This order of substituent effects has important implications for the deduction of the detailed nature of fluorine in stabilization of enolate ions. It implies for example, that 1,1,1,3-tetrafluoroacetone, in which the resulting enolate would have three remote fluorines and one α fluorine, should be slightly more acidic than 1,1,3,3-tetrafluoroacetone where the resulting enolate has two remote and two α substituents. Similarly, it would be predicted that the more acidic site of 1,1,3-trifluoroacetone would be the less fluorinated methyl group to produce the enolate **IV** in preference to **V**.

IV

V

These postulates thus suggest that fluorine substituents can in fact have a destabilizing component in their interactions with planar carbanion centres which becomes manifest in highly fluorinated enolates of acetone.

The observed gas phase acidity of acetyl fluoride also supports this postulate. The acidity of acetyl fluoride is found to be roughly 1.5 kcal/mol greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

than that of fluoroacetone indicating that a fluorine substituted β to the charge centre is more effective in stabilization of the enolate ion than is an α fluorine substituent. The greater inductive effect resulting from closer proximity of the α fluorine to the carbanion centre in fluoroacetone enolate than in acetyl fluoride enolate is therefore counterbalanced by the repulsive electrostatic interaction which makes β fluorine substitution more energetically favourable.

Conclusion

The experimental data presented here lend some support to the hypothesis that fluorine substituents may play an ambiguous role in the stabilization of planar carbanions. Unlike the inference from solution acidity data, however, they do not support a *net* destabilization of planar carbanions with increasing fluorine substitution. Rather, the gas phase acidities show an *irregular* increase in carbanion stability with increasing fluorine substitution with multiple fluorine substitution frequently giving rise to carbanion formation which maximizes the number of remote substituents. The differences between the gas phase and solution results must therefore be largely a result of ion-pair and ion–solvent interactions in the solution acidity data which obscures the intrinsic electronic substituent effect.

Further studies of sp^2 and sp^3 hybridized fluorocarbanions are currently underway in our laboratory to investigate whether or not these phenomena are general for carbanions other than enolate ions.

Introduction

Depuis quelques années plusieurs articles (1, 2) ont démontré des méthodes simples de fabrication de capillaires polarographiques pouvant résister aux milieux extrêmement corrosifs pour le verre. C'est ainsi que maintenant il est possible de faire des analyses de métaux directement dans les milieux tel que HF, NaOH concentré par des techniques dérivées de la polarographie. Lors d'une étude sur la réduction de l'antimoine $Sb^{3+} \rightarrow Sb^0$ dans HF/H_2O, 40% en poids un déplacement anodique de la vague en présence de Cl^- a été mis en évidence. Ce déplacement a été attribué à un changement de la double couche à l'électrode de mercure. D'autre part, il est possible, par la même technique dans ces milieux, d'analyser la formation de complexes métalliques tels que:

$$Cd^{2+} + nCl^- \rightleftarrows CdCl_n^{(2-n)+}$$

Partie expérimentale

Appareil

Un polarographe modèle 174A (Princeton Applied Research) a été utilisé avec un système à trois électrodes. Une électrode de calomel saturée séparée de la solution à étudier par une jonction en Teflon poreuse a été utilisée comme réf. 3.

Produit

Les solutions ont été préparées à partir de HF 48% en volume (Allied Chemical). Les solutions de Cd^{2+} ont été faites à partir de CdO (Baker Anal. Reagent) et tout comme les solutions de chlorures sont issues de KCl (Baker).

Résultats et discussion

L'étude par polarographie a été faite pour la réduction du cadmium $Cd^{2+}/CdHg$ dans les milieux HF/H_2O et en milieu KF aqueux (0,1 à 2 *M*). L'addition de Cl^- dans ces milieux lors de l'analyse par polarographie nous donne un déplacement cathodique de la vague de réduction (Fig. 1). La réversibilité du système a été vérifier par l'analyse de la vague E vs. $\log [i/(i_d - i)]$ donne des droites dont les pentes sont de 29 mV. De plus, des études de voltamétrie cyclique ont démontré la réversibilité.

En utilisant la théorie de Deford–Hume (4) il est possible de déterminer les constantes de formation pour différents complexes à l'aide des données polarographiques, sachant que la réduction du Cd^{2+} est réversible. L'équation pour trouver $F_0(X)$, $F_0(X)$ étant une quantité expérimentalement mesurable (à force ionique constante) est:

$$[1] \quad F_0(X) = \sum_j \frac{K_j C_x{}^j f_x{}^j}{f_{nxj}} = \text{antilog } 0{,}435 \frac{nF}{RT} \times [(E_{1/2}{}^0)_s - (E_{1/2})_c] + \log \frac{I_s}{I_c}$$

où $(E_{1/2}{}^0)_s$ est le potentiel de demi-vague lorsqu'il n'y a pas d'espèces complexantes; $(E_{1/2})_c$, potentiel de demi-vague avec espèce complexante dans le milieu; I_s et I_c, les courants de diffusion sans et avec espèces complexantes. Le terme $\log (I_s/I_c)$ peut être négligé (5) car il contribue très peu à la fonction $F_0(X)$. L'expression $[(E_{1/2})_s - (E_{1/2})_c]$ est remplacée par $\Delta E_{1/2}$/ecs. Pour une réduction de deux électrons comme dans le cas du cadmium on aura:

$$[2] \quad F_0(X) = \text{antilog} - 33{,}28\,(\Delta E_{1/2})$$

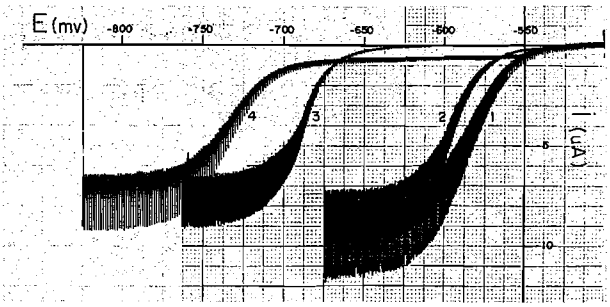

FIG. 1. Polarogrammes de Cd^{2+}/Cd^0 (Hg) dans HF 27,6 *M*, en présence de KCl; (*1*) 10^{-3} *M* CdO/HF 27,6 *M*; (*2*) *ibid* +0,0003 *M* KCl; (*3*) *ibid* +0,1 *M* KCl; (*4*) *ibid* +0,3 *M* KCl.

En connaissant $F_0(X)$ on peut obtenir les fonctions $F_i(X)$ pour un complexe de degré supérieur. Ainsi:

[3] $F_i(X) = [F_0(X) - \beta_0]/c_x$

où β_0 est la constante de formation de l'ion seul et est égal à l'unité. c_x est la concentration analytique ajoutée de l'espèce complexante.

En traçant $F_i(X)$ versus c_x, l'extrapolation à $c_x = 0$ donnera β_1, la constante de formation du complexe de degré 1.

Le complexe du degré le plus élevé sera celui qui donne une droite parallèle à l'axe de la concentration. Nous devons remarquer que les constantes de formation des complexes de degré supérieur comportent une incertitude vu que l'extrapolation est plus ou moins précise pour donner β_i supérieur.

Le tableau 1 regroupe pour les différentes concentrations de HF les β_0, β_1, β_2 pour le système $CdCl_2$, $CdCl^+$, Cd^{2+} obtenu par graphique.

A l'aide des constantes il est possible de calculer le % de chacun des complexes présents pour différentes concentrations HF/H_2, les figs 2, 3 et 4.

Il apparaît clairement que le complexe $CdCl_2$ est plus facile à former en milieu pauvre en fluorure

TABLEAU 1. Système Cd—F—Cl

[HF] (*M*)	β_0	β_1	β_2

Complexes of dithiobenzoic acids. III. ^1H and ^{13}C nuclear magnetic resonance studies of a series of *tetrakis*(dithiobenzoato)molybdenum(IV) complexes[1]

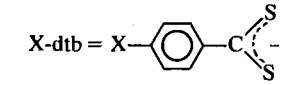
T. ROBERIE, N. S. BHACCA, D. LANKIN, AND J. SELBIN

Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803, U.S.A.

Received May 16, 1980

T. ROBERIE, N. S. BHACCA, D. LANKIN, and J. SELBIN. Can. J. Chem. **58**, 2314 (1980).

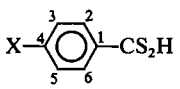
A series of dithiocarboxalato (X-dtb) complexes of molybdenum(IV), $Mo(X\text{-}dtb)_4$, where the *para* substituent X = H, CH_3, CH_3O, F, C_6H_5, CHO, C_6H_5CO, or $(n\text{-}C_4H_9)_2N$, the parent acids and tetraalkylammonium salts were studied by ^1H and ^{13}C nmr in order to monitor the expected charge density shifts as a function of the group X. Analysis of the ^{13}C nmr data unexpectedly revealed an absence of delocalization of electron density either from molybdenum to ligand or from ligand to molybdenum.



T. ROBERIE, N. S. BHACCA, D. LANKIN et J. SELBIN. Can. J. Chem. **58**, 2314 (1980).

Afin de pouvoir évaluer les déplacements de densité de charge résultant de la présence des groupes X, on a étudié, par la rmn du ^1H et du ^{13}C, une série de complexes dithiocarboxalato (X-dtb) du molybdenum(IV) $Mo(X\text{-}dtb)_4$ où le substituant X en position *para* = H, CH_3, CH_3O, F, C_6H_5, CHO, C_6H_5CO ou $(n\text{-}C_4H_9)_2N$ ainsi que les acides et les sels de tétraalkylammonium apparentés. L'analyse des données de la rmn du ^{13}C revèle une absence surprenante de délocalisation de la densité électronique soit du molybdène vers le ligand ou du ligand vers le molybdène.

[Traduit par le journal]



Introduction

In a previous paper (1) we reported the preparation and characterization of a number of (mostly new) dithiocarboxalato complexes of molybdenum(IV), $Mo(X\text{-}dtb)_4$, where the bidentate sulfur ligands are of the general type:

and X is H, CH_3, CH_3O, Cl, F, C_6H_5, CHO, C_6H_5CO, CH_3CO, or $(n\text{-}C_4H_9)_2N$. Visible–ultraviolet and infrared spectral data for the ligands, their tetraalkylammonium salts, and the molybdenum complexes were also reported and discussed. We now report the results of both ^1H and ^{13}C nmr studies of as many of those ligands, salts, and complexes as were stable enough and soluble enough to yield reproducible data. The primary purpose of the ^{13}C nmr study was to attempt to monitor the expected shifts of charge density either from ligand-to-metal or metal-to-ligand as a function of the electronic nature of the X group in the ligand molecule.

The compounds studied were the following acids (**1**), salts (**2** and **3**), and molybdenum(IV) complexes (**4**):

1

2

3

a (X = H)
b (X = CH_3)
c (X = CH_3O)
d (X = F)

4

e (X = C_6H_5)
f (X = CHO)
g (X = CH_3CO)
h (X = C_6H_5CO)

The more stable methylthioesters were used for nmr studies in place of the acids **1***a* and **1***d*.

Experimental

The preparations of the various ligands, salts, and complexes have already been described (1). The proton noise decoupled ^{13}C nmr spectra were obtained at ambient temperature on a JEOL FX-100 spectrometer. The solvent was $CDCl_3$ in all cases. Tetramethylsilane was added to the samples to serve as an internal standard. The ^1H nmr spectra were obtained at 60 MHz on a Varian A-60A spectrometer. The metal complexes were run at 60°C in saturated $CDCl_3$ solutions. A Varian Model 4343 temperature control was used to maintain the probe at this temperature. Ethylene glycol was used for the high temperature calibration.

Results and Discussion

The ^1H nmr data for the eight soluble Mo(IV) dithiocarboxalato complexes and for analogous complexes of both Ti(IV) and Sn(IV), ($Ti(\mathbf{1}a\text{-}H)_3Cl$, $Ti(\mathbf{1}c\text{-}H)_3Cl$, and $Sn(\mathbf{1}a\text{-}H)_2Cl_2$) were collected along with the data for the corresponding free acids and their tetraalkylammonium salts. The data reveal that the signals of the *ortho* protons of the Mo(IV) complexes are shifted slightly upfield (by 0.11–0.21 ppm) from their positions in the ligand acids, whereas the *meta* protons are essentially all unshifted. A possible explanation (*vide infra*) for this behavior is some sort of nonbonding

[a]The methyl ester of the ligand acid, used in place of the less stable acid.
[b]Corrected for the downfield shift due to the methyl group.
[c]Methyl carbon of the methylthioester.

d-orbital shielding effect associated with the partially occupied metal *d*-orbitals. Support, but not conclusive evidence, for this suggestion comes from the corresponding data for the Ti(IV) and Sn(IV) complexes which are d^0 and d^{10} systems, respectively, and where we have found no such shielding effect. However, we must recognize that in neither of these two cases are there *four* bidentate ligands crowded around the central metal as in the case of Mo(IV).

The ^{13}C nmr spectra of the six dithiobenzoic acids and the two thioesters were examined in the 0–320 ppm range, as were the spectra for the eight dithiobenzoate salts and the eight molybdenum(IV) complexes. The experimental data are collected in Table 1 for the acids, salts, and complexes.

The assignments of the four resonances observed in the aromatic (~110–160 ppm) region are relatively straightforward. For the methylester of the parent compound, dithiobenzoic acid, the assignment of the 132.0 resonance to C_4 is made on the basis that aromatic carbons *para* to an electron-withdrawing group generally fall in the 130–134 ppm range. The C_1 assignment follows from the absence of a nuclear Overhauser effect for this quaternary arene carbon, leading to its much reduced intensity relative to C_2 and C_3. These latter two assignments were made that the 128.5 resonance of benzene itself would be more affected by an *ortho* substituent, hence C_2 must be at 126.6, than by a *meta* substituent, hence C_3 resonates at 128.1. The dithio carbon assignment is unequivocal from previous studies of thioketones where this carbon appears above 200 ppm. The assignment of the methyl carbon in the parent as well as *para*-substituted derivatives is likewise straightforward from previously assigned CH_3 groups in monosubstituted benzenes with the same substituents. The assignments for the carbonyl carbon (where X = $COCH_3$ or COC_6H_5) are from previous assignments for acetophenone and benzophenone, respectively.

The assignment of the arene resonances in all of the *para-substituted* ligands were made in accord with shift increment calculations, made possible by the simple relationship (2)

$$\delta_c = 128.5 + \sum_i A_i(X)$$

where the arene carbon chemical shift, δ_c, is obtained by adding the sum of the chemical shift increments $A_i(X)$ for substituent X in the ith position. The shift parameters for the new groups obtained in this study are listed in Table 2. The excellent agreement we found between our calculated and observed resonances for the arene carbons (never larger than 3 ppm, but generally within a few tenths of a ppm) gives us confidence in our assignments. Further support for these assignments comes from the data for $^{19}F-^{13}C$ coupling constants recorded in Table 3 for the ester, salt, and complex of the *para* fluoro ligand.

Table 4 presents the displacements of the carbon chemical shifts of the dithiobenzoic acids after their complexation to molybdenum. As can be seen in Table 4 the largest effect, ~9 ppm upfield shift, due to the complexation is exhibited at the thiocarbonyl carbons. A somewhat lesser effect, ~3 ppm upfield shift, occurs at both the C_1 and C_2 (*ortho*) carbons whereas virtually no effect is felt by the C_3 (*meta*) and C_4 (*para*) carbons. The data in Table 4 strongly suggest the unexpected result that *there is essentially no delocalization of electron density from molybdenum orbitals into the π aromatic system or vice versa*. Such an effect would be expected to show up most clearly at the C_1 and C_4 carbons. The ~9 ppm upfield shift of the thiocarbonyl carbons as well as the smaller upfield shifts for C_1 and C_2 may be due to a nonbonding *d*-orbital shielding effect similar to that which has been proposed to account for proton shifts in transition metal hydrido complexes (3). On the other hand, the upfield shifts may have nothing at all to do with Mo, but rather may be a consequence of the clustering of four bidentate groups around the metal.

When we plotted the carbon-13 chemical shifts of the C_1, C_3, and C_4 carbons in the tetraalkylammonium salts and in the molybdenum complexes versus those same shifts in the free acids, we found excellent linear agreement. A sample of such plots is shown in Fig. 1. Particularly in the case of the C_3 and C_4 chemical shifts for the acids and their mo-

When we plotted the carbon-13 chemical shifts of the C_1, C_3, and C_4 carbons in the tetraalkylammonium salts and in the molybdenum complexes versus those same shifts in the free acids, we found excellent linear agreement. A sample of such plots is shown in Fig. 1. Particularly in the case of the C_3 and C_4 chemical shifts for the acids and their mo-

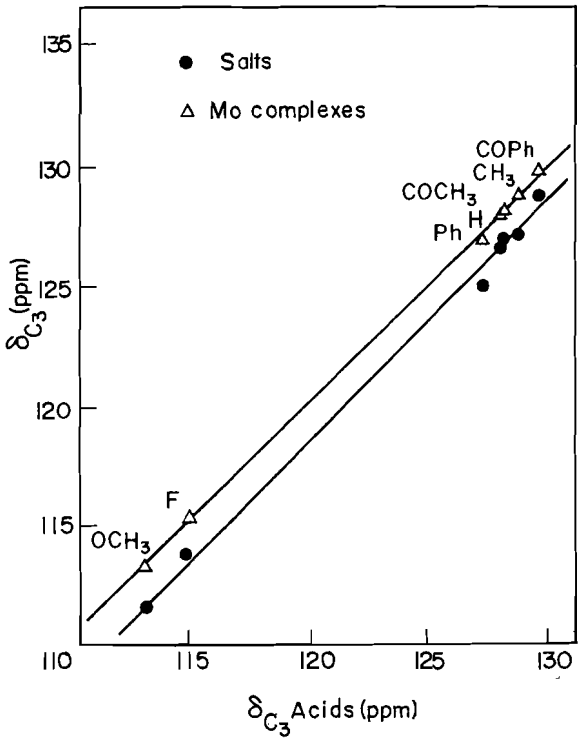

FIG. 1. ^{13}C chemical shifts of the C_3 carbon in the molybdenum complexes and the salts versus the ^{13}C chemical shifts of the C_3 carbon in the free acids (or methylesters).

lybdenum complexes we feel this agreement provides substantial evidence that there must be little or no delocalization of charge (either M → L or L → M) in these complexes. Thus any appreciable resonance interaction of the molybdenum with the π-aromatic system would be expected to involve both C_1 and C_4 carbons in these *para*-substituted ligands, which would alter the electron densities at these particular carbon atoms which should in turn be reflected in the ^{13}C chemical shifts; but it is not.

To further test our hypothesis we plotted the C_1 shifts in the salts, acids, and molybdenum complexes against both Hammett σ_p^+ constants and Taft σ_R^0 constants (4). The correlation coefficients for the salts, acids, and complexes which we found are for σ_p^+: 0.990, 0.941, and 0.966, respectively; and for σ_R^0: 0.962, 0.905, and 0.976, respectively. Although the correlations are not as good for the acids as they are for the salts and complexes, the plots do show that the electronic effects of the various substituents in the *para* position are at least similar in the free acids, the salts, and the complexes. Moreover the slopes of the corresponding three lines in our plots are very similar, suggesting that the transmission of the electronic effect of the substituent X is virtually unaltered in the acids, salts, and complexes. Thus these comparisons provide additional, if only slight evidence for a lack of delocalization of electron density from molybdenum to ligand or vice versa. We might note also that plots of the *electronegativities* of the substituents versus the C_4 chemical shifts in both the complexes (or acids) and the salts also showed good correlation, the correlation coefficients being 0.968 and 0.976, respectively. This correlation result is also expected (5) if there is no additional electron density effect imposed by the molybdenum–ligand interaction in the complexes.

The partitioning of tetrahedral intermediates of the hydrolysis of benzimidatonium ions in acid solutions

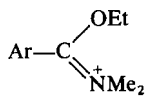
ROBERT A. MCCLELLAND AND JANET P. POTTER

Scarborough College, University of Toronto, West Hill, Ont., Canada M1C 1A4

Received March 20, 1980

ROBERT A. MCCLELLAND AND JANET P. POTTER. Can. J. Chem. **58**, 2318 (1980).

The products (a benzoate ester or an *N*,*N*-dimethylbenzamide) have been accurately determined for the hydrolysis of the *O*-ethyl-*N*,*N*-dimethylbenzimidatonium ion (**1**) and its 4-nitro derivative (**2**) in dilute and moderately concentrated H_2SO_4 solutions. In dilute acid the ratio of amide:ester is very small (0.0005–0.001). It is proposed that the ester product arises from the zwitterionic form of the tetrahedral intermediate of the hydrolysis. The small amount of amide is due to an S_N2 hydrolysis reaction and to the non-catalyzed breakdown of the neutral form of the tetrahedral intermediate, the relative contributions of the two being unknown. Although ester remains the major product throughout, at some intermediate acid concentration (20% H_2SO_4 for **1** and 35% H_2SO_4 for **2**) a sharp increase in the amide:ester ratio is observed, followed by a levelling-off. This change is shown to be associated with tetrahedral intermediate partitioning, and not the S_N2 reaction. It is argued that the strong acid product ratio represents the breakdown of the tetrahedral intermediate via cationic transition states. Two kinetically equivalent reactions are involved, the breakdown of the *N*-protonated tetrahedral intermediate producing a protonated ester and amine and the H^+-catalyzed breakdown of the neutral tetrahedral intermediate producing a protonated amide and alcohol. Analogous pathways are also observed for the decomposition in acid of the amide acetals $ArC(OMe)_2NMe_2$, and the two systems are compared. A similar effect of the aromatic substituent on the partitioning ratio is noted, but the tetrahedral intermediate exhibits a greater tendency for amine expulsion. A kinetic analysis produces the estimate of 10^{11} s^{-1} for the rate constant for the breakdown of the zwitterionic form of the tetrahedral intermediate. This very large rate explains why its decomposition remains important even in concentrated acids, where the amount of tetrahedral intermediate which actually exists as zwitterion must be extremely low.



ROBERT A. MCCLELLAND et JANET P. POTTER. Can. J. Chem. **58**, 2318 (1980).

On a déterminé avec précision les quantités relatives des produits (un ester benzoique ou un *N*,*N*-diméthylbenzamide) de l'hydrolyse de l'ion *O*-éthyl *N*,*N*-diméthylbenzimidatonium (**1**) et de son dérivé nitré en position 4 (**2**) en solutions diluées et moyennement concentrées de H_2SO_4. En solution acide diluée le rapport amide/ester est très petit (0,0005–0,001). On croît que l'ester provient de la forme zwitterionique de l'intermédiaire tétraédrique de l'hydrolyse. La faible quantité d'amide est due à une réaction d'hydrolyse du type S_N2 et à la décomposition non catalysée de la forme neutre de l'intermédiaire tétraédrique dont les contributions relatives sont inconnues. Bien que l'ester demeure le produit principal de la réaction à des concentrations intermédiaires d'acide (20% et 35% de H_2SO_4 pour les composés **1** et **2** respectivement), on observe une nette augmentation du rapport amide/ester suivie d'un équilibre. On montre que ce changement est associé à la répartition de l'intermédiaire tétraédrique et non pas à une réaction S_N2. On suggère que le rapport de produits en milieu fortement acide représente la décomposition de l'intermédiaire tétraédrique via un état de transition du type cationique. Deux réactions cinétiquement équivalentes sont impliquées: la décomposition de l'intermédiaire tétraédrique *N*-protoné qui fournit un ester protoné et une amine et la décomposition catalysée par l'ion H^+ de l'intermédiaire tétraédrique neutre qui produit un amine et un alcool. On observe également un cheminement analogue lors de la décomposition des acétals des amides $ArC(OMe)_2NMe_2$ en milieu acide et on compare les deux systèmes. On note un effet semblable du substituant aromatique sur le rapport de répartition, mais l'intermédiaire tétraédrique montre une plus grande tendance à expulser l'amine. Une analyse cinétique permet d'évaluer à 10^{11} s^{-1} la constante de vitesse de décomposition de la forme zwitterionique de l'intermédiaire tétraédrique. Cette très grande vitesse explique pourquoi la décomposition demeure importante même en solutions concentrées d'acide où la quantité d'intermédiaire tétraédrique qui existe de fait sous forme de zwitterion doit être entièrement faible.

[Traduit par le journal]

We recently reported a kinetic and mechanistic study of the hydrolysis of amide acetals (1). These molecules model (2) in some respects the tetrahedral intermediates encountered in amide hydrolysis (3–7), ester aminolysis (8–13), and imidate hydrolysis (6, 9, 10, 12–20). As we pointed out (1), there is a difference in the behavior of the types of species in acid solutions. Whereas the tetrahedral intermediates generally breakdown with predominant, if not exclusive, loss of amine, the decomposition of the amide acetals occurs with loss of both amine and alcohol.

We report here an investigation undertaken to attempt to account for this difference, namely a study of the partitioning in relatively acidic solutions of the tetrahedral intermediates generated in the hydrolysis of the benzimidatonium ions **1** and **2**.

previously described (21). *O*-Ethyl-*N,N*-dimethylbenzimidatonium (**1**) borofluorate and *O*-ethyl-*N,N*-dimethyl-4-nitrobenzimidatonium (**2**) borofluorate were prepared by the *O*-ethylation of the appropriate *N,N*-dimethylbenzamide with triethyloxonium borofluorate (22), following a standard procedure (6). Amide and a 10–20% molar excess of alkylating agent were dissolved in anhydrous methylene chloride. The solution was allowed to stand overnight and anhydrous ether was added to precipitate the imidatonium salt. This was filtered in a water-free environment (glove box), and washed with a large quantity of anhydrous ether in order to remove unreacted amide. *O,N,N*,4-Tetramethylbenzimidatonium borofluorate was prepared by the reaction of the substituted benzamide and trimethyloxonium borofluorate (23), as previously described (6). We find that samples of this alkylating agent, either when obtained commercially (Cationics) or synthesized in our laboratories (23), do not consist entirely of methyl groups, but contain a small fraction (1–5%) of ethyl groups. This contamination is undoubtedly caused by incomplete replacement of ethyl by methyl in the synthesis from triethyloxonium borofluorate (23), and results in the presence of a small amount of *O*-ethyl imidatonium ion. This impurity, which only amounts to 1–5%, does not have any effect on the linearity of the first-order kinetic plots for the hydrolysis of the contaminated *O*-methyl imidatonium ion, but significantly interferes with our gc product analysis. For this reason we switched to *O*-ethyl for the latter.

Product Analysis

Gas Chromatographic Method

Imidatonium borofluorate (0.5 g) was dissolved in 100 mL of aqueous acid and immediately shaken three times with 100 mL of methylene chloride. The aqueous layer was placed in a water bath thermostatted at 25°C and after an appropriate period of time (see below) extracted with 300 mL of ether, followed by concentration of the ether layer. This sample was injected into a Varian Gas Chromatograph containing a 2 m × 6 mm column of 10% Carbowax 20 M on Chromosorb P with a column temperature of 130°C (unsubstituted system) or 180°C (4-nitro substituted compound).

This method provides the ratio of the ester product of the hydrolysis, ethyl benzoate or ethyl 4-nitrobenzoate, and the amide product of the hydrolysis, *N,N*-dimethylbenzamide or *N,N*-dimethyl-4-nitrobenzamide. This ratio was determined by comparing the relative areas under the gc peaks of the two products. The relative response of the two compounds on the gc instrument was determined using mixtures of authentic samples of the ester and amide, these mixtures being prepared in such a way that the relative amount of the two compounds present approximated that in the mixtures being obtained on hydrolysis. These synthetic mixtures also verified that the flame ionization detector of the gas chromatograph does have a linear response to the two products at the concentration levels involved. In general, with any sample four to six injections were made in a given experiment and the relative areas of each averaged.

This method requires that, under the conditions employed to hydrolyze the imidatonium ion, no ester can have hydrolyzed. (This is also true for the amide but the ester hydrolysis is much more rapid (5, 24).) Rate constants for the hydrolysis of the esters at 25°C were estimated by interpolation or extrapolation of literature values for methyl benzoate (24), with the reasonable assumption (25) being made that there are only minor differences with the two ethyl esters of this study. This rate constant was then used to determine the period of time for which the hydrolysis of the imidatonium ion could be allowed to run before significant hydrolysis of the ester occurred. As a general rule no study was carried out for a longer period of time than that which would result in 5% hydrolysis of the ester product. This problem becomes more severe as the sulfuric acid concentration is increased, due to the fact that the rates of hydrolysis of the benzimidatonium ions decrease with increasing acidity (6) whereas the rates of hydrolysis of the ethyl benzoates increase, at least up to 50–55% H_2SO_4 (24). This means that in the more concentrated acids the imidatonium hydrolysis cannot be allowed to proceed to completion before work-up and product analysis. In these cases we did verify that unreacted imidatonium ion does not affect this analysis. Eventually this problem does become too severe. The method cannot be employed in acids more concentrated than those reported in our results.

A second possible source of error in our analysis is contamination of the imidatonium ion by unreacted amide. We attempted to avoid this in several ways. An excess of alkylating agent was used in the preparation of the salt. This salt was washed with large quantities of ether, which will dissolve the amide but not the salt. Finally the aqueous acid solutions of imidatonium salts were immediately shaken with several portions of methylene chloride. Our reasoning behind this procedure is that the benzamides should distribute very strongly towards the organic phase, while the imidatonium salts remain in the aqueous phase. The hydrolysis of the latter fortunately is slow, with half-lives greater than 60 min even in water, so that little hydrolysis occurs during these initial washings. Even if hydrolysis does occur, it is still not a problem since the ester is also extracted into the organic phase. In other words, we start our analysis from the time immediately after the last washing.

Experimental justification that this procedure does provide the true product ratio comes from two observations. (*a*) In the hydrolysis of both imidatonium ions in dilute acids, a very small amount of amide is observed. Even in the unlikely event that all of this were to be due to unreacted amide, its quantity is very small. (*b*) In the more concentrated acids where the imidatonium ion hydrolysis could not be allowed to proceed to completion, experiments were carried out over varying periods of time corresponding to varying extents of hydrolysis. We find, however, as we should, the same ratio of the two products. If further hydrolysis of the ester were occurring, the amide:ester ratio would have shown an increase with time as more ester hydrolyzes. If, on the other hand, the initial sample were contaminated with amide, the amide:ester ratio would have shown a decrease with time, as more product with the actual amide:ester ratio is formed.

Nuclear Magnetic Resonance Method

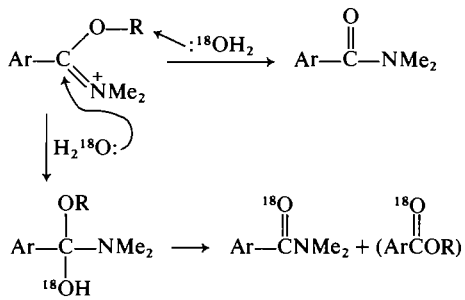
This method was used to provide a further check on the gc results obtained with the 4-nitro compound in 40–50% H_2SO_4. The imidatonium ion salt (1 g) was dissolved in 100 mL of acid and left for 5–7 half-lives of hydrolysis. The resulting mixture was extracted with ether, the ether was then completely removed, and the nmr spectrum recorded. The relative yield of *N,N*-dimethyl-4-nitrobenzamide was determined by comparing the integration of the *N,N*-dimethyl doublet at δ 3.0 and δ 3.2 with the total integration of the aromatic protons. These are due to amide, ester, and carboxylic acid, the last compound being present since in this experiment the ester product has undergone further hydrolysis. We assume that once the contribution from the amide to the total aromatic integration is subtracted out, whatever remains is due to ester. This procedure is far less precise than the gc technique

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

because of the problems associated with exact nmr integration. It does, however, verify unambiguously that a significant quantity of amide is being formed from this ion in these acids.

^{18}O Tracer Study

O-Ethyl-*N,N*-dimethyl-4-nitrobenzimidatonium borofluorate (0.3 g) was dissolved in 48.6% H_2SO_4 (6 g) containing 7.3% ^{18}O. The labelled acid was prepared as previously described (26). After a period of time corresponding to 5 half-lives of hydrolysis of the imidatonium ion, the mixture was extracted with ether, the ether layer washed with aqueous Na_2CO_3 to remove 4-nitrobenzoic acid, dried ($MgSO_4$), and the ether removed. The resulting material, a mixture of ethyl 4-nitrobenzoate and *N,N*-dimethyl-4-nitrobenzamide, was analyzed on an AEI Model MS 902 mass spectrometer equipped with a Vacuumetrics ratiometer. Peaks due to both the ester and amide appeared in the mass spectrum. We measured, as described previously (26), the intensity ratio of the peaks at 179:177, these peaks being due to the amide. The amount of ^{18}O in the amide was then calculated, using the formula described previously (26), to be 8.1 ± 0.6%.



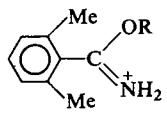
Kinetics

First-order rate constants for the hydrolysis of *O,N,N*,4-tetramethylbenzimidatonium borofluorate were measured at 25°C and ionic strength 0.1 by following spectroscopically the increase in absorbance at 240 nm which accompanies hydrolysis. Rate constants were calculated from the slopes of plots of ln $(A_\infty - A)$ versus time. Rate constants for the hydrolysis of **1** and **2** were measured in a similar way.

Results and Discussion

Importance of S_N2 Hydrolysis

Table 1 lists the relative amounts of amide product and ester product obtained in the hydrolysis of the imidatonium ions in various sulfuric acid solutions. The precautions and checks which ensure that the experimental method is providing the actual product ratio of the hydrolysis are described in the Experimental section. Another point which must be addressed before these ratios can be discussed in terms of tetrahedral intermediate partitioning is whether the amide does in fact come from the intermediate. An alternative route to this product is the S_N2 displacement outlined in reaction [1] (27, 28).



[1]

The S_N2 reaction has been observed in competition with tetrahedral intermediate formation (6, 27) with benzimidatonium ions, but only at higher sulfuric acid concentrations (60–65% H_2SO_4) and higher temperatures (85°C). Previous results would suggest that its importance is relatively small in more dilute acids at 25°C (6), except for benzimidatonium ions with *ortho* substituents (28).

We have carried out the appropriate labelling experiment for the hydrolysis of the 4-nitrobenzimidatonium ion in 48% H_2SO_4 at 25°C. These conditions do produce a substantial amount of amide (Table 1). Within experimental uncertainty this amide is found to contain an oxygen atom from the solvent, a result which unambiguously demonstrates (reaction [1]) that this product is derived from the tetrahedral intermediate, and not an S_N2 reaction.

For the hydrolysis of **2** in more dilute acids, and for the hydrolysis of **1** at all the acidities of Table 1, the yield of amide is small, and the labelling experiment could not satisfactorily be carried out. The following analysis does, however, provide some idea of the significance of the S_N2 reaction. The hindered benzimidatonium ions **3** hydrolyze via the S_N2 reaction to an extent greater than 99% in dilute acids (28). Extrapolation from higher temperatures provides a rate constant for the hydrolysis of **3***b* in 1.9% H_2SO_4 at 25°C of 4×10^{-8} s^{-1}. The *N,N,O*-trimethylbenzimidatonium ion hydrolyzes via the S_N2 reaction almost exclusively in 63% H_2SO_4 at 85.2°C (6, 27) with a rate constant of 2×10^{-6} s^{-1}. Under the same conditions, the rate constant for the hydrolysis of **3***a*, obtained by a short extrapolation,

3*a*, R = Me
b, R = Et

is 4×10^{-6} s^{-1} (28). If it is assumed that there is the same difference in rate between **3***b* and the *O*-ethyl-*N,N*-dimethylbenzimidatonium ion **1**, and more-

TABLE 1. Molar ratio of ester-to-amide in the products of hydrolysis at 25°C of the *O*-ethyl-*N,N*-dimethylbenzimidatonium ion (**1**) and the *O*-ethyl-*N,N*-dimethyl-4-nitrobenzimidatonium ion (**2**)

For personal use only.

over that this difference is independent of temperature and acidity, the rate constant for S_N2 hydrolysis of **1** in 1.9% H_2SO_4 at 25°C is 2×10^{-8} s^{-1}. We have measured spectroscopically the rate constant for the hydrolysis of **1** in this acid at 25°C and obtain a value of 5×10^{-5} s^{-1}. Comparison of the two numbers suggests that a fraction 0.0004 of the hydrolysis is the S_N2 reaction. Although there is obviously uncertainty in the S_N2 rate because of the extrapolations and assumptions, this figure is remarkably similar to the fraction of amide actually produced (Table 1). For dilute acid solutions it seems reasonable to conclude therefore that a significant amount of amide is due to the S_N2 reaction, and is not derived from a tetrahedral intermediate. This is also probably true for **2**, although we can be less certain because the effect of substituents on the S_N2 reaction has not been fully evaluated.

Both ions show a relatively sharp increase in the yield of amide at some intermediate acidity (Table 1). The labelling experiment demonstrates for **2** that this change is associated with a change in partitioning of the tetrahedral intermediate. We feel that this is true for **1** also, although the actual increase in amide yield is not as great. Extrapolation, as described previously, shows that if the fraction of S_N2 hydrolysis is 0.0004 in dilute acid it should rise gradually, but only reach a value of 0.002 by 30–35% H_2SO_4, where the observed amide:ester ratio has risen to 0.006. This would imply that about two-thirds of the amide product in these acids comes from the tetrahedral intermediate. Considering the uncertainty in the extrapolations, a figure somewhere between 40 and 90% seems a more conservative estimate. It is difficult, however, to rationalize the sharp change in amide yield totally in terms of the S_N2 reaction.

Mechanisms

The general scheme which we proposed (1) for the primary decomposition pathways of an amide acetal is shown in reaction [2].

In neutral and basic solutions, decomposition occurs in a non-catalyzed reaction involving the neutral amide acetal S^0 and resulting in imidatonium ion and alcohol (C—O cleavage). In acid solutions decomposition involves two kinetically equivalent pathways, H^+-catalyzed C—O cleavage of S^0, and a non-catalyzed breakdown of the *N*-protonated amide acetal S^+. The latter reaction involves a C—N cleavage, and produces a dialkoxycarbonium ion and amine. The ratio of the two competing reactions is given by eq. [3].

$$[3] \quad \left(\frac{C—O}{C—N}\right)_{H^+} = \frac{k^{H}_{C-O}K^{+}}{k^{+}_{C-N}}$$

Table 2 lists the value of this ratio for the unsubstituted benzamide acetal and its 4-nitro derivative. It can be seen that both modes of cleavage are observed, particularly with the unsubstituted compound. There is a substantial substituent effect, the origin of which was discussed previously (1).

Table 3 lists values of the various constants of eq. [2]. These values refer to water and were estimated in the following way from actual kinetic results (1). For the 4-nitro derivative, the constants k^{O}_{C-O}, k^{H}_{C-O}, and pK^+ were determined previously in 30% dimethoxyethane (DME):water and 70% DME:water and these have simply been extrapolated to 0% DME. Values of the same three constants were obtained for

the unsubstituted compound, but only in 70% DME:water. The values in water have been estimated using the extrapolated values of the 4-nitro derivative and assuming that the substituent effect is the same as it is in 70% DME:water. Values of $k^{\pm}_{C-N}$ were not measured previously since C—N cleavage is not observed under the conditions used for the kinetic studies. However, from the values of k^{H}_{C-O} and pK^{+} estimated in water and the product ratios (Table 2) which were measured in water, $k^{\pm}_{C-N}$ can be calculated using eq. [3].

The tetrahedral intermediates of the hydrolysis of the imidatonium ions of the present study obviously break down in acid with a considerably smaller relative amount of C—O cleavage, a fact which has been recognized previously (6, 19). Equation [4] provides a general mechanism which will be used to account for the various observations.

[4]

This scheme is based on the generally accepted mechanism for imidate hydrolysis and ester aminolysis (12), omitting the anionic form of the tetrahedral intermediate which is not likely to be important in the acids involved here. This mechanism incorporates the basic features of the amide acetal system of reaction [2], with the addition of the zwitterion $T^{\pm}$, a structure obviously unattainable by an amide acetal.

The general analogy between the amide acetal and imidatonium ion systems is illustrated by the following. The acid C—O cleavage reaction of an amide acetal is a general acid-catalyzed reaction (and we have taken this to indicate that C—O bond breaking and proton transfer are concerted (29–34)). For the amide acetal $4\text{-}CH_3C_6H_4C(OMe)_2NMe_2$, a Bronsted α value of 0.61 was obtained (1). The microscopic reverse of this reaction is the general base catalyzed addition of methanol to the *O,N,N*,4-tetramethylimidatonium ion, and this must have a β value of 1 − α or 0.39 (29). We have measured rate constants for the hydrolysis of this ion. The reaction is general base catalyzed, as expected (19), and the Bronsted value is 0.39 (Table 4). (The exact agreement is probably somewhat fortuitous since slightly different α or β values are likely to be found for methanol and water (30).)

Partitioning of Tetrahedral Intermediate

Qualitatively, we interpret the behavior of the tetrahedral intermediates in the following way. In dilute acids the ester and amine products which predominate arise from breakdown of the zwitterion $T^{\pm}$. The very small amount of amide and alcohol products formed can be attributed to the S_N2 reaction and to the non-catalyzed breakdown of the neutral intermediate T^0 (or to a reaction which is

TABLE 4. Rate constants at 25°C and ionic strength 0.1 for the hydrolysis of the *O,N,N*,4-tetramethylbenzimidatonium ion

Catalyst	Rate constant
CH_3COO^-	$24 \times 10^{-5}\ M^{-1}\ s^{-1}$
$HCOO^-$	$9.8 \times 10^{-5}\ M^{-1}\ s^{-1}$
CH_2ClCOO^-	$4.4 \times 10^{-5}\ M^{-1}\ s^{-1}$
H_2O	$4.5 \times 10^{-5}\ s^{-1}$

kinetically equivalent to this). The relative importance of these two pathways cannot be rigorously assessed, although as discussed previously the possibility does exist that the S_N2 reaction accounts for almost all of the amide product. Whatever the case, greater than 99.9% of the tetrahedral intermediates formed in dilute acid give rise to ester and amine products, via the zwitterionic form.

At some intermediate acid concentration there is a sharp increase in the relative yield of amide, followed by a levelling off. This change is associated with a change in the partitioning of the tetrahedral intermediate, and not the S_N2 reaction, and our proposal is that this represents a change-over from breakdown via neutral transition states to breakdown via cationic transition states. The ester and amine products arise from the cationic tetrahedral intermediate T^+, while amide and alcohol products come from the kinetically equivalent H^+-catalyzed breakdown of T^0.

The same two reactions are observed in acid solutions with amide acetals. Both systems show a similar dependency in their partitioning on the aromatic substituent (Table 2), the 4-nitro group significantly favoring expulsion of alcohol or C—O cleavage. This common behavior is in fact one of the pieces of evidence supporting our proposal that the strong acid reactions of the tetrahedral intermediates resemble those of the amide acetals.

There is also a difference in the two systems, in that for a given substituent considerably less alcohol expulsion is seen with the tetrahedral intermediate (Table 2). To explain this we note the presence of the OH group in the cations which are being formed from the tetrahedral intermediates (reaction [5]).

By serving as a hydrogen bond donor to a solvent water molecule, this group assists in the solvation of the positive charge (36). This results in a stabilization relative to an analogous cation where such hydrogen bonding is not possible. The amount of the stabilization which can be gained by such hydrogen bonding is dependent on the inherent stability of the cation in the first place, with less stable cations deriving a greater amount of stabilization (36). This means that there will be a greater relative increase in stabilization in changing from the dialkoxycarbonium ion to a protonated ester than in changing from the imidatonium ion to the protonated amide. Since the transition states leading to these cations will see the same effect, a *relative* favoring of C—N cleavage over C—O cleavage can be expected for the tetrahedral intermediate.

This effect of hydrogen bonding is seen very clearly in comparing the rates of water addition to the various cations. (For the protonated ions this involves the applying of a factor correcting for the amount of protonation to the rate of an acid-catalyzed hydrolysis (37).) The *O,N,N*-dimethylbenzimidatonium ion is only four times more reaction than protonated *N,N*-dimethylbenzamide (6). The phenyldimethoxycarbocation (38), on the other hand, hydrates 10^3–10^5 more readily than proton ated ethyl benzoate (24), the uncertainty in this number arising from the considerable extrapolation from concentrated acid solutions required to make the protonation correction.

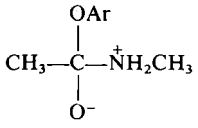
A detailed quantitative treatment taking into account the interconversions and breakdowns of all three forms of the tetrahedral intermediate is difficult. One problem concerns the question as to whether the three forms of the intermediate can be regarded as being in equilibrium before breakdown, or whether it is necessary to account for proton transfer steps (11, 12, 29). We feel that the former is probably close to being the case in our system, particularly for the interconversion of T^0 and T^+. Equilibrium will exist if each of the three forms is converted to at least one of the other forms faster than it decomposes. This is undoubtedly true for T^0 since its rate of nitrogen protonation in these strong acids will be extremely rapid. It is probably also true for T^+. This will be deprotonated by solvent to form T^0 with a rate constant of the order of 10^4– 10^6 s^{-1}, an estimate based on the assumptions that the pK^+ value is 5–6, and that the reverse reaction, the protonation of T^0 by H^+, is diffusion limited with a rate constant of 10^{10}–10^{11} M^{-1} s^{-1}. The breakdown of T^+ to amide and protonated ester should be slower, even if as discussed previously it occurs at a rate several orders of magnitude greater than that of an amide acetal (see values of k_{C-N}^{+} in Table 3). The problem arises with $T^{\pm}$, which is known to undergo breakdown extemely rapidly, sufficiently rapidly that in some systems it is not in equilibrium with the other forms (11, 12, 29). Its protonation by H^+ to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

form T^+ is however diffusion limited, and at the very high H^+ concentrations of this study, this reaction is also extremely rapid.

A second problem lies in the fact that our data refer to non-dilute acids, and this means that activity coefficients must be included. This is clearly difficult to do, particularly when it is considered that the activity coefficients of the proton, T^0, T^+, $T^\pm$, and the three transition states of reaction [4] are involved. To simplify matters we will assume that the $T^+ \rightleftarrows T^0$ equilibrium follows the H_0 acidity function, as does the rate of the H^+-catalyzed decomposition of T^0 ($k^H_{C-O}[H^+] = k^H_{C-O}h_0$). All other activity coefficients are ignored or assumed to cancel. We will also assume equilibrium exists between all three forms before breakdown. This treatment, of course, represents a considerable oversimplification, and we make no claim to rigor in the analysis. A semi-quantitative description is provided, however, of the important features.

These various assumptions produce eq. [6] for the partitioning of the tetrahedral intermediate in acid solutions.



$$[6] \quad \frac{\text{Amide}}{\text{Ester}} = \left(\frac{C{-}O}{C{-}N}\right) = \frac{k^O_{C-O} + k^H_{C-O}h_0}{\frac{k^\pm_{C-N}}{K^\pm} + \frac{k^+_{C-N}}{K^+}h_0}$$

In dilute acid (low h_0) the C—O/C—N ratio is independent of acidity, with a value given by eq. [7].

$$[7] \quad \left(\frac{C{-}O}{C{-}N}\right)_{\text{low } h_0} = \frac{k^O_{C-O}K^\pm}{k^\pm_{C-N}}$$

This ratio is of course very small experimentally. A second acidity independent region is predicted for concentrated acids (high h_0) where, as has been discussed, the breakdown involves the amide acetal type of mechanisms. The (C—O/C—N) ratio is given by eq. [3], and has been discussed already.

Another parameter which can be obtained is the ratio $k^H_{C-O}K^\pm/k^\pm_{C-N}$, a quantity which is related to the acidity region where the change-over occurs from one behavior to the other. For the 4-nitro compound, the value of this ratio is $10^{-3}\ M^{-1}$. As discussed previously, the value of k^H_{C-O} should be similar to that for the analogous amide acetal, that is, $10^5\ M^{-1}\ s^{-1}$. A value of $K^\pm$ of 10^3 can also be estimated, using correlations suggested by Guthrie (2). (For Ar = Ph of reaction [4], these correlations produce $pK^+ = 4.8$ and $p(K^+)' = 8.1$.) Taken together the estimate for $k^\pm_{C-N}$ is $10^{11}\ s^{-1}$. This value is extremely large,[1] but it is not at all unreasonable when compared to rate constants measured or estimated for the decomposition of other zwitterions (12*b*, 20, 33, 39–43). For example, the rate of decomposition of **6** was calculated to be $3 \times 10^9\ s^{-1}$ (12*b*), a number of the same order of magnitude as the estimate for $T^\pm$. Moreover the rate for the latter should be somewhat larger, since its OEt should provide a greater push for amine expulsion than an OAr group.

6

This very large rate of zwitterion breakdown explains why this mode of decomposition can remain important into relatively concentrated acids where the amount of tetrahedral intermediate in zwitterionic form is extremely low. For example, in 20% H_2SO_4 approximately half of the ester product observed in the hydrolysis of the unsubstituted benzamidation ion is derived from the zwitterion with the remainder being derived from the *N*-protonated tetrahedral intermediate. However, in this acid the relative concentration at equilibrium of the zwitterion is only $1/10^{10}$ that of the *N*-protonated intermediate. Their equal contributions to product formation can be explained by the 10^{10} greater rate of decomposition of the zwitterion.

[1]It is sufficiently large that the assumption that $T^\pm$ is in equilibrium with T^+ may be open to question. As suggested by a referee it is possible that the rate of breakdown of $T^\pm$ may be faster, and what is being observed is a change-over from rate-determining deprotonation to rate-determining cleavage. Although this possibly cannot be definitely ruled out, the analogy to the amide acetal chemistry in concentrated acids does suggest that there should be some breakdown by cationic transition states, as we have suggested in our general scheme.

Aromatization and microbial hydroxylation of 3-^{18}O-testosterone

HERBERT L. HOLLAND AND GREGG J. TAYLOR
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received May 28, 1980

HERBERT L. HOLLAND and GREGG J. TAYLOR. Can. J. Chem. **58**, 2326 (1980).

3-^{18}O-Testosterone (**1**) is transformed to estradiol (**4**) by human placental microsomes, and to the 6β- and 11α-hydroxy derivatives **2** and **3** by *Rhizopus arrhizus*, without significant loss of label. Neither process is therefore one which involves reversible Schiff base formation at C-3 at any stage.

HERBERT L. HOLLAND et GREGG J. TAYLOR. Can. J. Chem. **58**, 2326 (1980).

La testostérone (**1**) marquée avec du ^{18}O en position 3 est transformée en estradiol (**4**) par les microsomes du placenta humain et en dérivés hydroxy-6β et 11α (**2** et **3**) sous l'action du *Rhizopus arrhizus*; ces réactions se produisant sans perte significative du marqueur. Aucune des étapes de chacune de ces méthodes ne fait donc intervenir la formation réversible d'une base de Schiff au niveau du carbone en position 3.

[Traduit par le journal]

Introduction

The intermediacy of Schiff bases during enzymatic transformations of substrates which contain a carbonyl group is well established for many systems; examples include the vitamin B_6 dependent reactions and tetrahydrofolate dependent transfer of a C_1 unit at the formaldehyde oxidation level (1).

Schiff base formation has been proposed to occur during enzymatic transformations of steroids. It has been suggested that the 3-ketosteroid Δ^4,Δ^5-isomerase from *Pseudomonas testosteroni* operates on a substrate bound to the enzyme as a Schiff base involving the C-3 carbonyl of the steroid and a primary amino group of the protein (2) (Fig. 1). This mechanism is supported by kinetic (2, 3) and spectroscopic (2) evidence in model studies. Conversely, Wilton (4) has shown that saturation of the Δ^4 double bond of 3-^{18}O-testosterone **1** by mammalian C-5α- or C-5β- reductases (to give **5** and **6**) involves retention of label, thus precluding the formation of a Schiff base intermediate in this case. A necessary corollary of reversible Schiff base formation is the exchange of the carbonyl oxygen of the substrate with water, leading to loss of label in the case of ^{18}O carbonyl labelled substrates; this point has not, however, been experimentally proven for the Δ^4,Δ^5-isomerase system.

In the present study we have used **1** as a substrate for both the human placental aromatase enzyme system (leading to estradiol, **4**), and the microbial C-6β and C-11α hydroxylation reaction of *Rhizopus arrhizus* (leading to **2** and **3** respectively). Both enzyme systems require Δ^4-3-keto functionality in the substrate, and both could potentially involve an intermediate Schiff base complex analogous to **7** (Fig. 1), in the former case with

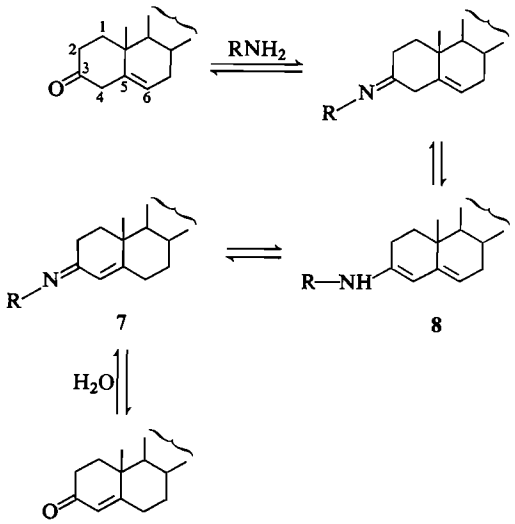

FIG. 1. Proposed mechanism of 3-ketosteroid Δ^4,Δ^5-isomerization (2).

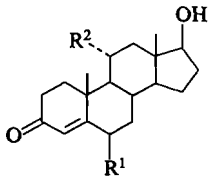
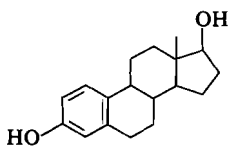
binding of substrate to the enzyme during oxidative removal of C-19, followed by hydrolysis prior to oxidation of Ring A and liberation of the phenol **4**.



Results and Discussion

3-^{18}O-Testosterone (**1**), prepared in quantitative yield by acid catalysed exchange with ^{18}O-water in 2-propanol (4), was transformed to estradiol (**4**) in yields approaching 10% by a microsomal suspension obtained from human placentae. The results of these incubations are presented in Table 1. It is apparent from the retention of label in estradiol that any mechanism for the aromatase enzyme system which involves a Schiff base complex (analogous to structure **7** of Fig. 1) can be discounted.



The slight loss of label in both recovered starting material and **4** is attributable to nonenzymic ex-

change of label with water during the incubation. Control experiments confirm that work-up conditions do not lead to loss of label from **4** or recovered substrate, provided that the latter is isolated directly from the initial ethyl acetate extract before basification (see Experimental). In addition, incubation of **1** under normal conditions but with a deactivated microsome preparation resulted in comparable loss of label.

The demonstration that the conversion of **1** to **4** does not involve a Schiff base complex is of interest in view of the demonstrated capacity of human placental mitochondria to isomerize Δ^5-3-ketosteroids (5), a process which may involve such a mechanism (*vide supra*).

In a separate series of experiments we have studied the hydroxylation of **1** at C-6β and C-11α by the fungus *Rhizopus arrhizus* ATCC 11145 (Table 1). Previous work by the Oxford group (6) has established that the site of hydroxylation of an oxygenated steroid by a given fungus is often controlled by the position of oxygenation (usually carbonyl or alcohol) in the substrate, an effect which appears to be due to binding of the substrate to the active site of the enzyme through the polar oxygenated positions of the former. Alternatively, hydroxylation may be substrate specific, as in the C-6β hydroxylation by *Rhizopus arrhizus* which requires a Δ^4-3-ketosteroid and proceeds through a $\Delta^{3,5}$ intermediate (7). In either case, the substrate may bind to the enzyme as a Schiff base, which, in the case of hydroxylation at C-6β, could undergo subsequent ketimine–enamine tautomerism followed by oxidation and hydrolysis (**1** → **7** → **8** → **2**). The latter hypothesis is particularly attractive in view of the apparent similarities of the C-6β hydroxylation and Δ^4,Δ^5-isomerization processes, and the relative ease of the ketimine–enamine tautomerism compared with the analogous keto–enol interconversion (8–10). Our results (Table 1) clearly show, however, that hydroxylations at both the C-6β and C-11α positions of **1** proceed with retention of the oxygen label at C-3, so that once again Schiff base intermediates cannot occur. The slight loss of label with respect to substrate is again attributed to aqueous exchange during the lengthy incubation period (15 h). Under conditions which afforded acceptable yields of **2** and **3**, starting material could not be recovered.

We therefore conclude that interaction of the C-3 carbonyl oxygen of **1** with the enzyme during 11α hydroxylation does not involve reversible Schiff base formation, and that the C-6β hydroxylation, as previously reported (7), involves keto–enol rather than ketimine–enamine tautomerism.

Experimental

Apparatus, Materials, and Methods

Melting points were determined on a Kofler heating stage and are uncorrected. Infrared spectra were recorded with a Perkin-Elmer 237B, ^{1}Hmr spectra with a Bruker WP-60 using $CDCl_3$ as solvent and TMS as internal standard, and mass spectra were obtained with an AEI MS 30. ^{18}O content was estimated by repeated scanning of the relevant ions and application of the appropriate corrections for natural isotopic abundances; values are accurate to ±1%. Thin-layer and preparative-layer chromatography were performed on Merck silica gel plates.

Rhizopus arrhizus ATCC 11145 was maintained on 4.5% malt agar slopes.

3-^{18}O-Testosterone (1)

This was prepared by a modification of the method of Wilton (4). Acid washed testosterone (200 mg) was added to a solution of 1 mL of HCl (4 m*M* in 2-propanol) and ^{18}O-water (95 at.% ^{18}O) (1 mL) in dry 2-propanol (20 mL) contained in an acid washed reaction vessel. The vessel was then flushed with nitrogen and maintained at 60–62°C for 24 h. The solvent and reagents were then removed and recovered on a vacuum line. The reaction was repeated using an additional 200 mg of starting material, employing the recovered reagents plus additional HCl. A quantitative yield of product was obtained in both runs. Mass spectral analysis indicated the following isotopic compositions: batch 1, 78% ^{18}O; batch 2, 63% ^{18}O. The material, although stored in a desiccator, showed a slight loss of isotopic enrichment over a period of 5–8 months (cf. values in Table 1).

Incubation of 3-^{18}O-Testosterone with Rhizopus arrhizus

The fungus was grown in a medium consisting of a solution of glucose (50 g), peptone (20 g), and corn steep liquor (5 mL) in tap water (1 L). A one-litre Erlenmeyer flask, containing 150 mL of the above medium, was sterilized by autoclaving at 15 psi for 20 min and allowed to cool. A sample of actively growing *Rhizopus arrhizus* was transferred from an agar slope to the above flask, which was then incubated on a rotary shaker (180 rpm) at 28°C for 72 h. The mycelium was then separated by filtration, washed by short maceration with distilled water, and resuspended in 0.1 *M* phosphate buffer (pH 7.0, 150 mL) in a one-litre Erlenmeyer flask. A solution of 3-^{18}O-testosterone (100 mg) in ethanol (2 mL) was then added to the flask, and incubation continued under the above conditions for a further 15 h. The mycelium and buffer were then separated by filtration and each extracted separately with dichloromethane. The mycelial extract yielded no detectable steroids (tlc). The buffer extract was evaporated to dryness to give a residue (110 mg) which after preparative layer chromatography (3% methanolic chloroform, two elutions) afforded 6β-hydroxy-3-^{18}O-testosterone (**2**) (27 mg from ethyl acetate/hexane) and 11α-hydroxy-3-^{18}O-testosterone (**3**) (44 mg from ethyl acetate/hexane), both identified by tlc and spectral (^{1}Hmr) comparisons with authentic unlabelled material. ^{18}O content is presented in Table 1.

Incubation of 3-^{18}O-Testosterone with Placental Microsomes

Human placentae (full term) were obtained immediately upon delivery at the St. Catharines General Hospital, and were transported on ice. The placentae were then washed in ice-water (or saturated KCl solution) and minced. The minced tissue was added to 200–300 mL of tris buffer of the following composition (g/L): sucrose (85.6), dithiothreitol (0.015), nicotinamide (0.005), tris HCl (0.24), tris base (0.06). The resulting suspension was homogenized in a Waring blender with frequent ice-cooling. The homogenate was then centrifuged at 10 000 g and 0°C for 30 min. The pellet was discarded and the resultant supernatant was centrifuged at 100 000 g and 0°C for 1 hour. The supernatant was then discarded and the resultant pellets were resuspended in the above buffer (50–100 mg/mL) using a Teflon homogenizer. The microsome suspensions prepared in this way retained their activity for several months when stored frozen at −20°C.

For the transformation of testosterone to estradiol, 5 units of glucose-6-phosphate dehydrogenase (Sigma type XV from Baker's Yeast, 10 units/mL in 5 m*M* sodium citrate) were added to a solution of glucose-6-phosphate (70 mg) and NADP (40 mg) in 0.1 *M* sodium phosphate buffer (pH 7.2, 15 mL). This mixture was incubated at 37°C for 30 min in order to generate NADPH. At this point, 5 mL of thawed placental microsome suspension was added, followed by the steroid substrate (2 mg in 400 μL 95% ethanol). Incubation at 37°C in a rotary incubator–shaker was carried out for 45–50 min. The incubation mixture was then extracted with ethyl acetate, and the extract dried over sodium sulphate and evaporated. Recovered starting material could be isolated directly from this fraction by plc. For the isolation of estradiol, the residue was dissolved in toluene and the resulting solution extracted with 0.1 *M* NaOH. The basic extract was then neutralized (0.1 *M* HCl) to pH 7 and extracted with ether. The ethereal extract was dried and evaporated. Estradiol was obtained from the residue by plc. The isotopic content is listed in Table 1.

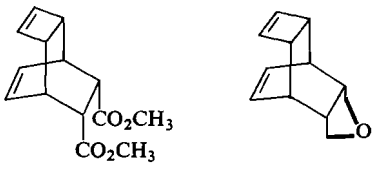
The reactions of benzeneselenenyl chloride with three derivatives of tricyclo[4.2.2.0^{2,5}]deca-3,7-diene have been investigated in four solvent systems: methylene chloride, acetic acid, acetic acid/$LiClO_4$, and methanol. Under conditions of kinetic control only products of *exo–anti* attack upon the cyclobutene moiety are isolable when the solvent system is methylene chloride or acetic acid. This observation also holds in acetic acid/$LiClO_4$ except in the case of dimethyl tricyclo[4.2.2.0^{2,5}]deca-3,7,9-triene-7,8-dicarboxylate where the major product is that of cross-bonding with solvent incorporation. In methanol products of solvent incorporation, transannular cross-bonding and lactonization (where possible) are observed. A general mechanistic scheme is proposed to account for these observations in accord with earlier results for the analogous arenesulphenylations.

DENNIS G. GARRATT, M. DOMINIC RYAN et ANN KABO. Can. J. Chem. **58**, 2329 (1980).



On a étudié la réaction du chlorure de benzènesélényle avec trois dérivés du tricyclo[4.2.2.0^{2,5}]décadiène-3,7 dans 4 systèmes de solvant: le chlorure de méthylène, l'acide acétique, l'acide acétique/$LiClO_4$ et le méthanol. Dans des conditions de contrôle cinétique, on n'a isolé que les produits résultant de l'attaque *exo–anti* sur le noyau cyclobutène dans le chlorure de méthylène ou l'acide acétique. Cette observation vaut également pour le système acide acétique/$LiClO_4$ à l'exception du tricyclo[4.2.2.0^{2,5}]-décatriène-3,7,9 dicarboxylate-7,8 de diméthyle où le produit principal est celui qui est réticulé avec incorporation de solvant. Dans le méthanol, on observe la formation de produits incorporant le solvant, de produits réticulés de façon transannulaire et de produits lactonisés (si il y a formation). On propose un mécanisme général qui tient compte à la fois de ces observations ainsi que des résultats obtenus antérieurement dans le cas d'arènesulphénylations analogues.

[Traduit par le journal]

The reactions of electrophiles with tricyclo-[4.2.2.0^{2,5}]deca-3,7-diene, **1**, and its derivatives usually occur via a predominantly *exo–syn* attack upon the cyclobutene moiety yielding products of 1,2-addition, **2**, or under certain conditions, trans-annular cyclization, **3** and/or **4** (2–10).

Mehta and Pandey (8) have recently reported the somewhat unprecedented nonstereospecific addition of benzenesulphenyl chloride to the cyclobutene moieties of dimethyl *endo,endo*-tricyclo[4.2.2.0^{2,5}]-deca-3,9-diene-7,8-dicarboxylate, **5**, and 4-oxatetra-cyclo[5.4.2.0^{2,6}.0^{8,11}]trideca-9,12-diene, **6**, yielding in each case a 3:1 mixture of *trans* and *cis* adducts. These results are at variance to those of Zefirov *et al.* (9) who simultaneously reported stereospecific *syn*

addition to **5** in nonpolar media such as carbon tetrachloride, and transannular cyclization to yield pentacyclic γ-lactones, **7** and/or **8**, in protic media such as acetic acid (eq. [2]). More recent studies by Kanematsu and co-workers (7) are at variance with both of the above, their analysis being consistent with stereospecific *anti* addition and the formation of a cross-bonded δ-lactone, **9**, instead of the γ-lactones previously described. No evidence was found for the

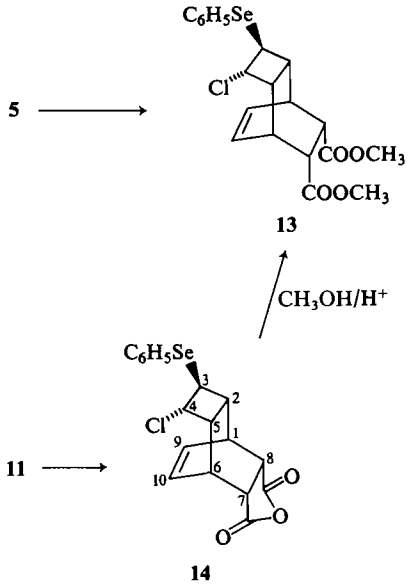
analogous parallel bonded δ-lactone, **10**. Zefirov and co-workers have subsequently changed their interpretation to correspond with that of Kanematsu *et al.* and have supplied data from X-ray crystallographic investigations which substantiate the new findings (11–20) (eq. [3]).

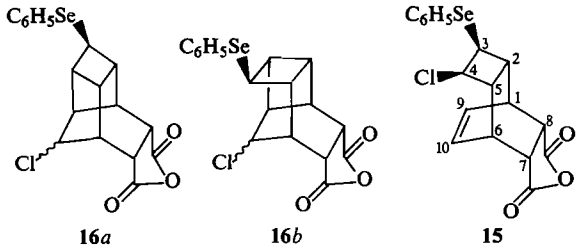
During the course of our studies of the mechanism of areneselenenyl halide additions to olefinic substrates (21–33), we undertook an investigation of the reactions of benzeneselenenyl chloride with *endo*-tricyclo[4.2.2.$0^{2,5}$]deca-3,9-diene-7,8-dicarboxylate anhydride, **11**, dimethyl tricyclo[4.2.2.$0^{2,5}$]deca-3,7,9-triene-7,8-dicarboxylate, **12**, species **5**, and some related bicyclic alkenes (31). It was our aim to determine whether or not stereochemical constraints imposed by the configuration of the alkene would lead to nonstereospecific or perhaps *syn*-stereospecific addition, in contrast to the *normal stereospecific anti* mode of attack (22, 23, 26, 27, 31, 33–41).



11 **12**

Results and Discussion

The reaction of benzeneselenenyl chloride with **5** at ambient temperature in methylene chloride, anhydrous acetic acid, or anhydrous acetic acid in the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

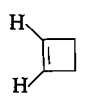
presence of 2.5 mole-equivalents of lithium perchlorate (relative to **5**) yields **13** in essentially quantitative yield. Under equivalent conditions benzeneselenenyl chloride gives upon addition to **11** the adduct **14**. Treatment of **14** with acidic (aqueous HCl) methanol gives **13**. Assignment of **13** and **14** as

the *trans* isomers of *exo* electrophilic attack upon the cyclobutene double bonds of **5** and **11**, respectively, follows from a comparison of the ms, ir, and ^1H and ^{13}C nmr spectral parameters with those of their sulphur analogues. The configuration of the sulphur analogue of **13** has been previously unambiguously determined by single crystal X-ray crystallographic studies by Zefirov and co-workers (13, 15).

In addition to the above, two further compounds, **15** and **16**, were observed as transient products during the course of the reaction of benzeneselenenyl chloride with **11**. Compound **15** is assigned as the product of *exo–syn* addition to the cyclobutene double bond. The ratio of **14** to **15** between 40 and 55% reaction was observed to be approximately 4:1 and to increasingly favour **14** as the reaction progresses. Compound **16** accounts for no more than 5% of the total product mixture during the course of the reaction, and unfortunately could not be isolated in a pure state. Attempts to separate **16** from **14** and **15** by chromatography on silica gel or Florisil led to the isomerization of **16** to **14** and/or **15**, irrespective of the nature of the eluting solvent. The absence of olefinic protons and the presence of an intact anhydride functionality allows us to tentatively assign **16** as either the cross-bonded, **16***a*, or parallel-bonded, **16***b*, pentacyclic anhydride.

With respect to the assignments of **13**, **14**, and **15** the following points are of note. First, the olefinic protons at C9 and C10 in **14** appear as two distinct doublets of doublets of doublets at δ 6.35 and 6.62 ppm, due presumably to unsymmetrical *endo* substitution, with a vicinal olefinic $^1H—^1H$ coupling of 7.0 Hz. In contrast, the olefinic protons at C9 and C10 of compound **15** appear as an apparent triplet centered at δ 6.56, indicative of essentially symmetric *endo* substitution at C3 and C4. This tentatively establishes **15** as the *cis* isomer of *exo–syn* addition (13, 42) as previously indicated.

Assignments were further corroborated by an analysis of chemical shifts and coupling constants of the protons at C3 and C4. The *exo* proton at C4 in the *trans* isomer **14** resonates at δ 4.17, exhibiting significant shielding due to the *cis* vicinal phenylseleno group as compared to the *endo* proton at C4 in the *cis* isomer **15** which resonates at δ 4.48. The *exo* and *endo* protons at C3 and C4, respectively, in species **14** exhibit a complex multiplet characteristic of the AB portion of an ABXX′ spin system.



Confirmation that attack occurs at the cyclobutene double bond, and *not* at the double bond of the bicyclo[2.2.2]octene system, is based upon an analysis of their ^{13}C nmr spectra, and those of a series of model compounds (see Experimental and ref. 31). Chemical shift assignments have been based upon previously studied substituent effects and the magnitude of $^{13}C—^1H$ and $^{13}C—^{77}Se$ coupling interactions.

One-bond $^{13}C—^1H$ interactions are particularly useful, since it has been shown that the magnitude of the coupling increases markedly with increasing *s* character of the carbon hybridization (43, 44). Of paramount importance is the observation that the value of $^1J_{C,H}$ increases significantly in small rings, relative to moderately sized monocyclic or acyclic systems. Furthermore, the $^1J_{C,H}$ values for a series of low molecular weight polycyclic hydrocarbons have been found to correlate, at least qualitatively, with increasing ring strain. For example, the magnitude of $^1J_{C,H}$ for the olefinic carbon in cyclobutene, **17**, is greater than that in bicyclo[2.2.2]octene, **18**, by 5.5

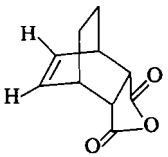
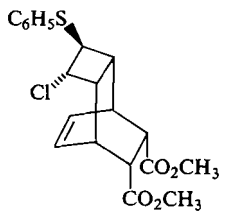
Hz (170 vs. 164.5). The value of the olefinic couplings is seen to increase slightly to 165.9 in dimethyl *endo,endo*-bicyclo[2.2.2]oct-5-ene-2,3-dicarboxylate, **19**, and even further to 167.4 Hz in *endo*-bicyclo-[2.2.2]oct-5-ene-2,3-dicarboxylic anhydride, **20**. We are thus able to assign the resonances at δ 129.1 ($^1J_{C,H}$ = 167.6 Hz) and δ 138.2 ($^1J_{C,H}$ = 171.9 Hz) to the cyclohexene and cyclobutene moieties of **11**, respectively. An examination of the olefinic one-bond $^{13}C—^1H$ couplings in **14** and **15** (167, 166 vs. 168, 167) supports our assignments in terms of attack on the cyclobutene double bond.

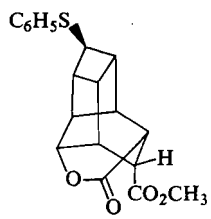


17

18

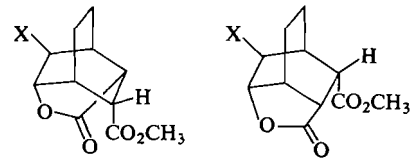


19



20

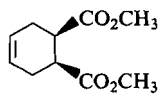
While the assignment of configuration to adducts **13–15** is quite straightforward, the rationalization for their formation proved to be somewhat more difficult. In particular, the observation of a single species **13** derived from **5** in protic media, such as acetic acid and acetic acid/$LiClO_4$ (Zefirov's dopping–addition conditions (12)) was unanticipated. Under equivalent conditions, for example, we found that benzenesulphenyl chloride reacts with **5**, in acetic acid, to give a 39:61 mixture of the *trans* adduct **21** and the δ-lactone, methyl (1*RS*,4*SR*,12*RS*)-4-phenylthio-9-oxapentacyclo[6.4.0.$0^{2,5}$.$0^{3,7}$.$0^{6,11}$]-dodeca-10-one-12-carboxylate, **22**. The identity of **22** was confirmed by the synthesis of an authentic sample by the procedure of Zefirov *et al.* (12).



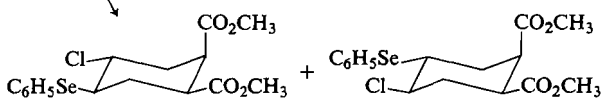
21

22

We note at this point that many investigators have claimed that selenenyl and sulphenyl halides must react by very similar, if not identical, mechanisms (45) because of the isosteric relationship found between organoselenium and organosulphur compounds. In this regard the absence of lactone products and/or products of solvent-incorporation, particularly in acetic acid/$LiClO_4$ (18, 46–50), was quite surprising. Our previous observation (31) that both benzeneselenenyl and benzenesulphenyl chlorides react with **19** in methylene chloride solution under ambient laboratory conditions of temperature, light, and atmosphere, to give mixtures of the γ- and δ-lactones, **23** and **24** (eq. [5]), served to substantiate our initial expectations.



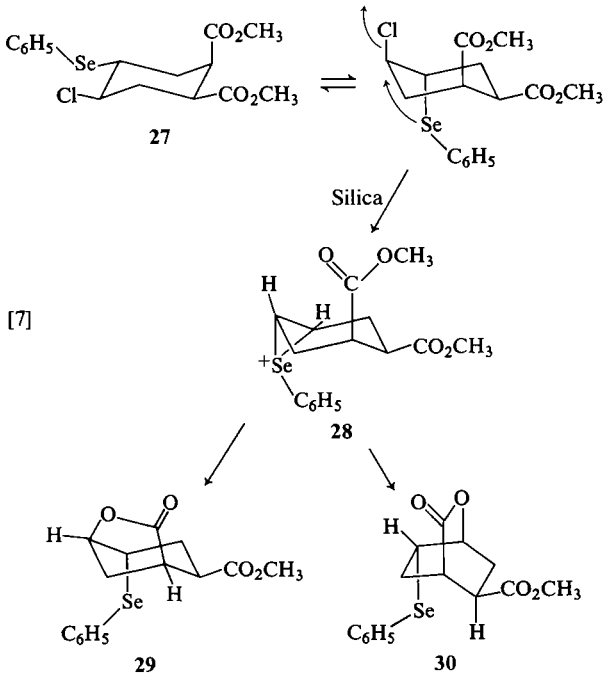
[5] **19** → X = ArSe, ArS



24 **23**

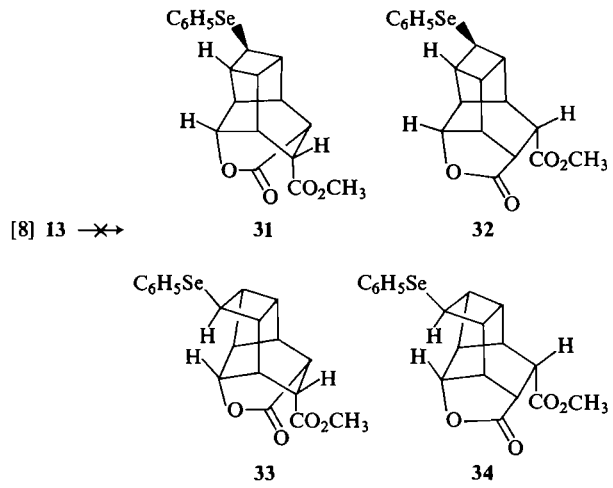
Intrigued by the very different propensities of **19** and **5** towards lactonization, we chose to investigate the related monocyclic diester **25**. Treatment of **25** with benzeneselenenyl chloride in methylene chloride did not, however, give the expected lactones. Instead, a mixture of 1:1 adducts **26** and **27**, formed in the ratio of 1:3, was isolated. Assignment of **26** and **27** was made on the assumption (33, 45) that the

[6]



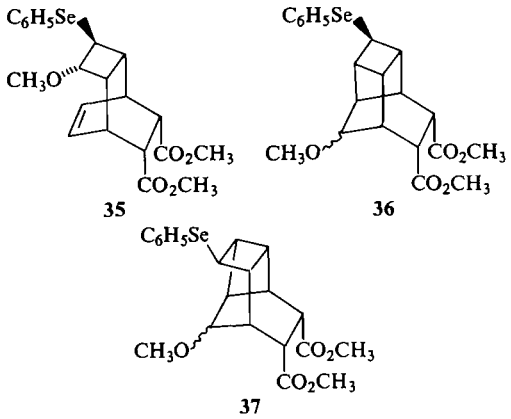
25

26 **27**



configurational-selectivity would be governed by steric approach control and that therefore attack occurs on the face of the double bond *anti* with respect to the diester moiety. Furthermore, only **27** has the correct configuration to allow lactonization with neighbouring group participation by selenium, through formation of the seleniranium ion **28**. Attempts to separate **26** and **27** by tlc on silica gel, using methylene chloride as eluant, were only partially successful. Compound **27** was converted under these conditions to a 2:1 mixture of the respective γ- and δ-lactones **29** and **30** in approximately 80% yield, based on **27**. Further chromatographic separations allowed for a mass conversion-isolation of greater than 95% based upon the total amount of **26** + **27** available. It is of interest to note that **26** is apparently isomerized to **27**, presumably via an elimination–readdition sequence on silica gel, thus

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

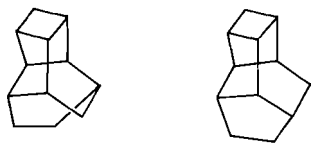


demonstrating the facile reversibility of these additions.

Attempts on our part to force the lactonization of **13** in a manner analogous to that above, either on preparative tlc plates or in a slurry of finely divided silica, were unsuccessful.

An alternative approach to the lactones **31**–**34**, however, now presented itself. Studies being carried out in our laboratory indicated that molecular rearrangements might occur during selenenyl chloride additions to alkenes when polar solvents such as methanol are used (33).

The reaction of **5** with benzeneselenenyl chloride in methanol gives, in contrast to our results in methylene chloride and acetic acid, three products in the relative proportions of 2:1:1. The major species was identified as **13**. The two remaining compounds are pentacyclic lactones. Surprisingly, no evidence is found for products of solvent-incorporation, such as **35**, **36**, or **37**. While one of the lactones could be readily assigned as **31**, methyl (1*RS*,4*SR*,12*RS*)-4-phenylseleno-9-oxapentacyclo[6.4.0.0^{2,5}.0^{3,7}.0^{6,11}]-dodeca-10-one-12-carboxylate, the product of δ-lactonization with cross-bonding, the configuration of the remaining lactone is still in doubt.

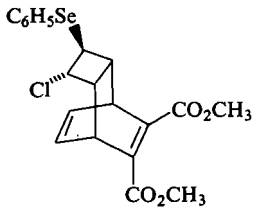


A tentative assignment of configuration to this lactone as **32** may, however, be made on the basis of force field calculations. In a recent publication Osawa *et al.* (51) proposed a steric interpretation of electrophilically induced transannular cyclization of juxtaposed double bonds. They observed that the course of an electrophilic addition to a molecule having two isolated double bonds in close proximity gives a transannular cross- or parallel-bridged product depending on the thermo-dynamic stability of the products. When the difference in calculated steric energies between neutral hydrocarbon skeletons of the cross and parallel adducts exceeds 10 kcal mol^{-1}, the more stable product is formed exclusively, whereas if the energy difference is less than 10 kcal mol^{-1} both types of transannular products may be formed.

If one makes the hypothesis, which seems reasonable, that the ring strain inherent in **31** and **32** bears the same relationship to the strain energy in **33** and **34** that the somewhat simpler hydrocarbon, tetracyclo[4.2.2.0^{2,5}.0^{3,7}]decane, **38**, has with respect to tetracyclo[4.4.0.0^{2,5}.0^{3,8}]decane, **39** (dihydrobasketane), then one would predict **31** and **32** to be favoured thermodynamically over **33** and **34**. This

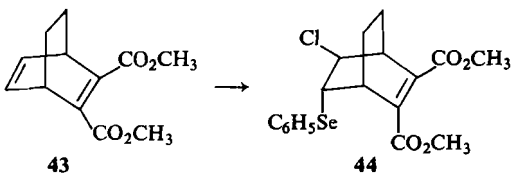
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

follows from the calculated strain energies of **38** and **39** which are 54.35 and 67.03 kcal mol^{-1} as based on the Engler force field (52, 53) or 57.43 and 66.66 kcal mol^{-1} as based on the 1971–1972 Allinger force field (54–56). Extending this form of argument to the saturated hydrocarbon analogues of **31** and **32**, one notes that the calculated strain energies for pentacyclo[6.4.0.$0^{2,5}$.$0^{3,7}$.$0^{6,11}$]dodecane, **40**, and pentacyclo[5.4.1.$0^{2,9}$.$0^{3,6}$.$0^{4,8}$]dodecane, **41**, are 59.55 and



40 **41**

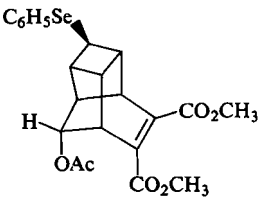
62.84 kcal mol^{-1} (51–53) respectively, or 61.21 and 68.53 kcal mol^{-1} (51, 54–56), respectively. From these data one predicts that **31** will be thermodynamically more stable than **32**. Indeed, we observe an isomerization of our second lactone, presumably **32**, upon standing, to **31** (room temperature, CD_2Cl_2).



The reaction of benzeneselenenyl chloride with triene **12** gives, in either methylene chloride or acetic acid, a single product **42**, identified by comparison of its ^{13}C nmr parameters with those of the sulphur analogue, as the *trans* adduct of *exo–anti* attack, (eq. [9]). No evidence was found for attack upon either the C7—C8 or C9—C10 double bonds.

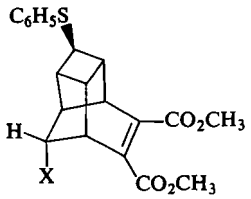
[9] **12** $\xrightarrow[\text{or HOAc}]{CH_2Cl_2}$ **42**

This result is of interest, since the related diene, dimethyl bicyclo[2.2.2]octa-2,5-diene-2,3-dicarboxylate, **43**, is observed to add benzeneselenenyl chloride to give **44**, (eq. [10]).



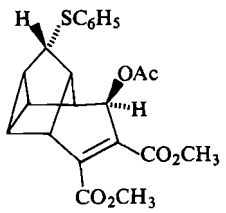
[10] **43** → **44**

Presumably, the absence of products derived from attack upon the C9—C10 double bond of **12** is the result of a deactivating effect by the dicarboxylate functionalities at C7—C8 and enhanced reactivity at C3—C4 by release of Baeyer ring strain upon addition to the cyclobutene moiety.



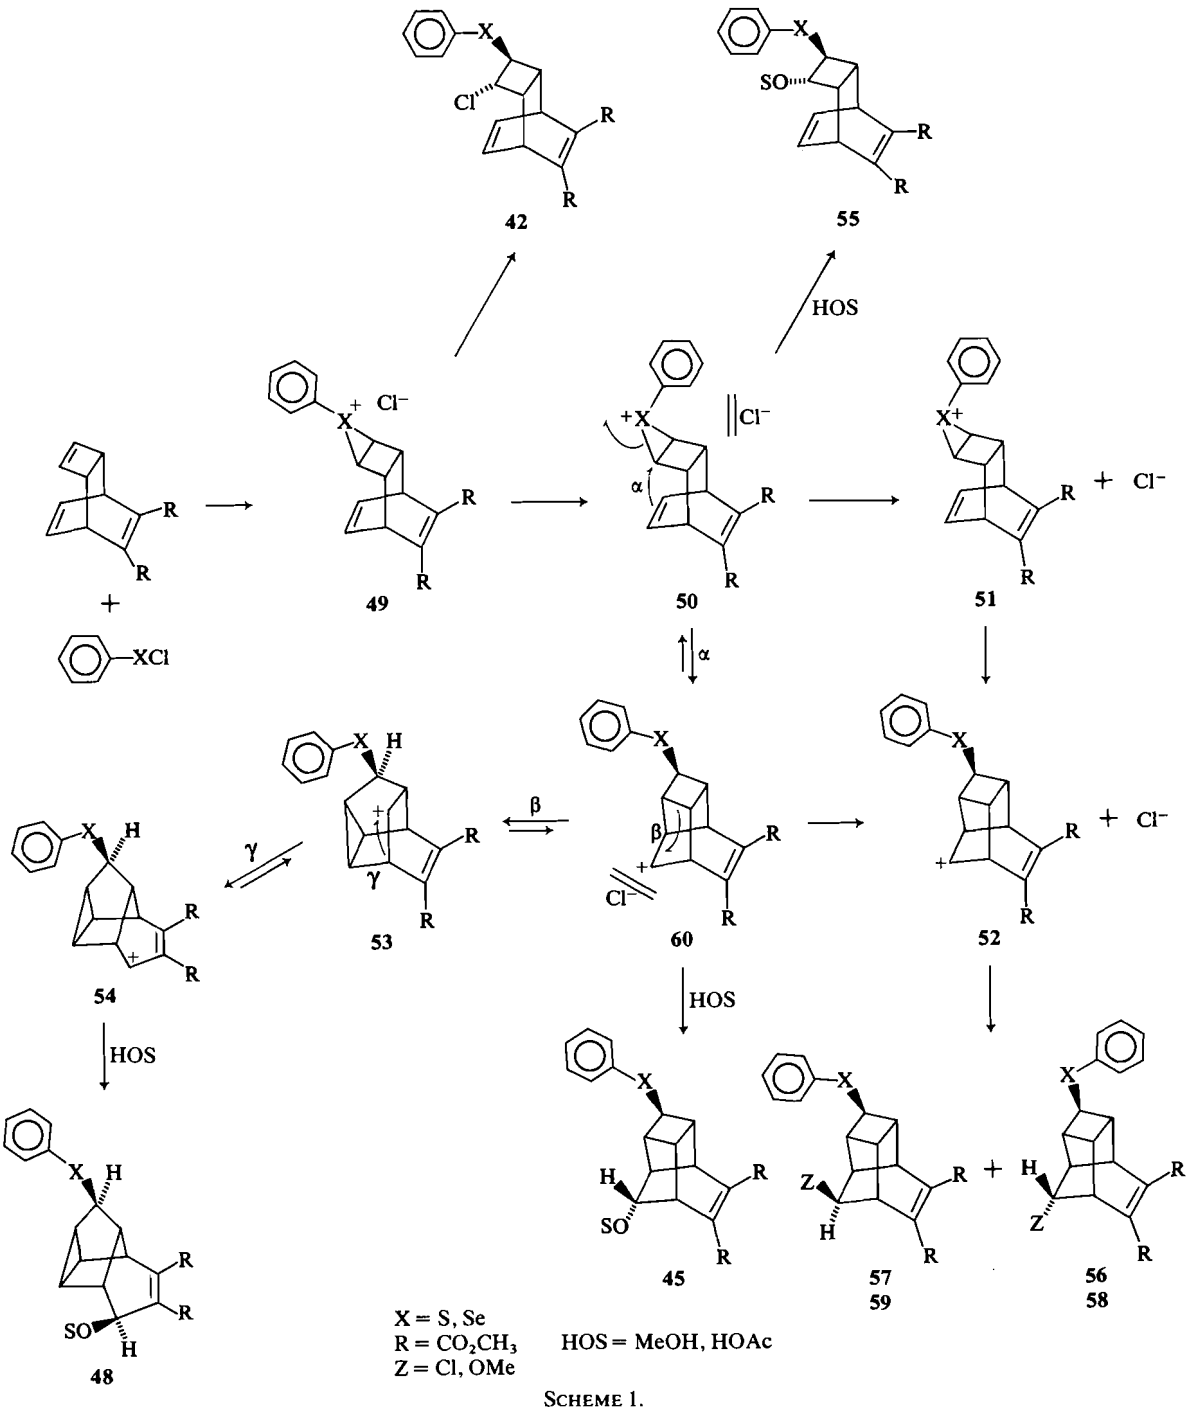
In contrast to our results with dienes **5** and **11**, the addition of benzeneselenenyl chloride to triene **12** in acetic acid/$LiClO_4$ gives, as the major product, the acetate of transannular addition, dimethyl *exo*-4-phenylseleno-*endo*-8-acetoxytetracyclo[4.2.2.$0^{2,5}$.$0^{3,7}$]deca-9-ene-9,10-dicarboxylate, **45**! The ratio of **42** to **45** is found to be 37:63 when 2.2 mole-equivalents (based on **12**) of lithium perchlorate are present.

It is constructive at this point to compare our data for areneselenenylation with those for arenesulphenylation carried out under identical conditions. As noted above, the reaction of benzeneselenenyl chloride with **12** gives only **42** in acetic acid. In contrast, we observe a 1:1 mixture of **42′** and **45′**, the sulphur analogues of **42** and **45**, respectively, when benzenesulphenyl chloride is allowed to react with



45

12 in acetic acid. Furthermore, while benzeneselenenyl chloride yields only **42** and **45** in acetic acid/$LiClO_4$, benzenesulphenyl chloride gives a complex mixture of at least five products! We have been able to identify and assign **42′**, **45′**, the cross-bonded chloride **46**, the cross-bonded perchlorate **47**, and the novel rearranged acetate **48**. The relative proportions of **42′**:**45′**:**46**:**47**:**48** were determined to be 8:59:11:9:13. The structures of these species are assigned in accord with the previously reported 2-nitrophenylthio derivatives (19).

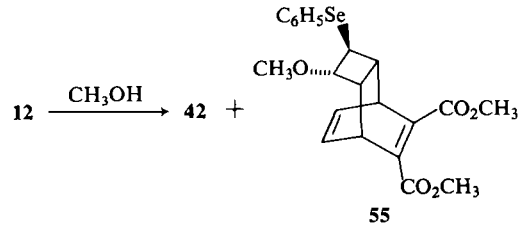


46 X = Cl
47 X = $OClO_4$

48

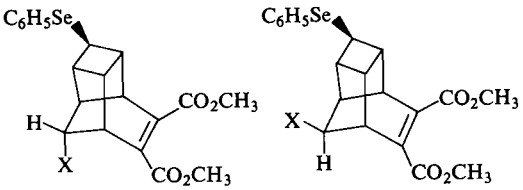
In comparing these reactions of benzeneselenenyl chloride and benzenesulphenyl chloride with substrates **5**, **11**, and **12**, it becomes apparent that areneselenenylation is much less affected by the change from a relatively nonpolar solvent, such as methylene chloride, to a moderately polar protic solvent, such as acetic acid or acetic acid/$LiClO_4$ than is arenesulphenylation. If one makes the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.



SCHEME 1.

assumption that the reaction hypersurfaces for areneselenenylation and arenesulphenylation are similar after the rate-determining step (45), the differences observed in product distributions might be accounted for in terms of the more efficient neighbouring group or bridging ability of selenium relative to sulphur. As the polarity of the reaction medium increases one begins to observe, in both reaction series, a competition between bridged ionic intermediates such as the seleniranium intimate ion-pair **49**, or its sulphur analogue **49′** (see Scheme 1), and the more loosely associated species, such as the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

solvent-separated ion-pairs **50**, **50′**, the dissociated species **51**, **51′**, and free carbonium ions **52–54**.

In accord with this concept of a series of ion-pairs is the observation that benzeneselenenyl chloride reacts with **12** in methanol to give in addition to the *trans* chloride **42**, the analogous methoxy product **55**, the epimeric cross-bonded chlorides **56**, **57**, and the analogous epimeric methoxy adducts **58**, **59** (eq. [11]). When the reaction is carried out at 23–25°C

[11]

56 X = Cl
58 X = OMe

57 X = Cl
59 X = OMe

the relative proportions of **42**:**55**:**56**:**57**:**58**:**59** are found to be 55:14:6:1:14:10. Of particular note is the observation that both epimeric chlorides and methoxy adducts of cross-bonding are formed in methanol, whereas in acetic acid/$LiClO_4$ only one acetoxy species, **45**, is formed. This latter result suggests the possible role of a specifically solvated carbonium ion ion-pair such as **60** prior to formation of a free carbonium ion of type **52**.

Summary

Within the limits of our initial objectives, these results show a number of differences between the addition reactions of areneselenenyl and arenesulphenyl chlorides. Of particular importance is the observation of nonstereospecific addition to the cyclobutene double bond of **11** under conditions of kinetic control, followed by isomerization stereospecifically to the adduct of *exo–anti* addition! While this observation suggests the possible presence of two competitive reaction pathways, further mechanistic speculation should await more comprehensive studies including those which would specifically deal with the nature of the rate-determining step.

Experimental

General

All new compounds were separated and purified using preparative tlc performed on Analtech precoated plates, silica gel GF. Yields were determined by weighing the collected fractions and by nmr. The ^1H nmr spectra were obtained on a Varian Associates T60, EM 360, or HA 100 spectrometer. The ^{13}C nmr spectra were recorded on a Varian CFT20 or FT80-16K spectrometer operating in the Fourier Transform mode at 20.0 MHz. Infrared spectra were recorded on a Unicam 1100 or Perkin Elmer 257 spectrophotometer as CCl_4 solutions in NaCl cavity cells. Melting points were obtained on a Fisher-Johns block and are reported uncorrected. All new compounds gave acceptable elemental analyses: C, H, Cl, S, Se ± 0.35%. Elemental analyses were carried out by Scandinavian Microanalysis Laboratories, Herlev, or by Mr. H. Séguin, NRCC, Ottawa.

Benzeneselenenyl chloride was available commercially (Aldrich). Recrystallized prior to use from CCl_4, mp 63–64.5°C.

Benzenesulphenyl chloride was prepared from thiophenol (Aldrich) in 96% yield via the direct chlorination in CCl_4 at 0°C. Distilled under reduced pressure, bp 72°C/4 Torr. *Caution: this substance, although in use by various investigators for over thirty years, may spontaneously explode. A screw-capped bottle of triply distilled benzenesulphenyl chloride containing approximately 5–10 mL of the substance stored under argon, exploded in a refrigerator destroying not only the container but the desiccator in which it was stored!*

endo-*Tricyclo*[*4.2.2.0*^{2,5}]*deca-3,9-diene-7,8-dicarboxylate anhydride*, **11**, was prepared by the cycloaddition of maleic anhydride with 1,3,5,7-cyclooctatetraene (Aldrich) in chlorobenzene under reflux. Crystallized from benzene: mp 170–171°C; ir (KBr): 1850, 1760 cm^{-1}; ^1H nmr identical to that previously reported (31); ^{13}C nmr ($CDCl_3$): 36.9 (d, C1,6) $^1J_{C,H}$ = 140.8 Hz; 43.3 (d, C2,5) $^1J_{C,H}$ = 145.2 Hz; 138.2 (d, C3,4) $^1J_{C,H}$ = 171.9 Hz; 44.0 (d, C7,8) $^1J_{C,H}$ = 140.1 Hz; 129.1 (d, C9,10) $^1J_{C,H}$ = 167.6 Hz; 172.6 (s —C(=O)O—).

endo-*Bicyclo*[*2.2.2*]*oct-5-ene-2,3-dicarboxylate anhydride*, **20**, was prepared by the cycloaddition of maleic anhydride with 1,3-cyclohexadiene (Aldrich) in benzene under reflux. Recrystallized from benzene: mp 146–147°C; ir (NaCl, CCl_4): 1795, 1870 cm^{-1}; ^1H nmr ($CDCl_3$): 6.28 (m, 2H), 3.22 (bs, 2H), 2.98 (s, 2H), 1.55 (A_2B_2, 4H); ^{13}C nmr ($CDCl_3$): 31.6 (d, C1,4) $^1J_{C,H}$ = 143.8 Hz, $^2J_{CCH}$ = 6.2 Hz; 44.7 (d, C2,3) $^1J_{C,H}$ = 137.9; 133.0 (d, C5,6) $^1J_{C,H}$ = 167.4 Hz; 22.9 (t, C7,8) $^1J_{C,H}$ = 135.0 Hz; 172.9 (s —C(=O)O—).

Bicyclo[*2.2.2*]*oct-2-ene*, **18**, was purchased from Chemical Samples: ^{13}C nmr: 29.6 (d, C1,4) $^1J_{C,H}$ = 134.0 Hz; 134.3 (d, C2,3) $^1J_{C,H}$ = 164.5 Hz; 25.8 (t, C5,6,7,8) $^1J_{C,H}$ = 131.0 Hz, $^2J_{CCH}$ = 6.2 Hz.

Dimethyl endo,endo-*tricyclo*[*4.2.2.0*^{2,5}]*deca-3,9-diene-7,8-dicarboxylate*, **5**, was prepared from **11** by acid (HCl, 12 mol dm^{-3}) catalyzed esterification in anhydrous methanol. The diester was separated from unreacted anhydride on a silica gel column eluted with methylene chloride; ^1H nmr: 6.03 (m, 2H), 5.87 (bs, 2H), 3.60 (s, 6H), 2.5–3.3 (m, 6H); ^{13}C nmr: 37.6 (d, C1,6) $^1J_{CH}$ = 140.2 Hz, $^2J_{CCH}$ = 6.7 Hz, $^3J_{CCCH}$ = 6.8 Hz; 44.5 (d, C2,5) $^1J_{CH}$ = 145.5, $^2J_{CCH}$ = 5.2 Hz; 137.8 (d, C3,4) $^1J_{CH}$ = 169.8 Hz, $^2J_{CCH}$ = $^3J_{CCCH}$ = 6.4 Hz; 46.5 (d, C7,8) $^1J_{CH}$ = 133.5 Hz; 128.2 (d, C9,10) $^1J_{CH}$ = 167.3 Hz; 173.3 (s, CO_2CH_3) $^2J_{CCH}$ = 2.8 Hz; 51.6 (q, CH_3O_2) $^1J_{CH}$ = 146.8 Hz.

Dimethyl endo,endo-*bicyclo*[*2.2.2*]*oct-5-ene-2,3-dicarboxylate*, **19**, was prepared from **20** by acid (HCl, 12 mol dm^{-3}) catalyzed esterification in anhydrous methanol. Recrystallized from methanol: mp 64–67°C; ir: 1750 cm^{-1}; ^1H nmr: 6.35 (m, 2H), 3.42 (s, 6H), 3.00 (bs, 2H), 2.92 (bm, 2H), 1.52 (A_2B_2, 4H); ^{13}C nmr: 32.1 (d, C1,4) $^1J_{CH}$ = 140.2 Hz, $^2J_{CCH}$ = 6.2 Hz; 47.1 (d, C2,3) $^1J_{CH}$ = 133.5 Hz; 131.9 (d, C5,6) $^1J_{CH}$ = 165.9 Hz, $^2J_{CCH}$ = 3.4 Hz; 24.1 (t, C7,8) $^1J_{CH}$ = 132.0 Hz; 172.8 (s, CO_2CH_3); 51.0 (q, CH_3O_2) $^1J_{CH}$ = 146.8 Hz.

3,4-exo, exo-*Dibromo*-endo-*tricyclo*[*4.2.2.0*^{2,5}]*deca-9-ene-7,8-dicarboxylate anhydride* was prepared in accord with the pro-

For personal use only.

$^3J_{CCCH}$ = 3.8 Hz, $^3J_{COCH}$ = 3.7 Hz; 51.6 (q, CH_3O_2) $^1J_{CH}$ = 147.4 Hz.

Dimethyl 3 - exo - phenylseleno - 4 - endo - chlorotricyclo - [4.2.2.0^{2,5}]deca-7,9-diene-7,8-dicarboxylate, **42**, was prepared in 97% yield by the reaction of benzeneselenenyl chloride with triene **12** in either methylene chloride or acetic acid; ^{13}C nmr: 42.4 (d, C1); 46.5 (d, C2); 49.2 (d, C3); 59.6 (d, C4); 43.7 (d, C5); 40.8 (d, C6); 141.7, 142.8 (s, C7,8); 134.7 (d, C9); 132.4 (d, C10); 165.2, 165.5 (s, CO_2CH_3); 52.0 (q, CH_3O_2); tlc, silica gel R_f = 0.54 when eluted with 1:9 EtOAc–toluene.

Dimethyl 3-exo-phenylthio-4-endo-chlorotricyclo[4.2.2.0^{2,5}]-deca-7,9-diene-7,8-dicarboxylate, **42′**, was prepared using benzenesulphenyl chloride as above in methylene chloride solution; ^{13}C nmr: 41.5 (d, C1); 44.4 (d, C2); 50.5 (d, C3); 57.2 (d, C4); 43.9 (d, C5); 41.3 (d, C6); 142.4, 142.6 (s, C7,8); 135.0 (d, C9); 133.9 (d, C10); 165.4, 165.5 (s, CO_2CH_3); 52.0, 52.3 (q, CH_3O_2); tlc, silica gel, R_f = 0.82 using 1:4 EtOAc–toluene.

Dimethyl (1RS,4SR,8SR)-4-phenylseleno-8-acetoxytetracyclo[4.2.2.0^{2,5}.0^{3,7}]deca-9-ene-9,10-dicarboxylate, **45**, gave ^{13}C nmr: 41.4 (d, C1); 39.6 (d, C2); 45.1 (d, C3); 52.0 (d, C4); 48.2 (d, C5); 38.3 (d, C6); 42.0 (d, C7); 78.1 (d, C8—OAc); 138.2, 139.9 (s, C9,10); 170.1 (s, $OCOCH_3$); 20.5 (q, $OCOCH_3$); 166.7, 167.7 (s, CO_2CH_3); 52.1 (q, CH_3O_2); tlc silica gel, R_f = 0.38 using 1:4 EtOAc–toluene.

Dimethyl (1RS,4SR,8SR)-4-phenylthio-8-acetoxytetra-cyclo-[4.2.2.0^{2,5}.0^{3,7}]deca-9-ene-9,10-dicarboxylate, **45′**, gave ^{13}C nmr: 41.3 (d, C1); 39.3 (d, C2); 46.5 (d, C3); 49.1 (d, C4); 47.3 (d, C5); 38.2 (d, C6); 44.3 (d, C7); 77.9 (d, C8 —OAc); 137.9, 139.7 (s, C9,10); 170.0 (s, $OCOCH_3$); 20.5 (q, $OCOCH_3$); 166.7, 167.7 (s, CO_2CH_3); 51.9 (q, CH_3O_2).

Dimethyl 5-phenylthio-10-acetoxytetracyclo[4.4.0.0^{2,4}.0^{3,7}]-deca-8-ene-8,9-dicarboxylate, **48**, gave ^{13}C nmr: 41.9 (d, C1); 21.7 (d, C2); 13.0 (d, C3); 24.0 (d, C4); 48.8 (d, C5); 46.9 (d, C6); 30.5 (d, C7); 138.1 (s, C8); 145.8 (s, C9); 87.3 (d, C10—OAc); 170.0 (s, $OCOCH_3$); 20.8 (q, $OCOCH_3$); 164.7, 167.4 (s, CO_2CH_3); 52.0 (q, CO_2CH_3).

Dimethyl 3 - exo - phenylseleno - 4 - endo - methoxytricyclo-[4.2.2.0^{2,5}]deca-7,9-diene-7,8-dicarboxylate, **55**, gave ^{13}C nmr: 43.8 (d, C1); 45.3 (d, C2); 50.9 (d, C3); 86.6 (d, C4—OCH_3); 44.2 (d, C5); 40.3 (d, C6); 138.4, 139.5 (s, C7,8); 52.0 (q, CH_3O_2); 135.4 (d, C9); 131.9 (d, C10); 53.8 (q, CH_3O); tlc, silica gel, R_f = 0.60 using 1:9 EtOAc–toluene as elutant.

Dimethyl (1RS,4SR,8SR)-4-phenylseleno-8-methoxytetra-cyclo[4.2.2.0^{2,5}.0^{3,7}]deca-9-ene-9,10-dicarboxylate, **58**, gave ^{13}C nmr: 41.0 (d, C1); 39.3 (d, C2); 45.1 (d, C3); 48.3 (d, C4); 44.2 (d, C5); 37.4 (d, C6); 43.2 (d, C7); 82.9 (d, C8); 53.8 (q, CH_3O); tlc, silica gel, R_f = 0.43 using 1:9 EtOAc–toluene as elutant.

Dimethyl (1RS,4SR,8RS)-4-phenylseleno-8-methoxytetra-cyclo[4.2.2.0^{2,5}.0^{3,7}]deca-9-ene-9,10-dicarboxylate, **59**, gave ^{13}C nmr: 41.1 (d, C1); 39.6 (d, C2); 42.8 (d, C3); 48.0 (d, C4); 45.3 (d, C5); 37.6 (d, C6); 42.0 (d, C7); 82.0 (d, C8); 52.8 (q, CH_3O); tlc, silica gel, R_f = 0.43 using 1:9 EtOAc–toluene as elutant.

Methyl (1RS,4SR,12RS)-4-phenylthio-9-oxapentacyclo-[6.4.0.0^{2,5}.0^{3,7}.0^{6,11}]dodeca-10-one-12-carboxylate, **22**, was prepared in accord with the procedure of Zefirov *et al.* (12) and gave ir (CCl_4): 1805, 1755 cm^{-1}; ^{13}C nmr: 35.3 (d, C1); 45.1 (d, C2); 48.9 (d, C3); 61.6 (d, C4); 45.3 (d, C5); 31.6 (d, C6); 50.7 (d, C7); 84.2 (d, C8); 176.0 (s, C=O, C10); 39.4 (d, C11); 44.8 (d, C12); 171.5 (s, CO_2CH_3); 52.4 (q, CH_3O_2).

Methyl (1RS,4SR,12RS)-4-phenylseleno-9-oxapentacyclo-[6.4.0.0^{2,5}.0^{3,7}.0^{6,11}]dodeca-10-one-12-carboxylate, **31**, was isolated from the reaction of benzeneselenenyl chloride with **5** using methanol as solvent. Infrared (CCl_4): 1811, 1760 cm^{-1}; ^{13}C nmr: 36.0 (d, C1); 45.8 (d, C2); 48.7 (d, C3); 60.9 (d, C4); 46.4 (d, C5); 34.5 (d, C6); 50.3 (d, C7); 84.4 (d, C8); 175.8 (s, C=O, C10); 37.3 (d, C11); 44.3 (d, C12); 171.6 (s, CO_2CH_3); 51.5 (q, CH_3O_2).

Methyl (1RS,4SR,12SR)-4-phenylseleno-9-oxapentacyclo-[6.4.0.0^{2,5}.0^{3,7}.0^{6,12}]dodeca-10-one-12-carboxylate, **32**, gave ^{13}C nmr: 38.5 (d, C1); 44.6 (d, C2); 48.7 (d, C3); 59.5 (d, C4); 46.0 (d, C5); 36.2 (d, C6); 50.2 (d, C7); 76.1 (d, C8); 175.1 (s, C=O, C10); 39.3 (d, C11); 43.5 (d, C12); 172.3 (s, CO_2CH_3); 51.3 (q, CH_3O_2).

Received April 30, 1980

ANGEL LUIS ESTEBAN and ERNESTO DÍEZ. Can. J. Chem. **58**, 2340 (1980).

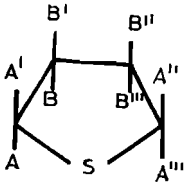
The ^{1}H nmr spectrum of tetrahydrothiophene has been analyzed. The best set of coupling values (Hz) is: $^2J_A - {}^2J_B = 2.18$, $^3J_B^c = 5.53$, $^3J_B^t = 7.31$, $^3J_{AB}^c = 6.80$, $^3J_{AB}^t = 6.37$, $^4J_A^c = -0.32$, $^4J_A^t = 0.25$, $^4J_{AB}^c = 0.26$, $^4J_{AB}^t = -0.47$ (A and B refer to α- and β- protons and c and t denote respectively the same and opposite sides of the ring). The variances observed between the values of this set and those reported by Lozach *et al.*, particularly the interchange of the $^4J_A^c$ and $^4J_A^t$ couplings, are discussed and it is concluded that our set is the one that reproduces the most fine details of the spectrum profile. The proposed set has been selected as being the most physically meaningful, from amongst 24 equally valid sets of couplings, on the basis of a better agreement with the ^3J_B and $^4J_{AB}$ values calculated from a Karplus relationship and from the INDO-FPT method respectively. In these calculations it was assumed that the molecule was interconverting rapidly (on the nmr time scale) between two puckered conformations with C_2 symmetry. A detailed discussion of the dependence of the couplings on the height of the pseudorotational barrier and on the temperature indicate that the minimum values of the potential energy correspond to these conformations.

ANGEL LUIS ESTEBAN et ERNESTO DÍEZ. Can. J. Chem. **58**, 2340 (1980).

On a analysé les spectres rmn du ^{1}H du tétrahydrothiophène. Le meilleur ensemble de valeurs de couplage (Hz) est: $^2J_A - {}^2J_B = 2{,}18$, $^3J_B^c = 5{,}53$, $^3J_B^t = 7{,}31$, $^3J_{AB}^c = 6{,}80$, $^3J_{AB}^t = 6{,}37$, $^4J_A^c = -0{,}32$, $^4J_A^t = 0{,}25$, $^4J_{AB}^c = 0{,}26$, $^4J_{AB}^t = -0{,}47$ (A et B font référence aux protons α et β et c et t dénotent respectivement le même et le côté opposé du cycle). On discute des différences observées entre les valeurs de cet ensemble et celles rapportées par Lozach et ses collaborateurs, particulièrement l'échange mutuel des couplages $^4J_A^c$ et $^4J_A^t$ et on a conclu que notre ensemble est celui qui reproduit le mieux les détails les plus subtils du spectre. On a choisi l'ensemble proposé comme étant celui qui physiquement est le plus significatif parmi 24 ensembles de couplages également valables, en se basant sur un meilleur accord entre les valeurs de ^3J_B et $^4J_{AB}$ calculées respectivement à partir de la relation de Karplus et de la méthode INDO-FPT. Dans ces calculs, on a fait l'hypothèse que la molécule subit rapidement une interconversion (à l'échelle du temps de la rmn) entre deux conformations gauches avec une symétrie C_2. Une discussion détaillée de l'effet de la hauteur de la barrière pseudo-rotationnelle et de la température sur les couplages, indique que les valeurs minima de l'énergie potentielle correspondent à ces conformations.

[Traduit par le journal]

Introduction



The ^{1}H nmr spectra of five-membered saturated rings of the type $(CH_2)_4X$, (X = O, S, Se, etc.), are being analysed by us (1, 2) with the aim of obtaining precise values of the proton–proton coupling constants to study the conformational behaviour in solution of these molecules. The spectra of tetrahydrofuran (THF, X = O) (1) and tetrahydroselenophene (THS, X = Se) (2) have been analysed by using a computer program written to carry out efficiently the spectral analysis for the $(AB)_4$ spin systems with C_{2v} symmetry (1). In this paper we report the complete analysis of the spectrum of tetrahydrothiophene (THT, X = S) which presents special difficulties arising from the small effect on the spectrum profile of the coupling differences ^2D, $^3D_{AB}$, and $^4D_{AB}$, as well as of the sign of ^4D_A, (the adopted notation is illustrated in the chart). A detailed study of the spectral dependence on these parameters has made possible a reliable determination of their values from spectra with optimum resolution. Some of our results differ from those obtained by Lozach *et al.* (3) who carried out a similar analysis in which these requirements were not so extensively satisfied. The values of the vicinal couplings for THT were first reported by Lambert *et al.* (4). The values for $^3J_B^c$ and $^3J_B^t$ were determined from the analysis of the ^{13}C satellites of THT-2,2′,5,5′-d_4 and those of $^3J_{AB}^c$ and $^3J_{AB}^t$ from the analysis of the proton spectrum of THT-2,2′,3,3′-d_4. These spectra were obtained with deuterium decoupling and the influence on the latter of $^3D_{AB}$ is so small that precise values for $^3J_{AB}^c$ and $^3J_{AB}^t$ cannot be determined from it.

The interpretation of the couplings of THF and THS in CS_2 solution could be satisfactorily made assuming the same conformational behaviour found in vapour phase studies, i.e., approximately free pseudorotation for THF (1) and fast inversion

$$^2J_A = J_{AA'} \qquad ^2J_B = J_{BB'}$$

$$^2S = {}^2J_A + {}^2J_B \qquad ^2D = {}^2J_A - {}^2J_B$$

$$^3J^c_{AB} = J_{AB} \qquad ^4J^c_A = J_{AA'''}$$

$$^3J^t_{AB} = J_{AB'} \qquad ^4J^t_A = J_{AA''}$$

$$^3J^c_B = J_{BB'''} \qquad ^4J^c_{AB} = J_{AB'''}$$

$$^3J^t_B = J_{BB''} \qquad ^4J^t_{AB} = J_{AB''}$$

$$^nS_M = {}^nJ^c_M + {}^nJ^t_M \qquad n = 3, 4$$

$$^nD_M = {}^nJ^c_M - {}^nJ^t_M \qquad M = A, B, AB$$

between the two stable half-chair conformations with C_2 molecular symmetry for THS (2). For THT the far ir spectrum has been interpreted (5) in terms of a model of hindered pseudorotation with a potential barrier of 773 cm^{-1} separating two stable half-chair conformations. Likewise, the experimental electron diffraction data (6) were found to be in good agreement with the theoretical results obtained by assuming C_2 molecular symmetry. A detailed study of the dependence of couplings on the height of the barrier to pseudorotation and on the temperature confirm that, as for THF and THS, the conformational behaviour of THT in CS_2 solution is very similar to that in the vapour phase.

Spectral Analysis

The proton spectrum of THT was obtained on a Varian XL-100 spectrometer. The sample used, a solution of THT in CS_2 with TMS as an internal reference (molar fractions, $\chi_{THT} = 0.12$, $\chi_{TMS} = 0.08$ and $\chi_{CS_2} = 0.80$) was degassed by the freezing and thawing technique and sealed under vacuum. Sweep widths of 0.5 Hz cm^{-1} and sweep rates of 0.005 Hz s^{-1} were employed. Radiofrequency of low power (40 dB) was applied to avoid saturation. Under these experimental conditions the half-height line width was of 0.09 Hz. Peak frequencies were determined to $\pm$ 0.01 Hz by linear interpolation between readings from a frequency counter.

The analysis of the THT spectrum was carried out following the same steps as in the analysis of the similar THS spectrum (2) but particular difficulties arose because of the small effect on the THT spectrum of the coupling differences ^2D, $^3D_{AB}$, and $^4D_{AB}$, as well as of the sign of ^4D_A. In the first step, accurate values of the parameters $^3S_{AB}$, $^4S_{AB}$, ^3S_B, ^3D_B, ^4S_A, and ^4D_A were obtained from a fit of the line frequencies that depend only on these parameters. The spectrum calculated with these values and by taking $^2D = {}^3D_{AB} = {}^4D_{AB} = 0$ Hz and $^2S = -22$ Hz barely differs from the experimental spectrum, as can be seen in Fig. 1 where both spectra are shown for the high field signal zone. In the second step the values of ^2D, $^3D_{AB}$, and $^4D_{AB}$ were modified stepwise to correct these small differences in order to get a calculated spectrum as close as possible to the observed one, which allowed us to perform a reliable spectral assignment. Spectra were computed assuming that $^3D_B < 0$, $^4D_{AB} > 0$, and $^4D_A < 0$. The two first assumptions can be made to fit the experimental spectrum because, as has been discussed in ref. 1, there are several sets of couplings yielding an identical spectrum. The sign of ^4D_A was taken as negative, $^4D_A = -0.57$ Hz, by comparison with the value $^4D_A = -0.44$ Hz of THS, but the possibility of the positive sign for ^4D_A was also examined and is described below. In the third step, after accomplishing a satisfactory agreement between the experimental and the calculated spectra, an iterative refinement of the magnetic parameters was carried out from an assignment of 430 transitions out of 620 calculated transitions with an intensity greater than 0.05. The influence of ^2S on the spectrum is so small that one of the two couplings ^2J was kept constant in the iterative process, $^2J_B = -12.6$ Hz, since otherwise the problem would have remained undetermined. The first columns in Table 1 give the iterated magnetic parameter values, Set 1, together with their standard errors. The average deviation between observed and calculated line frequencies was 0.0153 Hz. An excellent agreement was obtained between the experimental spectrum and the simulated calculated spectrum as can be seen in Fig. 1, where both spectra appear for the high field signal zone, and in Fig. 2, where they appear for five signal zones selected from those where the effect of the ^2D, $^3D_{AB}$, and $^4D_{AB}$ parameters, and that of the ^4D_A sign, are more relevant.

Errors in the couplings and "vector errors" show similar features as in THF and THS (1, 2) except for the couplings ^2J. Since the ^2J_B coupling was kept constant in the iterative process the vector error ($\sim 0.7\ ^2S$) does not appear. This, in the case of THF and THS, has the largest error. The errors of the vector errors ($\sim 0.7\ ^3D_{AB}$), 0.022; ($\sim 0.7\ ^4D_{AB}$), 0.015; and ($\sim {}^2J_A$), 0.009 Hz, are the largest ones owing to the fact that the spectrum barely depends on the $^3D_{AB}$, $^4D_{AB}$, and ^2D parame-

ters. Correspondingly, the couplings $^3J_{AB}$, $^4J_{AB}$, and ^2J_A present the largest errors amongst all couplings and the greatest correlation coefficients appear between the couplings $^3J_{AB}$, −0.99, and $^4J_{AB}$, −0.95. The actual errors of the parameters must be larger than those resulting from the fitting and can be estimated, from the effect of the parameters on the spectrum, to be ± 0.02 Hz for the couplings ^4J_A and ^3J_B and for the combinations $^3S_{AB}$ and $^4S_{AB}$, and ±0.05, ±0.1, and ±0.2 Hz for the differences ^2D, $^4D_{AB}$, and $^3D_{AB}$, respectively.

The interchange of the couplings $^4J_A^c$ and $^4J_A^t$, i.e. the change in the sign of ^4D_A, does not alter the spectrum if $^2D = {}^3D_{AB} = {}^4D_{AB} = 0$ Hz. Although the effect of these differences on the THS spectrum is small, the change in sign of ^4D_A sufficiently alters the spectrum so as to make possible its determination. When the values of the couplings $^4J_A^c$ and $^4J_A^t$ of Set 1 are interchanged most of the calculated lines are shifted less than 0.01 Hz. In the high field signal zone only one of each ten lines is shifted more than 0.01 Hz, without exceeding 0.02 Hz, whilst in the low field signal zone two of each ten lines are shifted more than 0.01 Hz, some of them reaching 0.033 Hz. From this calculated spectrum an assignment was made, including the same lines as in the previous one, and an iterative refinement of the magnetic parameter values was carried out. The interated parameter values, Set 2 in Table 1, practically do not differ from those of Set 1, except for the interchange of the couplings $^4J_A^c$ and $^4J_A^t$, and their standard errors are only slightly greater than those of Set 1. The average deviation between observed and calculated line freqencies, 0.0170 Hz, was only 0.0017 Hz greater than for Set 1. However, the agreement between the experimental spectrum and the simulated calculated spectrum is not as good as that obtained with Set 1 (see Fig. 2). This is mainly appreciated in zones where two very close lines are shifted in opposite directions by the change in the sign of ^4D_A. Such is the case for the two lines with experimental frequencies 265.25 and 265.32 Hz, whose calculated frequencies (intensities) are 265.25 (0.6) and 265.32 (1.0) Hz for Set 1 but 265.27 (0.6) and 265.29 (1.0) Hz for Set 2. On the other hand, the band with experimental frequency 265.99 Hz has three transitions assigned, those for Set 1 are spread over only 0.028 Hz, whilst for Set 2 they are spread over 0.076 Hz. Both situations, calculated lines too close or too separated, appear also in a few other signal zones making it evident that the sign of ^4D_A cannot be positive.

According to the small effect of the ^2D parameter on the THT spectrum the absolute values of the partial derivatives of the transition frequencies with respect to ^2D, $|\delta\nu_{k1}/\delta^2D|$, do not exceed 0.05 with the exception of about 30 weak lines, with intensities between 0.05 and 0.25, where these derivatives are close to 1.0. Most of these weak lines are obscured by others in their vicinity with a larger intensity but there are a few that can be picked out in the experimental spectrum. Such is the case for the four asterisked lines in Figs. $2c_1$ and $2d_1$ that can be used to test the reliability of the calculated values of ^2D, $^4D_{AB}$, and $^3D_{AB}$ as well as the sign of ^4D_A, since these lines are much more affected than their neighbours by changes in these parameters. As can be seen in Fig. $2c_3$, the reversing of the sign of ^4D_A causes the calculated ratio between the intensities of the bands at 198.16 and 198.28 Hz to be remarkably greater than the experimental ratio. When ^2D is changed by a given amount the asterisked lines are shifted approximately the same amount whilst the neighbouring lines remain practically un-

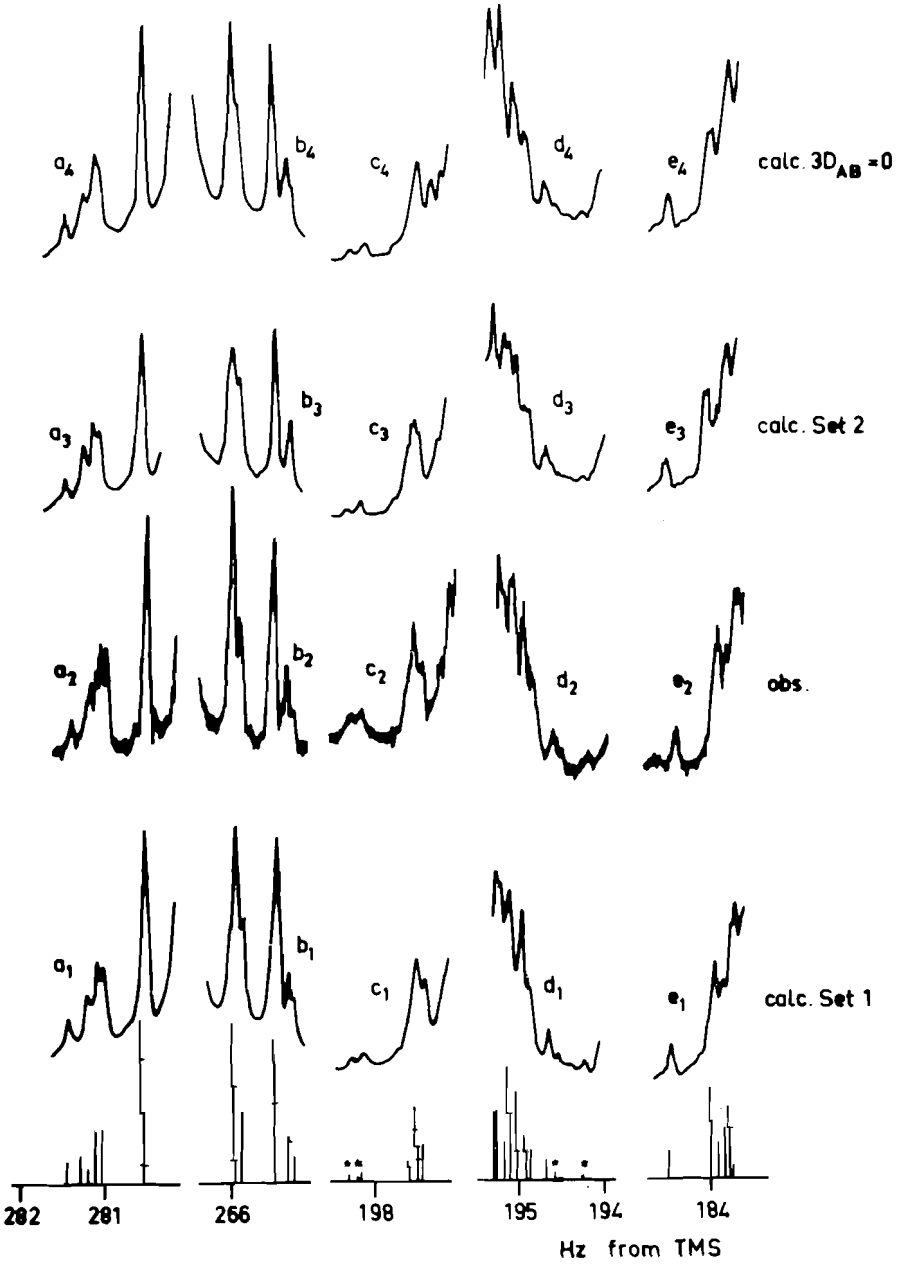

FIG. 2. THT spectrum for five signal zones selected from those where the effect of the ^2D, $^3D_{AB}$, and $^4D_{AB}$ differences, and that of the ^4D_A sign, are more relevant. From bottom to top appears the spectrum calculated with the Set 1 values, the observed spectrum, the spectrum calculated with the Set 2 values, and the spectrum calculated by taking $^3D_{AB} = 0$ Hz.

changed. When $^4D_{AB}$ is changed by a small amount, the asterisked lines are only shifted approximately a quarter of this amount but their intensities are also influenced, reducing to a half if $^4D_{AB}$ is decreased by 0.2 Hz and to zero if $^4D_{AB} = 0$ Hz. The effect of changing $^3D_{AB}$ is even less than for $^4D_{AB}$, and practically only affects the two outer lines. When $^3D_{AB}$ is changed by a small amount these two lines are shifted only approximately a tenth part of this amount. For $^3D_{AB} = 0$ they are shifted 0.05 Hz and these small shifts cause the two bands with experimental frequencies 198.16 and 198.28 Hz to appear too separated, 0.20 Hz, in the calculated spectrum, as can be seen in Fig. $2c_4$. Other disagreements between the experimental and the calculated spectra are due to shifts smaller than 0.03 Hz of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

lines whose frequencies practically do not depend on ^2D. So the shoulder at 265.89 Hz, of the band at 265.99 Hz, does not clearly appear in Fig. $2b_4$ because the line assigned to the shoulder is shifted 0.01 Hz closer to the three lines assigned to the band. When the sign of $^3D_{AB}$ is reversed, the differences between the experimental and the calculated profiles are more evident, but if an iterative process is carried out using the resulting parameters as initial values, the sign of $^3D_{AB}$ is restored and the final values of the parameters are those of Set 1.

Discussion

The two sets of couplings resulting from our analysis of the ^{1}Hmr spectrum of THT with signs for the ^4D_A difference negative, Set 1, and positive, Set 2, are listed in Table 1 together with those reported by Lozach *et al.* (3), Set 3, and by Lambert *et al.* (4), Set 4. As discussed in the previous section, the choice of Set 1 as the correct solution, instead of Set 2, is unquestionable in spite of the small effect of the sign of ^4D_A on the THT spectrum. The actual errors of the $^3J_{AB}$, $^4J_{AB}$, and ^2D parameters are larger than those in the remaining couplings due to the small influence of $^3D_{AB}$, $^4D_{AB}$, and ^2D on the spectrum. Errors in the individual couplings, $^3J_{AB}$ and $^4J_{AB}$, arise mainly from the error involved in their differences, $^3D_{AB}$ and $^4D_{AB}$, as the error in their combinations $^3S_{AB}$ and $^4S_{AB}$ is only 0.02 Hz.

In Set 3, of Lozach *et al.*, the sign of ^4D_A is incorrect and therefore the couplings $^4J^c_A$ and $^4J^t_A$ are interchanged. With regard to the rest of the couplings the differences between the values of Sets 3 and 1 do not exceed ± 0.05 Hz except those of ^2D, $^3J^c_{AB}$, and $^3J^t_{AB}$, which are around ± 0.3 Hz. The differences between our $^3J_{AB}$ values and theirs arise mainly from the difference of -0.58 Hz in the $^3D_{AB}$ values, since the $^3S_{AB}$ values are closer (difference 0.07 Hz). The errors of the $^3J_{AB}$, $^4J_{AB}$, and ^2D parameters are larger in Set 3 than in Set 1 owing probably to the fact that the spectral resolution attained by Lozach *et al.*, for net THT, is not so good as that in this work, for a solution of THT in CS_2. The difference of resolution is evident by comparison of Fig. 1 with Fig. 2 of ref. 3. A very good spectral resolution is indispensable to obtain accurate values of these parameters owing to the small influence of the $^3D_{AB}$, $^4D_{AB}$, and ^2D differences over the THT spectrum.

Remarks similar to the aforementioned for the vicinal coupling values of Set 3 can be made for those of Set 4, of Lambert *et al.* The difference $^3D_{AB}$ of Set 4, equal to 0.00 Hz, is closer to the value of -0.15 Hz of Set 3 than to the value of 0.43 Hz of Set 1. Notwithstanding, we consider that our value is the most reliable. The $^3J_{AB}$ values of Set 4 were determined from the analysis of the proton spectrum of THT-2,2′,3,3′-d_4 obtained with deuterium decoupling. This spectrum corresponds to a spin system $[AB]_2$ and the influence on it of $^3D_{AB}$ is so small that this parameter can only be accurately determined from spectra with a resolution much better than that shown in the spectra reported in ref. 4.

As discussed in ref. 1, by carrying out certain concerted coupling interchanges from Set 1, 23 other parameter sets are obtained that yield an identical fit of the experimental spectrum. The final decision on selecting the physically meaningful set should be based upon a consideration of the relative magnitudes of $^3J^c_B$ and $^3J^t_B$, as well as $^4J^c_{AB}$ and $^4J^t_{AB}$ (or $^3J^c_{AB}$ and $^3J^t_{AB}$). These can be estimated from relations between coupling constants and conformational geometric parameters.

In the calculation of the ^3J_B, $^3J_{AB}$, and $^4J_{AB}$ couplings it was assumed that, as it seems to occur for the THF and THS molecules (1, 2), the conformational behaviour of the THT molecule in CS_2 solution is the same as in the vapour phase, i.e., a fast inversion between two puckered conformations with C_2 symmetry (5, 6). The vicinal ^3J couplings were calculated by using the Karplus equation with the coefficients given by Pachler and Wessels for ethane (7), where θ is the dihedral angle

$$[1] \quad {}^3J = 8.0 - 1.0\cos\theta + 6.0\cos 2\theta$$

H—C—C—H. The long-range ^4J couplings across a H—C—C—C—H′ path depend mainly on the dihedral angles ϕ, H—C—C—C, and ϕ', C—C—C—H′ and were calculated by using the INDO-FPT method (8) applied to propane with standard geometries. The dihedral angles were estimated from the electron diffraction values (6) of the intracyclic torsion angles S—C—C—C, $\psi_{AB} = \pm 40.4°$, and C—C—C—C, $\psi_B = \mp 52.5°$, assuming tetrahedral values for the bond angles; $\theta = \psi$ for $^3J^c$, $\theta = \psi - 120°$ for $^3J^t$, $(\phi, \phi') = (120° - \psi_B, 120° + \psi_{AB})$ for $^4J^c_{AB''}$, and $(\phi, \phi') = (120° - \psi_B, 240° + \psi_{AB})$ for $^4J^t_{A'B''}$ (angles ϕ and ϕ' are measured in the same sense from the C—C—C plane (9) and the unprimed H is in position B″).

The calculated coupling values, given in column 1 of Table 2, substantiate that $^3J^c_B < {}^3J^t_B$ and $^4J^c_{AB} > {}^4J^t_{AB}$ (and also, $^3J^c_{AB} > {}^3J^t_{AB}$), supporting the choice of Set 1, Table 1, as the most physically meaningful amongst the 24 parameter sets that yield an identical fit of the experimental spectrum. However, to confirm this selection, two points should be discussed in detail, the reliability of the J values given

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

by eq. [1] and by the INDO-FPT method, and the fact that the THT molecule in CS_2 solution has the same conformational behaviour as in the vapour phase.

The calculated vicinal coupling values are greater than the experimental ones (as in the case for THF (1) and THS (2)), owing to the use of an empirical Karplus equation for ethane without further corrections for the effects of bond angle changes and for the relative orientation of substituents. The latter effect is thought to be small, since it depends on the substituent electronegativity (10) and this one is very similar for the —S— and CH_3— groups. Corrections to the ^3J couplings, calculated from data in Table 3 of ref. 10 taking the effects of the —CH_2— and —S— groups equal to the effect of the —CH_3 group, are within −0.2 and −0.5 Hz. The effects of bond angle changes can be more important in this case, but their estimation (11) necessitates the knowledge of the values of the bond angles HCC and CCH′ which have not been measured with the required accuracy. Taking all this into consideration, the correlation between calculated and experimental ^3J couplings can be judged as satisfactory. The conclusion that $^3J^c_B < {}^3J^t_B$ can be safely established from the calculated ^3D_B value of −3.3 Hz, but the conclusion that $^3J^c_{AB} > {}^3J^t_{AB}$ has a limited significance because the values of the $^3J_{AB}$ couplings are very close. The second conclusion is not necessary for choosing Set 1. This choice can likewise be based on the firmer $^4J^c_{AB} > {}^4J^t_{AB}$ conclusion.

The $^4J_{AB}$ values calculated by the INDO-FPT method are in acceptable agreement with the experimental ones. According to Barfield *et al.* (9) the INDO-FPT method, as well as the sum of the EHMO and VB-SOT results, reproduces the experimental trends of the ^4J couplings: (*i*) couplings between equatorial protons ($\phi = \phi' = 180°$) are in the range +1 to +2 Hz, (*ii*) couplings between axial and equatorial protons ($\phi = 60°$, $\phi' = 180°$) are in the range 0.4 to 0.8 Hz and are probably negative in sign, and (*iii*) couplings between axial protons ($\phi = \phi' = 60°$) are in the range −0.3 to −0.9 Hz. The $^4J_{AB}$ values calculated from the sum of the EHMO and VB-SOT results (using the values in the last column of Table II of ref. 9), are $^4J^c_{AB} = 0.4$ Hz and $^4J^t_{AB} = 0.0$ Hz. Although these values are more positive than the experimental ones, they support, as do those calculated by the INDO-FPT method, the conclusion that $^4J^c_{AB} > {}^4J^t_{AB}$. This conclusion is in agreement with the aforementioned experimental trends of the ^4J couplings. In effect, the $^4J^c_{AB}$ coupling occurs, half the time, between near equatorial protons ("W" arrangement) and half between near axial protons. The average of both contributions must be positive. For the $^4J^t_{AB}$ coupling one contribution is probably negative, coupling between near axial–equatorial protons, and the other corresponds to a coupling path that differs from the "W" arrangement. Therefore, a smaller value for $^4J^t_{AB}$ than for $^4J^c_{AB}$ is reasonably expected.

The assumption that the THT molecule in solution has the same conformational behaviour as in the vapour phase, has been checked by comparison of the experimental J values with the calculated ones for different potential barriers to pseudorotation and, also, by analysing the dependence on temperature of the ^3J_B couplings. These studies require the simulation of the puckered conformations from the (q_0, ϕ) pseudorotational coordinates and the determination of the respective populations from the energy levels and wave-functions of the Hamiltonian for hindered pseudorotation (Case 3, formula 12 of ref. 12),

$$[2]\quad H(\phi) = BP_\phi^2 + (1/2)V_2(1 - \cos 2\phi) + (1/2)V_4(1 - \cos 4\phi) \ldots$$

The wave equation was solved by using the method described in ref. 13. Puckered conformations were generated by using the B_1 ring-puckering geometrical model that will be described elsewhere (14). The value taken for puckering amplitude, $q_0 = 0.474$ Å, was obtained by application of the Cremer and Pople method (15) to the electron diffraction molecular geometry of THT (6).

Calculated coupling constants of THT for different values of the two- and fourfold barriers to pseudorotation, V_2 and V_4, are given in Table 2. When V_2 increases, taking $V_4 = V_6 = 0$, (in fact, in the vapour phase the determined values of V_4 and V_6 are small (16) for $(CH_2)_4X$ molecules), the conformational behaviour changes from fast inversion between two puckered conformations with C_2 symmetry, $V_2 = -\infty$, to free pseudorotation, $V_2 = 0$, and to fast inversion between two puckered conformations with C_s symmetry, $V_2 = \infty$. The respective calculated values of ^3J, columns 1 to 3 of Table 2, increase for $^3J^c$ and decrease for $^4J^t$. Consequently, the value of $^3D_{AB}$ increases from 0.3 Hz for $V_2 = -\infty$, to 1.7 Hz for $V_2 = 0$, and to 3.8 Hz for $V_2 = \infty$. The experimental value $^3D_{AB} = 0.4$ Hz is close to the first one, corroborating that the preferred conformations are those with C_2 symmetry. The calculated value for free pseudorotation is larger than the experimental one and, in fact, for

TABLE 2. Calculated coupling constants[a] (J, Hz) of THT at 313 K for different values of the two- and fourfold barriers to pseudorotation[b] (V_2 and V_4, cm^{-1}). The Δ^3J values are the differences between the ^3J values at 365 K and at 215 K

[a]The ^3J and ^4J couplings were calculated respectively by the empirical Karplus eq. [1] and by the INDO-FPT method.
[b]Parameter B in [2] was considered equal to 2.35 cm^{-1} (5).
[c]V_2 and V_4 taken from ref. 5 and $\Delta^3J_B^c$ and $\Delta^3J_B^t$ from ref. 4.

molecules undergoing almost free pseudorotation, larger values of ^3D have been observed: ^3D = 1.9 Hz in cyclopentane (17) and $^3D_{AB}$ = 1.5 Hz, ^3D_B = 2.7 Hz in THF (1).

The temperature dependence of the ^3J_B couplings of THT in $CHCl_3$ solution has been observed by Lambert *et al.* (4). They found the following differences between the ^3J_B values at 365 K and at 215 K: $\Delta^3J_B^c$ = 0.60 Hz and $\Delta^3J_B^t$ = −0.10 Hz. The Δ^3J values, calculated by using the vapour phase barrier to pseudorotation of THT (5), are given in column 4 of Table 2 as well as the coupling values at 313 K. The calculated values $\Delta^3J_B^c$ = 0.57 Hz and $\Delta^3J_B^t$ = −0.29 Hz are in good agreement with the experimental ones, especially the former. In relation with the calculated coupling values, the agreement with the experimental ones is of similar quality as in the case of fast inversion between two puckered conformations with C_2 symmetry (column 1 of Table 2). The agreement is better for ^3D_B but worse for $^3D_{AB}$.

The calculated Δ^3J values depend on the height of the pseudorotational barrier. For $V_2 = -\infty$, C_2 molecular symmetry, and for $V_2 = V_4 = 0$, free pseudorotation, the couplings are independent of the temperature, $\Delta^3J = 0$. When V_2 changes from $-\infty$ to 0, the magnitude of each Δ^3J first increases and then, after reaching a maximum, decreases. The maxima which appear for $V_2 \simeq -550$ and $V_4 = 169$ cm^{-1}, are $\Delta^3J_B^c = 0.74$, $\Delta^3J_B^t = -0.37$, $\Delta^3J_{AB}^c = 0.29$, and $\Delta^3J_{AB}^t = -0.15$ Hz. After the maxima, for $V_2 = -220$ and $V_4 = 169$ cm^{-1}, the Δ^3J values, given in column 5 of Table 2, are very similar to those calculated for the experimental barrier to pseudorotation, given in column 4 of Table 2. However, the calculated ^3D_B and $^3D_{AB}$ values are in better agreement with the experimental ones in the latter than in the former case. Therefore, the barrier to pseudorotation of THT in solution seems to be close to that in the vapour phase. The error of the height of the pseudorotational barrier, −773 cm^{-1}, can be estimated at ±220 cm^{-1} (the calculated values of $^3J_B^c$ and $^3J_B^t$ are respectively 0.74 and −0.39 Hz, for $V_2 = -550$ cm^{-1}, and 0.41 and −0.20 Hz for $V_2 = -990$ cm^{-1}).

In conclusion, the above discussion supports the supposition that THT in CS_2 or $CHCl_3$ solution behaves conformationally as in the vapour phase and the choice of Set 1, Table 1, as the most physically meaningful. These conclusions are open to criticism because of the approximations used: calculation of the J values by an empirical Karplus equation and by the INDO-FPT method, assumption of a model of hindered pseudorotation, etc. However, the consistency of the results obtained by application of this approach to the $(CH_2)_4X$ molecules (1, 2) confirms its validity.

Oxidation products of arachidonic acid. IV. Model studies on the attachment of the C(13)—C(20) side-chain in the synthesis of tetrahydrofurans and pyrans 1, 2, and 3

GEORGE JUST AND DANILO CROSILLA

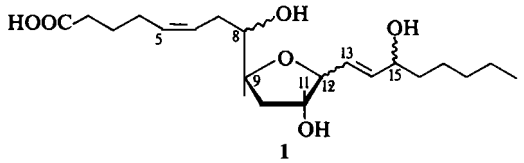
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received April 28, 1980

GEORGE JUST and DANILO CROSILLA. Can. J. Chem. **58**, 2349 (1980).

The synthesis of methyl 15-hydroxy-8(*R*)-methoxy-11(*R*)-*p*-nitrobenzoyloxy-9(*S*),12(*R*)-oxy-eicosa-13-ynoate, an arachidonic acid metabolite derivative, is described. As well, methods for the attachment of the C(13)—C(20) prostaglandin side-chain to furanosides were studied and the results are described. The reduction of the C-15 keto group on a model compound was performed and was found to have the same behavior as in the prostaglandins.

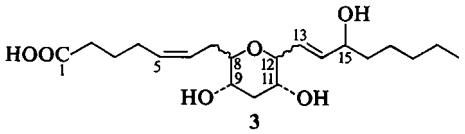
A partial structure proof of Pace-Asciak's compound, 9,12-oxy-8,11,15- trihydroxy-13-enoic acid is given.



GEORGE JUST et DANILO CROSILLA. Can. J. Chem. **58**, 2349 (1980).

On décrit la synthèse de l'hydroxy-15 méthoxy-8(*R*) *p*-nitrobenzoyloxy-11(*R*) oxy-9(*S*), 12(*R*) eicosyne-13 oate de méthyle, un dérivé métabolique de l'acide arachidonique. On a également étudié les méthodes de fixation des carbones en position 13 à 20 de la chaîne latérale de la prostaglandine aux furannosides et on décrit les résultats. On a réalisé la réduction du groupe cétonique en position 15 sur un composé type et on a trouvé qu'il se comporte comme celui des prostaglandines.

On donne une preuve partielle de structure du composé de Pace-Asciak, l'acide oxy-9,12 trihydroxy-8,11,15 ène-13 oique.



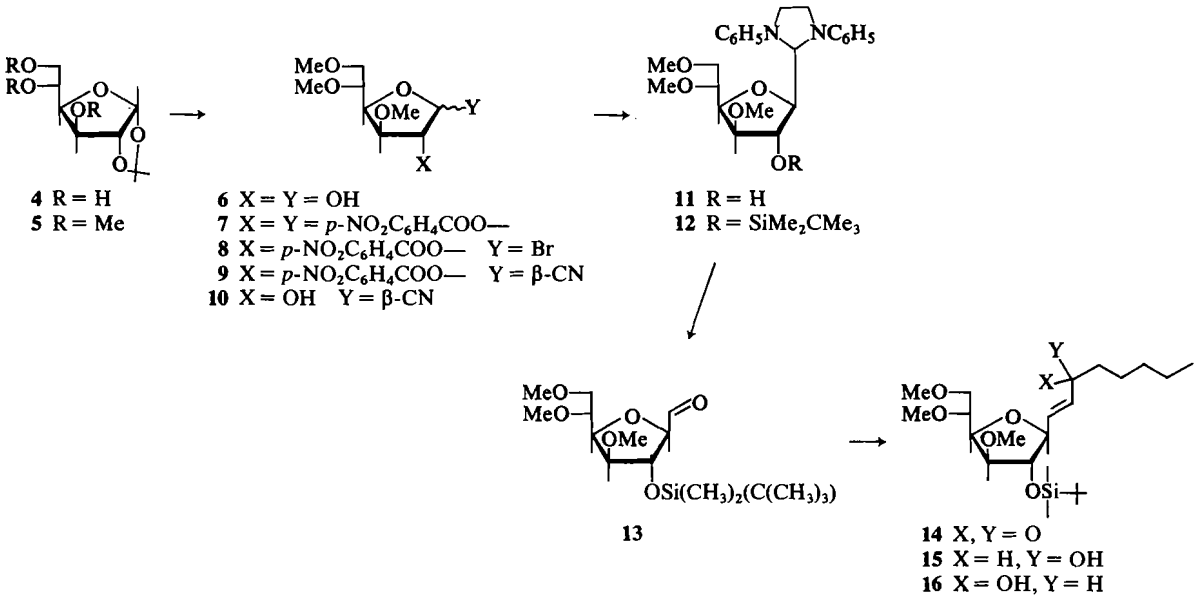
[Traduit par le journal]

In connection with the synthesis of oxidation products of arachidonic acid of type **1**, **2**, and **3**, isolated by Pace-Asciak and Wolfe (1) and Axelrod and co-workers (2), we had to work out procedures for attaching the C(13)—C(20) side-chain to furanose derivatives (for rationale of the choice of stereochemistry of the model compounds, see refs. 1, 3). In this paper, we wish to describe some model studies on this attachment and the synthesis of a derivative of type **1** having an acetylenic bond at Δ^{13}, which strongly supports the structure assigned to **1**.

1

2 5,6-dihydro-**1**

3



As a model, we used 1,2-*O*-isopropylidene-3,5,6-tri-*O*-methyl-α-D-glucofuranose (**5**), which is easily obtained by methylation (4) of the commercially available glucofuranose **4**. Hydrolysis of **5** with hydrochloric acid, followed by acetylation with *p*-nitrobenzoyl chloride in pyridine (5) gave **7** as a mixture of anomers. Treatment with hydrogen bromide in benzene at 0°C (6) transformed **7** to bromides **8**, which, when submitted to the action of mercuric cyanide in nitromethane (6), gave the β-cyanide **9** as one isomer only, as established by nmr which showed the C(1) hydrogen as a broad singlet ($J_{1,2} \cong 0$–1) indicating a $H_{1,2}$-dihedral angle of approximately 90°C. Alkaline hydrolysis gave the cyano alcohol **10**, which was reduced with Raney nickel in the presence of diphenylethylene diamine (7, 8) to the imidazoline **11**. It was protected as its *tert*-butyldimethylsilyl ether **12** (9). Hydrolysis of the nitrogen heterocycle with Dowex H^+ resin (7, 10) gave the aldehyde **13**, still having the same stereochemistry at the "anomeric center", since the coupling constant $H_{1,2}$ (glucose numbering) was still close to 0 Hz. Reaction of aldehyde **13** with dimethyl 2-oxoheptylphosphonate (11, 12) gave the α,β-unsaturated ketone **14**, which was reduced with sodium borohydride to a 1:1 mixture of diastereomeric alcohols (13) **15** and **16**. The less polar isomer was obtained pure by flash chromatography (14). Reduction of ketone **14** with L-Selectride (15) gave predominantly (85:15) the more polar isomer. No attempt was made to establish the configuration at C(15).

We next proceeded to apply this method to the molecule which had the proper functionalities for obtaining the desired arachidonic acid metabolite **2**. Acetylenic furanose **17** (3) was hydrogenated in ethyl acetate at 40 psi with platinum oxide to afford the saturated compound **18**. The isopropylidene group in compound **18** was hydrolyzed in an acetic acid – water mixture at 60°C to give the hemi-acetal **19** as a mixture of C-12 isomers. This diol was acylated with *p*-nitrobenzoyl chloride and pyridine

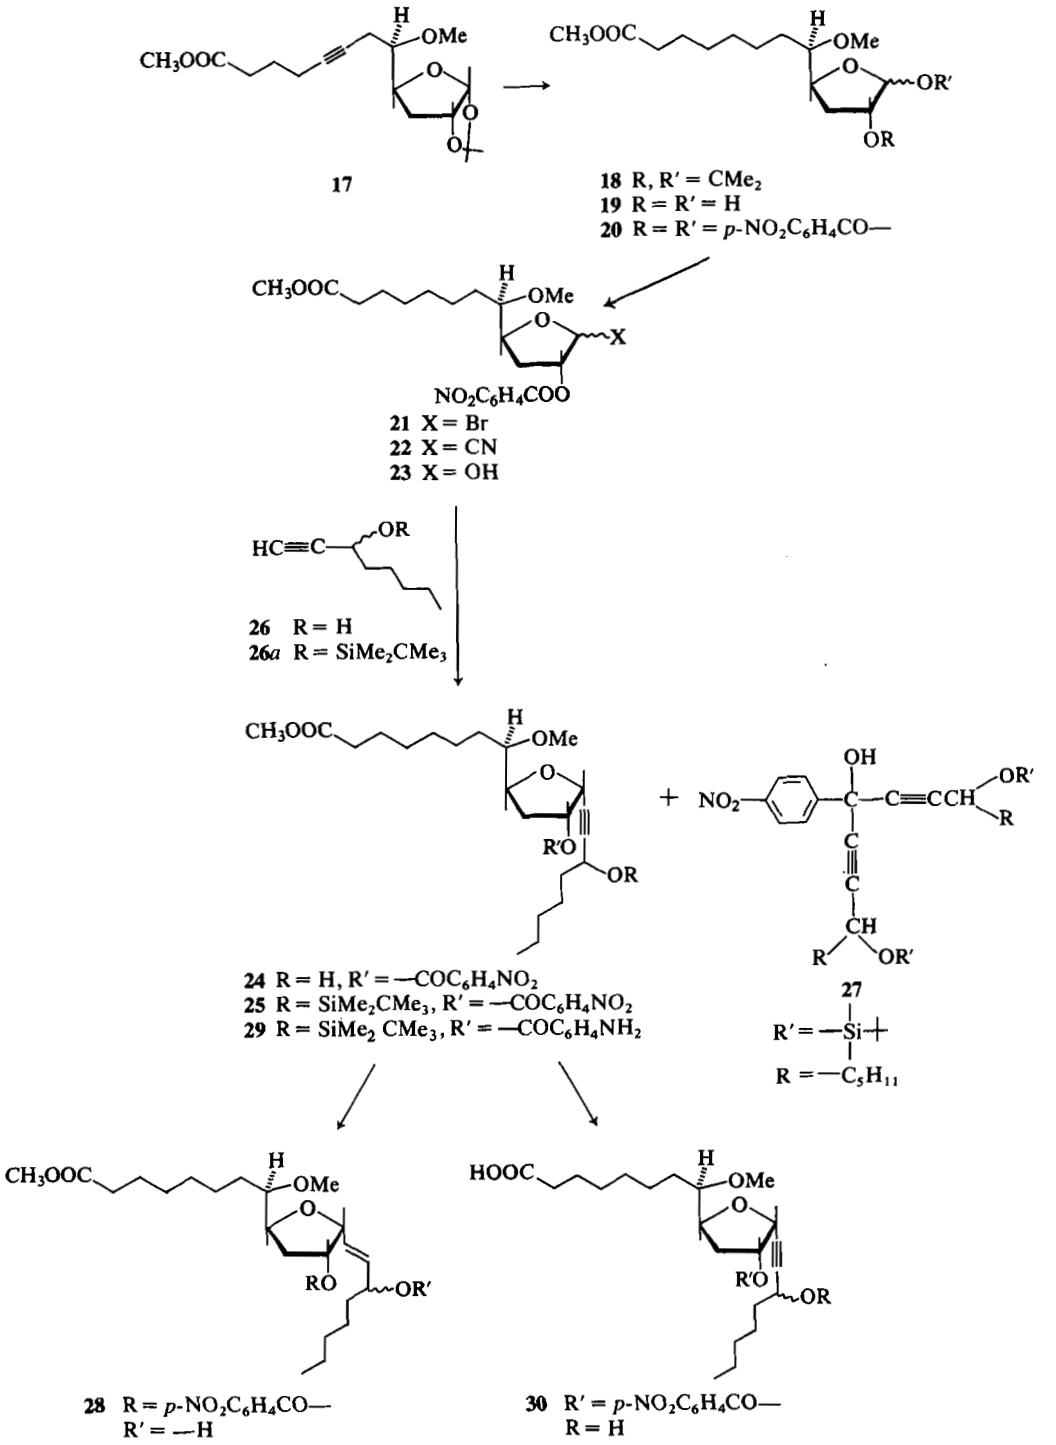
to afford the di-*p*-nitrobenzoate **20** as a mixture of C-12 isomers. Treatment of the di-*p*-nitrobenzoate with hydrogen bromide, followed by mercuric cyanide in the same manner as was done for compound **7**, afforded the cyano compound **22** as a mixture of (*R*) and (*S*) C-12 isomers. All the spectral data obtained for this compound were consistent with the proposed structure.

The next step in the synthesis would have been the hydrolysis of the *p*-nitrobenzoate function. However, all attempts to do so resulted in failures, and no clean hydrolysis product could be obtained. It is obvious that different protecting groups, which do not interfere in the reduction of the cyano function and would therefore obviate the hydrolysis step, will have to be used for successful completion of the sequence.



The second approach consisted in trying to add an appropriately substituted acetylenic anion to glycosyl bromide **21**, based on analogous work described by Buchanan *et al.* (16).

Oct-1-yn-3-ol (**26**) was converted to its *tert*-butyldimethylsilyl ether **26***a*, and its lithium salt reacted with glycosyl bromide **21** in dry tetrahydrofuran–hexamethylphosphoramide at −78°C. Four compounds were isolated from the reaction mixture by preparative tlc: (1) tertiary carbinol **27** (R_f 0.91) which arose by reaction of the acetylenic anion with a *p*-nitrobenzoate ester; (2) hemi-acetal **23** (R_f 0.18) which is the product of the reaction of **21** with water; (3) acetylenic silyl ether **25** (R_f 0.75); (4) acetylenic silyl ether **25** (R_f 0.60).

The compounds having R_f values of 0.75 and 0.60 were found to be the desired adducts epimeric at C-15. The stereochemistry at C-12 was assigned, based on the coupling constant between the C-12 and C-11 protons. The ^{1}Hmr spectrum of compound **25**, which has a R_f value of 0.75 and was the major component, displayed singlets at 0.20 ppm for the methyl groups on silicon, at 3.40 ppm for the methyl ether, at 3.60 ppm for the methyl ester, a multiplet between 4.80 and 5.10 ppm for the proton on C-11, a doublet at 6.00 ppm with a coupling constant of $J_{11,12}$ = 4 Hz, and a quartet at 8.00 ppm for the aromatic protons. Because of the large coupling constant between the C-11 and C-12 hydrogens an (*R*) stereochemistry was assigned to the C-12 carbon. The infrared spectrum had a carbonyl absorption at 1740 cm^{-1}, an aromatic absorption at 1610 cm^{-1}, and a nitro absorption at 1530 cm^{-1}. The spectral data for the compound having a R_f value of 0.60 were only slightly different from those of the above compound (having a R_f value of 0.75). The ^{1}Hmr spectrum of this isomer also had a coupling constant of 4 Hz for the hydrogens on C-11 and C-12. Because of the great similarity between their spectral data, the stereochemistry at C-15 could not be assigned to the two isomers.

Hydrolysis of either epimer **25** with 80% aqueous acetic acid at 80°C for 3 hours gave either epimer of **24**. All attempts to reduce either isomer of **24** to the corresponding olefin **28** by means of chromous sulfate (17, 18) or nickel boride (19, 20) failed, and resulted either in reduction of the nitro group of the benzoate function to give **29**, or the formation of mixtures from which no major fraction could be isolated. Attempts to hydrolyse the *p*-nitrobenzoate also failed, resulting either in the hydrolysis of the methyl ester function to the carboxylic acid **30**, or the formation of mixtures.

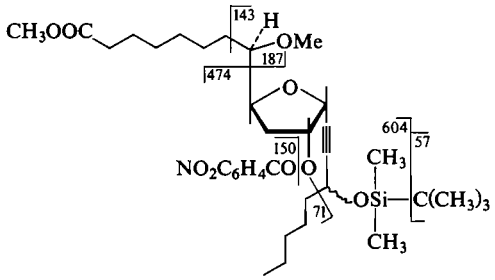
*Mass Spectral Comparisons of 15/16, 25, and 2*a

Comparison of **25** with the methylated and silylated natural product **2***a* reveals that the only basic difference is that there is a $\Delta^{13,14}$ acetylenic bond in **25** instead of an olefinic bond. Since compound **25** is a mixture and differs only in the chirality of the C-15 carbon, and since they have almost identical mass spectra, only one of them, that with R_f 0.75, will be discussed.



Examination of the mass spectrum of Pace-Asciak's compound **2***a* reveals that the C(1)—C(8) side-chain cleaves between C-7 and C-8 giving a

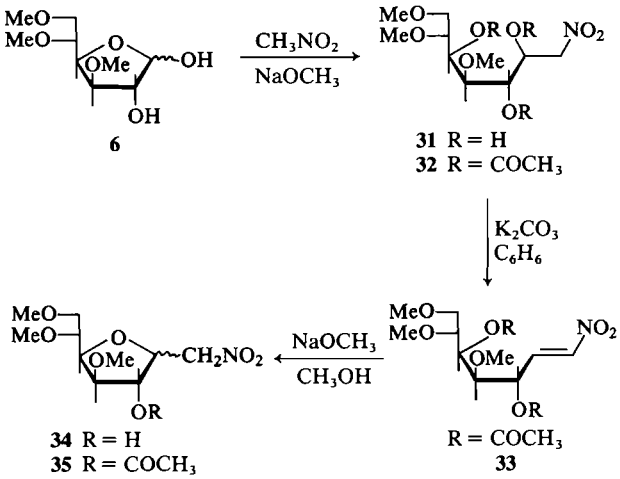
2*a*

fragment of mass 143 *m/e* having a small relative intensity. Examination of the mass spectrum of compound **25** (R_f 0.75), shown below, also displays the analogous fragment with a relative intensity of 4.8%. The base peak of compound **2***a* is the result of the fragmentation between C-8 and C-9, which corresponds exactly to the base peak of compound **25**. As well, both mass spectra display high intensities of a fragment of mass 71 *m/e* corresponding to the C_5H_{11} ion.

25

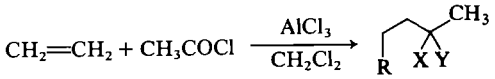


Comparison of the mass spectrum of a mixture of compounds **15** and **16** with the mass spectrum of compound **2***a* reveals that the fragment having a mass of 71 *m/e*, corresponding to C_5H_{11}, is very predominant in both. Cleavage between C-14 and C-15 in **2***a*, giving a fragment having a mass of 173 *m/e*, is also evident. Compounds **15** and **16** do not have a silyl ether at this position, but do cleave in the same manner giving a fragment with a mass of 101 *m/e*. A third fragment of Pace-Asciak's compound had a mass of 199 *m/e* corresponding to the cleavage between C-12 and C-13. The exact cleavage is observed in compounds **15** and **16** as shown below:

15, 16

From these brief comparisons, some evidence can be found in support of the structure **2***a* proposed by Pace-Asciak and Wolfe.

A third approach which was studied consisted of attaching a nitro alkane to a furanose, followed by dehydration and cyclization, as outlined (**6** → **31** → **32** → **33** → **34**). Reaction of furanose **6** with nitromethane gave nitrosugar **31** (21). Acetylation of **31** could only be carried out using acidic conditions, giving the unstable triacetate **32**, which spontaneously decomposed to give a 1:1 mixture of **32** and **33**



6

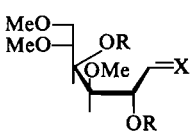
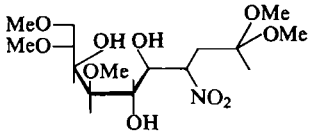
34 R = H
35 R = $COCH_3$

R = $COCH_3$
33



during work-up. When the mixture of **32** and **33** was treated with potassium carbonate (22) in benzene at 20°C for 6 h, an 82% yield of nitroolefin **33** was isolated. Cyclization with methanolic sodium methoxide gave what appeared to be furanose **34**. Acetylation provided acetate **35**. The structures of **34** and **35** were established by nmr only, but gave us confidence to proceed with a more elaborate nitroalkane **38**, which was prepared by an adaptation of the sequence described by Bakuzis *et al.* (23). The procedure consisted of treating acetyl chloride with ethylene and aluminum trichloride to give 1-chloro-3-butanone, and hence to the corresponding ketal **38**.



36 R = Cl X, Y = O
37 R = NO_2 X, Y = O
38 R = NO_2 X = Y = OMe

Reaction of **38** with **6** did not give any condensation product, and we therefore converted **6** to the corresponding free aldehyde **41** by first forming the thioacetal **39** (24, 25), converting the resulting diol to the acetonide **40** (26), and hydrolyzing the dithioacetal **40** to the aldehyde **41** (27, 28). Treatment of the aldehyde **41** with nitroalkane **38** and diisopropylamine in dimethylformamide (23), at room temperature for 3 h, afforded the adduct **42**, presumably as a mixture of diastereomers, in good yield.

39 R = H X = $(SEt)_2$
40 R, R = CMe_2, X = $(SEt)_2$
41 R, R = CMe_2, X = O

42

Having established that the addition of a more complex nitroalkane proceeded on the free aldehyde only, this sequence was applied to the synthesis of tetrahydrofuran **1**. This successful approach will be the subject of a separate communication (29).

Experimental

General

Melting points were determined on a Gallenkamp block and are uncorrected. Mass spectra (ms) were obtained on an AE1-MS-902 mass spectrometer or on an LKB-900 mass spectrometer using a direct insertion probe. Infrared (ir) spectra were obtained on Unicam SP1000 and 297 spectrophotometers. Ultraviolet spectra were obtained on a Cary 17 and rotations on a Perkin-Elmer 141 Polarimeter. Proton magnetic resonance (^{1}Hmr) spectra were recorded on Varian T-60, T-60A, and on Brucker FT 90 spectrometers using tetramethylsilane (TMS) as an internal standard. Chemical shifts are given in the δ scale in parts per million. Doublets (d), triplets (t), and quartets (q) were recorded at the center of the peaks, and multiplets (m) as their range of absorption; other abbreviations used: singlet (s) and broad (b). Chemical shifts were described as they appeared, even though they might represent a more complex splitting pattern.

Analytical thin-layer chromatography (tlc) was performed on silica gel-coated plates (Machery Nagel Polygram G or Merck Silica Gel 60) and on a preparative scale on silica gel (Merck HF 254) coated glass plates (20 cm × 20 cm × 1 mm). Merck silica gel 60, Woelm alumina (neutral), and Camag alumina (supplied by Ventron) were used for normal chromatography. Silica Woelm 32-63 was used for flash chromatography.

Solvents were reagent grade unless otherwise specified. All evaporations were done under reduced pressure (water aspirator) with a bath temperature of 25–40°C unless otherwise specified.

Elemental analyses were performed by Midwest Microlab Ltd., Indianapolis, IN.

1,2-O-Isopropylidene-3,5,6-tri-O-methyl-α-D-glucofuranose (5)

Sodium hydride (1.73 g of a 55% oil dispersion, 40 mmol), washed with *n*-pentane and after removal of the residual *n*-pentane, was added to dry dimethyl sulfoxide (18 mL). The resulting mixture was heated to 50°C for 45 min and then added to triol **4** (2.2 g, 10 mmol) in dry dimethyl sulfoxide (50 mL). A gel formed upon stirring for 30 min at 25°C, the viscous solution was cooled to 20°C, and methyl iodide (2.5 mL, 40 mmol) was added slowly. Water (500 mL) was then added, and the product was extracted with ether (3 × 100 mL). The extracts were washed with water (5 × 20 mL), dried ($MgSO_4$), and evaporated to give 2.5 g (95%) of **5**, as an oil; $[\alpha]_D^{22}$ −31.6° (*c* 6,90, chloroform). Infrared (film): ν_{max} 2970, 2920, 2880, 2800, 1370 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (s, 3H, CCH_3), 1.50 (s, 3H, CCH_3), 3.40 (s, 3H, OCH_3), 3.45 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.40–3.90 (m, 4H), 3.90–4.30 (m, 1H), 4.60 (d, $J_{2,1}$ = 4 Hz, 1H, C(2)H), 5.90 (d, $J_{1,2}$ = 4 Hz, 1H, C(1)H) ppm; ms (70 eV) *m/e*: 263 ($M^+ + 1$), 247 ($M^+ - 15$), 173 ($M^+ - CH(OCH_3)(CH_2OCH_3)$), 89, 45.

3,5,6-Tri-O-methyl-D-glucofuranose (6)

Ketal **5** (262 mg, 1 mmol) was heated at 70°C for 1.5 h in 10 mL of 0.5 *N* hydrochloric acid. After cooling and neutralization with sodium carbonate to pH 7.0, water was removed by azeotroping with toluene. The product was dissolved in hot ethyl acetate, filtered, and the solution was dried ($MgSO_4$). Removal of the ethyl acetate afforded 210 mg (95%) of the oily product **6**, as a mixture of anomers; $[\alpha]_D^{22}$ −34.5° (*c* 4.53, chloroform). Infrared (film) ν_{max}: 3400 (hydroxyl), 2960, 2910, 2800 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.40 (s, 3H, OCH_3), 3.45 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.40–4.40 (m, 8H), 5.10 and 5.40 (s and d, 1H, C(1)H) ppm; ms (70 eV, probe temperature (PT) 37°C) *m/e*: 177 ($M^+ - CH_3OCH_2$), 89, 45; (PT 65°C) *m/e*: 204 ($M^+ - 18$), 89.

1,2-Di-O-p-nitrobenzoyl-3,5,6-tri-O-methyl-D-glucofuranose (7)

To the hemi-acetal **6** (444 mg, 2 mmol) in dry pyridine (5 mL) was added the *p*-nitrobenzoyl chloride (1.2 g, 6.5 mmol) in dry pyridine (25 mL) at 0°C under a nitrogen atmosphere. The mixture was stirred for 1 h at 0°C and set aside at −10°C for 2 days. The mixture was then allowed to warm to 20°C and added to a rapidly stirred ice-water mixture (250 mL) and the stirring was continued until all the ice had melted. The product, **7**, a mixture of α- and β-anomers (720 mg, 70%), was filtered, washed with ether, and recrystallized from acetone–water, mp 143–146°C; $[\alpha]_D^{22}$ −20.7° (*c* 4.51, chloroform). Infrared (KBr) ν_{max}; 2980, 2920, 2820, 1740 (carbonyl), 1620 (aromatic), 1540 (nitro) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.55 (s, 3H, OCH_3), 3.60 (s, 3H, OCH_3), 3.70 (s, 3H, OCH_3), 3.40–4.10 (m, 3H), 4.10–4.30 (m, 1H), 4.40–4.70 (m, 1H), 5.70–5.90 (m, 1H, C(2)H), 6.70 and 6.90 (s and d, 1H, $J_{1,2}$ = 4 Hz, C(1)H), 8.10–8.50 (m, 8H, aromatic protons) ppm; ms (70 eV) *m/e*: 475 ($M^+ - CH_2OCH_3$), 150, 89. *Anal.* calcd. for $C_{23}H_{24}N_2O_{12}$: C 53.07, H 4.61, N 5.30; found: C 53.12, H 4.71, N 5.15.

2-O-p-Nitrobenzoyl-3,5,6-tri-O-methyl-β-D-glucofuranosyl Cyanide (9) and 2-O-p-Nitrobenzoyl-3,5,6-tri-O-methyl-D-glucofuranosyl Bromide (8)

A solution of the di-*p*-nitrobenzoate **7** (520 mg, 1 mmol) in dry benzene (4 mL) under a nitrogen atmosphere was saturated at 0°C with gaseous hydrogen bromide in the course of 30 min. The *p*-nitrobenzoic acid was filtered off and washed with more benzene. The benzene was then removed under vacuum (40°C) and the residue coevaporated with more benzene (4 mL). The syrupy material was dissolved in nitromethane (3 mL, dried by distillation over phosphorous pentoxide), and treated with mercuric cyanide (500 mg), predried at 140°C/15 Torr for 3 h. The whole reaction mixture was stirred at room temperature for 20 h under a nitrogen atmosphere. The insoluble portion was filtered off and washed with benzene. The filtrates were combined and evaporated under diminished pressure. The oil was then dissolved in ethyl acetate (5 mL) and washed with 5% potassium iodide solution (2 × 2 mL), water (2 × 2 mL), and dried ($MgSO_4$). Concentration under reduced pressure afforded the crude product **9** as an oil. Purification on an alumina column with a methylene chloride – chloroform (2:1) mixture afforded 204 mg (54%) of **9**, mp 111–113°C (methanol); $[\alpha]_D^{22}$ −46.0° (*c* 0.28, chloroform). Infrared (KBr) ν_{max}: 3000, 2940, 2910, 2830, 1730 (carbonyl), 1610 (aromatic), 1530 (nitro) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.50 (s, 3H, OCH_3), 3.55 (s, 3H, OCH_3), 3.65 (s, 3H, OCH_3), 3.40–4.00 (m, 3H), 4.00–4.50 (m, 2H), 4.90 (s, 1H, C(1)H), 5.70 (s, 1H, C(2)H), 8.20–8.40 (m, 4H, aromatic protons) ppm; ms (70 eV) *m/e*: 336 (($M^+ + 1$) − 45), 335 ($M^+ - CH_2OCH_3$), 150, 89,

45. *Anal.* calcd. for $C_{17}H_{20}O_8N_2$: C 53.68, H 5.26, N 7.36; found: C 52.97, H 5.15, N 7.03.

*3,5,6-Tri-*O*-methyl-*β*-*D*-glucofuranosyl Cyanide (10)*

A solution of *p*-nitrobenzoate **9** (190 mg, 0.5 mmol) in tetrahydrofuran (3 mL) and 0.097 *N* aqueous sodium hydroxide (5.7 mL, 0.55 mmol) was stirred overnight at room temperature. The tetrahydrofuran was evaporated and the product extracted with ethyl acetate (2 × 20 mL). The organic layer was washed with water (1 × 10 mL), 10% sodium bicarbonate solution (1 × 10 mL), and with water (1 × 10 mL) again, then dried ($MgSO_4$). Purification on a silica gel column using chloroform–ether (5:1) as the eluent afforded 102 mg (62%) of pure **10** as an oil; $[\alpha]_D^{22}$ −60.1° (*c* 10.44, chloroform). Infrared (film) ν_{max}: 3400 (hydroxyl), 2990, 2940, 2840 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.35 (s, 3H, OCH_3), 3.40 (s, 3H, OCH_3), 3.45 (s, 3H, OCH_3) 3.30–3.80 (m, 5H), 4.10–4.30 (m, 1H), 4.40–4.60 (m, 2H) ppm; ms (70 eV) *m/e*: 232, 89. *Anal.* calcd. for $C_{10}H_{17}NO_5$: C 51.95, H 7.36, N 6.06; found: C 51.92, H 7.39, N 5.81.

*1,3-Diphenyl-2-(3,5,6-tri-*O*-methyl-*β*-*D*-glucofuranosyl)imidazolidine (11)*

Cyanide **10** (231 mg, 1 mmol) was added to a vigorously stirred suspension of Raney nickel (1.8 g, 3.0 mL) in a solution of sodium hypophosphite (NaH_2PO_2) (943 mg) and *N*,*N*-diphenylethylenediamine (399 mg, 1.88 mmol) in pyridine, acetic acid, and water (2:1:1, 14 mL). The mixture was stirred at room temperature for 1.25 h and then filtered. The residue was extracted with chloroform (2 × 10 mL) and the combined extracts were diluted with chloroform and washed with water (3 × 20 mL), dried ($MgSO_4$), and concentrated to afford **11**. Purification on a silica gel column using ether–hexane (5:1) as the eluent afforded 300 mg (70%) of the pure product **11** as an oil; $[\alpha]_D^{22}$ −29.7° (*c* 4.00, chloroform). Infrared (film) ν_{max}: 3600, 3440 (hydroxyl), 2900, 2840, 1600 (aromatic), 1500 cm^{-1}; ^{1}Hmr (CCl_4) δ: 3.10 (s, 3H, OCH_3), 3.25 (s, 3H, OCH_3), 3.35 (s, 3H, OCH_3), 3.00–4.00 (m, 11H), 4.10–4.20 (m, 1H), 5.50 (d, 1H), 6.40–7.30 (m, 10H, aromatic protons) ppm; ms (70 eV) *m/e*: 101, 89, 45.

*1,3-Diphenyl-2-(2-*O*-(tert-butyldimethyl)silyl-3,5,6-tri-*O*-methyl-*β*-*D*-glucofuranosyl)imidazolidene (12) from Alcohol 11*

To alcohol **11** (250 mg, 0.58 mmol) in dry dimethylformamide (1 mL) was added *tert*-butyldimethylsilyl chloride (106 mg, 0.70 mmol) and imidazole (99 mg, 1.45 mmol). The resulting solution was stirred overnight at room temperature. Water (15 mL) was then added and the product extracted with ether (3 × 10 mL). The combined ethereal extracts were washed with water (3 × 10 mL), dried ($MgSO_4$), and concentrated. Crystallization from methanol afforded 250 mg (80%) of pure silyl ether **12**, mp 113–114°C; $[\alpha]_D^{22}$ −11.4° (*c* 5.33, chloroform). Infrared (KBr) ν_{max}: 2960, 2940, 2890, 2880, 1600 (aromatic), 1500, 1470, 1380 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.15 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 9H, $C(CH_3)_3$), 3.30 (s, 4H), 3.60 (s, 9H), 3.20–3.80 (m, 5H), 3.90 (bd, 1H), 4.30 (s, 1H), 5.50 (d, 1H), 6.50–7.40 (m, 10H, aromatic protons) ppm: ms (15 eV) *m/e*: 542 (M), 223. *Anal.* calcd. for $C_{30}H_{46}N_2O_5Si$: C 66.42, H 8.49, N 5.16; found: C 66.22, H 8.49, N 5.18.

*2,5-Anhydro-3-*O*-(tert-butyldimethyl)silyl-4,6,7-tri-*O*-methyl-*D*-glycero-*D*-gulo-heptose (13)*

The protected aldehyde **12** (542 mg, 1 mmol) was stirred at 50°C in a 2:1 mixture of tetrahydrofuran and water (30 mL) containing Dowex 50W-X8 (H^+) resin (3.2 g) for 1 h. The resin was then filtered, and the tetrahydrofuran removed under vacuum. The product was extracted with ether (3 × 10 mL), dried ($MgSO_4$), and concentrated to afford 300 mg (86%) of pure aldehyde **13** as an oil; $[\alpha]_D^{22}$ +12.2° (*c* 8.80, chloroform). Infrared (film) υ_{max}: 2960, 2930, 2890, 2860, 2810, 1760 (carbonyl), 1460 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.10 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 9H, $C(CH_3)_3$), 3.20 (s, 3H, OCH_3), 3.30 (s, 3H, OCH_3), 3.35 (s, 3H, OCH_3), 3.20–3.70 (m, 4H), 3.70–4.00 (m, 2H), 4.25 (s, 1H), 9.10 (s, 1H, CHO) ppm.

*E-1-(2-(*tert*-Butyldimethyl)silyl-3,5,6-tri-*O*-methyl-*β*-*D*-glucofuranosyl)-3-keto-1-octene (14)*

Sodium hydride (58% oil dispersion, 32 mg, 0.078 mmol) in dry 1,2-dimethoxyethane (4 mL) was cooled to 20°C and dimethyl 2-oxoheptylphosphonate (190 mg, 0.178 mL, 0.86 mmol) was added dropwise, with stirring, under a nitrogen atmosphere. After the addition, the solution was stirred at room temperature for 1 h. To this solution, the aldehyde **13** (300 mg, 0.86 mmol) in 1,2-dimethoxyethane (2 mL) was added dropwise, and the mixture was stirred at room temperature for 1.5 h. Dilution with water (10 mL) followed by ether extractions (3 × 10 mL) gave, after drying ($MgSO_4$) and purification on a silica gel column using an ether–hexane (1:1) mixture as the eluent, 300 mg (78%) of oily **14**; $[\alpha]_D^{22}$ −52.1° (*c* 5.07, chloroform). Infrared (film) ν_{max}: 2960, 2930, 2860, 2830, 1700, 1670 (carbonyl), 1630 (olefin) cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.10 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 9H, $C(CH_3)_3$), 1.00–1.90 (m, 9H), 2.40 (bt, 2H), 3.20 (s, 3H, OCH_3), 3.25 (s, 3H, OCH_3), 3.30 (s, 3H, OCH_3), 3.30–4.20 (m, 7H), 5.95 (B portion of an ABX system, 1H, $J_{1,2}$ = 14 Hz, $J_{1,3}$ = 1 Hz, OC(3)HC(2)H=C(1)*H*CO), 6.50 (A portion of an ABX system, 1H, $J_{2,1}$ = 14 Hz, $J_{2,3}$ = 6 Hz, C(3)HC(2)*H*=C(1)CHO) ppm; ms (15 eV) *m/e*: 444 (M^+), 387 ($M^+ - 57$), 355 ($M^+ - 89$), 89.

*E-1-(2-*tert*-Butyldimethyl)silyl-3,5,6- tri-*O*-methyl-*β*-*D*-glucofuranosyl)-3-hydroxyl-1-octene (15, 16)*

To the ketone **14** (150 mg, 0.34 mmol) in absolute ethanol (3 mL) at 0°C was added sodium borohydride (13 mg, 0.34 mmol), and the mixture stirred for 1 h at 0°C. Buffer (pH 4.4, 3 mL) was added and the solution allowed to warm up to room temperature. Evaporation *in vacuo*, and ether extraction (3 × 5 mL) gave 130 mg (85%) of **15/16** as a mixture of diastereomers. Infrared (film) ν_{max}: 3460 (hydroxyl), 2960, 2930, 2860, 2820, 1460 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.10 (s, 6H, $Si(CH_3)_2$), 0.90 (s, 12H, $C(CH_3)_3$, CH_2CH_3), 1.00–1.60 (m, 8H), 2.40 (bs, 1H), 3.20 (s, 3H, OCH_3), 3.30 (s, 3H, OCH_3), 3.30–3.70 (m, 6H), 3.75–4.00 (m, 2H), 5.40 (m, 2H, CH=CH) ppm; ms (70 eV) *m/e*: 428 ($M^+ - 18$), 389 ($M^+ - C(CH_3)_3$), 89, 57, 45. *Anal.* calcd. for $C_{23}H_{46}O_6Si$: C 61.88, H 10.31; found: C 62.03, H 10.32.

*E-1-(2-*tert*-Butyldimethyl)silyl-3,5,6-tri-*O*-methyl-*β*-*D*-glucofuranosyl)-3-hydroxyl-1-octene (15, 16)*

A tetrahydrofuran solution of L-Selectride (0.45 mL of a 1 *M* solution) was added over a 1 min period to a stirred solution of the ketone **14** (200 mg, 0.45 mmol) in tetrahydrofuran (1 mL) at −78°C, under a nitrogen atmosphere. After 1 hour the acetone–dry ice bath was replaced with an ice-water bath and 3 mL of a 7:5 mixture of 10% sodium hydroxide and 30% hydrogen peroxide was added, and the resulting solution was stirred overnight at room temperature. The aqueous layer was separated and extracted with hexane (3 × 10 mL). The combined organic layers were washed with water (2 × 2 mL), 10% sodium bisulfite solution (2 × 2 mL), and with saturated salt solution (1 × 2 mL). The organic solution was then dried ($MgSO_4$), filtered, and concentrated under reduced pressure to afford 100 mg (50%) of pure oily alcohols **15** and **16** as an approximately 85 (more polar): 15 (less polar) mixture of diastereomers, as established by thin layer chromatography. Infrared (film) ν_{max}: 3450 (hydroxyl), 2960, 2930, 2860, 1460 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.10 (s, 6H, $Si(CH_3)_2$), 0.90 (bs, 12H), 1.40 (m, 8H), 2.00 (bs, 1H), 3.30 (s, 3H, OCH_3), 3.35 (s, 3H, OCH_3), 3.40 (s, 3H, OCH_3), 3.40–4.20 (m, 8H), 5.55 (m, 2H, CH=CH) ppm.

*Methyl 11(*R*),12(*R*)-Isopropylidenedioxy-8(*R*)-methoxy-9(*S*),12(*R*)-oxy-dodecanoate (18)*

The alkyne **17** (940 mg, 2.88 mmol) was hydrogenated over-

For personal use only.

night at 40 psi with platinum oxide (25 mg) catalyst in ethyl acetate (15 mL). The catalyst was then filtered and washed with more ethyl acetate (5 mL). Removal of the ethyl acetate from the combined organic layers under diminished pressure afforded crude product **18**, as an oil. Purification by flash chromatography (silica gel), using petroleum ether – ethyl acetate (3:1) as the eluent, afforded 577 mg (61%) of the pure product **18** as an oil; $[\alpha]_D^{22}$ −9.4° (*c* 6.05, chloroform). Infrared (film) ν_{max}: 2980, 2940, 2860, 1740 (carbonyl), 1460, 1430, 1380 cm^{-1}; ^{1}Hmr (CCl_4) δ: 1.25 (s, 3H, $C(CH_3)$), 1.40 (s, 3H, $C(CH_3)$), 1.20–2.00 (m, 12H), 2.00–2.40 (m, 2H), 3.10–3.30 (m, 1H), 3.35 (s, 3H, OCH_3), 3.60 (s, 3H, $COOCH_3$), 3.80–4.20 (m, 1H), 4.50–4.70 (m, 1H), 5.60 (d, 1H) ppm; ms (70 eV) *m/e*: 315 (M^+ − 15), 187, 155, 143, 85. *Anal.* calcd. for $C_{17}H_{30}O_6$: C 61.82, H 9.17; found: C 62.02, H 9.09.

*Methyl 11(*R*),12-Dihydroxy-8(*R*)-methoxy-9(*S*),12-oxy-dodecanoate (19)*

The isopropylidene compound **18** (330 mg, 1 mmol) was stirred in a mixture of acetic acid (2.9 mL) and water (5.5 mL) for 16 h at 60°C. Sodium chloride and saturated sodium chloride solution was then added and the product extracted with ethyl acetate (3 × 10 mL). The organic layers were washed with a mixture of saturated sodium bicarbonate and saturated sodium chloride solution until neutral. Drying ($MgSO_4$) and concentration afforded 190 mg (66%) of pure diol **19**, as an oil. Infrared (film) ν_{max}: 3400 (hydroxyl), 2940, 2860, 1740 (carbonyl) cm^{-1}; ^{1}Hmr ($CDCl_3$–D_2O) δ: 1.20–2.50 (m, 14H), 3.40 and 3.45 (s and s, 3H, OCH_3), 3.60 (s, 3H, $COOCH_3$), 3.10–3.50 (m, 1H), 4.00–4.50 (m, 2H), 5.10 and 5.30 (s and d, 1H) ppm; ms (70 eV) *m/e*: 241, 187, 125.

*Methyl 11(*R*),12-Di-*p*-nitrobenzoyloxy-8(*R*)-methoxy-9(*S*),12-oxy-dodecanoate (20)*

To dry pyridine (5 mL), under a nitrogen atmosphere, was added *p*-nitrobenzoyl chloride (302 mg, 1.63 mmol) and the mixture kept at 0°C. The diol **19** (150 mg, 0.52 mmol) in dry pyridine (1 mL) was added dropwise, and the resulting mixture was kept at 0°C for 1.5 h and then allowed to warm up to room temperature for 0.5 h. Water (60 mL) was then added and the product extracted with ether (3 × 10 mL). The combined ethereal extracts were washed with 1% hydrochloric acid (until acidic), water (1 × 10 mL), and dried ($MgSO_4$). Concentration under diminished pressure afforded 275 mg (90%) of di-*p*-nitrobenzoate **20** as an oil. Flash chromatography using petroleum ether – ethyl acetate (3:1) as the eluent afforded an analytically pure sample as a 1:1 mixture of epimers. Infrared (film) ν_{max}: 3110, 3080, 3050, 2840, 2860, 1730 (carbonyl), 1610 (aromatic), 1530 (nitro), 1435 cm^{-1}. ^{1}Hmr (CCl_4) δ: 1.10–1.70 (m, 10H), 1.90–2.60 (m, 4H), 3.20 (s, 3H, OCH_3), 3.40 and 3.60 (s and s, 3H, $COOCH_3$), 3.10–3.40 (m, 1H), 4.20–4.60 (m, 1H), 5.50 (bd, 1H), 6.35 and 6.60 (s and d, 1H), 7.90–8.20 (m, 8H, aromatic protons) ppm; ms (70 eV) *m/e*: 557 (M^+ − 31), 422 (M^+ − 166), 187, 166, 150. *Anal.* calcd. for $C_{28}H_{32}N_2O_{12}$: C 57.14, H 5.44, N 4.76; found: C 57.40, H 5.47, N 4.57.

*Methyl 12-Cyano-8(*R*)-methoxy-11(*R*)-p-nitrobenzoyloxy-9(*S*),12-oxy-dodecanoate (22) and Methyl 12-Bromo-8(*R*)-methoxy-11(*R*)-p-nitrobenzoyloxy-9(*S*),12-oxy-dodecanoate (21)*

The di-*p*-nitrobenzoate **20** (140 mg, 0.24 mmol) in benzene (1 mL) was reacted in the same manner as compound **7** to give the bromo compound **21**. Compound **21** was then reacted in the same manner as compound **8**, with powdered mercuric cyanide (133 mg) in nitromethane (1 mL) to afford crude compound **22**.

Purification by column chromatography (Al_2O_3), using petroleum ether – ethyl acetate (1:1) as the eluent, afforded 65 mg (61%) of the pure product **22** as an oil. Infrared (film) ν_{max}: 3110, 3080, 3060, 2940, 2860, 1730 (carbonyl), 1610 (aromatic), 1530 (nitro), 1435, 1410, 1350 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20–1.80 (m, 10H), 2.10–2.40 (m, 4H), 3.30–3.60 (m, 1H), 3.50 (s, 3H, OCH_3), 3.60 (s, 3H, $COOCH_3$), 4.00–4.60 (m, 1H), 4.70 (bs, 1H), 5.50–5.80 (m, 1H), 8.20 (bs, 4H) ppm.

*Methyl 15-Hydroxy-8(*R*)-methoxy-11(*R*)-p-nitrobenzoyloxy-9(*S*),12(*R*)-oxy-eicosa-13-ynoate (24)*

The silyl compound **25** (30 mg, 0.045 mmol (R_f 0.76)) was heated to 80°C for 3 h in 80% aqueous acetic acid (1 mL). Water (10 mL) was then added and the product extracted with ether (3 × 5 mL). The combined ethereal extracts were washed with saturated sodium bicarbonate solution (5 × 10 mL), water (1 × 5 mL), dried ($MgSO_4$), and concentrated under diminished pressure to afford the crude product. Purification by preparative plate chromatography, using petroleum ether – ethyl acetate (2:1) as the solvent, afforded 20 mg (81%) of pure oily alcohol **24** as a mixture of C-15 diastereomers. Infrared (film) ν_{max}: 3430 (hydroxyl), 2940, 2860, 1740 (carbonyl), 1720 (carbonyl), 1650, 1610 (aromatic), 1530 (nitro), 1350 cm^{-1}; ^{1}Hmr (90 MHz, $CDCl_3$) δ: 0.95 (bt, 3H), 1.25–2.50 (m, 22H), 3.30–3.55 (m, 2H), 3.50 (s, 3H, OCH_3), 3.75 (s, 3H, $COOCH_3$), 3.95–4.20 (m, 1H), 4.40–4.60 (m, 1H), 5.05–5.25 (m, 1H), 6.25 (d, 1H, $J_{12,11}$ = 4 Hz), 7.95–8.60 (q, 4H) ppm; ms (70 eV) *m/e*: 517, 425, 414, 190, 150.

*Methyl 15-(*tert*-Butyldimethyl)silyloxy-8(*R*)-methoxy-11(*R*)-p-nitrobenzoyloxy-9(*S*),12(*R*)-oxy-eicosa-13-ynoate (25)*

The lithium salt of the side-chain derivative **26***a* was prepared by treating **26***a* (375 mg, 1.5 mmol), in dry tetrahydrofuran (2 mL), with a 1.6 *M* solution of *n*-butyllithium in hexane (1 mL). This was stirred for 30 min, and added, dropwise, to a solution of the bromo compound **21** (251 mg, 0.5 mmol) in dry tetrahydrofuran (3 mL) and hexamethylphosphoramide (0.2 mL), at −78°C, under a nitrogen atmosphere. This mixture was stirred for 2 h at −78°C and quenched with buffer solution (pH 4.4). The tetrahydrofuran was removed under diminished pressure, water (5 mL) was added, and the product extracted with ether (3 × 10 mL). The combined ethereal extracts were washed with water (5 × 5 mL), dried ($MgSO_4$), and evaporated to afford the crude product **25**. Purification by preparative chromatography, using ethyl acetate – petroleum ether (1:3) as the solvent, afforded 80 mg (24%) of one diastereomer (R_f 0.76) and 60 mg (18%) of the other diastereomer (R_f 0.60).

Compound with R_f 0.76

Infrared (film) ν_{max}: 2960, 2930, 2860, 1740 (carbonyl), 1610 (aromatic), 1530 (nitro), 1460, 1435 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.20 (s, 6H, $Si(CH_3)_2$), 1.00 (s, 12H), 1.20–2.40 (m, 22H), 3.20–3.50 (m, 1H), 3.40 (s, 3H, OCH_3), 3.60 (s, 3H, $COOCH_3$), 3.80–4.10 (m, 1H), 4.20–4.60 (m, 1H), 4.80–5.10 (m, 1H), 6.00 (d, 1H, $J_{12,11}$ = 4 Hz, $OCHC{\equiv}C$), 7.70–8.30 (q, 4H, aromatic protons) ppm; ms (70 eV) *m/e*: 604 (M^+ − 57), 590 (M^+ − 71), 474 (M^+ − 187), 187, 150, 71, 57.

Compound with R_f 0.60

$[\alpha]_D^{22}$ 6.4° (*c* 1.05, chloroform); ^{1}Hmr (CCl_4) δ: 0.10 (s, 6H, $Si(CH_3)_2$), 1.00 (s, 12H), 1.10–2.50 (m, 22H), 3.20–3.50 (m, 1H), 3.40 (s, 3H, OCH_3), 3.60 (s, 3H, $COOCH_3$), 4.20–4.90 (m, 3H), 5.80 (d, 1H, $J_{12,11}$ = 4 Hz, $OCHC{\equiv}C$), 7.50–8.30 (q, 4H, aromatic protons) ppm; ms (70 eV) *m/e*: 646 (M^+ − 15), 604 (M^+ − 71), 474 (M^+ − 187), 187, 150, 71, 57, 45. *Anal.* calcd. for $C_{35}H_{55}NO_9Si$: C 63.54, H 8.32, N 2.12; found: C 63.80, H 8.40, N 1.92.

*3-(*tert*-Butyldimethyl)silyloxy-oct-1-yne (26*a*)*

To the alcohol **26** (1.26 g, 10 mmol) in dry dimethylformamide (3 mL) under nitrogen atmosphere was added *tert*-butyldimethylsilyl chloride (1.81 g, 12 mmol) and imidazole (1.70 g, 25 mmol). The resulting mixture was stirred overnight at room temperature. Water (30 mL) was then added and the product extracted with ether (3 × 50 mL). The combined ethereal ex-

For personal use only.

tracts were washed with water (5 × 20 mL), dried ($MgSO_4$), and concentrated under diminished pressure to afford 2.20 g (92%) of the silylated compound **26***a*. Infrared (film) ν_{max}: 3320, 2960, 2940, 2860, 1470 cm^{-1}; ^{1}Hmr (CCl_4) δ: 0.20 and 0.22 (s and s, 6H, $Si(CH_3)_2$), 1.00 (bs, 12H), 1.20–1.80 (m, 8H), 2.30 (d, 1H, C≡CH), 4.20–4.50 (m, 1H) ppm.

*Methyl 11(*R*)-*p*-Aminobenzoyloxy-15-hydroxy-8(*R*)-methoxy-9(*S*),12(*R*)-oxy-eicosa-13-ynoate (29)*

The alkyne **25** (40 mg, 0.07 mmol) in *N*,*N*-dimethylformamide (0.4 mL) was added to a stirred mixture of 0.71 *N* $CrSO_4$ solution (0.4 mL) and water (0.1 mL) under a nitrogen atmosphere. The resulting solution turned from blue to green instantaneously and it was then stirred at room temperature for an additional 1.5 h. The solution was saturated with ammonium sulfate and extracted with ether (3 × 5 mL). The combined ethereal extracts were washed with water (3 × 5 mL), dried ($MgSO_4$), and concentrated under diminished pressure to afford the crude product **29**. Purification by preparative plate chromatography, using ethyl acetate – petroleum ether (2:1) as the solvent, afforded 30 mg (79%) of pure amine **29** as an oil. Infrared (film) ν_{max}: 3480 (amine), 3380 (hydroxyl), 2940, 2860, 1730 (carbonyl), 1630, 1610 (aromatic), 1430 cm^{-1}; ^{1}Hmr (90 MHz, $CDCl_3$) δ: 0.90 (bt, 3H), 1.20–1.90 (m, 18H), 2.00–2.50 (m, 4H), 3.45 (s, 3H, OCH_3), 3.39–3.60 (m, 3H), 3.70 (s, 3H, $COOCH_3$), 4.10–4.60 (m, 3H), 4.95–5.10 (m, 1H), 6.10 (d, 1H, $J_{12,11}$ = 4 Hz), 7.20 (q, 4H, aromatic protons) ppm; ms (70 eV) *m/e*: 517 (M^+), 486 (M^+ − 31), 330 (M^+ − 187), 187, 120 ($NH_2C_6H_4CO$), 92, 71, 45.

*1-Deoxy-1-nitro-4,6,7-tri-*O*-methyl-*D*-glycero(*D*-ido and *D*-gulo)-heptitols (31)*

The diol **6** (444 mg, 2 mmol) was dissolved in a mixture of methanol (2 mL) and nitromethane (1 mL) under a nitrogen atmosphere. To this was added a solution of sodium metal (70 mg) in dry methanol (1 mL). The resulting mixture was stirred overnight. The solvent was then removed under reduced pressure and the solid mass dissolved in water (5 mL). The aqueous solution was passed through a column of IR-120 (H^+ form) Amberlite resin (5 mL). The eluate was concentrated under reduced pressure and dried by azeotropic distillation with benzene (2 × 20 mL) to afford 510 mg (90%) of crude adduct**31**, homogeneous by thin layer chromatography, as an oil. Infrared (film) υ_{max}: 3350 (hydroxyl), 2980, 2920, 2810, 1560 (nitro) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.10 (s, 3H, OCH_3), 3.20 (s, 6H, 2 OCH_3), 3.00–3.70 (m, 7H), 3.75–3.90 (m, 1H), 4.00–4.40 (m, 4H) ppm.

*3,5-Di-*O*-acetyl-1,2-dideoxy-1-nitro-4,6,7-tri-*O*-methyl-*D*-gluco-hept-1-enitol (33) and 1-Deoxy-1-nitro-2,3,5-tri-*O*-acetyl-4,5,7-tri-*O*-methyl-*D*-glycero(*D*-ido and *D*-gulo)-heptitols (32)*

A solution of the triol **31** (283 mg, 1 mmol) in acetic anhydride (6 mL) containing catalytic amounts of *p*-toluenesulfonic acid (50 mg) was stirred overnight at room temperature. The reaction mixture was then slowly poured on an aqueous solution of sodium bicarbonate and stirred for 30 min. The product was extracted with chloroform (3 × 10 mL). The extracts were washed with water (3 × 10 mL), dried ($MgSO_4$), and concentrated to afford the crude product (mixture of triacetate **32** and nitro-olefin **33**). This mixture was then dissolved in dry benzene (6 mL) and powdered anhydrous potassium carbonate (142 mg) was added. The suspension was stirred for 6 h at room temperature, and filtered through a Celite pad. The filtrate was concentrated to afford the crude product **33** as an oil. Purification through a silica gel column using ether as the eluent afforded 315 mg (90%) of pure nitro-olefin **33** as an oil, $[\alpha]_D^{22}$ −4.4° (*c* 3.20, chloroform). Infrared (film) ν_{max}: 2970, 2920, 2820, 1760 (carbonyl), 1660 (olefin), 1530 (nitro) cm^{-1}; uv λ_{max} (ethanol) 220 (ε 5560), 290 (ε 1500) (CH=CH—NO_2) nm; ^{1}Hmr (90 MHz, $CDCl_3$) δ: 2.00 (s, 3H, $OCOCH_3$), 2.20 (s, 3H, $OCOCH_3$), 3.40 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.65 (s, 3H, OCH_3), 3.30–3.80 (m, 3H), 3.90 (dd, 1H, $J_{4,5}$ = 3 Hz, $J_{4,3}$ = 6 Hz, C(4)H), 5.20 (dd, 1H, $J_{5,4}$ = 3 Hz, $J_{5,6}$ = 7 Hz, C(5)H), 5.80 (m, 1H, $J_{3,4}$ = 6 Hz, $J_{3,2}$ = 4 Hz, $J_{3,1}$ = 2 Hz, C(3)H), 7.02 (B portion of an ABX system, 1H, $J_{1,2}$ = 14 Hz, $J_{1,3}$ = 2 Hz, C(1)H), 7.42 (A portion of an ABX system, 1H, $J_{1,2}$ = 14 Hz, $J_{2,3}$ = 4 Hz, C(2)H) ppm; ms (70 eV) *m/e*: 305 (M^+), 290 (M^+ − $OCOCH_3$), 89, 45, 43.

*3,5,6-Tri-*O*-methyl-*D*-glucose 1,1-Diethylmercaptal (39) Using Zinc Chloride as the Catalyst*

The alcohol **6** (22 mg, 1 mmol) was added to ethanethiol (620 mg, 10 mmol, 0.74 mL). The mixture was cooled in an ice bath and anhydrous zinc chloride (250 mg) was added. The flask was stoppered and allowed to stand overnight in the freezer (−4°C). The ethanethiol was blown away with nitrogen and warming and the residue dissolved in ethyl acetate (5 mL). Sodium bicarbonate solution (5 mL) was added and the mixture filtered through a Celite pad. The precipitate was washed with more ethyl acetate (5 mL) and the combined filtrate and washings were separated from the aqueous layer. The aqueous layer was reextracted with ethyl acetate (3 × 5 mL). The combined extracts were dried ($MgSO_4$) and concentrated to afford 260 mg (79%) of pure product **39** as an oil. Infrared (film) ν_{max}: 3450 (hydroxyl), 2970, 2730, 2830, 1450, 1370 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (t, 6H, CH_2CH_3), 2.50–3.00 (m, 4H, CH_2CH_3), 3.40 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.70 (s, 3H, OCH_3), 3.20–4.20 (m, 9H) ppm; ms (15 eV) *m/e*: 328 (M^+), 296 (M^+ − 32), 193 (M^+ − $(CH_3CH_2S)_2CH$), 135, 119, 89, 45, 31.

4-Chlorobutan-2-one (36)

To dry methylene chloride (60 mL) was added aluminum trichloride (16.0 g, 0.12 mol), at 0°C, under a nitrogen atmosphere. Acetyl chloride (7.85 g, 7.13 mL, 0.1 mol) was added to this, dropwise, under a nitrogen atmosphere. Ethylene was then bubbled in at a rapid flow rate. Bubbling was continued for 30 min after the rapid uptake ceased. The ice bath was then removed and the mixture stirred for 1 hour at room temperature, poured on an ice-water mixture, and stirred for an additional hour. Extraction with methylene chloride (3 × 20 mL), drying of the extracts with $MgSO_4$, and removal of the solvent under reduced pressure afforded the crude product **36**. The product was purified by distillation to give 7.62 g (72%) of pure chloro compound **36**, bp 105–110°C. Infrared (film) ν_{max}: 2970, 1720 (carbonyl) cm^{-1}; ^{1}Hmr (CCl_4) δ: 2.10 (s, 3H, CH_3), 2.80 (t, 2H, CH_2CO), 3.60 (t, 2H, CH_2Cl) ppm.

4-Nitrobutan-2-one (37)

The chloro compound **36** (1.98 g, 0.0186 mol), potassium iodide (150 mg), and sodium nitrite (1.28 g, 0.0186 mol) were stirred overnight in dry dimethylsulfoxide (15 mL) at room temperature. Water (150 mL) was then added and the product extracted with ether (3 × 10 mL). The combined extracts were washed with water (3 × 10 mL), dried ($MgSO_4$), and evaporated under reduced pressure to afford the crude product **37**. The product was purified by distillation to give 1.1 g (50%) of the nitro ketone **37**, bp 90–93°C/2 Torr. Infrared (film) ν_{max}: 3000, 2960, 2920, 1720 (carbonyl), 1550 (nitro) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.30 (s, 3H, CH_3), 3.20 (t, 2H, CH_2CO), 4.60 (t, 2H, CH_2NO_2) ppm.

2,2-Dimethoxy-4-nitrobutane (38)

The ketone **37** (480 mg, 4.1 mmol) was stirred overnight at room temperature with trimethylorthoformate (477 mg, 4.5 mmol, 0.492 mL) and methanol (0.2 mL) containing catalytic amounts of *p*-toluenesulfonic acid. Water (30 mL) and saturated sodium bicarbonate solution (1 mL) were then added and the resulting solution extracted with ether (3 × 30 mL). The extracts were dried ($MgSO_4$) and evaporated to afford the crude product **38**. Distillation (bp 60–65°C/1 Torr) of the crude product af-

For personal use only.

forded 600 mg (90%) of pure nitro ketal **38**. Infrared (film) ν_{max}: 2990. 2940, 2830, 1550 (nitro), 1440, 1380, 1350 cm^{-1}; ^{1}Hmr (CCl_4) δ: 1.20 (s, 3H, CH_3), 2.30 (bt, 2H, $CH_2C(OCH_3)_2$), 3.10 (s, 6H, 2 OCH_3), 4.30 (t, 2H, CH_2NO_2) ppm.

2,4-O-Isopropylidene-3,5,6-tri-O-methyl-D-glucose 1,1-Diethylmercaptal (40)

To a solution of the dithioacetal **39** (328 mg, 1 mmol) in acetone (15 mL) was added anhydrous copper sulfate (750 mg) and 3 drops of concentrated sulfuric acid at room temperature. The resulting mixture was stirred overnight. The solution was then neutralized by bubbling in ammonia at room temperature until alkaline (pH 9). The blue precipitate was filtered (Celite) and concentrated to afford the crude product **40**. This was purified by flash chromatography (silica gel), using petroleum ether – ethyl acetate (4:1) as the eluent. Concentration of the appropriate fractions afforded 290 mg (78%) of pure isopropylidene compound **40** as an oil; $[\alpha]_D^{22}$ +4.2° (*c* 5.45, chloroform). Infrared (film) ν_{max}: 2970 (hydrocarbon), 2930, 2830, 1450, 1380, 1260 cm^{-1}; ^{1}Hmr (CCl_4) δ: 1.20 (t, 3H, CH_2CH_3), 1.30 (t, 3H, CH_2CH_3), 1.40 (s, 6H, $C(CH_3)_2$), 2.40–3.00 (m, 4H, CH_2CH_3), 3.30 (s, 3H, OCH_3), 3.40 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.20–4.10 (m, 7*H*) ppm; ms (15 eV) *m/e*: 368 (M^+), 233 ($M^+ - (CH_3CH_2S)_2CH$), 191, 135, 89.

2,4-O-Isopropylidene-3,5,6-tri-O-methyl-D-glucose (41)

The dithioacetal **40** (310 mg, 0.84 mmol) was stirred for 2.5 h with mercuric chloride (420 mg, 1.5 mmol) and mercuric oxide (420 mg, 1.94 mmol) in a mixture of water (0.2 mL) and acetone (3 mL), at room temperature. The mixture was then filtered through a Celite pad and the precipitate washed with acetone. The combined filtrate and washings were rid of acetone by evaporation and the resulting oil was treated with chloroform (10 mL). A white precipitate formed which was filtered off and washed with more chloroform (10 mL). The combined filtrates were washed with water (1 × 10 mL), 5% potassium iodide solution (2 × 5 mL), and again with water (1 × 10 mL). Drying ($MgSO_4$) of the chloroform layer and evaporation afforded 196 mg (89%) of pure aldehyde **41** as an oil; $[\alpha]_D^{22}$ +29.3° (*c* 0.72, chloroform). Infrared (film) ν_{max}: 3000, 2940, 2900, 2840, 1740 (carbonyl), 1460, 1380, 1370 cm^{-1}; ^{1}Hmr (CCl_4) δ: 1.38 (s, 3H, $C(CH_3)$), 1.42 (s, 3H, $C(CH_3)$), 3.30 (s, 6H, 2 OCH_3), 3.40 (s, 3H, OCH_3), 3.30–3.80 (m, 5H), 4.10 (bd, 1H), 9.60 (bs, 1H, CHO) ppm; ms (70 eV) *m/e*: 247 ($M^+ - 15$), 173 ($M^+ - CH(OCH_3)(CH_2OCH_3)$), 101, 89, 45, 31.

Nitro Alcohol (42)

The aldehyde **41** (170 mg, 0.65 mmol) was stirred at room temperature for 4 h with 2,2-dimethoxy-4-nitrobutane (**38**) (114 mg, 0.70 mmol) and diisopropylamine (73 mg, 0.72 mmol) in dry dimethylformamide (1 mL). Methanol (3 mL) was then added and the solution stirred for an additional 3 h. The methanol was then removed under vacuum and water (10 mL) was added. The product was extracted with ether (3 × 5 mL). The combined extracts were dried ($MgSO_4$) and concentrated to afford the crude product **42**. Purification through a silica gel flash column, using ethyl acetate – petroleum ether (2:1) as the eluent, afforded 232 mg (84%) of an oily mixture of diastereomeric nitroalcohols **42**; $[\alpha]_D^{22}$ +6.9° (*c* 0.29, chloroform). Infrared (film) ν_{max}: 3440 (hydroxyl), 2920, 2940, 2830, 1550 (nitro), 1380 cm^{-1}; ^{1}Hmr ($CDCl_3$) (R_f 0.36, ether) δ: 1.30 (s, 6H), 1.40 (s, 3H), 2.20–3.00 (m, 3H), 3.10 (s, 3H, OCH_3), 3.20 (s, 3H, OCH_3), 3.30 (s, 3H, OCH_3), 3.40 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.20–4.20 (m, 7H), 5.00 (m, 1H, $CHNO_2$) ppm; ^{1}Hmr ($CDCl_3$) (R_f 0.42, ether) δ: 1.40 (bd, 9H), 2.00–3.00 (m, 3H), 3.10 (s, 3H, OCH_3), 3.20 (s, 3H, OCH_3), 3.40 (s, 3H, OCH_3), 3.50 (s, 3H, OCH_3), 3.60 (s, 3H, OCH_3), 3.10–4.40 (m, 7H), 4.80–5.10 (m, 1H, $CHNO_2$) ppm; ms (70 eV) *m/e*: 379 ($M^+ - NO_2$), 89, 45.

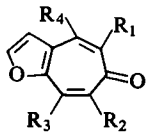
SAFAA H. ETAIW, MOHAMED EL-BORAI, and MOHAMED I. ISMAIL. Can. J. Chem. **58**, 2358 (1980).

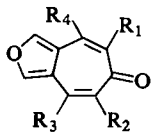
The polarographic reduction of nine furotropone derivatives has been studied in Thiel buffers and in DMF. The reduction of compounds having two methyl or two phenyl groups proceeds via two electron waves along the whole pH range studied. The reduction of furotropone and derivatives having one substituent or three methyl groups proceeds via one reversible electron wave in acid media while in neutral and alkaline media two waves each corresponding to 1 F are observed. Above pH 12, the limiting current decreases and one wave appears, corresponding to 1 F. The values of n were determined coulometrically using the Ilkovic equation. All waves are diffusion controlled while the electrode process along these waves is irreversible. The rate constant, the free energy of activation, and the electron affinities of these compounds were computed.

SAFAA H. ETAIW, MOHAMED EL-BORAI et MOHAMED I. ISMAIL. Can. J. Chem. **58**, 2358 (1980).



On a étudié la réduction polarographique de neuf dérivés de la furotropone dans des tampons de Thiel et dans la DMF. La réduction des composés possédant deux groupes méthyles ou phényles se fait par l'intermédiaire d'une vague à deux électrons dans tout l'intervalle du pH étudié. La réduction de la furotropone et de ses dérivés portant un substituant ou trois groupes méthyles se fait par l'intermédiaire d'une vague reversible à un électron en milieu acide tandis qu'en milieu neutre ou basique, on observe deux vagues correspondant chacune à 1 F. A un pH supérieur à 12, le courant limite diminue et il apparait une vague correspondant à 1 F. En faisant appel à l'équation d'Ilkovic et à la coulométrie on a déterminé les valeurs de n. La diffusion contrôle toutes les vagues alors que les réactions d'électrodes accompagnant ces vagues sont irréversibles. On a calculé la constante de vitesse, l'énergie d'activation et les affinités électroniques de ces composés.

[Traduit par le journal]



Introduction

Investigation of the polarographic reduction of the carbonyl or the quinonoid compounds has revealed that reduction at the dropping mercury electrode depends on the molecular structure, the composition of the solution (in particular hydrogen ion concentration), and electrode potential (1–9). In strong acid media, the reduction takes place by the uptake of one reversible electron forming a free radical while at high pH values two electrons are involved in the reduction process (1). The electroreduction of thiophenotropones was studied by Guilard and Fournari (10). They claimed that the polarograms consist of two reduction waves (pH 6.7), each corresponds to 1 F, producing the corresponding thiophenotropolones. In a previous article (11) we reported a detailed study on the electrochemical reduction of eleven thiophenotropones. The tropilidene ring proved to be inactive towards reduction and the reduction process was found to occur in three different ways depending on the pH value of the medium and the molecular structure.

In the course of our research, we have examined the electroreduction as well as the electrode kinetics of nine furotropone compounds **I** and **II** in Thiel buffer solutions of varying pH values. The electron affinities of these compounds were calculated regarding their polarographic behaviour in DMF.

Experimental

The furotropones were prepared according to the recommended procedure described by El-Borai *et al.* (12). The solids were purified by recrystallization from the appropriate solvents and their purity and identity were checked by mp determination, ^{1}Hmr, elemental analysis, and thin-layer chromatography. The polarograms were recorded by radiometer PO_4 type recording polarograph using a dropping electrode with $m = 2.45$ mg s^{-1} and $t = 3.6$ s at a height of 52 cm Hg and a kalousek polarographic cell with a thermostating jacket. The temperature was maintained with an ultrathermostat at 25 ± 0.1°C. A series of Thiel buffer solutions were used while after pH 12 a concentrated solution of NaOH was used to raise the pH of the medium. The compounds **I**, **II**, and **III** were dissolved in 20 vol% ethanol–water mixture. The polarograms in DMF were carried out using 0.1 *M* I^{-1} of *N*-tetrabutyl ammonium perchlorate as supporting electrolyte. Depolariser concentrations studied were 1×10^{-3} *M* at a μ of 0.1 (NaCl). A saturated calomel electrode (sce) was used as reference electrode. A radiometer pH meter type 63 fitted with a combined glass electrode type Gk 2301 C was employed for determination of pH. The instrument was accurate to ±0.01 pH unit. The electrolysis at controlled potential was made using a potentiostat Tacussel of type ASA 4/60. The electrolysis cell used was as that described by Peltier *et al.* (13).

Results and Discussion

The electroreduction of 1×10^{-3} *M* of furotropone derivatives recalls that of the carbonyl compounds (1, 11, 14–16). The polarograms of **I***a–c*, *f* and **II***a*, *b* show the same behaviour while those of **I***d*, *e* and **II***c* are identical (Fig. 1). The polarograms of **I***a*, *c*, *f* and **II***a*, *b* exhibit one reduction wave, A, in solutions of pH ≤ 4.3. Wave A corresponds to 1 F. However, the polarograms of **I***b* exhibit this behaviour in solutions of pH 2.3–7.5. Above pH 4.3 or 7.5, the polarograms consist of two reduction waves (A, B) of equal heights each corresponding to 1 F. The $E_{1/2}$ of wave A shifts to an apparent less negative potential while that of wave B suffers a slight shift in the same direction by increasing the pH value. At pH > 13 the height of wave B decreases until it vanishes at pH ≥ 13.4 and one wave, C, appears to correspond to 1 F. On the other hand, the polarograms of **I***d*, *e* and **II***c* consist of one reduction wave, D, over all the pH range from 2.3 to 12. The wave corresponds to 2 F and has a total height more or less equal to that of both waves A and B. As the pH increases, the height decreases until it attains the current corresponding to 1 F at pH ≃ 13.5.

The coulometric analysis under controlled potential and a μ of 0.1 proved that waves A, B, and C correspond to the uptake of one electron while wave D corresponds to the uptake of two electrons. Also, using the Ilkovic equation the number of electrons can be evaluated. The diffusion coefficient of the depolariser was determined from the molar volume applying "the Stocks–Einstein relation" [1].

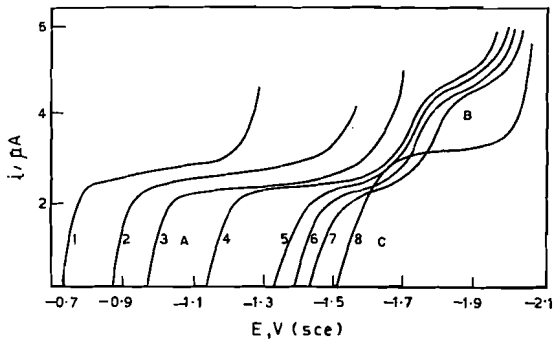

FIG. 1. The polarograms of 1 m*M* of **I***a* in Thiel buffer solutions at 25 ± 0.1°C, run and pH: (*1*) 2.30; (*2*) 3.50; (*3*) 4.30; (*4*) 5.50; (*5*) 7.50; (*6*) 8.70; (*7*) 10.20; (*8*) 13.40.

[1] $D_0 = 3.31 \times 10^{-5} (D/M)^{1/3}/\eta$ cm^2 s^{-1}

The values of the diffusion coefficient obtained by this method are reported in Table 1. The number of electrons evaluated using coulometry and Ilkovic equation are quite close to each other.

The waves A, B, C, and D proceed irreversibly as was indicated by the values of the slope of the straight lines obtained by applying the fundamental equation for polarographic data (17) and by the values of the transfer coefficient α (18). Also, all the waves are diffusion controlled as was indicated by the effect of mercury height on the limiting current, Table 1.

The $E_{1/2}$ of all waves shifts to less negative potential, however, the magnitude of shift for wave A is larger than that for wave B. The correlation of $E_{1/2}$ with pH is straight or in broken lines, depending on the nature of the wave and the molecular structure (Fig. 2). The number of protons involved in the reduction process for each wave was determined using relation [2] (Table 1).

[2] $\Delta E_{1/2}/\Delta\text{pH} = (0.059/\alpha n_a)(ZH^+)$

The correlation of i_1 with pH is straight or curved lines (Fig. 3), indicating that the limiting current decreases slightly as the pH increases. The validity of the Ilkovic equation was tested at pH 4.5 and 10.2. A satisfactory linear relation passing through the origin is obtained for waves A, B, and D. The values of i_1/C are constant, which suggests the possible application of the polarographic method for the determination of furotropone derivatives. Rate constants, k_e^0, and the free energy of activation, ΔG^*, are computed applying the different approaches proposed for analysis of irreversible

TABLE 1. Polarographic results[a] obtained for I and II

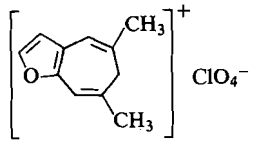
[c]Wave A.
[d]Wave B.

waves by Delahay (19) Strassner and Delahay (20), and Koutecky (21) and modified by Issa and Tharwat (22) (Table 1).

$$[3]\quad i_{irr}/(i_{rev} - i_{irr}) = 0.886\, K_e^0\, (t/d)^{1/2}$$

$$[4]\quad \log k_e^0 = \log \left(\frac{i_{irr}}{i_{rev} - i_{irr}}\right)_{E=0} + \log \frac{1}{0.886}\left(\frac{d}{t}\right)^{1/2}$$



$$[5]\quad \Delta G^* = 5778.8\,(5.097 - \log k_e^0)$$

The low values of K_e^0 and the high values of ΔG^* support the irreversible nature of the waves.

Reduction Mechanism

In order to get precise information about the electroreduction of furotropone derivatives, one must consider the reduction of furotropilidene. Thus, we investigated the electroreduction of a perchlorate salt of type **III**.

The polarogram of 1×10^{-3} *M* of **III** in Thiel buffer solutions consists of one reduction wave

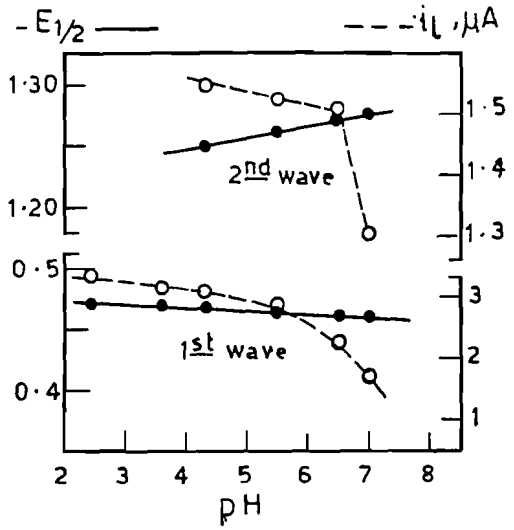
corresponding to 1 F at pH < 4.5. Within the pH range 4.5–7, a second wave appears, it almost has equal height as the first one (Fig. 4). Above pH 7 the polarograms suffer deformation since the compounds are hydrolysed. Khopin and Zhdanov (23) obtained similar results on studying the electroreduction of tropylium perchlorate salt. The first wave corresponds to the uptake of one electron forming a free radical which undergoes dimerisation. At pH > 4.5, the new wave can be attributed to the formation of furotropilidene since the reduction processes at these pH values involved the uptake of two electrons, as supported by coulometric analysis, and one proton.

$$\left.\begin{aligned}(C_{11}H_{11}O)^+ + e &\rightleftharpoons (C_{11}H_{11}O)^\cdot \\ 2(C_{11}H_{11}O)^\cdot &\rightarrow (C_{11}H_{11}O)_2\end{aligned}\right\} \quad \text{first wave, pH} < 4.5$$

$$\left.\begin{aligned}(C_{11}H_{11}O)^+ + 2e &\rightleftharpoons (C_{11}H_{11}O)^- \\ (C_{11}H_{11}O)^- + H^+ &\rightarrow C_{11}H_{12}O\end{aligned}\right\} \quad \text{pH} > 4.5$$



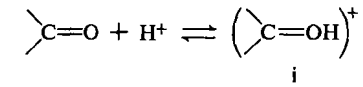


FIG. 4. The correlation of $E_{1/2}$ and i_l with pH for 0.5 m*M* **III**.

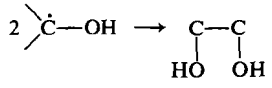
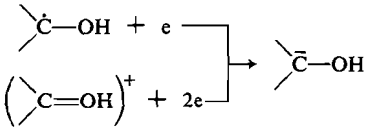
These results were further supported by electrolysis at controlled potential (13). The electrolysis was carried out in aqueous solution at pH 6 and at −1.37 V. After the extraction of the product of electrolysis, it was analysed by vapour phase chromatography. The electrochemical reduction was quantitative and three isomers of **III** were separated in proportions previously reported by El-Borai *et al.* (24). Thus the tropilidene ring is inactive towards reduction at the dropping mercury electrode under these experimental conditions.



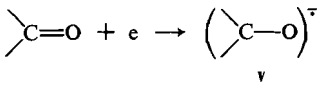
Wave A corresponds to the reduction of cation **i** and then forms the free radical **ii** which dimerises to form pinacol, **iii**.

i

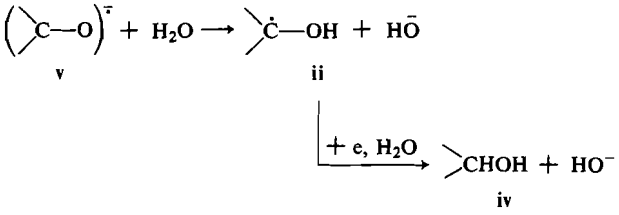


ii

iii



Wave B expresses the transformation of radical **ii** to alcohol **iv**.



iv

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Wave C corresponds to the direct reduction of the basic form to the anion radical **v** which is stable at pH ≥ 13.4.

On the other hand, wave D involves the formation of the anion radical **v** which reacts with one proton in acid media or with one mole of water in alkaline media to reproduce **ii**. Radical **ii** undergoes further reduction to form alcohol **iv**.

Effect of Molecular Structure on $E_{1/2}$

Consulting the half wave potentials of furotropone derivatives at one and the same pH value, one can conclude that the increase of electron density on the tropilidene ring, consequently the polarisation of the carbonyl group, renders the half wave potentials to be shifted to more negative values. The derivatives of **I** have more negative half wave potentials than the corresponding derivatives of **II**. Also, the increase of donor character of the substituent shifts the reduction wave A to more negative potential so that it intermingles with wave B to form wave D as observed in the polarograms of **Id**, *e* and **IIc**. In these compounds the carbonyl group tends to be completely polarised in the ground state facilitating the formation of the anion free radical **v** on reduction.

The Correlation of Half Wave Reduction Potentials with Absolute Electron Affinities

The potential determining step in the polarographic reduction of a compound has been assumed to be the reversible addition of an electron to the molecule so that the half wave reduction potential is a measure of the electron affinity of the compound according to eq. [6].

$$[6] \quad -E_{1/2} = \text{E.A.} - \Delta G_{sol} - \text{constant}$$

The constant term depends upon the reference electrode and is 5.07 eV for the saturated calomel electrode. The difference in solvation energies for the negative ion and the neutral, ΔG_{sol}, is often assumed to be constant for CT acceptors; in spite of the fact that the correlation of half wave reduction potentials with absolute E.A. values for aromatic hydrocarbons indicates that this quantity is not constant, at least in the case of dioxane and dimethoxyethanol as solvents (25). Briegleb (26) and Farragher and Page (27) calculated average values of −3.66 and −2.37 eV for ΔG_{sol}, respectively.

Chen and Wentworth (28) used the absolute E.A. values of 22 acceptors and calculated an average value of -2.58 ± 0.26 eV for ΔG_{sol}. Thus eq. [7] can be used to calculate the E.A. values from half wave reduction potentials vs. the saturated calomel electrode (29–34).

$$[7] \quad \text{E.A.} = -E_{1/2} + 2.49 \pm 0.26 \text{ eV}$$

The half wave potentials of furotropones recorded in DMF and the corresponding electron affinities are listed in Table 2. The correlation of E.A. values with $E_{1/2}$ values of furotropones gives an excellent linear relationship, (Fig. 5).

Theoretical and experimental conformational preferences of the aldehyde and fluoroaldehyde groups in 2-methylbenzaldehyde, 2-trifluoromethylbenzaldehyde, and 4-chloro-2-methylbenzoyl fluoride. Proximate couplings

TED SCHAEFER, SALMAN R. SALMAN,[1] AND TIMOTHY A. WILDMAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

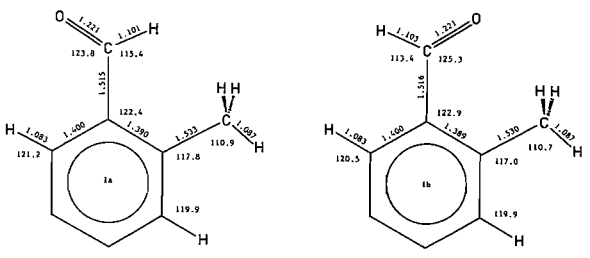
Received May 29, 1980

TED SCHAEFER, SALMAN R. SALMAN, and TIMOTHY A. WILDMAN. Can. J. Chem. **58**, 2364 (1980).

On the basis of long-range spin–spin coupling constants, the O-*syn* conformation of 2-methylbenzaldehyde in CCl_4 solution at 305 K is favored over the O-*anti* form by a free energy of 0.5$_3$ kJ/mol. This number is compatible with other experiments, as well as with STO-3G MO calculations in which the geometry of the substituents is optimized. The latter yield 0.52 kJ/mol in the internal energy difference. In benzene solution, 2-trifluoromethylbenzaldehyde exists in the O-*anti* form to the extent of at least 95% at 305 K. In CCl_4 solution at this temperature, the population of the O-*syn* conformer of 4-chloro-2-methylbenzoyl fluoride is likely 75% or more of the total, in semiquantitative agreement with STO-3G optimization procedures. Substantial proximate couplings exist between ^1H and ^{19}F nuclei in the sidechains of the latter two compounds and are compared with INDO MO FPT computations. These yield negative values for $^5J_o^{CHO,CF_3}$ in 2-trifluoromethylbenzaldehyde, whereas the experimental value is 2.23 Hz.

TED SCHAEFER, SALMAN R. SALMAN et TIMOTHY A. WILDMAN. Can. J. Chem. **58**, 2364 (1980).

En se basant sur les constantes de couplage spin–spin à longue distance on peut conclure que la conformation O-*syn* du méthyl-2 benzaldéhyde en solution dans le CCl_4 à 305 K est favorisée par rapport à la forme O-*anti* par une différence d'énergie libre de 0,53 kJ/mol. Cette valeur est compatible avec d'autres expériences ainsi qu'avec des calculs OM STO-3G dans lesquels on maximise la géométrie des substituants. Ces derniers donnent une différence d'énergie interne de 0,52 kJ/mol. En solution dans le benzène, au moins 95% du trifluorométhyl-2 benzaldéhyde existe sous la forme O-*anti* à 305 K. En solution dans le CCl_4 à cette température, probablement 75% ou plus du fluorure de chloro-4 méthyl-2 benzyle existe dans la conformation O-*syn*; cette conclusion est en accord semi-quantitatif avec les méthodes de maximisation du STO-3G. Des couplages approximatifs substantiels existent entre les noyaux de ^1H et de ^{19}F des chaînes latérales des deux derniers composés et on les compare aux valeurs obtenues par calculs OM INDO FPT. Ces derniers conduisent à des valeurs négatives de $^5J_o^{CHO,CF_3}$ pour le trifluorométhyl-2 benzaldéhyde alors que la valeur expérimentale est de 2,23 Hz.



[Traduit par le journal]

Introduction

The conformational behaviour of the aldehyde and the fluoroaldehyde groups has been investigated for benzaldehyde and benzoyl fluoride and a number of their derivatives by a variety of techniques (1–18). In solution at least (1, 14), the twofold barrier to rotation about the exocyclic carbon–carbon bond is 31.4 kJ/mol for benzaldehyde and 29.3 kJ/mol for benzoyl fluoride, so that at ambient temperatures the molecules are effectively planar. Substitution at both *ortho* positions by chlorine atoms or methyl groups causes a twist about the exocyclic bond (12, 19), as shown by the appearance of spin–spin couplings over six bonds, $^6J_p^{H,CHO}$ and $^6J_p^{H,CFO}$, involving the *para* ring protons in such derivatives. The stereospecificity of long-range couplings from ring protons to the sidechain protons or ^{19}F nuclei allows deductions about the degree of twisting.

Asymmetric substitution patterns in the ring yield rapidly interconverting O-*syn* and O-*anti* isomers, whose populations can also be deduced from long-range couplings (8–11). At sufficiently low temperatures, ^{13}C or ^1H nmr spectra of both isomers are detectable and their peak areas give the population ratios (2, 3). The latter are not always in agreement with those found at room temperature, a fact perhaps attributable to varying solvent effects (20) in the experiments; particularly if the conformational isomers have rather different dipole moments (11).

If these moments are rather similar, then the two methods should agree. For example, the O-*anti* form, **1***a*, of 2-methylbenzaldehyde, cannot have a dipole moment very different from that of the O-*syn* form, **1***b* (structure **1**). Because ^1H and ^{13}C nmr data at low temperatures are available (2, 3), it is of

interest to see whether the use of stereospecific coupling constants at ambient temperatures will yield compatible population ratios or whether there exists a fundamental flaw in the assumptions (11) about such couplings.

In another vein, considerable effort has been expended in the elucidation of so-called "through-space" coupling constants (21–24). These exist when the coupled nuclei, although separated by four or more formal bonds, approach each other rather closely; or when the bonds containing these nuclei are juxtaposed in certain orientations. Considered rigorously, all couplings are transmitted through space, so that these couplings should probably be called proximate. Such couplings may well occur in the O-*anti* forms, **2***a*, of 2-trifluoromethylbenzaldehyde and **3***a*, of 4-chloro-2-methylbenzoyl fluoride (structure **3**).

2*a* O-*anti* **2***b* O-*syn*

Structure **2**

Structure **3**

Accordingly, the ^{1}H nmr spectra of **1** to **3** (the chlorine substituent in **3** unfortunately was necessary to allow a precise spectral analysis) were analyzed. The spectral parameters yield the *a*:*b* ratio and also emphasize the elusiveness of a satisfactory model for the proximate couplings in at least one of these compounds.

Experimental

Compounds **1** and **2** came from Aldrich and Chemical Procurement Laboratories, respectively. **3** was prepared from the acid by reaction with diethylaminosulfur trifluoride (DAST) in the accepted way (25). Nuclear magnetic resonance samples were prepared as degassed solutions in 5 mm od glass tubes and contained a small amount of tetramethylsilane (TMS). Compounds **1** and **3** were examined as 9.5 and 10.0 mol% solutions in CCl_4, respectively, whereas **2** had to be used as 6.0 mol% solution in C_6D_6 for reasons of chemical shift dispersion.

The ^{1}H nmr spectra were calibrated in the frequency sweep mode on an HA100 spectrometer at a probe temperature of 305 K. Markers were placed at ca. 5 Hz intervals, frequencies of sweep and lock (provided externally for stability) oscillators were read, and interpolation between these marker frequencies gave peak positions whose root-mean-square deviations were typically ≤ 0.02 Hz. Weak irradiation with a second radiofrequency field (26) yielded the relative signs of coupling constants.

Molecular orbital calculations were performed on an IBM System 360/168, or an Amdahl 470/V7, at the STO-3G (27) and INDO or CNDO (28) levels of molecular orbital theory.

Results and Discussion

Spectral Analyses

Performed with the computer program LAME (29, 30), the analyses gave the spectral parameters for **1** to **3**. Full results are given for 2-methylbenzaldehyde in Table 1, while the couplings to the sidechains in **2** and **3** are found in Table 2. Figure 1 displays the observed and calculated methyl ^{1}H nmr spectra for **1**.

Conformational Equilibrium in 2-Methylbenzaldehyde, 1

As discussed in detail previously (11), there is no evidence that $^5J_m^{H,CHO}$ is other than zero for H-3 in **1***a* or H-5 in **1***b*. Furthermore, the sum of the $^5J_m^{H,CHO}$ values in **1** is 0.76_8 Hz and is 0.76_0 Hz in benzaldehyde (31), suggesting a negligible intrinsic substituent perturbation of $^5J_m^{H,CHO}$ in **1**. Accordingly, the ratio of O-*syn* to O-*anti* forms is 55/45 in CCl_4 at 305 K.

At 113 K in $CHFCl_2$ solution (2), peak areas of ^{13}C and/or ^{1}H nmr spectra of the separate conformers yield the above ratio as 36 to 64. From the

enthalpy and entropy data obtained in that work (2), it is clear that the O-*syn* population can become greater than 50% at 305 K (formally 72 ± 20%). In another investigation (3) at 128 K in a $CCl_2F_2/CHFCl_2$ solution, the ratio was 50/50 as obtained from ^{13}C nmr peak areas of the two conformers. The dipole moments of two conformers may differ by only 5% (see a later section) and therefore medium perturbations of the conformational equilibrium are probably small.

Shift reagents added to a solution of **1** in CCl_4 caused chemical shift dispersion interpretable as arising from a roughly 50/50 mixture of **1***a* and **1***b* (4).

We take these comparisons to mean that $^5J_m^{H,CHO}$ is a reliable indicator of the conformer preferences in **1**.

The negligible magnitude of $^6J_p^{H,CHO}$ in **1** suggests that the aldehyde group is essentially coplanar with the aromatic framework. Indeed, the barrier to interconversion of the conformers is ca. 28 kJ/mol (2, 3), similar to benzaldehyde and much larger than kT at 305 K. Therefore effectively planar conformations are a reasonable conclusion.

Molecular Orbital Calculations on 1

A standard geometry (32) at the STO-3G level gave the O-*syn* form as 11 kJ/mol less stable than the O-*anti* conformer. Therefore a geometry optimization was performed, beginning with benzaldehyde itself. No reliable structural data are available for this molecule, the geometry of the aldehyde group in acetaldehyde having been assumed for the microwave studies (16, 33). The structural results are set out in structure **1**. The O-*syn* form is favored by 0.52 kJ/mol, presumably the major part of the internal energy difference. The experimental value is 0.53 ± 0.05 kJ/mol in the free energy for a 9.5 mol% solution in CCl_4 at 305 K. The contribution of internal motions to the internal energy and to the entropy could be calculated from statistical

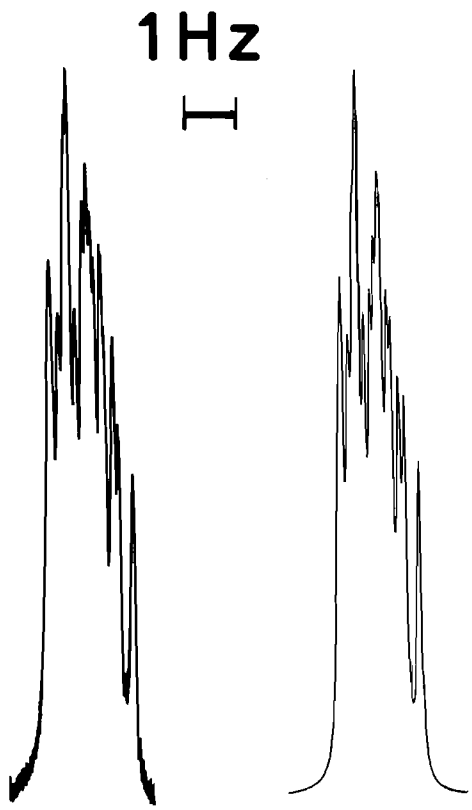

FIG. 1. The experimental and theoretical methyl proton ^1H nmr spectra at 100 MHz for a 9.5 mol% solution of 2-methylbenzaldehyde in CCl_4 at 305 K. The spectrum was recorded while decoupling the aldehyde proton. The theoretical spectrum used the parameters in Table 1. There is some disagreement in the middle region of the two spectra, attributable to slight differences in line width or shape and/or to variations of up to 0.02 Hz in some of the long-range couplings. Iteration on ring proton transitions only did not produce variations larger than 0.002 Hz in the crucial couplings, $^5J_m^{H,CHO}$. The assumed linewidth at half height was 0.10 Hz. The coupling between the aldehyde and methyl protons amounts to ca. 0.04 Hz in magnitude.

mechanics. However, one must know the molecular partition function. This requires a good knowledge of the potential energy surface for all internal motions, but this knowledge is unavailable. The STO-3G results may be considered encouraging.

STO-3G calculations underestimate dipole moments, being 1.92 D for benzaldehyde (3.21 K is the gas phase value (33)), and 2.00 and 1.71 D for the O-*anti* and O-*syn* forms, respectively. INDO MO dipole moments are usually more realistic. They are 2.75 D for benzaldehyde (11) and 2.58 and 2.71 D for the O-*anti* and O-*syn* forms, respectively, for the geometries in structure **1**. The small difference between the INDO MO dipole moments suggest relatively small solvent perturbations of the conformational equilibrium.

For the geometries in structure **1**, INDO MO

FPT calculations gave $^5J^{CHO,CH_3}$ as 0.00 Hz for the O-*anti* form and 0.32 Hz for the O-*syn* form. Therefore the calculations predict 0.17 Hz for the observed equilibrium, an overestimate of about 0.1 Hz. It appears that proximate coupling between the aldehyde and methyl protons is indeed very small.

Conformational Behavior of 2-Trifluoromethylbenzaldehyde, 2

Coupling between the aldehydic proton and H-3 in **2** was not observed, so that at least 95% of **2** exists in the O-*anti* form, **2***a* (in 2-fluorobenzaldehyde the sum of the $^5J_m^{H,CHO}$ values is 0.86 ± 0.04 Hz (11), whereas $^5J_5^{H,CHO}$ is 0.82 ± 0.02 Hz in **2**). In other words, a close proximity of the C=O and C—F dipoles in the orientation implied by **2***b* is unlikely. Alternatively, the C—H dipole of the aldehyde group may be attracted to the C—F dipoles in the CF_3 group.

The 0.06 Hz magnitude of $^6J_p^{H,CHO}$ is compatible with a slight average twist, perhaps as large as 10 to 12° (19), of the aldehyde group about the C—C bond in **2***a*; suggesting that interaction of the CHO and CF_3 moieties is net repulsive even when the C—H bond is *syn* to CF_3.

$^5J_o^{CHO,CF_3}$ is 2.23 Hz and is no doubt a proximate coupling (no coupling was observed for the *para* isomer). Extensive INDO MO FPT calculations with standard (32) and other reasonable geometries always yield this coupling as negative, as do CNDO MO FPT approaches. As there exists no doubt of the experimental sign (both multiple resonance experiments and the peak distribution in the aldehyde ^{1}H nmr spectrum gave positive signs), the theoretical results are disconcerting in view of the good agreement between theory and experiment for other proximate ^{1}H,^{19}F couplings involving the CF_3 group, e.g., that in 2-trifluoromethylphenol (34).

Conformational Equilibrium for 4-Chloro-2-methylbenzoyl Fluoride, 3

$^5J_m^{H,F}$ in benzoyl fluoride derivatives is somewhat dependent on intrinsic (nonstereospecific) substituent perturbations (13, 31, 35). For example, $^5J_m^{H,F}$ in benzoyl fluoride is 1.33 Hz (31), whereas it is 1.29 (1.30) Hz (35) in the presence of a *para* chlorine (methyl) substituent. Because of synthetic difficulties (13) no compound has been prepared in which a conformer analogous to either **3***a* or **3***b* is the only one in solution. Therefore it is not known whether the coupling to H-3 in **3***a* or to H-5 in **3***b* vanishes. However, because the internal rotational barrier in benzoyl fluoride is again large compared to *kT* (6, 7, 14), a discussion in terms of O-*syn* and O-*anti* conformers is sensible at ambient temperatures.

Whether the two conformers are those in which the lowest energy corresponds to coplanarity of the CFO and ring moieties cannot be said. However, in 2,6-dimethylbenzoyl fluoride substantial twisting (perhaps by 20°) about the exocyclic C—C bond was indicated by the observed $^6J_p^{H,F}$ and by the proximate $^5J_o^{F,CH_3}$ values (12).

A consistent description of the conformational equilibrium of **3** can be reached as follows. The sum of the two $^5J_m^{H,F}$ numbers in **3** is 2.23 Hz. If $^5J_3^{H,F}$ and $^5J_5^{H,F}$ are zero in the O-*anti* and O-*syn* forms, respectively, it follows that the O-*anti* conformer is 25% abundant in CCl_4 solution at 305 K. For this population distribution, the INDO MO FPT calculations (12) of $^5J_o^{F,CH_3}$ give good agreement (1.87 Hz) with the observed value of 1.84 Hz for a twist angle of 1° in both forms. If the latter rises to 20°, the calculated $^5J_o^{F,CH_3}$ drops to 0.33 Hz for the indicated conformer populations (the calculations assumed that one C—H bond of the methyl group eclipses the C_2—C_3 bond of the ring).

The error in the estimate of the conformer distribution is uncertain; yet, because the two $^5J_m^{H,F}$ couplings differ by a factor of three, it is very likely that the O-*syn* form is by far the most abundant.

Molecular Orbital Calculations on 2-Methylbenzoyl Fluoride

Partial optimization of the geometry at the STO-3G level of MO theory gave the results in structure **3**. The O-*syn* form is calculated as 6.64 kJ/mol lower in energy (enthalpy, apart from a $P\Delta V$ term and the contribution of internal motions) than the O-*anti* form, corresponding to 93% O-*syn*. The free energy difference between **3***a* and **3***b* is 2.8 kJ/mol in CCl_4 solution at 305 K, corresponding to ≥75% O-*syn*. If the entropy difference between the conformers is small and if the chlorine substituent *para* to the COF group exerts a minor influence on conformational stability, the STO-3G numbers overestimate the preference for the O-*syn* form by about 4 kJ/mol.

