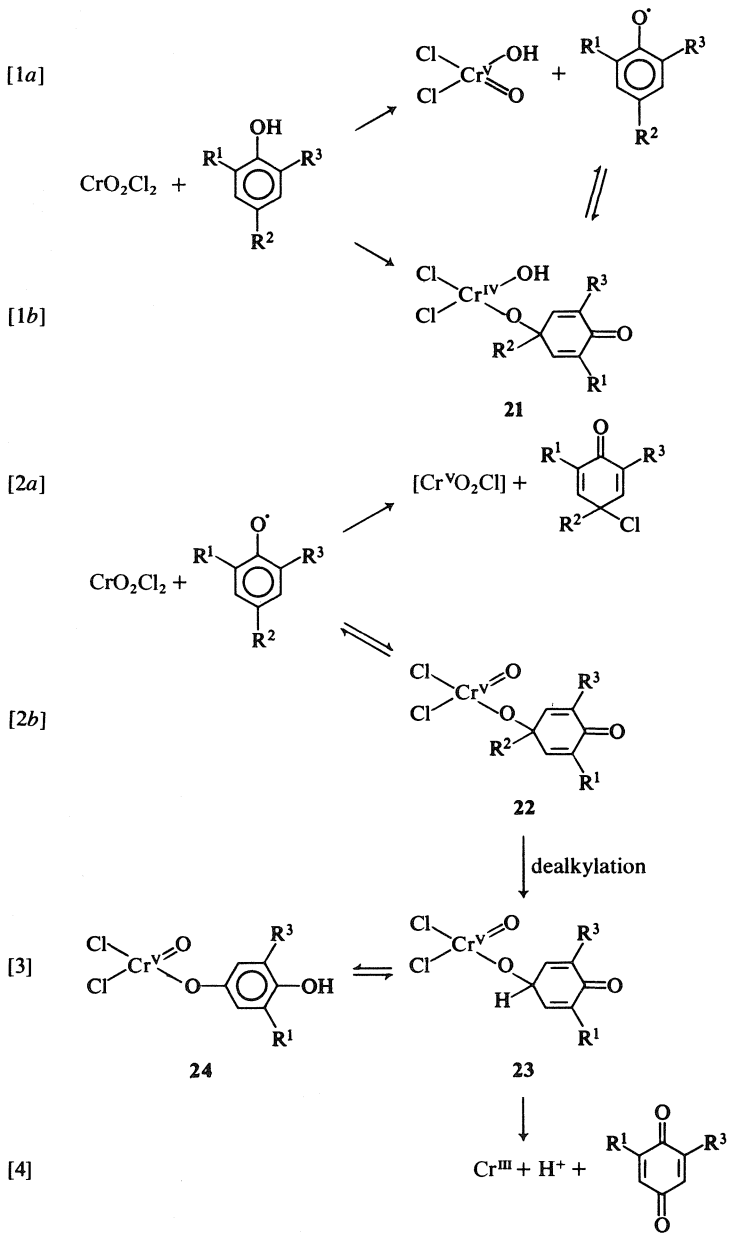
amounts in the present study and accounted for 80% of the reacted phenol. The occurrence of large amounts of orthoquinone appears to be unique to this reaction. The reaction of 2,4-ditertbutylphenol, **6**, which might be expected to favour orthoquinone formation even more, gave the monotertbutylparaquinone as the major product, together with a significant amount of the tertbutyl-migrated product **8**. Since these two products account for 90% of reactant phenol, it cannot be assumed that orthoquinone was lost through secondary reactions. The fact that tertbutyl migration occurs on reaction of **6** but not of **1** suggests that there is an intermediate with considerable carbenium ion character prior to the loss of the tertbutyl group from a tritertbutyl moiety, but that migration cannot occur due to steric constraints. Following loss of a tertbutyl group on the way to formation of quinone, the system appears to be no longer susceptible to migration. In the case of **6**, the steric restraint to migration is absent on the side of the ring lacking an orthotertbutyl substituent and migration of the alkyl group can occur. It is presumably at the same stage of the reaction that the deuterium migration takes place when 2,6-dimethyl-4-deuteriophenol is oxidized.

There is no doubt that the formation of free radicals is an important step (probably the first) in this complicated reaction (*5c*). However, it also seems most likely that carbenium ions or analogous species are involved. The series of reactions [1]–[4] seems to explain all of the results obtained with alkyl phenols.

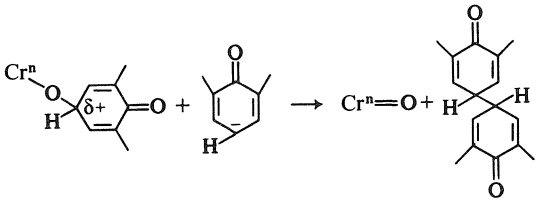
Since the exact oxidation and coordination states of the chromium species are unknown, those illustrated in [1] to [4] are only exemplary of the kinds of species that might be involved. Reactions [1*a*] and [1*b*] are generically similar in that either one, or both, fragments from homolytic cleavage of the phenolic O—H bond are captured by chromyl chloride. The products of [1*a*] and [1*b*] are designated to be in equilibrium to satisfy the requirement that the phenoxyl radical and a phenoxonium-like species be interchangeable for reasons to be enlarged upon below. The same applies to the reactants and products of reaction [2*b*].

The formation of esters **21** and **22** is expected to lead to the concentration of a great deal of positive charge on the carbocycle, if not to the formation of a free phenoxonium ion, and it is from such a species that dealkylation, or alkyl migration, will occur. Following loss of the alkyl group, rapid collapse of the hydroquinone ester intermediate **23/24** to the quinone will occur with facility.



Reactions [2*a*] and [2*b*] are both ligand transfer reactions from Cr^{VI} to the phenoxyl radical. Under chromyl chloride deficient conditions the production of large amounts of **4** (see Table 1) indicates that [2*a*] competes kinetically very favourably with [2*b*]. However, the absence of **4** under conditions of excess chromyl chloride indicates that the oxygen attachment [2*b*], leading ultimately to quinone, is thermodynamically favoured. This reasoning also requires that **4** be somehow recycled back through species such as **21** or **22**. The production of **4** by ligand transfer has been observed previously in the oxidation of **1** by cupric chloride (3).

The observation of orthoquinone formation from **1**, but not from other phenols, is difficult to rationalize. If the carbocycle in **21** and **24** has a great deal of carbenium ion character, it might be presumed that attachment to the Cr—O moiety might be favoured for those carbons carrying an alkyl rather than a hydrogen substituent. The formation of a mixture of ortho- and paraquinone for the case where $R^1 = R^2 = R^3$ = tertbutyl does not therefore seem unreasonable. Similarly, the replacement of R^1 = tertbutyl by R^1 = hydrogen might be expected to diminish the tendency to produce orthoquinone, as observed. However, the expectation that replacement of R^2 = tertbutyl by R^2 = H would encourage production of orthoquinone is not realized and only the paraquinone is obtained on oxidation of 2,6-ditertbutylphenol (*5b*). It is likely in this case, however, that the anticipated monotertbutylorthoquinone product would not be stable against self-condensation like the orthoquinone **3**.



The observed NIH shift accompanying oxidation of 2,6-dimethyl-4-deuteriophenol to the paraquinone **16** is expected to occur in species such as **21** and **22**. Retention of deuterium in the diphenoquinone **17** was unexpected since this product is likely to result from simple coupling of phenoxyl radicals. It was confirmed in the present study that production of **17** by oxidation of xylenol-*d* with ferricyanide occurred with complete loss of deuterium. It is for this reason that equilibria between chromate esters **21** and **22** and the phenoxyl radical have been postulated in reactions [1] and [2*b*], thus allowing for the generation of some NIH-shifted radicals. An alternative but unlikely possibility is that some or all of the diphenoquinone results from the heterolytic displacement reaction [5].

The oxidations of chloro- and bromophenols presumably also occur by reactions analogous to [1] and [2]. The halogenation, or halogen exchange, reactions are explained by a rapid reaction [2*a*] followed by a reversion of the chlorocyclohexadie-

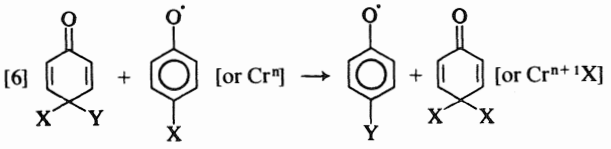
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

none back to a phenoxy species by a halogen abstraction process. The halogen may be removed in the form of an atom either by a phenoxyl radical or a metal complex species, depicted in [6], or as a halide ion by a Lewis acid to generate a phenoxonium ion. Such reactions are expected to occur

in both *ortho* and *para* positions. When the carbon atom which undergoes halogenation in reaction [2*a*] already bears a halogen atom, interchange can occur. If the carbon atom bears a hydrogen atom, enolization of the cyclohexadienone produces a chlorinated phenol.

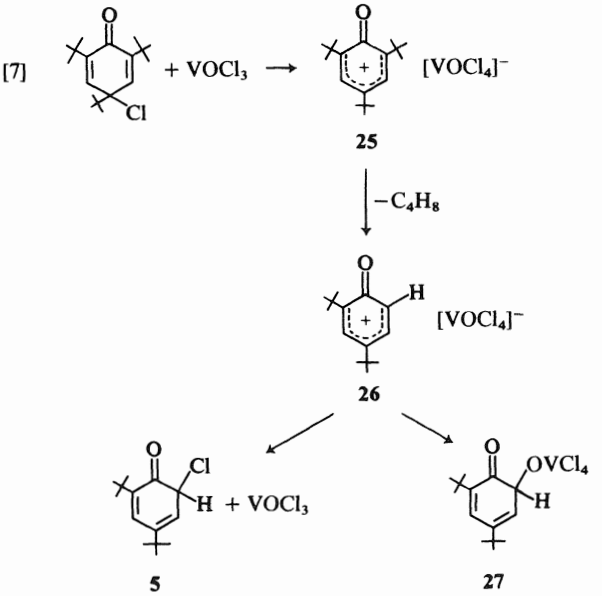
As in the case of alkyl phenols, it seems that the halogenation and dehalogenation steps are kinetically favoured while the oxygenation process is thermodynamically favoured.

Reactions of Phenols with Vanadyl Chloride



The reactivity patterns observed with $VOCl_3$ are quite different from those observed with CrO_2Cl_2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



in a number of respects. The rather effective dealkylation of **1**, the production of modest yields of quinones and of chlorinated products are reminiscent of the CrO_2Cl_2 reaction, but the production of large amounts of orthodealkylated chlorophenol or C—C coupled dimers and the absence of the corresponding paradealkylated products (see Table 2) are peculiar to the $VOCl_3$ reaction. Since it is quite common for mild Lewis acids to selectively catalyze orthoalkylation (8), selective orthodealkylation catalyzed by $VOCl_3$, or some related species, is not too surprising. The relatively low reactivity of phenols with less than three alkyl substituents makes it unlikely that they are the intermediates responsible for the dealkylated products from oxidation of **1**. However, the similarities of product distributions are sufficiently strong to suggest common reactive intermediates in the cases of di- and tritertbutylphenols.

The differences in reactivity between trialkyl- and dialkylphenols are probably related to the marginal ability of $VOCl_3$ to generate phenoxyl radicals. It is well established that phenol itself and cresols form relatively stable trialkyl vanadate(V) esters with $VOCl_3$ (9), although monoalkylphenols can undergo oxidative coupling under certain conditions (7). The present results indicate that the phenols **5** and **6** react slowly with $VOCl_3$ under the conditions used but that, once brought into reaction, they produce some of the products also arising from the much more reactive **1**.

The ease with which **4** is transformed to **5** by $VOCl_3$ makes it very likely that **5** is produced by way of **4** and that the formation of **4** is a kinetically favoured reaction, as in the case of CrO_2Cl_2. The regiospecific deposition of the chlorine at the *para*-position in **4** and the *ortho*-position in **5** fits the pattern expected if **4** is formed by chlorine atom transfer from $VOCl_3$ to a tritertbutylphenoxyl radical (cf. the $CuCl_2$ reaction, ref. 3) and **5** is formed by way of a carbenium ion intermediate as, for example, in eq. [7]. Collapse of the ion pair **26** by chloride ion transfer will lead to the irreversible formation of **5**, whereas collapse by oxygen attachment will give **27**, a potential precursor to the C—C coupled products **10** and **11** and the orthoquinone, **3**.[2] The failure to produce C—C coupled products by reaction of **4** with $VOCl_3$ suggests that the presence of phenol, or phenoxide, is critical to the coupling reaction. Clearly, the production of quinone from **4**

by way of a species such as **27** (or the 4-dealkylated analogue) does not need the intervention of a phenoxyl moiety. The reason why the production of paraquinone is greatly favoured over that of orthoquinone whilst the reverse is true of chlorination remains obscure. A very interesting reversal of specificity between the CrO_2Cl_2 and $VOCl_3$ systems is observed in the oxidation of **9**. With CrO_2Cl_2 this compound gave the 1,4-quinone **2** in ca. 90% yield and no isolable diphenoquinone **14**. On the other hand, $VOCl_3$ gave a product containing diphenoquinone (and diphenol **15**) in twenty-fold excess over 1,4-quinone. These selectivities presumably reflect the relative rates of 4–4 homocoupling of the free phenoxy radical and of the attachment of radicals to oxygen to form metallate esters. The coupling reaction clearly dominates with the mildly oxidizing $VOCl_3$, whereas the oxygen attachment dominates in the case of CrO_2Cl_2. The fact that 2,6-dimethylphenol gives a substantial yield of the diphenoquinone **17**, in addition to the 1,4-quinone **16**, illustrates that the rates of the two alternative pathways are quite similar.

A Comparison of $CuCl_2$, $VOCl_3$, and CrO_2Cl_2

The differences between the three title oxidants in their behaviour towards tertbutylphenols is strongly related to the relationship between the oxidizing power of the metal ion and its acidity. In the case of copper, the oxidizing power is sufficient

[2]The mechanism whereby such a coupling takes place is not clear. Since some of the chlorine ligands of **27** are likely to have been replaced by phenoxide, the possibilities of both intramolecular and intermolecular coupling processes exist. The high specificity for 2,2′-coupling does suggest specific involvement of the vanadium.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

to generate phenoxyl radicals and these radicals can easily abstract chlorine atoms from copper; they cannot, however, abstract oxygen as evidenced by the fact that the presence of water does not measurably impair the chlorine atom transfer (3). Thus, the only product obtained from $CuCl_2$ oxidation of **1** is the cyclohexadienone **4**. Although $VOCl_3$ is seemingly less able to oxidize phenols to the radical, the greater acidity of the highly charged ion[3] facilitates dealkylation and other reactions typical of carbenium ions, in addition to rendering the formation of the chlorocyclohexadienone, **4**, reversible. It is believed that this reversibility is the key to formation of quinones, since it allows transit beyond the kinetically favoured **4** to the thermodynamically favoured quinones and chlorophenols, and the failure of copper(II) to effect these reactions may be attributed to its low acidity. The very high effective charge of Cr^{VI} seems to render the transfer of oxygen ligand sufficiently fast to diminish considerably the leakage of radicals, or carbenium ions, into halogenation and C—C coupling reactions, and gives a much greater selectivity for the production of quinones than is obtained with $VOCl_3$.

Oxometal Complexes as Models for Heme-containing Oxidases

There has been considerable discussion of the possibility that the peroxidase I and II compounds (and analogous compounds of other heme proteins) and the active intermediate in functioning cytochrome P-450 may be "ferryl" species (6). Both chemical evidence and theoretical calculations have been put forward to support the claim that oxometal complexes such as CrO_2Cl_2 can mimic important characteristics of oxidase activity (1, 2), in particular the NIH proton shift and halogen shift (10). From the present investigation it is concluded that the similarity between the behaviour of CrO_2Cl_2 and heme proteins is superficial and of very limited use. The most evident failure of CrO_2Cl_2 to mimic cytochrome P-450 lies in the fact that it does not induce 1,2-halogen shifts, but does effect halogenation in the 3-position relative to the transferred oxygen. Because CrO_2Cl_2 does effect an NIH proton shift, it cannot be taken to indicate more than the fact that there is probably an intermediate with carbenium ion character whose genesis may result from a number of quite different reactions (e.g., halide ion abstraction, electron abstraction, opening of an epoxide). Given the observed and potential complexity of the $VOCl_3$ and CrO_2Cl_2 reactions described above, it would not be surprising if one of the reaction pathways bore more resemblance to that occurring in a functioning heme oxidase. Although the present results do not exclude the possibility of oxygen atom transfer from Cr^{VI} or V^V as a two-electron single-step ligand transfer process, they certainly do not require it and it is considered that the one-electron process of eq. [2*b*] is more likely. While Cr^V species in the past have been regarded as, at best, very unstable transients, a recent report indicates that oxochromium(V) compounds with simple organooxygen ligands can be produced as very stable entities by one-electron reduction of Cr^{VI} (11).

[3]The exact nature of the acidic species remains undetermined. The possible involvement of hydrolytically-produced HCl and oxidation levels other than those of V^V and Cr^{VI} cannot be excluded.

Experimental

Materials

Both CrO_2Cl_2 and $VOCl_3$ were prepared according to published procedures (12) and redistilled immediately prior to use. Hydrocarbon solvents were freshly distilled from sodium benzophenone before use. Phenols were obtained as reagent grade materials from Aldrich Chemical Co. and were subject to either a single recrystallization or distillation before use.

Analytical Procedure for Products of Tritertbutylphenol Oxidation

The reaction products were subject to gradient elution chromatography on silica gel. Tritertbutylphenol was rapidly eluted by hexane, other phenols moved rapidly with toluene. The cyclohexadienone **4** required chloroform or methylene chloride for an appreciable elution rate and the quinones required ethanol. A gradient elution based on this sequence of solvents gave a sufficiently good separation of all major reaction products to allow their subsequent purification and characterization. Following identification of the major products, a more exact analysis of the composition of the eluate fractions was carried out by ^1H nmr and a complete material balance deduced.

Under the above conditions the products eluted in the following order: 2,4,6-tritertbutylphenol, 2-chloro-4,6-ditertbutylphenol (13), 2,2′-dihydroxy-3,3′,5,5′-tetraterbutylbiphenyl (14), 1-chloro-3,6,8-tritertbutyldibenzofuran, 2,4-ditertbutylphenol,[4] 4-chloro-2,4,6-tritertbutylcyclohexadienone (15), 2,6-ditertbutylbenzo-1,4-quinone (16), 4,6-ditertbutylbenzo-1,2-quinone (17).

The only product not commonly available, or previously described in the literature, was the cross-coupled dibenzofuran, **11**, produced in the $VOCl_3$ oxidation reaction (see Table 2). The structure assignment of this compound was based on the previous observation of dibenzofuran formation in oxidative degradation of hindered phenols (14) and on the following physical evidence. The compound had a melting range of 105–106°C. Infrared spectrum: complete absence of bands due to OH or dienone carbonyl. ^1H nmr spectrum: three non-equivalent tertbutyl resonances (1.63, 1.57, and 1.43 τ in $CDCl_3$) each of relative intensity 9 and a complex multiplet (7.3–7.8 τ) due to aromatic protons of total relative intensity 4. Mass spectrum *m/e* (abundance): 370 (M^+, 8), 355 ($M - CH_3$, 15). Each of the cited peaks was accompanied by the appropriate ^{37}Cl satellite indicating the presence of a single chlorine. *Anal.* calcd. for

$C_{24}H_{31}OCl$: C 77.9, H 8.37, O 4.32, Cl 9.4; found: C 77.8, H 8.35, O 4.2, Cl 9.19.

Oxidation of Tritertbutylphenol by CrO_2Cl_2

The following is a description of a representative reaction. A solution of **1** (2.5 g) in hexane (50 mL) was cooled under nitrogen to −65°C with vigorous stirring. After temperature equilibration, a freshly distilled sample of CrO_2Cl_2 (1.5 g) was injected into the reaction vessel. Although the reaction appeared to be almost instantaneous, the dark green slurry was stirred for a further two hours before warming to room temperature. The solvent was removed under vacuum and the residual solid was shaken with water and extracted several times with diethyl ether. Following drying over anhydrous $MgSO_4$ and evaporation of the ether, the product was fractionated by column chromatography.

The oxidation of other phenols was carried out in essentially the same way.

Oxidations using $VOCl_3$

The procedure with $VOCl_3$ was essentially the same as that used with CrO_2Cl_2 except that most of the $VOCl_3$ reactions were carried out at room temperature. Heptane was employed for the reaction of **1** at 90°C. The reaction of $VOCl_3$ with the tritertbutylphenoxyl radical was effected by adding the $VOCl_3$ to a hexane solution of the radical prepared by standard procedures (15).

Synthesis and Oxidation of 2,6-Dimethyl-4-deuteriophenol

The title phenol was prepared by a method analogous to that used by Butte and Price (18). A solution of 2,6-dimethylphenol (1.22 g, 0.01 mol) and sodium methoxide (0.54 g, 0.01 mol) in D_2O (10 mL) was sealed in a thick-walled, pyrex tube and heated at 100°C for four days. Following neutralization with CO_2 and extraction with ether, the recovered xylenol was found to have undergone ca. 80% exchange at the 4-position by ^{13}C nmr and mass spectroscopy. This xylenol was subject to oxidation by CrO_2Cl_2 in hexane and the resulting quinone and diphenoquinone were easily separated on a silica column. The deuterium retention was measured by conventional mass spectroscopy.

N_{1s} core binding energies for 2-, 3-, and 4-substituted pyridines determined by X-ray photoelectron spectroscopy. Correlations with theoretical models, substituent parameters, and gas phase basicities

R. S. BROWN AND A. TSE

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 9, 1979

R. S. BROWN and A. TSE. Can. J. Chem. **58**, 694 (1980).

N_{1s} binding energies for 36 pyridines substituted at the 2-, 3-, and 4-positions have been determined by X-ray photoelectron spectroscopy. The differences in BE relative to pyridine are analysed in terms of existing theoretical approaches (electrostatic, ground potential, and relaxation potential models) and compared with $\Delta BE_{C_{1s}}$ values calculated for analogous monosubstituted benzenes. One finds good correlations of $\Delta BE_{N_{1s}}$ with solution determined σ-substituent values although some substituent values deviate from the correlation probably due to solution effects which are not present in the gas phase. Correlations between $\Delta BE_{N_{1s}}$ and ^{14}N nmr chemical shifts are poor, particularly for electron withdrawing substituents. The relationship between $BE_{N_{1s}}$ and gas phase basicity values (ΔG^0) is good, and it appears as if the $BE_{N_{1s}}$ is more sensitive to the substituent than ΔG^0. MINDO/3 calculations on the methoxypyridines and their conjugate acids employing full geometry optimizations are presented and analysed in order to determine the effect of geometric relaxation on the gas phase basicity.

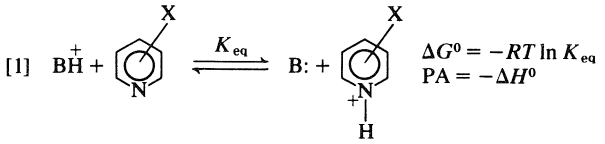
R. S. BROWN et A. TSE. Can. J. Chem. **58**, 694 (1980).

On a déterminé les énergies de liaison N_{1s} de 36 pyridines substituées en positions 2, 3 et 4 par la spectroscopie photoélectronique de rayons-X. On a analysé la différence des EL relatives à la pyridine en fonction d'approches théoriques existantes (modèles électrostatique, de potentiel de l'état fondamental et de potentiel de relaxation) et on les a comparées aux valeurs de $\Delta EL_{C_{1s}}$ calculées pour les benzènes monosubstitués analogues. On trouve de bonnes corrélations entre les $\Delta EL_{N_{1s}}$ et les valeurs σ des substituants déterminées en solution bien que certaines valeurs de substituants dévient de la corrélation probablement par suite des effets de solution qui ne sont pas présents dans la phase gazeuse. Les corrélations entre les $\Delta EL_{N_{1s}}$ et les déplacements chimiques en rmn ^{14}N ne sont pas bonnes, particulièrement dans le cas des substituants électroattracteurs. La relation entre les $EL_{N_{1s}}$ et les valeurs de basicité de la phase gazeuse (ΔG^0) sont bonnes et il semble que les $EL_{N_{1s}}$ sont plus sensibles aux substituants qu'à ΔG^0. On présente des calculs MINDO/3 sur les méthoxypyridines et leurs acides conjugués en utilisant une optimisation maximale de la géométrie et on les analyse dans le but de déterminer l'effet de la relaxation géométrique sur la basicité de la phase gazeuse.

[Traduit par le journal]

I. Introduction

During the last decade, much attention has been devoted to the effect of a substituent on the binding energies (BE's) of a core 1*s* electron. Initial work in this area involved mechanisms by which a substituent X altered the C_{1s} BE in some substituted benzenes (1), and models were developed which explained the substituent effect in terms of ground state inductive and/or mesomeric effects (1), and excited state or relaxation effects (2) in which the entire molecule relaxes electronically accompanying core ionization. The work was gradually extended to recognise the formal similarity between loss of a core electron, and gain of a proton (3) which led to correlations between gas phase basicities and core BE's (3, 4).



As part of a project designed to experimentally determine situations under which the correlations between gas phase basicities and core BE's fail, we required a large number of pyridine N_{1s} ionization energies. Considering the amount of work expended on the substituted benzenes, it seemed rather surprising that virtually no work (with the exception of that of Davis and Shirley (2*d*)) had been performed on the substituted pyridines. A regular series of 2-, 3-, and 4-substituted pyridines would offer considerable experimental benefits over the analogous benzenes for several reasons. Firstly in terms of C_{1s} BE's, the monosubstituted benzenes should in principle show four different ionizations, but in practise these are badly overlapped so that assignment of the BE belonging to a particular carbon is ambiguous. Since the pyridine N_{1s} ionization is far removed from others, there would be no difficulty in determining the effect of a remote substituent on the N_{1s} BE. Comparison of these shifts with those predicted from CNDO/2 calculations for the substituted benzenes (1*f*) would offer definitive experimental evidence to test the strength of the CNDO/2 model. Secondly these N_{1s} BE's would provide clear data to test the scope of both the ground potential model (GPM) and relaxation potential model (RPM) (2) as well as other more empirical substituent parameters (σ^+ or σ values) which had been derived from solution chemical processes only remotely related to the ionization process. Thirdly, since there is much available data (5) on gas phase basicities (ΔG^0) and

proton affinities (PA or $-\Delta H^0$) for substituted pyridines determined by equilibrium studies according to eq. [1], these values could be correlated with the BE's for an extended series of pyridines.

In section II we present the BE's for 36 pyridines and discuss them in section III in terms of the above correlations. Section IV describes the experimental procedures.

II. Results

Core binding energies ($BE_{N_{1s}}$) for a series of 2-, 3-, and 4-X-pyridines (X = NO_2, CF_3, CN, F, Cl, Br, (H), CH_3, OH, OCH_3, $COCH_3$, NH_2, and $N(CH_3)_2$) are presented in Table 1 along with their gas phase basicities where available (5).[1] Additionally the ΔBE and $\delta\Delta G^0$ values representing the change in binding energy and gas phase basicity respectively relative to pyridine are included in the table. Each BE value is the average of at least three sequential cycles which alternatively scanned the N_{1s} region and the reference neon Auger (6) region and has a precision of ± 0.03 eV unless noted. Since the shifts are rather small, being at most ± 1 eV from pyridine, the precision is important for the correlations discussed in section III.

III. Discussion

A comparison of the BE for each substituted pyridine with that of pyridine allows one to establish the ΔBE or "chemical shift" provided by a certain substituent on the N_{1s} ionization. For the monosubstituted benzenes the experimental determination of ΔBE for the C_{1s} ionizations is not as simple since the bands are badly overlapped. For the latter cases, one approach (1*f*, *e*) has been to

$$[2]\quad \Delta BE_i = k_c q_i + \sum_{j \neq i} \frac{q_i}{R_{ij}}$$

estimate the relative chemical shift (ΔBE_i) of an atom *i* as being affected by the charge on that atom (q_i) and the charges on the adjacent atoms modified by their distance (R_{ij}) from the test atom where k_c is a constant which commonly has a value of ~22 eV/unit charge. This particular model (the electrostatic potential model) (1*e*) assumes therefore that the change in BE is simply related to the ground-state environment of the molecule and is often found to provide satisfactory agreement with experiment (1). Correlations with this model assume that differences in relaxation terms accom-

[a] $BE_{N_{1s}}$ values are reported as the average of at least 3 runs and have a precision $\geq \pm 0.03$ eV.
[b] Calibrated against an internal standard N_e Auger line (KE = 804.56 eV) (6).
[c] $\Delta BE_{N_{1s}} = BE_{N_{1s}}$ (pyridine) − $BE_{N_{1s}}$ (substituted pyridine); a positive value indicates the base is easier to ionize than pyridine. ΔEB (kcal/mol) = 23.06 (ΔEB (eV)).
[d] $\delta\Delta G^0 = \Delta G^0$ (pyridine) − ΔG^0 (substituted pyridine); a negative value for $\delta\Delta G^0$ indicates the base is stronger than pyridine.
[e] Values are from ref. 5*a* and from R. W. Taft, private communication; we thank Prof. Taft for generously informing us of his corrected basicities. Values in brackets are those from ref. 5*d* (see footnote 1).
[f] 2-Hydroxypyridine exists in the gas phase in equilibrium with 2-pyridone, and different N_{1s} BE's are seen for each. For assignment of the N_{1s}BE for 2-OH pyridine see ref. 4*h*.
[g] The N_{1s} ionization region for 3-$N(CH_3)_2$-pyridine shows a single broad peak (half-width = 1.9 eV) which was deconvoluted assuming two equal half-width ionizations. We assign the low binding energy peak to the pyridine N_{1s} in analogy to the 3- and 4-substituted systems: precision ±0.1 eV.

[1] Most ΔG^0 and ΔH^0 values for substituted pyridines are derived from a single laboratory and can be found in ref. 5. The values in ref. 5*d* were kindly supplied by Prof. D. H. Aue, Department of Chemistry, University of California, Santa Barbara, and can be found in D. H. Aue and M. T. Bowers. *In* Gas phase ion chemistry. *Edited by* M. T. Bowers. Academic Press, New York, NY. 1979.

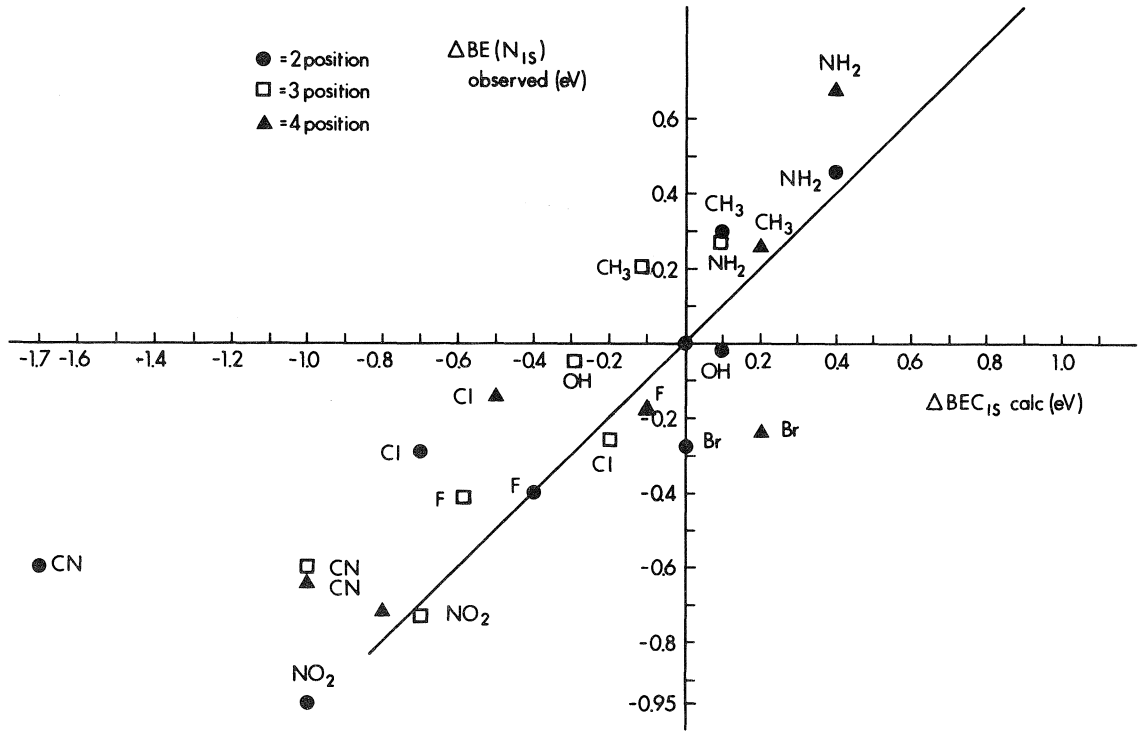

FIG. 1. A plot of $\Delta BE_{N_{1s}}$ against $\Delta BE_{C_{1s}}$ (calculated) for substituted pyridines and benzenes, respectively. Values for $\Delta BE_{C_{1s}}$ are from ref. 1*f*.

panying ionization within a series of molecules will cancel so that the dominant factors influencing chemical shifts are ground-state inductive and/or mesomeric effects. It is therefore instructive to compare the $\Delta BE_{N_{1s}}$ values for the substituted pyridines with the predicted $\Delta BE_{C_{1s}}$ values for various positions of substituted benzenes (1*f*) (Fig. 1).

In principle the slope of the graph in Fig. 1 should be unity if substituents influence C_{1s} and N_{1s} ionizations to the same extent, and the line should pass through the origin. A least squares analysis shows the slope to be near unity (1.14) but there is sufficient scatter in the points ($r = 0.82$) to indicate some shortcoming in the correlation. Notably the 3-CH_3, 4-Br, and 2-CN positions deviate badly. The probable source of the lack of correlation is related to deficiencies in the CNDO/2 parameterization (7), the inapplicability of applying a point charge electrostatic model to π-systems, or the inability of the electrostatic model to account for relaxation effects in the ions.

Correlations of Observed $\Delta BE_{N_{1s}}$ with CNDO/2 Calculations based on the Ground Potential (GPM) and Relaxation (RPM) Models

The GPM developed by Davis *et al.* (1*c*) calculates the electrostatic potential of an electron at a nucleus as being

$$e^2 < \sum_i 1/r_i > -e^2 \sum_j Z_j/R_{ij}$$

where r_i and R_{ij} refer to the distance between the parent nucleus and the i^{th} electron and j^{th} other nucleus respectively, and Z_j indicates the nuclear charge on the j^{th} nucleus. Based on CNDO wave functions, the shift in electrostatic potential (ΔV) at a given nucleus can be related to ΔBE as $\Delta BE = -\Delta V$. Figure 2 shows a correlation between the observed and calculated $\Delta BE_{N_{1s}}$ for the series of 2-, 3- and 4-pyridines based on this approach. Standard bond lengths and angles were assumed for the substituents (7*a*), and the geometry of the pyridine ring was taken to be that of pyridine itself as determined by gas phase electron diffraction (7*b*, *c*). Figure 2 shows a general agreement between experiment and theory that could be considered acceptable considering the crudeness of the model. Qualitatively, ionizations calculated to be larger or smaller respectively than pyridine are experimentally found to be as predicted but quantitatively the agreement is poor. Comparison of experimental and calculated shifts based on the GPM have been found to be more or less satisfactory in other systems (1*c*, *d*, 8). In the present case the best fit

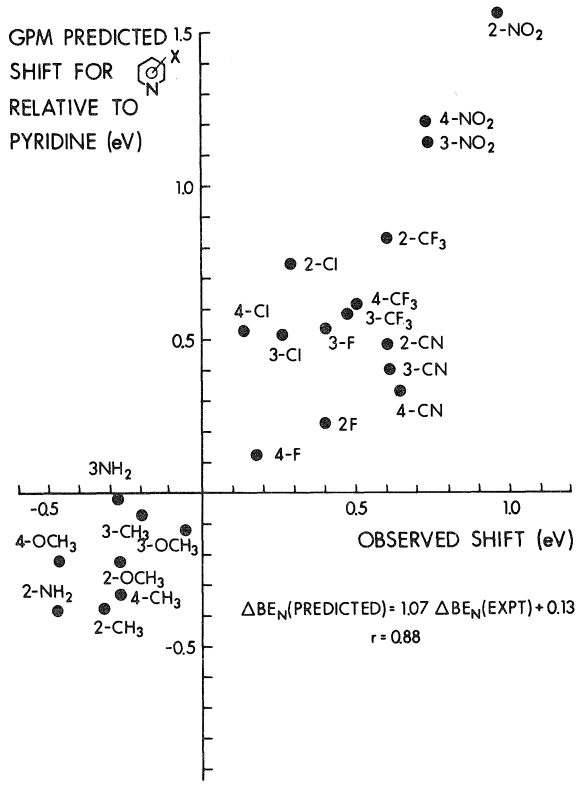

FIG. 2. A plot of $\Delta BE_{N_{1s}}$ (observed) against $\Delta BE_{N_{1s}}$ (calculated) on the basis of the ground potential model (GPM).

straight line has a near unit slope as predicted from the theory; $\Delta BE_{N_{1s}}$ (calcd) = 1.07 $\Delta BE_{N_{1s}}$ (obsd) + 0.13 (r = 0.88). the reason for the lack of quantitative agreement could be related to a number of shortcomings in the CNDO method (parameterizations) or incorrect geometries or more fundamental difficulties in treating delocalized π-systems with point charge models (1*c*).

Since the GPM approach is based solely on ground state factors and ignores electronic relaxation accompanying core ionization (which is expected to be substituent and position dependent), it might be expected that allowances made for the latter effect would improve the correlation. One such approach within the CNDO framework is the relaxation potential model (RPM) (2) in which for the purposes of calculating the nitrogen "hole state" an equivalent core approximation is used whereby the ionized atom (N) is replaced by the next highest element (O). Equations [3] and [4] outline the approach, where

$$[3] \quad \Delta BE = -\Delta V_n - \Delta V_R$$

$$[4] \quad V_R = \tfrac{1}{2}[V_n(Z+1) - V_n]$$

V_R is the relaxation potential, V_n is the potential experienced by an electron at nucleus n, and $Z + 1$ represents the equivalent core. The RPM approach has provided better agreement with experimental ΔBE's when molecular polarizability affects V_R markedly (2*e*, 3, 8).

A plot of the RPM against experimental $\Delta BE_{N_{1s}}$ is shown in Fig. 3. Visually the graph appears similar to that in Fig. 2 except that the calculated $\Delta BE_{N_{1s}}$ values are somewhat smaller particularly for the 2- and 4-substituents (i.e., the intercept of the graph is lowered from that in Fig. 2) and the best fit straight line is ΔBE (calcd) = 1.04 ΔBE (obsd) − 0.06 (r = 0.88). It would appear that inclusion of the relaxation terms in the model offers no improvement in correlation over that found for the GPM. However it is instructive to qualitatively assess the position dependence of including relaxation in the calculations. Table 2 lists the calculated differences in N_{1s}-BE ($\delta\Delta BE_{N_{1s}}$ (GPM − RPM)) which gives some measure of the importance of electronic relaxation of the substituents at various positions. One expects that, if relaxation is important, the $\delta\Delta BE_{N_{1s}}$ values in Table 2 would be large, and decrease when it is of lesser importance. In all cases it would appear that for a given substituent the order of importance of relaxation is 2 > 4 > 3. Hence for a given substituent, the inclusion of relaxation in the model is between two and three times as important for 2- and 4-substituents as for 3-substituents. This

amounts simply to saying that 2- and 4-substituents can better respond to N_{1s} photoionization through electronic polarization than can 3-substituents.

Correlations between ΔBE and σ-Substituent Parameters

For chemical processes the substituent effects are described by σ-parameters derived according to eq. [5] where

[5] $y = \rho\sigma + b$

y is the change in reactivity of the system relative to a suitable reference and σ is the substituent parameter; ρ is the sensitivity factor. For N_{1s} ionization (eq. [6]) the process can also be correlated by existing substituent parameters (9).[2]

[6] 

A graph of $\Delta BE_{N_{1s}}$ vs. σ-values is given in Fig. 4, and the best fit straight line is $\Delta BE_{N_{1s}} = -1.07\sigma + 0.06$ eV ($r = 0.985$). Considering that the substituent values were determined in aqueous media for a chemical process only remotely related to N_{1s} photoionization the correlation is remarkably good. The fact that both 3- and 4-substituents lie on the same line (within the precision of the experiment) would tend to indicate that the mechanisms by which they interact with the N_{1s} core hole are not markedly different. While direct resonance interactions are *not* of significance in stabilizing the core hole (the resonance structures involve the valence electrons), one might have thought that the changes in nitrogen charge density accompanying core ionization might be influenced considerably more by good electron donors such as OR or NR_2 at the 4-position. This should have been observed as a significant upward deviation from the graph for 4-NH_2, $N(CH_3)_2$, and OCH_3, contrary to what is actually observed. These groups are better electron donors at the 4- than at the 3-position according to their σ values, but the graph would tend to indicate similar mechanisms by which the substituent interacts with charged species produced by either benzoic acid ionization or pyridine N_{1s} photoionization. Correlations of 1*s* BE values with σ-substituent values has been observed (9*b*) in a limited series of anilines. While the σ-values are not explicitly derived for photoionization processes, relaxation due to polarization in response to benzoic acid ionization *is* incorporated into the substituent σ-value by measuring the overall substituent effect at various positions. Hence for electron donors, the measured σ-values at the 4-position are more negative than at the 3-position. It is interesting to note that the *p*-OH group which is according to either σ or σ^+ values a good electron

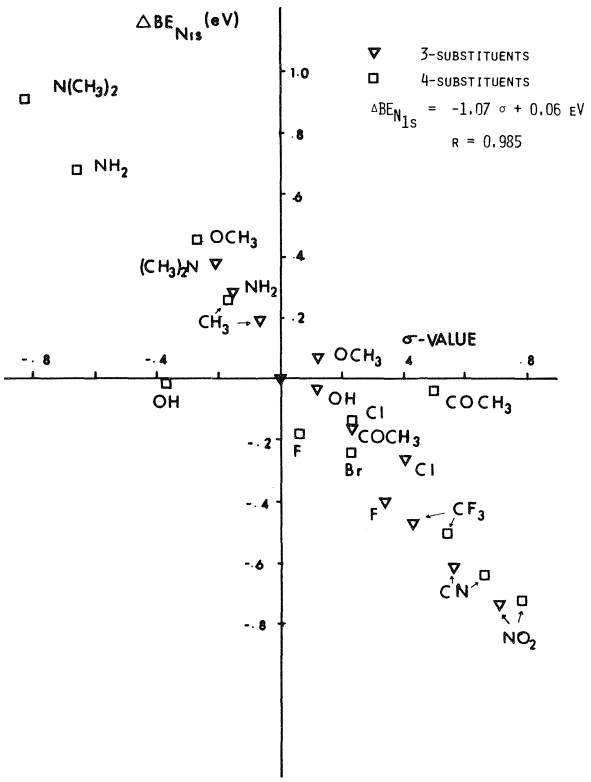

FIG. 4. A plot of $\Delta BE_{N_{1s}}$ (observed) against σ-substituent parameters from ref. 9.

[2]All of the present σ and σ^+ parameters have been abstracted from ref. 9. Correlation coefficients (r) were obtained from standard least-squares plots and are perhaps not in themselves particularly valuable in determining the precisions of structure–activity relations in that graphs which visually appear to have quite poor statistical fits still have large r-values. See ref. 10 for a discussion of this point.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

donor, falls badly off the correlation in Fig. 4. This substituent is known (10, 11) to show marked H-bonding effects in solution. The present gas phase results which are free from solvent effects would indicate that the OH group at the 3- and 4-positions is not particularly different from H in terms of its overall substituent effect in this process. A similar conclusion might be drawn for 4-$COCH_3$ from Fig. 4. This substituent appears to be far too electron withdrawing from solution data to correlate well with the graph.

Correlations between $\Delta BE_{N_{1s}}$ Values with Pyridine ^{14}N nmr Chemical Shifts

The connection between binding energy and nmr chemical shifts was first discussed by Basch (12) and early correlations between $\Delta BE_{C_{1s}}$ and δ ^{13}C chemical shifts for a series of closely related halomethanes were presented (13). The correlations for an expanded set of substituted methanes and *p*-substituted fluorobenzene ^{19}F chemical shifts have been reviewed by Lindberg (14), who concluded that useful correlations between nmr and ESCA (electron spectroscopy for chemical analysis) shifts should be expected "provided that the objects for correlation are wisely chosen". A comparison of $\Delta BE_{N_{1s}}$ data from Table 1 with existing ^{14}N chemical shift values for a limited series of pyridines (Fig. 5) (15) shows a rather poor correlation ($r < 0.65$) in that large changes in ΔBE do not appear to lead to predictable ^{14}N shifts particularly for electron withdrawers. Gelius *et al.* (16) have questioned the overall applicability of comparisons between nmr and ESCA chemical shifts since the factors responsible for each shift depend upon different terms; the present data would appear to support this conclusion at least for pyridines.

Correlations between $\Delta BE_{N_{1s}}$ and Gas Phase Basicity ($\delta\Delta G^0$)

Much effort has been expended in determining correlations between ΔBE's and $\delta\Delta G^0$ relative to a suitable reference material according to eq. [1] (3, 4).

Figure 6 illustrates the correlation between $\Delta BE_{N_{1s}}$ for these substituted pyridines and their existing gas phase basicities relative to pyridine ($\delta\Delta G^0$). The best fit straight line including 24 bases substituted at the 2-, 3-, and 4-position is $\Delta BE_{N_{1s}} = -1.40\ (\delta\Delta G^0) + 2.0$ kcal/mol ($r = 0.980$).[3] It is

[3]The best fit straight line for (*a*) 2-X pyridines: $\Delta BE_{N_{1s}} = -1.5\ (\delta\Delta G^0) + 3.65$ kcal/mol ($r = 0.980$, 10 data); (*b*) 3-X pyridines: $\Delta BE_{N_{1s}} = -1.36\ (\delta\Delta G^0) + 1.55$ kcal/mol ($r = 0.988$, 7 data); (*c*) 4-X pyridines; $\Delta BE_{N_{1s}} = -1.34\ (\delta\Delta G^0) + 0.16$ kcal/mol ($r = 0.996$, 10 data).

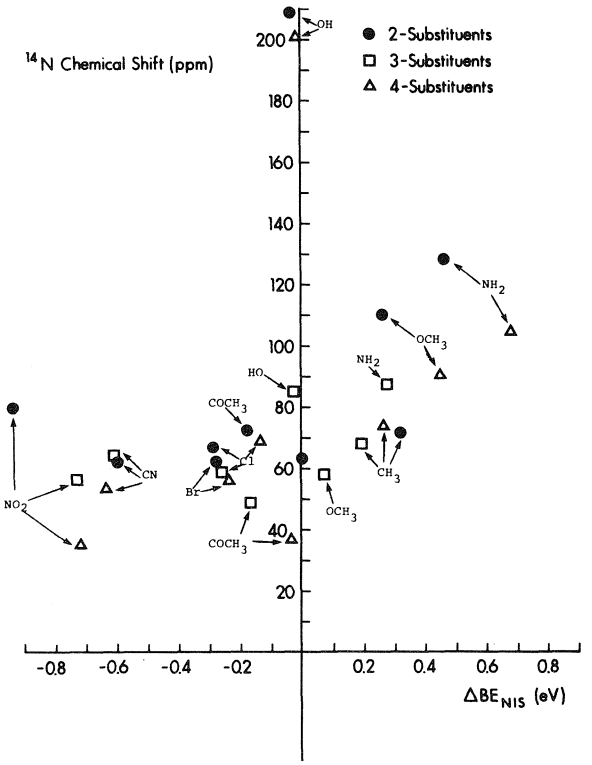

FIG. 5. A plot of $\Delta BE_{N_{1s}}$ (observed) against ^{14}N chemical shifts (in ppm relative to CH_3NO_2) abstracted from ref. 15. The NH_2, OH, and NO_2 values were determined in acetone, while the remainder were obtained from neat liquids.

important to note that the slope[3] of the line is somewhat greater than the theoretically modelled (−) unit slope (2*c*, 3) indicating the substituent influences ΔBE to a greater extent than $\delta\Delta G^0$. This has been observed in correlations with oxygenated molecules (4*a*, *d*) and phosphines (4*e*). However, it is in contrast to a (−) unit slope assumed for some aliphatic and aromatic amines (including pyridine) (4*f*), although the latter authors explicitly stated that the unit slope did not represent a best fit. Inspection of Fig. 6 shows the fit is generally quite good although there are some exceptions (*vide infra*). One could on the basis of the calculated best line for Fig. 6 predict some unknown basicities given the values in Table 1, and we anticipate the $\delta\Delta G^0$ values would be good to ±2.0 kcal/mol.

One should note an interesting *lack* of correlation in the methoxy pyridines whose order of basicity is 2< 3< 4, while the ΔBE values are 3< 2< 4. The reason for the lack of correlation is not clear and therefore MINDO/3 calculations were utilized to attempt to provide some insights.

MINDO/3 Calculations on Methoxy Pyridines

The photoionization process is a vertical one in

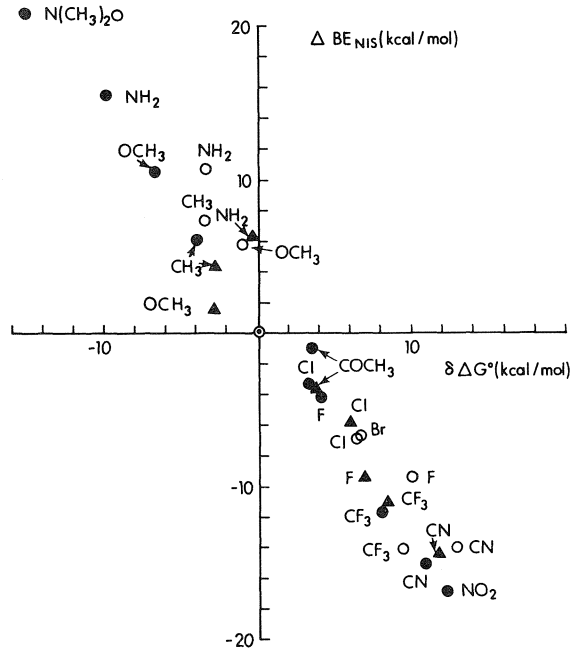

FIG. 6. A plot of $\Delta BE_{N_{1s}}$ (observed) against the differences in gas phase basicities ($\delta\Delta G^0$) for 2-, 3-, and 4-substituted pyridines. Open circles (○) are for 2-, while (▲) are for 3-, and closed circles (●) are for 4-substituents.

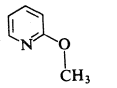
the Franck–Condon sense requiring that the geometry of the ground and ion states remain the same. Hence factors influencing the photoemission process are those related to electronic (inductive and mesomeric) effects on the ground and ion states.

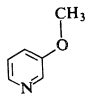
On the other hand, basicity values may be considered adiabatic in the sense that the protonated bases are fully relaxed electronically as well as geometrically, as required by equilibrium conditions. Lack of correlation between ΔBE and $\delta\Delta G^0$ values can at least conceptually be considered to arise from either differences in the site of ionization and protonation (4*f*, *h*) or geometric relaxation of the protonated species which cannot be important in the ionization process (4*g*).

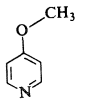
MINDO/3 calculations have been found to give reasonable heats of formation (ΔH_f) for a wide variety of compounds (17) and have been used to provide some insight into the protonation of some dihydropyridines (17*b*). It therefore appeared reasonable that the application of this method to the protonation of the methoxypyridines might provide some correlation with the experimental PA's.[4] For the purposes of comparison, standard free energies ($\delta\Delta G^0$) for eq. [1] have been converted to standard enthalpy changes (δPA) by a common small correction for the changes in the ratio of rotational symmetry numbers for the various B: and $\overset{+}{B}H$. The actual calculations were performed on each of the species in Scheme 1 as follows and the ΔH_f values obtained are listed in Table 3 along with those for various ring-protonated positions for 3-methoxypyridine.

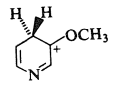
The ΔH_f for the fully geometry-optimized methoxypyridines were calculated according to the MINDO/3 geometry optimization procedure (17). For all species, the plane of the methoxy group was found to be tilted very slightly downward from the plane of the ring, minimizing "ortho" buttressing but still keeping large interactions between the ring and oxygen "*p*" type lone pair. Then a proton was added to each species maintaining the same ground-state ring geometry and the ΔH_f for this so-called "vertical ion" calculated. In principle the calculated difference in ΔH_f for the vertical ion and ground state base should be influenced primarily by electronic relaxation. Finally, a full geometry optimization was performed to yield a ΔH_f for the "adiabatic" ion, which now incorporates geometric relaxation.

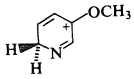
According to the calculation, addition of a proton to form the vertical ion is endothermic by 133.9 kcal/mol. Geometric relaxation here appears to involve reorientation of the OCH_3 group and releases some 2.4 kcal/mol so that the overall process of adding a "bare" proton to 3-methoxypyridine is endothermic by 131.5 kcal/mol. Absolute comparison of this value to the PA of 3-methoxypyridine (221 kcal/mol) (19)[5] is valid only if we consider the ΔH_f for H^+ however, differences in the calculated ΔH_f's for each reaction should provide relative PA's since the $\Delta H_f(H^+)$ cancels in the subtraction. The analogous values for the 2- and 4-isomers are 130.9 and 127.3 kcal/mol and according to the calculation the ordering of calculated proton affinity in 3-OCH_3 is less basic than 2-OCH_3 by 0.6 kcal/mol, and less basic than 4-OCH_3 by 4.2 kcal/mol. The experimental proton affinity ordering shows 2-OCH_3 to be less basic than 3-OCH_3 by 2 kcal/mol and less basic than 4-OCH_3 by 6 kcal/mol, contrary to the MINDO/3 result. While it is perhaps optimistic to expect this semi-empirical technique to provide accurate relative values, it does at least show the correct relative order for 2- and 4-methoxypyridine. Calculations performed on optimized ring-protonated 3-methoxypyridine (Table

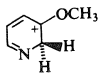












[4]Recently *ab initio* calculations at the STO-3G level (5*b*, 18) have been found to provide excellent correlations with experimental proton affinities of some substituted benzenes and some pyridines (5*b*).

[5]Based on a proton affinity of 202.3 kcal/mol for NH_3.

TABLE 3. MINDO/3 heats of formation for methoxy pyridines and methoxy pyridinium ions[a]

Species	ΔH_f (kcal/mol) B:	Vertical BH^+	Adiabatic BH^+
	−20.96	113.69	109.32
	−22.24	113.36	108.71
	−13.36	120.60	118.16
	−12.82	120.82	118.10
	−15.83	115.63	111.43
	—	—	148.08
	—	—	145.81
	—	—	147.78

[a]All structures optimized according to MINDO/3 procedure (17). Methoxy group is found to lie ~2° out of the plane of the pyridine ring in all structures.

3) indicate that it is energetically more unfavorable by some 25–30 kcal/mol to break the aromaticity, than to protonate on nitrogen.

It would appear from the calculation that geometric relaxation in passing from the "vertical" ion to the "adiabatic" ion releases more energy when the substituent is at the 2- and 4-positions (~4.5 and 4.2 kcal/mol respectively) than at the 3-position (2.5 kcal/mol), since the substituent is better able to interact with the positive charge in the former cases. Analysis of the calculated geometric changes in *all* cases shows that the primary geometric relaxation involves (using the numbering of Scheme 1) a compression of the N_1—C_4 distance by ~0.05 Å, lengthening of the C_2—C_6 distance by ~0.10 Å and shortening of the ring—O distance by

0.03–0.04 Å relative to the unprotonated free base. Differential charge analysis shows the (+) charge to be borne mostly by N_1, NH, the ring carbon to which the substituent is attached, and methyl hydrogens.

It would appear then that there are not large energetically favorable geometric changes accompanying pyridine protonation. Such changes are expected, however, when the protonated atom changes its hybridization (bond angles) significantly (4*g*).

IV. Experimental

Binding energies of gaseous samples were determined using a MacPherson 36 ESCA spectrometer with a MgKα X-ray source (1253.64 eV) and calibrated against an internal standard neon Auger line (804.56 eV kinetic energy) (6). The data were least-squares analysed (20) assuming Gaussian peaks, and the reported values are the averages of at least three runs which alternately scanned the reference line five times, and the nitrogen 1*s* line twenty or more times depending on the volatility. Since a number of the samples were found to be involatile they were introduced into the ionization region of the machine by a heated inlet assembly consisting of a 1/16 in id stainless steel tube bifilar wrapped with nichrome wire. The tube was affixed to an aluminium target chamber which was heated by four 30-Ω Hot Watt pencil heaters in series. The target chamber was affixed to the analyser by a machinable glass insulator which minimized heat conduction to the latter. A thermocouple inserted into the target chamber body allowed determination of the temperature at that point. Electrical feed-throughs allowed entry of the leads for the heating assembly and thermocouple. Determination of the BE's for standards with this assembly reproduced known values, indicating that no anomalous field-effects of the heaters were influencing the BE values. Utilizing this assembly, temperatures of 100–180°C could routinely be reached although in principle temperatures of > 250°C should be attainable.

The following pyridines were commercially available and purified by sublimation and/or distillation prior to use: 2,3,4-CH_3, 2-Br, 2,3-Cl, 2F, 2,3,4-NH_2, 2,4-$N(CH_3)_2$, 2,3,4-CN, 2,3,4-OH, 2,3,4,-$COCH_3$. Their purities were checked by either glpc or tlc.

The substituted pyridines 3-F (21), 2- and 4-NO_2 (22), 3-NO_2 (23), 4-OCH_3 (24), and 3-OCH_3[6] were prepared according to published procedure. 4-Chloropyridine was prepared from basification of the commercial hydrochloride salt with aqueous $NaHCO_3$. The mixture was extracted with methylene chloride, dried (Na_2SO_4), and stripped of solvent to give a red liquid which was distilled (67–69°C/35 Torr) to yield 4-chloropyridine as a colorless liquid. All glassware was treated with NH_4OH and oven dried prior to use. Omission of this step led to decomposition of the 4-halopyridines on distillation.

4-Bromopyridine was prepared analogously to 4-chloropyridine, and micro-distilled (80°C/20 Torr) to give a colorless liquid.

4-Fluoropyridine was prepared by a modified procedure of Lyle and Taft (25) and Desai (26). Four-aminopyridine (3.6 g, 0.038 mol) was dissolved in 16 mL of 48% fluoroboric acid, and cooled to 0°C. Diazotization was accomplished by the addition of 3 g (0.04 mol) $NaNO_2$ in small portions with stirring at such a rate as to keep the temperature < 10°C. After complete addition, the mixture was stirred at 0°C for 1 h and then decomposed by warming to 25°C. After the cessation of N_2 evolution, the solution was quickly cooled to 0°C and neutralized by the addition of solid $NaHCO_3$. Extraction of this mixture with 100 mL CH_2Cl_2, drying of the extracts (Na_2SO_4) and solvent removal gave 0.5 g (13.6%) of 4-fluoropyridine, bp 60–62°C/150 Torr, which was stored over a pellet of NaOH to prevent decomposition.

3-Dimethylaminopyridine was prepared in 47.5% yield overall by the procedure of Clarke *et al.* (27) and purified by micro-distillation (100°C/0.3 Torr) (lit. (28) bp 108–110°C/12 Torr).

The CF_3-substituted pyridines were generously provided by Drs. A. E. Feiring, W. A. Sheppard, and M. Raasch and Mr. E. Wonchoba of the Central Research and Development Department, E. I. DuPont de Nemours and Co., Wilmington, DE 19898.

[6]Prepared analogously to the procedure for 4-OCH_3 (24) and isolated by preparative glpc.

Received November 23, 1979

OCTAVIAN ENEA, CARMEL JOLICOEUR, and LOREN G. HEPLER. Can. J. Chem. **58**, 704 (1980).

Measurements at 25°C with flow calorimeters and densimeters have led to heat capacities and densities of aqueous solutions of 15 unsaturated heterocyclic compounds containing nitrogen. From the results of these measurements we have obtained apparent molar heat capacities and volumes of the solutes. Extrapolations to infinite dilution have led to corresponding standard state apparent and partial molar heat capacities and volumes, which have been analyzed in terms of atomic and group additivity relationships.

OCTAVIAN ENEA, CARMEL JOLICOEUR et LOREN G. HEPLER. Can. J. Chem. **58**, 704 (1980).

On a déterminé les capacités calorifiques et les densités de 15 composés hétérocycliques non saturés contenant de l'azote en solution aqueuse en effectuant des mesures à 25°C à l'aide d'un calorimètre et d'un densimètre dynamiques. A partir des résultats de ces mesures, on a obtenu les capacités calorifiques molaires apparentes et les volumes molaires apparents des solutés. Par extrapolation à dilution infinie, on obtient les capacités calorifiques et les volumes molaires partiels et apparents dans l'état standard qui sont analysés en fonction des relations d'additivité atomique et de groupe.

Introduction

Thermodynamic properties of aqueous solutions of nonelectrolytes have been of interest for a long time. Most early research in this area focussed on free energies (solubilities, activity coefficients, etc.), followed by increasing interest in the temperature dependences of free energies and thence the corresponding enthalpies. More recently, there has been substantial interest in such properties as volumes and heat capacities, which are first and second derivatives of free energies with respect to pressure and temperature, respectively. Reasons for these latter interests are generally of two kinds. (*i*) There is frequently interest in measuring thermal and volumetric properties of aqueous solutions so that the derived thermodynamic functions ($\bar{C}_p{}^0$ and $\bar{V}^0$ in this paper) can be used for thermodynamic calculations of properties of solutions at different temperatures and pressures. (*ii*) Thermodynamic properties, including partial molar heat capacities and volumes, are proving to be useful probes for investigating relationships between structures of solute molecules, solute–solvent interactions, and the "structures" of aqueous solutions.

Various atomic and group additivity schemes for both partial molar heat capacities and volumes have been proposed and used in connection with both (*i*) and (*ii*) above.

In this paper we report the results of our calorimetric and volumetric measurements at 25°C on aqueous solutions of 15 unsaturated nitrogen heterocyclic compounds. Results are given in forms that are appropriate to interests (*i*) and (*ii*) above and are also discussed briefly in relation to additivity schemes.

Experimental

All of our heat capacity measurements have been made with Picker flow calorimeters of the type that has been described in several publications (1–3) from the Université de Sherbrooke. Operation of the calorimeters has been checked as recently recommended (4). Densities of solutions were measured with flow densimeters that have been described previously (5). The results of all measurements refer to 25.0°C.

Compounds from Aldrich were purified by distillation (pyridazine and quinoline), by vacuum sublimation (2,2′-bipyridyl, 4,4′-bipyridyl, *sym*-triazine, quinazoline, imidazole, pyrimidine, and 4-phenylpyrimidine), or by repeated recrystallizations from appropriate solvents (quinoxaline, pyrazole, and benzimidazole). Aldrich gold label compounds (pyrazine, benzotriazole, and 1,10-phenanthroline) were used as received. Purities of all compounds were tested by melting point and by gas chromatography. In addition, water content of each sample was determined by Karl Fischer titration.

Most solutions were prepared from known masses of organic solute and freshly deionized and deaerated water. A few other solutions were prepared by dilution of these original solutions. Finally, the pH of each solution was measured to ensure that acid–base reactions between solute and water were negligible.

[1]Research reported here was done during 1978 when Octavian Enea was on leave in Sherbrooke and Lethbridge from the Université de Poitiers.

Results

Results of measurements with the Picker flow calorimeter are heat capacities per unit volume of solution, which we express in terms of J K^{-1} cm^{-3}. Combinations of these heat capacities with the densities permits calculation of specific heat capacities expressed in terms of J K^{-1} (g of solution)$^{-1}$. These latter heat capacities are then used in obtaining the desired apparent molar heat capacities that we represent by ϕ_C and express in terms of J K^{-1} mol^{-1}. Similarly, densities lead to apparent molar volumes that we represent by ϕ_V and express in terms of cm^3 mol^{-1}. For these calculations of apparent molar properties we have used equations of the type

$$[1] \quad \phi_Y = [Y(\text{solution}) - n_1 Y_1^0]/n_2$$

in which the symbols have the following meaning: Y is the extensive property (heat capacity or volume here) of a specified quantity of solution, n_1 is the amount (moles) of solvent in this specified quantity of solution, Y_1^0 is the property (heat capacity or volume) of 1 mol of pure solvent, and n_2 is the amount (moles) of solute in the specified quantity of solution.

To obtain apparent molar heat capacities and apparent molar volumes at infinite dilution, where apparent molar properties become identical with the corresponding partial molar properties, we have fitted our experimental results[2] for dilute solutions to the equations

$$[2] \quad \phi_C = \phi_C^0 + B_C m$$

and

$$[3] \quad \phi_V = \phi_V^0 + B_V m$$

in which $\phi_C^0 = \bar{C}_p^0$ and $\phi_V^0 = \bar{V}^0$ are the desired properties at infinite dilution and B_C and B_V are adjustable parameters. Our derived ϕ_C^0, B_C, ϕ_V^0, and B_V values are listed in Table 1. We estimate that *total* uncertainties (chemicals, calorimetry, densities, extrapolations) in our ϕ_C^0 and ϕ_V^0 values are about ± 5 J K^{-1} mol^{-1} and ± 0.5 cm^3 mol^{-1} for most solutes; uncertainties for the less soluble compounds are a little larger. In Table 1 we also list values for the same quantities obtained previously (6) for aqueous pyridine.

[2]A complete set of the experimental results is available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

Earlier investigators have proposed various additivity schemes for ϕ_C^0 (6–18) and ϕ_V^0 (6, 15–24). These additivity schemes, all useful in various ways, were developed in relation to the ϕ_C^0 and ϕ_V^0 values that were then available; hence these earlier schemes are not generally applicable to unsaturated heterocyclics of the sort under consideration here for the first time.

The ϕ_C^0 values listed in Table 1 for isomers show that atomic group additivity schemes that do not take into account the arrangements of these atoms or groups cannot account very accurately for the experimental results. For example, the ϕ_C^0 values for aqueous pyrazine, pyrimidine, and pyridazine should be the same on the basis of any simple atomic or group additivity scheme. But the experimental ϕ_C^0 values cover a range of 16 J K^{-1} mol^{-1}. Experimental ϕ_C^0 values for the isomeric imidazole and pyrazole differ by 28 J K^{-1} mol^{-1} while those for the isomeric 2,2′-bipyridyl, 4,4′-bipyridyl, and 4-phenylpyrimidine cover a range of 52 J K^{-1} mol^{-1}. Finally, the ϕ_C^0 values for the isomeric quinazoline and quinoxaline differ by 27 J K^{-1} mol^{-1}. All of these ranges and differences are larger than likely uncertainties (± 5 J K^{-1} mol^{-1}) in the ϕ_C^0 values.

We also consider the ϕ_C^0 values for isomers in another way, as follows. For the isomeric pyrazine, pyrimidine, and pyridazine we calculate the average $\phi_C^0 = 210.1$ J K^{-1} mol^{-1} and find that differences between experimental values and this average amount to 7.3, 1.2, and 8.6 J K^{-1} mol^{-1}. Similar calculations for other isomers lead to similar average values and thence to differences between experimental values and averages for sets of isomers. The average of all these 10 differences is 13.1 J K^{-1} mol^{-1}, which is more than twice the uncertainty assigned to most of our ϕ_C^0 values.

Similar considerations of ϕ_V^0 values lead to the following. The largest range of values for any set of isomers is 1.31 cm^3 mol^{-1} for the imidazole–pyrazole pair. The average of the various differences calculated from ϕ_V^0 values as described in the preceding paragraph amounts to 0.39 cm^3 mol^{-1}, which is less than the uncertainty (± 0.5 cm^3 mol^{-1}) assigned to most individual ϕ_V^0 values.

Our consideration in the three preceding paragraphs show that a simple additivity scheme for ϕ_V^0 values *might* fit the experimental results with an average accuracy comparable to the experimental accuracy, while a similar additivity scheme for ϕ_C^0 values cannot fit with an average accuracy better than about two or three times the uncertainty in the

individual values. Because the considerations described so far have not been concerned with relationships between ϕ_C^0 and ϕ_V^0 values for different sets of isomers or those compounds that are not isomeric with others listed in Table 1, we now turn to testing two specific additivity schemes.

We first consider atomic additivity schemes for ϕ_C^0 and ϕ_V^0 values according to which

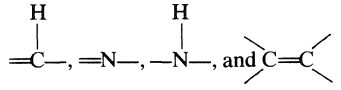
$$[4] \quad \phi_Y^0 = n_C(C)_Y + n_H(H)_Y + n_N(N)_Y$$

Here n_C, n_H, and n_N represent the numbers of indicated atoms in the molecule of interest while $(C)_Y$, $(H)_Y$, and $(N)_Y$ represent the contributions of the indicated atoms to the molar ϕ_Y^0 values. We have chosen to apply eq. [4] in the form

$$[5] \quad \phi_Y^0/n_N = (N)_Y + (n_C/n_N)(C)_Y + (n_H/n_N)(H)_Y$$

which permits convenient multiple linear regression for the desired $(C)_Y$, $(H)_Y$, and $(N)_Y$ values.

Application of eq. [5] to ϕ_V^0 values leads to $(C)_V$, $(H)_V$, and $(N)_V$ equal to 4.86, 9.45, and 5.34 cm^3 mol^{-1}, respectively. We have used these values in eq. [4] to calculate ϕ_V^0 values for all solutes listed in Table 1 and then have found that the average magnitude of the difference between calculated and experimental values is 2.07 cm^3 mol^{-1}, which is



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

about four times the uncertainty assigned to most individual ϕ_V^0 values.

Similar application of eq. [5] to ϕ_C^0 values leads to $(C)_C$, $(H)_C$, and $(N)_C$ equal to 13.11, 48.71, and -21.13 J K^{-1} mol^{-1}, respectively. We have used these values in eq. [4] to calculate ϕ_C^0 values for all solutes listed in Table 1 and then have found that the average magnitude of the difference between calculated and experimental values is 27.41 J K^{-1} mol^{-1}, which is about five times the uncertainty assigned to most individual ϕ_C^0 values.

We thus see that this simple atomic additivity scheme works about as well (or badly) for ϕ_C^0 values as for ϕ_V^0 values for our unsaturated heterocyclic solutes, fitting both sets of results with an average accuracy corresponding to about five times the uncertainty assigned to most experimental values.

We also consider simple group additivity schemes as follows, based upon

groups that we henceforth represent by (CH), (N), (NH), and (CC), with subscripts Y, C, and V as used previously. Instead of applying multiple linear regression to all of the ϕ_Y^0 values in Table 1 to obtain "best" values of the four parameters $(CH)_Y$, $(N)_Y$, $(NH)_Y$, and (CC) simultaneously, we have applied the following stepwise procedure. Application of

$$[6] \quad \phi_Y^0/n_N = (N)_Y + (n_{CH}/n_N)(CH)_Y$$

to ϕ_Y^0 values for the first five compounds listed in Table 1 permits simple least squares evaluation of desired $(CH)_Y$ and $(N)_Y$ group values. Next, average $(NH)_Y$ values are obtained by application of

$$[7] \quad (NH)_Y = \phi_Y^0 - 3(CH)_Y - (N)_Y$$

to results listed in Table 1 for aqueous imidazole and pyrazole. Finally, average $(CC)_Y$ values are obtained from ϕ_Y^0 values for the last nine compounds listed in Table 1.

The procedure described in the paragraph above has led to $(CH)_C$, $(N)_C$, $(NH)_C$, and $(CC)_C$ values equal to 71.99, -47.69, 27.87, and 10.80 J K^{-1} mol^{-1}, respectively. We have used these group contribution values to calculate ϕ_C^0 values for all solutes listed in Table 1 and have then found that the average magnitude of the difference between calculated and experimental values is 31.56 J K^{-1} mol^{-1}, which is about six times the uncertainty assigned to most individual ϕ_C^0 values.

Application of a similar procedure for ϕ_V^0 values leads to $(CH)_V$, $(N)_V$, $(NH)_V$, and $(CC)_V$ values equal to 14.52, 5.45, 11.60, and 8.99 cm^3 mol^{-1}. The average magnitude of differences between resulting calculated and experimental ϕ_V^0 values is 1.87 cm^3 mol^{-1}, which is a little less than four times the uncertainty assigned to most individual ϕ_V^0 values.

This group additivity scheme fits the ϕ_V^0 and ϕ_C^0 results with an average accuracy of about four and six times the uncertainties of individual experiment results.

A comparison of the crystal structures of Sb_2Tl_7, Cu_5Zn_8 (γ-brass), and Ir_3Ge_7

ERWIN HELLNER AND ELKE KOCH

Institut für Mineralogie, Petrologie und Kristallographie der Philipps-Universität, D-3550 Marburg/Lahn, Germany

Received October 3, 1979

ERWIN HELLNER and ELKE KOCH. Can. J. Chem. **58**, 708 (1980).

The crystal structures of Sb_2Tl_7, Cu_5Zn_8, and Ir_3Ge_7 are discussed with the aid of shortest distances of Dirichlet domains and of voids in their frameworks. It will be pointed out that all three frameworks must be regarded as different though relations between the atomic parameters are obvious. The Sb_2Tl_7 structure represents a superstructure of an *I* lattice. The frameworks of Sb_2Tl_7 and of Cu_5Zn_8 contain tetrahedral voids only, while in Ir_3Ge_7 voids with a larger coordination number also exist.

ERWIN HELLNER et ELKE KOCH. Can. J. Chem. **58**, 708 (1980).

Les structures cristallines des composés Sb_2Tl_7, Cu_5Zn_8 et Ir_3Ge_7 sont discutées par les distances les plus courtes des domaines Dirichlet et par les cavités contenus dans leurs enchaînements ("frameworks"). On va demontré que, tous les trois enchaînements sont à regarder en differentes, quoique les rélations évidents entres les paramètres atomiques sont données. La structure de composé Sb_2Tl_7 représente une superstructure d'une reséau *I*-centrée. Les enchaînements des structures de Sb_2Tl_7 et de Cu_5Zn_8 ne contiennent que des cavités tétraédriques, tandis que des cavités supplementaires avec une plus grande nombre de coordination existent dans la structure de Ir_3Ge_7.

In a recent paper Stokhuizen, Chieh, and Pearson (1) compared the crystal structures of Sb_2Tl_7, Cu_5Zn_8 (γ-brass), and Ir_3Ge_7 to each other. In the following, the common features and the differences of these three crystal-structure types shall be discussed in more detail. For this the approach of frameworks and sphere packings has been applied, using a symbolism which consists of capital letters representing invariant lattice complexes and numbers and small letters describing coordination polyhedra (2–5).

The parameters of the three crystal structures are listed in Table 1. The Sb_2Tl_7 structure is built up by four symmetrically different kinds of atoms. The crystal structure as a whole may be regarded as a slightly deformed *I* lattice, the translation period of which amounts to one third of the lattice constants of this structure. The idealized parameters for such an I_{333} lattice (for short I_3 in the cubic system) are also recapitulated in Table 1 (cf. ref. 1). In addition, for each of the four point positions those parameters referring to a sphere-packing condition are given (8, 9). The atomic parameters for Sb_2Tl_7 differ slightly as well from the idealized I_3 parameters as from the sphere-packing parameters. The Tl(1) position by itself forms an *I* lattice and therefore refers to a sphere packing. The shortest distance between Tl(1) atoms, however, is much longer than the shortest distance in the Sb_2Tl_7 structure. The Tl(2) position and the Sb position consist of arrangements of cubes (8*c*) and octahedra (6*o*), respectively, around the points of that *I* lattice. Therefore these configurations are symbolized by *I*(8*c*) and by *I*(6*o*). In both cases the distances between atoms of neighbouring polyhedra are shorter than the edges of the polyhedra themselves. On the contrary the Tl(3) arrangement is very closely related to a sphere packing consisting of tetrahedra with common vertices ($4t_c$), the centers of which form a point configuration of the cubic invariant lattice complex W^*. Therefore, the Tl(3) configuration may be symbolized by $W^*(4t_c)$.

In an ideal *I* lattice there exist for each point eight nearest neighbours (8*c*) and six further neighbours (6*o*) in the second coordination shell forming together a rhomb-dodecahedron (14*rd*). The differences between the distances from the center to these two kinds of neighbours are 15% only. The total coordination number, therefore, may be considered as 14. The Dirichlet domain (or Wirkungsbereich or Wigner-Seitz cell) for a point of a cubic *I* lattice is a cuboctahedron with 24 vertices and 14 faces the dual of the rhomb-dodecahedron. The hexagonal faces correspond to the eight nearest neighbours and the quadrangular faces to the six further ones.

In Table 2 the shortest distances between atoms in Sb_2Tl_7 are collected. For each of the four symmetrically different kinds of atoms fourteen distances are clearly shorter than the following ones, but it is impossible to separate them in eight plus six in a distinct way.

Stokhuizen, Chieh, and Pearson (1) designated the coordination number eight for Tl(1), Tl(3), and Sb and the coordination number ten for Tl(2). The table of distances on which these coordination numbers are based contains, however, an error and an inconsistency: (*1*) each Tl(2) atom possesses only one Tl(2) neighbour at a distance of 3.20 Å; (*2*) the distance 3.55 Å between a Tl(2) and a Tl(3) atom

—Tl(3)	4.94	50%	1×

is only reported in connection with Tl(2). Taking these facts into account the coordination number of Tl(2) becomes eight and that of Tl(3) becomes ten.

For each of the four different kinds of atoms in Sb_2Tl_7 the computation of Dirichlet domains yields cuboctahedra which are deformed in different ways. Figure 1 shows these differences. Their similarity with the Dirichlet domains of the points of an ideal *I* lattice, however, may be taken as a further argument for describing the Sb_2Tl_7 structure as superstructure of an *I* lattice.

On the other hand the Tl(3) atoms by themselves build up a three-dimensional framework $W^*(4t_c)$, with large voids around the points of an *I* configuration. Each of these voids is centered by a Tl(1) atom and filled up by a Tl(2) cube and an Sb octahedron. This framework $W^*(4t_c)$ has also been found in α-Mn, sodalite $Na_4Cl[AlSiO_4]_3$, and related structures.

In Cu_5Zn_8 the site analogous to Tl(1) in Sb_2Tl_7 is not occupied. Each Tl(2) cube corresponds to two tetrahedra with different size and orientation in Cu_5Zn_8. They are built up by Zn(1) and Cu(1) and may be symbolized by $I(4t^+)$ and $I(4t^-)$, respectively. The Cu(2) atoms, like the Sb atoms, are arranged in an *I*(6*o*) configuration with relatively larger octahedra. The arrangement of the Zn(2) atoms, like that of the Tl(3) atoms, may be regarded as a $W^*(4t_c)$ configuration, though the deviation from the sphere-packing parameters is larger than for Tl(3). The comparison between the atomic coordinates of Sb_2Tl_7 and of Cu_5Zn_8 indicates a similarity of both frameworks. Closer inspection of the neighbourhood for the four different kinds of atoms

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

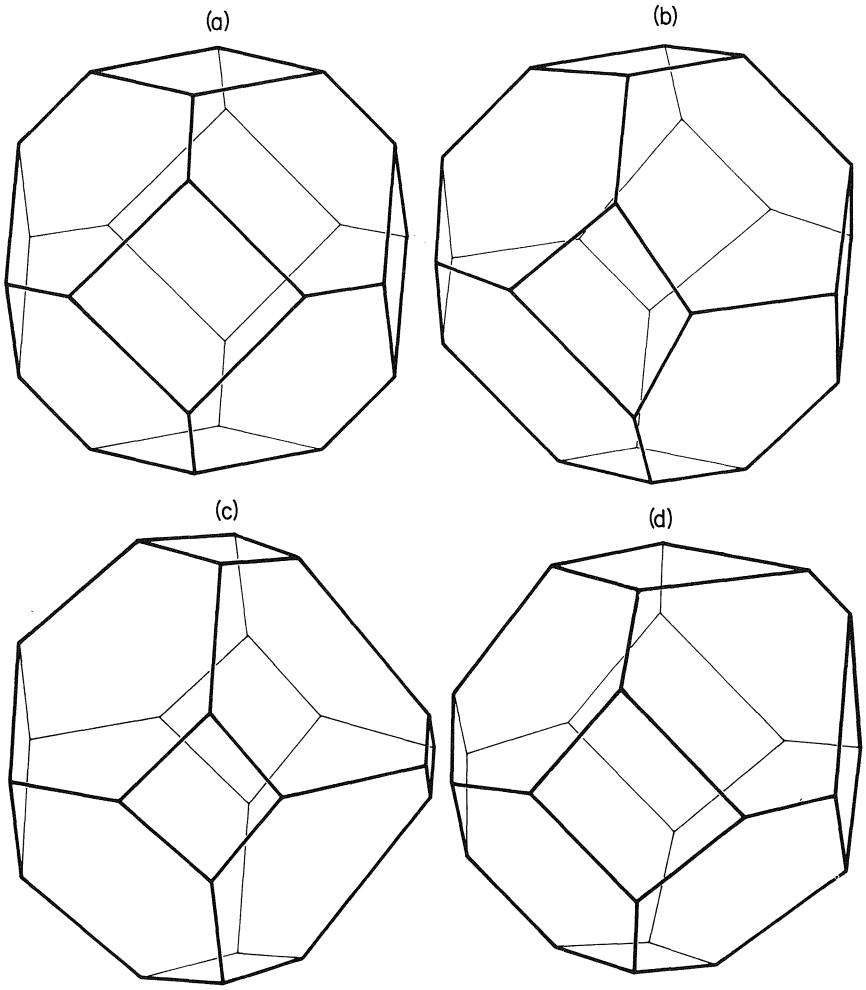

FIG. 1. Dirichlet domains for Sb_2Tl_7: (*a*) Tl(1), (*b*) Tl(2), (*c*) Sb, (*d*) Tl(3).

in Cu_5Zn_8, however, shows essential differences between both crystal structures (see Table 3).

If the Cu_5Zn_8 framework would be similarly connected as that of Sb_2Tl_7, except for the two omitted atoms per unit cell, the total coordination numbers should amount to 13 for Zn(1), Cu(1), and Cu(2) and 14 for Zn(2). Table 3 shows that, as far as distances are concerned, the coordination number is 11 for Zn(2), 12 for Zn(1) and Cu(1), and 13 for Cu(2). These numbers are in agreement with those stated by Pearson, Brandon, and Brizard (10). On the contrary Brandon, Chieh, Pearson, and Riley (11) used the coordination number 12 for all different kinds of atoms in Cu_5Zn_8. Such a delimitation of 12 nearest neighbours, however, is not possible in a reasonable way (cf. Table 3). The calculation of Dirichlet domains, always giving a "maximal" coordination number, yields polyhedra with 13 faces for Zn(1), Cu(1), and Cu(2) and 15 faces for Zn(2) (Fig. 2). Those three faces of the Zn(1) polyhedron which refer to the distance of 2.73 Å and those two faces of the Zn(2) polyhedron which refer to the distance of 3.47 Å, however, do not correspond to any face of the I_3 cuboctahedron. For this reason connections exist within the framework of Cu_5Zn_8 which do not correspond to any connection within the Sb_2Tl_7 framework and the two frameworks must be regarded as different.

This difference also manifests itself in the site and the number of polyhedral voids in both frameworks built up by all the atoms of the structures. Each polyhedral void in a framework corresponds to a vertex of the Dirichlet domain of a framework atom. This vertex may be regarded as the center of the void, because it is the point with equal distances to all the vertices of the polyhedron (cf. ref. 12). A space partition into voids of a framework constructed in this way is always unique.

In both frameworks under consideration no other than tetrahedral voids exist, that is 324 within the unit cell of Sb_2Tl_7 and 310 within the unit cell of Cu_5Zn_8. While in Sb_2Tl_7 all these voids correspond directly to the voids of an ideal I_3 lattice, in Cu_5Zn_8 this relation exists for a small part of the voids only. In Tables 4 and 5 the size and the coordinates of the centers are listed for all voids in the frameworks of Sb_2Tl_7 and of Cu_5Zn_8, respectively. It is possible to construct infinitely many other space partitions into tetrahedra for these structures. One of these possibilities has been used by Brandon *et al.* (11) for the purpose of calculating "average root-mean-square error parameters per tetrahedra" for a γ-brass structure. However, each space partition into tetrahedra differing from that deducible from Dirichlet domains has the following property: there must exist tetrahedra with distances between their centers and vertices which are longer than the shortest distances between the tetrahedra centers and the nearest neighbours out of the framework.

TABLE 4. Tetrahedral voids in the Tl_7Sb_2 framework: position of their centers, the volume, and the distance from the centers to the vertices of the tetrahedra

Centers of the voids			Volume (Å³)	Distance (Å)
12(*d*)	$0\ \frac{1}{2}\ \frac{1}{4}$		4.71	2.10
24(*g*)	$x\ 0\ \frac{1}{2}$	$x = 0.0350$	4.40	2.20
48(*i*)	$\frac{1}{4}, x, \frac{1}{2}-x$	$x = 0.1594$	5.09	2.19

The framework of Ir_3Ge_7 shows distinct differences to both frameworks discussed above. As in Cu_5Zn_8 the Tl(1) position is unoccupied in Ir_3Ge_7, but in contrast to Cu_5Zn_8, Ge(2) cubes exist analogous to the Tl(2) cubes in Sb_2Tl_7. Because of the missing atoms in their centers, the Ge(2) cubes are much smaller than the Tl(2) cubes. The coordinates of Ge(2) meet the sphere-packing condition (Table 1) in good approximation. The configuration of the Ir atoms is comparable to that of Cu(2). Instead of tetrahedra with common vertices around a *W** configuration, in Ir_3Ge_7 the *W** site itself is

—Ge(1)	4.38	69%	2×

occupied by the Ge(1) atoms. They build up a three-dimensional connected framework with only one kind of voids, i.e., cuboctahedra (24*co*), the centers of which form an *I* lattice. The distances within the framework of Ir_3Ge_7 are given in Table 6. The Dirichlet domains show nine faces for Ir, 16 faces for Ge(1), and 13 faces for Ge(2). Because of the replacement of the $W^*(4t_c)$ configuration by the W^* configuration no relationships to the I_3 cuboctahedra are recognizable. The structure of Ir_3Ge_7 may, however, be designated as homeotype of both the others (5, 13).

Ir_3Ge_7 may not be regarded as a tetrahedrally closed packed structure. In addition to tetrahedral voids it contains other kinds of voids with higher coordination numbers. The best way of looking at it seems to be the following: Ge(1) and Ge(2) together build up the heterogeneous framework [W^* +

$I(8c)$] with four kinds of voids: cubes ($8c$) around I, i.e. 1(a) 000, tetragonal antiprisms ($8a$) around $I(6o)$, i.e. 12(e) $x00$, $x = 0.3481$, and tetrahedra ($4t$) with centers in 24(h) $xx0$, $x = 0.2734$ and in 48(k), xxz, $x = 0.1843$, $z = 0.3813$. The tetragonal antiprismatic voids in the Ge framework are occupied by Ir atoms.

Synthesis of a protein modifying agent. A water-soluble stable free radical[1,2]

SANGRAM SISODIA, R. DEAN MARTZ, N. BOSWORTH, GARY LAMMERT, AND J. D. REINHEIMER[3]

Severance Chemistry Laboratories, The College of Wooster, Wooster, OH 44691, U.S.A.

Received August 31, 1979

SANGRAM SISODIA, R. DEAN MARTZ, N. BOSWORTH, GARY LAMMERT, and J. D. REINHEIMER. Can. J. Chem. **58**, 714 (1980).

Two synthetic routes to prepare a water-soluble stable free radical were investigated. The first product, sodium-2,4-dinitro-5-(4′-amino-2′,2′,6′,6′-tetramethylpiperidine-1-oxyl)benzene sulfonate, was water soluble but the sulfonate group was not readily replaceable with nucleophiles. The second synthetic route yielded *N*(4′-(2′,2′,6′,6′-tetramethylpiperidine-1-oxyl))-3,5-dinitro-4-sodium sulfonate benzamide, which was water soluble and its sulfonate group was readily replaced by nucleophiles.

SANGRAM SISODIA, R. DEAN MARTZ, N. BOSWORTH, GARY LAMMERT et J. D. REINHEIMER. Can. J. Chem. **58**, 714 (1980).

On a exploré deux méthodes de synthèse d'un radical libre stable soluble dans l'eau. La première méthode conduit au dinitro-2,4 (amino-4′ tétraméthyl-2′,2′,6′,6′ pipéridineoxyl-1)-5 benzène sulfonate de sodium soluble dans l'eau mais dont le groupe sulfonate ne peut être remplacé facilement par les nucléophiles. La deuxième méthode permet d'obtenir le composé *N*[(tétraméthyl-2′,2′,6′,6′ pipéridineoxy-1)-4′] dinitro-3,5 sulfonate-4 de sodium benzamide qui est soluble dans l'eau et dont le groupe peut être facilement remplacé par des nucléophiles.

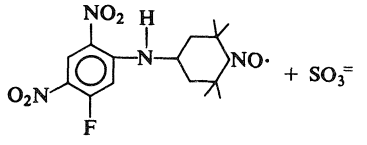
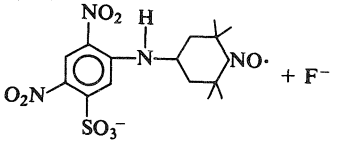
Introduction

Protein structure has been investigated by many "reporter groups" which are part of modifying agents. Reporter groups may be radioactive isotopes, elements which are not normally found in the native protein such as ^{19}F, stable free radicals such as the nitroxyl group, as well as chromophoric groups. The stable reporter groups are observed by means of magnetic resonance spectrometers (1–4) or uv and visible spectrometers. The purpose of this research was to synthesize a stable water-soluble free radical which could form a covalent bond to a protein.



Covalent bonds between a modifying agent and a protein may be formed by an aromatic nucleophilic substitution reaction (5). If the reagent contains sulfonate as the replaceable group, the advantage of water solubility may be realized (6). Gerig *et al.* (7) prepared **1** from the commercially available stable free radical **4** and 4,6-dinitro-1,3-difluorobenzene. The relative ease of replacement of the first fluorine in 4,6-dinitro-1,3-difluorobenzene by amino groups, as well as the lessened reactivity of the second fluorine, was described by Zahn and Meienhoffer (9) and exploited by Cautrecasas and co-workers (8). The fluorine in **1** is still sufficiently reactive to be replaced by reactive amino groups in human serum albumin (7).

Replacement of the fluorine in **1** by $SO_3^=$, eq. [1], gave a water-soluble substance, **2**. This new substance was characterized by infrared and elemental analysis. The compound, **2**, was added to solution(s) of nucleophiles, but the SO_3^- group was not replaced.



Equation [2] presents a synthesis from a different difunctional starting material. The more reactive acid chloride was readily replaced to form **5**, but the aromatic chlorine was still sufficiently reactive to be readily replaced in the subsequent step to form **6**. In contrast to **2**, the sulfonate group of **6** was replaced in aqueous solution. Compound **6** is recommended as a water-soluble reagent which contains the chromophore NO_2 and the stable nitroxyl radical as "reporter groups".

Non-radical analogs of **1**, **2**, **4**, **5**, and **6**, in which the oxygen of the radical was replaced by H, were used in preliminary experiments. These experiments were used as a guide to establish conditions for eqs. [1] and [2].

Experimental

The ^{1}H nmr spectra were observed in DMSO-d_6 with a Varian T-60 spectrometer. The ir spectra were observed in KBr pellets with a Perkin Elmer 700 and later with a Perkin Elmer 283 spectrometer. The starting materials, 4,6-dinitro-1,3-difluorobenzene, **4**, and 4-amino-2,2,6,6,-tetramethylpiperidine were commercial chemicals from Aldrich Chemical Co. The other reagent, **3**, was prepared by literature methods (9, 10).

Compound **2**, sodium-2,4-dinitro-5-(4′-amino-2′,2′,6′,6′-tetramethylpiperidine-1-oxyl)benzene sulfonate, was prepared from **1** (7). A solution of **1**, 0.3 g in 50 mL of alcohol and 25 mL of water, was slowly added over a period of 25 min to a solution of sodium sulfite, 0.50 g in 25 mL of water. The temperature was maintained at 45°C during the addition. The alcohol was removed with a rotary evaporator and the product was salted out with NaCl. The product, **2**, was removed by filtration and recrystallized twice from HOH/NaCl; ir (KBr pellet) ν_{max}: 3300 (N—H), 1600 and 1375 (NO_2), 1350 (N—O) (11), 1210 and 1060 (sh)(SO_3^-).

Compound **5**, *N*(4′-(2′,2′,6′,6′-tetramethylpiperidine-1-oxyl))-3-5-dinitro-4-chlorobenzamide was prepared as follows. Anhydrous Na_2CO_3, 0.2 g, compound **3**, 0.20 g, and 2.5 mL chloroform were placed in a round-bottomed flask with a magnetic stirrer. Compound **4**, 0.2 g, was dissolved in 3.5 mL of chloroform and added (dropwise) to the reaction mixture over a period of 20 min. A precipitate appeared; the chloroform was removed by evaporation and the solid washed three times with 10 mL of water. The crude yield was 58–60%, mp 236–238°C (dec.) after 2 recrystallizations from alcohol/water; ir (KBr pellet) ν_{max}: 1670 (C=O), 1540 and 1450 (NO_2), 1330 (NO·).

To prepare compound **6**, *N*(4′(2′,2′,6′,6′-tetramethylpiperidine-1-oxyl))-3,5-dinitro-4-sodiumsulfonate benzamide, a solution of **5**, 0.050 g in 10 mL of ethanol and 5 mL of water, was added over a period of 25 min to 0.08 g of sodium sulfite dissolved in 5 mL of water. The temperature was maintained at 45°C. The ethanol was removed by means of a rotary evaporator, and the solution cooled in a refrigerator overnight. The product was removed by filtration and recrystallized from NaCl/HOH. The yield was 57–69% and the product did not melt below 400°C; ir (KBr pellet) ν_{max}: 1660 (C=O), 1550 and 1370 (NO_2), 1330 (NO·), 1250 and 1090 (SO_3^-). *Anal.* calcd. for $C_{16}H_{20}SO_9N_4Na$: C 41.13, H 4.28, N 11.99; found: C 40.93, H 4.50, N 11.80.

Dianions of glyoxylic acid thioketals: convenient α-keto acid equivalents

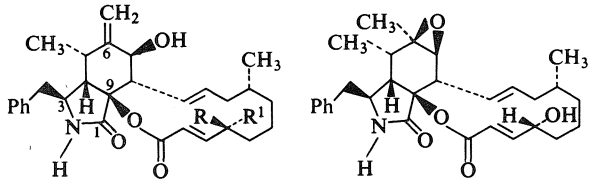
GORDON S. BATES[1] AND S. RAMASWAMY

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received October 15, 1979

GORDON S. BATES and S. RAMASWAMY. Can. J. Chem. **58**, 716 (1980).

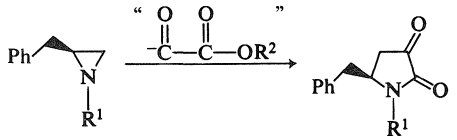
By varying the solvent, reaction temperature, and bases (i.e., gegenions present), optimum conditions for the alkylation of the dianions of glyoxylic acid derivatives **8** and **9** were established. It was found that the easily prepared, thermally stable, tetrahydrofuran-soluble potassium dianion of bis(ethylthio)acetic acid was readily alkylated by alkyl halides, tosylates, epoxides, and *N*-tosyl aziridines. The latter alkylation is being used to develop a possible cytochalasin synthesis.



The alkylated products may be readily converted into the corresponding α-keto acids or methyl 2,2-bismethoxycarboxylates.

GORDON S. BATES et S. RAMASWAMY. Can. J. Chem. **58**, 716 (1980).

On a établi des conditions idéales d'alkylation des dianions de dérivés **8** et **9** de l'acide glyoxylique en faisant varier le solvant, la température et les bases (i.e., ions opposés). On a trouvé que le dianion de potassium de l'acide bis(éthylthio) acétique, soluble dans le tétrahydrofuranne que l'on peut préparer facilement et qui est thermiquement stable, peut être alkylé facilement par les halogénures d'alkyles, les tosylates, les époxydes et les *N*-tosyl-aziridines. On utilise la dernière alkylation pour développer une synthèse réalisable de la cytochalasine. Les produits alkylés peuvent être transformés facilement en acides α cétoniques correspondants ou en carboxylates de bisméthoxy-2,2 de méthyle.



[Traduit par le journal]

In connection with a preliminary investigation directed at a synthesis of the microbial metabolites cytochalasins A, B, and F (1, 2)[2] we required a glyoxylic acid (ester) anion equivalent (3).[3] Our strategy involves alkylation of such an anion with an aziridine unit **1** which incorporates the chirality at C-3 of the cytochalasins, eventually followed by lactam formation to give compound **2**. This intermediate contains an oxygen function at what will eventually become the C-9 position of the target molecules, and thus overcomes a possible difficulty arising from attempted oxidation at this hindered position later in the synthesis (2*g*). Cleavage of the aziridine by a nucleophile will result in a developing negative charge on the nitrogen atom. To facilitate the opening of the aziridine, the group R^1 (attached to nitrogen) should thus be capable of stabilizing this negative charge, and in addition should not itself be very susceptible to nucleophilic attack. The *p*-toluenesulphonyl group appeared to fulfil the necessary criteria (4).[4] L-Phenylalanine was converted to the corresponding chiral amino alcohol (5), which was subsequently ditosylated and cyclized to the desired crystalline chiral aziridine derivative **1** (R^1 = *p*-$MeC_6H_4SO_2$—) which was used in our subsequent studies.

Cytochalasin A R = R^1 = O
Cytochalasin B R = H, R^1 = OH

Cytochalasin F

1 **2**

The glyoxylic acid (ester) anion equivalent should possess a number of characteristics: ready availability, ease of preparation, high reactivity, and thermal stability. In addition, alkylation of this synthon should proceed in high yield to give a product which is stable and easily purified and yet is readily convertible into the desired α-keto acid (ester). An investigation of the literature yielded several likely candidates for the required synthon. The monoanions of glyoxylic ester derivatives **3**–**7**

$(R^1O)_2CHCO_2R^2$	$(R^1S)_2CHCO_2R^2$
3 $R^1 = R^2 = Me$	**5** $R^1 = Et, R^2 = Me$
4 $R^1 = R^2 = Et$	**6** $R^1 = —[CH_2]_2—, R^2 = Et$
	7 $R^1 = —[CH_2]_3—, R^2 = Et$
	8 $R^1 = Et, R^2 = H$
	9 $R^1 = —[CH_2]_3—, R^2 = H$

(6) were investigated. However, when we attempted to open the aziridine **1** (R^1 = *p*-$MeC_6H_4SO_2$—)

with the anions of any of the above compounds, either starting material was recovered or an unidentifiable mixture was obtained. Assuming that the problem was the instability of the ester anions (loss of $^{-}OR^{2}$ produces a ketene derivative), we reasoned that the dianions of the corresponding carboxylic acids[5] should be much more stable, and in addition the dianion should be more reactive than the monoanion. Although the use of dianions of carboxylic acids containing α-thioalkyl (8), α-thioaryl (9), α-selenoaryl (10), α-alkoxy (11), and α-aryloxy (12) stabilizing groups have been reported, and although various thioketals (13) of glyoxylic acid are known, we found no reference to the dianions of the latter compounds (14).[6] We thus decided to study dianions derived from **8** and **9**. The former acid was conveniently prepared in quantitative yield either by cautious addition of dichloroacetic acid to a tetrahydrofuran (THF) suspension of 3 equiv. of sodium hydride, followed by addition of an excess of ethanethiol, or by thioketalization of glyoxylic acid monohydrate. Compound **9** was prepared by alkaline hydrolysis of the corresponding ethyl ester (6*e*, 13*c*) or by the thioketalization procedure (13*e*).

Optimum alkylation conditions were then established by varying the solvent, reaction temperature, and metallation reagents (i.e., gegenions present), etc. Initially, the soluble lithium dianions of carboxylic acids **8** and **9** were prepared by addition of 2 equiv. of *n*-BuLi to a THF solution of the free-flowing, stable, non-hygroscopic dicyclohexylammonium salts of the carboxylic acids.[7] However, it was later found that the *n*-BuLi could be added directly to a THF solution of **8** or **9** to yield a solution of the corresponding dianion with no apparent nucleophilic attack on the carboxylates. Our first alkylation experiments (see Table 1) were very encouraging. Iodomethane rapidly and quantitatively alkylated the lithium dianions of either **8** or **9** (entry 1). However, as can be seen in the table, it quickly became apparent that the dianion derived from **9** was much more reactive than that derived from **8**. This difference may be attributed to a directed anion at C-1 of the dithiane ring of the dianion (13*d*) of **9** or simply to steric reasons. Unfortunately, even the lithium dianion of **9** was only alkylated by very reactive alkylating agents and failed completely to react with the aziridine derivative **1** ($R^{1} = p\text{-}MeC_6H_4SO_2$—).

Although the use of dianions derived from **9** is recommended in cases of alkylating agents with low reactivity, we decided to optimize alkylation conditions for the more readily obtainable and less expensive **8**. Benzyl chloride was used as the alkylating agent in the optimization studies. The solvent and temperature variation studies are shown in Table 2. A good yield of alkylated product was obtained by carrying out the reaction in refluxing THF (entry 2), indicating that the lithium dianion is thermally stable. The use of cosolvents such as HMPA which can coordinate with the lithium cation, thus making the dianion more nucleophilic, resulted in moderate-to-good yields of alkylation product (entries 3–5). A report (15) that the rate of alkylation of the butyrophenone anion with bromoethane depends greatly on the cation present

[b]HMPA = hexamethylphosphoric triamide; TMEDA = *N,N,N′N′*-tetramethylethylenediamine; DME = 1,2-dimethoxyethane.

[5]For recent reviews of di- and poly-alkali metallated compounds see ref. 7.

[6]Recently, a report of the acylation of the lithium dianion of diphenoxyacetic acid has appeared (14*a*); see ref. 11*b* for alkylation of this anion, and ref. 14*b* for a recent report of the use of the dianion of **9**.

[7]Dicyclohexylamine (1.1 equiv.) was added to a solution of the acid (1.0 equiv.) in hexane. The mixture was stirred for 1 h at 25°C and the precipitate collected by filtration (yield ~90%). Such salts are a convenient precursor to carboxylic acid dianions in general. In addition, they may be recrystallized from a number of organic solvents, thus affording an excellent method of purification for carboxylic acids.

[a] All reactions 0.1 *M* in carboxylic acid at 25°C; metallation carried out at 0°C; 1.1 equiv. benzyl chloride used; 5 equiv. HMPA used where indicated.
[b] The second equiv. of base was added, after 15 min, to the thick slurry of the monoanion. The mixture was stirred 30 min before the addition of benzyl chloride.
[c] Potassium salt was dried in vacuo over P_2O_5 for 24 h.
[d] 5% KH or freshly sublimed KO*t*Bu present in reaction.

(K > Na > Li) suggested the next modification. An increase in the ionic nature of the dianion of **8** should also be possible by using different gegenions. This change hopefully would result in increased reactivity without a significant decrease in the stability of the dianion reagent. Table 3 summarizes the results of varying the gegenions associated with the dianion. Since all of the monoanions of **8** (Li, Na, or K cation) are virtually insoluble in THF, it was necessary that the base used to accomplish the second deprotonation be soluble in THF. The soluble dianions were thus generated by reaction of 1 equiv. of *n*-BuLi with the appropriate monoanion. The use of a sodium–lithium pair of cations (entry 3) had the desired effect; now a good yield of alkylated product could be obtained by stirring the reaction overnight at room temperature. Even more dramatic was the use of the potassium–lithium cation pair (entry 5); a virtually quantitative alkylation occurred in 1 h. An attempt to deprotonate a sample of previously prepared potassium salt (entry 6) resulted in a poor yield of alkylated material. Apparently, the freshly precipitated monoanion is sufficiently soluble in THF to react readily with the *n*-BuLi, but if aggregation of the salt occurs the reactivity is greatly decreased (presumably due to difficulty in overcoming the lattice energy of the salt). Entry 7 suggests that metathesis, to yield a highly reactive dipotassium salt, is unlikely to be operating as a major pathway in the alkylation of the mixed cation reagent. A final improvement would be the use of a soluble potassium base which is strong enough to doubly deprotonate acid **8**. Potassium bis(trimethylsilyl)amide

[f] Reaction time 18 h.

(16) was found to be ideal for this purpose.[8] Reaction of 2 equiv. of this base with **8** in THF at 0°C readily generated the *soluble* potassium dianionic species. Alkylations[9] were then carried out with a variety of substrates (Table 4). Although most reactions were complete in less than 1 h at 25°C, the mixtures were left for 2.5 h since their mixing efficiencies decreased with time owing to the precipitation of the *insoluble* potassium monoanion of the alkylated product. Of particular note are entries 4, 7, and 8 which show that tosylates (17) cleanly

[8] The pK_{BH^+} of this base has been estimated to be ~29 (ref. 16), thus establishing an upper limit for the pK_{BH^+} of the dianion of **8**.

[9] The potassium dianion of **9** also is readily alkylated in excellent yield by a wide variety of substrates.

10 11 12 13

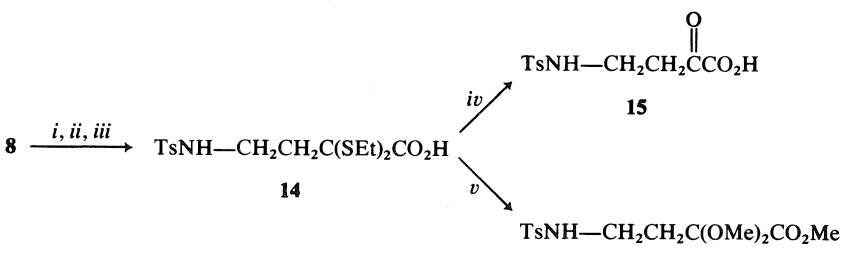
Ts = p-$MeC_6H_4SO_2$—

alkylate the dianion in good yield, entry 12 which illustrates the site-specific opening of an epoxide, and most importantly, the almost quantitative cleavage of the aziridine ring (entries 13 and 14). This latter reaction yields the desired α-keto acid equivalent by a transformation which we were unable to achieve using existing methods. Compound **12** has been successfully transformed into pyrrolidinone **2** (R^1 = p-$MeC_6H_4SO_2$—) in high yield and investigations are currently underway to elaborate this compound into the cytochalasin nucleus.

The somewhat lower yields obtained with isopropyl derivatives (entries 5, 6, and 7) and with cyclohexyl tosylate (entry 8) are undoubtedly due to competing elimination reactions, although no attempt was made to isolate the resulting alkenes. However, the significant decrease in elimination with isopropyl tosylate (entry 7) is in agreement with the well-known greater reactivity of tosylates compared with halides in substitution reactions (18). The relatively good yield of substitution product with cyclohexyl tosylate was somewhat surprising in a ring system so extremely prone to elimination.

The reactions were rapid, high yielding, and simple to carry out. There was no need to remove the oil from the potassium hydride used to generate the bis(trimethylsilyl)amide base, since the work-up included an extraction to yield essentially pure carboxylic acid.

The 2,2-bis(ethylthio)carboxylic acids may be readily converted into the corresponding α-keto acids by *N*-bromosuccinimide hydrolysis (19) or directly into the corresponding methyl 2,2-bis-methoxycarboxylates by treatment with iodine–methanol (20). These latter compounds are useful starting materials for the synthesis of α-methyleneketals (21), α-cyclopropylideneketals (22), the monoketals of vicinal diketones (23), and the corresponding carbonyl compounds (20–22, 24). The hydrolysis and transketalisation–esterification procedures are illustrated in Scheme 1 for compound **14** which is a potential precursor for 4-amino-2-hydroxybutanoic acid, a chemical modifier of the aminoglycoside antibiotic kanamycin (25).



Experimental

General

All reactions were carried out under a nitrogen or argon atmosphere. Stirring was accomplished using Teflon-coated magnetic stirring bars. Tetrahydrofuran and dimethoxyethane were freshly distilled from sodium benzophenone ketyl under a nitrogen atmosphere. Hexamethylphosphoric triamide and *N,N,N′,N′*-tetramethylethylenediamine were distilled from calcium hydride and stored over Linde 4 Å molecular sieves. Sephadex LH-20 (25–100 μ) was purchased from Pharmacia Fine Chemicals. Potassium hydride was obtained as a 25% dispersion in mineral oil from Alpha Division, Ventron Corporation. All other reagents were obtained from the Aldrich Chemical Company, Inc. and were used without further purification. Ethyl, isopropyl, and cyclohexyl tosylates were prepared by reaction of an excess of the appropriate alcohol for 12 h at 0°C with *p*-toluenesulphonyl chloride in pyridine followed by a standard work-up. Full experimental details for the exploratory experiments summarized in Tables 1–3 are available from the authors upon request.

Melting points were taken on a Gallenkamp melting point apparatus and are corrected. Proton magnetic resonance spectra were obtained on Varian Associates T-60 and HA-100 spectrometers. Spectra were run in deuteriochloroform solution with tetramethylsilane as an internal reference. The multiplicity, integrated peak area, and coupling constants (Hz) (if observable) are indicated in parentheses after each signal. Infrared spectra were recorded in chloroform solution using a Perkin-Elmer 700 spectrometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. High resolution mass spectra were obtained using an AEI MS-50 mass spectrometer. Specific rotations were determined using a Perkin-Elmer 241 MC polarimeter which was calibrated using a standardized sucrose solution. Elemental analyses were performed at the Microanalytical Laboratory, University of British Columbia.

The following abbreviations are used: THF = tetrahydrofuran, Bz = benzene, Et = C_2H_5, EtOAc = ethyl acetate, EtOH

i, 2 equiv. $KN(SiMe_3)_2$; *ii*, **13**; *iii*, H_3O^+; *iv*, NBS, MeCN, H_2O; *v*, I_2, MeOH

= ethanol, Et_2O = ethyl ether, py = pyridine, TsOH = *p*-toluenesulphonic acid monohydrate, TsCl = *p*-toluenesulphonyl chloride, b = broad, s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet.

Bis(ethylthio)acetic Acid **8**

Procedure 1

At 0°C and with vigorous stirring, 1.29 g (10 mmol) of Cl_2CHCO_2H was added to a suspension of 1.9 g (40 mmol) of 50% NaH dispersion in 100 mL of THF. Then 1.86 g (30 mmol) of EtSH was added slowly to the suspension. The resulting thick reaction mixture was stirred overnight at 25°C. (Mechanical stirring is necessary on larger scale reactions.) Sufficient H_2O was added to the mixture to dissolve the salts, and the THF was removed under reduced pressure. The aqueous phase was extracted with 2 × 25 mL of hexanes, and was then acidified with aqueous 2 *N* HCl. The milky mixture was extracted with 4 × 50 mL EtOAc, the organic phase dried over anhydrous $MgSO_4$, and the solvent evaporated to give 1.6–1.8 g (90–100%) of **8** as a pale yellow liquid.

Procedure 2

A solution of 0.92 g (10 mmol) of glyoxylic acid monohydrate, 1.37 g (22 mmol) of EtSH, and 0.19 g (1 mmol) of TsOH in 25 mL of Bz was refluxed (pot temperature 45°C) for 3 h. The reaction mixture was diluted with 100 mL of Et_2O and washed with 2 × 20 mL H_2O and 1 × 20 mL aqueous saturated NaCl. The organic phase was dried over anhydrous $MgSO_4$, and the solvent evaporated to give 1.75 g (97%) of **8** as a pale yellow liquid.

The material from either preparation is of sufficient purity for most reactions but may be distilled (110°C, 0.02 Torr) if necessary. The reactions have been carried out on 250 mmol scales with equally good yields; ir: 3800–2300 and 1705 cm^{-1}; ^{1}Hmr δ: 1.25 (t, 6, J = 7), 2.72 (q, 4, J = 7), 4.35 (s, 1), 9.9 (s, 1). *Anal.* calcd. for $C_6H_{12}O_2S_2$ (180.29): C 39.97, H 6.71, S 35.57; found: C 39.63, H 6.91, S 35.33. *Mol. Wt.* calcd. for $C_6H_{12}O_2S_2$: 180.0279; found (high resolution ms): 180.0281.