Solvent stabilization of the conformers should be similar for both forms because INDO MO computations on the STO-3G geometries in structure **3** yielded very similar dipole moments, 3.38 and 3.46 D for the O-*syn* and O-*anti* forms, respectively. The slightly larger dipole moment calculated for the O-*anti* form *is* consistent with a small shift towards the latter in solution.

It is of interest that, for the STO-3G geometries, INDO MO FPT calculations suggest that $^5J^{F,CH_3}$ is −0.45 Hz, in obvious disagreement with experiment and with the calculations mentioned in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

previous section. The latter agreed with the observed value of 1.84 Hz. This fact can be traced to the geometry of the CFO group in the two computations. In the previous calculation, the geometry of the COF group was taken as that in acetyl fluoride (also assumed in the microwave work (6)). In the O-*anti* form a large coupling (26 Hz) is predicted between ^{19}F and the proton in the methyl C—H bond eclipsing the ring (rear-lobe interaction (22)). It is this coupling which dominates the calculated average. In the STO-3G geometry, this rear-lobe coupling sinks to 2.1 Hz because the distance between the fluorine atom and the carbon atom of the methyl group has increased by 0.45 Å.

It is tempting to suggest that the observed 1.84 Hz for $^5J^{F,CH_3}$ proves the existence of an appreciable amount of the O-*anti* conformer of **3** because the INDO MO FPT calculations find substantial positive values only for the rear-lobe orientation of the C—F and C—H bonds and because (22) this prediction is independent of the intervening electronic structure. However, it is clear that, although the $^5J^{F,H}$ numbers for the ring protons also indicate the presence of appreciable amounts of the O-*anti* form, the quantitative agreement with $^5J^{F,CH_3}$ mentioned in the previous section must be viewed as a coincidence. The sensitivity of $^5J^{F,CH_3}$ to internuclear distances probably means that this coupling must be restricted to a qualitative indicator of conformational populations.

Conclusions

Satisfactory agreement exists between various experimental determinations and optimized STO-3G calculations of the conformational equilibrium for 2-methylbenzaldehyde. 2-Trifluoromethylbenzaldehyde exists predominantly (>95%) in the O-*syn* conformation in benzene solution. For 4-chloro-2-methylbenzoyl fluoride in CCl_4 solution experiment and theory are in semi-quantitative agreement; the O-*syn* form being present to the extent of 75% or more. The proximate coupling, $^5J_o^{CHO,CF_3}$, in 2-trifluoromethylbenzaldehyde is 2.2 Hz; in disagreement with the negative values calculated by INDO MO FPT for reasonable geometries.

Acknowledgments

CHOI CHUCK LEE, ERIC C. F. KO, and ZVI RAPPOPORT. Can. J. Chem. **58**, 2369 (1980).

In the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc – 30% H_2O, the presence of up to 30 equiv. of added NaOAc or 25 equiv. of added Et_4NBr did not significantly change the extent of scrambling of the label from C-2 to C-1 in the reaction product. The mean scrambling value observed for **1**-Br-2-^{14}C under a variety of conditions was 14.7 ± 0.7%. On the other hand, in the similar solvolysis of trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C), the extent of scrambling in the product was found to decrease with increasing amounts of added NaOAc. The observed scramblings varied from a mean of 27.7% to 5.7%, respectively, for reactions without and with 10 *M* added NaOAc. With **1**-Br-2-^{14}C, the possibility is considered that ionization proceeds only to an ion-pair in which the scrambling via 1,2-phenyl shift is not affected by the presence of added OAc^-. In the case of **2**-Br-2-^{14}C, further dissociation to the free trianisylvinyl cation took place and in the dissociated ion, competition between the scrambling process and capture reactions with all the nucleophiles present resulted in a decrease in the extent of scrambling with the presence of the more nucleophilic OAc^-. Using the extents of scrambling as well as product data, various ratios including k_{SOH}/k_r, k_{OAc}/k_r, k_{OAc}/k_{H_2O}, and k_{OAc}/k_{HOAc}, are evaluated.

CHOI CHUCK LEE, ERIC C. F. KO et ZVI RAPPOPORT. Can. J. Chem. **58**, 2369 (1980).

Lors de la solvolyse du bromure (Br-**1**-^{14}C-2) de triphénylvinyle (^{14}C-2) dans une solution aqueuse de AcOH à 70%, l'addition de 30 équiv. de AcONa ou de 25 équiv. de Et_4NBr n'affecte pas d'une façon significative le degré de distribution au hasard du marqueur entre C-2 et C-1 dans le produit de la réaction. La valeur moyenne observée pour le mélange est de 14,7 ± 0,7% dans le cas du Br-**1** ^{14}C-2 sous différentes conditions. D'autre part, on a trouvé que la solvolyse du bromure (Br-**2**-^{14}C-2) de trianisylvinyle (^{14}C-2) dans les mêmes conditions provoquent une distribution au hasard dont le degré diminue avec une augmentation de AcONa ajoutée. Les taux de distribution au hasard observés varient d'une moyenne de 27,7% à 5,7% respectivement dans les réactions se faisant avec ou sans addition de AcONa 10 *M*. Dans le cas du Br-**1**-^{14}C-2, on considère la possibilité d'une ionisation se faisant au moyen d'une paire d'ions dans lesquels la distribution au hasard, qui provient d'un glissement 1,2 du phényle, n'est pas affectée par la présence du AcO^-. Dans le cas du Br-**2**-^{14}C-2, une dissociation plus poussée du cation trianisylvinyle se produit et dans l'ion dissocié la compétition entre les réactions de distribution au hasard et celle de capture avec tous les nucléophiles présents provoque une diminution du degré de distribution au hasard avec la présence du AcO^- plus nucléophile. En utilisant les degrés de distribution au hasard observées ainsi que les données relatives aux produits obtenus on a évalué plusieurs rapports comprenant: k_{SOH}/k_r, k_{AcO}/k_r, k_{AcO}/k_{H_2O} et k_{AcO}/k_{AcOH}.

[Traduit par le journal]

β-Aryl rearrangements arising from 1,2-aryl shifts across the double bond of triarylvinyl cations have been extensively studied (1, 2). Degenerate rearrangements from 1,2-phenyl or 1,2-anisyl shifts in triphenylvinyl or trianisylvinyl cationic systems have been investigated under a variety of conditions (3–9). It is generally agreed that the dissociated "free" trianisylvinyl cation can be formed from trianisylvinyl substrates (6, 7, 9, 10). However, the extent of scrambling observed during solvolyses of triphenyl[2-^{14}C]vinyl triflate (**1**-OTf-2-^{14}C) in HOAc, HCOOH, or CF_3COOH was found to be unaffected by the presence of 1.1 equiv. of the conjugate base of the respective solvents (3). Moreover, in the solvolysis of triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc – 30% H_2O, the presence of about 3 equiv. of NaOAc or NaBr did not change the extent of degenerate rearrangement (8). It was, therefore, suggested that the rearrangement in the triphenylvinyl cationic system proceeds at the ion-pair stage rather than at the free cation stage (3, 8). This suggestion is consistent with the expected substituent effects on the stability of cationic intermediates in solvolytic reactions. The triphenylvinyl cation would be less stable than the trianisylvinyl cation, and its reaction should proceed to an earlier intermediate stage than the dissociated "free' cation in Winstein's solvolysis scheme (11, 12). Indeed, in the decomposition of triphenyl[2-^{14}C]vinylphenyltriazene (**1**-NNNHPh-2-^{14}C) which presumably proceeds via the free cation, no rearrangement was observed when the decomposition was carried out in HOAc,

CF_3COOH, or acetone–H_2O–$HClO_4$ (7). On the other hand, the decomposition of trianisyl[2-^{14}C]-vinylphenyltriazene (**2**-NNNHPh-2-^{14}C) in HOAc and in HOAc + 1.7 equiv. NaOAc resulted in about 38% and 17% scramblings, respectively, of the label from C-2 to C-1. The decrease in scrambling in the presence of NaOAc was attributed to a competition between the rearrangement process and reaction of the dissociated trianisylvinyl cation with the more nucleophilic acetate ion (7).

Vinylic solvolyses are often carried out in the presence of an added base, such as the conjugate base of the solvent, in order to avoid the possible addition–elimination (Ad_E–E) reaction with the liberated acid (13). Since capture of the cation by either the solvent or its conjugate base would lead to the same product, it would be of interest to ascertain whether the solvent or the conjugate base is the capturing nucleophile. Previous analyses on changes in the selectivity constants for triarylvinyl cations (14, 15) and on the effects of different acetate concentrations on *cis* ⇄ *trans* isomerization accompanying solvolyses of *cis*- and *trans*-1,2-dianisyl-2-phenylvinyl bromides (16) have led to the suggestion that the acetate ion is the capturing nucleophile in HOAc, at least for relatively stable α-arylvinyl cations. Another approach to an evaluation of the capture ratio for a triarylvinyl cation by OAc^- and by HOAc (k_{OAc}/k_{HOAc}) can be based on data from degenerate rearrangements. For a mechanism as depicted in Scheme 1, where I and I′ are the unrearranged and rearranged cation or ion-pair intermediates, eq. [1] holds for reactions at completion.

SCHEME 1

[1] $[RY]/[R'Y] = 1 + (k_{SOH}/k_r)$

For the decomposition of **2**-NNNHPh-2-^{14}C in HOAc or HOAc–NaOAc (7), I and I′ would be the unrearranged and rearranged trianisyl[2-^{14}C]vinyl and trianisyl[1-^{14}C]vinyl cations, giving rise to trianisyl[2-^{14}C]vinyl and trianisyl[1-^{14}C]vinyl acetates (**2**-OAc-2-^{14}C and **2**-OAc-1-^{14}C) as products. Furthermore, a statistical factor of 2 should be applied in the k_r process (17), giving rise to eq. [2].

[2] [**2**-OAc-2-^{14}C]/[**2**-OAc-1-^{14}C] = $1 + (k_{SOH}/2k_r)$

Using the mean scrambling values of 38.1 and 16.8%, respectively, for the decomposition of **2**-NNNHPh-2-^{14}C in HOAc and in HOAc with 1.7 equiv. (0.24 *M*) NaOAc (7), and since neat HOAc corresponds to a concentration of 17.5 *M*, eqs. [3] and [4] are derived from eq. [2].

[3] $17.5k_{HOAc}/2k_{r(An)} = 0.62$

[4] $(17.5k_{HOAc} + 0.24k_{OAc})/2k_{r(An)} = 3.95$

From eqs. [3] and [4], the dimensionless k_{OAc}/k_{HOAc} is calculated to be 3.9×10^2.

The above k_{OAc}/k_{HOAc} ratio of about 390 is, of course, calculated for the selective capture, by OAc^- and HOAc, of the "hot" trianisylvinyl cation derived from the decomposition of **2**-NNNHPh-2-^{14}C which presumably took place via the diazonium ion. Under solvolytic conditions, this ratio may very well be quite different. In any event, when the concentration of HOAc compared to that of OAc^- is large, there is the possibility that the previously observed (3, 8) insensitivity of the extent of scrambling to the presence of added OAc^- ion in the less selective triphenylvinyl cationic system may be due to a predominant product formation from capture of a free ion by the excess HOAc. Such an alternative explanation would invalidate the suggestion that the rearrangement occurs in the ion-pair stage for the triphenylvinyl cationic system. In an attempt to clarify the situation, we have carried out further solvolytic studies with triphenyl[2-^{14}C]vinyl bromide (**1**-Br-2-^{14}C) in 70% HOAc – 30% H_2O (by volume) in the presence of large amounts of added NaOAc or Et_4NBr. The solvent system of 70% HOAc – 30% H_2O was chosen (8) because reaction of **1**-Br-2-^{14}C in pure HOAc, with or without added NaOAc, was impractically slow. For comparison, experiments were also carried out to study the effects of added NaOAc and/or Et_4NBr on the extent of scrambling observed during solvolyses of trianisyl[2-^{14}C]vinyl bromide (**2**-Br-2-^{14}C) in 70% HOAc – 30% H_2O.

Results and Discussion

The labeled **1**-Br-2-^{14}C and **2**-Br-2-^{14}C were prepared as previously described (3, 5, 9). The solvolyses in 70% HOAc, carried out in sealed tubes, have also been described earlier (8). With **1**-Br-2-^{14}C as substrate, the reactions were effected in the presence of up to 30 equiv. of added NaOAc at 150 ± 2°C for 2 days. One experiment was also done in the presence of 25 equiv. of Et_4NBr, but the reaction time was increased to 4 days. The reaction products, 1,2,2-triphenyl[1,2-^{14}C]ethanone (**3**-1,2-^{14}C) or **3**-1,2-^{14}C and triphenyl[1,2-^{14}C]vinyl acetate (**1**-OAc-1,2-^{14}C), were degraded via $LiAlH_4$

[a]From titration of the liberated bromide.
[b]Data from ref. 8. The recovered unconsumed reactant was found to show essentially no scrambling (0.5% or less) (8).
[c]The only product was 1,2,2-triphenylethanone. A control experiment showed that an initial addition of 25 m*M* triphenylvinyl acetate to the reaction mixture was completely hydrolyzed to the ketone.
[d]NaBr was used instead of Et_4NBr (8).
[e]Salting out of the substrate resulted in its incomplete dissolution. The lower extent of reaction was apparently due to this incomplete dissolution.
[f]The product was 86% ketone and 14% acetate as estimated by nmr. A control experiment showed that an initial addition of 25 m*M* triphenylvinyl acetate to the reaction mixture resulted in its extensive but not complete hydrolysis to the ketone.
[g]After 4 days.

reduction to 1,2,2-triphenyl[1,2-^{14}C]ethanol (**4**-1,2-^{14}C) followed by $KMnO_4$ oxidation to diphenyl [^{14}C]ketone (**5**-^{14}C) to give the extent of scrambling of the label from C-2 to C-1. These procedures have also been reported previously (3, 8). The results, together with some related data from an earlier study (8), are summarized in Table 1.

With **2**-Br-2-^{14}C as substrate, the solvolyses were carried out at 120 ± 1°C for different lengths of time in the presence of various amounts of added NaOAc and/or Et_4NBr. The product mixture, **2**-OAc-1,2-^{14}C and 1,2,2-trianisyl[1,2-^{14}C]ethanone (**6**-1,2-^{14}C), was also reduced with $LiAlH_4$ to 1,2,2-trianisyl[1,2-^{14}C]ethanol (**7**-1,2-^{14}C) and then oxidized to dianisyl[^{14}C]ketone (**8**-^{14}C) to give the extent of scrambling, again using previously described procedures (9). In some of the experiments with **2**-Br-2-^{14}C, the possibility of scrambling in the recovered, unconsumed reactant was also investigated using a previously reported method (9). After the $LiAlH_4$ treatment of a mixture of product and unconsumed reactant, the latter was converted to trianisyl[1,2-^{14}C]ethene (**9**-1,2-^{14}C) which was separated from the **7**-1,2-^{14}C by passage through an alumina column. Ozonolysis of **9**-1,2-^{14}C gave **8**-^{14}C and the extent of scrambling in the unconsumed reactant. The results are summarized in Table 2.

From Table 1, it is seen that for the solvolysis of **1**-Br-2-^{14}C in 70% HOAc at 150 ± 2°C for 2 days, both the extent of reaction and the extent of scrambling in the product were virtually independent of large changes in the concentration of the added NaOAc or in the NaOAc:substrate ratio. In the presence of 750 m*M* NaOAc (Expt. 9, Table 1), an appreciable salting out of the **1**-Br-2-^{14}C took place resulting in the incomplete dissolution of the substrate. The lower extent of reaction observed in this experiment apparently reflected the reaction of only a fraction of the substrate that was in solution.

A rate increase at higher NaOAc concentrations could have been anticipated as a result of a normal salt effect (18). Alternatively, if products were formed from the free, dissociation triphenylvinyl cation, a greater extent of product formation with a consequent decrease in external ion return and an increase in rate would be expected at higher salt concentrations. The insensitivity of the extent of reaction to changes in [NaOAc] would suggest that neither of these effects were very large in the solvolysis of **1**-Br-2-^{14}C in 70% HOAc.

Previously, it was shown that the extent of scrambling in the product from solvolysis of **1**-Br-2-^{14}C in 70% HOAc was independent of reaction time (8), and this was as expected since no significant scrambling was observed in the recovered, unconsumed reactant (8). However, it is of interest to note that the presence of added Br^- ion did decrease the rate of reaction (Expt. 3 and 10, Table 1). Such a common ion rate depression has often been attributed to a return to covalent reactant from the dissociated ions. If such an external ion return were involved in the present studies with **1**-Br-2-^{14}C, one would expect the observation of scrambling in the recovered reactant, but this was not the case.

Thus the results from the solvolysis of **1**-Br-2-^{14}C in 70% HOAc still present a dilemma in their in-

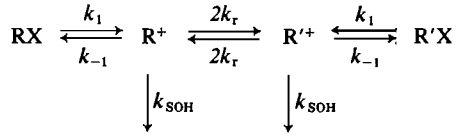
terpretation. On the one hand, the insensitivity of the extent of scrambling to the presence of added OAc^- or Br^- would suggest that the species undergoing scrambling is not affected by the added nucleophiles, and such a species could be an ion-pair. On the other hand, the common ion rate depression indicates the probable formation of and returns from dissociated free ions, and this is inconsistent with the absence of scrambling in the recovered reactant. Resolution of this dilemma will require further experimentation, including more detailed kinetic studies and possibly an investigation to ascertain if anion exchange occurs between the substrate and some added [^{82}Br]bromide. It is, however, of interest to report at this time the results given in Table 1, which show that added NaOAc, even in an amount sufficiently large to salt out some of the substrate (Expt. 9, Table 1), still failed to cause any detectable change in the extent of scrambling.

It has been pointed out that in the present studies with 1-Br-2-^{14}C, the product was mainly 1,2,2-triphenyl[1,2-^{14}C]ethanone (3-1,2-^{14}C). As indicated in footnotes *c* and *f* of Table 1, under the reaction conditions employed, most, if not all, of any acetate product, 1-OAc-1,2-^{14}C, that might have been formed would be hydrolyzed to the ketone. However, for the reaction in 70% HOAc in the presence of 0.75 *M* added NaOAc (Expt. 9, Table 1), some acetate product did survive, the ratio of ketone: acetate being 86:14. Recent reactivity–selectivity studies in mixed solvents assumed that the ratio of the capture products was given by the ratio of the bimolecular rates of reaction with the solvent components (19). With this assumption and using 12.2 *M* and 16.7 *M*, respectively, as [HOAc] and [H_2O] for 70% HOAc – 30% H_2O, eq. [5] may be written for Expt. 9, Table 1.

$$[5] \quad (12.2k_{HOAc} + 0.75k_{OAc})/16.7k_{H_2O} = 14/86$$

The product ratio of 14/86 is the minimum since some of the acetate formed must have been hydrolyzed to the ketone. If it were assumed further that capture by acetate is dominant over capture by HOAc, i.e. $0.75k_{OAc} \gg 12.2k_{HOAc}$, then from eq. [5] a minimum value for k_{OAc}/k_{H_2O} of 3.6 is obtained. Thus if the assumption of $0.75k_{OAc} \gg 12.2k_{HOAc}$ holds, the finding that some acetate has survived in Expt. 9, Table 1, would suggest that product forming capture by OAc^- is faster than by H_2O.

An interesting question is whether the possible involvement of ion-pairs in 70% HOAc can be extrapolated to pure HOAc. The occurrence of 1,2-phenyl shifts in the ion-pair stage was suggested by the similar extent of scrambling (6–7%) observed in the solvolysis of 1-OTf-2-^{14}C in HOAc and in HOAc containing 0.55 *M* NaOAc (3). The coincidence that 6–7% scrambling was also obtained in the solvolysis of 1-Br-2-^{14}C or 1-Br-2-^{13}C in HOAc–AgOAc (4) would be inconsistent with an ion-pair mechanism since the difference in the counter ions would be expected to affect the extent of scrambling in the ion-pairs. However, these difficulties could be rationalized from consideration of the scrambling data obtained in the solvolyses of 1-Br-2-^{14}C in aqueous HOAc (8). While solvolysis of 1-Br-2-^{14}C in pure HOAc is too slow for practical study, reactions of 1-Br-2-^{14}C in HOAc–H_2O containing different amounts of the two solvent components have been carried out. The extent of scrambling was found to increase with increasing amounts of HOAc, the scramblings varying from a mean of 9.6% in 50% HOAc to a mean of 18.4% in 90% HOAc (8). An extrapolated value of about 20% scrambling would be obtained for pure HOAc, and this value is quite different from the 6–7% scrambling found for the acetolysis of 1-OTf-2-^{14}C, indicating that the leaving group indeed exerts an effect on the extent of scrambling. It is probable that the reactions of 1-Br-2-^{14}C with HOAc–H_2O and with HOAc–AgOAc may follow different mechanisms. It may be suggested that in the presence of AgOAc, a quadrupolar type of intermediate, formulated as **10**, may be obtained. Such an intermediate could give rise to a product with a lesser extent of scrambling than that observed for solvolysis in HOAc–H_2O. A similar type of interaction may be proposed to account for the observation of a net retention of the *cis*- or *trans*-configuration in the reaction of *cis*- or *trans*-1-phenylpropen-1-yl bromide with CF_3COOAg in isopentane (20).



10

In considering the scrambling results given in Table 2 for the solvolysis of 2-Br-2-^{14}C in 70% HOAc, an obvious difference in behavior from that of 1-Br-2-^{14}C is that the extent of scrambling in the product is decreased by the presence of added NaOAc. It should be noted, however, that relatively small changes in [NaOAc] did not give a measurable decrease in scrambling, as may be seen from Table 2 in that the mean scrambling value for Expt. 1–5 is the same as that observed for Expt. 9, and similarly, there is no significant difference in the mean scrambling for Expt. 13–16 and the scrambling for Expt. 17. Since the precision in measuring ^{14}C scramblings in this and previous studies could show variations as large as ±1%, it is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

not surprising that small changes would not be detectable. In considering all the scrambling data in Table 2 as a whole, it is clear that there is a decrease in the extent of scrambling with increasing amounts of added NaOAc.

It is also apparent from Table 2 that for a given concentration of added NaOAc, and with the Et_4NBr concentration of up to 177 m*M*, the scrambling found in the product did not change with the extent of reaction (e.g. Expt. 1–5, Table 2, no NaOAc, scrambling of 27.7 ± 0.3%; Expt. 13–16, Table 2, 178 m*M* NaOAc, scrambling of 24.7 ± 0.6%). This independence of scrambling in the product with reaction time is consistent with the finding that in some of these experiments which did not go to completion, the recovered, unconsumed reactant showed very little scrambling (1% or less). Yet under these conditions, the presence of added Et_4NBr did cause a decrease in reaction rate as indicated by the % reaction determined for the individual runs. Thus similar to the behavior of **1**-Br-2-^{14}C, when the solvolysis of **2**-Br-2-^{14}C was carried out in the presence of up to 177 m*M* Et_4NBr, there was a rate depression but the recovered reactant was not significantly scrambled. When the concentration of Et_4NBr was much higher (0.5–2.0 *M*, Expt. 6–8, Table 2), significant extents of scrambling were observed in the recovered reactant, indicating return from scrambled ionic species to covalent reactant. In these three experiments (Expt. 6–8, Table 2), the scrambling in the product also increased with an increase in the extent of reaction, and this is as expected for a reaction which involves returns to give scrambled reactant (8, 9).

SCHEME 2

The behavior of **2**-Br-2-^{14}C during its solvolysis in 70% HOAc as discussed above may be explained by a mechanism as depicted in Scheme 2, where X^- is Br^- and R^+ and R'^+ are the unrearranged and rearranged trianisyl[2-^{14}C]vinyl and trianisyl[1-^{14}C]vinyl cations, respectively. In this scheme, the product-forming ionic species is the dissociated cation, and processes leading to the formation of scrambled reactant, R'X, are also included. At complete reaction, eq. [6] can be used to calculate

$$[6] \quad [ROS]/[R'OS] = 1 + (k_{SOH}/2k_{r(An)})$$

$k_{SOH}/k_{r(An)}$, even if there were returns to R'X after partial reaction (6). Since eq. [6] does not involve the concentration of the substrate, the extent of scrambling should be independent of substrate concentration, and this is found (cf. e.g. Expt. 23 and 24, Table 2).

For the solvolysis of **2**-Br-2-^{14}C in the presence of 177 m*M* Et_4NBr or less, the extent of returns from the $k_{-1}[Br^-]$ process is relatively small. Hence the scrambling found in the recovered reactant is low (1% or less) and it does not significantly affect the extent of scrambling in the product with changing extents of reaction. At high concentrations of added Br^- as in Expt. 6–8, Table 2, the extent of returns from the $k_{-1}[Br^-]$ process is sufficiently large to give significant amounts of scrambling in the recovered reactant, and the scrambling in the product also varies with changes in the extent of reaction as was observed. Moreover, since the dissociated ion can undergo competitively 1,2-anisyl shift and capture reactions with the various nucleophiles that are prssent, the addition of the more nucleophilic OAc^- ion to the reaction mixture would favor the formation of more unrearranged product at the expense of the 1,2-shift process, resulting in the observed decrease in scrambling with increasing amounts of added OAc^-.

In the product forming processes, k_{SOH} is the pseudo first order rate constant for the bimolecular capture of the cation by all the nucleophiles present. A separation of the effects of added OAc^- in the 70% HOAc – 30% H_2O solvent system may be facilitated by the definitions given in eqs. [7] and [8].

$$[7] \quad k_{SOH} = k_{HOAc}[HOAc] + k_{H_2O}[H_2O] = 12.2k_{HOAc} + 16.7k_{H_2O}$$

$$[8] \quad k_{SOH'} = k_{OAc}(OAc^-] + k_{HOAc}[HOAc] + k_{H_2O}[H_2O] = k_{OAc}[OAc^-] + k_{SOH}$$

Using the scrambling data in Table 2 for experiments that were carried to completion or the mean scrambling values for the various series of experiments in which the scrambling was independent of reaction time, applying eq. [6], $k_{SOH'}/k_{r(An)}$ can be calculated from eq. [9].

$$[9] \quad (100 - \%\text{scrambling})/\%\text{scrambling} = 1 + (k_{SOH'}/2k_{r(An)})$$

These calculated $k_{SOH'}/k_{r(An)}$ results are given in Table 2. For Expt. 1–5 in which no acetate was added, the $k_{SOH'}/k_{r(An)}$, of course, is the same as $k_{SOH}/k_{r(An)}$. It is seen that $k_{SOH'}/k_{r(An)}$ increases with increasing amounts of added OAc^-, and this change

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

is in the direction expected since the addition of OAc^- favors product formation, the $k_{SOH'}$ process, at the expense of scrambling, the $k_{r(An)}$ process.

For Expt. 1–5, Table 2, with no added acetate and with a mean scrambling value of 27.7%, and for Expt. 10, Table 2, with 30 m*M* of added acetate and a scrambling value of 25.9%, eqs. [10] and [11], respectively, can be written.

[10] $k_{SOH}/k_{r(An)} = 3.2$

[11] $k_{SOH'}/k_{r(An)} = (0.03k_{OAc} + k_{SOH})/k_{r(An)} = 3.7$

From eqs. [10] and [11], eqs. [12] and [13] can be obtained.

[12] (From [11]/[10]) $k_{OAc}/k_{SOH} = 5.2\,M^{-1}$

[13] (From [12] × [10]) $k_{OAc}/k_{r(An)} = 5.2 \times 3.2 = 16.6\,M^{-1}$

The ratios of k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ have a unit of M^{-1} because k_{SOH} is a pseudo first order rate constant and no composite concentration for the $HOAc–H_2O$ solvent system was used in the calculations. These ratios, calculated for different amounts of added OAc^-, are included in Table 2.

It is seen from Table 2 that these selectivity ratios, k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$, are not constant, showing variations with changing amounts of added OAc^-. Clearly, the activities of the acetate ion rather than its concentrations are involved in the rates of reaction, and correction of such effects would be more drastic at higher concentrations. Thus there should be a decrease in these ratios with increasing concentrations of added acetate. Reduction of the activities of the solvent components by their involvement in the solvation shells of the added salts should also change the k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ ratios, but in an opposite direction, causing an increase in these ratios with increasing concentrations of added acetate. These two opposing effects could qualitatively explain the trend of behavior for k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ with changing concentrations of added acetate. With increasing $[OAc^-]$, there is initially a sharp decrease in these selectivity ratios, but on further increases in acetate concentration, these ratios decline more gradually, reaching an essentially constant level and then eventually rises slightly at very high acetate concentrations, conforming to expectation from two opposing effects.

Ionic strength and salt effects might also affect the selectivity ratios, k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$. The rate of reaction between oppositely charged ions, i.e. the capture of the trianisylvinyl cation by the acetate anion or the k_{OAc} process, should decrease with increasing ionic strength, whereas the rearrangement by 1,2-shift and the capture of the cation by the neutral solvent components, the k_r and k_{SOH} processes, should be less affected. The net result would be a decrease in k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ with increasing concentrations of added salts. However, on considering, for example, Expt. 13–16, Table 2, it is seen that in these experiments with 178 m*M* of added NaOAc, the absence or presence of 177 m*M* of added Et_4NBr gave essentially the same extent of scrambling and the same calculated k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ ratios. The ionic strength of the reaction mixture is obviously different in the absence or in the presence of added Et_4NBr, but its lack of influence on the extent of scrambling would suggest that the effect of ionic strength cannot be a major factor in causing the variations in the k_{OAc}/k_{SOH} and $k_{OAc}/k_{r(An)}$ ratios.

In the experiments with **2**-Br-2-^{14}C as recorded in Table 2, no systematic analysis was done on the acetate to ketone (**2**-OAc-1,2-^{14}C:**6**-1,2-^{14}C) ratios in the reaction products; although in a few cases when the product was examined by nmr, both **2**-OAc-1,2-^{14}C and **6**-1,2-^{14}C were detected. In contrast to the extensive hydrolysis of the acetate to ketone during the solvolysis of **1**-Br-2-^{14}C, the shorter reaction times employed in the studies with **2**-Br-2-^{14}C presumably may have been more favorable for the survival of some of the acetate product. A few control experiments on product distribution have been carried out with non-radioactive **2**-Br. The solvolysis of 5.9 m*M* **2**-Br in 70% HOAc at 120°C for 4 min (conditions similar but not identical to Expt. 1, Table 2) resulted in the formation of 27% acetate (**2**-OAc) and 73% ketone (**6**). When this experiment was repeated but with 5.9 m*M* of **2**-OAc added initially to the reaction mixture, analysis of the product mixture showed that 57% of the added acetate has survived and was not hydrolyzed to the ketone. Thus correcting for the 57% survival of acetate under these conditions, the 27% acetate that was formed should have been 27/0.57 = 47%. Similarly, the solvolysis of 5.9 m*M* **2**-Br in 70% HOAc at 120°C for 4 min and with the presence of 183 m*M* NaOAc (conditions similar but not identical to Expt. 13, Table 2) gave a 50:50 ratio for **2**-OAc and **6**. Again a reaction under the same conditions but with 5.9 m*M* of **2**-OAc also present showed 71% survival of the added acetate. Correcting for the 71% survival, the 50% acetate that was formed should have been 50/0.71 = 70% under these conditions.

From the above product analyses, using the corrected **2**-OAc contents of 47% and 70%, respectively, for reactions without and with the presence of 183 m*M* added NaOAc, and relationships as em-

For personal use only.

ployed in eq. [5], eqs. [14] and [15] are obtained.

[14] $12.2k_{HOAc}/16.7k_{H_2O} = 47/53$

[15] $(0.183k_{OAc} + 12.2k_{HOAc})/16.7k_{H_2O} = 70/30$

From [14] and [15], the selectivity ratios, k_{HOAc}/k_{H_2O}, k_{OAc}/k_{H_2O}, and k_{OAc}/k_{HOAc}, for the trianisylvinyl cation, can be calculated as 1.2, 1.3×10^2, and 1.1×10^2, respectively. It is of interest to note that the k_{HOAc}/k_{H_2O} value of 1.2 indicates a similar magnitude for the nucleophilicities of the two solvent components in 70% HOAc, in contrast to the much larger difference in nucleophilicities for the two pure solvents, HOAc and H_2O (21, 22). Probably, in a mixed solvent system, extensive intermolecular H-bonding may tend to equalize the nucleophilicities of the two solvent components. The k_{OAc}/k_{HOAc} value of 1.3×10^2 calculated from the present work is different from the value of 3.9×10^2 derived from data obtained in the decomposition of **2**-NNNHPh-2-^{14}C (7), although the two values are in the same order of magnitude. It is reasonable to expect such differences since the trianisylvinyl cation in the two studies are generated by different methods in different solvent systems.

Experimental

Solvolyses of Triphenyl[2-^{14}C]vinyl Bromide (1-Br-2-^{14}C)

Except for modifications in the relative amounts of substrate and added salt, the procedure used in the present work on the solvolysis of **1**-Br-2-^{14}C in 70% HOAc was essentially the same as reported previously (8). A typical experiment is described below (Expt. 4, Table 1).

A solution of 100 mg (0.30 mmol) of **1**-Br-2-^{14}C and 123 mg (1.5 mmol) of NaOAc in 20 mL of 70% HOAc in a sealed tube was heated in an oil bath at 150 ± 2°C for 2 days. After cooling in an ice bath, the tube was opened and about 200 mg of ordinary 1,2,2-triphenylethanone was added as carrier. The material was then extracted with $CHCl_3$ (3 × 25 mL) and the extract washed with dilute $NaHCO_3$ solution and with H_2O. The liberated Br^- in the combined aqueous phase was titrated potentiometrically with $AgNO_3$ to give the extent of reaction. The organic extract, after drying over $MgSO_4$, was worked up as described previously (8), including separation of the product from the unconsumed reactant by passage through an alumina column, conversion of the product to 1,2,2-triphenyl[1,2-^{14}C]ethanol by $LiAlH_4$ reduction, and $KMnO_4$ oxidation of the latter to diphenyl-[^{14}C]ketone to give the % scrambling, using procedures already reported (3, 8).

Solvolyses of Trianisyl[2-^{14}C]vinyl Bromide (2-Br-2-^{14}C)

The solvolyses of **2**-Br-2-^{14}C in 70% HOAc were carried out at 120 ± 1°C. The reaction conditions for the various experiments are given in Table 2. As an illustration, Expt. 15, Table 2, is described below.

A solution of 25.5 mg (0.060 mmol) of **2**-Br-2-^{14}C, 146 mg (1.78 mmol) of NaOAc and 372 mg (1.77 mmol) of Et_4NBr in 10 mL of 70% HOAc in a sealed tube was heated at 120 ± 1°C for 12 min. After cooling in an ice bath, the tube was opened and about 200 mg each of ordinary **2**-Br and **2**-OAc were added as carriers. The material was extracted with $CHCl_3$ (3 × 25 mL) and the extract washed with a dilute $NaHCO_3$ solution and then with H_2O. The Br^- in the combined aqueous phase was determined by potentiometric titration, the excess Br^- over the amount added as Et_4NBr gave the extent of reaction. The work-up procedure for the organic material was the same as described by Lee, Weber, and Obafemi (9), which included the following treatments. $LiAlH_4$ reduction effected the conversion of the product mixture (acetate **2**-OAc-1,2-^{14}C and ketone **6**-1,2-^{14}C) to 1,2,2-trianisyl[1,2-^{14}C]ethanol (**7**-1,2-^{14}C), and the unconsumed reactant to 1,2,2-trianisyl[1,2-^{14}C]ethene (**9**-1,2-^{14}C). After separation through an alumina column, the alcohol **7**-1,2-^{14}C was oxidized to dianisyl[^{14}C]ketone (**8**-^{14}C) to give the extent of scrambling in the product, while the olefin **9**-1,2-^{14}C was degraded by ozonolysis, also giving rise to **8**-^{14}C and the scrambling, if any, in the unconsumed reactant.

Reçu le 17 avril 1980

EDGAR SOULIÉ, GÉRARD FOLCHER et BASIL KANELLAKOPULOS. Can. J. Chem. **58**, 2377 (1980).

Les ions non de Kramers peuvent avoir un niveau électronique fondamental non dégénéré. Si en outre le premier niveau électronique excité est à plus de 0,3 cm^{-1} du niveau fondamental, la résonance paramagnétique électronique ne peut pas être excitée en bande X. C'est le cas chaque fois que la susceptibilité magnétique de poudre présente un paramagnétisme indépendant de la température. Un exemple de cette situation est présenté, $U(cupferron)_4$, en contradiction avec les spectres rpe publiés.

EDGAR SOULIÉ, GÉRARD FOLCHER and BASIL KANELLAKOPULOS. Can. J. Chem. **58**, 2377 (1980).

For non-Kramers ions, the electronic ground state may be nondegenerate. Then, if the first electronic excited level lies more than 0.3 cm^{-1} above the ground state, no electron paramagnetic resonance can occur between them in the X band. This is the case whenever a temperature-independent paramagnetism is observed in the magnetic susceptibility of the powder. An example of this situation, conflicting with published epr spectra, is provided by $U(cupferron)_4$.

Conditions d'observation de la résonance paramagnétique électronique et susceptibilité magnétique

La transition résonnante entre deux niveaux d'énergie électronique ne peut avoir lieu que s'il existe deux tels niveaux, distants de $h\nu$ avec $\nu = 9{,}6 \pm 0{,}5$ GHz en bande X. Dans le cas des ions de Kramers à nombre impair d'électrons, les niveaux d'énergie dégénérés en champ nul sont généralement décomposés par le champ magnétique, et il existe une valeur du champ telle que l'écart en énergie atteigne juste le quantum hyperfréquence. Sous réserve de l'ordre de grandeur du temps de relaxation électronique, un signal de rpe est donc le plus souvent observable.

Dans le cas des ions non de Kramers, à nombre pair d'électrons, le niveau d'énergie fondamental en champ nul peut être un singulet et les niveaux excités s'en écartent tous de plusieurs cm^{-1} ou plusieurs dizaines ou centaines de cm^{-1}. Aucune transition résonnante ne peut alors être induite. Corrélativement, la suceptibilité magnétique à basse température est une constante (paramagnétisme de Van Vleck) (fig. 1).

En effet, l'effet Zeeman ne peut pas agir comme perturbation du premier ordre sur un niveau fondamental singulet, de sorte que dans la formule de Van Vleck (1) le coefficient $\varepsilon^{(1)}$ relatif au niveau fondamental est nul.

$$\chi^{para}_{molaire}(T) = \frac{N\beta}{k} \sum_{états\ i} \left[\frac{(\varepsilon_i^{(1)})^2}{T} - 2\varepsilon_i^{(2)} \right] \times \exp\left[-\frac{E_i^{(0)}}{T} \right] \Big/ \sum_{états\ i} \exp\left[-\frac{E_i^{(0)}}{T} \right]$$

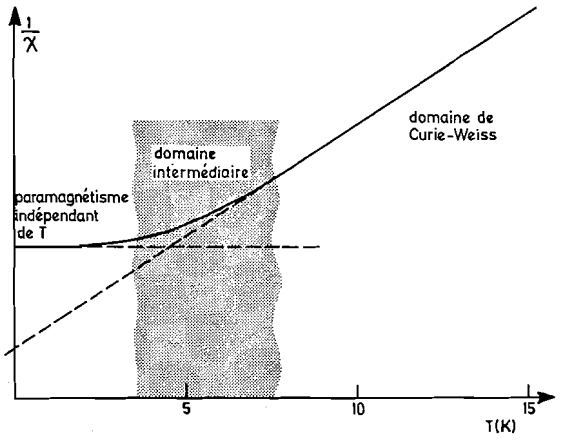

FIG. 1. Variation thermique de la susceptibilité paramagnétique χ d'un ion à nombre pair d'électrons dans le cas fréquent d'un niveau fondamental singulet et d'un premier niveau excité distant de quelques cm^{-1}. La susceptibilité est habituellement constante à très basse température, tandis qu'elle suit une loi de Curie–Weiss au-dessus d'une certaine température. Le domaine de température intermédiaire correspond au peuplement d'un premier état électronique excité, dont on peut, au moins grossièrement, estimer l'énergie: environ 2,5 cm^{-1} dans le cas représenté.

où

$$\varepsilon_i^{(1)} = \langle \psi_i | L_z + 2S_z | \psi_i \rangle$$

$$\varepsilon_i^{(2)} = \sum_{j(E_j^{(0)} \neq E_i^{(0)})} \frac{|\langle \psi_i | L_z + 2S_z | \psi_j \rangle|^2}{E_i^{(0)} - E_j^{(0)}}$$

pour la susceptibilité parallèle.

Une seconde possibilité est que le niveau fondamental soit un doublet non magnétique, c'est-à-dire non décomposé par le champ magnétique, quelle que soit sa direction.

Cette situation se rencontre avec les états sous-tendant la représentation irréductible E du groupe O en symétrie cubique. Là encore, l'effet Zeeman du premier ordre est nul, il n'y a pas de signal observable par RPE, et la suceptibilité magnétique est une constante à température suffisamment basse. Il se peut enfin que le niveau fondamental soit un "quasi-doublet", dont les composantes sont très peu distantes. (D'après le théorème de Jahn–Teller, un niveau fondamental doublet au sens strict n'est pas possible.) Pour qu'une transition résonnante soit possible il faut que l'écart en champ nul ΔE soit inférieur à l'énergie du quantum hyperfréquence, donc $\nu < 0{,}3\,\text{cm}^{-1}$. L'effet Zeeman du second ordre, qui est alors du même ordre de grandeur que ΔE sépare davantage les composantes de ce doublet approché (fig. 2). Williams a montré (2) que contrairement au cas habituel, le champ magnétique hyperfréquence doit être parallèle au champ magnétique statique, car le facteur $g_\perp$ est nul, rigoureusement. Le cas d'un niveau fondamental quasi-doublet diffère des deux précédents par l'allure de la courbe de susceptibilité magnétique. Pour $kT > 5\,\Delta E$ soit $kT > \simeq 2{,}2$ K, la susceptibilité est pratiquement la même que celle d'un *vrai* doublet et suit la loi de Curie–Weiss.

Pour résumer cette discussion, une condition nécessaire (mais non suffisante) à l'observation d'un signal de résonance paramagnétique électronique d'un ion non de Kramers est que la susceptibilité magnétique ne reste pas quasi-constante au-dessous d'une température de l'ordre de 2 K.

Les faits expérimentaux

Aucune étude magnétochimique sur un composé de l'uranium(IV) n'a, à notre connaissance, montré l'existence d'un niveau fondamental "quasi-dégénéré" ($\Delta E < 0{,}3\,\text{cm}^{-1}$). La possibilité d'une résonance paramagnétique électronique[1] due à l'uranium(IV) est donc exceptionnelle. Une telle résonance a peut-être été observée sur un monocristal de CaF_2 dopé à l'uranium(IV) (3).

On a par contre montré (4) que le signal de résonance observé avec UF_4 (5) était en fait dû à des impuretés de fer et de nickel. Pour de nombreux composés d'uranium(IV), par exemple UCl_4 (6), $U(C_5H_5)_4$ (7), $U(acac)_4$ et $U(SO_4)_2{\cdot}4H_2O$ (8), le paramagnétisme devient constant à basse température (fig. 2). Une résonance associée à l'uranium(IV) est impossible dans ces composés.

Or, Miyake, Yoshimura et Imoto ont publié le spectre de résonance électronique du tétrakis-(cupferrato)-uranium(IV) (9), $U(C_6H_5{-}N_2O_2)_4$, en abrégé $U(cupf)_4$ et plus récemment celui du tétrakis-(néocupferrato)-uranium(IV) (10) obtenu à 77 K. Nous n'avons jamais pu obtenir de spectre du complexe dérivé du cupferron avec le spectromètre Varian V 4500-15, ni à 77 K, ni à 4,2 K.

Yoshimura *et al.* (11) ont mesuré la susceptibilité magnétique de $U(cupf)_4$ en fonction de la température depuis la température de l'hélium liquide jusqu'à la température ambiante. Leur fig. 2 (11) fait ressortir que l'inverse de la susceptibilité paramagnétique ne tend pas vers zéro mais vers une valeur finie correspondant à $\chi^{para}_{\text{molaire}} = 0{,}0175\,\text{cm}^3/\text{mol}$. Nos propres mesures confirment l'allure de la fig. 2. de Miyake *et al.*, bien que les valeurs que nous obtenons soient sensiblement plus faibles: $\chi^{para}_{\text{molaire}} \simeq 0{,}012\,\text{cm}^{-3}/\text{mol}$.

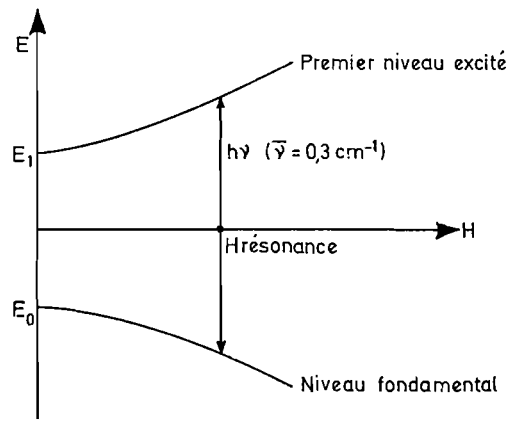

FIG. 2. Diagramme des niveaux d'énergie en fonction du champ magnétique appliqué dans le cas d'un "quasi-doublet" (au sens défini dans le texte). On notera que comme toute perturbation agissant au second ordre, l'effet Zeeman électronique augmente l'écart entre deux niveaux d'énergie par rapport à sa valeur en champ nul. La condition de résonance $h\nu = E_1(H) - E_0(H)$ implique donc $h\nu > E_1(H = 0) - E_0(H = 0)$, c'est-à-dire $E_1 - E_0 < 0{,}3\,\text{cm}^{-1}$ pour la rpe en bande X.

Conclusion

Nous en concluons donc que le signal de résonance que Miyake *et al.* (9) ont observé n'est pas dû à l'uranium(IV), mais à une impureté que nous n'avons pu identifier d'après leur spectre.

On ne doit pas être surpris par la présence d'un spectre d'impureté, en raison de la grande sensibilité de la résonance paramagnétique électronique. Ainsi avons-nous toujours obtenu deux signaux à température ambiante avec une solution aqueuse 1 M de tétrachlorure d'uranium. Nous avons attribué le signal sextuplet au manganèse divalent, et l'autre au fer trivalent. Les concentrations respectives de ces ions étaient $3 \times 10^{-6}\,M$ et $2 \times 10^{-5}\,M$. Par conséquent, l'élimination des signaux d'impureté exige d'amener les concentrations de certaines impuretés (métaux de transition) en-dessous de valeurs très faibles.

Enfin, nous suggérons que pour les composés d'uranium(IV) et plus généralement d'ions à nombre pair d'électrons, la susceptibilité paramagnétique de poudre soit toujours mesurée jusqu'à une température assez basse pour faire apparaître le palier de Van Vleck. Si ce palier n'apparaît pas à 4,2 K, comme cela se produit pour

[1] Il s'agit en fait plutôt d'une résonance paraélectrique comme l'a montré Williams (réf. 2, voir fig. 1).

$U[C_8H_4(C_6H_5)_4]_2$ (12), il faut diminuer la température jusqu'à 1 K ou mieux à 0,5 K, de telle façon qu'un niveau électronique fondamental "quasi-doublet", au sens indiqué plus haut, puisse le cas échéant être mis en évidence. C'est alors seulement qu'on pourrait entreprendre la recherche d'un signal rpe autentique.

Sulfonation of strychnine and some related compounds by sulfur dioxide – manganese dioxide (the Leuchs reaction)

Received March 12, 1980

JOHN T. EDWARD, PATRICK G. FARRELL, SYED A. SAMAD, RICHARD WOJTOWSKI, and SIN CHEONG WONG. Can. J. Chem. **58**, 2380 (1980).

On the basis of pK measurements, ^{13}C nmr, and chemical arguments, the zwitterionic structures **3** and **4** have been assigned to the two minor products obtained by sulfonating strychnine or brucine in water with a mixture of sulfur dioxide and manganese dioxide. The same reagent sulfonates the quaternary salts of strychnine and brucine to give betaines, but fails to sulfonate many other strychnine derivatives as well as a number of other alkaloids examined.

JOHN T. EDWARD, PATRICK G. FARRELL, SYED A. SAMAD, RICHARD WOJTOWSKI et SIN CHEONG WONG. Can. J. Chem. **58**, 2380 (1980).

La sulfonation de la strychnine ou de la brucine en solution aqueuse par un mélange de bioxyde de soufre et de bioxyde de manganèse conduit entre autre à deux produits secondaires **3** et **4** auxquels on a attribué une structure de zwitterion en se basant sur des mesures de pK, sur la rmn du ^{13}C et sur des arguments chimiques. Le même réactif sulfone les sels quaternaires de la strychnine ou de la brucine en donnant des bétaines mais n'arrive pas à sulfoner les autres dérivés de la strychnine ainsi qu'un certain nombre d'autres alcaloïdes étudiés.

[Traduit par le journal]

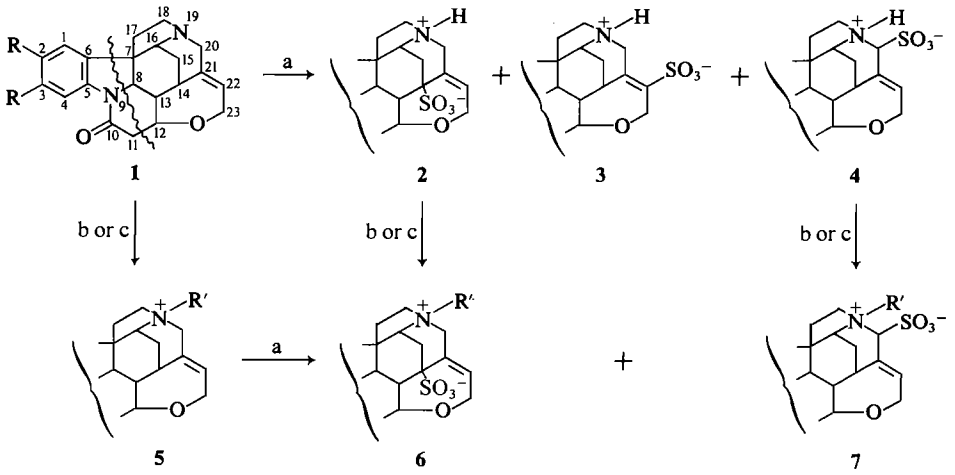
In arriving at a structure for strychnine (**1**; R = H) and brucine (**1**; R = OMe), Robinson (1) and Woodward and Brehm (2) relied heavily on experimental data of Hermann Leuchs, who published 125 papers between 1908 (3) and (posthumously) 1949 (4). While the final structure has served to rationalize most of Leuchs' vast accumulation of data (see G. F. Smith (5) for an excellent review), one reaction has remained unexplained and, to our knowledge, unparalleled. This is a sulfonation reaction brought about by sulfur dioxide and manganese dioxide in warm water, which we propose to name the "Leuchs sulfonation reaction".

In 1908 Leuchs and Schneider (6) obtained a compound $C_{21}H_{22}O_5N_2S \cdot H_2O$ as colourless crystals from the clear solution obtained by bubbling sulfur dioxide through a warm aqueous solution of strychnine containing suspended manganese dioxide. This compound was designated strychninesulfonic acid-I (SSA-I) when it was found that work-up of the mother-liquors afforded isomeric acids SSA-II SSA-III (7). A similar series of isomeric brucinesulfonic acids (BSA-I, BSA-III, and BSA-IV) was obtained by applying the same reaction to brucine (8, 9).

Leuchs and his collaborators continued to study these sulfonic acids for more than 30 years (10–21), but most of their findings do not advance our understanding of the structures of the compounds. However, they did interrelate SSA-I and BSA-I by the observation that oxidation of 2-aminostrychninesulfonic acid-I (obtained by nitration of the aromatic ring followed by reduction) and of BSA-I with chromic acid removed the benzene ring and gave the same sulfonic-carboxylic acid (16). This showed that the sulfonic acid group is not attached to the aromatic ring in SSA-I and BSA-I. Likewise, it is not attached to the 11-position, because all of the various strychnine- and brucinesulfonic acids react at this position with benzaldehyde to form benzylidine derivatives (20).

These results indicate that the sulfonic acid group of SSA-I and BSA-I must be attached to some skeletal position to the right of the wavy line shown in **1**. Smith (5) suggested that the most likely positions for all the sulfonic acids would be on the carbon atoms adjacent to the basic nitrogen N(19), which would account for the isomerism. The formation of the sulfonic acids would then involve dehydrogenation followed by bisulfite addition.

On repeating Leuchs' procedures, we succeeded in obtaining strychninesulfonic acids -I, -II, and -III. Similarly, we obtained brucinesulfonic acids -I, -III, and -IV. Leuchs found this last compound difficult to isolate because of its tendency to form mixed crystals with BSA-III (9) but our modified procedure gave pure BSA-III and -IV.



A comparison of the optical rotations of our products with those of Leuchs is given in Table 1. These suggest BSA-IV is the brucine analogue of SSA-II, and BSA-III that of SSA-III. The relations are confirmed by pK_{BH^+} measurements discussed below.

Reagents: a, SO_2/MnO_2; b, MeI or Me_2SO_4; c, $PhCH_2Br$

SCHEME 1

TABLE 1. Comparison of the optical rotations of strychninesulfonic acids (SSA) and brucinesulfonic acids (BSA) with those reported by Leuchs

	$[\alpha]_D^{25}$			$[\alpha]_D^{25}$	
SSA	Leuchs	This work	BSA	Leuchs	This work
I	−233°	−228°	I	−242°	−232°
II	−138°	−139°	IV	−122°	−121°
III	+163°	+176°	III	+157°	+151°

strychnine and brucine, the sulfonic acids must exist in neutral solution as zwitterions Z. This accords with their solubility characteristics. Thus SSA-I is almost insoluble in water, but dissolves readily in ammonium hydroxide, by loss of a proton from $\overset{+}{\diagdown\!\diagup}$N(19)—H to form the anion A, and in 20% hydrochloric acid, by addition of a proton to the sulfonic group to form the cation C, or to the amide group to form a tautomeric cation.

C Z A

X-ray diffraction studies of strychninesulfonic acid-I supplied by us to Professor L. Cartz and his colleagues (22) showed it to have the structure **2** (R = H), with the sulfonic acid group located at the allylic 14-position. This suggests the possible implication of the Δ^{21} double bond in the sulfonation reaction, a possibility supported by the failure of dihydrostrychnine (Δ^{21} saturated) to be sulfonated. On the other hand, the basic N(19) atom seems not to be involved in the reaction, because strychnine methosulfate (**5**; R = H, R′ = Me; counterion $MeOSO_3^-$) is sulfonated under Leuchs' conditions to give a sulfonic acid betaine. This betaine has the structure **6** (R = H, R′ = Me), since it is also obtained by treatment of SSA-I in alkaline solution (i.e., in the form A) with methyl iodide. Similarly, sulfonation of benzylstrychninium bromide (**5**; R = H, R′ = CH_2Ph; counterion Br^-) gave the betaine **6** (R = H, R′ = CH_2Ph). In addition, this reaction gave a second betaine, which could also be obtained by benzylation of SSA-III in alkaline solution; for reasons discussed below, we assign the structure **7** (R = H, R′ = CH_2Ph) to this betaine.

In similar fashion, brucine methosulfate (**5**; R = OMe, R′ = Me; counterion ion $MeOSO_3^-$) gave two betaines, one **6** (R = OMe, R′ = Me) and the other **7** (R = OMe, R′ = Me).

The pK_{BH^+} values for the reaction

$$Z \rightarrow A + H^+$$

of SSA-I, SSA-II, BSA-I, BSA-III, and BSA-IV were obtained by a solubility method (23, 24). Strychninesulfonic acid-III proved too soluble, and its pK_{BH^+} was determined by paper electrophoresis (23). The pK_{BH^+} values are listed in Table 2, along with the differences (ΔpK_{BH^+}) from the pK_{BH^+} in water of the unsubstituted bases, in this case strychnine or brucine (23).

This difference depends on the proximity of the sulfonic acid group to the ionizing $\overset{+}{\diagdown\!\diagup}$NH group. For the series of zwitterions **8** Rumpf (25) found ΔpK_{BH^+} to change with the number n of methylene

TABLE 2. The effect of the sulfonic acid group upon the pK_{BH+} values for strychnine and brucine

Compound	pK_{BH+}	ΔpK_{BH+} Experimental	ΔpK_{BH+} Calculated*	n
SSA-I	7.53	−0.9	−0.6	3
SSA-II	7.54	−0.9	−0.6	3
SSA-III	3.2	−5.2	−4.9	1
BSA-I	7.45	−1.0	−0.6	3
BSA-IV	7.43	−1.0	−0.6	3
BSA-III	3.12	−5.3	−4.9	1

*The ΔpK_{BH+} values of **8** for the n values shown.

carbon atoms between SO_3^- and NH_3^+:

n	1	2	3	4	5	10
ΔpK_{BH+}	−4.88	−1.43	−0.58	+0.02	+0.32	+0.72

The reason for the change in sign of ΔpK_{BH+} with n is discussed elsewhere (26); for the moment it suffices to note that the ΔpK_{BH+} for **8** ($n = 3$) is close to the ΔpK_{BH+} of SSA-I and BSA-I, which also have the ionizing NH^+ and SO_3^- groups separated by three carbon atoms. It consequently seems likely that

$$^-O_3S—(CH_2)_n—NH_3^+$$

8

ΔpK_{BH+} is determined mainly by the distance between SO_3^- and NH^+, i.e., by n, and only to a minor extent by the bulk of the molecule between the charged groups (counter to conventional Kirkwood–Westheimer theory (27)). On this basis, the ΔpK_{BH+} values of SSA-II, SSA-III, BSA-IV, and BSA-III suggest the n values indicated in the right-hand column of Table 2.

Further structural information was obtained from ^{13}C magnetic resonance spectroscopy. The ^{13}C signals of strychnine, SSA-I, SSA-II, and SSA-III in 70% aqueous perchloric acid are given in Table 3, together with their assignments and the multiplicity of each signal in the proton-coupled spectra.

Strychnine in dilute acid is protonated on N(19) (23); in 70% $HClO_4$ it is additionally protonated on the amide group, as shown by characteristic changes in the uv spectra. The assignments of Table 3 follow directly from those reported for the free base (28, 29), the hydrochloride (29), and the trifluoroacetate (28).

The ^{13}C spectrum of SSA-I, when compared with that of strychnine, is characterized by a large downfield shift (31 ppm) of the C(14) signal. This is due partly to the change from a tertiary to a quaternary carbon atom, and partly to the electronegativity of the sulfur atom of the sulfonic acid group. Other signals experiencing relatively large changes in position are C(12), C(15), C(18), C(21), and C(22),

TABLE 3. ^{13}C chemical shifts of strychnine and its sulfonic acids in 70% aqueous perchloric acid

*With respect to TMS; s = singlet, d = doublet, and t = triplet in the proton-coupled spectra.

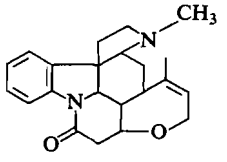
which (with the exception of C(18) are all close to C(14).

The ^{13}C spectrum of SSA-II indicated that substitution has occurred on an sp^2-hybridized carbon atom. A proton-coupled doublet in the low-field portion of the spectrum of strychnine becomes a singlet in the spectrum of SSA-II. This, together with the information that the sulfonic group is probably 3 carbon atoms away from N(19) (Table 2), would place the sulfonic group on C(22) and give the structure **3**. As expected, the other signals experiencing relatively large changes from their positions in strychnine are those for C(13), C(14), C(20), C(21), and C(23), all close to C(22).

The ^{13}C spectrum of SSA-III indicates that substitution has occurred on an sp^3-hydridized methylene carbon atom (a proton-coupled triplet in the upfield portion of the spectrum of strychnine has changed into a doublet at lower field). This, together with the information that the sulfonic group is probably one carbon atom away from N(19) (Table 2), would place the sulfonic group on either C(18) or C(20). The shifts of the signals of nearby carbon atoms are more compatible with the C(20)-sulfonic acid of structure **4**.

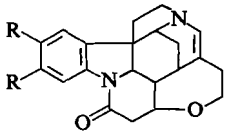
These structures are supported by the rates of alkaline hydrolysis of the amide groups of the three sulfonic acids. SSA-II and SSA-III have about the same rate of hydrolysis in 2.5 N aqueous sodium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.



hydroxide whereas the rate for SSA-I is about 10 times slower,[1] and all hydrolyze more slowly than strychnine. These rates are in accord with the structures advanced above if the effect of the sulfonate group on the hydrolysis is taken to be a rate-retardation (through space). Some support for this assumption as to the influence of a negatively charged group upon the rate of base-catalyzed amide hydrolysis is obtained from the observation that the hippurate ion is hydrolyzed approximately 16 times more slowly than benzamide in 2.5 *N* aqueous sodium hydroxide at 70°C.[1]

The mechanism of Leuchs' reaction remains obscure. The reaction of manganese dioxide with sulfurous acid has been known since 1819 (30) to yield dithionate and some sulfate, through one- and two-electron oxidations:



$$SO_3^- \xrightarrow{-e^-} \cdot SO_3^- \longrightarrow {}^-O_3S{-}SO_3^-$$

$$\cdot SO_3^- + H_2O \xrightarrow{-e^-} H_2SO_4$$

Reaction of $\cdot SO_3H$ with the allylic radicals produced by oxidation of strychnine with manganese dioxide could yield **2** and **4** (R = H). Analogous sulfonations of naphthols by sulfur dioxide – manganese dioxide are known (31). However, it is difficult to understand why the reaction proceeds only with strychnine, brucine, and their quaternary salts. The reaction fails with other alkaloids (codeine, quinine, cinchonine, rubijervine), and even with strychnine derivatives such as base-D (**9**) (32). It also fails with neostrychnine and neobrucine (**10**, R = H or OMe).

9

10

Experimental

Optical rotations were measured with a Perkin-Elmer 141 automatic polarimeter, infrared spectra with a Perkin-Elmer 257 spectrophotometer, and ^{13}C magnetic resonance spectra with a Bruker 22.63 MHz spectrometer locked to the resonance of D_2O contained in a capillary. Elemental analyses were performed by A. Bernhardt, West Germany.

*Sulfonation of Strychnine (**1**; R = H)*

Manganese dioxide was prepared by adding ethanol to a stirred solution of potassium permanganate (110 g) in water until a spot added to filter paper no longer showed a purple colour. The brown precipitate was filtered and washed thoroughly with water and, still wet, suspended in 1500 mL of distilled water. This brown suspension was added in ca. 100 mL portions to a solution of strychnine (40 g) in aqueous sulfur dioxide (2200 mL) at 50–55°C, while sulfur dioxide was bubbled through the solution. After the last of the manganese dioxide had dissolved, sulfur dioxide was bubbled through the solution at 50–55°C for another hour. From the hot solution strychninesulfonic acid-I (fraction A, 28 g) was removed by filtration.

The filtrate, after successive cooling, concentration, and finally chemical treatment, afforded the following fractions of crystalline material.

Fraction B (8.7 g), after 24 h in refrigerator; shown by tlc to be approximately 1:1 SSA-I and -II;

Fraction C (3.6 g), after concentration to 700 mL; shown by tlc to be approximately 1:2 SSA-I and -II;

Fraction D (1 g), after another 24 h in refrigerator; SSA-I.

Concentrated sulfuric acid (30 mL) was added to the filtrate from D and the solution was heated on the water bath for 10 h. Solid barium oxide was added to the hot solution with stirring to approximately pH 10. Inorganic material ($BaSO_4$, $Mn(OH)_2$) was removed by filtration from the alkaline solution, which was then cautiously neutralized with dilute sulfuric acid and filtered again. The neutral filtrate was concentrated to 50 mL and left in the refrigerator for 3 days, yielding fraction E (2.2 g), shown by tlc to contain SSA-I and -II and inorganic salt. The filtrate was concentrated and chromatographed on Florisil (180 g). Elution with water yielded some crystalline fractions of SSA-III (contaminated with inorganic material) and then noncrystalline fractions. These were evaporated to dryness, taken up in hot ethanol, and treated with potassium hydroxide in ethanol until the solution was strongly basic. An inorganic deposit was removed quickly by filtration of the hot solution. The filtrate after 4 days in the refrigerator deposited white needles (6 g) of the potassium salt of SSA-III, $[\alpha]_D^{20}$ +176° (water), giving only one spot on tlc with several different solvents.

Strychninesulfonic acid-I (22 g), $[\alpha]_D^{20}$ −228° (0.1 *N* NaOH) was obtained by recrystallization of fractions A and D from hot water.

Fractions B and C were combined and digested rapidly with 4 portions (25 mL) of boiling water to remove SSA-I. The final residue was recrystallized from a large amount of water, and yielded pure SSA-II (5 g), $[\alpha]_D^{20}$ −139° (0.1 *N* NaOH).

The potassium salt of SSA-III was dissolved in water, acidified with hydrochloric acid, and the solution evaporated to dryness. The residue was extracted quickly with hot anhydrous ethanol. The residue from evaporation of the ethanol, after wasteful crystallization from water, gave SSA-III, mp 289–291°C, $[\alpha]_D^{20}$ +176° (0.1 *N* NaOH).

*Sulfonation of Brucine (**1**; R = OMe)*

At 80–90°C

Following essentially the procedure described above for strychnine, manganese dioxide from 62 g of potassium permanganate was added to a solution of brucine hydrate (25 g) in water (400 mL) at 80–90°C through which sulfur dioxide was bubbled. The final solution (1400 mL) was treated with concentrated sulfuric acid (30 mL), heated on a water bath for 8 h, and allowed to stand at room temperature for 3 days. A crystalline deposit (fraction A (8.5 g)) was removed by filtration, and the filtrate after 3 days in the refrigerator deposited fraction B, which was removed, washed with cold water, and dried in air.

Fraction A was shown by tlc to be made up of BSA-III, BSA-IV, and some BSA-I. It was refluxed with stirring with nitromethane (500 mL) and the mixture left overnight at room temperature. The solid was removed by filtration, and the extraction in this manner repeated three times. The insoluble residue was recrystallized from water (500 mL), and gave pale tan plates of BSA-IV (2.1 g), $[\alpha]_D^{20}$ −121° (0.1 *N* NaOH).

[1]S. C. Wong, unpublished results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

The residue after evaporation of the combined nitromethane extracts was recrystallized from water (300 mL), with decolorization by sugar charcoal, giving feathery, colorless needles of BSA-III (3.9 g), $[\alpha]_D^{20}$ +151° (0.1 *N* NaOH).

Fraction B was shown by tlc to be BSA-I with a little BSA-III. It was stirred with boiling nitromethane, and the mixture left overnight at room temperature. The residue, recrystallized from water (150 mL) yielded colorless needles of BSA-I (9.5 g), $[\alpha]_D^{20}$ −232° (0.1 *N* NaOH).

At 97°C

The reaction was carried out as above but at about 97°C. After standing for 3 days at room temperature, the solution deposited fraction A (7.5 g), and the filtrate after 3 days in the refrigerator deposited fraction B (18 g).

Fraction A was shown by tlc to be BSA-III with a little BSA-I. After three recrystallizations from water, BSA-III (4.7 g) was obtained as colorless feathery needles, $[\alpha]_D^{20}$ +151° (0.1 *N* NaOH).

Fraction B was removed by filtration and washed with water. It was shown by tlc to be BSA-I with a little BSA-III. It was extracted three times with nitromethane, following the procedure for fraction B in the previous experiment, and then crystallized from water, to give BSA-I (9.5 g).

Anhydro-19-methylstrychninium-14-sulfonic Acid Hydroxide (6; R = H, R′ = Me)

From Strychnine Methosulfate (5; R = H, R′ = Me; Counterion $MeOSO_3^-$)

Strychnine methosulfate (33) (15 g) dissolved in water (750 mL) was treated with manganese dioxide (15 g) and sulfur dioxide according to the procedure described above. The solution on cooling deposited a white solid (9.6 g; 70% yield), which was recrystallized from water; white needles, mp 345–350°C (dec.), $[\alpha]_D^{20}$ −159° (in water), ν_{max}(KBr): 1170, 1060 (SO_3^-) cm^{-1}.

Anal. calcd. for $C_{22}H_{21}O_5N_2S \cdot 2H_2O$: C 56.9, H 6.1, N 6.0; found: C 56.7, H 6.1, N 6.0.

From Strychnine-14-sulfonic Acid (SSA-I) (2; R = H)

Methyl iodide (0.05 mL) was added to a solution of SSA-I (0.25 g) in 5% aqueous sodium hydroxide (20 mL). The product crystallized from the reaction mixture on standing at room temperature and proved identical (mp, ir) with the product above.

Sulfonation of Benzylstrychninium Bromide (5; R = H, R′ = CH_2Ph; Counterion Br^-)

Benzylstrychninium bromide, mp 308°C, was prepared by reaction of strychnine with benzyl bromide in 95% ethanol. The compound (20 g) was sulfonated under standard conditions to give a crystalline product (19.9 g) which showed three spots on thin-layer chromatography. Column chromatography of a portion (1.5 g) of the product on silica gel gave a first fraction of anhydro-19-benzylstrychninium-14-sulfonic acid hydroxide (**6**; R = H, R′ = CH_2Ph) (1.27 g; 85%), crystallizing from methanol in white flakes, mp 325–330°C, $[\alpha]_D^{20}$ −60° (MeOH), ν_{max}(KBr): 1170, 1060 (SO_3^-) cm^{-1}.

Anal. calcd. for $C_{28}H_{28}N_2O_5S \cdot 2H_2O$: C 62.2, H 6.0, N 5.2; found: C 62.2, H 5.9, N 5.4.

The same compound (mp, ir) crystallized from a solution of SSA-I (208 mg) and sodium bicarbonate (300 mg) in water treated with benzyl bromide (0.1 mL).

Later fractions from the chromatographic column gave anhydro-19-benzylstrychninium-20-sulfonic acid hydroxide (**7**; R = H, R′ = CH_2Ph) (35 mg; 2%), white flakes from methanol, mp 250°C (dec.), $[\alpha]_D^{20}$ +55° (MeOH), ν_{max}(KBr): 1190, 1050 (SO_3^-) cm^{-1}.

Anal. calcd. for $C_{28}H_{28}N_2O_5S \cdot 2H_2O$: C 62.2, H 6.0, N 5.2; found: C 62.5, H 5.9, N 5.2.

The same compound (mp, ir) was obtained by benzylation of SSA-III.

Sulfonation of Brucine Methosulfate (5; R = OMe, R′ = Me, Counterion $MeOSO_3^-$)

Brucine methosulfate (12 g) in water (800 mL) was sulfonated by the standard procedure. The resultant clear solution on standing for several days at room temperature deposited four crops of colorless needles of anhydro-19-methylbrucinium-14-sulfonic acid hydroxide (**6**; R = OMe, R′ = Me) (7.1 g; 64%), mp 350°C (dec.), $[\alpha]_D^{20}$ −113° (water), ν_{max}(KBr): 1140, 1055 (SO_3^-) cm^{-1}.

Anal. calcd. for $C_{24}H_{28}N_2O_7S \cdot H_2O$: C 56.9, H 6.0, N 5.5; found: C 57.0, H 5.9, N 5.6.

The same compound (mp, ir) was obtained by treatment of BSA-I (205 mg) in 1 mL of 10% aqueous sodium bicarbonate with methyl iodide (0.04 mL).

The mother liquors from the four crops of **6** (R = OMe, R′ = Me) were concentrated to 400 mL and left at room temperature for one week. Colorless flakes of anhydro-19-methylbrucinium-20-sulfonic acid hydroxide (**7**; R = OMe, R′ = Me) (1.3 g; 12%) crystallized out; mp 300–305°C (dec.), $[\alpha]_D^{25}$ −32° (water), ν_{max}(KBr): 1150, 1060 (SO_3^-) cm^{-1}.

Anal. calcd. for $C_{24}H_{28}N_2O_7S \cdot 2H_2O$: C 55.1, H 6.1, N 5.3; found: C 54.8, H 6.1, N 5.2.

The same compound (mp, ir) crystallized from a solution of BSA-III (100 mg) and sodium bicarbonate (50 mg) in water (0.5 mL) when treated with methyl iodide (0.02 mL).

Determination of Dissociation Constant by Paper Electrophoresis

The procedure of ref. 23 was followed, the relative mobility being given by the ratio of the distances moved in 45 min by strychninesulfonic acid-III (as a mixture of Z and A) to the distances moved by the standard picrate ion, which was essentially completely ionized (p*K* 0.38) at pH values higher than 2, and which could be located by its yellow color. Acrylamide was used as a neutral marker of electroendosmotic flow, and the zones of sulfonic acid and of marker were revealed by a permanganate–acetone spray (23) applied while the paper strips were still wet.

Acknowledgments

We are grateful to Dr. G. Welch, Dr. M. Kaufman, and Dr. G. A. Baramki for preliminary exploratory work, to Dr. D. M. Waldron-Edward for the loan of the paper electrophoresis apparatus, to Dr. A. S. Perlin, Dr. N. Cyr, and Dr. W. Dawson for ^{13}C nmr spectral measurements, and to the National Research Council of Canada for financial support.

Synthetic applications of α-hydroxydiazenes. III.[1] Uncatalyzed and phenol catalyzed hydroalkylation of alkenes and of azobenzene with alkylazodiphenylmethanols

DOMINIC W. K. YEUNG[2] AND JOHN WARKENTIN[3]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 18, 1980

DOMINIC W. K. YEUNG and JOHN WARKENTIN. Can. J. Chem. **58**, 2386 (1980).

Alkylazodiphenylmethanols $(C_6H_5)_2C(OH)N{=}NR$, (R = $CH(CH_3)_2$, CH_2CH_3, CH_3), when decomposed in the presence of olefinic substrates or in the presence of azobenzene, hydroalkylate those substrates. Addition of R and H across the double bond of an unsymmetric alkene occurs with the regiochemistry expected for a radical mechanism, in which the group R adds first. Radical intermediates from decomposition of alkylazodiphenylmethanols have been demonstrated earlier with spin trapping experiments. The fact that addition of phenol can enhance the yield of hydroalkylation product suggests that the process is a radical chain reaction, with chain carrying steps consisting of the reactions:

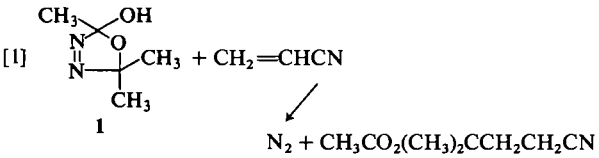
(*i*) $R\cdot + CH_2{=}CHY \rightarrow RCH_2\dot{C}HY$

(*ii*) $RCH_2\dot{C}HY + (C_6H_5)_2C(OH)N_2R \rightarrow RCH_2CH_2Y + (C_6H_5)_2CO + N_2 + R\cdot$

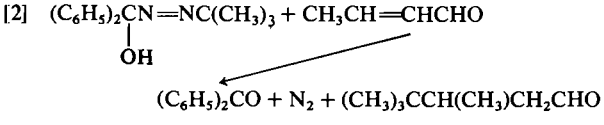
One deuterioalkylation and some yield-optimizing experiments are also reported.

DOMINIC W. K. YEUNG et JOHN WARKENTIN. Can. J. Chem. **58**, 2386 (1980).

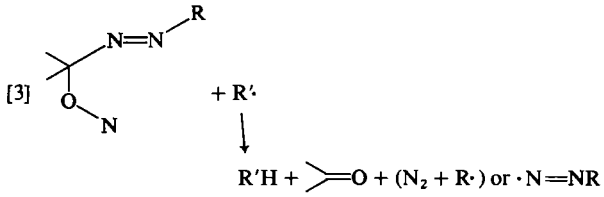
La décomposition des alkylazodiphénylméthanols $(C_6H_5)_2C(OH)N{=}NR$, (R = $CH(CH_3)_2$, CH_2CH_3, CH_3), en présence d'oléfines ou d'azobenzène conduit à l'hydroalkylation de ces substrats. L'addition de R et de H sur la double liaison d'un alcène asymétrique se produit selon la régiochimie attendue pour un mécanisme radicalaire dans lequel le groupe R s'additionne en premier. On a déjà démontré, par des expériences antérieures de piégeage de spin, l'existence de radicaux intermédiaires au cours de la décomposition des alkylazodiphénylméthanols. Le fait que l'addition du phénol puisse augmenter le rendement de l'hydroalkylation suggère que la réaction se déroule selon une réaction en chaîne propagée par les réactions suivantes:



(*i*) $R\cdot + CH_2{=}CHY \rightarrow RCH_2\dot{C}HY$



(*ii*) $RCH_2\dot{C}HY + (C_6H_5)_2C(OH)N_2R \rightarrow RCH_2CH_2Y + (C_6H_5)_2CO + N_2 + R\cdot$



On rapporte également une deutérioalkylation et quelques expériences ayant pour but d'améliorer les rendements.

[Traduit par le journal]

A few years ago we reported some novel addition reactions to π-bonded systems, by reagents containing the alpha (α) hydroxydiazene (azocarbinol) functionality. For example, **1** reacted with acrylonitrile to yield 4-acetoxy-4-methylvaleronitrile, eq. [1] (1). Similarly, **2** reacted with crotonaldehyde to afford 3,4,4-trimethylpentanal, eq. [2] (2). Hydro-*tert*-butylations of π-bonded substrates with **2** occurred in higher overall yields if phenol was present at low concentration (2) and this observation, together with evidence for the intermediacy of *tert*-butyl radicals in thermolysis of **2** (3, 4) and 2-acetoxy-2-propyl radicals in thermolysis of **1** (5) led to the proposal of a radical chain mechanism for decomposition of those hydroxydiazene systems. The key step in that mechanism is radical abstraction of hydroxyl hydrogen from the hydroxydiazene in concert with C—N bond cleavage, thus avoiding formation of an alkoxy radical intermediate, eq. [3], and providing enough lower-

[1] 

[2] 

[3] 

ing of the free energy from formation of coproducts to allow even stabilized R· (e.g. phenoxy) to act as chain carriers.

It was of interest to try to establish the generality of the hydroalkylation reaction represented by eq.

[2] by testing systems which would have to generate secondary or primary free radicals. We also wanted to establish optimum conditions for hydroalkylation, and to attempt deuterioalkylation by the simple expedient of shaking the hydroxydiazene with D_2O prior to thermolysis. We report results of such work in this paper.

Methods and Results

2-Propylazodiphenylmethanol, **3**, was prepared from 2-propylmagnesium bromide and diphenyldiazomethane (6) as outlined in eqs. [4]–[6]. Ethylazodiphenylmethanol, **4**, was prepared by an analogous route. The appropriate benzophenone alkylhydrazones, eq. [4], can of course also be prepared from benzophenone and alkylhydrazine,[4] and the oxidation step, eq. [5], can also be carried out with bromine in acetic acid instead of lead tetraacetate, albeit in lower yield. Typical procedures are described below.

[4] $(C_6H_5)_2C{=}\overset{+}{N}{=}\overset{-}{N} + (CH_3)_2CHMgBr \xrightarrow[(2)\ H_3O^+]{(1)\ \text{Ether}} (C_6H_5)_2C{=}NNHCH(CH_3)_2$

[5] $(C_6H_5)_2C{=}NNHCH(CH_3)_2 + Pb(OAc)_4 \xrightarrow{CH_2Cl_2} (C_6H_5)_2\underset{\displaystyle OAc}{\underset{|}{C}}N{=}NCH(CH_3)_2$

[6] $(C_6H_5)_2\underset{\displaystyle OAc}{\underset{|}{C}}N{=}NCH(CH_3)_2 + 2CH_3Li \xrightarrow[(2)\ H_3O^+]{(1)\ -10°C} (C_6H_5)_2\underset{\displaystyle OH}{\underset{|}{C}}N{=}NCH(CH_3)_2$

3

Benzophenone-2-propylhydrazone

A solution of diphenyldiazomethane (2) (45.0 g, 0.23 mol) in 200 mL of anhydrous ether was added, during one hour, to a stirred solution of ice-cold, freshly-prepared 2-propylmagnesium bromide (0.34 mol). After addition was completed, the mixture was stirred for 30 min, during which time most of the red colour faded and a yellow precipitate was formed. The mixture was treated with cold, aqueous ammonium chloride, the ether layer was separated, and the aqueous layer was extracted twice with ether. The combined ethereal layers were dried over sodium sulfate before the ether was removed with a rotary evaporator. Benzophenone-2-propylhydrazone was obtained as a sticky, yellow oil in 90% yield; ir (CCl_4): 3275 (NH); ^1H nmr (CCl_4) δ: 1.08 (d, 6H), 3.12–3.65 (m, 1H), 4.89 (s, broad, 1H), 6.39–7.45 (m, 10H); *Mol. Wt.* (ms): 238.

Benzophenone Ethylhydrazone

This compound, prepared by the analogous procedure, was obtained as an oil in 80% yield; ir (CCl_4): 3260 (NH); ^1H nmr (CCl_4) δ: 1.12 (t, J = 7 Hz, 3H), 3.22 (q, J = 7 Hz, 2H), 4.92 (s, broad, 1H), 7.03–7.50 (m, 10H); *Mol. Wt.* (ms): 224.

Benzophenone Methylhydrazone

A mixture of benzophenone (0.30 mol), methyl hydrazine (0.33 mol), and glacial acetic acid (30 mL) in methanol (100 mL) was heated to reflux under nitrogen. After 2 h the flask was cooled with ice and the colourless crystals were filtered off. Recrystallization from hot methanol gave benzophenone methylhydrazone, mp 41–42°C (lit. (6), mp 42–43°C), in 65% yield.

2-Propylazodiphenylmethyl Acetate

A solution of benzophenone-2-propylhydrazone (11.9 g, 0.050 mol) in dichloromethane (50 mL) was added in the course of 20 min to a stirred, ice-cooled solution of lead tetraacetate (25 g, 0.055 mol) in dichloromethane (150 mL). An atmosphere of dry nitrogen was maintained over both solutions to prevent air oxidation of hydrazone to azohydroperoxide. After addition had been completed the mixture was stirred for 20 min more before ice water (150 mL) was added. The brown sludge which formed was removed by filtering the entire mixture through a bed of Celite. The organic layer was separated and washed, first with water and then with bicarbonate solution (5%), until it was free of acetic acid. After drying over Na_2SO_4 and evaporation of the solvent with a rotary evaporator, a pale yellow solid was obtained. Recrystallization from methanol gave 2-propylazodiphenylmethyl acetate, 70%, mp 69.5–70.5°C; ir: 1765 cm^{-1}; ^1H nmr (CCl_4) δ: 1.21 (d, J = 7 Hz, 6H), 2.03 (s, 3H), 3.87 (sept, J = 7 Hz, 1H), 7.08–7.48 (m, 10H). *Anal.* calcd. for $C_{18}H_{20}N_2O_2$: C 72.93, H 6.81, N 9.46; found: C 73.14, H 6.82, N 9.76.

Ethylazodiphenylmethyl Acetate

The above procedure gave, from benzophenone ethylhydrazone (0.050 mol), ethylazodiphenylmethyl acetate, 60%; mp 77–78°C; ir (CCl_4): 1765 cm^{-1}; ^1H nmr (CCl_4) δ: 1.29 (t, J = 7 Hz, 3H), 2.05 (s, 3H), 4.00 (q, J = 7 Hz, 2H), 7.08–7.52 (m, 10H). *Anal.* calcd. for $C_{17}H_{18}N_2O_2$: C 72.80, H 6.43, N 9.93; found: C 72.77, H 6.52, N 9.65.

Methylazodiphenylmethyl Acetate

The analogous procedure gave, from benzophenone methylhydrazone (0.050 mol), methylazodiphenylmethyl acetate in 45% yield; mp 124–125°C (lit. (9), mp 125–126°C); ir: 1750 cm^{-1}; ^1H nmr (CCl_4) δ: 2.06 (s, 3H), 2.86 (s, 3H), 7.13–7.53 (m, 10H).

2-Propylazodiphenylmethanol, 3

A solution of 2-propylazodiphenylmethyl acetate (14.8 g, 0.050 mol) in 200 mL of anhydrous ether, under nitrogen, was cooled to −10°C. Methyllithium (75 mL of 1.7 *M* reagent in ether, 0.13 mol) was added to the stirred solution by drops from a syringe, during 10 min. After 15 min more, ammonium chloride solution (saturated, ice-cold, 250 mL) was added slowly. After separation of the ether layer the aqueous phase was extracted three times with ether. The ethereal fractions were combined and dried with Na_2SO_4 before concentration (without heating) with a rotary evaporator. The pale yellow solid, after recrystallization from pentane, melted at 54–55°C (dec.); 70% yield; ^1H

[4] Such preparations, as well as handling of the hydrazones whatever their origin, must be done with care to prevent air oxidation to azohydroperoxides (7). The latter can be treated with triphenylphosphine to convert them to the desired azocarbinols (8). We have used this alternative approach to synthesize some azocarbinols and have developed a more convenient procedure (A. Nazran, to be published).

For personal use only.

nmr (CCl_4) δ: 1.30 (d, J = 7 Hz, 6H), 4.03 (sept, J = 7 Hz, 1H), 5.63 (s, 1H), 7.07–7.53 (m, 10H). This product could not be analyzed and infrared spectra of freshly-prepared material showed a band at 1650 cm^{-1} (CO of benzophenone) which increased in intensity during successive scans as spontaneous decomposition progressed.

Ethylazodiphenylmethanol, 4

Deacylation of ethylazodiphenylmethyl acetate, as described above for the 2-propyl analogue, gave **4** as an unstable solid; mp 44–45°C (dec.); ^1H nmr (CCl_4) δ: 1.35 (t, J = 7 Hz, 3H), 4.05 (q, J = 7 Hz, 2H), 5.60 (s, 1H), 7.03–7.53 (m, 10H).

Methylazodiphenylmethanol, 5

Deacylation of methylazodiphenylmethyl acetate, as described above for the 2-propyl analogue, gave crude **5** as an oil; ^1H nmr (CCl_4) δ: 3.73 (s, 3H), 5.47 (s, 1H), 6.97–7.70 (m, 10H). Attempts to purify **5** were unsuccessful and subsequent experiments involving **5** were done with freshly-prepared but crude material.

Hydroalkylations of unsaturated compounds with 3, 4, and 5 were carried out in solvent benzene. In a typical procedure the unsaturated substrate (0.008 mol) was added to a solution of α-hydroxydiazene (0.002 mol) in benzene (4.0 mL) and the mixture was shaken until homogeneous. It was then warmed if necessary to initiate decomposition (typically to between 35° and 50°C was sufficient) and kept in that temperature range for 12–20 h. Evolution of gas was observed in all cases, either immediately after mixing or soon after warming to 35°C. Long after reaction appeared to be over, as judged by cessation of bubbling, the solution was subjected to bulb-to-bulb distillation, leaving behind telomeric material and benzophenone. The distillate was analyzed by glpc, with a column (10 ft × ¼ in.) packed with Carbowax 20 M (15%) on Chromosorb A (60–80 mesh) at 80–120°C with a helium flow rate between 45 and 60 mL/min, in a Varian Aerograph A90P3 instrument. Analytically pure products were isolated in this way for identification. Yields were estimated by addition of *tert*-butylbenzene to serve as internal standard, without correction for thermal conductivity differences.

Deuteriomethylation of Norbornene with 5-OD

A solution of methylazodiphenylmethanol (**5**, 1.0 g, 4.4 mmol) in benzene (10 mL) was stirred vigorously with D_2O (5 mL) for about 10 min before norbornene (1.6 g, 17.0 mmol) was added all at once. The resulting mixture was kept at 35°C, with vigorous stirring, for 36 h. The organic layer was separated and dried before bulb-to-bulb distillation, followed by addition of *tert*-butylbenzene and gas chromatography. A sample of 2-deuterio-*exo*-3-methylnorbornene was analyzed for deuterium content by ms: D_1 87%; D_0 13%.

Discussion

Results of reactions of hydroxydiazenes with olefinic substrates and with azobenzene are gathered in Tables 1–3. It is clear that **3**, **4**, and **5** act as agents for hydroalkylating olefinic and azo double bonds. It is also evident from the yield data that the efficiency of addition is very sensitive to substrate structure and that addition of an H-atom donor (phenol in the present case) can improve the yield of addition product. These observations can be accounted for in terms of the radical chain chemistry postulated for analogous hydro-*tert*-butylation with *tert*-butylazodiphenylmethanol (2).

The initiation step has not been identified but it is unlikely to be unimolecular homolysis according to eqs. [7] or [8], because the corresponding methyl ethers and acetates are very stable in benzene

[7] $(C_6H_5)_2\underset{\underset{OH}{|}}{C}-N=NR \longrightarrow (C_6H_5)_2\underset{\underset{OH}{|}}{C}\cdot + N_2 + R\cdot$

[8] $(C_6H_5)_2\underset{\underset{OH}{|}}{C}N=NR \longrightarrow (C_6H_5)_2\underset{\underset{OH}{|}}{C}\cdot + \cdot N=NR$

$(C_6H_5)_2\underset{\underset{OCH_3}{|}}{C}N=NR$ and $(C_6H_5)_2\underset{\underset{OCOCH_3}{|}}{C}N=NR$

under the reaction conditions. Possible mechanisms of initiation include molecule induced homolysis (17–20) and H-abstraction by dissolved ground state oxygen (2, 3). Once R· is generated in the presence of hydroxydiazene, phenol, and alkene, the expected chemistry is that of eqs. [9]–[15]. That is, R· can abstract from hydroxydiazene, or from phenol,[5] in unwanted reactions that lower the yield of RCH_2CH_2Y. Radical R· can also add to alkene, eq. [11], leading to a new radical which faces the same choices that R· has; H-abstraction from hydroxydiazene or from phenol and addition to alkene, eqs. [12]–[14].

[9] $R\cdot + (C_6H_5)_2\underset{\underset{OH}{|}}{C}N=NR \longrightarrow RH + (C_6H_5)_2CO + N_2 + R\cdot$

[10] $R\cdot + C_6H_5OH \longrightarrow RH + C_6H_5O\cdot$

[11] $R\cdot + CH_2=CHY \longrightarrow RCH_2\dot{C}HY$

[12] $RCH_2\dot{C}HY + (C_6H_5)_2\underset{\underset{OH}{|}}{C}N=NR \longrightarrow RCH_2CH_2Y + (C_6H_5)_2CO + N_2 + R\cdot$

[13] $RCH_2\dot{C}HY + C_6H_5OH \longrightarrow RCH_2CH_2Y + C_6H_5O\cdot$

[14] $RCH_2\dot{C}HY + \eta CH_2=CHY \longrightarrow$ telomers and polymers

[15] $C_6H_5O\cdot + (C_6H_5)_2\underset{\underset{OH}{|}}{C}N=NR \longrightarrow C_6H_5OH + (C_6H_5)_2CO + N_2 + R\cdot$

These reactions offer a rationale for the sensitivity of yields to structure and for the effects of phenol on the yields of hydroalkylation products. Rate constants for radical addition to $CH_2=CHY$ (eqs. [11], [14]) and for H-abstraction by $RCH_2\dot{C}HY$ (eqs. [12], [13]) depend on the substituent Y and it is not surprising that the outcome

[5] In the general case one should consider other H-donors, such as an olefinic substrate with a labile H-atom (e.g. allylic H), or the reaction products.

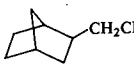
[g]Melting point 86–87°C (lit. (13), mp 88.0–88.4°C).
[h]The yield of crude product was nearly quantitative, as judged by the ^{1}H nmr spectrum in the high field region. Isolation losses of this air-sensitive hydrazine were severe.



of the competition is olefin dependent in the presence or absence of phenol. There must be at least two counteracting effects of added phenol. First, it ought to lower the yield of RCH_2CH_2Y by capturing R· that would otherwise have added to alkene (eq. [10]). Second, it ought to raise the yield of RCH_2CH_2Y by capturing $RCH_2\dot{C}HY$ that would otherwise have added to alkene in telomerization or polymerization reactions (eq. [14]). Although one might predict that for some CH_2=CHY the yield should drop to zero at high phenol concentrations, because all R·'s get caught by phenol before they can add, one can not readily predict the effects of low phenol concentrations.

The experimentally observed effects are depicted graphically as Figs. 1–4, which show that yield optimization occurs at relatively high phenol concentration (ca 1.0–1.5 *M*). The other trend indicated by the figures is that the yields rise more rapidly with increasing [φOH] before the optimum is reached than they decline after the optimum concentration is exceeded. A qualitative diagram, Fig. 5, illustrates the probable origin of these trends.[6] In Fig. 5, the function A represents the fraction of $RCH_2\dot{C}HY$ that leads to RCH_2CH_2Y. That fraction should level off to a value of unity at high phenol concentrations but it should not go to zero when phenol is absent, because of other H-donors, notably azocarbinol, present. Function B represents, qualitatively, the fraction of R· that adds to alkene. That fraction will not be unity at [φOH] = 0, again because of H-donors like azocarbinol present in the medium, and it ought to go to zero at high [φOH]. The yield of RCH_2CH_2Y, expressed as a fraction, is the product of the fractions represented by curves A and B at a given [φOH]. Curve C, the yield curve,

[6]Quantitative analysis of the yield data could lead to values of ratios of rate constants and of rate constants themselves. Additional data will have to be gathered before that is attempted.

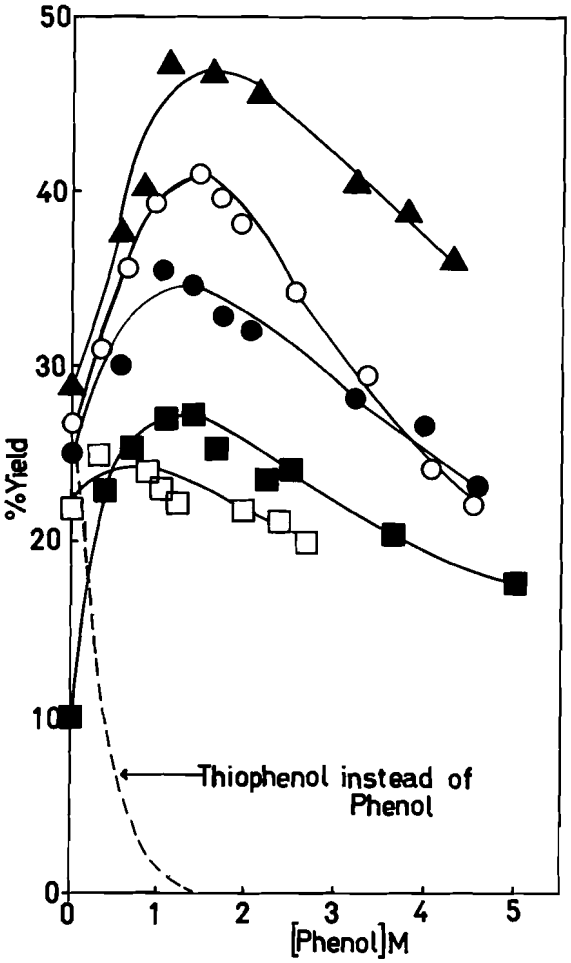

FIG. 1. Optimization of yield of adduct from 3 and crotonaldehyde. Crotonaldehyde concentrations (M, initial): △ 1.978, ○ 1.394, ● 3.484, ■ 0.348, □ 6.484, --- 1.394.

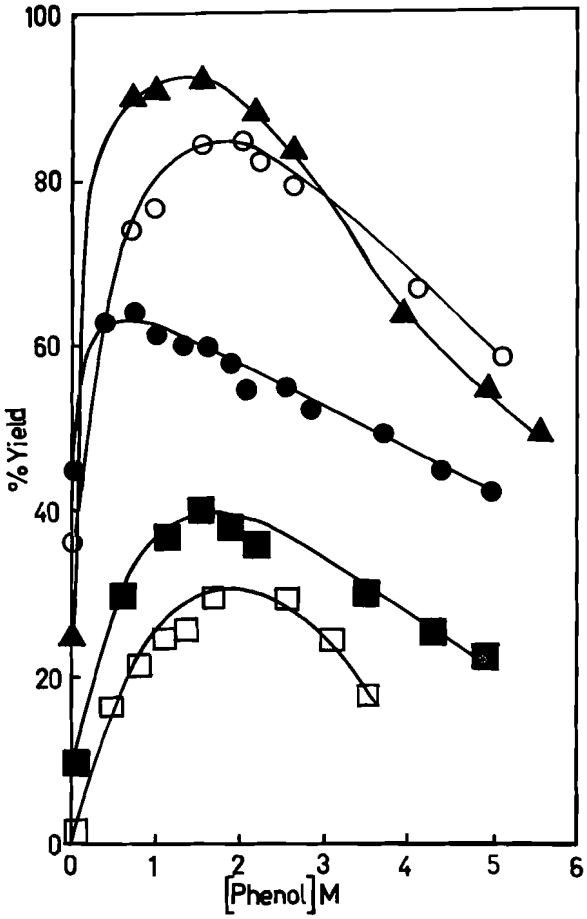

FIG. 2. Optimization of yield of adduct from 3 and acrylonitrile. Acrylonitrile concentrations (M, initial): ▲ 1.394, ○ 1.978, ● 0.348, ■ 3.484, □ 6.948.

was generated by multiplying points at corresponding [φOH] on curves A and B. From curves A and B, which were generated with the top curve of Fig. 1 as model, it follows that the rising part of the yield curve C represents a composite of two rapidly changing functions, operating in opposite senses, whereas the descending part represents a composite of one such function and a constant. Thus the general shape of the optimization curves in Figs. 1 and 2 appears to be accounted for satisfactorily.

The effect of added thiophenol (Fig. 1) can also be understood in terms of Fig. 5. Since thiophenol is much better than phenol as a H-donor to radicals,[7] the sloped portions of curves A and B should be much steeper than they are for the case of phenol. Thus the yield of RCH_2CH_2Y will be the product of unity and zero at relatively low [φSH] and a maximum, if any, at still lower [φSH] is not detectable.

Figure 2 shows the results of optimization experiments for hydro-2-propylation of acrylonitrile with 3. The yield curves are similar to those for addition to crotonaldehyde, with some notable differences. For instance, the maximum yield in the crotonaldehyde case is obtained with ca. 2 *M* crotonaldehyde and 1.5 *M* phenol. Lower or higher aldehyde concentrations lead to significant drops with roughly equal values at either 6.5 *M* or 0.35 *M* initial concentrations. In the acrylonitrile case the best yield is that for ca. 1.4 *M* substrate and 1.0 *M* phenol and the effects of going to higher substrate concentrations are more severe. There is also a discernible shift of the yield maxima, to higher phenol concentration, with increasing substrate concentration. Figure 3 illustrates the differences

[7]The chain transfer constant for 1-butanethiol is larger by a factor near 10^5 than that for phenol, toward polystyryl radicals (22). The analogous factor, toward polyvinylacetate radicals, is about 10^2 (22). Thiophenol is probably a chain transfer agent at least as good as butanethiol, in view of resonance stabilization, albeit little, in the phenylthiyl radical.

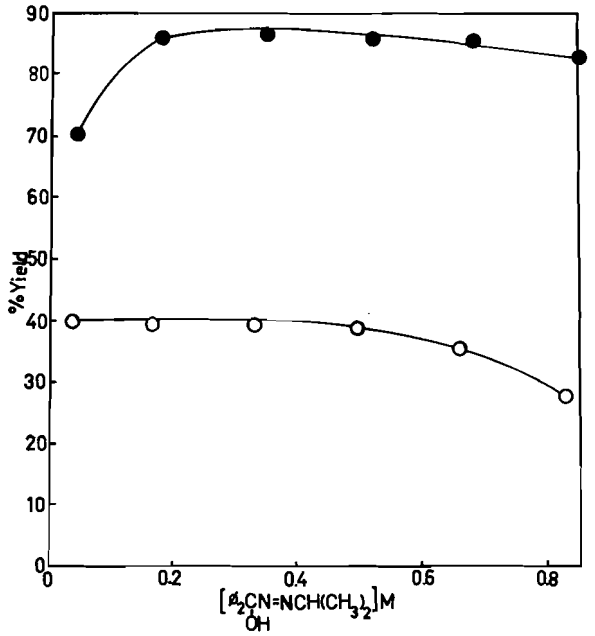

FIG. 3. Dependence of yield of adducts from **3** and olefinic substrates on initial concentration of **3**. Initial concentrations of phenol and substrate: ● [Phenol] = 0.712 M, [Acrylonitrile] = 1.445 M; ○ [Phenol] = 0.697 M, [Crotonaldehyde] = 1.396 M.

between the crotonaldehyde and acrylonitrile systems in the absence of phenol. That figure shows the points lying on the vertical axes of Figs. 1 and 2, plotted against substrate concentration at constant initial concentration of **3**. At low substrate concentration acrylonitrile gives the better yield while at high substrate concentration the reverse is true. The trends in Figs. 1, 2, and 3 are undoubtedly complex in origin, since it is likely that the two substrates are rather similar in their reactivities toward radicals.[8] Presumably the corresponding radical adducts have different k_p/k_{abstr} ratios for the two curves of Fig. 3 to cross.

Hydromethylation of norbornene occurs in the sense expected for radical (or polar) addition to that substrate. A large preference for initial *exo* attack is well known (22) and the tendency for overall *syn* addition by a radical mechanism has been accounted for in terms of steric effects (23). Our assignment of *exo* geometry for the methyl group in the hydromethylation and deuteromethylation products (Table 3) is based on the ^{13}C nmr spectra (16). Assignment of the location of deuterium, 80% *exo* and 20% *endo*, is based on the above mentioned

[8]For addition of CF_3 radicals the reactivity ratio, $k(CH_2{=}CHCN)/k(CH_2{=}CHCOCH_3)$ is about 0.13 (21). Although these are not ideal models for the additions in question, it is unlikely that acrylonitrile and crotonaldehyde are very different in their reactivities toward the 2-propyl radical.

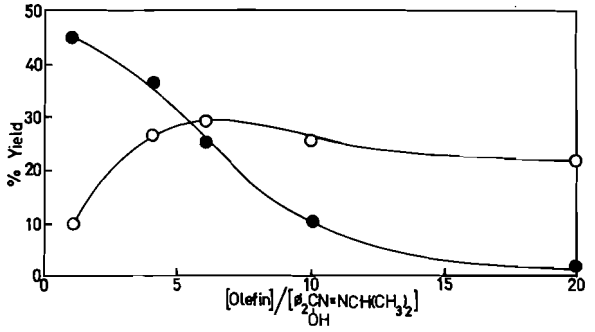

FIG. 4. Dependence of yield of adducts from **3** and olefinic substrates on the feed ratio. Substrates: ● acrylonitrile, ○ crotonaldehyde.

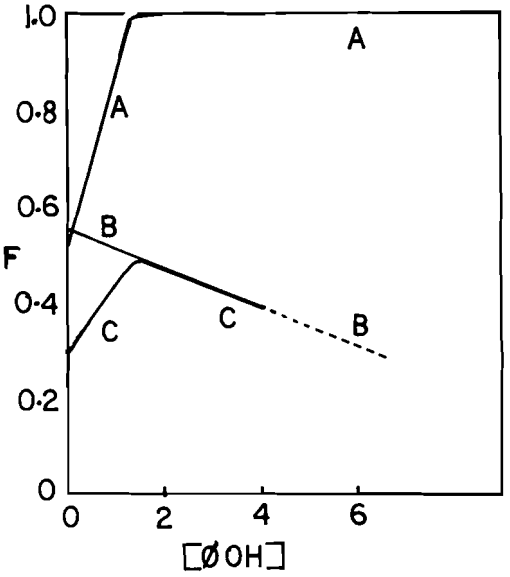

FIG. 5. Scenario for the variation with phenol concentration of: the fraction (F) of $RCH_2\dot{C}HY$ that becomes RCH_2CH_2Y, curve A; the fraction (F) of R· that becomes $RCH_2\dot{C}HY$, curve B; the fraction (F) of R· that becomes RCH_2CH_2Y, curve C. The latter is generated by taking the product of corresponding F-values on curves A and B; see text.

preferences for *syn* (*exo*, *exo*) addition of other addends. Although the generality of hydroxyl deuterium transfer to carbon has not been demonstrated with the one example cited, it is hard to imagine that it might fail entirely because of the expected isotope effect in the chain transfer step. Thus, hydroxydiazenes appear to be attractive reagents for deuteroalkylation of olefinic substrates.

In keeping with our earlier finding (3) azobenzene hydroalkylates much more efficiently than do olefinic substrates. Yields of raw product are nearly quantitative in some cases but losses incurred during separation of the sensitive 1-alkyl-1,2-diphenylhydrazines from excess azobenzene and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

from benzophenone are substantial. The high efficiency of addition to azobenzene must mean that the rate constant for addition to form a resonance stabilized hydrazyl radical (24) is very much larger than that for abstraction of H from hydroxydiazene by R·. It is interesting that the hydrazyl radicals apparently abstract readily from the hydroxydiazene, suggesting again that the abstraction is concerted with other bond-breaking processes, for such a hydrazyl should be incapable of abstracting hydroxyl H from a simple alcohol.

In summary, the additions reported are potentially useful for the synthesis of ^{2}H- or ^{3}H-labelled and unlabelled small molecules. The radical chain mechanism used as a basis for discussion is a proposal which, although it appears to fit the observations, must still be regarded as tentative.[9]

[9]An alternative mechanism, involving fragmentation of hydroxydiazene to ketone and alkyldiazene, $R_1R_2C(OH)N_2R_3 \rightleftarrows R_1R_2CO + HN_2R_3$, with the latter responsible for the hydroalkylation observed, must be considered. There is evidence for that process occurring, particularly under acidic or basic conditions but also under nominally neutral conditions (25–27). Preliminary experiments designed to test for the alkyldiazene pathway suggest that it is not general under our conditions although it could be a competitive mechanism.

Muonium atoms observed in liquid hydrocarbons

YASUO ITO,[1] BILL W. NG, YAN-CHING JEAN,[2] AND DAVID C. WALKER
Chemistry Department and TRIUMF,[3] University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received July 3, 1980

YASUO ITO, BILL W. NG, YAN-CHING JEAN, and DAVID C. WALKER. Can. J. Chem. **58**, 2395 (1980).

Muonium atoms have been observed in *n*-hexane, *c*-hexane, and tetramethylsilane at 295 or 273 K by the MSR technique. The yield of muonium in these non-polar liquids is found to be quite comparable to that observed previously in water, methanol, and ethanol. This suggests that neither the dielectric constant of the medium nor the free-electron mobility has a major influence on the formation process. This in turn supports the view that muonium formation does not mainly result from intraspur reactions in the terminal spur of the muon's track.

The chemical lifetime of muonium in these hydrocarbons is curtailed by spurious impurities so that high purity is required. In addition, however, there may be a chemical reaction between muonium and the hydrocarbon itself because the maximum lifetime found increases in the order of increasing bond energy. Reaction rate constants with added solutes have also been measured, and these observations open up the possibility of studying hydrophobic solutes and extending hydrogen-isotope studies to biologically-important media.

YASUO ITO, BILL W. NG, YAN-CHING JEAN et DAVID C. WALKER. Can. J. Chem. **58**, 2395 (1980).

On a observé des atomes de muonium dans le *n*-hexane, le *c*-hexane et dans le tétraméthylsilane à 295 ou 273 K par la technique de RSM. On a trouvé que le rendement en muonium dans ces liquides non polaires est tout à fait comparable à celui observé antérieurement dans l'eau, le méthanol et l'éthanol. Ceci suggère que ni la constante diélectrique du milieu ni la mobilité des électrons libres n'a d'influence sur la formation des muonium. Cette conclusion appuie le fait que la formation des muonium ne provient pas principalement de réactions à l'intérieur de la dernière cavité de la trajection du muon.

La présence d'impuretés parasites diminue la durée de vie du muonium dans ces hydrocarbures; il faut donc opérer avec des solvants d'une très grande pureté. De plus, il semble qu'une réaction chimique se produit entre le muonium et l'hydrocarbure puisqu'on a trouvé que la durée maximale de vie augmente avec l'énergie de liaison. On a mesuré également les constantes de vitesse en présence de solutés; ces observations ouvrent la possibilité d'étudier des solutés hydrophobes et d'étendre les études d'effets isotopiques de l'hydrogène aux milieux biologiquement importants.

[Traduit par le journal]

Introduction

The atom formed when a positive muon acquires an orbital electron is called muonium[4] and was first identified when energetic muons were stopped in gases (1). Although studied for more than a decade in gases and solids (2), only recently was the same species observed through its characteristic spin precession frequency of 1.4 MHz G^{-1} in a pure liquid, initially in water (3). It has subsequently been detected in methanol and ethanol at 295 K (4, 5) and in ether at ~162 K (6).

Muonium atoms (symbolized by Mu) are relatively short-lived due to the intrinsic lifetime of the muon which decays to a positron and two neutrinos with a mean lifetime of 2.2 μs. In the presence of reactive solutes the chemical existence of free Mu may be reduced further by reaction, and the chemical rate constant can be determined. In pure liquids there is also a spontaneous spin relaxation process of unknown origin characterized by the decay constant λ_0 (see later). This is significantly larger in neat alcohols than it is in water.

Muonium is of considerable interest from at least

[1]On leave from: Research Center for Nuclear Science and Engineering, University of Tokyo, Tokyo, Japan.

[2]Present address: Physics Department, University of Missouri, Kansas City, MO.

[3]TRIUMF stands for Tri University Meson Facility on the campus of the University of British Columbia.

[4]It should, more properly, have been called muium (despite the less mellifluous sound) in conformity with protium, deuterium, and tritium, because the suffix "onium" generally refers to species formed when a particle combines with its antiparticle, as in positronium and charmonium (though hydronium is an oddity).

four points of view (2, 7). First, there is interest in the intrinsic properties and mode of formation of this unusual chemical species. Second, it can be used as a nuclear spin probe for radicals. Third, since Mu has essentially the same ionization energy and Bohr radius as a hydrogen atom, but 1/9th its mass, it is regarded as a super-light isotope of protium, deuterium, and tritium, and can be used as a sensitive probe of mass-dependent kinetic isotope effects. Fourth, since Mu is readily identified and monitored by single event nuclear physics counting techniques, it can be used as a handle on H-atom reactions which are not otherwise accessible to direct observation by conventional methods.

For these reasons its study has been intensely pursued during the past three years. For liquid phase studies most of this work has been in aqueous solution, but there is interest in trying to determine the reactivity of Mu in non-polar, hydrocarbon media. Of particular relevance to our own studies on micelles (8) is the reaction rate constant towards solutes held in the hydrocarbon centre of the micelle.

Experimental

Muonium is studied by the muon and muonium spin rotation methods (μSR and MSR) which have been described in detail elsewhere (2, 7, 9). Longitudinally spin-polarized muons from pion decays are made to impinge on a chemical sample where they come to rest and become incorporated in several different possible chemical states: either in diamagnetic states, or as free Mu atoms, or in free radicals (10). In the present experiments the 4.1 MeV "surface" μ^+ beam of the M20 channel at TRIUMF was used. The liquid samples were contained in Teflon cells having thin Mylar windows, as before (11). The sample cell was placed inside a pair of Helmholtz coils which provided a transverse magnetic field of 9.3 G for MSR and 80 G for μSR measurements.

In a typical experiment one obtains a time histogram of the MSR signal which is fitted by χ^2-minimization to eq. [1] (2, 7).

$$[1] \quad N = N_0 \exp(-t/\tau_\mu)[1 + A_\mu \cos(\omega_\mu t + \phi_\mu) + A_M \exp(-\lambda t) \cos(\omega_M t - \phi_M)] + B$$

where N_0 is a normalization factor, B the time-independent background, τ_μ the muon lifetime (2.2 μs), ω_μ and ω_M the muon and Mu spin-precession frequencies in the magnetic field, ϕ_μ and ϕ_M are the initial phases of these precessions, A_μ and A_M are the asymmetries of diamagnetic and muonium species, and λ is the muonium decay constant. The last three parameters are those of interest in the present study. All muons appear in diamagnetic states in CCl_4 (2, 7), therefore A_μ in CCl_4 is used as the 100% asymmetry reading (A_0). Thus the fraction of muons forming diamagnetic states (P_D) equals A_μ/A_0, and the fraction forming muonium (P_M) equals $2A_M/A_0$; the 2 arising from the fact that only half of the total muonium atoms have parallel electron and muon spins and are observable. In addition, λ is interpreted as a chemical rate constant (k_M) in the presence of a reactive solute at concentration [S] by application of eq. [2],

$$[2] \quad \lambda = \lambda_0 + k_M[S]$$

where λ_0 is the relaxation rate constant observed in the neat solvent (4, 7).

Oxygen had to be removed from the samples by continuous bubbling with helium gas throughout an experiment (12). In order to avoid excessive evaporation of either solvent or solute, the gas was passed through a prebubbler containing the same material, and to avoid back diffusion of O_2 a bubbler was also used on the gas line after the cell. The solvents studied were of reagent or spectroscopic grade to start with, but they were each further purified by collecting the middle fraction from a simple distillation column. In the case of *n*-hexane, cyclohexane, and tetramethylsilane (TMS), an attempt was made to reduce the concentration of unsaturated impurities by prior treatment of the starting materials with H_2SO_4, then washing with H_2O and drying over zeolite-4A before distillation. In the case of eicosane ($C_{20}H_{42}$), which is solid at 25°C, the material was deoxygenated by bubbling with He at ~50°C (where it is liquid) and then thermosealed in a polyethylene bag which then acted as the target cell. For dilute solutions of cyclohexane in methanol, methanol in water, and phenol in *n*-hexane the same solution was used in the prebubbler so that the solute concentration should not change during the course of the experiment because the gas should contain the equilibrium admixture of solution vapours before reaching the cell. All data reported were obtained from experiments conducted at ~295 K and 273 K.

Results

Typical time-histograms of the spin polarization are shown in Figs. 1, 2, and 3. The lines are the computer fits of the data to eq. [1] with the muon's exponential decay ($e^{-t/\tau}$) and the background (B) already removed. These MSR data were obtained in the low transverse magnetic field (9.3 G) and produce information on muonium signals precessing at the higher frequency. Thus the amplitude of the initial asymmetry is converted to P_M (as described in the Experimental section) and its decay is given as a decay constant λ. P_D values were obtained from the same solutions, but in separate μSR experiments conducted at higher field (80 G) in order to obtain good fits for the lower frequency precessions. In all cases two independent spectra were obtained, one from each of the positron telescopes. Figs. 1, 2, and 3 show the right-hand side spectra only but the data reported in Table 1 are the arithmetic means from the two detectors.

Figure 1*a* shows the histogram for water containing 20% methanol. The muonium asymmetry signal is seen to be relatively long-lived, falling to half magnitude in about 2 μs (in pure water the mean lifetime is normally 4 μs). By comparison the signal in neat methanol (Fig. 1*b*) is much shorter-lived, being ~0.4 μs and the fitting to eq. [1] is correspondingly less exact. Figure 2 shows the fitted histograms for purified TMS at 273 K and *n*-hexane at 295 K where the muonium lifetimes are ~1.5 and and ~1.0 μs respectively. For purified cyclohexane (not shown) at 295 K the lifetime of Mu is smaller but the asymmetry fit is good. However, in eicosane the fit is too poor to report, probably because of the presence of too much O_2 trapped in this solid hydrocarbon.

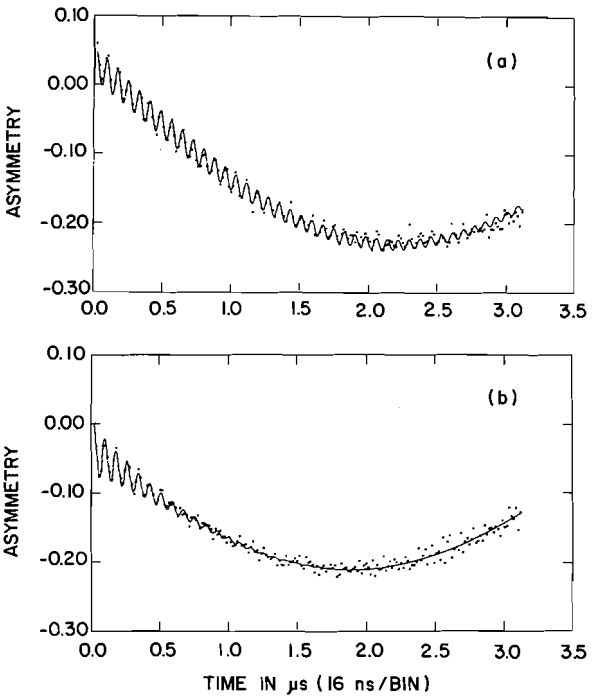

FIG. 1. MSR data and computer fits to eq. [1] for: (*a*) 20% by volume methanol in water; (*b*) purified methanol. The much faster decay of the muonium signal (higher frequency precession) in (*b*) compared to (*a*) is readily seen.

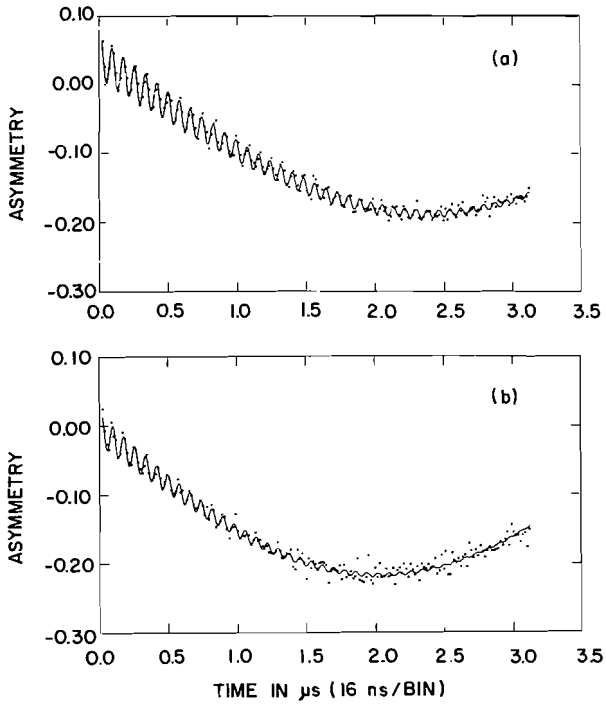

FIG. 2. MSR data and computer fits to eq. [1] for: (*a*) purified tetramethylsilane (TMS); and (*b*) purified *n*-hexane.

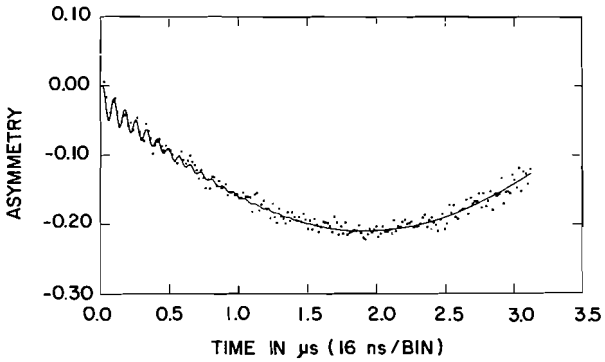

FIG. 3. MSR data and computer fit to eq. [1] for 1.9×10^{-4} *M* phenol in *n*-hexane.

The overall results are presented in Table 1, where the values obtained for P_D, P_M, P_L ($= 1 - P_D - P_M$), and λ are given for *n*-hexane, cyclohexane, TMS, methanol, and water. Data have previously been obtained for methanol (4, 5) and water (3, 11) and the means of the published values are given in Table 1 for comparison purposes. P_D values for all these liquids have been reported before as hot fractions (7).

During the course of these experiments several samples of each liquid were studied following different purification procedures and with different rates of bubbling by helium gas in the reaction cells. It became clear that both inherent impurities (probably carbonyl compounds and unsaturated hydrocarbons) as well as traces of O_2 in the liquids contributed to the muonium decay in all cases except water. O_2 is about 100-fold more soluble in the organic solvents than it is in water, and it probably diffuses into the cell because grease cannot be used at the pressure points between Teflon and Mylar in the cell construction when organic liquids are to be studied. Thus it was found that λ generally decreased somewhat when the gas bubbling rate was increased.

It should be emphasized, therefore, that the data reported here correspond to the longest-lived muonium signals that we obtained in the respective liquids. This does not affect P_M and P_D (indeed they are also the best "fits"), but it means that the values of λ given should merely be taken as *upper limits* at the moment.

Once the muonium decay constant λ has been determined for a particular sample of liquid it can be used as λ_0 in eq. [2] and the liquid employed as a solvent in the study of reaction rate constants of solutes. The example of phenol in *n*-hexane is shown in Fig. 3 and the result given in Table 2.

Discussion

These are the first reported observations of muonium in hydrocarbons, and the data show that

TABLE 1. Results obtained for P_D, P_M, P_L, and λ in *n*-hexane, *c*-hexane, tetramethylsilane (TMS), methanol, and water[a,b]

Liquid	P_D	P_M	P_L	$\lambda_0/10^6\ s^{-1}$
n-Hexane	0.65±0.02	0.13±0.02	0.22±0.04	1.0 ±0.5
c-Hexane	0.69±0.02	0.20±0.02	0.11±0.04	1.5 ±0.4
TMS	0.53±0.03	0.21±0.02	0.26±0.04	0.64±0.07
Methanol	0.62±0.01	0.23±0.02	0.15±0.02	2.3 ±0.4 (0.74)[c]
[d]	(0.61)	(0.19)	(0.20)	(0.75)
Water	0.62±0.01	0.20±0.01	0.18±0.01	0.25±0.08
[d]	(0.62)	(0.19)	(0.19)	(0.25)

[a] P_D, P_M, and P_L are the fractions of incident muons which are observed as diamagnetic species, free muonium atoms, or as neither of these ($P_L = 1 - P_D - P_M$), respectively. λ is the observed muonium spin relaxation rate constant.
[b] The values quoted are the mean of the values obtained independently from the left- and right-hand detectors. The error limits given cover the two values and each of their statistical errors only.
[c] Calculated for neat methanol from 20% methanol in water, from Table 2.
[d] Mean values of the data published previously in refs. 3, 4, 5, 11, and 16.

TABLE 2. Results obtained for λ in solutions (plus parameters calculated therefrom)

Composition	λ/s^{-1}	λ_0(solvent)/s^{-1}	$k_M/M^{-1}\ s^{-1}$	Calculated λ_0(solute)/s^{-1}
20% (vol) methanol in water	5.1×10^5	3.6×10^5[a]	3×10^4	0.74×10^6
1.9×10^{-4} *M* phenol in *n*-hexane	2.3×10^6	1.0×10^6	$7(\pm 2) \times 10^9$	—

[a] λ_0 in the sample of water used was considerably larger than is normal in pure water.

the yield of muonium atoms in these non-polar liquids is very similar to that found in water, methanol, and ethanol. In addition the chemical lifetime in highly purified saturated hydrocarbons is found to be comparable to that in water, and probably longer-lived than in aliphatic alcohols.

The main consequences of these findings are two-fold: first, they expand considerably the media and types of reactions in which the MSR technique can be used to study muonium chemistry; and second, they have strong implications concerning the proposed mechanisms by which muonium is formed.

(i) Muonium Reactivity

The origin of λ_0 in water has been discussed (11) but not resolved. There are reasons for believing it is not due to chemical reactions of Mu with either impurities or water itself based on its measured temperature dependence (13). Instead, it may be an artifact arising from the MSR equipment or technique rather than the chemical medium (9, 11). On the other hand, Mu reacts with neat methanol as reported by Percival *et al.* (4, 5) and as seen in Fig. 1. This reaction is probably a hydrogen abstraction reaction, as found with H atoms, but there is a very large inverse kinetic isotope effect (k_M/k_H equal to $\sim 10^{-2}$). Abstraction of hydrogen may also contribute to λ in the neat hydrocarbons studied here. Bearing in mind the fact that these values of λ are only upper limits (see previous section), the reported λ nevertheless increases systematically in the series TMS/*n*-hexane/*c*-hexane, as the $-CH_3$ groups are replaced by $>CH_2$ groups. This is to be expected if H-abstraction reactions contribute to λ since the C—H bond strength of methylene is slightly less than that of methyl.

In addition, the presence of O_2 is important in some solutions. For instance, in neat methanol $\lambda = 2.3 \times 10^6$ (Table 1), whereas from 20% methanol in water (Fig. 1*a*) one obtains $\lambda = 5.1 \times 10^5\ s^{-1}$ corresponding to λ_0 for neat methanol of $0.74 \times 10^6\ s^{-1}$ (Table 2). Since the methanol contains the same impurities in both cases, the difference in λ_0 probably arises from different residual O_2 concentrations. For the 20% solution the O_2 solubility will resemble that of water where the deoxygenation procedure used here has been shown to be adequate (12). That O_2 is involved in neat methanol is corroborated by the data of Percival *et al.* (4) which was obtained using freezing/pumping/thawing cycles to remove O_2 (see Table 1).

An example of the determination of the reaction rate constant of Mu with a solute in a hydrocarbon (for comparison with water) is provided by phenol in hexane as shown in Fig. 3 and Table 2. The value of k_M is found to be $(7 \pm 2) \times 10^9\ M^{-1}\ s^{-1}$ in hexane (Table 3), which is some three-fold faster than k_M for phenol in water (11). This in turn suggests that the enhanced reactivity seen for phenol embedded

TABLE 3. Comparison of P_M and $(1 - P_D)$ with properties of the liquid: (*i*) the fraction of electrons which escape intraspur neutralization in low LET radiolysis[a] (G_{fi}/G_t); (*ii*) the electron mobility (μ)[b]; and (*iii*) the static dielectric constant (ε)

Liquid	P_M	$(1 - P_D)$	G_{fi}/G_t	μ	ε
Water	0.20	0.38	0.62	0.002	78
Methanol	0.23	0.38	0.38	0.0006	33
TMS	0.21	0.47	0.16	100	1.8
c-Hexane	0.20	0.31	0.03	0.4	1.8
n-Hexane	0.13	0.35	0.03	0.08	1.8

[a] G_{fi} is the free ion yield (15) and G_t the total ionization yield taken to be 4.5 (±0.5) in all cases.
[b] μ is in $cm^2\ V^{-1}\ s^{-1}$, data from Allen (16).

in a micelle (8) may be due to the change from water to hydrocarbon as the environment for the reaction, rather than being connected with k_{diff} or with the collision frequency following an encounter.

Even though the origin of λ_0 in the different neat liquids remains unanswered, the empirical values can be used through eq. [2] to determine k_M in media, such as saturated hydrocarbons, in which the chemical lifetime of Mu is at least a few tenths of a microsecond. Thus one can use systems which resemble biologically-important media much more realistically than dilute aqueous solutions do.

(ii) Muonium Formation Mechanism

The values of P_D and P_M correspond to the primary disbursement of muons into diamagnetic states (including free or solvated μ^+, or molecules such as MuH, MuOH, $C_6H_{13}Mu$, etc.) or as free muonium atoms, respectively. To be observed with their spin polarizations precessing in phase, these states must have been formed within about 3×10^{-10} s of the time the energetic incident muon reached thermal energy, and they must still be present by the beginning of the detection period, $\sim 10^{-7}$ s. In all the cases reported here (though not in ice, for instance (4, 5)) there is a fraction of the incident muons, comparable in size to P_M, which does not appear as P_M or P_D. This is the "missing fraction" P_L (3). It may arise because of muon depolarization from either paramagnetic or diamagnetic states prior to $\sim 10^{-7}$ s or because of the initial incorporation of muons in free radicals, some of which have been studied at high fields (10).

The observation of a missing fraction in water when muonium was first identified in liquids (3), lead to the suggestion that some depolarization occurred by intraspur reactions, and thus to a "spur model" for muonium formation (4, 5) based on that for positronium formation (14). According to the spur model, muonium is formed by combination of a thermalized μ^+ with a free electron formed in the terminal spur of the muon's track. The immediate fate of μ^+ (and Mu), and therefore the measured yields of P_D and P_M, according to this model, should depend on both the chemical composition of the medium and those physical properties (such as dielectric constant and electron mobility) which determine the effective size and lifetime of spurs, and on the extent to which intraspur neutralization reactions occur.

However, the fact that P_M, as with P_D and P_L, is found to be nearly the same for both non-polar hydrocarbons and highly polar hydroxylic liquids, strongly suggests that the formation of muonium by intraspur neutralization reactions is not a dominant mechanism. Table 3 indicates how strikingly these data seem contrary to a spur model. It shows that P_M (and $(1 - P_D)$ to take account for possible changes in P_L) are essentially independent of: (*i*) the probability that the solvent positive ions and their concomitant electrons escape neutralization by each other in typical spurs produced in radiolysis by low linear-energy-transfer (LET) radiation; and (*ii*) the mobility of free electrons in the liquid. Thus one sees that P_M and $(1 - P_D)$ are essentially the same in water and in the hexanes, despite the fact that ~62%[5] of the cations in water avoid neutralization in the normal low LET distribution of spur sizes, whereas only ~3% do in the hexanes. Therefore, according to the spur model, P_M in hexane should have been much greater than both P_D in hexane and P_M in water. Both of these are clearly contrary to the results.

It could be argued that the terminal spur is likely to be a very small one, probably a single ion-pair spur. In which case μ^+ would be in competition with one solvent positive ion for the one free electron. The solvent ion has the advantage of always being formed very close to the electron but the muon has a higher mobility (at least prior to solvation), so it is not unreasonable to expect 20 to 40% of the muons to be neutralized — in a medium of a certain dielectric constant. For very short times water and hexane, for instance, have similar dielectric constants (high frequency values), but for times longer than the dielectric relaxation time ($\sim 10^{-11}$ s) they are dramatically different (see Table 3). The probability that an ion and an electron will neutralize when they are separated by distance r is given by eq. [3],

$$[3] \quad P(r) = 1 - \exp(-r_c/r) = 1 - \exp(-q^2/\varepsilon kTr)$$

where r_c is the Onsager critical escape radius (17), corresponding to the distance at which thermal

[5] For water, P_D equals very closely the electron (and ion) escape probability from low LET spurs (both happen to be ~62%). The values for other liquids, however, do not follow this correspondence at all.

motion overcomes the coulombic attraction, q is the unit change, ε the dielectric constant, and kT the thermal energy. For water ($\varepsilon = 78$), r_c is a mere 8 Å whereas for hexane $r_c \sim 300$ Å. Consequently, given a normal distribution of electron thermalization distances, a large fraction of ions escape neutralization in single ion-pair spurs in water, whereas only a very small fraction do in hexane. So the overall probability of Mu formation in hexane should be very much greater than in water, even if the formation occurs in small spurs.

It should also be noted that the spur model, as originally proposed to account for the inhibition of muonium depolarization by the presence of NO_3^- (4, 5), requires a large fraction of *sequential* intraspur encounters (μ^+ combining with e^- to form Mu followed by Mu encountering a further paramagnetic species). Sequential intraspur encounters are virtually impossible in a single ion-pair spur: they require either large spurs or overlapping spurs in a high LET track.

The probability of an ion being neutralized in a spur, and the time-scale over which it occurs, depend on the dielectric constant, the mean electron thermalization distance and the electron mobility. The latter property varies by more than five orders-of-magnitude for the liquids studied here (see Table 3). Mobility does not change simply according to the solvation energy but is exceptionally high for TMS which is a nearly-spherical molecule (18). This confers on the electrons in TMS a higher escape probability and shorter spur lifetime.

Recently there has been a suggestion (19) that the lifetime for muonium formation must be less than the solvation time of μ^+, otherwise μ^+ will be incorporated in a diamagnetic molecule. It was pointed out, however, that "radiation-chemical" intraspur neutralization reactions do not cease upon solvation of the ions and electrons (20, 21). In fact, the ease with which the neutralization energy is dissipated may well require some degree of solvation by at least one of the charged species involved. It is the dramatically different solvating powers of water and hexane which, again, put these two solvents on totally different planes as media for simple thermal neutralization reactions.

On the other hand, in the alternative model — the "hot model" — an epithermal muonium atom either forms a diamagnetic state (by abstracting a H atom, for instance) or is thermalized as Mu. The relative yields of P_D and P_M therefore depend primarily on the *chemical* composition and bonding rather than on physical properties: so they may well be similar for all saturated hydrogenated molecules, such as the hexanes, alcohols, and water.

This conclusion is further corroborated by the fact that an external electric field of 20 kV cm^{-1} had no effect on P_D in all the hydrocarbons studied so far (22).

Finally, one should examine why the spur model seems to have some support with respect to positronium formation (14, 23) yet is contradictory to the general points discussed herein, and to specific scavenger studies in water (20), with respect to muonium formation. There are three important differences between muons and positrons which will contribute to the end-of-tract events. First, as noted previously (21), the ionization energies of positronium and muonium are, respectively, less than and greater than the ionization energy of the molecules constituting the common liquids discussed here. Therefore, only in the case of the positron is there a gap in the kinetic energy below which it cannot undergo charge-exchange with the medium. Second, the linear-energy-transfer during the last few hundreds of eV of energy of the positron is thought to be some two orders-of-magnitude larger than that of the muon (24). The concept of a particle creating a sizable spur with its last 100 eV, or so, of energy is, therefore, much more reasonable for the positron than it is for the muon. Third, because of its much smaller mass, the thermalizing positron is more likely to be back-scattered, or to move under the influence of the Coulombic field, or to tunnel back into its track of radiation-produced free electrons.

Acknowledgments

Mechanistic study of the reaction of vitamin B_{12s} with 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane

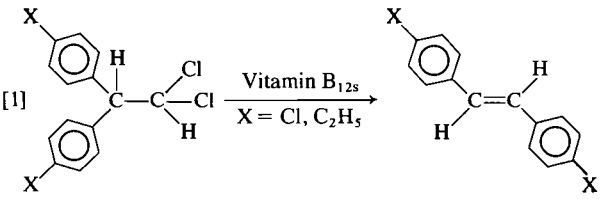
FARUK NOME AND DINO ZANETTE

Departamento de Química, Universidade Federal de Santa Catarina, 88.000 Florianópolis, S.C., Brasil

Received May 29, 1980

FARUK NOME and DINO ZANETTE. Can. J. Chem. **58**, 2402 (1980).

The reaction of vitamin B_{12s} with 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane results in the formation of *trans*-4,4′-dichlorostilbene in a two-step process. In the first step, there is a nucleophilic attack by the cobalt(I) at C-1 resulting in the displacement of chloride ion and formation of an alkyl cobalamin with a chlorine atom on the α-carbon. The second step is a cobalt chloride α-elimination which proceeds through a carbenoid type intermediate that readily rearranges to the product.



FARUK NOME et DINO ZANETTE. Can. J. Chem. **58**, 2402 (1980).

La vitamine B_{12s} réagit avec le dichloro-1,1 bis(*p*-chlorophényl)-2,2 éthane et conduit en deux étapes à la formation du dichloro-4,4′ stilbène *trans*. La première étape est une attaque nucléophile du cobalt(I) au niveau du carbone en position 1 qui provoque le déplacement de l'ion chlorure et conduit à la formation d'une cobalamine alkylée avec un atome de chlore sur la carbone en position α. La seconde étape consiste en une élimination α de cobalt et de chlore qui se fait via un intermédiaire du type carbénoïde qui se transpose facilement pour donner le produit final.

[Traduit par le journal]

Introduction

The reactions of vitamin B_{12} with a wide variety of inorganic and organic compounds, in aqueous and micellar environments, have been reported (1–6). It was recently demonstrated (7), that the reaction of vitamin B_{12s} with 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane (DDD) results in the formation of *trans*-4,4′-dichlorostilbene (DCS). A similar reaction using 1,1-dichloro-2,2-bis(*p*-ethylphenyl)ethane resulted in the production of *trans*-4,4′-diethylstilbene (eq. [1]) (7). The above

[1]

described reactions appear to be mechanistically interesting since, for the product to be formed, two chlorine atoms must be eliminated and a phenyl migration should occur.

It is our purpose to report some studies on the interactions of vitamin B_{12s} with several possible intermediates, the results of which clarify the mechanism of this dechlorination reaction.

Experimental

All melting points are uncorrected. Infrared spectra were determined with a Perkin-Elmer 720 spectrophotometer. Nuclear magnetic resonance spectra were run in $CDCl_3$ on a Varian HA-100 spectrometer using tetramethylsilane as internal reference. Ultraviolet spectra were obtained in methanol by means of a Varian 634 spectrophotometer.

Vitamin B_{12a}, aquocobalamin, was purchased from Merck Chemical Co., 1,1-dichloro-2,2-bis(*p*-ethylphenyl)ethane from Chemical Service, and 1,1-dichloro-2,2-bis(*p*-chlorophenyl)-ethane (DDD) from Aldrich Chemical Co. The purity of the three reagents mentioned above was found to be satisfactory by thin-layer chromatographic analysis.

The intermediate 1-chloro-2,2-bis(*p*-chlorophenyl)ethane (DDMS) was prepared by a slight modification of a previously described procedure (8) and crystallized several times from ethanol, mp 51–51.5°C (lit. (8) mp 51–51.5°C). The observed nmr spectra (A_2B_2 aromatic protons, multiplet centered at 7.19 ppm, doublet at 3.95 ppm, and triplet at 4.25 ppm, integration 8:2:1) was identical with that reported elsewhere (9).

A sample of 2-chloro-1,2-diphenylethanol was prepared by the treatment of benzoin with thionyl chloride, in order to form desyl chloride, followed by sodium borohydride reduction (10). The compound presented fine structure in the 250–260 nm region, with a molar absorptivity of about 500, and when treated with zinc dust in acetic acid and crystallized afforded diamond-shaped irridescent plates of *trans*-stilbene as already described (10).

The compound 1-chloro-1,2-bis(*p*-chlorophenyl)ethane (DDMF) was prepared by treatment of a 10.0 g dry sample of 2,2-bis(*p*-chlorophenyl) acetic acid with lithium aluminum hydride in diethyl ether forming 2,2-bis(*p*-chlorophenyl)ethanol (yield 90%). Reaction of the alcohol (6.0 g) with thionyl chloride (1.7 mL) resulted in the formation of DDMF and DCS. The reaction mixture was purified by column chromatography using a 60 cm × 25 mm silica gel column and hexane (Ecibra) as the eluent. The uv spectra showed fine structure with maxima at 276.5, 268, and 261 nm; nmr showed an aromatic proton multiplet centered at 7.13 ppm, a doublet at 3.27 ppm, and a triplet at 4.90 ppm, integration 8:2:1. Besides, chemical treatment of a sample with alcoholic KOH resulted in quantitative transformation of DMF to DCS, as would be expected. All the other compounds were the best available reagent grade.

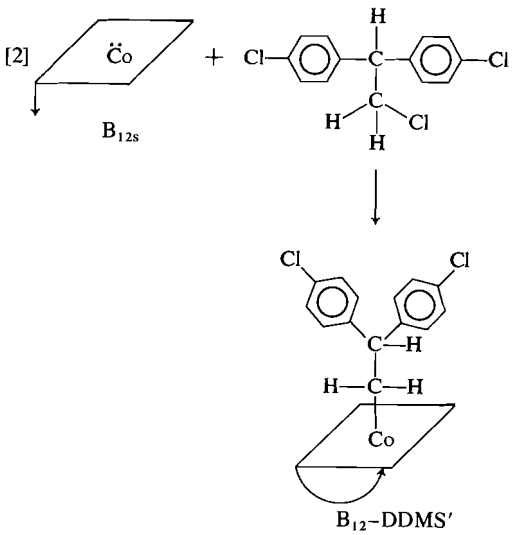
In a typical reaction, a solution of aquocobalamin (400 mg in 25 mL of water) was purged with purified nitrogen in a closed vessel through rubber septa for 2 h. A capillary tube punched just through the rubber septum provided the vent. Subsequent to deoxygenation, 200 mg of $NaBH_4$ was added, and the mixture

0008-4042/80/232402-04$01.00/0

©1980 National Research Council of Canada/Conseil national de recherches du Canada

allowed to react for 10 min. A solution of polyhalogenated hydrocarbon (30 times molar excess, dissolved in 250 mL of methanol, also purged for 2 h with purified nitrogen), was added and allowed to react. The reactions were monitored by thin-layer chromatography (using silica gel GF_{254}, type 60, Merck, and petroleum ether, fraction 30–60, Ecibra, as developing solvent). The colored solution was then extracted with several portions of chloroform to remove the organic fraction. The chloroform extract was rotary evaporated to dryness, and dried *in vacuo* in a Abderhaldem type apparatus over P_2O_5. The different products were separated by column chromatography using silica gel and then used for subsequent analysis. In all the reactions more than 90% of the organic compounds were recovered. In the reaction of vitamin B_{12s} with DDMS a vitamin B_{12} complex was formed. The alkyl cobalamin was purified by column chromatography using silica gel (Merck) and methanol as eluent. All the procedures for the isolation of the vitamin B_{12}–DDMS′ complex were done in the absence of light in order to prevent its photolysis.

Results and Discussion



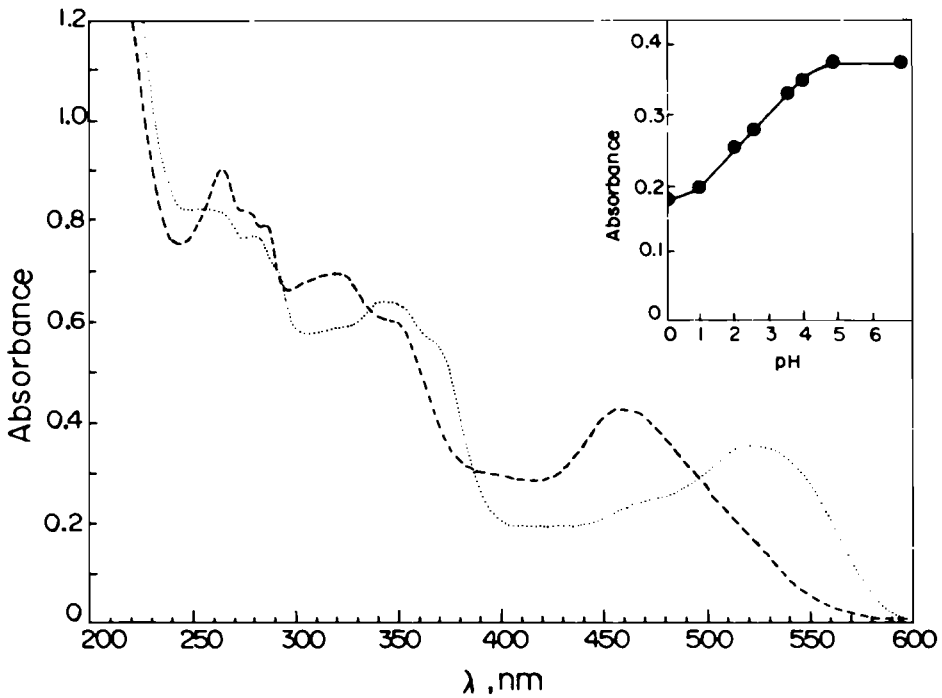
Vitamin B_{12s}, generated by the $NaBH_4$ reduction of aquocobalamin, appears to be the reactive species in the dechlorination of DDD. Indeed vitamin B_{12r}, generated by photolysis of methylcobalamin in a nitrogen atmosphere, does not react with DDD to produce DCS. Furthermore, if the Co(I) nucleophile is generated by an independent method, like treatment of the vitamin B_{12}–DDMS′ complex with base in a nitrogen atmosphere, DCS is also formed upon reaction with DDD. The first step of the reaction must be a nucleophilic attack of the cobalt(I) on DDD resulting in the formation of a vitamin B_{12}–DDD′ complex, a reaction which involves formation of a cobalt–carbon sigma (σ) bond and which is expected for a cobalt(I) supernucleophile such as vitamin B_{12s} (1, 2, 11).

Since DDD is present in large excess as compared with vitamin B_{12s} and the reaction goes to completion, it is obvious that the vitamin B_{12}–DDD′ complex must be unstable and regenerates the cobalt(I) nucleophile or vitamin B_{12r}, the latter of which is reduced by sodium borohydride to the vitamin B_{12s} form.

The main question to be answered in order to clarify the reaction pathway is whether the reaction proceeds via any isolable intermediate which subsequently reacts with vitamin B_{12s} to form DCS or, if the vitamin B_{12}–DDD′ complex directly decomposes to generate DCS.

There are three possible reactive intermediates to be formed upon decomposition of the vitamin B_{12}–DDD′ complex. Namely, 1,1-bis(*p*-chlorophenyl)-2-chloroethane (DDMS), 1,2-bis(*p*-chlorophenyl)chloroethane (DDMF), and 1,2-bis(*p*-chlorophenyl)-2-chloroethanol (DDMFOH). Thus in order to test the different reaction pathways, the compounds DDMS, DDMF, and an analog of DDMFOH were synthesized and their reactions with vitamin B_{12s} were investigated under conditions identical to those for which the reaction of DDD was studied.

DDMS reacts with vitamin B_{12s} in stoichiometric 1:1 proportion and all the excess of DDMS added can be recovered as unreacted material. Since DCS was not detected in the reaction mixture, and DDMS reacts in stoichiometric rather than catalytic proportions, it cannot be the reactive intermediate. Equation [2] describes the reaction occurring under our experimental conditions. Vitamin B_{12s} displaces chloride ion (detected by $AgNO_3$ titration) through a nucleophilic substitution process, forming a product which displays all the characteristics of a typical alkyl cobalamin. Treatment of the vitamin B_{12}–DDMS′ complex with hydroxide ion, using hexadecyldimethyl-2-hydroxyethyl ammonium bromide as catalyst, results in the formation of 1,1-bis(*p*-chlorophenyl)ethylene and vitamin B_{12a} as products, a result which is consistent with the proposed structure for the alkylcobalamin. Figure 1 shows a spectrum of the purified reaction product. As can be seen, the γ-band at 350 nm which is typical of vitamin B_{12a} is absent, and no sharp absorption band is observed in the 320–370 nm region. Indeed, the observed spectrum (Fig. 1, dotted line) is very similar to that reported for methyl cobalamin (2). Upon addition of 0.1 *M* hydrochloric acid, the alkylcobalamin turns yellow, reflecting the shift in the protonation equilibria of the benzimidazol in the fifth coordination position upon alkylation of the cobalt (Fig. 1, dashed line). Using the change in the absorption spectrum upon protonation, the pK_a for the base-on – base-



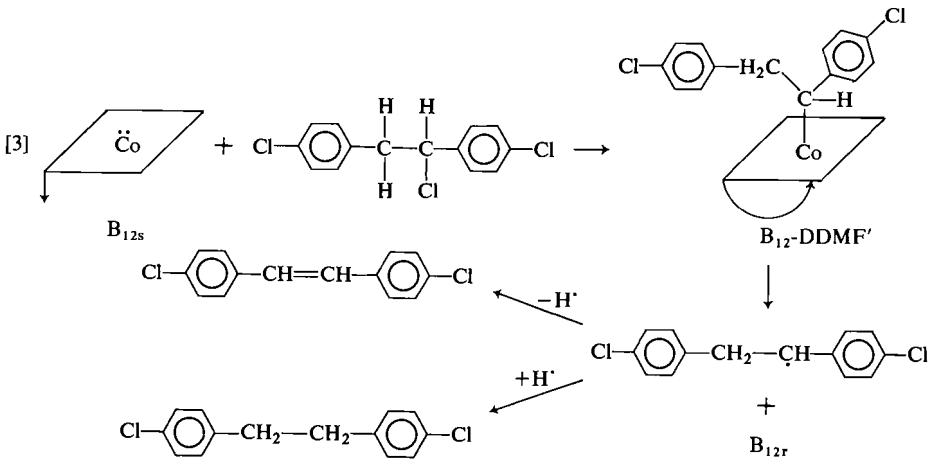


FIG. 1. Absorption spectrum of the vitamin B_{12}–DDMS′ complex at pH 7.0 (...) and pH 1.0 (---). The insert shows the absorbance at 462 nm as a function of pH.

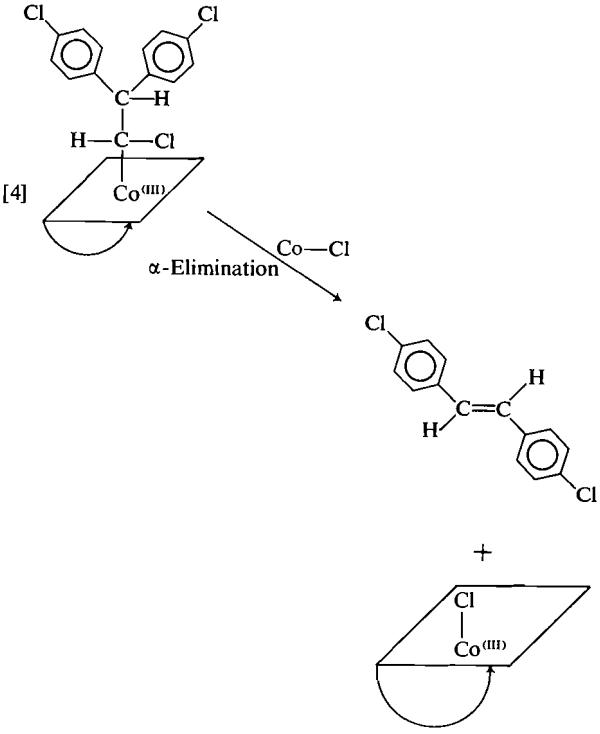

off equilibria was determined spectrophotometrically to be 2.5 (insert of Fig. 1). The obtained value is in close agreement with that normally reported for alkyl cobalamins (2).

Since DDMS was excluded as the reaction intermediate, the pathways involving phenyl migration and leading to the formation of DDMF and DDMFOH were analyzed. Under our experimental conditions 2-chloro-1,2-diphenylethanol, a chemical analog of DDMFOH without the chloro substituents in *para* position, did not react with vitamin B_{12s} to produce *trans*-stilbene and was therefore excluded as a possible reaction intermediate. Considering that the effect of the phenyl group should be somewhat between those of the *p*-ethylphenyl and *p*-chlorophenyl substituents, the choice of 2-chloro-1,2-diphenylethanol as an analog of DDMFOH seems reasonable since both DDD and 1,1-dichloro-2,2-bis(*p*-ethylphenyl)ethane react with vitamin B_{12s} to form the corresponding *trans*-stilbene. The interaction of DDMF with the cobalt(I) nucleophile was then investigated; eq. [3] describes our experimental results. Two organic products were detected in the analysis of the reaction mixture, namely DCS and 1,2-bis(*p*-chlorophenyl)ethane. Since the participation of vitamin B_{12s}, in the presence of $NaBH_4$, is catalytic, the vitamin B_{12}–DDMF′ complex formed upon nucleophilic attack of the cobalt(I) on DDMF must be unstable. The instability of the vitamin B_{12}–DDMF′ complex is not unexpected, since many examples are available showing the lack of stability of a cobalt–carbon bond involving a secondary carbon atom (2, 8). Thus, the reaction of isopropyl iodide with vitamin B_{12s} resulted in the production of vitamin B_{12r} via homolytic bond rupture of the initially formed alkyl cobalamin (11). Our results are entirely consistent with this type of mechanism, since homolytic cobalt–carbon bond cleavage of the vitamin B_{12}–DDMF complex would generate a free radical, which upon uptake or loss of a hydrogen atom will result in the formation of DCS and 1,2-bis(*p*-chlorophenyl)ethane respectively. Considering that in the reaction of vitamin B_{12s} with DDD only DCS was detected as reaction product, and that 1,2-bis(*p*-chlorophenyl)ethane could not be detected even in trace amounts, our evidence indicates that DDMF is not a reaction intermediate.

Thus, the reaction most likely proceeds directly from the vitamin B_{12}–DDD′ adduct to DCS without the participation of any isolable reaction intermediate; eq. [4] describes such a possibility. The vitamin B_{12}–DDD′ complex reacts via a cobalt chloride α-elimination to yield DCS and a vitamin B_{12} – chloride complex, in which the cobalt atom is formally in the Co(III) oxidation state. Hydrolysis of this complex will result in liberation of vitamin

B_{12a} and free chloride ion. The reaction described in eq. [4] is not unprecedented by any means, indeed it is analogous to the Simmons–Smith procedure (12), and to the reaction of organic *gem*-

dihalides with copper (13) among others (14), since the α-elimination will generate a carbene or carbenoid type intermediate which will readily rearrange to the products. Attempts to trap a free carbene using cyclohexene were unsuccessful, a result which was somewhat expected since DCS itself may act as a carbene trapping agent. Besides, alkylcarbenes generally undergo rearrangement so rapidly that additions to double bonds and insertion reactions, which are normally expected for carbene itself, are seldom found with alkyl carbenes. Our results seem to be more consistent with a carbenoid type intermediate rather than a totally free carbene. Accordingly, the rearrangement should occur concurrently with the α-elimination.

We are currently working on the development of a procedure for the synthesis of cyclopropane derivatives based on a modification of the above described reaction, using simple cobalt complexes.

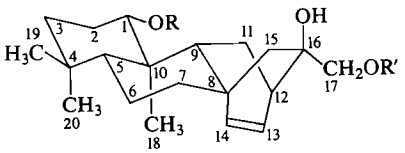
Received July 3, 1980

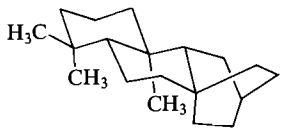
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

WILLIAM A. AYER, JO-ANN H. FORSYTHE, LOUIS T. J. DELBAERE, and CAROLINE U. DELBAERE. Can. J. Chem. **58**, 2406 (1980).



The crystal structure of 1-*O*-acetyl-17-*p*-bromobenzoylsideritol (*ent*-1α-acetoxy-16β-hydroxy-17-*p*-bromobenzoyloxyatis-13-ene) is presented. This crystal structure establishes unequivocally the structure of sideritol (**1**).

WILLIAM A. AYER, JO-ANN H. FORSYTHE, LOUIS T. J. DELBAERE et CAROLINE U. DELBAERE. Can. J. Chem. **58**, 2406 (1980).



On présente la structure du cristal du *O*-acétyl-1 *p*-bromobenzoyl-17 sidéritol (*ent* acétoxy-1α hydroxy-16β *p*-bromobenzoyloxy-17 atisène-13). La structure du cristal établit de façon non équivoque la structure du sidéritol (**1**).

[Traduit par le journal]

Some time ago we proposed (1) structure **1** for sideritol, a diterpenoid isolated from *Sideritis angustifolia* Lag. (2). This was the first reported example of an oxygenated nitrogen-free diterpenoid of the *ent*-atisane type. The absolute configuration of **1** was established by correlation with *ent*-17-noratisane (**2**). The location of the secondary alcohol function at C-1 (as opposed to C-7) was based on the observation that the corresponding ketone showed a weakly positive Cotton effect in the circular dichroism (c.d.) spectrum. The stereochemistry at C-16 was assigned on the basis of the fact that the methylene group of the hydroxymethyl group (C-17) shows a significant downfield shift (in the ^1H nuclear magnetic resonance (^1H nmr) spectrum) when the C-13, C-14 double bond is hydrogenated (1). Although all the evidence presented is consistent with the assigned structure, we felt it desirable to confirm the assignment by means of a single crystal X-ray diffraction study. This seemed especially important with regard to the assignment of the position of the secondary hydroxyl group, since the c.d. assignment is based on steroidal analogies, and it is known that the presence of axial methyl groups at C-4 and C-10 in ring A ketones may lead to a distortion of ring A (3, 4), which might invalidate the argument.

2

p-Bromobenzoylation of 1-*O*-acetylsideritol (**3**) in pyridine at room temperature provided the nicely crystalline 17-*O*-*p*-bromobenzoate **4**, mp 199–201°C, which crystallizes from ethyl acetate with the following crystal data:

$C_{29}H_{37}O_5Br$ mw = 545.1
$P2_1$, a = 15.307(3), b = 25.989(6), c = 6.929(2) Å, β = 101.5°, V = 2701.2 Å^3, Z = 4, ρ_c = 1.34 g/cm^3, $F(000)$ = 1144e.

Examination of the two strongest peaks on the Harker section (v = 1/2) and possible cross vectors provided the positions of the bromine atom of each of the two crystallographically independent molecules. Structure factors calculated for these bromine atoms produced an R index ($R = [\Sigma_{hkl}||F_o| - |F_d||]/[\Sigma_{hkl}|F_o|]$, where F_o and F_c are the observed and calculated structure factors, respectively) of 0.377. The remaining non-hydrogen atoms of the two molecules were located by means of subsequent difference maps calculated after including additional atoms in block-diagonal least-squares

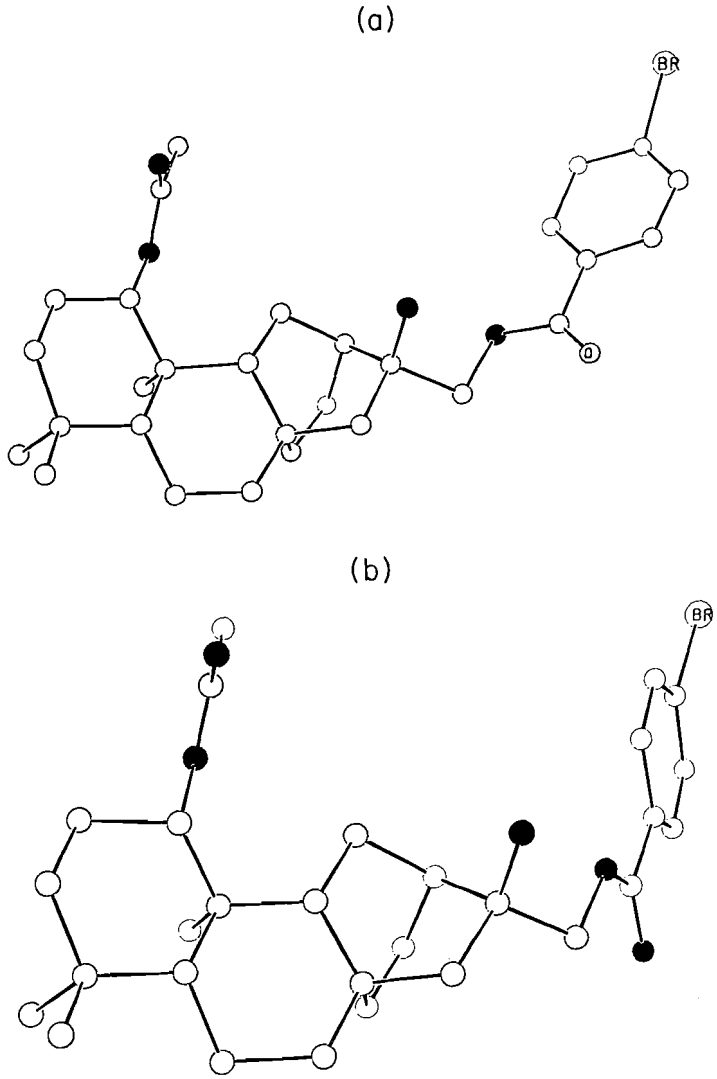

FIG. 1. Perspective view of the two crystallographically independent molecules (*a* and *b*) of 1-*O*-acetyl-17-*p*-bromobenzoylsideritol (**4**). The oxygen atoms of the molecules are illustrated as solid dark circles.

refinement. The quantity minimized was $\Sigma_{hkl}(|F_o| - k|F_c|)^2$, where k is the scale factor relating the observed and calculated structure amplitudes. The isotropic temperature factor refinement gave an index of 0.144. Further block-diagonal least-squares refinement, with anisotropic temperature factors for only the bromine and oxygen atoms lowered R to 0.108. Refining anisotropic temperature factors for all of the non-hydrogen atoms produced a final R index of 0.077.[1]

[1]Tables of atomic parameters, bond lengths and angles, and structure factors are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Perspective drawings of the two crystallographically independent molecules of **4** are shown in Fig. 1 (*a*) and (*b*). The conformation of the *p*-bromobenzoyl group around the C17—O17 bond varies in the two molecules due to crystal packing forces. There are two hydrogen bonds between the two crystallographically independent molecules, both from the tertiary hydroxyl group at C-16 of one molecule to the carbonyl oxygen atom of the acetyl group at C-1 of the other molecule; the distance between the oxygen atoms involved are 2.76 Å and 2.71 Å, respectively. The crystal structure shows that ring A is not distorted by the non-bonded interaction of the axial methyl groups at C-4 and

TABLE 1. Torsion angles (deg) around ring A of the two molecules of **4**

Atoms	Torsion angle (deg)		
	Molecule I	Molecule II	Average
C1—C2—C3—C4	−57	−57	−57
C2—C3—C4—C5	52	55	54
C3—C4—C5—C10	−48	−59	−54
C4—C5—C10—C1	45	58	51
C5—C10—C1—C2	−48	−63	−55
C10—C1—C2—C3	55	68	62

C-10. Table 1 gives the torsion angles around ring A for both independent molecules of **4**. The average torsion angles indicate that ring A has a regular chair conformation; the individual torsion angle differences between the two molecules are probably due to crystal packing forces. This, of course, does not mean that the ring A ketone is free from distortion. The crystal structure does, however, establish unequivocally the structure of sideritol.

Experimental

Mass spectra were recorded on an A.E.I. Model MS-9 mass spectrometer, ^{1}H nmr spectra were recorded on a Varian HR-10 spectrometer with tetramethylsilane as internal standard, and infrared spectra on a Perkin-Elmer Model 421 dual grating spectrometer.

The X-ray intensity data were collected from a crystal measuring 0.08 × 0.06 × 0.53 mm with a Picker FACS-1 diffractometer and a θ–2θ scan. The scan speed was 2° min^{-1} over a range of $(1.5 + 0.285 \tan\theta)°$ with Ni-filtered CuK_α radiation (λ = 1.5418 Å). A total of 1696 unique reflections with $2\theta < 80°$ were measured and 1257 had $I > 3\sigma(I)$. Lorentz and polarization corrections were applied but no absorption corrections were made. All crystallographic computations were carried out using the X-ray 70 system (5) on the Amdahl 470/V6 system at the University of Alberta.

*1-O-Acetyl-17-*p*-bromobenzoylsideritol (*ent*-1α-acetoxy-16β-hydroxy-17-*p*-bromobenzoyloxyatis-13-ene) (**4**)*

1-*O*-Acetylsideritol (**3**) (50 mg), pyridine (2 mL), and *p*-bromobenzoyl chloride (130 mg) were allowed to stir at room temperature for 24 h. The reaction mixture was then diluted with water and extracted with ether. The ether extracts were washed, dried, and concentrated. Chromatography over silica gel (eluent ethyl acetate) provided 1-*O*-acetyl-17-*p*-bromobenzoylsideritol (**4**) (41 mg), mp 199–201°C (from ethyl acetate). Ir (Nujol) cm^{-1}: 3500 medium (OH), 1720 (sh), 1708 strong (C=O), 1585 medium (aromatic); ^{1}H nmr ($CDCl_3$): δ 7.72 (4H, quartet, aromatic H's), 5.98 (2H, multiplet, H-13 and H-14). 4.55 (1H, apparent doublet of doublets, *J*'s 6 and 8 Hz, H-1β), 4.02 (2H, quartet, —CH_2—O—), 2.48 (1H, multiplet, H-12, 1.97 (3H, singlet, OCOCH_3), 0.86 (3H, s), 0.79 (3H, s), 0.73 (3H, s). Rydberg orbitals and the Woodward–Hoffmann procedure

C. SANDORFY

Département de chimie, Université de Montréal, Montréal (Qué.), Canada H3C 3V1

Received May 6, 1980

This paper is dedicated to Prof. R. U. Lemieux on the occasion of his 60th birthday

C. SANDORFY. Can. J. Chem. **58**, 2409 (1980).

It is argued that account should be taken of Rydberg states when the course of photochemical reactions is interpreted through correlation diagrams based on the principle of conservation of orbital symmetry. This is expected to be important for molecules whose lowest excited state has Rydberg character and a symmetry different from that of the lowest valence-shell type excited state.

C. SANDORFY. Can. J. Chem. **58**, 2409 (1980).

Il est nécessaire de tenir compte de l'existence d'états Rydberg quand on interprête le cours des réactions chimiques à la base de diagrammes de corrélation invoquant la conservation de la symétrie orbitale. Cela peut être important pour les molécules dont l'état excité de plus basse énergie a un caractère Rydberg et une symétrie différente de celle que possède la molécule dans son état excitée de valence de plus basse énergie.

One of the classical examples of the application of the principle of orbital symmetry conservation to the feasibility of thermal and photochemical reactions is the formation of cyclobutane from two ethylene molecules (1, 2). The first task is to choose the proper combinations of orbitals for two ethylenes approaching each other along the line containing the symmetry axis perpendicular to the molecular planes of both ethylenes, in the most symmetrical way. If π_1 and π_2 are the π orbitals of the two ethylenes which are filled and π^*_1 and π^*_2 those which are empty in the ground state, the proper combinations are $\pi_1 + \pi_2$ and $\pi_1 - \pi_2$ for the ground state and $\pi^*_1 + \pi^*_2$ and $\pi^*_1 - \pi^*_2$ for the excited states. The next step is to write down the relevant orbitals for the product, cyclobutane. For this, two pairs of π orbitals of the reactants have to transform into two σ orbitals of the product. Then we have a correlation diagram and if only we admit that the orbitals conserve their symmetry we can assess the height of the transition state that has to be reached in order to get from the reactants to the products. The characteristic symmetry elements in this case are the two planes perpendicular to the plane of the paper and S and A signify symmetrical and antisymmetrical with respect to these. Figure 1, adapted from Woodward and Hoffmann, illustrates the procedure. As is now well known the thermal reaction is "symmetry-forbidden", since in order to get from the reactants to the products while conserving symmetry the SA orbital of the ground state would become an antibonding orbital of high energy of the product. This would imply an unreasonably high activation energy. On the other hand, if one of the electrons is already in the AS excited state of the reactants it would correlate to a bonding orbital of the same symmetry of cyclobutane so that the photochemical reaction is symmetry allowed.

It is not intended to criticize this highly successful procedure. One might, however, make the following comment. Much depends on the selection of the relevant reactant and product orbitals. There is no argument about the ground state. As to the excited states of ethylene, however, it is known that the π^* orbital is in near coincidence with the 3*s* Rydberg orbital which does *not* have the same symmetry as the π^* orbital (3, 4). In the ultraviolet spectrum of ethylene itself the V $\leftarrow$ N (π,π^*) transition gives rise to a broad band whose maximum corresponding to the vertical transition is near 162 nm (61 700 cm^{-1}) from where it extends to about 210 nm (48 000 cm^{-1}) exhibiting complicated fine structure in the adiabatic part. The 3*s* $\leftarrow$ N Rydberg band ($^1B_{1u} \leftarrow {}^1A_g$; the (π,π^*) band is $^1B_{3u} \leftarrow {}^1A_g$ with the *X* axis taken along the C—C bond, and the *Z* axis perpendicular to the molecular plane) is superimposed to the wing of the intense (π,π^*) band and is centered at 174 nm (57 400 cm^{-1}). In many ethylene derivatives the Rydberg band is at lower frequencies and is clearly separated from the (π,π^*) band (3, 5–7). It is not intended to draw conclusions related to the course of the ethylene to cyclobutane reaction itself; it is only used as a model. It is conceivable, however, that in this or other similar cases the photochemical reaction chooses to proceed through the $(\pi,3s)$ excited state rather than through the (π,π^*) state. Then instead of the AS orbital (Fig. 1) we have a totally symmetrical (SS) Rydberg orbital.

Then, if conservation of orbital symmetry is stipulated this orbital cannot become the AS σ orbital of cyclobutane. However, the 3*s* Rydberg band of cyclobutane itself is at nearly the same energy as the one of ethylene and it is tempting to speculate that cyclobutane is first formed in *its* 3*s* state. In this way, orbital symmetry would be conserved.

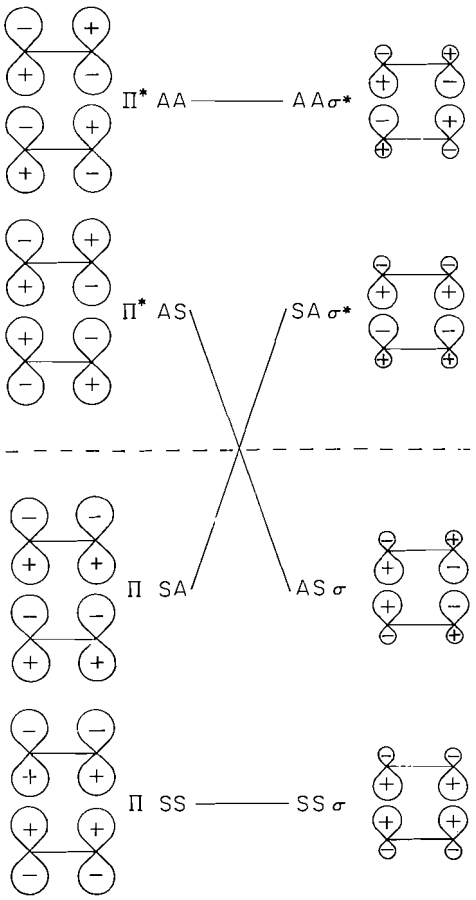

FIG. 1. Correlation diagram for the formation of cyclobutane from two molecules of ethylene. Adapted from R. B. Woodward and R. Hoffmann, The conservation of orbital symmetry. With permission from the authors and Verlag Chemie, GMBH.

Most known photochemical reactions lead to products in their electronic ground states. There are, however, cases in which the product is first obtained in an excited state and then it rids itself from the excitation energy by radiationless transition (8). If this was the case the yield would have a pronounced pressure dependence. It is to be remembered in this respect that Rydberg orbitals because of their large size are very sensitive to intermolecular interactions (9); therefore trimolecular collisions might be important for the kinetics of reactions occurring in such states. Many organic molecules have low-lying Rydberg states. Indeed, they are the lowest for many (10). Whether these considerations have any relevance to the particular case of the ethylene → cyclobutane reaction or not, the Rydberg route might turn out to be important for a number of photochemical reactions.

Similar considerations would apply to the method proposed by Salem *et al.* (11, 12) and by Dauben, Salem, and Turro (13) for the interpretation of the course of photochemical reactions. According to this method photochemical reactions proceed through primary products having the characteristics of diradicals. The procedure consists in enumerating the relevant reactant and primary product states and then constructing a correlation diagram so that symmetry and multiplicity are conserved. As the writer commented previously low-lying Rydberg states might play a role in this scheme too (10).

Caution should be exercised. States that are Rydberg at molecular distances may not remain so at the long internuclear distances involved with bond formation or dissociation. Every case would require a particular treatment. All that this brief note has been aiming at is to draw attention to a problem which might well turn out to be important for photochemistry.[1]

The phenolic hydroxyl content of lignin in spruce wood

J.-M. YANG AND D. A. I. GORING

Pulp and Paper Research Institute of Canada and Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2A7

Received October 1, 1979[1]

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

J.-M. YANG and D. A. I. GORING. Can. J. Chem. **58**, 2411 (1980).

Values of the phenolic hydroxyl content of the lignin in the secondary wall and cell corner middle lamella of the tracheids in black spruce wood were found by ultraviolet microscopy to be 0.12 and 0.06 PhOH/C_9 respectively. The overall value for the lignin in black spruce wood was 0.10 PhOH/C_9.

J.-M. YANG et D. A. I. GORING. Can. J. Chem. **58**, 2411 (1980).

Nous avons découvert, en utilisant la microscopie aux ultraviolets, que les valeurs absolues de la teneur en groupes hydroxyles phénoliques de la lignine dans la paroi secondaire et dans la lamelle moyenne aux coins de cellule des tranchéides d'épinette noire étaient de 0,12 et 0,06 PhOH/C_9 respectivement. La valeur globale de la lignine de l'épinette noire était de 0,10 PhOH/C_9.

Introduction

The proportion of phenylpropane units in lignin which contain free phenolic hydroxyl groups is a fundamental structural parameter of the lignin macromolecule (1, 2). Several techniques have been used for the determination of the PhOH[2] content of lignins from wood by the various laboratory and commerical methods of delignification (3). However, to date, no measurements have been reported of the PhOH content of lignin *in situ* in the wood. The purpose of the work described in the present paper was to make such measurements.

The spectroscopic $\Delta\varepsilon$ method of Aulin-Erdtman (4) has been used widely to determine the PhOH content of lignin. Applied microscopically in the ultraviolet it showed that the PhOH content of the lignin in the secondary walls of softwood tracheids is twice as great as that in the middle lamella (5). However, the $\Delta\varepsilon$ method is not absolute in the sense that it can be used by itself to determine the PhOH content. The method must be calibrated either by the use of model compounds (6, 7) or by measurements on a sample of lignin for which the PhOH content has been determined independently. A reliable chemical method for the determination of PhOH has been developed by Adler *et al.* (1) and Gierer *et al.* (8) in which the methoxyl group *vicinal* to the free phenolic hydroxyl group is converted into methanol by periodate oxidation and determined by gas chromatography.

In the present work the $\Delta\varepsilon$ method was calibrated by measurements on solutions of a milled wood lignin for which the PhOH content was measured by periodate oxidation. The calibration factor thus obtained was applied to $\Delta\varepsilon$ data determined microscopically on sections of spruce wood. In this manner values of the PhOH content of the lignin in the secondary wall and middle lamella of the tracheids in the wood were obtained.

Experimental

The milled wood lignin (MWL) was prepared from black spruce wood by the method of Björkman (9). Its elemental composition, methoxyl content, and carbohydrate content, are given in Table 1. Assuming the methoxyl content of "pure" MWL to be 15.7% (10), the sample used in the present work was taken to be 14.7/15.7 ≡ 94% pure. The impurity was probably acetic acid not completely removed in the preparation of the sample.

For measurement of $\Delta\varepsilon_{300}$, a 0.1% solution of MWL in *p*-dioxane was made up. Two millilitres of this solution was diluted to 25 mL with a 50/50 mixture of dioxane/water to give the neutral solution. The alkaline solution was made up by a similar dilution in a phosphate/NaOH buffer of pH 12. Ultraviolet spectra of the MWL solutions and solvent blanks were then recorded and $\Delta\varepsilon_{300}$ calculated from the difference in absorbances at 300 nm, ΔA_{300}, from

$$[1] \quad \Delta\varepsilon_{300} = \Delta A_{300}/Cl$$

in which C is the concentration of MWL corrected for the purity of the sample and l is the absorbance cell length (1 cm).

The experiment was then repeated using pure *p*-dioxane as the neutral solvent for dilution instead of the 50/50 mixture of dioxane/water.

The method of Gierer *et al.* (8) was used for the measurement of PhOH by gas chromatography. Chromasorb W was coated

with Triton X-100 dissolved in methanol. The stationary phase was then packed into a 2 m copper column in a Hewlett-Packard 402 High Efficiency Gas Chromatograph. About 40 mg of MWL was soaked in 1 mL of glacial acetic acid and then reacted with 7 mL of 0.133 mol/L periodate in 3:2 glacial acetic acid/distilled water at 4°C in a dark room. After the reaction, 3.5 μL of benzene was added as an internal standard. Three microlitres of the reaction products were injected into the column with a helium flow rate of 25 mL/min, a hydrogen flow rate of 25 mL/min, and an air flow rate of 200 mL/min.

As shown in Fig. 1, three peaks were obtained in the gas chromatogram after the periodate oxidation. They were for benzene, methanol, and methyl acetate. The methyl acetate was produced by reaction of some of the methanol with the glacial acetic acid.

The column was calibrated by substitution of pure methanol and pure methyl acetate for the MWL in the experiment described in the previous paragraph. As shown in Fig. 1, the methyl acetate gave a single peak while the methanol gave two peaks due to some conversion of the methanol into methyl acetate. Calibration curves were obtained by injecting known weight ratios of methanol/benzene and methyl acetate/benzene, measuring peak weight ratios by cutting out and weighing and plotting true weight ratios to peak weight ratios. The calibration curves were then used to determine the moles of MeOH and MeOAc produced by periodate oxidation of a known weight of MWL.

The moles of PhOH per C_9 residue in the MWL was then calculated from

$$[2]\quad \mathrm{PhOH/C_9} = \frac{184\,(\text{moles of MeOH} + \text{moles of MeOAc})}{\text{Weight of MWL}}$$

in which the monomer weight in MWL is taken to be 184 and the weight of the MWL is corrected for the purity of the sample.

Assuming that $\Delta\varepsilon_{300}$ is proportional to $\mathrm{PhOH/C_9}$ we may write

$$[3]\quad \mathrm{PhOH/C_9} = k\Delta\varepsilon_{300}$$

in which k is a constant. The value of k was then computed from $\Delta\varepsilon_{300}$ and $\mathrm{PhOH/C_9}$ obtained from eqs. [1] and [2] respectively. It is interesting to note that since corrections are made in both eqs. [1] and [2] for the purity of the MWL, the value of k obtained from eq. [3] is not affected by an error in the purity of the sample.

For measurements with the ultraviolet microscope, small chips 1 mm^2 × 7 mm were cut from the rings between 80 and 85 of a 183-year old black spruce tree (*Picea mariana* (Mill) BSP). The chips were embedded in Epon and ultrathin transverse sections of nominal thickness of 0.9 μm were cut with a diamond knife mounted on a Porter-Blum ultramicrotome. The sections were collected, soaked in a buffer solution of pH 12 for 30 min, and then some of them were transferred to a buffer solution of pH 6 for a further 30 min.

The sections were transferred to quartz slides and the transmittance at 300 nm was measured with a Leitz ultraviolet microscope. The microscopic methods used were essentially those of Scott *et al.* (11) and are given in greater detail elsewhere (12).

Absorbance was measured in the microscope for the S2 layer of the secondary wall and for the middle lamella at the cell corners. From the difference in absorbance from pH 12 to pH 6, $\Delta\varepsilon_{300}$ was computed by means of eq. [1]. For this purpose it was necessary to know the thickness of the section with accuracy. Accordingly the thickness of several sections was measured with a Zeiss interference microscope and the absorbance at 300 nm of the S2 layer on the same sections was measured on the uv microscope. From these data the relationship between section thickness and A_{300} was established, by means of which the values of ΔA_{300} could be normalized to correspond to a section thickness of 1.00 μm. The details of this procedure are given elsewhere (12).

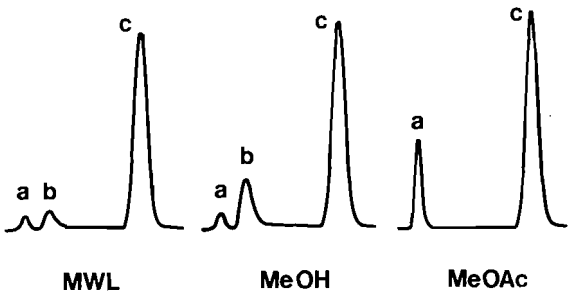

FIG. 1. Chromatograms obtained from MWL, methanol, and methyl acetate: peak *a*, methyl acetate; peak *b*, methanol; peak *c*, benzene.

Results

Considerable trial and error was necessary in preparing the solutions of MWL for the measurement of $\Delta\varepsilon_{300}$. It was found that a 0.1% solution of MWL in dioxane could be diluted 10-fold with the pH 12 buffer to give a clear, stable solution. However, this was not the case for the neutral system. A similar procedure with the pH 6 buffer or with distilled water gave a turbid solution and caused precipitation of the lignin. However, when the 0.1% solution of MWL in dioxane was diluted with a 50/50 mixture of dioxane and distilled water, the resulting solution was clear and stable and could be used for the measurement of $\Delta\varepsilon_{300}$.

As shown by the results in Table 2, $\Delta\varepsilon_{300}$ was virtually unchanged when dioxane instead of 50/50 dioxane/water was used for the dilution. This result indicates that the absorbance of the neutral solution is unaffected by the use of dioxane instead of water as solvent and thus supports the validity of the measurement of $\Delta\varepsilon_{300}$ by the method discussed above. The mean of the two results was used in the calculation of k by means of eq. [1].

Three determinations of the PhOH content of the MWL were made by the periodate oxidation method. The mean and mean deviation are given in Table 2.

The ultraviolet absorbances at pH 6 and pH 12 for the S2 layer and the cell corner middle lamella were measured 50 times each and a mean taken.

TABLE 2. $\Delta\varepsilon_{300}$ and $\mathrm{PhOH/C_9}$ for MWL

Parameter	Value
$\Delta\varepsilon_{300}$(dioxane/water)	2.45 $cm^{-1}g^{-1}L$
$\Delta\varepsilon_{300}$(dioxane)	2.35 $cm^{-1}g^{-1}L$
$\Delta\varepsilon_{300}$(mean)	2.40 $cm^{-1}g^{-1}L$
$\mathrm{PhOH/C_9}$	0.205 (±0.006)
k	0.085 cm g L^{-1}

TABLE 3. Calculation of the absolute values of $PhOH/C_9$ in the lignin of the secondary wall and middle lamella of spruce wood

Parameter	S2	ML
ΔA_{300}	0.028 (±0.005)	0.053 (±0.012)
Section thickness (μm)	1.00	1.00
Wt. conc. lignin (g g^{-1}) (14)	0.23	0.85
Vol. conc. lignin (g cm^{-3})	0.20	0.74
Δε (cm^{-1} g^{-1} L) (eq. [1])	1.4	0.7
$PhOH/C_9$ (eq. [3])	0.12	0.06

Values of ΔA_{300} normalized to a section thickness of 1 μm were then obtained. Three such sets of measurements were made and the mean value of ΔA_{300} and the mean deviation are given in Table 3.

The weight concentration of lignin for the secondary wall and cell corner middle lamella for spring wood in spruce was taken from the published data of Fergus *et al.* (13). By dividing by the factor of 1.15 to allow for the volume of the water swollen cell wall (14) the volume concentration of the lignin was obtained. Δε was then calculated from eq. [1] and from the values of Δε, the $PhOH/C_9$ for the secondary wall and middle lamella were calculated by means of eq. [3] to be 0.12 and 0.06, respectively.

As shown in Table 3 the experimental variation in ΔA_{300} is substantial and in the case for the cell corner middle lamella amount to ±23%. This large deviation is a clear manifestation of the difficulty of reproducing the measurement of ΔA_{300} from section to section. It is interesting to note, however, that the deviation in the ratio of $\Delta A_{300}(S2)/\Delta A_{300}(ML)$ was only about ±5% (12). This suggests that the variation in ΔA_{300} is due, in part, to the error in the determination of the thickness of the sections.

Discussion

The most significant characteristic of the results is the low values for the $PhOH/C_9$ ratio. If it is assumed that 72% of the lignin is in the secondary wall and 28% in the middle lamella and that the lignins in these two regions have the $PhOH/C_9$ ratios given in Table 3, the overall $PhOH/C_9$ of the lignin in black spruce can be calculated to 0.10. This result is considerably lower than the values of 0.19–0.20 reported by Chang *et al.* (15) for milled wood lignin and cellulolytic enzyme lignin from Norway spruce. The $PhOH/C_9$ values given in Table 3 are also lower than those reported in a previous paper from this laboratory (5). However, the previous results were not absolute but were based on the data published by Chang and coworkers (15).

It is interesting to note that Chang *et al.* (15) anticipated the low values of the PhOH content of the lignin in the wood. They noted that the phenolic hydroxyl content of the milled wood and cellulolytic enzyme lignins decreased with increase in molecular weight. They also found that reballmilling of cellulolytic enzyme lignin produced a decrease in the molecular weight and an increase in the $PhOH/C_9$ ratio. The authors then state "These results indicate that the molecular weight of lignin *in situ* is much higher than in the isolated lignins, and that its content of free phenolic hydroxyl groups ... may be even less than in the .. (cellulolytic enzyme lignin) preparations". Thus the high values of the $PhOH/C_9$ ratio in milled wood lignin may be artifacts caused by the isolation procedure and the lower values found in the present work for lignin in wood tissue may be more correct.

In spite of the agreement with the predictions of Chang *et al.* (15), we should consider the question as to whether the low values found for the $PhOH/C_9$ ratio in the present work are produced by some flaw in the experimental procedure followed. There seems to be three possible sources of error, as follows: (*1*) the determination of $PhOH/C_9$ by the method of periodate oxidation of MWL; (*2*) the determination of $\Delta\varepsilon_{300}$ for the dissolved MWL; (*3*) the microscopic determination of $\Delta\varepsilon_{300}$ on wood tissue with the uv microscope.

With respect to the accuracy of the method of periodate oxidation, it is interesting to note that the $PhOH/C_9$ ratio of 0.205 given in Table 2 is in good agreement with the value of 0.195 found by Chang *et al.* (15) using a similar method on milled wood lignin from Norway spruce. These authors also obtained a value of 0.202 using the Δε methods of Aulin-Erdtman (4) and Wexler (7). Thus it seems likely that the determination of the $PhOH/C_9$ ratio of the milled wood lignin used in the present work is correct.

The determination of $\Delta\varepsilon_{300}$ for the dissolved MWL may be questioned because of the use of different solvent systems for the neutral and alkaline solutions. However, the fact that the results were unchanged when pure dioxane was substituted from 50/50 dioxane/water for the neutral solution supports the reliability of the results obtained.

The most likely cause of error lies in the determination of $\Delta\varepsilon_{300}$ with the ultraviolet microscope. Usually absorbance measurements in the ultraviolet region are made on lignin in very dilute solutions (0.1 g L^{-1}) in a cell with path length of 1 cm. With the microscope the path length is the thickness of the section ($\sim 10^{-4}$ cm) and the concentration of lignin is from 200 to 800 g L^{-1}. In a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

previous investigation (11), Beer's law was shown to be valid for aqueous solutions of lignosulphonate over a concentration range of 0.05 → 250 g L^{-1}. However, this may not be the case for $\Delta\varepsilon_{300}$. At the higher concentrations the ionization of the PhONa salt may be suppressed to give a smaller value of $\Delta\varepsilon_{300}$ than would have been obtained in a more dilute solution. It is interesting to note that, if this is the case, the error would be expected to be larger for the cell corner middle lamella because of the higher concentration of lignin in this tissue region. Thus the ratio of 2 previously found for the PhOH content in the cell wall lignin to that in the cell corner lignin may, in fact, be erroneously high (5).

A further source of error lies in the interference of the conjugated α-carbonyl groups. Goldschmid (16) has pointed out that the presence of such groups causes the 300 nm difference curve maximum to decrease. Sarkanen *et al.* (17, 18) have shown that the difficulty may be circumvented by borohydride reduction of the lignin prior to the determination. This step was not attempted in the present investigation. Instead it was assumed that the ratio of conjugated α-carbonyl groups to PhOH groups was the same in the MWL and the protolignin in the wood, in which case the effect would not produce an error in the determination of $PhOH/C_9$.

Further work will be necessary in order to test the findings of the present investigation. Perhaps the best approach, following in the footsteps of Bailey (19), would be to devise a suitable method for the preparation of gram quantities of pure middle lamella lignin directly from wood. Such a fractionation would permit unambiguous physical and chemical characterization of this important morphological region in wood. It is interesting to note that since this paper was first submitted for publication, Hardell *et al.* (20) have described a fractionation of spruce wood into different tissue regions. In qualitative agreement with our previous result (5), these authors found that the phenolic hydroxyl content of the lignin in the secondary wall was at least twice that of the lignin the middle lamella. However, no determination of the $PhOH/C_9$ ratio was reported.

Conformation and crystalline structure of (2→1)-β-D-fructofuranan (inulin)

R. H. MARCHESSAULT,[1] T. BLEHA,[2] YVES DESLANDES,[1] and J.-F. REVOL[3]

Department of Chemistry, Université de Montréal, C.P. 6210, Succursale A, Montréal (Qué.), Canada H3C 3V1

Received May 20, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

R. H. MARCHESSAULT, T. BLEHA, YVES DESLANDES, and J.-F. REVOL. Can. J. Chem. **58**, 2415 (1980).

The crystalline conformation of inulin a (2→1)-β-D-fructofuranan has been determined based on conformational analysis coupled with X-ray and electron diffraction data. The energy contour maps as a function of three torsional angles ϕ, ψ, ω in the backbone were calculated taking into account van der Waals, torsional, and electrostatic interactions. Although several minima were observed, only two models are possible when one considers the information obtained from the diffraction data. The two models correspond to five-fold helices, one 5_4 (left-handed) and the other 5_1 (right-handed) with an advance per monomer of 2.16 Å, but with different conformational angles: $\omega = 60°$ and 180° respectively. Compared to the crystalline state torsion angles of polyethylene oxide analogs of inulin, large differences are noted. Steric interactions of the substituents and the exoanomeric effect are believed responsible for the observed conformational differences.

R. H. MARCHESSAULT, T. BLEHA, YVES DESLANDES et J.-F. REVOL. Can. J. Chem. **58**, 2415 (1980).

La conformation cristalline de l'inuline, un (2→1)-β-D-fructofuranan, a été déterminée en utilisant l'analyse conformationelle et les données expérimentales obtenues de la diffraction des rayons-X et de la diffraction électronique. Les cartes d'isoénergie en fonction des trois angles de torsion: ϕ, ψ, ω le long de la chaine furent calculées en considérant les interactions de van der Waals, les angles de torsion, et les interactions électrostatiques. Quoique plusieurs minima soient observés dans les cartes d'isoénergie, seulement deux modèles sont possibles si on considère l'information supplémentaire obtenue des clichés de diffraction (rayons-X et diffraction electronique sur cristaux uniques). Les deux modèles corespondent à des hélices de symétrie d'ordre 5, une 5_4 (hélice main gauche) et l'autre 5_1 (hélice main droite) ayant une avance par monomère de 2.16 Å; cependant elles ont differentes valeurs de l'angle de torsion: $\omega = 60°$ et 180° respectivement. A l'état solide, d'importantes différences sont observées entre les angles de torsion de l'inuline et celle de ses analogues de la famille des oxydes de polyéthylène. Les interactions stériques de substituants et l'effet éxo-anomérique sont probablement responsables pour ces différences.

Introduction

Although much progress has been made on the prediction of the conformational states of polysaccharides, almost all the work was concentrated on pyranose forms and little is known about the conformational structure of furanose polysaccharides. While a majority of carbohydrates in nature exist in the pyranose form, a number of biologically important molecules contain carbohydrate moieties with a 5-membered acetal ring. The furanose ring for example occupies a central position in the chemical structure of nucleic acids and in the important natural product of plants: sucrose.

For conformational studies of molecules such as polysaccharides a combined theoretical and experimental approach is the most powerful procedure (1–3). The role of theory in this procedure consists in assigning the preferred conformations on the basis of potential energy calculation for an isolated macromolecule. Although the evaluation of conformational energy is usually based on simple empirical potential functions the method as a whole has been remarkably successful for selecting the correct conformation when combined with some experimental evidence.

All previous stereochemical treatments have been devoted to pyranose polysaccharides and no attempts have been made for the furanose types, apart from the nucleic acid studies. One may expect that the conformational properties of pure furanans differ substantially from those for nucleic acids, mainly due to the absence of phosphate groups and the possibility of stacking interactions between bases in the latter. The enhanced flexibility of the furanose ring in comparison with the relatively rigid pyranose ring is the principal additional complicating factor in these calculations. As a first step in the explorations of furanans we decided to study inulin: a poly(2→1)-β-D-linked fructose (Fig. 1). Polyfructosans represent the most frequently occurring group of furanose polysaccharides (4). Besides inulin, the furanans include also levan which is poly(2→6)-β-D-linked fructose.

Inulin is a plant polysaccharide with a degree of polymerization of about 30 which varies with the

plant species and the life cycle. It serves as a reserve carbohydrate in the plant kingdom and is synthesized by successive addition of D-fructofuranose groups to sucrose (Gp-Ff), via the trisaccharide Gp-Ff-Ff (1-kestose), tetrasaccharide Gp-Ff-Ff-Ff (nystose), etc. Inulin solutions are universally used as a measure of the efficiency of glomerulal filtration in kidneys (5). Recently, oligomers of the inulin type have been identified as an important group of antigens forming immunobiological complexes with some myeloma immunoglubulins (6). Thus a knowledge of preferred conformations is basic to a development of the molecular biology aspects of inulin. Furthermore, as can be seen from the molecular formula in Fig. 1, inulin exhibits a unique structural feature within the family of polysaccharides, i.e. no bond of the furanose ring is part of the macromolecule backbone. Thus it is a biopolymer which has a close structural relation to the polyethyleneoxide class of synthetic polymers with general formula $-(O-CH_2-CR_1R_2)_n-$. However, it is not a polyether but a polyacetal.

In the present paper we wish to report the results of the conformational analysis for inulin type oligomers and polymers. From the calculated conformational energies the most probable helical conformations in the solid state are predicted and compared to some X-ray and electron diffraction data.

Conformational Analysis

A procedure as in the recent treatment of (1→6)-α-D-glucan conformations (7) was used. This involved an evaluation of the potential energy of the isolated inulin dimer molecule (inulobiose) as a function of three torsional angles ϕ, ψ, ω in the main backbone of the molecule. Figure 1 represents inulobiose in the extended all-*trans* conformation which corresponds to $\phi = \psi = \omega = 180°$. It is to be noted that in the fructofuranose moiety the anomeric carbon is C2. The definition of torsional angles $\phi = \theta(C1—C2—O—C1')$, $\psi = \theta(C2—O—C1'—C2')$, and $\omega = \theta(O—C1'—C2'—O')$ follows the proposed convention (8).

The geometrical parameters for the fructofuranose moiety were taken from the neutron-scattering investigation of crystalline sucrose (9). The glycosidic angle C1'O1'C2' was taken to be 114.0° and both O6 hydroxyl groups in inulobiose were fixed in a *trans* position with respect to C4—C5 bonds. Preliminary calculations revealed this position of the hydroxyl group as sterically favored in comparison with the *gauche* orientation as found in the sucrose structure. The ring conformation in this geometry is described as "envelope" (E_3) in which C3 is displaced out of the plane of the other four atoms: C2, O2, C5, C4 atoms (Fig. 2). This displacement in the opposite (*exo*) direction to C6 and O atoms represents the primary ring puckering and its value is 0.542 Å above the plane of atoms in question (10).

The potential energy of inulobiose was calculated taking into account van der Waals, torsional, and electrostatic interactions, also the energy of possible H-bonds between the two rings was considered. For van der Waals, torsional, and H-bond contributions the same potential functions as previously described (7) were used. All hydrogen atoms have been included in the calculations. An attempt has been made to include the electrostatic interactions between the point charges localized on each atom using the Coulomb law and dielectric constant $\varepsilon = 2$. The electrostatic term is usually of little importance in conformational analysis of polysaccharides (1) but may play an important role in polymers with a polyoxide main chain. Partial charges were evaluated using the following set of

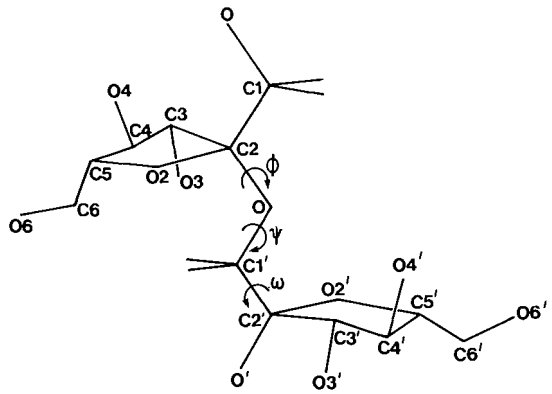

FIG. 1. Inulin-type difructosan molecule (inulobiose) in all-*trans* conformation $\phi = \psi = \omega = 180°$. Ring hydrogen atoms are not shown.

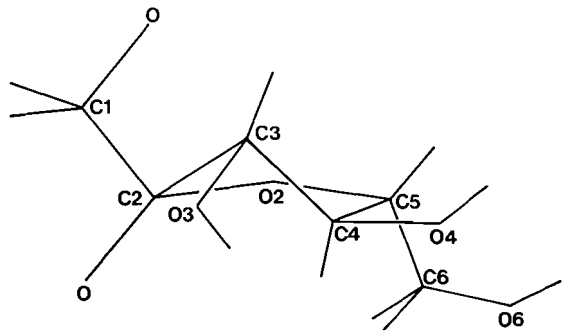

FIG. 2. Representation of ring puckering in fructofuranose moiety with C3 atom displaced out of plane formed by C2', O2', C5', and C4' atoms. Hydrogen atoms are omitted.

fixed bond dipoles: 0.82 D, 0.38 D, and 1.53 D for C—O, C—H, and O—H, respectively.

The ϕ,ψ isoenergy maps were constructed with a 10° grid. Each map was for a fixed value of ω which was changed at 20° intervals over the range $-180° < \omega < 180°$. Simultaneously, the helical parameters n (the number of residues per turn) and h (the projected height of the residue onto the helix axis) were calculated for each ϕ,ψ pair using the virtual bond method of generating the helical chains (11, 12).

Results

As for the dextran case (7), the allowed three dimensional conformational space is a "cylinder" with an irregular cross-section. The cylinder is extended parallel to the ω axis. Figures 3 and 4 show the ϕ,ψ sections computed for $\omega = 180°$ and $\omega = 60°$, respectively, without inclusion of the electrostatic term in the calculations. The allowed conformational space is restricted to the area around the position $\phi = 90°$, $\omega = 180°$. Variation of ω from $-180°$ to 180° results in only small changes in the cross-sectional shape of the allowed conformational ϕ,ψ space whose limit was arbitrarily set at an energy contour of 15 kcal/mol relative to the lowest calculated minimum on the map.

The minor influence of ω on the overall shape of "available" conformational space follows from the calculations regardless of electrostatic interactions. However, the situation is different when the local minima within a given cross-section are considered. For example, in the conformational map for $\omega = 180°$ (Fig. 3) the lowest minimum lies at $\phi = 70°$, $\psi = 120°$ and this mimimum is also the absolute minimum found for the whole (ϕ,ψ,ω) space in calculations performed without the electrostatic term. The second local minimum found for $\omega = 180°$ occurs at $\phi = 90°$, $\psi = 190°$ is about 1.62 kcal/mol higher than the absolute minimum. Finally, the third local minimum found in the "available" conformational space in Fig. 3 is situated at (140°,260°) 3.33 kcal/mol over the absolute minimum. Only this latter minimum is stabilized by one intramolecular hydrogen bond.

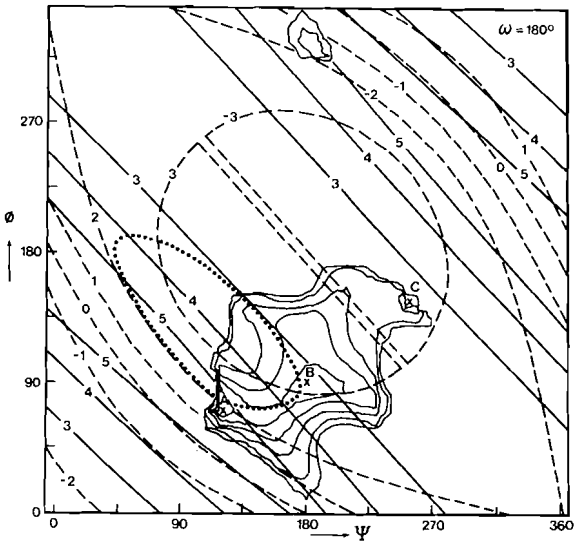

FIG. 3. ϕ,ψ conformational energy map for $\omega = 180°$. Relative isoenergy contours indicate energy values in kcal/mol relative to the lowest calculated minimum in the map. The full, dashed, and dotted curves represent the iso-n and iso-h contours and helices with $p = 10.8$ Å respectively.

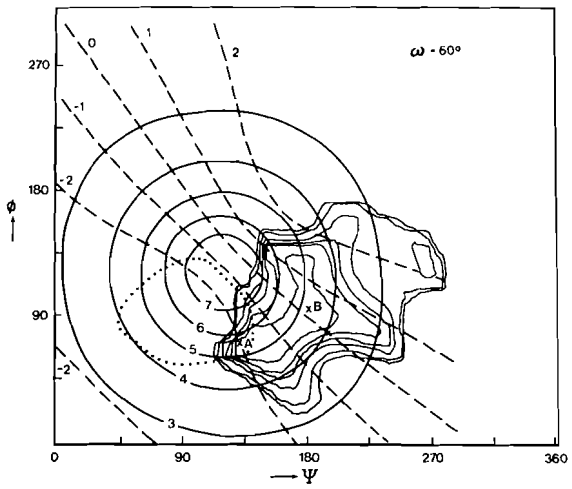

FIG. 4. ϕ,ψ conformation energy map for $\omega = 60°$. Relative isoenergy contours indicate energy values in kcal/mol relative to the lowest calculated minimum in the map. The full, dashed, and dotted curves represent the iso-n and iso-h contours and helices with $p = 10.8$ Å respectively.

The inclusion of the electrostatic term in the calculation changes the position of the minima and their relative stability. The local minimum (140°, 260°) is only 0.07 kcal/mol over the absolute minimum, now at (140°,140°), and the third mimimum (90°,190°) has the energy 4.06 kcal/mol. This and similar comparisons of conformational maps for other values of ω revealed that inclusion of the electrostatic term in our calculations manifests itself by enhanced stabilization of all conformations with intramolecular H-bond or bonds. This feature is due to the relatively high negative charges carried by hydrogen atoms of hydroxyl groups and their fixed position in the assumed rigid geometry of the inulobiose molecule. Since the contribution of H-bonds has already been included in the potential functions used it was judged that calculations with an electrostatic term overestimate the H-bond contribution. Therefore, most of our discussion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

and subsequent conclusions are based on calculations without the electrostatic term.

The position and the sequence of minima for the ϕ,ψ map for $\omega = 60°$ (Fig. 4) duplicate the results for $\omega = 180°$. The lowest minimum is at (70°,135°), followed by conformations (90°,180°) with energy 0.55 kcal/mol and (130°,270°) with energy 3.62 kcal/mol. None of these minima are stabilized by an intramolecular H-bond. The maps in Figs. 3 and 4 are energetically preferred cross-sections of the general ϕ,ψ,ω hypersurface. This is supported by Fig. 5 showing the plot of minima energy for various ϕ,ψ maps, as a function of ω. Surprisingly, the third staggered position at $\omega = -60°$ results in a minimum with higher energy than an additional unexpected minimum at $\omega = -110°$.

Except for the range from $\omega = -80°$ to $\omega = 20°$ the lowest minimum (type A) in the ϕ,ω maps is always situated around $\phi = 70° \pm 10°$ and $\psi = 115° \pm 25°$. Only in the interval $-80° < \omega < 20°$ is this type of conformation slightly less favorable than conformations of type B: $\phi = +105° \pm 25°$, $\psi = -175° \pm 5°$; e.g. for $\omega = -60°$ the conformation (80°,130°) is 1.13 kcal/mol over the lowest minimum (130°, 180°). It should be noted that both above-mentioned minima are separated by a very low potential barrier. The third minimum (C) at about $\phi = 135° \pm 5°$ and $\psi = 265° \pm 5°$ is almost independent of ω, but is also the least important of the three.

The conformational maps for the ϕ,ψ,ω hypersurface clearly show that ϕ and ψ variations define the most important torsional potential interactions in the inulobiose molecule. The ϕ,ψ coupling restricts the polyoxyethylene-like main chain in (2→1)β-D-linked fructofuranans to a fairly narrow conformational space. On the other hand the ω torsional potential brings flexibility to the molecule since variation in ω brings about only a slight change in potential energy (within 5 kcal/mol for lowest minimum on each ϕ,ψ map (Fig. 5)). The most convenient aid for the selection of the main chain conformation of inulin in the solid state is the simultaneous use of the inulobiose ϕ,ψ isoenergy maps with n,h helical parameter maps. Using the virtual bond method (11, 12) we evaluated the helical parameters n and h for inulin in the whole ϕ,ψ,ω conformational space. The maps of n, the number of residues per turn of the helical chain and h, the projected height of the residue along the helix axis are given in Figs. 3 and 4 for two typical cases $\omega = 180°$ and $\omega = 60°$. Negative h values denote left-handed helices. For the map with $\omega = 180°$ the allowed space corresponds to helices with n from 2 to 6 all being right-handed except for the small area around the (140°,260°) minimum. The lowest minimum (type A) at (70°,120°) corresponds approximately to the integral right-handed helix with a five-fold screw axis and helix pitch ($p = n \times h$) equal to 8.94 Å. The minimum at (90°,190°) (type B) is close to a 3_1 symmetrical right-handed helix with 9.61 Å pitch. In the map with $\omega = 60°$ the allowed space corresponds both to right- and left-handed helices with n from 2 to 8. The lowest minimum on this map, at (70°,135°), implies again a 5_1 helix but left-handed with $p = 9.61$ Å. For the second minimum (90°,180°) $n = 4.58$ and $h = 0.04$ Å. Finally, the third minimum (120°,270°) predicts a right-handed helix with $n = 2.34$ and $h = 2.14$ Å.

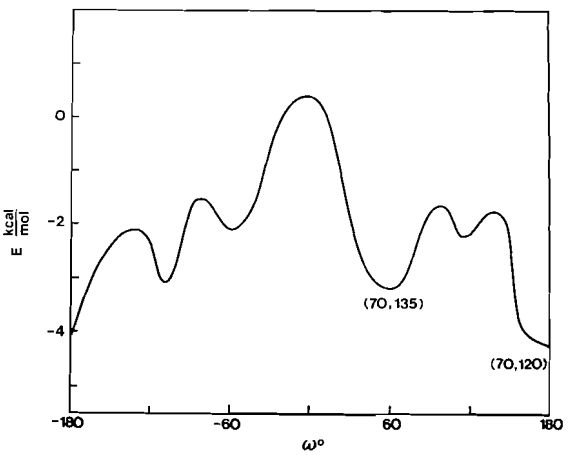

FIG. 5. The energy of lowest minimum on particular ϕ,ψ maps as a function of ω. Figures on the curve identify the ϕ,ψ positions of lowest minimum energy.

Recent work on the molecular and crystal structure of 1-kestose (13), which is a trisaccharide Gp-Ff-Ff containing the inulobiose moiety, fully supports the validity of the assumed geometry of the fructofuranose ring. For the second fructose unit in 1-kestose the *exo* E_3 envelope conformation is reported with the C3 atom displaced 0.63 Å from the plane of the other four atoms. The principal torsional angles determined for the inulobiose moiety in 1-kestose are as follows: $\phi = 80.5°$, $\psi = 190.3°$, and $\omega = 179.2°$ (13). As shown in Fig. 3 for $\omega = 180°$ this structure lies in the allowed conformational space and is situated very near to the local minimum B at (90°, 190°). In accordance with the computation, experimental data (13) confirmed also that there is no intramolecular hydrogen bond stabilizing the inulobiose structure in 1-kestose.

In the absence of other supporting experimental data it is difficult to predict unambiguously the crystalline chain conformation of inulin solely on the basis of energy calculations. Most probably this structure should have parameters similar to A or B type minima in the conformational map (Fig. 3), i.e. a helix with a three- to five-fold screw axis.

Diffraction Data

The electron and X-ray diffraction study on the inulin single crystals provided additional information for the interpretation of the stereochemical analysis. The sample used in this investigation was from Nutritional Biochemicals Corp., Cleveland, OH, and was used "as received". The agreement between the observed X-ray data (cf. below) and the information in the literature (14) was taken as confirmatory evidence that the sample was genuine. Liquid chromatography confirmed that the sample was polydisperse and easily degraded on heating in water (15).

Single crystals of inulin were prepared as follows: a 0.05% aqueous solution of inulin was dissolved in water at 45°C and cooled to about 1°C. After several days the solution appeared quite turbid and the crystals were collected by centrifugation. After successive washings in ethanol part of the suspension was used for the electron microscopy observations and the other part was spread on a Teflon plate. The film so obtained was extremely brittle and all attempts to prepare oriented films or fibers were ineffective. In another attempt to obtain oriented X-ray fiber diagrams it was assumed that during the film drying process the large faces of the crystals would align parallel to the plate surface. Therefore, the small pieces of dry film representing single crystal mats were vertically stacked together. With the X-ray beam parallel to the surface of the stack, an X-ray diagram was recorded on flat film using Cu Kα radiation. Probably due to the imperfect alignment of single crystals in the mats as well as of the single crystals themselves only a poorly oriented fiber diagram was obtained where the layer line assignments could only be made with difficulty. The density of dried inulin film was measured via flotation in a density gradient (CCl_4–$CHCl_3$) column and was found to be 1.54 ± 0.05 g cm^{-3}.

For electron microscopy observations, drops of the ethanol suspension of inulin single crystals were evaporated on carbon-coated grids. Observations were made with a Philips EM 300 transmission electron microscope operating at 60 kV for images and 100 kV for diffraction. The single crystals to be observed were either shadowed with tungsten or unshadowed. Gold was evaporated on some of the single crystal preparations for diffraction calibration.

An electron micrograph along with an electron diffraction pattern typical of inulin single crystals are shown in Fig. 6. The lamellar character of the crystals is undeniable but the perfection is far less than was observed in similar materials, e.g. wood xylan (16). In that case the hexagonal shape was almost perfect whereas here only occasional 120° angles are visible in the particulate product. At the edges of the thickened crystals single layer lamellae about 40–50 Å thick were always visible. The best diffraction data were recorded from moderately thickened uniform areas of the crystals and a sample diffractogram is shown in Fig. 6 along with a schematic interpretation.

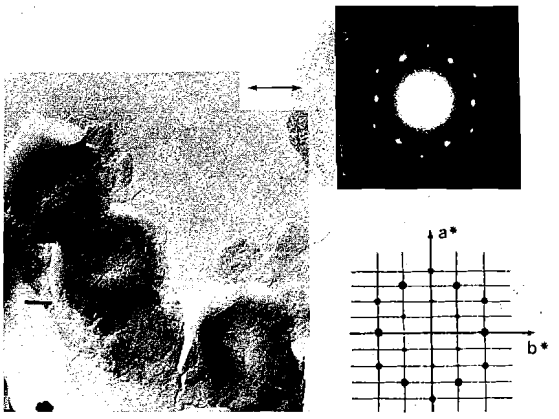

FIG. 6. Electron micrograph and electron diffraction pattern of single crystals of inulin along with a schematic relating the pseudohexagonal cell to the diffraction data. The 200 and 110 reflections in the schematic are masked by the central beam in the electron diffractogram (the arrow represents 0.5 μm).

Overall electron diffraction data indicate hexagonal symmetry in the base plane ($h\ k\ 0$). However, an orthorhombic (pseudo-hexagonal) unit cell provided the more correct base plane parameters a and b determined from electron diffraction data for this "dry" form with $a = 16.71$ Å and $b = 9.65$ Å. The "fiber repeat" was derived by a comparison of the electron diffractogram data and the X-ray diffraction data. Comparing all resolved ($h\ k\ 0$) reflections from the electron diffractogram with the X-ray data allowed indexation of the remaining X-ray reflections. The best fit between the calculated and observed d-spacings was found for $c = 10.8$ Å. Table 1 lists the d-spacings and their assignment.

One of the principal difficulties in this study was in appreciating the effect of hydration on the relative intensities of the diffraction data. An illustration of this difficulty can be had from Fig. 7 where diffractometer traces as a function of exposure to room humidity (r.h.) are shown. The first trace presumably corresponds closely to what would be observed in the electron microscope and shows a sharp reflection at $d = 8.35$ Å. This reflection is one of those observed in the electron diffractogram (0% r.h.) but it is absent in the 95% r.h. diffractometer scan. This problem had been alluded to previously by Katz and Derksen (14) but the data of Fig. 7 serves to illustrate one of the difficulties in com-

TABLE 1. Comparison of calculated and observed d spacing in "dry" form of crystalline inulin

paring electron diffraction data, necessarily recorded *in vacuo*, and X-ray data on polysaccharides.

From the comparison of the unit cell volume and the measured density it follows that there are 10 fructofuranose moieties per unit cell which is consistent with the presence of two chains in the unit cell with a five-fold screw axis (integral helix) along the c direction and a helix pitch $p = \pm 10.8$ Å. In this way the experimental data provided an additional restriction for the selection of the inulin chain conformation in the stereochemical analysis.

The ϕ,ψ variation of helix pitch for $p = \pm 10.8$ Å is plotted in Figs. 3 and 4. For $\omega = 60°$ (Fig. 4) it is possible to construct a model, left-handed (60°, 135°) which satisfies both conditions, i.e. $p = -10.8$ Å and a 5-fold. At $\omega = 180°$ (Fig. 3) a second model is found for the conformation about (75°,130°). Thus two low energy models can be proposed for the crystalline inulin chains. The model with $\omega = 180°$ (lowest energy) is shown in Fig. 8. The proposed conformation for $\omega = 180°$ is in an energy trough which includes the observed ϕ,ψ for the inulobiose end of 1-kestose; the latter almost coincides with the calculated energy minimum B in the map shown in Fig. 3.

Discussion

The area of allowed ϕ,ψ conformations which have been reported for all classes of polysaccharides with various types of linkages differs in their preference for a particular portion of ϕ,ψ space (17). So far no other polysaccharides exhibit

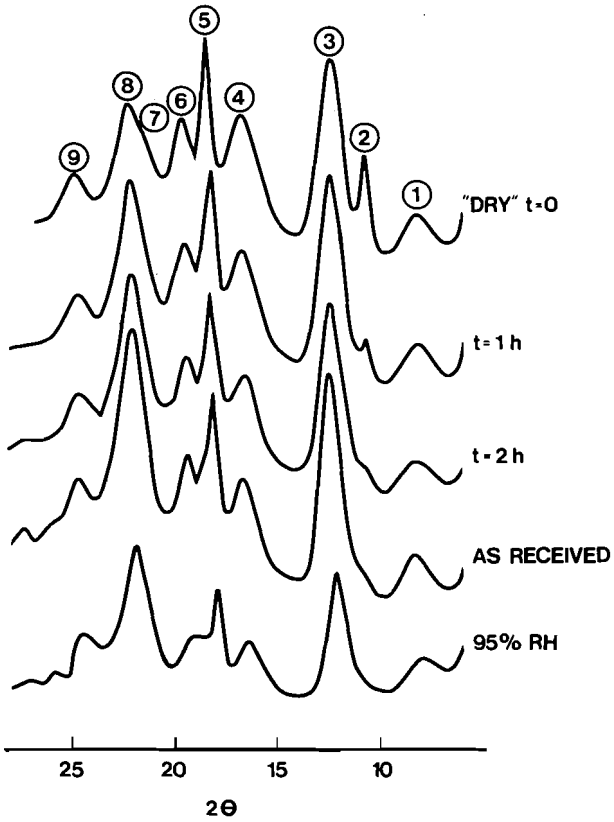

FIG. 7. X-ray diffractometer traces of a single sample of inulin powder recorded at various times after removal from a vacuum oven at 90°C. The last trace was recorded after the sample had been exposed to 95% relative humidity for 24 h.

minima in the same region of ϕ,ψ space as inulobiose, however for the structurally similar (1→6) linked α-D-glucans the allowed conformations are centered approximately around (0°,180°) (7).

Comparison with the polyoxyethylene class of synthetic macromolecules with general formula $[—CR_1R_2—O—CH_2—]_n$ is instructive for appreciating the strong (ϕ,ψ) coupling, as shown in Fig. 3. Only the conformational structure of the simplest synthetic polymers of this class has been determined (4, 5). In inulin the steric interactions of the "side group" correspond to $R_1 = R_2 = C_4O_4H_8$ and this ring substitution biases (ϕ,ψ) to rather unexpected values as may be seen by comparison with the crystalline state conformation of substituted polyoxyethylenes (18, 19) (Table 2). It should be noted that the regular (2→1)-β-D linkage in inulin results in an "isotactic" structure for inulin. The ω values for crystalline poly(alkyleneoxides) are either 180° or near to 60°, polyoxyethylene having two crystalline polymorphs. Both this comparison

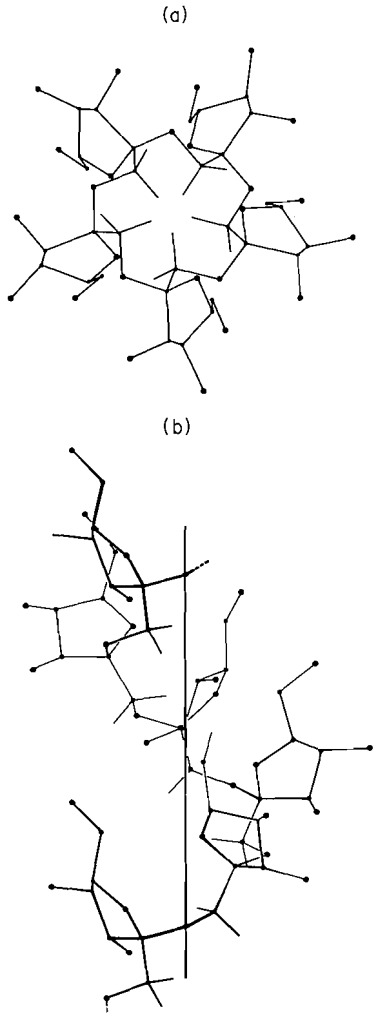

FIG. 8. The proposed conformation of the inulin (ω = 180°) chain in (*a*) *X–Y*, (*b*) *Y–Z* planes. The chain axis is along the *Z* axis and corresponds to a 5_1 helix. Hydroxyl and ring hydrogens are omitted.

as well as the potential energy diagram in Fig. 5 confirm that approximately 180° or 60° values for ω should be expected in the crystalline chain conformation of inulin.

Another comparison involving the ω values from Table 2 shows that all polymers prefer (approximately) the *trans* position, inulin being the most divergent from this rule. A similar comparison of ϕ values shows, however, that the ϕ values for poly(alkylene oxides) and inulin are quite different. This is probably related to the exoanomeric effect (20, 21) which provides additional non-bonded interaction due to oxygen–oxygen lone pair interactions of O2 and the glycosidic oxygen.

Some models of inulin were suggested previously (5, 6, 22). Phelps (22) claimed that the known

TABLE 2. Molecular conformation of isotactic poly-alkylene oxides $[—CHR—O—CH_2—]_n$ and inulin

R	ϕ	ψ	ω	Symmetry	Reference

Inulin	75	130	180	(5/1) helix	This work

physicochemical data for the inulin molecule pointed to its conformation being a helix of four fructofuranose units per turn while Middleton (5) recommended a slightly lower value about 3.9 units per turn to avoid presumed steric repulsion of *n*th and (*n* + 4)th unit. Both these studies dealt with the conformation of inulin in solution and as is evident from our conformational maps several helix types are inside the favored area for ω = 180°. The conformation of inulin in solution can be expected to range, on the average, over all possible (ϕ,ψ,ω) combinations within the "allowed area" using the standard method of configurational statistics (23) to establish the probability of a given structure. Finally, the conformational energy maps in Figs. 3 and 4 should be relevant also in the structure-immunobiological activity relationship for fructofuranans (6, 24). Some myeloma immunoglobulins with anti-fructofuranan specificity have different complexing behaviour to (2→1)-β-D-linked and (2→6)-β-linked fructofuranan substrates (6). The conformational results presented in this paper can undoubtedly help in the elucidation of this difference.

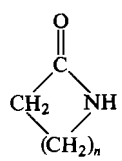
The acid-catalysed hydrolysis of lactams of ring size 4–7, and of *N*-ethylacetamide, has been studied at various temperatures in 0–70% aqueous sulfuric acids. The kinetics have been analysed by means of the *r*-hydration parameter treatment and the transition-state activity coefficient (TSAC) approach. Except for the β-lactam, all substrates show a strong positive rate dependence on water activity, indicating a tetrahedral intermediate type of mechanism ($A_{\delta}^{T}2$), similar to that found for simple (acyclic) amide hydrolyses; only the β-lactam shows a negative rate – water activity dependence, which is interpreted in terms of a unimolecular ($A_{N}^{R}1$) mechanism, involving rate-determining acylium ion formation. Similarly, all substrates except the β-lactam show a pronounced destabilization of the transition-state as acidity is increased, typical of oxonium ion species. The behaviour of the β-lactam resembles that of methyl mesitoate hydrolysis. Basicity constants for lactams of ring size 4–9 show a definite dependence on ring size, with the δ-lactam being unusually basic. Both rate and p*K* dependence on ring size are discussed in terms of ring strain and steric effects. The activation parameters, particularly $\Delta S^{\neq}$, are fully consistent with the conclusions drawn concerning transition-state hydration.

PETER WAN, TOMASZ A. MODRO et KEITH YATES. Can. J. Chem. **58**, 2423 (1980).

Opérant à diverses températures et dans des solutions où la concentration d'acide varie de 0 à 70%, on a étudié l'hydrolyse acido-catalysée des lactames cycliques de 4 à 7 chainons ainsi que de la *N*-éthylacétamide. On a analysé les cinétiques en traitant le paramètre d'hydratation *r* et en utilisant comme approche le coefficient d'activité de l'état de transition (CAET). A l'exception du β-lactame, tous les substrats ont une vitesse qui dépend fortement et d'une façon positive de l'activité de l'eau, ce qui suggère un mécanisme de type $A_{\delta}^{T}2$, faisant intervenir un intermédiaire tétraédrique semblable à celui trouvé au cours des hydrolyses d'amides simples (acycliques); seul le β-lactame a une vitesse qui depend d'une façon négative de l'activité de l'eau. Ceci est interprété en fonction d'un mécanisme unimoléculaire ($A_{N}^{R}1$) impliquant la formation de l'ion acylium dans l'étape déterminante. De la même manière, à l'exception du β-lactame, tous les substrats sont fortement déstabilisés dans l'état de transition lorsque l'acidité augmente; ceci est typique de l'ion oxonium. Le comportement du β-lactame ressemble à celui observé lors de l'hydrolyse du mésitoate de méthyle. Les constantes de basicité des lactames cycliques comportant de 4 à 9 chainons dépendent nettement de la taille du cycle, alors que le δ-lactame est anormalement basique. On discute de l'effet de la dimension du cycle sur la vitesse et le p*K* en fonction de la tension du cycle et des effets stériques. Les paramètres d'activation, et en particulier le $\Delta S^{\neq}$, sont en parfait accord avec les conclusions tirées au sujet de l'hydratation de l'état de transition.



[Traduit par le journal]

Introduction

The acid-catalyzed hydrolysis of amides has been extensively investigated and the subject thoroughly reviewed (1). Although there has been general agreement for a long time on the predominant ($A_{O}^{T}2$) mechanism (2) of hydrolysis of simple amides, conclusive evidence has not been available until recently (3). The problem has been partly a result of inadequacies of the various treatments of kinetic acidity dependence which were available, and partly due to the difficulty of ruling out kinetically indistinguishable alternatives.

One of the fundamental problems associated with the mechanisms of amide (or lactam) hydrolysis is the site of protonation of the amido group. McClelland and Reynolds (4) appear to have resolved the question in favour of predominant oxygen protonation, in the equilibrium sense, but this does not eliminate the N-protonated form as a kinetically important species on the reaction pathway. There are four reasonable and distinct mechanistic schemes which must be considered in amide or lactam hydrolysis. Three of these (A-2 types) involve bimolecular rate-determining attack of water on the conjugate acid form (whether O- or N-protonated). The fourth (A-1 type) involves unimolecular rate-determining cleavage of the acyl–nitrogen bond of the N-protonated form. Smith and Yates (2) have categorized each of these mechanistic possibilities, using symbols analogous to the standard mechanistic symbols for acid- and base-catalyzed ester hydrolysis.

The acid-catalyzed hydrolysis of lactams has not been extensively studied, although various workers (5–7) have compared relative rates of hydrolysis for ring sizes from 4–7 atoms (n = 1–4).

n = 1, β-lactam; n = 2, γ-lactam;
n = 3, δ-lactam; n = 4, ε-lactam

Mhala and Jagdale (8) have obtained the hydrolysis rate profile (as a function of acidity) for the ε-lactam at 97°C in sulfuric acid. Use of the Bunnett *w*-parameter treatment (9) led to a curved relationship and hence somewhat inconclusive results. Apart from these studies, hydrolysis rate – profiles have not been reported in the literature. For this reason we undertook a systematic study of lactams with n = 1–6, over the range 0–60% sulfuric acid, to examine their relative rates of hydrolysis and basicities as a function of ring size; also to determine, if possible, the general mechanism of lactam hydrolysis by using two more recently developed (10, 11) theoretical treatments of kinetic-acidity dependence.

Results and Discussion

Kinetics

The rates of hydrolysis of the β-, γ-, δ-, and ε-lactams, at different acid concentrations, were followed by ^{1}H nmr spectroscopy (see Experimental section). The rates of hydrolysis of *N*-ethylacetamide were also followed over the same range of acidity, to serve as a reference model for simple amide hydrolysis. All the reactions followed pseudo first order kinetics:

$$-\mathrm{d[lactam]}/\mathrm{d}t = k_2[\mathrm{lactam}][\mathrm{H^+}]$$
$$= k_\psi[\mathrm{lactam}]$$

The hydrolyses were generally measured at elevated temperatures due to the slowness of most of the reactions and the results extrapolated at 25°C using the Arrhenius relationship, for comparison purposes. These rate constants are listed in Table 1. The β-lactam, however, hydrolyses much more rapidly than the other substrates and was studied at 33°C. The rate profiles, as a function of acidity, are shown in Fig. 1. In all cases except for the β-lactam, the rate of hydrolysis passes through a maximum in the region 20–25% H_2SO_4. Such maxima are typical of many amide (2) and ester (12) hydrolyses, and are attributed to two opposing effects of increasing the acid concentration. On the one hand increased acidity raises the concentration of the reactive conjugate acid form of the substrate, but at the same time reduces the available water (i.e. the water activity) needed to complete the hydrolysis. This is true only of A-2 hydrolyses, since in A-1 reactions water does not intervene before or during the rate determining step. It can be seen from Fig. 1 (inset) that the β-lactam not only reacts much faster than all other substrates, but shows no sign of a rate maximum. The possibility of a very high maximum occurring outside the range of accessible rate measurements can almost certainly be ruled out for this lactam, since the rate increases monotonically (see Table 1) up to 82.5% H_2SO_4. It can be seen that over most of the acidity range studied, the rates are in the order

β- ≫ δ- > ε- > γ- > *N*-ethylacetamide

This is shown more quantitatively in Table 2 where the relative rate constants are compared at 20% H_2SO_4, which is near the rate maximum in most cases. The reasons for the very large rate enhancements (over *N*-ethylacetamide) in the six- and particularly the four-membered ring lactam will be discussed later.

Basicity Constants

Since none of the substrates studied possess strong chromophoric groups, basicity determinations were carried out essentially by the method of Lee and Sadar (13), using nmr spectroscopy. The ionization ratios (I = [SH$^+$]/[S]) obtained for aliphatic amides do not in general follow the H_A acidity function very well (14)

$$\log I = -mH_A + \mathrm{p}K_{\mathrm{SH^+}}$$

This function was based almost exclusively on aromatic amides (15), and the slopes m obtained with aliphatic amides are far from the required value of unity. It was therefore decided to use a recently developed and more generalized method (16) of determining the basicity constants. This employs the concept of "excess acidity" or the X-function, and is believed to give reliable estimates of p$K_{\mathrm{SH^+}}$ for any type of weak base. In this method pK values are obtained from

$$\log I - \log C_{\mathrm{H^+}} = m^*X + \mathrm{p}K_{\mathrm{SH^+}}$$

the intercepts of plots of ($\log I - \log C_{\mathrm{H^+}}$) versus X. The p$K_{\mathrm{SH^+}}$ values obtained for *N*-ethylacetamide and lactams with n = 1–6 are given in Table 3. It can be seen that the order of basicity is

δ- ≳ 9- > 8- > ε- > *N*-ethylacetamide > γ- > β-

which is quite different from the order of rates of hydrolysis for the five substrates studied kinetically.

It must be pointed out that the present p$K_{\mathrm{SH^+}}$ values differ significantly from previously reported values (17, 18), although as shown in Fig. 2 the trends in basicity with ring size are quite similar. We believe the values reported in the present work are more reliable, partly because no specific Hammett type acidity function was used in arriving at these values and partly because most of the previous data were obtained in anhydrous acetic acid and the pK's corrected to the aqueous scale (19). Also the two sets of values reported by Huisgen and

TABLE 3. Lactam pK_{SH^+} values

Lactam (or amide)	pK_{SH^+}	Rate maximum of acidity
N-Ethylacetamide	−0.49	~21% acid
β-Lactam (4)	−0.96	No observed maximum
γ-Lactam (5)	−0.65	~25%
δ-Lactam (6)	−0.18	~19.5
ε-Lactam (7)	−0.46	~20%
8-Lactam	−0.38	—[a]
9-Lactam	−0.18	—[a]

[a]Rates of hydrolysis not measured for these lactams.

co-workers (17), employing potentiometric and indicator methods, would suggest that lactams are much more basic than any other type of amide. Typical pK_{SH^+} values reported for aliphatic and aromatic secondary amides are in the range −0.7 to −4.0 (20). It is generally true that acyclic amides are weak bases with p*K* values less than zero,[2] whereas most of the values reported by Huisgen *et al.* (17) are positive. If the latter values were correct, it would suggest that lactams are anywhere from a factor of ten to a hundred times more basic than other types of amide. This does not seem reasonable in terms of structural factors, since it would be expected that the δ-lactam for example, which is relatively free of ring strain effects, would have a p*K* value close to those of typical open chain aliphatic amides. These structural effects will be discussed later. It is interesting that for the lactams which show a hydrolysis rate maximum, the acidity at which this occurs is in roughly the same order as the basicities of the substrates, which it should be if the previous explanation for the rate maxima is correct (see Table 3).

[2]This presented a problem in anchoring the H_A scale (15) since no simple amides could be found with p*K* values greater than zero, which would ionize significantly in the pH region. Even the pyridine-1-oxides subsequently used by Johnson, Katritzky, and Shakir (21) had negative p*K*'s in most cases.

Hydration Parameter Treatment

For the generalized reaction [1] it has been shown (22)

$$S + H^+ \underset{}{\overset{\text{fast}}{\rightleftharpoons}} SH^+ \quad [1]$$

$$SH^+ + rH_2O \xrightarrow{\text{slow}} \neq \longrightarrow \text{products}$$

(when certain assumptions are made) that the Bronsted rate equation may be written as

$$[2] \quad \log k_\psi + \log [(I + 1)/I] = r \log a_w + \text{constant}$$

where k_ψ is the observed pseudo first order rate constant, *I* is the ionization ratio $[SH^+]/[S]$, and a_w is the activity of water (32). Consequently a plot of the left side of eq. [2] versus log a_w should yield a straight line with slope *r*, which gives a measure of the change in hydration in going from the protonated species to the rate determining transition state. For typical A-2 ester hydrolyses *r* is about +2, and for A-1 pathways about −0.2 to −0.6 (12). Each of the lactams (except the β-lactam) and *N*-ethylacetamide, give two straight line regions,[3] as shown for the γ-lactam in Fig. 3. In the low acidity region an *r* value between +2 and +4 is obtained, as shown in Table 4, followed by a changeover around 40–45% H_2SO_4, to a lower but still positive slope of about +0.6 to +1.4. The implication here is that there are two A-2 mechanisms operating in lactam hydrolysis; one with a highly hydrated transition state, involving several water molecules, and as the acidity is increased (and the availability of water is decreased), a fairly sharp changeover occurs to a mechanism in which only one water molecule on average participates in

[3]The actual data used to construct these plots are given in the Tables of Supplementary Data. Complete set of data may be obtained, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

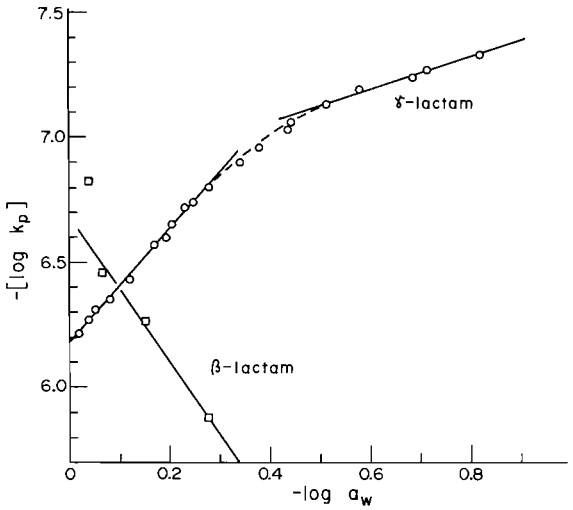

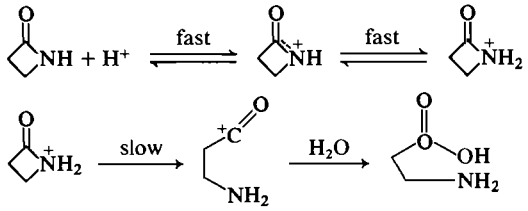

FIG. 3. Typical *r*-hydration parameter plots for lactam hydrolysis.

forming the tetrahedral-intermediate type of transition state.

The β-lactam is unusual, as shown in Fig. 3. The *r*-hydration parameter plot shows a distinctly *negative* dependence on water activity throughout, indicating a transition state which is less hydrated than its preceding conjugate acid. This is reasonable for an A-1 mechanism generating an acylium ion, since such an ion would almost certainly be much less hydrated than an oxonium ion-like lactam conjugate acid[4]

There is one other reasonable mechanistic possibility for the β-lactam, which would involve nucleophilic attack by water at C_β, with ring opening to give β-hydroxypropionic acid. An analogous mechanism has been shown to occur for β-lactone hydrolysis (23) using ^{18}O labelling. However, this mechanism can be ruled out in the present case, since the exclusive product of β-lactam hydrolysis is β-alanine, at all acidities.

Activation Parameters

For the δ-lactam, five different temperatures were used in the extrapolation of rate constants to 25°C. For both the γ- and ε-lactams six temperatures were employed.[5] In most cases, excellent linear Arrhenius plots were obtained, with correlation coefficients in the range 0.994–0.997. Values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were obtained at different acidities, and typical values (at an acidity near the rate maximum) are given in Table 5. These values are fairly typical for A-2 reactions. Of more interest is the variation of $\Delta S^{\neq}$ with acid concentration. There are definite trends for each lactam, with $\Delta S^{\neq}$ changing from a larger negative value of around −27 to −30 eu in the more dilute acid region, to less negative values around −19 to −21 eu in more concentrated acids. This is shown in Fig. 4 for the γ-lactam, and implies that a change from a more- to a less-restricted transition state is occurring as the acidity is increased (or as a_w is decreased). This is fully consistent with the conclusion from the *r*-hydration parameter treatment, and indeed the changeover regions in the *r*-plots coincide reasonably well with the regions of levelling off of the $\Delta S^{\neq}$ values at higher acidities.

Unfortunately the β-lactam reacts too rapidly over most of the acidity range studied to allow accurate determination of its activation parameters. For the proposed A-1 mechanism for this lactam, both $\Delta H^{\neq}$ and $\Delta S^{\neq}$ would be expected to be significantly different from the values in Table 5, as

[4]Note that an A-1 mechanism leading to an acylium ion intermediate can only reasonably be written as proceeding via the minor N-protonated form.

[5]*N*-Ethylacetamide was studied at 25°C only, and the β-lactam at 33°C only.

TABLE 4. *r*-Hydration parameters for lactam hydrolysis

Substrate	Initial *r*-value	Final *r*-value	Acidity of changeover region
N-Ethylacetamide	2.1	0.6	~46% H_2SO_4
γ-Lactam	2.1	0.6	~47% H_2SO_4
δ-Lactam	4.4	1.0	~42% H_2SO_4
ε-Lactam	4.5	1.4	~41% H_2SO_4
β-Lactam	−2	—	—

well as the variation of $\Delta S^{\ddagger}$ with acidity.

TSAC Approach

For a reaction scheme such as that in reaction [1], application of transition state theory gives the following expression (11) for the observed rate constant

$$k_{\psi} = \frac{k_0}{K_{SH^+}} \frac{f_s}{f_{s\ddagger}} a_{H^+}$$

where k_0 is the rate constant for the slow step, K_{SH^+} is the substrate basicity constant, f_s and $f_{s\ddagger}$ are the substrate and transition state activity coefficients, respectively, and a_{H^+} is the hydronium ion activity. Rearranging and taking logarithms gives eq. [3],

$$[3] \quad \log (f_{s\ddagger}^*/k_0) = \log a_{H^+}^* - \log k_{\psi}^{corr} + \log f_s + pK_{SH^+}$$

where k_{ψ}^{corr} is the observed pseudo first order rate constant corrected for partial protonation of the substrate; i.e.

$$k_{\psi}^{corr} = k_{\psi}(1 + I)$$

where I is one ionisation ratio as defined in eq. [2]. Since activity coefficients for single ions are experimentally inaccessible, they are expressed as relative to a standard reference ion (24), usually the tetraethylammonium ion (TEA^+). This is indicated by starring such terms as $a_{H^+}^*$ and $f_{s\ddagger}^*$. The quantities on the right side of eq. [3] are all experimentally accessible, and since $\log f_{s\ddagger}^*$ must approach zero in dilute aqueous solution, $\log k_0$ can be obtained from the intercept of a plot of $\log (f_{s\ddagger}^*/k_0)$ versus acid concentration. Therefore it is possible to study the medium variation of $f_{s\ddagger}^*$, which should reflect the solvation requirements of the transition state.[6] This can then be interpreted in terms of possible transition state structures, by comparing the $\log f_{s\ddagger}^*$ behaviour with that of known stable cationic species, or with species involved in mechanisms which have been well-established.

Since $\log a_{H^+}$ values are already available (33), it was only necessary to measure $\log f_s$ values for the substrates of interest. This was done using a standard method (25) (see Experimental section) and the results are given in Table 6. The observed variations in $\log f_s$ (initial salting out, followed by a tendency to salt in at higher acidities) are typical of the behaviour of many weakly basic organic molecules (25). It was unfortunately impossible to measure $\log f_s$ for the β-lactam due to its high reactivity, so the values for *N*-ethylacetamide[7] were used to calculate $\log f_{s\ddagger}^*$ for this substrate. This should not cause any serious error since the total variations in all the $\log f_s$ values from 0–70% H_2SO_4 are of the order of one logarithmic unit or less. Plots of $\log f_{s\ddagger}^*$ versus acidity[3] are given for all the substrates in Fig. 5. It can be seen that the γ-, δ-, and ε-lactams, as well as *N*-ethylacetamide, show a

[6]The logarithms of activity coefficients determined in aqueous acidic media, with dilute aqueous solution as standard state, can be thought of as measures of the free energy change in transferring 1 mol of the species from pure water to the acid in question. When $\log f$ is positive the species is destabilized by acid, or "salts out". When $\log f$ is negative it is stabilized by acid, or "salts in".

[7]These were chosen as models for $\log f_s$ for the β-lactam since *N*-ethylacetamide hydrolyses most slowly of all the substrates studied. Hence its $\log f_s$ values should be the most reliable.

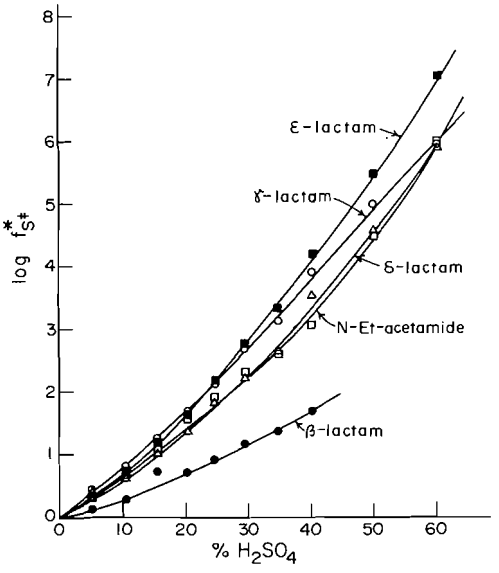

FIG. 5. Medium dependence of transition state activity coefficients for lactam hydrolysis.

strong destabilization with increasing acidity, with log $f_{s\ddagger}$* reaching values of 6–7 at around 60% H_2SO_4. This corresponds to a desolvation energy of about 8–9 kcal mol^{-1} over the range of acidity studied. This behaviour is typical of both stable oxonium ion species and of transition states in A_{Ac^2} ester hydrolysis (11). The curves in Fig. 5 are also very similar to the behaviour of log $f_{s\ddagger}$* found in various benzamide hydrolyses (3*a*). From these plots we can only conclude that all four of these substrates hydrolyse by way of an A-2 mechanism (more specifically A_O^T2), via a tetrahedral intermediate with strong oxonium ion character.[8]

[8]The curves in Fig. 5 do not suggest any change in mechanism at higher acidities, since the log $f_{s\ddagger}$ curves are smoothly monotonic, with no sharp breaks. In this sense the TSAC approach is less sensitive than the *r*-parameter treatment in determining the details of the mechanism.

The log $f_{s\ddagger}$* behaviour of the β-lactam is quite different. Although transition state destabilization does occur as the acidity is increased, this is much less pronounced than for the other substrates. The rate of change of log $f_{s\ddagger}$* with acidity is a factor of 2–3 less than that for the other lactams. Indeed the behaviour of the β-lactam is similar to that found for methyl mesitoate hydrolysis (11), which is known to involve an acylium ion mechanism. It seems clear from Fig. 5 that the β-lactam hydrolysis involves quite different mechanistic behaviour, and it is again concluded that this substrate reacts by an A-1 process (more specifically A_N^D1), via an acylium ion-like transition state.

As mentioned previously, the intercepts of the log ($f_{s\ddagger}$*/k_0) versus acidity plots give values of log k_0 which refer to the reactivity of the conjugate acid form of the substrate, in the limiting ideal dilute solution region. These values are thus corrected for differing degrees of protonation, and possibly different activity coefficient effects, and would be inaccessible experimentally in most cases due to the slowness of the reactions. The values of k_0 obtained are given in Table 2. It is interesting that the relative rates shown by these k_0 values are in the same order as those found from the observed pseudo first order rate constants, namely

β- ≫ δ- > ε- > γ- > *N*-ethylacetamide

The very high reactivity of the β-lactam conjugate acid relative to that of the other protonated species is thereby confirmed.

Effects of Ring Size

The relative rates of hydrolysis of all substrates except the β-lactam can be rationalized by considering two effects: substrate basicity and ring size effects. For reaction [1] the rate law can be written as

$$v = k_2K[H^+][S]$$

and

$$k_\psi = k_2 K[H^+]$$

where activity coefficient terms have been omitted for simplicity. Since $K (= 1/K_{SH^+})$ is the equilibrium constant for protonation of the substrate, the observed rate constant k_ψ should depend on lactam basicity. Comparing the data in Tables 2 and 3 it can be seen that the strongest base (δ-lactam; $pK_{SH^+} = -0.18$) also has the fastest rate of hydrolysis, followed by the ε-lactam ($pK_{SH^+} = -0.46$), with *N*-ethylacetamide ($pK_{SH^+} = -0.49$) and the γ-lactam ($pK_{SH^+} = -0.65$) reacting more slowly. Thus the three lactams reacting by the standard A_O^T2 mechanism have rates in the same order as their basicities. However, since relative substrate basicities are numerically smaller than relative rate factors, ring size effects must be important in determining relative reactivities. Brown and co-workers (26) have proposed the generalization that for cyclic compounds, reactivity depends on changes in internal strain (I-strain), as the transition state is approached. This I-strain is made up of various components, including bond angle distortion and bond opposition effects (26*c*). Since the rate-determining step in the A_O^T2 hydrolysis is addition of a water molecule to the carbonyl carbon to give a tetrahedral intermediate, the change from sp^2 to sp^3 hybridization should most favour the δ-lactam, which can accommodate the sp^3 carbon of the intermediate without any ring strain. (Also partial bond oppositions between the carbonyl–oxygen bond and the neighbouring C—H and N—H groups will be relieved.) For the γ-lactam, the relief of bond angle distortion would also be favourable, but formation of a tetrahedral intermediate would increase bond opposition forces. In the protonated form the five-membered ring is approximately planar with the sp^2 hybridized nitrogen and the N—H bond in the plane of the ring. On attack of water, the nitrogen hybridization reverts to sp^3 and the lone pair and N—H bond interactions with neighbouring bonds will disfavour the reaction.

A ground state effect is also operative in making the six-membered ring more reactive than the five-membered analogue. Fuji and co-workers (7) have shown that for a suitably substituted six-membered lactam, under conditions of thermodynamic control, the ring opens and prefers to close back to form a five-membered lactam. This shows that other things being equal, a five-membered lactam ring is more stable than the corresponding six-membered ring. Therefore the ground state energy of the γ-lactam is lower than what might have been expected, with the consequence that the activation energy for hydrolysis is increased (see Table 4). The ε-lactam presumably does not possess such ground state stabilization, and this, coupled with less serious bond opposition forces, and some ring strain at the transition state, causes this substrate to show reactivity intermediate between the δ- and γ-lactams. The β-lactam is different in the sense that although bond angle deformation would be significantly relieved in tetrahedral intermediate formation, bond opposition forces would be substantially increased. Also, since this ring is by far the most strained in either lactam or conjugate acid form, the strain can be relieved most readily by unimolecular ring opening.

The variations in basicity shown in Fig. 2 can most easily be explained simply in terms of ring strain effects in the neutral and protonated forms. Apart from the δ-lactam, basicity increases fairly monotonically with ring size and probably levels off somewhere around ring size 9 or 10 (this trend was also observed by Huisgen and co-workers (17)). If the two canonical forms of the O-protonated lactam are considered, the basicity will depend strongly on the ability of nitrogen to donate its pair of electrons to give a delocalized cation. Hence structure **II** will

I **II**

be more important in the conjugate acid than the analogous contributing structure in the neutral lactam. This will cause more serious ring strain the smaller the size of the lactam ring, and hence tend to reduce the basicity. As the rings become very large, such strain factors will become less important and the basicity would be expected to level off at a p*K* value similar to that of a typical secondary amide. Only the δ-lactam is unusual in that its base strength is much higher than expected. It is commonly observed (27) that for five-membered rings *exo* double bonds are preferred, while for six-membered rings *endo* double bonds are more stable, although these preferences are not easily rationalized. Therefore contributions from canonical form **II** in the protonated δ-lactam should be more important than in the γ-lactam case (and possibly the other lactams as well), leading to a higher basicity for the δ-lactam than its ring size would lead one to expect from the trends in Fig. 2. The β-lactam also may be unusual in the sense that although the major protonated species is still the O-protonated form, the stabilization produced by the nitrogen lone pair delocalization may be so

reduced that the N-protonated form (required for the A_N^D1 process) is relatively more important than it is for other lactam protonations.

Experimental

General

Infared spectra were taken from liquid films. Nuclear magnetic resonance spectra were run on Varian T60 and CFT-20 instruments, using $CDCl_3$ as solvent with TMS as internal standard, when required. Melting and boiling points are uncorrected.

Materials

CIL Reagent Grade sulfuric acid was appropriately diluted with distilled water and standardized at 25°C using an Anton Paar Model DMA 02C precision density meter and standard tables of densities (28). The γ-lactam (2-pyrrolidone) and δ-lactam (2-piperidone) were obtained from Aldrich. The ε-lactam (ε-caprolactam) was obtained from Eastman and recrystallized from ethanol to constant mp (66–67°C). The β-lactam (2-azetidinone) was prepared by the method of Birkofer and Schramm (29), with all reactions carried out under a nitrogen atmosphere. Mp 70–71°C (lit. (29) mp 72–74°C). Ir: 1760 cm^{-1} (strong); 3226 cm^{-1} (medium). Nmr: δ2.9 (m, 2H); δ3.2 (m, 2H); δ6.13 (broad, 1H). *N*-Ethylacetamide was prepared from acetic anhydride and ethylamine hydrochloride as follows. The anhydride (32 g) was added to a solution of the hydrochloride (20 g) in 500 mL water. A solution of sodium acetate (24 g) in 130 mL water was then added slowly, and the mixture cooled in an ice-bath. The solution was stirred for 2 h, followed by removal of the water under vacuum. The resulting slurry was filtered to give a viscous oil, which was fractionally distilled to give *N*-ethylacetamide (13 g) as a colorless liquid. Bp 104–106°C/20 mm (lit. (30) bp 104–105°C/18 mm). Further purification by column chromatography (alumina, methylene chloride) gave the essentially pure (>99%) amide, as determined by glpc. Ir: 1695 cm^{-1} (strong); 3225 cm^{-1} (medium). Nmr: δ1.1 (t, 3H); δ1.9 (s, 3H); δ3.2 (m, 2H); δ7.2 (broad, 1H).

Rate Measurements

The hydrolysis of *N*-ethylacetamide was followed at 25 ± 0.3°C, by taking samples periodically and recording their nmr spectra. The hydrolysis is slow enough ($t_{1/2}$ is several months at 25°C) that recording spectra at 33°C (the temperature of the spectrometer) should not materially affect the results. The growing area of the methyl signal due to acetic acid was followed, with the total area of the two methyl peaks (of the reactant and product) taken as 100%. Authentic samples of acetic acid were added at the end of the reaction and no additional peaks were observed. Plots of ln $[A_0]/[A_t]$ versus time were linear with correlation coefficients greater than 0.992 in almost all cases. For convenience, the hydrolyses of the lactams were studied at elevated temperatures (except for the β-lactam), again by following changes in the nmr spectra. Samples were quenched in ice before recording spectra. For the γ-lactam the methylene signal at the γ-position was used, since the change from a triplet in the lactam to a multiplet in the product was easy to detect. The spectrum of the hydrolysis product was indistinguishable from that of an authentic sample of 4-aminobutanoic acid in the appropriate sulfuric acid solution. In the case of the δ-lactam, the methylene signal at C_δ was followed. Again, comparison of the nmr spectrum of the product with that of an authentic sample of 6-aminovaleric acid showed no differences. A similar procedure was used to follow the hydrolysis of the ε-lactam. Mhala and Jagdale (8) also obtained a rate profile for this lactam at 97.0°C, which was one of the temperatures used in the present work. Although the shapes of the two profiles are similar, the rate maxima occur at different acidities. Since the acidity of the rate maximum for any amide or lactam hydrolysis should be near the position of half-protonation of the substrate (or pK_{SH^+} value), the position of the rate maximum found by Mhala and Jagdale (ca. 10% H_2SO_4) would suggest a substrate of much higher basicity than that found for any known amide or lactam. The position of the maximum found in the present work (ca. 20% H_2SO_4) is much nearer to both the pK_{SH^+} values measured, and to previously reported rate maxima for amide hydrolyses.

The hydrolysis of the β-lactam was followed at 33 ± 1°C, again using proton magnetic resonance spectroscopy. The hydrolysis product was in all cases β-alanine, as shown by comparison with authentic samples. At higher acidities the reaction is too fast to follow, but it was found that at 82% H_2SO_4, the hydrolysis is even faster than at 60% H_2SO_4, with $t_{1/2} < 10$ s. The actual rate constants determined at different temperatures are listed in the Tables of Supplementary Data.[3] These were converted to the values at 25°C given in Table 1 by extrapolation of plots at log k/T versus $1/T$.

*p*K *Determinations*

Lee and Sadar (13) have shown that ionization ratios, which are relatively free of errors due to medium effects, can be obtained from nmr spectra using the relationship

$$I = [SH^+]/[S] = (\Delta - \Delta_S)/\Delta_{SH^+} - \Delta$$

where Δ_S is the chemical shift difference between two sets of protons in the free base and Δ_{SH^+} is the chemical shift difference between the same two sets of protons in the conjugate acid form. Because the proton signals in the lactams do not occur as singlets, and because difficulty was encountered in following some proton chemical shifts, ^{13}C nmr was used for all substrates except the β-lactam, which reacts too rapidly for the use of ^{13}C spectra. Each signal could be followed readily and no multiplets were involved. For the β-lactam ^1H nmr was used, based on the central peaks of the two sets of triplets. Values of log I obtained this way were plotted according to the equation

$$\log I - \log C_{H^+} = m^*X + pK_{SH^+}$$

where X is the "excess acidity" (16) of the solution in question, and C_{H^+} is the stoichiometric hydrogen ion concentration. The pK_{SH^+} values in Table 3 were obtained from the intercepts. Medium effects on amide and lactam ionization ratios will be discussed in a forthcoming paper (31). They are not sufficiently serious in the present case to warrant extended discussion at this time, since the main use of the pK_{SH^+} values was for the TSAC treatment. Since K_{SH^+} is a constant in eq. [3], any uncertainty caused by medium effects would only affect the intercepts of the $\log f_{\neq}^*$ plots, and not $\log f_{s\neq}^*$ variation itself.

Substrate Activity Coefficients

The standard distribution method (25) was used, in which a stock solution of substrate in an inert organic solvent ($CHCl_3$) immiscible with water is shaken mechanically with the appropriate aqueous sulfuric acid until equilibrium is reached, and the concentration of substrate in both phases is then determined by ultraviolet spectrophotometry at 200–210 nm on a Cary 14 instrument. From these concentrations the two distribution coefficients D_0 (between water and the organic solvent), and D_x (between a given aqueous acid and the organic phase) can be obtained. The substrate activity coefficient f_s is then given by $f_s = D_0/D_x$. Since the substrates are very soluble in the aqueous phase, it was not possible to determine directly the small concentration left in the organic phase, after equilibration, because of interference by the chloroform absorption. As a result the concentration in the aqueous phase had to be determined very accurately, and the concentration left in the organic phase was

calculated from this and the known initial concentration. In the more strongly acidic solutions, it was also necessary to correct the aqueous phase concentration for partial protonation, using the K_{SH^+} values already determined.

Deuterium and phosphorus-31 nuclear magnetic resonance of cholesteryl palmitate in dipalmitoylphosphatidylcholine model membranes

ROBERT J. CUSHLEY, HEINER GORRISSEN, AND STEPHEN R. WASSALL

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received June 27, 1980

Dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

ROBERT J. CUSHLEY, HEINER GORRISSEN, and STEPHEN R. WASSALL. Can. J. Chem. **58**, 2433 (1980).

Cholesteryl palmitate (CP) has been incorporated into vesicles of dipalmitoylphosphatidylcholine and dipalmitoylphosphatidylcholine/20 mol% cholesterol, in amounts up to 5 mol%. By means of ^{31}P lanthanide induced shifts the average diameter of these vesicles was calculated to be ~270 Å.

The ^{2}H spectral linewidths of selectively deuterated CP incorporated into liquid crystalline dipalmitoylphosphatidylcholine vesicles are ≤150 Hz, implying a low degree of order for the ester acyl chain. Addition of 20 mol% cholesterol to the vesicles increases the linewidths which, nevertheless, remain ≤185 Hz. The corresponding ^{2}H longitudinal relaxation times (≤450 ms) indicate that the fast segmental motions of the ester chain are slower than for the phospholipid chains.

ROBERT J. CUSHLEY, HEINER GORRISSEN et STEPHEN R. WASSALL. Can. J. Chem. **58**, 2433 (1980).

On a incorporé le palmitate de cholestéryle (PC) en quantité allant jusqu'à 5 mol% dans les vésicules de dipalmitoylphosphatidylcholine et de dipalmitoylphosphatidylcholine/20 mol% cholestérol. Au moyen des déplacements chimiques du ^{31}P induits par les lanthanides on a calculé que le diamètre moyen de ces vésicules est d'environ 270 Å. Les largeurs des raies des spectres rmn ^{2}H des PC deutérés sélectivement et incorporés dans les vésicules de dipalmitoylphosphatidylcholine cristallins à l'état liquide sont ≤150 Hz; ceci implique un faible degré d'ordre de la chaîne ester acyclique. L'addition de 20 mol% de cholestérol aux vésicules augmente la largeur des raies qui néanmoins restent à 185 Hz. Les temps de relaxation longitudinale correspondants du ^{2}H (≤450 ms) indiquent que les rapides mouvements des segments de la chaîne ester sont plus lents que ceux des chaînes phospholipides.

[Traduit par le journal]

Introduction

We have been studying the structure and properties of cholesteryl esters in various phospholipid membrane systems using a diversity of magnetic resonance techniques. In our initial study (1) we utilized ^{31}P nmr spectroscopy and found that cholesteryl palmitate (CP) increased the permeability of model membranes to ions, whereas cholesteryl linoleate did not. The behavior of the saturated ester CP in egg phosphatidylcholine bilayer systems was studied by epr of spin-labeled CP in multilayers (2, 3), as well as ^{13}C nmr difference spectroscopy (4) and ^{2}H nmr (using CP selectively deuterated in the acyl chain) (5, 6).

The epr studies indicated that only a small fraction of added ester (~0.85 mol%) intercalates between the phospholipid molecules while any excess ester forms solid patches (2). The epr studies of spin-labeled CP favor a "horseshoe" conformation for the intercalated, spin-labeled ester in the phospholipid multilayers with the ester linkage at the bilayer surface and with the chain and steroid moiety extending down into the bilayer interior. When selectively deuterated CP in an egg phosphatidylcholine multilamellar liposome system was studied using ^{2}H nmr spectroscopy, a smaller fraction of added ester (~0.2 mol%) was found to intercalate between egg phosphatidylcholine molecules (5). If the phospholipid is changed from phosphatidylcholine to sphingomyelin the amount of intercalated CP reaches 1.5 mol% (7).

When egg phosphatidylcholine bilayers are made by sonication of aqueous dispersions to form highly curved unilamellar vesicles, ester intercalation increases substantially, reaching as high as 5 mol% (6) while the ester chains appear more disordered compared to CP in multilamellar liposomes (5).

The present study is an attempt to determine the behavior of saturated cholesteryl ester in a highly curved bilayer composed of the completely saturated phospholipid, dipalmitoylphosphatidylchloline, both in the presence and absence of cholesterol (20 mol%). To do this, we used ^{2}H nmr spectroscopy of selectively deuterated cholesteryl palmitate in dipalmitoylphosphatidylcholine unilamellar vesicles.

Nuclear magnetic resonance experiments were also performed to determine whether the size of dipalmitoylphosphatidylcholine vesicles is affected by the incorporation of CP or CP/cholesterol. A ^{31}P nmr-lanthanide shift reagent technique was employed (8). Addition of the shift reagent to a sonicated dispersion separates the ^{31}P resonances from the inside and outside surfaces of the vesicles, and, from the relative intensity of the signals, an average vesicle radius may be estimated.

Experimental

Materials

Cholesterol was obtained from Fisher Scientific Company and recrystallized from benzene before being used. Dipalmitoylphosphatidylcholine and cholesteryl palmitate were purchased from Sigma Chemical Company. Deteurium depleted water was obtained from Aldrich Chemical Company. Praseodymium nitrate was bought from Alfa Inorganics. Hexadecanoic-d_{31} acid, hexadecanoic-5,5,6,6,-d_4 acid, and hexadecanoic-11,11,12,12-d_4 acid were purchased from Merck, Sharp and Dohme, Canada, Ltd., whereas hexadecanoic-16,16,16-d_3 acid was obtained from Serdary Research Laboratories, London, Ont., Canada.

Syntheses of hexadecanoic-2,2-d_2 and 3,3-d_2 acids were described previously (6).

Deuterated cholesteryl esters were prepared from the corresponding deuterated fatty acids and cholesterol by the method of Grover and Cushley (9).

Preparation of Lipid Vesicles

Lipids were weighed directly into sample tubes and codissolved in a small amount (~2 mL) of chloroform–methanol (3:1). The solvent was then removed by evaporation under a stream of nitrogen and subsequent overnight pumping under high vacuum. Distilled or deuterium depleted water was added to the lipid mixture, the tube shaken vigorously on a vortex mixer and the resultant dispersion sonicated for ~15 min at ~50°C using a Biosonik III probe-type sonicator. The vesicles were then centrifuged for 15 min on a small laboratory centrifuge, in order to eliminate titanium fragments and undispersed lipid. The vesicles (~10% w/v) were used immediately for the nmr experiments. Samples in which a quantitative determination of the phospholipid and/or cholesteryl ester was required were subjected to an additional preparative ultracentrifugation for 3 h at 160 000 g on a Spinco Model L ultracentrifuge in order to remove any traces of residual undispersed lipid and multilamellar liposomes (10). The amount of phosphatidylcholine present in the suspension was quantified by phosphorus determination (11) while cholesteryl ester was determined as described by Rudel and Morris (12) or by ^{2}H nmr (6).

Nuclear Magnetic Resonance

Deuterium nmr experiments were performed at 15.4 MHz on a Varian XL 100-15 spectrometer interfaced to a NIC 1080 computer and operating in the pulse Fourier transform mode. Field stabilization was by means of an external ^{19}F field-frequency lock. Sufficient rf power was achieved by use of a 300 W ENI power amplifier. All experiments were performed at temperatures between 30–60°C as indicated throughout the text, the temperature being controlled by means of a gas-flow system.

Transverse relaxation times (T_2*) were measured from the ^{2}H nmr peak width at half-height, $\Delta\nu_{1/2}$. These spectra were obtained from the free induction decays (FID's) following a periodic sequence of 60–90° pulses. Longitudinal relaxation times (T_1) were measured by the inversion-recovery method (13),

$$[180°, \tau, 90°, \text{sample and add}, \tau_R]_N$$

where τ is the delay between the two pulses of the sequence, τ_R is the delay between subsequent pulse sequences ($\tau_R \geq 5T_1$ to ensure complete return to equilibrium), and N is the number of acquisitions. The errors in the relaxation measurements are reported in Tables 1 and 2. In all experiments a phase-alternating pulse sequence was used to minimize baseline errors.

The same spectrometer system and operating conditions were employed in the ^{31}P (40.5 MHz) nmr experiments. FID's were recorded in the presence of ^{1}H noise-decoupling (1 kHz bandwidth) and were collected both before and after addition of $Pr(NO_3)_3$ to the sonicated dispersions. Enough $Pr(NO_3)_3$ solution, approximately 50 μL of a 0.1 *M* solution to 2 mL samples of ~10% w/v vesicle dispersion, was added to produce a 150–200 Hz separation between signals from the inner and outer monolayers. Signal intensities were measured by integration of the spectra while ^{31}P chemical shifts were measured relative to an external H_3PO_4 (85%) reference. In order to eliminate Nuclear Overhauser Effects (NOE's) ^{1}H decoupling was gated on only during acquisition of the FID. Furthermore, sufficient time ($\geq 5T_1$) was left between successive rf pulses to allow complete recovery of the nuclear signals.

Results

Dipalmitoylphosphatidylcholine vesicles have been prepared which incorporate up to 5 mol% cholesteryl palmitate (CP). In order to prepare vesicles containing more than 1 mol% ester, excess CP must be added to the lipid mixture prior to sonication. The final amount of CP incorporated into the membrane may depend upon the length and power of sonication, and the temperature at which the sonication step is carried out.

The concentration of CP incorporated into the dipalmitoylphosphatidylcholine vesicles was measured in two ways. First, the amount of phospholipid in the suspension was quantified by the colorimetric determination of phosphorus (11), while the CP was determined using the phthalic dialdehyde method described by Rudel and Morris (12). Second, the ^{2}H nmr signal intensities for CP-d_{31} and natural abundance DOH in a carefully weighed amount of distilled water in the dipalmitoylphosphatidylcholine – cholesteryl palmitate-d_{31} vesicle system at 45°C were compared (6). The two methods agreed to within ±10%.

When 20 mol% cholesterol is added to the lipid preparation no reduction in the solubility of CP in the dipalmitoylphosphatidylcholine vesicle system is observed.

We have found that the ^{2}H nmr linewidths of deuterated CP in dipalmitoylphosphatidylcholine vesicles are independent of ester concentration. In addition, we observed that the ^{2}H nmr lineshape, hence $\Delta\nu_{1/2}$, was identical whether the vesicles were sized by preparative ultracentrifugation (see Experimental Section) or not, therefore, for the majority of the experiments the vesicles were not subjected to the ultracentrifugation step.

Deuterium nmr spectra for cholesteryl palmitate selectively deuterated at several positions along the acyl chain and incorporated into dipalmitoylphosphatidylcholine vesicles are shown in Fig. 1. The temperature of these runs was 45°C, which is just above the gel to liquid crystalline phase transition (T_m = 41°C) of the phospholipid. Included in Fig. 1 are the Lorentzian lineshapes giving the best

fit to the experimental spectra. In most cases, a single Lorentzian function was found to give a good fit to the experimental spectrum. In spite of the good agreements between experimental and theoretical lineshapes, the possibility exists that our ^{2}H nmr spectra may actually be composed of a superposition of Lorentzian lines of different widths. From the signal-to-noise for our spectra we are unable to distinguish any superposition, hence, only a single Lorentzian function was fitted to the lineshape.

The ^{2}H nmr linewidths and the corresponding transverse relaxation times T_2* (where T_2* = $1/\pi\Delta\nu_{1/2}$) for a series of selectively deuterated esters at two temperatures above T_m, 45°C and 55°C, are given in Table 1. The linewidths are largest for the segment near the ester linkage, tend to decrease toward the terminal methyl group, and decrease when the temperature increases from 45°C to 55°C.

We have also obtained a ^{2}H nmr spectrum of CP-16,16,16-d_3 in dipalmitoylphosphatidylcholine vesicles at 30°C, i.e. below the gel to liquid crystalline phase transition of the phospholipid. The spectrum (not shown) was taken after performing an initial ^{2}H nmr run at 45°C and consisted of a signal approximately 200 Hz wide with an intensity of ~90% of that obtained at 45°C. Due to the large linewidth the 30°C run required 25 h in order to obtain sufficient signal-to-noise. After that time, the sample was warmed to 45°C and another spectrum taken at the higher temperature. The signal intensity in the final 45°C spectrum was ~80% of the intensity found in the original 45°C spectrum.

Deuterium nmr spectra of CP, selectively deuterated at various chain positions, in dipalmitoylphosphatidylcholine vesicles containing 20 mol% cholesterol, are presented in Fig. 2. The spectra were obtained at 45°C and have superimposed upon them the single Lorentzian function giving the best fit. Comparison with the spectrum for a similar position in the absence of cholesterol (Fig. 1) indicates that cholesterol produces a general increase in linewidth with an especially large increase at positions 11 and 12. The ^{2}H nmr linewidths and corresponding transverse relaxation times of selectively deuterated CP's in dipalmitoylphosphatidylcholine vesicles containing 20 mol% cholesterol are presented in Table 1. As seen above with vesicles composed of deuterated CP/dipalmitoylphosphatidylcholine alone, increasing the temperature from 45°C to 55°C results in a narrowing of the ^{2}H signal, and consequent increase in T_2*.

We have also measured the longitudinal relaxation times T_1 for selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles and these are presented in Table 2. For all positions except the terminal methyl group the measured T_1's are very low (< 40 ms) while the T_1 for CP-16,16,16-d_3

amounts of spectrometer time in order to achieve sufficient signal-to-noise.

The ^{31}P nmr spectra of sonicated dispersions of dipalmitoylphosphatidylcholine/CP and dipalmitoylphosphatidylcholine/20 mol% cholesterol/CP at 50°C following the addition of the lanthanide shift reagent $Pr(NO_3)_3$ are shown in Fig. 3. Addition of Pr^{3+} results in a downfield shift for phosphorus nuclei on the outer surfaces of the vesicles, whereas the upfield line is produced by phospholipids on the inner surfaces and is essentially unshifted. The ratio of the relative intensities of outside and inside ^{31}P nmr signals are $I_{out}/I_{in} = 1.9 \pm 0.2$ for dipalmitoylphosphatidylcholine/CP vesicles and $I_{out}/I_{in} = 1.7 \pm 0.2$ for dipalmitoylphosphatidylcholine/cholesterol/CP vesicles. Within the experimental uncertainty (±10%) these values agree with the value obtained for pure dipalmitoylphosphatidylcholine vesicles.

The outside–inside relative intensity may also be estimated by comparing the intensity of the upfield lines in Fig. 3 with that of the single ^{31}P signal observed for the same sample before the introduction of shift reagent. The ratios determined in this way are $I_{out}/I_{in} = 2.1 \pm 0.2$ and 1.9 ± 0.2 for dipalmitoylphosphatidylcholine/CP vesicles and dipalmitoylphosphatidylcholine/cholesterol/CP vesicles, respectively. However, these values may be slightly high, since some aggregation was seen to occur in the dispersions over the duration of the nmr experiment. This results in a progressive reduction in intensity of the narrow signals in the spectra recorded and makes the above comparison between spectra obtained before and after the lanthanide treatment subject to error. Therefore, the earlier stated ratios are preferred.

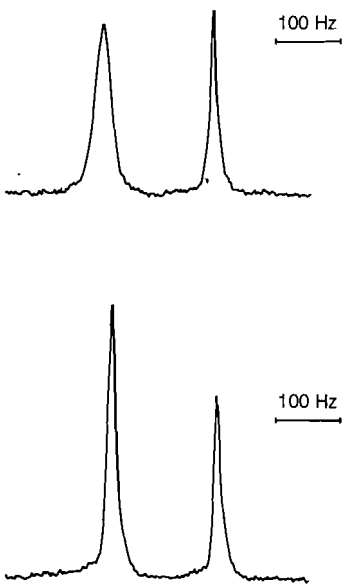

FIG. 3. Proton noise-decoupled ^{31}P nmr spectra at 50°C of sonicated dispersions after the addition of Pr^{3+}. The upper spectrum is for dipalmitoylphosphatidylcholine/CP vesicles whilst the lower one is for dipalmitoylphosphatidylcholine/cholesterol/CP vesicles. Spectral parameters: pulse width = 15 μs (90° flip angle); pulse delay $\tau_R = 15$ s; sweep width = 2000 Hz; No. of data points = 2K zero filled to 4K; line broadening = 2 Hz.

The linewidths of the upfield lines (at -1.5 ± 0.1 ppm) in the spectra of Fig. 3 are 13 Hz for the dipalmitoylphosphatidylcholine/CP vesicles and 12 Hz for the dipalmitoylphosphatidylchloline/cholesterol/CP vesicles while the widths of the signals (at -1.6 ± 0.1 ppm) of the corresponding samples prior to the addition of shift reagent are 15 and 16 Hz, respectively. On the other hand, the downfield signals are 31 Hz wide in the absence of cholesterol (at $+3.0 \pm 0.1$ ppm) and 17 Hz wide in the presence of cholesterol (at $+2.7 \pm 0.1$ ppm). The outside ^{31}P signals in the presence of cholesterol are unexpectedly, but reproducibly, less broadened.

Discussion

The results indicate that dipalmitoylphosphatidylcholine vesicles can incorporate up to 5 mol% CP, an amount identical to that incorporated into egg phosphatidylcholine vesicles (6). The solubility of the ester is not greatly reduced in the gel phase as evidenced by the ^2H nmr experiments conducted with a dipalmitoylphosphatidylcholine/CP-16,16,16-d_3 vesicle system both above and 10°C below the gel to liquid crystalline phase transition of the phospholipid. Indeed, the 10% loss in signal intensity observed at 30°C is attributed mostly, if not completely, to a small amount of vesicle aggregation (14). The additional ~10% loss in line intensity found when the sample was reheated above the phase transition lends support to this conclusion.

In an earlier study of the sphingomyelin/CP model membrane system (7), we also saw that ester solubility is independent of whether the phospholipid is in the gel or liquid crystalline phase. Our results contrast with the conclusion reached by Janiak *et al.* (15), who studied the related system, cholesteryl myristate/dimyristoylphosphatidylcholine/H_2O, using polarizing light microscopy, X-ray diffraction, and differential scanning calorimetry, and concluded that essentially all ester is forced out of the bilayer below the phospholipid phase transition temperature.

The 5 mol% maximum observed for the incorporation of CP in dipalmitoylphosphatidylcholine vesicles is several times higher than that found in

For personal use only.

multilamellar liposomes prepared from the same phospholipid (28) and the same situation has also been encountered for the egg phosphatidylcholine/CP system (5, 6). The apparent increase in ester solubility upon going from liposomes to small vesicles may simply reflect sonication forcing an excess amount of cholesteryl ester into the bilayer, so that the final sample represents a supersaturated system. If this is the case, then the vesicles would try to achieve equilibrium by ejecting cholesteryl ester from the bilayer over a period of time. However, since the vesicles themselves have only a limited stability, such a process would be extremely difficult to prove.

On the other hand, ester solubility may actually be higher in a membrane of high curvature such as a unilamellar vesicle. A study by Pries and Klynstra (16) has established that areas of the intimal layer in animal aortas are enriched 4- to 5-fold in cholesteryl ester concentration, demonstrate enhanced permeability, and were said to be "predisposed to atherosclerosis" development. Such areas may contain cell membranes with small invaginations (endocytitic vacuoles) which, being more highly curved than the rest of the cell membrane, might dissolve more ester and lead to increased permeability of the intimal layer. We have previously established that cholesteryl palmitate enhances the permeability of model membranes (1).

Addition of 20 mol% cholesterol to the dipalmitoylphosphatidylcholine/CP-d_{31} vesicle system does not appear to decrease the amount of ester incorporated. This is in contrast to our previous observations on the egg phosphatidylcholine/CP-d_{31} system (6) in which 20 mol% cholesterol decreased the ester solubility at least by a factor of 2.

The size of the dipalmitoylphosphatidylcholine vesicles, as indicated by ^{31}P nmr, is not significantly changed either by the incorporation of CP or by the further incorporation of 20 mol% cholesterol. This behavior is identical to that reported previously for egg phosphatidylcholine vesicles (6). It is established in two ways. The first is based on the constant ratio, to within the experimental uncertainty, of the outside to inside phospholipid determined from ^{31}P nmr following addition of paramagnetic ions to the sonicated dispersions (Fig. 3). The average ratio found is I_{out}/I_{in} = 1.8 which is in agreement with the results obtained by de Kruijff *et al.* (17) for dipalmitoylphosphatidylcholine vesicles containing up to 50 mol% of cholesterol. Assuming an identical packing density of lipid in the two monolayers of a vesicle and taking a bilayer thickness of ~35 Å (18), an average vesicle diameter of ~270 Å is calculated from the ratio. This is well within the range of sizes that have been published for dipalmitoylphosphatidylcholine vesicles (19, 20).

The widths at half height $\Delta\nu_{1/2}$ of the ^{31}P nmr signals obtained with the sonicated dispersions of dipalmitoylphosphatidylcholine/CP and of dipalmitoylphosphatidylcholine/cholesterol/CP at 50°C are virtually identical to that for pure dipalmitoylphosphatidylcholine vesicles. This observation provides verification of unaltered vesicle size upon incorporation of CP or CP/cholesterol since the ^{31}P linewidth for a sonicated phospholipid dispersion is sensitive to the rate of vesicle tumbling and, hence, to vesicle size (17). The same conclusion may be reached from consideration of the unshifted (upfield) ^{31}P signals observed after addition of $Pr(NO_3)_3$ (Fig. 3).

Although it has no bearing on the present discussion, we have noted a smaller degree of broadening for the lanthanide shifted (downfield) resonance of the dipalmitoylphosphatidylcholine/cholesterol/CP vesicles which, we believe, has not been observed previously.

The ^{2}H nmr linewidths for selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles decrease from 150 Hz at the 2 position to 7 Hz at the 16 position at 45°C (Table 1). Most of the variation occurs near the ends of the chain, with less change apparent in the central portion. The values are similar to those observed previously in egg phosphatidylcholine/*deutero*-CP vesicles (6). Such a profile in linewidth is in contrast to the characteristic plateau region observed by Stockton *et al.* (21) for selectively deuterated fatty acids incorporated into egg phosphatidylcholine vesicles. Furthermore, the linewidths reported for the corresponding chain positions of the fatty acid are, with the exception of the methyl group for which essentially the same widths are obtained, at least 4 times larger depending on temperature and chain position. This indicates that the behavior of the ester acyl chain in the bilayer is significantly different from that of a fatty acid. The similarity of the methyl linewidths is not surprising since the terminal methyl groups of hydrocarbon chains are known to have a high degree of motional freedom (22).

Reductions in linewidth at all positions along the acyl chain of selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles accompany an increase in temperature from 45 to 55°C, whereas the additon of 20 mol% cholesterol increases the linewidths (Table 1). The trend in both cases is qualitatively in agreement with that observed for specifically deuterated stearic acids in-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

tercalated in egg phosphatidylcholine vesicles (23). Stockton *et al.* (21), however, noted a decrease in vesicle tumbling rate due to an increase in vesicle size upon the addition of cholesterol which was partly responsible for the line broadening with the fatty acid. Our ^{31}P results, on the other hand, show that the size of the dipalmitoylphosphatidylcholine/CP vesicles is not altered by the presence of 20 mol% of cholesterol. Increased ^{2}H linewidths, including the especially large increase at chain positions 11 and 12, have also been reported for selectively deuterated CP in egg phosphatidylcholine vesicles (6).

A "plateau" in the spin–lattice relaxation rates $1/T_1$ is not apparent in the results obtained for selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles (Table 2). Brown *et al.* (24) observed such a plateau for chain positions 2 to 10 in deuterated dipalmitoylphosphatidylcholine bilayers. Table 2 indicates a continuous decrease in $1/T_1$ towards the methyl end of the chain, the T_1's determined for the methylene segments of the ester being a factor of 2–3 shorter than for the corresponding chain positions of the phospholipid at comparable temperature. The largest difference (~3-fold) occurs near the ester linkage of CP (segments 2–6), whilst at positions 11 and 12 the difference is ~2-fold. Once again, the terminal methyl group is an exception, with the T_1 value for CP-16,16,16-d_3 being very close to that found for the CD_3 segment of dipalmitoylphosphatidylcholine-d_{62} (22). Raising the temperature is seen to increase the T_1's recorded for specifically deuterated CP in dipalmitoylphosphatidylcholine vesicles (Table 2), and is the same trend in T_1 reported for dipalmitoylphosphatidylcholine bilayers (24).

The positive temperature dependence of the T_1's observed for selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles (Table 2) suggests that the molecular motions giving rise to the spin–lattice relaxation are in the short correlation time limit ($\omega_o^2\tau_c^2 \ll 1$). Hence, treating these fast motions as isotropic, an approximation which has been shown to be valid for the deuterated acyl chain segments of liquid crystalline dipalmitoylphosphatidylcholine bilayers (24), the relaxation rate $1/T_1$ may be related to a single, effective correlation time τ_c by (25)

$$[1] \quad \frac{1}{T_1} \approx \frac{3}{8}\left(\frac{e^2qQ}{\hbar}\right)^2 \tau_c$$

and e^2qQ/h is the static quadrupolar coupling constant and is 168 kHz for C—D bonds (26). Since the T_1 values measured for the methylene segments of deuterated CP are ~2–3 times shorter than the values for the corresponding chain positions in deuterated dipalmitoylphosphatidylcholine, we conclude, on the basis of eq. [1], that the effective correlation times must be ~2–3 times longer for the ester acyl chain. These longer τ_c's may be due to a slowing down of fast segmental motions of the ester chain as a result of steric interactions with the bulky cholesterol moiety. This effect would not be surprising if, for example, deuterated CP intercalated into the phospholipid bilayer in the form of a "horseshoe" as seems to be the case for spin-labelled CP (3). Space filling models show that hindrance to ester chain motions by the cholesterol moiety would then be expected to decrease markedly around chain positions 11 and 12 because the rigid cholesterol ring only extends to about these segments.

Assuming that the molecular motions contributing to the transverse relaxation observed for selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles may be divided into two classes, one with a correlation time τ_c satisfying the condition $\omega_o^2\tau_c^2 \ll 1$ plus a second, much slower class, the linewidth may be written as the sum of two terms

$$[2] \quad \Delta\nu_{1/2} = \frac{1}{\pi T_2^*} = \frac{1}{\pi T_1} + \frac{1}{\pi(T_2)_{slow}}$$

This basic approach was adopted by Stockton *et al.* (21) to interpret the linewidths obtained with selectively deuterated stearic acids intercalated into egg phosphatidylcholine bilayers. They identified the slow motions producing line narrowing with vesicle tumbling together with lateral diffusion of lipid molecules in the bilayer. By replacing $1/\pi(T_2)_{slow}$ in eq. [2] by a term involving the segmental order parameter and an effective vesicle correlation time they were able to determine a profile of order along the fatty acid chain. A similar treatment was used in our earlier study of selectively deuterated CP in egg phosphatidylcholine vesicles (6) but, subsequently, we have discovered that the assumption that vesicle tumbling is the slow motion largely responsible for line narrowing may not be valid for cholesteryl esters in vesicles. This conclusion rests on the observation that the width of the ^{2}H resonance for CP-d_{31} in phospholipid vesicles appears to be independent of the suspending medium viscosity (29). Hence, in the case of selectively deuterated CP in dipalmitoylphosphatidylcholine vesicles, we choose not to specify the nature of the slow motions, and we prefer not to use the formalism of Stockton *et al.* (21). Neither do we wish to employ the alternate, more detailed, theory developed by Petersen and Chan (27), in which the effects of

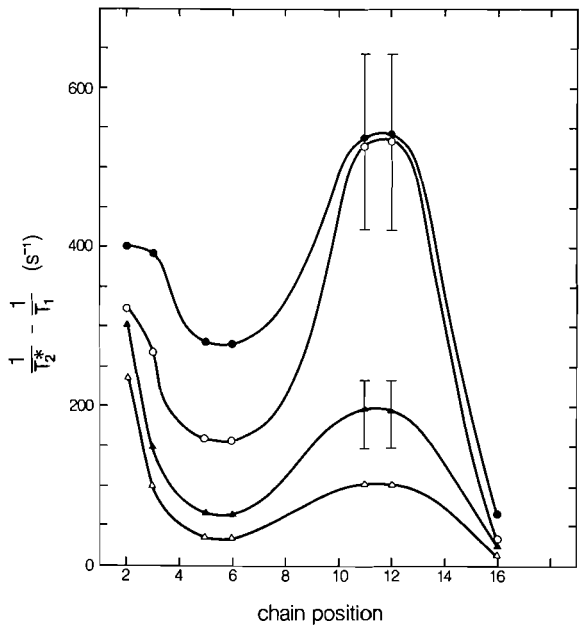

FIG. 4. Plot of $1/T_2^* - 1/T_1$ vs. chain position for selectively deuterated cholesteryl palmitate in dipalmitoylphosphatidylcholine or dipalmitoylphosphatidylcholine/20 mol% cholesterol vesicles: △, dipalmitoylphosphatidylcholine at 55°C; ▲, dipalmitoylphosphatidylcholine at 45°C; ○, dipalmitoylphosphatidylcholine/cholesterol at 55°C; ●, dipalmitoylphosphatidylcholine/cholesterol at 45°C. The indicated error bars are representative for positions 5,6 and 11,12 only; the actual error is higher at positions 2 and 3, and lower at position 16. Errors are lower at 55°C than at 45°C.

motional averaging due to slow reorientation of the lipid chain as a whole were included. Instead, we prefer to remain with the more general quantity $1/(T_2)_{slow}$ defined by eq. [2] and simply say that it reflects changes in disorder and/or rate of molecular motion along the ester chain.

The $1/(T_2)_{slow}$ values calculated for specifically deuterated CP in dipalmitoylphosphatidylcholine vesicles are plotted versus chain position in Fig. 4, as are the equivalent values estimated in the presence of 20 mol% cholesterol. The T_1's obtained for the samples without cholesterol were used in the latter estimations, and we feel this is not a serious approximation in the light of previous experience (6). A minimum around chain positions 5 and 6 followed by a maximum at positions 11 and 12 are characteristics of the plots, which clearly do not exhibit the plateau region seen for the C2–C10 part of the acyl chain in the order parameter profiles of deuterated phospholipids (21). This is another indication that the behavior of the ester chain differs considerably from that of the phospholipid chain. On the other hand, the fact that the $1/(T_2)_{slow}$ values are greater at the lower temperature and following the addition of cholesterol, corresponding to increased order and/or slower rates of motion for the ester chain, is qualitatively consistent with the changes observed for the phospholipid.

The origin of the maximum in $1/(T_2)_{slow}$ at chain positions 11 and 12 is unknown. In the absence of cholesterol, it appears to become less pronounced at the higher temperature when the dipalmitoylphosphatidylcholine bilayer is more disordered. The maximum is also seen to be greatly accentuated when order in the dipalmitoylphosphatidylcholine bilayer is made greater by addition of 20 mol% cholesterol. A similar change has been observed with egg phosphatidylcholine/deuterated CP vesicles (6). Explanation of the effect(s) responsible for the observations at the 11, 12 positions will require additional work.

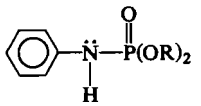
Received March 14, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

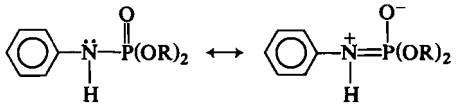
G. W. BUCHANAN, F. G. MORIN, and R. R. FRASER. Can. J. Chem. **58**, 2442 (1980).



^{15}N nuclear magnetic resonance chemical shifts and one-bond ^{15}N—^{31}P couplings are reported for a series of five *N*-arylphosphoramidates and four *N*-arylphosphorimidates. Results are interpreted in terms of an extensively delocalized N lone pair in the phosphoramidates, with p_π–p_π donation into the aromatic ring being dominant over p_π–d_π donation from nitrogen to phosphorus.

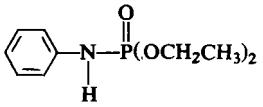
G. W. BUCHANAN, F. G. MORIN et R. R. FRASER. Can. J. Chem. **58**, 2442 (1980).

On rapporte les ^{15}N rmn déplacements chimiques et les constantes de couplage entre ^{15}N et ^{31}P à travers une liaison pour cinq *N*-arylphosphoramidates et quatre *N*-arylphosphorimidates. Pour les phosphoramidates, on dit que la paire d'électrons sur l'azote est extrêmement délocalisée, et que la donation p_π–p_π vers le cycle de benzol est plus importante que la donation p_π–d_π de l'azote au phosphore.



Introduction

Recently there has been considerable interest in the substituent effects of phosphorus-containing groups in electrophilic aromatic substitution reactions (1). In the case of a phosphorylated aniline (below), the phosphorus substituent can alter the behavior of the nitrogen lone pair and thereby



influence the site of electrophilic attack. Theoretically, there can be a competition between two opposing effects. The first is resonance p_π–p_π donation of the N lone pair to the adjacent aromatic ring, a well-recognized phenomenon in organic chemistry (2), which would lead to an increase in the electron densities (relative to benzene) at the *ortho* and *para* positions, and to *ortho–para* directing effects.

The competing phenomenon is p_π–d_π back donation from the N lone pair to a vacant 3*d* orbital of phosphorus, which would, if present, result in little discrimination between *o*, *m*, and *p* sites in electrophilic aromatic substitution reactions, i.e.:

Recently, ^{13}C nmr results (3), based on a dual substituent parameter approach (4), have been interpreted in terms of a dominance of N lone pair delocalization into the aromatic ring for the phosphorylated aniline shown below (R = CH_2CH_3).

By contrast, this substituted benzene was found to give *very low* discrimination between *o*, *m*, and *p* sites in electrophilic aromatic nitration (1), a result interpretable either in terms of strong involvement of the N lone pair in p_π–d_π back donation to phosphorus, or to reaction of the conjugate acid only.

In view of the uncertain nature of these results, we were motivated to examine some phosphorylated anilines by a technique which might provide direct information re: the nature of N—P bonding. ^{15}N nuclear magnetic resonance could present such an alternative, as it has been demonstrated (5) that both ^{15}N—^{31}P one bond couplings and ^{15}N shieldings are sensitive probes for structure and bonding in heterocyclic phosphoramidates.

Results and Discussion

The structures and numbering scheme for the compounds examined (**1–9**), are shown in Fig. 1, while Table 1 contains the ^{15}N—^{31}P couplings and ^{15}N chemical shifts. For both the phosphoramidate series and phosphorimidate series, the *p*-NO_2 derivatives were also synthesized (X = Y = H; Z = NO_2), but low solubilities precluded spectral determination.

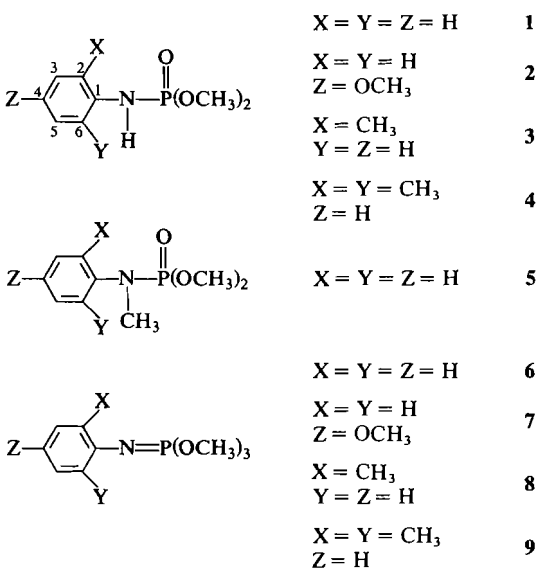

FIG. 1. Structures and numbering scheme.

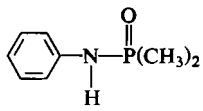
TABLE 1. One bond $^{15}N—^{31}P$ couplings[a] and ^{15}N chemical shifts

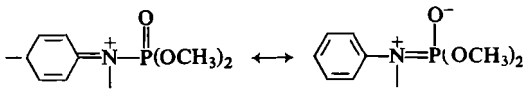
Compound	$^1J_{NP}$ (Hz) ± 0.2	δ_N (ppm from NH_3) ± 0.1
1	42.6[b]	71.0
2	42.9[b]	63.8
3	44.3[b]	64.6
4	43.2[b]	56.0
5	42.8[c]	57.1
6	42.5[c]	71.3
7	42.6[c]	66.6
8	42.9[c]	66.9
9	44.1[c]	57.1



[a]Signs likely negative.
[b]For ca. 1.5 *M* solutions in $CDCl_3$.
[c]For ca. 1.5 *M* solutions in 3:1 ϕNH_2–$CHCl_3$.

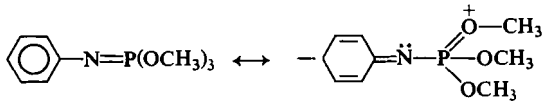
One Bond Couplings

Although we have not determined them experimentally, the signs of the $^{15}N—^{31}P$ couplings in all these materials are almost assuredly negative (6). Several mechanisms may contribute to the coupling, but it has been demonstrated by a finite perturbation method (6), that the Fermi contact contribution can account for the observed coupling of −26.9 Hz in $[(CH_3)_2N]_3PO$.



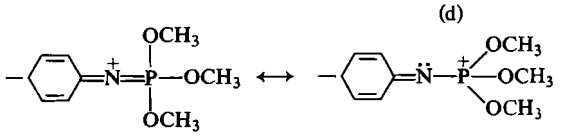
Via a series of double irradiation experiments (7), the sign of $^1J_{PN}$ in the phosphinamide below has been determined to be negative, the value being −0.5 Hz. If the Fermi contact mechanism dominates, then increasingly electronegative substituents bonded to N or P should make $^1J_{PN}$ more negative (6). Thus, the value of −42.6 Hz for **1** is, at least qualitatively, reasonable.

When purely trigonal planar geometry at N was



used in the Fermi contact calculations (6) for $[(CH_3)_2N]_3PO$, the calculated $^1J_{NP}$ was −39 Hz i.e. remarkably close to values for **1–9**. Furthermore, it has been found (5) for heterocyclic phosphoramidates, that $^1J_{PN}$ is -40.0 ± 2.5 Hz for compounds having sp^2 hybridized N atoms (8). In compounds with lower *s* character (i.e. sp^3 N), the value for $^1J_{NP}$ is ca. −10 Hz, again consistent with the Fermi contact formalism.

Accordingly, we interpret the ^1J results for **1–5** in terms of predominantly sp^2 hybridized N, but based on these data alone, we cannot distinguish between the relative contributions from the two resonance forms presented below.



(a) (b)

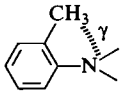
For the phosphorimidates **6–9**, the $^1J_{PN}$ data again suggest sp^2 hybridized N, but one cannot, using ^1J data, evaluate the importance of contributions from resonance forms (c), (d), and (e) as shown below.

(d)

(c) (e)

Chemical Shifts of ^{15}N

Recently, it has been demonstrated (9) that ^{15}N nmr chemical shifts can be used to monitor steric inhibition to N lone pair delocalization into the aromatic ring of substituted anilines. Thus, assessment of the relative importance of resonance forms (a) and (b) above in the phosphoramidates should be possible using chemical shift trends.



Both steric and electronic effects have been examined. The *para* —OCH_3 in **2** causes an upfield shift of 7.2 ppm vs. **1**, and the same trend is apparent in **7** vs. **6**. The magnitudes of these shifts are similar to those in substituted anilines (10).

Very substantial γ steric shifts are evident as well. Comparing data for **1** and **3**, replacement of one *ortho* H by a CH_3 produces an upfield shift of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

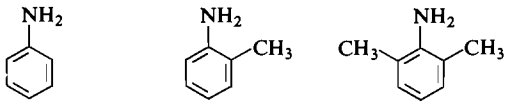
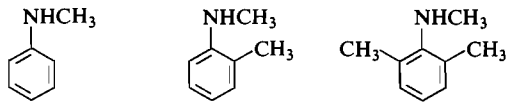
6.4 ppm at N. Such an effect can be attributed to the γ steric interaction depicted below



For secondary alkylamines (11), regression analysis of ^{15}N chemical shifts led to a value of −2.1 ppm for each γ interaction. In the present series of compounds, however, the γ shifts are considerably larger, since in **4**, containing two *ortho* CH_3 groups, the second CH_3 induces an additional shielding at N of 8.6 ppm.

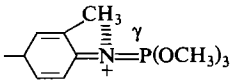
The present findings can be compared to those for the *N*,*N*-dimethylanilines (9) shown below, where successive *ortho* methylations produce 10.7 and 16.8 ppm upfield shifts at N, respectively.



$\delta_N = 44.6$ $\delta_N = 33.9$ $\delta_N = 17.1$

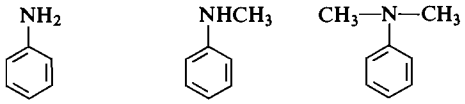
In the *ortho*-alkylated materials, it was suggested that steric inhibition to N lone pair delocalization into the aromatic ring was the major cause of the upfield shielding effects at ^{15}N, and photoelectron spectral data are corroborative (12). For aniline itself, *ortho*-methylation produces much smaller γ effects at N (13).

$\delta_N = 56.5$ $\delta_N = 54.2$ $\delta_N = 51.0$



Unfortunately studies on the intermediate case, i.e. the N-methyl anilines, which would represent the closest analogy to the phosphoramidates **3** and **4** were not available. We have therefore measured the ^{15}N shifts for *N*-methylaniline, 2-methyl-*N*-methylaniline, and 2,6-dimethyl-*N*-methylaniline and the results are shown below.

$\delta_N = 54.0$ $\delta_N = 51.8$ $\delta_N = 41.5$



The first *ortho* group causes a minor shielding (2.2 ppm), whereas the second methyl induces a further shielding of 10.3 ppm. It appears then that the second *ortho* methyl generally has a larger influence on the ^{15}N shift than does the first in both the *N*-methyl aniline series and series **1**, **3**, **4**.

For the phosphorimidates **8** and **9**, one cannot invoke steric inhibition of resonance arguments to rationalize the upfield ^{15}N shifts on successive *ortho*-methylation. Clearly, contributions from resonance forms such as those depicted below are not subject to steric interference of N lone pair delocalization.

Thus, one can regard the upfield shifts in **8** and **9** vs. **6** as manifestations of normal γ effects, as depicted above. The ^{13}C shifts for carbons *para* to N in **6**, **8**, and **9** are nearly identical, in agreement with this argument (15), the values being 119.9, 120.0, and 120.2 ppm respectively.

In the case of the *N*-methyl phosphoramidate **5**, the ^{15}N resonance is shifted *upfield* by 13.9 ppm relative to **1**. By definition, this is termed an "α" effect, and can be contrasted with results for primary alkylamines (14), in which introduction of an "α" CH_3 group leads to an average *deshielding* at N of 8.7 ppm. There is, however, precedent for upfield α-methylation effects in aromatic amines, as is depicted below (13).

$\delta_N = 56.5$ $\delta_N = 52.8$ $\delta_N = 44.6$

A rationale for the aromatic amine results was recently put forward (9), involving reduced N lone pair delocalization into the aromatic ring as the N becomes more progressively alkylated. It was calculated (9), that the C(1)—N torsional angle remains unchanged as a result of N-methylation, and that the upfield α-methylation shift results from a change in the N lone pair energy relative to the benzene orbital energies.

The ^{13}C data (15) for phosphoramidates **4** and **5** vs. **1**, show substantially deshielded C-4 resonances (3–4 ppm) in the *ortho*-alkylated molecules vs. the non-hindered compound **7**, indicative of steric inhibition to N lone pair donation caused by *ortho* methylation.

Thus, we can conclude that N lone pair delocalization into the aromatic ring *is* an important process in phosphoramidates such as **1**, and accordingly the large amount of *meta* nitration product observed (1) is not likely to result from p_π–d_π back donation from N to P. Rather it is an indication that the reaction may proceed via the conjugate acid as originally suggested by Modro and Pioch (1).

Solvent Effects

Several practical problems arose during this work with respect to low ^{15}N signal intensity.[1] It is well known (16) that on irradiation of protons, the negative magnetogyric ratio for ^{15}N leads to a theoretical maximum of -3.93 for the nuclear Overhauser enhancement factor in the case of purely dipole–dipole H—^{15}N relaxation. Contributions from other mechanisms, however, can produce essentially zero ^{15}N signal intensity (16), and such mechanisms can be operative in compounds **5–9** in which there are no directly bonded H's on N to facilitate dipole–dipole relaxation. One method which we have used previously (5) to overcome this problem is the addition of $Cr(acac)_3$, but no beneficial effect of this reagent was observed for **5–9**.

Considerable success was obtained, however, by use of a 3:1 volume:volume mixture of aniline–$CHCl_3$ in place of $CDCl_3$ as solvent. In the case of **6** for example, a tenfold increase in the signal to noise ratio was observed in the ^1H decoupled spectrum. Furthermore no measurable solvent induced shifts or ^1J changes were noted between these two media. Several factors may be operative to increase the signal to noise ratio. Addition of aniline may increase the solution viscosity and thus lower the T_1. Additional protons in the medium will, on solute–solvent encounter, contribute to dipole–dipole relaxation of the ^{15}N nucleus, leading to a shortened T_1. Also, as the protons are decoupled, an *intermolecular* nuclear Overhauser effect resulting from the dipole–dipole relaxation can occur.

One could in principle test for the relative contributions of each effect noted above by measuring the viscosities, the ^{15}N T_1's and the nOe, but due to the lengthy time required for such experiments, they have not been carried out.

Experimental

Materials

Phosphoramidates **1**, **2**, and **3** were prepared by the following procedure. To a stirred solution of the corresponding aromatic amine (0.01 mol), triethylamine (0.01 mol), and CCl_4 (0.02 mol) in ether (20 mL) at 0°C, was added dropwise dimethyl phosphite (0.01 mol). The reaction mixture was stirred at room temperature overnight, solids removed by filtration, and the residue was evaporated to dryness. Recrystallization from the indicated solvent gave phosphoramidates in yields between 50–60%.

Compound **1**, recrystallized from hexane, mp 88–89°C (lit. (18) mp 88°C). Compound **2**, recrystallized from ethyl acetate and then hexane, mp 72.5–73.0°C (lit. (19) mp 109–110°C); ^1H nmr δ: 3.8 (d, J_{HP} = 12 Hz, CH_3O—P, 6H), 3.75 (s, CH_3—O—Ar, 3H), 7.0 (q, aromatic 4H), 7.3 (bs, —NH, 1H). Compound **3**, recrystallized from cyclohexane, mp 110–112°C (lit. (19) mp 110°C).

Phosphorimidates **6–9** were synthesized by reaction of the corresponding aromatic azide (20) with trimethyl phosphite. A typical procedure follows. In a 3-necked round bottom flask equipped with reflux condenser, stopper, and dropping funnel, was placed a stirring bar and trimethyl phosphite (0.022 mol) in ether (20 mL). The aromatic azide (0.02 mol) in ether (15 mL) was added dropwise with stirring. Stirring was continued overnight and then the solvent removed on a rotary evaporator. Only **6** could be distilled without rearrangement to *N*-methylphosphoramidates, however, **7**, **8**, and **9** showed expected ^1H and ^{13}C spectra after brief heating at < 50°C under vacuum to remove excess starting material.

Compound **6**, n_D^{20} = 1.5232 (lit. (18) n_D^{20} = 1.5232); compound **7**, n_D^{20} = 1.5281 (lit. (21) n_D^{20} = 1.5275); compound **8**, mp 40–41°C (lit. (19) bp 93–97°C/0.05 Torr); compound **9**, mp 36–36.5°C. *Anal.* calcd.: % C 54.32, H 7.45, N 5.76, P 12.73; found: % C 54.07, H 7.52, N 5.82, P 12.75.

The *N*-methyl compound **5** was prepared from **6** by heating in a pressure flask to 70°C in the presence of 1.0 equivalents of CH_3I (21). The product was purified by bulb to bulb distillation and gave a ^1H nmr spectrum consistent with its structure (21) i.e. δ: 3.2 (d, J_{HP} = 9.0 Hz, CH_3N, 3H), 3.8 (d, J_{HP} = 12.0 Hz, CH_3OP, 6H), 7.1–7.4 (m, 5H, aromatic).

Phosphoramidate **4** was prepared from phosphorimidate **9** as follows. Compound **9** (1.0 g) was adsorbed on a column of silica gel (30.0 g) in diethyl ether, and drawn onto the column. After standing for 24 h, the product was eluted with ether in 92% yield. Subsequent recrystallization from ethyl acetate–hexane gave **4**, mp 128–129°C; ^1H nmr δ: 2.4 (s, CH_3—, 6H), 3.8 (d, J_{HP} = 11.0 Hz, CH_3OP, 6H), 4.7 (bs, N—H, 1H), 7.0 (s, 3H, aromatic). *Anal.* calcd. for **4**: % C 52.40, H 7.04, N 6.11, P 13.51; found: % C 52.36, H 7.15, N 6.21, P 13.39.

N-Methyl-*o*-toluidine and *N*-methyl-2,6-dimethylaniline were prepared as described previously (22).

Spectra

The ^{15}N spectra were recorded with a Varian FT-80 nmr system at a frequency of 8.0603 MHz, using 10 mm sample tubes. Except as noted below all ^{15}N spectra were run using the deuterium of the solvent $CDCl_3$ for locking. In the cases of **5–9**, a coaxial D_2O capillary was used as a lock. The ^{15}N chemical shifts were measured relative to neat ^{15}N enriched aniline, and converted to the scale of δ_{NH_3} = 0 (17) using the conversion factor of 56.5 ppm for aniline → anhydrous ammonia (11).

Typical experimental conditions were: pulse width 30° to 50°; acquisition time 8 s; number of data points, 8000, sw = 500 Hz; and the number of transients ranged from 4000 to 20 000; ^{15}N enriched samples of **1** and **6** were used to optimize the instrument parameter settings.

[1]The practical problems in obtaining natural abundance ^{15}N spectra have been recently summarized (17).

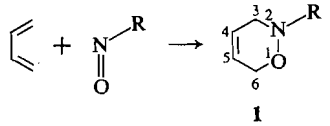
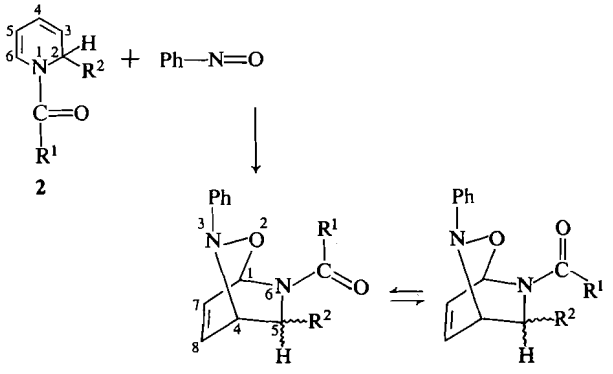
EDWARD E. KNAUS, KAMLAKAR AVASTHI, and C. S. GIAM. Can. J. Chem. **58**, 2447 (1980).

The regiospecific ($\pi 2 + \pi 4$) cycloaddition reaction of *N*-carbonyl-1,2-dihydropyridines **2** with nitrosobenzene afford a mixture of 3-phenyl-2-oxa-3,6-diazabicyclo[2.2.2]oct-7-ene rotamers **3** and **4**. Rotamers **3** and **4**, which differ in configuration at the carbonyl to nitrogen (amide) bond, exhibit dual resonances for C(1)H, C(5)H, and the N(6) acetyl (methoxycarbonyl) substituents. An ^{1}H nmr temperature study indicated that rotamers **3***a* and **4***a* coalesce at about 100°C.



EDWARD E. KNAUS, KAMLAKAR AVASTHI et C. S. GIAM. Can. J. Chem. **58**, 2447 (1980).

La réaction de cycloaddition régiospécifique ($\pi 2 + \pi 4$) des *N*-carbonyldihydro-1,2 pyridines **2** avec le nitrosobenzène donne un mélange des rotamères **3** et **4** du phényl-3 oxa-2 diazo-3,6 bicyclo[2.2.2] octène-7. Les rotamères **3** et **4** dont la configuration diffère au niveau de la liaison carbonyle–azote (amide) montrent des doubles résonances pour C(1)H, C(5)H et pour les substituants sur le N(6) acétyle (méthoxycarbonyle). Une étude de rmn du ^{1}H en fonction de la température indique que les rotamères **3***a* et **4***a* se confondent aux environs de 100°C.



[Traduit par le journal]

The Diels–Alder reaction of dienamines with dienophiles is an attractive method for the synthesis of pharmacologically interesting bicyclic heterocycles (1). Several studies have shown that various *C*-nitroso compounds react readily with conjugated dienes to yield 3,6-dihydro-1,2-oxazines **1** (2, 3). It was therefore of interest to develop methods for the preparation of bicyclic heterocycles in which a 1,2-oxazine is fused to a tetrahydropyridine ring. The regiospecific ($\pi 2 + \pi 4$) cycloaddition reaction of *N*-substituted-1,2-dihydropyridines **2** with nitrosobenzene now provides a convenient route to exchanging 3-phenyl-2-oxa-3,6-diazabicyclo[2.2.2]oct-7-ene rotamers **3** and **4**.

Reaction of *N*-acetyl-2-phenyl-1,2-dihydropyridine **2***a* with nitrosobenzene proceeded smoothly in methylene chloride at 25°C under a nitrogen atmosphere with disappearance of the green color to afford a mixture of rotamers **3***a* and **4***a* (82.6%) which differ in configuration at the carbonyl to nitrogen (amide) bond. The ^{1}H nmr spectrum ($CDCl_3$, 25°C) exhibited dual absorptions at δ 6.06 and 6.87, 5.47 and 5.28, and 2.28 and 1.78 due to the C(1)H, C(5)H, and N(6)COMe groups of **3***a* and **4***a* respectively in a ratio of 18:82 as determined by integration. Double irradiation studies provide further evidence for the presence of the two rotational conformers **3***a* and **4***a*, which arise as a result of hindered internal rotation, since irradiation at 1.78 and 5.28 δ respectively results in saturation of the corresponding absorptions at 2.28 and 5.47 δ. An ^{1}H nmr temperature study effected on the 50:50

mixture of rotamers **3***a* and **4***a* in DMSO-d_6 indicated the coalescence temperature to be approximately 100°C where the N(6)COMe group appears as a sharp singlet at 2.15 δ. Upon cooling to 25°C the ratio of **3***a*:**4***a* returned to 50:50. The difference in the ratio of **3***a*:**4***a* in $CDCl_3$ (18:82) in comparison to DMSO-d_6 (50:50) is clearly a solvent effect. Dual absorptions for the —NCOMe group and protons on carbon adjacent to it have been observed in the ^{1}H nmr spectra of methyl 4-acetamido-4-deoxy-L-erythrofuranoside (4) and *N*-acetylimidazole (5). Protons adjacent to and in the nodal plane of the imide carbonyl group of *N*-acetylimidazole in a nonpolar solvent are shifted downfield as a result of the anisotropy of the acyl group (5) indicating that configurationally dependent changes in the chemical shifts of C(1)H and C(5)H are associated with their proximity to the acyl oxygen. On this basis it is expected that the C(1)H of **3***a* (6.06 δ) would appear at higher field than the C(1)H of **4***a* (6.87 δ) and the C(5)H of **3***a* (5.47 δ) would be deshielded relative to the C(5)H of **4***a* (5.28 δ). Similar shielding and deshielding effects were also observed for C(1)H and C(5)H for other compounds prepared as illustrated in Table 1.

Hart *et al.* (2) recently reported that nitrosobenzene adds regiospecifically to cyclohexadienones with the oxygen of the nitroso group being orientated toward the carbonyl group in the adduct. The regiospecificity of the cycloaddition reaction was rationalized using approximate frontal orbital theory. The most important interactions are between the HOMO of the dienone and the LUMO of nitrosobenzene. Coefficients are expected to be largest for these orbitals at C-3 of the *N*-substituted-1,2-dihydropyridine **2** and on the nitrogen of the nitroso group (2) leading to the formation of a C(3)N and C(6)O bond in the cycloaddition products.

The ^{1}H nmr spectra were also consistent with the assignment of the N—O orientation observed for the cycloadducts **3** and **4**. The coupling pattern observed for the mixtures of rotamers **3***a* and **4***a* in $CDCl_3$ fixed the low field bridgehead protons due to C(1)H adjacent to oxygen at 6.06 and 6.87 δ respectively and the high field bridgehead protons due to C(4)H adjacent to nitrogen at 4.6 δ. Kresze and Firl (6) have shown that the proton adjacent to oxygen, in adducts obtained from reaction of *p*-chloronitrosobenzene and a variety of 1,3-dienes, appears at lower field than that adjacent to nitrogen. The orientation of the N—O cycloaddition is therefore expected to be as illustrated for **3***a* and **4***a*.

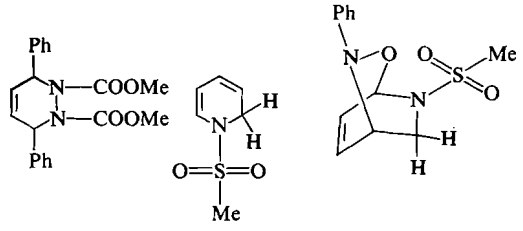
The stereochemistry of the C-5 substituent (R^2) present in **3** and **4** has not been established. Examination of a Dreiding Model indicates that the dihedral angle for a C(4)H—C(5)H *exo–endo* interaction is very similar to that for an *exo–exo* interaction. The ^{1}H nmr spectrum of rotamers **3***c* and **4***c* support this observation since $J_{4,5}$ *exo* and $J_{4,5}$ *endo* are both 3.25 Hz. However, the large difference in the chemical shifts for the acetyl methyl groups of **3***a* and **4***a* (0.5 δ), relative to the difference in **3***b* and **4***b* (0.06 δ) indicates that the C(6) phenyl substituent does exhibit a significant shielding effect. The much larger chemical shift difference for the C(1)H (0.81 δ) compared with the C(5)H for the two rotamers **3***a* and **3***b* would suggest the R^2 substituent is in the *exo* position.

Reaction of *N*-acetyl-2-butyl-1,2-dihydropyridine **2***b* with nitrosobenzene afforded a mixture of 3-phenyl-5-butyl-6-acetyl-2-oxa-3,6-diazabicyclo[2.2.2]oct-7-ene rotamers **3***b* and **4***b* (51.8%). ^{1}H nuclear magnetic resonance spectrometry indicated that the ratio of **3***b*:**4***b* in deuterochloroform was 69:31. It is not clear why the ratio of **3***b*:**4***b* is so different from that of compounds *a*, *c*, *d*, and *e* (see Table 1). Similar reactions of nitrosobenzene with *N*-methoxycarbonyl-1,2-dihydropyridine **2***c*, *N*-methoxycarbonyl-2-butyl-1,2-dihydropyridine **2***d*, and *N*-methoxycarbonyl-2-phenyl-1,2-dihydropyridine **2***e* gave rise to mixtures of rotamers **3***c* and **4***c* (67.1%), **3***d* and **4***d* (51.8%), and **3***e* and **4***e* (75.9%) in ratios of 41:59, 29:71, and 11:89 respectively (see Table 1). It is not surprising that the products obtained in the latter reactions consist of a mixture of rotamers **3** and **4** since hindered internal rotation about the nitrogen to carbonyl bond has been observed in

N—COOMe systems such as 1,2-dimethoxycarbonyl-3,6-diphenyl-1,2,3,6-tetra-hydropyridazine **5** (7).

Adducts **3** and **4** having a N(6)COOMe substituent were less stable than those having a N(6)COMe or N(6)SO_2Me substituent. N(6)methoxycarbonyl adducts **3***e* and **4***e* having a C(5)Ph substituent were more stable than **3***c* and **4***c* having a C(5)*n*-Bu substituent which undergoes dissociation quite readily. The mass spectra for all adducts **3** and **4** did not exhibit molecular ions.

It was also of interest to examine a reaction which would give rise to a product in which hindered internal rotation about N(6) of the 2-oxa-3,6-diazabicyclo[2.2.2] oct-7-ene ring system was not possible. Reaction of *N*-methanesulfonyl-1,2-dihydropyridine **6** with nitrosobenzene afforded the N(6)SO_2Me product **7** which exhibited single absorptions for all nonequivalent protons.



The reaction of 1,2-dihydropyridines with other

[a]Spectra were obtained in $CDCl_3$ at 25°C, chemical shifts are in δ units relative to tetramethylsilane, *J* are in Hertz, and all peaks had integrated areas appropriate to the structures. Double resonance experiments were used to confirm assignments and coupling constants *J*.
[b]The numbering system used is that shown for structures **3** and **4**.
[c]These chemical shifts were the same for both rotamers **3** and **4**.
[d]None of the compounds examined exhibited chemical shift nonequivalence for C(4)H. These peaks were d($J_{4,8}$ = 5.75 Hz) of d($J_{4,5}$ = 3.25 Hz) of d($J_{4,7}$ = 2 Hz).
[e]These peaks were d($J_{7,8}$ = 8 Hz) of d($J_{1,7}$ = 5.5 Hz) of d($J_{4,7}$ = 2 Hz).
[f]These peaks were d($J_{7,8}$ = 8 Hz) of d($J_{4,8}$ = 5.75 Hz) of d($J_{1,8}$ = 1.75 Hz).
[g]These peaks were d($J_{1,7}$ = 5.5 Hz) of d($J_{1,8}$ = 1.75 Hz).
[h]These peaks were d($J_{4,5}$ = 3.25 Hz).
[i]The ratio of rotamers as determined from integrals of C(1)H, C(5)H, and the R^2 substituent.
[j]The coupling constants *J*, for similar spin–spin interactions, were virtually identical for **3** and **4**.
[k]These peaks were t($J_{5,-CH_2}$ = 7 Hz) of d($J_{4,5}$ = 3.25 Hz).
[l]These peaks appeared as two closely overlapping d($J_{5,5}$ = 10 Hz) of d($J_{4,5}$ = 3.25 Hz).
[m]These peaks were d($J_{5,5}$ = 10 Hz) of d($J_{4,5}$ = 3.25 Hz).

electrophilic *C*-nitroso compounds (3) such as nitrosylcyanide, trifluoronitrosomethane, and nitrosocarbonyl compounds will be investigated to broaden the scope of this reaction.

Experimental

Melting points were determined with a Büchi capillary apparatus and are uncorrected. Infrared spectra (potassium bromide unless otherwise noted) were taken on a Perkin-Elmer 267 or Unicam SP 1000 spectrometer. Nuclear magnetic resonance spectra were determined for solutions in deuterochloroform or deuterodimethylsulfoxide with a Bruker WH-200 or WH-400 spectrometer. Double resonance studies were used to confirm assignments. *N*-Substituted-1,2-dihydropyridines **2***a–e* and **6** were prepared using published procedures (8–10).

*3,5-Diphenyl-6-acetyl-2-oxa-3,6-diazabicyclo[2.2.2]oct-7-ene Rotamers (***3**a *and* **4**a*)*

A solution of *N*-acetyl-2-phenyl-1,2-dihydropyridine **2***a* (3.15 g, 15.8 mmol) in 5 mL dry methylene chloride was added with stirring to a solution of nitrosobenzene (1.75 g, 16.3 mmol) in 30 mL dry methylene chloride, under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 90 min during which the green color disappeared completely. Removal of the solvent *in vacuo* below 30°C gave a solid which was triturated with 75 mL *n*-hexane. The insoluble product was filtered, washed with 25 mL *n*-hexane, and recrystallized from acetone to yield a mixture of rotamers **3***a* and **4***a* (4.0 g, 82.6%) as white needles, mp 131–132°C (dec.); ir: 1665 (s, CO) cm^{-1}. *Anal.* calcd. for $C_{19}H_{18}N_2O_2$: C 74.48, H 5.93, N 9.15; found: C 74.38, H 5.88, N 9.08.

*3-Phenyl-5-*n*-butyl-6-acetyl-2-oxa-3,6-diazabicyclo[2.2.2.]-oct-7-ene Rotamers (***3**b *and* **4**b*)*

N-Acetyl-2-*n*-butyl-1,2-dihydropyridine (1.86 g, 10.38 mmol) was added with stirring to a solution of nitrosobenzene (1.1 g, 10.2 mmol) under a nitrogen atmosphere at 25°C and the reaction was allowed to proceed for 3 h. Removal of the solvent *in vacuo* at 25°C gave a solid residue which was purified using a neutral alumina oxide (75 g) column. Elution with 200 mL ether gave a viscous liquid which crystallized from 12 mL benzene–hexane (4:1 v/v) to afford 1.217 g of **3***b* and **4***b*. Concentration of the mother liquor gave a second crop of crystals (0.321 g) for a combined yield of 51.8%, mp 83–86°C (dec.); ir: 1655 (s, CO) cm^{-1}. *Anal.* calcd. for $C_{17}H_{22}N_2O_2$: C 71.28, H 7.75, N 9.79; found: C 71.22, H 7.86, N 9.79.

*3-Phenyl-6-methoxycarbonyl-2-oxa-3,6-diazabicyclo[2.2.2]-oct-7-ene Rotamers (***3**c *and* **4**c*)*

N-Methoxycarbonyl-1,2-dihydropyridine **2***c* (1.39 g, 10 mmol) was added with stirring to a solution of nitrosobenzene (1.07 g, 10 mmol) in 30 mL dry methylene chloride under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 3 h during which the green color disappeared. Removal of the solvent *in vacuo* at 25°C gave a dark colored residue which on recrystallization from benzene–hexane (5:1 v/v) gave rotamers **3***c* and **4***c* as a pale yellow solid (1.65 g, 67.1%), mp 86°C (dec.); ir: 1720 (s, CO) cm^{-1}. *Anal.* calcd. for $C_{13}H_{14}N_2O_3$: C 63.39, H 5.73, N 11.38; found: C 62.88, H 5.49, N 11.50. A solid sample of **3***c* and **4***c* decomposed slowly on standing at 25°C over a period of a few days while ^1H nmr spectrometry indicated some dissociation in $CDCl_3$ after 1 h.

*3-Phenyl-5-*n*-butyl-6-methoxycarbonyl-2-oxa-3,6-diazabicyclo-[2.2.2]oct-7-ene Rotamers (***3**d *and* **4**d*)*

A solution of *N*-methoxycarbonyl-2-*n*-butyl-1,2-dihydropyridine **2***d* (0.918 g, 4.7 mmol) in 5 mL dry methylene chloride was added to a solution of nitrosobenzene (0.504 g, 4.7 mmol) in 30 mL dry methylene chloride with stirring under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 16 h after which the solvent was removed *in vacuo* at 25°C. The dark residue was purified by elution from a neutral alumina oxide column (30 g) using first 50 mL hexane and then 200 mL benzene. Removal of the solvent from the benzene eluate afforded **3***d* and **4***d* as an oil (0.582 g, 41.6%); ir (film): 1720 (s, CO) cm^{-1}. Repeated attempts to obtain a satisfactory elemental analysis were not successful.

*3,5-Diphenyl-6-methoxycarbonyl-2-oxa-3,6-diazabicyclo-[2.2.2]oct-7-ene Rotamers (***3**e *and* **4**e*)*

A solution of *N*-methoxycarbonyl-2-phenyl-1,2-dihydropyridine **2***e* (2.86 g, 13.3 mmol) in 5 mL dry methylene chloride was added with stirring to a solution of nitrosobenzene (1.43 g, 13.3 mmol) in 30 mL dry methylene chloride under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 3 h prior to removal of the solvent *in vacuo* below 30°C. The sticky semi-solid obtained was triturated with 100 mL hexane leaving a light green solid which was washed with 30 mL hexane to give **3***e* and **4***e* (3.26 g, 75.9%) as a crystalline light green solid, mp 129–131°C; ir: 1710 (s, CO) cm^{-1}. *Anal.* calcd. for $C_{19}H_{18}N_2O_3$: C 70.78, H 5.63, N 8.69; found: C 71.39, H 5.75, N 8.29.

*3-Phenyl-6-methanesulfonyl-2-oxa-3,6- diazabicyclo[2.2.2]-oct-7-ene (***7**)*

N-Methanesulfonyl-1,2-dihydropyridine **6** (1.9 g, 11.9 mmol) was added with stirring to a solution of nitrosobenzene (1.41 g, 13.1 mmol) in 30 mL dry methylene chloride under a nitrogen atmosphere at 25°C. The reaction was allowed to proceed for 3 h and the solvent was removed *in vacuo* below 30°C. The semi-solid residue obtained was triturated with hexane and then benzene. The insoluble residue was recrystallized from methylene chloride – hexane to afford **7** (1.63 g, 51.2%) as a white crystalline solid, mp 134–135°C (dec.); ir: 1155, 1340 (s, SO_2) cm^{-1}; ^1H nmr (DMSO-d_6) δ: 3.08 (s, 3H, SO_2Me), 3.2 (d, $J_{5,5}$ = 10.5 Hz of d, $J_{4,5}$ = 3.0 Hz, 1H, H-5*exo*), 3.82 (d, $J_{5,5}$ = 10.5 Hz of d, $J_{4,5}$ = 3.0 Hz, 1H, H-5*endo*), 4.96 (d, $J_{4,8}$ = 5.75 Hz of t, $J_{4,5}$ = 3.0 Hz of d, $J_{4,7}$ = 2.0 Hz, 1H, H-4), 5.86 (d, $J_{1,7}$ = 5.5 Hz of d, $J_{1,8}$ = 1.75 Hz, 1H, H-1), 6.24 (d, $J_{7,8}$ = 8.0 Hz of d, $J_{4,8}$ = 5.75 Hz of d, $J_{1,8}$ = 1.75 Hz, 1H, H-8), 6.76 (d, $J_{7,8}$ = 8.0 Hz of d, $J_{1,7}$ = 5.5 Hz of d, $J_{4,7}$ = 2.0 Hz, 1H, H-7), 6.92–7.08, 7.22–7.28 (m, 5H, Ph). *Anal.* calcd. for $C_{12}H_{14}N_2O_3S$: C 54.12, H 5.30, N 10.53, S 12.02; found: C 53.89, H 5.43, N 10.74, S 11.79.

Conformational preferences about both exocyclic carbon–carbon bonds in some phenyl derivatives of ethane, propene, and 4-picoline

TED SCHAEFER, LEONARD J. KRUCZYNSKI, BERT KRAWCHUK, RUDY SEBASTIAN, JAMES L. CHARLTON, AND DAVID M. MCKINNON

Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received January 18, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

TED SCHAEFER, LEONARD J. KRUCZYNSKI, BERT KRAWCHUK, RUDY SEBASTIAN, JAMES L. CHARLTON, and DAVID M. MCKINNON. Can. J. Chem. **58**, 2452 (1980).

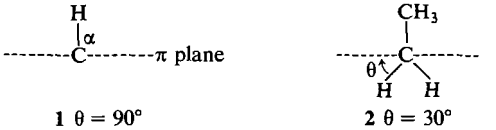
The ^1H nmr spectra in solution of 1-*R*-(3,5-dibromophenyl) ethanes (R = CH_3, C_2H_5, *n*-C_3H_7 to *n*-C_6H_{13}, OH, F, Br), of 1-amino-2-(3,5-dichlorophenyl) ethane, of 3,5-dichloroallylbenzene, and of 4-(3,5-dibromobenzyl) pyridine are analyzed at 305 K. For the ethane derivatives, the populations of *anti* and *gauche* conformers are derived from the vicinal proton–proton coupling constants. The conformation about the C_1—C_α bond in both *gauche* and *anti* forms is discussed in terms of long-range couplings to the ring protons and some approximate barriers about this bond are suggested for both conformers. Greater rigidity exists in the *gauche* than in the *anti* conformations. In some cases the measurements are compared with extensive molecular orbital calculations, for example, for phenethylamine. The low-energy conformations and the barriers about the C_1—C_α bond are deduced for the allyl and pyridyl compounds.

TED SCHAEFER, LEONARD J. KRUCZYNSKI, BERT KRAWCHUK, RUDY SEBASTIAN, JAMES L. CHARLTON et DAVID M. MCKINNON. Can. J. Chem. **58**, 2452 (1980).

Opérant à 305 K, on a analysé les spectres rmn du ^1H de solutions des *R*-1 (dibromo-3,5 phényl) éthanes (R = CH_3, C_2H_5, *n*-C_3H_7 à *n*-C_6H_{13}, OH, F, Br), d'amino-1(dichloro-3,5 phényl)-2 éthane, du dichloro-3,5 allylbenzène et de la (dibromo-3,5 benzyl)-4 pyridine. Dans le cas des dérivés de l'éthane, on a évalué les populations des conformères *anti* et *semi-décalée* à partir des constantes de couplage des protons vicinaux. On discute de la conformation autour de la liaison C_1—C_α des deux formes *anti* et *semi-décalée* en fonction des couplages à longue distance avec les protons du cycle et on suggère pour les deux conformères des barrières approximatives pour la rotation autour de cette liaison. Il existe une plus grande rigidité dans la conformation *semi-décalée* par rapport à la forme *anti*. Dans certains cas, on compare les mesures aux longs calculs élaborés d'orbitales moléculaires effectués par exemple pour la phénylamine. On a évalué les conformations de faible énergie et les barrières à la rotation autour de la liaison C_1—C_α pour les composés allyliques et pyridiniques.

[Traduit par le journal]

Introduction



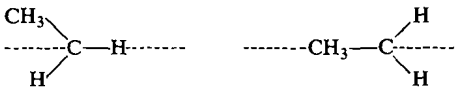
The use of stereospecific vicinal proton–proton coupling constants, $^3J^{H,H}$, in the derivation of *anti* and *gauche* populations of 1,2-disubstituted ethane derivatives is well known (1, 2). If the barrier to interconversion of the *anti* and *gauche* isomers is much larger than thermal energies, a condition reasonably well met by ethane derivatives near room temperature, then the assumption of effectively rigid[1] *gauche* and *anti* isomers in this procedure is reasonable.

On the other hand, in phenylethane derivatives the barrier to rotation about the C_1—C_α bond (sp^2—sp^3 bond) need not be large compared to thermal energies (3). Then the populations of the hindered rotor states, each of the latter corresponding to a different magnitude of a relevant coupling parameter, must be known when assessing conformational preferences. The *J* method (4) has been developed for this purpose and depends on the stereospecificity of the coupling over six bonds, ^6J_p, between an α proton and the ring proton or fluorine nucleus in the *para* position. As recently discussed in some detail (5), one may write

[1] $$^6J_p^{H,CH} = {}^6J_{90}\langle\sin^2\theta\rangle$$

where $^6J_{90}$ is the value of ^6J in **1** and $\langle\sin^2\theta\rangle$, the expected value of $\sin^2\theta$, can be calculated as a function of a presumed twofold barrier to internal rotation, V_2, in terms of a hindered rotor model (6). The experimental tests of this equation suggest strongly that $^6J_0$ ($\theta = 0°$) is negligibly small (5).

In an early experiment (3), the *J* method yielded **2** rather than **3** or **4** as the low-energy conformation about the C_1—C_α bond in 3,5-dibromophenylethane, in accord with a low resolution microwave study of phenylethane (7). In addi-



1 $\theta = 90°$ **2** $\theta = 30°$

[1]A rigorous procedure would consider the populations of torsional states within each conformer, each torsional state corresponding to a different ^3J.

3 4 $\theta = 60°$

tion, the twofold barrier, V_2, was deduced as $1.2_2 \pm 0.08$ kcal/mol (1 cal = 4.184 J), in exact if fortuitous agreement with recent heat capacity data on the parent compound (8).

Unfortunately, the J method becomes relatively insensitive to V_2 above about 3 kcal/mol. Yet ^6J is still a good indicator of the preferred conformation at large V_2 values, the magnitudes of which are then large compared to thermal energies at ambient temperatures.

This paper combines the two procedures to provide an illustration of how a reasonable characterization of the conformations about both C_1—C_α and C_α—C_β bonds in some phenylethane derivatives can be achieved. In addition, conformations about the C_1—C_α bond in allylbenzene and 4-benzylpyridine derivatives are provided. The ^1H nmr measurements occur at 100 MHz, necessitating the use of substituents at the *meta* positions of the phenyl group. The necessity is purely tactical. At 500 MHz the substituents would be superfluous.

Experimental

The alkyl compounds were prepared from the commercial *p*-amino-4-*n*-alkylbenzenes in the obvious way and gave correct mass spectra. The synthesis of the alcohol and of the alkyl halides is as follows. To a solution of *p*-aminophenethyl alcohol (7.3 g, 0.053 mol) in 70 mL of tetrahydrofuran (THF) cooled to 0°C, add 6 mL Br_2 dropwise over 5 min. Add NaOH (2.4 g, 0.06 mol) in 10 mL of H_2O dropwise. During this addition an aqueous phase separates. The mixture is stirred violently for 5 min. If the aqueous phase is now acidic, add a drop of NaOH. Repeat until the aqueous phase remains basic. The phases are separated and the THF is pumped off, yielding maroon crystals of 3,5-dibromo-4-aminophenethyl alcohol. The yield is almost quantitative.

The amino group is removed in the standard way. Replacement of the hydroxyl group by bromine or fluorine proceeds as follows. To a solution of 5.0 g (0.018 mol) of 3,5-dibromophenethyl alcohol in 50 mL of diethyl ether, add 0.0357 mol (3.33 mL) of PBr_3 dropwise, then powdered $NaHCO_3$ (0.1 g at a time) till the mixture is basic to litmus. The ether layer is dried over $MgSO_4$. Evaporation leaves a brown oil; the yield is about 50% of 3,5-dibromophenethyl bromide.

To a solution of 1.71 g (0.0061 mol) of the alcohol in 50 mL of CH_2Cl_2 (dried over 5 Å sieve) cooled to −78°C (CO_2/acetone), add 0.982 g (0.0061 mol) of Et_2NSF_3 (Peninsular Chemicals) dropwise. The reaction is carried out under positive N_2 pressure. Stir for 1 h at room temperature. Add aqueous bicarbonate till basic to litmus. Dry CH_2Cl_2 layer over $MgSO_4$ and evaporate, leaving a brown liquid. The yield is ca. 60%. These compounds are not completely pure but give the correct mass and ^1H nmr spectra.

The 1-amino-2-(3,5-dichlorophenyl) ethane was prepared by reduction of the corresponding benzyl cyanide, whereas 3,5-dichloroallylbenzene came from a Grignard reaction in the standard way. The 4-(3,5-dibromobenzyl) pyridine was prepared from the 4-aminobenzyl precursor.

Solutions of various concentrations (see below) in CS_2 in 5 mm od nmr sample tubes were degassed by the freeze–pump–thaw technique and were flame-sealed. The sample tubes contained small amounts of tetramethylsilane (TMS). The ring ^1H nmr spectra were calibrated at a probe temperature of 305 K on an HA100 spectrometer in the frequency sweep mode. Markers were placed at ca. 5Hz intervals and their frequencies relative to the TMS frequency were determined from the lock and sweep frequencies. Repeating such a procedure four times yielded interpolated peak frequencies whose rms deviations were typically 0.02 Hz or less. The ^1H nmr spectra of the shorter sidechains were also calibrated.

Molecular orbital calculations (9, 10) were performed on an Amdahl 470/V7 system.

Results and Discussion

Spectral Analyses

These were done with the computer program LAME (11, 12) in the usual way. The analyses of the ring proton spectra as AB_2X_2 (X = α CH_2 protons) systems were straightforward. The analysis of the α and β methylene proton spectra as AA′BB′ spin systems proceeded as follows. In all cases the long-range coupling of the *alpha* methylene protons to the three ring protons complicated the procedure. Furthermore, as is well known (13), when the *anti* and *gauche* populations about the C_α—C_β bond are almost equal, only the sum of the two vicinal couplings, $^3J + {}^3J'$, within the AA′BB′ fragment can be extracted reliably. This condition applied to the 1-hydroxy, 1-fluoro, and 1-amino ethane derivatives.

For the 1-bromoethane derivative, although reliable ^2J values could be found, the ^3J and $^3J'$ numbers were strongly correlated (Table 1). In contrast, for the 1-methylethane compound, the ^3J and $^3J'$ numbers were reliable but the ^2J values had a correlation coefficient of unity and are therefore not known individually (high gain spectra did not alleviate these uncertainties).

In Table 1, the spectral parameters are tabulated for 1-bromo-2-(3,5-dibromophenyl) ethane and for 1-methyl-2-(3,5-dibromophenyl) ethane and illustrate the analytical quality. Coupling constants of interest to this paper are given for the other compounds in Table 2. The $^4J^{H,H}$ values indicate the spectral precision. The error in the coupling constants is taken as three times the standard deviation.

Figure 1 displays part of the methyl proton spectrum for 1-methyl-(3,5-dibromophenyl) ethane. It shows that $^4J^{CH_2,CH_3}$ in the propyl group must be negative.

[h]$^{5}J_o^{F,H} = +0.45_3$ Hz, $^2J^{H,F} = 47.0_1$ Hz, $^3J^{H,F} = 24.4_3$ Hz.

Conformation about the C_α—C_β Bond

The parameterization of Abraham and Gatti (1) was employed. Because $^3J + {}^3J'$ is most reliably known (Table 2), except for the methyl compound (Table 1), their eq. [5*c*] is appropriate. On the assumption that the entropy of one *gauche* form **5** is that of the *anti* form (*gauche* is favored by a statistical factor of 2), the enthalpy differences are 0.46 kcal/mol for CH_3 (*anti* more stable), 0.37 (Br), −0.04 (F), −0.02 (OH), and −0.15 (NH_2). The error is presumably about 0.1 kcal/mol (1).

5

1-Methyl-2-(3,5-dibromophenyl) Ethane

The present enthalpy difference agrees with the quoted 0.5 kcal/mol (14) for *n*-propylbenzene in CCl_4 solution and also with rough gas phase populations deduced from vibronic bands in a supersonic free jet (15). The equal populations of the *gauche* and *anti* conformers are also in accord with the observed $^4J^{CH_2,CH_3}$ of −0.17 Hz within the propyl group (Table 1) if theoretical ^4J values based on the valence bond – sum over triplets method (16) are used in a conformational averaging procedure. The theory yields −0.19 Hz. The alternative calculational methods (16) yield numbers up to 0.3 Hz at variance with the present experimental value. This coupling ranges between 0 ± 0.03 and -0.12 ± 0.03 Hz in a series of *n*-propyl derivatives (17).

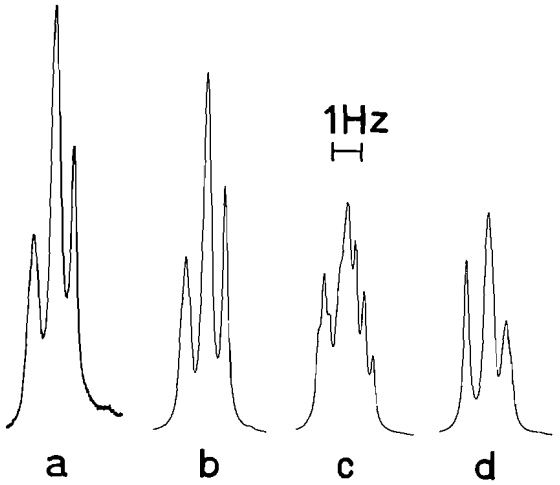

FIG. 1. One multiplet of the methyl ^{1}H nmr spectrum at 100 MHz and 305 K of an 11 mol% solution of 1-methyl-2-(3,5-dibromophenyl) ethane is displayed in *a*. In *b* to *d* the calculated multiplet is shown for $^4J^{CH_2,CH_3}$ equal to −0.17, 0.0, and +0.17 Hz, respectively. Clearly, this coupling is negative.

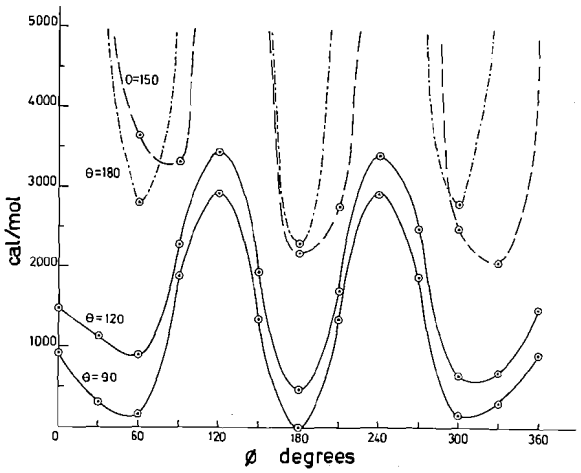

FIG. 2. A conformational energy diagram for 1-fluoro-2-phenylethane as calculated by the INDO MO approximation. The angles θ and φ are defined in **6** and **7** of the text. Only those conformations having an energy of ≤ 5 kcal/mol relative to θ = 90°, φ = 180° (perpendicular *anti* conformer) are shown.

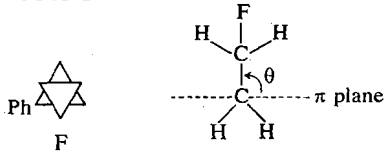

1-Bromo-(3,5-dibromophenyl) Ethane

The *anti–gauche* distribution is similar to that in the methyl compound. It may be noted that the respective $^2J^{H,H}$ values in the sidechain (Table 1) are apparently equal to those in toluene (18) and in methyl bromide (19). A similar comparison holds for phenylethane (20), toluene, and methane. Because the conformational averages of the H—H vector in the *alpha* methylene group with respect to the benzene π system must be quite different in the three phenyl compounds, doubt arises about the use of $^2J^{H,H}$ in conformational deductions for benzyl derivatives.

1-Fluoro-2-(3,5-dibromophenyl) Ethane

The negligible enthalpy difference between the *gauche* and *anti* rotamers *may* have to do with the small size of the fluorine atom, although arguments based on simple-minded steric effects are often wrong (21–23) when applied to ethane derivatives. For example, the *gauche* conformers of *n*-propyl derivatives are preferred by 0.47 ± 0.31, 0.5, and 0.28 ± 0.1 kcal/mol for the fluoride (24), chloride (25), and bromide (25), respectively.

In Fig. 2 the conformational energies are illustrated for 1-fluoro-2-phenylethane, as obtained from an INDO MO calculation with a standard geometry (26). The angles θ and φ are understood from **6** and **7**. According to these calculations, when θ = 90° the *gauche* form is 0.13 kcal/mol less stable than the *anti* form. On the other hand, STO 3G calculations gave the *gauche* form as 7.4 kcal/mol more stable for the same geometry (θ = 90° and unrelaxed bond angles). It is unlikely that the *meta* substituents and the solvent could cause the large discrepancy between the experimental and the STO 3G numbers. A full geometry optimization may reduce the discrepancy. An approximate analysis (27) of 1-fluoro-2-phenylethane ^{1}H nmr spectra for CS_2 solutions can be interpreted as yielding an *anti* fraction of 0.28, whereas the present study gives 0.32 for the 3,5-dibromophenyl derivative at 305 K.

6 φ = 60° **7** θ = 90°

It is interesting that $^5J_o^{H,F}$, the coupling involving the *ortho* protons, is +0.45 Hz. INDO MO FPT calculations give values ranging from −866 Hz for an unlikely crowded conformation (θ = 90°, φ = 0°) to +10.7 Hz. For a vanishing enthalpy difference, the computed value of $^5J^{H,F}$(θ = 90°, φ = 180°, 60°) is +0.32 Hz. According to Fig. 2, conformations for which θ = 120° are also appreciably populated. For example, if the θ = 120°, φ = 180° population is averaged in, the calculated $^5J^{H,F}$ increases by about 0.05 Hz. Of course, a proper averaging procedure would account for all hindered rotor states. These are not known (however, see below for a treatment of the θ torsion).

It is unlikely that the relatively low energies of the θ = 90° or 120°, φ = 0° conformers (C—F bond eclipsing the C_1—C_α bond) in Fig. 2 are realistic. The INDO results suggest such conformations are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

about 2 kcal/mol more stable than those in which the C—F bond eclipses an alkyl C—H bond. A strong $\pi-\pi$ stabilization involving the *p* orbitals on the fluorine and the aromatic π system would cause such a preference, but is here considered as an artifact of the parameterization (as a matter of record, STO 3G gives $\theta = 90°$, $\phi = 0°$ as 14.5 kcal/mol less stable than $\theta = 90°$, $\phi = 180°$).

1-Hydroxy-2-(3,5-dibromophenyl) Ethane

The enthalpy differences favoring the *gauche* forms in 1 mol% (ca. 0.16 *M*) and 13 mol% solutions in CS_2 are 0.09 and 0.02 kcal/mol, respectively. The values of δ_{OH} are 1.62 and 3.88 ppm, respectively at 305 K. Extrapolation of δ_{OH} for a series of dilute solutions gave 1.01 ± 0.01 ppm for the shift at infinite dilution. Considerable self-association occurs at concentrations as high as 1 mol%, apparently favoring the *anti* form, presumably because the *gauche* form contains an intramolecular hydrogen bond involving the π electrons, so that intermolecular hydrogen bonding is more extensive in the extended conformation of the molecule.

For comparison, $J + J'$ is 13.0, 13.6_2, 13.9_2 Hz for 1.0, 5.0, 12.8 mol% solutions, respectively, of 2-phenylethanol in CS_2 at 305 K. Hence the *anti* form is favored by enthalpy differences of 0.02, 0.23, 0.33 kcal/mol for these solutions. If the accuracy is 0.1 kcal/mol, the 3,5-dibromophenyl substituent favors a *gauche* conformer somewhat more than does a phenyl substituent.[2]

Of course, the aim of the later sections is the characterization of the conformational preferences about the C_1—C_α bond in both *gauche* and *anti* forms by means of ${}^6J_p{}^{H,CH_2}$. This coupling is extractable at 100 MHz only for the 3,5-dibromophenyl compounds.

1-Amino-2-(3,5-dibromophenyl) Ethane

In C_6D_{12} (the compound is unstable in CS_2) the *gauche* form is energetically favored by 0.1_5 kcal/mol. Some PCILO computations (28) suggest minor influences of *meta* or *para* hydroxyl groups. A comprehensive theoretical investigation of phenethylamine, using a variety of semiempirical as well as *ab initio* STO 3G MO calculations, gives conflicting preferences of the *gauche* and *anti* forms (29). Empirical potential functions favor the *gauche* conformer (30). The STO 3G energies favor the *anti* form by 0.9 kcal/mol, whereas the semiempirical MO energies favor the *gauche* form by 1.1 kcal/mol. Insofar as the C_6D_{12} solvent is inert, our ${}^3J$ data agree with none of the MO methods (PCILO is somewhat related to MO approaches). The empirical force field calculations may be interpreted as favoring the *gauche* form of phenethylamine in the vacuum by ca. 0.2 kcal/mol in enthalpy (26). Apparently a water solvent will not change this conclusion by more than 0.1 kcal/mol for the neutral molecule.

Enrichment with ${}^{15}N$ could lead to nmr data relatable to the conformational preferences of the amino group.

Of course, the conformational preference about the carbon–carbon bond linking the phenyl moiety to the sidechain is also of interest. Here the long-range couplings between the ring protons and the *alpha* methylene protons become useful. Because most conformational theory is available for the amine, the next section begins with this molecule.

Conformational Preferences about the C_1—C_α Bond

As discussed in the introduction, conformation **2** is the low-energy form of phenylethane and ${}^6J_p{}^{H,CH_2}$ is directly related to the preferred conformation and the twofold barrier, V_2, of 1.2 kcal/mol (38). For the *anti* conformer of phenethylamine the calculations find the conformer analogous to **2** as stable, with a V_2 (Fig. 6 of ref. 29) ranging from 1.4 to 5 kcal/mol for different methods. If the molecule existed in the *anti* form only, the ${}^6J_p{}^{H,CH_2}$ of -0.37 Hz (Table 2) would give a $\langle \sin^2 \theta \rangle$ of 0.30 ± 0.02 and therefore a V_2 of more than 3 kcal/mol. Of course, the *anti* (extended) form would not be expected to have a much larger V_2 than phenylethane and the large apparent V_2 most probably arises from the presence of *gauche* conformers. For the *gauche* conformer, one intuits a conformation about the C_1—C_α bond in which one *alpha* C—H bond lies approximately in the aromatic plane (analogous to **3**). A rigid conformation of this kind would yield a ${}^6J_p$ of -0.47 Hz and relaxation of rigidity would *increase* the magnitude of ${}^6J_p$. The observed -0.37 Hz is therefore only in agreement with a conformation of type **2** for the *gauche* form also. Theory (29) agrees and explains this result as due to an electrostatic attraction between one N—H bond and the negatively charged carbon center *ortho* to the sidechain.

Now, it is evident from models that a conformation about the C_1—C_α bond of type **4** exhibits large steric hindrance to rotation about the C_1—C_α bond in the *gauche* form of the molecule. A reasonable picture emerges as follows. Attribute a V_2 of 1.2

[2]A 10 mol% solution of 2-(*p*-fluorophenyl) ethanol in CS_2 favors the *anti* form by 0.2_1 kcal/mol at 305 K.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

kcal/mol to the *anti* form with a ^6J_p of −0.48 Hz, as in phenylethane. Then write 0.72 ^6J (*gauche*) + 0.28 (−0.48) = −0.37, where 0.28 is the *anti* population according to the ^3J numbers above. That yields ^6J in the *gauche* form as −0.33 Hz. If the *gauche* conformer were in a rigid form **2**, ^6J would be −0.31 ± 0.01 Hz because $^6J_{90}$ is −1.24 ± 0.04 Hz (3). For example, for 2,6-dichlorophenylethane, where V_2 must be > 5 kcal/mol, ^6J is −0.29 ± 0.02 Hz (3).

It follows that the barrier to rotation about the C_1—C_α bond is rather large, > 4 kcal/mol, in the *gauche* form of phenethylamine, as compared to the much smaller barrier in the *anti* form. The large difference in barriers is then a consequence of intramolecular hydrogen bonding in conformation **2** and probably of steric hindrance in conformation **4** of the *gauche* form.

The procedure above yields ^6J values of −0.33, −0.39, −0.30, and −0.38 Hz for the *gauche* forms corresponding to the substituents OH, F, Br, and CH_3 respectively. The largest V_2 therefore occurs for Br, as expected on steric grounds. The ^6J values are only compatible with a conformation **2** at C_1—C_α in both *anti* and *gauche*, so that the barrier to interconversion of the latter forms should be similar to the 3.5 kcal/mol in ethyl bromide (31, 32). The barrier to rotation about the C_1—C_α bond in the *gauche* form of the alcohol is the same as that in the amine. This is consistent with an enthalpy preference of 1.6 kcal/mol for the intramolecular hydrogen bond deduced from stretching band intensities (33). The 1 mol% solution of the alcohol gave ^6J as −0.36 ± 0.01 Hz (comparison with the 13 mol% solution indicated that ^6J is definitely of smaller magnitude in the 1 mol% solution) and yields ^6J in the *gauche* form as −0.31 Hz. To within experimental error this is the same as deduced for the higher concentration.

For the fluoride, the ^6J number implies a C_1—C_α barrier of 3 ± 1 kcal/mol in the *gauche* form. The INDO value in Fig. 2 is 2.7 kcal/mol (difference between $\theta = 90°, \phi = 60°$ and $\theta = 180°, \phi = 60°$) but of course, the present model assumes that V_2 in the *anti* form is 1.2 kcal/mol whereas INDO finds 2.3 kcal/mol for an *unrelaxed* geometry in the $\theta = 180°$ conformation (analogous to **4**), an overestimate of ca. 1 kcal/mol if the *anti* form has a C_1—C_α barrier of 1.2 kcal/mol.

The 1-alkyl substituents (R = CH_3 to *n*-C_6H_{13} in Table 2) cause ^6J values lying between −0.42 and −0.44 Hz, so that one has ^6J as −0.43 ± 0.02 Hz. Therefore the *gauche* barrier about C_1—C_α is 3.5 ± 1 kcal/mol, again in a region where the *J* method is insensitive.[3] Bromine (35) has a larger van der Waals volume than the methyl group (36) and the C—Br bond is also longer than the C—C bond. Therefore the higher barrier for the *gauche* 1-bromo compound is reasonable. The vibronic data (15) suggest two conformers of roughly equal abundance for the alkyl compounds. Models indicate that reasonable *gauche* conformations involve steric hindrance between the third CH_2 moiety and the *ortho* C—H bonds during rotation about the C_1—C_α bond for all the alkylethanes in Table 2.

If such steric interactions are important in these *gauche* alkyl conformations, replacement by other hydrocarbon groupings might well alter the barrier about the C_1—C_α bond. Therefore the two compounds below were examined.

3,5-Dichloroallylbenzene and 4-(3,5-Dibromobenzyl) Pyridine

^6J_p is −0.49 Hz in the allyl derivative, implying a barrier of 1.1 ± 0.2 kcal/mol about the C_1—C_α bond, the same as in phenylethane to within experimental error. (INDO MO FPT computations gave $^6J_{90}$ as −1.18 Hz, about 0.04 Hz larger than calculated for toluene, the latter agreeing with experiment. The stated error encompasses this range of $^6J_{90}$ values.) The INDO calculations, which give remarkably good conformational energy differences for hydrocarbons like phenylcyclopropane (37) and toluene (38), for example, suggest that for allylbenzene the stable conformation is of type **2** and that the olefinic bond is eclipsed by an *alpha* C—H bond (as in propene) in such a manner that the vinyl group points away from the benzene ring. The alternative eclipsed conformation, analogous to a *gauche* form for *n*-propylbenzene, in which the vinyl group points towards the aromatic moiety is 1.2 kcal/mol less stable. Accordingly, its population is small at ambient temperatures and the large barrier about C_1—C_α expected for such a conformer is not reflected in the observed barrier. In fact, for the favored conformer above, the distance of closest approach of the one olefinic C—H bond with an *ortho* C—H bond, as rotation occurs about the C_1—C_α bond, is somewhat less than the corresponding distance in phenylethane (Dreiding models).

In the pyridine derivative, ^6J is 0.45 ± 0.03 Hz,

[3]Spin–lattice relaxation times for ^{13}C nuclei of *p*-methoxybenzylidene-*p*-*n*-butylaniline in the isotropic phase (34) suggest that rotation about the C_1—C_α bond (*n*-butyl moiety) is hindered by 2.3 kcal/mol. This must be an *average* over the *anti* and *gauche* forms. If ^6J_p for the butyl compound in Table 2 is treated similarly one obtains an apparent barrier of 2.1 kcal/mol for rotation about the C_1—C_α bond.

corresponding to a $\langle \sin^2 \theta \rangle$ of $0.36_5 \pm 0.02$ and a V_2 of 1.6 ± 0.3 kcal/mol. To within experimental error, this is the same as the barriers derived for 4,4′-difluorodiphenylmethane and for 3,5-dibromodiphenylmethane (39). The discussion for these compounds concluded that the gable conformation, analogous to **2**, was preferred and that this conformation minimizes steric interactions between C—H bonds on neighbouring rings.

Concerning Various Assumptions

As in all other discussions of ^6J_p (5) it is assumed that the coupling is independent of the *meta* halogen substituents. This is certainly true for a variety of toluene derivatives, including *sym*-tetrafluorotoluene.[4] A recent ^{1}H nmr spectrum of ethylbenzene at 500 MHz (40) appears to have a ^6J identical to that in the 3,5-dibromo derivative. We also have reason to believe that ^6J_p in styrene and 3,5-dibromostyrene are identical.

Further, if the barriers about the C_1—C_α bond in the compounds discussed in this paper have their origin mainly in the steric hindrance between the sidechain and *ortho* C—H bonds, the *meta* substituents should play a minor role in determining their magnitudes. If the relative rigidity in the *gauche* form is indeed as marked as in the 1-bromo compound, it may be that the assumed statistical factor of 2 favoring the *gauche* form is an overestimate. In the absence of good partition functions the reduction in magnitude of this factor remains as an unsolved problem.

Of course, if the barrier about the C_1—C_α bond in the *anti* forms is greater than in phenylethane, a corresponding decrease in the barrier about the C_1—C_α bond in the *gauche* forms is implied by the present model. For example, if the barrier in the *anti* form of the phenethylamine derivative is as high as 2 kcal/mol, one deduces that the barrier in the *gauche* form is still > 4 kcal/mol.

If an alternative formulation (41) of the substituent dependence of the vicinal coupling constants in 1,2-disubstituted ethanes is employed, the *gauche* forms become ca. 0.1 kcal/mol more stable than above. However, the rigidity of the *gauche* forms, as obtained by calculations of ^6J in these forms, does not change appreciably.

Conclusions

A combination of the Karplus and J methods yields a plausible picture of the conformational populations about the C_α—C_β bond in 2-phenylethane derivatives, as well as the conformational preferences and rotational barriers about the C_1—C_α bond in the *gauche* and *anti* rotamers. The former are rather more rigid than the latter.

The total synthesis of (±)hinesol and (±)epihinesol

JACQUES LAFONTAINE, MARCEL MONGRAIN, MIREILLE SERGENT-GUAY, LUC RUEST, AND PIERRE DESLONGCHAMPS

Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received December 28, 1979

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

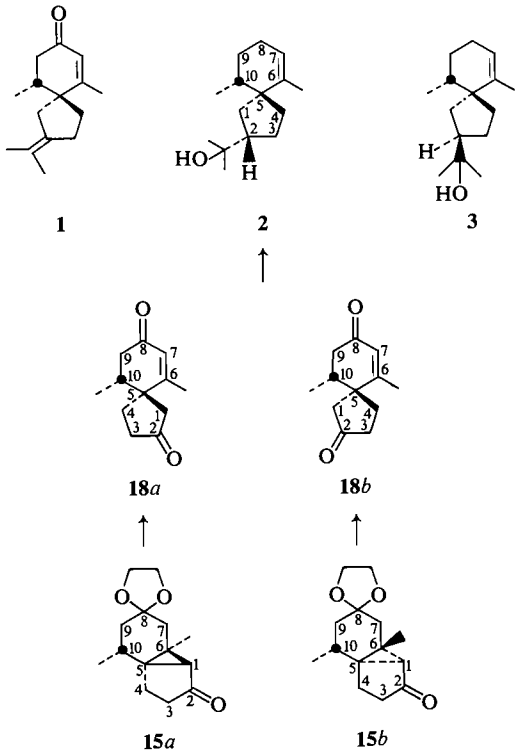
JACQUES LAFONTAINE, MARCEL MONGRAIN, MIREILLE SERGENT-GUAY, LUC RUEST, and PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 2460 (1980).

The tricyclic ketal ketones **15***a* and **15***b* have been obtained in an isomeric ratio of 9:1 (**4** → **5** → **6** → **7** → **8** → **9** → **10** → **11** → **12** → **13** → **14** → **15***a* + **15***b*). Compound **15***a* was converted in seven (or eight) steps to (±)epihinesol (**3**) (**15***a* → **29** → **32** → **48** → **49** → **47** (or **32** → **39** → **38** → **44** → **47**) → **50** → **3**) and compound **38** was transformed into (±)hinesol (**2**) in five steps (**38** → **76** → **77** → **62** → **63** → **2**). The identity of epihinesol and agarospirol was confirmed by formation of a common epoxide.

JACQUES LAFONTAINE, MARCEL MONGRAIN, MIREILLE SERGENT-GUAY, LUC RUEST et PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 2460 (1980).

Les cétones cétales tricycliques **15***a* et **15***b* sont obtenues dans un rapport de 9 à 1 (**4** → **5** → **6** → **7** → **8** → **9** → **10** → **11** → **12** → **13** → **14** → **15***a* + **15***b*). Le composé **15***a* a donné le (±)épihinésol (**3**) en sept (ou huit) étapes (**15***a* → **29** → **32** → **48** → **49** → **47** (ou **32** → **39** → **38** → **44** → **47**) → **50** → **3**) et le composé **38** est transformé en (±)hinésol (**2**) en cinq étapes (**38** → **76** → **77** → **62** → **63** → **2**). L'identité de l'épihinésol et de l'agarospirol a été confirmée par formation d'un seul et même époxyde.

Introduction



β-Vetivone (**1**) and hinesol (**2**) (Scheme 1) are naturally occurring members of the spiro[4.5]decane group of sesquiterpenes. Epihinesol (**3**) which is the isopropylol isomer of hinesol (**2**), has been proposed as the structure for the sesquiterpene agarospirol (1). The literature concerning the isolation, structure elucidation, and synthesis of these compounds has been reviewed (2, 3). More recent literature can be found in refs. 4–12.

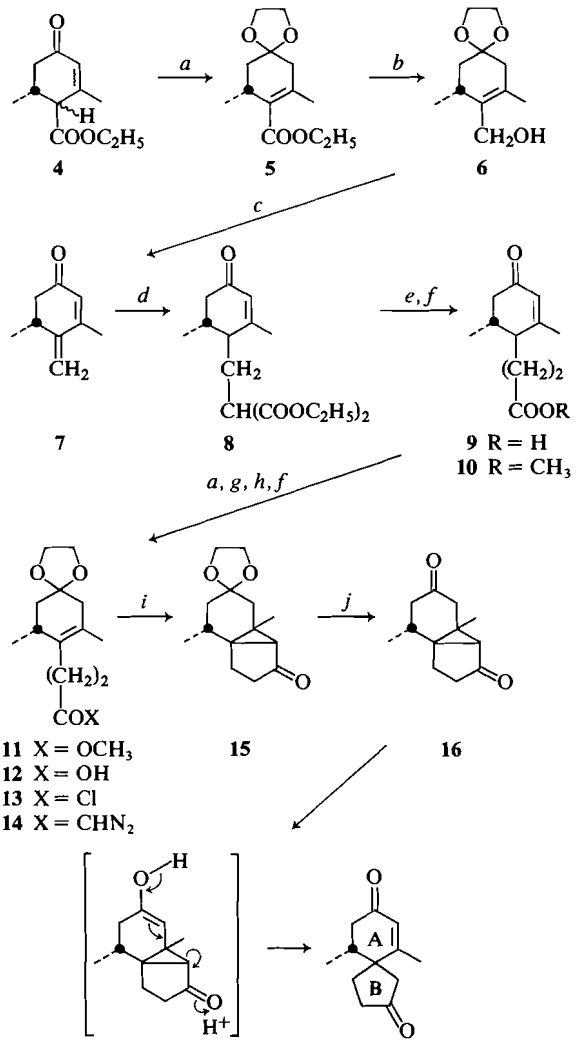
We have reported in 1970 in a preliminary form (13) a synthesis of (±)epihinesol (**3**). We have since then successfully completed a synthesis of (±)-hinesol (**2**) by using the same key intermediate that we have utilized for the construction of (±)-epihinesol (**3**). We wish now to report in detail the synthesis of (±)hinesol (**2**) and (±)epihinesol (**3**).[1]

Synthetic Strategy

Skeleton

The conversion of the ketal diazoketone **14** (Scheme 2) into the spiro[4.5]decane enediketone **18** via the intermediates **15** and **16** constitutes the central idea of our synthetic scheme. The spiro compound **18** is indeed a very appealing key intermediate as ring A is complete for β-vetivone (**1**) and it should be easily converted to that of the hinesols. Furthermore, ring B of **18** has a ketone functionality to introduce either the isopropylidene group which is present in β-vetivone or the isopropylol group which is found in hinesol (**2**) and epihinesol (**3**).

SCHEME 1



Our strategy was therefore based on the fol-

[1](±)Hinesol (**2**) and (±)epihinesol (**3**) have been converted into (±)β-vetivone (**1**) (14); our work can therefore be regarded as a synthetic route to (±)β-vetivone (**1**).

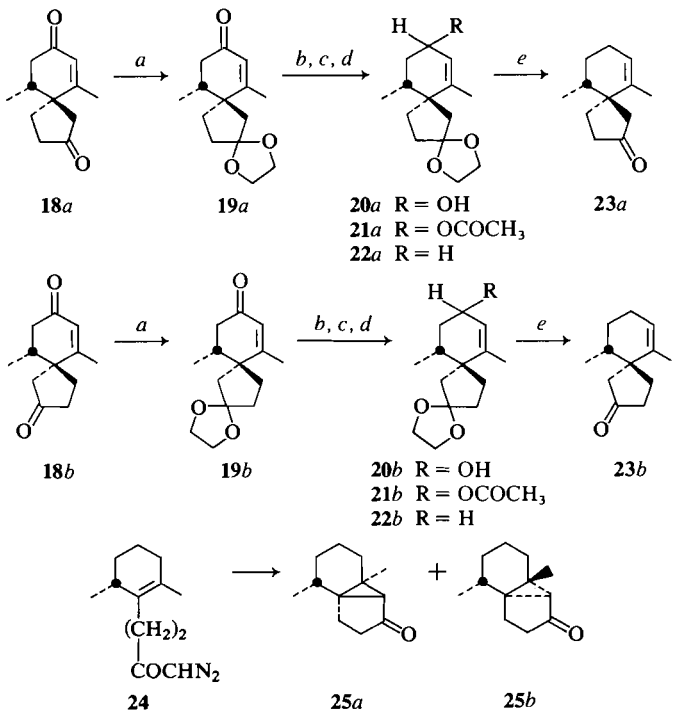
SCHEME 2

lowing facts: (*a*) the conversion of the ketal diazoketone **14** into the tricyclic ketal ketone **15** should be easily realized because this method is frequently used for internal cyclopropane ring formation (15–17), (*b*) the acid hydrolysis of **15** to give the cyclopropyl diketone **16** should proceed normally, and (*c*) compound **16** should undergo, under acidic conditions, a facile opening of the cyclopropane ring via the enol intermediate **17** to yield the desired spiro enedione **18**. The conversion of **16** into **18** could also be envisaged under basic conditions.

We were also convinced that the preparation of the ketal olefin diazoketone **14** could be realized starting from the substituted cyclohexenone methyl ester **10**. This was based on the well-known fact that ketalization of an α,β-cyclohexenone proceeds with concomitant migration of the double bond to give a β,γ-unsaturated ketal. Thus, **10** would first be transformed into the ketal methyl ester **11**. Basic hydrolysis of **11** would then give the ketal carboxylic acid **12** which could then be converted into the ketal diazoketone **14** via the acid chloride **13** by standard procedures. Finally, since the cyclohexenone methyl ester **10** is a relatively simple compound, its preparation should not create any major difficulty.

Control of Stereochemistry

The ketal diazoketone **14** which contains only one chiral center can give in principle two different adducts, the tricyclic ketal ketone **15***a* (Scheme 1) with the two methyl groups in a *cis* arrangement or the isomeric compound **15***b* having the two methyl groups in the *trans* configuration.



The *cis* (**15***a*) and the *trans* (**15***b*) isomers should give the spiro bicyclic enediketones **18***a* and **18***b* respectively. If **18***a* is obtained, completion of the synthesis requires the introduction of the isopropyl side chain in α-position to the carbonyl group (carbon-3) in the cyclopentane ring. On the other hand, if the other spiro bicyclic enediketone **18***b* is obtained, the isopropyl side chain will have to be attached directly to the ketone function (carbon-2) in **18***b*. Consequently, if one of the two isomers, **15***a* or **15***b* is formed preferentially, our synthetic route would permit a synthesis of β-vetivone with control of stereochemistry. We felt that there was a good possibility of obtaining some selectivity in the formation of the cyclopropane ring because the two faces of the double bond in the ketal diazoketone **14** have different environments.

We could not predict in advance how to control the extra chiral center which exists in the case of hinesol (**2**) and epihinesol (**3**). We were, however, confident of finding a solution by studying the reactivity of some of the key intermediates which would be obtained during the course of this investigation.

*Synthesis of the Ketal Diazoketone **14** and its Conversion into **15** and **18***

The enone ethyl ester **4** (Scheme 2) which is readily available by the condensation of two equivalents of ethyl acetoacetate and one of acetaldehyde (18) was selected as the starting material.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

(*a*) $(CH_2OH)_2$, *p*-TsOH, benzene; (*b*) $LiAlH_4$, ether;
(*c*) $(CH_3CO)_2O$, pyridine; (*d*) Li, NH_3, ether;
(*e*) acetone, water, *p*-TsOH.

SCHEME 3

The enone ethyl ester **4** was first transformed into the ketal ethyl ester **5** which was then reduced to yield the crude ketal alcohol **6**. Treatment of **6** with aqueous acid gave the dienone **7** which was obtained pure by distillation.[2]

Michael addition of diethyl malonate to the dienone **7** gave the enone diethyl ester **8**.[3] The crude product **8** underwent hydrolysis and decarboxylation under reflux with aqueous acid to yield the enone monocarboxylic acid **9**. On esterification, **9** gave the enone methyl ester **10** which was purified by distillation.[4] The anticipated conversion of the enone methyl ester **10** into the ketal diazoketone **14** was realized without any difficulty.

On refluxing in benzene in the presence of copper, the ketal diazoketone **14** was smoothly converted into a mixture of the *cis* and the *trans* isomers **15***a* and **15***b* in a 9:1 ratio (Scheme 1). Both isomers could be obtained pure by chromatography. Treatment of the *cis* and the *trans* isomers **15***a* and **15***b* with hydrochloric acid (2 *N*) in tetrahydrofuran gave a good yield of the bicyclic enediketones **18***a* and **18***b* respectively.

We have firmly established the configuration of the *cis* and the *trans* tricyclic ketal ketones **15***a* and **15***b* by carrying out a chemical correlation between the bicyclic enediketones **18***a* and **18***b* and the two known bicyclic ketones **23***a* and **23***b* respectively (Scheme 3). Selective ketalization of **18***a* gave **19***a* which was reduced to the alcohol **20***a*. Acetylation of **20***a* gave the allylic acetate **21***a* which on chemical hydrogenolysis (21) produced the ketal olefin **22***a*. Acid hydrolysis of **22***a* gave the bicyclic ketone **23***a*. Compound **23***a* forms a mixture of two dinitrophenylhydrazone (DNP) derivatives (mp 107–108°C) which were separated by thin layer chromatography. These two DNP derivatives melt at 127–129°C and 150–151°C respectively. They are *syn* and *anti* geometrical isomers which are interconvertible at the temperature of their melting

[2]We first suspected that the dienone **7** would be unstable, readily aromatizing to yield 3,4,5-trimethylphenol. We found the contrary, compound **7** was remarkably stable under refluxing conditions with either potassium hydroxide (4 *N*) or potassium *tert*-butoxide in *tert*-butanol or hydrochloric acid (2 *N*). The conversion of dienone **7** into 3,4,5-trimethylphenol was finally achieved under refluxing conditions with perchloric acid in acetic acid!

[3]Cf. an analogous case in ref. 19.

[4]McCurry has prepared the same enone ester **10** utilizing a slightly different route (20). The ketal alcohol **6** was first converted into the corresponding ketal chloride **6** (OH=Cl) which was then displaced by the sodium salt of diethyl malonate.

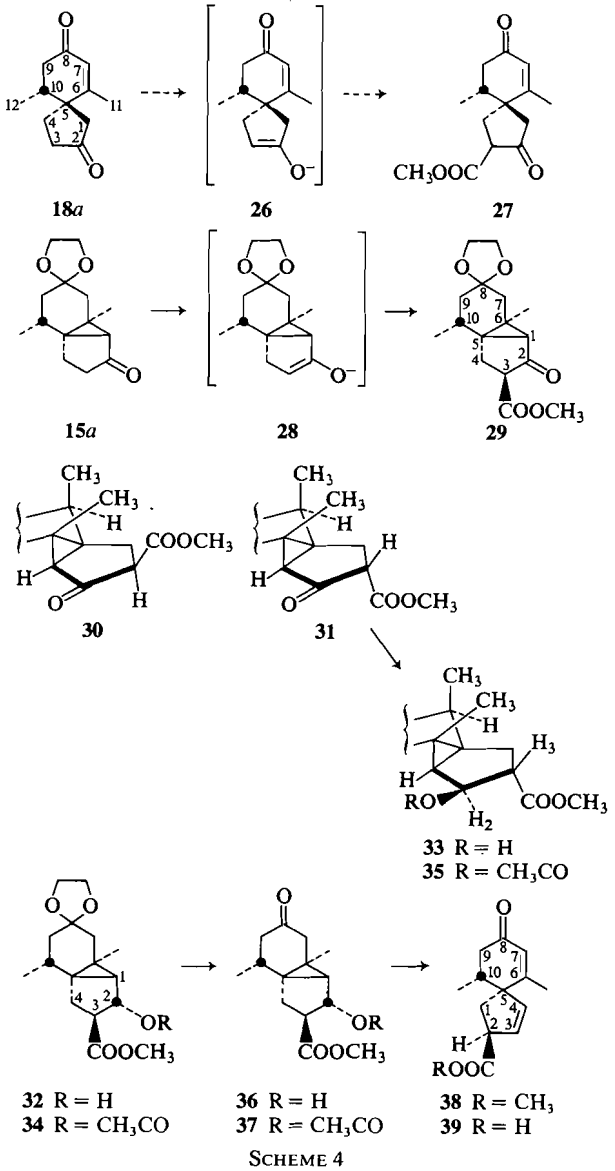
points. They have been found to be identical with authentic samples.[5]



The isomeric bicyclic enediketone **18***b* was also converted by essentially the same procedure (**18***b* → **19***b* → **20***b* → **21***b* → **22***b* → **23***b*) to the isomeric bicyclic ketone **23***b* which was found to be identical with an authentic sample (22). The bicyclic ketone **23***b* gave also a mixture of two DNP derivatives (mp 78–88°C) which can be separated. They are *syn* and *anti* isomers (mp 113–114°C and 160–161°C) which are also interconvertible at their respective melting point temperatures.[6]

McCurry (20) has obtained the same mixture of *cis* and *trans* tricyclic ketal ketones **15***a* and **15***b* from the diazoketone **14**. He has also shown that the diazoketone **24** leads to a similar mixture of *cis* and *trans* tricyclic ketones **25***a* (89%) and **25***b* (11%). The isomeric ratios are essentially the same in both series (**14** and **24**), the presence of the ketal function in **14** has therefore no effect on the selectivity of the reaction. The selectivity can be explained if one considers the steric hindrance caused by the secondary methyl group; the carbenoid species resulting from the diazoketone in **14** (or in **24**) would simply prefer to attack on the face of the double bond which is *anti* to the secondary methyl group yielding the *cis* isomer **15***a* (or **25***a*) in preponderance.

Synthesis of (±)Epihinesol

The bicyclic enone **18***a* being the preponderant isomer, the next task consisted in finding a method for the introduction of an isopropylol or an isopropylidene group at carbon-3 (α to the carbonyl) in the five-membered ring (Scheme 4). A good approach appeared to be the introduction of a carbomethoxy group (**18***a* → **27**). Two main reasons guided this choice: (*a*) the subsequent manipulation of the ketone functions in **27** could presumably be easily achieved in the presence of the ester function, and (*b*) a carbomethoxy group is suitable for conversion by a Grignard reaction or its equivalent into an isopropylol group which in turn can be dehydrated to yield an isopropylidene group.

The introduction of a carbomethoxy group can be envisaged by the reaction of the enolate salt **26** with dimethyl carbonate. It could, however, be difficult to generate specifically the salt **26** as the hydrogens at positions 1, 9, and 11 of compound **18***a* might be equally susceptible to removal, yielding undesired enolate salts. Appropriate elimination of the carbonyl group at carbon-8 of **18***a* would still leave one competitive position (carbon-1) for enolate formation. These considerations led us to the conclusion that the precursor of the bicyclic enediketone **18***a*, the tricyclic ketal ketone **15***a*, would be a superior intermediate for the introduction of a carbomethoxy group. In compound **15***a*, only the desired enolate salt **28** can be formed. Furthermore, since compound **15***a* possesses a highly unsymmetrical rigid skeleton, there

SCHEME 4

[5]We are grateful to Professor James A. Marshall for an authentic sample of a mixture of the two DNP derivatives (mp 107–108°C) of the bicyclic ketone **23***a* (14). In this case also, separation gave two pure DNP derivatives (mp 127–129°C and 150–151°C).

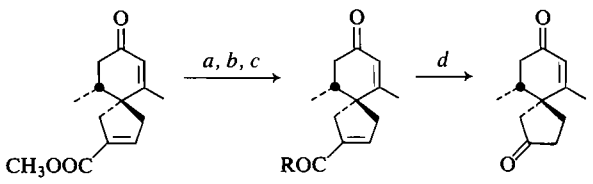
[6]We are grateful to Professor Drury Caine (22) for an authentic sample of the bicyclic ketone **23***b*. This sample gave also two DNP derivatives (mp 113–114°C and 160–161°C).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

was a very good possibility of obtaining only one of the two possible epimeric β-keto esters (**29**). It was important to us to achieve a control of stereochemistry at carbon-3 because this would permit a stereocontrolled synthesis of hinesol (**2**) or epihinesol (**3**).

Treatment of the *cis* tricyclic ketal ketone **15***a* with dimethyl carbonate in the presence of sodium hydride gave a crude product to which we have assigned the structure **29** with the carbomethoxy group *trans* to the tertiary methyl group. Examination of molecular models showed clearly that when the carbomethoxy group is *cis* to the tertiary methyl group, there is considerable steric hindrance between the two groups. Formulas **30** and **31** represent the two situations. The tricyclic ketal β-keto ester **29** was reduced with sodium borohydride to yield the tricyclic ketal alcohol ester **32** having the hydroxyl group *cis* to the tertiary methyl group. This assignment was simply based on the fact that the hydride reagent should reduce the carbonyl group from its least hindered face (cf. **31** → **33**). The tricyclic ketal alcohol ester **32** was further characterized by the preparation of the corresponding acetate derivative **34**. The assignment of the relative configuration of the carbomethoxy group was confirmed by a nuclear Overhauser effect study. Irradiation of the tertiary methyl group (1.24 δ) of compound **34** caused a 14% enhancement of the multiplet at 2.75 δ which corresponds to the hydrogen at carbon-3. This result shows that H3 is *cis* to the tertiary methyl group (cf. **35**).[7]

The next important operation was to verify if cyclopropane cleavage to yield a spiro[4.5]decane system would take place with the tricyclic ketal alcohol ester **32**. A brief treatment (10 min) of **32** with hydrochloric acid (1 *N*) gave the corresponding tricyclic ketone alcohol ester **36** which was further characterized as the acetate derivative **37**. If **36** was left for a longer period of time under these same acidic conditions, a new product was isolated which has the desired structure, the dienone ester **38**. When the reaction was carried out under reflux conditions for 4 hours, **32** as well as **36** gave the corresponding crystalline dienone carboxylic acid **39** directly in good yield. Treatment of the dienone ester **38** under similar conditions gave the dienone carboxylic acid **39**. Even if the desired product was the dienone ester **38**, we found it more convenient for purification purposes to use the experimental conditions leading to the dienone carboxylic acid **39** which could then be easily converted into the dienone ester **38** by esterification.



[7]We are grateful to Professors R. R. Fraser and J. K. Saunders who carried out this study for our laboratory.

The structure of the dienone ester **38** was rigorously established by carrying out a chemical correlation with the known bicyclic diketone **18***b* (Scheme 5). Treatment of the dienone ester **38** with sodium methoxide in methanol gave the conjugated ester **40** in good yield. The conjugated ester **40** was then hydrolysed to the corresponding carboxylic acid **41**. A Curtius degradation was realized by transforming **41** into its acid chloride **42** which was then converted into the azide **43**. Heating the azide **43** in water followed by the addition of dilute acid gave a product which was found identical with the bicyclic diketone **18***b* obtained previously.

The stereochemistry of the dienone ester **38** (Scheme 4) corresponds to that of epihinesol (**3**) and three further operations should yield the final product: (*a*) reduction of the cyclopentene double bond, (*b*) reductive elimination of the ketone carbonyl group, and (*c*) transformation of the carbomethoxy group into the isopropylol group.

The dienone ester **38** was first reduced with lithium tri-*tert*-butoxyaluminium hydride to give the allylic alcohol **44** (Scheme 6). We have postulated that the secondary hydroxyl group is *cis* to the secondary methyl group in **44** because this is the result of an attack by the bulky hydride on the pseudo-axial face of the conformation **45** of the dienone **38**. It is also possible that compound **38** exists in the other conformation **46** with the secondary methyl group in the pseudo-axial orientation where this methyl group has only one *gauche* interaction with the cyclopentene ring. If this is the case, reduction would simply occur on the least hindered face of the carbonyl group yielding the same allylic alcohol **44**. The allylic alcohol ester **44** was converted into the crystalline diol **47** by a Grignard reaction. The diol **47** was further characterized by the isolation of the monoacetate alcohol **50** upon acetylation.

The diol **47** was also obtained by reversing the sequence of operations. The isopropylol group was first introduced by a Grignard reaction on the tricyclic ketal alcohol ester **32** which gave the

40 **41** R = OH; **42** R = Cl; **43** R = N_3 **18***b*

(*a*) HCl 1 *N*, THF, reflux; (*b*) $(COCl)_2$, pyridine, CH_2Cl_2; (*c*) NaN_3, acetone; (*d*) THF, water, reflux and HCl 1 *N*, 0°C.

tricyclic ketal diol **48**. Treatment of **48** with aqueous acid yielded the expected dienone alcohol **49** which upon reduction with lithium aluminium hydride gave a product identical to diol **47**.

The hydrogenolysis of the allylic alcohol and the specific reduction of the cyclopentene double bond of the diol **47** were realized in a single operation. Treatment of the diol **47** with lithium in monoethylamine (23) gave epihinesol (**3**) in 55% yield. When the same reaction was carried out on the monoacetate alcohol **50**, epihinesol (**3**) was obtained in almost quantitative yield. The final proof that we had indeed produced epihinesol was carried out on the corresponding acetate **51** which was found to have the same retention time on vapor phase chromatography as that of an authentic sample of epihinesol acetate.[8,9]

The use of lithium in monoethylamine to specifically reduce the cyclopentene double bond (**47** or **50** → **3**) deserves some special comment. First, it is clear that we have not been able to selectively reduce this double bond by the usual method of hydrogenation using various catalysts. Unsuccessful experiments yielding complex mixtures were carried out with compounds **38**, **40**, **44**, **47**, **49**, **53**, and **54**. The dehydro β-vetivone **53** was obtained by dehydration of **49**. The allylic alcohol **54** was prepared by hydride reduction of **53**. Catalytic reduction of the allylic alcohol **55** prepared from **40** led to the hydrogenolysis product **57**. The same result was obtained from the corresponding allylic acetate **56**.

The disubstituted double bond of the cyclopentane ring should normally be hydrogenated at a faster rate than the trisubstituted double bond of the cyclohexane ring. The resistance to hydrogenation of the cyclopentene double bond can be explained by the steric hindrance caused by the two methyl groups of ring A; due to the spiro nature

(*a*) CH_3MgI, ether; (*b*) $(CH_3CO)_2O$, pyridine; (*c*) HCl 2 *N*, THF; (*d*) $LiAlH_4$, ether; (*e*) Li, $C_2H_5NH_2$, ether; (*f*) $(CH_3CO)_2O$, CH_3COONa;

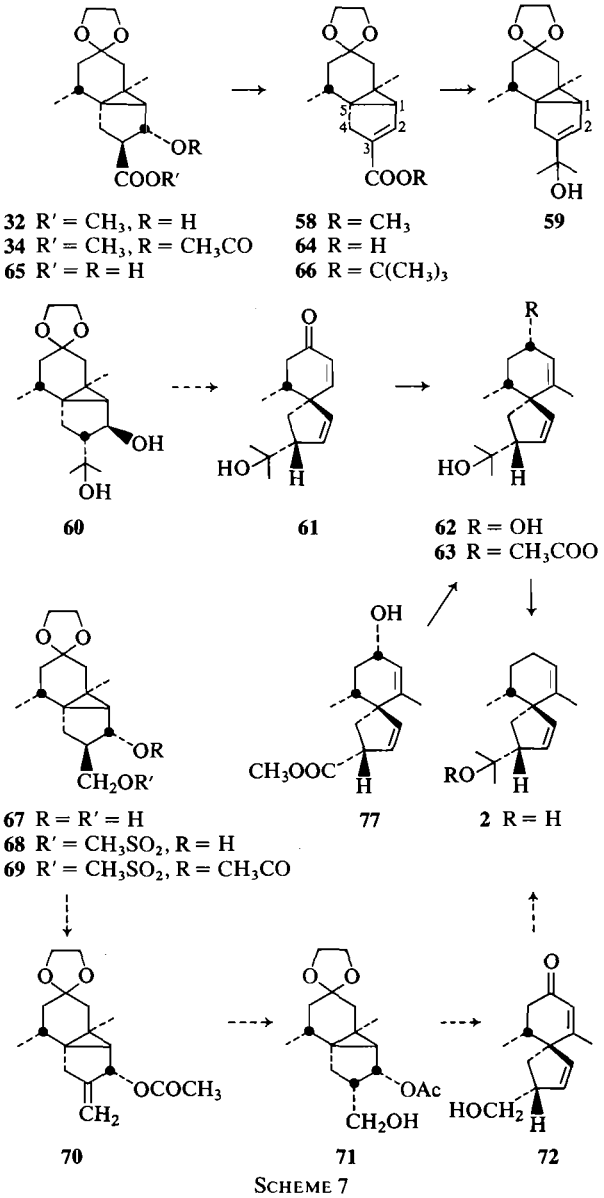
SCHEME 6

of these compounds, the cyclohexene ring is perpendicular to the plane of the cyclopentene ring (cf. **45**) and the two methyl groups of the cyclohexene ring protect both faces of the cyclopentene double bond. The catalyst cannot approach this double bond in the usual way to effectuate a reduction. We have finally used lithium in monoethylamine when we became aware that Benkeser *et al.* (23) had shown that this reagent also reduces disubstituted double bonds at a faster rate than trisubstituted double bonds.

[8]Hinesol and epihinesol have very similar infrared and proton nmr spectra and have an identical retention time on vpc. Their corresponding acetates have also very similar spectroscopic properties but have different retention times (vpc). We are very grateful to Professor J. A. Marshall who has carried out the vpc identification of our synthetic epihinesol acetate. We have since observed that hinesol and epihinesol differ in their ^{13}C nmr spectra (cf. Experimental).



[9]Epihinesol (**3**) should in principle be identical with agarospirol (1), but the published nmr spectrum of agarospirol is not identical with the spectrum of epihinesol (**3**). We have not been able to obtain a sample of agarospirol. However, agarospirol gives a crystalline epoxide of which the proton nmr spectrum is essentially identical with the epoxide **52** obtained from epihinesol (**3**). We are grateful to Professor S. C. Bhattacharyya for this identification. It is therefore very likely that agarospirol is identical with epihinesol (**3**) if one makes the assumption that the published nmr spectrum comes from an impure sample of agarospirol.

Synthesis of (±)Hinesol (2)

It was possible to achieve the synthesis of (±)-epihinesol (**3**) with a complete control of stereochemistry from the tricyclic ketal ketone **15***a* because we were able to obtain the tricyclic ketal β-keto ester **29** in a specific manner. The next task was to achieve the synthesis of (±)hinesol (**2**), again having a control of stereochemistry for the isopropylol side chain.

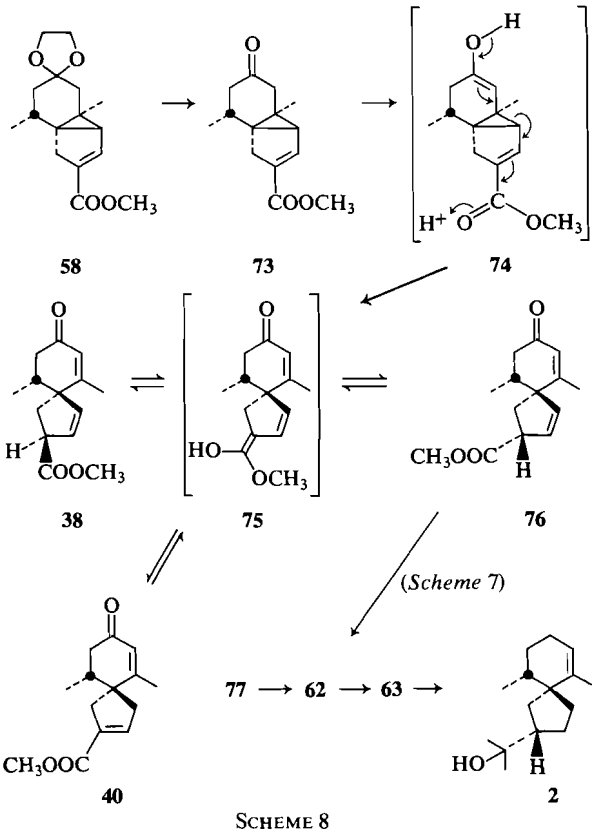
The first approach that we considered was to reverse the chirality at carbon-3 in tricyclic compounds derived from the β-keto ester **29**. Our first attempt is outlined in Scheme 7. The plan was to dehydrate compound **32** to the conjugated methyl ester **58** followed by conversion of **58** into **59**. We then hoped that **59** could be transformed via hydroboration into the tricyclic ketal diol **60** which has the correct chirality at carbon-3 for the construction of hinesol (**2**). The formation of **60** was anticipated because it is the result of hydroboration on the least hindered face of the double bond in **59**. Treatment of **60** with aqueous acid would provide **61** which could then be transformed into hinesol (**2**) by a procedure (**61** → **62** → **63** → **2**) similar to that used in the synthesis of epihinesol (**3**).

SCHEME 7

Direct dehydration of the tricyclic ketal alcohol ester **32** was not successful. However, we found that treatment of the tricyclic ketal ester acetate **34** with potassium *tert*-butoxide in dry *tert*-butanol under reflux for 30 h gave a mixture of two carboxylic acids, the tricyclic ketal acid **65** and the conjugated acid **64**. The tricyclic ketal acid **65** could also be made by basic hydrolysis of **32** and esterification of the conjugated acid **64** with diazomethane gave the desired methyl ester **58**.

The fact that we obtained the two carboxylic acids **64** and **65** from **34** showed that the reaction medium was not completely dry. We have, however, succeeded in obtaining a completely dry mixture of potassium *tert*-butoxide in *tert*-butanol by adding a small quantity of maleic anhydride. Under this new condition, the medium becomes completely dry because maleic anhydride reacts with all the hydroxide in yielding maleic acid salt which does not interfere with the desired transformation. Thus, when compound **34** was refluxed for 72 h in *tert*-butanol containing two equivalents of potassium *tert*-butoxide and one equivalent of maleic anhydride, we obtained an essentially quantitative yield of the desired tricyclic ketal conjugated methyl ester **58**. When the same reaction was left for a longer period of time, the *tert*-butyl ester **66** was also formed, very likely via a *trans*-esterification mechanism with potassium *tert*-butoxide!

Reaction of the tricyclic ketal conjugated methyl ester **58** with methyl lithium gave the expected isopropylol derivative **59** in good yield. However, all attempts to carry out hydroboration of **59** with diborane or disyamyl borane failed to give the desired tricyclic ketal diol **60** and this approach was abandoned.



In our second attempt, we decided to transform the tricyclic ketal alcohol ester **32** into the acetate mesylate **69** in the hope that this product could undergo dehydromesylation to give the tricyclic ketal olefin **70**. Again hydroboration of **70** should give compound **71** which has its CH_2OH group properly oriented to eventually give hinesol (**2**) via

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

the intermediate **72**. This route had also to be abandoned because we have not been able to effect the dehydromesylation (**69** → **70**). The diol **67** was obtained by lithium aluminium hydride reduction of the tricyclic ketal alcohol ester **32**. The diol **67** was then mesylated to give **68** which after acetylation gave the acetate mesylate **69**.

At this stage, we completely changed our strategy in the following way. We first studied the mild acid hydrolysis of the tricyclic ketal conjugated ester **58**. Under acid conditions, **58** should first give the ketone **73** (Scheme 8) which should then enolise to give **74** which would undergo cyclopropane opening to yield a spiro[4.5]decane in which the ester should first be in its enol form **75**. The enol form **75** would then be protonated to give an ester. Since the formation of **75** would be generated under mild acid conditions, it will be protonated only once, and there should be no further equilibration of the resulting ester under these conditions. There are three different ways to protonate **75**. It can occur in two different ways at carbon-2, yielding the two isomeric esters **38** and **76**, or it can occur at carbon-4 giving the known conjugated ester **40**. We were hoping that protonation would occur at carbon-2 only, and that the protonation might occur stereospecifically to give the ester **76** only!

Treatment of **58** under mild acid gave a mixture of the two non-conjugated esters **76** (35%) and **38** (65%) but the conjugated ester **40** was not observed. This result showed that protonation is equally facile on either side of the enol of the ester function in **75**. It showed also that it is more difficult to protonate the position 4 in intermediate **75**. This led us to think that it might be possible to find some experimental conditions where the two non-conjugated esters **38** and **76** could be equilibrated while preventing the formation of the conjugated ester **40** which is the thermodynamically more stable isomer. We had already observed that when compound **38** was treated with sodium methoxide in methanol *under reflux*, it led to the exclusive formation of the conjugated ester **40**. We repeated this experiment *at room temperature* and under those new conditions the conjugated ester **40** was not observed but the unconjugated ester **38** underwent equilibration with its isomer **76**. We obtained a mixture of **76** and **38** in a 7:3 ratio. The major isomer **76** could be obtained pure by column chromatography. Having obtained **76**, we used the same strategy as in the case of epihinesol (**3**). Compound **76** was first reduced to give **77** (Scheme 7) which was then converted into **62** and then **63**. Reduction of **63** with lithium in monoethylamine gave a mixture of three products, from which (±)hinesol (**2**) was isolated.

SCHEME 8

Experimental

The ir spectra were taken on a Perkin-Elmer 257 spectrophotometer. The ultraviolet (uv) spectra were registered on a Varian Techtron 635 spectrophotometer. Proton nmr spectra were recorded on a Varian A-60 or a Bruker WP-60 instrument. The following abbreviations have been used: s, singlet; d, doublet; d of d, doublet of doublet; t, triplet; m, multiplet; and br, broad. Chemical shifts are reported in δ values relative to tetramethylsilane as internal standard. The ^{13}C nmr spectra were recorded on a Bruker H-90 instrument. Vapor phase chromatographic (vpc) analyses were carried out on a Varian, model 90-P.

The mass spectra were recorded on a Hitachi-Perkin-Elmer RMU-6 mass spectrometer. Microanalyses were carried out by Mr J. Tamas, Laboratoire de Microanalyses, Université de Sherbrooke; Schwarkkopf Microanalytical Laboratories, N.Y.; and by Dr C. Daessle, Organic Microanalyses, Montreal. Anhydrous magnesium sulfate was used as the drying agent in working reactions. Low boiling petroleum ether (bp 30–60°C) was used.

Ketal Ester **5**

Ketone ester **4** (50 g, 0.25 mol) (18) was dissolved in benzene (1 L) and mixed with ethylene glycol (30 mL) and *p*-toluenesulfonic acid (50 mg). The reaction mixture was refluxed for 40 h using a Dean–Stark water separator. The cooled reaction mixture was washed with saturated sodium carbonate and saturated sodium chloride. The dried solution was evaporated to give the crude ketal ester **5** (66 g) which was used without further purification. An analytical sample was prepared by microdis-

tillation *in vacuo*; ir ($CHCl_3$): 1725 cm^{-1}; nmr ($CDCl_3$) δ: 4.25 (2H, q, J = 7 Hz, OCH_2CH_3), 3.97 (4H, s, $2\,OCH_2$), 1.85 (3H, d, J = 1.8 Hz, CH_3—C3), 1.30 (3H, t, J = 7 Hz, OCH_2CH_3), and 1.07 (3H, d, J = 7 Hz, CH_3—C5); ms *m/e*: 240 (M^+). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 65.00, H 8.33; found: C 64.63, H 8.29.

Ketal Alcohol 6

A solution of crude ketal ester **5** (66 g, 0.27 mol) in ether (200 mL) was slowly added to a suspension of lithium aluminium hydride (7 g) in ether (200 mL) and tetrahydrofuran. The mixture was heated at reflux for 10 h. After cooling to 0°C, water was carefully added to destroy the remaining lithium aluminium hydride followed by saturated sodium sulfate (200 mL) before extraction of the mixture with ether. The organic phase was dried and evaporated to give crude ketal alcohol **6** (48 g); ir ($CHCl_3$): 3350 and 1075 cm^{-1}; nmr ($CDCl_3$) δ: 4.28 (2H, s, CH_2OH), 3.93 (4H, s, $2\,OCH_2$), 1.73 (3H, s, CH_3—C3), and 1.15 (3H, d, J = 6 Hz, CH_3—C5); ms *m/e*: 198 (M^+).

Dienone 7

A solution of crude ketal alcohol **6** (48 g, 0.24 mol) in tetrahydrofuran (200 mL) and 2 *N* hydrochloric acid (200 mL) was stirred at room temperature for 10 h. The mixture was extracted with ether and the organic phase was dried and evaporated to give crude dienone **7** (25 g, 75%). The product was purified by distillation *in vacuo*; bp 65–68°C/0.8 Torr; uv (EtOH) λ_{max}: 273 nm (ε 16 300); ir ($CHCl_3$): 1665 cm^{-1}; nmr ($CDCl_3$) δ: 5.91 (1H, s, H—C2), 5.44 (2H, m, $=CH_2$), 2.86 (1H, m, H—C5), 2.38 (2H, m, H—C6), 2.09 (3H, d, J = 1.5 Hz, CH_3—C3), and 1.20 (3H, d, J = 7 Hz, CH_3—C5); ms *m/e*: 136 (M^+). *Anal.* calcd. for $C_9H_{12}O$: C 79.41, H 8.82; found: C 79.12, H 9.17.

3,4,5-Trimethylphenol

Dienone **7** (100 mg, 0.73 mmol) was added to glacial acetic acid (10 mL) containing perchloric acid (0.6 mL) and the mixture was heated at reflux for 24 h. After cooling, the mixture was basified by the addition of 10% sodium hydroxide and extracted with ether. The aqueous phase was reacidified and extracted with three volumes of ether. The latter organic extracts were dried and evaporated to give 3,4,5-trimethylphenol (60 mg, 60%); mp 109°C (from dichloromethane – petroleum ether); ir ($CHCl_3$): 3590, 3350, 1600, 1480, and 1135 cm^{-1}; nmr ($CDCl_3$) δ: 6.50 (2H, s, aryl—H), 4.60 (1H, br s, O—H), 2.22 (6H, s, $2\,CH_3$ on C3 and C5), and 2.08 (3H, s, CH_3—C4). The spectra of this compound were identical with those of a sample of authentic 3,4,5-trimethylphenol.

Enone Diester 8

Sodium metal (1.5 g) was added to a solution of dienone **7** (34 g, 0.25 mol) and diethyl malonate (48 g, 0.3 mol) in absolute ethanol under a nitrogen atmosphere. The reaction mixture was stirred at room temperature during 18 h and finally for 15 min at reflux. After cooling, water was added and the solution was neutralized with 0.5 *N* hydrochloric acid. Extraction with ether followed by drying and evaporation gave enone diester **8** (68 g, 92%). An analytical sample was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 1725 and 1665 cm^{-1}; nmr ($CDCl_3$) δ: 5.87 (1H, s, H—C2), 4.25 (4H, q, J = 7 Hz, $2\,OCH_2CH_3$), 3.55 (1H, m, $CH(CO_2C_2H_5)$), 2.00 (3H, d, J = 1.5 Hz, CH_3—C3), 1.28 (6H, t, J = 7 Hz, $2\,OCH_2CH_3$), and 1.05 (3H, d, J = 7 Hz, CH_3—C5); ms *m/e*: 296 (M^+). *Anal.* calcd. for $C_{16}H_{24}O_5$: C 64.86, H 8.10; found: C 64.11, H 8.22.

Enone Monocarboxylic Acid 9

Enone diester **8** (25 g, 0.1 mol) was added to hydrochloric acid (2 *N*, 500 mL) and the mixture was refluxed during 20 h. After cooling, the aqueous phase was extracted several times with ether. The combined organic extracts were dried and evaporated to give the crude enone monocarboxylic acid **9**; ir ($CHCl_3$): 3250 and 1725 cm^{-1}; nmr ($CDCl_3$) δ: 10.71 (1H, s, CO_2H), 6.05 (1H, br s, H—C2), 2.03 (3H, d, J = 1.5 Hz, CH_3—C3), and 1.08 (3H, d, J = 7 Hz, CH_3—C5).

Enone Methyl Ester 10

An excess of ethereal diazomethane was added to a solution of the crude enone monocarboxylic acid **9** in ether. The ether was evaporated to leave a yellow oil (22 g). An analytical sample of **10** was prepared by microdistillation *in vacuo*; ir ($CHCl_3$) 1730 and 1655 cm^{-1}; nmr ($CDCl_3$) δ: 6.05 (1H, br s, H—C2), 3.80 (3H, s, OCH_3), 2.03 (3H, d, J = 1.5 Hz, CH_3—C3), and 1.08 (3H, d, J = 7 Hz, CH_3—C5); ms *m/e*: 210 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_3$: C 68.57, H 8.57; found: C 68.80, H 8.58.

Ketal Methyl Ester 11

Enone methyl ester **10** (39 g, 0.18 mol) was dissolved in benzene (1 L) and mixed with ethylene glycol (40 mL) and *p*-toluenesulfonic acid (200 mg). The reaction mixture was refluxed for 40 h using a Dean–Stark water separator. The cooled reaction mixture was washed with saturated sodium carbonate and saturated sodium chloride. The organic phase was dried, the solvent removed by distillation at reduced pressure, and the residue was purified by chromatography on Florisil. Ketal methyl ester **11** (34 g, 72%) was obtained by elution with benzene – petroleum ether (1:1); ir ($CHCl_3$): 1730 and 1070 cm^{-1}; nmr ($CDCl_3$) δ: 3.90 (4H, s, $2\,OCH_2$), 3.65 (3H, s, OCH_3), 1.65 (3H, d, J = 1.5 Hz, CH_3—C3), and 1.08 (3H, d, J = 7 Hz, CH_3—C5); ms *m/e*: 254 (M^+). *Anal.* calcd. for $C_{14}H_{22}O_4$: C 66.14, H 8.66; found: C 66.42, H 8.78.

Ketal Carboxylic Acid 12

Ketal methyl ester **11** (9.0 g, 0.035 mol) was added to a solution of potassium hydroxide (2.2 g) in water (50 mL). The mixture was refluxed during 3 h. After cooling, the reaction mixture was washed with ether, poured into a buffer solution (dipotassium phthalate – sodium hydroxide; pH = 5.5; 3.5 L), and extracted with ether. The organic phase was dried and evaporated to give ketal acid **12** as a difficult to crystallize solid (6 g); mp 72–73°C; ir ($CHCl_3$): 3100 and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 10.71 (1H, s, O—H), 3.98 (4H, s, $2\,OCH_2$), 1.68 (3H, s, CH_3—C3), and 1.10 (3H, d, J = 7 Hz, CH_3—C5). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 65.00, H 8.33; found: C 64.83, H 8.30.

Ketal Diazoketone 14 (via the Acid Chloride 13)

Ketal acid **12** (1.5 g, 6.2 mmol), dissolved in a solution of anhydrous benzene (40 mL) and anhydrous pyridine (0.7 mL), was added to a cooled (0°C) solution of freshly distilled oxalyl chloride (0.55 mL) in benzene (30 mL). The first 20 mL were added dropwise and the last 20 mL were added very rapidly. The mixture was stirred at room temperature for 2 h before filtration through cotton wool directly into a solution of diazomethane (1.5 g) in ether. The solution was immediately stripped of solvent at low temperature and the residue purified by chromatography on Florisil. Ketal diazoketone **14** was obtained as a yellowish oil (1.5 g) by elution with benzene; ir ($CHCl_3$): 2100 and 1645 cm^{-1}; nmr ($CDCl_3$) δ: 5.35 (1H, s, $COCHN_2$), 3.95 (4H, s, $2\,OCH_2$), 1.67 (3H, s, CH_3—C3), and 1.10 (3H, d, J = 7 Hz, CH_3—C5).

Tricyclic Ketal Ketones 15a and 15b

A solution of ketal diazoketone **14** (49.2 g) in anhydrous benzene (300 mL) was added during 1 h to a refluxing mixture of copper powder (18 g) and anhydrous benzene (500 mL) under a nitrogen atmosphere. After an additional 3.5 h at reflux, the mixture was cooled, filtered, and the benzene was evaporated. Potassium hydroxide solution (2 *N*, 700 mL) was added and the mixture was stirred at room temperature for 24 h. After cooling, the mixture was extracted with ether (4 × 250 mL). The organic extracts were dried and evaporated to leave a mixture of **15***a* and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

15*b* (27 g). Vapor phase chromatographic analysis (SE-30 5% on Chromosorb W, 5 ft × ¼ in., 190°C, retention time: **15***a*, 5.2 min and **15***b*, 4.1 min) indicated a mixture of **15***a* and **15***b* in a 9:1 ratio.

A portion of the crude product (3.6 g) was purified by column chromatography with Florisil (benzene–ether, 9:1) to yield pure tricyclic ketal ketone **15***b* (150 mg) and pure tricyclic ketal ketone **15***a* (2.0 g).

Isomer **15**b: mp 62–63°C (ether – petroleum ether); ir ($CHCl_3$): 1700 cm^{-1}; nmr ($CDCl_3$) δ: 3.93 (4H, s, 2 OCH_2), 1.22 (3H, s, CH_3—C6), and 1.05 (3H, d, J = 6.5 Hz, CH_3—C10); ^{13}C nmr ($CDCl_3$): 215.0 (C2), 108.0 (C8), 64.4 (CH_2O), 64.2 (CH_2O), 44.8 (C5 or C6), 43.3 (C10), 42.8 (C3), 38.5 (C7), 38.1 (C9), 30.5 (C1), 29.2 (C5 or C6), 23.5 (C4), 19.3 (secondary CH_3), and 18.9 (tertiary CH_3); ms *m/e*: 236 (M^+).

Isomer **15**a: oil, an attempted microdistillation led to decomposition; ir ($CHCl_3$): 1700 cm^{-1}; nmr ($CDCl_3$) δ: 3.87 (4H, s, 2 OCH_2), 1.19 (3H, s, CH_3—C6), and 1.16 (3H, d, J = 6.5 Hz, CH_3—C10); ^{13}C nmr ($CDCl_3$): 214.9 (C2), 107.8 (C8), 63.8 (CH_2O), 63.7 (CH_2O), 44.7 (C10), 43.1 (C5 or C6), 42.6 (C3), 39.4 (C7), 37.8 (C9), 32.1 (C1), 29.8 (C5 or C6), 24.0 (C4), 18.9 (secondary CH_3), and 18.1 (tertiary CH_3); ms *m/e*: 236 (M^+).

Bicyclic Enediketone ***18***a

Tricyclic ketal ketone **15***a* (320 mg, 1.35 mmol) dissolved in tetrahydrofuran (20 mL) was mixed with aqueous hydrochloric acid (1 *N*, 5 mL) and heated (65°C, oil bath) for 1 h. The mixture was then poured into an excess of aqueous sodium bicarbonate (0.5 *N*) and extracted four times with dichloromethane. The extract was dried, filtered, and evaporated to dryness. Crystallization (ether–pentane) of the crude product (270 mg) and chromatography of the residual mother liquor afforded pure bicyclic enediketone **18***a* (242 mg, 90%); mp 102–102.5°C; ir ($CHCl_3$): 1750, 1670, and 1620 cm^{-1}; nmr ($CDCl_3$) δ: 5.84 (1H, br s, H—C7), 2.1–2.5 (9H, m), 1.94 (3H, d, J = 1.3 Hz, CH_3—C6), and 1.01 (3H, d, J = 6.7 Hz, CH_3—C10); ^{13}C nmr ($CDCl_3$): 216.7 (C2), 197.6 (C8), 163.5 (C6), 127.2 (C7), 48.1 (C10), 47.2 (C5), 42.0 (C9), 38.5 (C1), 36.8 (C3). 27.4 (C4), 21.1 (CH_3—C2), and 15.8 (CH_3—C10). *Anal.* calcd. for $C_{12}H_{16}O_2$: C 75.00, H 8.33; found: C 74.21, H 7.96.

Bicyclic Enediketone ***18***b

(a) From Tricyclic Ketal Ketone ***15***b

Tricyclic ketal ketone **15***b* (70 mg, 0.29 mmol) dissolved in tetrahydrofuran (5 mL) was mixed with hydrochloric acid (1 *N*, 1 mL) and heated (65°C, oil bath) for 1.5 h. The mixture was then poured into an excess of aqueous sodium bicarbonate (0.5 *N*) and extracted four times with dichloromethane. The extract was dried, filtered, and evaporated to dryness. Crystallization (ether–hexane) and chromatography of the residual mother liquor gave pure bicyclic enediketone **18***b* (50 mg, 86%) identical with the product obtained in procedure *b* (from conjugated acid **41**) described below.

(b) From Conjugated Carboxylic Acid ***41***

Conjugated carboxylic acid **41** (1.30 g, 5.9 mmol), dissolved in a solution of anhydrous dichloromethane (50 mL) and anhydrous pyridine (1.0 g), was added dropwise to a cooled (0°C) solution of oxalyl chloride (2.2 g) in dichloromethane (100 mL) under a nitrogen atmosphere. After completion of the addition (1.5 h) the mixture was stirred for an additional 3 h at room temperature. Filtration and evaporation gave the crude acid chloride **42** (1.35 g); ir ($CHCl_3$): 1735, 1655, 1620, and 1602 cm^{-1}; nmr ($CDCl_3$) δ: 7.27 (1H, s, H—C3), 5.85 (1H, s, H—C7), 1.97 (3H, d, J = 1.5 Hz, CH_3—C6), and 1.00 (3H, m, CH_3—C10).

Sodium azide (455 mg) in water (20 mL) was added dropwise to a cooled (0°C) solution of acid chloride **42** (1.35 g, 5.7 mmol) in acetone (20 mL) under a nitrogen atmosphere. The resulting solution was stirred for 3 h before the addition of saturated sodium chloride (100 mL) and extraction with dichloromethane. The organic phase was dried and evaporated to give the crude azide **43** (1.35 g); ir ($CHCl_3$): 2120, 1680, 1655, 1620, and 1605 cm^{-1}; nmr ($CDCl_3$) δ: 6.92 (1H, s, H—C3), 5.83 (1H, s, H—C7), 1.92 (3H, d, J = 1.0 Hz, CH_3—C6), and 0.97 (3H, m, CH_3—C10).

Azide **43** (1.35 g, 5.5 mmol) was added to a solution of tetrahydrofuran (100 mL) and water (100 mL). The mixture was refluxed during 2.5 h. After cooling to 0°C, aqueous hydrochloric acid (1 *N*, 50 mL) was added. The reaction mixture was stirred at 0°C for 2 h before the addition of saturated sodium chloride (100 mL) and extraction with dichloromethane. The organic phase was dried and evaporated. The residue was purified by thick layer chromatography on silica gel with ether–benzene (1:1). An analytical sample of **18***b* was obtained by crystallization from dichloromethane – petroleum ether (771 mg, 68% from conjugated carboxylic acid **41**); mp 68–69°C; uv (EtOH) λ_{max}: 241 nm (ε 14 600); ir ($CHCl_3$): 1730, 1655, and 1610 cm^{-1}; nmr ($CDCl_3$) δ: 5.92 (1H, s, H—C7), 1.98 (3H, d, J = 2.0 Hz, CH_3—C6), and 1.03 (3H, d, J = 6.5 Hz, CH_3—C10); ^{13}C nmr ($CDCl_3$): 216.7 (C2), 197.6 (C8), 163.4 (C6), 127 (C7), 48.0 (C5), 45.9 (C10), 42.1 (C9), 39.0 (C3), 36.7 (C1), 33.3 (C4), 21.6 (CH_3—C6), and 16.7 (CH_3—C10); ms *m/e*: 192 (M^+), 150, and 149. *Anal.* calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.85, H 8.52.

Bicyclic Ketal Enone ***19***a

Bicyclic enediketone **18***a* (790 mg, 4.11 mmol) was dissolved in anhydrous benzene (80 mL), and ethylene glycol (400 mg) and *p*-toluenesulfonic acid (38 mg) were added. The mixture was refluxed for 4 h using a Dean–Stark water separator. The cooled reaction mixture was diluted with ether (100 mL) and washed with aqueous sodium carbonate (10%, 100 mL) and water (100 mL). The organic phase was dried and evaporated to leave an oil which was purified by column chromatography on Florisil with ether–benzene (1:19) (935 mg, 96%). An analytical sample of **19***a* was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 1665, 1620, and 1120 cm^{-1}; nmr ($CDCl_3$) δ: 5.77 (1H, br s, H—C7), 3.92 (4H, s, 2 OCH_2), 1.98 (3H, d, J = 1.5 Hz, CH_3—C6), and 1.00 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 236 (M^+). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.18, H 8.47; found: C 71.31, H 8.80.

Bicyclic Ketal Alcohol ***20***a *and its Acetate* ***21***a

Bicyclic ketal ketone **19***a* (450 mg, 1.9 mmol) dissolved in anhydrous ether (10 mL) was added to a suspension of lithium aluminium hydride (200 mg) in ether (15 mL). The mixture was then refluxed for 6 h and treated with saturated sodium sulfate solution. The aqueous phase was extracted with ether. Drying and evaporation of the organic phase gave ketal alcohol **20***a*; ir ($CHCl_3$): 3600 and 3450 cm^{-1}; nmr ($CDCl_3$) δ: 4.16 (1H, m, C*H*—OH).

The crude ketal alcohol **20***a* was dissolved in pyridine (10 mL) and acetic anhydride (10 mL) and left at room temperature. After 24 h the solvents were evaporated at reduced pressure using a water bath at 45°C. The residue was dissolved in chloroform (25 mL) and the solution was washed with saturated sodium bicarbonate. Drying and evaporation of organic phase gave the crude ketal acetate **21***a* which was purified by thick layer chromatography on silica gel with ether–benzene (1:2); ir ($CHCl_3$): 1715 cm^{-1}; nmr ($CDCl_3$) δ: 5.25 (2H, m, H—C7 and H—C8), 3.91 (4H, s, 2 OCH_2), 2.03 (3H, s, $COCH_3$), 1.80 (3H, s, CH_3—C6), and 1.03 (3H, d, J = 6 Hz, CH_3—C10); ms *m/e*: 280 (M^+).

Bicyclic Ketal Olefin ***22***a

Ketal acetate **21***a* (350 mg, 1.25 mmol) dissolved in ether (12 mL) was added to a solution of lithium (400 mg) in liquid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

ammonia. After stirring for 3 h, solid ammonium chloride was added until the blue color disappeared. The solution was diluted with water and extracted several times with ether. The organic extracts were dried and evaporated. Chromatography of the residue on Florisil gave pure ketal olefin **22***a* (250 mg) as an oil after elution with ether – petroleum ether (9:1); nmr ($CDCl_3$) δ: 5.38 (1H, m, H—C7), 3.89 (4H, s, 2 OCH_2), 1.71 (3H, s, CH_3—C6), and 0.90 (3H, d, J = 1.5 Hz, CH_3—C10). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.68, H 9.91; found: C 76.13, H 9.91.

*Bicyclic Enone 23*a

Purified bicyclic ketal olefin **22***a* (60 mg, 0.27 mmol) was dissolved in a solution of acetone (5 mL) and water (1 mL). *p*-Toluenesulfonic acid (15 mg) was added and the solution was stirred at room temperature. After 5 h the acetone was evaporated at reduced pressure and the residue was extracted with ether. The ether extracts were dried and evaporated. The residue was purified by thick layer chromatography on silica gel with ether–benzene (1:2) to give pure bicyclic enone **23***a* (44 mg) as an oil; nmr ($CDCl_3$) δ: 5.41 (1H, m, H—C7), 1.66 (3H, d, J = 1.5 Hz, CH_3—C6), 0.92 (3H, d, J = 6 Hz, CH_3—C10).

2,4-Dinitrophenylhydrazine (200 mg) was added to methanol (20 mL) containing concentrated sulfuric acid (6 drops). The above solution (10 mL) was added to bicyclic enone **23***a* (87 mg, 0.49 mmol) and the resulting solid was recrystallized five times from methanol (83 mg); mp 107–108°C; ms *m/e*: 358 (M^+). Thick layer chromatography on silica gel with benzene – petroleum ether (1:1) separated two products with R_f 0.64 and 0.49. Heating of either of these products returned the mixture. Analytical samples were prepared by recrystallization from methanol. Compound **I**, R_f 0.64; 43 mg (64%); mp 125–127°C; ms *m/e*: 358 (M^+). *Anal.* calcd. for $C_{18}H_{22}N_4O_4$: C 60.32, H 6.19; found: C 60.42, H 6.22. Compound **II**, R_f 0.49; 20 mg (11%); mp 150–151°C; ms *m/e*: 358 (M^+). *Anal.* calcd. for $C_{18}H_{22}N_4O_4$: C 60.32, H 6.19; found: C 59.45, H 6.20.

*Bicyclic Ketal Enone 19*b

Bicyclic enediketone **18***b* (403 mg, 2.1 mmol) was dissolved in anhydrous benzene (80 mL) and ethylene glycol (300 mg) and *p*-toluenesulfonic acid (23 mg) were added. The mixture was refluxed for 4 h using a Dean–Stark water separator. The cooled reaction mixture was diluted with ether (100 mL) and washed with aqueous sodium carbonate (10%, 100 mL) and water (100 mL). The organic phase was dried and evaporated to leave an oil which was purified by thick layer chromatography on silica gel with ether–benzene (1:1) (393 mg, 80%). An analytical sample of **19***b* was prepared by microdistillation *in vacuo*; uv (EtOH) λ_{max}: 242 nm (ε 13 900); ir ($CHCl_3$): 1650, 1602, and 1110 cm^{-1}; nmr ($CDCl_3$) δ: 5.85 (1H, s, H—C7), 3.97 (4H, s, 2 OCH_2), 2.03 (3H, d, J = 1.5 Hz, CH_3—C6), and 1.03 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 236 (M^+). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.18, H 8.47; found: C 69.51, H 8.57.

*Bicyclic Ketal Alcohol 20*b *and its Acetate 21*b

Lithium tri-*tert*-butoxyaluminium hydride was added to a solution of bicyclic ketal ketone **19***b* (412 mg, 1.75 mmol) in ether (100 mL). The mixture was stirred at room temperature for 18 h before saturated sodium chloride (200 mL) was added and the mixture extracted with ether (2 × 200 mL). The organic extracts were dried and evaporated. The oily residue was purified by thick layer chromatography on silica gel using ether–benzene (1:4) to give bicyclic ketal alcohol **20***b* (343 mg, 83%) as an oil; ir ($CHCl_3$): 3600 and 3460 cm^{-1}; nmr ($CDCl_3$) δ: 5.39 (1H, br s, H—C7), 4.17 (1H, br s, H—C8), 3.92 (4H, s, 2 OCH_2), 2.53 (1H, s, O—*H*), 1.83 (3H, d, J = 1.0 Hz, CH_3—C6), and 1.02 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 238 (M^+).

Bicyclic ketal alcohol **20***b* (350 mg, 1.47 mmol) was dissolved in pyridine (15 mL) and acetic anhydride (10 mL) and stirred in the dark at room temperature. After 5 h the solution was cooled to 0°C and methanol (50 mL) was added. The solvents were evaporated and the residue was diluted with saturated sodium chloride (100 mL) and extracted with dichloromethane (3 × 100 mL). Drying and evaporation of the organic extracts gave the crude acetate **21***b* (395 mg); ir ($CHCl_3$): 1730 and 1250 cm^{-1}; nmr ($CDCl_3$) δ: 5.37 (2H, m, H—C7 and H—C8), 3.92 (4H, s, 2 OCH_2), 2.04 (3H, s, $COCH_3$), 1.84 (3H, br s, CH_3—C6), and 1.05 (3H, d, J = 6 Hz, CH_3—C10); ms *m/e*: 280 (M^+).

*Bicyclic Ketal Olefin 22*b

Ketal acetate **21***b* was reduced during 2 h with lithium in liquid ammonia as described above for ketal acetate **21***a*. The crude product was purified by thick layer chromatography on silica gel using ether–benzene (1:2) to give 125 mg (45%). An analytical sample of **22***b* was prepared by microdistillation *in vacuo*; nmr ($CDCl_3$) δ: 5.40 (1H, br s, H—C7), 3.92 (4H, s, 2 OCH_2), 1.75 (3H, br s, CH_3—C6), and 0.92 (3H, d, J = 7.0 Hz, CH_3—C10); ms *m/e*: 222 (M^+). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.55, H 10.09.

*Bicyclic Enone 23*b

Bicyclic ketal olefin **22***b* (75 mg, 0.34 mmol) was dissolved in a solution of acetone (20 mL) and water (2 mL). *p*-Toluenesulfonic acid (20 mg) was added and the solution was stirred at room temperature. After 5 h, the acetone was evaporated at reduced pressure and the residue was diluted with saturated sodium carbonate solution (50 mL). Extraction with dichloromethane (3 × 50 mL) followed by drying and evaporation gave crude bicyclic ketal olefin **23***b* as an oil. Purification by thick layer chromatography on silica gel using benzene as eluent gave the pure product **23***b* (25 mg, 41%); ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 5.50 (1H, s, H—C7), 1.66 (3H, d, J = 1.0 Hz, CH_3—C6), and 0.90 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 178 (M^+).

A 2,4-dinitrophenylhydrazine solution (3 mL) was added to bicyclic enone **23***b* (25 mg, 0.14 mmol) and the resulting solid was recrystallized from methanol (43 mg); mp 78–88°C. Thick layer chromatography on silica gel with benzene – petroleum ether (1:1; three elutions) separated two products with R_f 0.64 and 0.55. Heating of either of these two products returned the mixture. Each derivative was recrystallized three times from methanol. Compound **I**, R_f 0.64; 21 mg (42%); mp 113–114°C; ms *m/e*: 358 (M^+). Compound **II**, R_f 0.55; 7 mg (14%); mp 160–161°C; ms *m/e*: 358 (M^+).

Tricyclic Ketal β*-Keto Ester 29*

Tricyclic ketal ketone **15***a* (9.5 g, 40.3 mmol) in anhydrous dimethyl carbonate (200 mL) was added to sodium hydride (5.3 g) and the mixture was refluxed under a nitrogen atmosphere during 10.5 h. After cooling to 0°C, a solution of acetic acid (200 mL) in ether (1.2 L) was carefully added. After dilution with water (1 L) the product was extracted with ether (2 × 500 mL). The organic phase was dried and evaporated to leave an amorphous solid (11.85 g); ir ($CHCl_3$): 1725 and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 3.87 (4H, s, 2 OCH_2), 3.75 (3H, s, OCH_3), 1.22 (3H, s, CH_3—C6), and 1.21 (3H, d, J = 7.0 Hz, CH_3—C10); ms *m/e*: 294 (M^+).

Tricyclic Ketal Alcohol Ester 32

Sodium borohydride (1.6 g) was added to a solution of crude tricyclic ketal β-keto ester **29** (6.5 g, 22.1 mmol) in methanol (200 mL) at 0°C. After stirring for 3 h at the same temperature the solvent was evaporated and the residue was treated with saturated sodium chloride solution (300 mL). Extraction with ether (3 × 300 mL) followed by drying and evaporation of the ethereal extracts gave the crude tricyclic ketal alcohol ester **32** as an oil. This was purified by column chromatography on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Florisil using ether–benzene (15:85). An analytical sample of **32** was prepared by microdistillation *in vacuo*; 3.47 g (64% from **15**); ir ($CHCl_3$): 3580, 3460, 1720, and 1100 cm^{-1}; nmr ($CDCl_3$) δ: 4.88 (1H, m, H—C2), 3.86 (4H, s, 2 OCH_2), 3.72 (3H, s, OCH_3), 2.64 (1H, s, O—H), 1.35 (3H, s, CH_3—C6), and 1.06 (3H, d, J = 7 Hz, CH_3—C10); ms *m/e*: 296 (M^+). *Anal.* calcd. for $C_{16}H_{24}O_5$: C 64.84, H 8.17; found: C 64.54, H 8.12.

Tricyclic Ketal Ester Acetate 34

Tricyclic ketal alcohol ester **32** (325 mg, 1.1 mmol) was dissolved in pyridine (3 mL) and acetic anhydride (3 mL). The reaction mixture was stirred in the dark for 18 h. After cooling to 0°C, methanol (20 mL) was added and the solvents were evaporated at reduced pressure. The residue was diluted with water (100 mL) and extracted with dichloromethane (3 × 50 mL). The organic extracts were dried and evaporated to leave a solid. Crystallization from ether – petroleum ether gave pure tricyclic ketal ester acetate **34** (282 mg, 77%); mp 62–63°C; ir ($CHCl_3$): 1750–1720 cm^{-1}; nmr (100 MHz) ($CDCl_3$) δ: 5.68 (1H, t, J = 6.0 Hz, H—C2), 3.85 (4H, s, 2 OCH_2), 3.67 (3H, s, OCH_3), 2.75 (1H, m, H—C3), 2.41–2.03 (3H, m, H2—C1 and H—C10), 2.00 (3H, s, $COCH_3$), 1.86 (2H, s, H2—C7), 1.74 (1H, d, J = 6.0 Hz, H—C4), 1.46 (2H, m, H2—C9), 1.24 (3H, s, CH_3—C6), and 1.07 (3H, d, J = 7.0 Hz, CH_3—C10); ms *m/e*: 338 (M^+), 296, 295, and 278. *Anal.* calcd. for $C_{18}H_{26}O_6$: C 63.89, H 7.74; found: C 63.67, H 7.64.

Tricyclic Ketone Alcohol Ester 36

Hydrochloric acid (1 *N*, 50 mL) was added to a solution of tricyclic ketal alcohol ester **32** (212 mg, 0.74 mmol) in methanol (50 mL). After stirring for 10 min at room temperature the solution was neutralized by the addition of solid sodium carbonate and the methanol was evaporated. The product was extracted with dichloromethane and the organic extracts were dried and evaporated. Thick layer chromatography on silica gel with ether–benzene (1:1) gave tricyclic ketone alcohol ester **36** as an oil (151 mg, 80%). An analytical sample was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 3580, 3460, 1720, and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 4.97 (1H, t, J = 6.0 Hz, H—C2), 3.75 (3H, s, OCH_3), 1.38 (3H, s, CH_3—C6), 1.09 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 252 (M^+), and 238. *Anal.* calcd. for $C_{14}H_{20}O_4$: C 66.65, H 7.99; found: C 66.39, H 8.06.

Tricyclic Ketone Acetate Ester 37

Tricyclic ketone alcohol ester **36** (133 mg, 0.53 mmol) was dissolved in a mixture of pyridine (1.5 mL) and acetic anhydride (1.5 mL) and left for 18 h at room temperature. After evaporation, water was added and the solution was extracted with dichloromethane. The organic extract was dried and evaporated to yield a crystalline product. Crystallization from ether – petroleum ether gave pure tricyclic ketone acetate ester **37** (115 mg, 74%); mp 119–120°C; ir ($CHCl_3$): 1720 (broad) cm^{-1}; nmr ($CDCl_3$) δ: 5.70 (1H, t, J = 6.0 Hz, H—C2), 3.70 (3H, s, OCH_3), 2.02 (3H, s, $COCH_3$), 1.72 (1H, d, J = 6 Hz, H—C4), 1.30 (3H, s, CH_3—C6), and 1.07 (3H, d, J = 6.5 Hz, CH_3—C10).

Dienone Ester 38

(a) From Tricyclic Ketone Alcohol Ester 36

A solution of tricyclic ketone alcohol ester **36** (150 mg, 0.51 mmol) in methanol (10 mL) was added to hydrochloric acid (1 *N*, 10 mL). After stirring for 30 min at room temperature the solvent was evaporated. The residue was diluted with sodium carbonate solution (10%, 100 mL) and extracted with dichloromethane (3 × 100 mL). The organic extracts were dried and evaporated to leave a solid which was recrystallized from petroleum ether to yield dienone ester **38** (91 mg, 77%); mp 78–79°C. The physical and chemical properties of this compound were identical with those of the product obtained in procedure *b*.

(b) From Dienone Carboxylic Acid 39

Ethereal diazomethane (18 mg/mL, 32 mL) was added to a solution of dienone acid **39** (1.73 g, 7.85 mmol) in dichloromethane (100 mL). After stirring for 10 min at room temperature the solvent was evaporated. The solid residue was crystallized from petroleum ether (1.65 g, 90%); mp 78–79°C; uv (EtOH) λ_{max}: 237 nm (ε 15 900); ir ($CHCl_3$): 1725, 1655, and 1610 cm^{-1}; nmr ($CDCl_3$) δ: 6.02 (1H, d of d, J = 6.0, 2.0 Hz, H—C4), 5.83 (1H, s, H—C7), 5.57 (1H, d of d, J = 6.0, 2.5 Hz, H—C3), 3.73 (1H, m, H—C2), 3.73 (3H, s, OCH_3), 1.83 (3H, d, J = 1.5 Hz, CH_3—C6), and 0.90 (3H, m, CH_3—C10); ms *m/e*: 234 (M^+) and 192. *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.75; found: C 71.76, H 8.03.

Dienone Carboxylic Acid 39

(a) From Tricyclic Ketal Alcohol Ester 32

Hydrochloric acid (1 *N*, 400 mL) was added to a solution of tricyclic ketal alcohol ester **32** (12.0 g, 40.5 mmol) in tetrahydrofuran (400 mL). After refluxing for 4 h the solvents were evaporated. The residue was diluted with water (500 mL), basified by the addition of solid potassium hydroxide, and then extracted with ether (2 × 200 mL). The aqueous phase was acidified with concentrated hydrochloric acid and extracted with dichloromethane (3 × 300 mL). The dichloromethane extracts were dried and evaporated. The solid residue was crystallized from ether (7.3 g, 82%); mp 163–165°C; uv (EtOH) λ_{max}: 240 nm (ε 15 800); ir ($CHCl_3$): 3600–2400, 1705, 1655, and 1610 cm^{-1}; nmr ($CDCl_3$) δ: 11.52 (1H, s, OH), 6.07 (1H, d of d, J = 6.0, 2.5 Hz, H—C4), 5.70 (1H, br s, H—C7), 5.59 (1H, d of d, J = 6.0, 2.5 Hz, H—C3), 3.92 (1H, m, H—C2), 1.85 (3H, d, J = 1.5 Hz, CH_3—C6), and 0.92 (3H, m, CH_3—C10); ms *m/e*: 220 (M^+). *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.64, H 7.11.

(b) From Tricyclic Ketone Alcohol Ester 36

Treatment of tricyclic ketone alcohol ester **36** under the conditions of procedure *a* gave the dienone carboxylic acid **39** in 84% yield; mp 163–164°C.

(c) From Dienone Ester 38

Treatment of dienone ester **38** under the conditions of procedure *a* gave the dienone carboxylic acid **39** in 94% yield; mp 163–165°C.

Conjugated Ester 40

Sodium methoxide (200 mg) was added to a solution of dienone ester **38** (1.45 g, 6.2 mmol). After refluxing for 6 h the solvent was evaporated. The residue was diluted with water (100 mL) and extracted with ether (3 × 100 mL). The organic extracts were dried and evaporated to leave an oil which was purified by thick layer chromatography on silica gel with ether–benzene (1:3) (1.18 g, 82%). An analytical sample of **40** was prepared by microdistillation *in vacuo*; uv (EtOH) λ_{max}: 235 nm (ε 17 500); ir ($CHCl_3$): 1705, 1655, 1610, and 1240 cm^{-1}; nmr ($CDCl_3$) δ: 6.84 (1H, br s, H—C3), 5.84 (1H, s, H—C7), 3.80 (3H, s, OCH_3), 1.95 (3H, d, J = 1.5 Hz, CH_3—C6), and 1.00 (3H, m, CH_3—C10); ms *m/e*: 234 (M^+) and 192. *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.75; found: C 71.77, H 7.88.

Conjugated Carboxylic Acid 41

Conjugated carboxylic acid **41** was obtained from conjugated ester in 88% yield following the procedure employed for the preparation of dienone carboxylic acid **39**. An analytical sample was prepared by recrystallization from dichloromethane – petroleum ether; mp 151°C; uv (EtOH) λ_{max}: 238 (ε 13 600); ir ($CHCl_3$): 3600–2400, 1675, 1655, 1635, and 1605 cm^{-1}; nmr ($CDCl_3$) δ: 10.55 (1H, s, O—H), 6.84 (1H, br s, H—C3), 5.79 (1H, d, J = 1.0 Hz, H—C7), 1.95 (3H, d, J = 1.0 Hz, CH_3—C6), 0.98 (3H, m, CH_3—C10); ms *m/e*: 220 (M^+) and 178. *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.22, H 7.22.

Allylic Alcohol Ester ***44***

Lithium tri-*tert*-butoxyaluminium hydride (1.7 g) was added to a solution of dienone ester **38** (500 mg, 2.14 mmol) in ether (100 mL). The mixture was stirred at room temperature for 4 h before hydrochloric acid (1 *N*, 200 mL) was added and the mixture extracted with ether (2 × 200 mL). The organic extracts were dried and evaporated. The oily residue was purified by thick layer chromatography on silica gel with ether–benzene (1:1) to give allylic alcohol ester **44** (310 mg, 62%) as an oil; ir ($CHCl_3$): 3600, 3450, and 1720 cm^{-1}; nmr ($CDCl_3$) δ: 5.84 (1H, d of d, J = 5.5, 2.0 Hz, H—C4), 5.42 (1H, br s, H—C7), 5.34 (1H, d of d, J = 5.5, 2.5 Hz, H—C3), 4.20 (1H, br s, H—C8), 3.70 (3H, s, OCH_3), 2.74 (1H, s, OH), 1.60 (3H, m, CH_3—C6), and 0.82 (3H, d, J = 6.0 Hz, CH_3—C10); ms *m/e*: 236 (M^+) and 218.

Bicyclic Diol ***47***

(a) From Allylic Alcohol Ester ***44***

Anhydrous ether (20 mL) and magnesium metal (250 mg) were placed in a dried flask under a positive pressure of nitrogen. A solution of methyl iodide (3.0 g) in anhydrous ether (25 mL) was added dropwise. A solution of allylic alcohol **44** (310 mg, 1.31 mmol) in anhydrous ether was then added at such a rate that maintained a gentle reflux. After the addition was completed, the mixture was refluxed for an additional 2 h before pouring it onto crushed ice (100 g) and extraction with ether (3 × 150 mL). The ethereal phase was dried and evaporated. The residue was crystallized from ether–pentane to give bicyclic diol **47** (222 mg, 72%) whose physical and spectral properties were identical with those of the product obtained by procedure *b* below.

(b) From Bicyclic Dienone Alcohol ***49***

Lithium aluminium hydride (300 mg) was added to a solution of bicyclic dienone alcohol **49** (578 mg, 2.47 mmol) in anhydrous ether (100 mL). The mixture was refluxed for 5 h. After cooling, water (200 mL) was added slowly and the resulting mixture extracted with ether (3 × 200 mL). The organic extracts were dried and evaporated. The solid residue was crystallized from ether–pentane to give bicyclic diol **47** (512 mg, 88%) and an analytical sample was prepared by recrystallization from the same solvent mixture; mp 118–120°C; ir ($CHCl_3$): 3600 and 3440 cm^{-1}; nmr ($CDCl_3$) δ: 5.90 (1H, d of d, J = 6.0, 2.0 Hz, H—C4), 5.42 (3H, s, CH_3—C7), 5.40 (1H, d of d, H—C3), 4.28 (1H, m, H—C8), 2.92 (1H, m, H—C2), 2.08 (2H, s, O—H), 1.63 (3H, s, CH_3—C6), 1.21 and 1.17 (total 6H, two s, isopropyl methyls), and 0.88 (3H, d, J = 6.0 Hz, CH_3—C10); ms *m/e*: 236 (M^+), 218, and 200. *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.23, H 10.24; found: C 76.35, H 10.35.

Tricyclic Ketal Diol ***48***

Anhydrous ether (50 mL) and magnesium metal (1.5 g) were placed in a dried flask under a positive pressure of nitrogen. A solution of methyl iodide (11 g) in anhydrous ether (50 mL) was added at a rate that maintained a gentle reflux. A solution of tricyclic ketal alcohol ester **32** (2.32 g, 7.9 mmol) in anhydrous ether (100 mL) was then added dropwise. After the addition was completed the mixture was refluxed for 3 h, allowed to cool, and poured onto a mixture of crushed ice and ammonium sulfate (200 g). Extraction with ether (3 × 200 mL) followed by drying and evaporation gave an oil which was purified by thick layer chromatography on silica gel with ether methanol (95:5) yielding tricyclic ketal diol **48**: (2.05 g, 88%); ir ($CHCl_3$): 3610 and 3460 cm^{-1}; nmr ($CDCl_3$) δ: 4.80 (1H, m, H—C2), 3.90 (4H, s, 2 OCH_2), 1.38 (3H, s, CH_3—C6), 1.24 and 1.20 (total 6H, two s, isopropyl methyls), and 1.09 (3H, d, J = 7.0 Hz, CH_3—C10); ms *m/e*: 296 (M^+) and 278.

Bicyclic Dienone Alcohol ***49***

Hydrochloric acid (2 *N*, 13 mL) was added to a solution of tricyclic ketal diol **48** (1.47 g, 5.14 mmol) in freshly distilled tetrahydrofuran (200 mL). After refluxing for 4 h under a positive pressure of nitrogen the solvent was evaporated. The residue was mixed with saturated sodium chloride (100 mL) and extracted with chloroform (3 × 100 mL). The chloroform extracts were dried and evaporated. The oily residue was purified by chromatography on Florisil and the crystalline compound **49** was obtained by elution with ether–benzene (1:3) (944 mg, 81%). An analytical sample was prepared by recrystallization from ether–pentane; mp 65–66°C; uv (EtOH) λ_{max}: 239 nm (ε 15 200); ir ($CHCl_3$): 3600, 3450, and 1665 cm^{-1}; nmr ($CDCl_3$) δ: 6.05 (1H, d of d, J = 6.0, 2.0 Hz, H—C4), 5.85 (1H, d, J = 1.0 Hz, H—C7), 5.62 (1H, d of d, J = 6.0, 3.0 Hz, H—C3), 3.02 (1H, m, H—C2), 2.08 (1H, s, O—H), 1.88 (3H, d, J = 1.0 Hz, CH_3—C6), 1.27 and 1.23 (total 6H, two s, isopropyl methyls), and 0.97 (3H, m, CH_3—C10); ms *m/e*: 234 (M^+) and 216. *Anal.* calcd. for $C_{15}H_{22}O_2$: C 76.88, H 9.46; found: C 77.13, H 9.63.

Bicyclic Monoacetate Alcohol ***50***

Bicyclic diol **47** (236 mg, 1.0 mmol) was dissolved in pyridine (5 mL) and acetic anhydride (5 mL) and left at room temperature in the dark. After 3 h the solvents were evaporated at reduced pressure and the residue was diluted with water (50 mL). Extraction with ether (3 × 50 mL) followed by drying and evaporation of the organic extracts gave the crude product. Purification by thick layer chromatography on silica gel using ether–benzene (1:10) gave pure bicyclic monoacetate alcohol **50** (252 mg, 91%). An analytical sample was prepared by recrystallization from ether–pentane; mp 84–85°C; ir ($CHCl_3$): 3600, 3450, 1715, and 1245 cm^{-1}; nmr ($CDCl_3$) δ: 5.87 (1H, d of d, J = 6.0, 2.0 Hz, H—C4), 5.33 (1H, d of d, J = 6.0, 2.5 Hz, H—C3), 5.23 (1H, br s, H—C7), 5.17 (1H, br s, H—C8), 2.83 (1H, m, H—C2), 1.98 (3H, s, $COCH_3$), 1.63 (3H, br s, CH_3—C6), 1.18 and 1.12 (6H, two s, isopropyl methyls), and 1.90 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 278 (M^+) and 218. *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.60, H 9.69.

(±)Epihinesol (3)

(a) From Bicyclic Diol ***47***

Finely divided lithium metal (70 mg) was added to ethylamine (25 mL). After 20 min a solution of bicyclic diol **47** (55 mg, 0.23 mmol) in ether was added. After stirring for 2.5 h, solid ammonium chloride was added until the blue color of the reaction mixture had just disappeared. The amine was evaporated and water (50 mL) was added to the residue. Extraction with ether (2 × 50 mL) followed by drying and evaporation of the organic phase gave the crude product. Purification by thick layer chromatography on silica gel using ether–benzene gave (±)-epihinesol (**3**) (29 mg, 56%) whose physical and chemical properties were identical with those of the product obtained by procedure *b* below.

(b) From Bicyclic Alcohol Acetate ***50***

(±)Epihinesol (**3**) was obtained from bicyclic monoacetate alcohol **50** in 92% yield by the procedure described above in *a*; ir ($CHCl_3$): 3600 and 3400 cm^{-1}; nmr ($CDCl_3$) δ: 5.05 (1H, m, H—C7), 1.66 (3H, d, J = 1.15 Hz, CH_3—C6), 1.15 (6H, s, isopropyl methyls), and 0.90 (3H, d, J = 6.5 Hz, CH_3—C10); ^{13}C nmr (CCl_4): 141.35 (C6), 122.25 (C7), 72.53 (C13), 54.79 (C2), 37.17 (C1 or C3), 33.79 (C5), 31.45 (C9), 30.09 (C1 or C3), 28.98 (C14 and C15), 28.59 (C4), 26.38 (C10), 24.18 (C11), 22.23 (C8), and 17.09 (C12); ms *m/e*: 222 (M^+) and 204.

Epihinesol Acetate ***51***

Sodium acetate (100 mg) was added to a solution of (±)-epihinesol (**3**) (84 mg, 0.38 mmol) in acetic anhydride (4 mL) and the mixture was heated to reflux. After 5 h the mixture was cooled to room temperature, saturated sodium carbonate (100 mL) was added, and the mixture was extracted with chloroform (3 × 100 mL). The organic extracts were dried and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

evaporated to leave an oily residue which was purified by thick layer chromatography on silica gel using benzene. The purified product (77 mg, 77%) revealed the presence of only one component by vpc analysis; ir ($CHCl_3$): 1720 and 1270 cm^{-1}; nmr ($CDCl_3$) δ: 5.05 (1H, br s, H—C7), 1.90 (3H, s, $COCH_3$), 1.66 (3H, d, J = 1.5 Hz, CH_3—C6), 1.43 (6H, s, isopropyl methyls), and 0.90 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 264 (M^+) and 204.

Epihinesol Expoxide ***52***

A solution of *m*-chloroperbenzoic acid (195 mg) in chloroform (5 mL) was added to (±)epihinesol (**3**) (193 mg, 0.87 mmol) in chloroform (10 mL). After 36 h at 0°C the reaction mixture was diluted with chloroform (150 mL) and washed with saturated sodium carbonate (50 mL). The organic phase was dried and evaporated. The residue was purified by crystallization from petroleum ether (165 mg, 75%). An analytical sample of **52** was prepared by recrystallization from the same solvent; mp 94–95°C; ir ($CHCl_3$): 3600, 3460, and 800 cm^{-1}; nmr ($CDCl_3$) δ: 2.94 (1H, t, J = 2.5 Hz, H—C7), 1.31 (3H, s, CH_3—C6), 1.23 (6H, s, isopropyl methyls), and 0.82 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 238 (M^+). *Anal.* calcd. for $C_{15}H_{26}O_2$: C 75.58, H 11.00; found: C 75.36, H 10.82.

Dehydro β-Vetivone ***53***

p-Toluenesulfonic acid (1.4 g) was added to a solution of bicyclic dienone alcohol **49** (1.4 g, 6.0 mmol) in dry benzene (200 mL). The reaction mixture was refluxed for 4 h under a positive pressure of nitrogen. The cooled reaction mixture was diluted with saturated sodium carbonate (100 mL) and extracted with ether (2 × 100 mL). The organic extracts were decolorized with activated carbon and dried. Evaporation of the solvents left an oil which was purified by thick layer chromatography on silica gel using ether–benzene (1:9) to give crystalline dehydro β-vetivone **53** (1.03 g, 80%). An analytical sample was prepared by recrystallization from pentane; mp 79–80°C; uv (EtOH) λ_{max}: 244 nm (ε 16 800); ir ($CHCl_3$): 1665 and 1625 cm^{-1}; nmr ($CDCl_3$) δ: 6.65 (1H, d, J = 5.5 Hz, H—C4), 5.90 (1H, s, H—C7), 5.67 (1H, d, J = 5.5 Hz, H—C3), 1.88 (9H, m, CH_3—C6 and geminal methyls), and 0.87 (3H, m, CH_3—C10); ms *m/e*: 216 (M^+). *Anal.* calcd. for $C_{15}H_{20}O$: C 83.29, H 9.32; found: C 83.08, H 9.38.

Bicyclic Allylic Alcohol ***54***

Lithium tri-*tert*-butoxyaluminium hydride (5.0 g) was added to a solution of dehydro β-vetivone **53** (850 mg, 3.93 mmol) in anhydrous ether. The mixture was refluxed for 7 h. Saturated sodium chloride was added to the cooled reaction mixture followed by extraction with dichloromethane (3 × 200 mL). The organic extracts were dried and evaporated. The unstable residue was purified by thick layer chromatography on silica gel using ether–benzene (1:1) to give crystalline bicyclic allylic alcohol **54** (577 mg, 67%). An analytical sample was prepared by recrystallization from purified pentane (mp 100–101°C); ir ($CHCl_3$): 3600 and 3450 cm^{-1}; nmr ($CDCl_3$) δ: 6.55 (1H, d, J = 5.5 Hz, H—C4), 5.55 (1H, d, J = 5.5 Hz, H—C3), 5.48 (1H, br s, H—C7), 4.28 (1H, m, H—C8), 1.73 (6H, br s, geminal methyls), 1.58 (3H, br s, CH_3—C6), and 0.78 (3H, d, J = 6.0 Hz, CH_3—C10); ms *m/e*: 218 (M^+) and 200. *Anal.* calcd. for $C_{15}H_{22}O$: C 82.52, H 10.15; found: C 80.96, H 10.26.

Allylic Alcohol ***55***

Lithium tri-*tert*-butoxyaluminium hydride (1.5 g) was added to a solution of conjugated ester **40** (348 mg, 1.47 mmol) in ether (100 mL). The mixture was stirred at room temperature for 4 h before hydrochloric acid (1 *N*, 100 mL) was added and the mixture extracted with ether (2 × 200 mL). The organic extracts were dried and evaporated. The oily residue was purified by thick layer chromatography on silica gel using ether–benzene (1:1) to give allylic alcohol **55** (310 mg, 88%) as an oil; uv (EtOH) λ_{max}: 224 nm (ε 8 600); ir ($CHCl_3$): 3580, 3460, and 1700 cm^{-1}; nmr ($CDCl_3$) δ: 6.75 (1H, m, H—C3), 5.41 (1H, m, H—C7), 4.25 (1H, m, H—C8), 3.77 (3H, s, OCH_3), 1.67 (3H, m, CH_3—C6), 0.90 (3H, d, J = 6.0 Hz, CH_3—C10); ms *m/e*: 236 (M^+) and 218.

Allylic Acetate ***56***

Allylic alcohol **55** (150 mg, 0.63 mmol) was dissolved in pyridine (4.8 mL) and acetic anhydride (2.4 mL) and the reaction mixture was left in the dark for 24 h. Methanol (10 mL) was carefully added followed by evaporation *in vacuo*. The residue was diluted with saturated sodium chloride (100 mL) and the mixture extracted with dichloromethane (2 × 100 mL). The organic extracts were dried and evaporated to leave an oily residue which was purified by thick layer chromatography on silica gel using ether–benzene (1:5) to give pure allylic acetate **56** (133 mg, 76%); uv (EtOH) λ_{max}: 222 nm (ε 8 500); ir ($CHCl_3$): 1720 and 1705 cm^{-1}; nmr ($CDCl_3$) δ: 6.77 (1H, br s, H—C3), 5.35 (2H, m, H—C7 and H—C8), 3.78 (3H, s, OCH_3), 2.06 (3H, s, $COCH_3$), 1.68 (3H, m, CH_3—C6), and 0.71 (3H, d, J = 6.0 Hz, CH_3—C10); ms *m/e*: 278 (M^+) and 218.

Diene Ester ***57***

(a) From Allylic Alcohol ***55***

A solution of allylic alcohol **55** (124 mg, 0.52 mmol) in ethyl acetate was added to a rapidly stirred, prehydrogenated mixture of 10% palladium on carbon (35 mg) and ethyl acetate (10 mL) under a hydrogen atmosphere. The theoretical amount of hydrogen (11.8 mL) was consumed during 32 min and the mixture was filtered immediately with the aid of Celite. Evaporation of the filtrate and purification of the oily residue by thick layer chromatography on silica gel using ether–benzene (1:1) gave pure diene ester **57** (78 mg, 68%); uv (EtOH) λ_{max}: 225 nm (ε 6 950); ir ($CHCl_3$): 1700 and 1625 cm^{-1}; nmr ($CDCl_3$) δ: 6.73 (1H, br s, H—C3), 5.35 (1H, br s, H—C7), 3.75 (3H, s, OCH_3), 1.77 (3H, m, CH_3—C6), and 0.78 (3H, m, CH_3—C10); ms *m/e*: 220 (M^+).

(b) From Allylic Acetate ***56***

Allylic acetate **56** (65 mg, 0.23 mmol) was hydrogenated following procedure *a*. The purified product (33 mg, 64%) was obtained after thick layer chromatography on silica gel using ether–benzene (1:2). The physical and chemical properties of diene ester were identical to those of the product obtained from allylic alcohol **55**.

Tricyclic Ketal Conjugated Methyl Ester ***58***

(a) From Tricyclic Ketal Ester Acetate ***34***

Maleic anhydride (147 mg, 1.5 mmol) was added to a stirred solution of potassium *tert*-butoxide (purified by sublimation; 340 mg, 3 mmol) in anhydrous *tert*-butanol under a positive pressure of nitrogen. After a few minutes, tricyclic ketal ester acetate **34** (506 mg, 1.5 mmol) was added and the mixture was refluxed for 3 days. After cooling, the reaction mixture was added to brine (30 mL) and extracted with ether (3 × 20 mL). The organic extracts were washed with saturated sodium chloride (3 × 2 mL), dried, and the solvent evaporated to give pure crystalline **58** (416 mg, quantitative). An analytical sample was prepared by recrystallization from pentane (mp 67.5–68°C; uv (EtOH) λ_{max}: 265 nm (ε 8 350); ir ($CHCl_3$): 1707 and 1620 cm^{-1}; nmr ($CDCl_3$) δ: 6.76 (1H, br d of d, J = 4, 2 Hz, H—C2), 3.91 (4H, s, 2 OCH_2), 3.72 (3H, s, OCH_3), 1.11 (3H, d, J = 6.5 Hz, CH_3—C10), and 0.86 (3H, s, CH_3—C6); ms *m/e*: 278 (M^+). *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 69.16, H 8.34.

In another experiment using the following conditions, potassium *tert*-butoxide (228 mg, 1.94 mmol), freshly sublimed maleic anhydride (63 mg, 0.65 mmol), dry *tert*-butanol (23 mL), and tricyclic ketal ester acetate **34** (240 mg, 0.735 mmol), it was

found that compound **34** was converted into compound **58** (88%) after 1 h at room temperature.

(b) From Tricyclic Ketal Conjugated Carboxylic Acid 64

Ethereal diazomethane was added to a solution of tricyclic ketal conjugated carboxylic acid **64** (33 mg, 0.12 mmol) in ether (5 mL) until the yellow color persisted. After 20 min at room temperature the solvent was evaporated to leave tricyclic ketal conjugated methyl ester **58** in quantitative yield, identical with the material obtained from tricyclic ketal ester acetate **34** in *a* above.

Tricyclic Ketal Isopropylol 59

Methyl lithium (2 *M* in ether; 3 mL, 6 mmol) was added dropwise to a solution of tricyclic ketal conjugated methyl ester **58** (123 mg, 0.44 mmol) in anhydrous ether (15 mL) at 0°C under a positive pressure of nitrogen. The solution was stirred at 0°C for 20 min and then at room temperature. After 18 h the mixture was cooled to 0°C and water (25 mL) was added dropwise. Extraction with ether (3 × 15 mL) followed by drying and evaporation gave the desired tricyclic ketal isopropylol **59** (119 mg, 97%). An analytical sample was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 3605, 3470, and 1660 cm^{-1}; nmr ($CDCl_3$) δ: 5.56 (1H, m, H—C2), 3.89 (4H, s, 2 OCH_2), 1.33 (6H, s, isopropyl methyls), 1.11 (3H, d, J = 7 Hz, CH_3—C10), 0.83 (3H, s, CH_3—C6); ms *m/e*: 278 (M^+). *Anal.* calcd. for $C_{17}H_{26}O_3$: C 73.35, H 9.41; found: C 73.31, H 9.51.

Diene Diol 62

Methyl lithium (2 *M* in ether; 4.4 mL, 8.8 mmol) was added dropwise to a solution of diene alcohol ester **77** (134 mg, 0.57 mmol) in anhydrous ether (20 mL) at 0°C under a positive pressure of nitrogen. The solution was stirred 2 h at 0°C and then at room temperature. After 20 h the mixture was cooled to 0°C and saturated sodium chloride solution (20 mL) was added dropwise. The phases were separated and the aqueous phase was extracted with ether (3 × 10 mL). The combined organic extracts were dried and evaporated to give diene diol **62** as an oil. The product was purified by column chromatography on silica gel using ether. An analytical sample was prepared by microdistillation *in vacuo* (125 mg, 93%); ir ($CHCl_3$): 3610, 3450, 1665, and 1610 cm^{-1}; nmr ($CDCl_3$) δ: 5.96 (1H, d of d, J = 5.5, 1.75 Hz, H—C4), 5.5 (1H, m, H—C7), 5.50 (1H, d of d, J = 5.5, 3 Hz, H—C3), 4.3 (1H, m, H—C8), 1.66 (3H, m, CH_3—C6), 1.25 and 1.19 (total 6H, two s, isopropyl methyls), and 0.85 (3H, d, J = 6 Hz, CH_3—C10); ms *m/e*: 218 (M^+ − 18), 203 (M^+ − (18 + 15)), and 200 (M^+ − 36). *Anal.* calcd. for $C_{15}H_{24}O_2$: C 76.23, H 10.24; found: C 75.97, H 10.12.

Diene Alcohol Acetate 63

Diene diol **62** (125 mg, 0.53 mmol) was dissolved in pyridine (4 mL) and acetic anhydride (3.5 mL) and the reaction mixture was left in the dark under a positive pressure of nitrogen for 18 h. After cooling to 0°C, methanol was carefully added. The mixture was left to warm to room temperature before the addition of water (25 mL) and extraction with ether (4 × 15 mL). The organic extracts were washed with saturated sodium chloride (3 × 2 mL), dried, and evaporated to leave a yellow oil. Filtration through a column of silica gel with ether–benzene (1:1) gave crystalline diene alcohol acetate **63** (131 mg, 89%). An analytical sample was prepared by recrystallization from ether–pentane; mp 104–104.5°C; ir ($CHCl_3$): 3600, 3470, 1730, and 1667 cm^{-1}; nmr ($CDCl_3$) δ: 5.94 (1H, d of d, J = 5.75, 1.5 Hz, H—C4), 5.48 (1H, d of d, J = 6, 2.5 Hz, H—C3), 5.4 (2H, m, H—C7 and H—C8), 2.06 (3H, s, CH_3CO), 1.67 (3H, m, CH_3—C6), 1.27 and 1.20 (total 6H, two s, isopropyl methyls), 0.85 (3H, d, J = 6Hz, CH_3—C10); ms *m/e*: 278 (M^+).

Tricyclic Ketal Alcohol Carboxylic Acid 65

Aqueous sodium hydroxide (50%; 3 mL) was added to a stirred solution of tricyclic ketal alcohol ester **32** (312 mg, 1.05 mmol) in methanol (3 mL). After 4 h at room temperature, the methanol was evaporated and water (30 mL) was added. The mixture was extracted with ether, the aqueous phase acidified to pH = 6 with dilute hydrochloric acid and then extracted with dichloromethane (4 × 20 mL). The latter extracts were dried and evaporated to leave tricyclic ketal alcohol carboxylic acid **65** as a white solid (167 mg, 56%); mp 110–111°C; ir ($CHCl_3$): 3600, 3500–2500, and 1710 cm^{-1}; nmr ($CDCl_3$) δ: 6.77 (2H, br s, OH and CO_2H), 4.87 (1H, m, H—C2), 3.86 (4H, s, 2 OCH_2), 1.33 (3H, s, CH_3—C6), and 1.08 (3H, d, J = 6.5 Hz, CH_3—C10); ms *m/e*: 282 (M^+).

Tricyclic Ketal Conjugated Carboxylic Acid 64 and Tricyclic Ketal Alcohol Carboxylic Acid 65

Tricyclic ketal ester acetate **34** (103 mg, 0.3 mmol) was added to a solution of potassium *tert*-butoxide (104 mg, 0.9 mmol) in dry *tert*-butanol under a positive pressure of nitrogen. The mixture was refluxed for 30 h, cooled to 0°C, and brine (20 mL) was added. The mixture was extracted with ether (3 × 10 mL) which was washed with saturated sodium chloride, dried, and evaporated to give only *tert*-butanol. The aqueous phase was made slightly acidic (pH = 6–7) with dilute hydrochloric acid and extracted with ether (4 × 15 mL). These extracts were washed with saturated sodium chloride, dried, and evaporated to give tricyclic ketal conjugated carboxylic acid **64** (41 mg, 51%); ir ($CHCl_3$): 3500–2500, 1680, and 1620 cm^{-1}; nmr ($CDCl_3$) δ: 6.84 (1H, m, H—C2), 3.87 (4H, s, 2 OCH_2), 1.12 (3H, d, J = 7 Hz, CH_3—C10), and 0.87 (3H, s, CH_3—C6). The aqueous phase was further acidified to pH = 4 and extracted with ether (4 × 15 mL). These extracts were washed with saturated sodium chloride, dried, and evaporated to give tricyclic ketal alcohol carboxylic acid **65** (30 mg, 35%).

Tricyclic Ketal Conjugated tert-*Butyl Ester 66*

The procedure employed above for the preparation of the analogous methyl ester **58** was followed. In this case the following quantities were used; potassium *tert*-butoxide (792 mg, 7 mmol), *tert*-butanol (16 mL), maleic anhydride (232 mg, 2.36 mmol), and tricyclic ketal ester acetate **34** (800 mg, 2.36 mmol). A 5-day reaction time was used. The title compound was obtained in quantitative yield and could be crystallized with difficulty from pentane (mp 33–34°C). An analytical sample was prepared by microdistillation *in vacuo*; uv (EtOH) λ_{max}: 251 nm (ε 7 550); ir ($CHCl_3$): 1705 and 1627 cm^{-1}; nmr ($CDCl_3$) δ: 6.66 (1H, m, H—C2), 3.93 (4H, s, 2 OCH_2), 1.48 (9H, s, O—*tert*-butyl), 1.12 (3H, d, J = 7 Hz, CH_3—C10), and 0.87 (3H, s, CH_3—C6); ms *m/e*: 320 (M^+). *Anal.* calcd. for $C_{19}H_{28}O_4$: C 71.22, H 8.81; found: C 71.60, H 8.85.

Tricyclic Ketal Diol 67

Tricyclic ketal alcohol ester **32** (367 mg, 1.24 mmol) was added to a suspension of lithium aluminium hydride (170 mg) in anhydrous ether (100 mL). The mixture was heated at reflux for 5 h. After cooling, water (50 mL) was carefully added to destroy the remaining lithium aluminium hydride followed by saturated sodium chloride (100 mL) before extraction with ether (4 × 150 mL). The organic phase was dried and evaporated to leave an oily residue from which diol **67** (160 mg, 48%) was crystallized using ether. An analytical sample was prepared by crystallization from the same solvent (mp 114–115°C); ir ($CHCl_3$): 3580 and 3400 cm^{-1}; nmr ($CDCl_3$) δ: 5.47 (1H, m, H—C2), 3.88 (4H, s, 2 OCH_2), 3.60 (2H, m, CH_2—OH), 2.83 (2H, br s, 2 OH), 1.35 (3H, s, CH_3—C6), and 1.04 (3H, d, J = 7.0 Hz, CH_3—C10); ms *m/e*: 268 (M^+). *Anal.* calcd. for $C_{15}H_{24}O_4$: C 67.14, H 9.01; found: C 67.06, H 8.78.

Tricyclic Ketal Alcohol Mesylate 68

Tricyclic ketal diol **67** (77.2 mg, 0.29 mmol) was added to a solution of methane sulfonyl chloride (24.5 μL, 0.32 mmol) and pyridine (56 μL, 0.43 mmol) in dichloromethane maintained at 0°C. After an additional 3 days at 0°C, sodium bicarbonate solution (20%; 15 mL) was added, the mixture was extracted with dichloromethane (3 × 10 mL), and the organic extracts were washed with saturated sodium chloride until the aqueous wash was neutral. The organic phase was dried and evaporated to leave a mixture of starting material and the monomesylate **68**. The mixture was separated by thick layer chromatography on silica gel using ether to give tricyclic ketal diol **67** (33 mg) and tricyclic ketal alcohol mesylate **68** (51 mg, 51%). An analytical sample was not prepared due to the high lability of the product; ir ($CHCl_3$): 3600, 3460, 1365, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 4.45 (1H, m, H—C2), 4.20 (2H, d, J = 5.75 Hz, CH_2—OSO_2), 3.87 (4H, s, 2 OCH_2), 3.03 (3H, s, —OSO_2—CH_3), 1.34 (3H, s, CH_3—C6), and 1.06 (3H, d, J = 6.5 Hz, CH_3—C10).

Tricyclic Ketal Acetate Mesylate 69

The crude product (**67** and **68**, 166 mg) obtained from the mesylation of tricyclic ketal diol **67** (104 mg, 0.4 mmol) was dissolved in dry pyridine (3 mL) and acetic anhydride (2.5 mL) was added. After 18 h in the dark at room temperature, the solution was cooled to 0°C and methanol (2.5 mL) was carefully added. The solution was left to warm to room temperature before water (20 mL) was added and the mixture was extracted with ether (4 × 15 mL). The organic extracts were washed with brine (4 × 2 mL), dried, and evaporated to leave a mixture of diacetate and acetate mesylate **69**. The mixture was separated by thick layer chromatography on silica gel using ether to give the diacetate (57.5 mg) of **67** and tricyclic ketal acetate mesylate **69** (88 mg, 58% from diol **67**); ir ($CHCl_3$): 1730, 1365, and 1180 cm^{-1}; nmr ($CDCl_3$) δ: 5.39 (1H, m, H—C2), 4.23 (2H, d, J = 5 Hz, CH_2—OSO_2—), 3.88 (4H, s, 2 OCH_2), 3.04 (3H, s, —OSO_2—CH_3), 2.05 (3H, s, $COCH_3$), 1.29 (3H, s, CH_3—C6), and 1.10 (3H, d, J = 6.5 Hz, CH_3—C10).

Equilibration of Dienone Esters 76 and 38

Sodium methoxide (125 mg, 2.3 mmol) was added to dienone ester **38** (478 mg, 2 mmol) in anhydrous methanol (60 mL) and the mixture was left at room temperature for 4 h under an atmosphere of nitrogen. The methanol was evaporated, water (50 mL) was added and the mixture was extracted with ether (4 × 30 mL). The organic extract was washed with water, dried, filtered, and evaporated to yield a mixture (478 mg) of dienone ester **76** and **38** in a 7:3 ratio. Column chromatography with silica gel using benzene–ether (98:2) gave pure dienone ester **76** (175 mg) followed by a mixture of dienone ester **76** and **38**.

Dienone ester 76: mp 68.5–69°C; ir ($CHCl_3$): 1740, 1665, and 1625 cm^{-1}; nmr ($CDCl_3$) δ: 6.05 (1H, d of d, J = 5.5, 2.0 Hz, H—C4), 5.94 (1H, br s, H—C7), 5.60 (1H, d of d, J = 5.5, 2.5 Hz, H—C3), 3.78 (3H, s, OCH_3), 3.70 (1H, m, H—C2), 1.89 (3H, d, J = 1.5 Hz, CH_3—C6), and 0.92 (3H, d of d, J = 6.5 Hz, CH_3—C10); ms m/e: 234 (M^+), 219 ($M^+ - 15$), 202 ($M^+ - 32$), and 175 ($M^+ - 59$). *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 71.24, H 7.59.

Dienone Esters 38 and 76 from Tricyclic Ketal Conjugated Methyl Ester 58

Tricyclic ketal conjugated methyl ester **58** (35 mg, 0.126 mmol) dissolved in tetrahydrofuran (3 mL) was treated with hydrochloric acid (3 N, 2 mL) at room temperature. After stirring for 18 h, the mixture was poured into water and extracted four times with dichloromethane. The extract was dried and evaporated. The residue was dissolved in ether (4 mL) and treated with an excess of ethereal diazomethane (to esterify the small percentage of carboxylic acid formed). After evaporation, the product was purified by thin layer chromatography to yield a mixture (30 mg, ≈100%) of dienone esters **38** (65%) and **76** (35%). Crystallization of this mixture from ether–hexane gave pure dienone ester **38** (19 mg). Crystallization of the mother liquor (10 mg) with hexane gave pure dienone ester **76** (8 mg).

Diene Alcohol Ester 77

Sodium borohydride (55 mg, 1.45 mmol) was added to a solution of dienone ester **76** (134 mg, 0.57 mmol) in methanol (15 mL), maintained at 0°C by an ice bath. After an additional 4 h at 0°C, the solvent was evaporated and the residue was diluted with water (15 mL). The mixture was extracted with ether (4 × 10 mL). The ethereal extracts were washed with saturated sodium chloride (2 × 3 mL), dried, and evaporated to leave a colorless oil (140 mg). Filtration through a column of silica gel using ether gave the purified diene alcohol ester (135 mg, 100%). An analytical sample was prepared by microdistillation *in vacuo*; ir ($CHCl_3$): 3600, 3450, 1740, 1665, and 1625 cm^{-1}; nmr ($CDCl_3$) δ: 5.90 (1H, d of d, J = 5.5, 2 Hz, H—C4), 5.54 (1H, m, H—C7), 5.47 (1H, d of d, J = 5.5 Hz, H—C3), 4.27 (1H, m, H—C8), 3.75 (3H, s, OCH_3), 3.53 (1H, m, H—C2), 1.64 (3H, m, CH_3—C6), and 0.83 (3H, t, J = 6 Hz, CH_3—C10); ms m/e: 236 (M^+) and 218 ($M^+ - 18$). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 70.93, H 8.52.

(±)Hinesol 2

Finely divided lithium metal (300 mg) was added to ethylamine (25 mL). When the metal was completely dissolved, a solution of bicyclic diene alcohol acetate **63** (130 mg, 0.47 mmol) in ether (5 mL) was added. After stirring for 6 h at room temperature, solid ammonium chloride was added until the blue color of the reaction mixture had just disappeared. The ethylamine was evaporated, water (50 mL) was added to the residue. Extraction with ether (4 × 20 mL) followed by drying and evaporation of the organic phase gave the crude product. This material was subjected to a column chromatography with silica gel. Elution with benzene gave a mixture (67 mg) of (±)-hinesol (**2**) and an unidentified product. Elution with ether gave another unidentified product (37 mg).

(±)Hinesol (**2**) was obtained pure (18 mg, 18%) by carrying out a second column chromatography with silica gel using a mixture of benzene and pentane (9:1). (±)Hinesol (**2**) (18 mg, 18%); ir (CCl_4): 3640, 3510, and 1660 cm^{-1}; nmr ($CDCl_3$) δ: 5.33 (1H, m, H—C7), 1.68 (3H, d, J = 1.5 Hz, CH_3—C6), 1.16 (6H, s, $(CH_3)_2C$), and 0.92 (3H, d, J = 6.5 Hz, CH_3—C10); ^{13}C nmr (CCl_4): 139.53 (C6), 121.34 (C7), 70.84 (C13), 51.15 (C2), 36.52 (C9), 35.61 (C1 or C3), 32.82 (C10), 31.78 (C5), 28.66 (C14 and C15), 28.46 (C1 or C3), 27.81 (C8), 27.36 (C4), 23.98 (C11), and 16.12 (C12).

Photochemistry of *N*-nitroso-*N*-alkyl amino acids: a facile oxidative decarboxylation

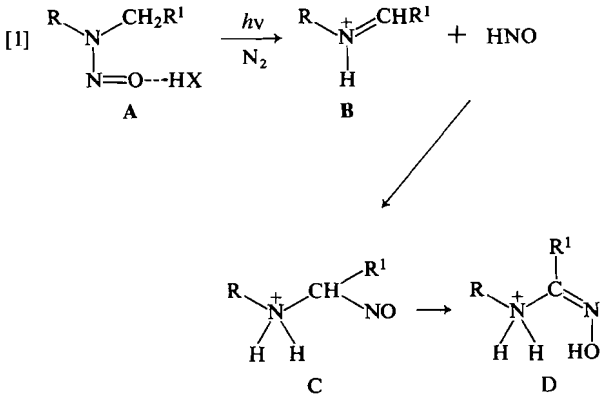
YUAN L. CHOW, DOUGLAS P. HORNING, AND JOËL POLO
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 3, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

YUAN L. CHOW, DOUGLAS P. HORNING, and JOËL POLO. Can. J. Chem. **58**, 2477 (1980).

Several *N*-alkyl or *N*-phenyl-*N*-nitroso α-amino acids were synthesized and were shown to photolytically rearrange to amidoximes with concurrent decarboxylation in solution or solid states without the presence of externally added acids. In contrast, *N*-nitrosonipecotinic acid, a *N*-nitroso β-amino acid, as well as *N*-nitrosopiperidine in the presence of acetic acid were not photolabile. The photolability of *N*-nitroso α-amino acids was ascribed to the presence of an intramolecular association between the nitrosamino and carboxyl groups through hydrogen bonding. The species having the hydrogen bonding through the nitroso oxygen in the *Z*-configuration was believed to be photolabile and decomposed to alkylideneimines as the primary product. The mechanism of the oxidative photorearrangement was discussed.



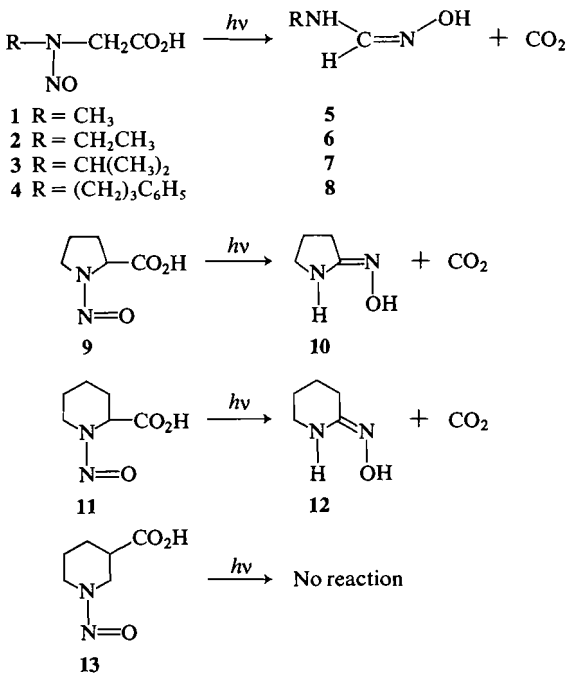
YUAN L. CHOW, DOUGLAS P. HORNING et JOËL POLO. Can. J. Chem. **58**, 2477 (1980).

On a synthétisé plusieurs acides α-aminés *N*-alkyles ou *N*-phényl-*N*-nitrosés et on a montré qu'ils se transposent photochimiquement en amidoximes tout en se décarboxylant et solution ou à l'état solide sans nécessiter d'addition d'acide. A l'opposé, l'acide *N*-nitrosonipécotinique, un acide β-aminé ayant un groupement *N*-nitroso, aussi bien que la nitrosopipéridine ne sont pas photolabiles en présence d'acide acétique. On attribue la photolabilité des *N*-nitroso α-amino acides à une association intramoléculaire entre les groupements nitrosoamino et carbonyle au moyen d'une liaison hydrogène. On croit que les espèces du groupement nitroso dans une configuration *Z* sont photolabiles et se décomposent principalement en alkylidèneimines. On discute du mécanisme de cette transposition photochimique.

[Traduit par le journal]

Introduction

It has been established by us (1, 2) as well as others (3, 4) that the presence of a strong acid is necessary for the efficient photorearrangement of dialkylnitrosamines[1] to give alkylideneimines and/or amidoximes therefrom (eq. [1]). However, we have also observed that an undegassed dilute methanol solution of *N*-nitroso-dimethylamine or -piperidine ($< 10^{-2}$ *M*) can be photodecomposed with reasonable quantum efficiency (0.2–0.4) when irradiated with a quartz filter (9). In apparent contradiction to this it has been reported (10) that dialkylnitrosamines photolytically decompose in *neutral* or *acidic* solutions without much difference in quantum efficiency. In preparative scale (ca. 0.1 *M* solution), it is demonstrated that irradiation of dialkylnitrosamines in neutral solution causes virtually no decomposition within the same or longer time interval required to cause clean photodecomposition in acidic solution. Our explanation of the apparent discrepancy is that in the undegassed solutions "acids" produced on irradiation catalyze the photodecomposition of nitrosamines. The small amounts and low concentrations of nitrosamines may make the quantum efficiency appear relatively high. Indeed, nitrosamines carrying activated α-hydrogen, such as *N*-nitrosodibenzylamine, can be partially photolyzed to afford dibenzylammonium nitrate on preparative scale but *only after prolonged irradiation* (4).



[1] 

Fifteen years ago, we published a brief communication (1) demonstrating the efficient photorearrangement of nitrosamines derived from α-amino acids in neutral solutions. Subsequently, various nitrosamines were shown to be environmental carcinogens widely distributed in food, tobacco smoke, cosmetics and drinks, etc. (11). Furthermore, it was shown these nitrosamines could be formed in the respective locales and even

[1]It must be emphasized that *N*-nitrosamides (5–7) and arylalkylnitrosamines (8) behave very differently in being photolabile in neutral solvents. Dibenzylnitrosamine (4) and *N*-nitrososarcosine methyl ester (9) undergo photolysis very slowly under nitrogen, but somewhat faster under oxygen, indicating that nitric acid is formed and catalyzes the photolysis.

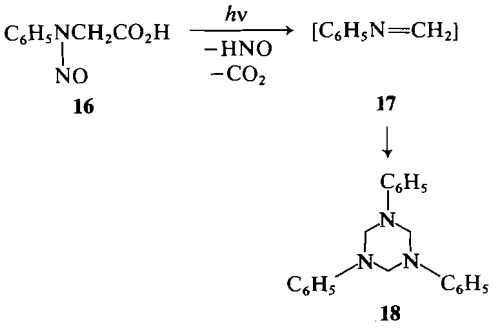
in the animal digestive system by *in situ* nitrosation (12). It is imperative that the chemical behavior of these nitrosamines be clarified as a basis for exploring their carcinogenic activity and controlling their formation. In this report we wish to reconfirm the need of acids for efficient photodecomposition of nitrosamines.

Results

As it was established that a strong acid was needed to induce efficient photodecomposition of simple nitrosamines (2, 3), it was thought a nitrosamine bearing a carboxylic acid group in the proximity (e.g., at the α-position) capable of donating the proton to the nitrosamino group might possess an intramolecular hydrogen bonded structure corresponding to that shown in eq. 1 and undergo photodecomposition efficiently. To demonstrate this proposal, *N*-nitrosated *N*-alkyl α-amino acids were chosen as the model compounds and some of these nitroso α-amino acids **1–4**, **9**, **11**, and **16** were synthesized from the corresponding D,L-α-amino acids. Except for nitroso amino acid **4**, other compounds were reported previously (1, 13–15). Nitroso amino acid **3** prepared by us melted 60° higher than reported (14) but was unambiguously characterized by spectroscopic data. The ^1H and ^{13}C nmr data for **1–4**, **9**, **11**, and **13** have been discussed separately with those for other nitroso compounds and their configurations and conformations in solid state as well as in solution (16) deduced. All these nitroso amino acids exhibited ir absorptions for the carbonyl at ca. 1720 cm^{-1} and for the nitrosamino group at ca. 1450 cm^{-1}. They showed typical uv absorptions for the nitrosamino group at ~350 nm (ε ~ 100) and 240 nm (ε ~ 10 000).

N-nitroso-*N*-phenylglycine (16) decomposed at the melting point to give CO_2 and *N*-nitroso-*N*-methylaniline. It was reported that the salts of some nitroso α-amino acids could be pyrolyzed to give the corresponding nitrosamines (16, 17). Pyrolytic decarboxylation of nitroso amino acids themselves to give the corresponding nitrosamines was, however, not a general reaction. Heating of *N*-nitrosopipecolinic acid (**11**) in toluene gave off CO_2 (73%) readily but also deposited much tar in which the presence of an unknown amide and a trace amount of *N*-nitrosopiperidine was noted.



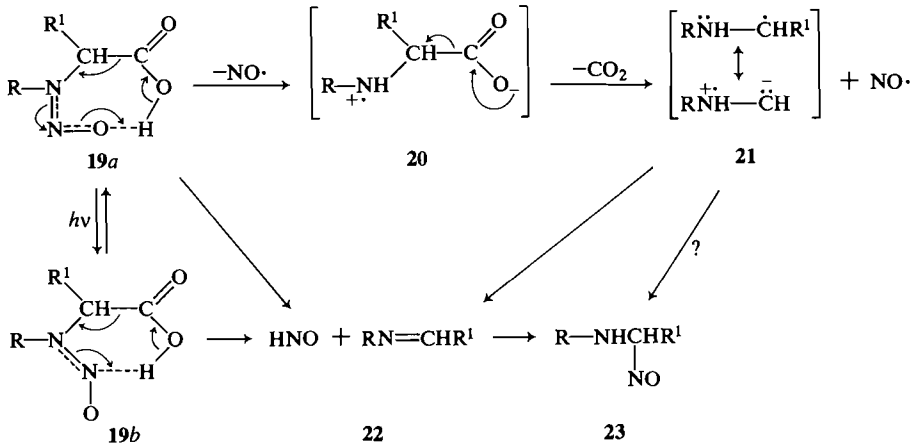
Alcoholic solutions of nitroso α-amino acids **1–4**, **9**, and **11** were smoothly photolyzed under nitrogen to give off CO_2, which may be trapped as barium carbonate, and to cause the disappearance of the $n \rightarrow \pi^*$ band at 350 nm. The uv spectra did not change at all when the solutions were kept in the dark at room temperature. The photolysates were evaporated to give crude products which showed ir and ^1H nmr spectra virtually identical to those of the amidoximes **5–8**, **10**, and **12**. The last two compounds were obtained previously in the photorearrangement of *N*-nitrosopyrrolidine and *N*-nitrosopiperidine (1, 2). Recrystallization of the crude products from benzene or cyclohexane afforded good to excellent yields of the amidoximes. In some cases, a small amount of the parent α-amino acids was present but readily separated by crystallization.

Whereas the *E–Z* isomerism could exist, only one isomer for each of the amidoximes **5–8**, **10**, and **12** was isolated and characterized. In analogy to **10** and **12**, the *Z*-configuration was assigned to formidoximes **5–8**. The assignments were supported by the fact that the chemical shifts of these formamidoxime protons at 7–6.6 ppm were very similar to those of *anti*-aldoxime protons at ca. 6.8 ppm (18). The strong and broad ir absorptions at 3200–2700 cm^{-1} also indicated the presence of intramolecular hydrogen bonding (19) which necessitated the *Z*-configuration. In addition, these compounds exhibited the characteristic C=N stretching mode at ca. 1680 cm^{-1} and the N—O stretching mode at ca. 900 cm^{-1}. Photolysis of nitroso α-amino acids **9** and **11** in ether or in acidic aqueous solution gave, in addition, hygroscopic amorphous solids which possessed very similar ir and ^1H nmr patterns to those of pyrrolidonoxime **2** and piperidonoxime **10**, respectively. The amorphous solid obtained from photolysis of **11** was converted to **10** either on attempted recrystallization by heat-

ing in solution or on treatment with a dilute aqueous hydrochloric acid. The amorphous solid obtained from photolysis of **9** exhibited nmr signals at 3.67(t), 2.83(t), and 2.23(m) and decomposed to a sticky resin on exposure to the air. These two compounds were tentatively assigned as the corresponding *E*-isomers of the amidoximes **10** and **12**, respectively. Although the presence of an acid for the photolysis of **9** and **11** is not essential, the yields of amidoximes **10** and **12** were higher and cleaner when hydrochloric acid or acetic acid was added in the photolysis. However, the rates of the photodecomposition were not affected even in the presence of 0.06 *N* hydrochloric acid or acetic acid. A thin solid film of **9** spread on a glass plate was also decomposed to **10** in a good yield.

Photolysis of a suspension of *N*-nitroso-*N*-(3-phenylpropyl) glycine (**4**) in water under nitrogen was interesting as it exhibited the emergence and subsequent dissipation of the absorptions at 328, 505, 540, and 720 nm, typical of a *C*-nitroso compound, upon irradiation. The formation of a *C*-nitroso intermediate was also indicated by the formation of a blue color which disappeared on prolonged irradiation. However, the product pattern was rather complex giving **8**, *N*-formyl-3-phenylpropylamine (**14**), 3-phenylpropylaminonitrosomethane (**15**), 3-phenylpropylamine, formaldehyde, the starting amino acid, and two more minor components that were not identified. The formamide **14** was identified by direct gc comparison with an authentic sample. Formaldehyde was isolated as the 2,4-dinitrophenylhydrazone from the distillate. The parent α-amino acid and 3-phenylpropylamine were isolated. One of the gc peaks was tentatively assigned to *C*-nitroso compound **15** on the basis of the mass spectra. This compound existed as an equilibrium mixture of the monomer and dimer in the gas chromatographic column showing a broadened gc peak with a shoulder. The ascending side of the peak showed a characteristic mass spectral pattern, very different from that of **8** but ascribable to the monomer of **15**. The tail-end of the peak showed a mass spectral pattern which could be rationalized as that of the dimer of **15** with reasonable fragmentation pathways. These fragmentation mechanisms are discussed in the thesis by one of us (J. Polo, see ref. 9).

Nitroso α-amino acid **16** was photolyzed readily either in ether or alcohol solution to afford excellent yields of hexahydro-*N*,*N*′,*N*″-triphenyl-*s*-triazine **18** which, unfortunately, was readily oxidized to a red oil and polymeric solid during work-up. With some difficulty, **18** was obtained in a pure state and showed a peculiar melting pattern as observed before (2). On storage, **18** deteriorated rapidly to a red tar. The formation of **18** suggested that formylideneaniline **17** must be formed as the intermediate since **18** could also be prepared from aniline and formaldehyde via the intermediacy of **17** (20).



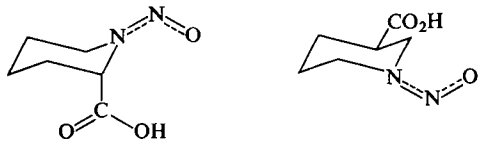
In contrast to the facile photolysis of *N*-nitroso α-amino acids as described above, *N*-nitrosonipecotinic acid (**13**), in ether, alcohol, or aqueous solution did not undergo photodecomposition noticeably even under prolonged irradiation. Nor did *N*-nitrosopiperidine undergo any significant photodecomposition in methanol when one or several equivalents of acetic acid were added.

Photolyses of *N*-nitroso α-amino acid in methanol were also carried out in the presence of cyclohexene or styrene in order to see if aminium radical addition reaction (21) could be observed. In these photolyses only amidoxime **5** and **10** were obtained, but no addition product to the olefins was isolated.

Discussion

In summary, the described results indicate, first of all, that a carboxylic acid located at an α-position of nitrosamines can act as a proton donor causing the nitrosamino group to become photosensitive. The demonstration assumes greater significance in terms of an entropic driving force when compared with the failure of *N*-nitroso β-amino acid **13** as well as *N*-nitrosopiperidine in the presence of acetic acid to undergo photodecomposition. Secondly, the photolysis of *N*-nitroso α-amino acids formally involves elimination of carbon dioxide and HNO to form alkylideneimines such as **17**, as the first step, which may react further to form amidoximes or hexahydro-*s*-triazines. Indeed, this photolysis is an efficient route to prepare amidoximes **5**–**8**, **10**, and **12** that are not readily obtained by other routes. The overall reaction pattern bears striking similarity to that of the acidic photolysis of dialkylnitrosamines (21). Mechanistically, the two types of photolyses may also share much similarity.