1,3-Dithiane-2-carboxylic Acid **9**

Procedure 1

A solution of 1.92 g (10 mmol) of ethyl 1,3-dithiane-2-carboxylate (6*e*, 13*c*), prepared from ethyl diethoxyacetate (26) and 1,3-propanedithiol, in 10 mL of aqueous 1 *N* KOH and 10 mL *tert*-butyl alcohol was stirred overnight at 25°C. The alcohol was evaporated and the aqueous phase acidified with aqueous 2 *N* HCl. The mixture was extracted with 4 × 50 mL EtOAc, the organic phase dried over anhydrous $MgSO_4$, and the solvent evaporated to give 1.5 g of **9** as a pale yellow solid.

Procedure 2

A solution of 0.92 g (10 mmol) of glyoxylic acid monohydrate, 1.19 (11 mmol) of 1,3-propanedithiol, and 0.19 g (1 mmol) of TsOH in 25 mL Bz was refluxed for 1 h. The reaction was cooled to 25°C and the organic phase extracted with 3 × 10 mL aqueous saturated $NaHCO_3$. The aqueous phase was washed with 1 × 25 mL Et_2O, then cautiously acidified with aqueous 6 *N* HCl and finally extracted with 4 × 50 mL EtOAc. The organic phase was dried over anhydrous $MgSO_4$, and the solvent evaporated to give 1.4 g of **9** as a pale yellow solid, mp 115–116°C (pentane–Bz); ir: 3400–2500 and 1710 cm^{-1}; ^{1}Hmr δ: 2.1 (m, 2), 2.55 (m, 2), 3.4 (m, 2), 4.15 (s, 1), 10.3 (s, 1). *Anal.* calcd. for $C_5H_8O_2S_2$ (164.25): C 36.56, H 4.91, S 39.04; found: C 36.33, H 4.94, S 38.70. *Mol. Wt.* calcd. for $C_5H_8O_2S_2$: 163.9966; found (high resolution ms): 163.9967.

Standard Procedure for Alkylation of **8**

To a suspension of 3.2 g (20 mmol) of 25% KH in mineral oil in 100 mL of THF at 0°C was added 3.55 g (22 mmol) of $HN(SiMe_3)_2$. After 1 h at 25°C, the slightly turbid solution was cooled to 0°C, and a solution of 1.8 g (10 mmol) of **8** in 10 mL of THF was added dropwise over 10 min with stirring. Any precipitate that formed was allowed to dissolve before additional acid was added. After 15 min, 11 mmol of alkylating agent was added to the dianion solution and the reaction mixture was stirred at 25°C for 2.5 h (18 h for epoxides and *N*-tosyl aziridines). Sufficient H_2O was added to dissolve the thick precipitate which had formed and the THF was evaporated. The resulting mixture was transferred to a separatory funnel with the aid of a little H_2O, and the aqueous solution was washed with hexanes to remove the mineral oil (from the KH) and excess alkylating agent. The aqueous phase was acidified with aqueous 2 *N* HCl, and extracted several times with Et_2O. The organic extract was dried over anhydrous $MgSO_4$ and evaporated to yield the alkylated product. The trace of yellow-coloured material in the crude products could be conveniently removed by filtration of the product through a short column of LH-20 Sephadex using $CHCl_3$ as eluent. The coloured material moves rapidly off the column, followed shortly by the colourless acid. The material balance is quantitative.

N-(p-*Toluenesulphonyl)aziridine* **13**

A mixture of 6.1 g (100 mmol) of 2-aminoethanol and 38.1 g (200 mmol) TsCl in 50 mL py was allowed to react at 0°C for 18 h. The thick slurry was slowly poured into a stirred mixture of 50 g of ice, 250 mL of CH_2Cl_2, and 60 mL of aqueous concentrated HCl. The CH_2Cl_2 layer was separated and the aqueous phase was extracted with 3 × 75 mL of CH_2Cl_2. The combined organic phase was filtered through a cotton plug and the solvent was evaporated (27). Addition of 100 mL of Et_2O to the residue caused an immediate precipitation to occur. Filtration of the pale yellow solid gave 31.5 g (85%) of the desired ditosylate of sufficient purity for the next reaction. A pure sample was prepared by recrystallization from Et_2O, mp 84–85°C; ir: 3350, 1605, 1370, 1340, 1180, and 1160 cm^{-1}; ^{1}Hmr δ: 2.38 (s, 3), 2.41 (s, 3), 3.20 (q, 2, J = 6), 4.05 (t, 2, J = 6), 5.35 (t, 1, J = 6), 7.25 (m, 4), 7.72 (m, 4). *Anal.* calcd. for $C_{16}H_{19}NO_5S_2$ (369.46): C 52.02, H 5.18, N 3.79, S 17.36; found: C 51.85, H 5.21, N 3.85, S 17.19. *Mol. Wt.* calcd. for $C_{16}H_{19}NO_5S_2$: 369.0705; found (high resolution ms): 369.0732.

To a solution of 18.45 g (50 mmol) of the above ditosylate in 50 mL of THF was added 50 mL of aqueous 1 *N* KOH. The resulting solution was stirred at 25°C for 5 min and the THF was evaporated. The aqueous residue was extracted with 4 × 75 mL of CH_2Cl_2. The organic phase was filtered through a cotton plug and the solvent evaporated. Recrystallization from EtOH gave 9.5 g (97%) of **13**, mp 52–53°C; ir: 1605, 1330, 1165 and 920 cm^{-1}; ^{1}Hmr δ: 2.3 (s, 4), 2.4 (s, 3), 7.2 (d, 2, J = 8.5), 7.7 (d, 2, J = 8.5). *Anal.* calcd. for $C_9H_{11}NO_2S$ (197.26): C 54.80, H 5.62, N 7.10, S 16.25; found: C 54.66, H 5.58, N 7.07, S 16.08. *Mol. Wt.* calcd. for $C_9H_{11}NO_2S$: 197.0511; found: (high resolution ms): 197.0500.

N-(p-*Toluenesulphonyl)-2S-(benzyl)aziridine* **1**

L-Phenyl alanine ($[\alpha]_D^{25}$ −33.6° (*c* 1.54, H_2O) was converted into *S*-(−)-2-amino-3-phenylpropan-1-ol ($[\alpha]_D^{25}$ −24.6° (*c* 1.72, $CHCl_3$) according to the procedure of Seki *et al.* (5). Ditosylation of this aminoalcohol according to the procedure outlined above for 2-aminoethanol gave an 83% yield of the chiral ditosylate, mp 100–101.5°C (EtOAc–hexane); ir: 3600, 1600, 1370, 1170, 1150, 1090, 990, 940, and 800 cm^{-1}; ^{1}Hmr δ: 2.35 (s, 3), 2.40 (s, 3), 2.70 (m, 2), 3.55 (m, 1), 3.90 (m, 2), 5.25 (d, 1, J = 8), 6.8–7.8 (m, 13); $[\alpha]_D^{25}$ −47.7° (*c* 1.69, $CHCl_3$). *Anal.* calcd. for $C_{23}H_{25}NO_5S_2$ (459.59): C 60.11, H 5.48, N 3.05, S 13.95; found: C 59.97, H 5.30, N 3.00, S 13.76. *Mol. Wt.* calcd. for $C_{16}H_{18}NO_5S_2$ (M − 91): 368.0627; found (high resolution ms): 368.0631.

2-Oxo-4-(p-toluenesulphonamido)butanoic Acid ***15***

A solution of 1.88 g (5 mmol) of acid **14** in 10 mL of CH_3CN was added dropwise at 0°C to a stirred solution of 5.34 g (30 mmol) of *N*-bromosuccinimide in 100 mL of aqueous 10% CH_3CN. After 15 min solid Na_2SO_3 was added and the CH_3CN evaporated. The aqueous solution was adjusted to pH 4.5 by the addition of solid NaOAc and was continuously extracted overnight with Et_2O to remove the succinimide. The aqueous phase was then acidified to pH 1.0 with concentrated HCl and was continuously extracted with a fresh portion of Et_2O. The organic extract was dried over anhydrous $MgSO_4$ and evaporated. The residue was recrystallized from $CHCl_3$ to give 582 mg (43%) of the keto acid as a white solid, mp 135.5–136°C ($CHCl_3$); ir (Nujol): 3500–2500, 1770, 1725, 1600, and 1150 cm^{-1}; ^{1}Hmr (acetone-d_6) δ: 2.35 (s, 3), 3.1 (m, 4), 7.35 (d, 2, J = 8.5), 7.75 (d, 2, J = 8.5), 8.3 (s, 1). *Anal.* calcd. for $C_{11}H_{13}NO_5S$ (271.29): C 48.70, H 4.83, N 5.16, S 11.82; found: C 48.52, H 4.70, N 5.25, S 11.60. *Mol. Wt.* calcd. for $C_{11}H_{13}NO_5S$: 271.0515; found (high resolution ms): 271.0519.

Methyl 2,2-Bismethoxy-4-(p-toluenesulphonamido)butanoate ***16***

A solution of 1.88 g (5 mmol) of acid **14** and 1.33 g (5.25 mmol) of I_2 in 50 mL of CH_3OH was refluxed for 12 h. The brown solution was cooled to room temperature and a few mL aqueous dilute $Na_2S_2O_3$ was added to destroy the excess I_2. The solvent was evaporated and the residue was dissolved in EtOAc and the organic phase was washed with aqueous 2% $Na_2S_2O_3$, dried over anhydrous $MgSO_4$, and evaporated. The residue was recrystallized to yield 1.07 g (65%) of **16** as colourless needles, mp 121–122°C (Et_2O); ir: 1740, 1601, 1330 cm^{-1}; ^{1}Hmr δ: 2.10 (t, 2, J = 7), 2.42 (s, 3), 2.95 (q, 2, J = 7), 3.28 (s, 6), 3.75 (s, 3), 5.28 (bt, 1, J = 7), 7.32 (d, 2, J = 8.5), 7.78 (d, 2, J = 8.5). *Anal.* calcd. for $C_{14}H_{21}NO_6S$ (331.39): C 50.74, H 6.39, N 4.23, S 9.68; found: C 50.60, H 6.45, N 4.23, S 9.44. *Mol. Wt.* calcd. for $C_{13}H_{17}NO_5S$ (M − 32): 299.0810; found (high resolution ms): 299.0808.

The reaction between 2,2-diphenyl-1-picrylhydrazyl and bromine

PATRICIA F. CURRIE, J. WILSON QUAIL, AND JOHN A. WEIL[1]

Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received June 18, 1979

PATRICIA F. CURRIE, J. WILSON QUAIL, and JOHN A. WEIL. Can. J. Chem. **58**, 723 (1980).

The reaction between 2,2-diphenyl-1-picrylhydrazyl and bromine in solution has been studied at several temperatures. Despite the literature, reporting simple phenyl bromination products, a substantial yield of nitration products is observed. These have been identified by use of thin-layer chromatography, mass spectrometry, nuclear magnetic resonance, and elemental analysis. Among various products, 2-(*p*-nitrophenyl)-2-phenyl-1-picrylhydrazine is a major one at room temperature and above. It is thought that this compound is formed by reaction of DPPH with NO_2, displaced from *ortho* nitro groups in the picryl rings by bromine. Yields were found to vary, depending on experimental conditions, with the temperature and the rate of bromine addition as primary controlling factors.

PATRICIA F. CURRIE, J. WILSON QUAIL et JOHN A. WEIL. Can. J. Chem. **58**, 723 (1980).

On a étudié à différentes températures, la réaction entre la diphényl-2,2 picryl-1 hydrazyle et le brome en solution. Contrairement aux résultats rapportés dans la littérature où on ne mentionne que la formation des produits résultant de la bromation du groupe phényle, on a obtenu des produits nitrés avec des rendements importants. On les a identifiés par chromatographie sur couche mince, par spectrométrie de masse, par rmn et par l'analyse élémentaire. Parmi les différents produits, la (*p*-nitrophényl)-2 phényl-2 picryl-1 hydrazine est majoritaire à la température ambiante et au dessus. On pense que ce composé se forme par la réaction de la DPPH avec le NO_2 alors que le brome déplace le groupe nitro en position *ortho* sur le cycle picryle. On trouve que les rendements varient suivant les conditions expérimentales avec la température et la vitesse d'addition du brome qui seraient des facteurs primaires contrôlant la réaction.

[Traduit par le journal]

Introduction

In the course of preparing brominated hydrazyl free radicals, e.g., 2-(*p*-bromophenyl)-2-phenyl-1-picrylhydrazyl, for certain electron spin resonance studies, it was found that the literature preparation (1) failed to give satisfactory yields of the desired product. Instead, treatment of the starting material, 2,2-diphenyl-1-picrylhydrazyl, with bromine leads to substantial yields of 2-(*p*-nitrophenyl)-2-phenyl-1-picrylhydrazine. The results of a study of the reaction are presented herein.

Adopting a previously used notation (2), the compound 2,2-diphenyl-1-picrylhydrazyl is denoted as $DH_2\cdot$. More generally, the various corresponding *p*-substituted diphenylpicrylhydrazines are represented by DG_aG_b—H, and their hydrazyl radical forms as $DG_aG_b\cdot$. Here G represents any group attached at the phenyl sites *para* to nitrogen 2.

Because of its unusual stability, $DH_2\cdot$ has long been of special interest. Numerous mono- and di-*p*-phenyl substituted compounds have been prepared (2, 3) and their epr spectra studied (4). In particular, the reaction of NO_2 with $DH_2\cdot$ in organic solvents to form $DH(NO_2)$—H and $D(NO_2)_2$—H has been studied in some detail (2). The compound DHBr—H has been reported (*5a*, *b*) prepared by the method of Goldschmidt and Renn (1). This synthesis involves the addition of a $CHCl_3$ solution of Br_2 to a $CHCl_3$ solution of $DH_2\cdot$ with resulting formation of DHBr—H. Our attempts to prepare DHBr—H by this method resulted in the formation of $DH(NO_2)$—H in substantial yields. The effect of reaction conditions has now been investigated and methods of separation of the reaction products have been developed.

Experimental

The $DH_2\cdot$ was prepared by oxidation of 2,2-diphenyl-1-picrylhydrazine (DH_2—H) (Eastman 7365) with PbO_2 in benzene. Shiny black crystals ($DH_2\cdot$):C_6H_6, mp 129–134°C, were obtained (6). (For brevity, the solvated molecule will simply be referred to as $DH_2\cdot$.) Reagent grade Br_2 was used to prepare 3% by weight solutions in the solvent ($CHCl_3$ or C_6H_6). Hydrazyls $DHNO_2\cdot$ and $D(NO_2)_2\cdot$ were prepared according to the procedure in ref. 2.

A weighed quantity of $DH_2\cdot$, typically 1–3 g, was dissolved in the solvent of choice and maintained at the desired temperature. An amount of 3% Br_2 in the same solvent was added with stirring (molar ratio 2 $DH_2\cdot/Br_2$). Temperature ranges were ice temperature, IT = 0–2°C, room temperature, RT = 20–25°C, or elevated temperature, ET = 60–70°C. Two experiments were performed at each temperature range, varying the rate of Br_2 addition. Rapid addition of Br_2 was completed in ~1 min. Slow addition of Br_2 took 1.5 h. During rapid Br_2 addition the solution turned from its intense purple $DH_2\cdot$ color to orange–brown. Slow Br_2 addition resulted in intense purple–brown color; here the intense coloration and observable epr spectra indicated the presence of hydrazyl compounds. To simplify subsequent analysis, the product solutions were reduced to transform all hydrazyls to their corresponding hydrazines by shaking with sufficient sodium dithionite and ~5–10 mL of 3% hydrogen peroxide to cause the solution color to become orange–brown.

At IT, $CHCl_3$ was used as the solvent. At RT and ET, the usual solvent was C_6H_6; substitution of $CHCl_3$ at RT made no

difference to subsequent product analysis results. During reaction, no significant temperature change from ambient was observed.

In two experiments, the parent hydrazine DH_2—H was treated slowly in $CHCl_3$ (IT) and C_6H_6 (ET) with a 3% Br_2 solution. In both instances the color remained orange–red so that the reduction procedure was unnecessary. One slow addition experiment was performed with $DH(NO_2)\cdot$ at ET, and with $D(NO_2)_2\cdot$ at IT, RT, and ET.

Adsorption chromatography was utilized to separate reaction products. Columns of alumina (Alcoa F-20 or Brinkmann Aluminum Oxide 90 basic) proved to be satisfactory. These columns were eluted successively with benzene, chloroform, and ethanol, the general order of elution being (*a*) any (non-reduced) hydrazyls, (*b*) unreacted DH_2—H, (*c*) brominated products, and (*d*) nitrated products. The purity of the fractions was checked by thin-layer chromatography (tlc); where necessary these were rechromatographed to obtain uncontaminated products. Following evaporation of the eluant, recrystallization of the residue was carried out using a variety of solvents, including benzene – petroleum ether, chloroform – petroleum ether, anhydrous ether, acetic acid, and ethanol. Recrystallization tended to be difficult; the hydrazines show a strong tendency to precipitate in a "tarry" form containing solvent of crystallization, and heating isolated products *in vacuo* to remove solvent tended to result in decomposition of the hydrazine.

Thin-layer chromatography was employed not only as a rapid method for indicating the purity of isolated chromatographic fractions, but also as a rough guide to the nature of the fraction, since phenyl-nitrated and phenyl-brominated products have significantly different R_f values. Commercial plates (Brinkmann 5538 silica gel 60, 0.2 mm precoated tlc sheets) were used without further activation, with toluene as the developer. The compounds were observed as colored spots. The R_f values of unknowns were compared with those of authentic samples: $D(NO_2)_2$—H, 0.043; $DH(NO_2)$—H, 0.232; DH_2—H, 0.453; DHBr—H, 0.494; DBr_2—H, 0.523.

Combustion C,H,N analyses of the product hydrazines $DH(NO_2)$—H, DHBr—H, and DBr_2—H, as well as their respective versions in which an NO_2 group in the picryl ring has been replaced by Br, gave reasonable results. The respective melting temperatures (°C) of the compounds in this set were 110–115 (1:1 complex with acetic acid), 182–184, 158–162, 93–97, 148–154, 174–177°C. A summary of product yields is given in Table 1.

Mass spectra were recorded on an AEI MS-12 mass spectrometer at 70 eV with an ion source temperature of 150–220°C. Single bromine substitution in a molecule was readily identified by its characteristic isotope cluster. It was also observed that multiple (mainly dibromo) substitution occurred, but in minor amounts. The mass spectra of DH_2—H, $DH_2\cdot$, and $DH(NO_2)$—H have been reported by Filby and Kalus (7). Fragmentation of the parent molecular ion occurs via fission of the N—N bond and in some species is accompanied by hydrogen addition. The picrylamine portion of the molecule is observed as a prominent ion at *m/e* 228 in all three compounds. An intense peak at *m/e* 168 in DH_2—H and $DH_2\cdot$ indicates formation of a diphenylnitrene cation (or isomer thereof). In $DH(NO_2)$—H, the peak at *m/e* 214 is ascribed to the phenyl-*p*-nitrophenylamine cation radical. Presence of bromine in the diphenylnitrene portion of the molecule is expected to give a fragment of *m/e* 247 (and 249), whereas bromine substituted for NO_2 in the picrylamine portion would produce a fragment of *m/e* 261 (and 263). Both of these peaks have been observed in the spectra of purified products. Comparison spectra of DHBr—H, 2-bromo-4,6-dinitroaniline, and 4-bromo-2,6-dinitroaniline (8) do display prominent peaks at *m/e* 247 (249) and at 261 (263) for the latter two, respectively.

TABLE 1. Product yields after slow addition of Br_2 to $DH_2\cdot$ in solution

Compound	Percentage of total weight recovered[a]		
	IT[b]	RT[b]	ET[b]
$DH(NO)_2$—H	9–14	15–22	37–49
DHBr—H + DBr_2—H	76–81	53–62	0–20
"Picryl brominated"[c]	~5	~20	40–49
DH_2—H	~5	~3	0–2

[a]Calculated on the basis of the total weight of purified products recovered.
[b]IT = 0–2°C; RT = 20–25°C; ET = 60–70°C.
[c]Species in which Br has replaced NO_2.

Some of the products were examined qualitatively by epr, using a Bruker B-ER418S spectrometer. The spectral patterns of $DH_2\cdot$, DHBr·, and $DBr_2\cdot$ are very similar, while $DH(NO_2)\cdot$ and $D(NO_2)_2\cdot$ exhibit sufficiently different characteristic spectra (2) to be useful for product identification.

Proton magnetic resonance spectra were recorded on a Bruker WP-60 spectrometer. Samples of DH_2—H, $DH(NO_2)$—H, and DHBr—H from the reaction mixture were studied at 60 MHz in dichloromethane-d_2 over the range −100°C to +50°C. At +50°C the picryl protons were observed as a single line. Below room temperature the spectra of the picryl protons resolved in all cases into AB quartets, consistent with the results of Heidberg *et al.* (9) for DH_2—H.

The location of the substituted Br (for one NO_2 in the $DH_2\cdot$ picryl ring) was determined by proton nmr studies of the two relatively abundant picryl-brominated reaction products **1** and **2**, derivatives of $DH(NO_2)$—H and DHBr—H respectively, as follows.

The dinitrophenyl ring protons of compound **1** in dichloromethane-d_2 at 27.3°C gave an AB quartet (δ_1 = 8.60, δ_2 = 8.67, J = 2.5 Hz; chemical shifts measured relative to the proton in $CHDCl_2$, taken as δ = 5.25). The quartet did not change appreciably as the temperature was raised to +50°C, and a similar result was obtained in chloroform up to 70°C. This indicates that no dynamic averaging of proton parameters, such as is observed (9) for the picryl protons in DH_2—H, occurs. For the protons in a 4-bromo-2,6-dinitrophenyl group attached to nitrogen, one would expect such nmr coalescence to occur at a lower temperature than is observed for the corresponding picryl group, as indeed was observed with the *N*-methylaniline compounds.[2] Thus, the non-equivalence of the protons indicates that the Br atom has substituted for the 2-NO_2 group to yield 2-(*p*-nitrophenyl)-2-phenyl-1-(2-bromo-4,6-dinitrophenyl)hydrazine. In dichloromethane-d_2 at −63.5°C, two AB quartets with unequal intensities (ratio 1:0.51) were observed (δ_1 = 8.34, δ_2 = 8.54, J = 2.3 Hz, and δ_1' = 8.59, δ_2' = 9.04, J = 2.5 Hz).

Compound **2** in benzene-d_6 at +28°C gave an AB quartet (δ_1 = 7.78, δ_2 = 7.89 relative to C_6HD_5, J = 2.7 Hz). This quartet only sharpened somewhat as the temperature was raised to 50°C. Here too, the non-equivalence of the protons indicates that the Br has substituted for the 2-NO_2 group, to yield 2-(*p*-bromophenyl)-2-phenyl-1-(2-bromo-4,6-dinitrophenyl)hydrazine. In dichloromethane-d_2 at +28°C, **2** gave a single line at δ = 8.56, apparently due to accidental equivalence of the 3,5 protons. As the temperature of the nmr probe was reduced, the single line changed and evolved at −73°C into two AB quartets with rela-

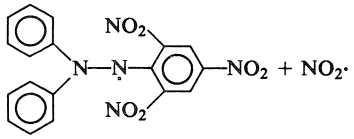
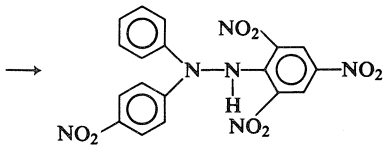
tive intensities 1:0.30 ($\delta_1 = 8.29$, $\delta_2 = 8.53$, $J = 2.5$ Hz, and $\delta_1' = 8.57$, $\delta_2' = 9.10$, $J = 2.4$ Hz).



The temperature dependence of the nmr spectra of **1** and **2** in dichloromethane-d_2 is similar to that observed by Heidberg and Scheve (10) for *N*-acetyl-*N*-methyl (d_3)-2-chloro-4,6-dinitroaniline in toluene-d_8. The complexity of the nmr spectra of **1** and **2** at low temperature is attributed to the existence of *cis* and *trans* isomers of both **1** and **2**, resulting from partial double bonding between atoms N-1 of the hydrazine and C-1 of the attached phenyl group, induced primarily by the presence of the two nitro groups on the phenyl ring. Similar effects have been observed[2] in low-temperature nmr spectra of 2,2-di(*p*-bromophenyl)-1-(2-bromo-4,6-dinitrophenyl)hydrazine.



Results and Discussion

In all of the experiments involving both slow and rapid addition of bromine to $DH_2\cdot$, $DH(NO_2)$—H has been identified as a product. The proportion of $DH(NO_2)$—H isolated at various temperatures (Table 1) followed the order IT rapid < IT slow < RT rapid < RT slow < ET rapid < ET slow. The reaction scheme proposed to account for the formation of this product involves the replacement by bromine of one (or more) nitro groups of the picryl ring, freeing nitrogen dioxide, which can then attack $DH_2\cdot$:

[1] 

[2] 

Temporary formation of NO_2Br in reaction [1] is not excluded.

It is noteworthy that no 2,2-diphenyl-1-(2-bromo-4,6-dinitrophenyl)hydrazyl (or the corresponding hydrazine) was isolated as a reaction product. Apparently this hydrazyl reacts efficiently with bromine and/or nitrogen dioxide to form products substituted in the *p*-phenyl position. Traces of product $D(NO_2)_2$—H also were detected by tlc and mass spectrometry.

Indirect evidence for the presence of free nitrogen dioxide during the reaction was obtained as follows. Nitrogen gas was bubbled through the reaction mixture during the addition of bromine. The exiting gas was passed through the Griess–Ilovsay solution of sulfanilic acid and α-napthylamine (11). Red color development in the test solution indicated the presence of nitrogen dioxide. Intense color development occurred at elevated temperatures, and decreased with decreasing temperature. Blank runs excluding either $DH_2\cdot$ or bromine failed to give a positive color test.

The detailed mechanism of the nitration reaction is presently unknown. Attack of the picryl ring by a bromine atom seems indicated. Exposure of the reaction mixture to ultraviolet light (Hanovia Model 30620 quartz lamp with a Vycor filter) during addition of Br_2 at IT and ET significantly enhanced the yields of $DH(NO_2)$—H. A blank run at IT exposing only $DH_2\cdot$ in solution indicated formation of some nitrated product, but with a low yield.

Presumably, in our system, asymmetry caused by the steric effects of the diphenylamine group on the picryl ring causes one nitro group *ortho* to the amine linkage, by definition the 2-nitro group, to be further out of the ring plane than the 4- and 6-nitro groups, causing it to be the most reactive to free radical attack; such asymmetry has been reported for $DH_2\cdot$ in the solid state (12). We note that the Br atom is substantially less bulky than the NO_2 group. A free radical mechanism has been postulated to occur in the analogous reaction of $DH_2\cdot$ with 2,4,6-tri-*tert*-butylbenzenethiol (13*a*, *b*). However, the authors indicate that one of the reaction products is formed by displacement of a nitro group from the *para*- rather than the *ortho*-position of the picryl ring by a 2,4,6-tri-*tert*-butylphenylthiyl radical.

Phenyl bromination only at *para*-positions was found (by nmr) to occur when the parent compound DH_2—H was reacted with bromine at IT and ET. The products recovered were DHBr—H, unreacted DH_2—H, and a minor amount of DBr_2—H. There was no evidence of formation of nitrated product. To our knowledge there has been no previous report of direct bromination of the hydrazine DH_2—H. It has been noted (2) that $D(NO_2)_2$—H can also be obtained with DH_2—H as the starting material, using NO_2.

At ET, when $DH(NO_2)\cdot$ was reacted slowly with Br_2, mass spectral data indicated the formation of $D(NO_2)_2$—H, as well as derivative **1** (with bromine substitution in the picryl ring of $DH(NO_2)$—H).

However, the bulk of the material recovered was unreacted $DH(NO_2)$—H.

The hydrazyl $D(NO_2)_2\cdot$ was less reactive with Br_2 in solution than either $DH_2\cdot$ or $DH(NO_2)\cdot$. Mass spectra indicated no substitution of bromine occurred in the molecule. No rigorous identification of products was made; one of the products appeared to have lost one NO_2 from the picryl ring but most of the recovered material was the parent hydrazine $D(NO_2)_2$—H.

M. Akbar Ali. Can. J. Chem. **58**, 727 (1980).

New Schiff base ligands formed from 2-methoxybenzaldehyde and 2,4-dimethoxybenzaldehyde with *N*-methyl-*S*-alkyldithiocarbazates and their nickel(II) and copper(II) complexes have been prepared and characterised by elemental analysis and magnetic and spectroscopic measurements. The Schiff bases behave as neutral tridentate chelating agents forming stable nickel(II) complexes of stoichiometry $NiLX_2 \cdot xC_2H_5OH$ (L = 2-methoxy- or 2,4-dimethoxybenzaldehyde Schiff bases of *N*-methyl-*S*-methyldithiocarbazate; X = I^-, SCN^-; x = 0, 1). Conductivity, magnetic, and spectral data support an octahedral structure for the nickel(II) complexes. The $CuLCl_2$ complexes were also isolated. Magnetic and spectral evidence are in accord with a chloro-bridged dimeric structure. The chloro-complex of copper(II) with the 2-methoxybenzaldehyde Schiff base displays a room-temperature magnetic moment of 1.81 BM, which remains virtually constant over the temperature range 343–123 K.

Hydrated copper(II) chloride promotes complete hydrolysis of the 2,4-dimethoxybenzaldehyde and 2-methoxybenzaldehyde Schiff bases of *N*-methyl-*S*-benzyldithiocarbazate with the concomitant formation of copper(II) complexes of the parent *N*-methyl-*S*-benzyldithiocarbazate of general formula, $Cu(N—SR)Cl_2$ (R = $C_6H_5CH_2$—).

M. Akbar Ali. Can. J. Chem. **58**, 727 (1980).

On a préparé des nouveaux ligands de bases de Schiff à partir de la réaction du méthoxy-2 et du diméthoxy-2,4 benzaldéhyde avec le *N*-méthyl-*S*-alkyldithiocarbazate et leurs complexes de Ni(II) et de Cu(II) et on les a caractérisés par l'analyse élémentaire et par des mesures magnétiques et spectroscopiques. Les bases de Schiff se comportent comme des agents chélatants tridentates neutres en formant des complexes stables de Ni(II) de formule $NiLX_2 \cdot xC_2H_5OH$ (L = méthoxy-2 ou diméthoxy-2,4 benzaldéhyde bases de Schiff du *N*-méthyl-*S*-alkyldithiocarbazate; X = I^-, SCN^-; x = 0, 1). La conductivité, les données magnétiques et les données spectrales sont en faveur d'une structure octaédrique des complexes de nickel. On a également isolé des complexes de type $CuLCl_2$. Les preuves magnétiques et spectrales sont en accord avec une structure de dimère ayant un chlore en position de pont. Le moment magnétique du complexe chloré de Cu(II) avec la base de Schiff dérivant du méthoxy-2 benzaldéhyde à la température ambiante, est 1.81 BM et il reste virtuellement constant sur une échelle de température de 343–123 K.

Le chlorure cuivrique hydraté favorise l'hydrolyse complète des bases de Schiff du diméthoxy-2,4 ainsi que du méthoxy-2 benzaldéhyde et de la *N*-méthyl-*S*-benzyldithiocarbazate avec la formation concomittante de complexes de Cu(II) du *N*-méthyl-*S*-benzyldithiocarbazate apparenté de formule générale $Cu(N—SR)Cl_2$ (R = $C_6H_5CH_2$—).

[Traduit par le journal]

Introduction

Metal complexes of tridentate chelating agents containing the ONS donor set have received considerable attention over the past few years (1–6), since some of these ligands have been shown to yield copper(II) complexes with anomalous magnetic properties. As part of a general investigation of metal complexes of ligands containing the ONS donor sequence, some nickel(II) and copper(II) complexes of Schiff bases formed from 2-methoxybenzaldehyde and 2,4-dimethoxybenzaldehyde with *N*-methyl-*S*-alkyldithiocarbazates are presented herein.

Experimental

All the physical measurements and analytical procedures employed in the present work have been described in detail previously (7).

Preparation of the Methoxybenzaldehyde Schiff Base of N-*Methyl*-S-*methyldithiocarbazate (ONS)*

N-Methyl-*S*-methyldithiocarbazate was prepared according to the method of Akbar Ali *et al.* (8). *O*-Methoxybenzaldehyde (6.8 g) was dissolved in 95% ethanol (50 mL) and the solution so obtained was mixed with a hot solution of *N*-methyl-*S*-methyldithiocarbazate (6.8 g) in the same solvent (50 mL). The mixture was heated on a steam bath for about 30 min and left standing for about 3 h, whereupon the crystals which had formed were filtered off: mp 145°C, yield 11.0 g. *Anal.* calcd. for $C_{11}H_{14}N_2OS_2$: C 51.94, H 5.55, N 11.01; found: C 52.21, H 5.52, N 11.21.

Preparation of the 2,4-Dimethoxybenzaldehyde Schiff Base of N-*Methyl*-S-*methyldithiocarbazate (MeONS)*

To a filtered solution of *N*-methyl-*S*-methyldithiocarbazate (6.8 g) in hot absolute ethanol (100 mL) was added a solution of 2,4-dimethoxybenzaldehyde (8.75 g) in the same solvent (50 mL). The mixture was heated on a steam bath for about 1 h and allowed to stand overnight. The compound was obtained as creamy white crystals: mp 149°C (yield, 8.0 g). *Anal.* calcd. for $C_{12}H_{16}N_2O_2S_2$: C 50.68, H 5.67, N 9.85; found: C 50.56, H 5.71, N 9.67.

Preparation of the O-*Methoxybenzaldehyde Schiff Base of* N-*Methyl*-S-*benzyldithiocarbazate (ONSBz)*

N-Methyl-*S*-benzyldithiocarbazate was prepared following the method of Akbar Ali and Teoh (8). The Schiff base was prepared by a method similar to that used for the ONS Schiff base except that *N*-methyl-*S*-benzyldithiocarbazate was used instead of *N*-methyl-*S*-methyldithiocarbazate: mp 203°C (yield, 10.0 g). *Anal.* calcd. for $C_{17}H_{18}N_2OS_2$: C 61.79, H 5.49, N 8.48; found: C 61.59, H 5.46, N 8.64.

Preparation of the 2,4-Dimethoxybenzaldehyde Schiff Base of N-Methyl-S-benzyldithiocarbazate (MeONSBz)

This compound was prepared following the procedure of Bose (9) by using *N*-methyl-*S*-benzyldithiocarbazate and 2,4-dimethoxybenzaldehyde. *Anal.* calcd. for $C_{18}H_{20}N_2O_2S_2$: C 59.97, H 5.57, N 7.77; found: C 60.18, H 5.62, N 7.72.

Preparation of Metal Complexes

Unless otherwise stated all the complexes were dried *in vacuo* over P_4O_{10}.

Preparation of Ni(ONS)I_2

A solution of nickel iodide was first prepared by heating nickel nitrate hexahydrate (3.0 g) and sodium iodide (3.0 g) in absolute ethanol and filtering off the precipitated sodium nitrate. To this nickel iodide solution was added a solution of the Schiff base (1.5 g) in acetone (100 mL) and the mixture was heated at reflux for ca. 1 h. It was then allowed to cool down to room temperature and the reddish-brown crystals which had formed were filtered off and washed with a little acetone followed by benzene and ether. *Anal.* calcd. for $C_{14}H_{14}N_2OS_2$: C 23.31, H 2.49, Ni 10.36; found: 24.07, H 2.45, Ni 10.10.

Preparation of Ni(ONS)$(NCS)_2$

A solution of nickel(II) thiocyanate prepared by heating nickel(II) nitrate hexahydrate (3.0 g) and sodium thiocyanate (3.0 g) in absolute ethanol was mixed with solution of the Schiff base (1.5 g) in a mixture of butanol (20 mL) and 2,2-dimethoxypropane (10 mL). The mixture was heated under reflux for about 2 h and the solvents were then evaporated slowly on a steam bath whereby deep green crystals of the complex were obtained. These were filtered off and washed successively with methanol and acetone. *Anal.* calcd. for $C_{13}H_{14}N_4OS_4Ni$: C 36.39, H 3.29, Ni 13.69; found: C 36.29, H 3.19, Ni 13.50.

Preparation of Cu(ONS)Cl_2

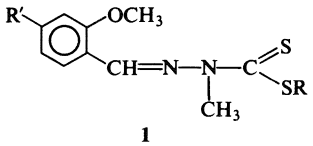
A solution of copper(II) chloride dihydrate (1.7 g) in absolute ethanol (50 mL) was mixed with a solution of the Schiff base (2.5 g) in acetone (100 mL) and the resultant solution was heated on a steam bath until green crystals appeared.

The crystals were filtered off and washed several times with ethanol and acetone. *Anal.* calcd. for $C_{11}H_{14}N_2OS_2CuCl_2$: C 33.98, H 3.63, Cu 16.34, Cl 18.20; found: C 33.50, H 3.22, Cu 16.70, Cl 18.60.

Preparation of Cu(MeONS)Cl_2

The compound was prepared by a similar method as described for Cu(ONS)Cl_2. *Anal.* calcd. for $C_{12}H_{16}N_2O_2S_2CuCl_2$: C 34.41, H 3.85, Cu 15.17; found: C 34.20, H 3.76, Cu 15.30.

Preparation of Ni(MeONS)$I_2 \cdot C_2H_5OH$



Butanol (30 mL) was added to a solution of nickel iodide (1.4 g) in absolute ethanol (50 mL) followed by the addition of ligand (1.42 g) in acetone (50 mL). The reaction mixture was heated under reflux for ca. 1 h and then allowed to evaporate on a steam bath with occasional addition of acetone. When the volume of the reaction mixture dropped to about 30 mL, some brown crystals began to settle down. At this stage 2,2-dimethoxypropane (10 mL) was added and the mixture further heated on a steambath whereupon the brown crystals formed were filtered off and washed with a few millilitres of acetone followed by benzene. *Anal.* calcd. for $C_{14}H_{22}N_2O_2S_2NiI_2$: C 26.15, H 3.45, Ni 9.13; found: C 26.17, H 2.73, Ni 9.40.

Reactions of ONSBz and MeONSBz with $CuCl_2 \cdot 2H_2O$

A solution of the appropriate Schiff Base (ca. 1.7 g) in benzene (50 mL) was mixed with a hot solution of $CuCl_2 \cdot 2H_2O$ (1.7 g) in methanol (50 mL) and the reaction mixture was heated under reflux for about 3 h whereupon the green crystals formed were filtered off and washed with benzene and methanol. *Anal.* calcd. for $C_9H_{12}N_2S_2CuCl_2$: C 31.17, H 3.50, Cu 18.32, Cl 20.10; found: C 31.44, H 3.45, Cu 18.40, Cl 20.55 (for the reaction of MeONSBz with $CuCl_2$). For the reaction of MeONSBz with $CuCl_2$, found: Cu 18.30, Cl 20.45.

Results and Discussion

The Schiff bases (**1**; R = CH_3 or $CH_2C_6H_5$; R′ = H or OCH_3) were obtained readily by condensation of appropriate aldehydes with *N*-methyl-*S*-alkyldithiocarbazates.

1

The metal complexes which were isolated in the present study are presented in Table 1 together with some of their properties. For steric considerations the present Schiff bases can act either as ONS tridentates, coordinating via the methoxyl group, the azomethine nitrogen and the thioketo sulphur atoms or as SS bidentates coordinating through the two sulphur atoms. However, previous studies by Akbar Ali *et al.* have shown that such ligands prefer ONS coordination to SS coordination (5, 6). Some important ir bands of the Schiff bases and their metal complexes are shown in Table 2. The assignments shown in the table are only tentative and based on comparisons of the ir spectra with those of similar compounds (6, 7, 10). Two strong peaks appear at ca. 1600 and 1592 cm^{-1} in the ir spectra of all the present Schiff bases. These are assigned to the C=N stretchings of the azomethine group (6). The shifts of these bands to lower frequencies by 10–15 cm^{-1} in the ir spectra of the complexes indicate that bond formation takes place through the azomethine nitrogen atom (11).

A strong band at about 1002 cm^{-1} in the ir spectra of the subject Schiff bases may be attributed to the $\nu_{(H_3C-O)}$ (12–14). This band is also shifted to lower frequencies (Table 2) in the spectra of the metal complexes suggesting that the methoxyl group is also involved in coordination to the metal ions. Further evidence in favour of methoxyl oxygen coordination comes from the presence of a medium to weak band at about 600 cm^{-1} in the spectra of the complexes. This band does not correspond to any ligand band in this region and consequently may be assigned to the metal–oxygen stretching frequency (13).

Bands at ca. 1235 and 942 cm^{-1} in the ir spectra of the Schiff bases may be assigned to the coupled modes of ν_{CS} and ν_{CN} (6, 7, 10). It has been observed in the case of metal complexes of thiocarbohydrazide (10), *S*-benzyldithiocarbazate (6) and

some of its derivatives (7) that these coupled ν_{CS} and ν_{CN} modes in the spectra of the ligands are raised to higher frequencies in the spectra of the complexes. This fact has been attributed to the coordination of the thioketo sulphur which causes an increase in the C—N bond order and nullifies any lowering of ν_{CS} upon coordination (6, 7, 10). In the present study, although the $\nu_{CN} + \nu_{CS}$ band does not show any appreciable raise in frequency in the spectra of the complexes compared to those in the ligands, the $\nu_{CS} + \nu_{CN}$ band is raised to higher frequencies (Table 2), indicating that the thioketo sulphur atom is involved in coordination.

The preceding ir evidence supports the fact that the subject Schiff bases are behaving as ONS tridentates and not as SS bidentates as has been found in the case of similar ligands studied by other workers (5, 6).

The Nickel(II) Complexes

Reaction of the Schiff bases with nickel(II) iodide and nickel(II) thiocyanate in a mixture of ethanol and 2,2-dimethoxypropane resulted in the formation of crystalline complexes of empirical formula, $NiLX_2\cdot nC_2H_5OH$ (where L = ONS, MeONS; X = I^- or NCS^-; n = 0 or 1). These compounds were found to be stable in a dry atmosphere, but slowly decomposed in the presence of moisture. Attempts to prepare similar iodo- and thiocyanato-complexes of nickel(II) with the Schiff bases containing the benzyl groups on one of the sulphurs were unsuccessful. In each case the unreacted ligands could be isolated almost quantitatively. Similarly all the ligands studied herein failed to yield any complex with nickel(II) chloride and nickel(II) bromide. The inability of the Schiff bases to produce any complex with nickel in the presence of hard donors such as the chloride and bromide ions seems to suggest that symbiosis phenomenon may be playing a very important role in the formation of the iodo- and thiocyanato-complexes. The nickel(II) ion has been termed as a fairly hard ion (15) and consequently, its coordination to soft donors present in the subject Schiff bases would be favoured only in the presence of soft anions such as the iodide and thiocyanate ions which most probably symbiotically motivate the nickel(II) to act as a soft acceptor.

The presence of ethanol in $Ni(MeONS)I_2\cdot C_2H_5OH$ is confirmed by the presence of a broad band at 3660 cm^{-1} in its ir spectrum. The O—H stretching frequency generally appears as a broad band at 3660 cm^{-1} in the ir spectrum of free ethanol (16) and this is observed at a lower frequency in coordinated ethanol (17). The presence of O—H stretch at 3660 cm^{-1} in the ir spectrum of the above iodo-complex is an indication that the ethanol molecule is present as ethanol of crystallization and not as a coordinated ethanol molecule. The conductivity data of all the complexes isolated in the present study are set aside in Table 1.

The nickel(II) complexes, although show some dissociation in nitromethane, have conductance values much lower than that expected for a uni-univalent electrolyte in this solvent. On the basis of these data the complexes may be formulated as $[NiLX_2]$. Support in favour of anion coordination also comes from the ir spectrum of the thiocyanato-complex. Because of its ambidentate nature, the NCS^- ion is known to coordinate in different

modes (18) and ir spectroscopy has been very helpful in distinguishing between these modes (19). The C≡N stretching frequency has been observed in the range 2040–2080 cm^{-1} for *N*-bonded thiocyanate and in the range 2080–2120 cm^{-1} for *S*-bonded thiocyanate. A number of metal complexes are known where the C—N stretching frequencies are observed at 30–60 cm^{-1} higher than that in the terminal thiocyanate groups (20–27). This has been attributed to the presence of M—NCS—M bridges. Furthermore, it has been suggested that extensive splitting of the band corresponding to the antisymmetric stretch occurs in the ir spectra of complexes containing both terminal and bridging thiocyanato-groups (23, 27). The ir spectrum of $[Ni(ONS)(NCS)_2]$ exhibits two strong bands at 2090 and 2130 cm^{-1} with definite shoulders at 2100 and 2140 cm^{-1}. This is strong evidence that both terminal and bridging thiocyanato-groups are present. Since the ligand behaves as a tridentate and there are two thiocyanate ions per nickel(II) ion, a thiocyanate-bridged six-coordinate structure shown below would be in keeping with the observed ir and conductivity data.

The room-temperature magnetic moments of the nickel complexes (Table 1) are normal for a six-coordinate nickel(II) in an octahedral or pseudo-octahedral field (28). The solid reflectance elec-

tronic spectral data (Table 1) also support an octahedral structure for the present nickel(II) complexes. The spectra exhibit two bands at about 9.9 and 15.0 kK attributable to the transitions $^3A_{2g} \rightarrow {}^3T_{2g}(P)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ respectively of octahedral nickel(II). The third expected band corresponding to the transition $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ is probably hidden beneath the charge-transfer band. The presence of donor atoms of unequal field strengths in the ligands is expected to cause some distortion from the regular O_h symmetry with the consequent broadening of the ν_1 and ν_2 bands. Although no such splittings have been observed in the present spectra, the ν_1 band has been found to be very broad with definite shoulders. This suggests that some distortion might have been present. On the basis of their stoichiometry, low solubility, electronic spectra, and magnetic moments, a dimeric or a polymeric structure involving the iodo- or thiocyanato-bridge is assigned to the present nickel(II) complexes. From a comparison of the electronic spectra of the two iodo-complexes, it appears that the ligand field strength of the *S*-methyl derivative is greater than that of the *S*-benzyl derivative.

The Copper(II) Complexes

The Schiff bases, ONS and MeONS, react with copper(II) chloride forming crystalline complexes of general formula, $CuLCl_2$, which behave as non-electrolytes in nitromethane. Reactions of these ligands with either copper(II) perchlorate or copper(II) nitrate under similar conditions did not yield any isolable products. The Schiff bases, however, reacted with copper(II) bromide yielding some orange products which were found to be diamagnetic in nature. Since these compounds could not be obtained in an analytically pure form, they are not characterized herein. However, from the diamagnetic nature of these complexes, it can be safely inferred that the subject ligands reduce copper(II) bromide to yield a copper(I) complex. As the Schiff bases behave as neutral ONS tridentates and there are two chloride ions per copper(II) ion in the coordination sphere, the $CuLCl_2$ complexes may be thought to possess either a monomeric five-coordinate structure or a dimeric or polymeric chlorine-bridged structure. The electronic spectra of these complexes (Table 1) display a broad band at ca. 13.5 kK, which do not resemble spectra of other known five-coordinate copper(II) species (29), but are close to the spectra of distorted octahedral copper(II) complexes (30). The room temperature magnetic moments of the $CuLCl_2$ complexes are about 1.81 BM which are quite normal for a $3d^9$ ion. The magnetic susceptibilities of the $Cu(ONS)Cl_2$ complex were measured over the temperature range 343–93 K. The compound obeys the Curie–Weiss law of the form shown below, where χ_M^{corr} is the molar susceptibility corrected for diamagnetism, $N\alpha = 60 \times 10^{-6}$ cgs units is the assumed value of the T.I.P., and all the other symbols have their usual meanings.

$$\chi_M^{corr} = Ng^2\beta^2/k(T - \theta) + N\alpha$$

A plot of $1/\chi_M^{corr} - N\alpha)$ vs. T gave a straight line from which the value of the Weiss constant θ was obtained. The small value of the Weiss constant ($\theta = +14$ K) indicates that the compound is a normal Curie–Weiss paramagnet and there is no appreciable magnetic interaction in the complex.

When the Schiff bases, ONSBz and MeONSBz, reacted with copper(II) chloride, instead of the expected Schiff base complexes, the complexes isolated were those of the parent *N*-methyl-*S*-alkyldithiocarbazates. The identities of these complexes were confirmed from the analytical data (Table 1) and from a comparison of their ir, magnetic, and electronic spectral data with those reported by Akbar Ali and Teoh (7). The ir spectra of these complexes do not display the $\nu_{C=N}$ band of the Schiff bases, but instead they show the ν_{NH_2} and δ_{NH_2} bands of the parent amines (Table 2). This shows that in the presence of copper(II) chloride the Schiff bases are hydrolysed with the concomitant formation of copper(II) complexes of the parent *N*-methyl-*S*-alkyldithiocarbazates. In a recent communication (9) it has been claimed that the MeONSBz ligand gives copper(II) chloride and bromide complexes. This author was unable to isolate the reported complexes by following the procedure reported in the literature (9). Each time the Schiff bases were found to be hydrolysed resulting in copper(II) complexes of the parent amines. Nickel(II) (31–34) and copper(II) (35) have been shown to catalyse the hydrolysis of the C=N bond of Schiff bases with the concomitant formation of a metal complex of parent amines. The activation of the azomethine group toward hydrolytic cleavage may be considered to be analogous to the activation of the azo group (36) in the cobalt(II) catalysed hydrolysis of the latter. The coordination of the azomethine nitrogen facilitates the electron cloud being drawn away from the C=N bond and thereby weakens it, so that it becomes more susceptible to hydrolytic cleavage. This mechanism is very similar to the interpretation provided by Kroll (37) of the catalytic hydrolysis of amino acid esters by heavy metal ions.

Ab initio MO predictions for the geometries and energies of the Σ and Π states of some conjugated free radicals

N. Colin Baird and Kathleen F. Taylor

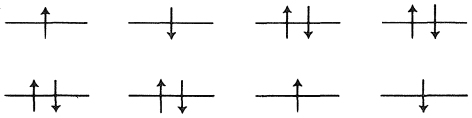
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 5, 1979

N. Colin Baird and Kathleen F. Taylor. Can. J. Chem. **58**, 733 (1980).

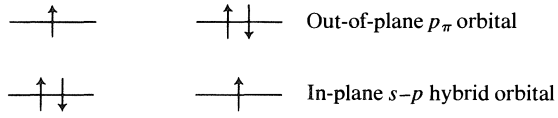
Ab initio MO calculations are reported for the lowest Σ and Π doublet states of the radicals **1**–**10**. Configuration interaction is included, using the restricted open-shell MO's as a base. The important geometric variables are optimized in calculations using the STO-3G basis set; in some cases energies and geometries are redetermined using the 4-31G basis. In most cases the energy separation between the Σ and Π doublet states is calculated to be small; the results are very dependent upon the basis set whenever the radical is localized upon a nitrogen atom. For radicals XYZ with different terminal groups, a valid prediction of the structure is obtained only if the basis set properly distinguishes between the π energies of X=Y and Y=Z bonds. Small basis sets appear to underestimate the π energy of carbonyl bonds, and thus are overbiased in favour of X=C—O· structures. Unsymmetrical structures are predicted for the Σ states of some radicals, even when the terminal groups are identical.

N. Colin Baird et Kathleen F. Taylor. Can. J. Chem. **58**, 733 (1980).



On rapporte des calculs *ab initio* des orbitales moléculaires (OM) des états doublets Σ et Π des radicaux **1** à **10**. On y inclut les interactions de configuration en utilisant comme base la couche incomplète restreinte des OM. Lors des calculs, on amplifie les variables géométriques importantes en utilisant l'ensemble STO-3G comme base; dans certains cas, on redétermine les énergies et les géométries en utilisant la base 4-31G. Dans la plupart des cas, on calcule que l'énergie de séparation entre les états doublets Σ et Π doit être faible. Si le radical est localisé sur l'atome d'azote, les résultats dépendent beaucoup de l'ensemble de base utilisé. Pour les radicaux XYZ avec des groupes terminaux différents, on n'obtient une prédiction satisfaisante de structure que si l'ensemble de base distingue clairement les énergies π des liaisons X=Y et Y=Z. Des petits ensembles de base semblent sous-évaluer l'énergie π des liaison des composés carbonylés et favorisent ainsi indûment les structures X=C—O·. On prédit des structures dissymétriques pour les états Σ de quelques radicaux, même quand les groupes terminaux sont identiques.

[Traduit par le journal]



Introduction

Molecules which have very low-lying excited states are expected whenever the highest-occupied molecular orbital differs little in stability from one or more others *and* this collection of nearly-degenerate MO's is not completely filled with electrons.

In examples which involve free radicals, a singly-occupied orbital is of similar stability to one or more doubly-occupied (or empty) MO's. When only a pair of orbitals is involved, there are two states of interest, both doublets:

If the two MO's are degenerate, so are the two states (aside from a small splitting due to spin–orbit interaction). An example is the hydroxyl radical, OH, in which the orbitals of concern essentially are 2*p* atomic functions of the oxygen atom. Although the amino radical, NH_2, is isoelectronic with hydroxyl, the two comparable MO's are not degenerate if the molecule is bent, since one is a 2*p* orbital (that perpendicular to the plane) whereas the other primarily is a 2*s*, 2*p* hybrid of nitrogen. Since the hybrid orbital is substantially more stable than is the 2*p*, the energy splitting between the two doublet states in NH_2 is not small (~31 kcal mol^{-1} experimentally (1)). The states are usually designated Σ or Π, according to the type of MO which the unpaired electron occupies.

Energy splittings which are intermediate between those for OH and NH_2 should arise in radicals when the two MO's are not exactly degenerate but are more comparable in stability than are those of NH_2. In the present study, we undertook to explore free radicals which are isoelectronic with allyl and which possess one or more heteroatoms (nitrogen and/or oxygen) which bear lone pairs of electrons. For such species, the doublet states should be separated by only a small gap whenever the nonbonding MO of the π system is similar in stability to the nonbonding σ orbital which contains the lone pair.

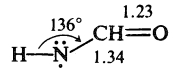
Method of Calculation

For each of the free radicals **1–10** (see Table 1) a geometry search was performed for the more important structural variables using the STO-3G basis set with standard molecular exponents (2). Configuration interaction was included between all $M_S = +\frac{1}{2}$ distributions (i.e. all single, double, and triple excitations) of the π electrons and the higher-lying σ nonbonding electrons,[1] as detailed in Table 1. At the optimum STO-3G + CI geometry, the energy was recalculated, often with a larger number of nonbonding MO's in the CI, and in many cases[2] also using the same number of configurations (typically 45) and the more extensive 4-31G basis set (3). Since all radicals were assumed to be planar, the lowest Σ and Π states are of different symmetry. The single-determinant wavefunctions were obtained using Roothaan's restricted open-shell SCF method (4). The final energies and geometries are listed in Table 1. In a few cases, the geometries were reoptimized at the 4-31G + CI level; these results are reported in the text.

Results and Discussion

In the Σ state of the free radicals considered herein, there are four π electrons — two bonding and two nonbonding — in the dominant electron configuration. Conjugated molecules XYZ which have a closed-shell of σ electrons and four π electrons usually are expected to have symmetrical structures; examples here are carbon dioxide, and the allyl anion for which our STO-3G + CI calculations predict both CC bond lengths to be 1.39 Å. In fact it is an unsymmetrical ("alternating") structure which is predicted by the calculations to be optimum for the lowest Σ state of the carbon-centered radicals (**7**, **8**, and **10**), see Table 1. The alternation of bond lengths is extreme in HCO_2·; the short bond is similar to that of 1.26 Å predicted by this method for the double bond in formaldehyde, and the longer bond is about that expected for a single CO linkage. The difference between the lengths of the two bonds is much less in the equivalent nitrogen radical **10**, although the unpaired spin density is 90% localized on the nitrogen Z whose bond is longer.[3] The free radical **9** has only one heteroatom, and thus the unpaired electron is localized at Z and a very unsymmetrical structure (compared to that for the Π state) results, see Table 1.



7 **9** **10**

For the formamido radical **8** the STO-3G calculations predict only a single potential minimum for the Σ state, with the unpaired σ electron and the π lone pair localized almost completely on the oxygen, i.e. a "Σ_O" structure:

8 "Σ_O" **8** "Σ_N"

In contrast, STO-3G calculations without CI included predict the existence of minima both for Σ_O, and for Σ_N structure in which the unpaired σ electron and π lone pair are localized on the nitrogen (6). To investigate further this discrepancy between the predictions, the geometry of the Σ_N form was optimized by 4-31G + CI calculations; a minimum of this type was again found, as illustrated in the results shown below.

The 4-31G + CI energy for this Σ_N minimum (−168.0318 au), however, is less stable than that predicted for the Σ_O form (even without any reoptimization of the latter), in agreement with the non-CI calculations reported previously. The difficulties in the calculations are that, to obtain a realistic prediction, the MO method which is used must be able to differentiate accurately (*a*) the relative energies of the two types of double bonds compared to the single bonds, and (*b*) the energy of addition of an electron to a singly-occupied p_π orbital of nitrogen compared to that for an s–p hybrid AO. Calculations for the NH_2 free radical (6) show that the STO-3G basis favours too strongly an s–p hybrid for the lone pair over a purely p orbital, whereas the 4-31G basis is better balanced. (Compared to the experimental advantage of ~31 kcal in favour of the Π state (1) the STO-3G splitting is

[1]For a few cases, optimized geometries for the Π state are available from our previous work, but with CI included only among different distributions of the π electrons (5); as indicated in Table 1, these have been used directly, as re-optimization with inclusion of the excitation of σ electron pairs should have little effect.

[2]Calculations with the 4-31G + CI method were not done for all the radicals, for reasons discussed in the text and because of memory limitations of our computer.

[3]The optimum bond angle about the nitrogen is a good indicator of the delocalization of unpaired spin density. A CNH angle of about 105° is obtained when the nonbonding atomic orbital on N is doubly-occupied, whereas it is 130° or more when the AO is singly-occupied. Thus the angles of 111° and 125° for **10** indicate a small amount of spin density at X and a much larger quantity at Z.

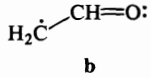
14 kcal too high, whereas that from 4-31G is 4 kcal mol^{-1} too low.) However, both basis sets predict that the π components of C=N and C=O bonds are almost equally strong, whereas from recent thermochemical data it is known that the carbonyl is substantially stronger. In particular, for the reaction

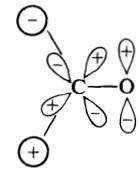


$$H_3C—NH^{\cdot} + H_2C=O \rightarrow H_2C=NH + H_3C—O^{\cdot}$$

the experimental enthalpy[4] is $+11 \pm 3$ kcal mol^{-1} whereas ΔE predicted for it with (without) CI in calculations using the STO-3G and 4-31G bases is $+0.7(-2.9)$ and $-1.9(-3.0)$ kcal mol^{-1} respectively.[5] Thus the calculations will favour too greatly the Σ_O structure for formamido over the Σ_N. (Indeed it is possible that with a properly-balanced basis set the Σ_O and Σ_N minima could be essentially degenerate). Semiempirical calculations could suffer from the same difficulties if they are not properly balanced.

A similar problem involving bond energies exists in the calculation of the geometry and resonance stabilization energy for the Π state of radical **9** (5). With the STO-3G + CI method, the calculated CC and CO bond lengths each are about midway between those expected for double and single bonds, due to significant resonance between the extreme forms **a** and **b**:

a



b

The resonance stabilization for the intermediate structure occurs because the calculations predict near-equal strengths for the π components of C=O and C=C bonds, i.e. that $\Delta E \sim 0$ for the reaction

$$H_3C—CH_2^{\cdot} + H_2C=O \rightarrow H_2C=CH_2 + H_3C—O^{\cdot}$$

A similar result is obtained at the 4-31G + CI level. In reality, the enthalpy for the reaction above is $+15.5$ kcal mol^{-1}, i.e. the π component of a C=O bond is much stronger than that of a C=C bond (5). Experimentation with various basis sets shows that the ingredients which are essential to predict this dominance are a double-ζ representation of the $2s$ orbital of oxygen, and a $3d_{yz}$ orbital on the carbonyl carbon atom. The function of the latter AO is to stabilize the nonbonding $2p_y$ lone pair of oxygen by the participation of bonding through to the hydrogens:

With CI, a double-ζ basis for $2s$ orbitals on oxygen, and a $3d_{yz}$ orbital on all carbon and oxygen atoms, the ΔE for the reaction above is calculated[6] to be $+9$ kcal mol^{-1}. (Presumably, further improvements in the basis set will further improve the agreement.)

Given the uncertainties in the structures and location of the unpaired electrons and lone pairs in radicals with nonidentical terminal groups, the energy gaps calculated for **8** and for **9** must be regarded as very tentative. Since comparable difficulties do not exist for $HCO_2^{\cdot}$, the prediction that its Σ and Π states lie very close energetically is probably realistic. (The unpaired and lone pair electrons are restricted to oxygen in both the symmetric and the alternating forms.) Semiempirical INDO calculations by Koenig *et al.* also predict a Π ground state for this species, although the geometry searches for the Σ states assumed equality in the CO distances (8).

Kikuchi has reported STO-3G calculations without CI for $HCO_2^{\cdot}$; the OCO angle was optimized but assumed values for the bond lengths were used (9). Both the Σ and Π states were found to prefer the unsymmetrical geometry, and the Σ state was predicted to be the more stable by a margin of 7 kcal mol^{-1}. As we have discussed elsewhere (5), the prediction for the Π state geometry is unreliable if CI is neglected, due to the doublet instability problem. Unrestricted SCF calculations do yield a symmetrical Π state (9).

For **10**, the preference of 37 kcal mol^{-1} in favour of the Π state over the Σ state is slightly lower than that computed for $NH_2^{\cdot}$; both are too high probably by about the same amount (~ 14 kcal mol^{-1}) due to the too-strong bias of the STO-3G basis in favour of s–p hybrids rather than p AO's for lone pairs on nitrogen.

Radicals **1** through **6** of Table 1 have nitrogen atoms as the central group. Thus for the Σ states there is the possibility that the unpaired electron is located mainly at the centre of the radical rather than at the terminal position(s). In such cases, a symmetrical structure is expected since the potential field experienced by the π electrons at X and Z

[4]Calculated from ΔH_f's of $+26.4 \pm 3.2$ kcal mol^{-1} for H_2C=NH (*7a*), +45 for H_3C—NH (*7b*), −26.0 for H_2CO (*7c*), and +3.5 for CH_3O (*7c*).

[5]Calculated using optimum STO-3G, non-CI geometries in all cases.

[6]In particular, the energies for C_2H_4, C_2H_5, CH_2O, and CH_3O are −77.1238, −77.6641, −112.4793, and −113.0052 au when the $3d$ exponents are 2.0, the oxygen $2s$ exponents are 1.66 and 2.67, and the geometries used are optimum STO-3G structures.

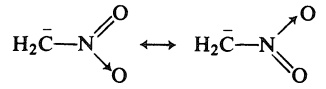
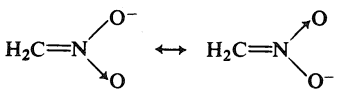
is comparable. This condition is met in radicals **1** (nitrogen dioxide), **4**, and **5**, and indeed the Σ state of each radical in this set is predicted to have equal XY and YZ bond lengths. In **1** and **4**, significant unpaired spin density is delocalized onto the terminal groups, with the result that the angles about the central nitrogen are smaller for them than for NH_2· and for **5**. The Σ state of NO_2 corresponds to the $^2A_1$ ground state, for which the NO length is known to be 1.19 Å and the ONO angle 134° (11). Recalculation of the structure with the 4-31G + CI basis gives 1.20 Å and 134° respectively, in much better agreement with the experimental result than is the minimal basis set result. The energy gap for NO_2 between the ground Σ state and the Π state (i.e. $^2A_2$) with the 4-31G + CI geometry is 28 kcal mol^{-1}, in fair agreement with that of 42 ± 7 kcal mol^{-1} determined in a definitive multi-configuration SCF calculation by Gillespie *et al.* (10). The minimal basis set value for the energy gap is some 18 kcal mol^{-1} lower, due again to the overestimated bias in favour of *s–p* hybrids of nitrogen. Similarly the minimal basis set predicts a Π ground state for HNNNH, but this is reversed to Σ at the 4-31G level (see Table 1). Based upon the experience with nitrogen dioxide, the latter result is the more reliable and the Σ state probably would be favoured even further by optimization of geometry with an extended basis set. Experimentally, for the dimethyl derivative of **4**, i.e. CH_3—NNN—CH_3, the esr spectrum indicates that most of the spin density is located on equivalent terminal groups, and from this it is concluded that it is a Π state which is detected (11). (An INDO calculation reported by the same authors predicts the Σ state to be more than the Π state by 5 kcal mol^{-1}.) The esr spectrum of the derivative of the trinitrogen chain which has alkyl and —SiR_3 groups indicates that both substituents probably are on the same nitrogen (12), i.e. that it is a derivative of **6** (see Table 1). Our calculations for the Σ state of H_2NNN predict that it is more stable than is **4**, and has an alternating structure of the $H_2\ddot{N}$—N=N· type.

For HNNO (**2**) and to a lesser extent for H_2CNO (**3**), the unpaired electron of the Σ state is predicted in STO-3G + CI calculations to be almost completely localized on the terminal oxygen atom, corresponding to the structures HN=N—Ö· and H_2C=N—Ö· respectively (see Table 1). Because in the Π states the unpaired electron is also present mainly on the oxygen atom and there is also a double bond from nitrogen to the other terminal atom, the calculated energy gap between the states is quite small. In both **2** and **3** it is the Σ state which is predicted to be the lower. Unfortunately the lack of reliable thermochemistry concerning the strengths of the π components of N=N and N=O bonds prevents us from determining any bias in the calculations in favour of O-centered radicals from that source. Experimentally, the esr spectra of iminoxyl radicals R_2CNO (where R is an alkyl or aryl group) have been interpreted in terms of a Σ_O structure (13) and similarly for the radicals Ar—N=N—O (14).



Conclusions

According to past experience, the geometry predicted by *ab initio* MO theory for a molecule usually agrees very well with its experimental structure. Our calculations for free radicals indicate that this generalization does not necessarily hold whenever two or more resonance structures with comparable energies, but with inequivalent assignments of π bonds and lone pairs, can be drawn; e.g.



$$:X{=}Y{-}\ddot{Z}\cdot \leftrightarrow \cdot\ddot{X}{-}Y{=}Z:$$

To give an accurate prediction in such cases, the MO method must be able to distinguish accurately the π bond energies of X=Y and Y=Z linkages as well as the energies of the π and the in-plane nonbonding orbitals of the three atoms involved. Even when the differential error is small (~0.01 au compared to the total bonding energy (~1 au)), an incorrect structure could be predicted.

We believe that similar difficulties arise in calculations for closed-shell species as well as for radicals. Thus, using a minimal basis set, the optimum structure predicted for the nitromethyl anion is that of a carbanion with an NO double bond (15):

At the 4-31G level, however, the optimum structure has a CN double bond (16) with the negative charge of the π system located presumably at the oxygens:

In order to judge which is the more realistic prediction, it is necessary to know the relative abilities of the two basis sets in handling the (unknown) balance between the π bond energies of C=N and N=O bonds and the relative energies of a lone pair of π electrons on carbon and oxygen.

The $Fe_{1-x}S$–PbS–ZnS phase system

J. E. DUTRIZAC

Metallurgical Chemistry Section, Mineral Sciences Laboratories, CANMET, Department of Energy, Mines and Resources, Ottawa, Ont., Canada K1A 0G1

Received November 23, 1979

J. E. DUTRIZAC. Can. J. Chem. **58**, 739 (1980).

High temperature phase relationships have been determined for the binary systems FeS–PbS, $Fe_{0.92}S$–PbS, $Fe_{0.92}S$–ZnS, and PbS–ZnS, and for the ternary system $Fe_{0.92}S$–PbS–ZnS. All the systems were of the eutectic-type with eutectic points being noted at 53 mol% FeS – 47 mol% PbS and 850°C, 53 mol% $Fe_{0.92}S$ – 47 mol% PbS and 852°C, 90 mol% $Fe_{0.92}S$ – 10 mol% ZnS and 1178°C, 87 mol% PbS – 13 mol% ZnS and 1050°C, and at 46 mol% $Fe_{0.92}S$ – 41 mol% PbS – 13 mol% ZnS and 850°C, respectively. Solid solubilities were less than 1 mol% except for an appreciable solubility of $Fe_{1-x}S$ in ZnS.

J. E. DUTRIZAC. Can. J. Chem. **58**, 739 (1980).

On a déterminé les relations de phase à haute température des systèmes binaires suivants: FeS–PbS, $Fe_{0.92}S$–PbS, $Fe_{0.92}S$–ZnS et PbS–ZnS et du système ternaire $Fe_{0.92}S$–PbS–ZnS. Tous ces systèmes forment des eutectiques. On a déterminé les points eutectiques des systèmes ayant respectivement les compositions molaires suivantes: FeS–PbS 53–47%: 850°C; $Fe_{0.92}S$–PbS 53–47%: 852°C; $Fe_{0.92}S$–ZnS 90–10%; 1178°C; Pbs–ZnS 87–13%: 1050°C et $Fe_{0.92}S$–PbS–ZnS 46–13%: 850°C. Les solubilités des solides sont inférieures à 1 mol% à l'exception de la solubilité non négligeable de $Fe_{1-x}S$ dans ZnS.

[Traduit par le journal]

Introduction

The $Fe_{1-x}S$–PbS–ZnS phase system is of concern to pyrometallurgists treating either iron and zinc-rich lead concentrates or pyritic zinc–lead sulphide ores and concentrates of the type found, for example, in northeastern New Brunswick. Regardless of whether the iron sulphide mineral present in the ore is pyrrhotite (FeS–Fe_7S_8) or pyrite (FeS_2), an iron sulphide of approximate composition FeS will be formed on heating. Pyrite decomposes to pyrrhotite and sulphur vapour (1 atm) at about 740°C (1, 2) and the pyrrhotite itself evolves sulphur, approaching the stoichiometric compound at elevated temperatures. Although $Fe_{1.00}S$ melts incongruently, the composition $Fe_{0.92}S$ was found to melt congruently at about 1190°C (3).

The $Fe_{1-x}S$–ZnS binary has been investigated several times, but the melting relationships are still not fully resolved. Friedrich (4) observed a eutectic-type system with a eutectic at 5.5 mol% ZnS and 1170–1180°C; his experiments were carried out in open cells. The eutectic behaviour was confirmed by Kullerud (5), who reported a eutectic at 6 mol% ZnS and 1170°C, by Avetisyan and Gnatyshenko (6), who found the eutectic at 6 mol% ZnS and 1180°C and by Kerby (7), who noted the point at 6 mol% ZnS and 1135°C. All workers are in accord concerning the high solubility of FeS in ZnS and that the liquidus temperature rises sharply on the ZnS side of the eutectic.

The $Fe_{1-x}S$–PbS system was first investigated by Wiedmann (8), who reported a simple eutectic at 48 mol% FeS and 782°C. Later, Friedrich (9) using the same open cell technique observed the eutectic at 51 mol% FeS and 863°C. Kopylov (10) reported a eutectic at 52 mol% FeS and 860°C and Kerby (7) observed the point at 52 mol% FeS and 835°C.

The PbS–ZnS binary was studied by Friedrich (4) using open cells; he observed simple eutectic behaviour with the eutectic at 13 mol% ZnS and 1045°C. Kerby (7) remeasured this system with sealed cells and reported a eutectic at 22 mol% ZnS and 988°C.

The FeS–PbS–ZnS ternary has been studied only by Avetisyan and Gnatyshenko (6), who used open cells under a nitrogen atmosphere. They observed a single ternary eutectic at 49.8 mol% FeS, 37.5 mol% PbS, and 12.7 mol% ZnS and 820°C. The liquidus surface rose abruptly in the direction of ZnS once the eutectic valley had been passed.

Because of the importance of this system in pyrometallurgy, it was decided to re-evaluate the $Fe_{1-x}S$–PbS–ZnS phase diagram using sealed-cell DTA techniques. This was effected by measuring the bounding binaries and by determining several "cuts" across the ternary itself. The results were checked by quenching-petrographic methods and by X-ray diffraction and electron microprobe techniques.

Experimental

Lead sulphide (PbS) was obtained from Atomergic Chemetals Ltd. and was 99.999% pure with respect to metallic impurities; unlike some "pure" PbS materials examined, this was also low in sulphate, hydroxide, etc. Zinc sulphide (ZnS) was purchased from Electronic Space Products and was 99.9995% pure with respect to metallic impurities; it was received in the wurtzite

ZnS (theoretical)	—	—	67.09	32.90	

modification which was converted to the sphalerite structure by heating in a vacuum sealed ampoule to 900°C for a few hours. The iron sulphides FeS and $Fe_{0.92}S$ were synthesized using established procedures (11). The various starting materials were analyzed chemically and by Guinier X-ray diffraction analysis, and the results are presented in Table 1. The X-ray data show the general absence of oxide lead compounds and the predominately sphalerite form of the ZnS. When the wurtzite modification was used, data interpretation was greatly complicated because in some experiments the wurtzite would, on heating, convert to sphalerite which would revert to wurtzite on further heating (>900°C) before the liquidus was reached. In other runs the wurtzite would "melt" before any wurtzite ⇄ sphalerite reactions occurred.

The sulphides were mixed in suitable proportions and were vacuum sealed in 4 mm id silica glass DTA tubes; the sulphides did not attack the silica glass although they seemed to promote devitrification at the highest temperatures employed. For the purpose of calculating mole percentages, the formula of the congruently melting iron sulphide was expressed as $Fe_{0.92}S$. The samples were run on a Stone DTA System equipped with a palladium holder and Pt–Pt:10%Rh thermocouples. The sulphides were heated against a calcined alumina reference, and the system was calibrated against the melting point of gold (1063°C). Programming rates of 5, 10, or 15°C/min were used depending on the system response, and data were recorded on both heating and cooling. Selected samples were analyzed microscopically and by X-ray diffraction analysis after they had been heated and cooled.

To estimate solid solubilities, suitable compositions were melted in vacuum-sealed silica glass ampoules (8 mm id) and then annealed for 2 to 3 days at a temperature just below the appropriate eutectic. Longer annealing times did not yield significantly different results and it was assumed that equilibrium was fairly quickly attained in the fine eutectic structures produced. The samples were then quenched in water and examined microscopically and by electron microprobe analysis to estimate the maximum extent of solid solubility.

Results and Discussion

(a) $Fe_{1-x}S$–PbS

The phase diagram for the FeS–PbS binary system is presented in Fig. 1 and the corresponding diagram for the $Fe_{0.92}S$–PbS system is given in Fig. 2. PbS melted at 1115°C in agreement with the reported value. FeS and $Fe_{0.92}S$ fused at 1165°C and 1190°C, respectively, and both these values are in accord with the published data (3). Aside from the different melting points for the iron sulphides,

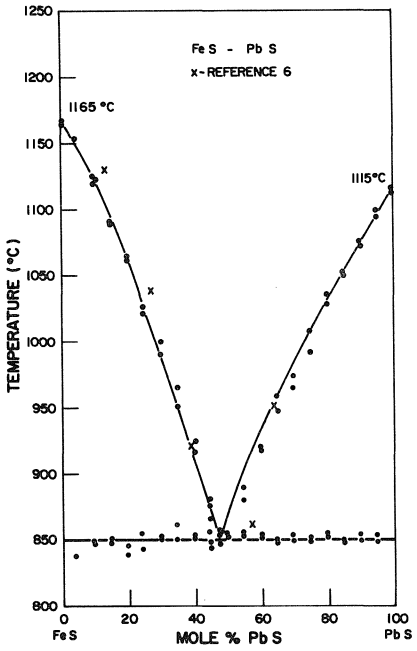

FIG. 1. High temperature portion of the FeS–PbS phase diagram; eutectic temperature is 850°C.

the two systems are very similar. Both are of the simple eutectic type with the eutectic composition being at 53 mol% $Fe_{1-x}S$ and 47 mol% PbS; the eutectic temperature was 850°C for FeS–PbS and 852°C for $Fe_{0.92}S$–PbS. The eutectic composition is in essential agreement with earlier work (7, 9, 10). The eutectic temperature is supported by the studies of Friedrich (9), 863°C, and Kopylov (10), 860°C, but is substantially higher than Kerby's value of 835°C; examination of his PbS suggested oxide contamination which may have caused his lower melting temperatures. The ×'s marked on the FeS–PbS binary are liquidus temperatures taken from the ternary data of Avetisyan and Gnatyshenko (6), and the agreement is acceptable.

The only phases identified by X-ray diffraction analysis of cooled samples were PbS (galena) and

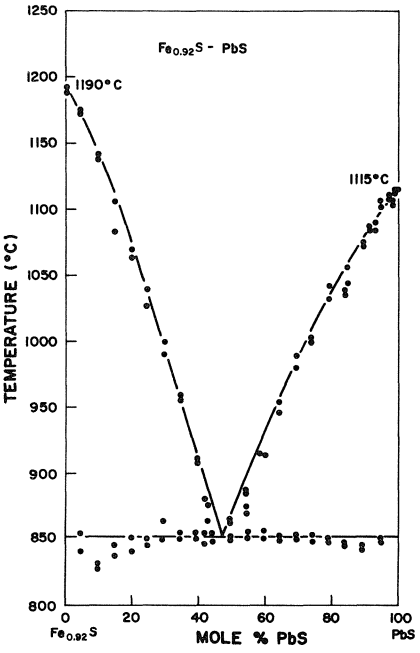

FIG. 2. High temperature portion of the $Fe_{0.92}S$–PbS phase diagram; eutectic temperature is 852°C.

iron sulphides of the type $Fe_{1-x}S$. Electron microprobe examination of various samples annealed at 840°C for 2–3 days and then quenched indicated less than 0.5 wt% Fe in the primary PbS and less than 0.5 wt% Pb in the primary $Fe_{1-x}S$. Microscopic examination likewise confirmed that solid solubilities were considerably less than 1 wt% in these binary systems.

(b) $Fe_{0.92}S$–ZnS

The determined phase diagram for the $Fe_{0.92}S$–ZnS binary system is presented in Fig. 3; because of the steep liquidus on the ZnS side of the eutectic, liquidus points were not usually detected by the DTA apparatus. The liquidus falls from the 1190°C melting point of $Fe_{0.92}S$ to the eutectic which occurs at 90 mol% $Fe_{0.92}S$ – 10 mol% ZnS and 1178°C, and then rises sharply. The eutectic temperature observed in this study is consistent with previous work (4–6) except that of Kerby (7), which appears low at 1135°C. The eutectic composition observed in the present study is slightly richer in zinc than was previously observed.

The only phases detected in this system were $Fe_{1-x}S$ and iron-rich sphalerite. Samples annealed at 1165°C for 2–3 days and quenched indicated that the iron sulphide contained less than 0.5 wt% Zn. Since very fine ZnS inclusions could be seen in the $Fe_{1-x}S$ phase, the amount of zinc actually in solution in $Fe_{1-x}S$ might be lower than this amount.

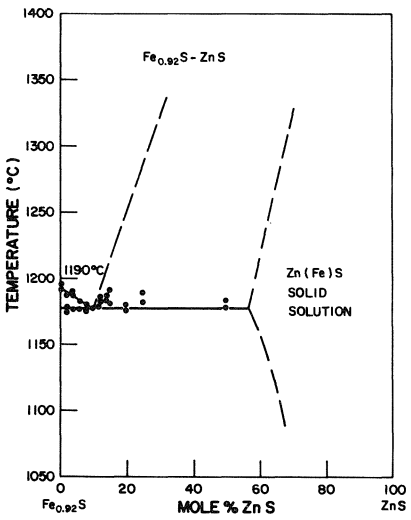

FIG. 3. The $Fe_{0.92}S$–ZnS phase diagram showing the approximate range of $Fe_{1-x}S$ solubility in ZnS; eutectic temperature is 1178°C.

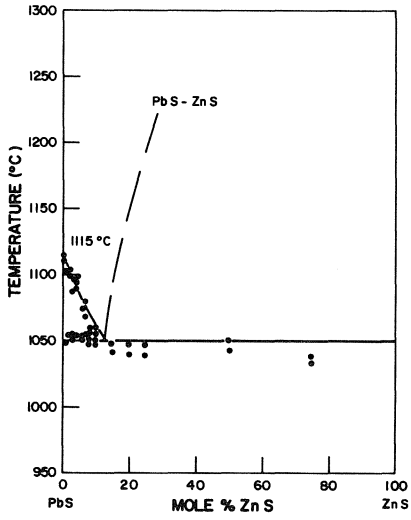

FIG. 4. The PbS–ZnS phase diagram; the eutectic temperature is 1050°C.

Barton and Toulmin (12) found the maximum Zn content of $Fe_{1-x}S$ to be less than 0.24 atom%. The ZnS phase dissolves considerable amounts of iron sulphide at 1165°C. Electron microprobe examination of the quenched samples indicated 26–27 wt% Fe and this corresponds to about 43 mol% FeS in the ZnS. The solubility of FeS in ZnS is somewhat variable because the sulphur fugacity of the system is not buffered. Kullerud (5) reported 45 mol% FeS solubility at 1190°C; Barton and Toulmin (12) observed a molar FeS solubility of 56% at 850°C and 52% at 580°C for (Zn,Fe)S in equilibrium with FeS and metallic iron; lower solubilities were noted

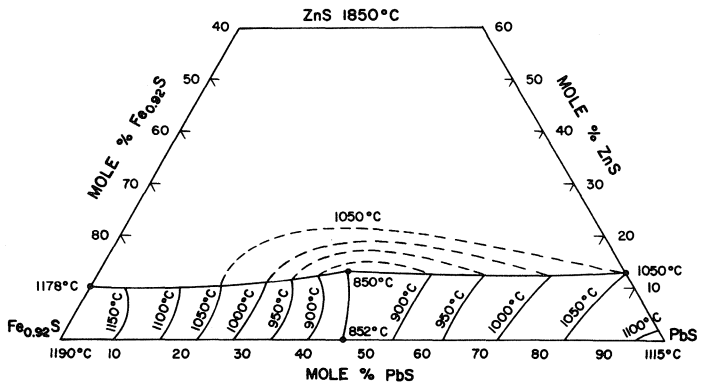

FIG. 5. The $Fe_{0.92}S$–PbS–ZnS ternary phase diagram.

when $Fe_{1-x}S$ was used. Neuhaus and Cemic (13) reported a value of 51 mol% FeS at 900°C and 5 kbars pressure.

(c) PbS–ZnS

Figure 4 illustrates the liquidus relationships in the PbS–ZnS binary system. The eutectic was observed at about 13 mol% ZnS and 1050°C, in general agreement with Friedrich (4) who reported a eutectic at 13 mol% ZnS and 1045°C. Neither study agrees with the recent work of Kerby (7), but it is felt that his purchased lead sulphide was badly oxidized. The slight curvature in the liquidus on the PbS side of the system was also noted by Friedrich (4). Microscopic examination of solidified melts in the vicinity of the eutectic composition indicated that the eutectic contained more than 12 mol% ZnS but less than 15 mol% of this component.

Electron microprobe study of samples annealed just below the eutectic temperature and then quenched suggested that solid solubilities were less than 0.5 mol% at either end of the phase diagram; the zinc sulphide contained 0.4 wt% Pb and the lead sulphide assayed 0.2 wt% Zn.

(d) $Fe_{0.92}S$–PbS–ZnS

Liquidus relationships in the $Fe_{0.92}S$–PbS–ZnS ternary were elucidated by measuring seven pseudobinary cuts across the system. In the interest of brevity, the seven pseudobinaries are not presented but are available from the author on demand. The various binary and pseudobinary systems were then used to construct the ternary phase diagram shown in Fig. 5. The ternary is of the simple eutectic type with the ternary eutectic point at 46 mol% $Fe_{0.92}S$ – 41 mol% PbS – 13 mol% ZnS and 850°C. The ternary eutectic composition is similar to that of Avetisyan and Gnatyshenko (6), 49.8 mol% FeS – 37.5 mol% PbS – 12.7 mol% ZnS, although those authors noted the ternary eutectic temperature at 820°C. The liquidus surfaces fall

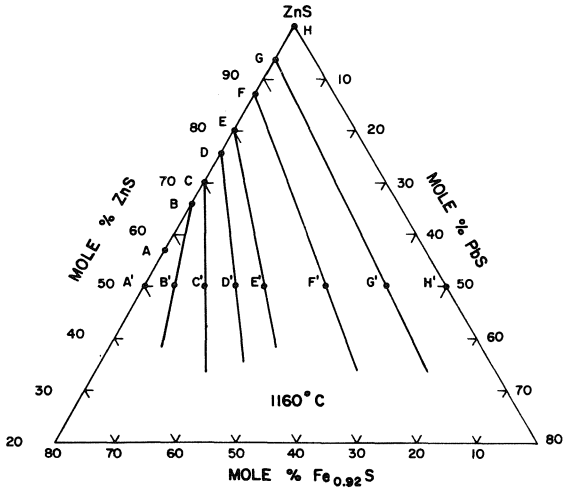

FIG. 6. The solubility of $Fe_{1-x}S$ in solid ZnS as a function of total composition in the $Fe_{0.92}S$–PbS–ZnS ternary system.

rather gradually from either $Fe_{0.92}S$ or PbS, but rise steeply on the ZnS-rich side of the figure. The steep ZnS liquidus combined with the location of the ternary eutectic close to the $Fe_{0.92}S$–PbS binary causes ZnS to be a difficult impurity in the processing of iron and/or lead mattes.

(e) Ternary Solid Solutions

Study of the bounding binary systems revealed that solid solubilities were low except for $Fe_{1-x}S$ in ZnS. To test for solid solubilities in the ternary system, nine ternary compositions were prepared and heated to 1200°C in vacuum sealed tubes for 2 to 4 h. The tubes were then cooled to 1040°C and held at that temperature for 2 to 3 days. After water quenching, the samples were examined microscopically and by the electron microprobe to evaluate the extent of solid solubility. Solubilities in $Fe_{0.92}S$ and PbS were always less than 1%, in agreement with the binary data. Extensive $Fe_{1-x}S$ solubility in ZnS as well as the possibility of trace PbS solid solubility was indicated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

A series of compositions consisting of 50 mol% ZnS and various amounts of $Fe_{0.92}S$ and PbS were prepared and annealed at 1160°C; i.e., just below the $Fe_{1-x}S$–ZnS binary eutectic temperature. These compositions are indicated (A′–H′) on Fig. 6, and the corresponding compositions of the solid zinc sulphide phases are given by A–H, respectively. The solubility of lead in the ZnS phase was always less than 1 wt%; at 1160°C and 5 mol% PbS in the charge, the ZnS phase assayed 0.25 wt% Pb; the corresponding value for a charge containing 40 mol% PbS was 0.76 wt% Pb. The iron concentration of the ZnS phase depends strongly on the activity of FeS in the associated melt. This value was 6 mol% FeS in ZnS when the charge contained 10 mol% FeS, and 43 mol% FeS along the $Fe_{0.92}S$–ZnS binary (Fig. 6).

Conclusions

High temperature phase relationships have been determined for the binary systems FeS–PbS, $Fe_{0.92}S$–PbS, $Fe_{0.92}S$–ZnS, and PbS–ZnS, and for the ternary system $Fe_{0.92}S$–PbS–ZnS. All the systems were of the eutectic-type with eutectic points being noted at 53 mol% FeS – 47 mol% PbS and 850°C, 53 mol% $Fe_{0.92}S$ – 47 mol% PbS and 852°C, 90 mol% $Fe_{0.92}S$ – 10 mol% ZnS and 1178°C, 87 mol% PbS – 13 mol% ZnS and 1050°C, and at 46 mol% $Fe_{0.92}S$ – 41 mol% PbS – 13 mol% ZnS and 850°C, respectively. Solid solubilities were less than 1 mol% except near the $Fe_{1-x}S$–ZnS binary where an appreciable solubility of $Fe_{1-x}S$ in ZnS was observed.

The preparation of polymeric siloxyphosphine rhodium(I) complexes

ZOFIA C. BRZEZIŃSKA AND WILLIAM R. CULLEN

Chemistry Department, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received May 10, 1979

ZOFIA C. BRZEZIŃSKA and WILLIAM R. CULLEN. Can. J. Chem. **58**, 744 (1980).

Hydrolysis in dioxane/water (4:1 by volume) of performed rhodium(I) complexes of the phosphines $Cl_3Si(CH_2)_nP(C_6H_5)_2$ (n = 2, 8) either alone or in the presence of excess ligand or Cl_3SiCH_3 affords insoluble polymeric globules. Typical products have idealized formulae $\{[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{200}\}_x$, $\{[O_{3/2}Si(CH_2)_8P(C_6H_5)_2]_4Rh_2Cl_2\}_x$, and $\{[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl\}_x$ and seem to contain only rhodium(I). Apart from the last example the polymers in toluene suspension react with H_2 and CO at 60°C. In the case of CO the uptake ranges from 0.27–1.30 mol of CO per atom of rhodium. The main products appear to be Rh(CO)Cl derivatives.

ZOFIA C. BRZEZIŃSKA et WILLIAM R. CULLEN. Can. J. Chem. **58**, 744 (1980).

Les complexes préformés de rhodium(I) et de phosphines $Cl_3Si(CH_2)_nP(C_6H_5)_2$ (n = 2, 8) seuls ou en présence d'un excès de ligand ou de Cl_3SiCH_3 fournissent par hydrolyse dans un mélange de dioxanne/eau (4:1) des globules de polymères insolubles. Les produits typiques ont la formule théorique suivante $\{[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{200}\}_x$, $\{[O_{3/2}Si(CH_2)_8P(C_6H_5)_2]_4Rh_2Cl_2\}_x$, et $\{[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl\}_x$ et semblent contenir seulement du rhodium(I). A l'exception du dernier exemple, les polymères en suspension dans le toluène réagissent avec H_2 et CO a 60°C. Dans le cas du CO, la fixation se situe entre 0.27 et 1.30 mol de CO par atome de rhodium. Les produits principaux semblent être des dérivés du Rh(CO)Cl.

Introduction

Most supported catalysts of the class known as heterogenized homogeneous catalysts use polystyrene or inorganic materials such as silica or glass as the support (1, 2). We are interested in preparing hydrogenation catalysts which have silicone backbones because of the possibility of easy chemical modification of the supporting material and in the hope that such catalysts might have significantly different properties from those based on other systems.

Our chosen method of synthesis, as outlined in reactions [1]–[3], depends on the hydrolysis of the preformed complexes **2**, **3**, and **4** either alone or in the presence of excess ligand, or excess CH_3SiCl_3.[1]

[1] $[Cl_3Si(CH_2)_nP(C_6H_5)_2]_3RhCl + mCH_3SiCl_3 \xrightarrow{H_2O} [O_{3/2}Si(CH_2)_nP(C_6H_5)_2]_3RhCl\cdot(O_{3/2}Si(CH)_3)_m$

2, 3 → **B**(n,m)

n = 2(**2**), 8(**3**); m = 0–200

[2] $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2 + mCH_3SiCl_3 \rightarrow [O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2\cdot(O_{3/2}Si(CH_3)_3)_m$

4 → **C**(2,m)

m = 0–200

[3] $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl + mCl_3Si(CH_2)_2P(C_6H_5)_2 \xrightarrow{H_2O} [O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}Si(CH_2)_2P(C_6H_5)_2)_m$

2 → **D**

m = 0.7

This method is formally analogous to the synthesis of more conventional organometallic macromolecular complexes by polymerization and copolymerization of vinylic moieties on a ligand attached to a metal centre (3, 4); for example, vinylcyclopentadienyl manganese tricarbonyl can be homopolymerized or copolymerized with styrene. This method of synthesizing polymer-supported metal centres has not been explored to its full potential.

The synthesis of the polymer precursors **2**, **3**, and **4** and the carbonyl monomer $[Cl_3Si(CH_2)_2P(C_6H_5)_2]$-Rh(CO)Cl, **1**, has been described elsewhere (5). We have also discussed (5) the model complexes L_3RhCl, $L_4Rh_2Cl_2$, and $L_2Rh(CO)Cl$ where L = $[(CH_3)_3SiO]_2(CH_3)Si(CH_2)_2P(C_6H_5)_2$ which were

[1]In the symbol (n,m) n is the number of CH_2 groups (either 2 or 8) between the phosphorus and silicon atoms in the original ligand and m is the number of moles of CH_3SiCl_3 co-polymerized with 1 mol of the ligand. In a homopolymer m is 0.

especially prepared so that they would have similar properties to the anticipated macromolecules **A**–**D**,[1] yet would be soluble and hence allow facile study.

Experimental Section

The monomers $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$, $[Cl_3Si(CH_2)_nP(C_6H_5)_2]_3RhCl$ (n = 2, 8), and $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2$ were prepared as previously described (5). All manipulations of air and moisture sensitive compounds were carried out in Schlenk apparatus under nitrogen.

A constant pressure and temperature apparatus was used for measurements of gas uptake.

Electron micrographs were obtained using an ETEC Autoscan microscope with ORTEC Multichannel X-ray analyzer model 6200. Samples were placed on an aluminum specimen stub coated with a dispersion of graphite in isopropyl alcohol. The stub was placed in a vacuum carbon evaporator where the surface was coated with a thin layer of graphite. Infrared spectra were recorded on Perkin-Elmer model 457 and 225 spectrophotometers.

Polymerization of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$

(*A*) A benzene solution (ca. 3.5 mL) of 5.93 g (6.89 mmol) of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$ prepared *in situ* was introduced dropwise into 5 mL of a vigorously stirred mixture of dioxane and water (4:1 v/v). The suspension of the resultant pale yellow precipitate was stirred for 2 h. A solution of 4 g of $NaHCO_3$ in ca. 50 mL of water was added to the suspension. The product was filtered off, washed with water, 10% aqueous $NaHCO_3$, water, dioxane, and benzene, and dried *in vacuo* for 24 h.

The solid product was extracted with refluxing dichloromethane in a Soxhlet extractor for 24 h. The insoluble polymer **A** was dried *in vacuo* for 24 h (3.92 g, 81.7% yield), dec. 255-265°C. *Anal.* calcd. for $C_{29}H_{28}ClO_4P_2RhSi_2$: C 50.0, H 4.3, Cl 5.1, Rh 14.8, P 8.9; found: C 50.0, H 3.8, Cl 12.3, Rh 14.8, P 9.1, ir(Nujol): ν(C≡O) 1965(s) cm^{-1}.

(*B*) A benzene solution (ca. 1.5 mL) of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$ (0.086 g, 0.1 mmol) prepared *in situ* was added dropwise into 1 mL of an aqueous solution of 0.1 g KOH. A pale yellow precipitate formed immediately. It was filtered off, washed with water, benzene, and then dried *in vacuo* for 24 h; ir(Nujol): ν(C≡O) 1965(s) cm^{-1}.

(*C*) Triethylamine (0.1 g, 1.0 mmol) was added to $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$ (0.086 g, 0.1 mmol) which had been prepared *in situ* in 1.5 mL of benzene. The mixture was added dropwise to ca. 2 mL of water. A pale yellow precipitate formed immediately. It was filtered off, washed with water, benzene, and then dried *in vacuo* for 24 h; ir(Nujol): ν(C≡O) 1965(s) cm^{-1}.

Homopolymerization of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl$ *in Dioxane/Water Mixture*

A benzene solution (1.5 mL) of 0.402 g (34.1 mmol) of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl$ prepared *in situ* was introduced dropwise into 4 mL of a vigorously stirred mixture of dioxane and water (3:1 v/v). The suspension of the resulting pale yellow precipitate was stirred for an additional 2 h. The precipitate changed colour to orange upon addition of ca. 8 mL of an aqueous solution of 0.5 g of $NaHCO_3$. The product was filtered off, washed with water, 10% aqueous $NaHCO_3$, water, dioxane, and benzene, and then dried *in vacuo* for 24 h.

Copolymerization of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl$ *with* Cl_3SiCH_3 *in Dioxane/Water Mixture*

Methyltrichlorosilane (4.030 g, 27.0 mmol) was added to 1.5 mL of a benzene solution of $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl$ (0.318 g, 0.27 mmol) prepared *in situ*. The mixture was polymerized by a procedure analogous to the homopolymerization described above (11.5 mL dioxane/water in 4:1 v/v ratio).

Analytical and Spectroscopic Data for Polymers and Copolymers of Different Rh(I) Phosphine Complexes

All the polymeric complexes used for any further reactions were prepared by hydrolysis with dioxane/water (4:1) as described above and were Soxhlet extracted with CH_2Cl_2 for 24 h and dried under vacuum for 24 h. All the homopolymers proved to be pyrophoric upon exposure to air.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl$, **B**(2,0): 85.3% yield, dec. 220–230°C. *Anal.* calcd. for $C_{42}H_{42}ClO_{9/2}P_3RhSi_3$: C 54.0, H 4.5, Cl 3.8, P 10.0, Rh 11.0, Si 9.0; found: C 50.8, H 4.5, Cl 6.2, P 9.5, Rh 10.5, Si 8.9. Ir(Nujol): ν(Rh—Cl) 285(w); 255(sh) cm^{-1}.

$[OSi(CH_3)(CH_2)_2P(C_6H_5)_2]_3RhCl$: not analyzed; the product was completely soluble in CH_2Cl_2.

$[O_{3/2}Si(CH_2)_8P(C_6H_5)_2]_3RhCl$, **B**(8,0): 84.1% yield, dec. 185–195°C. *Anal.* calcd. for $C_{60}H_{78}ClO_{9/2}P_3RhSi_3$: C 60.8, H 6.6, Cl 3.0, P 7.7, Rh 8.7, Si 7.1; found: C 59.2, H 6.3, Cl 4.6, P 7.6, Rh 8.4, Si 6.9. Ir(Nujol): ν(Rh—Cl) 285(w); 255(sh) cm^{-1}.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2$, **C**(2,0); 70.2% yield, dec. 220–230°C. *Anal.* calcd. for $C_{56}H_{56}Cl_2O_6P_4Rh_2Si_4$: C 50.3, H 4.2, Cl 5.3, P 9.3, Rh 15.4, Si 8.4; found: C 50.6, H 4.5, Cl 6.6, P 9.0, Rh 15.1, Si 8.3. Ir(Nujol): ν(Rh—Cl) 290(w); 265(sh) cm^{-1}.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{75}$, **B**(2,75): 73.5% yield, dec. 255–265°C. *Anal.* calcd. for $C_{117}H_{269}ClO_{117}P_3RhSi_{78}$: C 23.6, H 4.5, Cl 0.6, P 1.6, Rh 1.7; found: C 23.6, H 5.3, Cl 1.4, P 1.5, Rh 1.7.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{150}$, **B**(2,150): 78.2% yield, dec. 255–265°C. *Anal.* calcd. for $C_{192}H_{492}ClO_{229.5}P_3RhSi_{153}$: C 21.0, H 4.5; found: C 20.2, H 4.5.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{200}$, **B**(2,200): 71.2% yield, dec. 255–265°C. *Anal.* calcd. for $C_{242}H_{642}ClO_{304.5}P_3RhSi_{203}$: C 20.3, H 4.5; found: C 20.2, H 4.3.

$[O_{3/2}Si(CH_2)_8P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_{100}$, **B**(8,100): 86.8% yield, dec. 250–260°C. *Anal.* calcd. for $C_{160}H_{378}ClO_{154.5}P_3RhSi_{103}$: C 24.4, H 4.8; found: C 24.4, H 4.8.

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2\cdot(O_{3/2}SiCH_3)_{200}$, **D**(2,200): 70.2% yield, dec. 270–280°C. *Anal.* calcd. for $C_{256}H_{656}Cl_2O_{306}P_4Rh_2Si_{204}$: C 20.9, H 4.5, Cl 0.5, P 0.8, Rh 1.4, Si 38.8; found: C 21.0, H 4.4, Cl 0.2, P 0.8, Rh 1.5, Si 38.6.

Polymerization of $Cl_3Si(CH_2)_2P(C_6H_5)_2$

The trichlorosilylphosphine, $Cl_3Si(CH_2)_2P(C_6H_5)_2$ (1.740 g, 5.0 mmol), in benzene solution (3 mL) was polymerized by a mixture (2.5 mL) of dioxane and water (4:1 v/v) by the usual procedure, yielding a white solid which was not extracted with CH_2Cl_2. *Anal.* calcd. for $O_{3/2}Si(CH_2)_2P(C_6H_5)_2$: Cl 0.0; and for $O(Cl)Si(CH_2)_2P(C_6H_5)_2$: Cl 12.1; found: Cl 9.2.

Reactions of the Polymers with CO

The homopolymeric complex (1.33×10^{-1} mmol) or the copolymeric complex (5.4×10^{-2} mmol) was suspended in

3 mL of toluene in the reaction flask of the gas uptake apparatus. The carbon monoxide pressure was 760 mm Hg and the temperature 60°C. The total gas uptake was measured for each complex after 3 days. The degree of conversion was calculated by comparison of the observed gas consumption and the expected carbon monoxide uptake value for one molecule of CO for each atom of rhodium. Each complex was filtered, washed with benzene, and dried *in vacuo*.

Reaction of B(2,75) and B(2,0) with H_2

The hydrogen uptake was monitored with **B**(2,0) (0.124 g) or **B**(2,75) (0.269 g) suspended in 3 mL of toluene at 60°C. The pressure was 690 mm. At the end of each reaction the suspensions were filtered and the solid dried in a stream of nitrogen (2 h).

Results and Discussion

Synthesis of the Polymeric Complexes

Since the range of physio-chemical analytical techniques which can be applied to obtain useful information about insoluble solids is very limited, preliminary studies were made on the hydrolysis of **1** $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$ (reaction [4]) because of the presence of the CO group. This can act as a built-in probe since ν(CO) is very sensitive to changes in the environment of the metal

[4] $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$

1

$$\xrightarrow[-HCl]{+H_2O} [O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_2Rh(CO)Cl$$

A

It was found that when a benzene solution of **1** is added to dioxane/water (4:1 by volume) an insoluble solid precipitates in good yield. The solid product was extracted with refluxing dichloromethane (24 h) to give the polymer **A**. The ν(CO) frequency for **A** is 1965 cm^{-1}, which is close to that of **1** (1970 cm^{-1} (5)), indicating that the environment of the metal center is not greatly changed in the process of polymerization.

The microanalytical data for **A** agree well with the idealized formula except for the halogen content, which at 12.3% is more than twice that expected. Since the extra halogen is not on the rhodium (ν(CO) for a Rh(III) carbonyl would be considerably shifted (6)) it is possibly the result of incomplete hydrolysis. Polymerization of the ligand $Cl_3Si(CH_2)_2P(C_6H_5)_2$ alone under the same conditions yields a product which also has a high chlorine content (9.2%).

Although base hydrolysis (KOH or $(C_2H_5)_3N$) of **1** gives a polymer with the same ν(CO), when this technique is applied to the polymerization of **2**, $[Cl_3Si(CH_2)_2P(C_6H_5)_2]_3RhCl$, the products darken on exposure to H_2 (1 atm, 60°C, toluene suspension). In these cases the H_2 uptake is greater than 1 mol per rhodium atom; being in some experiments as much as 1.82 (7). The darkening and high hydrogen uptake are probably due to reduction to rhodium metal, as has been established in other systems using electron microscopy (8). Base catalyzed cohydrolysis of **2** with Cl_3SiCH_3 also gives products with similar undesirable properties (7) even when the ratio of **2** to Cl_3SiCH_3 is varied from 1:20 to 1:200.

Because of these results the hydrolysis and cohydrolysis of **2** (reaction [1]) was performed using the dioxane/water method developed for **1**.[2] Thus the polymers **B**(2,*m*)[1] were obtained.

The solids **B**(2,*m*) have satisfactory properties (Table 1) on exposure to hydrogen. Thus they do not darken and take up less than 1 mol of H_2 per mole of rhodium. However, the results are not very reproducible and, as can be seen in particular for **B**(2,100), Table 1, a number of preparations give differing uptake figures. Polymers which are satisfactory in all respects (although some homopolymers are pyrophoric), giving low and reproducible H_2 uptake without darkening, are obtained only when the initially precipitated solids are Soxhlet extracted with CH_2Cl_2 for 24 h. This procedure was used for all subsequent preparations.

It seems that the ease of hydrogen uptake is related to the "diluteness" of the rhodium centres. Possibly the addition of 1 mol of H_2 per rhodium atom represents the polymeric counterpart of the known oxidative addition reaction of H_2 to Wilkinson's complex (9) (reaction [5]).

[5] $[(C_6H_5)_3P]_3RhCl + H_2 \rightleftharpoons [(C_6H_5)_3P]_3Rh_2ClH$

Only in one case does the hydrolysis–extraction method fail to yield an insoluble polymer. This is the polymer produced from $[Cl_2(CH_3)Si(CH_2)_2P(C_6H_5)_2]_3RhCl$, which dissolves upon extraction with dichloromethane. The lower cross-linked structure of the polymer produced by hydrolysis of the $SiCl_2$ groups probably accounts for this solubility.

The microanalytical data obtained for the solids **B**, **C**, and **D** are occasionally not those expected for the idealized formulae. The Cl content found for all the homopolymers and for some copolymers, e.g., **B**(2,75), is higher than expected, again presumably due to incomplete hydrolysis. The Si content found is in good agreement with the calculated values for the polymers tested. So are the values for P and Rh found in the homopolymers and copolymers **B**(2,75) and **D**(2,200); for all the other copolymers the percentage of P, Rh, and Cl are too low for meaningful determination. The carbon content in all the copolymers and **C**(2,0) is found as predicted but it is low in all the other homopolymers in spite of the

[2]DMF/water mixture gives irreproducible results (9).

TABLE 1. Representative hydrogen uptake data for the polymers **B**(2,*m*)[a]

Polymer	Dioxane/water	H_2 uptake per Rh atom	Polymer colour after exposure[b]
B(2,0)	3/1	0.27	Yellow
B(2,50)	4/1	0.75	Yellow
B(2,100)	4/1	0.50–0.97	Yellow
B(2,200)	5/1	1.0	Yellow
B(2,0)[c]	4/1	0.12	Light orange
B(2,100)[c]	4/1	0.50	Light orange

[a]Toluene suspension (4.5×10^{-2} mmol of Rh atom; 3 mL), 60°C, and 1 atm H_2.
[b]All initially orange.
[c]Polymer was extracted with CH_2Cl_2.

use of an improved analytical method (10) which seems to prevent the formation of silicon carbide.

The infrared spectra of the polymers seem to indicate that few if any rhodium(III) centres, resulting from oxidative addition of HCl to rhodium(I), are present. Thus the homopolymeric complexes show weak broad bands in the ν(Rh—Cl) region at 285 cm^{-1} with a shoulder at 255 cm^{-1} (**B**(2,0) and **B**(8,0)) and at 290 cm^{-1} with a shoulder at 265 cm^{-1} (**C**(2,0)) but there is no band near 2100 cm^{-1} due to ν(Rh—H). The copolymers do not absorb in the ν(Rh—Cl) or ν(Rh—H) regions although it must be noted that absence of these bands could be due to dilution effects (by $O_{3/2}SiCH_3$) and the intrinsically low intensity of both these stretching bands.

An interesting trend in the values for the decomposition points of the polymers is seen in the data in Table 2. None of the polymers actually melt; they all decompose at disappointingly low temperatures over a range of about 10°C leaving either black or grey residues. All the homopolymers decompose at temperatures 30–50°C lower than the corresponding copolymers. For example **B**(2,0) decomposes at 220–230°C whereas **B**(2,75), **B**(2,150), and **B**(2,200) decompose at 255–265°C. The homopolymer **B**(8,0) with "8-carbon" ligands decomposes at the lowest temperature whereas the copolymer with an excess of the phosphine, **D**, is almost as stable as **C**(2,200), which has the highest decomposition temperature of all. All the other copolymers decompose at roughly the same temperature (ca. 260°C) regardless of their composition.

TABLE 2. Decomposition points of the polymeric complexes

Polymer	Decomposition point (°C)
B(2,0)	220–230
B(8,0)	185–195
D	260–265
C(2,0)	220–230
B(2,75)	255–265
B(2,150)	255–265
B(2,200)	255–265
B(8,100)	250–260
C(2,200)	270–280

The secondary image electron micrographs of the polymer **B**(2,75) are shown in Fig. 1 at a range of magnifications. The freshly prepared polymer consists of relatively smooth globules clustered together in bigger conglomerates. The rhodium is distributed evenly as revealed by X-ray EM micrographs and no clusters are observed at the magnification used.

In order to gain more knowledge of the nature of the polymers some were treated with CO and H_2 because of the known reactions of rhodium(I) centres with these reagents. Thus L'_3RhCl gives $L'_2Rh(CO)Cl$ and L'_3RhH_2Cl, and $L'_4Rh_2Cl_2$ gives $L'_2Rh(CO)Cl$ and $L'_4Rh_2H_2Cl_2$ ($L' = (C_6H_5)_3P$) (9, 11, 12).

The polymeric complexes **B**(2,0) and **B**(2,75) were exposed to H_2 both in a toluene suspension and in the solid state. Data in Fig. 2 show the amount of H_2 uptake vs. time for the reaction carried out in toluene. After 33 h the homopolymer takes up 11.5% and the copolymer 56% of the H_2 compared with the amounts calculated for 1:1 uptake (reaction [5]). However, the infrared spectra of all the hydrogenated products show no ν(Rh—H) peaks in the expected region, 2050–2150 cm^{-1}. This may be because of the generally low intensity of ν(Rh—H) although the possibility of instability of the hydrido species cannot be overlooked in spite of mull preparation in an argon atmosphere.

The model complexes L_3RhCl and $L_4Rh_2Cl_2$ react with H_2 to give L_3RhH_2Cl and $L_4Rh_2H_2Cl_2$, respectively (5). The reactions are reversible at 25°C.

Some results of the reactions of some polymeric complexes with CO are listed in Table 3. In toluene suspension the amount of uptake varies widely and seems to indicate that accessibility to the metal centres is greater in the copolymers which show high uptake values. The infrared spectra of the exposed polymers show ν(CO) bands at 1965 or 1968 cm^{-1}. The chlorine bridged homopolymer **C**(2,0) and the copolymer **B**(2,75) also show a weaker absorption at 2080 cm^{-1} and **B**(2,75) has a band at 1995 cm^{-1}. The absorptions at ~1965 cm^{-1} indicate that the CO reacts to give a polymer in which the metal centre has a similar environment to that found in the polymeric carbonyl complex **A** with *trans*-phosphines.

It is not unusual to find more than one ν(CO) band in polymers of this type, and one to four have been observed for $P_2Rh(CO)Cl$ derivatives derived from

the polyphosphinite derivative of poly(methallyl alcohol) (13).

The ν(CO) frequencies for *cis*-phosphine complexes of the type (chelate-P_2)Rh(CO)Cl (14–16) and the dicarbonyl *cis*-$(CO)_2$PRhCl (17–19), are higher than for *trans*-P_2Rh(CO)Cl. However, it is difficult

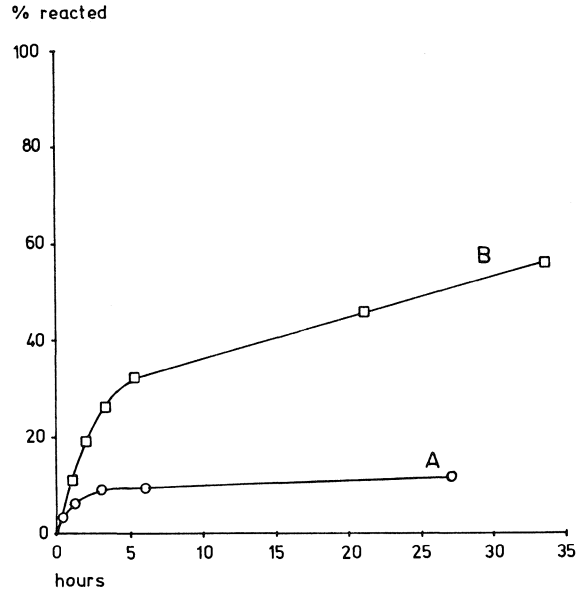

FIG. 2. Hydrogen uptake by **B**(2,0) and **B**(2,75). Curve *A* was obtained from 1.33×10^{-1} mmol of **B**(2,0); curve *B* from 4.5×10^{-2} mmol of **B**(2,75). Reaction conditions; temperature 60°C; P_{H_2}, 690 mm; toluene as solvent (3 mL).

to assign the bands at 2080 and 1995 cm^{-1} (Table 3) to particular species.

The model complexes L_3RhCl and $L_4Rh_2Cl_2$ both give L_2Rh(CO)Cl quantitatively and irreversibly.

Exposure of the solid polymer **B**(2,0) to HCl(g) (1 atm) at 25°C results in an uptake of more than 2 mol of HCl per mole of rhodium (7). This absorption is not reversed by pumping at 25°C. The infrared spectrum of the solid polymer shows no band in the ν(Rh—H) region and no change in absorption in the ν(Rh—Cl) region so the HCl is probably strongly chemisorbed. There seems to be no HCl uptake by the polymers **B**(2,0) or **B**(2,75) in toluene suspension (60°C). Instead, it seems that the first effect of dropping the polymers into the toluene in an appara-

tus which has been pre-equilibrated with HCl(g) is the evolution of the chemisorbed HCl.

From the results presented above it seems that the polymers contain mainly rhodium(I) centres and that the accessibility of these centres is inversely related to their concentration. They also react with CO and H_2 much less readily than their soluble model compounds L_3RhCl and $L_4Rh_2Cl_2$. Thus it is to be anticipated that the homogeneous hydrogenation of, say, styrene would be catalyzed much more readily by the soluble complexes than by toluene suspensions of the polymeric analogues. This is found to be so and these results together with other related findings are presented in the following paper.

Polymers of idealized formulae $[O_{3/2}Si(CH_2)_nP(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_m$, **B**(*n*,*m*), $[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2\cdot(O_{3/2}SiCH_3)_m$, C(2,*m*), and $[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}Si(CH_2)_2P(C_6H_5)_2)_{0.7}$, **D** are hydrogenation catalysts for olefins in benzene suspension at 25°C and 1 atm H_2. With respect to styrene, the activity order is **B** > **D** ~ **C**. All the catalysts lose activity on recycling but the copolymers retain their activity over a greater number of cycles with **D** being the best catalyst in this regard. Possible reasons for this behaviour are discussed.

ZOFIA C. BRZEZIŃSKA, WILLIAM R. CULLEN et GIORGIO STRUKUL. Can. J. Chem. **58**, 750 (1980).

Les polymères de formule théorique $[O_{3/2}Si(CH_2)_nP(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_m$, **B**(*n*,*m*), $[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2\cdot(O_{3/2}SiCH_3)_m$, C(2,*m*), et $[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}Si(CH_2)_2P(C_6H_5)_2)_{0.7}$ **D** catalysent l'hydrogénation des oléfines en suspension dans le benzène à 25°C et sous 1 atm de H_2. Par rapport au styrène, l'ordre d'activité est **B** > **D** ~ **C**. Tous les catalyseurs perdent leur activité lorsqu'on les recycle mais les copolymères retiennent leur activité pendant un grand nombre de cycles. Sous ce rapport, **D** est le meilleur catalyseur. On discute des raisons possibles de ce comportement.

[Traduit par le journal]

Introduction

When analogues of the well known homogeneous catalyst $[(C_6H_5)_3P]_3RhCl$ are supported on inert materials to give a "heterogenized homogeneous catalyst" (1–4) (polystyrene derivatives or silica are often used) olefin hydrogenation rates appear to be influenced by the same factors as are observed in homogeneous solution (5–10). However, the activity of the supported catalyst is almost invariably far inferior to its homogeneous counterpart (2, 3).

Silicones are well known polymers with a wide variety of uses (11) however, surprisingly, they have been little investigated as supports for "heterogenized homogeneous catalysts" (12–15). In these earlier studies the preformed silicone was functionalized to afford a polymeric phosphine which was subsequently used to prepare an appropriate metal derivative by ligand exchange. We have prepared silicone polymers by hydrolyzing preformed monomeric complexes of rhodium(I) (1) either alone or in the presence of CH_3SiCl_3 or $(C_6H_5)_2PCH_2CH_2SiCl_3$ to give a range of polymeric solids of the following idealized formulae:

$[O_{3/2}Si(CH_2)_nP(C_6H_5)_2]_3RhCl\cdot(O_{3/2}SiCH_3)_m$ **B**(*n*,*m*)

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_4Rh_2Cl_2\cdot(O_{3/2}SiCH_3)_m$ C(2,*m*)

$[O_{3/2}Si(CH_2)_2P(C_6H_5)_2]_3RhCl\cdot(O_{3/2}Si(CH_2)_2(PC_6H_5)_2)_{0.7}$ **D**

The present article describes their application as catalysts for the hydrogenation of olefins, in particular, styrene.

Experimental Section

Gas–liquid chromatography was done using an Aerograph A-90-P instrument. Saturated and unsaturated hydrocarbons were separated using 10% Carbowax 1500 on 60/80 mesh Chromosorb W-AW.

All liquid olefins were passed through an alumina column prior to use in reactions. A double manifold apparatus was used for hydrogenation reactions carried out at 1 atm. Usually a few reactions were carried out simultaneously in 25 mL round-bottomed flasks equipped with a Teflon-rubber septum plug and magnetic stirrer and connected to the apparatus via a water-cooled condenser (17). The temperature of the stirred glycerine bath in which the flasks were immersed was maintained constant (±0.1°C) by a thermoregulator and relay circuit which operated a 25 W elongated electric light bulb.

The catalyst prepared as previously described (1) was weighed out into the flask in a helium filled glove-box and the solvent and olefin were introduced into the flask using standard inert atmosphere techniques. Progress of the reaction was monitored by glc; samples being withdrawn periodically through the septum.

Results and Discussion

Hydrogenation of Olefins Using the Complex B(2,0)

Cyclohexene, styrene, 1-heptene, and 1-octene are hydrogenated at 25°C (1 atm H_2), using a suspension of **B**(2,0) in benzene (Table 1). The reduction of cyclohexene, following the general trend expected for internal olefins, proceeds at a slower rate. Isomerization *and* hydrogenation take place in the case of 1-heptene and 1-octene. Styrene affords only ethylbenzene.

These results parallel those obtained for other supported catalysts (7) although it has been reported that when ethanol is used as solvent the cyclohexene hydrogenation proceeds faster than that of styrene. In the case of **B**(2,0) the color of the polymer remains orange only when it is suspended in benzene or toluene. Addition of co-solvents such

TABLE 1. Hydrogenation of olefins using **B**(2,75) as catalyst[a]

Olefin	Conversion (%)	Saturated product yield (%)	Isomerized product yield (%)
Cyclohexene	8.1	8.1	—
Styrene	88.5	88.5	—
1-Heptene	86.4	46.3	40.1
1-Octene	88.8	42.9	45.9

[a]The olefin (3 mmol) in benzene solution (3 mL) was hydrogenated (1 atm H_2) using the catalyst (1.33×10^{-2} mmol, based on the number of Rh(I) atoms) at 25°C. The reaction was stopped after 23 h.

as triethylamine and ethanol causes a color change to grey, and in pure ethanol the polymer turns black presumably because of rhodium metal formation (1). This solvent effect has not been noted before.

The rate of hydrogenation of styrene, as model substrate, increases by a factor of about two on changing the temperature from 35°C to 60°C. The rate also increases by increasing the concentration or the amount of catalyst (17). These results parallel those obtained in other systems (5, 6, 9).

In order to evaluate the effect of varying the polymeric catalyst, the hydrogenation of styrene was studied at constant concentration and constant solution volume. The weight of catalyst was chosen so as to have a constant "concentration" of rhodium atoms present in suspension.

The data presented in Fig. 1 show that the "P_3RhCl" polymers **B**(*n*,*m*) are generally considerably more active than their "$P_4Rh_2Cl_2$" analogues **C**(*n*,*m*). In homogeneous solution the catalytic activity of $[(C_6H_5)_3P]_3RhCl$ appears to be due (18) to the formation of a phosphine dissociated species, reaction [1], which in the presence of hydrogen forms an important catalytic species, $[(C_6H_5)_3P]_2RhH_2Cl$ (reaction [2]). Otherwise dimerization takes place, reaction [3], and this equilibrium lies far to the right.

[1] $[(C_6H_5)_3P]_3RhCl \rightleftharpoons [(C_6H_5)_3P]_2RhCl + (C_6H_5)_3P$

[2] $[(C_6H_5)_3P]_2RhCl + H_2 \rightarrow [(C_6H_5)_3P]_2RhH_2Cl$

[3] $2[(C_6H_5)_3P]_2RhCl \rightleftharpoons [(C_6H_5)_3P]_4Rh_2Cl_4$

The dimer itself is described as a good hydrogenation catalyst (19) but with little substantiation. We have shown that model complexes for the silicone polymers **B**, **C**, and **D**, L_3RhCl and $L_4Rh_2Cl_2$ (20) (L = $[(CH_3)_3SiO]_2Si(CH_3)CH_2CH_2P(C_6H_5)_2$) are *both* active catalysts for styrene hydrogenation with the dimer being less active. In this respect the heterogeneous reaction parallels the homogeneous one. However comparable hydrogenation rates are obtained using the polymeric analogues as catalysts only if the concentrations of both catalyst and olefin are increased by a factor of 10 (17). This loss of activity on heterogenization is a general phenomenon as mentioned in the Introduction.

In the set of first cycle hydrogenations shown in Fig. 1 there is not much difference between the behaviour of the homo- or copolymers of a given type with the exception of **B**(8,0) which is appreciably less active than **B**(8,100). This behaviour is changed little by preconditioning the polymer in benzene suspension under an atmosphere of hydrogen prior to the addition of styrene (Fig. 2). Figure 2 also shows that there is an increase in the

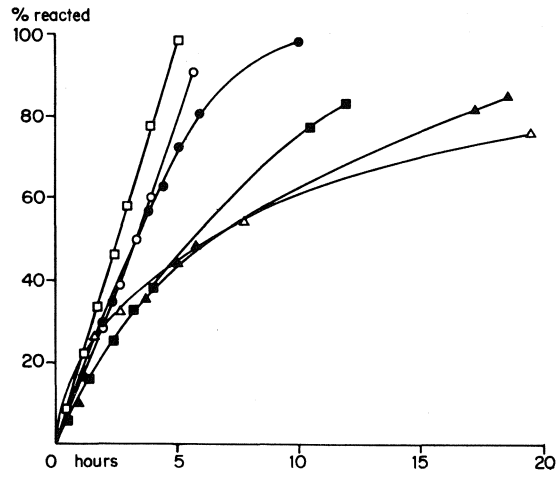

FIG. 1. First cycle of hydrogenation of styrene in benzene with different polymers as catalysts. activity of this catalyst in the second cycle and that the activity drops steadily on subsequent recycling. There is no appreciable loss of rhodium from the catalyst to the reaction solution as judged by its color before the fifth run (Table 2). Other workers have reported similar increases after the first cycle for silica (21) and polystyrene (22) supported catalysts.

A typical example of the more usual behaviour observed on recycling is seen in Fig. 3 where there is a gradual drop in activity of the catalyst **B**(2,0) until it reaches a negligible level in the fifth cycle. The polymer used as catalyst here is air sensitive (1) and when it is deliberately exposed to air between cycles the loss of activity is much more rapid than shown in Fig. 3.

The results obtained for a number of these recycling experiments are summarized in Table 2, and in the case of the "P_3RhCl" polymers copolymerization with CH_3SiCl_3 helps maintain activity but it has little effect on prolonging the already low activity of the "$P_4Rh_2Cl_2$" polymers. The most stable catalyst **D** contains excess ligand although its initial activity is low (Fig. 4). This is not unexpected since studies in homogeneous systems show that excess phosphine slows down reaction rates, presumably because of its effect on the reactions shown in reactions [1] to [3] and similar effects have been noted for other supported catalysts (12, 21, 23–25). This excess phosphine should stabilize the polymer by preventing rhodium elution (22, 25–28) as found in the present case. This should also result in a catalyst which maintains its activity over a greater number of cycles if dimer production is the cause of activity loss on recycling (reaction [3]). As the present results show the "$P_4Rh_2Cl_2$" polymers **C**(2,*m*) have a lower activity; and dimer formation has been observed on polystyrene based catalysts of the P_3RhX type (29).

TABLE 2. Effect of recycling catalysts for styrene hydrogenation[a]

Catalyst	Number of cycles required for activity to drop to zero[b]	Cycles in which rhodium loss is observed
B(2,0)	5	4 and 5 (4 < 5)
B(8,0)	6	5 and 6 (5 < 6)
C(2,0)	3	1
D	5[c]	—
B(2,75)	5[d]	3 and 5 (3 < 5)
B(2,150)	5[d]	3 and 5 (3 < 5)
B(2,200)	5[e]	—
B(8,100)	5	—
C(2,200)	3	—

[a]The conditions for all experiments were as described in the caption for Fig. 1.
[b]Zero is defined rather loosely. Recycling was stopped when the activity was approximately that shown in the fifth run in Fig. 2.
[c]Polymer had lost only half its activity (Fig. 4).
[d]There is little loss of activity in the first three cycles.
[e]There is little loss of activity in the first four cycles.

Inhibition of dimer formation could also partly account for the slower initial drop in activity found on recycling the copolymers (Table 2) since the rhodium centres will be further away from each other. Related to this is the observation that copolymerization of the dimeric complexes does not improve their activity or behaviour on recycling.

When the length of the spacer arm between the metal and the matrix is increased, the resulting catalysts **B**(8,*m*) maintain their activity over a greater number of cycles and, apart from the initial anomalous behaviour of **B**(8,0), their activity is always higher than **B**(2,*m*) in a given cycle. This is possibly also due to some inhibition of dimer for-

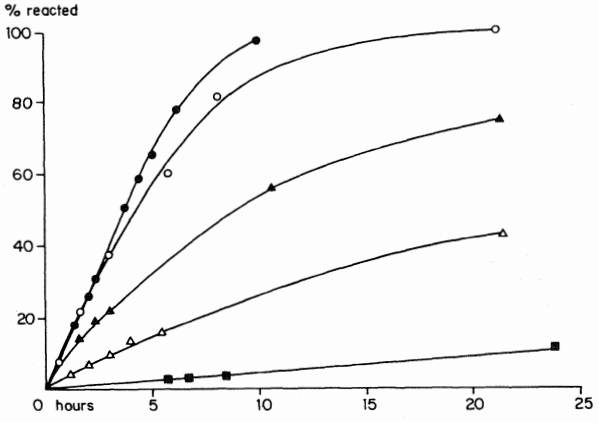

FIG. 3. Recycled **B**(2,0) as catalyst for styrene hydrogenation. Reaction conditions are as described in the caption to Fig. 1. Cycles: ●, 1st; ○, 2nd; ▲, 3rd; △, 4th; ■, 5th.

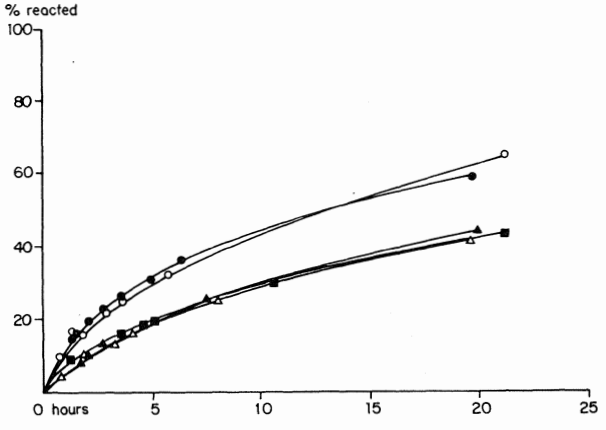

FIG. 4. Recycled **D** as catalyst for styrene hydrogenation. Reaction conditions are as described in the caption to Fig. 1. Cycles: ●, 1st; ○, 2nd; ▲, 3rd; △, 4th; ■, 5th.

mation. In addition, the long arms probably allow the active sites to behave much more like species in solution. In this connection epr studies of polysaccharide supported nitroxides (30, 31) show that longer spacer arms give more freedom of mobility to the anchored sites and the spectra become similar to those of the species in solution. The increase of the spacer arms beyond a length equivalent to a C_8 chain causes no further change (30, 31).

The above model accounts for most of the gross features observed in the catalytic hydrogenation of styrene. However, it is probably an oversimplification since, for example, some of the polymers are air sensitive (1) and in spite of careful handling they could become exposed to traces of air during cycling. The used catalyst could be particularly sensitive in this regard since it almost certainly contains some rhodium hydride species (reaction [2]).

Although the model complex L_3RhCl reacts with H_2 at 25°C to give L_3RhH_2Cl, and $L_4Rh_2Cl_2$ affords a mixture of compounds whose main constituent is $L_4Rh_2H_2Cl_2$ under the same conditions (both hydrogenations are reversible), the polymers **B**(2,0) and **B**(2,75) themselves take up hydrogen slowly in toluene suspension at 60°C (1). The amounts taken up are only 11.5% and 56% of the amount calculated for 1-to-1 uptake after 33 h. Furthermore, the catalytic activity of **B**(8,0) is little affected by preconditioning with H_2 (Fig. 2). Thus hydrides with compositions similar to L_3RhH_2Cl and $L_4Rh_2H_2Cl_2$ are probably not formed to a great extent during the styrene hydrogenation reactions.

Undoubtedly some loss of activity on recycling some catalysts is due to elution of metal (Table 2). This is generally assumed to be related to the dissociation equilibrium shown in reaction [1] (the right-to-left reaction is responsible for the stability of the polymer **D** as described above). Loss of rhodium from supported hydroformylation catalysts supported on silica and polystyrene has been related to oxygen exposure (25). Elution of rhodium also occurs from related polysiloxane supported hydroformylation catalysts (16) and in this case a mechanism involving initial loss of phosphine is advanced. Although there is no evidence for phosphine loss in the present study, it is always a possibility.

More extensive deactivation per cycle is observed when the polymer **B**(2,0) is used to hydrogenate cyclohexene under the same conditions used for styrene (17). In addition the degree of conversion to cyclohexane is less than to ethylbenzene in a given time in all cycles.

An unusual phenomenon is observed when the hydrogenation reactions are run in "solution volumes" different from the standard 3 mL usually used. Data plotted in Fig. 5 show that the degree of hydrogenation of styrene catalyzed by **B**(2,0) is smaller at a given time for larger volumes. On recycling the difference slowly disappears. Polymer **C**(2,200) shows this phenomenon to a lesser extent and polymer **D** hardly at all. When cyclohexene is the substrate and **B**(2,0) the catalyst, conversion is slightly *higher* in solutions of greater volume. These results are quite reproducible and are not due to variation of stirring speed. Rate effects on changing the speed of stirring have been observed by others (12).

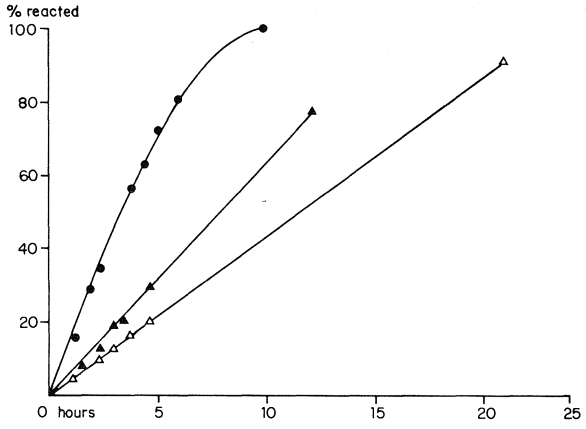

FIG. 5. Effect of solution volume on the hydrogenation of styrene catalyzed by **B**(2,0). Reaction conditions are as described in the caption to Fig. 1 and the amounts of styrene and catalyst are proportional to the solution volume. Solution volume; ●, 3 mL; ▲, 9 mL; △, 12 mL.

In summary, all the polymers **B**, **C**, **D** are effective catalysts for olefin hydrogenation but their activity decreases on recycling. This deactivation could be caused by (*a*) dimerization of the **B** polymers to form macromolecules related to **C**, (*b*) "poisoning" of the catalyst by traces of oxygen, (*c*) elution of rhodium from the catalyst perhaps also caused by exposure to oxygen. However, it is possible that loss of activity is partly due to physical changes in the polymeric matrix of the catalyst which occur either during the hydrogenation reaction or in the handling between cycles. Electron microscope studies reveal that the physical appearance of the polymeric beads is greatly changed once they have been used in a hydrogenation reaction (1, 17).

A total synthesis of (±)-stemarin, a diterpenoid with a unique bicyclic C/D ring system

RONALD B. KELLY, MARY LOU HARLEY, AND SANDRA J. ALWARD

Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5

Received January 7, 1980

This paper is dedicated to Professor Karel Wiesner on the occasion of his sixtieth birthday

RONALD B. KELLY, MARY LOU HARLEY, and SANDRA J. ALWARD. Can. J. Chem. **58**, 755 (1980).

A total synthesis of (±)-stemarin, a diterpenoid with a unique C/D ring system, is described. The synthesis features photoaddition of allene to an α,β-unsaturated ketone and two skeletal rearrangements. Application of the synthetic strategy described herein to a synthesis of stemodinol and aphidicolin is anticipated.

RONALD B. KELLY, MARY LOU HARLEY et SANDRA J. ALWARD. Can. J. Chem. **58**, 755 (1980).

On décrit une synthèse totale de la (±) stémarine, un diterpène ayant un système cyclique C/D particulier. La synthèse est caractérisée par l'addition photochimique d'un allène sur une cétone α,β non saturée et par deux transpositions moléculaires. On envisage d'appliquer la stratégie décrite à la synthèse du stémodinol et de l'aphidicoline.

[Traduit par le journal]

Because of their unique structures, the diterpenoids stemarin (**1**) (1), stemodinol (**2**), and their relatives (2, 3) are attractive candidates for total synthesis. While contemplating syntheses of these diterpenoids, it occurred to us that they might be obtained via rearrangement of epimeric intermediates such as **3***a* and **3***b* where migration of bond *a* would lead to the stemarin skeleton and migration of bond *b* to the stemodinol skeleton. Since bond migration would be controlled by the stereoalignment of the migrating bond relative to the leaving group (OTs), **3***a* should rearrange to the stemarin skeleton and its epimer (**3***b*) to the stemodinol skeleton. We now wish to describe a total synthesis of stemarin (**1**) by application of this strategy.[1]

The tosylate **3***a* was prepared from the totally synthetic (5) racemic ketone **4** along lines previously employed in these laboratories (6) involving photoaddition of allene to **4** and subsequent skeletal rearrangement. Thus, stereo- and regiospecific photoaddition of allene to **4** afforded, in 78% yield, the adduct **5** (mp 121°C; ir: 1662 and 900 (olefin) cm^{-1}; nmr δ: 4.90 (m, 2H, vinylic protons))[2] which, on treatment with methyl iodide in THF in the presence of LDA at −10°C, gave (74% yield) the ketone **6** (mp 124°C; nmr δ: 1.16 (d, J = 6.5 Hz, 3H, secondary methyl)). The ketone **6** was converted in the usual manner, in 90% yield, into the ketal **7** (mp 131°C; nmr δ: 3.64 (br s, 4H, ethylene of ketal)).

[1]A synthesis of aphidicolin (4) by a similar strategy can be envisaged; for syntheses of aphidicolin by a different approach, see refs. 4*b*, *c*.

[2]Throughout, the ir spectra (in Nujol unless specified) and the nmr spectra (in $CDCl_3$) are entirely consistent with assigned structures. Satisfactory elemental analyses were obtained for all crystalline compounds and correct molecular ions were found in the mass spectra of the remaining compounds.

Oxidation of **7** with osmium tetroxide – periodate under conditions previously employed for the cleavage of exocyclic methylenes (*6a*) gave, in 77% yield, the cyclobutanone **8** (mp 155°C; ir: 1779 (cyclobutanone) cm^{-1}; nmr: devoid of signals for vinylic protons). Reduction of **8** with $NaBH_4$ afforded quantitatively the cyclobutanol **9** (mp 164°C; ir: 3450 (OH) cm^{-1}; nmr δ: 4.22 (m, 1H, H—C—OH)). The cyclobutanol **9** was subjected to the first of two skeletal rearrangements featured in this synthesis. This was accomplished by heating it with hydrochloric acid in aqueous THF, whereupon it underwent deketalization then retroaldalization and spontaneous aldol condensation to produce two epimeric keto alcohols, **10** and its C-12 epimer.[3]

The keto alcohols, after separation by chromatography on silica gel in ether–petroleum, were obtained in 98% yield in the ratio of 3:1. The minor epimer **10** (mp 197°C; ir: 3520 (OH) cm^{-1}; nmr δ: 3.63 (m, 1H, H—C—OH), no methyl doublet) was converted quantitatively into the thioketal **11** (mp 172°C; nmr δ: 3.22 (m, 4H, ethylene of ketal)). Reduction of **11** with Raney nickel afforded, in 94% yield, the alcohol **12** (mp 136°C; ir: 3460 (OH) and 1720 (ester) cm^{-1}; nmr δ: 3.54 (m, 1H, H—C—OH)). The alcohol **12** was converted into the tosylate *3a* which, being unstable, was used immediately it was obtained without purification. In *3a*, the configuration at C-12 follows from the subsequent rearrangement *3a* → **13**, requiring the alignment of the migrating bond *a* to be *anti* to the tosylate group as shown.

Heating of *3a* in DMSO at 60°C with methylsulfinyl carbanion (7) smoothly brought about the second rearrangement to produce, in 79% yield, the olefin **13** (oil; ir (film): 1730 (ester) and 898 (olefin) cm^{-1}; nmr δ: 1.58 (d, J = 2 Hz, 3H, vinylic methyl) and 4.90 (m, 1H, vinylic proton)). In the penultimate step, **13** was converted, with *m*-chloroperbenzoic acid, into the epoxide **14** (oil; nmr δ: 1.28 (s, 3H, methyl attached to oxirane ring)). The configuration assigned to the oxirane ring follows from the reduction of **14** to stemarin (**1**).

Finally, reduction of **14** with $LiAlH_4$ afforded racemic stemarin (**1**) (mp 178°C) in 63% yield. The synthetic diterpenoid was found to be identical with an authentic sample of stemarin by the following criteria: identical ir and nmr spectra; identical behavior on tlc in a variety of solvents.

[3]For precvious examples of this type of rearrangement accomplished in these laboratories and an explanation of the mechanism, see ref. 6.

Acknowledgments

Complexation of Zn(II) to a native sequence tripeptide of human serum albumin studied by ^{13}C nuclear magnetic resonance

HELEN LAKUSTA, CHARLES M. DEBER, AND BIBUDHENDRA SARKAR

The Research Institute, The Hospital for Sick Children, Toronto, Ont., Canada M5G 1X8 and the Department of Biochemistry, University of Toronto, Toronto, Ont., Canada M5S 1A8

Received October 12, 1979

HELEN LAKUSTA, CHARLES M. DEBER, and BIBUDHENDRA SARKAR. Can. J. Chem. **58**, 757 (1980).

Serum albumins from several species, which specifically bind and transport several divalent metals in blood, contain an Asp-X-His or Glu-X-His amino acid triad as their NH_2-terminal sequence. We have synthesized a tripeptide, Asp-Ala-His-*N*-methylamide, corresponding to the native sequence of the human serum albumin *N*-terminus, and examined its interaction with Zn(II) ions in aqueous solution using carbon-13 nmr techniques. Variations in carbon chemical shifts and spin–lattice relaxation times (T_1's) as a function of pH and increments of added Zn(II) were used to delineate sites of Zn(II):peptide interactions. Trends in T_1 values indicated that local motions of several of the tripeptide carbons were restricted by an induced order accompanying metal binding. Analysis of spectral data suggested that Zn(II) is coordinated to the His imidazole nitrogen atom and the Asp β-carboxylate oxygen atom(s) in each peptide molecule. Similar experiments using a tripeptide analogue, Gly-Gly-His-*N*-methylamide, demonstrated that in the absence of a side chain carboxylate group, Zn(II) ions will complex the peptide through the His imidazole group and the *N*-terminal Gly α-amino group. These results support the possibility of a biologically functional role for the Asp-X-His triad as a liganding template for Zn(II)/protein binding.

HELEN LAKUSTA, CHARLES M. DEBER, et BIBUDHENDRA SARKAR. Can. J. Chem. **58**, 757 (1980).

Les sérums d'albumine provenant de différentes espèces, qui se lient spécifiquement et transportent plusieurs métaux bivalents dans le sang, contiennent des triades d'acides aminés Asp-X-His ou Glu-X-His comme séquence *N*-terminale. Nous avons synthétisé le tripeptide Asp-Ala-His-*N*-méthylamide correspondant à la séquence *N*-terminale naturelle du sérum d'albumine humain et on a étudié son interaction avec les ions Zn(II) en solution aqueuse en utilisant les techniques de la rmn du ^{13}C. Pour délimiter les sites des interactions Zn(II):peptide, on a utilisé les variations des déplacements chimiques du carbone, des temps de relaxation spin–réseau (T_1) en fonction du pH et des quantités de Zn(II) ajouté. La tendance observée pour les valeurs de T_1 indique que des mouvements localisés de plusieurs carbones du tripeptide sont restreints par un ordre induit accompagnant le mode de liaison du métal. L'analyse des données spectrales indiquent que le Zn(II) est coordonné à l'azote du noyau imidazole de l'histidine et à l'atome (atomes) d'oxygène de la fonction carboxylate en position β de l'acide aspartique de chaque molécule de peptide. Des expériences semblables utilisant le tripeptide analogue Gly-Gly-His-*N*-méthylamide démontrent qu'en l'absence d'une chaîne latérale ayant au groupement carboxylate les ions Zn(II) se complexeront au peptide au niveau du groupe imidazole de l'histidine et du groupe amine en α de la glycine *N*-terminale. Ces résultats suggèrent la possibilité d'un rôle fonctionnel biologique de la triade Asp-X-His comme modèle de ligand du mode de liaison Zn(II)/protéine.

[Traduit par le journal]

Serum albumin is a multifunctional plasma protein which has been shown to bind several divalent metal ions and has been implicated in the transport processes of both Cu(II) (1–3) and Zn(II) (4–6). Albumin-bound Zn(II) has been found to account for approximately 98% of the exchangeable fraction of Zn(II) in serum (7). This fraction is known to be associated with the transport process of Zn(II) (4, 6, 7).

The affinity of Zn(II) both for the imidazole side chain of histidyl residues, and for the carboxylate group of dicarboxylic acid residues, has been established by chemical modification studies and through X-ray crystallographic analysis. For example, Zn(II) binding to His or Glu, or both, residues occur in several metalloenzymes including carboxypeptidase A (8), thermolysin (9), carbonic anhydrase B (10), and carbonic anhydrase C (11). Studies of Zn(II):albumin coordination have also implicated a His imidazole side chain in the binding

of Zn(II) (12, 13). Examination of the NH_2-terminal regions of serum albumins from species such as human (Asp-Ala-His-) (14), bovine (Asp-Thr-His-) (15), and rat (Glu-Ala-His-) (14), reveals the presence not only of a common His-3 residue, but also a second common feature: the occurrence of a carboxylic acid-containing residue (Glu or Asp) at position 1. In the binding of albumin to Cu(II), which is known to prefer nitrogen ligands (see, for example, ref. 16) the α-amino group of the NH_2-terminal residue participates in binding along with the His-3 imidazole nitrogen atom (in addition to the two intervening peptide nitrogens) (15, 17, 18). However, a compilation of binding sites in protein–metal ion complexes of 3*d* cations such as Zn(II) demonstrates the widespread occurrence and enhanced stability of mixed imidazole/oxygen coordination systems (19). In the present work, we sought to determine if a further functional role can be ascribed to the albumin Asp (or Glu) NH_2-terminal residue, namely, the utilization of the side chain carboxylate moiety in Zn(II) binding.

Macromolecules such as serum albumin (584 amino acids in the monomer) are sufficiently complex that it becomes advantageous to investigate metal binding to smaller molecules containing the functional groups representative of the protein metal-binding site (for examples of this approach, see ref. 20). In this context, we have synthesized two tripeptides: Asp-Ala-His-*N*-methylamide (AAHNMA) (see Fig. 1), which contains the native sequence of the three *N*-terminal residues of human serum albumin; and Gly-Gly-His-*N*-methylamide (GGHNMA), which also contains the combination of an α-amino group and a His residue separated by one amino acid, but lacks the side chain carboxyl group on the *N*-terminal residue. The *C*-terminal residues of these tripeptides are bound into amide linkages to simulate the peptide bond of the protein. Copper(II)-binding properties of AAHNMA (21) correspond closely to those observed for albumin–Cu(II) binding (17). Analytical potentiometric studies of the Zn(II):AAHNMA system have also demonstrated that the tripeptide forms stable complexes with Zn(II) (22); however, while this technique is extremely valuable for quantitative measurements of metal:peptide affinity constants and species stoichiometries (see, for example, ref. 23), it cannot provide direct information as to the actual site(s) of metal:peptide interaction.

Since Zn(II) ion has neither intrinsic color nor unpaired electrons, the range of spectroscopic techniques available for investigation of its binding properties is limited. However, Zn(II) is

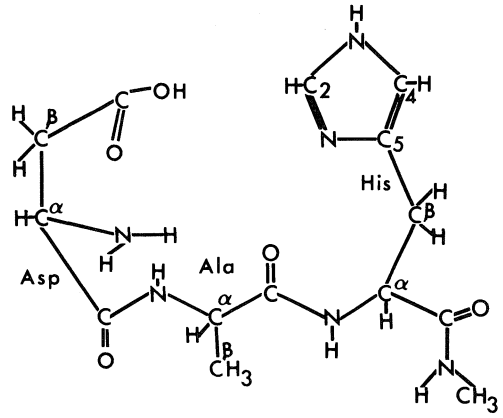

FIG. 1. Structure of Asp-Ala-His-*N*-methylamide, with component carbon atoms labelled as referred to in the text.

diamagnetic and does not cause the line broadening induced by paramagnetic ions; thus nuclear magnetic resonance spectra of Zn(II)/peptide complexes should be sharp and informative. In the present article, we have employed carbon-13 nuclear magnetic resonance to examine structural and dynamic properties of Zn(II):AAHNMA and Zn(II):GGHNMA complexes in aqueous solution.

Experimental

The tripeptides L-aspartyl-L-alanyl-L-histidine-*N*-methylamide (L-Asp-L-Ala-L-His-*N*-methylamide = AAHNMA) and glycyl-glycyl-L-histidine-*N*-methylamide (Gly-Gly-His-*N*-methylamide = GGHNMA) were prepared according to published procedures (21, 24).

Carbon-13 nmr spectra were recorded on a Varian XL-100 nmr spectrometer of field strength 23.5 kG (25.16 MHz for carbon-13) at a probe temperature of ca. 30°C. All chemical shifts were reported in ppm upfield from external carbon disulfide; these may be converted to ppm vs. external tetramethylsilane by subtracting chemical shifts given from 193.8 ppm.

Spin–lattice relaxation times (T_1's, reported in ms) were determined using the inversion–recovery method (25) employing a pulse sequence of $-(180°-t-90°-5T_1)-$. Values of T_1 were generally calculated by measuring peak intensity as a function of the variable time, t, and using a non-linear least-squares fitting procedure for the equation:

$$[1] \quad A = A_0(1 - 2\,e^{-t/T_1})$$

where A is the peak intensity at time t, and A_0 is the peak intensity at time $t = \infty$. Standard error in reported T_1's is approximately 10%. T_1 values (collected in Table 1) are reported as NT_1 values, where N is the number of protons directly bonded to any given carbon atom.

Spectra were recorded using natural abundance carbon-13, which necessitated sample concentrations of about 0.3 *M* to minimize spectra collection times. Samples were prepared in D_2O; values of pH (uncorrected for D_2O) were adjusted using either KOD or high purity concentrated HNO_3. Stock Zn(II) nitrate solutions (2 *M*) were prepared using "69 Grade" metallic zinc (see text) and high purity concentrated HNO_3. Solutions of Mn(II) and Cu(II) were prepared from reagent grade $MnCl_2 \cdot 4H_2O$ and $CuCl_2$, respectively.

Results

Carbon-13 Nuclear Magnetic Resonance Studies on L-*Asp*-L-*Ala*-L-*His*-N-*methylamide*

Assignments of resonances were made by comparisons with published chemical shifts of constituent amino acids (for a survey, see ref. 26); specific assignments within the peptide carbonyl regions of the spectra were obtained from the pH dependencies of their chemical shifts (*vide infra*). Through the range of pH 2–10, AAHNMA loses, in succession, protons from the Asp carboxyl side chain ($pK_a = 2.93$), the His imidazole ring ($pK_a = 6.32$), and the amino terminus ($pK_a = 7.73$) (24). In Fig. 2, the assigned His C=O reflects the titration of an imidazole moiety near neutral pH, and the assigned Asp C=O reflects the titration of an amino group between pH 7 and 10. The Asp side chain carboxylate carbon reflects both its own titration at acidic pH and the titration of the Asp amino group terminus at basic pH. The remaining carboxyl resonance shows essentially no change and is therefore assigned to the Ala residue. Chemical shifts of carbons adjacent to titratable groups also display corresponding behavior, notably the His C_2, C_5, and C_β resonances, and the Asp C_β resonance.

Titration of AAHNMA with Zn(II) nitrate (maintaining constant pH) also results in a series of significant chemical shift changes, presumably associated with Zn(II)–peptide binding. The largest chemical shift changes, as great as 4 ppm, are displayed by His imidazole resonances (shown in Fig. 3 at pH 7) in accord with the tendency of Zn(II) to bind imidazole nitrogens.

Titrations of AAHNMA with Zn(II) nitrate at pH 9 (Fig. 4) were limited to a lower range of Zn(II)–peptide ratios, due to the tendency toward precipitation with increasing additions of Zn(II). Further, as Zn(II) is added at pH 9, spectral lines begin to broaden, and spectra beyond a 1:2 Zn(II)–peptide ratio were virtually broadened into the baseline. This effect is illustrated in Fig. 5, where spectrum (*b*) differs from (*a*) only in that the pH is 9 rather than 7. Local rigidification of atoms specifically involved as bridging sites in aggregate or polymer formation at pH 9, such as His imidazole or pyrrole-type nitrogens (27–29), could produce the observed spectral effect of differentially broadened resonances.

Spin–Lattice Relaxation Times (T_1's) of Asp-Ala-His-N-*methylamide*

Systematic measurements of AAHNMA T_1's can, in principle, provide information regarding stoichiometry of complex(es) present, and restrictions to molecular motion along the peptide chain (for a discussion, see ref. 30). Table 1 summarizes the NT_1 values obtained for AAHNMA as a function of pH and of Zn(II)–peptide ratios. In general, pH had little or no effect on NT_1's of free peptide. However, at pH 7.0, where the most extensive data were collected, a large decrease in observed NT_1's of Zn(II)-bound vs. free AAHNMA was noted upon the addition of Zn(II). At a 1:4 Zn(II)–peptide ratio, most NT_1's have already dropped by about a factor of three (although NT_1's of the two methyl groups have decreased by lesser factors). This trend continues with NT_1's decreasing by a further factor of two when the ratio of Zn(II)–peptide was doubled to 1:2 (indicated as 2:4 in Table 1). Above this ratio, however, few significant changes in NT_1's occur.[1]

At pH 9.0, reliable NT_1 values could be obtained only on the free peptide and at a 1:4 ratio, where NT_1's largely parallel those for the 1:4 ratio at pH 7.

Carbon-13 Nuclear Magnetic Resonance Studies on Gly-Gly-His-N-*methylamide*

Results of pH titrations (in the range 2–10) with GGHNMA are given in Fig. 6. As with AAHNMA, resonance assignments were based upon empirical correlations with chemical shifts of constituent amino acids (26). The assignment of the appropriate carbonyl resonance to the *N*-terminal Gly peptide carbonyl carbon was made on the basis of its titration behavior (i.e., shift of 8 ppm downfield) reflecting the deprotonation of the *N*-terminal amino group ($pK_a = 7.87$). The NH_2-terminal Gly C_α resonance shows similar behavior, while the His C_2 and C_5 resonances reflect deprotonation of the imidazole moiety ($pK_a = 6.39$).

Additions of Zn(II) nitrate to GGHNMA at pH 7 resulted in the spectral changes presented in Fig. 7.

[1]The assay of trace paramagnetic metals in 69 Grade metallic zinc indicated that Cu(II) and Fe(III) might be present up to a total of ca. 0.1 ppm (about 10^{-7} *M* in a 1 *M* solution of $Zn(NO_3)_2$). Copper(II) is known to bind AAHNMA and related peptides specifically through the histidyl residue, the amino terminus, and the peptide nitrogens (21, 23, 32). Although addition of Cu(II) (as the chloride) to AAHNMA up to a maximum concentration of 10^{-5} *M* did result in a decrease of a few percent in the observed NT_1's (see ref. 31 for examples of paramagnetic ion effects on NT_1 values) — for example, Ala C_β decreases from 1350 to 1210 ms; His C_β from 400 to 370 ms — this clearly did not account for the drop in NT_1's accompanying the addition of Zn(II). In another experiment, the paramagnetic Mn(II) ion was added at pH 7 (as the chloride) to AAHNMA, to a maximum concentration of 3×10^{-5} *M*, a Mn(II) level high enough to have resulted in a decrease in peptide NT_1's, even via non-specific binding to AAHNMA (33). The resulting NT_1's (e.g., Ala C_β, 1120 ms; His C_β, 390 ms) paralleled those observed in the presence of Cu(II), indicating that Mn(II) did not have a significant effect on peptide relaxation times under these conditions.

TABLE 1. Spin–lattice relaxation values (NT_1's) (ms) measured for L-Asp-L-Ala-L-His-*N*-methylamide and its Zn(II) complexes*

pH	Ratio Zn(II)–peptide	Ala-CH_3	His *N*-methyl-amide	His C_β	Asp C_β	Ala C_α	Asp C_α	His C_α	His C_4	His C_2

*Spectra recorded at 25 MHz on solutions of 120–150 mg/mL peptide + added Zn(II) nitrate at the indicated Zn(II)–peptide ratios and values of pH (uncorrected for D_2O). Estimated uncertainty in NT_1's: ±10%. Values not given represent overlaps of resonances, or insufficient data for reliable determination. See Experimental section for further details of experimental parameters.

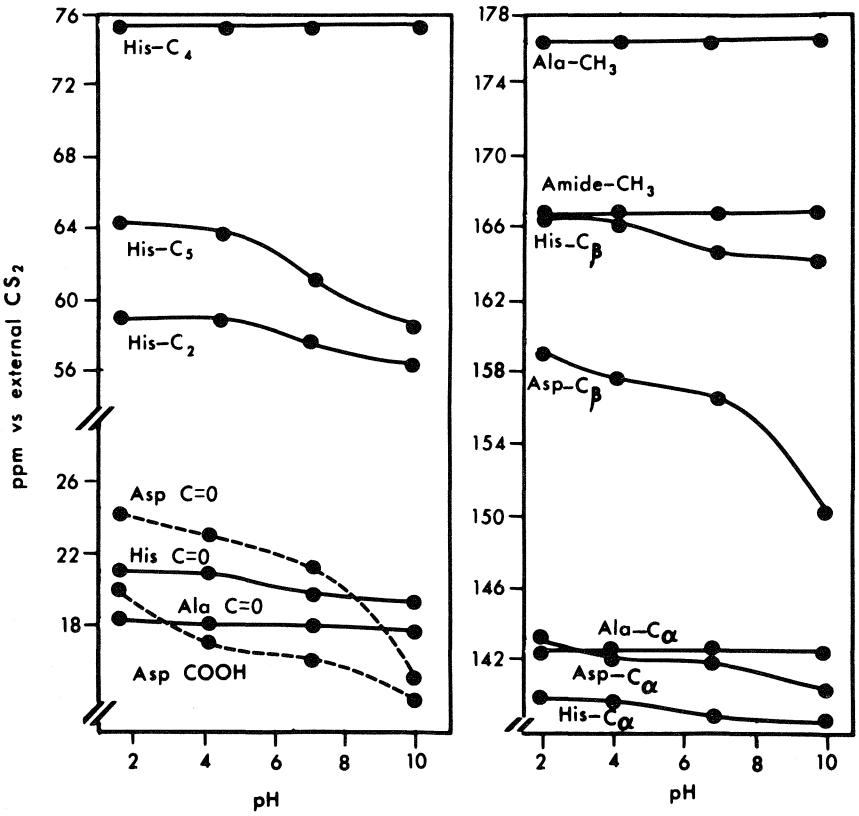

FIG. 2. Dependence of carbon-13 resonances of L-Asp-L-Ala-L-His-*N*-methylamide on pH over the range 2–10. Data were collected on samples containing 55 mg/mL peptide in D_2O solutions. Values of pH are uncorrected for D_2O. The pH was adjusted with KOD or HNO_3 as required.

As with AAHNMA (see Fig. 3), initial addition of Zn(II) produced immediate changes in His resonances, implicating the imidazole group in Zn(II) binding. However, in contrast to the carbonyl region of AAHNMA spectra, which remained relatively insensitive to initial portions of added Zn(II), the amino terminal Gly carbonyl resonance (ca. 24 ppm at pH 7, see also Fig. 6) displays clear titration behavior, moving downfield ca. 5.5 ppm over the range of 0 to 1:1 ratios of Zn(II)–GGHNMA. The Zn(II) had no appreciable effect on other GGHNMA carbonyl chemical shifts.

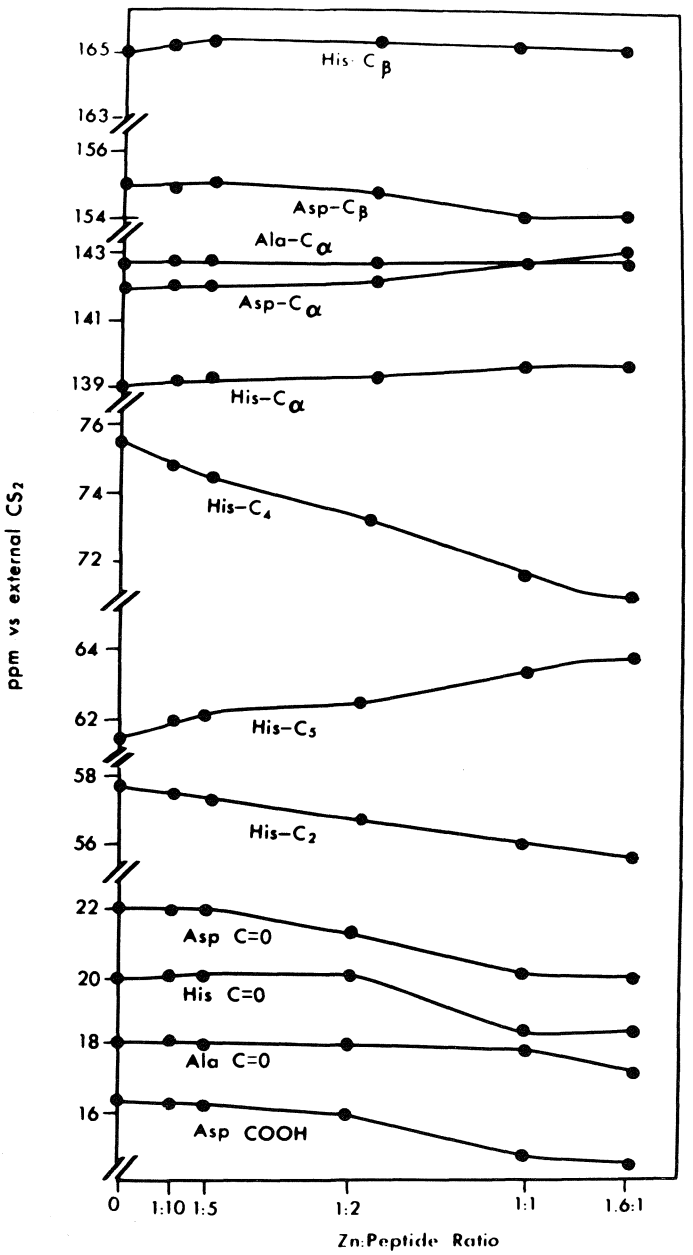

FIG. 3. Variations in chemical shifts of carbon atoms of L-Asp-L-Ala-L-His-*N*-methylamide as a function of added Zn(II) nitrate at pH = 7. Data were collected on samples containing 55 mg/mL peptide in D_2O solutions. Values of pH (uncorrected for D_2O) were adjusted as required after additions of $Zn(NO_3)_2$ with KOD. Chemical shifts of resonances due to Ala C_β (ca. 176.5 ppm) and His-*N*-methylamide (ca. 166.5 ppm) were essentially unchanged over this range of Zn(II) additions.

A preliminary set of NT_1 values for the Zn(II)–GGHNMA system was obtained on the same sample used to compile the spectra represented by Fig. 7. It was found that GGHNMA NT_1 values drop substantially upon additions of $Zn(NO_3)_2$, by at least a factor of two at 1:2 Zn(II)–peptide ratios (and for some resonances, by a factor of four at that ratio). For example, values of NT_1 were 2260 ms for His *N*-methylamide (free GGHNMA) vs. 1120 ms (1:2 Zn(II)–peptide). NT_1's did not appear to vary significantly upon additions of Zn(II) between 1:2 and 1:1.

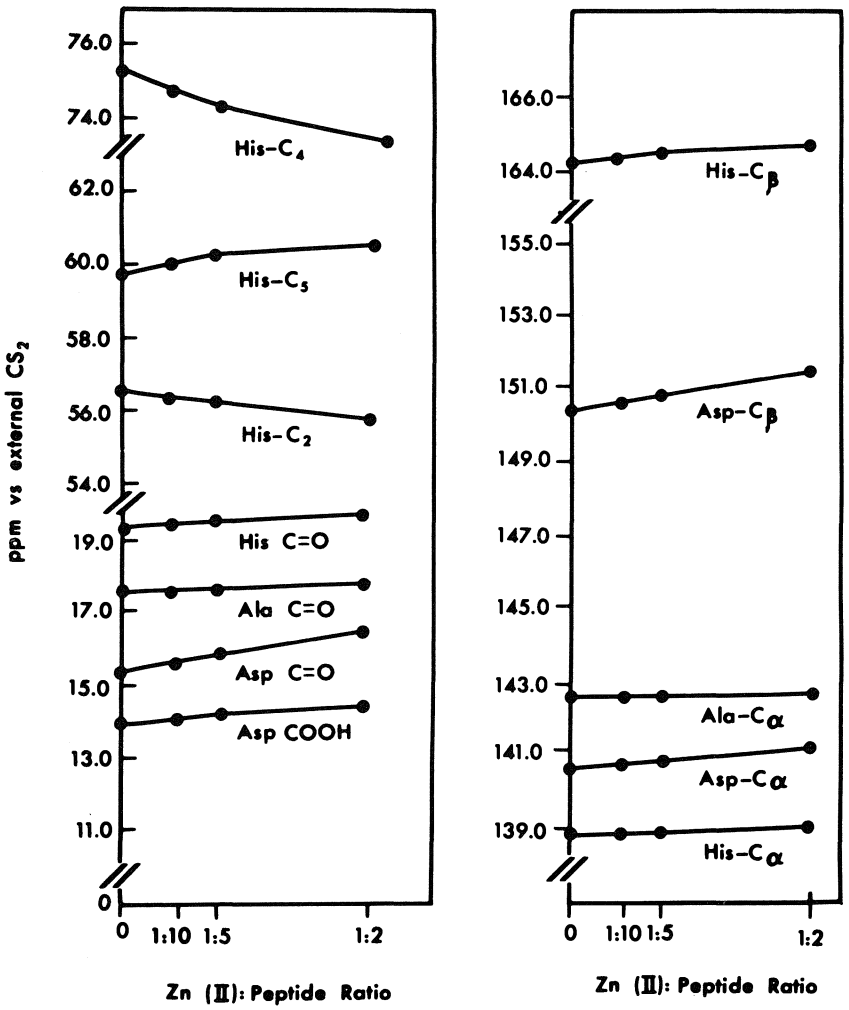

FIG. 4. Variations in chemical shifts of carbon atoms of L-Asp-L-Ala-L-His-*N*-methylamide as a function of added Zn(II) nitrate at pH = 9. Data were collected on samples containing 55 mg/mL peptide in D_2O solutions. Values of pH (uncorrected for D_2O) were adjusted as required after additions of $Zn(NO_3)_2$ with KOD. Chemical shifts of resonances due to Ala C_β (ca. 176.5 ppm) and His-*N*-methylamide (ca. 166.5 ppm) were essentially unchanged over this range of Zn(II) additions.

Discussion

Chemical shift data for AAHNMA at pH 7 (Fig. 3) demonstrate that His imidazole carbon resonances change positions over a wide range of Zn(II) additions (0 to 1:1), consistent with the suggestion that Zn(II) binding involves the histidyl side chain. The apparent lack of complex formation inferred from T_1 data at pH 4 (where the His imidazole ring is essentially protonated) supports this suggestion. Data on Gly-Gly-His-*N*-methylamide (as summarized in Figs. 6 and 7) indicate that Zn(II) also binds to this peptide, with His imidazole again a site of strong interaction.

One crucial difference between spectral effects noted with GGHNMA (vs. AAHNMA) is the downfield shift (ca. 6 ppm, Fig. 7) of the GGHNMA *N*-terminal Gly carbonyl resonance over the range of added Zn(II). (In the AAHNMA case, the Asp carbonyl shifts ca. 1 ppm downfield between 1:2 and 1:1 Zn(II)–peptide ratios.) Such an effect is likely the result of metal-assisted deprotonation of the GGHNMA Gly-*N*-terminal amino group at pH 7, and implicates the amino group as a site of direct Zn(II):GGHNMA interaction. These findings lead to the conclusion that *in AAHNMA it is the Asp carboxylate rather than the Asp amino terminal group which serves as a Zn(II) coordination site.*

The overall drop in NT_1's by factors of 5–6 (Table 1) in several AAHNMA carbons suggests that complexation results in a restriction of segmental motion throughout much of the peptide, most likely due to an induced order accompanying

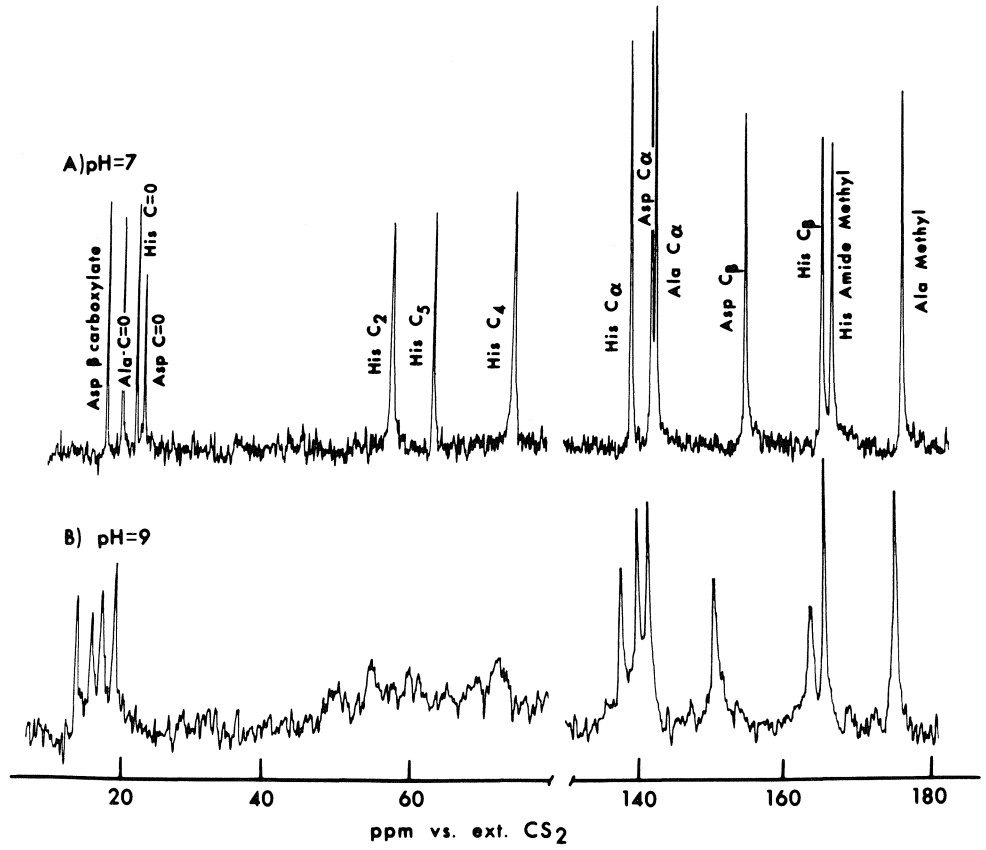

FIG. 5. Carbon-13 nmr spectra (25 MHz) of L-Asp-L-Ala-L-His-*N*-methylamide + Zn(II) nitrate (*a*) at pH = 7, and (*b*) at pH = 9. The ratio of Zn(II):peptide in both spectra is 1/2. Concentration: ca. 55 mg/mL in D_2O. See text for a further discussion of these spectra.

binding which tends to stabilize the peptide in its binding conformation. In fact, the NT_1 data suggest rigidification of a large portion of the tripeptide carbons, including the imidazole ring, His C_α, His C_β, Ala C_β, Asp C_α, and Asp C_β (see Fig. 1). In structural terms, these results suggest that in the Zn(II):AAHNMA complex, the Zn(II) binds the peptide at liganding sites located at opposite ends of the molecule (in effect, bridging them to form a closed loop). The fact that the Asp side chain C_β carbon experiences the same relative decreases in NT_1's as several of its neighboring carbons is consistent with the binding of Zn(II) to the Asp side chain carboxylate group. Since nitrogen-type coordination sites (34, 35) and oxygen-type sites (8, 9) both occur widely in Zn(II) chemistry, the preference for Zn(II) to bind the AAHNMA Asp carboxylate group rather than the Asp α-amino group may reflect a greater affinity at pH 7 of Zn(II) for the negatively-charged carboxylate group rather than the (still protonated) α-amino group.

Aspects of AAHNMA NT_1 data (Table 1) indicate that the predominant species at pH 7 may have a stoichiometry of one Zn(II):two peptides. Such a bis-complex is suggested from NT_1's which do not decrease significantly after a 1:2 Zn(II):peptide ratio is reached.[2] The NT_1's observed for the two AAHNMA methyl groups are in reasonable accord with those anticipated on stoichiometric grounds for bis-complex formation; note that these groups are external to the rigidified array of carbons which would be bridged by Zn(II) complexation. However, chemical shift data for the Zn(II):AAHNMA

[2]The necessity of recording T_1 data at relatively high peptide concentrations (ca. 100 to 150 mg/mL) probably gives rise to species of stoichiometry higher than might be the case for more dilute solutions or under physiological conditions. By comparison, analytical potentiometric analysis of the Zn(II):AAHNMA system, performed at concentrations of [Zn(II)] = 0.046 m*M* and [AAHNMA] = 0.44 m*M* (compared with [AAHNMA] = 300 m*M* in nmr experiments) over the pH range ca. 6–8, indicates that two predominant species are present: a 1:1 Zn(II):AAHNMA complex which accounts for 60% of bound Zn(II) at pH 7, and a 1:2 Zn(II):AAHNMA complex which accounts for 40% of bound Zn(II) at pH 8 (22).

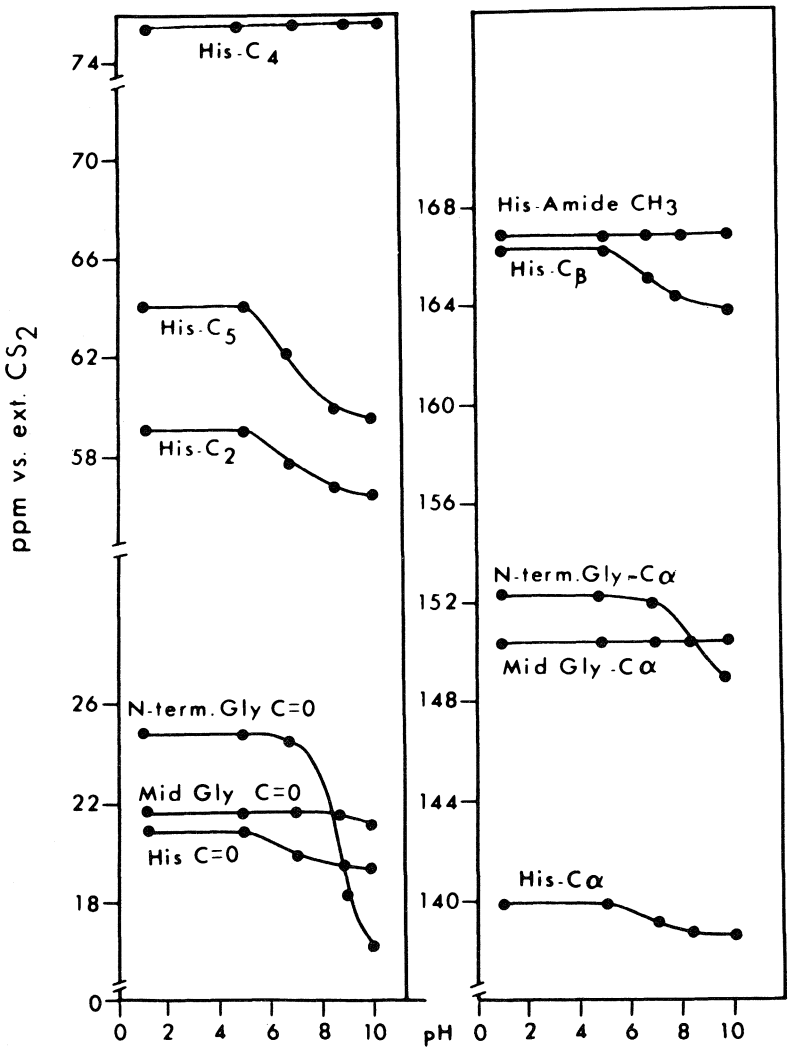

FIG. 6. Dependence of carbon-13 resonances of Gly-Gly-L-His-*N*-methylamide on pH over the range 2–10. Data were collected on samples containing 100 mg/mL peptide in D_2O solutions. Values of pH are uncorrected for D_2O.

system (Fig. 3) suggest that the peptide undergoes a "titration" process (chemical shifts change ca. 1 ppm) between 1:2 and 1:1 Zn(II):peptide ratios. This may be a spectral manifestation of the conversion of some bis-species to 1:1 Zn(II):AAHNMA species with increasing Zn(II) concentration, and/or the interaction of added Zn(II) atoms with the AAHNMA free α-amino group which would still be available as a ligating site.

From the overall chemical shift data, and model building studies, one may infer a possible structure for the Zn(II) complex with AAHNMA, in which Zn(II) is coordinated to each AAHNMA molecule at two sites: the imidazole nitrogen atom of the His residue and the carboxyl group of the Asp residue. Remaining coordination sites would be occupied by solvent molecules. If indeed the bis-complex is the predominant stoichiometric species in the present experimental system, carbon-13 spectra indicate that the two component peptide molecules are geometrically symmetric on the nmr time scale at probe temperature; the data do not provide direct information concerning the spatial relationship, or dihedral angles of individual peptide chains. In the bis-complex, models suggest octahedral coordination for the Zn(II) atom; the tetrahedral bis-complex was found to be sterically unwieldly with the above four (two His, two Asp) ligands coordinated. Sites of Zn(II):peptide coordination remain the same, regardless of whether the stoichiometry of the complex is one Zn(II):one peptide or one Zn(II):two peptides.

If the peptide binds Zn(II) through His imidazole and Asp carboxyl groups only, the chelate ring size

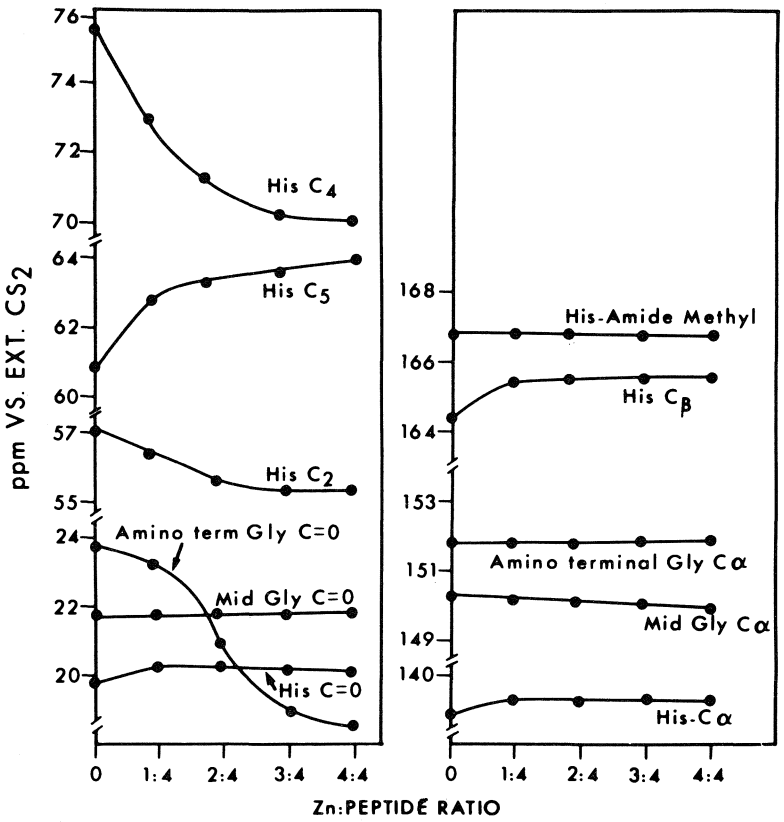

FIG. 7. Variations in chemical shifts of carbon atoms of Gly-Gly-L-His-*N*-methylamide as a function of added Zn(II) nitrate at pH = 7. Data were collected on samples containing 100 mg/mL peptide in D_2O solutions. Values of pH (uncorrected for D_2O) were adjusted as required after additions of $Zn(NO_3)_2$ with KOD.

is rather large (13-membered). Since the stability of a chelate complex generally decreases as the size of the chelate ring increases (36), it is possible that one (or more) of the intervening potential ligand atoms on the peptide may also stabilize the complex via Zn(II) binding (although no experimental manifestation of this possibility emerged from the nmr data). Alternatively, the free peptide itself, containing substituents with a variety of charge and bulk, may possess a narrow range of allowed conformations in solution. This could include a particular set of conformers where proximity of carboxylate and imidazole groups facilitates Zn(II) binding even though the resulting ring size may be large.

The sequence of 584 amino acids of human serum albumin (37, 38) contains 16 His residues and 100 carboxylic acid residues (39 Asp's; 61 Glu's). Although the globular nature of transport proteins obviously does not preclude the proximity of functional groups from sequentially-distant amino acids, only twice in the protein does the combination occur of a side chain carboxyl group and a His residue separated by one intervening amino acid: the *N*-terminus and in a Asp-Glu-His triad (residues 35–37) (or Glu-Asp-His (21)). Note that this triad can bind Zn(II) in the manner deduced herein for AAHNMA, whether it occurs at the N-terminus or at interior portions of the protein sequence. The contrasting results determined by ^{13}C nmr for Zn(II) binding with AAHNMA, vs. its binding with a peptide lacking the side chain carboxyl group, GGHNMA, support the possibility of involvement in Zn(II):serum albumin binding of the side chain carboxyl group of Glu or Asp residues when they occur in a 1–3 relationship with His residues.

Theoretical study of magnetic susceptibilities of small molecules by SCF-LCAO-MO-MINDO/3 method

PRABHAT K. K. PANDEY AND P. CHANDRA

Department of Chemistry, Banaras Hindu University, Varanasi-221005, India

Received March 27, 1979[1]

PRABHAT K. K. PANDEY and P. CHANDRA. Can. J. Chem. **58**, 767 (1980).

Magnetic susceptibilities of small hydrocarbons and water are calculated by employing gauge-invariant atomic orbitals within MINDO/3 approximation. A comparison with available INDO calculations indicates that MINDO/3 gives reasonable values for diamagnetic contribution, but in general overestimates the paramagnetic contribution to magnetic susceptibility.

PRABHAT K. K. PANDEY et P. CHANDRA. Can. J. Chem. **58**, 767 (1980).

On a calculé les susceptibilités magnétiques des petites molécules d'hydrocarbures et de l'eau en utilisant un étalon invariable d'orbitales atomiques à l'intérieur d'une approximation MINDO/3. Une comparaison avec les calculs INDO disponibles indiquent que MINDO/3 donne des valeurs raisonables pour la contribution diamagnétique, mais surestime en général la contribution paramagnétique à la susceptibilité magnétique.

Introduction

The general theory of magnetic susceptibilities was first developed by Van Vleck (1) using Raleigh–Schrodinger perturbation theory up to second order. Further developments in these calculations were hampered because of the lack of the knowledge of the excited state wavefunctions although there have been quite a few attempts in this direction employing average energy approximation (2). In recent years few *ab initio* calculations utilizing both variational (3) as well as SCF perturbation theories (4) have been carried out. Ditchfield *et al.* (5) and Arrighini *et al.* (6) have used minimal and fairly extended basis sets, respectively, in their calculations. Their calculated results agree only moderately well with experiments. Moreover, these results were dependent on the choice of the origin of the coordinate system. The use of gauge-invariant atomic orbitals (GIAO's) avoids these difficulties and an SCF perturbation theory along these lines was developed by Davies (7) and by Hall and Hardisson (8), but their formulation was restricted to π-electron systems only. All these theories constitute the basis of an extensive review by Ditchfield (9). The general SCF perturbation theory of magnetic susceptibilities using GIAO's was first proposed by Ditchfield (10) and by Hall (11). The theory at *ab initio* level (12) is fairly complicated and costly to implement even for small molecules. We have, therefore, employed MINDO/3 (13) approximation within the framework of above theory and have compared the results with those obtained (14–16) by CNDO and INDO approximation (17). This study was a part of our plan of studying various molecular properties (18), e.g. dipole moments, dipole moment derivatives (19), esr isotropic hyperfine couplings (20), and nmr spin–spin couplings (21) employing MINDO/3 approximation.

[1]Revision received December 3, 1979.

Theory

The details of MINDO/3 approximation (13) and those of magnetic susceptibility calculations are described elsewhere (9, 10, 15). Employing GIAO's together with London's approximation (22), we obtain the following expressions for magnetic susceptibility in terms of its components (15).

$$[1]\quad (\chi)_{zz} = (\chi^{p})_{zz} + (\chi^{d})_{zz} = (\chi)_{zz}(\text{local}) + (\chi)_{zz}(\text{non-local})$$

$$[2]\quad (\chi)_{zz}(\text{local}) = (\chi)_{zz}(\text{intra}) + (\chi)_{zz}(\text{cross})$$

$$[3]\quad (\chi)_{zz}(\text{non-local}) = (\chi^{d})_{zz}(\text{inter}) + (\chi^{p})_{zz}(\text{two-centre})$$

$$[4]\quad (\chi^{p})_{zz}(\text{two-centre}) = (\chi^{p})_{zz}(\text{inter}) + (\chi)_{zz}{}^{R}(\text{cross})$$

$$[5]\quad (\chi)_{zz}(\text{intra}) = (\chi^{d})(\text{intra}) + (\chi^{p})(\text{intra})$$

where

$$[6]\quad (\chi^{d})_{zz}(\text{intra}) = -\sum_{A}\sum_{\mu\nu}^{A} P_{\mu\nu}{}^{(0)}(H_{\mu\nu}{}^{(2,0)})_{zz}$$

$$[7]\quad (\chi^{p})_{zz}(\text{intra}) = -\sum_{A}\sum_{\mu\nu}^{A} (P_{\mu\nu}{}^{(1)})_{z}{}^{L}(H_{\mu\nu}{}^{(1,0)})_{z}$$

$$[8]\quad (\chi^{d})_{zz}(\text{inter}) = -\sum_{A>B}\sum_{\mu}^{A}\sum_{\nu}^{B} P_{\mu\nu}{}^{(0)}(H_{\mu\nu}{}^{(2,0)})_{zz}$$

C_2H_2	−19.03 [−19.04]	11.33 [12.17]	1.08 [1.08]	0.0 [0.0]	0.0 [0.0]
C_2H_6	−24.43	10.40	0.13	−2.51	8.15
cyclo-C_3H_6	−32.54	17.09	−0.19	−4.57	16.29
H_2O	−8.82	4.08	1.78	−0.02	0.0

[9] $$(\chi^p)_{zz}(\text{inter}) = -\sum_{A>B}\sum_{\mu}^{A}\sum_{\nu}^{B}(P_{\mu\nu}{}^{(1)})_z{}^R(H_{\mu\nu}{}^{(1,0)})_z$$

[10] $$(\chi)_{zz}{}^L(\text{cross}) = -\sum_{A}\sum_{\mu\nu}^{A}(P_{\mu\nu}{}^{(1)})_z{}^R(H_{\mu\nu}{}^{(1,0)})_z$$

[11] $$(\chi)_{zz}{}^R(\text{cross}) = -\sum_{A>B}\sum_{\mu}^{A}\sum_{\nu}^{B}(P_{\mu\nu}{}^{(1)})_z{}^L(H_{\mu\nu}{}^{(1,0)})_z$$

$P_{\mu\nu}{}^{(0)}$ being the unperturbed density matrix. The perturbed density matrix $P_{\mu\nu}{}^{(1)}$ is obtained by using SCF perturbation theory. The matrix elements of $H_{\mu\nu}{}^{(1,0)}$ and $H_{\mu\nu}{}^{(2,0)}$ are obtained following the procedure outlined by Ditchfield (9).

Results and Discussion[2]

The experimental geometries were employed in our calculations. In ethane, ethylene, and acetylene the C—C bond axis was chosen to be z-axis with origin at the centre of the C—C bond. Ethylene molecule was assumed to lie in x–z plane. In cyclopropane, the ring was assumed to lie in x–y plane with origin at the centre of one of the C—C bonds which was assumed to be along the x-axis. Water molecule was taken in x–z plane with origin at oxygen atom and the z-axis being the C_2-axis.

The calculated values of MINDO/3 magnetic susceptibilities for various molecules are presented in Tables 1 to 4. Wherever possible, INDO values are listed for comparison and are given in parentheses. We have also repeated MINDO/3 calculations with hydrogen orbital exponent, $\zeta_H = 1.0$, for two molecules, and these values are given in square brackets in each table.

Table 1 lists the diamagnetic and paramagnetic contributions to susceptibilities in xx, yy, and zz directions. In most of the cases (except ethylene) considered, it is seen that whereas MINDO/3 and INDO diamagnetic contributions are comparable, the MINDO/3 paramagnetic contributions to susceptibilities are invariably larger compared to their INDO counterparts. Thus although MINDO/3 predicts all the molecules studied to be diamagnetic in agreement with experiment (23) the total susceptibilities are less negative compared to the calculated INDO values as well as experimental data. On the other hand INDO values are seen to be in fair agreement with experiment.

Table 2 lists one- and two-centre contributions to the magnetic susceptibilities as defined in eqs. [6] to [11]. It is clear from this table that the major contribution to susceptibilities comes from one-centre terms. This can be better visualized by a glance at Table 3, which shows that the local contributions account for about 90% of the total susceptibilities. An atomwise analysis of susceptibility data is presented in Table 4, which again shows the dominance of intra atomic terms (χ^d)(intra) and (χ^p)(intra) over cross contributions. These conclusions of MINDO/3 calculations are in agreement with those of the INDO calculations.

In order to understand the difference between MINDO/3 and INDO susceptibilities, it is worthwhile to examine the orbital energies of these molecules as obtained by the above two approximations. These orbital energies, for three molecules, are shown in Fig. 1. As is obvious from this figure, the separation of various occupied orbitals in MINDO/3 and INDO methods are comparable, although INDO orbital energies are consistently lower than MINDO/3 orbital energies. The diamagnetic contribution to the magnetic susceptibility which depends only on unperturbed density matrix (which in turn depends upon occupied orbitals only) are thus comparable in the two methods. The χ^d for CH_4 is −13.4 and −15.6 in MINDO/3 and INDO respectively (Table 1). Similar trends are observed in other molecules given in Table 1. We also carried out INDO calculations on CH_4, C_2H_4, and C_2H_2 molecules and find perfect agree-

[2]All susceptibility values are given in units of (erg G^{-2} mol^{-1} × 10^{-6}). The conversion factor to SI unit (m^3/mol) is 10^{-12}.

ment with Ditchfield's (9) reported values except in the *yy* component of ethylene where our INDO value turns out to be $(\chi^d)_{yy} = -21.36$ and $(\chi^p)_{yy} = 27.23$ in contrast to the values reported in ref. 9 ($(\chi^d)_{yy} = -24.5$ and $(\chi^p)_{yy} = 6.8$). The reason for this discrepancy is not clear.

It is also seen from Fig. 1 that the separation of virtual orbitals from occupied orbitals is smaller in MINDO/3 compared to that in INDO method. Furthermore, MINDO/3 virtual orbitals are more closely spaced than INDO virtual orbitals. The paramagnetic contribution to the susceptibility depends on first order density matrix. The calculation of perturbed eigenvectors and hence perturbed density matrix involves terms containing $(\varepsilon_l^{(0)} - \varepsilon_j^{(0)})^{-1}$, where $\varepsilon_l^{(0)}$ and $\varepsilon_j^{(0)}$ refer to energies of *l*th unoccupied and *j*th occupied orbitals, respectively. Since these quantities are much larger in MINDO/3 than in INDO, the paramagnetic contribution to susceptibilities from these two methods should be very different. This fact is reflected in our calculations where the MINDO/3 paramagnetic susceptibilities are found to be almost always greater than the corresponding INDO values.

In his CNDO calculations of susceptibilities Bley (15) has shown that the calculated susceptibilities were sensitive to hydrogen orbital exponent, ρ_H. We have repeated our MINDO/3 calculations with hydrogen orbital exponent value of 1.0 (instead of usual 1.3) for two molecules and the results are given in square brackets in Tables 1 to 4. These results indicate that MINDO/3 susceptibilities are rather insensitive to hydrogen orbital exponent variation. Bley's (15) calculations further show that CNDO and INDO ($\rho_H = 1.2$) susceptibilities do not differ significantly. Thus these susceptibilities are insensitive to one-centre exchange integrals. Since MINDO/3 and INDO exchange integrals are similar ($(sp|sp)_{INDO} = 0.08924$, $(sp|sp)_{MINDO/3} = 0.08931$, $(pp'|pp')_{INDO} = 0.02085$, $(pp'|pp')_{MINDO/3} = 0.02279$ au, for carbon) the difference in MINDO/3 and INDO calculated susceptibilities cannot be attributed to these integrals.

In conclusion we might say that since virtual orbitals are described rather poorly by MINDO/3, the use of MINDO/3 should be restricted to only those properties which do not require the use of virtual orbitals. These conclusions are further supported from our studies on spin–spin couplings (21).

An examination of parameters describing the dependence of rate constants on temperature for solvolysis of various organic esters in water and aqueous mixtures

MICHAEL JESSE BLANDAMER,[1] ROSS ELMORE ROBERTSON,[2] AND JOHN MARSHALL WILLIAM SCOTT[3]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 30, 1979[4]

MICHAEL JESSE BLANDAMER, ROSS ELMORE ROBERTSON, and JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **58**, 772 (1980).

The consequences are examined of fitting rate constants and temperatures for a solvolytic reaction to the equation $\log k = A/T + B \log T + C$. The coefficients A, B, and C for 150 reactions involving organic derivatives are linearly dependent. Possible mechanistic reasons for this underlying pattern of behaviour are considered. The linearity stems from the least squares analysis used to obtain the coefficients and as a result these quantities are not truly independent. Consequently, the validity of employing this type of analysis based on the three parameter equation is questioned.

MICHAEL JESSE BLANDAMER, ROSS ELMORE ROBERTSON et JOHN MARSHALL WILLIAM SCOTT. Can. J. Chem. **58**, 772 (1980).

On a examiné les conséquences de l'introduction des constantes de vitesse et de la température des réactions de solvolyse dans l'équation: $\log k = A/T + B \log T + C$. Les coefficients A, B et C pour 150 réactions impliquant des dérivés organiques dépendent linéairement les uns des autres. On considère les raisons possibles qui du point de vue du mécanisme expliqueraient ce type fondamental de comportement. Cette linéarité provient de l'analyse des moindres carrés utilisée pour obtenir ces coefficients et il en résulte que ces quantités ne sont pas réellement indépendantes. En conséquence la validité de l'utilisation de ce type d'analyse fondée sur les trois paramètres de l'équation est remise en question.

[Traduit par le journal]

In recent years, Robertson and co-workers (1, 2) have reported first order rate constants, k, as a function of temperature, T, for a range of solvolytic reactions in water and in aqueous mixtures. One of the first (3) features to be identified concerned the curvature of plots of $\log k$ against T^{-1}. This turned out to be a common feature for this class of reactions in water (1), confirming the earlier observation reported by Glew and Moelwyn-Hughes (4). The latter authors described the dependence of k on T in terms of an energy of activation, E_A, and the corresponding temperature coefficient, dE_A/dT. However, Robertson (1) expressed the latter quantity in terms of a heat capacity of activation, $\Delta C_p^{\ddagger}$, derived using transition state theory (5). One aim of this series of studies (1) has been to link the magnitude of $\Delta C_p^{\ddagger}$ (generally negative) with either the nature of the solute undergoing hydrolysis or the effect of added cosolvent (e.g. *tert*-butyl alcohol (6)) on a given solvolytic reaction. The heat capacities, $\Delta C_p^{\ddagger}$, together with corresponding enthalpies, $\Delta H^{\ddagger}$, and entropies, $\Delta S^{\ddagger}$, of activation are calculated from a set of parameters (i.e., A_i, B_i, and C_i) obtained by fitting the dependence of n rate constants at n temperatures for a given reaction i, to eq. [1] where $n \geq 8$

$$[1] \quad \log k_{in} = A_i/T_n + B_i \log T_n + C$$

The justification for using an equation of this form was based on the similarity with the Valentiner equation (7) which has been used extensively to describe the dependence of acid dissociation constants on temperature (8, 9). In practice the kinetic data were fitted to eq. [1] using conventional least squares technique (see below). Then, by invoking the formalism of transition state theory (5) $\Delta C_p^{\ddagger}$ can be calculated (1) from B_i, while at a given temperature $\Delta H^{\ddagger}$ can be calculated from A_i and B_i, $\Delta S^{\ddagger}$ from B_i and C_i. In this paper we do not consider this aspect of the calculation and the assumptions underlying transition state theory. Rather we concentrate attention on the analysis of the raw kinetic data using eq. [1]. We review the reasons which prompted this reconsideration and then consider some of the features associated with fitting the data to eq. [1] which are perhaps not immediately apparent. Finally we comment on the significance of our findings in the context of the analysis of kinetic data for solvolytic reactions in water and aqueous mixtures.

Correlations between Derived Parameters

In this paper, we confine our attention to the data reported by Robertson and co-workers (1, 2). For a given solvolytic reaction i, the first order rate constants at ambient pressure, k_{in}, are the arithmetic mean of 3 or 4 determinations, the overall standard deviation being less than 1%. The temperatures were

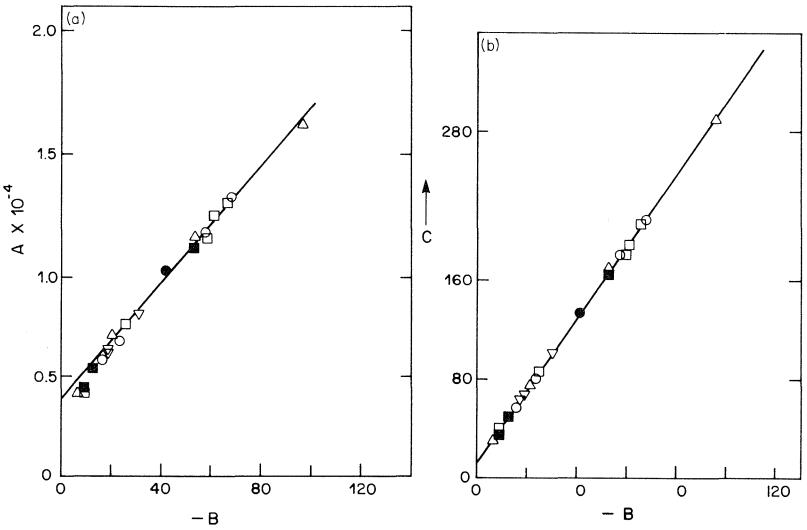

FIG. 1. Derived coefficients for solvolysis of *tert*-butyl chloride in water and in aqueous mixtures; (*a*) plot of A against B and (*b*) plot of C against B; solvent systems are (1) water (●; ref. 10), and aqueous mixtures where the cosolvent is (2) ethyl alcohol (○; ref. 11); (3) isopropyl alcohol (□; ref. 6); (4) *tert*-butyl alcohol (△; ref. 11); (5) acetonitrile (▽; ref. 12); and (6) tetrahydrofuran (■; ref. 11).

measured to a precision better than ± 0.001 K, in the majority of cases, and held constant to better than ± 0.01 K. The rate constants for each reaction were measured over a range >20 K (within the overall limiting range $273.15 \leq T \leq 383$ K) at temperatures which were *roughly* equally spaced but the individual temperatures were not set at predetermined values.

Many of the sets of kinetic data (1, 2) were refitted to eq. [1] using a FORTRAN program for the CDC computers at the Universities of either Calgary or Leicester (England). We were then able to check previously reported values of A_i, B_i, and C_i. In all cases, the agreement was good. Reassessment of eq. [1] was prompted by consideration of the coefficients describing the effects of various cosolvents on the kinetics of hydrolysis of *tert*-butyl chloride in water. We recall that for a given system, the accepted basis for a least square analysis is the independence of the derived coefficients. It was of interest to discover that for the complete set of data describing these solvent effects, the plots of A_i against B_i and C_i against B_i form two straight lines, Fig. 1. Within this pattern there are a number of interesting features which we discuss below. However, even more unexpected was the discovery that the parameters characterizing the solvolysis of 121 organic compounds in water shared a similar pattern. We show a selection of the data points in Fig. 2. There is some slight scatter in the plot of A_i against B_i but the data points in the plot of C_i against B_i fall very close to a straight line, bearing in mind that these parameters cover the following ranges: $-0.4 \times 10^4 \leq A_i \leq -2.93 \times 10^4$; $-194 \leq B_i \leq 19$; $24 \leq C_i \leq 576$. A least squares analysis gave the following two equations for 121 systems.

$$[2] \quad \begin{cases} A_i = (140.0 \pm 4.8)B_i - ((48.4 + 1.7) \times 10^2) \\ C_i = -(2.882 \pm 0.003)B_i + (14.2 \pm 1.2) \end{cases}$$

Indeed, with little change in these standard deviations it is possible to include, in the same correlation, the coefficients for reactions in mixed solvents making a total of 150 systems. It also follows that for these 150 systems, A_i is a linear function of C_i. Since the data cover a wide variety of reactions, mechanisms, and solvent systems, numerous speculations and interpretations are prompted. Such patterns are often sought because they summarize a lot of information in a convenient form. At the same time, however, the question is often raised as to their physical significance. We have in mind here the reevaluation by Exner (14) of isokinetic relationships and similar plots of $\Delta H^{\ominus}$ against $\Delta S^{\ominus}$ for equilibrium parameters. In the present case, we were concerned that the correlations (eq. [2]) were somehow predetermined by the way in which the data were analysed. This is the problem which we address in the remainder of this paper. We have assumed that the input experimental data are correct, but we wish to consider the consequence of using a least square analysis to fit the data to eq. [1].

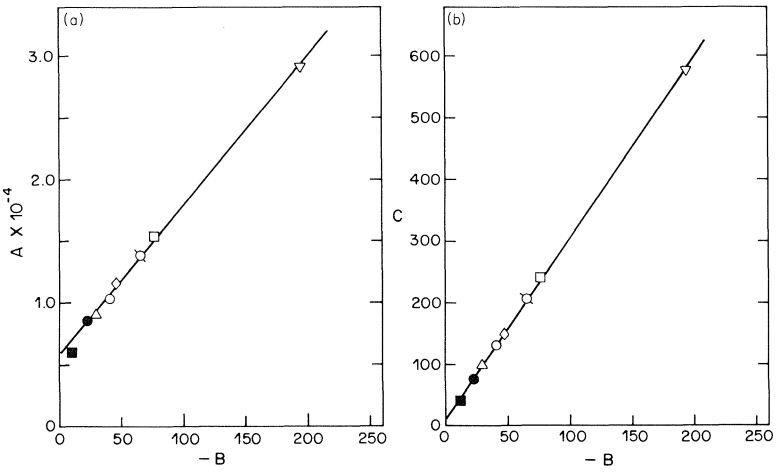

FIG. 2. Derived coefficients for solvolysis of various organic compounds in water; (*a*) plot of A against B and (*b*) plot of C against B; the data points refer to (1) methyl bromide (●; ref. 1); (2) *tert*-butyl chloride (○; ref. 10); (3) 1-adamantyl nitrate (□; ref. 12); (4) 2,4-dimethylbenzyl nitrate (▽; ref. 13); (5) allyl bromide (△; ref. 1); (6) *n*-butylmethane sulphonate (■; ref. 1); (7) 2-chloro-2-bromopropane (◇; ref. 1); (8) 2,6-dimethylbenzyl nitrate (⌀; ref. 13).

Analysis of Analytical Procedures

As a first step, we set up an ideal data set of pairs of rate constants and temperatures: k_1, T_1, k_2, $T_2 \ldots k_n$, T_n. These n points describe the rate data for a given compound in a given solvent at n temperatures, the latter being at constant intervals e.g., 5 K. We now assume that each rate constant is modified by some multiplicative perturbation to produce a new set of rate constants such that $k_{1w} = P_1k_1$, $k_{2w} = P_2k_2 \ldots k_{nw} = P_nk_n$, all being measured at the same n temperatures. Possible origins of these perturbations are discussed below.

If the ideal data set is fitted to eq. [1] using the least squares technique to obtain the three coefficients A, B, and C, then in matrix notation we obtain the following equation.

$$[3]\quad \begin{bmatrix} \sum_n \ln k_i \\ \sum_n \ln k_i \ln T_i \\ \sum_n T_i^{-1} \ln k_i \end{bmatrix} = \begin{bmatrix} A \\ B \\ C \end{bmatrix} \begin{bmatrix} \sum_n T_i^{-1} & \sum \ln T_i & n \\ \sum_n T_i^{-1} \ln T_i & \sum_n (\ln T_i)^2 & \sum_n \ln T_i \\ \sum_n (T_i^{-1})^2 & \sum T_i^{-1} \ln T_i & \sum_n T_i^{-1} \end{bmatrix}$$

We now suppose that the perturbed set of data is fitted to eq. [1], the coefficients A_i, B_i, and C_i being obtained. Then it is readily shown that

$$[4]\quad \begin{bmatrix} x \\ y \\ z \end{bmatrix} = \begin{bmatrix} \Delta A \\ \Delta B \\ \Delta C \end{bmatrix} \begin{bmatrix} \lambda_1 & \lambda_2 & n \\ \lambda_3 & \lambda_4 & \lambda_2 \\ \lambda_5 & \lambda_3 & \lambda_1 \end{bmatrix}$$

where

$$[5]\quad \Delta A = A_1 - A, \Delta B = B_1 - B, \text{ and } \Delta C = C_1 - C$$

and

$$[6]\quad \sum_n \ln P_i = x$$

$$[7]\quad \sum_n \ln P_i \ln T_i = y$$

$$[8]\quad \sum_n T_i^{-1} \ln P_i = z$$

The λ-coefficients are defined as follows

$$[9]\quad \sum_n T_i^{-1} = \lambda_1$$

$$[10]\quad \sum_n \ln T_i = \lambda_2$$

$$[11]\quad \sum_n T_i^{-1} \ln T_i = \lambda_3$$

$$[12]\quad \sum_n (\ln T_i)^2 = \lambda_4$$

$$[13]\quad \sum_n (T_i^{-1})^2 = \lambda_5$$

Standard matrix inversion and manipulation yields

the following equation for the three Δ-quantities

$$[14]\quad \begin{bmatrix}\Delta A\\ \Delta B\\ \Delta C\end{bmatrix} = \begin{bmatrix}x\\ y\\ z\end{bmatrix} \begin{bmatrix}a & b & 0\\ c & 0 & b\\ 0 & c & a\end{bmatrix}$$

where

$$[15]\quad a = (\lambda_4\lambda_1 - \lambda_3\lambda_2)/\text{det}$$

$$[16]\quad b = (\lambda_3 n - \lambda_2\lambda_1)/\text{det}$$

$$[17]\quad c = (\lambda_5\lambda_2 - \lambda_3\lambda_1)/\text{det}$$

and det is the determinant related to the 3 × 3 matrix on the right-hand side of eq. [4]. We note that the quantities a, b, and c depend solely on the temperatures and the value of n. If these do not change irrespective of the form of the perturbation quantities, $P_i \ldots P_n$, we conclude that the quantities det_i, a_i, b, and c are fixed. Equation [14] can be written in linear form

$$[18]\quad \Delta A = ax + by$$

$$[19]\quad \Delta B = cx + bz$$

$$[20]\quad \Delta C = cy + az$$

Equations [18], [19], and [20] can be solved to yield

$$[21]\quad c\Delta A - a\Delta B + b\Delta C = 2bcy$$

This is the required relation which shows that ΔA, ΔB, and ΔC are linearly related to the perturbation variable y or, by other manipulations of [18], [19], and [20], to x and z.

Discussion

The major finding of this work concerns the recognition that the changes in A, B, and C, are linearly related to the perturbation variable y. This further means these changes must be individually related to y or linearly related to each other. It is possible to identify a number of factors described by the perturbation parameters, P_1, P_2, . . . P_n.

With reference to the solvolytic reactions in water, the common denominator is the solvent and the manner in which this solvent plays a key role in the solvolytic reaction (1). In addition, the overall pattern observed between the coefficients A, B, C may indicate that there is a common feature associated with the activation process. Thus we have stressed the role of the solvent in solvating the developing anion formed as the R—X bond stretches on going from the initial to the transition state. Indeed, we have argued that the transition state is characterized by a critical degree of charge development on the developing anion. Through a series of solvolytic reactions in water we can identify the perturbation parameters as describing substituent effects on the alkyl group R. Thus the position of a given point on the A, B, C, vector summarizing the kinetics of solvolysis of a particular solute may be taken as a reference. Data points for other solutes on this vector may be characterized by a δ_R-parameter along the lines suggested by Leffler and Grunwald (15).

A similar analysis to that outlined above may be used to describe medium effects, δ_m (15), with reference to the effect of added cosolvent on the kinetic data for a given solvolytic reaction, e.g. solvolysis of *tert*-butyl chloride in water. It is interesting to note that small amounts of an organic solvent (e.g., *tert*-butyl alcohol) move the parameters A, B, C in a direction which characterizes those cosolvents which initially enhance water–water interactions (16). However, as the mole fraction of these cosolvents increases to beyond a critical mole fraction, there is a breakdown in water–water interactions. The coefficients A, B, and C now move in the opposite direction relative to their values in water. Indeed, the new trend is consistent with the change in coefficients produced when acetonitrile is added, a solvent which operates to disrupt water–water interactions even at low mole fractions (16).

These arguments, based on the importance of substituent or solvent effects on the A, B, and C parameters are tempting and attractive. However, they overlook the original key premise of the least squares analysis, namely that the derived A, B, and C quantities are independent. These quantities are not independent. In fact even if the perturbation quantities P_i describe some consistent or random experimental error, the analysis conspires to produce derived coefficients which are simply related. Clearly we need to reconsider certain aspects of the way in which the kinetic data have been analysed. The key question concerns the extent to which the data can be regressed to obtain a set of independent coefficients. For example, we need to know if such an analysis would significantly alter the values of $\Delta C_p^{\ddagger}$ which have been used in discussions of reaction mechanism. The development of an analytical technique with this essential requirement and applicable to kinetic data will form the basis of another communication from this laboratory.

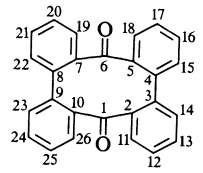
Received October 29, 1979

T. STANLEY CAMERON, CHRISTINE CHAN, DAVID G. MORRIS, and ALISTAIR G. SHEPHERD. Can. J. Chem. **58**, 777 (1980).

The crystals belong to the orthorhombic space group $C222$, with $a = 9.226$, $b = 12.092$, $c = 16.513$ Å, $Z = 4$. A single crystal X-ray diffraction analysis has shown that the title compound, in which all carbon atoms are sp^2 hybridized, exists with the ten membered ring in a slightly twisted tub conformation. The ^{13}C nmr spectrum is also reported.



T. STANLEY CAMERON, CHRISTINE CHAN, DAVID G. MORRIS et ALISTAIR G. SHEPHERD. Can. J. Chem. **58**, 777 (1980).

Les cristaux de la molécule de tétrabenzocyclodécanedione-1,6 sont orthorhombiques avec $a = 9.226$, $b = 12.092$, $c = 16.513$ Å, groupe d'espace $C222$, $Z = 4$. Une analyse par diffraction de rayon-X sur un cristal unique a montré que le composé étudié, dans lequel tous les atomes de carbone sont dans l'état d'hybridation sp^2, a le cycle à 10 atomes sous une conformation bateau légèrement croisée. On donne également le spectre rmn du ^{13}C de la molécule.

[Traduit par le journal]

Introduction

The conformational properties of a large number of medium ring cycloalkanes have been determined by a combination of X-ray diffraction analysis and nmr spectroscopy, aided by strain energy calculations particularly in respect of even-membered rings; within this range of ring size a number of diversely substituted compounds has also been studied (1, 2). These studies have prompted us to determine the solid state conformation of tetrabenzocyclodecan-1,6-dione **1**, chosen because the carbons of the ten-membered ring in particular are all sp^2 hybridized.

1

Experimental

Crystals of **1** were prepared according to ref. 3 and were recrystallized from toluene to fine colourless needles.
Crystal data:

$C_{26}H_{16}O_2$ fw = 360.4
Orthorhombic, $C222_1$, $a = 9.226(1)$, $b = 12.092(4)$, $c = 16.513(3)$ Å, $V = 1842$ Å^3, $Z = 4$, $\rho_c = 1.299$ g cm^{-3} (18 ± 2°C; CuK$_{\alpha 1}$, $\lambda = 1.54051$ Å (graphite monochromator), $\mu = 5.6$ cm^{-1}), $F(000) = 752$.

The crystal system and approximate cell dimensions were determined from Weissenberg photographs. Systematic extinctions $h\,k\,l$, $h + k \neq 2n$, $00l$, $l \neq 2n$ uniquely indicated space group $C222_1$. The cell dimensions were refined on a Picker FACS-1 four circle diffractometer from twelve general reflections with 2θ between 65 and 70°; 802 unique reflections with $2\theta < 120$° measured of which 725 had $I > 3\sigma(I)$. The data were reduced to a common scale by a routine procedure (4) and were corrected for Lorentz and polarization but not for absorption or extinction factors.

The structure was solved by a multisolution application of the tangent formula (5) and was refined by a large block least squares ($\Sigma W(\Delta F)^2 = \min$). The weights were calculated from $W = (\sigma^2|F_o| + 0.000225F_o^2)^{-1}$ where σ is the individual esd for each reflection calculated from the diffractometer counting statistics. This program is part of an X-ray system written by Sheldrick (6). The positions of the hydrogen atoms were determined from a difference Fourier synthesis calculated when the conventional R was 0.12. The subsequent refinement in which the carbon and oxygen but not hydrogen atoms had anisotropic temperature factors used 715 reflections (ten reflections were removed on account of extinction effects) and it converged[2] with $R = 0.039$, $w_R = 0.039$, and $R = 0.068$ for all measured reflections.

The scattering factors were taken from International Tables for X-ray crystallography (7) and were corrected for the anomalous dispersion effect.

Atomic parameters are given in Table 1. Interatomic distances and bond angles are given in Table 2. Figure 1 shows a single molecule and Fig. 2 gives the packing in the unit cell.

Discussion

The crystal is constructed from isolated molecules **1** with each molecule containing one of the C_2 symmetry axes of the unit cell. The presence of this C_2 axis presents a problem for the numbering of the atoms in the compound. By chemical convention

the atoms of the ring should be numbered sequentially first, starting with the carbonyl carbon atom, and then followed by the remaining atoms of the phenyl groups. This gives the numbering scheme shown in **1**. However the two-fold axis bisects the C(3)—C(4) and C(8)—C(9) bonds so that crystallographically C(3) is equivalent to C(4), C(8) to C(9), etc. The chemical nomenclature has been maintained in Table 1 and readers should refer to **1** to establish which are the crystallographically equivalent atoms.

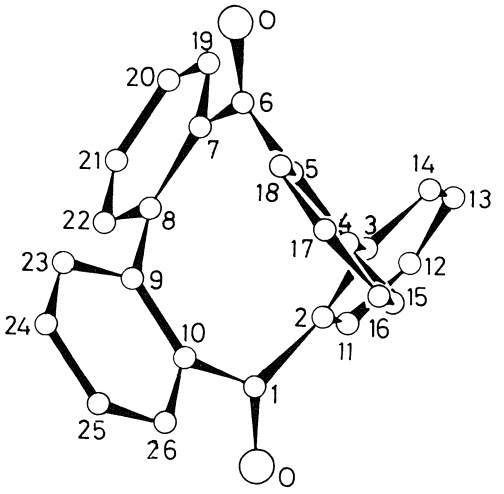

FIG. 1. View of a single molecule.

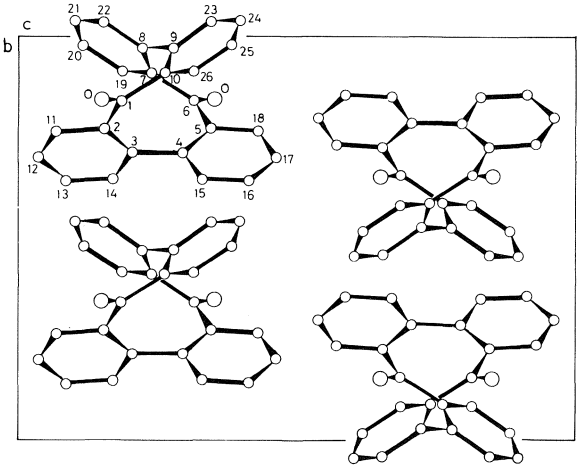

FIG. 2. Unit cell viewed along *a*.

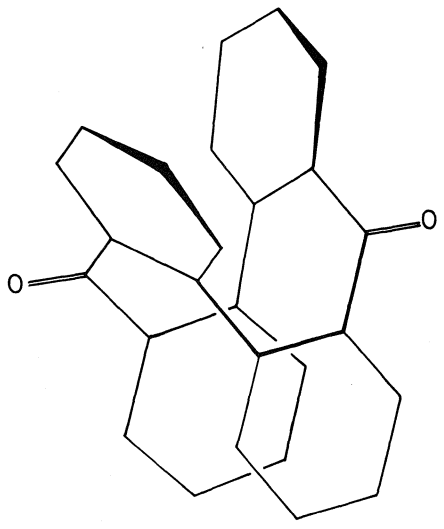
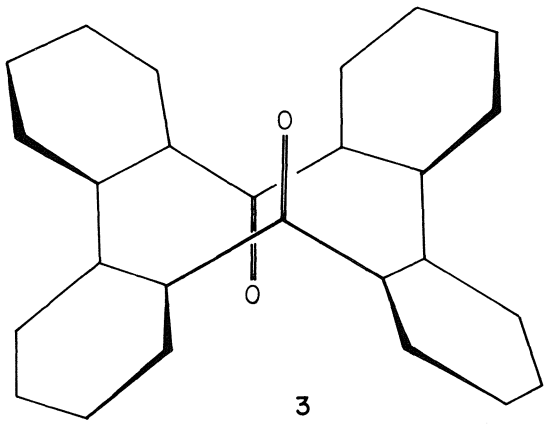


The molecule contains no improper rotation axes and so is optically active. The unit cell too has neither mirror planes nor inversion centres and therefore the sample appears to be an example of the spontaneous resolution of optical isomers (8).

The planes of the two phenyl rings connected by C(3)—C(4) and by C(8)—C(9) are inclined at a mean angle of 84(2)° and the planes of the phenyl groups are inclined at a mean angle of 39(2)° to the plane of the carbonyl group. Within the ten-membered ring, there are three distinct types of carbon–carbon bonds; two biphenylic bonds link the phenyl groups, four phenone bonds join the phenyl and carbonyl groups, and finally there are four aromatic bonds which are also part of the phenyl rings. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



two biphenylic bond lengths are both 1.506(5) Å and compare with 1.496(3) Å in biphenyl itself (9) where the two rings are co-planar and with mean values (10) of 1.496(5) and 1.498(5) Å in the two forms of 9,10,19,20-tetrahydrobenzo[*a*,*c*,*g*,*i*]-cyclododecane where the planes of the rings are inclined at 85° and 63° respectively. The two unique phenone C—C bond lengths are 1.498(5) and 1.499(5) Å. These are not significantly different from those observed (11) in benzophenone (mean 1.48(2) Å) where the carbonyl and phenyl planes are each inclined at 30°. The endocyclic phenyl C—C bond lengths are 1.396(5) and 1.394(5); these are towards the long end of the range of C—C lengths (1.410(5)–1.371(5) Å) found in these phenyl groups but the distinction is not significant. Similarly the carbonyl C=O length of 1.215(5) Å is unexceptional.

A close known structural analogue (10) for the compound is 9,10,19,20-tetrahydrobenzo[*a*,*c*,*g*,*i*]-cyclododecane. The unit cell of the dodecane however does possess an inversion centre and so both optical isomers are present in the one cell. A second crystal form of the dodecane is known (10), in this case the molecule adopts a different conformation and is itself centrosymmetric. The conformation of the ten-membered ring **1** is a slightly twisted "tub" (**2**) with the carbonyl dipoles

2

oriented in opposite directions. An examination of a molecular model suggests that a *meso* form is also possible for the present compound (**3**); this conformation has a mirror plane along the two C=O bonds and has an inversion centre in the middle of the ring. A rough physical measurement on the model suggests that the planes of the phenyl and carbonyl groups would be mutually inclined at 65° and there are no severe non-bonded hydrogen interactions. Thus there seems to be no intrinsic reason why the

3

meso form cannot be prepared; so far, however, it has not been observed.

The ^{13}C nmr spectrum of **1** has been determined (Varian XL100, 0.1 *M* in $CDCl_3$). A single set of signals is obtained at 197.74 C(1), C(6) with aromatic absorptions at 140.20(s), 138.47(s), 130.94(d), 130.24(d), 129.64(d), and 127.97(d) ppm; the parenthesized letters denote multiplicity in the proton noise decoupled spectrum.

Linnett double quartet theory in organic chemistry: structure, reactivity and resonance

RICHARD FRANCIS LANGLER,[1] JUNE ELLEN TRENHOLM, AND JOHN SPENCER WASSON
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 4, 1979

RICHARD FRANCIS LANGLER, JUNE ELLEN TRENHOLM, and JOHN SPENCER WASSON. Can. J. Chem. **58**, 780 (1980).

A reexamination of Linnett's nonpairing spatial orbital theory, as it is qualitatively employed, has led to a number of conclusions. Firstly, in our view the theory has been inconsistently applied to the prediction of molecular geometries and may be ambiguous in dealing with saturated systems. Secondly, it does not provide a guide to chemical reactivity, in contrast to claims made for it. Finally, NPSO theory does provide a useful extension of resonance theory as it is qualitatively employed in organic chemistry, contrary to an existing claim that NPSO theory makes resonance theory obsolete.

RICHARD FRANCIS LANGLER, JUNE ELLEN TRENHOLM et JOHN SPENCER WASSON. Can. J. Chem. **58**, 780 (1980).

Une nouvelle étude de la théorie des orbitales spatiales non appariées de Linnett, telle qu'elle est qualitativement employée, a conduit à plusieurs conclusions. Premièrement, la théorie est à notre avis utilisée indûment à prédire les géométries moléculaires et elle peut être ambigue dans le cas des systèmes saturés. Deuxièmement, la théorie ne constitue pas un guide de réactivité chimique contrairement à ce qui a été dit à ce sujet. Finalement, la théorie OSNA, loin de rendre désuette la théorie de la résonance telle qu'elle est employée qualitativement en chimie organique, en constitue plutôt un prolongement pratique.

[Traduit par le journal]

In 1961 Linnett (1) proposed a new structural theory which he named the Nonpairing Spatial Orbital (NPSO) theory but which is much more frequently referred to as Linnett Double Quartet (LDQ) theory. LDQ theory acknowledges the tendency of the elements in the "First Short Period" to achieve octets in forming stable molecules but presumes that "the importance of the pairing of electrons" has been overemphasized.

LDQ octets are not visualized as four spin pairs occupying four regions in space. Instead an octet is regarded as the sum of two tetrahedral quartets of electrons. A quartet contains electrons of the same spin (one quartet for electrons of spin $+\frac{1}{2}$ and one quartet for electrons of spin $-\frac{1}{2}$). The two quartets are *independently oriented*.

Molecular structures[2] are elaborated by maximizing electronic separations and minimizing electronic repulsions. Priority, it is assumed, must be given to maximizing the separation of electrons having the same spin.

Subsequent to the publication of the parent article a substantial number of papers and books have appeared which present and extend LDQ theory (2–25). NPSO theory has been developed as a valence bond approach to the electronic structure of molecules and provides results which are in excellent agreement with full configuration interaction analyses for π systems in small molecules (24). Apparently LDQ theory is not easily applied to molecules as large as naphthalene (24).

Qualitatively, LDQ theory has been applied to predicting bond lengths, bond angles, stabilities of various species, paramagnetism/diamagnetism of molecules, and regioselectivity in Diels–Alder reactions.

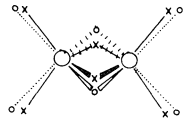
In previous discussions of O_2 (1, 22, 23) three structures[3] have been considered i.e., **1**–**3**. The relative stabilities of these structures, as indeed is the case for all LDQ structures, are assessed by assuming that the electrons are spatially fixed points. The lowest energy structure is that which offers the greatest separation of these fixed point electrons.[4] Structure **1** is assigned to the $^1\Sigma_g^+$ state of O_2 and structure **2** is assigned to the $^1\Delta_g$ state of O_2. Notwithstanding the presence of six "close pairs" in structure **1**, each of which has, at least nominally, an infinite repulsive force operant, **1** is a modest 15.1 kcal/mol higher in energy than **2**. Structure **2**, on the other hand, has a slightly greater total electronic repulsion than structure **3** but is supposed to be 22.6 kcal/mol higher in energy than **3**.[5] Thus analysis of apparent electronic separations is qualitatively helpful but can be somewhat misleading quantitatively.

The construction of LDQ structures for molecules is approached by developing separate structures for the molecule under consideration: one

[1]Correspondence should be directed to Dr. R. F. Langler, Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0.

[2]The role of the nuclei is ignored.

[3]We have adopted Linnett's convention of using x and o to represent electrons of opposed spins.



[4]Luder (23) has used Coulomb's law to evaluate the stabilities of the various O_2 structures.

[5]From time to time one or both quartets have their centres shifted from the nucleus (1, 10*b*), viz. structure **3**. This device has received no comment from the advocates of LDQ theory and no rules have been proposed for its use in qualitative structural deductions.

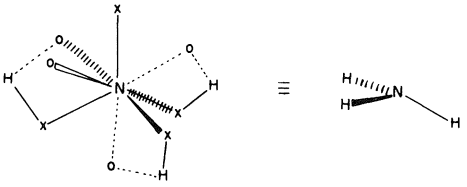
structure has only x electrons and the other has only o electrons. The two component structures for NO_2 are shown as **4** and **5**. Structure **4** requires an ONO angle of 180° while structure **5** requires an ONO angle of 125°. While the conclusion that the ONO angle is between 125–180° is not very precise, LDQ structures commonly offer reasonable bond angle predictions. A comparison of some predicted bond angles made by LDQ theory and by Pauling's hybridization approach are presented in Table 1. It should be noted that Linnett's restriction of LDQ theory to compounds primarily involving elements of the "First Short Period" makes it less useful than either Pauling's approach (26) or Gillespie's VSEPR theory (27). Although Luder (23) has extended LDQ theory to deal with geometries more complex than the tetrahedron, he has made no systematic attempt to compare predicted bond angles with observed bond angles in real molecules.