Owing to steric proximity to the nitrosamino group, the α-carboxyl group is more acidic (e.g., pK_a 3.2 for **1**). In our preliminary communication

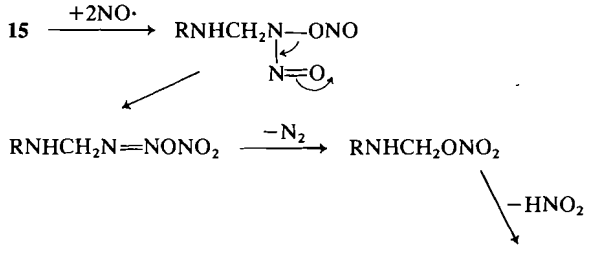


19a 20 21

19b 22 23

(1), it was proposed that these *N*-nitroso α-amino acids should be able to have an intramolecular association in the ground state through hydrogen bonding as depicted in **19***a* (*Z*-configuration) or **19***b* (*E*-configuration); these were assumed to be photolabile species. As nitrosamines are known to carry a high concentration of electron density at the oxygen atom and are alkylated with a carbonium ion at this position (22), **19***a* is favored as the photolabile species. In the *E*-configuration **19***b*, a hydrogen bonding with the lone pair electrons of the nitroso nitrogen is possible but, probably, less strong in view of the sp^2 orbital involved. Indeed, in the solid state, all these nitroso α-amino acids are known to have the *Z*-conformation **19***a* which is maintained in solution in the cases of **3** and **16** as demonstrated by ^1H and ^{13}C nmr spectroscopy (13, 16). However, **1**, **2**, **4**, **9**, and **11** isomerize slowly in solution to *Z*–*E* mixtures (13, 16). It has been shown that nitrosamines can undergo light induced *Z*–*E* isomerization in solution (23). As this isomerization is expected to occur concurrently during photoexcitation of nitroso α-amino acids, it is difficult to determine whether **19***a* or **19***b* is responsible for photoelimination. Since, qualitatively, **3** is much more efficiently photodecomposed than **1**, **2**, and **4**, it is apparently reasonable to assume that the *Z*-configuration **19***a* with the hydrogen bonding at the nitroso oxygen is responsible for the photolability in so far as these nitroso α-amino acids are concerned.

Such considerations based on ground state configuration become rather uncertain when the axial conformation of the carboxyl group (13) in **9** is taken into account to estimate the probability of the intramolecular hydrogen bonding (see **9***a*). According to Dreiding models, if a coplanar C_2C_6N—NO portion is assumed, the O---ON distance appears to be too far apart (>4 Å) to be in an effective hydrogen bonding distance. This suggests that the intramolecular association of the nitroso and carboxyl groups is far weaker than the acyclic cases discussed above. This situation is reflected in much slower photolysis of **9** than those of acyclic nitroso α-amino acids **1**–**4** when they are irradiated



9*a* **13***a*

in a preparative scale in methanol solutions under comparable conditions. Most probably, conformational changes upon excitation bring the nearby groups in closer proximity to allow facile proton transfer which triggers the photodecomposition.

Regardless of *Z* or *E* configuration, such an intramolecular association with the strategically located acid group is undoubtedly necessary in rendering the nitrosamino group photolabile as indicated by certain evidence. Firstly, it is improbable, if not impossible, for **13** to assume a hydrogen bonded structure (see **13***a*); accordingly, **13** is not photolabile, as observed. Secondly, for efficient photolysis of *N*-nitrosopiperidine, the presence of a strong acid, such as hydrochloric, sulfuric, perchloric acid, etc., is required, but the presence of acetic acid shows no effects. Thirdly, the failure of externally added hydrochloric acid to influence the rates of photolysis of *N*-nitroso α-amino acids **1** and **9** indicated that the intramolecular proton donation dominates the catalytic process.

The intermediacy of alkylideneimine **22** and *C*-nitroso compound **3**, in analogy to acidic photolysis of nitrosamine, is clearly indicated by the formation of **18** (the trimer of **17**) from **16** and the formations of 3-phenylpropylamine, formalde-

hyde, and C-nitroso compound **16** from **4**. Under such mild conditions, formamide **14** is not likely derived from hydrolysis of **18** but more likely formed by photoinduced disproportionation of *C*-nitroso compound **15**, followed by the elimination as shown below. The formation of nitrates in photolysis of *C*-nitroso compounds has been well established (24). However, it is not well understood why **15** tautomerizes much more slowly in water than in methanol. It is probable that **15** is less soluble in water and preferentially stabilized by dimerization.

Mechanistically, the photoinduced elimination of carbon dioxide and HNO may be explained by the aminium radical route **20** → **21** → **22**, as aminium radicals are known to be the primary radical species in acidic photolysis of nitrosamines (25). Alternatively, a concerted elimination as shown in **19** may also look attractive. Such a process is indistinguishable from the above route since **20** could eliminate carbon dioxide rapidly to give resonance stabilized (26) α-amino radical **21**. Although attempts to trap the aminium radical **20** with cyclohexene or styrene have not been successful, this type of radical has been proposed as an intermediate in photosensitized decarboxylation of *N*-phenylglycines (27). It is also possible to write recombination of radical **21** with nitric oxide to give **23** directly. In view of good indications of the formation of **22**, such a process appears less likely.

Experimental

Unless specified otherwise the following general conditions were used. Infrared spectra (ir) were taken with a Perkin-Elmer Model 457 as liquid films or Nujol mulls. Ultraviolet spectra (uv) were recorded on a Unicam SP 800 or a Cary 17 spectrophotometer. Nuclear magnetic resonance spectra (nmr) were recorded on a Varian A56/60 or a Varian XL-100 spectrophotometer equipped with a Nicolet 1080 computer using TMS as internal standard. Melting points were measured on a Fisher-Johns hot stage and were not corrected. Elemental analyses were performed by Mr. M. K. Yang with a Perkin-Elmer 240 microanalyzer.

Preparation of N-*Nitroso* α-*Amino Acids.*

Commercially available proline, pipecolinic acid, sarcosine, and *N*-phenylglycine were recrystallized as the starting material. *N*-ethyl-, *N*-isopropyl-, and *N*-(3-phenylpropyl)glycine were prepared according to the reported procedure (14). These α-amino acids were nitrosated with sodium nitrite in aqueous solution containing hydrochloric acid to afford the nitroso compounds **1**–**4**, **9**, **11**, and **16**. The physical properties of most of these compounds were already reported in the literature (1, 13, 16).

N-Nitrososarcosine (**1**) was recrystallized from ethyl acetate: mp 69–70°C (13); ir: 1730 and 1440 cm^{-1}. The nmr spectrum recorded immediately after dissolution in $CDCl_3$ gave the two sets of singlets at 4.28–3.90 ppm and 4.98–3.13 ppm with the intensity ratio of 9:1. The ratios changed gradually to 1:1 after standing at room temperature in the dark.

N-Nitroso-*N*-ethylglycine (**2**) was obtained as yellow crystals: mp 83–85°C; ir: 3100–2600, 1730(s), 1460(s), 1305(s), 1210(s), 1110(s), and 700(s) cm^{-1}.

N-Nitroso-*N*-isopropylglycine (**3**) was recrystallized from water: mp 137–138°C (lit. (14) mp 76–78°C); ir: 3000–2600, 1730(s), 1240(s), 1070(m), 890(m), 690(m), and 650(s) cm^{-1}. *Anal.* calcd. for $C_5H_{10}N_2O_3$: C 41.09, H 6.90, N 19.17; found: C 41.22, H 6.85, N 19.22.

N-Nitroso-*N*-(3-phenylpropyl)glycine (**4**) was recrystallized from water: mp 106–108°C; ir: 3100–2840, 1730(s), 1450(m), 1310(s), 1285(s), 1210(s), 740(m), and 700(s) cm^{-1}. *Anal.* calcd. for $C_{11}H_{14}N_2O_3$: C 59.45, H 6.35, N 12.60; found: C 59.43, H 6.47, N 12.86.

N-Nitrosoproline (**9**): mp 104–106°C; ir: 3000–2500, 1720(s), 1370(s), 1200(m), 720(s), and 680(s) cm^{-1} (1).

N-Nitrosopipecolinic acid (**11**); mp 93–95°C; ir: 3200–2500, 1720(s), 1465(s), 1405(1), 1330(s), 1248(s), 1190(s), 1015(s), 930(s), and 740(s) cm^{-1} (1).

N-Nitroso-*N*-phenylglycine (**16**); mp 98–100°C (dec.) (15); ir: 3200–2600, 1720(s), 1590(m), 1495(m), 1295(s), 1262(m), 1150(s), and 962(s) cm^{-1}; ^1H nmr: 10.2, 7.20, and 4.75(s) ppm; ^{13}C nmr: 39.6, 120.1, 127.1, 129.6, 141, and 167.2 ppm. Nitroso compound **14** decomposed at the melting point to give an oil which was distilled to afford *N*-nitroso-*N*-methylaniline.

N-Nitrosonipecotinic acid (**13**) was recrystallized from ether: mp 110–112°C; ir: 3000–2500, 1700(s), 1462(s), 1348(s), 1290(s), 1170(s), 1000(m), 935(m), 865(m), and 660(s) cm^{-1}. The nmr spectrum of **13** showed complex signals in the 5.3–7.0 region obviously due to the *Z*–*E* isomers.

Photolysis of N-*Nitroso* α-*Amino Acids in Alcohol*

A solution of *N*-nitroso α-amino acid (~0.01 mol) in methanol or ethanol (120–150 mL) was purged with nitrogen and irradiated with a 200 W Hanovia medium pressure mercury lamp at the cooling water temperature. The uv absorption of the nitroso compound at ca. 350 nm decreased gradually as the irradiation progressed and disappeared completely in one to two hours. A small sample of the original solution kept in the dark at room temperature showed no decrease in the uv absorption. The photolysate was evaporated to afford a solid which showed virtually the same ir and nmr spectra as those of the corresponding amidoximes. A hot solution of this solid was filtered to give a small amount of α-amino acid. The filtrate was cooled to give crystalline amidoximes. Their physical properties are given below.

N-Methylformamidoxime (**5**, 572 mg, 72%) was obtained from benzene recrystallization as white plates: mp 134–135°C; ir: 3400(m), 3100–2900(b, m), 1680(m), 1320(m), 1290(m), 920(m), 900(m), and 750(m) cm^{-1}; ^1H nmr (D_2O): 7.00(s, 1H) and 2.88(s, 3H) ppm; ms *m/e* (%): 74.0486 (M^+, 69, calcd. for $C_2H_6N_2O$: 74.0480), 57(57), 42(54), 30(100), and 28(84). Sublimation at room temperature and at 1.5 Torr yielded an analytical sample. *Anal.* calcd. for $C_2H_6N_2O$: C 32.43, H 8.16, N 37.81; found: C 32.58, H 8.21, N 37.59.

N-Ethylformamidoxime (**6**) was recrystallized from benzene

as white crystals (449 mg, 69%): mp 81–83°C; ir: 3360(m), 3200(m, b), 2800(b, s), 1680(s), 1490(m), 1260(m), 1160(m), 940(s), 890(s), 750(m), and 730(m) cm^{-1}; ^1H nmr: 6.70(s,1H), 3.11(q, J = 7Hz, 2H), 2.10 (s, D_2O exch.), and 1.17 (6, J = 7 Hz, 3H) ppm; ms m/e (%): 88.0639 (M^+, 93, calcd. for $C_3H_8N_2O$: 88.0630), 73(67), 71(42), 55(58), 44(100), 43(62), 42(38) and 30(67). *Anal.* calcd. for $C_3H_8N_2O$: C 40.90, H 9.15, N 31.79; found: C 40.97, H 9.03, N 31.52.

N-Isopropylformamidoxime (**7**) was sublimed as white crystals (540 mg, 76%): mp 46–48°C; ir: 3380(m), 3250(b, m), 1675(s), 1380(d, m), 1340(m), 1270(m), 900(m), and 855(m) cm^{-1}; ^1H nmr (D_2O): 7.07 (s, 1H), 3.52 (sp, J = 7 Hz, 1H), and 2.20 (d, J = 7 Hz, 6H) ppm; ms m/e (%): 102.0799 (M^+, 36, calcd. for $C_4H_{10}N_2O$: 102.0793), 87(47.1), 71(15.5), 69(33), 60(32), 58(23), 44(100), 43(94), 42(69), 41(66), and 39(25). *Anal.* calcd. for $C_4H_{10}N_2O$: C 47.04, H 9.87, N 27.43; found: C 46.77, H 9.66, N 27.25.

N-(3-Phenylpropyl)formamidoxime (**8**) was recrystallized from cyclohexane as white plates (1.02 g, 82%): mp 100–101°C; ir: 3350(m), 3050(m), 2750(b, m), 1680(s), 1490(m), 1450(m), 1330(m), 1240(m), 900(s), 770(s), 740(s), and 690(s) cm^{-1}; ^1H nmr: 7.90 (bs, D_2O exch., 1H), 7.16 (m, 5H), 6.60 (bd, J = 6 Hz, changes to a sharp singlet after D_2O addition, 1H), 5.00 (bs, D_2O exch., 1H), 3.06 (bt, J = 8 Hz, changes to a sharp triplet after D_2O addition, 1H), 2.66 (t, J = 8 Hz, 2H), and 1.80 (qi, J = 8 Hz, 2H) ppm; ^{13}C nmr δ: 145.5(d), 142.0(s), 128.4(d), 125.9(d), 44.5(t), 33.7(t), and 32.8(t); ms m/e (%): 178.1125 (M^+, 18, calcd. for $C_{10}H_{14}N_2O$: 178.1125), 146(100), 117(60), 91(71), 73(60), and 57(58). *Anal.* calcd. for $C_{10}H_{14}N_2O$: C 67.39, H 7.92, N 15.72; found: C 67.48, H 7.96, N 15.80.

Photolysis of **4** *in Water*

A suspension of nitroso compound **4** (820 mg, 3.7 mmol) in water (230 mL) was photolyzed at room temperature under nitrogen for 4 h. On irradiation, the solution developed a violet-blue color and new absorptions at 328, 505, 540, and 725 nm which reached the maximum intensities after 30 min and faded away gradually to give a clear light brown solution at the end of the photolysis. The solution was concentrated under atmospheric pressure to about 40 mL. The distillate, on treatment with an ethanolic 2,4-dinitrophenylhydrazine solution, gave an orange precipitate of the 2,4-DNPH of formaldehyde, mp and mixture mp 164–166°C (from ethanol–water). The concentrated photolysate (pH = 6–7) was extracted with CH_2Cl_2 (3 × 20 mL) to give, after drying ($MgSO_4$) and evaporation, a brown semi-solid (346 mg). This crude mixture was triturated with hot cyclohexane to give a solution which on cooling afforded **8** (30 mg, 5%) as light brown plates; mp 91–94°C. The insoluble part was taken up in CH_2Cl_2 (20 mL) and washed several times with diluted HCl solution (0.5 *N*). The organic phase was further washed with water, dried ($MgSO_4$), and evaporated to yield a brown oil (280 mg); ir: 3200 (b, m), 1700(s), 1600(m), 1500(m), 1450(s), 1350(s), 1130(m), 750(m), and 700(s) cm^{-1}. This oil was analyzed by gc–ms (10% SE-30, 150°C to 250°C at 10°C/min) to give two major and two minor peaks: rt 2.5 min, **15**, 10%; rt 2.7 min, unknown, 5%; rt 3.6 min, unknown, 5%; rt 6.1 min, **14**, 23%. The peak at rt 2.5 min was shown to be composed of two components showing a shoulder on the decreasing side. The ascending side of the peak showed the mass peaks at m/e (%): 161(38), 148(57), 120(37), 118(17), 117(19), 105(50), 91(60), 74(100), and 42(30); the tail-end of the peak showed those at m/e (%): 251(13), 160(14), 147(29), 146(86), 117(40), 91(100), 71(13), and 56(81). The peak at rt 6.1 min was identified as *N*-formyl-3-phenylpropylamine **14** by the peak matching with an authentic sample and mass spectral pattern: 163 (M^+, 34), 118(62), 117(52), 105(18), 91(47), 77(15), and 59(100).

The aqueous photolysate was acidified to pH = 2–3 and extracted with ether (2 × 30 mL) to give, after drying ($MgSO_4$) and evaporation, unreacted *N*-3-(phenylpropyl)glycine (65 mg, 8%); mp 103–105°C. The water phase was then basified with 10% NaOH solution to pH = 10 and extracted with ether (3 × 20 mL) to give 3-phenylpropylamine (62 mg, 12%), as a yellow oil.

Formylation of 3-phenylpropylamine with chloral in $CHCl_3$ according to the procedure of Blicke and Lu (28) gave formamide **14** (70%) which was purified by distillation (bp 140°C/1 Torr); ir: 3280(m), 1655(s), 1520(m), 1490(m), 1450(m), 1380(m), 740(m), and 690(s) cm^{-1}; ms m/e (%): 163 (M^+, 7), 146(100), 117(31), 91(87), 65(18), and 59(25).

Photolysis of N-*Nitrosoproline* **9**

In Ether

On irradiation of an ether solution (200 mL) of **9** (535 mg, 3.7 mmol) at room temperature, under nitrogen, it gradually turned cloudy and an amorphous resin deposited on the wall of the photocell. After 75 min the absorptions at 381 and 368 nm disappeared completely. Concentration of the ether solution gave 2-pyrrolidonoxime **10** (185 mg, 50%) as white crystals; mp 150–152°C (from water); mixed with an authentic sample 156–158°C (2). The mother liquor was evaporated to give a resin which was taken up in hot benzene to give, on cooling, another crop of **10** (65 mg, 18%). The filtrate was evaporated to yield an amorphous solid which turned to a sticky resin on exposure to air. This solid was not soluble in acetone.

In Water and in the Presence of Hydrochloric Acid

Nitroso compound **9** (1.5 g, 0.01 mol) was photolyzed in water (200 mL) containing hydrochloric acid (7 mL, 2.8 *N*), at room temperature, under nitrogen. After 4 h of irradiation, the absorption band at 350 nm disappeared completely. The photolysate was filtered through a basic Dowex 3 (50 mL) column and the resulting filtrate (pH ≈ 5–6) was evaporated to dryness to give a yellowish oil. The residue was treated with hot isopropyl alcohol (25 mL) to leave a hygroscopic residue (350 mg); ^1H nmr δ: 3.67(t), 2.83(t), and 2.23(m). Cooling of the filtrate gave 2-pyrrolidonoxime hydrochloride (600 mg, 42%) as white crystals; mp 197–200°C (from isopropyl alcohol); ir: 2500–3200(b), 1690(s), 1555(w), 1310(m), 1060(s), and 990(s) cm^{-1}; ^1H nmr (D_2O) δ: 3.73 (t, J = 7 Hz, 2H), 2.9 (t, J = 7 Hz, 2H), and 2.27 (m, 2H). *Anal.* calcd. for $C_4H_8N_2O \cdot HCl$: C 35.17, H 6.64, N 20.51; found: C 35.58, H 6.85, N 20.07. Further evaporation of the mother liquor gave another crop of the hydrochloride of **10** (520 mg, 36%).

Photolysis of N-*Nitrosopipecolinic Acid* **11**

In Ether

An ether solution (200 mL) containing **11** (600 mg, 3.8 mmol) was photolyzed at room temperature, under nitrogen for 2 h until over 90% of the absorption at 350 nm had disappeared. The fluffy precipitate formed during the photolysis was filtered and turned to a resin upon exposure to air; ir: 3400–2500 (b, m), 1600–1650(s), and 1130(s) cm^{-1}. The ether solution was concentrated under vacuum and after cooling gave 2-piperidonoxime 12 (300 mg, 76%) as white crystals; mp 114–116°C (from benzene – petroleum ether); mixture mp with an authentic sample 114–116°C; ir and nmr spectra were identical to those of the authentic sample (2). The mother liquor was evaporated to dryness to give an amorphous solid with a strong pungent smell and whose ir spectrum was similar to that of **12**.

In Water and in the Presence of Hydrochloric Acid

A solution of **11** (1.82 g, 11.5 mmol) in water (200 mL) containing hydrochloric acid (2.85 *N*, 4.2 mL) was photolyzed for 9 h. The water phase was evaporated to dryness to give a yellowish residue which was taken up in ethanol. Addition of benzene gave hydrochloride of **12** (640 mg, 37%) as a white precipitate; mp 210–215°C; ir: 3150(m), 1665(s), and 1510(s) cm^{-1},

superimposable with that of an authentic sample of **12** hydrochloride (2). Further addition of petroleum ether gave an amorphous solid whose ir spectrum was similar to that of hydrochloride of **12**. Treatment of the amorphous solid with 1 *N* HCl and extraction with CH_2Cl_2 gave the hydrochloride of **12** (285 mg, 17%).

In another experiment, a solution of **11** (1.57 g, 10 mmol) in water (250 mL) and acetic acid (1.3 g, 20 mmol) was photolyzed for 4 h. Hydrochloric acid (2 *N*, 5 mL) was added to the photolysate and the resulting solution was boiled for 5 min. Usual work-up of the solution gave hydrochloride of **12** (560 mg, 37%) but no amorphous material. The mother liquor was dissolved in water, neutralized with Na_2CO_3, and extracted with ether to give **12** (530 mg, 46%).

In the Solid State

An ether solution of **9** (100 mg) was spread on a glass plate (20 × 20 cm) and the ether evaporated to give a thin film. This plate was irradiated through a Pyrex filter at room temperature for 4 h. The plate was washed with methanol and the solution evaporated. The residue was recrystallized from cyclohexane to give **10** (55 mg) and a small amount of pipecolinic acid.

Photolysis of N-*Nitroso*-N-*phenylglycine* **16**

A methanol solution (200 mL) of **16** (1.0 g) was photolyzed under nitrogen for 3 h until the absorption at 370 nm disappeared. The solvent was evaporated during which the solution became darker colored. The residue was taken up in ether and filtered. The ether solution was diluted with petroleum ether and cooled to give white crystals and some red oil. After filtration the crystals were washed with methanol to afford hexahydro-*N*,*N'*,*N''*-triphenyl-*s*-triazine **18** as white crystals which melted at 130–133°C but resolidified at 138°C and remelted again at 190–195°C (20); ir: 3100, 3060, 3040, 1595, 1575, 1500, 1228, 755, and 695 cm^{-1}; uv (EtOH): 280 nm (ε, 1770); ^1H nmr δ: 7.20 (m, 5H) and 4.94 (s, 2H). *Anal.* calcd. for $C_{21}H_{21}N_3$: C 80.10, H 6.67, N 13.33; found: C 80.49, H 6.54, N 13.38.

A solution of **18** rapidly gained color during heating or standing at room temperature. Concentration of the solution always gave red oil, the crystals, and some amorphous solid. On storage, crystalline **18** decomposed to a red oil in several days. Photolysis of **16** in ether, ethanol, or water gave similar results.

Comparative Photolysis of N-*Nitroso* α-*Amino Acids*

Solutions of **1** in methanol, and in methanol containing 0.06 *N* hydrochloric acid and acetic acid, were prepared. These solutions were photolyzed in a merry-go-round machine for 10 and 20 min without actinometry. The decrease of the 350 nm peaks was about the same for 3 solutions in each case. The same experiments were run with **11** to give similar results.

Methanol solutions (100 mL) containing nitroso α-amino acid **1**, **2**, **3**, and **11** (5×10^{-2} *M*) were irradiated in the same small scale apparatus with the same lamp. The reaction was followed by uv spectroscopy up to 65% completion for which **1**, **2**, and **3** required 1.1–1.3 h and **11** 2.5 h.

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

MARGARET M. KAYSER and PETER MORAND. Can. J. Chem. **58**, 2484 (1980).

Metal hydride reductions of planar cyclic anhydrides such as methylmaleic or 3-substituted phthalic anhydrides occur preferentially at the sterically more hindered carbonyl function. This regioselectivity cannot be rationalized in terms of "the most favourable pathway for non-perpendicular attack by a nucleophile" since both carbonyl groups present are equally accessible to non-perpendicular approach. A study which takes into account the alkaline cation and inductive, mesomeric, and steric effects has been conducted for the reduction of several conjugated and aromatic anhydrides. A qualitative interpretation for the regioselectivities observed in these reductions (as well as in reductions already reported in the literature) is suggested. An early transition state for the catalyzed versus late transition state for the non-catalyzed process is proposed.

MARGARET M. KAYSER et PETER MORAND. Can. J. Chem. **58**, 2484 (1980).

Les réductions d'aldéhydes cycliques plans, tels l'anhydride maléique et l'anhydride phtalique substitué en position 3, au moyen d'hydrures métalliques se produisent préférentiellement au niveau de la fonction carbonyle la plus stériquement encombrée. On ne peut pas rationaliser cette régiosélectivité en fonction de la voie la plus favorable à une attaque non perpendiculaire du nucléophile puisque les deux groupes carbonyles présents sont également accessibles à une approche non perpendiculaire. On a réalisé une étude qui tient compte du cation alcalin et des effets inductifs, mésomériques et stériques lors de la réduction de plusieurs anhydrides conjugués et aromatiques. On suggère une interprétation qualitative de la régiosélectivité observée au cours de ces réductions (aussi bien qu'au cours des réductions déjà mentionnées dans la littérature). On propose un état de transition au début de la réaction catalysée par rapport à un état de transition apparaissant à la fin de la réaction non catalysée.

[Traduit par le journal]

Introduction

It has been demonstrated that unsymmetrically substituted cyclic anhydrides (1) and imides (2) are often reduced by metal hydrides preferentially or specifically at the sterically more hindered carbonyl group. Such regioselectivity has been rationalized in terms of the most favourable pathway for non-perpendicular attack (see Fig. 1) by a nucleophile on the carbonyl function (1,3,4). This rationalization, although very useful in explaining the selectivity of reduction in many unsymmetrical cyclic anhydrides and imides, is nonetheless only *one* of the factors contributing to the regioselectivity observed in these reactions (1,3).

Planar cyclic anhydrides (e.g. methylmaleic anhydride **1** or 3-nitrophthalic anhydride **9**) represent compounds in which the type of steric interactions discussed above is not operative, yet in most cases these anhydrides, also, are reduced preferentially at the more hindered carbonyl group (Table 1).

Metal Hydride Reductions of Substituted Maleic Anhydrides

Methylmaleic anhydride **1**, chloromaleic anhydride **2**, and phenylmaleic anhydride **3** are reduced with a high degree of selectivity at the carbonyl group adjacent to the substituent (Table 1). Methoxy substituted anhydrides **4** and **5** react preferentially at the carbonyl function adjoining the methoxy group. The regioselectivity of these reductions cannot be justified in terms of steric hindrance to non-perpendicular nucleophilic attack since the preferred reaction path leading to either carbonyl function is equally accessible.

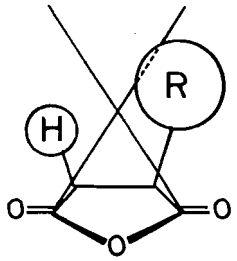

FIG. 1. At a distance of approximately 2 Å, approach to the carbonyl function next to the more highly substituted carbon atom is effectively "less hindered" than approach to the carbonyl group adjoining the unsubstituted carbon atom.

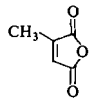

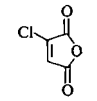

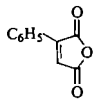

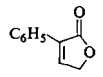

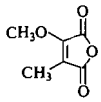

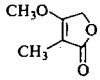

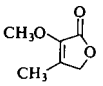

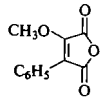

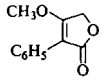

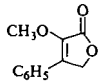

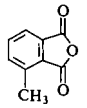

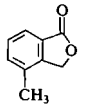

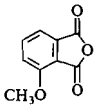

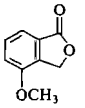

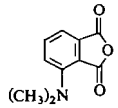

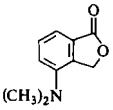

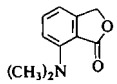

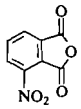

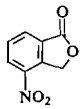

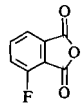

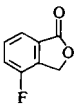

We would like to mention briefly explanations that have been offered to rationalize the above results. Knight and Pattenden (5) proposed two

mechanisms, one suggesting initial complexation of the cation with the less-hindered carbonyl oxygen, followed by transfer of hydride to the more hindered carbonyl function **11** (6), and the other invoking an intermediate oxonium ion and an intramolecular four-centre mechanism **12** (5). These mechanisms do not take into account the catalytic activity of the counterion (1, 7, 8) and lack generality

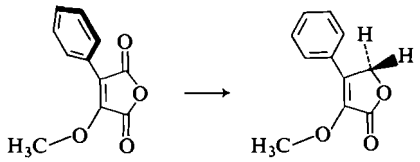
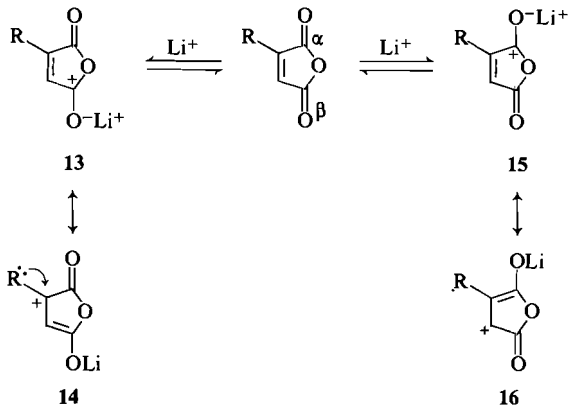
(since they can only be used to rationalize a specific case).

An alternate argument suggesting that the steric interactions between the substituent and the carbonyl group in **1** and **2** are relieved when the reaction proceeds from the reactants to the tetrahedral transition state assumes that the transition state in this case is "product-like" and consequently the observed regioselectivity reflects stability of the product. However, under normal reaction conditions fast, exothermic, kinetically-controlled reductions are believed to proceed through a "reactant-like" transition state (9). Thus we are faced with the controversial problem of fundamentally similar reactions having entirely different



11

12



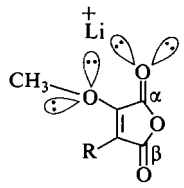
transition states (9). Moreover, preferential reduction of the carbonyl function neighbouring the methoxy rather than the phenyl substituent in **5** refutes "the more stable product" argument. The phenyl group which is twisted in the anhydride, could assume a position in conjugation with the double bond if the adjacent carbonyl group were reduced to give the lactone **5***b*. Yet despite this strongly stabilizing effect (favouring **5***b*) the only product obtained is lactone **5***a*.

5 **5***b*

We have suggested before (1) that there are two principal factors involved in controlling the regioselectivity in reductions by metal hydrides, namely, (*a*) preferential association of the cation with *one* of the carbonyl groups, and (*b*) rate of hydride transfer to the activated (by complexation with the cation) intermediate. For the conjugated and aromatic anhydrides reported in this paper, the major contribution is undoubtedly due to the factor (*b*).

The resistance of an enolized carbonyl group to reduction by metal hydrides has been recently demonstrated by Barton *et al.* (10). In the substituted maleic anhydrides both carbonyl groups can

13 **15**



14 **16**

FIG. 2. The association of a cation with the carbonyl group is reversible. Thus, as the unstable intermediate **15** is reduced, the equilibrium shifts to the right. The overall effect is a highly regioselective reduction of the α-carbonyl group.

form enolates.[1] However, the unstable intermediate **15** will undergo preferential reduction even in the presence of **13**, since the latter possesses a higher degree of enolate character due to stabilization of the canonical form **14** by the substituent (see Fig. 2). Additional contributing factors such as the positive inductive effect of the methyl group in compound **1** and the formation of a cyclic chelated complex with the cation in methoxy substituted anhydrides **17** favour complexation with a cation, further promoting reduction at the α-carbonyl function.

Metal Hydride Reductions of ortho-*Substituted Phthalic Anhydrides*

Phthalic anhydrides constitute another class of compounds for which "steric hindrance along the preferred reaction path" argument cannot be used to rationalize observed regioselectivities. McAlees *et al.* (11) investigated sodium borohydride reductions of four *ortho*-substituted phthalic anhydrides

17

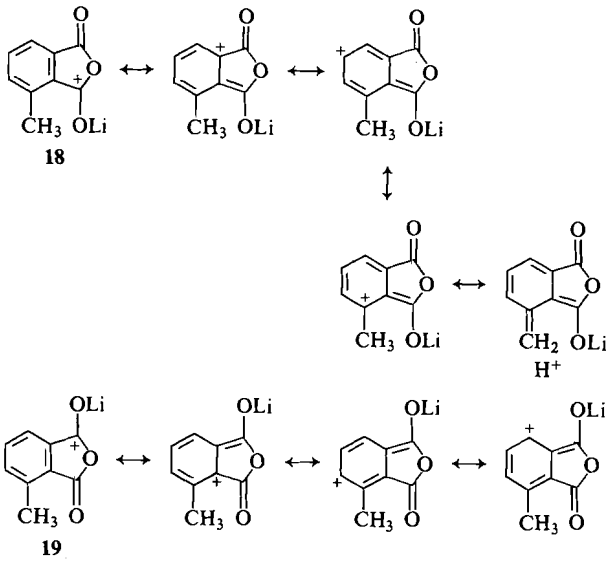
[1]The large proportion of 1,4 addition observed in $NaBH_4$ reductions of **2** and **3** confirms the importance of the contributing canonical forms such as **14** and **16** (see Experimental). The preference of $LiAlH_4$ for 1,2 addition to conjugated ketones (while $LiBH_4$ gives higher yields of 1,4 addition products) has been discussed by A. Loupy and J. Seyden-Penne, Tetrahedron Lett. 2571 (1978).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

6, **7**, **8**, and **9** (Table 1). In all cases examined, hydride addition occurs preferentially at the carbonyl function *ortho* to the substituent. To account for the product distribution observed, the authors propose that nucleophilic attack at the carbonyl group *ortho* to the substituent results in relief of steric compression between this carbonyl group and the substituent. This argument implies an sp^3-hybridized ("product-like") transition state. It is generally assumed that steric effects are the major influence of a substituent in the *ortho* position, except when the substituent is of relatively small size (e.g. F) and induction and resonance become prominent (12, 13). Taking this into account, we decided to investigate the reduction of 3-fluorophthalic anhydride **10** in order to assess the extent of the *ortho* effect.

The reduction of **10**, under a variety of experimental conditions, yielded chiefly lactone **10***a* resulting from hydride addition to the carbonyl group *ortho* to the fluorine substituent. The isomeric lactone was always a minor product. These observations weaken considerably the interpretation based on the *ortho* effect and "product-like" transition state. Evidently, if the steric acceleration (due to the *ortho* effect) is not the principal factor governing regioselectivity of reduction in *ortho*-substituted phthalic anhydrides, the reaction must be controlled by inductive and mesomeric influences.

In view of the importance of catalysis by alkaline cation in metal hydride reductions (7, 8, 14, 15), an electron-donating substituent should promote complexation of a cation with the carbonyl group and consequently accelerate the reduction. Conversely, an electon-withdrawing group should decelerate the reaction. In the 3-substituted phthalic anhydrides we have two possible sites for reaction but since the intensity of inductive effect decreases sharply with distance, the activating or deactivating effect of the substituent in position 3 is felt most strongly by the adjacent (i.e. *ortho*) carbonyl function. Thus, we should expect increased selectivity for the *ortho* carbonyl group in phthalic anhydrides bearing an electron-donating substituent in position 3, while compounds with electron-attracting substituents should show a higher proportion of reduction at the *meta* carbonyl group. However, the problem becomes more complex when association with a cation is accompanied by electron delocalization (as is the case in aromatic and conjugated systems). In such instances when delocalization does occur, the relative rates of hydride transfer to the two possible intermediates may offset entirely



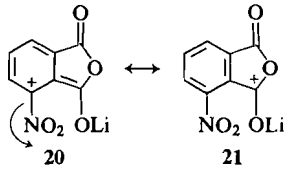


FIG. 3. The more stable intermediate **18** will be reduced at a slower rate than the less stable intermediate.

the regioselectivity anticipated on the basis of preferential association with the cation.

Let us consider an example. In the course of the reduction of 3-methylphthalic anhydride **6** the inductive electron-donating influence of the substituent promotes complexation with a cation at the *ortho* carbonyl group. But, at the same time, hydride transfer to the activated carbonyl function is retarded due to the greater stabilization of the intermediate **18** versus **19**. This augments the possibility of reduction at the *meta* carbonyl group (Fig. 3). When the substituent is electron-attracting, the deactivating inductive effect on the *ortho* carbonyl group is offset by the mesomeric effect. The enolized contributing structure **20** is quite unstable. The 3-nitrophthalic anhydride complex with a Li^+ cation may be expected to possess a higher proportion of non-enolized form **21**, which is particularly disposed toward reduction.

We may conclude that the ratios of the two lactones obtained represent a net effect of the opposing inductive and mesomeric influences. These ratios are different for various compounds (**6**, **7**, **8**, **9**, and **10**) since the magnitudes of the contributing effects are characteristic for each substituent.

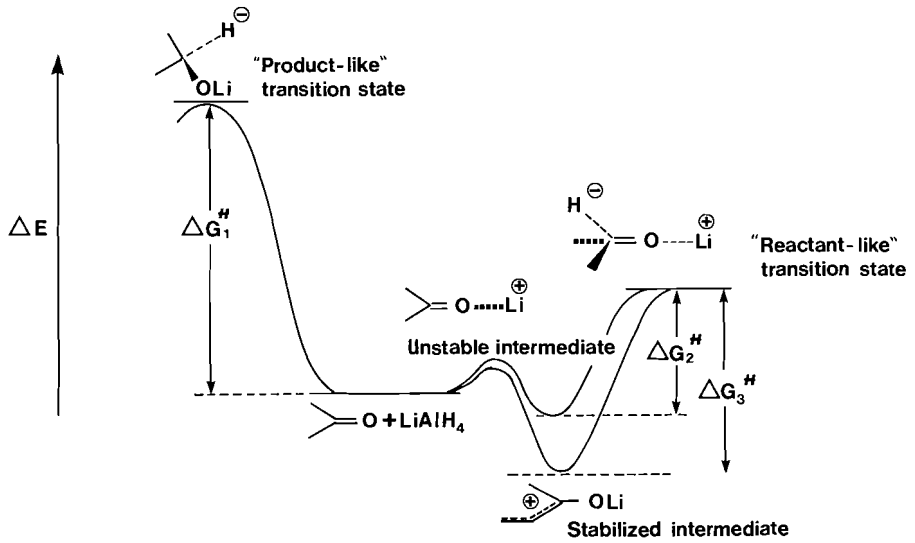

FIG. 4. Catalyzed and non-catalyzed reaction paths in metal hydride reductions.

The situation encountered in the reductions of phthalic anhydrides parallels that of the substituted maleic anhydrides. However, while in compound **1** inductive and mesomeric effects act in unison promoting reaction at the same (α) carbonyl function, in phthalic anhydrides the two influences oppose each other.

It is important at this stage to point out that although electrophilic assistance by an alkaline cation is necessary in reductions of saturated carbonyl compounds (7, 8), it is not "essential" when aromatic or conjugated systems are reduced (16). Apparently the electron-withdrawing aromatic ring (or a double bond) sufficiently lowers the energy level of the LUMO $\pi^*_{C=O}$, so that reaction can occur even in the absence of a cation, albeit at a slower rate. It is entirely possible that metal hydride reductions of aromatic compounds (especially those substituted with electron-withdrawing groups) may proceed through catalyzed or non-catalyzed processes. The slow, non-catalyzed reduction may be fundamentally different from the fast, exothermic reaction of the saturated ketone or aldehyde activated by complexation with an alkaline cation. In fact, it may very well proceed through the late, "product-like" transition state. In such a case the *ortho* effect of a substituent would become an important factor in determining the regioselectivity of the reaction.

The variations in the ratios of the two lactones obtained in reductions with $NaBH_4$ and $LiAlH_4$ support this interpretation. The most revealing is the series of reductions performed on 3-nitrophthalic anhydride **9**. The reduction of **9** with $NaBH_4$ in tetrahydrofuran (11), in the absence of an "effective" catalyst (Na^+ is a poor catalyst in comparison to Li^+), yields only lactone **9***a*. This suggests that the non-catalytic process and consequently the *ortho* effect is operative. When the same reaction was carried out in the presence of catalytic amounts of HCl, a mixture of two lactones (**9***a*:**9***b* = 83:17) was obtained. The percentage of **9***b* was still higher (33%) when the reduction was carried out in the presence of Li^+ cation.

Summary

In this paper we have suggested that the reduction by metal hydrides of aromatic and conjugated systems (especially those substituted with electron-withdrawing groups) may proceed through two competitive mechanisms: (*a*) one catalyzed by an alkaline cation and involving a "reactant-like" transition state; (*b*) the other non-catalytic process in which the transition state is "product-like".

The first mechanism is controlled by electronic effects while the *ortho* effect and the stability of the product are the dominant factors in the second. The catalyzed and non-catalyzed processes may be represented by the diagram depicted in Fig. 4.

Experimental

Melting points were determined on a Thomas–Hoover capillary melting point apparatus and are uncorrected. Infrared spectra were obtained on a Beckman IR-20 spectrophotometer and proton nmr spectra in $CDCl_3$, with TMS as internal standard, on a Varian HA-100 instrument. Tetrahydrofuran was distilled under nitrogen from lithium aluminum hydride into oven-dried flasks containing the lithium aluminum hydride.

The general procedures for the reductions were as follows. (*a*) Lithium aluminum hydride (0.005 mol) was placed in an oven-dried, three-neck flask into which 50 mL of tetrahydrofuran were subsequently distilled. The flask was fitted with an inlet post for syringes, gas outlet tube, thermometer, and magnetic stirrer. The flask, swept with a slow stream of nitrogen, was cooled in a dry ice – acetone bath. An anhydride (0.01 mol) dissolved in 25–30 mL of distilled tetrahydrofuran was injected into the flask. The temperature of the reaction mixture was maintained below −50°C throughout the addition process. The stirred solution was slowly warmed to 0°C over a period of 2 h. The flask was then cooled again to −20°C and 5 mL of 6 *N* HCl were added slowly. The reaction mixture was left overnight. The layers were separated and the aqueous layer extracted with ether. The combined organic layers were dried, the solvent evaporated, and the product analyzed by 100 MHz proton nmr. (*b*) Reductions with sodium borohydride were carried out as follows. A solution of an anhydride (0.01 mol) in dry tetrahydrofuran (50 mL) was added dropwise to a stirred, ice-cold suspension of $NaBH_4$ (0.01 mol) in tetrahydrofuran (50 mL). The reaction mixture was allowed to warm to room temperature and stirring was continued for an additional 2–3 h. During that period 3–4 drops of 6 *N* HCl were added to the reaction mixture. After quenching with 3 *N* HCl the layers were separated and the acidic aqueous layer was extracted with ether. The combined organic layers were dried over anhydrous $MgSO_4$ and the solvents removed. The crude product was analyzed by 100 MHz proton nmr. (*c*) An alternate procedure for the reduction with sodium borohydride involved addition of lithium chloride (0.01 mol) dissolved in tetrahydrofuran before the suspension of $NaBH_4$ (0.01 mol) in THF was added to the reaction vessel.

Reduction of Methyl Maleic Anhydride 1

Methyl maleic anhydride was reduced with $LiAlH_4$ as described in the general procedure. Upon work-up a yellow oil was recovered (82–87% yield). 100 MHz proton nmr of the crude product showed 4-hydroxy-3-methyl *cis* crotonic acid lactone **1***a* to be the major product. The mixture contained some unreacted anhydride (acid) and a small quantity of the isomeric lactone **1***b* (**1***a*:**1***b* = 90:10). The lactone **1***a* was purified by distillation at reduced pressure (17); ν_{max}: 1780 cm^{-1}; δ:2.16 (s, 3H, CH_3), 4.74 (s, 2H, CH_2O), 5.80 (m, 1H, H—C=C). The isomeric lactone **1***b* (18) showed δ:1.92 (m, CH_3), 7.22 (m, H—C=C—C=O).

The reduction of **1** with $NaBH_4$ according to the general procedure (*b*) gave lactone **1***a* as the principal product (**1***a*:**1***b* = 85:15).

Reduction of Chloromaleic Anhydride 2

Chloromaleic anhydride **2** was reduced with $LiAlH_4$ as described in the general procedure. The isolated product was a dark, brown oil sparingly soluble in chloroform. The crude material was repeatedly extracted with chloroform to give a mixture of products (30%). 100 MHz proton nmr analysis showed the ratio of two lactones to be **2***a*:**2***b* = 90:10. Separation on thick layer chromatography plates provided a sample of pure lactone **2***a* (19); ν_{max}: 1770 cm^{-1}; δ:4.85 (d, 2H, CH_2—O), 6.18 (t, 1H, H—C=C), and **2***b* (20): ν_{max}: 1770 cm^{-1}; δ:4.92 (d, 2H, CH_2—O), 7.54 (t, 1H, H—C=C—C=O).

The reduction of **2** with $NaBH_4$ according to the procedure (*b*) yielded lactonic product (35%) **2***a*:**2***b* = 87:13. The remaining crude material contained the unreacted diacid (ca. 10–15%) and reduction products (ca. 30%) resulting from 1,4 hydride addition to chloromaleic anhydride **2**.

Reduction of Phenylmaleic Anhydride 3

Phenylmaleic anhydride **3** was prepared according to the method of Miller *et al.* (21). It was reduced with $LiAlH_4$ according to the general procedure (*a*) to give a mixture of the lactones **3***a* and **3***b* in the proportions **3***a*:**3***b* = 75:25 (100 MHz nmr analysis). The total yield of the lactonic product was ca. 50%.

Separation by thick layer chromatography furnished both lactones displaying identical physical and spectroscopic properties to those published previously (22,23). Lactone **3***a*, ν_{max}: 1760 cm^{-1}; δ: 5.20 (d, 2H, CH_2—O), 6.34 (t, 1H, H—C=C), 7.35 (m, 5H); lactone **3***b*, ν_{max}: 1760 cm^{-1}; δ: 4.96 (2H), 7.46 (m, 4H), 7.80 (m, 2H).

The reduction of **3** with $NaBH_4$ (procedure (*b*)) gave a mixture of the two lactones **3***a* and **3***b* (ca. 30% **3***a*:**3***b* = 67:33), unreduced diacid (ca. 30%), and two saturated lactones (ca. 40%), 3-phenyl-γ-butyrolactone and 2-phenyl-γ-butyrolactone in the approximate ratio 2:1. These two last products are the result of 1,4 hydride addition, followed by 1,2 hydride addition.

Reduction of 3-Nitrophthalic Anhydride 9

Reduction of 3-nitrophthalic anhydride **9** by $LiAlH_4$ according to the general procedure yielded yellow crystalline product (80%). The 100 MHz proton nmr showed the presence of two lactones in the ratio **9***a*:**9***b* = 67:33.

4-Nitrophthalide **9***a*, mp 135–136°C (lit. (24) mp 136°C); ν_{max}: 1780 cm^{-1}; δ: 5.75 (s, 2H, CH_2—O), 7.82 (1H), 8.38 (2H). 7-Nitrophthalide **9***b*, mp 163°C; ν_{max} 1765 cm^{-1}; δ: 5.40 (s, 2H), 7.95 (m, 3H); *m/e*: 179 (M^+).

Reduction of **9** with $NaBH_4$ according to procedure (*b*) gave a mixture of two lactones (75%) **9***a*:**9***b* = 83:17.

Reduction of 3-Fluorophthalic Anhydride 10

Oxidation of 1-fluoronaphthalene with $KMnO_4$ gave 3-fluorophthalic acid in 47% yield, mp 185–187°C. Upon sublimation the 3-fluorophthalic acid was dehydrated to the corresponding anhydride **10**, mp 118–119°C; ν_{max}: 1805, 1875 cm^{-1}; δ: 7.70 (m).

Reduction of **10** with $NaBH_4$ according to the general procedure (*b*) yielded 32% of the lactonic product (**10***a*:**10***b* = 70:30) and 3-fluorophthalic acid. Separation on thick layer chromatography plates provided pure samples of the two lactones.

4-Fluorophthalide **10***a*, mp 160–162°C (lit. (25) mp 162–163°C); ν_{max}: 1790 cm^{-1}; δ: 5.32 (s, 2H, CH_2—O), 7.22 (m, 2H), 7.66 (m, 1H). 7-Fluorophthalide **10***b*, mp (62–64°C); ν_{max}: 1785 cm^{-1}; δ: 5.38 (s, 2H, CH_2—O), 7.60 (m, 3H).

Reduction of **10** with $NaBH_4$ according to general procedure (*c*) yielded a lactonic mixture (49%) **10***a*:**10***b* = 84:16.

ROSS STEWART and K. C. TEO. Can. J. Chem. **58**, 2491 (1980).

The rates of reduction of 17 aryl trifluoromethyl ketones by sodium borohydride in 2-propanol have been measured. The rho (ρ) value is +3.12, excluding the 4-amino and 4-dimethylamino groups, which both lower the rate to a greater extent than their σ values predict. The close correspondence between substituent effects for hydride addition in the methyl and trifluoromethyl series (excluding the amino groups) suggests that normal substituent effects are to be expected for oxidation processes involving hydride removal in trifluoromethyl compounds. The present results are consistent with the oxidation of aryl trifluoromethyl carbinols by permanganate taking place by hydrogen atom abstraction. The effect of substituents on the rate of reduction of the trifluoromethyl ketones is almost identical to that on the equilibrium constant for formation of the ketone hydrates. The application of the reactivity–selectivity principle to the reduction reaction is also considered. Reduction of the 4-ethyl compound has $\Delta H^{\ddagger} = 2.7$ kcal mol^{-1} and $\Delta S^{\ddagger} = -38$ cal deg^{-1} mol^{-1}.

ROSS STEWART et K. C. TEO. Can. J. Chem. **58**, 2491 (1980).

On a mesuré les vitesses de réduction de 17 aryl trifluorométhylcétones par le borohydrure de sodium dans le propanol-2. La valeur rho (ρ) est de +3.12 en excluant les groupements amino-4 et diméthylamino-4 qui tous deux diminuent dans une proportion plus grande que celle prévue par leurs σ. L'étroite correspondance entre les effets de substituant lors de l'addition d'hydrure sur les cétones méthylées et trifluorométhylées (en excluant les groupement amino) suggère que les effets normaux de substituants sont à prévoir dans les réactions d'oxydation qui font intervenir une élimination d'hydrure dans les composés trifluorométhylés. Les résultats sont en accord avec l'hypothèse selon laquelle l'oxydation des aryltrifluorométhylcarbinols par le permanganate se fait par élimination d'hydrogène. L'effet des substituants sur la vitesse de réduction des trifluorométhylcétones est presqu'identique à celui sur la constante d'équilibre de la réaction de formation des énols. On considère également l'application du principe de réactivité–sélectivité à la réaction de réduction. Pour la réduction du composé portant un groupe éthyle en position 4 le $\Delta H^{\ddagger} = 2.7$ kcal mol^{-1} et le $\Delta S^{\ddagger} = 38$ cal deg^{-1} mol^{-1}.

Introduction

Hydride transfer processes constitute an important class of oxidation–reduction reactions. Indeed, for organic compounds hydride transfer is one of the most frequently used 2-electron (2-equivalent) routes (1) between oxidants and reductants. A reaction that on first inspection appears to be a hydride transfer is the oxidation of alcohols to aldehydes or ketones by aqueous alkaline potassium permanganate (2). Since the isotope effect shows that the carbon–hydrogen bond is cleaved in the rate-controlling step and since the alkoxide ion is known to be an intermediate in the reaction, hydride transfer appears to be an attractive mechanism for the oxidation step, the driving force being provided by the negative charge on the alkoxide oxygen atom.

[1] $R_2CHOH + OH^- \rightleftharpoons R_2CHO^- + H_2O$

[2] $R_2CHO^- + MnO_4^- \longrightarrow R_2C{=}O + HMnO_4^{2-}(Mn^{V})$

[3] $(3\,Mn^{VI} \longrightarrow Mn^{VII} + 2\,Mn^{IV})$

However, there is one piece of evidence that has been known for some time that is inconsistent with such a mechanism for the rate-controlling step. When aryl trifluoromethyl carbinols, $ArCHOHCF_3$, are oxidized by aqueous permanganate there is no effect of ring substituents on the rate-controlling step; that is, the Hammett rho (ρ) value is roughly zero (2*b*). There is a substituent effect on the oxidation of these and other alcohols but in those cases in which the effect can be partitioned between step [1] and step [2] the substituent effect turns out to reside completely in step [1]. Furthermore, the sodium borohydride reduction of ketones is known to be a clear case of hydride addition to the carbonyl group (3) and since Bowden and Hardy (4) have shown that hydride *addition* to aryl methyl ketones[1] has a large positive rho, +3.06, it is to be expected that hydride *removal* would have a substantial negative rho.

Accordingly, the alternative mechanism, hydrogen-atom transfer, which is not expected to

[1]The ρ_{eq} for hydroxide addition to the carbonyl group of benzaldehydes is +2.76 (5).

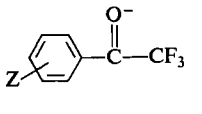
For personal use only.

be as strongly affected by substituents, has been favoured (1). The driving force here would presumably be the relatively greater stability of the ketyl anion than the alkoxide ion.



$$R_2CHO^- + MnO_4^- \longrightarrow R_2\dot{C}{-}O^- + HMnO_4^{-}\,(Mn)^{VI}$$

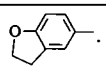
$$R_2\dot{C}{-}O^- + MnO_4^- \longrightarrow R_2C{=}O + MnO_4^{2-}\,(Mn)^{VI}$$

The above argument depends on the trifluoromethyl group, which has profound effects on reactivity in other systems (6), not having such an overwhelming electron-withdrawing effect that it obliterates the effects of the ring substituent Z on removal of a hydride unit from **1**. A test of the latter possibility can be made by comparing the effect of hydride addition to **2** with that for the analogous aryl methyl ketones. Accordingly, we have determined the effect of ring substituents on the reduction of aryl trifluoromethyl ketones by sodium borohydride.

1

2

Two ancillary benefits accrue from such a study. First, aryl trifluoromethyl ketone reduction has been widely used in biomimetic studies (7) and the present work should serve as a benchmark for substituent effects in such systems. Secondly, the reactivity difference between the methyl and trifluoromethyl systems is expected to be very large and should provide a further test of the reactivity–selectivity principle in aromatic systems (8).



Results and Discussion

The reaction was initially investigated in several solvent systems. Aqueous solution has the advantage of being the medium in which the permanganate oxidation had been conducted; nonhydroxylic solvents such as dioxan have the advantage of not having hydrate or hemiacetal formation competing with the reduction. In the event, it was found that these systems gave very poor kinetic results and 2-propanol, the medium previously used in borohydride kinetic studies, was found to be preferable. Hemiacetal formation competes with the reduction but is much slower, being undetectable in the case of the 4-amino compound and proceeding at only 0.2% of the reduction rate for the unsubstituted compound.

The yield of alcohol is high, as expected (see Experimental). The rate data are given in Table 1.

TABLE 1. Second-order rates for reduction of aryl trifluoromethyl ketones by sodium borohydride in 2-propanol, 20°C

Substituent	k_2 (L mol^{-1} s^{-1})	Substituent	k_2 (L mol^{-1} s^{-1})
4-$(CH_3)_2N$	1.23	4-CH_3	198
4-NH_2	0.45	4-C_2H_5	276
4-HO	39.9	4-$(CH_3)_3C$	292
5′-Coumaranyl[a]	44.8	3-CH_3	386

Effect of Substituents

A Hammett plot, log k against σ, for 16 compounds is shown in Fig. 1. (The σ value for the coumaranyl group has not yet been determined; our results give a $\bar{\sigma}$ value of -0.38 for this group.) The rho value is 3.86 with a correlation coefficient of 0.9718.

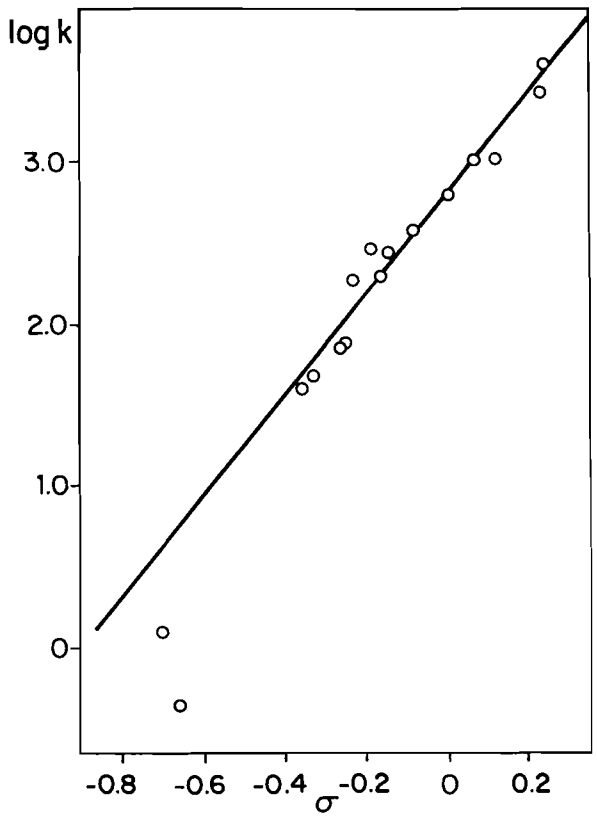

FIG. 1. Hammett plot for the reduction of substituted trifluoroacetophenones by sodium borohydride in 2-propanol at 20°C, $\rho = +3.12$, excluding 4-$(CH_3)_2N$ and 4-NH_2.

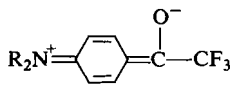
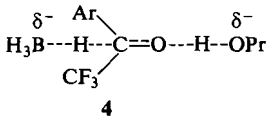
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.



It is clear that the amino groups deviate markedly from the best line drawn for the other groups and the direction of deviation suggests that a σ^+ correlation would be more satisfactory. In fact, a plot of log k against σ^+ is not particularly good (correlation coefficient 0.9480), nor is a Yukawa–Tsuno plot (9), for which the highest correlation coefficient (0.9758) is obtained with the coefficient r set equal to 0.15.

For purposes of comparing the effect of ring substituents on the reduction of the methyl and trifluoromethyl series, either of the following treatments seems to be satisfactory. A direct comparison can be made of the six substituents that are common to the two series, excluding 4-methoxy which is grossly deviant in the Bowden and Hardy series. An excellent correlation is obtained when log k_{CF_3} (y axis) is plotted against log k_{CH_3} (x axis), the slope being 0.872 and the correlation coefficient 0.9969. This result suggests that borohydride reduction in the trifluoromethyl series is only slightly less sensitive to ring substituents than is the reaction with the methyl compounds.

An alternative approach is to use the rho value determined using all the groups in Fig. 1 except amino and dimethylamino. The rho of 3.12 (correlation coefficient 0.9798) is very slightly larger than the value of 3.06 found by Bowden and Hardy for the methyl ketones. Thus, in the case of hydride addition, replacing the hydrogen atoms of the methyl group with fluorine atoms causes virtually no change in the transmission of ring effects to the reaction site.



With regard to the hydride abstraction mechanism for the permanganate oxidation of trifluoromethyl carbinols, referred to in the Introduction, one can conclude that the trifluoromethyl group will not, in fact, obliterate the effect of ring substituents. Thus, the present results are consistent with the mode of carbon–hydrogen bond breaking in the alkoxide–permanganate reaction being homolytic. That is, as earlier argued (*1b*), hydrogen-atom transfer probably occurs, giving the ketyl anion as the initial product.

It does not seem possible to accommodate the effect on the borohydride reduction of all groups by any of the standard Hammett treatments and, accordingly, we simply assign a ρ value of 3.12 to the reaction, excluding the amino groups, which are more electron-donating (rate-retarding) than their σ values would suggest. It is clear, though, that the effect of these groups can be ascribed to conjugation in the neutral ketones, with the structure **3** being stabilized by the nearby trifluoromethyl group; just as in the ketone hydrate equilibrium, where a good σ^+ correlation has been obtained (10).

3

For the compounds common to the two series, borohydride reduction and hydration, there is a significant correlation. Figure 2 shows a plot of the logarithm of the reduction rate constant against the logarithm of the equilibrium constant for hydration. The slope of the line is only slightly greater than unity, 1.12. This result is consistent with Wigfield's view (3) that in the transition state for borohydride reduction in 2-propanol the hydride transfer is well advanced and is accompanied by proton transfer from the solvent to the carbonyl oxygen atom. Such a transition state, **4**, will closely resemble the carbonyl hydrate molecule if the new bonds are almost complete.[2]

4

The Reactivity–Selectivity Principle (RSP)

The borohydride reduction of a trifluoromethyl ketone is more than 10^5 times faster than that of the analogous methyl ketone yet the effect of substituents in the two series is little different, neglecting the amino compounds, which were not studied in the methyl series. This is in agreement with general experience that Hammett rho selectivity indices are not generally affected by reactivity changes. If they were, curved Hammett plots should be observed for series that cover a wide range of rates. Although Fig. 1 shows an apparent curvature (and in the direction expected if the RSP operated within the series) it seems unlikely that this effect is a simple manifestation of the RSP. Since the rates are very fast and the heats of activation very low any curvature would be expected to

[2]The fact that the borohydride reduction correlates better with σ than with σ^+ whereas the hydration equilibria are correlated better with σ^+ than with σ is paradoxical, considering that Fig. 2 indicates a similarity in substituent effects. A firmer distinction could be made between σ and σ^+ dependence in the reduction if groups more electron donating than *para*-halo were included. However, such compounds have reaction times of only a few seconds or less and it is impossible to measure faster rates by the technique we have used. Flow systems are difficult to use with 2-propanol because of competing hemiacetal formation and we were unable to obtain reproducible results with aprotic solvents.

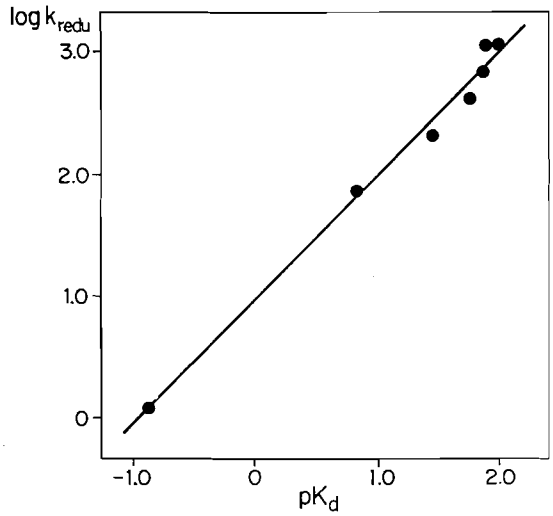


FIG. 2. Logarithm of the rate constant for borohydride reduction as a function of the logarithm of the equilibrium constant for hydration of the same ketone. The hydration constants (in the form pK_d, where d indicates dehydration) are from ref. 10. Slope = 1.12.

arise from the most reactive member of the series reacting less rapidly than predicted by a linear Hammett relation. This, in turn, would mean that the less reactive members would give a truer value of the reaction constant rho. In the present case, however, this would require a rho value considerably greater than 4.0 and it is difficult to imagine the trifluoromethyl series having a rho so much larger than that for the methyl series.

Activation Parameters

The activation enthalpy for the sodium borohydride reduction of 4-ethyl-α,α,α-trifluoroacetophenone is 2.7 kcal mol^{-1} (11.3 kJ mol^{-1}). The activation entropy is −38 cal deg^{-1} mol^{-1} (−159 J deg^{-1} mol^{-1}), falling in the range found for other borohydride reductions (4*a*, 11). The extremely small $\Delta H^{\ddagger}$ corresponds to a temperature coefficient of only 2% per degree at room temperature. Most ketone reductions by borohydride have $\Delta H^{\ddagger}$ values between 5 and 11 kcal mol^{-1}, and one might conclude that the reaction is enthalpy controlled. However, it is clear that the entropy of activation for the 4-amino compound, for example, must be very much more negative than that of the 4-ethyl compound since $\Delta\Delta G^{\ddagger}$ at 20°C for these two compounds is 3.7 kcal mol^{-1}, considerably greater than the $\Delta H^{\ddagger}$ for the 4-ethyl compound. That is, at least for the less reactive compounds, the reaction must be partly or entirely entropy controlled.

A Comment on the Use of the Hammett Relation for Comparing Reactivities in Two Series

The Hammett relation in its various forms correlates a vast body of physico-chemical data (9). However, because of the variability introduced by modified substituent constants σ^+, σ^-, σ^0 etc., the magnitude of a reported reaction constant rho may give a false impression of the sensitivity of the reaction to a change in ring substituents. Thus, for the borohydride reduction considered herein, the calculated rho value can be reported as +3.86 (using σ and all substituents) or the very much smaller value +1.83 (using σ^+ and all substituents), with comparable correlation coefficients in the two cases.

As a consequence we have found it more meaningful to compare directly two series of reactions, in one case the CF_3 and CH_3 ketones carrying the same ring substituents, and in the other case two different reactions, reduction and hydration, of the same CF_3 ketones. Such comparisons are not always possible nor, indeed, desirable, but they may be preferable to the powerful generality of the Hammett approach when it is unclear which set of substituent constants should be used.

Experimental

Materials

2-Propanol was distilled from sodium borohydride before use. Dioxan was distilled from sodium and benzophenone under nitrogen. The known ketones were prepared as previously described (10) and purified by chromatography. The ultraviolet and infrared spectroscopic data for all compounds are summarized in Table 2. Satisfactory nmr and high resolution mass spectra were obtained for all ketones used.

4-Amino-α,α,α-trifluoroacetophenone

Freshly prepared active manganese dioxide (12) (88 g) was stirred with a solution of 4-dimethylamino-α,α,α-trifluoroacetophenone (10) (2.0 g) in chloroform (450 cm^3) at room temperature for 91 h. The manganese dioxide was filtered off and washed with chloroform. Refiltration and evaporation of the combined solutions afforded 1.83 g of brown crystalline solid. The crude product was purified over an alumina column using ether/pentane and gave three fractions, the first consisting of 0.4 g of the monomethylamino compound (see below), the second containing 0.1 g of a mixture of this compound and the amino compound, and the third consisting of 0.4 g of the desired amino compound, mp 89.0–91.0°C.

Anal. calcd. for $C_8H_6NOF_3$: C 50.80, H 3.20, N 7.41; found: C 50.93, H 3.26, N 7.30.

4-Methylamino-α,α,α-trifluoroacetophenone

This compound was obtained as a fraction in the oxidative demethylation described above, mp 96.5–97.0°C.

Anal. calcd. for $C_9H_8NOF_3$: C 53.21, H 3.97, N 6.89; found: C 53.24, H 4.13, N 6.81.

5'-Coumaranyl-α,α,α-trifluoroacetophenone

A mixture of coumaran (5.6 g) and powdered anhydrous aluminum chloride was stirred in dry carbon disulfide (20 cm^3) for 15 min (13). Trifluoroacetic anhydride was added, and the mixture warmed until gas evolution ceased. The reaction mixture was decomposed with cold 5 *M* hydrochloric acid and extracted with ether, which was evaporated to give 6.2 g of a bright orange solid. The crude product was chromatographed over alumina and a pure sample obtained via glc.

[b]Liquid film, unless otherwise noted.
[c]The 3-Cl and 4-NO_2 compounds, which appear in the accompanying paper, both have their carbonyl band at 1730 cm^{-1}.
[d]In carbon tetrachloride.

Anal. calcd. for $C_{10}H_7O_2F_3$: C 55.57, H 3.26; found: C 55.83, H 3.31.

4-Ethoxy-α,α,α-trifluoroacetophenone

4-Bromophenetole (5.6 g) was converted to the Grignard reagent and treated with trifluoroacetic anhydride (3.0 g). Work-up gave 5.8 g of impure liquid which was purified by glc.

Anal. calcd. for $C_{10}H_9O_2F_3$: C 55.05, H 4.16; found: C 55.09, H 4.29.

4-tert-Butyl-α,α,α-trifluoroacetophenone

The Grignard procedure, as above, was used. The product was sublimed and gave a mp of 47.5–48.0°C.

Anal. calcd. for $C_{12}H_{13}OF_3$: C 62.60, H 5.69; found: C 62.59, H 5.50.

4-Ethyl-α,α,α-trifluoroacetophenone

The Grignard procedure gave a liquid which was purified by glc.

Anal. calcd. for $C_{10}H_9OF_3$: C 59.41, H 4.49; found: C 59.44, H 4.46.

3-Methyl-4-methoxy-α,α,α-trifluoroacetophenone

This compound was prepared from 2-methoxytoluene using the Friedel–Crafts reaction. A glc separated sample crystallized to give mp 28.0–29.5°C.

Anal. calcd. for $C_{10}H_9O_2F_3$: C 55.05, H 4.06; found: C 55.08, H 4.30.

3,4-Dimethyl-α,α,α-trifluoroacetophenone

The Grignard reagent from 3,4-dimethylbromobenzene was treated with trifluoroacetic anhydride and gave after work-up and glc purification a pure liquid sample.

Anal. calcd. for $C_{10}H_9OF_3$: C 59.41, H 4.49; found: C 59.70, H 4.55.

Kinetic Procedure

The rate was followed by measuring the disappearance of the ketone absorption peak in the ultraviolet. The substrate dissolved in dioxan (20–50 μL) was added to 3.0 cm^3 of a thermally equilibrated sample of 2-propanol in the spectrometer. The initial absorbance reading A_0 was taken and then 20–50 μL of a freshly prepared and standardized 2-propanol solution of sodium borohydride of concentration b was added. Three inversions of the cell were made and readings of absorption and time were begun. (For the very fast reactions the measured rate constant had some dependence on the way that the cell was handled after the borohydride was added.) The second-order rate constant was obtained by plotting $\log 4b(C_0 - C_t)/C_0(4b - C_t)$ against time, where C is concentration determined from absorbance using Beer's law. A linear regression analysis was performed on a programmable calculator and the second-order rate constant obtained from the slope.

Initial concentrations of ketone varied from $1.0 \times 10^{-5}M$ to $7.19 \times 10^{-5}M$, and the initial molar ratio of ketone to borohydride varied from 0.94 to 58. Good second-order plots were obtained.

The 4-hydroxy ketone behaves differently in that the reduction of the carbonyl group is accompanied by the appearance of a peak at 362 nm, which rises and eventually falls if sufficient borohydride is present. The absorption peak for the phenoxy anion of the ketone occurs at this wavelength and presumably the phenolic group in the hydroxy ketone is protonating the alkoxide reduction product. (There is no indication that the borohydride is being converted to molecular hydrogen by the phenol.) The overall rate of disappearance of ketone was corrected for partial conversion to phenoxide, based on the rate of appearance of the peak at 362 nm.

Substituent Constants

The σ values used are those of McDaniel and Brown (14) except for 4-$(CH_3)_2N$, for which a value of 0.70 has been used (15). The σ^+ values come from Okamoto and Brown (16) except for the following additions and emendations: (*a*) 4-$(CH_3)_2N$, −1.74; 5'-coumaranyl, −0.984; 4-CH_3O, −0.778; 4-C_2H_5O, −0.811 (17); (*b*) 4-NH_2, −1.31; 4-HO, −0.92; 4-C_2H_5, −0.30 (18); and (*c*) 3-CH_3, −0.098 (19).

Preparative Scale Reductions

The ketone (50–200 mg in 3 cm^3 of 2-propanol) was stirred with a 50% excess of sodium borohydride at room temperature. Acidification, filtration, and passage through an alumina column, followed by elution with ether and evaporation gave the following yields of alcohol (20, 21), with reaction times in parentheses: 4-$(CH_3)_2N$, 98% (16 h); unsubstituted, 85% (0.5 h); 3-NO_2, 95% (1 h).

The 4-dimethylamino alcohol has not been previously prepared. 4-Dimethylaminophenyl trifluoromethyl carbinol: mp 101–102°C.

Anal. calcd. for $C_{10}H_{12}NOF_3$: C 54.79, H 5.52, N 6.39; found: C 54.88, H 5.58, N 6.33.

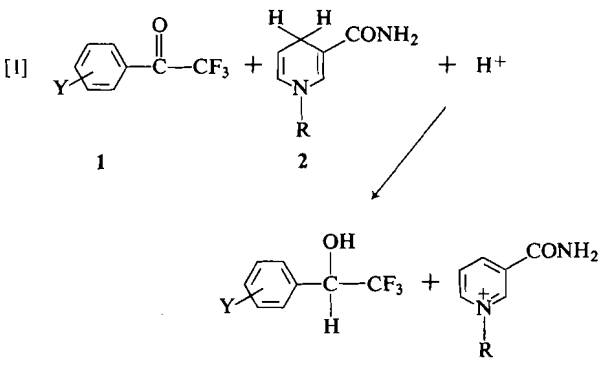
ROSS STEWART, K. C. TEO, and L. K. NG. Can. J. Chem. **58**, 2497 (1980).

The reaction of 15 aryl trifluoromethyl ketones with *N*-carbamoylmethyl-1,4-dihydronicotinamide has been studied in aqueous sulfolane buffer. The unsubstituted ketone and those containing electron-withdrawing groups in the ring have the following reaction characteristics: (*a*) a high yield of alcohol is obtained, (*b*) the observed reaction rate is independent of ring substituent; however, when corrections are made for degree of hydration of the ketones the rate is correlated with Hammett σ values with a rho of +1.98, (*c*) a secondary isotope effect of approximately 1.08 and primary isotope effects of 1.45–1.62 are observed at 43.4°C for the reaction of the dihydronicotinamide containing one or two atoms of deuterium at C-4, (*d*) $\Delta H^{\ddagger} = 15.2$ kcal mol^{-1}, and $\Delta S^{\ddagger} = -27.0$ cal deg^{-1} mol^{-1} for the unsubstituted compound, uncorrected for ketone hydration; $\Delta S^{\ddagger}$ for reaction of the unhydrated ketone and dihydronicotinamide is estimated to be −45 to −50 cal deg^{-1} mol^{-1}. The mechanism for the reduction is consistent with hydride transfer from reductant to oxidant, very possibly accompanied by blind-alley formation of an adduct between ketone hydrate and dihydronicotinamide. Ketones containing electron-donating groups in the ring react with the dihydronicotinamide in some undetermined way, giving little or no alcohol as product.

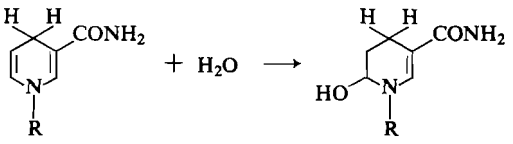


ROSS STEWART, K. C. TEO et L. K. NG. Can. J. Chem. **58**, 2497 (1980).

On a étudié la réaction de 15 aryl trifluorométhylcétones avec la *N*-carbamoylméthyldihydro-1,4 nicotinamide dans un tampon aqueux de sulfolane. La cétone non substitué et celle contenant des groupements électro-attracteurs sur le cycle ont les caractéristiques réactionnelles suivantes: (*a*) on obtient un fort rendement en alcool, (*b*) la vitesse de la réaction observée est indépendante du substituant fixé sur le cycle; cependant quand on fait des corrections pour tenir compte du degré d'hydratation des cétones, la vitesse se rapproche des valeurs σ de Hammett avec un rho de +1.98, (*c*) on observe un effet isotopique cinétique secondaire d'environ 1.08 et des effets isotopiques cinétiques primaires de 1.45–1.62 à 43.4°C pour la réaction de la dihydronicotinamide contenant un ou deux atomes de deutérium en C-4, (*d*) le $\Delta H^{\ddagger} = 15.2$ kcal mol^{-1} et le $\Delta S^{\ddagger} = -27$ cal deg^{-1} mol^{-1} pour les composés non substitués (ces valeurs ne sont pas corrigées pour tenir compte de l'hydratation de la cétone); pour la réaction de la cétone non hydratée et de la dihydronicotinamide on évalue que le $\Delta S^{\ddagger}$ se situe entre −45 et −50 cal deg^{-1} mol^{-1}. Le mécanisme de la réduction est en accord avec un transfert d'hydrure du réducteur à l'oxydant accompagné très probablement de la formation d'un adduit entre l'énol et la dihydronicotinamide. Les cétones ayant sur le cycle des groupements électro-donneurs réagissent avec la déhydronicotinamide d'une façon non encore connue en donnant peu ou pas d'alcool.

[Traduit par le journal]

Introduction



α,α,α-Trifluoroacetophenone (**1**, Y = H) has come to occupy an important place in the investigation of the mechanism of reduction of carbonyl compounds by nicotinamide coenzymes such as NADH and model compounds thereof (**2**) (1–7).

Steffens and Chipman studied the reaction of trifluoroacetophenone with *N*-alkyldihydronicotinamides and observed a disparity between the kinetic isotope effect and the partition isotope effect (as measured by the relative amounts of protium and deuterium in the alcohol reduction product) when the dihydronicotinamide was monodeuteriated at the 4-position (1). They concluded that an intermediate exists on the reaction pathway since the rate-determining and product-determining steps appear to be different. Recently van Eikeren *et al.* have carefully examined the course of the reaction of *N*-propyl and *N*-benzyl dihydronicotinamide with several carbonyl compounds, principally pyridine-2-carboxaldehyde but including trifluoroacetophenone (8, 9). They have shown that the hydration of dihydronicotinamides, which is a well known side reaction in dihydropyridine reductions, is catalyzed by the carbonyl compound under conditions where the usual acid-catalyzed reaction is quite slow.

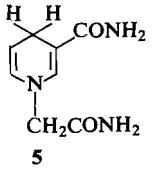
[2] 

3



Furthermore, they showed that several carbonyl compounds, including trifluoroacetophenone, react in aqueous systems with the dihydronicotinamide to give adducts such as **4**.

[3] 

4

Although the normal acid-catalyzed reaction of dihydronicotinamides to give **3** is first order, the carbonyl-catalyzed hydration process and reaction [3] are both second order, and are kinetically equivalent to the oxidation process, eq. [1]. Thus following the disappearance of the dihydronicotinamide, the usual practice, can lead to a kinetic isotope effect that is too small, since only some of the dihydronicotinamide reacts by C—H(D) bond cleavage.

We have had a long-standing interest in the mechanism of organic oxidation processes and also in the hydration equilibria of trifluoroacetophenones. Accordingly, we have examined the reaction of a series of ring-substituted trifluoroacetophenones with *N*-carbamoylmethyl-1,4-dihydronicotinamide, **5**, in order to learn more about the oxidation process. We had earlier shown that **5** has reasonably good stability in aqueous solution, both in its reduced and in its oxidized forms (10).

5

Trifluoroacetophenone is highly hydrated in aqueous solution (11–13) and earlier workers realized that this caused the measured rate constant for reduction of this compound to be lower than the true bimolecular rate constant for reaction of carbonyl compound and reducing agent. We can calculate the equilibrium constant for hydration of aryl trifluoromethyl ketones in any mixture of water with sulfolane or dimethyl sulfoxide between 1 mole percent water and pure water (11). We have chosen to use 21.8% sulfolane – 78.2% water (v/v) buffered at an apparent pH of 8.3 for our studies. These conditions provide sufficient substrate solubility, coupled with decomposition rates that are tolerable. A higher pH would stabilize the dihydronicotinamide but would (*a*) increase the rate of decomposition of the pyridinium product (not a critical factor unless redox equilibrium were established) and (*b*) cause the aryl trifluoromethyl ketones containing strongly electron-withdrawing groups to form adducts with hydroxide ion (ionization of the ketone hydrates) (13). Higher sulfolane concentrations cause the equilibrium between ketone and ketone hydrate to become sluggish and thus complicate the kinetic treatment.

The effect of polar aprotic solvents such as dimethyl sulfoxide (DMSO) on ketone hydration and its effect on the oxidation process has not always been appreciated. Thus, when the reduction of trifluoroacetophenone by *N*-propyldihydronicotinamide was studied in mixtures of water and DMSO it was assumed that an increase in the water content of the system decreases the concentration of the free ketone (7). In fact, aqueous DMSO is unusual in that mixtures up to 85 mole percent DMSO actually produce a *higher* degree of hydration of trifluoroacetophenone than does pure water (12).

Results and Discussion

The rate measurements were made by following the disappearance in the ultraviolet of the 347.5 nm peak of **5** by one of the following means. The concentration of **1** was varied (Fig. 1) and the rate constant k_2' for the reaction of **1** with **5** determined from the slope. In each experiment an accompanying reaction was run in which the ketone was omitted and the first-order hydrolysis rate of **5**, k_{dec}, determined. We found that the latter quantity showed a greater variation than expected, the cause of which could not be traced. An enormous number of kinetic experiments would have to be performed to encompass all the envisaged substituent, isotopic, and temperature variations using the above procedure; thus, in some cases we simply subtracted the decomposition rate from the observed rate to obtain the pseudo first-order rate constant for the bimolecular process(es). Despite the variations in the decomposition rate referred to above, the error introduced when a considerable excess of ketone is used is quite small. The

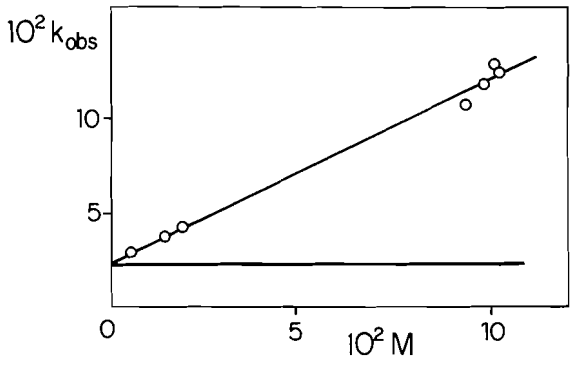

FIG. 1. Variation of k_{obs} with concentration of trifluoroacetophenone, T = 43.4°C. The horizontal line represents the decomposition rate of **5** (average of blanks accompanying reaction of **5** with ketone).

second-order rate constant k_2' was then obtained using eq. [4], where [ketone] is the total quantity of ketone added.

$$[4] \quad k_2' = (k_{obs} - k_{dec})/[\text{ketone}]$$

The values of k_2' obtained by one of the above procedures were then corrected for hydration of the ketone by using the equilibrium constant that is known, or that can be calculated, for each of the ketones (see Experimental) to give k_2, the true bimolecular rate constant for reaction of ketone and dihydronicotinamide. The results for 15 ketones are given in Table 1.

Substituent Effects

When the values of log k_2 and log k_2' are plotted against the Hammett substituent constant σ an interesting pattern emerges (Fig. 2). For the unsubstituted compound and those containing electron-withdrawing groups there is virtually no effect of substituent on the rate of reaction of the nicotinamide with the ketones, when no correction is made for the degree of hydration of the ketones. This tells us that the effect of substituents on the rate of reaction of these compounds is virtually identical to the effect of substituents on the equilibrium constant for hydration of the same compounds. For these compounds the rate constant corrected for the varying degrees of hydration of the ketones shows a large substituent effect. In the eight substituents ranging from Y = H to Y = 3-NO_2 the rho value is +1.98 (correlation coefficient 0.9908), showing that the reaction is subject to a strong electronic effect.

There is clearly a sharp break in the curve for the uncorrected rate constant k_2' as the σ values become negative, with the rate of reaction showing an increase with increasing electron donation by the substituent Y. When Y = 4-$(CH_3)_2N$ the degree of hydration is quite small and the values of k_2 and k_2' are almost identical. The two curves thus coalesce here, as expected.

The break in the curves in Fig. 2 is clearly caused by a second reaction of the dihydronicotinamide supplanting the reduction of ketone to alcohol, the following yields of alcohol being found using glc: 3-NO_2 (75%), 3-CF_3 (87%), unsubstituted (73%), 4-CH_3O (21%), 4-C_2H_5O (17%), 4-NH_2 (0.1%), 4-$(CH_3)_2N$ (0.1%).

We have been unable to positively identify the components of the mixture formed by the reaction of **5** with the amino compounds, but they appear to

include decomposition products of the dihydronicotinamide. The report of the formation of the adduct **4** appeared in the literature (8) after this work was completed and the analogous compound may also be a component of the mixture formed from the amino ketones. The possible catalytic effect of aromatic amino groups on the decomposition of **5** was checked by measuring its rate of decomposition in the presence of varying amounts of aniline and dimethylaniline. A catalytic effect was, indeed, observed but it is far too small to account for the rates of disappearance of **5** in the presence of the amino ketones. Thus, in order to double the rate of decomposition of **5** the presence of a roughly 80-fold excess of dimethylaniline was required, whereas this effect can be achieved with less than a 3-fold excess of 4-dimethylaminotrifluoroacetophenone.

Isotope Effects

The effects of deuterium substitution at the 4-position of **5** was examined for a number of ketones. The compound **5**-d_1 was prepared by the reduction of the pyridinium compound using sodium dithionite and D_2O; **5**-d_2 was prepared by a sequence of reductions and oxidations in the same manner.

5-d_1 **5**-d_2

Table 2 gives the values of $k_2'^{HH}$, $k_2'^{HD}$, and $k_2'^{DD}$ which are, respectively, the rate constants for the reaction of **5**, **5**-d_1, and **5**-d_2 with trifluoroacetophenone and four of its derivatives containing electron-withdrawing groups. Since such compounds give high yields of alcohol we assume that the isotope effects apply to the carbonyl reduction process. Both primary (p) and secondary (s) isotope effects will be associated with the hydrogen transfer process and, provided the kinetic data are sufficiently precise, both can be determined using the following relations.

$$[5]\quad k^{HH}/k^{DD} = p.s$$

$$[6]\quad k^{HD} = \frac{1}{2}\frac{k^{HH}}{p} + \frac{1}{2}\frac{k^{HH}}{s}$$

$$[7]\quad k^{DD}p^2 - 2k^{HD}p + k^{HH} = 0$$

Equations [5] and [6] (14) can be combined to give eq. [7], a quadratic which can be solved to give two roots, one of which corresponds to the primary isotope effect p. It can be easily shown that the other root is the secondary isotope effect s. We assign p to the larger and s to the smaller root. Equation [7] is sensitive to errors in the rate constants and imaginary roots can result if the rate data are not sufficiently precise.

Figure 3 shows rate plots for **5**, **5**-d_1, and **5**-d_2 reacting with 3-$CF_3C_6H_4COCF_3$. It is apparent from the slopes of the lines that isotopic substitution does not produce large rate changes. For this system the roots of eq. [7] are 1.19 and 1.43, the former presumably being s and the latter p. Because of the sensitivity of the roots of eq. [7] to experimental error in any one of the rate constants k^{HH}, k^{HD}, or k^{DD} we have concluded that it is preferable to calculate an average value of s for all systems that give real roots and then to apply this value to calculate p for the various systems studied. The rationale here is that s is not likely to be far from unity and is less likely to be affected by structural and mechanistic changes than is p. Indeed, previous workers who have used compounds analogous to **5** and **5**-d_1 have simply taken s to be unity and then calculated p from rate data on this basis (1, 8, 15). We have averaged the smaller of the real roots

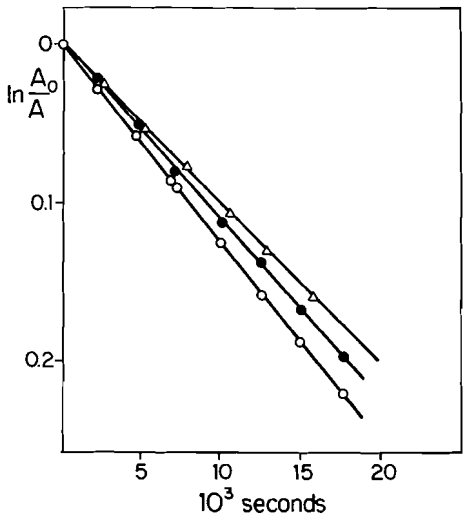

FIG. 3. Reaction of 3-$CF_3C_6H_4COCF_3$ with **5** (open circles), **5**-d_1 (closed circles), and **5**-d_2 (triangles). $T = 43.4°C$.

for all systems studied, giving a value for s of 1.08 (standard deviation ±0.11). The reaction site in the dihydronicotinamide changes from sp^3 to sp^2 during the reaction and such changes almost always produce small positive secondary deuterium isotope effects (16, 17) and our estimated value of 1.08 seems not unreasonable (see, however ref. 18). The primary isotope effects listed in Table 2 are based on this value of s and it is assumed that s does not change with changing temperature or substituent.

The values of p in Table 2 range from 1.45 to 1.83. Any variations of p with structure or with temperature are concealed by the limited precision of the rate data. One can conclude, however, that for the ketone reduction process the primary isotope effect is small and relatively insensitive to substituents in the ring of the ketone being reduced.

Activation Parameters

The data for the unsubstituted ketone in Table 2 give an apparent value of $\Delta H^{\ddagger}$ of 15.2 kcal mol^{-1} (63.5 kJ mol^{-1}) for reaction with **5**, the activation entropy being −27.0 cal deg^{-1} mol^{-1} (−113 J deg^{-1} mol^{-1}). These values are uncorrected for ketone hydration. Since the thermodynamic parameters of the dehydration step and the activation parameters of the reduction step(s) comprise the experimentally observed activation parameters, the entropy of activation of the reduction can be estimated as follows. The equilibrium hydration of the 4-methoxy compound has $\Delta H = -6.7$ kcal mol^{-1} and $\Delta S = -19.4$ cal deg^{-1} mol^{-1} (11), values which were observed to not change greatly when fairly large amounts of sulfolane were added. If ΔS for the hydration of the unsubstituted compound is also near −20 kcal mol^{-1} the entropy of activation for the rate-controlling step of the reduction must be a fairly large negative value, somewhere between −45 and −50 cal deg^{-1} mol^{-1}.

The primary isotope effects for reaction of the deuterated compound **5**-d_2 with trifluoroacetophenone corresponds to an energy difference of only 0.3 kcal mol^{-1} and the kinetic data are not sufficiently precise to allow the partition of this quantity between enthalpy and entropy with any precision. However, for both **5**-d_1 and **5**-d_2 a higher enthalpy of activation appears to be the source of most of the isotope effect.

Mechanism

It is clear from Fig. 2 that there are at least two different reactions taking place between aryl trifluoromethyl ketones and the dihydronicotinamide.

Consider first the reduction of ketone to alcohol, which predominates for ketones lacking an electron-donating substituent. This process is characterized by (*a*) a substantial positive rho, (*b*) a small primary isotope effect, and (*c*) a large negative entropy of activation. The simplest mechanism to be considered with respect to these criteria is hydride transfer to give pyridinium ion and alkoxide ion. Sodium borohydride reduction, which is a direct model for hydride transfer, has a rho of 3.12 in 2-propanol (19), somewhat larger than the value of 1.98 we observe. (The latter rho may be actually slightly larger since some of the competing reaction may be contributing to the reaction of the compounds containing less strongly electron-attracting groups.) Hydride transfer reactions often have modest isotope effects (20, 21) but they are not often as small as those observed herein. And finally, the entropy of activation seems rather large in magnitude for a simple bimolecular reaction between neutral molecules.

A number of possible intermediates have been suggested for reactions of dihydropyridines with oxidants, including charge-transfer complexes, complexes of radicals with radical-cations, and covalent adducts such as **4** (7, 8, 22, 23). A rapidly and reversibly formed intermediate lying on the reaction path, such as a charge-transfer or other complex, will have little effect on the overall rho or on the entropy of activation, provided it is not the major component at equilibrium. Though the size of the isotope effect would be a function of whatever species are involved in the carbon–hydrogen bond-breaking step, the present state of the art does not allow mechanism to be assigned on this basis with any degree of confidence (20, 24). Thus our

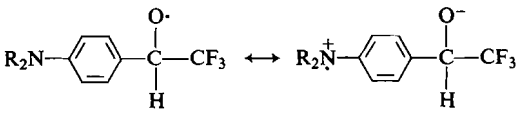
results are silent with respect to direct hydride transfer or net hydride transfer via an intermediate complex present in small concentration.

Adducts such as **4** are not on the reaction path; they could be slowly reconverted to reactants and eventually to redox products (8). If the measured rate of disappearance of dihydronicotinamide were due only to adduct formation the rho value would correspond to this process and there would be no isotope effect. A possible model for the adduct is the ketone hydrate and it may be significant that the effect of substituents on the equilibrium governing formation of the latter is identical to that which we observe in this work (25). The isotope effect can only be reconciled with this mechanism if the redox reaction has a substantial isotope effect and contributes significantly to the measured rate. Furthermore, the rho values for the redox reaction and adduct formation must not be drastically different in order that the isotope effect be relatively insensitive to substituent, as is observed. The large negative entropy of activation, 45–50 cal deg^{-1} mol^{-1}, is consistent with adduct formation, providing the transition state includes the three molecules required to form the adduct. Putting it another way, the measured value of -27 cal deg^{-1} mol^{-1} is consistent with adduct formation from a molecule of ketone hydrate and a molecule of dihydronicotinamide.



The results for the alcohol producing reaction appear to be best accommodated by the following mechanism (Scheme 1): a net hydride transfer, probably accompanied by some reversible formation of an adduct such as **4**, as suggested by van Eikeren *et al.* (8).

SCHEME 1

Were hydride transfer alone occurring one might have expected to find a somewhat higher rho, a somewhat higher primary isotope effect, and a somewhat less negative entropy of activation.

For ketones containing such groups as amino the reaction is mysterious, particularly so since we cannot identify the components in the mixture of products. It is difficult to see how a reaction between an aryl ketone and a dihydropyridine can have a negative rho, since the ketone itself is stabilized by groups such as amino. One possibility is hydrogen-atom transfer from the dihydropyridine to give the radical **6**, which would be stabilized by resonance in a way not open to ketones with electron-withdrawing groups in the ring. Such a radical might then decompose to give a mixture of products.

6

Summary

The reduction of aryl trifluoromethyl ketones to alcohols by *N*-carbamoylmethyl-1,4-dihydronicotinamide is facilitated by electron-withdrawing groups in the aryl ring but this effect is cancelled in aqueous systems by competing ketone hydrate formation. The mechanism appears to be hydride transfer, very possibly accompanied by blind-alley formation of an adduct between ketone hydrate and dihydronicotinamide. Electron-donating groups in the aryl ring favour a competing reaction that does not produce alcohol.

Experimental

Materials

The preparation of the ketones has been previously described (11–13, 19, 26) except for the following compounds.

3-Trifluoromethyltrifluoroacetophenone was prepared in 48% yield by the Grignard synthesis using *m*-trifluoromethylbromobenzene and trifluoroacetic acid (19); bp 59°C at 20 Torr. *Anal.* calcd. for $C_9H_4OF_6$: C 44.65, H 1.67; found: C44.75, H 1.69.

3-Chlorotrifluoroacetophenone was prepared by the Grignard method from *m*-iodochlorobenzene, bp 50°C at 9 Torr. *Anal.* calcd. for $C_8H_4OF_3Cl$: C 46.29, H 1.94; found: C 46.15, H 2.08.

N-Carbamoylmethyl-1,4-dihydronicotinamide **5** was prepared as previously described (10). The 4-deuterio compound **5**-d_1 was prepared in 83% yield (0.99 *d* at C-4 by nmr) by reduction of the pyridinium salt, using sodium dithionite and D_2O, using the general method of Caughey and Schellenberg (27). Four and one-half cycles of oxidation by chloranil followed by dithionite reduction in D_2O (27) gave the dideuterio compound **5**-d_2 containing 1.90 atoms of deuterium at C-4 by nmr. It was observed that the methylene protons of the carbamoylmethyl group at N-1 were almost completely deuterated in the product. It was assumed that this isotopic substitution had no effect on the redox reaction.

The pK_{BH^+} of **5** was determined spectrophotometrically using the 347.5 nm peak in the aqueous sulfolane system used for the kinetic experiments. An apparent pK_{BH^+} of 6.46 was obtained, based on glass electrode standardized against aqueous buffer. The pH of the aqueous sulfolane buffer system (21.8% sulfolane by volume) used in the kinetic experiments was 8.3 on the same basis. The buffer was 0.1 molar in each of triethanolamine and triethanolammonium chloride and 0.4 molar in sodium perchlorate.

Kinetic Procedure

The ketones and the dihydronicotinamide were dissolved in the aqueous sulfolane buffer to give stock solutions that were thermally equilibrated before the kinetic runs were begun. The peak for **5** at 347.5 nm has some ketone absorption in the case of

amino and alkoxy compounds. Since these were the compounds that gave higher rates than expected, additional experiments were undertaken using wavelengths as high as 380 nm. Although such measurements on the side of the absorption curve lacked some precision, they did not show any trend that would suggest the rates measured at 347.5 nm are spurious.

The second-order rate constant k_2' was corrected for ketone hydration as follows. The dehydration of trifluoromethyl ketones is governed by eq. [7], where Z is ketone and ZH_2O is ketone hydrate, W_0 is the hydration parameter, and pK_d the negative logarithm of the equilibrium constant for the reaction $ZH_2O \rightleftharpoons Z + H_2O$ in the standard state water (11, 12).

[7] $$W_0 = pK_d + \log [Z]/[ZH_2O]$$

[8] $$pK_d = 1.62\sigma^+ + 1.96$$

At 31.4°C eq. [8] holds for these ketones and K_d (standard state water) can be calculated for those compounds whose K_d values have not been previously determined (12). W_0 for 21.8% (v/v) aqueous sulfolane is 0.12 (11) and using this quantity and eqs. [7] and [8] gives eq. [9].

[9] $$\log [ZH_2O]/[Z] = 1.62\sigma^+ + 1.84$$

A temperature correction was made, based on the known heat of hydration of the 4-methoxy compound, $\Delta H = -6.7$ kcal mol^{-1} (11). Since the temperature correction is not large, $([ZH_2O]/[Z])^{43.4°} = ([ZH_2O]/[Z])^{31.4°}/1.55$, it is assumed that variations of ΔH with substituent do not give rise to significant errors.

In all cases examined the ketone – ketone hydrate relaxation rate was much faster than the reaction of the dihydronicotinamide.

The reaction products were isolated as follows. After standing for six days the reaction mixture on which the kinetics had been followed was extracted with an equal volume of ether–pentane (v/v = 1, four times). The combined organic extract was washed, dried, concentrated, and then subjected to analysis by gas–liquid chromatography and mass spectrometry. Authentic samples of alcohols were used for comparison of the chromatographic peaks in the reaction products.

Horseradish peroxidase. XL. The oxidation of native enzyme to Compound II

ALEXANDER D. NADEZHDIN AND H. BRIAN DUNFORD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 1, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

ALEXANDER D. NADEZHDIN and H. BRIAN DUNFORD. Can. J. Chem. **58**, 2504 (1980).

The oxidation of native horseradish peroxidase to Compound II by photochemically generated inorganic free radicals $SO_4^{\cdot-}$, $Cl_2^{\cdot-}$, and $Br_2^{\cdot-}$ was observed. The rates of Compound II accumulation for different rates of free radical generation and different reagent concentrations have been measured. The interpretation of the experimental data allowed us to estimate the rates of the reactions $SO_4^{\cdot-}$ + HRP, $Br_2^{\cdot-}$ + HRP, and $Cl_2^{\cdot-}$ + HRP: (3–6) × 10^6 M^{-1} s^{-1}, (2.2–3.0) × 10^6 M^{-1} s^{-1}, and $\gtrsim 10^8$ M^{-1} s^{-1} respectively. Also obtained for all three oxidants were the ratios of the number of free radicals responsible for the heme oxidation to the total number of them attacking the enzyme.

ALEXANDER D. NADEZHDIN et H. BRIAN DUNFORD. Can. J. Chem. **58**, 2504 (1980).

On a observé l'oxydation de la peroxydase du raifort naturelle en un composé II par les radicaux inorganiques libres $SO_4^{\cdot-}$, $Cl_2^{\cdot-}$, $Br_2^{\cdot-}$ produits photochimiquement. On a mesuré la vitesse d'accumulation du composé II pour différentes vitesses de formation de radical libre et pour différentes concentrations de réactif. L'interprétation des données expérimentales nous permet d'évaluer la vitesse des réactions $SO_4^{\cdot-}$ + HRP, $Br_2^{\cdot-}$ + HRP et $Cl_2^{\cdot-}$ + HRP: (3–6) × 10^6 M^{-1} s^{-1}, (2.2–3.0) × 10^6 M^{-1} s^{-1} et $\gtrsim 10^8$ M^{-1} s^{-1} respectivement. On a également obtenu, pour les trois oxydants, les rapports entre le nombre de radicaux libres responsables de l'oxydation de l'hème et le nombre total de ceux qui attaquent l'enzyme.

[Traduit par le journal]

Introduction

Pulse and steady state radiolysis techniques have been used for more than a decade (1–5) for the study of enzyme reactions with free radical reductants such as e^-, ·H, or oxidants like ·OH, SCN^-, $Cl_2^{\cdot-}$, or $Br_2^{\cdot-}$. Rate constants, most of which are over 10^{10} $M^{-1}s^{-1}$, have been reported (1, 5, 7). In some cases the spectral changes caused by attack of free radicals were assigned to specific radical sites on the protein surface (6). Combined pulse radiolysis and enzyme inactivation studies of lysozyme, ribonuclease, trypsin, and α-chymotrypsin led to successful identification of the amino acid residues essential for enzymatic activity (2, 3). As was shown in ref. 4, many radicals by themselves are inefficient in the inactivation of trypsin.

In the case of the iron-containing hemoproteins, ferrocytochrome *c* and catalase, no appreciable oxidation of the heme iron by ·OH radicals was observed, while hydrated electrons reduce the heme group of ferricytochrome *c* very effectively but do not change the valence state of catalase iron (1, 5).

In this paper we report the results of a photochemical study of horseradish peroxidase (HRP) reactions with three inorganic free radicals $SO_4^{\cdot-}$, $Br_2^{\cdot-}$, and $Cl_2^{\cdot-}$. Sulfate radicals were produced in the water solution containing HRP and sodium persulfate under uv light irradiation according to the photochemical reaction (8):

$$[1]\quad S_2O_8^{2-} \xrightarrow{h\nu} 2SO_4^{\cdot-}$$

When sufficient amounts of sodium chloride and bromide were added to the system all primary $SO_4^{\cdot-}$ radicals were scavenged by Cl^- or Br^- and $Cl_2^{\cdot-}$ or $Br_2^{\cdot-}$ were produced (9–11):

$$SO_4^{\cdot-} + Cl^- \rightarrow SO_4^{2-} + Cl^{\cdot}$$

$$Cl^{\cdot} + Cl^- \rightarrow Cl_2^{\cdot-}$$

$$SO_4^{\cdot-} + Br^- \rightarrow SO_4^{2-} + Br^{\cdot}$$

$$Br^{\cdot} + Br^- \rightarrow Br_2^{\cdot-}$$

Materials and Methods

HRP (grade I) was purchased from Boehringer Mannheim GMBH as an ammonium sulfate precipitate. The stock solution was prepared by extensive dialysis against quintuply distilled water. The purity number (A_{403}/A_{280}) was in excess of 3.1. All other chemicals were reagent grade and used without further purification. The pH of all solutions was adjusted by adding dilute NaOH or H_2SO_4. All experiments were performed at room temperature. The light of a medium pressure mercury lamp was used for the photolysis. It was collimated with quartz lenses and a quartz filter was used for cutting off light of wavelengths shorter than 275 nm which destroys the enzyme. Monochromatic light with λ = 313 nm was obtained by using a resonance filter (Baird Atomic). Irradiations were carried out in a 1 cm spectrophotometric quartz cell which was transferred immediately at the end of photolysis to a Cary 219 spectrophotometer for recording the optical spectra. Concentrations of HRP used were fairly small so its absorbance did not exceed 0.1 in the spectral region 360–280 nm, important for the photochemical reaction [1]. HRP as well as its Compound II prepared by a conventional method, described in ref. 12, were stable

under irradiation without persulfate for the periods of time typical for the photochemical experiments.

The following procedure was developed for determination of the $SO_4^{\cdot-}$ production rate. When the water solution containing $S_2O_8^{2-}$, ethyl alcohol, and tetranitromethane, $C(NO_2)_4$, was irradiated with uv light, the change in the optical spectrum was observed corresponding to accumulating nitroform anion, $C(NO_2)_3^-$, the product of tetranitromethane reduction. The rate of $C(NO_2)_3^-$ formation was directly proportional to $[S_2O_8^{2-}]$ and did not depend on tetranitromethane or alcohol concentrations over the concentration ranges: $[S_2O_8^{2-}] = 5 \times 10^{-4}$ to $10^{-2} M$, $[C(NO_2)_4] = 3 \times 10^{-5}$ to $6 \times 10^{-4} M$, $[C_2H_5OH] = 5 \times 10^{-2}$ to $4 \times 10^{-1} M$. No appreciable change of the spectra was observed in the dark or in the absence of either one of the three components under irradiation. Such behaviour was explained in terms of the following mechanism: $SO_4^{\cdot-}$ radicals formed in the primary photochemical step (reaction [1]) attack ethyl alcohol, producing free radicals which reduce tetranitromethane giving $C(NO_2)_3^{\cdot}$ as the final product. Hence the number of $SO_4^{\cdot-}$ radicals produced by light is equal to the number of $C(NO_2)_3^{\cdot}$ formed times n, where n depends on the total stoichiometry. The value of $n = 1 \pm 0.2$ was determined by using monochromatic light with $\lambda = 313$ nm for the photolysis of the system $S_2O_8^{2-}$–C_2H_5OH–$C(NO_2)_4$, and the following expression

$$n \cdot d[C(NO_2)_3^-]/dt = 2.3\, I_0 \cdot [S_2O_8^{2-}] \cdot \varepsilon_{313} \cdot \psi_{313} \cdot l$$

where I_0 is the light intensity at $\lambda = 313$ nm, measured by a standard procedure (13), ε the molar absorptivity of persulfate, ψ the quantum yield of reaction [1] equal to 0.75 (8), and l is the optical path length of the cell.

Results and Discussion

The effect of uv light on the solution containing HRP and $S_2O_8^{2-}$ is illustrated in Fig. 1 where the optical spectra before (curve 1) and after (curves 2 and 3) irradiation are shown. The well resolved isosbestic points at 338, 411, 450, and 524 nm and the directions of the changes clearly indicate the formation of the HRP Compound II, i.e. one-electron oxidation of the heme (14). The addition of a small excess of *p*-cresol to the irradiated solution led to almost complete (more than 95%) conversion back to the native enzyme (spectrum shown by the dotted line in Fig. 1). This provides another proof of Compound II formation in the course of HRP oxidation by $SO_4^{\cdot-}$ radicals. However, the photochemically formed Compound II was somewhat less stable than that obtained by conventional chemical methods (12) and this instability increased with increasing time of irradiation. Nevertheless, in the initial stages of photolysis the Compound II stability was good enough to enable quantitative measurements of the light induced spectral changes and to obtain the values of $R_{II} = d[\text{Compound II}]/dt$.

The irradiation of HRP–$S_2O_8^{2-}$ solutions containing NaCl or NaBr in amounts sufficient for scavenging of all primary $SO_4^{\cdot-}$ radicals produced qualitatively the same spectral change, i.e. the same product. Although the absolute rate of Compound II accumulation was dependent on the nature of the anions present, it did not depend on their amount provided [NaCl] or [NaBr] was over $10^{-2} M$. The measured values of R_{II} together with $SO_4^{\cdot-}$ radical generation rates for different concentration conditions with or without chloride or bromide salts are listed in Table 1.

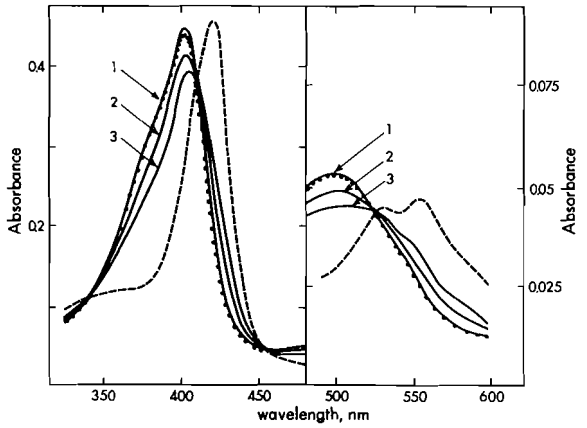

FIG. 1. Effect of uv light on the system HRP + $S_2O_8^{2-}$. The spectra shown are: 1, before irradiation; 2, after 250 s of irradiation; 3, after an additional 500 s under the light; .... after adding *p*-cresol to the irradiated solution; ---- spectrum of Compound II prepared by conventional method (12). [HRP] = $4.3 \times 10^{-6} M$, $[S_2O_8^{2-}] = 10^{-2} M$, pH = 6.3, 22°C.

The interpretation of the data must be empirical, since the radicals interact with the enzyme at several sites at least two of which are not equivalent. Nevertheless, a more detailed analysis is possible than in recent studies of the oxidation of Compound II to I (15, 16). Only a part of all $SO_4^{\cdot-}$ radicals captured by HRP react directly with the heme, the other part attacks different places on the enzyme surface, i.e. carbohydrate chains (17) or amino acid residues. If α is the ratio of the number of sulfate radicals responsible for the heme oxidation to the total number of $SO_4^{\cdot-}$ attacking HRP molecules (as shown in Fig. 2) then the rate of Compound II formation will be given by eq. [2]:

$$[2] \quad R_{II} = \alpha \cdot k\,[SO_4^{\cdot-}]\,[HRP]$$

where k is the total reaction rate constant of $SO_4^{\cdot-}$ scavenging by HRP. The recombination of $SO_4^{\cdot-}$

$$R^{\cdot} + HRP \begin{cases} \text{heme} \xrightarrow{\alpha k} \text{Compound II} \\ \text{protein} \xrightarrow{(1-\alpha)k} \text{Modified protein} \end{cases} + R^-$$

FIG. 2. Simplified scheme of HRP interaction with free radical oxidants. $R^{\cdot}$ corresponds to $SO_4^{\cdot-}$, $Br_2^{\cdot-}$, or $Cl_2^{\cdot-}$.

radicals also occurs

[3] $SO_4^{\bar{}} + SO_4^{\bar{}} \xrightarrow{k_3} S_2O_8^{2-}$

According to the steady state approximation the rate of photochemical generation of $SO_4^{\bar{}}$ radicals (R_{ph}) must be equal to the overall rate of their consumption:

[4] $R_{ph} = k\,[SO_4^{\bar{}}]\,[HRP] + 2k_3\,[SO_4^{\bar{}}]^2$

Combining [4] with [2] one gets

$$R_{ph} = \frac{1}{\alpha} R_{II} + \frac{2k_3}{\alpha^2 k^2 [HRP]^2} \cdot R_{II}$$

or

[5] $$\frac{R_{ph}}{R_{II}} = \frac{1}{\alpha} + \frac{2k_3}{\alpha^2 k^2} \cdot \frac{R_{II}}{[HRP]^2}$$

According to [5] the plot of R_{ph}/R_{II} vs. $R_{II}/[HRP]^2$ will be a straight line. When $Cl_2^{\bar{}}$ or $Br_2^{\bar{}}$ is used instead of $SO_4^{\bar{}}$ the equation will still be valid provided the values of k, k_3, and α correspond to the new radicals.

In Fig. 3 the data from Table 1 are plotted according to eq. [5] for all three systems and straight line plots are obtained. The values of α and $2k_3/\alpha^2 k^2$ provided by the slopes and intercepts for

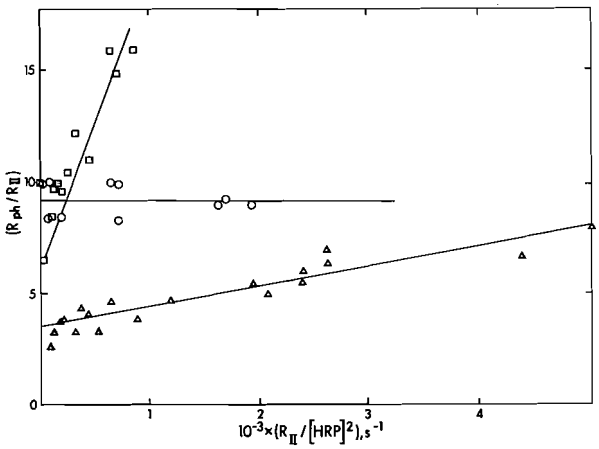

FIG. 3. Experimental data from Table 1 plotted according to eq. [5] in the coordinates R_{ph}/R_{II} and $R_{II}/[HRP]^2$. △△, $S_2O_8^{2-}$ + HRP; ⊙⊙, $S_2O_8^{2-}$ + HRP + NaCl; □□, $S_2O_8^{2-}$ + HRP + NaBr.

TABLE 2. The values of α, $2k_3/\alpha^2k^2$, and k

Radical	α	$2k_3/\alpha^2k^2$, M s	k, M^{-1} s^{-1}
$SO_4^{\bar{\cdot}}$	0.3	8.5×10^{-4}	$(3–6) \times 10^6$
$Br_2^{\bar{\cdot}}$	0.16	1.25×10^{-2}	$(2.2–3.0) \times 10^6$
$Cl_2^{\bar{\cdot}}$	0.11	$\lesssim 1 \times 10^{-4}$	$\gtrsim 10^8$

all three oxidants are listed in Table 2. The rate constants ($2k_3$) of the $SO_4^{\bar{\cdot}}$, $Br_2^{\bar{\cdot}}$, and $Cl_2^{\bar{\cdot}}$ recombination measured by different methods and gathered in ref. 18 are: $(0.75–3.6) \times 10^9$, $(1.6–2.6) \times 10^9$, and $(0.3–1.7) \times 10^{10}$ $M^{-1}s^{-1}$ respectively. Using these data and the values $2k_3/\alpha^2k^2$ from Table 2 we estimated the rate constants of HRP oxidation by $SO_4^{\bar{\cdot}}$, $Br_2^{\bar{\cdot}}$, and $Cl_2^{\bar{\cdot}}$ (k) and noted them in the last column of Table 2. Since no appreciable slope was observed in the $Cl_2^{\bar{\cdot}}$ plot in Fig. 3 only the lower limit of the $k(Cl_2^{\bar{\cdot}} + HRP)$ could be estimated.

Quite a surprising result of this study is that the rate constants for HRP oxidation by the powerful oxidants $SO_4^{\bar{\cdot}}$ and $Br_2^{\bar{\cdot}}$ are relatively low as compared with those for catalase or hemoglobin oxidation by ·OH radicals (over 10^{10} $M^{-1}s^{-1}$) (7) or for the reactions of $Br_2^{\bar{\cdot}}$ with tyrosine, tryptophan, and cysteine (over 10^7 $M^{-1}s^{-1}$) (2). The obvious conclusion is that the most easily oxidized amino acids mentioned above are not exposed on the surface of HRP.

Another feature is that there are about five different sites of the protein moiety in case of $Br_2^{\bar{\cdot}}$, eight of them in case of $Cl_2^{\bar{\cdot}}$, or two in case of $SO_4^{\bar{\cdot}}$ oxidized per one directly oxidized heme center. These oxidized locations on the protein surface can serve as good reductants for the newly formed Compound II which would account for its lower stability. On the other hand the oxidation of so many residues on the surface per one native enzyme – Compound II transformation has little effect on the enzyme integrity or its optical spectrum. This can be seen in Fig. 1 where the spectrum of the solution obtained after addition of *p*-cresol to the photochemically formed Compound II is shown. An appreciable part of HRP surface in solution is covered by carbohydrate chains (17), the destruction of which might not affect the integrity or catalytic activity of HRP and its compounds.

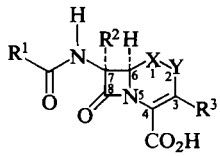
Received March 31, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

TERRENCE W. DOYLE, JAMES L. DOUGLAS, BERNARD BELLEAU, TERRY T. CONWAY, C. F. FERRARI, DONALD E. HORNING, GARY LIM, BING-YU LUH, ALAIN MARTEL, MARCEL MENARD, L. R. MORRIS, and MARTIN MISIEK. Can. J. Chem. **58**, 2508 (1980).



The general synthetic scheme to nuclear analogs of cephalosporins described in previous papers of this series is reviewed and the synthesis of a series of sidechain derivatives is given. Thus, systems of the following type were formed: carbacephems (A), 2-isocephems (B), *N*-2-isocephems (C), and *O*-2-isocephems (D). The *in vitro* microbiological activity of these compounds (with appropriate side-chains attached) is given, with comparison to analogous cephalosporins. Systems of type A, B, and C were only prepared with a 3-H or CH_3 substituent and had modest antibacterial activity. The *O*-2-isocephems (D) were prepared with a wide variety of sidechains at 3 and 7 and were found to have biological activity quite comparable to the cephalosporins. A more detailed biological examination (both *in vitro* and *in vivo*) of the *O*-2-isocephem analog (**19***i*) of cephalothin was made.

TERRENCE W. DOYLE, JAMES L. DOUGLAS, BERNARD BELLEAU, TERRY T. CONWAY, C. F. FERRARI, DONALD E. HORNING, GARY LIM, BING-YU LUH, ALAIN MARTEL, MARCEL MENARD, L. R. MORRIS et MARTIN MISIEK. Can. J. Chem. **58**, 2508 (1980).

On passe en revue le schéma de synthèse générale des analogues nucléaires des céphalosporines décrit antérieurement dans cette série et on rapporte la synthèse des dérivés de la chaîne latérale. On a ainsi préparé les systèmes suivants: carbacéphèmes (A), isocéphèmes-2 (B), *N*-isocéphèmes-2 (C) et *O*-isocéphèmes-2 (D). On donne l'activité microbiologique *in vitro* de ces composés (avec les chaînes latérales appropriées) par comparaison avec les céphalosporines analogues. On a préparé les composés de types A, B et C avec des substituants H-3 où CH_3 et ils ont une activité antibactérienne modérée. On a préparé les *O*-isocéphèmes-2 (D) ayant une grande variété de chaînes latérales en positions 3 et 7 et on leur a trouvé une activité tout à fait comparable à celle des céphalosporines. On a réalisé un examen biologique (*in vitro* et *in vivo*) plus détaillé de l'analogue *O*-isocéphème-2 (**19***i*) de la céphalothine.

[Traduit par le journal]

While literally thousands of semisynthetic penicillins and cephalosporins, obtained by manipulation of the C6 (or C7) amide side chains or the C3 side chain in the cephalosporins, are known, it is only relatively recently that β-lactam antibiotics extensively modified in the nucleus have been reported (for a recent review see ref. 1). Whether natural or synthetic in origin, these analogs have shattered many of the notions regarding the requirements for optimal activity which were current when we started our work. Our initial goals were rather modest ones, being to first examine whether or not it was necessary to retain the sulfur atom at position one in the cephalosporin ring **1** (Fig. 1) (X = S, Y = CH_2), and secondly if the heteroatom could be transposed to position 2 (X = CH_2, Y = O, S, N, etc.). In the previous papers of this series we have reported the syntheses of a variety of nuclear analogs of the cephalosporins in which the sulfur atom has been replaced by variously substituted carbon atoms and position two by various heteroatoms, as well as retaining a carbon atom

1

FIG. 1

(e.g. X has been CH_2, CHCl, $CH(CH_3)$, C=O, and Y has been O, S, SO, SO_2, NCO_2Et, NCH_3, CH_2, C=O, CHOR, CHBr, in Fig. 1) (2*a*–*l*). While this work was in progress, a number of other workers reported the syntheses of cephalosporin analogs having the type of substitutions in which we were interested. Lowe and co-workers (3) have reported the syntheses of the 2-isocepham and 2-isocephem systems (X = CH_2, Y = S), as have Bryan and co-workers (4). The latter workers have also reported the syntheses of a 1,2-benzofused cephalosporin (5) and several cephams incorporating two nitrogen atoms at positions 2 and 3 as well as a carbonyl at position 1 (6). A large series of

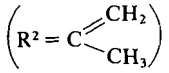
1-oxadethiacephalosporins has been synthesized and these are reported to have quite good antibacterial activity (7). In addition to these cephalosporins, a number of papers have appeared which describe the total syntheses of a number of other β-lactam nuclear analogs, i.e., *N*-2-isopenams (8), 2-isopenams (9), clavulanic acid (10), oxapenems (11), penems (12), and thienamycin (13). In this paper we wish to more fully describe the biological activities of the compounds we have reported earlier (2) and to describe the synthesis and biological activities of a number of additional analogs.

Chemistry

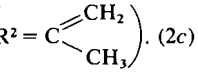
Initially our goal was the development of a general stereoselective synthesis which would provide access to a variety of isocephalosporins. As the work proceeded, the following general considerations evolved.

1. The substituted β-lactam would be synthesized first in a stereospecific manner so as to provide an amide at the eventual C7 position which would be *cis* to the second ring.



2. The substituent on the nitrogen atom of the initially-formed β-lactam would be used to form the second ring.[1]

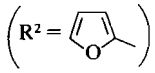
3. The attached carbon atom at C4 in the initial azetidinone would be sp^2 hybridized so as to minimize problems inherent in the synthetic scheme chosen to form the β-lactam.



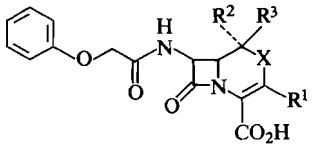
O-2-*Isocephems*

The synthetic scheme utilized for the majority of analogs we have synthesized may be illustrated by the synthesis of **8***a* ($R^1 = CH_3$) (Scheme I) (2*b*). Condensation of the amine **2** ($R^1 = CH_3$ throughout) with cinnamaldehyde gave **3** ($R^2 = CH{=}CH\phi$) which on treatment with azidoacetyl chloride in the presence of triethylamine gave the *cis* β-lactam **4***a* in good yield.[2] Ozonolysis of **4***a* gave **4***b* which was reduced by sodium borohydride to **4***c*. Compound **4***c* was converted to its mesylate **4***d* and hydrolysed to give a key intermediate **5***a*. When **5***a* was treated with base, cyclization occurred to the bicyclic β-lactam **6***a*. Reduction of **6***a* to the amine **7***a*, coupling to phenoxyacetic acid using EEDQ (14),[3] and hydrogenolysis of the benzyl ester gave the desired acid **8***a* ($R^1 = CH_3$, $R^2 = R^3 = H$). The syntheses of **8***b–d* were carried out similarly (2*b*) using the appropriately substituted amines **2**, or in the case of **8***b* starting from **9** (2*a*).

In the case of the *O*-2-isocephems carrying substituents at position 1, we employed either methacrylaldehyde or furfural as the aldehyde in the Schiff base forming step. Thus, treatment of **3**



with azido acetyl chloride and TEA gave the β-lactam **4**



(2*c*)

Ozonolysis followed by sodium borohydride reduction gave two diastereoisomeric alcohols (**4**, $R^2 = \overset{*}{C}HOHCH_3$) which were separated by chromatography and carried through the same sequence of reactions to yield **8***e* and **8***f*. From the 4-furyl β-lactam **4**

was obtained **8***g* (2*d*) (Fig. 2).

One goal was the production of analogs having a 3-acetoxymethyl group in place of the 3-methyl group of **8***a*. Initially we had intended to produce these compounds via functionalization of **8***a* or **6***a*. A number of attempts to functionalize the 3-methyl group using NBS or other free radical oxidizing

FIG. 2

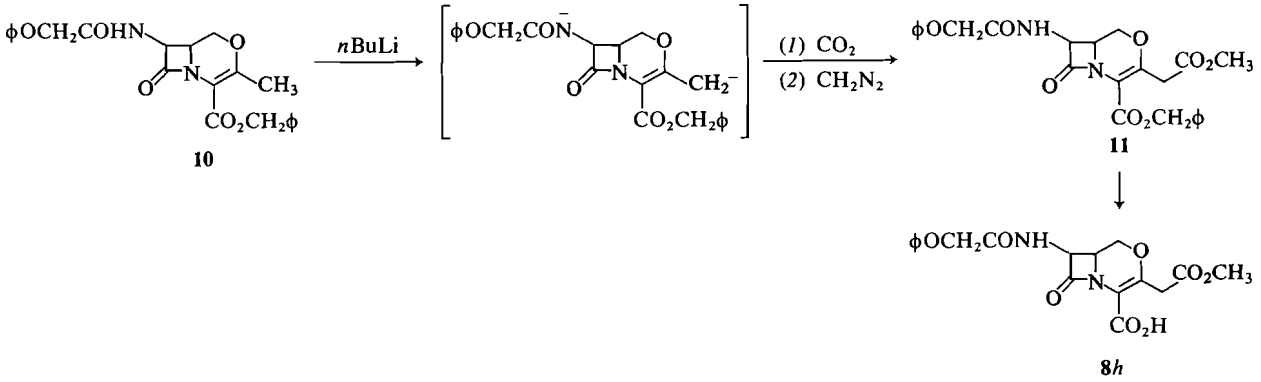
[1]Initially we attempted to use a variety of nitrogen blocking groups which we hoped to remove selectively, e.g. trityl, benzhydryl, and benzyl. The results were poor and the alternate approach of incorporating the *N*-blocking group in the final structure was decided on. The group at SKF has successfully utilized the first approach in their synthesis of the 2-isocephem system (4).

[2]The stereoselectivity of this and all other cycloadditions we have carried out in the course of our work has been very high, there being no detectable amounts of *trans* isomer formed.

[3]*N*-Ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline has been used extensively in the course of our studies for coupling sidechains to the nuclei.

SCHEME 1

agents failed (2*h*).[4] As part of this study, the treatment of the benzyl ester of **8***a* with a variety of strong bases, followed by treatment with electrophiles, was examined. For the most part, this resulted in the decomposition of starting material and no isolable products or in recovery of the starting material unchanged. Treatment of **10** with *n*-butyllithium followed by quenching with carbon dioxide resulted in the formation of a mixture of carboxylic acids, which was further treated with diazomethane to yield the methyl ester **11** in 3.5% overall yield from **10**. Hydrogenolysis of **11** gave the carboxylic acid **8***h* (Scheme 2).



In view of the disappointing yield of **11**, further attempts to prepare the desired 3-acetoxymethyl compounds via direct functionalization of **6***a*, **8***a*, or **10** were abandoned. Routes based on amines such as **2** where $R^1 = CH_2OR$ also failed due to the fact that the presence of an α hetero atom rendered the subsequent hydrolysis of the ketals impossible without concomitant destruction of the β-lactam.[5] Fortunately, at about this time we discovered an alternate route to the desired compounds (2*h*). As part of our strategy to utilize the enol **5***a* to synthesize various other heteroatom substituted cephalosporins, the conversion of **5***a* to the dimesylate **12***a* or the mesylate triflate **12***b* had been carried out. This conversion was normally carried out by treating a mixture of the enol **5***a* plus either methane sulfonyl choride or triflic anhydride with one equivalent of triethylamine (TEA). On one occasion an excess of TEA was used and upon workup, instead of the desired **12**, compound **13** was obtained (Scheme 3). While **13** was unstable, it could be readily handled in solution. Halogenation of **13** with either bromine or iodine gave **14** as a mixture of geometrical isomers in excellent yields. When **14** was treated with potassium acetate in DMF, the desired 3-acetoxymethyl-*O*-2-isocephem **15***a* (R^1 = Bz) was produced in good yield. Attempted displacement of the 3-acetoxymethyl group by thiols failed. The hydrolysis of **15***a* to **15***c* did not proceed in good yield. Consequently, the solvolysis of **14***b* (R^1 = PNB) was carried out using potassium formate to yield **15***b* which could be hydrolysed to **15***c*. Treatment of **15***c* with sodium cyanate in trifluoroacetic acid gave the carbamate **15***d*. Mesylation of **15***c* gave **15***e* which was used to prepare **16***a–c* by displacement. While the displacements using the thiolates proceeded in good yield, that using 1-methyltetrazol-5-ol gave **16***c* in 22.5% yield. Compound **16***a* could also be prepared directly from **14***a* (R^1 = PNB). Thus, treatment of **14***a* with one equivalent of 1-methyltetrazole-5-thiol and TEA in CH_2Cl_2 gave **14***c* which was treated with potassium acetate in DMF to give **16***a*.

With compounds **6***a*, **15***a*, **15***d*, **16***a–c* readily available, the conversion of these to suitably substituted cephalosporin analogs was attempted next. We used two general methods to accomplish this goal. Reduction of the azide using hydrogen sulfide – triethylamine proceeded in good yield to give the amines **17***a*, *b* and **17***d–g*. In the case of **15***a* an alternate scheme was used. Hydrogenolysis of **15***a* over platinum accomplished both reduction of the azide and cleavage of the benzyl ester simultaneously to yield **17***c*. Compounds **17***a*, *b*, *d–g* were coupled to the appropriate carboxylic acids using EEDQ. Thus, from **17***a* we obtained **18***a–d*, from **17***b* compounds **18***e–g*, from **17***d* compound **18***h*, from **17***e* compounds **18***i–l*, from **17***f* compound **18***m*, and from **17***g* compound **18***n* (Scheme

[4]The SKF group has reported the successful bromination of the 2-isocephem system with NBS (4).

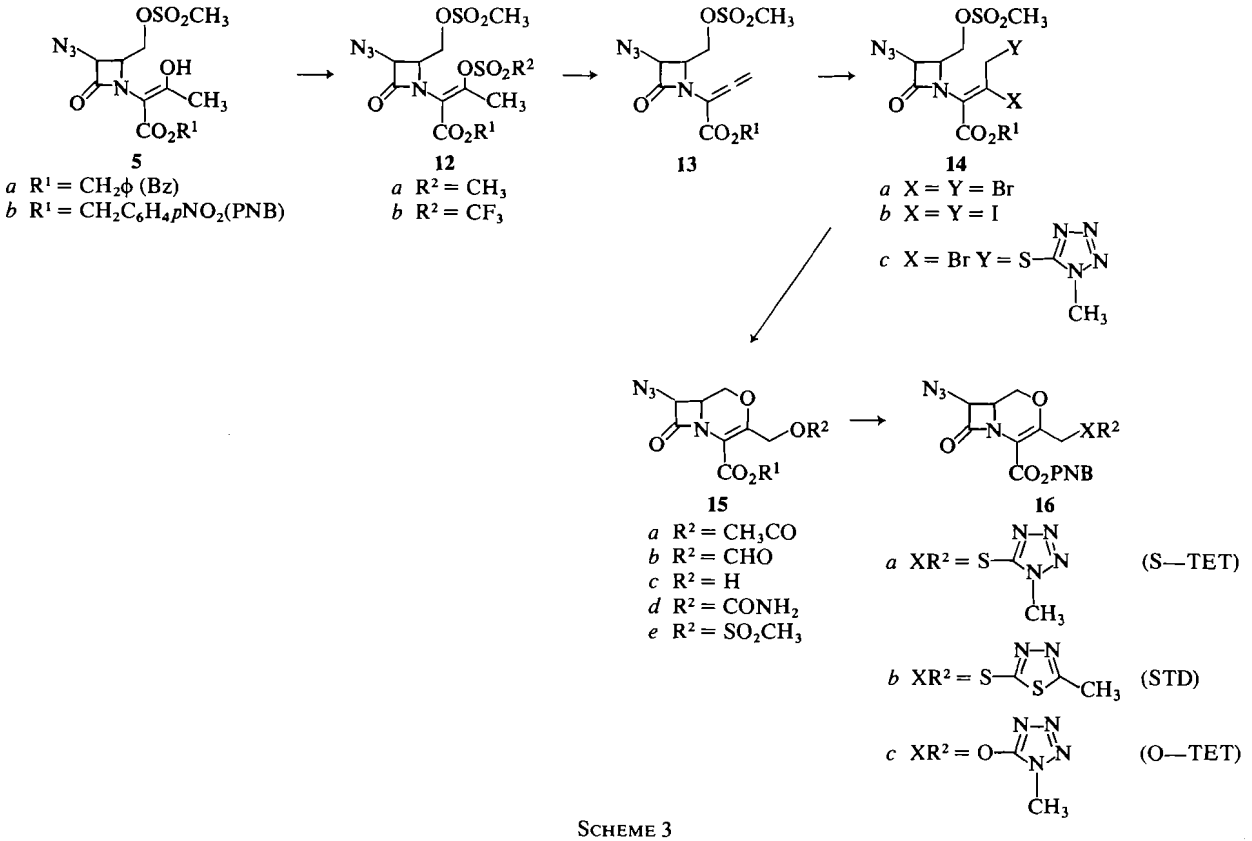
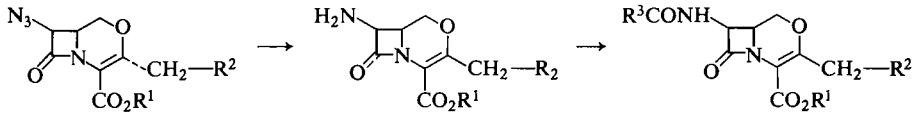


SCHEME 2

4), Hydrogenolysis of the benzyl or *p*-nitrobenzyl esters proceeded smoothly to give the corresponding carboxylic acids. In the cases of **18***b*, **18***c*, **18***e*, the secondary blocking groups on the sidechains were simultaneously deblocked. The azido function of **18***l* was reduced simultaneously with PNB removal to give **19***r*. A number of the final products were obtained via direct coupling of the acid chloride or mixed anhydrides to the amino acid. Thus, **17***c* was coupled with 4-chloromethylphenylacetyl chloride to give **20**. Reaction of **20** with thiourea gave **19***m*. Similarly, 2-(1-carbomethoxypropen-2-yl-aminomethyl)phenylacetic acid was coupled to **17***c* or **21** via the mixed anhydride procedure to yield **19***j* and **19***e*, respectively (Scheme 5). Compounds **19***k* and **19***l* were prepared via the method of Crast *et al.* (15).



2-Isocephems, N-2-Isocephems, and Carbacephems

The facile ring closure of the enol mesylate **5***a* to give the *O*-2-isocephem system **6***a* encouraged us to further explore the chemistry of **5***a* with a view to preparing isocephalosporins having other hetero-

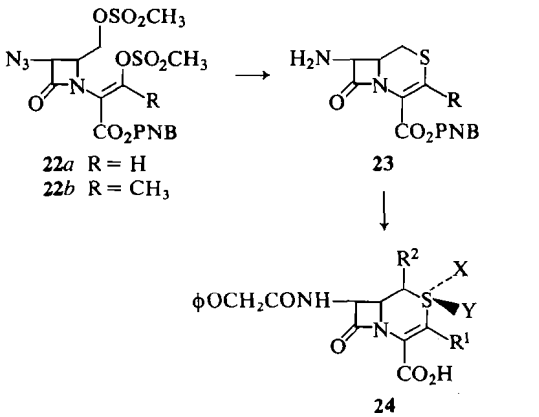
atoms at position 2. A number of attempts were made to prepare the ene thiol directly from the enol with no success. Consequently the enols were converted to their mesylates **22***a* or **22***b* as described earlier. Treatment of the dimesylate with hydrogen sulfide – triethylamine (Scheme 6) gave the desired 2-isocephem systems **23***a* and **23***b*. These were converted to their amides **24***a* and **24***b*. Compound **24***b* was converted by oxidation into the sulfoxide **24***c* and the sulfone **24***d*. Treatment of **24***c* with *tert*-butyl hypochlorite gave **24***e* (2*g*).



Similarly, treatment of **25***a* with monomethylamine (Scheme 7) or with ammonia followed by ethyl chloroformate gave the *N*-2-isocephems **26***a* and **26***b*. These were converted to **27***a* and **27***b*, respectively, in the usual fashion (2*f*).

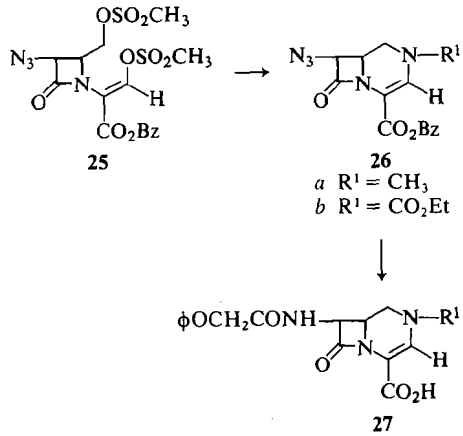

SCHEME 5

Encouraged by the successful syntheses of **24** and **27**, we next examined the reactions of **12***b* with various carbon nucleophiles (Scheme 8). Treatment of **12***b* with the sodium salts of dimethyl, dibenzyl, and di-*tert*-butyl malonate gave the cyclized products of **28***a*, *b*, and *c*, respectively. Compounds **28***a* and *b* were converted to compounds **30***a–e* (2*j*). When **28***c* (R = *tert*-butyl) was treated with acid and the resultant dicarboxylic acid **28** (R = H) decarboxylated there was obtained the Δ^2-cephalosporin analog **29**. This was converted

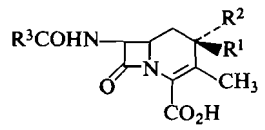
to **30***d* as described earlier (2*k*). Starting from **29** we have also synthesized compounds **30***e–j* (2*l*).



7-Methoxy Isocephalosporins

In view of the reported broadening of the antibacterial spectrum of cephalosporins by substitution with a 7-α-methoxy group (16), we decided to prepare 7-methoxy analogs of the 2-iso and the *O*-2-isocephems (2*i*). The method of Spitzer and Goodson (17) was chosen to introduce a thiomethyl group (Scheme 9). Thus, **31***a* (A = R^2 = H, R^3 = PNB, X = S) was treated with LDA followed by methoxycarbonylmethyl disulfide to give **31***b* (A = SCH_3, R^2 = H, R^3 = PNB, X = S). The Schiff base was hydrolysed to the amine which was acylated. Treatment of the sulfide with mercuric acetate in methanol (18) followed by hydrogenolysis of the

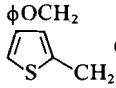
ester group gave **32***a* (R^1 = ϕOCH_2, R^2 = H, X = S). Compounds **32***b* and **32***c* were prepared similarly.

Biological Activity



In vitro antibiotic activities for the cephalosporin analogs prepared were determined by a two-fold serial dilution assay in Difco nutrient broth by the method of Pursiano *et al.* (19). Results in terms of minimum inhibitory concentrations (MIC) in μg/mL are given in Tables 1–4. Bacterial strains utilized included gram positive organisms (*Streptococcus pyogenes*, *Staphylococcus aureus* Smith), a β-lactamase producing gram positive organism (*S. aureus* BX 1633), gram negative organisms (*Escherichia coli* Juhl, *Klebsiella pneumoniae* 9977, *Proteus mirabilis*), β-lactamase producing gram negative organisms (*E. coli* 9675, *K. pneumoniae* 15130, *P. morganii*, *Enterobacter cloacae*), and *Pseudomonas aeruginosa*. None of the compounds tested were active against *Pseudomonas* so it is not included in the tables. In the tables the effects of changing substituents at the 1, 2, 3, and 7 positions are demonstrated. As well, comparisons to cephalosporins are made.

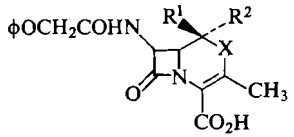
SCHEME 9



The limited amount of data in Table 1 demonstrates that substitution at position 1 seems to be deleterious to antibiotic activity. In particular, compare the lower activity of **8***f* or **8***g* with **8***a* and **24***e* with **24***c*.

Table 2 demonstrates the effect of varying the 2 substituent on antibiotic activity. For example, the nuclear analogs **8***a*, **24***a*, **24***b*, **27***b*, and **30***d* show that the 2-O analog is most active while the 2-S, CH_2, and 2-NCO_2Et analogs are of reduced activity but roughly equivalent to one another. However, oxidation of the 2-S gives sulfoxide **24***c* and sulfone **24***d* with close to the activity of **8***a*. Similarly, the 2-keto analog **30***g* has activity comparable to **8***a*. Except for the 2-β-acetoxy analog **30***j*, other sub-

stituents at the 2-carbon (**30***a*–*c*, *e*, *f*, *h*) generally produced lessened activity. Thus it would appear that electron donation to the $\Delta^{3,4}$ double bond decreases antibiotic activity, and steric bulk at the 2 position also decreases activity.

Since the *O*-2-isocephem nucleus appeared to have the greatest potential for high antibiotic activity, an extensive series of 3 and 7 substituted analogs was prepared. Table 3 shows the effect of varying substituents at position 3. Increasing hydrophilic character at 3 (**8***a*, **8***c*, **8***d*) leads to an increase in activity against non-β-lactamase producing gram positive organisms but loss of activity against other organisms. For the 3-methylene substituted compounds, the order of activity is (with minor exceptions) as follows: S-tetrazole more active than S-thiadiazole, more active than acetoxy, more active than O-tetrazole, same as carbamate, more active than H. These are similar to the trends seen with cephalosporin 3-sidechains (20). The effect of varying 7-sidechains can be seen in Tables 3 and 4. In general, the phenylglycine group confers the highest activity followed by the thienylacetyl and the groups of compounds **19***m*, *j*, *k*, and *l*, with the phenoxyacetyl, cyanoacetyl, mandeloyl, and phenylmalonyl groups conferring the lowest activity. It should be noted that compounds with the phenylglycine sidechain (except for **19***b*) had poor chemical stability. These trends in activity seen with the various 7-sidechains parallel the trends seen with the cephalosporins with some exceptions. Notably the mandeloyl sidechain confers much poorer activity on the O-isocephem than one would expect from the corresponding cephalosporins.

A direct comparison between *O*-2-isocephems and cephalosporins with the same side-chains is given in Table 4. With certain combinations of sidechains, the *O*-2-isocephem is more active (**8***a*, **19***a*, *d*, *p*, *s*), with others the cephalosporin is more active (**19***h*, *j*, *k*, *l*, *m*, *q*), while the rest are more or less equivalent. With regard to individual strains of bacteria, the following generalizations can be made: the cephalosporins are more active than *O*-2-isocephems against staphylococci and β-lactamase producing strains of *E. coli*, *Klebsiella*, and *Proteus*. Thus it would seem that the *O*-2-isocephem and cephalosporin nucleii have about the same inherent activity but that the *O*-2-isocephem nucleus is more susceptible to β-lactamases. The 7-methoxy substituent appears to give some protection against β-lactamases but overall activity is reduced considerably (2*i*).

More extensive microbiological testing was carried out with several *O*-2-isocephems. Compound **19***i* (2*h*) (the cephalothin analog) can be taken as typical. Data comparing **19***i* (resolved) with cephalothin are presented in Fig. 3. Both are highly active against *S. aureus* with cephalothin being slightly better. Against the gram negative organisms, **19***i* is superior for the more sensitive strains, but this advantage is reduced for the more resistant strains (presumably which include many β-lactamase producers).

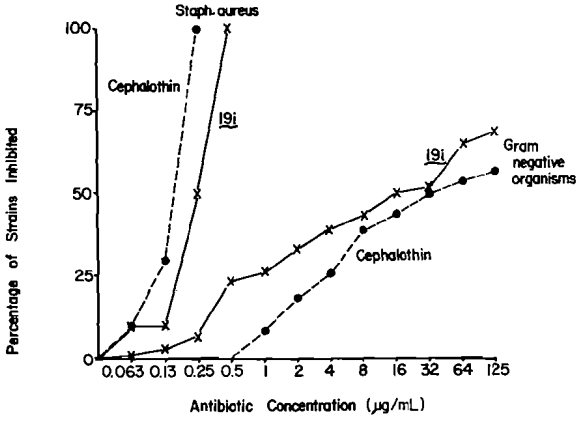
Table 5 shows the *in vivo* activity of compound **19***i* compared to cephalothin. Blood levels in mice are essentially equivalent. Both provide high protection for mice experimentally infected with *Streptococcus pyogenes* with **19***i* being somewhat superior.

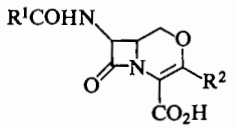
In summary, various nuclear modifications of cephalosporins (carba, 2-iso, *N*-2-iso, *O*-2-iso) were found to have antibiotic activity. More extensive testing of *O*-2-isocephem analogs, both *in vitro* and *in vivo*, showed these compounds to have antibiotic activity similar to cephalosporins with only minor differences in detail.

Experimental

General

The ir spectra were recorded on a Unicam SP-200G spectrometer. The nmr spectra were determined on a Varian A60-A spectrometer using tetramethylsilane as an internal standard. Melting points were uncorrected and were determined on a Gallenkamp melting point apparatus. The analyses were performed by Micro-Tech Laboratories, Skokie, IL. Many of the final compounds were relatively unstable and were best submitted for microbiological testing without purification. Such products usually did not give satisfactory elemental analyses. However, spectral data indicated that they were ≥90% pure in most cases (unless otherwise indicated below). Extraction solutions were dried over sodium sulfate. All chromatographic purifications were carried out on activity III silica gel by the dry column technique.





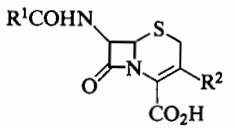


FIG. 3. Antibiotic susceptibility of 10 strains of *Staphylococcus aureus* and 54 strains of gram negative organisms to cephalothin and **19***i* in Mueller–Hinton medium. (Five strains each of *Enterobacter aerogenes* and *Ent. cloacae*, 10 strains each of *Escherichia coli*, *Klebsiella pneumoniae* and *Proteus mirabilis*, 5 strains each of *Proteus rettgeri* and *P. vulgaris*, 4 strains of *P. morganii*.)

[b]Protective effect after administration in mice experimentally infected with *Streptococcus pyogenes*. PD_{50} is drug dose per treatment protecting 50% of infected mice from death; mice treated 1 and 3.5 h after infection.

All cephalosporins used for comparison were either from the Bristol Laboratories (Syracuse) reference collection or were prepared from 7-ACA or 7-ADCA by the same method as used to prepare the corresponding *O*-2-isocephem.

The following abbreviations are used: THF, tetrahydrofuran; DMF, dimethylformamide.

7-β-Phenoxyacetamido-3-carbomethoxymethyl-Δ³-O-2-isocephem-4-carboxylic Acid **8**h

A solution of benzyl 7-β-(aminophenoxyacetoyl)-3-methyl-Δ³-*O*-2-isocephem-4-carboxylate **10** (2.11 g, 5 mmol) in 100 mL of THF was cooled to −70°C under a slow nitrogen stream. A solution of 1.66 *M* butyllithium (6.34 mL, 10.5 mmol) was slowly added keeping the reaction temperature at −70°C. A slow stream of dry carbon dioxide gas was then introduced into the reaction mixture, the cooling bath was removed, and the carbon dioxide introduction continued until the reaction temperature reached 25°C.

The reaction mixture was poured into 200 mL of 10% hydrochloric acid, saturated with sodium chloride, and extracted three times with diethylether (150 mL portions). The combined extracts were washed three times with brine, dried (anhydrous sodium sulfate), and evaporated *in vacuo* to give 2.09 g of a yellow gum. This gum was partitioned between diethylether and 10% sodium bicarbonate solution three times. The bicarbonate solutions were then washed with diethylether (2 × 50 mL) and with methylene chloride (2 × 50 mL). The bicarbonate solution was then acidified to pH 2 with concentrated hydrochloric acid and extracted three times with methylene chloride (100 mL portions). The methylene chloride extracts were washed twice with brine, dried (anhydrous sodium sulfate), and evaporated *in vacuo* to give 0.31 g of a colorless gum. This gum was used as such in the next step.

A solution of diazomethane in diethylether was slowly added to a solution of benzyl 7-β-(aminophenoxyacetoyl)-3-carboxymethylene-Δ³-*O*-2-isocephem-4-carboxylate (0.88 g) in 100 mL of diethylether, until a permanent yellow color (excess diazomethane) was produced. The reaction mixture was then stirred at room temperature for 10 min. The reaction was acidified with 10% hydrochloric acid and extracted twice with 100 mL portions of diethylether. The extract was washed with 10% sodium bicarbonate solution (2 × 75 mL), with brine (100 mL), dried (anhydrous sodium sulfate), and evaporated *in vacuo* to give 0.72 g of crude product which was dry column chromatographed over 36 g of activity III silica gel. Elution with chloroform gave a fraction containing 240 mg of methyl ester **11**. The nmr and ir spectra are in agreement with the assigned structure. This material was used as such in the next step.

A mixture of benzyl 7-β-(aminophenoxyacetoyl)-3-carbomethoxymethylene-Δ³-*O*-2-isocephem-4-carboxylate **11** (147 mg), 10% Pd–C (100 mg), 25 mL of ethanol (USP), and 15 mL of THF was hydrogenated in a Parr hydrogenator at 17 psig for 1 h. The catalyst was filtered off and the filtrate evaporated to dryness *in vacuo* to give 87 mg of a white foam, **8***h*.

The potassium salt of acid **8***h* was prepared by dissolving the foam in a small amount of methylisobutylketone and adding a saturated solution of potassium 2-ethylhexanoate in butanol. The resultant precipitate was filtered off and washed with methylisobutylketone and then diethylether; mp 139–144°C (dec.) (cor.).

p-Nitrobenzyl 7-β-Azido-3-formyloxymethyl-Δ³-O-2-isocephem-4-carboxylate **15**b

A solution of di-iodide **14***b* (6.6 g, 9.6 mmol) in 100 mL of DMF plus 0.1 mL of water was maintained at 0°C while powdered potassium formate (2.54 g, 30 mmol) was added. The cooling bath was removed and the mixture was stirred vigorously for 5 h. The mixture was added to 100 mL of ice water. The aqueous mixture was extracted with CH_2Cl_2 (100 + 50 mL). The combined organic extracts were washed with dilute aqueous NaCl (5 × 100 mL), dried, and the solvent was evaporated *in vacuo* to give the crude product **15***b* (5.3 g) as a brown oil. The product was used as such in the subsequent reaction. The product could be purified by chromatography on silica gel. Elution with Et_2O/EtOAc 3:1 gave pure **15***b*, mp 104–105°C.

p-*Nitrobenzyl 7-β-Azido-3-hydroxymethyl-Δ³-O-2-isocephem-4-carboxylate* **15**c

A solution of compound **15***b* (5.3 g, 13 mmol), acetone (53 mL), water (26 mL), and 12 *M* HCl (3.2 mL) was stirred at 28°C for 7 h, then mixed with water (100 mL) and extracted with CH_2Cl_2 (60 + 25 + 15 mL). The combined extracts were washed with water containing a little NaCl (4 × 100 mL) dried, and the solvent was evaporated *in vacuo* to give a brown oil, 3.6 g. The product was purified by chromatography on silica gel (90 g). Elution of the column first with Et_2O, then with Et_2O/EtOAc 3:1 gave a product which was recrystallized from acetone/Et_2O to give alcohol **15***c*, 950 mg (17.5% yield from compound **14***b*), mp 147–148°C.

p-*Nitrobenzyl 7-β-Azido-3-carbamoyloxymethyl-Δ³-O-2-isocephem-4-carboxylate* **15**d

A mixture of compound **15***c* (375 mg, 1.0 mmol), benzene (15 mL), sodium cyanate (130 mg, 2.0 mmol), and trifluoroacetic acid (0.16 mL, 2.1 mmol) was stirred for 2 h at 23°C. Water (25 mL) and EtOAc (15 mL) were added to the mixture and it was shaken and separated. The aqueous layer was extracted with another 15 mL of EtOAc. The combined organic phases were washed with water and saturated NaCl (30 mL each), dried, and the solvent was evaporated *in vacuo* to give carbamate **15***d* as an amorphous solid, 400 mg (95% yield).

p-*Nitrobenzyl 7-β-Azido-3-[5-thio(1-methyl)tetrazolyl]-methyl-Δ³-O-2-isocephem-4-carboxylate* **15**e

A solution of methanesulfonyl chloride (0.50 mL, 6.5 mmol) in 10 mL of CH_2Cl_2 was added dropwise to a stirred solution of compound **15***c* (2.41 g, 6.43 mmol), Et_3N (0.97 mL, 7.0 mmol), and CH_2Cl_2 (75 mL) at −10°C. The solution was maintained at −10°C for ½ h and 23°C for 1 h, then washed with 5% HCl, 2% $NaHCO_3$, and water (85 mL each). The solvent was evaporated *in vacuo* to give mesylate **15***e* as an amorphous solid, 2.86 g (98% yield).

p-*Nitrobenzyl 7-β-Azido-3-[5-thio(1-methyl)tetrazolyl]-methyl-Δ³-O-2-isocephem-4-carboxylate* **16**a, p-*Nitrobenzyl 7-β-Azido-3-[2-thio(5-methyl)-1,3,4-thiadiazolyl]methyl-Δ³-O-2-isocephem-4-carboxylate* **16**b, *and* p-*Nitrobenzyl 7-β-Azido-3-[5-oxo(1-methyl)tetrazolyl]methyl-Δ³-O-2-isocephem-4-carboxylate* **16**c

A solution of mesylate **15***e* (4.53 g, 10 mmol), Et_3N (1.4 mL, 10 mmol), CH_2Cl_2 (90 mL), and 10 mmol of 1-methyltetrazole-

5-thiol, 2-methylthiadiazole-5-thiol, or 1-methyltetrazole-5-ol was stirred at 23°C for 16 h. In the cases of the first two, the solution was washed with 5% HCl and water (100 mL each), dried, and the solvent was evaporated *in vacuo* to give the product.

The tetrazole **16***a* was recrystallized from EtOAc, 3.70 g (78% yield), mp 150–152°C.

The thiadiazole **16***b* was obtained as an oil, 4.65 g (95% yield).

In the case of **16***c*, the solvent was evaporated *in vacuo*, replaced by $CHCl_3$ (500 mL), Et_3N (10 mmol), 1-methyltetrazole-5-ol (10 mmol), and the solution was heated under reflux for 20 h. The solution was washed and concentrated (in the manner for **16***a* and **16***b*) to give crude **16***c*. This material was purified by chromatography on silica gel (730 g) and was eluted

For personal use only.

from the column with Et_2O/EtOAc 3:1. It was recrystallized from EtOAc to give **16***c*, 1.07 g (22.5% yield), mp 174–176°C (dec.).

p-*Nitrobenzyl 7-β-azido-3[5-thio(1-methyl) tetrazolyl]methyl-* Δ^3*-O-2- isocephem-4-carboxylate* **16***a from* **14**b

The dibromide **14***a* (R^1 = PNB) was prepared in exactly the same manner as the corresponding benzyl ester (2*h*). 1-Methyltetrazole-5-thiol (565 mg, 4.85 mmol) was added to a solution of dibromide **14***a* (2.90 g, 4.85 mmol) in 35 mL of CH_2Cl_2 at 0°C. A solution of Et_3N (0.67 mL, 4.85 mmol) in 7 mL of CH_2Cl_2 was added and the solution was stirred at 23°C for 30 min. The solution was washed with water (2 × 40 mL), dried, treated with charcoal, and filtered. The solvent was evaporated *in vacuo* to give compound **14***c*, 2.70 g, in about 30% purity.

Potassium acetate (835 mg, 8.54 mmol) was added to a solution of **14***c* (2.70 g) in 27 mL of DMF at 0°C. The mixture was stirred at 23°C for 18 h, then diluted with 80 mL of CH_2Cl_2 and washed with 1% NaCl solution (6 × 80 mL). The organic phase was dried and absorbed onto silica gel (7.5 g) which was placed on a silica gel column (30 g). The column was eluted with Et_2O then with Et_2O/CH_2Cl_2 1:1. Evaporation of the solvent from the appropriate fractions gave compound **16***a*, 344 mg (15% yield), identical in all respects to that prepared above.

Azide Reductions using Hydrogen Sulfide – Triethylamine **17**d–g

A solution of equimolar amounts of the azido compound and triethylamine in CH_2Cl_2 (~10% solution) was cooled to 0°C and saturated with H_2S. After 1 to 1.5 h the solution was acidified (10% HCl), the CH_2Cl_2 was evaporated *in vacuo*, and the mixture was extracted with CH_2Cl_2. The CH_2Cl_2 extract was filtered to remove elemental sulfur and the solvent was evaporated *in vacuo* to give product **17***e* (86% yield), **17***f* (85% yield), or **17***g* (61% yield). Compound **17***d* was obtained in 100% yield simply by evaporation of the solvent *in vacuo* after the H_2S addition. These crude products were used as such in subsequent reactions.

EEDQ Coupling Reactions

A solution of equimolar amounts of EEDQ, the acid to be coupled, and the appropriate amine in methylene chloride (from 5–20 wt% solutions) was let stand at room temperature (~23°C) for the specified time (see Table 6). The resulting solution was washed with dilute solutions of HCl, $NaHCO_3$, and NaCl. The organic layers were dried over Na_2SO_4 and the solvent evaporated at reduced pressure.

Ester Removal by Hydrogenolysis

The hydrogenolysis of the various benzyl and *p*-nitrobenzyl esters to yield the desired acids was carried out as follows: a solution of *x* mg of the ester in 100 × mL of solvent was hydrogenated under the conditions shown in Table 7. When the reaction was complete the catalyst was removed by filtration. For those products carrying a phenylglycyl side chain one equivalent of HCl was added to the hydrogenation mixture. The solution was evaporated at reduced pressure to give the product as its hydrochloride salt. For non-basic products the reaction solution was extracted with aqueous sodium bicarbonate. The aqueous extracts were acidified and back extracted into EtOAc. The solvent was evaporated at reduced pressure to yield the product.

Compounds **19**d, e, j, k, l, m

These compounds were prepared from **17***c* or **21** as described in Table 8.

Compound **17***c* and 4-chloromethylphenylacetyl chloride were reacted by the method used to prepare **19***i* (2*h*) to give amide **33**. A solution of **33** (635 mg, 1.5 mmol) in 6 mL of acetone was mixed with a solution of thiourea (120 mg, 1.6 mmol) in 3 mL of acetone and maintained at 23°C for 72 h. The precipitate was collected by filtration and washed with acetone to give **19***m*, 397 mg, in about 80% purity.

To a suspension of potassium 2-(1-carbomethoxypropen-2-ylaminomethyl)phenylacetate (1.2 g, 38 mmol) in 23 mL of tetrahydrofuran was added 3 drops of dimethylbenzylamine. The mixture was cooled to −40°C and isobutyl chloroformate (520 mg, 38 mmol) was added. After 5 min, the solution was added to a cooled (0°C) solution of compound **17***c* or **21** (1.8 mmol) and *N*-methylmorpholine (0.71 mL) in 13 mL of water. The solution was stirred for 1 h at 0°C, then acidified to pH 5.2 with hydrochloric acid. Ethyl acetate was added and the mixture was stirred for 1 h at 23°C. The product was collected by filtration and dried *in vacuo*. Compound **19***e* was obtained analytically pure while **19***j* was obtained in about 80% purity.

Synthesis of camphor-1,4-homoenol (7-hydroxy-1,2-dimethyl[3,3,0,$0^{2,7}$]tricyclooctane)

WILLIAM M. DADSON AND THOMAS MONEY

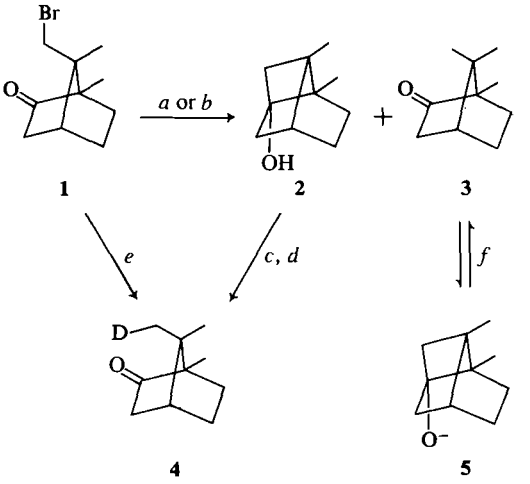
Chemistry Department, The University of British Columbia, Vancouver, B.C., Canada V6T 1W5

Received April 7, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

WILLIAM M. DADSON and THOMAS MONEY. Can. J. Chem. **58**, 2524 (1980).

A simple synthesis of camphor-1,4-homoenol has been accomplished by reductive cyclization of 8-bromocamphor.



WILLIAM M. DADSON et THOMAS MONEY. Can. J. Chem. **58**, 2524 (1980).

Une synthèse simple du 7-hydroxy-1,2-dimethyl[3,3,0,$0^{2,7}$]tricyclo octane (le camphore-1,4-homoenol) à partir d'une cyclisation reductive est décrite.

[Traduit par le journal]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

During recent attempts to extend the use of camphor in monoterpenoid (1) and sesquiterpenoid synthesis (2) we treated 8-bromocamphor (**1**) (3) with calcium/liquid ammonia at −33°C and obtained a mixture of camphor (**3**) (~33% yield by glc) and a new compound (~56% yield by glc) which was easily isolated as a colorless crystalline solid by column chromatography. The spectroscopic properties (ν_{max} (CCl_4): 3620, 3335 cm^{-1}; δ($CDCl_3$, 270 MHz): 0.90 (3H, s) 1.01 (3H, s)) of the new compound were consistent with those expected for the 1,4-homoenol (**2**) of camphor and this structural assignment was confirmed when treatment with Me_3COK/Me_3COD/80°C/3 h followed by Me_3COK/Me_3COH/80°C/16 h provided 8-deuteriocamphor (**4**) with spectral characteristics[1] (δ($CDCl_3$, 400 MHz): 0.82 (2H, t, J = 1.8 Hz), 0.91 (3H, s), 0.96 (3H, s)) identical to those of an authentic sample prepared by reduction of (+)-8-bromocamphor with tri-*n*-butyltin deuteride (6–8). In more recent experiments it has been shown that treatment of 8-bromocamphor (**1**) with magnesium powder in refluxing THF (9*c*) provides camphor-1,4-homoenol (**2**) in excellent yield (96%) and we recommend this method of synthesis. The formation of camphor-1,4-homoenol (**2**) in the above reactions could involve cleavage of the carbon–bromine bond followed by nucleophilic addition to the carbonyl group (9) or intramolecular alkylation of an intermediate radical anion (10). Treatment of **2** with sodium hydride in HMPA at 80°C for 2 minutes provided camphor (**3**) in 98% yield. It is interesting to note, however, that this homoketonization (11) reaction does not occur at ≤40°C and indeed treatment of **2** with NaH/HMPA/40°C/1 h in the presence of methyl iodide or benzyl chloride provides

(*a*) Ca/NH_3 (liq); (*b*) Mg/THF; (*c*) Me_3COK/Me_3COD/80°C/3 h; (*d*) Me_3COK/Me_3COH/80°C/16 h; (*e*) *n*-Bu_3SnD/C_6H_6; (*f*) Me_3COK/Me_3COH/250°C/sealed tube

the corresponding ethers. The *p*-bromobenzoate of **2** has also been synthesized and its structure confirmed by X-ray crystallographic analysis (12).

During their elegant investigations on homoenolization of bicyclic ketones, Nickon *et al.* (13) noted that the C(3), C(6), C(8), and C(10) hydrogen atoms in camphor (**3**) were exchanged during prolonged treatment with Me_3COK/Me_3COH at 185–250°C (sealed tube) and the intermediacy of the highly strained 1,4-homoenolate ion (**5**) was proposed to account for exchange at the C(8) position.[2] The synthesis of camphor-1,4-homoenol (**2**) and its subsequent conversion to 8-deuteriocamphor (**4**) provides strong support for this mechanism.

[1]Mass spectra of camphor and deuterio derivatives have been reported in ref. 4, and ^{13}C nmr of camphor in ref. 5.

[2]Related investigations by Stothers and co-workers (14) have shown that γ-homoenolization also occurs when 3,3-dimethylbicyclo[3,3,0]octan-2-one is treated under similar reaction conditions.

The potential of reductive cyclization in natural product synthesis has previously been recognised by several research groups (9, 10) and homoketonization of camphor-1,4-homoenol (**2**) could provide a new method of generating nucleophilic activity at the C(8) position in camphor. This aspect of the chemistry of (**2**) is currently being investigated.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. The glc analysis was carried out on a Hewlett-Packard Model 5831-A gas chromatograph using a 6 ft × ⅛ in. column (3% OV-17; Chromosorb W(HP), 80–100 mesh) and nitrogen as carrier gas. The carrier gas flow rate was about 35 mL/min. The 60 MHz nmr spectra were recorded on a Varian Associates Model T-60, 100 MHz spectra on a Varian Associates Model HA-100 or Model XL-100, and 270 MHz spectra on a 270 MHz instrument constructed from a Bruker console, a Nicolet computer Model 293A with a Diablo disk, and a 270 MHz superconducting magnet supplied by Oxford Instruments. The 400 MHz spectra were recorded on a Bruker WH-400 instrument and ^{13}C nmr spectra on a Varian CFT-20 instrument. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as internal reference and signal multiplicity and integrated areas are indicated in parentheses. Infrared spectra were recorded on a Perkin-Elmer 137 spectrophotometer and optical rotations were measured with a Perkin-Elmer Model 241 MC polarimeter. Low resolution mass spectra were recorded on a Varian/Mat Model CH4B mass spectrometer and high resolution mass spectra were determined on the AEI Model MS902 or Model MS 50 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

Camphor-1,4-homoenol (2)

Method A

A solution of 8-bromocamphor (**1**) (1.0 g) in dry THF (5 mL) was added to magnesium powder (1.05 g) and THF (2 mL) and the reaction mixture refluxed for 16 h. After acidification with HCl (6 *N*) the mixture was extracted with ether and the extract washed with potassium carbonate solution. Removal of dried solvent provided camphor-1,4-homoenol (**2**) as a colorless solid (632 mg, 96% yield, glc purity 99%) which crystallized from petroleum ether (35–60°C) as colorless needles, mp 98–100°C (sealed tube), $[\alpha]_D$ +14.1° (*c* 0.87, $CHCl_3$); ν_{max} (CCl_4): 3620, 3335 cm^{-1}; δ($CDCl_3$, 270 MHz): 0.90 (3H, s), 1.01 (3H, s); *Mol. Wt.* calcd. for $C_{10}H_{16}O$: 152.1201; found (mass spectrometry): 152.1202.

Method B

8-Bromocamphor (**1**) (1.0 g) in dry ether (5 mL) was added to a solution of calcium (850 mg) in liquid ammonia (200 mL) at −33°C. After 30 min methanol was added and the decolorized reaction mixture diluted with water (50 mL) and extracted with ether. Removal of solvent provided a colorless solid (560 mg, 85% yield) which, by glc analysis (3% OV-17 column), was shown to be a mixture of camphor (**3**) (~30%) and its 1,4-homoenol (**2**) (~70%). Column chromatography (alumina, Grade III; elution with ether – petroleum ether (35–60°C) (1:1)) yielded pure camphor 1,4-homoenol (**2**) with spectroscopic properties indicated above.

8-Deuteriocamphor (4)

From 8-Bromocamphor (1)

Tri-*n*-butyltin deuteride (5.0 g) in dry benzene (5 mL) was added under nitrogen to 8-bromocamphor (**1**) (3.2 g) and azobisisobutyronitrile (2.2 g) (8*a*) in dry benzene (10 mL) and the mixture stirred for 3 h at 50°C, then 24 h at room temperature. The ether extract of the reaction mixture was washed with 5% KOH (4 × 25 mL), water, 10% KF (4 × 25 mL), and water (8*b*). Removal of solvent provided impure product which was purified by column chromatography (silica; elution with hexane–ether (5:1)) and sublimed to provide 8-deuteriocamphor (**4**) in 46% yield (glc purity 99%); ν_{max} ($CHCl_3$): 2200, 1745, 1415 cm^{-1}; δ($CDCl_3$, 400 MHz): 0.82 (2H, t, J = 1.8 Hz), 0.91 (3H, s), 0.96 (3H, s); δ(^{13}C) ($CDCl_3$): 9.2, 19.1, 19.4 (t, J = 19 Hz); ms *m/e*: 153 (54%, M^+), 138 (7), 111 (28), 109 (74), 96 (100), 84 (38), 69 (28).

From Camphor-1,4-homoenol (2)

A mixture of camphor-1,4-homoenol (**2**) (250 mg), potassium *tert*-butoxide (1.0 g), and *tert*-butanol-OD (10 mL) was refluxed for 3 h. The reaction mixture was diluted with water (25 mL) and extracted with ether. Removal of solvent provided a solid product (crude 3,3,8-trideuteriocamphor) which was refluxed with potassium *tert*-butoxide (1.0 g) and *tert*-butanol (10 mL) for 16 h. Work-up in the usual way provided a pale yellow solid (157 mg, 62% yield) which, on sublimation, yielded 8-deuteriocamphor (**4**) contaminated with a small amount (ca. 10%) of camphor.[3]

Camphor-1,4-homoenol p-*Bromobenzoate*

A solution of camphor-1,4-homoenol (**2**) (250 mg) and *p*-bromobenzoyl chloride (1.0 g) in dry hexamethylphosphoramide (2 mL) was stirred at room temperature under nitrogen for 24 h. After dilution with water, the mixture was extracted with ether and the extract washed with sodium bicarbonate solution. Removal of solvent provided a pale yellow semisolid (360 mg) which was purified by column chromatography (alumina, Grade III; elution with petroleum ether (35–60°C)). The colorless oil (150 mg) obtained was crystallized from petroleum ether (35–60°C) to give the *p*-bromobenzoate of **2**, mp 85–86°C; ν_{max} (CCl_4): 1725, 1270 cm^{-1}; δ(CCl_4, 100 MHz): 0.92 (3H, s), 1.00 (3H, s); ms *m/e*: 334–336 (9%, M^+), 183–185 (100), 134 (16), 121 (25), 95 (53). *Anal.* calcd. for $C_{17}H_{19}O_2Br$: C 60.89, H 5.67, Br 23.88%; found: C 60.82, H 5.73, Br 23.67%.

Pyrrole chemistry. XXII. A "one-pot" synthesis of some 4-acylpyrrole-2-carboxaldehydes from pyrrole

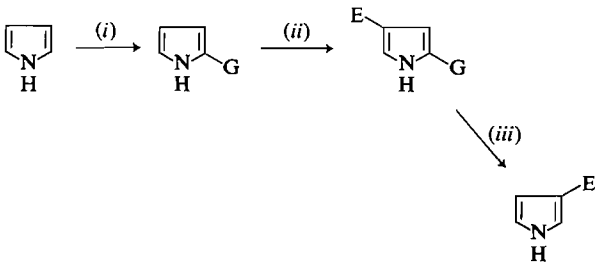
HUGH J. ANDERSON, CHARLES E. LOADER, AND AIDAN FOSTER

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received May 29, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HUGH J. ANDERSON, CHARLES E. LOADER, and AIDAN FOSTER. Can. J. Chem. **58**, 2527 (1980).



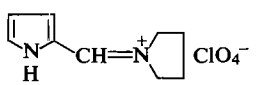
The Vilsmeier–Haack intermediates formed from pyrrole and from 1-methylpyrrole may be acylated under normal Friedel–Crafts conditions. Hydrolytic work-up then gives 4-acylpyrrole-2-carboxaldehydes in good yield. The methoxide/methanol treatment of the 4-trichloroacetylated intermediate leads to methyl 2-formylpyrrole-4-carboxylate. These are all "one-pot" syntheses from pyrrole. The formyl group has been removed from several of the products thus affording some 3-acylpyrroles in two operations.

HUGH J. ANDERSON, CHARLES E. LOADER et AIDAN FOSTER. Can. J. Chem. **58**, 2527 (1980).

Les intermédiaires de Vilsmeier–Haack, formés à partir du pyrrole et du méthyl-1 pyrrole, peuvent être acylés dans les conditions normales de Friedel–Crafts. Par hydrolyse, on obtient alors avec un bon rendement les acyl-4 pyrrole carboxaldéhydes-2. L'intermédiaire trichloroacétyle-4, traité au méthylate dans le méthanol, conduit au formyl-2 pyrrole carboxylate-4 de méthyle. Tous ces produits sont préparés en une seule étape à partir du pyrrole. L'élimination du groupe formyle de plusieurs de ces composés permet alors d'obtenir en deux étapes les acyl-3 pyrroles.

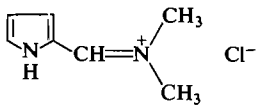
[Traduit par le journal]

The pathway to 3-substituted pyrroles shown in Scheme 1 has been used very widely. However, each of the three steps has its own limitations.



SCHEME 1

It is necessary to introduce an electron-withdrawing group in step (*i*) which can be removed in step (*iii*). Among the groups which may be introduced into position-2 of pyrrole in highest yield are the formyl (1) and trichloroacetyl (2). However, in step (*ii*) we found that yields were low for Friedel–Crafts acylation and related reactions of the 2-aldehyde (3). Others found both yield and isomer problems with nitration (4) of the 2-aldehyde. While the 2-trichloroacetyl derivative gave excellent results in a wide variety of electrophilic 4-substitutions (5) it must be removed by base hydrolysis to the 2-acid followed by decarboxylation. Some authors have been fairly successful in the decarboxylation of 3-substituted-2-acids (6), but we (3) and others (7, 8) found some yields to be poor and others to be good when an electron-withdrawing 4-substituent was present on the 2-acid in the absence of any alkyl group.



We have reported the satisfactory 4-substitution reactions of the pyrrole 2-thiol ester (9) and of the 2-nitrile (10), together with subsequent removal of these directing groups. However, the preparation of the 2-thiol ester gave only about 50% yield and its eventual removal required quite large amounts of Raney nickel. We have recently (11) improved on earlier preparations of the 2-nitrile, but the final removal of this group involved two steps: first, reduction to the aldehyde, and then decarbonylation. Nevertheless, this approach afforded satisfactory syntheses of 3-acetylpyrrole and methyl pyrrole-3-carboxylate (10).

The easy and efficient removal of the 2-aldehyde group by Raney nickel decarbonylation suggested that a special effort should be made to improve step (*ii*) for the 2-aldehyde. Sonnet (12) has shown how the 2-aldehyde may be converted to an iminium perchlorate **1**, which then undergoes 4-substitution in generally good yield, affording the product of step (*ii*) on hydrolytic work-up.

In the course of our investigation (11) of the preparation of the 2-nitrile through the Vilsmeier–Haack intermediate, we realized that this intermediate, **2**, was a close analogue of Sonnet's

substrate, **1**. Consequently, we began to consider the possibility of combining the customary efficient synthesis of the 2-aldehyde with Sonnet's type of electrophilic attack on the iminum salt intermediate in the aldehyde synthesis, to be followed by the usual hydrolytic work-up affording a 4-substituted-2-aldehyde. When the iminum salt **2** was prepared using oxalyl chloride and dimethylformamide in either dichloromethane or 1,2-dichloroethane the clear, pale yellow solution underwent a slight warming and darkening on adding aluminum chloride. Addition of neat acetyl chloride caused some further warming and a color change through red to brown. Nuclear magnetic resonance spectral observation of the neat solution enabled the course of the reaction to be followed. Conversion to a 2,4-disubstituted pyrrole took about two hours of stirring at room temperature. The hydrolytic work-up and separation of the organic layer was followed by continuous ether extraction of the aqueous layer affording, from the combined organic layers, about 80% of pale yellow product which was almost pure 4-acetylpyrrole-2-carboxaldehyde. When combined with the Raney nickel decarbonylation reported before (10), the overall yield of 3-acetylpyrrole from pyrrole was close to 70%. Thus the three steps of Scheme 1 have been accomplished in two fairly simple preparative operations which give excellent results for this synthesis of a useful 3-substituted pyrrole.

Another useful starting material is methyl pyrrole-3-carboxylate which we had prepared previously (10) by the Friedel–Crafts trichloroacetylation of the 2-nitrile, followed by methanolysis of the trichloroacetyl group to the ester, and then removal of the nitrile directing group by reduction to the aldehyde and decarbonylation. Trichloroacetylation of the intermediate **2** was found to be satisfactory, so we proceeded to work up the product by a succession of methanolysis and hydrolysis steps leading, in one continuous sequence of operations, from pyrrole to methyl 2-formylpyrrole-4-carboxylate in about 80% yield of isolated product. Again, the success of the decarbonylation operation (10) means the preparation of methyl pyrrole-3-carboxylate can be accomplished rapidly and easily in two steps affording a 65–70% overall yield from pyrrole.

The Friedel–Crafts benzoylation of the intermediate **2** was not quite so successful, giving only about 55% of 4-benzoylpyrrole-2-carboxaldehyde. This time our earlier method for the removal of the aldehyde grouping by decarbonylation with active Raney nickel was unsatisfactory. The action of Raney nickel on 4-benzoylpyrrole-2-carboxaldehyde gives very poor yields (<25%) of 3-benzolypyrrole and there was some evidence of complex formation between the nickel and the pyrrole. We had found in earlier work (unpublished) that catalytic decarbonylation of 1-methyl-3-acetylpyrrole-2-carboxaldehyde using palladium on charcoal at about 220°C, according to the method reported by Tsuji and Ohno (13) for some other aldehydes, gave a good yield of 1-methyl-3-acetylpyrrole. The yields obtained for decarbonylation of related pyrroles with the 1-H unsubstituted were poorer than obtained from Raney nickel decarbonylation. However, 4-benzoylpyrrole-2-carboxaldehyde gave a 68% yield of 3-benzoylpyrrole.

As Sonnet (12) had already demonstrated the versatility of the iminium salt in a variety of reactions, we have examined some different or less successful types. One interesting reaction is the use of ethyl chlorothiolformate as an acylating agent. This had proved a satisfactory operation on the 2-nitrile (10) and was now found to give good yields with the iminium salt, provided the final hydrolysis was carried out under acidic rather than basic conditions.

The Friedel–Crafts formylation of the iminium salt using either methyl or butyl dichloromethyl ether failed to improve on the modest yield reported by Sonnet (12) for this type of reaction. However, our experience has been that conditions are critical for the formylation and yields often improve with further modifications.

We have found that the use of two moles of the DMF – oxalyl chloride complex does not introduce a second iminium grouping onto the pyrrole ring, even in the presence of aluminum chloride. Nor does the reagent attack furan under the conditions successful for pyrrole. The reagent does substitute the 5-position of 2-methylfuran, but the Friedel–Crafts acylation of the intermediate so formed does not take place, as shown by the absence of further change in the nmr spectrum.

The reagent, chlorosulfonyl isocyanate (CSI), offered the possibility of introducing the cyano group (14) in position-4 of the iminium salt. This is a very powerful reagent and can react with pyrrole to give 2,4-disubstitution when used in excess (11). However, to our surprise, the product isolated from the treatment of intermediate **2** with CSI, followed by DMF, was 4-chloropyrrole-2-carboxaldehyde. The same product was obtained when CSI was added in the presence of aluminum chloride.

We also attempted to carry out a Houben–Hoesch reaction on the complex **2** using ethyl cyanoformate and hydrogen chloride. No change was observed in the nmr spectrum of the reaction

For personal use only.

mixture, nor did aluminum chloride promote the reaction. On work-up the only product was pyrrole-2-carboxaldehyde.

Experimental

Instruments and conditions were as described in ref. 10 except where indicated below.

4-Acetylpyrrole-2-carboxaldehyde

A solution of the pyrrole–Vilsmeier complex **2** was prepared in 1,2-dichloroethane on a five mmol scale as described before (11). To this was added aluminum chloride (11 mmol, Fluka), followed by acetyl chloride (5 mmol), rapidly and at room temperature. A small amount of warming occurred and the solution soon darkened. The ^1H nmr spectrum (neat) of the dark oil that had separated after 2 h indicated complete conversion to a 2,4-disubstituted pyrrole. The mixture was then poured onto about 50 mL of ice and water, 50% aqueous sodium hydroxide (4 mL) was added, and the mixture was stirred rapidly for about 10 min. The mixture was than made slightly acidic with concentrated hydrochloric acid and the organic and aqueous layers were separated. The aqueous layer was continuously extracted with ethyl ether for 8 h. The combined organic layer and ether extract was dried ($MgSO_4$), evaporated, and the solid residue recrystallized from benzene giving 0.55 g (80%) 4-acetylpyrrole-2-carboxaldehyde, mp 141–142°C (lit. (10) mp 141.5–142°C). Mixture mp undepressed.

4-Benzoylpyrrole-2-carboxaldehyde (Prepared by J. Doull)

The procedure above, using 5 mmol benzoyl chloride, gave a black solid. This was dissolved in ethyl acetate and filtered through a short plug of neutral alumina. Crystallization from ethyl acetate – petroleum (bp 60–80°C) gave 0.55 g (55%) of 4-benzoylpyrrole-2-carboxaldehyde, mp 138.5–139°C; ir ν: 1615, 1670 cm^{-1}; nmr ($CDCl_3$) δ: 9.45 (1H, d, J = 1.2 Hz), 7.8–7.2 (7H, m); *m/e*: 199. *Anal.* calcd. for $C_{12}H_9NO_2$: C 72.35, H 4.55, N 7.03; found: C 72.32, H 4.56, N 7.03.

Methyl 2-Formyl-4-pyrrolecarboxylate

Using the acetylation procedure above, the complex **2** (5 mmol) was treated with aluminum chloride (1.47 g, 11 mmol) and trichloroacetyl chloride (0.56 mL, 5 mmol).

The nmr spectrum of the pyrrole–Vilsmeier complex, as prepared in 1,2-dichloroethane, was determined using tetramethylsilane as external standard; δ: 11.36 (1H), 9.37 (1H), 8.08 (1H), 7.74 (1H), 7.12 (1H). Following the addition of aluminum chloride the spectrum was again determined; δ: 10.3 (1H, very broad), 8.61 (1H), 8.11 (1H), 7.80 (1H), 7.20 (1H). Trichloroacetyl chloride was added and, after 2 h at room temperature, the spectrum showed δ: 11.5 (1H, broad), 9.50 (1H, d), 9.19 (1H), 8.90 (1H).

After 2 h at room temperature, methanol (10 mL) was added and, after 5 min stirring, a solution of sodium (0.8 g, 35 mmol) in methanol (10 mL) was added and stirring continued for 2 h. The reaction product was then poured into cold water, stirred 10 min, and acidified with concentrated hydrochloric acid. The entire mixture was continuously extracted with ethyl ether. After drying ($MgSO_4$), the solvent was removed, giving a dark brown solid. The crude material in ethyl acetate was passed through a short plug of alumina and then was recrystallized from benzene–petroleum (60–80°C) to give 0.61 g (80%) of methyl 2-formylpyrrole-4-carboxylate, mp 126–128°C (lit. (10) mp 127–128°C). Mixture mp undepressed.

Pyrrole-2,4-dicarboxaldehyde

A solution of complex **2** (5 mmol) was treated with nitromethane (0.64 mL, 12 mmol) and aluminum chloride (1.47 g, 11 mmol), then cooled to 0°C. Dichloromethyl methyl ether (0.68 mL, 5 mmol) was added all at once and the cooling bath removed shortly after. The solution was stirred for 30 min at room temperature and worked up in the usual manner giving a yellow-brown solid. Recrystallization from toluene–petroleum gave 0.25 g (40%) of pyrrole-2,4-dicarboxaldehyde, mp 149–151°C (lit. (9) mp 151.5–152°C). Mixture mp undepressed.

Ethyl 2-Formylpyrrole-4-thiolcarboxylate

A solution of complex **2** (5 mmol) was treated with aluminum chloride (1.47 g, 11 mmol) and ethyl chlorothiolformate (0.59 mL, 5 mmol) at room temperature and stirred for 2 h. The product was poured into cold water (50 mL) and stirred rapidly for 45 min. The layers were separated and the aqueous layer extracted three times with chloroform. After drying the combined organic extracts ($MgSO_4$), the solvent was removed to give a pale brown solid. Recrystallization from benzene–petroleum (60–80°C) produced 0.57 g (62%) of ethyl 2-formylpyrrole-4-thiolcarboxylate, mp 71–73°C (lit. (10) mp 72.5–74°C). Mixture mp undepressed.

1-Methyl-4-acetylpyrrole-2-carboxaldehyde

(*a*)[1] To a suspension of aluminum chloride (40 g, 0.30 mol) in dichloromethane (250 mL) and acetyl chloride (7.1 mL, 0.10 mol) was added a solution of 1-methylpyrrole-2-carboxaldehyde (8.8 g, 0.08 mol) in dichloromethane (50 mL). The mixture was refluxed for 2 h, then poured on ice and stirred until melted. The layers were separated and the aqueous layer extracted three times with chloroform. The organic layer and the extracts were combined, dried ($MgSO_4$), and the solvent was removed. The crude solid product was dissolved in 1:3 chloroform–benzene, passed through a short column of neutral alumina, and sublimed to give 10.0 g (83%) of 1-methyl-4-acetylpyrrole-2-carboxaldehyde, mp 104–105°C; ir ν: 1657 cm^{-1}; nmr ($CDCl_3$) δ: 9.75 (1H, d), 7.57 (1H, m), 7.40 (1H, m), 4.05 (3H, s), 2.47 (3H, s); *m/e*: 151. *Anal.* calcd. for $C_8H_9NO_2$: C 63.56, H 6.00, N 9.27; found: C 63.55, H 6.03, N 9.25.

(*b*) Following the procedure for acetylation of the pyrrole complex **2**, a 5 mmol solution of the 1-methylpyrrole complex afforded a 78% yield of 1-methyl-4-acetylpyrrole-2-carboxaldehyde, mp 100–103°C. Mixture mp undepressed.

1-Methylpyrrole-2,4-dicarboxaldehyde

Following the procedure for formylation of pyrrole complex **2**, a 5 mmol solution of 1-methylpyrrole gave 0.42 g (61%) of 1-methylpyrrole-2,4-dicarboxaldehyde, mp 93–95°C (lit. (15) mp 95–96°C). Mixture mp undepressed.

Reaction of Pyrrole–Vilsmeier Complex 2 with Chlorosulfonyl Isocyanate

To a solution of **2** (5 mmol) in a bath at −25°C was added chlorosulfonyl isocyanate (0.43 mL, 5 mmol) in 1,2-dichloroethane (5 mL). The mixture was slowly allowed to reach room temperature. The nmr spectrum showed no evidence of reaction, so stirring was continued overnight. The usual work-up gave 0.30 g (50%) of 4-chloropyrrole-2-carboxaldehyde, mp 128.5–129°C (lit. (12*b*) mp 129–129.5°C).

The reaction was also carried out using acetonitrile as solvent giving the same product in 52% yield. The presence of 11 mmol of aluminum chloride in the reaction mixture also gave about the same result.

3-Benzoylpyrrole

4-Benzoylpyrrole-2-carboxaldehyde (100 mg) was mixed with palladized charcoal (10 mg, 5% Pd on C. Matheson, Coleman and Bell). The mixture was placed at the bottom of a long glass tube (normally used for small scale sublimations). The glass tube was connected to an eudiometer system, to measure the volume

[1]Taken from the M.Sc. thesis of H. Nagy, Memorial University of Newfoundland, 1970.

of gas evolved, and to a vacuum system. The tube was evacuated and then filled with nitrogen. The tube was then opened to the eudiometer and was heated to about 210°C in a sublimation apparatus. Gas evolution, apart from that due to expansion, became noticeable at about 180°C and became brisk at 210°C and a small amount of distillate (later indentified as water from the palladized charcoal) appeared on the sides of the tube. When gas evolution ceased (about 97% of the calculated volume of CO was produced), the eudiometer was disconnected and the tube was again evacuated (0.1 Torr). A colorless oily liquid soon began to collect on the cold surface of the tube and slowly crystallized. When distillation ceased the apparatus was allowed to cool and the section containing the distillate was cut from the tube. The distillate was recrystallized from chloroform–petroleum (bp 80–100°C) to give 58 mg, (68%) of 3-benzoylpyrrole mp 99.5–100°C (lit. (6) 96–97°C); ir (Nujol) ν: 1623 cm^{-1}; nmr ($CDCl_3$) δ: 6.66 (2H, m), 7.18 (1H, m), 7.27–7.90 (5H, m).

Using a similar procedure the following were also prepared by this method.

3-Acetylpyrrole

3-Acetylpyrrole was obtained as a pure colorless sublimate (67% yield), mp 113–114.5°C (lit. (10) 115–116°C). Mixture melting point with authentic material was undepressed.

Methyl Pyrrole-3-carboxylate

Methyl pyrrole-3-carboxylate was obtained as a colorless sublimate (44% yield) mp 87–88°C (lit. (10) 87–87.5°C). Mixture melting point with authentic material was undepressed.

1-Methyl-3-acetylpyrrole

1-Methyl-3-acetylpyrrole was obtained as a liquid distillate. The product was redistilled to give a colorless liquid (73% yield), bp 148–150°C/15 Torr; ir (film) ν: 1652 cm^{-1}; nmr δ: 2.30 (3H, s), 3.60 (3H, s), 6.49 (2H, m), 7.16 (1H, m); *m/e*: 171. *Anal.* calcd. for C_7H_9NO: C 68.27, H 7.37; found: C 68.34, H 7.40.

Stereoelectronic control in acetal formation

NORMAND BEAULIEU,[1] ROBERT A. DICKINSON,[2] AND PIERRE DESLONGCHAMPS

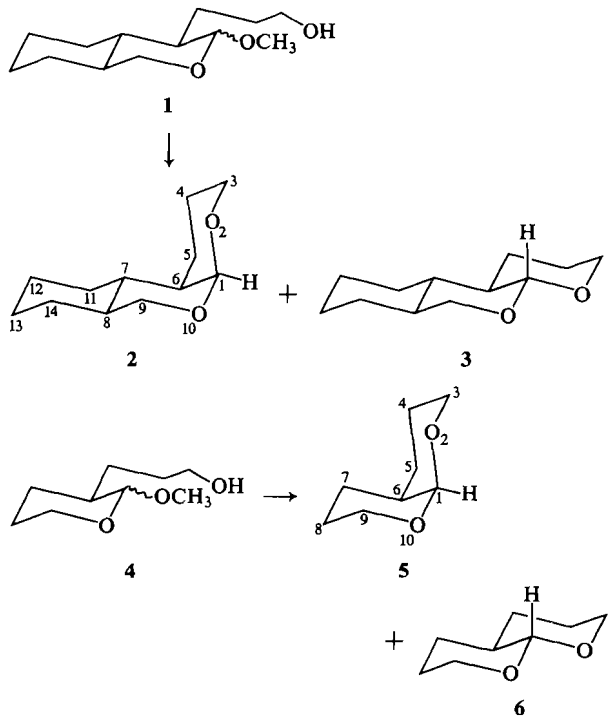
Laboratoire de Synthèse Organique, Département de Chimie, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received February 26, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

NORMAND BEAULIEU, ROBERT A. DICKINSON, and PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 2531 (1980).

The cyclization under acidic conditions of bicyclic and monocyclic hydroxypropyl methoxytetrahydropyrans **1** and **4** is reported. At room temperature, compound **1** gives only *cis* tricyclic acetal **2**. At reflux, compound **2** equilibrates to yield a mixture of *cis* and *trans* tricyclic acetals **2** (45%) and **3** (55%). Compound **4** gives directly the equilibrium mixture of *cis* and *trans* bicyclic acetals **5** (55%) and **6** (45%) at room temperature. The specific formation of **2** from **1** constitutes strong experimental evidence that acetal formation is controlled by stereoelectronic effects. The anomeric effect can be estimated (≃1.5 kcal/mol) from the equilibrium study of **2** and **3**. This value confirms the result previously obtained by Descotes (9).



NORMAND BEAULIEU, ROBERT A. DICKINSON et PIERRE DESLONGCHAMPS. Can. J. Chem. **58**, 2531 (1980).

On rapporte la cyclisation, sous conditions acides, des hydroxy-propylméthoxytétrahydropyrannes bicyclique et monocyclique **1** et **4**. A température ambiante, le composé **1** donne uniquement l'acétal tricyclique *cis* **2**. A reflux, le composé **2** forme un mélange des acétals tricycliques *cis* **2** (45%) et *trans* **3** (55%). Le composé **4**, à température ambiante, donne directement le mélange à l'équilibre des acétals bicycliques *cis* **5** (55%) et *trans* **6** (45%). La formation spécifique de **2** à partir de **1** constitue une preuve convaincante démontrant que la formation d'acétal est contrôlée par des effets stéréoélectroniques. L'effet anomère peut être évalué à partir de l'analyse du mélange à l'équilibre de **2** et **3**; la valeur trouvée de ≃1.5 kcal/mol s'accorde bien avec les résultats déjà obtenus par Descotes (9).

The influence of stereoelectronic effects on the configuration and the conformation of the acetal function has been recognized for a long time, particularly in carbohydrates where these effects have been discussed in terms of the anomeric and the *exo*-anomeric effects (1).

A pertinent question which follows is whether or not these stereoelectronic effects have an important influence on the formation or the cleavage of the acetal function. The first experimental evidences that acetal hydrolysis is indeed controlled by stereoelectronic effects have been obtained recently by Kirby and Martin (2, 3). The reverse process, i.e. acetal formation, should therefore be controlled by stereoelectronic effects. We wish to report an experiment which shows that this is indeed the case.

In this work, we describe the study of the cyclization of bicyclic hydroxypropyl methoxytetrahydropyran **1** (Scheme 1) and monocyclic hydroxypropyl methoxytetrahydropyran **4** under mild acidic conditions. Theoretically, compound **1** may yield both *cis* and *trans* tricyclic acetals **2** and **3** or either of them, whereas compound **4** may cyclize to the corresponding *cis* and/or *trans* bicyclic acetals **5** and **6**.

SCHEME 2

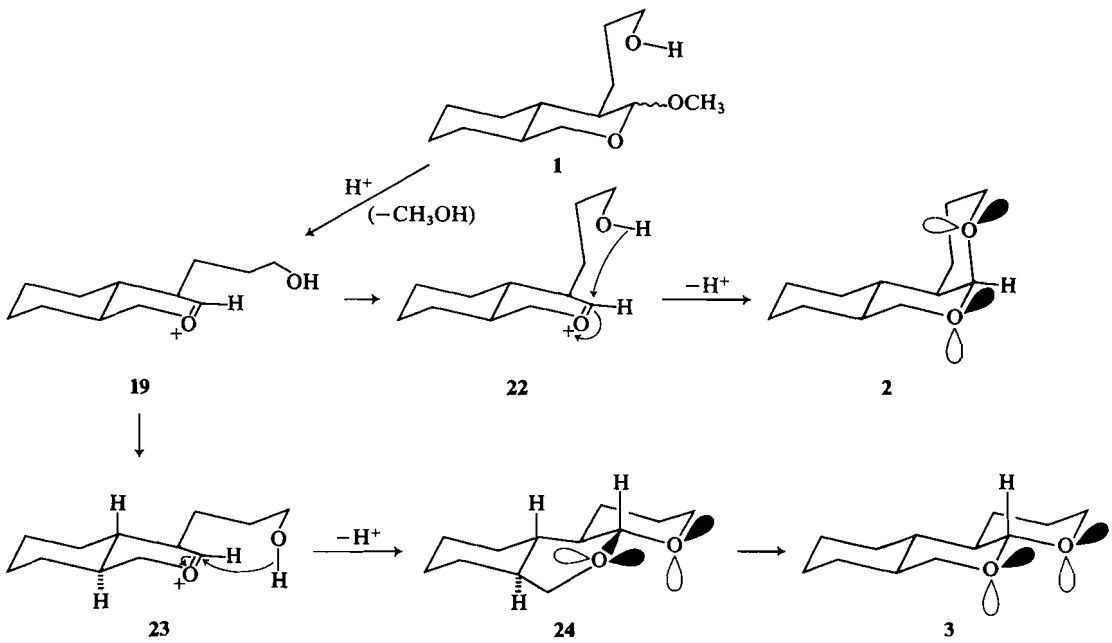
lated (LDA, allyl bromide, HMPT, −78° and −40°C) to produce a mixture of **7** (11%), bicyclic allyl lactone **8** (85%), and bicyclic bis-allyl lactone **9** (4%) which were separated by column chromatography.

Treatment of bicyclic allyl lactone **8** with sodium methoxide in methanol yielded a mixture of **8** (68%) and **10** (33%) which were separated by vpc. Epimerization of compound **8** with *p*-toluenesulfonic acid in benzene yielded a mixture of **8** (64%) and **10** (36%). As compound **8** is the major epimer, the allyl side chain in **8** is therefore oriented equatorially. The ^{13}C nmr spectra of compounds **8** and **10** confirm this assignment.[3]

Reduction of bicyclic allyl lactone **8** (DIBAL in THF, −78°C) followed by methanolysis (CH_3OH, *p*-TsOH, room temperature) resulted in bicyclic allyl methoxytetrahydropyran **11** as a mixture of isomers at the anomeric center (axial/equatorial ratio = 3:1). Hydroboration ($(CH_3)_2S \cdot BH_3$ in THF, 0°C) (5) of **11** gave the desired bicyclic hydroxypropyl methoxytetrahydropyran **1** as a mixture of axial and equatorial isomers (ratio 3:1). This mixture of **1** was used for our study.

[3]In the axial isomer **10** carbon-4 appears at a higher chemical shift (32.8 ppm) than the equatorial isomer **8** (37.9 ppm) due to the γ effect (4).

Basic hydrolysis of ethyl bis-allyl acetate **12** (6) (KOH, C_2H_5OH, reflux, 12 h) gave the corresponding bis-allyl acetic acid **13** which was converted into dibromocarboxylic acid **14** (92% yield) by the photochemically induced addition of hydrogen bromide (*hν*, pentane (7)). Treatment of dibromocarboxylic acid **14** with triethylamine in dichloromethane yielded bromolactone **15** (93% yield) which was further transformed (CH_3COONa, HMPT, room temperature, (8)) into acetate lactone **16** (49% yield).



Reduction of acetate lactone **16** with diisobutyl aluminium hydride in tetrahydrofuran produced the corresponding acetate hemiacetal **17**. Treatment of **17** with methanol in the presence of *p*-toluenesulfonic acid gave **18** which was hydrolyzed with potassium carbonate to yield hydroxypropyl methoxytetrahydropyran **4** as a mixture of *cis* and *trans* isomers (1 ≃ 1 ratio, nmr) which produces a single peak on vpc. The isomeric mixture of **4** was used in our study.

Cyclization of Compounds 1 and 4

Methanolysis (CH_3OH, *p*-TsOH (1 equiv.), room temperature, 72 h) of bicyclic hydroxypropyl methoxytetrahydropyran gave the *cis* tricyclic acetal **2** only. The appearance of a small quantity of

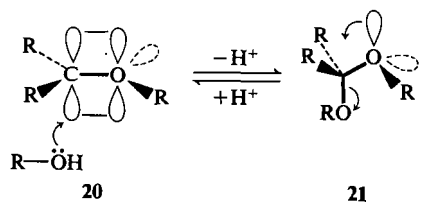
SCHEME 3

the *trans* tricyclic acetal **3** occurred only after 5 days. When the *cis* tricyclic acetal **2** was refluxed under the above conditions (CH_3OH, *p*-TsOH), isomerization took place to yield an equilibrium mixture of *cis* and *trans* tricyclic acetals **2** (45%) and **3** (55%). *Cis* and *trans* tricyclic acetals **2** and **3** were separated by vpc.

Methanolysis (CH_3OH, *p*-TsOH (1 equiv.), room temperature, 5 days) of hydroxypropyl methoxytetrahydropyran **4** gave an equilibrium mixture of *cis* and *trans* bicyclic acetals **5** (55%) and **6** (45%). This reaction was followed by thin layer chromatography which showed the gradual and simultaneous appearance of **5** and **6**. Compounds **5** and **6** were separated by vpc. They are known compounds and their equilibration under acidic conditions has been previously reported (9).



The structures of tricyclic acetals **2** and **3** were established by ^1H and ^{13}C nmr on comparison with the spectra of bicyclic acetals **5** and **6**.

Discussion

The specific conversion of compound **1** into the *cis* tricyclic acetal **2** is clearly the result of a kinetically controlled reaction because under more vigorous conditions the *cis* acetal **2** equilibrates with the slightly more stable *trans* acetal **3** (thermodynamic control). As a consequence, the formation of *trans* acetal **3** must require an energetically higher transition state than that for the formation of *cis* acetal **2**.

The first step during the cyclization reaction must be the formation of the bicyclic hydroxy oxenium ion **19** by the loss of methanol from the starting product **1** (Scheme 3). The hydroxyl group in **19** has then the choice to attack the β or the α face of the oxenium ion which would give the *cis* or the *trans* tricyclic acetals **2** and **3** respectively. However, under kinetically controlled conditions, the α attack cannot compete with the β attack as the *cis* acetal **2** is the only product formed.

These results can be explained if stereoelectronic effects are taken into consideration. Indeed, if we accept that acetal formation will take place with minimum energy, only when the intermediate oxenium ion can develop an electron pair which will become antiperiplanar to the newly formed C—O bond in the final product (stereoelectronic control (10), cf. **20** → **21**), the above results can be easily rationalized.

20 **21**

It can readily be seen that the β attack on **19** (i.e. **22**) can give the *cis* acetal **2** with stereoelectronic control, because the oxygen of ring B in **2** has an electron pair oriented antiperiplanar to the newly

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

formed C—O bond. On the other hand, the α attack on **19** with stereoelectronic control cannot yield the *trans* acetal directly in its more stable conformation **3**. The α attack on **19** (i.e. **23**) must first give conformer **24** of *trans* acetal having its ring B twisted; in **24**, the oxygen of ring B has an electron pair oriented antiperiplanar to the newly formed C—O bond. Conformer **24** would then undergo a conformational change to the more stable conformation **3** of *trans* tricyclic acetal. The transition **19** → **23** → **24** requires more energy than the transition **19** → **22** → **2**, so the formation of *trans* acetal **3** should be a higher energy process than the formation of *cis* acetal **2**.

This conclusion is in accord with the above experimental results which clearly show that *trans* tricyclic acetal **3** is produced only when the experimental conditions allow the cyclization process to become thermodynamically controlled. If stereoelectronic effects are neglected, we would have predicted that the formation of **3** would be as facile as that of **2** from **19**. Consequently, the above results constitute strong evidence that acetal formation is stereoelectronically controlled.

The direct conversion of compound **4** into the equilibrium mixture of *cis* and *trans* bicyclic acetals **5** and **6** shows that this reaction is under thermodynamic control even at room temperature. Consequently, this experiment is not valid to either prove or disprove the influence of stereoelectronic effects in acetal formation. In this case, the formation of *trans* acetal can compete with the formation of *cis* acetal. The reason might simply be that it is easier to go through a twisted acetal conformer with the monocyclic compound **4** than with the bicyclic compound **1**.

At equilibrium, there is a larger percentage of the *cis* acetal in the bicyclic series (**5**, 55%) (9) than in the tricyclic series (**2**, 45%). This difference can be explained by the fact that the *cis* bicyclic acetal is conformationally mobile (*cis* decalin system) whereas the *cis* tricyclic acetal **2** is conformationally rigid. There is therefore an entropy factor which favors the *cis* over the *trans* acetal in the bicyclic series only, and this is reflected in the equilibrium value.

Descotes (9) had carried out the equilibration of *cis* and *trans* acetals **5** and **6** in order to evaluate the anomeric effect and obtained a value of 1.4 kcal/mol. Our equilibration study with *cis* and *trans* acetals **2** and **3** confirms his conclusion.

If the same value are taken for the steric interactions in the *cis* acetal **2** (one *gauche* interaction = 0.85 kcal/mol and one interaction for an axial OR group to cyclohexane = 0.8 kcal/mol), the *cis* acetal **2** should be less stable than the *trans* acetal **2** by 1.65 kcal/mol. The equilibration studies show that the *cis* acetal **2** is less stable than the *trans* acetal **3** by 0.14 kcal/mol (65°C, 45%), the anomeric effect is therefore evaluated to be about ≃1.5 kcal/mol from this experiment.

Experimental

Vapor phase chromatographic (vpc) analysis and separations were carried out on a Varian Aerograph instrument, model 2868 with thermal conductivity detector (column 1: SE-30, 15% Chromosorb W, 60–80 mesh, 5 ft × ¼ in.; 2: SE-30, 10% Chromosorb W, 60–80 mesh, 5 ft × ¼ in.; 3: SE-30, 5% Chromosorb W, 100–200 mesh, 5 ft × ¼ in.). The infrared (ir) spectra were taken on a Perkin-Elmer 257 spectrophotometer. Proton nuclear magnetic resonance (nmr) spectra were recorded on a Bruker WP-60 instrument. The ^{13}C nmr spectra were recorded on a Bruker HX-90 spectrometer equipped with a Nicolet 1083 computer (8K memory for data) operating in the Fourier transform mode. Sweep widths of 5000 Hz were used with a line broadening factor of 0.5 Hz. The compounds were studied as approximately 0.7 *M* solutions in $CDCl_3$ with internal TMS as reference, Mass spectral assays were obtained using a Hitachi-Perkin-Elmer RMU-6A and a Vg Micromass ZAB-2F mass spectrometer. Microanalyses were carried out by Schwarzkopf Microanalytical Laboratories, New York and by Guelph Chemical Laboratories Ltd, Guelph, Ont.

Bicyclic lactone **7** was obtained by Baeyer–Villiger oxidation (11) of *trans*-hydrindanone (12).

Bicyclic Equatorial Allyl Lactone **8**

A solution of diisopropylamine (10 mmol) in anhydrous tetrahydrofuran (50 mL) was mixed with *n*-butyllithium (10 mmol, 2.2 *M* in hexane) at room temperature. After 20 min, the solution was cooled at −78°C and a solution of bicyclic lactone **7** (769 mg, 5 mmol) in anhydrous tetrahydrofuran (20 mL) was added dropwise and the mixture was left for 1 h. Allyl bromide (6 mmol) in hexamethylphosphoramide (7 mmol) was then added. The reaction mixture was then left for 3 h at −40°C. A saturated solution (20 mL) of ammonium chloride was added, and the resulting mixture was extracted with ether (100 mL). The organic phase was washed with dilute hydrochloric acid (10%, 2 × 25 mL) and brine. The organic phase was dried with magnesium sulfate, filtered, and evaporated to yield an oil (876 mg). Vapor phase chromatographic analysis indicated a mixture of bicyclic allyl lactone **8** (85%), starting bicyclic lactone **7** (11%), and bicyclic bis-allyl lactone **9** (4%). These compounds were separated by column chromatography with silica gel using ether–hexane (1:4) as eluant.

Bicyclic Allyl Lactone **8**: vpc: retention time, 20.7 min (153°C, column 3); ir (CCl_4); 1744 and 1638 cm^{-1}; nmr ($CDCl_3$) δ: 1.0–2.0 (10H), 2.0–3.0 (3H, multiplet, C=C—CH_2—CH—CO), 3.85 and 4.27 (2H, AB part of an ABX system, J_{AX} = 10.5 Hz, J_{BX} = 4.0 Hz, and J_{AB} = 11.0 Hz, CH_2O), 5.16 (2H, complex doublets, $J_{(trans)} \simeq 16$ Hz, and $J_{(cis)} \simeq 10$ Hz, C=CH_2), and 5.87 (1H, multiplet, —CH=C). Data for ^{13}C nmr ($CDCl_3$): 172.7 (C1), 117.9 (C12), 134.5 (C11), 73.9 (C5), 46.9 (C3), 39.1 (C2), 37.9 (C4), 32.4 (C10), 30.4 (C9), 27.3 (C6), 25.2 (C7), and 24.8 (C8); ms *m/e* (70 eV): 194 (M^+). *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.23, H 9.28; found: C 73.97, H 9.42.

Bicyclic Bis-allyl Lactone **9**: ir ($CHCl_3$): 1745 and 1638 cm^{-1}; nmr ($CDCl_3$) δ: 1.0–2.0 (10H), 2.0–3.0 (4H, multiplet, two CH_2—C=C), 3.85 and 4.27 (2H, AB part of an ABX system, J_{AX} = 10.5 Hz, J_{BX} = 4.0 Hz, J_{AB} = 11.0 Hz, CH_2O), 5.16 (4H, complex doublets, $J_{(trans)} \simeq 16$ Hz, $J_{(cis)} \simeq 10$ Hz, two C=CH_2), and 5.87 (2H, multiplet, two C—CH=C); ms *m/e* (70 eV): 234 (M^+).

Bicyclic Axial Allyl Lactone 10

Bicyclic equatorial allyl lactone **8** (42 mg, 0.22 mmol) was added to a solution of sodium methoxide (24 mg, 0.44 mmol) in methanol (4 mL), and the mixture was refluxed under nitrogen for 24 h. The methanol was evaporated, the residue was acidified with dilute hydrochloric acid (2 *N*, 3 mL) and extracted with ether. The organic phase was washed with brine, dried over sodium sulfate, filtered, and evaporated to dryness. The vpc analysis showed a major product (equatorial allyl **8**) and a minor product (axial allyl **10**) which were separated (vpc) yielding pure equatorial allyl lactone **8** (14 mg) and pure axial allyl lactone **10** (7 mg).

Bicyclic Axial Allyl Lactone 10: vpc: retention time, 24.4 min (153°C, column 3); ir (CCl_4): 1748 and 1640 cm^{-1}; nmr ($CDCl_3$) δ: 1.0–2.0 (10H), 2.5 (3H, multiplet, C=C—CH_2—CH—CO), 3.79 and 4.31 (2H, AB part of an ABX system, J_{AX} = 10.5 Hz, J_{BX} = 5.0 Hz, J_{AB} = 11.0 Hz, CH_2O), 5.03 (2H, complex doublets, $J_{(trans)} \simeq 16$ Hz, $J_{(cis)} \simeq 10$ Hz, C=CH_2), and 5.87 (1H, multiplet, —CH=C); ^{13}C nmr ($CDCl_3$): 174.9 (C1), 116.9 (C12), 136.0 (C11), 74.9 (C5), 44.8 (C3), 40.3 (C2), 32.8 (C4 and C10), 28.3 (C9), 28.0 (C6), 25.8 (C7), and 25.1 (C8); ms *m/e* (70 eV): 194 (M^+).

Epimerization of Bicyclic Equatorial Allyl Lactone 8

Bicyclic equatorial allyl lactone **8** (39 mg, 0.20 mmol) was refluxed in benzene (5 mL) containing *p*-toluenesulfonic acid (38 mg, 0.20 mmol) during 14 h. Dilute sodium bicarbonate (5%, 5 mL) was added and the mixure was extracted with ether (3 × 20 mL). The organic extract was dried over sodium sulfate, filtered, and evaporated to yield a product (38 mg, 97%) which was shown by vpc to be a mixture of equatorial (64%) and axial (36%) bicyclic allyl lactones **8** and **10**.

Bicyclic Allyl Methoxytetrahydropyran 11

A solution of bicyclic equatorial allyl lactone **8** (595 mg, 3.07 mmol) in anhydrous tetrahydrofuran (40 mL) was treated at −78°C with diisobutylaluminium hydride (4 mmol, 1 *M* in hexane) during 2 h. The mixture was warmed up to room temperature and was slowly added to aqueous acetic acid (10%, 100 mL); it was then extracted with ether (3 × 50 mL). The organic phase was washed with sodium bicarbonate (5%, 3 × 50 mL), dried over sodium sulfate, filtered, and evaporated. The residue was treated with anhydrous methanol (50 mL) containing trimethyl orthoformate (1 mL) and a catalytic amount of *p*-toluenesulfonic acid. After 15 h at room temperature, potassium carbonate (300 g) was added followed by the addition of water (40 mL). The reaction mixture was extracted with ether (3 × 50 mL), the organic extract was dried over sodium sulfate, filtered, and evaporated to dryness yielding crude bicyclic allyl methoxytetrahydropyran **11** (503 mg, 78%). This product was purified by vpc: retention time, 9 min (160°C, column 2); ir ($CHCl_3$): 1645 cm^{-1}; nmr ($CDCl_3$) δ: 0.8–2.5 (15H), 3.25 and 3.40 (3H, two singlets, ratio 3:1, axial and equatorial OCH_3), 3.2–4.5 (2.25H, CH_2O and axial anomeric hydrogen), 4.45 (0.75H, broad doublet, equatorial anomeric hydrogen), and 4.7–6.1 (3H, multiplet, CH=CH_2); ms *m/e* (70 eV): 210 (M^+), 178 (M^+ − CH_3OH).

Bicyclic Hydroxypropyl Methoxytetrahydropyran 1

A solution of bicyclic allyl methoxytetrahydropyran **11** (183 mg, 0.87 mmol) in anhydrous tetrahydrofuran (5 mL) was treated at 0°C with dimethyl sulfide – borane complex (0.4 mmol) during 2 h. Aqueous sodium hydroxide (3 *N*, 2 mL) followed by hydrogen peroxide (30%, 2 mL) was then added and the mixture was stirred for 90 min at 0°C. Water (20 mL) was added and the mixture was extracted with chloroform (4 × 25 mL). The organic extract was dried over sodium sulfate, filtered, and evaporated to yield crude bicyclic hydroxypropyl methoxytetrahydropyran **1**. Infrared ($CHCl_3$): 3350–3600 and 1200–1250 cm^{-1}; nmr ($CDCl_3$) δ: 0.80–2.30 (15H), 3.38 and 3.52 (3H, two singlets, ratio 3:1, axial and equatorial O—CH_3), 3.3–4.0 (4.25H, two CH_2O and axial anomeric hydrogen), 4.63 (0.75H, broad doublet, equatorial anomeric hydrogen).

cis *Tricyclic Acetal 2*

Bicyclic hydroxypropyl methoxytetrahydropyran **1** (199 mg, 0.87 mmol) was treated with anhydrous methanol (20 mL) containing *p*-toluenesulfonic acid (165 mg, 0.87 mmol) at room temperature during 72 h. Potassium carbonate (300 mg) was added and after 30 min, the mixture was evaporated. The residue was dissolved in water (20 mL) and the aqueous phase was extracted with ether. The organic phase was dried over sodium sulfate, filtered, and evaporated to yield an oil. The vpc and tlc analyses indicated the presence of *cis* tricyclic acetal **2**, and the absence of the *trans* isomer **3**. Purification by thin layer chromatography with silica gel using ether gave pure *cis* tricyclic acetal **2** (106 mg, 62%); vpc: retention time, 20.7 min (150°C, column 2); ir ($CHCl_3$): 1000–1200 cm^{-1}; nmr ($CDCl_3$) δ: 0.5–2.5 (15H), 3.5–4.3 (4H, multiplet, two OCH_2), and 4.75 (1H, broad singlet, anomeric hydrogen); ^{13}C nmr ($CDCl_3$): 98.9 (C1), 67.7 (C9), 66.7 (C3), 40.9 (C8), 40.5 (C6), 35.6 (C7), 28.8 (C11), 27.8 (C14), 26.4 (C13), 25.8 (C12), 23.8 (C4), and 20.5 (C5); ms *m/e* (70 eV): 196 (M^+).

Isomerization of cis *and* trans *Tricyclic Acetals 2 and 3*

Cis tricyclic acetal **2** (40 mg, 0.2 mmol) was dissolved in anhydrous methanol (5 mL) containing *p*-toluenesulfonic acid (0.2 mmol) and the solution was stirred at room temperature. After 24 h, tlc analysis showed the presence of *cis* tricyclic acetal **2** only. The solution was then refluxed during 24 h; analysis by tlc indicated the gradual appearance of a new product. The reaction mixture was evaporated and sodium bicarbonate (5%, 20 mL) was added and the resulting mixture was extracted with dichloromethane (3 × 30 mL). The organic phase was dried over sodium sulfate, filtered, and evaporated. Vapor phase chromatographic analysis indicated a mixture (39 mg, 97%) of *cis* (45%) and *trans* (55%) tricyclic acetals **2** and **3**. These compounds were separated by vpc (retention time, 12.5 min for compound **2** and 19 min for compound **3** (135°C, column 3)).

Trans *Tricyclic Acetal 3*: ir ($CHCl_3$): 1000–1200 cm^{-1}; nmr ($CDCl_3$) δ: 0.5–2.5 (15H), 3.5–4.3 ((5H, multiplet, two OCH_2 and anomeric hydrogen); ^{13}C nmr ($CDCl_3$): 105.1 (C1), 71.9 (C9), 67.3 (C3), 45.1 (C7), 43.9 (C6), 41.6 (C8), 28.2 (C11), 27.6 (C14), 26.1 (C13), 25.6 (C12), 25.1 (C4), and 19.4 (C5); ms *m/e* (70 eV): 196 (M^+).

Bis-allyl Acetic Acid 13

Ethyl bis-allyl acetate **12** (4.23 g, 0.03 mol) (6) was mixed with a solution of potassium hydroxide (2.5 g, 40 mmol) in ethanol (95%, 75 mL) and the mixture was refluxed during 12 h. The solvent was evaporated, water (50 mL) was added, and the aqueous phase was extracted with ether (2 × 25 mL). The aqueous phase was then acidified with concentrated hydrochloric acid and extracted with ether (3 × 50 mL). The organic phase was dried with magnesium sulfate, filtered, and evaporated to yield crude bis-allyl acetic acid **13** (3.25 g, 92%) which was used without further purification. An analytical sample was prepared by vpc; vpc: retention time, 7 min (115°C, column 1); ir ($CHCl_3$): 2400–3400 (broad), 1715 and 1642 cm^{-1}; nmr ($CDCl_3$) δ: 2.1–2.5 (5H), 4.7–6.0 (6H, multiplet, CH=CH_2), and 11.8 (1H, singlet, OH); ms *m/e* (70 eV): 140 (M^+). *Anal.* calcd. for $C_8H_{12}O_2$: C 68.53, H 8.63; found: C 68.40, H 8.64.

Dibromocarboxylic Acid 14

Bis-allyl acetic acid **13** (1.125 g, 8.0 mmol) was dissolved in pentane (300 mL). (The pentane used was treated with concentrated sulfuric acid during 4 days followed by washing with water, drying with magnesium sulfate, and distillation over cal-

cium hydride.) Nitrogen gas was bubbled through the solution during 5 min. Hydrogen bromide gas was then bubbled through the solution (20 min) which was exposed to the radiation of an ultraviolet lamp (450 W). Nitrogen gas was again bubbled through the solution, ether was added, and the organic phase was washed with sodium thiosulfate (5%, 4 × 50 mL) and brine (50 mL). The organic phase was dried with magnesium sulfate, filtered, and evaporated to yield an oil which was crystallized from hexane (2.21 g, 90%); mp 37–37.5°C; ir ($CHCl_3$): 3400–2400 (broad), 1712 cm^{-1}; nmr ($CDCl_3$) δ: 1.6–2.6 (9H, multiplets), 3.35 (4H, triplet, J = 6 Hz, two CH_2Br), and 11.4 (1H, singlet, OH); ms *m/e* (70 eV): 220 and 221 ($M^+ - Br$). *Anal.* calcd. for $C_8H_{14}Br_2O_2$: C 31.82, H 4.67; found: C 31.92, H 4.84.

Bromolactone 15

Triethylamine (0.6 mmol) was added to a solution of dibromocarboxylic acid **14** (160 mg, 0.53 mmol) in anhydrous dichloromethane (15 mL) and the mixture was left at room temperature during 3 h. The organic solution was washed with dilute hydrochloric acid (10%, 3 × 5 mL), dried with magnesium sulfate, filtered, and evaporated to yield crude bromolactone **15** (109 mg, 93%). An analytical sample was prepared by microdistillation; bp 131°C (0.5 Torr); vpc: retention time, 12 min (175°C, column 2); ir ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 1.5–2.6 (9H, multiplet, 3.35 (2H, triplet, J = 6 Hz, CH_2Br), and 4.2 (2H, triplet, J = 5.5 Hz, CH_2O); ms *m/e* (70 eV): 141 ($M^+ - Br$). *Anal.* calcd. for $C_8H_{13}BrO_2$: C 43.46, H 5.93; found: C 43.26, H 6.31.

Acetate Lactone 16

Sodium acetate (10 mmol) was added to a solution of bromolactone **15** (796 mg, 3.6 mmol) in hexamethylphosphoramide (40 mL) and the mixture was heated at 60°C during 2 h. After cooling to room temperature, ether (75 mL) was added. The organic phase was washed with water (6 × 50 mL), dried over sodium sulfate, filtered, and evaporated. The residue was purified by column chromatography with silica gel using a mixture of ethyl acetate and hexane (1:4) to yield pure acetate lactone **16** (370 mg, 49%), which was found identical with an authentic sample (13). Infrared ($CHCl_3$): 1740 cm^{-1}; nmr ($CDCl_3$) δ: 4.38 (2H, diffuse triplet, J = 6 Hz, CH_2O of the ring), 4.15 (2H, triplet, J = 6 Hz, CH_2OAc), and 2.06 (3H, singlet, CH_3COO).

Hydroxypropyl Methoxytetrahydropyran 4

Diisobutylaluminium hydride (0.9 mmol, 1 *M* in hexane) was added to a solution of acetate lactone **16** (171 mg, 0.85 mmol) in anhydrous tetrahydrofuran under nitrogen atmosphere. After stirring at −78°C during 2 h, dilute hydrochloric acid (0.5 *N*, 40 mL) was added and the mixture was extracted with ether (3 × 50 mL). The organic phase was dried over sodium sulfate, filtered, and evaporated to yield crude **17** (153 mg, 88%) which was used without further purification. Infrared ($CHCl_3$): 3200–3600 and 1735 cm^{-1}; nmr ($CDCl_3$) δ: 0.8–2.0 (9H, multiplet), 2.15 (3H, singlet, CH_3COO), and 3.3–4.0 (6H, multiplet), CH_2OCHOH and CH_2OCO).

Crude product **17** (153 mg, 0.76 mmol) was treated with methanol (4 mL) containing a catalytic amount of *p*-toluenesulfonic acid during 12 h at room temperature. Potassium carbonate (50 mg) was then added and the mixture was stirred during 6 h at room temperature. The reaction mixture was evaporated to dryness *in vacuo*, water (10 mL) was added, and the aqueous mixture was extracted with ether (3 × 25 mL). The organic phase was dried over sodium sulfate, filtered, and evaporated to yield crude product **4** (101 mg, 76%). A sample was obtained pure by vpc. This sample is a 1:1 mixture of *cis* and *trans* isomers; vpc: retention time, 5 min (175°C, column 2); ir ($CHCl_3$): 3200–3600 cm^{-1}; nmr ($CDCl_3$) δ: 1.2–2.0 (9H, multiplets), 3.43 and 3.35 (3H, two singlets, ratio ≃ 1:1, OCH_3 of *cis* and *trans* isomers), 3.5–3.9 (5H, multiplet, two CH_2O and OH), 4.55 and 4.1 (1H, two doublets, anomeric H of *cis* and *trans* isomers).

cis *and* trans *Bicyclic Acetals 5 and 6*

Hydroxypropyl methoxytetrahydropyran **4** (96 mg, 0.47 mmol) dissolved in anhydrous methanol (4 mL) containing *p*-toluenesulfonic acid (89 mg, 0.47 mmol) was left at room temperature during 5 days. (The reaction was followed by tlc and *cis* and *trans* bicyclic acetals **5** and **6** appeared from the beginning to the end of the reaction as a mixture.) Sodium carbonate (100 mg) was added and after stirring for 30 min, the mixture was evaporated. The residue was dissolved in water (15 mL) and extracted with ether (3 × 25 mL). The organic phase was dried over sodium sulfate, filtered, and evaporated to yield a mixture of *cis* bicyclic acetal **5** (56%) and *trans* bicyclic acetal **6** (44%) which were analyzed and separated by vpc (column 2 (130°C)).

Cis *Bicyclic Acetal* **5** *(9)*: vpc: retention time, 5 min (130°C, column 2); ir ($CHCl_3$): no OH or carbonyl absorption and 1000–1200 cm^{-1}; nmr ($CDCl_3$) δ: 1.0–2.0 (9H), 3.25–4.0 (4H, multiplet, two CH_2O), and 4.70 (1H, singlet, anomeric hydrogen); ^{13}C nmr ($CDCl_3$): 98.0 (C1), 64.3 (C3 and C9), 34.6 (C6), 25.3 (C4 and C8), and 23.0 (C5 and C7); ms *m/e* (70 eV): 142 (M^+).

Trans *Bicyclic Acetal 6 (9)*: vpc: retention time, 6.7 min (130°C, column 2); ir ($CHCl_3$): 1000–1200 cm^{-1}; nmr ($CDCl_3$) δ: 0.9–2.2 (9H), 3.28–4.20 (5H, multiplet, two CH_2O and anomeric hydrogen); ^{13}C nmr ($CDCl_3$): 105.4 (C1), 67.5 (C3 and C9), 40.6 (C6), 28.8 (C4 and C8), and 26.1 (C5 and C7); ms *m/e* (70 eV): 142 (M^+).

The half-wave reduction potentials, measured by cyclic voltammetry, and n,π^* triplet energies, measured by phosphorescence spectroscopy, were determined for a series of eighteen symmetrically and unsymmetrically substituted benzophenones. Attempts are made to correlate the results with Hammett substituent constants. Better correlations are observed when the data are correlated with a two-parameter function consisting of Hammett substituent constants and a set of substituent parameters describing variations in free radical stability. Significant deviations from "normal" behaviour are observed for benzophenones substituted by both electron-donating and electron-withdrawing substituents. These deviations are attributed to merostabilization of the radical-like species, and an empirical approach designed to evaluate the importance of this effect is developed. *Ab initio* calculations of molecular orbital energies in *meta*- and *para*-substituted benzaldehydes are used to evaluate the substituent effects on $E_{1/2}^{red}$ and E_T^{n,π^*} in terms of the effect on the energies of the *n*- and π^*-orbitals.

WILLIAM J. LEIGH, DONALD R. ARNOLD, ROBERT W. R. HUMPHREYS et PO CHEONG WONG. Can. J. Chem. **58**, 2537 (1980).

On a déterminé les potentiels de réduction de demi-vague mesurés par voltamétrie cyclique et les énergies de l'état triplet, n,π^* mesurées par spectroscopie de phosphorescence, pour une série de 18 benzophénones substituées symétriquement et asymétriquement. On a essayé d'établir une corrélation entre les résultats et les constantes de substituant de Hammett. On a observé les meilleures corrélations quand les données sont reliées à une fonction à deux paramètres se composant des constantes de substituant de Hammett et à un ensemble de paramètres de substituant décrivant les variations de stabilité du radical libre. On a observé des déviations importantes par rapport au comportement "normal" dans le cas des benzophénones substituées à la fois avec des substituants donneurs et des substituants accepteurs d'électrons. Ces déviations sont attribuées à une mérostabilisation de l'espèce radicalaire et on a développé une approche empirique pour évaluer l'importance de cet effet. On a utilisé des calculs *ab initio* d'énergies d'orbitales moléculaires dans des benzaldéhydes substitués en *méta* et en *para* pour évaluer les effects de substituants sur $E_{1/2}^{red}$ et E_T^{n,π^*} en fonction de l'effet sur les énergies des orbitales *n* et π^*.

[Traduit par le journal]

Introduction

One of the early successes of molecular orbital theory was the recognition that the half-wave reduction potential of polynuclear aromatic hydrocarbons correlates with the energy calculated for the lowest unoccupied molecular orbital (LUMO; that is, the π^*-orbital) of the aromatic hydrocarbon (1). This correlation was also found to apply for a series of polynuclear aromatic aldehydes, where the LUMO was treated as the corresponding hydrocarbon radical (for example, the benzyl radical was used as the model for the LUMO of benzaldehyde) (1*a*, 2). This reasoning was then more generally extended and it was proposed that the half-wave reduction potential of a substituted aromatic carbonyl compound could be used as an indication of the energy of its π^*-orbital (1*a*, 2, 3). Since it was known that there is a correlation of half-wave reduction potentials of substituted benzophenones with Hammett substituent constants (4, 5), the conclusion was reached that the substituents were, in fact, influencing the energy of the π^*-orbital (3).

It was also found that there is a correlation between the n,π^* triplet energy of a series of substituted aromatic carbonyl compounds and their half-wave reduction potentials (3). This was attributed to the variation in the energy of the π^*-orbital, with the assumption that the energy of the *n*-orbital remained fairly constant within the series. The sequence was completed by the recognition that there is a correlation (albeit, not a particularly good one) between Hammett substituent constants and the n,π^* triplet energy of aromatic carbonyl compounds (5).

Superficially, these results are all consistent. The substituent effect on the half-wave reduction potential and the n,π^* triplet energy of substituted aromatic carbonyl compounds correlates with Hammett substituent constants as a result of the substituent influencing the energy of the π^*-orbital. Electron-withdrawing groups lower, while electron-donating groups raise the energy of the π^*-orbital; the energy of the *n*-orbital is relatively unaffected since it lies in the nodal plane of the π-system (3, 6).

To attribute the effect of substituents entirely to variations in the energy of the π^*-orbital must be an oversimplification and is in fact correct only when the variation in substituent produces little change in electron demand. It is unreasonable to assume that polar substituents should have no effect on the energy of the *n*-orbital. The *n*-orbital in aromatic carbonyl compounds has been shown by spectroscopic studies to be significantly delocalized into the π-system (7).

The use of the benzylic-type radical as a model for the π^*-orbital in aromatic carbonyl compounds implies that the π^*-orbital energy is affected primarily by factors which influence the stability of the free radical. While this may be a valid model in certain cases, it obviously provides a rather poor description of the n,π^* triplet state and radical anion of carbonyl compounds containing polar substituents, since substituent effects on free radical stabilities are normally small and do not correlate well with Hammett σ-values (8). In fact, the observation of a Hammett correlation for the substituent effect on the rate of a free radical reaction is usually taken as evidence that the transition state has appreciable polar character (8). In the series of polynuclear aromatic aldehydes mentioned above (1*a*), the arylmethyl radical satisfactorily represents the π^*-orbital only because the variation in polar factors within the series is small relative to the variation in arylmethyl radical stability.

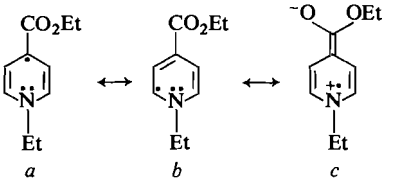
As a first approximation, it would appear more reasonable to consider the correlation of half-wave reduction potential and the n,π^* triplet energy of substituted aromatic carbonyl compounds with Hammett substituent constants in terms of the variation in charge redistribution between the ground state and the radical anion and the triplet. The rationale for this is obvious in the case of the radical anion, since electron density on the molecule is increased.

We can represent the benzophenone radical anion as the hybrid of two parent valence bond structures **1** and **2**. In benzophenone, structures of type **1** (in which the negative charge is localized on the electronegative oxygen and the unpaired electron is delocalized into the aromatic π-system) are dominant in the hybrid. It is known from esr studies that the spin density in the benzophenone radical anion is largely on the carbonyl carbon (9); further, the spin distribution in the radical anion is very similar to that in the diphenylmethyl radical.[3] The reduction potentials of substituted benzophenones should then correlate with Hammett substituent constants if, and only if, the substituent effect on radical stability is comparatively small, since the negatively charged oxygen is in a position analogous to that in the benzoate anion. Valence bond structures of type **2** (in which the unpaired electron is localized on the oxygen and the negative charge is delocalized into the aromatic π-system) may be more important contributors to the hybrid structure when X and Y are strong electron-withdrawing groups (12), and their stability should of course be subject to an even larger polar substituent effect.

The n,π^* triplet state of benzophenone can be represented as the hybrid of valence bond structures **3** and **4** (13). While the n,π^* triplet is of course

μ = 2.98 D μ = 1.79 D

a neutral species, it is apparent from the measured dipole moments of both the excited state and the ground state that the electron density on the oxygen atom decreases upon excitation (14). The observed substituent effect is again consistent with this shift in electron density, if the variation in radical stability is insignificant.



[3]The experimental spin densities for the *ortho*-, *meta*-, and *para*-positions in the benzophenone radical anion are 0.123, −0.042, and 0.157 respectively (Q = 25 G) (10). The corresponding spin densities in the diphenylmethyl radical are 0.127, −0.053, and 0.144 (Q = 25 G) (11).

It seems reasonable, in view of the small effect of substituents on benzylic radicals (15), that as an approximation, the contribution to the stability of the radical anion and triplet due to free radical stabilization might be ignored, in which case the relative stability will correlate reasonably well with Hammett substituent constants. However, in the special situation where X and Y have the opposite electron demand (i.e. when X is a strong electron-donating substituent and Y a strong electron-withdrawing substituent), there may be a more significant effect on radical stability. This would then be revealed as a deviation from Hammett behaviour.

It has been recognized for some time that radicals can be stabilized by direct simultaneous substitution with both electron-withdrawing and electron-donating groups (16). This additional stability has been attributed to the contribution of low energy charge-separated valence bond structures to the resonance hybrid. The classic example of Kosower's radical (**5**) serves to illustrate this con-

5

cept (17); there are many others (18). The term merostabilization[4] has been suggested to describe this effect (18*a*). This term, which derives from the similarity of structures of type **5***c* to the electronic situation in merocyanine dyes, emphasizes the importance of the charge-separated valence bond structure in contributing to free radical stabilization and we have accepted it.

While the concept of merostabilization is now firmly established (16–18) in free radical chemistry, there is little evidence of the more general application of this phenomenon to other classes of molecules containing unpaired electrons.[5] We have initiated a program designed to systematically assess the importance of merostabilization as a factor contributing to the stability of radical ions, triplet states, and biradical species. The first reports from this program described electron spin resonance (esr) evidence of merostabilization extending electron delocalization in appropriately substituted diphenylmethylenes (19). The variation in the zero-field splitting parameter (*D*) for a series of 4-substituted and 4,4′-disubstituted (methoxy-, cyano-, dimethylamino-, and nitro-) diphenylmethylenes is consistent with the average separation of the unpaired electrons being greater for the unsymmetrically substituted derivatives.

We have recently described a preliminary account of the effect of merostabilization on the n,π^* triplet energies of a limited series of substituted benzophenones, and developed an approach to quantitatively assess its contribution to the triplet energy as a function of the difference in electron demand between the two substituents (20). In this paper, we provide a further assessment of the importance of merostabilization in benzophenone n,π^* triplets through the inclusion of a broader range of substituents, as well as assess its effect on the stability of the corresponding radical anions. Merostabilization in substituted diphenylmethylenes is also reexamined. As well, we will examine the relative contributions of polar and radical-stabilizing effects to the stability of benzophenone n,π^* triplets and radical anions through the use of a two-parameter linear free energy approach, and rationalize the results in terms of simple valence bond theory. We then provide a more rigorous analysis employing calculated (*ab initio*) molecular orbital energies in a series of substituted benzaldehydes.

Results

The benzophenones **6***a–r* were either synthesized by standard techniques or obtained commercially, and were rigorously purified before use (see Experimental).

Half-wave reduction potentials were measured by cyclic voltammetry in acetonitrile solution using a platinum working electrode and a $Ag/AgNO_3$ (0.1 *M*) reference electrode. All the voltammagrams were typical of reversible or quasi-reversible reductive one-electron transfer. The half-wave potentials, taken as the midpoints of the forward and reverse waves, are therefore thermodynamically significant. These results are summarized in Table 1.

Phosphorescence emission spectra were recorded at 77 K in ethanol–methanol (4:1) and ether–isopentane–alcohol (EPA, 5:5:2). A number of these spectra have been observed previously (5). We chose to remeasure them in order to provide a greater degree of internal consistency in our triplet energy values. The emission spectra in both solvents all showed the five-fingered pattern characteristic of emission from the n,π^* triplet state. Triplet energies were calculated from the positions of the short wavelength 0–0 band maxima and are summarized along with the half-wave reduction

[4]The effect has been alternatively labelled "push-pull substitution" (18*d*) and "capto-dative bonding" (18*k*).

[5]For an example of merostabilization of a 1,4-biradical, see ref. 18*f*.

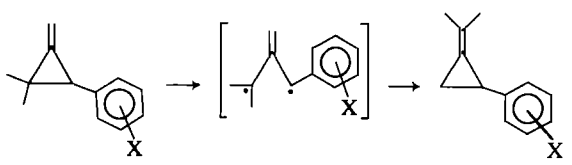
potentials in Table 1. The spectra were all measured on the same instrument under identical conditions, were rechecked at various times during the course of the study, and are reproducible to within 1 nm. Thus, although our values may differ slightly from those previously reported (5), the triplet energies reported here can be assumed to be internally consistent and the differences significant in the following discussion.

Ab initio calculations of the *n*-, π- and π*-orbital energies in benzaldehyde, *meta*- and *para*-cyanobenzaldehyde, and *meta*- and *para*-hydroxybenzaldehyde were carried out using the Gaussian 76 program (21) with an STO-3G minimal basis set and standard valence-shell scaling factors on a CDC 6400 computer. Standard bond lengths and angles (22) were employed throughout, and a planar conformation assumed for all derivatives (23). The calculated energies of the lowest unoccupied and the three highest occupied molecular orbitals are compiled in Table 2.



Discussion

The effect of substituents on free radical stability is not nearly as well understood as is the effect on ionic reactions and stabilities, despite the numerous efforts that have been directed to this end. Attempts are traditionally made to correlate the rates of reactions involving radical intermediates, such as hydrogen abstraction from substituted toluenes or radical addition to substituted benzenes, with Hammett substituent constants (8). The acceptable correlations that are often observed are generally considered as evidence for polarization of the transition state, the ρ-value providing a measure of the nucleo- or electrophilicity of the attacking radical. In reactions for which the transition state has predominantly free radical character, poor correlations with Hammett substituent constants and ρ-values close to zero are generally observed. Improved fits are often obtained by using σ^+-values for electron-donating substituents and σ^--values for electron-withdrawing substituents in order to allow for additional resonance interaction between the substituent and the radical site. Obviously, the best approach would be to use a set of parameters that accurately describes the variation in radical stability with substituent, independent of polar factors.

A number of workers have constructed substituent parameter scales specifically for use with free radical reactions (24*a–i*). These are without exception based on the relative rates of reactions proceeding through radical intermediates. Contributions from polar factors are found (or assumed) in all cases, and the radical substituent parameters are evaluated by fitting the data to a two-parameter Hammett equation such as eq. [1].

$$[1] \quad \log k_X/k_H = \rho\sigma + r\sigma^{\cdot}$$

Although it is generally accepted that both electron-donating and accepting substituents are effective in stabilizing a free radical, the rather poor agreement in the relative magnitudes and even in the order of the substituent parameters from series to series exemplifies the difficulty of separating polar from radical-stabilizing effects. The most recent and probably most successful attempt to eradicate polar factors in a free radical reaction is provided by Creary (25), who determined the relative rates of isomerization of a large number of *meta*- and *para*-substituted 2-aryl-3,3-dimethyl methylenecyclopropanes (**7**) in isooctane at 100°C. The small ρ-value (−0.16) obtained from a plot of relative rate vs. σ_m for several *meta*-substituted derivatives demonstrates that the transition state for this isomerization is almost (at least) devoid of polar character. However, Creary made no attempt to construct a $\sigma^{\cdot}$-scale from his data.

7

TABLE 2. Calculated (*ab initio*) orbital energies for substituted benzaldehydes

Compound	$-E_n$ (au)	$-E_{\pi_1}$ (au)	$-E_{\pi_2}$ (au)	E_{π^*} (au)
Benzaldehyde	0.3429	0.2899	0.2666	0.1843
4-Cyanobenzaldehyde	0.3625	0.3137	0.2838	0.1497
3-Cyanobenzaldehyde	0.3599	0.3078	0.2868	0.1626
4-Hydroxybenzaldehyde	0.3361	0.2955	0.2392	0.1925
3-Hydroxybenzaldehyde	0.3466	0.2807	0.2542	0.1804

We have examined the various existing $\sigma^\cdot$-scales (24*b–i*) and a scale constructed from Creary's data (25) ($\sigma^\cdot = \log k_X/k_H$), by plotting them against the hyperfine coupling constants due to the α-protons in the esr spectra of substituted benzyl radicals (15*a*). Actually, had more substituents been investigated, this system in itself could provide a far more accurate substituent parameter scale than those involving relative rates since the hyperfine constants provide a measure of unpaired electron delocalization in the radical itself, and the complicating factors that must be dealt with in the analysis of relative rates of a radical reaction are not present. It has been noted that relative variations in benzyl proton hyperfine constants provide a fairly accurate representation of variations in benzyl radical stability with substituent (26). Also, Afanas'ev (24*a*) incorporated β-proton hyperfine constants in his derivation of a scale of σ^r-values describing substituent effects on methyl radical stabilities. Least squares analysis of plots of $a_{CH_2}^X/a_{CH_2}^H$ (15*a*) vs. $\sigma^\cdot$ reveal that the best fits are obtained with the E_R-values of Yamamoto and Otsu (24*f*) (cc = 0.890) and the log k_X/k_H values calculated from the data of Creary (25) (cc = 0.977). Creary's data thus seem the most suitable indication of substituent effects on radical stabilities.[6]

The term merostabilization has been suggested to describe the additional stabilization imparted to free radicals bearing substituents of opposite electron demand (18*a*). This concept, though recognized as early as 1952 (16), has only recently received any degree of attention in the literature (18*a–n*), and is the subject of a recent review (18*m*). Contributions to the stability of a radical from merostabilization should not be predictable from consideration of $\sigma^\cdot$-values, since one would expect the magnitude of the effect to be proportional to the ability of the substituents to support charge separation in the radical (i.e. σ or $\sigma^\pm$). We have developed the following approach to qualitatively assess (and predict) the importance of merostabilization in radicals and radical-like species (20).

[6] $\sigma^\cdot$-values from the data of Creary (25) are ($\sigma^\cdot = \log k_X/k_H$): 4-OMe, 0.24; 4-Me, 0.11; 4-CF_3, 0.08; 4-CN, 0.46; 4-Br, 0.14; 3-CF_3, −0.07; 3-CN, −0.12.

In the absence of merostabilization, one might expect substitution by one group X in a radical system to cause half the effect of substitution by two symmetrically positioned X-groups. For example, the estimated energy (E_{est}) for a monosubstituted system is the average of the observed energies (E_{obs}) of the symmetrically disubstituted and unsubstituted derivatives. In general then, the energy estimated ($E_{est}^{X,Y}$) for any unsymmetrically substituted radical can be written:

$$[2] \quad E_{est}^{X,Y} = (E_{obs}^{X,X} + E_{obs}^{Y,Y})/2$$

We can now define the *merostabilization energy* ($E_{mero}^{X,Y}$) of such a system as the difference between the estimated and observed values of the energy:

$$[3] \quad E_{mero}^{X,Y} = E_{obs}^{X,Y} - E_{est}^{X,Y}$$

This derivation should of course be equally valid for any measurable quantity which reflects the stability of the radical system.