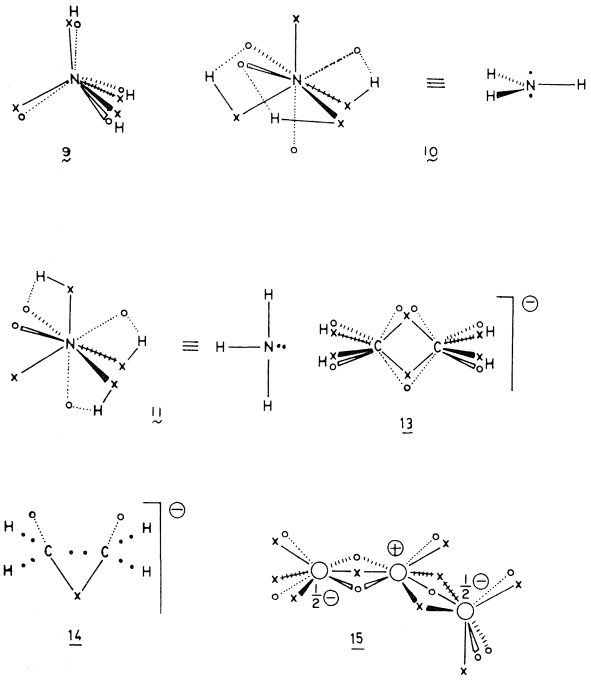
Structure and Reactivity



LDQ theory provides models for the repulsion minimized arrangement of sets of electrons which have the same spin viz. doublet (linear), triplet (trigonal planar), quartet (tetrahedral), quintet (trigonal bipyramidal), and sextet (octahedral). In this way repulsive interactions between electrons of the same spin are always minimized. To deduce molecular structures one must find the arrangement for the two valence shell spin sets which minimizes repulsions between them without altering the basic geometry for each spin set since "distortions will result in an increase of energy" (1).

Therefore the LDQ structures for Ne, F^-, O^{2-}, N^{3-}, and C^{4-} locate each valence electron in a corner of a cube which maintains the tetrahedral arrangement of each spin set while optimizing the separation of the two quartets (see structure **6**). Similarly the double singlet of $H:^-$ would be linear (as depicted by Luder for the double singlet of Be (10)). One would then expect to draw structure **7** or structure **8** as repulsion minimized LDQ structures for methane. Linnett (1) suggests that the x and o quartets should be superimposed, thus introducing four "close pairs" and facilitating the choice of tetrahedral geometry for methane, although such a procedure has "some resulting increase in inter-electron repulsion energy" (1). Since, for O_2 the best structure i.e., **3** was selected on the grounds that "the electrons, on an average, are more widely separated" (1), the choice of **7** or **8** for methane would seem to be more readily made than would be the case if the electrons were "close paired" first. Structure **8** could then be selected on the grounds that it reduces internuclear repulsions between the protons.

An analysis of possible structures for ammonia would bring one to the choice between **10** and **12** in a self-consistent way. The difficulty of selecting **12** over **10** is not tied to LDQ theory since commonly recognized structural features such as internuclear

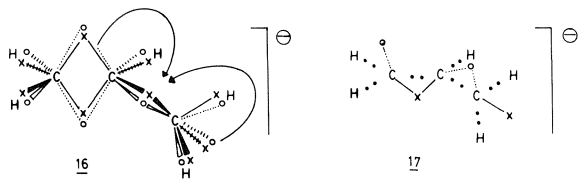


8

12

TABLE 1. Bond angles

Compound	Angles	Pauling prediction	LDQ prediction	Actual angle (Reference)
O_3	OOO	120°	125°	117° (22)
HCO_2H	OCO	120°	120–125°	123° (27)
CH_3N_3	CNN	120°	125°	120° (27)
NO_2	ONO	120°	125–180°	134° (27)
H_2CCH_2	HCH	120°	109°	117° (26)
H_2CCH_2	HCC	120°	125°	121° (27)



repulsions/steric effects dictate the incorrect choice of **10** independent of the bonding theory applied. In fact this approach to the use of LDQ structures would better prepare one for the information that amines are optically unstable, racemizing through a low energy trigonal transition state. Furthermore, it overcomes the difficulty of assuming that the lone pair is initially "close paired" and separates somewhat after formation of the ammonia molecule (13).

A similar analysis for water avoids the necessity to assume separation of "close pairs" after molecular formation (13).

In many cases LDQ structures must have σ bonding electrons spatially separated. For example, the one-electron reduction of ethylene would furnish a radical anion which could have the LDQ structure **13**. Such a structure is completely unacceptable, requiring, as it does, three spatially coincident electrons (two of which must have the same spin!). Separation of the electrons in the σ bonds would provide some release of the intolerable electronic repulsions in **13** (see **14**).

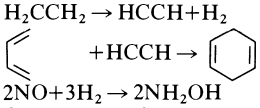
Ozone has a structure which is easily deduced from LDQ theory (structure **15**). Since the allyl anion is isoelectronic with O_3, Linnett (22) has suggested that they have the same structures. However, if the σ bonds have "close paired" electrons a structure for the allyl anion analogous to that for ozone is precluded. Instead the allyl anion would have structure **16**. Close pairing of the bonding electrons in **16** makes it physically impossible, in terms of a model, for the central carbon atom to share three electrons with each terminal methylene.[6] Again separation of the bonding electrons permits an electronically viable structure, viz. **17**.

Electronic separations in two-electron bonds are commonly assumed in cationic structures, viz. $H_2S_2^+$. It should be noted that such electronic separation in two electron bonds distorts the geometry somewhat.

Reactivity

Linnett has suggested that some chemical reactions may be understood in terms of the resistance that species with "remote pairs" might have to the formation of products which require "close pairs". Several examples have been advanced (1, 22).

[1] $2NO \rightarrow ONNO$ $\quad \Delta H > 0$



[2] $3(^1\Sigma_g^+O_2) \rightarrow 2O_3$ $\quad \Delta H < 0$

[3] $2(CH_3)_2CO \rightarrow C(CH_3)_4 + CO_2$ $\quad \Delta H < 0$

[6] The position of the electrons in structure **16** is indicated in the standard way. The arrows show where the electron and the orbitals should be if there are to be two CC bonds of bond order 1.5 each.

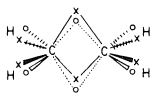
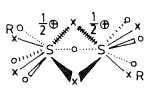
TABLE 2. ΔH predictions based on electronic separations

Reaction	ΔCP*	Predicted ΔH	Observed ΔH (kcal/mol)
1. $H_2 + O_2 \rightarrow HOOH$	+6	>0	−32.58
2. $H_2+N_2 \rightarrow HN{=}NH$	+3	>0	+48.7
3. $H_2CCH_2 \rightarrow HCCH+H_2$	−3	<0	+41.7
4. 	+3	>0	−40.8
5. $2NO+3H_2 \rightarrow 2NH_2OH$	+11	>0	−30.8
6. $CO_2+H_2 \rightarrow HCO_2H$	+1	>0	+4.0
7. $2H_2+CH_3CN \rightarrow C_2H_5NH_2$	+3	>0	−31.1
8. $4S_2 \rightarrow S_8$	+24	>0	−98.2
9. $CH_3NC+2H_2 \rightarrow (CH_3)_2NH$	+3	>0	−40.1
10. $H_2+CO \rightarrow H_2CO$	+3	>0	−1.5



*ΔCP represents the change in the number of "close paired" electron pairs: ΔCP > 0 means the reaction creates close pairs and ΔCP < 0 means the reaction results in the separation of close pairs.

In eq. [1], it was argued, the total number of bonding electrons is constant but the formation of ONNO results in the creation of "close pairs" not present in two molecules of NO. The formation of O_3 from the $^1\Sigma_g^+O_2$ state would be exothermic because the product has much greater electronic separation than the starting material. Equation [3] is rationalized in the same way as eq. [2]. Table 2 presents a selection of reactions to which we have applied this type of analysis. The results in Table 2 clearly establish that there is no correlation between the hypothetical change in electronic separations and the ΔH for these reactions.



LDQ theory has been used to predict the relative bond strength of a single species in cases where there are a number of structural possibilities with different bond orders. However, there has been no examination of its implications for bond strengths in related but different ground state molecules. The presently accepted structures for acetylene and ethylene are given as **18** and **19**. Ethane and

18

19

20

ethylene have all bonding electrons "close paired". Acetylene has only the CH electrons "close paired". It should follow[7] that acetylene, which has the greatest electronic separation in the CC bond, has the greatest bond strength per pair of bonding electrons. Moreover ethylene and ethane should have essentially the same CC bond strength per pair of bonding electrons since both compounds have "close paired" CC bonding electrons (requiring a destabilization of 6 kcal/mol for each close pair). In fact acetylene has a CC bond strength of 64.6 kcal/mol per bonding pair, ethylene has a CC bond strength of 73.5 kcal/mol per bonding pair, and ethane has a CC bond strength of 83.1 kcal/mol per bonding pair (27). A similar analysis leads to an erroneous conclusion about the relative CN bond strengths per bonding pair for a carbon–nitrogen triple bond in comparison with a carbon–nitrogen double bond (C≡N, 69 kcal/mol per bonding pair and C=N 73.5 kcal/mol per bonding pair (27)).

The erroneous assumptions implicit in the LDQ structures for CC and CN multiple bonds could be responsible for the failure of the theory to anticipate the signs of ΔH for reactions 3 and 7 (Table 2). It seems likely that these assumptions are at fault as well in at least some of the other cases in Table 2.

If the electrons of the ethylenic four-electron bond were permitted to separate spatially, which could be readily achieved by allowing some separation of the electrons in the CH bonds, then the apparent differences in electronic repulsions for ethylene and acetylene would be removed. The result would be that the LDQ technique for predicting the sign of ΔH would no longer be applicable to reaction 3 in Table 2. An extension to systems containing four-electron bonds involving oxygen and nitrogen would remove still more cases from Table 2.

LDQ theory offers some advantages in rationalizing the stability of some radical cations. For example, structure **20** can be drawn for the disulfide radical cations which are unusually stable radical cations. Two features of these species are immediately clearer from such a structure than would be the case with a structure involving a Pauling "three-electron bond," viz. the bond order of 1.5 for the SS linkage and the equal electron densities of the two sulfur atoms. In structure **20**, as

[7]This conclusion presupposes that electronic correlation is the major factor controlling bond energies.

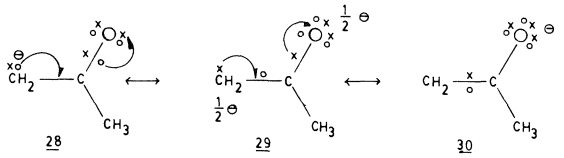
with all LDQ structures where, in MO terms, the HOMO is doubly occupied and the LUMO singly occupied, one antibonding electron and one bonding electron are depicted as two non-bonding electrons. This device causes occasional difficulties as we have shown during the discussion of the ethylene anion (**13**) if one attempts to keep all σ bonding electrons "close paired".

Resonance



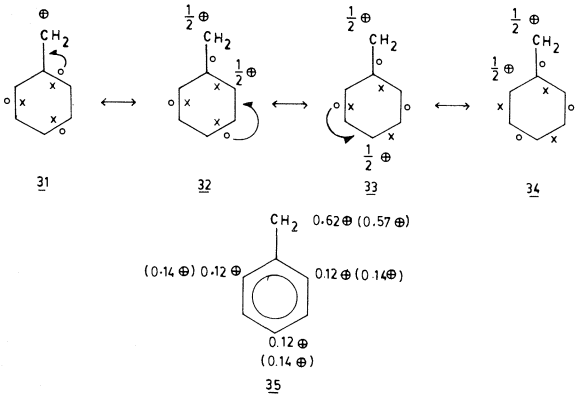
Qualitative utilization of resonance theory, as it is commonly employed, requires the formulation of a structure from which other structures are generated by electron pair delocalization through atomic *p* orbitals. It has proved to be a very powerful tool for understanding molecular structure and chemical reactions.

LDQ theory, it has been claimed (10, 11, 23, 25) reduces the number of resonance contributors describing a given π system. In fact, LDQ theory increases the number of resonance contributors available for the description of real species.[8] For example, the allyl cation is conventionally discussed in terms of the resonance contributors **21** and **22**. LDQ theory adds contributor **23** to the melée.[9] The allyl cation is adequately described electronically by contributor **23** alone. A completely parallel discussion can be advanced for the allyl anion.

The allyl radical would have contributors **24–27** available. In this case the addition of LDQ contributors **25** and **27** adds nothing to the insight offered by the conventional forms **24** and **26**. As a final example of the application of LDQ contributors to qualitative resonance considerations,

we have considered the acetonyl anion (shown as structures **28–30**). In this case the best description of the electronic distribution in the anion would be obtained by utilizing the LDQ contributor **29** and the conventional contributor **30**.

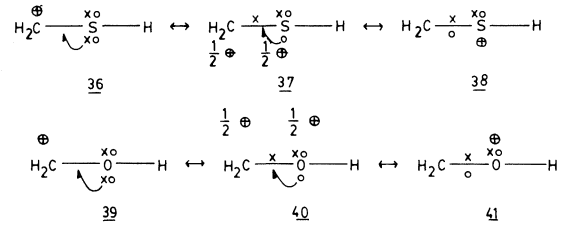
It should now be clear that LDQ contributors do not reduce the number of contributors available to describe π systems and are not systematically superior to conventional contributors. Whether the most useful description of a particular system is obtained by (*i*) LDQ contributors alone, (*ii*) a combination of LDQ contributors and conventional contributors, or (*iii*) by conventional contributors alone depends entirely upon the system under consideration. The advent of LDQ theory has not brought about "the time to abandon the hypothesis of resonance hybrids" (23).



The strength of LDQ theory lies in providing descriptions of the electronic structures of molecules, particularly those with π systems. LDQ resonance contributors offer greater precision than conventional contributors for those systems in which atoms have fractional charges. This greater precision holds the promise of rapid and convenient resonance analyses which are more quantitative than analyses which are presently carried out without the aid of detailed numerical calculations.

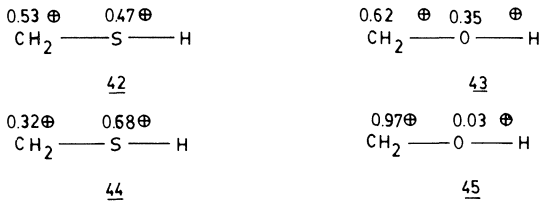
A case in point is provided by the benzyl cation. Conventional resonance contributors depict a full positive charge localized on the benzylic carbon, the *ortho* carbon atoms, and the *para* carbon atom. Quantitatively, the problem then becomes how to assess the relative importance of the various contributors. It is clear that the form with the full charge on the benzylic carbon is the most important contributor since in attaching greater weight to that contributor one minimizes the disruption of the aromatic sextet. LDQ contributors offer a simple way to reduce the disruption of the π system in the ring, thus simplifying the problem of weighing the contributors. Thus equal weight for the contributors **31–34** leads to the conclusion shown in structure **35**. The results of simple HMO calculations for electron densities in the benzyl cation are shown in brackets after the LDQ conclusions.

Unfortunately, greater precision in the representation of resonance contributors does not *ipso facto* result in greater accuracy in the conclusion obtained. Resonance contributors have been widely used in rationalizing the results of chemical reactions. Such analyses frequently presume that the outcome of a reaction is completely dependent



[8]From this point, we shall adopt Linnett's practice of a conventional line to represent two spin paired σ bonding electrons, but we shall retain the xo convention for non-bonding and π electrons.

[9]While contributors such as **21** and **22** can be understood as conventional structures or as LDQ structures, structure **23** is uniquely obtained from LDQ theory. Therefore we shall refer to **21** and **22** as conventional contributors and **23** as an LDQ contributor.



upon the nature of the transition state/intermediate which is described in resonance terms without reference to other features of the reaction (particularly the nature of the solvent involved). The inevitable consequence has been that resonance theory has been used to derive oversimplified descriptions which have introduced errors in the handling of contributors.

A case in point is provided by carbocations substituted by oxygen or sulfur. Two simple systems are shown as structures **36–38** and **39–41**. It has

been suggested that π bonding "should be more effective for oxygen than sulfur because of the more diffused nature of the sulfur orbital" (28). However, it seems likely that this view, which was derived from the results of reactions in solution, is in error. The conclusions of Wolfe and co-workers (29) for the π electron densities, based on a non-empirical SCF–MO treatment of these cations, are shown in structures **42** and **43**; **42** is **37**. Structure **43** can be obtained approximately by equal weighing of contributors **39** and **40**. Thus greater precision and accuracy are available if LDQ contributors are added to the basic set of resonance contributors which are employed in describing a π system. However, if rules are to be developed which permit a general semiquantitative assessment of π systems, it is essential that more theoretical calculations be done.

Finally, resonance contributors which deal primarily with electrons in π systems should lead to conclusions such as **42** and **43**. Often resonance arguments are not accompanied by careful assessment of inductive effects. Such omissions can lead to serious error. Structures **44** and **45** are included to illustrate the drastic alteration of electronic distribution which can result from inclusion of inductive effects.

Effet de cation sur la réactivité ambidente des anions: la nette tendance à la O-alkylation manifestée par les énolates de lithium de composés β-dicarbonylés

P. SARTHOU,[1] G. BRAM ET F. GUIBE[2]

Groupe de Recherche No 12, Centre National de la Recherche Scientifique, B.P. 28, 94320 Thiais, France

Reçu le 27 septembre 1979

P. SARTHOU, G. BRAM et F. GUIBE. Can. J. Chem. **58**, 786 (1980).

L'étude de la réactivité spécifique des paires d'ions d'énolates alcalins de composées β-dicarbonylés montre que les énolates de lithium, en dépit de la forte interaction enolate–cation qui les caractérise, présentent, notamment par rapport à ceux de sodium, une tendance marquée à la O-alkylation. Cette forte O-/C-nucléophilie de la paire d'ion lithium n'est pas sensiblement affectée par la polarité du milieu (du DME ou THF au DMF) mais dépend de la nature du réactif alkylant: elle est maximum lorsque celui-ci est un sulfonate ou un sulfate d'alkyle de réactivité électrophile modérée; elle est atténuée dans le cas des halogénures d'alkyle et des sulfonates d'alkyle très électrophiles (triflates). Il est proposé que la tendance à la O-alkylation manifestée par l'énolate de lithium est pour partie la conséquence d'une interaction Li^+ – groupe partant de l'électrophile (cas des sulfonates notamment) et pour partie une propriété intrinséque de la paire d'ions énolate–lithium; celle-ci est interprétée en terme de pouvoirs de solvatation comparés des états de transition de la C- et de la O-alkylation vis à vis des cations.

Certains des résultats concernant la réactivité nucléophile des paires d'ions dans le DMF sont en désaccord avec des résultats antérieurs de la littérature. Les raisons de ce désaccord sont examinées.

P. SARTHOU, G. BRAM, and F. GUIBE. Can. J. Chem. **58**, 786 (1980).

The study of the specific reactivity of the ion pairs of alkaline enolates of β-dicarbonyl compounds shows that the lithium enolates, in spite of their characteristically strong enolate–cation interactions display, especially when compared to sodium enolates, a marked tendency towards O-alkylation. This strong O-/C-nucleophilicity of the lithium ion pairs is not very sensitive to changes in medium polarity (from THF or DME to DMF) but depends on the nature of the alkylating agent, being enhanced with moderately electrophilic alkyl sulfonates or sulfate but lessened with alkyl halides or with very electrophilic sulfonates (triflate). It is suggested that the lithium enolate tendency towards O-alkylation is partly the result of a Li^+ – leaving group interaction (especially in the case of the sulfonates) and partly an intrinsic property of the enolate–lithium ion pair; this latter property is discussed in terms of the respective solvation abilities towards cations of the C- and O-alkylation transition states.

Some of our results about the nucleophilic reactivity of ion pairs in DMF are at variance with previous reports in the literature. The origin of the discrepancy is discussed.

L'orientation des réactions d'alkylation d'ions ambidents énolate–carbeniate est soumise à différents facteurs: solvant, nature du cation associé, nature du réactif alkylant, etc. (1–8). En ce qui concerne l'effet du cation associé, il est généralement admis que plus forte est l'interaction énolate–cation, plus grande est la tendance à la C-alkylation; ainsi dans la série des énolates alcalins on observe habituellement que le rapport C/O alkylation croit dans l'ordre $N^+R_4 < Cs^+ < K^+ < Na^+ < Li^+$, l'interaction anion–cation étant d'autant plus énergique que la taille du cation est réduite (1–5, 7, 8). Toutefois, en nous intéressant *spécifiquement* à la réactivité des *paires d'ions* nous avons pu montré que l'énolate de lithium de l'acétylacétate d'éthyle conduit, dans le diméthoxyéthane (DME) et avec TsOEt à un rapport C/O alkylation nettement supérieur à ceux des énolates de Na^+ et K^+ et proche de celui de la paire d'ions Cs^+ (9). Cette O-nucléophilie relative importante de l'énolate de lithium a ensuite été confirmée sur toute une série de réactifs alkylants à groupe partant sulfonate ou sulfate (10).

Cette propriété de la paire d'ion lithium ne peut être imputée à un relachement de l'interaction énolate–cation; celle-ci est au contraire considérablement renforcée comme en témoignent par exemple les résultats cinétiques dans le DME (9) qui montrent que l'énolate de lithium de l'acétylacétate d'éthyle est beaucoup moins réactif que l'énolate de sodium vis à vis de TsOEt ou d'autres agents alkylants. Dès 1955, Kornblum *et al.* avait montré (12) que les nitrites d'argent conduisaient avec les halogénures (bromure et iodure) d'alkyle à un rapport O/N alkylation très élevé et interprété ce résultat par une interaction Ag^+-groupe partant halogénure. Par analogie, nous avions proposé (9–10) l'existence d'une interaction lithium – groupe partant tosylate ou sulfate pour rendre compte de nos résultats.[3] Une telle interaction, susceptible d'une part de diminuer d'autant

l'interaction énolate–cation dans l'état de transition et d'autre part de polariser la liaison carbone – groupe partant et de conduire ainsi à une réaction à "caractère S_N1" (12) plus marqué devrait en effet favoriser l'alkylation sur le site le plus électronégatif de l'énolate ambident.

Dans le but de vérifier le bien-fondé de l'explication proposée et de façon plus générale de préciser les facteurs qui déterminent le comportement ambident des formes associées des énolates alcalins (lithium notamment) de composés β-dicarbonylés, nous avons poursuivi notre étude en nous intéressant à la nature du groupe partant de l'électrophile et aux effets de milieu.

Effet du groupe partant de l'électrophile

Il paraissait important tout d'abord de vérifier si la tendance à la O-alkylation de l'énolate de lithium des composés β-dicarbonylés se manifestait seulement vis à vis de réactifs alkylants à groupe partant oxygéné dur tels que sulfonate ou sulfate ou si cette propriété s'étendait aussi aux électrophiles plus mous tels que les iodures d'alkyle.

Les taux de O-alkylation obtenus dans les réactions des énolates alcalins de l'acétylacétate d'éthyle avec les halogénures d'alkyle sont de façon générale très faible; aussi avons-nous utilisé pour cette étude l'énolate de la carbéthoxycoumaranone-3 **1** qui présente une forte tendance à la O-alkylation (13, 14). Le solvant choisi est le THF, l'énolate de lithium de **1** s'étant révélé insuffisamment soluble dans le DME.

1

Les résultats obtenus (analyse par chromatographie en phase gazeuse) sont représentés dans le tableau 1. A des fins de comparaison, nous avons reporté dans le tableau 2 certains des résultats (10) concernant les énolates de l'acétylacétate d'éthyle vis à vis de sulfonates ou de sulfate d'alkyle dans le DME. Les données du tableau 1 montrent que l'énolate de lithium de **1** conduit à une proportion d'éther d'énol plus élevé que celle de l'énolate de sodium et du même ordre de grandeur que celle de l'énolate de potassium. La présence dans le milieu de perchlorate à cation commun ne modifie pas sensiblement les rapport C-/O-alkylation obtenus. Ceci montre, comme celà avait déjà été fait dans le cas de l'acétylacétate d'éthyle sur la base de la structure des éthers d'énol obtenus (cf. réf. 9 et paragraphe suivant) que l'espèce réactive est la

paire d'ions, à la quasi-exclusion de l'énolate dissocié.

La valeur du rapport $R = (C/O)_{Na^+}/(C/O)_{Li^+}$ permet de caractériser l'accroissement de la O-nucléophilie de l'énolate de lithium relativement à celle de l'énolate de sodium. La valeur de ce rapport (environ 1.25) pour le système **1**-EtI est voisine de celle observée pour l'acétylacétate d'éthyle avec les sulfonates très électrophiles (trifluorométhane-sulfonate, fluorosulfonate). Elle reste nettement inférieure à celle observée (de 2.2 à 3.7) pour l'acétylacétate d'éthyle avec le sulfite d'éthyle, le sulfate d'éthyle et les sulfonates d'éthyle de réactivité modérée (méthane sulfonate, *p*-toluène sulfonate).

En résumé, la tendance à la O-alkylation des enolates de lithium dépend de façon substantielle de la nature du groupe partant de l'électrophile. Elle est maximum avec les groupes partants oxygénés durs à faible pouvoir nucléofuge. Toutefois, elle se manifeste également, quoique à un moindre degré, lorsque le groupe partant est une entité molle telle que I^-.

de paires d'ions, ions triples) est un phénomène fréquent (5); il s'observe notamment dans le cas des énolates alcalins de l'acétylacétate d'éthyle ainsi que le montrent des résultats cinétiques (9) ou spectrométriques ir (15). La question se posait donc de savoir si ces phénomènes étaient capables d'influer de façon significative sur l'orientation des réactions d'alkylation; dans le même ordre d'idées il a été montré par exemple (16) que l'orientation de l'alkylation d'ions phénates était fortement influencée par le caractère homogène ou hétérogène du milieu réactionnel. Nous avons donc effectué une étude de l'alkylation des énolates de lithium et de sodium de l'acétylacétate d'éthyle par le tosylate et le bromure d'éthyle dans le DMF. Ce solvant est suffisamment polaire pour rendre peu vraisemblable la formation d'agrégats de paires d'ions mais, contrairement à ce qui a lieu dans un solvant plus dissociant comme le HMPT (17, 18), on peut encore y observer à côté de la réactivité des ions dissociés, celle des paires d'ions (19, 20). L'analyse des produits a été réalisée par chromatographie en phase gazeuse. Les résultats de cette étude sont reportés dans le tableau 3.

La réaction d'alkylation conduit à quatre produits: les produits de mono-C- et di-C-alkylation et les deux isomères O-*cis* et O-*trans* de l'éther d'énol (Schéma 1). La présence de ces deux isomères montre (5, 9, 15, 18, 19) qu'il y a réaction concurrente de la paire d'ions et de l'énolate dissocié. En effet la géométrie de l'ion énolate est conservée durant la réaction d'alkylation[4] et la paire d'ions chélate (énolate en U) conduit à l'éther d'énol O-*cis* tandis que l'ion dissocié à structure transoïde (W ou S-*trans*) conduit à l'éther d'énol *trans*.

A partir du schéma d'Acree (8, 20, 21) appliqué à la réaction de l'énolate (Schéma 1), il est possible en se basant sur les résultats bruts du tableau 3 d'accéder au rapport C-/O-alkylation caractéristique de la paire d'ions (rapport $k_{C,pi}/k_{O,pi}$). Désignons par O_{pi} et O_i les concentrations en éther d'énol et par C_{pi} et C_i les concentrations en produit de C-alkylation provenant respectivement de la paire d'ions (pi) et de l'énolate dissocié (i). Les réactions du schéma 1 sont toutes bimoléculaires; α désignant le coefficient de dissociation de l'énolate, E_T l'énolate total, les équations cinétiques sont donc de la forme:

$$[1] \quad dO_{pi}/dt = (1 - \alpha(t))k_{O,pi}E_T(t)$$

$$[2] \quad dO_i/dt = \alpha(t)k_{O,i}E_T(t)$$

$$[3] \quad dC_{pi}/dt = (1 - \alpha(t))k_{C,pi}E_T(t)$$

$$[4] \quad dC_i/dt = \alpha(t)k_{C,i}E_T(t)$$

De [1] et [2], on tire, après intégration:

$$[5] \quad \frac{k_{C,pi}}{k_{O,pi}} = \frac{C_{pi}}{O_{pi}}$$

et le rapport des concentrations de C_{pi} et O_{pi} est donc constant et égal au rapport $k_{C,pi}/k_{O,pi} = k_C/k_{Opi}$ caractéristique de la paire d'ions.

La détermination de O_{pi} (et de O_i) est immédiate puisque, compte tenu de ce qui précède, on a:

$$O_{pi} = O_{cis} \text{ et } O_i = O_{trans}$$

Le cas de la C-alkylation est plus complexe; la structure du produit C-alkylé est en effet unique, qu'il provienne de l'énolate dissocié ou de la paire

[4]Dans le cas des formes associées, ceci n'est strictement valable que pour les paires d'ions Li^+ et Na^+. En ce qui concerne les cations plus volumineux, le problème est plus complexe et a été discuté dans le cadre du principe de Curtin-Hammet (ref. 9, note de la p. 3145).

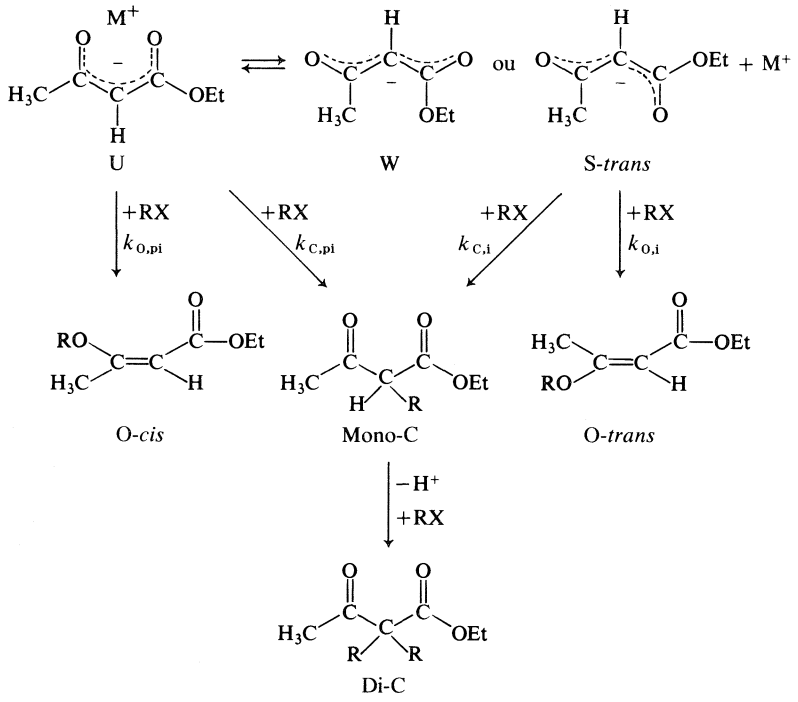

SCHÉMA 1

d'ions. On peut écrire:

$$C_i = O_i \cdot C_i/O_i = O_{trans} \cdot (C/O)_i$$

$(C/O)_i$ représentant le rapport C-/O-alkylation de l'énolate dissocié. Comme $C_{pi} = C_{total} - C_i$ il vient:

$$C_{pi} = C_{total} - O_{trans} \cdot (C/O)_i$$

et le rapport $(C/O)_{pi}$ caractéristique de la paire d'ions est finalement égal à:

$$[6] \quad (C/O)_{pi} = \frac{C_{total} - O_{trans}(C/O)_i}{O_{cis}}$$

C_{total} désigne la somme des concentrations en produit mono- et di-C-alkylé, ce dernier provenant en fait de la réaction ultérieure d'une partie du produit mono-C-alkylé.

La relation [6] montre qu'il est possible de calculer le rapport $(C/O)_{pi} = k_{C,pi}/k_{O,pi}$ à partir des seules données du tableau 3 si l'on connait la valeur de $(C/O)_i$. Nous avons pris pour modèle de l'énolate dissocié l'énolate de potassium crypté (cryptand (2.2.2) spécifique du potassium) pour lequel on sait que l'interaction énolate–cation est très faible (15). On a ainsi:

$$(C/O)_i = (C/O)_{E^-(K^+2.2.2)} = 1.6$$

pour EtBr (à 25°C)

$$(C/O)_i = (C/O)_{E^-(K^+2.2.2)} = 0.15$$

pour EtOTs (à 25°C).

L'éther d'énol résultant de l'alkylation de l'énolate de potassium crypté a une structure exclusivement *trans* en accord avec le caractère très relaché de l'interaction énolate–cation dans ce complexe. Notons que la valeur C/O = 0.15 obtenue avec TsOEt est très proche de celle de l'énolate dissocié dans le HMPT (C/O = 0.13) reporté par Kurts et coll. (17).

Les valeurs des rapports $(C/O)_{pi}$ calculés à l'aide de la relation [6] sont reportées sur le tableau 4. Les résultats des tableaux 3 et 4 conduisent aux commentaires suivants.

Bien que l'addition de sels inertes à cation commun (perchlorate) entraine dans tous les cas une augmentation des rapports C/O et O-*cis*/O-*trans* (régression de l'équilibre de dissociation d'Acree vers la paire d'ions) les rapports $(C/O)_{pi}$ correspondants ne sont pas sensiblement modifiés; ceci n'est pas surprenant puisque la présence de sel ajouté est peu susceptible de modifier l'interaction anion–cation au sein d'une paire d'ions déjà formée. En retour la quasi-constance du rapport $(C/O)_{pi}$, aux erreurs expérimentales près, nous paraît confirmer le bien-fondé de la méthode utilisée dans l'estimation de la réactivité des paires d'ions.

Dans le DMF comme dans le DME la paire d'ions lithium conduit à plus de O-alkylation que la paire d'ions sodium. Ceci est manifeste avec TsOEt où le rapport $R = (C/O)_{Na^+,pi}/(C/O)_{Li^+,pi} = 2.20$ est voisin de celui (R = 2.7) observé dans le

ENa	EtBr	0.1 *M*	33
		0.3 *M*	44

DME (tableau 2). Avec EtBr les taux de O-alkylation sont faibles et les risques d'erreur importants. Néanmoins on observe là encore une diminution du taux de O-alkylation (R = 1.5) en passant de l'énolate de lithium à l'énolate de sodium, ce qui semble confirmer les résultats obtenus précédemment avec l'énolate de la carboethoxycoumaranone-3 (R = 1.25).

Pour une paire d'ions donnée, le taux de O-alkylation est plus élevé (2 fois environ) dans le DMF que dans le DME. Ceci peut s'expliquer par le meilleur pouvoir solvatant des cations du premier solvant; les paires d'ions, tout en conservant leur structure de chélate, seraient plus relachées dans le DMF d'où une tendance accrue à la O-alkylation. La baisse du taux de O-alkylation dans le THF peut aussi être liée à la formation d'agrégats; dans le cas de phénates, Kornblum et Lurie ont montré que le taux de O-alkylation était diminué lorsque la réaction était conduite en milieu hétérogène (16).

Notons qu'une estimation de la réactivité des paires d'ions des énolates alcalins (K^+, Na^+) de l'acétylacétate d'éthyle dans le DMF a été proposée avant nous par d'autres auteurs (22, 23). La méthode utilisée n'est pas basée sur l'analyse des éthers d'énol obtenus mais pour l'essentiel sur des mesures cinétiques. Les constantes de nucléophilie totale des paires d'ions $k_{t,pi} = k_{O,pi} + k_{C,pi}$ et le coefficient α de dissociation des énolates sont déterminés à partir de mesures de réactivité effectuées à diverses concentrations en énolate ou en présence de quantités variables de sels chimiquement inertes à cation commun (tetraphénylborates alcalins). La constante de nucléophilie totale de l'ion libre $k_{t,i} = k_{O,i} + k_{C,i}$ et son rapport C-/O-alkylation sont obtenus à partir de mesures de réactivité effectuées sur l'énolate de potassium en présence d'agents complexants (éther-couronnes). Le rapport $(C/O)_{pi}$ est alors calculé à l'aide de la relation [7]

$$[7] \quad (C/O)_{\text{expérimental}} = A(C/O)_i + B(C/O)_i$$

où

$$A = \alpha(k_{t,i}/k_{\text{expérimental}})$$

et

$$B = (1-\alpha)k_{t,pi}/k_{\text{expérimental}}$$

représentent les contributions respectives de l'énolate dissocié et de la paire d'ions à la réaction. La valeur de $(C/O)_{pi}$ ainsi trouvée pour l'énolate de sodium (0.61) est considérablement plus faible que la nôtre (environ 2.25). Nous pensons que cette différence résulte du caractère erroné de la relation [7]. La stricte application de la relation d'Acree, à savoir $k_t = \alpha k_i + (1-\alpha)k_p$, au rapport $(C/O)_{\text{expérimental}}$ conduit à la relation [8]:

$$[8] \quad (C/O)_{exp} = \frac{\alpha k_{C,i} + (1-\alpha)k_{C,p}}{\alpha k_{O,i} + (1-\alpha)k_{O,p}}$$

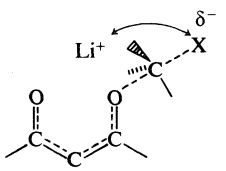
qui ne peut se ramener à une combinaison linéaire, telle que [7], des rapports $k_{C,i}/k_{O,i} = (C/O)_i$ et $k_{C,p}/k_{O,p} = (C/O)_p$. Une telle impossibilité traduit le fait que, dans des conditions de milieu données, les contributions respectives de la forme dissociée et de la forme associée à la réaction de C-alkylation d'une part et à la réaction de O-alkylation d'autre part ne sont pas les mêmes. Ceci apparait clairement lorsqu'on relie les rapports C_{pi}/C_i et O_{pi}/O_i, qui mesurent ces contributions, à l'aide de la relation:

$$C_{pi}/C_i = O_{pi}/O_i \frac{C_{pi}/O_{pi}}{C_i/O_i}$$

soit

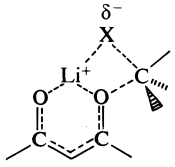
$$[9] \quad C_{pi}/C_i = (O_{pi}/O_i)\frac{(C/O)_{pi}}{(C/O)_i}$$

$(C/O)_{pi}$ étant toujours supérieur à $(C/O)_i$ quel que soit le cation (9) il s'ensuit que la contribution de la paire d'ions est plus importante dans le cas de la C-alkylation.



Discussion generale et conclusion

L'ensemble des résultats de cette étude confirme le caractère fortement O-nucléophile de l'énolate de lithium des β-ceto esters. Cette tendance à la O-alkylation ne parait pas dépendre de la polarité du milieu; elle n'est pas sensiblement affectée lorsqu'on passe du DME ou du THF au DMF. Ce fait parait exclure l'hypothèse selon laquelle la réaction de O-alkylation conduisant à l'éther d'énol

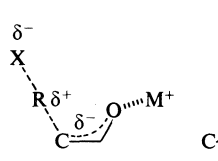


Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

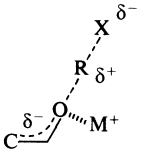
cis se déroulerait au sein d'agrégats ioniques complexes; les résultats observés traduisent donc très vraisemblablement la réactivité intrinsèque des paires d'ions monomères.

Les rapports C-/O-alkylation observés dépendent par contre de façon marquée du réactif alkylant. La tendance à la O-alkylation de l'énolate de lithium (comparée à celle de l'énolate de sodium) est particulièrement exaltée lorsque l'électrophile est un tosylate ou un sulfate de réactivité faible ou modérée; il est vraisemblable que dans ces cas une interaction Li^+ – groupe partant oxygéné joue un rôle dans l'orientation de la réaction, comme celà avait déjà été suggéré (9). La tendance à la O-alkylation de l'énolate de lithium (toujours comparée à celle de l'énolate de sodium) persiste néanmoins, quoique à un degré moindre, avec les autres agents alkylants et notamment les halogénures. Ceci rend à notre sens difficile une explication basée exclusivement sur l'existence d'une interaction lithium – groupe partant de l'électrophile et ce pour plusieurs raisons. Une telle interaction, vraisemblable en milieu de polarité modérée (DME, THF) et dans le cas où le groupe partant est une base oxygénée dure telle que TsO^- (l'effet ionisant de sels de lithium sur certains tosylates à radical R allylique ou β-aryléthylique a été mis en évidence à diverses reprises (24, 25)), parait beaucoup plus problématique avec un groupe partant tel que I^- ou Br^-, particulièrement au sein d'un solvant aussi polaire que le DMF capable lui-même de solvater énergiquement le cation Li^+. L'interaction Li^+ – groupe partant est en outre difficile à concilier avec un arrangement colinéaire du groupe entrant, du carbone siège de la substitution et du groupe partant lorsque ce dernier est monoatomique comme I^- ou Br^- (cf. **2**). Cette colinéarité apparait pour-

2



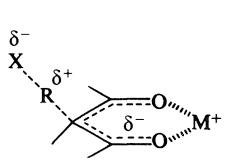
3



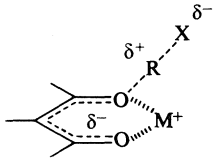
tant, après les travaux de Eschenmoser et coll. (26) comme une condition fondamentale de la réaction S_N2.

En l'absence de résultats concernant des réactifs alkylants chiraux, un processus assisté avec rétention de configuration selon un mécanisme à quatre centre (cf. **3**) ne peut être définitivement rejeté. A notre connaissance toutefois il n'existe pas dans la littérature d'exemples de tel processus dans le cas de réaction S_N2 sur le carbone et les études théoriques montrent que le processus S_N2 avec rétention de configuration doit être considérablement défavorisé par rapport au processus conduisant à l'inversion de configuration (27, 28). Georgoulis et coll. ont cependant mis récemment en évidence (29) une rétention partielle de configuration dans la réaction S_N2 de l'éthylate de lithium sur le chloro-3 butène-1 dans l'éthanol; dans ce dernier cas, la structure allylique et secondaire du radical R de l'électrophile, favorable à la formation d'un état de transition à caractère fortement carbocationique, rend la liaison carbone–chlore particulièrement sensible à l'effet ionisant du cation lithium de la paire d'ion $EtOLi^+$.

Pour l'ensemble des raisons invoquées ci-dessus la forte O/C-nucléophilie de l'énolate de lithium est vraisemblablement *en partie* une propriété propre à la paire d'ions et indépendante de la nature de l'électrophile. Nous suggérons que cette propriété est liée à la structure β-dicétonique chélatante de l'énolate et peut s'expliquer en termes de solvatation du cation par les états de transition. Dans le cas d'un énolate de monocétone (ou d'un phénate) l'entité énolate doit mieux solvater le cation dans l'état de transition **4** conduisant à la C-alkylation et où l'atome d'oxygène n'est pas directement impliqué dans la réaction avec l'électrophile que dans l'état de transition **5** conduisant à la O-alkylation.



4



5

En d'autres termes l'affinité de **4** pour le cation est supérieure à celle de **5**; on s'attend donc à ce que la C-alkylation soit favorisée en présence de cation et ce d'autant plus que la tendance à l'association de ce dernier est forte, c'est-à-dire dans l'ordre $Li^+ > Na^+ > K^+$ ... etc. Dans le cas des composés β-dicarbonylés qui possèdent un site oxygéné supplémentaire, les deux états de transition **6** et **7**

6

7

ont tous deux une structure permettant encore une solvatation efficace du cation et aucune prédiction simple ne peut plus être faite quant à l'influence de ce dernier. Les variations du rapport C-/O-

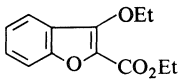
alkylation observées en passant d'un cation à un autre vont traduire les variations des capacités respectives de solvatation des deux états de transition vis à vis des cations considérés. Notamment la *nette tendance* à la O-alkylation manifestée par la paire d'ions lithium traduit à notre sens une affinité marquée de l'état de transition **7** pour Li^+.[5] Dans cette optique, il serait intéressant d'étudier la compétition C-/O-alkylation au niveau *spécifique des paire d'ions* d'énolates de monocétones ou de phénates alcalins pour lesquels on doit s'attendre (cf. ci-dessus) à un rapport C/O maximum dans le cas de Li^+. Malheureusement leur faible tendance à l'association, comparée à celle des énolates de composés β-dicarbonylés, ainsi que l'impossibilité de contrôler dans ce cas les contributions respectives des paires d'ions et des ions dissociés par l'étude des produits de la réaction rend un tel projet difficile à mettre en œuvre.

Partie experimentale

I. Matières premières

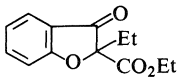
Le THF anhydre (Merck) est agité en présence d'alumine (type 507 C, Fluka, 100 g/L de solvant) pendant plusieurs heures; après filtration il est distillé juste avant utilisation sur $LiAlH_4$ et sous azote. Le DMF est distillé sous vide (20 Torr) avant l'utilisation. L'iodure, le bromure et le tosylate d'éthyle (Merck) ont été distillés; pé(EtOTs) = 173°C/15 Torr.

$LiClO_4$ (Fluka) est séché sous vide 24 h à 100°C avant utilisation. $NaClO_4$ (Merck) est séché à 90°C et conservé sur P_2O_5 dans un dessicateur. L'acétylacétate d'éthyle (Merck-Schuchardt) est distillé avant emploi; pé = 81°C/20 Torr. La carbéthoxycoumaranone-3 **1** est préparée en trois étapes à partir de l'acide salicylique selon Brandström et Forsblad (30). La préparation des énolates alcalins de l'acétylacétate d'éthyle a déjà été décrite (9). La même méthode est utilisée pour ceux de la carbéthoxycoumaranone-3.



II. Analyses spectroscopiques

Les spectres rmn ont été réalisés sur un appareil Varian T-60 en utilisant le TMS comme référence interne. Les spectres infrarouges ont été enregistrés sur un appareil Perkin-Elmer 457. Les spectres de masse ont été réalisés sur un appareil AEI MS 30 opérant à 70 ev. Les spectres uv ont été enregistrés sur un appareil Beckman DB-GT.



III. Préparation et caractérisation des dérivés éthylés

La préparation et la caractérisation des divers produits d'éthylation de l'acétylacétate d'éthyle a déjà été décrite (9).

Les dérivés O- et C-éthylé **8** et **9** de la carbéthoxycoumaranone-3 ont été préparés par action de l'iodure d'éthyle sur l'énolate de sodium dans l'éthanol. La carbéthoxycoumaranone-3 (3.4×10^{-3} mol) est ajoutée à une solution d'éthylate de sodium équimolaire dans l'éthanol (5 mL). Le mélange, qui prend rapidement en masse, est agité à chaud pendant quelques

8

9

minutes pour permettre la formation quantitative de l'énolate. Après addition de EtI (2×10^{-2} mol, excés), le mélange réactionnel est porté au reflux pendant 6 h. Après évaporation de l'éthanol, les produits organiques sont dissous dans un mélange éther–pentane 1:1, et la phase organique extraite au carbonate de sodium aqueux 10% pour éliminer la carbéthoxycoumaranone-3 n'ayant pas réagi. Cette dernière opération doit être réalisée rapidement pour éviter toute décarbéthoxylation (31) du produit C-éthylé **9**. Le rendement brut en produits d'alkylation, composés de **8** et **9** dans le rapport 1:2 environ (rmn), est pratiquement quantitatif. A partir de ce mélange, des échantillons purs de **8** et **9** on été obtenus par chromatographie préparative sur couche mince (gel de silice, élutions répétées au mélange hexane – éther éthylique 9:1). Le dérivé O-éthylé **8** a par ailleurs été obtenu seul, à l'exclusion de **9**, par réaction de l'énolate de sodium (5×10^{-2} mol) avec le sulfate d'éthyle équimolaire dans le DMSO (20 mL) à température ambiante pendant 18 h.

*Caractéristiques des produits **8** et **9***

*Carbéthoxy-2 éthoxy-3 coumarone (**8**)*

Huile (cristallisant en dessous de 10°C); uv (EtOH) λ_{max} (ε): 286 nm (34 000) (litt. (32): acide coumarone carboxylique-2 λ_{max} (EtOH): 274.5 nm); ir (CCl_4) ν: 1712 (C=O) cm^{-1} (litt. (31): carbéthoxy-2 méthoxy-3 coumarone ν: 1706 (C=O) cm^{-1}); rmn ($CDCl_3$) δ: 7.9–7.1 (4H, m, protons aromatiques), 4.55 (2H, q), 4.51 (2H, q), 1.47 (3H, t), 1.43 (3H, t, protons des groupements éthoxy) ppm; spectrométrie de masse *m/e*: 234 (M^+, 82%), 206 (25%), 161 ($M-CO_2C_2H_5$, 35%) 160 (100%).

*Carbéthoxy-2 éthyl-2 coumaranone-3 (**9**)*

Huile; uv (EtOH) λ_{max} (ε): 253 nm (12 000), 328 nm (5 000) (litt. (33): diméthyl-2,6 coumaranone-3 λ_{max} (EtOH): 260 nm, 327 nm); ir (CCl_4) ν: 1729 (C=O) cm^{-1} (cétone) et 1758 cm^{-1} (ester); rmn: $CDCl_3$ δ: 7.95–7.1 (4H,m, protons aromatiques), 2.65–1.93 (2H, m), 0.93 (3H, t), protons du groupement éthyle sur le carbone (système ABX_3), 4.31 (2H, q), 1.27 (3H, t, protons du groupement carbéthoxy); spectrométrie de masse *m/e*: 234 (M^+, 100%), 206 (58%), 162 (71%), 161 ($M-CO_2C_2H_5$, 97%), 147 (88%).

IV. Dosage par chromatographie en phase gazeuse

Appareil Perkin Elmer F11 à ionisation de flamme d'hydrogène. Gaz vecteur: azote. Colonne SE 30 15% sur Chromosorb W HMDS (80–100 mesh) de diamètre $\frac{1}{8}$ in. et de longeur 2 m. Dosage des dérivés de l'acétylacétate d'éthyle: température 103°C, pression d'azote en tête de colonne: 1.4 bar. Dosage des dérivés de la carbéthoxycoumaranone-3: température 200°C, pression: 1.4 bar.

La technique de dosage par cpg, notamment des deux isomères *cis* et *trans* de l'éther d'énol de l'acétylacétate d'éthyle a déjà été décrite en détail (9). La principale difficulté provient de l'isomérisation possible de l'isomère *cis* en isomère *trans* durant le dosage. On peut vérifier si l'appareil isomérise ou non un moment de l'analyse, et ainsi savoir si les résultats obtenus sont significatifs, en injectant les produits d'alkylation de l'énolate de lithium par TsOEt où l'éther d'énol est entièrement *cis* (9).

Il est possible que les proportions plus élevées d'éther d'énol *trans* observées par Kurts et coll. dans des conditions similaires aux notres (18, 19) soient dues à ce phénomène d'isomérisation.

[5]L'affinité plus marquée de l'état de transition **7** pour Li^+ (comparée à celle de **6** pour Li^+) pourrait s'expliquer par une plus grande densité électronique de **7** si on considère que même dans le produit final (produit alkylé) la densité électronique de l'ether d'énol O-*cis* dérivé de **7** est sans doute plus élevée que celle de la β-dicétone (mono-C) dérivée de **6**. Nous remercions l'un des examinateurs pour cette suggestion.

Intramolecular Michael-type additions.[1] II.[2] Synthesis of derivatives of 7-thia-2-azabicyclo[3.2.1]oct-3-ene, a novel heterocyclic ring system

MARION E. M. BAGGS AND BRIAN GREGORY[3]

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received July 12, 1979[4]

MARION E. M. BAGGS and BRIAN GREGORY. Can. J. Chem. **58**, 794 (1980).

The isothiouronium salt derived from dimethyl 4-chloromethyl-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate reacted with ammonium hydroxide to give dimethyl 7-thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene-4,8-dicarboxylate, which could be converted back to a dihydropyridine using iodomethane. Replacement of ammonium hydroxide by sodium hydroxide afforded a tetrahydro- and a dihydrothieno[3,4-*c*]pyridine as by-products. 3,5-Diacetyl-4-chloromethyl-1,4-dihydro-2,6-dimethylpyridine reacted with thiourea, followed by ammonium hydroxide, to give 3-acetyl-2-methylpyrrole, 4-acetyl- and 4,8-diacetyl-7-thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene. The structure and stereochemistry of the novel 7-thia-2-azabicyclo[3.2.1]octenes are established using spectroscopic methods. The mechanism of their formation is discussed in terms of Baldwin's rules.

MARION E. M. BAGGS et BRIAN GREGORY. Can. J. Chem. **58**, 794 (1980).

Les sels d'isothiouronium dérivés du chlorométhyl-4-dihydro-1,4 diméthyl-2,6 pyridine dicarboxylate-3,5 de méthyle réagissent avec l'hydroxyde d'ammonium pour donner le thia-7 aza-2 diméthyl-1,3 bicyclo[3.2.1]octène-3 dicarboxylate-4,8 de méthyle, qui peut être retransformé en dihydropyridine à l'aide de l'iodométhane. L'emploi de l'hydroxyde de sodium au lieu de l'hydroxyde d'ammonium fournit comme produits secondaires le tétrahydro et le dihydro thiéno[3,4-*c*] pyridine. La diacétyl-3,5 chlorométhyl-4 dihydro-1,4 diméthyl-2,6 pyridine réagit avec la thiourée suivie de l'hydroxyde d'ammonium pour conduire aux dérivés acétyl-3 méthyl-2 pyrrole, acétyl-4 et diacétyl-4,8 thia-7 aza-2 diméthyl-1,3 bicyclo[3.2.1] octène-3. On a établi la structure et la stéréochimie des nouveaux thia-7 aza-2 bicyclo[3.2.1] octènes en utilisant des méthodes spectroscopiques. On discute du mécanisme de leur formation en fonction des règles de Baldwin.

[Traduit par le journal]

The acid-catalysed intramolecular addition of nucleophiles to dihydropyridines is well-known, having provided challenges in structure elucidation, e.g., the primary acid product from NADH (4), and useful synthetic routes to indole alkaloid skeleta (5). In contrast, intramolecular Michael-type addition to the dihydropyridine system is rare.[5] Thus, a 4-carboxy Hantzsch ester has been observed to readily form diethyl 1,3,5-trimethyl-7-oxa-2-aza-6-oxobicyclo[3.2.1]oct-3-en-4,8-dicarboxylate in acid media, presumably by β-protonation, followed by intramolecular Michael-type addition of the carboxylate anion to the iminium salt (7).

Based on the examination of Dreiding and space-filling molecular models, we concluded that 4-thiolmethyl-1,4-dihydropyridines **3***a–c* should, in basic media, undergo intramolecular Michael-type addition to generate 7-thia-2-azabicyclo-[3.2.1]oct-3-enes **4***a–c*. We are unaware of any previous reports of compounds containing this ring system. Although it had been claimed that reaction of the 4-chloromethyl-1,4-dihydropyridine **1***b* with sodium hydrosulfide gave the 4-thiolmethyl compound **3***b* (8), more recent work has shown that the product is, in fact, the 8-thia-2-azabicyclo[3.2.1]octene **5***b* (9). Similar bicyclic products have been obtained from other 4-chloroalkyl-1,4-dihydropyridines (3, 10, 11). It is clear that in the basic reaction conditions employed, ring expansion takes place to give an intermediate 4,5-dihydroazepine-4-thiol, which then undergoes intramolecular Michael-type addition. Ring expansion at such an early stage obviously precludes this reaction sequence as a route to **4**.

It is well known that thiols may be obtained by base-catalyzed decomposition of isothiouronium salts (12). Earlier, we have shown (13) that the chloromethyl-1,4-dihydropyridines **1***a–c* react with thiourea without ring expansion and give the isothiouronium salts **2***a–c* (Scheme 1). When the salt **2***a* was refluxed with sodium hydroxide in aqueous ethanol, a complex mixture was obtained. The major component was a colorless solid $C_{12}H_{17}NO_4S$ which showed infrared bands attributable to saturated and unsaturated ester carbonyl groups and NH, while the ultraviolet absorption spectrum resembled that of a 1,4,5,6-tetrahydronicotinic ester (14), thus eliminating 1,4-di-

[1]Although the term Michael addition (1) originally applied to the addition of anions derived by removal of a proton α to a carbonyl group, to unsaturated esters, ketones, etc., the scope has since broadened. The use of the term Michael-type addition in this and subsequent publications in this area follows that of March (2).

[2]Reference 3 may be regarded as Part I of this series.

hydropyridine (15–17) and 4,5-dihydroazepine (16) structures. The mass spectrum was dominated by intense peaks corresponding to the molecular ion and loss of CH_2SH radical. Such a fragmentation pattern could have arisen from the 1,4-dihydropyridine structure **3***a* (cf. 18), which is inconsistent with the ultraviolet data, or from the 7-thia-2-azabicyclo[3.2.1]oct-3-ene structure **4***a* by initial C—S bond cleavage followed by hydrogen radical transfer and loss of CH_2SH radical as shown in Scheme 2. The fragmentation was quite different to that observed for the 8-thia-2-azabicyclo-[3.2.1]oct-3-enes (3, 9–11). In addition to singlets due to two non-equivalent methyl esters and two methyl groups attached to sp^3 (δ 1.80) and sp^2 (δ 2.11) carbon atoms, the ^{1}Hmr spectrum showed a broad singlet (NH), one-proton and two-proton doublets, and a broadened one-proton quartet. The latter multiplets clearly denote the presence of a —CH—CH—CH_2— moiety, consis-

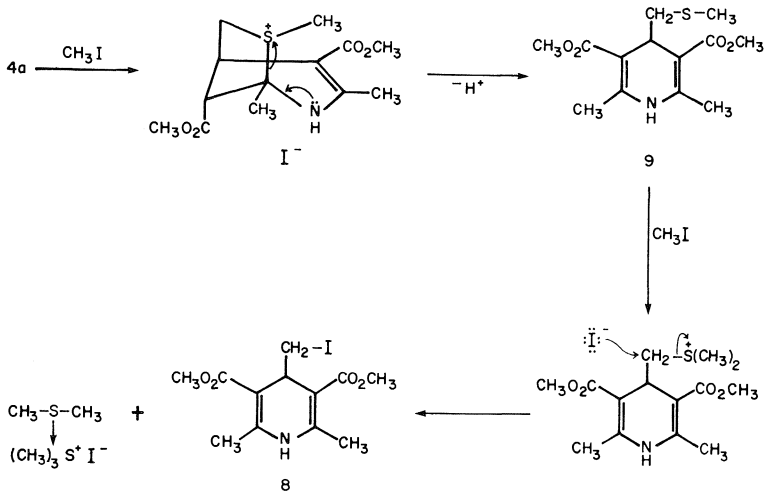
15 16 R = H 17 R = CH_3 12

tent with structure **4***a*, although, surprisingly, the protons of the methylene group are apparently equivalent. In the belief that the spectroscopic properties of this compound were best represented by structure **4***a*, and that the protons of the methylene group were accidentally equivalent (19), it was resolved to synthesize analogues in which the methoxycarbonyl groups were replaced by other electron-withdrawing groups in the hope that one or more would show non-equivalent methylene protons (see below).

Minor products isolated from the action of aqueous ethanolic sodium hydroxide on **2***a* included the yellow crystalline 1,3,5,7a-tetrahydrothieno[3,4-*c*]-pyridine-3(1*H*)-one **6**, clearly formed by attack of the thiolate anion derived from **3***a* on a neighbouring ester, and the corresponding oxidation product 7.[6] The oxidation of **6** to **7** was accomplished, in a separate experiment, by the action of dilute nitric acid. No evidence was found in the ^{1}Hmr spectrum of **7** for the presence of the fully-aromatic enol tautomer (20). When ammonium hydroxide was used to decompose the isothiouronium salt **2***a*, the yield of the bicyclic compound **4***a* was considerably improved and this method was used in subsequent work.



Further evidence to support structure **4***a* has been obtained through chemical studies. When compound **4***a* was heated at 74°C in a sealed tube with iodomethane in dimethylformamide, predictably the products were trimethylsulfonium iodide and the 4-iodomethyl-1,4-dihydropyridine **8**. These compounds are believed to be formed by methylation at sulfur, followed by C—S cleavage assisted by the nitrogen lone pair as shown in Scheme 3. Loss of proton would give the 4-methylthiomethyl-1,4-dihydropyridine **9** which, after methylation at sulfur, displacement of dimethyl sulfide by iodide anion, and final methylation of dimethyl sulfide, accounts for the products. The ease of regeneration of the dihydropyridine ring system precludes the involvement of a gross rearrangement in the base-catalysed decomposition of **2***a* and thus provides support for **4***a*.

When the diethyl ester **2***b* was reacted with ammonium hydroxide, the spectroscopic properties of the product were again in accord with the bicyclic structure **4***b*, although the ^{1}Hmr spectrum showed that the protons attached to C(6) were, once more, equivalent.

Separation of the mixture produced by the action of ammonium hydroxide on the diacetyl compound **2***c* afforded, as major product, a colorless crystalline product $C_{12}H_{17}NO_2S$ whose spectroscopic properties were in complete accord with structure **4***c*. Thus the ultraviolet absorption spectrum exhibited a major long-wavelength band at 325 nm. The bathochromic shift of about 22 nm by comparison with the corresponding esters is a reflection of the increased efficiency of electron acceptance from the nitrogen lone pair shown by a ketone carbonyl compared with an ester carbonyl. Such an effect has been observed previously with acyclic and cyclic compounds containing 4-aminopent-3-en-2-one or 3-aminocrotonate chromophores (see Table 1). A comparison of the ultraviolet spectra of the 7-thia compounds **4***a–c* with the 8-thia compounds **5***a,c* shows that the major absorption band occurs 10–12 nm to longer wavelength for the former compounds. The reason for this is not clear at the present time, since the chromophore is perfectly planar (as judged from Dreiding models) in each ring system; the possibility of interaction of the enamine system with orbitals on sulfur in **4** cannot be ruled out. The infrared spectrum of **4***c* exhibited stretching vibrations due to NH (3423 cm^{-1}), saturated ketone (1707 cm^{-1}), and an unsaturated ketone absorption at 1628 cm^{-1}, con-

[6]Benary (8) has obtained the ethyl ester of **7** by the action of potassium hydrosulfide on diethyl 4-iodomethyl-2,6-dimethylpyridine-3,5-dicarboxylate. For recent reviews of thienopyridines see refs. 20 and 21.

siderably lowered due to conjugative interaction with the lone pair on nitrogen in the manner characteristic of β-amino-αβ-unsaturated ketones (26). The most significant features of the ^{1}Hmr spectrum of **4***c* were the signals due to the —CH—CH—CH_2— system. In particular, the hydrogens of the methylene group were nonequivalent and appeared as a doubled AB quartet (see Fig. 1). The low field half of this latter signal appeared at δ 3.36 and showed coupling constants of 9.52 Hz, due to geminal coupling,[7] and 4.39 Hz due to coupling with the hydrogen at C(5). The high field half appeared at δ 3.19 and showed again the geminal coupling of 9.52 Hz and an additional coupling of 0.7 Hz. Examination of a Dreiding molecular model of **4***c* showed that the dihedral angle between H_d and H_b was near to 90° resulting in a value of *J* near to zero, while the dihedral angle between H_c and H_b was approximately 35°. Accordingly, the signal at δ 3.19 (*J* values 9.52 Hz and 0.7 Hz) was assigned to H_d, while the signal at δ 3.36 (*J* values 9.52 Hz and 4.39 Hz) was assigned to H_c. In addition to these signals, the spectrum showed a doublet at δ 3.06 (J = 3.17 Hz) due to H_a at C(8) and a multiplet, closely resembling a broadened triplet, at δ 4.07 due to H_b at C(5). The

[7]Although no attempts have been made to determine the sign of the geminal coupling, such couplings, with the exception of epoxides and ethyleneimines, are usually negative (ref. 19, p. 270).

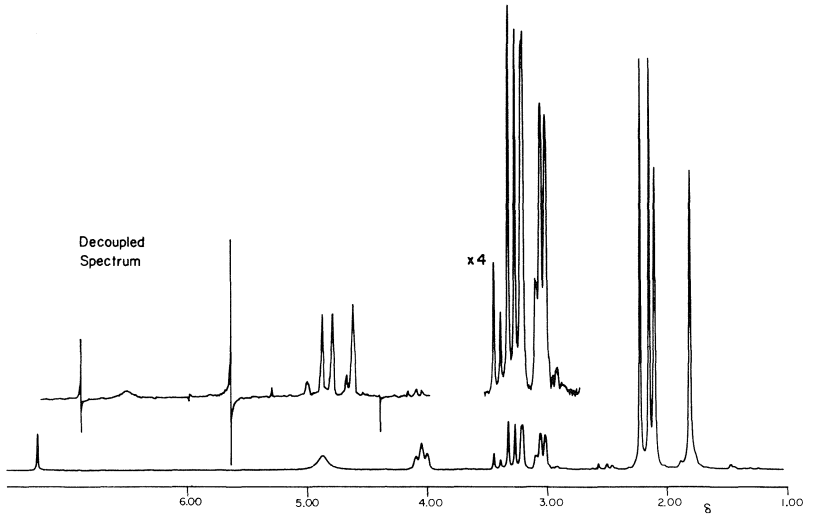

FIG. 1. ^{1}Hmr spectrum of **4***c*.

dihedral angle of 55° made by H_a with H_b is in good agreement with the observed coupling constant of 3.17 Hz; accordingly the acetyl group at C(8) is assigned the *endo* configuration. Irradiation at δ 4.07 caused the doublet at δ 3.06 to collapse to a singlet, while the doubled AB signal collapsed to an AB double doublet (see Fig. 1 inset).

In addition to compound **4***c*, other products isolated from this reaction include 2-methyl-3-acetylpyrrole, whose origin in this reaction is presently under investigation, and a compound $C_{10}H_{15}NOS$. The structure of this latter compound follows from the similarity of its ultraviolet absorption spectrum with that of **4***c*, the lack of one of the 3-proton acetyl absorptions found in the ^{1}Hmr spectrum of **4***c* and the lack of the saturated carbonyl absorption found in **4***c*.[8] The ^{1}Hmr surprisingly shows 2-proton doublets for protons at C(6) and C(8). This minor product is assigned structure **11** and probably results from retroaldolization at some stage of the reaction sequence.

A comparison of the uv (Table 1) and ^{1}Hmr (Table 2) spectra of **4***a–c* and **11** demonstrates the close similarity of the data and leaves little doubt they they all contain the same ring system. Further, the similarity of J_{ab} in **4***a–c* shows that the substituent at C(8) occupies the same configuration in each compound and is assigned an *endo* configuration; it is likely that this is the more thermodynamically stable configuration (cf. ref. 3).

[8]A weak absorption at 1710 cm^{-1} was observed in the ir spectrum of **11**. The origin of this peak is not clear; no spurious singlet due to impurity was observed in the nmr and repeated purification by preparative tlc failed to remove the band at 1710 cm^{-1}.

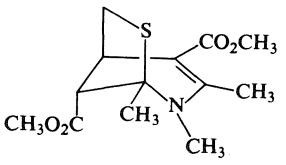
*Chemical shift values (δ) are expressed in ppm downfield from internal TMS; coupling constants (*J*) are expressed in Hz.



Attention has recently been drawn by Baldwin *et al.* to the importance of the Dunitz angle (27) in addition reactions to the carbonyl group and this has been extended to general rules for the prediction of the ease of cyclization reactions. In particular, cyclizations designated 5-*endo*-trig are disfavored (28, 29) although this may not hold when the nucleophilic atom or group is derived from a second row element (29). In the case of the formation of the 7-thia-2-azabicyclo[3.2.1]oct-3-enes, the Michael addition depicted in **12** may be regarded as, at once, a 5-*endo*-trig cyclization from the viewpoint of the thus formed 5-ring, but 7-*exo*-trig when the thus formed 7-ring is considered. In such a situation, it is clear that the disfavored 5-*endo*-trig cyclization is the more important and that the formation of the bicyclic system should not be facile, although the second-row nucleophile may invalidate these considerations. However, examination of a model of **12**

SCHEME 4

shows that the approach of the nucleophile is in a direction far removed from a Dunitz-type angle. For these reasons we considered the possibility that the formation of **4***a–c* may involve the formation of an equilibrium amount of the tautomer **13** followed by cyclization of its conjugate base **14** as shown in Scheme 4.[9] Such a pathway would offer several advantages, e.g., tautomerism to give **13**, which has the bulky thiolmethyl and R groups *trans*, and would automatically lead to the 8-*endo*-esters and ketones. Further, the intramolecular nucleophilic addition to the imine carbon is a simultaneous 5-*exo*-trig/7-*endo*-trig cyclization onto the potent Michael-acceptor iminoacrylate system. Examination of Dreiding models of **14** shows that the sulfide anion can approach the imine carbon closely and from a Dunitz angle. Since the *N*-methyl derivative of **3***a* would be incapable of tautomerism to a 3,4-dihydropyridine analogous to **13**, we have reacted dimethyl 4-chloromethyl-1,4-dihydro-1,2,6-trimethyl-pyridine-3,5-dicarboxylate with thiourea followed by ammonium hydroxide. The formation of the *N*-methyl bicyclic compound **18**, albeit in low yield,

18

shows that if the tautomerism **3** to **13** takes place at all, it is certainly not essential for the formation of the bicyclic compounds **4***a–c*.

[9]In a related study, we have shown that dimethyl 4-(diacetylmethyl)-4,5-dihydro-2,7-dimethylazepine-3,6-dicarboxylate cyclizes in basic media to give an 8,8-diacetyl-2-azabicyclo-[3.2.1]oct-3-ene (30). We have suggested that this reaction may involve initial tautomerism to a 4,5-dihydro-3*H*-azepine followed by 5-*exo*-trig/6-*endo*-trig Michael-type addition to the iminocrotonate system (30), rather than disfavored 5-*endo*-trig addition to the aminocrotonate system of a 4,5-dihydro-1*H*-azepine.

Experimental

Melting points were determined using a Fisher-Johns melting point apparatus. Infrared spectra were obtained in chloroform solution using a Perkin-Elmer 237B grating infrared spectrometer. Ultraviolet spectra were measured on a Unicam SP800D using solutions in 95% ethanol. Spectra were calibrated using the bands at 2850.7 and 1601.4 cm^{-1} of polystyrene (ir) or at 279.4 and 360.9 nm of a holmium oxide filter (uv). The ^{1}Hmr spectra were obtained using Bruker WP80DS Fourier Transform (designated (A)) or Varian EM360 (designated (B)) nmr spectrometers, using deuterochloroform as solvent unless specified otherwise. All chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Mass spectra were determined at 70 eV ionizing energy using a Hitachi-Perkin-Elmer RMU-6E mass spectrometer. Only the most intense peaks are listed; normalized intensities are given in parentheses. Initial and final total ion current values differed by $< 5\%$. Accurate mass measurements were obtained relative to known accurate masses of perfluorokerosene peaks using a Varian MAT 311 mass spectrometer. New compounds were homogeneous by tlc and elemental analyses were performed by Atlantic Microlab, Inc., Atlanta, GA. The identity of known compounds was established by mp, mixture mp, and comparisons of ir, ^{1}Hmr, and ms with those of authentic specimens. All evaporations were carried out using a rotary evaporator operating at 12 Torr and using a bath temperature of $\geq 40°C$.

Dimethyl 7-Thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene-4,8-dicarboxylate, **4**a

(*a*) Dimethyl 4-chloromethyl-1,4-dihydro-2,6-dimethyl-pyridine-3,5-dicarboxylate **1***a* (5 g) and thiourea (2 g) were refluxed in ethanol (95%, 125 mL) for 3.7 h. The solution was then cooled and evaporated *in vacuo* to yield the solid isothiouronium salt **2***a*, which, without further purification, was heated with concentrated ammonium hydroxide (25 mL) at 85°C for 1 h. After cooling, the reaction mixture was extracted using ethyl acetate (1 × 75 mL, 1 × 30 mL). The bulked organic layer was washed with water (3 × 10 mL), dried ($MgSO_4$), filtered, and evaporated to give an oil (4.445 g) which was shown using tlc to consist of one major component and several minor ones. Trituration of the oil with ethyl acetate induced crystallization, and filtration afforded crystalline product (0.878 g). The mother liquors were evaporated and the residue chromatographed on a column of silica gel N (300 g) using 60–80°C petroleum ether/ethyl acetate as elution solvent to give a further quantity of crystalline **4***a* (2.166 g). The combined yield of the chromatographically homogeneous product was 3.044 g (61%). After one crystallization from ethyl acetate and sublimation at 90°C/0.01 Torr, the colorless crystalline bicyclic compound **4***a* had mp 115–117°C; uv λ_{max} (ε): 268 nm (sh, 3900), 303 nm (10 900); ir ν_{max}: 3422 (NH s, free), 1739 (saturated ester), 1688 (unsaturated ester) cm^{-1}; ^{1}Hmr (A) δ:1.80 (s, 3H, methyl at C(1)), 2.11 (s, 3H, methyl at C(3)), 3.04 (d, 1H, $J = 3.30$ Hz, H at

C(8)), 3.22 (d, 2H, J = 2.64 Hz, H's at C(6)), 3.62 (s, 3H, methyl ester), 3.63 (s, 3H, methyl ester), 3.79 (br q, 1H, J approx. 2.8 Hz, H at C(5)), and 4.52 (br s, 1H, NH); ms *m/e*: 271(28, M^+), 240(11), 239(9), 225(13), 224(100), 211(7), 208(6), 196(6), 192(15), 180(10), 166(70), 134(15), 115(16), 107(12), 106(26), 84(7), 79(8), 77(8), 65(7), 59(10), and 42(12). *Anal.* calcd. for $C_{12}H_{17}NO_4S$: C 53.13, H 6.32, N 5.16, S 11.79; found: C 53.17, H 6.35, N 5.22, S 11.79.

(*b*) To the crude isothiouronium salt **2***a* prepared from the chloromethyl-1,4-dihydropyridine **1***a* (9 g) as in the previous experiment, was added ethanol (63 mL, 95%) followed by sodium hydroxide (2.259 g) in water (27 mL). After refluxing for 2 h in an oil bath at 105°C, the ethanol was removed by evaporation *in vacuo* and water (45 mL) was added. The aqueous reaction mixture was extracted using benzene (360 mL, 300 mL, and then 200 mL) and the bulked benzene extract washed with water, dried ($MgSO_4$), filtered, and evaporated to give a pale yellow oily solid (3.816 g) which, after chromatography on silica gel, yielded dimethyl 7-thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene-4,8-dicarboxylate, **4***a* (2.5 g, 28%) identical with the product from the previous experiment. The aqueous sodium hydroxide extract, which had contained a solid near the aqueous sodium hydroxide/benzene interface, was filtered to yield a yellow solid (1.935 g), which tlc showed to consist of two compounds. Separation was achieved by dissolution in chloroform (50 mL) followed by extraction with hydrochloric acid (5 × 15 mL, 6 *M*). The chloroform extract was washed with water (2 × 25 mL), dried ($MgSO_4$), and evaporated to give a solid which was further purified by recrystallization from ethyl acetate to yield yellow crystals of methyl 1,3,5,7a-tetrahydro-4,6-dimethylthieno[3,4-*c*]-pyridin-3(1*H*)-one-7-carboxylate **6** (1.63 g, 21%) mp 227–227.5°C; uv λ_{max} (ε): 236 (11 900), 241.5 (sh, 11 600), 267 (10 700), 391 nm (6300); ir ν_{max}: 3415 (NH, free), 3295 (NH, bonded), 1698 (vinylogous urethane), 1675 (vinylogous thiolurethane), 1640 (C=C) and 1611 (C=C) cm^{-1}; ^{1}Hmr (B) ($CDCl_3$/DMSO-d_6) δ: 2.11 (s, 3H, C-methyl), 2.17 (s, 3H, C-methyl), 3.62 (s, 3H, methyl ester), 3.67 (d, 2H, CH_2), 3.90 (t, 1H, CH); signals at 3.62, 3.67, and 3.90 were partly obscured due to overlapping; ms *m/e*: 239(22, M^+), 238(6), 224(24), 211(8), 208(11), 193(12), 185(10), 178(8), 165(100), 150(14), 134(15), 133(8), 106(7), 105(7), 77(6), 67(6), and 42(11). *Anal.* calcd. for $C_{11}H_{13}NO_3S$: C 55.21, H 5.48, N 5.85, S 13.40; found: C 55.28, H 5.53, N 5.84, S 13.33.

The aqueous acid layer was washed once with chloroform (20 mL), made slightly basic using sodium carbonate, and then extracted using chloroform (3 × 25 mL). The bulked chloroform extract was washed with water (5 mL), dried ($MgSO_4$), filtered, and evaporated to give an almost colorless residue (0.3 g, 4%) of methyl 1,3-dihydro-4,6-dimethylthieno[3,4-*c*]pyridin-3(1*H*)-one-7-carboxylate **7** which was sublimed at 70°C/0.01 Torr and then resublimed at 90°C/0.01 Torr to give colorless **7** mp 130–131°C; uv λ_{max} (ε): 215 (17 900), 239 (sh, 9400), 264 (sh, 6900), 285 (sh, 5300); ir ν_{max}: 1725 (aryl ester) and 1685 (unsaturated γ-thiol-lactone) cm^{-1} (31); ^{1}Hmr (B) δ: 2.76 (s, 3H, C-methyl), 2.84 (s, 3H, C-methyl), 3.96 (s, 3H, methyl ester), and 4.57 (s, 2H, CH_2); ms *m/e*: 237(98, M^+), 222(39), 206(39), 205(100), 194(14), 178(21), 177(75), 176(18), 149(14), 108(18), and 91(18). *Anal.* calcd. for $C_{11}H_{11}NO_3S$: C 55.70, H 4.67, N 5.90, S 13.49; found: C 55.76, H 4.70, N 5.94, S 13.49.

Oxidation of Methyl 1,3,5,7a-Tetrahydro-4,6-dimethylthieno[3,4-c]pyridin-3(1H)-one-7-carboxylate, 6

The tetrahydrothienopyridine **6** (60 mg) was shaken with dilute nitric acid (1.9 mL, 4 *M*) until dissolution was complete, and then for a further 5 min. The reaction mixture was quickly adjusted to pH 8–8.5 by addition of sodium carbonate solution and then extracted using ether (3 × 10 mL). The bulked ether extract was washed with water (2 mL), dried ($MgSO_4$), filtered, and evaporated. Sublimation of the residue at 70°C/0.01 Torr gave colorless needles of methyl 1,3-dihydro-4,6-dimethylthieno[3,4-*c*]pyridin-3(1*H*)-one-7-carboxylate **7** (32 mg, 54%) mp 130–131°C, and was identical with the compound obtained in the previous experiment.

Reaction of Dimethyl 7-Thia-2-aza-1,3-dimethylbicyclo[3.2.1]-oct-3-ene-4,8-dicarboxylate **4***a with Iodomethane*

A solution of the bicyclic compound **4***a* (0.506 g) and iodomethane (2.5 mL) in dry dimethylformamide (2.5 mL) was heated at 74°C for 2 h in a sealed tube during which time crystals were deposited. After cooling and addition of dry benzene (30 mL), filtration afforded pale yellow crystals which, after recrystallization from ethanol, gave colorless crystals of trimethylsulfonium iodide (0.202 g, 53%) mp 206–207°C (lit. (32) mp 203–207°C) undepressed on admixture with authentic material; ^{1}Hmr (B) (trifluoracetic acid) δ: 3.03 (s).

The benzene filtrate was washed with water (2 mL), sodium thiosulfate solution (2 × 2 mL, 10%), water (7 × 2 mL), dried ($MgSO_4$), filtered, and evaporated to give colorless crystals of dimethyl 1,4-dihydro-4-iodomethyl-2,6-dimethylpyridine-3,5-dicarboxylate **8** (0.335 g, 49%) mp 153–154°C (lit. (10) 155–157°C) which was not depressed on admixture with authentic material synthesized by the action of sodium iodide on the corresponding chloromethyl compound **1***a* in acetonitrile (ref. 33). The ir, ms, and ^{1}Hmr spectra of the iodomethyl compound obtained from the bicyclic compound **4***a* were identical with those of the iodomethyl compound obtained from **1***a* and with those reported by Ashby and Eisner (9) with the exception of the signal due to the methylene group which appears at δ 3.29 (d, J = 5.0 Hz) (Ashby and Eisner report δ 2.24).

Diethyl 7-Thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene-4,8-dicarboxylate, **4***b*

Diethyl 4-chloromethyl-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate **1***b* (2.2 g) and thiourea (0.8 g) in ethanol (50 mL, 95%) were refluxed for 3.5 h, cooled, and evaporated *in vacuo*. The crude isothiouronium compound **2***b*, without further purification, was heated at 80–85°C with concentrated ammonium hydroxide (10 mL) for 1 h, cooled, and worked up, as in previous experiments, to give a brown oily product (1.699 g) which was purified by preparative tlc on silica gel plates using ethyl acetate/60–80°C petroleum ether (1:1) to give bicyclic compound **4***b* as a colorless glass (1.37 g, 63%); uv λ_{max} (ε): 262 (3800), 302 nm (9200); ir ν_{max}: 3423 (NH), 1730 (saturated ester), 1680 (unsaturated ester), 1595, 1475 cm^{-1}; ^{1}Hmr (A) δ: 1.13 (t, 3H, J = 7.04 Hz, methyl of saturated ethyl ester), 1.18 (t, 3H, J = 7.07 Hz, methyl of unsaturated ethyl ester), 1.76 (s, 3H, methyl at C(1)), 2.06 (s, 3H, methyl at C(3)), 2.98 (d, 1H, J = 3.15 Hz, H at C(8)), 3.16 (d, 2H, J = 2.70 Hz, H's at C(6)), 3.77 (br q, J approx. 2.9 Hz, H at C(5)), 4.05, 4.07 (overlapping q, 4H, J = 7.04 Hz, CH_2's of ethyl esters), 4.79 (br s, 1H, NH); ms *m/e*: 299(36, M^+), 252(100), 224(47), 208(13), 206(7), 196(40), 180(75), 152(37), 134(7), 129(20), 125(7), 108(9), 107(10), 106(15), 84(11), 57(14), and 42(12); m* 199 (252 → 224), 171.5 (252 → 208). Accurate mass on molecular ion: calcd. for $C_{14}H_{21}NO_4S$: 299.11908; found: 299.11902.

The Reaction of the Isothiouronium Salt from 3,5-Diacetyl-4-chloromethyl-1,4-dihydro-2,6-dimethylpyridine with Ammonium Hydroxide

3,5-Diacetyl-4-chloromethyl-1,4-dihydro-2,6-dimethyl-pyridine **1***c* (1.2 g) and thiourea (0.42 g) were refluxed, with stirring, in ethanol (95%, 25 mL) for 2.5 h. The solution was then cooled and evaporated *in vacuo*. The crude, solid isothiouronium salt **2***c* was then, without further purification, heated with concentrated ammonia (10 mL) at 74°C for 1 h.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

After cooling, the solution was extracted with ethyl acetate (2 × 35 mL) and the bulked organic extract washed with water (10 mL), dried ($MgSO_4$), filtered, and evaporated to give a residual brown oil (0.789 g) which was shown by tlc to contain at least 5 components. Separation was achieved by preparative tlc on three 20 cm × 20 cm × 0.15 cm silica gel GF_{254} plates using ethyl acetate/60–80°C petroleum ether (1:1). The following components, in order of decreasing R_f, were isolated and characterized.

(*i*) 3-Acetyl-2-methylpyrrole (0.073 g, 12%) purified by recrystallization from 60–80°C petroleum ether and then sublimation at 64°C/0.05 Torr to give colorless needles, mp 90–90.5°C (lit. (34–36) mp 94–95, 86–87, 75°C); uv λ_{max} (ε): 210 (8300), 243 (8000), 282 nm (6300); ir ν_{max}: 3453 (NH, free), 3288 (NH, bonded), 1650 (carbonyl) cm^{-1}; ^{1}Hmr (B) δ: 2.41 (s, 3H, methyl), 2.53 (s, 3H, methyl), 6.46 (d, 1H, $J_{4,5}$ = 4 Hz, H at C(4)), 6.54 (d, 1H, $J_{4,5}$ = 4 Hz, H at C(5)), 9.39 (br s, 1H, NH); ms *m/e*: 123 (65, M^+), 108(100), 80(17), 53(20), 53.5(9), 52(7), 51(5), 43(8), and 39(8); m* at 94.9 (123 → 108 req m* 94.83), 59.5 (108 → 80 req m* 59.3), and 35.2 (80 → 53 req m* 35.11).

(*ii*) 4-Acetyl-7-thia-2-aza-1,3-dimethylbicyclo[3.2.1]oct-3-ene **11** (0.034 g, 3%) mp 180–181.5°C, purified by repeated preparative tlc; uv λ_{max} (ε): 273 (2000), 325 nm (9100); ir ν_{max}: 3415 (NH), 1710 (weak), 1632 (sh), 1627 (aminoenone carbonyl), 1565, 1462 cm^{-1}; ^{1}Hmr (A) δ: 1.75 (s, 3H, methyl at C(1)), 2.16 (s, 3H, methyl at C(3)), 2.21 (s, 3H, acetyl), 2.27 (d, 2H, *J* = 2.44 Hz, H's at C(8)), 3.39 (d, 2H, *J* = 2.93 Hz, H's at C(6)), 3.50 (br t, 1H, *J* = 2.93 Hz clearly discernible, H at C(5)), 4.70 (br s, 1H, NH); ms *m/e*: 197(44, M^+), 164(9), 154(17), 151(16), 150(100, $C_9H_{12}NO$ requires 150.0920; found 150.0915), 136(16), 121(9), 108(16), 107(11), 106(8), 99(10), 84(10), 58(9), 57(80), 44(9), 43(33), and 42(16). Accurate mass on molecular ion: calcd. for $C_{10}H_{15}NOS$: 197.08741; found: 197.0879.

*Dimethyl 7-Thia-2-aza-1,2,3-trimethylbicyclo[3.2.1]oct-3-ene-4,8-dicarboxylate, **18***

Dimethyl 4-chloromethyl-1,4-dihydro-1,2,6-trimethylpyridine-3,5-dicarboxylate (37) (0.632 g) and thiourea (0.240 g) were refluxed in ethanol (95%, 15 mL) for 4½ h. The resulting solution was cooled, evaporated *in vacuo*, and the solid residue extracted with dry ether (2 × 15 mL) to remove an oily impurity. The solid was then heated at 100°C for 1 h with concentrated ammonium hydroxide (3 mL). After cooling, the reaction mixture was extracted using ethyl acetate (2 × 35 mL) and the organic extract washed with water (3 × 10 mL), dried ($MgSO_4$), filtered, and evaporated to give a pale brown oil (0.266 g). Purification was effected by preparative tlc twice on one 20 cm × 20 cm × 0.15 cm silica gel GF_{254} plate. When the almost pure product was held at 70°C/0.01 Torr for 15 min, a more volatile impurity was removed. Distillation of the residue at 95°C/0.01 Torr afforded an oil which solidified on standing to give colorless crystalline **18** (0.090 g, 14%) mp 78–80°C; uv λ_{max} (ε): 261 (2800), 316 nm (12 200); ir ν_{max}: 1735 (saturated ester) and 1675 cm^{-1} (unsaturated ester); ^{1}Hmr (A) δ: 1.90 (s, 3H, methyl at C(1)), 2.28 (s, 3H, methyl at C(3)), 2.88 (s, 3H, N-methyl), 3.18 approx. (m, 3H, H's at C(6) and C(8)), 3.65 (s, 3H, methyl ester), 3.66 (s, 3H, methyl ester), and 3.83 (overlapping broadened triplets, 1H, H at C(5)); ms *m/e*: 285(57, M^+), 254(22), 238(79), 226(24), 194(14), 181(13), 180(100), 129(85), 120(15), 98(21), and 56(16); accurate mass on molecular ion: calcd. for $C_{13}H_{19}NO_4S$: 285.10347; found: 285.10307.

Spin trapping for hydroxyl in water: a kinetic evaluation of two popular traps[1]

PAUL R. MARRIOTT, M. JOHN PERKINS,[2] AND DAVID GRILLER
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received November 19, 1979

PAUL R. MARRIOTT, M. JOHN PERKINS, and DAVID GRILLER. Can. J. Chem. **58**, 803 (1980).

Two spin traps, 4-(*N*-methylpyridinium)*tert*-butyl nitrone (4-MePyBN) and 5,5-dimethyl-1-pyrroline-1-oxide (DMPO) were examined for their effectiveness at trapping hydroxyl in water. At pH 6 and 22°C, rate constants for trapping hydroxyl were found to be $0.5 \times 10^9\ M^{-1}\ s^{-1}$ (4-MePyBN) and $2.0 \times 10^9\ M^{-1}\ s^{-1}$ (DMPO). The hydroxyl adduct of DMPO decayed by a first order process with a half-life of 870 s. This was at least three times greater than that of the 4-MePyBN adduct. These and other results suggest that DMPO is the superior trap for this particular application and is well suited for use in biological systems.

PAUL R. MARRIOTT, M. JOHN PERKINS et DAVID GRILLER. Can. J. Chem. **58**, 803 (1980).

On a examiné deux pièges à spin la (*N*-méthylpyridinium)-4 *tert*-butyl nitrose (MePy-4BN) et l'oxyde-1 de diméthyl-5,5 pyrroline-1 (ODMP), pour leur efficacité dans la capture du groupe hydroxyle dans l'eau. On a trouvé, à 22°C et à un pH = 6, que les constantes de vitesse de la capture du groupe hydroxyle dans l'eau sont de: $0.5 \times 10^9\ M^{-1}\ s^{-1}$ (MePy-4BN) et $2.0 \times 10^9\ M^{-1}\ s^{-1}$ (ODMP). L'adduit hydroxyle du ODMP se décompose selon une réaction du premier ordre avec une demi-vie de 870 s. Cette période est au moins trois fois plus élevée que celle de l'adduit du MePy-4BN. Ces résultats ainsi que d'autres suggèrent que le ODMP est le piège idéal dans cette application particulière et il est indiqué pour être utilisé dans les systèmes biologiques.

[Traduit par le journal]

Introduction

The technique of spin trapping (1) was developed and proved in the general area of organic chemistry. However, it has recently seen increasing use in the biological field (2) where direct detection of free radicals is made extremely difficult by the complex nature of the systems under study. For example, spin trapping has been used to detect superoxide, $O_2^{-}\cdot$, formation in chloroplasts (3) in aerobic microsomal reduction of nitro-compounds (4) and in melanin photoreactions (5). It has also been used to identify hydroxyl radical production in systems involving aminoquinone antibiotics (6), bleomycin and iron(II) (7), photooxidation of chlorophylls (8), and microsomal lipid peroxidation (9).

In essence, the spin trapping experiment involves capture of a short-lived radical, R·, by a spin trap, to give a persistent spin adduct, SA·, which can be detected by epr spectroscopy. Most often the trap is a nitrone or nitroso compound and therefore the spin adducts are nitroxides.

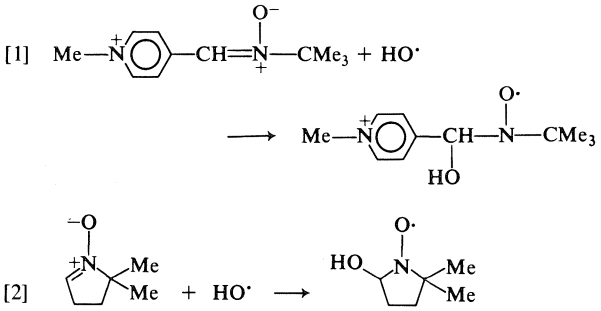
$$R\cdot + \text{trap} \rightarrow SA\cdot$$

Although spin trapping is conceptually simple, the results can be misleading if they are not quantified. For example, a positive result can arise in systems where radicals are involved in a minor side reaction. Conversely, failure to observe a spin adduct does not prove the absence of radicals. It may simply reflect low rates of trapping or the formation of a short-lived spin adduct.

For the results of a trapping experiment to be of significance several criteria should be met and, where possible, quantified. These are: (*a*) the spin trap must be inert towards all reagents in the system except free radicals; (*b*) radicals should react rapidly with the spin trap so that competing reactions which destroy them are minimized; (*c*) the spin adducts must be long lived so that they can easily be detected; and (*d*) the epr parameters of the spin adducts must be sensitive to the nature of the radicals trapped.

Each of these four criteria has been examined in a few specific systems but rarely in a completely systematic way. As examples we note: (*a*) the failure of a spin trap due to its oxidation in a hydroperoxide–hematin system (10); (*b*) the measurement of rate constants[3] for spin trapping of benzoyloxy (11), alkoxycarbonyl (12), alkoxyl (13), phenyl (14), and alkyl radicals (15) although in media which are not always appropriate to biological work (16); (*c*) the measurement of the half-lives of spin adducts (15, 17) such as that of $O_2^{-}\cdot$ to 5,5-dimethyl-1-pyrroline-1-oxide (17); and (*d*) the extensive discussion of the sensitivity of epr parameters to the nature of the trapped radical particularly when phenyl-*tert*-butyl nitrone (PBN) was the spin trap (18).

[1]NRCC No. 18063.



[2]Visiting scientist 1979; permanent address: Department of Chemistry, Chelsea College, University of London, Manresa Road, London, England SW3 6LX.

[3]These experiments have all been based on competitive reaction schemes and thus depend on the reliability of absolute rate constants drawn from other sources. Their accuracy should be assessed with this in mind.

In this work we have evaluated factors (*a*)–(*d*) for an important biological application of spin trapping, that of detecting hydroxyl radicals in water. Two traps have been investigated; 4-(*N*-methylpyridinium)*tert*-butyl nitrone (4-MePyBN) (19) which is a water soluble trap representative of the PBN family and 5,5-dimethyl-1-pyrroline-1-oxide (DMPO) (20). The results suggest that DMPO is the superior reagent in this particular application.

Experimental

Materials

4-MePyBN and DMPO were obtained from Spin Trap Producers (Guelph, Ontario) and Aldrich respectively. DMPO required purification before use (17) (see below). All other materials were reagent grade and were used without further purification.

Electron Paramagnetic Resonance Measurements

Radicals were generated by photolyzing samples directly in the cavity of a Varian E 104 EPR spectrometer using a high pressure mercury arc lamp. The output of the lamp was filtered through an aqueous mixture of cobalt and nickel sulphates which removed much of the visible and most of the infrared radiation. The lamp was deliberately defocused to ensure uniform irradiation across the sample and the light intensity was adjusted using neutral density filters so that the rate of growth of spin adducts could be easily adjusted. Radical concentrations were determined using a standard procedure (21).

Sample Preparation

Samples were prepared in the dark and under nitrogen. Reagents were purged with nitrogen before mixing. In a typical experiment, a 1% aqueous hydrogen peroxide solution (sodium phosphate buffered) containing spin trap (~0.1 *M*) and (as required) organic substrate (~0.1 *M*) was transferred to a standard aqueous epr sample cell (0.2 mm id) and was then photolyzed in the cavity of the spectrometer. Under the low light intensities used in these experiments, photolysis of solutions in the absence of hydrogen peroxide gave no signals in the case of 4-MePyBN and *exceedingly* weak signals with DMPO which were not sufficiently strong to interfere with any of the experiments. However, samples containing hydrogen peroxide and 4-MePyBN gave weak signals before photolysis at pH 6 due to the ·OH adduct in the absence of methanol and to the $\cdot CH_2OH$ adduct when methanol was present in excess. This problem became progressively worse with increasing pH to the extent that at pH 7–8 the kinetic experiments could not be carried out. These results indicate that there is a slow, direct reaction between the trap and hydrogen peroxide which liberates hydroxyl. Under similar conditions, weak signals were observed with DMPO but were always < 1% of the final signal intensity. Despite these epr observations, nmr spectra of reaction mixtures at pH 6 showed no detectable change over the timescale of the experiment (1 h).

In order to remove the coloured impurity associated with DMPO (17), sample solutions containing this trap were shaken with activated charcoal and were filtered through glass wool prior to photolysis. This purification procedure tends to remove a small amount (~10%) of the spin trap itself. Therefore, in kinetic experiments the relative concentrations of trap and organic substrate were measured by nmr integration before epr experiments were carried out. We caution against the practice of storing stock solutions of spin traps since these often deteriorate with time (17).

Results and Discussion

The spin trapping experiments carried out in this work are described by the following reaction scheme:

$$[3]\quad HOOH \xrightarrow{h\nu} 2HO\cdot$$

$$[4]\quad HO\cdot + \text{trap} \xrightarrow{k_4} SA(HO\cdot)$$

$$[5]\quad HO\cdot + RH \xrightarrow{k_5} H_2O + R\cdot$$

$$[6]\quad R\cdot + \text{trap} \xrightarrow{k_6} SA(R\cdot)$$

Clean spectra of SA(HO·) and SA(R·) were generated respectively in the absence or in the presence of a large excess of an organic substrate. Samples of this kind were used to measure epr parameters and the decay kinetics of the spin adducts. For measurements of rate constants for spin trapping (k_4), the concentrations of RH and trap were adjusted so that the respective spin adducts were formed at similar rates and could both be detected in the same sample.

At the concentrations used in these experiments, no signals were observed due to the HOO· spin adduct although these have been reported when higher concentrations of hydrogen peroxide and lower concentrations of spin trap were used (18*a*). These results are consistent with the relatively slow rate of reaction between hydroxyl and hydrogen peroxide ($k_7 = 4.5 \times 10^7\ M^{-1}\ s^{-1}$ at pH 7) (22) as compared with the much faster rate constant for spin trapping (see below).

$$[7]\quad HO\cdot + H_2O_2 \xrightarrow{k_7} H_2O + HOO\cdot$$

Electron Paramagnetic Resonance Parameters

Electron proton resonance parameters for the spin adducts studied are given in Table 1 and where comparison was possible were in good agreement with literature data. Parameters for the 4-MePyBN spin adducts show a very small dependence on the type of radical being trapped. The consequences of this situation are illustrated in Fig. 1 which shows the spectrum of a solution containing the HO· and $\cdot CH_2OH$ spin adducts of 4-MePyBN. The simulation shown in the figure was obtained by adding spectra calculated from the epr parameters of the

individual spin adducts and confirms the analysis. However, it is quite clear that the similarity of spectra for spin adducts of 4-MePyBN will cause difficulties in identifying the nature of the trapped radicals and in quantifying relative radical concentrations. This problem of spectral clarity is often encountered with PBN type traps (18) and must be regarded as a serious disadvantage.[4] By way of

[4]As a further illustration, trapping of hydroxyl by PBN in a dimethylsulphoxide based solvent has been reported (6) although the observed hyperfine parameters were slightly different to those normally observed for the hydroxyl adduct (18). A similar experiment with DMPO (P. R. Marriott, unpublished results) shows that the radical trapped was more likely to have been methyl; a result consistent with the rapid reaction of hydroxyl with dimethylsulphoxide (23).

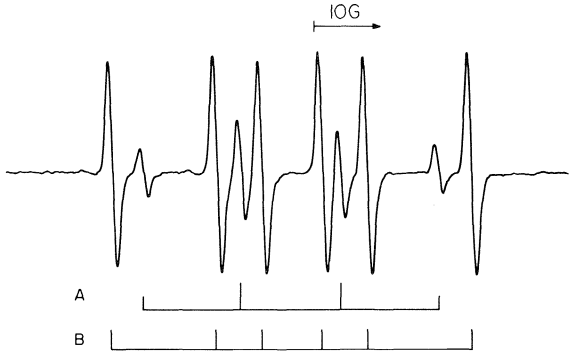

FIG. 2. Electron paramagnetic resonance spectrum of ·OH (*A*) and ·CH_2OH (*B*) spin adducts of DMPO.

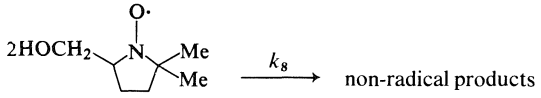
comparison, Fig. 2 shows the analogous spectrum obtained using DMPO as trap. Its simplicity and clarity contrast sharply with the case of 4-MePyBN. The higher signal-to-noise ratio in the spectrum is a consequence of kinetic properties.

Decay Kinetics of Spin Adducts



Rate constants for the decay of the hydroxyl adduct of DMPO at various pH are given in Table 2. At concentrations less than 4×10^{-5} *M* the decay was first order with a half-life of 870 s and the rate constants were independent of the concentrations of spin trap and hydrogen peroxide when each of these was varied by a factor of five. At higher concentrations the decay tended towards second order kinetics. The half-life of the hydroxyl adduct of DMPO is at least an order of magnitude greater than that of the O_2^{-}· adduct which is pH dependent ($\tau_{1/2} \sim 80$ s at pH 6 and ~35 s at pH 8 (17)).

TABLE 2. First order rate constants for the decay of the hydroxyl adduct of DMPO at 22°C

pH	Initial radical concentration (*M*)	Rate constant (s^{-1})
6.0	1.5×10^{-5}	4.7×10^{-4}
7.0	5.4×10^{-5}	8.4×10^{-4}
8.0	5.4×10^{-5}	9.8×10^{-4}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

The $\cdot CH_2OH$ spin adduct of DMPO was far more persistent than that for hydroxyl and decayed with second order kinetics. The rate constant for the decay, k_8, was found to be 184 M^{-1} s^{-1} at pH 7.

[8]

The kinetic order for the decay of the hydroxyl adduct of 4-MePyBN could not be accurately determined because the maximum attainable concentration was not high enough for the decay to be monitored over several half-lives. However, an indication of the longevity of the spin adduct is that a 1.4×10^{-6} M solution decayed with a half-life of ~270 s at 22°C. By contrast the $\cdot CH_2OH$ adduct of 4-MePyBN was quite persistent, although this may in part reflect slow radical generation via the thermal reaction of hydrogen peroxide and trap (see Experimental section).

Rate Constants for Spin Trapping

Rate constants for spin trapping were determined in competition experiments where the known rate constant for reaction of hydroxyl with methanol (k_5) (ref. 24, taking the average of rate constants obtained by a variety of techniques) was chosen as a suitable kinetic standard. The concentrations of spin trap and methanol were varied until both $\cdot OH$ and $\cdot CH_2OH$ spin adducts could be detected in the same sample. The incident light intensity was also adjusted so that the growth in the spin adduct concentrations from the start of photolysis took place over a convenient time scale (ca. 5 min) for measurements to be taken. Near to the start of photolysis the chemistry of the system can be described by reactions [3]–[6]. This is because the time scale of this experiment is short compared to that for the unimolecular decay of the spin adducts and spin adduct concentrations are so low that radical–radical reactions do not contribute to the reaction scheme. Furthermore, since $R\cdot$ is efficiently trapped and its concentration is small compared to those of other components in the system, it follows that at the start of photolysis,

$$[9] \quad d[R\cdot]/dt = k_5[HO\cdot][RH] - k_6[R\cdot][trap] = 0$$

while

$$[10] \quad d[SA(R\cdot)]/dt = k_6[R\cdot][trap]$$

and

$$[11] \quad d[SA(HO\cdot)]/dt = k_4[HO\cdot][trap]$$

Combining these equations, we obtain

$$[12] \quad \frac{k_4}{k_5} = \frac{d[SA(HO\cdot)]/dt}{d[SA(R\cdot)]/dt} \cdot \frac{[RH]}{[trap]}$$

Since k_5, [RH], and [trap] are known, k_4, the rate constant for spin trapping is determined by measuring the initial rate of growth of the spin adducts.

Rate constants for trapping hydroxyl by DMPO and 4-MePyBN are given in Table 3. They were independent of the ratio of trap-to-methanol concentrations when this was varied by a factor of five. Experiments with 4-MePyBN were restricted to pH 6 because of problems with the "dark spectra" (see above) and must have greater error limits than those with DMPO because of the difficulties of integration.

As a check on the efficacy of this experimental procedure, the rate constant for attack of hydroxyl at 2-propanol was determined using 2-propanol instead of methanol as the organic substrate. Using the value of k_4 obtained above the rate constant k_5 for reaction at 2-propanol was found to be 1.5×10^9 M^{-1} s^{-1}, in excellent agreement with pulse radiolysis data ($k_5 = 1.5 \times 10^9$ M^{-1} s^{-1} (24)). It should be noted that attack at 2-propanol occurs at both methyl and methine hydrogen atoms (reactions [13], [14]) (25), although only one spectrum was detected, presumably because the spin adducts due the two carbon centered radicals have similar epr parameters.

$$[13] \quad HO\cdot + (CH_3)_2CHOH \rightarrow H_2O + \dot{C}H_2(CH_3)CHOH$$

$$[14] \quad HO\cdot + (CH_3)_2CHOH \rightarrow H_2O + (CH_3)_2\dot{C}OH$$

These results suggest that the rate constant for spin trapping of hydroxyl by DMPO is a satisfactory standard for measuring rates of reaction of hydroxyl with organic substrates by the above spin trapping method.

Summary

In this work we have evaluated the use of two spin traps, DMPO and 4-MePyBN, as scavengers for hydroxyl radicals in water using criteria (*a*)–(*d*). We find that DMPO is the superior trap because (*a*) it is unaffected by changing pH while 4-MePyBN is

TABLE 3. Rate constants (k_4) for the spin trapping of hydroxyl at 22°C

Spin trap	pH	k_4/k_5[a]	$k_4 \times 10^{-9}$ (M^{-1} s^{-1})
4-MePyBN	6	1.1	0.5
DMPO	6	4.1	2.0
DMPO	7	5.5	2.7
DMPO	8	5.3	2.6

[a]Using methanol as competitor, $k_5 = 4.8 \times 10^8$ M^{-1} s^{-1} (24).

not; (*b*) it scavenges hydroxyl 4.0 times more rapidly than 4-MePyBN; (*c*) its hydroxyl spin adduct is 3.2 times longer lived than that of 4-MePyBN; and (*d*) the epr spectra of DMPO spin adducts are more sensitive to the nature of the adduct radical than those of 4-MePyBN.

These results show that the outcome of spin trapping experiments are likely to be particularly sensitive functions of the properties of the spin traps. They suggest that a more quantitative approach to spin trapping and careful selection of the spin traps for particular applications is likely to yield more reliable results.

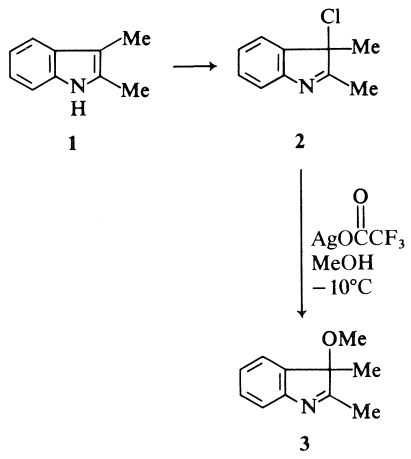
The bromination of 2,3-dimethylindole in acetic acid followed by hydrolysis has been shown to yield the known dimer **16** of 3-hydroxy-2,3-dimethylindolenine **15** and not 3-hydroxymethyl-2-methylindole **12** as reported previously by others. Bromination of 2,3-dimethylindole in the presence of triethylamine has yielded 3-bromo-2,3-dimethylindolenine **17** as a crystalline solid which is stable at room temperature in a nitrogen atmosphere in the presence of triethylamine but decomposes vigorously in the absence of base. Under mildly acidic conditions **17** reacts rapidly with methanol to yield 3-methoxy-2,3-dimethylindolenine **3** in good yield. With *tert*-butyl hypochlorite in the presence of triethylamine, 2,3-dimethylindole gives 3-chloro-2,3-dimethylindolenine **2** which has chemical properties similar to **17** reacting readily with methanol to give **3**. Similarly tetrahydrocarbazole was converted to the analogous chloroindolenine **5** and bromoindolenine **18** both of which readily underwent methanolysis to give **6** in good yield. A mechanism for the acid catalyzed methanolysis of 3-chloro- and 3-bromoindolenines is proposed.



GARY I. DMITRIENKO, EDWARD A. GROSS et SUSAN F. VICE. Can. J. Chem. **58**, 808 (1980).

On a montré que la bromation du diméthyl-2,3 indole dans l'acide acétique, suivie d'une hydrolyse, conduit au dimère connu **16** de l'hydroxy-3 diméthyl-2,3 indolénine **15** et non à l'hydroxyméthyl-3 méthyl-2 indole **12** tel que rapporté antérieurement. La bromation du diméthyl-2,3 indole en présence de triéthylamine conduit au dérivé bromo-3 diméthyl-2,3 indolénine **17** sous forme d'un solide cristallin stable à température normale sous atmosphère d'azote et en présence de triéthylamine mais il se décompose rapidement en l'absence de base. Dans des conditions légèrement acides, le composé **17** réagit rapidement avec le méthanol pour conduire au méthoxy-3 diméthyl-2,3 indolénine **3** avec un bon rendement. Le diméthyl-2,3 indole réagit avec l'hypochlorite de *tert*-butyle en présence de triéthylamine pour donner le chloro-3 diméthyl-2,3 indolénine **2** dont les propriétés chimiques sont semblables à celles du composé **17**. Il réagit rapidement avec le méthanol pour conduire au composé **3**. De la même manière, la tétrahydrocarbazole se transforme en chloro et bromoindolénine (**5** et **18**) qui par méthanolyse fournissent chacun avec un bon rendement le composé **6**. On propose un mécanisme pour expliquer la méthanolyse catalysée par un acide des chloro-3 et bromo-3 indolénines.

[Traduit par le journal]

In the course of studies aimed at the synthesis of biologically active indole derivatives, we sought a simple route to 3-alkoxy-2,3-dialkylindoles. A survey of the literature revealed two relatively recent reports of the preparation of 3-alkoxyindolenines. Gassman *et al.* have reported that treatment of 2,3-dimethylindole with *tert*-butyl hypochlorite or sodium hypochlorite at low temperature yields a thermally unstable compound with spectroscopic characteristics compatible with its formulation as the 3-chloroindolenine **2** (1). Treatment of this compound with an equivalent of silver trifluoroacetate in methanol was reported to yield the 3-methoxyindolenine **3** in good yield (Scheme 1).

Since our synthetic objective required the preparation of relatively large amounts of methoxyindolenines, the requirement in this procedure for a relatively expensive reagent, silver trifluoroacetate, was unattractive.

SCHEME 1

More recently, Owellen has modified Gassman's procedure and applied it to the synthesis of the methoxyindolenine of tetrahydrocarbazole (2). Thus, treatment of tetrahydrocarbazole (Scheme 2) at low temperature in benzene or methylene chloride with *tert*-butyl hypochlorite and triethylamine, yielded a solution of the chloroin-

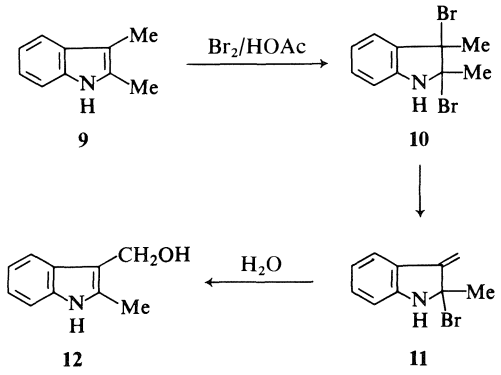
SCHEME 2

dolenine **5** which reacted with sodium methoxide in methanol to give largely the methoxyindolenine **6** accompanied by smaller amounts (about 20%) of the imido ether product **7**. The formation of an imido ether by-product limits the usefulness of this approach to the synthesis of 3-methoxyindolenines.

No other reports of the preparation of 3-alkoxy-2,3-dialkylindolenines could be found in the literature. There was, however, a report by Plant and Tomlinson of a rather simple preparation of 11-hydroxytetrahydrocarbazolenine, **8** (Scheme 3) by bromination–hydrolysis of tetrahydrocarbazole.[3] It was felt that this procedure might be changed into a synthesis of alkoxyindolenines rather than hydroxyindolenines simply by replacement of water by an appropriate alcohol.



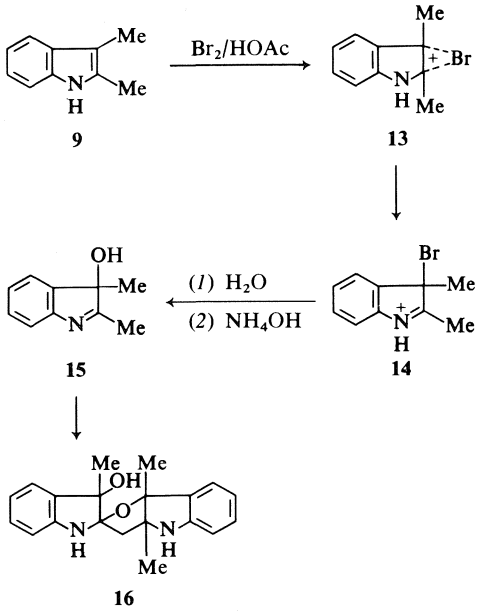
SCHEME 3

Since we were interested in a general synthetic approach, we were perplexed by another report by Plant and Tomlinson which indicated that application of the bromination–hydrolysis sequence to 2,3-dimethylindole gave not the 3-hydroxyindolenine but rather, 3-hydroxymethyl-2-methylindole **12** (6). Examination of the reported experimental details revealed that the structural assignment of this product rested on elemental analytical data and on an assumed mechanism illustrated in Scheme 4. It was assumed that the initial product was a dibromide **10** which underwent elimination of HBr to give the indicated allylic bromide **11** which in turn reacted with water by an S_N1' or S_N2' reaction to give 3-hydroxymethyl-2-methylindole.