We expect the merostabilization energy to correlate with some parameter indicating the difference in electron demand between the two substituents. This quantity should increase as X becomes a better electron-donating group and Y a better electron-withdrawing group. A convenient parameter can be defined as:

$$[4] \quad \Delta\sigma_{X,Y}^{\pm} = \sigma_Y^- - \sigma_X^+$$

where X and Y are electron-donating and accepting groups, respectively. $\Delta\sigma_{X,Y}^{\pm}$ will be zero for symmetrically substituted derivatives and positive for unsymmetrically substituted derivatives and thus describes the ability of the substituent pair to enhance charge separation in the free spin system. Our preliminary account (20) revealed the value of this approach in assessing the contribution from merostabilization to the n,π^* triplet energies of a limited series of substituted benzophenones.

We are now in a position to understand the cause and nature of the substituent effects on the half-wave reduction potential and n,π^* triplet energy of benzophenone, and the *D*-value obtained from the esr spectrum of diphenylmethylene. These three systems illustrate the interplay between polar and

radical-stabilizing effects on the stability of radical-like systems. We shall see in the following detailed discussion that although the relative contribution from polar and radical-stabilizing factors to the substituent effects on stability varies from one extreme to the other, merostabilization plays a significant role in each. Furthermore, the extent to which it contributes to the stability of these systems can be easily evaluated using the approach outlined above.

Benzophenone Half-wave Reduction Potentials

Half-wave reduction potentials of benzophenones **6***a–r* are plotted versus Hammett substituent constants $\sum\sigma$ in Fig. 1. The line drawn is that obtained from least squares analysis of the points *for the symmetrically substituted derivatives* **6***a–f* (cc = 0.998). The 4,4′-dicyano derivative **6***g* was excluded from this correlation (*vide infra*); if it is included in the analysis, the correlation is somewhat poorer (cc = 0.980), though the slope of the line changes negligibly. The Hammett correlation observed for **6***a–f* can be rationalized through consideration of the expected substituent effects on the relative stability and contributions of **1** and **2** to the valence bond hybrid structure.

In the dominant contributor to the resonance hybrid (**1**) (9), the negative charge resides on the carbonyl oxygen (cf. benzoate anion) and the unpaired electron resides on the carbonyl carbon (cf. diphenylmethyl radical). Substituent effects on the stability of this valence bond structure might therefore be expected to be represented by some blend of σ- and $\sigma^{\cdot}$-values. The excellent correlation of $E_{1/2}^{red}$ with $\sum\sigma$ observed for **6***a–f* demonstrates that the $\sigma^{\cdot}$-contribution is small, since any appreciable contribution to radical anion stability from radical-stabilizing effects should result in marked deviations from linearity in the Hammett plot (all these substituents stabilize the benzyl radical). The pronounced deviation from Hammett behaviour observed for 4,4′-dicyanobenzophenone (**6***g*) may be an indication of the varying contribution from structure **2** to the resonance hybrid. It has been suggested that when X and Y are strong electron-withdrawing groups, the contribution from **2** should increase since delocalization of an electron pair will occur at the expense of unpaired electron delocalization (12). Furthermore, Exner and co-workers (4*b*) observed acceptable correlations with σ^{-} in their investigation of substituent effects on benzophenone half-wave reduction potentials. However, theoretical and experimental (esr) determinations of spin densities in 4,4′-disubstituted benzophenone radical anions (27) indicate that the spin density in the carbonyl group *decreases* with increasing electron-accepting power of the substituents. It would seem therefore that **1** best represents the situation in benzophenone radical anions; the marked deviation observed for **6***g* may then be the result of the very strong radical-stabilizing effect of the *para*-cyano substituent.

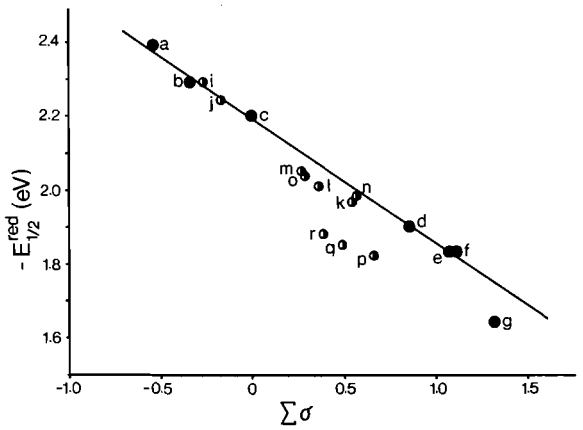

FIG. 1. Hammett correlation: half-wave reduction potentials of benzophenones **6***a–g*, *i–r* vs. $\sum\sigma$.

The half-wave reduction potentials of **6***a–g* were fit by standard regression analysis to a two-parameter Hammett relation employing σ-values and the $\sigma^{\cdot}$-values calculated from Creary's data (25). The relation obtained (eq. [5]) illustrates in a more quantitative fashion the dominance of polar

$$[5]\quad E_{1/2}^{red}(\text{eV}) = -2.21 + 0.363\sum\sigma + 0.086\sum\sigma^{\cdot}(\text{cc} = 0.996)$$

factors in the substituent effect on benzophenone half-wave reduction potentials. The indication that radical-stabilizing effects account for about 20% of the total substituent effect would admittedly be more convincing if the Hammett correlation in Fig. 1 did not appear to be so good. We feel that this figure is reasonable, however, in view of the fact that free radical stabilities are, in general, considerably less sensitive to variations in substituent than are the stabilities of the corresponding ions (8). Equation [5] is represented in graphical form in Fig. 2.

Included in Figs. 1 and 2 are the points for the unsymmetrically substituted benzophenones **6***i–r*. As can be seen, the reduction potentials of the majority of these derivatives deviate significantly from the correlation observed for **6***a–g*. Furthermore, the deviations are seen to increase with increasing electron-donating/withdrawing power of the substituents. We attribute these deviations from "normal" behaviour to merostabilization;

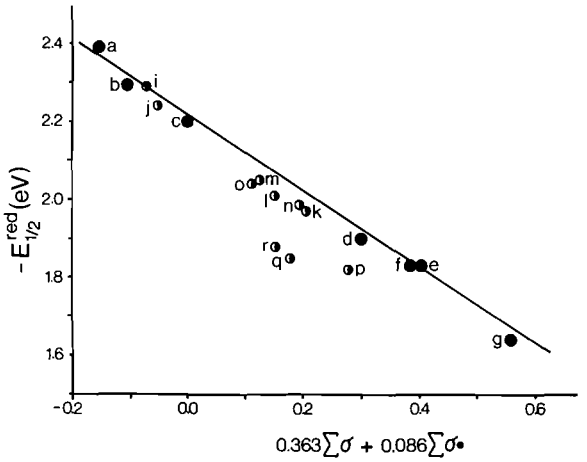

FIG. 2. Two-parameter Hammett correlation: half-wave reduction potentials of benzophenones **6***a–g*, *i–r* vs. $(0.363\sum\sigma + 0.086\sum\sigma^{\bullet})$; $\sigma^{\bullet} = \log k_X/k_H$ from data of Creary (25).

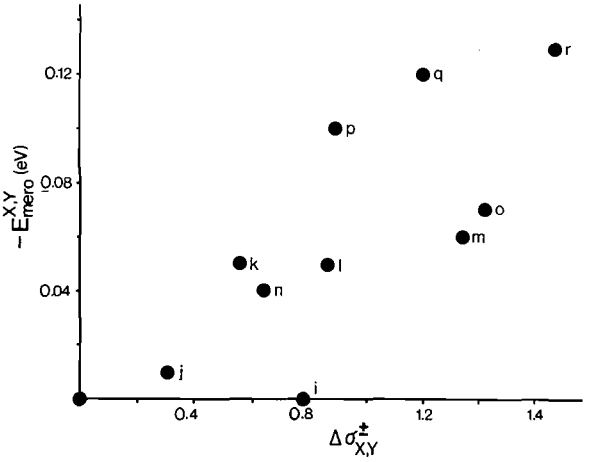

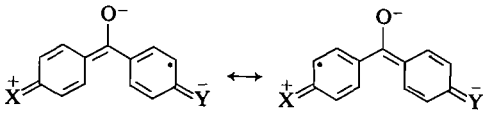

FIG. 3. Merostabilization in benzophenone radical anions: $-E_{mero}{}^{X,Y}$ vs. $\Delta\sigma^{\pm}_{X,Y}$ for half-wave reduction potentials of **6***i–r*.

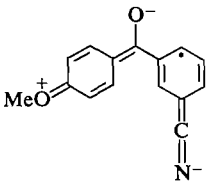

unsymmetric substitution allows for greater delocalization of the unpaired electron due to the increased importance of charge-separated resonance structures such as **1***d*.

Merostabilization energies were calculated for **6***i–r* from eqs. [2] and [3] and are shown plotted vs. $\Delta\sigma^{\pm}_{X,Y}$[7] in Fig. 3 for the benzophenone half-wave

1*d*

reduction potentials. While the correlation is obviously not particularly good (cc = 0.61), the overall trend in the plot illustrates the increasing importance of merostabilization with increasing difference in electron demand between the two substituents X and Y. While the *para*-trifluoromethyl derivatives **6***k–m* do not vary much as the X group changes, the importance of merostabilization is seen to increase quite regularly with increasing electron-donating power of the X-group for the *para*-cyano derivatives **6***p–r*. It is noteworthy that

6*o*′

merostabilization appears to be significant even for the monosubstituted derivatives **6***k* and **6***p*, and for the *meta*-substituted **6***n* and **6***o*. We did not expect merostabilization to be important in **6***n* and *o*, since direct resonance interaction of the type illustrated in **1***d* is not possible with the *meta*-cyano group. However, charge-separated resonance structures (such as **6***o*′) can be drawn for these derivatives. While these structures do not allow delocalization of spin density onto the *meta*-carbon atoms, they should contribute somewhat to the lower reduction potentials observed for **6***n* and *o*.

Benzophenone n,π* *Triplet Energies*

Reasonable agreement is observed between the *n*,π* triplet energies determined in EPA (5:5:2) and ethanol–methanol (4:1) (Table 1). Good agreement is also noted with literature values for those compounds which have been previously studied. We have plotted the triplet energies against Hammett substituent constants $\sum\sigma$ in Fig. 4. The rather severe scatter in the plots has been noted previously (5). As was done in the previous section, we shall first consider the symmetrically substituted derivatives **6***a–h* and attempt to rationalize the observed substituent effect on triplet energy in the absence of complicating factors such as merostabilization.

The measured dipole moments of the ground and *n*,π* states of benzophenone indicate a shift in electron density away from the oxygen atom upon excitation (14). This is reasonable since excitation to these states involves promotion of an electron in an orbital strongly localized on oxygen to one with some component of electron density on both carbon and oxygen. This shift in electron density should be revealed in a polar substituent effect on

[7] σ^{+}- and σ^{-}-values were taken from ref. 28, as were σ_m- and σ_p-values. $\sigma^{-}_{CF_3} = +0.56(29)$; $\sigma^{-}_{3\text{-}CN} = +0.64(30)$.

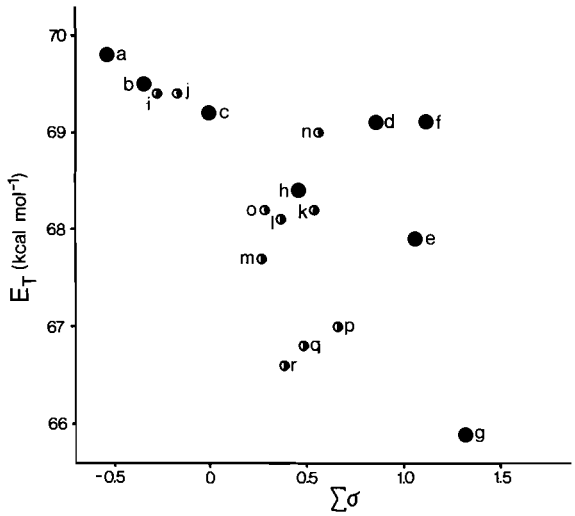

FIG. 4. Hammett correlation: n,π^* triplet energies of substituted benzophenones **6***a–r* vs. $\sum\sigma$ (EPA, 77 K).

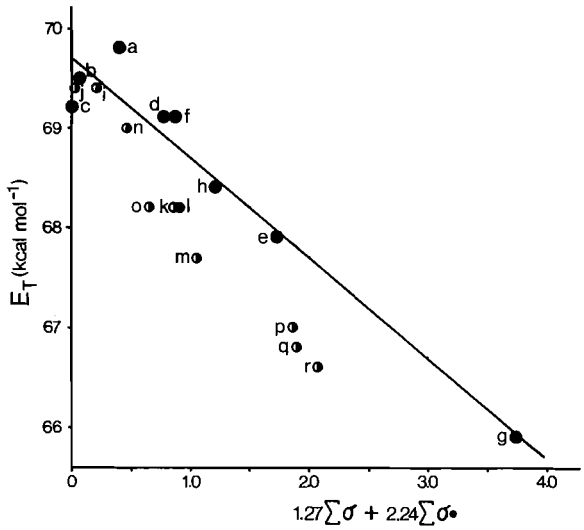

FIG. 5. Two-parameter Hammett correlation: n,π^* triplet energies of substituted benzophenones **6***a–r* vs. ($1.27\sum\sigma + 2.24\sum\sigma^\bullet$); (EPA; 77 K). $\sigma^\bullet = \log k_X/k_H$ from data of Creary (25).

triplet energy; however, this effect is expected to be small since the difference in dipole moments between ground and excited states is rather small. To the extent that the benzylic radical is a reasonable model for the π^*-orbital in aromatic ketones, we would also expect radical-stabilizing factors to contribute to the observed substituent effect on triplet energy. This expected blend of polar and radical-stabilizing factors provides a qualitative rationalization of the observed substituent effect. The triplet energy of 4,4′-dicyanobenzophenone (**6***g*) falls below the line due to the particularly strong radical-stabilizing effect of the cyano group (24, 25), while those of the two *meta,meta′*-disubstituted derivatives (**6***d, f*) are above the line due to the radical-destabilizing effect of *meta*-substitution (25).

This can be expressed more quantitatively in the form of the two-parameter relation employing σ- and σ•-values. Equation [6] was obtained from standard regression analysis of the triplet energies of **6***a–h* in EPA.[8]

$$[6]\quad E_T(\text{kcal mol}^{-1}) = 69.7 - 1.27\sum\sigma - 2.24\sum\sigma^\bullet \quad (\text{cc} = 0.941)$$

The triplet energies of this series (**6***a–r*) are shown plotted against the two-parameter relation (eq. [6]) in Fig. 5. While this equation successfully fits **6***b*, *d–h* to good linear behaviour, it correlates very poorly with benzophenone (**6***c*) and 4,4′-dimethoxybenzophenone (**6***a*).[9] Though the unacceptably low correlation coefficient obtained for the symmetric derivatives precludes attaching a great deal of quantitative significance to eq. [6], the observation that *all* the symmetric derivatives now correlate fairly well with "effective" substituent constants obtained from the two-parameter treatment illustrates the blend of polar and radical-stabilizing effects on the n,π^* triplet state of benzophenone.

The contribution from merostabilization to the n,π^* triplet energy results in the apparently random scatter observed for the unsymmetrically substituted derivatives in Figs. 4 and 5. While certain patterns are evident upon close inspection of these plots, the situation becomes considerably clearer upon examination of Fig. 5. The triplet energies of these derivatives are all lower than what would be expected on the basis of consideration of the "normal" blend of polar and radical-stabilizing factors.

Merostabilization energies were calculated for **6***i–r* using eqs. [2] and [3] and the triplet energies in Table 1. These are shown plotted against $\Delta\sigma^{\pm}_{X,Y}$ in Fig. 6 for the EPA data. The trend in these plots is significant; merostabilization energy increases quite regularly with the ability of the substituents to support charge separation in the free spin system. Again, merostabilization appears to be important

[8]Similar treatment of the ethanol–methanol results yielded

$E_T = 69.7 - 1.18\sum\sigma - 2.34\sum\sigma^\bullet$ (cc = 0.898)

[9]We note in passing that exclusion of **6***a, b* from the analysis yields a considerably better correlation ($E_T = 69.3 - 0.77\sum\sigma - 2.60\sum\sigma^\bullet$; cc = 0.990). We are unable to justify excluding these two derivatives, however.

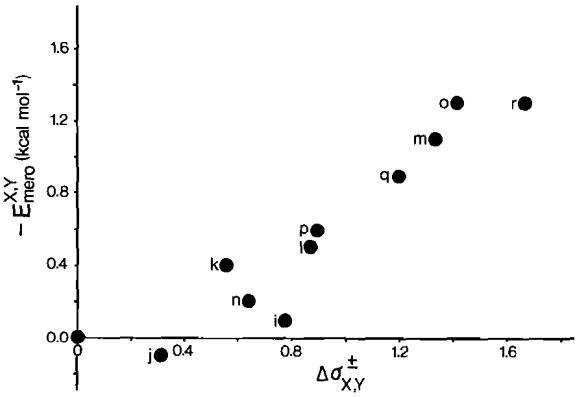

FIG. 6. Merostabilization in benzophenone n,π^* triplets: $-E_{mero}^{X,Y}$ vs. $\Delta\sigma^{\pm}_{X,Y}$ for n,π^* triplet energies (EPA) of **6***i*–*r*.

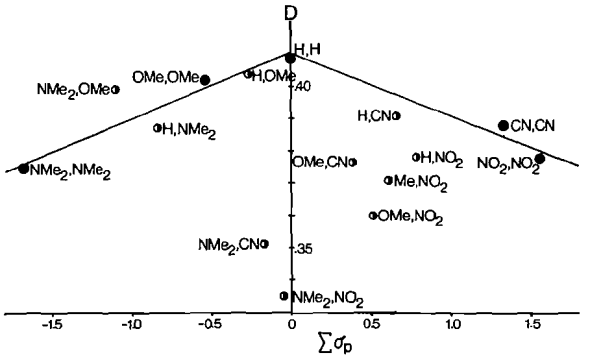

FIG. 7. Hammett correlation: zero-field splitting parameter D of substituted diphenylmethylenes (19*b*) vs. $\sum\sigma_p$.

even for the mono- and *meta*-substituted derivatives.

Diphenylmethylene D-*Values*

In our initial reports in this series (19*a*, *b*), we examined the variation in the zero-field splitting parameter D for a series of *para*-substituted and *para*,*para'*-disubstituted diphenylmethylenes. D is inversely proportional to the cube of the distance between electrons with unpaired spins in a triplet; any increase in electron delocalization is therefore reflected in a decrease in the D-value (31). Our immediate observation was the lack of any correlation between D-values and Hammett substituent constants, a decrease in D-value relative to that of diphenylmethylene being observed for all substituted systems. This is of course in accord with the expected substituent effect on spin density delocalization in the diphenylmethyl radical, the accepted model for diphenylmethylene (19*b*). For diphenylmethylenes simultaneously substituted with electron-donating and withdrawing groups anomalously low D-values were observed, which we attributed to merostabilization. We compared the decrease in D for the merostabilized derivatives relative to diphenylmethylene to the sum of the effects for the two corresponding monosubstituted derivatives. We are now in a position to express the effect of merostabilization in substituted diphenylmethylenes in a more quantitative way using the approach outlined above.

The Hammett plot (D vs. $\sum\sigma_p$) for our series (19*b*) is shown in Fig. 7. The trend in the plot observed for the symmetrically substituted derivatives is consistent with the expected substituent effect on diphenylmethyl radical stability. We would expect the D-values to correlate well with the σ^*-values calculated from Creary's work; unfortunately, nitro- and *N*,*N*-dimethylamino groups were not included in his study, so a meaningful correlation cannot be obtained.[10] It is, however, interesting to note the trends observed for the 4-nitro-4'-X and 4-cyano-4'-X derivatives in Fig. 7. The regular decrease in D which occurs as X becomes a progressively better electron-donating group is indicative of the role of merostabilization in extending electron delocalization in this system. We can calculate the extent to which merostabilization lowers the D-value of an unsymmetrically substituted diphenylmethylene in a manner analogous to the derivation of merostabilization energy in eqs. [2] and [3]. We have plotted $D_{mero}^{X,Y}$ vs. $\Delta\sigma^{\pm}_{X,Y}$ in Fig. 8. Once again the trend in the plot is consistent with the notion that the importance of merostabilization increases with increasing ability of the substituents to support charge separation in the free spin system.

Theoretical Considerations

In correlations between $E_{1/2}^{red}$ and the calculated energy of the π^*-orbital in aromatic carbonyl compounds, the corresponding hydrocarbon radical has been used as a model for the LUMO of the carbonyl compound (i.e. the benzyl radical is the model for the LUMO of benzaldehyde) (1*a*). This model predicts variations in the energy of the π^*-orbital on the basis of changes in free radical stability only, and neglects polar contributions. When the correlation is limited to polynuclear aromatic aldehydes, this may be acceptable since the variation in polar factors should be considerably less than the variation in radical stability within the series. Indeed, the reduction potentials within this

[10] A correlation coefficient of 0.949 is obtained from a four-point plot of D vs. $\sum\sigma^*$ (H, H; H, OMe; OMe, OMe; CN, CN).

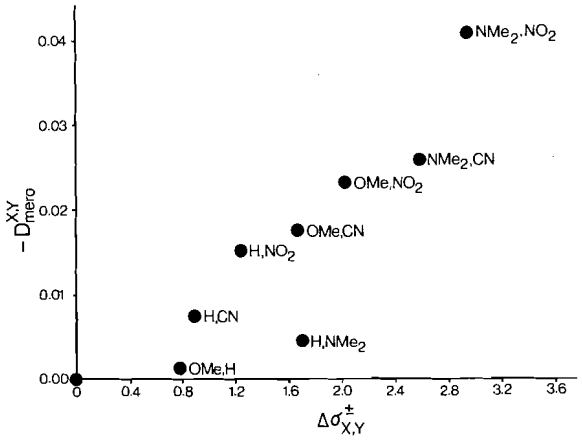

FIG. 8. Merostabilization in diphenylmethylenes: $-D_{mero}^{X,Y}$ vs. $\Delta\sigma^{\pm}_{X,Y}$.

series do not correlate with the strengths of the corresponding carboxylic acids (32).

In contrast to the results of other studies (3*c*), we find no correlation between n,π^* triplet energy and half-wave reduction potential for our extended series of substituted benzophenones. In view of the differing relative contributions from polar and radical-stabilizing factors to the substituent effects on these quantities, we do not find this particularly surprising. The obvious implication is that more is being affected by substitution than simply the energy of the π^*-orbital.

We have carried out *ab initio* calculations of the energies of the *n*-, π-, and π^*-orbitals in a series of substituted benzaldehydes. These minimal basis set calculations incorrectly indicate the π-orbital to be the HOMO. While further refinements are obviously necessary to correct the orbital ordering, we believe the calculated changes in individual orbital energies with substituent are meaningful. The results of the calculations are collected in Table 2.

The most significant thing revealed by these calculations is the indication that the energy of the *n*-orbital is substantially affected by substitution in both the *meta*- and *para*-positions. Furthermore, these calculated *n*-orbital energies correlate respectably with Hammett σ-values (Fig. 9). This is consistent with the conclusions of Goodman and co-workers (7) that the *n*-orbital is significantly delocalized into the aromatic π-system in benzaldehyde. The calculations also reveal the expected variation in the energy of the π^*-orbital, though it does not vary in the same way as the stability of substituted benzyl radicals. The curvature in the plot of $E_{\pi^*}^{calc}$ vs. σ (Fig. 9) is consistent with *both* polar and radical-stabilizing effects contributing to the energy of the π^*-orbital.

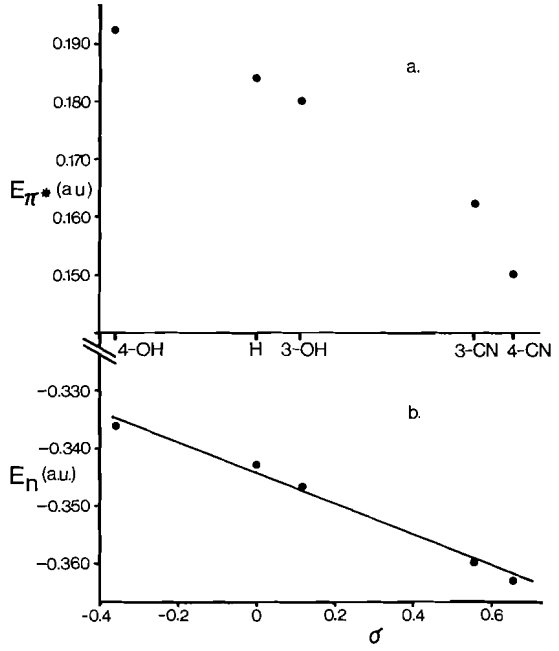

FIG. 9. Hammett correlation: calculated (*ab initio*) orbital energies of substituted benzaldehydes vs. σ; (a) E_{π^*} vs. σ; (b) E_n vs. σ.

The calculated substituent effect on orbital energies in the ground state of benzaldehyde can be used to provide an understanding of that on the n,π^* triplet energy and half-wave reduction potential of benzophenone. The substituent effect on the stabilities of both the triplet and the radical anion is the composite of a polar effect on the energies of the *n*- and π^*-orbitals and a radical-stabilizing effect on the energy of the π^*-orbital. Since the *n*-orbital in the triplet contains one less electron than in the radical anion, we would naively expect the magnitude of the polar effect on the triplet energy to be much smaller than that on the reduction potential. On the other hand, since the population of the π^*-orbital is the same in both states, we would expect the contribution from radical-stabilizing effects on the n,π^* triplet energies to equal that on the reduction potentials. The coefficients obtained from the two-parameter Hammett treatments (eqs. [5] and [6]) are consistent with these expectations. The coefficients describing the σ-dependence are 8.4 kcal mol^{-1} for $E_{1/2}^{red}$ and 1.3 kcal mol^{-1} for E_T^{EPA}, while those describing the σ^*-dependence are 2.0 and 2.2 kcal mol^{-1}, respectively. Also consistent with this are the roughly equal slopes obtained from least squares analysis of the merostabilization energy plots for the reduction potentials (1.6 $\pm$ 0.5 kcal mol^{-1}) and triplet energies (1.2 $\pm$ 0.3 kcal mol^{-1}) (Figs. 3 and 6). Merostabilization

produces equal effects on the energies of these two states due to a stabilizing effect on the energy of the π^*-orbital.

Summary and Conclusions

The observed substituent effects on benzophenone half-wave reduction potentials and n,π^* triplet energies can be rationalized in terms of contributions from a polar effect on the energy of the n- and π^*-orbitals and a radical-stabilizing effect on the energy of the π^*-orbital. While polar factors apparently dominate the effect on $E_{1/2}^{red}$, radical-stabilizing factors do contribute somewhat. Furthermore, this contribution is of the same magnitude as that on the n,π^* triplet state, in which radical-stabilizing factors dominate. Although the effect of merostabilization in enhancing the stability of these extended, radical-like systems in which the substituents are rather remote from the radical site is smaller than that in systems in which the substituents are attached directly to the radical site (18), it is by no means insignificant. The roughly equal extent to which it contributes to the stability of benzophenone radical anions and n,π^* triplets provides evidence that merostabilization affects the energy of the π^*-orbital in these systems. Further publications will describe the effects of merostabilization on the ground and excited state properties of aryl ethylenes and cyclopropanes.

Experimental

All melting points are corrected. The ^{1}Hmr spectra were recorded on a Varian T60 spectrometer and are reported in parts per million downfield from TMS. Infrared spectra were recorded on a Perkin-Elmer 180 grating infrared spectrometer and are reported in wave numbers, calibrated against the 1601.8 cm^{-1} polystyrene absorption. Ultraviolet spectra were recorded on a Cary-Varian 210 ultraviolet spectrometer and are reported in nanometers.

Half-wave reduction potentials were measured by cyclic voltammetry with a Princeton Applied Research (PAR) Model 175 universal programmer, PAR Model 173 potentiostat/galvanostat, and a Houston Omnigraphic 2000 X-Y recorder. Electrolytic measurements were carried out using a three electrode cyclic voltammetric cell. The working electrode was a platinum wire. The reference electrode was $Ag/AgNO_3$ (0.1 *M*) with 0.1 *M* TEAP as supporting electrolyte in acetonitrile solution under an atmosphere of dried argon. Substrate concentrations were typically 20 mg/25 mL 0.1 *M* TEAP. The voltammagrams were scanned at 20 mV/s, 100 mV/s, and 200 mV/s. The half-wave reduction potentials were calculated as the average of the midpoints between the forward and reverse waves for the 20 mV/s and 100 mV/s scans. The half-wave reduction potential of benzophenone was measured at various times during the course of the study to check the reproducibility of the measurements, and did not vary by more than 5 mV.

Phosphorescence emission spectra were recorded with an Aminco-Bowman Model 4-8202 spectrophotofluorometer with phosphoroscope attachment and quartz Dewar and a Houston Omnigraphic 2000 X-Y recorder. All spectra were calibrated with a Pen-ray low pressure mercury vapour calibration lamp and were measured repeatedly. The triplet energies were calculated from the position of the short wavelength maximum and are the average of at least four measurements.

Samples were prepared by dissolving the benzophenone (1–2 mg) in 5 mL solvent, placed in evacuable Suprasil tubes, and degassed (four freeze–pump–thaw cycles).

Acetonitrile was refluxed with calcium hydride under dry nitrogen for three days and distilled as required. Absolute ethanol was obtained by refluxing 95% ethanol over magnesium turnings and iodine for 24 h followed by distillation. Methanol was Fisher certified A.C.S. and used as obtained. EPA (5:5:2) was prepared from diethyl ether (500 mL; Anachemia; stirred with sodium for seven days and distilled under dry nitrogen), 2-methylbutane (500 mL; J. T. Baker; passed down an alumina column and distilled slowly), and absolute alcohol (200 mL; as above with one additional distillation from Mg/I_2) and was stored over 4A molecular sieves in the cold under dry nitrogen.

Tetraethylammonium perchlorate (TEAP; Aldrich) was recrystallized three times from 90% ethanol. Silver nitrate (Engelhard A.C.S.) was recrystallized three times from aqueous ethanol and stored in the dark.

4,4'-Dimethoxybenzophenone (**6***a*, Aldrich), 4,4'-dimethylbenzophenone (**6***b*, Fisher), and benzophenone (**6***c*, BDH) were each recrystallized three times from purified ethanol.

3,3'-Bis(trifluoromethyl)benzophenone (**6**d) was prepared by the method of Lichtenberger and Weiss (33), and was purified by recrystallization from ethanol, treatment with Norite in boiling ethanol, and one recrystallization from benzene–hexane (mp 97–98°C (33)).

4,4'-Bis(trifluoromethyl)benzophenone (**6**e) was prepared by the method of Lichtenberger and Weiss (33), recrystallized twice from ethanol, treated with Norite in boiling chloroform, and recrystallized again from ethanol (mp 111–112°C (34)).

4,4'-Dibromobenzophenone (**6**h) was prepared from 4-bromobenzoyl chloride, aluminum trichloride, and bromobenzene (see general Friedel–Crafts procedure below), and was recrystallized three times from 95% ethanol (mp 173–174°C).

4,4'-Dicyanobenzophenone (**6**g) was prepared as described previously (35), treated with Norite in boiling chloroform, and recrystallized twice from methanol (mp 158–159°C).

3,3'-Dicyanobenzophenone (**6**f)

3,3'-Dibromobenzophenone (36) (11.0 g, 0.032 mol) and cuprous cyanide (7.22 g, 0.081 mol) were placed in a 100 mL round-bottom flask fitted with magnetic stirrer, reflux condenser, and calcium chloride drying tube. Anhydrous *N,N*-dimethylformamide (40 mL) was added and the mixture was refluxed for 12 h. The resulting brown-black mixture was allowed to cool, and then poured into 15% aqueous sodium cyanide (400 mL) and heated on the steam bath for 1.5 h. The brown crystalline precipitate was extracted with benzene (5 × 50 mL). The combined benzene extracts were washed with water (4 × 50 mL), dried over anhydrous sodium sulfate, and filtered. Evaporation of the solvent on the rotary evaporator yielded a yellow solid, which was recrystallized from chloroform–methanol (1:1) to give an off-white solid (5.4 g, 0.024 mol, 73%). The nmr spectrum of this crude product was almost identical to that of 3-cyanobenzaldehyde (37); tlc showed it to be contaminated with a small amount of faster moving material (presumably monocyanated product). A portion of this material was chromatographed on a silica gel column with benzene (75%) – hexane. The first few fractions contained mixtures of the two products. Subsequent fractions (pure by tlc) were combined, evaporated, and the resulting white solid was recrystallized once from chloroform–ether (1:4) and once from chloroform–methanol (1:1) to yield colourless prisms (mp 148–148.5°C); λ_{max} (EtOH): 221(47 950), 248(15 140), 286(sh,

1211), 335(11); ir (KBr): 3070(w), 2235(s), 2224(s), 1667(s), 1601(s), 1429(m), 1290(s), 1163(s), 1009(m), 755(s); ^{1}Hmr ($CDCl_3$) δ: 7.3–8.2(m). *Anal.* calcd. for $C_{15}H_8N_2O$: C 77.57, H 3.47; found: C 77.29, H 3.33.

4-Methoxybenzophenone (6i) was prepared from benzoyl chloride, aluminum trichloride, and anisole and was recrystallized twice from 90% methanol and twice from ether–hexane (7:3) (mp 61–62°C).

4-Methylbenzophenone (6j) was prepared from benzoyl chloride, aluminum trichloride, and toluene, and was recrystallized once from hexane and twice from 85% ethanol (mp 51–52°C).

4-(Trifluoromethyl)benzophenone (6k) was prepared by the addition of 4-(trifluoromethyl)phenylmagnesium bromide to benzoyl chloride (see preparation of **6*l***) and was purified by column chromatography on silica gel with benzene (75%) – hexane, followed by one recrystallization from 95% ethanol and one recrystallization from chloroform (10%) – methanol (mp 116–116.5°C (38)).

4-Methyl-4'-(trifluoromethyl)benzophenone (6l)

4-(Trifluoromethyl)phenylmagnesium bromide (0.04 mol) was prepared in the usual manner from 4-bromobenzotrifluoride (8.76 g, 0.04 mol) and magnesium turnings (1.23 g, 0.05 g-atom) in anhydrous diethyl ether. The deep red solution obtained after stirring for four hours was diluted to 30 mL and transferred by syringe to the dropping funnel of an apparatus consisting of a 100 mL 3-neck round-bottom flask, reflux condenser, magnetic stirrer, and dropping funnel under an atmosphere of dry nitrogen. Toluoyl chloride (15.4 g, 0.1 mol) and anhydrous diethyl ether (30 mL) were placed in the flask and degassed by bubbling nitrogen through for 10 min. The Grignard reagent was then added dropwise over four hours with vigorous stirring, while the reaction mixture was kept at room temperature with a water bath. The mixture was stirred at room temperature overnight, poured into 5% aqueous hydrochloric acid, and heated on the steam bath for two hours, during which time a large amount of solid formed. The mixture was cooled and extracted with ether (4 × 75 mL). The combined ether extracts were washed with 5% aqueous hydroxide (2 × 70 mL), once with water (30 mL), once with saturated brine (30 mL), dried over anhydrous sodium sulfate, and filtered. Evaporation of the solvent on the rotary evaporator yielded a yellow-orange solid which was dissolved in hot 95% ethanol (75 mL), filtered, and refrigerated. The yellow crystals were collected by filtration (3.2 g, 0.012 mol, 30%). Column chromatography (silica gel; benzene (75%) – hexane) followed by two recrystallizations from methanol afforded the product as colourless plates (mp 145–146°C). Ultraviolet λ_{max} (EtOH): 243(21 590), 268(26 130), 332(204); ir (KBr): 1648(s), 1605(s), 1408(s), 1330(s), 1312(s), 1289(m), 1170(br s), 1130(br s), 1068(s); ^{1}Hmr ($CDCl_3$) δ: 2.48(s, 3H), 7.35(d, 2H), 7.75(d, 2H), 7.84 (br s, 4H). *Anal.* calcd. for $C_{15}H_{11}F_3O$: C 68.18, H 4.20; found: C 68.11, H 4.12.

4-Methoxy-4'-(trifluoromethyl)benzophenone (6m) was prepared from 4-(trifluoromethyl)phenylmagnesium bromide and 4-anisoyl chloride (see preparation of **6*l***) and was purified by column chromatography (silica gel; benzene (75%) – hexane) followed by one recrystallization from chloroform–ether and one recrystallization from methanol (mp 123–124°C (38)).

3-Cyanobenzophenone (6n) was prepared from 3-cyanobenzoyl chloride, aluminum trichloride, and benzene, and was recrystallized three times from 90% ethanol (mp 91–92°C (39)).

3-Cyano-4'-methoxybenzophenone (6o) was prepared from 3-cyanobenzoyl chloride, aluminum trichloride, and anisole, and was purified by column chromatography (silica gel; benzene (50 → 80%) – hexane) followed by two recrystallizations from 90% ethanol (mp 95–97°C (40)).

4-Cyanobenzophenone (6p) was prepared from 4-cyanobenzoyl chloride, aluminum trichloride, and benzene, and was purified by recrystallization from 90% ethanol, column chromatography (alumina; benzene), and one further recrystallization from 90% ethanol (mp 114–115°C (40)).

4-Cyano-4'-methylbenzophenone (6q) was prepared from 4-cyanobenzoyl chloride, aluminum trichloride, and toluene, and was recrystallized three times from ethanol (mp 163–164°C (40)).

4-Cyano-4'-methoxybenzophenone (6r) was prepared from 4-cyanobenzoyl chloride, aluminum trichloride, and anisole, and was recrystallized twice from methanol, once from chloroform–methanol, and once more from methanol (mp 129.5–131°C (40)).

General Friedel–Crafts Procedure

The benzoyl chlorides were either commercially available or obtained by refluxing the benzoic acid in thionyl chloride for 12 h, followed by removal of excess thionyl chloride by vacuum distillation.

The chloride (0.1 mol) is dissolved in benzene, toluene, anisole, or bromobenzene (100 mL) and placed in a 250 mL 2-neck round-bottom flask fitted with magnetic stirrer, condenser, and HCl trap. Anhydrous aluminum trichloride (0.11 mol) is then added over 15 min through the side arm with vigorous stirring and occasional cooling. The HCl trap is then replaced with a drying tube and the mixture is stirred at room temperature for 12 h (24 h for the additions of the cyanobenzoyl chlorides). The mixture is poured into ice water (250 mL) and stirred for one hour, during which time the organic layer turns off-white or yellow in colour. Benzene (50 mL) is added, the layers are separated, and the aqueous portion is extracted with benzene (3 × 25 mL). The combined organic portions are washed once with 5% aqueous sodium hydroxide (30 mL), once with water (30 mL), once with saturated brine (15 mL), dried over anhydrous sodium sulfate, and filtered. Solvents are removed on the rotary evaporator, and the resulting solid recrystallized from ethanol or methanol. Yields were generally 50% or better.

Acknowledgements

We wish to express our appreciation to Dr. C. M. Elson, Department of Chemistry, St. Mary's University, Halifax for making available the potentiostat to measure the reduction potentials.

The synthesis of 8-aza-3-deazaguanosine [6-amino-1-(β-D-ribofuranosyl)-*v*-triazolo[4,5-*c*]pyridin-4-one] via a novel 1,3-dipolar cycloaddition reaction

ROBERT A. EARL AND LEROY B. TOWNSEND[1]

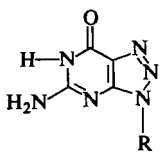
Received March 25, 1980

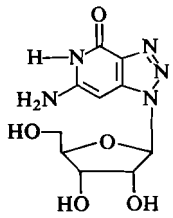
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

ROBERT A. EARL and LEROY B. TOWNSEND. Can. J. Chem. **58**, 2550 (1980).



8-Aza-3-deazaguanosine (**2**) has been prepared via a route which used a 1,3-dipolar cycloaddition reaction to provide a key intermediate. The reaction of 2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl azide (**13**) with methyl 4-hydroxy-2-butynoate (**11**) provided a good yield of crystalline methyl 5-hydroxymethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**14**). A series of functional group transformations were then used to convert **14** into methyl 5-cyanomethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazolo-4-carboxylate (**19**). Treatment of **19** with liquid ammonia effected not only a smooth removal of the blocking groups, but also an aminolysis of the ester function which was then followed by a ring annulation to provide 8-aza-3-deazaguanosine (**2**). The structures of these nucleosides were established on the basis of proton nmr spectral data and nuclear Overhauser enhancement data. The nucleosides obtained in this study were also converted through a chemical degradation sequence into nucleosides which had been obtained during an earlier work from our laboratory. The present study also provides unequivocal proof of the structures of some triazole nucleosides obtained in the earlier study.

ROBERT A. EARL et LEROY B. TOWNSEND. Can. J. Chem. **58**, 2550 (1980).



On a préparé l'aza-8 déaza-3 guanosine (**2**) en faisant appel à une réaction de cycloaddition dipolaire-1,3 pour obtenir l'intermédiaire clé. La réaction de l'azoture de tri-*O*-benzoyl-2′,3′,5′ β-D-ribofurannosyle (**13**) avec l'hydroxy-4 butyne-2 oate de méthyle (**11**) conduit avec un bon rendement à l'hydroxyméthyl-5 (tri-*O*-benzoyl-2,3,5 β-D-ribofurannosyle)-1 *v*-triazolecarboxylate-4 de méthyle (**14**). On a utilisé une série de réactions impliquant les groupements fonctionnels pour transformer le composé **14** en cyanométhyl-5 (tri-*O*-benzoyl-2,3,5 β-D-ribofurannosyle)-1 *v*-triazolecarboxylate-4 de méthyle (**19**). Lorsqu'on traite le composé **19** par l'ammoniac liquide, on obtient non seulement une déprotection douce, mais également une aminolyse de la fonction ester suivie d'une annélation du cycle qui conduit à l'aza-8 diaza-3 furannosine (**2**). On a établi la structure de ces nucléosides en se basant sur la rmn du proton et sur des données d'accroissement Overhauser nucléaire. On a également transformé ces nucléosides, par dégradation chimique, en des nucléosides obtenues antérieurement dans notre laboratoire. La présente étude apporte également une preuve univoque de structure de quelques nucléosides triazoles obtenus dans une étude antérieure.

[Traduit par le journal]

The isolation of (1) and characterization of the antibiotic pathocidin as 8-azaguanine (**1***a*) has created considerable interest in the synthesis of other aza, deaza, and aza/deaza guanine and guanosine analogs. Research activity in this area has resulted in the synthesis of 8-azaguanine (2) (**1***a*), 8-azaguanosine (3, 4) (**1***b*), and 2′-deoxy-8-azaguanosine (4); 3-deazaguanine (5) and 3-deazaguanosine (5); 1-deazaguanosine (6); 1-deaza-8-azaguanosine (7), and several (8, 9) guanosine analogs containing a bridgehead nitrogen.

1 *a*, R = H
b, R = β-D-ribofuranosyl

2

Interesting biological and chemotherapeutic activities have been reported for some of the 8-azaguanosine (10) and 3-deazaguanosine (11) derivatives. However, little or no antitumor (*in vitro* or *in vivo*) activity was noted (12) for 1-deaza or 1-deaza-8-azaguanosine or their corresponding bases. Also, to date, only very weak antiviral activity has been reported (9) for one of the bridgehead-nitrogen guanosine analogs.

The interesting biological and chemotherapeutic activities observed in the 8-azaguanosine (10) and 3-deazaguanosine (11) series suggested that similar or enhanced activities might be expected for the guanosine analog 8-aza-3-deazaguanosine **2**. Also, a recent report (12) indicates that there may be a correlation between the biological activity and the pK_a's of certain guanosine analogs. On the basis of this study it was suggested (12) that 8-aza-3-deazaguanosine should possess a pK_a very similar

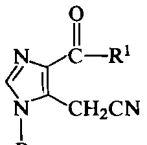
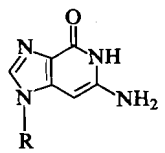
to that of the naturally occurring compounds (guanosine and 8-azaguanosine) and might be expected to exhibit definite biological and chemotherapeutic activities.

On the basis of the above, we initiated a program designed to synthesize 8-aza-3-deazaguanosine (**2**). In our initial approach, we synthesized (13) 4,6-dichloro-*v*-triazolo[4,5-*c*]pyrimidine (**3***a*) by a diazo ring-closure reaction involving 3,4-diamino-2,6-dichloropyridine (14) and carried out a fusion reaction of **3***a* with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**4**). However, this standard pro-



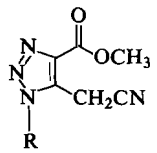
3 *a*, R = H
b, R = 2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl



4

cedure for nucleoside synthesis was found (13) to yield a mixture of isomeric, acetylated ribonucleosides from which the 1-isomer (**3***b*) could be isolated in small amounts only after tedious chromatography. Based on these results, this standard approach seemed too cumbersome to be practical since numerous functional group transformations would be required in order to convert **3***b* into 8-aza-3-deazaguanosine (**2**).

Considerable success has been reported (5) in the synthesis of 3-deazaguanosine derivatives via the base-catalyzed ring-closure of imidazole precursors, e.g., **5***c* and **5***d* to **6***a* and **6***b*, respectively.



5*a*, R = H, R¹ = OCH_3
b, R = 2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl
R¹ = OCH_3
c, R = H, R¹ = NH_2
d, R = β-D-ribofuranosyl
R¹ = NH_2

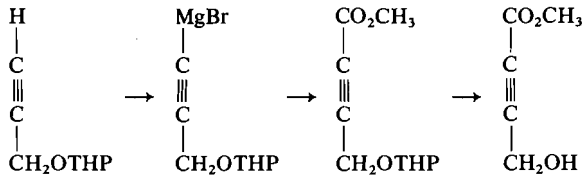
6*a*, R = H
b, R = β-D-ribofuranosyl

This report (5) suggested that this approach might be useful[2] for the synthesis of 8-aza-3-deazaguanosine provided that suitable triazole precursors were available.

Unfortunately, a survey of the literature revealed that the *v*-triazole precursor, *per se*, methyl 5(4)-cyanomethyl-*v*-triazole-4(5)-carboxylate (**7***a*) was unknown. To the best of our knowledge, other useful starting materials such as the *v*-triazole analogue of **5***c* were also unknown. Thus we were faced with the task of synthesizing a triazole derivative such as**7***a*. Based on the imidazole work (5), a condensation of **7***a* with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**4**) would be expected to yield the triazole nucleoside derivative **7***b*. However, such a condensation using the imidazole derivative was found (5) to give both possible positional isomers. The ratio of these positional isomers could be changed depending on the amount of

7*a*, R = H
b, R = 2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl

catalyst employed. In the case of the proposed triazole series, a third positional isomer is possible and would most likely be formed, based on our experience with 4,6-dichloro-*v*-triazolo[4,5-*c*]-pyridine (13) (**3***a*) and other related compounds (16). This suggested to us that we would again probably encounter serious problems with the separation of isomers possessing very similar chromatographic mobilities.



Another more novel approach to the synthesis of a *v*-triazole nucleoside such as **7***b* would be through the 1,3-dipolar cycloaddition of a ribofuranosyl azide derivative to a suitable acetylenic compound. This approach would enjoy the advantage of producing only two positional isomers. Several reports have appeared (17, 18) whereby glycosyl azides have been successfully added to acetylenic compounds to produce *v*-triazole nucleosides with a high degree of regioselectivity (the glycosyl and ester functions being located at the 1- and 4-positions of the triazole ring, respectively). In addition to a high degree of regioselectivity, these reactions (17, 18) also appeared to occur with com-

[2]It is interesting to note, however, that a similar approach has failed to yield 3,7-dideazaguanine from pyrrole precursors (15).

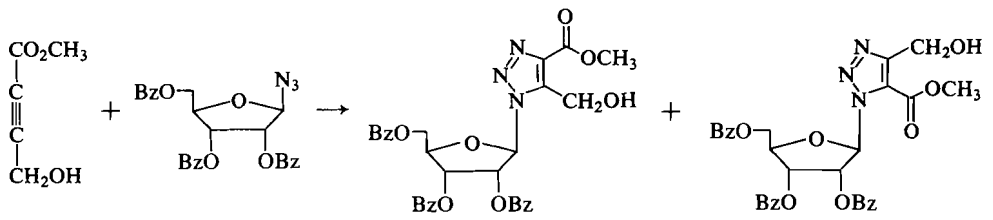
plete retention[3] of configuration at C-1 of the glycosyl moiety.

The 1,3-dipolar cycloaddition route looked very promising as a route for the synthesis of a functionalized triazole nucleoside such as **7***b*. A search of the literature revealed that the highly functionalized acetylenic derivative, methyl 4-hydroxy-2-butynoate (**11**), was a known (20) compound. The compound **11** had been prepared (20) previously, however, we were unable to reproduce the reported (20) yields and also encountered serious problems with emulsion formation during the workup of the carboxylation mixture using this procedure. Therefore, we modified (21) the original procedure, which eliminated the problem with emulsions and provided a 65% yield of **11** (based on **8**).[4]

8 **9** **10** **11**

It had been our intention to convert the hydroxymethyl group of **11** into a cyano methyl group to yield methyl 4-cyano-2-butynoate (**12***b*), since a reaction of **12***b* with a ribofuranosyl azide derivative should furnish a triazole nucleoside of the type represented by **7***b*. However, our attempts to bring about this modification were unsuccessful. Bromination of **11** using a published (20) procedure did not yield a pure product and gplc analysis indicated the presence of at least three new compounds in the reaction mixture. A pmr spectrum of the crude product indicated the presence of allenic compounds. Allenic compounds have been encountered by others (23) when attempting to iodinate certain acetylenic alcohols under very mild conditions. Other methods for bromination (24) and iodination (25) were also unsuccessful in converting **11** into a halo derivative. Similarly, methods (26) for the preparation of mesylates and tosylates from acetylenic alcohols did not give useful products from **11**. Although all of these methods showed evidence of giving some of the desired products, the highly reactive nature of these propargyl compounds ensure a difficult isolation. This isolation problem is due primarily to their tendency to undergo rearrangement (23) to allenic compounds or to react further (26) with bases present in the reaction mixture to give hydrolysis products or quaternary ammonium compounds.



12*a*, X = Br
b, X = CN

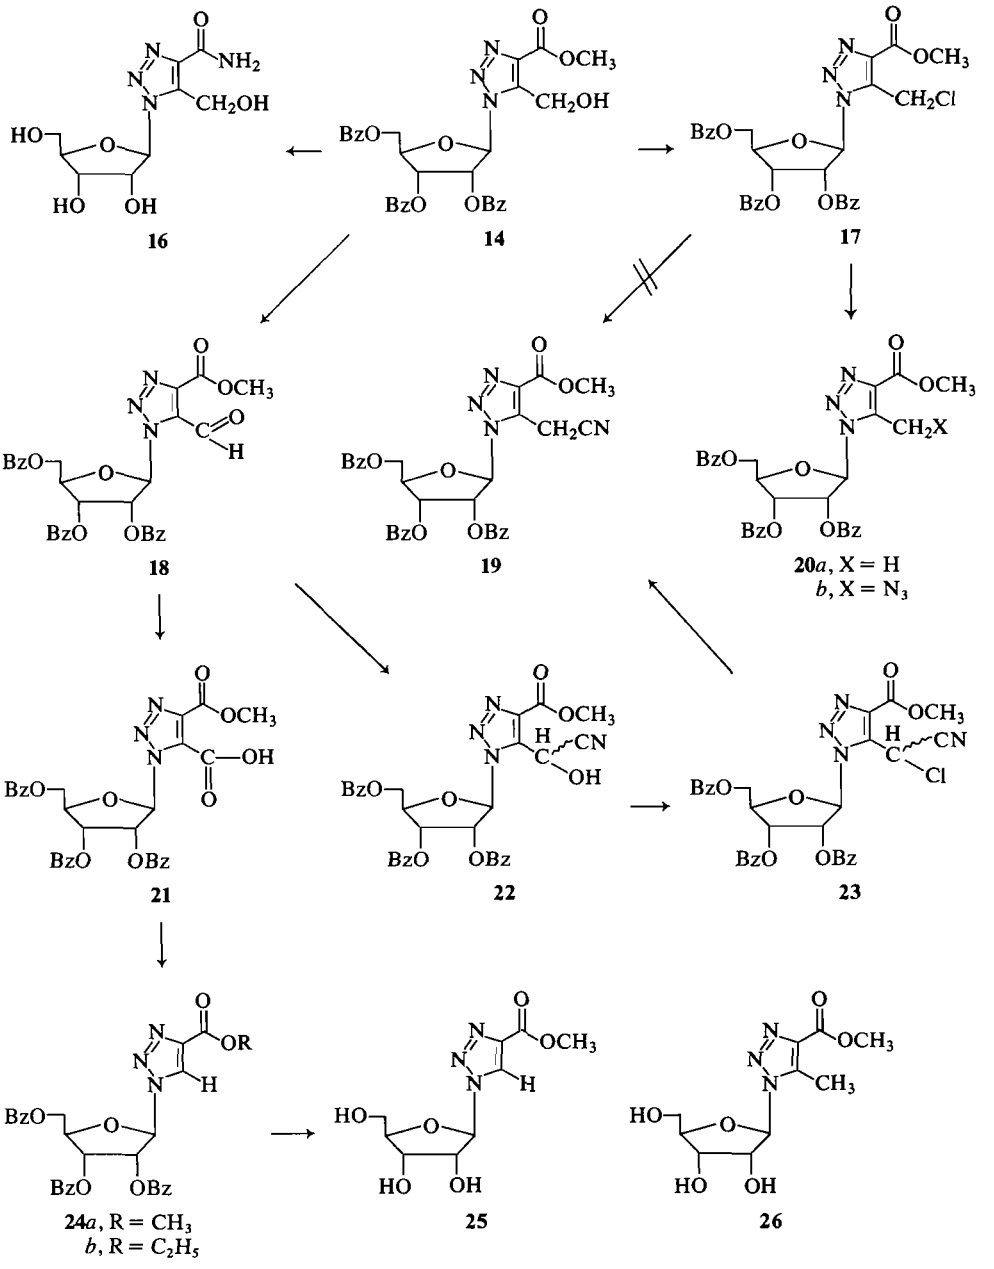
In view of the problems we encountered while trying to modify methyl 4-hydroxy-2-butynoate (**11**), we decided to carry out a 1,3-dipolar cycloaddition reaction using **11** as the dipolarophile and to carry out further functional group transformations on the nucleoside rather than the acetylenic precursor. We chose 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl azide as a starting material since it has a known β configuration and is available (27) in pure, crystalline form. The reaction between crystalline 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl azide (**13**) and methyl 4-hydroxy-2-propynoate (**11**) was found to proceed best when the temperature of the reaction was maintained in the range of 50–70°C with little or no solvent. Under these conditions, the reaction required 5 to 7 days for completion but the reaction was very clean resulting in the production of two close-running (tlc) nucleoside components in a ratio of ca. 4:1 (pmr).

When methanol was added to the hot reaction mixture, the predominant isomer, tentatively (17) assigned structure **14** (methyl 5-hydroxymethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate), crystallized from solution in a 60% yield. Chromatography of the product obtained from the supernatant yielded an additional 15% of the major isomer (**14**) as well as a 6% yield of the minor, slower running (tlc) nucleoside component. Elemental analysis and proton nmr spectral data indicated that the isolated products were isomeric since both products had the same empirical formula and displayed signals for a carbomethoxy and a hydroxymethyl group as well as the ribose moiety. Both compounds displayed anomeric signals (H-1′) with rather small coupling constants (1.8 Hz for **14** and 1.5 Hz for **15**) indicating (28) that they were both probably β-isomers. Furthermore, the anomeric signal for **15** (δ 7.07) was shifted downfield 0.21 ppm compared to the corresponding signal for **14** (δ 6.86) which sug-

[3]An apparent exception to this observation did not actually involve the cycloaddition of an azide to an acetylenic compound. Instead this reaction involved the reaction of a glycosyl azide with a carbanion followed by a ring closure reaction (see refs. 4 and 19).

[4]After this work was completed, a similar procedure for the removal of the tetrahydropyranyl protecting group was reported (22).

11 13 14 15



gested that our tentative (17) structural assignments were correct. It has been demonstrated previously in the case of benzimidazole (29*a*), imidazole (5), pyrimidine (29*b*), and 1,2,4-triazole nucleosides (29*c*, *d*) as well as in the case of certain nitrogen bridgehead nucleosides (29*e*) that when a ribosyl moiety is attached to a nitrogen atom α to a carbon atom bearing a carbonyl function (such as an ester group) then the anomeric signal is shifted downfield as compared to the situation where the ribosyl moiety is not adjacent to a carbonyl function. On the basis of this observation, the predominant isomer must have the structure indicated by **14** whereby H-1′ is located away from the carbomethoxy group.

Methanolic ammonia readily converted **14** into the crystalline carboxamide derivative **16**. Chlorination of **14** using thionyl chloride – DMF – methylene chloride provided a quantitative yield of the chloromethyl derivative **17**, isolated as a solid foam. This very reactive chloromethyl derivative (**17**) was readily reduced using catalytic hydrogenation (5% Pd/C) to provide the crystalline methyl derivative **20***a*. The structure of **20***a* was supported by its elemental analysis as well as by the appearance of a new 3-proton singlet in the pmr spectrum at δ 2.64 (methyl group). A reaction of the chloromethyl derivative (**17**) with sodium azide in acetonitrile furnished an 88% yield of the azidomethyl derivative **20***b*. Although the R_f (tlc) values of **17** and **20***b* were nearly identical, the compounds gave different colors when sprayed with 10% sulfuric acid and heated. The tlc indicated that 1 h of reaction at 70°C was probably sufficient for complete reaction. Potassium cyanide in DMSO (25°C) rapidly (3–5 min) converted the chloromethyl derivative **17** into a new product whose R_f was slower than that of the starting material. Although tlc suggested that the product was homogeneous, the pmr spectrum indicated that it was probably a mixture. The spectrum (pmr) was unexpectedly complex showing 5-"singlets" in the region δ 3.4–3.9 where the methoxy singlet should appear. At first, it appeared that the product was perhaps a dimer resulting from a bimolecular condensation of a cyanomethyl group with a carbomethoxy group. However, the mass spectrum was very complex showing peaks with masses much higher than that expected for a dimer. Furthermore, the mass spectrum did not show a molecular ion for the desired monomeric cyanomethyl derivative **19**. The reaction between chloromethyl derivative **17** and "naked" (30) cyanide ion (KCN–acetonitrile – 18-crown-6, 18 h, 45°C) also gave an unidentified product as above.

We, therefore, explored an alternate route for the synthesis of **19** which would not require a nucleophilic displacement with a strong base. During the course of this study, we found that the hydroxymethyl derivative **14** was readily converted (31) (85%) into the corresponding aldehyde **18** by treatment with activated (32) manganese dioxide in toluene at reflux. This compound was readily identified due to the presence of a sharp one-proton singlet in the pmr at δ 10.31 for the formyl proton. The aldehyde **18** could be converted into the cyanohydrin **22** (based on tlc data) using (33) a transcyanohydrination reaction between **18** and acetone cyanohydrin. However, the aldehyde **18** was so reactive that a simple treatment of **18** with 3 to 5 mol of hydrogen cyanide (34) in methylene chloride (25°C) converted it, quantitatively, into the cyanohydrin **22**. The cyanohydrin **22** was isolated as a crisp foam that was stable indefinitely, provided that it was kept dry. Thin layer chromatography resolved the diastereomeric mixture into two spots; however, attempts at column chromatography resulted in partial or complete reversion of **22** into the starting aldehyde **18**. The cyanohydrin was readily converted into the chlorocyanomethyl derivative **23** using thionylchloride–DMF–methylenechloride. Chromatography gave the diastereomeric mixture (**23**) as an analytically pure foam that showed a single spot (tlc) in two different chromatographic solvent systems. Hydrogenation of **23** (5% Pd/C) gave a nearly quantitative yield of the elusive cyanomethyl derivative **19** in the form of an analytically pure white foam. The tlc mobilities for **19** were different from those of the unidentified product(s) obtained from attempted displacement of the chloro group of **17** with cyanide ion. Later experiments demonstrated

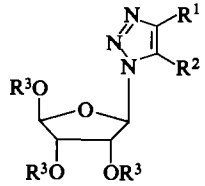
that the hydroxymethyl derivative **16** could be converted into the cyanomethyl derivative **19** in an overall yield of 57% with only the chlorocyanomethyl derivative requiring purification by chromatography.

Treatment of the cyanomethyl derivative **19** with methanolic ammonia (25°C, 18 h) gave a highly colored reaction mixture from which impure 5-cyanomethyl-1-(β-D-ribofuranosyl)-*v*-triazole-4-carboxamide (**27**) (ca. 25% yield) and 8-aza-3-deazaguanosine (**2**) could be isolated. When **19** was treated[5] with liquid ammonia (25°C) for 5 days, a light purple reaction mixture was obtained. Evaporation of the liquid ammonia followed by tritura-

[5]It should be noted that the ring closure of **19** to give **2** took place under much milder conditions than those required (5) for the corresponding reaction in the imidazole series. This is likely due to the greater electron withdrawing ability of a triazole ring as compared to an imidazole ring which renders the amide protons of **27** more acidic than those in **5***d*. This facilitates abstraction (5) of an amide proton of **27** which is followed by rapid ring closure.

19 27 2

tion with ether and then acetone yielded a yellow-orange colored powder whose pmr spectrum indicated that it was nearly pure 8-aza-3-deazaguanosine (100% crude yield). The crude 8-aza-3-deazaguanosine (**2**) was converted into its sodium salt and absorbed on a Dowex 1 resin (formate form) column. Elution with 0.05 *N* formic acid gave pure 8-aza-3-deazaguanosine, mp 239–241°C in the form of a light, violet colored powder. The pmr spectrum of 8-aza-3-deazaguanosine (**2**) was very similar to that reported (5) for 3-deazaguanosine (**6***b*) showing an anomeric signal at δ 5.83 (δ 5.51 for **6***b*) which was split into a doublet with $J = 5$ Hz (6 Hz for **6***b*). The ring proton (H-7) appeared as a singlet at δ 5.50 (δ 5.52 for **6***a*). The uv spectrum of 8-aza-3-deazaguanosine was also very similar to that reported (5) for 3-deazaguanosine, however, these similarities are not sufficient to allow any conclusions regarding configuration or position of attachment of the ribose moiety in **2**. We had assumed a β-configuration for **2** and its triazole nucleoside precursors on the basis of the known (27) β-configuration of the starting azide **13**. A pmr spectrum (Table 1) of the aldehyde derivative **18** provided conclusive evidence (28) that the cycloaddition had proceeded with retention of configuration at C-1 of the ribose ring since the anomeric signal appeared as a sharp singlet at δ 7.01. The position of attachment of the ribosyl moiety in **2** and **14**, **16–23** remained to be established since we did not feel secure with assignments based on the relative positions of the anomeric signals of the original isomeric cycloadducts (**14** and **15**). We therefore carried out a chemical degradation of the major cycloadduct (**14**) in order to relate it to a nucleoside (**24***a*) of known structure. Oxidation of the hydroxymethyl group of **14** using Jones reagent (35) provided (88%) the carboxylic acid derivative **21**. The pmr spectrum of **21** showed considerable peak broadening suggesting the presence of paramagnetic species. Washing solutions of **21** with dilute mineral acid and even column chromatography did not improve the quality of the spectra. The crude product was triturated with dilute acetic acid, dried, and used without further purification for decarboxylation. Decarboxylation of **21** was carried out in toluene at reflux to give a crude product. This solid was crystallized[6] from methanol to give a 65% yield of methyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**24***a*) whose physicochemical data (mp, pmr, and $[\alpha]_D$) were in excellent agreement with the published (17) data for **24***a*. Recrystallization of the crude decarboxylation product from ethanol gave the corresponding ethyl ester **24***b*. However, the published structure of **24***a* was not unequivocal since the assignment of a structure for **24***a* was based only on trends in pmr chemical shifts previously noted (36) for model *N*-methyl derivatives of triazoles. Therefore, compounds **24***a* and **20***a* were deblocked with methanolic sodium methoxide to provide **25** and **26**, respectively. The physicochemical properties of **25** were identical to those previously reported (37) for this compound. These nucleosides (**25** and **26**) were then examined for the presence of nuclear Overhauser enhancements (38, 39). When H-2′ of **25** was irradiated, an nOe of 18.5% was noted for H-5 (Table 2). Similarly, irradiation of H-1′ caused a 10% enhancement of H-5 in **25**. These results could only occur if the ribose moiety of **25** is attached to N-1 of the triazole ring since attachment at N-3 would place H-5 too far away from H-1′ and H-2′ to expect any significant nOe. Furthermore, when the methyl group at C-5 of **26** was irradiated, an enhancement of 16.5% was noted for H-1′ which provided additional evidence that the ribosyl group is in the position indicated. Thus, a combination of pmr and nOe spectral data provided unequivocal proof that **14**, **16–26** possessed the structures as tentatively assigned by us. These data have also provided proof that the cycloaddition reactions reported (17) by earlier workers proceeded with the regioselectivity that they had earlier indicated.



This work has demonstrated once again (40) the

[6]Recrystallization of the crude decarboxylation product from ethanol gave a 65% yield of the corresponding ethyl ester. This behavior is difficult to explain without invoking the presence of some impurity which is acting as a transesterification catalyst.

usefulness of the 1,3-dipolar cycloaddition reaction for a quick entry into 5-membered heterocycles with varied functionality. It has also demonstrated that highly functionalized acetylenic derivatives such as methyl 4-hydroxy-2-butynoate (**11**) may be used successfully as dipolarphiles while still obtaining a high degree of regioselectivity in the cycloaddition reactions.

The synthesis of **2** and some closely related derivatives via an alternate route has recently been reported (41).

Experimental

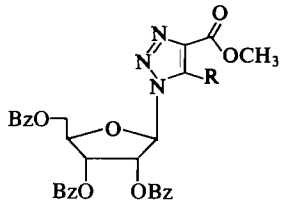
Melting points were determined with a Thomas–Hoover capillary melting point apparatus and are uncorrected. The pmr spectra were recorded on Varian EM-360 and EM-390 spectrophotometers using DMSO-d_6 and $CDCl_3$ as solvents with tetramethylsilane as internal standard. Rotations were obtained with a Perkin–Elmer Model 141 digital readout polarimeter and were determined on samples dissolved in DMSO and having a concentration of 1 g/100 mL, unless otherwise stated. Thin layer chromatography (tlc) was carried out using glass plates precoated with a layer (0.25 mm) of Silicar 7GF silica gel as supplied by Analtech, Inc. ("Uniplate"). Compounds were detected using an ultraviolet lamp (Mineralight, 254 mm) or by spraying the tlc plates with 10% sulfuric acid in water (v/v) followed by heating at 120°C. Column chromatography was carried out using Silica Gel 60 F_{254} (70–230 mesh) as obtained from E. Merck, Darmstadt, West Germany. Columns were packed with dry silica gel and then eluted with one void volume of the eluting solvent before a concentrated solution of impure compound was applied to the top of the column. Elution was carried out using Solvent System A: (SSA) (chloroform–acetone, 19:1 (v/v)) unless otherwise noted. All concentrations of solutions were carried out, *in vacuo*, at 25–35°C unless otherwise noted. Solutions were dried over anhydrous sodium sulfate unless stated otherwise.

Nuclear Overhauser experiments were carried out using a JEOL TPJ-PFT 100 instrument and using an EC-100 data system. Compounds were dissolved in and then freeze dried from deuterium oxide (3 cycles) in order to replace exchangeable protons with deuterium. The deuterated compounds were then dissolved in DMSO-d_6 and deoxygenated by freezing under vacuum and thawing under a nitrogen atmosphere (3 cycles). The solutions (concentration, 5 mg in 0.5 mL DMSO) were then sealed in the nmr tubes while under vacuum.

Methyl 4-Hydroxy-2-butynoate (11)

Caution! Methyl 4-hydroxy-2-butynoate (**11**) is a potent vesicant which causes painful burns on contact with skin. All operations should be carried out in an efficient fume hood and gloves should be worn at all times.

Propargyl alcohol was converted into 1-(tetrahydropyran-2-yloxyprop-2-yne (**8**) in 78% yield using a published (42) general procedure. The THP-propargyl alcohol had a bp of 75–77°C (15–20 Torr), $n_D^{22°}$ = 1.4594 (lit. (20) bp 78°C (25 Torr, $n_D^{20°}$ = 1.4570); pmr (90 MHz, neat) δ: 4.63 (s, 1H, H-1′), 4.03 (d, 2H, C≡C—H, J = 1 Hz), 1.18–1.93 (br m, 6H, H-2′, H-4′).



A solution of 280.4 g (2 *M*) of the THP-propargyl alcohol **8** in 2 L of dry tetrahydrofuran was added, dropwise, during 0.75 h to a stirred solution of ethylmagnesium bromide (2 *M*, purchased from Aldrich Chemical Company as a 3 *M* solution in diethyl ether) in diethyl ether (ca. 660 mL). Vigorous boiling and gas (C_2H_4) evolution took place during the addition. The solution was then stirred an additional 1.5 h at 25°C. The acetylenic Grignard reagent, **9**, was then added dropwise under a nitrogen atmosphere, to a vigorously stirred, cold (−10 to −15°C) solution of methyl chloroformate (275.2 g, 2.9 *M*) in 0.5 L of dry tetrahydrofuran during 2 h. The temperature was maintained at −10 to −15°C with continued mechanical stirring for another 0.5 h, and then was stirred at 0°C for an additional 1.5 h. The mixture was stored at +5°C for 18 h and then the supernatant was removed from the magnesium salts by filtration. The salts were washed with cold (0°C) toluene (3 × 300 mL), the filtrates were combined and concentrated, *in vacuo*, to ca. 1-L volume, and the dark-brown solution washed with saturated brine (5 × 200 mL). The solution was dried and concentrated *in vacuo* to remove the toluene. The residue was dissolved in anhydrous methanol (1.25 L), Dowex 50 (50 mL of H^+ form, prewashed with anhydrous methanol) was added, and the mixture stirred for 1.5 h at 25°C. The ion exchange resin was removed by filtration and the resin was then washed with anhydrous methanol (2 × 100 mL). The solvent and by-product (2-methoxytetrahydropyran) were removed by first using a water aspirator and then an oil pump at 0.5 Torr pressure. This residue was then treated a second time with anhydrous methanol (1 L) and Dowex 50 (50 mL) followed by concentration as described above. The dark, oily residue was distilled *in vacuo* through a Claison head to give **11** (147.8 g, 64.8%), bp 66–69°C/0.2 Torr, (lit. (20) bp 70°C/0.5 Torr), $n_D^{22°}$ = 1.4720; ir (neat): 3410 (strong, br, OH), 2240 (strong, C≡C), 1715 (strong, ester) cm^{-1}; pmr (DMSO-d_6) δ: 5.57 (t, 1H, OH), 4.31 (d, 2H, CH_2OH, J = 6 Hz), 3.79 (s, 3H, OCH_3). *Anal.* calcd. for $C_5H_6O_3$: C 52.63, H 5.30; found: C 52.67, H 5.46.

Methyl 5-Hydromethxyl-1-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl)-v-triazole-4-carboxylate (14) and Methyl 5-Carbomethoxy-4-hydroxymethyl-1-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl-v-triazole-4-carboxylate (15)

Crystalline 2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl azide (**27**) (**13**, 58.5 g, 0.12 *M*), methyl 4-hydroxy-2-butynoate (**11**, 13.7 g, 0.12 *M*), and 5 mL of toluene were heated and gently stirred at 50–55°C for 5 days. At the end of days 1, 2, and 3, additional amounts of **11** (1 mL each addition) were added. The temperature was raised to 70°C and heating was continued for an additional 2 days. After seven days, the azide could not be detected in the tlc. Methanol (134 mL) was added, the mixture was heated to boiling, cooled to 25°C, and the product allowed to stand for 3 days. The crystalline product was collected by filtration to give 46.6 g of product (mp 75–79°C). This solid was recrystallized once from ethanol to give the pure product **14** (needles), 43.1 g (59.8%), $[\alpha]_D^{22°}$ 30.2°, mp 87–89.5°C (bubbly, viscous melt). *Anal.* calcd. for $C_{31}H_{27}N_3O_{10}$: C 61.89, H 4.52, N 6.99; found: C 61.73, H 4.43, N 6.79. See Table 1 for pmr spectral data. The supernatants were combined and concentrated to give 38 g of a syrup which was chromatographed over silica gel (270 g) (column, 7 × 35 cm). Elution was carried out with SSA. The first liter of eluent was discarded and then 20-mL fractions were collected. Fractions 30–50 contained additional amounts of pure **14**, 11.05 g (15.3%, total yield 75.1%). Fractions 51–80 (17 g) contained the slower moving isomer **15** and were saved for rechromatography.

A portion (6.18 g) of the concentrates containing the slower moving isomer was rechromatographed over silica gel (270 g of

[a]Chromatography was carried out using 20 cm × 5 cm glass plates coated with a 250 μm layer of silica gel 7GF as supplied by Analabs. Each spot contained 0.1 mg of compound applied as a solution in chloroform.
[b]SSA = Solvent system composed of chloroform–acetone, 19:1 (v/v). SSB was a mixture of benzene – ethyl acetate, 17:3 (v/v).
[c]1-*O*-Acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose was used as the standard.

silica gel, column 7 cm × 35 cm). Elution was carried out using SSA and 17 mL fractions were collected. Fractions 35–45 contained the slower moving isomer **15**, 1.55 g, $[\alpha]_D^{25°}$ 20.1°. *Anal.* calcd. for $C_{31}H_{27}N_3O_{10}$: C 61.89, H 4.52, N 6.99; found: C 62.07, H 4.78, N 6.88.

5-Hydroxymethyl-1-(β-D-ribofuranosyl)-v-triazole-4-carboxamide (16)

A solution of **14** (3 g, 5.0 mmol) in 50 mL of methanolic ammonia (saturated at 0°C) was sealed in a pressure bottle at 25°C for 2 days. A single spot (R_f 0.3, $CHCl_3$–CH_3OH, 7:3, v/v) was observed with some difficulty by tlc since it absorbed uv light only very slightly, but the spot charred when it was sprayed with 10% H_2SO_4 and then heated. The solvent was removed *in vacuo* and the residue triturated repeatedly with anhydrous ether (5 × 40 mL) to give a white crystalline solid, 1.15 g (89.3%), mp 136–138°C. The solid was dissolved in 20 mL of boiling ethanol containing a few drops of water and the solution concentrated to 9 mL by boiling. The product (**16**) crystallized out of solution as white spears on cooling to room temperature, 1.08 g, mp 138.5–141°C; $[\alpha]_D^{25°}$ −82.6°. *Anal.* calcd. for $C_9H_{14}N_4O_6$: C 39.42, H 5.15, N 20.43; found: C 39.72, H 5.21, N 20.40.

Methyl 5-Formyl-1-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl)-v-triazole-4-carboxylate (18)

Activated (32) manganese dioxide (89 g) was suspended in 750 mL of boiling toluene and water was then removed using a Dean–Stark trap. Compound **14** (29.75 g, 49.5 mmol) was added and the mixture stirred and heated at reflux temperature for 3 h while removing water by azeotropic distillation. Another 30 g of manganese dioxide was added, and the mixture stirred and heated an additional 5 h with continued removal of water. The mixture was then filtered, while still hot, through a dry-packed bed of Celite (5 cm × 10 cm), and the filter-cake washed with hot acetone (5 × 100 mL). The filtrates were combined and concentrated *in vacuo* to yield a light yellow colored foam (**18**, 26.1 g, 87%) (one spot, tlc, SSA). A small sample (0.5 g) was chromatographed over silica gel (50 g) using SSA to yield 430 mg of a white foam; $[\alpha]_D^{25°}$ −31.0°. The aldehyde eventually crystallized on standing; white crystals, mp 185–186°C (ethyl acetate – ligroin, 1:5, v/v). *Anal.* calcd. for $C_{31}H_{25}N_3O_{10}$: C 62.10, H 4.20, N 7.01; found: C 61.94, H 4.13, N 6.86.

Methyl 5-(α-Cyano-α-hydroxymethyl)-1-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl)-v-triazole-4-carboxylate (22)

Unchromatographed methyl 5-formyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**18**, 8.15 g, 13.5 mmol) was dissolved in 18 mL of methylene chloride, the solution was cooled to −50°C, and the flask and contents weighed. Liquid (34) hydrogen cyanide was added (ca. 1 mL) and weighing by differences indicated that 1.05 g (38.9 mmol) of HCN was present. The flask was tightly stoppered and allowed to stand at ambient temperature for 6.3 h when tlc indicated that only a trace of aldehyde was present. The cyanohydrin showed two spots (R_f 0.25 and 0.31, SSA) on tlc (diastereoisomeric mixture). The cyanohydrin was unstable on silica gel and if the tlc plates were allowed to stand for more than a few minutes before development, the amount of aldehyde in the mixture increased. Concentration *in vacuo* (**in the hood**) yielded a syrup which readily formed a white foam under oil pump vacuum, 8.47 g (99.4%). A sample was dissolved in chloroform and treated with a small amount of Norite. Filtration through dry-packed Celite and then concentration *in vacuo* yielded a white foam; $[\alpha]_D^{25°}$ 22.7°. *Anal.* calcd. for $C_{32}H_{26}N_4O_{10}$: C 61.34, H 4.18, N 8.94; found: C 61.24, H 4.19, N 8.67.

Methyl 5-(α-Chloro-α-cyanomethyl)-1-(2,3,5-tri-O-benzoyl-β-D-ribofuranosyl)-v-triazole-4-carboxylate (23)

The cyanohydrin **22** (8.26 g, 13.2 mmol) was dissolved in 42 mL of dry methylene chloride and then 1.43 mL of dry dimethylformamide and 1.42 mL of thionyl chloride were added in succession. The reaction mixture was allowed to stand in a sealed flask (25°C) for 4 h. Methanol (0.75 mL) was then added and the mixture allowed to stand for another hour at 25°C. The

solution was evaporated *in vacuo* and then co-evaporated twice with toluene (2 × 50 mL) followed by drying overnight, *in vacuo*. This syrup was then dissolved in ethyl acetate (200 mL) and washed in succession with water (50 mL), saturated aqueous sodium bicarbonate solution (2 × 20 mL), water (50 mL), and then saturated brine. The solution was dried and then concentrated *in vacuo* to yield a tan colored foam (8.14 g, 96%). The foam was dissolved in chloroform (12 mL) and applied to the top of a silica gel column (5 cm × 50 cm, 270 g of silica gel). The column was eluted with chloroform–acetone (24:1, v/v) and 18 mL fractions were collected. Fractions 70–85 contained the product (4.79 g, 56%). Concentration of fraction 75 yielded an analytical sample (540 mg) as a colorless foam; $[\alpha]_D^{25°}$ −23.1°. *Anal.* calcd. for $C_{32}H_{25}ClN_4O_9$: C 59.58, H 3.91, N 8.69, Cl 5.50; found: C 59.35, H 3.74, N 8.45, Cl 5.75.

*Methyl 5-Cyanomethyl-1-(2,3,5-tri-*O*-benzoyl-β-*D*-ribofuranosyl)-*v*-triazole-4-carboxylate (19)*

Method 1

The α-chloro-α-cyano derivative **23** (4.23 g, 6.56 mmol), 1.5 g of 5% Pd/C, ethyl acetate (75 mL), and triethylamine (1.0 mL, 7.16 mmol) were added in that order, while purging with nitrogen, to a hydrogenation flask. The mixture was stirred for 4.5 h, under a hydrogen atmosphere at ambient temperature and pressure. The solids were removed by filtration through dry-packed Celite (bed, 1.5 cm × 5 cm) and the filter-cake washed with ethyl acetate (3 × 10 mL). The filtrates were combined and washed in succession with 1% (v/v) aqueous hydrochloric acid (2 × 20 mL), water (15 mL), and then saturated brine (15 mL). After drying, the solvent was removed *in vacuo* to yield a light tan colored syrup, 3.82 g (95.5%). A small sample (500 mg) was chromatographed in the usual manner (SSA, silica gel) to yield a white foam (450 mg). *Anal.* calcd. for $C_{32}H_{26}N_4O_9$: C 63.02, H 4.29, N 9.18; found: C 63.01, H 4.41, N 8.86.

Method 2

Pure methyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-hydroxymethyl-*v*-triazole-4-carboxylate (**14**, 29.75 g, 49.5 mmol), 119 g of activated manganese dioxide, and 750 mL of toluene were heated at reflux temperature and with azeotropic removal of water as previously described. Workup as before yielded the aldehyde **18** as a light yellow foam (26.1 g, 87%). The crude aldehyde was treated, as previously described, with liquid hydrogen cyanide (3.6 g, 133 mmol) in methylene chloride for 3 h at 25°C. Concentration, *in vacuo*, gave the cyanohydrin **22** in the form of a pale yellow foam, 26.1 g. The crude cyanohydrin was then treated with 14.9 g (125 mmol) of thionyl chloride and 9 mL of DMF in 250 mL of methylene chloride to yield, after the usual washing and drying operations, 26.6 g of a brown foam. Chromatography over 469 g of silica gel (dry-packed and eluted using SSA) gave the pure α-chloro-α-cyanomethyl derivative (**23**, 18.4 g). This was then subjected to catalytic hydrogenation over 5% Pd/C (6 g) to yield 17.3 g of essentially pure (pmr, tlc) methyl 5-cyanomethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**19**) in an overall yield of 57.6% based on the starting methyl 5-hydroxymethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**14**).

*6-Amino-1-(β-D-ribofuranosyl)-*v*-triazolo[4,5-c]pyridin-4-one(8-aza-3-deazaguanosine) (2)*

Methyl 5-cyanomethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**19**, 16.8 g, 27.5 mmol) was dissolved in liquid ammonia (100 mL). The solution was sealed in a steel reaction vessel and allowed to stand at room temperature for 4 days. The ammonia was then allowed to evaporate and the residue was triturated with anhydrous ether (6 × 200 mL) to give a yellow-orange powder (8.7 g). This powder was triturated with acetone (8 × 50 mL) to give 7.8 g (100%) of crude product. A sample (1 g) of the product was dissolved in 1.03 *N* sodium hydroxide solution (3.90 mL) and the dark, purple solution was applied to the top of a glass column (2 cm × 35 cm) prepacked with Dowex 1 resin (formate form). The column was washed with 200 mL of water. The copumn was then eluted with dilute formic acid (0.05 *N*) with 23 mL fractions being collected. The progress of the chromatography was monitored by uv at 286.5 nm. Fractions 17–40 (550 mL) contained the product and were combined and concentrated, *in vacuo*, to ca. 6 mL of a clear, light violet solution. Ethanol (34 mL) was added to the solution which was then concentrated to ca. 20 mL by boiling. Ethanol (20 mL) was added again and the solution concentrated to 20 mL once more by boiling. The solution was slowly cooled to 25°C and the product separated out as a pale, purple colored powder that was washed with ethanol (4 × 5 mL) and then ethyl ether (2 × 5 mL). The dried solid weighed 283 mg (29.3% recovery), mp 239–241°C (vig. bubbling). Ultraviolet λ_{max} (pH 1): 286.5 nm (ε, 14 700); λ_{min} (pH 1): 245 nm (ε, 1 700); λ_{max} (MeOH): 287.5 nm (ε, 16 700); λ_{min} (MeOH): 245 nm (ε, 900); λ_{max} (pH 11): 230 nm (ε, 19 500), 286 (7 200), 314.5 (7 100); λ_{min} (pH 11): 256.5 nm (ε, 1 900), 298.5 (6 200). Proton magnetic resonance (DMSO-d_6) δ: 10.64 (br s, 1H, N—H), 6.10 (s, 2H, NH_2), 5.83 (d, 1H, H-1′, $J_{H-1',H-2'}$ = 5 Hz), 5.50 (s, 1H, H-7), 4.64 (t, 1H, H-2′), 4.20 (t, 1H, H-3′), 3.97 (q, 1H, H-4′), 3.48 (m, 2H, H-5′, 5″); $[\alpha]_D^{25°}$ −123.2°. *Anal.* calcd. for $C_{10}H_{13}N_5O_5$: C 42.40, H 4.63, N 24.73; found: C 42.64, H 4.54, N 24.76.

*Methyl 1-(2,3,5-Tri-*O*-benzoyl-β-D-ribofuranosyl)-5-chloromethyl-*v*-triazole-4-carboxylate (17)*

Dry DMF (4.0 mL) and thionyl chloride (4.0 mL) were added, in one portion, to a stirred solution of methyl 1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-hydroxymethyl-*v*-triazole-4-carboxylate (**14**, 4.0 g, 6.65 mmol) in dry methylene chloride (200 mL). After 20 min, no starting material (R_f 0.2; SSA) was present as determined by tlc, instead a single new faster moving spot (R_f 0.6) had appeared. Methanol (4 mL) was added, dropwise, to the stirred solution (5 min) and the solution allowed to stir another 10 min. The solution was then washed in succession with ice-water (3 × 25 mL), saturated, aqueous sodium carbonate solution (20 mL), water (20 mL), and finally saturated brine (20 mL). The solution was dried (Na_2SO_4) and then concentrated *in vacuo* to afford a syrup (4.12 g, 100%) which did not crystallize even after a sample was purified by chromatography over silica gel (SSA). The compound (chromatographic sample) gave a strongly positive Beilstein test; $[\alpha]_D^{25°}$ −26.6°. *Anal.* calcd. for $C_{31}H_{26}ClN_3O_9$: C 60.05, H 4.23, N 6.78, Cl 5.72; found: C 59.97, H 4.22, N 6.56, Cl 5.91.

*Methyl 5-Methyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (20a)*

The chloromethyl derivative **17** (182 mg, 0.29 mmol) and triethylamine (100 μL) were added to a suspension of 5% Pd/C (182 mg) in ethyl acetate (5 mL). The mixture was stirred under an atmosphere of hydrogen for 20 h and then filtered through a dry-packed bed of Celite. The filter-cake was washed with small portions of ethyl acetate (3 × 4 mL), the filtrates were then combined and concentrated to give a mass of white needles. These needles were recrystallized from ethanol (4 mL) to give 91 mg (53.6%) of **20***a* as white needles, mp 106–108°C, $[\alpha]_D^{25°}$ −25.4°. *Anal.* calcd. for $C_{31}H_{27}N_3O_9$: C 63.36, H 4.65, N 7.17; found: C 63.16, H 4.43, N 6.99.

*Methyl 5-Methyl-1-(β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (26)*

The tri-*O*-benzoyl derivative **20***a* (900 mg, 1.54 mmol) was suspended in dry methanol (30 mL). A solution of sodium methoxide (2 mL of a 1.0 *N* solution) was added to this suspension and the mixture heated at reflux temperature for 5 min. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

solution was cooled to room temperature and Dowex 50 (H^+ form, prewashed with methanol) was then added, portionwise (about 1 mL required), until the "pH" was ca. 5. The resin was removed by filtration and washed with methanol (4 mL). The supernatant was concentrated *in vacuo* and the residue triturated with diethyl ether (3 × 20 mL) to remove methyl benzoate. The remaining residue was recrystallized from ethyl acetate (8 mL) to yield pure **26**, 185 mg (44%), mp 125–127°C. *Anal.* calcd. for $C_{10}H_{25}N_3O_6$: C 43.96, H 5.53, N 15.38; found: C 43.77, H 5.56, N 15.45.

*Methyl 5-Azidomethyl-1-(2,3,5-tri-*O*-benzoyl- β-*D*-ribofuranosyl)-*v*-triazole-4-carboxylate (**20**b)*

Powdered sodium azide (1.0 g, dried 18 h/25°C/0.1 Torr) was added to a stirred solution of the chloromethyl derivative **17** (3.2 g, 5.16 mmol) in dry DMF (20 mL) and stirring was continued for an additional 4 h at 25°C. Thin layer chromatography (SSA) indicated that the reaction was probably complete at this time since the grey-black spot of starting material had been replaced by a yellow-orange spot with the same R_f (detection: 10% sulfuric acid, 110°C). The mixture was stirred an additional 1.5 h at 70°C, allowed to stand at room temperature without stirring for 18 h, and then evaporated to dryness. The residue was dissolved in ethyl acetate (50 mL) and washed with saturated brine, dried, and evaporated to dryness to yield 2.82 g (88%) of a yellow syrup. The syrup was chromatographed using SSA (silica gel column, 5 cm × 35 cm) with 23 mL fractions being collected. Fraction 17 contained a single spot (630 mg) and was used to obtain an analytical sample as a pale yellow foam. Fractions 16, 18–23 were combined (to yield 1.14 g) and were nearly as pure as fraction 17. However, these combined fractions did contain a trace of a slower moving spot. *Anal.* calcd. for $C_{31}H_{26}N_6O_9$: C 59.42, H 4.18, N 13.41; found: C 59.60, H 4.27, N 13.17.

*Methyl 1-(2,3,5-Tri-*O*-benzoyl-β-*D*-ribofuranosyl)-5-carboxy-*v*-triazole-4-carboxylate (**21**)*

Methyl 5-hydroxymethyl-1-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-*v*-triazole-4-carboxylate (**14**, 1.5 g, 2.5 mmol) was dissolved in acetone (120 mL). This solution was stirred and cooled at 10–15°C while 2.5 mL of Jones reagent (35) was added over a period of 2 h. A small amount of the aldehyde intermediate (**18**) could still be detected so the solution was cooled to 0°C and an additional 0.2 mL of Jones reagent was added and the mixture stirred for another hour at 0°C. Isopropanol (0.5 mL) was then added and stirring was continued until the yellow color of dichromate ion was discharged (about 1 min). Water (150 mL) was added and then the solution was concentrated (25°C) to ca. 150 mL. The product was isolated by extraction with ether (3 × 100 mL). The extracts were combined and washed in succession with 0.1 *N* aqueous hydrochloric acid (2 × 40 mL), water (2 × 40 mL), and then saturated brine (2 × 40 mL). This solution was dried and then evaporated to give a green colored gum. This gum was triturated with 49:1 water – acetic acid (400 mL, v/v) to give a powdery solid. Repetition of this procedure using 97:3 water – acetic acid (400 mL, v/v) furnished 1.34 g (87%) of a white powder. The pmr spectra (see Table 1) of crude and chromatographed samples showed considerable line broadening suggesting the presence of some inorganic (Mn^{2+}) ion. The ir spectrum ($CHCl_3$ smear) displayed a moderate absorption at 2638 cm^{-1} indicating the presence of a carboxylic acid group (OH bonded). This product was not characterized but used without further purification for decarboxylation.

*Ethyl 1-(2,3,5-Tri-*O*-benzoyl-β-*D*-ribofuranosyl)-*v*-triazole-4-carboxylate (**24**b) and Methyl 1-(2,3,5-Tri-*O*-benzoyl-β-*D*-ribofuranosyl)-*v*-triazole-4-carboxylate (**24**a)*

The crude carboxylic acid (**21**, 1.0 g, 1.63 mmol) was dissolved in toluene (50 mL) and heated at reflux temperature for 26 h. The solution was filtered and the filtrate was evaporated to afford a solid residue. This solid was triturated with ethanol (7 mL) and then collected by filtration to afford 602 mg (64.8%) of **24***b*; mp 171–174°C. One recrystallization from ethanol (30 mL) gave pure **24***b* (518 mg); mp 175–176.5°C. *Anal.* calcd. for $C_{31}H_{27}N_3O_9$: C 63.58, H 4.65, N 7.18; found: C 63.30, H 4.60, N 7.22.

Decarboxylation was carried out on a 1.0 g (1.63 mmol) sample of crude **21**. However, the product from this reaction was recrystallized from methanol (50 mL) to give 602 mg (64.8%) of **24***a* as white crystals; mp 191–193.5°C (lit. (17) mp 195°C). Further recrystallization from methanol did not raise the mp; $[\alpha]_D^{25°}$ −74.3° (*c* 1.0, $CHCl_3$) (lit. (17) $[\alpha]_D$ −73.7° (*c* 0.55, $CHCl_3$)); $[\alpha]_D^{25°}$ −58.7° (*c* 1.0, DMSO). The pmr spectral data (Table 1) was nearly identical to that previously reported (17) for **24***a*. *Anal.* calcd. for $C_{30}H_{25}N_3O_9$: C 63.04, H 4.41, N 7.35; found: C 63.06, H 4.54, N 7.25.

*Methyl 1-(β-D-Ribofuranosyl)-v-triazole-4-carboxylate (**25**)*

The tri-*O*-benzoyl derivative **24***a* (493.8 mg, 0.864 mmol) was deblocked with sodium methoxide and methanol using the same procedure as used for the preparation of **26**. The crude product weighed 200 mg (89%) and had a mp of 147–150°C. Recrystallization from ethyl acetate (10 mL) containing a few drops of methanol gave a pure product in the form of white needles, 164 mg (73%); mp 150–151.5°C (lit (37) mp 151–153°C); $[\alpha]_D^{25°}$ −80.5°. *Anal.* calcd. for $C_9H_{13}N_3O_6$: C 41.79, H 5.07, N 16.22; found: C 41.89, H 5.13, N 16.39.

Acknowledgements

The authors wish to thank Drs. C. Whitehead, A. F. Lewis, B. Clough, and J. Kobe for their many useful discussions and suggestions. Indeed, we are particularly indebted to Dr. J. Kobe for his patience and assistance in setting up the nOe experiments. We gratefully acknowledge the support of the NCI for research contract NCI-CM-77142 which supported this work.

A mild, general preparation of *N*-acyl aziridines and 2-substituted 4(*S*)-benzyloxazolines

GORDON S. BATES[1] AND MICHAEL A. VARELAS[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received July 2, 1980

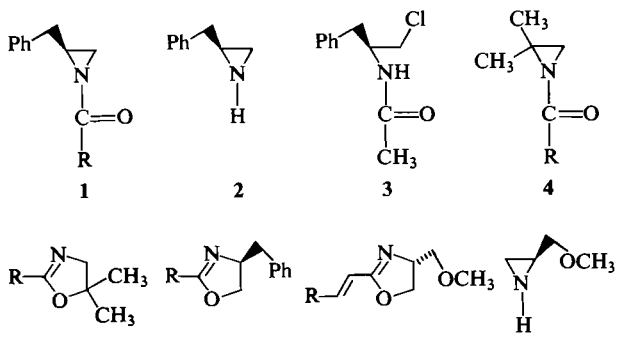
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

GORDON S. BATES and MICHAEL A. VARELAS. Can. J. Chem. **58**, 2562 (1980).

The conversion of a wide range of carboxylic acids into their acyl imidazolides with subsequent addition of an aziridine rapidly gives a quantitative yield of the corresponding *N*-acyl aziridines.

Iodide (or bromide) ion catalysed rearrangement of *N*-acyl 2(*S*)-benzylaziridines **1** to oxazolines **6** proceeds quantitatively.

GORDON S. BATES et MICHAEL A. VARELAS. Can. J. Chem. **58**, 2562 (1980).



La transformation d'une grande variété d'acides carboxyliques en leurs dérivés imidazolures d'acyles, suivie de l'addition d'une aziridine, donne rapidement et quantitativement les *N*-acyl-aziridines correspondantes. L'ion iodure (ou bromure) catalyse la transposition des *N*-acyl-*S*-benzyl-2 aziridines **1** en oxazolines **6** avec un rendement quantitatif.

[Traduit par le journal]

In connection with another project in our laboratory, we required a convenient, high yielding synthesis of a variety of *N*-acyl 2(*S*)-benzylaziridines (**1**). The reaction of an aziridine with a ketene or an acyl halide (1) and, more recently, condensation with a carboxylic acid in the presence of dicyclohexylcarbodiimide (2) are routes to the formation of *N*-acyl aziridines. However, the lack of generality, potential racemization of centres located α to the carbonyl of the acyl group, and the sluggishness of the reaction in the case of the carbodiimide coupling process are among the drawbacks to the synthetic utility of these existing methods.

We observed while carrying out preliminary investigations of the reaction between the sodium salt of 2(*S*)-benzylaziridine (**2**) and various acetylating agents that in contrast to reactions with acetic anhydride, which cleanly yielded the expected *N*-acetyl aziridine (**1**, R = CH_3), reaction of this salt with acetyl chloride gave a mixture of chlorine-containing compounds. This latter material, which consisted mainly of compound **3**, is presumably derived from nucleophilic opening by chloride of the initially formed *N*-acetyl aziridine. A compound which is at least as reactive as an anhydride but which possesses an essentially neutral, and thus poorly nucleophilic, leaving group appeared to be the desired general acylating reagent. Acyl imidazolides ideally fit both criteria and in addition are readily available from carboxylic acids.

We wish to report that conversion of a carboxylic acid into its acyl imidazolide (3) using 1,1′-carbonyldiimidazole with subsequent addition of one equivalent of an aziridine rapidly gives a quantitative yield of the corresponding *N*-acyl aziridine. This route is general and is applicable to very hindered carboxylic acids as well as to systems for which the acyl chloride is very unstable (e.g. formyl). As mentioned above, our main interest involved derivatives of aziridine **2**. This compound, which is stable for months when stored on a few pellets of potassium hydroxide in a refrigerator, was prepared by a Wenker cyclization (4) of 2(*S*)-amino-3-phenylpropan-1-ol (5). Formation of the desired *N*-acyl aziridines (**1**) proceeded rapidly and quantitatively with a wide variety of carboxylic acids (see Table 1). This method is also applicable to other aziridines. For instance, a quantitative condensation has been carried out between 2,2-dimethylaziridine (6) and the acyl imidazolides of the following carboxylic acids: acetic, propionic, isobutyric, pivalic, and nicotinic. The resulting acyl aziridines **4** may be cleanly rearranged in good yields under acidic conditions to oxazolines **5** using existing methods (2). This new technique is, however, superior to the carbodiimide coupling process

TABLE 1. Optical rotations for compounds **1** and **6**[a,b]

R	$[\alpha]_D^{24}$ ($c \sim 2.0$, $CHCl_3$)	
	Acyl aziridine **1**	Oxazoline **6**
H-	+22.0	−89.4
CH_3-	+59.7	−50.7
C_2H_5-	+61.3	−37.0
$(CH_3)_2CH$-	+66.4	−34.2
$(CH_3)_3C$-	+96.2	−38.2
c-C_6H_{11}-	+39.8	−13.0
C_6H_5-	+49.4	+4.7
3-Pyridyl-	+69.2	−4.3
E-C_3H_5-	+84.6	−52.5
E,E-C_5H_7-	+68.4	−51.8

[a]All compounds had ^{1}H nmr, ir, elemental analysis, and exact parent mass spectrum measurements fully consistent with the proposed structures.
[b]All compounds were formed in >98% yield from the carboxylic acid.

(2) mentioned above, being both faster (2 h vs. 16 h) and higher yielding (100% vs. 50% in the case of the nicotinic derivative).

Our initial observations of a chloride-promoted isomerization suggested that the well-known rearrangement of certain *N*-acyl aziridines (7) should also be possible with the benzylaziridine system **1**. If compound **1** could be isomerized to the corresponding oxazoline **6**, one would have a useful protecting group for carboxylic acids which incorporates a chromophore for use as a chromatographic marker. In addition to many other potential applications (8), such a system may also be useful as a resolving agent for racemic modifications of chiral carboxylic acids (9). Indeed, we found that a quantitative isomerization to the desired oxazoline could be achieved by briefly refluxing a solution of the acyl aziridine in the presence of a catalytic amount of tetrabutylammonium iodide (10) or bromide.

Although the method described above may not be used *directly* for crotonic acid derivatives, since reaction of crotonic acid with 1,1′-carbonyldiimidazole yields a mixture whose ^{1}Hmr spectrum is consistent with the main product being 3-(1-imidazole)-butanoyl imidazolide, the route may be adapted to such compounds. Reaction of crotonyl chloride with one equivalent of **2** at low temperature in the presence of triethylamine gave the *N*-crotonyl aziridine which could be smoothly rearranged to the corresponding oxazoline with no loss of stereochemistry in the side chain. This transformation is important in light of a recent report (11) of the use of chiral oxazolines **7** in the synthesis of highly optically active (~96% ee) 3-substituted alkanoic acids. Since the methodology described in the present paper appears to be general, and as *O*-methyl serine is available in optically pure form (12), we propose our route as a convenient alternative synthesis of compounds **7** via aziridine **8**.

Other workers have shown that hydrolysis of oxazolines to the carboxylic acids (esters) proceeds with little exchange of any protons α to the carboxyl function (13). We have prepared α-deuterated *iso*-butyric acid by repeated quenching of the dianion of this acid with D_2O. A level of 95% deuterium incorporation was achieved after three treatments. The labelled acid was then converted into its chiral oxazoline using the imidazolide route. Mass spectral and ^{1}Hmr measurements showed no loss of deuterium in the product. Thus, the method described in this paper is suitable even for protection of chiral carboxylic acids containing an epimerizable centre since there is little potential for loss of chirality at centres located α to the carbonyl of the original acyl group. The 2(*S*)-amino-3-phenylpropan-1-ol obtained after acidic hydrolysis (13) of oxazolines **6** may be recovered (ca. 85%) and used for recycling to aziridine **2**. There is no difference in the specific rotation of this recovered material and that of the original amino alcohol.

The overall transformation of a carboxylic acid into oxazoline **6** may thus be conveniently carried out in a few hours in a "one pot" reaction to provide an essentially pure product in almost quantitative yield. A variety of solvents including tetrahydrofuran, chloroform, and benzene may be used for the reaction with no change in the yield.

Experimental

General

All reactions were carried out under a nitrogen or argon atmosphere. Stirring was accomplished using Teflon-coated magnetic stirring bars. Tetrahydrofuran was freshly distilled from sodium benzophenone ketyl under a nitrogen atmosphere. All reagents were obtained from the Aldrich Chemical Company, Inc. and were used without further purification.

Melting points were taken on a Gallenkamp melting point apparatus and are uncorrected. Proton magnetic resonance spectra were obtained on Varian Associates T-60 and HA-100 spectrometers. Spectra were run in deuteriochloroform solution with tetramethylsilane as an internal reference. The multiplicity, integrated peak area, and coupling constants (Hz) (if observable) are indicated in parentheses after each signal. Infrared spectra were recorded in chloroform solution using a Perkin-Elmer 700 spectrometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. High resolution mass spectra were obtained using an AEI MS-50 mass spectrometer. Specific rotations were obtained in chloroform solution unless otherwise stated and were determined using a Perkin-Elmer 241 MC polarimeter which was calibrated using a standardized sucrose solution. Elemental analyses were performed at the Microanalytical Laboratory, University of British Columbia.

The following abbreviations are used: THF = tetrahydrofu-

ran, Et = C_2H_5, EtOAc = ethyl acetate, EtOH = ethanol, Et_2O = ethyl ether, b = broad, s = singlet, d = doublet, t = triplet, q = quartet, s = septet, m = multiplet.

2(S)-Amino-3-phenylpropan-1-ol

To a solution of 33.0 g (200 mmol) of L-phenylalanine ($[\alpha]_D^{24}$ −34.7, *c* 1.9 H_2O) dissolved in 800 mL of absolute EtOH was slowly added 32.7 g (275 mmol) of $SOCl_2$. The solution was then refluxed for 4 h. The reaction mixture was cooled to room temperature and the solvent and excess $SOCl_2$ were then evaporated. The crude ethyl ester hydrochloride was dissolved in 500 mL of 50% aqueous EtOH and added slowly (initial hydrogen evolution) to 37.8 g (1.0 mol) of $NaBH_4$ dissolved in 500 mL of 50% aqueous EtOH. The reaction mixture was then refluxed for 4 h, cooled to room temperature, and the bulk of the EtOH evaporated. The residual aqueous phase was saturated with solid NaCl and extracted with 3 × 500 mL of EtOAc. Occasionally a precipitate of borate ester was observed. Hydrolysis of this ester with aqueous 2 *N* NaOH released the amino alcohol. The aqueous mixture was extracted with additional EtOAc and this extract was combined with the bulk extract above. The organic phase was dried over anhydrous $MgSO_4$ and evaporated to yield 29 g (96%) of essentially pure 2(*S*)-amino-3-phenylpropan-1-ol. Recrystallization from EtOAc–hexane yielded fine white needles, mp 89–91°C; ^{1}Hmr δ: 2.20 (bs, ca. 3), 2.46 (dd, 1, *J* = 8.0, 16.0), 2.75 (dd, 1, *J* = 5.0, 16.0), 2.95–3.20 (m, 1), 3.21–3.50 (m, 1), 3.60 (dd, 1, *J* = 4.0. 12.0), 7.20 (m, 5); $[\alpha]_D^{24}$ −25.8 (*c* 2.2); *Anal.* calcd. for $C_9H_{13}NO$ (151.21): C 71.49, H 8.67, N 9.26; found: C 71.59, H 8.82, N 9.12. *Mol. Wt.* calcd. for $C_9H_{13}NO$: 151.0997; found: 151.0999.

2(S)-Benzylaziridine **2**

A solution of 15.1 g (10.0 mmol) of 2(*S*)-amino-3-phenylpropan-1-ol in 6.0 mL (12 mmol) of aqueous 2 *M* H_2SO_4 was evaporated on a rotary evaporator (50°C, 10 Torr). The salt was then heated at 140°C for 3 h at 0.1 Torr to complete formation of the hydrogen sulphate. The reaction mixture was cooled to room temperature and 25 mL (50 mmol) of aqueous 2 *N* NaOH was added to the crude hydrogen sulphate. The mixture was then distilled at atmospheric pressure. The distillate was collected in an ice-cooled flask containing 50 mL of Et_2O and a few mL of aqueous 2 *N* NaOH. A little water was occasionally added to the distillation flask whenever the residue began to crystallize. When the distillate no longer had a milky appearance, the Et_2O was separated and the aqueous phase was saturated with solid NaCl. The aqueous phase was extracted with 3 × 50 mL of Et_2O. The combined Et_2O extract was dried over anhydrous $MgSO_4$ and evaporated. The residue was subjected to a Kugelrohr distillation (air bath 80°C, 1 Torr) from a pellet of NaOH to yield 9.5 g (73%) of colourless aziridine. The product was stored on a few pellets of KOH in a refrigerator; ir: 3350 cm^{-1}; ^{1}Hmr δ: 1.38 (d, 1, *J* = 3.5), 1.75 (d, 1, *J* = 6.0), 2.04–2.30 (m, 1), 2.62 (dd, 1, *J* = 15.0, 5.0), 2.78 (dd, 1, *J* = 15.0, 6.0), 7.25 (s, 5); $[\alpha]_D^{24}$ −9.8 (*c* 1.95); *Anal.* calcd. for $C_9H_{11}N$ (133.20): C 81.16, H 8.32, N 10.52; found: C 81.11, H 8.45, N 10.22. *Mol. Wt.* calcd. for $C_9H_{11}N$: 133.0891; found: 133.0888.

Acetylation of the Sodium Salt of 2(S)-Benzylaziridine
With Acetic Anhydride

To a suspension of 24 mg (1 mmol) of pentane-washed NaH in 2 mL of THF was added 133 mg (1 mmol) of aziridine **2**. After 10 min at room temperature, 102 mg (1 mmol) of acetic anhydride was added and the reaction mixture was stirred at room temperature for 1 h. The reaction mixture was then poured into Et_2O and washed with H_2O. The Et_2O layer was dried with anhydrous $MgSO_4$ and evaporated to yield 170 mg (97%) of (+)-1-(acetyl)-2(*S*)-benzylaziridine. The spectral data of this compound are described below and are identical to those of the compound prepared via the imidazolide route.

With Acetyl Chloride

A procedure identical to the above was carried out except that acetyl chloride was substituted for acetic anhydride. Workup of the reaction yielded a mixture of several compounds, none of which was the *N*-acetyl aziridine isolated above. Purification of the mixture by thin-layer chromatography yielded the major component (ca. 50%) of the mixture which was identified as compound **3**; ir: 1660 cm^{-1}; ^{1}Hmr δ: 1.90 (s, 3), 2.90 (d, 2, *J* = 8.0), 3.45 (dd, 1, *J* = 4.0, 11.0), 3.58 (dd, 1, *J* = 5.0, 11.0), 4.1–4.6 (m, 1), 5.6–6.0 (bs, 1), 7.25 (s, 5); $[\alpha]_D^{25}$ 3.86 (*c* 1.2); *Anal.* calcd. for $C_{11}H_{14}NOCl$ (211.70): C 62.41, H 6.67, N 6.62, Cl 16.75; found: C 62.13, H 6.50, N 6.44, Cl 16.54. *Mol. Wt.* calcd. for $C_{11}H_{14}NOCl^{35}$: 211.0764; found: 211. 0777.

General Procedure for Preparation of Compounds 1 and 6

To a solution of 10 mmol of carboxylic acid in 10 mL of THF was added 1.62 g (10 mmol) of 1,1′-carbonyldiimidazole in several portions over 5 min. The solution was stirred at room temperature for 30 min (2 h for hindered carboxylic acids) and then 10 mmol of **2** was added. The reaction mixture was then stirred at room temperature for an additional 1 h (2 h for hindered acyl imidazolides). If the *N*-acyl aziridine was the desired product, the reaction mixture was then diluted with Et_2O and the mixture washed with H_2O to remove imidazole. The organic phase was dried over anhydrous $MgSO_4$ and evaporated to yield the *N*-acyl aziridine. If the chiral oxazoline was the desired product, then ca. 180 mg (0.5 mmol) of tetrabutylammonium iodide (or bromide) was added to the *N*-acyl aziridine – imidazole mixture and the reaction mixture was refluxed for 2.5 h. After the reaction mixture had been cooled to room temperature, it was diluted with Et_2O and washed with H_2O. The solvent was dried over anhydrous $MgSO_4$ and was evaporated to provide a 100% yield of material which was generally >98% pure by gas–liquid chromatographic analysis.

Preparation of N-*Acyl-2,2-dimethylaziridines* **4**

A similar procedure as is described above for the preparation of compounds **1** was used. 2,2-Dimethylaziridine, which was used in place of **2**, was prepared according to the method described in ref. 6. It is not necessary to break the reaction flask containing the crude hydrogen sulphate; aqueous NaOH may be added directly to the reaction flask in a similar manner to that described above for the preparation of **2**.

α-*Deuterio-*iso-*butyric Acid*

To a mixture of 176 mg (2 mmol) of freshly distilled *iso*-butyric acid and 202 mg (2 mmol) of diisopropylamine in 10 mL of THF was added 3.0 mL (4 mmol) of 1.34 *M n*-butyllithium at −78°C. The reaction was stirred for 30 min at −78°C and was then quenched with 1 *N* DCl in D_2O. The deuterated acid was isolated by a standard workup and the above procedure repeated twice more on the same sample of acid. The ^{1}Hmr and mass spectra of the deuterated *iso*-butyric acid showed a deuterium incorporation level of 95%.

This acid was converted into the chiral oxazoline using the procedure given above. The ^{1}Hmr and mass spectra of the deuterated oxazoline showed a deuterium incorporation level of 93%.

SUZANNE R. MACAULAY. Can. J. Chem. **58**, 2567 (1980).

Isomerization of straight chain decyn-1-ols mediated by the sodium salt of 1,3-diaminopropane was studied as a function of time, temperature, and the initial position of the triple bond. At 50°C 9-decyn-1-ol, the thermodynamically favoured isomer, was formed rapidly regardless of the initial position of the triple bond. At lower temperatures the appearance of intermediate isomers was observed. The homopropargylic isomer was found to be remarkably stable, and under suitable conditions, conversion of 2- to 3-decyn-1-ol was carried out in 68% isolated yield.

SUZANNE R. MACAULAY. Can. J. Chem. **58**, 2567 (1980).

On a étudié l'isomérisation des décynols-1 à chaîne linéaire en présence d'un sel de sodium du diamino-1,3 propane, en fonction du temps, de la température et de la position initiale de la triple liaison. A 50°C, l'isomère thermodynamiquement favorisé, le décyn-9 ol-1, se forme rapidement indépendamment de la position de la triple liaison. A des températures plus basses on observe la formation d'un isomère intermédiaire. On a trouvé que l'isomère homopropargylique est remarquablement stable et dans des conditions convenables la transformation du décyn-2 ol-1 en décyn-3 ol-1 se fait avec un rendement de 68%.

Introduction

Since Favorskii's accidental discovery of an acetylene isomerization nearly a century ago (1), base mediated rearrangements of alkynes have been studied extensively (2, 3). Straight chain hydrocarbons containing one triple bond are rearranged by a wide variety of bases generating mixtures of isomeric allenes and acetylenes. In the generally accepted mechanism the base is thought to abstract a proton from a carbon next to the triple bond to give an anion which may be protonated to yield an isomeric allene. Further reversible 1,3-proton shifts lead to new alkynes and allenes. The proportion of products obtained reflects the relative thermodynamic stabilities of the components.

It has been suggested that in cases where the base is the salt of a diamine such as ethylenediamine (4) or 1,3-diaminopropane (5), the base may be able to abstract and donate a proton in a cyclic fashion (Scheme 1). In this postulated mechanism the proton shifts take place without discrete carbanionic intermediates.

Until recently, application of base mediated alkyne isomerizations in synthetic organic chemistry has been limited to a few special cases in which the triple bond is moved to an adjacent position and in which the difference in thermodynamic stability between the starting material and product is marked. For instance, 2-alkynes are significantly more stable than 1-alkynes (2) and several systems have been used to transform the latter into the former (6, 7). The reverse process, which depends upon formation and precipitation from solution of an acetylide salt has also been carried out in good yield (8, 9).

SCHEME 1

The discovery of the "acetylenic zipper" reaction has widened the scope of base mediated alkyne isomerizations (5, 10–12). Using a very strong base, the potassium salt of 1,3-diaminopropane (DAP) in DAP, the migration of a triple bond more than ten carbons along a straight chain has been effected. The product, the salt of the terminal acetylene, is thought to form irreversibly and is obtained in high yield and purity. The reaction is exceptional in that it provides a direct route to terminal acetylenes and acetylenic alcohols which are extremely useful intermediates in the synthesis of many natural products including ω-hydroxy fatty acids and insect pheromones.

In recent work we have modified this reaction to make it safer and more convenient by developing a reagent in which potassium hydride is replaced by

sodium hydride (13). Our reagent, sodium aminopropylamide (NaAPA), has been shown to isomerize alkynes[2] and alkyn-1-ols (13) with internal triple bonds to the corresponding terminal acetylenes in good yield. As would be expected, slightly higher temperatures and longer reaction times are required. The present study was undertaken to investigate some of the factors which affect the rate and course of acetylene rearrangements with our modified system.

Results

The system chosen for study was the decyn-1-ol series, as this set of positional isomers is sufficiently large that isolation of acetylenic intermediates from the rearrangement reactions should yield diagnostic information on the course of the isomerizations. All eight isomeric decyn-1-ols were prepared by known procedures, and mixtures of the alkyn-1-ols, as their trimethylsilylethers, were found to be readily resolved using glc (see Experimental). The rearrangements of 2-decyn-1-ol, the isomer with the triple bond furthest removed from the unsubstituted terminus, and 5-decyn-1-ol, the isomer with the acetylenic linkage at an intermediate position in the chain, were followed at several different temperatures.

All isomerizations were performed in the same manner. The reagent was prepared by reaction of sodium hydride with 1,3-diaminopropane, the solvent of the reaction, at 70°C for one hour. After cooling to the desired temperature (50, 0, or −15°C), the substrate in DAP was added, and after the required time reactions were quenched with water. The isolated derivatized product mixtures were analyzed by glc and in every case a minimum of 96% of total peak area was attributable to decyn-1-ols. The same ratio of products was observed on workup of whole reaction mixtures as with aliquots removed from reactions. Results are displayed graphically in Figs 1 to 5. Tabulated data may be obtained from the Depository of Unpublished Data.[3]

The reactions at 50°C show several interesting features. As can be seen from Fig. 1, isomerization of 2-decyn-1-ol results in rapid production of 9-decyn-1-ol, with concomitant decay of the starting material. The terminal acetylene comprises 50% of the mixture in 0.25 h and rises to slightly over 70% of the total decyn-1-ol composition after 2 h. All possible decyn-1-ols are present; those with the triple bond in the 4, 5, 6, 7, or 8 position are formed only in small amounts and level off at about three percent each as the proportion of 9-decyn-1-ol grows. The homopropargylic isomer, 3-decyn-1-ol, rises to 18% of the total mixture by 0.25 h and then decreases to about 8% in the later stages of the

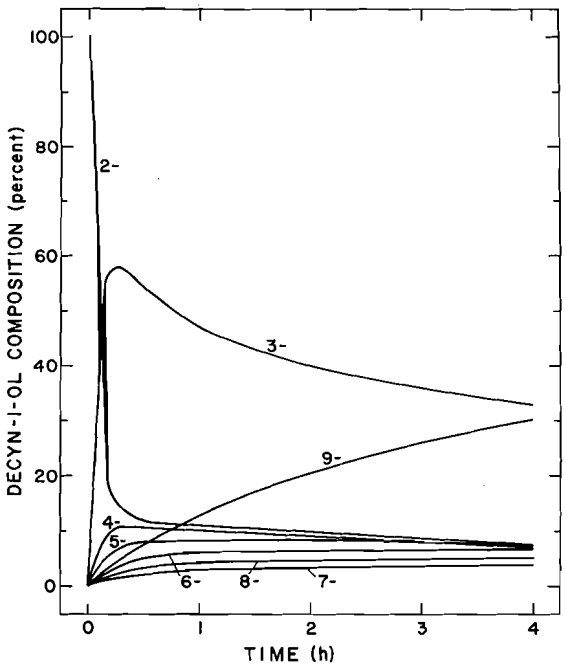

FIG. 3. Isomerization of 2-decyn-1-ol with NaAPA at 0°C.

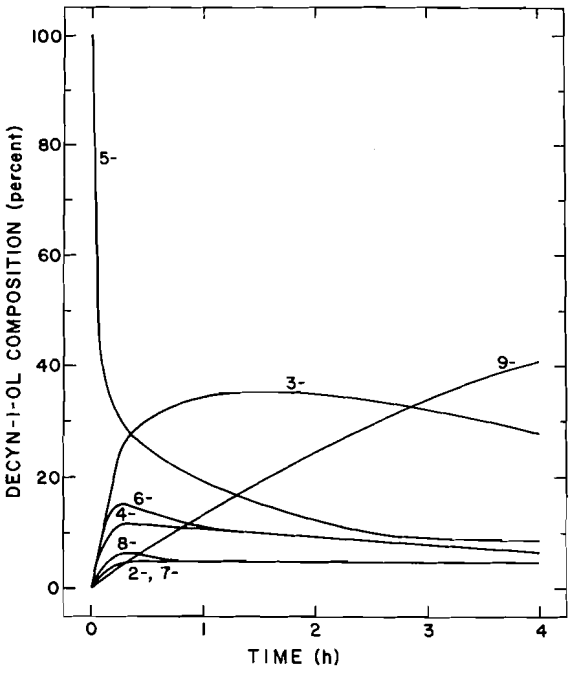

FIG. 4. Isomerization of 5-decyn-1-ol with NaAPA at 0°C.

reaction. The relative proportions of the products change only slightly after 2 h. It is interesting to compare the results obtained for the isomerization of 5-decyn-1-ol (Fig. 2) at the same temperature. The curves are virtually superimposable after 0.25 h reaction time. The terminal acetylene is

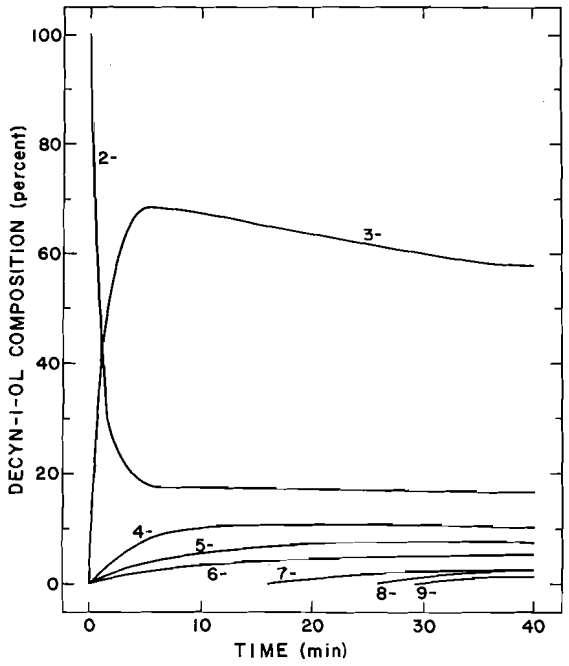

FIG. 5. Isomerization of 2-decyn-1-ol with NaAPA at −15°C.

formed rapidly and 3-decyn-1-ol comprises 20% of the mixture after 0.25 h. The remaining isomers again are formed in relatively low amounts.

The product distribution with time found in the isomerization of 2-decyn-1-ol at 0°C (Fig. 3) shows some similarity to that at 50°C. The relative proportion of terminal acetylene increases steadily, although at a slower rate, and the other isomers, except for the homopropargylic compound, again are present only in small amounts. In contrast, 3-decyn-1-ol is formed to the extent of 58% by 0.25 h. In the reaction of 5-decyn-1-ol at 0°C (Fig. 4) the proportion of starting material does not decrease quite as sharply as in the former cases. The terminal isomer is seen to increase gradually, and the homopropargylic isomer again rises to a higher concentration than do the other internal alkynes.

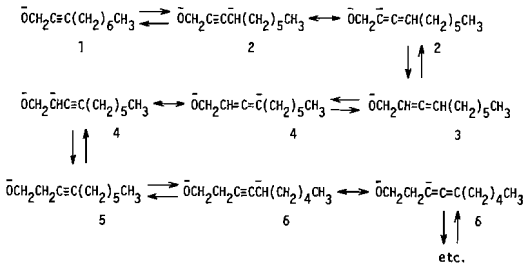
The rearrangement of 2-decyn-1-ol with NaAPA was carried out just above the freezing point of the mixture, at −15°C, and the reaction was followed at shorter time intervals (Fig. 5). In this case the 3-decyn-1-ols component comprised 68% of the total decyn-1-ols after 5 min, and the composition of the system showed little further change after about 0.5 h.

The rearrangement of 2-decyn-1-ol with NaAPA at −15°C was allowed to proceed for 5 min before quenching; 3-decyn-1-ol was isolated in 68% yield, based upon recovered starting material (54% conversion). Quenching of a similar reaction with

deuterium oxide after the same length of time resulted in no detectable deuterium incorporation in either the isolated product, 3-decyn-1-ol, or in the recovered starting material, 2-decyn-1-ol.

The stability of the terminal 9-decyn-1-ol to the reaction conditions was tested at 50 and 0°C. At the lower temperature no rearrangement was observed after 4 h, but at 50°C after the same length of time, the mixture was composed of 96.4% 9-decyn-1-ol, 1.5% 8-decyn-1-ol, and 2.1% unidentified material.

No allenes or dienes were observed by infrared or proton nmr spectroscopy in any of the product mixtures. No acidic products were detected.



Discussion

At 50°C the reactions of both 2- and 5-decyn-1-ol with NaAPA proceed to give good yields of 9-decyn-1-ol. After about two hours the system appears to reach equilibrium, with both starting materials giving the same distribution of products. At 0°C, however, 9-decyn-1-ol is formed only slowly and after four hours makes up less than half of the total decyn-1-ol mixture. For synthetic purposes raising the temperature is more efficient in driving the reaction to completion than is allowing the isomerization to proceed for a long time. This appears to be so even though the terminal alkyne is not formed irreversibly at the higher temperature.

Our results support the "random walk" mechanism first proposed by Brown and Yamashita (5) for the "acetylenic zipper" reaction. The products from the reaction of 5-decyn-1-ol with NaAPA include alkynes resulting from the migration of the triple bond toward both the oxygen substituted and unsubstituted end of the carbon chain. Although all of the products isolated were acetylenic, the intermediacy of allenes cannot be discounted, and the present results are consistent with the general mechanism in which a series of reversible 1,3-proton shifts effect the migration of the triple bond along the methylene chain.

The most striking finding of this work is the exceptional stability of 3-decyn-1-ol. The homopropargylic isomer was formed in significant proportions in all of the rearrangement reactions studied including those where the triple bond of the starting material was closer to the unsubstituted terminus. This reaction is of synthetic utility; the propargylic isomer was converted to 3-decyn-1-ol in 68% isolated yield.

Scheme 2 shows the possible alkoxides that may be present in the isomerization of 2- to 3-decyn-1-ol with NaAPA. If discrete carbanions are involved then structures **1** through **6** will be intermediates. If, however, the cyclic mechanism is operative then

SCHEME 2

only **1**, **3**, and **5** need be present. Protonation of **1** and **2** would give 2-decyn-1-ol, and of **4**, **5**, and **6** would give 3-decyn-1-ol. The deuterium oxide quenching of the isomerization mixture with 2-decyn-1-ol as the starting material resulted in no detectable incorporation of deuterium into the recovered starting material or into the 3-decyn-1-ol that was produced. This result leads to the conclusion that the predominant species in solution are **1** and **5** and that the anions **2**, **4**, and **6** are not present in large amounts. Either the protonation of the intermediate anions by the solvent of the reaction is rapid so that **2**, **4**, and **6** do not accumulate, or the 1,3 proton shifts take place via the cyclic pathway. As no allenes were found, **3** also must be a minor component.

The extra stability of Δ-3 isomers has been observed previously by other workers in the cases of ethers (14), acetals (15), and acids (16), but the phenomenon is not yet understood.

Further work is being carried out to exploit the synthetic usefulness of the propargyl to homopropargyl transformation, and to investigate the nature of the stability of the Δ-3 isomer.

Experimental

The ^1H nmr spectra were recorded on an HA-100 spectrometer using deuterochloroform with internal tetramethylsilane as reference. The ^{13}C nmr spectra were obtained using an XL-100-15 instrument in the Fourier Transform mode at 25.16 MHz with proton noise decoupling. Deuterochloroform was used as solvent and also provided the internal deuterium lock. Gas chromatographic separations were carried out on a Finnigan 9500 instrument with an SP 2100 capillary column (J and W Scientific, 30 m) with a flame ionization detector, and were run isothermally at 120°C. Mass spectra were recorded on a Finnigan 4000E gc/ms instrument with an Incos 2300 data system, using the same column.

All reactions were performed in flame dried glassware and were carried out under a slight positive pressure of dry nitrogen.

Five of the decyn-1-ols, 2-, 3-, 5-, 7-, and 9-decyn-1-ol, were donated by Dr. W. F. Steck, National Research Council.

4-Decyn-1-ol

According to the method of Struble and Swailes (17), to the tetrahydropyranyl ether of 5-hydroxypent-1-yne (3.36 g, 20 mmol) in dimethoxyethane (distilled from CaH_2, 25 mL) was added lithium amide (0.5 g, 20 mmol). After refluxing for 5 h, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

mixture was cooled and *n*-pentyl bromide (3.0 g, 20 mmol) was added. The reaction was refluxed overnight, then cooled, poured onto ice water, and extracted with ether (3×). The combined ethereal extracts were washed with NaCl solution, dried over Na_2SO_4, filtered, and evaporated to yield 4.65 g of crude product. The THP protecting group was removed by refluxing the product in methanol (100 mL) with a catalytic amount of *p*-toluenesulfonic acid for 4 h. Methanol was removed by distillation and the residue partitioned between ether and water. The ether layer was washed with $NaHCO_3$ solution, NaCl solution, and dried over Na_2SO_4. Evaporation of the solvent and distillation at 90–100°C (0.1 Torr) yielded 4-decyn-1-ol 1.8 g (58% yield); ir ν_{max} (neat film): 3450 cm^{-1}; ^1H nmr δ: 3.70 (t, J = 7 Hz, 2H, OCH_2), 2.0–2.4 (m, 4H, $CH_2C{\equiv}C$), 1.70 (m, 2H, $CH_2CH_2C{\equiv}C$), 1.36 (m, 6H, CH_2), 0.90 (t, 3H, CH_3); ^{13}C nmr δ: 79.33 and 80.90 (C4, C5), 61.71 (C1), 31.78 and 31.08 (C2 and C8), 28.79 (C7), 22.19 (C9), 18.68 (C6), 15.38 (C3), 13.92 (C10).

6-Decyn-1-ol

6-Decyn-1-ol was prepared in the same manner as 4-decyn-1-ol starting with the tetrahydropyranyl ether of 7-hydroxyhept-1-yne and *n*-propyl bromide. Distillation afforded 6-decyn-1-ol in 50% yield: bp 90–100°C (0.1 Torr); ir ν_{max} (neat film): 3450 cm^{-1}; ^1H nmr δ: 3.58 (t, J = 7 Hz, 2H, OCH_2), 2.0–2.3 (m, 4H, $CH_2C{\equiv}C$), 1.4–1.8 (CH_2, 8H), 0.94 (t, J = 6 Hz, 3H, CH_3); ^{13}C nmr δ: 80.32, 80.10 (C6, C7), 62.83 (C1), 32.33 (C2), 28.96 (C4), 25.03 (C3), 22.58 (C9), 20.80 (C5), 18.75 (C8), 13.47 (C10).

8-Decyn-1-ol

According to the method of Wojtkowiak and Romanet (6), the tetrahydropyranyl ether of 9-decyn-1-ol (6 g, 25 mmol) was dissolved in a solution of KOH in ethanol (4 *N*, 50 mL) and heated in a sealed metal container at 190°C for 1.5 h. Ethanol was removed by evaporation and the residue partitioned between ether and water. The aqueous phase was washed with ether (2×) and the combined ethereal phases were washed with water until neutral, dried over Na_2SO_4, filtered, and the solvent removed to yield a yellow oil that was treated with methanol and *p*-toluenesulfonic acid to remove the THP group. Distillation (100°C, 0.1 Torr) yielded 8-decyn-1-ol (3.0 g, 70% yield), glc indicated a purity of 92%, with no starting material; ir ν_{max} (neat film): 3350 cm^{-1}, no absorption between 2500–1500 cm^{-1}; ^1H nmr δ: 3.57 (t, J = 7 Hz, 2H, OCH_2), 2.1 (br m, $w_{1/2}$ = 15 Hz, 2H, $CH_2C{\equiv}C$), 1.75 (t, J = 2 Hz, 3H, $C{\equiv}C{-}CH_3$), 1.2–1.7 (m, 10H, CH_2); ^{13}C nmr δ: 79.18 (C8), 75.24 (C9), 62.40 (C1), 32.60 (C2), 28.97 (C6), 28.97 (C5), 28.79 (C4), 25.67 (C3), 18.63 (C7), 3.25 (C10).

Gas–Liquid Chromatographic Separation of the Isomeric Decyn-1-ols

The alcohols were converted to trimethylsilylethers with *N,O*-bis-(trimethylsilyl)acetamide. Retention times relative to the TMS ether of *n*-decanol present in each analysis were: *n*-decanol 1.00, 9-decyn-1-ol 1.07, 4-decyn-1-ol 1.09, 5-decyn-1-ol 1.14, 6-decyn-1-ol 1.16, 3-decyn-1-ol 1.20, 7-decyn-1-ol 1.22, 2-decyn-1-ol 1.29, and 8-decyn-1-ol 1.39.

The response factor for each isomer was determined to be 1.00 ± 0.05. The values obtained by integration were taken without correction.

Isomerization Reactions

Unless otherwise stated, the general procedure used in the isomerization reactions was as follows.

Sodium hydride (NaH, Ventron, 57% in mineral oil, 340 mg; 8 mmol) was placed in a flame dried 50 mL flask fitted with magnetic stirring bar and rubber septum through which a slight positive pressure of dry N_2 was maintained. The NaH was freed of mineral oil by 3 successive washes with petroleum ether. 1,3-Diaminopropane (DAP, corrosive! 6 mL, previously distilled at reduced pressure from BaO and stored over activated molecular sieves 4A) was added by syringe to the flask, and the mixture was stirred in a constant temperature oil bath set at 70 ± 2°C. After 1 h the resultant brown solution was cooled to the desired temperature: (*1*) 50°C, in the constant temperature oil bath; (*2*) 0°C, in an ice/water bath; or (*3*) −15°C in an ethylene glycol/Dry Ice bath. The substrate (304 mg, 2 mmol) in DAP (2 mL) was injected into the flask. At the desired time the reaction, or aliquot, was worked up by pouring the mixture into ice/water and extracting 3 times with ether. The combined ether phases were washed successively with water, HCl solution, water, NaCl solution, and water, then dried over Na_2SO_4, filtered, and the solvent evaporated.

Isomerization of 9-Decyn-1-ol at 0° and 50°C

9-Decyn-1-ol was subjected to the standard reaction conditions at 0°C. The glc analysis of aliquots removed at 0.25 h, 1 h, and 4 h showed no new peaks, only the starting 9-decyn-1-ol.

The preceding reaction was repeated at 50°C. After 4 h glc analysis indicated the mixture consisted of 96.4% 9-decyn-1-ol, 1.5% 8-decyn-1-ol, and 2.1% unidentified material.

Isomerization of 2-Decyn-1-ol at 0°C for 15 Minutes

The standard reaction was carried out with 2-decyn-1-ol. The crude mixture (270 mg) was chromatographed on silica gel (Bio Rad 200–400 mesh, 20 g, 2.5 × 10 cm) eluting with ether/hexane mixtures. A nonpolar fraction (30 mg) was obtained which appeared to consist of mineral oil. A polar fraction (220 mg, 72%) of decyn-1-ols was obtained with 50% ether, 50% hexane. The glc analysis showed the decyn-1-ol mixture to consist of 2- (13%), 3- (60%), 4- (10%), 5- (6%), 6- (4%), 7- (2%), 8- (3%), and 9- (2%): ir ν_{max} (neat film): 3350 cm^{-1} (br s); no absorption between 2600–1500 cm^{-1}.

Preparation of 3-Decyn-1-ol from 2-Decyn-1-ol

To the isomerization reagent (prepared from 680 mg, 16 mmol, NaH and 14 mL DAP; twice normal scale) at −15°C was added 2-decyn-1-ol (616 mg, 4 mmol) in DAP (2 mL). After 5 min the reaction was quenched and worked up as described above to give 650 mg of an oil that was chromatographed on a silica gel column (Bio-Rad 200–400 mesh) eluting with ether/hexane mixtures. Product was collected in 3 fractions: (*1*) recovered starting material 80 mg; (*2*) starting material and 3-decyn-1-ol (1:2) 120 mg; and (*3*) 3-decyn-1-ol 250 mg. The yield of 3-decyn-1-ol was 54%, 68% based on recovered starting material.

Deuterium Oxide Quenching of Isomerization of 2-Decyn-1-ol

The isomerization of 2- to 3-decyn-1-ol (2 mmol scale) at −15°C was repeated and the reaction quenched with D_2O (25 mL). Chromatography yielded pure fractions of 2-decyn-1-ol (40 mg) and 3-decyn-1-ol (100 mg).

Integration of ^1H nmr spectra of both compounds showed no observable deuterium incorporation at the carbons next to the triple bond; 2-decyn-1-ol δ: 4.20 (t, J = 2 Hz, 2H, OCH_2), 2.18 (t of t, J = 2 Hz, 7 Hz, 2H, $C{\equiv}CCH_2$), 1.2 to 1.6 (m, 10H, CH_2), 0.88 (t, J = 7 Hz, 3H, CH_3); 3-decyn-1-ol δ: 3.63 (t, J = 6 Hz, 2H, OCH_2), 2.38 (t of t, J = 2 Hz, 6 Hz, 2H, $OCH_2CH_2C{\equiv}C$), 2.0–2.3 (m, 3H, $C{\equiv}CCH_2$, OH, D_2O exchange 2.0H), 1.2–1.6 (m, 8H, CH_2), 0.88 (t, J = 7 Hz, 3H, CH_3).

Examination of the $(M-15)^+$ peaks of the mass spectra of the TMS derivatives of the recovered 2-decyn-1-ol and 3-decyn-1-ol showed no evidence for D incorporation.

Reactions of phthalans with dienophiles.[1] I. Synthesis of naphthalenes from phthalans and activated acetylenes

LUIS CONTRERAS AND DAVID B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

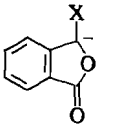
Received June 9, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

LUIS CONTRERAS and DAVID B. MACLEAN. Can. J. Chem. **58**, 2573 (1980).

Diethoxyphthalans and activated acetylenes react at temperatures of 140–160°C to yield substituted naphthalenes. It is proposed that the reaction occurs through the intermediacy of 1-ethoxyisobenzofurans generated thermally from the phthalans. The transient 1-ethoxyisobenzofurans are postulated to add to the acetylenes in a cycloaddition reaction to yield tricyclic intermediates that are transformed to naphthalenes at the elevated temperature of the reaction. Reactions with unsymmetrical acetylenes provided information on the regioselectivity of the reaction.

LUIS CONTRERAS et DAVID B. MACLEAN. Can. J. Chem. **58**, 2573 (1980).



Les diéthoxyphtalannes et les acétylènes activés réagissent à des température allant de 140 à 160°C pour conduire à des naphtalènes substitués. On suggère que la réaction se produit par l'intermédiaire des éthoxy-1 isobenzofurannes produits thermiquement à partir des phtalannes. On propose que les intermédiaires éthoxy-1 isobenzofurannes s'additionnent aux acétylènes selon une réaction de cycloaddition pour conduire à des intermédiaires qui se transforment en naphtalènes à la température élevée de la réaction. Les réactions avec les acétylènes qui ne sont pas substitués d'une façon symétrique fournissent des informations sur la régiosélectivité de la réaction.

[Traduit par le journal]

There have been great strides made recently in synthetic methods leading to the preparation of polysubstituted naphthalenes. The compounds are of interest not only in their own right but also as intermediates in the synthesis of anthracene and naphthacene derivatives. All three classes of compounds contain members that are of pharmacological interest (1, 2).

The traditional route to polynuclear aromatic systems has been through Friedel–Crafts alkylation and acylation reactions but these reactions are often not regiospecific (3, 4). However, the method has been used successfully in recent work reported by Johnson and co-workers (5, 6) in the syntheses of anthraquinones and anthracyclinones.

Nucleophilic condensation reactions, many of which use phthalide anions **1** as key intermediates, have been developed in the past few years for the construction of polynuclear aromatic systems. Thus **1***a* has been condensed with Michael acceptors by Trueb and Eugster (7) and by Sammes and co-workers (8, 9). Hauser and co-workers (10, 11) have used **1***b* as a starting material in several elegant syntheses of natural products and Kraus and Sugimoto (12) have employed **1***c* to yield 1,4-dihydroxynaphthalenes. Other anionic condensations have also been employed. Among these are methods developed by Hauser *et al.* (13, 14, 15), Baldwin and Bair (16),

1*a* X = H
1*b* X = SO_2Ar
1*c* X = CN

Raphael and co-workers (17), Snieckus and co-workers (18, 19), and Wildeman *et al.* (20).

Diels–Alder additions have also played a prominent role in the construction of polynuclear aromatic systems. *o*-Quinodimethides generated in the presence of a dienophile have been employed successfully by several groups (21–26). Similarly isobenzofuran (27) and derivatives of it are highly reactive in cycloaddition reactions. Applications of their use in the construction of linear polycyclic systems have recently appeared (28–30). Other cycloadditions of note in this context are those reported by Sammes and Wallace (31) and by Kraus *et al.* (32).

We describe here a new synthetic method leading to polysubstituted naphthalenes. We have found that activated acetylenes react with phthalans or substituted phthalans when heated for several hours either neat or in solution in a sealed tube. Unsubstituted phthalans and disubstituted acetylenes lead to 1,2,3,4-tetrasubstituted naphthalenes while reaction between a phthalan and a monosubstituted acetylene led to a 1,2,4-trisubstituted naphthalene. By using phthalans substituted in the aromatic ring

more highly substituted naphthalenes have been prepared and others are potentially available.

1,1-Diethoxyphthalan **2***a* (33) was prepared by alkylation of phthalide **3***a* with triethyloxonium fluoroborate (34) followed by treatment of the intermediate **4***a* with sodium ethoxide at 20°C. 5,6-Dimethoxy-1,1-diethoxyphthalan **2***b* was prepared similarly from **3***b* without isolation of the intermediate salt. Instead, the reaction mixture containing **4***b* was treated with sodium ethoxide according to the procedure of Deslongchamps *et al.* (35). The reactions are summarized in Scheme 1. The ^1H and ^{13}C nmr data recorded for **2***a* and **2***b* are in agreement with the assigned structures.

Treatment of **2***a* or **2***b* with dimethyl acetylenedicarboxylate at 140–170°C for 6 h gave compounds **5***a* and **5***b*, respectively. The reactions may be carried out in sealed glass tubes in the presence of solvent or at atmospheric pressure under reflux with a similar outcome in each case. The structures of **5***a* and **5***b* were deduced from their compositions, $C_{16}H_{16}O_6$ and $C_{18}H_{20}O_8$, respectively, from their functionality, and from their spectroscopic properties. It is clear from the following that both compounds are naphthalenes having the structures shown in Scheme 2. The infrared spectra of **5***a* and **5***b* showed two bands in the carbonyl region at 1735 and 1670 cm^{-1} attributed to ester absorption. The lower absorption is assigned to an intramolecularly hydrogen-bonded ester carbonyl group (36). The hydroxyl absorption resulting from intramolecular hydrogen bonding was not clearly visible as it underlay and was obscured by the C—H absorption. The ^1H nmr spectra of **5***a* and **5***b* both showed a peak at 12.1 δ for a hydrogen-bonded hydroxyl proton (37), as well as other peaks consistent with the assigned

b R = OCH_3

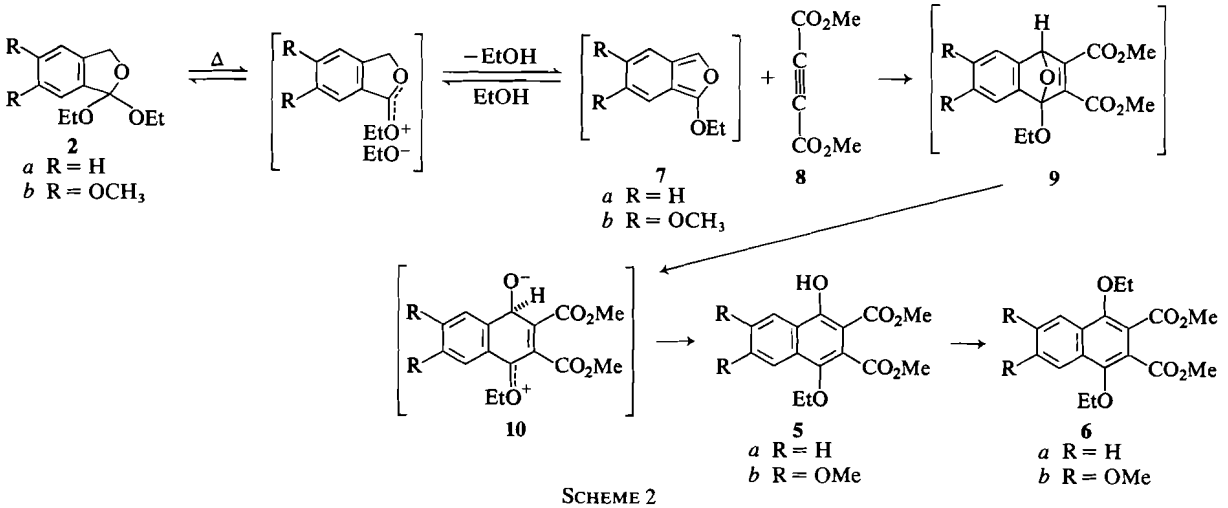

SCHEME 1

structures. Ethylation of **5***a* and **5***b* with ethyl iodide and sodium hydride in tetrahydrofuran (THF) (38) gave the symmetrical compounds **6***a* and **6***b*, each in 60% yield. The infrared spectra of **6***a* and **6***b* show only one absorption attributed to the ester carbonyl group (1735 cm^{-1}). The ^1H nmr spectrum of **6***a* has four aromatic protons forming an AA′BB′ pattern with two multiplets centered at 7.65 and 8.22 δ. The other signals in the spectrum are in accord with the proposed structure. The ^1H nmr spectrum of **6***b* showed a singlet of area 2 attributed to the aromatic protons at 7.46 δ, and signals attributed to the methoxy groups on the aromatic ring and of the ester group at 3.98 and 4.03 δ, each of area 6. Signals attributed to the ethyl groups appear at 1.48 (t) and 4.18 (q) δ associated with the methyl and methylene groups, respectively.

The ^{13}C nmr spectra of **5***a*, **5***b*, **6***a*, and **6***b* were recorded and the data obtained are in accord with the structures but resonances have not been assigned to the aromatic carbon atoms. However, on the basis of the ^{13}C data it is possible to differentiate the hydrogen bonded ester from the nonbonded ester group in **5***a* and **5***b*. The two signals appear at 170.2 and 168.2 in **5***a* and 170.3 and 168.4 in **5***b* for the bonded and nonbonded ester functions, respectively.

The formation of **5***a* and **5***b* can be rationalized as shown in Scheme 2. The reaction is considered to take place through the formation of a transient 1-ethoxyisobenzofuran intermediate **7**, generated *in situ*, which readily undergoes cycloaddition ($4\pi s + 2\pi s$) with ester **8** to yield the tricyclic intermediate **9**. It is proposed that the intermediate **9** undergoes C—O bond cleavage to **10** at the elevated temperature of the reaction and that the latter collapses to **5**. We do not have direct evidence for the generation of the intermediates **7**, **9**, or **10**. However, Hamaguchi and Ibata (39) have proposed the presence of an intermediate similar to **7** when methyl *o*-diazomethylbenzoate was decomposed in the presence of $Cu(acac)_2$. The 1-methoxyisobenzofuran intermediates were considered to form by interaction between a carbene, formed by decomposition of the diazo group, and the carbonyl group. The intermediates were trapped with alcohol (methanol or ethanol) or dienophiles such as *N*-phenylmaleimide, dimethyl fumarate, and dimethyl acetylenedicarboxylate to give phthalide ortho esters and Diels–Alder adducts, respectively.

The question of regioselectivity in Diels–Alder reactions arises when both the diene and dienophile are unsymmetrically substituted. Regioselectivity in the cycloaddition of **7***a* with unsymmetrical acetylenes such as ethyl propiolate **11**, ethyl tetrolate **12**,

SCHEME 2

and phenyl propiolate **13** was studied. It was found that "ortho adducts" (*vide infra*) in these reactions were formed as major products (Scheme 3).

The structures of compounds **14**–**19** are based on their compositions, their functionality, and their spectroscopic properties from which it is evident that all are substituted naphthalenes. It was possible to differentiate between the pairs **14** and **15**, **16** and **17**, and **18** and **19**, by the infrared absorption of the ester group, the chemical shift of the hydroxyl proton in the ^{1}H nmr spectrum, and the chemical shift of the carbonyl group in the ^{13}C nmr spectrum. For example, the infrared spectrum of **14** showed a band for a normal ester carbonyl group. The ^{1}H nmr spectrum showed a peak of 5.90 δ for a free hydroxyl proton and the ^{13}C nmr spectrum showed a signal at 167.3 ppm which is characteristic of a carbonyl carbon in an ester. In contrast, the infrared spectrum of **15** showed a band for an ester carbonyl group at 1655 cm^{-1} consistent with an intramolecularly hydrogen-bonded ester function (36). The ^{1}H nmr spectrum of **15** showed a peak at 11.70 δ for a hydrogen-bonded hydroxyl proton (37) and the ^{13}C nmr spectrum of **15** showed a peak at 171.1 ppm attributed to a hydrogen-bonded ester function. Similar differences were found between **16** and **17** and **18** and **19**, as shown in Table 1.

The preference for "ortho adducts" may be rationalized by using the frontier molecular orbital (FMO) theory (40). In its simplest form the FMO theory predicts that in Diels–Alder reactions between 1-substituted-1,3-butadienes, in which an electron-donating substituent such as NR_2, OMe, Me, etc., is present at C-1, and monosubstituted dienophiles, with an electron-withdrawing substituent such as COOR, CN, NO_2, etc. or a conjugated

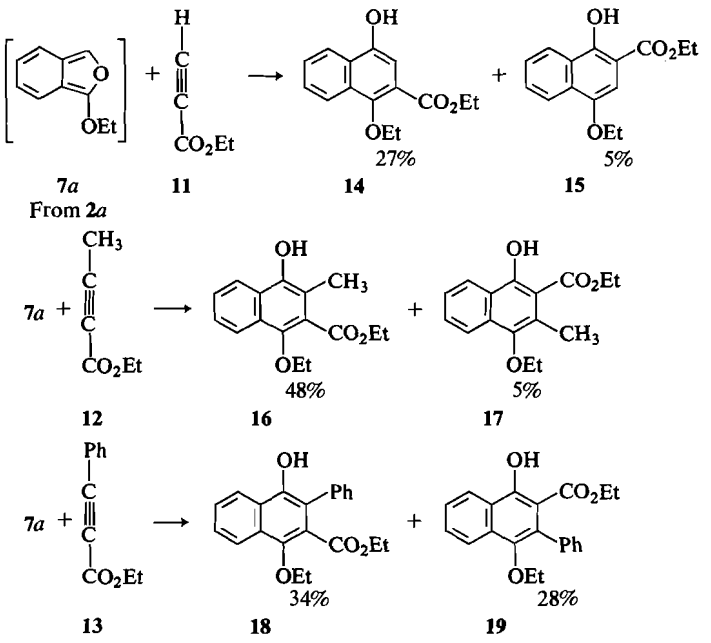

TABLE 1. Infrared, ^{1}H, and ^{13}C nuclear magnetic resonance data for substituted naphthalenes derived from unsymmetrically substituted acetylenes

	Infrared (cm^{-1})		^{1}H nmr	^{13}C nmr
Compound	OH	C=O	OH	C=O
14	3610, 3420	1720	5.90	167.3
15		1655	11.70	171.1
16	3610, 3380	1730	5.50	168.6
17		1655	12.10	172.6

substituent such as phenyl, vinyl, etc., the unoccupied molecular orbital of lowest energy (LUMO) of the dienophile will interact strongly with the highest occupied molecular orbital (HOMO) of the diene. The coefficients of these orbitals are largest at C-4 of the diene and at C-2 of the dienophile. Thus, bonding to give "ortho adducts" is favoured. In the present instance 1-ethoxyisobenzofuran **7***a* may be considered analogous to a 1-substituted-1,3-butadiene with an electron-releasing substituent. Thus the reaction of **7***a* with dienophiles **11** and **12** leads to a preponderance of "ortho adduct" in agreement with theory. In the case of reaction with phenyl propiolate, however, there is very little discrimination between the two modes of reaction.

This reaction sequence provides a convenient route to naphthalenes having oxygen substituents at C-1 and C-4 and a variety of substituents at C-2 and C-3, depending on the choice of dienophile. Substitution in the second ring may be controlled by the choice of phthalan. The 1,4-dioxygenated naphthalenes available by this method are potentially useful

SCHEME 3

intermediates in the syntheses of 1,4-naphthaquinones.

Experimental

Apparatus, Methods, and Materials

Melting points were recorded on a Kofler micro hot stage apparatus and are uncorrected. Infrared spectra (ir) were recorded on a Perkin Elmer 283 spectrophotometer in chloroform solution unless otherwise stated. The ^{1}H nmr spectra were recorded on a Varian EM-390 or Bruker WH-90 Fourier transform spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-d_1 using tetramethylsilane (TMS) as the internal standard. The chemical shifts were measured in relation to TMS and are quoted in δ values. The symbols s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet are used in reporting spectra. The ^{13}C nmr spectra were recorded on a Bruker WH-90 Fourier transform spectrometer at 22.62 MHz. Some spectra were also recorded on a Bruker WP-80 Fourier transform spectrometer at 20.115 MHz. Mass spectra were routinely run on all samples to check their molecular weight, either on a C.E.C. 21-110B double focussing or a V.G. Micromass 7070 mass spectrometer. Samples were introduced through a direct inlet system and run at 70 eV. High resolution mass spectrometry was used to confirm the composition of several compounds and mass measurements were made by procedures described elsewhere (41). Analytical thin layer chromatography was performed on pre-coated tlc silica gel plates (60F 254, Merck). Preparative thin layer chromatography was performed on pre-coated plc silica gel plates (60F 254, Merck) with layer thickness 2 mm. For column chromatography silica gel (60F 254, Merck), silica gel (Baker, 60–200 mesh), and alumina neutral (Fisher, activity I, 80–200 mesh) were used. Reverse phase chromatography was performed on tlc plates (KC_{18} Whatman) and on a Lobar prepacked column size A (240-10) RP-8 (40–63 μm) for liquid chromatography (Merck).

The microanalyses were performed by Microanalytical Laboratories, Ltd., Toronto, Ontario and Guelph Chemical Laboratories, Ltd., Guelph, Ontario.

1,2-Dichloroethane and methylene chloride were dried and distilled from phosphorus pentoxide. Tetrahydrofuran was dried by refluxing and distilling from sodium and benzophenone under dry nitrogen, and was collected directly from the still just prior to use.

Triethyloxonium Fluoroborate

The title compound was prepared by the method of Meerwein (34). Yield: 92%; mp 91–92°C.

O-Ethylphthalide Fluoroborate **4**a

Phthalide **3***a* (8.8 g, 6.56 mmol) and triethyloxonium fluoroborate (12.5 g, 6.57 mmol) in 15 mL of dry 1,2-dichloroethane were stirred for 48 h at room temperature in a dry box. The solid was separated by filtration (14.3 g, 88%) and washed with 1,2-dichloroethane and dry ether. It melted at 106–108°C (lit. (33) 107–108°C); ^{1}H nmr (CD_3NO_2); 1.20 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 4.76 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 5.83 (s, 2H, Ar—CH_2), and 7.16–7.86 (m, 4H, aromatic).

1,1-Diethoxyphthalan **2**a

O-Ethylphthalide fluoroborate **4***a* (14.3 g, 5.27 mmol) was added at room temperature to a solution of sodium ethoxide in ethanol (prepared from 2.5 g of sodium in 50 mL of absolute ethanol) under a nitrogen atmosphere. The solution was stirred for 1 h, then quenched with 50 mL of 15% aqueous sodium carbonate and extracted thoroughly with ether. The extract was then dried over K_2CO_3, filtered, evaporated, and distilled under vacuum (bp 60°C at 0.1 Torr) to give 11.3 g (94%) of **2***a*; ^{1}H nmr: 1.15 (t, 6H, 2 × OCH_2CH_3, J = 6.0 Hz), 3.25–3.85 (m, 4H, 2 × OCH_2CH_3), 5.03 (s, 2H, $ArCH_2$), and 7.20–7.50 (m, 4H, aromatic); hrms: calcd. for $C_{12}H_{16}O_3$: 208.109; found: 208.110.

5,6-Dimethoxy-1,1-diethoxyphthalan **2**b

5,6-Dimethoxyphthalide **3***b* (42) (14.0 g, 72.1 mmol) and triethyloxonium fluoroborate (15.0, 79.0 mmol) were dissolved in 25 mL of dry 1,2-dichloroethane and stirred at room temperature for two days under an argon atmosphere. The

dark solution was transferred to a dropping funnel and added to a solution of sodium ethoxide in ethanol (prepared from 3 g of sodium in 70 mL of absolute ethanol) under a nitrogen atmosphere at −20°C. After completion of the addition the reaction mixture was allowed to warm slowly to room temperature and then was quenched with 100 mL of 15% aqueous sodium carbonate. The resulting solution was extracted with methylene chloride, the extract dried over K_2CO_3, and the solvent evaporated to give a yellow oil which was distilled (bp 121°C at 0.05 Torr) to yield 14 g (72%) of **2***b*; ^{1}H nmr: 1.18 (t, 6H, 2 × OCH_2CH_3, J = 6.0 Hz), 3.30–3.80 (m, 4H, 2 × OCH_2CH_3), 3.92 (s, 6H, 2 × OCH_3), 5.02 (s, 2H, ArCH_2), 6.77 (s, 1H, aromatic), 6.95 (s, 1H, aromatic); hrms: calcd. for $C_{14}H_{20}O_5$: 268:131; found: 268.131. *Anal.* calcd. for $C_{14}H_{20}O_5$: C 62.68, H 7.52%; found: C 62.59, H 7.64%.

Reaction of 1,1-Diethoxyphthalan **2**a *with Dimethyl Acetylenedicarboxylate* **8**

In a Carius tube were placed 500 mg (2.40 mmol) of **2***a* and 434 mg (3.05 mmol) of **8** in 5 mL of chloroform. The tube was cooled and sealed under vacuum, then heated in a furnace for 6 h at 170°C. The tube was cooled, opened, and the contents removed. Upon evaporation of the solvent the oily residue was subjected to high vacuum distillation to remove the more volatile starting material. The product was collected as an oil (560 mg, 76%), crystallized from dry ether, and melted at 85–86°C. It proved to be dimethyl 1-hydroxy-4-ethoxynaphthalene-2,3-dicarboxylate **5***a* and had the following spectroscopic properties: ir ν_{max}: 1735 and 1670 cm^{-1}; ^{1}H nmr: 1.47 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 3.97 (s, 6H, 2 × OCH_3), 4.12 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 7.65 (m, 2H, aromatic), 8.07 (m, 1H, aromatic), 8.47 (m, 1H, aromatic), and 12.13 (s. 1H, ArO*H*); hrms: calcd. for $C_{16}H_{16}O_6$: 304.094; found: 304.097. *Anal.* calcd. for $C_{16}H_{16}O_6$: C 63.15, H 5.30; found: C 63.27, H 5.29%.

Reaction of **2**a *with* **8** *at Atmospheric Pressure*

Compound **2***a* (1.04 g, 5 mmol) and **8** (1.4 g, 10 mmol) were heated together at 145°C for 5 h under an argon atmosphere. The brown oil was subjected to high vacuum distillation to remove the more volatile starting materials. The product (1.17 g, 76%) was collected as a yellow oil. The oil was crystallized from dry ether and identified as **5***a*.

Ethylation of **5**a

Compound **5***a* (304 mg, 1 mmol) was dissolved in 20 mL of dry THF, sodium hydride (2 mmol) was added, followed by the addition of 8 mmol of ethyl iodide. The solution was heated in an oil bath at 80°C for 24 h, the solvent was removed, the residue taken up in benzene, and the benzene extract washed with water, dried over sodium sulfate, and evaporated. The solid residue (205 mg, 62%) was crystallized from pentane and melted at 87–89°C. It proved to be dimethyl 1,4-diethoxynaphthalene-2,3-dicarboxylate **6***a* and had the following spectroscopic properties: ir ν_{max}: 1735 cm^{-1}; ^{1}H nmr: 1.48 (t, 6H, 2 × OCH_2CH_3, J = 6.0 Hz), 3.88 (s, 6H, 2 × OCH_3), 4.20 (m, 4H, 2 × OCH_2CH_3), 7.65 and 8.22 (m, 4H, AA′BB′, aromatic; hrms: calcd. for $C_{18}H_{20}O_6$: 332.125; found: 332.124. *Anal.* calcd. for $C_{18}H_{20}O_6$: C 65.05, H 6.07; found: C 65.31, H 6.21%.

Reaction of 5,6-Dimethoxy-1,1-diethoxyphthalan **2**b *with* **8**

In a Carius tube were placed 564 mg (2.1 mmol) of **2***b* and 298 mg (2.1 mmol) of **8** in 6 mL of chloroform. The tube was cooled and sealed under vacuum, then heated in a furnace for 6 h at 150°C. The tube was cooled, opened, and the contents were removed. Evaporation of the solvent yielded an oil that was subjected to high vacuum distillation. The more volatile starting materials were removed and the product (550 mg, 71%) was crystallized from methanol to give dimethyl 6,7-dimethoxy 1-hydroxy-4-ethoxynaphthalene-2,3-dicarboxylate **5***b*, melting at 149–151°C. Infrared ν_{max}: 1735 and 1670 cm^{-1}; ^{1}H nmr: 1.47 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 3.95 (s, 6H, 2 × OCH_3), 4.03 (s, 6H, 2 × OCH_3), 4.10 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 7.30 (s, 1H, aromatic), 7.68 (s, 1H, aromatic), and 12.10 (s, 1H, ArO*H*); hrms: calcd. for $C_{18}H_{20}O_8$: 364.115; found: 364.113. *Anal.* calcd. for $C_{18}H_{20}O_8$: C 59.33, H 5.53; found: C 59.50, H 5.64%.

Reaction of **2**b *with* **8** *at Atmospheric Pressure*

Compounds **2***b* (1.32 g, 5 mmol) and **8** (1.40 g, 10 mmol) were heated together for 5 h at 155°C under an argon atmosphere. The excess of dienophile was removed under high vacuum distillation. The orange solid was crystallized from methanol to give 1.2 g (67%) of **5***b*.

Ethylation of **5**b

The compound **5***b* (364 mg, 1 mmol) was ethylated in the same way that **5***a* was converted to **6***a*. The resulting product (231 mg, 60%) was crystallized from ether and identified as dimethyl 6,7-dimethoxy-1,4-diethoxynaphthalene-2,3-dicarboxylate. It melted at 152–153°C and had the following spectroscopic properties: ir ν_{max}: 1735 cm^{-1}; ^{1}H nmr: 1.48 (t, 2 × OCH_2CH_3, J = 6.0 Hz), 3.98 (s, 6H, 2 × OCH_3), 4.03 (s, 6H, 2 × OCH_3), 4.18 (q, 4H, 2 × OCH_2CH_3, J = 6.0 Hz), and 7.46 (s, 2H, aromatic); hrms: calcd. for $C_{20}H_{24}O_8$: 392.145; found: 392.147. *Anal.* calcd. for $C_{20}H_{24}O_8$: C 61.22, H 6.17; found: C 61.03, H 6.10%.

Reaction of **2**a *with Ethyl Propiolate* **11**

Ortho ester **2***a* (1.04 g, 5 mmol) and **11** (835 mg, 8.5 mmol) were heated together for 4 h at 115–120°C under an argon atmosphere. The excess of dienophile was then removed by distillation leaving 1.1 g of brown oil that was separated into two components by column chromatography (silica gel, TLC grade, benzene–hexane 50:50). The first component (65 mg, 5%) to be eluted proved to be ethyl 1-hydroxy-4-ethoxynaphthalene-2-carboxylate **15**. It crystallized from hexane and melted at 99–101°C and had the following spectroscopic properties: ir ν_{max}: 1665 cm^{-1}; ^{1}H nmr: 1.45 and 1.53 (overlapping t's 6H, 2 × OCH_2CH_3), 4.18 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 4.46 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 7.04 (s, 1H, aromatic), 7.59 (m, 2H, aromatic), 8.33 (m, 2H, aromatic), and 11.70 (s, 1H, ArO*H*); hrms: calcd. for $C_{15}H_{16}O_4$: 260.104; found: 260.106. *Anal.* calcd. for $C_{15}H_{16}O_4$: C 69.21, H 6.20; found: C 68.74, H 6.28%.

The second component (355 mg, 27%) eluted from the column was an isomer of the previous compound. It proved to be ethyl 1-hydroxy-4-ethoxynaphthalene-3-carboxylate **14**. It melted at 139–141°C after crystallization from acetone–hexane and had the following spectroscopic properties: ir ν_{max}: 3610, 3420, and 1720 cm^{-1}; ^{1}H nmr: 1.49 and 1.53 (overlapping t's, 6H, 2 × OCH_2CH_3), 4.13 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 4.45 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 5.90 (br s, 1H, ArO*H*), 7.33 (s, 1H, aromatic), 7.59 (m, 2H, aromatic), and 8.21 (m, 2H, aromatic); hrms: calcd. for $C_{15}H_{16}O_4$: 260.104; found: 260.108. *Anal.* calcd. for $C_{15}H_{16}O_4$: C 69.21, H 6.20; found: C 68.75, H 6.41%.

Reaction of **2**a *with Ethyl Tetrolate* **12**

Ortho ester **2***a* (1.04 g, 5 mmol) and **12** (1.12 g, 10 mmol) were heated for 4 h at 165–170°C under a nitrogen atmosphere. The excess of dienophile was removed by distillation leaving 1.1 g of brown oil that was separated into two components by column chromatography (silica gel, TLC grade, methylene chloride – petroleum ether 50:50). The first component eluted (73 mg, 5%) proved to be ethyl 1-hydroxy-3-methyl-4-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

ethoxynaphthalene-2-carboxylate **17**. It crystallized from hexane and melted at 82–84°C and had the following spectroscopic properties: ir ν_{max}: 1655 cm^{-1}; ^1H nmr: 1.45 and 1.48 (overlapping t's, 6H, 2 × OCH_2CH_3, J = 6.0 Hz), 2.58 (s, 3H, 1 × CH_3), 3.92 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 4.47 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 7.52 (m, 2H, aromatic), 8.00 (m, 1H, aromatic), 8.40 (m, 1H, aromatic), and 12.10 (s, 1H, ArO*H*); hrms: calcd. for $C_{16}H_{18}O_4$: 274.120; found: 274.123. *Anal.* calcd. for $C_{16}H_{18}O_4$: C 70.05, H 6.62; found: C 70.36, H 6.43%.

The second component (657 mg, 48%) eluted from the column was an isomer of the previous compound. It proved to be ethyl 1-hydroxy-2-methyl-4-ethoxynaphthalene-3-carboxylate **16**. It melted at 91–92°C after crystallization from hexane and had the following spectroscopic properties: ir ν_{max}: 3610, 3380, and 1730 cm^{-1}; ^1H nmr: 1.40 and 1.43 (overlapping t's, 6H, 2 × OCH_2CH_3), 2.25 (s, 3H, 1 × CH_3), 4.08 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 4.46 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 5.50 (s, 1H, ArO*H*), 7.43 (m, 2H, aromatic), and 8.00 (m, 2H, aromatic); hrms: calcd. for $C_{16}H_{18}O_4$: 274.120; found: 274.121. *Anal.* calcd. for $C_{16}H_{18}O_4$: C 70.05, H 6.63; found: C 70.25, H 6.33%.

Reaction of **2***a with Ethyl Phenylpropiolate* ***13***

Ortho ester **2***a* (1.04 g, 5 mmol) and **13** (1.90 g, 11 mmol) were heated together for 4 h at 165–170°C under an argon atmosphere. The solution was cooled, the excess of dienophile was removed by distillation and the residue (1.8 g) of brown oil was chromatographed on silica gel, TLC grade, using benzene–hexane 50:50 as eluant. The first fraction (437 mg, 28%) was crystallized from hexane and melted at 84–85°C. It proved to be ethyl 1-hydroxy-3-phenyl-4-ethoxynaphthalene-2-carboxylate **19** and had the following spectroscopic properties: ir ν_{max}: 1650 cm^{-1}; ^1H nmr: 0.73 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 1.03 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 3.55 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 3.97 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 7.35 (s, 5H, phenyl), 7.40–7.90 (m, 2H, aromatic), 8.10 (m, 1H, aromatic), 8.47 (m, 1H, aromatic), and 12.10 (s, 1H, ArO*H*); hrms: calcd. for $C_{21}H_{20}O_4$: 336.136; found: 336.134. *Anal.* calcd. for $C_{21}H_{20}O_4$: C 74.98, H 5.99; found: C 74.86, H 5.99%.

The second fraction from the column (576 mg, 34%) was an oil that failed to crystallize. The oil was purified by distillation in a Kugelrohr apparatus. It proved to be ethyl 1-hydroxy-2-phenyl-4-ethoxynaphthalene-3-carboxylate **18** which had the following spectroscopic properties: ir (neat) ν_{max}: 3530 and 1730 cm^{-1}; ^1H nmr: 0.93 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 1.45 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 4.00 and 4.17 (overlapping q's, 2 × OCH_2CH_3), 5.43 (br s, 1H, ArO*H*), 7.10–8.40 (m, 4H, aromatic), and 7.42 (s, 5H, phenyl); hrms: calcd. for $C_{21}H_{20}O_4$: 336.136; found: 336.134. *Anal.* calcd. for $C_{21}H_{20}O_4$: C 74.98, H 5.99; found: C 74.80, H 6.01%.

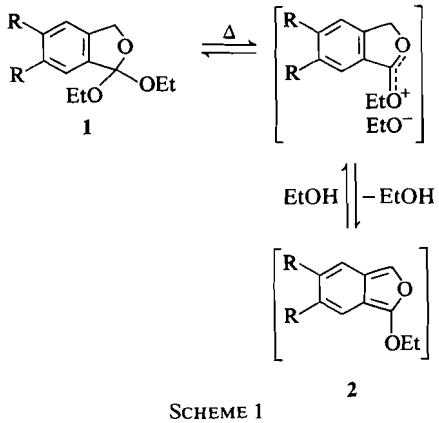
Reactions of phthalans with dienophiles.[1] II. Synthesis of naphthalenes and dihydronaphthalenes by reaction of ethyl maleate and maleic anhydride with 1,1-diethoxyphthalan

LUIS CONTRERAS AND DAVID B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 8, 1980

LUIS CONTRERAS and DAVID B. MACLEAN. Can. J. Chem. **58**, 2580 (1980).



The reactions of 1,1-diethoxyphthalan with diethyl maleate and with maleic anhydride have been studied. The reaction with diethyl maleate in a sealed tube gave a mixture of diethyl 1-hydroxynaphthalene-2,3-dicarboxylate and its *O*-ethyl derivative. The same reactants at atmospheric pressure gave the ethoxy ester above along with a mixture of isomeric diethyl 1,2-dihydro-1-hydroxy-4-ethoxynaphthalene-2,3-dicarboxylates. The reaction with maleic anhydride gave only diethyl-1-ethoxynaphthalene-2,3-dicarboxylic acid anhydride. These reactions provide further insight into the mechanism of the reaction of phthalans with dienophiles.

LUIS CONTRERAS et DAVID B. MACLEAN. Can. J. Chem. **58**, 2580 (1980).

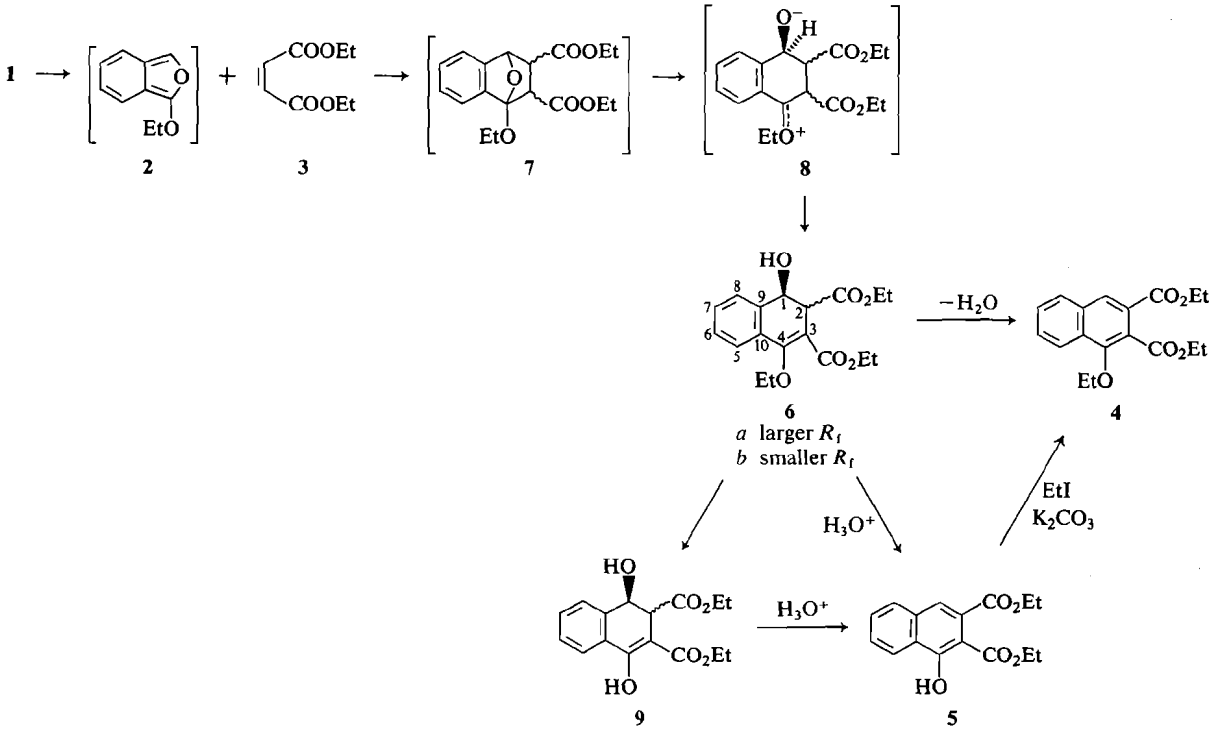
On a étudié les réactions du diéthoxy-1,1 phtalane avec le maléate de diéthyle et l'anhydride maléique. La réaction avec le maléate de diéthyle dans un tube scellé a donné un mélange d'hydroxy-1 naphtalènedicarboxylate-2,3 de diéthyle et de son dérivé *O*-éthyle. A pression atmosphérique, les mêmes réactifs ont conduit au dérivé précédent l'ester éthoxy, accompagné d'un mélange des dihydro-1,2 hydroxyéthoxy-4 naphtalènes dicarboxylate-2,3 de diéthyle isomères. La réaction avec l'anhydride maléique a seulement donné l'anhydride de l'acide éthoxy-1 naphtalène dicarboxylique-2,3. Ces réactions fournissent de plus une conaissance plus approfondie du mécanisme de la réaction des phtalanes avec les diénophyles.

[Traduit par le journal]

The previous paper (1) in this series described the reactions of phthalans with activated acetylenes. It was postulated that 1,1-diethoxyphthalans **1** were converted to transient 1-ethoxyisobenzofurans **2** (Scheme 1) that underwent a 4 + 2 cycloaddition with the dienophiles to give, as final reaction products, polysubstituted naphthalenes. In this communication, we have extended the study to ethylenic dienophiles and describe here the reaction of 1,1-diethoxyphthalan with ethyl maleate and maleic anhydride. Both compounds yield trisubstituted naphthalenes as reaction products but tetrasubstituted dihydronaphthalenes were also obtained from ethyl maleate. Other recently developed routes to substituted naphthalenes have been cited in ref. 1.

SCHEME 1

Treatment of the ortho ester **1** with diethyl maleate **3** in chloroform at 170°C for 72 h in a sealed glass tube gave two products, **4** and **5** (Scheme 2), in approximately 30% and 10% yield, respectively. However, when the reaction was carried out at atmospheric pressure for 6 h at 165°C, the product consisted of three compounds that were separated by column chromatography. The first was the trisubstituted naphthalene **4** (48%). The second (larger R_f) was one of the racemic diastereomers of diethyl-1-hydroxy-4-ethoxy-1,2-dihydronaphthalene-2,3-dicarboxylate **6***a* (18%). The third compound (smaller R_f) **6***b* (34%) was an isomer of **6***a*.



The structures of **4** and **5** are based on a knowledge of their compositions, $C_{16}H_{16}O_5$ and $C_{18}H_{20}O_5$, respectively, and on examination of their spectra. The infrared spectrum of **5** showed two bands in the carbonyl region at 1730 and 1655 cm^{-1} attributed to ester absorptions. The lower field absorption was assigned to an intramolecularly hydrogen-bonded ester carbonyl group (1). The ^1H nmr spectrum of **5** showed a peak at 12.10 δ for a hydrogen-bonded hydroxyl proton. The two methyl groups of the two carboethoxy functions have the same chemical shift and appear as a triplet at 1.40 δ. The methylene protons appear as two

SCHEME 2

overlapping quartets centred at 4.40 and 4.50 δ. The aromatic region showed two multiplets, one of area 3H centred at 7.68 δ, and the other a multiplet of area 1H centred at 8.43 δ. There was also a singlet for 1H at 7.45 δ, assigned to H-4. Compound **5** has been converted by ethylation into **4**. A multi-step synthesis (2) of **5** has been previously reported, but it was not obtained in crystalline form. In another study, the dimethyl ester of 1-hydroxy-2,3-naphthalene dicarboxylic acid was prepared (3); the spectroscopic properties reported for it are very similar to those of **5**.

The ^{13}C nmr spectrum of **5** showed two signals for the carbonyl carbon atoms of the ester groups. The signal at 170.2 ppm is attributed to the internally hydrogen-bonded ester function and the signal at 169.2 ppm to the nonbonded ester group.

The infrared spectrum of **4** showed only one absorption for the ester carbonyl group at 1730 cm^{-1}. The ^1H nmr spectrum of **4** showed signals attributed to the three ethyl groups at 1.37 (t), 1.38 (t), and 1.43 (t) associated with the methyl groups and at 4.20 (q), 4.38 (q), and 4.47 (q) associated with the methylene groups. The aromatic region consists of 3 multiplets centred at 7.58, 7.92, and 8.12 δ for 2H, 1H, and 1H, respectively. The singlet of the proton at H-4 is deshielded (8.32 δ) relative to that of H-4 in **5**.

The ^{13}C nmr chemical shifts of **4** showed two signals for the ester carbonyl group at 165.6 and 167.9 ppm, respectively.

The enol ethers ***6a*** and ***6b*** were identified on the basis of their spectra. The infrared spectrum of the enol ethers, ***6a*** and ***6b***, showed bands for hydroxyl absorption at 3480 cm^{-1} and for carbonyl absorption at 1730 cm^{-1}. The ^1H nmr spectrum of ***6a*** contains three sets of overlapping ethyl resonances whose peaks are centred at 1.05, 1.38 and 1.42 δ, which are assigned to the methyl groups; the methylene groups appear as two overlapping quartets centred at 4.04 and 4.37 δ. Also overlapping with the methylene peaks is the signal for the proton at C-2 giving a total of 7 hydrogens in this region. The benzylic proton appears as a broad doublet of doublets with a coupling constant, J = 6.0 Hz, due to vicinal coupling to H-2 and to the hydroxyl proton. The latter signal was not located in the spectrum. The broad signal ascribed to H-1 collapsed to a doublet, J = 6.0 Hz, on addition of D_2O. The four aromatic protons form a multiplet over the range 7.20–7.80 δ. When the ^1H nmr spectrum of ***6a*** was run in dimethylsulfoxide

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12

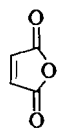
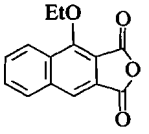
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

(DMSO-d_6), the benzylic proton was shifted to 5.16 δ and appeared as a triplet with $J = 6.0$ Hz. This signal collapsed to a doublet with $J = 6$ Hz when D_2O was added, suggesting a coupling to the hydroxyl proton with the same coupling constant as with H-2. The hydroxyl proton appeared as a doublet with $J = 6.0$ Hz at 5.80 δ in DMSO-d_6. This signal disappeared when D_2O was added. The ^1H nmr spectrum of **6***b* had a spectrum similar to **6***a* except that the vicinal coupling between the benzylic proton on C-1 and H-2 is now 4.5 Hz, indicative of the change in configuration at C-2 and a different dihedral angle between H-1 and H-2.



The ^{13}C nmr spectra of **6***a* and **6***b* were also found to be similar. The aliphatic region of both spectra showed the presence of two methine carbon atoms in which C-1 of **6***b* is shielded by −0.5 ppm while C-2 is deshielded by 4.2 ppm relative to the same centres in **6***a*. Also present in this region are other signals corresponding to the carbon atoms of the ethoxy groups. The low field region showed that the carbonyl carbon at C-2 of **6***a* is deshielded by 1.7 ppm with respect to **6***b*. However, it is not possible from these data (^1H nmr and ^{13}C nmr spectra) to assign unequivocally the relative configuration at C-2 in **6***a* and its diastereoisomer **6***b*.

The formation of **4**, **5**, **6***a*, and **6***b* can be rationalized through the intervention of 1-ethoxyisobenzofuran **2** (Scheme 2), which undergoes cycloaddition with **3** to give the intermediate **7**. This intermediate can undergo C—O bond cleavage to the zwitterion **8**, as proposed for the analogous adduct from acetylene addition (1), which then collapses to the enol ethers **6***a* and **6***b*. The isolation of the compounds **6***a* and **6***b* is indirect evidence for the formation of the tricyclic intermediate **7**. From the ratio of **6***a* to **6***b*, one might be tempted to draw conclusions about the *exo–endo* ratio of the addition, but this would be unwise for several reasons, not least of which is that isomerization might have occurred during work-up. Moreover, it has been found that the *exo–endo* ratio of adducts from various cycloaddition reactions of isobenzofurans with dienophiles varies. Whereas Kende *et al.* (4), Wiersum and Mijs (5), and Chacko *et al.* (6) have observed the predominance of *endo* isomers in these reactions, Hamaguchi and Ibata (7) found an *endo–exo* ratio of 1:1 in adducts that they prepared. In all cases, the *endo–exo* ratio was determined by nmr spectral analysis. The geometry in the *exo* adduct prevents the coupling of the protons at the bridge junction and the adjacent protons in the nmr spectrum but coupling is observed in the *endo* adducts (4, 5). Since no general rule can be formulated for such reactions and since the tricyclic compound **7** was not isolated, it is not possible to predict or ascertain the *endo–exo* ratio in the reaction of **1** with **3**.



In another experiment the compound **9**, together with **4**, (15%) was isolated from the reaction of **1** with **3** as a mixture of diastereoisomeric enolic forms in 65% yield. The product **9** apparently arises by hydrolysis of **6** in the course of silica gel column chromatography. The infrared spectrum of **9** showed bands for hydroxyl absorption at 3480 cm^{-1} and carbonyl absorption at 1665 and 1735 cm^{-1}. Although the ^1H nmr spectrum of **9** was complex, it showed peaks at 2.80 and 12.80 δ for free and hydrogen-bonded hydroxyl protons, respectively. These signals collapsed when D_2O was added. Treatment of **9** with *p*-toluenesulfonic acid yielded **5** by dehydration in quantitative yield.

It was also found that the enol ethers **6***a* and **6***b* on treatment with acid yielded **5** which indicated that they undergo hydrolysis of the enol ether faster than they undergo dehydration. None of the compound **4** was observed on dehydration of **6***a* or **6***b* with *p*-toluenesulfonic acid in benzene.

When maleic anhydride **10** was used as dienophile, one product **11** was separated by crys-

10

11

tallization in 56% yield. The infrared spectrum of **11** showed two bands in the carbonyl region at 1845 and 1785 cm^{-1}, attributed to the anhydride group (8). The ^1H nmr spectrum of **11** showed peaks for the ethoxy group at 1.55 and 4.82 δ corresponding to methyl and methylene groups, respectively. In the aromatic region, there was a multiplet between 7.50–8.20 δ for 3H, a multiplet centred at 8.47 δ for 1H, and a singlet at 8.07 δ for 1H assigned to H-4.

The ^{13}C nmr spectrum showed signals at 72.9 (t) and 16.0 (q) ppm that can be attributed to the ethoxy group. The low field region showed two signals for the anhydride carbonyl group at 161.5 and 163.5 ppm, respectively. The higher field signal is assigned to the C-2 carbonyl carbon atom, because of the steric effect of the ethoxy group. The resonances of the aromatic carbon atoms are not assigned.

The reactions described above show that phthalans, on reaction with ethylenic dienophiles, may be used to prepare 1,2,3-trisubstituted naphthalenes or 1,2,3,4-tetrasubstituted 1,2-dihydronaphthalenes. The formation of the dihydro compounds provides indirect evidence for the transient formation of the tricyclic intermediate **7**.

Experimental

Apparatus, Methods, and Materials

The reader is referred to the preceding paper in this series (1).

Reaction of 1 with Diethyl Maleate 3 in a Sealed Tube

Ortho ester **1** (344 mg, 2 mmol), prepared as previously described (1), diethyl maleate (419 mg, 2 mmol), and chloroform (2 mL) were placed in a Carius tube. The tube was cooled and sealed under vacuum. The mixture was heated in a furnace for 72 h at 170°C. The tube was cooled, opened, and the contents were removed. Upon evaporation of the solvent, the yellow oil obtained on vacuum distillation was subjected to preparative tlc (silica gel, benzene) to give two fractions. The first fraction (55 mg, 10%) was a yellow oil that crystallized from hexane and melted at 54–56°C. It was identified as diethyl 1-hydroxynaphthalene-2,3-dicarboxylate **5**. Infrared ν_{max}: 1730 and 1665 cm^{-1}; ^1H nmr: 1.48 (t, 6H, 2 × OCH_2CH_3, J = 6.0 Hz), 4.40 and 4.45 (overlapping q's, 4H, 2 × OCH_2CH_3), 7.45 (s, 1H, aromatic), 7.68 (m, 3H, aromatic), 8.43 (m, 1H, aromatic), and 12.10 (s, 1H, ArO*H*). *Anal.* calcd. for $C_{16}H_{16}O_5$: C 66.66, H 5.55; found: C 66.07, H 5.36%. *Exact Mass* calcd. for $C_{16}H_{16}O_5$: 288.099; found (hrms): 288.099.

The second fraction (214 mg, 30%) was a yellow oil that failed to crystallize. The oil was purified by distillation in a Kugelrohr apparatus and proved to be diethyl-1-ethoxynaphthalene-2,3-dicarboxylate **4**. Infrared (neat liquid) ν_{max}: 1730 cm^{-1}; ^1H nmr: 1.37, 1.38, and 1.43 (overlapping t's, 9H, 3 × OCH_2CH_3), 4.20, 4.38 and 4.47 (overlapping q's, 6H, 3 × OCH_2CH_3), 7.58 (m, 2H, aromatic), 7.92 (m, 1H, aromatic), 8.12 (m, 1H, aromatic), and 8.32 (s, 1H, aromatic). *Anal.* calcd. for $C_{18}H_{20}O_5$: C 68.35, H 6.32, found: C 68.29, H 6.39%. *Exact Mass* calcd. for $C_{18}H_{20}O_5$: 316.131; found (hrms): 316.132.

Ethylation of 5

A mixture of **5** (97 mg, 0.3 mmol), ethyl iodide (2.5 g, 1.6 mmol), and potassium carbonate (2.5 g, 18 mmol) in 20 mL of anhydrous acetone was refluxed for 50 h. The acetone was evaporated and the residue was taken up in benzene. The benzene was washed with 5% aqueous potassium hydroxide, dried over sodium sulfate, and evaporated to give a yellow oil (76.5 mg, 72%) whose spectroscopic properties were identical with those of **4** reported above.

Reaction of 1 with 3 at Atmospheric Pressure

Ortho ester **1** (1.04 g, 5 mmol) and **3** (1.72 g, 10 mmol) were heated together for 6 h at 165–170°C under an atmosphere of argon. The excess of dienophile was removed by distillation under vacuum giving 1.8 g of yellow oily residue. Column chromatography of the oil (silica gel for tlc, benzene–acetone 95:5) yielded three fractions. The first fraction (688 mg, 43%) was the already reported **4**; the second fraction (500 mg) proved to be a mixture of two components that was separated by preparative tlc using the same conditions as in column chromatography. This fraction was comprised of 76 mg (5%) of the compound present in the first fraction and 300 mg (18%) of a second component (larger R_f) that proved to be diethyl-1-hydroxy-4-ethoxy-1,2-dihydronaphthalene **6***a*. Infrared (neat liquid) ν_{max}: 3480 and 1730 cm^{-1}; ^1H nmr: 1.05 (t, 3H, OCH_2CH_3, J = 6.0 Hz), 1.38 and 1.42 (overlapping t's, 6H, 2 × OCH_2CH_3), 4.04 (m, 5H, 2 × OCH_2CH_3 and H-2), 4.31 (q, 2H, OCH_2CH_3, J = 6.0 Hz), 5.08 (d, d, 1H, H-1, J = 6.0 Hz; with added D_2O this signal collapses to a doublet, J = 6.0 Hz), and 7.20–7.80 (m, 4H, aromatic); ^1H nmr (DMSO-d_6): 0.95–1.40 (m, 9H, 3 × OCH_2CH_3), 3.70–4.28 (m, 7H, 3 × OCH_2CH_3 and H-2), 5.16 (t, 1H, H-1, J = 6.0 Hz, with added D_2O this signal collapses to a doublet, J = 6.0 Hz), 5.80 (d, 1H, CO*H*, J = 6.0 Hz, this signal disappears in added D_2O), and 7.36–7.75 (m, 4H, aromatic). *Exact Mass* calcd. for $C_{18}H_{22}O_6$: 334.142; found (hrms): 334.146.

The third fraction (568 mg, 34%) isolated from the column proved to be an isomer, **6***b*, of the previous substance. It was also obtained as an oil and had the following physical properties: ir (neat liquid) ν_{max}: 3480 and 1730 cm^{-1}; ^1H nmr: 1.13, 1.30 and 1.38 (overlapping t's, 9H, 3 × OCH_2CH_3), 2.18 (bs, 1H, CO*H*, disappears in added D_2O), 4.05 (m, 5H, 2 × OCH_2CH_3 and H-2), 5.00 (d, 1H, H-1, J = 4.5 Hz), and 7.30–7.80 (m, 4H, aromatic). *Exact Mass* calcd. for $C_{18}H_{22}O_6$: 334.142; found (hrms): 334.140.

When the reaction was repeated under the same conditions as above, except that a different batch of silica was used, two compounds were isolated. The first fraction (238 mg, 15%), an oil, was identified as **4** and the second fraction (970 mg, 63%), also an oil, was identified as **9**. Infrared (neat liquid) ν_{max}: 3480, 1735 and 1665 cm^{-1}; ^1H nmr: 1.03–1.43 (m, 6H, 2 × OCH_2CH_3), 2.80 (bs, 1H, CO*H*), 3.90–4.36 (m, 5H, 2 × OCH_2CH_3 and H-2), 5.10 (bs, 1H, H-1), 7.43–8.10 (m, 4H, aromatic), and 12.80 (s, 1H, CO*H*). *Exact Mass* calcd. for $C_{16}H_{18}O_6$: 306.107; found (hrms): 306.110.

Conversion of 6a, 6b, and 9 to 5

In each case, the compound was refluxed in benzene in the presence of catalytic quantities of *p*-toluenesulfonic acid for 30 min. The solution was washed with brine and dried over sodium sulfate to give **5** in 92–95% yield, identified by its spectroscopic properties.

Reaction of 1 with Maleic Anhydride 10

Ortho ester **1** (1.04 g, 5 mmol) and **10** (500 mg, 5 mmol) were heated together for 10 min at 165°C under a nitrogen atmosphere. The solution was cooled and the solid residue was crystallized from acetone to give 668 mg (56%) of white crystals that melted at 170–172°C and were identified as 1-ethoxynaphthalene-2,3-dicarboxylic acid anhydride. Infrared ν_{max}: 1845 and 1785 cm^{-1}; ^1H nmr: 1.55 (t, 3H, OCH_2CH_3, J = 7.5 Hz), 4.82 (q, 2H, OCH_2CH_3, J = 7.5 Hz), 7.50–8.20 (m, 3H, aromatic), 8.07 (s, 1H, aromatic), and 8.47 (m, 1H, aromatic). *Anal.* calcd. for $C_{14}H_{10}O_4$: C 69.42, H 4.16; found: C 68.98, H 4.17%. *Exact Mass* calcd. for $C_{14}H_{10}O_4$: 270.057; found (hrms): 270.054.

The barrier to rotation in 2,2′′-dimethyl-*o*-terphenyl and several 3,3′′-derivatives (rotational isomers of 1,2-di-*o*-tolylbenzene)

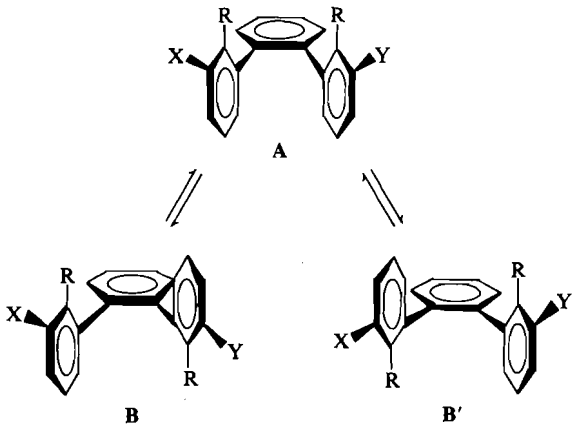
REGINALD H. MITCHELL[1] AND JOSEPH SHUE-HEN YAN

Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received June 9, 1980

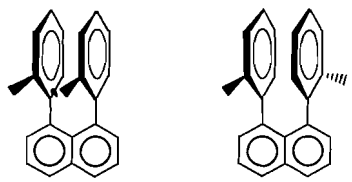
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

REGINALD H. MITCHELL and JOSEPH SHUE-HEN YAN. Can. J. Chem. **58**, 2584 (1980).



The synthesis and measurement of the barrier to rotation ($\Delta G_c^{\ddagger}$) in 2,2″-dimethyl-*o*-terphenyl (62 kJ/mol) and the following 3,3″-disubstituted derivatives is described (Cl, Cl, 74 kJ/mol), (Cl, CN, 70 kJ/mol), (CN, CN 70 kJ/mol), (CHO, 75 kJ/mol). For 3,3″-bis-CH_2Br, $\Delta\nu$, the separation of the —CH_3 peaks in the ^{1}Hmr spectrum, was too small to obtain $\Delta G_c^{\ddagger}$.

REGINALD H. MITCHELL et JOSEPH SHUE-HEN YAN. Can. J. Chem. **58**, 2584 (1980).

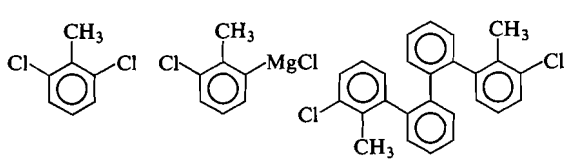


On décrit la synthèse et la mesure de la barrière à la rotation ($\Delta G_c^{\ddagger}$) du diméthyl-2,2″ *o*-terphényle (63 kJ/mol), et des dérivés 3,3″ disubstitués suivants: (Cl, Cl, 74 kJ/mol), Cl, CN, 70 kJ/mol), (CN, CN, 70 kJ/mol), (CHO, CHO, 75 kJ/mol). Dans le cas du composé bis CH_2Br-3,3″, le $\Delta\nu$, la séparation des pics du CH_3 dans le spectre rmn, est trop faible et ne permet pas d'obtenir le $\Delta G_c^{\ddagger}$.
[Traduit par le journal]

Introduction

Adams and Yuan (1), in their review on the stereochemistry of diphenyls in 1933, pointed out that suitably substituted *o*-terphenyls should be capable of existing as isomers. Huang (2) in 1954 synthesized 2,2′′-dimethoxy-*o*-terphenyl **1** and then in 1959 (3), 2,2′′-dichloro- *o*-terphenyl **2**, in an attempt to substantiate this postulate, but was unable to isolate separate isomers **A** and **B**, (**B′**). The

more recent interest in rotational gear or cog-wheel effects, together with the ability to determine thermodynamic parameters by ^{1}Hmr has restimulated investigation of such systems, for example, triptycenes (4), polyarylbenzenes (5) and 1,8-diphenyl- (6) and 1,8-di-*o*-tolylnaphthalenes (7). In the case of the latter, stable *cis*-**3** and *trans*-**4** isomers could be isolated. However, thus far the barrier to rotation



3 4

in simple 2,2′′-disubstituted-*o*-terphenyls appears still not to have been reported. This paper thus reports that measurement for 2,2′′-dimethyl-*o*-terphenyl and a number of 3,3′′-substituted examples.

Results and Discussion

Syntheses

Because of our interest in benzannelated annulenes (8) we required the bis-bromomethyl-*o*-terphenyl **5**. This was synthesized as follows. Reaction of commercial 2,6-dichlorotoluene **6** with magnesium in tetrahydrofuran gave the mono-Grignard reagent **7** which could be coupled with *o*-dibromobenzene in the presence of nickel(II) acetylacetonate as catalyst (9) to give 3,3′′-dichloro-2,2′′-dimethyl-*o*-terphenyl **8** in 60% yield as colourless crystals, mp 102–104°C. These were identified by their ^{1}Hmr spectrum (see below), their mass spectrum molecular ion ($M^{+\cdot}$) at *m/e* 326 (with

correct isotope pattern for two chlorine atoms) and by elemental analysis. The *quater* phenyl **9**, mp 173–175°C, $M^{+\cdot}$ at *m/e* 402, was also obtained in 3% yield as a minor product from this coupling reaction. This method for the synthesis of *o*-terphenyls appears to be easier than most earlier (10) syntheses.

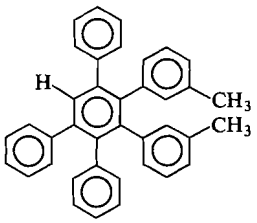
Conversion of the dichloride **8** to the dinitrile **10** was readily accomplished by the von Braun reaction using cuprous cyanide in *N*-methylpyrrolidin-2-one in 85–95% yield. Compound **10** was obtained as white crystals, mp 151–153°C. The structure was confirmed by its ir band at 2240 cm^{-1} (C≡N) and $M^{+\cdot}$ at *m/e* 308. About 5% of the mono-nitrile **11**, mp 100–102°C, was also obtained, $M^{+\cdot}$ at *m/e* 313. The *o*-cyano group deshields the neighbouring methyl protons in the ^{1}Hmr spectrum of both **10** and **11** by about 0.2 ppm from those in **8**.

	R	X	Y
1	OCH_3	H	H
2	Cl	H	H
5	CH_3	CH_2Br	CH_2Br
8	CH_3	Cl	Cl
10	CH_3	CN	CN
11	CH_3	CN	Cl
12	CH_3	CHO	CHO
13	CH_3	CH_2OH	CH_2OH
14	CH_3	H	H

Reduction of the dinitrile **10** to the dialdehyde **12** was achieved by diisobutyl aluminum hydride in benzene in 86% yield. The dialdehyde **12**, mp 141–143°C, showed the aldehyde protons at δ 10.2 in its ^{1}Hmr spectrum, the —C=O stretch at 1685 cm^{-1} in its ir spectrum, and $M^{+\cdot}$ at *m/e* 314. The dialdehyde **12** was reduced with sodium borohydride in THF in essentially quantitative yield to the diol **13**, mp 135–137°C, ir band at 3250 cm^{-1} (—OH), and —OH proton at δ 1.62 (readily exchangeable with D_2O). Treatment of the diol with PBr_3 in benzene then led to the desired bis(bromomethyl) compound **5**, mp 129–130°C in 74% yield. The mass spectrum of **5** showed the expected 1:2:1 isotope pattern centered at *m/e* 446 for its molecular ion, and the —CH_2Br protons at δ 4.35 in its ^{1}Hmr spectrum.

The parent 2,2′′-dimethyl-*o*-terphenyl **14** was obtained by conversion of dichloride **8** to its Grignard reagent and reaction with water. Compound **14**, mp 84–86°C, gave $M^{+\cdot}$ at *m/e* 258 as the base peak in its mass spectrum. With the syntheses of such compounds achieved, the barrier to rotation could thus be measured.

Proton Magnetic Resonance Results



For ^{1}Hmr spectra that are relatively simple, e.g. where the low temperature spectrum consists of two peaks and these collapse to a single peak at higher temperature, the coalescence temperature (T_c) method to estimate $\Delta G_c^{\ddagger}$ (the transition state free energy at coalescence) is most often used (see, for example, ref. 11). This method simply involves measurement of T_c and the frequency separation (Δν) of the peaks concerned at the low temperature limit. Then $\Delta G_c^{\ddagger}$ can be calculated from eq. [1] (12).

$$[1] \quad \Delta G_c^{\ddagger}(\text{kJ/mol}) = 0.01913T_c(9.972 + \log T_c/\Delta\nu)$$

The results for the systems under study here are shown in Table 1.

It is important to note that while this method is simple, it has its limitations, for example, the linewidth of the signals must be small in comparison to Δν. This is reasonably true here.[2] Further, $\Delta G_c^{\ddagger}$ values so obtained should only be compared within similar examples such that $\Delta S^{\ddagger}$ is approximately constant (otherwise a complete lineshape analysis is preferred). This would also seem to be reasonable for the systems under study.

From the data given in Table 1, it can be seen that for the parent **14**, the barrier to rotation is ca. 62 kJ/mol,[3] and that 3,3′′-substituents add a further 8–13 kJ/mol to this barrier. The closest analogies to **14** in the literature appear to be the pentaaryl benzene **15** and the di-*o*-tolylnaphthalene **3**, where

15

the barriers are 65 kJ/mol (5*c*) and 101 kJ/mol (7), respectively. For **3** without the *o*-methyl groups (i.e. for 1,8-diphenylnaphthalene) the barrier is 63 kJ/mol (6). Clearly our results compare favourably with these, and for **14** the change in barrier on adding an *o*-substituent might reasonably be ex-

[2]Except for **5** where $\Delta G_c^{\ddagger}$ was not able to be obtained.

[3]The main error comes from estimation of T_c (±2°C) which gives an error in $\Delta G_c^{\ddagger}$ of about ±0.5 kJ/mol.

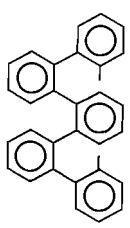
TABLE 1. Thermodynamic data for the barrier to rotation in 3,3''-disubstituted-2,2''-*o*-terphenyls[a]

Compound	X	Y	Δν (Hz)	T_c (°C)	$\Delta G_c^{\ddagger}$ (kJ/mol)
14	H	H	9.0	9	61.9
8	Cl	Cl	7.1	58	73.7
11	Cl		8.0	42	69.7
		CN	7.1	38	69.1
10	CN	CN	7.7	42	69.8
12	CHO	CHO	6.0	62	75.1
5	CH_2Br	CH_2Br	< 1	—	—



[a]Spectra were determined using ca. 25 mg of sample in 0.5 mL $CDCl_3$ on a Perkin-Elmer R32 (90 MHz) spectrometer: Δν was measured at ca. −40°C.

pected to be smaller than for **3** where the rings are closer to each other.

For the *o*-terphenyl system **14**, the size of the 3,3''-substituent (other than for H) only makes a small difference in the magnitude of the barrier, and follows the order H < CN < Cl, CHO, in fair agreement with other systems (13). It is of interest to note that in the mono-CN, mono-Cl **11**, the barrier is the same as for the di-CN **10**, some 4 kJ/mol less than for the di-Cl **8**. Presumably the linear —C≡N group can slide by more readily than the more spherical —Cl. Some modification of the hybridization at C-2 and 2'' may also be occurring because of the change at C-3,3''.

In the case of **3** and **4** where separate isomers were found to exist, the *trans*-isomer **4** had its methyl protons more shielded. This seems likely also in our system, and for the parent **14** the $-CH_3$ resonances appear at δ 2.0 and δ 2.1 (−40°C); thus the *cis*-isomer **14A** is assigned to δ 2.1 and the *trans*-isomer **14B** to δ 2.0. This is also consistent with previous work on a variety of cyclophanes (14).

Now that we have shown that in simple *o*-terphenyls the barrier to rotation can be measured by the ^{1}Hmr method, we anticipate that this will stimulate work with other 2,2''-substituents. Indeed during the preparation of this manuscript, Hammerschmidt and Vögtle (15) have reported the barrier for bis-*o*-terphenyl **16** to be 71.1 kJ/mol, in

16

excellent agreement with our results, despite the more complicated 2''-substituent which itself has rotational possibilities.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. The ^{1}Hmr spectra were determined in $CDCl_3$ (unless otherwise stated) on a Perkin-Elmer R12A (60 MHz) or R32 (90 MHz) spectrometer and are reported in ppm downfield from tetramethylsilane as internal standard. The ir spectra were recorded on a Pye-Unicam SP1000 spectrometer.

Mass spectra were determined on a Hitachi Perkin-Elmer RMU-7 or Finnigan 3300 mass spectrometer at 70 eV. Microanalyses were performed by this department. All evaporations were carried out under reduced pressure on a rotary evaporator at ca. 40°C. Extracts were dried with anhydrous sodium sulfate.

3,3''-Dichloro-2,2''-dimethyl-o-terphenyl ***8***

The Mono-Grignard Reagent ***7***

A solution of 2,6-dichlorotoluene **6** (50.5 g, 0.314 mol) in dry tetrahydrofuran (150 mL) was added dropwise over 30 min to gently warmed Mg (7.63 g, 0.314 mol) under N_2. When the addition was complete the reaction mixture was heated under reflux for 3 h and then diluted with a further portion of THF (50 mL).

The Coupling

A solution of *o*-dibromobenzene (37 g, 0.0157 mol) in dry THF (100 mL) was added dropwise over 30 min to the stirred Grignard **7** held at −70°C under N_2. $Ni(Acac)_2$ (16) (0.8 g, 20 mmol) was then added and the reaction mixture was allowed to warm to ~20°C for 1 h and then refluxed for 12 h. After cooling and addition of ice water, the organic layer was washed with aqueous HCl, water, and then dried and evaporated. The residual brown oil was preabsorbed and chromatographed on silica gel using pentane as eluant to yield firstly the product dichloride **8** (65 g, 60%, individual yields varied between 35–60% over several runs). Recrystallization from cyclohexane yielded colourless crystals, mp 102–104°C; ^{1}Hmr (60 MHz, 25°C) δ: 7.5–6.7 (m, 10H, ArH) and 2.11 and 2.05 (s, 3H each, $-CH_3$); $M^{+\cdot}$ *m/e*: 326 (correct isotope pattern, 57), 291 (17), 256 (18), 166 (17), 165 (61), 126 (59), 125 (32), and 119 (100). *Anal.* calcd. for $C_{20}H_{16}Cl_2$: C 73.61, H 4.94; found: C 73.46, H 4.88.

Eluted subsequently was 3,3'''-dichloro-2,2''''-dimethyl-*o*-quaterphenyl **9** (1.9 g, 3%), colourless crystals from cyclohexane, mp 173–175°C; ^{1}Hmr (60 MHz, 25°C) δ: 7.5–6.3 (m, 14H, ArH), and 1.65 and 1.48 (s, ca. 3H each, $-CH_3$); $M^{+\cdot}$ *m/e*: 402 (100). *Anal.* calcd. for $C_{26}H_{20}Cl_2$: C 77.61, H 4.98; found: C 77.47, H 4.99.

3,3''-Dicyano-2,2''-dimethyl-o-terphenyl ***10***

Cuprous cyanide (25 g, 0.275 mol) was added to a solution of dichloride **8** (20.5 g, 62.9 mmol) in *N*-methyl-2-pyrrolidinone (65 mL) and then the reaction was heated under reflux for 12 h. A further portion of CuCN (25 g) in *N*-methyl-2-pyrrolidinone (65 mL) was then added and reflux continued for a further 12 h. After cooling to ca. 100°C, the reaction mixture was poured onto ice (200 g) and concentrated ammonia ("880", 200 mL). After mixing thoroughly, the precipitate was removed by filtration and washed well with dilute ammonia before extraction with dichloromethane. The organic layer was washed, dried, and evaporated and the residual brown oil was chromatographed over silica gel using pentane–dichloromethane (3:7) as eluant to yield firstly 3-chloro-3''-cyano-2,2''-dimethyl-*o*-terphenyl, **11**, (1.05 g, 5%), mp 100–102°C; ir (KBr): 2240 (—C≡N) cm^{-1}; ^{1}Hmr (60 MHz, 25°C) δ: 7.6–6.7 (m, 10H, ArH), 2.30 and 2.25 (s, total 3H, *o*-NC—ϕ—CH_3), and 2.10 and 2.05 (s, total 3H, *o*-Cl—ϕ—CH_3); $M^{+\cdot}$ *m/e*: 317 (100), 302 (16), and 282 (57). *Anal.* calcd. for $C_{21}H_{16}ClN$: C 79.37, H 5.04, N 4.41; found: C 79.58, H 5.01, N 4.43. Eluted next was the product **10** (18.5 g, 95%), white crystals from ethanol, mp 151–153°C; ir (KBr) 2240 (—C≡N) cm^{-1}; ^{1}Hmr (60 MHz, 25°C) δ: 7.6–7.0 (m, 10H, ArH) and 2.30 and 2.25 (s, 6H total, $-CH_3$); $M^{+\cdot}$ *m/e*: 308 (100), 307 (35), and

292 (47). *Anal.* calcd. for $C_{22}H_{16}N_2$: C 85.68, H 5.23, N 9.09; found: C 85.48, H 5.19, N 8.67.

2,2''-Dimethyl-o-terphenyl 3,3''-Dicarboxaldehyde **12**

Diisobutylaluminum hydride (113 mmol) in hexane (86 mL) was added dropwise under N_2 to a solution of dinitrile **10** (14.5 g, 47.1 mmol) in dry benzene (140 mL) at 20°C with mechanical stirring. After 12 h, the viscous pale yellow solution was decomposed (with ice bath cooling) by addition of methanol (7 mL), then methanol–water (1:1, 10.5 mL), and then concentrated HCl – water (1:2, 40 mL) such that the resultant solution was slightly acidic. The mixture was extracted with dichloromethane and the organic layer was washed, dried, and evaporated. The resulting brown oil was filtered through a short column of silica gel in pentane–dichloromethane (1:9) to yield the product dialdehyde **12** (12.7 g, 86%). A portion was recrystallized from carbon tetrachloride as white crystals, mp 141–143°C; ir (KBr) 1685 (—CHO) cm^{-1}; ^{1}Hmr (60 MHz, 25°C) δ: 10.2 (s, 2H, —CHO), 7.7–7.0 (m, 10H, ArH), and 2.40 and 2.37 (s, total 6H, —CH_3); $M^{+\cdot}$ *m/e*: 314 (100), 299 (60), and 243 (41). *Anal.* calcd. for $C_{22}H_{18}O_2$: C 84.05, H 5.77; found: C 84.37, H 5.52.

3,3''-Bis(hydroxymethyl)-2,2''-dimethyl-o-terphenyl **13**

A solution of dialdehyde **12** (13.3 g, 42 mmol) in *undried* tetrahydrofuran (95 mL) was added dropwise to a stirred slurry of $NaBH_4$ (1.2 g, 32 mmol) in THF (15 mL) at 20°C. After 12 h the mixture was decomposed with water (5 mL) and concentrated HCl (5 mL). The aqueous layer was saturated with NaCl and extracted with dichloromethane. The organic layers were dried and evaporated to give crude dialcohol **13** (13 g, 98%). A portion was recrystallized from benzene to yield white crystals, mp 135–137°C; ir (KBr): 3240 (—OH) cm^{-1}; ^{1}Hmr (60 MHz, 25°C) δ: 7.5–6.7 (m, 10H, ArH), 4.53 (s, 4H, —CH_2OH), 2.00 (s, 6H, —CH_3), and 1.62 (bs, 2H, —CH_2O*H*, exchanged with D_2O); $M^{+\cdot}$ *m/e*: 318 (100), 300 (63), 285 (69), 282 (86), 270 (84), 296 (88), 267 (85), and 255 (76). *Anal.* calcd. for $C_{22}H_{22}O_2$: C 82.98, H 6.97; found: C 82.88, H 6.95.

3,3''-Bis(bromomethyl)-2,2''-dimethyl-o-terphenyl **5**

A solution of PBr_3 (20 mL, 0.20 mol) in dry benzene (200 mL) was added dropwise over 3 h to a vigorously stirred solution of crude diol **13** (13 g, 41 mmol) in dry benzene (400 mL) containing 5 drops of pyridine at 20°C. After 12 h, ice water was added and the organic layer was washed with aqueous $NaHCO_3$ and water and then dried and evaporated. The resulting brown oil was chromatographed on silica gel using pentane–dichloromethane (7:3) as eluant to yield product bromide **5** (13.5 g, 74%). Recrystallization from cyclohexane gave white crystals, mp 129–130°C; ^{1}Hmr (60 MHz, 25°C) δ: 7.5–6.7 (m, 10H, ArH), 4.35 (s, 4H, —CH_2Br), and 2.07 (s, 6H, —CH_3); $M^{+\cdot}$ *m/e*: 446 (41, correct 1:2:1 isotope pattern), 367 and 365 (48), 366 and 364 (100). *Anal.* calcd. for $C_{22}H_{20}Br_2$: C 59.88, H 4.54; found: C 59.99, H 4.51.

2,2''-Dimethyl-o-terphenyl **14**

A solution of dichloride **8** (3 g, 9.2 mmol) in dry tetrahydrofuran (50 mL) was added dropwise over 30 min to active (17) Mg (2 mmol) in THF and then refluxed for 3 h. After cooling, water was added and the product was extracted into dichloromethane. The organic layer was washed, dried, and evaporated, and the residual oil chromatographed on silica gel using pentane as eluant to yield **14** (1.66 g, 70%) as an oil, which could only be crystallized from pentane with difficulty, mp 84–86°C; ^{1}Hmr (60 MHz, 25°C) δ: 7.15 (s, 4H, central ring ArH), 7.1–6.7 (m, 8H, outer ring ArH), and 1.87 (s, 6H, ArCH); $M^{+\cdot}$ *m/e*: 258 (100), 243 (62), and 228 (35). *Anal.* calcd. for $C_{20}H_{18}$: C 92.98, H 7.02; found: C 92.69, H 7.00.

Use of a bacteriophage to depolymerize a polysaccharide to an oligosaccharide; comparison of the ^1H and ^{13}C nuclear magnetic resonance spectra of the polymer and its hexasaccharide repeating unit[1]

GUY G. S. DUTTON, ANGELA V. SAVAGE, AND MICHEL VIGNON[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received May 1, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

GUY G. S. DUTTON, ANGELA V. SAVAGE, and MICHEL VIGNON. Can. J. Chem. **58**, 2588 (1980).

A β-D-galactosidase associated with bacteriophage ϕ18 has been used to depolymerize the capsular polysaccharide of *Klebsiella* serotype K18 into the hexasaccharide corresponding to one repeating unit of the polymer. The nmr spectra of the polymer and of the oligosaccharide are comparable, leading to the conclusion that the conformations in solution of the repeating unit of the two substances are similar.

GUY G. S. DUTTON, ANGELA V. SAVAGE et MICHEL VIGNON. Can. J. Chem. **58**, 2588 (1980).

Le bactériophage ϕ18, qui contient une β-D-galactosidase, a été utilisé pour dépolymériser le polyoside capsulaire de *Klebsiella* K18 en hexasaccharide correspondant à une unité répétitive. Les spectres de rmn du polyoside et de l'hexasaccharide sont comparables ce qui nous amène à conclure que les conformations de l'unité répétitive des deux composés en solution sont semblables.

Nuclear magnetic resonance (nmr) spectroscopy may be used to study the solution properties of oligo- and polysaccharides, but a direct comparison of the nmr parameters of a polysaccharide and those of the oligosaccharide, corresponding to one repeating unit of the polysaccharide, is hard to achieve. This difficulty arises since few polysaccharides are known to have regular structures and selective cleavage into one, specific oligosaccharide is often impossible by chemical means.

During the last few years studies (e.g. 1–3) on the structure of the capsular polysaccharides associated with *Klebsiella* bacteria have shown these polymers to be built up of regular repeating units and, incidentally, to exhibit many different structural patterns. Furthermore, for many of these capsular polysaccharides there exists a specific bacterial virus (or bacteriophage) containing an endoglycanase (4). Each enzyme is capable of hydrolyzing a particular capsular polysaccharide into oligosaccharides corresponding to one (or more) repeating units. Since the pure, capsular polysaccharides are readily obtained in gram amounts this technique of using the appropriate bacteriophage also makes available the corresponding oligosaccharide. This paper reports a comparative nmr study on the polysaccharide from *Klebsiella* serotype K18 and the related oligosaccharide.

Results and Discussion

Preparation of the Hexasaccharide

The capsular polysaccharide from *Klebsiella* K18 has been shown (5) to be based on a repeating unit having three sugar units in the main chain and a side chain also containing three sugar residues (3 + 3 type); see Figs. 1 and 3, wherein the sugar residues are labelled for convenience **A–F**.

A bacteriophage was isolated from sewage, propagated on *Klebsiella* K18, and purified through isopycnic centrifugation on cesium chloride, according to standard procedures (6). This bacteriophage contains a β-D-galactosidase and thus incubation with the capsular polysaccharide from *Klebsiella* K18, which contains only one β-D-galactopyranosyl unit, yields a linear hexasaccharide corresponding to **F—E—D—C—A—B** (Figs. 2 and 4). The incubation mixture was desalted on Sephadex G-10, dialyzed against distilled water, and the concentrated dialyzate was fractionated on a column of Biogel P-2 to give the pure hexasaccharide.

Proton Nuclear Magnetic Resonance Measurements

The native K18 polysaccharide and the derived hexasaccharide were separately exchanged with D_2O and the proton spectra were run at 250 MHz at a temperature of 80–90°C. The spectra are shown in Figs. 1 and 2 and were compared with respect to the chemical shifts and T_1 relaxation times of the anomeric protons (7). The relevant data are presented in Table 1 from which it may be seen that there is little difference in the chemical shifts of the

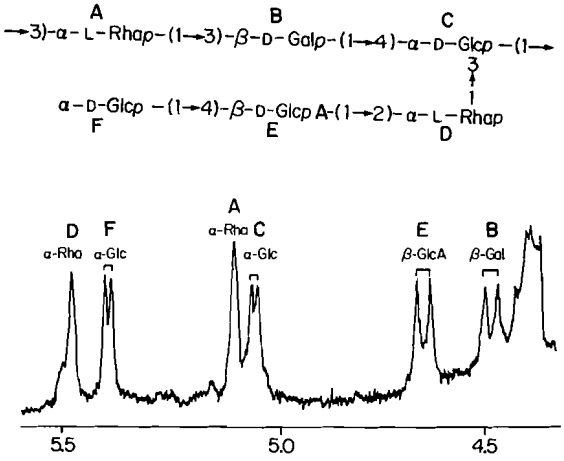

FIG. 1. 250 MHz proton spectrum (anomeric region) of polysaccharide K18.

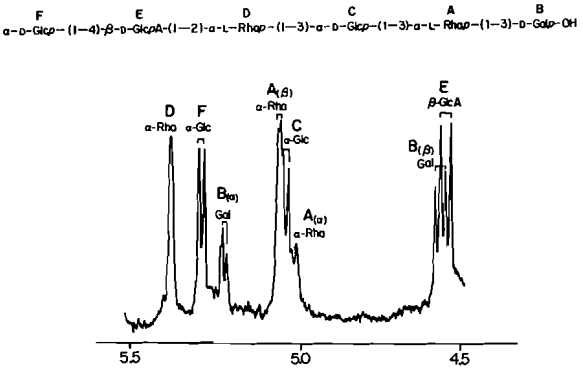

FIG. 2. 250 MHz proton spectrum (anomeric region) of hexasaccharide (for details see text).

anomeric protons in the polysaccharide and the hexasaccharide, except for the β-D-galactopyranosyl residue (unit **B**) which becomes the reducing group in the oligosaccharide; this shift confirms that the phage enzyme is a β-D-galactosidase. It is also clear from Figs. 1 and 2 that the anomeric proton in the α-L-rhamnopyranosyl residue (unit **A**), joined to the reducing galactose residue, is split on account of the mutarotation equilibrium.

The most noteworthy change in T_1 values is that of an α-D-glucopyranosyl residue (unit **C**). This may be attributed to the fact that in the polysaccharide unit **C** represents a branch point whereas the oligosaccharide is linear. It must, however, be pointed out that the T_1 data for unit **C** in the hexasaccharide may not be too accurate due to overlap of the signal from H-1 of unit **C** with that of H-1 from unit **A**. The change in T_1 values for the β-D-galactopyranosyl residue (unit **B**) is to be anticipated since this becomes the reducing terminus of the oligosaccharide (7). It may, however, be observed that the axial H-1 of the β-D-galactose anomer has a significantly shorter relaxation time than the equatorial proton of the α-anomer, due to 1–3 diaxial interactions. The ratio of the α/β times is 1.67 in agreement with the results of Hall and Preston (7).

The polysaccharide contains two sugars that are β-linked; one in the main chain (**B**) and the other in the side chain (**E**). It is of interest that there is no significant difference in their T_1 values. The same is true of the two α-D-glucopyranosyl units, one terminal (**F**) and one constituting a branch point (**C**). For the two α-L-rhamnopyranosyl residues (**A** and **D**) the T_1 values are different, but not greatly so.

^{13}C *Nuclear Magnetic Resonance Measurements*

The anomeric carbons of the polysaccharide K18 and of the hexasaccharide were assigned by selective heteronuclear irradiation of the corresponding anomeric protons; the spectra are shown in Figs. 3 and 4 and the chemical shifts of the anomeric carbon atoms are given in Table 2. The only significant changes are those of the β-D-galactopyranosyl residue (**B**) which becomes the reducing end of the oligosaccharide; two signals corresponding to the mutarotational equilibrium are clearly distinguishable at 97.15 and 93.10 ppm for the anomeric carbon, and at 61.85 and 61.65 ppm for the primary alcohol group (C-6), of unit **B** in the hexasaccharide. Minor shifts are evident for units **D** and **F**. It is of interest that the signal due to the anomeric carbon atom of the α-L-rhamnopyranosyl unit (**A**), glycosidically linked to the reducing D-galactopyranosyl residue (**B**), does not exhibit any splitting as observed in the corresponding proton spectrum.

Conclusions

This investigation demonstrates that the use of viral enzymes is a convenient method for obtaining oligosaccharides corresponding to one (or more) repeating units of the polysaccharide. In the case of *Klebsiella* capsular polysaccharides, the structures so far reported are based on repeating units of tri- to hepta- saccharides and the derived oligosaccharide may be either linear or branched, depending upon the structure of the original polymer and the nature of the glycosidase. For those polysaccharides that contain acid labile groups, e.g. pyruvic acid acetals (1-carboxyethylidene substituents), it has been demonstrated elsewhere (8) that depolymerization by viral enzymes is the only practical method of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

obtaining an oligosaccharide corresponding to an intact repeating unit.

While it is recognized that changes in chemical shifts, either proton or ^{13}C, represent a relatively unsophisticated basis of comparison, measurement of T_1 values is more sensitive. In either case, the differences reported here for the K18 polysaccharide and the hexasaccharide are minor and lead to the conclusion that the conformations in solution of these two compounds are very similar.

Experimental

Propagation of Bacteriophage

The bacteriophage used was *Klebsiella* phage ϕ18, isolated originally from sewage (6). The host for this phage is *Klebsiella* serotype K18, the structure of whose capsular polysaccharide is known (5). For all phage work the standard procedures given by Adams (9) were used and full details of phage propagation and purification have been given elsewhere (6).

An initial stock of bacteriophage ϕ18 was obtained by the confluent lysis technique (9) and propagation was carried out sequentially in 250, 500, and 1000 mL wash bottles with sintered glass air inlets. *Klebsiella* K18 was grown in these bottles in standard broth (5 g bactopeptone, 3 g bacto-beef extract, and 2 g sodium chloride per L) with strong aeration until the optical density was 1.0–1.2 at 660 nm (1 cm cell) when $\sim 10^9$ colony forming organisms per mL were present. The medium was infected with 3 PFU (plaque forming units) of phage ϕ18 per cell; lysis occurred 30 min later and incubation was continued for a further 1 h.

A total of 1300 mL of medium containing 10^{10} PFU/mL was obtained and the phage were precipitated with polyethylene glycol 6000 (6). Subsequent isopycnic centrifugation (6) through a gradient of cesium chloride gave a total of $\sim 6 \times 10^{12}$ PFU.

Depolymerization of Polysaccharide K18

Capsular polysaccharide from *Klebsiella* K18 (350 mg) was dissolved in 50 mL of phosphate-buffered physiological saline (PBS) and 6×10^{12} PFU of phage ϕ18 in 20 mL of PBS were added. The solution was incubated for 48 h at 37°C and the progress of the reaction was monitored viscometrically (6). The reaction mixture was lyophilized, redissolved in 3 mL of water, and desalted on a column (100 cm × 19.5 cm^2) of Sephadex G-10. The column was eluted with a water–pyridine – glacial acetic acid buffer (500:5:2; pH 4.5) at a flow rate of 25 mL/h and carbohydrate material was localized using the Molisch test.

The desalted material (340 mg) was dialyzed against 3 × 1 L of distilled water and lyophilization yielded 45 mg of nondialyzable material (13%) and 290 mg of oligosaccharides. The dialyzable material was dissolved in 3 mL of the buffer (pH 4.5) applied to the top of a column of Biogel P-2 and was eluted with the same buffer. Fractions (3 mL) were collected and assayed by the phenol – sulfuric acid method (10). A fraction (F-1, 185 mg) was eluted in the void volume, a fraction (F-2, 50 mg) contained a mixture of oligosaccharides, corresponding to two and three repeating units, and a pure fraction (F-3, 30 mg) was the hexasaccharide.

Nuclear Magnetic Resonance Measurements

The capsular polysaccharide K18 and the hexasaccharide obtained by bacteriophage degradation were each exchanged several times with D_2O. The proton spectra were run at 80–90°C and both ^1H and ^{13}C nmr spectra were recorded on a Cameca 250 MHz (62.80 MHz) spectrometer; anomeric carbon atoms were assigned by selective heteronuclear spin decoupling.

The measurements of proton T_1 values were made with WH Bruker (270 MHz) and WM Bruker (250 MHz) instruments on 1% (w/v) solutions in 99.96% D_2O at 87°C. The inversion recovery method was used for T_1 determination (two pulse sequence $(T...180...t...90)_n$) with 10–15 t values. The peak heights of the different anomeric protons were measured as a function of delay times (t) and these data were then used for a computer program.

Acknowledgements

This research was carried out under a Canada–France exchange program. We are grateful to the National Research Council of Canada and le Centre National de la Recherche Scientifique for a Fellowship (to M.R.V.) to spend a year at the University of British Columbia, to MacMillan Bloedel Ltd for a Scholarship (to A.V.S.), and to the Natural Sciences and Engineering Research Council of Canada for continuing financial support (to G.G.S.D.).

We thank Dr. R. Wylde (Montpellier) for her interest in this work, Dr. K. Bock (Lyngby) for measuring T_1 values and the use of his computer program, and Dr. S. Stirm (Giessen) for the bacteriophage ϕ18.

The mass spectrometric behavior of 3α,5-cyclo-5α-cholestan-6β-yl alkyl ethers[1]

FREDERICK J. BROWN,[2] IAN J. MASSEY, AND CARL DJERASSI[3]
Department of Chemistry, Stanford University, Stanford, CA 94305, U.S.A.

Received May 20, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

FREDERICK J. BROWN, IAN J. MASSEY, and CARL DJERASSI. Can. J. Chem. **58**, 2592 (1980).

The 3α,5-cyclo-6β-methoxy (*i*-methyl ether) moiety is a common protective grouping in steroid partial synthesis. Therefore, the mass spectrometric behavior of 6β-hydroxy-3α,5-cyclo-5α-cholestane, the corresponding methyl, ethyl, and *tert*-butyl ethers, the analogous ketone, and the parent hydrocarbon has been investigated in order to determine the mechanisms of the characteristic fragmentations of these compounds. Such knowledge is essential for unequivocal structure elucidation by mass spectrometry and also bears on the current interest in the stereospecificity of electron impact induced eliminations. Deuterium labeling of carbon atoms 1,2,3,4,7,8,9, and 19 of 6β-methoxy-3α,5-cyclo-5α-cholestane established the course of methanol extrusion and the identity of the highly diagnostic A ring cleavage ion $M^{+\cdot} - 55$. Mechanisms are proposed for these key fragmentations. The mass spectra of the methyl, ethyl, and *tert*-butyl ethers of cholesterol are analyzed, and the features distinguishing these compounds from the isomeric 3,5-cyclosteroids are noted.

FREDERICK J. BROWN, IAN J. MASSEY et CARL DJERASSI. Can. J. Chem. **58**, 2592 (1980).

La fonction cyclo-3α,5 méthoxy-6β (éther méthylique *i*) est un groupe protecteur courant dans les synthèses partielles de stéroides. Par conséquent, on a étudié le comportement en spectrométrie de masse de l'hydroxy-6β cyclo-3α,5 cholestane-5α, des éthers méthylique, éthylique et *tert*-butylique correspondants, de la cétone analogue et de l'hydrocarbure de base dans le but de déterminer les mécanismes des fragmentations caractéristiques de ces composés. Une telle connaissance est essentielle à la détermination univoque de la structure par spectrométrie de masse et présente également de l'intérêt pour la compréhension de la stéréospécificité des éliminations induites par impact électronique. Le marquage des atomes de carbone-1,2,3,4,7,8,9 et 19 du méthoxy-6β cyclo-3α,5 cholestane-5α par du deutérium a permis d'établir le mode d'élimination du méthanol et l'identité de l'ion caractéristique $M^{+\cdot} - 55$ résultant du clivage du cycle A. On propose des mécanismes pour ces fragmentations fondamentales. On a analysé les spectres de masse des éthers méthylique, éthylique et *tert*-butylique du cholestérol et on a noté les particularités qui distinguent ces composés des cyclo-3,5 stéroïdes isomères.

Introduction

The continuing discoveries of new marine sterols possessing unique side chains (2) have spawned a number of intriguing hypotheses concerning the biological origins (2*a*, *c*) and roles of such compounds (3). Investigations directed toward probing these questions, as well as the unequivocal structure proofs of the new sterols themselves, rely on the partial syntheses of these compounds from tetracyclic steroidal precursors. Invariably these syntheses involve protecting the nuclear Δ^5-3β-alcohol moiety as a 3,5-cyclosteroid (4) during elaboration of the side chain (5, 27). In addition, these 3,5-cyclosteroids have proven valuable in recent preparations of plant hormones (6) and A-nor steroids (7). Although mass spectrometry plays a vital role in the structure confirmation of intermediates in these syntheses, a systematic study of the mass spectral behavior of the important 3,5-cyclosteroids has not been published. This fact, in conjunction with a recent report of the stereoselective electron impact induced elimination of methanol from arylcyclohexyl methyl ethers (8), prompted us to investigate the mass spectrometric behavior of 6β-methoxy-3α,5-cyclo-5α-cholestane, some homologous 3,5-cyclocholestanes, and the isomeric cholesterol ethers.

The mass spectra of 6β-hydroxy-3α,5-cyclo-5α-cholestane (**1**) (9) and the corresponding methyl (**2**) (10), ethyl (**3**) (11), and the heretofore unknown *tert*-butyl[4] (**4**) ethers are reproduced in Fig. 1. In each case the elimination of ROH (R = H, CH_3, C_2H_5, and *t*-C_4H_9, respectively) from the molecular ion generates a prominent peak at *m/z* 368. In light of the recent report of stereoselective methanol elimination from cyclohexyl methyl ethers upon electron impact ionization (8), we were interested in determining whether the expulsion of an ROH molecule from these 3,5-cyclosteroids involved a site- and/or stereospecific hydrogen abstraction. To this end 6β-methoxy-3α,5-cyclo-5α-cholestane (**2**; *i*-cholesteryl methyl ether) was labeled with deuterium specifically at carbon atoms 1, 2, 3, 4, 7, 8, 9, and 19 (see Table 1).

In every case the deuterated *i*-cholesteryl methyl ether, **2**, was obtained from the correspondingly labeled cholesterol by tosylation and subsequent solvolysis in anhydrous, potassium acetate-

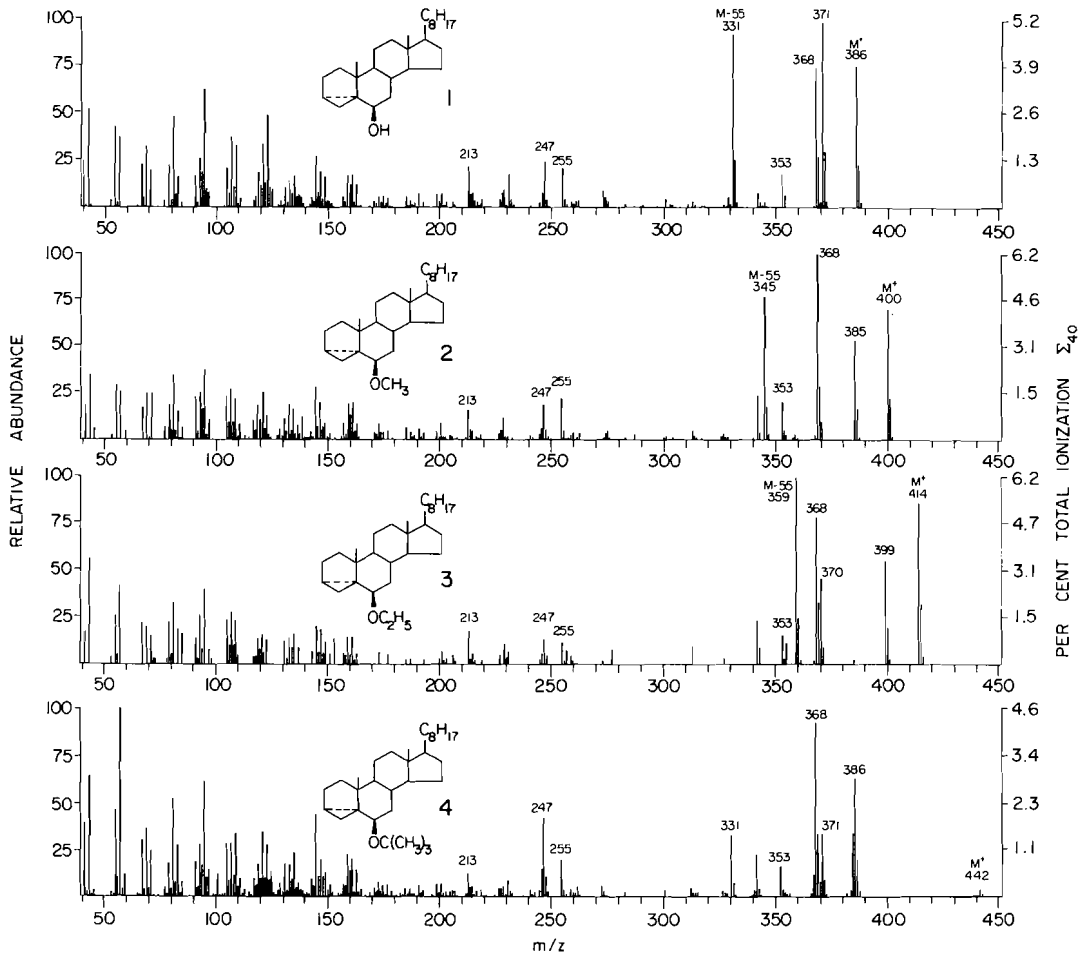

FIG. 1. Electron impact mass spectra of 3α,5-cyclo-5α-cholestanes measured on a Varian-MAT 711 spectrometer at 70 eV. Identities of designated ions (corroborated by labeling data and high resolution mass measurements): *m/z* 213 loss of ring D, H, ROH; *m/z* 255 loss of C_8H_{17}, ROH; *m/z* 247 loss of rings A and B plus one hydrogen atom (deuterium labeling of **2** demonstrated that C-8 (60%) and C-9 (27%) were the origins of the itinerant hydrogen atom, in general agreement with the data for the analogous fragmentation of cholesterol (17)).

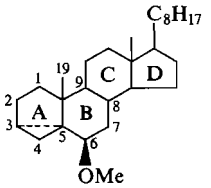
buffered methanol (4*a*). The syntheses of 7,7-d_2-, 8β-d_1-, and 9α-d_1-cholesterol have been described in a previous paper from this laboratory (13). The 2,2,4,4-d_4 and 3α-d_1 analogs were prepared via the enol acetate of 4-cholesten-3-one (13) by the procedure of Ockels and Budzikiewicz (14). Cholesterol-4β-d_1 was obtained from 4,6-cholestadien-3-one (13) by the method employed by Fétizon *et al.* (15) in the androstane series, while the 4,4-d_2 compound was synthesized from 4-oxocholesteryl benzoate according to the procedure of Barton *et al.* (16). 1,4-Cholestadien-3-one was converted to cholesterol-1α-d_1 as described by Tökés *et al.* (17). Cholesterol-19,19-d_2 was obtained by electrochemical[5] reduction (18) of 5-cholesten-3β-ol-19-al 3-acetate (19).

[5]We thank Dr. L. Throop (Syntex Research, Palo Alto, CA) for the use of his electrochemical apparatus.

The isotopic composition of each of the labeled 6β-methoxy-3α,5-cyclo-5α-cholestanes is given in Table 1, along with the deuterium-induced shifts observed for two key peaks in the mass spectra. These deuterated compounds were invaluable for defining the mechanisms of some of the diagnostic fragmentations of the 3,5-cyclosteroids as well as for implicating the protons abstracted in the course of methanol extrusion from **2**.



Results and Discussion

m/z *368 Ion*

An intense peak, resulting from the elimination of ROH from the molecular ion, is seen at *m/z* 368 in all of the spectra of Fig. 1. A number of studies of substituted cyclohexanols have established that electron impact induced loss of water occurs predominantly by *cis* 1,3- and 1,4-eliminations in-

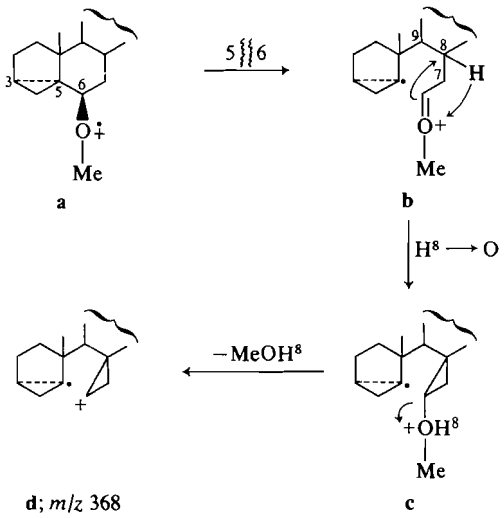
volving abstraction of a proximal proton by the oxygen atom (20). The expulsion of methanol from cyclohexyl methyl ethers has been shown to proceed by an identical process (8, 21). However, one would predict 1,4-elimination from the intact steroid *i*-methyl ether **2** to be precluded since the 9α-proton, being situated on the opposite face of the steroid from the 6β-methoxy group, is prohibited from approaching to within close proximity of the 6β-oxygen atom. *Cis* 1,3-elimination would involve the stereospecific abstraction of either the 4α- or 8β-hydrogen atoms.

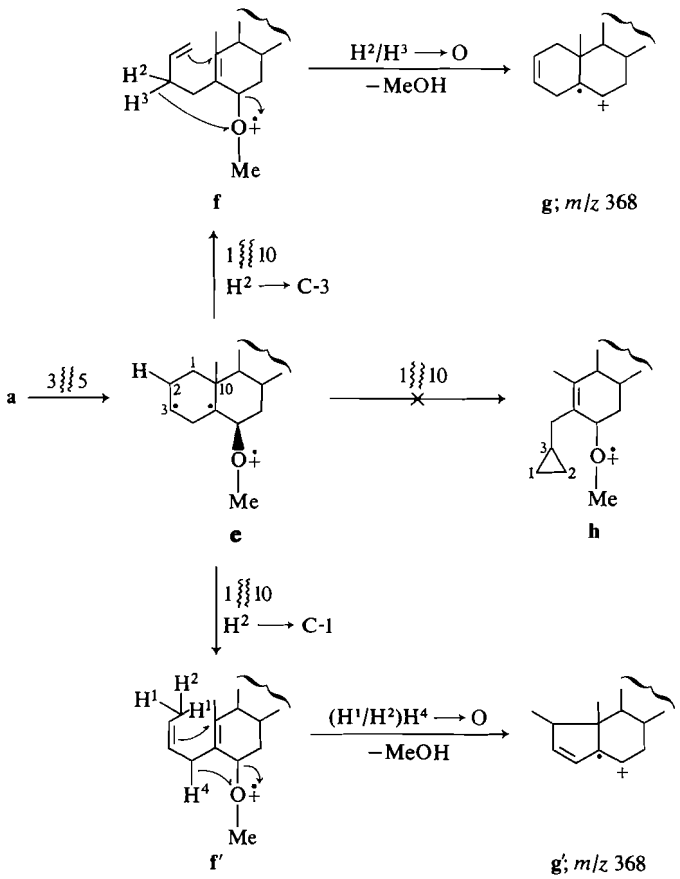
Despite these predictions, the labeling data in Table 1 for the 4,4-d_2- and the 4β-d_1-*i*-cholesteryl methyl ethers demonstrate that the proton loss from C-4 is small (10%) and *not* stereospecific. Moreover, the inaccessible 9α-hydrogen atom is abstracted to the same extent as the accessible 8β-proton (9%). Certainly these facts prove that the expulsion of methanol is not occurring by simple elimination from the intact steroid. The multiple origins of the abstracted hydrogen atom (C-7: 18%; C-8: 9%; C-9: 9%; C-4: 10%, C-3: 14%; C-2: 22%; C-1: 12%[6]) demonstrate that fairly extensive cleavage and/or rearrangement of the steroid skeleton must occur prior to the loss of methanol, just as was observed for the extrusion of water from cholesterol under electron impact (17).

The rigidity of the 3,5-cyclosteroid nucleus limits the closest approach of the 6β-oxygen atom to either the 4α- or 8β-proton to approximately 2.6 Å (according to a Dreiding model). This interatomic distance falls considerably outside of the maximum 1.8 Å limit established for hydrogen abstractions by oxygen atoms in alcohols (22) and ketones (23). Thus simple elimination of methanol is disfavored and other initial bond cleavages predominate.