In more recent work, Leete has synthesized authentic 3-hydroxymethyl-2-methylindole and has shown that the physical properties of this material are grossly different from those of Plant and Tomlinson's compound **12** (7). Unfortunately, Leete's observation has often been ignored in discussions of the bromination of 2,3-dimethylindole in recent review articles (8).

In order to clarify the situation, we have now repeated the bromination–hydrolysis of 2,3-dimethylindole as reported by Plant and Tomlinson.[4] We have found that bromination of 2,3-

SCHEME 4



dimethylindole in glacial acetic acid followed by the addition of water and basic aqueous workup gives a crude product from which a crystalline solid mp 225°C (lit. (6) mp 225°C) could be obtained in 36% yield by fractional crystallization. This product was easily identified as the known dimer **16** by comparison with an authentic sample (10). The dimer was shown unambiguously to have the structure **16** some years ago on the basis of chemical studies by Berti *et al.* (10*c*) and Dave and Warnhoff (10*b*) and by an X-ray crystallographic study by McLean *et al.* (10*a*). No 3-hydroxymethyl-2-methylindole could be detected by nmr analysis of the crude product.

The most obvious mechanistic rationale for the formation of the dimer was that indicated in Scheme 5. It was felt that bromination likely yielded a protonated 3-bromoindolenine **14**, perhaps via a bromonium ion **13**. Nucleophilic substitution of bromide by water could give the 3-hydroxyindolenine **15** which could dimerize to give

[3]Plant and Tomlinson initially assigned the structure of this product as 10-hydroxy-1,2,3,10-tetrahydrocarbazole (3). Sometime later, Patrick and Witkop (4) and also Plant and Tomlinson (5) revised the structure to 11-hydroxy-2,3,4,11-tetrahydrocarbazole.

[4]For a preliminary account of some of this work see ref. 9.

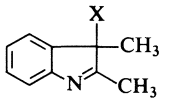
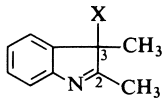


SCHEME 5

16 in a well known process (10, 11). Thus the reaction of 2,3-dimethylindole with bromine is not anomalous and appears to proceed in the same fashion as reported for tetrahydrocarbazole. The nature of the ultimate product is different because of the unusual tendency of 2-methyl-3-alkyl-3-hydroxyindolenines to dimerize (11).

Since this approach to the formation of 3-hydroxyindolenines appeared to have some generality after all, we next turned our attention to the preparation of 3-alkoxyindolenines in an analogous manner. We have now found that treatment of a methanol solution of 2,3-dimethylindole with an equimolar amount of bromine in acetic acid or methylene chloride at −5°C followed by basic aqueous workup yields the 3-methoxyindolenine **3** as an oil identical with the material prepared by the method of Gassman *et al.* (1). Similarly, tetrahydrocarbazole has been found to give the corresponding methoxyindolenine **6** uncontaminated by the spiro imido ether **7**.



In our initial study, we assumed the intermediacy of a 3-bromoindolenine in the bromination–hydrolysis and bromination–methanolysis of 2,3-dimethylindole (9). Further investigation has led to the isolation of this intermediate. We have now found that treatment of 2,3-dimethylindole in methanol or methylene chloride with an equimolar amount of bromine in methylene chloride in the presence of an excess of triethylamine followed by basic aqueous workup yields 3-bromo-2,3-dimethylindolenine as a crystalline solid. The structure of this product follows from nmr, ir, and

TABLE 1. Indolenines: infrared spectra

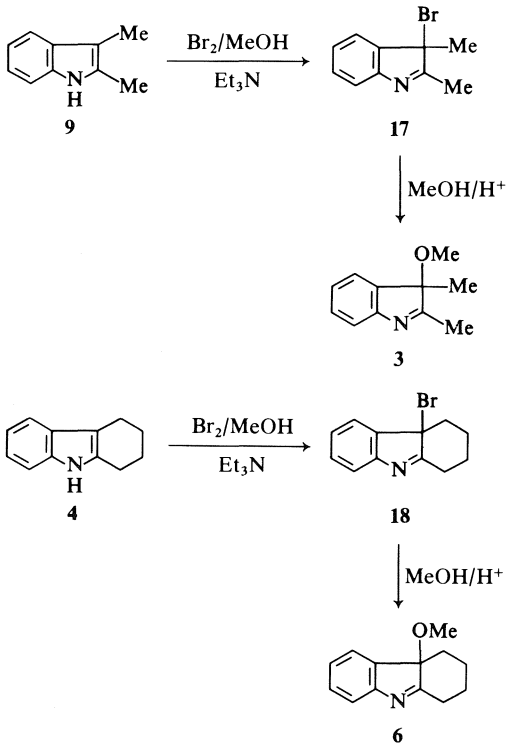
OMe	2.20	1.41
Cl	2.42	1.75
Br	2.43	1.83

uv spectral data. The ir spectrum shows no signal for indole N—H stretch but instead a band at 1605 cm^{-1} which can be assigned to an indolenine C—N stretch (see Table 1 for comparison with other indolenines). In the nmr spectrum there are two 3-proton singlets; one at δ 1.83 (C3—CH_3) and one at δ 2.43 ppm (C2—CH_3). The chemical shift of the C3—CH_3 group in the bromoindolenine **17** agrees reasonably well with that calculated (δ 1.90) on the basis of empirical substituent effects on chemical shifts (see Table 2) (12). Under the same conditions tetrahydrocarbazole gives an analogous bromoindolenine **18** (cf. Scheme 6).



Treatment of a methylene chloride solution of **17** or **18** with methanol followed by basic aqueous workup gave the corresponding methoxyindolenines in good yield. The best yields of methoxyindolenines were obtained by treatment of a methylene chloride solution of **17** or **18** with methanol containing sufficient *p*-toluene sulfonic acid to neutralize all triethylamine present.

The fact that **17** and **18** do not react with methanol in the presence of triethylamine but react readily in the absence of base strongly suggests that methanolysis of 3-bromoindolenines is an acid catalyzed process and thus likely proceeds via an

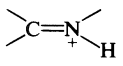
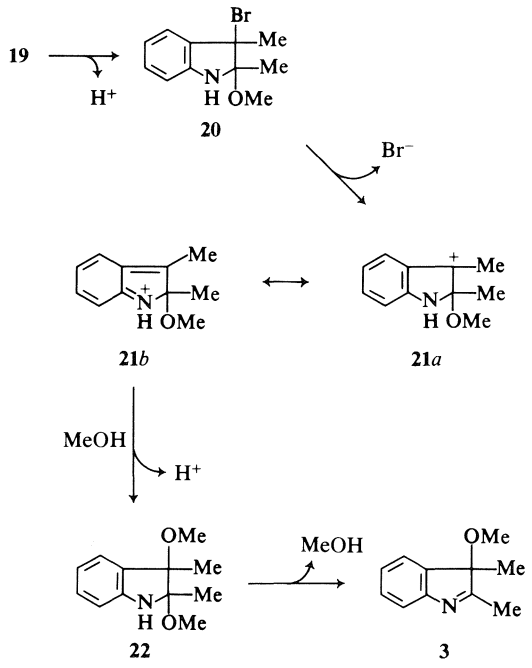
N-protonated bromoindolenine intermediate (Scheme 7). The S_N2 displacement of bromide ion from **19** is highly unlikely for steric reasons. Furthermore the positive charge in **19** would strongly disfavour development of additional positive charge as would be required in a simple S_N2 or S_N1 transition state.

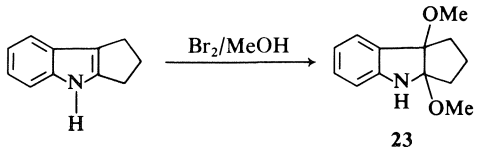


SCHEME 6



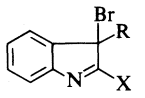
SCHEME 7

One reaction which would be expected to be favoured by protonation of the indolenine nitrogen is addition of methanol to the



bond to give, after deprotonation, the 2-methoxy-3-bromoindoline **20** (see Scheme 8). S_N1-type ionization of **20** would be expected to occur readily yielding a highly resonance stabilized carbonium ion **21**.

Addition of methanol followed by deprotonation would yield **22** which upon elimination of methanol



SCHEME 8

would give the observed methoxyindolenine. The failure of the reaction to proceed in the presence of base could be due to the failure to form significant amounts of the addition product **20** in the absence of acid catalysis. Consistent with this reaction scheme is the isolation of the 2,3-dimethoxyindoline **23** from the bromination–methanolysis of 2,3-cyclopentanoindole.[5]

Although a number of 3-bromoindolenines **24** possessing a heteroatom substituent at C-2 have been reported (13), **17** and **18** are the first 3-bromo-2,3-dialkyl indolenines to be isolated. As a result, some comments on the stability of **17** and **18**, especially in comparison with known 3-chloro-2,3-dialkylindolenines, are in order.

The bromoindolenine **17** is stable in the solid state at −78°C for at least several weeks. In the presence of small amounts of triethylamine **17** undergoes negligible decomposition after several hours at room temperature. Upon complete removal of triethylamine (as judged by nmr) *in vacuo*, **17** is stable in the solid form for at least forty minutes at room temperature if kept in a dry nitrogen atmosphere but decomposes with vigorous evolution of HBr to a deep blue-purple, highly insoluble solid upon exposure to a normal atmosphere.

The corresponding 3-chloroindolenine **2** has been detected in methylene chloride solution (1). It has been reported to be highly unstable, undergoing complete rearrangement to **25** or **26** upon brief warming from −78 to +15°C followed by rapid cooling in methylene chloride. Evaporation of a methylene chloride solution of **2** to dryness was reported to give an intractable product (1). The apparent instability of **2** relative to the 3-bromoindolenine **17** was puzzling. One possible explanation of this phenomenon lay in the fact that **17** was produced in the presence of base and solutions of **17** which were evaporated to dryness contained at least traces of triethylamine whereas solutions of **2** as prepared by Gassman and co-workers (1) did not contain base. To test this possibility, we have now prepared **2** by treatment of 2,3-dimethylindole with *tert*-butyl hypochlorite and triethylamine in methylene chloride followed by basic aqueous workup. The chloroindolenine **2** prepared in this way was isolated as a crystalline solid with stability comparable to that described for **17**. It seems clear now that the rearrangement process which converts **2** to **25** or **26** is an acid catalyzed process. The instability of the bromoindolenine **17** in the absence of base is likely due to initial rearrangement analogous to that reported for **2**, followed by as yet ill-defined, oligomerization reactions of **27** or **28** (Scheme 9).

It has been pointed out by Owellen (2) that solutions of the chloroindolenine **5** are unusually stable relative to **2**, undergoing no detectable decomposition at 70°C in benzene. Our observations suggest that this phenonmenon may be due to the fact that

SCHEME 9

benzene solutions of **5** were generated in the presence of triethylamine whereas the methylene chloride solutions of **2** were base free.

The chloroindolenines formed by chlorination of complex tryptamine-derived alkaloids have been reported to be relatively stable materials which can be recrystallized from alcohols without difficulty (14). It is interesting to speculate, based on our observations, that the stability of these compounds is due, at least in part, to the presence of a basic nitrogen atom within the chloroindolenine molecules themselves which inhibits acid catalyzed modes of decomposition.

The ease with which the 3-bromoindolenine **17** reacted with methanol to give the 3-methoxyindolenine **3** prompted us to question the reported need (1) for silver trifluoroacetate to catalyze the methanolysis of the 3-chloroindolenine **2**. We have now found that the crystalline chloroindolenine **2** reacts with methanol, containing no silver salts, very readily to give **3** in high yield. Similarly we have prepared the 3-chloroindolenine of tetrahydrocarbazole **5** by our method and converted it to the methoxyindolenine **6** simply by reaction with methanol.

It is clear now that the bromination of simple 2,3-dialkylindoles such as 2,3-dimethylindole and tetrahydrocarbazole proceeds via a 3-bromoindolenine which is a stable isolable compound in the presence of base. In the presence of acid 3-

bromoindolenines are unstable yielding highly coloured oligomeric products in an inert solvent and giving high yields of 3-methoxyindolenines in methanol. The latter reaction is clearly the method of choice for the preparation of simple 3-methoxy-2,3-dialkylindolenines. Chlorination of 2,3-dialkylindoles with *tert*-butyl hypochlorite gives high yields of 3-chloroindolenines which behave in an analogous manner to the 3-bromoindolenines. Experiments aimed at determining the limitations of the bromination–methanolysis route to methoxyindolenines and at exploring the reaction of 3-bromoindolenines with nucleophiles other than simple alcohols are in progress.

Experimental

Melting points were determined on a Fisher Mel-temp melting point apparatus and are uncorrected. Infrared spectra were recorded on a Beckman IR-10 spectrometer and the frequency (cm^{-1}) of significant peaks is reported. A Beckman Model 35 spectrophotometer was used for uv spectra and wavelengths (nm) of absorption bands are reported followed by extinction coefficients (ε) in parentheses. Nuclear magnetic resonance spectra were recorded on a Varian T-60 spectrometer (chloroform-*d* solvent unless otherwise indicated) and chemical shifts are reported on the δ scale, followed in parentheses by an account of the multiplicity and number of protons concerned. Mass spectra were recorded on a Varian CH-7 or VG-7070 mass spectrometer.

Indoles

2,3-Dimethylindole and tetrahydrocarbazole were prepared by Fischer cyclization of the appropriate phenylhydrazone by the method of Dave and Warnhoff (11*b*) and had physical constants in agreement with literature values.

Bromination–Hydrolysis of 2,3-Dimethylindole

Bromination–hydrolysis of 2,3-dimethylindole was performed essentially according to the method of Plant and Tomlinson (6).

To a rapidly stirred solution of 2,3-dimethylindole (0.522 g, 3.6 mmol) in glacial acetic acid (2 mL) at 0°C in a nitrogen atmosphere was added an equimolar amount of bromine in glacial acetic acid (2 mL). The whole was rapidly diluted with ice-water and the mixture was made basic with aqueous ammonia. The basic mixture was extracted with ether. The ether extract was washed with saturated aqueous sodium chloride, dried over anhydrous sodium sulfate, and evaporated to dryness on a rotary evaporator to yield a tan coloured solid. The nmr spectrum of the crude product indicated the complete absence of 3-hydroxymethyl-2-methylindole. Recrystallization of the crude product from ether gave a crystalline product (0.209 g, 36% yield) mp 224–225°C identical in all respects with the dimer **16** prepared by autoxidation of 2,3-dimethylindole (10).

*Preparation of 3-Bromo-2,3-dimethylindolenine **17***

2,3-Dimethylindole (0.45 g, 3.1 mmol) was dissolved in anhydrous methanol (20 mL) containing triethylamine (1 mL). The solution was cooled to −5°C and a solution of bromine (1 equivalent) in methylene chloride (4 mL) was added dropwise with stirring in a nitrogen atmosphere. After 5 minutes, water was added and the mixture was extracted with methylene chloride. The dried organic phase was evaporated to dryness *in vacuo* at room temperature to yield a pale yellow crystalline solid (0.68 g, 3.0 mmol) which was stable at room temperature in a nitrogen atmosphere or in a stoppered flask at −78°C. Infrared (Nujol): 1605; uv (0.1% Et_3N in CH_2Cl_2): 285 (2860), 291 (sh); nmr: 1.83 (s, 3), 2.43 (s, 3), 6.9–7.5 (m, 4).

*Preparation of 3-Chloro-2,3-dimethylindolenine (**2**)*

2,3-Dimethylindole (0.450 g, 3.1 mmol) was dissolved in methylene chloride (20 mL). The solution was cooled to −11°C in a nitrogen atmosphere and *tert*-butyl hypochlorite (3.1 mmol) in methylene chloride (9 mL) was added dropwise with stirring followed by triethylamine (1 mL). After stirring for an additional five minutes the workup was as described for **17** to give **2** as a pale yellow solid which was stored at room temperature in a nitrogen atmosphere and was used for subsequent reactions without further purification; ir (Nujol): 1585; uv (0.1% Et_3N/CH_2Cl_2): 285 (2800), 308 (sh); nmr: 1.75 (s, 3), 2.42 (s, 3), 6.96–7.60 (m, 4).

*Preparation of 3-Methoxy-2,3-dimethylindolenine by Methanolysis of **17***

3-Bromo-2,3-dimethylindolenine **17** (0.473 g, 2.11 mmol) was dissolved in methylene chloride (10 mL) and the solution cooled to −5°C in a nitrogen atmosphere. Methanol (20 mL) was added in 1 mL portions with stirring. The solution was stirred an additional 5 minutes. Water (75 mL) was added, the mixture was made basic with 10% aqueous ammonia and extracted with methylene chloride. Removal of solvent from the dried organic phase gave a colourless oily product (0.37 g) which was chromatographically pure and identical in all respects with 3-methoxy-2,3-dimethylindolenine prepared by the method of Gassman and co-workers (1).

*Preparation of 3-Methoxy-2,3-dimethylindolenine by Methanolysis of the Chloroindolenine **2***

Treatment of the chloroindolenine **2** with methanol as described for **17**, gave a quantitative yield of 3-methoxy-2,3-dimethylindolenine.

Preparation of 3-Methoxy-2,3-dimethylindolenine from 2,3-Dimethylindole

2,3-Dimethylindole (0.500 g, 3.45 mmol) was dissolved in a mixture of methylene chloride (20 mL) and triethylamine (1 mL). A solution of bromine (4.11 mmol) in methylene chloride (5.3 mL) was added dropwise with stirring to the cooled (−5°C) solution in a nitrogen atmosphere. The mixture was stirred an additional five minutes and methanol (20 mL) was added. A solution of *p*-toluenesulfonic acid monohydrate in methanol was added dropwise until a permanent orange-red colour was obtained. After 5 min, basic aqueous workup yielded the methoxy indolenine **4** (0.549 g, 3.14 mmol) identical in all respects with material prepared by the method of Gassman *et al.* (1).

*Preparation of Bromotetrahydrocarbazolenine (**18**)*

Tetrahydrocarbazole (0.530 g, 2.92 mmol) was dissolved in methylene chloride (20 mL) and triethylamine (1 mL) was added. One equivalent of bromine in methylene chloride (4 mL) was added dropwise at room temperature in a nitrogen atmosphere. The mixture was stirred a further 5 minutes and then partitioned between water (75 mL) and methylene chloride (50 mL). Removal of solvent from the dried organic phase *in vacuo* at room temperature left a pale yellow oil (0.60 g, 2.4 mmol) which was used without further purification for subsequent reactions; ir (neat): 1590; nmr: 0.9–3.3 (m, 8), 6.9–7.6 (m, 4).

*Preparation of Chlorotetrahydrocarbazolenine (**5**)*

Treatment of tetrahydrocarbazole (0.50 g, 2.69 mmol) with *tert*-butyl hypochlorite in the same manner as described in the preparation of **2** gave the chloroindolenine **5** as a pale yellow

solid (0.522 g, 2.54 mmol) which was used without further purification for subsequent reactions; ir (neat): 1595; uv (0.1% Et_3N/CH_2Cl_2): 264 (approx. 2250), 290 (sh); nmr: 1.19–2.95 (m, 8), 6.75–8.07 (m, 4).

Preparation of Methoxytetrahydrocarbazolenine

From the Chloroindolenine 5

Treatment of a methylene chloride solution of the chloroindolenine **5** with methanol as described for **2** gave the methoxyindolenine **6** as a homogeneous colourless oil (0.27 g, 1.34 mmol) identical in all respects with the methoxytetrahydrocarbazolenine prepared by the method of Owellen (2).

From the Bromoindolenine 18

Treatment of a methylene chloride solution of **18** (prepared from 0.53 g of tetrahydrocarbazole) with methanol as described for **17** gave the methoxyindolenine **6** as a thick oil (0.56 g).

From Tetrahydrocarbazole

Tetrahydrocarbazole (0.53 g, 3.1 mmol) was dissolved in methylene chloride (20 mL) containing triethylamine (1.0 mL). The solution was cooled in ice and one equivalent of bromine in methylene chloride (4 mL) was added dropwise over a period of 5 minutes. After the addition of anhydrous methanol (20 mL), a solution of *p*-toluenesulfonic acid monohydrate (0.780 g) in methanol (5 mL) was added dropwise. Basic aqueous workup as described previously yielded a pale yellow oil (0.57 g) consisting of **6** contaminated with a small amount of tetrahydrocarbazole. Column chromatography of the crude product on silica gel with elution by 10% v/v diethyl ether – petroleum ether (60–80) gave a colourless oil which solidified on standing (0.45 g). This material was identical with an authentic sample of **6** prepared by the method of Owellen (2).

Synthesis, X-ray structure determination, and formation of 3,4,5-trichloroguaiacol occurring in kraft pulp spent bleach liquors

K. LINDSTRÖM AND F. ÖSTERBERG

Swedish Forest Products Research Laboratory, Box 5604, S-114 86 Stockholm, Sweden

Received October 2, 1979

K. LINDSTRÖM and F. ÖSTERBERG. Can. J. Chem. **58**, 815 (1980).

3,4,5-Trichloroguaiacol, which is formed during bleaching of chemical pulp and shown to bioaccumulate in fish, has been synthesized. The structure of the compound has been determined by means of X-ray analysis. The values of the ^{13}C nmr chemical shifts and melting point differ from those previously reported. A reaction mechanism is suggested for the formation of 3,4,5- and 4,5,6-trichloroguaiacol.

K. LINDSTRÖM et F. ÖSTERBERG. Can. J. Chem. **58**, 815 (1980).

On a synthétisé le trichloro-3,4,5 guaiacol, composé qui se forme lors du blanchissage des pulpes chimiques et qui s'accumule dans le poisson. On en a déterminé la structure au moyen de l'analyse par rayon-X. Les valeurs des déplacements chimiques par rmn du ^{13}C et du point de fusion diffèrent de celles rapportées antérieurement. On suggère un mécanisme réactionnel pour expliquer la formation des trichloro-3,4,5 et trichloro-4,5,6 guaiacol.

Introduction

After chemical pulping residual lignin gives rise to a brownish colour. Bleaching with chlorine as an oxidizing agent depolymerizes the residual lignin and makes it more hydrophilic by the introduction of ionizable functional groups such as carboxylic and phenolic groups. Since native lignin consists of a network of guaiacylpropane units, aromatic electrophilic substitution can occur during bleaching. Hence, the effluent from an alkaline extraction stage contains salts of various chlorinated high and low molecular weight aromatic acids and phenolic compounds.

Introduction of modern analytical techniques such as gas chromatography – mass spectrometry in combination with computers (gc–ms–com) and an increase in the environmental impact of industrial wastes during the last decade have raised interest in looking for hazardous substances in the environment. In particular, chlorinated organics of low or relatively low polarity have a high affinity for fat in living organisms and may therefore remain for longer periods in the body. Thus, native lignin degradation products like chlorinated guaiacols could be expected at least in low concentrations in fatty tissues of aquatic organisms.

In 1973 Rogers and Keith (1, 2) identified trichloroguaiacol and tetrachloroguaiacol in mixed bleachery effluents. A comprehensive analytical study was carried out to establish the structure of the trichloroguaiacol isomer. Out of four possible trichlorinated isomers they established the isolated trichloroguaiacol to be a mixture of the 3,4,5- and the 4,5,6-trichloro compounds.

Investigations of the low molecular weight chlorophenolic compounds in the chlorination (C-stage) and caustic extraction stages (E-stage) was carried out by Lindström and Nordin (3) using glass open-tubular columns in gc–ms analysis. By laboratory bleaching trials they also determined various chlorinated phenols, guaiacols, and catechols in relation to pulp yield. Chlorocatechols were found mainly in the C-stage and chloroguaiacols in the E-stage (3).

In 1975 Leach and Thakore (4) claimed to have isolated and identified 3,4,5-trichloroguaiacol which was shown to be toxic to juvenile rainbow trout. This led us to carry out a comprehensive investigation of the bioaccumulation of chlorophenolic compounds originating in spent bleach liquors (5).

By chlorination of guaiacol in chloroform we found, in agreement with Rogers and Keith (2), that basically only 4,5,6-trichloroguaiacol was formed (cf. also ref. 6). The ^{13}C nmr chemical shifts of this substance did not, however, agree with those reported by Thakore and Oehlschlager (7) who declared that they had isolated and determined the structures of the 3,4,5- and the 4,5,6-isomers.

The occurrence of isomeric trichloroguaiacols in spent bleach liquors, together with their property of facile bioaccumulation in fish, led us to synthesize and to determine the structure of the most abundant isomer.

This paper describes the synthesis, the structural determination, and the probable mode of formation of 3,4,5-trichloroguaiacol occurring in spent bleach liquors.

Results and Discussion

In a previous paper (3) the identity of three possible trichloroguaiacol isomers appearing in the ether extract of the kraft pulp mill caustic extraction stage was discussed. Gas chromatography (gc) on capillary columns gave poor resolution of two peaks of an ethylated phenolic fraction. Mass spectrometry (ms) of both the main peak and of a shoulder on that peak showed similar fragmentation patterns. However, the abundances of the typical isotopic chlorine clusters differed. The column used was a 25 m SE-30. By changing columns (25 m OV-17) all three peaks appeared well separated under isothermal conditions (200°C).

All four possible trichlorinated isomeric guaiacols are listed in Fig. 1. Figure 2 shows a limited reconstructed gas chromatogram (lmrgc, *m/e* 226; $M^+ - 28$) of an ethylated phenolic fraction from an ether extract of a caustic extraction stage. Since native lignin consists of mainly guaiacylpropane units where the propyl chain occupies the 4-position in the aromatic ring, this position must be chlorinated to yield free chloroguaiacols from lignin. Hence the number of isomers is reduced to three (**1**–**3**).

From a chemical point of view (see later) the 3,4,5- (**1**) and the 4,5,6-isomer (**2**) should be predominant in the liquor relative to the 3,4,6-isomer. Therefore peaks 3 and 4 (Fig. 2) were suspected to correspond to **1** and **2** or vice versa.

Chlorination of guaiacol in dichloromethane yields only one trichlorinated isomer corresponding to peak 4. Evaporation and recrystallization three times from petroleum ether yielded a compound with gc–ms data identical to that of peak 4 indicating the most likely isomer **2** (6).

Catechol was chosen instead of guaiacol as starting material for the synthesis of 3,4,5-trichloroguaiacol (1). The chlorination time required for obtaining an optimal yield of the

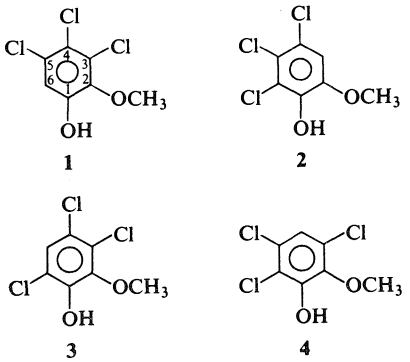

FIG. 1. Trichloroguaiacol isomers.

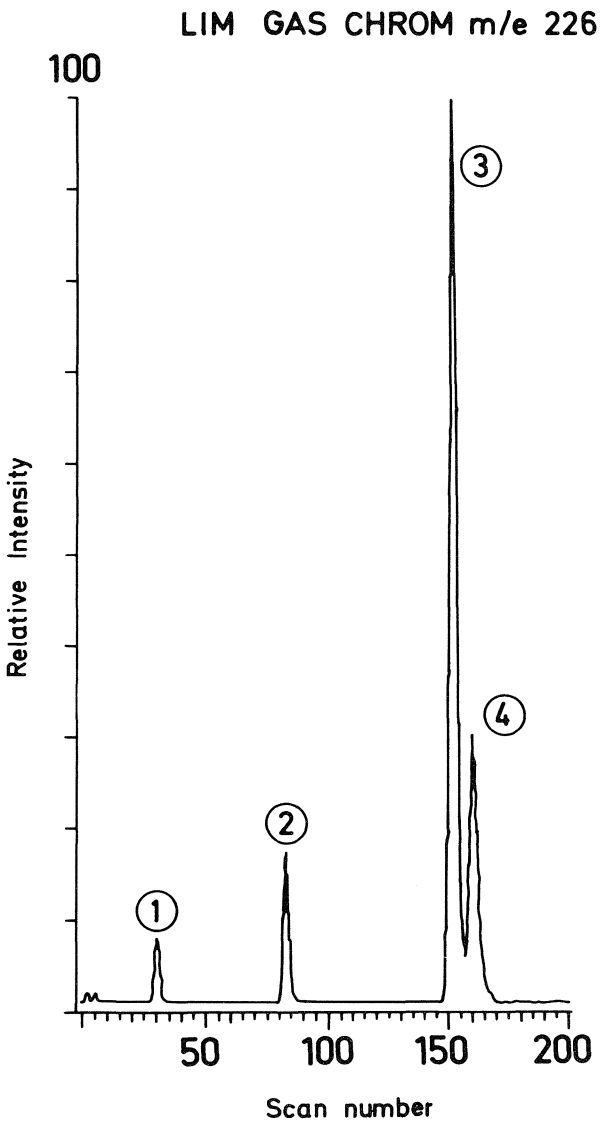

FIG. 2. A limited reconstructed gas chromatogram (lmrgc, *m/e* 226) of an ethylated ether extract of a caustic extraction stage phenolic fraction.

trichlorinated product is 10 min. After partial methylation (Fig. 3) the reaction mixture was separated by means of hplc as described under Experimental. As shown in Fig. 4 the two trichloroguaiacol isomers separated very well. The mass spectrum and retention time of peak 4′ indicated this substance to be identical to **2**. Peak 1′ was not fully resolved from peak 2′ (dichloroguaiacol isomer). After preparative chromatographic separation, the trichloroguaiacol isomer was easily removed from the dichloro impurity by repeated crystallization from petroleum ether (3 times).

To get complete information of the structure the

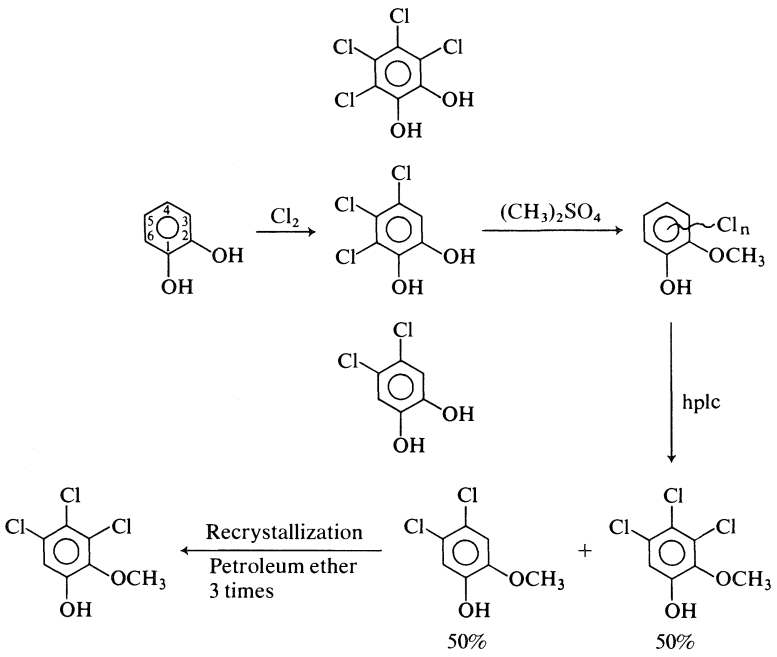

FIG. 3. Synthesis and purification of 3,4,5-trichloroguaiacol.

purified isomer was taken to X-ray analysis. As can be seen from Fig. 9 (Appendix) the substance studied is the 3,4,5-trichloroguaiacol isomer (1).

Upon methylation of the substances of peaks 1′ and 4′ (**1** and **2** in Fig. 1) capillary column gc gave only one distinct peak corresponding to 3,4,5-trichloroveratrol (Fig. 5) available at our laboratory. This indicates that peak 4 arises from the 4,5,6-trichloroguaiacol isomer (**2**).

Since the structure of **1**, and thereby indirectly that of **2**, was confirmed by means of X-ray analysis, values of the ^{13}C nmr chemical shifts and tentative assignments can now be presented for these two compounds as well as the corresponding melting points. The chemical shifts and the melting point of **1** do not agree with the values reported by Thakore and Oehlschlager (7). Whereas they reported a melting point of 127–128°C for **1**, we found 81–83°C; they found 105–107°C for **2** which is more in agreement with ours (112–114°C).

The ^{13}C nmr chemical shifts and tentative assignments are listed in Table 1. Due to deshielding by oxygen substituents $^{13}C1$ and $^{13}C2$ are shifted downfield relative to chlorine-bonded ^{13}C carbons. The reverse is true for hydrogen-bonded ^{13}C carbons which are relatively shielded. It seems likely that the relative positions of the signals of $^{13}C1$ and $^{13}C2$ for **1** are reversed to those of **2**. Probably a non-chlorine-bonded carbon is deshielded by an adjacent chlorine-bonded carbon so that $^{13}C2$ of compound **1** shifts to lower field compared to that of $^{13}C2$ of compound **2**. It is, however, likely that the differences in the shifts of $^{13}C4$ and $^{13}C5$ in isomers **1** and **2** should be very small.

Only the value of the ^{13}C chemical shift of C6 (isomer **1**, 115.5 ppm) reported by Thakore and Oehlschlager (7) is in agreement with those found by us. The differences in ^{13}C chemical shifts are up to 10 ppm. For instance, the value of $^{13}C3$ (isomer **1**) is reported to be 125.5 ppm compared to 131.0 ppm found by us. Similarly they reported a ^{13}C chemical shift of $^{13}C3$ (isomer **2**) at 120.8 ppm whereas we found a value of 110.8. The deviations of their values from ours of the ^{13}C chemical shifts and melting point are of such a magnitude that the compounds could not possibly be identical.

Usually isomer **1** predominates in kraft pulp mill spent bleach liquors (E-stage) yet isomer **2** is formed almost exclusively from chlorination of guaiacol. In an attempt to explain this phenomenon a dimeric substance (1-(4-acetoxy-3-*tert*-butyl-5-methoxyphenyl)-ethylene glycol-2-*O*-guaiacyl ether) was chlorinated in ethanol–water 1:1. Figure 6 shows a poor yield of about equal amounts of **1** and **2**. This supports the theory that, since the guaiacyl unit prior to and during chlorination is a 1,2-diether, chlorination proceeds initially at about equal rates in the 3- and 6-positions. Due to formation of hydrochloric acid pH decreases giving rise to a vinylic ether in the 1-position which is acid

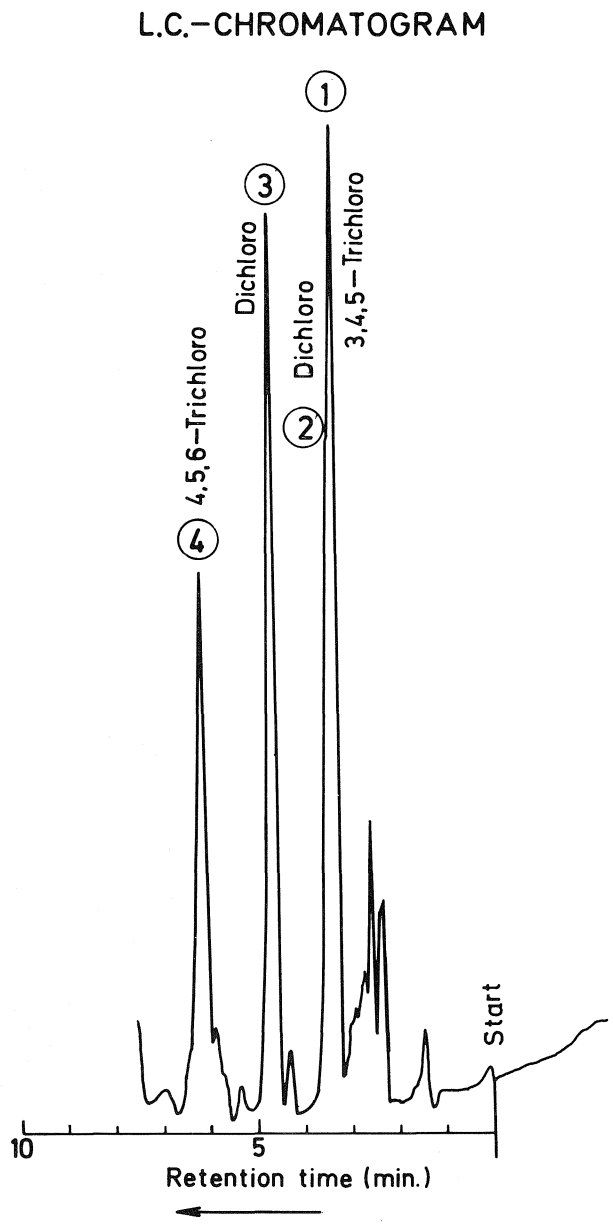

FIG. 4. The hplc separation of the reaction mixture.

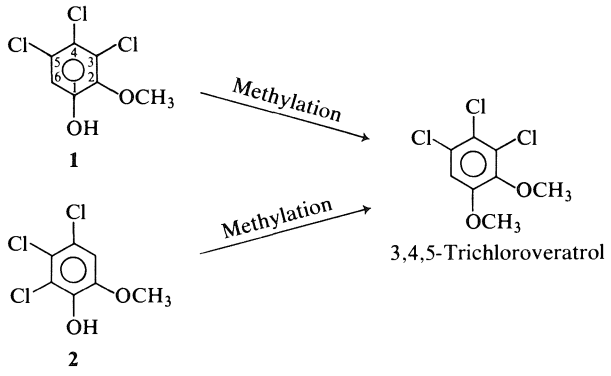

FIG. 5. Methylation of 3,4,5- and 4,5,6-trichloroguaiacol.

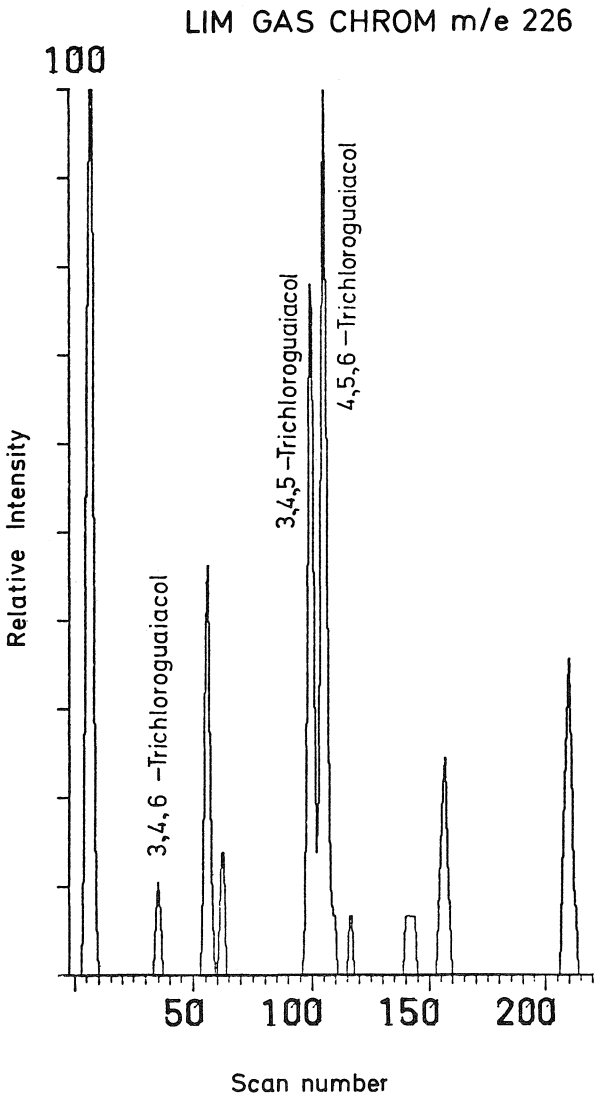

FIG. 6. The lmrgc (*m/e* 226) of an ether extract of a reaction mixture obtained from chlorination of 1-(4-acetoxy-3-*tert*-butyl-5-methoxyphenyl)-ethylene glycol-2-*O*-guaiacyl ether.

labile and decomposes mainly to **1** and **2** (Fig. 7). In native lignin, however, steric hindrance might occur in the 6-position (Fig. 8) which should favour formation of **1**.

If the pulp is not well washed, so that residual free guaiacol from the cooking stage remains in the pulp, then the 4,5,6-isomer (**2**) should predominate. It seems that bleached sulphite pulp yields more **2** but the reverse is true for bleached kraft pulp. Due to cooking to lower κ number more free guaiacol is formed during sulphite pulping and therefore formation of **2** exceeds that of **1**. During kraft pulping

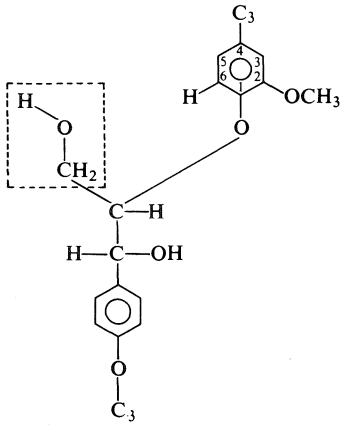

FIG. 8. Steric hindrance in the 6-position relative to the 3-position in lignin.

the higher κ number means that the macromolecular residual lignin is more effectively sterically hindered in the 6-position.

Experimental

Nuclear magnetic resonance spectra, ^1H and ^{13}C, were determined in deuterochloroform using a Varian CFT-20 60 MHz instrument. Tetramethylsilane was added to obtain a reference line. The gc–ms–com analysis was carried out using a 0.25 mm × 25 m OV-17 glass open-tubular column in a Finnigan gas chromatograph (9500) – mass spectrometer (3200F) with an on-line computer (6000). Helium carrier gas flow rate was 0.5 mL/min, split ratio 1:30, column temperature 200°C, injector temperature 250°C, and transfer line 250°C. Mass spectra were recorded every 2 s with a speed of 200 amu/s up to 400 amu at an electron energy of 70 eV.

The hplc separation, analytical scale, was carried out on a Waters high-performance liquid chromatograph equipped with double pumps and a solvent programmer. Chromatographic conditions: column, 3.2 × 250 mm Lichrosorb, 5 μm; flow rate, 2 mL/min; mobile phase (isocratic elution), petroleum ether – ethyl acetate – acetic acid, 175:25:1, all solvents freshly distilled; detector, 8 μL uv cell, measuring the absorption at 250 nm.

Preparative separation was carried out on the same instrument. Chromatographic conditions: column, Silicagel −60 (Merck) size C; flow rate, 9 mL/min; mobile phase, petroleum ether – ethyl acetate, initially 95:5 with a linear gradient elution to a final composition of 80:20 during 7.5 h; detector Uvicord II (LKB) with 100 μL cell measuring the absorption at 280 nm; fractionation, LKB Ultrorac 7000.

Synthesis and Purification

Six grams of catechol was dissolved in 100 mL of dichloromethane in a 250 mL three-neck round bottom flask equipped with a condenser and an inlet tube. Gaseous chlorine was bubbled violently through the solution for 10 min, followed by washing with 2 portions of 50 mL of slightly acidified water. Organic acids were eliminated by extraction with 2 × 50 mL aqueous sodium bicarbonate (0.1 mol per L). The reaction mixture was evaporated under reduced pressure and the residue redissolved in 100 mL ethanol. A small portion (0.1 mL) was taken out for gas chromatographic analysis. A 20% (1.2 g) recovery (estimated by gc) of 3,4,5-trichlorocatechol was obtained.

One equivalent, corresponding to 1 equiv. of estimated (gc) chlorocatechols, of an aqueous solution of sodium hydroxide (1 mol per L) was mixed with the ethanol solution in a 250 mL three-neck round bottom flask equipped with a dropping funnel, a condenser, and a magnetic stirrer; 0.5 equiv. of dimethylsulphate was dissolved in 10 mL ethanol. The solution was added

into the flask during 0.5 h. The reaction mixture was refluxed (1 h), cooled, and made alkaline (pH 11). Minor amounts of veratroles were extracted by 2 × 100 mL diethyl ether and discarded. After acidification with hydrochloric acid to pH 2 the ethanol solution was extracted with 2 × 100 mL diethyl ether. The ether extract was dried over anhydrous sodium sulphate, filtered, and evaporated. The residue was redissolved in ethyl acetate (3 mL).

One half of the ethyl acetate solution was injected onto the preparative column. A fraction starting after 170 min was collected during 25 min and the solvent evaporated under reduced pressure. The yield was 0.3 g (10%). Recrystallization was carried out three times from petroleum ether.

3,4,5-Trichloroguaiacol

The compound, white crystals, had mp 81–83°C; ^{1}H nmr δ: 7.05 (1 H, singlet, aromatic), 5.78 (1 H, singlet, OH), and 3.92 (3 H, singlet, OCH_3); ms *m/e* (% relative intensity): 230 (14) $M^+ + 4$, 228 (46) $M^+ + 2$, 226 (50) M^+, 215 (29) $M^+ - 11$, 213 (97) $M^+ - 13$, 211 (100) $M^+ - 15$.

Appendix

X-ray Structure Determination

Three-dimensional X-ray intensity data were collected at 25 ± 2°C by using a Syntex $P2_1$ four-circle diffractometer. The compound has a fairly large vapour pressure and had to be mounted in a capillary in order to be preserved during the data collection. The space group was determined by axial photographs and the monoclinic symmetry was checked by measuring reflections $h\,k\,l$ and $h\,\bar{k}\,l$. The unit cell parameters were refined by least-squares methods using reflections obtained with the diffractometer. Unit cell dimensions and details of the data collection are given in Table 2.

To check the stability of the crystal and the diffractometer, four check reflections were measured at regular intervals during the data collection, see Table 2. The methods for background measurement and intensity calculation have been described

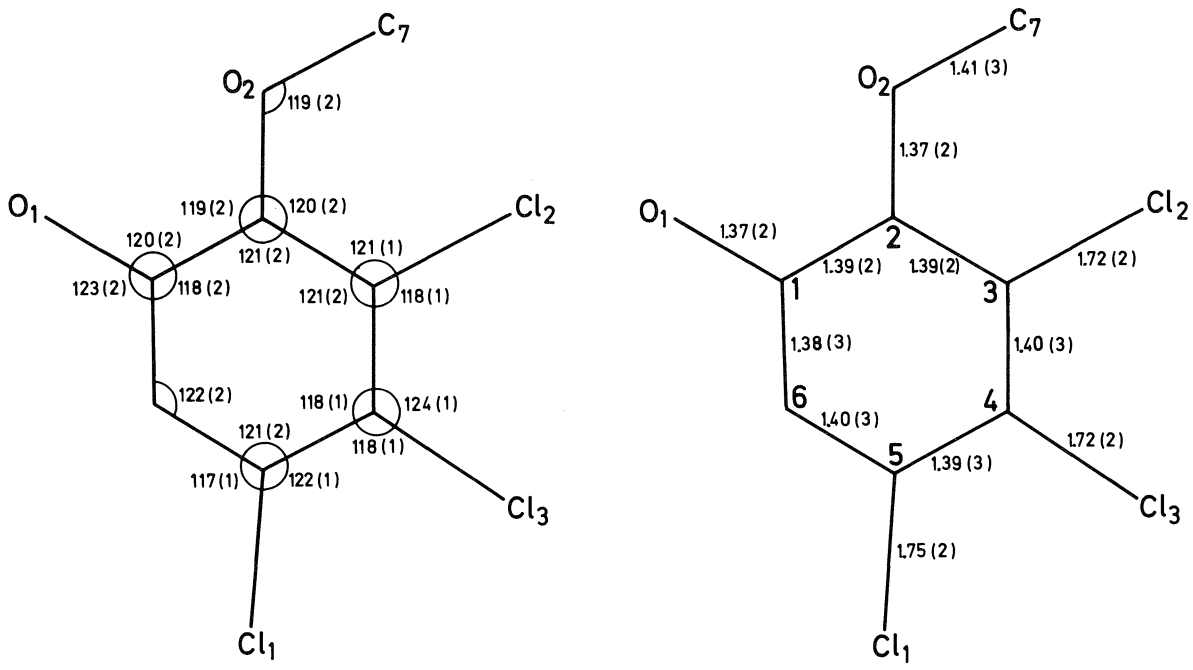

FIG. 9. Interatomic bond distances and angles within the molecule. Standard deviations are given within parentheses.

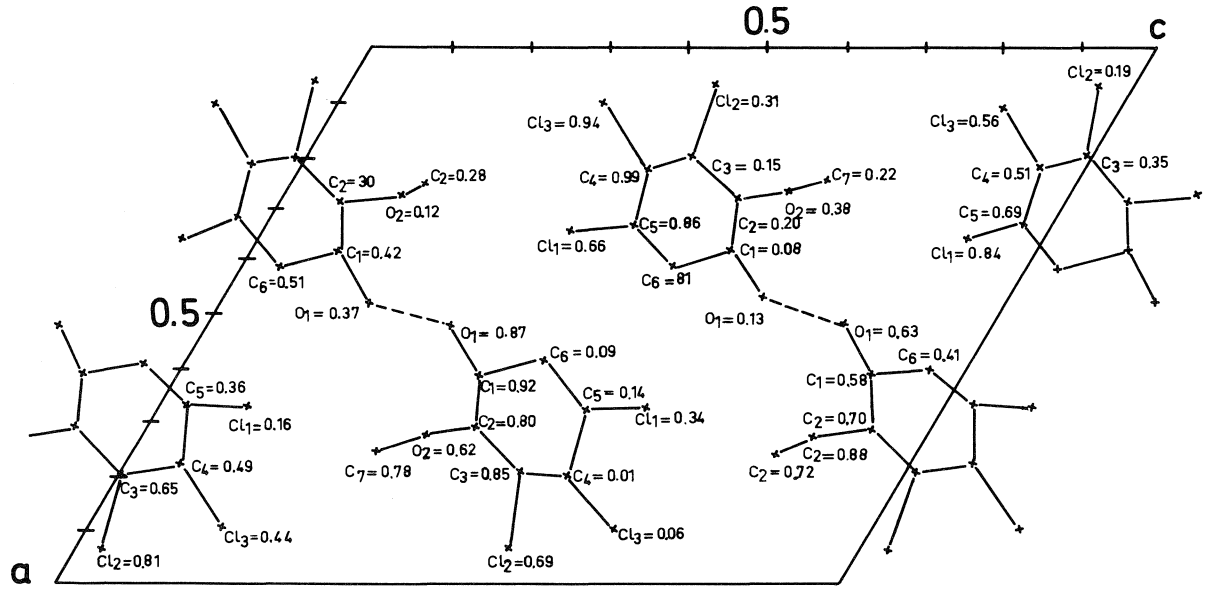

FIG. 10. Projection of the unit cell of the 3,4,5-structure. Hydrogen atoms have been excluded for clarity. The dashed lines indicate the location of an intermolecular hydrogen bond; $a = 14.50$; $b = 4.076$; $c = 18.38$; $\beta = 123.46°$; nr 14 = $P2_1/c$.

according to the procedure of the Syntex $P2_1$. The crystal used was small and had $\mu = 9.6$ cm^{-1}, hence no absorption correction was made on the intensity data. Only very thin crystals could be prepared so the reflections were weak and had to be measured over a long time for satisfactory counting statistics. The intensity decreases even further with increasing θ; because of this only the range $2\theta < 35°$ could be investigated.

Structure Determination and Refinement

A set of solutions was generated by the program MULTAN, using 95 reflections with E-values larger than 1.4.

For personal use only.

All non-hydrogen atoms except the methoxy carbon C7 were located in the *E*-map. The remaining carbon and hydrogen atoms were located in different Fourier maps obtained after isotropic refinement of the atom parameters found in the *E*-map. In the final model, a total of 109 parameters (one scale factor, 36 positional parameters, and 72 anisotropic thermal parameters on all non-hydrogen atoms), were refined to the following *R*-values: $R = 0.052$, $R_w = 0.045$. If reflections with $I \leq 1.96\sigma(I)$ are included, the residuals are: $R = 0.077$, $R_w = 0.049$. The parameters are given in Table 3. Because of the small number of reflections recorded, no attempt was made to refine the positions and thermal parameters of the hydrogen atoms. The positional parameters for these atoms taken from the electron density maps are given in Table 3. These parameters and an estimated isotropic thermal parameter, $B = 5.0$ for all hydrogen atoms, were included as fixed parameters in the final least-squares refinement.

Details of the refinement models are given in Table 2. Tables of $|F_o|$ and $|F_c|$ values may be obtained from the authors.

Distances and angles, shown in Fig. 9, are in good agreement with the expected values. The intermolecular hydrogen bond is 2.77 Å and the shortest intermolecular Cl–Cl distance 3.43 Å.

Structure Description

The X-ray study shows conclusively that the compound studied is the 3,4,5-isomer. The structure is built of planar molecules stacked approximately parallel to the *ac*-plane (see Fig. 10). The molecules are held together by an intermolecular hydrogen bond between H(O1) and a symmetry related O1 in an adjacent molecule.

IAN M. WALKER, A. B. P. LEVER, and PAUL J. MCCARTHY. Can. J. Chem. **58**, 823 (1980).

The characteristic electronic spectrum of the nitrite ion survives when the ion is bonded to metal ions through the oxygen atoms. The vibrational fine structure associated with the $n \rightarrow \pi^*$ electronic transition in the near uv region has been examined at 10 K in single crystals of $K_3[Hg(O_2N)_4](NO_3)$ and in a series of nickel complexes with *N*-alkylated ethylenediamines. When either non-coordinated, monodentate oxygen coordinating, or bidentate chelating through oxygen, nitrite ion in the crystals shows vibronic features which depend on nitrite environment. It is suggested that the electronic spectra of the nitrite ion may constitute a useful tool in structure elucidation.

IAN M. WALKER, A. B. P. LEVER et PAUL J. MCCARTHY. Can. J. Chem. **58**, 823 (1980).

Le spectre électronique caractéristique de l'ion nitrite est présent même quand il est lié aux ions métalliques par l'intermédiaire des atomes d'oxygène. On a examiné la structure fine vibrationnelle, associée à la transition électronique $n \rightarrow \pi^*$ dans la région du proche uv à 10 K, d'un monocristal de $K_3[Hg(O_2N)_4](NO_3)$ et dans une série de composés du nickel complexé avec des éthylènediamines *N*-alkylés. Quelque soit leur état de coordination, soit non-coordonné, coordonné par l'intermédiaire de l'oxygène, ou chélaté bidentate via l'oxygène, l'ion nitrite dans des cristaux présente des caractéristiques vibrationnelles qui dépendent de l'environnement du nitrite. On suggère que les spectres électroniques de l'ion nitrite peuvent constituer un outil pratique pour la détermination de structure.

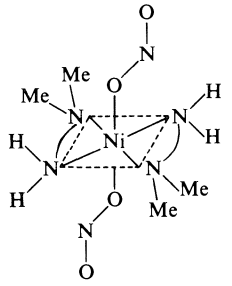
[Traduit par le journal]

Introduction

In several recent articles we have been concerned with details of crystal field splitting in complexes of nickel(II) (1, 2) and cobalt(II) (3) having lower than cubic symmetry. More recently we have studied some nickel ethylenediamine complexes having a *cis*-NiN_4O_2 chromophore in which the nitrite ligand coordinates through oxygen, and in which we encountered several spectral features which are characteristic of internal transitions of the nitrite ion. At the low temperatures used (10 K) many vibronic details of the electronic bands were found to be highly resolved. The nitrite ion in crystals and solutions of alkali nitrites possesses three characteristic spin-allowed absorption bands: two relatively weak transitions at 27.8 and 35.7 kK, which can be assigned as $n \rightarrow \pi^*$, and a strong $\pi \rightarrow \pi^*$ transition at 47.6 kK (4). The $n \rightarrow \pi^*$ transition of lowest energy shows considerable vibrational fine structure.

Vibronic details of coordinated nitrite ion in transition metal complexes have received little attention in the past. In 1967, Fee, Garner, and Harrowfield (5) noted that chromium(III) nitrite complexes of amines always show a structured absorption in the near uv with maximum absorption at ~350 nm (28.6 kK). This band is also found in the spectra of organic nitrites (RONO) and has been assigned to the $n \rightarrow \pi^*$ transition on the nitrite group in both cases (5). Fee *et al.* (5) believed that the n-level is located primarily on the nitrogen. The vibrational structure arises from progressions in the totally symmetric stretching and bending vibrations of the nitrito-group; this gives the absorption feature a highly characteristic appearance. The suggestion was made that the appearance of a structured uv band be taken as conclusive evidence of coordination through oxygen (O-coordination), and the authors assigned the structure of the chromium nitrito-complexes on this basis (5). On the other hand, the structured $n \rightarrow \pi^*$ transition is not generally observed in nitro compounds. This has been ascribed to the involvement of the lone pair on nitrogen in bonding to the metal (5). The near uv spectrum in nitro complexes is dominated by ligand-to-metal charge transfer processes (6–8).

In this article we present the spectra of nitrite ion in single crystals of complexes exhibiting several types of nitrite coordination, along with an account of what we believe to be the causes of the interesting variations in spectral detail encountered. The structural information available on these complexes is illustrated in idealized form in Table 1.



A remarkable additional feature of these spectra is the appearance of an additional absorption band around 22 kK in a number of the complexes

studied. This band also shows vibrational fine structure. We will argue that it can reasonably be attributed to a spin-forbidden n → π* transition of the coordinated nitrite ion gaining significant additional intensity under certain circumstances.

Experimental

Substituted ethylenediamines were obtained from Koch-Light (UK) or Aldrich (USA) and distilled before use. *meso*-Stilbenediamine was prepared and purified according to Irving and Parkins (9), and converted into the bis nitrito complex according to Goodgame and Hitchman (10). Single crystals of this compound were grown from a supersaturated solution of the complex in 50% v/v aqueous acetonitrile by seeding. Nitrito complexes of the substituted ethylenediamines were prepared by literature methods (10, 11). Single crystals were grown by slow evaporation of anhydrous methanol, ethanol, or acetonitrile solutions. $K_3[Hg(O_2N)_4]NO_3$ was prepared according to the method of Power *et al.* (12); single crystals were grown from an aqueous solution. Nickel analyses were performed by EDTA back titration using $ZnSO_4$ as titrant and eriochrome black T as indicator. (In the following, *a*-Et_2en is *N,N*-diethylethylenediamine, *m*-stien is *meso*-stilbenediamine; for the other abbreviations see Table 1.) *Anal.*: complex, % Ni calcd., % Ni found: $[Ni(a\text{-}Me_2en)_2(ONO)_2]$, 16.53, 16.74; $[Ni(a\text{-}Et_2en)_2(ONO)_2]$, 15.32, 15.42; $[Ni(s\text{-}Et_2en)_2(O_2N)]NO_2$, 15.32, 15.02; $[Ni(s\text{-}Et_2en)_2(O_2N)]BF_4$, 13.85, 13.87; $[Ni(TMen)(O_2N)_2]$, 21.99, 21.50; $[Ni(m\text{-stien})_2(O_2N)]NO_2$, 10.20, 10.02; $[Ni(en)_2(NO_2)]ClO_4$, 18.10, 17.85. Polarized crystal spectra were obtained on a Cary-14 spectrophotometer using a Displex cryogenic refrigerator and the procedure described earlier (1).

Results

We discuss first the uv–visible spectrum of sodium nitrite, after which we will examine data for some transition metal complexes. The low-energy edge of the n → π* ($^1A_1 \rightarrow {}^1B_2$) transition in alkali nitrites is indicative of what may be obtained from the uv spectrum under optimum conditions of resolution (13). In crystals of sodium nitrite at 4 K, progressions in 632 cm^{-1}, corresponding to the bending mode in the $^1B_2$ excited state, and 1018 cm^{-1}, corresponding to the symmetric stretch, are observed (13). It should be noted that these values are considerably reduced from those associated with the ground state vibrational frequencies (ν_{bend} = 829 cm^{-1}, $\nu_{stretch}$ = 1325 cm^{-1}). This appears to be due to the presence of an electron in the antibonding π* orbital in the excited state. These progressions are accompanied by lattice modes of 65, 110, 155, 180, and 218 cm^{-1}; this results in a very complex spectrum. The origin (0–0) line is extremely weak, but nonetheless de-

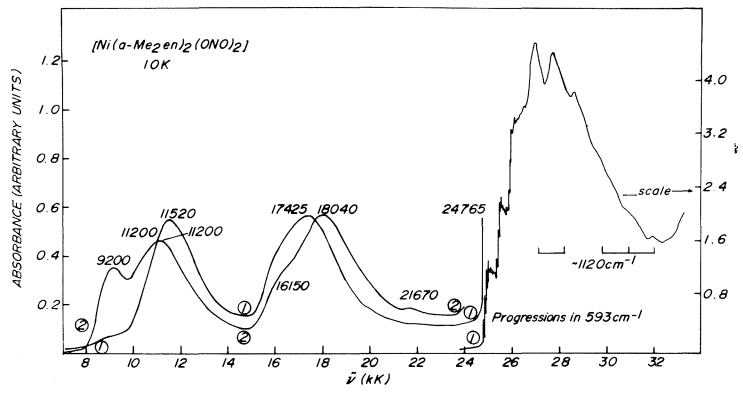

FIG. 1. Polarized crystal spectra at 10 K of $[Ni(a\text{-}Me_2en)_2(ONO)_2]$. In the near uv region the band is strongly polarized. Only the weaker polarization is shown, since the other appears to be almost 10 times as strong.

tectable at 25977 cm^{-1}. The band is polarized perpendicular to the plane of the anion, as expected from the symmetries of the states. The nitrite ions are well separated in the crystal, so no effects due to interionic coupling or exciton formation could be detected (13).

The spin-forbidden $n \rightarrow \pi^*$ ($^1A_1 \rightarrow {}^3B_2$) transition in $NaNO_2$ was identified in the visible region by Allen and Dixon (14). At 20 K the origin occurs at 18959 cm^{-1} and vibrational progressions in 644 and 1112 cm^{-1} are in evidence. These values are somewhat larger than those associated with the spin-allowed transition.

[Ni(a-$Me_2en)_2(ONO)_2$]

Crystals of this complex belong to space group $P2_1/c$ (15). The chromophore contains two monodentate nitrito groups *trans* to one another and possesses a center of symmetry. The polarized spectra of two crystals obtained along orthogonal extinction axes were recorded; the spectra at 10 K are shown in Fig. 1. As in all the nickel complexes, the vibrational structure above 24 kK is superimposed on a strongly polarized absorption due to the third ligand field transition of nickel ($^3A_2 \rightarrow {}^3T_1$(P) in O_h symmetry). The fine structure begins with a sharp spike at 24.77 kK; this can reasonably be assigned to the electronic origin (0–0) of the $n \rightarrow \pi^*$ transition. The position of the origin is about 1 kK lower in energy than the origin in $NaNO_2$, an effect which is undoubtedly due to coordination but is otherwise difficult to explain.

In polarization *1* at least 45 bands can be seen between 24.77 and 33 kK. The prominent vibration is the upper state ONO bend (593 ± 5 cm^{-1}); three members of this progression are visible. Above 27 kK one, or perhaps two, short progressions in the N—O stretch (1120 ± 20 cm^{-1}) are visible. Lattice modes are strongly in evidence here. There are 19 lines immediately following the origin line; these seem to be progressions in 47 and 71 cm^{-1}. A list of the sharp lines is given in the Appendix. The ligand field bands will be analyzed in a subsequent article (28).

[Ni(s-$Et_2en)_2(O_2N)$]NO_2

This compound belongs to space group $P\bar{1}$, and the *cis*-NiN_4O_2 chromophore contains a chelating O-bonded nitrito group (16). The X-ray structure shows that all four of the ligated nitrogens are hydrogen-bonded to the anionic nitrites in the lattice. In Fig. 2 *a* and *b* the whole spectrum is shown, but in this paper we discuss only the part above 20 kK; the rest will be treated elsewhere (29). The vibrational features are quite different from those of the preceding compound. Lattice modes are absent, but there appears to be more than one progression in the upper state bending mode. The three "origins" are at 25.23, 25.34, and 26.20 kK and the resulting progressions can be seen in both polarizations. The progression beginning at 26.20 kK may represent a combination ($\nu_{stretch} + n\nu_{bend}$) based on the origin at 25.23 kK. A combination progression has been observed with frequencies ($\nu_{bend} + n\nu_{stretch}$) in $NaNO_2$ (13). A short progression starting at 29.33 kK is in the N—O stretching mode (1015 cm^{-1}).

Between 20 and 25 kK lies a band comparable in strength to the crystal field bands. It contains poorly resolved structure in about 690 ± 80 cm^{-1}. This frequency seems to represent the upper state NO_2 bending mode. A comparable band is *not* found in the spectra of $[Ni(a\text{-}Me_2en)_2(ONO)_2]$. This band cannot be accounted for by any reasonable set of crystal field parameters. The vibrational feature of lowest energy is seen at about 20.2 kK, close to its position in $NaNO_2$ (14). It is not found in the corresponding isostructural nitrate salt (29) and

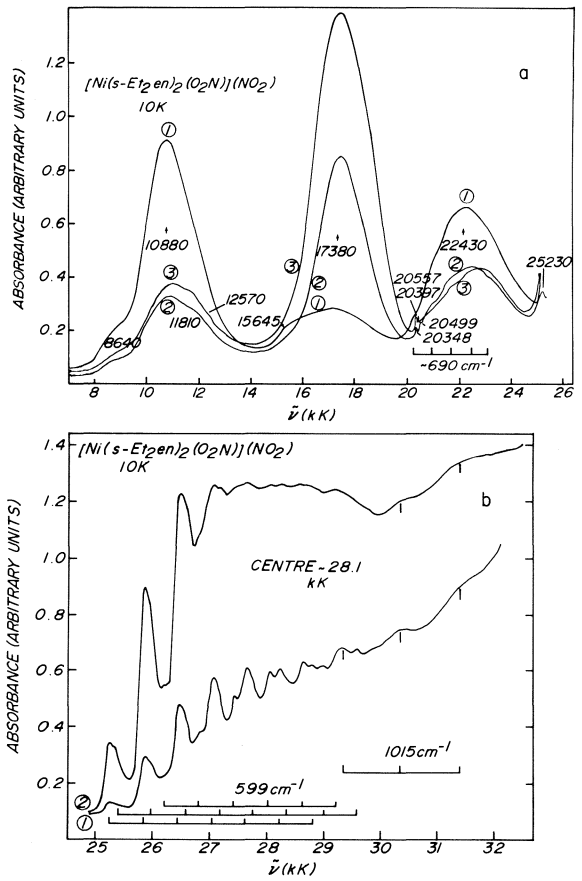

FIG. 2. Polarized crystal spectra at 10 K of [Ni(*s*-$Et_2en)_2(O_2N)]NO_2$. (*a*) 7–26 kK, (*b*) 25–32 kK. One intensity unit in (*b*) ≅ 1.3 units in (*a*).

is therefore most reasonably assigned to the singlet–triplet n → π* transition of nitrite. The mechanism governing the intensity of this band will be discussed below.

*[Ni(*s-$Et_2en)_2(O_2N)]BF_4$

The space group of crystals of this compound is $P2_1/c$ (17). The structure differs from that of the previous compound principally in having a lattice nitrite replaced by a tetrafluoroborate ion. As can be seen in Fig. 3, the vibrational structure in the uv of this compound presents a completely different aspect from that of the preceding compound. Well-resolved progressions in 600 cm^{-1} are absent from the near uv region, and only three progressions in the stretching mode are well resolved. The first begins at ca. 25.8 kK and the second and third progressions lie about 0.34 and 0.59 kK above the first. We therefore strongly suspect that the well-defined progressions in 599 cm^{-1} in [Ni(*s*-$Et_2en)_2(O_2N)]NO_2$ are due to the free nitrite in the lattice.

This compound also shows the structured band near 22 kK, and it contains vibrational structure in the NO_2 bending mode. The ligand field spectra of this compound will be discussed elsewhere (29).

*[Ni(*m-*stien)*$_2(O_2N)]NO_2$*

On the basis of a crystal field analysis we concluded that this compound has a *cis*-NiN_4O_2 chromophore. This has been confirmed by an X-ray crystallographic study.[2] Spectra of the complex are shown in Fig. 4. There appears to be an electronic origin at 24.89 kK and a strong progression in 600 ± 5 cm^{-1}. This is accompanied by six other progressions in 600 cm^{-1} built on the first progression plus lattice modes or low-energy vibrations of the chromophore. A second weaker progression begins at 25.89 kK. This may be a combination ($\nu_{stretch} + n\nu_{bend}$) progression, as was found in [Ni(*s*-$Et_2en)_2(O_2N)]NO_2$. This is also accompanied by three other progressions in 600 cm^{-1}. In all, we were able to record about 50 lines, the frequencies of which are given in the Appendix. While the individual vibronic components have the same energies in the two polarizations, the intensities vary. This causes the overall spectra to have a different appearance in the two polarizations.

The weak band near 22 kK is also present in this compound. It shows vibrational structure corresponding to the bending vibration (606 ± 15 cm^{-1}). The crystal field spectra of this complex will be discussed elsewhere (29).

[Ni(TMen)$(O_2N)_2]$

This complex is known from X-ray crystallography to belong to space group $P2_1/n$, and to possess two O-chelating nitrite groups (18). The spectra of this complex (Fig. 5) show the structured band near 22 kK on the low-energy side of the 26 kK band. The progression is in 660 ± 30 cm^{-1}. The uv region is masked by the onset of very intense absorption beginning about 28 kK. One can nonetheless see a small feature at 27.58 kK. In addition, there is a weak shoulder on the uv rise (not shown here) that is 1125 cm^{-1} above the 27.58 kK band. This appears to signal the onset of the spin-allowed n → π* transition of the nitrite ion. No strong progressions in 600 cm^{-1} are found in the near uv. This is consistent with the absence of free nitrite ion in the lattice.

*[Ni(*a-$Et_2en)_2(ONO)_2]$

Although the structure of this complex is unknown, previous studies characterize it as having O-bonded nitrite (10). The overall spectra of this compound (Fig. 6) show more similarity to those of

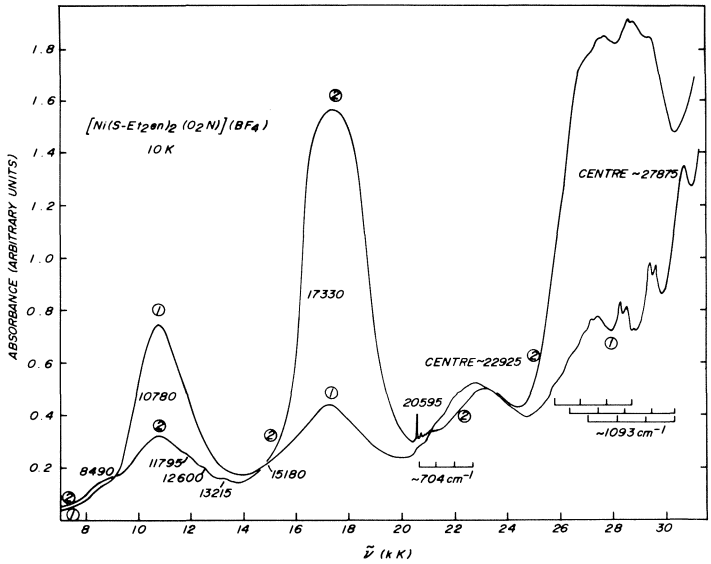

FIG. 3. Polarized crystal spectra at 10 K of $[Ni(s\text{-}Et_2en)_2(O_2N)]BF_4$.

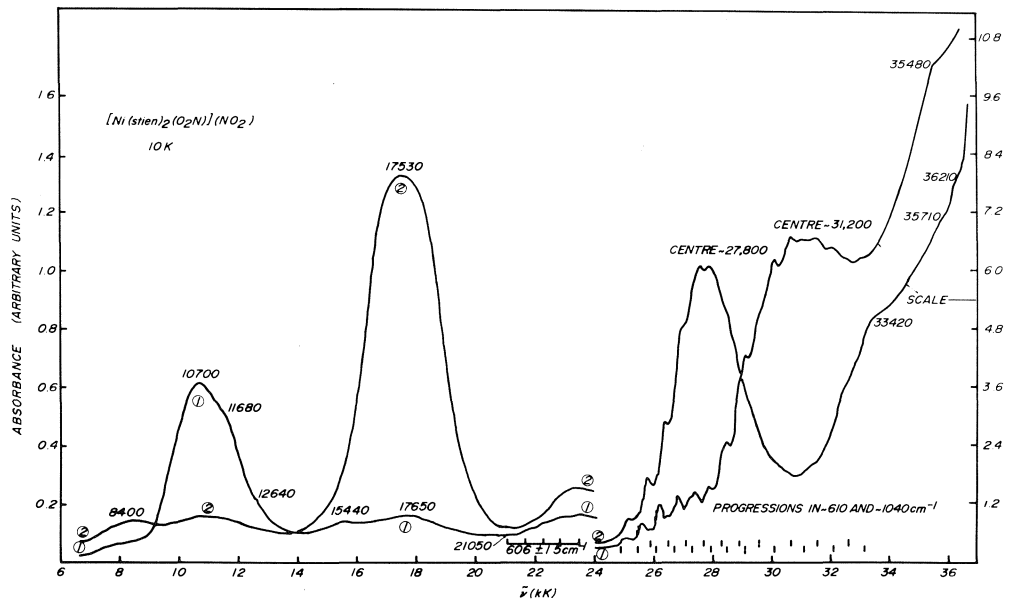

FIG. 4. Polarized crystal spectra at 10 K of $[Ni(m\text{-stien})_2(O_2N)]NO_2$.

$[Ni(a\text{-}Me_2en)_2(ONO)_2]$ than to the compounds known to have a *cis*-NiN_4O_2 chromophore. This is consistent with the presence of an all-*trans* rhombically distorted $NiN_2N_2'O_2$ chromophore which in turn implies monodentate nitrite. The vibrational structure (612 ± 20 cm^{-1}) in the near uv begins with two weak features ("origins") at 25.18 and 25.43 kK. This separation of ca. 250 cm^{-1} may indicate the presence in the lattice of two complexed nitrite ions which differ in symmetry. The vibrational structure on the weak band at 21 kK (631 ± 23 cm^{-1}) also suggests two distinct electronic origins separated by about 230 cm^{-1} with progressions in the nitrite bending vibration associated with each origin. A noteworthy feature of the spectra is the strong progression in 1064 ± 32 cm^{-1}, five members of which can be seen beginning at 27.99 kK.

$K_3[Hg(O_2N)_4]NO_3$

The compound belongs to space group *Pnma* (12). The structure of the complex anion has been

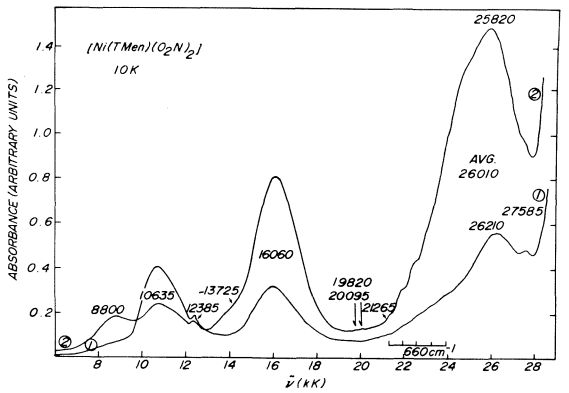

FIG. 5. Polarized crystal spectra at 10 K of [Ni(TMen)-$(O_2N)_2$].

shown from X-ray (19) and neutron diffraction studies (12) to consist of four chelating nitrito groups arranged in a roughly tetrahedral disposition about the central mercury. A mirror plane passes through the mercury atom and contains one nitrite. There are thus three non-equivalent chelating nitrites in the complex anion. The crystal spectrum at 10 K (Fig. 7) shows a single weak band centered at 24.1 kK with eight vibronic components; the progression is in 614 ± 15 cm^{-1}. This is readily assigned to the singlet–triplet n → π* transition.

The singlet–singlet transition is not visible in its entirety because of its enormous intensity in this crystal. There appear to be three "origin" lines at 26.00, 26.13, and 26.25 kK. It is tempting to assign these to each of the three non-equivalent chelating nitrite ions, although an explanation in terms of lattice modes must also be considered. A shoulder at 26.63 kK may be ascribed to the first member of a progression in the bending vibration.

$[Ni(en)_2(NO_2)]ClO_4$

The compound is isomorphous with $[Ni(en)_2(NO_2)]BF_4$, which is orthorhombic and belongs to space group $Pn2_1a$ (20). The $Ni(en)_2$ groups have approximate tetragonal symmetry and are joined into infinite chains by NO_2 groups bonding through oxygen and nitrogen. As expected, coordination of the lone pair on nitrogen totally changes the appearance of the spectrum in the near uv region (see Fig. 8). No structured band is present near 23 kK. There are many weak features on the crystal field bands, but these are best attributed to spin-forbidden transitions and/or vibronic crystal-field features. The overall positions of the bands are consistent with the nature of the chromophore, and are reminiscent of the spectrum of $Ni(en)_2(NO_2)_2$ studied by Bertini *et al.* (7). The exact nature of the band near 20 kK is, however, not certain. In $Ni(NH_3)_4(NO_2)_2$ and $[Ni(m\text{-stien})_2NO_2H_2O]ClO_4$ it has been assigned by Hitchman and Rowbottom to be due most probably to a nickel to nitrite π* transition.[2]

Discussion

Early workers (5, 13) in this area explained the absence of significant spectral shifts in the n → π* transition O-coordinated nitrite by reasoning that the highest non-bonding MO is chiefly nitrogen in character. Since nitrogen is not involved in coordination, the energy levels should not be shifted. This seemed logical, since the structured n → π* transition disappears and is replaced by intense ligand →

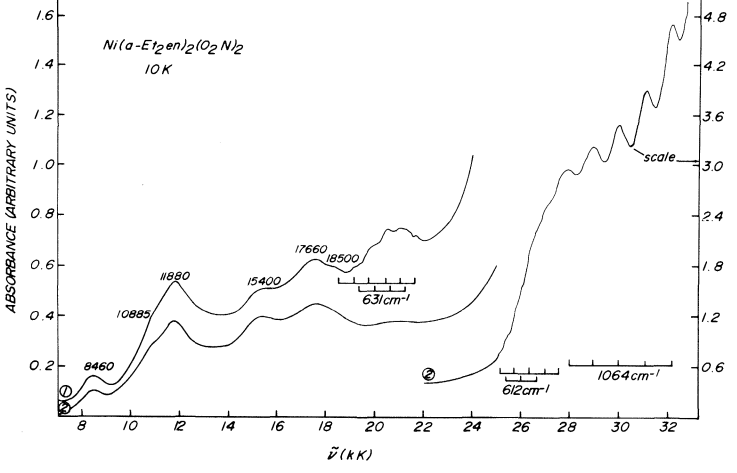

FIG. 6. Polarized crystal spectra at 10 K of $[Ni(a\text{-}Et_2en)_2(ONO)_2]$. Above 25 kK polarization *1* is similar to, but 2.5 times as intense as, polarization *2*.

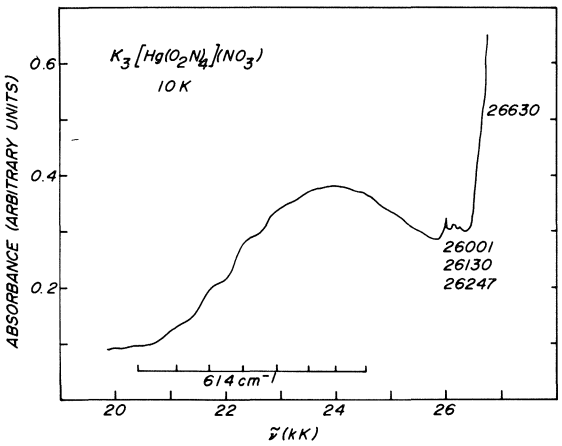

FIG. 7. Polarized crystal spectrum at 10 K of $K_3[Hg(O_2N)_4]NO_3$. Both polarizations are identical.

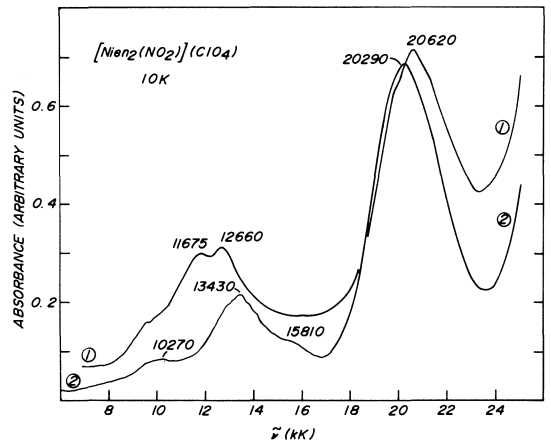

FIG. 8. Polarized crystal spectra at 10 K of $[Ni(en)_2(NO_2)]ClO_4$.

metal charge transfer bands once the n-level is tied up by bonding of nitrogen to a metal.

Strickler and Kasha (4), however, postulated that the highest-lying non-bonding MO's must be made up principally of oxygen AO's in order to explain the behavior of the n → π* transition in hydroxylic solvents. Their conclusions are in agreement with the early MO calculations of McEwen (21). More recent calculations (22) confirm this conclusion that the highest non-bonding MO's in NO_2^- are chiefly composed of oxygen 2*p* atomic orbitals.

In this work we present three examples in which chelating nitrite is present unobscured by non-coordinated nitrite, namely, $[Ni(s\text{-}Et_2en)_2O_2N]BF_4$, $[Ni(TMen)(O_2N)_2]$, and $K_3[Hg(O_2N)_4]NO_3$. In these three cases, the basic features of the spectra are substantially those of free nitrite, the only substantive modifications being in intensities of individual lines. It remains somewhat surprising to us that spectroscopic features dependent on oxygenic AO's should remain so unaffected when oxygen coordinates to nickel.

Our assignment of these transitions as n → π* for both the spin-allowed and spin-forbidden bands follows those of Barnes, Duncan, and Peacock (8) for metal ions which are non-oxidisable (e.g., Hg^{2+}, Y^{3+}, and Cd^{2+}).

The Band at 23 kK

The spin-forbidden n → π* singlet–triplet transition has attracted experimental attention for a number of years (23, 24). It is observed in aqueous solutions of a number of nitrite complexes at about 23 kK. It is normally extremely weak ($f \cong 10^{-7}$), but its intensity increases dramatically when the nitrite is coordinated in solution to heavy metal ions, such as Ag^+, Cd^{2+}, Pb^{2+}, or Tl^+ (23). The band is also much enhanced and vibrational structure is very well resolved in the cubic $Cs_2NaLn(NO_2)_6$ compounds (Ln = lanthanide cation) at 80 K (25). The nitrite ion is believed to coordinate via the nitrogen in these latter compounds. The bonding to the lanthanide is quite weak, and so the nitrite energy levels are not much perturbed.

In a recent article (24) calculations of oscillator strength have shown that the intensification mechanism for this band in crystals of $AgNO_2$ and $NaAg(NO_2)_2$ comes from spin–orbit induced mixing of nitrite states with appropriate states of the heavy metal. Substantial spin–orbit coupling constants and low-lying metal-to-ligand or ligand-to-metal charge-transfer states are shown to be of key importance. The increase of intensity, which is of the order of a thousand, is reasonably well reproduced by calculation.

That this band gains intensity in nickel complexes is undoubtedly due in part to the substantial spin–orbit coupling constant of nickel. The influence of nitrite geometry is also crucial. The band is clearly observed in our five compounds known to have chelating nitrito groups, and absent from $[Ni(en)_2(NO_2)]ClO_4$, which contains bridging NO_2 groups. The band does *not* appear in $[Ni(a\text{-}Me_2en)_2(ONO)_2]$ but *does* appear in $[Ni(a\text{-}Et_2en)_2(ONO)_2]$, even though we postulate that both contain the same basic coordination geometry. The reason for this is not clear. It may possibly be related to the fact that of all the O-coordinated nitrite studied here only the *a*-Me_2en complex is *known* to have the metal atom lying on

[a]"Origin" means lowest energy absorption feature of vibrational progression. The frequencies listed for the upper state vibrations in the Ni complexes are averages, and have a precision of ±20 cm^{-1} in most cases.
[b]Bending frequencies observed in the singlet–triplet band are in parentheses. All data from this work except $NaNO_2$ (14).
[c]Spectrum at 20–25°C in DMF.

an inversion centre. The presence of this symmetry element may restrict the coupling of the metal and nitrite states which would augment the intensity of this spin-forbidden band.

We note that all our chosen examples of chelating nitrito groups are acentric. It would be interesting to observe whether a chelating nitrito group in a centrosymmetric nickel complex would also exhibit this band. Unfortunately, we are unaware of any such complex.

When this band was observed in solid $NaNO_2$, Allen and Dixon (14) noted that the intensity distribution of the fine structure was similar to that observed by Sidman (13) for the singlet transition, with the most notable feature a long progression in the bending vibration. In all the compounds in which we observe the band, only progressions in the bending vibration are observed.

The Spin-allowed Band

In $NaNO_2$ at 4 K the origin of this band is found at 25977 cm^{-1}, and in KNO_2 at 4 K it is found to be 565 cm^{-1} to lower energy (13). Sidman has proposed an explanation of the shift in terms of the nitrite MO's and the polarizability of the positive ions.

In the compounds studied here, the lowest observable feature in this spin-allowed band is in general slightly lower than in $NaNO_2$ (see Table 2). there is no apparent correlation between the energy of the first band and the nitrite environment.

Comparison of the spectra of the compounds in this study, however, brings out two pertinent observations. First, all the compounds containing nitrite coordinating through oxygen show some progression(s), usually short, in the N—O stretch. Thus, as expected, $[Ni(en)_2(NO_2)]ClO_4$ shows none. While $K_3[Hg(O_2N)_4]NO_3$ appears to be an exception, since no N—O stretching vibration is observed, it should be remembered that the crystal's absorption is so intense that we were not able to observe the spectrum in the region where this type of progression is expected.

The second observation is that only those compounds containing monodentate O-bonded or free nitrite ion show *significant* progressions in the ONO bending mode. Such progressions are accordingly very strong in $[Ni(s\text{-}Et_2en)_2(O_2N)]NO_2$, $[Ni(m\text{-}stien)_2(O_2N)]NO_2$, and $[Ni(a\text{-}Me_2en)_2(ONO)_2]$, and are quite visible but more poorly resolved in $[Ni(a\text{-}Et_2en)_2(ONO)_2]$. They are not observed in $[Ni(en)_2NO_2]ClO_4$, nor in the spectra of the BF_4 and TMen complexes. Again an apparent exception is the Hg complex. But only two members of a possible progression are seen, and then only in a very thick crystal. It is accordingly quite possible that such progressions might also be in the BF_4 and TMen crystals, but are swamped out by the more obvious progressions in the N—O stretch. So the presence of *measurable* or *significant* progressions of about 600 cm^{-1} might be used as diagnostic for the presence of monodentate O-coordinated or free nitrite ion.

The absence of strong progressions in the upper state bending vibration when the nitrite ion is chelating requires some comment. In free (ionic) or unidentate nitrite ion, the bending motion is essentially a property of the ONO group. In chelating nitrite, on the other hand, the bending motion is expected to be strongly coupled to the motions of

the framework of the complex; this could result in substantial changes in transition probabilities.

There is a slight reduction of the frequency of the upper state bending vibration from the values in $NaNO_2$, 632 and 644 cm^{-1} for the singlet and triplet transitions, respectively. From the best-resolved spectra in the present study the values are about 600 and 630 cm^{-1}, respectively (Table 2). The former value is more reliable because of the better resolution of the structure on the singlet–singlet transition. The difference in value between the monodentate and free nitrite is small, but the former (593 cm^{-1}) is the lowest value observed. This is in line with the fact that δ(ONO) in the ground state of $NaNO_2$ is 839 cm^{-1} (13), while the values for several Ni–nitrito complexes vary from 813 to 827 cm^{-1} (10, 26). The slight lowering may be associated with the reduction of electron density in the N—O bonds due to coordination. This would tend to reduce the bending frequency. Because of poor resolution in the fine structure associated with the upper state N—O stretching frequency, there is rather large variation in the values observed. Therefore, the data offer no clear indication of the effect that coordination has on the N—O stretching frequency.

Finally, no clear correlation could be made between the structural parameters of the nitrite group and the various observed vibrational frequencies or the origin of the $n \rightarrow \pi^*$ transition.

Conclusions

We have shown that the low-temperature crystal spectra of complexes containing the NO_2^- group give some indication of the mode of attachment of the NO_2^- group to the metal ion. Specifically, in N-coordinated complexes, the native $n \rightarrow \pi^*$ transition on the nitrite group with attendant vibrational structure is absent (5). The same is true of complexes in which the NO_2^- is ligated to two metal atoms, e.g., $[Ni(en)_2(NO_2)]ClO_4$. When the NO_2^- ion is either uncoordinated or monodentate O-coordinated, the spin-allowed $n \rightarrow \pi^*$ transition shows considerable structure in the bending vibration. Chelating nitrito-groups show an enhanced singlet–triplet $n \rightarrow \pi^*$ transition, but in the singlet–singlet transition, only strong progressions in the stretching vibration. These observations may eventually be useful in identifying the types of nitrite groups present in a given complex.

Field ionisation/field desorption mass spectrometry of polynuclear metal carbonyls

DENNIS G. TUCK, GORDON W. WOOD, AND SAMUEL ZHANDHIRE
Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received November 13, 1979

DENNIS G. TUCK, GORDON W. WOOD, and SAMUEL ZHANDHIRE. Can. J. Chem. **58**, 833 (1980).

Field ionisation/field desorption mass spectra are reported for $Mn_2(CO)_{10}$, $Cd[Co(CO)_4]_2$ and some adducts, $In[Co(CO)_4]_3$, bipy·$Zn[Co(CO)_4]_2$, and bipy·$M[Mn(CO)_5]_2$ (M = Zn, Cd). The spectra are extremely simple, and the small number of easily identified species includes the molecular ion in some cases. The relative abundance of the fragments is discussed in terms of known stabilising factors in such compounds. No spectra could be obtained from $Co_2(CO)_8$ or $Fe_2(CO)_9$, which may be the result of their carbonyl-bridged structures.

DENNIS G. TUCK, GORDON W. WOOD et SAMUEL ZHANDHIRE. Can. J. Chem. **58**, 833 (1980).

On rapporte les spectres d'ionisation de champ et les spectres de masse par désorption de champ des composés suivants: $Mn_2(CO)_{10}$, $Cd[Co(CO)_4]_2$ et de quelques adduits tels: $In[Co(CO)_4]_3$, bipy·$Zn[Co(CO)_4]_2$, et bipy·$M[Mn(CO)_5]_2$ (M = Zn, Cd). Les spectres sont extrêmement simples et le petit nombre d'espèces facilement identifiées comprennent dans certains cas l'ion moléculaire. On discute de l'abondance relative des fragments en fonction des facteurs connus de stabilisation dans de tels composés. On n'a pas pu obtenir les spectres du $Co_2(CO)_8$ ou du $Fe_2(CO)_9$ ce qui peut être attribué aux structures de leurs groupes carbonyles pontés.

[Traduit par le journal]

Introduction

The use of mass spectrometry in inorganic and organometallic chemistry, although not as widespread as in the study of organic compounds, has increased considerably in recent years. The advantages of the technique, and some of the problems inherent in the interpretation of the results, have been discussed in various reviews (1). In terms of molecular weight or structure determination by electron impact mass spectrometry, some potentially serious problems include the low abundance of the molecular ion, which in some cases is not observed at all; the extensive fragmentation which frequently accompanies the high energy ionisation; and the high temperatures which are sometimes required to achieve a significant vapour pressure, and at which thermal decomposition may become significant.

The field ionisation mode of mass spectrometry adds a further dimension to such studies in that the much lower energies involved lead to simpler spectra than in electron impact work. Although a considerable literature exists on the application of this and the corresponding field desorption technique in the organic and biochemical areas (2), relatively few attempts have been made to investigate the behaviour of inorganic or organometallic molecules. Games *et al.* (3) have recently studied cationic complexes of some transition metals, and commented upon the simplicity of the spectra so obtained. We now report that the field ionisation/field desorption mass spectra of dinuclear and heteronuclear metal carbonyls, and of some simple adducts, emphasize the considerable promise which this field offers in the identification of organometallic compounds.

Experimental

Materials

The dinuclear carbonyls of manganese, iron, and cobalt were obtained from Alfa Inorganics. The remaining compounds were prepared by the electrochemical oxidation of zinc, cadmium, or indium in the presence of $Mn_2(CO)_{10}$ or $Co_2(CO)_8$ in organic media. Details of the preparation and characterisation of this latter group of compounds have been given elsewhere (4).

Mass Spectrometry

Mass spectra were obtained on a Varian MAT CH5 DF instrument interfaced to an INCOS 2000 data system. Sufficiently volatile samples were introduced through the direct inlet probe and field ionised; the remainder were applied to the field anode in solution and field desorbed. Details of these experimental procedures have been published elsewhere (5).

Results and Discussion

The results for the various compounds studied are collected together in Tables 1–8. The following detailed comments should be read in the light of those results.

$Mn_2(CO)_{10}$, $Fe_2(CO)_9$, and $Co_2(CO)_8$

The results for these binuclear carbonyls illustrates both the power of field ionisation mass spectrometry and one of its chief limitations. Thus for $Mn_2(CO)_{10}$, the molecular ion dominates the very simple spectrum (Fig. 1) in which the only other ion of significance is $Mn(CO)_5^{+\cdot}$ (1.5%). This result is in contrast to electron impact studies (6, 7) where $Mn_2(CO)_m^+$ ions ($10 > m > 0$), as well as $Mn_2^{+\cdot}$, were detected. Unfortunately, the structurally useful information in the spectrum of $Mn_2(CO)_{10}$ could not be duplicated for either the iron or the

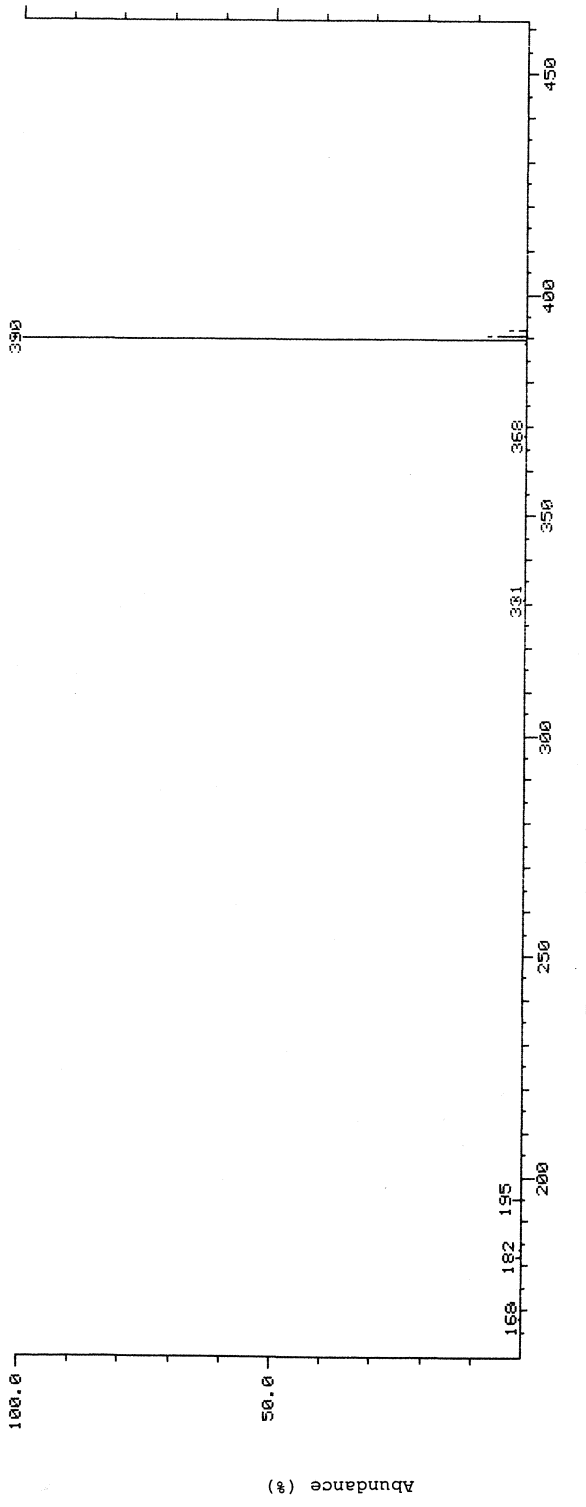

FIG. 1. Field ionisation mass spectrum of $Mn_2(CO)_{10}$.

cobalt compound, since it proved impossible to achieve the smooth vaporisation which is a prerequisite for FIMS with its relatively slow scanning rate (900 amu in 8–12 s in these experiments). After several trials, one sample of $Fe_2(CO)_9$ produced weak ions at m/z 197 and 147. Since the major isotopic species of $Fe(CO)_5^{+\cdot}$ has m/z 195.9, it is tempting to speculate that this species with an extra hydrogen may give rise to the m/z 197 base peak, but m/z 147 does not correspond to any combination of Fe, and CO and H. Even with numerous trials with samples from different sources, we were not successful in recording a reproducible spectrum of $Co_2(CO)_8$. In one experiment with slits open (nominal resolution ca. 200), we observed weak signals near m/z 342 and 171 on one scan, but at this resolution mass assignments cannot be made with certainty. Both color differences among samples and varying evaporation behavior from the probe strongly suggest that the introduction of this compound into the mass spectrometer is preceded by some decomposition.

Since $Fe_2(CO)_9$ and $Co_2(CO)_8$ are unique amongst the compounds studied in possessing bridging CO groups, as well as being the only failures experienced, it may be that there are reasons related to structural stability which prevent the generation of an adequate ion current in this mode of mass spectrometry.

Cd[Co(CO)$_4$]$_2$

The most abundant species in the spectra is the molecular ion, unambiguously identified by the manifold of ions arising from the presence of the various cadmium isotopes (Table 1), plus the ion at m/z = 457, which reflects the contribution of ^{13}C-containing molecules. The only other ions of detectable abundance are $Cd[Co(CO)_4]^+$, $Co(CO)_4^{+\cdot}$, and $Co(CO)_3^{+\cdot}$, consistent with a low probability dissociation pattern

$$Cd[Co(CO)_4]_2 \rightarrow Cd[Co(CO)_4] + Co(CO)_4 \rightarrow Co(CO)_3$$

From a structural point of view, it is interesting to note that the ion $Cd[Co(CO)_4]^+$ is not a radical cation, but rather a species in which the d^{10} Cd^{2+} ion is singly coordinated by a $Co(CO)_4^-$ ligand, and in which cobalt has an 18-electron configuration. Derivatives of this ion could well be stable in the solid state.

One final result in this spectrum concerns the peaks at m/z = 734.9, 735.7, 736.9, and 740.9, which correspond to the isotopic forms of $Cd_2[Co(CO)_4]_3^+$. Such species have not apparently been reported previously, but the formation of

similar cluster ions is common in FDMS. Structures in which each cobalt achieves an 18-electron configuration can be written for this ion, and further investigations of this species, and of its mode of formation, appear warranted.

$In[Co(CO)_4]_3$

Again, the spectrum of this high molecular weight species (M = 627.63) is dominated by the molecular ion base peak and the $In[Co(CO)_4]_2^+$ ion (14.2%), with $Co(CO)_4^{+\cdot}$ the only other detectable species. The isotope distribution for the $In[Co(CO)_4]_3^{+\cdot}$ ion agrees with the calculated intensities (see Table 2). This spectrum illustrates clearly how a field ionisation mass spectrum of such a molecule can provide complete and unambiguous characterisation, in that $InL_3^{+\cdot}$, InL_2^+, and $L^{+\cdot}$ ions are observed. The $InL_3^{+\cdot}$ ion is formally an indium(IV) species, of which no examples are known in the solid state; InL_2^+ is an indium(III) derivative, requiring no unpaired electrons, formally analogous to the $InMe_2^+$ cation (8, 9), and isoelectronic with the neutral $Cd[Co(CO)_4]_2$. It is worth noting that InL_2^+ species are the most abundant ions of the electron ionization mass spectra of indium(III) halides (10, 11).

Adducts of $Cd[Co(CO)_4]_2$

We have examined the neutral adducts with 2,2′-bipyridine (bipy) and *N,N,N′,N′*-tetramethylethylenediamine (TMED), and it should be pointed out here that these compounds almost certainly involve four coordination at cadmium (cf. the compound bipy·$Cd[Mn(CO)_5]_2$ discussed below).

Few attempts have been made to study the EI mass spectra of molecules of this type, and we therefore record in Table 3 the spectrum of $Cd[Co(CO)_4]_2$·TMED. The presence of the ions $TMED^+$, and $(CH_3)_2NCH_2^+$ demonstrate the extensive decomposition of the parent molecule and of the bidentate ligand in this mode of ionisation; in addition, $Cd[Co(CO)_4]^+$, Cd·$TMED^+$ and decomposition products of $Co(CO)_4$ are also observed. A total of more than 30 different species can be detected in the EI spectrum, but we have not attempted to identify these beyond the assignments shown in Table 3. In contrast, the field desorption spectrum of the same compound (Table 4) is extremely simple. The two ions TMED·$Cd[Co(CO)_4]^+$ (base peak) and $Cd[Co(CO)_4]_2^{+\cdot}$ represent the loss of $Co(CO)_4$ and TMED respectively from the parent complex; the cadmium-free fragments include $TMED^{+\cdot}$ and $Co(CO)_n^{+\cdot}$ (n = 3 or 4) clearly derived by the decomposition of the parent molecule. There is no information at present on whether this decomposition is the result of the ionisation process, or involves thermal decomposition prior to ionisation. Finally, we note that a weak molecular ion peak was observed in some spectra at 571.94 (calcd for ^{114}Cd species 571.86).

ple and easily interpreted spectra, which should allow clear identification of unknown neutral organometallic compounds. Taken together with the earlier work on desorption of cationic species from cationic coordination complexes (3), the broad applicability of this technique is thus established.

Secondly, it is useful to compare the species produced in the case of the neutral adducts of the zinc and cadmium DML_2 compounds (L = $Co(CO)_4$ or $Mn(CO)_5$). Table 8 shows that in each case other than bipy·Cd[Mn(CO)$_5$]$_2$, the predominant ion is DML^+ (D = bidentate donor, M = Zn or Cd, L = metal carbonyl group); even in the exception noted, this ion is highly abundant. The stability of this species is easily understood; the Co or Mn atom achieves an 18-electron configuration, as does the 3-coordinate Zn or Cd, and there are no unpaired electrons. In the next abundant ion, $ML_2^{+\cdot}$, the most stable structure would involve neutral metal carbonyl ligands with the inert gas configuration at the transition metal bonded to a two-coordinate +1 zinc or cadmium ion. The molecular ion $DML_2^{+\cdot}$ is important only for bipy·Cd[Mn(CO)$_5$]$_2$, and it is worth noting that the spectrum here is for a cold source, field ionisation experiment; it may well be that the difference between this result and those for the other molecules relates to different degrees of thermal decomposition prior to ionisation. This substance apart, the spectra are remarkably similar, and the ratios DML^+:$ML_2^{+\cdot}$:ML^+ are surprisingly constant throughout, implying that the relative stabilities of these ions are but little affected by change of bidentate ligand or metal carbonyl, within the range examined.

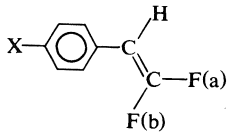
An investigation into the origins of polar substituent effects upon ^{19}F chemical shifts, using 4-substituted β,β-difluorostyrenes

WILLIAM F. REYNOLDS, VICTORIA G. GIBB, AND NICK PLAVAC
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received November 14, 1979

WILLIAM F. REYNOLDS, VICTORIA G. GIBB, and NICK PLAVAC. Can. J. Chem. **58**, 839 (1980).

^{19}F, ^{13}C, and ^{1}H chemical shifts have been determined for β,β-difluorostyrene and eight 4-substituted derivatives. The β-fluorine chemical shift difference, $\Delta\delta_F$, is used to evaluate the constant in the Buckingham equation. $A = 3.0 \times 10^{-11}$ esu for C—F bonds which is in excellent agreement with the value derived by Adcock and Khor. This allows accurate estimates of direct field effect contributions to ^{19}F chemical shifts in aryl fluorides. Substituent parameter correlations demonstrate that the primary polar effect on ^{19}F chemical shifts is field-induced π polarization. *Ab initio* molecular orbital calculations confirm that the substituent-induced ^{19}F chemical shifts reflect changes in fluorine π electron density.



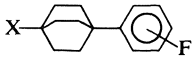
WILLIAM F. REYNOLDS, VICTORIA G. GIBB et NICK PLAVAC. Can. J. Chem. **58**, 839 (1980).

On a déterminé les déplacements chimiques du ^{19}F, du ^{13}C et du ^{1}H des β,β-difluorostyrènes et de 8 dérivés substitués en position 4. On utilise la différence de déplacement chimique, $\Delta\delta_F$, d'un fluor en β pour évaluer la constante de l'équation de Buckingham. Cette constante a pour valeur $A = 3.0 \times 10^{-11}$ ues dans le cas des liaisons C—F ce qui est en parfait accord avec la valeur calculée par Adcock et Khor. Ceci permet une évaluation précise des contributions de l'effet de champ direct sur le déplacement chimique du ^{19}F dans les fluorures d'aryles. Les corrélations des paramètres de substituant démontrent que l'effet polaire primaire, sur les déplacements chimiques du ^{19}F, est une polarisation π induite par le champ. Des calculs *ab initio* des orbitales moléculaires confirment le fait que les déplacements chimiques du ^{19}F induits par le substituant réflètent un changement de la densité des électrons π du fluor.

[Traduit par le journal]

Introduction

While in the past there has been considerable controversy about the origins of polar substituent effects upon ^{19}F chemical shifts in aryl fluorides (1, 2), recent work on several model systems has demonstrated that the main polar effect (except at very close range) is field-induced polarization of the aromatic π electron system (3–8). However, there is still uncertainty concerning the exact magnitude of the minor contributions to ^{19}F chemical shifts due to direct field effects (3–8). As previously pointed out (3), an excellent system for evaluating direct field effects is a series of 4-substituted β,β-difluorostyrenes, **I**:



I

Assuming identical through-bond contributions to $\delta_{F(a)}$ and $\delta_{F(b)}$ (9), $\Delta\delta_F (\equiv \delta_{F(a)} - \delta_{F(b)})$ should provide a monitor of direct (through-space) field effects.[1] This allows evaluation of the constant, A, in the Buckingham equation (11):

$$[1] \quad \Delta\delta_F = A(\Delta E_z)$$

where ΔE_z ($\equiv E_z$(C—F(a)) − E_z(C—F(b))) is the difference in electric field components acting along the two C—F bonds.[2] In turn, A can be used in the estimation of field effects in other systems.

This approach has been tried (3), using previously reported data for **I** (12). However, the data were not entirely satisfactory for this purpose since individual chemical shifts were only reported to ±0.1 ppm, compared to a total range of $\Delta\delta_F$ of only 0.9 ppm. In addition, only one strongly polar substituent (CN) was included in the data set (12). Adcock and Khor have independently estimated a value of A from data for phenylbicyclo[2.2.2]octanes, **II** (4):

II

However, Ewing and Toyne have also investigated **II** and concluded that direct field effects were negligible in this and similar systems (6, 8). Consequently a careful reinvestigation of **I** seemed justified in order to compare estimated values of A from two different systems. It was felt that this would remove the final uncertainty concerning

[1]This approach, when applied to the corresponding 4-substituted styrenes (9), has been cited as providing convincing proof for direct field effects on ^{1}H chemical shifts (10).

[2]The Buckingham equation also contains a term in E^2 (11). However this should make a neglible contribution at the distances involved (9). In addition, the Buckingham equation was derived for axially symmetric bonds. While strictly speaking this is not true for the C—F bonds in both **I** and aryl fluorides, this should not introduce any significant error.

contributions of direct field effects to ^{19}F chemical shifts.

There is also uncertainty about the relationship between field effects upon ^{19}F chemical shifts and upon fluorine electron densities (3, 4). While CNDO/2 molecular orbital calculations for **I** proved some insight into this relationship, the calculated changes in atomic charges were, in many cases, comparable to the uncertainties in the charges. Consequently, it was decided to carry out more accurate *ab initio* (STO-3G minimal basis set (13)) calculations on **I** since this type of calculation has already proved very useful for understanding ^{19}F chemical shifts (14). Results of the experimental investigation and calculations are reported below.

Results

^{19}F chemical shifts and ^{19}F–^{19}F coupling constants were determined by analysis of the AB ^{19}F spectra obtained with ^{1}H decoupling. ^{1}H chemical shifts and ^{1}H–^{19}F coupling constants were determined by ABX analysis of the ^{1}H and ^{19}F spectra for the difluorovinyl groups. ^{19}F–^{13}C coupling constants were also determined by ABX analysis, using the ^{19}F parameters from the AB analysis in conjunction with the ^{19}F–^{13}C splittings observed in the ^{1}H-decoupled ^{13}C spectra. Chemical shifts are tabulated in Table 1 and coupling constants in Table 2.

Substituent-induced changes in calculated fluorine and vinyl carbon atomic charges as well as changes in σ and π components of these charges are summarized in Table 3.

Discussion

(a) Chemical Shifts

Taft's σ_I and σ_R substituent constants (15) can be used to separate polar and resonance contributions

to chemical shifts. Results of these correlations are summarized in Table 4. In the case of the ^{19}F chemical shift correlations, significantly better correlations are obtained when the fluoro derivative is omitted (e.g. correlation coefficient, r, for $\delta_{F(b)}$ is respectively 0.993 and 0.997 with and without the fluoro derivative). However, the ρ_I and ρ_R values change to an insignificant degree. While the origins of the abnormal behaviour are unclear, similar problems have been noted in previous investigations, e.g. see ref. 9 where similar deviations were noted for vinyl ^{1}H chemical shifts in 4-fluorostyrene.

The correlations for $\delta_{F(a)}$ and $\delta_{F(b)}$ show the expected pattern of substituent effects. ρ_R is very similar for each fluorine, confirming that through bond effects are nearly equal for the two fluorines. ρ_I is 17% larger for $\delta_{F(a)}$ than for $\delta_{F(b)}$. σ_I provides a measure of the field effect of a substituent (16, 17). Since the field effect depends upon the component of the electric field acting along the C—F bond (11) and since this is greater for $\delta_{F(a)}$ (3), the enhanced ρ_I value for this fluorine can be attributed to direct field effects.

Although ρ_R values are very similar for $\delta_{F(a)}$ and

[d]Fluoro derivative omitted from correlation (see text).

$\delta_{F(b)}$, there is a sufficient difference (ca. 4%) to result in a noticeable resonance contribution to $\Delta\delta_F$ (particularly for the $N(CH_3)_2$ derivative). Consequently $\Delta\delta_F$ is not a precise measure of direct field effects. However, field effects for individual substituents can be estimated from $\rho_I\sigma_I$ for the $\Delta\delta_F$ correlation. These can be compared with values of ΔE_z estimated by classical electrostatic calculations. E_z values were estimated assuming that the substituent acts as a point dipole and using R—X aliphatic group dipole moments for hydrocarbon solvents (18). Calculations were carried out using standard geometries, except that the C(1)—C(α)—C(β) angle was taken as 128.5° (see Details of Calculations). Results are summarized in Table 5. A correlation of $\rho_I\sigma_I$ versus ΔE_z yields:[3]

$$[2] \quad \rho_I\sigma_I = (3.01 \pm 0.12) \times 10^{-11}\Delta E_z \qquad (r = 0.996)$$

However, since the calculations are sensitive to the assumed geometry (3), a more reasonable estimate of the uncertainity in A is probably (3.0 ± 0.5) ×

[3]The corresponding correlation of $\Delta\delta_F$ versus ΔE_z gives A = 3.3 × 10^{-11} esu (r = 0.947), within these error limits.

10^{-11} esu.[4] This is in excellent agreement with the estimate of Adcock and Khor of $(2.5–3.1) \times 10^{-11}$ based on ^{19}F chemical shifts for **II** (4). Therefore, it is felt that A is now sufficiently well defined for fluorine attached to sp^2 carbons that it is possible to make nearly quantitative calculations of direct field contributions to ^{19}F chemical shifts in aryl fluorides, thus resolving more than ten years of controversy in this area.