Nonetheless, the eventual expulsion of a hydroxyl-containing moiety from **1** and the related alkyl ethers **2**, **3**, and **4** is a facile process since it gives rise to a pronounced peak in each of the spectra of Fig. 1. Furthermore, this fragmentation is enhanced at low voltages; the *m/z* 368 ion accounts for 20% of the total ion current (Σ_{40}) displayed by **2** at 12 eV. Hydrogen abstraction from carbon atoms 7, 8, and 9 can be accounted for by a common mechanism in which the initial bond cleavage is the well established α-fission of an ether (24). Cleavage of the 5—6 bond of molecular ion **a** generates the relatively stable oxonium ion **b**. Scission of the 5—6 bond, producing a tertiary radical at C-5, should be preferred over the analogous fission of the 6—7 bond which would generate a primary radical. An investigation of acyclic ethers has demonstrated that an oxonium ion such as **b** will rearrange by transferring hydrogen to the oxygen atom via a 4-, 5-, or 6-membered cyclic transition state (25). Thus process **b** → **d**, or a similar mechanism involving hydrogen migration from C-7 or C-9, would explain the loss of protons from carbon atoms 7, 8, and 9 during methanol expulsion. As indicated by the data of Table 1, this mechanism accounts for the generation of approximately 40% of the *m/z* 368 ion.

Inspection of a Dreiding model of species **b** indicates that the oxygen atom cannot come within close proximity of the protons in ring A. Therefore, to explain the abstraction of hydrogen atoms from carbons 1, 2, 3, and 4, a second mechanism is



[6]This figure was generated by making the plausible assumption that proton abstraction from C-1 is non-stereospecific.

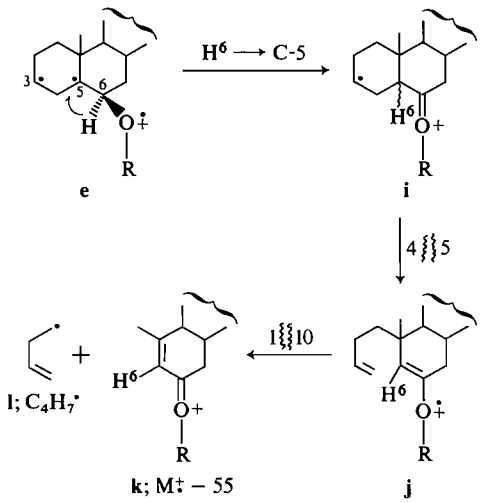
proposed by postulating that initial scission of the cyclopropyl ring of molecular ion **a** is competitive with the α-fission process **a** → **b**. Such a hypothesis is not unreasonable since homolysis of the 3-membered ring relieves much of the excessive strain present in the 3,5-cyclosteroid system. Furthermore, Dias and Djerassi (26) have shown that the mass spectrometric behavior of cyclopropanes can often be explained by invoking preferential rupture of the most highly substituted cyclopropyl bond. Application of this principle to *i*-cholesteryl methyl ether (**2**) suggests that fission of the 3,5-bond to give ion **e** could trigger the subsequent rearrangements leading to the elimination of methanol. Cleavage of the 1—10 bond and migration of a proton from C-2 to the radical site at either C-3 or C-1 yields the more stable dienes **f** or **f′**, respectively. The transfer of an allylic proton from C-3 (H^2 or H^3) of species **f** to the oxygen atom via a 6-membered cyclic transition state followed by expulsion of methanol (**f** → **g**) generates the ionized diene **g**. Alternatively, the migration of an allylic hydrogen atom from C-4 (H^4) or C-1 (H^2 or H^1) in ion **f′** leads to the analogous radical cation **g′**. Since this mechanism migrates the C-2 proton to either C-3 or C-1 prior to methanol expulsion, H^2 should be eliminated from the charge-retaining fragment to the same extent as loss of the C-3 proton plus 1/2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

the loss (statistical correction) of the two C-1 protons. This is indeed the case.



Alternatively, if the possibility of hydrogen migration from C-2 in ion **e** is ignored, 1—10 bond rupture leads to the cyclopropane species **h** in which all of the A ring protons are accessible for participation in the expulsion of methanol. In such a species the proton loss from C-1 and C-2 should be identical. However, Table 1 shows significant differences in the extent of hydrogen loss from C-1 (12%) and C-2 (22%). Hence mechanism **a** → **g** is postulated to explain hydrogen abstraction from carbon atoms 1, 2, 3, and 4, a process which accounts for approximately 60% of the $M^{\ddagger} - CH_3OH$ ion.

Thus the extrusion of methanol from 6β-methoxy-3α,5-cyclo-5α-cholestane is not a simple elimination process, but rather is preceded by cleavages associated with the methoxyl or cyclopropyl substituents. The subsequent hydrogen transfer in intermediates **b** and **f** then proceeds through the usual (25) cyclic transition states. These mechanisms should also be applicable to the loss of water from 6β-hydroxy-3α,5-cyclo-5α-cholestane (**1**) and the expulsion of an alcohol molecule from the corresponding ethyl (**3**) and *tert*-butyl (**4**) ethers.

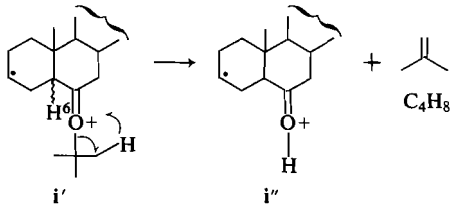
$M^{\ddagger} - 55$ Ion

A very strong peak at $M^{\ddagger} - 55$, corresponding to the loss of C_4H_7 from the molecular ion, is a ubiquitous feature of the mass spectra of steroids containing the 6β-methoxy-3α,5-cyclo moiety (27). This diagnostic ion is observed in the spectra (Fig. 1) of 6β-hydroxy-3α,5-cyclo-5α-cholestane (**1**, *m/z* 331), the corresponding methyl ether (**2**, *m/z* 345), and the ethyl ether (**3**, *m/z* 359). However, it is conspicuously absent in the spectra of both the parent hydrocarbon, 3α,5-cyclo-5α-cholestane (28) (**5**, spectrum not reproduced), and the *tert*-butyl ether **4**.

The labeling data in Table 1 indicate that the $M^{\ddagger} - 55$ ion arises from the elimination of carbon atoms 1, 2, 3, and 4 without any (reciprocal) hydrogen transfer. The absence of a corresponding peak in the mass spectrum of the hydrocarbon **5** proves that this fragmentation is not characteristic of the isolated 3,5-cyclosteroid functionality, but rather requires the concurrent presence of an oxygen substituent at carbon 6. The further observation that 3α,5-cyclo-5α-cholestan-6-one (29) (**6**, spectrum not reproduced) also fails to produce a $M^{\ddagger} - 55$ ion in the mass spectrometer suggests that a proton at carbon 6, as well as an oxygen atom, is essential. The following mechanism is consistent with these facts and again starts with the molecular

ion **e** in which the cyclopropane ring has suffered homolytic fission.

Migration of the activated C-6 proton to the adjacent radical site at C-5 in molecular ion **e** produces oxonium ion **i**. Subsequent scission of the 4—5 bond gives the ionized enol ether **j**. The even-electron, unsaturated oxonium ion **k**[7] is formed by cleavage of the 1—10 bond and expulsion of the homoallylic radical **l**. This mechanism applies equally well to the alcohol **1** (R = H) or the ethyl ether **3** (R = C_2H_5). 3α,5-Cyclo-5α-cholestan-6-one would not be expected to undergo process **e** → **k** because the proton at C-6 is no longer available, and thus the C-5 radical cannot be saturated by proton transfer (**e** → **i**) to trigger the requisite 4—5 bond scission (**i** → **j**). In the same vein, one would predict that the fragmentation pathway **e** → **k** would not be nearly as favorable for the hydrocarbon 3α,5-cyclo-5α-cholestane since the lack of a C-6 oxygen atom precludes the formation of such stable ions as **i**, **j**, or **k**.



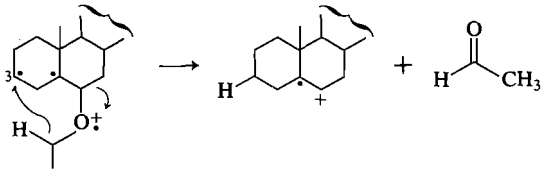
However, the question remains why the mass spectrum of the *tert*-butyl ether **4** does not exhibit a $M^{\ddagger} - 55$ ion. Certainly this compound meets all the prerequisites demanded by the proposed mechanism. The existence of a tertiary carbon atom in the ether substituent must present an alternative fragmentation pathway that is more favorable than the A ring cleavage process **e** → **k**. This hypothesis can, in fact, be documented.

The spectrum of **4** (Fig. 1) contains prominent peaks corresponding to the elimination of isobutylene or its equivalent (*m/z* 386) and isobutylene plus a methyl radical (*m/z* 371). This alkene loss undoubtedly occurs by the well known process of

[7]Djerassi *et al.* (30) have postulated that a species identical to **k** (R = H) is responsible for the $M^{\ddagger} - 55$ ion observed in the mass spectra of 6-keto steroids.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

hydrogen migration and olefin expulsion from an oxonium ion (24, 25). Thus, the *tert*-butyl analog of ion **i** (R = t-C_4H_9) can transfer a proton from the ether substituent to the oxygen atom with subsequent (or concomitant) fission of the carbon–oxygen bond to eliminate isobutylene and regenerate another oxonium ion (**i'** → **i''**). This second oxonium ion **i''** is precisely the intermediate species **i** (R = H) that is formed when *i*-cholesterol (**1**) fragments according to route **e** → **k**. Hence **i''** should undergo further bond fissions to extrude radical **l** (**i**, R = H → **k**). Indeed, this additional fragmentation does occur, as is evidenced by the presence of a

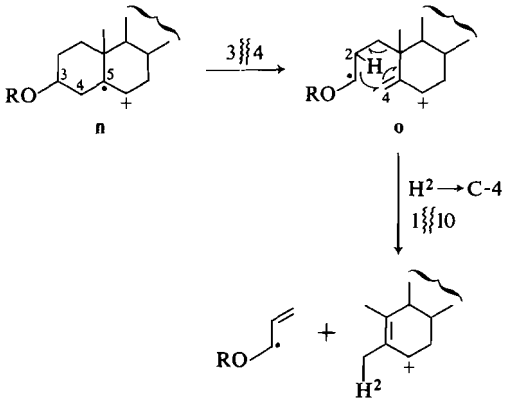


i' i''

peak at *m/z* 331 ($M^+ - (C_4H_8 + C_4H_7)$) in the mass spectrum of **4**.

In contrast to the *tert*-butyl ether **4**, the ethyl ether **3** does not eliminate a simple olefin. Instead the mass spectrum displays an ion at *m/z* 370 due to the loss of C_2H_4O. This fragmentation is most likely precipitated by migration of a heteroatom-activated secondary hydrogen atom from the α-carbon of the ethyl group to the C-3 radical in molecular ion **e**. Heterolytic fission of the carbon–oxygen bond then generates the ionized olefin **m**. The absence of the requisite α-proton prohibits the *tert*-butyl ether **4** from undergoing an analogous fragmentation, while the nonoccurrence of this aldehyde elimination in the *i*-methyl ether **2** is probably associated with the well-documented (25) propensity of secondary (rather than primary) hydrogens to undergo migration.

The elimination of a butene radical, comprised of carbon atoms 1, 2, 3, and 4 of the A ring, constitutes a very diagnostic fragmentation characteristic of 6β-hydroxy-3α,5-cyclo-5α-steranes and the corresponding alkyl ethers. The simultaneous presence of both an oxygen atom and a proton at carbon 6 appears to be a prerequisite for this cleavage. In the case of the *tert*-butyl ether **4** olefin expulsion precedes the A ring fragmentation. Thus all of the



e m; *m/z* 370

experimental observations are nicely explained by a single mechanism.

Alkyl Ethers of Cholesterol

Surprisingly, the mass spectrometric behavior of cholesteryl alkyl ethers has scarcely been investigated (31). For this reason, as well as to allow comparisons with the *i*-cholesteryl ether spectra of Fig. 1, the mass spectra of the methyl (**7**), ethyl (**8**) (11), and *tert*-butyl (**9**) (32) ethers of cholesterol are presented in Fig. 2. The spectra of Figs. 1 and 2 exhibit many similarities in the molecular ion region: $M^+ - 15$ (loss of a methyl radical[8]), *m/z* 368 (loss of ROH), and *m/z* 353 (loss of ROH plus a methyl radical).

However, all of the spectra of Fig. 2 display a significant peak at *m/z* 329 ($M^+ - C_3H_4OR$) which is absent in the spectra of Fig. 1. The analogous cleavage has been observed for cholesteryl trimethylsilyl ether (33) and Δ^5-3-aminosteroids (34). This diagnostic fragmentation is undoubtedly due to cleavage of the A ring, triggered by scission of the doubly activated 3—4 bond.

n o p; *m/z* 329

Hydrogen transfer from C-2 to C-4 and fission of the 1—10 bond completes the process to yield an even-electron allylic cation **p**. The cholesteryl ethers are also distinguished from the isomeric 3,5-cyclosteroidal ethers by the absence of the $M^+ - 55$ ion which is so characteristic of the latter compounds.

Cholesteryl ethyl ether (**8**) loses a molecule of acetaldehyde (or its equivalent) in the mass spectrometer, as did the corresponding 3,5-cyclosteroid **3**. A mechanism similar to **e** → **m** would explain this fragmentation (*m/z* 414 → *m/z* 370). Migration of a hydrogen atom from the α-carbon of the 3β-ether moiety to the ring B olefin would generate a radical cation analogous to **m**. Cholesteryl *tert*-butyl ether

[8]The mass spectrum of **2**-19,19-d_2 proved that 96% of the $M^+ - CH_3$ ion in **2** is due to loss of the C-19 angular methyl.

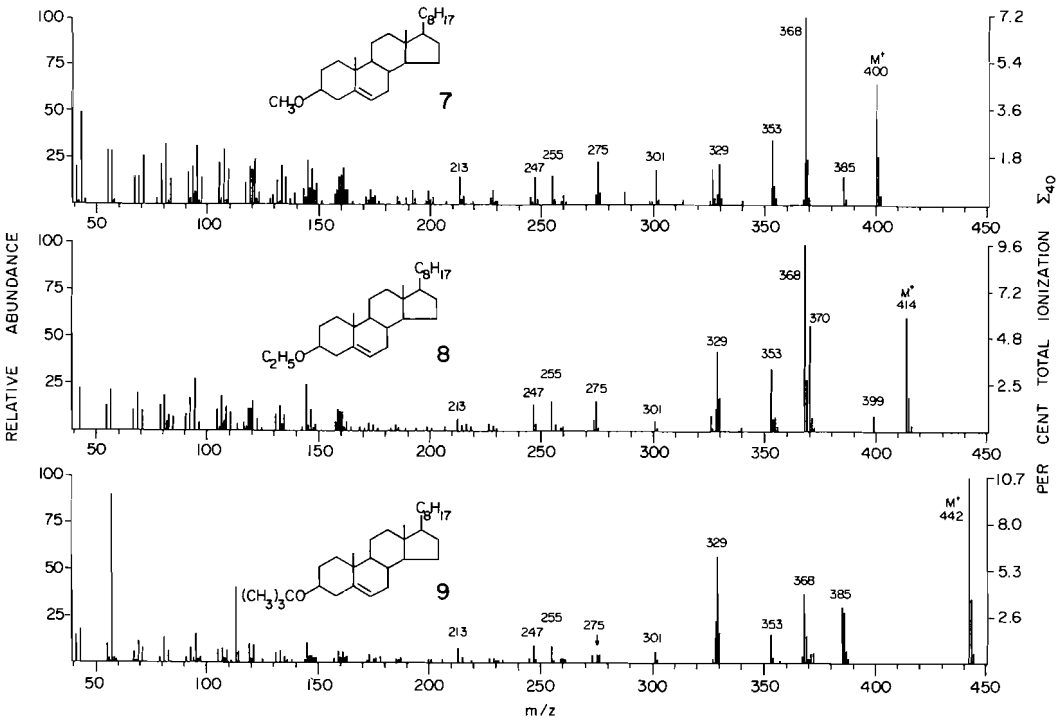


FIG. 2. Electron impact mass spectra of cholesteryl alkyl ethers measured on a Varian-MAT 711 spectrometer at 70 eV. Identities of designated ions (corroborated by labeling data and high resolution mass measurements): *m/z* 213, 247, 255, see Fig. 1; *m/z* 275 loss of C-1 through C-7 (17); *m/z* 301 loss of ring A, C-5, H (17).

(**9**) exhibits the loss of both isobutylene (*m/z* 386) and a *tert*-butyl radical (*m/z* 385), analogous to its 3,5-cyclosteroid counterpart **4**. Again, a similar mechanism is probably operating for both compounds.

Conclusions

Extensive deuterium labeling of 6β-methoxy-3α,5-cyclo-5α-cholestane (**2**) demonstrated that the electron impact induced loss of methanol is not a simple regiospecific elimination but rather is preceded by skeletal bond scissions. The multiple origins (carbons 1, 2, 3, 4, 7, 8, and 9) of the abstracted hydrogen atom are explained by postulating two competing fragmentation mechanisms which are respectively initiated by fission α to the ether substituent or rupture of the 3-membered ring. The prominent $M^+ - 55$ ion, which is highly diagnostic for 6β-hydroxy-3α,5-cyclo-5α-steroids and the corresponding ethers, was shown to result from the loss of carbon atoms 1, 2, 3, and 4 from ring A. A mechanism is proposed which accounts for the observed effects of substituents. The mass spectra of the methyl, ethyl, and *tert*-butyl ethers of cholesterol are analyzed. These compounds can be distinguished mass spectrometrically from the isomeric 3,5-cyclosteroidal ethers by the presence of a prominent ion at *m/z* 329 and the absence of a $M^+ - 55$ ion. The mass spectrometric behavior of more highly substituted analogs of the synthetically important 3,5-cyclosteroids can now be predicted on a mechanistically plausible basis.

Experimental

General Procedures

Mass spectra were obtained on either an AEI MS-9 spectrometer or a Varian-MAT 711 high-resolution mass spectrometer using direct inlet systems. The ^1H nmr spectra were obtained on a Varian XL-100-15 instrument using deuteriochloroform as solvent and tetramethylsilane as an internal standard. Infrared spectra were recorded on a Perkin-Elmer 700A spectrometer. Optical rotations were determined on an Autopol III polarimeter in a thermostated 1.00 dm micro cell. Melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected.

6β-tert-Butoxy-3α,5-cyclo-5α-cholestane (4)

A solution of 1.4 g cholesteryl tosylate and 2.2 g freshly fused potassium acetate dissolved in 100 mL anhydrous *tert*-butanol (freshly distilled from calcium oxide and stored over 4 Å molecular sieves) was refluxed under nitrogen for 44 h. The *tert*-butanol was removed under vacuum and the resulting residue was partitioned between ether and water. The organic layer was washed with water, dried, and evaporated to yield 1.2 g of an oily yellow solid which was chromatographed on a 60 g tlc-grade silica gel column with 5% ethyl acetate in hexane. An initial fraction yielded 0.16 g (14%) **4** as a clear, colorless oil which resisted all attempts at crystallization: $[\alpha]_D^{20}$ +22° (*c* 0.115, $CHCl_3$); ir (thin film): 3075 (cyclopropyl σ_{C-H}), 1365, 1385

Received May 13, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

TADAHIRO TAKEDA, YOSHIHIRO SUGIURA, YUKIO OGIHARA, and SEIICHI SHIBATA. Can. J. Chem. **58**, 2600 (1980).

N-(L-β-aspartyl)-α-D-glucopyranosylamine has been prepared, as a model of a corresponding derivative possibly present in glomerular basement membrane of rats, by the condensation of α-ethyl benzyloxycarbonyl-L-aspartate with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosylamine in the presence of diethylphosphorocyanidate. This was followed by hydrogenolysis, de-*O*-acetylation, and deethoxylation of the resulting 2,3,4,6-tetra-*O*-acetyl-*N*-(α-ethyl benzyloxycarbonyl-L-β-aspartyl)-α-D-glucopyranosylamine to remove the protecting groups. The ^{13}C nmr spectra of the corresponding glycosylamine derivatives are analyzed and discussed.

TADAHIRO TAKEDA, YOSHIHIRO SUGIURA, YUKIO OGIHARA et SEIICHI SHIBATA. Can. J. Chem. **58**, 2600 (1980).

La *N*-(L-β-aspartyl) α-D-glucopyrannosylamine, un modèle d'un dérivé correspondant qui est probablement présent dans la sous-membrane glomérulaire du rat, est obtenue par condensation du benzyloxycarbonyl L-α-aspartate d'éthyle sur la tétra-*O*-acétyl-2,3,4,6 α-D-glucopyrannosylamine en présence du phosphocyanidate diéthylique. Cette étape est suivie de l'élimination des groupes protecteurs par une hydrogénolyse, une dé-*O*-acétylation et une dééthoxylation de la tétra-*O*-acétyl-2,3,4,6 *N*(α-éthyl benzyloxycarbonyl L-β-aspartyl) α-D-glucopyrannosylamine qui en résulte. On a analysé les spectres rmn du ^{13}C des dérivés correspondants de la glycosylamine.

[Traduit par le journal]

Introduction

Shibata *et al.* (1) isolated from the glomerular basement membrane of rats, and purified, a new glycopeptide that has an activity consisting of induction of glomerulonephritis in homologous animals (nephritogenic activity) (2). The methylation analyses (3, 4), the concanavalin A test, and ^{13}C nmr spectral analyses (5) indicate that the sugar moiety of this glycopeptide has the Glc α-(1→6)Glc β-(1 → 6)Glc structure shown in Fig. 1. This is the first example of a new type of carbohydrate–protein linkage among natural compounds, of a direct, *N*-glycosyl linkage between a glycosyl and an amino acid residue. This paper reports the synthesis of *N*-acylated glycosylamines and studies on the ^{13}C nmr spectra of the above-mentioned glycopeptide and model compounds.

Results and Discussion

Marks and Neuberger (6) have described the synthesis and some properties of *N*-(L-β-aspartyl)-β-D-glucopyranosylamine. The preparation of this compound by a different procedure has also been described by Coutsogeorgopoulos and Zervas (7). Garg and Jeanloz (8) have also described the synthesis of *N*-(L-β- and α-aspartyl)-4-*O*-β-D-galactopyranosyl-β-D-glucopyranosylamines. All these syntheses produced β-D-glucopyranosylamine derivatives.

We now report the synthesis of the *N*-acetyl, *N*-(L-β-aspartyl)-α,β-D-glucopyranosylamine derivatives which were needed for ^{13}C nmr studies. 2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl azide (**1**) was obtained by the procedure of Bertho (9). The azide was hydrogenated in tetrahydrofuran over Adam's catalyst to give the amino compound (**2**). Compound **2** was acetylated and also condensed with α-ethyl benzyloxycarbonyl-L-aspartate to give **3** and **5**, respectively. These compounds were deblocked in the usual manner to give *N*-acetyl-, *N*-(L-β-aspartyl)-β-D-glucopyranosylamine **4** (mp 255°C) and **7** (mp 253°C), respectively. The basic physical and chemical properties are coincident with those reported earlier (7).

For synthesis of α-D-glucopyranosylamine derivatives, 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl azide (**9**) was prepared by treating 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl chloride (**8**) with sodium azide in hexamethylphospholic triamide (HMPT). This S_N2 reaction gave the inverted product in a yield of 65% and neighbouring group participation with retention of configuration is not observed (10). Hydrogenation of **9** in methanol gave the desired key intermediate glycosylamine derivative (**10**).

The α-ethyl benzyloxycarbonyl-L-aspartate was

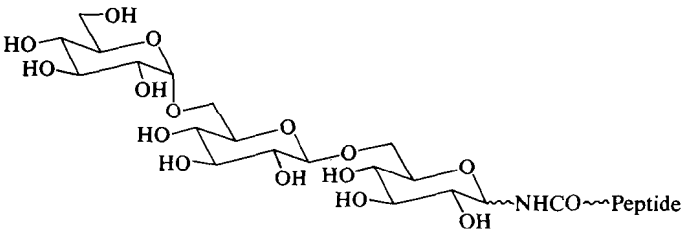

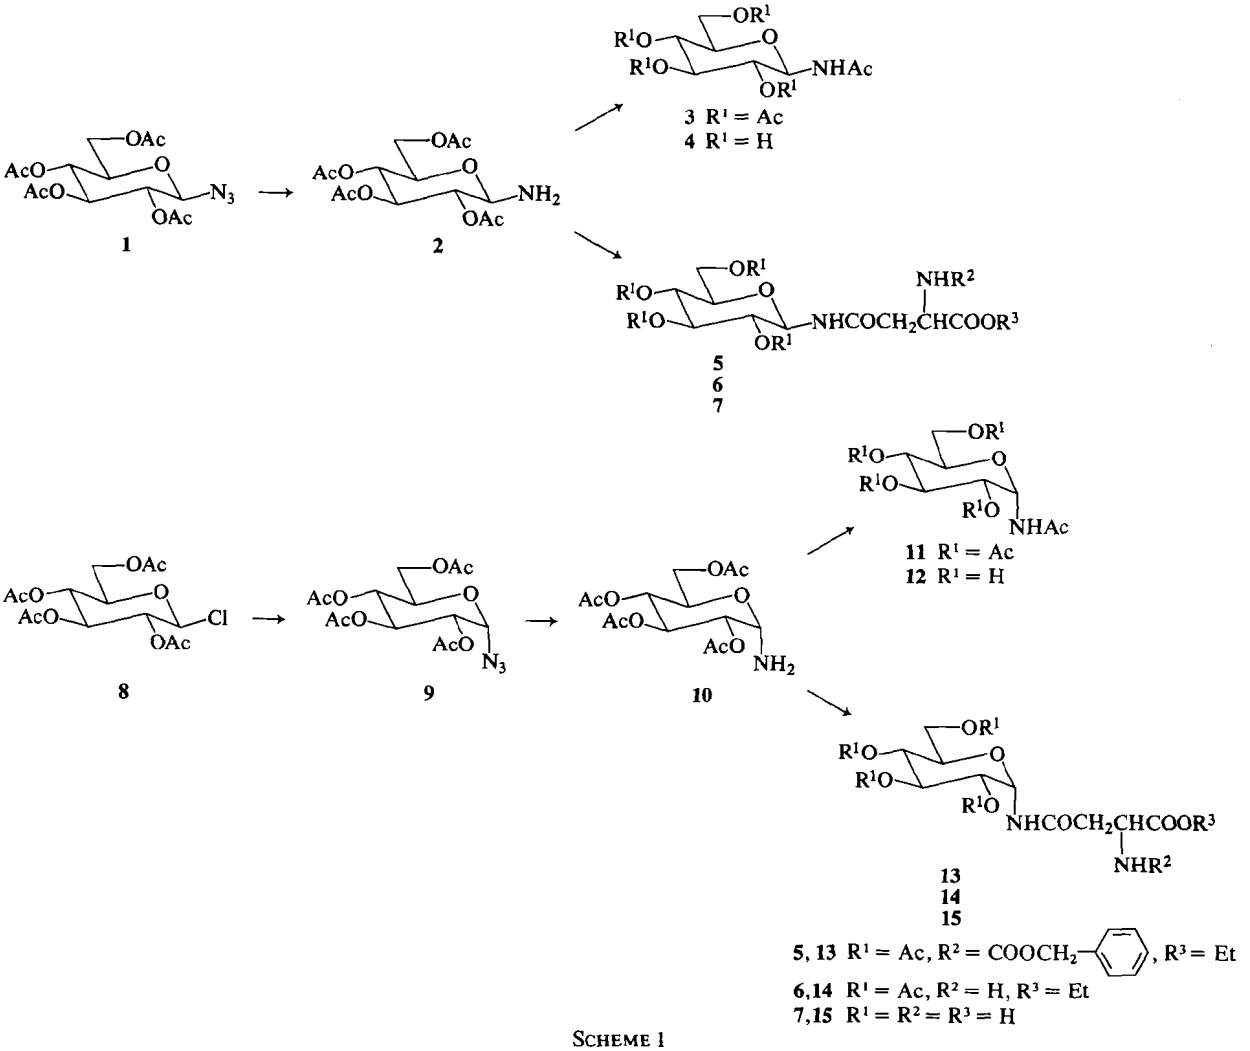

FIG. 1

readily prepared in high yield by the procedure of Wünsch and Zwiek (11) from benzyloxycarbonyl-L-aspartic acid.

The next step involved the condensation of α-ethyl benzyloxycarbonyl-L-aspartate with **10**, which gave the α-aspartyl-glucopyranosylamine derivative (**13**) in 90% yield using the DEPC method of Shioiri *et al.* (12). Removal of the benzyloxycarbonyl group by catalytic hydrogenation afforded the required tetra-*O*-acetyl-*N*-(L-β-aspartyl)-α-D-glucopyranosylamine (**14**). Thus, **14** was deacetylated and deethoxylated with triethylamine in 50% methanolic solution at room temperature to give a *N*-(L-β-aspartyl)-α-D-glucopyranosylamine (**15**) ($[\alpha]_D$ +34.1°). The *N*-acetylation of compound **10** followed by de-*O*-acetylation of the *N*-acetate af-

SCHEME 1

forded a *N*-acetyl-α-D-glucopyranosylamine (**12**) ($[\alpha]_D$ +15.0°). The synthetic route is illustrated in Scheme 1. The ^{13}C shifts of the glucosylamine derivatives are listed in Table 1.

The assignment of the α-D-configuration to the azide compound (**9**) was made by comparing its spectrum with that of β-D-azide compound (13). The signal of the anomeric carbon atom is always found at lowest field and normally C-1 of the β-anomer is at lower field than that of the α-anomer. The signals of C-4 and C-6 remain almost constant throughout the series of compounds described here and they are therefore readily assigned in most cases. The assignments of the closely spaced signals of C-3 and C-5 were made by the selective proton decoupling of H-3 and H-5, respectively. The ^{13}C nmr spectra indicate that the chemical shifts of the sugar moiety of compounds **12** and **15** are very similar to each other, and are obviously different from their respective β-isomers (**4**, **7**). A complete similarity of the *N*-glycosyl moieties of the glycopeptide and compound **15** was observed.

Consequently, a glycopeptide that has a nephritogenic activity has its *N*-glycosyl linkage in the α-D-configuration.

Experimental

General Methods

Melting points were determined with a Yanagimoto microapparatus and are uncorrected. The ^1H nmr spectra were recorded on a JNM MH-100 spectrometer with tetramethylsilane as the internal standard; abbreviations used: s, singlet; d, doublet; dd, doublet of doublets; t, triplet; and m, multiplet. The ^{13}C nmr spectra were obtained at 25.0 MHz in the pulsed Fourier transform mode on JEOL FX-100 instruments. Thin-layer chromatography was conducted on precoated silica gel plates (Merck GF-254) and column chromatography on silica gel (Merck Kieselgel 60).

[a]Compounds **7**, **15**, and glycopeptide were measured in D_2O (internal 1,4-dioxane (67.4 ppm)).

Materials

2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl azide, 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylamine were synthesized by well established procedures (9). α-Ethyl benzyloxycarbonyl-L-aspartate was prepared from benzyloxycarbonyl-L-aspartic acid according to the method of Wünsch and Zwiek (11).

*2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl Azide (9)*

A solution of 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl chloride (**8**) (7.2 g), prepared from penta-*O*-acetyl-β-D-glucopyranose according to Mills *et al.* (14), in 75 mL of HMPT was added to 15 g of sodium azide. The mixture was stirred for 3.5 h, then it was filtered and the filtrate concentrated to dryness. The residue was crystallized, and recrystallization from methanol gave 4.77 g (65%), mp 91–92°C; $[\alpha]_D^{24}$ +156.6° (*c* 1.06, $CHCl_3$); R_f 0.77 (benzene–acetone 4:1); ^1H nmr ($CDCl_3$) δ: 1.98, 2.00, 2.04, 2.06 (each s, 3H, CH_3CO), 4.06–4.30 (m, 3H, H-5, 6, 6'), 4.92 (q, J = 4, 8 Hz, 1H, H-2), 5.00 (t, J = 8 Hz, 1H, H-4), 5.33 (t, J = 8 Hz, 1H, H-3), 5.62 (d, J = 4 Hz, 1H, H-1). *Anal.* calcd. for $C_{14}H_{19}O_9N_3$: C 45.04, H 5.13, N 11.26; found: C 45.30, H 5.06, N 10.99.

*2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosylamine (10)*

A solution of 3.36 g of azide (**9**) in 15 mL of methanol was hydrogenated at room temperature and atmospheric pressure for 13 h in the presence of Adams' catalyst (0.45 g). After removal of the catalyst by filtration, the filtrate was concentrated to a syrup, which contained (tlc) three components (R_f 0.17, R_f 0.29, R_f 0.4). In this system the α-amine possessed R_f 0.17. The syrup was chromatographed on silica gel using benzene–acetone (4:1) to provide pure **10** (0.63 g, 21% yield), mp 62.5–63°C, $[\alpha]_D^{24}$ +108.7° (*c* 7.5, $CHCl_3$). *Anal.* calcd. for $C_{14}H_{21}O_9N$: C 48.41, H 6.09, N 4.03; found: C 48.50, H 6.19, N 3.83.

*N-Acetyl-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosylamine (11)*

A solution of 100 mg of **10** in 2 mL of pyridine and 2 mL of acetic anhydride was allowed to stand at room temperature for 8 h. The solution was poured into ice-water and extracted with $CHCl_3$. The $CHCl_3$ extracts were washed with water, dried, and concentrated to give a syrup; $[\alpha]_D^{20}$ +14.65° (*c* 4.0, $CHCl_3$). *Anal.* calcd. for $C_{16}H_{23}O_{10}N$: C 50.52, H 6.09, N 3.68; found: C 50.48, H 6.12, N 3.59.

N-Acetyl-α-D-glucopyranosylamine (12)

Compound **11** (100 mg) was *O*-deacetylated with triethylamine in 50% MeOH solution. The reaction solution was evaporated to give a syrup; $[\alpha]_D^{20}$ + 15.02° (*c* 0.9, H_2O). *Anal.* calcd. for $C_8H_{15}O_6N$: C 43.44, H 6.83, N 6.33; found: C 43.56, H 6.90, N 6.29.

*2,3,4,6-Tetra-*O*-acetyl-N-(α-ethyl Benzyloxycarbonyl-L-aspartyl)-α-D-glucopyranosylamine (13)*

To a solution of **10** (114 mg) in THF (5 mL) α-ethyl benzyloxycarbonyl-L-aspartate (96.3 mg), DEPC (diethyl phosphorocyanidate) (100 mg), and 0.15 mL of triethylamine were added. The mixture was stirred for 12 h at 0°C. The reaction mixture was diluted with AcOEt (50 mL), and successively washed with 5% HCl, water, saturated $NaHCO_3$, and saturated NaCl. Drying followed by evaporation gave a syrup which contained (tlc) a major (R_f 0.56) and a minor (R_f 0.76) component and some slower-moving components. The syrup was chromatographed on silica gel with the same solvent system as

on tlc (chloroform–methanol 4:1). The eluate of the major component was evaporated and crystallized from ethanol to give pure **13** (185 mg, 90%); $[\alpha]_D^{20}$ +64.6° (*c* 3.2, $CHCl_3$); ^1H nmr ($CDCl_3$) δ: 1.25 (t, 3H, $—CH_2CH_3$), 2.02, 2.03, 2.06, 2.08 (each s, 3H, $COCH_3$), 2.90 (q, 2H, $—CH_2CH_3$), 5.15 (s, 2H, $—CH_2—$ ), 5.65–5.90 (br, 1H, NH), 7.38 (m, 5H, arom. H). *Anal.* calcd. for $C_{28}H_{36}O_{14}N_2 \cdot 2H_2O$: C 50.91, H 6.10, N 4.24; found: C 50.46, H 5.93, N 4.27.

2,3,4,6-Tetra-O-*acetyl*-N-(α-*ethyl*-L-β-*aspartyl*)-α-D-*glucopyranosylamine* (*14*)

A solution of **13** (98 mg) in THF (8 mL) was hydrogenated in the presence of PtO_2 (30 mg) for 12 h at room temperature. The catalyst was filtered off, and the filtrate evaporated to dryness to give **14** (75.4 mg, 98%); $[\alpha]_D^{23}$ +54.1° (*c* 0.8, $CHCl_3$). *Anal.* calcd. for $C_{20}H_{30}O_{12}N_2$: C 48.98, H 6.17, N 5.71; found: C 49.06, H 6.22, N 5.82.

N-(L-β-*Aspartyl*)-α-D-*glucopyranosylamine* (*15*)

To a solution of **14** (18.9 mg) in 50% methanol (2 mL) 0.18 mL of triethylamine was added and kept overnight at room temperature. The solution was concentrated *in vacuo*. A syrup was obtained, yielding 16 mg (99%); $[\alpha]_D^{24}$ +34.1° (*c* 0.9, H_2O). *Anal.* calcd. for $C_{10}H_{18}O_8N_2$: C 40.82, H 6.17, N 9.53; found: C 40.74, H 6.03, N 9.64.

Acknowledgments

We wish to thank Professor R. U. Lemieux for valuable discussions and Miss C. Hamada for technical assistance. We thank Mrs. T. Kumagai for measuring the nmr spectra.

Azapropellanes as phase-transfer catalysts. I. Introduction and synthesis of (±)1-azoniatricyclo[4.4.4.0^{1,6}]tetradecane and (±)1-azoniatricyclo[4.4.3.0^{1,6}]tridecane salts[1]

JOHN M. MCINTOSH

Department of Chemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received May 22, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

JOHN M. MCINTOSH. Can. J. Chem. **58**, 2604 (1980).

The rationale for considering 1-azoniapropellane salts as potential chiral phase-transfer catalysts is presented. The synthesis of two examples of these types of molecules is outlined and their efficacy in phase-transfer catalyzed reactions is established.

JOHN M. MCINTOSH. Can. J. Chem. **58**, 2604 (1980).

On présente une analyse qui permet de considérer les sels de l'azonia-1 propellane comme des catalyseurs chiraux potentiels de transfert de phase. On décrit la synthèse de deux molécules types et on établi leur efficacité dans les réactions catalysées de transfert de phase.

[Traduit par le journal]

Although chemists have used the term biogenetic or biomimetic synthesis with increasing frequency, in fact the use of the central feature of biosynthesis, a catalyst capable of stereospecific transformations of chiral or achiral reactants has rarely been achieved (1). Recently, reports from a variety of sources have told of varying degrees of success in performing absolute asymmetric synthesis using chiral ammonium salts, frequently under phase-transfer conditions (2). The chiral element in these reactions is a catalyst functioning in an achiral bulk medium and thus, in one sense at least, is an approximation of enzyme-catalyzed reactions.

We became interested in this area when we, as well as others (3) recognized that all catalysts reported at that time carry their chirality in the carbon skeleton of an 'onium salt and not at the presumed sites of catalytic activity. Thus, trimethylammonium salts of chiral amines which also contain an adjacent polar group (e.g. ephedrine) have been commonly used. It must be noted that this multifunctionality appears to be necessary for induction in some cases and is similar to the enzyme situation where one group is required for binding before catalytic activity at another site can begin. However, the optical yields using these catalysts have been low. One possible explanation for the disappointing results is the small difference in stability and population of the possible conformations of such small molecules, each of which might lead to a different stereochemical result (2*j*). Some support for this suggestion can be found in the results obtained by Colonna *et al.* (4) using polymer-bound catalysts and in results of Wynberg and Greijdanus (5) using quaternary salts derived from quinine and quinidine. In these larger molecules, conformational preferences would be expected to be larger, leading to higher optical yields. The increased optical yields found in solvents of low dielectric constant (5) may reflect a solvent effect on conformer population. However, Wynberg's catalysts have an additional complicating factor: they possess a chiral nitrogen atom. Since the mechanistic picture of catalysis by 'onium salts involves a tight ion-pair between the site of positive charge and the working anion X^-, chirality at the positive nitrogen atom might be expected to influence strongly the stereochemistry of reactions of X^-. In this context, the solvent dielectric effect (5) would reflect a tighter ion-pair and thus a more effective transfer of chirality.

To separate these effects, it was desirable to use catalysts which contain chiral nitrogen atoms, but as little other chirality which might affect the reacting center as possible. However, as we have pointed out (6), simple quaternary ammonium salts cannot be expected to cause significant asymmetric induction unless three of the four tetrahedral faces of the nitrogen atom are blocked. Thus, we set out to design catalysts which would fulfill the following criteria: (1) they must have a chiral nitrogen atom; (2) they should be as rigid as possible to facilitate interpretation of stereochemical results; (3) three of

[1]Chemical Abstract names: octahydro-5,9a-butanoquinolizinium and octahydro-5,9a-propanoquinolizinium salts.

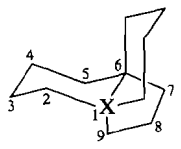
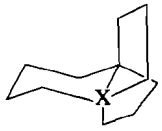
the faces of the nitrogen atom should be blocked; (4) introduction of various substituents in stereochemically defined ways should be possible.

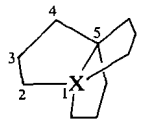


Such molecules are not easy to envisage and unlike the catalysts used heretofore, nature does not supply us with a plentiful source. For example, salts based on the quinuclidine ring system can be modified to satisfy conditions 1, 2, and 4, but not 3. We believe that molecules based on the propellane ring system offer a viable choice. In order to fulfill condition 3, the quaternary nitrogen atom must be located at the bridgehead position.

Molecules possessing the propellane structure, including those incorporating nitrogen atoms, have been known for many years and their chemistry and structural features have been extensively reviewed (7). One example (**4***N*) of a bridgehead nitrogen derivative has been prepared (8) and a closely related system has been derived from lupinine (9). All the carbocyclic compounds **1***C* (10), **2***C* (11), **3***C* (12), and **4***C* (12) are known.



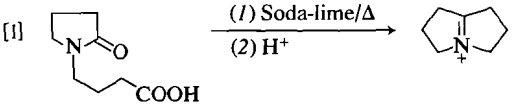
Compound **1***C* possesses D_3 symmetry and is therefore chiral (7). Replacing one bridgehead carbon atom with nitrogen generates an ammonium salt (**1***N*) which possesses C_3 symmetry which is also chiral. Optical inversion of either **1***C* or **1***N* requires chair–chair conformational inversion of all three cyclohexane rings. Similarly **2***C*, **2***N*, **3***C*, and **3***N* are chiral but **4***C* and **4***N* are not. While **1** and **2** are chiral, the exposed *face* of the nitrogen atom is not and another alteration in structure (e.g. appropriate substitution in one of the six-membered rings of **2***N*) would be required to achieve this. Thus the propellane system offers the possibility of examining both types of effects on asymmetric induction. Furthermore, the lack of a "handle" in **1***C* has precluded attempts at its resolution and no direct information as to its optical stability is available (13). On the other hand, **1***N* is ideally suited for attempted resolution via diastereomeric salts.



1*C* X = C
1*N* X = N^+

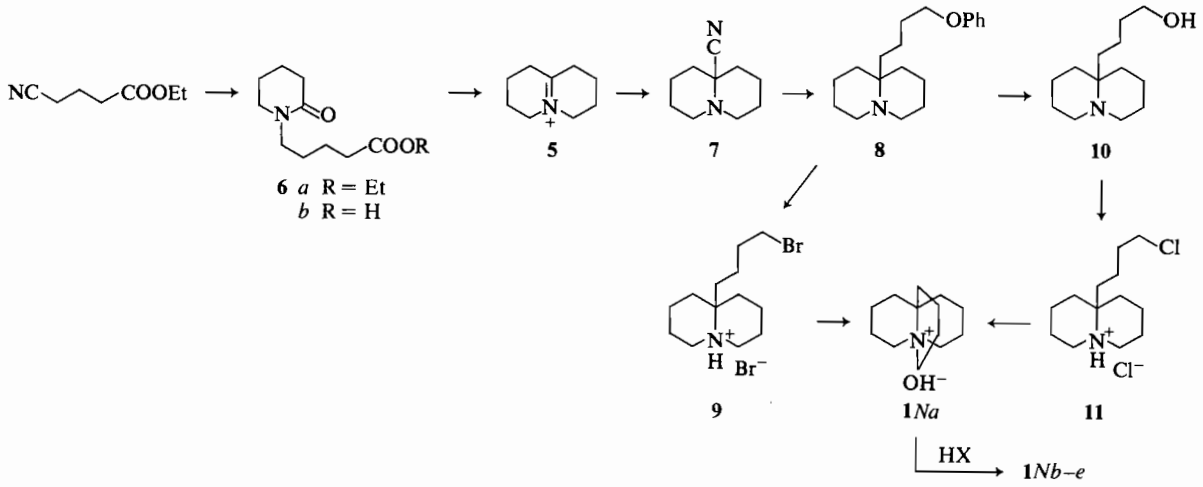
2*C* X = C
2*N* X = N^+

3*C* X = C
3*N* X = N^+



4*C* X = C
4*N* X = N^+

Subsequent introduction of polar substituents should also be possible and the spatial relationships between functionalities should be well-defined, allowing the analysis of substrate–catalyst interactions to a greater degree than in common catalysts.

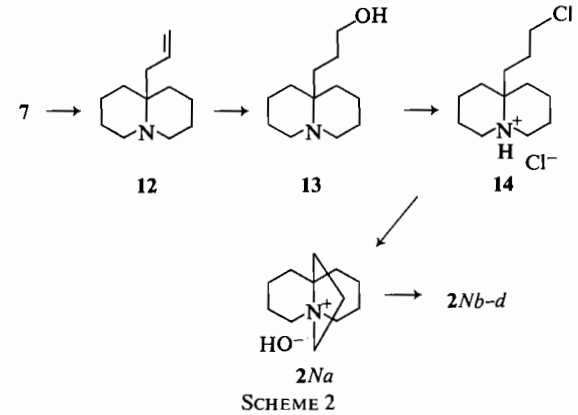


In this paper are reported the syntheses of **1***N* and **2***N*. In subsequent papers, the structures of these molecules as determined by a variety of methods, the preparation of substituted systems, and their utility as phase-transfer catalysts will be reported.

Results and Discussion

Salts **1***N* and **2***N* are bridged quinolizidines. Some question existed as to the feasibility of closing a 9a-substituted quinolizidine because previous work in our laboratory (14) and elsewhere indicated the structure of such compounds to contain a *trans*-fused ring system. However, nitrogen inversion is a facile process and the simplicity of such an approach dictated its investigation. The most attractive feature of this approach is that **1***N*, **2***N*, and a variety of derivatives substituted in one ring can be prepared from a single precursor-5,9a-dehydroquinolizidine (**5**) (15). Previous syntheses of 9a-substituted systems have all started with **5**. However, the preparation of **5** by mercuric acetate oxidation of quinolizidine did not appear attractive for the preparation of the amounts of material we envisaged might be required. After investigating other routes (14), we became aware of the work of Miyano (16) who showed that salts of the desired type were available from cyclization of *N*-substituted lactams (eq. [1])

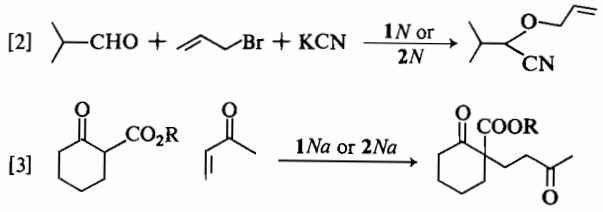
[1] 



Hydrogenation of ethyl 4-cyanobutanoate afforded a mixture of 2-piperidinone and *N*-(4-carbethoxy)-2-piperidinone (**6***a*) (Scheme 1). Hydrolysis of the ester followed by distillation of the acid **6***b* from soda-lime (16) and neutralization of the distillate with perchloric acid gave **5** in 46% overall yield from **6***a*. Conversion to **7** with potassium cyanide, followed by reaction with the Grignard reagent derived from 4-phenoxybutyl bromide gave **8** which was smoothly cleaved to **9** in hot concentrated hydrobromic acid. Alternatively, **8** could be reduced with sodium in liquid ammonia to alcohol **10** which on treatment with thionyl chloride

SCHEME 1

gave **11**. Treatment of either **9** or **11** with silver oxide gave high yields of **1***N*-hydroxide (**1***Na*). Neutralization of this with a variety of acids gave a series of derivatives (**1***Nb* (X = Br^-), **1***Nc* (X = picrate), **1***Nd* (X = $CF_3CO_2^-$), **1***Ne* (X = $CH_3CO_2^-$)) all of which were solids with the exception of **1***Ne*. In analogy with the reported **4***N*-bromide, **1***Nb* has only limited solubility in water, is insoluble in chloroform, and melts as a temperature in excess of 300°C. However, **1***Nd* can easily be dissolved in chlorinated solvents. The structure of **1***N* is supported by its ^{13}C spectrum which shows only five lines, as well as its field desorption mass spectrum and elemental analysis.



The same starting material **5** led also to **2***N* (Scheme 2). Because the Grignard reagent derived from 3-phenoxypropyl bromide is unstable (17), and that derived from 3-*tert*-butoxypropyl bromide failed to react with **5** or **7**, we resorted to modification of a 3-carbon unit already in place on the quinolizidine ring system. Reaction of **7** with allylmagnesium bromide gave **12** (14) which on hydroboration with disiamylborane (18) gave alcohol **13**. (Hydroboration of **12** with borane gives a mixture of **13** and its secondary alcohol isomer.) Conversion of **13** to **14** with thionyl chloride followed by silver oxide treatment gave **2***Na* which was converted into its bromide (**2***Nb*), picrate (**2***Nc*), and trifluoroacetate (**2***Nd*) salts.

SCHEME 2

The infrared spectra of alcohols **10** and **13** show very broad and weak hydroxyl absorptions in dilute solutions. All the free bases show strong Bohlmann bands (19) and the ^{13}C spectra support trans-fused ring systems. In addition C2 of **1***N*, C2, C7, and C9 of **2***N*, and C2 and C4 of **4***N* show significant carbon–nitrogen coupling as is expected from symmetrical salts such as these. The proton nmr spectra of **1***N* and **2***N* are reported in the Experimental without comment. A detailed analysis of these will appear in a future paper.

Finally, it must be noted that in order for our postulates to be viable, compounds **1***N* and **2***N* must function as phase-transfer catalysts. Using published procedures all of **1***N*, **2***N*, and **4***N* effectively catalyzed the formation of aldehyde cyanohydrin ethers (20) (Eq. [2]) and the reaction of 2-carbethoxycyclohexanone with methyl vinyl ketone (21) (eq. [3]). The latter reaction appears to be much faster using these catalysts than using those derived from cinchona alkaloids.

Experimental

Melting points are corrected; boiling points are uncorrected. Infrared spectra were run on Beckman IR-12 or Perkin-Elmer 297 instruments as films or in dilute chloroform solutions. The ^{1}H nmr spectra were run in $CDCl_3$, C_6D_6, or D_2O solutions as 60 or 100 MHz and are reported downfield from Me_4Si as internal standard; ^{13}C nmr spectra were run at 22.64 MHz in the same solvents and are also referenced to internal Me_4Si. Gas chromatographic analyses were performed on 10% SE-30 on Chromosorb W columns, solvents were removed at reduced pressure, and the drying agent was anhydrous sodium sulfate.

N-(4-Carbethoxybutyl)-2-piperidinone (6a)

Ethyl 4-cyanobutanoate (14.5 g, 0.1 mol) was dissolved in 130 mL of 95% ethanol and 0.35 g of platinum oxide was added. The mixture was stirred under one atmosphere of hydrogen for 2 days with periodic catalyst replacement. A total of 1.98 equivalent of hydrogen was absorbed. The solution was filtered, heated at reflux for 3 h, and evaporated. The residue was distilled to give 2.4 g of 2-piperidinone and 6.5 g (56%) of **6a**, bp 142–146°C (0.4 Torr).

N-(4-Carboxybutyl)-2-piperidinone (6b)

Ester **6a** (19.1 g, 0.08 mol) was dissolved in 50 mL of ethanol and 3.7 g (1.1 g) of sodium hydroxide in 10 mL of water was added. The solution was stirred at ambient temperature for 16 h. Most of the ethanol was evaporated, the residue diluted with water and acidified with 10% hydrochloric acid. The aqueous solution was extracted with chloroform (3 × 50 mL), the extracts washed with water, dried, and evaporated. Trituration of the residue with toluene gave 13.6 g (91%) of **6b** as white crystals, mp 83–85°C; ir ($CHCl_3$): 3550–2400, 2940, 2870, 1710, 1620, 1490, 1350 cm^{-1}; ^{1}H nmr ($CDCl_3$): 11.07 (1H, s), 3.60–3.12 (4H, m), 2.68–2.15 (4H, m), 2.02–1.40 (8H, m); ^{13}C nmr ($CDCl_3$); 176.7, 170.7, 47.9, 46.9, 33.8, 31.9, 26.4, 23.1, 22.2, 21.0. *Anal.* calcd. ($C_{10}H_{17}NO_3$): C 60.28, H 8.60, N 7.03; found: C 60.52, H 8.52, N 6.94.

5,9a-Dehydroquinolizidinium Perchlorate (5)

Acid **6b** (5 g, 0.025 mol) was ground with soda-lime (10 g) until an intimate mixture was obtained. The mixture was placed in a 100 mL round bottom flask fitted with a short-path distillation apparatus. The system was purged with nitrogen and the flask heated slowly with a free flame. Vigorous gas evolution occurred, followed by distillation of water (90–105°C) and then organic material (head temperature 160–170°C). After distillation had stopped, the two-phase distillate was diluted with 5 mL of 2% sodium hydroxide solution and extracted with pentane (3 × 25 mL). The combined extracts were dried, evaporated to ca. 5 mL, and poured into a cold solution of 8 mL 70% perchloric acid in 100 mL ethanol. Storage in the freezer overnight followed by filtration gave **5** (1.6 g, 57%) identical to the material reported by Leonard *et al.* (15); ^{13}C nmr ($CDCl_3$): 115.8, 54.2, 32.7, 20.5, 16.6.

Cyanoamine **7** was prepared as described by Leonard and Hay (21). Evaporation of the dried ethereal extract gave a liquid which solidified below −10°C, which was used without further purification. The infrared spectrum of **7** showed extremely weak absorption at 2220 cm^{-1}, a result typical of nitriles carrying oxygen or nitrogen substituents at the α-carbon (22).

9a-(4-Phenoxybutyl)quinolizidine (8)

A solution of 4-phenoxybutyl magnesium bromide in ether was prepared under nitrogen from 0.642 g (0.026 mol) of magnesium and 6.2 g (0.027 mol) of 4-phenoxybutyl bromide (Aldrich) in 50 mL of ether using iodine initiation. To this solution was added a solution of 2.2 g (0.013 mol) of **7** in 10 mL of ether. The addition required 30 min and a thick sludge was formed. The mixture was refluxed overnight, cooled, and treated with saturated aqueous ammonium chloride until effervescence ceased. Water (50 mL) was added, followed by enough concentrated hydrochloric acid to dissolve the precipitate (ca. 75 mL). The solution was extracted with ether (2 × 50 mL), the aqueous phase made basic with 12 *N* sodium hydroxide, and the milky solution extracted with ether (4 × 100 mL). The combined extracts were washed with water, dried, and evaporated to give 2.67 g of a cloudy oil which was shown to consist of 87% **8** and 18% **7** by gc. analysis. Separation of these was achieved using silica gel chromatography with ether as eluant. In this way pure **8** was obtained (1.7 g, 44%); ir ($CHCl_3$): 3010, 2930, 1600, 1583, 1490, 1463, 1450, 1290 cm^{-1}; ^{1}H nmr ($CDCl_3$): 7.42–6.71 (5H, m), 3.48 (2H, t, J = 6 Hz), 2.74–2.07 (4H, m), 2.00–1.00 (18H, m); ^{13}C nmr ($CDCl_3$): 160.3, 129.5, 120.7, 114.8, 67.9, 49.2, 35.5, 26.0, 20.5, 20.2. *Anal.* calcd. ($C_{19}H_{29}NO$): C 79.39, H 10.17, N 4.87; found: C 79.55, H 10.41, N 5.27. The picrate crystallized from ethanol and melted at 129–131°C.

In the normal course of events, the crude material was used directly in subsequent reactions as the products from **7** failed to cyclize in the final step.

9a-(4-Bromobutyl)quinolizidinium Hydrobromide (9)

Ether **8** (0.395 g, 1.38 mmol) was dissolved in 6 mL concentrated hydrobromic acid and the system was purged with nitrogen. The initially heterogeneous mixture became homogeneous when heated. The solution was refluxed for 2 h, the cooled solution diluted with 25 mL of water, and adjusted to pH = 4 with 3 *N* sodium hydroxide. The phenol was extracted with ether (2 × 30 mL) and the aqueous solution evaporated to dryness. The residue was extracted with hot chloroform (3 × 25 mL), the hot solution treated with charcoal, filtered, dried, and evaporated to a volume of 10 mL. Addition of ether caused precipitation of the product (0.395 g, 84%) which melted at 177–178°C; ^{1}H nmr ($CDCl_3$): 3.47 (2H, t, J = 6 Hz), 3.27–2.85 (4H, m), 2.30–1.23 (19H, m).

9a-(4-Hydroxybutyl)quinolizidine (10)

Ether **8** (1.0 g, 3.5 mmol) was dissolved in a mixture of 30 mL liquid ammonia, 15 mL of *tert*-butanol and 15 mL of ether. Sodium (1.6 g, 70 mmol) was added in small pieces over 10 min to give a deep blue solution. After stirring for 2.5 h the solution was colorless. Methanol (8 mL) was added and the ammonia was allowed to evaporate. The residue was diluted with 100 mL of saturated aqueous sodium chloride solution and extracted with ether (3 × 50 mL). The extracts were evaporated, the residue dissolved in 20 mL 10% hydrochloric acid and stirred overnight. Ether extraction removed cyclohexenone. The aqueous solution was made basic with 12 *N* sodium hydroxide solution and extracted with ether (3 × 50 mL). Evaporation of the dried extracts gave an oil which crystallized on trituration with pentane. Alcohol **10** was obtained (0.55 g, 74%) as a white solid, mp 93–94°C; ir ($CHCl_3$): 3550–2500 (weak), 2940, 1450, 1300, 1115, 910 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.66 (2H, t, J = 5 Hz), 2.90–2.23 (4H, m), 1.90–0.95 (19H, m); ^{13}C nmr ($CDCl_3$): 62.6, 55.5, 49.0, 35.2, 33.9, 25.7, 21.4, 20.0. *Anal.* calcd. ($C_{13}H_{24}NO$): C 73.88, H 11.92, N 6.63; found: C 74.11, H 12.12, N 6.70.

9a-(4-Chlorobutyl)quinolizidinium Hydrochloride (11)

Alcohol **10** (0.2 g, 0.9 mmol) was dissolved in 3 mL of dichloromethane and 0.33 g (2.7 mmol) of thionyl chloride was added. Immediate gas evolution occurred. The solution was stirred at ambient temperature overnight and then evaporated. The residue crystallized on trituration with ether and was purified by treating a hot chloroform solution with charcoal and precipitating the product (0.154 g, 61%) with ether. Compound **11** was a white crystalline material, mp 183–184°C, ir ($CHCl_3$): 2950, 2740–2200, 1460, 1430, 1240 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.61

For personal use only.

(2H, t, J = 5 Hz), 3.33–2.50 (4H, m), 2.50–1.21 (11H, m); ^{13}C nmr ($CDCl_3$): 62.9, 49.4, 48.1 44.4, 32.5, 22.5, 20.3, 19.8, 17.9. *Anal.* calcd. ($C_{13}H_{25}Cl_2N$): C 58.64, H 9.46, Cl 26.63; found: C 57.94, H 9.03, Cl 27.26.

*1-Azoniatricyclo[4.4.4.0^{1,6}]tetradecane Hydroxide (1*Na*)*

Bromide **9** (500 mg, 1.4 mmol) was dissolved in 2 mL of water and added to 3.6 g (1.03 equiv.) of silver oxide. The slurry was stirred overnight, filtered through Celite, and evaporated to dryness at 20°C. The product was an oil (0.27 g, 91%) which was best purified by conversion to its bromide (see below). Analytically pure **1***Na* was obtained from **1***Nb* by treatment with 1.1 equiv. of silver oxide in water and isolation as described above; ^{1}H nmr (D_2O): 4.00 (3H, m), 3.00 (3H, bd), 2.72–2.32 (3H, m), 2.32–1.55 (12H, m), 1.26 (3H, bd); ^{13}C nmr (D_2O): 65.4, 56.1 (t), 29.3 (t), 19.4, 17.1. *Anal.* calcd. ($C_{13}H_{25}NO$): C 73.88, H 11.92, N 6.63; found: C 73.55, H 12.00, N 6.41.

*Preparation of Salts of 1*N

A solution of **1***Na* in water was treated with enough concentrated hydrobromic acid to bring the pH to 2. The precipitate was filtered and recrystallized from methanol–ether to give **1***Nb*, mp > 300°C. *Anal.* calcd. ($C_{13}H_{24}NBr$): C 56.94, H 8.82, N 5.11; found: C 57.00, H 8.78, N 5.02. The only peak shown in the field desorption mass spectrum (fdms) was at *m/e* 194.

In a similar manner, using solid picric acid, the salt **1***Nc* was prepared, mp > 300°C; ^{1}H nmr (D_2O): 4.05 (3H, m), 2.72 (3H, bd), 2.63–2.30 (3H, m), 2.13–1.54 (12H, m), 1.23 (3H, bd). *Anal.* calcd. ($C_{19}H_{26}N_4O_7$): C 54.02, H 6.20, N 13.26; found: C 54.14, H 6.24, N 13.29.

Treating a chloroform solution of **1***Na* with excess trifluoroacetic acid, followed by evaporation, gave an oil which crystallized on trituration with ether. Salt **1***Nd* was a white solid, mp 118–120°C. Its proton and ^{13}C nmr were identical to **1***Na*. *Anal.* calcd. ($C_{15}H_{24}F_3NO_2$): C 58.62, H 7.87, N 4.56; found: C 58.52, H 7.80, N 4.23.

9a-Allylquinolizidine (12)

To the Grignard reagent prepared from 1.5 g (0.012 mol) of allyl bromide and 0.29 g of magnesium (0.012 mol) in 25 mL of ether was added a solution of 1.0 g (6.1 mmol) of **7** in 10 mL of ether. After the final addition, the solution was refluxed for 3 h and worked up as described for compound **8**. There was obtained 1.00 g (92%) of a clear oil identical to that prepared previously (14).

9a-(3-Hydroxypropyl)quinolizidine (13)

Disiamyl borane was prepared by reaction of 10.0 mL of a 1 *M* borane solution in THF with 1.4 g 2-methyl-2-butene. To this solution was added a solution of 0.461 g (2.6 mmol) of **12** in 10 mL of THF over 10 min. The mixture was stirred at 0°C for 30 min and ambient temperature for 4 h. Water was added dropwise until effervescence ceased. Aqueous sodium hydroxide (8.0 mL of 10% solution) was added, followed by dropwise addition of 2.5 mL of 30% hydrogen peroxide. The mixture was stirred for 1 h, the aqueous phase saturated with potassium carbonate, the phases separated, and the aqueous layer extracted with ether (2 × 30 mL). The combined organic phases were evaporated, dissolved in ether, and extracted with 2 × 10 mL 10% hydrochloric acid and then water (2 × 10 mL). The combined aqueous phases were made basic with 10 *N* sodium hydroxide and extracted with ether (3 × 30 mL). The ether extract was dried and evaporated to give **13** as a colorless solid (0.41 g, 81%) mp 108–110°C; ir ($CHCl_3$): 3500–2400 (weak), 2930, 1450, 1360, 1295 cm^{-1}; ^{1}H nmr ($CDCl_3$); 3.64 (2H, t, J = 6 Hz), 2.90–2.36 (5H, m), 1.86–1.10 (16H, m); ^{13}C nmr ($CDCl_3$): 63.5, 54.7, 48.7, 34.2, 29.5, 24.8, 21.6, 19.9. *Anal.* calcd. ($C_{12}H_{23}NO$): C 73.04, H 11.75, N 7.10; found: C 72.81, H 11.63, N 7.00.

9a-(3-Chloropropyl)quinolizidinium Hydrochloride (14)

To a solution of 100 mg (0.51 mmol) of **13** in 4 mL chloroform was added 2 mL of thionyl chloride. Immediate gas evolution was evident. The solution was refluxed for 3 h, evaporated, and the residual oil was crystallized from acetone solution by addition of ethyl acetate. Chloride **14** was obtained (82 mg, 64%) as a colorless crystalline material, mp 158–160°C; ir ($CHCl_3$): 2950, 2850–2400, 1467, 1430, 1320 cm^{-1}; ^{1}H nmr ($CDCl_3$): 3.65 (2H, t, J = 5 Hz), 3.35–2.83 (4H, m), 2.70–1.40 (17H); ^{13}C nmr ($CDCl_3$): 62.6, 49.4, 44.8, 32.4, 25.7, 22.4, 20.9, 17.7. *Anal.* calcd. ($C_{12}H_{23}Cl_2N$): C 57.14, H 9.19, N 5.55, Cl 28.11; found: C 56.92, H 9.00, N 5.39, Cl 28.41.

*1-Azoniatricyclo[4.4.3.0^{1,6}]tridecane Hydroxide (2*Na*)*

To a solution of 128 mg (0.51 mmol) of **14** in 5 mL of water was added 1.0 g (4 equiv.) of silver oxide. The slurry was stirred for 24 h at ambient temperature, filtered through Celite, and evaporated below 30°C, initially at 15 Torr pressure and finally at 0.05 Torr. The oil which was obtained (85 mg, 85%) was used directly in the test reactions described below.

*Preparation of Salts of 2*N

A portion of hydroxide **2***Na* was neutralized with concentrated hydrobromic acid. The solution was evaporated to dryness, dissolved in absolute ethanol, and reevaporated. The semi-solid residue crystallized from ethanol to give white microcrystals of **2***Nb*, mp > 300°C; *m/e* (fdms) 180. *Anal.* calcd. ($C_{12}H_{22}BrN$): C 55.39, H 8.52, N 5.38, Br 30.71; found: C 55.21, H 8.15, N 4.98, Br 29.98. In a similar manner, using a saturated ethanolic picric acid solution, the picrate **2***Nc* was prepared as a bright yellow powder, mp > 300°C.

The trifluoroacetate **2***Nd* was prepared by adding excess trifluoroacetic acid to **2***Na* and evaporating at 0.05 Torr. The salt was an oil which showed the following spectral characteristics: ^{1}H nmr ($CDCl_3$): 3.80–3.55 (2H, m), 3.55–3.11 (4H, m), 2.20 (4H, bs), 2.05–1.56 (12H, m); ^{13}C nmr ($CDCl_3$): 72.7, 59.0, 55.9, 31.7, 29.4, 19.7, 17.5, 16.9.

Phase-transfer Reactions

Reaction of isobutyraldehyde and allyl bromide in methylene chloride with aqueous potassium cyanide using **1***Nd*, **2***Nd*, or **4***Na* as catalyst as previously described (20) gave the allyl ether of isobutyraldehyde cyanohydrin in yields of 50–60% in 16 h.

Reaction of 2-carboethoxycyclohexanone and methyl vinyl ketone in methylene chloride solution using catalytic amounts of **1***Na*, **2***Na*, or **4***Na* as previously described (2*g*) gave the Michael addition product in yields of 90–95%. The reaction was complete in 1 h at 25°C.

Facile cleavage of some 2-acetamido-2-deoxy-β-D-gluco- and galactopyranosides using aqueous HF[1]

HAROLD J. JENNINGS AND CZESLAW LUGOWSKI[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 19, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HAROLD J. JENNINGS and CZESLAW LUGOWSKI. Can. J. Chem. **58**, 2610 (1980).

Treatment of pneumococcal C-substance (PnC) with 48% aqueous HF resulted in not only the intended removal of all the phosphate esters but also in the highly specific hydrolysis of the glycosidic bond between the 2-acetamido-2-deoxy-β-D-galactopyranose and ribitol residues. Some of the structural features associated with this facile hydrolysis were elucidated from studies on the treatment of model methyl glycosides and oligosaccharides with the same reagent. These studies indicate that an increase in the rate of hydrolysis is associated with glycosides of 2-acetamidohexapyranoses having a *trans* diequatorial disposition of the aglycon and 2-acetamido groups. These studies also indicate that the nature of the aglycon is also a contributing factor, because although simple alkoxy and terminal open-chain glycitols are readily cleaved from glycosides satisfying the above criteria, hydrolysis does not occur where the aglycon is another cyclized sugar moiety. Thus chitotriose can only be degraded to chitobiose using this reagent following the reduction of its terminal reducing moiety.

HAROLD J. JENNINGS et CZESLAW LUGOWSKI. Can. J. Chem. **58**, 2610 (1980).

L'action d'une solution aqueuse à 48% de HF sur la substance pneumocoque C (PnC) n'enlève pas seulement tous les groupements esters phosphoriques mais hydrolyse également de façon fortement spécifique la liaison glycosidique entre les unités acétamido-2 déoxy-2 β-D-galactopyrannose et le ribitol. On a éclairci quelques aspects structuraux associés à cette hydrolyse facile, en se basant sur les études réalisées en traitant des modèles de glycosides de méthyle et d'oligosaccharides avec le même réactif. Ces études indiquent qu'une augmentation de la vitesse d'hydrolyse se produit avec les glycosides d'acétamido-2 hexapyrannoses ayant les groupements aglycone et acétamido-2 en position *trans* diéquatoriale. Ces études indiquent également que par sa nature l'unité aglycone est un facteur contributif, parce que les groupes alkoxy simples et glycitols terminaux à chaîne ouverte sont facilement enlevés selon les critères ci-dessus mentionnés. L'hydrolyse ne se produit pas quand l'unité aglycone est un noyau de sucre cyclique. Ainsi l'emploi de ce réactif sur le chitotriose suivi de la réduction de son unité terminale permet seulement de la dégrader en chitobiose.

[Traduit par le journal]

Introduction

Aqueous hydrofluoric acid is an extremely specific reagent for the low-temperature cleavage of different types of phosphate esters (1). The specificity is such that it has been used to remove phosphate esters from complex oligosaccharides without cleaving its *O*-glycosidic linkages (2). However, exceptions to this rule have been recently reported. On treatment with aqueous HF at 4°C the terminal erythritol residue of a tetrasaccharide was cleaved from the penultimate α-L-rhamnopyranose residue (3) which can probably be attributed to the general acid-lability of rhamnopyranosides. Perhaps more surprisingly an ethylene glycol residue of a tetrasaccharide, obtained from C-substance (PnC), was also cleaved from the penultimate 2-acetamido-2-deoxy-β-D-galactopyranose residue (4), and the direct treatment of PnC with aqueous HF also resulted in the cleavage of ribitol from an identical residue (4). These latter results prompted further studies on model compounds to determine some of the structural features associated with this facile and highly specific cleavage of a 2-acetamidohexapyranoside and to ascertain the possible general utility of this reagent for the specific degradation of other oligosaccharides and polysaccharides.

Experimental

Materials

C-Substance (PnC) was obtained from *Streptococcus pneumoniae* type 1 and was *N*-acetylated as previously described (4). The phosphocholine-substituted trisaccharide (1) was obtained by the Smith degradation of this *N*-acetylated PnC (4). Tri-*N*-acetylchitotriose was the gift of Dr. Martin Young of this laboratory and the methyl α- and β-D-glycosides of both 2-acetamido-2-deoxygluco- and mannopyranose were prepared and purified by the method of Beychok *et al.* (5). Oligosaccharides were reduced with sodium borohydride and the reduced oligosaccharides were purified by gel-filtration.

Gel-filtration

Gel-filtration was performed on a Sephadex G-25 column (1.6 cm × 90 cm) using a 0.02 *M* pyridine acetate buffer at pH 5.4 and the column was monitored using a Waters Associates differential refractometer (model R403).

Hydrolysis with HF

The glycosides and oligosaccharides were treated with aque-

ous HF (48%) in a concentration of 5 mg/mL at 4°C in polyethylene tubes. Samples (0.2–2.0 mL) were withdrawn at intervals and the HF was removed from them under reduced pressure in a desiccator over solid NaOH during a period of 2 h. The extent of hydrolysis attained in each case was determined by specific analyses of each of the residues as described below.

Analytical Methods

All hydrolyses of glycosides and oligosaccharides were monitored by the quantification of the release of terminal substituent groups and/or in the case of the breakage of some glycosidic bonds by the estimation of newly formed hemiacetal. The methods employed are listed below. Reducing sugars were determined by the Nelson–Somogyi copper reduction method (6) and D-glucose was specifically determined using "Glucostat" reagent (Worthington Biochemicals Corp., Freehold, NJ). Phosphate was determined by the method of Chen *et al.* (7). Ribitol, glucosaminitol, and galactosaminitol were identified and quantified by gas–liquid chromatographic analysis of their peracetates (8), using the peracetylated derivatives of inositol galactosaminitol and glucosaminitol as internal standards respectively. Gas–liquid chromatography was performed on a Hewlett-Packard 5830A instrument equipped with a flame ionization detector and a model 18850A electronic integrator. The glass column employed contained 3% OV-275 on gas Chrom Q at 200°C for ribitol and 250°C for the hexaminitols.

Results and Discussion

In the treatment of PnC (Fig. 1) with 48% aqueous HF at 4°C to remove phosphocholine residues and backbone phosphodiester groups, an additional hydrolysis of the *O*-glycosidic bond in the 1-*O*-2-acetamido-2-deoxy-β-D-galactopyranosyl-D-ribitol moiety also occurred (4). That the lability of this *O*-glycosidic bond of the 2-acetamidogalactose residue, under the extremely mild conditions employed, was of the same order as that of the P—O bonds of the phosphate esters was rather surprising, but was further substantiated by the monitoring of the release of phosphate and ribitol from PnC on treatment with 48% aqueous HF (Fig. 2). Both moieties were released simultaneously and at 48 h the greater part of both had been removed. Thus using these conditions the preferential release of phosphate from PnC could not be achieved. In order to elucidate some of the structural features associated with this facile and highly specific hydrolysis of the ribitol aglycon from the 2-acetamido-2-deoxygalactose residue, a number of methyl glycosides and oligosaccharides were subjected to identical treatment with aqueous HF. These hydrolyses established some of the individual structural features conducive to this facile cleavage and also demonstrated that the terminal disaccharide of the repeating unit of PnC is a unique combination of all these features.

The hydrolyses of the methyl 2-acetamido-2-deoxyglycopyranosides are shown in Fig. 2 and were monitored by the quantification of the newly-

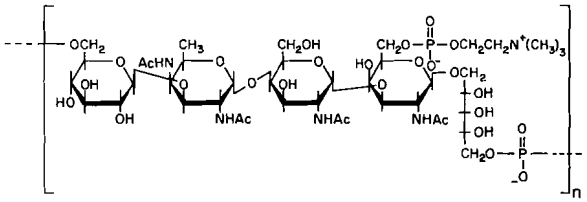

FIG. 1. The repeating unit of *N*-acetylated PnC.

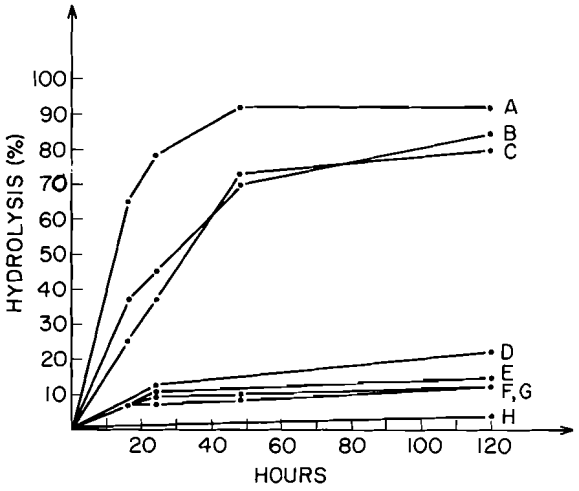

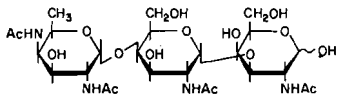

FIG. 2. The rate of hydrolysis of the following substrates using 48% aqueous HF. The expected amounts of released terminal moieties on which these rates were calculated are shown in brackets: A, *N*-acetylated C-substance (phosphate); B, methyl 2-acetamido-2-deoxy-β-D-glucopyranoside (hemiacetal); C, *N*-acetylated C-substance (ribitol); D, methyl 2-acetamido-2-deoxy-α-D-mannopyranoside (hemiacetal); E, methyl 2-acetamido-2-deoxy-β-D-mannopyranoside (hemiacetal); F, methyl 2-acetamido-2-deoxy-α-D-glucopyranoside (hemiacetal); G, methyl β-D-glucopyranoside (hemiacetal); H, methyl α-D-glucopyranoside (hemiacetal).

formed hemiacetal. That the β-D-configuration is more conducive to hydrolysis was ascertained by a comparison of the rates of hydrolysis of methyl-2-acetamido-2-deoxy-α- and β-D-glycopyranosides. Of the two anomers the β-D-anomer was hydrolysed much more rapidly (by approximately eight-fold at 120 h) and in fact proved to be an excellent model for PnC because the hydrolysis of each proceeded at almost identical rates. These experiments on the methyl glycosides also established the contribution of the 2-acetamido group to the ease of hydrolysis when methyl α- and β-D-glucopyranosides (configurational analogues of the formerly treated methyl glycosides minus the 2-acetamido group) were treated with 48% aqueous HF. Even the most labile of these methyl glucopyranosides (β-D-anomer) proved to be less readily hydrolysed than the α-D-anomer of methyl 2-

acetamido-2-deoxyglucopyranoside. Although the above results using 48% aqueous HF are similar to those obtained on the same methyl glycosides using other mineral acids (9, 10), there are two important differences which would preclude the use of these latter mineral acids to effect the same specific and quantitative cleavage of the β-D-glycosides of 2-acetamidohexoses. These mineral acids are employed at higher temperatures and simultaneously remove *N*-acetyl groups thus stabilizing any remaining unhydrolysed glycosidic bonds (11). By contrast aqueous HF is a very mild hydrolytic reagent and does not break *N*-acyl bonds (1). A further structural feature associated with an increase in the rate of hydrolysis of 2-acetamidohexapyranosides was elucidated by experiments on methyl 2-acetamido-2-deoxy-α- and β-D-mannopyranosides (Fig. 1). In contrast to the D-*gluco* epimers both anomers were found to be relatively stable to aqueous HF and no enhanced sensitivity to hydrolysis of the methyl β-D-glycoside could be detected. Thus the axial orientation of the 2-acetamido group of the D-*manno* epimers ($^4_1$C conformation) retards this enhancing effect of the β-D-orientation of the aglycon. Thus in summary all these experiments of the methyl glycosides indicate that only a *trans* diequatorial disposition of the aglycon and vicinal 2-acetamido group is conducive to an enhanced acid lability of the aglycon.

Because of the highly selective nature of the hydrolyses of the methyl glycosides of 2-acetamido-2-deoxy-β-D-galacto- and glucopyranose it was decided to ascertain whether aqueous HF could be used to selectively cleave the β-D-glycoside bonds of these residues in oligosaccharides or polysaccharides. The model employed was chitotriose which, although having the required terminal β-D-glucosidic bonds of 2-acetamido-2-deoxy-D-glucopyranose, proved to be relatively insensitive to hydrolysis with aqueous HF (Table 1). On reduction of chitotriose, however, prior to treatment with aqueous HF, the newly formed terminal 2-acetamido-2-deoxyglucosaminitol residue could then be easily and selectively removed leaving chitobiose as the other product of hydrolysis. In addition to providing a method for the stepwise degradation of this type of oligosaccharide this experiment also provided evidence that only an open-chain glycitol aglycon of a 2-acetamido-2-deoxy-β-D-gluco- or galactopyranose residue is subject to this facile cleavage. Certainly this is consistent with the facile removal of the terminal ribitol aglycon from the repeating unit of PnC (Fig. 1) (4). It is interesting to note that in cases where the structural features are not conducive to the ease of hydrolysis that the formation of a glycitol aglycon alone does not greatly enhance the rate of hydrolysis. The retarding effect of the α-D-configuration of the penultimate 2-acetamido-2-deoxygalactose of oligosaccharide **1** from PnC remained dominant even after the reduction of **1**, because on treatment with aqueous HF no 2-acetamido-2-deoxygalactosaminitol was released (Table 1). Also the reduction of cellobiose did not result in any significant increase in the poor acid lability of its β-D-glycosidic linkage.

1

TABLE 1. Hydrolysis of oligosaccharides using aqueous HF[a]

Oligosaccharide	Released terminal moiety	Hydrolysis (%)
Chitotriose	Glucosamine[b]	<1
Reduced Chitotriose	Glucosaminitol	44[c]
	Hemiacetal	43
Oligosaccharide **1** from *N*-acetylated C-substance (reduced)	Galactosaminitol	<1
	Hemiacetal	5
Cellobiose	Glucose	1
	Hemiacetal	2
Cellobiitol	Glucose	1
	Hemiacetal	2

[a]All hydrolyses carried out at 4°C for 120 h.
[b]Estimates as glucosaminitol after reduction of the hydrolysis products.
[c]Complete hydrolysis could be attained by prolongation of the period of hydrolysis.

Total synthesis of tetracyclic sesquiterpenoids: (±)-ishwarone

EDWARD PIERS AND TSE-WAI HALL

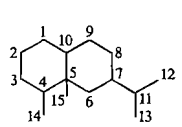
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received June 9, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

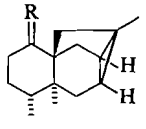
EDWARD PIERS and TSE-WAI HALL. Can. J. Chem. **58**, 2613 (1980).

A stereoselective total synthesis of the racemic modification of the tetracyclic sesquiterpenoid ishwarone (**2**) is described. Treatment of the known ketal aldehyde **19** with dibromomethylenetriphenylphosphorane gave the dibromo alkene **20**, which was transformed efficiently into the propargylic alcohol **21**. The latter compound was converted via the intermediates **22–24** into the octalone **12**, which in turn was transformed by standard methodology into the corresponding ketal **7**. Treatment of **7** with bromoform – aqueous sodium hydroxide in the presence of a phase-transfer catalyst, followed by acid hydrolysis of the resultant crude product, gave the crystalline keto dibromide **27**. When a solution of the corresponding ketal **26** in tetrahydrofuran–hexamethylphosphoramide containing methyl iodide was treated with *tert*-butyllithium, the monobromo ketals **28** (58%) and **29** (38%) were formed. Compound **28** was converted by means of conventional reactions into the keto alcohol **32**. Attempts to transform the latter substance into (±)-ishwarone (**2**) proved unsuccessful. When the olefinic ketal **7** was allowed to react with dimethyl diazomalonate in the presence of copper bronze, the diester **44** was produced in good yield. The latter intermediate was converted via standard methodology into the keto dimesylate **47** which, upon reaction with lithium chloride in ether – hexamethylphosphoramide, gave the corresponding dichloride **48**. Treatment of **48** with potassium *tert*-butoxide in tetrahydrofuran resulted in an intramolecular alkylation to provide the tetracyclic keto chloride **50**. Reduction of **50** with lithium triethylborohydride in tetrahydrofuran afforded (±)-ishwarol (**51**) which, upon oxidation with pyridinium chlorochromate in dichloromethane, furnished (±)-ishwarone (**2**).



EDWARD PIERS et TSE-WAI HALL. Can. J. Chem. **58**, 2613 (1980).

On décrit la synthèse totale stéréosélective de la modification racémique du sesquiterpène tétracyclique ishwarone (**2**). Le traitement du cétaldéhyde connu **19** par le dibromométhylènetriphénylphosphorane conduit à l'alcène dibromé **20** qui est transformé efficacement en alcool propargylique **21**. Ce dernier conduit par les intermédiaires **22–24** à l'octalone **12** qui a son tour est transformé par des méthodes normales en cétal correspondant **7**. Le composé **7** traité par une solution aqueuse de bromoforme – hydroxyde de sodium en présence d'un catalyseur de transfert de phase, suivi d'une hydrolyse acide du produit brut donne la dibromocétone cristalline **27**. Lorsque l'on traite le cétal correspondant, **26**, en solution dans un mélange de tétrahydrofuranne–hexaméthylphosphoramide contenant de l'iodure de méthyle, par le *tert*-butyllithium il y a formation des cétals monobromés **28** (58%) et **29** (38%). Le composé **28** par des réactions conventionnelles conduit à l'alcool cétonique **32**. On n'a pas réussi à transformer cet alcool en (±)-ishwarone (**2**). Si on fait réagir le cétal oléfinique avec du diazomalonate de méthyle en présence d'un bronze de cuivre, il se forme le diester **44** avec de très bons rendements. Ce dernier intermédiaire, par des méthodes normales, est transformé en céto dimésylate **47** qui, par réaction avec le chlorure de lithium dans le mélange éther–hexaméthylphosphoramide, donne le composé dichloré correspondant **48**. Ce composé, en présence de *tert*-butylate de potassium dans le tétrahydrofuranne, subit une alkylation intramoléculaire qui conduit à la cétone tétracyclique chlorée **50**. Cette dernière est réduite par le triéthylborohydrure de lithium dans le tétrahydrofuranne en (±)-ishwarol **51** qui par oxydation avec le chlorochromate de pyridinium dans le dichlorométhane fournit la (±)-ishwarone (**2**).



[Traduit par le journal]

Introduction

The natural products belonging to the eremophilane–valencane class of sesquiterpenoids[1] possess the general carbon skeleton shown in **1**.[2] Ishwarone (**2**), a structurally novel member of this general

1

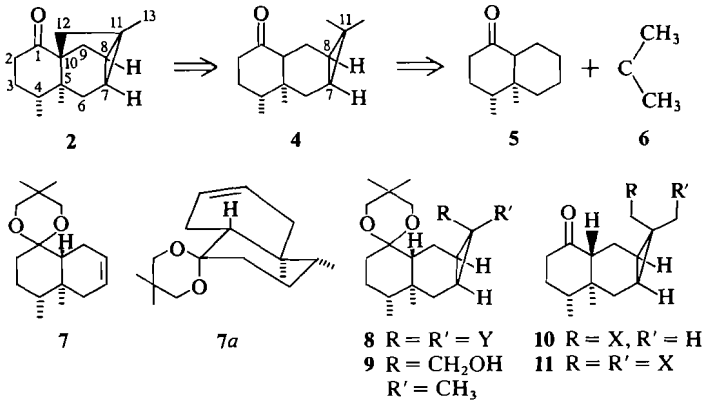
2 R = O
3 R = H_2

class, was first isolated from *Aristolochia indica* in 1935 (2), although the unique tetracyclic structure of this material was not recognized until the structural elucidation was completed some 34 years later (3). Subsequently, the parent hydrocarbon ishwarane (**3**) was also shown to be a natural product, having been isolated from *Aristolochia indica* (4) and *Cymbopetalum penduliforum* (Dunal) Baill (5).

Although the total synthesis of (±)-ishwarane (**3**) has been accomplished independently by two groups (6, 7), the preparation of ishwarone (**2**) had not been reported prior to the completion of our work.[3] We report herein the details of our synthesis of the racemic modification of this interesting natural product.[4]

[1]For a recent review, see ref. 1.

[2]The numbering system shown in **1** is that normally employed for eremophilane–valencane sesquiterpenoids.



[3]For a preliminary report outlining a portion of the work described herein, see ref. 8. Very recently, a short, elegant synthesis of (±)-ishwarone via a route entirely different from ours was reported (9).

[4]For an excellent general account of sesquiterpenoid syntheses completed prior to approximately the middle of 1970, see ref. 10.

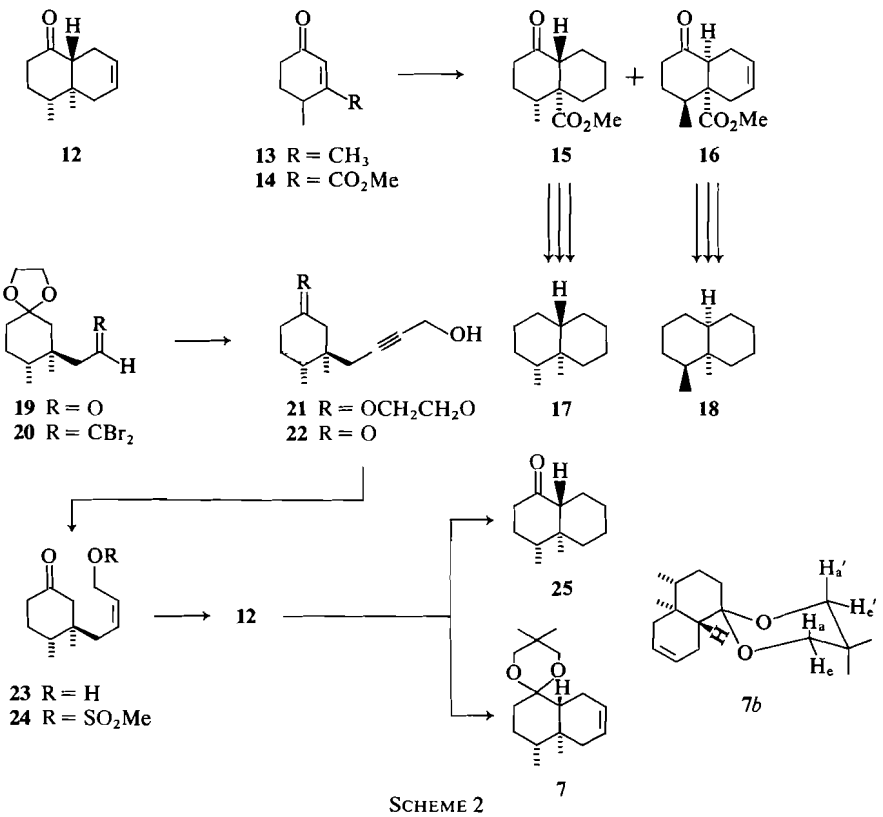
SCHEME 1

Synthetic Plan

An examination of the structure of ishwarone (**2**) makes it quite clear that any plan to effect the synthesis of this material should focus on an efficient construction of the structurally novel feature present in the compound, the tricyclo[3.2.1.$0^{2,7}$]octane ring system. Although retrosynthetic analyses reveal a number of possible "key" reactions which might be employed for this purpose, our synthetic plan was based on the following disconnective analysis (see Scheme 1). Disconnection of the C(10)—C(12) bond of ishwarone (**2**) provides the synthon **4**, which upon further (theoretical) cleavage (C(7)—C(11) and C(8)—C(11)) gives the dimethyldecalone **5** and a three-carbon fragment **6**.

On the basis of this analysis, it was decided to attempt the synthesis of (±)-ishwarone (**2**) via the following general route (Scheme 1). It appeared at the outset that a stereoselective preparation of the bicyclic ketal **7** would be relatively straightforward. Addition of a symmetrical carbene (or carbenoid) $:CY_2$ to this compound would be predicted to take place from the less hindered side of the carbon–carbon double bond, opposite to the angular methyl group (cf. **7***a*). Synthetic differentiation between the two Y groups of the expected product **8** to produce an intermediate **9**, followed by hydrolytic removal of the ketal protecting group, conversion of the hydroxyl functionality into a good leaving group (X), and intramolecular alkylation of the resultant product **10** would provide (±)-ishwarone (**2**). Alternatively, compound **8** might also be converted into an intermediate such as **11**. Alkylative cyclization of the latter material, followed by reductive removal of the second X functionality would also produce the desired final product **2**.

Regarding the nature of Y, two possibilities were considered, bromine and carboalkoxy. The addition of dibromocarbene to alkenes is a well-known process, and recent work has shown that the two bromine atoms in unsymmetrical *gem*-dibromocyclopropanes can be differentiated synthetically (11–14). Similarly, the copper–catalyzed addition of dialkyl diazomalonates to alkenes to provide the corresponding *gem*-dicarboalkoxycyclopropanes has been well documented (15). Therefore, our first synthetic objective became the olefinic ketal **7**. For reasons already mentioned, it was expected that addition of dibromocarbene or dimethyl diazomalonate to this substance would produce the corresponding adducts **8** (Y = Br or CO_2Me), which, in turn, might be transformed into intermediates of the type **10** or **11**, respectively.



Preparation of the Bicyclic Olefinic Ketal 7 (see Scheme 2)

The synthesis of compound **7** would, presumably, require the prior preparation of the corresponding ketone **12**. At first sight, an obvious method for preparing the latter substance would involve the Diels–Alder reaction of 1,3-butadiene with 3,4-dimethyl-2-cyclohexen-1-one (**13**) (16). However, it is known that Diels–Alder cycloadditions of 2-cyclohexen-1-ones with 1,3-dienes are quite sluggish reactions[5] and that 3-substituted cyclohexenones are even more reluctant to act as dienophiles. Indeed, attempted reaction of 3,4-dimethyl-2-cyclohexen-1-one (**13**) (16) with 1,3-butadiene under a variety of conditions (including the use of Lewis acid catalysts) failed to provide any of the desired octalone adduct.[6] In an attempt to increase the reactivity of the dienophile, 3-carbomethoxy-4-methyl-2-cyclohexen-1-one

[5]For a recent, brief discussion of this problem and for a report regarding the successful Lewis acid catalyzed Diels–Alder reactions of 1,3-butadiene with 2-cyclohexen-1-one and 2-methyl-2-cyclohexen-1-one, see ref. 17.

[6]For details regarding these attempts, see ref. 18.

SCHEME 2

(**14**) was prepared.[7] Although attempted Diels–Alder reaction of **14** with 1,3-butadiene under purely thermal conditions proved to be unsuccessful,[8] a 1:1 cycloaddition adduct was obtained when a solution of **14** and excess 1,3-butadiene in dichloromethane in the presence of aluminum trichloride was heated at 95–100°C (sealed tube) for 1 day. However, the product, in addition to being obtained in only modest yield (~50% at best), was shown unambiguously to consist of an approximately 1:1 mixture of the two bicyclic keto esters **15** (desired product) and **16**.[9] Separation of these two diastereomers by means of column chromatography on silica gel gave the desired isomer **15**, mp 96–97°C, in approximately 20–25% yield. Thus, the nonstereoselective, low-yielding nature of this Diels–Alder reaction, along with the fact that the ester functionality of the desired product **15** would still have to be transformed into a methyl group, made this approach appear to be quite unattractive. Therefore, an alternative preparation of the keto olefin **12** was devised, employing a route which, although more lengthy, was quite efficient and highly stereoselective.

Recently, in connection with a very elegant synthesis of (±)-eremophilone, Ziegler and co-workers (21) reported the stereoselective conversion of 3,4-dimethyl-2-cyclohexen-1-one (**13**) into the ketal aldehyde **19**. It appeared that the latter compound would serve as a convenient precursor for the keto olefin **12**. This proved to be the case. Thus, treatment of **19** with dibromomethylenetriphenylphosphorane (derived from the reaction of carbon tetrabromide with triphenylphosphine in the presence of zinc dust) (22) gave the dibromo alkene **20**. When the latter substance was allowed to react with two equivalents of *n*-butyllithium at −78°C (22) and the

[7]Hydrogenation (H_2, tris(triphenylphosphine)rhodium chloride, benzene, room temperature, atmospheric pressure) of the less substituted double bond of methyl 6-methyl-1,4-cyclohexadienecarboxylate (19), followed by allylic oxidation (CrO_3, CH_3CO_2H) of the resultant product (methyl 6-methylcyclohexenecarboxylate) afforded the keto ester **14** in 46% overall yield. For further details, see ref. 18.

[8]The successful thermal Diels–Alder reaction of 3-carbomethoxy-2-cyclohexen-1-one with 1,3-butadiene has been reported (20).

[9]The structures of **15** and **16** were established by unambiguous correlations with the known dimethyldecalins **17** and **18**, respectively, which had been prepared previously in our laboratory. For details, see ref. 18. We are very grateful to Dr. P. M. Worster for his assistance in making these correlations possible.

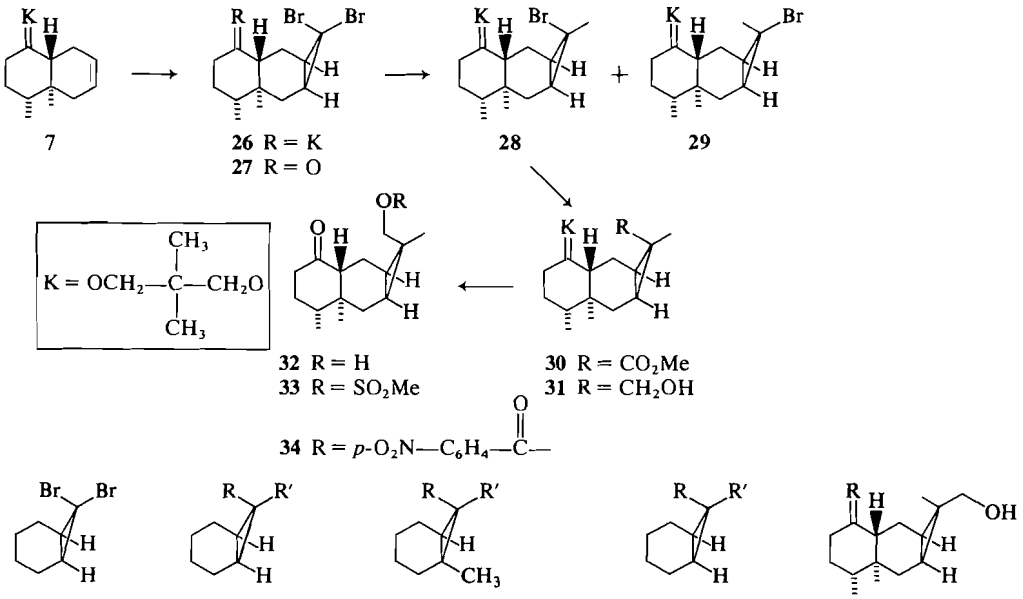
resultant lithium acetylide was trapped (23) with gaseous formaldehyde at 0°C, the substituted propargylic alcohol **21** was produced (75% from **19**). Hydrolysis (hydrochloric acid in aqueous methanol) of the ketal functionality afforded (92%) the crystalline keto alcohol **22**, mp 43–45°C, which was smoothly hydrogenated (palladium-on-barium sulfate) in ethanol containing a small amount of *purified* quinoline (24)[10] to yield the *cis* allylic alcohol **23**. Conversion (methanesulfonyl chloride, triethylamine dichloromethane) of this material into the rather unstable allylic mesylate **24**, followed by immediate treatment of the latter compound with 4 equivalents of potassium *tert*-butoxide in *tert*-butyl alcohol at room temperature, gave the desired octalone **12** (60% from the propargylic alcohol **22**). Conformational analysis of **12**, as compared with a similar analysis of the corresponding *cis*-fused diastereomer, would lead one to predict that the *trans*-fused isomer **12** should be the thermodynamically more stable octalone. Therefore, since the intramolecular alkylation was done in the presence of excess base, the expected product was **12**. Further evidence for this stereochemical conclusion was provided as follows. Hydrogenation (palladium-on-carbon, methanol) of **12** gave the corresponding decalone **25**, which was also recovered unchanged from potassium *tert*-butoxide – *tert*-butyl alcohol.

The first stage of the synthetic work was completed by conversion, under standard conditions, of the octalone **12** into the corresponding ketal derivative **7**, mp 100.5–102.5°C. Although the spectral data obtained from this material was largely straightforward and was fully consistent with the structural assignment, one rather unusual feature of the ^{1}H nmr spectrum should be discussed briefly, since this feature was seen in some of the subsequent synthetic intermediates as well. In the ^{1}H nmr spectrum of **7**, the protons of the methylene groups of the ketal functionality gave rise to an interesting pattern of signals consisting of an overlapped pair of doublets and a pair of doublet of doublets. If one considers the more stable chair conformation of the ketal ring (cf. **7***b*), then the signals can be assigned as follows. The overlapped pair of doublets (J = 11 Hz in each case) at δ 3.74 and 3.63 can be attributed to the two axial protons (H_a, H_a') each of which is geminally coupled to the corresponding equatorial proton (H_e, H_e', respectively). On the other hand, the equatorial protons H_e and H_e' each give rise to a doublet of doublets. These signals, which appear at δ 3.32 and 3.27, exhibit coupling constants of 11 Hz and ~2.5 Hz. Thus, in addition to being coupled to the axial protons, H_e and H_e' are mutually coupled (long-range W-type coupling) (26).



The acquisition of the olefinic ketal **7** set the stage for investigations into the use of this material for the synthesis of (±)-ishwarone (**2**).

Attempted Synthesis of (±)-Ishwarone (2) via the Dibromo Ketal 26 (see Scheme 3)

Treatment of the ketal olefin **7** with bromoform and aqueous sodium hydroxide containing a small amount of ethanol and the phase-transfer catalyst triethylbenzylammonium chloride (27) afforded, in good yield, a crude product which consisted mainly of the desired dibromocarbene adduct **26**. However, the ir spectrum of this material exhibited a weak absorption in the "carbonyl region," indicating that the ketal functionality had been partially lost. Furthermore, allowing this crude material to stand at room temperature, or attempted purification by means of distillation (reduced pressure) or column chromatography (silica gel), led to the acquisition of material which exhibited an increase in the intensity of the carbonyl absorption. In order to avoid these difficulties, the crude product obtained from the carbene addition reaction was hydrolyzed immediately with aqueous hydrochloric acid in methanol, and the resultant product was purified by column chromatography on silica gel. The highly crystalline ketone **27**, mp 130–131.5°C, was thus obtained in 80% yield. Reketalization of **27** under standard conditions gave (93%) the desired synthetic intermediate **26**.

Recently, Kitatani *et al.* (12) have shown that the two bromine atoms of 7,7-dibromobicyclo[4.1.0]heptane (**35**) can be differentiated synthetically by alkylation of the carbenoid (α-bromocyclopropyllithium) species derived from **35** by means of a bromine–lithium exchange reaction. For example, it was reported that treatment of **35** with *n*-butyllithium in tetrahydrofuran at −95°C, followed by addition of methyl iodide and warming of the resultant mixture to room temperature, gave 7-*exo*-bromo-7-methylbicyclo[4.1.0]heptane (**36**) as the sole alkylation product (60% yield). On the other hand, addition of *n*-butyllithium to a cold (−95°C) solution of **35** in tetrahydrofuran–hexamethylphosphoramide *containing methyl iodide*, gave, after subsequent warming of the solution to room temperature, a mixture of **36** and the epimer **37**, in a ratio of approximately 80:20 (86% yield). Therefore, it was decided to attempt a similar differentiation of the two bromine atoms of compound **26**. After a considerable amount of experimentation, it was found that when a pentane solution of 2 equiva-

[10]It was found that this reduction did not proceed well unless the quinoline employed was freshly purified as described by Vogel (25).

SCHEME 3

lents of *tert*-butyllithium was added to a cold (−95°C) solution of 1 equivalent of the dibromide **26** in tetrahydrofuran containing 3.5 equivalents of methyl iodide and 10% by volume of hexamethylphosphoramide, and the resultant solution was stirred at −95°C for 1 hour and at −78°C for 4 hours, a mixture of the two epimeric methylated products **28** and **29** (ratio approximately 3:2, respectively) was produced. Separation of these isomers by means of column chromatography on silica gel gave the two pure substances as oils in yields of 58 and 38%, respectively.

The stereochemical assignments with respect to the alkylation products **28** and **29** were made primarily on the basis of ^{1}H nmr spectroscopy. The C-7 methyl groups of the substituted bicyclo[4.1.0]-heptanes **36–39** have been shown to give rise to singlets at δ 1.70, 1.76, 1.76, and 1.83, respectively (12). Thus, in these substances, the *endo* methyl groups (**36**, δ 1.70; **38**, δ 1.76) resonate at higher field than the corresponding *exo* methyl groups (**37**, δ 1.76 ; **39**, δ 1.83). The ^{1}H nmr spectrum of the major isomer obtained from the reaction described above exhibited the methyl group on the cyclopropane ring as a singlet at δ 1.74, while the corresponding signal in the ^{1}H nmr spectrum of the minor isomer appeared at δ 1.62. Therefore, it seemed to be very reasonable to conclude that the major and minor products possessed the stereo-structures **28** and **29**, respectively. Further evidence in favor of these assignments will be presented later (*vide infra*).

Treatment of compound **28** with 2 equivalents of *tert*-butyllithium in ether at −78°C, followed by trapping of the resultant cyclopropyllithium reagent with freshly distilled methyl chloroformate, afforded the ketal ester **30** in 71% yield. Reduction of the latter substance with lithium aluminum hydride in ether gave the corresponding alcohol **31** which, upon hydrolysis with hydrochloric acid in methanol, was smoothly transformed into the keto alcohol **32** (69% from **30**).

Appropriate ^{1}H nmr data obtained from compounds **31** and **32**, compared with that derived from the related alcohols **40–43**,[11] provided corroborative evidence for the stereochemical assignments made for this series of compounds. Thus, the singlets due to the methylene protons of the hydroxymethyl group of compounds **31** and **32** appeared at δ 3.58 and 3.56, respectively. These chemical shifts are very similar to that of the corresponding signal (singlet, δ 3.65) of 7-*endo*-hydroxymethyl-7-methylbicyclo-[4.1.0]heptane (**40**). On the other hand, the ^{1}H nmr spectra of compounds **42** and **43** exhibited the —C*H*$_2$OH singlet at δ 3.30 and 3.26, respectively, values which compare favorably with the corres-

[11]Compounds **40** and **41** were obtained from **36** (12) and **37** (12), respectively, via a route which paralleled exactly the conversion of **28** into **31**. In similar fashion, the bromo ketal **29** was transformed into the ketal alcohol **42**, which was subsequently hydrolyzed (cf. **31** → **32**) to provide the corresponding ketone **43**. For details regarding these conversions, see ref. 18.

ponding signal (singlet, δ 3.20) of 7-*exo*-hydroxymethyl-7-methylbicyclo[4.1.0]heptane (**41**).

The use of the keto alcohol **32** as an intermediate in the synthesis of (±)-ishwarone (**2**) required bond formation between the carbinol carbon and the bridgehead position adjacent to the carbonyl group. However, conversion of **32** into a derivative in which the hydroxyl group had been transformed into a good leaving group proved to be problematic. For example, attempts to prepare and isolate (even under very mild conditions) the corresponding mesylate **33** were consistently unsuccessful, presumably due to the high propensity of the cyclopropylcarbinyl mesylate system to undergo solvolytic rearrangements.[12] On the other hand, treatment of compound **32** with *p*-nitrobenzoyl chloride in pyridine at 0°C afforded (91%) the *p*-nitrobenzoate **34**, which turned out to be a fairly stable oil. However, all attempts to effect intramolecular alkylation of **34** (*p*-nitrobenzoate anion as a leaving group) failed to produce any (±)-ishwarone (**2**). Use of different bases (e.g. potassium *tert*-butoxide, potassium hydride) in a variety of solvents (e.g. *tert*-butyl alcohol, tetrahydrofuran) resulted either in the recovery of starting material or produced the keto alcohol **32**.

The projected conversion of **32** into (±)ishwarone (**2**) remains an attractive possibility. In fact, it appears to be highly likely that some method which would effect this transformation could be found. However, at this stage of our work, lack of sufficient quantities of compound **32** precluded the possibility of more exhaustive investigations. Furthermore, at the same time at which this possibility was being studied, an alternative synthetic route to (±)-ishwarone (**2**) was also under investigation. This alternative, which is described in the following section of this paper, proved to be successful and, therefore, further efforts to prepare larger quantities of **32** and attempts to effect cyclization of this material were discontinued.

Total Synthesis of (±)-Ishwarone (2) via the Ketal Diester 44 (see Scheme 4)

Treatment of the ketal olefin **7** with excess dimethyl diazomalonate in the presence of copper bronze at 130–140°C (15) gave, in 64% yield, a single, crystalline (mp 132–133.5°C) adduct which, on the basis of steric approach control (*vide supra*), could be confidently assigned structure **44**.[13] Reduction of

SCHEME 4

the latter material with lithium aluminum hydride in ether, followed by treatment of the resultant ketal diol **45** (mp 173–174.5°C) with dilute hydrochloric acid in acetone, afforded the keto diol **46**, mp 138–139.5°C (79% from **44**). The corresponding oily dimesylate **47**, obtained by treatment of **46** with an excess of methanesulfonyl chloride in dichloromethane containing triethylamine, proved to be an isolable material, although it was not very stable. Furthermore, all attempts to effect conversion of the dimesylate into the tetracyclic monomesylate **49** via a base-promoted intramolecular alkylation failed. Although it appears to be highly probable that the required transformation had indeed occurred, the desired product **49** (a cyclopropylcarbinyl mesylate) was, again, apparently not sufficiently stable under the reaction conditions to allow for isolation. In order to overcome this difficulty, it was felt that if the mesylate groups of **47** were replaced by a "poorer" leaving group, such as chloride ion, then the corresponding tetracyclic system (such as **50**) might be stable enough to serve as a suitable synthetic intermediate.

When a solution of the keto dimesylate **47** in ether–hexamethylphosphoramide containing excess lithium chloride was stirred at room temperature, the corresponding dichloride **48** (mp 133–135°C after recrystallization from hexane)[14] was obtained in 91% yield. Treatment of **48** with a slight excess of freshly prepared potassium *tert*-butoxide in tetrahydrofuran at room temperature afforded the desired

[12]Although structurally simple cyclopropylcarbinyl mesylates and arenesulfonates have been isolated, these compounds are quite unstable and undergo solvolysis very readily (see refs. 28 and 29 for examples).

[13]For a recent report which describes the copper bronze-catalyzed addition of dimethyl diazomalonate to *trans*-Δ²-octalin, see ref. 30.

[14]A sample of the keto dichloride **48** which was obtained by means of preparative thin-layer chromatography (silica gel) using 7:3 hexane–ether as developing solvent, and which was not recrystallized, exhibited mp 74–76°C, as reported in our preliminary communication (8).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

tetracyclic keto chloride **50** (91% yield). Although this cyclopropylcarbinyl chloride could be isolated, it was not very stable and, therefore, was used immediately for the next step in the synthetic sequence. Reduction of **50** with lithium triethylborohydride (31) in tetrahydrofuran provided (88% from the keto dichloride **48**) the alcohol **51**.[15] Oxidation of the latter material with pyridinium chlorochromate (32) in dichloromethane gave crystalline (mp 80–81°C) (±)-ishwarone (**2**), which exhibited spectral data which were in excellent agreement with those reported for the natural product itself (3). In order to obtain further confirmation regarding the structure of the synthetic material, (±)-**2** was subjected to Wolff–Kishner reduction, as previously described (3). The product, (±)-ishwarane (**3**) was identical in all respects with an authentic sample of (±)-**3**.[16]

Experimental

General

Melting points, which were determined on a Fisher-Johns melting point apparatus, and distillation temperatures are uncorrected. Infrared spectra were recorded on a Perkin-Elmer model 710 spectrophotometer. Proton magnetic resonance spectra were measured using Varian Associates spectrometers, models T-60 and/or HA-100 or XL-100. Signal positions are given in δ units, with tetramethylsilane as the internal standard; the multiplicity, integrated peak areas, and proton assignments are indicated in parentheses. High resolution mass spectrometric measurements were recorded on an A.E.I. model MS-50 mass spectrometer. Gas–liquid chromatographic analyses were carried out with a Hewlett-Packard model 5832A gas chromatograph containing a 6 ft × 0.125 in. column (10% OV-210 on 100–120 mesh HP Chromosorb W). Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver, B.C.

*Preparation of the Ketal Dibromide **20***

To a suspension of zinc dust (5.35 g) in a solution of triphenylphosphine (21.0 g, 80.2 mmol) in 280 mL of dry dichloromethane was added 26.57 g (80.1 mmol) of carbon tetrabromide, and the resultant mixture was stirred at room temperature under an atmosphere of nitrogen for 27 h. A solution of 8.51 g (40.1 mmol) of the ketal aldehyde **19** (21) in a minimum amount of dry dichloromethane was added. After the reaction mixture had been stirred for an additional 2 h, approximately 200 mL of petroleum ether (bp 30–60°C) was added and the resulting mixture was filtered. The collected solid material was dissolved in 60 mL of dichloromethane, the resultant solution was diluted again with 200 mL of petroleum ether, and filtered. This process was repeated twice and all of the filtrates were combined. Removal of the solvent gave a residue which consisted of a mixture of a light yellow oil and a white solid. This material was diluted with a small amount of ether and filtered. The collected solid material was washed with ether. Removal of the solvent from the filtrate, followed by distillation (air-bath temperature 114–124°C/0.3 Torr) of the residual material gave 11.33 g (77%) of the ketal dibromide **20** as a very pale yellow oil; ir (film): 1615 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.86 (d, 3H, secondary methyl, J = 6 Hz), 0.92 (s, 3H, tertiary methyl), 1.86–2.32 (8-line multiplet, AB part of ABX system, 2H, allylic protons, $J_{AX} = J_{BX} \approx 7$ Hz, $J_{AB} \approx 15$ Hz), 3.91 (m, 4H, ethylene ketal protons), 6.43 (overlapped d of d, X part of ABX system, 1H, vinyl proton, $J_{AX} = J_{BX} \approx 7$ Hz). *Exact Mass* calcd. for $C_{13}H_{20}{}^{79}Br^{81}BrO_2$: 367.9840; found: 367.9810.

*Preparation of the Ketal Propargyl Alcohol **21***

To a cold (−78°C) stirred solution of the ketal dibromide **20** (7.86 g, 21.4 mmol) in 100 mL of dry tetrahydrofuran under an atmosphere of nitrogen was added 21 mL of a solution of *n*-butyllithium in hexane (2.37 *M*, 49.8 mmol). The mixture was stirred at −78°C for 1.5 h, and then was allowed to warm to 0°C. Gaseous formaldehyde, obtained by thermolysis of 8 g of paraformaldehyde at 160–190°C (oil bath temperature), was swept into the reaction mixture with a stream of nitrogen. After the reaction mixture had been stirred vigorously for another 30 min, 30 mL of saturated aqueous ammonium chloride was added. The resultant mixture was diluted with water and then extracted thoroughly with ether. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous yellow oil which, upon distillation (air-bath temperature 135–145°C/0.4 Torr) afforded 5.0 g (98%) of the propargyl alcohol **21** as a colourless oil; ir (film): 3475 (broad), 2325, 2255 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.82 (d, 3H, secondary methyl, J = 6 Hz), 0.90 (s, 3H, tertiary methyl), 2.14 (unresolved t, 2H, —$CH_2C{\equiv}C$—), 3.87 (m, 4H, ethylene ketal protons), 4.19 (t, 2H, —CH_2OH, $J \approx 2$ Hz). *Exact Mass* calcd. for $C_{14}H_{22}O_3$: 238.1546; found: 238.1569.

*Preparation of the Keto Propargyl Alcohol **22***

To a solution of the ketal **21** (5.27 g, 22.1 mmol) in 300 mL of methanol was added 22 mL of water and 22 mL of 3 *N* hydrochloric acid. After the solution had been stirred at room temperature for 3 h, most of the methanol was removed under reduced pressure. The residue was diluted with water and thoroughly extracted with ether. The combined ether extract was washed with saturated aqueous sodium bicarbonate, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 130–140°C/0.5 Torr) of the residual material gave 3.95 g (92%) of the ketone **22** as a viscous, colourless oil which crystallized on standing. Recrystallization of a small amount of this material from ether – petroleum ether gave an analytical sample which exhibited mp 43–45°C; ir ($CHCl_3$): 3500, 2320, 2260, 1705 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (s, 3H, tertiary methyl), 0.93 (d, 3H, secondary methyl, J = 6 Hz), 4.29 (t, 2H, —CH_2OH, $J \approx 2$ Hz). *Anal.* calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.28, H 9.30.

*Preparation of the Keto Allylic Alcohol **23***

To a stirred solution of the keto propargylic alcohol **22** (2.73 g, 14.1 mmol) in 50 mL of ethanol was added 549 mg of 5% palladium-on-barium sulfate and four drops of purified quinoline. After the resultant mixture had been subjected to hydrogenation at room temperature and atmospheric pressure until one equivalent of hydrogen had been absorbed, it was filtered through Celite. Removal of the solvent from the filtrate, followed by distillation (air-bath temperature 132–140°C/

[15]This material, (±)-ishwarol (3), consisted mainly of one isomer, expected to be that with the hydroxyl group in an axial orientation, *cis* to the angular methyl group. In the ^1H nmr spectrum of **51**, the carbinol proton appeared as an unresolved multiplet (δ 3.42) with a width at half-height of about 6 Hz, thus indicating that this proton was equatorially oriented.

[16]We are very grateful to Professor Ronald B. Kelly for a sample of synthetic (±)-ishwarane (**3**).

For personal use only.

0.4 Torr) of the residual material, provided 2.62 g (95%) of the keto alcohol **23** as a colourless oil, which according to glc analysis consisted of one component; ir (film): 3450 (broad), 3050, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80 (s, 3H, tertiary methyl), 0.93 (d, 3H, secondary methyl, $J = 6$ Hz), 4.12 (d, 2H, $—CH_2OH$, $J = 5.5$ Hz), 5.12–6.00 (m, 2H, vinyl protons). *Exact Mass* calcd. for $C_{12}H_{20}O_2$: 196.1457; found: 196.1463.

Preparation of the Keto Mesylate ***24***

To a cold (0°C) solution of the alcohol **23** (2.71 g, 13.8 mmol) in 50 mL of dry dichloromethane containing 2.1 g (20.8 mmol) of dry triethylamine was added slowly 1.75 g (15.3 mmol) of methanesulfonyl chloride. The solution was stirred at 0°C under an atmosphere of nitrogen for 30 min and was then poured into ice water. The resultant mixture was extracted quickly with cold ether. The combined extract was washed thrice with ice cold water, once with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent (temperature ≤25°C) gave 3.64 g (96%) of the crude keto mesylate **24** as a yellow oil; ir (film): 3060, 1710, 1350, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (s, 3H, tertiary methyl), 1.03 (d, 3H, secondary methyl, $J = 6$ Hz), 3.08 (s, 3H, $—OSO_2CH_3$), 4.78 (d, 2H, $—CH_2OMs$, $J = 6$ Hz), 5.64–5.95 (m, 2H, vinyl protons). Since compound **24** was quite unstable, it was not purified further and was used directly for the next synthetic transformation.

Preparation of the Octalone ***12***

To a solution of potassium *tert*-butoxide (3.2 g, 28.5 mmol) in 175 mL of dry *tert*-butyl alcohol under an atmosphere of nitrogen was added, dropwise, a solution of the crude keto mesylate **24** (3.64 g, 13.3 mmol) in 30 mL of dry *tert*-butyl alcohol. After the orange mixture had been stirred at room temperature for 2.5 h, it was treated with aqueous ammonium chloride and the resultant mixture was extracted thoroughly with ether. The combined ether extract was washed with water and dried over magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 62–75°C/0.2 Torr) of the residual reddish brown oil afforded 1.56 g (63% from the keto alcohol **23**) of the bicyclic keto olefin **12** as a colourless oil which, according to glc analysis, consisted of a single component; ir (film): 3050, 1705, 1660 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.68 (s, 3H, tertiary methyl), 0.94 (d, 3H, secondary methyl, $J = 6$ Hz), 5.68 (broad signal, 2H, vinyl protons). *Anal.* calcd. for $C_{12}H_{18}O$: C 80.85, H 10.18; found: C 80.51, H 10.01.

Preparation of the Decalone ***25***

To a stirred solution of the octalone **12** (223 mg, 1.25 mmol) in 10 mL of methanol was added 52 mg of 5% palladium-on-carbon and the resultant mixture was subjected to hydrogenation at room temperature and atmospheric pressure until hydrogen absorption ceased. Successive filtration, evaporation of the solvent from the filtrate, and distillation (air-bath temperature 160–172°C/16–20 Torr) of the residual material gave 186 mg (83%) of the decalone **25** as a colourless oil; ir (film): 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.66 (s, 3H, tertiary methyl), 0.88 (d, 3H, secondary methyl, $J = 6$ Hz). *Exact Mass* calcd. for $C_{12}H_{20}O$: 180.1507; found: 180.1514. When a solution of **25** in *tert*-butyl alcohol containing potassium *tert*-butoxide was stirred at room temperature for 22 h, it was recovered unchanged.

Preparation of the Ketal Olefin ***7***

A solution of the octalone **12** (5.2 g, 29.2 mmol), 2,2-dimethyl-1,3-propanediol (4.5 g, 43.3 mmol), and *p*-toluenesulfonic acid (520 mg) in 200 mL of dry benzene was refluxed for 20 h under a Dean–Stark water separator. The cooled solution was diluted with ether, washed with saturated aqueous sodium bicarbonate, water, and brine, and then dried over anhydrous magnesium sulfate. Removal of the solvent provided a pale yellow oil which solidified on standing at 0°C. Recrystallization of this material from hexane furnished 6.52 g (85%) of the desired ketal olefin **7**; mp 100.5–102.5°C; ir ($CHCl_3$): 3030, 1650 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.69, 0.80, 1.18 (s, s, s, 3H each, tertiary methyls), 0.84 (d, 3H, secondary methyl, $J = 6$ Hz), 2.86 (m, 2H, allylic protons, $w_{1/2} \approx 10$ Hz), 2.34 (m, 2H, allylic protons, $w_{1/2} \approx 16$ Hz), 2.81 (poorly resolved d of d, 1H, bridgehead proton, $J \approx 4$ Hz, 12 Hz), 3.27, 3.32 (two d of d, 2H, equatorially oriented protons of ketal functionality (cf. **7***b*), $J \approx 11$ Hz, 2.5 Hz in each case), 3.63, 3.74 (overlapped d of d, 2H, axially oriented protons of ketal functionality (cf. **7***b*), $J = 11$ Hz in each case), 5.42–5.86 (m, 2H, vinyl protons). *Anal.* calcd. for $C_{17}H_{28}O_2$: C 77.22, H 10.67; found: C 77.08, H 10.55.

Preparation of the Keto Dibromide ***27***

To a rapidly stirred mixture of 358 mg (1.36 mmol) of the ketal olefin, 82 mg (0.36 mmol) of triethylbenzylammonium chloride, a catalytic amount of ethanol, and 5.0 g (19.8 mmol) of bromoform was added, dropwise, 10 mL of 50% aqueous sodium hydroxide. The heterogeneous mixture was warmed to 40–50°C, kept at this temperature for 3 h, and poured into cold water. The resultant mixture was extracted thoroughly with dichloromethane. The combined organic extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a dark brown oil. This material was dissolved in 20 mL of methanol containing 1 mL of 1 *N* hydrochloric acid, and the resultant solution was stirred at room temperature for 4 h. After most of the methanol had been removed under reduced pressure, the residual material was diluted with saturated aqueous sodium bicarbonate and the resultant mixture was extracted with ether. The combined ether extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent furnished a dark oil which was subjected to column chromatography on 200 g of silica gel. The column was eluted with 1 : 4 ether – petroleum ether (bp 30–60°C). Combination of all of the fractions containing the desired product afforded 378 mg (80%) of the keto dibromide **27** as pale yellow crystals. An analytical sample, obtained by recrystallization of a small amount of this material from ether, exhibited mp 130–131.5°C; ir ($CHCl_3$): 3100, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.57 (s, 3H, tertiary methyl), 0.93 (d, 3H, secondary methyl, $J = 6.0$ Hz), 1.12–1.34 (m, 1H), 2.50–3.45 (diffuse, 11H). *Exact Mass* calcd. for $C_{13}H_{18}{}^{79}Br^{81}BrO$: 349.9474; found: 349.9467.

Preparation of the Ketal Dibromide ***26***

A solution of the keto dibromide **27** (350 mg, 1.0 mmol), 2,2-dimethyl-1,3-propanediol (1.5 g, 14.4 mmol), and *p*-toluenesulfonic acid (10 mg) in 25 mL of dry benzene was refluxed under a Dean–Stark water separator for 20 h. The cooled solution was diluted with ether, washed with saturated aqueous sodium bicarbonate, and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous yellow oil which was subjected to column chromatography on 50 g of silica gel. Elution of the column with 1:4 ether – petroleum ether (bp 30–60°C) afforded 405 mg (93%) of the ketal dibromide **26** as a pale yellow oil; ir (film): no carbonyl absorption; ^1H nmr ($CDCl_3$) δ: 0.66, 0.72, 1.16 (s, s, s, 3H each, tertiary methyls), 0.83 (d, 3H, secondary methyl, $J = 5$ Hz), 2.73 (d of d, 1H, bridgehead proton, $J \approx 3$ Hz, 12 Hz), 3.14–3.78 (m, 4H, ketal protons). *Exact Mass* calcd. for $C_{18}H_{28}{}^{79}Br^{81}BrO_2$: 436.0475; found: 436.0456.

Preparation of the Ketal Monobromides ***28*** *and* ***29***

A solution of the ketal dibromide **26** (268 mg, 0.61 mmol) and methyl iodide (500 mg, 3.52 mmol) in 4 mL of dry tetrahydrofuran containing 0.4 mL of dry hexamethylphosphoramide was cooled, under an atmosphere of nitrogen, to −95°C. A solution of *tert*-butyllithium in pentane (0.7 mL, 1.93 *M*, 1.35 mmol) was added. The mixture was allowed to stir at −95°C for 1 h, was warmed to −78°C, and then left for an additional 4 h. Water (10 mL) was added, and the resultant mixture was extracted with hexane. The combined hexane extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which, on the basis of a glc analysis, appeared to consist mainly of two components, in a ratio of approximately 3 : 2. The crude product was subjected to chromatography on 25 g of silica gel, with 9 : 1 hexane–benzene being employed as the eluting solvent mixture.

The major product **28** (130 mg, 58%), which was the first component to be eluted from the column, was obtained as a pale yellow oil; ^{1}H nmr ($CDCl_3$) δ: 0.64, 0.72, 1.13 (s, s, s, 3H each, tertiary methyls), 0.79 (d, 3H, secondary methyl, J = 6 Hz), 1.74 (s, 3H, cyclopropyl methyl), 2.69 (d of d, 1H, bridgehead proton, $J \approx$ 3 Hz, 12 Hz), 3.06–3.74 (m, 4H, ketal protons). *Exact Mass* calcd. for $C_{19}H_{31}{}^{79}BrO_2$: 370.1552; found: 370.1567.

The minor isomer **29** (85 mg, 38%), was also obtained as a pale yellow oil; ^{1}H nmr ($CDCl_3$) δ: 0.64, 0.71, 1.12 (s, s, s, 3H each, tertiary methyls), 0.77 (d, 3H, secondary methyl, J = 6 Hz), 1.62 (s, 3H, cyclopropyl methyl), 2.69 (unresolved d of d, 1H, bridgehead proton, $J \approx$ 3.5 Hz, 13 Hz), 3.08–3.74 (m, 4H, ketal protons). *Exact Mass* calcd. for $C_{19}H_{31}{}^{79}BrO_2$: 370.1552; found: 370.1537.

Preparation of the Ketal Ester ***30***

To a cold (−78°C) solution of the ketal bromide **28** (144 mg, 0.39 mmol) in 8 mL of anhydrous ether under an atmosphere of nitrogen was added slowly 0.45 mL of a solution of *tert*-butyllithium in pentane (1.93 *M*, 0.87 mmol). After the solution had been stirred at −78°C for 1 h, methyl chloroformate (0.25 mL, 3.23 mmol) and dry hexamethylphosphoramide (0.8 mL) were added successively. The mixture was maintained at −78°C for another 4 h and then was diluted with water. The resultant mixture was extracted with petroleum ether. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave a yellow oil which was subjected to column chromatography on 15 g of silica gel, with 1 : 9 ether – petroleum ether (bp 30–60°C) being used as the eluting solvent mixture. The fractions containing the ketal ester **30** were combined, yielding 97 mg (71%) of the desired material as pale yellow crystals; mp 120–123°C; ir ($CHCl_3$): 1720 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.66, 0.78, 1.16, 1.24 (s, s, s, s, 3H each, tertiary methyls), 0.80 (d, 3H, secondary methyl, J = 5 Hz), 2.58–2.84 (unresolved d of d, 1H, bridgehead proton), 3.12–3.78 (m, 4H, ketal protons), 3.66 (s, 3H, —CO_2CH_3). *Exact Mass* calcd. for $C_{21}H_{34}O_4$: 350.2432; found: 350.2457.

Preparation of the Ketal Alcohol ***31***

To a solution of lithium aluminum hydride (104 mg, 2.73 mmol) in 5 mL of anhydrous ether was added a solution of the ketal ester **30** (97 mg, 0.28 mmol) in 7 mL of anhydrous ether. The mixture was stirred under an atmosphere of nitrogen for 20 h at room temperature. The excess reducing agent was destroyed by addition of powdered sodium sulfate decahydrate. The resultant mixture was filtered and the collected solid material was washed thoroughly with ether. The combined ethereal filtrate was washed with brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 63 mg (71%) of the ketal alcohol **31** as a very viscous oil; ir (film): 3400 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.66, 0.78, 1.10, 1.15 (s, s s, s, 3H each, tertiary methyls), 0.80 (d, 3H, secondary methyl, J = 5 Hz), 2.52–2.90 (unresolved d of d, 1H, bridgehead proton), 3.00–3.84 (m, 4H, ketal protons), 3.60 (s, 2H, —CH_2OH). *Exact Mass* calcd. for $C_{20}H_{34}O_3$: 322.2506; found: 322.2508.

Preparation of the Keto Alcohol ***32***

To a solution of the ketal alcohol **31** (63 mg, 0.20 mmol) in a mixture of acetone (3 mL), methanol (3 mL), and water (1 mL) was added 6 drops of 1 *N* hydrochloric acid. The mixture, under an atmosphere of nitrogen, was stirred at room temperature for 3 h. Most of the solvent was removed under reduced pressure, the residue was diluted with saturated aqueous sodium bicarbonate, and the resultant mixture was extracted with ether. The combined ether extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by purification of the resultant crude material by means of preparative tlc on silica gel (2 : 1 benzene – ethyl acetate used as developing solvent mixture) gave 46 mg (97%) of the keto alcohol **32** as a colourless oil; ir ($CHCl_3$): 3500, 1705 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.66, 1.13 (s, s, 3H each, tertiary methyls), 0.86 (d, 3H, secondary methyl, J = 6.0 Hz), 3.56 (s, 2H, —CH_2OH). *Exact Mass* calcd. for $C_{15}H_{24}O_2$: 236.1771; found: 236.1776.

Preparation of the Keto p*-Nitrobenzoate* ***34***

To a solution of the keto alcohol **32** (45 mg, 0.19 mmol) in 5 mL of dry dichloromethane was added dry pyridine (100 mg, 1.27 mmol) and recrystallized *p*-nitrobenzoyl chloride (100 mg, 0.54 mmol). The mixture was allowed to stand at 0°C for 24 h, and then was poured into water. The resultant mixture was extracted with ether. The combined ether extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by purification of the resultant yellow oil by means of preparative tlc on silica gel (2 : 1 benzene – ethyl acetate used as developing solvent mixture), gave 67 mg (91%) of the expected product **34** as a viscous, clear oil; ir (film): 1720, 1705, 1609, 1525, 1345 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.66, 1.20 (s, s, 3H each, tertiary methyls), 0.90 (poorly resolved d, 3H, secondary methyl, $J \approx$ 6 Hz), 4.38 (s, 2H, —CH_2OCOAr), 8.28 (m, 4H, aromatic protons). *Exact Mass* calcd. for $C_{22}H_{27}NO_5$: 385.1889; found: 385.1889.

Preparation of the Ketal Diester ***44***

To a stirred mixture of the ketal olefin 7 (786 mg, 2.98 mmol) and copper bronze (64 mg), heated with an external oil bath at 130–140°C under an atmosphere of nitrogen, was added dropwise 2.04 g (12.9 mmol) of dimethyl diazomalonate. After the addition was complete, the mixture was stirred at 130–140°C for an additional 1.5 h, and then was cooled. Dichloromethane was added to the resultant solid material, and the mixture was filtered through a short Florisil column. The column was eluted with further volumes of dichloromethane. Removal of the solvent from the combined eluant gave a crude semi-solid material which was triturated in the presence of ether. The mixture was filtered. Removal of the solvent from the filtrate gave a yellow oil which was subjected to column chromatography on 230 g of silica gel. Elution of the column with 1 : 3 ethyl acetate – petroleum ether (bp 30–60°C), afforded 930 mg (80%) of a colourless oil which crystallized on standing. Recrystallization from hexane produced 750 mg (64%) of the ketal diester **44**; mp 132–133.5°C; ir ($CHCl_3$): 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.66, 0.82, 1.15 (s, s, s, 3H each, tertiary

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

methyls), ~0.81 (poorly resolved d, 3H, secondary methyl), 2.62–2.84 (poorly resolved d of d, 1H, bridgehead proton), 3.12–3.72 (m, 4H, ketal protons), 3.68, 3.74 (s, s, 3H each, $-CO_2CH_3$ groups). *Anal.* calcd. for $C_{22}H_{34}O_6$: C 66.98, H 8.69; found: C 67.09, H 8.50.

Preparation of the Ketal Diol ***45***

To a solution of lithium aluminum hydride (500 mg, 13.2 mmol) in 50 mL of anhydrous ether was added, over a period of 30 min, a solution of the ketal diester **44** (532 mg, 1.35 mmol) in 50 mL of anhydrous ether. The mixture was stirred at room temperature under an atmosphere of nitrogen for 20 h. After the reaction mixture had been diluted with approximately 20 mL of dichloromethane, the excess reducing agent was destroyed by addition of excess powdered sodium sulfate decahydrate. The resultant mixture was filtered through Celite and the collected solid material was washed thoroughly (trituration) with dichloromethane. The combined filtrate was dried over anhydrous magnesium sulfate. Removal of the solvent gave 429 mg (94%) of a crystalline solid which exhibited mp 170–172°C. An analytical sample of the ketal diol **45**, obtained by recrystallization of a small amount of this material from acetone, exhibited mp 173–174.5°C; ir (Nujol): 3300 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.63, 0.75, 1.10 (s, s, s, 3H each, tertiary methyls), ~0.78 (d, 3H, secondary methyl), 2.56–2.79 (poorly resolved d of d, 1H, bridgehead proton), 3.04–3.98 (complex m, 8H, $-CH_2OH$ groups and ketal protons). *Anal.* calcd. for $C_{20}H_{34}O_4$: C 70.97, H 10.12; found: C 70.89, H 10.00.

Preparation of the Keto Diol ***46***

To a solution of the ketal diol **45** (371 mg, 1.10 mmol) in 60 mL of reagent grade acetone and 5 mL of water was added 5 drops of 4 *N* hydrochloric acid. The solution was stirred at room temperature under a nitrogen atmosphere for 3 h. Anhydrous sodium bicarbonate was added and most of the solvent was removed under reduced pressure. The residue was diluted with water and the resultant mixture was extracted thoroughly with dichloromethane. The combined organic extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a pale yellow semisolid which was triturated with a small amount of ether. Filtration furnished 147 mg of the desired keto diol **46**. Concentration of the filtrate gave another 85 mg (total yield 232 mg, 84%) of the desired product which exhibited mp 138–139.5°C; ir (Nujol): 3300, 1700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.66 (s, 3H, tertiary methyl), 0.93 (d, 3H, secondary methyl, J = 6 Hz), 3.44, 3.63 (AB pair of d, 2H, $-CH_2OH$, J = 12 Hz), 3.75, 3.91 (AB pair of d, 2H, $-CH_2OH$, J = 12 Hz). *Anal.* calcd. for $C_{15}H_{24}O_3$: C 71.39, H 9.59; found: C 71.00, H 9.52.

Preparation of the Keto Dimesylate ***47***

To a cold (0°C) solution of the keto diol **46** (232 mg, 0.92 mmol) in 20 mL of dry dichloromethane under an atmosphere of nitrogen was added, successively, dry triethylamine (290 mg, 2.87 mmol) and methanesulfonyl chloride (266 mg, 2.32 mmol). The mixture was stirred at 0°C for 30 min, was diluted with ether, washed four times with ice-cold water and once with brine, and dried over anhydrous magnesium sulfate. Removal of the solvent gave 370 mg of a slightly yellow viscous oil; ir (film): 1700, 1355, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.66 (s, 3H, tertiary methyl), 0.90 (unresolved d, 3H, secondary methyl), 3.03, 3.06 (s, s, 3H each, $-OSO_2CH_3$ groups), 3.93, 4.14 (AB pair of d, 2H, $-CH_2OMs$, $J \approx 11$ Hz), 4.32 (s, 2H, $-CH_2OMs$). Since the dimesylate **47** was quite unstable, the crude material was used immediately for the next synthetic step.

Preparation of the Keto Dichloride ***48***

To a solution of the crude dimesylate **47** (370 mg) in 15 mL of anhydrous ether and 30 mL of dry hexamethylphosphoramide was added 2.1 g of anhydrous lithium chloride. The mixture was stirred overnight under an atmosphere of nitrogen and then poured into 150 mL of water. The resultant mixture was extracted thoroughly with ether. The combined ether extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent gave a pale yellow oil which solidified on cooling to 0°C. Recrystallization from hexane gave 242 mg (91% from the keto diol **46**) of the keto dichloride **48**; mp 133–135°C; ir ($CHCl_3$): 1706 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.62 (s, 3H, tertiary methyl), 0.92 (d, 3H, secondary methyl, J = 6 Hz), 3.36, 3.67 (AB pair of d, 2H, $-CH_2Cl$, J = 11 Hz), 3.61, 3.83 (AB pair of d, 2H, $-CH_2Cl$, J = 12 Hz). *Anal.* calcd. for $C_{15}H_{22}Cl_2O$: C 62.29, H 7.67; found: C 62.27, H 7.85.

Preparation of the Tetracyclic Keto Chloride ***50***

To a solution of freshly prepared potassium *tert*-butoxide (103 mg, 0.92 mmol) in 10 mL of dry tetrahydrofuran was added a solution of 178 mg (0.62 mmol) of the keto dichloride **48** in 5 mL of dry tetrahydrofuran. The resulting yellow solution was stirred under an atmosphere of nitrogen at room temperature for 1.5 h. Aqueous ammonium chloride was added and the resulting mixture was extracted thoroughly with pentane. The combined extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent gave 141 mg of the crude keto chloride **50**, which, due to its unstable character was used immediately for the next synthetic step. The crude product **50** exhibited ir (film): 1700 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.73 (s, 3H, tertiary methyl), 0.87 (d, 3H, secondary methyl, J = 6 Hz), 3.60 (s, 2H, $-CH_2Cl$).

*(±)-Ishwarol (****51****)*

To a cold (0°C) solution of the crude keto chloride **50** (141 mg) in 10 mL of dry tetrahydrofuran was added 2.8 mL (1 *M*, 2.8 mmol) of a solution of lithium triethylborohydride in tetrahydrofuran. The mixture was stirred at room temperature under an atmosphere of nitrogen for 20 h. After the excess reducing agent had been destroyed by addition of 4 mL of water, 3 mL of 3 *N* sodium hydroxide and 3 mL of 30% hydrogen peroxide were added successively. The mixture was stirred at room temperature for 4 h, was diluted with water, and then thoroughly extracted with ether. The combined ether extracts were washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 100–110°C/0.5 Torr; lit. (3) bp 114°C/1 Torr) of the residual oil gave 119 mg (88% based on the keto dichloride **48**) of (±)-ishwarol (**51**) as a colourless oil; ir (film): 3350 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.77 (d, 3H, secondary methyl, J = 5.5 Hz), 1.03, 1.13 (s, s, 3H each, tertiary methyls), 3.42 (m, 1H, —C*H*OH).

*(±)-Ishwarone (****2****)*

To a suspension of chromium trioxide (282 mg, 2.82 mmol) in 20 mL of dichloromethane was added 330 mg (2.86 mmol) of pyridinium hydrochloride. The mixture was stirred for 1 h. To the resultant orange suspension–solution was added a solution of 119 mg (0.54 mmol) of the alcohol **51** in a small amount of dichloromethane. The reaction mixture was stirred at room temperature for 2 h, was diluted with ether, and then filtered through a short column of Florisil. The column was eluted with ether. Removal of the solvents from the combined eluant, followed by distillation (air-bath temperature 120–130°C, water aspirator) of the residual oil, gave 86 mg (73%)

of a colourless oil which solidified on cooling. Recrystallization from pentane gave an analytical sample of (±)-ishwarone (**2**); mp 80–81°C; ir ($CHCl_3$): 1705 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.56 (m, 1H, cyclopropyl proton), 0.74, 1.16 (s, s, 3H each, tertiary methyls), 0.87 (d, 3H, secondary methyl, $J = 7$ Hz). *Exact Mass* calcd. for $C_{15}H_{22}O$: 218.1671; found: 218.1679.

(±)-Ishwarane (3)

To 20 mL of diethylene glycol was added 0.5 g of sodium metal and the mixture was warmed (steam bath) until all of the sodium had reacted. To the resultant solution was added 31 mg (0.14 mmol) of (±)-ishwarone (**2**) and 3 mL of hydrazine hydrate. The solution was distilled slowly (the distillate was saved) until the internal temperature reached 180°C, and was then allowed to reflux for 18 h. The solution was again slowly distilled (the distillate was saved) until the internal temperature had reached 210°C, and was then allowed to reflux for an additional 6 h. The cooled solution was combined with the two distillates obtained as described above, and poured into water. The resultant mixture was extracted with ether. The combined ether extract was washed with water and brine and dried over anhydrous magnesium sulfate. Removal of the solvent, followed by distillation (air-bath temperature 90–110°C, water aspirator) of the residual material gave 23 mg (81%) of (±)-ishwarane (**3**) as a colourless oil. This material exhibited ir and ^1H nmr spectra, as well as glc retention time, identical with those of an authentic sample of racemic ishwarane (**3**) (6).

C-Nucleoside studies. Part XI. *Cine*-substitution in 1,4-dinitropyrazoles; application to the synthesis of formycin via nitropyrazole derivatives

J. GRANT BUCHANAN, ALAN STOBIE, AND RICHARD H. WIGHTMAN

Department of Chemistry, Heriot-Watt University, Riccarton, Currie, Edinburgh EH14 4AS, Scotland

Received May 28, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

J. GRANT BUCHANAN, ALAN STOBIE, and RICHARD H. WIGHTMAN. Can. J. Chem. **58**, 2624 (1980).

Reaction of 1,4-dinitro-3-methylpyrazole with a variety of nucleophiles led to the formation of 5-substituted 3-methyl-4-nitropyrazoles **11–15** by a process of *cine*-substitution. This reaction has been applied as the key step in a novel synthesis of formycin. Treatment of 1,4-dinitro-3-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)pyrazole (**17**) with cyanide ion produced 3(5)-cyano-4-nitro-5(3)-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)pyrazole (**19**) in 89% yield. Catalytic reduction to the 4-amino compound **20** (84%), and subsequent reaction with formamidine acetate yielded formycin triacetate **21** (79%). Methanolysis of **21** produced formycin (**1**) in 90% yield.

J. GRANT BUCHANAN, ALAN STOBIE et RICHARD H. WIGHTMAN. Can. J. Chem. **58**, 2624 (1980).

La réaction de la dinitro-1,4 méthyl-3 pyrazole avec divers nucléophiles, par une *ciné* substitution conduit à la formation des méthyl-3 nitro-4 pyrazoles substitués en position 5 **11** à **15**. On a utilisé cette réaction comme l'étape fondamentale d'une nouvelle synthèse de la formycine. La dinitro-1,4 (tri-*O*-acétyl-2,3,5, β-D-ribofurannosyl)-3 pyrazole (**17**) traitée par l'ion cyanure fournit la cyano-3 (5) nitro-4 (tri-*O*-acétyl-2,3,5 β-D-ribofurannosyl)-5 (3) pyrazole (**19**) avec un rendement de 89%. Une réduction catalytique conduit, avec un rendement de 84%, au composé amino-4 **20** qui par une réaction subséquente avec l'acétate de formamidine donne le triacétate de formycine **21** (79%). La méthanolyse du composé **21** fournit la formycine (**1**) avec un rendement de 90%.

[Traduit par le journal]

The *C*-nucleoside antibiotic formycin (**1**) (1–3) is a naturally-occurring isomer of adenosine, in which the imidazole ring has been replaced by a pyrazole. Formycin has antiviral and antitumour properties, and is thought to be able to substitute for the adenosine moiety in a variety of enzymic reactions occurring at the nucleotide level (3). The biological activity (3) of formycin and the related metabolite formycin B (**2**) (1) has stimulated interest in the synthesis of these compounds. Acton and co-workers (4) have reported a total synthesis of formycin B, which can be converted into formycin by the method of Townsend and co-workers (5). More recently, Kalvoda (6) has synthesized formycin and formycin B by a different route. We have been interested in developing a general synthetic approach to *C*-nucleoside antibiotics and their analogs proceeding via ribofuranosylalkyne intermediates such as **3** (7), **4** (8), and **5** (9), and in this paper we describe a synthesis of formycin by means of this approach.[1]

We have previously reported the conversion of the ribofuranosylalkyne **5** into 3(5)-β-D-ribofuranosyl-4-nitropyrazole (**6**) (9). Clearly, for the further transformation of this intermediate into formycin (**1**) it is necessary to introduce a carbon-containing substituent at the unsubstituted 3(5)-position of the pyrazole ring. As a means of achieving this, we were attracted by the report by Habraken and Poels (11) that 1,4-dinitropyrazoles such as **7** react readily with secondary amines, for example morpholine, to give 5-substituted pyrazoles typified by **8**. A reasonable mechanism for this interesting "*cine*"-substitution process could involve intermediates of type **9** and **10**. Since 1,4-dinitropyrazoles such as **7** are readily prepared by *N*-nitration, with acetyl nitrate, of the appropriate *C*-nitropyrazole (11, 12), we decided to investigate whether this substitution would also occur with other nucleophiles, and in particular carbanions. Our expectations were fulfilled.

Thus, when an ethereal solution of 3-methyl-1,4-dinitropyrazole (**7**) (11) was added to refluxing liquid ammonia, 3-methyl-4-nitro-5-aminopyrazole (**11**) (13) was produced in near-quantitative yield. Treatment of **7** with potassium hydroxide in ethanol produced the ethyl ether **12** (14) in quantitative yield, whilst reaction of **7** with ethane thiol and potassium hydroxide gave the corresponding sulphide **13**. A phosphorus nucleophile could also be introduced; reaction of **7** and trimethylphosphite gave an Arbusov-type reaction to yield the phosphonate **14** in 77% yield. Finally, and most importantly for our present purposes, when an ethanolic solution of **7** was added to excess potassium cyanide in aqueous ethanol, a rapid reaction ensued to yield 3-methyl-4-nitro-5-cyanopyrazole (**15**) (15)

in 85% yield.[2] It thus appears that this *cine*-substitution process is a fairly general reaction of 1,4-dinitropyrazoles, and we were hopeful that such a substitution with cyanide ion could be used as the key step in the synthesis of formycin from nitropyrazole **6**.

When 3(5)-β-D-ribofuranosyl-4-nitropyrazole (**6**) (10) was treated with acetic anhydride in pyridine, a tetraacetyl derivative was formed, which could be deacetylated selectively on the pyrazole nitrogen by brief exposure to methanol containing a trace of pyridine. The resultant tri-*O*-acetyl derivative **16** was subjected to *N*-nitration using cupric nitrate trihydrate and acetic anhydride (16) to yield a single isomer **17** in 87% yield. That **17** had the assigned structure, and not the isomeric structure **18**, was clearly indicated (11) by the ^{1}H nmr spectrum; the pyrazole ring proton resonated at 9.11, a downfield shift of 0.9 ppm from the corresponding signal in the precursor **16**. When a solution of dinitropyrazole **17** was added to excess potassium cyanide in aqueous ethanol, the desired *cine*-substitution process occurred readily, and 3(5)-cyano-4-nitro-5(3)-(tri-*O*-acetyl-β-D-ribofuranosyl) pyrazole (**19**) was isolated in 89% yield, as a crystalline benzene solvate. No loss of acetate protecting groups was observed during the short reaction time (10 min) used.

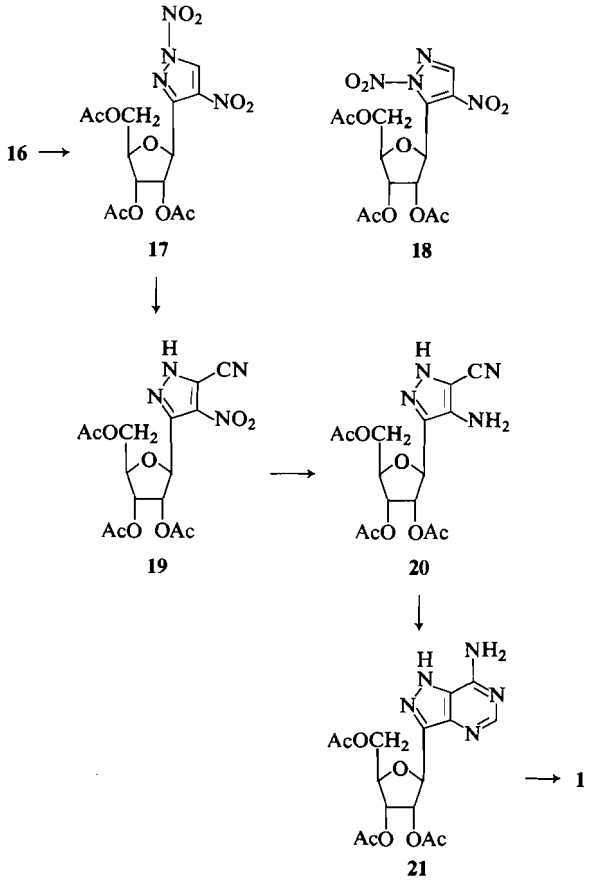
The nitro group in **19** could be reduced cleanly to an amino function by catalytic hydrogenation, and the resultant 4-aminopyrazole **20**, obtained as a syrup in 84% yield, was subjected to cyclization with formamidine acetate in refluxing ethoxyethanol. Reaction was complete (tlc) within 20 min, and isolation by chromatography yielded formycin triacetate (**21**) in 77% yield.

Deacetylation of the triacetate **21** with sodium methoxide in methanol produced formycin (**1**), isolated as its crystalline monohydrate in 90% yield. This material proved identical (melting point and mixture melting point, ir, uv, tlc, optical rotation) with genuine formycin monohydrate.

The synthesis described should be capable of adaptation and extension to the synthesis of a range of analogues of formycin containing specific modifications in either the sugar (17) or heterocyclic rings.

Experimental

The general methods used were as stated in Part II (18). Column chromatography was carried out using Kieselgel H type 60 (Merck); an external pressure was applied to the top of columns. Thin-layer chromatography was carried out on precoated aluminium-backed plates (Kieselgel HF_{254} type 60 (Merck)).



3-Methyl-4-nitro-5-aminopyrazole (11)

1,4-Dinitro-3-methylpyrazole (7) (0.40 g) in ether (5 mL) was slowly added to refluxing liquid ammonia (10 mL). The mixture was stirred at reflux for 0.5 h, and the solvents then allowed to evaporate. The residue was partitioned between ethyl acetate and water; the organic layer was dried ($MgSO_4$) and evaporated to leave a crystalline residue. Recrystallization from ethyl acetate yielded **11** (0.32 g, 97%), mp 230–233°C (lit. (13) mp 228°C); ^{1}Hmr (CF_3CO_2H) δ: 2.80 (s, CH_3); ms (70 eV) *m/e*: 142 (M^+).

3-Methyl-4-nitro-5-ethoxypyrazole (12)

A solution of 1,4-dinitro-3-methylpyrazole (7) (0.10 g) in ethanol (1 mL) was slowly added to a solution of potassium hydroxide (0.50 g) in ethanol (10 mL). After 5 min, the mixture was neutralized with acetic acid, and the solvents evaporated. Partition between ethyl acetate and water, drying and evaporation of the organic layer, and crystallization of the residue from

[2]Analogous reactions can also be achieved with the anions of ethyl acetoacetate and diethyl malonate (D. M. Service and R. H. Wightman, unpublished results).

dichloromethane–petrol gave **12** (0.10 g, 98%); mp 118–121°C (lit (14) mp 126°C); ^{1}Hmr (60 MHz, $CDCl_3$) δ: 1.40 (t, J = 6 Hz, 3H, CH_3), 2.60 (s, 3H, CH_3), 4.40 (q, J = 6 Hz, 2H, CH_2).

Ethyl-5-(3-methyl-4-nitropyrazolyl)sulphide (13)

A solution of **7** (0.20 g) in ether (1 mL) was slowly added to a stirred suspension of powdered potassium hydroxide (0.50 g) in ether (10 mL) and ethanethiol (2 mL). After 1 h, the mixture was neutralized with acetic acid, the solvents evaporated, and the residue partitioned between ethyl acetate and water. Evaporation of the dried organic layer gave pale yellow crystals which were recrystallized from dichloromethane–petrol to give the sulphide **13** (0.21 g, 97%); mp 105–108°C; ^{1}Hmr (60 MHz, $CDCl_3$) δ: 1.40 (t, J = 6 Hz, 3H, CH_3), 2.65 (s, 3H, CH_3), 3.04 (q, J = 6 Hz, 2H, CH_2). *Anal.* calcd. for $C_6H_9N_3O_2S$: C 38.49, H 4.85, N 22.45, S 17.13; found: C 38.50, H 4.81, N 22.27, S 16.96.

Dimethyl-5-(3-methyl-4-nitropyrazolyl)phosphonate (14)

A solution of **7** (0.20 g) in benzene (2 mL) was added to a solution of trimethylphosphite (1 mL) in benzene (10 mL). The mixture was stirred at room temperature for 15 h. The product precipitated from the reaction mixture, and was recrystallized from methanol–ether to yield phosphonate **14** (0.21 g, 77%); mp 180–182°C; ir (KBr) ν_{max}: 1600 (C=N), 1500 (NO_2), 1220 (P=O), 1030 (P—O) cm^{-1}; ^{1}Hmr (60 MHz, DMSO-d_6) δ: 2.55 (s, 3H, CH_3) 3.8 (d, J = 12 Hz, 6H, OCH_3). *Anal.* calcd. for $C_6H_{10}N_3O_5P$: C 30.64, H 4.29, N 17.87, P 13.17; found: C 30.68, H 4.35, N 17.97, P 13.01.

3-Methyl-4-nitro-5-cyanopyrazole (15)

A solution of 1,4-dinitro-3-methylpyrazole **7** (10 g) in ethanol (120 mL) was added slowly to a stirred solution of potassium cyanide (53 g) in water (236 mL) and ethanol (743 mL). After addition was complete, stirring was continued for 5 min, and the solution then neutralized with acetic acid. Solvents were evaporated and the residue extracted with ethyl acetate. The dried extracts were evaporated to give a light yellow solid residue, which was recrystallized from toluene to yield cyano compound **15** (7.5 g, 85%); mp 176–179°C (lit. (15) mp 180–181°C); ir ν_{max}: 2260 (C≡N) cm^{-1}.

3-(2,3,5-Tri-O-acetyl-β-D-ribofuranosyl)-4-nitropyrazole (16)

A solution of triol **6** (2.0 g) in pyridine (100 mL) and acetic anhydride (50 mL) was left to stand for 15 h. Solvents were removed under vacuum, and the residue stirred for 5 min with methanol (20 mL) containing a few drops of pyridine. Evaporation, and chromatography of the residue on silica gel, eluting with light petroleum – ethyl acetate (2:1) yielded triacetate **16** (2.85 g, 94%) as a syrup; $[\alpha]_D$ +107.7° (*c* 0.59, $CHCl_3$); ir (film) ν_{max}: 3300 (NH), 1750 (C=O), 1510 and 1375 (NO_2) cm^{-1}; ^{1}Hmr (100 MHz, $CDCl_3$) δ: 2.12 (s, 3H, $COCH_3$), 2.15 (s, 6H, $2COCH_3$), 4.2–4.5 (m, 3H, H-4′, H-5′), 5.2–5.7 (m, 3H, H-1′ – 3′), 8.21 (s, 1H, H-5). *Anal.* calcd. for $C_{14}H_{17}N_3O_9$: C 45.28, H 4.62, N 11.32; found: C 45.41, H 4.73, N 11.17.

1,4-Dinitro-3-(2,3,5-tri-O-acetyl-β-D-ribofuranosyl)pyrazole (17)

Triacetate **16** (1.0 g) was added to a mixture of cupric nitrate trihydrate (3.0 g) and acetic anhydride (23 mL) which had been prestirred for 1 h. The mixture was stirred overnight, poured into water, and extracted with ethyl acetate. The washed and dried organic layer was evaporated to yield a syrup which was purified by chromatography on silica, eluting with light petroleum – ether (1:1), to yield the dinitro compound **17** (0.97 g, 87%) as a pale yellow syrup; $[\alpha]_D$ +2.5° (*c* 0.8, $CHCl_3$); ir (film) ν_{max}: 1750 (C=O), 1660 and 1280 (N—NO_2), 1520 and 1370 (C—NO_2) cm^{-1}; ^{1}Hmr (100 MHz, $CDCl_3$) δ: 2.11, 2.12, 2.13 (3s, 9H, $COCH_3$), 4.1–4.6 (m, 3H, H-4′, H-5′), 5.3–5.8 (m, 3H, H-1′, H-2′, H-3′), 9.11 (s, 1H, H-5). *Anal.* calcd. for $C_{14}H_{16}N_4O_{11}$: C 40.39, H 3.87, N 13.46; found: C 40.35, H 3.76, N 13.25.

3(5)-Cyano-4-nitro-5(3)-(2,3,5-tri-O-acetyl-β-D-ribofuranosyl)-pyrazole (19)

A solution of dinitro compound **17** (3.40 g) in ethanol (35 mL) and ethyl acetate (35 mL) was added dropwise over 5 min to a stirred solution of potassium cyanide (5.0 g) in water (25 mL) and ethanol (100 mL). After a further 5 min, the mixture was neutralized with acetic acid and diluted with ethyl acetate (500 mL) and water (200 mL). The layers were separated, and the aqueous phase extracted once with more ethyl acetate. The dried organic layers were evaporated to yield a syrup, which crystallized on adding benzene. This material was recrystallized from benzene–petrol. The mother liquors from the crystallization were chromatographed on silica gel, eluting with benzene–acetone (9:1), and the residue after evaporation of product-containing fractions was crystallized from benzene–petrol. The nitrile **19** was obtained in a combined yield of 3.16 g, 89%, as a crystalline benzene solvate; mp 101–110°C (with loss of benzene); $[\alpha]_D$ + 141.0° (*c* 0.59, $CHCl_3$); ir (KBr) ν_{max}: 3300 (N—H), 2250 (C≡N), 1760, 1740 (C=O), 1580 (C=N), 1510 and 1365 (C—NO_2) cm^{-1}; ^{1}Hmr (100 MHz, $CDCl_3$) δ: 2.10, 2.14, 2.18 (each s, 3H, $COCH_3$), 4.1–4.7 (m, 3H, H-4′, H-5′), 5.18 (t, J = 6 Hz, 1H, H-3′), 5.44 (t, J = 5 Hz, 1H, H-2′), 5.66 (d, J = 5 Hz, 1H, H-1′), 7.34 (s, 3H, 0.5 C_6H_6). *Anal.* calcd. for $C_{15}H_{16}N_4O_9 \cdot 0.5C_6H_6$: C 49.65, H 4.40, N 12.87; found: C 50.20, H 4.26, N 12.88.

3(5)-Cyano-4-amino-5(3)-(2,3,5-tri-O-acetyl-β-D-ribofuranosyl)-pyrazole 20

A solution of **19** (0.55 g, as benzene solvate) in ethanol (30 mL) was hydrogenated overnight using 5% palladium on charcoal

For personal use only.

(0.1 g) as catalyst. The mixture was filtered through Celite, which was washed well with ethyl acetate. The residue after evaporation was chromatographed on silica, eluting with benzene–acetone (9:1) to yield the amino compound **20** (0.39 g, 84%) as a syrup; $[\alpha]_D$ −4.8° (*c* 0.42, $CHCl_3$); ir (film) ν_{max}: 3400–3200 (NH), 2230 (CN), 1750 (C=O) cm^{-1}; ^{1}Hmr (100 MHz, $(CD_3)_2CO$) δ: 1.98, 2.00, 2.04 (each s, 3H, $COCH_3$), 4.1–4.6 (m, 4H), 4.8–5.5 (m, 2H). *Exact Mass* calcd. for $C_{15}H_{18}N_4O_7$: 366.1175; found (ms): 366.1159.

2′,3′,5′-Tri-O-acetyl Formycin (21)

A solution of aminonitrile **20** (0.10 g) and formamidine acetate (0.085 g) in ethoxyethanol (2 mL) was heated under reflux for 20 min, when tlc indicated complete reaction. The solvent was removed under vacuum, and the residue chromatographed on silica gel, eluting with benzene–acetone (1:1) to yield formycin triacetate **21** (0.083 g, 77%) as a foam; $[\alpha]_D$ −36.2° (*c* 0.75, acetone); uv (MeOH) λ_{max}: 293.4, 229.6, 206.4 nm; ir (KBr) ν_{max}: 3500–3300 (NH), 1750 (C=O) cm^{-1}; ^{1}Hmr (100 MHz, $(CD_3)_2CO$) δ: 1.94 (s, 6H, $COCH_3$), 2.02 (s, 3H, $COCH_3$), 4.0–4.6 (m, 3H, H-4′, H-5′), 5.26 (d, J = 5 Hz, 1H, H-1′), 5.56 (t, J = 5 Hz, 1H, H-3′), 5.86 (t, J = 5 Hz, 1H, H-2′), 6.4–7.0 (b, 2H, exchangeable, NH_2), 8.08 (s, 1H, H-2). *Anal.* calcd. for $C_{16}H_{19}N_5O_7$: C 48.85, H 4.87, N 17.81; found: C 49.00, H 5.04, N 17.41.

Formycin (1)

A solution of sodium methoxide (5.6 mL of 0.1 *M* solution) was added to formycin triacetate **21** (0.18 g). After 1 h, the mixture was neutralized with acetic acid and evaporated. The residue, dissolved in water, was applied to a column of Dowex 50-X8 (H+ form). This was washed with water and the product was then eluted with dilute ammonia. The product fractions were evaporated and the residue dissolved in water. Some water was evaporated under vacuum and the solution set aside overnight, when the product crystallized. Formycin (**1**) (0.11 g, 90%) was obtained as its monohydrate; mp 148–153°C (lit. (5) mp 148–150°C); mixture mp with authentic material 149–154°C; $[\alpha]_D$ −41.2° (*c* 0.95, 0.1 *M* HCl) (lit. (5), $[\alpha]_D$ −40.0° (*c* 1, 0.1 *M* HCl)); ms (70 eV) *m/e*: 267 (M^+), 164 (heterocycle + 30). The ir and uv spectra of the synthetic material were superimposable on those of authentic material.

Acknowledgements

We thank Professor J. C. Gilbert (Department of Pharmacy, Heriot-Watt University) for a gift of authentic formycin, and the Science Research Council for a studentship (to A.S.).

An investigation of the Kishner elimination as a route to dideoxy sugars

L. KIRTHI G. WICKREMESINGHE AND KEITH N. SLESSOR

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received May 30, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

L. KIRTHI G. WICKREMESINGHE and KEITH N. SLESSOR. Can. J. Chem. **58**, 2628 (1980).

Methyl 4,6-*O*-benzylidene-2-*O*-*p*-toluenesulphonyl-α-D-*ribo*hexopyranosid-3-ulose has been used as a substrate for an investigation of the Kishner elimination as a route to deoxygenated sugars. The conditions of the reaction of the ketotosylate with hydrazine have a large effect on the outcome of the reaction and the products produced. Conditions have been investigated which provide methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**), methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*hexopyranoside (**3**), methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*hexopyranoside (**2**), and methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*hexopyranosid-3-ulose (**8**) in good to moderate yields.

L. KIRTHI G. WICKREMESINGHE et KEITH N. SLESSOR. Can. J. Chem. **58**, 2628 (1980).

On a utilisé le *O*-benzylidène-4,6 *O*-*p*-toluènesulphonyl-2 α-D-*ribo*hexopyrannoside-ulose-3 de méthyle comme substrat pour étudier la réaction de Kishner comme voie d'accès aux sucres désoxygénés. Les conditions de la réaction du cétotosylate avec l'hydrazine influencent grandement le résultat de la réaction et les produits obtenus. On a mis au point des conditions qui conduisent au *O*-benzylidène-4,6 α-D-*érythro*hexéno-2 pyrannoside de méthyle (**4**), au *O*-benzylidène-4,6 didéoxy-2,3 α-D-*érythro*hexopyrannoside de méthyle (**3**), au *O*-benzylidène-4,6 déoxy-3 α-D-*ribo*hexopyrannoside de méthyle (**2**) et au *O*-benzylidène-4,6 déoxy-2 α-D-*érythro*hexopyrannoside ulose-3 (**8**) avec des rendements variables.

Introduction

A major feature of the utilization of carbohydrates as chiral precursors to chiral insect pheromones (1) is the removal of several hydroxyl groups in a mild and efficient manner. A method, which could remove two vicinal oxygen functionalities simultaneously, seemed advantageous and thus we chose to investigate the Kishner elimination (2). Leonard and Gelfand (3) had studied the scope of the Kishner reaction and observed that elimination varied with the ability of the α-substituent to assume anionic character. Investigations by Wharton *et al.* (4, 5) indicated the elimination proceeded through an alkenyldiazene and the principal product was an alkene (Fig. 1).

Our choice of substrate for this investigation was methyl 4,6-*O*-benzylidene-2-*O*-toluenesulphonyl-α-D-*ribo*hexopyranosid-3-ulose (**1**) since the sulphonate at position 2 is a good leaving group adjacent to the keto function. The availability of expected products and ease of identification of other species involved favored the choice of this substrate and simplified the undertaking of a thorough study.

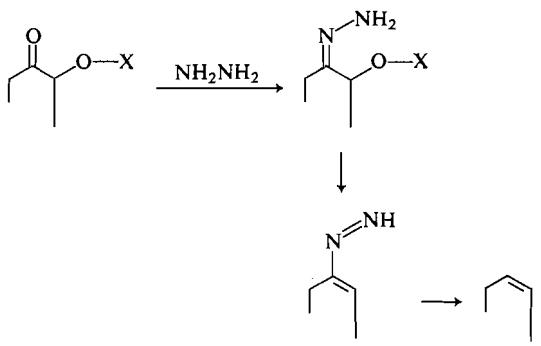

FIG. 1. Mechanism of the Kishner elimination.

Results and Discussion

Treatment of methyl 4,6-*O*-benzylidene-2-*O*-toluenesulphonyl-α-D-*ribo*hexopyranosid-3-ulose (**1**) with hydrazine under reflux conditions for 48 h, gave 3-deoxy-D-*ribo* (**2**)- and 2,3-dideoxy-D-*erythro* (**3**)-hexopyranosides which were isolated in 5% and 50% yields, respectively. When this reaction was carried out under nitrogen,the unsaturated 2-ene (**4**) was produced in place of dideoxy (**3**). If the latter reaction was further refluxed open to the atmosphere for 24 h, the complete conversion of ene (**4**) to dideoxy (**3**) was observed as indicated by tlc. It is likely, therefore, that dideoxy (**3**) is produced by reduction of ene (**4**) with diimide generated *in situ*. Aerial oxidation of hydrazine produces diimide which has a pronounced tendency to transfer hydrogen to nonpolar multiple bonds (6, 7). The major product under these conditions, a 3-deoxy-D-*ribo* sugar (**2**), can be thought to arise from nucleophilic addition of water to the intermediate alkenyldiazene. The susceptibility of alkenyldiazenes to nucleophilic attack has been previously suggested to account for the variation in the yield of alkene in the Kishner elimination (5). The increase

in yield of this 3-deoxy *ribo* sugar, when the reaction was carried out in hydrazine hydrate, supports this hypothesis.

Two aspects of this nucleophilic attack are worthy of consideration. Of the two modes of addition, 1,2 seems favored since an α-hydroxy hydrazone which must tautomerize to the diazene, a relatively difficult process, is considered to be the rate determining step in the Wolff–Kishner reduction (8). In support of this, the rate of formation of 3-deoxy *ribo* (**2**) from the 2-*O*-*p*-toluenesulphonate (**1**) was much faster than from the 2-hydroxyl (**5**) (Fig. 2). However, when ethanol was used as solvent, hydrolysis gave **5** in 40% yield, a product which may well have arisen via an intermediate produced by 1,4-addition. The formation of the *ribo* isomer (**2**) necessitates the stereoselective α-attack but reasons for this are unclear. Nucleophilic 1,4-additions to a similar system, methyl 4,6-*O*-benzylidene-2,3-dideoxy-3-phenylazo-D-*erythro*hex-2-enopyranoside, have been shown to result in only one isomer (9), the stereochemistry of which is dependent on the nature of the nucleophile.

Treatment of α-keto tosylate (**1**) with hydrazine at room temperature or with hydrazine in ethanol under reflux gave neither the 3-deoxy sugar (**2**) nor

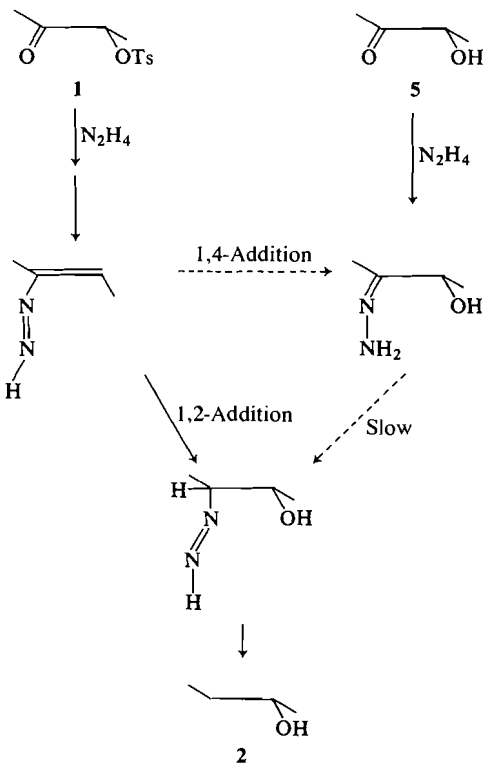

FIG. 2.

the dideoxy sugar (**3**). These observations indicate that high temperature and a large excess of hydrazine are necessary requirements for the formation of these materials. The reaction of **1** with hydrazine in ethanol at room temperature was characterized by the formation of crystalline transient material which on isolation gave results consistent with a carbinol hydrazine. Hydrolysis of this moderately stable substance **9** either during tlc or directly with ethanol led predominantly to the parent compound **1**. No C=O or C=N were apparent in the ir but strong broad NH and/or OH were present. Collins and Overend (10) have reported a similar addition compound of hydroxylamine with a pyranosid-2-ulose. These types of addition compounds are intermediates in Schiff base formation and under acidic conditions addition is rate-determining, whereas under neutral or basic conditions dehydration becomes rate controlling (11).

With the disappearance of the supposed carbinol hydrazine **9** two new products appear. Methyl 2-*O*-*p*-toluenesulphonyl-α-D-allopyranoside (**6**) is presumably formed by diimide reduction of the 3-keto (**1**) by preferred equatorial attack. The second product, an azine (**7**), was characterized by its elemental composition and spectral data. A mass spectrum indicated a dimeric structure due to its molecular peak at *m/e* 524. An infrared spectrum indicated the C=N stretch at 1630 cm^{-1} with no NH or OH absorption. This compound exhibited unusual solubility properties, being sparingly soluble in chloroform and recrystallizable from dimethylsulfoxide. A chloroform solution decomposed to give methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*hexopyranosid-3-ulose (**8**). Since the immediate precursor of the azine **7** would be its hydrazone, at a low hydrazine concentration hydrazone/azine equilibrium should be favoured towards the azine. In fact, the yield of azine was doubled when the concentration of hydrazine was reduced from ten equivalents to five equivalents. Attempts to isolate pure hydrazone resulted in a mixture which was approximately 60% *syn* hydrazone. Recrystallization resulted in formation of azine **7**. Hydrolysis of the anticipated hydrazone resulted in two routes for the formation of 2 deoxy *erythro* 3-ulose (**8**). From the combined studies a reaction pathway for keto tosylate (**1**) reactions with hydrazine is outlined in Fig. 3. As is clear from the scheme, several of the intermediates were not isolated, in some cases due to the difficulties in purification, others such as the diazenes due to their instability.

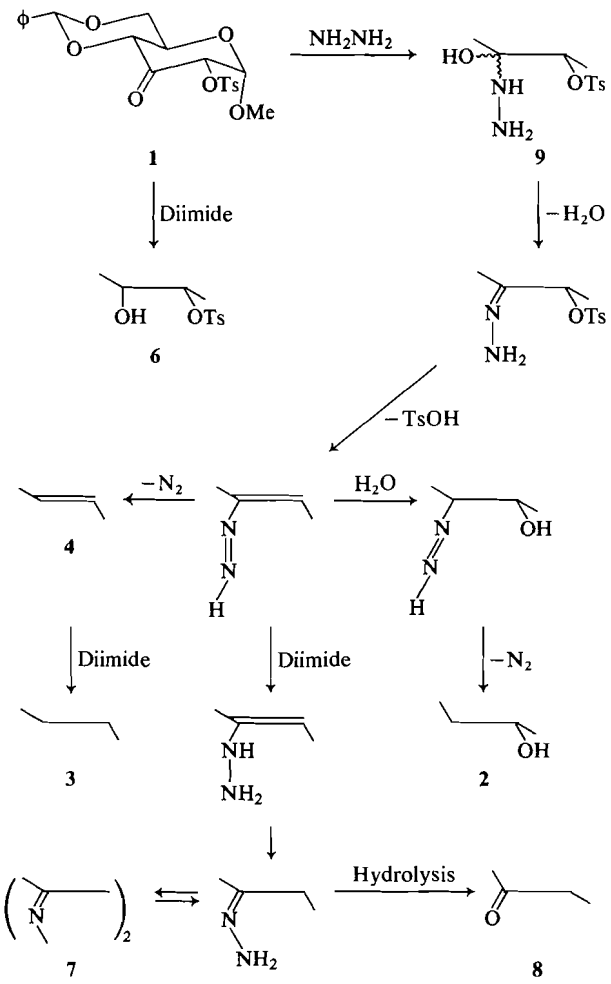

FIG. 3. Proposed routes to products.

Although the Kishner elimination did not provide high yields of dideoxygenated products, i.e., **3** and **4**, this study clearly shows the variety of compounds that can be produced in moderate yield by a small change in experimental conditions. This work provides an alternate explanation to the reported di-Wolff–Kishner reduction of D-galactose (12). An alkenyl diazene produced from D-galactose hydrazone could undergo (*i*) fragmentation, (*ii*) fragmentation–diimide reduction, (*iii*) 1,2-addition of water/fragmentation, illustrating the formation of all three observed products (Fig. 4).

Experimental

Evaporations were conducted on a Büchi rotary evaporator at bath temperatures not exceeding 50°C. Melting points were determined on a Fisher-Johns apparatus and are uncorrected. Optical rotations were measured on a Perkin-Elmer Model P22 spectropolarimeter. The ^{1}H nmr spectra were recorded on a Varian A-56/60A or XL-100. All chemical shift values are given in ppm downfield from internal TMS ($\delta = 0$); coupling constants (J) are given in Hz. Mass spectra were recorded by Mr. G. Owen on a Hitachi-Perkin-Elmer RMU-6E spectrometer using an ionization potential of 80 eV. Infrared spectra were recorded on a Perkin-Elmer 457 grating spectrophotometer. Silica gel G, E. Merck type 60, was used for tlc; toluene – diethyl ether, 1:1, was used as the solvent system. Detection of sugars was accomplished by spraying with sulphuric acid (10%) and heating the plate. Microanalyses were performed by Mr. M. K. Yang. Hydrazine (97%) was obtained from Matheson Coleman and Bell, OH, and kept over Linde molecular sieve Type 4A. Hydrazine hydrate was obtained from Fisher Scientific. Commercial ethanol (95%) was distilled over potassium hydroxide and then kept over Linde molecular sieve Type 4A. The authentic samples of the 3-deoxy sugar (**2**), the dideoxy sugar (**3**), the ene (**4**), and the 2-deoxy ketose (**8**) were prepared by Dr. A. S. Tracey.

Methyl 4,6-O-Benzylidene-2-O-p-toluenesulphonyl-α-D-ribohexopyranosid-3-ulose (1)

Prepared from methyl 4,6-*O*-benzylidene-2-*O*-*p*-toluenesulphonyl-α-D-glucopyranoside (13) by oxidation with dimethyl sulfoxide and phosphorus pentoxide in dimethyl formamide as described by Onodera *et al.* (14); mp 163–164°C, $[\alpha]_D^{25}$ +41° (*c* 0.25, $CHCl_3$) (lit. (15) mp 162–164°C, $[\alpha]_D^{28}$ +44° (*c* 1, $CHCl_3$)).

Reactions of Methyl 4,6-O-Benzylidene-2-O-p-toluenesulphonyl-α-D-ribohexopyranosid-3-ulose (1) with Hydrazine

(a) *Hydrazine in the Presence of Oxygen*

The α-keto tosylate (**1**) (500 mg, 1.15 mmol) was added to hydrazine (10 mL) and heated under reflux open to the atmosphere. With the immediate dissolution of the starting material, the reaction mixture turned greenish-yellow. After 5 min, tlc revealed the complete absence of the starting material and the presence of a new component having R_f 0.28 in addition to the compound(s) at the origin; after 1/2 h, a second component (R_f 0.72) was detected and the greenish-yellow colouration faded during this period. The reaction mixture was maintained at reflux temperature for 2 days, after which an absence of compound(s) at the origin was indicated by tlc. The reaction mixture was allowed to cool, poured into ice-cold water (125 mL) and extracted with chloroform (25 mL × 3). The organic layer was washed with water (25 mL) and evaporated. The residue was partitioned between 75% aqueous methanol – petroleum ether (bp 30–60°C); the petroleum ether layer was washed with 75% aqueous methanol (25 mL), dried over sodium sulphate, filtered, and evaporated to yield the component having R_f 0.28, which was crystallized from hexane (25 mg, 5%). The aqueous methanol layer was mixed with water (100 mL) and then extracted with chloroform (25 mL × 3). The combined chloroform extracts were dried over sodium sulphate, filtered, and evaporated to yield the component having R_f 0.72, which was crystallized from 2-propanol (150 mg, 50%).

The component having R_f 0.28 was identified as methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*hexopyranoside (**2**); mp 185–186°C (a mixture mp with an authentic sample was undepressed), $[\alpha]_D^{25}$ +125° (*c* 0.28, $CHCl_3$) (lit. (16) mp 186°C, $[\alpha]_D^{24}$ +126° (*c* 1, $CHCl_3$)). The ir, nmr, and mass spectra were identical with an authentic sample.

The component having R_f 0.72 was identified as methyl 4,6-*O*-benzylidene-2,3-dideoxy-α-D-*erythro*hexopyranoside (**3**); mp 82–83°C (a mixture mp with an authentic sample was undepressed), $[\alpha]_D^{25}$ +120° (*c* 0.24, $CHCl_3$) (lit. (17) mp 82–84°C, $[\alpha]_D^{21}$ +118° (*c* 1, $CHCl_3$)). The ir, nmr, and ms were identical with an authentic sample.

When the refluxing was discontinued after 1/2 h and the reac-

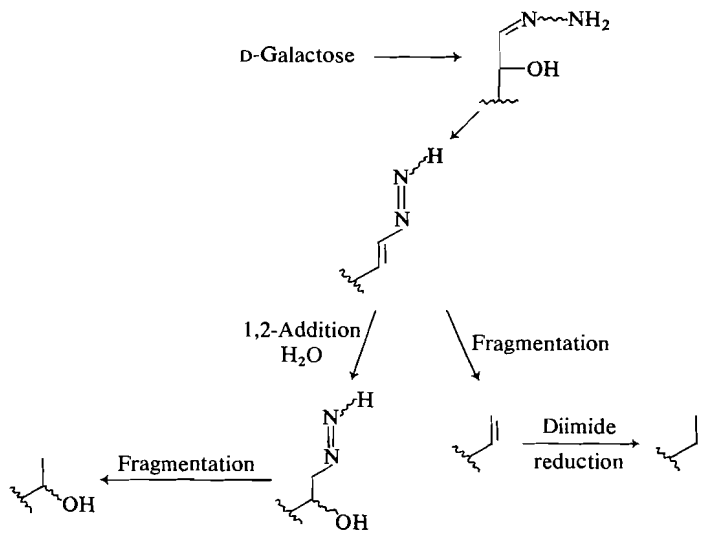

FIG. 4. Possible reaction pathways in the hydrazine reaction of D-galactose (12).

tion mixture was worked up as indicated above, a crude product mixture (300 mg) was obtained. Crystallization using 2-propanol afforded the 3-deoxy sugar (**2**) (90 mg, 30%). Two unidentified components (R_f 0.03, 0.05) and a trace amount of the ene (**4**) were present in the mother liquor (tlc).

(b) *Hydrazine under Nitrogen*

The α-keto tosylate (**1**) (500 mg, 1.15 mmol) was heated at reflux temperature in hydrazine (10 mL) under nitrogen. As in the previous reaction, the progress of the reaction was monitored by tlc, which indicated the appearance of the 3-deoxy sugar (**2**) (R_f 0.28) after 5 min and a new component (R_f 0.76) after 1/2 h. The reaction mixture was refluxed under nitrogen for 2 days and was worked up as in the previous experiment. The presence of a trace of the dideoxy sugar (**3**) (R_f 0.72) was detected by tlc. The 3-deoxy sugar (**2**) was isolated in 53% (165 mg) yield; a mixture mp with an authentic sample was undepressed.

The component having R_f 0.76 was recrystallized from methanol (30 mg, 6%) and was identified as methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**); mp 118–120°C (a mixture mp with an authentic sample was undepressed), $[\alpha]_D^{25}$ +138° (*c* 0.28, $CHCl_3$) (lit. (18) mp 119–120°C, $[\alpha]_D^{22}$ +130° (*c* 0.54, $CHCl_3$)). The ir, nmr, and ms were identical with an authentic sample.

When the reaction (*b*) was repeated with the exception that, after 2 days, the reaction mixture was refluxed in open atmosphere for 24 h, the final product distribution was the same as in (*a*) (tlc).

(c) *Hydrazine Hydrate*

The α-keto tosylate (**1**) (2.5 g, 5.75 mmol) was heated under reflux in hydrazine hydrate (50 mL). Slow dissolution of the starting material gave a light yellow solution after 15 min. The presence of **2** and the complete absence of the starting material were shown by tlc. The reaction mixture was maintained at reflux open to the atmosphere for 48 h and was worked up as in (*a*) to yield the 3-deoxy sugar (**2**) (1.05 g, 70%) and the dideoxy sugar (**3**) (75 mg, 3%). A trace of methyl 4,6-*O*-benzylidene-2-deoxy-*arabino*pyranoside was detected by tlc (R_f 0.32).

(d) *Hydrazine in Ethanol*

The α-keto tosylate (**1**) (500 mg, 1.15 mmol) in ethanol (25 mL) containing hydrazine (368.6 mg, 11.5 mmol) was stirred at room temperature. Dissolution of the sparingly soluble starting material was followed by the appearance of a milky white residue. This residue became thick during the first 1/2 h and then redissolved (~1 h) to give a colourless solution. The presence of a new component (**6**) having R_f 0.55 in addition to the starting material (R_f 0.66) was shown by tlc. After 3.5 h, the presence of starting material could not be detected by tlc; after 1.5 days, the formation of a white residue was observed. This white residue was filtered after 4 days and was recrystallized from dimethyl sulfoxide to give the azine (**7**) (100 mg, 33%). The filtrate was mixed with water (50 mL) and extracted with petroleum ether (30–60°C). The organic fraction was refrigerated to give a white residue (**6**) which was recrystallized from ethanol to yield methyl 4,6-*O*-benzylidene-2-*O*-*p*-toluenesulphonyl-α-D-*allo*pyranoside (**6**) (50 mg, 10%); mp 164°C, $[\alpha]_D^{25}$ +32° (*c* 0.21, $CHCl_3$) (lit. (19) mp 166–167°C, $[\alpha]_D^{25}$ +36°). Infrared, nmr, and ms were consistent with this assignment.

Compound **7** showed no mobility on tlc and was sparingly soluble in chloroform to give solutions which turned yellow, indicating decomposition. Thin-layer chromatography of a chloroform solution indicated that the major decomposition product was methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**8**) (R_f 0.37). Compound **7** was identified as methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*hexopyranosid-3-uloazine; mp >180°C (dec.), $[\alpha]_D^{25}$ +68° (*c* 0.074, DMSO); ir (KBr): 2900 (CH), 1630 (C=N), 700 and 750 (phenyl) cm^{-1}; nmr (DMSO-d_6) δ: 2.3 (dd, 1H, H-2_a, J_{2a-2e} = 16, $J_{1,2}$ = 4.5 Hz), 3.2 (d, 1H, H-2_e), 3.22 (s, 3H, OMe), 3.84 (d, 2H, H-6,6'), 4.2–4.5 (m, 2H, H-4,5), 5.0 (d, 1H, H-1), 5.8 (s, 1H, benzylidene H), 7.4 (s broad, 5H, phenyl); ms (240°C) *m/e*: 525 (M + 1, 1.1), 524 (M, 2.1), 494 (1.9), 493 (4.8), 492 (M − MeOH, 6.1), 462 (3.3), 461 (12.7), 460 (M − 2MeOH, 26.7), 149 (Ph—CH=O=CH_2CHO, 13.9), 107 (33.7), 106 (84.2), 105 (100); *Anal.* calcd. for $C_{28}H_{32}N_2O_8$: C 64.12, H 6.10, H 5.34%; found: C 63.89, H 6.19, N 5.21%.

When the above reaction was repeated with five equivalents of hydrazine (184.3 mg, 5.75 mmol), the azine **7** was obtained in 60% yield. Methyl 4,6-*O*-benzylidene-2-*O*-*p*-toluenesulphonyl-α-D-allopyranoside (**6**) and methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**) were present in trace amounts (tlc).

The α-keto tosylate (**1**) (2.5 g, 5.75 mmol) in ethanol (125 mL) containing hydrazine (461 mg, 14.5 mmol) was stirred at room temperature. Slow dissolution of the starting material gave a colourless solution which assumed a faint yellow colour. After

3 h, tlc indicated the appearance of the ene (**4**) (R_f 0.76). After 24 h, the reaction mixture was worked up by adding water (300 mL) and extracting with petroleum ether (bp 30–60°C) (75 mL × 4). The organic fraction was dried over sodium sulphate, filtered, and evaporated. Recrystallization of the crude product with methanol yielded methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**) (600 mg, 40%).

Isolation of the milky white residue observed at the beginning of the ethanolic hydrazine reactions could be achieved by filtration of the reaction mixture to yield small amounts (~10% yield) of **9**. Chromatographic (tlc) behaviour of the compound **9** was similar to the starting material **1** (R_f 0.66). Melting point 110°C (dec.); ir (KBr): 3350 (broad, NH, OH), 2900 (CH), 1350 and 1170 (sulfonate) cm^{-1}; nmr ($CDCl_3$) δ: 2.3 and 2.45 (two broad singlets 1:2, Me-φ), 3.3 and 3.37 (two singlets 1:2, OMe), 3.4–4.2 (~10 H), 5.52 (s, 1H, benzylidene H), 7.0–8.0 (m, ~9H). *Anal.* calcd. for $C_{21}H_{26}N_2O_8S$: C 54.07, H 5.58, N 6.0%; found: C 54.76, H 5.72, N 5.79%.

When the compound **9** (20 mg, 0.064 mmol) was stirred in ethanol (1.5 mL) a clear yellowish solution was formed which, in turn, gave a white residue corresponding to the starting material **1** (tlc). The presence of a trace of methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**) (R_f 0.76) was indicated by tlc.

*Reaction of Methyl 4,6-*O*-benzylidene-α-D-*ribo*hexopyranosid-3-ulose (5) with Hydrazine at Reflux*

The α-hydroxy-keto sugar (**5**) (325 mg, 1.15 mmol) was treated with hydrazine (10 mL) under reflux. Immediate dissolution of the starting material was observed. After 15 min, the absence of starting material was shown by tlc. The reaction mixture was maintained at reflux for 48 h and was worked up as usual to obtain the 3-deoxy sugar (**2**) (40%) and the dideoxy sugar (**3**) (5%).

When the above reaction was worked up after refluxing for 1/2 h a crude product mixture (150 mg) was obtained. Analysis (tlc) of this mixture revealed the presence of a trace of the 3-deoxy sugar (**2**) and two unidentified components (R_f 0.03, 0.05).

*Methyl 4,6-*O*-Benzylidene-2-deoxy-*α*-D-*erythro*hexopyranosid-3-ulose (8)*

(a) The α-keto tosylate (**1**) (2.5 g, 5.75 mmol) in ethanol (100 mL) containing hydrazine (1.85 g, 57.5 mmol) was stirred at room temperature. After 12 h, an aqueous solution of copper(II)sulphate pentahydrate (14 g in 50 mL) was added. Immediate evolution of a gas and formation of a greenish residue were observed. The presence of one major component (R_f 0.37) was indicated by tlc. After stirring for 6 h, the reaction mixture was filtered and washed with ethanol (25 mL). The filtrate was mixed with water (300 mL) and extracted with chloroform (75 mL × 3). The organic fraction was washed with water (100 mL), dried over sodium sulphate, filtered, and evaporated. This residue contained traces of the *allo*-tosylate (**6**) (R_f 0.55) and methyl 4,6-*O*-benzylidene-α-D-*ribo*hexopyranosid-3-ulose (**5**) (R_f 0.20) in addition to the 2-deoxy ketose (**8**). The residue was recrystallized from 2-propanol to yield methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*hexopyranosid-3-ulose (**8**) (750 mg, 50%); mp 170–171°C (a mixture mp with an authentic sample was undepressed), $[\alpha]_D^{25}$ +160° (*c* 0.25, ethyl acetate) (lit. (20) mp 170–171°C, $[\alpha]_D^{20}$ +153° (*c* 0.5, ethyl acetate)).

(b) The α-keto tosylate (**1**) (500 mg, 1.15 mmol) in ethanol (25 mL) containing hydrazine (368.6 mg, 11.5 mmol) was stirred at room temperature. After 12 h, benzaldehyde (5.0 mL) and acetic acid (0.5 mL) were added. The reaction mixture was stirred (2 h) until there was no apparent increase of the 2-deoxy ketose (**8**) as indicated by tlc. The reaction mixture was mixed with water (100 mL) and extracted with chloroform (25 mL × 3). The organic fraction was washed with water (25 mL), dried over sodium sulphate, and evaporated to a syrup. This was chromatographed on silica (petroleum ether bp 30–60°C/ether 20:1) to yield methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*-hexopyranosid-3-ulose (**8**) (90 mg, 30%).

*Methyl 4,6-*O*-Benzylidene-α-D-ribo*hexopyranosid-3-ulose (5)*

The α-keto tosylate (**1**) (500 mg, 1.15 mmol) in degassed ethanol (25 mL) containing hydrazine (368.6 mg, 11.5 mmol) was stirred under nitrogen. After 12 h, an aqueous solution of copper(II)sulphate pentahydrate (2.9 g in 10 mL) was added. The reaction mixture was worked up as usual after stirring for 6 h. The crude product mixture indicated the presence of a major component (**5**) (R_f 0.20 tlc) and two minor components, methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*erythro*hexopyranosid-3-ulose (**8**) (R_f 0.37) and methyl 4,6-*O*-benzylidene-α-D-*erythro*hex-2-enopyranoside (**4**) (R_f 0.76). Recrystallization of the crude product mixture from toluene yielded methyl 4,6-*O*-benzylidene-α-D-*ribo*hexopyranosid-3-ulose (130 mg, 40%); mp 194°C (a mixture mp with an authentic sample was undepressed), $[\alpha]_D^{25}$ +120° (*c* 0.20, pyridine) (lit. (21) mp 190–192°C, $[\alpha]_D^{23}$ +113° (*c* 1, pyridine)).

Effects of organic solvents on immobilized enzyme catalyses.[1] Chymotrypsin immobilized on Sephadex

DIANA H. PLIURA AND J. BRYAN JONES

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 5, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

DIANA H. PLIURA and J. BRYAN JONES. Can. J. Chem. **58**, 2633 (1980).

The esterolytic activities of native chymotrypsin (CT) and immobilized CT-Sephadex have been studied in the presence of up to 20% of the organic solvents methanol, ethanol, 2-propanol, *tert*-butyl alcohol, dioxane, or DMSO. The general cosolvent-induced inhibition of the native enzyme was attenuated for immobilized CT. Most noticeably, the apparent catalytic rate constants for the CT-Sephadex-catalyzed hydrolysis of *N*-acetyl-L-tyrosine ethyl ester were invariant over the 2–20% dioxane concentration range surveyed. In contrast, the activity of the native enzyme in 20% dioxane was only 3% the activity recorded in the absence of cosolvent. Increasing the hydrophobic character of the protic cosolvents destabilized the native enzyme but stabilized CT-Sephadex. Both native and immobilized CT displayed remarkable stability in 20% aqueous DMSO ($t_{\frac{1}{2}} > 200$ days). At least part of the DMSO-induced inhibition of native CT and CT-Sephadex was offset by increasing the apparent pH of the reaction medium. The altered kinetic patterns for CT-Sephadex are best explained by the effects of diffusional limitations on the apparent enzyme activity. The best compromise solvent for preparative applications of CT-Sephadex was found to be *tert*-butyl alcohol.

DIANA H. PLIURA et J. BRYAN JONES. Can. J. Chem. **58**, 2633 (1980).

On a étudié les activités estérolytiques de la chymotrypsine naturelle (CT) et de la CT immobilisée sur du Séphadex dans des solutions contenant jusqu'à 20% des solvants organiques suivants: le méthanol, l'éthanol, le propanol-2, l'alcool *tert*-butylique, le dioxanne ou le DMSO. L'inhibition de l'enzyme naturel généralement induite par le co-solvant est atténuée dans le cas de la CT immobilisée. De façon plus notable, la constante de vitesse catalytique apparente de l'hydrolyse catalysée par la CT-Séphadex du *N*-acétyl L-tyrosinate d'éthyle demeure inchangée dans l'échelle de concentration allant de 2 à 20% en dioxanne. Au contraire, l'activité de l'enzyme naturel dans le dioxanne à 20% représente seulement 3% de l'activité enregistrée en l'absence de co-solvant. L'augmentation du caractère hydrophobe des co-solvants protiques déstabilise l'enzyme naturel mais stabilise la CT-Séphadex. Les deux enzymes montrent une stabilité remarquable dans le DMSO aqueux à 20% ($t_{\frac{1}{2}} > 200$ jours). Une partie de l'inhibition de la CT naturelle et de la CT-Séphadex induite par le DMSO est compensée au moins par l'augmentation du pH apparent du milieu réactionnel. Les modèles du CT-Séphadex modifiés cinétiquement s'expliquent mieux par les effets de limitation de diffusion de l'activité apparente de l'enzyme. On a trouvé que l'alcool *tert*-butylique est le meilleur solvant de compromis pour les applications préparatives de la CT-Séphadex.

Introduction

The practical value of utilizing enzymes to effect specific transformations in organic synthesis is being increasingly recognized both in academic and industrial laboratories. Already enzyme uses are well documented in a broad variety of reactions (1*b*,*c*). For many current and future applications of enzymes, the addition of organic cosolvents becomes desirable in order to enhance the limited solubility of the often hydrophobic substrates in aqueous solution. Alternatively, the effects of organic solvents can be exploited to influence the equilibrium of an enzyme-catalyzed reaction. Advantage has been taken of this to induce hydrolytic enzymes to catalyze the synthesis, rather than their usual cleavage, of esters (2) and oligopeptides (3).

Unfortunately, organic cosolvents usually exert deleterious effects on catalysis by enzymes (4) and significant activities in nonaqueous media are the exception rather than the rule. However, recent reports indicate that the adverse effects of organic cosolvents can be reduced by using immobilized enzyme derivatives (5–8). Furthermore, immobilization of enzymes (9–11) extends their utility as catalysts by alleviating problems of separation, cost, and supply, and permits reactors capable of continuous operation to be built. With a view towards identifying the best cosolvents to use in preparative applications of immobilized enzymes, we have initiated a systematic investigation of the effects of common organic solvents on such catalysts. In this paper we report on the behaviour of chymotrypsin immobilized on the organic support Sephadex.

The covalent attachment of CT[2] to cyanogen bromide-activated Sephadex provides CT-Sephadex, a representative immobilized enzyme preparation. Sephadex was chosen as our first sup-

[1]Enzymes in organic synthesis 18. For Part 17, see ref. 1*a*. Abstracted from the Ph.D thesis of D.H.P., University of Toronto, 1977.

port since it is one of the best studied and documented organic polymers used so far (10). Also, the CT-Sephadex conjugate possesses high residual activity and retains both the intrinsic catalytic properties and substrate specificity of the native enzyme (12, 13). The retention of such properties was an important factor in our choice of support since, by maintaining the same intrinsic rate constants for both free and immobilized enzyme, any cosolvent-induced alterations in the kinetic patterns of the immobilized derivative can be interpreted in terms of the effects of partitioning, diffusion, and of the environment of the matrix surface (5–8). The cosolvents surveyed, methanol, ethanol, 2-propanol, *tert*-butyl alcohol, dioxane, and DMSO are representative of the water-miscible organic solvents tolerated by CT (1*b*).

Experimental

Materials

α-Chymotrypsin (EC 3.4.21.1) from bovine pancreas was obtained as a lyophilized powder from Worthington Biochemical Corp. and was used without further purification. Sephadex G-200 (grade 40-120μ) was purchased from Pharmacia Fine Chemicals and cyanogen bromide from Eastman Chemicals. *N*-acetyl-L-tyrosine ethyl ester (NATEE) was a product of Sigma Chemical Co. All other chemicals were of the highest purity available.

Preparation of CT-Sephadex

The general procedure described by Axen and Ernback (14) was followed for the covalent coupling of CT to cyanogen bromide-activated Sephadex G-200. After completion of the coupling reaction and exhaustive washing of the conjugate under conditions that ensured the removal of all adsorbed protein (14), the product was carefully shrunk by slowly washing with ice-cold water/acetone mixtures of gradually increasing acetone concentration, and finally with cold acetone. The product was dried *in vacuo* over P_2O_5 for 2 days and then stored in closed vessels at 4°C.

The protein content of the conjugate was determined by amino acid analysis of the levels of phenylalanine, leucine, alanine, glycine, and glutamic acid and using the reported amino acid composition of CT of molecular weight 25 000 (15). The CT-Sephadex conjugate had a protein content of 57.3 ± 0.5 mg CT/g dry conjugate and a specific activity towards NATEE of 110 μmol/min/mg enzyme, corresponding to 37% residual activity after immobilization.

Kinetic Studies

The activities of both soluble and immobilized enzyme were measured by the pH-stat method (16). Kinetics of NATEE hydrolysis were monitored at 25°C under N_2 in a 10 mL capacity reaction vessel. In order to minimize external diffusion effects, reaction mixtures were stirred vigorously. Solutions of native CT in 1 m*M* aqueous HCl at 0°C were prepared as required. The powdered CT-Sephadex conjugate was allowed to preswell at 4°C in distilled water for 24 h, and the pH of the aqueous immobilized enzyme suspensions was adjusted to 9.8 prior to kinetic studies.

Specific Activity

The specific activity of immobilized CT was assayed against a solution of NATEE (9 mL, 11 m*M*) in 2% (v/v) aqueous methanol, 0.1 *M* in KCl and of $pH_{(app)}$ 9.8. Samples of CT-Sephadex were introduced by adding 0.25–1.0 mL of a well-stirred aqueous suspension. The total assay volume was adjusted to 10 mL by the addition of doubly distilled water when necessary. Typically, the CT-Sephadex suspension contained 2–4 mg conjugate (dry weight)/mL.

pH–Activity Profiles

The esterolytic activities of native and immobilized CT at different pH values were assayed using a solution of NATEE (10 m*M*, 1.0 *M* in KCl), containing either 2% (v/v) methanol or 20% (v/v) organic solvent. Rates of hydrolysis expressed in μmol/min were measured from the linear portions of the titration curves. When necessary, corrections were made for nonenzymic hydrolysis at high pH.

Determination of Apparent Kinetic Parameters

The apparent rate constants for native CT and CT-Sephadex catalyzed hydrolyses of NATEE were determined at 25°C in 1.0 *M* KCl solutions containing 0–20% (v/v) organic cosolvent. For the native enzyme, the esterolytic activities were monitored at $pH_{(app)}$ 7.8 employing a substrate concentration range of 0.2–20 m*M* NATEE and enzyme concentrations of $2–10 \times 10^{-8}$ *M*. The $Km_{(app)}$ and $k_{c(app)}$ values for CT-Sephadex were determined at $pH_{(app)}$ 9.8. Typical enzyme concentrations were $4–8.4 \times 10^{-7}$ *M*. Substrate concentration ranges from 0.2–12 m*M* NATEE were employed. The rate constants were determined by standard linear regression analyses of Lineweaver–Burk plots.

Determination of Catalyst Stability

Native CT

Solutions of $pH_{(app)}$ 7.8 of chymotrypsin (1 mg enzyme/mL), 0.1 *M* in KCl, both with and without 20% (v/v) organic solvent, were stored in stoppered vessels at 20°C. Aliquots of enzyme solution (10–50 μL) were withdrawn at intervals during a 2 month incubation period and their enzymic activities assayed at 25°C using NATEE (10 m*M*) in 2% (v/v) aqueous methanol, 0.1 *M* in KCl, $pH_{(app)}$ 7.8.

Immobilized CT

Powdered CT-Sephadex was allowed to preswell in distilled water for 24 h. An aliquot was then withdrawn and organic solvent was added to a concentration of 20% (v/v). The ionic strengths of all such CT-Sephadex suspensions were adjusted to 0.1 *M* KCl and the suspensions were then stored at $pH_{(app)}$ 9.8 in closed vessels at 20°C. The activity of each was monitored periodically by withdrawing a 1 mL aliquot (containing ~3 mg of conjugate) from the well-stirred suspension and assaying at 25°C using NATEE (9 mL, 11 m*M*) in 2% (v/v) aqueous MeOH, 0.1 *M* in KCl, $pH_{(app)}$ 9.8. During the 2 month incubation period, periodic pH adjustments were made to maintain $pH_{(app)}$ at 7.8 for native enzyme and 9.8 for CT-Sephadex.

Results

Solvent Effects on Kinetic Parameters

Because electrolytes are known to modify the catalytic properties of CT (1*b*), chymotryptic catalyses are usually carried out at high concentrations of electrolyte in order to minimize complications that arise from fluctuations in ionic strength during hydrolysis. To establish the optimum electrolyte concentration for the kinetic studies, experiments were performed to evaluate the kinetic parameters of native and immobilized CT at different concentrations of KCl. When diffusion restric-

For personal use only.

tions are operating, the observed kinetic constants for an immobilized enzyme depend on the substrate concentration (17). Therefore, a fixed substrate concentration range was maintained as the KCl concentration, or the organic solvent concentration in subsequent experiments, was varied. The results are recorded in Table 1.

For native CT, the catalytic activity, as indicated by the specificity constant k_c/Km, is seen to increase monotonically with added electrolyte over the entire KCl concentration range surveyed. In contrast, the apparent catalytic activity for CT-Sephadex is independent of ionic strength at electrolyte concentrations greater than 0.01 *M* KCl. For CT-Sephadex both $k_{c(app)}$ and Km$_{(app)}$ decrease with increasing KCl concentration in the range 0.01–1.0 *M* KCl. In contrast, for native CT, k_c increases while Km decreases with increasing ionic strength. A 1.0 *M* KCl concentration was used in subsequent kinetic studies since this concentration maximized chymotryptic activity for both the native and immobilized enzyme while remaining compatible with solutions containing up to 20% of the organic cosolvents employed.[3]

The effects of organic solvents on the kinetic parameters of native CT and CT-Sephadex were found to differ significantly for the soluble and immobilized catalysts. The data are summarized in Table 2. For the native CT-catalyzed hydrolysis of specific ester substrates such as NATEE, the observed k_c is equal to the deacylation rate constant (18). Nucleophilic cosolvents, particularly methanol, reduce the hydrolytic rate by transesterification of the acyl enzyme intermediate (19), resulting in a decrease in k_c from 178 s^{-1} in the absence of methanol to 97 s^{-1} in 20% methanol. Contrary to the anticipated effects of transacylation, the low value of the $k_{c(app)}$ for CT-Sephadex increases from 12.2 s^{-1} in 4.5% methanol to 81 s^{-1} in 20% methanol (Table 2). Significantly, the nonlinear Lineweaver–Burk plots for CT-Sephadex in 2% aqueous methanol or 2% aqueous ethanol are symptomatic of immobilized enzyme reactions subject to severe diffusion limitations (17*c*, 20).

At least part of the deleterious effects of the nonnucleophilic solvents *tert*-butyl alcohol and dioxane has been attributed to competitive inhibition (21). Accordingly, over the concentration range surveyed, Km for soluble CT increases 10-fold with *tert*-butyl alcohol, or 30-fold with dioxane, while k_c remains invariant. After immobilization of the enzyme, the diminished $k_{c(app)}$ values remain constant for both solvent systems. In contrast, Km$_{(app)}$ for the immobilized enzyme is remarkably insensitive to changes in *tert*-butyl alcohol or dioxane concentrations.

[3]The 20% limit on the maximum organic solvent concentrations used in this study was dictated by the sluggishness of the pH-stat electrode response beyond this level.

TABLE 1. The effects of KCl concentration on the kinetic parameters of native CT and CT-Sephadex[a]

[a]Esterolytic activity towards NATEE in 4.5% (v/v) methanol, at 25°C and pH 7.8 for native CT and pH 9.8 for the immobilized derivative.

In general, organic solvent-mediated inhibition of CT is attenuated after immobilization of the enzyme. Compared with the esterolytic activity in aqueous solution, for which k_c/Km = 268 mM^{-1} s^{-1}, native CT retains only 12–17% activity in the presence of 20% DMSO, 2-propanol, or *tert*-butyl alcohol and only 3–7% activity at high concentrations of methanol, ethanol, or dioxane. On the other hand, $k_{c(app)}/K$m$_{(app)}$ constants for CT-Sephadex at high solvent concentrations stay in the range of 35% (for methanol, ethanol) – 70% (for *tert*-butyl alcohol, dioxane) of the values observed at low cosolvent concentrations. Nevertheless, in a given solvent medium $k_{c(app)}/K$m$_{(app)}$ for CT-Sephadex is routinely less than the catalytic activity of the soluble enzyme.

Solvent Effects on pH–Activity Profiles

The solvent effects on the pH–activity profiles of both free and immobilized CT are depicted in Fig. 1. In highly aqueous (2% MeOH) solutions, the pH optimum for the CT-Sephadex-catalyzed hydrolysis of NATEE is displaced approximately 2 pH units toward more alkaline values relative to the 7.8 pH optimum for native CT. In 20% methanolic or 20% ethanolic solutions, the activities of both soluble and immobilized CT are reduced at each pH value but there are no significant effects on the pH optima. In contrast, in 20% aqueous DMSO solution the pH–activity profiles for soluble CT and CT-Sephadex are shifted toward more alkaline pH values. The DMSO-induced inhibition of both CT catalysts can be offset by increasing the apparent pH of the reaction medium by ~0.65 pH units. Whereas a 20% aque-

[a]Apparent kinetic constants for the native and immobilized CT-catalyzed hydrolysis of NATEE in aqueous organic solvent solutions, 1.0 M in KCl at 25°C and $pH_{(app)}$ 7.8 for native enzyme or $pH_{(app)}$ 9.8 for CT-Sephadex.
[b]Nonlinear Lineweaver–Burk plots under these conditions.

ous dioxane solution eliminates the pH optima for native CT, the general shape and position of the pH–activity profile for CT-Sephadex remains unchanged in this solvent system.

Solvent Effects on CT-Stability

The stabilities of native CT and CT-Sephadex in water and in 20% organic solvent solutions were monitored at room temperature for 2 months. The half-lives observed are recorded in Table 3. In general, attachment of CT to Sephadex considerably extends the half-life of the enzyme. In the cosolvents methanol, ethanol, 2-propanol, and *tert*-butyl alcohol the half-lives of the native enzyme are 16, 9, 7, and 2.5 days respectively. In marked contrast, the half-life of CT-Sephadex increases from 30 up to 80 days as the carbon moiety of the alcohol becomes increasingly hydrophobic. Both native CT and CT-Sephadex show remarkable stability in aqueous DMSO solutions. The soluble enzyme retains half the original activity after 7 months in 20% aqueous DMSO at $pH_{(app)}$ 7.8 while CT-Sephadex has a half-life of approximately 10 months in the same solvent at $pH_{(app)}$ 9.8.

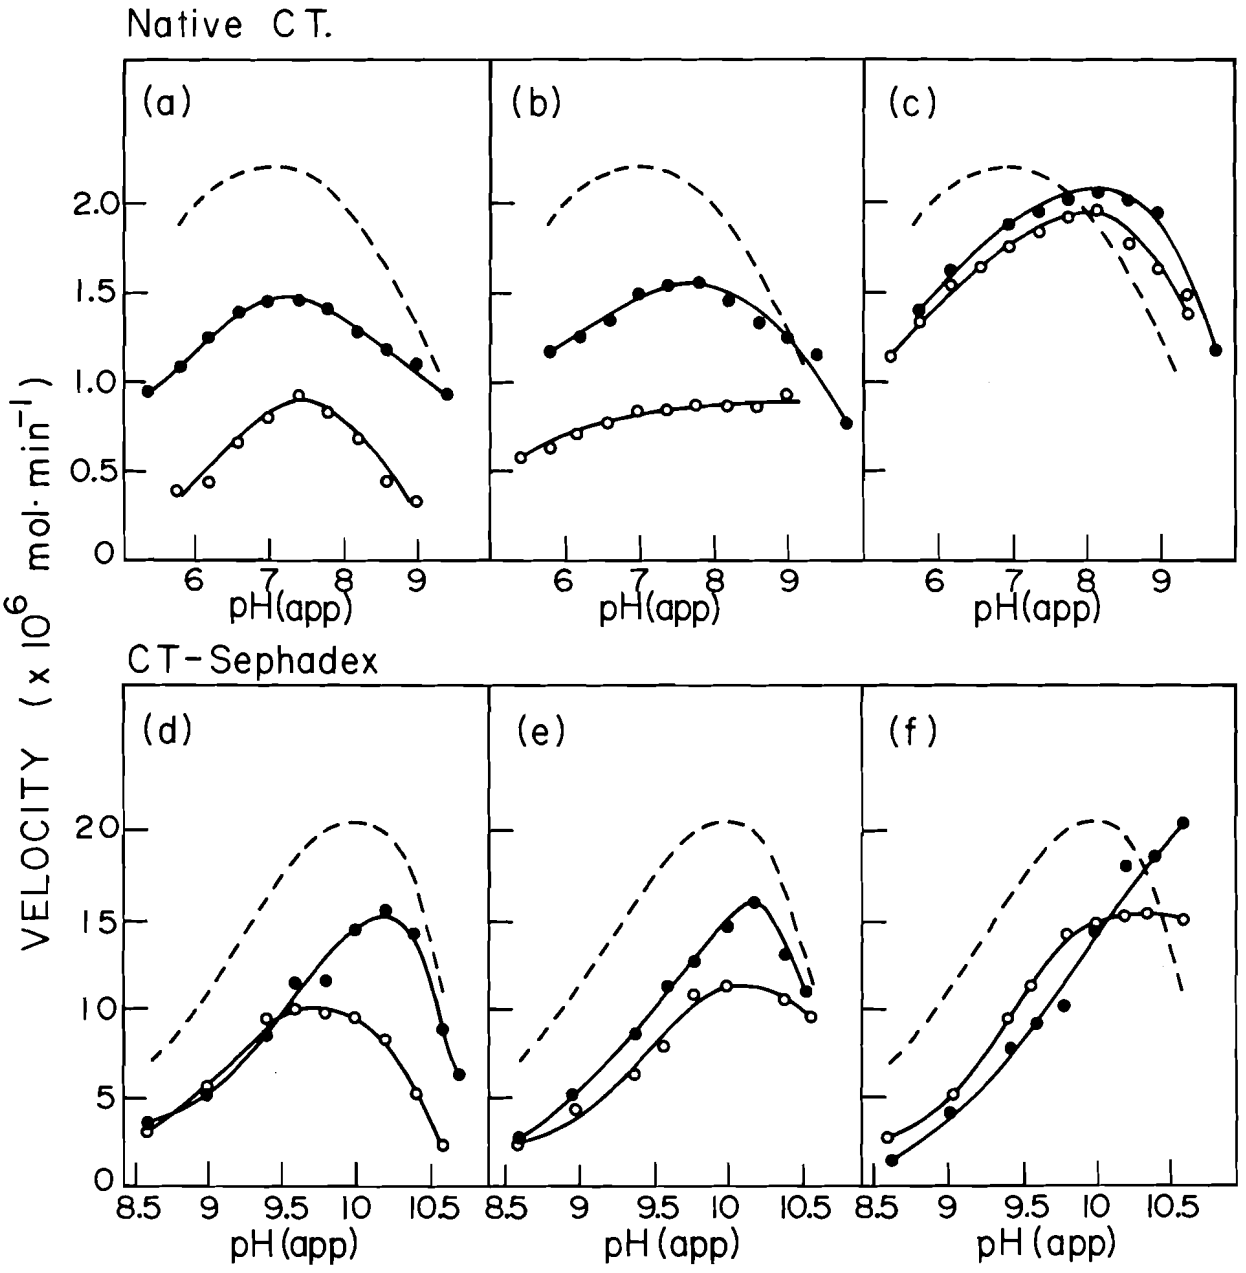

FIG. 1. The effects of 20% organic solvent on the pH–activity profiles for native CT and CT-Sephadex. Activities were assayed using solutions of NATEE (10 m*M*), 1.0 *M* in KCl, at 25°C containing 2% MeOH (----) or 20% organic solvent (——). Enzyme concentrations were 3.3×10^{-8} *M* for native CT (Fig. 1*a–c*) and 8.4×10^{-7} *M* for CT-Sephadex (Fig. 1*d–e*). (a) and (d) ○, MeOH; ●, EtOH. (b) and (e) ○, dioxane; ●, *i*-PrOH. (c) and (f) ○, *t*-BuOH; ●, DMSO.

Solvent Effects on the Configuration of CT-Sephadex

For flexible hydroxylic supports such as Sephadex G-200, changes in the porosity of the matrix can affect the accessibility of the substrate to the enzyme and thereby alter the activity of the immobilized enzyme (12, 22, 23). It was therefore necessary to determine the hydrated volume of CT-Sephadex in the various 20% organic solvent mixtures. Significant (up to 50%) reductions in volume were observed (Table 4). In general, the flexibility of the Sephadex G-200 support is reduced after cyanogen bromide activation and enzyme coupling (12). The Table 4 results support this conclusion. The hydrated volume of the CT-Sephadex conjugate is even further reduced, by 20–30%, in

alcoholic solutions but it virtually unaffected by the addition of 20% dioxane.

Discussion

Although immobilization of the enzyme as its CT-Sephadex conjugate by the cyanogen bromide technique causes no inherent alteration in the *intrinsic* catalytic parameters (12, 13), our results demonstrate that the effects of organic cosolvents on the *observed* kinetic parameters for native and immobilized CT are significantly different (Table 2). In the absence of changes in specific rate constants due directly to chemical modifications, altered kinetic patterns for immobilized enzymes have been attributed to diffusional inhibition and/or the partitioning of solute molecules (including substrates and products) due to specific interactions with the matrix (17*c*, 20).

For an immobilized enzyme the severity of diffusional restrictions is reflected in the magnitude of the effectiveness factor η (17*a*), defined as V_i/V_f where V_i is the observed rate of reaction for the immobilized enzyme and V_f would be the rate observed for the same amount of enzyme free in solution. At all cosolvent concentrations surveyed, a comparison of the extrapolated values for the k_c/Km ratio for soluble and immobilized enzyme yields first-order effectiveness factors having values of < 0.05 at low organic solvent concentration or ranging from 0.15 in 20% 2-propanol or DMSO to as high as 0.88 in 20% dioxane. In no case does η reach unity. Diffusional inhibition therefore contributes to the observed kinetic parameters for all the systems surveyed. Consequently, effects due to solvent partitioning and/or to stabilization of the enzyme by the microenvironment of the matrix cannot be readily evaluated from this kinetic investigation.

Engasser and Horvath (8) have described quantitatively the case when chemical inhibition by a substance such as an organic cosolvent that is neither substrate nor product, and diffusional inhibition act simultaneously. They found that the combined effect in decreasing the rate of reaction is smaller than the sum of the individual effects. Experimentally, Axen and co-workers (24) have demonstrated that CT-Sephadex acting under diffusional restrictions on a substrate with high turnover number was not influenced by concentrations of *N*-acetyl-D-tryptophan of up to four times the K_I for soluble enzyme. However, by using a substrate with low turnover number, and thereby minimizing diffusional inhibition, the immobilized enzyme derivative showed the same inhibition profiles as the native enzyme. For the CT-Sephadex catalyst used in the present study, the high $Km_{(app)}$ values, the alkaline shifts in pH optima, and the persistently low $k_{c(app)}/Km_{(app)}$ ratios are symptomatic of a catalyst operating under diffusional limitations (8, 17*c*). Therefore, as expected for diffusion-restricted catalysts, the inhibition of catalytic activity by organic solvents is attenuated for the immobilized enzyme. The data of Table 2 show this effect very clearly.

Insoluble polysaccharide supports such as Sephadex undergo configurational changes, due to shrinking or swelling, as the solvent medium is altered (12, 22, 23). For some of the organic solvents surveyed at least part of the observed reduction in catalytic activity for CT-Sephadex can be attributed to the shrinkage of CT-Sephadex (Table 4) and to the concomitant decrease in the accessibility of substrate to enzyme. However, this cannot be the only factor because there is no direct correlation between observed activity and support volume. For instance, the observed $k_{c(app)}/Km_{(app)}$ ratio of 11.3 mM^{-1} s^{-1} in 20% aqueous *tert*-butyl alcohol is twice the value observed in 20% aqueous methanol even though the hydrated volume of CT-Sephadex in these media is effectively the same (Table 4).

The alkaline shifts in the pH activity profiles for CT-Sephadex (Fig. 1), relative to the pH opti-

For personal use only.

mum for the native enzyme, are the result of enzymically generated pH gradients when product diffusion is restricted (17*c*, 20). Such pH gradients can be minimized by reducing the rate of hydrogen ion production and, by increasing the concentration of a suitable competitive inhibitor, the pH optimum for the esterolytic activity of CT-Sephadex can be shifted back toward pH 7.8, the pH optimum for native CT (24). For the six organic cosolvents surveyed in our study the intrinsic activity of the immobilized enzyme was not inhibited sufficiently to effect a shift of this type in the pH optimum toward more acid pH values, even at organic cosolvent concentrations as high as 20%.

The effects of organic solvents on the hydrated volume of CT-Sephadex must also be considered in evaluating solvent effects on the apparent pH optima. In 20% alcoholic solution, the hydrated volume of CT-Sephadex decreases by 20–30% (Table 4). This effective collapse of the flexible, porous support further restricts proton and product diffusion and creates a more pronounced pH gradient. Under these conditions, the attendant alkaline shift in the apparent pH optima counters any displacement of pH optima toward acidic values caused by chemical inhibition (24).

The apparent pH optima for the CT catalysts undergo an alkaline shift in 20% aqueous DMSO (Fig. 1). Similar cosolvent induced shifts in pH–activity profiles have been observed with soluble adenosine triphosphatase (25) and with immobilized acid phosphatase (26). At $pH_{(app)}$ 9.8 the esterolytic activity of CT-Sephadex in 20% DMSO is only 50–60% of that observed at low organic solvent concentration. This inhibition can be negated by increasing, by approximately 0.6 pH units, the apparent pH of the 20% DMSO solution (Fig. 1). Hence, at least part of the DMSO-induced inhibition summarized in Table 2 can be attributed to perturbations in the pK_a's of ionizable groups on the enzyme (27, 28).

The stability of an immobilized enzyme in the presence of organic cosolvents is an important property with respect to the potential utility of the immobilized enzyme. Unfortunately, the inherent stability parameters of immobilized enzymes are difficult to evaluate for catalysts operating under severe diffusional restrictions (17*c*, 20). In the limiting case, when the system is diffusion-controlled, the observed activity of the bound enzyme may remain constant, despite the fact that protein may have undergone considerable denaturation (29) or solvent-induced conformational change (30). In the present study the half-life of CT-Sephadex exceeds that of soluble CT for any given solvent mixture. However, this enhanced stability is purchased at the expense of measurable catalytic activity. In a 20% aqueous 2-propanol medium, the 9-fold increase in half-life after immobilization (Table 3) only marginally offsets the 7-fold decrease in the activity for CT-Sephadex (Table 2). In contrast, for a 20% aqueous *tert*-butyl alcohol solution, the greater than 30-fold increase in the half-life of the enzyme following immobilization more than compensates for the 3-fold decrease in k_c/Km which occurs.

For the protic solvents examined soluble CT becomes increasingly destabilized as the hydrophobic character of the solvent is increased (Table 3). However, CT-Sephadex is more stable in 20% *tert*-butyl alcohol ($t_{\frac{1}{2}} > 80$ days) than in 20% methanol ($t_{\frac{1}{2}} = 30$ days). The preferential exclusion of the more hydrophobic cosolvents such as *tert*-butyl alcohol from the hydrophilic microenvironment of Sephadex accounts for this enhanced stability. Conversely, Johanson and Mosbach (31) demonstrated the preferential absorption of ^{14}C-*n*-butanol within the hydrophobic copolymer methylacrylate-acrylamide, while no partitioning of ethanol was detected. Obviously, the judicious selection of a support matrix makes it possible to exclude or include low molecular weight hydrophobic compounds at will. This could have considerable practical ramifications in the synthetic applications of immobilized enzymes.

Other general solvent effects to which changed enzymic activities have been attributed, including changes in dielectric constant (32), increased substrate solubility (21), and decreased water availability (6), are not discernible under the conditions of the present study.

Of the solvents investigated, DMSO clearly has the most favourable overall properties. The stabilities of both native CT and CT-Sephadex are enhanced in 20% DMSO (Table 3) and the levels of catalytic activities remain high (Table 2). Much higher levels of DMSO are also tolerated well.[3] For example, Khurgin *et al.* (33) have shown that as long as the water of hydration remains >4%, CT continues to catalyze hydrolysis of its ester substrates. For practical applications in general, the use of DMSO may be limited by the fact that the hydrophobic organic compounds of most synthetic interest do not dissolve well in it. In view of this, *tert*-butyl alcohol, for which the transesterification disadvantage of primary and secondary alcohols (19) is precluded, could prove the best compromise choice for enhancing substrate solubility in reactions with enzymes immobilized on hydrophilic organic supports such as Sephadex.

The chemistry of thujone. III. Thujone as a chiral synthon for the preparation of sesquiterpenes. Synthesis of (+)-β-cyperone

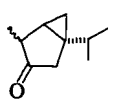
JAMES P. KUTNEY,[1] JOHN BALSEVICH, AND PETER GRICE

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Y6

Received June 26, 1980

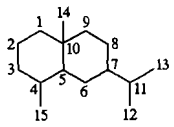
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

JAMES P. KUTNEY, JOHN BALSEVICH, and PETER GRICE. Can. J. Chem. **58**, 2641 (1980).



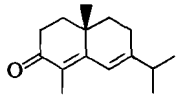
Robinson annelation of thujone (**1**) with methyl and ethyl vinyl ketones proceeds stereospecifically to afford the tricyclic enones **6** and **4** respectively. Enone **4** was converted to the glycol **13** which on treatment with 48% hydrobromic acid gave (+)-9-bromo-β-cyperone (**14**). Reduction with triphenyltin hydride yielded (+)-β-cyperone (**3**). Enone **6** was converted via standard means to the cyclopropyl alcohol **9**, a potential precursor of (+)-junenol (**10**).

JAMES P. KUTNEY, JOHN BALSEVICH et PETER GRICE. Can. J. Chem. **58**, 2641 (1980).



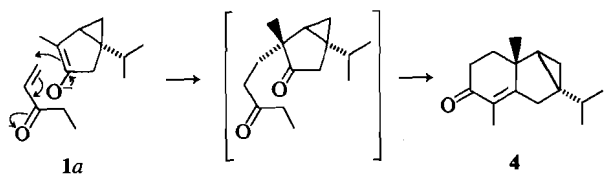
Les annellations de Robinson de la thujone (**1**) avec les méthyle et éthyle vinylcétones sont stéréospécifiques et conduisent respectivement aux énones tricycliques **6** et **4**. On a transformé l'énone **4** en glycol **13** qui, par traitement avec l'acide bromohydrique à 48%, donne la (+)-bromo-9 β-cypérone (**14**) dont la réduction, par l'hydrure de triphénylétain, fournit la (+) β-cypérone (**3**). On a transformé l'énone **6** par des méthodes normales en alcool cyclopropylique **9**, un précurseur potentiel du (+)-junénol (**10**).

[Traduit par le journal]



Previous research in this laboratory has shown that thujone[2] (**1**) is a useful starting material in the synthesis of several insect juvenile hormone analogues (1, 2). We have investigated the possibility of employing thujone in the synthesis of optically active sesquiterpenes with the eudesmane carbon skeleton (**2**) and wish to report the synthesis of (+)-β-cyperone (**3**).

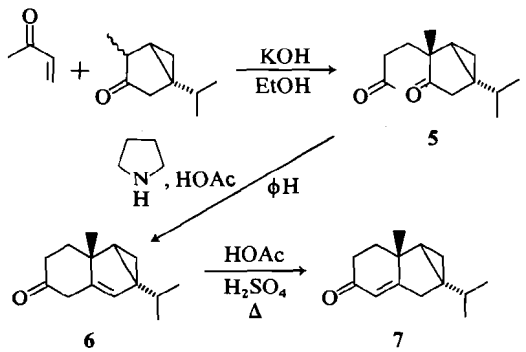
1



2

3

Earlier synthetic studies (3) in the cyperone series made use of the Robinson annelation with both (+)- and (−)-dihydrocarvone. These reactions, however, led to mixtures of isomers. Consideration of the geometry of the thujone enolate **1***a* led to the conclusion that alkylation should take place from the less hindered face of the enolate with a high degree of selectivity. Hence, annelation of thujone with ethyl vinyl ketone, or an equivalent reagent, was expected to lead to the tricyclic enone **4**, a molecule possessing ample functionality to allow elaboration to a variety of sesquiterpenes.



Initially, a study was carried out using methyl vinyl ketone for the Robinson annelation. Reaction

1*a* **4**

of thujone with methyl vinyl ketone in ethanol containing a catalytic amount of potassium hydroxide gave the diketone **5**.[3] This compound, isolated in 61% yield, was established as isomerically pure by means of its carbon-13 and proton magnetic resonance spectra (i.e. no anomalous resonances were present).

It is of interest to note that treatment of diketone **5** in refluxing ethanol with potassium hydroxide failed to effect cyclization to **7** and it was essential

5 **6** **7**

[1]Author to whom correspondence may be addressed.

[2]Thujone is the major component (ca. 80%) of the steam distillate from the slash (waste) of Western red cedar.

[3]The assignment of the absolute stereochemistry was corroborated by the subsequent synthesis of (+)-β-cyperone employing this approach (see **i** →→ **4**).

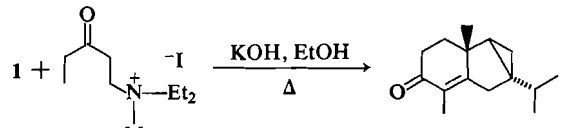
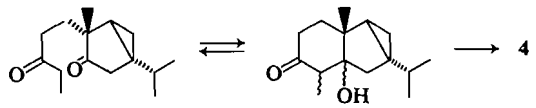
to achieve this objective by the use of pyrrolidine and acetic acid as shown. In this latter cyclization process the initial product formed is the β,γ-unsaturated ketone **6**. Isolation of **6** is presumably due to the initial formation of the pyrrolidine dienamine intermediate which then undergoes hydrolysis to the product.

The assignment of the double bond in **6** was based on its ultraviolet (λ_{max}: 211 nm, ε = 5 700) and infrared (ν(C=O): 1716 cm^{-1}) spectra, and by its isomerization, in refluxing acetic acid, to the α,β-unsaturated ketone **7** (uv λ_{max}: 234 nm, ε = 13 600; ir ν (C=O, C=C): 1666 cm^{-1}).



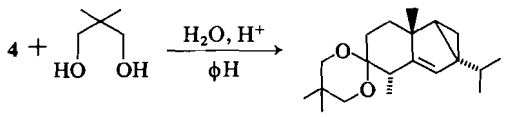
The isomerization of **6** to **7** does not occur readily with acetic acid at room temperature (recovery of starting material after 4 h) but can be achieved in refluxing acetic acid containing a catalytic amount of sulfuric acid.

Ketalisation of **6** by conventional means gave the ketal **8** in almost quantitative yield. Hydroboration of **8** afforded a mixture of alcohols in which the secondary alcohol **9** predominated. The latter compound was isolated in 65% yield by chromatographic purification. The stereochemistry of the 6-hydroxyl function was evident from its proton magnetic resonance spectrum, the large coupling constant (J = 9 Hz) between H-5 and H-6 indicating (4) a diaxial arrangement of these hydrogen atoms. Work is now in progress to convert **9** into (+)-junenol (**10**).

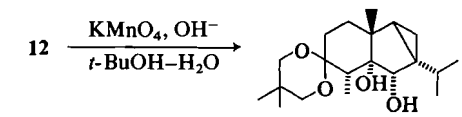


8 **9** **10**

Alternatively, reaction of thujone with ethyl vinyl ketone (generated *in situ* by the action of potassium hydroxide on **11**) in boiling ethanol gave the tricyclic enone **4** in 51% yield. The direct cyclization to **4** under the potassium hydroxide conditions provides an interesting difference from the result obtained in the above-mentioned study where this reagent failed to effect the cyclization of **5**. Presumably the equilibrium between the diketone **i**, formed *in situ* under the conditions employed, and the cyclized aldol product **ii** favors the latter. Furthermore it appears reasonable that the dehydration reaction (**ii** → **4**) is also a facile process, thereby allowing the isolation of **4** directly.



11 **4**

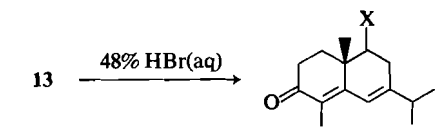


i **ii**

Ketalisation of **4** proceeded with concomitant migration of the double bond to the 5,6 position to give **12** in 89% yield. The latter assignment was evident from the proton magnetic resonance spectrum which exhibited a resonance for a vinyl proton

12

at δ 5.34 (1H, bs). This compound was found to be homogeneous by spectroscopic investigation (270 MHz ^{1}Hmr, ^{13}Cmr) and it was assumed that the 4-methyl group would adopt the more stable α (equatorial) configuration. Treatment of the ketal **12** with potassium permanganate and sodium hydroxide in aqueous *tert*-butyl alcohol (5) gave the diol **13** in 79% yield. Reaction was assumed to have



13

taken place from the less hindered (α) face of the molecule. Treatment of **13** with aqueous hydrobromic acid (6) gave the bromodienone **14** in 69% yield. Treatment of the latter with an excess of triphenyltin hydride in benzene gave (+)-β-cyperone (**3**) in 60% yield.

This product gave spectra comparable[4] to those reported in the literature (7, 8) and had an optical rotation of $[\alpha]_{5461}$ +673° (lit. (7) $[\alpha]_{5461}$ +681°) indicating an optical purity of >98.8%.

Hence it has been shown that thujone (**1**) is an extremely efficient chiral synthon and leads to sesquiterpenoids of very high optical purity. Further applications of this approach are under investigation in our laboratory.

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer using methanol as the solvent. Infrared spectra were recorded on a Perkin-Elmer 457 spectrophotometer. Spectra were obtained with samples as neat films. The ^{1}Hmr spectra were recorded on either a Varian HA- or XL-100 or a 270-MHz spectrometer; ^{13}Cmr spectra were recorded on a Varian CFT-20 instrument. Deuteriochloroform was used as the solvent with TMS as internal standard. Mass spectra were recorded on an Atlas CH-4B or AEI MS-902 instrument. Optical rotations were recorded on a Perkin-Elmer 141 polarimeter. Rotations were obtained using a cell with a pathlength of 10 cm. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Column chromatography utilized Merck silica gel 60 (70–230 mesh). Preparative and thin layer chromatography utilized Merck silica gel GF_{254}. Petroleum ether refers to the fraction with boiling point 30–60°C.

Diketone 5

A solution of thujone (60 mL, 0.34 mol) and potassium hydroxide (1 g, 0.015 mol) in ethanol (500 mL) under an atmosphere of nitrogen was treated with methyl vinyl ketone (33 mL, 0.41 mol) at a dropwise rate over a period of 8 h. The reaction was stirred for a further 16 h at ambient temperature and then concentrated *in vacuo*. The residue was suction filtered through a short column of silica gel (tlc grade, 80 g) using petroleum ether/ether (3:1 v/v) as eluent (~ 200 mL). The solvent was evaporated and the residue was distilled through a Vigreux column to afford **5** as a pale yellow oil (46 g, 61%); bp 114°C at 0.3 Torr; ir ν_{max}: 3050, 1730, 1716; ^{1}Hmr δ: 2.01 (3H, s), 0.92 (3H, d, J = 7 Hz), 0.85 (3H, s), 0.82 (3H, d, J = 7 Hz), 0.51 (1H, m), −0.11 (1H, dd, J = 4 and 6 Hz); ^{13}Cmr δ: 219.04, 207.25, 50.71, 40.93, 38.25, 32.56, 30.68, 29.87, 27.22, 19.90, 19.79, 18.00, 15.89; ms *m/e*: 222 (M^+), 165, 161, 151, 139, 136, 121 (base peak); $[\alpha]_D$ −46.9° ($CHCl_3$, *c* 3.8). *Anal.* calcd. for $C_{14}H_{22}O_2$: C 75.63, H 9.97; found: C 75.80, H 9.86.

β,γ-Unsaturated Ketone 6

A solution of the diketone **5** (40 g, 0.18 mol) in benzene (400 mL) under an atmosphere of nitrogen was treated with acetic acid (10.5 mL, 0.18 mol) and pyrrolidine (14 mL, 0.17 mol). The reaction mixture was heated at reflux with azeotropic removal of water. After 18 h the reaction was cooled to ambient temperature and treated with sodium acetate (10 g) in aqueous acetic acid (100 mL, 1:1 v/v). After 10 min the reaction mixture was diluted with petroleum ether (200 mL) and separated. The organic portion was washed with hydrochloric acid (3 × 80 mL, 2 *N*), water (2 × 80 mL), sodium bicarbonate solution (1 × 80 mL, 5% w/v), and dried ($MgSO_4$). After evaporation of the solvent, the residue was distilled to afford **6** as a pale yellow oil (29 g, 79%); bp 102°C at 0.4 Torr; uv λ_{max} (ε): 211 (5700), 230 sh (3800), 250 sh (2000) 290 (1300) nm; ir ν_{max}: 3042, 1716, 1650; ^{1}Hmr δ: 5.43 (1H, bs), 1.19 (3H, s), 0.93 (3H, d, J = 7 Hz), 0.81 (3H, d, J = 7 Hz), 0.66 (1H, dd, J = 4 and 8 Hz), 0.28 (1H, t, J = 4 Hz); ^{13}Cmr δ: 207.96, 142.41, 127.57, 46.52, 43.14, 40.41, 38.53, 38.28, 33.58, 30.85, 20.82, 20.60, 19.97, 19.63; ms *m/e*: 204 (M^+), 189, 161, 147, 133, 119, 105 (base peak); $[\alpha]_D$ +313.6° ($CHCl_3$, *c* 2.7). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 82.32, H 9.79.

α,β-Unsaturated Ketone 7

A solution of the ketone **6** (1.0 g, 4.9 mmol) in glacial acetic acid (30 mL) containing sulfuric acid (1 drop) was heated at reflux. After 1 h the reaction was cooled to ambient temperature, diluted with water (100 mL), and extracted with petroleum ether (3 × 30 mL). The combined organic portion was washed with sodium bicarbonate solution (2 × 30 mL, 5% w/v) and dried (Na_2SO_4). After removal of the solvent *in vacuo* the residue was chromatographed on silica gel (80 g) using petroleum ether/ether (3:1 v/v) as eluent. Compound **7** was obtained as a colorless oil (700 mg, 70%); uv λ_{max} (ε): 234 (13 600) nm; ir ν_{max}: 3060, 1666, ^{1}Hmr δ: 5.57 (1H, bs), 1.30 (1H, septet, J = 6.5 Hz), 1.10 (3H, s), 0.90 (3H, d, J = 6.5 Hz), 0.88 (3H, d, J = 6.5 Hz), 0.81 (2H, m); ^{13}Cmr δ: 198.56, 181.04, 119.10, 41.52, 37.84, 37.17, 35.05, 34.87, 33.90, 33,35. 22.47, 20.65; ms *m/e*: 204 (M^+), 189, 176, 161, 147, 133 (base peak), 109; $[\alpha]_D$ +88.4° ($CHCl_3$, *c* 4.3). *Anal.* calcd. for $C_{14}H_{20}O$: C 82.30, H 9.87; found: C 82.60, H 9.71.

Ketal 8

A solution of ketone **6** (37 g, 0.18 mol) in benzene (400 mL) was treated with ethylene glycol (32 mL, 0.57 mol) and *p*-toluenesulfonic acid dihydrate (2 g). The resultant mixture was heated at reflux with azeotropic removal of water. After 4 h the reaction mixture was cooled to ambient temperature, diluted with petroleum ether (200 mL), washed with sodium hydroxide solution (2 × 100 mL, 1 *N*), water (3 × 100 mL), and dried (Na_2SO_4). The solvent was removed *in vacuo* and the residue distilled to give **8** as a pale yellow oil (43 g, 96%); bp 106°C at 0.2 Torr; ir ν_{max}: 3040, 1090; ^{1}Hmr δ: 5.38 (1H, s), 3.92 (4H, m), 1.19 (1H, dd, J = 4 and 8 Hz), 1.08 (3H, s), 0.96 (3H, d, J = 7 Hz), 0.90 (3H, d, J = 7 Hz), 0.61 (1H, dd, J = 4 and 8 Hz), 0.24 (1H, t, J = 4 Hz); ^{13}Cmr δ: 144.58, 126.78, 110.54, 64.34, 64.23, 46.70, 40.11, 37.48, 36.09, 33.70, 31.88, 30.89, 20.82, 20.54, 19.28; ms *m/e*: 248 (M^+, base peak), 233, 203, 186, 171, 161, 147; $[\alpha]_D$ +187.4° ($CHCl_3$, *c* 4.2). *Anal.* calcd. for $C_{16}H_{24}O_2$: C 77.38, H 9.73; found: C 77.60, H 9.83.

Alcohol 9

A 0.5 *M* solution of borane in tetrahydrofuran/1,2-dimethoxyethane (1:1) (400 mL, 0.2 mol) under an atmosphere of nitrogen was treated with a mixture of ketal **8** (20 g, 0.081 mol) and propylene oxide (5 mL). After 1.5 h at ambient temperature the reaction was cooled to 0°C and cautiously treated with aqueous sodium hydroxide (200 mL of 2 *N*) over a period of 30 min. Hydrogen peroxide (200 mL of 30%) was added and the reaction stirred for a further 30 min. Petroleum ether (200 mL) was added and the mixture separated. The organic portion was washed with saturated aqueous sodium bicarbonate (2 × 150 mL) and dried (Na_2SO_4). After removal of the solvent the residue was chromatographed on silica gel (2 × 400 g) using petroleum ether/ethyl acetate (3:1 v/v), then petroleum ether/ethyl acetate/methanol (3:1:0.5 v/v) as eluents. Compound **9** was obtained as a colorless viscous oil (14.1 g, 65%); ir ν_{max}: 3410, 3060, 1102; ^{1}Hmr δ: 4.59 (1H, d, J = 9 Hz), 3.9 (4H, m), 1.01 (3H, d, J = 7 Hz), 0.99 (3H, d, J = 7 Hz), 0.98 (3H, s), 0.63 (1H, t, J = 5 Hz), 0.26 (1H, dd, J = 5 and 7 Hz); ^{13}Cmr δ: 109.31, 75.67, 64.34, 63.62, 48.36, 36.38, 35.41, 34.44, 34.06, 30.96, 30.51, 29.86, 21.90, 20.60, 20.00, 8.13; ms *m/e*: 266 (M^+), 223, 204, 167, 161, 111, 109, 99 (base peak); $[\alpha]_D$ − 14.8° ($CHCl_3$, *c* 1.5). *Anal.* calcd. for $C_{16}H_{26}O_3$: C 72.14, H 9.84; found: C 72.01, H 9.89.

Tricyclic Enone 4

A solution of thujone (60.8 g, 0.4 mol), 1-diethylamino-3-pentanone-methiodide (**11**) (120 g, 0.44 mol), and potassium hydroxide (33 g, 0.5 mol) in ethanol (600 mL) was heated at reflux for 90 min. The solution was cooled and water (1000 mL) and petroleum ether (600 mL) were added. The organic layer was separated and washed with hydrochloric acid (2 × 250 mL, 1 *N*), and water (250 mL), then dried (Na_2SO_4), and evaporated. The residue was distilled collecting the fraction bp 126–128°C at 0.16 Torr. Yield 44 g (51%) of colourless oil; uv λ_{max} (ε): 245 (12 300) nm; ir ν_{max}: 3042, 1678, 1647; ^{1}Hmr δ: 1.65 (3H, d, J = 1.5 Hz), 1.07 (3H, s), 0.91 (3H, d, J = 7 Hz), 0.89 (3H, d, J = 7 Hz), 0.76 (2H, m); ^{13}Cmr δ: 197.84, 174.53, 124.74, 41.97, 36.38, 36.18, 35.93, 35.63, 35.15, 34.15, 33.43, 21.71, 19.87,

19.69, 11.39; ms *m/e*: 218 (M^+), 203, 175, 161, 147 (base peak); $[\alpha]_D$ +86.8° ($CHCl_3$, *c* 4). *Anal.* calcd. for $C_{15}H_{22}O$: C 82.52, H 10.16; found: C 82.53, H 10.05.

Ketal 12

A solution of enone **4** (14.9 g, 68.3 mmol), 2,2-dimethyl-1,3-propanediol (15 g, 144 mmol), and *p*-toluenesulphonic acid (0.19 g, 1 mmol) in benzene (300 mL) was heated at reflux with azeotropic removal of water for 20 h. The solution was cooled and petroleum ether (200 mL, bp 30–60°C) was added. The solution was washed with saturated aqueous sodium bicarbonate (1 × 200 mL) and water (2 × 200 mL), then dried (Na_2SO_4), and evaporated. The residue was dissolved in a mixture of petroleum ether and ether (200 mL, 9:1 v/v) and filtered through a short column of silica gel (50 g). The filtrate was evaporated to leave the pure ketal as a colourless oil; yield 18.4 g (89%); ir ν_{max}: 3056, 1110; ^{1}Hmr δ: 5.34 (1H, bs), 3.83–3.22 (4H, m), 2.70 (1H, m), 2.18 (1H, q, J = 7 Hz), 1.16 (3H, s), 1.11 (3H, d, J = 7 Hz), 1.07 (3H, s), 0.94 (3H, d, J = 7 Hz), 0.86 (3H, d, J = 7 Hz), 0.69 (3H, s), 0.59 (1H, dd, J = 4 and 8.5 Hz), 0.22 (1H, t, J = 4 Hz); ^{13}Cmr δ: 149.04, 124.74, 100.32, 70.48, 69.69, 47.40, 40.21, 39.72, 36.33, 30.88, 29.77, 23.73, 23.29, 22.25, 20.92, 20.66, 20.56, 19.01, 9.33; ms *m/e*: 304 (M^+), 200, 185, 161, 141 (base peak), 103; $[\alpha]_D$ +149.3° ($CHCl_3$, *c* 2.1). *Anal.* calcd. for $C_{20}H_{32}O_2$: C 78.90, H 10.59; found: C 79.00, H 10.62.

Diol 13

A mixture of ketal **12** (5.3 g, 15.7 mmol), sodium hydroxide (4 g, 100 mmol), and potassium permanganate (5 g, 31.6 mmol) in aqueous *tert*-butanol (1000 mL, 1:1 v/v) was stirred at 0°C for 40 min. Solid sodium metabisulphite was added until a clear solution resulted. The solution was evaporated to ca. half its original volume and then extracted with dichloromethane (3 × 75 mL). The combined extracts were washed with water (2 × 100 mL), dried (Na_2SO_4), and evaporated to leave the diol as a colourless glass, yield 4.67 g (79%); ir ν_{max}: 3470, 1110; ^{1}Hmr δ: 4.81 (1H, s), 3.73 (1H, d, J = 11 Hz), 3.53 (1H, d, J = 11 Hz) 3.30 (2H, dt, J = 11, 2 Hz), 2.51 (2H, dt, J = 13.5, 3 Hz), 1.63 (5H, m), 1.44 (2H, m), 1.33 (1H, t, J = 3 Hz), 1.18 (3H, s), 1.09 (3H, d, J = 7 Hz), 1.06 (3H, s), 1.00 (3H, d, J = 7 Hz), 0.96 (3H, d, J = 7 Hz), 0.95–0.85 (1H, m), 0.75 (3H, s), 0.14 (1H, ddd, J = 8, 5, 1 Hz); ^{13}Cmr δ: 99.12, 80.09, 69.95, 69.14, 47.13, 42.78, 35.52, 35.34, 34.78, 31.75, 29.73, 23.23, 22.25, 20.72, 19.90, 18.37, 11.22, 6.29; ms *m/e*: 338.2447 (M^+, $C_{20}H_{34}O_4$ requires 338.2457); $[\alpha]_D$ +10.4° ($CHCl_3$, *c* 4.64). *Anal.* calcd. for $C_{20}H_{34}O_4$: C 71.01, H 10.01; found: C 71.28, H 10.31.

Bromodienone 14

Diol **13** (1.85 g, 5.48 mmol) was dissolved in petroleum ether (30 mL) and added to ice cold hydrobromic acid (30 mL, 48%). The mixture was rapidly stirred at 0°C for 2 h. The mixture was poured into water (150 mL) and extracted with dichloromethane (3 × 50 mL). The combined extracts were washed with saturated aqueous sodium bicarbonate (2 × 50 mL), dried (Na_2SO_4), and evaporated. The residue was taken up in a mixture of petroleum ether and ether (100 mL of 9:1 v/v) and filtered through a short plug of silica gel (10 g). The filtrate was evaporated to leave the bromodienone as a colourless oil, yield 1.10 g (68%); uv λ_{max} (ε): 293 (24 100) nm; ir ν_{max}: 1660, 1622, 1580; ^{1}Hmr δ: 6.36 (1H, s), 4.2 (1H, t, J = 8 Hz), 2.9–2.1 (7H, m), 1.88 (3H, s), 1.18 (3H, s), 1.16 (6H, d, J = 7 Hz); ^{13}Cmr δ: 198.3, 154.7, 128.6, 119.1, 61.6, 38.69, 36.15, 35.6, 34.8, 33.5, 31.4, 29.9, 16.23, 10.71; ms *m/e*: 296.0768 (M^+, $C_{15}H_{21}OBr^{79}$ requires 296.0775); $[\alpha]_D$ +430° ($CHCl_3$, *c* 1).

(+) β-Cyperone 3

Bromodienone **15** (0.35 g, 1.18 mmol) was dissolved in dry benzene (5 mL) and added to a solution of triphenyltin hydride (0.72 g, 2.05 mmol) in dry benzene. AIBN (16 mg, 0.1 mmol) was added and the mixture heated to 80°C under nitrogen for 2 h. A further portion of AIBN (16 mg) was added and the reaction maintained at 50°C for 16 h. The mixture was evaporated and the residue chromatographed on silica gel to give (+)-β-cyperone as a colourless oil, yield 0.154 g (60%); (ε): 297 (32 970) nm; ir ν_{max}: 1655, 1620, 1580; ^{1}Hmr δ: 6.29 (1H, s), 2.85–2.05 (5H, m), 1.78 (3H, s), 1.75–1.30 (4H, m), 1.2–1.0 (9H, m); ^{13}Cmr δ: 199.15, 156.22, 126.48, 118.35, 37.27, 36.53, 36.19, 33.94, 33.27, 23.77, 21.54, 21.14, 10.12; uv λ_{max} ms *m/e*: 218 (M^+); $[\alpha]_{5461}$ +673° ($CHCl_3$, *c* 0.108).

Direct transformation of carboxylic acids to thiol esters induced by phenyl dichlorophosphate

HSING-JANG LIU AND SUBRAMANIAM IYER SABESAN

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

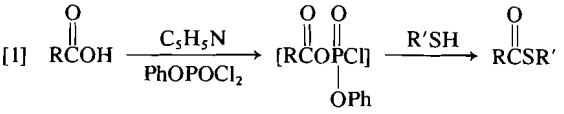
Received July 9, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HSING-JANG LIU and SUBRAMANIAM IYER SABESAN. Can. J. Chem. **58**, 2645 (1980).

The condensation of carboxylic acids and thiols is greatly facilitated by the use of phenyl dichlorophosphate as an activating agent giving thiol esters in good yields.

HSING-JANG LIU et SUBRAMANIAM IYER SABESAN. Can. J. Chem. **58**, 2645 (1980).



L'emploi du dichlorophosphate de phényle comme agent activant facilite grandement la condensation des acides carboxyliques sur les thiols qui donne les thioesters avec de bons rendements.

The thiol ester is a versatile functional group which facilitates the formation of carbon–carbon bonds and the preparation of a number of important functionalities (1). The growing importance of thiol esters in organic synthesis has stimulated the recent extensive research (1*h*, 2) toward improved methods for their direct preparation from carboxylic acids.[1] A year ago, we described a convenient procedure (2*h*) for the condensation of carboxylic acids and thiols under mild reaction conditions using *N*,*N*-dimethylphosphoramidic dichloride as an activating agent. Further investigation of other phosphorus-containing analogs has revealed that the commercially available[2] (and relatively inexpensive) phenyl dichlorophosphate is a superior reagent which effects the condensation under equally mild conditions giving thiol esters in generally better yields than those obtained using *N*,*N*-dimethylphosphoramidic dichloride. In this article we wish to report these results.

In the presence of phenyl dichlorophosphate and pyridine, the condensation of carboxylic acids and thiols (eq. [1]) occurs smoothly at room temperature. A total of fifteen functionally diverse carboxylic acids were studied using a simple general procedure involving the sequential addition of pyridine (3 equiv.), a thiol (2 equiv.), and phenyl dichlorophosphate (1.5 equiv.) to a solution of a carboxylic acid in 1,2-dimethoxyethane (5 mL/mmol of carboxylic acid). Although in each case the appearance of product on tlc analysis of the reaction mixture was rapid (< 20 min), the reaction was conveniently[3] allowed to continue overnight (15–16 h) to ensure the complete consumption of starting material.

[1] $RCOH \xrightarrow[PhOPOCl_2]{C_5H_5N} [RCOPCl]\ (OPh) \xrightarrow{R'SH} RCSR'$

The generality of the reaction is apparent from the results compiled in Table 1. We wish to emphasize that the reaction conditions employed are near-neutral and sufficiently mild to be widely applicable to acid (entries 7, 8, 12, 13, 17, and 18) and/or base (entries 13, 17, and 18) sensitive compounds. Furthermore, unlike most of the existing methods,[4] the present procedure is applicable to thiols of a broad spectrum of structural types ranging from 1°–3°, as well as phenyl and benzyl ones. The reaction is independent of the steric environment of the thiol; *tert*-butyl mercaptan (entries 6, 10, 15, and 17) gave products in yields comparable with those from sterically less hindered ones.

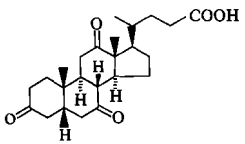
The utility of the direct transformation of carboxylic acid to thiol ester without the isolation of an active acid derivative is emphasized in the conversion of cyanoacetic acid into the corresponding *tert*-butyl (entry 17) and benzyl (entry 18) thiol esters. The acid chloride of cyanoacetic acid is known to undergo spontaneous polymerization (4) and attempts to prepare thiol ester derivatives via cyanoacetyl chloride (either isolated or generated *in situ*) met with little success.

We have briefly examined the use of chlorophosphates $(PhO)_2POCl$ and $(EtO)_2POCl$ as activating agents under the conditions described above and have found them to be less effective than phenyl dichlorophosphate. For example, when the condensation of cyanoacetic acid and benzyl mercap-

[1]For examples of other methods for thiol ester formation, see refs. 1*a*, 1*b*, 1*h*, 1*i*, 1*u*, and 3.

[2]Since completion of the present studies, *N*,*N*-dimethylphosphoramidic dichloride has been marketed by Fluka.

[3]The disappearance of the starting material is difficult to monitor by conventional means (tlc/gc).



[4]For a relevant discussion, see ref. 3*c*.

[a]Melting point 28–29°C (ether–cyclohexane).
[b]Melting point 48–49°C (ether–cyclohexane).
[c]Melting point 207–208°C (chloroform–ether).
[d]Melting point 181–182°C (methanol–ether).
[e]Except where otherwise stated, the ir spectra were obtained on neat liquid.
[f]Only diagnostic signals are cited.
[g]Obtained in chloroform.
[h]Taken in KBr pellet.
[i]Obtained in carbon tetrachloride.
[j]Except where otherwise stated, the nmr spectra were obtained on solutions in carbon tetrachloride with tetramethyl silane as internal reference.
[k]Taken in chloroform-*d*.
[l]Taken in methanol-d_4.
[m]Molecular ions are given with the exception of entries 11, 15, and 17 in which cases molecular ions were not detected.
[n]Calculated values are given in parentheses.

tan was carried out using $(PhO)_2POCl$ or $(EtO)_2POCl$, low yields (<30%) of the desired product were obtained.

Experimental

General and Material

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared spectra were recorded on a Perkin-Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer. Nuclear magnetic resonance spectra were recorded on Varian A-60 and 90 MHz Perkin-Elmer 32 spectrometers. Mass spectra were recorded using an A.E.I. Model MS 50 mass spectrometer. Elemental analyses were performed by the microanalytical laboratory of this department. Pyridine was distilled over potassium hydroxide and 1,2-dimethoxyethane was freshly distilled over lithium aluminum hydride. Commercially available carboxylic acids, thiols, and phenyl dichlorophosphate (Aldrich) were used without purification.

Conversion of Carboxylic Acids to Thiol Esters

The conditions used for the transformation of the carboxylic acids studied to the corresponding thiol esters were identical to those illustrated below with ethoxyacetic acid. Physical data and yields of all products are compiled in Table 1.

To a solution of ethoxyacetic acid (208 mg, 2 mmol) in 1,2-dimethoxyethane (10 mL) at 0°C, were added pyridine (475 mg, 6 mmol), benzyl mercaptan (496 mg, 4 mmol), and phenyl dichlorophosphate (633 mg, 3 mmol). After stirring at room temperature under an argon atmosphere for 16 h, the reaction mixture was poured into ice-cold aqueous 1 *N* NaOH (20 mL) and extracted with chloroform. The extracts were washed with aqueous 1 *N* NaOH and saturated aqueous sodium chloride. Drying ($MgSO_4$), filtration, and concentration gave an oily product which was purified by column chromatography on silica gel. Elution with benzene gave benzyl ethoxyethanothioate (420 mg; 100% yield).

A nuclear Overhauser effect difference study of the solution conformation of (6*R*)-prostaglandin I_1[1]

GEORGE KOTOVYCH[2] AND GERDY H. M. AARTS
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 23, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

GEORGE KOTOVYCH and GERDY H. M. AARTS. Can. J. Chem. **58**, 2649 (1980).

Proton magnetic resonance studies at 400 MHz allowed the complete assignment of the spectra for (6*R*)-prostaglandin I_1 in phosphate buffer and in $CDCl_3$ solutions. The spectral analysis was based on the nuclear Overhauser effect difference measurements, which also provide accurate chemical shifts and coupling constants. Conformational differences in the two solvents for the ring portion of the molecule are indicated.

GEORGE KOTOVYCH et GERDY H. M. AARTS. Can. J. Chem. **58**, 2649 (1980).

Les études de rmn du ^1H à 400 MHz permettent d'identifier complètement les spectres de la (6*R*)-prostaglandine I_1 en solutions dans un tampon de phosphate et dans le $CDCl_3$. On a analysé les spectres en se basant sur la mesure de la différence d'effet Overhauser nucléaire qui fournit également avec précision les déplacements chimiques et les constantes de couplage. On a indiqué les différences conformationnelles de la partie cyclique de la molécule dans les deux solvants.

Introduction

Since the discovery of prostacyclin (PGI_2) in 1976 (1), and its structure determination (2), the design of stable prostacyclin analogs has received considerable attention (ref. 3, and references therein). Prostacyclin is extremely important in the cardiovascular system; prostacyclin and chemical analogs may find a use in therapy for states in which excessive platelet aggregation takes place in the circulation (ref. 4, and references therein). Prostacyclin is unstable, and in blood at 37°C it has a half-life of 2–3 minutes, whereas at pH 10.5 at 25°C it has a half-life of 100 hours (4). Because of the PGI_2 instability, and its extreme biological importance, a variety of stable analogs has been prepared, among them 5,6-dihydroprostacyclin, or prostaglandin I_1 (PGI_1) (5–9). The chemical proof of the stereochemistry at C-6 of the PGI_1 isomers was provided by Nelson (7). The stereochemistry at C-5 and C-6 of all products associated with the synthesis of 13,14-dehydroprostacyclin methyl ester has also been assigned (10). The nomenclature for prostacyclin analogs has been discussed (11) and the two epimers (at C-6) are designated (6*R*)-PGI_1, and (6*S*)-PGI_1.

The biological activity of these two epimers has been extensively studied (9, 12–15). Crane *et al.* (12) studied six analogs of PGI_2 and their ability to inhibit platelet aggregation. Their results indicate that the orientation of the α chain may play a key role in explaining the potency of these compounds with respect to PGI_2. The results also indicate that platelets are much more sensitive to structural variations in the PGI_2 molecule than smooth muscle of the gerbil colon or rat uterus. This suggests specificity in the platelet receptor which may prove useful for pharmacological manipulation (12). We have studied the conformation of (6*R*)-PGI_1 (Fig. 1), also referred to as *endo* or α-PGI_1, using high-field proton magnetic resonance techniques. In this way, we hope to correlate the structure and activity of these compounds in solution.

Materials and Methods

The (6*R*)-PGI_1 was a gift from Dr. R. A. Johnson of the Upjohn Co., Kalamazoo, MI. The present measurements were

carried out both in phosphate buffer (0.2 *M*) in D_2O and in $CDCl_3$. The $CDCl_3$ was purified by treating it with Al_2O_3 (B.D.H. Chemicals) and vacuum degassing it several times using the freeze–pump–thaw technique. The required amount of $CDCl_3$, 0.40 mL, was added to the preweighed (6*R*)-PGI_1, 2.8 mg. The solution was then transferred to an nmr tube, and was vacuum degassed several times. Subsequently, the nmr tube was sealed. Several samples were prepared for the nmr measurements in this manner. In addition, a (6*R*)-PGI_1 solution in $CDCl_3$ was prepared to exchange the —OH and —COOH protons for deuterons. This was accomplished by preparing an additional sample with a drop of D_2O, degassing the sample, and then sealing off the nmr tube. The concentration of (6*R*)-PGI_1 in all samples was ~0.02 *M*. The buffer was made up using 99.96% D_2O (Merck, Sharp and Dohme Canada Ltd.) and KH_2PO_4 (Amachem) and the pH was adjusted to 7.0 (uncorrected meter reading) using 40% (w/w) NaOD in D_2O (Merck, Sharp and Dohme Canada Ltd.). The buffer was then dried by pumping off the solvent, and the exact amount of degassed D_2O was added to the dried buffer *in vacuo*. The final phosphate concentration was 0.2 *M* and the uncorrected pH was 7.0. This procedure was followed to minimize the solvent HDO resonance in the nmr spectrum. The (6*R*)-PGI_1 was weighed out in a container and the required amount of buffer solution was added for a final concentration of 0.02 *M*. The solution was transferred into the nmr tube, vacuum degassed three times, and the nmr tube was sealed. Two samples were prepared in this manner. With the exception of the pH adjustment, all sample preparations were carried out in a dry box under a nitrogen gas atmosphere. All glassware was cleaned extensively to eliminate paramagnetic impurities (16). The reference compounds TSP-d_4 for the buffer solution and TMS for the $CDCl_3$ solution were added to the solutions as reference standards after the completion of all other nmr experiments.

The nmr measurements were carried out in the Fourier transform mode using the Bruker WH-400/DS NMR spectrometer and the Aspect 2000 Data System utilizing 16 or 32K of data memory. All of the experiments were carried out at ambient temperature (298 K). The deuterium resonance of the solvents was used for the lock signal. The homonuclear decoupling experiments were also performed in the pulse mode. The chemical shifts and coupling constants were calculated to first order at 400 MHz and are reported with an accuracy of about ±0.010 ppm and ±0.20 Hz, respectively. For maximum accuracy, spectra were expanded to a width of 2 Hz/cm.

The nuclear Overhauser effect (nOe) difference experiments were carried out at 400 MHz. This involves the measurement of the intensity change of a proton resonance upon saturating another proton. A strong nOe indicates that the two protons are in close proximity. The experimental procedure will be described briefly (17–19). The decoupler, operating in the gated mode, was set on resonance for a time (12 s) greater than 5 times the longest T_1 value for the protons of the molecule to build up the nOe. It was gated off during acquisition. Four free induction decay signals were accumulated. The memory was then negated and the experiment was repeated with the decoupler off-resonance (control spectrum). The off-resonance frequency was placed to high field of TMS. These four free induction decay (FID) signals were thus compared with the original four. In order to achieve steady state, the first 16 scans were eliminated. The cycle was repeated until the required number of transients was accumulated. After collecting the FID's, the signal was Fourier transformed. A 90° pulse (10.7 μs) was used as well as some exponential line broadening. Experiments were carried out as a function of the irradiating field power levels using both the homo and the gated modes of operation. All of the results are self consistent. Very small nOe's of about 1–2% were detected, as can be seen from the spectra. The measurements on (6*R*)-PGI_1 in $CDCl_3$ with a trace of D_2O were carried out at saturating power levels. However, in order not to perturb neighboring multiplets when a given multiplet is irradiated, subsaturating power levels were used for the other measurements. These power levels were sufficiently high so that all nOe's were observed.

Results

Several techniques were used in the assignment of the proton resonances as well as in determining the chemical shifts and coupling constants in both solvents. These include the nOe difference experiments, double resonance, and inversion recovery techniques. The resonances for H-2, H-13 and 14, H-17 to 19, and H-20 were assigned on the basis of their characteristic chemical shifts. In the $CDCl_3$ solution, some of the other proton resonances including H-3, H-8, H-12, and H-15 were assigned on the basis of homonuclear proton decoupling experiments. The multiplets corresponding to the H-7α, H-7β, H-10α, and the H-10β protons were thus also identified, and were definitively assigned using the nOe difference experiments. Several of the decoupling experiments will be briefly described. Decoupling of the multiplet corresponding to H-2, H-8, and H-12, which have nearly equivalent shifts, results in a change in the multiplicity for H-13 and H-11 (decoupling of H-12) and for H-9 (decoupling of H-8). Changes in the high-field region were also observed, where H-3 and H-7α resonate. Further decoupling of either the H-9 or the H-11 multiplets results in a doublet of doublets for both H-10α and H-10β. Decoupling of H-14 results in a triplet for H-15. The triplet is due to the coupling with H-16 and 16*. Finally, decoupling of H-3 results in a singlet for H-2. In this way the H-3 chemical shift was verified.

The H-9 and H-11 multiplets were conclusively assigned on the basis of the nOe experiments. When H-9 is saturated (Fig. 2B), an nOe is observed for H-6, H-8, and H-10β, all of which are in the β configuration with respect to the ring. This proves the assignment of H-9. In Fig. 2C, saturation of H-11 results in an nOe for H-10β, H-8 and /or H-12, and H-13 and H-14. These results confirm the assignment of H-11. In fact, the chemical shifts of H-9, H-15, and H-11 from low to high field, respectively, fall in the same order as was observed for PGI_2 previously (20). The chemical shift for H-10β is obtained from both of these experiments. Saturation of H-6 (Fig. 3B) results in an enhancement for H-9, H-8, H-7β, and for two multiplets at high field. H-7β is assigned since H-6, H-8, and H-9 are all β to the ring. The two high-field multiplets may possibly be assigned to H-3 and H-5 and 5*. Partial

saturation of H-11 may cause a small nOe to H-12 and H-10β. In Fig. 3C, H-7β and H-10β are saturated. An nOe is observed for H-14, H-13, H-9, H-11, H-6, H-10α, and H-7α. All of these enhancements are as expected from the model for (6*R*)-PGI_1. The chemical shift for H-7α is thus obtained. The enhancement to both H-9 and H-11 simultaneously on saturating H-10β confirms the assignment of H-10β to low field of H-10α. This was previously observed for PGI_2 (20), and prostaglandin E_2 (21). This conclusion is in agreement with the torsion angle dependency of chemical shifts for five-membered prostanoid precursors (22). Finally, chemical shifts for H-3 and H-7α were confirmed by an nOe experiment in which the H-2, H-8, and H-12 multiplet was irradiated. The nOe observed for H-7α is mainly due to the close proximity of H-12. As well, irradiation of H-15 results in an nOe for a multiplet at high field, assigned to H-16 and 16*. This assignment was confirmed by a decoupling experiment centered on H-16 and 16*, resulting in a doublet for the H-15 multiplet. On the basis of these experiments, the chemical shifts for the protons were obtained. These are listed in Table 1, together with the coupling constants. The data in Table 1 were prepared on the basis of normal spectra expanded to a sweep width of 2 Hz/cm, as well as from the nOe difference experiments and decoupling experiments. The data are based on at least two independent samples, namely, in $CDCl_3$ with a trace of D_2O, and in dried $CDCl_3$ solutions. Due to the essentially equal chemical shifts for H-8 and H-12 (as well as for H-2), protons H-7α, H-7β, H-9, H-11, H-13, and probably H-14 will be affected by virtual coupling (26–28). For these protons, measured splittings are reported. All of the other coupling constants, as well as the chemical shifts, are reported to first order. A computer fit to H-9 using a five-spin analysis for protons H-8, H-9, H-10α, H-10β, and H-12 was tried. However, the calculated spectra were very sensitive to the chemical shift difference between H-8 and H-12, as expected. As neither multiplet could be observed separately, these calculations were not pursued further. H-10β is also obscured by the overlap with H-7β, making the computer fit difficult.

The nOe experiments in Figs. 2 and 3 were carried out on a sample in $CDCl_3$ with a trace of D_2O. The complete exchange of the —OH protons with D_2O was shown by irradiating the small HDO resonance seen in Figs. 2 and 3. An nOe was not observed for any protons. On the other hand, very small nOe's, arising from the simultaneous irradiation of the very broad OH peak, appear when the nOe experiments were carried out on purified

$CDCl_3$ samples. This can be seen in Figs. 4B and 4C. When H-9 is saturated (Fig. 4B), very small enhancements are observed for H-14, H-13, H-15, H-10α, and a negative nOe for H-11. When H-6 is irradiated (Fig. 4C), enhancements are also observed for H-14, H-13, H-15, and H-10α. The nOe's experienced by H-15 and H-10α are just above the noise level. In both experiments an enhancement may also be experienced by H-12 but as this proton overlaps the H-8 multiplet, the effect cannot be quantitated. These nOe's are in addition to the expected nOe's observed in Figs. 2 and 3 and are indicated in parentheses in Figs. 4B and 4C. These very small nOe's are experienced by protons in close proximity to the —OH groups at C-11 and C-15. The effects of intra- and intermolecular exchange on nOe measurements have been well documented (23). Caution must be used in interpreting data obtained in this manner.

The assignment of the resonances in buffer solutions was carried out in the same manner as for the

$CDCl_3$ solutions. Consequently, these experiments will be described in less detail. For example, decoupling of H-3 yields a singlet for H-2, and the H-7β multiplet can be studied more readily. Decoupling of H-13 and H-14 results in a triplet for H-15. From this triplet, the coupling constants $J(15–16) = J(15–16^*)$ were evaluated (Table 2). Finally, the H-4 proton multiplet was assigned on the basis of integration experiments.

The results of the nOe difference experiments in phosphate buffer are shown in Figs. 5 and 6. When H-9 is irradiated (Fig. 5B) an nOe is observed for H-6 (and possibly H-11), H-10β, and H-8. These data are in agreement with the measurements in $CDCl_3$ (Fig. 2B). Irradiation of H-15 (Fig. 5C) produces an enhancement to H-16 and 16*, allowing these chemical shifts to be determined. In Fig. 5D, the H-6 and H-11 multiplets are irradiated, resulting in an nOe for H-14 and H-13, H-9, H-10β, H-8, H-7β (and possibly H-12), and H-5 and H-5*. As in the $CDCl_3$ solutions, it is difficult to distinguish between the overlapping H-3 and the H-5* multiplets. The peak at ~1.36 ppm cannot be definitely assigned, but since this corresponds to the chemical shift for protons H-4 and H-7α, it has been labelled in this manner. Since H-6 and H-11 have almost the same chemical shift, these two protons cannot be irradiated separately. This experiment proves the assignment of H-6 and H-11, which are β to the ring, since an nOe is observed for H-7β, H-8, H-9, and H-10β. The enhancement to H-13 and H-14 confirms the assignment of H-11. Proton H-12α, which has almost the same chemical shift as H-7β, will experience a much smaller nOe due to irradiation of H-11β in comparison to the nOe experienced by H-7β, due to irradiation of H-6.

[c] Value obtained from decoupled spectra.

The multiplicity for the H-11 multiplet as well as for the H-10α multiplet is obtained by irradiation of H-10β (Fig. 6B). Enhancements for these protons, together with the nOe to H-9, are as expected since all of these are β to the ring. The expanded spectrum for H-10α shows that accurate coupling constants can be obtained for a multiplet that is buried under many other resonances in the normal spectrum. In addition, this experiment confirms the assignment of H-10β to low field of H-10α, as for the $CDCl_3$ solutions. In Fig. 6C, H-8 is irradiated (with partial saturation of H-10β) resulting in an enhancement for H-13, H-14, H-9, H-11, and possibly H-6, and a very small enhancement to H-10α (due to partial saturation of H-10β). This confirms the assignment for H-8. Finally, irradiation of H-7β (with partial saturation of H-2 and H-12) (Fig. 6D) results in nOe's for H-13, H-14, H-6 (and possibly H-11), H-8, H-3, and H-7α. The chemical shifts for H-3 and H-7α are thus obtained.

In these nOe difference experiments, the overlap of the H-6 and H-11 multiplets causes uncertainty as to which of these protons is experiencing the nOe. In Fig. 6B the enhancement is only to H-11 when H-10β is irradiated, as H-6 is too far removed. In addition to this nOe experiment, the multiplicity and appearance of the H-6 and H-11 multiplets is known from inversion recovery experiments using the 180°—τ—90° two-pulse sequence (24). An attempt was made, on the basis of the splittings observed for the two separate multiplets, to be more specific about the relative nOe's experienced by H-6 and H-11 in experiments shown in Figs. 5B, 6C, and 6D. This proved unsuccessful and hence, in the above description, nOe's to both protons are listed.

Discussion

The nOe difference experiments have been applied previously to a variety of systems including the study of PGI_2 (20), prostaglandin E_2 (21), and

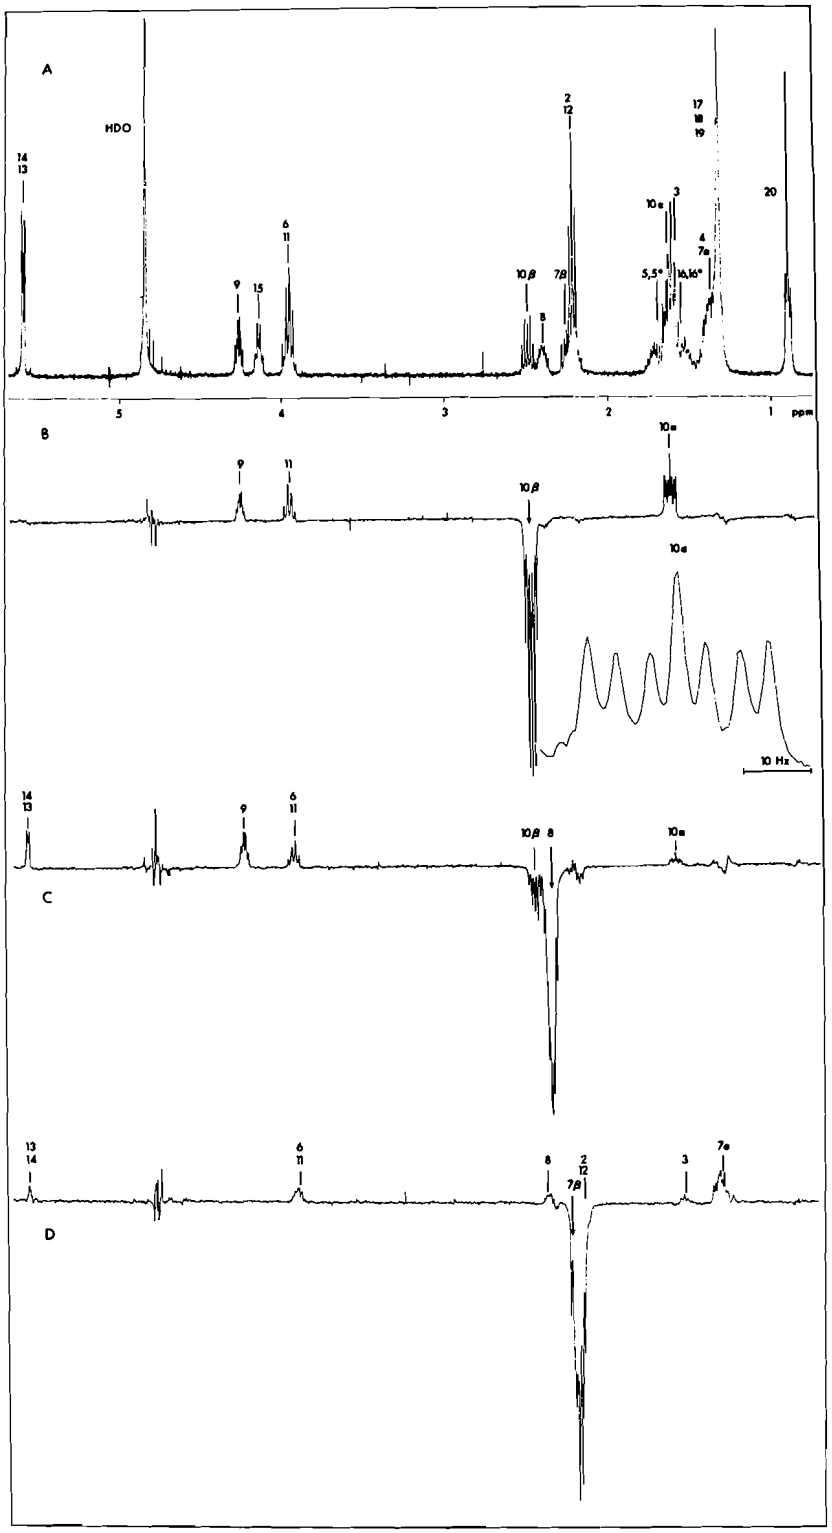

FIG. 6. Results of the nOe difference experiments performed on (6*R*)-PGI$_1$ in phosphate buffer in D_2O, pH 7.0. The normal spectrum is seen in (A) together with the proton assignments. In (B), H-10β is irradiated and an expanded spectrum for H-10α is shown. In (C), H-8 is irradiated whereas in (D), H-7β is irradiated. The protons experiencing the nOe are indicated. In (C), due to the small differences in chemical shift, H-10β was also partially saturated, causing the enhancement to H-10α. In (D), the H-2 and H-12 multiplet was also partially saturated when the irradiation frequency was centered on H-7β.

carbohydrates (25). Very small effects can be measured since a control spectrum without an nOe is subtracted from the spectrum with an nOe. Instrumental instabilities are corrected for by automation of the experiment so that four FID's are collected with on-resonance saturation and then the four FID's corresponding to the control are subtracted. The choice of four is required to keep the amplitude and phase constant in both channels using quadrature detection. This procedure is followed until the required S/N ratio is obtained.

In the present study, the nOe measurements proved invaluable in the assignment of the proton resonances in both solvents, in the determination of chemical shifts, and in the evaluation of the coupling constants. Changes in the conformation of the two five-membered rings with solvent, however, cannot be verified only on the basis of the nOe measurements because of the overlap of certain multiplets. For example, saturation of H-9 in $CDCl_3$ results in an nOe to H-6, H-8, and H-10β but an nOe is not observed to H-11 (Fig. 2B). However, in buffer solution (Fig. 5B), an nOe is observed for H-8, H-10β, and the overlapping H-6 and H-11 multiplets. Due to the overlap of H-6 and H-11, conformational comparisons concerning the involved protons for both solvents cannot be made. The overlap of H-7β and H-10β in $CDCl_3$ means that both of these protons must be simultaneously irradiated and all of the neighboring protons β to the ring (Fig. 3C) (H-6, H-9, and H-11) experience the nOe. No conclusion can be drawn about H-8 which is too close in chemical shift to the point of irradiation. As well, H-8 overlaps H-2 and H-12. On the other hand, in buffer solution, H-10β, H-8β, and H-7β can all be irradiated separately, with the expected results (Figs. 6B–D), but again the overlap of the H-6 and the H-11 multiplets does not allow conclusions to be drawn about different conformations in the two solvents. However, the nOe measurements are invaluable in the assignment of the proton multiplets.

The proton chemical shifts and coupling constants in $CDCl_3$ solutions are presented in Table 1, whereas these data in phosphate buffer are presented in Table 2. All data are calculated to the first order. Measured splittings are reported for the multiplets which are affected by the virtual coupling arising from the overlap of the H-8 and H-12 multiplets in $CDCl_3$ solutions. The assignment of H-7α and H-7β in buffer solution would have been very difficult, if not impossible, to carry out due to the overlap of the H-6 and H-11 multiplets. As the chemical shifts for these protons should not change with solvent, the chemical shift data in $CDCl_3$ allowed the assignments in buffer solution.

A comparison of the coupling constant data in both solvents (Tables 1 and 2) can be made. The value in brackets is observed in phosphate buffer: $J(9—10\alpha) = 2.8$ (4.4) Hz, $J(9—10\beta) = 6.2$ (7.2) Hz, $J(10\alpha—11) = 6.2$ (9.3) Hz, and $J(10\beta—11) = 6.2$ (7.2) Hz. These coupling constants are obtained from multiplets not affected by virtual coupling. As the C-11 OH group moves further away from the (C-8)—(C-9) bond on changing the solvent from $CDCl_3$ to buffer, these coupling constants increase. Hence these data suggest a conformational change in the C-8 to C-12 five membered ring. The C-11 OH group will be further away from the (C-8)—(C-9) bond in buffer solution than in $CDCl_3$ due to solvation of this OH group by the water. Finally, a comparison of the chemical shift data in phosphate buffer (Table 2) with the data obtained for PGI_2 (20) shows that the highest change is for H-7α (1.36 ppm) and for H-7β (2.23 ppm) since for PGI_2 these chemical shifts are 2.38 ppm and 2.65 ppm, respectively. These high-field shifts, in addition to that for H-5, must be due to the saturation of the (C-5)—(C-6) double bond.

In summary, the nOe difference experiments proved invaluable in assigning the multiplets for (6*R*)-PGI_1 in $CDCl_3$ solutions and in phosphate buffer. Problems associated with interpreting nOe results carried out in dried $CDCl_3$, which has a broad OH peak, are discussed. Changing the solvent from $CDCl_3$ to phosphate buffer appears to change the conformation of the C-8 to C-12 five-membered ring. The C-11 OH group is more accessible to the water, since it is further away from the (C-8)—(C-9) bond in phosphate buffer than in $CDCl_3$ solution.

Photocyclisation des (oxo-3)-butyl glycopyranosides

GEORGES REMY, LOUIS COTTIER ET GÉRARD DESCOTES

Laboratoire de Chimie Organique 2, Université de Lyon 1, 69622 Villeurbanne, France

Reçu le 11 avril 1980

Ce papier est dédié au Prof. Raymond U. Lemieux pour son 60ème anniversaire

GEORGES REMY, LOUIS COTTIER et GÉRARD DESCOTES. Can. J. Chem. **58**, 2660 (1980).

La formation d'hydroxyspirocétals par photocyclisation selon Norrish II des (oxo-3)-butyl glycopyranosides est décrite en fonction de la configuration du carbone anomère, de la nature des substituants en position 2 et des conditions opératoires. La photocyclisation privilégiée des glycosides β avec rétention de configuration s'interprète par la stabilité plus grande du radical résultant de l'arrachement de l'hydrogène anomérique axial.

GEORGES REMY, LOUIS COTTIER, and GÉRARD DESCOTES. Can. J. Chem. **58**, 2660 (1980).

3-Oxo butyl glycopyranosides undergo Norrish type II photocyclization giving hydroxyspiroketals. The influence of the anomeric configuration and of different substituents at C-2 has been studied. The favored photocyclization of various β-glycosides occurs with retention of configuration and is interpreted in terms of the greater stability of the radical formed by abstraction of the axial anomeric hydrogen atom.

La photocyclisation d'(oxo-3)-butyl-2 tétrahydropyranne selon une réaction de type Norrish II est une voie de synthèse de spirocétal (1) qui peut être éventuellement envisagée pour la synthèse de produits naturels tels que phéromones (2) et polyéthers antibiotiques ionophores (3).

Cependant, la création photolytique du carbone cétalique avec des hétérocycles oxygénés substitués en C-6 s'effectue sans aucune stéréosélectivité. Aussi, la formation de système spirocétalique en série glucidique a été entreprise en vue de préciser l'influence de la configuration au niveau du carbone anomère et d'étudier celle de la nature des substituants situés sur le carbone C-2.

Synthèse des (oxo-3)-butyl glycosides

Les anomères α **6** et β **4** (oxo-3)-butyl tétra-*O*-acétyl-2,3,4,6-D-glucopyranosides sont obtenus par une réaction de type Koenigs–Knorr de l'hydroxy-4 butanone-2 sur les dérivés halogénés **1** (4) ou **2** (5) avec des rendements respectifs de 24 et 40% (Schéma 1). Les configurations anomériques de **6** et **4** sont attribuées grâce aux déplacements et aux constantes de couplage du proton anomère (**6**: δ 5.09, d, $J_{1,2}$ = 4 Hz; **4** δ 4.73, d, $J_{1,2}$ = 8 Hz).

Si le dérivé chloré **2** permet d'obtenir uniquement 1′(oxo-3)-butyl tri-*O*-acétyl-3,4,6-α-D-glucopyranoside **7** avec un rendement de 24%, la substitution effectuée sur le dérivé bromé **3** conduit préférentiellement selon la nature du catalyseur (6, 7) à l'anomère α **7** ou β **5** (rendement 40% avec 80% d'α et 25% avec 90% de β). La configuration de ces composés désacétylés en C-2 est confirmée par rmn (**7** δ H-1 4.93, d, $J_{1,2}$ = 4 Hz; **5**, δ H-1 4.50, d, $J_{1,2}$ = 8 Hz) et par leur acétylation donnant respectivement les glycosides **6** et **4**.

L'application de la réaction de Ferrier et Prasad (8) au tri-*O*-acétyl-3,4,6-D-glucal utilisant l'hydroxy-4 butanone-2 permet d'obtenir principalement le glycoside insaturé α **8** thermodynamiquement le plus stable (Schéma 1). Un abaissement de température (−10°C) diminue la formation de produits secondaires et augmente à 70% le rendement de la réaction.

L'(oxo-3 butyl)di-*O*-acétyl-4,6 didéoxy-2,3-α-D-*érythro* hexopyranoside **9** est obtenu par hydrogénation catalytique de **8** avec un rendement limité à 66% du fait de réactions d'hydrogénolyse précédemment observées (9, 10) dans des séries voisines.

Photolyse des (oxo-3)-butyl glycosides

La photolyse en solution benzénique des composés précédemment synthétisés conduit selon leurs structures à des spiro C-1 sucres **10**, **11**, **12** et **13** avec des rendements n'excédant pas 45%.

Avec les produits tétraacétylés **6** et **4**, si l'anomère α **6** ne se photolyse que très lentement (100 h), sans donner de produits définis, par contre l'anomère β **4** subit en 40 h une transformation complète en spiroglycoside **10** de configuration β confirmée par étude rmn ^{1}H et ^{13}C (Tableau 1) et par cristallographie (11). En effet, la conformation du cycle tétrahydropyrannique est bloquée à l'état cristallin sous la forme $^{1,4}B$ avec la liaison C—O du cycle tétrahydrofurannique en position "mat" démontrant ainsi la configuration β-D des isomères **10**. Cette conformation se retrouve à l'état dissous du fait de la multiplicité des signaux des protons H-2 et H-3 (doublet de doublet au lieu de triplet pour H-3) et de la valeur des constantes de couplage H-2, H-3 ($J_{2,3}$ = 3 Hz pour **10** *cis* et 2 Hz pour **10** *trans*; $J_{3,4}$ = 8 Hz).

La configuration *cis* ou *trans* au niveau du cycle

SCHÉMA 1

tétrahydrofurannique découle des données rmn que nous avons précédemment signalées en série hétérocyclique (1, 12) ($\Delta\delta$ CH_3 ($\mathbf{6}_t - \mathbf{6}_c$) = 0.26 ppm; $\Delta\delta$ C-1 ($\mathbf{6}_t - \mathbf{6}_c$) = 3.2 ppm; $\Delta\delta$ CH_3 ($\mathbf{6}_t - \mathbf{6}_c$) = −0.2 ppm).

Comme les composés **6** de configuration α, le dérivé triacétylé **7** de même configuration se dégrade très lentement (80 h) en donnant avec un faible rendement (16%) les mêmes spiro C-1 sucres triacétylés **11** que ceux provenant de la photolyse de l'anomère β **5** (Schéma 2). L'acétylation de chacun des isomères des spiro sucres **11** permet de déterminer leur structure car les produits obtenus correspondent respectivement à **10** *cis* et **10** *trans*. La conformation $^{1,4}B$ n'a été confirmée par rmn que pour l'isomère **11** *trans* du fait de la présence du doublet de doublet pour le proton H-3 ($J_{2,3}$ = 4 Hz; $J_{3,4}$ = 8.5 Hz).

Enfin, l'irradiation photochimique du sucre insaturé **8** et du didéoxy-2,3-α-D-hexopyranoside **9** donne au bout de 24 et 48 h, les quatre stéréoisomères **12** et **13** attendus avec des rendements globaux de 26 et 33%. Seule l'isomérie *cis–trans* a été déterminée par rmn. L'hydrogénation catalytique de chacun des isomères de **12** donnant respectivement les isomères saturés **13** correspondant, l'examen du tableau 1 montre que les produits **12***a*, *b* et **13***a*, *b* ont une configuration *cis* (**13** $\Delta\delta CH_3$

SCHÉMA 2

$(\mathbf{13}_t - \mathbf{13}_c) = 0.10$ ppm; $\Delta\delta$C-1 $(\mathbf{13}_t - \mathbf{13}_c) \geq 3$ ppm; $\Delta\delta CH_3$ $(\mathbf{13}_t - \mathbf{13}_c) \geq -0.4$ ppm). On peut noter que la présence de la double liaison de **12** inverse les déplacements chimiques des groupements méthyles carbinoliques qui sont alors plus déblindés pour les isomères **12***a*, *b cis*.

Discussion

En série hétérocyclique oxygénée, diverses observations montrant les différences de réactivité photochimique d'acétals cycliques diastéréoisomères ont déjà été signalées (1, 13). La photolyse d'hydrogène anomérique équatorial parait plus difficile et diverses études de rpe (14*a*) et des calculs théoriques (14*b*) confirment la plus grande stabilité du radical acétalique orientant son orbitale non liée en position axiale dans une structure non plane.

Les résultats obtenus en série osidique confirment de façon beaucoup plus nette ces premières indications. En effet, la présence d'un groupe hydroxyle en C-2 permet aux (oxo-3)-butyl glycosides **7** et **5** de se photocycliser en spiro C-1 sucres **11** de configuration β selon une réaction stéréosélective. En outre, ce même type de photocyclisation devient stéréospécifique pour les seuls anomères β **4** qui présentent un groupe acétate en C-2. La participation du groupe acétate déjà observée lors de la conversion radicalaire d'acétals en lactones (15) peut donc être envisagée lors de la formation des radicaux intermédiaires de type **A** et **B**, ce qui limiterait les processus d'isomérisation de **B** en **A** et entrainerait diverses réactions secondaires. Ainsi, un effet "antianomère" pour le radical intermédiaire permet d'expliquer les différences de réactivité observées pour les photolyses des anomères α et β **6**, **7** et **4**, **5** (Schéma 3).

Avec le glycoside insaturé **8**, la stabilisation du radical allylique intermédiaire par la délocalisation des électrons π de la double liaison entraine vrai-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

semblablement une certaine planéité du radical permettant l'attaque de chaque côté du plan pour donner les quatre stéréoisomères **12** en une photocyclisation non stéréosélective.

Enfin, l'isomérisation du biradical intermédiaire correspondant à la photolyse du composé didéoxy **9** ne doit pas être aussi rapide qu'en série tétrahydropyrannique du fait de la formation des quatre diastéréoisomères **13**.

Conclusion

La photocyclisation d'oxo-3-butyl glycosides entrainant la formation de spiro C-1 sucres est fonction de la configuration du carbone anomère et de la nature des substituants du carbone 2. Un effet "anti anomère" semble favoriser la photocyclisation des glycosides β **4** et **5** par arrachement privilégié de l'hydrogène anomérique axial conduisant intermédiairement au biradical **A** de configuration β thermodynamiquement le plus stable. Une participation du groupe acétate en C-2 permet d'expliquer les différences de vitesse de photolyse entre les composés acétylés **6** et **4** et non acétylés **7** et **5**. Si la présence du groupe hydroxyle en C-2 rend stéréosélective la photocyclisation des anomères α **7** et β **5**, celle du groupe acétate entraine la stéréospécificité de la cyclisation du seul anomère β **5** avec rétention de configuration. L'influence de la configuration du substituant en C-2 est actuellement étudiée en vue de généraliser cette photocyclisation.

Partie expérimentale

Synthèse des (oxo-3)-butyl glycosides

Les points de fusion non corrigés ont été déterminés sur un appareil Buchi. Les spectres ir et rmn ont été tracés à température ambiante avec un Perkin-Elmer 237, un Varian A. 60, A. 100 ou XL 100 et un Bruker WP 80 CW. Les séparations chromatographiques ont été réalisées en faisant passer 0.6 à 5 g de produit brut sur 50 à 150 g de silice (Merck 0.040–0.60 mm) contenus dans une colonne de 50 cm (ϕ 3.5 cm).

*Bromure de tétra-*O*-acétyl-2,3,4,6-α-*D*-glucopyranosyle 1*

Il a été obtenu selon Lemieux (4).

*Chlorure de tri-*O*-acétyl-3,4,6-β-*D*-glucopyranosyle 2*

Il a été obtenu selon Birgl et Keppler (5).

*Bromure de tri-*O*-acétyl-3,4,6-α-*D*-glucopyranosyle 3*

A une solution de dichloro-1,2 éthane saturée par de l'acide bromhydrique gazeux est ajoutée sous forte agitation du tétra-*O*-acétyl-1,3,4,6-α-D-glucopyranoside (0.630 g, 1.73×10^{-3} mol) (16). Au bout de 8 min, le mélange est hydrolysé avec de l'eau glacée puis extrait au chloroforme (3 × 20 mL). Après neutralisation, séchage et évaporation de la phase organique, le produit brut est chromatographié (toluène/acétate d'éthyle: 1:1) donnant 0.450 g de **3** (rendement 71%); rmn ($CDCl_3$) δ: 2.00 à 2.15 (9H, 2s, —C(=O)—CH_3), 2.65 (1H, s, OH), 3.67 (1H, dd, H-2), 3.90 à 4.45 (3H, m, H-5, H-6, H-6'), 5.10 (1H, t, $J_{H-4,H-5}$ = 9 Hz, H-4), 5.33 (1H, t, $J_{H-3,H-4} = J_{H-2,H-3}$ = 9Hz, H-3), 6.48 (1H, d, $J_{H-1,H-2}$ = 4 Hz, H-1).

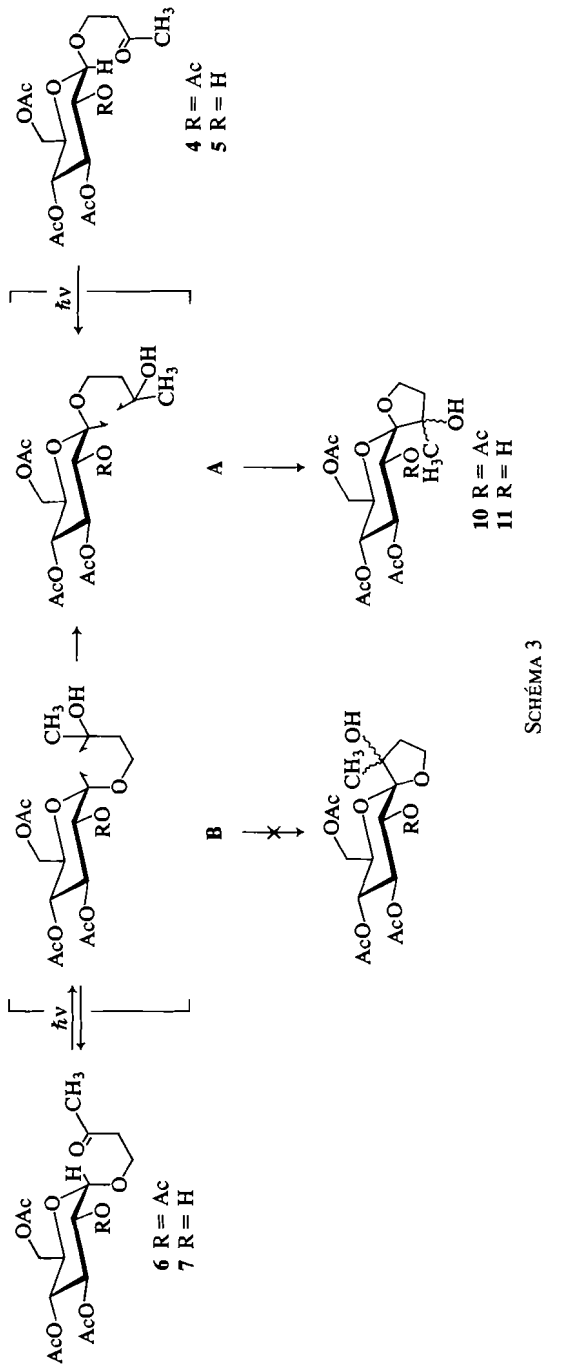

Schéma 3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

Ce composé se dégradant rapidement est utilisé dès son obtention.

*(Oxo-3)-butyl-tétra-*O*-acétyl-2,3,4,6-α-D-glucopyranoside 6*

Le composé **6** a été obtenu soit par isomérisation de l'anomère β **4**, soit par acétylation de **7**.

Isomérisation de **4**. A une solution de **4** (2 g, 4.8 × 10^{-3} mol) dans du dichlorométhane (50 mL) sont ajoutés 2 g de sulfate de calcium puis 1.2 mL (5.6 × 10^{-3} mol) d'une solution de tétrachlorure de titane dans du dichlorométhane. Après 12 h d'agitation, le mélange réactionnel est hydrolysé avec 50 g de glace. Après décantation, lavage, séchage et évaporation de la phase organique le produit résiduel est chromatographié (éther) donnant 550 mg de produit **6** (rendement 28%).

Acétylation de **7**. A la solution froide (0°C) de **7** (100 mg, 0.23 × 10^{-3} mol) dans la pyridine (un millilitre) est ajouté un millilitre d'anhydride acétique. Après deux heures d'agitation à 0°C, le mélange est hydrolysé avec de l'eau (50 mL) puis extrait au chloroforme. Après un lavage acidulé, neutralisation au bicarbonate, décantation et séchage de la phase organique, l'évaporation du solvant laisse un résidu qui, chromatographié (éther), donne 77 mg de **6** (rendement 80%).

Liquide incolore: $[\alpha]_D^1$ 99° (*c* 1.0, $CHCl_3$): ir: 1740 cm^{-1}; rmn 100 MHz (CD_3COCD_3) δ: 1.9 à 2.2 (15H, m, —C(=O)—CH_3), 2.80 (2H, t, *J* = 6.5 Hz, —CH_2—C(=O)—), 3.78 (1H, m, H-5), 3.90 à 4.20 (3H, m, H-6, —O—CH_2—), 4.23 (1H, dd, $J_{H\text{-}6,H\text{-}6'}$ = 5 Hz, $J_{H\text{-}6,H\text{-}5}$ = 12 Hz), 4.78 (1H, dd, H-2), 5.00 (1H, t, $J_{H\text{-}4,H\text{-}5}$ = 9.25 Hz), 5.05 (1H, d, $J_{H\text{-}1,H\text{-}2}$ = 4 Hz, H-1), 5.38 (1H, dd, $J_{H\text{-}3,H\text{-}2}$ = 10 Hz, $J_{H\text{-}3,H\text{-}4}$ = 9.25 Hz, H-3). *Anal.* calc. pour $C_{18}H_{26}O_{11}$: C 51.67, H 6.26; trouvée: C 51.62, H 6.26.

*(Oxo-3)-butyle-tétra-*O*-acétyl-2,3,4,6-β-D-glucopyranoside 4*

Au mélange d'hydroxy-4 butanone-2[1] (7.65 g, 0.087 mol), de cyanure mercureux (7.52 g, 0.03 mol) et de sulfate de calcium (4.08 g, 0.03 mol) dans 80 mL de benzène et 80 mL de nitrométhane est ajouté le bromure **1** (12.3 g, 0.03 mol). Le milieu est porté à 45°C. Lorsque tout le bromure a réagi (ccm, méthanol/éther/dichloro-1,2 éthane 0.5:29.5:70), les produits minéraux sont filtrés et lavés avec du chloroforme. Les phases organiques réunies sont neutralisées avec du bicarbonate de sodium, lavées et séchées. Après évaporation du solvant, le résidu est dilué avec de l'éther (10 mL); puis aprés précipitation au bout de 48 h, la solution éthérée est filtrée donnant 5.11 g de **4** (rendement 43%). Solide; *F* 93°C (litt. (18) *F* 94°C); $[\alpha]_D^1$ − 11.3° (*c* 1.0, $CHCl_3$); ir: 1770 et 1720 cm^{-1}; rmn 100 MHz (CD_3COCD_3) δ: 1.90 à 2.10 (15H, 4s, —C(=O)—CH_3), 2.72 (2H, t, H-8, H-8'), 3.83 (1H, dt, $J_{H\text{-}7,H\text{-}8}$ = 6 Hz, H-7'). 3.95 (1H, ddd, H-5), 4.05 (1H, dt, $J_{H\text{-}7,H\text{-}7'}$ = 10 Hz, $J_{H\text{-}7,H\text{-}8}$ = 6 Hz, H-7), 4.11 (1H, q, $J_{H\text{-}6',H\text{-}5}$ = 2.5 Hz, H-6'), 4.30 (1H, q, $J_{H\text{-}6,H\text{-}6'}$ = 12 Hz, $J_{H\text{-}5,H\text{-}6}$ = 5 Hz, H-6), 4.73 (1H, q, H-1), 4.87 (1H, t, $J_{H\text{-}2,H\text{-}1}$ = 8 Hz, H-2), 5.1 (1H, t, $J_{H\text{-}4,H\text{-}5}$ = 9.5 Hz, H-4), 5.27 (1H, td, $J_{H\text{-}3,H\text{-}1}$ = 1 Hz, $J_{H\text{-}3,H\text{-}4}$ = 9.5 Hz, $J_{H\text{-}3,H\text{-}2}$ = 8 Hz, H-3).

*(Oxo-3)-butyl-tri-*O*-acétyl-3,4,6-α-D-glucopyranoside 7*

Une solution d'hydroxy-4 butanone-2 (5.28 g, 0.96 mol) dans du nitrométhane (25 mL) et du benzène (25 mL) est agitée pendant une heure avec du sulfate de calcium (4 g) et du cyanure mercureux (5 g, 0.06 mol). Après addition du dérivé chloré **2** (6.2 g, 0.019 mol), le mélange est chauffé à 45°C pendant 20 h. Après filtration la phase organique est lavée à l'eau bicarbonatée, séchée, puis évaporée. Le produit brut est chromatographié (éther) donnant 2.68 g de **7** (rendement 36%). Liquide incolore; $[\alpha]_D^{17}$ +1.38° (*c* 1.0, $CHCl_3$); ir: 3450, 1780, 1720 cm^{-1}; rmn (CD_3COCD_3) δ: 1.90 à 2.10 (9H, m, —C(=O)—CH_3), 2.20 (3H, s, —CH_2—C(=O)—CH_3), 2.85 (2H, t, *J* = 7 Hz, —CH_2—C(=O)—), 3.60 à 4.30 (7H, m, H-5, H-6, H-6', H-2, —O—CH_2—, OH), 4.93 (1H, d, $J_{H\text{-}1,H\text{-}2}$ = 4 Hz, H-1), 4.94 (1H, t, $J_{H\text{-}4,H\text{-}5}$ = 9.5 Hz, H-4), 5.23 (1H, t, $J_{H\text{-}3,H\text{-}4}$ = $J_{H\text{-}3,H\text{-}2}$ = 9.5 Hz, H-3). *Anal.* calc. pour $C_{16}H_{24}O_{10}$: C 51.06, H 6.43; trouvée: C 50.83, H 6.53.

Le composé **7** peut être également obtenu à partir du bromure **3** selon les mêmes conditions opératoires qu'avec le dérivé chloré **2**.

*(Oxo-3)-butyl-tri-*O*-acétyl-3,4,6-β-D-glucopyranoside 5*

Le composé a été obtenu selon Reynolds et Evans (7) (rendement 25%). Liquide; $[\alpha]_D^{24}$ +21.5° (*c* 1.0, $CHCl_3$); ir: 3460, 1740 cm^{-1}; rmn 100 MHz (CD_3COCD_3) δ: 1.80 à 2.30 (12H, m, —C(=O)—CH_3), 2.74 (2H, t, *J* = 6 Hz, —CH_2—C(=O)—), 3.40 (1H, d, *J* = 8 Hz, OH), 3.70 à 4.40 (6H, m, H-5, H-6, H-6', H-2, —O—CH_2—), 4.50 (1H, d, $J_{H\text{-}1,H\text{-}2}$ = 8 Hz, H-1), 4.87 (1H, t, $J_{H\text{-}4,H\text{-}5}$ = $J_{H\text{-}3,H\text{-}4}$ = 9.8 Hz, H-4), 5.10 (1H, dd, $J_{H\text{-}3,H\text{-}4}$ = 9.8 Hz, $J_{H\text{-}3,H\text{-}2}$ = 8.5 Hz, H-3). *Anal.* calc. pour $C_{16}H_{24}O_{10}$: C 51.06, H 6.43; trouvée: C 51.44, H 6.47.

*(Oxo-3)-butyl-di-*O*-acétyl-4,6-didéoxy-2,3-α-D-*érythro*-hexeno-2 pyranoside 8*

Dans une solution de dichlorométhane (30 mL) contenant l'hydroxy-4 butanone-2 (0.475 g, 5.4 × 10^{-3} mol) et le sulfate de calcium (200 mg) sont ajoutés à −10°C, le tri-*O*-acétyl-3,4,6-D-glucal (1 g, 3.6 × 10^{-3} mol) et l'éthérate de trifluorure de bore (0.18 mol). Lorsque tout le glucal a réagi (ccm benzène/éther 1:1) la réaction est arrêtée par addition de carbonate de sodium (0.64 g) et d'eau (50 mL). Après filtration, extraction, lavage, séchage et évaporation le produit brut est chromatographié (benzène/éther 1:1) donnant 0.7 g de **8** (rendement: 70%). Huile jaune; $[\alpha]_D^{23}$ +89° (*c* 1.0 $CHCl_3$); ir: 1750 cm^{-1}; rmn ($CDCl_3$) δ: 2.05 à 2.25 (9H, 3s, —C(=O)—CH_3), 2.75 (2H, t, *J* = 6 Hz, —CH_2—C(=O)—), 3.55 à 4.32 (5H, m, H-5, H-6, H-6', —O—CH_2—), 5.05 (1H, s, H-1), 5.30 (1H, d, $J_{H\text{-}4,H\text{-}3}$ = 9 Hz, H-4), 5.83 (2H, s, H-2, H-3). *Anal.* calc. pour $C_{14}H_{20}O_7$: C 55.89, H 6.71; trouvée: C 55.64, H 6.78.

*(Oxo-3)-butyl-di-*O*-acétyl-4,6-didéoxy-2,3-α-D-*érythro*-hexopyranoside 9*

L'hydrogénation de **8** (615 mg) sur charbon palladié (13 mg) dans l'éthanol (20 mL) conduit à un produit brut qui, chromatographié, donne **9** (407 mg, 66%). Liquide incolore: $[\alpha]_D^{23}$ +91° (*c* 1.0, $CHCl_3$); ir: 1740 cm^{-1}; rmn (C_6D_6) δ: 1.4 à 2.9 (13H, m, H-2e, H-2a, H-3e, H-3a, —C(=O)—CH_3), 2.30 (2H, t, *J* = 6 Hz, CH_2—C(=O)—), 3.20 à 4.50 (5H, m, H-5, H-6, H-6', —O—CH_2—), 4.60 (1H, s, H-1). 4.90 (1H, d, $J_{H\text{-}4,H\text{-}5}$ = 8 Hz, H-4). *Anal.* calc. pour $C_{14}H_{22}O_7$: C 55.62, H 7.34; trouvée: C 55.33, H 7.28.

Photolyse des (oxo-3)-butyl glycosides

La photolyse des oxo-3-butyl glycosides a été réalisée selon les conditions opératoires déjà décrites (14) avec un filtre Vycor. La dégradation est suivie par ccm.

Glycoside 4: 10.45 g (25 × 10^{-3} mol) de **4** dans 500 mL de benzène (5 × 10^{-2} mol L^{-1}), sont irradiés pendant 40 h. Après évaporation, le produit brut 10.33 g est chromatographié

[1]Ce cétol nous a été gracieusement donné par la Société BASF que nous remercions vivement.

Resolution of conflicting migratory reports in ring expansion of 3-keto steroids to oxygen and nitrogen[1]

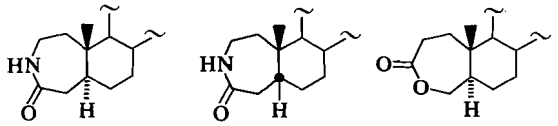
VINOD DAVE, J. B. STOTHERS, AND E. W. WARNHOFF
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 27, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

VINOD DAVE, J. B. STOTHERS, and E. W. WARNHOFF. Can. J. Chem. **58**, 2666 (1980).

The migration of C-2 and/or C-4 to O or N in the Beckmann, Schmidt, and Baeyer–Villiger reactions of 3-keto steroids has been studied with the aid of ^{13}Cmr spectroscopy. Authentic specimens of the eight possible lactone and lactam products from both 5α- and 5β-cholestan-3-one have been prepared; their physical properties and ^{13}Cmr assignments are given. Seven ring expansion reactions reported to give only one product have been found to give both possible migration products. The much studied reactions of 5α-cholestane-3,6-dione and its derivatives have been reexamined. The results emphasize again the necessity of using ^{13}C spectra both as an analytical tool and as the best criterion of purity in work with these molecules.



VINOD DAVE, J. B. STOTHERS et E. W. WARNHOFF. Can. J. Chem. **58**, 2666 (1980).

Faisant appel à la spectroscopie de rmn du ^{13}C et opérant sur des céto-3 stéroides, on a étudié la migration des carbones en positions 2 et/ou 4 vers l'oxygène ou l'azote dans les réactions de Beckmann, de Schmidt et de Baeyer–Villiger. On a préparé des échantillons authentiques des 8 lactones et lactames qui pourraient se produire à partir des 5α et 5β cholestanones-3 et on rapporte leurs propriétés physiques ainsi que leurs caractéristiques spectrales en rmn du ^{13}C. On a trouvé que les 7 réactions d'extension de cycle, qui d'après les publications ne donnent qu'un seul produit, donnent deux produits possibles de migration. On a examiné les réactions les plus étudiées de la 5α-cholestanedione-3,6 et de ses dérivés. Les résultats démontrent à nouveau la nécessité des spectres du ^{13}C comme outil d'analyse et comme critère du pureté dans des travaux portant sur ces molécules.

[Traduit par le journal]

In a thorough examination with the aid of ^{13}Cmr spectroscopy, it was shown recently that a number of ring expansion reactions of the cyclohexanone ring of 3-keto steroids to C, N, or O exhibit no migratory preference for either C-2 or C-4, and that product ratios are essentially 1:1 (1). For the ring expansions to N or O, although some workers have recognized that both products are formed (e.g. 2–9), it was pointed out that there are still a number of unsubstantiated reports of a single product resulting from these reactions (e.g. 10–20). Some of these cases (10, 14, 15, 18, 20) involve variations on the standard Beckmann and Baeyer–Villiger conditions and could conceivably give other than ~1:1 ratios of products for unknown reasons. Certainly the Beckmann rearrangement with 3-keto steroids can yield single products provided that configurationally pure oxime isomers are rearranged under mild nonequilibrating conditions (21, 22). Since these ring expansion reactions are being used in the synthesis of alkaloids (4, 7, 21) and some physiologically active steroids (23–25), as well as to prepare authentic samples for structure proof (10, 16, 26), it is essential to be certain of the structure and purity of any ring expansion products. For this purpose, melting point, tlc, and even ^{1}Hmr spectra are unreliable criteria of purity with these compounds. Therefore, we have used ^{13}Cmr absorption to reexamine some of these reports of single products with the object of reconciling them with our earlier conclusions (1).

To enable analysis of the ^{13}Cmr spectra of reaction products, authentic specimens of the pairs of lactam and lactone ring expansion products of both 5α- and 5β-cholestan-3-one were prepared. One lactone **3***a* and two lactams **1***a* and **2***a* had been

1 **2** **3**

(*b*) Pregnan-20-one
(*c*) 17β-Hydroxyandrostane
(*d*) 17β-Acetoxyandrostane
(*e*) Solasodane

made previously for these studies (1). The three new lactones **4***a*, **5***a*, and **6***a* were prepared by Baeyer–Villiger expansion of the appropriate α-bromo ketones as outlined in Scheme 1, in extension of Bolliger and Courtney's finding that migration of the halogenated carbon in 2α-halo-5α-cholestan-3-ones is suppressed (16). The remaining two lactams **7***a* and **8***a* were prepared by known proce-

The components of each pair are readily identified and analyzed quantitatively by the peaks in bold face type. It is relevant to note here for later reference that the C-19 *proton* signal of each pair has the same chemical shift, and therefore this signal can not be used as a criterion of purity.

The original report of the Beckmann rearrangement of 5α- and 5β-cholestan-3-one oximes by Shoppee and Sly (28) concluded that each reaction gave a single lactam. This claim was revised after Shoppee *et al.* (26) prepared authentic specimens of both 5α-lactams by a different route; it became clear that the 5α Beckmann product was a mixture. We have now confirmed, as Shoppee *et al.* (26) suspected, that the Beckmann rearrangement of 5β-cholestan-3-one also gives both lactams (see Experimental). Concurrently, Doorenbos and Wu (29) had claimed that the Schmidt reaction on 5α- and 5β-cholestan-3-one gave a single lactam in each case, a claim which was discounted by Kobayashi *et al.* (8) and corrected in our earlier paper (1).

In the Beckmann rearrangements described by Shoppee *et al.*, both lactams were to be expected because not only were the *syn*/*anti* isomers not separated,[2] but also the conditions employed may have been vigorous enough to equilibrate the geometrical isomers. However, with the method of Craig and Naik (20), the mild, heterogeneous conditions make expectations less obvious. In this method the oxime of 5α-cholestan-3-one **12***a* (*syn*/*anti* ratio unspecified) was treated with TsCl–pyridine at 0°C, and the resulting sulfonate ester was chromatographed on activity I–II alumina (acid or alkaline). The product was stated to be pure 3-aza-*A*-homo-5α-cholestan-4-one **1***a*. Astonishingly, when this same rearrangement procedure, with substitution of $PhSO_2Cl$ for TsCl, was used by Nace and Watterson (14) on the 3-oxime of 5α-pregnane-3,20-dione **11**, the product obtained in 93% yield was stated to be the opposite rearrangement isomer, pure 4-aza-3-one **7***b* with no evidence in the ^{1}Hmr spectrum (single C-19 ^{1}Hmr peak) of any other product. However, as already pointed out, the appearance of only one C-19 methyl signal in the ^{1}Hmr spectrum is not valid proof of purity with these isomeric ring expansion compounds. This fact together with the improbability of the same reaction on two such closely related compounds giving diametrically opposite results prompted reexamination of both reactions.

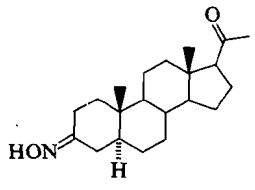
The oxime tosylate of **12***a* and the benzenesulfonate of oxime **11** were prepared according to specifications (14, 20); the ^{1}Hmr spectrum of the oxime tosylate of **12***a* was that of a ~ 1:1 mixture of two isomers. Chromatography of both sulfonates on activity I alumina gave crude lactam products whose ^{13}Cmr spectra revealed that in fact the product of each reaction was a ~1:1 mixture of both possible lactams,[3] thus removing the apparent contradiction between the two reports.

In more recent work (13), it was asserted that a mixture of 5α-cholestan-3-one oximes was isomerized to a single oxime (presumably **13***a*) and precipitated almost quantitatively as the hydrochloride by dry HCl gas in ether. Subsequent Beckmann rearrangement of the liberated oxime by $SOCl_2$ was reported to give the 4-aza-*A*-homo-3-one **7***a*. Since there was no obvious reason why either oxime isomer should be favoured over the other, the work was repeated. In our hands, after regeneration at room temperature from its hydrochloride, the oxime was found by ^{13}Cmr spectroscopy to be a ~2:1 mixture of *syn*/*anti* isomers rather than a single isomer. Beckmann rearrangement of this material as specified (13) gave a ~1:2 mixture of both lactams **1***a* and **7***a* in accordance with stereospecific *anti* migration of the oxime mixture.

The most recent report of a single product from Beckmann rearrangement of 5α-cholestan-3-one oxime is that of Kim *et al.* (10) who used the Ph_3P–CCl_4 reagent. The product which precipitated and was recrystallized was stated to be pure 3-aza-*A*-homo-4-one **1***a*, apparently because the melting point was not depressed by the lactam (mixture) from the Schmidt reaction on 5α-cholestan-3-one, erroneously thought to be pure **1***a*. On repetition of the reaction, we find that there is steroidal material both in the precipitate (together with Ph_3P—O and Ph_3P) and in the filtrate. The steroidal material consists of a lactam portion plus an appreciable amount of dimeric substance, $C_{54}H_{92}N_2$, of uninvestigated structure. The ^{13}Cmr spectra of the lactam fraction in both the precipitate and the filtrate revealed each to be a mixture of the two lactams **1***a* and **7***a*. Hence, all four of these Beckmann reactions discussed above give 1–2:1 mixtures of lactams in agreement with our previous findings (1).

Turning to the Baeyer–Villiger reaction, we note that the reports (16, 19) of 5α-3-ketones **12***a* and **12***c* with CF_3CO_3H giving 4-oxa-*A*-homo-5α-3-ones **3***a*

[2]Although it was claimed that a single oxime was obtained (28), in fact a ~ 1:1 mixture of *syn*/*anti* isomers is formed from 5α-cholestan-3-one under various conditions which we have tried.



[3]The lactone, which Nace and Watterson (14) obtained by treatment of their lactam product with NO_2–pyridine–CCl_4 must also be a mixture of both isomers **3***b* and **4***b* in spite of its single C-19 ^{1}Hmr signal at δ 0.93.

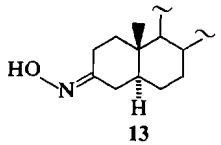
and **3***c* have already been shown to be false; the ^{13}Cmr spectrum of the product from **12***a* shows both lactones **3***a* and **4***a* to be present in ~1:1 ratio (1). Therefore, $LiAlH_4$–$AlCl_3$ reduction of the lactone so prepared must have led to a mixture of cyclic ethers rather than the pure 4-oxa-*A*-homo-5α-cholestane claimed (11).

More subtle is the report (17) that although perbenzoic acid treatment of 17β-acetoxy-5α-androstan-3-one (**12***d*) gave both possible lactones **3***d* and **4***d*, recrystallization of the mixture gave pure 4-oxa-*A*-homo-3-one **3***d*. Repetition of this reaction with *m*-chloroperbenzoic acid under the conditions of Caspi *et al.* (17) gave a ~1:1 mixture of the two lactones **3***d* and **4***d* instead of the 7:3 ratio reported. However, two recrystallizations of this mixture from ethyl acetate did indeed give pure lactone **3***d* as claimed, although the evidence originally presented (17) did not establish this point.



The reported (15) formation of only lactone **3***a* from 5α-cholestan-3-one oxime and CH_3CO_3H–$CHCl_3$ was suspect since the oxime is a mixture of *syn*/*anti* isomers. Not having access to 85% H_2O_2, we were unable to repeat the described experiment, but treatment of the oxime with *m*-ClPBA–$CHCl_3$ gave lactonic material contaminated by two less polar materials (chloronitro steroids?). The ^{13}Cmr spectrum of the product showed it to be mostly a ~1:1 mixture of both lactones **3***a* and **4***a*.

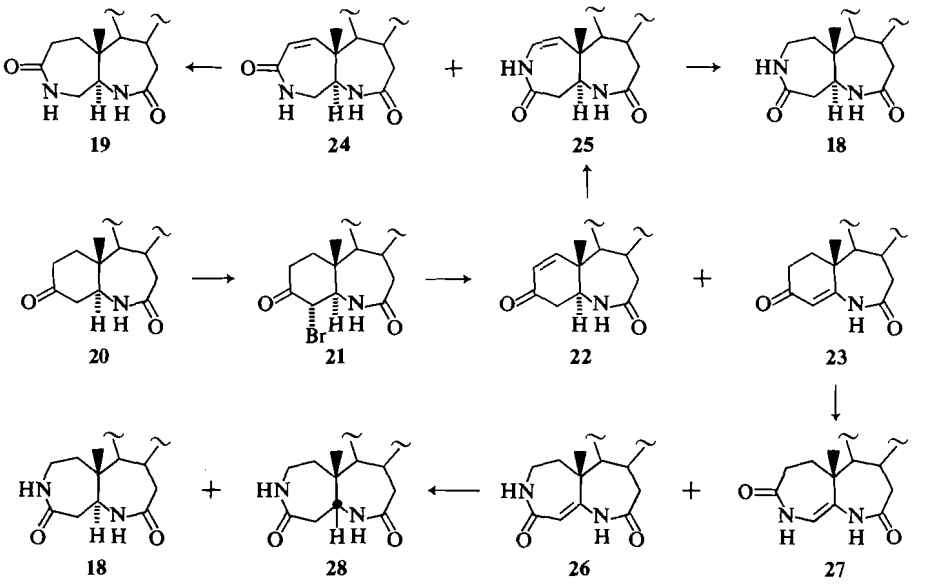
17

Catalytic oxidation of 5α-cholestan-3β-ol with RuO_4–$Pb(OAc)_4$–HOAc was stated to give a lactone which was either **3***a* or **4***a* (18). In our hands, several repetitions of the reaction, both as described and with variations, gave only 5α-cholestan-3-one with no trace of lactone.

The report (12) that steroidal alkaloid derivatives 5α- and 5β-solasodan-3-one **14***f* and **14***g* gave single lactones **3***e* and **5***e* is surprising in view of the fact that the same workers found that the 5α-ketone (and the corresponding Δ^4-unsaturated ketone) gives both possible lactams **1***e* and **7***e* in both the Beckmann and Schmidt reactions (30, 31). Undoubtedly the lactones are actually mixtures of both possible migration products.

The final matter taken up was the ring expansion of 5α-cholestane-3,6-dione **17***a* and its derivatives. Originally it was reported that the Schmidt (32, 33) and Baeyer–Villiger (34, 35) reactions on the 6-oxo group of 3-oxygenated 5α-cholestan-6-one gave a single product **15**. More recently the reactions were actually found to give a mixture of both lactones (36) and both lactams (5) **15** and **16**. In similar manner, the Schmidt reaction on the 3,6-diketone **17***a* was earlier (32) thought to give a single dilactam **18***a*, identical with the lactam from the Schmidt reaction on the 3-oxo-*B*-homo lactam **20***a*. A more recent reexamination (37) of the Schmidt reaction on **20***a* found both dilactams **18***a* and **19***a*. However, specific structural assignments could not be made. Our interest was two-fold: to assign the dilactam structures unambiguously, and to determine the migration ratio for the 3-oxo-*B*-homolactam **20***a* to learn whether the N bonded to C-5 exerts any effect on the migration.

Assignment of the dilactam structures was achieved by separate unequivocal syntheses of each according to Scheme 2. The Schmidt reaction on the lactam Δ^1-enone **22***a* gave both rearrangement products **24***a* and **25***a* which were readily identified from their ^{1}Hmr and ultraviolet spectra.[4] Hydrogenation of **24***a* and **25***a* gave the pure isomeric 5α-lactams **18***a* and **19***a*. However, the amount of **18***a* was small enough that an attempt was made to get more by reduction of **26***a* which was available as one of the products of Beckmann rearrangement of **23***a*. Unfortunately, hydrogenation of **26***a* in the presence of Pt–HOAc or Pd–KOH–MeOH gave ~90% of the 5β-H and only ~10% of 5α-H according to the ^{13}C-19 signals at δ 22.8 and 14.8 ppm. Therefore more **18***a* was eventually obtained by thick layer separation of the



[4]Likewise, the Schmidt reaction on 5α-cholest-4-en-3-one gave both rearrangement products (see Experimental) contrary to an earlier report (50).

product mixture from the Schmidt reaction on **20***a*. The ^{13}Cmr assignments for most of the compounds in Scheme 2 are listed in Table 4. The ^{13}Cmr spectrum of the product of the Schmidt reaction on **20***a* contained a number of ill-resolved signals, and therefore the product ratio **18***a*:**19***a* was determined from the ratio of the ^{13}C-19 methyl peaks only and found to be 55:45. This ratio is so slightly different from 1:1 that the effect of the electron-withdrawing lactam N at C-5 on the migratory aptitude of C-4 in **20***a* is apparently negligible.

In conclusion, most of the reported exceptions to a ~1:1 mixture of migration products in ring expansion of 3-keto steroids are seen to vanish when the reaction products are subjected to ^{13}Cmr analysis. However, in the Beckmann rearrangement, if the usual ~1:1 oxime ratio has been altered by some treatment, and if the rearrangement conditions do not equilibrate the *syn*/*anti* oximes, then the product composition will be determined by the oxime ratio in a stereospecific *anti* migration. Of course, exceptions to an equimolar mixture of products can also be caused by a polar substituent too close to the site of reaction as is apparently the case in the Beckmann rearrangement of **29** (23). If

29 R = a variety of substituents
R¹ = H, alkyl, or acyl

the double bond is absent, both migration products are obtained, but with the double bond present only C-3 is reported to migrate.

Experimental

General

Reagents, instruments, procedures, and ^{13}Cmr operating conditions are the same as in ref. 1. Reaction mixtures were stirred with rotating magnetic bars. The following abbreviations are used in describing ^1Hmr spectra: s singlet, d doublet, t triplet, q quartet, b broad, sp split, and m multiplet.

The following C-19 methyl peak chemical shifts in $CDCl_3$ were observed for the authentic cholestane A-ring lactones and lactams: **1***a* 0.90, **7***a* 0.90, **4***a* 0.93, **3***a* 0.93, **2***a* 0.99, **8***a* 1.00, **6***a* 1.01, and **5***a* 1.02 ppm.

The ^{13}Cmr spectra for the pure compounds are collected in Tables 1, 2, 3, and 4. Most spectra were run with 10–20 mg/0.25 mL, but to avoid line broadening from association, two dilactams were run in more dilute solution ~6 mg/0.4 mL.

[a]In ppm from internal TMS for $CDCl_3$ solutions; similar values in parentheses may be interchanged. The shieldings for C-20 to C-27 are given in footnote *a* to Table 1. The shieldings for C-15 to C-18 are listed in Table 3.

*3-Oxa-*A*-homo-5α-cholestan-4-one (**4a**)*

To a stirred suspension of CF_3CO_3H (prepared from 70 mg of 63% aqueous H_2O_2, 360 mg of $(CF_3CO)_2O$, and 1.5 mL of CH_2Cl_2) and 200 mg of Na_2HPO_4 was added a solution of 200 mg of 4α-bromo-5α-cholestan-3-one (38) in 2 mL of CH_2Cl_2. After 4 h at room temperature, the CH_2Cl_2 was evaporated in a stream of nitrogen. The residue was dissolved in ether, washed with 10% aqueous Na_2CO_3 and water, dried, and concentrated to leave 165 mg of colorless solid 4aα-bromo-3-oxa-*A*-homo-5α-cholestan-4-one; ir($CHCl_3$): 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ:4–5 (m, 2- and 4aβ-H's) ppm; M^+ calcd. for $C_{27}H_{45}{}^{79}BrO_2$:480.2602; found: 480.2600. Since tlc and the ^{13}Cmr spectrum indicated it to be a single compound, it was used without further purification.

To a stirred suspension of $CrCl_2$ in water (prepared from 1.5 g of $CrCl_3 \cdot 6H_2O$, 3.0 g of Zn dust, 2.4 g of $HgCl_2$, 0.8 mL of concentrated HCl, and 6 mL of H_2O) under nitrogen was added a solution of 140 mg of the above bromo lactone in 2 mL of $CHCl_3$ and 4 mL of HOAc. After 12 h most of the solvent was evaporated in a stream of air. The residue was extracted with ether, washed with 10% aqueous Na_2CO_3 and water, dried, and concentrated to leave 105 mg of colorless solid. Chromatography on a 10-g silica gel plate developed in benzene–ether (84:16) afforded 64 mg of solid from a band at R_f 0.41. Recrystallization from ether–MeOH and from $CHCl_3$–MeOH gave 44 mg of colorless plates of pure **3-oxa-5α-lactone 4***a*, mp 179.5–180.5°C with previous sintering, $[\alpha]_D^{25}$ +45.5° (*c* 1.55, $CHCl_3$); ir ($CHCl_3$): 1725 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.93 (C-19 Me), 2.87 (1 H, dd, 4aβ-H), and 4–5 (2 H, m, 2-H's) ppm; M^+ calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3497. *Anal.* calcd. for $C_{27}H_{46}O_2$: C 80.54, H 11.51; found: C 80.62, H 11.29.

*4-Oxa-*A*-homo-5β-cholestan-3-one (**5a**)*

Baeyer–Villiger oxidation of 200 mg of 2β-bromo-5β-cholestan-3-one (39) with CF_3CO_3H as in the preceding experiment gave 190 mg of off-white solid **2β-bromo-4-oxa-A-homo-5β-cholestan-3-one**; ir ($CHCl_3$): 1750 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ:3.99 (1 H, sp d, 4aβ-H), 4.67 (1 H, dd, 4aα-H), and 4.96 (1 H, sp d, 2α-H) ppm; M^+ calcd. for $C_{27}H_{45}{}^{79}BrO_2$: 480.2602; found: 480.2597. Since the tlc and the ^{13}Cmr spectrum indicated it to be almost pure, it was used without further purification.

Chromous chloride reduction of 175 mg of the above bromo lactone was performed as in the preceding experiment. Work-up gave 155 mg of colorless solid which was chromatographed on a 20-g silica gel plate developed in benzene–ether (90:10). A band at R_f 0.40 yielded 96 mg of colorless solid which on two recrystallizations from $CHCl_3$–MeOH gave 77 mg of pure **4-oxa-5β-lactone 5***a*, mp 164–165°C, $[\alpha]_D^{25}$ +48.5° (*c* 1.57, $CHCl_3$); ir ($CHCl_3$): 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ:1.02 (C-19 Me), 3.90 (1 H, dd, 4aβ-H?), and 4.67 (1 H, dd, 4aα-H) ppm; M^+ calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3499. *Anal.* calcd. for $C_{27}H_{46}O_2$: C 80.54, H 11.51; found: C 80.83, H 11.50.

*3-Oxa-*A*-homo-5β-cholestan-4-one (**6a**)*

The Baeyer–Villiger oxidation of 290 mg of 4β-bromo-5β-cholestan-3-one (40) was carried out in 5 mL of $CHCl_3$ with 580 mg of *m*-chloroperbenzoic acid (Aldrich 75%) at room temperature for 4 days. After work-up, the crude product was chromatographed on a column of 10 g of silica gel. Benzene–ether mixtures eluted 160 mg of colorless solid **4aβ-bromo-3-oxa-A-homo-5β-cholestan-4-one**, ir ($CHCl_3$): 1750 (C=O) cm^{-1}, which tlc and ^{13}Cmr absorption indicated was pure enough for direct use; M^+ calcd. for $C_{27}H_{45}{}^{79}BrO_2$: 480.2602; found: 480.2596.

Chromous chloride reduction of 110 mg of the bromo lactone as in the preceding two experiments gave 62 mg of colorless solid. Recrystallization from MeOH gave 30 mg of colorless plates of **3-oxa-5β-lactone 6***a*, mp 164–167°C (capillary), $[\alpha]_D^{20}$ +58° (*c* 1.42, $CHCl_3$); ir ($CHCl_3$): 1730 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.01 (C-19, Me), 3.21 (1 H, t, 4aβ-H?), and 3.9–4.5 (2 H, m, 2-H's) ppm; M^+ calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3495.

4-Aza-A-homo-5α-cholestan-3-one (7a)

5α-Cholest-1-en-3-one was prepared by the method of Green and Long (41) from 200 mg of 2α-bromo-5α-cholestan-3-one, 160 mg of $CaCO_3$, and 7 mL of dimethylacetamide and was purified by thick-layer chromatography on a 20-g silica gel plate developed twice in $CHCl_3$–benzene (90:10). The main uv active band at R_f 0.45 yielded 94 mg of the conjugated ketone. One recrystallization from ether–MeOH gave 72 mg of colorless plates, mp 97–98°C (lit.(41) mp 98°C).

A solution of 215 mg of the Δ^1-enone, 215 mg of $HONH_2 \cdot HCl$, and 215 mg of NaOAc in 2 mL of water and 20 mL of MeOH was refluxed for 1.5 h. After distillation of most of the MeOH, the residue was dissolved in ether, washed with water, and concentrated to give 210 mg of viscous oily **oxime**. Thin-layer chromatography (benzene–ether, 92:8) showed the complete absence of Δ^1-enone and the presence of two overlapping more polar spots.

A solution of the 210 mg of oxime, 210 mg of *p*-TsCl, and 5 mL of dry pyridine was stirred at room temperature for 3 h. After evaporation of the pyridine in a stream of nitrogen, ice was added to the residue. After 15 min, extraction with chloroform yielded the oily **Δ^1-oxime *p*-toluenesulfonate** which was used directly for the Beckmann rearrangement by Oka and Hara's procedure (2).

A mixture of the oxime tosylate from above and 0.2 mL of concentrated aqueous HCl in 20 mL of MeOH was refluxed with stirring. Within 0.5 h all solid had dissolved. At the end of 2 h most of the MeOH was distilled, and the residue was neutralized with aqueous NaOH. The product was extracted with $CHCl_3$, washed with water, dried, and concentrated to leave 205 mg of off-white solid. Chromatography on two 20-g silica gel plates developed in EtOAc–MeOH (95:5) afforded 115 mg of solid from the band at R_f 0.31. One recrystallization from $CHCl_3$–MeOH gave 82 mg of colorless needles of **4-aza-A-homo-5α-cholest-1-en-3-one** (**9***a*), mp 224–226°C (lit.(8) mp 232°C), $[\alpha]_D^{8.5}$ +32.8° (*c* 1.51, $CHCl_3$); uv (MeOH): 213 (13 000) nm; ir ($CHCl_3$):3420 (NH), 1650 (C=O), and 1610 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ:1.00 (C-19 Me), 2.67 (1 H, q, 4aα-H), 3.36 (1 H, dq, 4aβ-H), 5.73 (1 H, sp d, 2-H), 6.31 (1 H, d, 1-H), and 7.03 (1 H, bd, NH) ppm; M^+ calcd. for $C_{27}H_{45}NO$: 399.3501; found: 399.3502.

A solution of 45 mg of unsaturated lactam **9** in 12 mL of MeOH was hydrogenated at atmospheric pressure and room temperature in the presence of 15 mg of 10% Pd/C catalyst. The crude reduction product was recrystallized twice from MeOH to give 24 mg of colorless granules of the **4-aza-5α-lactam** **7***a*, mp 265–280°C (dec.), mp 270–276°C (dec. sealed capillary), $[\alpha]_D^{19.5}$ +2.7° (*c* 1.52, $CHCl_3$);[5] ir ($CHCl_3$): 3430 (NH) and 1655 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.90 (C-19 Me), 3.1–3.6 (1 H?, bb, 4aβH), and 6.52 (1 H, bs, NH) ppm; M^+ calcd. for $C_{27}H_{47}NO$: 401.3658; found: 401.3659.

4-Aza-A-homo-5β-cholestan-3-one (8a)

The procedure of Clinton *et al.* (42) was used to prepare **2-hydroxymethylene-5β-cholestan-3-one** from 2.0 g of 5β-cholestan-3-one, 2.3 g of HCOOEt, and 562 mg of NaOMe in 27 mL of dry benzene. The crude hydroxymethylene ketone obtained from the Na salt amounted to 1.4 g of colorless solid, mp 80–85°C (lit.(42) mp 90–100°C), which was free of starting ketone and was used without further purification; ir ($CHCl_3$): 1650 (conj. C=O) and 1595 (conj. C=C) cm^{-1}; M^+ calcd. for $C_{28}H_{46}O_2$: 414.3497; found: 414.3497.

The method of Shimizu *et al.* (43) was adapted. A solution of 1.4 g of the above hydroxymethylene ketone, 840 mg of dichlorodicyano quinone and 20 mL of benzene was stirred and refluxed for 1 h. The precipitated solid was filtered and washed with benzene. The filtrate was washed with basified (KOH) aqueous $Na_2S_2O_4$ and water, dried, and concentrated to leave 900 mg of off-white oily solid **unsaturated keto aldehyde**; ir ($CHCl_3$): 1685 (center of fine-structured C=O) and 1610 (conj. C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 7.53 (1 H, s, 1-H) and 10.0 (1 H, s, CH=O) ppm; M^+ calcd. for $C_{28}H_{44}O_2$: 412.3341; found 412.3342. The product, which gave a single tlc spot, was used without further purification.

With ref. 43 as guide, a mixture of 900 mg of the above unsaturated aldehyde, 2.2 g of tris(triphenylphosphine)chlororhodium(I), and 25 mL of benzene was stirred and refluxed under nitrogen for 4 h. The solid in the cooled reaction mixture was removed by filtration and washed with benzene. The filtrate was concentrated, dissolved in CCl_4, and chromatographed on a column of 40 g of neutral alumina (activity IV). Hexanes–benzene mixtures eluted 700 mg of colorless solid **5β-cholest-1-en-3-one**. A sample recrystallized from ether–MeOH gave colorless plates, mp 105–105.5°C (lit. (39) mp 106.5°C), $[\alpha]_D^{20.5}$+154° (*c* 0.93, $CHCl_3$) (lit.(8) $[\alpha]_D$ +107°); ir ($CHCl_3$): 1670 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 (C-19 Me), 2.79 (1 H, dd, 4β-H), 5.90 (1 H, d, *J* = 10 Hz, 2-H), and 6.85 (1 H, d, *J* = 10 Hz, 1-H) ppm; M^+ calcd. for $C_{27}H_{44}O$: 384.3392; found: 384.3391.

A solution of 275 mg of 5β-cholest-1-en-3-one, 275 mg of $HONH_2 \cdot HCl$, and 275 mg of NaOAc in 3 mL of water and 3 mL of MeOH was refluxed for 2 h. After distillation of the MeOH, the residue was dissolved in ether, washed with water, dried, and concentrated to leave 270 mg of colorless solid oxime, ir ($CHCl_3$): 3580 and 3280 (OH) cm^{-1}, no C=O absorption; M^+ calcd. for $C_{27}H_{45}NO$: 399.3501; found: 399.3499. Thin-layer chromatography (benzene–ether, 95:5) revealed the complete absence of starting ketone and the presence of two overlapping more polar spots.

A mixture of 270 mg of the above oxime, 270 mg of *p*-TsCl, and 6 mL of dry pyridine was stirred at room temperature for 3 h. After removal of most of the pyridine in a stream of nitrogen, the residue was dissolved in $CHCl_3$, washed with water, dried, and concentrated to leave the oily **oxime tosylate**; ir ($CHCl_3$): 1380 and 1180 (sulfonate) cm^{-1}, no OH absorption; ^{1}Hmr ($CDCl_3$) δ: 2.40 and 2.46 (two s, $ArCH_3$ of *syn* and *anti* isomers), 5.86 (1 H, d, *J* = 10 Hz, 2-H), and 6.23 (1 H, d, *J* = 10 Hz, 1-H) ppm, the aromatic H peaks were also doubled because of *syn–anti* isomers; M^+ calcd. for $C_{34}H_{51}NO_3S$: 553.3589; found: 553.3592.

The crude tosylate from above was stirred and refluxed for 2.5 h with 0.7 mL of concentrated aqueous HCl in 40 mL of MeOH. Within 0.5 h all solid had dissolved. After distillation of most of the MeOH, the residue was dissolved in $CHCl_3$, washed with water, dried, and concentrated to leave 245 mg of off-white solid. Two recrystallizations from $CHCl_3$–MeOH gave 140 mg of colorless needles of **4-aza-A-homo-5β-cholest-1-en-3-one** (**10***a*), mp 185–198°C (dec.), $[\alpha]_D^{21}$ +118° (*c* 1.44, $CHCl_3$); uv (MeOH): 213 (13 000) nm; ir ($CHCl_3$): 3410 (NH) 1660 (C=O), and 1610 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.12 (C-19 Me), 2.85 (1 H, dd, 4aα-H), 3.66 (1 H,m, 4aβ-H), 5.72 (1 H, bd, *J* = 13 Hz, 2-H), 6.25 (1 H, d, *J* = 13 Hz, 1-H), and 6.74 (1 H, bm, NH) ppm; M^+ calcd. for $C_{27}H_{45}NO$: 399.3501; found: 399.3502.

A solution of 70 mg of the unsaturated lactam **10** in 35 mL of MeOH was hydrogenated at atmospheric pressure and room temperature in the presence of 30 mg of 10% Pd/C catalyst for 1 h. Two recrystallizations of the reduction product from $CHCl_3$–MeOH gave 60 mg of colorless needles of the **4-aza-5β-lactam** **8***a*, mp 188–190°C, $[\alpha]_D^{21}$ +29.7° (*c* 1.52, $CHCl_3$) (lit. (26) mp 195°C, $[\alpha]_D$ +21°)[6]; ir($CHCl_3$): 3410 (NH) and 1660 (C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (C-19 Me), 2.72 (1 H, bq, 4aα-H), 3.80 (1 H, m, 4aβ-H), and 6.41 (1 H, bm, NH) ppm; M^+ calcd. for $C_{27}H_{47}NO$: 401.3658; found: 401.3659.

[5] There is no evidence that the compound reported in ref. 26 to be lactam **7***a*, mp 295°C, $[\alpha]_D$ −8°, was a pure compound.

[6] It is by no means clear that the lactam described in ref. 26 was a pure compound.

Beckmann Rearrangements

(*a*) The procedure of Craig and Naik (20) was followed. To a solution of 150 mg of 5α-cholestan-3-one oxime in 1.5 mL of dry pyridine at 0°C was added 95 mg of *p*-TsCl. After 0.5 h the pyridine was evaporated at 0.1 Torr and room temperature. The residual solid was chromatographed on a 3-g column of Woelm neutral alumina (activity I) packed in benzene. After elution of 6 mg of recovered oxime with benzene–ether mixtures, further elution with benzene–ether (50:50) and EtOAc–MeOH (60:40) afforded 110 mg (73%) of colorless crystalline lactam giving a single tlc spot (EtOAc–MeOH, 95:5). The ^{13}Cmr spectrum showed the presence of both **1***a* and **7***a*. Comparison of peak heights for the following pairs of signals: 54.1 vs. 53.9 (C-9), 43.3 vs. 49.5 (C-5), 38.8 vs. 38.7 (C-10), and 21.3 vs. 21.0 (C-11) ppm revealed a composition slightly richer in **1***a* with a ratio of **1***a*:**7***a* of ~52:48.

(*b*) The 3-monoxime **11** of 5α-pregnane-3,20-dione was prepared according to the directions of Nace and Waterson (14) and then rearranged under both sets of conditions used by these authors; ir ($CHCl_3$): 3580 and 3280 (NOH) and 1705 (C=O) cm^{-1}. The ^{13}Cmr spectrum ($CDCl_3$–DMSO-d_6) showed the presence of both *syn* and *anti* oximes. For a sample recrystallized four times, comparison of peak heights at 46.3 (C-5 of OH *syn* to C-2) and 45.3 (C-5 of OH *anti* to C-2) ppm revealed a *syn*/*anti* ratio of ~43:57.

(*i*) *Benzenesulfonate–Alumina*

To a solution of 62 mg of the monoxime in 1 mL of dry pyridine at 0°C was added a solution of 42 mg of $PhSO_2Cl$ in 0.5 mL of dry pyridine. After 0.5 h, during which the reaction mixture was allowed to warm to room temperature, there was no oxime left (tlc). Solvent was evaporated at 0.1 Torr and room temperature, and the residual colorless solid[7] was chromatographed on a 2.8-g column of Woelm neutral alumina (activity I). Elution with ether and with EtOAc–MeOH (88:12) gave 49 mg (79%) of colorless crystalline lactam (single tlc spot), mp 250–268°C (dec.) with a phase change at 230°C (lit.(14) mp 275–277°C (dec.)); ir ($CHCl_3$): 3420 (NH), 1700 (C=O), and 1660 (N—C=O) cm^{-1}. The mass spectrum indicated about 8% of an impurity corresponding in mass to bis lactam. The ^{13}Cmr spectrum showed the presence of both **1***b* and **7***b*. Comparison of peak heights for the following pairs of signals: 53.8 vs. 53.6 (C-9), 43.1 vs 49.7 (C-5), and 21.2 vs. 21.0 (C-11) ppm , revealed a composition slightly richer in **1***b* with a ratio of **1***b*:**7***b* of ~53:47.

Four recrystallizations of this material from MeOH–CH_2Cl_2 removed the bis lactam and gave 22 mg of colorless granules, mp 278–281°C (with subl. and dec. on the hot stage), mp 260–265°C (dec. in a sealed capillary), (lit. (14) mp 275–277°C (dec.)); M^+ calcd. for $C_{21}H_{33}NO_2$: 331.2511; found: 331.2511.

Comparison of the same sets of peaks in the ^{13}Cmr spectrum showed no change in the **1***b*:**7***b* ratio.

(*ii*) *Thionyl Chloride–Dioxane*

To a stirred solution of 259 mg of monoxime in 30 mL of dry dioxane cooled in an ice bath was added a solution of 2.3 mL of distilled $SOCl_2$ in 6 mL of dry dioxane during 7 min. The reaction was allowed to warm slowly to room temperature over an hour. After addition of water and NH_4OH, the product was extracted with CH_2Cl_2 to yield 218 mg (84%) of off-white solid. Aside from ~8% of starting oxime, tlc (benzene–ether–HOAc, 75:22:3) showed only one spot corresponding to the more polar lactam. Two recrystallizations from MeOH gave 115 mg of crystals of very wide mp 218–280°C which was chromatographed on a 3.5-g column of silica gel. Elution with benzene, benzene–ether, and ether–EtOAc (50:50) gave 17 mg of recovered oxime. Further elution with ether–EtOAc to EtOAc–MeOH (80:20) afforded 70 mg of colorless solid lactam. One recrystallization from CH_2Cl_2–MeOH gave 55 mg of granules, mp 260–295°C (dec. on the hot stage), mp 268–285°C (dec. in a sealed capillary) (lit (14) mp 270–276°C); ir ($CHCl_3$): same as in (*i*); M^+ calcd. for $C_{21}H_{33}NO_2$: 331.2511; found: 331.2511.

The ^{13}Cmr spectrum showed the presence of both **1***b* and **7***b*. Comparison of peak heights for the following pairs of signals: 53.8 vs. 53.6 (C-9), 43.1 vs. 49.4 (C-5), and 21.2 vs. 21.0 (C-11) ppm, revealed a composition richer in **7***b* with a ratio of **1***b*:**7***b* of ~40:60.

(*c*) The procedure of Ogura *et al.* (13) was repeated. A mixture of 1.0 g of 5α-cholestan-3-one, 1.0 g of $HONH_2$·HCl, 1.0 g of NaOAc, 5 mL of water, and 50 mL of MeOH was stirred and refluxed for 3 h. Distillation of MeOH, addition of water, and filtration gave 950 mg (91%) of colorless oxime, mp 192–198°C (lit.(44) mp 199°C).

The ^{13}Cmr spectrum showed the presence of both *syn* (OH and C-2) and *anti* (OH and C-2) oximes. Comparison of peak heights for the following pairs of signals: 46.4 (*syn*) vs. 45.3 (*anti* C-5), 37.2 (*syn*) vs. 38.4 (*anti* C-1), and 34.4 (*syn*) vs. 27.3 (*anti* C-4) ppm, revealed a composition slightly richer in the *anti* isomer with a *syn*/*anti* ratio of ~47:53.

Dry HCl gas was bubbled into a solution of 500 mg of the above oxime in 20 mL of ether. After 0.5 h the precipitated solid was filtered, triturated with aqueous $NaHCO_3$, and extracted with ether. Concentration of the dried ether solution at room temperature left 430 mg of colorless oxime, mp 195–198°C with a phase change at ~175°C (lit.(13) mp 195–196°C).

The ^{13}Cmr spectrum showed the presence of both *syn* (OH and C-2) and *anti* (OH and C-2) oximes. Comparison of peak heights for the following pairs of signals: 46.4 (*syn*) vs. 45.3 (*anti* C-5), 37.2 (*syn*) vs. 38.4 (*anti* C-1), and 34.4 (*syn*) vs. 27.3 (*anti* C-4) ppm, revealed a composition richer in the *syn* isomer with a *syn*/*anti* ratio of ~65:35.

To a solution of 100 mg of the above regenerated oxime in 2.5 mL of dry dioxane at 40°C was added 0.3 mL of redistilled $SOCl_2$. After 10 min at 40°C, the reaction mixture was basified with aqueous $NaHCO_3$ and extracted with $CHCl_3$. Evaporation of the dried $CHCl_3$ solution left 93 mg (93%) of semi-solid lactam which gave a single tlc spot more polar than the starting oxime.

The ^{13}Cmr spectrum showed the presence of both **1***a* and **7***a*. Comparison of peak heights for the following pairs of signals: 54.1 vs. 53.8 (C-9), 43.3 vs. 49.5 (C-5), 38.8 vs. 38.6 (C-10), and 21.1 vs. 21.0 (C-11) ppm, revealed a composition richer in **7***a* with a **1***a*:**7***a* ratio of 35:65 in agreement with stereospecific *anti* rearrangement for the oxime mixture used.

(*d*) The procedure of Kim *et al.* (10) was followed for both oxime preparation and rearrangement. The oxime so prepared was a 50:50 mixture of *syn* and *anti* isomers from comparison of the C-5 ^{13}Cmr signals at 46.5 (*syn*) and 45.3 ppm (*anti*). A solution of 500 mg of 5α-cholestan-3-one oxime and 630 mg of triphenylphosphine in 12 mL of CCl_4 was refluxed for 5 h. After cooling in ice, the reaction mixture was filtered. The gummy solid (~500 mg), containing Ph_3P and Ph_3PO as well as steroidal product, was chromatographed on ten 20-g preparative plates developed thrice in benzene–EtOAc–MeOH (85:5:10). The band (I_2) at R_f 0.67 gave 41 mg of off-white lactam.

The ^{13}Cmr spectrum showed the presence of both **1***a* and **7***a*. Comparison of peak heights for the following pairs of signals: 54.1 vs. 53.9 (C-9), 43.3 vs. 49.5 (C-5), 38.8 vs. 38.7 (C-10), and 21.3 vs. 21.0 (C-11) ppm, revealed a composition slightly richer in **1***a* with a ratio of **1***a*:**7***a* of ~55:45.

The band at R_f 0.33 gave 85 mg of a colorless solid. Two recrystallizations from $CHCl_3$–MeOH afforded 25 mg of granules of dimeric steroid, mp 295–305°C (dec.); ir: 1650 cm^{-1}; *m*/*e*:768.7, $C_{54}H_{94}N_2$ requires 768.7.

[7]The crude oxime tosylate was reported to be a red oil in ref. 14.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

Since most of the steroidal material had remained in the filtrate, a portion of the evaporated filtrate was chromatographed on a 20-g silica gel plate as described above. The lactam isolated in this way was also subjected to ^{13}Cmr analysis which showed the presence of both **1***a* and **7***a*. Comparison of peak heights for the following pairs of signals: 54.1 vs. 53.9 (C-9), 43.3 vs. 49.5 (C-5), 38.8 vs. 38.7 (C-10), and 21.3 vs. 21.0 (C-11) ppm, revealed a composition slightly richer in **7***a* with a ratio of **1***a*:**7***a* of ~45:55.

(*e*) A mixture of 115 mg of 5β-cholestan-3-one, 115 mg of $HONH_2 \cdot HCl$, 115 mg of NaOAc, 3 drops of water, and 4 mL of MeOH was stirred and refluxed for 6 h. The MeOH was distilled and the residue partitioned between water and ether to yield 108 mg of oxime, mp 65–70°C; ir ($CHCl_3$): 3580 and 3300 (OH) cm^{-1}, no C=O absorption. Thin-layer chromatography (benzene–ether, 90:10) showed a single spot more polar than starting ketone.

The procedure of Shoppee and Sly (28) was used for the Beckmann rearrangement. To a solution of the 108 mg of oxime in 4 mL of dry dioxane at 40°C was added 0.23 mL of distilled $SOCl_2$ during 20 s. The solution became yellow and then brown. After 20 min the reaction was quenched by addition of aqueous $NaHCO_3$. Extraction with $CHCl_3$ yielded 97 mg of viscous brown oil. Thick layer chromatography on a 20-g silica gel plate (EtOAc–MeOH, 94:6) to remove a small amount of 5β-cholestan-3-one and colored material afforded, from the band at R_f 0.5, 47 mg of colorless oily solid lactam; ir ($CHCl_3$): 3420 (NH) and 1655 (amide C=O) cm^{-1}; M^+ calcd. for $C_{27}H_{47}NO$: 401.3658; found: 401.3655.

The ^{13}Cmr spectrum showed the presence of both **2***a* and **8***a*. Comparison of peak heights for the following pairs of signals: 43.0 vs. 45.5 (C-5), 26.0 vs. 27.0 (C-6), and 21.3 vs. 20.9 (C-11) ppm, revealed a composition slightly richer in **2***a* with a ratio of **2***a*:**8***a* of ~53:47.

Baeyer–Villiger Rearrangements

(*a*) The rearrangement of 17β-acetoxy-5α-androstan-3-one was carried out according to the directions of Caspi *et al.* (17) except that *m*-chloroperbenzoic acid was substituted for perbenzoic acid. A solution of 150 mg of the steroid and 250 mg of *m*-ClPBA (Aldrich 75%) in 5 mL of $CHCl_3$ was allowed to stand at 0°C for 6 days. Thin-layer chromatography (benzene–ether, 75:25) showed the absence of starting material and the presence of a single more polar spot. The solution was diluted with $CHCl_3$ and washed successively with aqueous Na_2SO_3, aqueous $NaHCO_3$, and water. Evaporation of the dried solution left 150 mg (95%) of colorless solid lactone.

The ^{13}Cmr spectrum showed the presence of both **3***d* and **4***d*. Comparison of peak heights for the following pairs of signals: 64.6 (C-2 of **4***d*) vs. 69.9 (C-4a of **3***d*), 53.7 vs. 53.5 (C-9), and 43.3 vs. 48.5 (C-5) ppm, revealed a composition slightly richer in **3***d* with a ratio of **3***d*:**4***d* of ~55:45.

Two recrystallizations from EtOAc furnished 58 mg of colorless plates, mp 250–252°C (with subl. on the hot stage), mp 235–245°C (in a sealed capillary) (lit. (17) mp 240–242°C); ir ($CHCl_3$): 1730 (lactone + acetate C=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.78 (C-18 Me), 0.94 (C-19 Me), 2.03 (CH_3C=O), 3.67 (1 H, d, J = 13 Hz, 4aαH), 4.29 (1 H, dd, J = 13, 8 Hz, 4aβ-H), and 4.59 (1 H, dd, 17α-H) ppm; M^+ calcd. for $C_{21}H_{32}O_4$: 348.2300; found; 348.2300; ^{13}Cmr analysis revealed this material to be pure **3***d* (see Table 2).

(*b*) The procedure of Bull *et al.* (15) was followed except that *m*-ClPBA was substituted for peracetic acid. To a refluxing solution of 1.10 g of *m*-ClPBA (Aldrich, 75%) in 5 mL of $CHCl_3$ was added a solution of 250 mg of 5α-cholestan-3-one oxime in 2 mL of $CHCl_3$. The reaction mixture immediately turned blue, and by the end of 1 h it was colorless. The cooled solution was washed with aqueous Na_2SO_3, aqueous $NaHCO_3$, and water. Evaporation of the dried solution left 320 mg of a colorless oil. Analysis by tlc (benzene–ether, 90:10) showed the absence of oxime and the presence of a major spot less polar than oxime together with two even less polar spots (chloronitro steroids?). The product was chromatographed on two 20-g preparative plates developed in benzene–ether (85:15). The band at R_f 0.46 (I_2 detection) gave 82 mg of colorless solid lactone; ir ($CHCl_3$): 1725 (lactone C=O) cm^{-1}; M^+ calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3499.

The ^{13}Cmr spectrum showed the presence of both **3***a* and **4***a*. Comparison of peak heights for the following pairs of signals: 70.0 (C-4a of **3***a*) vs. 64.7 (C-2 of **4***a*), 53.6 vs 53.8 (C-9), 48.5 vs. 43.4 (C-5), and 21.1 vs. 21.3 (C-11) ppm, revealed a composition slightly richer in **3***a* with a ratio of **3***a*:**4***a* of ~56:44.

(*c*) When the RuO_4-catalyzed oxidation of 75 mg of 5α-cholestan-3β-ol was carried out at 40°C according to procedure (*b*) of Nakata (18) with 750 mg of $Pb(OAc)_4$, 0.29 mL of 0.056 M RuO_4 in CCl_4, and 7.5 mL of HOAc, there was isolated 60 mg of crude product which did not contain any lactone **3***b* or **4***b* by tlc comparison with authentic specimens. Recrystallization from ether–MeOH gave 48 mg of 5α-cholestan-3-one. When the reaction was done with 2 drops of concentrated H_2SO_4 added, or when the reaction was run in refluxing HOAc, the only product was still 5α-cholestan-3-one. When the reaction was done with double addition of RuO_4 and $Pb(OAc)_4$, 2α-acetoxy-5α-cholestan-3-one was isolated in addition to 5α-cholestan-3-one.

Reactions Related to the Schmidt Reaction on 5α-Cholestane-3,6-dione

*6-Aza-*B*-homo-5α-cholestane-3,7-dione (20a)*

The oxime was prepared from 250 mg of 3β-acetoxy-5α-cholestan-6-one (46–48) by reflux with 250 mg of $HONH_2 \cdot HCl$ and 250 mg of NaOAc in 20 mL of MeOH. To a solution of 264 mg of the oxime in 5 mL of dioxane at 10°C was added 0.3 mL of distilled $SOCl_2$. The bath was allowed to warm to room temperature during 0.5 h. Addition of concentrated NH_4OH and extraction with $CHCl_3$ yielded 233 mg of semi-solid **6-aza-*B*-homo-3β-acetoxy-5α-cholestan-7-one**. This crude product was saponified by reflux with KOH–MeOH to give 163 mg of 3β-hydroxylactam. A solution of 163 mg of the alcohol in 6 mL of HOAc was oxidized at room temperature with a solution of 65 mg of CrO_3 in 0.5 mL of water. Dilution with water and ether extraction gave the crude keto lactam which was chromatographed on a 20-g silica gel plate developed in EtOAc. Extraction of the band at R_f 0.44 gave 73 mg of colorless 6-aza-*B*-homo-5α-cholestane-3,7-dione (**20***a*), mp 231–234°C (lit.(47) mp 236–237°C), $[\alpha]_D^{22}$ +13.5° (*c* 1.36, $CHCl_3$); ir ($CHCl_3$): 3400 (NH), 1720 (C=O), and 1660 (NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.06 (C-19 Me), 3.66 (1 H, m, 5α-H), and 6.56 (1 H, bd, NH) ppm; M^+ calcd. for $C_{27}H_{45}NO_2$: 415.3450; found: 415.3452.

*6-Aza-*B*-homocholest-4-ene-3,7-dione (23a) and 6-Aza-*B*-homo-5α-cholest-1-ene-3,7-dione (22a)*

The bromination of **20***a* was carried out with a modification of the procedure of Singh *et al.* (45). To a stirred solution of 375 mg (0.90 mmol) of keto lactam **20***a* in 3 mL of HOAc was added 280 mg (0.88 mmol) of $Py \cdot HBr \cdot Br_2$ during 5 min. All solid dissolved within 10 min, and the orange solution was kept at room temperature for 30 min. The reaction mixture was diluted with water and extracted with ether. The dried organic layer was evaporated and the residual oily **4α-bromo ketone 21***a* was used directly for dehydrobromination, ir ($CHCl_3$): 3380 (NH), 1740 (C=O), and 1670 (NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 4.65 (1 H, d, J = 11 Hz, 4β-H) ppm.

A mixture of the above crude **21***a*, 375 mg of $CaCO_3$, and 6 mL of dimethylacetamide was stirred and refluxed for 1.5 h. After distillation of the solvent *in vacuo*, the residual solid was tritu-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

rated with $CHCl_3$ and filtered. The amber colored concentrated filtrate was chromatographed on two 20-g silica gel plates developed in EtOAc.

The band at R_f 0.59 gave 177 mg (47%) of **6-aza-*B*-homocholest-4-ene-3,7-dione** (**23*a***). Two recrystallizations of 50 mg from MeOH afforded 18 mg of colorless granules, mp 178–180°C with previous sintering, $[\alpha]_D^{0.5}$ +377° (*c* 1.30, $CHCl_3$); uv (MeOH): 275 (12 000) nm; ir ($CHCl_3$): 3380 (NH), 1660 (C=O, NC=O), and 1610 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.18 (C-19 Me), 5.73 (1 H, s, 4-H), and 8.11 (1 H, bs, NH) ppm; M^+ calcd. for $C_{27}H_{43}NO_2$: 413.3293; found 413.3292.

The band at R_f 0.36 from the above plates gave 105 mg of colorless oily solid which was rechromatographed on a 20-g silica gel plate developed twice in ether–MeOH (96:4). A band at R_f 0.45 gave 46 mg (12%) of recovered keto amide **20*a***. A band at R_f 0.59 gave 50 mg (13%) of **6-aza-*B*-homo-5α-cholest-1-ene-3,7-dione** (**22*a***). Two recrystallizations from MeOH gave colorless plates, mp 216.5–218.5°C, $[\alpha]_D^{22}$ +77° (*c* 0.93, $CHCl_3$); uv (MeOH): 225 (13 000) nm; ir ($CHCl_3$): 3400 (NH) and 1670 (conj. C=O + NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.07 (C-19 Me), 3.95 (1 H, bdd, 5α-H), 5.92 (1 H, d, J = 10 Hz, 2-H), 7.00 (1 H, bs, NH), and 7.00 (1 H, d, J = 10 Hz, 1-H) ppm; M^+ calcd. for $C_{27}H_{43}NO_2$: 413.3293; found: 413.3290.

If the original bromination was carried out with 1.5 mmol of **20*a*** and 1.6 mmol of Py·HBr·Br_2, and if **20*a*** was added to Py·HBr·Br_2, the Δ^1-keto lactam **22*a*** was not isolated. Instead, the minor product was **6-aza-*B*-homocholest-1,4-diene-3,7-dione** (**30*a***), mp 237–240°C from EtOAc, $[\alpha]_D^{21}$ +526° (*c* 1.47, $CHCl_3$); uv (MeOH): 243 (15 100) and 286 (7130) nm; ir ($CHCl_3$): 3380 (NH), 1660 (conj. C=O, NC=O), 1625 and 1600 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.33 (C-19 Me), 6.02 (1 H, d, J = 1 Hz, 4-H), 6.20 (1 H, dd, J = 1, 10 Hz, 2-H), 7.04 (1 H, d, J = 10 Hz, 1-H), and 9.14 (1 H, s, NH) ppm; M^+ calcd. for $C_{27}H_{41}NO_2$: 411.3137; found: 411.3133.

*Schmidt Reaction on 6-Aza-*B*-homo-5α-cholest-1-ene-3,7-dione (22*a*)*

To a stirred mixture of 50 mg of **22*a***, 5 mL of $CHCl_3$, and 0.2 mL of concentrated H_2SO_4 at 5°C was added 70 mg of powdered NaN_3 during 5 min. The bath was allowed to warm to room temperature while the mixture was stirred for 1 h. After neutralization of the acid with aqueous NaOH, the mixture was diluted with $CHCl_3$ and washed with water. Evaporation of the dried $CHCl_3$ solution left 44 mg of oily solid which was chromatographed on a 10-g silica gel plate developed in EtOAc–MeOH (88:12).

From the band at R_f 0.62 was extracted 6 mg of **3,6-diaza-*A*-homo-*B*-homo-5α-cholest-1-ene-4,7-dione** (**25*a***), mp 280–290°C (dec.); uv (MeOH): 226 (8300) nm; ir ($CHCl_3$): 3400 (NH), 1690 and 1665 (2 NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 50°C) δ: 1.25 (C-19 Me), 2.88 (1 H, dd, 4aα-H), 3.98 (1 H, bt, 5α-H), 5.06 (1 H, d, J = 11 Hz, 1-H), 5.77 (1 H, dd, J = 5, 11 Hz, 2-H), 6.11 (1 H, bd, J = 5 Hz, 3-NH), and 7.21 (1 H, bs, 6-NH) ppm; ^{13}Cmr (CD_3COOD) δ: 12.2 (C-18), 16.6 (C-9), 47.3 (C-10), 58.7 (C-5), 120.5 (C-2), and 125.3 (C-1) ppm; M^+ calcd. for $C_{27}H_{44}N_2O_2$: 428.3402; found: 428.3400.

From the band at R_f 0.24 was extracted 17 mg of colorless solid which after one recrystallization each from EtOAc and EtOAc–MeOH gave 11 mg of granules of **4,6-diaza-*A*-homo-*B*-homo-5α-cholest-1-ene-3,7-dione** (**24*a***), mp 278–290°C (dec.), $[\alpha]_D^{22}$ +37° (*c* 0.84, $CHCl_3$); uv (MeOH): rising end absorption only ε_{205} 15 000; ir ($CHCl_3$): 3400 and 3200 (NH), 1660 (2 NC=O), and 1620 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (C-19 Me), 3–4 (3 H, m, 4aH's, 5α-H), 5.78 (1 H, d, J = 13 Hz, 2-H), 6.33 (1 H, d, J = 13 Hz, 1-H), and 7.56 (2 H, m, 2 NH) ppm; M^+ calcd. for $C_{27}H_{44}N_2O_2$: 428.3402; found: 428.3400.

*3,6-Diaza-*A*-homo-*B*-homo-5α-cholestane-4,7-dione (18*a*)*

A solution of 6 mg of Δ^1-dilactam **25*a*** in 1.5 mL of HOAc was hydrogenated in the presence of 3 mg of PtO_2. Filtration and evaporation left a colorless solid, saturated dilactam **18*a***; M^+ calcd. for $C_{27}H_{46}N_2O_2$: 430.3559; found: 430.3559. The ^{13}Cmr spectrum was identical with that of the less polar dilactam of the Schmidt reaction on keto lactam **20*a***.

*4,6-Diaza-*A*-homo-*B*-homo-5α-cholestane-3,7-dione (19*a*)*

A solution of 17 mg of the unsaturated dilactam **24*a*** in 3 mL of MeOH was hydrogenated in the presence of 10 mg of 10% Pd/C catalyst. Filtration and evaporation left 17 mg of colorless solid. Recrystallization from MeOH gave 6 mg of granules of the saturated dilactam **19*a***, mp 295–305°C (dec.) (lit.(37) mp > 300°C. (dec.)); ir ($CHCl_3$): 3400 (NH) and 1652 (NC=O) cm^{-1}; M^+ calcd. for $C_{27}H_{46}N_2O_2$: 430.3559; found: 430.3559. Thin layer comparison showed this compound to have the same R_f as the more polar dilactam from the Schmidt reaction on **20*a***.

*Beckmann Rearrangement of 6-Aza-*B*-homocholest-4-ene-3,7-dione (23*a*)*

A mixture of 167 mg of **23*a***, 167 mg of $HONH_2$·HCl, 167 mg of NaOAc, and 7 mL of MeOH was refluxed for 4 h. Distillation of MeOH, addition of water, and extraction with ether gave 170 mg of semi-solid oxime. A solution of the oxime and 170 mg of *p*-TsCl in 5 mL of dry pyridine was allowed to stand at room temperature for 1.5 h. After evaporation of the pyridine in a stream of nitrogen, the residue was dissolved in benzene and chromatographed on a column of 8 g of Woelm neutral alumina (grade I). Elution with benzene to benzene–ether (50:50) gave 53 mg of oxime tosylate. Elution with EtOAc gave 111 mg of unsaturated dilactams contaminated with oxime. The 53 mg of recovered oxime tosylate was rechromatographed on 3.8 g of the same alumina. EtOAc eluted 40 mg of unsaturated dilactam which was combined with the 111 mg. Thick-layer chromatography on three 20-g silica gel plates developed thrice in EtOAc–MeOH (90:10) gave three bands. The band at the solvent front gave 72 mg of recovered oxime on extraction.

Extraction of the band at R_f 0.73 yielded 38 mg of colorless **4,6-diaza-*A*-homo-*B*-homocholest-4a-ene-3,7-dione** (**27*a***). Two recrystallizations from MeOH gave 25 mg of granules, mp 265–285°C (dec. on the hot stage), mp 258–290° (dec. in a sealed capillary) (lit.(49) mp 290–296° (dec.)), $[\alpha]_D^{21}$ +111° (*c* 1.05, $CHCl_3$); uv (MeOH): 254 (12 800) nm; ir ($CHCl_3$): 3400 (NH) and 1660 (NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.09 (C-19 Me), 5.95 (1 H, bd, J = 7 Hz, 4a-H), 7.86 (1 H, bs, NH), and 8.09 (1 H, bd, J = 7 Hz, NH) ppm; M^+ calcd. for $C_{27}H_{44}N_2O_2$: 428.3402; found: 428.3400.

Extraction of the third band at R_f 0.49 afforded 32 mg of colorless **3,6-diaza-*A*-homo-*B*-homocholest-4a-ene-4,7-dione** (**26*a***). Recrystallization from $CHCl_3$–MeOH gave 21 mg of plates, mp 285–305°C (dec. range), $[\alpha]_D^{21}$ +123° (*c* 1.04, $CHCl_3$); uv (MeOH): 240 (11 600) nm; ir ($CHCl_3$): 3420 and 3395 (NH), 1655 (NC=O), and 1610 (C=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.20 (C-19 Me), 3.25 (2 H, m, 2-H's), 5.83 (1 H, s, 4a-H), 7.41 (1 H, bs, NH), and 8.30 (1 H, bs, NH) ppm; M^+ calcd. for $C_{27}H_{44}N_2O_2$: 428.3402; found: 428.3400.

*3,6-Diaza-*A*-homo-*B*-homo-5β-cholestane-4,7-dione (28*a*)*

(*a*) *Pd/C–MeOH–KOH*: A mixture of 10 mg of 10% Pd/C catalyst, 10 mg of KOH, and 1 mL of MeOH was saturated with hydrogen for 0.5 h. A solution of 10 mg of Δ^{4a}-dilactam **26*a*** in 2.5 mL of MeOH was added and hydrogenated for 24 h.[8] Filtration and evaporation left a residue which was dissolved in $CHCl_3$ and washed with water. Evaporation of the dried solution left 8 mg of colorless solid saturated dilactam, *m/e*: 430; $C_{27}H_{46}N_2O_4$ requires 430. The ^{13}Cmr spectrum revealed that the product was ~90% of the 5β-isomer.

(*b*) *PtO_2–HOAc*: A mixture of 5 mg of PtO_2 and 0.5 mL of

[8]The isomeric Δ^{4a}-dilactam **27*a*** did not absorb hydrogen under either of these sets of conditions.

HOAc was saturated with hydrogen for 45 min. A solution of 10 mg of Δ^{4a}-dilactam **26***a* in 1.5 mL of HOAc was added and hydrogenated for 8 h.[8] Filtration and concentration left 10 mg of saturated dilactam. Thin-layer chromatography in EtOAc–MeOH (88:12) showed a single spot more polar than **26***a*; *m/e*: 430; $C_{27}H_{46}N_2O_4$ requires 430. The ^{13}Cmr revealed that the product was ~90% of the 5β-isomer.

*Schmidt Reaction on 6-Aza-*B*-homo-5α-cholestane-3,7-dione (20a)*

The keto lactam **20***a* (50 mg) was dissolved in 1.5 g of polyphosphoric acid with the aid of heating at 85°C for 0.5 h. Then 100 mg of NaN_3 was added, and the reaction mixture was kept at 85°C for 15 h with occasional stirring. Ice was added, and the acid was neutralized with KOH pellets. Extraction with $CHCl_3$ yielded 36 mg of oily solid. Chromatography on a 10-g silica gel plate developed in EtOAc–MeOH (80:20) afforded 26 mg of bis lactam product from the band at R_f 0.29; ir ($CHCl_3$): 3400 and 3220 (NH), and 1660 (NC=O) cm^{-1}; *m/e*: 430.

The ^{13}Cmr spectrum showed the presence of both **18***a* and **19***a*, but the only well-resolved signals were those of ^{13}C-19 at 14.8 (**18***a*) and 14.3 (**19***a*) ppm. Comparison of peak heights gave a ratio of **18***a*:**19***a* of ~55:45.

For separation of the isomers, a larger scale reaction was run. To a stirred mixture of 100 mg of **20***a*, 10 mL of $CHCl_3$, and 0.4 mL of concentrated H_2SO_4 at 5°C was added 150 mg of NaN_3 during 10 min. The cooling bath was allowed to warm to room temperature, and the reaction mixture was stirred for 1.5 h. Work-up gave 100 mg of colorless solid. Analytical tlc in $CHCl_3$–MeOH–EtOAc (75:12.5:12.5, four developments) revealed the absence of **20***a* and the presence of two more polar spots, R_f 0.50 and 0.38, in a ~1:1 ratio. The crude product was chromatographed on four 20-g preparative plates developed four times in the same solvent system.

Extraction of the band at R_f 0.45 (I_2 detection) gave 39 mg of colorless solid. Recrystallization from MeOH afforded pure 3-aza dilactam **18***a*, mp 280–285°C (dec.) (lit.(37) mp 283°C (dec.)); ir ($CHCl_3$): 3400 (NH) and 1660 (NC=O) cm^{-1}; ^{1}Hmr ($CDCl_3$, 50°C) δ: 0.90 (C-19 Me), 2.9–3.3 (2H, m, 2-H's), 3.7–3.9 (1H, m, 5α-H), 5.99 (1H, d, NH), and 6.53 (1H, bs, NH) ppm; M^+ calcd. for $C_{27}H_{46}N_2O_2$: 430.3559; found: 430.3559. The ^{13}Cmr spectrum was identical with that of the sample made by hydrogenation of **25***a*.

Extraction of the band at R_f 0.41 (I_2 detection) yielded 34 mg of colorless solid. Recrystallization from MeOH gave pure 4-aza dilactam **19***a* identical with the sample from hydrogenation of **24***a*.

Schmidt Reaction on Cholest-4-en-3-one

To a well-stirred mixture of 500 mg of cholest-4-en-3-one and 5.0 g of polyphosphoric acid at 70°C was added 100 mg of NaN_3. The reaction mixture was stirred occasionally with a spatula during the next 5 h. A second portion of 100 mg of NaN_3 was added, and the reaction was continued for 12 h more. Ice was added and the acid neutralized with KOH pellets. Extraction with $CHCl_3$ yielded 425 mg of oily solid. Since tlc indicated some unreacted starting material, the crude product was recycled as described above to afford 365 mg of oily solid free of starting ketone. Chromatography on two 20-g preparative silica gel plates developed in EtOAc–ether (75:25) separated two bands (uv detection).

Extraction of the band at R_f 0.73 gave 30 mg of solid. Two recrystallizations from benzene–acetone gave 19 mg of colorless granules of **4-aza-A-homocholest-4a-en-3-one**, mp 235–239°C with a phase change at 195°C, $[\alpha]_D^{20}$ −12.3° (*c* 1.50, $CHCl_3$) (lit.(8) mp 236°C, $[\alpha]_D$ −11.5°); uv(MeOH): 244 (11 600) nm; ir ($CHCl_3$): 3400 (NH), 1670 and 1655 (O=CNC=C) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.09 (C-19 Me), 5.52 (1H, d, J = 6 Hz, 4a-H), and 6.96 (1H, bd, NH) ppm; M^+ calcd. for $C_{27}H_{45}NO$: 399.3501; found: 399.3499.

Extraction of the band at R_f 0.29 yielded 160 mg of off-white solid. One recrystallization from benzene–acetone gave 102 mg of colorless granules of **3-aza-A-homocholest-4a-en-4-one** identical with the specimen prepared by Beckmann rearrangement of the oxime of cholest-4-en-3-one reported earlier (1).

Chlorosulphation of amino sugars: synthesis of methyl 2-acetamido-4-amino-2,4,6-trideoxy-β-D-glucopyranoside (bacillosamine) from a D-glucosamine derivative[1]

DAVID R. BUNDLE AND STAFFAN JOSEPHSON[2]

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received June 16, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

DAVID R. BUNDLE and STAFFAN JOSEPHSON. Can. J. Chem. **58**, 2679 (1980).

Chlorosulphation of methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside **3** under controlled conditions provided either methyl 6-chloro-2,6-dideoxy-2-phthalimido-β-D-glucopyranoside **4** or methyl 4,6-dichloro-2,4,6-trideoxy-2-phthalimido-β-D-galactopyranoside **5**. Chlorination at C-4 occurs to the exclusion of that at C-3, in sharp contrast to the chlorosulphation of methyl β-D-glucopyranoside which is known to give both the 4,6-dichloro-*galacto*- and 3,6-dichloro-*allo*-pyranosides. Conversion of the chlorinated phthalimido derivatives **4** and **5** to the corresponding 2-acetamido-2-deoxyhexopyranosides **6** and **7** permitted reduction of the chloro functions by palladium, W-4 Raney nickel, and nickel boride. Reduction of methyl 2-acetamido-6-chloro-2,6-dideoxy-β-D-glucopyranoside **6** by Raney nickel gave methyl 2-acetamido-2,6-dideoxy-β-D-glucopyranoside **8**. Selective dechlorination at C-4 was achieved by palladium catalysed reduction of methyl 2-acetamido-4,6-dichloro-2,4,6-trideoxy-β-D-galactopyranoside **7**. Nickel boride or Raney nickel reduction of **7** effected selective dechlorination at C-6 to give methyl 2-acetamido-4-chloro-2,4,6-trideoxy-β-D-galactopyranoside **9**. Azide displacement of the 4-chloro group of **9** provided a simple route to the 2,4-diamino sugar bacillosamine. A side product of the azide displacement reaction was the unsaturated sugar, methyl 2-acetamido-2,4,6-trideoxy-α-L-*threo*-hex-4-enopyranoside, **14**.

DAVID R. BUNDLE et STAFFAN JOSEPHSON. Can. J. Chem. **58**, 2679 (1980).

La chlorosulfuration du déoxy-2 phtalimido-2 β-D-glucopyrannoside de méthyle **3** dans des conditions contrôlées conduit soit au chloro-6 didéoxy-2,6 phtalimido-2 β-D-glucopyrannoside de méthyle **4** soit au dichloro-4,6 tridéoxy-2,4,6 phtalimido-2 β-D-galactopyrannoside de méthyle **5**. La chloration a lieu en position C-4 à l'exclusion de celle en C-3; ceci contraste nettement avec la chlorosulfuration du β-D-glucopyrannoside de méthyle qui, comme on le sait, conduit aux dichloro-4,6 *galacto* et dichloro-3,6 *allo* pyrannosides de méthyle. La transformation des dérivés phtalimido chlorés en acétamido-2 déoxy-2 hexopyrannosides correspondants permet la réduction subséquente de fonctions chlorées par le palladium, le nickel de Raney W-4 et le borure de nickel. La réduction de l'acétamido-2 chloro-6 didéoxy-2,6 β-D-glucopyrannoside de méthyle **6** par le nickel de Raney donne l'acétamido-2 didéoxy-2,6 β-D-glucopyrannoside de méthyle **8**. La déchloration sélective en position C-4 se fait grâce à la réduction, catalysée par le palladium, de l'acétamido-2 dichloro-4,6 tridéoxy-2,4,6 β-D-galactopyrannoside de méthyle **7**. La réduction du composé **7** par le borure de nickel ou le nickel de Raney enlève sélectivement le chlore au niveau du carbone en position 6 et conduit à l'acétamido-2 chloro-4 tridéoxy-2,4,6 β-D-galactopyrannoside de méthyle **9**. Le déplacement du chlore en position 4 du composé **9** par l'azoture fournit une voie d'accès simple à la bacillosamine un sucre diaminé en 2,4. On obtient comme produit secondaire de cette réaction de déplacement par l'azoture le sucre insaturé, acétamido-2 tridéoxy-2,4,6 α-L-*thréo* hexèno-4 pyrannoside de méthyle **14**.

[Traduit par le journal]

Introduction

Chlorosulphation of neutral sugars has provided a rapid and efficient procedure for synthesis of chloro-deoxy pentoses, hexoses, and their glycosides (1–3). Furthermore, certain hexopyranoside chlorosulphates undergo displacement by nucleophiles such as bromide and azide (4, 5). Reduction (6–9), substitution, and elimination (7) reactions performed on chloro-deoxy sugars have provided ready access to modified pyranosides and furanosides. Despite the ease and synthetic flexibility of the chlorosulphation reaction, it has not previously been applied to amino-sugars. Whereas 2-acetamido-2-deoxy-D-glucopyranose reacts with sulphuryl chloride under standard conditions (1) to yield a black tar, we have shown that 2-deoxy-2-phthalimido-D-glucose yields 6-chloro-2,6-dideoxy-2-phthalimido-α-D-glucopyranosyl chloride 3,4-bischlorosulphate.[3]

Encouraged by this observation and prompted by the need for a sample of the diamino sugar, 2-acetamido-4-amino-2,4,6-trideoxy-D-glucopyranose, we have investigated the chlorosulphation of methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside, with the intention of exploiting the resultant chloro-deoxy derivatives for the introduction of new functionalities (cf. refs. 4–9).

Results and Discussion

Methyl tri-*O*-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (**2**) was prepared from tri-*O*-acetyl-2-deoxy-2-phthalimido-αβ-D-glucopyranosyl bromides (**1**) (10) by reaction with methanol in benzene solution utilizing mercuric cyanide (11) as the promoter. Transesterification (cf. ref. 12) of the triacetate **2** by sodium methoxide provided crys-

5 $R^1 = OH, R^2 = H, R^3 = Cl, R^4 = CH_2Cl$

talline methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (**3**) in ~65% yield from tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromide (**1**). Chlorosulphation of glycoside **3** using 3.5 molar equivalents of sulphuryl chloride for 4 hours at −20° to −10°C provided the chlorosulphated 6-chloro-6-deoxy glycoside. Dechlorosulphation yielded the crystalline methyl 6-chloro-2,6-dideoxy-2-phthalimido-β-D-glucopyranoside **4** in 70% yield from **3**. When chlorosulphation of the methyl glycoside **3** was performed with 7.7 molar equivalents of sulphuryl chloride and allowed to reach 20°C an optimum 59% yield of methyl 4,6-dichloro-2,4,6-trideoxy-2-phthalimido-β-D-galactopyranoside (**5**) was obtained after dechlorosulphation. The preparation of **5** could also be achieved by refluxing the crude methyl 6-chloro-2,6-dideoxy-2-phthalimido-β-D-glucopyranoside-3,4-bischlorosulphate with tetraethylammonium chloride in chloroform solution. The exclusive formation in either case of 4,6-dichloro-galactopyranoside **5** may be contrasted with the reaction between sulphuryl chloride and methyl β-D-glucopyranoside (13). In this case both the 4,6-dichloro-*galacto*- and 3,6-dichloro-*allo*-pyranosides were formed. Methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside **3** undergoes the usual (1, 2) displacement at C-6 at temperatures above −30°C and above 0°C a slower displacement with inversion occurs at C-4 but not C-3, leading to the 4,6-dichloro-galactopyranoside **5**. Extended reaction times and the use of undistilled, technical grade sulphuryl chloride result in reduced yields of the 4,6-dichloro-derivative **5**. The absence of detectable quantities of a 3,6-dichloro-*allo*-pyranoside from the reaction products probably relates to the stereochemistry of the C-2 phthalimido function. This argument is based on the fact that the plane of the phthalimido ring systems is perpendicular (10) to the mean plane of the pyranose ring. In this position the carbonyl disposed toward the α-face of the pyranose ring would render unfavourable the transition state leading to a 3-chloro-*allo*-pyranoside derivative.

The object of this work was to use chlorosulphation as a route to the diamino-sugar, 2-acetamido-4-amino-2,4,6-trideoxy-D-glucose. Although previously synthesized (14), this sugar was required as the glycoside, methyl 2-acetamido-4-amino-2,4,6-trideoxy-β-D-glucopyranoside (**15**), to facilitate comparison of ^{13}C and ^1H nmr parameters with those of the 2,4-diamino-6-deoxyhexose identified as a component of pneumococcal C substance (15, 16). As the derivative (**15**), the synthesis may be envisaged as starting from methyl 4,6-dichloro-2,4,6-trideoxy-2-phthalimido-β-D-galactopyranoside (**5**) and proceeding by selective dechlorination at C-6 with W-4 Raney nickel (6, 7, 9). When the phthalimido derivatives **4** and **5** were subjected to these conditions, reduction of the aromatic ring occurred to the exclusion of dechlorination at C-6. Conversion of the phthalimido compounds **4** and **5** to their acetamido analogues **6** and **7** gave derivatives amenable to smooth catalytic reduction.

Methyl 2-acetamido-6-chloro-2,6-dideoxy-β-D-glucopyranoside (**6**) was reduced to the 6-deoxy glucoside **8** (quinovosamine) in 71% yield. Similar conditions, freshly prepared W-4 Raney nickel and triethylamine in ethanol solution, selectively dechlorinated the 4,6-dichloro-galactoside (**7**) to methyl 2-acetamido-4-chloro-2,4,6-trideoxy-β-D-galactopyranoside (**9**) in 80% yield. In repeated experiments nickel boride (17) was found to be a more convenient catalyst for this reduction of **7** to **9**. The ease with which nickel boride is prepared coupled with reproducible selectivity for dechlorination at C-6 indicate this to be the catalyst of choice in this case. No 4,6-dideoxy-*xylo*-hexopyranoside or 4-

deoxy-6-chloro-*xylo*-hexopyranoside **10** were detected in crude hydrogenation mixtures by ^{13}C nmr. However, when **7** was hydrogenated over palladium on charcoal in the presence of sodium hydroxide, dechlorination at C-4 was observed together with some reduction at C-6. The ratio of the two products **10** and **9** was ~4:1. This observation was surprising in view of the fact that chloro-deoxy sugars are usually unreactive to palladium catalysed reduction. One notable exception is the palladium catalysed reduction of methyl 4-*O*-benzoyl-3-bromo-2,6-dichloro-2,3,6-trideoxy-α-D-mannopyranoside to methyl 4-*O*-benzoyl-6-chloro-2,3,6-trideoxy-α-D-*erythro* hexopyranoside, where activation of the 2-chloro group to reduction has been attributed to the presence of a bromo substituent (18). In this case and the conversion of **7** to **10** the chloro substituents were both axial. Selective dechlorination by nickel catalysts at C-6 was expected based on earlier findings (9) but the stereospecificity is in marked contrast to the results with neutral hexosides (7). In this regard Raney nickel dechlorination of the neutral hexoside, methyl 4,6-dichloro-4,6-dideoxy-β-D-galactopyranoside, yields methyl 6-chloro-4,6-dideoxy-β-D-*xylo*-hexopyranoside in addition to the preponderant product, methyl 4-chloro-4,6-dideoxy-β-D-galactopyranoside (9). Chlorosulphation in conjunction with nickel catalysed selective dechlorination, therefore, provides the crucial derivative **9**, for the synthesis of bacillosamine, in three steps from methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (**3**).

Methyl 2-acetamido-6-chloro-2,6-dideoxy-β-D-glucopyranoside (**6**) was converted to the crystalline 6-azido derivative **11** from which methyl 2-acetamido-6-amino-2,6-dideoxy-β-D-glucopyranoside **12** was obtained in 77% yield. Since both displacement and reduction steps were achieved in high yield a similar reaction sequence was envisaged for the preparation of bacillosamine methyl glycoside **15** from the 4-chloro derivative **9**. In this way a second inversion at C-4 restores the *gluco*-configuration to the pyranose ring (cf. ref. 7). Displacement of the 4-chloro function by azide was expected to provide methyl 2-acetamido-4-azido-2,4,6-trideoxy-β-D-hexopyranoside (**13**). However, when **9** was heated with potassium azide in DMF (dried over molecular sieve) at 120°C no reaction occurred and at 150°C extensive decomposition was observed. Crown ethers have been shown (4, 5) to effectively promote difficult nucleophilic substitutions on the pyranose ring. Reaction of the 4-chloro derivative **9** with potassium azide and 18-crown-6 in DMF at 150°C gave a 1:2 mixture of the desired product **13** and methyl 2-acetamido-2,4,6-trideoxy-β-L-*threo*-hex-4-enopyranoside (**14**). If the solvent, DMF, was first rigorously dried (by distillation from calcium hydride at reduced pressure) the reaction of **9** proceeded in similar fashion but the ratio of products **13** and **14** increased to 2:1. Despite rigorous drying of DMF and the use of activated molecular sieve the proportion of elimination product **14** could not be reduced below 30%, a reflection of the stereochemistry of the 4-chloro derivative, **9**. The optimized yield of **13** from **9** was 59%. By conducting the reaction of **9** with a weak nucleophile such as sodium benzoate a quantitative yield of the 4,5 unsaturated sugar **14** may be secured. A related product, the 6-azido derivative **17** was obtained when methyl 2-acetamido-4,6-dichloro-2,4,6-trideoxy-β-D-galactopyranoside (**7**) was reacted with azide (cf. ref. 7). Reduction of the 4-azido glucoside **13** yielded the desired product, methyl 2-acetamido-4-amino-2,4,6-trideoxy-β-D-glucopyranoside, **15**. Satisfactory elemental analyses were not obtained for this compound despite ^{13}C and ^{1}H nmr indications of high purity. The di-*N*-acetyl derivative was analytically pure, although the substitution pattern of this compound is not pertinent to the native state.

The glycal-like compounds **14** and **17** are interesting compounds for further manipulation but in this paper we report only the reduction of the 6-deoxy derivative **14**. Compound **17** gave multiple products on reduction but the unsaturated sugar **14** was reduced by palladium and hydrogen to a single product which was acetylated to give methyl 3-*O*-acetyl-2,4,6-trideoxy-β-D-*xylo*-hexopyranoside (**16**). The specificity of the hydrogenation reaction was somewhat surprising and in view of this the arguments based upon nmr, which lead to the conclusion that **16** is the product of reduction, are discussed. Reduction of **14** followed by acetylation could be expected to provide both C-5 epimers, methyl 2-acetamido-3-*O*-acetyl-2,4,6-trideoxy-α-L-*arabino*-hexopyranoside and the D-*xylo*-hexopyranoside **16**. However, ^{13}C nmr of the reaction product indicated the presence of one hexoside and in addition, ^{1}H nmr evidence is consistent only with the formation of the *xylo*-hexopyranoside **16**. Methyl 2-acetamido-3-*O*-acetyl-2,4,6-trideoxy-α-L-*arabino*-hexopyranoside could potentially exist in solution as either the $^{4}C_{1}$(L) or $^{1}C_{4}$(L) chair con-

14 $R^1 = OH, R^2 = CH_3$
17 $R^1 = OH, R^2 = CH_2N_3$

For personal use only.

formation. The 400 MHz ^{1}H nmr evidence for reduced **14** includes a large (8.3 Hz) $J_{1,2}$ coupling constant. This excludes the $^1C_4$(L) chair conformation immediately. However, the $^4C_1$(L) conformation requires both $J_{4a,5}$ and $J_{4e,5}$ to have small (< 4–5 Hz) couplings, and since the axial H-4 resonance is a multiplet with large (~10 Hz) coupling constants the data are consistent only with the assigned structure, **16**.

Until very recently the occurrence of 2,4-diamino sugars has been limited to a small number of polysaccharides (15, 16, 19, 20). Extensive synthetic work has provided numerous 2,4-amino-deoxyhexoses of the D and L series (21, 22). Application of recently developed methods of polysaccharide analysis (23, 24) to a pneumococcal polysaccharide (25) and *Shigella sonnei* lipopolysaccharide (26) has revealed two additional examples of 2-acetamido-4-amino-6-deoxyhexopyranoside containing structures. The same substitution pattern (2-acetamido-4-amino-) also occurs in the pneumococcal C substance (16). In view of this recurring feature we have used chlorosulphation to provide an abbreviated route to the 2,4-diamino glucoside derivative **15** bearing the acetamido substituent at C-2 and amino group at C-4. In addition to the novel application of chlorosulphation to amino sugars this approach has also provided valuable ^{13}C nmr parameters for the β-hexopyranoside **15**, which were previously unavailable. Furthermore in the form synthesized here compound **15** provides a valuable comparative model for the degradative methods (nitrous acid deamination) (23, 25, 26) used to confirm the presence in polysaccharides of these rare and labile sugars.

Chlorosulphation of amino-deoxy sugars is of significant potential since it leads directly to amino-chloro-deoxy derivatives which are useful intermediates for further manipulation. As demonstrated here selective dechlorination can be executed at either primary or secondary positions with readily available catalysts. Although the 2-phthalimido function was used to avoid chlorosulphation at the reactive hydrogens of the 2-amino or 2-acetamido function of D-glucosamine, alternate protecting groups such as the di-*N*-benzoyl derivatives reported by Inch and Fletcher (27) would also fulfill this requirement.

Experimental

Thin layer chromatography was performed with Merck precoated silica gel 60F-254 plates and detection of compounds was achieved by quenching of uv fluorescence and by charring after spraying plates with 5% sulphuric acid in ethanol. Column chromatography was performed on silica gel G60 (70–230 mesh) with redistilled solvents. The loading of all columns was 1:100. Separations were also performed using a LC Prep 500 (Waters Associates). In these instances as much as 8–10 g of sample was purified in a single operation using solvent systems similar to those employed for conventional chromatography. Sulphuryl chloride (technical grade) was redistilled through a column containing 5 Å molecular sieve (Linde). W-4 Raney nickel was prepared according to the literature method (28). For the reproducible dechlorination of chloro-deoxy sugars only the most active catalyst was effective and the literature method (28) must be followed closely (cf. ref. 6). Nickel boride was prepared according to Boar *et al.* (17). DMF was dried by heating for 4 h at 90°C with calcium hydride followed by distillation under reduced pressure, or by stirring over phosphorous pentoxide for 1 week, followed by decanting and distillation under reduced pressure (~5 Torr). Until use DMF was stored over activated 3 Å molecular sieve (29). LH20 Gel was prepared and used according to the manufacturer's (Pharmacia) instructions.

Methyl 3,4,6-Tri-O-acetyl-2-deoxy-2-phthalimido-β-D-glucopyranoside (2)

The syrupy anomeric mixture of 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucopyranosyl bromides (**1**) (63.9 g) prepared according to Lemieux *et al.* (10) was dried under vacuum and dissolved in dry benzene (145 mL). This solution was added dropwise to a stirred suspension of mercuric cyanide (33.7 g) and Drierite (9.4 g) in dry benzene (195 mL), containing anhydrous methanol (19 mL). After 24 h at room temperature, tlc in the solvent ethyl acetate – Skellysolve B 1:1 showed no starting material and a new component with R_f 0.30. The reaction mixture was filtered and the residue washed with ethyl acetate. Extraction of the combined organic filtrates with 30% potassium iodide (100 mL), 5% sodium thiosulphate (200 mL), and water, followed by concentration, provided a syrup (52 g). Crystallization of the syrup from ethyl acetate and Skellysolve B provided 40.2 g (68%) of crystalline **2** in three successive crops. The crystals had mp 160.5–162.0°C; $[\alpha]_{589}$ +44.7 (*c* 1.1, chloroform) (lit. (30) mp 156–157°C, $[\alpha]_D$ +45.5 (*c* 3.23 chloroform)); R_f 0.30 (ethyl acetate – Skellysolve B 1:1); ^{13}C nmr ($CDCl_3$) δ: 99.1(C1), 71.9(C5), 70.9(C3), 69.1(C4), 62.0(C6), 57.0(OCH_3), 54.6(C2). *Anal.* calcd. for $C_{21}H_{23}NO_{10}$: C 56.12, H 5.16, N 3.12; found: C 56.08, H 5.32, N 3.09.

Methyl 2-Deoxy-2-phthalimido-β-D-glucopyranoside (3)

Sodium (1 g, 43.5 mmol) was dissolved in dry methanol (300 mL) and this solution was added to the tri-*O*-acetate **2** (40.0 g) in 200 mL of dry methanol. After 2 h at room temperature de-*O*-acetylation was complete and the solution was deionized with Rexyn (H^+) resin. Removal of the resin and concentration provided a syrup, which crystallized from methanol – ethyl acetate to give pure **3** (22.7 g 79%) mp 202.5–204.0°C; $[\alpha]_{589}$ −8.62 (*c* 1.0, methanol); R_f 0.45 (ethyl acetate – methanol–water 85:10:5); ^{13}C nmr (CD_3OD) δ: 100.6(C1), 78.2(C5), 72.6(2C, C3 and C4), 62.6(C6), 58.3(C2), 57.0(OCH_3). *Anal.* calcd. for $C_{15}H_{17}NO_7$: C 55.73, H 5.30, N 4.33; found: C 55.87, H 5.46, N 4.33.

Methyl 6-Chloro-2,4-dideoxy-2-phthalimido-β-D-glucopyranoside (4)

Methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside (**3**) (8 g, 25 mmol) was dissolved in dry pyridine (8 mL) to which 15 mL of absolute chloroform was added. This solution was cooled to −70°C and stirred with an overhead stirrer. Freshly distilled sulphuryl chloride (7 mL, 87 mmol) was added dropwise. After 30 min at −70°C the temperature was maintained between −10° and −20°C for 4 h. The reaction mixture was poured into 50 mL of 10% sulphuric acid and chloroform (300 mL) was added. The organic phase was extracted with 5% potassium bicarbonate solution (150 mL) and water. Concentration to a syrup provided

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

9.0 g of the chlorosulphated derivative of **4**. The syrup was dissolved in methanol (190 mL) and stirred with solid potassium bicarbonate (12.0 g) and 0.1 g sodium iodide. After 20 min dechlorosulphation was complete and, following evaporation, the solid residue was partitioned between 200 mL of chloroform and 50 mL of saturated sodium chloride. The chloroform solution was washed with 5% sodium thiosulphate (50 mL) and dried. The syrup crystallized from ethanol to give 5.0 g of crystals mp 197.5°–199°C; $[\alpha]_{589}$ −11.5° (*c* 1.0, methanol); ^{13}C nmr (CD_3OD) δ: 100.6(C1), 77.1(C5), 73.4(C3), 72.4(C4), 58.3(C2), 57.0(OCH_3), 45.3(C6). *Anal.* calcd. for $C_{15}H_{16}NO_6Cl$: C 52.72, H 4.72, N 4.10, Cl 10.38; found: C 52.58, H 4.79, N 3.97, Cl 10.22.

Methyl 4,6-Dichloro-2,4,6-trideoxy-2-phthalimido-β-D-galactopyranoside (5)

Methyl 2-deoxy-2-phthalimido-β-D-glucopyranoside **3** (12.0 g, 37 mmol) was dissolved in dry pyridine (45 mL) and 90 mL of absolute chloroform was added. The stirred solution was cooled to −70°C and sulphuryl chloride (freshly distilled, 23 mL 285 mmol) was added dropwise. The resulting solution became very viscous and a further 115 mL of chloroform was added to the reaction mixture. After 1 h at −70°C the reaction was stirred for 5 h at room temperature. The reaction mixture was quenched and worked up in a similar manner to that described for the 6-chloro compound **4**. The dechlorosulphated syrup (12 g) which resulted consisted of two components, as judged by tlc, R_f 0.37 and 0.11 (solvent, ethyl acetate – Skellysolve B, 1:1). The separation of these components was accomplished both by conventional column chromatography and on larger (8 g) scales by hplc with the solvent ethyl acetate – Skellysolve B 1:1. The title compound **5** (7.9 g, 59%) was obtained as a syrup, whilst the slower component (1.9 g, 15%) corresponded to the 6-chloro derivative **4**. The optimum yield of **5** was obtained with reaction times between 4 h and 8 h; longer time resulted in reduced overall yields although the ratio of **5**:**4** increased. Compound **5** crystallized from ethanol mp 149.5–151.5°C; $[\alpha]_{589}$ +20.5° (*c* 1.0, methanol); R_f 0.37 (ethyl acetate – Skellysolve B 1:1); ^{13}C nmr (CD_3OD) δ: 101.2(C1), 75.2(C5), 68.1(C3), 64.2(C4), 57.1(OCH_3), 54.8(C2), 43.7(C6). *Anal.* calcd. for $C_{15}H_{15}NO_5Cl_2$: C 50.02, H 4.20, N 3.89, Cl 19.69; found: C 50.13, H 4.20, N 3.82, Cl 19.54.

Methyl 2-Acetamido-6-chloro-2,6-dideoxy-β-D-glucopyranoside (6)

Compound **4** (5.7 g, 16.7 mmol) was dissolved in ethanol (400 mL) containing hydrazine hydrate (6 mL of an 85% solution in water), the solution was refluxed for 2 h, then filtered, evaporated, dried, and redissolved in methanol–water (3:1, 50 mL); acetic anhydride (5 mL) was added and the solution was stirred overnight. The solid obtained from this solution after solvent removal was dried and then purified on a silica gel column with chloroform–methanol (4:1). The compound obtained from the column was recrystallized from ethanol to give pure **6** (3.0 g, 71% yield) mp 178.5–180.0°C; $[\alpha]_{589}$ −29.5° (*c* 1.0, methanol); R_f 0.38 (same solvent as above); ^{13}C nmr (CD_3OD) δ: 103.4(C1), 76.8(C5), 75.8(C3), 72.9(C4), 57.2(C2), 57.0(OCH_3), 45.4(C6), 23.0($NHCOCH_3$). *Anal.* calcd. for $C_9H_{16}NO_5Cl$: C 42.61, H 6.36, N 5.52, Cl 13.98; found: C 42.76, H 6.54, N 5.63, Cl 13.87.

Methyl 2-Acetamido-4,6-dichloro-2,4,6-trideoxy-β-D-galactopyranoside (7)

Compound **5** (9.5 g, 26.4 mmol) was dissolved in ethanol (600 mL) containing hydrazine hydrate (10 mL of an 85% solution in water). The solution was refluxed for 2 h, filtered, evaporated, and dried. The residue was dissolved in methanol–water (100 mL, 3:1) and acetic anhydride (10 mL) was added. The solution was stirred overnight, evaporated, and dried. Recrystallization from ethanol gave pure **6** (5.6 g, 78%), the mother liquor was evaporated, and the residue was purified on a silica gel column using chloroform–methanol (4:1) as solvent; this gave more of the pure compound **7** (1.2 g), total yield 93%. Melting point 216.0–216.5°C; $[\alpha]_{589}$ +12.7° (*c* 1.0, methanol); R_f 0.56 (solvent as above); ^{13}C nmr (CD_3OD) δ: 104.0(C1), 75.0(C5), 71.7(C3), 63.8(C4), 57.0(OCH_3), 53.8(C2), 43.8(C6), 23.0($NHCOCH_3$). *Anal.* calcd. for $C_9H_{15}NO_4Cl_2$: C 39.72, H 5.56, N 5.15, Cl 26.06; found: C 39.51, H 5.77, N 5.11, Cl 25.96.

Methyl 2-Acetamido-2,6-dideoxy-β-D-glucopyranoside (8)

Compound **6** (0.51 g, 2.0 mmol) in ethanol (40 mL) containing W-4 Raney nickel catalyst (~1 g) and triethylamine (1.0 mL) was hydrogenated at 50 psi for 24 h. Filtration and evaporation gave a solid which was purified on a silica gel column with chloroform–methanol (4:1) as solvent. This gave pure **8** (0.31 g, 71% yield), mp 235–237°C (recrystallized from ethyl acetate – Skellysolve B); $[\alpha]_{589}$ −58.3° (*c* 1.0, methanol); R_f 0.38 (solvent as above); ^{13}C nmr (D_2O) δ: 103.1(C1), 76.4(C5), 74.9(C3), 73.1(C4), 58.3(OCH_3), 56.9(C2), 23.4($NHCOCH_3$), 17.9(C6). *Anal.* calcd. for $C_9H_{17}NO_5$: C 49.31, H 7.82, N 6.39; found: C 49.17, H 7.87, N 6.32.

Methyl 2-Acetamido-4-chloro-2,4,6-trideoxy-β-D-galactopyranoside (9)

Method A, Raney Nickel

Compound **7** (3.0 g, 11.0 mmol) in ethanol (60 mL) containing W-4 Raney nickel catalyst (~3 g) and triethylamine (4 mL) was hydrogenated at 50 psi for 36 h. Filtration and evaporation gave a solid residue, which was purified on a silica gel column with chloroform–methanol (4:1) as solvent. This gave, after recrystallization from ethanol, pure **9** (2.1 g, 80% yield), mp 166.0–167.5°C; $[\alpha]_{589}$ +6.7° (*c* 1.0, methanol); R_f 0.50 (solvent as above); ^{13}C nmr (CD_3OD) δ: 103.9(C1), 73.3(C5), 70.7(C3), 67.9(C4), 57.0(OCH_3), 53.6(C2), 23.1($NHCOCH_3$), 18.3(C6). *Anal.* calcd. for $C_9H_{16}NO_4Cl$: C 45.50, H 6.79, N 5.89, Cl 14.92; found: C 45.66, H 6.94, N 5.97, Cl 14.81.

Method B, Nickel Boride

Nickel chloride (1.3 g, 10 mmol) dissolved in 120 mL of ethanol was stirred under nitrogen and treated dropwise with a solution of sodium borohydride (0.75 g, 19.8 mmol) in water (10 mL) (17). The substrate **7** (1.5 g, 5.5 mmol) in 20 mL of ethanol containing 2 mL of triethylamine was added to the black suspension. The mixture was hydrogenated at 70 psi for 6 h. The reaction products were worked up and purified as described in method A. The yield of **9** after recrystallization from ethanol was 0.95 g, 72%, mp 166–167°C.

Methyl 2-Acetamido-6-chloro-2,4-dideoxy-β-D-xylo-hexapyranoside (10)

The 4,6-dichloro derivative **7** (2.3 g, 9 mmol) in ethanol (50 mL) was hydrogenated over palladium on charcoal at 70 psi for 18 h in the presence of one equivalent of sodium hydroxide. Filtration and evaporation gave a syrup, which was chromatographed on silica gel with chloroform–methanol (4:1). The material eluted as a single component and crystallized from ethanol–Skellysolve B to yield crystals of **10** (1.5 g, 75% yield), mp 185–186°C; $[\alpha]_{589}$ −21.2° (*c* 1.2, methanol); R_f 0.52 chloroform–methanol (4:1). The mother liquors were enriched for the 4-chloro-6-deoxy derivative **9**, which by C-13 was judged to comprise 15% of the reaction product. Compound **10** gave ^{13}C nmr data and a proton spectrum recorded at 400 MHz in full agreement with the assigned structure; ^{1}H nmr (400 MHz) ($CDCl_3$) δ: 1.51(s, 1H, $J_{3,4a} \approx J_{4a,5} = 11.1$ Hz, $J_{4e,4a} = 13.0$ Hz, H-4a), 2.09(s, 3H, $NHCOCH_3$), 2.20(m, 1H, $J_{3,4e} = 5.2$ Hz, $J_{4e,5} = 2.0$ Hz, $J_{4a,4e} = 13.0$ Hz, H-4e), 3.28(m, 1H, $J_{1,2} = 8.2$ Hz, $J_{2,3} = 9.8$ Hz, $J_{NH,2} \approx 4.0$ Hz, H-2), 3.55(s, 3H, OCH_3),

3.54–3.71(m, 3H, H-5, H-6), 3.86(m, 1H, $J_{2,3}$ = 9.8 Hz, $J_{3,4a}$ = 11.1 Hz, $J_{3,4e}$ = 5.2 Hz, H-3), 4.25(d, 1H, $J_{1,2}$ = 8.2 Hz); ^{13}C nmr (CD_3OD) δ: 103.7(C1), 72.9(C5), 70.3(C3), 58.6(C2), 56.8(OCH_3), 47.2(C6), 38.1(C4), 22.9($NHCOCH_3$). *Anal.* calcd. for $C_9H_{16}NO_4Cl$: C 45.50, H 6.79, N 5.89, Cl 14.92; found: C 45.63, H 6.76, N 5.86, Cl 14.80.

Methyl 2-Acetamido-6-azido-2,6-dideoxy-β-D-glucopyranoside (11)

Compound **6** (0.51 g, 2.0 mmol), potassium azide (0.16 g, 2.0 mmol), and dicyclohexano-18-crown-6 (0.80 g, 2.1 mmol) in dry DMF (30 mL) was refluxed for 45 min. Evaporation followed by purification on a silica gel column with chloroform–methanol (4:1) as solvent gave after recrystallization from ethanol – Skellysolve B pure **10** (0.42 g, 81% yield), mp 204–206°C; $[\alpha]_{589}$ −40.6° (*c* 1.0, methanol); R_f 0.33 (solvent as above); ir (KBr pellet): 2088 (N≡N) cm^{-1}; ^{13}C nmr (CD_3OD) δ: 103.4(C1), 77.2(C5), 75.9(C3), 73.0(C4), 57.2(C2), 56.9(OCH_3), 52.8(C6), 22.9($NHCOCH_3$). *Anal.* calcd. for $C_9H_{16}N_4O_5$: C 41.54, H 6.20, N 21.15; found: C 41.62, H 6.34, N 21.04.

Methyl 2-Acetamido-6-amino-2,6-dideoxy-β-D-glucopyranoside (12)

Compound **11** (100 mg, 0.38 mmol) was dissolved in ethanol (40 mL) containing platinum oxide catalyst. The solution was hydrogenated at atmospheric pressure for 2 h, then filtered and evaporated. The solid residue was purified on a LH20 column with methanol as solvent, followed by recrystallization from propan-2-ol–methanol, to give pure **12** (70 mg, 77% yield), mp 180°C (dec.); $[\alpha]_{589}$ −23.7° (*c* 1.0, methanol); ^{13}C nmr (D_2O) δ: 103.2(C1), 76.7(C5), 75.0(C3), 72.8(C4), 58.3(OCH_3), 56.7(C2), 42.7(C6), 23.4 ($NHCOCH_3$). *Anal.* calcd. for $C_9H_{18}N_2O_5$: C 46.15, H 7.75, N 11.96; found: C 45.98, H 7.84, N 12.05.

Methyl 2-Acetamido-4-azido-2,4,6-trideoxy-β-D-glucopyranoside (13) and Methyl 2-Acetamido-2,4,6-trideoxy-α-L-threo-hex-4-enopyranoside (14)

Compound **6** (350 mg, 1.47 mmol) was added to a cooled solution of dicyclohexano-18-crown-6 (650 mg, 1.24 mmol) and potassium azide (130 mg, 1.6 mmol), which had first been refluxed for 10 min. The solution was refluxed for 1 h, evaporated, and purified on a silica gel column with chloroform–methanol (95:5) as solvent. This gave pure **13** (210 mg, 59% yield) and **14** (100 mg, 34% yield). Compound **13** mp 207–209°C (recrystallized from ethyl acetate – Skellysolve B); $[\alpha]_{589}$ −2.7° (*c* 1.2, methanol); R_f 0.37 (chloroform–methanol 7:1); ir (KBr pellet) 2107 (N≡N) cm^{-1}; ^{13}C nmr (CD_3OD) δ: 103.1(C1), 75.2(C5), 71.8(C3), 70.2(C4), 57.7(C2), 56.8(OCH_3), 22.9($NHCOCH_3$), 18.7(C6). *Anal.* calcd. for $C_9H_{16}N_4O_4$: C 44.26, H 6.60, N 22.94; found: C 44.28, H 6.75, N 23.04.

Compound **14** mp 108–110°C (recrystallized from ethyl acetate – Skellysolve B); $[\alpha]_{589}$ −9.7° (*c* 1.1, methanol); R_f 0.40 (chloroform–methanol 7:1); ^{1}H nmr ($CDCl_3$) δ: 1.82 (t, 3H, $J_{4,6}$ = 1.0 Hz, H-6), 1.97 (s, 3H, CH_3CONH—), 3.43 (s, 3H, CH_3O), 4.90 (m, 2H, H-1 and H-4); ^{13}C nmr ($CDCl_3$) δ: 148.7(C5), 99.6(C1), 99.2(C4), 64.2(C3), 56.3(OCH_3), 50.2(C2), 23.0($NHCOCH_3$), 19.7(C6). *Anal.* calcd. for $C_9H_{15}NO_4$: C 53.72, H 7.51, N 6.96; found: C 53.55, H 7.47, N 7.10.

Methyl 2-Acetamido-4-amino-2,4,6-trideoxy-β-D-glucopyranoside (15)

Compound **13** (200 mg 0.82 mmol) was dissolved in ethanol (50 mL) containing platinum oxide catalyst and the solution was hydrogenated at atmospheric pressure. After 2 h the solution was filtered, evaporated, and the solid residue was purified on a LH20 column with methanol as solvent. This gave pure **15** (130 mg, 73% yield); $[\alpha]_{589}$ −50.1° (*c* 1.0, CH_3OH); ^{1}H nmr (D_2O) δ: 1.24 (d, 3H, $J_{5,6}$ = 6.2 Hz, H-6), 1.95 (s, 3H, $NHCOCH_3$), 2.47 (t, 1H, $J_{3,4}$ = 9.4 Hz, H-4), 3.40 (s, 3H, OCH_3), 4.34 (d, 1H, $J_{1,2}$ = 8.2 Hz, H-1); ^{13}C nmr (D_2O) δ: 103.0(C1), 72.9(C5), 71.6(C3), 58.9(C4), 58.4(OCH_3), 57.3(C2), 23.2($NHCOCH_3$), 18.1(C6). *Anal.* calcd. for $C_9H_{18}N_2O_4$: C 49.53, H 8.31, N 12.84; found: C 48.70, H 8.18, N 11.71. Methyl 2,4-diacetamido-2,4,6-trideoxy-β-D-glucopyranoside prepared from **15** was analytically pure.

Methyl 2-Acetamido-3-O-acetyl-2,4,6-trideoxy-β-D-xylo-hexopyranoside (16)

Compound **14** (400 mg, 2.0 mmol) was dissolved in ethanol (60 mL) containing palladium (10% on charcoal) catalyst and the mixture was hydrogenated at atmospheric pressure for 3 h, filtered, and then evaporated. Purification on a silica gel column gave a compound that was not pure according to ^{13}C nmr. The compound was dissolved in chloroform (30 mL) to which pyridine (2 mL) and acetic acid anhydride (0.5 mL) was added. The reaction was stirred overnight and then evaporated to a syrup which was purified on a silica gel column with the solvent chloroform–methanol (7:1). This gave pure **16** (290 mg, 59%) mp 205–206°C (recrystallized from ethyl acetate – Skellysolve B); $[\alpha]_{589}$ −57.4° (*c* 1.0, methanol); R_f 0.50 (solvent as above); ^{1}H nmr ($CDCl_3$) 400 MHz, δ: 1.28 (d, 3H, $J_{5,6}$ = 6.2 Hz, H-6), 1.51 (m, 1H, $J_{3,4a} \approx J_{4a,5}$ = 11.3 Hz, $J_{4e,4a}$ = 12.6 Hz, H-4a), 1.98 (s, 3H, $OCOCH_3$), 2.02(m, 1H, $J_{3,4e} \approx J_{4e,5}$ = 4.9 Hz, $J_{4e,4a}$ = 12.6 Hz, H-4e), 2.05 (s, 3H, $NHCOCH_3$), 3.77 (m, 1H, $J_{1,2}$ = 8.3 Hz, $J_{2,3}$ = 10.5 Hz, $J_{2,NH}$ = 8.9 Hz, H-2), 3.64 (m, 1H, $J_{4a,5}$ = 11.3 Hz, $J_{4e,5}$ = 4.9 Hz, $J_{5,6}$ = 6.2 Hz, H-5), 3.47 (s, 3H, OCH_3), 4.37 (d, 1H, $J_{1,2}$ = 8.3 Hz, H-1), 5.04 (m, 1H, $J_{2,3}$ = 10.5 Hz, $J_{3,4a}$ = 11.3 Hz, $J_{3,4e}$ = 4.9 Hz, H-3), 5.57 (d, 1H, $J_{2,NH}$ = 8.9 Hz, NH); ^{13}C nmr (CD_3OD) δ: 103.2(C1), 72.4(C5), 68.8(C3), 56.6(OCH_3), 55.5(C2), 39.2(C4), 22.6($NHCOCH_3$), 20.9(C6), 20.6($COCH_3$). *Anal.* calcd. for $C_{11}H_{19}NO_5$: C 53.87, H 7.81, N 5.71; found: C 54.02, H 7.90, N 5.64.

Methyl 2-Acetamido-6-azido-2,4,6-trideoxy-α-L-threo-hex-4-enopyranoside (17)

Compound **6** (400 mg, 1.5 mmol) was added to a cooled solution of dicyclohexano-18-crown-6 (1200 mg, 3.2 mmol) and potassium azide (250 mg, 3.1 mmol) in DMF (30 mL), which had first been refluxed for 10 min. The solution was refluxed for 1 h, evaporated, and purified on a silica gel column with chloroform–methanol (7:1) as solvent. This gave pure **17** (270 mg, 75% yield), mp 92–94°C (recrystallized from ethanol – Skellysolve B); $[\alpha]_{589}$ +10.0° (*c* 1.1, methanol); R_f 0.40 (solvent as above); ^{13}C nmr (CD_3OD) δ: 148.6(C5), 103.7(C1), 101.3(C4), 65.8(C3), 56.8(OCH_3), 53.6(C2), 53.2(C6), 22.6($NHCOCH_3$). *Anal.* calcd. for $C_9H_{14}N_4O_4$: C 44.63, H 5.83, N 23.13; found: C 44.83, H 6.01, N 22.98.

Received May 6, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

KELVIN K. OGILVIE, NICOLE Y. THERIAULT, JAN-MARCUS SEIFERT, RICHARD T. PON, and MONA J. NEMER. Can. J. Chem. **58**, 2686 (1980).

A series of phosphorodichloridites has been prepared incorporating the most commonly used phosphate protecting groups in oligonucleotide synthesis. The groups include trichloroethyl, tribromoethyl, cyanoethyl, benzyl, methyl, *p*-chlorophenyl, and nitrophenethyl. The trichloroethyl and the nitrophenethyl appear to be the most stable groups while the cyanoethyl and methyl offer specific advantages. The benzyl and *p*-chlorophenyl groups are subject to limitations on their utility. Condensations can be carried out in a range of solvents including THF, pyridine, and DMF and at temperatures from −78°C to 20°C with a slight drop in yield with increasing temperature, at least for dinucleotide condensations.

KELVIN K. OGILVIE, NICOLE Y. THERIAULT, JAN-MARCUS SEIFERT, RICHARD T. PON et MONA J. NEMER. Can. J. Chem. **58**, 2686 (1980).

On a préparé une série de phosphodichloridures incorporant les groupements protecteurs phosphates les plus fréquemment utilisés dans la synthèse des oligonucléotides. Les groupements comprennent le trichloroéthyle, le tribromoéthyle, le cyanoéthyle, le benzyle, le méthyle, le *p*-chlorophényle et le nitrophenéthyle. Les groupements trichloroéthyle et nitrophenéthyle semblent être les plus stables tandis que le groupements cyanoéthyle et méthyle offrent des avantages spécifiques. Les groupements benzyle et *p*-chlorophényle sont d'une utilisation limitée. Les condensations peuvent être réalisées dans une variété de solvants incluant le THF, la pyridine et le DMF à des températures allant de −78°C à 20°C avec une légère diminution du rendement quand la température augmente au moins lors de condensation impliquant les dinucléotides.

[Traduit par le journal]

Introduction

For the development of a complete procedure for the synthesis of ribonucleotides, three important aspects must be investigated. These include the development of a complete set of protecting groups for the nucleoside units; the determination of an effective method of condensation, and the choice of a compatible phosphate protecting group when necessary (triester approach).

We have been developing a complete and effective method for the synthesis of oligoribonucleotides (1–5). The key feature of the protection of the nucleoside units in our procedure is the use of the *tert*-butyldimethylsilyl (TBDMS) group for the protection of the 2′-oxygen ribonucleosides. We have described in detail the synthesis of protected ribonucleosides having all possible degrees of silylation from A, C, G, and U, the *N*-benzoyl derivatives of C and G, and the methoxytrityl derivatives of A, C, G, U, C^{Bz}, and G^{Bz} for a total of 63 silylated derivatives (2, 3). We have also described (5) the use of the levulinyl group for protecting the 3′-position of 2′-silylated ribonucleosides, and this has completed the development of the first phase of our method.

For the question of condensation of silylated nucleosides to form nucleotide chains we have used the dichloridite procedure (1–5) originally introduced by Letsinger *et al.* (6). The utility of the procedure was established through the stepwise synthesis (4) of the heptanucleotide GCAACCA and the block condensation synthesis (5) of a hexadecauridylic acid. We have shown (7) the TBDMS group to be compatible with nine of the condensing agents currently used in oligonucleotide synthesis. We have concluded from this study (7) that the phosphorodichloridite procedure offers the most rapid and clean procedure for the synthesis of oligoribonucleotides.

During most of the above developmental work, we have been using the trichloroethyl group as the phosphate protecting group. In this report we de-

[1]This article constitutes Part XIII in a series on silyl protecting groups in nucleoside and nucleotide chemistry. For the previous article in both series, see K. K. Ogilvie, M. J. Nemer, N. Theriault, R. Pon, and J.-M. Seifert, Nucleic Acids Research Special Publication No. 7. 1980. p. 147.

scribe the synthesis of the dichloridites from the most commonly used phosphate protecting groups. We have compared them in the synthesis of ribonucleotides using the dichloridite procedure. We also describe in this report the effects of solvent and temperature on the yields in condensation steps. The ability to remove the phosphate protecting groups from silylated ribonucleotides is also described.

Discussion

Several important phosphate protecting groups have been introduced during the development of the triester synthesis of oligonucleotides. The benzyl group was used during the first successful chemical synthesis (8) of a nucleotide. This original synthesis did not appear to be practical and the benzyl group was considered to be too sensitive to acid hydrolysis (and nucleophilic attack) to be generally useful.

The cyanoethyl group (CE), introduced by Tener (9) for diesters, was used by Letsinger *et al.* (10) as the phosphate protecting group in his discovery of the modern triester synthesis of oligonucleotides. The cyanoethyl group is stable to the usual acid conditions, but is readily eliminated by mild base (e.g. dilute NH_3, 10 min, 20°C).

The β,β,β-trichloroethyl group (TCE) was introduced to nucleotide triester synthesis by Eckstein and Rizk (11). This group is stable to acid and mild base, but can be removed with Zn/Cu in DMF. The β,β,β-tribromoethyl group has also been used (12, 13) and is reported to be more easily removed than the TCE group.

The phenyl (14) and substituted (15, 16) phenyl groups have been described for the synthesis of nucleotide triesters. These groups are stable to acid but are base labile. Until recently, cleavage of the nucleotide chain by the conditions used to remove the phenyl groups has been an undesired complication. However, the introduction of the oximate method of deprotection (17, 18) seems to have significantly reduced this problem.

Pfleiderer and Uhlmann (19) have recently suggested the use of substituted phenethyl groups for the synthesis of nucleotide triesters. These groups are stable to acid and vary in their resistance to base cleavage.

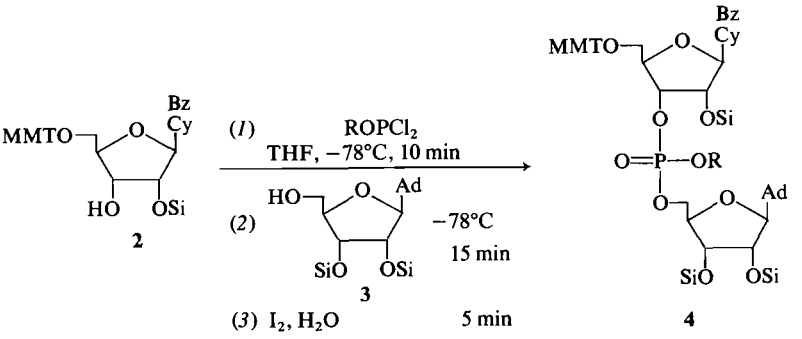
The methyl protecting group has not been widely used, but has gained some recent attention (20, 21). The small size of the group has potential advantages both in synthesis and subsequent biological testing (22).

In order to evaluate these protecting groups in the dichloridite procedure for condensing TBDMS-protected ribonucleosides, the following dichloridites were prepared:

Compound	Number	Abbreviation
$Cl_3CCH_2OPCl_2$	**1***a*	(TCE)$OPCl_2$
$Br_3CCH_2OPCl_2$	**1***b*	(TBE)$OPCl_2$
ϕCH_2OPCl_2	**1***c*	(ϕCH_2)$OPCl_2$
CH_3OPCl_2	**1***d*	CH_3OPCl_2
$NCCH_2CH_2OPCl_2$	**1***e*	(CE)$OPCl_2$
	1*f*	(*p*Clφ)$OPCl_2$
	1*g*	(PE)$OPCl_2$
	**1***h*	(NPE)$OPCl_2$

The dichloridites were all prepared by the reaction of the appropriate alcohol with phosphorus trichloride according to the equation

$$ROH + PCl_3 \rightarrow ROPCl_2 + HCl$$



Most of the dichloridites have been reported previously (see Experimental). Preparations of **1***c* are reported (22) to lead to explosions and the reported preparations (23) of **1***e* lead to very low yields. We have modified the general procedures by conducting the reactions in ether as solvent at −78°C and, in the case of **1***e*, adding pyridine to the solution. Products were generally isolated by short-path distillation in a Kugelrohr apparatus. Yields were quite acceptable, being generally 40–80%.

Synthesis of Ribonucleotides

The phosphorodichloridite procedure was first used by Letsinger *et al.* for the synthesis of deoxynucleotides (6) and we have reported extensively on its use in the synthesis of ribonucleotides (1–5, 7). The general procedure is outlined in Scheme 1 for the synthesis of the fully protected CpA. The results of the condensations are collected in Table 1.

From Table 1 it can be seen that the only reagent that did not give satisfactory results was the benzyl phosphorodichloridite (**1***c*). The yield of **4***c* was only 29% while the yields in all the other condensations ranged from 40–80%, being generally in the vicinity of 70%. The benzyl group appears to be quite sensitive to the reaction conditions. We have conducted experiments with **1***c* and deoxynucleosides[2] and find the yields to be very low (~20%). It is clear from the table that the most commonly used protecting groups are all very compatible with the phosphorodichloridite procedure. Compounds

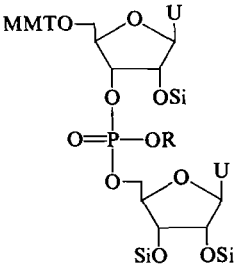
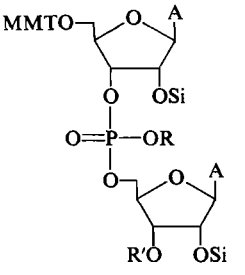
SCHEME 1



5*a–c* and **6***a–d* were also prepared in the yields indicated (Table 1).

General Reaction Conditions



We have previously indicated (2, 3) that the ratio of reactants (e.g. **2**:**1**:**3**) of 1:1.1:0.8 gives the best results for ribonucleotide synthesis. From Table 1, it can be seen that slight variation from this ratio does not have much effect. Most of our experiments have been carried out using longer times than are necessary. For example, we have generally used times of 30–45 min (at −78°C) for step (*1*) (Scheme 1) and 40–60 min (−78°C) followed by 60 min at 20°C for step (*2*). Entries 1 and 2 in Table 1 show that very short reaction times can be used (5 min for *1*, and 15 min for *2*). We now routinely use 5–15 min for step (*1*) and 15–30 min for step (*2*) followed by rapid warming to room temperature and oxidation by iodine–water (5 min).

Solvent

While most condensations have been reported in THF as solvent, other solvents work equally well and may have advantages in specific situations. Entries 2–6 show that reactions carried out at −78°C in THF, DMF, collidine, and pyridine all show similar yields. Collidine has the practical disadvantage that it freezes at −78°C and must occasionally be removed from the cooling bath in order to mobilize the thick sludge by partial warming. Collidine is also difficult to remove in any quantity at the end of the reaction. Pyridine and DMF have the advantage that most nucleosides and their derivatives are soluble in these solvents. This allows the dichloridite procedure to be applied to nucleosides protected with groups other than TBDMS which are less soluble in organic solvents such as THF than are the TBDMS substituted nucleosides. DMF shows a significant decrease in yield for reactions carried out above 0°C as discussed below.

5*a* R = TCE
b R = TBE
c R = CH_3

6*a* R = TBE, R′ = Si
b R = TBE, R′ = Lv
c R = NPE, R′ = Si
d R = CH_3, R′ = Lv

Temperature

The question of the temperature at which the reactions must be carried out is an important one. While the original (6) and subsequent reports (1–4, 20) have used −78°C, such low temperatures are not generally necessary. We have found (5) that block condensations work very well in THF at 0°C. In this report, we have compared reactions at −78°C, 0°C, and 20°C. From Table 1, it is apparent that reactions at 0°C have similar yields to those at −78°C. However, a definite decrease in yield occurs in all solvents at 20°C. For THF and pyridine, the yields (64%) are easily acceptable, but for DMF, the drop to 48% is more severe.

In the DMF reactions, all solutions show color. At −78°C, the solution is a pale yellow, becoming a definitive yellow at 0°C and nearly orange at 20°C. Others (25, 26) have reported that DMF reacts with PCl_3 in a manner shown below (R = Cl).

It is quite probable that in our reactions a reaction between (TCE)$OPCl_2$ and DMF may occur to produce a compound of the type **8***b* which could rearrange to **9***b*. Either of these two species could

b R = OCH_2CCl_3

react with nucleosides and thereby reduce the yields of desired products.

Stability of Phosphate Protecting Groups to Acid and Hydrazine

In order to allow chain extension it must be possible to remove the 5′-methoxytrityl group without affecting the phosphate protecting group. All of the compounds **4** were treated with acid to remove the methoxytrityl group.

$$\underset{\mathbf{4}\,a\text{–}f}{\text{MMT-C}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(R)A}^{\text{Si}}_{\text{Si}}} \xrightarrow{\text{H}^+} \underset{\mathbf{7}\,a\text{–}f}{\text{HOC}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(R)A}^{\text{Si}}_{\text{Si}}}$$

The conditions used were either 80% HOAc at room temperature for 24 h or 2% benzenesulfonic acid in chloroform–methanol (7:3) for 2 h. Yields of **7** were generally 80–85% except for R = benzyl or methyl where yields were 65–70%.

All of the compounds **4** were treated with hydrazine solution (7) for 10 min. None of the phosphate groups were affected. Normally, only 5 min are required to remove the levulinyl group which we use to protect the 3′-position (7)

$$\underset{\mathbf{4}\,a\text{–}f}{\text{MMT-C}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(R)A}^{\text{Si}}_{\text{Si}}} \xrightarrow{\text{H}_2\text{NNH}_2} \text{No reaction}$$

Complete Deprotection of MMT-C$^{\text{Bz}^{\text{Si}}_{\text{P}}}$(R)A$^{\text{Si}}_{\text{Si}}$ to CpA (Removal of the Phosphate Protecting Group)

A. Trichloroethyl and Tribromoethyl Derivatives

Compounds **7***a*, *b* were treated with Zn/Cu in DMF at 55°C for 5 h followed by half-saturated methanolic ammonia at 20°C for 48 h and TBAF for 1 h at 20°C.

$$\underset{\mathbf{7}a}{\text{HOC}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(R)A}^{\text{Si}}_{\text{Si}}} \xrightarrow[(2)\ \text{NH}_3\ (3)\ \text{TBAF}]{(1)\ \text{Zn/Cu}} \text{CpA}$$

For trichloroethyl protected nucleotides, we have never observed any internucleotide cleavage. Only the desired nucleotide product is observed. For the tribromoethyl compounds, the reaction with zinc is over within 2 h.

The actual yield of fully deprotected nucleotide (e.g. CpA) based on the amount of starting material (e.g. **7***a*) ranges from 40–90% and seems to be most dependent upon the quality of the zinc–copper couple. The nucleotide product in both cases is completely degraded by RNAse A.

B. The Benzyl and Methyl Groups

The benzyl group can be removed from nucleotides using 1-amines such as 3-butylamine as recently described for methyl groups (21). The reaction is very clean. Thus, when **7***c* was treated with *tert*-butylamine at 50°C for 14 h, a quantitative yield of the debenzylated material is obtained. Exactly the same result is obtained for the methyl protecting group. Subsequent treatments with NH_3 and TBAF yield the product CpA.

$$\text{HOC}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(R)A}^{\text{Si}}_{\text{Si}} \xrightarrow[(2)\ \text{NH}_3\ (3)\ \text{TBAF}]{(1)\ t\text{-BuNH}_2} \text{CpA}$$

R = ϕCH_2 **7***c*, CH_3 **7***d*

This deprotection sequence is very clean and only the desired nucleotide product CpA is obtained which is completely degradable by RNAse A. Overall yields are generally 80–95%. The only disadvantage of the CH_3 and benzyl protecting groups would appear to be the condensation yields.

C. Cyanoethyl

The cyanoethyl group is a very easy group to remove, requiring only mild ammonia. In the case of **7***e*, the conditions to remove the *N*-benzoyl group also remove the cyanoethyl group. Thus, treatment of **7***e* for 2 days with NH_3 followed by TBAF gives the products CpA as the only nucleotidic product in virtually quantitative yield (> 90% in all cases). The product is completely degradable by enzymes

$$\underset{\mathbf{7}e}{\text{HOC}^{\text{Bz}^{\text{Si}}_{\text{P}}}\text{(CE)A}^{\text{Si}}_{\text{Si}}} \xrightarrow[(2)\ \text{TBAF}]{(1)\ \text{NH}_3} \text{CpA}$$

D. p-*Chlorophenyl*

Recently a method has been described for the removal of chlorophenyl groups from phosphate triesters which involves a minimum of internucleotide cleavage (17, 18). We have found that this procedure does not appear to be compatible with the silyl protecting groups. For example, when **4***f* was treated first with N^1,N^1,N^2,N^2-tetramethylguanidinium pyridine 2′-carboxaldoximate (TGPC) at 20°C for 48 h followed successively by treatment with 2% benzenesulfonic acid in chloroform methanol (7:3) for 90 min at 20°C, half-saturated methanolic ammonia for 48 h at 20°C, and finally TBAF at 20°C for 60 min, three products were obtained and identified as CpA, Cp, and A. In this

case, the Cp and A constitute 10–15% of the total uv-absorbing product and must arise by chain cleavage.

$$\text{MMT-C}^{\text{Bz}}{}^{\text{Si}}_{\text{P}}(p\text{Cl}\phi)\text{A}^{\text{Si}}_{\text{Si}} \xrightarrow[(2)\ 2\%\ \text{BSA}\ (3)\ \text{NH}_3, \text{CH}_3\text{OH}\ (4)\ \text{TBAF}]{(1)\ \text{TGPC}} \text{CpA} + \text{Cp} + \text{A}$$

Since purification of products from the above reaction only occurred after the final step, it was possible that the chain degradation occurred as a result of a combination of reagents rather than the action of a single reagent. However, subsequent investigation seemed to indicate that the problem arises at the oximate deprotection step.

When MMT-U^{Si}_{P} (pClϕ)U^{Si}_{Si} was treated with the oximate reagent followed by treatment with 80% HOAc for 30 min at 80°C and the products isolated by tlc, several products were obtained including U and Up (~25%), UpU (~15%), and $U^{Si}_{P}U^{Si}_{Si}$ (~50%). Clearly, loss of the silyl group had occurred during these steps. In addition, the UpU obtained was only 85% degraded by pancreatic RNAse A. Since the material was completely degraded by snake venom, the UpU would appear to be contaminated by about 15% of the 2′–5′ isomer.

In a subsequent reaction U^{Si}_{P} (pClϕ)U^{Si}_{Si} was treated with oximate and the product was isolated on tlc sheets before further deprotection. The product mixture consisted of UpU (~2%), a second band that appeared to be a mixture of partially silylated UpU (~6%) and a third and major band (~92%) which was mostly fully silylated UpU. Band no. 2 after treatment with TBAF gave a product that had the same chromatographic properties as UpU, which was not degraded by RNAse A, but was completely degraded by snake venom. The third band on treatment with TBAF gave a material which was identical to UpU and which was completely degraded to Up and U (1.0:1.0) by pancreatic RNAse A.

When U^{Si}_{P}(pClϕ)U^{Si}_{Si} was treated successively with oximate and TBAF and worked up on paper chromatography, the products isolated were U + Up (~18%) and UpU (82%). Only 93% of the UpU was degraded by RNAse A.

The p*-Nitrophenethyl Group*

This group has recently been proposed as a new phosphate protecting group (19) and we have found it to be compatible both with the phosphodichloridite procedure and the silyl protecting groups. The *p*-nitrophenethyl group was removed from **6***c* in 2 h at room temperature using neat 1,5-diazabicyclo[4.3.0]non-5-ene as has been previously suggested (19*b*).

Conclusion

As a result of this study on the dichloridite procedure for the synthesis of ribonucleotides, we can conclude (*1*) that a variety of solvents may be used and thus accommodate a range of specific needs; (*2*) the procedure works over a range of temperatures from −78°C to 20°C with yields decreasing slightly as temperature increases; (*3*) most commonly used phosphate protecting groups are amenable to the procedure. It is clear that the trichloroethyl group appears to offer the advantage of stability to a variety of reagents. The benzyl group, while easily removed, is not sufficiently stable to the condensation procedure. The methyl and cyanoethyl groups appear to offer advantages with regard to deprotection. The oximate method of removal of the chlorophenyl group would appear to require further investigation to be compatible with the silyl protecting group.

Experimental

General Methods

All general procedures and techniques including chromatography, uv, nmr, elemental analyses, melting points, electrophoresis, and enzyme analyses are as previously described (2, 5). All protected nucleosides were prepared according to the procedures already fully described (2, 3, 5). The preparation of the tetrabutylammonium fluoride (TBAF) in THF reagent has been described (2). The zinc–copper reagent was prepared according to the literature (27) and used in DMF at 50°C for 5 h (28). All alcohols used in the preparation of phosphorodichloridites were obtained commercially with the exception of 4-nitrophenethanol which was prepared according to literature procedures (29, 30). Alcohols were distilled before use as was the phosphorus trichloride used in the preparations of the dichloridites.

Preparation of the Dichloridites **1**a–h

The dichloridites (TCE)$OPCl_2$ (**1***a*), (pClϕ)$OPCl_2$ (**1***f*), CH_3OPCl_2 (**1***d*) were prepared according to their respective literature preparations (31–33) and their properties are listed in Table 2.

The general procedure for the preparation of the other dichloridites can be illustrated by the preparation of β-cyanoethylphosphorodichloridite (**1***e*) which has only been described in very low yields in the literature (24). Hydracrylonitrile (0.5 mol in ether (30 mL)) was added slowly to a cooled solution (−78°C) of pyridine (1 mol, pyridine was not used in any of the other preparations) in ether (30 mL) containing PCl_3 (0.5 mol). After a total of 1 h at −78°C the solution was filtered from pyridinium hydrochloride and the ether was removed under reduced pressure at room temperature to leave a clear liquid. This liquid was carefully distilled in a Kugelrohr apparatus to give a 59% yield of the desired product (**1***e*). Properties are listed in Table 2.

The dichloridites (TBE)$OPCl_2$ (**1***b*), (PE)$OPCl_2$ (**1***g*), and (NPE)$OPCl_2$ (**1***h*) were prepared in a similar fashion except that the addition of alcohol was carried out at 0° to −78°C over a 15 min period followed by warming the solution to room temperature for 30–50 min. Pyridine was not used. The product yields were 56, 45, and 78% respectively.

The benzylphosphodichloridite (**1***c*) was prepared at −78°C but no solvent was used. That is, the benzyl alcohol was added

TABLE 2. Properties of phosphorodichloridites

Dichloridite	Yield (%)	Boiling point (°C)	Density (g/mL)	^{31}P δ rel 85% H_3PO_4	Refractive index	Reference

directly to PCl_3, maintained at −78°C for 30 min, followed by warming to room temperature for 30 min. The yield of **1***c* was 30%. While this may seem low, it should be noted that previous literature reports (23) indicate that these reactions usually end in explosions. No explosions have occurred during our preparation.

General Procedure for the Synthesis of Dinucleotides

The general procedure can be illustrated by the synthesis of **4***a*. To a solution of 2,4,6-collidine (0.14 mL, 1 mmol) in dry THF (0.35 mL) maintained at −78°C in a small flask equipped with a septum cover was added via a syringe, (TCE)$OPCl_2$ (39 μL, 0.265 mmol). (The pressure inside the flask is maintained via a syringe equipped as a drying tube and inserted through the septum.) To the solution was added **2***a* (174 mg, 0.24 mmol) dissolved in 0.35 mL of dry THF. After a total of 5 min, a solution of **3** (98 mg, 0.19 mmol) in THF (0.65 mL) was added (via syringe). The solution was maintained at −78°C for 15 min. The reaction mixture was warmed to room temperature and to it was added a solution of iodine (114 mg, 0.43 mmol) and a drop of pyridine in THF:H_2O (2:1, 1.5 mL). After 5 min at room temperature, the solvent was evaporated to dryness. The residue was dissolved in chloroform (20 mL) which was washed with 20 mL of water containing 1 mL of a 5% sodium bisulfite solution. The aqueous layer was back-extracted four times with chloroform (10 mL). The combined chloroform solutions were concentrated to a small volume at reduced pressure and applied to three silica gel plates developed three times in ether. The product was eluted with acetone followed by ethyl acetate. After evaporation of the solvent, 216 mg of a product **4***a* (77%) was obtained (**4***a*, mp 129–134°C, λ_{max} (EtOH): 305, 261, 237 nm, R_f(Et_2O) 0.14, R_f(EtOAc) 0.68).

This general procedure was used in all the syntheses listed in Table 1 with the variations of time and temperature noted in the table. For condensations in collidine (as solvent) at low temperatures, the solution solidifies and must occasionally be removed from the bath and shaken vigorously with slight warming to allow the slurry to be stirred.

Removal of Protecting Groups

1. The Methoxytrityl Group

Two procedures are used interchangeably for removal of the methoxytrityl group. (*a*) 80% HOAc at room temperature for 24 h. The temperature is kept at 20–25°C to avoid any debenzamidation of *N*-benzoylcytidine units. We have observed that, on heating, as much as 5–10% of *N*-benzoylcytidine units may be converted to uridine. At room temperature, 80% HOAc usually requires 14–24 h to affect complete demethoxytritylation. At the end of the reaction, the solvents are removed at reduced pressure and the residue applied to tlc plates for product isolation. While only the desired product is observed on analytical tlc, isolated yields are generally 80–85% from preparative tlc plates.

(*b*) 2% Benzenesulfonic acid (34) in chloroform–methanol (7:3) for 2 h at room temperature. At the end of the reaction period, the solution is diluted to 50 mL with $CHCl_3$ and extracted with 5% sodium bicarbonate solution (2 × 40 mL). The bicarbonate wash solutions are back-extracted with chloroform (2 × 30 mL) and the combined chloroform extracts are washed once with water (50 mL). The chloroform is then removed at reduced pressure and the residue is applied to tlc plates. Yields are generally 80–90%.

2. Treatment With Hydrazine Solution

Compounds **4***a–f* (5 mg each) were dissolved in ~70 μL of the standard hydrazine solution (0.25 mL hydrazine–hydrate (1:1)/10 mL pyridine–acetic acid (4:1)). The solution was stirred at room temperature for 10 min and then stopped by the addition of two drops of acetylacetone. Thin-layer chromatography showed that none of the starting compounds had been affected by this treatment.

3. Phosphate, Amine, and Hydroxyl Protecting Groups

A. Trichloroethyl and Tribromoethyl

The detritylated nucleotide (either purified or direct from the detritylation procedure) is treated with Zn/Cu couple in DMF (~20 mg of Zn/Cu per 20 mg of dinucleotide in 2 mL) at 50°C for 2 h. The mixture is cooled to room temperature and is diluted with 2 mL of half-saturated methanolic ammonia and stirred at room temperature for 2 days. At the end of this time, the solution is centrifuged to eliminate metal and salts, the solvent is concentrated at reduced pressure, and the residue is applied to Eastman Chromagram sheets developed in solvent A. The product moves to the solvent front away from salts and other impurities. The product is eluted with methanol which is evaporated and the residue is treated with 2 mL TBAF in THF (0.68 mmol/mL) for 1–2 h at room temperature. The THF is evaporated and the residue dissolved in water (3–5 mL). The cloudy solution is applied to a column of Dowex 50W-X8 (Na^+ form, 1 × 30 cm) which is eluted with 50 mL of water. The combined eluted solvent is evaporated (lyophilized) and the residue is applied to Whatman 3 mm paper developed in solvent A (2). Yields are calculated from the OD units (260 nm) and are generally 40–80% based on the starting fully protected nucleotide.

B. Benzyl and Methyl Groups (20)

These phosphate protecting groups are very easily removed. Immediately after detritylation of the fully protected nucleotide (20 mg) and removal of acetic acid, the residue is dissolved in *tert*-butylamine (10–20 mL) and heated at reflux for 14–20 h. The solvent is removed at reduced pressure (tlc shows complete and clean deprotection for both benzyl and methyl groups) and the residue is then treated directly and successively with methanolic ammonia and TBAF as described above in A. Overall isolated yields are 80–95% and it is worth indicating that a very clean product isolation step is observed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

C. Cyanoethyl

The cyanoethyl group is removed in the same step that removes *N*-benzoyl groups. Consequently, the detritylated product is treated directly with half-saturated methanolic ammonia for 2 days followed by TBAF. Once again, a very clean product is obtained and the deprotection occurs in > 90% yields.

D. p-Chlorophenyl

The procedure used to remove the *p*-chlorophenyl group was essentially that described by Gilham and co-workers (18) and Reese and Yau (17). The nucleotide (~20 mg) was stirred in 0.36 mL of N^1,N^1,N^2,N^2-tetramethylguanidinium pyridine 2-carboxaldoximate at room temperature and, after 16 h, 5 μL of 1,1,3,3-tetramethylguanidine was added and stirring was continued for an additional 25 h. The product was then isolated on Eastman Chromagram sheets developed in ether–chloroform–methanol (5:4:1). The product remains at the origin while all other reagents move near the solvent front. The product can be eluted with methanol and treated with acid, ammonia, and TBAF as described in A above.

E. p-Nitrophenethyl

Compound **6***c* (50 mg, 36.8 μmol) was dissolved in 1,5-diazabicyclo[4.3.0]non-5-ene (DBN, 400 μL) and stirred at room temperature. Thin-layer chromatography showed the reaction to be complete after 2 h at which point the solution was concentrated at reduced pressure; 80% HOAc (4 mL) was added and after 24 h at room temperature, the solvents were removed at reduced pressure. The residue was dissolved in chloroform (20 mL) which was extracted with saturated aqueous ammonium chloride solution (3 × 15 mL) to remove the DBN. The chloroform was removed at reduced pressure and the residue treated with TBAF solution (3 mL) as described above. The product ApA was isolated cleanly from paper chromatography in overall yields of 50–70%.

Pillaromycin-A: structural and synthetic studies related to the sugar moiety, pillarose[1]

BERT FRASER-REID AND DAVID LOUIS WALKER[2]

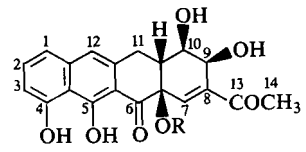
Guelph–Waterloo Centre for Graduate Work in Chemistry, Waterloo Campus, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received April 28, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

BERT FRASER-REID and DAVID LOUIS WALKER. Can. J. Chem. **58**, 2694 (1980).

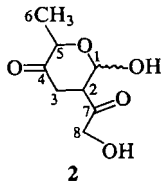
The photo-induced alkylation of enone **6** with ethylene glycol gave an adduct from which the α-D-*threo* (**16**) and α-D-*erythro* (**17**) modifications of structure **2** have been elaborated. It was thereby shown that **2** is not the structure of pillarose. Addition of vinyl magnesium bromide to the ketone **24***b* gave a slight excess of one allylic alcohol, **25**, which upon treatment with osmium tetroxide and hydrogen peroxide gave directly the α,α′-ketodiol **3***a*. The epimer of the latter **33***b* was available via carboxymethylenation of ketone **24***b*, reduction of ester, and hydroxylation. Benzoylation of these epimers gave **3***b* and **33***c* respectively and it was concluded that the former, methyl 2,3,6-trideoxy-4-*C*-[oxo(benzoyloxymethyl)methyl]-α-D-*threo*-hexopyranoside, **3***b*, is the enantiomer of the "methyl 8-*O*-benzoyl pillaroside" obtained from the antibiotic pillaromycin A.



BERT FRASER-REID et DAVID LOUIS WALKER. Can. J. Chem. **58**, 2694 (1980).

L'alkylation photo induite de l'énone **6** par l'éthylèneglycol donne un adduit à partir duquel on a étudié soigneusement les composés α-D-*thréo* (**16**) et α-D-*érythro* (**17**) qui résultent des modifications de la structure du composé **2**. On a ainsi montré que le composé **2** ne représente pas la structure de la pillarose. L'addition du bromure de vinylmagnésium sur la cétone **24***b*, donne un léger excès de l'alcool allylique **25** qui, traité par le tétraoxyde d'osmium et l'eau oxygénée, conduit directement au cétodiol-α,α′ **3***a*. L'épimère de ce dernier **33***b* est préparé par la carboxyméthylénation de la cétone **24***b* et la réduction de l'ester suivie d'une hydroxylation. Par benzoylation, les épimères conduisent respectivement à **3***b* et **33***c* et on a conclu que le premier des deux soit le méthyltridéoxy-2,3,6 *C*-(oxo(benzoyloxyméthyl)-méthyl)-4 α-D-*thréo* hexopyrannoside **3***b* est l'énantiomère du "méthyl-*O*-benzoyl-8 pillaroside" obtenu à partir de l'antibiotique pillaromycine A.

[Traduit par le journal]



Introduction

Current interest in the anthracycline antibiotics runs very high (1) because of the antitumor activity displayed by many members of this family. Pillaromycin A, **1***a*, isolated from cultures of *Streptomyces flavovirens*, was no exception since it displayed colchicine-like antitumor activity, and relatively low toxicity (2*a*). From the standpoint of structure, considerable interest centres around the differences in the aglycones of **1***a* (2*b*) and those of daunomycin and its analogues. For example in **1***b*, (*a*) the acetyl side chain is at C8 rather than C9, (*b*) the site of unsaturation in ring A is unusual, (*c*) the sugar is attached at the ring junction rather than at C7, and (*d*) the sugar is linked through a tertiary rather than secondary oxygen.

a R = Pillarose
b R = H

2

3

The structure originally assigned to the sugar moiety, pillarose, was equally unique in being a tricarbonyl sugar with a two-carbon branch located at C2 (2*c*). We therefore set out to confirm this assignment, in the course of which we showed that the structure was in fact **3** and not **2**, by synthesizing all related structures (3). Since then, other synthetic routes to **3** have been developed in the laboratories of Paulsen (4) and Brimacombe (5).

In this paper, we give details of our synthesis of (+)-**3** and reexamine some of the data used for making the original structure assignments (2).

Some Anomalies in Structural Assignment of 2

At the outset a number of questions could be raised about the assignments leading to structure **2** (2*c*).

1. An equilibrium between the hemiacetal, **2**, and hemiketal, **4**, was clearly possible, although no mention of its occurrence had been made, and no glycosides arising from **4** had been reported.

SCHEME 1

2. Treatment of **1***a* with methanolic hydrogen chloride was said to produce methyl glycosides of **2** without any ketalisation at the C7 and C4 carbonyl groups.

3. Sodium borohydride reduction of **2** was said to occur at the "isolated" carbonyl; however, the dihydropillaroside obtained is assigned as **5**, which would have resulted from reduction at the more hindered carbonyl.

4. Since the dihydropillaroside obtained by borohydride reduction did not show a carbonyl group in the ir, the hemiketal form **5** seemed to be suggested. However, such a hemiketal would also have been reduced by borohydride.

5. Sodium periodate oxidation of pillarose was found to give acetaldehyde, carbon dioxide, formaldehyde, and succinaldehydic acid. However, the last-named substance could not have arisen from **2**.

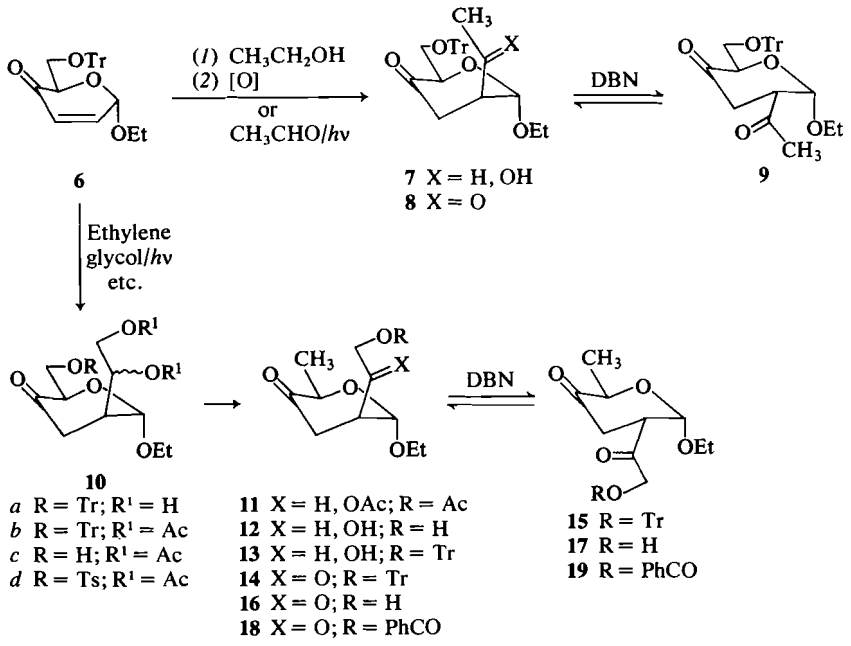
Synthesis of the Proposed Pillarosides 18 and 19 Related to 2

The original structural studies (2) did not assign configurations at C2 and C5; hence a synthesis of structures **18** and **19**, which represent the possible *relative* stereochemistries, was devised.

The photochemically-induced addition of alcohols to enones had been developed in our laboratory as a valuable and simple method of alkylation (6), and we had found that the addition of ethanol to enone **6** (8) led to the epimeric mixture of alcohols **7** from which diketone **8** could be obtained by oxidation with Collin's reagent (9). Alternatively **8** may be obtained by photo-induced addition of acetaldehyde to **6** (7).

Compound **8** was therefore a convenient substance for studying the epimerization at C2. Sodium methoxide in methanol failed to epimerize **8** at room temperature, and at elevated temperatures decomposition occurred. However 1,5-diazabicyclo[4.3.0]-non-5-ene (DBN) in tetrahydrofuran at room temperature led after 1 hour to a 3:2 mixture of **8** and **9** judging from the H1 signals at 5.25 and 5.45 ppm. Prolonged treatment with the base, or use of elevated temperatures, did not affect the proportions of **8** and **9**.

The information obtained in these studies was now applied towards the synthesis of analogues of **2**. Photoaddition of ethylene glycol to enone **6** (7) and acetylation of the resulting diol afforded **10***b* in 80% yield. Deoxygenation at C6 was carried out using standard procedure leading to the diacetate **11**. The latter was then deacetylated and the diol **12** was tritylated giving **13**. Compounds **10–13** are epimeric mixtures at C7 and hence did not crystallize. Fortunately the transformations could be readily monitored by nmr and mass spectroscopy. Thus when the difference was removed by oxidation of the epimeric alcohols **13**, the ketone **14** crystallized readily.



As with the prototype **8**, treatment of **14** with DBN gave the equatorial isomer **15**, judging from the nmr spectra. Unfortunately the epimers **14** and **15** were not resolved on tlc; however, when the mixture was detritylated the two alcohols **16** and **17** were resolved on tlc. However, these substances proved to be very sensitive and did not survive prolonged contact on a silica column during chromatographic fractionation. Hence upon completion of the detritylation, and removal of the triphenylmethanol on a short column, the mixture of **16** + **17** was benzoylated giving **18** + **19**. These were also resolved on tlc and were stable to column chromatography, which therefore afforded each diketone as a crystalline substance. The identity of **18** as the axial C2 epimer was verified by independent preparation from crystalline **14**.

Some Differences between Methyl 8-O-Benzoyl Pillaroside and 18 and 19

Asai (2) had reported the isolation of a crystalline methyl glycoside of 8-*O*-benzoyl pillarose. Our compounds **18** and **19** are in the α-D series, but one of them had to be the same as his with the possible exceptions that (*i*) ours is an ethyl glycoside, (*ii*) his could be an L-sugar, or (*iii*) his could be a β-anomer. None of these differences would be expected to affect grossly the ^{1}Hmr spectra of these analogues. However the data assembled in Table 1 show some striking differences in the entries in the first three rows. Particularly noteworthy are the differences in the chemical shifts for H1, H2, and CH_3.

From the standpoint of chemical behaviour, our experience (*vide supra*) had shown that **16** and **17**

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12

SCHEME 2

were decomposed by attempted fractionation on a column of silica gel. It therefore seemed unlikely that such delicate structures would have survived the highly acidic conditions used for the cleavage of pillaromycin A (*2a*) or for the glycosidation of pillarose (*2c*).

Spectroscopic Analysis of Pillaromycin A

In the original investigations an X-ray study had been made of the aglycone pillaromycinone, **1***b*, by itself (11); but in view of the discrepancies noted in Table 1 and the anomalies discussed above, it was decided to obtain an X-ray study of the entire antibiotic, pillaromycin A, **1***a*.[3] It was thereby found that the structure of pillarose was **3** and not **2**, and from the absolute stereochemistry which had been established for the aglycon pillaromycinone **1***b* (11), it was possible to further establish that pillarose was the L-*threo* modification of **3** (10).

Structure **2** is two mass units less than **3**, hence the

[a]Obtained on PS-100 and HR-220 spectrometers by Dr. I. Miura of Columbia University, New York.
[b]The numbering of the aglycon, *1b*, is typical for the anthracyclines (1), and is different from that used in the original publications on pillaromycin-A (2).

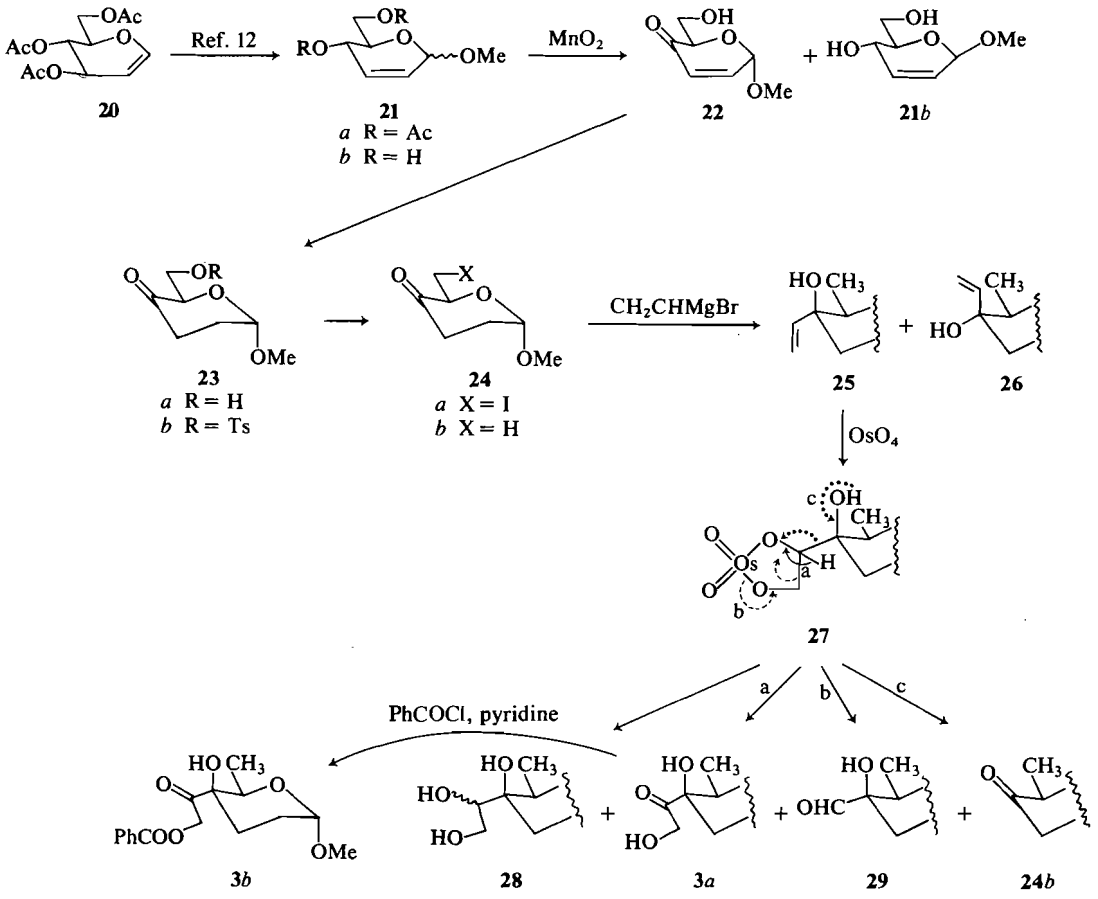
crystalline antibiotic[3] was examined by Field Desorption Mass Spectroscopy[4]; *m/e* 543 (29%), 542 (100), 526 (2), 370 (2), 336 (2), 173 (1). The *m/e* 370 peak represents the aglycon + H, the corresponding glycosyl portion (i.e., 3 minus the anomeric OH) appearing at *m/e* 173. The molecular weight of the complete sugar is therefore confirmed at 190.

Carbon and proton magnetic resonance data for the antibiotic in pyridine-d_5 are shown in Table 2.

Periodate Oxidation

The periodate oxidation results which were called into question in Scheme 1, since they could not be reconciled with structure **2**, may now be reinterpreted in the light of the revised structure **3**. The origin of the key fragment succinaldehydic acid is now apparent.

Synthesis of Methyl 8-O-Benzoyl-α-D-pillarose, 3b, and its C4 Epimer, 33c



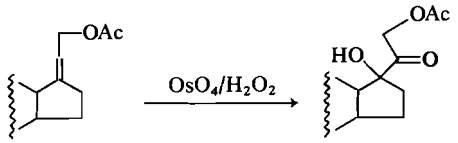
For the purposes of verifying the structure, it was decided to prepare the D-enantiomer of the crystalline methyl 8-*O*-benzoyl-α-D-pillaroside obtained by Asai (*2c*). The starting material for our studies was the enone **22**, the crystalline benzoate of which has been prepared in our laboratory by a lengthy route (8). The Ferrier reaction of **20** with methanol gives **21***a*αβ as an inseparable mixture, unlike the corresponding ethyl glycosides where the α-anomer crystallizes out (12). Actually **21***a*α can be obtained pure via precipitation as the di *p*-nitrobenzoate (12); however, this route proved to be very time consuming and costly in *p*-nitrobenzoyl chloride.

Earlier work in our laboratory had reported the surprising result that certain β-D-hex-2-enopyranosides were not oxidized by manganese dioxide (13). Accordingly the anomeric mixture of diols **21***b*αβ was treated with manganese dioxide, whereupon only the α-anomer responded. The product mixture, **22** and **21***b*β, was then freed of the latter by extraction into water. The overall yield of **22** from **20** by this route was 45% and its authenticity could be verified by comparison with our previously reported material (8).

The conversion of **22** into the 6-deoxy ketone **24***b* in 62% overall yield utilized the standard protocol. The physical constants of **24***b* compared well with those of the enantiomer prepared by Paulsen *et al.* (4) and Brimacombe *et al.* (5).

Inspection of models did not indicate any over-

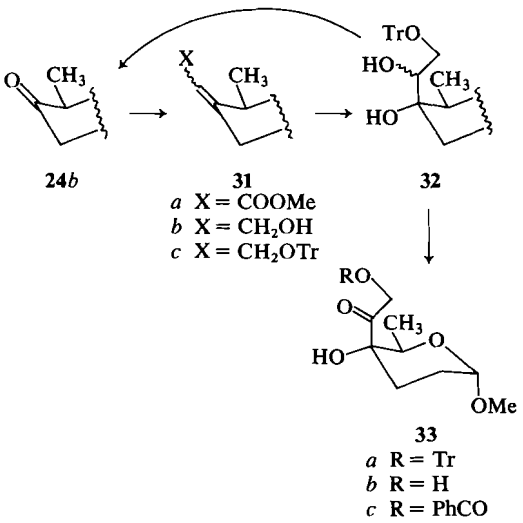
[3]We are grateful to Dr. M. Asai of Takeda Industries Ltd., Osaka, for a 10 mg sample of pillaromycin A.
[4]The source was 68°C anode 10 kV, 20 MA.



SCHEME 3

whelming preference for α or β approach of a reagent to the trigonal centre at C4. We therefore prepared the ester **31***a* (Scheme 4) in the expectation that the desired stereochemistry at C4 could be generated either by addition of a two-carbon nucleophile to ketone **24***b*, or by hydroxylation of the double bond of **31**.

Addition of vinyl magnesium bromide to **24***b* gave two alcohols which were isolated chromatographically in yields of 47 and 35%. Their spectra did not permit an unambiguous assignment of stereochemistry, but the major isomer was chosen for further processing because the H1 signal appeared as a triplet. Subsequent transformations confirmed that the major isomer was **25** and the minor **26**.



With regard to the hydroxylation of the double bond we knew that hydroxylation of Δ^{17}-sterols with osmium tetroxide/hydrogen peroxide led to α ketols such as **30** (14). Although the mechanism of the reaction is not known it was decided to treat **25** in the hope that the secondary position would be oxidized before the primary. In the event, osymylation of **25** gave a complex mixture from which the triol **28**, actually a mixture of epimers, was isolated as an oil whichdecomposed rapidly. However, overoxidation products included the desired ketodiol **3***a* as well as compounds **29** and **24***b*. Pathways a, b, and c leading to **3***a*, **29**, and **24***b* from the intermediate osmate ester **27** are suggested in Scheme 3.

The alternative approach to the carbon skeleton of **3** involving addition of oxygen to the trigonal centre at C4 was now examined (Scheme 4). A Wadsworth–Emmons–Wittig reaction on **24***b* afforded the *E,Z* mixture **31***a* which was reduced to the alcohols and protected with trityl chloride *E,Z*

30

For personal use only.

SCHEME 4

31*c*. Because of the insolubility of the latter in *tert*-butanol it was not possible to carry out a catalytic hydroxylation. However, reaction with osmium tetroxide in pyridine and chromatographic isolation afforded **32** in 27% overall yield from **24***b*.

The stereochemistry of this diol was not known until subsequent transformations confirmed it to be **32**. Oxidation of **32** with Collin's reagent (9) regenerated ketone **24***b*. However, the Pfitzner–Moffat reagent (15) did oxidize **32**, judging from tlc, although ketol **33***a* could not be separated from the noncarbohydrate by-products until it had been detritylated. The overall yield of **33***b* from **32** was 27%.

Conclusion

The epimers **3***a* and **33***b* were now benzoylated so as to enable comparisons with methyl 8-*O*-benzoyl pillaroside. As indicated in Table 1, the benzoate **3***b* was obtained as a crystalline substance, but **33***c* failed to crystallize. Further comparison of the data in Table 1 indicate that methyl 4-*C*-(2-benzoyloxy-1-oxoethyl)-2,3,6-trideoxy-α-D-*threo*-hexopyranoside, **3***b*, is the enantiomer of Asai's methyl 8-*O*-benzoyl pillaroside (2*c*).

Experimental

Melting points were determined in capillary tubes in a Mel-Temp block and are uncorrected. Elemental analyses were performed by Micro-analyses Laboratory, Toronto, Ontario. The nmr spectra ($CDCl_3$, TMS) were determined on a Varian T-60, a Varian HA 100, or a Varian HR-220 spectrometer, the *J* values quoted being the spacing measured directly from the spectra. Infrared spectra were determined on a Beckman model IR-10 spectrometer using 0.1 mm sodium chloride solution cells (chloroform as solvent). Optical rotations were determined on a Carl Zeiss model LEP nür 370740 Lichtelektrishes Prazision polarimeter at 23°C.

Thin-layer chromatography was performed on glass plates coated with silica gel (HF-254, E. Merck) to a thickness of 0.3 mm. The following solvent systems were used to develop the plates: ethyl acetate – petroleum ether (30–60°C) (1:4); ethyl acetate – petroleum ether (30–60°C) (1:1); ethyl acetate; or benzene. For column chromatography E. Merck silica gel (0.063–0.20 mm, 70–230 mesh A.S.T.M.) was used.

The general procedure for detritylation was to dissolve the tritylated compound in chloroform, lower the temperature to −30°C, and add a −30°C solution of hydrogen chloride in chloroform to this. The hydrogen chloride/chloroform solution was prepared by bubbling hydrogen chloride into the chloroform for approximately 0.5 min. This addition would not, in most cases, be enough to complete the reaction (tlc was run 15 min after addition). One further addition of the same volume of hydrogen chloride/chloroform, however, normally was sufficient to complete the reaction. Throughout the reaction the temperature was maintained at −30°C.

Ethyl 2-C-Acetyl-2,3-dideoxy-6-O-triphenylmethyl-α-D-threo-hexapyranosid-4-ulose, **8**

The enone **6** (8) (1.0 g; 2.42×10^{-3} mol) was irradiated in ethanol (400 mL) and benzophenone (0.12 g; 6.38×10^{-4} mol) for 5 h at which time tlc showed completion of the reaction. Column chromatography (petroleum ether (30–60°C) – ethyl acetate (13:7)) afforded **7** (0.858 g; 75%) as an epimeric mixture at C7. This photoproduct was oxidized in methylene chloride (25 mL) with Collin's reagent (9) (5.0 g; 1.94×10^{-2} mol) for 0.5 h. The solution was diluted with diethyl ether (75 mL), stirred for an additional 5 min, and then filtered through Celite. The filtrate was washed with a 5% solution of hydrochloric acid, a saturated solution of sodium bicarbonate, and then dried over anhydrous sodium sulphate. Evaporation under reduced pressure yielded **8** (0.82 g; 96%) which crystallized on standing. Recrystallization from diethyl ether afforded needles, mp 107.5–108°C; $[\alpha]_D^{23}$ +152.6° (*c* 1.25, chloroform); nmr (HR-220) δ: 2.23 (s, 3, H_3C—CO), 2.47 (dd, 1, $J_{2,3e}$ = 4.4 Hz, $J_{3e,3a}$ = 15.5 Hz, H-3e), 2.79 (dd, 1, $J_{2,3a}$ = 12.0 Hz, H-3a), 3.03 (m, 1, H-2), 3.40 (dd, 1, $J_{5,6'}$ = 6.0 Hz, $J_{6,6'}$ = 10.0 Hz, H-6′), 3.49 (dd, 1, $J_{5,6}$ = 2.7 Hz, H-6′), 4.23 (dd, 1, H-5), 5.25 (d, 1, $J_{1,2}$ = 5.2 Hz, H-1). *Anal.* calcd. for $C_{29}H_{30}O_5$: C 75.96, H 6.59; found: C 75.91, H 6.44.

Ethyl 2,3-Dideoxy-2-C-acetyl-6-O-triphenylmethyl-α-D-erythro-hexopyranosid-4-ulose, **9**

The diketone **8** (0.68 g; 1.48×10^{-3} mol) was dissolved in dry tetrahydrofuran (40 mL) and a solution of diazabicyclononene (0.20 g; 1.62×10^{-3} mol) in tetrahydrofuran (10 mL) was added to this. After 1 h the solution was poured into ice-water (60 mL) and extracted twice with chloroform (100 mL). The chloroform layer was washed with 5% hydrochloric acid and then with a saturated solution of sodium bicarbonate, dried over anhydrous sodium sulphate, and finally evaporated under reduced pressure. The resulting oil (0.64 g; 94%) showed two products on tlc (petroleum ether (30–60°C) – ethyl acetate (4:1)). The more polar component, R_f 0.19, was **9** and the less, R_f 0.21, was **8**. Column chromatography afforded **8** (0.28 g), a mixture of **8** and **9** (0.11 g), and **9** (0.15 g). Attempts to crystallize **9** failed.

Nuclear magnetic resonance (HR-220) δ: 2.18 (s, 3, H_3C—CO), 2.54 (dd, 1, $J_{2,3e}$ = 6.7 Hz, $J_{3e,3a}$ = 17 Hz, H-3e), 2.92 (dd, 1, $J_{2,3a}$ = 10.0 Hz, H-3a), 3.35 (m, 1, H-2), 3.42 (dd, 1, $J_{5,6'}$ = 6.0 Hz, $J_{6,6'}$ = 10.0 Hz, H-6), 3.54 (dd, 1, $J_{5,6}$ = 2.6 Hz, H-6), 4.19 (dd, 1, H-5), 5.45 (d, 1, $J_{1,2}$ = 3.9, H-1).

*Ethyl 2,3,6-Trideoxy-2-C-[1-oxo-2-(triphenylmethoxy)ethyl]-α-D-*threo-*hexopyranosid-4-ulose*, ***14***

The intermediates **10**, **11**, **12**, and **13** were all epimeric mixtures at C7 and hence did not crystallize. The course of the transformations was monitored by nmr.

Crystalline enone **6** (8) (6.0 g; 1.45×10^{-2} mol) and benzophenone (0.45 g; 2.48×10^{-3} mol) were dissolved in acetonitrile (300 mL) and ethylene glycol (1500 mL) was then added. The solution was irradiated under a stream of nitrogen for 5 h. The acetonitrile and ethylene glycol were evaporated under reduced pressure, 0.01 Torr and a bath temperature of 80°C being required to remove ethylene glycol. Subsequent column chromatography (diethyl ether–benzene (1:1)) of the residue yielded photoproduct diol, **10***a*, (5.02 g; 72%) which was acetylated in pyridine (60 mL) with acetic anhydride (5 mL) at 0°C over 18 h. Normal workup yielded **10***b* (5.57 g; 94%) as a thick oil; ir: 1730 cm^{-1} (saturated ketone). The nmr spectrum of the oil showed two doublets for H1 at 5.28 ppm ($J_{1,2}$ = 4.1 Hz) and 5.08 ppm ($J_{1,2}$ = 5.0 Hz) in 2:1 ratio.

This material was dissolved in chloroform (160 mL) and detritylated with HCl as described in "General Methods" above. Chromatographic purification afforded the alcohol **10***c* (2.66 g) which was tosylated (pyridine (60 mL); TsCl (3.2 g)) at 0°C for 24 h. Normal workup gave **10***d* as a thick yellow oil (3.71 g) showing the required nmr signal for the *p*-toluenesulfonyl group (δ = 2.44 ppm).

The sulphonate ester **10***d* (3.71 g; 7.88×10^{-3} mol) was dissolved in methyl ethyl ketone (180 mL) and sodium iodide (2.3 g; 1.57×10^{-2} mol) was added with stirring and the solution brought to reflux. Thin-layer chromatography (diethyl ether – benzene (1:1)) after 1.5 h showed one new product (R_f 0.56 as compared to 0.52 for **10***d*). At 2 h the reaction mixture was poured into ice-water and extracted three times with chloroform (300 mL). The combined chloroform layers were washed once with a 2% solution of sodium thiosulphate and then a saturated sodium bicarbonate solution. After drying over anhydrous sodium sulphate, evaporation under reduced pressure gave a product, presumed to be the desired 6-iodide, since the nmr spectrum no longer showed the 2.44 ppm signal for the toluenesulphonyl group.

The oil (3.142 g) was dissolved in reagent acetone and treated with Raney nickel under reflux for 12 h. The solution was filtered through Celite and the Raney nickel washed with reagent acetone. Evaporation of the filtrate gave **11** (2.16 g; 97%) as a pale yellow mobile oil. Its nmr spectrum showed a doublet (3H) at δ 1.28 ppm for the C6 hydrogens, and the mass spectrum gave a peak at *m/e* 257 corresponding to the loss of the aglycon (OEt) from the molecular ion.

The 6-deoxy sugar **11** (2.16 g; 7.14×10^{-3} mol) was deacetylated by treatment with a mixture of methanol (70 mL), water (25 mL), and triethylamine (5 mL) for 4 h (R_f 0.27, EtOAc). The reaction mixture was evaporated to dryness under reduced pressure and final traces of water were azeotroped with benzene. The orange oil **12** (1.53 g; 7.02×10^{-3} mol; 98%) was dissolved in pyridine (40 mL) and trityl chloride (4.0 g; 1.44×10^{-2} mol) was added. The tritylation was complete after 48 h. Normal work-up gave a thick orange oil which after column chromatography (diethyl ether – benzene (1:9)) afforded **13** (2.42 g; 75%). This material was oxidized with Collin's reagent (8.25 g) as described for **7** above. The customary workup gave **14** (2.32 g; 93%) which crystallized from its oil on standing. Recrystallization from diethyl ether gave needles, mp 108–109°C; $[\alpha]_D^{23}$ +108.0° (*c* 1.80, chloroform); nmr (HR-220) δ: 1.24 (d, 3, $J_{5,6}$ = 6.8 Hz H_3C—C), 2.45 (dd, 1, $J_{2,3e}$ = 5.1 Hz, $J_{3e,3a}$ = 16.2 Hz, H-3e), 2.61 (dd, 1, $J_{2,3a}$ = 8.6 Hz, H-3a), 3.44 (m, 1, H-2), 3.90 (ABq, 2, $J_{8,8'}$ = 17.8 Hz, H-8,8′), 4.14 (q, 1, H-5), 5.11 (d, 1, $J_{1,2}$ = 4.5 Hz, H-1). *Anal.* calcd. for $C_{29}H_{30}O_5$: C 75.96, H 6.59; found: C 76.04, H 6.72.

*Ethyl 2-*C*-(2-Benzoyloxy-1-oxoethyl)-2,3,6-trideoxy-α-D-*threo-*hexopyranosid-4-ulose*, ***18***

Compound **14** (1.25 g; 2.72×10^{-3} mol) was dissolved in chloroform (80 mL) and detritylated as described in the "General Methods" above. Column chromatography (diethyl ether – benzene (1:1)) yielded **16** (0.30 g; 51%) as a mobile oil, $[\alpha]_D^{23}$ +174.0° (*c* 2.79, chloroform); ir (chloroform) ν_{max}: 3510, 1726 cm^{-1}; nmr (HR-220) δ: 1.32 (d, 3, $J_{5,6}$ = 6.8 Hz, H_3C—C), 2.49 (dd, 1, $J_{2,3e}$ = 4.5 Hz, $J_{3e,3a}$ = 16.5 Hz, H-3e), 2.77 (dd, 1, $J_{2,3a}$ = 10.4 Hz, H-3a), 3.14 (m, 1, H-2), 4.22 (q, 1, H-5), 4.37 (ABq, 2, $J_{8,8'}$ = 19.6 Hz, H-8, 8′), 5.04 (d, 1, $J_{1,2}$ = 5.5 Hz, H-1).

The alcohol **16** (0.22 g; 1.02×10^{-3} mol) was benzoylated in pyridine (10 mL) with benzoyl chloride (0.5 mL) at 0°C over 12 h. Normal work-up yielded **18** (0.29 g, 89%) which crystallized from its oil on standing. Recrystallization from diethyl ether – hexane (1:1) at 0°C afforded white flaky crystals, mp 85.5–86°C; $[\alpha]_D^{23}$ +219.0° (*c* 1.34, chloroform); nmr (HR-220) δ: 1.32 (d, 3, $J_{5,6}$ = 6.8 Hz, H_3C—C), 2.50 (dd, 1, $J_{2,3e}$ = 4.4 Hz, $J_{3e,3a}$ = 16.3 Hz, H-3e), 2.81 (dd, 1, $J_{2,3a}$ = 11.2 Hz, H-3a), 3.24 (m, 1, H-2), 4.23 (q, 1, H-5), 5.00 (ABq, 2, $J_{8,8'}$ = 17.0 Hz, H-8,8′), 5.15 (d, 1, $J_{1,2}$ = 5.2 Hz, H-1). *Anal.* calcd. for $C_{17}H_{20}O_6$: C 63.74, H 6.29; found: C 63.78, H 6.31.

*Ethyl 2-*C*-(2-Benzoyloxy-1-oxoethyl)-2,3,6-trideoxy-α-D-*erythro-*hexopyranosid-4-ulose*, ***19***

Compound **14** (2.96 g, 6.45×10^{-3} mol) was treated with diazabicyclononene in tetrahydrofuran as described above for **8**. The resulting mixture of epimers **14** + **15** (2.78 g) was detritylated with hydrogen chloride as described in "General Methods" above. Column chromatography (diethyl ether – benzene (1:1)) gave a substance (0.49 g) which was benzoylated at 0°C in pyridine (20 mL) with benzoyl chloride (2 mL) over 12 h. Normal work-up afforded a two component mixture (0.66 g; 91%) as visualized by tlc (diethyl ether – benzene (1:9)). Column chromatography gave the above described **18** (0.41 g; R_f 0.19) and **19** (0.17 g; R_f 0.13). The latter crystallized from ether to give white fibers, mp 85.5–87°C; $[\alpha]_D^{23}$ +77.2° (*c* 0.93, chloroform); nmr (HR-220) δ: 1.29 (d, 3, $J_{5,6}$ = 6.8 Hz, H_3C—C), 2.54 (dd, 1, $J_{2,3e}$ = 5.9 Hz, $J_{3e,3a}$ = 16.0 Hz, H-3e), 2.94 (dd, 1, $J_{2,3a}$ = 9.2 Hz, H-3a), 3.58 (m, 1, H-2), 4.26 (q, 1, H-5), 4.97 (s, 2, H-8, 8′), 5.38 (d, 1, $J_{1,2}$ = 4.6 Hz, H-1). *Anal.* calcd. for $C_{17}H_{20}O_6$: C 63.74, H 6.29; found: C 63.85, H 6.53.

*Methyl 2,3-Dideoxy-α-D-*glycero-*hex-2-enopyranosid-4-ulose*, ***22***

Triacetyl glucal **20** (25.0 g; 9.2×10^{-2} mol) in benzene (85 mL), dry methanol (8.5 mL), and boron trifluoride-etherate (6.5 mL) was stirred for 0.75 h (12). The solution was neutralized with saturated aqueous sodium bicarbonate, dried over anhydrous sodium sulphate, and evaporated. The resulting oil **21***aαβ* was deacetylated in methanol (340 mL), water (210 mL), and triethylamine (17 mL) during 3.5 h. Customary work-up (see above) gave **21***bαβ* which in turn was treated with active manganese dioxide (95.0 g) in chloroform (4000 mL) for 18 h. The chloroform was filtered and concentrated to a volume of approximately 200 mL, and then washed with water (2 × 50 mL) to remove unreacted **21***bβ*. Evaporation of the remaining chloroform solution afforded **22** (6.5 g; 45% from **20**). Recrystallization from cold diethyl ether gave **22** as white fibers, mp 82.5°C; $[\alpha]_D^{23}$ +36.1° (*c* 2.66, chloro-

For personal use only.

form); nmr (T-60) δ: 3.52 (s, 3, OMe), 3.95 (d, 2, $J_{5,6} = J_{5,6'} = 4.6$ Hz, H-6,6′), 4.46 (t, 1, H-5), 5.20 (d, 1, $J_{1,2} = 4.0$ Hz, H-1), 6.12 (d, 1, $J_{2,3} = 11.0$ Hz, H-3), 6.90 (dd, 1, H-2). *Anal.* calcd. for $C_7H_{10}O_4$: C 53.16, H 6.37; found: C 53.09, H 6.28.