The electrostatic calculations predict negligible field effects for $\delta_{F(b)}$ since the field acts almost at right angles to C—F(b). However the σ_I,σ_R^0 correlation gives a significant ρ_I value for $\delta_{F(b)}$ (Table 4). This must reflect the field-induced π polarization (the π polarization effect of a polar substituent is also proportional to σ_I (16)). In the absence of direct field effects, substituent-induced changes in carbon π electron density result in proportional changes in π electron density and chemical shift of the fluorine bonded to carbon (3). This must be true for $\delta_{F(b)}$ since this parameter is directly proportional to $\delta_{C(\beta)}$ (9) for the corresponding styrene derivatives:

$$[3]\quad \delta_{F(b)} = (0.95 \pm 0.03)\delta_{C(\beta)}(\text{styrene}) \quad (r = 0.997)$$

If ρ_I for $\delta_{F(b)}$ is assigned entirely to π polarization, then the ρ_I value for $\delta_{F(a)}$ indicates that the polar effect for this probe is about 85% (4.90/5.75) due to π polarization and ca. 15% (0.85/5.75) due to direct field effects. This is consistent with previous conclusions about the relative importance of field and π polarization effects in similar systems (3–8), although indicating a slightly greater contribution from field effects than suggested by Toyne and Ewing (6).

$\delta_{C(1)}$, $\delta_{C(\alpha)}$, and δ_H for **I** give substituent parameter correlations (Table 4) which are very similar to previously reported correlations for styrenes (9, 19), suggesting that the two fluorines do not significantly alter the substituent effects in styrene derivatives. However, the range of $\delta_{C(\beta)}$ for **I** is very significantly reduced comparted to 4-substituted styrenes (9), although still proportional to $\delta_{C(\beta)}$ for the latter system:

$$[4]\quad \delta_{C(\beta)}(\mathbf{I}) = (0.185 \pm 0.036)\delta_{C(\beta)}(\text{styrene}) \quad (r = 0.996)$$

Non-additive ^{13}C chemical shifts are now well documented for *para*-disubstituted benzene derivatives (19–22) and to a lesser extent for 4,β-disubstituted styrenes (23). However, eq. [4] illustrates what is apparently the most extreme example of non-additivity yet found (perfect additivity would require unit slope). In 4,β-disubstituted styrenes, non-additivity has been attributed to variable electron demand by the β-substituted vinyl group (23). However, this cannot be the case for **I** since this should lead to a non-linear relationship for eq. [4], while the actual correlation shows no evidence of non-linearity. Rather, the fluorines must alter the shift-to-charge ratio for ^{13}C chemical shifts (22). This point is further discussed in part *c*.

(b) ^{19}F–^{19}F, ^{1}H–^{19}F, and ^{13}C–^{19}F Coupling Constants

The *geminal* (^{19}F–^{19}F) and *vicinal* (^{1}H–^{19}F) vinyl coupling constants for **I** closely parallel the corresponding ^{1}H–^{1}H coupling constants in styrene (9) in that the *geminal* coupling constant is much more sensitive to substituent effects than either *vicinal* coupling constant (see Table 2). $^2J_{F-F}$ is sensitive to both polar and resonance effects (Table 4). It is not possible to unambiguously assign the two $^1J_{C-F}$ coupling constants to F(a) and F(b) since the ^{13}C satellite peaks in the ^{19}F spectra were too weak to be observed. However, the two coupling constants show a similar pattern of substituent effects as $\delta_{F(a)}$ and $\delta_{F(b)}$ (similar ρ_R values but a larger ρ_I value for one coupling). In view of this parallel, it seems

[4]To convert A to SI units, this value should be multiplied by 0.33×10^{-4} after which its units are mV^{-1}.

logical to assign the coupling which is more sensitive to polar effects as $^1J_{C-F(a)}$. This is consistent with the corresponding $^{13}C-^1H$ coupling constants in 4-substituted styrenes (24). $^1J_{C-F(a)}$ should be more sensitive to field-induced σ bond polarization (24).

(c) Calculated Electron Densities and Comparison with ^{19}F and ^{13}C Chemical Shifts

The *ab initio* molecular orbital calculations for β,β-difluorostyrene (Table 3) indicate that the difluorovinyl group acts as a weak π donor to the phenyl group (total π electron transfer of 0.0088 electrons) and a weak σ acceptor (total σ electron transfer of 0.0134 electrons). These competing effects result in a minimal overall effect for the difluorovinyl group.

The most interesting result concerns the relationship between δ_F and the fluorine π charge density $q_F\pi$. Figure 1 shows that there is an excellent linear relationship between these parameters. The most impressive feature of Fig. 1 is that it involves a plot of actual chemical shifts for two different fluorines in the same molecule against their actual calculated π charge density rather than a plot of substituent-induced changes in chemical shifts and π charge densities. This is possible because the calculations give a π charge density difference for the parent compound (−0.0110), corresponding to a calculated chemical shift difference, $\Delta\delta_F$ (−1.63 ppm), which is in excellent agreement with the experimental value for this compound ($\Delta\delta_F$ = −1.78 ppm). We believe that Fig. 1 represents the clearest evidence yet obtained for a linear relation between ^{19}F chemical shifts and fluorine π charge densities in a system where the fluorine is bonded to an sp^2 carbon.

By contrast, the fluorine total atomic charges do not predict $\Delta\delta_F$ for the parent compound, since the difference in atomic charge between F(a) and F(b) has the wrong sign (+0.00322). Consequently, one can only plot substituent-induced chemical shifts versus substituent-induced changes in atomic charges (i.e. defining $\delta_{F(a)}$, $\delta_{F(b)}$, $q_{F(a)}$, and $q_{F(b)}$ all as zero for X = H). When this is done, it is found that these are different slopes for $\delta_{F(a)}$ (758 ± 44 ppm/unit charge) and $\delta_{F(b)}$ (890 ± 45 ppm/unit charge). The σ charge densities in Table 3 suggest that two slopes are obtained because the calculations indicate field-induced σ-bond polarization which is relatively much greater than the observed field effects upon chemical shifts. This can be confirmed by correlating $q_F\sigma$ and $q_F\pi$ with the theoretical field, T_F, and resonance, T_R^0 substituent

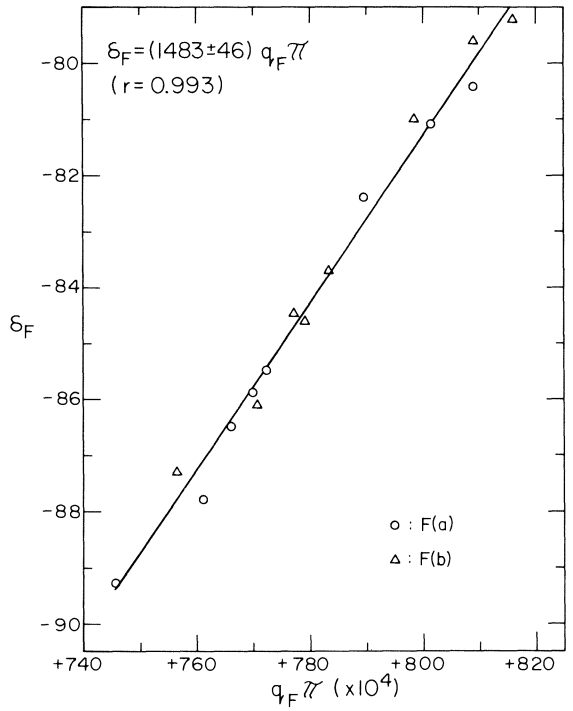

FIG. 1. Plot of ^{19}F chemical shifts (δ_F) for β,β-difluorostyrenes versus calculated π components of net atomic charges for fluorine ($q_F\pi$) (× 10^4). Positive sign of $q_F\pi$ corresponds to decreased electron density relative to a neutral fluorine atom.

parameters which have been derived for use with calculated charge densities (16, 17). The correlations (Table 4) show a much greater polar effect for $q_{F(a)}\sigma$ relative to $q_{F(b)}\sigma$ ($\rho_{F(a)}/\rho_{F(b)}$ = 2.19) compared to the corresponding chemical shift correlations ($\rho_{F(a)}/\rho_{F(b)}$ = 1.17). However, the correlations for $q_F\pi$ closely parallel the chemical shift correlations. This confirms that ^{19}F chemical shifts respond to π rather than total or σ charge density changes (14). It also provides an answer for an apparent dichotomy in the literature (3, 4). It appears that the main field effect upon fluorine atomic charges is due to field-induced σ bond polarization while the main field effect upon the ^{19}F chemical shifts is due to the weaker polarization of the partial C—F π bond (as previously suggested (4)).

$q_{F(b)}\pi$ gives an extremely precise linear relationship with $q_{C(\beta)}\pi$:

$$[5]\quad q_{F(b)}\pi = (0.154 \pm 0.002)q_{C(\beta)}\pi \qquad (r = 0.9997)$$

This confirms that, as suggested in part (*a*), $\delta_{F(b)}$ simply reflects substituent-induced changes in carbon π electron density and concomitant changes in fluorine π electron density.

Correlation of $q_{C(\beta)}\pi$ for **I** versus the corresponding parameter for styrene (16) yields:

[6] $q_{C(\beta)}\pi(\mathbf{I}) = (0.78 \pm 0.02)q_{C(\beta)}\pi(\text{styrene})$ $(r = 0.997)$

This demonstrates that the decreased substituent dependence for $\delta_{C(\beta)}$ shown in eq. [4] is only partly due to decreased substituent effects on $q_{C(\beta)}\pi$. Correlations of chemical shifts with π charge densities shown:

[7] $\delta_{C(\beta)}(\text{styrene}) = 193q_{C(\beta)}\pi(\text{styrene})$ $(r = 0.988)$

[8] $\delta_{C(\beta)}(\mathbf{I}) = 44q_{C(\beta)}\pi(\mathbf{I})$ $(r = 0.989)$

The former correlation gives a typical value for the shift-to-charge ratio (25, 26) while eq. [8] shows an abnormally small value. While the theoretical reasons for substituent-induced variations in the empirical shift-to-charge ratio are as yet unclear (21, 22), eq. [7] strongly suggests that it is the decrease in this parameter which is mainly responsible for the non-additive C(β) chemical shifts in **I**.

Summary and Conclusion

Consideration of field effects on the ^{19}F chemical shift difference, $\Delta\delta_F$, for 4-substituted β,β-difluorostyrenes yields a value of the constant in the Buckingham equation, $A = 3.0 \times 10^{-11}$ esu, in excellent agreement with a previous independent estimate from another system (4). Therefore it is now possible to make near quantitative estimates of direct field effects on ^{19}F chemical shifts in aryl fluorides. Clear evidence is presented for a linear relationship between ^{19}F chemical shifts and fluorine π electron density and further evidence is obtained that non-additive ^{13}C chemical shifts are mainly due to changes in the shift-to-charge ratio.

Experimental and Details of Calculations

4-Substituted β,β-difluorostyrenes were generally synthesized by the method of Naae (27) which involves a Wittig reaction of $(C_6H_5)_3P$ plus CF_2Br_2 with the appropriate 4-substituted benzaldehyde. Dry CH_2Cl_2 was used as a solvent. The reaction mixture was dumped into rapidly stirred pentane. The pentane layer was separated and the pentane was evaporated off. The β,β-difluorostyrene was then purified, either by distillation (X = H, CH_3, OCH_3, F, Cl, CF_3) or by thin layer chromatography (X = CN, NO_2, $N(CH_3)_2$). $[(CH_3)_2N]_3P$ was used in place of triphenylphosphine for the synthesis of the $N(CH_3)_2$ derivative, using glyme as solvent.

The compounds which, with the exception of the CF_3 derivative, were known compounds were characterized by their ^1H and ^{19}F spectra which showed characteristic ABX spectra for the difluorovinyl groups and AA′BB′ spectra for the *para*-disubstituted benzene functions. Purities were confirmed by ^{13}C nmr spectra.

^{19}F and ^1H spectra were obtained on a Varian XL-100 operating in continuous wave mode at respective frequencies of 94.19 and 100.06 MHz and at 31°C. Solutions contained 1 mol% compound in C_6D_{12} with 1% $CFCl_3$ and 0.1% $Si(CH_3)_4$ as reference peaks. Peak positions were obtained as averages of several measurements with a precision of 0.001 ppm. Further dilution of the parent compound and NO_2 and $N(CH_3)_2$ derivatives indicated that the observed chemical shifts differed from infinite dilution values by no more than 0.01 ppm. ^{13}C spectra were obtained on the same spectrometer operating in pulsed Fourier Transform mode. Samples were 0.4 *M* solutions of the compound in CCl_4 containing 8% C_6D_{12} as a lock signal.

Ab initio (STO-3G minimal basis set (13)) molecular orbital calculations were carried out on a SEL 32/75 computer using the program SUPERGAUSS 78, a modified version of GAUSSIAN 76 (28), developed by M. R. Peterson and R. A. Poirier. A partial energy minimization gave a value of the C(1)—C(α)—C(β) angle of 128.5°. Other geometries were identical to those given previously (16, 17). Planar NH_2 and OH were used in place of $N(CH_3)_2$ and OCH_3 for reasons of computational economy.

Complete and partial miscibility in ternary system: triethylamine–methylethylketone–water

ALAN N. CAMPBELL

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 12, 1979

ALAN N. CAMPBELL. Can. J. Chem. **58**, 846 (1980).

The equilibrium diagram of the system triethylamine–methylethylketone–water has been investigated completely with respect to the occurrence of solid phases and of the lower and upper solution temperatures of the $L_1 \leftrightharpoons L_2$ equilibria, where L_1 and L_2 are equilibrium liquid phases. The $L_1 \leftrightharpoons L_2$ surface is not completely realizable because this surface is intersected by the $L \leftrightharpoons V$ surface. In this respect the system forms a contrast to the previously investigated system nicotine–methylethylketone–water, where the complete $L_1 \leftrightharpoons L_2$ surface is realizable experimentally.

ALAN N. CAMPBELL. Can. J. Chem. **58**, 846 (1980).

On a effectué une étude détaillée du diagramme de phase triéthylamine–méthyléthylcétone–eau du point de vue de l'existence des phases solides et de la plus faible et de la plus haute température atteinte par la solution dans les équilibres $L_1 \leftrightharpoons L_2$ où L_1 et L_2 sont les phases liquides à l'équilibre. La surface $L_1 \leftrightharpoons L_2$ n'est pas complètement réalisable parce qu'elle rencontre la surface $L \leftrightharpoons V$. Sous ce rapport, le système est en opposition avec le système suivant déjà étudié: nicotine–méthyléthylcétone–eau (1) où la surface complète $L_1 \leftrightharpoons L_2$ est réalisable expérimentalement.

[Traduit par le journal]

Introduction

The system nicotine–water represented by a completely closed oval is to be found in most elementary text books of physical chemistry. It is not so well known that the system methylethylketone–water is almost identical, almost, but not quite, since the lower part of the oval is cut off by the ice-line. The two binary systems together yield the ternary system nicotine–methylethylketone–water, and this has been studied by Campbell, Kartzmark, and Falconer (1). The two zones of heterogeneity unite in a tunnel, in the solid model, without temperature maximum.

The system triethylamine–water is equally well known in elementary text books as the standard example of a binary system with lower critical solution temperature: the system methylethylketone–water has an upper critical solution temperature. The triethylamine–water system is also interesting in that while miscibility is complete below 18°C, immediately above that temperature, say at 20°C, the gap is large and extends over 58 wt.% triethylamine. It was thought that the addition of a small amount of triethylamine to the methylethylketone–water system would produce complete miscibility and indeed this has been found to be the case.

Experimental

Triethylamine was estimated conductimetrically by titration with standard hydrochloric acid. The densities of all possible homogenous mixtures, at 16°C, were determined and plotted on a very large triangular diagram (21.5 inch side). From a knowledge of the triethylamine content and the density of any given homogenous mixture the composition could be obtained from the intersection of the horizontal representing the triethylamine content and the line of density. The densities were determined in a pyknometer of 50 cm^3 capacity, and are therefore not good enough for the determination of partial molar volume. In any case, the amounts of equilibrium layers available were limited so that for the determination of densities 5 cm^3, or sometimes 2 cm^3, pyknometers were used.

The densities are to be found in the Depository of Unpublished Data.[1] For all three binary systems, the plot of molar volume vs. mole fraction is, within the limits of experimental accuracy, a straight line.

The densities were plotted around the periphery of a triangular diagram. Points of equal density were joined by straight lines. Fortunately for the accuracy of the method, these lines formed sharp angles with the horizontals representing triethylamine content. Large part of the diagram at 25°C was heterogeneous so that, in some cases, weighed quantities of suitable component had to be added to ensure homogeneity.

For temperatures up to 70°C, mixtures were stirred magnetically overnight in a completely closed glass apparatus. The apparatus was immersed in a thermostat at the required temperature. After the attainment of equilibrium, samples were removed by means of air pressure. For temperatures above 70°C, the apparatus of Fig. 1 was used. At these temperatures, the vapour pressure is above 1 atm and samples of both layers could be withdrawn by opening the appropriate cock: the liquid passed immediately into a water condenser and was bottled off. Because of the danger of explosion the apparatus was completely enclosed in an electric furnace, whose temperature was controlled by a powerstat to a constancy of 1 or 2°C. The apparatus was charged at room temperature, using such volumes as would ensure that no mixing would occur when samples were withdrawn at high temperature. To the objection that there was no stirring it can be urged that the area of contact is large and the

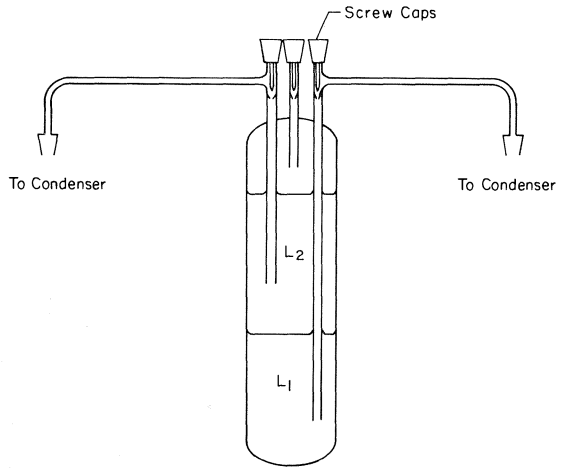

FIG. 1. High temperature apparatus.

rate of diffusion high at elevated temperatures. At any rate, the uniformity of the results seems to dispose of any contention that equilibrium was not attained. The experimental results are to be found in Depository and are expressed graphically in Figs. 2 and 3.

The solid model is terminated in the direction of lower temperature by the occurrence of the areas representing solid triethylamine, solid methylethylketone, and solid water: there are no compounds of the three components. The binary eutectic troughs should, and no doubt do, meet in a ternary eutectic point. It has been shown, however, by Randall and McKenna (2) that the binary eutectic of the system methylethylketone–water lies at −88.88°C and 99.91% methylethylketone, i.e. 9.9 wt.% water depresses the freezing point of methylethylketone about 2°C. The system triethylamine–methylethylketone had not been investigated and this was done by the author. Freezing point curves were determined with a copper–constantan thermocouple, cooling being done with liquid nitrogen. The data are in Depository and are represented graphically in Fig. 4. The eutectic lies at −130°C and 96.5 wt.% triethylamine. Obviously then the ternary eutectic lies close to this point, and is probably indistinguishable from it, since Randall and McKenna's eutectic contains so little water.

Since complete homogeneity in the ternary system was not attained at 160°C, the author turned to an apparatus which he had previously designed for a study of the L ⇆ V critical temperatures (3). The advantage of this apparatus is that thick-walled capillaries can be used and high temperatures and pressures attained. In the present study, two critical temperatures exist, viz. that of the equilibrium $L_1 \leftrightarrows L_2$ and that of the equilibrium $L_2 \leftrightarrows V$, i.e. in the field of view of the telescope used to follow the course of the experiment, two menisci are visible. If the temperature of homogeneity of the $L_1 \leftrightarrows L_2$ equilibrium lies below that of the $L_2 \leftrightarrows V$ equilibrium, the $L_1 \leftrightarrows L_2$ meniscus will disappear, leaving the $L_2 \leftrightarrows V$ meniscus. For concentrations below 30% of triethylamine, this was the case and for this range of concentration, the surface of homogeneity could be outlined. The work of Campbell and Kartzmark (3) showed that the critical temperatures L ⇆ V of ternary mixtures lie on a smooth surface connecting the critical temperatures of the three components. The critical temperature of water is 374°C, that of triethylamine is quoted as 262°C (4). If the approximate rule that the boiling point on the Kelvin scale is roughly two-thirds of the critical temperature, also on the Kelvin scale, is applied the following approximate critical temperatures are obtained: triethylamine, t_c = 270.9°C, methylethylketone, t_c = 256.0°C. From these approximate data it is apparent that the $L_1 \leftrightarrows L_2$ critical temperature (L_1 and L_2 equilibrium liquid phases) cannot be observed if it is higher than say 250 to 370°C, depending on composition. When this is the case, the $L_2 \leftrightarrows V$ meniscus disappears, leaving $L_1 \leftrightarrows V$. It was found experimentally that for mixtures having more than 30% triethylamine, the $L_1 \leftrightarrows L_2$ temperature could not be observed, in other words, the $L_1 \leftrightarrows L_2$ surface passes through the L ⇆ V surface about this limit of concentration. The method of experiment was to prepare a series of mixtures with fixed triethylamine content, and to find the temperatures of disappearance of the $L_1 \leftrightarrows L_2$ meniscus. In some cases, the temperature of disappearance of the L ⇆ V meniscus was also observed.

Another temperature to be considered is that below which homogeneity is attained. As this is invariably in the neighbourhood of room temperature it was sufficient to cool in ice water or, occasionally, to warm slightly. The method finally adopted was to use constant quantities of triethylamine (4, 8, and 16%) and vary the amounts of water and methylethylketone. The composition was then calculated on the basis of the sum of water and methylethylketone only (with constant triethylamine content). For each mixture, two and occasionally three temperatures were observed at which menisci disappeared. The numerical results are to be found in Depository and are expressed graphically in Fig. 5.

Discussion

Figures 2 and 3 represent the effect of rising temperature on the ternary equilibrium. At 0°C, at which temperature the binary system triethylamine–water is completely homogeneous, but the binary system methylethylketone–water is not, it is apparent that the addition of a few percent of triethylamine renders the methylethylketone–water system completely homogeneous. At 25°C, where both binary systems are heterogeneous, over a large area of composition, there is still a large area of the diagram which represents homogeneity. At 50°C, the two areas of heterogeneity have fused, leaving only small homogeneous areas; the curve MEK–TriE is always richer in triethylamine than the equilibrium curve H_2O–TriE. At 70°C, the same is true. The diagrams for 100, 120, 140, and 160°C are very similar. There is no approach to homogeneity with rising temperature.

Figure 4 represents the results of the thermal analysis of the methylethylketone–triethylamine system. The eutectic lies at −130°C and 96.5 wt.% triethylamine.

Examination of Fig. 5 shows that with increase of triethylamine content, the temperature of disappearance of the $L_1 \leftrightarrows L_2$ meniscus rises so that the $L_1 \leftrightarrows L_2$ surface passes through the L ⇆ V surface somewhat beyond 16% triethylamine. This means that though the $L_1 \leftrightarrows L_2$ dome is completely realisable for the system nicotine–methylethylketone–

water (1), it has only a partial existence for the present system.

With 4 and 8% triethylamine, the content of methylethylketone has little effect on the temperature of disappearance of the $L_1 \leftrightharpoons L_2$ meniscus but, with 16% triethylamine, the temperature rises sharply with increasing water content. The low temperature disappearance of the $L_1 \leftrightharpoons L_2$ meniscus is but little influenced by triethylamine content but it is lowest for 4% triethylamine. The critical temperature L ⇋ V appears to be around 320°C, in the presence of 16% triethylamine.

From the data of the previous paper (1) on nicotine–methylethylketone–water a solid model was constructed which has been used in teaching here. A similar model can be constructed from the data of this paper.

Acknowledgement

I am indebted to Dr. J. E. Desnoyers for the following comment: "Your systems approach what is now called microemulsions. For example, we have shown that triethylamine–water mixtures exist as microphases at low temperatures and I suspect that methylethylketone is stabilizing these microstructures."

The X-ray crystal structures of $SeBr_3SbF_6$ and $TeBr_3AsF_6$

JACK PASSMORE, E. KEITH RICHARDSON, TOM K. WHIDDEN, AND PETER S. WHITE

Department of Chemistry, University of New Brunswick, P.O. Box 4400, Fredericton, N.B., Canada E3B 5A3

Received August 27, 1979

JACK PASSMORE, E. KEITH RICHARDSON, TOM K. WHIDDEN, and PETER S. WHITE. Can. J. Chem. **58**, 851 (1980).

The crystal structures of $SeBr_3SbF_6$ and $TeBr_3AsF_6$ were determined by X-ray diffraction methods. Single crystals of $SeBr_3SbF_6$ are orthorhombic, space group $P2_12_12_1$ with $a = 9.454(5)$ Å, $b = 12.623(6)$ Å, $c = 8.272(4)$ Å, and $Z = 4$. Single crystals of $TeBr_3AsF_6$ are monoclinic, space group $P2_1/c$, with $a = 7.994(3)$ Å, $b = 10.118(3)$ Å, $c = 12.306(3)$ Å, $\beta = 99.66(2)°$, and $Z = 4$. The cations in each salt have essentially C_{3v} symmetry and the average Se—Br distance in $SeBr_3SbF_6$ is 2.269(8) Å and the average Br—Se—Br angle is 100.9(3)°. Analogous data for $TeBr_3AsF_6$ are: Te—Br = 2.432(3) Å; Br—Te—Br = 97.92(9)°. Anions in each salt are essentially octahedral. The bond angles in isoelectronic Group V and Group VI trihalide molecules and cations are compared and found to be very similar. However, those found for Group VI trihalide cations are greater than (5 pairs) those observed in isoelectronic Group V molecules determined in the solid state, and angles estimated for Group VI cations in gas phase are greater (8 pairs) than those found for the related gas phase Group V trihalide partners. This result implies that geometries, at least in part, are determined by the relative sizes of the constituent atoms. The crystallography of the related salts $SeBr_3AsF_6$ and SBr_3MF_6 (M = As, Sb) was studied by single crystal and powder diffraction methods. Salts containing the same anion were found to be isostructural.

JACK PASSMORE, E. KEITH RICHARDSON, TOM K. WHIDDEN et PETER S. WHITE. Can. J. Chem. **58**, 851 (1980).

On a déterminé la structure des cristaux du $SeBr_3SbF_6$ et du $TeBr_3AsF_6$ par la méthode de diffraction de rayons-X. Les cristaux uniques du $SeBr_3SbF_6$ sont orthorhombiques, groupe d'espace $P2_12_12_1$ avec $a = 9.454(5)$ Å, $b = 12.623(6)$ Å, $c = 8.272(4)$ Å et $Z = 4$. Les cristaux uniques du $TeBr_3AsF_6$ sont monocliniques, groupe d'espace $P2_1/c$ avec $a = 7.994(3)$ Å, $b = 10.118(3)$ Å, $c = 12.306(3)$ Å, $\beta = 99.66(2)°$ et $Z = 4$. Les cations dans chacun des sels ont essentiellement une symétrie C_{3v} avec une distance moyenne de liaison SeBr, dans le $SeBr_3SbF_6$, de 2.269(8) Å et un angle moyen Br—Se—Br de 100.9(3)°. Dans le cas du $TeBr_3AsF_6$ ces données sont de: Te—Br = 2.432(3) Å et Br—Te—Br = 97.92(9)°. Dans chaque sel les anions sont essentiellement octaédriques. On a comparé les angles de liaisons des molécules isoélectroniques trihalogénées et des cations des groupes V et VI et on a trouvé des valeurs identiques. Cependant dans le cas des cations trihalogénés du groupe VI ces valeurs sont plus grandes (5 paires) que celles observées dans le cas des molécules isoélectroniques du groupe V et déterminées à l'état solide; les angles évalués pour les cations du groupe VI en phase gazeuse sont plus grands (8 paires) que celles trouvées pour les dérivés trihalogènes du groupe V à l'état gazeux. Ce résultat montre que les grandeurs relatives des atomes du composé déterminent les structures, au moins en partie. On a étudié la cristallographie des sels apprentés: $SeBr_3AsF_6$ et SBr_3MF_6 (M = As, Sb) par les méthodes de diffraction des cristaux uniques et des poudres. On a trouvé que les sels contenant les mêmes anions sont isostructuraux.

[Traduit par le journal]

Introduction

The structures of a number of MX_3^+ derivatives of the Group VI tetrahalides have been characterized by X-ray diffraction methods. The known structures which contain essentially discrete MX_3^+ ions include SF_3BF_4 (1), SeF_3MF_6 (M = Nb, Ta) (2), $SeF_3Nb_2F_{11}$ (3), $TeF_3Sb_2F_{11}$ (4), SCl_3ICl_4 (5), $SeCl_3AlCl_4$ (6), and $TeCl_3AlCl_4$ (7). In all cases cations have essentially C_{3v} symmetry with very small or no differences in the M—X bond lengths and the internally similar X—M—X angles about the central metal atom. Interionic contacts are generally weak and complete an octahedral environment around the central Group VI atom.

Recently SBr_3MF_6, $SeBr_3MF_6$, and $TeBr_3AsF_6$ (M = As, Sb) have been prepared (8) as stable crystalline solids. Raman spectra were consistent with an ionic formulation and C_{3v} symmetry for the cations. Single crystals of $SeBr_3SbF_6$ and $TeBr_3AsF_6$ were obtained and the structures of these salts were determined by X-ray diffraction methods and are reported below along with the unit cell parameters of the other tribromochalcogen salts listed above.

Experimental

Preparation of Single Crystals of $SeBr_3AsF_6$, $SeBr_3SbF_6$, and $TeBr_3AsF_6$

A detailed account of the preparation of the above salts is presented in ref. 8. Single crystals of $SeBr_3AsF_6$ were obtained by recrystallizing the product of the reaction of elemental selenium, bromine, and AsF_5 in SO_2 by adding a small amount of AsF_3 (SO_2:AsF_3 = 5:1), holding the solution at room temperature and slowly distilling off the solvent (3–5 h) into a cold trap held at 0°C. Crystals of $SeBr_3SbF_6$ were obtained directly as the product of the reaction of $Se_4(SbF_6)_2$, Br_2, and AsF_5 in SO_2 solution. Crystals of $TeBr_3AsF_6$ were also obtained directly as the product of the reaction of tellurium, bromine, and AsF_5 in SO_2 solution.

Crystal Data for SBr_3MF_6, $SeBr_3MF_6$, and $TeBr_3AsF_6$ (M = As, Sb)

Single crystals of $SeBr_3MF_6$ and $TeBr_3AsF_6$ were mounted and sealed in rigorously dried Pyrex capillaries as described in ref. 9. Unit cell parameters (Table 1) were obtained by photographic methods and, for $SeBr_3SbF_6$ and $TeBr_3AsF_6$, were refined from diffractometer data. Unit cell data for $SeBr_3AsF_6$ were refined by a least-squares procedure (10) using 21 out of 33 observed spacings on an X-ray powder photograph as input.[1]

[1]Tables of observed and calculated $1/d^2$ values for $SeBr_3AsF_6$, SBr_3AsF_6, and SBr_3SbF_6 are available at a nominal charge from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

$SeBr_3AsF_6$ and $TeBr_3AsF_6$ were monoclinic with systematically absent reflections that uniquely defined the space group as $P2_1/c$ (C_{2h}^5, No. 14, ref. 11) and $SeBr_3SbF_6$ was orthorhombic with absences uniquely defining its space group as $P2_12_12_1$ (D_4^2, No. 19, ref. 11).

The crystal data for SBr_3MF_6 (M = As, Sb; Table 1) were obtained from X-ray powder photographs using a least-squares fit (10) of the cell parameters to the observed spacings.[1] The crystal system and space group of the salts were unknown and therefore each was refined using the corresponding $SeBr_3MF_6$ unit cell dimensions as starting values in both $P2_1/c$ and $P2_12_12_1$ and the space group which gave the best fit of observed to calculated $1/d^2$ values assumed to be correct. Due to the diffuse nature of the powder patterns and consequent inaccuracy of the spacing measurements, only 14 out of 27 spacings were included in the refinement procedure for SBr_3AsF_6 and for SBr_3SbF_6 13 out of 24 spacings were included. The small number of observations in each procedure (~3 times the number of adjustable parameters) suggests that the final error estimates (Table 1) are over-optimistic.

X-ray intensity data for $SeBr_3SbF_6$ and $TeBr_3AsF_6$ were collected in the manner described in ref. 12 (experimental details presented in Table 2). The standard reflection measured during data collection for $SeBr_3SbF_6$ had a maximum deviation from its mean value of 2.3σ where $\sigma = (\Delta I^2/n)^{1/2}$. During the collection for $TeBr_3AsF_6$ three reflections were measured and their combined net intensity used as a standard. The maximum deviation from the mean for this figure was 3.76σ for one very different standard. When this figure was not included in the calculation the maximum deviation was reduced to 2.11σ.

The Determination of the Structure of $SeBr_3SbF_6$

Data reduction and structure refinement utilized the X-RAY76 program package (13). Atomic scattering factors for neutral atoms were taken from Cromer and Mann (14) and those for selenium, bromine, and antimony were corrected for anomalous dispersion (15). Corrections for Lorentz, polarization, and absorption factors (16) were made in the pre-treatment of data (see Table 2). A total of 124 reflections with $E \geq 1.50$ were used as input to MULTAN (17) and an E-map phased on the solution with the highest combined figure of merit revealed the atomic co-ordinates of the selenium, bromine, and antimony atoms. These positions were refined by least-squares after which an F_o synthesis gave the positions of the six fluorine atoms. With all atoms included in the calculation the least-squares procedure converged at a value of 0.170 for the conventional residual

function $R = \sum w(|F_o| - |F_c|)/\sum w|F_o|$ with $w = 1$. The weights in the procedure were changed to $1/[\sigma(F_o)^2 + 0.03F_o^2]$ where $\sigma(F_o)$ is derived from counter statistics (18). A minimum net intensity of 40 counts was used to define unobserved reflections. The refinement procedure converged at $R = 0.104$, $R_w = 0.142$ for 798 observed reflections. A ΔF synthesis showed a maximum residual electron density in the unit cell of 2.87 $e^-/Å^3$ at a position 0.83 Å from Sb1. The average shift/error value for the final cycle of refinement was 0.114 with a maximum shift/error of 0.581 associated with a fluorine thermal parameter. The quality of the crystals appeared too poor for any further improvement in the data set. Final atomic positional parameters for $SeBr_3SbF_6$ are presented in Table 3. Final anisotropic thermal parameters and tables of calculated and observed structure factors have been put in the Depository of Unpublished Data.[2]

The Determination of the Structure of $TeBr_3AsF_6$

Pre-treatment of data and structure refinement was carried out in a manner similar to that for $SeBr_3SbF_6$ except that the absorption correction was applied when $R = 0.130$ to ensure that the correction improved the model. The initial positional parameters for tellurium were determined using Patterson methods. An F_o synthesis phased with this position gave atomic co-ordinates for 4 large peaks which, from chemical considerations, were identified as the bromine and antimony atoms. Subsequent least-squares refinement and F_o synthesis gave the positions of the six fluorine atoms and with all atoms included in the calculation refinement converged at $R = 0.130$. The absorption correction was applied (Table 2 lists the transmission factors) and the weights in the least-squares procedure changed from 1 to $1/\sigma(F)^2$ where $\sigma(F)$ is directly derived from $\sigma(I)$ (18). The final residuals for 1726 reflections with 1044 classed as observed are $R = 0.048$, $R_w = 0.054$. The average shift/error for the final cycle of refinement was 0.022 with a maximum shift/error of 0.136 associated with a fluorine atom. The maximum residual electron density in the unit cell is 1.42 $e^-/Å^3$ at a position 1.97 Å from Br2. Final atomic positional parameters for $TeBr_3AsF_6$ are presented in Table 3. Final anisotropic thermal parameters and tables of calculated and observed structure factors have been deposited.[2]

Results and Discussion

Relevant bond lengths and angles for $SeBr_3SbF_6$ and $TeBr_3AsF_6$ are presented in Tables 4 and 5 respectively. Figures 1 and 2 show the crystal packing in $SeBr_3SbF_6$ and $TeBr_3AsF_6$. The three strongest anion–cation contacts in each structure complete a distorted octahedron about the central Group VI atom. The vertex-sharing packing of these anion and cation octahedra gives rise to an infinite three-dimensional net in $SeBr_3SbF_6$ (Fig. 1) and to a layered structure in $TeBr_3AsF_6$ (Fig. 2) where the cation octahedra form very distorted close-packed layers parallel to the *bc* plane with anions present in interstitial sites on either side of the layer. In terms of a VSEPR model (19), these contacts would be grouped around the lone pair of the MBr_3^+ cation. However, the relatively low average value of the F—M—F angles between the interionic contacts (86° in $SeBr_3SbF_6$; 93.2° in $TeBr_3AsF_6$) would suggest that, if the lone pair is stereochemically active in these cations, its activity is less than in the Group VI trifluoride cations. The

[a]Mean ∠F—Sb—F, 90.08; mean ∠F—As—F, 90.01; mean ∠Br—Se—Br, 100.97; mean ∠Br—Te—Br, 97.91.

comparable angles in SF_3BF_4 (1), SeF_3NbF_6 (2) and $SeF_3Nb_2F_{11}$ (3) (average), and $TeF_3Sb_2F_{11}$ (4) are significantly larger, with values of 97°, 97.6°, and 100.9° respectively.

Contact between layers in $TeBr_3AsF_6$ consists of weak Br–F interactions (3.07 Å, 8.4% less than the sum of van der Waal's radii, 3.35 Å, ref. 20). Slightly stronger Br–F contacts are present in $SeBr_3SbF_6$ (2.96 Å). The Te–F contacts in $TeBr_3AsF_6$ (average 2.84 Å, 20.2% less than the sum of van der Waal's radii) are somewhat stronger than the Se–F contacts in $SeBr_3SbF_6$ (average 2.77 Å, 17.9% less than the sum of van der Waal's radii), consistent with tellurium having a greater positive charge than selenium and the more basic nature of AsF_6^- relative to SbF_6^-. The crystal data in Table 1 show that MBr_3AsF_6 salts are isomorphous and monoclinic (SeI_3AsF_6 has also been found to be isomorphous with the AsF_6^- salts studied herein (9)) and MBr_3SbF_6 salts are isomorphous and orthorhombic. Alkali metal $[AsF_6]^-$ and $[SbF_6]^-$ salts are also structurally different (21).

The cations are pyramidal with essentially C_{3v} symmetry. M—Br bond distances within each cation (Table 4) are statistically equivalent (average Se—Br distance, 2.269(8) Å; average Te—Br distance, 2.432(3) Å) while the Br—M—Br bond angles (Table 5) show minor differences. The average bond distances in $SeBr_3^+$ and $TeBr_3^+$ are significantly shorter than that in the isoelectronic species $AsBr_3$ (2.324(2) Å) and $SbBr_3$ (2.490(3) Å). Similar relationships are found between other trihalochalcogens and isoelectronic Group V trihalides (Table 6). The reduction in bond distance between isoelectronic pairs is reflected in changes in stretching forces constants (8) and presumably can be attributed to the difference in effective nuclear charge on the central atoms of the isoelectronic pairs.

The order of bond angle changes observed in Table 6, i.e. $XI_3 > XBr_3 > XCl_3 > XF_3$ (X = N, P, As, Sb, S^+, Se^+, Te^+) and $NX_3 > PX_3 > AsX_3 > SbX_3$ and $SX_3^+ > SeX_3^+ > TeX_3^+$ (X = F, Cl, Br, I) are explicable either by VSEPR theory (19) or by consideration of the relative sizes of the constituent atoms of the molecules or cations. The observation has been made (1) that molecules and cations that are isoelectronic pairs, e.g. PF_3 and SF_3^+, have the same bond angles despite the bond shortening in the cation. This conclusion was based on a comparison of data between the molecular species in the gas phase and the ion in the solid state. It is more meaningful, however, to compare the bond angles of isoelectronic pairs in the same environment, e.g., both in the gas phase. Bond angles for the Group V trihalides are smaller in the solid state than in the gas phase, with the exception of phosphorus and arsenic triiodides. The magnitudes of these differences (Δ) are shown in Table 7. The more electropositive the central atom and the greater the electronegativity of the halide, the greater the intermolecular interactions and the more the species tends towards having a polymeric structure with an octahedral environment about the central atom (90° angles). As the cation–anion interactions for the corresponding Group VI species are generally stronger than interactions between neutral Group V molecules (see Table 7), the bond angle in the isolated cation is reasonably predicted to be greater than that observed in the solid state by at least the difference observed for analogous data in isoelectronic Group V trihalides. If the corrections, Δ, in Table 7 are added to the Group VI trihalide angles the angles in all eight cases are

greater than those observed for the gas phase isoelectronic Group V trihalide species. Alternatively, angles determined for Group V trihalides in the solid state may be compared with those of their Group VI congeners and, for the five cases in which data are available, the cation angles are larger. Thus, notwithstanding relatively large errors in the data, for all related pairs, the Group VI trihalide

[a]Δ = angle in gas phase − angle in solid state.
[b]*r* = intermolecular contact/Σ van der Waals' radii.
[c]Data obtained from references given in Table 6.
[d]These are estimates of the correction (deg) necessary to derive bond angles for isolated trihalide cations from solid state data.

angles are greater than those of the isoelectronic Group V partners. This result is consistent with a model in which the geometry, at least in part, is determined by the relative sizes of the constituent atoms (36–38). The replacement of the Group V atom by a unipositive Group VI atom of smaller size naturally leads to a larger angle. In the context of VSEPR theory, this observation implies that the strength of bond–bond repulsions relative to that of lone pair-bond repulsions is greater in the cation than in the neutral Group V congener. This result does not obviously follow from simple electrostatics. It is of interest to note that the bond angles in Group VI dihalides (with two lone pairs) are generally equal to or greater than those of the corresponding Group V trihalides, having one lone pair (39). Although the wide usefulness of the VSEPR theory is acknowledged, this and other difficulties with the application of a second-order VSEPR model have been the subject of recent interest (40).

The data in Table 6 allow some predictions as to the bond lengths and angles in as yet uncharacterized species. There is a reduction in bond length by a factor of 1.026 ± 0.002 in going from the neutral to the charged species. The data therefore predict a bond length of 2.164(5) Å for SBr_3^+, 2.368(5) Å for SI_3^+, 2.492(5) Å for SeI_3^+, and 2.650(5) Å for TeI_3^+. During our exploration of a hard sphere model of these species a number of simple relationships between ligand–ligand separation and various other observables were explored. In one such relationship it was found that a relatively constant ratio (0.920 ± 0.006) exists

between the chlorine–chlorine separation in neutral or charged trichlorides and the bromine–bromine distance in comparable tribromides. The predicted Br—Br distance in SBr_3^+ is thus 3.355 Å and, from simple trigonometry, the bond angle is predicted to be 101.1 ± 0.9°. Similarly, the bond angles in the Group VI tri-iodide cations can be estimated from the ratio between ligand–ligand separations in the Group V tribromides and triiodides, assuming that the ratio is the same for Group V molecules and Group VI cations (see Table 6).

The anions in both $SeBr_3SbF_6$ and $TeBr_3AsF_6$ are, within experimental error, regular octahedra. Some distortions would be expected due to the anion–cation contacts but, within the accuracy of the experiment, none was observed. The average Sb—F and As—F distances are 1.86(4) Å and 1.71(1) Å respectively. Average F—Sb—F and F—As—F bond angles are 90(2)° and 90.0(7)°, respectively.

NOTE ADDED IN PROOF: The structure of TeI_3AsF_6 has recently been determined in our laboratory and the distances and angles were found to be consistent with those estimated.

Synthesis of maytansinoids: synthesis of an intermediate from D-glucose for the construction of maytansine[1]

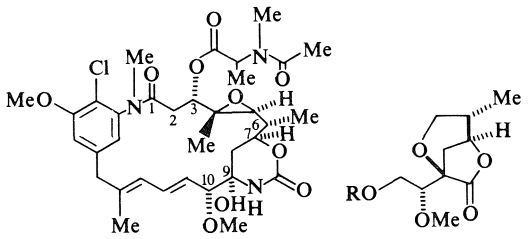
PAK-TSUN HO

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received December 20, 1979

This paper is dedicated to Prof. Karel Wiesner on the occasion of his 60th birthday

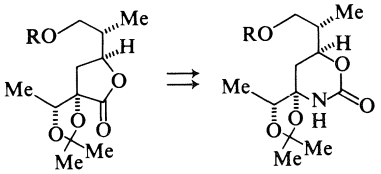
PAK-TSUN HO. Can. J. Chem. **58**, 858 (1980).



D-Glucose was converted to the lactone **1**, an intermediate containing the appropriate functionalities and correct stereochemistry for the construction of maytansine.

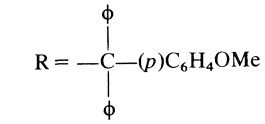
PAK-TSUN HO. Can. J. Chem. **58**, 858 (1980).

On transforme le D-glucose en lactone **1**, un intermédiaire contenant les fonctions et la stéréochimie appropriées en vue de la synthèse de la maytansine.



[Traduit par le journal]

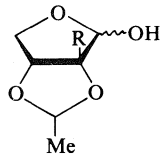
Maytansine **I** is one of the clinically interesting macrolide maytansinoids (1). Because of the extremely low isolation yields of maytansine and its congenors, multifaced synthetic approaches toward this complex macrolide have been carried out by a number of research groups in the past several years (2), and the successful synthesis of *N*-methylmaysenine has recently been reported from two research groups (3). Earlier work in this laboratory on the model studies for the synthesis of maytansine led to the stereocontrolled preparation of the model lactone **i** and the simple conversion **i** to compound **ii**, a cyclic carbamate unit of maytansine (4). In the present communication we describe the efficient synthesis of the γ-lactone **1** from D-glucose. The promising lactone intermediate now has both correct relative and absolute stereochemistry and suitable functionalities for further elaboration to maytansine.



I

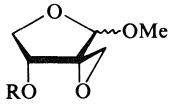
1

i **ii**



The starting material in the synthesis was the readily available sugar **2** for which a convenient synthesis from D-glucose had been developed in this laboratory (5). Reaction of **2** with tosyl chloride (1 equiv.) in pyridine at 0°C gave the tosylate **3**[2] in excellent yield. Treatment of compound **3** with *p*-toluenesulfonic acid (20% by weight) in anhydrous methanol at refluxing temperature for 3 days, followed by addition of methanolic potassium hydroxide at room temperature, led to the formation of the epoxide **4** (two glycosides) in 80% yield. For characterization, the two methyl glycosides **4** were easily separated by chromatography on silica gel (acetone–chloroform–hexane 1:6:3) to give the β- and α-glycoside in a ratio 8:2. The crystalline β-methyl glycoside had mp 60°C $[\alpha]_D$ −272° (*c* 1.0, chloroform), and it gave ^{1}H nmr signals at δ 4.80 (1H, s, C-1 proton), 3.42 (3H, s, methoxyl), and 3.20 ppm (2H, ABq, epoxide). The α-methyl glycoside was an oil, $[\alpha]_D$ +74.1° (*c* 1.2, chloroform), and gave ^{1}H nmr signals at δ 4.78 (1H, s, C-1 proton), 3.40 (3H, s, methoxyl), and 3.04 ppm (2H, ABq, epoxide). Compound **5** was

[1]Issued as NRCC No. 18122.



[2]Satisfactory physical and spectral data have been obtained for all new compounds.

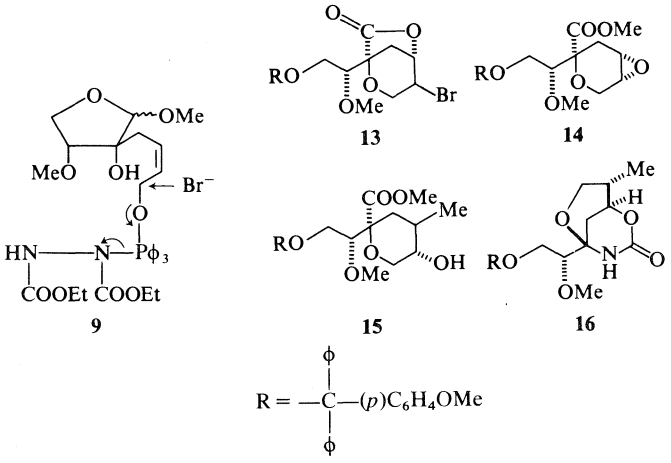
4 R = H
5 R = Me

6 R = $CH_2C{\equiv}CCH_2OTHP$
7 R = $CH_2C{\equiv}CCH_2OH$
8 R = $CH_2CH{=}CHCH_2OH$

10 R = OMe, H
11 R = OH, H
12 R = O

obtained in 80% yield by reaction of **4** with sodium hydride and excess methyl iodide in anhydrous tetrahydrofuran at 0°C. Condensation of **5** with 3-tetrahydropyranyloxy-1-propynyl dimethyl alane (4 equiv.) in toluene solution (10°C, 1.5 days) resulted in the formation of the oily compound **6** in 80% yield (6). Removal of the tetrahydropyranyl group from **6** with catalytic amount of *p*-toluenesulfonic acid in 90% aqueous methanol (40°C, 1 h) furnished quantitatively the alcohol **7**. For the β-glycoside, $[\alpha]_D$ −86° (*c* 1.5, chloroform), ^{1}H nmr signals at δ 4.73 (1H, s, C-1 proton), and 4.22 ppm (2H, broad s, —CH_2OH); for the α-glycoside, $[\alpha]_D$ +80.3° (*c* 3.6, chloroform), ^{1}H nmr signals at δ 4.53 (1H, s, C-1 proton), and 4.21 ppm (2H, broad s, —CH_2OH). Hydrogenation of compound **7** on 5% Pd–$CaCO_3$ in benzene solution in the presence of a small amount of quinoline yielded the olefin **8** as a syrup in 92% yield.



The operation which faced us now was the formation of the unsaturated spiroheterocyclic system by cyclization of the unsaturated diol **8**. After considerable experimentation, a simple and efficient cyclization procedure was developed. A solution of diethyl azodicarboxylate (2 equiv.) in tetrahydrofuran was added to a solution of **8**, triphenylphosphine (2 equiv.), and anhydrous lithium bromide (2.5 equiv.) in tetrahydrofuran at 0°C under argon. After stirring 30 min, anhydrous methanol was added to the reaction mixture and the solution was allowed to stir for an additional 2 h at room temperature. Purification on silica gel yielded the cyclization product **10** as a syrup in 87% yield. For the β-glycoside, $[\alpha]_D$ −132.8° (*c* 1.4, chloroform), ^{1}H nmr signals at δ 5.78 (2H, m, vinylic protons), 4.82 (1H, s, C-1 proton), 4.35 (2H, broad s, C=C—CH_2—O—), and 2.34 ppm (2H, broad s, C=C—CH_2—); for the α-glycoside, $[\alpha]_D$ +108.2° (*c* 1.1, chloroform), ^{1}H nmr signals at δ 5.80 (2H, m, vinylic protons), 4.60 (1H, s, C-1 proton), 4.30 (2H, broad s, C=C—CH_2—O—), and 2.10 ppm (2H, broad s, C=C—CH_2—). The use of lithium bromide and methanol in this one-step cyclization process is essential. When the reaction was carried out without lithium bromide, a nitrogen-containing compound was isolated and there was no desired product formed.[3] The cyclization reaction presumably proceeds via a bromide intermediate, formed by the attack of lithium bromide on the complex, or an adduct such as **9**, followed by ring closure resulting from a nucleophilic attack by the tertiary hydroxyl under basic conditions. The high efficiency of this one-step cyclization reaction may provide a useful method for the synthesis of a variety of unsaturated heterocycles. The utilization and generality of the cyclization reaction will be discussed elsewhere.

Compound **10**, on treatment with 70% aqueous trifluoroacetic acid at room temperature for 30 h, afforded quantitatively **11**, which was oxidized with a mixture of dimethyl sulfoxide and acetic anhydride (1:1) at room temperature to the corresponding γ-lactone **12** in 87% yield, mp 85°C, $[\alpha]_D$ −122.8° (*c* 1.7, chloroform); ν_{max}: 1790 (lactone) cm^{-1}; ^{1}H nmr signals at δ 5.80 (2H, m, vinylic protons), 4.35 (4H, m, —CH_2—$\overset{O}{\overset{\|}{C}}$O— and C=C—$CH_2$—O—), 3.80 (1H, t, C-3 proton), 3.44 (3H, s, methoxyl), and 2.28 (2H, broad s, C=C—CH_2—) ppm.

Further elaboration of the spirolactone **12** was accomplished in the following way. Reaction of **12** with potassium hydroxide in aqueous methanol at room temperature, followed by treatment of the resulting hydroxyacid with *p*-anisyldiphenylmethyl chloride (1.2 equiv.) in pyridine yielded the crude product which was dissolved in aqueous potassium hydroxide (pH 9.5) and reacted with a small excess of bromine – potassium bromide at 5°C to give the crystalline bromolactone **13** in 72% yield, mp 156°C; $[\alpha]_D$ −24.3° (*c* 1.0, chloroform); ν_{max}: 1790 (lactone) cm^{-1}. The epoxide **14** was obtained quantitatively by treatment of **13** with $LiOH \cdot H_2O$ (2 equiv.) in methanol at room temperature for 2 h. Its infrared spectrum showed ν_{max}: 1730 cm^{-1} for the ester. Finally, compound **14**, on treatment with lithium dimethylcuprate (2 equiv.) in ether solution (5 h, 0°C), was converted in 80% yield to a mixture

[3]Reactions of diols with diethyl azodicarboxylate and triphenyl phosphine to give cyclic ethers have been reported (see ref. 7).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

containing 65% of the desired compound **1** accompanied by the regio-isomer hydroxyester **15**. The lactone **1** showed $[\alpha]_D$ −3.5 (*c* 1.0, chloroform) and ν_{max}: 1780 (γ-lactone) cm^{-1}. It gave ^1H nmr signals at δ 4.65 (1H, q, —C(=O)—O—CH—), 3.75 (3H, s, aromatic methoxyl), 3.48 (3H, s, methoxyl), and 1.03 ppm (3H, d, methyl). Thus, construction of the promising intermediate **1** for the synthesis of maytansine was completed. Further, the lactone **1**, under the same conditions described in the model investigation (4), was converted in good yield to the carbamate **16**, ν_{max}: 3410 (NH), 1710 (carbamate) cm^{-1}; ^1H nmr signals at δ 6.20 (1H, s, NH exchanged with D_2O), 4.38 (1H, q, —CH—O—C(=O)—NH—), and 1.05 ppm (3H, d, methyl). In accordance with the chemistry of maytansinoids, the correct stereochemistry of hydroxyl at C-9 will be readily produced by acid-catalyzed hydration (1*a*). The utilization of the intermediate **1** in the total synthesis of maytansine is currently underway.[4]

[4]A novel synthesis of "western–southern" region of maytansine has been accomplished and is reported in the accompanying communication.

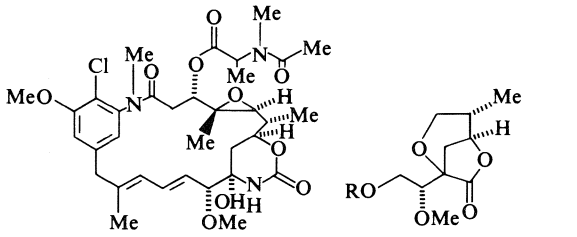
Synthesis of maytansinoids: the aromatic moiety of maytansine[1]

PAK-TSUN HO
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received January 17, 1980

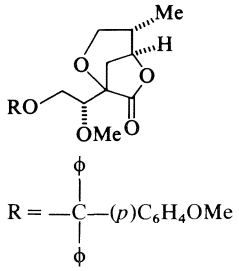
PAK-TSUN HO. Can. J. Chem. **58**, 861 (1980).

A simple and novel synthesis of the tetrasubstituted aromatic compound related to the "western–southern" region of maytansine has been achieved.



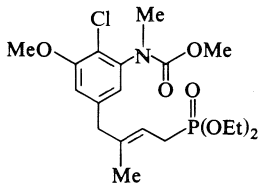
PAK-TSUN HO. Can. J. Chem. **58**, 861 (1980).

On a réalisé une synthèse simple et nouvelle d'un composé aromatique tétrasubstitué relié à la région "sud–ouest" de la maytansine.



[Traduit par le journal]

In the studies toward the total synthesis of clinically interesting maytansine **I**, we have described recently the stereospecific synthesis of optically active lactone **II** and its derived carbamate as synthons for construction of maytansine (1). We now report a novel and efficient synthesis of the tetrasubstituted aromatic intermediate **1** which serves as the crucial synthon of the "western–southern" region of maytansine.[2]



Compound **2**[3] was prepared in almost quantitative yield by reaction of commercially available 6-amino-*m*-cresol with trimethylacetyl chloride in methylene dichloride and aqueous sodium bicarbonate at room temperature, followed by methylation with potassium carbonate and methyl iodide in acetone at refluxing temperature. When **2** was treated with *n*-butyllithium (2.2 equiv.) in tetrahydrofuran at room temperature for 6 h, dilithiation of **2** occurred in the position *ortho* to the amino group (3). Reaction of the dianion with carbon dioxide at −70°C resulted in the formation of the crystalline acid **3** (mp 160°C) in 86% yield, based on **2** consumed; ν_{max}: 3440 (NH), 3300–2500 (acid), and 1690 (acid and amide) cm^{-1}; ^1H nmr signals at δ 10.12 (1H, broad s, COOH exchanged with D_2O), 8.23 (1H, broad s, NH exchanged with D_2O), 7.30 (1H, s, aromatic proton), and 6.90 ppm (1H, s, aromatic proton). The two singlets at 7.30 and 6.90 ppm for the two aromatic protons in the ^1H nmr spectrum of compound **3** clearly indicate that the carboxylic function is correctly located in the position *ortho* to the amide group. Hydrolysis of **3** with 25% aqueous hydrochloric acid under reflux for 16 h furnished the aniline hydrochloride derivative **4** in 95% yield, mp 162°C. Conversion of **4** to the chloro derivative **5** (mp 152°C) was accomplished in 90% yield by treatment with sodium nitrite (1 equiv.) in aqueous hydrochloric acid at 0°C, followed by heating the resulting solution with cuprous chloride (1.5 equiv.) at 60°C for 2 days. Consecutive treatment of compound **5** with ethyl chloroformate (1.5 equiv.) – triethylamine in acetone and sodium azide – water at 0°C gave the corresponding acyl azide. Curtius rearrangement of the crude azide in benzene (60°C, 30 min), followed by addition of methanol to the resulting

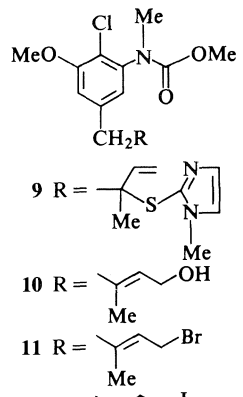
7 R = N(Me)—COOMe, R′ = Me

8 R = N(Me)—COOMe, R′ = CH_2Br



isocyanate (80°, 1 h) led to the isolation of the crystalline urethane derivative **6**, mp 79°C; ν_{max}: 3410 (NH) and 1730 (urethane) cm^{-1}. Methylation of compound **6** with sodium hydride and methyl iodide in tetrahydrofuran solution at 0°C gave the *N*-methyl derivative **7** (mp 101°C). The yield from **5** was 82%. When **7** was treated with *N*-bromosuccinimide (1.1 equiv.) in carbon tetrachloride, either with irradiation using a sunlamp or in the presence of catalytic amount of benzoyl peroxide under reflux for 4 h, the crystalline bromide **8** (mp 91°C) was obtained in 80% yield. The overall yield from starting material **2** was 49%.

The aromatic compound **8**, now readily available in good quantities, contains all substituents for further elaboration to the trisubstituted olefin **1**. Condensation of **8** with the lithium salt (1.2 equiv.), prepared from 1-methylimidazo-2-yl α-methylallyl sulfide and *n*-butyllithium (4), in tetrahydrofuran at −70°C for 1 h produced compound **9** as the α-alkylated product in 95% yield, ^{1}H nmr signals at δ 6.73 (2H, 2 overlapping s, aromatic protons), 5.98 (1H, m, vinylic proton), 4.83 (2H, m, vinylic protons), 3.03 (2H, s, benzylic protons), and 1.32 ppm (3H, s, methyl). It has been shown that [2,3]-sigmatropic rearrangement of trisubstituted allylic sulfoxides produces *trans*-trisubstituted allylic alcohols with high degree of stereoselectivity (4, 5). Oxidation of compound **9** to the corresponding sulfoxide with *m*-chloroperbenzoic acid (1 equiv.) in methylene dichloride at 0°C, followed by addition of diethylamine in methanol at room temperature overnight, afforded a mixture of the *E*- and *Z*-allylic alcohols (ratio 64:36) in 75% yield. The desired *E*-allylic alcohol **10** could be separated from its *Z*-isomer (ether, silica gel) as white crystals (mp 86°C). Treatment of **10** with *N*-bromosuccinimide – triphenyl phosphine complex (1.2 equiv.) in benzene (25°C, 2.5 h) gave the bromide **11** in 75% yield, ^{1}H nmr signals at δ 6.73 (2H, 2 overlapping s, aromatic protons), 5.70 (1H, t, vinylic proton), 4.04 (2H, d, C=C—CH_2Br), and 3.03 ppm (2H, s, benzylic protons).

The low stereoselectivity in the [2,3]-sigmatropic process was not satisfactory, so an efficient and highly stereoselective alternate synthesis of the bromide **11** was developed. When compound **9** was treated with a large excess of methyl bromide in dimethylformamide containing anhydrous lithium bromide (20°C, 10 h),[4] the material which was obtained in 60% yield was the *E*-allylbromide **11** contaminated with about 10% of its *Z*-isomer.[5] In a similar manner, reaction of compound **9** with methyl iodide in dimethylformamide in the presence of sodium iodide produced the rather unstable

A

9 R =

10 R =

11 R =

12 R =

iodide **12** in better yield (80∼85%). A possible pathway for this facile reaction was that the first stage of the reaction is quaternization of the basic nitrogen of imidazole to form the reactive intermediate **A**, which, by the attack of bromide anion on the double bond, would then proceed to yield the allylic rearrangement product **11**. The above simple procedure with high stereoselectivity may provide a useful general method for the preparation of *trans*-trisubstituted allylhalides.

Reaction of **12** with triethyl phosphite (1.2

[4]Reaction of 2-alkylthiothiazoline with methyl iodide in DMF to give alkyliodide has been reported (see ref. 6).

[5]Determined by comparison with the ^{1}H nmr of a standard solution of *E*- and *Z*-isomers.

equiv.) in toluene under reflux for 1.5 h afforded the phosphonate derivative **1** in 90% yield, ^{1}H nmr signals at δ 6.71 (2H, 2 overlapping s, aromatic protons), 5.35 (1H, t, vinylic proton), and 2.60 ppm (2H, q, C=C—CH_2—P—). With the intermediate **II** and **1** now readily available, further work directed at the construction of maytansine and its eventual total synthesis is in progress.

Bimolecular production of gas phase ionic hydrates by ion cyclotron resonance spectroscopy

R. L. Clair and T. B. McMahon

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received December 27, 1979

R. L. Clair and T. B. McMahon. Can. J. Chem. **58**, 863 (1980).

The gas phase ion–molecule reactions of α,α,α′,α′ tetrafluorodimethyl ether both alone and in mixtures with water have been examined. The dominant feature of the ion chemistry of these mixtures is the sequential bimolecular production of the hydrated hydronium ion, $H_5O_2^+$. Two independent mechanistic pathways for production of $H_5O_2^+$ are outlined arising from reaction of H_3O^+ with $(CF_2H)_2O$ and from CF_2H—O=CHF^+ with H_2O. Implications for examination of solvent switching equilibria are discussed.

R. L. Clair et T. B. McMahon. Can. J. Chem. **58**, 863 (1980).

On a examiné les réactions en phase gazeuse de l'ion moléculaire de l'éther α,α,α′,α′ tétrafluorodiméthylique pur ou mélangé à l'eau dans différentes proportions. Le fait dominant de la chimie de l'ion dans ces mélanges est la production bimoléculaire séquentielle de l'ion hydronium hydraté, $H_5O_2^+$. On propose deux mécanismes indépendants de production de $H_5O_2^+$ provenant de la réaction de H_3O^+ avec $(CF_2H)_2O$ et de la réaction de CF_2H—O=CHF^+ avec l'eau. On discute des implications de ces réactions pour l'examen du solvant dans l'établissement de l'équilibre.

[Traduit par le journal]

Examination of gas phase ion–molecule clustering equilibria, such as reaction [1], provides valuable information concerning the *absolute* energetics of solvation of ions, A^+, by solvents, S (1).

[1] $A^+ + S \overset{[M]}{\rightleftharpoons} AS^+$

The study of such equilibria is usually inaccessible to trapped-ion ion cyclotron resonance (ICR) experiments since stabilizing collisions with the excited $(AS^+)^*$ initially formed must take place within a time which is shorter than the intrinsic lifetime of $(AS^+)^*$ (2, 3). This condition usually necessitates the use of pressures which are sufficiently high to prevent efficient trapping of ions in the ICR cell (4). In the present communication we wish to report several *sequential bimolecular reactions* which lead to efficient production of cluster ions, AS^+, which can subsequently participate in solvent switching equilibria, reaction [2], to allow determination of accurate relative solvation energetics (5, 6).

[2] $AS_1^+ + S_2 \rightleftharpoons AS_2^+ + S_1$

As part of a continuing program of investigation of gas phase proton affinities of molecules less basic than water, the gas phase ion chemistry of α,α,α′,α′ tetrafluorodimethyl ether and binary mixtures of $(CH_2H)_2O$ with weak bases was recently examined. At 70 eV electron energy, the dominant ion in the mass spectrum of $(CF_2H)_2O$ is

Bimolecular production of gas phase ionic hydrates by ion cyclotron resonance spectroscopy

R. L. Clair and T. B. McMahon

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 5A3

Received December 27, 1979

R. L. Clair and T. B. McMahon. Can. J. Chem. **58**, 863 (1980).

The gas phase ion–molecule reactions of α,α,α′,α′ tetrafluorodimethyl ether both alone and in mixtures with water have been examined. The dominant feature of the ion chemistry of these mixtures is the sequential bimolecular production of the hydrated hydronium ion, $H_5O_2^+$. Two independent mechanistic pathways for production of $H_5O_2^+$ are outlined arising from reaction of H_3O^+ with $(CF_2H)_2O$ and from CF_2H—O=CHF^+ with H_2O. Implications for examination of solvent switching equilibria are discussed.

R. L. Clair et T. B. McMahon. Can. J. Chem. **58**, 863 (1980).

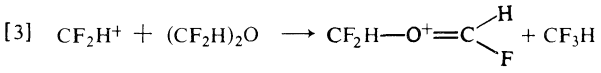
On a examiné les réactions en phase gazeuse de l'ion moléculaire de l'éther α,α,α′,α′ tétrafluorodiméthylique pur ou mélangé à l'eau dans différentes proportions. Le fait dominant de la chimie de l'ion dans ces mélanges est la production bimoléculaire séquentielle de l'ion hydronium hydraté, $H_5O_2^+$. On propose deux mécanismes indépendants de production de $H_5O_2^+$ provenant de la réaction de H_3O^+ avec $(CF_2H)_2O$ et de la réaction de CF_2H—O=CHF^+ avec l'eau. On discute des implications de ces réactions pour l'examen du solvant dans l'établissement de l'équilibre.

[Traduit par le journal]

Examination of gas phase ion–molecule clustering equilibria, such as reaction [1], provides valuable information concerning the *absolute* energetics of solvation of ions, A^+, by solvents, S (1).

[1] $A^+ + S \overset{[M]}{\rightleftharpoons} AS^+$

The study of such equilibria is usually inaccessible to trapped-ion ion cyclotron resonance (ICR) experiments since stabilizing collisions with the excited $(AS^+)^*$ initially formed must take place within a time which is shorter than the intrinsic lifetime of $(AS^+)^*$ (2, 3). This condition usually necessitates the use of pressures which are sufficiently high to prevent efficient trapping of ions in the ICR cell (4). In the present communication we wish to report several *sequential bimolecular reactions* which lead to efficient production of cluster ions, AS^+, which can subsequently participate in solvent switching equilibria, reaction [2], to allow determination of accurate relative solvation energetics (5, 6).



[2] $AS_1^+ + S_2 \rightleftharpoons AS_2^+ + S_1$

As part of a continuing program of investigation of gas phase proton affinities of molecules less basic than water, the gas phase ion chemistry of α,α,α′,α′ tetrafluorodimethyl ether and binary mixtures of $(CH_2H)_2O$ with weak bases was recently examined. At 70 eV electron energy, the dominant ion in the mass spectrum of $(CF_2H)_2O$ is

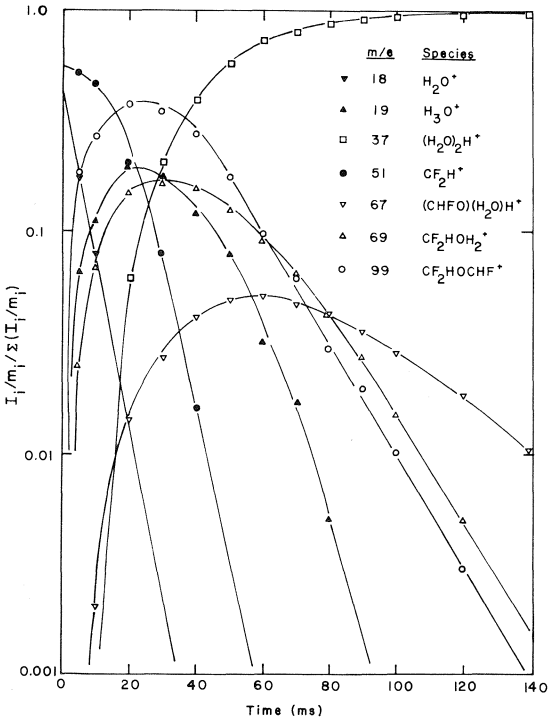
the difluoromethyl cation, CF_2H^+, which is found to react rapidly with the parent ether to produce an ion at *m/e* 99, reaction [3].

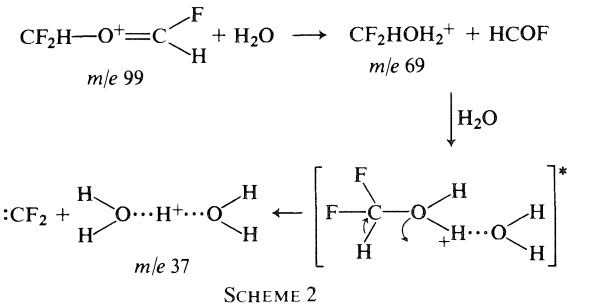
[3] $CF_2H^+ + (CF_2H)_2O \longrightarrow CF_2H{-}O^+{=}C(H)(F) + CF_3H$

This ion is found to be unreactive toward the ether. If, however, H_2O is added to the system, a rich and varied ion chemistry results as demonstrated by the variation of relative ionic abundances with time shown in Fig. 1 for a 2:1 mixture of $(CF_2H)_2O$ and H_2O at 70 eV and 3×10^{-6} Torr total pressure. The ultimate ionic product in this mixture is a species at *m/e* 37 which is revealed by a combination of ICR double resonance and deuterium labelling (D_2O) experiments to be the hydrated hydronium ion, $H_5O_2^+$. These experiments revealed that two independent pathways exist for sequential bimolecular production of $H_5O_2^+$ (for other examples of bimolecular production of gas phase cluster ions, see ref. 7).

The first of these pathways, outlined in Scheme 1, is initiated by reaction of the hydronium ion, H_3O^+, which reacts with $(CF_2H)_2O$ to form an intermediate proton bound dimer of water and tetrafluorodimethyl ether followed by elimination of CF_3H to yield a proton bound dimer of water and formylfluoride, HCOF. This species subsequently undergoes a nucleophilic displacement reaction in which the weak base, formylfluoride, is displaced from H_3O^+ by the stronger base, H_2O.

SCHEME 1





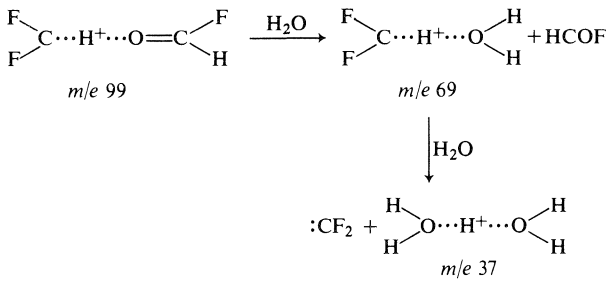


FIG. 1. Variation of relative ionic abundances with reaction time for a 2:1 mixture of $(CF_2H_2)_2O$ and H_2O at a total pressure of 3×10^{-6} Torr following a 6 ms 70 eV ionizing electron beam pulse.

The second sequence of reactions leading to production of $H_5O_2^+$ is initiated by *m/e* 99 produced in reaction of CF_2H^+ with $(CF_2H)_2O$, reaction [3]. The mechanistic details of this sequence are dependent on the assumed structure of *m/e* 99 which in turn depends on the nature of the reactivity of CF_2H^+. The difluoromethyl cation may be regarded either as an electrophilic carbonium ion, or, as has been recently suggested, as protonated difluorocarbene (8). As an electrophile, CH_2H^+ may react with the ether either via fluoride abstraction (9) or by addition to the basic oxygen (10) followed by elimination of CF_3H. In either case, the ion at *m/e* 99 will have the structure of a difluoromethyl cation co-ordinated with formyl fluoride and will undergo the series of reactions with H_2O outlined in Scheme 2. The first step of this mechanism involves nucleophilic displacement of HCOF by H_2O from CF_2H^+ to produce an ion at *m/e* 69 which may be regarded as protonated difluoromethanol. This

SCHEME 2

SCHEME 3

species then undergoes addition of H_2O followed by elimination of difluorocarbene to yield $H_5O_2^+$.

Alternatively, if CF_2H^+ reacts as protonated difluorocarbene, *m/e* 99 may be regarded as a proton bound dimer of difluorocarbene and formylfluoride giving rise to the sequence of reactions outlined in Scheme 3. In this case, both steps involve displacement of a base (either HCOF or $:CF_2$) by H_2O. The latter reaction is exothermic even though $:CF_2$ is known to be a stronger proton base than water (8), because of the exceptionally strong linkage involved in [—O···H···O—] proton bonds (1). Further investigations involving $^{13}CF_2H^+$ and CF_2D^+ are planned to deduce which of these schemes is operative in this system.

We are currently extending our studies of bimolecular production of cluster ions to the gas phase ion chemistry of other weak bases with tetrafluorodimethyl ether and other polyfluorinated ethers, with the ultimate aim of developing a scale of relative solvation energetics based on examination of equilibria such as reaction [2].

Received November 9, 1979

OSVALD KNOP, WOLFGANG J. WESTERHAUS, and MICHAEL FALK. Can. J. Chem. **58**, 867 (1980).

Available evidence suggests that (*1*) the stretching frequencies of highly-bent hydrogen bonds decrease with increasing temperature, regardless of whether the bonds are static or dynamic in character, to a single acceptor or to several competing acceptors; and (*2*) departures from symmetric trifurcation (or bifurcation) toward asymmetric situations lower the stretching frequency. In further support of these criteria isotopic probe ion spectra between 10 K and room temperature have been obtained for taurine and for trigonal $(NH_4)_2MF_6$ (M = Si, Ge, Sn, Ti). Evidence of a low-temperature transition at 100(10) K in trigonal $(NH_4)_2SnF_6$ is presented, and existence of the previously reported transition at 38.6 K in trigonal $(NH_4)_2SiF_6$ is confirmed. Symmetry changes associated with these transitions are discussed.

OSVALD KNOP, WOLFGANG J. WESTERHAUS et MICHAEL FALK. Can. J. Chem. **58**, 867 (1980).

Les preuves disponibles suggèrent (*1*) que les fréquences de vibration des liaisons hydrogène fortement coudées décroissent avec une augmentation de la température que les liaisons aient un caractère statique ou dynamique, que l'on ait un accepteur unique ou plusieurs accepteurs en concurrence, et (*2*) que les écarts par rapport à une trifurcation (ou bifurcation) symétrique vers des situations asymétriques diminuent la fréquence de vibration. Comme preuves supplémentaires à l'appui de ces critères, nous avons déterminé les spectres, entre 10 K et la température de la pièce, de la sonde isotopique NH_3D^+ dans la taurine et dans les composés $(NH_4)_2MF_6$ trigonaux (M = Si, Ge, Sn, Ti). On met en évidence l'existence d'une transition à 100(10) K du $(NH_4)_2SnF_6$ trigonal et on confirme l'existence de la transition à 38.6 K du $(NH_4)_2SiF_6$ antérieurement signalée. On discute des changements de symétrie associés à ces transitions.

In Part VII (1) we investigated the ir spectra of the NH_3D^+ probe ion in NH_4SnF_3, NH_4CuSO_3, cubic $(NH_4)_2SiF_6$, and $(NH_4)_2SnCl_6$ between 10 K and room temperature. The ammonium ion in the first two crystals is situated on a threefold axis in such a way that one of the N—H bonds, N—H_a, is required to be on this axis; this follows from the site symmetry of the ion as determined by the non-hydrogenic portion of the crystal structure. The axial hydrogen H_a will then be equidistant from three equivalent acceptor atoms X related by the threefold axis. In cubic $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$ the site symmetry T_d requires all four N—H bonds to be on threefold axes and each H atom to have three equivalent acceptors X related by the respective threefold axis. In all four compounds the $\nu_1(NH_3D^+)$ frequency[3] decreases with increasing temperature. From this observation we concluded the following. At $T \rightarrow 0$ K the axial hydrogens are indeed confined to the threefold axes, i.e. the N—H···3X hydrogen bonds are symmetrically trifurcated. With increasing temperature the hydrogen-bond strength increases, the H atom becomes progressively more associated with *one* acceptor atom at a time, and the hydrogen bond acquires a pronouncedly dynamic character. The decrease of the ND stretching frequency $\nu_1(NH_3D^+)$ with increasing temperature is the opposite of the temperature behaviour of normal N—H···X bonds, for which $d\nu_1/dT \geq 0$.

However, the existence of a negative temperature coefficient of the hydrogen stretching frequency is not restricted to the specific situations in the four ammonium compounds. There are indications that the sign of dv/dT in fact provides a diagnostic criterion for distinguishing, not only between normal and symmetrically trifurcated hydrogen bonds, but between normal and *all highly bent* (and thus weak, cf. ref. 2) hydrogen bonds, regardless of whether the bonds are static or dynamic in character, to a single acceptor or to several competing acceptors. Furthermore, we suggest that departures from symmetric trifurcation (or bifurcation) toward asymmetric situations will lower the stretching frequency. Thus when a crystal contains hydrogen bonds of several types but chemically similar, the $\nu_T \rightarrow 0$ K stretching frequency[4] that corresponds to a symmetrically trifurcated (or bifurcated) bond will be the highest. The following observations may be cited in support; some of them have been discussed in these terms previously (3), whilst those under *3* and *6* are new.

(*1*) The axial component $\nu_1(a)$ of the $\nu_1(NH_3D^+)$ absorption in NH_4SnF_3 and NH_4CuSO_3 has a much higher frequency than the nonaxial component $\nu_1(n)$ (1). The former corresponds to a symmetrically trifurcated N—H···3X bond, the latter to strong normal N—H···X bonds.

(*2*) The $\nu_1(NH_3D^+)$ frequencies in cubic $(NH_4)_2SiF_6$ and $(NH_4)_2SnCl_6$ are among the highest observed in ammonium fluorides and chlorides respectively (4).

(*3*) *Taurine*, $^+H_3N{\cdot}CH_2CH_2SO_3^-$, is known to contain two normal N—H···O and one asymmetrically bifurcated N—H···2O bonds (5). The highest-frequency ND stretching component of the $^-O_3S{\cdot}CH_2CH_2NH_2D^+$ probe ion in the ir spectrum of this crystal decreases significantly with increasing temperature (Fig. 1), whilst the peak frequencies of all the other bands in the ND stretching region remain stationary or increase slightly.

(*4*) $K_2SnCl_4{\cdot}H_2O$ contains a single type of water molecule. Its hydrogen-bonding engagement can be represented as Cl···H—O—H···2Cl. The bifurcated bond is symmetric. Those isotopically isolated OH and OD stretching frequencies that decrease with increasing temperature are higher than the OH and OD stretching frequencies that increase with temperature (3).

(*5*) $BaCl_2{\cdot}2H_2O$ contains water molecules of two types, one engaged in two normal O—H···Cl bonds and the other, in one normal O—H···Cl and one asymmetrically bifurcated O—H···2Cl bond. The highest of the four ν_{OH} (HDO) frequencies, and the highest of the four ν_{OD} (HDO) frequencies, in the ir spectrum of the isotopically isolated HDO molecule decreases on warming the crystal from 95 K to room temperature, whereas the other ν_{OH} (HDO) and ν_{OD} (HDO) frequencies increase (6, 7); these changes are parallelled in the Raman spectrum (7). Thus there can be no doubt that the frequencies with a negative dv/dT correspond to the bifurcated bond.

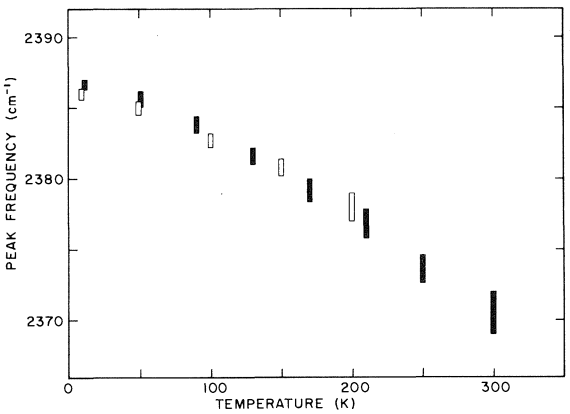

FIG. 1. Temperature variation of the frequency of the ND stretching absorption of the $^-O_3S{\cdot}CH_2CH_2NH_2D^+$ probe ion corresponding to the bifurcated N—H···2O hydrogen bond in taurine. Open rectangles, 1% D; full rectangles, 5% D.

(*6*) *Trigonal* $(NH_4)_2MF_6$ fluorides afford a further example of ammonium ions exhibiting anomalous behaviour. We have investigated the temperature dependence of the NH_3D^+ probe spectrum in several of these compounds. Because of their fairly detailed nature the results are described separately in the next section. They support the above generalization and are consistent with the conclusions drawn by Sergienko *et al.* (8–10) for trigonal $(NH_4)_2SiF_6$ and $(NH_4)_2GeF_6$ from the temperature variation of the integrated ir intensities of $\nu_3(NH_4^+)$ and $\nu_4(NH_4^+)$ bands.

Trigonal $(NH_4)_2MF_6$ *(M = Si, Ge, Sn, Ti)*

The coordination geometry of the ammonium ion in the trigonal $(NH_4)_2MF_6$ fluorides is favourable to the formation of a symmetrically trifurcated N—H···3F bond. The site symmetry of the ion is C_{3v}, hence a $\nu_1(NH_3D^+)$ doublet with an idealized 1:3 intensity ratio is expected and observed.[5] The

[4]In the absence of low-temperature transitions. If a transition occurs, the frequency values to be compared are those just above T_{tr}.

[5]At 10 K the intensity ratio for the Ti and Ge compounds is much smaller than the ideal value, but it increases rapidly to about $\frac{1}{4}$ for the titanate at 100 K and about $\frac{1}{3}$ for the germanate (Fig. 2). This behaviour is consistent with the expected dependence of the ND oscillators on the hydrogen-bond strength and on its temperature variation.

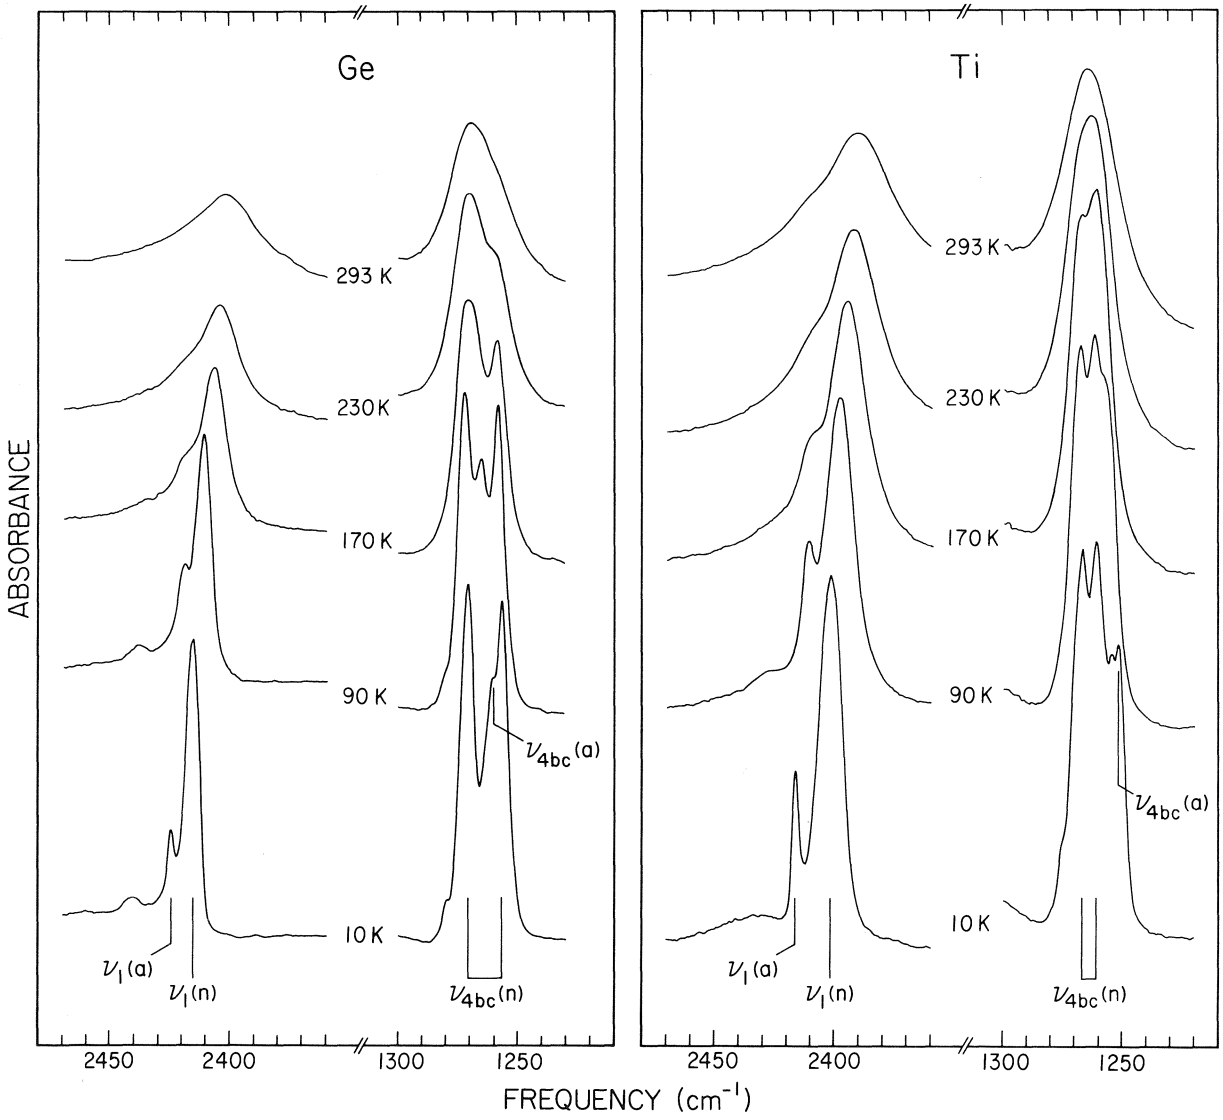

FIG. 2. The ND stretching and bending regions of the spectrum of $(NH_4)_2GeF_6$ and $(NH_4)_2TiF_6$ (2% D) at different temperatures. Features other than those identified as components of the ν_1 and ν_{4bc} fundamentals of NH_3D^+ originate in the secondary isotopic species $NH_2D_2^+$ or in the coupling of vibrations of neighbouring NH_3D^+ ions in the crystal.

weaker component thus unambiguously corresponds to $\nu_1(a)$, i.e. to the symmetrically trifurcated bond. In the four compounds investigated to date (M = Si, Ge, Sn, Ti) (4, 11, 12) the frequency of $\nu_1(a)$ is always higher than that of $\nu_1(n)$, the $\nu_1(a) - \nu_1(n)$ difference at 100 K ranging from 8.5 to 12.5 cm^{-1} (Table 1). The frequencies of both components decrease in the order Si > Ge > Ti > Sn. The 100 K values of $\nu_1(a)$ correlate linearly with the effective ionic radii r^{vi} (M^{4+}) (13): $\nu_1(a) = 2458.8 - 76.0r^{vi}$, $r^2 = 0.96$, $\sigma = 2.0$ cm^{-1}; for $\nu_1(n)$ the trend is evident but the correlation is not as high. The frequency decrease attendant on varying M is thus attributable to a volume effect.

The ν_1 and ν_{4bc} absorptions in the four compounds at different temperatures are shown in Figs. 2–4, and the temperature dependence of the frequencies and halfwidths (= full width at half height) is represented in Figs. 5–7. As would be expected for a symmetrically trifurcated bond, the $\nu_1(a)$ frequency falls off with increasing temperature,[6] by an amount comparable to the decrease in cubic $(NH_4)_2SiF_6$ (1). However, the $\nu_1(n)$ frequency *also* decreases with increasing temperature, which indi-

[6]A corresponding decrease in the frequencies of the $\nu_3(NH_4^+)$ ir absorption in trigonal $(NH_4)_2SiF_6$ and $(NH_4)_2GeF_6$ is reported in ref. 8, the band maxima shifting, between 150 and 300 K, by −14 and −12 cm^{-1} respectively.

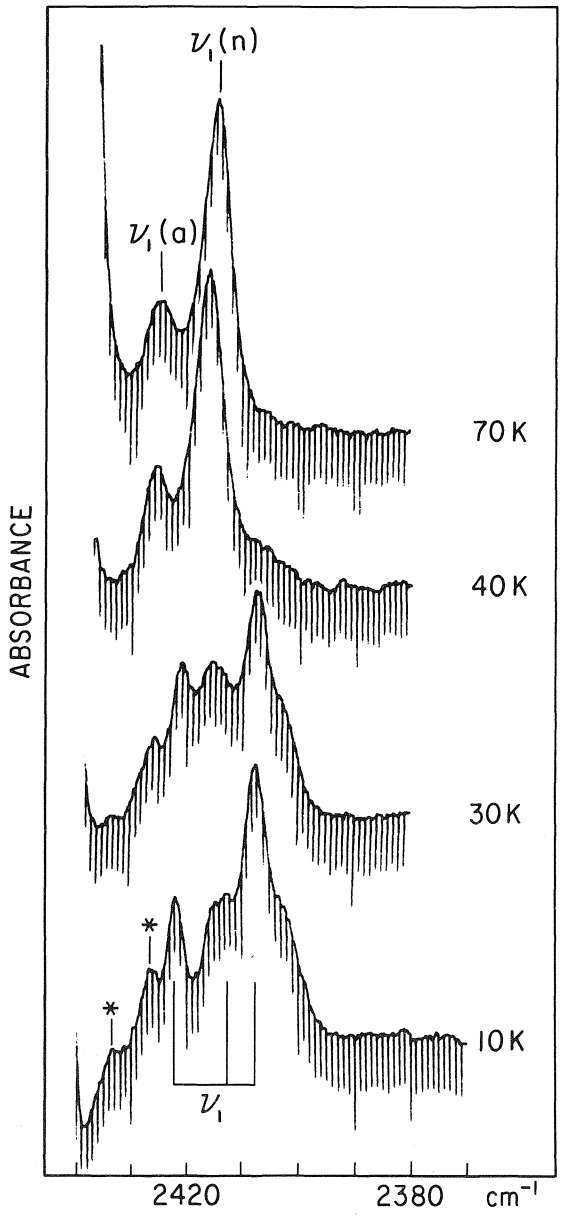

FIG. 3. The ND stretching region of the spectrum of trigonal $(NH_4)_2SiF_6$ (2% D) above and below the phase transition at 38.6 K (cf. caption of Fig. 2). Features marked with an asterisk are due to satellites of the ND stretching of cubic $(NH_4)_2SiF_6$ near 2442 cm^{-1} (not shown).

cates that the three equivalent nonaxial N—H_n···F bonds are highly bent. Examination of Fig. 1 of ref. 12 shows that in the most symmetric possible orientation the N—H_n bond would be in asymmetrically trifurcated situations N—H_n···(2F + F′)[7] but effectively closer to symmetric bifurcation,

[7]In the hexafluorosilicate, H_n···F ~ 2.08 Å, NH_nF ~ 144°; H_n···F′ ~ 2.42 Å, NH_nF' ~ 133°. For the symmetrically trifurcated bond, H_a···F″ ~ 2.31 Å, NH_aF'' ~ 123°.

TABLE 1. Frequencies (cm^{-1}) of the NH_3D^+ probe ion in trigonal $(NH_4)_2MF_6$ (M = Si, Ge, Ti, Sn) at 100 K

Vibration	Frequency			
	Si	Ge	Ti	Sn
$\nu_1(a)$	2424.5(5)	2419.3(5)	2410.7(5)	2407.2(8)
$\nu_1(n)$	2412.7(5)	2410.8(8)	2398.2(5)	2396.5(8)
$\nu_{4bc}(a)$	1275.3*	1266.0(5)	1259.7(8)	1256.0(5)
$\nu_{4b}(n)$, $\nu_{4c}(n)$	1278.2* 1256.8*	1272.3(5) 1258.5(5)	1268.3(5) 1262.2(5)	1267.7(8)

*From ref. 4. Estimated uncertainty, ±1 cm^{-1}.

analogous to orientation C in NH_4CuSO_3 (Fig. 2 of ref. 1). This orientation would be compatible with the observation that $\nu_1(a) > \nu_1(n)$ and $d\nu_1(n)/dT < 0$; it also receives support from a recent ^1H and ^{19}F nmr study of the hexafluorotitanate (14). Orientations analogous to A and A′ in NH_4CuSO_3, corresponding to a N—H_n···F bond in a plane passing through the threefold axis and thus to a normal N—H···F bond (H_n···F ~ 1.95 Å, NH_nF ~ 171°), on the other hand, would be expected to have a positive $d\nu_1(n)/dT$ and a considerably lower $\nu_1(n)$ frequency.

Schlemper and Hamilton (15), in their account of a crystal-structure determination of trigonal $(NH_4)_2SiF_6$ at room temperature by neutron diffraction, suggest that the ammonium ion occurs in two orientations (related by reflection in a plane perpendicular to the threefold axis through the N atom) disordered at room temperature and not necessarily in a 1:1 abundance ratio because of the polarity of the threefold axis; the transition observed at 38.6 K (16) may then correspond to an ordering of the two orientations. If this were the case, one would expect the $\nu_1(a)$ and $\nu_1(n)$ components of $\nu_1(NH_3D^+)$ to be split, or at least the absorption to be broadened, at temperatures above T_{tr}.

Only single, sharp ($\Delta\nu_{1/2}$ = 6–7 cm^{-1} at 40 K) $\nu_1(a)$ and $\nu_1(n)$ bands were observed in the probe spectra of trigonal $(NH_4)_2SiF_6$ between 40 and 150 K (Figs. 3 and 5),[8] confirming the previously reported result for 80 K (12). If orientational disorder of the ammonium ion occurs above T_{tr}, the $\nu_1(a)$ and $\nu_1(n)$ frequency differences corresponding to the two orientations at 40 K must each be less than about 4 cm^{-1}, the limit of visual recognition of an unresolved 1:1 Gaussian doublet of the observed total halfwidth. This limit would be larger if the intensity ratio differed from 1:1 as a consequence of unequal abundance of the two orientations. However, the appreciable dissimilarity of the fluorine

[8]See Experimental for the reason why the temperature range was not extended beyond 150 K.

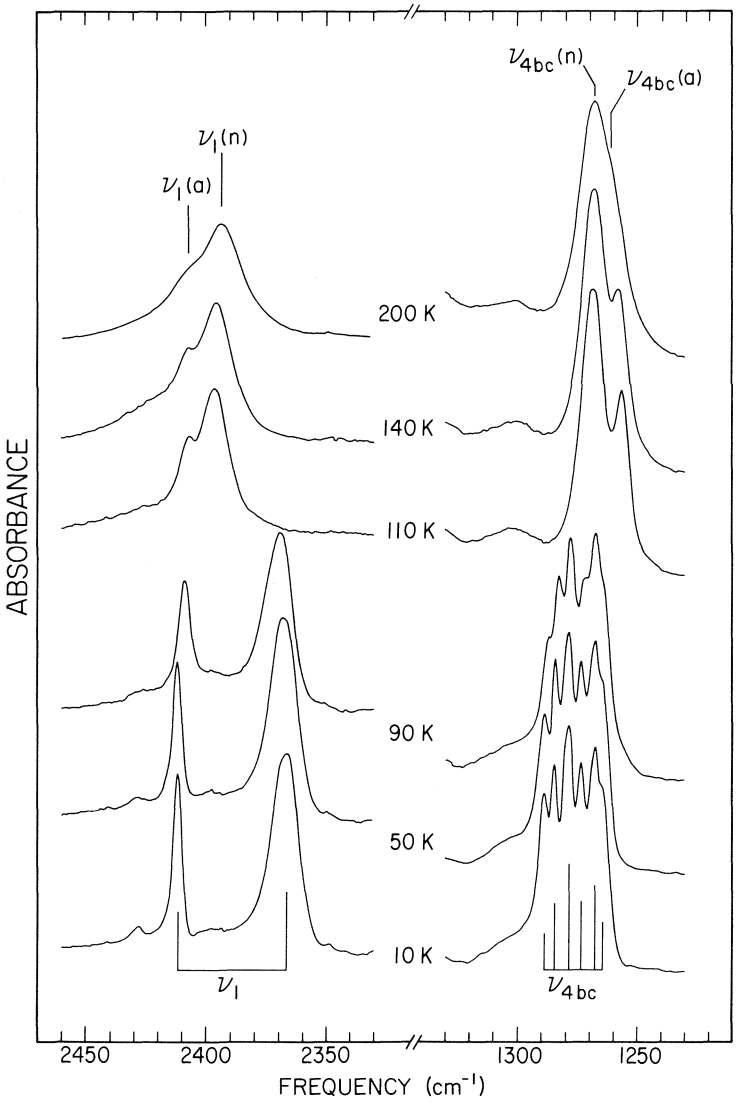

FIG. 4. The ND stretching and bending regions of the spectrum of trigonal $(NH_4)_2SnF_6$ (1% D) above and below the phase transition at ca. 100 K (cf. caption of Fig. 2).

environments of the NH_4^+ ion above and below the plane through N and perpendicular to C_3 would make us expect a splitting that is readily recognizable.

Below 40 K the 1:3 ν_1 doublet is transformed into a composite absorption (Fig. 4 and Table 2) which we interpret as a 1:1:2 triplet corresponding to site symmetry C_{2h} or C_s of the ammonium ion. Reduction of the site symmetry of the ion from T_d associated with low-temperature transitions of cubic $(NH_4)_2MX_6$ to lower-symmetry polymorphs has been detected by the NH_3D^+ probe spectra in several compounds (ref. 4 and results to be published), but the transition in trigonal $(NH_4)_2SiF_6$ appears to be the first such transition to be observed on cooling an $(NH_4)_2MX_6$ crystal that is trigonal at room temperature. Inasmuch as analogous transitions occur in cubic A_2MX_6 in which $A \neq NH_4$, it is almost certain that in the trigonal hexafluorosilicate the ammonium ion at $T \leq T_{tr}$ merely responds to a distortion (and possibly a rotational displacement) of the SiF_6 octahedra; its presence in the crystal cannot be regarded, by itself, as the cause of the transition. This agrees with the view of Stephenson *et al.* (16) but is contrary to the explanation proffered by Schlemper and Hamilton.

A hitherto unreported transition was detected in trigonal $(NH_4)_2SnF_6$ (Figs. 4 and 7). The ν_1 absorption below T_{tr} was a 1:3 doublet, with a splitting of 45 cm^{-1} at 10 K (Table 2). The ν_{4bc} absorption con-

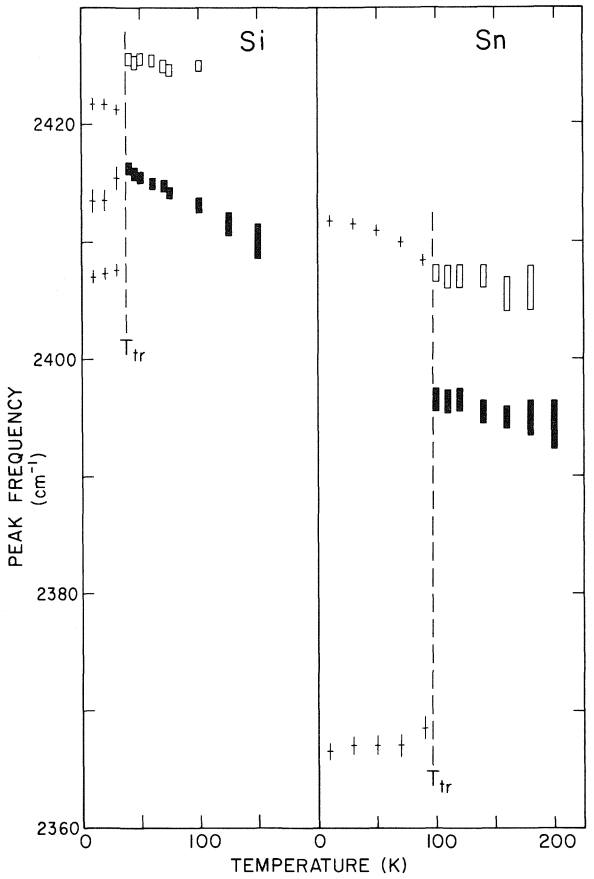

FIG. 7. Temperature variation of the component ND stretching frequencies of trigonal $(NH_4)_2SiF_6$ and $(NH_4)_2SnF_6$ above and below the respective transition temperatures. Open rectangles, $\nu_1(a)$; full rectangles, $\nu_1(n)$.

sisted of six components, two of which had approximately twice the unit intensity. It was interpreted as an octet corresponding to an ammonium ion at a site of symmetry C_1, which makes the apparent 1:3 ν_1 doublet an unresolved quartet. The symmetry of the low-temperature phase is thus not the same as in the low-temperature phase of the hexafluorosilicate. The large splitting of the ν_1 absorption and the temperature variation of the two component frequencies are noteworthy (Fig. 7). The narrow minor band has a high frequency which decreases with increasing temperature and at T_{tr} merges with the $\nu_1(a)$ frequency of the trigonal phase. The peak frequency of the more intense, composite band, on the other hand, is substantially lower and increases with temperature. The weighted mean frequency below T_{tr} is nearly stationary and appreciably lower than the weighted mean frequency above T_{tr}, which indicates an overall strengthening of the hydrogen-bond interaction in the low-temperature phase. The strengthening is

TABLE 2. Frequencies (cm^{-1}) of the NH_3D^+ probe ion at 10 K in the low-temperature phases of $(NH_4)_2SiF_6$ and $(NH_4)_2SnF_6$

Vibration	Frequency

ν_{4bc}	‡	1288.8 1284.7 1278.6† 1273.6 1267.6† 1264.6

*Band of approximately three times the unit intensity (composite band).
†Band of approximately twice the unit intensity.
‡Interference with the ν_{4bc} band of the cubic phase.

also observed in the silicate, but the frequency difference in that case amounts to only about one sixth of that in the stannate. Furthermore, on the assumption that to a high ν_1 frequency there corresponds a low ν_{4bc} frequency and vice versa, the point obtained by plotting the average of the two highest ν_{4bc} component frequencies of the stannate against the lower ν_1 component frequency in the ν_{4bc} vs. ν_1 plot for ammonium halides (Fig. 3 of ref. 4) falls close to the point for NH_4AlF_4 (C.N. 8, normal hydrogen bonds), whilst the point corresponding to the average of the four lowest ν_{4bc} component frequencies and to the higher ν_1 frequency remains in the region characteristic of trigonal $(NH_4)_2MF_6$ above T_{tr}.[9] One thus concludes that on passage through T_{tr} the character of the axial N—H_a bond in the trigonal phase remains preserved, but the three N—H_n bonds change from asymmetric trifurcation (quasi-bifurcation) to normal N—H_n···F bonds of a strength appropriate to the acceptor strength of F in a composite MF_6 anion. In this respect the low-temperature phase of trigonal $(NH_4)_2SnF_6$ resembles more closely NH_4SnF_3 and NH_4CuSO_3 than the low-temperature phase of trigonal $(NH_4)_2SiF_6$, quite apart from the difference in the site symmetries of the ammonium ion and thus in the crystallographic symmetry of the two phases.

The NH_3D^+ probe spectrum of $(NH_4)_2GeF_6$ leaves no doubt of the absence of an NH_4^+ disorder analogous to that proposed for trigonal $(NH_4)_2SiF_6$ in ref. 15. The 80 K spectrum reported previously (12) and, more fully, the 10–293 K spectra presented in Fig. 2 and the frequencies and bandwidths

[9]Averaging the three highest ν_{4bc} frequencies and the three lowest ν_{4bc} frequencies respectively changes the positions of the points only slightly.

plotted in Fig. 5 show no indication of a transition in this temperature range and no evidence of $\nu_1(a)$ or $\nu_1(n)$ splitting. A similar observation is made for $(NH_4)_2TiF_6$ (refs. 4 and 11; Figs. 2 and 5), except that the $\nu_1(n)$ band is significantly broadened. However, no evidence of a transition between 4.2 and 400 K was observed in a recent ^1H and ^{19}F nmr study of this compound (14). Furthermore, it was concluded that reorientation of TiF_6 octahedra is unimportant below 250 K, so that the observed broadening of $\nu_1(n)$ could not be attributed to this source. We do not have an explanation of the broadening at present.

Although no use is made of the ν_{4bc} absorption in the above arguments, the frequency of the $\nu_{4bc}(a)$ component in the germanate and titanate increases with temperature (Fig. 6) and thus reflects the anomalous behaviour of the ammonium ion. The increase is consistent with the observed negative $d\nu_1/dT$ in these crystals and further strengthens the views presented in the preceding section. The temperature variation of the $\nu_{4b}(n)$ and $\nu_{4c}(n)$ frequencies is much smaller. The order of the components in the (ideally) 2:3:3 triplet is not the same in the four trigonal $(NH_4)_2MF_6$: it is 3:2:3 for Si and Ge but 2:(3 + 3) for Sn and 2:3:3 for Ti. This and the broadening of the $\nu_1(n)$ absorption seem to suggest that the ammonium ion in the hexafluorotitanate may differ somewhat in its behaviour from the ammonium ion in the Group IVA compounds.

Finally, we wish to correct the account of our earlier results on trigonal $(NH_4)_2MF_6$ (4) on two points. The systematic examination of the probe-ion spectra from 10 K up, in conjunction with the improved control of sample temperature obtainable with our current cryogenic system, reveals that the frequencies reported earlier refer in fact to a temperature closer to 100 K than to 77 K (cf. Table 1 for the new 100 K values). Because of the proximity of the actual sample temperature in the earlier runs to T_{tr} the ν_{4bc} absorption in the spectra of the hexafluorostannate contained the component bands of both phases. This admixture, however, was not recognized, as we were not aware of the existence of the transition at the time. As a result the $\nu_{4bc}(a)$ band of the trigonal (high-temperature) phase was assigned wrongly. The $\nu_{4bc}(a)$ frequency as assigned in Table 1 has a temperature behaviour appropriate to a symmetrically trifurcated N—H···3F bond (Fig. 6).

Experimental

Trigonal $(NH_4)_2SnF_6$ was prepared by dissolving freshly precipitated stannic acid in 48% HF and adding the requisite amount of NH_4F dissolved in a minimum volume of water. The first crystals formed by slow evaporation on a steam bath were collected and carefully handpicked. The other compounds used in this investigation were from commercial sources. They were purified by recrystallization and authenticated by comparison with previously reported ir spectra. Details of deuteration and ir apparatus and technique (hydrocarbon mulls) will be found in refs. 1 and 4.

It was difficult to avoid contamination of sample of trigonal $(NH_4)_2SiF_6$ with the cubic polymorph attendant on even the gentlest grinding of handpicked crystals of the pure trigonal form (cf. ref. 12). Crushing at liquid-nitrogen temperature reduced the problem but did not eliminate it completely.

As seen in Fig. 2, the three components of ν_{4bc} and the two components of ν_1 in the spectra of the trigonal $(NH_4)_2MF_6$ are well resolved at low temperatures but overlap at higher temperatures. The frequency and halfwidth of each component were estimated by allowing roughly for the effect of the overlap; they become increasingly uncertain at higher temperatures. This is reflected in the increasing size of the error bars which represent twice the estimated standard error, and in the discontinuation of the plots in Figs. 5 and 6 above certain temperatures. The ν_1 doublet of trigonal $(NH_4)_2SiF_6$ was in addition increasingly overlapped at higher temperatures by the ν_1 singlet of the cubic form, so that the region of reasonably accurate frequency values was greatly diminished and the halfwidth of the axial component could not be accurately determined. Similarly, the ν_{4bc} bands of the trigonal form were so much overlapped by the corresponding band of the cubic form that no analysis was attempted.

The assignments of the two nonaxial and one axial components of ν_{4bc} were aided by the large shift of the latter toward higher frequencies with increasing temperature (Fig. 6).

The transition temperature in the hexafluorosilicate could be bracketted, from the ir spectra, between 35 and 40 K, in good agreement with the calorimetric value, 38.6 K (16). In the hexafluorostannate T_{tr} was estimated to be 100 K with an uncertainty of ±10 K.

A new synthesis of 2,10,11-trioxatricyclo[4.4.4.0^{1,6}]tetradecane

NORMAND BEAULIEU[1] AND PIERRE DESLONGCHAMPS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke, (Qué.), Canada J1K 2R1

Received December 3, 1979

NORMAND BEAULIEU and PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 875 (1980).

A simple and convenient synthesis of tricyclic orthoester **1** (2,10,11-trioxatricyclo[4.4.4.0^{1,6}]tetradecane) is described.

NORMAND BEAULIEU et PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 875 (1980).

Une synthèse simple de l'orthoester tricyclique **1** (trioxa-2,10,11 tricyclo[4.4.4.0^{1,6}]tétradécane) est rapportée.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

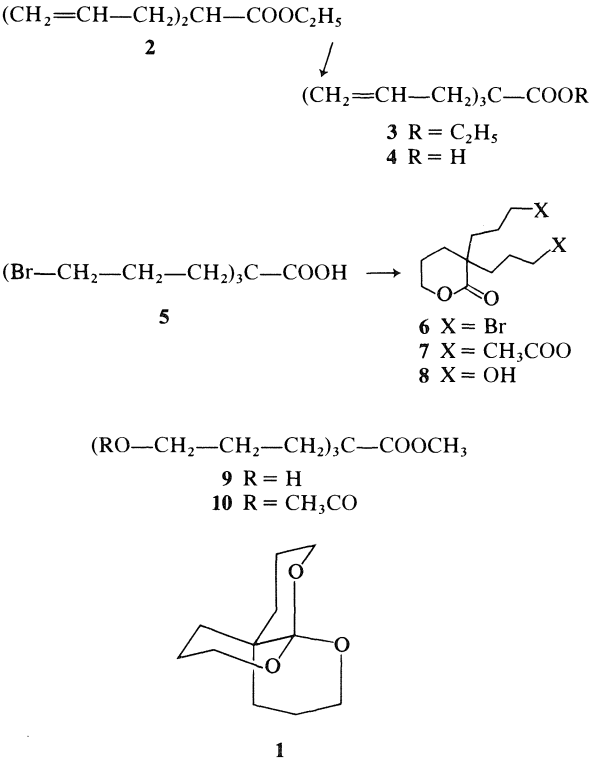
2,10,11-Trioxatricyclo[4.4.4.0^{1,6}]tetradecane (**1**) is an interesting tricyclic orthoester which was found to be unusually resistant toward acid hydrolysis (1). This low reactivity was predicted on the basis of the stereoelectronic rules which we have proposed for hydrolytic reactions (1, 2).



This compound, whose structure has recently been confirmed by X-ray analysis (3), was synthesized in 1955 by McElvain and McKay (4) using a very ingenious route. Their strategy includes "entre autres", three Diels–Alder condensations between the highly reactive, but rather sensitive, ketene acetal functionality and acrolein. We wish to report a new synthesis of tricyclic orthoester **1** in which there is improvement on the number of steps, reaction conditions, ease of product isolation, and overall yield.

Ethyl bis-allyl acetate **2**, which can be conveniently prepared by alkylation of diethyl malonate (5) with allyl bromide followed by decarboxylation (NaCl in DMSO–H_2O, (6)), was used as starting material.

Ethyl bis-allyl acetate **2** was alkylated (LDA, CH_2=CH—CH_2—Br, HMPT, −78°C, (7)) to give ethyl tri-allyl acetate **3** (≥90% yield). Basic hydrolysis of **3** (KOH, C_2H_5OH, reflux, 15 days) gave the corresponding carboxylic acid **4** (95% yield) which was converted into the known (4) tribromocarboxylic acid **5** (≥90% yield) by the photochemically induced addition of hydrogen bromide (*hν*, pentane, (8)). Treatment of tribromocarboxylic acid **5** with triethylamine in dichloromethane furnished the expected dibromolactone **6** (≥90% yield) which was further transformed (CH_3COONa, HMPT, room temperature, 2 h, (9)) into the diacetate lactone **7** (50% yield).

Basic hydrolysis of diacetate lactone **7** (K_2CO_3, CH_3OH, room temperature, 30 min) followed by the addition of excess acid (HCl, 2 *N*) gave crude diol lactone **8** which yielded tricyclic orthoester **1** (88%) upon reflux in benzene. The tricyclic orthoester **1** was also obtained (66%) by treatment of diacetate lactone **7** under acidic conditions 2.4 *N* HCl – DME (1:1), room temperature, 2 h) followed by the addition of benzene and distillation.

Diacetate lactone **7** was also hydrolysed with triethylamine in methanol (4 days, room temperature, (10)) to yield crude triol methyl ester **9** which was characterized spectroscopically and by its conversion into triacetate methyl ester **10**. Treatment of triol methyl ester **9** with *p*-toluenesulfonic

acid in benzene at room temperature gave also tricyclic orthoester **1** (95%).

Tricyclic orthoester **1** was unchanged after treatment with a mixture of hydrochloric acid (0.1 *N*) and dimethoxyethane at room temperature. However, after 3 h at reflux under these conditions, orthoester **1** was converted into diol lactone **8**.

The above results, which are in accord with the report of McElvain and McKay (4), confirm our previous observation that compound **1** is a remarkably stable orthoester towards acid hydrolysis.

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. Vapor phase chromatographic (vpc) analyses were carried out on a Varian Aerograph instrument, model 920 (column: SE-30%, Chromosorb W, 60–80, 5 ft × $\frac{1}{4}$ in.). Proton nuclear magnetic resonance (nmr) spectra were recorded on a Varian A-60 or a Bruker WP-60 spectrometer. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The mass spectra (ms) were taken on a Hitachi-Perkin-Elmer RMU-6 and a Vg Micromass ZAB-2F mass spectrometer.

Ethyl Bis-allyl Acetate 2

Sodium metal (5.75 g) was added to absolute ethanol (250 mL). When the sodium had completely reacted, diethyl malonate (40 g, 0.25 mol) was slowly added. Allyl bromide (32 g, 0.27 mol) was then added dropwise during 90 min and the mixture was refluxed for 30 min. The mixture was then acidified with glacial acetic acid, filtered, and evaporated. The residue was mixed with water (50 mL) and the mixture was extracted with ether (4 × 40 mL). The ethereal extract was dried over sodium sulfate, filtered, and evaporated to yield diethyl monoallyl malonate (42.4 g, 85%); nmr ($CDCl_3$) δ: 1.35 (6H, triplet, J = 8 Hz, O—CH_2CH_3), 2.6–2.9 (2H, multiplet, allylic CH_2), 3.4–3.7 (1H, multiplet, CH), 4.1–4.5 (4H, quadruplet, J = 8 Hz), and 5.1–6.3 (3H, multiplet, olefinic H).

Using a similar procedure (Na (5.1 g), absolute ethanol (150 mL), and allyl bromide (29 g)), diethyl monoallyl malonate (42.4 g) was converted into diethyl bis-allyl malonate (38.6 g, 76%); nmr ($CDCl_3$) δ: 1.3 (6H, triplet, J = 8 Hz, O—CH_2CH_3), 2.75 (4H, doublet, J = 8 Hz, allylic CH_2), 4.1–4.5 (4H, quadruplet, J = 8 Hz, OCH_2), and 5.0–6.2 (6H, multiplet, olefinic H).

Diethyl bis-allyl malonate (10.0 g, 0.04 mol) was mixed with sodium chloride (3 g, 0.05 mol), water (2.7 g, 0.15 mol), and dimethylsulfoxide (40 mL) and the mixture was refluxed during 100 h. After cooling at room temperature, water (150 mL) was added and the mixture was extracted with ether (3 × 75 mL). The ethereal extract was dried over sodium sulfate, filtered, and evaporated to dryness. The oil obtained was distilled under reduced pressure to yield pure ethyl bis-allyl acetate **2** (5.46 g, 78%); bp 70°C, 4 Torr vpc retention time: 4 min (110°C); ir ($CHCl_3$): 1731 and 1642 cm^{-1}; nmr ($CDCl_3$) δ: 1.35 (3H, triplet, J = 8 Hz, CH_2CH_3), 2.3–3.0 (5H, multiplet), 4.32 (2H, quadruplet, J = 8 Hz, CH_2CH_3), and 5.24 – 6.4 (6H, multiplet, olefinic H); ms m/e: 168 (M^+). *Anal.* calcd. for $C_{10}H_{16}O_2$: C 71.43, H 9.53; found: C 71.16, H 9.73.

Ethyl Triallyl Acetate 3

n-Butyl lithium (25 mmol, 1.6 *M* in hexane) was added dropwise to a solution of diisopropylamine (3.3 mL, 25 mmol) in tetrahydrofuran (60 mL) under an atmosphere of nitrogen. After 15 min at room temperature, the solution was cooled to −78°C and a solution of ethyl bis-allyl acetate **2** (3.36 g, 20 mmol) in tetrahydrofuran (50 mL) was added dropwise. After 30 min, a solution of allyl bromide (3.2 g, 26 mmol) in hexamethylphosphoramide (28 mmol) was added and the reaction mixture was left at −78°C during 2 h. A saturated solution (40 mL) of ammonium chloride was added and the mixture was left to warm up to room temperature. The mixture was then extracted with ether (100 mL). The organic extract was washed with hydrochloric acid (5%, 2 × 50 mL), brine (50 mL), dried with magnesium sulfate, filtered, and evaporated. Distillation of the residue gave pure ethyl triallyl acetate **3** (4.06 g, 97%); vpc retention time: 14.5 min (110°C); ir ($CHCl_3$): 1730 and 1645 cm^{-1}; nmr ($CDCl_3$) δ: 1.3 (3H, triplet, J = 9 Hz, OCH_2CH_3), 2.4 (6H, doublet, J = 8 Hz, allylic CH_2), 4.2 (2H, quadruplet, J = 9 Hz, OCH_2CH_3), 4.9–6.4 (9H, multiplet, olefinic H); ms m/e: 208 (M^+, weak), and 163 ($M^+ - OC_2H_5$).

Triallyl Acetic Acid 4

Ethyl triallyl acetate **3** (4.06 g, 20 mmol) was mixed with ethanol (95%, 150 mL) and potassium hydroxide (5.6 g) and the mixture was heated at reflux for 15 days. After evaporation of the ethanol, water (50 mL) was added and the mixture was extracted with ether (2 × 50 mL). The aqueous phase was acidified with concentrated hydrochloric acid and extracted with ether (4 × 100 mL). This ethereal extract was dried with sodium sulfate, filtered, and evaporated to yield crude triallyl acetic acid **4** (3.25 g, 93%); ir ($CHCl_3$): 3600–2400, 1715, and 1645 cm^{-1}; nmr ($CDCl_3$) δ: 2.0–2.8 (6H, broad singlet, allylic CH_2), 4.8–6.3 (9H, multiplet, olefinic H), and 10.7 (1H, singlet, OH); ms (chemical ion – isobutane, 100 eV): 180 (M^+).

Tribromocarboxylic Acid 5

Triallyl carboxylic acid **4** (1.52 g, 9.05 mmol) was dissolved in pentane (300 mL). (The pentane used was treated with concentrated sulfuric acid during 4 days followed by washing with water, drying with magnesium sulfate, and distillation over calcium hydride.) Nitrogen gas was bubbled through the solution during 5 min. Hydrogen bromide gas was then bubbled through the solution (40 min) which was exposed to the radiation of an ultraviolet lamp (450 W). Nitrogen gas was again bubbled through the solution, ether (200 mL) was added, and the organic phase was washed with sodium thiosulfate (10%, 4 × 75 mL) and brine (50 mL). The organic phase was dried with magnesium sulfate, filtered, and evaporated to yield an oil which was crystallized from hexane (4.5 g, 95%); mp 91.5–93°C (lit. (4) mp 92–94°C); ir ($CHCl_3$): 3600–2400 and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 1.5–2.0 (12 H, broad multiplet), 3.3–3.5 (6H, multiplet, CH_2Br), and 10.6 (1H, singlet, OH); ms (chemical ion − isobutane, 100 ev): 421, 423, 425, 427 (1:3:3:1) (M^+), 374, 376, 378, 380 (1:3:3:1) ($M^+ - CO_2H$), 341, 343, 345 (1:2:1) (M^+ − Br), and 180 (M^+).

Dibromolactone 6

Triethylamine (200 μL) was added to a solution of tribromocarboxylic acid **5** (235 mg, 0.55 mmol) in dichloromethane (25 mL) and the mixture was left at room temperature during 3 h. The organic solution was washed with water, dried with magnesium sulfate, filtered, and evaporated to yield essentially pure dibromolactone **6** (189 mg, 99%); ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.6–2.0 (12 H, multiplet), 3.2–3.5 (4H, broad triplet, CH_2Br), and 4.1–4.4 (2H, broad triplet, CH_2O); ms m/e (70 eV): 260, 261 (1:1) (M^+ − HBr).

Diacetate Lactone 7

Sodium acetate (820 mg, 10 mmol) was added to a solution of dibromolactone **6** (189 mg, 0.63 mmol) in hexamethylphosphoramide (30 mL) and the mixture was heated at 60°C during 2 h. After cooling to room temperature, dichloromethane (60 mL) was added. The organic phase was washed with hy-

drochloric acid (10%, 4 × 40 mL), dried with magnesium sulfate, filtered, and evaporated. Residual hexamethylphosphoramide was removed by distillation *in vacuo*. The residue was purified by preparative thin layer chromatography (tlc) on silica gel using ether as eluant to yield pure diacetate lactone **7** (87 mg, 52%); ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 1.5–1.9 (12 H, multiplet), 2.0 (6H, singlet, CH_3CO), 3.9–4.2 (4H, broad triplet, CH_2OAc), and 4.1–4.4 (2H, broad triplet, CH_2O); ms *m/e*: 240 ($M^+ - OCOCH_3$).

Tricyclic Orthoester 1

Method A

Potassium carbonate (10 mg) was added to a solution of lactone diacetate **7** (11 mg, 0.037 mmol) in methanol (3 mL) and the mixture was left for 30 min. Hydrolysis was complete, as shown by tlc, the solution was acidified with hydrochloric acid (2 *N*) and left for 24 h (no change on tlc). The mixture was refluxed for 3 h, and again there was no sign of orthoester **1** (tlc). Benzene was added and the mixture was refluxed for 4 h using a Dean-Stark water separator. Evaporation of the benzene solution gave tricyclic orthoester **1** which was purified by preparative thin layer chromatography (silica gel, ether) (5.8 mg, 88%).

Method B

Lactone diacetate **7** (6.1 mg, 0.02 mmol) was dissolved in a mixture of hydrochloric acid (2.4 *N*, 0.5 mL) and dimethoxyethane (0.5 mL) and the solution was left at room temperature for 2 h. Thin layer chromatography showed complete hydrolysis. Benzene was added and the mixture was refluxed for 2 h using a Dean-Stark water separator. After evaporation of the solvent and purification by preparative tlc, the tricyclic orthoester **1** was obtained pure (2.5 mg, 66%).

Method C

Lactone diacetate **7** (4.7 mg, 0.016 mmol) was dissolved in a mixture of methanol (5 mL) and triethylamine (50 μL) and left at room temperature for 4 days. Evaporation gave a crude product identified as the triol ester **9**; ir ($CHCl_3$): 3650–3200, and 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.4–1.9 (15 H, multiplet), 3.5–3.8 (6H, broad triplet, CH_2O), and 3.7 (3H, singlet, CH_3O).

The triol ester **9** was dissolved in benzene (1 mL) in the presence of *p*-toluenesulfonic acid (11 mg) and the mixture was left at room temperature for 2 h. Formation of orthoester **1** was complete as shown by tlc. Potassium carbonate (100 mg) was added, the mixture was stirred for 30 min and evaporated to dryness. Water (10 mL) was added and the aqueous solution was extracted with ether (3 × 20 mL). The organic phase was dried over sodium sulfate, filtered, and evaporated to yield tricyclic orthoester **1** (2.7 mg, 95%).

Large Scale Preparation of Tricyclic Orthoester 1

The tricyclic orthoester **1** (216 mg, 56%) was prepared from tribromocarboxylic acid **5** (834 mg, 1.97 mmol) by utilizing method A described above. Orthoester **1**: mp 114–115°C (lit. (4) mp 114–115°C); nmr ($CDCl_3$) δ: 1.66 (12 H, multiplet), and 3.98 (6H, multiplet, CH_2O); ms *m/e*: 198 (M^+).

Triacetate Ester 10

Lactone diacetate **7** (5.5 mg, 0.018 mmol) was mixed with methanol (5 mL) and triethylamine (50 μL) and left at room temperature for 4 days. Evaporation of the solvent gave crude triol ester **9**. Acetic anhydride (3 mL) and pyridine (3 mL) were added and the mixture was left for 15 h. Evaporation gave a mixture of diacetate lactone **7** (1.1 mg, 20%) and triacetate ester **10** (3.9 mg, 56%) which were separated by tlc. Triacetate ester **10**: ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 1.4–1.9 (12 H, multiplet), 2.0 (9H, singlet, CH_3CO), 3.5–3.8 (6H, broad triplet, CH_2O) and 3.7 (3H, singlet, CH_3O); ms (chemical ion – isobutane, 100 eV): 315 ($M^+ - CH_3CO_2$).

Hydrolysis of Tricyclic Orthoester 1

Orthoester **1** (8.2 mg, 0.042 mmol) was mixed with dimethoxyethane (4 mL) and hydrochloric acid (0.1 *N*, 1 mL) and left for 5 h at room temperature. The analysis indicated that hydrolysis of **1** did not take place. The mixture was then heated at reflux for 3 h and tlc indicated complete hydrolysis. The solvent was evaporated and a mixture of acetic anhydride (2 mL) and pyridine (2 mL) was added. After 15 h at room temperature, the solution was evaporated and the residue was purified by tlc to yield pure diacetate lactone **7** (8.5 mg, 68%).

The preparation and oxidation of disulfides as a route to sulfone-sulfides

TERENCE PATRICK AHERN, HARVEY OWEN FONG, RICHARD FRANCIS LANGLER,[1] AND PETER MICHAEL MASON

Chemistry Department, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received December 3, 1979

TERENCE PATRICK AHERN, HARVEY OWEN FONG, RICHARD FRANCIS LANGLER, and PETER MICHAEL MASON. Can. J. Chem. **58**, 878 (1980).

Mercaptide/alkoxide competition in substitution and addition reactions is discussed as it applies to the preparation of disulfides. Oxidation of an asymmetric disulfide with H_2O_2 is shown to exhibit high regioselectivity which may be rationalized in the same terms employed for other sulfide oxidations, viz. substituent electron withdrawing ability (X_p) and steric effects.

TERENCE PATRICK AHERN, HARVEY OWEN FONG, RICHARD FRANCIS LANGLER et PETER MICHAEL MASON. Can. J. Chem. **58**, 878 (1980).

On discute de la compétition existant entre les thiolates et les alcoolates lors des réactions d'addition et de substitution, telles qu'elles sont appliquées à la préparation des disulfures. On a montré que l'oxydation d'un disulfure asymétrique par H_2O_2 est hautement régiosélective et qu'elle peut être expliquée comme dans le cas des oxydations d'autres sulfures, par l'effet des substituants électroattracteurs (X_p) et des effets stériques.

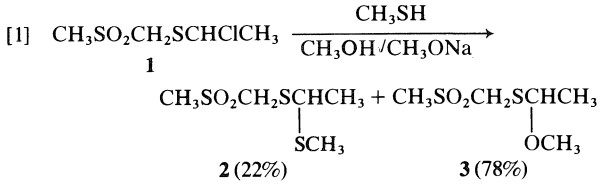
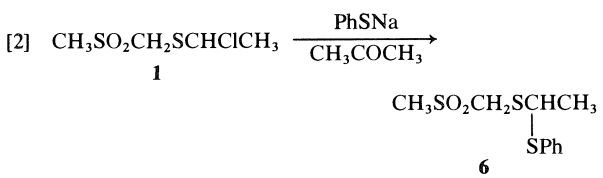
Introduction



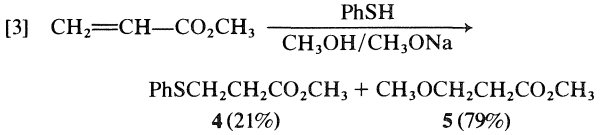
In connection with our work on the chlorinolyses of sulfur compounds (1–10), we have become interested in the preparation of β-sulfone-sulfides. These compounds permit the assessment of sulfonyl moieties as directing groups in asymmetric sulfide chlorinations (3). We have recently reported (2) the results generated by our approach to sulfone-sulfide synthesis via mercaptosulfone intermediacy.

The present report details results on the preparation and oxidation of disulfides with a view to obtaining the corresponding β-sulfone-sulfides. The conversion of a disulfide to a β-sulfone-sulfide requires the intermediacy of a β-sulfoxide-sulfide. While there are a variety of reagents (11–16) which permit the conversion of disulfides to β-sulfoxide-sulfides, very few reagents will accomplish the conversion of a sulfoxide-sulfide to a sulfone-sulfide.



Results and Discussion

Disulfides may be prepared by condensation of a mercaptan with an aldehyde or ketone (17–19) or by base catalyzed condensation of a mercaptan and an α-chlorosulfide.[2]



Although some mercaptide anions and α-chlorosulfides may be cleanly condensed in an alcoholic medium (4), eq. [1] illustrates one possible complication.

The results shown in eq. [1] can be rationalized by presuming an S_N1 mechanism which becomes dominant due to the enhanced stability of an alkyl substituted sulfenium ion over an unsubstituted sulfenium ion (4). Consistent with this proposal, **6** is formed, without complication, in acetone.

In a related Michael addition reaction (eq. [3]) a similar complication has been observed.

The results in eq. [3] may be rationalized by presuming that mercaptide anion addition is rever-

[1]Enquiries should be directed to Dr. R. F. Langler, Chemistry Department, Mount Allison University, Sackville, N.B., Canada E0A 3C0.

[2]The desired α-chlorosulfide may be prepared by chlorination of the desired sulfide with sulfuryl chloride or *N*-chlorosuccinimide, provided due consideration is given to substituent electronegativities. (3).

sible while alkoxide anion addition is not.[3] In any case it is clear that alcoholic media may present unwelcome complications in these condensation reactions.

We have selected the symmetric disulfide **7** to begin our examination of disulfide oxidations.

[4] $PhCH(SCH_3)_2$ (**7**) $\xrightarrow[\text{Dioxane}]{30\%H_2O_2}$ $PhCH(SO_2CH_3)(SCH_3)$ (**8**, 8%)

The formation of **8** from oxidation of **7** as shown in eq. [4] is rather surprising since peroxidic oxidations normally give exclusively disulfoxides as outlined in eq. [5].

[5] $(CH_3O_2CCH_2S)_2CH_2$ (**9**) $\xrightarrow[\text{Dioxane}]{30\%H_2O_2}$ $(CH_3O_2CCH_2SO)_2CH_2$ (**10**, 58%)

The twofold oxidation of **9** produced no detectable amount of sulfone-sulfide in accord with a previous study of sulfide oxidations (22). Clearly, the oxidation of disulfides with peroxides is an unsuitable approach to the preparation of sulfone-sulfides.[4]

Sodium permanganate in aqueous dioxane has been reported (23) to permit the selective oxidation of sulfoxides in preference to sulfides. In that paper some difficulty was encountered with solvent oxidation. We have elected to employ potassium permanganate in aqueous THF[5] as a reagent system with somewhat improved availability and stability. To test this modified reagent system we have prepared[6] and oxidized the sulfoxide-sulfide **11**. The results are depicted in Scheme 1. The conversion of **11** to **13** illustrates the importance of the reaction conditions.

It was our objective to examine the oxidation of **6** which could, in principle, form a pair of regioisomeric sulfone-sulfoxide-sulfides each of which would exist as a pair of diastereomers. We have chosen to begin this portion of the work by examining a simpler system in order to establish a way to distinguish between regioisomers and diastereomers. We, therefore, subjected the sulfone-sulfide **1** to oxidation with one equivalent of *m*-chloroperbenzoic acid (mCPBA) as shown in Scheme 2. Nuclear magnetic resonance indicated that the sulfone-sulfoxide **14**[7] was an equimolar mixture of two compounds. Oxidation of **14** furnished the homogeneous disulfone **15** in greater than 90% yield, thereby establishing that **14**, as expected (25–27), was a mixture of diastereomers.

We were now prepared to examine the oxidation of **6** to assess regioselectivity in that reaction. While the problem of regioselectivity in 1,3-disulfide oxidations does not appear to have been scrutinized previously, that of regioselectivity in 1,2-disulfide oxidations has been.

Bhattacharya and Hortmann (28) have reported the disulfide oxidations shown in eq. [6] to be regiospecific.

They have concluded that "oxidation appeared to occur (in the absence of steric effects) at the sulfur atom farthest removed from the relatively

[6] $PhCH_2SSPh + mCPBA \longrightarrow PHCH_2SO_2SPh$

$CH_3CH_2SSPh + mCPBA \longrightarrow CH_3CH_2SO_2SPh$

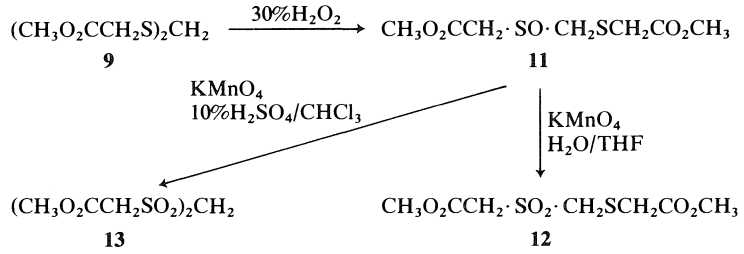
more electron withdrawing group." Oxidation of 1,2-disulfides, as these authors point out, may proceed through 1,2-disulfoxides (29). In the closely related sodium metaperiodate oxidations of 1,2-disulfides Oae *et al.* (30) report no indication of 1,2-disulfoxide formation. These same factors, viz. steric effects and the electron withdrawing ability of substituents, have been cited to rationalize peroxydisulfate oxidations of simple sulfides (31).

Application of these factors to **6** leads to the expectation that oxidation should occur with high regioselectivity, at the sulfur bearing the phenyl group on the grounds that (*i*) a mesylmethyl group is more electronegative than a phenyl group ($X_pCH_3SO_2CH_2 = 2.85$, $X_pPh = 2.49$ (3)), and (*ii*) the central sulfur atom is much closer to the bulky mesyl group[8] than is the thiophenyl sulfur atom.

Oxidation of **6** with an equivalent of H_2O_2 afforded a mixture **16** of two compounds which displayed different chemical shifts for all corresponding non-aromatic protons, e.g., two doublets (all lines approximately equal in intensity) appeared at δ 1.23 and two singlets appeared at δ 3.03 in the nmr spectrum. Oxidation of the mixture with $KMnO_4/H_2O/THF$ afforded an homogeneous disulfone-sulfide, tentatively assigned structure **17** in about 50% yield. Crude **16** from another run was

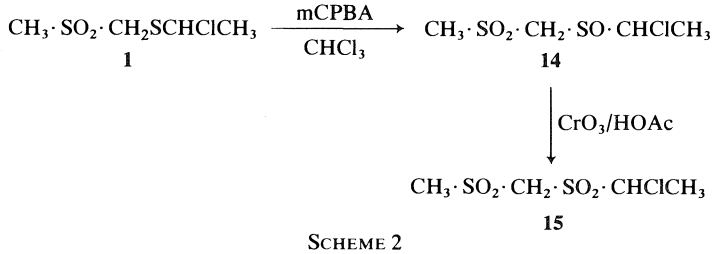
[3]The sulfide ester **4** was prepared in good yield when the reaction was conducted in pyridine (2).

[4]A paper has appeared (21) which reports that $KMnO_4$ in cold acetone furnishes sulfone-sulfides from symmetric disulfides. Reaction times are 8–10 days.



[5]Even dioxane freshly distilled from $KMnO_4$ reacted significantly faster with permanganate than THF.

[6]Sulfoxide-sulfides may also be obtained from sulfinate esters (24).



[7]Compound **14** was shown to be free of unreacted **1** and disulfone **15** by the addition of authentic samples of each to **14** which gave rise to the expected new signals in the nmr.

[8]The nature of the steric effect of the mesyl (or methylsulfonyl) group has been discussed previously (1).

SCHEME 1

SCHEME 2

SCHEME 3

subjected to column chromatography which furnished a homogeneous sample of one diastereomer. Permanganate oxidation of the homogeneous diastereomer furnished the same disulfone-sulfide **17** in essentially the same yield as obtained from the diastereomeric mixture (*vide* Scheme 3). These results establish that **16** was indeed a diastereomeric mixture and that oxidation of **6** was highly regioselective.

The first evidence concerning which sulfur atom of **6** was oxidized to yield **16** was obtained from the mass spectrum of **16**. A moderate intensity ion was observed at *m/e* 125 (relative abundance ca. 50%) in accord with the presence of a phenylsulfinyl group. The mass spectrum of **17** showed the base peak at *m/e* 153 ($M^{\ddagger} - PhSO_2$). The loss of substituted sulfonyl groups as neutral fragments from molecular ions has been amply precedented (32–34). Furthermore, the aromatic regions in the nmr spectra of **6** and **16** show broad singlets whereas the nmr of **17** shows two distinct aromatic signals in accord with the presence of an electronegative SO_2 group attached directly to the phenyl ring.

A brief deuterium exchange experiment furnished polydeuterated **17**. The nmr and mass spectrum indicated about 70% exchange at C4 and 11% exchange at C2. This result is clearly inconsistent with the alternative disulfone-sulfide structure for **17**. The selectivity in the exchange experiment on **17** could be rationalized on the basis of a slightly greater acidity for the methylene protons than for the methine proton.

In conclusion we have found that (*i*) nucleophilic competitions make substitution and addition reactions in alcohols unreliable when mercaptide anions are the intended nucleophiles, and (*ii*) regioselectivity in a 1,3-disulfide oxidation appears to be subject to the same considerations advanced for 1,2-disulfide oxidations, i.e., the electron withdrawing ability (X_p) of substituents and steric effects.

Experimental

General

The ir spectra were recorded on a Perkin-Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian T60 instrument using TMS as the internal standard. The mass spectra were recorded on a Dupont-CEC model 21-104 mass spectrometer. Samples were directly introduced using an all glass probe and the spectra run at 30 eV with a source temperature of 150°C. Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected.

*Reaction of **1** with Sodium Methyl Mercaptide in Methanol*

Sodium metal (0.155 g) was dissolved in methanol (25 mL) and the solution cooled to 5°C. Methanethiol (3 mL) was slowly distilled into the solution. The α-chlorosulfide **1** (1.236 g) (3) was added and the reaction mixture stirred at ambient temperature for 24 h. Water (25 mL) was added and the resultant mixture washed with chloroform (five 50 mL aliquots). The combined organic layers furnished a mixture of the sulfone-sulfide-ether **3** and the sulfone-disulfide **2**. The mixture was chromatographed on silica gel (100 g) with diethyl ether elution (100 mL aliquots).

Fraction 3 (108.2 mg) was sulfone-disulfide **2**, ir ($CHCl_3$): 1315 and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 4.46 (1H, q, J = 6 Hz), 4.30 (1H, d, J = 14 Hz), 3.90 (1H, d, J = 14 Hz), 2.96 (3H, s), 2.03 (3H, s), and 1.60 (3H, d, J = 6 Hz); ms *m/e*: 200 (M^+, 23.9%) and 75 (100%).

Fraction 4 (194.6 mg) was an equimolar mixture of **2** and **3**. Fractions 5–8 were combined and concentrated affording the sulfone-sulfide-ether **3** (585 mg), ir ($CHCl_3$): 1315 and 1115 cm^{-1}; nmr ($CDCl_3$) δ: 5.03 (1H, q, J = 6 Hz), 3.96 (2H, s), 3.36 (3H, s), 3.00 (3H, s), and 1.53 (3H, d, J = 6 Hz); ms *m/e*: 184 (M^+, 1.5%) and 59 (100%).

Reaction of Methyl Acrylate and Sodium Thiophenoxide in Methanol

Sodium metal (4.224 g) was dissolved in methanol (200 mL) and benzenethiol (19.8 g) added. The solution was cooled and methyl acrylate (15.62 g) in methanol (50 mL) was added dropwise over 0.5 h. The reaction mixture was refluxed 1 h. Water (250 mL) was added and the resultant mixture washed with methylene chloride (four 200 mL aliquots). The combined organic layers afforded a mixture of the ether-ester **5** and the sulfide-ester **4**. The mixture was rectified at reduced pressure affording **5** (9.949 g, bp 32–34°C/3 Torr) and **4** (4.524 g).

The sulfide-ester **4** was identical with previously described material (2).

The ether-ester **5** had ir ($CHCl_3$): 1730 cm^{-1}; nmr ($CDCl_3$) δ: 3.73 (3H, s), 3.73 (2H, t), 3.39 (3H, s) and 2.60 (2H, t); ms *m/e*: 118 (M^+, 28.5%), 59 (28.5%), and 45 (100%).

*Preparation of **6***

A solution of sodium thiophenate (0.912 g) in acetone (3 mL) was added to a solution of the chlorosulfone-sulfide **1** (1.000 g) (3) in acetone (9 mL) and the reaction mixture stirred at ambient temperature for 24 h. Water (25 mL) was added and the resultant mixture washed with chloroform (four 50 mL aliquots). The combined organic layers were dried and concentrated affording crude sulfone-disulfide **6** (1.282 g). The crude product was chromatographed on silica gel (100 g) employing 4:1 ether–chloroform (50 mL fractions). Fractions 6–8 were combined and concentrated and the residue recrystallized affording clean **6** (0.901 g, mp 40–41°C); ir ($CHCl_3$): 1320 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.30 (5H, broad s), 4.80 (1H, q, J = 6 Hz), 4.33 (1H, d, J = 14 Hz), 3.90 (1H, d, J = 14 Hz), 2.96 (3H, s), and 1.60 (3H, d, J = 6 Hz); ms *m/e*: 262 (M^+, 19.6%), 137 (86.0%), 109 (54.2%), and 73 (100%). *Anal.* calcd. for $C_{10}H_{14}O_2S_3$: C 45.77, H 5.37; found: C 45.63, H 5.59.

*Peroxidation of **7***

The disulfide **7** (10 g) (19) was dissolved in pyridine (100 mL), triethylamine (10 mL), and water (10 mL). After stirring overnight the reaction mixture was diluted with chloroform, acid washed, dried, and rectified at reduced pressure affording acid free disulfide (7.76 g, bp 144°C/5 Torr).

The disulfide (4.661 g) was dissolved in dioxane (50 mL) and H_2O_2 (30%, 2.870 g) added. The reaction mixture was refluxed for 0.5 h, after which it was concentrated and chromatographed on silica gel (400 g). Elution of the column with chloroform (100 mL aliquots) furnished the sulfone-sulfide **8** (0.438 g) from fractions 20–28. After recrystallization from 95% ethanol the sulfone-sulfide had mp 109–111°C and R_f 0.25 (with chloroform development); ir ($CHCl_3$): 1320 and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 7.43 (5H, s), 4.86 (1H, s), 2.86 (3H, s), and 2.46 (3H, s); ms *m/e*: 137 (100%) and 121 (25%). *Anal.* calcd. for $C_9H_{12}O_2S_2$: C 49.97, H 5.59; found: C 50.17, H 5.48.

*Peroxidation of **9***

The disulfide-diester **9** (5.007 g) (35) was dissolved in dioxane (25 mL) and H_2O_2 (30%, 2.522 g) was added. The reaction was refluxed for 0.5 h and the solvent evaporated. The residue was recrystallized from methanol affording disulfoxide-diester **10** (3.347 g, mp 90–94°C); ir ($CHCl_3$): 1740 and 1050 cm^{-1}; nmr ($CDCl_3$) δ: 4.36 (6H, m) and 3.86 (6H, s); ms *m/e*: 106 (16.9%), 74 (33.8%), 59 (61.9%), and 45 (100%). *Anal.* calcd. for $C_7H_{12}O_6S_2$: C 32.80, H 4.71; found C 32.76, H 4.59.

*Preparation of **11***

The disulfide-diester **9** (5.005 g) (35) was dissolved in dioxane (25 mL) and H_2O_2 (30%, 2.522 g) was added. The reaction was refluxed for 0.5 h and the solvent evaporated. The crude product was chromatographed on silica gel (350 g) employing 9:1 diethyl ether – methanol (100 mL aliquots) as eluent. Fractions 13–17 were combined and concentrated affording clean diester-sulfoxide-sulfide **11** (2.376 g) as an oil; ir ($CHCl_3$): 1745, 1740, and 1050 cm^{-1}; nmr ($CDCl_3$) δ: 4.30 (1H, d, J = 12 Hz), 4.20 (1H, d, J = 12 Hz), 3.90 (1H, d, J = 12 Hz), 3.80 (1H, d, J = 12 Hz), 3.80 (3H, s), 3.76 (3H, s), and 3.57 (2H, s); ms *m/e*: 119 (84.7%), 91 (23.6%), and 45 (100%).

*Permanganate Oxidation of **11** in THF*

The diester-sulfoxide-sulfide **11** (1.000 g) in THF (5 mL) was added to a mixture of $KMnO_4$ (0.444 g) in 20% v/v aqueous THF (100 mL). The reaction mixture was stirred at ambient temperature for 10 min. Water (100 mL) was added and the resultant mixture washed with chloroform (four 100 mL aliquots). The combined organic layers were dried and concentrated. The crude diester-sulfone-sulfide (0.962 g) was chromatographed on silica gel employing diethyl ether (50 mL fractions) as eluent. Fractions 7–12 were combined and concentrated affording clean diester-sulfone-sulfide **12** (0.680 g) as an oil; ir ($CHCl_3$): 1750, 1328, and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 4.37 (2H, s), 4.33 (2H, s), 3.83 (3H, s), 3.77 (3H, s), and 3.67 (2H, s); ms *m/e*: 197 (7.5%), 119 (100%), 91 (30%), and 45 (88.6%).

*Conversion of **11** to **13***

A solution of the diester-sulfoxide-sulfide **11** (1.003 g) in chloroform (25 mL) was added to 10% v/v sulfuric acid in water (35 mL) dropwise over 15 min. During the addition $KMnO_4$ (5.024 g) was added in small portions. Upon completion of the additions, the reaction mixture was stirred at room temperature for 1 h. The reaction mixture was cooled and sodium bisulfite added until the mixture became colorless. The layers were separated and the aqueous layer washed with chloroform. The combined chloroform layers were dried and concentrated affording the diester-disulfone **13** (1.15 g). Upon recrystallization the disulfone **13** had ir ($CHCl_3$): 1750, 1350, and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 5.33 (2H, s), 4.46 (4H, s), and 3.90 (6H, s); ms *m/e*: 288 (M^+, 13%), 151 (100%), 79 (46.5%), and 74 (60.5%). Other properties were in accord with a previous report (36).

Preparation of ***14***

A solution of the chlorosulfone-sulfide **1** (2.241 g) (3) in chloroform (50 mL) was cooled to −6°C and *m*-chloroperbenzoic acid (85%, 2.534 g) added in small portions. The ice in the cooling bath was allowed to melt and the reaction mixture was stirred overnight. Chloroform (150 mL) was added and the resultant solution washed with 1% NaOH (two 50 mL aliquots). The organic layer was dried and concentrated. The residue was recrystallized from 95% ethanol affording diastereomeric chlorosulfone-sulfoxide **14** (0.799 g, mp 78–80°C); ir ($CHCl_3$): 1325, 1150, and 1060 cm^{-1}; nmr ($CDCl_3$) δ: 5.26 (0.5H, q, J = 7 Hz), 5.00 (0.5H, q, J = 7 Hz), 4.33 (2H, broad s), 3.23 (3H, s), and 1.93 (3H, d, J = 7 Hz); ms *m/e*: 141 (12.6%), 127 (11.5%), and 63 (100%).

Oxidation of ***14***

The chlorosulfone-sulfoxide **14** (0.100 g) in glacial acetic acid (1 mL) was added to a mixture of chromium trioxide (0.065 g) in glacial acetic acid (2 mL). The reaction mixture was heated to 90–100°C for 0.5 h. Water (15 mL) was added and the resultant mixture washed with chloroform (three 25 mL aliquots). The combined organic layers were washed with 2.5% w/v NaOH (two 25 mL aliquots), dried, and concentrated. The product was homogeneous chlorodisulfone **15** (by nmr) (0.097 g). Upon recrystallization it was shown to be identical with previously prepared chlorodisulfone **15** (3) by nmr, ir, mp, and mixture mp.

Oxidative Conversion of ***6*** *to* ***17***

Hydrogen peroxide (30%, 0.432 g) was added to a solution of the sulfone-disulfide **7** (0.500 g) in dioxane (25 mL) and the solution refluxed for 0.5 h. The solvent was evaporated and the residue chromatographed on silica gel (50 g) employing diethyl ether (50 mL fractions) as eluent. Fractions 5–7 were combined and concentrated affording the disulfone-sulfide **17** (0.137 g, mp 147–148°C); ir ($CHCl_3$): 1320 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 8.03 (2H, m), 7.70 (3H, m), 4.86 (1H, q, J = 7 Hz), 4.73 (1H, d, J = 14 Hz), 3.90 (1H, d, J = 14 Hz), 3.03 (3H, s), and 1.50 (3H, d, J = 7 Hz); ms *m/e*: 294 (M^+, 1.9%), 153 (100%), 125 (28.2%), and 73 (96.1%). *Anal.* calcd. for $C_{10}H_{14}O_4S_3$: C 40.79, H 4.79; found: C 40.83, H 4.61.

Preparation of ***16***

The sulfone-disulfide **6** (2.023 g) was added to a solution of hydrogen peroxide (30%, 0.874 g) in dioxane (100 mL) and the reaction mixture refluxed for 0.5 h. The solvent was evaporated and the residue chromatographed on silica gel (200 g) employing diethyl ether (100 mL fractions) for elution. Fractions 34–36 were combined and concentrated affording one of the diastereomers of **16** as a pure oil (0.317 g); ir ($CHCl_3$): 1320, 1110, and 1060 cm^{-1}; nmr ($CDCl_3$) δ: 7.63 (5H, broad s), 4.60 (1H, q, J = 6 Hz), 4.36 (1H, d, J = 14 Hz), 3.90 (1H,d, J = 14 Hz), 3.10 (3H, s), and 1.33 (3H, d, J = 6 Hz); ms *m/e*: 155 (40.3%), 125 (48.3%), 109 (100%), and 73 (32.2%).

The other diastereomer differed principally in its nmr spectrum which was obtained by subtraction of the nmr of the pure diastereomer from the nmr of a mixture of diastereomers. the second diastereomer had nmr ($CDCl_3$) δ: 7.53 (5H, s, broad), 4.43 (1H, q, J = 6 Hz), 4.36 (1H, d, J = 14 Hz), 3.80 (1H, d, J = 14 Hz), 2.96 (3H, s), and 1.36 (3H, d, J = 6 Hz).

Oxidation of **6** (2 g) furnishes ca. 1:1 mixture of diastereomers (1.92 g).

Conversion of ***16*** *to* ***17***

Both the crude diastereomeric mixture **16** and the purified diastereomer described above gave essentially the same results outlined below.

The sulfone-sulfoxide-sulfide **16** (0.202 g) in THF (5 mL) was added to potassium permanganate (0.076 g) in 20% v/v aqueous THF (100 mL). The reaction was stirred at ambient temperature for 10 min. Water (100 mL) was added and the mixture washed with chloroform (four 100 mL aliquots). The organic layers afforded disulfone-sulfide **17** (0.173 g) which was homogeneous by tlc and nmr. Recrystallization afforded **17** which was identical with previously obtained material by ir, nmr, mp, and mixture mp.

Received February 4, 1980

In Table 1, the uv spectral data for compound **5** in MeOH and MeOH—H^+ are incorrect. They should read:

Compound	Solvent	Wavelength, nm (log ε)				
5	MeOH	425(4.12)	306(4.22)	289(4.22)	259(4.31)	224(4.21)
5	MeOH—H^+	419(4.23)	291(4.35)		257(4.18)	226(4.18)

In Table 2, compound **4**[a] does not have an NHMe 3H singlet at δ 3.42. In compound **7**[a], the two overlapping singlets at δ 3.62 and δ 3.54 are not 3H singlets, but rather 6H singlets.

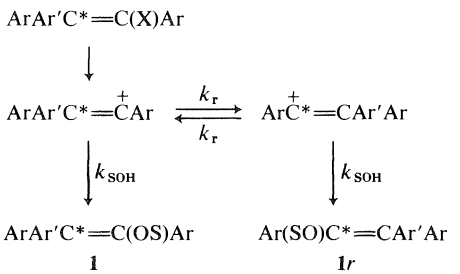
CHOI CHUCK LEE, ERIC C. F. KO, and ZVI RAPPOPORT. Can. J. Chem. **58**, 884 (1980).

Errors reported in the literature on the migratory aptitudes of some aryl groups in triarylvinyl cations have been corrected. From the corrected as well as some new data, the relative migratory aptitudes for Ph:Tol:An in triarylvinyl cations in acetic acid media are calculated to be 1:4 – 5:162, based on $k_{r(Tol)}/k_{r(Ph)}$ derived from migrations in the tritolylvinyl and 2-phenyl-1,2-ditolylvinyl cations and $k_{r(An)}/k_{r(Ph)}$ derived from migrations in the 2-anisyl-1,2-diphenylvinyl and triphenylvinyl cations.

CHOI CHUCK LEE, ERIC C. F. KO et ZVI RAPPOPORT. Can. J. Chem. **58**, 884 (1980).

On corrige les erreurs publiées dans la littérature lors de l'étude des aptitudes migratoires de quelques groupes aryles dans les cations triarylvinyles. A partir des données corrigées aussi bien qu'à partir de nouvelles données, on a calculé les aptitudes migratoires relatives Ph:Tol:An dans les cations triarylvinyles en milieu acide acétique et on a trouvé une valeur de 1:4 – 5:162 en se basant sur la valeur $k_{r(Tol)}/k_{r(Ph)}$ déduite des migrations dans les cations tritolylvinyle et phényl-2 ditolyl-1,2 vinyle et sur la valeur $k_{r(An)}/k_{r(Ph)}$ dérivée des migrations dans les cations anisyl-2 diphényl-1,2 vinyle et triphénylvinyle.

[Traduit par le journal]



In studies of degenerate rearrangements arising from 1,2-aryl shifts across the double bond in triarylvinyl cations generated from isotopically labeled triarylvinyl substrates, when the mechanism as shown in Scheme 1 applies, a treatment by the method of Bonner and Collins (1) would give, after complete reaction, the relationship shown in eq. [1]. When Ar and Ar′ are the same, a statistical factor of 2 should be applied and for substrates of

$$[1] \quad [\mathbf{1}]/[\mathbf{1r}] = 1 + (k_{SOH}/k_r)$$

the type $(Ar)_2C^*{=}C(X)Ar$, eq. [1] should be modified to eq. [2]. In our previous work, this

$$[2] \quad [\mathbf{1}]/[\mathbf{1r}] = 1 + (k_{SOH}/2k_r)$$

statistical factor has, however, been neglected and eq. [1] was used to calculate values of k_{SOH}/k_r whether Ar and Ar′ are the same or different (2–6). When a single triarylvinyl system is being considered, such as the effect of different solvent compositions on the extent of isotopic scrambling in the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**2**-Br-*2*-^{14}*C*) in aqueous acetic acid (6), values of k_{SOH}/k_r calculated from eq. [1] would give a set of internally consistent data for comparison. However, when different triarylvinyl systems are being compared, as in calculations of migratory aptitudes (2, 5), errors have resulted because the statistical factor of 2 has been omitted. An objective of the present paper is to correct these errors.

SCHEME 1

Rappoport *et al.* (2) have studied the degenerate rearrangement arising from 1,2-anisyl shifts in the 2-anisyl-1,2-diphenylvinyl cationic system using a deuterated phenyl group as label. Among the results reported was the finding that reaction of *trans*-2-anisyl-1-phenyl-2-($^2H_5$)phenylvinyl bromide (*trans*-**3**-Br-2-Ph-d_5) with HOAc–AgOAc resulted in 92.7 ± 1.8% degenerate rearrangement (46.3% scrambling of the Ph-d_5 label from C-2 to C-1), giving a $k_{r(An)}/k_{SOH}$ ratio, in HOAc, of 6.35 (equivalent to $k_{SOH}/k_{r(An)}$ of 0.16 calculated from eq. [1]). A comparison was then made with the results from the acetolysis of triphenyl[2-^{14}C]vinyl triflate (**2**-OTf-*2*-^{14}*C*) (7), or the reaction of triphenyl[2-^{14}C]-vinyl bromide (**2**-Br-*2*-^{14}*C*) with HOAc–AgOAc (8), both of which gave 6–7% scrambling of the ^{14}C-label from C-2 to C-1. Using eq. [1], $k'_{SOH}/k_{r(Ph)}$ in

HOAc was calculated to be about 13 for the triphenylvinyl cationic system. Assuming that k_{SOH} for *trans*-**3**-Br-2-Ph-d_5 and k'_{SOH} for **2**-OTf-*2*-^{14}C or **2**-Br-*2*-^{14}C were about equal in the HOAc solvent, a ratio for the relative migratory aptitudes, $k_{r(An)}/k_{r(Ph)}$, of 13/0.16 or 81 was obtained (2). In this treatment, however, a statistical factor of 2 should have been applied in the triphenylvinyl system. Using eq. [2], $k'_{SOH}/2k_{r(Ph)}$ is 13 and the corrected ratio for $k_{r(An)}/k_{r(Ph)}$ is 162 instead of 81.

In a similar way, Lee *et al.* (5) have compared the 1.5–2.0% scrambling obtained in the reaction of HOAc–AgOAc with *cis*- or *trans*-2-phenyl-1,2-di-*p*-tolyl[2-^{13}C]vinyl bromide (*cis*- or *trans*-**4**-Br-*2*-^{13}C) with the 13–14% scrambling observed in the analogous reaction of HOAc–AgOAc with tri-*p*-tolyl[2-^{13}C]vinyl bromide (**5**-Br-*2*-^{13}C) (4). Using eq. [1] and the mean values of 1.7 and 13.5% scramblings, respectively, for the reactions of *cis*- or *trans*-**4**-Br-*2*-^{13}C and **5**-Br-*2*-^{13}C, the $k_{SOH}/k_{r(Ph)}$ and $k'_{SOH}/k_{r(Tol)}$ ratios obtained would be 57 and 5.4. Again assuming k_{SOH} and k'_{SOH} to be about equal, the relative migratory aptitudes for $k_{r(Tol)}/k_{r(Ph)}$ would be 57/5.4 or about 10. Since the statistical factor of 2 should have been applied in the tri-*p*-tolylvinyl system, $k'_{SOH}/2k_{r(Tol)}$ is 5.4 and the corrected ratio for $k_{r(Tol)}/k_{r(Ph)}$ should be 57/(2 × 5.4) or about 5.

As the results discussed above were obtained from reactions in HOAc in the presence of AgOAc, it is of interest to evaluate another migration ratio using data from another reaction. A 3:2 mixture of *cis*- and *trans*-**4**-Br-*2*-^{13}C as well as **5**-Br-*2*-^{13}C were solvolyzed in 70% HOAc – 30% H_2O (by volume), one of the solvents used in a recent study with **2**-Br-*2*-^{14}C (6). The reaction product was the ketone (eq. [3]); any acetate product that might have been formed would be hydrolyzed under the reaction conditions. The ketone was reduced with $LiAlH_4$ to the corresponding 1,2,2-triarylethanol. Analysis of the alcohol by ^{13}C nmr as described previously (4, 5) gave the extent of scrambling of the ^{13}C-label from C-2 to C-1. The results are summarized in Table 1.

$$[3]\quad Ar(Ar')^{13}C{=}CBrAr \xrightarrow[30\%\ H_2O]{70\%HOAc} Ar(Ar')^{13}CHCOAr + Ar^{13}COCH(Ar')Ar$$

It is also of interest to ascertain whether there is any significant extent of return from isotopically scrambled ionic intermediates to scrambled unconsumed reactant. Since ^{13}C nmr cannot be used to analyze the ^{13}C contents in the vinylic carbons by the method used in the present study (4, 5) because of the lack of nuclear Overhauser enhancement, the corresponding ^{14}C-labeled *cis*- and *trans*-**4**-Br-*2*-^{14}C and **5**-Br-*2*-^{14}C were subjected to solvolysis in 70% HOAc – 30% H_2O under conditions that would give about 50 and 75% reaction. $LiAlH_4$ reduction of the mixture of reaction product and unconsumed reactant gave a mixture of 1,2,2-triarylethanol and triarylethene, the latter being derived from the unreacted triarylvinyl bromide (9). Separation of the ethylene from the alcohol was effected by passage through an alumina column, and ozonolysis of the ^{14}C-labeled triarylethene, with added carrier if necessary, showed that in all 4 experiments (Table 1, footnote *b*) there was no significant scrambling of the label in the recovered unconsumed reactant. Thus similar to the behavior of **2**-Br-*2*-^{14}C in aqueous acetic acid (6), in the solvolysis of *cis*- and *trans*-**4**-Br-*2*-^{14}C and of **5**-Br-*2*-^{13}C in 70% HOAc – 30% H_2O, the return process apparently could not compete with product formation, and the extent of scrambling did not change with reaction time. Therefore the mechanism shown in Scheme 1, in which the cation formation from the substrate is irreversible as far as scrambling is concerned, should hold in these systems and eqs. [1] and [2] can be applied in treating the data of Table 1.

Using the mean values of 3.5 and 18.6% scrambling, respectively, for the reactions of *cis*- and *trans*-**4**-Br-*2*-^{13}C and **5**-Br-*2*-^{13}C in 70% HOAc – 30% H_2O (Table 1), eqs. [1] and [2] would give $k_{SOH}/k_{r(Ph)}$ as 26.6 and $k'_{SOH}/2k_{r(Tol)}$ as 3.4. Again assuming $k_{SOH} = k'_{SOH}$, $k_{r(Tol)}/k_{r(Ph)}$ would be 26.6/(2 × 3.4) or about 4. It has been pointed out (2, 3) that $k_{SOH}/k_{r(Ar)}$ calculated from expressions such as eq. [1] may involve large errors, especially when the observed extent of scrambling is very small or very large. Instead of using mean values, if the observed

TABLE 1. Isotopic scramblings from solvolyses of a 3:2 mixture of *cis*- and *trans*-2-phenyl-1,2-di-*p*-tolyl[2-^{13}C]vinyl bromide (*cis*- and *trans*-**4**-Br-*2*-^{13}C) and of tri-*p*-tolyl[2-^{13}C]vinyl bromide (**5**-Br-*2*-^{13}C) in 70% HOAc – 30% H_2O at 150° ± 1°C

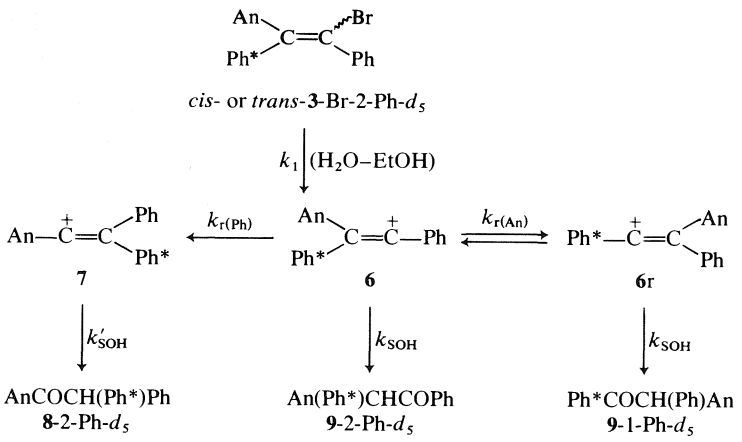
extremes of 4.0 and 3.1% scrambling for *cis*- and *trans*-**4**-Br-*2*-^{13}C were utilized in calculations with eq. [1], $k_{SOH}/k_{r(Ph)}$ would range between 23.0 and 30.3. Similarly, for the extremes of 19.3 and 17.7% scrambling for **5**-Br-*2*-^{13}C, the calculated $k'_{SOH}/2k_{r(Tol)}$ would be 6.4 to 7.3, and $k_{r(Tol)}/k_{r(Ph)}$ would range between 3.2 and 6.4, rather than the value of 4 derived from using the mean scrambling values in the calculations. In the same way, for the reactions in HOAc–AgOAc (5), the use of the observed extreme values of 1.5 to 2.0% scrambling for *cis*- and *trans*-**4**-Br-*2*-^{13}C and 13–14% scrambling for **5**-Br-*2*-^{13}C would give $k_{r(Tol)}/k_{r(Ph)}$ ranging between 4.2 and 6.3, instead of 5 calculated using the mean scrambling values. Thus with the data from these two reactions in HOAc–AgOAc and in 70% HOAc – 30% H_2O, the calculated migration ratios for Tol/Ph are within experimental errors. Considering these results together with the corrected value for $k_{r(An)}/k_{r(Ph)}$ of 162 as discussed earlier, the relative migratory aptitudes of Ph:Tol:An in triarylvinyl cations in acetic acid media would be 1:4 – 5:162. These values are certainly of the order expected when compared with the well-known migratory aptitudes of these aryl groups reported for pinacol–pinacolone type of rearrangements in saturated carbocationic systems (10,11). It should be pointed out, however, that this set of migratory aptitudes for Ph:Tol:An is based on $k_{r(Tol)}/k_{r(Ph)}$ derived from migrations in the tritolylvinyl and 2-phenyl-1,2-ditolylvinyl cations, in which the migration terminus has an α-tolyl substituent, and $k_{r(An)}/k_{r(Ph)}$ derived from migrations in the 2-anisyl-1,2-diphenylvinyl and triphenylvinyl cations, in which the migration terminus has an α-phenyl substituent. It would be of interest to evaluate additional data on relative migration ratios from the 2-anisyl-1,2-ditolylvinyl and 2-tolyl-1,2-diphenylvinyl cationic systems in order to ascertain what effects the migration terminus may have on these migratory aptitudes.

Another evaluation of $k_{r(Tol)}/k_{r(Ph)}$ has been made by Lee *et al.* (5) using data from reactions of *cis*- and *trans*-**4**-Br-*2*-^{13}C and **5**-Br-*2*-^{13}C with CF_3COOH–CF_3COOAg but without taking into account the statistical factor of 2 for the reaction with **5**-Br-*2*-^{13}C. From the reported 34–35% and 46–47% scramblings, respectively, for *cis*- and *trans*-**4**-Br-*2*-^{13}C, and **5**-Br-*2*-^{13}C, the recalculated $k_{r(Tol)}/k_{r(Ph)}$, in trifluoroacetic acid, ranges between 2.5 and 3.6. This range of values appears to be somewhat lower than those obtained for reactions in HOAc–AgOAc or 70% HOAc – 30% H_2O, but it still overlaps with the range of 3.2 to 6.4 for the reaction in 70% HOAc – 30% H_2O. Since the stability and lifetime of a triarylvinyl cation should affect the extent of aryl migrations in the cation, some solvent dependency for migratory aptitudes might be expected. For the $k_{r(Tol)}/k_{r(Ph)}$ ratios discussed in the present work, no solvent dependency is found in HOAc–AgOAc and in 70% HOAc – 30% H_2O. However, in the more polar CF_3COOH–CF_3COOAg, when compared with HOAc media, the effect is apparently becoming observable, although the large range of values obtained may still fall within the extremes of the regions of experimental errors.

It should also be pointed out that in the work with *cis*- and *trans*-**3**-Br-2-Ph-d_5 (2), an An/Ph migration ratio has been calculated based on the processes given in Scheme 2, in which solvolysis in aqueous EtOH is used as an illustration. From Scheme 2, using the treatment of Bonner and Collins (1) and neglecting isotope effects, eqs. [4] and [5] were derived (2), eq. [5] being a specific example of the more general eq. [1]. For solvolysis in 60% EtOH,

$$[4]\quad [\mathbf{8}\text{-2-Ph-}d_5]/([\mathbf{9}\text{-2-Ph-}d_5] + [\mathbf{9}\text{-1-Ph-}d_5]) = k_{r(Ph)}/k_{SOH}$$



$$[5]\quad [\mathbf{9}\text{-2-Ph-}d_5]/[\mathbf{9}\text{-1-Ph-}d_5] = 1 + (k_{SOH}/k_{r(An)})$$

since **8** and **9** were formed to the extent of 5 and 95%, respectively (2,12), using eq. [4], $k_{SOH}/k_{r(Ph)}$ was calculated to be 19. The extent of degenerate rearrangement (2 × % scrambling of the Ph-d_5 label from C-2 to C-1 in **9**) in 60% EtOH was found to be 88.6–90.7%, and using eq. [5], $k_{r(An)}/k_{SOH}$ was found to be about 4.0. Hence the order of reactivity for $k_{r(An)}$:k_{SOH}:$k_{r(Ph)}$ in 60% EtOH was 76:19:1. In a similar way, using data from the reaction of *cis*- and *trans*-**3**-Br-2-Ph-d_5 with HOAc–AgOAc, the ratios for $k_{r(An)}$:k_{SOH}:$k_{r(Ph)}$ were calculated to be 120:19:1. Thus it was concluded that the migration ratio of An/Ph in rearrangement processes in the 2-anisyl-1,2-diphenylvinyl cation (**6**) was in the range of 76–120 (2).

On checking the integration using the method of Bonner and Collins (1) for the processes in Scheme 2, an error was found in eq. [4], which should be

$$[4a]\quad [\mathbf{8}\text{-2-Ph-}d_5]/[\mathbf{9}\text{-2-Ph-}d_5] = k_{r(Ph)}/k_{SOH}$$

corrected to [4*a*]. For solvolysis in 60% EtOH, with a degenerate rearrangement of 88.6–90.7%, the product distribution for **8**-2-Ph-d_5, **9**-2-Ph-d_5, and **9**-1-Ph-d_5 should be about 5, 52, and 43%, respectively. Thus from eq. [4*a*], $k_{SOH}/k_{r(Ph)}$ is about 10, instead of the reported 19, and the ratios for $k_{r(An)}$:k_{SOH}:$k_{r(Ph)}$ should be 40:10:1, not the reported 76:19:1. Similarly, for the reaction with HOAc–AgOAc, the corrected ratios for

SCHEME 2

$k_{r(An)}$:k_{SOH}:$k_{r(Ph)}$ should be 63:10:1. These corrected values suggest that in the rearrangement processes in cation **6**, the An/Ph migration ratio is in the range of 40–63, not the reported 76–120.

It is not surprising that the An/Ph migration ratio of 40–63, evaluated from the processes in Scheme 2, is much lower than the value of 162 derived earlier from the data obtained in the reactions of *trans*-**3**-Br-2-Ph-d_5 and **2**-Br-*2*-^{14}C with HOAc–AgOAc. In the rearrangement processes depicted in Scheme 2, there is a greater driving force for the $k_{r(Ph)}$ process since the 1,2-phenyl shift from the α-phenyl substituted cation **6** gives rise to a more stable α-anisyl substituted cation **7**, whereas the $k_{r(An)}$ process results in a degenerate rearrangement between α-phenyl substituted cations **6** and **6r**, both of which have the same energy. When the data from reactions of *trans*-**3**-Br-2-Ph-d_5 and **2**-Br-*2*-^{14}C with HOAc–AgOAc are compared, the scramblings arise from degenerate rearrangements in both reactions, which differ only in the migrating An and Ph groups, the phenyl substituents at the migration origin and migration terminus being the same. There is no inherently higher driving force for $k_{r(Ph)}$ over $k_{r(An)}$ as in Scheme 2, and hence the higher value of 162 was obtained for $k_{r(An)}/k_{r(Ph)}$.[2]

Experimental

Solvolyses of cis- *and* trans-*2-phenyl-1,2-di*-p-*tolyl[2-*^{13}C*]-vinyl Bromides (*cis- *and* trans-*4-Br*-2-^{13}C*) or Tri*-p-*tolyl-[2-*^{13}C*]vinyl Bromide (5-Br*-2-^{13}C*) in 70% HOAc – 30% H_2O*

A 3:2 mixture of *cis*- and *trans*-**4**-Br-*2*-^{13}C as well as **5**-Br-*2*-^{13}C were prepared as reported previously (4, 5). The solvolyses were carried out in a similar way as was described for the analogous reactions with triphenyl[2-^{14}C]vinyl bromide (**2**-Br-*2*-^{14}C) (6). A general procedure is given below.

A solution (47 m*M*) of 690 mg (1.9 mmol) of *cis*- and *trans*-**4**-Br-*2*-^{13}C or 712 mg (1.9 mmol) of **5**-Br-*2*-^{13}C in 40 mL of 70% HOAc – 30% H_2O (by volume) was placed in a sealed tube and heated in an oil bath at 150 ± 1°C for the desired length of time as recorded in Table 1. After cooling in an ice bath the tube was opened, H_2O was added, and the mixture was extracted three times with 25 mL portions of $CHCl_3$. The extract was washed with H_2O and dried over $MgSO_4$. The liberated bromide ion in the combined aqueous phase was determined by potentiometric titration (12) to give the extent of reaction. From the organic extract, removal of the $CHCl_3$ gave an oil which may contain the product, triarylethanone, as well as the unconsumed reactant, triarylvinyl bromide. $LiAlH_4$ reduction (4, 5) would convert the product to the corresponding 1,2,2-triarylethanol and any unconsumed reactant to triarylethene (9). Separation of the alcohol from the olefin was effected by passage through an alumina column in a similar way as recently described for the separation of 1,2,2-trianisyl[1,2-^{14}C]ethanol and 1,2,2-trianisyl[1,2-^{14}C]ethene (13). The triarylethanols so obtained from the reactions with *cis*- and *trans*-**4**-Br-*2*-^{13}C and with **5**-Br-*2*-^{13}C were analyzed by ^{13}C nmr in the same way as reported earlier (4, 5) to give the results summarized in Table 1.

Studies with cis- *and* trans-*4-Br*-2-^{14}C *and with 5-Br*-2-^{14}C

The ^{14}C-labeled substrates were prepared in the same way as the analogous ^{13}C-labeled bromides. Four solvolyses in 70% HOAc – 30% H_2O at 150 ± 1°C in sealed tubes were carried out with 47 m*M cis*- and *trans*-**4**-Br-*2*-^{14}C for 70 and 140 min and with 47 m*M* **5**-Br-*2*-^{14}C for 50 and 90 min, and these correspond to about 50 and 75% reactions for each substrate (Table 1). Work up of the reaction mixture was effected in the same way as described for the experiments with the ^{13}C-labeled substrates. After $LiAlH_4$ reduction and separation of the alcohol from the olefin through the alumina column, the 1,2,2-triaryl[2-^{14}C]ethene, derived from the unconsumed reactant, was diluted with inactive carrier and subjected to degradation by ozonolysis (13) to give the corresponding diaryl ketone, whose ^{14}C activity indicated no appreciable scrambling of the label in the recovered reactant in all four experiments.

[2]The corrected values from the present work have also been given in a recent book (14).

Synthesis and physical studies of pyridine and imidazole containing tridentate metal binding ligands

R. S. BROWN AND J. HUGUET

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 26, 1979

R. S. BROWN and J. HUGUET. Can. J. Chem. **58**, 889 (1980).

Several tridentate ligands incorporating pyridine and substituted imidazoles were prepared and their physical properties studied as models for the enzyme carbonic anhydrase (CA). The H^+ and M^{2+} binding abilities (pK_a and $pK_{M^{2+}}$) were determined. In the case of the imidazole ligands, *N*-methylation reduces the metal binding ability of the ligand by some 3–4 $pK_{M^{2+}}$ units over the analogues in which the imidazole has N—H. ^{1}H-nmr studies of the simple ligands as a function of $[Zn^{2+}]$ show that the ligands are bound symmetrically as 1:1 and 2:1 complexes depending upon the ligand/metal ratio. Increasing the steric bulk of the ligands by introduction of 4,5-diisopropyl substituents on the imidazole inhibits the 2:1 (ligand/metal) complex. Titration experiments of several ligands bound to equimolar Zn^{2+} and Co^{2+} are described and analysed.

R. S. BROWN et J. HUGUET. Can. J. Chem. **58**, 889 (1980).

On a préparé plusieurs ligands tridentates incorporant la pyridine et des imidazoles substituées et on a étudié leurs propriétés physiques en tant que modèles de l'enzyme anhydrase carbonique (AC). On a déterminé les capacités de liaison H^+ et M^{2+} (pK_a et $pK_{M^{2+}}$. Dans le cas des ligands de l'imidazole, la capacité de liaison du métal par le ligand des produits *N*-méthylés est réduite de quelques 3–4 unités $pK_{M^{2+}}$ par rapport aux analogues non méthylés. Les études de rmn du ^{1}H sur les ligands simples en fonction de la $[Zn^{2+}]$ montrent que les ligands sont liés symétriquement sous la forme de complexes 1:1 et 2:1 dépendant du rapport ligand/métal. L'augmentation de l'encombrement stérique du ligand par l'introduction des substituants diisopropyle-4,5 sur l'imidazole inhibe le complexe 2:1 (ligand/métal). On décrit et analyse des expériences de titrage de plusieurs ligands liés équimoléculairement au Zn^{2+} et Co^{2+}.

Introduction

Some time ago we initiated a project to synthesize and study synthetic analogues for the Zn^{2+}-binding site of Carbonic Anhydrase (CA) (1).[1] X-ray diffraction studies of CA suggest the active site consists of a Zn^{2+}-ion coordinated pseudotetrahedrally to three histidine imidazoles; the fourth ligand site is said to be occupied by an ionizable H_2O believed important for the catalytic process (2).

Our intent was to construct a series of tridentate ligands (**1–9**) and through their study provide some verification for any of the several proposed mechanisms of action of CA (2–5).[2] The ligands were screened by subjecting them to the following physical studies prior to the initiation of any catalysis studies. Firstly, the ligands must be shown to have a high affinity for divalent metals so the metal binding constants for Zn^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+} were determined. Secondly one must show that the ligands are indeed (symmetrically) tridentate when bound to Zn^{2+} so the ^{1}H-nmr spectra of the simple ligands (**1–4**) in D_2O containing varying ligand: Zn^{2+} ratios were obtained.

Lastly, the hydration ability of CA is tied to an ionizable group with a $pK_a \sim 7$ with the basic form being most active (1*e*). While the ionization of a Zn^{2+}—OH_2 is attractive mechanistically (for a compendium of literature pertaining to this point, see ref. 7) it has (to our knowledge) never been demonstrated that simple Zn^{2+} coordination can reduce the pK_a of H_2O so drastically (8).[3] Although the following account shows that each of ligands **1–9** possesses some deficiency which casts considerable doubt on their applicability as "models" for CA, several important observations are reported which provide information defining the minimum features such models must possess.

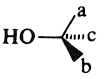
Results and Discussion

(i) H^+ and M^{2+} Binding Constants

Hydrogen (pK_a) and metal ($pK_{M^{2+}}$) binding con-

[1] CA is a metallo-enzyme which catalyses the hydration of CO_2, certain aldehydes (1*a*), and hydrolysis of esters such as *p*-nitrophenylacetate (1*b*, *c*) and 2-hydroxy-5-nitrotoluenesulfonic acid sultone (1*d*).

[2] While this study was in progress a report on the synthesis and preliminary study on two tris-imidazole carbinols appeared which in some respects paralleled this work (2-TIC or tris(2-imidazolyl) carbinol, $pK_{1\ Zn^{2+}} = 6.77$, $pK_{1\ Co^{2+}} = 7.20$; $pK_1 = 6.12$, $pK_2 = 3.59$, ref. 6). NOTE ADDED IN PROOF: Recently Boggess and Boberg (25) reported some first row transition metal complexes of tris-2-pyridyl carbinol, and some of their physical properties.



[3] Two reported examples for 5-coordinate Zn^{2+} show pK_a's for Zn^{2+}—OH_2 of 9.0 (8) and 8.69 (3*b*). That reported for $(NH_3)_5Co^{3+}$—OH_2 is 6.4 (5), the lower value presumably being due to the greater metal charge. A referee has suggested that the change in ligand field experienced by the d^6 Co^{3+} in passing from CO^{3+}—OH_2 to Co^{3+}—OH^- is also an important factor.

stants were determined by potentiometric titration methods outlined by Alberts and Serjeant (*9a*) and Rossotti and Rossotti (*9b*). Data were analysed by a modified computer version[4] of the Simms' method (10) and the pK_a's are presented in Table 2 while the metal stability constants for ligands **1**–**9** are presented in Table 3.

From Table 2, one sees no predictable trend in the basicities for **1**–**4** although on the average the *N*-methylimidazoles are more basic. Where comparison can be made between those ligands containing N—CH_3 and N—H imidazoles (i.e., **2** and **5**; **4** and 2-TIC (6)) the latter appears to be more basic at least at pK_1 and pK_2. The pK_a's of the 4,5-disubstituted imidazoles were determined in increasingly organic media for reasons of solubility and therefore cannot rigorously be compared with those values determined in water. As can be seen from the two sets of data reported for **6**, in the more organic environment the pK_a's are on the average lower, consistent with expectations based on solvent polarity, and clearly 4,5-substitution increases the basicity as expected.[5]

Ligand **9**, in which the 4,5-dimethylimidazole is extended from carbinol centre by a methylene unit, is the most basic particularly at pK_2 and pK_1. Presumably the large pK_2 value (when compared with **6**, **7**, or **8**) is due to increased separation of the positive charges (6).

From Table 3, the general ordering for metal stability constants for **1**–**6** is $Zn^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+}$ and a first and second binding constant indicative of a 1:1 (L:M^{2+}) and 2:1 (L:M^{2+}:L) complex was obtained for each. Ligands **7** and **8** with 4,5-diisopropyl substituents appear from space-filling models to encapsulate the metal sufficiently to inhibit 2:1 complexation, and the stability constants obtained indicate *no* second binding constant. It is worthy of note that for CA_1 the order of stability constants is $Cu^{2+} > Zn^{2+} > Ni^{2+} > Co^{2+}$ at pH 5.5 (11) and the metal–ligand geometry is demonstrated to be distorted tetrahedral at least for Zn^{2+} and Co^{2+} (11). While we have no details for the coordination numbers for **1**–**6**:M^{2+} complexes

TABLE 2. pK_a's for ligands **1**–**9** determined by potentiometric titration[a]

Ligand	pK_3	pK_2	pK_1

other than those implied from uv studies with Co^{2+} (*vide infra*), **7**, **8**, and **9** appear from models only to allow tetrahedral geometry if they are bound symmetrically. It would appear from Table 3 that Zn^{2+} is bound to **7** and **9** stronger than is Co^{2+} perhaps as a result of the enforced tetrahedral geometry. The data for **8** seem to indicate that Zn^{2+} and Co^{2+} binding are equivalently weak. Finally it is of note that **9** binds metal in the order $Cu^{2+} > Zn^{2+} > Ni^{2+} > Co^{2+}$ parallel to that for CA_1, although the former values are about 4 p*K* units lower than those for the enzyme.

A pattern emerges when one considers the stability constants for N—CH_3 imidazole derivatives **2**, **8**, and **4** when compared to their N—H imidazole analogues (**5**, **7**, and 2-TIC (**6**)) respectively. In every case *N*-methylation reduces the metal binding ability of the ligands by some 3–4 p*K* units. While we have no unambiguous reason for the stronger binding ability of N—H vs. N—CH_3 imidazoles, the phenomenon may be related to a better solvation of the former when bound to metal as in reaction [1].

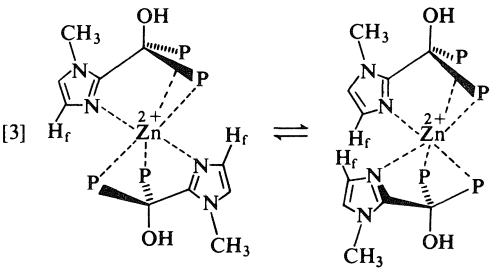
(ii) Nuclear Magnetic Resonance Studies

^{1}H-nmr spectra of roughly 10^{-2} *M* solutions of ligands **1–4** were determined in D_2O as a function of increasing [$ZnBr_2$]. After subsequent additions of Zn^{2+}, the pD (pD = pH(meter reading) + 0.4, ref. 12) of the test solutions decreased due to release of protons from the ligand accompanying metal binding, and the pD of the solutions at the end of the Zn^{2+} additions was in the order of 4. This is important since the previous (*vide supra*) potentiometric titrations to determine $pK_{Zn^{2+}}$ constants invariably showed the complexes to be fully formed by pH ~3.5. Chemical shifts for ligands **1–4** and the Zn^{2+} complexes for **1** and **2** are given in Table 4.

Some interesting trends that provide information about the structure of the complexes are apparent from consideration of the data for **1**; the pyridine-H spectral region is illustrated in Fig. 1. Assignments are easily verified by comparing the spectra of **1** and d-**1** (Fig. 2). Subsequent additions of Zn^{2+} showed the build-up of an additional set of resonances at the expense of those for **1**, and finally when the **1**/Zn^{2+} ratio was 2, a clean spectrum was produced indicative of a symmetrically bound 2:1 complex (Fig. 1). Now it appears that H_D is the low field resonance at δ 8.54 coupled to H_C at δ 8.25 (J_{CD} = 7.6 Hz). By elimination H_A in the 2:1 complex is shifted *upfield* to δ 7.7 and is coupled to H_B at δ 7.40 (J_{AB} = 5.4 Hz). This upfield shift probably occurs because H_A in the 2:1 complex lies very close to and above the plane of a pyridine group of a second ligand,[6] (13) and is therefore shielded by the latter's ring current. Unambiguous confirmation of these assignments is provided by the spectrum of the analogous 2:1 complex of d-**1** in Fig. 2.

These observations are important when considering the spectra for **2** and its Zn^{2+} complexes illustrated in Fig. 3. The middle spectrum again shows downfield shifts for H_D and H_C and an upfield shift for H_A; the position of H_B remains roughly unchanged. A sizeable downfield shift of 0.74 ppm is observed for the imidazole N—CH_3, as well as some small signals attributable to some residual uncomplexed **2**. Increasing [Zn^{2+}] causes a new set of resonances to appear at the expense of those from **2** and its 2:1 complex, until a symmetric pattern is obtained when the Zn^{2+}/**2** ratio is 15. We believe this final spectrum is that of the 1:1 complex of **2** and note that the pyridine H_A has shifted downfield once it is removed from the proximity with the second ligand. The spectral parameters for d-**2** confirm the assignments (Table 4 and Fig. 4).



From the above, one can reasonably conclude that these molecules exist as symmetrically bound complexes in solution, and that both the 2:1 and 1:1 complexes exist depending on the ligand: Zn^{2+} ratio. It is noteworthy that for the equilibrium (reaction [2]),

$$[2]\quad 2L + Zn^{2+} \rightleftarrows \underset{\text{(1:1 complex)}}{L + L{:}Zn^{2+}} \rightleftarrows \underset{\text{(2:1 complex)}}{L{:}Zn^{2+}{:}L}$$

the rate of interchanging the species is slow on the nmr timescale since separate resonances are observed for each species.

Rotation within the 2:1 Complex of 2

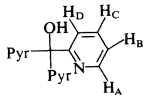
From the middle spectra in Fig. 3 and Fig. 4 it can be seen that the imidazole hydrogens, H_e and H_f, appear as a singlet at δ 7.10 and a pair of fortuitously equal intensity broadened singlets at δ 6.44 and δ 6.62 respectively. Variable temperature ^{1}H-nmr studies on this sample showed that at temperatures above 320 K, the latter two peaks coalesce into a singlet centred at δ 6.52. From reaction [3] in the symmetrically bound 2:1 complex H_f of one imidazole can be positioned between two pyridines of the second ligand (**10**) or between an imidazole and a pyridine of the second ligand (**11**). This should give rise to two different shieldings for H_f.[7]

[3] 

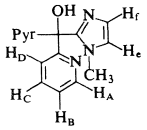
10 **11**

From $\Delta\nu_{H_f}$ (20 cps at 100 MHz) and a coalescence temperature of 320 K, one can calculate[8] that site exchange (**10** ⇄ **11**) occurs with a rate constant of 44 s^{-1} and that the activation energy for the process is about 16 kcal/mol.

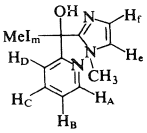
(iii) Complex Titration

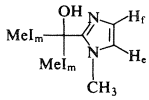


Of particular importance to the activity of CA, and therefore to any system designed to mimic CA, is the activity related ionization of a group with a pK_a of 7 (3). Tetrahedrally coordinated Zn^{2+}—OH_2 has been theorized to have such a low pK_a in the



[6]This same effect has been noted before in the nmr spectrum of [$Fe^{II}Bipyr_3$]Cl_2 (13).





[7]At a temperature of 5°C, the high resolution ^{1}H-nmr spectrum of this complex shows two equal intensity imidazole N-CH_3 resonances separated by 2 Hz, in agreement with an equilibrium mixture of **10** and **11** as well as two sets of aromatic resonances very close together.

[8]For equal populations of two equilibrating species A and B (**10** and **11**) the residence time (τ) in site A or B is given as $\tau = 0.225/\Delta\nu$ where $\Delta\nu = \nu_A - \nu_B$ (23).

enzyme, and most recent work has favored this process (3, 7). Arguments against the ionization of Zn^{2+}—OH_2 centre on the lack of precedent (1*a*, 14) and ideas that Zn^{2+}—$\bar{O}H$ may not be sufficiently nucleophilic to account for the rate of hydration of CO_2 by CA.

On the other hand, ionization of Zn^{2+}-bound imidazole has been proposed to account for the low pK_a (4) with some experimental justification in simple complexes (4*a*), although it is observed in comparison of $(NH_3)_5Co^{3+}OH_2$ and $(NH_3)_5Co^{3+}$Im—H that Co^{3+} coordination in the latter reduces the

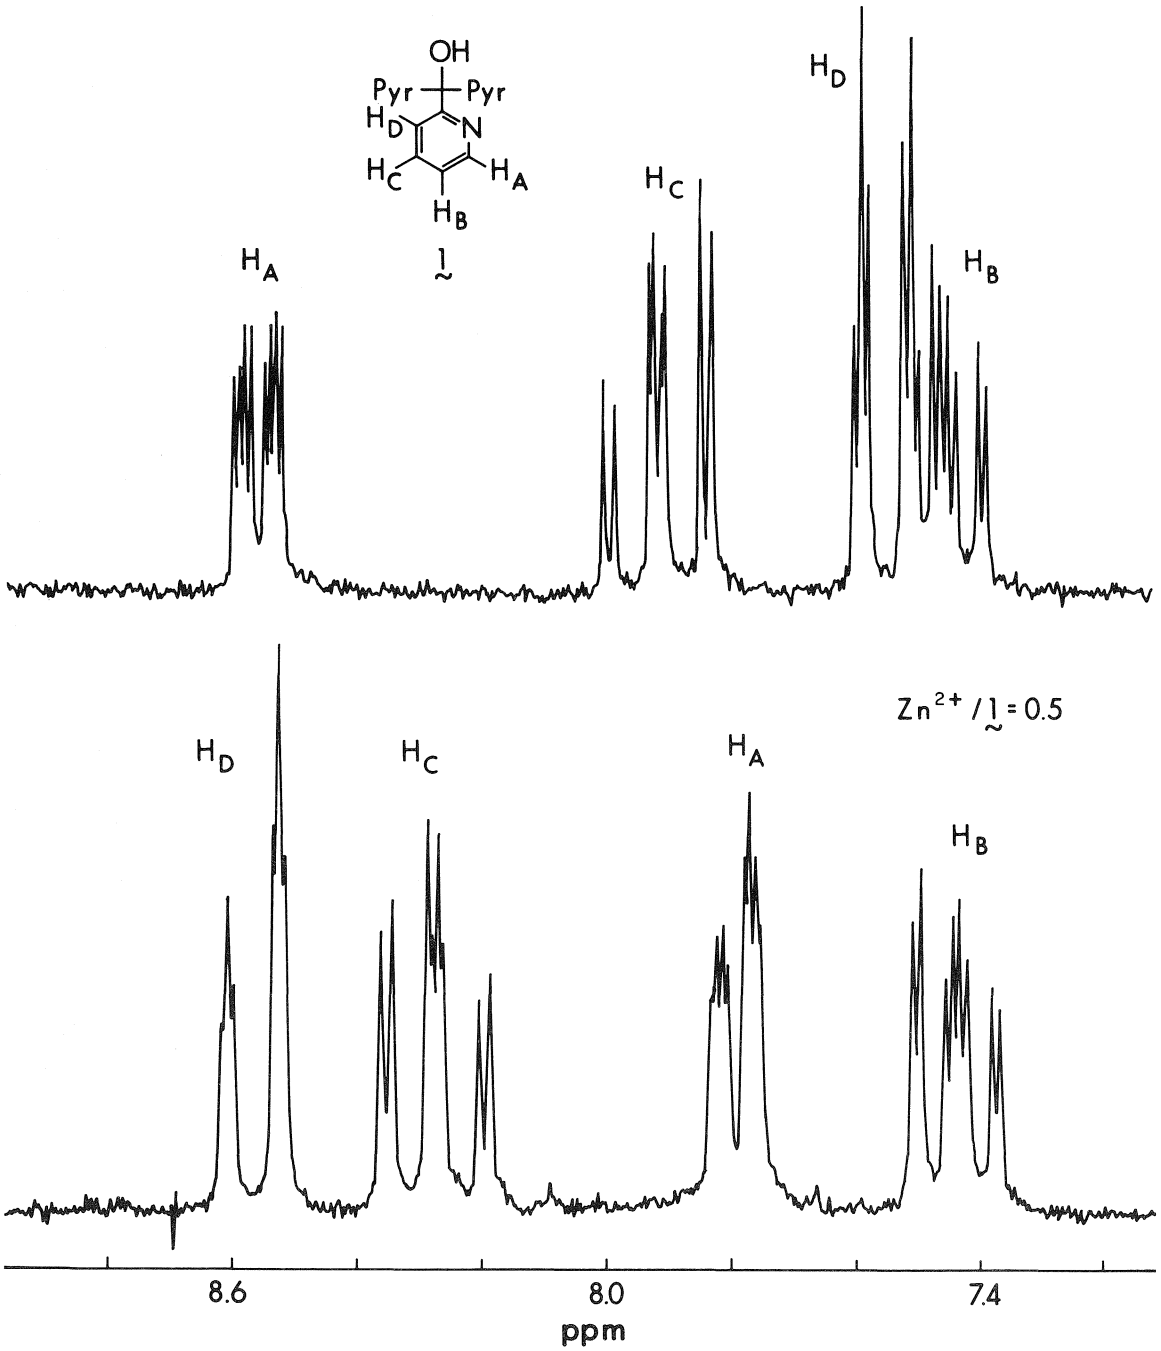

FIG. 1. The ^{1}H-nmr spectra of **1** and its 2:1 Zn^{2+} complex in D_2O. See Table 3.

ImH pK_a from 14 to only 10 while the pK_a of H_2O in the former is reduced from 15.5 (accounting for H_2O concentration) to 6.4 (5).

In order to cast some light on the above question, ligands **2** and **5**, differing only by *N*-methylation of the imidazole, were complexed to an equivalent amount of M^{2+} and titrated with NaOH. In both cases, titration of the free bases (0.025 mmol) in a solution containing 0.1095 mmol HNO_3 showed complete release of all added protons after pK_1 had been passed, and that this process was completely reversible. When bound to equimolar Zn^{2+}, **5** showed complete release of added H^+ by ~pH 3.5 indicating that metal binding was complete by that

point, and the additional release of 0.025 mmol H^+ (1.0 equiv. based on **5**:Zn^{2+}) upon further titration indicative of Zn^{2+}—OH_2 *or* Zn^{2+}—ImH ionization with an apparent pK_a of 6.98. Ultraviolet spectra of the solution on either side of the apparent pK_a showed no substantial changes and the solution remained clear until at least pH 10, indicating the free [Zn^{2+}] was very low. Analogous titration of **2** in the presence of Zn^{2+} curiously showed the release of only 0.8 equiv. (based on **2**—Zn^{2+}—OH_2) of H^+ at the apparent pK_a of 6.50 and not the expected 1.0. The inability to account for all the H^+ as-

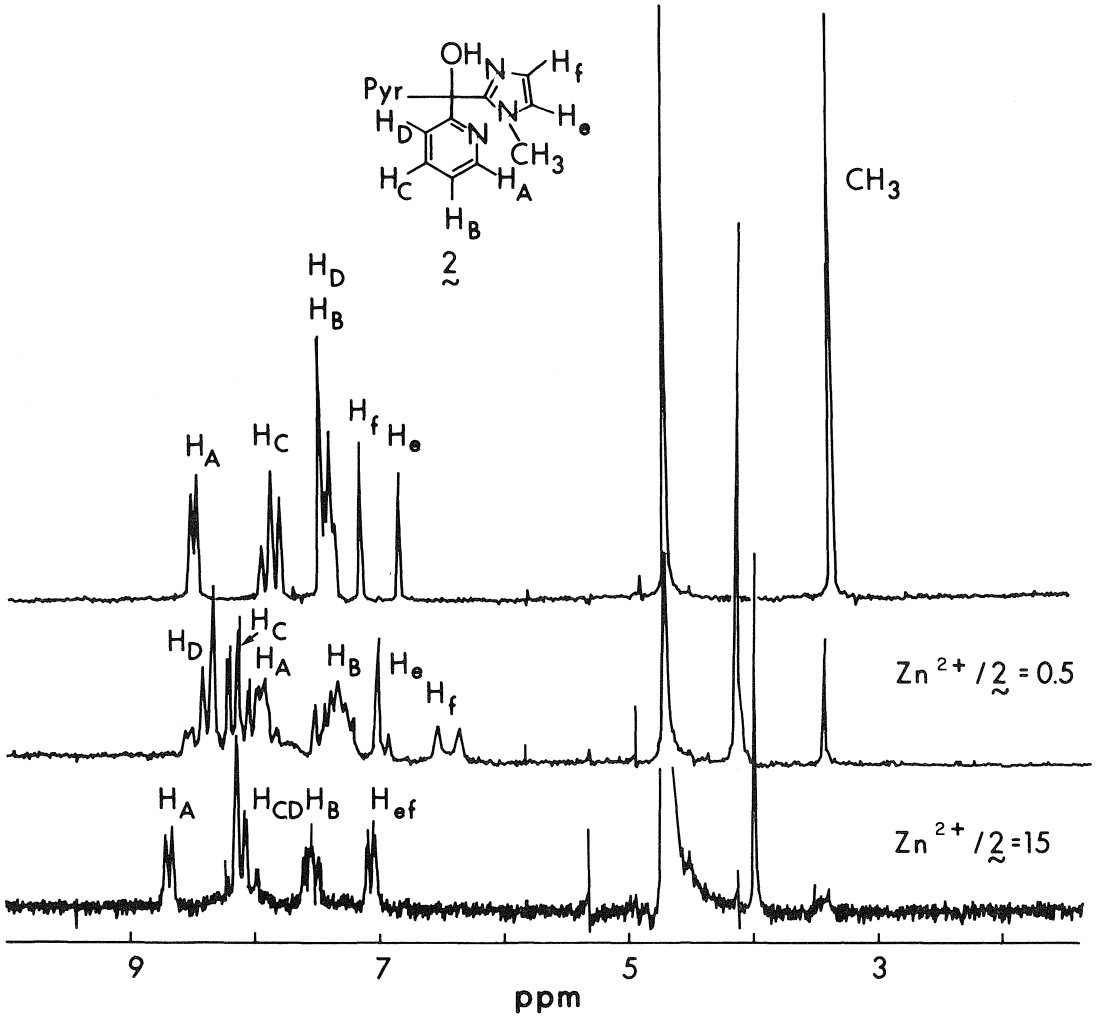

FIG. 3. The ^{1}H-nmr spectrum of **2** as a function of increasing $[Zn^{2+}]$. See text and Table 3 for assignments. The resonance at δ 4.8 is attributable to HOD.

sociated ionization of the complex *may* be associated with either incomplete formation of a 1:1 complex (i.e., some free ligand and some 2:1 complex which is not expected to have such a low pK_a (3*b*, 15)) or an equilibrium distribution of 4,5- and 6-coordinate Zn^{2+}:ligand complexes, the latter two not having such a low pK_a (15). Again, uv spectra of the solutions above and below the apparent pK_a showed minimal differences.

One might on the basis of these observations conclude that the apparent pK_a is best explained by ionization of a Zn^{2+}—OH_2, but this is almost certainly suspect since neither titration is reversible. ^{1}H-nmr spectra of Zn^{2+}:**2** and Zn^{2+}:**5** which had been titrated past the apparent pK_a's showed that the species formed was symmetric on the nmr timescale, although the ^{1}H-nmr absorptions were too broad to be definitive. We tentatively speculate that one possible explanation for the irreversibility of the titrations might be dimer formation as in path *a* or *b* of reaction [4], although one would think that these "dimers" would revert back to L:Zn^{2+}—OH_2 quickly in acid solution.

While some precedence for the existence of oxy and hydroxy bridged Zn^{2+} dimers is available (16) such bridged species are more commonly found with first row transition elements such as Co^{II}, Cu^{II}, Ni^{II}, and Fe^{III} (17).

The Co^{2+} complexes of **2** and **5** also show an apparent pK_a at 8.75 and 8.04 respectively. Ultraviolet spectra of each above and below the apparent pK_a do not show evidence of tetrahedrally bound Co^{2+} since no blue color is observed (18). Hence in these systems what appears to be simple

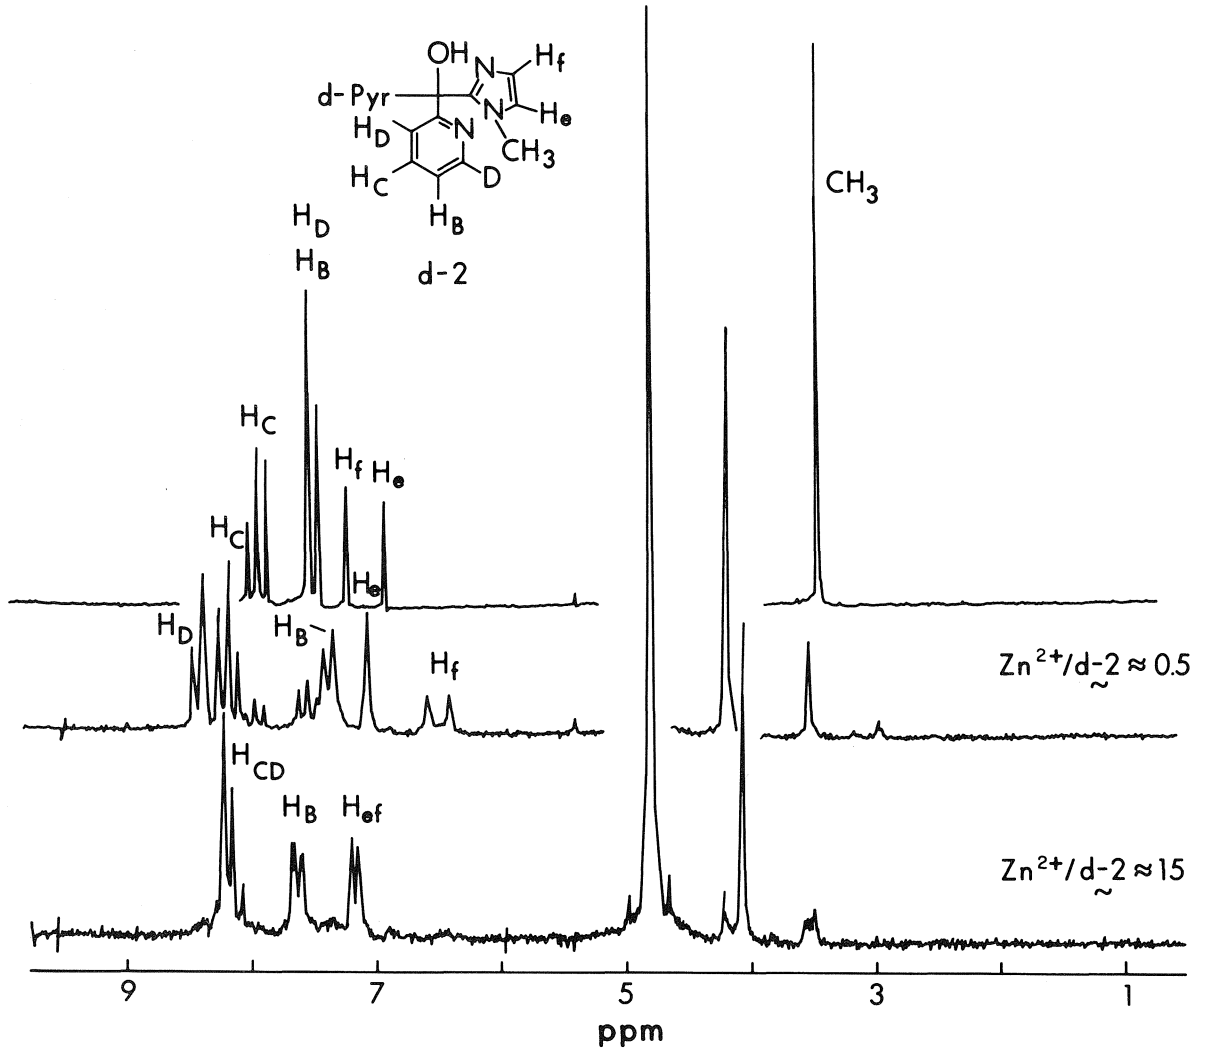

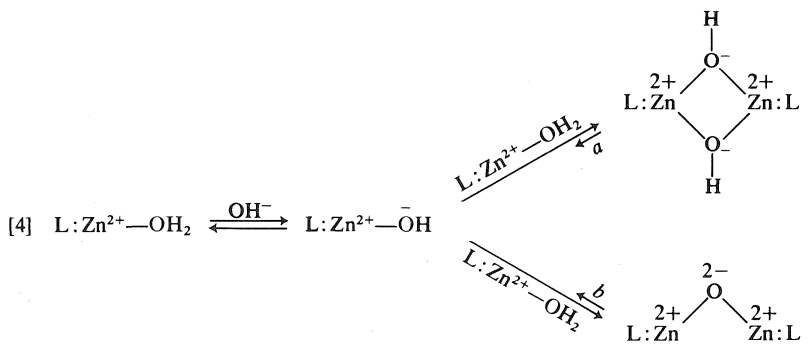

FIG. 4. The ^1H nmr of d-**2** as a function of increasing $[Zn^{2+}]$. The large resonance at δ 4.8 is attributable to HOD. For a discussion of the resonances attributable to H_f see text.

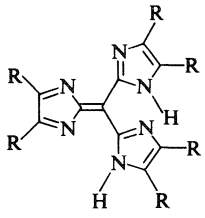

M^{2+}—OH_2 titration is not sufficient to enforce a tetrahedral geometry for Co^{2+}, but does not rule out that possibility for Zn^{2+}.

In order to circumvent this irreversibility ligands **6**–**8** having progressively bulkier substituents at the 4,5-positions were investigated. From space filling models, not only do **7** and **8** enforce tetrahedral binding for the metal, but the possibility of oxy-

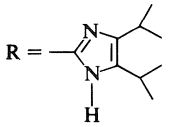
For personal use only.

bridged dimers is reduced since there should be severe buttricing between the isopropyl groups on adjacent ligands. Titration of Zn^{2+}:**6** performed analogously to those of Zn^{2+}:**5** and Zn^{2+}:**2** showed the consumption of 1.0 equiv. of ^{-}OH at about pH 7, but this was tied to the reversible formation of an intensely blue-colored solution which indicates the ligand itself suffers some modification. Ligand **7**, even at acid pH, when complexed with Zn^{2+} gave a bright pink solution. We note that upon drying (for microanalytical purposes) both **6** and **7** tended to dehydrate (as evidenced by the buildup of an M^{+}—H_2O peak in the mass spectrum) to form intensely colored crystals which appear to possess extensive conjugation as might be expected for a fulvene-like **12** (reaction [5]). ^{1}H-nmr experiments on these crystals in $CDCl_3$ solution showed complete molecular symmetry as expected if the alkyl groups were tautomerically equivalent on the nmr timescale.

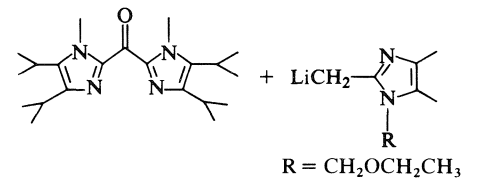


[5] **6** or **7** $\xrightarrow[\Delta]{-H_2O}$ 

12

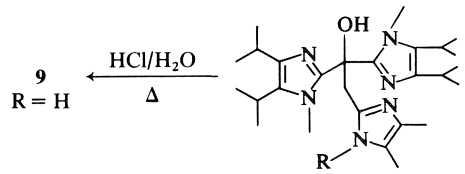
R = CH_3, $CH(CH_3)_2$

In order to circumvent this dehydration, the OH group was replaced with H according to the scheme in reaction [6].



[6] **7** $\xrightarrow[\Delta]{NaOH/H_2O,\ Na_2S_2O_4}$ 

R = 



The corresponding methane was present as evidenced by a ^{1}H-nmr singlet at δ 5.4, and the material appeared reasonably stable as its HCl salt. Unfortunately in basic media, the methine H proved extremely susceptible to air oxidation which reconverted it back to **7** which again suffered deleterious dehydration to form what we believe is **12**.

Ligand **8** on the other hand showed no propensity to form colored solutions (again supporting dehydration of **6** or **7**) and was therefore titrated (for reasons of solubility **8** required a titration medium of 80% aqueous dioxane) in the presence of equimolar Zn^{2+}. In this case, curiously at "pH" 7 two equivalents of $\bar{O}H$ were consumed and the process was reversible. Control experiments under the same conditions but in the absence of **8** showed again the consumption of 2 equivalent $\bar{O}H$ at a "pH" of 7 which is clearly tied to the formation of $Zn(OH)_2 \cdot xH_2O$, but the latter species appears quite soluble in the medium. Thus it would appear that because Zn^{2+} binds to **8** only weakly ($pK_{Zn^{2+}} \simeq$ 4, Table 2) that at elevated "pH", OH^{-} simply sequesters the metal away from the ligand.

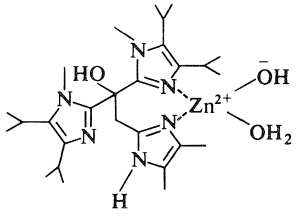
Our final ligand in this series (**9**) from the above experiences was designed to prevent 2:1 ($L:M^{2+}$) binding, oxy or hydroxy-bridged dimers, and the deleterious dehydration in the presence of Zn^{2+} and OH^{-}. As well, for reasonable metal binding, at least one imidazole (NH) was required, and **9** was prepared as shown in reaction [7].

[7] 

R = $CH_2OCH_2CH_3$

13

R = $CH_2OCH_2CH_3$



9 R = H

Deprotection of **13** in refluxing 10% HCl water proved to be very slow, requiring nearly two weeks to completely form **9**.

In 60% aqueous dioxane an equimolar mixture of **9** and Co^{2+} gave a blue colored solution (λ_{max} 580 nm, $\varepsilon_{min} = 60$ assuming complete 1:1 binding). Normally ε_{max} for tetrahedral cobalt is between 100 and 1000, depending on the system (18). In the presence of equimolar Zn^{2+}, **9** was titrated and showed the reversible consumption of 1 equiv. of OH^{-} at an apparent pK_a of 5.8 in the above medium. In the absence of **9**, Zn^{2+} under the same conditions showed precipitation of $Zn(OH)_2$ and the consumption of 2 equiv. of OH^{-} at around "pH" 7.

Interaction of **9** with Zn^{2+} is strong enough to hold the latter in solution, and the consumption of OH^{-} is consistent with Zn^{2+}:OH_2 titration (although the "pK_a" seems too low) or more likely

with ^-OH displacement of one of the weakly bound N—CH_3 imidazoles as in reaction [8].

[8] **9**:$Zn^{2+}OH_2 + OH^-$ ⇄ 

At this point we attempted some catalysis studies on solutions of **9**:Zn^{2+}—OH_2 at various "pH's" for both the hydrolysis of *p*-nitrophenyl acetate, and the hydration of acetaldehyde. Comparison of the reaction rates with metal, metal + ligand, and ligand at "pH" values between 5 and 10 showed no substantial differences so the complex present in this medium is not catalytically viable.

Conclusion

Although for various reasons, each of ligands **1–9** has some serious deficiency in terms of their ability to be considered as "models" for the metal binding site of CA, several important observations have been made which cast light on the minimum features such "models" should possess.

(*1*) N—CH_3 imidazole ligands bind metal rather poorly when compared with their N—H analogues. One clearly requires large $pK_{M^{2+}}$ values for a potential "model" for CA so that the metal will not be sequestered away from the ligand at elevated pH.

(*2*) Deleterious 2:1 (L:M^{2+}) binding can be overcome by placing large alkyl groups at the 4,5-imidazole positions. However such substitution in the tris-imidazole carbinol series appears to lead to facile dehydration to produce highly colored fulvene-like materials. Such dehydration can be overcome by removing the carbinol OH group, or methylating the imidazole nitrogen, however the former substitution of OH by H produces an extremely easily air-oxidized methane, and the latter *N*-methylation leads to rather poor metal binding ability.

(*3*) The small ligands **1–4** from nmr studies in D_2O solution can exist as 2:1 or 1:1 (L:M^{2+}) species, the latter being favored at high [metal].

Experimental Section

Routine ir and nmr spectra were obtained using a Nicolet FT-IR Spectrophotometer ($CHCl_3$ cast film) and a Varian A-60 spectrometer (D_2O or $CDCl_3$). Ligand/Zn^{2+} ^{1}H-nmr spectra were determined on a Varian HA-100-15 spectrometer with Fourier transform modifications provided by a Digilab FTS NMR-3 System. pK_a determinations were performed in a jacketted cell kept at 30 ± 0.1°C and under a nitrogen atmosphere. The pH was measured using a Radiometer TTT2 titrator and PHA 943 B titration module in conjunction with a Radiometer 6K2402B combined electrode, and recorded as a function of added 0.1000 *N* NaOH (delivered by a Radiometer ABU 12 autoburette), on a Radiometer SBR 3 titrigraph. Standard pH 4 and pH 7 buffers were used to check the electrode linearity and standardize the pH meter at the beginning of each series of experiments. The ionic strength was maintained constant by using a medium 0.16 *M* in KNO_3. Data were analysed by a computer version[4] of the Simm's method (10) and reported pK_a's are the average of at least three determinations. Metal binding constants were determined analogously to those reported (6). Stock solutions of Co^{2+}, Ni^{2+}, Zn^{2+}, and Cu^{2+} were prepared from their reagent grade hydrated nitrate salts and were standardized by EDTA titration. Typically a three to four-fold excess of ligand over metal was titrated as above and the data analysed to give metal binding constants which are reported as the average of three determinations.

*Bis(2-pyridyl)-2-(*N*-methylimidazolyl)carbinol (2)*

A solution of 0.9 g (0.11 mol) of *N*-methylimidazole (19) in 50 mL dry ether under N_2 was cooled to −30°C (suspension) and treated with 7.5 mL of 1.6 *M* *n*-butyllithium in hexane, followed by stirring at room temperature for 30 min. It was then cooled to −40°C and a solution of bis-2-pyridyl ketone (20) in 5 mL ether and 5 mL THF was added dropwise. After stirring at room temperature overnight the mixture was quenched with H_2O and the product was isolated by chloroform extraction. The combined extracts were dried ($MgSO_4$), and stripped of solvent to give a paste which was decolorized with charcoal and recrystallized from Skelly B / benzene to give 1.8 (61%) of white crystals: mp 153–155°C; ir 3350 (br), 1590, 1430, 1360, 1100 cm^{-1}; nmr (D_2O) Table 3; mass spectrum *m/e* 266 (M^+), 249 (M^+ − OH); *Anal.* calcd. for $C_{15}H_{14}N_9O$: C 67.67, H 5.26, N 21.05; found: C 67.98, H 5.37, N 21.07.

*Bis(2-pyridyl-6-*d*)-2-(*N*-methylimidazolyl)carbinol (d-2)*

It was prepared analogously to **2** but using bis-(2-pyridyl-6*d*) ketone. Nuclear magnetic resonance (D_2O) Table 3; mass spectrum *m/e* 268 (M^+), 251 (M^+ − OH).

*Bis-(2-pyridyl-6*d*)ketone*

A solution of 21 g (0.132 mol) of 2-bromopyridine-6*d* in 300 mL dry ether under N_2 was treated with 90 mL of 1.6 *M* *n*-butyllithium in hexane at −65°C. After two cycles of allowing the solution to warm to −45°C, and recooling to −65°C, 8 mL (0.067 mol) of diethylcarbonate was added keeping the temperature at −60°C. Stirring was continued for 2 h (−65°C) and then at room temperature overnight. Workup consisted of the addition of 8 g H_2SO_4 in 10 mL H_2O, followed by ether extraction. The combined extracts were dried (Na_2SO_4), and stripped of solvent to give a dark oil which after distillation gave a yellow oil, bp 120–140°C/0.15 Torr. Crystallization from toluene at −60°C afforded 6 g (24%) of off-white crystals, mp 51–53°C; ir 1680, 1575, 1430, 1320, 1300 cm^{-1}; ^{1}H-nmr ($CDCl_3$) δ 7.5 (2H, dd), 7.91 (2H, dd), 8.13 (2H, dd); mass spectrum *m/e* 186 (M^+), 79 (M^+ − *d*-Pyr—C=O).

*2-Bromopyridine-6*d

6-Bromo-2-lithiopyridine (21) was quenched at −40°C with an excess of methanol-d_1, and the mixture after workup, afforded 2-bromopyridine-6-*d*, in 82% yield. ^{1}H-nmr showed complete absence of the 2-H.

*Tris-(2-pyridyl-6-*d*)carbinol (d-1)*

In a procedure analogous to that described by Wibaut *et al.* (20) for the preparation of **1**, 2-lithiopyridine-6-*d* and bis-(2-pyridyl-6*d*)ketone were reacted to give 41% of d-**1**, mp 128–129°C (lit. (20) 127–128°C for **1**); ^{1}H-nmr (D_2O) Table 3;

mass spectrum *m/e* 266 (M^+), 249 ($M^+ - OH$), 187 (M^+ − 6-*d* pyr).[9]

*Bis(2-*N*-methylimidazolyl)-2-pyridyl Carbinol (**3**)*

To a suspension of 0.5 mol of 2-*N*-methylimidazolyl lithium in 600 mL dry ether at 0°C was added 0.25 mol of ethyl picolinate and the mixture was stirred 4 h. It was then decomposed with 20 mL of 10% H_2SO_4 and extracted with chloroform. The combined extracts were dried ($MgSO_4$) and solvent removed to give an oil from which unreacted *N*-methyl imidazole was removed by distillation (55°C/3 Torr). The residue was recrystallized from Skelly B/benzene to give 6 g (9%) of **3**, mp 131–133°C; ^{1}H-nmr ($CDCl_3$) Table 3; mass spectrum *m/e* 269 (M^+), 191 (M^+ − pyr); *Anal.* calcd. for $C_{14}H_{15}N_5O$: C 62.45, H 5.57, N 26.02; found: C 62.80, H 5.75, N 26.12.

*Bis(2-pyridyl)-2-(*N*-ethoxymethyl)imidazolyl Carbinol (**5**b)*

To a solution of 0.04 mol of 2-(*N*-ethoxymethyl)imidazolyl lithium (6) in 200 mL THF at −60°C was added a solution of 7.36 g (0.04 mol) of bis(2-pyridyl) ketone in 50 mL THF. After addition the deep blue solution was stirred an additional hour at −60°C and then overnight at room temperature. Quenching with H_2O, followed by several ethylacetate extractions which were combined and dried ($MgSO_4$) and then stripped of solvent yielding an oily paste which was recrystallized from ether to give 4.5 g (36%) of the product, mp 62–63.5°C; ^{1}H-nmr ($CDCl_3$) δ 0.95 (3H, t), 3.20 (2H, q), 5.20 (2H, s), 7.07 (2H, d), 7.25 (3H, m), 7.75 (4H, m), 8.50 (2H, d).

*Bis(2-pyridyl)-2-imidazolyl Carbinol (**5**)*

Deprotection of **5***b* (see above) was accomplished according to published procedure (6), and the free base liberated by basification, mp 225–235°C (decomp.): ^{1}H-nmr (D_2O) Table 3; ir 3200 (br), 1570, 1430, 744 cm^{-1}; mass spectrum *m/e* 252 (M^+), 235 ($M^+ - OH$), 185 (M^+ − imidazolyl), 146 (M^+ − pyr). Ligands **4**, **6**, **7**, and **8** were synthesized analogously to published procedure (6) the latter three starting from either 4,5-dimethylimidazole (22) or 4,5-diisopropylimidazole (22).

*Tris-2-[(*N*-ethoxymethyl)-4,5-dimethylimidazolyl]carbinol (**6**b)*

From 15.4 g (0.091 mol) of 2-(*N*-ethoxymethyl-4,5-dimethylimidazolyl) lithium reacted with 3.6 g (0.03 mol) diethyl carbonate in 200 mL THF at −60°C was isolated 7.5 g crude orange crystals (50%) which were recrystallized from hexane/ether to give **6***b*, mp 114–116.5°C: 90 MHz, ^{1}H-nmr ($CDCl_3$) δ 0.98 (3H, t), 2.03 (3H, s), 2.15 (3H, s), 3.15 (2H, q), 5.13 (2H, 5), 6.31 (1H, br); mass spectrum *m/e* 488 (M^+) 443 ($M^+ - OCH_2CH_3$) 429 ($M^+ - CH_2OCH_2CH_3$). The free ligand (**6**) was liberated analogously to published procedure (6) followed by basification, mp > 275°C (darkens): ^{1}H-nmr (D_2O) δ 2.26 (s). *Anal.* calcd. for $C_{25}H_{40}N_6O_4$: C 61.45, H 8.25, N 17.20; found: C 61.27, H 8.15, N 17.44.

*Tris-[2-(*N*-ethoxymethyl)-4,5-diisopropylimidazolyl]carbinol (**7**b)*

From 13.5 g (0.064 mol) of 2-lithio-*N*-ethoxymethyl-4,5-diisopropyl imidazole and 2.40 mL (0.021 mol) of diethyl carbonate was isolated 8.5 g (62%) of **7***b* (recrystallized from ethyl acetate), mp 121–123°C: ^{1}H-nmr ($CDCl_3$) δ 1.15 (45H, m), 3.05 (12H, m), 5.20 (6H, s), 6.75 (1H, br): mass spectrum *m/e* 656 (M^+), 639 ($M^+ - OH$), 597 ($M^+ - CH_2OCH_2CH_3$). The free base (**7**) was isolated analogously as for **6**: ^{1}H-nmr ($CDCl_3$) δ 1.26 (36 H, d), 3.01 (6H, hept.). *Anal.* calcd. for $C_{28}H_{46}N_6O$: C 69.70, H 9.54, N 17.43; found: C 69.33, H 9.54, N 17.49.

*Tris-2-(*N*-methyl-4,5-diisopropylimidazolyl)carbinol (**8**)*

From 0.058 mol of 2-(*N*-methyl-4,5-diisopropylimidazolyl) lithium and 0.019 mol diethylcarbonate was isolated ~50% of an oil containing **8** and its analogous ketone. One gram of this mixture was chromatographed over silica gel (ethylacetate) to give the desired **8** as an oil: ^{1}H-nmr (acetone-d_6) δ 1.15 (18H, d), 1.32 (18H, d), 3.5 (6H, m), 3.27 (9H, m), 6.42 (1H, s, br); *Anal.* calcd. for $C_{31}H_{52}N_6O$: C 70.99, H 9.92, N 16.03; found: C 71.17, H 10.04, N 14.64.

*Bis-2-[*N*-methyl-4,5-diisopropylimidazolyl]ketone*

Heating of neat **8** at 180°C/atm pressure for 5 min yielded an oil which was recrystallized from ether, mp 197–199°C; ^{1}H-nmr ($CDCl_3$) δ 1.23 (12H, d), 1.34 (12H, d), 3.1 (4H, m), 3.85 (6H, s); mass spectrum, *m/e* 358 (M^+), 343 ($M^+ - CH_3$); *Anal.* calcd. for $C_{21}H_{34}N_4O$: C 70.39, H 9.49, N 15.64; found: C 70.23, H 9.50, N 15.60.

*Bis-2-[*N*-methyl-4,5-diisopropylimidazolyl]-2-[*N*-methoxymethyl-4,5-dimethylimdazolylmethyl]carbinol, **9***

To 1.29 g (0.0084 mol) *N*-methoxymethyl-2,4,5-trimethylimidazole in 180 mL dry THF at −60°C was added 1 equiv. (0.0084 mol) *n*-BuLi in hexane. To this mixture was added 3.09 g (0.0084 mol) of bis-2-[*N*-methyl-4,5-diisopropylimidazolyl]-ketone in 10 mL THF. After workup, and recrystallization from ether, 2.7 g (63%) of the product was obtained, mp 133–134°C. ^{1}H-nmr ($CDCl_3$) δ 1.11 (12H, d), 1.26 (12H, d), 1.98 (3H, s), 2.09 (3H, s), 2.93 (4H, m), 3.23 (9H, d), 3.87 (2H, s), 5.35 (2H, s); mass spectrum, *m/e* 512 (M^+), 497 ($M^+ - CH_3$) 359 (M^+ − *N*-methoxymethyl-4,5-dimethylimidazolylmethyl). *Anal.* calcd. for $C_{29}H_{48}N_6O_2$: C 67.83, H 9.35, N 16.37; found: C68.03, H 9.42, N 16.51.

The free base (**9**) was obtained by refluxing the above material in 10% HCl for two weeks and basification, mp 168–170°C (darkens). ^{1}H-nmr ($CDCl_3$) δ 1.23 (24H, d), 2.10 (6H, s), 2.93 (10H, m), 3.57 (2H, s); mass spectrum, *m/e* 468 (M^+), 450 ($M^+ - H_2$), 359 (M^+ − 4,5-dimethylimidazolylmethyl).

Tris-2-[4,5-diisopropylimidazolyl]methane

Under nitrogen, 100 mg of the tris-2-[4,5-diisopropylimidazolyl]carbinol·*x*HCl salt was dissolved in 10 mL 3 *N* NaOH and 10 mL ethanol and brought to reflux, before 100 mg of sodium dithionite dissolved in the minimum amount of H_2O was added in one portion. After 1 min, the mixture was acidified with concentrated HCl, and then all volatiles were removed under vacuum. The residue was triturated with acetone which was filtered and evaporated to afford a yellowish solid, mp 120–180°C (decomp.), mass spectrum, *m/e* 466 ($M^+ - x$HCl), 451 ($M^+ - x$HCl − CH_3).

This material proved to be relatively stable as the HCl salt but upon basification in the presence of air discolored badly due to air oxidation followed by dehydration.

[9]Reference 20 reports a preparation of bis-(2-pyridyl) ketone in 10% yield from 2-pyridyl lithium and ethyl picolinate.

Solvent effect on the rate of N(III)/Cl(V) reaction

SAMIR S. EMEISH[1]

Department of Chemistry, Bedford College, London NW1 4NS, U.K.

Received October 19, 1979

SAMIR S. EMEISH. Can. J. Chem. **58**, 902 (1980).

Kinetics of the reaction between N(III) and Cl(V) have been studied in water and water–dioxan solutions. The rate equation of the reaction in each solvent could be written as

$$\text{Rate} = k_3[HNO_2][ClO_3^-][H^+]$$

and the rate rises as the dielectric constant of the medium is lowered. This observation is in accord with suggested mechanistic details involving the intermediate H_2NClO_5.

SAMIR S. EMEISH. Can. J. Chem. **58**, 902 (1980).

On a étudié la cinétique de la réaction entre N(III) et Cl(V) dans l'eau et dans des solutions eau–dioxanne. On peut exprimer l'équation de vitesse de la réaction sous la forme suivante

$$\text{Vitesse} = k_3[HNO_2][ClO_3^-][H^+]$$

La vitesse augmente quand la constante diélectrique du milieu diminue. Cette observation est en accord avec le mécanisme suggéré qui implique un intermédiaire du type H_2NClO_5.

Introduction

The oxidation of N(III) by Cl(V) in buffered aqueous acidic media has been studied extensively (1). The mechanistic details of the reaction are well established and the activated complex H_2NClO_5 has been proposed (2). Few studies investigating the effect of progressive variation in the solvent upon the rate of reaction have been reported.

The effect of variation of dielectric constant of the medium by addition of dioxan to aqueous solvent (3) on the rate of N(III)/Cl(V) reaction is presented in this work.

Experimental

Chemicals used were of the Analar grade (except for technical grade HCl). Analar dioxan was freed from possible traces of H_2O_2 by being run through chromatographic alumina before being used. Stock solutions of nitrite were stabilised by traces of NaOH.

The reaction was studied in water, 34 wt% dioxan, and 67 wt% dioxan. Table 1 gives some properties of these three solvents used. The diminution in V_{total} was determined by separate experiments at 25°C and this diminution has been taken into account in expressing concentrations. The values of the dielectric constant (D) were calculated from the results of Akerlof and Short (4).

Reproducible results were obtained, in each solvent, under normal laboratory conditions. Reaction was initiated in thermostatted solutions by thoroughly mixing sodium nitrite and potassium chlorate plus hydrochloric acid. Samples were taken at intervals and analysed for N(III) by the Shinn method as modified by Kershaw and Chamberlin (5).

[1]Present address: P.O. Box 2385, Amman, H. K. Jordan.

20	40	59.25	61.06	67.34	20.45

Results

N(III) in dilute aqueous acidic solutions ($[H^+] \approx 0.02$ mol dm^{-3}) will be present as HNO_2 and NO_2^-. The ionization constant of nitrous acid in aqueous solutions is well known. Corresponding constants of the acid in water–dioxan solutions have not been reported. Therefore the ionization constant of nitrous acid was determined spectrophotometrically in water and water–dioxan solutions similar to those used in the kinetic study of the reaction.

Nitrite and nitrous acid absorb in the same wavelength region, but with different molar absorption coefficients at the same wavelength. The absorption spectrum of nitrite in the region 400–300 nm consists of one featureless band with a peak at 354 nm. That of nitrous acid in the same region shows five peaks at 386, 372, 358, 346, and 336 nm with three well marked intervening troughs at 380, 364, and 357 nm (see Fig. 1). This observation corresponds well with the published data (6). General aspects of these features are maintained over the three media investigated although minor shifts in the wavelengths of absorption occur, e.g.,

*Values for $[HNO_2]$ and for $[NO_2^-]$ were calculated from the absorption spectrum of the corresponding acidified nitrite solution, via

$$A = \varepsilon_1 c_1 l + \varepsilon_2 c_2 l$$

and the values for $[H^+]$ were then calculated from

$$[H^+] = [Cl^-]_0 + [NO_2^-] - [Na^+]_0$$

†$F(I) = [I^{1/2}/(1 + I^{1/2})] - 0.25I$.

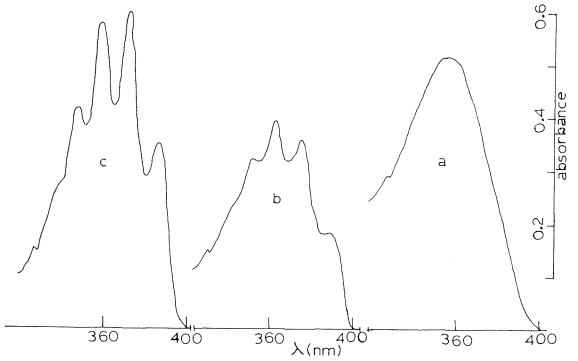

FIG. 1. Absorption spectra of N(III) in different acidic aqueous media: (*a*) 2.248 × 10^{-2} mol dm^{-3} $NaNO_2$; (*b*) 1.124 × 10^{-2} mol dm^{-3} $NaNO_2$ + 5.50 × 10^{-3} mol dm^{-3} HCl; (*c*) 1.124 × 10^{-2} mol dm^{-3} $NaNO_2$ + 5.50 × 10^{-2} mol dm^{-3} HCl.

the strongest absorption appears to lie at 372 nm in water while the corresponding peak is at 373 nm in 34 wt% dioxan and at 374 nm in 67 wt% dioxan.

Determined values for the molar absorption coefficients (ε) of nitrite and of nitrous acid in the three media are listed in Table 2. The values for ε of HNO_2 were determined by recording the spectra of solutions of NO_2^- containing excess HCl in the region 400–310 nm at timed intervals after acidification (Fig. 1). The absorption values (A) at the desired wavelength were then plotted vs. time and the curve was extrapolated to $t = 0$ to yield (A_0) corresponding to the initial concentration of the acid. This was done to minimize errors due to the loss of HNO_2 through decomposition. Table 3 gives the values for pK_I of nitrous acid in the three media. These values were calculated by

$$pK_I = -\log [H^+][NO_2^-]/[HNO_2]$$

where K_I is the concentration equilibrium constant at the ionic strength I.

The confidence in the technique adopted for the determination of K_I of HNO_2 is justified because the average value 3.08_5 for pK_I in aqueous solution (Table 3) compares favourably with 3.05 obtained through the equation of Tumavuori and Lumme (7). This equation has been used in the calculation of pK_I of the acid in water solutions at any I required in the present work. Furthermore, the same technique was used to determine pK_I of benzoic acid in

10	0.60	—	5.15
15	0.97	1.47	—
20	1.55	2.41	10.8
25	2.42	3.74	14.93
30	4.00	6.00	21.73
35	6.18	8.73	31.18
40	9.52	12.52	46.32

close agreement with the literature value of 4.16. In 25 wt% dioxan a value for pK_I of benzoic acid of 4.6 (average of four experiments) also compares well with the results of Lynch and LaMer (8).

The rate of reaction between N(III) and Cl(V), in each solvent, at constant T and I (maintained by $NaNO_3$), may be represented by

$$-\mathrm{d[N(III)]}/\mathrm{d}t = k_3[HNO_2][ClO_3^-][H^+]$$

which is the same rate equation reported for this reaction when studied in aqueous buffered solutions (1, 2). The mean (± standard deviation) values of the rate constant, k_3, in the three media are shown in Table 4. These values were calculated by the above rate equation, at various concentrations of reactants at 25°C.[2]

Application of the Arrhenius relation on the effect of variation of temperature, at constant I, upon the rate of reaction, in each solvent (see Table 5) produced the following values for the activation energy of the reaction between N(III) and Cl(V): in aqueous media, 68.3 kJ mol^{-1}; in 34 wt% dioxan, 64.3 kJ mol^{-1}; in 67 wt% dioxan, 59.0 kJ mol^{-1}. These results indicate that the higher value for activation energy is obtained in the more polar medium (9).

[2]Details of the range of concentrations of reactants and the values of initial rates in each medium may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Discussion

Basically, the kinetic observations of the reaction in aqueous buffered and in aqueous non-buffered acidic solutions are similar. A mechanism of the reaction has been proposed (2) to proceed through the formation of an overall equilibria producing the complex H_2NClO_5 as

[1*a*] $H^+ + HNO_2 + ClO_3^-$

[1*b*] $H^+ + HNClO_5^-$ ⇌ H_2NClO_5

[1*c*] $H_2NO_2^+ + ClO_3^-$

[1*d*] $HNO_2 + HClO_3$

followed by overall transformations,

[2] $H_2NClO_5 \xrightarrow{\text{r.d.s.}} NO_3^- + ClO_2^- + 2H^+$

[3] $ClO_2^- + HNO_2 \longrightarrow NO_3^- + ClO^- + H^+$

[4] $ClO^- + HNO_2 \longrightarrow NO_3^- + Cl^- + H^+$

The last two preequilibria steps ([1*c*] and [1*d*]) seem worth consideration as mechanistic steps because each is a two-body collision and definite concentrations of $H_2NO_2^+$ and $HClO_3$ could be maintained proportional to HNO_2 and ClO_3^- respectively in an acidic solution containing both species. The electron transfer in the oxidation process, as represented by the above schemes, probably takes place in the activated complex, and the electron transfer might be virtually uninfluenced by the medium.

The dependence of the rate of reaction on the dielectric constant (D) of the medium is governed by

$$\ln k = \ln k_0 - Nz_a z_b e^2/DRTr$$

which predicts a linear plot of ln k vs. $1/D$ with a positive slope for oppositely charged ions. Figure 2 shows the linearity produced by plotting ln k_3 vs. $1/D$ as obtained in the present study. The straight line has a positive slope and the value of k_3 at $D = \infty$ is 1.35 dm^6 mol^{-2} s^{-1}.

It has been observed (10) that water–dioxan mixtures should be more basic than water, so that an intrinsic increase in the dissociation constant of a weak acid (such as HNO_2) as dioxan is increased in the mixture is expected. However, it is also important to consider the relatively large effects of solvation and whilst all the species, HNO_2, H^+, and

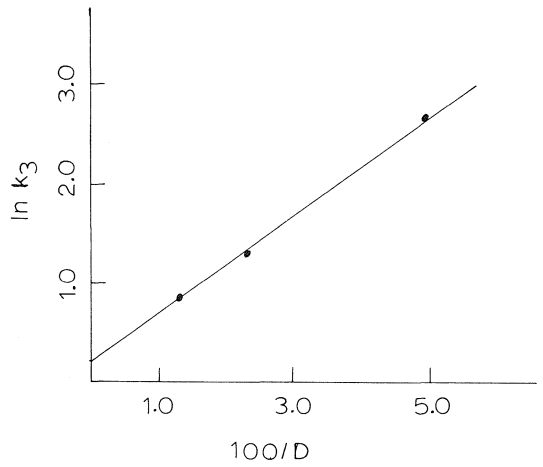

FIG. 2. Relation between the rate constant of reaction and the dielectric constant of medium.

NO_2^- have sites which can interact with the oxygen or hydrogen atoms of the solvent, the ionic species are undoubtedly the more involved in solvation. This selective effect should act to lower the dissociation constant as dioxan is increased. The diminution in volume observed when water is mixed with dioxan implies an appreciable interaction between the two components of the solvent, thus ions would be in competition with dioxan for water. Hence, at the outset, it is not at all clear how change of solvent would affect the concentration of HNO_2.

Variation in D from 80 to 20 has little effect on rate. The involvement of several preequilibria prior to the rate determining step makes it difficult to use the effect of variation of the dielectric constant of the medium in a unique way to pin-point the species actually interacting to produce the activated complex. Thus, supposing

$$H_2NO_2^+ + ClO_3^- \rightleftharpoons H_2NClO_5$$

represents the detail, where this step would be enhanced by a fall in D as is observed, but, for example,

$$H^+ + HNClO_5^- \rightleftharpoons H_2NClO_5$$

has the same charge characteristics and therefore would not be eliminated by the observations.

It has already been established that $2H^+$, NO_2^-, and ClO_3^- are in overall equilibrium with the activated complex. One H^+ is required for the protonation of NO_2^- and a second is mechanistically required per activated complex. This second H^+ would be more freely available in the more basic solvent. However, the major identified feature of the present work is a rise in pK of HNO_2 (rather as expected) leading to a rise in $[HNO_2]$, coupled with a rise in the overall rate constant. The rise in rate constant has been calculated for the "actually existing" reactant species.

Pulse nmr has been used to determine the temperature dependence of T_1 at 9.2, 18, and 60 MHz and also $T_{1\rho}$ at 9.2 MHz and T_{1D} at 18 MHz, for the proton resonance of solid acenaphthalene. The data indicate a discontinuity at ~130 K, coincident with the main thermal anomaly in the specific heat curve, and suggest the occurrence of two distinct molecular motions with activation energies 14.2 kJ mol^{-1} and 18.9 kJ mol^{-1}. Calculations using non-bonded atom–atom potential functions explain qualitatively the results of the nmr study and it is suggested that the two motional processes may be due to two sets of crystallographically different acenaphthalene molecules.

On a utilisé la rmn à impulsion pour déterminer l'effet de la température sur T_1, à 9.2, 18 et 60 MHz et également sur $T_{1\rho}$ à 9.2 MHz et sur T_{1D} à 18 MHz dans le cas de la résonance du proton de l'acénaphtalène solide. Les données indiquent une discontinuité à ~ 130 K coincidant avec la principale anomalie thermique dans la courbe de chaleur spécifique et suggère l'existence de deux mouvements moléculaires distincts avec des énergies d'activation de 14.2 et 18.9 kJ mol^{-1}. Les calculs utilisant les fonctions de potentiel atome–atome non liés expliquent qualitativement les résultats de l'étude de rmn et on suggère que les deux mouvements peuvent être dus à deux ensembles de molécules d'acénaphtalène différents du point de vue cristallographique.

[Traduit par le journal]

Introduction

Acenaphthalene (**1**) was chosen for study because previous wide-line nmr investigations (1) indicated that an in-plane motion of the molecules occurred in the solid state at about 130 K (on an nmr timescale). Since the molecule has no symmetry axis for in-plane motions, any motion must involve disorder. The wide-line nmr results rule out motion about a two-fold axis, and the disorder introduced must be extreme. This is confirmed by the lack of success of

1

attempted investigations of the room-temperature structure by X-ray diffraction techniques (2–4). A low temperature structure (85 K) was determined by Wellberry (5) using film data. There were two quite different sites for the molecules in the low temperature structure, and a phase transition was indicated from photographs to occur at about 130 K. However, even knowing the low-temperature structure, it was not possible to unambiguously determine the room-temperature structure (5).

The purpose of the present work was to obtain more quantitative data concerning the motion of the acenaphthalene molecules in the solid state and, if possible, to relate these data to the low-temperature X-ray structure of Wellberry (5). The relaxation times of nuclei in the solid state are very sensitive to the presence of molecular motions, as these provide a relaxation mechanism for the nuclear spins. Furthermore, the temperature dependence of the nuclear relaxation times may be quantitatively related to the activation energy for the reorientation process (6). In the present work we have investigated the temperature dependence of T_1 (the spin–lattice relaxation time) at several frequencies, $T_{1\rho}$ (the spin–lattice relaxation time in the rotating frame) and T_{1D} (the dipolar relaxation time). The quantitative description of these parameters and their relationships to each other will be described in detail in the text.

Also, we have recently found it possible to predict the barriers to rotation in molecular solids using the crystal structure and non-bonded atom–atom potential functions to describe the lattice energy. The

approach has had some success for planar aromatic compounds (7), cage-like aliphatic compounds (8), adamantane and hexamethylenetetramine (9), and several planar heterocyclic molecules (10–12). In the case of admantane it was possible to deduce a molecular mechanism for the order–disorder process which occurs in the solid (9). We have employed these calculations in the present work to attempt to relate the results of the relaxation time measurements to the low-temperature X-ray structure.

Experimental

Acenaphthalene was purified as previously described (1). Pulse nmr measurements were made at 18.0 MHz using a home-built spectrometer (10) and at 60 and 9.2 MHz using a Bruker SXP variable frequency spectrometer. Each separate relaxation time was obtained from a least-squares fit to the appropriate experimental data. Calculations of the theoretical temperature dependence of the different relaxation times and of the lattice energies were performed using Fortran IV programs written by the authors.

Results and Discussion

A. Spin–Lattice Relaxation Time Measurements

The effect of a single motion process on the spin–lattice relaxation time of a nucleus is described by eq. [1]

$$[1] \quad \frac{1}{T_1} = C\left[\frac{\tau_c}{1 + \omega_0^2\tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2\tau_c^2}\right]$$

where ω_0 is the frequency of measurement, τ_c is the characteristic correlation time of the motion, and C is a constant characteristic of the motion (6, 13).

If the correlation times for the motional process obey an Arrhenius-type temperature dependence, eq. [2], the temperature dependence of T_1 may be related to an activation energy for the motional process (6, 13):

$$[2] \quad \tau_c = \tau_0 e^{-E_a/RT}$$

Thus a plot of log T_1 vs. $1/T$ should yield a "V" shaped curve with a minimum where $\omega_0\tau_c = 0.62$ and with limiting low- and high-temperature slopes equal to E_a/R and $-E_a/R$, respectively. As the frequency of measurement is increased, the minimum in the curve which occurs when $\omega_0\tau_c = 0.62$ will shift to higher temperature, and measurements at a series of frequencies will yield a series of curves with different minima which are all coincident when $\omega_0\tau_c \ll 1$ at high temperatures. Often, if a minimum is not found at one frequency, it may be observed by making measurements at another.

The spin–lattice relation times of acenaphthalene have been measured over the temperature range 100 to 290 K at 9.2, 18, and 60 MHz and are shown in Fig. 1. As can be seen from Fig. 1, all vary markedly with temperature, confirming the conclusion of the previous wide-line nmr investigation (1) that motion of the acenaphthalene molecules is occurring. However, the situation is more complex than the case of a single, simple motional process discussed above. There is evidence in each set of measurements of a discontinuity at 130 K which coincides with the major thermodynamic transition recently observed (14, 15). The T_1 curves are not simple "V" shapes, but indicate two distinct minima, seen most clearly in the 60 MHz curve where both minima lie on the high temperature side of the discontinuity. The data thus qualitatively suggest the possibility that supercooling of a high temperature phase, or some similar lack of thermal equilibration, might give rise to a false second minimum. This possibility was investigated by rapidly cooling the sample to 129 K, then warming it rapidly to 273 K. At both temperatures the results of the T_1 measurements were the same as those obtained previously using precautions to ensure thermal equilibration.

B. $T_{1\rho}$ and T_{1D} Measurements

For a single motional process, $T_{1\rho}$ is defined (16)

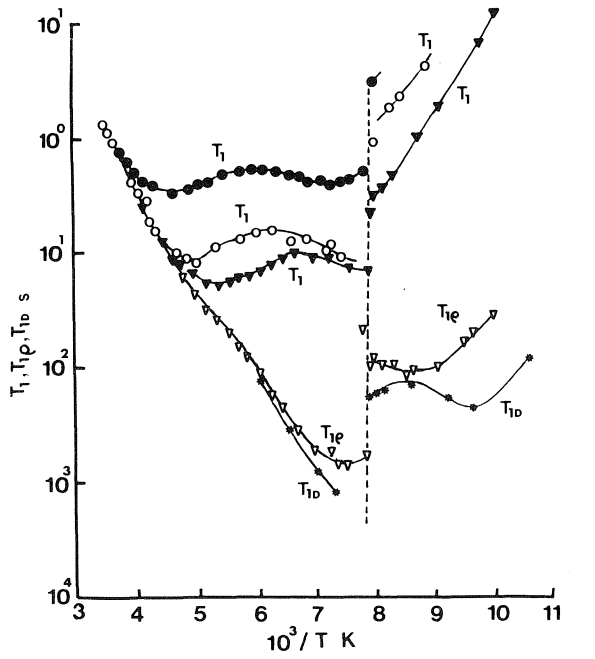

FIG. 1. Experimental temperature dependence of T_1 at 9.2 MHz ●; 18.0 MHz ○; and 60.0 MHz ▼; and of $T_{1\rho}$ at 9.2 MHz ▽; and of T_{1D} at 18.0 MHz *, for the proton resonance of acenaphthalene in the solid state. The curves indicated in the figure are for clarity only. Vertical dashed line corresponds to phase transition at 130 K.

as in eq. [3]:

$$[3] \quad \frac{1}{T_{1\rho}} = C\left[\frac{5}{2}\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{\tau_c}{1+4\omega_0^2\tau_c^2} + \frac{3}{2}\frac{\tau_c}{1+\omega_1^2\tau_c^2}\right]$$

H_1 is typically of the order of 1–50 G. A plot $T_{1\rho}$ vs. $1/T$ is again a "V" shaped curve, but the $T_{1\rho}$ minimum occurs when $\omega_1\tau_c = 0.5$ (usually in the same temperature region as the C.W. nmr line-narrowing transition). The temperature dependence of T_{1D} is less well described than that of T_1 or $T_{1\rho}$. In the high-temperature limit, it is described (17) by an equation similar to that for $T_{1\rho}$ (eq. [4*a*]),

$$[4a] \quad \frac{1}{T_{1D}} = C_1\left[\frac{\tau_c}{1+\omega_0^2\tau_c^2} + C_2\frac{\tau_c}{1+4\omega_0^2\tau_c^2}\right] + C_3\tau_c$$

where C_1, C_2, C_3 are constants dependent on the strength of the dipolar interaction. Evaluation of these constants experimentally is difficult. In the low temperature limit ($\tau_c > T_2$), the relaxation may be described (18) by eq. [4*b*]:

$$[4b] \quad \frac{1}{T_{1D}} = \frac{2(1-P)}{\tau_c}$$

where $(1 - P)$ is a geometrical parameter which accounts for any correlation in the local fields before and after the motion has occurred. The behaviour of T_{1D} in the transition region between these two limiting situations, i.e., at the minimum in the log T_{1D} vs. $1/T$ curve, is much less well understood.

Thus, both $T_{1\rho}$ and T_{1D} are more sensitive to low frequency motions than is T_1, and were measured, particularly in the region of the transition, to see if they could provide additional information about the motional processes. These data are shown also in Fig. 1. The data are consistent with the T_1 results, coinciding with them in the high temperature limit (Fig. 1). Both curves show two minima; that corresponding to the low energy occurs at temperatures below the temperature of the main heat capacity anomaly.

Qualitatively, these data indicate that there are two distinct motional processes occurring in the acenaphthalene crystal, since two distinct minima are apparent in Fig. 1. If just one unique motion were occurring, the theory predicts a single minimum in the curve for each different relaxation time (Fig. 1).

C. Analysis of the Relaxation Time Data in Terms of Two Motional Processes

The present analysis is based on the assumption that the spin exchange is fast enough to average the relaxation due to the two processes and that the relaxtion of all ^1H nuclei in the sample can be described by a single exponential (as is observed within experimental error), with a time constant given by eq. [5]:

$$[5] \quad \frac{1}{T_{1\ \mathrm{obs}}} = \frac{f_a}{T_1(a)} + \frac{f_b}{T_1(b)}$$

where $T_1(a)$ and $T_1(b)$ are the relaxation times of the nuclei due to the two motional processes if they occurred alone, and f_a and f_b are the relative fractions of nuclei participating in the two processes (19, 20). Both $T_{1(a)}$ and $T_{1(b)}$ have the form indicated in eq. [1] and are characterized by unique correlation times $\tau_c(a)$ and $\tau_c(b)$.

Similarly, $T_{1\rho}$ may be defined as in eq. [6] where $T_{1\rho(a)}$ and $T_{1\rho(b)}$ are each defined as in eq. [3]:

$$[6] \quad \frac{1}{T_{1\rho}} = \frac{f_a}{T_{1\rho(a)}} + \frac{f_b}{T_{1\rho(b)}}$$

Since the theory for T_{1D} in the region of the transition is ill defined, the T_{1D} data have not been quantitatively interpreted.

Figure 2 shows the complete experimental results of the T_1 and $T_{1\rho}$ measurements together with the theoretical curves calculation using eqs. [5] and [6] and assuming that $f_a = f_b$; the values used for the parameters relating to the two motions are given in Table 1. A reasonable fit to the experimental data is found (Fig. 2). The model yields activation energies of 14.2 kJ mol^{-1} and 18.9 kJ mol^{-1} for the two motions and adequately accounts for all the high temperature experimental results for T_1 at different frequencies and also the $T_{1\rho}$ and T_{1D} data, i.e., it explains the high energy motion quite well. The low temperature portion of each curve down to the discontinuity is also well fitted. However, the region of the curve between the two minima is fitted much less well, the experimental separation of the two minima being much less complete than predicted. This could be caused by a distribution of correlation times, mainly in the low energy motion, which arise from the same general type of motion with a distribution of energies and environments within the sample. This would result in the minimum due to the low energy motion being broader and flatter than predicted by eqs. [1] and [3]. This effect would be carried over into eqs. [5] and [6] and the agreement between the observed and calculated data would improve. This type of fitting was not attempted, as it was felt that it would not add significantly to the phycial understanding of the problem and that the estimates of the activation energies were in general adequate without this additional parametrization.

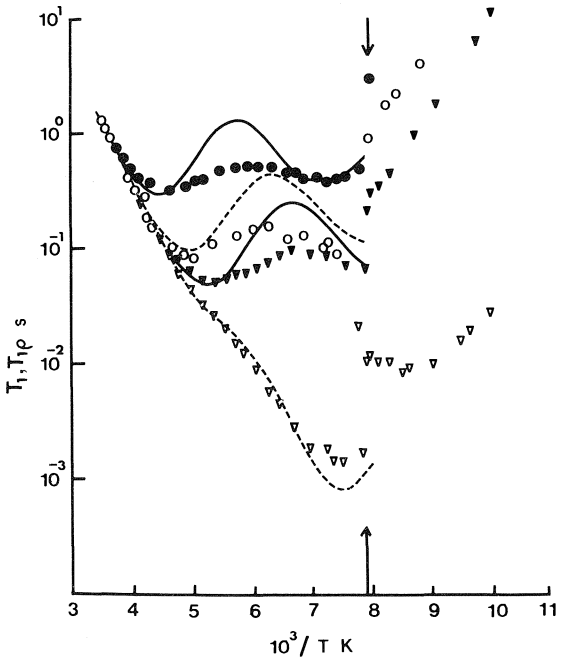

FIG. 2. Experimental temperature dependence of T_1 at 9.2, 18.0, and 60.0 MHz and of $T_{1\rho}$ at 9.2 MHz for the proton resonance of acenaphthalene in the solid state together with the theoretical temperature dependencies of these parameters (solid curves) calculated using the parameters given in Table 1.

TABLE 1. Parameters used to compute the theoretical T_1 and $T_{1\rho}$ curves from application of eqs. [1], [2], [3], and [5] with $f_a = f_b$ in eq. [5]

	E_a (kJ mol^{-1})	τ_0 (s)	C (s^{-2})
Motion 1	14.2	0.65×10^{-14}	0.7×10^9
Motion 2	18.9	0.70×10^{-13}	0.82×10^9

Thus, the relaxation time data indicate the occurrence of two different types of motions in solid acenaphthalene with similar activation energies. One further piece of information may be extracted from these data concerning the general nature of these two motional processes. The two minima occur at approximately the same values of T_1 (seen best in the 60 MHz T_1 data in Fig. 2). This is reflected in the similarity of the constants C (Table 1) for the two processes. C may be related to the change in the intermolecular contribution to the second moment (ΔSM) as in eq. [7]:

$$[7] \quad C = (2/3)\gamma^2\Delta\mathrm{SM}$$

Thus the two motional processes must cause similar reductions in the second moment. One situation which would fit this requirement would be the existence of two crystallographically different types of acenaphthalene molecules in the lattice, which could undergo very similar motions. These motions would be such as to cause similar reductions in the intermolecular contribution to the second moment, but would have slightly different energy barriers. Such a situation has indeed been reported by Wellberry (5) for the low temperature phase of this molecule, and it may be that each of the disordering motions involves half of the molecules in the lattice.

An alternative explanation of the relaxation-time data is that each of the two motional processes detected may each be due to just one quarter of the molecules, the remaining one-half of the molecules moving too quickly for their motion to be detected by the relaxation-time data (i.e., $\omega_0\tau_c \ll 1$ just above the transition). This explanation gives better agreement with the absolute values of the reduced second moments from the C.W. nmr study (eq. [7]). In this case, the activation energies for the two observed motions would be given as in Table 1, and the remaining molecules would move with activation energies less than 8 kJ mol^{-1}.

D. Potential Energy Calculations of the Rotational Barriers in Solid Acenaphthalene

As indicated in the Introduction, these calculations have been successful in a number of instances in predicting the barriers to rotation in molecular solids. Calculations have been performed on acenaphthalene using the low temperature crystal structure data of Wellberry (5) to investigate firstly if there are different barriers for crystallographically different acenaphthalene molecules as indicated by the nmr data above, and secondly, to try to predict the number of sites for each molecule in the high temperature phase. The previous C.W. nmr investigations (1) ruled out the possibility of the motion being about a two-fold axis as this would not average the intramolecular contribution to the second moment.

The low-temperature structure found at 85 K is an ordered structure with eight molecules per unit cell, involving four crystallographically different types labelled A, B, C, D packed in the characteristic "herring bone" type of arrangement. The lattice sites of the A and B molecules are similar as are those of the C and D molecules. The model for the calculations was exactly as described previously and the interatomic potentials used were the "exp-6" type (eq. [8]).

$$[8] \quad V_{ij} = -A/r_{ij}^6 + B\exp C/r_{ij}$$

The parameters A, B, C for each of the interatomic interactions H$\cdots$H, H$\cdots$C, and C$\cdots$C were taken from the work of Williams (21).

The inspection of the experimental atomic co-ordinates (5) revealed that the molecules were all non-planar and quite non-symmetric except where re-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

quired by the space group. In the absence of any gas-phase data on the molecular structure, idealized molecules were generated using the best defined molecule from the X-ray data. It was thought that the type "C" molecule, apart from its slight non-planarity, was the most reasonable approximation to the true structure. This molecule was made exactly planar, the other molecules generated from it and the hydrogen atoms generated 1.08 Å on each carbon such that the C—H vector bisected the C—C—C angle of the central carbon to which it was attached.

The sublimation energy for the low temperature lattice was calculated to be 86.2 kJ mol^{-1}, in reasonable agreement with the experimental value of 71.2 kJ mol^{-1} (high temperature form). Calculations were then performed in which the test acenaphthalene molecule was rotated around a chosen axis and the potential between it and the lattice evaluated as a function of rotation angle, the rest of the molecules in the lattice being kept fixed at their positions of minimum potential. Several qualitative conclusions may be drawn from the initial calculations. Firstly, the rotation of the molecules must be in their molecular planes and, secondly, the axis for the rotation must be through the centre of gravity of the molecule which is approximately C_{10}. All other choices of axis gave rotation potentials which quickly became extremely repulsive.

The calculated potential energies of each of an A, B, C, and D molecule (5), as a function of angle of in-plane rotation, are shown in Fig. 3. The A and B molecules are quite similar to one another in this respect, and are qualitatively different from the C and D molecules which have much lower barriers to in-plane rotation. This qualitative finding is promising, in view of the conclusions drawn above from the nmr results. However, the quantitative results are unfortunately ambiguous. The energy barrier to rotation is *twice* the difference between peaks and valleys in the profiles of Fig. 3, (22, 23). The predicted energy barriers for A, B, and C or D molecules are thus 40–60 kJ mol^{-1}, and <20 kJ mol^{-1} respectively, appreciably higher than the experimentavalues (Table 1). The potential parameters used in the calculations (21) were those with the "hard" repulsive contributions. The calculated energy barriers could be lowered somewhat through use of an alternative parametrization incorporating "soft" repulsions, now thought (23) to be superior. However, even this would not resolve the ambiguity in the interpretation of the nmr data, viz. do the two motions observed correspond to the motion of first half of the molecules (probably C and D) followed at higher temperatures by the other half (A and B), or are one-half of the molecules (C plus D) already

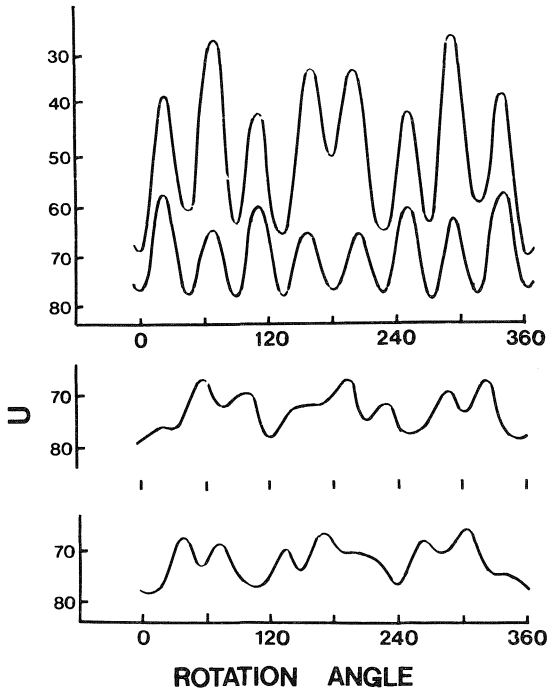

FIG. 3. Calculated potential energy curves for the movement of an acenaphthalene molecule in its molecular plane. From top to bottom, types A, B, C, D molecules as given in the low temperature crystal structure (5). U (kJ mol^{-1}) is lattice sum for a central molecule calculated using atom–atom approximation (7). Minima correspond to sublimation energy, and differences between maxima and minima to *half* the activation energy (22, 23).

in motion at the lowest temperature available (Fig. 2), and the two *observed* motions due to first the B and at higher temperatures the A molecules moving on the nmr timescale?

Even the effective order of the axis around which the molecules move is unclear from these calculations. For each molecule there are a number of minima which occur during the rotation, but it was felt that small differences between these could be critical in determing the order of the axis of rotation. Due to inadequacies in the model (correlated motions may well be important in determining the disordered structure), and more importantly in the present case, in the atomic coordinates, the calculations could not be considered to be of sufficient accuracy to be used for this purpose. It is thought, however, that if an accurate low-temperature structure becomes available that calculations of this type would then be useful for determining the order of the rotation axis and thus in predicting the nature of the room-temperature structure. The available experimental evidence on the nature of the disorder axis is that the wide-line nmr results (1) rule out a two-fold axis, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

recent calorimetric results (14, 15) yield a total entropy change corresponding to $R \ln 4$ for the transition region. In one of these studies (15) the transition region was consistent with a contribution from two transitions, each corresponding to $\Delta S = R \ln 2$. This is in agreement with a situation where half of the molecules (presumably C and D) move around a four-fold axis at lower temperatures followed by the other half (A and B), also around a four-fold axis, at higher temperatures.

One other comparison between the experimental results (Fig. 1) and the potential energy calculations (Fig. 3) seems capable of providing some additional insight. The observation of the $T_{1\rho}$ and T_{1D} minima, at temperatures below the phase transition at about 130 K, clearly indicates the existence of a large-amplitude motion in the low-temperature phase, as discussed above. These minima are relatively shallow, a factor of ~ 8 more so than the corresponding minima observed for the high-temperature phase.

One possible explanation for this qualitative difference could involve the participation of motion between inequivalent sites, in the case of the low-temperature phase (Fig. 3). It is known (24–26) that motion between inequivalent sites (i.e. "non-random" motion (24–26)) tends to decrease the relaxation efficiency. It can be shown that, for a simplified two-site model:

$$\frac{T_1(\text{min}) \text{ for random motion}}{T_1(\text{min}) \text{ for non-random motion}} = \frac{4 \exp(\Delta E/RT)]^2}{[1 + \exp(\Delta E/RT)}$$

where ΔE is the energy difference between the two sites (potential energy minima). On the basis of this admittedly over-simplified model, ΔE must be about 0.8 kcal mol^{-1} to account for the difference in the two $T_{1\rho}$ minima (Fig. 1), if the entire difference is ascribed to this effect operating in the low temperature phase only. This suggestion seems to be qualitatively in agreement with the calculated potential energy profiles (Fig. 3). The statistical population of such sites (about 5% at 130 K) could readily have been missed in the X-ray diffraction experiments of Welberry (5).

Conclusions

The pulse nmr investigation of the dynamic structure of acenaphthalene has made more quantitative our understanding of the order–disorder phase transition, clearly identifying two separate motional processes of activation energies 14.2 kJ mol^{-1} and 18.9 kJ mol^{-1}. These are tentatively assigned to the motion of two sets of acenaphthalene molecules in crystallographically different sites in the crystal. Studies of molecular motion in crystalline acenapthalene have also been made via dielectric measurements, and yield results in good general agreement with the present nmr data (27).

Investigation of the disordering by potential energy calculations has met with only limited success. Qualitatively the axis of rotation has been determined and the molecules in the unit cell appear to fall into two groups in terms of their barriers to rotation. However, it is felt that the results are not accurate enough to permit the determination of the order of the disordering axis due to the inadequate nature of the atomic co-ordinates. It is suggested that a redetermination of the low temperature structure be made and also a determination of the disordered structure just above the phase transition where the room-temperature disorder will exist, but the real thermal errors may be low enought to permit the complete determination of the structure in high temperature phase.

Etude paramétrique de l'enrichissement en carbone-13 dans la décomposition polyphotonique de CF_3Cl[1]

M. GAUTHIER, C. WILLIS ET P. A. HACKETT

Groupe de photochimie laser, Division de chimie, Conseil national de recherches du Canada, Ottawa (Ont.), Canada K1A 0R6

Reçu le 21 novembre 1979

M. GAUTHIER, C. WILLIS et P. A. HACKETT. Can. J. Chem. **58**, 913 (1980).

Le rendement et la teneur en ^{13}C du produit C_2F_6 ont été mesurés suite à la décomposition polyphotonique infrarouge de CF_3Cl. On a étudié ces facteurs en fonction de la fréquence d'activation ω, de la pression P de CF_3Cl, de la température T et de l'énergie incidente E_0. Comme pour CF_3Br et CF_3I, le rendement augmente selon $P^2E_0{}^2$.

M. GAUTHIER, C. WILLIS, and P. A. HACKETT. Can. J. Chem. **58**, 913 (1980).

The yield and ^{13}C content of the product C_2F_6 were measured following the multiphoton infrared decomposition of CF_3Cl. These factors were studied as a function of the activation frequency ω, of the pressure of CF_3Cl, of the temperature T, and of the incident energy E_0. As in the case of CF_3Br and CF_3I the yield increases according to $P^2E_0{}^2$.

Introduction

L'intérêt n'a cessé de s'accroître ces dix dernières années pour les nouvelles méthodes de séparation isotopique sous rayonnement laser (1). En particulier, l'absorption sélective de la radiation intense d'un laser CO_2 par les halocarbures polarise l'attention dans la recherche d'un procédé rentable pour la séparation du ^{13}C (2, 3). Nous résumons dans cet article une étude paramétrique complète de la décomposition polyphotonique du CF_3Cl, faisant suite aux premiers résultats déjà présentés sur CF_3X, X = Cl, Br, I (4–6).

Ambartzumian et coll. (7, 8) ont d'abord montré que la décomposition du CCl_4 donne les produits C_2Cl_4 et C_2Cl_6 enrichis en ^{13}C par irradiation infrarouge de la bande $\nu_4 + \nu_1 + \nu_2$. Plusieurs halométhanes ont ensuite été étudiés pour la séparation des isotopes du carbone par la décomposition sélective des molécules contenant ^{12}C (9, 10) ou des molécules contenant l'isotope ^{13}C dont l'abondance naturelle est seulement 1.11% (2–8). Bittenson et Houston (9) ont décomposé sélectivement $^{12}CF_3I$ avec un laser CO_2 et obtiennent un "facteur de séparation" près de 600 à basse pression (0.1 Torr) et basse température (−80°C). Knyazev et coll. (10) ont aussi décomposé sélectivement $^{12}CF_3I$ mais en séparant cette fois l'activation polyphotonique sélective par un laser infrarouge de la dissociation des molécules activées par un laser ultraviolet, un processus intéressant pour la décomposition des isotopes lourds.

Nous avons déjà montré que la décomposition sélective de $^{13}CF_3Br$ par un laser infrarouge à la température ambiante donnait des facteurs de séparation encore plus grands que pour la décomposition de $^{12}CF_3I$ à basse température (4).

Le rendement et la sélectivité de la décomposition dépendent des quatre paramètres fondamentaux: la fréquence ω et la fluence F de la radiation, la pression P, et la température T de l'absorbant. De plus, la géométrie de l'irradiation détermine le domaine de fluences auquel sera soumis le gaz à décomposer et affecte les mécanismes de la décomposition (6, 11, 12).

Partie expérimentale

Montage

Le schéma du montage est représenté à la fig 1. Un cylindre en Pyrex de 5 cm de diamètre et de 18 cm de longueur est fermé à chaque bout par une fenêtre de NaCl (Harshaw Laser Grade). Le faisceau d'un laser TEA CO_2 (Lumonics, modèle 103) passe par une ouverture de 1.4 cm de diamètre pour s'assurer de prendre la partie centrale qui a une densité d'énergie uniforme et est focalisé dans la cuve par une lentille en germanium (f = 10 cm).

Pour les irradiations à basse température, nous avons utilisé une cuve modifiée de mêmes dimensions mais pourvue à l'intérieur d'un tube de Pyrex de 8 mm hélicoidal avec une dixaine de tours qui était refroidi avec un courant d'azote de débit ajustable produit de l'évaporation d'azote liquide.

L'énergie incidente et l'énergie transmise sont mesurées avec des détecteurs pyroélectriques. Dans toutes les expériences une fréquence de 40 impulsions à la minute a été utilisée.

Analyse

Le CF_3Cl (Matheson) est purifié peu avant l'utilisation par distillation à basse température jusqu'à l'élimination de toute impureté détectable au spectromètre de masse. La cuve est raccordée directement au spectromètre de masse (Hitachi Perkin-Elmer RMU-6D) et aux pressions supérieures à 0.5 Torr, on analyse les produits après avoir piégé une partie du CF_3Cl dans un bain d'isopentane à −160°C. A cette température la tension de vapeur de l'hexafluoroéthane est de 75 mTorr, bien supérieure à la quantité produite. Les rendements et les teneurs en ^{13}C sont tirés des hauteurs des pics m/e 119, 120 et 121 de l'ion $C_2F_5{}^+$. Le CF_3Cl ne contribuera en aucun cas à ces masses. L'étalonnage donne une relation linéaire entre la hauteur des

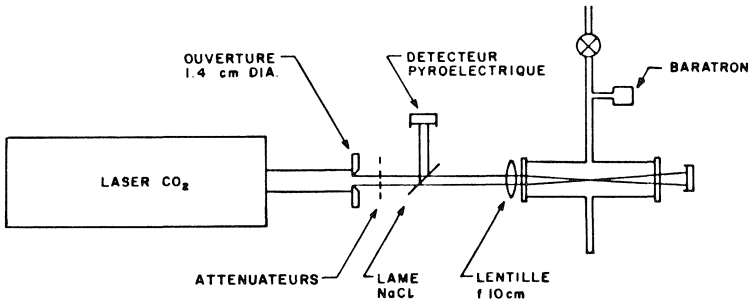

FIG. 1. Schéma du montage.

pics 119 + 120 + 121 et la pression de C_2F_6 à l'entrée du spectromètre.

La teneur en ^{13}C du produit s'exprime selon

$$[1] \quad x' = \frac{I_{121} + \frac{1}{2}I_{120}}{I_{119} + I_{120} + I_{121}}$$

Les résultats sont présentés sous la forme suivante

$$[2] \quad {}^{13}N = x'N$$

$$[3] \quad {}^{12}N = (1 - x')N$$

où N est le nombre de moles d'hexafluoroéthane produit par impulsion. Dans toutes les expériences, la décomposition est maintenue inférieure à 1% et le facteur de séparation primaire peut s'exprimer selon

$$[4] \quad \beta = \frac{x'}{x}\frac{1 - x}{1 - x'}$$

où $x = 0.0111$ est la teneur en ^{13}C du produit naturel (13).

Résultats

Comme pour CF_3Br (6), le rendement N est indépendant du nombre d'impulsions utilisé. La seule diminution observée est facilement explicable par la diminution de la pression de CF_3Cl.

Dépendance spectrale de la décomposition

Le spectre de la bande de valence ν_1 de CF_3Cl à 1106 cm^{-1} est montré à la fig. 2*a*. La bande d'absorption du $^{13}CF_3Cl$ apparaît à basse température (fig. 2*b*) avec un déplacement isotopique de 29 cm^{-1}. Une irradiation à des fréquences correspondant à cette absorption donne un produit enrichi en ^{13}C et le facteur de séparation augmente à mesure que l'absorption de $^{13}CF_3Cl$ devient prépondérante (5).

La décomposition de $^{12}CF_3Cl$ représentée par la courbe de ^{12}N à la fig. 2 diminue considérablement à mesure que la fréquence d'activation s'éloigne de la bande ν_1. Par contre la décomposition de $^{13}CF_3Cl$ passe par un maximum qui apparaît déplacé vers le rouge de 7 cm^{-1} par rapport au centre de la bande d'absorption de $^{13}CF_3Cl$ à 1077 cm^{-1}.

Pour étudier l'influence des autres paramètres, nous utiliserons une irradiation à 1077.3 cm^{-1}, correspondant au centre de la bande ν_1 de $^{13}CF_3Cl$, donc dans la région intermédiaire entre les maxima des deux spectres de décomposition des deux variétés isotopiques.

Influence de la pression

Le rendement en hexafluoroéthane en fonction de la pression apparaît à la fig. 3. Remarquons d'abord l'augmentation en P^2 pour ^{13}N aussi bien que pour ^{12}N pour la gamme de pressions utilisées. L'influence de la pression sur le facteur de séparation (qui est proportionnel à $^{13}N/^{12}N$) est moins

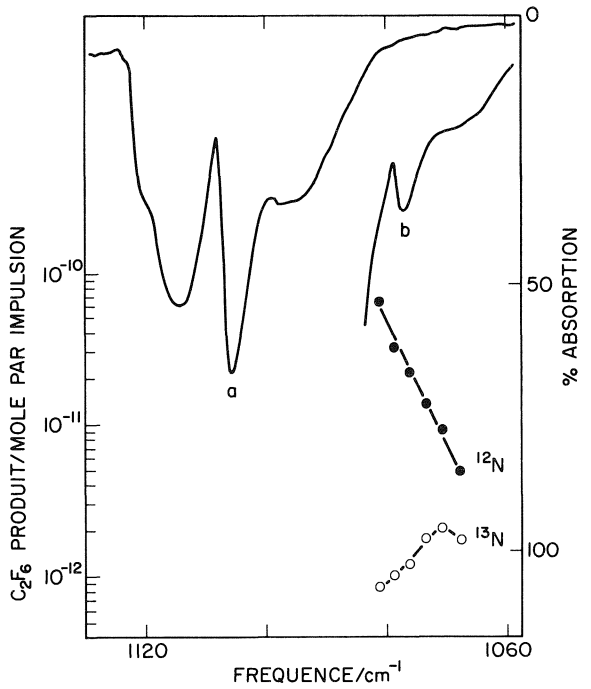

FIG. 2. Production d'hexafluoroéthane en fonction de la fréquence d'activation pour une pression de CF_3Cl de 0.5 Torr, une énergie incidente de 1.8 J et une température de 22°C. A une fréquence de 1081.1 cm^{-1}, la décomposition est pratiquement non sélective mais le facteur de séparation augmente rapidement pour atteindre $\beta = 45$ à 1067.5 cm^{-1} (5). On montre aussi les spectres d'absorption infrarouge de CF_3Cl dans une cuve de 5 cm de longueur: *a*: pression: 1.5 Torr et température: 22°C; *b*: pression: 100 Torr et température: −67°C.

importante pour CF_3Cl que pour CF_3Br (6). Bien que la pente de ^{13}N soit un peu plus faible, aucun nivellement n'est observé montrant que la réaction de mélange isotopique n'est pas importante au-dessous de 2 Torr.

[5] $^{13}CF_3 + {}^{12}CF_3Cl \rightarrow {}^{13}CF_3Cl + {}^{12}CF_3$

Qualitativement on peut donc proposer un mécanisme identique de production de l'hexafluoroéthane léger et de l'hexafluoroéthane enrichi.

Influence de l'énergie incidente

On montre à la fig. 4, l'augmentation du rendement en hexafluoroéthane en fonction de l'énergie incidente. Ce rendement en E_0^2 a été démontré clairement aussi pour CF_3Br et CF_3I. De même pour le facteur de séparation qui est indépendant de l'énergie incidente pour les trois trifluorométhanes. Comme on l'a déjà souligné (6), on n'a aucune raison de prévoir un comportement différent pour $^{13}CF_3Cl$ ou $^{12}CF_3Cl$ quant à la probabilité de décomposition en fonction de l'énergie incidente. En effet, sans qu'il soit nécessaire d'établir un modèle, par exemple un modèle géométrique de décomposition donnant les fluences-seuils (3), les

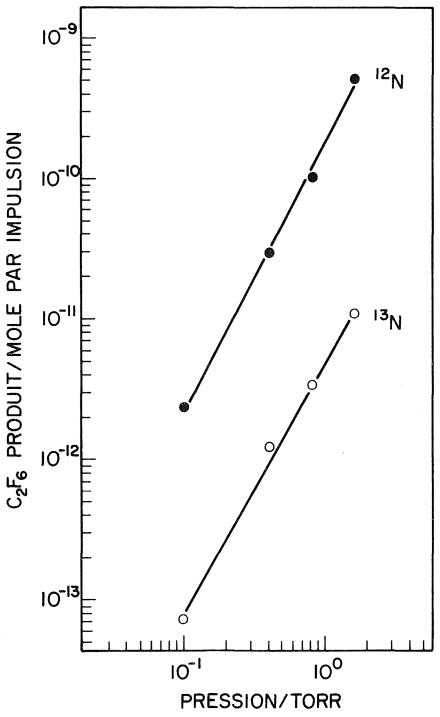

FIG. 3. Production d'hexafluoroéthane en fonction de la pression de CF_3Cl pour une fréquence d'activation de 1077.3 cm^{-1}, une énergie incidente de 1.8 J et une température de 22°C. Le facteur de séparation passe de $\beta = 3$ à $\beta = 1$ quand la pression augmente de 0.1 à 2 Torr.

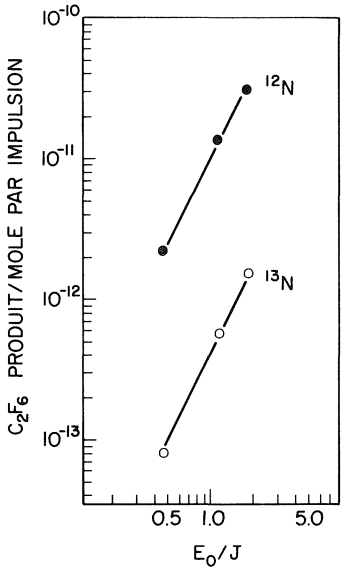

FIG. 4. Production d'hexafluoroéthane en fonction de l'énergie incidente pour une fréquence d'activation de 1077.3 cm^{-1}, une pression de 0.5 Torr et une température de 22°C. Dans ces conditions, le facteur de séparation est constant à 3.8 ± 0.4.

probabilités de décomposition peuvent être établies comme des volumes de réactions qui augmentent au même rythme pour les deux espèces isotopiques si on augmente l'énergie incidente, de sorte que le rapport de ces volumes, donc le facteur de séparation, ne varie pas.

Influence de la température

La fig. 5 représente la variation observée de ^{13}N et ^{12}N en fonction de la température. Ces résultats sont différents de ce qui est obtenu avec CF_3COCF_3 (3) à cause du mécanisme de décomposition différent. Puisque la décomposition de $^{13}CF_3Cl$ diminue aussi à basse température, il ne s'agit donc pas seulement d'un effet spectroscopique tel que suggéré ultérieurement (5) ou tel qu'observé dans d'autres systèmes (3).

Discussion

De toute évidence, le modèle du double cône de décomposition ($N \propto PE_0^{3/2}$) ne s'applique pas pour CF_3Cl qui donne un rendement en

[6] $N \propto P^2E_0^2$

Le mécanisme proposé est le suivant. L'activation polyphotonique se fait selon les réactions [7] et [8].

[7] $^{13}CF_3Cl \xrightarrow{\langle^{13}n\rangle\hbar\omega} {}^{13}CF_3Cl^*$

[8] $^{12}CF_3Cl \xrightarrow{\langle^{12}n\rangle\hbar\omega} {}^{12}CF_3Cl^*$

Dans nos expériences, le choix de la fréquence d'activation, mais aussi le choix de la pression, et de l'énergie incidente tendent à favoriser la réac-

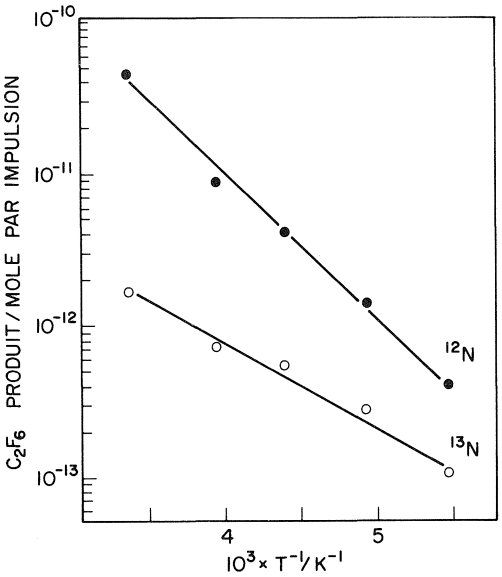

FIG. 5. Production d'hexafluoroéthane en fonction de la température pour une fréquence d'activation de 1077.3 cm^{-1}, une concentration dans la zone irradiée de 2.7×10^{-8} mol cm^{-3} et une énergie incidente de 1.8 J. Le facteur de séparation augmente jusqu'à $\beta = 25$ si on diminue la température jusqu'à $-90°C$.

tion [7] pour activer sélectivement, en vue de la décomposition, les molécules qui contiennent l'isotope ^{13}C. Les quantités $\langle {}^{13}n \rangle$ et $\langle {}^{12}n \rangle$ sont les nombres moyens de photons absorbés par molécule de chaque espèce isotopique. Ces quantités ne sont pas mesurables mais il est possible par contre de mesurer $\langle n \rangle$, le nombre moyen de photons absorbés par molécule irradiée soit par simple absorption (3) ou par un moyen optoacoustique (14).

Ces molécules possédant une activation vibrationnelle peuvent soit se décomposer spontanément, la réaction [9], si elles ont atteint un niveau d'énergie suffisant, soit se décomposer à la suite d'une collision avec une autre molécule activée, la réaction [10], et contribuer ainsi à la formation du produit hexafluoroéthane par recombinaison des radicaux trifluorométhyle.

[9] $CF_3Cl^* \rightarrow CF_3 + Cl$

[10] $CF_3Cl^* + CF_3Cl^* \rightarrow CF_3 + Cl + CF_3Cl$

[11] $CF_3 + CF_3 \rightarrow C_2F_6$

Une activation sélective de $^{13}CF_3Cl$ sera traduite par un produit C_2F_6 enrichi en ^{13}C. D'autre part, les molécules activées peuvent être perdues soit par collision avec une molécule "froide", la réaction [12], soit par diffusion hors du "volume actif", la réaction [13].

[12] $CF_3Cl^* + CF_3Cl \rightarrow CF_3Cl + CF_3Cl$

[13] $CF_3Cl^* \rightarrow CF_3Cl$

La réaction [13] inclut de même la diffusion de molécules froides dans le volume irradié et c'est cette réaction qui domine la compétition avec la réaction [10] dans notre système pour donner les bons exposants dans l'expression [6]. La formation d'hexafluoroéthane est contrôlée par les constantes de vitesse des réactions [11], [14] et [15].

[14] $CF_3 + Cl \rightarrow CF_3Cl$

[15] $Cl + Cl \rightarrow Cl_2$

Même si la vitesse de production de C_2F_6 à partir des radicaux trifluorométhyle dépend des concentrations réelles de CF_3, le rendement par impulsion N doit être indépendant de la concentration à moins que des réactions du type de la réaction [16] soient importantes.

[16] $CF_3 + Cl_2 \rightarrow CF_3Cl + Cl$

Cette réaction n'est pas importante dans ce mécanisme de même que la réaction [5] qui ne doit pas affecter le rendement en C_2F_6 mais ne changerait que le facteur de séparation (4–6). Aucune indication n'apparaît dans les présents résultats pour postuler la présence de deux sources de produits comme dans le cas de CF_3Br (6).

En somme le mécanisme se résume comme suit: (*a*) production d'une distribution de molécules activées ^{13}A et ^{12}A (= $[^{13}CF_3Cl^*]_i$ et $[^{12}CF_3Cl^*]_i$) dans un volume actif en forme de double cône, (*b*) décomposition, principalement par collision entre deux molécules activées, et (*c*) compétition de cette réaction avec la diffusion hors du volume actif. Tel que démontré précédemment (15), le nombre de molécules décomposées par impulsion suit la formule empirique $aP + bP^2$ où l'importance des coefficients a et b dépend fortement de l'énergie incidente. D'autre part, 70% de l'énergie de l'impulsion laser est comprise dans le pic initial de 80 ns FWHM (3) et les molécules activées subsistent pour une période relativement plus longue, plusieurs microsecondes (16). On peut donc supposer que chaque impulsion du laser produit la quantité $^{13}A + {}^{12}A$ de molécules activées; cette quantité augmente selon PV, le produit de la pression de l'absorbant et V, le volume actif, donné par la géométrie de l'irradiation. Dans le cas présent, on peut imaginer un certain volume à l'intérieur duquel le pompage est effectif: posons F comme la fluence à la surface de ce volume. F dépend de la nature de l'absorbant, de ω et de T mais est indépendant de P (17). Donc,

[17] $F = E_0/\pi r^2$

où E_0 est l'énergie incidente et r est le rayon du cône. On peut alors montrer facilement que

[18] $V \propto E_0^{3/2}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

une relation importante observée dans plusieurs systèmes pour l'activation polyphotonique en régime focalisé. Le pompage se fait alors à une vitesse proportionnelle à $PE_0^{3/2}$. La fraction de A $(= {}^{13}A + {}^{12}A)$ qui mène à la décomposition est donnée par le mécanisme selon

$$[19] \quad f = \frac{k_{10}A^2}{k_{10}A^2 + k_{13}AS}$$

où S est la surface de diffusion du volume actif. D'après l'expression [17],

$$[20] \quad S \propto E_0$$

Par substitution, on obtient alors une vitesse de décomposition

$$[21] \quad v \propto (1 + (k'PE_0^{1/2})^{-1})^{-1}PE_0^{3/2}$$

où $k' \propto k_{10}/k_{13}$. Deux cas limites peuvent se présenter (6) et les résultats présents ($v \propto P^2E_0^2$) montrent que l'expérience se situe à des rapports surface/volume élevés où la perte par diffusion des molécules activées est importante.

L'influence de la température représentée à la fig. 5 confirme ce mécanisme. En effet, pour une énergie incidente constante, on aura

$$[22] \quad N = c({}^{13}A + {}^{12}A)^2$$

où c est une constante indépendante de la température qui inclut la stoichiométrie et qui tient compte de la recombinaison éventuelle des radicaux selon la réaction [14]. De cette expression on obtient directement une relation entre les nombres de molécules activées ${}^{13}A$ et ${}^{12}A$ et les rendements ${}^{13}N$ et ${}^{12}N$.

$$[23] \quad ({}^{13}A)^2 = x^{13}N/a$$

$$[24] \quad ({}^{12}A)^2 = (1 - x)^{12}N/a$$

Si les raisonnements sur la fréquence d'activation développés pour CF_3COCF_3 sont applicables ici, on prévoit alors que l'activation de ${}^{13}A$ ne variera pas avec T et que l'activation de ${}^{12}A$ diminuera avec T puisque la fréquence d'activation se situe du côté bleu de la bande d'absorption polyphotonique de ${}^{13}CF_3Cl$ et du côté rouge pour ${}^{12}CF_3Cl$. La quantité $(x^{13}N)^{1/2}$ doit donc être constante et c'est ce qui est représenté à la fig. 6 (${}^{13}A$). De plus, la variation de $((1 - x)^{12}N)^{1/2}$ représentée à la fig. 6 (${}^{12}A$) donne une pente d'Arrhenius correspondant à une énergie d'activation de $795 \pm 25\ cm^{-1}$ qui concorde avec l'une des fréquences fondamentales de la molécule: 350, 478, 560, 762, 1106 et 1217 cm^{-1} (18).

En somme, ces résultats montrent que l'effet de la température combine l'influence des bandes chaudes et du mécanisme cinétique et résulte en une perte de produits enrichis en ${}^{13}C$. Le facteur de séparation augmente si on diminue la température mais au dépend du rendement puisque la probabilité de décomposition diminue non seulement pour ${}^{12}CF_3Cl$ mais aussi pour ${}^{13}CF_3Cl$. A part les différences spectroscopiques qui sont au détriment de CF_3I (5) les trois molécules CF_3X obéissent aux mêmes mécanismes de décomposition et se comportent de la même façon dans une étude paramétrique. L'efficacité de la production de ${}^{13}C$ par photon absorbé est présentement à l'étude.

The first part of this paper describes the experimental search for a donor which would complex preferentially one of the isomers of 1,2-dicyanoethylene. This involved measuring the association constants (K_c^{DA}) of the charge-transfer (ct) complexes of several dimethoxynaphthalenes (DMN) with maleonitrile (MN) and fumaronitrile (FN). From the measured K_c^{DA}, we found that MN complexes more strongly than FN with 1,4- and 1,5-DMN but that FN complexes more strongly with 2,3-DMN than does MN. These results are explained in terms of more than one favourable geometry for the ct complexes, since the donors are relatively large compared to the acceptors.

Irradiation of the ct complexes between 1,4-, 1,5-, or 2,3-DMN and 1,2-dicyanoethylene led to isomerization of the olefins. The photostationary state depends on the absorption spectra of the ct complexes formed between the donor and the isomeric olefins. From spectroscopic and photo-CIDNP studies, we find evidence that the isomerization in polar solvents takes place via the triplet state of the olefin. The triplet is formed from the radical ion pair resulting after excitation of the ct complex.

P. C. WONG et D. R. ARNOLD. Can. J. Chem. **58**, 918 (1980).

La première partie de cette publication décrit la recherche expérimentale d'un donneur qui complexerait préférentiellement l'un des isomères du dicyano-1,2 éthylène. Cette recherche implique la mesure des constantes d'association (K_c^{DA}) des complexes de transfert de charge (tc) de plusieurs diméthoxynaphtalènes (DMN) avec le maléonitrile (MN) et le fumaronitrile (FN). Nous trouvons, à partir des mesures de K_c^{DA}, que les complexes du MN avec le DMN-1,4 et -1,5 sont plus stables que ceux du FN, mais les complexes du FN avec le DMN-2,3 sont plus stables que ceux du MN. On explique ces résultats en fonction de plus d'une géométrie favorable des complexes de tc puisque les donneurs sont relativement plus nombreux par rapport aux accepteurs.

L'irradiation des complexes de tc entre les DMN-1,4, -1,5 ou -2,3 et le dicyano-1,2 éthylène conduit à une isomérisation des oléfines. L'état photostationnaire dépend des spectres d'absorption des complexes de tc formés entre le donneur et les oléfines isomères. A partir des études spectroscopiques de photo-PNDIC nous trouvons la preuve que l'isomérisation dans les solvants polaires se fait via un état triplet de l'oléfine. Le triplet se forme à partir de la paire d'ions radicalaires résultant de l'excitation du complexe de tc.

[Traduit par le journal]

Introduction

We have previously reported (1) that the direct irradiation of the charge-transfer (ct) complexes between 1,2,3-triphenylcyclopropene and fumaronitrile (FN), and between *trans*-stilbene (TS) and FN, lead to *trans–cis* isomerization of the olefin. The proposed mechanism for the isomerization involves the triplet state of the olefin which is formed from the excited ct complexes. In the stilbene – 1,2-dicyanoethylene system, irradiation of the TS–FN ct complex leads to a mixture rich (>85%) in *cis*-stilbene (CS) which forms a weaker ct complex with FN than TS (both smaller association constant (K_c^{DA}) and ct transition extinction coefficient (ε_λ^{DA})).

This has encouraged us to search, in general, for donors (or acceptors) which would complex preferentially one of the acceptor (or donor) olefin isomers. Irradiation of the ct complex would then lead to enrichment of the other olefin isomer. The present approach may become a new synthetically useful method for obtaining a specific olefin isomer. Furthermore, if the ct bands of the two complexes formed from the *trans* and the *cis* olefin with a common donor (or acceptor) are well separated, then the *trans*:*cis* ratio of the photostationary state mixture can be "fine-tuned" upon varying the excitation wavelengths. This then affords a new photochromic system which is potentially useful.

In spite of the large body of theoretical studies on ct complexes, it is still difficult to predict the strength of the ct complex being formed (K_c^{DA}), the extinction coefficient of the ct transition (ε_λ^{DA}), and the relative orientation of the two components within the complex in solution (2). In the systems we have studied, we hoped to see differences in the complexing ability between the isomeric donors and acceptors as a function of the position and configuration of the substituents. Maleonitrile (MN) and fumaronitrile (FN) have nearly identical reduction potentials (1*a*, 3); therefore we expected that any difference in the relative complexing abil-

ity toward a common donor molecule would come mainly from the difference in their geometries. We reasoned that if the attractive interactions favour the eclipsed form, with the electron withdrawing substituents in the acceptor aligning with the electron donating substituents in the donor, then, MN should be a stronger acceptor than FN towards donors like 2,3-dimethoxynaphthalene (2,3-DMN) and 1,4-DMN while the opposite would be true towards 1,5-DMN. Actually, there is some evidence that the eclipsed form results in a stronger ct interaction than does the staggered form in a similar system. Staab and co-workers have synthesized and recorded the absorption spectra of a series of [2.2]- (4) and [3.3]-paracyclophanes (5) bearing two electron donating substituents on one aromatic ring and two electron withdrawing substituents on the other. The intramolecular ct spectra of the "pseudo geminal" (eclipsed form) isomers differ remarkedly from those of the "pseudo ortho" (staggered form) isomers. Upon analysing their absorption spectra, using a HMO calculation, they found that the former compounds are stabilized relative to the latter compounds by ct interaction (6).

In this paper, we report the association constants (K_c^{DA}) and extinction coefficients (ε_λ^{DA}) of the ct complexes formed between isomeric donors (1,4-DMN, 1,5-DMN, and 2,3-DMN) and isomeric acceptors (FN and MN). The photochemistry and photophysics of these ct complexes have also been investigated. Irradiation of the ct complexes leads to isomerization of the olefins. The photostationary state ratio of the olefin isomers is dependent on the absorption spectra of the ct complexes. The photophysical processes leading to the isomerization have been examined using spectroscopic and photochemically induced dynamic nuclear polarization (photo-CIDNP) techniques.

Results

Both the ultraviolet–visible spectrophotometric (uv–vis) method and the proton nuclear magnetic resonance (^{1}Hmr) method were employed in measuring the association constants (K_c^{DA}) of the dimethoxynaphthalene – 1,2-dicyanoethylene ct complexes. Chloroform was used as the solvent for this part of the study so that comparison with reported data is possible (7). Irradiations were carried out using benzene as solvent . There is significant difference in the ct absorption spectra for the complexes formed between a common donor and FN and MN. Figures 1, 2, and 3 show these spectra in chloroform; similar spectra were observed in benzene solution. The absorbance (optical density,

OD) is higher in the long wavelength region (i.e., between 350–380 nm) with the 1,4-DMN (or 1,5-DMN) – MN complex than the 1,4-DMN (or 1,5-DMN) – FN complex. On the other hand, when 2,3-DMN is the donor, the OD of the 2,3-DMN – FN complex is higher than that of the 2,3-DMN – MN complex in this region.

With the uv–vis method two experimental conditions were employed: (*1*) with $[A]_0 \gg [D]_0$ and (*2*) with $[D]_0 \gg [A]_0$ (where $[A]_0$ and $[D]_0$ are the total concentrations of the acceptor and the donor respectively). Two different approaches for evaluating the K_c^{DA} and ε_λ^{DA} were used, namely, the Benesi–Hildebrand (B–H) method (8) and the Foster–Hammick–Wardley (F–H–W) method (9). The results are summarized in Tables 1, 2, and 3.

Using the ^{1}Hmr method, the analogous B–H plots (7) also gave linear relationships. The results are summarized in Table 4. The K_c^{DA} values for the 1,5-DMN complexes were not measured due to the relative insolubility of 1,5-DMN. The heats of formation for the 1,4-DMN complexes were obtained from van't Hoff plots of the temperature dependent K_c^{DA} values determined by the ^{1}Hmr method.

Irradiation ($\lambda > 360$ nm) of the 1,4-DMN – FN ct complex in benzene solution caused little chemical change other than isomerization of the olefin. The quantum yield of isomerization of FN to MN was 2.4×10^{-3} ($\pm 10\%$) at 362 ± 6 nm. Prolonged irradiation led to a photostationary state of FN:MN = 63:37 in this solvent. The isomerization also occurred upon irradiation at $\lambda > 400$ nm; however,

2,3-DMN	MN	16.8	284	1.69	10

since very little light is absorbed in this region, it was not possible to determine accurately the photostationary state. Irradiation ($\lambda > 360$ nm) of the 1,4-DMN – FN ct complex in acetonitrile also gave rise to isomerization. In this case also the approach to equilibrium was very slow.

Irradiation ($\lambda > 360$ nm) of the 1,5-DMN – FN ct complex in benzene solution likewise gave a photostationary state of FN:MN = 63:37. However, the photostationary state was FN:MN = 44:56 when the 2,3-DMN – FN ct complex was irradiated under these conditions. All the above photostationary states were reproducible starting from MN or a mixture of FN and MN while other reactions were negligible (< 5%).

The fluorescence lifetimes (τ_0) of the dimethoxynaphthalenes and the parameters obtained from the fluorescence quenching of the DMN's by the dinitriles are listed in Table 5. The Stern–Volmer plots at high quencher concentration were curved slightly upward. This is probably due to absorption of the incident light by the ground state ct complex. The quenching rate constants (k_q) in these cases were obtained by a method estab-

lished by Ware and co-workers (10):

$$[1] \quad K_{SV} = (I_0/I - 1)\,(1/[Q]) = K' + k_q\tau_0 + K'k_q\tau_0[Q]$$

$$[2] \quad K' = K_c^{DA}(\varepsilon_\lambda^{DA}/\varepsilon_\lambda^{D})$$

By plotting K_{SV} against [Q], a linear relationship was obtained. The K' and $k_q\tau_0$ values could then be obtained from the y-intercept and the slope of the straight line. The k_q's are all essentially diffusion controlled (see Table 5).

The photo-CIDNP experiments were performed with acetonitrile-d_3 as the solvent. In benzene-d_6 solution no CIDNP signal was observed under the same conditions. When a solution of 1,4-DMN and FN (or MN) was irradiated, the signal of the donor broadened (especially broadened are the 2,3,5,8 and the methoxy protons (Fig. 4)) in the initial period. At the same time we observed an emission signal for MN (or FN) while the FN (or MN) signal was not noticeably affected. The spectrum returned to its normal form gradually (minutes) after the light was switched off.

Discussion

By definition, an exciplex is a molecular complex which only exists in the excited state. An excited ct complex can be produced by either irradiation of the ct absorption band or by excitation of one of the uncomplexed components.

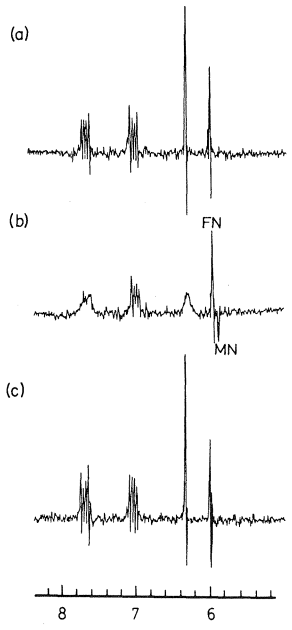

FIG. 4. Photo-CIDNP study of the 1,4-DMN – 1,2-dicyanoethylene system in acetonitrile-d_3; (*a*) before irradiation, (*b*) during irradiation, and (*c*) after irradiation.

A ground state ct complex is generally only slightly (a few kcal mol^{-1}) more stable than the free components. Direct irradiation of the ct band gives rise to a nonrelaxed state which possesses a lower energy content than the first excited singlet state of the components. This nonrelaxed state may also be obtained by exciting a free component (say the acceptor, A) to its first excited singlet state ($^1A^*$) and formation of an encounter complex with the donor (D) upon diffusion. The nonrelaxed state can (*a*) relax to an equilibrium state, which is called the ct fluorescence state in the ct complex system and the exciplex fluorescence state in the exciplex system, through reorientation of the components and the solvent molecules (11, 12), (*b*) decay in a radiationless manner back to the ground state, (*c*) give rise to triplet formation (13–15), or, (*d*) dissociate into the solvent-separated radical ions through the radical ion pair (15–17).

It is known that K_c^{DA} and ε_λ^{DA} obtained from the uv–vis method are often dependent upon the concentration conditions (e.g. $[D]_0 \gg [A]_0$, $[A]_0 \gg [D]_0$, or $[D]_0 = [A]_0$) while the product $(K_c^{DA} \cdot \varepsilon_\lambda^{DA})$ is not (7). Practically, since these two constants are essentially inversely related, an overestimation of one causes a corresponding underestimation of the other. The K_c^{DA} obtained from the ^{1}Hmr method is not concentration dependent; however, it is not useful for establishing ε_λ^{DA} which is of course important for photochemical studies. Therefore, it is desirable to use both methods whenever possible.

The only association constants for the ct complexes formed between a common donor (benzene) and both MN and FN have been reported by Schuler and Heusinger (18). They found that the K_c^{DA} for benzene–MN (0.43 M^{-1}) is larger than that of benzene–FN (0.16 M^{-1}) while the extinction coefficient of the former complex (ε_λ(275 nm) = 302) is less than that of the latter complex (ε_λ(275 nm) = 895). Using the ^{1}Hmr method, they obtained a slightly larger K_c^{DA} value (0.173 M^{-1}) for the benzene–FN complex which they attributed to the magnetic anisotropic effect of the benzene molecule on the substrate. This latter value is, in our opinion, unreliable since the observed chemical shift change was referred to the solvent (chloroform) signal which would also be shifted upfield as the concentration of the donor (benzene) increased. We have demonstrated in our case that the chloroform signal indeed shifted significantly as the concentration of the donor (e.g. 1,4-DMN) was increased. Therefore, in our ^{1}Hmr experiment, we took advantage of the deuterium lock for accurate chemical shift readings, referring to an inert internal reference (tetramethylsilane).

As shown in Tables 1, 3, and 4, there is generally

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

good agreement of the K_c^{DA} values for the DMN – 1,2-dicyanoethylene complexes using the uv–vis method and the ^{1}Hmr method. The only exceptions are two cases, 1,4- and 1,5-DMN with FN using the uv–vis method when $[A]_0 \gg [D]_0$. Possible causes for these anomalies may involve deviation in activity coefficients from unity, the presence of isomeric 1:1 complexes, contact ct complex, termolecular complexes, deviation from Beer's law, etc. (7, 19). Based upon our experimental results, it is difficult to choose from among these possibilities.

The relation between the ct extinction coefficient and the heat of formation of ct complex (ΔH^θ) has been considered by several authors (2, 19*a*, 20). There seems to be no consistent relationship between ε_λ^{DA} and ΔH^θ. We have also found that this is the case in our system (e.g. ε_λ^{DA} is larger for the 1,4-DMN–FN complex than the 1,4-DMN–MN complex but the opposite is true for the ΔH^θ values).

Our results indicate that MN has a greater complexing ability (larger K_c^{DA}) towards the donors, 1,4- and 1,5-DMN while the reverse is true when 2,3-DMN is the donor. This is in contrast with what we expected initially. Nevertheless, the results *do* prove that the relative complexing ability of the isomeric acceptors *is* dependent upon the structure of the donor. This is not easily rationalized from Mulliken's theory.

Based upon Mulliken's theory one would expect that the complexing power of structurally similar acceptors complexed to a common donor depends chiefly on their electron affinity (or reduction potential). Since FN and MN have essentially the same reduction potentials, the K_c^{DA} values for the DMN–FN complexes would be equivalent to those of the DMN–MN complexes. The observed difference in the K_c^{DA} values must then arise from the differences in the geometry of the components.

The difficulties involved in predicting the complexing abilities of the isomeric acceptors may result from the fact that the smaller acceptor can complex with the larger donor (DMN) in more than one region. The observed stability of these complexes would then be the average of all these various geometries. This problem may be minimized if the complexing regions of the donor and acceptor are of comparable size. For example, the ct complex formed between stilbene and tetracyanoethylene (TCNE) has the main ct interaction located at the central double bonds. We found that FN is a stronger acceptor ($K_c^{DA} = 0.17\,M^{-1}$) (16) than MN ($K_c^{DA} = 0.10\,M^{-1}$)[3] towards TS in benzene solution. These results favour a geometry of the ct complex where the two olefins are parallel and oriented at the central double bonds. The effects on K_c^{DA} values due to geometric factors are under further investigation in this laboratory for donors of smaller sizes or with additional steric effects, 1,3-benzodioxole and 2,3-dimethoxy-[2.2.2]bicyclooctene-2 for example.

Benzene was used as the solvent for the photochemical studies. The absorption spectra of the ct complexes in this solvent were essentially the same as in chloroform solution, shown in Figs. 1–3.

Prolonged irradiation ($\lambda > 360$ nm) of the ct band of the complex between FN and 1,4- or 1,5-DMN yielded a photostationary state which consisted of FN:MN = 63:37. On the other hand, the photostationary state was FN:MN = 44:56 when 2,3-DMN was the donor. An attempt to study the variation in the photostationary state as a function of excitation wavelength was abandoned because of the inefficiency of the isomerization as the result of the low absorbance of the complexes at longer wavelengths.

We have evidence that the photoisomerization is mainly due to the olefin triplet derived from the excited ct complex. Firstly, 2,3-DMN (0.3 *M*) does not absorb light with wavelengths > 360 nm and isomerization does occur upon irradiation at this wavelength. Secondly, even if a small amount of unfiltered light reaches free 2,3-DMN molecules, the singlet excited molecules of 2,3-DMN would be quenched by FN (under our experimental conditions, knowing the singlet quenching rate constants, we calculate that 99% of the singlet 2,3-DMN would be quenched by formation of the excited ct complex). Furthermore, the photostationary state in this case is different from that derived from triplet–triplet energy transfer employing high energy sensitizers (with the triplet energy, E_T, of the sensitizer > 50 kcal mol^{-1}, the photostationary state is FN:MN = 60:40 (1*a*)). These results can be fully accounted for with the mechanism described in Scheme 1.

In the present system, it is assumed that the triplets (^{3}*cis*-A* and ^{3}*trans*-A*) of the *cis*- and the *trans*-acceptor (A) olefins are of lower energies than the donor (D) triplet. It is also assumed that both *cis*-A and *trans*-A form ct complexes with D reversibly (steps 1 and 2). Excitation of the ct complexes (steps 3 and 6) lead to the corresponding excited ct complexes ([D.*cis*-A]* and [D.*trans*-A]*). Deactivation of these complexes (steps 4 and 7) gives the planar (more or less) olefin triplets which are known to promote isomerization via a common twisted triplet state (TTS) (steps 5 and 8) to give a fixed ratio of the ground state *trans*- and *cis*-A (step 9). From Fig. 3, one would expect

SCHEME 1

that the photostationary state would favour a higher ratio of MN upon excitation of the 2,3-DMN – 1,2-dicyanoethylene complexes. This is in accord with the observed photostationary state with FN:MN = 44:56.

With the 1,4-DMN – 1,2-dicyanoethylene system, we can not rule out the involvement of the triplet–triplet transfer mechanism for the photoisomerization of the dinitriles since the photostationary state observed is similar to that of the triplet sensitized mechanism (FN:MN = 60:40) and the quantum yield of isomerization of FN is small (2.4×10^{-3}). We favour Scheme 1, however, since the isomerization occurred upon excitation at wavelengths > 400 nm where 1,4-DMN does not absorb. Even in the event 1,4-DMN is being irradiated, we calculate that 97% of the singlet 1,4-DMN would be quenched under the experimental conditions. Furthermore, the photostationary state ratio of the dinitriles can be explained in the same way as the 2,3-DMN case. The 1,4-DMN – MN complex has higher adsorbance than the 1,4-DMN – FN (Fig. 1) in the actinic light region. The same arguments are also applicable to the 1,5-DMN – 1,2-dicyanoethylene case (Fig. 2).

The detailed mechanism for the formation of triplets upon irradiation of the ct complex has been examined. The first step upon decay of the non-relaxed excited state, $^1(D^+A^-)^{\neq}$, of the ct complex is the formation of the singlet radical ion pair (in polar solvent). This step is supported by the favourable free energy charge (ΔG) (Table 6) estimated through the use of the Weller equation [3] (details of this calculation have been described before (1*a*)) and the observed fluorescence quenching rate constants, k_q, which are all diffusion controlled (Table 5).

$$[3]\quad \Delta G = 23.06[E_{1/2}^{ox}(D) - E_{1/2}^{red}(A) - e_0^2/\varepsilon\alpha] - \Delta^1E_{0,0}\ \text{kcal mol}^{-1}$$

The amount of energy within the bracket in eq. [3] is the free energy of the radical ion pair (E(RIP)).

The singlet radical ion pair can recombine to give the ground states D and A, dissociate to solvated ions, and/or undergo intersystem crossing via hyperfine interaction to give a triplet radical ion pair. If the energy of the triplet radical ion pair is above the sum of the energies of a triplet excited component and a ground state of the other component, then the triplet radical ion pair can recombine to give this set of triplet and ground state components. Confirmation of these processes in exciplex systems where the triplet state can be observed spectroscopically has been successfully demonstrated through studies of the external magnetic field effect on triplet formation yields (15). Since the triplet state of olefins is normally very short-lived, it would be difficult to trace their formation mechanism by normal spectroscopic techniques. Photo-CIDNP affords the best technique for the present studies. It can distinguish the radical ion mechanism from the exciplex mechanism or the triplet–triplet energy transfer mechanism for the formation of olefin triplets, since the latter two mechanisms would not give rise to polarization. The photo-CIDNP results confirm the radical ion pair mechanism (Fig. 5) in polar solvents. The observed polarization is interpreted in terms of the modified Kaptein rule (21) described below.

Our photo-CIDNP results, on the 1,4-DMN – 1,2-dicyanoethylene system, are very similar to Taylor's results cited by Roth (22). Irradiation of a solution of 1,4-DMN and FN brought about broadening of the signals for 1,4-DMN (especially broadened are the 2,3,5,8 and methoxy protons), not much change for the FN signal, and an emission for maleonitrile (Fig. 4). Similar results were observed when 1,4-DMN – MN was irradiated (i.e., not much change for MN signal and an emission for fumaronitrile).

The signal broadening for 1,4-DMN indicates the existence of the 1,4-DMN radical cation which exchanges electrons with 1,4-DMN at a fast rate (23). The observed emission for MN (or FN) can be accounted for with the aid of the modified Kaptein rule, assuming that the triplet olefin is derived from the radical ion pair (Fig. 5). $\Gamma n_i = \mu \cdot \varepsilon \cdot a_i \cdot \Delta g \cdot \gamma =$ − (emission for α-H of MN (or FN)), since $\mu =$ − (singlet origin), $\varepsilon =$ + (cage product), a(α-H) = −, $\Delta g = 2.004–2.0031 =$ + (22, 24), and $\gamma =$ − (triplet exit channel). The reason for the FN (or MN) signal being unaltered may be that the polarization due to decay from the singlet radical ion pair and the triplet radical ion pair essentially cancel each other, since they have opposite polarization according to this rule.

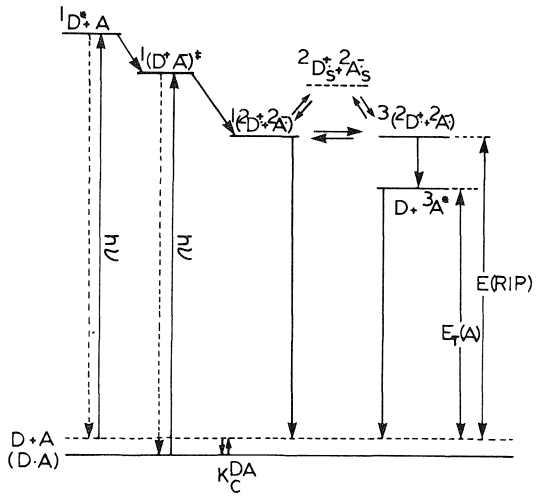

FIG. 5. Energy diagram for the formation of triplets upon direct excitation of a charge-transfer complex or upon photosensitized (electron-transfer) excitation in polar solvent.

The mechanism we propose is consistent with the studies of the effect of oxygen on the rate and quantum yield enhancement for the isomerization of olefins reported during the progress of this work. Hayashi and Nagakura (25) irradiated (at $\lambda >$ 300 nm) a solution of aromatic hydrocarbon and FN in both benzene and acetonitrile. They found rate enhancement for MN formation in the presence of oxygen. In benzene solution, with phenanthrene and triphenylene as the donor, they found that the exciplex fluorescence lifetime and the transient absorption lifetime of the radical ions were of the same magnitude, both of which decreased in the presence of oxygen. In acetonitrile solution, the transient absorption of the radical ions decays as a sum of a fast and slow component. These results suggest that, in nonpolar solvent, the exciplex (fluorescent ct state) which is rather polar is responsible for the triplet formation. In polar solvent, the radical ion pair which is the fast decay transient is responsible for the triplet formation. The presence of oxygen increases the intersystem crossing rate of the singlet exciplex and the singlet radical ion pair. Similar conclusions have been drawn by Lewis and Simpson (26) from a study on the isomerization of *trans*-stilbene upon irradiation of the TS–FN ct complex. They found that the quantum yield of isomerization of TS was larger in oxygenated solution than in degassed solution with both polar and nonpolar solvents.

Summary

From the measured K_c^{DA}, we found that maleonitrile (MN) complexes more strongly with 1,4- and 1,5-DMN than does fumaronitrile (FN), while the opposite is true when 2,3-DMN is the donor. These results are interpreted in terms of more than one favourable geometry for the ct complexes since the donors are relatively large compared to the acceptors.

Irradiation of the ct complexes between 1,4- (or 1,5- and 2,3-DMN) and 1,2-dicyanoethylene led to isomerization of the olefins. The photostationary state ratio of the olefin isomers depends upon the absorption spectra of the ct complexes. From the spectroscopic and photo-CIDNP studies, we have confirmed that the olefin isomerization in polar solvents involves the olefin triplet which is derived from the radical ion pair.

Experimental

General

Fumaronitrile (FN) (Aldrich Chemical Co.) was freshly sublimed twice under vacuum before use. Maleonitrile (MN) was prepared by iodine-catalyzed thermal isomerization of FN (27), and was purified by fractional distillation, column chromatography on neutral alumina (Woelm activity I) eluting with a 1:1 mixture of benzene and hexanes, followed by recrystallization from ether–pentane.

1,4-Dimethoxynaphthalene (1,4-DMN), 1,5-DMN, and 2,3-DMN were prepared from the corresponding dihydroxynaphthalenes (28) (Eastman Kodak Co.). 2,3-DMN was purified by recrystallization from methanol. 1,4-DMN was purified by column chromatography (neutral Woelm alumina activity I eluted with 5% benzene in hexanes) followed by recrystallization from methanol. 1,5-DMN was chromatographed (neutral Woelm alumina activity I eluted with benzene), vacuum sublimed, and recrystallized from 2-propanol three times before use.

Chloroform (Fisher spectroscopic grade) was dried and distilled over calcium chloride. Benzene (Fisher spectroscopic grade) was purified using the procedure employed by Kochevar

and Wagner (29). Acetonitrile (Aldrich Gold Label) was refluxed over calcium hydride under a dry nitrogen atmosphere for 12 h and distilled.

Ultraviolet–visible absorption spectra were recorded on either a Cary 118 or a Cary 219 spectrophotometer at room temperature (23°C) with 1 cm cuvettes. A Varian XL-100 nmr spectrometer equipped with deuterium lock and probe temperature control was employed for the ^{1}Hmr studies.

All irradiations were carried out using a General Electric 1 kW medium pressure mercury lamp with a quartz cooling jacket (Photochemical Research Associates). All solutions were placed in Pyrex irradiation vessels flushed with dry nitrogen and sealed with rubber septa. The progress of the reactions were followed by ^{1}Hmr (Varian T-60). Two filter systems were employed in the irradiations: filter A, a 1 cm saturated aqueous solution of sodium nitrite which transmits all light of wavelength > 400 nm, and filter B, a Corning 0-51 glass filter (4 mm) which transmits light > 360 nm.

Determination of Association Constants of Charge-transfer Complexes by Ultraviolet–Visible Method

Both cases where $[D]_0 \gg [A]_0$ and $[A]_0 \gg [D]_0$ were studied using the same procedure, therefore only the latter case is described below.

A chloroform solution of the donor (ca. 10 m*M*) was first prepared. Then a series of five solutions as prepared by weighing various amounts of the acceptor (ca. 0.15 *M* to 1.0 *M*) in 5 mL volumetric flasks before introducing 3 mL of the above solution through a pipette. The absorption spectrum of each of the above solutions was measured immediately after preparation.

Evaluation of the K_c^{DA} and ε_λ^{DA}, in all cases, employed both the Benesi–Hildebrand and Foster–Hammick–Wardley methods. The slopes and *y*-intercepts of the plots were computed using a standard linear least-squares program. The correlation coefficients are generally better than 0.99 and 0.96 for the B–H and the F–H–W method respectively.

Determination of Association Constants of Charge-transfer Complexes by ^{1}Hmr Method

This method was employed only in the $[D]_0 \gg [A]_0$ case since the dicyanoethylene concentration dependence of the substituted naphthalene chemical shifts was small in the $[A]_0 \gg [D]_0$ case. The same procedure as in the uv–vis method was employed in preparing the solutions except that the present solvent is a 1:19 v/v mixture of cyclohexane-d_{12} – chloroform containing 0.02% (by weight) of tetramethylsilane (TMS). The deuterated solvent was used to provide a field lock so that accurate chemical shift values could be obtained. The chemical shifts of the dicyanoethylene protons were determined relative to the chloroform ^{13}C satellite which is in turn relative to TMS. Since the chemical shift of the chloroform proton shifts upfield upon increasing the concentration of the donor, the observed changes in the acceptor chemical shift relative to chloroform must be corrected before use. Evaluation of K_c^{DA} and Δ_0^{DA} were performed in the same fashion as the analogous uv–vis method.

Irradiation of the 1,4-Dimethoxynaphthalene – 1,2-Dicyanoethylene Charge-transfer Complex

A benzene solution of 1,4-DMN (0.3 *M*) and FN (0.3 *M*) was irradiated through filter B. The reaction was followed by ^{1}Hmr. After prolonged irradiation (600 h), a photostationary state mixture of FN:MN = 62:38 was obtained. Other reactions were relatively unimportant (< 5%). This photostationary state was also obtained starting either from MN or a synthetic mixture of FN:MN = 64:36.

Isomerization of the dinitrile was also observed under the same conditions using filter A (>400 nm), irradiating in a region where the individual components are transparent. The isomerization appeared to be slower in acetonitrile solution than in benzene solution under the same conditions.

Prolonged irradiation (290 h) of a benzene solution of 1,4-DMN (0.3 *M*) through a Pyrex reaction vessel did not lead to any observable product.

Irradiation of the 1,5-Dimethoxynaphthalene – 1,2-Dicyanoethylene Charge-transfer Complex

Prolonged irradiation of a benzene solution of 1,5-DMN (0.08 *M*) and FM (0.6 *M*) through filter B gave a photostationary state mixture of FN:MN = 63:37. This mixture was also obtained starting either from MN or from a synthetic mixture of FN:MN (64:36) under identical conditions. The formation of other products was negligible (< 5%) after prolonged irradiation.

Isomerization of the dinitrile was also observed when acetonitrile was the solvent. 1,5-DMN was stable in benzene solution (0.08 *M*) upon prolonged irradiation through a Pyrex filter.

Irradiation of the 2,3-Dimethoxynaphthalene – 1,2-Dicyanoethylene Charge-transfer Complex

Irradiation of a benzene solution of FN (or MN) (0.3 *M*) and 2,3-DMN (0.3 *M*) through filter B led to isomerization of the alkene. The photostationary state obtained either from FN or MN or a mixture of FN and MN (50:50) consisted of FN:MN = 44:56. Isomerization of the dinitriles also occurred in acetonitrile solution. In all cases, the formation of other products was negligible (< 5%).

Quantum Yield Measurements

Quantum yield measurements were performed using a Jasco CRM-FA quantum yield apparatus with a 2 kW mercury–xenon lamp as the light source. The irradiation wavelength was 362 ± 6 nm. Ferrioxalate actinometry was employed (30). The sample, consisting of 1,4-DMN (80 m*M*) and fumaronitrile (80 m*M*) in benzene solution, was degassed (3 freeze–pump–thaw cycles) and sealed. All light was being absorbed (OD > 2.0 at all times). At 1.6% conversion, the quantum yield for isomerization of FN to MN was 2.4×10^{-3} (±10%).

Spectroscopic Studies

Fluorescence spectra were recorded on a Perkin-Elmer MPF-4 fluorescence spectrophotometer at room temperature (23°C). The samples were degassed under high vacuum using three freeze–pump–thaw cycles. Stern–Volmer plots were obtained by plotting the intensity of the spectra at the maximum versus concentration of the quencher.

Fluorescence life times (25°C) were measured by the single photon counting technique, details of which have been described elsewhere (31). The excitation source was a Photochemical Research Associates deuterium nanosecond flash lamp system. The decay curves were deconvoluted by iterative deconvolution.

The phosphorescence spectra were recorded on a spectrometer described before (32).

Photo-CIDNP Experiment

The light source was an Oriel Corporation 200 W Hg–Xe lamp focused and passed through a quartz light pipe into the solution in a 5 mm nmr tube which was spinning inside the probe of a Varian XL-100 nmr spectrometer (field strength 23.5 kG). Solutions were degassed by purging thoroughly with dry nitrogen. The concentration range was kept between 10 to 130 m*M*. The CIDNP signals were able to survive for minutes after the light was switched off. The amount of isomerized alkenes was negligible.

Axial dissymmetry induced magnetic nonequivalence in the ^{13}C nuclear magnetic resonance spectra of allenes[1]

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET, AND DENNIS G. GARRATT[2]

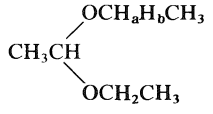
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received May 1, 1979[3]

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET, and DENNIS G. GARRATT. Can. J. Chem. **58**, 928 (1980).

The observation of the magnetic nonequivalence of isopropyl methyl carbon resonances as a result of axial dissymmetry in 27 appropriately substituted allenes is reported. The magnitude of the nonequivalence Δ is more dependent upon the adjacent substituent group than upon the substituents which are bonded to the remote sp^2 carbon of the allene. A mechanism based upon the transmission of substituent effects from the remote substituents to the collinear π orbitals is proposed.

PIERRE L. BEAULIEU, VERONIQUE M. MORISSET et DENNIS G. GARRATT. Can. J. Chem. **58**, 928 (1980).



La non équivalence magnétique des carbones des méthyles du groupe isopropyle dans 27 allènes adéquatement substitués est due à une dissymétrie axiale. L'amplitude, Δ, de la non équivalence dépend d'avantage des substituants adjacents que des substituants liés au carbone sp^2 le plus éloigné de l'allène. On propose un mécanisme basé sur la transmission des effets des substituants éloignés jusqu'aux orbitales π disposées en ligne droite.

[Traduit par le journal]

The presence of a nearby center of molecular asymmetry is known to induce magnetic nonequivalence of the protons in methylene and isopropyl groups, although accidental degeneracy is frequently encountered, the protons appearing to be equivalent in the spectrum (1). The analogous effect of molecular centrodissymmetry on carbon-13 chemical shifts has been reported by Roberts and co-workers using compounds of the general type: $(CH_3)_2CH(CH_2)_nCHRR'$ (2).

It is not necessary, however, that a molecule be chiral for carbons or protons to be diastereotopic. A typical example from ^1H nmr spectroscopy is the diethyl acetal of acetaldehyde. Replacement of H_a by deuterium creates two chiral centres, the resulting molecule being a diastereomer of the species in which H_b is replaced by deuterium (1*e*, 3).

In contrast to the above, one may study compounds in which the lack of symmetry is not connected with the presence of asymmetrically substituted atoms, but results from an axis of dissymmetry such as is found in biphenyls, allenes, alkylidenecycloalkanes, and spiranes (4). For example, Martin and co-workers (5) have studied a number of allenic compounds with respect to the axial dissymmetry induced magnetic nonequivalence of methylene and isopropyl methyl proton resonances. The absolute magnitude of these nonequivalences is, however, quite small. In view of the greater sensitivity of ^{13}C nmr spectroscopy, and since to our knowledge, no one has investigated this phenomena by this technique, we have carried out a series of measurements of the chemical shift nonequivalence of isopropyl methyl carbon resonances as induced by the axial dissymmetry of 27 appropriately substituted allenes (6).[4]

Experimental

The allenes used during this investigation were synthesized by standard literature procedures (7) as part of another series of investigations. Full spectroscopic characterization of these compounds is to be reported separately. The ^{13}C nmr spectra were recorded using a Varian Associates FT80 spectrometer with a broad band probe, operating at 20.000 MHz, with 16K memory. Initial proton decoupled spectra were run with a spectral width of 4505 Hz. Subsequent spectra were recorded using spectral widths of 2000–2809 Hz dependent upon fold-back problems. A pulse width of 5 μs corresponding to a flip angle of approximately 21.5° was routinely employed. All samples were run in $CDCl_3$ at concentrations of 35% w/v at a probe temperature of 31°C. Chemical shifts are reported in units of δ downfield from an internal TMS standard, ± 0.02 ppm.

[1]Issued as NRCC No. 18138.

[2]Author to whom correspondence may be addressed at the Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6.

[3]Revision received January 18, 1980.

[4]Krudy and Macomber (6*a*) have reported that the chirality of the dimethyl allenic phosphonic ester, $(CH_3O)_2$-P(O)C(*t*Bu)=C=CH*t*Bu, renders the two methoxy groups on phosphorous nonequivalent. Unfortunately only an averaged chemical shift was reported. Runge and Firl (6*b*) list three trisubstituted allenes containing isopropyl groups, where in two cases the isopropyl methyl carbons have a chemical shift difference of 0.1 ppm and the remaining compound shows apparent accidental coincidence.

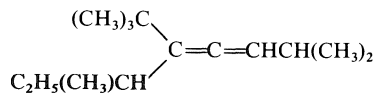
Results and Discussion



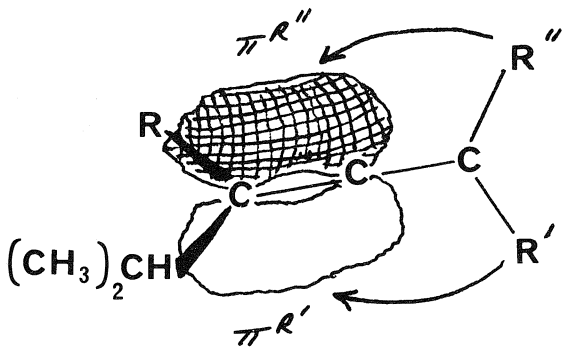
The ^{13}C nmr chemical shifts of the methyl carbons of isopropyl groups appear in Table 1. The degree of nonequivalence, Δ, of the methyl carbons *a* and *b* (where the designations *a* and *b* are more or less arbitrary) is seen to be very dependent upon the substituent pattern, the group bonded *geminal* to the isopropyl having the greatest influence. For example, when R = R″ = H and R′ is varied through the series: methyl–ethyl–isopropyl–*tert*-butyl (entries 1–4), the change in Δ is quite dramatic, 0.03 to 0.18 ppm, whereas when R = CH_3, R″ = H, and R′ is similarly varied (entries 10–14) Δ is relatively constant at 0.15 ± 0.02 ppm within experimental error. When R = *i*-C_3H_7 or *t*-C_4H_9, R″ = H (entries 19–22 and 24–27, respectively), a similar variation in R′ shows some fluctuations but with a general tendency towards larger values of Δ. The effect of changing R while holding R′ and R″ constant is perhaps best seen using entries 4, 14, 22, and 27. The variation of R from H to methyl–isopropyl–*tert*-butyl in this set gives values of Δ of: 0.18, 0.15, 0.38, and 0.83. The decrease between the values given for hydrogen and methyl suggests that there is a reversal in the factors giving rise to the shift difference. This is again suggested by the set of entries 7, 15, 18, and 30, where the absolute values of Δ are, respectively, 0.18, 0.14, 0.00, and 0.21.

TABLE 1. The observed ^{13}C nuclear magnetic resonance chemical shifts of diastereotopic isopropyl methyl carbons in allenes ($(CH_3)_2CHCR{=}C{=}CR'R''$)

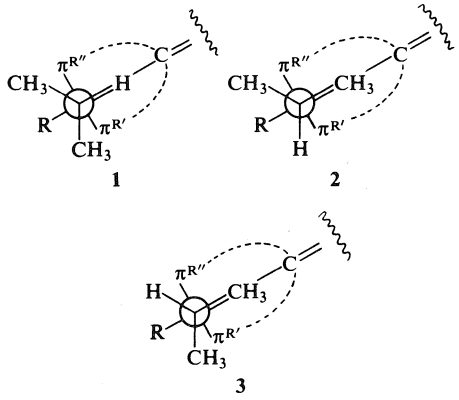
	Allene			Chemical shifts (δ ± 0.02 ppm)		
Entry	R	R′	R″	δ_a	δ_b	$\Delta = \delta_a - \delta_b$
1	H	CH_3	H	22.63	22.60	0.03
2	H	C_2H_5	H	22.45	22.40	0.05
3	H	*i*-C_3H_7	H	22.61	22.44	0.17
4	H	*t*-C_4H_9	H	22.59	22.41	0.18
5	H	CH_3	C_2H_5	22.63	22.53	0.10
6	H	CH_3	*i*-C_3H_7	22.75	22.57	0.18
7	H	CH_3	*t*-C_4H_9	22.65	22.47	0.18
8	H	C_2H_5	*t*-C_4H_9	22.59	22.59	0.00
9	H	*i*-C_3H_7	*t*-C_4H_9	22.54	22.51	0.03
10	CH_3	CH_3	H	21.60	21.44	0.16
11	CH_3	C_2H_5	H	21.70	21.55	0.15
12	CH_3	*i*-C_3H_7	H	21.69	21.54	0.15
13	CH_3	C_6H_{11}	H	21.74	21.57	0.17
14	CH_3	*t*-C_4H_9	H	21.70	21.55	0.15
15	CH_3	CH_3	*t*-C_4H_9	21.64	21.50	0.14
16	CH_3	C_2H_5	*t*-C_4H_9	21.72	21.72	0.00
17	CH_3	*i*-C_3H_7	*t*-C_4H_9	21.96	21.64	0.32
18	C_2H_5	CH_3	*t*-C_4H_9	21.99	21.99	0.00
19	*i*-C_3H_7	CH_3	H	22.50	22.21	0.29
20	*i*-C_3H_7	C_2H_5	H	22.57	22.31	0.26
21	*i*-C_3H_7	*i*-C_3H_7	H	22.73	22.39	0.34
22	*i*-C_3H_7	*t*-C_4H_9	H	22.73	22.35	0.38
23	*i*-C_3H_7	*i*-C_3H_7	*t*-C_4H_9	21.83	21.26	0.57
24	*t*-C_4H_9	CH_3	H	24.85	24.31	0.54
25	*t*-C_4H_9	C_2H_5	H	24.94	24.39	0.55
26	*t*-C_4H_9	*i*-C_3H_7	H	24.87	24.21	0.66
27	*t*-C_4H_9	*t*-C_4H_9	H	25.17	24.34	0.83
28	*t*-C_4H_9	CH_3	C_2H_5	24.95	24.95	0.00
29	*t*-C_4H_9	CH_3	*i*-C_3H_7	25.11	24.82	0.29
30	*t*-C_4H_9	CH_3	*t*-C_4H_9	24.98	24.77	0.21

We observed in total four cases of apparent accidental coincidence of the methyl carbon resonances (entries 8, 16, 18, and 28). Of interest is the observation that entries 16, 18, and 28 are all tetrasubstituted allenes, each of which contains the methyl, ethyl, isopropyl, and *tert*-butyl groups, but in different spatial arrangements. There are, furthermore, two cases (entries 1 and 9) where the value of Δ, 0.03 ppm, was just at our level of detectability.

In general Δ will be the summation of two terms: $\Delta = \Delta_{CP} + \Delta_{ID}$, where Δ_{CP} is dependent on conformer populations, and Δ_{ID} results from the intrinsic diastereotopism of the averaged environments of the isopropyl methyl carbons, and which will be as a consequence independent of conformer populations (8). The contribution of intrinsic diastereotopism to the magnetic nonequivalence of the diastereotopic carbons is determinable only in those cases where the individual conformers are observable. This, however, we have not been able to achieve. Since the contribution of intrinsic nonequivalence is usually small, the magnitude of the nonequivalence observed seems most reasonably to result from factors which enhance the local dissymmetry inherent in the molecule. One must be careful, however. For example, Raban (8) has shown that the value of Δ_{ID} may be small as a result of the fortuitous cancelling of large terms of opposite sign. Of interest in this respect is our observation that the (RS,RS) and (RS,SR) diastereomers of allene **31** (2,6-dimethyl-5-*tert*-butyl-3,4-octadiene) are readily distinguished from each other via ^{13}C nmr.



31



Examples of factors which may enhance the local dissymmetry are preferred conformations and hindrance to free rotation resulting from steric effects or conformational restrictions due to specific solvent interactions which alter the average molecular geometry.

One notes upon examining Dreiding molecular models that the substituents in the 1 and 3 positions of an allene (propadiene) are sufficiently remote that in most conformations the spatial orientation of one group should not influence the other by a direct steric interaction. As a result we anticipate that each group must very nearly achieve what might be termed time-averaged conformational symmetry with respect to the pertinent molecular plane of the allene (for example, the CH_2—C_{sp2}—H plane assuming non-spherical substituents such as C_2H_5 and n-C_3H_7). We therefore make the hypothesis that any conformational effects which are a result of the remote groups are transmitted via perturbations of the collinear π orbitals, $\pi^{R'}$ and $\pi^{R''}$, as is shown below:

Assuming that perturbations in these π orbitals reflect steric and electronic effects of the groups R′ and R″, one is able to envision the three staggered conformations, **1**–**3**.

Of note is the fact that R is oriented perpendicular to both $\pi^{R'}$ and $\pi^{R''}$. This effect, which is intrinsic to the allenic functionality, results in the groups which are *gauche* to the substituent R (for example, both methyls in conformer **1**) experiencing large interactions with $\pi^{R'}$ and $\pi^{R''}$. Furthermore, a staggered conformation with respect to the group R leads to an eclipsing of the third substituent (H in **1**, CH_3 in **2** and **3**) with the *sp*-hybridized allenic carbon. The relatively small values of Δ we believe reflect attenuation of the substituent effects with transmission of the dissymmetry over the two bonds of the allenic system.

It seems apparent from an examination of conformers **1**–**3** that variation of the group R will give rise to a larger effect than the corresponding substitutions at either R′ or R″, as is observed. Thus when R is a bulky substituent, such as *tert*-butyl, conformers **2** and **3** should be favoured over **1**. If the perfect staggered arrangements in **2** and/or **3** are retained, the methyls will experience very different local environments, and therefore exhibit a large Δ (see for example entries 19–22). However, a large methyl–R interaction may cause sufficient departure from these purely staggered arrangements, diminishing the immediate magnetic interaction between methyl and R, but causing an essential eclipsing interaction of the methyls and $\pi^{R'}$, $\pi^{R''}$. Under such conditions very little difference in chemical shifts may be anticipated (entry 28), unless R′ and R″ are quite different with respect to their ability to perturb the π orbitals (compare entries 28–30 with 24–27). It is noteworthy in this respect that a number of fluctuations or reversals are observed in Table 1, as was mentioned earlier.