*Methyl 2,3,6-Trideoxy-α-D-*glycero-*hexopyranosid-4-ulose*, **24**b

The enone **22** (6.5 g; 4.12×10^{-2} mol) in ethyl acetate (240 mL) was hydrogenated in the presence of 5% palladium/carbon (0.24 g). After 2 h, uptake of hydrogen (950 mL) was complete. The solution was filtered through Celite and evaporated to give **23***a* (6.5 g) as a mobile oil (ir: 3600, 1726 cm^{-1}) which was dissolved in pyridine (45 mL) and methylene chloride (20 mL), and treated with *p*-toluenesulfonyl chloride (16.0 g; 8.14×10^{-2} mol) for 18 h, at which time tlc showed that formation of the ester **23***b* was complete. The syrupy material (11.5 g; 3.65×10^{-2} mol), which had an extremely irritating odour, was dissolved in methyl ethyl ketone (290 mL), and stirred at room temperature with sodium iodide (30.0 g; 2.0×10^{-1} mol) for 17 h. Thin-layer chromatography (diethyl ether – benzene (1:1)) at this time showed that the tosylate **23***b* (R_f 0.42) had been converted to the iodide **24***a* (R_f 0.63). The solution was poured into ice-water and extracted twice with chloroform (300 mL) and the combined chloroform layers were washed with a dilute solution of sodium thiosulphate, dried over anhydrous sodium sulphate, and evaporated to give a mobile oil (7.7 g; 78%). This oil, **24***a*, (2.85×10^{-2} mol) was immediately refluxed in reagent grade acetone (600 mL) with Raney nickel (80 g) for 18 h at which time tlc (diethyl ether – benzene (1:1)) showed a single component (R_f 0.55). The solution was filtered through Celite and evaporated to give **24***b* (3.76 g; 92%) as a mobile oil, *m/e* 113 ($M^+ - OMe$); $[\alpha]_D^{23}$ −225° (*c* 0.7, chloroform) (lit. (4) $[\alpha]_D^{23}$ −232°; (5) −254°).

Grignard Addition of Vinyl Magnesium Bromide to **24**b

Dry tetrahydrofuran (140 mL) and magnesium turnings (1.65 g; 6.95×10^{-2} mol) were introduced into a 500 mL 3-necked round bottom flask fitted with a dry ice/isopropanol condenser and drying tube, an atmosphere of nitrogen being maintained. A few crystals of iodine were added with stirring, followed by vinyl bromide (8.5 mL; 1.20×10^{-1} mol), and the solution brought to reflux. The iodine colour disappeared after 5 min and the magnesium had completely reacted after 30 min. The Grignard solution was then cooled to 0°C and a tetrahydrofuran (20 mL) solution of the ketone **24***b* (2.0 g; 1.39×10^{-2} mol) was added dropwise. Thin-layer chromatography (diethyl ether – benzene (1:1)) showed the absence of ketone **24***b* (R_f 0.55) and the appearance of two products (R_f 0.40, 0.33) after 15 min. At 45 min a saturated ammonium chloride solution was added and the resultant solution extracted with chloroform (2 × 100 mL). The combined chloroform layers were washed with water, dried over anhydrous sodium sulphate, and evaporated. Subsequent column chromatography of the residue gave **26** (R_f 0.40; 0.85 g; 35% from **24***b*), and **25** (R_f 0.33; 1.11 g; 47% from **24***b*) as mobile oils.

For **25**, nmr (T-60) δ: 1.06 (d, 3, $J_{5,6} = 6.8$ Hz, H_3C—C), 1.4–2.1 (m, 4, H-2a, 2e, 3a, 3e), 2.4 (s, 1, OH), 3.34 (s, 3, OMe), 3.82 (q, 1, H-5), 4.68 (d, 1, $J_{1,2e} = 0$ Hz, $J_{1,2a} = 2.5$ Hz, H-1), 5.14 (dd, 1, $J_{7,8'} = 10.0$ Hz, $J_{8,8'} = 2.5$ Hz, H-8′) 5.35 (dd, 1, $J_{7,8} = 15.2$ Hz, H-8), 5.80 (dd, 1, H-7).

For **26**, nmr (T-60) δ: 1.06 (d, 3, $J_{5,6} = 6.8$ Hz, H_3C—C), 1.5–2.0 (m, 4, H-2a, 2e, 3a, 3e), 2.43 (s, 1, OH), 3.35 (s, 3, OMe), 3.84 (q, 1, H-5), 4.72 (t, 1, H-1), 5.31 (dd, 1, $J_{7,8'} = 11.0$ Hz, $J_{8,8'} = 2.5$ Hz, H-8′), 5.41 (dd, 1, $J_{7,8} = 18.5$ Hz, H-8), 6.37 (dd, 1, H-7).

Hydroxylation of **25**

The olefin **25** (1.02 g; 5.9×10^{-3} mol) was dissolved in dry *tert*-butanol (15 mL). Osmium tetroxide (0.03 g; 1.18×10^{-4} mol) in *tert*-butanol (30 mL) and a 6% solution (15 mL) of dry hydrogen peroxide in *tert*-butanol were added with stirring. After 18 h, tlc (diethyl ether – benzene (1:1)) showed no olefin (R_f 0.33) and four products (R_f 0.54, 0.26, 0.16, and 0.03). The osmium tetroxide was destroyed with excess sodium bisulphite and the solution was evaporated, taken up in water (75 mL), and extracted with chloroform (4 × 60 mL). The chloroform layer was dried and evaporated and the resulting residue chromatographed to give **24***b* (0.085 g; 10%; R_f 0.54); **29** (0.090 g; 8.7%; R_f 0.26), and **3** (0.255 g; 21%; R_f 0.155). The water layer was evaporated to dryness and the residue extracted with ethyl acetate. Evaporation of the ethyl acetate gave the epimeric mixture **28** (0.61 g; 50%; R_f 0.027); *m/e* 175 ($M^+ - OMe$). This substance decomposed on standing.

For **29**, nmr (T-60) δ: 1.1 (d, 3, $J_{5,6} = 6.8$ Hz, H_3C—C), 1.2–2.3 (m, 4, H-2a, 2e, 3a, 3e), 2.9 (broad singlet, 1, OH), 3.38 (s, 3, OMe), 4.20 (q, 1, H-5), 4.77 (d, 1, $J_{1,2e} = 0$ Hz, $J_{1,2a} = 2.0$ Hz, H-1), 9.55 (s, 1, H-7); *m/e*: 143 ($M^+ - OMe$).

For **3**, nmr (T-60) δ: 1.0 (d, 3, $J_{5,6} = 6.8$ Hz, H_3C—C), 1.4–2.3 (m, 4, H-2a, 2e, 3a, 3e), 3.1 (broad singlet, 1, OH), 3.38 (s, 3, OMe), 4.18 (q, 1, H-5), 4.50 (s, 2, H-8,8′), 4.68 (broad singlet, 1, H-1); *m/e*: 173 ($M^+ - OMe$), 160, 155, 145, 142, 113, and 85.

*Methyl 8-*O*-Benzoyl-α-D-pillaroside*, **3***b*

Methyl pillaroside **3***a* (0.24 g; 1.2×10^{-3} mol) was benzoylated in pyridine (10 mL) with benzoyl chloride (0.5 mL) at 0°C for 8 h. Normal work-up gave **3***b* (0.305 g; 83%) which crystallized on standing. Recrystallization from cold diethyl ether – hexane (1:1) gave plates, mp 107–108°C; $[\alpha]_D^{23}$ +94.6° (*c* 0.45, chloroform); nmr (T-60) δ: 1.15 (d, 3, $J_{5,6} = 6.8$ Hz, H_3C—C), 1.6–2.3 (m, 4, H-2a, 2e, 3a, 3e), 2.79 (broad singlet, 1, OH), 3.34 (s, 3, OMe), 4.22 (q, 1, H-5), 4.7 (broad singlet, 1, H-1), 5.22 (s, 2, H-8,8′), 7.3–8.2 (m, 5, aromatic). *Anal.* calcd. for $C_{16}H_{20}O_6$: C 62.33, H 6.54; found: C 62.40, H 6.42.

*Methyl 4-*C*-(2-Benzoyloxy-1-oxoethyl)-2,3,6-trideoxy-α-D-*erythro-*hexopyranoside*, **33**c

The entire sequence was carried out without chromatographic isolation of the intermediates **31** and **32** since these were geometric and epimeric mixtures respectively.

An ice-cold solution of potassium *tert*-butoxide (0.95 g; 9.3×10^{-3} mol) and trimethyl phosphonacetate (4.1 mL) in dry dimethylformamide (15 mL) was added dropwise to a 0°C solution of the ketone **24***b* (1.13 g; 7.84×10^{-3} mol) in dry dimethylformamide (25 mL). Thin-layer chromatography (diethyl ether – benzene (1:1)) after 1 h showed only one product of higher R_f (0.62). The dimethylformamide was then distilled (0.01 Torr and external temperature of 40°C). The resulting residue was taken up in water (20 mL) and extracted with diethyl ether (3 × 25 mL). The combined ether layers were dried over anhydrous sodium sulphate and evaporated to give a crude oil (1.4 g), whose nmr spectrum showed considerable contamination of the desired product **31***a*. The material was dissolved in dry diethyl ether (100 mL) and the solution cooled to 0°C. Excess lithium aluminum hydride (0.840 g) was added to this solution with stirring. Thin-layer chromatography (diethyl ether – benzene (1:1)) showed absence of **31***a* with one product of lower R_f after 0.5 h. The excess lithium aluminum hydride was destroyed with ethyl acetate and the solution filtered through Celite. Evaporation gave the cor-

For personal use only.

responding alcohol **31***b* (0.94 g) as a crude oil, which was treated with trityl chloride (2.5 g) in pyridine (10 mL) and methylene chloride (4 mL) over 18 h. Normal work-up and column chromatography (diethyl ether – benzene (1:9)) gave **31***c* (1.80 g), contaminated heavily, however, with trityl alcohol.

The crude olefin **31***c* (0.95 g) was dissolved in dry pyridine (15 mL) and osmium tetroxide (0.50 g) in pyridine was added with stirring. After 24 h (tlc showing completion) the osmium tetroxide was destroyed by addition of sodium bisulphite (0.9 g) in water (15 mL) and pyridine (10 mL). The solution was then extracted with chloroform (2 × 50 mL) and the combined chloroform layers were washed with a 5% solution of hydrochloric acid (until the aqueous layer remained acidic), a saturated solution of sodium bicarbonate, dried over anhydrous sodium sulphate, and evaporated. Column chromatography of the resultant residue (0.97 g) gave the diol **32** (0.46 g; 27% from **24***b*).

A portion of the diol **32** (0.28 g; 6.40×10^{-4} mol) was dissolved in benzene (20 mL) and dimethyl sulphoxide (0.6 mL); pyridine (0.5 mL), trifluoroacetic acid (0.25 mL), and *N,N'*-dicyclohexylcarbodiimide (1.0 g; 4.85×10^{-3} mol) were added with stirring. At 2.5 h oxalic acid dihydrate (0.70 g) was added and the stirring continued for 0.5 h. The reaction mixture was then diluted with chloroform (50 mL) and water (50 mL), the two layers separated, and the organic layer washed with a saturated solution of sodium bicarbonate, dried and concentrated to ~30 mL, and cooled to −30°C. Detritylation of **33***a* with hydrogen chloride in chloroform was effected as described in "General Methods". Column chromatography afforded the corresponding alcohol **33***b* (0.029 g; 23% from **32**) which was benzoylated in pyridine (3 mL) with benzoyl chloride (0.2 mL) at 0°C for 10 h. Normal work-up gave the title compound **33***c* (0.040 g; 91%) as an oil, $[\alpha]_D^{23}$ +74.8 (*c* 1.54, chloroform); nmr (T-60) δ: 1.22 (d, 3, $J_{5,6}$ = 6.8 Hz, H_3C—C), 2.0 (broad singlet, 4, H-2a, 2e, 3a, 3e), 3.39 (s, 3, OMe), 3.98 (q, 2, H-5, OH), 4.82 (t, 1, H-1), 5.18 (s, 2, H-8,8′), 7.3–8.2 (m, 5, aromatic).

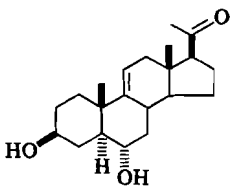
Received July 24, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

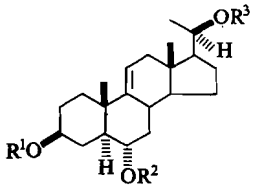
JOHN W. APSIMON, SATYANAND BADRIPERSAUD, JOHN A. BUCCINI, JOOP EENKHOORN, and MICHAEL W. GILGAN. Can. J. Chem. **58**, 2703 (1980).

A minor constituent of the saponin hydrolysate of the starfishes *Asterias forbesi* and *Asterias vulgaris* is shown to be (20*R*)-5α-pregn-9(11)-ene-3β,6α,20-triol by synthesis from 11-oxoprogesterone. The occurrence of the reduced progesterone side chain could have implications concerning the origins of progesterone-type compounds in saponin hydrolysates from starfish.



JOHN W. APSIMON, SATYANAND BADRIPERSAUD, JOHN A. BUCCINI, JOOP EENKHOORN et MICHAEL W. GILGAN. Can. J. Chem. **58**, 2703 (1980).

En se basant sur une synthèse réalisée à partir de l'oxo-11 progestérone, on a montré que le constituant secondaire du produit d'hydrolyse de la saponine des étoiles de mer *Asterias forbesi* et *Asterias vulgaris* est le 5α-pregnène-9(11) triol-3β,6α,20(*R*). La présence de la chaîne latérale réduite de la progestérone pourrait avoir des implications en ce qui a trait aux origines des composés du type progestérone contenus dans les hydrolysats de la saponine de l'étoile de mer.



[Traduit par le journal]

During our studies of the steroids from the saponins of the starfish *Asterias forbesi* we have reported the isolation and characterization, from the acid hydrolysate of the saponin mixture, of the dihydroxypregnane derivative **1** (1), a compound also detected by others in the same and related species (2–6). The conversion of this material into possible corticosteroid precursors has also been reported (7).

Column chromatography on silica gel or preparative thin layer chromatography also led to the isolation of a small amount of a new material that we now assign as the title compound **2**.[2] This material, mp 263–266°C, showed a molecular ion in its high resolution mass spectrum at 334.2500 indicating a molecular formula of $C_{21}H_{34}O_3$; this observation plus all other spectral data were in accord with the structure shown (see Experimental), only the question of stereochemical assignment at C-20 remaining. In separate experiments larger amounts of **2** have been isolated by high performance liquid chromatography (hplc) from the saponins of *Asterias vulgaris*.

1

	R¹	R²	R³
2	H	H	H
3	Ac	Ac	Ac
9	H	H	Ac

The structural assignment was confirmed and the stereochemistry at C-20 shown to be the *R*-configuration by an unequivocal synthesis of its triacetate **3** from **1** by sodium borohydride reduction in ethanol followed by acetylation. All spectral data of the synthetic and natural materials were identical. Literature precedent (8) and the coincidence of observed nuclear magnetic resonance (nmr) chemical shifts for the angular C-18 and C-19 methyl group signals with those calculated for a number of compounds by the use of Zurcher's tables (9) strongly support the assignment of the *R*-configuration at C-20 (see Table 1).

A further synthesis of **2** as its triacetate **3** was carried out as outlined in Scheme 1. This route not only provided further samples of **2** but also provided a number of compounds of use for the as-

[1]For part III see ref. 7*b*.

[2]Our trivial name for the major aglycone **1** is asterone. In some experiments, the herein described triol **2** appeared by gc to have about one half the retention time of asterone. This observation engendered the familiar term "half-asterone". The more logical trivial name asterogenol will be used in this article!

TABLE 1. Proton chemical shifts (δ values) in ppm of angular methyl groups for a variety of hydroxy pregnanes studied[a]

	Experimental values		Calculated values		
			C-19	C-18	
Compound	C-19	C-18	*R* and *S*	*R*	(*S*)
3	1.02	0.56	1.018	0.558	(0.608)
8	1.13	0.86	1.134	0.857	(0.917)
9	0.95	0.57	0.951	0.558	(0.608)
10	1.29	0.89	1.292	0.893	(0.943)
11	0.89	0.64	0.884	0.625	(0.675)
12	1.03	0.65	1.034	0.651	(0.701)
13	1.02	0.65	1.025	0.651	(0.701)

[a]All values determined on a Varian XL-100 nmr spectrometer using TMS as an internal standard with $CDCl_3$ as a solvent.

signment of ^1H and ^{13}C nmr signals. Thus, 11-oxoprogesterone **4** was converted into the known dienolacetate **5** (10) which upon treatment with sodium borohydride in ethanol afforded the pregnene triol **6**. Hydroboration–oxidation of this material led to tetra-ol **7** which (after acetylation to **8**) was dehydrated with perchloric acid in acetic acid at steambath temperature, providing asterogenol triacetate **3**. This compound could be partially hydrolysed to the monoacetate **9** with sodium hydroxide in methanol at room temperature for 1 h. Hydrolysis at reflux temperature in methanol led to asterogenol **2**. Acetylation of triol **6** gave the diacetate **10**, of use in the nmr signal assignments. Three pregnane derivatives (**11**, **12**, and **13**) available in our laboratory were also of use in this study.

A summary of the observed proton nmr chemical shifts of the angular methyl groups of a number of compounds studied are presented in Table 1 together with the values calculated from Zurcher's tables for both the 20*R* and 20*S* configurations. Because of the poor solubility of 20-hydroxy compounds these studies were performed on the corresponding 20-acetoxy derivatives. The close agreement between the experimental and observed values for the C-18 methyl group signals confirms the assignment of the *R* configuration at C-20. The ^{13}C nmr chemical shifts for these compounds are presented in Table 2 and are assigned using the data of Djerassi and

Reagents: *a*, Ac_2O, $HClO_4$, EtOAc; *b*, $NaBH_4$, EtOH; *c*, B_2H_6, H_2O_2, NaOH; *d*, Ac_2O, pyridine; *e*, HOAc, $HClO_4$; *f*, MeOH, aq. NaOH, room temp.; *g*, MeOH, aq. NaOH, reflux.

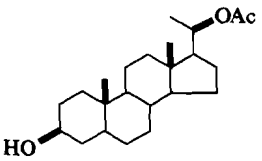
[a,b,c,d] These assignments could be interchanged.
[e] A coincidence of some signals noted.



co-workers (11) for substituent effects in monohydroxy androstanes and pregnanes and their corresponding acetyl derivatives together with the data for pregn-5-en-3β-ol and its acetyl derivative (12) except for compounds **3** and **9**. However, introduction of the 9(11) double bond changes the relative conformational relationships of positions α and β to the double bond. The work of Enzell and co-workers (13) was of particular use here in the assignments for unsaturated species. Of particular note in these data is the invariance of the signals for C-20 (72.8–72.9) and C-21 (19.9 ± 0.1 ppm), supporting the fact that the configuration at C-20 for all these compounds is identical. At the same time the same data for the ring A and B carbon atoms confirm the stereochemistry assigned for the oxygen functions at positions 3 and 6.

12

13

SCHEME 2

The occurrence of asterogenol (**2**) in the saponin mixtures of *Asterias forbesi* and *A. vulgaris* is worthy of note since it has been suggested that asterone **1** is not a true aglycone (6, 14), but rather it occurs from a retroaldol decomposition of the side chain of the true saponin during hydrolysis as outlined in Scheme 2. The appearance of species possessing a 20-hydroxyl group in a hydrolysis mixture cannot be accounted for on this basis, suggesting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

that at least some of the saponins present in the starfish species studied exist with the progesterone side chain as its reduced form. Furthermore we have treated crude saponin mixtures with sodium borohydride in ethanol followed by hydrolysis and hplc analysis. In these cases the yield of asterogenol is significantly increased, suggesting that, in fact, the progesterone side chain is present in the original saponin mixture, and thus that the aglycone **1** is not wholly an artefact.

Experimental

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. The nmr spectra were obtained on a Varian T-60 (^{1}H) or a Varian XL 100 (^{1}H and ^{13}C) spectrometer with tetramethylsilane as internal standard and deuteriochloroform as solvent. Chemical shifts are expressed in the δ scale and the following abbreviations apply: s, singlet; d, doublet; t, triplet; m, multiplet. Infrared spectra were determined on a Perkin-Elmer 237 B ir spectrophotometer and were run in methylene chloride unless otherwise stated. Ultraviolet spectra were obtained on a Perkin-Elmer 202 uv–visible spectrophotometer and were run in 95% ethanol. Mass spectra were determined on an A.E.I. M.S. 12 instrument at Trent University, Peterborough.

*Isolation of (20*R*)-5α-Pregn-9(11)ene-3β,6α,20-triol (2) from the Saponins of* Asterias forbesi

Preparative thin layer chromatography of the *Asterias forbesi* aglycones (from 4.3 g of saponin mixture) (2 mm silica gel plates) developing twice with ethyl acetate – methanol 20:1 allowed for ready separation of asterone (3β,6α-dihydroxy-5α-pregn-9(11)- en-20-one (**1**)). Those aglycones with an R_f less than 0.2 were eluted and rechromatographed, eluting with ethyl acetate – methanol 15:1. Elution of the band with an R_f less than 0.3 with methanol followed by recrystallization from methanol provided a crystalline aglycone (4 mg), mp. 263–266°C; $[\alpha]_D^{20}$ +8° (*c* 0.124 g/100 mL ethanol); ν_{max} (Nujol): 3360, 1033 cm^{-1}. *Exact Mass* calcd. for $C_{21}H_{34}O_3$: 334.2507; found (ms): M^+ 334.2500. Low resolution mass spectrum: 334 (M^+), 319 (*M*-15), 316 (*M*-18), 301 (*M*-15-18), 298 (*M*-(2 × 18)), 283 (301-18), 265 (283-18). *Anal.* calcd. for $C_{21}H_{34}O_3$: C 75.41, H 10.25%; found: C 75.13, H 10.11%.

*The Isolation of Asterogenol Acetate 3 from an Extract of the Common Starfish (*Asterias Vulgaris*)*

Live starfish (*Asterias vulgaris*, 18.9 kg) obtained off Halifax were cleaned of solid debris and then "milked" (1) by immersing them three times in fresh water (ca. 1 L/kg starfish at each immersion). The combined "milks" were filtered through four layers of cheese cloth, passed down a column of Amberlite XAD-2 (Rohm and Haas Company, 330 × 50 mm id), and washed in a procedure similar to that of Hori (15). The solution was passed through the column twice at 50–75 mL/min. The column was washed with two bed volumes of distilled water and eluted with 1.5 bed volumes each of 50% methanol/water and methanol. The solvents were evaporated *in vacuo* (residues: 50% methanol saponins, 1.4 g; 100% methanol saponins, 2.9 g).

The dried residues were suspended in 1 L redistilled ethyl acetate per g of residue. Immediately before heating 10 μL 60% perchloric acid were added per mL of ethyl acetate. The mixture was refluxed for 30 min, cooled, and extracted with water (2 × 100 mL), 1 *N* NaOH (2 × 100 mL), and water (2 × 100 mL). The solvent was evaporated and the brown residues thoroughly dried. The residues were acetylated with pyridine – acetic anhydride (20°C for 30 min), the acetates partitioned between 70% methanol/water and chloroform (2 × 1 vol.), and the chloroform-extractable material recovered (from the 50% methanol fraction, saponin, 1.03 g; 100% methanol fraction, saponin, 2.36 g).

Fractions and recoveries were monitored by gas–liquid chromatography (glc) on a Hewlett-Packard model 402 (column: 3% OV-101 on Chromsorb W-HP (Pierce Chemical Company) 122 cm × 4 mm id, 260°C, helium flow rate 60 mL/min); chromatography (tlc) on Silica Gel-F 254 plates (E. Merck, solvent system: chloroform–hexane – ethyl acetate (15:3:2). The steroids gave visible or uv fluorescent (360 nm) spots when sprayed with sulfuric acid and heated to 110°C for 2–5 min.

Column Fractionation of Aglycone Acetates

Alumina III (Woelm, for dry-column chromatography) columns (150 g, 18 cm long) were packed in 50 mm (flat width) nylon casing. A 5 cm layer of Celite 545 (Johns Manville) was added to protect the alumina origin. The aglycone acetate sample in chloroform was added to a similar amount of Celite, mixed, dried, and added to the top of the column. The column was irrigated with 100 mL chloroform–hexane – ethyl acetate (15:3:2). The appropriate parts of the column were extracted with ethyl acetate (aglycone acetates from 50% methanol fraction, saponins 0.30 g; 100% methanol fraction, 1.15 g).

Liquid Chromatography

The aglycone acetates from the 50% methanol fraction of saponins, which contained the bulk of the asterogenol acetate (**3**) as indicated by glc analysis, were applied as several small samples (up to 300 mg in chloroform solution) to a Porasil A 60 column (Waters Assoc., 1830 × 7.7 mm id) and the column was irrigated with hexane–chloroform – ethyl acetate (10:5:1) at 3 mL/min. The 100% methanol saponin aglycones, with asterogenol acetate as a minor constituent, were fractionated in a similar manner but with uv (Chromatronix model 200) and refractive index detectors (Laboratory Data Control, model 1107). The combination of the appropriate fractions yielded asterogenol acetate (**3**) (oil, 50 mg) which appeared pure by glc and tlc.

*(20*R*)-5α-Pregn-9(11)-ene-3β,6α,20-triol (2)*

Asterone (**1**) (2.0 g, 6.0 mmol) was dissolved in 200 mL of ethanol and was stirred at room temperature for 41 h with sodium borohydride (1 g). Water (100 mL) was added and the reaction mixture was stirred one more hour. The solvent was removed *in vacuo* and to the residue was added 0.5 L of water. The solids were filtered, washed with water, and dried by ethanol–benzene azeotropic removal of the water. A solid white residue (2 g) was obtained, the ir spectrum of which did not indicate any carbonyl absorption peak. For full characterization of this compound, see hydrolysis of asterogenol triacetate (**3**) below.

*(20*R*)-5α-Pregn-9(11)-ene-3β,6α,20-triol Triacetate (3)*

The above crude reaction product (1 g) was dissolved in pyridine (5 mL), acetic anhydride (50 mL) was added, and the reaction mixture was stirred at room temperature for 19 h after which the mixture was poured into water (100 mL). After stirring the mixture for 1 h, the aqueous solution was extracted with ether and the extracts were washed with 2 *N* aqueous HCl solution, saturated NaCl solution, saturated $NaHCO_3$ solution, and saturated NaCl solution. After drying over Na_2SO_4 the ether was removed *in vacuo* to give 1.5 g of a white foam. Pure asterogenol triacetate (**3**) was obtained by column chromatography (silica gel (45 g) prepared in petroleum ether containing 5% diethyl ether). The column was eluted with petroleum ether 30–60°C containing increasing amounts of ether to provide a

colourless oil (1.1 g) (i.e. 80% over two steps). Infrared (neat) ν_{max}: 1730 (C=O) cm^{-1}; nmr δ: 0.56 (s, 3, CH_3-18 H), 1.02 (s, 3, CH_3-19 H), 1.17 (d, 3, CH_3-21 H, J = 3 Hz), 2.04 (s, 9, CH_3COO), 4.8 (m, 3, H-C-OAc), 5.4 (6.5, 1, vinyl H); mass spectrum: 460 (1%, M^+), 400 (20, M − HOAc), 340 (48, M − 2HOAc), 280 (64, M − 3HOAc), 265 (43, M − 3HOAc − CH_3). *Anal.* not submitted due to instability of the compound. *Exact Mass* calcd. for $C_{27}H_{40}O_6$: 460.2825; found (high resolution mass spectrum): M^+ 460.2787.

11-Oxoprogesterone (4)

Material obtained from the Upjohn Co. was recrystallized from methanol, mp 178–179°C; uv λ_{max}: 238 (14 900); ir ν_{max}: 1701 (CO), 1667 (α,β-unsaturated CO) cm^{-1}; nmr δ: 0.65 (s, 3, CH_3-18 H), 1.42 (s, 3, CH_3-19 H), 2.12 (s, 3, CH_3CO), 5.72 (s, 1, vinyl H).

3-Acetoxypregna-3,5-diene-11,20-dione (5)

To a solution of 11-oxoprogesterone (**4**) (10.0 g, 30.5 mmol), dissolved in ethyl acetate (300 mL), was added a mixture of acetic anhydride (40 mL) and ethyl acetate (120 mL), followed by a solution of perchloric acid (0.04 mL) in ethyl acetate (40 mL). The resulting yellow solution was stirred for 20 min at room temperature. The reaction was stopped by addition of saturated sodium bicarbonate solution (100 mL). The mixture was added to a slurry of sodium bicarbonate (100 g) in water (200 mL) which was stirred until carbon dioxide evolution had ceased. The organic layer was separated and the aqueous layer was extracted with ether. The combined organic layers were washed with saturated sodium bicarbonate solution and with water, and were dried (Na_2SO_4). The solvent was removed *in vacuo* and the solid residue was recrystallized from methanol containing some pyridine to give 9.6 g of a colorless crystalline product (85%), mp 145–147°C (lit. (10) mp 143–145°C); uv λ_{max}: 233 (19 100) nm; ir ν_{max}: 1751 (acetate CO), 1708 and 1701 (CO) cm^{-1}; nmr δ: 0.64 (s, 3, CH_3-18 H), 1.20 (s, 3, CH_3-19 H), 2.12 (s, 3, CH_3CO), 2.14 (s, CH_3CO), 5.35 (m,1, vinyl H-6), 5.67 (s, 1, vinyl H-4).

(20R)-Pregn-5-ene-3β,11β,20-triol (6)

3-Acetoxy-pregna-3,5-diene-11,20-dione (**5**) (9.4 g, 25.4 mmol) was dissolved in ethanol (900 mL) and was stirred with sodium borohydride (4 × 1.5 g added over 12 days) at room temperature. Water (200 mL) was added and the reaction mixture was stirred for 2 h. The solvent was removed *in vacuo* and the residue was stirred with water (500 mL). The solids were collected by filtration and washed with water. Recrystallization from acetone gave 4.5 g of a crystalline product, mp 200–205°C. Three recrystallizations from methanol gave **6** (3.7 g, 43.5%), mp 227–228°C; ir (Nujol) ν_{max}: 3330 (OH) cm^{-1}; nmr (pyridine-d_5) δ: 1.32 (d, 3, CH_3-21H, J = 6 Hz), 1.42 (s, 3, CH_3-18H), 1.70 (s, 3, CH_3-19H), 3.88 (m, 2, C*H*OH-3H and 20H), 4.60 (m, 1, C*H*OH-11H), ~ 5 (vinyl H, under H_2O peak); ms *m/e*: 334 (28%, M^+), 316 (100, M − H_2O), 301 (14, M − H_2O − CH_3), 298 (11, M − $2H_2O$), 283 (15, M − $2H_2O$ − CH_3), 265 (7, M − $3H_2O$ − CH_3). *Anal.* calcd. for $C_{21}H_{34}O_3 \cdot 1H_2O$: C 71.56, H 10.29%; found: C 71.56, H 10.27%.

(20R)-Pregn-5-ene-3β,11β,20-triol-(3,20-diacetate) (10)

(20*R*)-Pregn-5-ene-3β,11β,20-triol(**6**)(1.9 g, 5.7 mmol) was dissolved in pyridine (10 mL). Acetic anhydride (100 mL) was added and the solution was left at room temperature for 3 days. The solution was poured into water and extracted with ether. The ether extracts were washed with saturated sodium bicarbonate solution, then with saturated sodium chloride solution, and were dried (Na_2SO_4). The solvent was removed *in vacuo* to give 1.9 g of a semi-solid residue. Recrystallization from methanol gave 1.2 g (51%) of crystalline product, mp 163–165°C. Two more recrystallizations from methanol afforded a product, mp 165–166°C; ir ν_{max}: 3600 (OH), 1722 (CO), 1650 (C=C) cm^{-1}; nmr δ: 0.89 (s, 3, CH_3-18H), 1.15 (d, 3, CH_3-21H, J = 6 Hz), 1.29 (s, 3, CH_3-19H), 2.05 (s, 6, CH_3CO), 4.3 (m, 1, *H*COH-11H), 4.7 (m, 2, HCOAc), 5.25 (m, 1, vinyl-H); ms *m/e*: 4.18 (0.3% M^+), 358 (100, M − HOAc), 340 (6, M − HOAc − H_2O), 325 (19, M − HOAc − H_2O − CH_3), 265 (6, M − 2HOAc − H_2O − CH_3). *Anal.* calcd. for $C_{25}H_{38}O_5$: C 71.74, H 9.15%; found: C 71.83, H 9.14%.

(20R)-5α-Pregna-3β,6α,11β,20-tetraol (7)

In a nitrogen atmosphere (20*R*)-pregn-5-ene-3β,11β,20-triol (**6**) (334 mg, 1 mmol) was dissolved into 20 mL of dry tetrahydrofuran. Sodium borohydride (0.15 g) was added and the mixture was cooled to 0°C. A solution of boron trifluoride etherate (0.70 g) in tetrahydrofuran (10 mL) was added dropwise within 15 min to the stirred mixture, which was allowed to come to room temperature and was then stirred for 3.5 h. At 0°C were added, in order, 3 mL 3 *N* aqueous sodium hydroxide solution and 3 mL of a 30% hydrogen peroxide solution. The reaction mixture was stirred overnight at room temperature. Saturated sodium chloride solution (20 mL) was added and after stirring one hour at room temperature, the layers were separated. The aqueous layer was further extracted with ether. The organic layers were combined and washed with saturated sodium chloride solution and dried (Na_2SO_4). The solvent was evaporated *in vacuo*. The residue (0.3 g) was recrystallized from chloroform to give 181 mg (52%) of colorless crystalline material, mp 250–252°C. A further recrystallization from acetone afforded material with mp 253–255°C; ir (Nujol) ν_{max}: 3600, 3300 (OH) cm^{-1}; nmr (pyridine-d_5) δ: 1.31 (d, 3, CH_3-21H, J = 6 Hz), 1.40 (s, 3, CH_3-18H), 1.47 (s, 3, CH_3-19H), 3.9 (m, 3, *H*COH), 4.5 (m, 1, *H*COH-11H); ms *m/e*: 352 (7%, M^+), 334 (57, M − H_2O), 316 (100, M − $2H_2O$), 301 (16, M − $2H_2O$ − CH_3), 298 (17, M − $3H_2O$), 283 (9, M − $3H_2O$ − CH_3), 265 (36, M − $4H_2O$ − CH_3). *Anal.* calcd. for $C_{21}H_{36}O_4$: C 71.56, H 10.29%; found: C 71.67, H 10.20%.

(20R)-5α-Pregna-3β,6α,11β,20-tetraol 3,6,20-Triacetate (8)

(20*R*)-5α-Pregna-3β,6α,11β,20-tetraol (**7**) (9.3 g, 26.7 mmol of crude product) was suspended in 30 mL of pyridine and 300 mL of acetic anhydride and stirred at room temperature for 20 h. The solution was poured into 1 L of ice water containing 50 mL of 2 *N* hydrochloric acid. After stirring for 1 h, the mixture was extracted with ether. The extracts were stirred with a slurry of water and sodium bicarbonate until carbon dioxide evolution had stopped, were washed with saturated sodium chloride solution, and were dried (Na_2SO_4). The solvent was evaporated *in vacuo* and the solid residue was recrystallized from a 1:1 mixture of diethyl ether – hexane to give 5.6 g (44%) of crystalline product, mp 204–206°C. Repeated recrystallization from ether afforded a product of mp 210–212°C; ir ν_{max}: 3600, 3500 (OH), 1722 (CO), 1655 (C=CH) cm^{-1}; nmr δ: 0.86 (s, 3, CH_3 − 18H), 1.13 (s, 3, CH_3-19H), 1.14 (d, 3, CH_3-21H, J = 6 Hz), 2.04 (s, 9, CH_3COO), 4.26 (m, 1, C*H*OH-11H), 4.7 (m, 3, CHOAc); ms *m/e*: 478 (< 1%, M^+), 418 (19, M − HOAc), 400 (16, M − HOAc − H_2O), 358 (55, M − 2HOAc), 340 (26, M − 2HOAc − H_2O), 298 (9, M − 3HOAc), 280 (11, M − 3HOAc − H_2O), 265 (14, M − 3HOAc − H_2O − CH_3). *Anal.* calcd. for $C_{27}H_{42}O_7$: C 67.76, H 8.85%; found: C 67.56, H 8.89%.

(20R)-5α-Pregn-9(11)-ene-3β,6α,20β-triol Triacetate (3)

(20*R*)-5α-Pregna-3β,6α,11β,20-tetraol 3,6,20-triacetate (**8**) (3.0 g, 6.3 mmol) was dissolved into 60 mL of glacial acetic acid containing 0.3 mL of perchloric acid. The solution was heated on a steambath for 1 h and was poured into a slurry of 300 g of sodium bicarbonate in 1 L of water. The mixture was extracted with ether. The ether extracts were washed with saturated

sodium chloride solution and were dried (Na_2SO_4). Evaporation of the solvent *in vacuo* gave 2.8 g of yellow oil. Column chromatography (120 g of silica gel, petroleum ether – methylene chloride) afforded 2.1 g (80%) of a colourless oil. The compound was identical in all respects to compound **3** prepared by the shorter synthesis as described above.

(20R)-5α-Pregn-9(11)ene-3β,6α,20-triol-(20-acetate) (9)

The above triacetate **3** (1.0 g, 2.2 mmol) was dissolved into 20 mL of methanol. A solution of 0.33 g of sodium hydroxide in 2 mL of water was added and the resulting yellow solution was stirred at room temperature for 3 h, after which it was acidified with acetic acid. The solvent was removed *in vacuo*. The residue was dissolved in methylene chloride and the solution was washed with saturated sodium bicarbonate solution and with water, and was dried (Na_2SO_4). Evaporation of the solvent gave 0.7 g of yellow oil which was purified by column chromatography (21 g of silica gel, methylene chloride – methanol) followed by recrystallization from acetone to give 0.40 g (50%) of a colorless crystalline product, mp 224–226°C; ir ν_{max}: 3590, 3420 (OH), 1730 (CO) cm^{-1}; nmr δ: 0.57 (s, 3, CH_3-18H), 0.95 (s, 3, CH_3-19H), 2.17 (d, 3, CH_3-21H, J = 6 Hz), 3.55 (m, 2, C*H*OH), 4.8 (m, 1, C*H*OAc), 8.60 (m, 1, vinyl-H); ms *m/e*: 376 (3%, M^+) 316 (100 – M – HOAc), 298 (7, M – HOAc – H_2O), 283 (19, M – HOAc – H_2O – CH_3), 265 (23, M – HOAc – $2H_2O$ – CH_3). *Anal.* calcd. for $C_{23}H_{36}O_4$: C 73.37, H 9.64%; found: C 73.33, H 9.73%.

(20R)-5α-Pregn-9(11)-ene-3β,6α,20-triol (Asterogenol)

(20*R*)-5α-Pregn-9(11)-ene3β,6α,20-triol-(20-acetate) (**9**) (0.10 g, 0.27 mmol) was dissolved into a mixture of methanol (8 mL) and a solution of sodium hydroxide (0.2 g) in water (1.0 mL). The solution was left at room temperature for 5 days, then it was diluted with water to a volume of 200 mL. The mixture was extracted with methylene chloride. The extracts were washed with water and dried (Na_2SO_4). The solvent was evaporated *in vacuo* and the solid residue was recrystallized from aqueous methanol to give 0.08 g (90%) of crystalline material, which on recrystallization afforded a product with mp 263–264°C; $[\alpha]_D^{20}$ +8.2 (*c* 0.242 g/100 mL ethanol); ir (Nujol) ν_{max}: 3360 (OH) cm^{-1}; ms *m/e*: 334 (52%, M^+), 316 (63%, M – H_2O), 301 (48%, H – H_2O – CH_3), 283 (30%, M – $2H_2O$ – CH_3), 265 (26%, M – $3H_2O$ – CH_3). *Anal.* calcd. for $C_{21}H_{34}O_3$: C 75.41, H 10.25%; found: C 75.25, H 10.20%. This material was identical in all respects to the naturally isolated material.

The conformational equilibrium in [^{13}C-1-*methyl*]-*cis*-1,4-dimethylcyclohexane

HAROLD BOOTH AND JEREMY RAMSEY EVERETT[1]

Department of Chemistry, University of Nottingham, Nottingham, England NG7 2RD

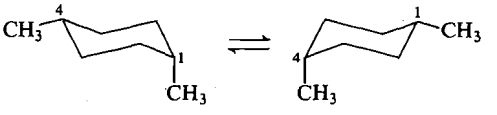
Received June 16, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HAROLD BOOTH and JEREMY RAMSEY EVERETT. Can. J. Chem. **58**, 2709 (1980).

The conformational equilibrium in [^{13}C-1-*methyl*]-*cis*-1,4-dimethylcyclohexane has been assessed by (*a*) direct integration of signals due to equatorial and axial methyl carbons in the ^{13}C nmr spectrum at 172 K and (*b*) by measurement of the ^{13}C chemical shifts of C-1 and C-4 in the spectrum at 300 K. It is concluded that a ^{13}C isotope effect on the position of the degenerate equilibrium in *cis*-1,4-dimethylcyclohexane is either nonexistent, or is too small to be detected by methods of analyses employed. The ^{13}C nmr data incidental to the study (chemical shifts, coupling constants, spin–lattice relaxation times, nuclear Overhauser enhancements, and 1-bond isotope shifts) are recorded for the title compound and its *trans*-isomer.

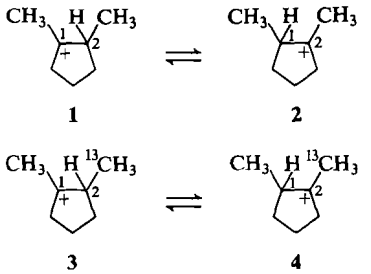
HAROLD BOOTH et JEREMY RAMSEY EVERETT. Can. J. Chem. **58**, 2709 (1980).



On a déterminé l'équilibre conformationnel du [^{13}C *méthyl*-1]-diméthyl-1,4 cyclohexane *cis* par: (*a*) l'intégration directe des signaux des carbones de méthyles en positions axiale et équatoriale dans le spectre rmn du ^{13}C à 172 K et (*b*) par la mesure des déplacements chimiques du ^{13}C des carbones en position 1 et 4 dans le spectre à 300 K. On a conclu que l'effet de l'isotope ^{13}C sur la position de l'équilibre dégénérée du diméthyl-1,4 cyclohexane *cis* est inexistant ou trop faible pour être décelé par les méthodes d'analyse utilisées. On a enregistré les données de la rmn du ^{13}C inhérentes à l'étude du composé étudié et de son isomère *trans* (déplacements chimiques, constantes de couplage, temps de relaxation spin–réseau, effets Overhauser nucléaire et déplacements isotopiques de la liaison-1).

[Traduit par le journal]

Introduction



A number of recent papers (1, 2) have described isotope effects on equilibrium processes. Using chemical shift measurements, Baldry and Robinson (1) were able to detect small changes in the position of chair–chair equilibria in cyclohexanes when a CH_3 substituent was replaced by a CD_3 substituent. Saunders *et al.* (2) using ^{13}C chemical shifts, found it relatively easy to detect changes in the position of tautomeric equilibria of degenerate cations (e.g. **1** ⇌ **2**) caused by replacement of CH_3 by CD_3, and of 3-CH_2 by 3-CD_2. Of considerable interest was the change in the position of equilibrium **1** ⇌ **2** caused by replacement of $^{12}CH_3$ by $^{13}CH_3$, a change detected by the slight difference in chemical shift between C-1 and C-2. The ion **4**, with the charge adjacent to ^{13}C, was preferred to the ion **3**. On the other hand, Wehrli *et al.* (3) recently examined cyclodecanone and measured the movements in ^{13}C chemical shifts which accompanied deuteration; effects were detected over distances of up to 6 bonds and were attributed to a direct, or intrinsic, isotope effect, rather than to any perturbation of a conformational equilibrium (4). Chertkov and Sergeyev (5) failed to detect (within 2%) any change in the conformational equilibrium of cyclohexane when eleven hydrogen atoms were replaced by deuterium atoms. However, the preference, in cyclohexanones, for axial deuterium over axial hydrogen, has been demonstrated by ORD measurements (6, 7).

We considered it worthwhile to attempt to determine the effect on the degenerate chair–chair equilibrium in *cis*-1,4-dimethylcyclohexane **5** ⇌ **6**

5 **6**

which would result from substitution of a $^{12}CH_3$ by a $^{13}CH_3$. The occurrence of *syn*-axial nonbonded interactions in cyclohexanes is thought to be a major factor in determining conformational enthalpies and, therefore, conformational equilibria. Furthermore, the CH_3/H *syn*-axial interactions may be considered to consist of both H/H and C/H interactions. The overall effect on the equilibrium **5** ⇌ **6** due to the isotopic replacement may have two

1 **2**

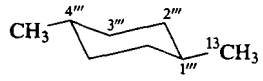
contributions: a *direct* one due to the difference in interaction energy, at the same distance, between $^{12}C/H$ and $^{13}C/H$ interactions, and an *indirect* one, due to the different geometry induced in (**7** ⇌ **8**) by



7 **8**
x $(1-x)$

the isotopic substitution. Neither effect is predictable. With regard to the geometry of **7**, compared to that of **5**, it seems likely (cf. ref. 8) that both ^{13}C—H and ^{13}C—C bond lengths are less than the corresponding bond lengths for ^{12}C. The relatively shorter ^{13}C—H bond length in **7** should result in reduced *syn*-axial repulsive interactions of the H/H variety. On the other hand a shortening of the $^{13}CH_3$—C bond causes a reduction in H/H and CH_3/H distances, leading to increased repulsive interactions.

Results and Discussion

The syntheses of *cis*-1,4-dimethylcyclohexane **7** ⇌ **8** and *trans*-1,4-dimethylcyclohexane **9**, each enriched to the extent of 90.6% with ^{13}C at one of the methyl carbons, employed well established methods which require no comment (see Experimental).

9

Two methods were used to measure the equilibrium constant for **7** ⇌ **8**. The first method involved the measurement of the relative areas of the well-separated signals due to equatorial methyl (1′-CH_3, 23.3 ppm) and axial methyl (1″-CH_3, 17.4 ppm) carbons in the ^{13}C nmr spectrum recorded at 173 K. This method is relatively inaccurate, whether instrumental integration or the preferred method of hand planimetry is employed. Whilst the planimeter is very accurate and capable of good reproducibility, the overall accuracy is limited by the uncertainty in choosing a straight line for the base of the signals. This uncertainty is obviously related to noise level and, therefore, to sample size and computer capability. The advantage of the method of relative areas is that it is direct and involves no assumptions, provided that the experimental parameters are chosen sensibly. In a multi-pulse Fourier transform ^{13}C experiment, recorded with ^{1}H decoupling, the relative signal areas are dependent on spin–lattice relaxation times and nuclear Overhauser enhancements. Table 1 shows that the T_1 values of 172 K are little different for carbons of axial and equatorial methyl groups. Table 1 also includes the nuclear Overhauser enhancements for equatorial and axial carbons at 172 K; again the difference is insignificant. We conclude that the signal areas for equatorial and axial carbons reflect accurately the molecular proportions of **8** and **7** respectively. The relatively small nuclear Overhauser enhancements (98–99%) for the methyl carbons are noteworthy since they imply that only about 50% of the total spin–lattice relaxation is due to dipole–dipole interaction. Since samples were not degassed, there is the expected contribution to relaxation from dissolved oxygen. Nevertheless, it seems that there must be an appreciable contribution from relaxation by spin rotation. From the low temperature area method, the equilibrium constant K (= **8**/**7**) was determined to be 1.00. As a precaution, the same method was applied to the degenerate system **5** ⇌ **6**. In this case the equilibrium constant was found to be 1.01 by instrumental integration and 0.97 from hand planimetry, giving an average of 0.99. We conclude that the $^{13}C/^{12}C$ isotope effect on the position of equilibrium **5** ⇌ **6** is nonexistent, or is too small to be detectable by the low temperature area method.

The second method used to measure the position of equilibrium in **7** ⇌ **8** involved chemical shift determinations and is, in principle, a more accurate method than the first. The basis of the method is the fact that the room-temperature averaged ^{13}C chemical shifts of the methine carbons C-4″ and C-4′ is different from the room-temperature averaged chemical shifts of the methine carbons C-1″ and C-1′. These averaged chemical shifts are, of course, identical in the degenerate equilibrium **5** ⇌ **6**. The general theory is as follows. Let x and $(1-x)$ be the mole fractions of **7** and **8** respectively; let δ_1 and δ_4 be the observed, averaged chemical shifts of C-1 and C-4, respectively, at room temperature. If $\delta_{1'}$ and $\delta_{4'}$ are the chemical shifts of C-1′ and C-4′, respectively, in **8**, whilst $\delta_{1''}$ and $\delta_{4''}$ are the corresponding shifts in **7**, we may write

$$\delta_4 = x\delta_{4''} + (1-x)\delta_{4'}$$
$$\delta_1 = x\delta_{1''} + (1-x)\delta_{1'}$$

Let the intrinsic 1-bond isotope shifts which accompany the replacement of a $^{12}CH_3$ by a $^{13}CH_3$ be I_e for ring carbon substituted by CH_3 (equatorial), and I_a for ring carbon substituted by CH_3 (axial). Then

$$I_e = \delta_{1'} - \delta_{4''}$$
$$I_a = \delta_{1''} - \delta_{4'}$$

TABLE 1. ^{13}C relaxation times (T_1), $^{13}C[^1H]$ nuclear Overhauser enhancements, and the equilibrium constant for **7** ⇌ **8** (solvent $CDCl_3/CFCl_3$)

	CH_3 axial	CH_3 equatorial
T_1 (s)	1.07±0.05[a]	1.00±0.05[a]
T_1 (s)	8.60±0.48[b]	8.60±0.48[b]
Nuclear Overhauser enhancement (%)	99[a]	98[a]
Equilibrium constant **8**/**7**	1.035 (instrumental integration)	
	1.028 (hand planimetry)	
	1.031 (average)	
	1.00[c] (corrected)	

[a]172 K.
[b]302 K.
[c]After correction for presence of **9**.

It is assumed that intrinsic isotope shifts over 4-bonds are negligible (cf. ref. 8). From the above relationships, it can easily be shown that

$$[1] \quad x = \frac{(\delta_{4''} - \delta_{4'}) + (\delta_4 - \delta_1) + I_e}{2(\delta_{4''} - \delta_{4'}) + (I_e - I_a)}$$

Now the observed signal for C-1 arises largely from molecules which are effectively doubly labelled (in ^{13}C) at C-1 and the adjacent methyl carbon, and is therefore the low-field doublet part of an AB spin system ($J_{AB} = {}^1J_{CC}$). The high-field doublet part of this system is a pair of satellites to the intense singlet due to the methyl carbon of singly labelled molecules. Analysis of the AB spectrum yields the chemical shift δ_1 and also the chemical shift of the methyl carbon in doubly labelled species. The observed signal for C-4 also arises largely from molecules containing a ^{13}C-enriched methyl carbon attached to C-1, but since the coupling ${}^4J_{CC}$ is very small, this signal is a single line, the position of which yields δ_4 directly.

The ^{13}C nmr spectrum of **7** ⇌ **8** recorded at temperatures below 195 K includes distinct resonances for CH_3 (equatorial) in **8**, CH_3 (axial) in **7**, C-1′ (low-field half of AB quartet), C-4′ (singlet), C-1″ (low-field half of AB quartet), and C-4″ (singlet). The chemical shifts $\delta_{1'}$, $\delta_{4'}$, $\delta_{1''}$, and $\delta_{4''}$ are readily obtained from this spectrum. Thus all the parameters required for the calculation of x through eq. [1] are available.

The most attractive feature of this method of assessing the position of equilibrium in **7** ⇌ **8** is that it involves the measurement of chemical shift differences in the spectrum of a *single* sample of a *single* compound. Most methods of determining conformational equilibria through measurement of chemical shifts utilize conformationally biased compounds as standards for chemical shift parameters. A basic weakness of such methods is that the validity of the models is always questionable; furthermore, chemical shift data are required from at least three compounds and are often recorded in separate solutions. The present method, although free from most of these objections, suffers from the drawback that the parameters $\delta_{1'}$, $\delta_{4'}$, $\delta_{1''}$, and $\delta_{4''}$ are derived from a low-temperature spectrum whereas δ_1 and δ_4 come from a room-temperature spectrum.

Spectral data for [^{13}C-1-*methyl*]-*cis*-1,4-dimethylcyclohexane are summarized in Table 2. Fourier transform spectra at 62.901 MHz employed 32 K data points over a spectral width of 2500 Hz, equivalent to digital resolution of 0.1526 Hz (0.002426 ppm), and corresponding to a possible error due to digitization of ±0.0763 Hz (±0.001213 ppm). The spectrum at 180 K includes a "triplet" at 31.67 ppm, comprising a singlet due to C-2″,6″ and a doublet (${}^3J_{CC}$ = 3.42 Hz) due to C-3′,5′ which is coupled to the equatorial methyl carbon. Since the combined signal due to C-2′,6′ and C-3″,5″ is an unresolved singlet at 29.20 ppm, it is evident that the 3-bond coupling between C-3″,5″ and the *axial* methyl carbon is less than 1.0 Hz. Table 2 indicates that the intrinsic 1-bond isotope effects for the *substituted ring carbons* are −0.011510 ppm for I_e and −0.011875 ppm for I_a. The corresponding isotope effects for the *methyl carbons* are −0.0075833 ppm for equatorial methyl and −0.0002067 ppm for axial methyl.

The directions of these intrinsic isotope effects, to high field, are in agreement with the usual finding, that substitution of a nucleus by a heavier isotope produces greater shielding for all nuclei involved (9). Whereas I_e and I_a are identical, within experimental error, the isotope effects for the methyl carbons appear to show a dependence on the orientation of the methyl group. In the spectrum of **7** ⇌ **8** at 300 K the "triplet" observed at 31.13 ppm consists of a singlet due to C-2,6 (${}^2J_{CC} = 0$) and a doublet (${}^3J_{CC}$ = 2.29 Hz) due to C-3,5. The doublet splitting represents the average of the ${}^3J_{CC}$ values for conformations **7** (< 1 Hz) and **8** (3.42 Hz), obtained from the spectrum at 180 K.

Before application of eq. [1], it was necessary to justify the assumption, implicit in [1], that the variation in ^{13}C chemical shifts with temperature is

approximately the same for cyclohexane carbon substituted by equatorial Me, as that substituted by axial Me. The temperature dependence of the ^{13}C chemical shifts for *cis*-1-ethyl-4-methylcyclohexane **10** ⇌ **11** were recorded over a range of 36 K

10 **11**

below the slow exchange limit (10). The results confirm the work of Schneider and Freitag (11), which demonstrated a linear deshielding, with increasing temperature, of ring carbons in cycloalkanes. In our case the plots of chemical shift against temperature indicated an approximately linear relationship for C-4 in both **10** and **11**. In **10**, C-4 was deshielded, with increasing temperature, by 3.18×10^{-3} ppm K^{-1}; the corresponding shift/temperature gradient for C-4 in **11** was 3.63×10^{-3} ppm K^{-1}. If we assume that similar ^{13}C shift/temperature gradients hold for C-4′ in **8** and C-4″ in **7**, then the discrepancy arising from the use of $(\delta_{4''} - \delta_{4'})$ at 180 K, rather than at 300 K, amounts to only 0.054 ppm. The entries in Table 2 yield the following chemical shift differences:

$$\delta_{4''} - \delta_{4'} = 6.760815 \text{ ppm}$$

$$\delta_4 - \delta_1 = 0.011510 \text{ ppm}$$

Application of these to eq. [1] leads to a value for x of 0.4999424, i.e. 0.500, within experimental error. We conclude that any isotope effect (caused by replacement of $^{12}CH_3$ by $^{13}CH_3$) on the position of equilibrium in **5** ⇌ **6** is either nonexistent, or is too small to be detected by the technique employed.

The ^{13}C nmr spectrum of the conformationally homogeneous [^{13}C-1-*methyl*]-*trans*-1,4-dimethylcyclohexane **9** was also measured and the relevant details appear in Table 3. As for the *cis*-isomer, chemical shifts for C-1‴ and CH_3-1‴ were obtained by analysis of the AB spin system arising from doubly labelled molecules. Table 3 indicates that the intrinsic 1-bond isotope effect for C-1‴ is $(\delta_{1'''} - \delta_{4'''} =) -0.01603$ ppm and for CH_3-1‴ is −0.00796 ppm. Encouragingly, these values are close to those determined for C-1′ and CH_3-1′ in conformation **8** of the *cis*-isomer **7** ⇌ **8**.

The ^{13}C—^{13}C coupling constants of Tables 2 and 3 are of interest in suggesting a tentative correlation of J values with stereochemistry. Thus ^1J(C-1′, CH_3) in **8** (i.e. *equatorial* methyl) is 35.40 Hz, significantly greater than ^1J(C-1″, CH_3) in **7** (i.e. *axial* methyl), which is 34.64 Hz. A larger effect, in the same sense, was noted by Barna and Robinson (12) for 4-*tert*-butyl-2-methylpiperidines and 4-*tert*-butyl-2-methylcyclohexanones, but was attributed to the proximity of nonbonding electrons or unsaturation. The coupling constant ^1J(C-1‴, CH_3) in *trans*-1,4-dimethylcyclohexane **9** is 35.89 Hz at 301 K and 35.64 Hz at 173 K, values which are close to the 36.0 (±0.3) Hz reported earlier for the comparable coupling in the major conformation of methylcyclohexane at 172 K (13). It is noteworthy that ^3J(C-3, CH_3) is 3.4–4.5 Hz for equatorial methyl, corresponding to a dihedral angle of 180°, whereas ^3J(C-3, CH_3) is ≲ 1 Hz for axial methyl, corresponding to a dihedral angle of 60°. A

TABLE 3. ^{13}C chemical shifts[a] at 25.15 MHz (δ values, ppm downfield from Me_4Si) and 301 K for carbons in [^{13}C-1-*methyl*]-*trans*-1,4-dimethylcyclohexane **9**

Karplus-type correlation of vicinal coupling ($^3J_{CC}$) with dihedral angle is now well established (14, 15). Of greater interest is the significant difference between ^3J(C-3‴, CH_3) in **9** (4.5 Hz) and ^3J(C-3′, CH_3) in **8** (3.4 Hz). (The former compares well with the value of 4.3 Hz recorded for methylcyclohexane, ref. 13.) One or both of two factors may contribute to an explanation of the difference: the remote axial methyl in **8** causes a slight flattening of the ring, relative to the effect of equatorial methyl (16–20), leading to a loss of coplanarity of the coupling pathway CH_3—C1—C2—C3. At the same time the change of the 4-methyl substituent from an equatorial orientation in **9** to an axial orientation in **8** may affect $^3J_{CC}$ because the electronegativity effect of methyl will depend on orientation (21).

Experimental

^{13}C spectra were recorded for solutions in $CFCl_3$–$CDCl_3$ (9:1 v/v) at 25.15 MHz on a JEOL JNM-PS-100 spectrometer interfaced to a Nicolet 1085 20 K computer, and at 62.90 MHz on a Bruker WM-250 spectrometer. General instructions for the preparation of 1,4-dialkylcyclohexanes have been given elsewhere (22).

*[^{13}C-1-*Methyl*]-1,4-dimethylcyclohexane*

4-Methylcyclohexanone (1.442 g, 0.0129 mol) was reacted with the Grignard reagent formed from magnesium turnings (0.34 g, 0.014 mol) and [^{13}C] iodomethane (2.0 g, 0.014 mol, 91.0 ^{13}C at.%). [1-*Me*-^{13}*C*]-1,4-Dimethylcyclohexanol (2.48 g, > 100%) was isolated as a pale yellow oil still containing some ether. The alcohol was dehydrated using 4-methylbenzenesulfonic acid (0.3838 g) to give [1-*Me*-^{13}*C*]-1,4-dimethylcyclohex-1-ene (0.9574 g, 0.0862 mol) as a colourless oil. The alkene (neat) was hydrogenated over PtO_2 (0.1026 g) to yield a mixture of *cis*- and *trans*-[1-*Me*-^{13}*C*]-1,4-dimethylcyclohexane (0.5432 g, 0.00481 mol) as a colourless oil (M^+: 113.1298, $C_7{}^{13}C_1H_{16}$ requires 113.1282). The mixture was completely separated using a 12 ft × ¾ in. aluminium column packed with 30% SE-30 coated on a support of acid-washed siliconized 60–80 mesh Chromosorb W. At a column temperature of 65°C and a flow rate of 30 cm^3 min^{-1}, the *trans*- and *cis*-isomers had retention times of 45.6 min and 57.0 min respectively. In the ^1H nmr spectrum ($CDCl_3$), the methyl proton of the *trans*-isomer, at δ 0.86 ppm, gave a doublet of doublets with separations of 122.5 Hz ($^1J_{CH}$) and 5.5 Hz ($^3J_{HH}$). The methyl protons of the *cis*-isomer, at δ 0.94 ppm, gave a doublet of doublets with separations of 122 Hz ($^1J_{CH}$) and 6.2 Hz ($^3J_{HH}$).

The conformational free energy difference for the trideuteromethyl substituent in cyclohexane

HAROLD BOOTH AND JEREMY RAMSEY EVERETT[1]

Department of Chemistry, University of Nottingham, Nottingham, England NG7 2RD

Received June 16, 1980

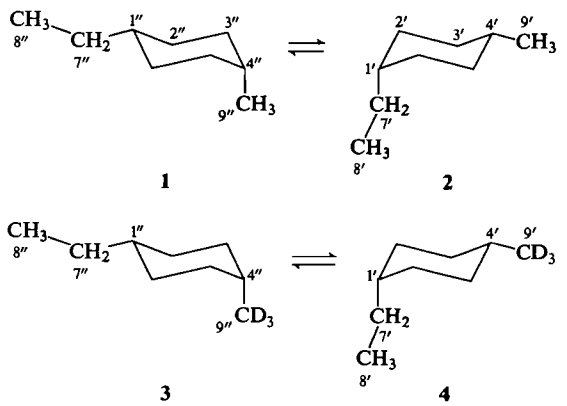
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

HAROLD BOOTH and JEREMY RAMSEY EVERETT. Can. J. Chem. **58**, 2714 (1980).

Studies at 169 K to 194 K of the ^{13}C nmr spectrum of *cis*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane show that the conformational enthalpy difference $-\Delta H°(C^2H_3)$ is 1.82 ± 0.07 kcal mol^{-1} and the conformational entropy difference $\Delta S°(C^2H_3)$ is -0.28 ± 0.4 cal K^{-1} mol^{-1}, values which do not differ significantly from the values for CH_3. However, analysis of the room temperature ^{13}C nmr spectrum of a mixture of *cis*-1-ethyl-4-methylcyclohexane and *cis*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane showed that $-\Delta G°(C^2H_3)$ at 298 K is 11.89 ± 1.46 cal mol^{-1} *less* than that for CH_3, i.e. C^2H_3 has a slightly greater preference than CH_3 for the axial orientation. The ^{13}C nmr spectrum of a mixture of *trans*-1-ethyl-4-methylcyclohexane and *trans*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane indicates that deuterium-induced ^{13}C nmr isotope shifts, all upfield, occur across 1, 2, 3, and 5 bonds.

HAROLD BOOTH et JEREMY RAMSEY EVERETT. Can. J. Chem. **58**, 2714 (1980).

Une étude des spectres de rmn du ^{13}C de l'éthyl-1 [*Me*-4-$^2H_3$]-méthyl-4 cyclohexane *cis*, mesurées entre 169 et 194 K, montrent que la différence d'enthalpie conformationnelle $-\Delta H°(C^2H_3)$ est de $1,82 \pm 0,07$ kcal mol^{-1} et la différence d'entropie conformationnelle $\Delta S°(C^2H_3)$ est de $-0,28 \pm 0,4$ cal K^{-1} mol^{-1}. Ces valeurs ne different pas de façon significative de celles de CH_3. Cependant l'analyse du spectre de rmn du ^{13}C à la température ambiante d'un mélange d'éthyl-1 méthyl-4 cyclohexane *cis* et d'éthyl-1 [*Me*-4-$^2H_3$] méthyl-4 cyclohexane *cis* a montré que le $\Delta G°(C^2H_3)$ à 298 K est de $11,89 \pm 1,46$ cal mol^{-1} plus faible que celle du CH_3 i.e. la préférence du C^2H_3 pour une orientation axiale est légèrement plus grande que celle du CH_3. Le spectre rmn du ^{13}C d'un mélange d'éthyl-1 méthyl-4 cyclohexane *trans* et d'éthyl-1 [*Me*-4-$^2H_3$] méthyl-4 cyclohexane *trans* indique que tous les déplacements chimiques vers les champs forts du ^{13}C induits par le deutérium se produisent à travers 1, 2, 3 et 5 liaisons.



[Traduit par le journal]

Introduction

There is a growing interest in the effects of isotopic replacement of nuclei on the position of conformational equilibria. As recently reported, we failed to detect, by nmr methods, a change in the conformational equilibrium in *cis*-1,4-dimethylcyclohexane after replacement of a methyl group by a ^{13}C-methyl group (1). However, a change resulting from the replacement of CH_3 by C^2H_3 should be detected with greater ease. For example, using chemical shift measurements, Baldry and Robinson (2) succeeded in showing that the conformational equilibrium in *trans*-[1-*Me*-$^2H_3$]-1,3-dimethylcyclohexane favours that conformation with C^2H_3 axial by about 11.0 cal mol^{-1}. Moreover, circular dichroism studies have established that axial deuterium is preferred to axial hydrogen at the 3- and 4-positions of 2,2-dimethylcyclohexanone (3, 4); the shorter bond length of C—^{2}H (as against C—^{1}H), and the smaller vibrational amplitudes may well provide sufficient explanation.

Results and Discussion

We chose to study the effect on the equilibrium in *cis*-1-ethyl-4- methylcyclohexane **1** ⇌ **2** caused by the replacement of CH_3 by C^2H_3. The ^{13}C nmr chemical shifts for carbons in **1** and **2**, and molecular proportions, are already available from a previous study in the temperature range 141 K to 177 K (5). As the difference between the chemical shifts of C-7″ and C-7′ is as much as 7 ppm, the room-temperature averaged shift of C-7 should be particularly sensitive to any change in the position of equilibrium, i.e. the averaged shift of C-7 in **3** ⇌ **4**

should differ significantly from that of C-7 in **1** ⇌ **2**. Moreover, a direct or *intrinsic* isotope effect on the chemical shift of C-7 is unlikely to occur across the

intervening six bonds. Initially, however, we analyzed the equilibrium **3** $\rightleftharpoons$ **4** by the low-temperature area method, followed by a comparison of the derived thermodynamic parameters $\Delta H°$ (C^2H_3) and $\Delta S°$ (C^2H_3) with those previously determined for C^1H_3 (5).

The syntheses of *cis*- and *trans*-1-ethyl-4-methylcyclohexane have already been reported (6). A second synthesis also proved satisfactory and as illustrated in Scheme 1 was readily adapted to the preparation of molecules specifically trideuterated at the 4-methyl positions. The complete separation of *cis*- and *trans*-isomers was carried out by preparative gas–liquid chromatography after the final stage. Examination of the *cis*- and *trans*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane by ^2H nmr spectroscopy proved conclusively that no scrambling of the deuterium had occurred during the synthesis.

Reagents:
(*1*) H_2, PtO_2 (*4*) $CH_3{\cdot}C_6H_4SO_2Cl$
(*2*) MeOH, H_2SO_4 (*5*) $LiAlD_4$, ether
(*3*) $LiAlD_4$, ether

SCHEME 1

The ^{13}C nmr spectrum of *cis*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane **3** $\rightleftharpoons$ **4** was recorded within the range 169 K to 194 K, where ring inversion is slow compared to differences in chemical shifts between structurally identical nuclei in the two conformations. The proportions of **3** and **4** were obtained from the relative areas of well separated signals due to C-1′ and C-1″; signals due to C-8′ and C-8″ were similarly employed and the two equilibrium constants were averaged. The results were analysed as reported earlier (5) for *cis*-1-ethyl-4-methylcyclohexane and the thermodynamic parameters for C^2H_3 were 1.82 ± 0.07 kcal mol^{-1} for $-\Delta H°$ and −0.28 ± 0.4 cal K^{-1} mol^{-1} for $\Delta S°$. Since the comparable parameters for CH_3 are 1.75 ± 0.04 for $-\Delta H°$ and −0.03 ± 0.2 for $\Delta S°$, it is obvious that the *low temperature area method* is insufficiently accurate to distinguish C^2H_3 from CH_3.

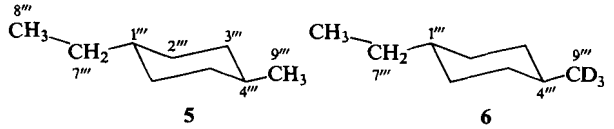
The theoretical background to the *room-temperature chemical shift method* is given below.

Let the mole fractions of **1** and **3** be x and y respectively. Let δ_7(H) and δ_7(D) be the observed chemical shifts of C-7 in **1** $\rightleftharpoons$ **2** and **3** $\rightleftharpoons$ **4**, respectively, at room temperature. Let $\delta_{7''}$ and $\delta_{7'}$ be the chemical shifts of C-7 in **1** and **2** respectively. In the absence of intrinsic isotope shifts, $\delta_{7''}$ and $\delta_{7'}$ are also the chemical shifts of C-7 in **3** and **4** respectively. Then

$$\delta_7(\mathrm{H}) = x\delta_{7''} + (1 - x)\delta_{7'}$$

and

$$\delta_7(\mathrm{D}) = y\delta_{7''} + (1 - y)\delta_{7'}$$



These equations give rise to

$$[1] \quad x - y = \frac{\delta_7(\mathrm{H}) - \delta_7(\mathrm{D})}{\delta_{7''} - \delta_{7'}}$$

Now the mole fraction x can be calculated for any temperature from the thermodynamic parameters previously determined (5) for Me and Et. The shifts $\delta_{7''}$ and $\delta_{7'}$ are known at eight temperatures between 160 and 194 K, and extrapolation of the two linear plots yields theoretical values for $\delta_{7''}$ and $\delta_{7'}$ at room temperature (298 K). Thus, provided that δ_7(H) − δ_7(D) can be measured, the mole fraction y can be calculated.

Equation [1] shows, as expected, that the sensitivity of the method of determining $(x - y)$ is a function of $(\delta_{7''} - \delta_{7'})$ i.e. of the ^{13}C nmr chemical shift difference, for the chosen carbon, between conformation **1** and conformation **2**. Carbon 7 was chosen for reasons already indicated, but two other carbons were considered, at C-1 and C-8. Carbon 8 was not useful because $(\delta_{8''} - \delta_{8'})$ is only 0.8 ppm, and although $(\delta_{1''} - \delta_{1'})$ is as great as 5.9 ppm, there is in this case the possibility of a direct isotope shift across 5 bonds.

The chemical shift difference δ_7(H) − δ_7(D) was determined from the ^{13}C nmr spectrum of a solution containing a *mixture* of *cis*-1-ethyl-4-methylcyclohexane **1** $\rightleftharpoons$ **2** and *cis*-1-ethyl-[4-*Me*-$^2H_3$]-4-methylcyclohexane **3** $\rightleftharpoons$ **4**. It was also essential to incorporate in this mixture the *trans*-isomers **5** and **6**. This allowed us to establish, under identical experimental conditions and for a similar structure,

5 **6**

For personal use only.

that intrinsic isotope shifts do not extend across 6 bonds, and also to measure accurately the intrinsic isotope shifts observed across a smaller number of bonds.

In the mixture containing **1** ⇌ **2**, **3** ⇌ **4**, **5** and **6**, the ratio of *cis*-molecules to *trans*-molecules was approximately 2:1 for both nondeuterated and deuterated species, whereas the ratio of nondeuterated to deuterated species was 1:1 for both *cis*- and *trans*-molecules, i.e.

$$([\mathbf{1}] + [\mathbf{2}])/[\mathbf{5}] = ([\mathbf{3}] + [\mathbf{4}])/[\mathbf{6}] \simeq 2$$

$$([\mathbf{1}] + [\mathbf{2}])/([\mathbf{3}] + [\mathbf{4}]) = [\mathbf{5}]/[\mathbf{6}] = 1$$

Although the use of a molar ratio of 1:1 for nondeuterated to deuterated species optimized the conditions for resolution of signals separated by small isotope shifts, it prevented *assignment* of the signals. Consequently the crucial experiment was exactly repeated after increasing the proportion of deuterated species from 50% to 55%.

In the ^{13}C nmr spectrum of the mixture, recorded at 62.901 MHz, the signals for C-7 in **1** ⇌ **2**, and for C-7 in **3** ⇌ **4**, were well resolved; the separation was 2.21 Hz (0.035 ppm), the signal for the deuterated molecule **3** ⇌ **4** being at *lower* field. On the other hand the signals for C-7‴ in the *trans*-molecules **5** and **6** were not resolved. Therefore we attribute the difference in chemical shift for C-7 in **1** ⇌ **2** and **3** ⇌ **4** as arising solely from an alteration in the position of conformational equilibrium caused by replacement of CH_3 by C^2H_3. ^{13}C Chemical shifts for carbons in **1** ⇌ **2**, **3** ⇌ **4**, **5** and **6** are recorded in Tables 1 and 2. Direct, or intrinsic isotope effects accompanying the change **5** → **6** were observed for carbons 9, 4, 3(5), and 1. It is important to note that all the intrinsic isotope shifts accompanying the change $^1H \rightarrow {}^2H$ are *upfield*. Consequently it was particularly reassuring that the observed shift for C-7 in **3** ⇌ **4** was *downfield* of that in **1** ⇌ **2**. In fact this downfield shift, indicating that $\delta_7(4) - \delta_7(D)$ is negative, establishes conclusively that mole fraction y is greater than mole fraction x, for $(\delta_{7''} - \delta_{7'})$ is positive. Consequently, it is clear that the substituent C^2H_3 has a greater preference for the axial orientation than CH_3. The extent of this preference was expressed as an energy difference between $\Delta G°(C^2H_3)$ and $\Delta G°(CH_3)$ of 11.89 ± 1.46 cal mol^{-1} (49.79 ± 6.11 J mol^{-1}). The principal errors arise from the extrapolation needed to determine $(\delta_{7''} - \delta_{7'})$ at room temperature, and from the digitization of the spectrum (±0.092 Hz). It was estimated that the possible error in the extrapolation was ±15.725 Hz. However, since $(\delta_{7''} - \delta_{7'})$ is 441.635 Hz, the proportional error arising from the extrapolation is rather less than that in $\delta_7(H) - \delta_7(D)$ due to digitization.

The determined value of $\Delta G°(C^2H_3) - \Delta G°(CH_3)$ is very close to the value of 46 J mol^{-1} obtained by Baldry and Robinson (2) from ^{13}C nmr shifts in *trans*-[1-*Me*-$^2H_3$]1,3-dimethylcyclohexane, although these workers neglected intrinsic isotope effects across 5 bonds. The intrinsic isotope effects measured in the present study are given in Table 2. Wehrli *et al.* (7) claimed that intrinsic isotope shifts for ^{13}C occurred over as many as 6 bonds in [2-$^2H_1$] cyclodecanone. However, it is possible that these effects are due in part to the perturbation of a conformational equilibrium (8, 9). In this connection it is perhaps significant that whereas all the isotope-induced ^{13}C shifts of the present study are upfield, several of those observed by Wehrli *et al.* are downfield. Anet and Dekmezian (9) have observed deuterium-induced ^1H shifts over 5 bonds when an axial hydrogen and an axial CD_3 were *syn*-diaxial in a substituted 1,3-

For personal use only.

dioxane. However, the same compound did not reveal deuterium-induced 4-bond or 5-bond ^{13}C shifts.

The solvents used in this study were $CDCl_3$ and $CFCl_3$–$CDCl_3$ (9:1 v/v). The addition of $CFCl_3$ to $CDCl_3$ is required to allow measurements at temperatures below 200 K, but the volatility of $CFCl_3$ poses problems when accumulations are made over long periods at room temperature. Consequently low temperature spectra were determined in $CFCl_3$–$CDCl_3$ whereas room temperature spectra employed neat $CDCl_3$. Chemical shift data for several alkylcyclohexanes have shown that only small changes (generally deshielding) accompany the change from $CFCl_3$–$CDCl_3$ to $CDCl_3$. For example, the ^{13}C nmr chemical shifts (at 302 K) for carbons in *trans*-1-ethyl-4-methylcyclohexane, **5**, measured on the same instrument, are listed in Table 3 for the two solvents. As anticipated, the largest solvent-induced changes are for carbons on the periphery of the molecule; the changes for ring carbons are insignificant. Bearing in mind that ($\delta_{7''} - \delta_{7'}$) for the system **1** ⇌ **2** is as great as 7.02 ppm, the error for this parameter in using a value taken from a determination in $CFCl_3$–$CDCl_3$ (rather than $CDCl_3$) is negligible.

Experimental

Spectra

The ^1H nmr spectra were measured at 99.8 MHz on a JEOL JNM-MH-100 spectrometer; ^2H nmr spectra were measured in $CHCl_3$ on a JEOL JNM-PS-100 spectrometer interfaced to a Nicolet 1085 20 K computer; the reference was $CDCl_3$ (δ = 7.17 ppm). The ^{13}C nmr spectra were recorded on the JEOL JNM-PS-100 instrument at 25.15 MHz and on a Bruker WM 250 spectrometer at 62.901 MHz. Low temperature ^{13}C nmr spectra were recorded as described previously (5).

Materials

The preparations of *cis*- and *trans*-1-ethyl-4-methylcyclohexane have been reported elsewhere (6).

Methyl cis- *and* trans-*4-Ethylcyclohexanecarboxylate*

4-Ethylbenzoic acid (4.4723 g) was hydrogenated over platinum oxide (0.203 g) in glacial acetic acid (25 cm^3) at room temperature and atmospheric pressure. After 18 h the uptake of hydrogen was 2133 cm^3 (theoretical 2000 cm^3). The mixture was filtered and acetic acid was removed under vacuum. Distillation of the residue gave a mixture of *cis*- and *trans*-4-ethylcyclohexanecarboxylic acid (3.5714 g, 79%) as a colourless oil, bp 88–94°C at 0.3 Torr (ref. 10 gives *cis*-, bp 127°C at 5 Torr and *trans*-, mp 49–49.8°C). Thin-layer chromatography on silica gel with $CHCl_3$–MeOH 95:5 gave 2 spots with R_f values 0.24 (major) and 0.06. The ^1H nmr spectrum in $CDCl_3$ showed signals for the 1-hydrogen at δ 2.64 (*cis*, quintet with separations of about 5 Hz) and δ 2.30 (*trans*, triplet of triplets with separations of 12 Hz and 3.5 Hz). Mass spectrometry gave M^+ 156.1120 ($C_9H_{16}O_2$ requires 156.1150).

The above mixture (2.50 g) was refluxed for 4 h with dry methanol (2.3 cm^3, 1.80 g) and concentrated sulphuric acid (0.15 cm^3). After addition of water (10 cm^3) the mixture was extracted several times with ether. The combined ether extracts were washed successively with saturated aqueous $NaHCO_3$ solution and saturated aqueous NaCl solution. Finally the ether was dried ($MgSO_4$), filtered, and distilled, leaving a residue of *cis*- and *trans*-4-ethylcyclohexanecarboxylate (2.418 g, 89%). A small sample was distilled as a pale yellow oil with an aniseed-like odour, bp 50°C (bath temp) at 14 Torr; tlc showed two spots, R_f 0.69 (major) and 0.06. The ^1H nmr spectrum showed the methoxy protons as singlets at δ 3.78 (*cis*-, major) and δ 3.76 (*trans*-), and the 1-hydrogen at δ 2.56 (*cis*-, quintet with separations of about 5 Hz) and δ 2.26 (*trans*-, triplet of triplets with separations of 12 Hz and 3.5 Hz). Mass spectrometry gave M^+ 170.1286 ($C_{10}H_{18}O_2$ requires 170.1307). Microanalysis yielded C 70.25, H 10.35; $C_{10}H_{18}O_2$ requires C 70.55, H 10.65%.

cis- *and* trans-*4-Ethylcyclohexane[α,α-$^2H_2$]methanol*

Lithium aluminium deuteride (0.9741 g, 0.0232 mol) was stirred in dry redistilled ether (40 cm^3) under argon. A solution of methyl *cis*- and *trans*-4-ethylcyclohexanecarboxylate (5.4107 g, 0.0318 mol) in dry ether (35 cm^3) was added to the slurry of $LiAl^2H_4$ at a rate sufficient to maintain boiling. After completion of the addition, the mixture was stirred for 10 min, cooled in ice, and quenched by addition of iced water (9 cm^3). Two molar H_2SO_4 (45 cm^3) was added and the mixture was extracted several times with ether. Distillation of the dried (K_2CO_3) extracts gave a mixture of *cis*- and *trans*-4-ethylcyclohexane[α,α-$^2H_2$]methanol (4.12 g, 0.0286 mol, 90%) as a colourless oil, bp 100°C (bath temp) at 0.1 Torr. The ^2H nmr spectrum showed a singlet at δ 3.27. Mass spectrometry gave $M^+ - H_2O$ at 126.1366 ($C_9{}^1H_{14}{}^2H_2$ requires 126.1378). Microanalysis gave C 74.7, H 13.65; $C_9{}^1H_{16}{}^2H_2O$ requires C 74.95, H 13.95%.

cis- *and* trans-*4-Ethylcyclohexanemethanol*

A similar experiment to the above, using a mixture of methyl *cis*- and *trans*-4-ethylcyclohexanecarboxylate (1.70 g) and lithium aluminium hydride (0.3008 g) gave *cis*- and *trans*-4-ethylcyclohexanemethanol (1.3805 g, 97%), bp 50°C (bath temp) at 0.005 Torr. The ^1H nmr spectrum showed the protons of —CH_2—O as doublets (with separations of 6.5 and 5.8 Hz) at δ 3.56 (*cis*-, major) and δ 3.45 (*trans*-), respectively. The mass spectrum gave $M^+ - H_2O$ at 124.1241 (C_9H_{16} requires 124.1252). Microanalysis yielded C 75.7, H 12.35; $C_9H_{18}O$ requires C 76.0, H 12.75%.

cis- *and* trans-*4-Ethylcyclohexane[α,α-$^2H_2$]methanol 4′-Methylbenzenesulphonate*

4-Methylbenzenesulphonyl chloride was purified by dissolution in ether and repeated washing with aqueous sodium carbo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.5 on 09/05/12
For personal use only.

nate (1 *M*) until the pH of the ether exceeded 6.0. The ether solution was dried over anhydrous Na_2SO_4, filtered, and evaporated. The crystals of pure sulphonyl chloride were crushed and dried under high vacuum.

The mixture of *cis*- and *trans*-4-ethylcyclohexane [α,α-$^2H_2$]methanol (7.009 g, 0.0486 mol) was dissolved in dry (KOH), redistilled pyridine (15.36 g) at 0°C. To the stirred mixture was added 4-methylbenzenesulphonyl chloride (10.2011 g, 0.0535 mol) in portions during 30 min. The mixture was stirred for 2 h at 2°C and then for a further 1.5 h as the temperature was allowed to rise to 14°C. A mixture of concentrated hydrochloric acid (30 cm^3) and ice water (100 g) was added to the white, pasty reaction mixture. Several extracts with ether were combined, dried ($MgSO_4$), filtered, and evaporated. The residue of *cis*- and *trans*-4-ethylcyclohexane [α,α-$^2H_2$]methanol 4′-methyl benzenesulphonate (14.71 g, 102%) was a colourless oil contaminated with ether. An attempted distillation of a small portion at 1 Torr caused decomposition. The ^2H nmr spectrum gave signals at δ 3.88 (—CD_2O—, *cis*-) and δ 3.65 (—CD_2O—, *trans*-). The mass spectrum gave M^+ at 298.1594 ($C_{16}{}^1H_{22}{}^2H_2O_3S$ requires 298.1572). Microanalysis yielded C 64.05, H 9.0; $C_{16}{}^1H_{22}{}^2H_2O_3S$ requires C 64.4, H 8.8%.

cis- *and* trans-*4-Ethylcyclohexanemethanol 4′-Methylbenzenesulphonate*

An experiment similar to the above, using a mixture of *cis*- and *trans*-4-ethylcyclohexanemethanol (1.33 g, 0.00937 mol) and 4-methylbenzenesulphonyl chloride (1.98 g, 0.0103 mol) gave *cis*- and *trans*-4-ethylcyclohexanemethanol 4′-methylbenzenesulphonate (2.5992 g, 0.00878 mol, 94%) as a colourless oil. The ^1H nmr spectrum included doublets (separations 7 and 6 Hz) at δ 4.00 (—CH_2O—, *cis*-) and δ 3.88 (—CH_2O—, *trans*-), respectively. The mass spectrum gave M^+ as 296.1429 ($C_{16}H_{24}O_3S$ requires 296.1446). Microanalysis yielded C 64.4, H 8.0; $C_{16}H_{24}O_3S$ requires C 64.85, H 8.15%.

cis- *and* trans-*1-Ethyl-4[*Me-$^2H_3$*]methylcyclohexane*

Lithium aluminium deuteride (2.4618 g, 0.0568 mol) was stirred in dry, redistilled ether (56 cm^3) under argon. The mixture of *cis*- and *trans*-4-ethylcyclohexane [α,α-$^2H_2$]methanol 4′-methylbenzenesulphonate (14.30 g, 0.0480 mol), dissolved in dry, redistilled ether (140 cm^3) was added to the slurry of $LiAl^2H_4$ at 20°C. The mixture was heated under reflux, with stirring, for 2.5 h during which time a precipitate appeared. The reaction mixture was poured into ice water (24 cm^3) and aqueous sulphuric acid (210 cm^3, 2 *M*) was added. Several ether extracts were combined, dried ($MgSO_4$), filtered, and distilled, giving a mixture of *cis*- and *trans*-1-ethyl-4[*Me*-$^2H_3$] methylcyclohexane (4.2642 g, 0.0331 mol, 78%) as a colourless oil, bp 140–144°C. Mass spectrometry gave M^+ at 129.1574 ($C_9{}^1H_{15}{}^2H_3$ requires 129.1597). A complete separation was achieved by preparative gas–liquid chromatography, as described earlier (6). In the ^1H nmr spectrum, *cis*-1-ethyl-4[*Me*-$^2H_3$]methylcyclohexane gave a triplet, separations 6 Hz, at δ 0.88 (CH_3); the *trans*-1-ethyl-4[*Me*-$^2H_3$]methylcyclohexane gave a triplet, separations 6 Hz, at δ 0.86 (CH_3). The ^2H nmr spectra gave singlets at δ 0.96 (C^2H_3, *cis*-) and δ 0.90 (C^2H_3, *trans*-).

Calculation of Thermodynamic Parameters

(a) Low Temperature Area Method

Low temperature ^{13}C nmr spectra were recorded for *cis*-1-ethyl-4[*Me*-$^2H_3$] methylcyclohexane **3** ⇌ **4** as indicated previously (5) for the corresponding nondeuterated compound. The results are summarized below (equilibrium constant K = [**4**]/[**3**]).

T (K)	T^{-1} (K^{-1})	K	ln K
169	0.005912	1.218	0.1968
173	0.005775	1.219	0.1976
177	0.005645	1.179	0.1647
182	0.005505	1.164	0.1515
186	0.005386	1.147	0.1368
190	0.005273	1.142	0.1327

The data were analyzed as described elsewhere (5). Bearing in mind the following experimentally derived parameters for the ethyl group: 1.60 ± 0.06 kcal mol^{-1} for $-\Delta H°$ and 0.64 ± 0.35 cal K^{-1} mol^{-1} for $\Delta S°$, and on the reasonable assumption of additivity, we obtain the following:

$$-\Delta H°(C^2H_3) = 1.79 \pm 0.07 \text{ kcal mol}^{-1}$$

(plot method)

$$-\Delta H°(C^2H_3) = 1.85 \pm 0.07 \text{ kcal mol}^{-1}$$

(curve fit method)

Averaged value for $-\Delta H°(C^2H_3) = 1.82 \pm 0.07$ kcal mol^{-1}.

$$\Delta S°(C^2H_3) = -0.10 \pm 0.32 \text{ cal K}^{-1} \text{ mol}^{-1}$$

(plot)

$$\Delta S°(C^2H_3) = -0.45 \pm 0.39 \text{ cal K}^{-1} \text{ mol}^{-1}$$

(curve fit)

Averaged value for $\Delta S°(C^2H_3) = -0.28 \pm 0.40$ cal K^{-1} mol^{-1}.

(b) Room Temperature Chemical Shift Method

Measurements gave

$$\nu_7(H) - \nu_7(D) = -2.21 \text{ Hz}$$

at 62.901 MHz and 298 K. Thus

$$\delta_7(H) - \delta_7(D) = -0.035134 \text{ ppm}$$

Graph extrapolation gave

$$\delta_{7''} - \delta_{7'} = 7.0211125 \text{ ppm}$$

at 298 K. From [1], $x - y = -0.0050041$. From the previously determined (5) values of $\Delta G°(CH_3)$, $\Delta S°(CH_3)$, $\Delta G°(Et)$, and $\Delta S°(Et)$, we deduce that mole fraction $x = 0.5209961$ at 298 K, and equilibrium constant K for **1** ⇌ **2** is 0.91940 at 298 K.

Hence mole fraction $y = 0.5260002$ at 298 K and equilibrium constant K for **3** ⇌ **4** is 0.90114 at 298 K. Thus

$$\Delta G°(C^2H_3) - \Delta G°(Et) = RT \ln 0.90114$$
$$= 61.554181 \text{ cal mol}^{-1}$$

at 298 K

Now

$$\Delta G°(CH_3) - \Delta G°(Et) = 49.660000 \text{ cal mol}^{-1} \text{ at 298 K}$$

Hence

$$\Delta G°(C^2H_3) - \Delta G°(CH_3) = 11.894181 \text{ cal mol}^{-1} \text{ at 298 K}$$

Since possible errors are ±0.001463 ppm in digitization and ±0.25 ppm in the extrapolation to find $(\delta_{7''} - \delta_{7'})$, the final result may be expressed as

$$\Delta G°(C^2H_3) - \Delta G°(CH_3) = 11.89 \pm 1.46 \text{ cal mol}^{-1} \text{ or } 49.79 \pm 6.11 \text{ J mol}^{-1}$$

Catalytic reduction of dimeric acetylated 2-deoxy-2-nitroso-α-D-glycopyranosyl chlorides

T. L. NAGABHUSHAN

Schering-Plough Corporation, 60 Orange Street, Bloomfield, NJ 07003, U.S.A.

Received July 7, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

T. L. NAGABHUSHAN. Can. J. Chem. **58**, 2720 (1980).

Reduction of tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride dimer with hydrogen and platinum oxide in the presence of methanol or ethanol afforded the corresponding alkyl tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrochloride. In the absence of an alcohol the product was tri-*O*-acetyl-2-amino-1,5-anhydro-2-deoxy-D-glucitol hydrochloride. The glycosylation/reduction process gave similar results with the *galacto* isomer.

A method is described for the ready and large-scale synthesis of D-galactosamine hydrochloride.

T. L. NAGABHUSHAN. Can. J. Chem. **58**, 2720 (1980).

La réduction du dimère du chlorure de tri-*O*-acétyl déoxy-2 nitroso-2 α-D-glucopyrannosyle par l'hydrogène et l-oxyde de platine en présence de méthanol ou d'éthanol conduit au chlorhydrate du tri-*O*-acétyl amino-2 déoxy-2 β-D-glucopyrannoside d'alkyle. En l'absence d'un alcool, le produit de la réduction est le chlorhydrate du tri-*O*-acétyl amino-2 anhydro-1,5 déoxy-2 D-glucitol. La réaction de glycosylation/réduction a donné des résultats analogues avec l'isomère de la série *galacto*.

On décrit une méthode simple de synthèse du chlorhydrate de D-galactosamine appropriée à l'échelle industrielle.

[Traduit par le journal]

Reactions of dimeric acetylated 2-deoxy-2-nitroso-α-D-glycopyranosyl chlorides reported here are new and render syntheses of methyl (and ethyl) β-D-glycosaminides and 2-amino-1,5-anhydro-2-deoxy-D-glycitols readily accomplished. The former reaction is particularly useful for large-scale production of D-galactosamine hydrochloride.

Hydrogenation of 3,4,6-tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**) (1) in a mixture of tetrahydrofuran and methanol or dioxane and methanol using platinum oxide as the catalyst afforded methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrochloride (**2**) as a crystalline compound in 70% yield. Evidence for its structure was obtained by the preparation of known crystalline derivatives **3**–**6**, using standard procedures (Table 1). Similarly, reduction of 3,4,6-tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-galactopyranosyl chloride (**7**) (1) provided methyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-galactopyranoside hydrochloride (**8**), also in 70% yield. Structure of **8** was, likewise, proved by conversion to the crystalline derivatives **9**–**12** (Table 1).

When the reductions of **1** and **7** were carried out in the presence of ethanol instead of methanol, the ethyl 3,4,6-tri-*O*-acetyl-2-amino-2-deoxy-β-D-glucopyranoside hydrochloride (**15**) and its *galacto* isomer **16** were obtained, respectively, in reasonably good yields (50%) (Table 1). With higher alcohols, however, the yields dropped drastically.

Catalytic hydrogenation of **1** in the absence of an alcohol afforded a crystalline compound in 40% yield which was shown to be 3,4,6-tri-*O*-acetyl-2-amino-1,5-anhydro-2-deoxy-D-glucitol hydrochloride (**13**) by proton magnetic resonance spectroscopy and conversion to the known tetraacetate **14** (Table 1). Thus, in the ^{1}Hmr spectrum the three *O*-acetyl groups appeared as singlets at δ 2.17 and δ 2.13 in the ratio 1:2. H-3 and H-4 showed triplets at δ 5.35 ($J_{2,3}$ = 9.0 Hz) and δ 5.03 ($J_{3,4}$ = 9.0 Hz), respectively. The remainder of the protons appeared as superimposed multiplets between δ 4.4 and δ 3.6.

The ease of reduction, retention of the equatorial stereochemistry at the 2-position, and the exclusive formation of the β-glycosidic linkage preclude isomerization of the nitroso dimer to the oxime form prior to reduction (2). It is thought that the observed stereoselective β-glycosaminide formation in the current work proceeds in three stages. First, the nitroso dimer is rapidly reduced to the azoxy structure. There is precedence for this, as shown by Lemieux *et al.* (3), who actually isolated the azoxy chlorides following careful hydrogenation of the dimeric forms of acetylated 2-deoxy-2-nitroso-α-D-glycopyranosyl chlorides in dioxane using a weak hydrogenation catalyst. It is recalled that, under proper conditions, dimeric nitrosyl chloride adducts of acetylated glycals react with alcohols by way of the nitroso-glycal intermediates formed through a series of reactions involving dissociation to the monomeric form, isomerization to the oximinochloride, and elimination of hydrogen chloride (2). In the second stage, the α-chloride reacts with the alcohol in the presence of the

catalyst with inversion of configuration and liberation of hydrogen chloride. Finally, the azoxy β-glycoside is reduced in the presence of the acid to give β-glycosaminide hydrochlorides. In the absence of a nucleophile, however, the azoxychlorides undergo hydrogenolysis at the anomeric center and further reduction to give 2-amino-1,5-anhydro-2-deoxy-glycitol hydrochlorides. The mechanisms of these reactions are under study with the hope that a general method can be developed for syntheses of β-glycosaminides from glycals.

Experimental

All melting points are uncorrected. Infrared spectra were measured with a Perkin-Elmer Model 137 "Infracord" spectrophotometer. Optical rotations were determined using a Carl Zeiss circular polarimeter Model 0.01°. Elemental analyses were performed by Dr. G. Weiler and Dr. F. B. Strauss, Microanalytical Laboratory, Oxford, England. Solvents were removed *in vacuo* at 45°C.

Physical constants and elemental analyses of the following compounds are given in Table 1.

Methyl 3,4,5-Tri-O-acetyl-2-amino-2-deoxy-β-D-glucopyranoside Hydrochloride (2) and its galacto *Isomer 8*

To a solution of freshly prepared dimeric 3,4,6-tri-*O*-acetyl-2-deoxy-2-nitroso-α-D-glucopyranosyl chloride (**1**, 3 g) (1) in dry tetrahydrofuran (17 mL) was added anhydrous methanol (20 mL) with vigorous swirling of the flask to prevent crystallization of **1**. (If the solution is not clear, a few drops of tetrahydrofuran are added. In no case should the mixture be warmed to get a clear solution.) The mixture was hydrogenated in the presence of platinum oxide catalyst (0.2 g, Engelhard Industries of Canada Ltd., Toronto, Canada) at atmospheric pressure and room temperature until the consumption of hydrogen ceased (12–15 h). The catalyst was removed by filtration through a bed of Celite and washed with water. The combined filtrates were concentrated and the residue dried. Crystallization of the product from methanol–ether provided 2.2 g (70%) of pure **2**.

In a similar manner the *galacto* isomer **8** was obtained in 70% yield by the hydrogenation of a solution of **7** (3 g) (1) in a mixture of tetrahydrofuran (10 mL) and methanol (20 mL).

Methyl 2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranoside (3) and its galacto *Isomer 9*

To a stirred solution of **2** (or **8**) (7.08 g) in water (16 mL) was added methanol (8 mL). The solution was cooled to 5°C and acetic anhydride (6.0 mL) was added followed by sodium carbonate (2.12 g). After 1 h, the cooling bath was removed and the mixture stirred for an additional 0.5 h. The mixture was concentrated and partitioned between chloroform (30 mL) and water. The organic layer was dried over sodium sulfate, evaporated to dryness, and crystallized from isopropanol to give 6.0 g (83.3%) of pure **3**. The *galacto* isomer **9** was crystallized in 89% yield from ethanol.

Methyl 2-Acetamido-2-deoxy-β-D-glucopyranoside (5) and its galacto *Isomer 11*

Triethylamine (3 mL) was added to a solution of **3** (or **9**) (1 g) in methanol (6 mL) and water (5 mL). The mixture was set aside for 18 h at room temperature. The solvents were removed and the residue dried and crystallized from methanol–ether to afford 0.6 g (94%) of pure **5**. The yield of the crystalline *galacto* isomer **11** (from methanol–ether) was 0.59 g (90.8%).

For personal use only.

D-Glucosamine (4) and D-Galactosamine (10) Hydrochlorides

These were prepared by acid hydrolysis of **3** and **9** respectively (4).

Methyl 2-Amino-2-deoxy-β-D-glucopyranoside Hydrochloride (6) and its galacto *Isomer 12*

O-Deacetylation of **2** (or **8**) (0.711 g) with triethylamine (2 mL) in methanol (2 mL) and water (2 mL), as above, afforded a syrup which was dissolved in a little methanol and acidified with 1 *N* methanolic hydrogen chloride. Removal of the solvent and crystallization of the residue from ethanol–acetone provided pure **6**, 0.348 g (76%) or **12**, 0.4 g (87.3%).

3,4,6-Tri-O-acetyl-2-amino-1,5-anhydro-2-deoxy-D-glucitol Hydrochloride (13)

A solution of **1** (1.35 g) (1) in dioxane (15 mL) was hydrogenated in the presence of platinum oxide catalyst (0.5 g) at 60 psi for 18 h. The catalyst was removed by filtration through a bed of Celite and washed with a little dioxane. The filtrate was discarded. The filter cake was next washed thoroughly with water and removal of water afforded a white crystalline compound. The compound was dried and recrystallized from methanol–ether to yield 0.49 g (37.7%) of pure **13**.

2-Acetamido-3,4,6-tri-O-acetyl-1,5-anhydro-2-deoxy-D-glucitol (14)

N-Acetylation of **13** in a manner similar to the one described above for the preparation of **3** afforded **14** in 90% yield.

Ethyl 3,4-6-Tri-O-acetyl-2-amino-2-deoxy-β-D-glucopyranoside Hydrochloride (15) and its galacto *Isomer 16*

These were prepared in essentially the same manner as **2** except that dioxane (10 mL) and absolute ethanol (20 mL) were used as cosolvents. The products **15** and **16** obtained in 50% yield from **1** and **8**, respectively, crystallized from methanol – excess ether on standing for a prolonged period of time at 4°C.

Ethyl 2-Acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranoside (17) and its galacto *Isomer 18*

N-Acetylations of **15** and **16** were performed as mentioned earlier. The yields of **17** and **18** were 85% and 82%, respectively. Acid hydrolysis of these compounds (4) and paper chromatographic analysis of the hydrolysates using butanol, pyridine, and water (6:4:3) as the mobile phase showed single ninhydrin and $AgNO_3$–NaOH positive spots which were indistinguishable from those of authentic **4** and **10**, respectively.

Structure of the type XXXIII *Streptococcus pneumoniae* (pneumococcal) capsular polysaccharide[1]

LARRY G. BENNETT[2] AND CLAUDE T. BISHOP

Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 10, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

LARRY G. BENNETT and CLAUDE T. BISHOP. Can. J. Chem. **58**, 2724 (1980).

The type XXXIII *Streptococcus pneumoniae* (pneumococcal) capsular polysaccharide contains D-glucose (2 mol), D-galactose (1 mol), D-glucuronic acid (1 mol), and 2-acetamido-2-deoxy-D-mannose (1 mol). Structural investigations by methylation analysis, specific degradations, and nmr spectroscopy showed that the repeating unit was a linear pentasaccharide of the following structure: →3)-α-D-Gal*p*-(1→3)-β-D-Man*p*NAc-(1→4)-α-D-Glc*p*-(1→4)-β-D-Glc*p*-(1→4)-α-D-Glc*p*A-(1→.

LARRY G. BENNETT et CLAUDE T. BISHOP. Can. J. Chem. **58**, 2724 (1980).

Le polysaccharide capsulaire du *Streptococcus pneumonial* (pneumocoque) de type XXXIII contient du D-glucose (2 mol), du D-galactose (1 mol), de l'acide D-glucoronique (1 mol) et l'acétamido-2 déoxy-2 D-mannose (1 mol). Les études de structures réalisées par l'anaylse des méthylations, par des dégradations spécifiques et par la spectroscopie de rmn montrent que le motif monomère est un pentasaccharide linéaire ayant la structure suivante: →3)-α-D-Gal*p*-(1→3)-β-D-Man*p*NAc-(1→4)-α-D-Glc*p*-(1→4)-β-D-Glc*p*-(1→4)-α-D-Glc*p*A-(1→.

[Traduit par le journal]

Introduction

Capsular polysaccharides constitute the major, type-specific immunological determinants of *Streptococcus pneumoniae* and studies of their serological properties have contributed greatly to our knowledge of immunochemistry (1). About 80 types of *S. pneumoniae* have been identified serologically but structural studies have been reported for only some 25 of the type-specific polysaccharides (2). Some serotypes of *S. pneumoniae* are more prevalent than others in clinical infections but the distribution of serotypes varies with time and the whole range may be implicated as potential sources of public health problems (3, 4).

S. pneumoniae type XXXIII has been found in a relatively low but persistent number of pneumococcal infections for more than 40 years (3, 4). One previous report indicated that the type XXXIII polysaccharide contained glucose, galactose, and galacturonic acid in unspecified proportions (5) and an earlier report stated that this polysaccharide contained 1.65% N and 11.24% acetyl groups but no amino sugars (6); neither of these reports presented any structural information. The present paper describes structural studies that permit definition of the repeating unit of *S. pneumoniae* type XXXIII capsular polysaccharide.

Results and Discussion

The polysaccharide as received gave one peak on elution from DEAE cellulose and from Sephadex G-200, showed no absorption in the uv at 260 or 280 nm, and gave a single precipitin band on immunodiffusion against homologous antiserum. There was therefore little if any contamination with other cellular components and the structural studies were performed on the polysaccharide as supplied.

Analysis of hydrolysates of the type XXXIII polysaccharide on an amino acid autoanalyzer revealed that 2-amino-2-deoxy-D-mannose was present in substantial amounts. Graded hydrolysis of the polysaccharide showed a maximum release of amino sugar after 18 h at 100°C in 2 *N* hydrochloric acid and colorimetric estimation (7) gave an amino sugar content of 19.7%. The nitrogen content (1.40%) of the native polysaccharide would correspond to an amino sugar content of 17.9% if all of the nitrogen was contributed by the 2-amino-2-deoxy-D-mannose. Proton and ^{13}C nmr spectra of the native polysaccharide and of a slightly depolymerized sample (mild acid hydrolysis) showed the presence of *N*-acetyl groups. Integration of the peak areas of the *N*-acetyl signal and the signal of a single anomeric proton gave a ratio of 3:1 showing that the amino sugar was fully *N*-acetylated. The nmr spectra also showed the presence of one *O*-acetyl group for every two *N*-acetyls; the location of the *O*-acetyl was not investigated.

The presence of uronic acid was confirmed by the carbazole test (8) and quantitative estimation (9) showed that it constituted 20.7% of the polysaccharide. However, as reduction of the uronic acid yielded D-glucose it must have been D-glucuronic

acid and not galacturonic acid as previously reported (5).

Accurate quantitative analysis of the neutral sugars in the polysaccharide was difficult because of the acid stability of the uronosyl and aminoglycosyl linkages. Hydrolysates of the native polysaccharide contained 8% D-galactose and 33% D-glucose. However, when the polysaccharide was reduced by carbodiimide-borohydride (10), subsequent hydrolysis yielded 17.1% D-galactose and 52.3% D-glucose. This is a ratio of 1:3 with one of the three glucoses coming from the uronic acid. These results, together with the quantitative data for uronic acid and amino sugar, were consistent with a pentasaccharide repeating unit; two D-glucoses, and one each of D-galactose, D-glucuronic acid, and 2-acetamido-2-deoxy-D-mannose. The enantiomeric forms of these components were established by glc of the trimethylsilylated (−)2-butyl glycosides (11, 12).

Methylation analysis of the native polysaccharide gave 2,4,6-tri-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-glucose in a ratio of 1:2.5 as determined by gas chromatography – mass spectrometry of their alditol acetates (13). The low recovery of the tri-*O*-methyl-D-galactose was attributed to its probable linkage to the stable uronosyl unit, a conclusion that was subsequently confirmed. The presence of 2-deoxy-4,6-di-*O*-methyl-2-(*N*-methylacetamido)-D-mannose was also observed as the sole amino sugar derivative. Quantitation of this latter component was not attempted because of uncertainties about complete hydrolysis and response factors on glc. When the methylated, native polysaccharide was reduced before hydrolysis, an extra component was found, 2,3-di-*O*-methyl-D-glucose, that must have arisen from the uronic acid. This was confirmed by reduction of the native polysaccharide before methylation when the same products were obtained as from the methylated native polysaccharide but the ratio of 2,4,6-tri-*O*-methyl-D-galactose to 2,3,6-tri-*O*-methyl-D-glucose was 1:3, one of the three moles of the glucose derivative having arisen from the reduced uronic acid.

The results of the methylation analyses showed that the pentasaccharide repeating unit was linear and contained two D-glucose residues both linked through *O*-4, one D-glucuronic acid also linked through *O*-4, one D-galactose linked through *O*-3, and one 2-acetamido-2-deoxy-D-mannose linked through *O*-3. The methylation results in conjunction with the nmr results showed that all of the residues were in the pyranose ring form.

Partial hydrolysis studies and periodate degradations provided information about the sequence of the residues in the pentasaccharide repeating unit. Acid hydrolysis of the native polysaccharide yielded two disaccharides isolated by chromatography on Bio-Gel P-2 and on thin layer plates. One disaccharide contained equimolar amounts of 2-acetamido-2-deoxy-D-mannose and D-glucose. Periodate oxidation of this disaccharide, followed by reduction and hydrolysis, yielded glycerol and erythritol. Since it was known that the 2-acetamido-2-deoxy-D-mannose was *O*-3 linked and that D-glucose was *O*-4 linked in the polysaccharide, the results of periodate oxidation indicated the partial structure, D-Man*p*NAc-1→4-D-Glc*p*, for this disaccharide. The other disaccharide contained equal amounts of D-glucuronic acid and D-galactose. Lyxitol was identified as a product of periodate oxidation, reduction, and hydrolysis of this disaccharide which could therefore be assigned the partial structure D-Glc*p*A-1→3-D-Gal*p*.

Periodate oxidation of the native polysaccharide gave results that were initially confusing and difficult to interpret. Despite prolonged exposure to periodate only 75 to 80% of the glucose content was oxidized. As expected, the D-glucuronic acid was oxidized while the D-galactose and 2-acetamido-2-deoxy-D-mannose were completely resistant to oxidation. When the periodate oxidized polysaccharide was reduced, subjected to mild acid hydrolysis, and the products were chromatographed on Bio-Gel P-2, an oligosaccharide was obtained that contained equimolar amounts of D-galactose, D-glucose, 2-acetamido-2-deoxy-D-mannose, and erythritol. Methylation analysis of this oligosaccharide gave 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-glucose; no attempt was made to characterize the methylation products from the amino sugar or from erythritol because that information was not necessary. These results showed that D-galactose was in the nonreducing terminal position and that D-glucose was linked through *O*-4. Given the known sequence of D-Man*p*NAc-1→4-D-Glc*p* from the previously characterized disaccharide and the isolation of D-Gal*p*-1→3-D-Man*p*NAc-1→erythritol from the twice oxidized polysaccharide (see below), it was clear that this oligosaccharide had the partial structure D-Gal*p*-(1→3)-D-Man*p*NAc-(1→4)-D-Glc*p*-(1→erythritol). Since the erythritol could only have come from the other *O*-4 linked glucose and since D-glucuronic acid was found to be 1→3 linked to galactose in the other disaccharide previously characterized, the full sequence of the pen-

tasaccharide is defined as: →4)-D-Glc*p*A-(1→3)-D-Gal*p*-(1→3)-D-Man*p*NAc-(1→4)-D-Glc*p*-(1→4)-D-Glc*p*-(1→. The reason for the periodate resistance, in the native polysaccharide, of the 4-*O*-linked D-glucose residue found in this oligosaccharide was not investigated. It could have been due to partial substitution of the 2- or 3-hydroxyl groups by the unlocated *O*-acetyl groups, or that D-glucose residue could have been protected by hemiacetal formation with the aldehydo groups generated by oxidation of the neighbouring D-glucose residue (14, 15).

The assignments of anomeric configurations to the glycosidic linkages in the pentasaccharide were based upon nmr spectra and optical rotations of some degradation products. The carbodiimide-borohydride reduced polysaccharide was subjected to periodate oxidation and borohydride reduction. Following this initial reduction of any hemiacetals or aldehydo functions, the product was again oxidized by periodate and reduced. The ^{13}C nmr spectrum of this polymer showed four signals in the region 100 to 105 ppm characteristic of anomeric or acetal carbons. A resonance at 103.3 ppm represented two carbons and together with the single carbon resonances at 100.5, 101.4, and 104.8 ppm provided clear evidence of the five-residue repeating unit.

When this twice-oxidized and reduced polysaccharide was hydrolysed with 0.5 *N* sulphuric acid at room temperature for 18 h, a single oligosaccharide was obtained by chromatography on Bio-Gel P-2. This oligosaccharide contained D-galactose, 2-acetamido-2-deoxy-D-mannose and erythritol and after periodate oxidation and borohydride reduction it yielded 2-acetamido-2-deoxy-D-mannosyl glycerol. The oligosaccharide was therefore D-Gal*p*-1→3-D-Man*p*NAc-1→erythritol, the major product to be expected after complete periodate oxidation of the proposed repeating unit. The proton nmr spectrum of this disaccharide erythritol glycoside showed anomeric signals at δ 5.35 ($J_{1,2}$ = 2.7 Hz) and δ 4.96 ($J_{1,2}$ = 1.4 Hz), and an apparent doublet at δ 4.70 (J = 3.3 Hz) that was attributed to a slowly exchanging *N*-acetamido proton. It was only present in fragments containing the *N*-acetamido groups and was absent after Hakomori methylations of the same fragments. Sequential periodate oxidation, reduction, and hydrolysis (16) removed the D-galactose residue and its anomeric proton signal at δ 5.35. The coupling constant of that signal ($J_{1,2}$ = 2.7 Hz) clearly showed that the D-galactosyl linkage was in the α-configuration. The product from this degradation was 2-acetamido-2-deoxy-D-mannosyl glycerol that had $[\alpha]_D^{25}$ −52.5° in water showing that this glycosidic linkage was β (cf. methyl α-D-mannopyranoside, $[\alpha]_D$ +80°; methyl β-D-mannopyranoside, $[\alpha]_D$ −49°).

The anomeric configuration of the glucuronosyl residue was established by the proton nmr spectrum of the aldobiouronic acid (D-Glc*p*A-1→3-D-Gal) described earlier. The spectrum showed a strong anomeric signal at δ 5.12 assignable to the uronosyl residue and two smaller signals at δ 5.2 and 4.6 assignable to the galactose residue. The chemical shift and coupling constant ($J_{1,2}$ = 3.0 Hz) of the uronosyl anomeric proton showed that it was the α-anomer.

The anomeric configurations of the two glucosyl residues were established by proton nmr of the polysaccharide and subsequent disappearance of one of the anomeric signals by β-elimination. Based upon the spectra of the oligosaccharides described above, the signals in the anomeric region of the spectrum of the native polysaccharide could be assigned as follows: a doublet at δ 5.20 ($J_{1,2}$ = 3.4 Hz) was from the α-D-galactosyl residue, a doublet at δ 4.92 ($J_{1,2}$ = 1.0 Hz) was from the 2-acetamido-2-deoxy-β-D-mannosyl residue, and a doublet at δ 4.66 ($J_{1,2}$ = 3.3 Hz) was the *N*-acetamido proton. A doublet at δ 5.37 ($J_{1,2}$ = 3.2 Hz) was assigned to the α-D-glucuronosyl proton. Two doublets remained and must then represent the two D-glucosyl units. It was clear from their coupling constants that one, δ 5.45 ($J_{1,2}$ = 3.3 Hz), represented an α-anomer and the other, δ 4.57 ($J_{1,2}$ = 7.4 Hz) a β-anomer. Since it was known from sequence studies that one of the D-glucosyl units was linked to *O*-4 of the glucuronosyl residue, a β-elimination reaction was the most direct way to determine which anomer was in that position (17, 18). The proton nmr spectrum of the β-elimination product showed the expected absence of three doublets in the anomeric region: the *N*-acetamido proton, the α-D-glucuronosyl proton, and the high field β-D-glucosyl proton. The remaining three doublets had appropriate chemical shifts and coupling constants for α-D-glucosyl, α-D-galactosyl, and 2-acetamido-2-deoxy-β-D-mannosyl anomeric protons. This was conclusive evidence that the β-D-glucosyl residue was located next to the glucuronosyl residue and the complete sequence could therefore be defined as: →3)-α-D-Gal*p*-(1→3)-β-D-Man*p*NAc-(1→4)-α-D-Glc*p*-(1→4)-β-D-Glc*p*-(1→4)-α-D-Glc*p*A-(1→.

Experimental

Biological Materials

The *S. pneumoniae* type XXXIII polysaccharide was from the collection of Dr. R. Brown (6) and was generously provided by Dr. K. Amiraian, New York State Department of Health, Albany, NY. Type XXXIII specific rabbit antiserum was a gift

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.42 on 09/05/12
For personal use only.

from Dr. J. Henrichsen, Pneumococcus Laboratory, Statens Seruminstitut, Copenhagen, Denmark. The polysaccharide as received was eluted as a single peak from Sephadex G-200 and from DEAE cellulose (19). On double diffusion (20) in 1% agarose gel the polysaccharide showed a single precipitin band against the specific type XXXIII antiserum. A 1% solution of the polysaccharide showed no absorbance at 260 or 280 nm.

Analytical Methods

Neutral sugars in hydrolysates were analysed by glc of their alditol acetates (20). The material to be analysed (1 mg sample) and inositol (200 μg, internal standard) were hydrolysed in 0.25 *M* sulphuric acid (0.5 mL) in a sealed vial at 100°C for 20 h. The hydrolysate was neutralized with barium carbonate and sugars in the aqueous solution were reduced by sodium borohydride. The resultant alditols were acetylated in acetic anhydride – pyridine and then analysed on a Hewlett-Packard 5830 A gas–liquid chromatograph. Separations were obtained on glass columns packed with either 3% ECNSS-M or 3% OV-275 on Gas-chrom Q. Peak areas were integrated automatically.

The uronic acid content of the polysaccharide was estimated colorimetrically (8) and by decarboxylation (9) with the latter method giving the more reproducible results. Amino sugars were analysed by an automatic amino acid analyser using an elution system previously described (21). A colorimetric method (7) was used to follow the release of amino sugar in graded hydrolyses.

General Methods

Carboxylate reduction of uronic acid residues in the polysaccharide was achieved by the carbodiimide-borohydride method (10). The various degradations based upon sequential periodate oxidation, reduction, and hydrolysis were done according to standard procedures (16). All methylations were done by the Hakomori procedure (22) and *O*-methylated sugars in hydrolysates were characterized by retention times and mass fragmentation patterns of their alditol acetates on glc–ms (13). Enantiomeric forms of the monosaccharides were established by glc of their trimethylsilylated (−)2-butyl glycosides (11, 12). The glc separations for this analysis were done at 220°C on glass capillary columns (50 m × 0.2 mm) wall-coated with OV-101. Peaks with the following retention times relative to trimethylsilylated methyl α-D-galactopyranoside corresponded to the indicated reference sugars: 1.10, 1.85, 1.88 (D-glucuronic acid); 1.12, 1.23, 1.30 (D-galactose); 1.32, 1.48 (D-glucose); 1.52, 1.76 (2-amino-2-deoxy-D-mannose).

Carbon-13 and proton magnetic resonance spectra were obtained on a Varian CFT-20 spectrometer at 20 MHz and 80 MHz respectively using a pulsed Fourier transform mode. ^{13}C spectra were obtained at 30°C with complete proton decoupling and the ^{2}H resonance of the deuterium oxide solvent providing a field frequency lock. Chemical shifts are reported as parts per million downfield relative to an external tetramethylsilane standard. Proton spectra were obtained at 85–90°C to shift the ^{1}H resonance of the water peak upfield from the anomeric proton signals. Chemical shifts are reported as parts per million downfield (δ) relative to internal sodium 3-trimethylsilyl propionate-2,2,3,3-d_2 or tetramethylsilane standard.

Isolation of Oligosaccharides

The type XXXIII polysaccharide (20 mg) was hydrolysed in *N* hydrochloric acid at 100°C for 3 h. The hydrolysate was evaporated to dryness under diminished pressure at 40°C. The residue was chromatographed on Bio-Gel P-2 (minus 400 mesh; 120 × 1.2 cm) in 0.1 *M* pyridine–acetate buffer, pH 5.0. A drop-counter was used to collect fractions (15 drops) and a clean separation of disaccharides (fractions 97–107) from monosaccharides (fractions 110–117) was obtained. Eluate was monitored by refractive index and by the phenol – sulphuric acid colorimetric assay (23). Two disaccharides were isolated from the disaccharide fraction by thin-layer chromatography on silica gel plates using ethyl acetate/acetic acid/methanol/water 12:3:3:2. These disaccharides were found to be Glc*p*A-1→3-Gal and Man*p*NAc-1→4-Glc as described in the results. Oligosaccharides resulting from periodate degradations were isolated by chromatography on Bio-Gel P-2 as described above and were characterized as reported in the results and discussion.

β-*Elimination Reaction*

The native polysaccharide (15 mg) was methylated (22) and the product (13.4 mg) was degraded with sodium methoxide (17). The proton magnetic resonance spectrum of the degraded material in deuterochloroform showed doublets at δ 6.05 ($J_{1,2}$ = ~3.4 Hz), δ 5.43 ($J_{1,2}$ = ~3.0 Hz), and δ 5.22 ($J_{1,2}$ = ~1.0 Hz). Permethylated trisaccharide α-D-Gal*p*-(1→3)-β-D-Man*p*NAc-1→erythritol gave a spectrum with doublets at δ 5.35 ($J_{1,2}$ = ~3.0 Hz) and δ 5.20 ($J_{1,2}$ = ~1.0 Hz).

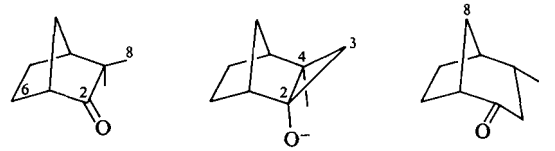
Evidence for cyclopropoxide intermediates in α-methyl H/D exchange of cyclic ketones under homoenolization conditions[1]

VIJAY PATEL AND J. B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 18, 1980

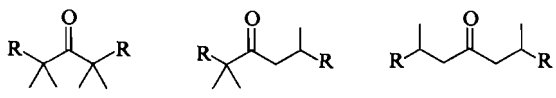
This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

VIJAY PATEL and J. B. STOTHERS. Can. J. Chem. **58**, 2728 (1980).



Base-catalyzed homoketonization of a series of polycyclic cyclopropanols provides strong evidence for the intermediacy of their anions for H/D exchange at α-methyl carbons in polycyclic ketones under homoenolization conditions.

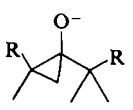
VIJAY PATEL et J. B. STOTHERS. Can. J. Chem. **58**, 2728 (1980).



L'homocétonisation, catalysée par une base, d'une série de cyclopropanols polycycliques fournit la preuve formelle de l'existence intermédiaire de leurs anions lors de l'échange H/D, au niveau des méthyles des carbones en position α des cétones polycycliques, dans des conditions d'homocétonisation.

[Traduit par le journal]

After their original discovery of homoenolization in camphenilone (**1**) through proton abstraction from C-6 (1), Nickon and Lambert also established that β-proton abstraction occurred at the α-methyl carbons (2). By implication, a homoenolate anion such as **2** was suggested for the intermediate species but experimental verification was not pursued. Subsequently, a variety of mono- and bicyclic ketones, each having *gem*-dimethyl substitution at the α-methylene positions, has been found to exhibit α-methyl H/D exchange in deuteriated base under homoenolization conditions (3–7). These examples include the tetramethylcycloalkanones with 4- to 8- and 10-membered rings (3, 4), fenchone (5), 3,3-dimethylbicyclo[3.2.1]octan-2-one (6), 3,3-dimethylbicyclo[2.2.2]octan-2-one (4) and its Δ^5 analog (7) as well as the isomeric 7,7-dimethylbicyclo[3.2.1]octan-6-one (4) and its corresponding unsaturated analogs (7). Although **2** can undergo cleavage in two ways, to regenerate **1** or to form **3**, a ring-expanded product was not detected (2) indicating that **2** → **3** is a minor process in *t*-BuO$^-$/*t*-BuOH at 185°C. Analogous results were found for the other examples and, in all cases, the recovery of starting material and/or rearranged products arising through homoenolization at skeletal carbons was high. One can conclude, therefore, that either bonding is not fully developed between C-2 and C-8 in the intermediate, or **2** is the intermediate and its opening to an incipient primary carbanion at C-3 is favored over formation of a tertiary carbanionic centre at C-4, i.e. toward the carbon more able to stabilize the negative charge (8). While the regioselectivity of α-methyl exchange found for several bicyclic ketones (5–7) pointed to the intermediacy of cyclopropoxide ions, the first direct evidence that a fully formed cyclopropoxide ion may indeed be involved was the finding that acyclic ketones such as **4** slowly rearrange to **5** (9). In fact with **4***b*, traces of **6***b* were detected after very long reaction times demonstrating that a second rearrangement can occur; this was more clearly illustrated with **4***c* and **5***c*, both of which furnish **6***c* in significant amounts (10). However, the balance between the factors determining the regioselectivity of cleavage of cyclopropoxide **7** may differ from



1 **2** **3**

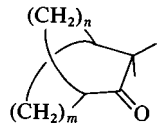
those governing ring opening of **2** and its polycyclic analogs, as has been suggested (9, 10). To date there is no evidence for the existence of cyclopropoxides such as **2** under homoenolization conditions. In this communication we wish to present results from an examination of base-catalyzed homoketonization of a series of substituted cyclopropanols **8** (R = H) which strongly support the intermediacy of cyclopropoxide ions for α-methyl exchange in polycyclic systems.



The requisite cyclopropanols were prepared employing the general sequence described by Girard and Conia for simpler systems (11). For **2**, methylation of norcamphor with lithium diisopropylamide (LDA) and methyl iodide gave 3-methylnorcamphor which was converted to the enolate with LDA and reacted with trimethylsilyl chloride and triethylamine in THF (12) to furnish **9**. Cyclopropanation (zinc–silver couple and methylene iodide) gave **8** (R = Me_3Si; $n = 1$, $m = 2$)[2] in 58% yield, isolated by bulb-to-bulb distillation. Cleavage of this ether with dilute HCl in THF afforded the corresponding alcohol, and its homoketonization via **2** was accomplished by rapid addition to a solution of t-BuO^-K^+ in anhydrous t-BuOH at 25°C. After 10 min, the solution was diluted with water and the ketonic products isolated by pentane extraction. Gas–liquid chromatography (glc) on 10% Carbowax or 6% FFAP revealed two products in a 63:37 ratio; pure samples of each were obtained by preparative glc. The same products in an 81:19 ratio resulted with the base solution at reflux (82°C). The major product in each case was easily shown by nmr to be **1**. The second, an isomeric ketone by ms, exhibited a ^{13}Cmr spectrum ($CDCl_3$) δ: 19.4 (CH_3); 22.4, 28.1, 38.6, 43.4 (CH_2's); 37.2, 40.4, 50.3 (CH's) and 213.8 (C=O) which is entirely consistent with **3** upon comparison with the

3	1	25	90	10

[a]Product proportions determined by glc analysis, ±2%.

^{13}C data for the parent ketone (13) with due allowance for the usual shielding effects of the methyl substituent. The methylene signal at 38.6 ppm is readily assigned to the methano bridge carbon (C-8) from the off-resonance spectrum (14). Its position is particularly significant since this is essentially the same as that for C-8 in the parent (38.3 ppm), strongly indicating an *endo* orientation for the methyl group in **3**. Thus, ring opening of **2** by cleavage of the C-2—C-4 bond proceeds with inversion of configuration at C-4, as generally observed for related systems with oxygen on tertiary carbon (15). In any event, these results establish that **2** opens preferentially via a primary carbanion (cleavage of the C-2—C-3 bond) to form **1**. The observed temperature dependency of the regioselectivity of homoketonization indicates that **2** → **1** will be even more highly favored at 185°C, the temperature of the homoenolization studies of **1**. Thus, **2** is a very reasonable intermediate for H/D exchange at the methyl sites in **1** under homoenolization conditions.

Results for some homologs of **2** are collected in Table 1. In each case, the substituted cyclopropanol **8** (R = H) was found to open preferentially to the corresponding dimethyl ketone **10**, with minor amounts of the ring-expanded product **11**. Similarly, **8** (R = H) from 3-methylbicyclo[2.2.2]oct-5-enone gave the dimethylbicyclooctenone as the major product.

Each of these cyclopropanol derivatives is a model intermediate for α-methyl exchange in the corresponding bicyclic ketone known to undergo H/D exchange at the methyl sites (2, 4–7). Our earlier work established that *exo*-methyl groups in these systems undergo exchange most readily and the present study was designed to test cyclopropoxides as potential intermediates for *exo*-methyl exchange. From the results it is apparent that **8** is a reasonable intermediate for the process. The ear-

lier studies (4–7) provided crude kinetic data showing methyl exchange to be very slow ($k \sim 10^{-7}$ s^{-1}). Consequently, small amounts of ring-expanded products, generated by the less-favored cleavage of **8**, may have escaped detection since presumably these would undergo aldol condensation readily. It may be noted that homoketonization of the 1-hydroxybicyclo[n.1.0]alkanes, n = 3–6, was reported earlier (16) and found to give >90% yields of the corresponding 2-methylcycloalkanones. Thus, one can conclude that α-methyl exchange in α,α,α′,α′-tetramethylcycloalkanones under homoenolization conditions (3, 4) also involves cyclopropoxide intermediates, although the precise model systems have not been examined.

A new preparative ring expansion for bicyclic ketones. Homoketonization of cyclopropoxide analogs[1]

YUMIKO HOYANO,[2] VIJAY PATEL, AND J. B. STOTHERS

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received June 18, 1980

This paper is dedicated to Prof. Raymond U. Lemieux on the occasion of his 60th birthday

YUMIKO HOYANO, VIJAY PATEL, and J. B. STOTHERS. Can. J. Chem. **58**, 2730 (1980).

Homoketonization of some readily prepared cyclopropoxides affords a new synthetic method for ring expansion of the [2.2.1] and [2.2.2] ring systems.

YUMIKO HOYANO, VIJAY PATEL et J. B. STOTHERS. Can. J. Chem. **58**, 2730 (1980).

L'homocétonisation de quelques oxydes cyclopropaniques facilement accessibles fournit une nouvelle méthode d'extension de systèmes cycliques [2.2.1] et [2.2.2].

[Traduit par le journal]

In the preceding communication (1) we have described the base-catalyzed homoketonization of some tricyclic systems containing a cyclopropanol moiety as model intermediates for α-methyl exchange in bicyclic ketones under homoenolization conditions. In the development of our experimental procedures, the 4-normethyl derivatives **1** were prepared and their cleavage via homoketonization was also examined. Significantly different regioselectivities were encountered such that a synthetic route to a variety of bicyclic ketones was revealed. We wish to present the results of these experiments to illustrate a new ring expansion procedure for some polycyclic systems.

Homoketonization of some readily prepared cyclopropoxides affords a new synthetic method for ring expansion of the [2.2.1] and [2.2.2] ring systems.

YUMIKO HOYANO, VIJAY PATEL et J. B. STOTHERS. Can. J. Chem. **58**, 2730 (1980).

L'homocétonisation de quelques oxydes cyclopropaniques facilement accessibles fournit une nouvelle méthode d'extension de systèmes cycliques [2.2.1] et [2.2.2].

[Traduit par le journal]

In the preceding communication (1) we have described the base-catalyzed homoketonization of some tricyclic systems containing a cyclopropanol moiety as model intermediates for α-methyl exchange in bicyclic ketones under homoenolization conditions. In the development of our experimental procedures, the 4-normethyl derivatives **1** were prepared and their cleavage via homoketonization was also examined. Significantly different regioselectivities were encountered such that a synthetic route to a variety of bicyclic ketones was revealed. We wish to present the results of these experiments to illustrate a new ring expansion procedure for some polycyclic systems.

[1]Part 91 in the series ^{13}Cmr Studies; for Part 90 see preceding communication.

Following the sequence developed by Girard and Conia (2) for several acyclic and monocyclic ketones, we have prepared a series of derivatives of general formula **1** (R = Me_3Si)[3] from the parent ketones **2**. Treatment of each ketone with lithium diisopropylamide followed by reaction with trimethylsilyl chloride and triethylamine afforded the trimethylsilyl enol ethers **3**; this procedure is a modification of that reported by House *et al.* (3). Cyclopropanation using a zinc–silver couple and methylene iodide gave **1** (R = Me_3Si) in reasonable yields, isolated by bulb-to-bulb distillation. In each case a single cyclopropyl ether was formed and the orientation of the cyclopropyl methylene carbon

relative to the other bridges in the ring system assigned from its ^{13}C shielding.[4] Cleavage of these ethers with dilute HCl in THF produced the corresponding cyclopropanol derivatives **1** (R = H).

Homoketonization of each cyclopropanol was carried out by its rapid addition to a solution of potassium *tert*-butoxide in anhydrous *tert*-BuOH at 25°C or at reflux (82°C). After 10 min, the reaction solution was diluted with water, the ketonic products isolated by pentane extraction, and analyzed by gas–liquid chromatography (glc) using 10% Carbowax or 6% FFAP columns. The cyclopropoxides, immediately formed in base, open rapidly by cleavage of bond *a* or *b* (see **1**) to give **4** or **5**, respectively, and subsequent enolization will epimerize the α-methyl group in **5**. Thus, the product mixtures were expected to contain two or three isomeric ketones depending on the carbon skeleton. The results for the six cyclopropanols studied are collected in Table 1. The ring-expanded ketones **4** were shown to be isomeric by ms and their ^{13}Cmr spectra lacked methyl absorption; the ^{13}C spectra for some of these ketones have been published (4, 5). The α-methyl ketones **5** were readily identified by their ^{13}C spectra, all of which have been reported previously (4, 6). Mixtures of *exo* and *endo* isomers were obtained in four cases while a single α-methyl ketone resulted in two systems. Because of the short reaction times, the mixtures are not necessarily at equilibrium. It may be noted that we have previously reported that *exo*-3-methylbicyclo[3.2.1]octan-2-one (**7**) cannot be epimerized under normal conditions (4), contrary to an earlier claim (7). In the present study, therefore, it was not surprising to find that **6** gave the single α-methyl isomer **7**.

From the data in Table 1 it is apparent that there is a delicate balance between the two modes of ring opening for these cyclopropoxides with the ratio of bond cleavage *a*:*b* varying between 95:5 and 5:95. Two opposing major factors governing the regioselectivity for a given system can be envisaged. Opening by cleavage of bond *b* may be inherently favored because the primary carbanion thereby generated (at C-3) is more stable and less hindered for protonation than the secondary carbanion formed (at C-4) by cleavage of bond *a* (8). However, the relief of ring strain resulting by cleavage of *a* may, in some systems, render it the favored mode, i.e. a dependence on product stability. The influence of the latter factor will be reflected in the proportion of ring-expanded product and will diminish as the size of the bridges in the ring system

TABLE 1. Base-catalyzed homoketonizations of **1** and **6**

Starting material		Temperature	Products (%)[a]	
1				
n	*m*	(°C)	**4**	**5** (*exo*/*endo*)
1	2	25	90	10 (1.6)
		82	85	15 (1.3)
2	2	25	73	27
		82	47	53
2 (Δ^6)	2	25	95	5 (0.5)[b]
3	1	25	30	70 (0.8)
3	2	25	~5[b]	~95[b] (0.7)[b]
6		25	23[c]	77[d,e]

[a]Unless otherwise indicated, the relative proportions (**4** and **5**) and the *exo*/*endo* ratios were determined by glc analysis; estimated precision ±2%.
[b]From ^{13}Cmr spectra, ±10%.
[c]Bicyclo[4.2.1]nonan-2-one.
[d]3-Methylbicyclo[3.2.1]octan-2-one.
[e]*Exo* isomer only, see text.

[3]For each new compound, the spectra (ir, ^1Hmr, ^{13}Cmr) were in agreement with the assigned structures. Precise mass measurements were obtained for each compound.

[4]The complete ^{13}C data will be presented in the full report.

increases. It can be seen that ring expansion is decreasingly favored in the saturated series in the order: [2.2.1], [2.2.2], [3.2.1], [3.2.2], with the unsaturated [2.2.2] skeleton exhibiting the greatest tendency for ring expansion; this is in qualitative agreement with expectations. For three of the systems, homoketonization is potentially useful for preparative purposes. Although **6** opens preferentially to the α-methyl ketone, its 3,3-dichloro derivative undergoes reductive fragmentation to the ring-expanded [4.2.1] skeleton (9). Hence, the two types of cyclopropyl derivatives provide many interesting synthetic possibilities. The temperature dependence of regioselectivity for homoketonization of **1** is similar to that found for the 4-methyl analogs (1), with lower temperatures favoring ring expansion.

The predominance of ring expansion in three of these homoketonizations provides a new synthetic method for these and closely related systems. Extensions to other systems are in hand to define the scope of the method more precisely, to establish the stereochemistry of bond *a* cleavage, and to investigate the reaction at lower temperatures. As an example of the synthetic utility of homoketonization for ring expansion, we have found that homologation of tricyclo[5.2.1.$0^{2,6}$]decan-8-one, as well as its Δ^3 and Δ^4 derivatives, to the corresponding tricyclo[5.3.1.$0^{2,6}$]undecan-8-ones is straightforward and the product is essentially free of the unexpanded α-methyl isomers.[5]

KING MO SUN and BERT FRASER-REID. Can. J. Chem. **58**, 2732 (1980).

C-Glycofuranosides with an activated methylene group at C1 of the glycosyl residue are amenable to epimerisation via a retro-Michael–Michael addition sequence. Advantage is taken of this phenomenon by converting methyl 2,3-*O*-isopropylidene-β,D-*ribo*-octofuranosid-6-ulose (**8**) into the corresponding α,L-*lyxo* isomer (**15**) by treatment with base. Both **8** and **15** are then converted into the (−) and (+) enantiomers of methyl nonactate (**14**) respectively, in ~ 45 percent yield.

KING MO SUN et BERT FRASER-REID. Can. J. Chem. **58**, 2732 (1980).

Les *C*-glycofurannosides ayant un groupement méthylène activé au niveau du carbone en position 1 de la portion glycosyle sont susceptibles d'être épimérisés par l'intermédiaire d'une addition de type rétro-Michael. On profite de ce fait pour transformer, au moyen d'une base, le *O*-isopropylidène-2,3 β-D-*ribo*-octofurannoside-6 ulose de méthyle (**8**) en son isomère le α,L-*lyxo* (**15**). Les deux composés **8** et **15** sont alors transformés respectivement en des énantiomères (−) et (+) du nonactate de méthyle avec un rendement de 45%.

1). This principle should facilitate asymmetric syntheses of *cis* and *trans* 2,5-dialkyltetrahydrofuran systems by "cyclic transfer"[1] from **4** and **5** respectively. In this communication we utilize this principle for a synthesis[2] of the (+) and (−) enantiomers of nonactic acid (**14**) from the same derivative of D-ribose.

1 **3**

X = CN, CO_2R, COR etc.

8	OMe	H	CH_2COCH_3

SCHEME 1

The known aldehyde, **6**, prepared readily from D-ribose (5), was converted into the syrupy ketone **8**[3] in 62% overall yield via a Wittig reaction to give the enol ether **7**, followed by hydrolysis (0.03*N* HCl, 15 min). Inspection of models suggested that chelation of the C8 carbonyl, dioxolane, and ring oxygens by Raney nickel (6) should lead to the desired (*S*) alcohol **9** upon hydrogenation. Indeed the ratio of **9** and **10** was 9:1, and the fact that these epimers were well resolved (R_f[4] 0.43 and 0.48 respectively) meant that the minor component could be separated on a silica column and transformed into **9** via sulfonation followed by solvolysis with sodium benzoate.

With the configuration of the C8 hydroxyl group secured, compound **9** was transformed into the aldose **11** which was subjected to the Moffatt two-step procedure (1) depicted in Scheme 1, whereupon the epimers **12** and **13** were obtained *exclusively* under conditions of kinetic control. The initial ratio of **12** and **13** was 1:3, but this could be raised to 3:2 by refluxing with sodium methoxide for 3 h (*vide infra*). Hence after three cycles of equilibration and separation, 90% of **13** had been converted into **12**[3] (R_f[4] 0.50 and 0.43, respectively).

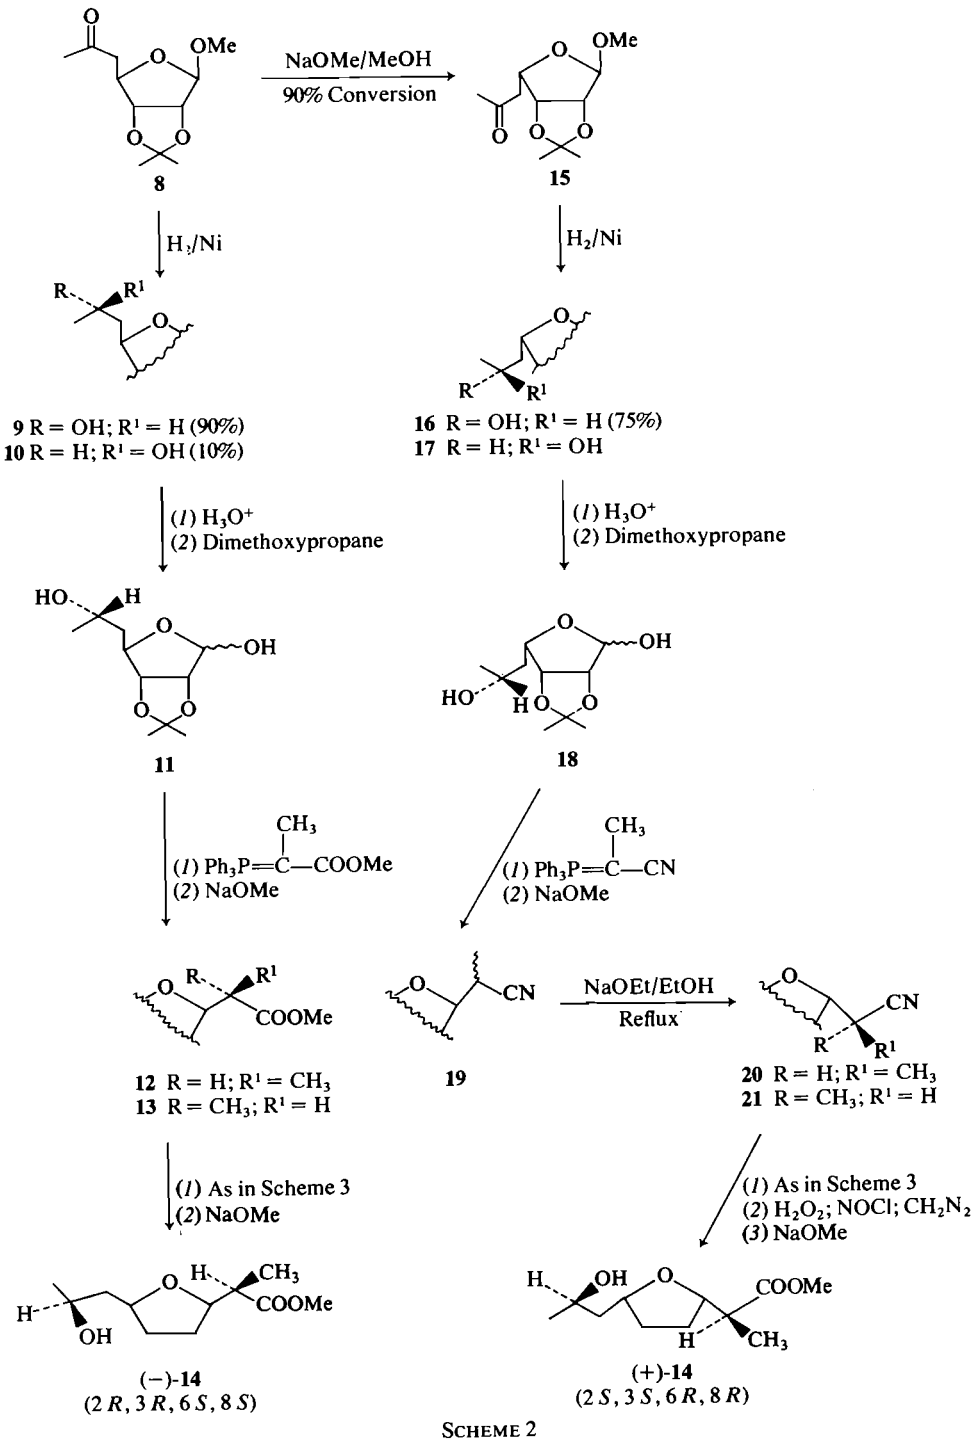
The final steps leading from **12** to (−) methyl nonactate (−)-**14**, in 78% overall yield, employed the Eastwood deoxygenation (7) as outlined in Scheme 3. Thus the benzoate of **12** was deacetonated, and the resulting diol converted into the amide acetal (**22**) which upon boiling in acetic anhydride afforded the alkene (**23**). Hydrogenation over palladium then afforded (−)-**14**, $[\alpha]_D^{20}$ −16.0° (lit. (4) value −17.8°). Identification of the product was established by comparison with an authentic sample.[5]

For the synthesis of the dextrorotatory enantiomer (+)-**14** we made use of the phenomenological observation (Scheme 1) which predicted that treatment of **8** with base would give **15** as the thermodynamically favoured isomer; indeed the ratio of **15** to **8** at equilibrium was 9:1. The sequences leading to **16**,[3] and thence to **18**, were identical with those used for **8** → **11**.

Our strategy now required the addition of a Wittig reagent to **18** and prolonged treatment with base in order to bring C1 into *syn* relationship with the acetonide. Our earlier studies with **12** and **13** (*vide supra*) had revealed that these α-alkylated esters were reluctant to move "down" into *syn*-relationship with the acetonide. However, in a model study the corresponding nitriles had been found to behave "normally." Hence compound **18** was converted in 93% yield into the epimeric mixture **19**. This mixture was then subjected to sodium ethoxide in refluxing ethanol, whereupon 80% epimerisation occurred giving **20** and **21** in equal amounts. Subjecting **21** and recovered **19** to a few cycles of epimerisation and separation afforded **20** in ~ 84% yield from **19**.

Deoxygenation of **20** was carried out as described for **12** (Scheme 3), and the nitrile was converted into the methyl ester (+)-**14** by treatment with hydrogen peroxide (8) and nitrosyl chloride (9). The identity of (+)-**14** ($[\alpha]_D^{20}$ +16.2° (lit. (4)

[1]For definition of this term see ref. 2.



[2]For racemic and asymmetric syntheses of nonactin, see refs. 3 and 4 respectively.

[3]This compound gave satisfactory hrms, 220 MHz ^{1}Hmr and ^{13}Cmr spectra.

[4]All R_f's in diethyl ether with the exception of **20** and **21** which were in $MeOH/CH_2Cl_2$ (1:23).

[5]We are indebted to Professor Ulrich Schmidt of the Universität Wien for authentic samples of nonactic acid derivatives (4).

SCHEME 2

value +16.2°)) was established by comparison with the previously prepared levorotatory enantiomer (−)-**14**.

Assuming virtually quantitative interconversion of the epimers (e.g. **10** → **9**, **13** → **12**, etc.) it is seen that the transformation of **8** into (−)-**14** and **15** into (+)-**14** may be carried out in ~45 percent overall yields. The synthetic plan can obviously be utilized to obtain specifically the C2 and/or C8 epimers of nonactic acid by accumulating the "other" compo-

Electrophilic additions to allenes. VI. The role of steric versus electronic effects in the reactions of arenesulphenyl halides with allenes[1]

DENNIS G. GARRATT[2] AND PIERRE L. BEAULIEU[3]
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received June 4, 1980

DENNIS G. GARRATT and PIERRE L. BEAULIEU. Can. J. Chem. **58**, 2737 (1980).

The role of steric and electronic effects during the rate and product determining steps for the addition of arenesulphenyl chlorides to 1,3-disubstituted allenes has been briefly examined. Both effects appear to be generally of minimal importance during the rate determining step. The available rate data indicate the presence of little, if any, build up of positive charge on sulphur. These results are interpreted in terms of an S_N2 attack on bivalent sulphur leading to an alkylidenethiiranium ion intermediate. Steric effects are of greater importance in the product determining step, particularly when the sulphenyl chlorides possess two bulky *ortho* substituents, as in the case of 2,4,6-triisopropylbenzenesulphenyl chloride.

DENNIS G. GARRATT et PIERRE L. BEAULIEU. Can. J. Chem. **58**, 2737 (1980).

On a examiné brièvement le rôle des effets stérique et électronique dans les étapes déterminant la vitesse de la réaction et la valeur des produits d'addition des chlorures d'arène-sulphényle sur les allènes disubstitués en positions 1,3. Les deux effets semblent n'avoir qu'une faible importance sur l'étape déterminant la vitesse de la réaction. Les données cinétiques disponibles indiquent la présence d'une faible charge positive sur le soufre. On interprète ces résultats en termes d'une attaque S_N2 sur le soufre bivalent conduisant à un ion alkylidènethiiranium intermédiaire. Les effets stériques jouent un rôle important dans l'étape déterminant la nature des produits formés en particulier quand le chlorure de sulphényle possède deux substituants encombrants en position *ortho* comme dans le cas du chlorure de triisopropyl-2,4,6 benzènesulphényle.

[Traduit par le journal]

In previous papers of this series we have reported the reactions of benzenesulphenyl chloride and some derivatives thereof with a series of 1,3-disubstituted allenes (1–3). In all cases studied the arylthio moiety was observed to attack regiospecifically on the central allenic carbon, with the *E* isomer formed preferentially or exclusively under conditions of kinetic control. The ratio of products was interpreted as corresponding to the percentage of attack on each face of the respective π systems, and therefore reflecting the direction of approach of the electrophile towards the allenic system. The preponderance of the *E* isomer led us to propose that one observes *steric approach control*, wherein the steric interactions in the product determining transition state are of the long range type between attacking reagent, *ArSCl*, and substrate molecule, *allene*, which is in its ground state geometry (2, 4).

[1] $R''SCl + RCH=C=CHR' \longrightarrow \left[RHC(-S^+R'')-C(Cl^-)=CHR' \right]^{\ddagger} \longrightarrow R''S-C(RHC(Cl))=CHR'$

In order to further ascertain the degree and nature of involvement of steric factors and/or electronic effects during the course of these reactions, we have carried out a series of kinetic and stereochemical investigations, the results of which we report herein.

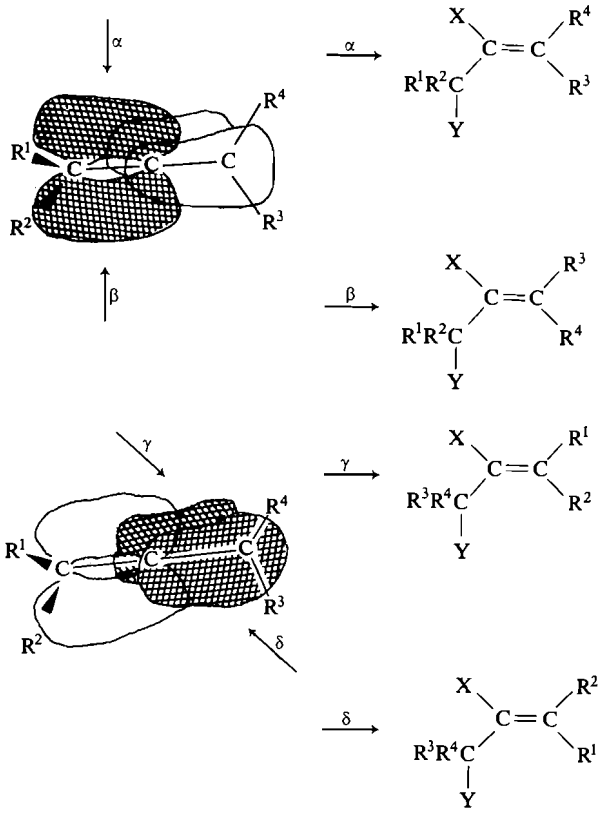
Results and Discussion

Kinetic Studies



The rates of addition of benzenesulphenyl chloride to nine 1,3-disubstituted allenes at 24.5°C in methylene chloride solution were determined using the stopped-flow technique. The rate of disappearance of sulphenyl chloride was followed by measuring the decrease in its absorption at 392 nm. The additions are found to exhibit normal second order kinetics, first order in allene, and first order in sulphenyl chloride, to at least 85% completion of the reaction (5). Specific rate constants are given in Table 1.

Of particular note upon examining Table 1 is the observation that benzenesulphenyl chloride shows only minor variations in rate of addition as the 1,3 alkyl groups are changed. Steric and polar effects of the alkyl substituents are apparently quite minimal. Considering only the first three entries, the effect of substituting two ethyl groups or two isopropyl groups for the methyl groups in 2,3-pentadiene (1,3-dimethylallene) is to cause minor decreases in rate of 17 and 46%, respectively. If only one methyl group from 2,3-pentadiene is changed to ethyl, isopropyl, or *tert*-butyl, one observes initially a slight increase in rate of 9% followed by slow decreases. Such variations are also seen if one holds, for example, the isopropyl group on 5-methyl-2,3-hexadiene constant and varies the methyl group from ethyl to isopropyl to *tert*-butyl. In fact such variations are typical of those previously observed for the analogously substituted *trans*-1,2-disubstituted ethylenes (6). These data thus tend to support our earlier hypothesis (5) that the rate determining transition state in the arenesulphenylation of allenes is stabilized equally well by a methyl group as by an ethylidene (=$CHCH_3$) group, and allows us to extend the comparison to ethyl, isopropyl, and *tert*-butyl in terms of, respectively, *n*-propylidene (=$CHCH_2CH_3$), isobutylidene (=$CHCH(CH_3)_2$), and neopentylidene (=$CHC(CH_3)_3$).

The real situation is, however, somewhat more complex. As noted in the first paper of this series (2), when the two substituents on a given terminal allenic carbon atom are different, there exist two possible directions of approach by the electrophile as shown in Scheme 1. If our hypothesis of steric approach control is correct the values of k_2 given in Table 1 may be partitioned into four terms, $k_2 = k_\alpha^E + k_\alpha^Z + k_\beta^E + k_\beta^Z$, each term reflecting the relative propensity for attack upon a given π orbital-lobe of the allenic system. Such a partition has been carried out and the values listed in Table 2. This partitioning was accomplished using the previously determined kinetically controlled product distributions as partition factors (3, 7).[4]

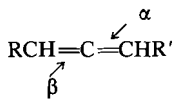

SCHEME I

An analysis of these substituent effects allows one to draw some further insights into the nature of the polar and steric effects during the rate determining step. These effects are perhaps most easily evaluated by regrouping the partitioned rate data of Table 2 into a series of subsets as shown in Table 3.

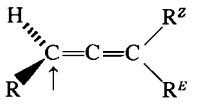
Subsets 1–4, for example, demonstrate the effect of varying a remote substituent on the allene, which is oriented *anti* with respect to the incoming electrophile,[5] while the substituent, R, on the double bond being attacked is held constant. Similarly, subsets 5–8 demonstrate the analogous effect wherein the remote substituent is oriented *syn* relative to the incoming electrophile.[5]

Regarding first of all subsets 1–4, we observe that varying the remote substituent from methyl to ethyl, isopropyl, and *tert*-butyl leads to only marginal rate enhancements or retardations when the substituent group is oriented *anti* with respect to the approaching electrophile. Somewhat surprisingly, perhaps, in view of the orthogonality of the π systems, the effect of the remote substituent appears to be coupled to the substituent group which is on the double bond undergoing attack. Thus, for example, a remote isopropyl group in the *anti* orientation relative to the approaching electrophile leads to a slight rate enhancement, 8%, over methyl when the group on the double bond being attacked is methyl, but gives a retarding effect relative to a remote methyl when the group on the double bond being attacked is ethyl, isopropyl, or *tert*-butyl. Transmission of substituent effects across both double bonds of the allenic system as observed above has been previously reported (5).

When the remote substituent group is oriented *syn* with respect to the incoming electrophile the results are more dramatic as can be seen from an examination of subsets 5–8. Replacing a *syn* methyl group by ethyl uniformly leads to a rate decrease. Similar decreases are observed upon substituting isopropyl for ethyl or *tert*-butyl for isopropyl, in accord with the relative spatial volume or steric bulk of each substituent. Once again we observe an apparent coupling between the magnitude of the effect and the nature of the substituent on the double bond being attacked. For example, when the remote substituent is *tert*-butyl and the group on the double bond undergoing attack is methyl, we observe a rate retardation of 85% relative to a remote methyl group. If, however, the group on the double bond being attacked is isopropyl the analogous substitution of *tert*-butyl for methyl on the remote terminus leads to a 91% rate retardation. This increase in steric retardation can be accounted for in terms of an additional steric effect caused by the isopropyl group on the double bond being attacked.

Subsets 9–12 and 13–16 allow us to evaluate the effect of changing a substituent on the double bond which is under attack while holding the remote substituents constant. From these data it is apparent that replacing methyl by either isopropyl or *tert*-butyl will lead to a rate retardation. The ethyl group, however, shows ambivalent behaviour giving rise to either rate enhancement or retardation depending upon the nature and orientation, i.e. *syn* or *anti*, of the remote substituent.



An alternative method of gaining information on the nature of the rate determining transition state is to vary substituents on the electrophile itself thus changing the bridging ability or degree of neighbouring group participation of the arylthio moiety while holding the allenic functionality constant (8). In a previous article (3) we noted that such variations had little effect on either the chemoselectivity or configurational-selectivity of the reaction except for a minor steric effect when the sulphenyl chloride has an *ortho*-nitro or *ortho*-methyl substituent. In Table 4 are given the specific rate constants for the reactions of nine arenesulphenyl chlorides with 3-methyl-1,2-butadiene (1,1-dimethylallene) and 2,3-pentadiene at 24.5°C in methylene chloride solution. From these data it is clear that varying the electron-donating or electron-withdrawing ability of a remote substituent on the sulphenyl chloride leads to only minor changes in the rate of addition. In terms of linear free energy relationships of, for example, the Hammett type, a plot of log k_2 versus σ or σ^+ is essentially linear with a ρ value very close to unity or slightly positive.[6] Such a result is best interpreted in terms of little, if any, build up of positive

[5]This orientation of approach leads specifically to the adduct of *E* configuration. *Syn* attack conversely gives an adduct of *Z* configuration.

[6]For the purposes of these plots the data for 2,5-dichlorobenzenesulphenyl chloride, 2-methylbenzenesulphenyl chloride, and 2,4,6-trimethylbenzenesulphenyl chloride have been omitted.

or negative charge on sulphur during the rate determining step.

To appreciate the significance of this result it is necessary to consider the possible modes of interaction for an olefinic double bond with a sulphenyl halide,[7] as shown in Scheme 2. This scheme has been discussed previously and will not be further elaborated in detail at this time (9, 10). The results presented herein are in agreement with our previously proposed mechanism (2) and appear to be most consistent with path 'a' of Scheme 2. We note that for path 'a' a rate determining transition state structure of the S_N2 sort is anticipated to have a charge distribution leading to a ρ value which is zero or slightly positive or negative in analogy to S_N2 displacement at carbon. If path 'b' is to be of importance, one would anticipate a ρ value of moderate magnitude, ± 2–4, the sign being dependent upon whether or not formation or collapse of the episulphurane species is rate determining. A zero ρ value as found during this study thus tends to rule out path 'b'.

Upon further examination of Table 4 the following additional points may be made. Firstly, while

[7]The following scenarios are valid irrespective of whether one is dealing with an isolated, conjugative, or cumulative double bond.

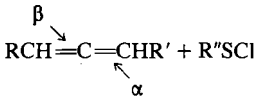
the *ortho*-chloro and *ortho*-methyl substituted arenesulphenyl chlorides are found to react somewhat slower than their *para* substituted analogues, there does not appear to be substantial steric retardation from these substituents in the rate determining step. The only anomalous result appears, at first sight, to be the rate constant for the reaction of 2,4,6-trimethylbenzenesulphenyl chloride with 2,3-pentadiene. The rate retardation found in this case is, however, easily explained. Using the configurational-selectivity data in Table 5, it is found that 40% of the product distribution results from attack by the sulphenyl chloride *syn* with respect to the remote methyl group on the allene. The presence of two *ortho* methyl groups on the sulphenyl chloride in this case leads to a rather sterically congested rate determining transition state and thus to a slower rate of addition. The absence of a rate retardation upon reaction of 2,4,6-trimethylbenzenesulphenyl chloride with 3-methyl-1,2-butadiene is seen to reflect the 90:10 chemoselectivity in favour of attack upon the most substituted double bond of this allenic system. In this case there is only a hydrogen atom in the same plane as the π orbital which is interacting with the sulphenyl chloride. Therefore, no steric effect is anticipated to be observable.

Product Studies

In order to further evaluate the nature of polar and steric effects in the product determining transition state,[8] we have investigated the reactions of a series of thirteen arenesulphenyl chlorides with ten 1,3-disubstituted allenes. Our hypothesis during this portion of our work is based upon the premise that the presence of *ortho* substituents on the phenyl ring of these electrophiles will lead to greater configurational-selectivity in the formation of adducts under conditions of kinetic control. Although the reactions of some of these sulphenyl chlorides have previously been reported (3), their product distributions are given here for purposes of comparison and completeness.

All reactions were carried out at ambient temperature using methylene chloride as solvent. The kinetically controlled product distributions, as given in Table 5, were determined by immediate ^{1}H nmr analysis of the reaction mixture. Reaction end-points were determined by the disappearance of the S—Cl chromophore (λ_{max} 392 nm) and/or a negative starch iodide test (12). Analysis of the spectral data, using the criteria previously established (2, 3), indicates that the 1:1 adducts are formed via regiospecific attack of the arylthio moieties on the central allenic carbons as shown in eq. [1].

In accord with our initial hypothesis (2, 3) the substitution of an *ortho* hydrogen by a larger group such as methyl, trifluoromethyl, or nitro leads to an increase in the configurational-selectivity as is reflected in the $\alpha(E{:}Z)$ and $\beta(E{:}Z)$ ratios. The substitution of both *ortho* hydrogens by alkyl groups, such as methyl or isopropyl, demonstrates this effect more dramatically. The *E* isomers in these latter two examples are formed with configurational-specificity in eleven out of sixteen of the cases investigated. This configurational-specificity is interpreted as the result of severe steric interactions between the two *ortho* groups and the remote *syn* oriented substituent on the allenic system which by virtue of the orthogonality of the two allenic π systems must lie in the same plane as the π orbital which is interacting with the sulphenyl chloride as is shown below.



E Favored *Z*

Data for two of the sulphenyl chlorides listed in Table 5 appear, at first sight, to be anomalous. Both 1-naphthalenesulphenyl chloride and 9-phenanthracenesulphenyl chloride show a lesser degree of configurational-selectivity towards favouring the *E* isomer under conditions of kinetic control than would have been expected upon replacing an *ortho*

[8]See ref. 3 for a preliminary discussion of this concept.

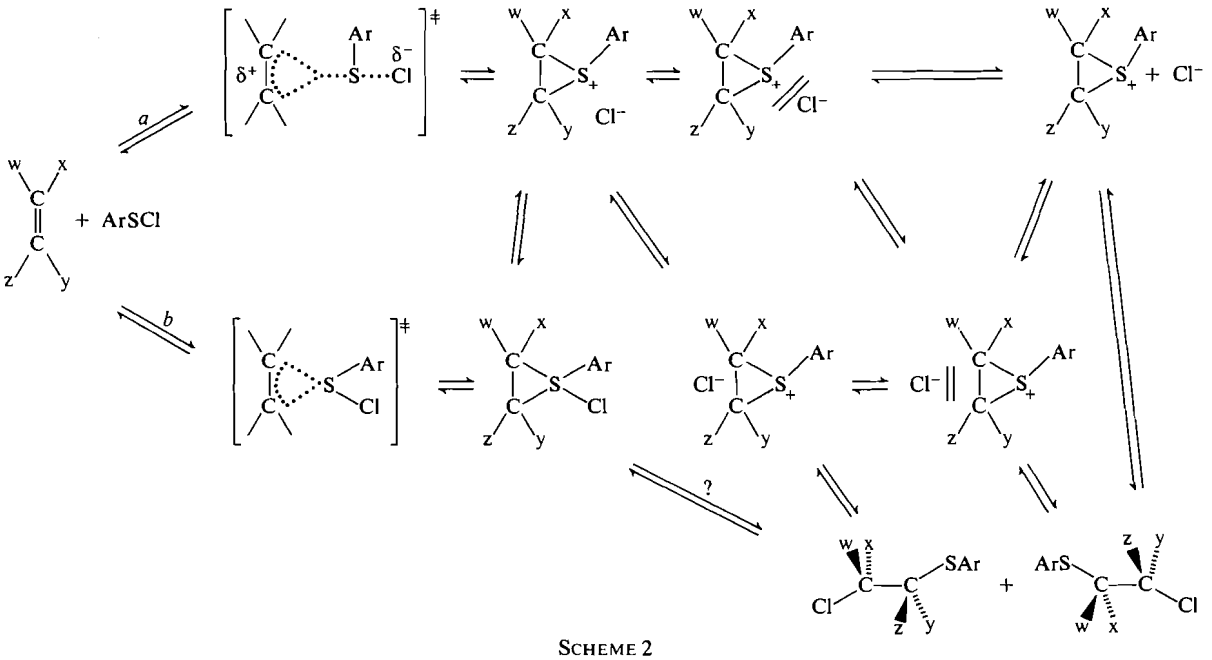
and a *meta* hydrogen by the benzo moiety. For example, the *E*:*Z* ratios of 40:60 and 42:58 observed for these sulphenyl chlorides upon reaction with 2,3-pentadiene are the only examples, to our knowledge, of the addition of sulphenyl halides to 1,3-disubstituted allenes wherein the *Z* isomer is formed preferentially under conditions of kinetic control. In view of these latter results it is surprising that normal *E*:*Z* ratios are observed for attack on 2,3-hexadiene, 5-methyl-2,3-hexadiene, and 5,5-dimethyl-2,3-hexadiene. While we do not completely understand the reasons for this anomalous behaviour it seems likely that the lower configurational-selectivity observed must reflect in part the planar configuration of these aryl groups compared to, for example, 2,4,6-trimethyl- or 2,4,6-triisopropylbenzenesulphenyl chloride, where the alkyl groups in the *ortho* positions occupy a larger volume in space close to the reaction center and thus present a bulkier local environment during the product determining step.

In summary, the data presented here and in earlier segments of this series allow us to define the reaction hypersurface for the interaction of sulphenyl chlorides with allenes as one which follows an Ad_E2 mechanism (13) similar to that first proposed by Kharasch and Buess for simple alkenes (14). The first step appears to be rate determining formation of an alkylidenethiiranium ion by S_N2 attack on sulphur. This intermediate subsequently undergoes nucleophilic attack by the halide ion in a fast step.

Experimental

General

The allenes used during this study were prepared by standard literature procedures as previously described (1–3). 2,3-pentadiene and 3-methyl-1,2-butadiene were purchased from Chemical Samples Co. The ^1H nmr spectra were recorded as $CDCl_3$ solutions using a Varian HA-100 spectrometer. All melting points and boiling points are uncorrected.



Sulphenyl Chlorides

4-Methyl-, 2-methyl-, 4-chloro-, 2,5-dichloro-, 3,4-dichloro-, 4-nitro-, 2,4-dimethyl-, 2,4,6-trimethyl-, 2,4,6-triisopropyl-, 2-trifluoromethyl-, 4-trifluoromethyl-, and benzenesulphenyl chloride were prepared by the direct chlorination, chlorine gas

bubbled through CCl_4, of the corresponding thiols at 0°C. 2,4-Dinitrobenzenesulphenyl chloride was prepared as previously described (2), mp 96–96.5°C, recrystallized from CCl_4. 2-Nitrobenzenesulphenyl chloride was purchased from Aldrich Chemicals, recrystallized from CCl_4, mp 76–76.8°C; 2-methylbenzenesulphenyl chloride, bp 89–95°C/0.5 Torr; 4-methylbenzenesulphenyl chloride, bp 85°C/1 Torr; 4-chlorobenzenesulphenyl chloride, bp 71–72°C/0.12 Torr; 2,4,6-triisopropylbenzenesulphenyl chloride, bp 130–136°C/0.45 Torr; ^{13}C nmr ($CDCl_3$): 155.8(s), 154.6(s), 122.5(d), 34.8 (d, $C_pCH(CH_3)_2$), 31.9 (d, $C_oCH(CH_3)_2$), 24.6 (q, $C_pCH(CH_3)_2$), 24.2 and 23.8 (q, $C_oCH(CH_3)_2$). 1-Naphthalenesulphenyl chloride and 9-phenanthracenesulphenyl chlorides were prepared via chlorination of the respective thiols with *N*-chlorosuccinimide in CH_2Cl_2 at room temperature.

Thiols

2-Trifluoromethyl-, 4-trifluoromethyl-, 2-methyl-, 2,4-dimethyl-, 2,4,6-trimethyl-, and 4-bromobenzenethiols were prepared from the commercially available bromides by the reaction of the analogous Grignard reagents with elemental sulphur in Et_2O. 1-Naphthyl and 9-phenanthrylthiols were prepared in a similar fashion; 1-naphthylthiol in 84% yield as a brownish oil, 9-phenanthrylthiol in 88% yield as light yellow crystals, mp 175–176°C. 2,4,6-Triisopropylbenzenethiol was prepared by the Zn/HCl reduction of the commercially available sulphonyl chloride followed by steam distillation, extraction, and high vacuum distillation in 70–85% yields along with some triisopropylbenzene as by-product. 4-Chloro-, 4-methyl-, 4-fluoro-, 4-methoxy-, 2,5-dichloro-, 3,4-dichloro-, and benzenethiol were the commercial products.

General Procedure

As previously described (2), to a solution of the sulphenyl chloride (1–2 mmol) in 10–15 mL of anhydrous CH_2Cl_2 was added an equivalent (1–2 mmol) of the respective allene. The mixture was stirred at room temperature until the reaction was observed to be complete (disappearance of the red-orange color S—Cl, or a negative starch-iodide test). The solvent was evaporated and the residual oil analyzed by ^1H nmr. Control experiments run in nmr tubes gave the same kinetically controlled product distributions. Satisfactory elemental analyses for C, H, S, and Cl were obtained for a representative sample of the new adducts (≅ 15% of the compounds prepared). In each case the analytical samples were mixtures of isomers, except in the case of adducts derived from 2,4,6-trimethylbenzenesulphenyl chloride and 2,4-6-triisopropylbenzenesulphenyl chloride.

Kinetics were carried out as previously described (5, 6, 8, 10).

Spectral parameters, Tables 7–19, are available from the authors upon request.

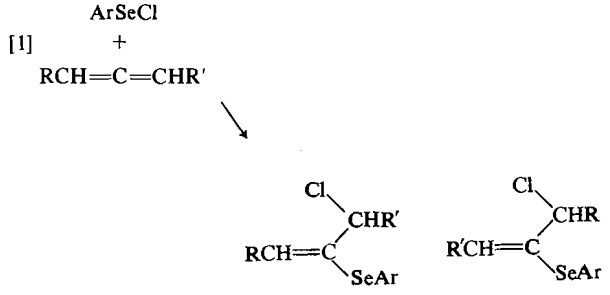
Received June 4, 1980

DENNIS G. GARRATT, PIERRE L. BEAULIEU, VERONIQUE M. MORISSET, and MARK UJJAINWALLA. Can. J. Chem. **58**, 2745 (1980).

The reactions of benzeneselenenyl chloride, bromide, and 2,4,6-trimethylbenzeneselenenyl bromide with alkyl 1,3-disubstituted allenes in methylene chloride solution have been investigated. While kinetic data are in accord with similar rate determining transition states, exhibiting strong steric effects for all three species, the product distributions show changes in both chemoselectivity and configurational-selectivity in accord with two different types of steric interaction mechanisms during the product determining transition states. A mechanism involving rate limiting formation of alkylideneseleniranium ions and/or alkylideneepiselenuranes, followed by isomerization between the alkylideneseleniranium ions by a path not involving allylic ions, prior to the product determining transition states, is proposed.



DENNIS G. GARRATT, PIERRE L. BEAULIEU, VERONIQUE M. MORISSET et MARK UJJAINWALLA. Can. J. Chem. **58**, 2745 (1980).

On a étudié les réactions, dans le chlorure de méthylène, des chlorure et bromure de benzènesélényles et du bromure de triméthyl-2,4,6 benzènesélényle avec les allènes disubstitués par des groupements alkyles en positions 1 et 3. Bien que les données cinétiques soient en accord avec des états de transition semblables, déterminants la vitesse et montrant des effets stériques importants pour les trois espèces, la distribution des produits révèle des variations à la fois dans la sélectivité chimique et dans la sélectivité configurationnelle; ces résultats impliquent l'existence de types différents de mécanismes d'interactions stériques pendant les états de transition déterminant la formation des produits. On propose un mécanisme dans lequel la vitesse de la réaction est limitée par la formation des ions alkylidèneséléniranium et/ou des alkylidèneépisélénuranes, comportant aussi une isomérisation des ions alkylidèneséléniranium par un processus n'impliquant pas les ions allyliques avant des états de transition qui déterminent la formation des produits.

[Traduit par le journal]

In a previous paper of this series we have reported the reactions of benzeneselenenyl chloride with a series of 1,3-disubstituted allenes (1). In all cases the phenylseleno moiety was observed to attack regiospecifically on the central allenic carbon, with the *Z* isomer formed preferentially or exclusively under conditions of kinetic control. Furthermore, chemoselectivity was observed in additions to unsymmetrically substituted allenes, in that the double bond with the most electron-donating and bulky substituent is preferentially attacked, the percentage of attack increasing as the electron-donating ability and bulk increases: $t\text{-}C_4H_9 > i\text{-}C_3H_7 > C_2H_5 > CH_3$.

In particular, attack on a double bond with a *tert*-butyl substituent appears to favour formation of the thermodynamically more stable *Z* alkenes. Thus attack on the double bond with a *tert*-butyl substituent gives an *E*:*Z* isomer ratio[3] of 9:91 for 5,5-dimethyl-2,3-hexadiene, 12:88 for 2,2-dimethyl-3,4-heptadiene, 11:89 for 2,2,6-trimethyl-3,4-heptadiene, and 0:100 for 2,2,6,6-tetramethyl-3,4-heptadiene. The directing effect, with respect to the *E*:*Z* configuration, of methyl, ethyl, or isopropyl groups appears to be essentially constant when the remote substituent is methyl, whereas some fluctuations are apparent when the remote group is changed to ethyl, isopropyl, or *tert*-butyl.

Assuming a stereospecificity at least as large as that for arenesulphenylation (2), we proposed a mechanism involving the preequilibration formation of alkylideneseleniranium ions **1** and/or alkylideneepiselenuranes **2** which in the product determining step collapse to the adducts via an *anti*

[3]The term configurational-selectivity has been coined to describe the preference for attack upon one face of the olefinic double bond relative to the other. In an allenic system such as is described in this article, preferential attack upon one such π lobe will lead to a predominance of either the *E* or *Z* alkene adduct.

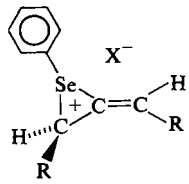
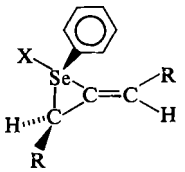
attack of chloride at the methine carbon of the ring, leading to the preferential formation of the *Z* isomer. This pathway is consistent with the observed second order kinetics, first order in selenenyl chloride and first order in allene, which serve to define the composition of the rate determining transition state in terms of one molecule of each species (3). Subsequent studies (4) were able to establish that the addition process is stereospecific.

This mechanistic scenario requires a somewhat larger preference for the *Z* isomer if the nucleophile is changed from chloride to, for example, bromide or iodide. Alternatively, it appears possible to force the preferential formation of the *E* isomer by destabilizing the *Z*-alkylideneseleniranium ion or *Z*-alkylideneepiselenurane through steric effects from suitable *ortho*-substituents placed on the phenyl group of the electrophile. We report herein experimental evidence which has a direct bearing upon these hypotheses.



Results

In order to ascertain the degree and type of involvement of steric factors in the rate and product determining transition states, we have examined the reactions of ten 1,3-disubstituted allenes with three areneselenenyl halides, **3–5**. All reactions were carried out at ambient temperature, 25°C, using methylene chloride as solvent. The kinetically controlled product distributions (Table 1) were determined by immediate ^{1}H nmr analysis of the reaction mixture. In every case it was possible to find at least one nonoverlapping signal from which the initial (kinetically controlled) isomer distribution could be calculated. It should be noted that an immediate *in situ* determination of the adduct isomer ratio is necessary because of the tendency of many of the adducts to isomerize. If the reaction mixtures are allowed to stand at 25°C for several hours or days, an equilibrium mixture is obtained. Assignment of product configurations is based upon previously established criteria (1, 5).



The rates of addition were determined using a Durrum-Gibson stopped-flow spectrophotometer. The rate of disappearance of benzeneselenenyl chloride, benzeneselenenyl bromide, and 2,4,6-trimethylbenzeneselenenyl bromide was followed by measuring the decrease in their respective absorptions at 433, 468, and 497 nm. The additions are found to exhibit second order kinetics, first order in allene and first order in selenenyl halide, to at least 90% completion of the reaction. Specific rate constants are given in Table 2. For purposes of comparison the analogous rate data for benzenesulphenyl chloride are also given in Table 2.

E-2

Discussion

An examination of Table 1 shows a number of trends. In particular, benzeneselenenyl chloride and benzeneselenenyl bromide show very similar product distributions, the configurational-selectivity of the additions[3] favouring the *Z* alkene under conditions of kinetic control. 2,4,6-Trimethylbenzeneselenenyl bromide, on the other hand, shows a configurational-selectivity which favours the *E* alkene! The most dramatic example of this change in selectivity is found in the product distributions for 2,2,6,6-tetramethyl-3,4-heptadiene (1,3-di-*tert*-butylallene) where the *E*:*Z* ratio changes from 0:100 for benzeneselenenyl chloride and bromide to a value of 100:0 for 2,4,6-trimethylbenzeneselenenyl bromide. Large reversals, but of a smaller magnitude, are also observed for 5,5-dimethyl-2,3-hexadiene, 2,2-dimethyl-3,4-heptadiene, 2,6-dimethyl-3,4-heptadiene, and 2,2,6-trimethyl-3,4-heptadiene. While the tendency may exist at this point to attribute the configurational-selectivity, i.e. the preferential formation of the *E*-isomer observed with 2,4,6-trimethylbenzeneselenenyl bromide, in terms of "steric approach control" as we have previously done for the analogous arenesulphenylations (5, 6), further study is warranted.

The kinetic data in Table 2, for example, are quite informative. The specific rate constants for

benzenesulphenyl chloride and benzeneselenenyl chloride show a number of trends. Perhaps most notable is the large rate decrease upon substituting sulphur for selenium. On closer examination, however, one observes that whereas benzenesulphenyl chloride shows only minor variations in k_2 as the 1,3 alkyl groups are changed, benzeneselenenyl chloride exhibits very large fluctuations. In particular, k_2 is seen to decrease quite dramatically as

R^2	R^4	R^6	X
H	H	H	Cl
H	H	H	Br
CH_3	CH_3	CH_3	Br

the alkyl substituents increase in steric bulk and, interestingly enough, electron-donating ability. These variations in k_2, as a function of the alkyl substituents on the allenes, are more readily seen in Table 3, where relative reactivities derived from the k_2's, in Table 2, are tabulated for each electrophile.

In the case of benzenesulphenyl chloride the steric and electronic effects of the alkyl substituents are clearly minimal. Considering only the first three entries in this column, the effect of substituting two ethyl groups or two isopropyl groups for the methyl groups in 2,3-pentadiene is to cause minor decreases in the rate of 17 and 46%, respectively. If only one methyl group from 2,3-pentadiene is changed to ethyl, isopropyl, or *tert*-butyl, one observes initially a slight increase in rate (9%) followed by slow decreases. Such variations are also seen if one holds, for example, the isopropyl group on 5-methyl-2,3-hexadiene constant and varies the methyl group from ethyl to isopropyl to *tert*-butyl. In fact, such variations are typical of those previously observed for the analogously substituted *trans*-1,2-disubstituted ethylenes (7). These data thus tend to support our initial arguments (8) that the rate determining transition state in arenesulphenylations of allenes is stabilized equally well by a methyl as by an ethylidene (=$CHCH_3$) group, and allow us to extend the comparison to ethyl, isopropyl, and *tert*-butyl in terms of, respectively, *n*-propylidene (=$CHCH_2CH_3$), isobutylidene (=$CHCH(CH_3)_2$), and neopentylidene (=$CHC(CH_3)_3$).

The data for benzeneselenenyl chloride, in contrast, are interpreted in terms of a much larger steric effect. Thus in substituting two ethyl groups for the methyls in 2,3-pentadiene the rate is decreased by two-thirds, the analogous substitution of two isopropyl groups leading to a decrease of 90%! While substitution of only one methyl group by ethyl gives rise to only a very small rate decrease (9%), the subsequent substitution of either an isopropyl or a *tert*-butyl group leads to relatively large rate retardations. For example, 5,5-dimethyl-2,3-hexadiene has a rate which is only 1.7% of that observed for 2,3-pentadiene, and 2,2,6-trimethyl-3,4-heptadiene exhibits a rate constant which is smaller still at only 0.31% of that observed for 2,3-pentadiene. In contrast to the above, the rate of benzenesulphenylation of 2,2,6-trimethyl-3,4-heptadiene is 37% of that observed for 2,3-pentadiene under equivalent conditions! Quite clearly the steric and electronic factors governing the nature of the rate determining transition states for the, on the surface, similar addition reactions (9) of benzenesulphenyl and benzeneselenenyl chlorides, are very different.

While these observations are quite instructive, the most significant aspect of the observations to be made from the data in Table 3 is the very similar structure–reactivity effects exhibited by the three

selenenyl halides. Such a correlation is perhaps more readily demonstrated by taking the ratios of k_2's as we have done in Table 4. Thus we see that the ratio of k_2's for benzeneselenenyl chloride and benzeneselenenyl bromide, $k_{C_6H_5SeCl}/k_{C_6H_5SeBr}$, is essentially constant; the mean being 4.68 ± 0.86. Similarly the ratio $k_{C_6H_5SeBr}/k_{2,4,6\text{-}(CH_3)_3C_6H_2SeBr}$, is relatively constant at 28.8 ± 4.7. Although some values fall outside the standard deviation, these most likely reflect experimental error in the determination of the k_2's, which normally falls in the range of $\pm$ 5–10% for the stopped-flow technique. In contrast the ratio of k_2's for benzenesulphenyl chloride and benzeneselenenyl chloride has a mean value of 0.203 ± 0.250; clearly showing no correlation of value between the rate determining steps for the two reactions.

The value of these kinetic data is two-fold. Firstly we have demonstrated that benzenesulphenyl chloride and benzeneselenenyl chloride have different rate determining transition state structures. Secondly we have determined that, in all probability, benzeneselenenyl chloride, benzeneselenenyl bromide, and 2,4,6-trimethylbenzeneselenenyl bromide have similar, if not identical, rate determining transition state structures. This latter point is very significant since this conclusion, in conjunction with the observation of different substituent effects upon the product determining transition states for benzeneselenenyl chloride and benzeneselenenyl bromide compared to 2,4,6-trimethylbenzeneselenenyl bromide, leads us to the further conclusion that the rate and product determining transition states are quite distinct from each other and thus must be separated from each other by at least one intermediate species. Our data therefore rule out the possibility of steric approach control as a rationalization of the product distributions obtained for the reactions of 2,4,6-trimethylbenzeneselenenyl bromide, despite the reversal of configurational-selectivities in favour of E:Z values which are greater than one.

Further support for this scenario is to be found in Table 5 wherein we compare the product distributions obtained from 2,4,6-trimethylbenzeneselenenyl bromide with those obtained from 2,4,6-trimethylbenzenesulphenyl bromide, 2,4,6-trimethylbenzenesulphenyl chloride, and benzenesulphenyl chloride. Although the data given for 2,4,6-trimethylbenzenesulphenyl bromide are most likely of little utility because of experimental difficulties in determining the chemoselectivity and configurational-selectivity under conditions of kinetic control, the comparisons to be made between the remaining data for the selenenyl bromide and the sulphenyl chlorides are indicative of different factors of both a steric and electronic origin as being important in the transition states for selenenylation vs. sulphenylation.

A comparison of the specific rate constants for the addition of benzeneselenenyl chloride to some 1,3-disubstituted allenes and the analogous E,Z isomeric 1,2-disubstituted ethylenes (11) (see Table 6) leads us to the conclusion that while steric effects are of importance to both reactions, there is no strong indication of the type of similar steric–electronic interaction mechanisms previously observed for the arenesulphenylation of these species.

The available data support a mechanism where the activation energy of the reaction is large compared with the barrier to interconversion between intermediates of opposite configuration (for example, the E and Z alkylideneseleniranium ions); the proportion of products will in no way, therefore, reflect the relative populations of the ground state configurations but will depend only on the activation energies of the processes leading to these products. Stated somewhat differently, this implies

[a]Ar = 2,4,6-trimethylphenyl.
[b]The adducts derived from 2,4,6-trimethylbenzenesulphenyl bromide were found to isomerize very rapidly even at −78°C. Values given in this column thus do *not* necessarily reflect kinetic control.
[c]See ref. 6.

that the ratio of two or more products formed from one starting material depends only upon the difference in the free energy levels of the product determining transition states (10).

A mechanistic scheme compatible with our observations is given in Scheme 1. Of particular note in considering the mode of interaction between a selenenyl halide and an allenic double bond is the direction of approach. Two scenarios are of obvious importance. The first might be considered the selenium analogue of the classic S_N2 class of substitution reactions. In this case the allenic π orbitals would be considered as nucleophiles and the halogen atom as the leaving group. During the rate determining transition state the trigonal bipyramidal geometry about selenium is considered to be characterized by two lone-pair electron pairs and the aryl group in the equatorial positions, with the entering and leaving groups occupying the remaining apical sites. Upon completion of bond breaking and bond formation, one obtains as the intermediate species an alkylideneseleniranium cation–halide ion ion-pair. If the entering and leaving groups do *not* form a collinear arrangement with the selenium atom, the second scenario becomes important.

In the second scenario, one makes the hypothesis that a tetracovalent selenium species, i.e. an

[a]See refs. 3*b* and 11.

alkylideneepiselenurane, **2**, is the first formed intermediate. This species may dissociate, forming upon fission of the selenium–halogen bond an alkylideneseleniranium ion. Alternatively, an alkylideneepiselenurane may collapse to product directly in a concerted manner. Data compatible with both of these scenarios and both of these species have been previously (12, 13) presented with respect to the related reaction with simple alkenes. The existence of episelenuranes and related species is, however, controversial (14–21). In accord with our previous discussion we postulate that the product determining transition states arise from the alkylideneseleniranium ion ion-pairs after partial or perhaps total equilibration of the various configurational types.

Using this scheme the configurational-selectivity is seen to be a function of two competitive steric effects. Our observations with benzeneselenenyl chloride and bromide ($E:Z < 1$) may be interpreted in terms of a repulsive steric interaction between the attacking nucleophile, Cl^- or Br^-, and the alkyl substituent on the olefinic carbon of the alkylideneseleniranium ion which is situated in the *E* configuration. All else being equal, one anticipates attack by Cl^- or Br^- upon the *Z*-alkylideneseleniranium ion to be preferred. However, we note that in the case of 2,4,6-trimethylbenzeneselenenyl bromide a second type of steric interaction must be present. Here the *Z*-alkylideneseleniranium ion is destabilized relative to its *E* isomer because of steric repulsions between the *ortho* methyl groups on the selenenyl bromide and the olefinic alkyl group situated *cis* with respect to the selenium atom.

An interpretation of the structure of the rate determining transition state is a more difficult problem. The available kinetic evidence defines the

composition of this transition state as containing one molecule of selenenyl halide and one molecule of allene. A large steric effect is observed with respect to alkyl substituents on the allenes but no change in the structure–reactivity profile is apparent upon substitution of *ortho* methyl groups for the *ortho* hydrogens on the electrophile. Also of note is the observation that the steric effect of an alkyl group on the allene is of major importance only when that group is isopropyl or *tert*-butyl. Indeed earlier studies, in this laboratory and elsewhere (3*a*), concerned with the kinetics of addition of benzeneselenenyl chloride to allene and all of its methyl substituted derivatives gave no evidence of a steric effect in the rate determining step, a linear correlation between log k_2 and $\Sigma\sigma^*$ being found.

The effect of a single ethyl group also appears to be predominantly electronic in nature, as can be seen by a comparison of the k_2's for 2,3-pentadiene and 2,3-hexadiene. Similar small variations between methyl and ethyl substituted allenes are noted on comparison of 5-methyl-2,3-hexadiene and 2-methyl-3,4-heptadiene, or 5,5-dimethyl-2,3-hexadiene and 2,2-dimethyl-3,4-heptadiene. The presence of a second ethyl group does, however, lead to a significant rate retardation as is seen upon comparing 2,3-hexadiene and 3,4-heptadiene. Such a result may be interpreted in terms of some type of very specific configurational interactions in the rate determining transition state which involves only the alkyl group on one terminus of the allenic functionality.

While conclusive evidence is lacking at this time, we tend to favour rate determining formation, or perhaps dissociation, of an episelenurane-like species over the alternative S_N2 type of attack. Our reasons for this are as follows. Firstly the appearance of large steric interactions would appear to reflect the congested environment about a tetracovalent selenium atom more readily than the anticipated 'loose' trigonal bipyramid arrangement in an S_N2 like transition state. The increased atomic radius of bromine relative to chlorine would then account for the approximately five-fold decrease in reactivity between benzeneselenenyl chloride and benzeneselenenyl bromide. The analogous 29-fold decrease in reactivity between benzeneselenenyl bromide and 2,4,6-trimethylbenzeneselenenyl bromide may be accounted for in a similar fashion, the increased congestion of the larger aryl moiety leading to the rate retardation.

Experimental

General

Melting points were determined on a Fisher-Johns block, and are reported uncorrected. The ^{1}H nmr spectra were run on Varian T-60 and HA-100 spectrometers. All spectral parameters are referenced to tetramethylsilane as an internal standard while using $CDCl_3$ or CD_2Cl_2 as solvent. The ^{1}H nmr parameters for the adducts are given in Tables 7 and 8 (C_6H_5SeBr and 2,4,6-$(CH_3)_3C_6H_2SeBr$ adducts only);[4] the analogous data for the C_6H_5SeCl adducts have been previously reported (1). Elemental analyses were performed by Scandinavian Microanalysis Laboratories, Herlev, Denmark. Mass spectra were run on an MS-9.

Allenes

2,3-Pentadiene was commercially available from Chemical Samples. 2,3-Hexadiene, 5-methyl-2,3-hexadiene, 5,5-dimethyl-2,3-hexadiene, 3,4-heptadiene, 2,6-dimethyl-3,4-heptadiene, 1,2-cyclononadiene, and 1,2-cyclotridecadiene were prepared by standard literature procedures from the commercially available alkenes (Chemical Samples) (22–24). 2,2,6,6-Tetramethyl-3,4-heptadiene, 2,2,6-trimethyl-3,4-heptadiene, 2,2-dimethyl-3,4- heptadiene, and 2-methyl-3,4-heptadiene were prepared by the method of Vermeer and co-workers (25, 26).

Diphenyl diselenide was prepared from bromobenzene by the method of Taboury (27) and Wuyts and Cosyne (28), as modified by Foster (29); mp 62.5–63°C (lit. (29) mp 63°C); ^{13}C nmr ($CDCl_3$) δ: 131.4, 129.0, 127.5, and 130.9; ms *m/e* [$\%\sum_{30}$]:314 (25.6), 234 (6.93), 154 (4.04), 157 (23.3), 77 (13.4).

Bis(2,4,6-trimethylphenyl)diselenide was prepared from 2-bromomesitylene (Aldrich) as above; mp 113.5–115°C, crystallized from 95% ethanol; ^{13}C nmr ($CDCl_3$) δ: 20.9 q, 24.0 q, 129.2 s, 143.6 s, 128.2 d, 139.0 s; ms *m/e*: 398 ($M^{+\cdot}$), 318 ($M^+ - Se$), 279 ($M^+ - Ar$), 368 ($M^+ - (CH_3)_2$), 199 ($M^+/2$), 183 ($M^+/2 - CH_3$), 119 ($Ar^{+\cdot}$). *Anal.* calcd. for $C_{18}H_{22}Se_2$ (mol wt. 396.2551$_4$): C 54.56, H 5.60; found: C 54.68, H 5.62.

Benzeneselenenyl chloride was the commercial product (Aldrich), recrystallized from CCl_4, mp 64.5°C; uv ($n \rightarrow \pi^*$ Se-Cl) λ_{max}: 433 nm, ε 264 dm^3 mol^{-1} cm^{-1}.

Benzeneselenenyl bromide was prepared from the diselenide by the dropwise addition of an equivalent of molecular bromine in CCl_4 solution at room temperature. Recrystallized from CCl_4, mp 56–57°C (lit. (30, 31) mp 61°C); uv ($n \rightarrow \pi^*$ Se-Br) λ_{max}: 468 nm, ε 238 dm^3 mol^{-1} cm^{-1}.

2,4,6-Trimethylbenzeneselenenyl bromide was prepared as above. Recrystallized from CCl_4, mp 66–67°C; uv ($n \rightarrow \pi^*$ Se-Br) λ_{max}: 497 nm, ε 183 dm^3 mol^{-1} cm^{-1}. *Anal.* calcd. for $C_9H_{11}SeBr$ (mol. wt. 278.056): C 38.59, H 3.99, Br 28.74; found: C 38.94, H 4.03, Br 29.34.

General Procedure

This procedure for the product studies was as previously described (1,5).

Kinetic Studies

All kinetic runs were carried out on a Durrum-Gibson stopped-flow spectrophotometer. Prior to any set of runs the instrument was allowed to stabilize for at least two hours. A constant temperature bath was maintained at 24.50 ± 0.03°C. The instrument was checked out and calibrated prior to each set of runs. Zero and 100% transmittance lines were determined by running pure solvent vs. the allene solution. Kinetic runs with each solution were carried out until a reproducible trace was stored on the oscilloscope. Measurements and calculations of k_2 were carried out in the standard way (3, 32).

Substituent effects in some autoxidation and hydrogen abstraction reactions have been studied in terms of the field (F_k) and resonance (R_k) components proposed by Swain and Lupton and the unique positional weighting factors f_j and r_j incorporated by Williams and Norrington with the aid of the following equation:

$$P_i = \alpha_i f_j F_k + \beta_i r_j R_k + e_i + P_i^0$$

where P_i's are the rate parameters, P_i^0 being that for a standard reference compound. The correlations are found to be quite satisfactory, showing the general validity of the above equation for the types of reactions considered. From the information obtained from the present correlation studies, an attempt has been made to resolve the conflict with regard to the nature of the transition state involved in the hydrogen abstraction reactions — that is, whether or not there is charge separation in the transition state. The results of the present studies seem to suggest that both the differences in the resonance stabilization energies of the ring-substituted benzyl radical and the contribution of polar structures to the transition state are to be invoked to explain the observed data.

LALIT N. PATNAIK, NIGAMANANDA MALLICK, M. K. ROUT et SWOYAM P. ROUT. Can. J. Chem. **58**, 2754 (1980).

On a étudié les effets des substituants, dans quelques réactions d'autoxydation et d'élimination d'hydrogène, en fonction des composants de champ (F_k) et de résonance (R_k) proposés par Swain et Lupton et en fonction des facteurs uniques d'appréciation de position f_j et r_j incorporés par William et Norrington à l'aide de l'équation suivante:

$$P_i = \alpha_i f_j F_k + \beta_i r_j R_k + e_i + P_i^0$$

où les P_i sont des paramètres de vitesse, P_i^0 est celui d'un composé étalon de référence. On a trouvé que les corrélations sont satisfaisantes, montrant ainsi la validité générale de l'équation ci-dessus, pour le genre de réactions considérées. A partir des informations obtenues au cours des présente études de corrélation, on a essayé de résoudre le conflit en ce qui concerne la nature de l'état de transition impliquée dans les réactions d'élimination d'hydrogène, soit de savoir s'il est exact ou pas qu'il y a une séparation de charges dans l'état de transition. Les résultats de la présente étude semblent suggérer qu'il faut faire appel à la fois aux différences entre les énergies de stabilisation par résonance du radical benzyle substitué sur le cycle à la contribution des structures polaires à l'état de transition pour expliquer les données observées.

[Traduit par le journal]

Introduction

The present report deals with studies on correlation of the rate parameters of some autoxidation and hydrogen abstraction reactions with Swain and Lupton's (1) substituent parameters F_k and R_k involving the unique positional weighting factors f_j and r_j, suggested by Williams and Norrington (2).

Use of multiparameter equations for correlation studies in radical reactions has also been proposed by Yamamoto and Otsu (3) and Streitwieser and Perrin (4), following the suggestion of Timberlake *et al.* (5), that no single substituent parameter like $\sigma, \sigma^+, \sigma^-, \sigma_R$, etc. would give the desired Hammett plot for such reactions. Yukawa and Tsuno (6) had first suggested multiparameter equations for ionic reactions. Afanas'ev (7) has proposed a two-parameter equation for radical reactions of compounds, in which the reaction centres are not sterically hindered, similar to the one suggested by Taft for aliphatic compounds (8). Afanas'ev's equation is based on the relationship between the spin density in free radicals and the rate constants of radical substitution reactions with $CH_3\cdot$. The data correlated in the present work will also be treated by means of the models mentioned above to bring out the relative merits of each of the models and the results will be reported in future communications.

Swain and Lupton's (1) approach towards the problem of structure-reactivity relationships, with regard to substituent effects, consists of expressing the Hammett substituent constants, σ_k, as a linear combination of their two components, the field (F_k)

and resonance (R_k) effects, i.e.,

[1] $\sigma_k = aF_k + bR_k$

where a and b are the empirical sensitivities or weighting factors independent of the substituents but different for each set of substituent constants (σ_m, σ_p, etc.). The constants F_k and R_k have been claimed to be better defined and physically more significant parameters for correlating or predicting substituent effects on a variety of free energy dependent processes than any other pair $\sigma_m, \sigma_p, \sigma_p^+$, etc.

The scope and significance of Swain and Lupton's work were greatly enhanced and refined by the work of Williams and Norrington (2), who proposed unique values for the positional weighting factors f and r in place of Swain and Lupton's empirical sensitivities a and b, which can be applied to *ortho-*, *meta-*, and *para-* positions of the benzene ring simultaneously. The values suggested are:

$$f_o = 1.248;\ f_m = 0.980;\ f_p = 1.000$$

$$r_o = 0.863;\ r_m = 0.347;\ r_p = 1.000$$

For a data set consisting of only *meta-* and *para-* derivatives, the suggested values are:

$$f_m = 1.002,\ f_p = 1.000,\ r_m = 0.424,$$

$$\text{and } r_p = 1.000$$

These values were found to give good correlation between physico-chemical properties of the side chain and substituent parameters of mixed or multiply substituted benzene derivatives.

The original Hammett equation, which is of the form

[2] $P_i = \rho_i\sigma_k + P_i^0$

(where P_i's are some free energy related property, P_i^0 being that for some standard reference state for the ith reaction set), now becomes, with Swain–Lupton and Williams–Norrington's modifications,

[3] $P_i = \alpha_i f_j F_k + \beta_i r_j R_k + P_i^0$

where f_j and r_j are the Williams–Norrington positional weighting factors for the position j and where F_k and R_k are the field and resonance components of the substituent k (Swain–Lupton). As a further refinement, Williams and Norrington (2) introduced a normally distributed error term, e_i, independent of the nature and position of the substituent in eq. [3], so that the final form of the Swain–Lupton–Williams–Norrington (SLWN) equation becomes:

[4] $P_i = \alpha_i f_j F_k + \beta_i r_j R_k + e_i + P_i^0$

Results and Discussion

The kinetic data of two types of oxidation reactions, namely, autoxidation, and hydrogen abstraction from hydrocarbons by radicals, already reported in the literature, have been chosen for investigation in the present study with a view to assessing their amenability to the above model eq. [4], proposed for the study of substituent effects, and to reexamining the conclusions of the earlier workers in the light of results obtained therefrom. The present work forms a part of our general programme on studies of substituent effects in polymerization reactions. In view of the close relationship between autoxidation and hydrogen abstraction reactions on one hand, and processes of polymerization on the other, these two particular types of oxidation reactions have been chosen for the present correlation studies. It is quite well known that most of the familiar autoxidations like drying of linseed oil paint, or the deterioration of rubber or plastics, or the autoxidation of styrene involve the process of polymerization in some way or other. The competitive kinetics of the autoxidation of substituted benzaldehydes are identical with those of copolymerizations (9). The abstraction of hydrogen atoms by alkoxy radicals from substrates in the liquid phase is of particular interest in relation to autoxidation phenomena (10). These radicals are produced in the chain branching decomposition of the initially formed hydroperoxides and are, therefore, responsible for the autocatalytic nature of most autoxidations. Hydrogen atom abstraction by radicals may also be important in the autoxidations in yet another way in being involved in the inhibition of autoxidations by substrates like phenols, amines, and toluenes.

The reaction dependent parameters α_i and β_i and the error term e_i of eq. [4] were evaluated by a method of multiple regression. The statistical parameters, standard deviation (S), correlation coefficient (C), the F-distribution, and the significance levels were calculated by the method suggested by Shorter (11).

(A) Autoxidation Reactions

(i) Autoxidation of Ring Substituted Styrenes

Correlation studies have been undertaken with three types of rate parameters reported by Howard and Ingold (12), for the autoxidation of the ring substituted styrenes. The data are summarised in Table 1, where k_p and k_t's are the rate constants for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12

m-NO_2	1.14	—	—
p-NO_2	1.25	—	—

TABLE 2. Correlation parameters

Rate parameter	*e*	α	β	*S*	*C*
Oxidation	0.0838	0.0358	−0.3148	0.049	0.89
k_p	0.0356	0.1726	−0.3076	0.034	0.98
k_t	−0.0591	0.2305	0.3311	0.14	0.92

the propagation and the bimolecular termination respectively. The correlation parameters are described in Table 2.

The results confirm the earlier view (12) that there is no good correlation between the relative rates of oxidation and polar properties of the substituents and that the second order termination (k_t) should be facilitated by electron attracting substituents (positive α and β).

The lack of correlation of the propagation rate constants k_p with a Hammett substituent parameter was rationalised (12) by invoking a dual action of the substituents in the reaction mechanism. The substituent in the styrene can affect the reactivity of either the styrene itself or the styryl peroxy radical. Electron attracting groups increase the reactivity of the styryl peroxy radical and decrease the reactivity of styrene, while the electron donating groups will have little contribution towards radical stability. The excellent correlation of k_p, obtained in the present study, with opposite signs of the regression parameters α and β clearly point to the dual mode of the substituent action. If the substituent effect in the peroxy radical is governed mainly by the inductive effect and that in the styrene by the resonance effect, then electron attracting groups should enhance the reactivity of the radical (positive α), while electron donating groups should facilitate the reactivity of styrene (negative β). We have earlier seen in connection with the polymerization reactions that different signs of α and β suggest weak contribution of polar structures to the transition state. This, in this particular case, would mean that structure **III** plays a more important role than structure **II** in stabilizing the transition state.

$$\underset{\mathbf{I}}{XC_6H_4CH{=}CH_2{\cdot}OOR} \leftrightarrow \underset{\mathbf{II}}{XC_6H_4\overset{+}{C}H{-}\dot{C}H_2\bar{O}OR} \leftrightarrow \underset{\mathbf{III}}{XC_6\dot{H}_4CH{-}CH_2{-}OOR}$$

The same conclusion was reached by Howard and Ingold (12) by considering substituent effects from a different angle.

(B) Hydrogen Abstraction Reactions

The rate data for the hydrogen abstraction reactions from toluenes by different attacking radicals as reported in the literature and used for the present correlation studies are described in Table 3, along with their sources.

The mechanism of hydrogen abstraction reactions, particularly with respect to the nature of the transition states involved, has, for sometime, been a subject of controversy.

The applicability of Hammett ρσ correlation in free radical abstraction of hydrogen from substituted toluenes has been one of the reasons for the formulation of the theory of polar effects in these reactions (13–15, 21, 22). The course of these reactions is described as follows:

$$X{\cdot} + RH \rightarrow \underset{\mathbf{I}}{[X{:}H{\cdot}R} \leftrightarrow \underset{\mathbf{II}}{\bar{X}{:}\,H^{+}{\cdot}R} \leftrightarrow \underset{\mathbf{III}}{X^{+}{:}H\,{:}\bar{R}]} \rightarrow XH + R{\cdot}$$

where X· is the attacking radical and RH is the generalised hydrogen donor or substituted toluene. A Hammett correlation implies that structures **II** or **III** contribute to the transition state. A common feature in all these correlations, till recently, has been a negative value for the reaction parameter ρ. Since all the reactions studied were with electrophilic radicals, a negative ρ suggests that structure **II** is more important than **III**. Recently, however, Pryor *et al.* (21) have, for the first time, reported a positive ρ value for the reaction of *tert*-butyl radicals with toluenes, which indicated a greater contribution of structure **III** to the transition state. A better correlation of these reactions with σ^+ rather than σ has also been advanced as additional evidence to prove charge separation in the transition state.

Zavitsas and Pinto (22), on the other hand, have proposed from an observed linear correlation of ρ and ΔH for hydrogen abstraction reactions from toluenes that a charge separation in the transition state either does not occur or is an "unnecessary" assumption. The observed ρ–ΔH relationship

[a]Br· from *N*-bromotetramethyl succinimide (NBTMS).
[b]Br· from Br_2. These two sets of data have been recalculated in the present work from the logarithms of relative rates.

would mean that the differences in the reactivities of a series of substituted toluenes toward any given radical are due to differences in the bond dissociation energies of the benzyl C—H bonds in each of these substrates and that these Bond Dissociation Energy (BDE) values are dependent on the electron donating or electron withdrawing characteristics of the substituents. The reported "better" correlation with σ^+ have also been challenged on the grounds that most of these reactions give better, or at least as good, correlation with σ^-. We also find in the literature quite a few reports on the excellent correlations with σ (20, 21, 23).

Zavitsas and Pinto's (22) proposition has been refuted by the exponents of the polar effect theory on the grounds that the observed linear correlation between ρ and ΔH for only five radicals (Br·, $Cl_3C\cdot$, Cl·, *t*-BuO·, $\cdot C_6H_5$) could be fortuitous and a reported positive ρ value by Pryor *et al.* (21) should be impossible according to Zavitsas's treatment.

Afanas'ev (7) applied his two parameter equation to the hydrogen abstraction reactions of free radicals with toluenes. The results show that the apparent polar effect of substituents as stipulated by Howard and Chenier (15*c*) and Pryor *et al.* (21) can result from the resonance interaction of electron-withdrawing and electron-donating substituents with π-electrons of the aromatic ring.

With this background of conflicting opinions about the mechanism of hydrogen abstraction reactions, it was considered worthwhile to reexamine some of the data reported in the literature, in the light of eq. [4]. Since the substituent constants employed in this equation (F and R) are of a more generalised nature than either σ or σ^+ and since eq. [4] enables one to find out the sensitivity of the reaction to the inductive and resonance effects separately, it was expected that the additional information obtained from the present studies would be helpful in deciding in favour of one of these two conflicting postulates. The correlation parameters and the regression line constants are described in Table 4.

Before attempting any critical discussion pertaining to hydrogen atom abstraction reactions from toluene in general, it is necessary to discuss certain characteristics of some of the individual systems to clarify certain points:

(*i*) Reactions of substituted toluenes toward Br· were studied by Pearson and Martin (18) using two widely differing brominating agents, *N*-bromotetramethyl succinimide (NBTMS), and molecular bromine, respectively. They obtained identical ρ values under identical reaction conditions and at temperatures as high as 80°C and as low as 19°C. From this, they concluded that the same reaction mechanism was operating for both the brominating agents.

It is indeed very interesting that the present correlation studies with the two differing reaction systems give identical α and β values, both in sign and magnitude, indicating the operation of the same reaction mechanism.

(*ii*) Hydrogen abstraction from substituted tol-

[d]Data from Gilliom and Ward (20).

uenes by *tert*-butoxy radicals was studied by two groups of workers, using the same radical source, *tert*-butyl hypochlorite and at the same temperature, but in different solvents (Table 3). The rate constants were reasonably expected to be different. But while Gilliom and Ward (20), who performed the reaction in benzene, report an excellent correlation of their data with the Hammett σ constants, Kennedy and Ingold (19), using carbon tetrachloride as the solvent, report even a better correlation of their data with σ^+. The latter workers have questioned the validity of Gilliom and Ward's correlation on the grounds that the hypochlorite–toluene reactions are more complex in benzene than in carbon tetrachloride, because of the likely participation of benzene in the reaction. In a subsequent paper, Gilliom and Howles (23) reaffirmed their earlier contention and expressed doubt about the genuineness of the rate data of *p*-phenoxy toluene reported by Kennedy and Ingold (19). In the present correlation study, Kennedy and Ingold's data gave good results with the exception of *p*-phenoxy toluene which showed a large deviation. Exclusion of this substituent from the data set markedly improved the correlation. Equally good results were also obtained with Gilliom and Ward's data, but with α and β values differing widely in magnitude, but with the same sign.

(*i*) All substituents, from Kennedy and Ingold (19)

$$\log k/k_0 = 0.082 - 0.338 f_j F_k - 1.395 r_j R_k$$

$$S = 0.173$$

$$C = 0.937$$

(*ii*) Excluding *p*-phenoxy, from Kennedy and Ingold (19)

$$\log k/k_0 = -0.033 - 0.329 f_j F_k - 1.274 r_j R_k$$

$$S = 0.062$$

$$C = 0.993$$

Significance = 99.9%

(*iii*) From Gilliom and Ward (20)

$$\log k/k_0 = 0.025 - 0.484 f_j F_k - 0.719 r_j R_k$$

$$S = 0.051$$

$$C = 0.990$$

Significance = 99.5%

Thus we find that so far as the present correlation is concerned, but for the *p*-phenoxy toluene, both sets of data are equally good. We have included the second and the third correlations in Table 4 (rows 5 and 7).

Particular attention has been drawn to these two reaction systems to emphasize two points:

(*a*) The magnitudes of α and β, like those of ρ, are solvent and temperature dependent. Attempts to make any generalizations from the magnitudes of α and β from reactions carried out under widely differing conditions of temperature and solvent such as those described in the tables may, therefore, be misleading.

(*b*) The sign of α and β, also that of ρ, apparently, is free from this short-coming. Pryor *et al.* (24) have critically discussed these points with regard to ρ. They have emphasized that it is only the sign, and not the magnitude of the reaction parameter, which has any mechanistic significance in drawing conclusions from the ρ values of a series of similar reactions. Since α and β are also reaction parameters related to ρ, it is also suggested that the sign, and not the magnitude, should be the critical factor for making generalisations.

A common feature of all the present correlations is the negative signs of both α and β. This perhaps means that the reactions in general are facilitated by electron donating groups. The magnitude of this effect is also in accord with the rate data. Reaction of $Cl_3C\cdot$ radical (17) which has the largest α and β values, shows the most pronounced sensitivity towards the presence of electron donating groups while that of *t*-BuO· (in benzene) (20) which has the lowest β value, and a low α value, shows the least sensitivity.

The discussion above does not tell *a priori* what bearing the signs and/or magnitudes of α and β of the reactions under study have on the nature of the transition state. It may be desirable to examine, if it is possible to determine with the help of these factors, whether the substituent effect is due to (*a*) differences in the resonance stabilization energies of the ring substituted benzyl radicals, or (*b*) polar contributions to the transition state, or (*c*) both. For this, again we draw attention to two particular pairs of reactions in Table 3, which have been carried out under identical (reactions 5 and 6, carbon tetrachloride, 40°C) or near identical (reactions 2 or 3, and 7, benzene, 80°C and 40°C respectively) conditions.

Taking the BDE ($D(PhCH_2—H) = 85$ kcal mol^{-1} (15*c*) and D(Cl—H) = 103.3 kcal mol^{-1} (25)), the exothermicity of the hydrogen abstraction by Cl· should be about 18.2 kcal mol^{-1}, a value comparable to that of the *t*-BuO· radical (22), 21 kcal mol^{-1}. According to Zavitsas and Pinto's argument (22), the α and β values for these two reactions should be nearly the same, that for the *t*-butoxy being a little higher. The total polar effect, as measured by both α and β, seems to point to this (compare reactions 5 and 6), despite large electronegativity differences between Cl· and *t*-BuO·. This observation is even more clearly manifested in the reverse direction, when one considers reactions 2 (or 3) and 7. Taking the (D(Br—H) = 87.5 kcal mol^{-1} (25)), the exothermicity of the hydrogen abstraction reaction by Br· should be about 2.5 kcal mol^{-1}. Although the electronegativity difference between Br· and *t*-BuO· is less than that between Cl· and *t*-BuO·, there is a large difference in the α and β value of the reactions of Br· and *t*-BuO·, those for Br· being much higher than those for *t*-BuO·. Such contradicatory observations can only be explained by considering both the electronegativity of the attacking radical and the extent of bond breaking and thus by invoking polar contributions to the transition state. The reported linear correlation by Zavitsas and Pinto (22) has obviously been a result of not taking into account the different reaction conditions.

More conclusive evidence (1) for the above suggestion is perhaps brought out by the magnitudes of the "Percent Resonance" (%R, sensitivity to resonance effects) of the different reaction series. This has been calculated by the following expression:

$$\%R = \frac{100\psi|\beta|}{\Phi|fF| + \psi|rR|}$$

where

$$\phi = \Sigma|fF - \overline{fF}|/n$$

and

$$\psi = \Sigma|rR - \overline{rR}|/n$$

Except for *t*-butoxy, the resonance percent for all the reactions is low, suggesting that resonance contributions to the stability of the transition state is not very significant, which, in turn, means that the transition state is predominantly formed by the polar structures. The high resonance contribution in case of *t*-butoxy is perhaps because of a lower degree of bond breaking the transition state and a smaller contribution from the dipolar structures **II** or **III**.

Acyl transfer in *o*-hydroxybenzenethiol

DAVID M. MCKINNON

Chemistry Department, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received March 31, 1980

DAVID M. MCKINNON. Can. J. Chem. **58**, 2761 (1980).

o-Hydroxybenzenethiol reacts with one equivalent of acetic anhydride to give a mixture of starting material, diacylated material, and *O*- or *S*-monoacylated products as determined by nmr. The same products are obtained by equilibration of a mixture of *o*-hydroxybenzenethiol and its diacetate. The mixture does not contain detectable amounts of 2-methylbenzothioxolan-2-ol.

DAVID M. MCKINNON. Can. J. Chem. **58**, 2761 (1980).

En se basant sur des données de la rmn, on conclut que le *o*-hydroxybenzènethiol réagit avec un équivalent d'anhydride acétique pour donner un mélange de produits de départ, de produits diacétylés et des produits *S*- ou *O*-monoacétylés. On obtient les mêmes résultats en équilibrant un mélange de *o*-hydroxybenzènethiol et de son diacétate. Le mélange des produits obtenus ne contient pas des quantités décelables de méthyl-2 benzothioxolanol-2.

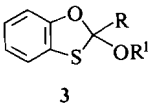
Introduction

In connection with another investigation it was desired to prepare *o*-mercaptophenyl acetate (**1***a*). Examination of the structure, however, suggested the likelihood of isomerism of this with *o*-hydroxyphenyl thiolacetate (**2***a*) via the cyclic orthoester form **3***a* and that, even more, these three compounds could possibly exist in some equilibrium mixture with *o*-hydroxybenzenethiol (**4**) and its diacetate (**5***a*). It is reported that 2-arylbenzoxathiolium salts, which may be made from *o*-mercaptophenol and an acyl equivalent (1–3), undergo hydrolysis to give materials of the type **1–5**. The pseudo base **3***b*, formed by attack of water on 2-phenylbenzoxathiolium perchlorate, underwent fast conversion to *o*-mercaptophenyl benzoate (**1***b*) which then slowly converted to *o*-hydroxyphenyl thiolbenzoate (**2***b*) (2). In addition, *o*-hydroxybenzenethiol dibenzoate (**5***b*) was isolated. These last two products must have arisen by intra- and intermolecular acyl transfer reactions.



Since the corresponding acetate analogs (**1***a*, **2***a*, **3***a*, **5***a*) would be more amenable to study by nmr spectroscopy, and, being more aliphatic, more related to studies on thiolester hydrolyses (4) or other acyl displacements from thiolesters (5), it seemed desirable to examine this sytem to determine the exact species present in the equilibrium mixture.

Results and Discussion

When *o*-hydroxybenzenethiol was treated with an equimolar quantity of acetic anhydride in the presence of triethylamine, and the reaction mixture worked up, the ^1H nmr of the product exhibited three peaks at 2.16 δ, 2.22 δ, and 2.26 δ, with a broad peak at 5.35 δ. These must be due, respectively, to three different types of methyl groups and an acidic proton bonded to oxygen and/or sulfur. The aromatic protons were evident as a complicated group of peaks between 6.7 and 7.5 δ. An identical spectrum was obtained from an equimolar mixture of **4** and **5***a* when treatedwith a trace of triethylamine. With more added triethylamine the acidic proton absorption shifted to 8.22 δ, characteristic of the triethylammonium ion proton.

Examination of the spectrum of an equimolar mixture of **4** and **5***a* without added triethylamine revealed at first that only a mixture of the two components was present, with the two peaks due to the methyl protons at 2.20 and 2.30 δ. These are tentatively assigned to the methyl protons of the *O*-ester and the *S*-ester in **5***a* on the following basis.

The spectrum of 2-methoxyphenyl thiolacetate **2***c* exhibited the acetate methyl peak at 2.27 δ. In 2-(methylthio)phenyl acetate (**1***c*) two peaks were evident in this range at 2.20 δ and 2.28 δ. The latter of these was slightly broadened and was therefore assigned to the *S*-methyl protons which are expected to exhibit through-space coupling with a ring proton[1] by analogy with some other methylthio compounds and, to some extent, with 2-methoxyphenol (6). Thus the peak at 2.20 δ is assigned to the acetate protons. For more information on chemical shifts in these compounds the *para* analogs were studied. *p*-Methoxyphenyl thiolacetate (**8***c*) exhibited the acetate methyl absorption at 2.26 δ and the *o*-methyl at 3.64 δ. Likewise *p*-(methylthio)phenyl acetate (**7***c*) exhibited two absorptions at 2.17 and 2.36 δ. The latter was slightly broadened and was therefore assigned to the *S*-methyl group. The absorptions in *p*-hydroxybenzenethiol diacetate (**10***c*), at 2.23 and 2.38 δ, were therefore assigned respectively to the *O*-acetyl and *S*-acetyl groups. These differences in δ values between *O*-acetyl and *S*-acetyl compounds are consistent with known differences in aliphatic thiolesters (7) and ordinary esters. Hence it appears that the thiolacetates absorb at a slightly lower field than acetates.

Examination of this mixture of **4** and **5***a* at selected intervals indicated the appearance of two new peaks at 2.18 and 2.21 δ until after 5 h there was no further change in the spectrum. Four methyl peaks were now evident. When this mixture was treated with a trace of triethylamine its spectrum changed immediately to that of the *o*-hydroxybenzenethiol/acetic anhydride/triethylamine experiment product, i.e. it had only three methyl peaks. Over the temperature range 30° to 100°C there was little effect on the spectrum of the mixture of **4** and **5***a*, but at 150°C the spectrum was identical to when triethylamine was present. On cooling, the single centre peak split into two to reproduce the original spectrum. This is consistent with there being a high energy barrier to interconversion of the two compounds. These peaks at 2.18 and 2.21 δ are assigned to the methyl protons in **1***a* and **2***a* respectively.

The proportions of the components of the mixture, as estimated by integration, were for the equilibrated mixture at room temperature **4**:**5***a*:**1***a*:**2***a*, 2:3:3:3; for **4**:**5***a*:(**1***a* + **2***a*) at 150°C, 1:1:4; and 1:1:2 when triethylamine was present.

It is possible that one of these peaks at 2.18 and 2.15 might be due to the intermediate "pseudo base" or orthoacetate structure **3***a* since the spectrum of this might be expected to have an approximately equal chemical shift. Data from acyclic compounds (8) suggest that this is at least a possibility and a closely related orthoester (**3**, R = Ph, R^1 = Et) absorbs in this region (9). Comparison of the ^{13}C nmr spectrum of the equilibrated mixture of **4** and **5***a* and the mixture of pure **4** and **5***a* demonstrated no increase in the number of methyl carbon absorptions. Evidently the chemical shifts of the acetate methyl carbons are rather insensitive to groups more than a few carbon atoms distant. Nevertheless it did reveal the presence of four types of carbonyl groups, two in the region 193 ppm, assigned to *S*-acyl, and two in the region 169 ppm, assigned to *O*-acyl. Comparable differences in values are found for coumarin and benzothiopyran-2-one (10). In addition, four tertiary carbons bonded to oxygen, i.e. the  type and four tertiary carbons bonded to sulfur, i.e. the  type were evident at around 152 and 119 ppm respectively. In all, the spectrum of the equilibrated mixture was consistent with a mixture of only compounds **1***a*, **2***a*, **4**, and **5***a*. There were no absorptions in a range suitable to justify the presence of the orthoacetate **3***a*. These orthoesters or equivalents must be intermediates in the formation of benzoxathiolium salts, but under acidic conditions only the salts are obtained (1, 2).

Likewise the mixture of **4** and **5***a* treated with triethylamine indicated no extra absorptions other than those of added triethylamine and **1***a* and **2***a*. However, the relative heights of the carbonyloxy and the carbonylthio absorptions from **1***a* and **2***a* respectively shifted in favor of the latter, probably because of enhanced nucleophilicity of the thiolate group. These results are interesting in that thiolate esters hydrolyse more readily than ordinary esters (4), usually attributed to a greater mesomeric effect of oxygen over sulfur, affecting coordination of the nucleophile at the carbonyl carbon. Also, this effect has been used to explain bond distance differences in thiolacetic acid (11). Hence in the system above, the production of **1***a* would be favored in the equilibrium mixture. However, the phenyl mercaptide ion would be a stronger nucleophile than phenoxide ion, which should favor the formation of **2***a*. Evidently in this system the two effects are closely balanced.

The ir spectrum of the equilibrated mixture was of little use on deciding its components. The only main features evident were two absorptions at 1725 and 1779 cm^{-1} assigned to thiolacetate and acetate

[1]T. Schaefer, unpublished results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.6 on 09/05/12
For personal use only.

carbonyl groups respectively. The effect of sulfur is to reduce the frequency of this carbonyl absorption (12). Attempts to separate these components by extraction with mild base failed, probably because of facile hydrolysis of the phenolic esters. Attempted separation by gas chromatography failed.

It is interesting to compare the results above with the *para* analog, where intermolecular reaction is impossible. *p*-Hydroxybenzenethiol (**9**) mixed with its diacetate (**10***c*) gave, by ^1H and ^{13}C nmr, additive spectra which exhibited little change, even after several days. Treatment of the mixture with triethylamine gave at first a rather complicated spectrum but over several hours this simplified until only one large methyl absorption at 2.235 was evident. The ^{13}C spectrum of the mixture showed a large absorption at 159.4 ppm assigned to *p*-mercaptophenyl acetate (**7***a*). This is further indicated by the ir spectrum, which showed only one large carbonyl absorption, at 1768 cm^{-1}. In this case then it appears that thiolester cleavage is the main reaction, implying that the phenolic group is a stronger nucleophile than with the *ortho* case. Possibly this reflects differences in hydrogen bonding (13).

It is reported that *o*-hydroxybenzenethiol may be made by treatment of *o*-hydroxybenzenediazonium chloride with potassium ethylxanthate, followed by hydrolysis of the crude product (14), presumably *o*-hydroxyphenyl ethylxanthate. In review of its similarity to the above, it was decided to investigate this and related systems also. Because of side reactions occuring in the diazotization reaction these were approached via the treatment of *o*-hydroxybenzenethiol with the methyl esters of chloroformic acid or chlorothionoformic acid in the presence of triethylamine. The products were obtained as colorless or pale yellow oils.

For the reaction of methylchloroformate with the equivalent quantity of *o*-hydroxybenzenethiol, work-up afforded an oil whose ^1H nmr exhibited only two methyl signals at 3.80 and 3.91 δ . Substantially similar spectra were obtained from an equimolar mixture of the diesters **5***d* and **4**, either on treatment with triethylamine, or on standing for 16 h. Since these two absorptions were at the same δ value as in **5***d*, the ^{13}C spectra of the three reactions were examined. Again all were similar in the number of peaks exhibited apart from added triethylamine, although absorption intensities varied. Absorptions corresponding to compounds **4** and **5***d* could be seen and four different methyl groups were evident. Also evident were two thiolcarbonate absorptions, around 169 ppm, but carbonate absorptions could not be differentiated properly from tertiary carbons bonded to oxygen, and tertiary carbons bonded to sulfur could not be differentiated from aromatic carbons despite Overhauser effects. Positions of absorption were assigned by comparison of spectra with methyl phenyl carbonate and methyl *S*-phenyl thiolcarbonate **6**. The ir spectra of the reactions exhibited two absorptions at 1735 and 1770 cm^{-1} respectively, assigned to thiolcarbonate and carbonate groups respectively.

Although in the ^1H nmr spectrum of the reaction product of *o*-hydroxybenzenethiol with methyl chlorothionoformate the only peak was evident in the region of methoxy groups, the ^{13}C nmr spectrum showed three such groups, at least two thiocarbonyl groups, and three aromatic carbons bonded to oxygen. Unfortunately, apart from *o*-hydroxybenzenethiol, it has not been possible to identify the actual components.

Experimental

Solutions were made up as approximately 60% mixtures in deuteriochloroform using tetramethylsilane as an internal standard. The ^1H nmr spectra were determined on a Varian model 56/60A spectrometer. The ^{13}C nmr spectra were obtained in the Fourier transform mode on a Bruker WH-90DS spectrometer (22.63 MHz), equipped with a Nicolet-1180 computer, the N.T.C.-FT-1180 software package, and quadrature phase detection. Normally spectra were recorded with complete proton noise decoupling; ir spectra were obtained on a Perkin-Elmer model 337 spectrophotometer using neat samples of reaction products.

o-*Hydroxybenzenethiol*

This was commercially available (Parish) or was synthesized according to Leukart (14).

p-*Hydroxybenzenethiol* (*9*)

The commercially available material (Parish) was purified by careful distillation *in vacuo*.

o-*Hydroxybenzenethiol Diacetate* (*5c*)

o-Hydroxybenzenethiol (3.78 g, 0.03 mol) and excess acetic anhydride (10 g) in benzene (10 mL) were treated with triethylamine (2 mL). The volatile materials were removed under reduced pressure and the mixture was fractionally distilled *in vacuo*. The volatile fraction boiling at 108–110°C at 0.4 Torr was collected. A colorless rather viscous liquid was obtained (63%). *Anal.* calcd. for $C_{10}H_{10}O_3S$: C 57.14, H 4.76, S 15.26; found: C 56.93, H 4.72, S 15.31.

o-*Hydroxybenzenethiol Bis(methyl) Carbonate* (*5d*)

o-Hydroxybenzenethiol (2.52 g, 0.02 mol) and methyl chloroformate (3.68 g, 0.04 mol) in anhydrous ether (25 mol) were treated with triethylamine (2 mL). The mixture was washed with 0.1 *N* hydrochloric acid and the ether dried over anhydrous magnesium sulfate. The solution was evaporated under reduced pressure and distilled *in vacuo*. The fraction bp 121–123°C at 0.4 Torr was collected (50%). *Anal.* calcd. for $C_{10}H_{10}O_5S$: C 49.58, H 4.14, S 13.22; found: C 49.63, H 4.21, S 12.98.

2-Methoxyphenyl Thiolacetate (*2c*)

This was made by a published procedure (15) from 2-

methoxybenzenethiol (Fluka) except that triethylamine was used as a basic catalyst.

2-(Methylthio)phenyl Acetate (1c)

2-(Methylthio)phenol (7 g, 0.05 mol) (16) was treated with an excess of acetic anhydride and triethylamine (5 mL). The mixture was warmed briefly and distilled *in vacuo*. The fraction bp 65°C at 0.4 Torr was collected (91%). *Anal.* calcd. for $C_9H_{10}O_2S$: C 59.34, H 5.49, S 17.58; found: C 59.21, H 5.69, S 17.43.

p-*Hydroxybenzenethiol Diacetate (10c)*

This was prepared according to a literature procedure (17).

O-*Methyl*-S-*phenyl Thiolcarbonate (6)*

Benzenethiol (5.5 g, 0.05 mol) was treated with excess methyl chloroformate in anhydrous ether (25 mL). Addition of triethylamine gave a vigorous reaction. The mixture was washed with 0.1 *N* hydrochloric acid and dried over anhydrous magnesium sulfate. Evaporation and distillation *in vacuo* afforded a colorless oil. The fraction bp 71–72°C at 0.4 Torr was collected (83%). *Anal.* calcd. for $C_8H_8O_2S$: C 57.14, H 4.77, S 19.04; found: C 57.26, H 4.83, S 18.99.

Reaction of o-*Hydroxybenzenethiol with One Equivalent of Acetic Anhydride*

The thiol (2.52 g, 0.02 mol) and acetic anhydride (2.02 g, 0.02 mol) were mixed together, and triethylamine (1 mL) added. The mixture warmed immediately. After 30 min the mixture was fractionally distilled at 0.4 Torr to remove acetic acid and triethylamine.

Reaction of o-*Hydroxybenzenethiol with Methyl Chloroformate*

The thiol (2.48 g, 0.02 mol) and methyl chloroformate (1.88 g, 0.02 mol) were mixed in ether (25 mL) and treated with triethylamine (2 mL). After the vigorous reaction the ether was washed with 0.1 *M* hydrochloric acid, dried, and evaporated. The mixture was then fractionally distilled at 0.1 Torr to remove traces of volatile impurities.

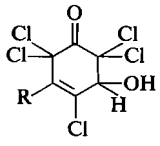
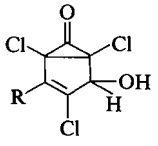
GEORGE M. STRUNZ, MASATOSHI KAKUSHIMA, ALAN D. GIBSON, ARCHIBALD W. MCCULLOCH, and PETER S. WHITE. Can. J. Chem. **58**, 2765 (1980).

Two new crystalline products were isolated from the chlorination of *m*-cresol in cold alkaline solution. These products have been identified as *E*,*Z*-2-chloro-5-methyl muconic acid and 5*Z*-carboxymethylene-3-chloro-4-methyl-2(5*H*) furanone.



GEORGE M. STRUNZ, MASATOSHI KAKUSHIMA, ALAN D. GIBSON, ARCHIBALD W. MCCULLOCH et PETER S. WHITE. Can. J. Chem. **58**, 2765 (1980).

Deux nouveaux produits cristallins ont été isolés de la réaction du *m*-cresol avec chlore en milieu alkalin froid. On a identifié ces produits comme l'acide *E*,*Z*-2-chloro-5-méthyle muconique et la furfuranone-2(5*H*)-5*Z*-carboxyméthylène-3-chloro-4-méthyle.



The reaction of phenol with hypochlorite in alkaline solution gives rise, *inter alia*, to 3,5,5-trichloro-1,4-dihydroxy-2-cyclopentene-1-carboxylic acid (**1**, R=H) (2–4). Mechanisms advanced for this transformation invoked Favorskii-type ring contraction, involving intermediates such as **2** (3) or **3** (4). It was demonstrated that *meta* alkyl substituted phenols afforded the corresponding 2-alkyl derivatives (**1**, R = methyl or *n*-propyl) under similar conditions (1, 5), and the reaction was exploited as the key step in the total synthesis of the fungal metabolite[4] cryptosporiopsin (5).

3

4

5

The capricious nature of the reaction, resulting from its sensitivity to minor variations in experimental conditions, has been noted (3, 4). In the course of studies with *m*-cresol aimed at optimization of yields of **1** (R = methyl), cf. ref. 1, the effects of variations in temperature, pH, chlorine flow rate, etc. were explored. Under certain conditions (see Experimental), two additional crystalline compounds were obtained as minor products.

We report here on the structures of these compounds, $C_7H_7O_4Cl$ and $C_7H_5O_4Cl$, which are products of oxidative cleavage of the aromatic ring.

The substance with the greater hydrogen complement displayed in its mass spectrum isotope peaks at *m/e* 190 and 192, corresponding to the molecular ion; the base peak at *m/e* 155 resulted from loss of chlorine.

In the infrared spectrum (KBr), a carbonyl band at 1695 cm^{-1} and broad absorption between 3600 and 2100 cm^{-1} are indicative of a conjugated carboxylic acid. The presence of an extended chromophore was manifested by an ultraviolet absorption maximum at 281 nm (ε 20 300).

The 100 MHz ^1H nmr spectrum, recorded in tetrahydrofuran-d_8, shows an AB system centred at δ 7.76 for two vicinally-coupled olefinic protons (J_{AB} = 11.7 Hz; $\Delta\nu_{AB}$ = 53.8 Hz). The high-field and

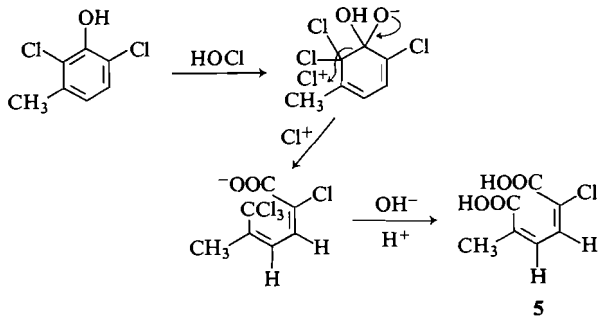
TABLE 1. ^{13}C nmr data for **5** (in tetrahydrofuran-d_8)

Carbon	δ_C (ppm)	Multiplicity*†	$^nJ_{CH}$ (Hz)
C-1	163.74	d	^3J 10.0
C-2	127.01	ddq	^3J 6.5, ^2J 3.0, ^5J 1.5
C-3	137.00	d	^1J 164.1
C-4	132.51	ddq	^1J 162.4, ^2J 2.3, ^3J 6.6
C-5	135.32	dq	^3J 3.5, ^2J 7.0
C-6	168.21	dq	^3J 12.3, ^3J 4.0
C-7 (Methyl)	21.64	qd	^1J 128.5, ^3J 6.7

*Abbreviations: d = doublet, q = quartet
†All quartet spacings were removed on irradiation of H-7, while the C-3 doublet was sharpened.

low-field protons of this system show, in addition, coupling (J = 1.5 and 0.5 Hz respectively) to the hydrogens of an allylic methyl group at δ 2.02. A broad peak at δ 10.55 is attributable to two acidic protons. The structure **4**, 2-chloro-5-methyl muconic acid is consistent with these spectra.

The proton noise decoupled ^{13}C nmr spectrum, as expected, shows resonances for one methyl, two carboxyl, and four olefinic carbons. The high resolution ^{13}C nmr spectrum (Table 1), recorded without decoupling and then with selective decoupling of the methyl hydrogens, provided unequivocal evidence for formulation **4** and in addition allowed assignment of the *EZ* geometry depicted in **5**.



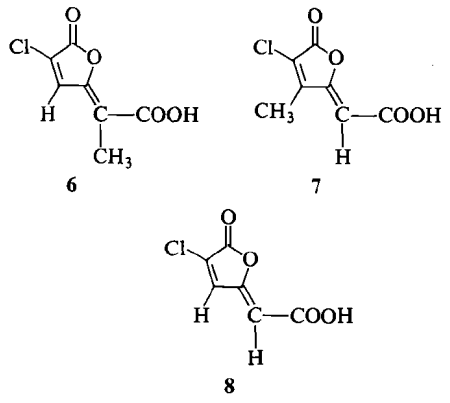
The magnitude of the coupling between the carboxyl carbon at δ 168.21 and the methyl hydrogens (^3J = 4.0 Hz) indicates that this carboxyl must be geminal with the methyl group, while the magnitude of the doublet coupling (^3J = 12.3 Hz) establishes that it is also oriented *trans* to an olefinic hydrogen (7). This stereochemistry is further confirmed by the characteristic *cis* coupling (^3J = 6.7 Hz) observed between the methyl carbon and the vicinal olefinic proton.

Since the two olefinic hydrogens are vicinal, the chlorine must be located α to the second carboxyl carbon. This is reflected by the chemical shift (δ 163.74) of the latter (8). Chlorine substitution at this centre would also be expected to reduce the magnitude of the coupling between the adjacent carboxyl and the β olefinic hydrogen (7). Thus, the magnitude of the observed coupling (^3J = 10.0 Hz) is compatible again only with a *trans* relationship of these atoms. The combined evidence therefore establishes structure **5**.

The selective decoupling experiment showed that the methyl hydrogens are also coupled to the α-(^2J = 7.0 Hz), β-($^3J \simeq$ 6.6 Hz), and δ-($^5J \simeq$ 1.5 Hz) olefinic carbons. These, and all other couplings observed, are entirely compatible with **5**.

The presence of another isomer (up to 25% of the 2-chloro-5-methyl muconic acid) was evident in the product from most runs. This was tentatively assigned the *ZZ* geometry on the basis of the signals for the vinyl protons in the ^1H nmr spectrum (AB system centred at δ 7.68, J_{AB} = 11.3 Hz, $\Delta\nu_{AB}$ = 163.8 Hz; high-field and low-field protons coupled to hydrogens of allylic methyl group at δ 2.09 (J = 1.6 and 0.6 Hz respectively).

A mechanism for the formation of **5** (from 2,6-dichloro-*m*-cresol) is suggested in Scheme 1. The presence of the minor, *ZZ* isomer may be rationalized in several ways. One facile mechanism for isomerization of a *cis–cis* muconic acid to the *cis–trans* form involves the formation of a lactone intermediate, cf. ref. 9.



SCHEME 1

Like its congener, the other crystalline by-product, $C_7H_5ClO_4$, also shows infrared absorption characteristic of a conjugated carboxylic acid (1695 and 3650–2250 cm^{-1}). An extended chromophore is again manifested in the ultraviolet spectrum (λ_{max} 281 nm (ε 20 000)). Besides the broad absorption associated with the acid proton (exchangeable), the 60 MHz ^1H nmr spectrum in acetone-d_6 solution consists of two sharp singlets: one, at δ 5.83 due to a vinyl proton, and the other, at δ 2.30, attributable to the hydrogens of an allylic methyl group. These features, together with a strong, sharp band at 1805 cm^{-1} in the infrared spectrum, cf. ref. 10, suggest an enol-lactone structure such as **6** or **7** (geometry not implied).

The structure **7** was firmly established by a single crystal X-ray analysis. Figure 1 is a perspective

view of the molecule with bond distances and angles shown in Table 2. Details relevant to the X-ray analysis are presented in the Experimental.

The mechanism in Scheme 2 could account for the formation of 7. This scheme bears a formal resemblance to the latter part of the pathway whereby the herbicide 2,4-D is metabolized by *Pseudomonas* spp. (10). The lactone 8 has been recognized as an intermediate in this pathway (10).

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared and ultraviolet spectra were recorded on Beckman Acculab 2 and DK-2A spectrophotometers respectively. Mass spectra were obtained with an Hitachi Perkin-Elmer RMU-6D mass spectrometer. The 60 MHz ^{1}H nmr spectra were recorded using a Varian T-60 instrument with tetramethylsilane as internal standard; the 100 MHz spectrum of 5 in tetrahydrofuran-d_8 was measured on a Varian HA-100 spectrometer using the tetramethylsilane resonance to provide the field-frequency lock. The ^{13}C nmr spectra were recorded in tetrahydrofuran-d_8 (90 mg/0.3 mL) on a Varian FT-80 spectrometer under the following conditions: frequency 20 MHz; acquisition time 0.99 or 1.98 s (data accuracy ±0.5 or ±0.25 Hz); spectral width 4132 Hz; flip angle 25° or 50°; internal ^{2}H lock to solvent; temperature about 35°C; ^{1}H irradiation at 80 MHz (*a*) $\gamma H_2/2\pi$ ca. 4000 Hz, bandwidth 2000 Hz (broadband decoupling); (*b*) $\gamma H_2/2\pi$ ca. 2900 Hz, bandwidth 1000 Hz, field applied for 2 s between data acquisitions to retain nOe (high-resolution spectrum); (*c*) as for (*b*), but with additional constant ^{1}H irradiation $\gamma H_2/2\pi$ 196 Hz at frequency of methyl ^{1}H resonance (single-frequency decoupling with nOe retained at all resonances).

Microanalyses were performed by Spang Microanalytical Laboratory, Eagle Harbor, MI.

Reaction of m-*Cresol with Alkaline Hypochlorite*

A solution of *m*-cresol (50 g, 0.46 mol) in 2.5 *M* aqueous sodium hydroxide (435 mL) was cooled to −2°C. Chlorine was passed slowly into the stirred mixture through a gas dispersion tube while the temperature was maintained around −2°C by judicious application of the cooling bath. During the first hour of this treatment, six 85 mL portions of cold 5 *M* sodium hydroxide solution were added, at roughly 10 min intervals; the chlorine flow was then continued for a second hour while the temperature

SCHEME 2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

was maintained at 10–15°C. At the end of this period the solution was still alkaline. The mixture was made acidic by addition of 12 *M* hydrochloric acid (30 mL), and was then filtered through a bed of Celite. The filtrate was extracted successively with eight portions of ether (total volume 1200 mL). The extracts were dried over magnesium sulfate and evaporated to dryness *in vacuo*. The residue (22.1 g) formed a semicrystalline mass on being set aside in a refrigerator. The product was partially dissolved in boiling chloroform (100 mL), and after standing at 23°C for 3 h, insoluble material was collected by vacuum filtration. In this manner 465 mg (0.53% from *m*-cresol) of **5** was obtained as almost colorless crystals. Recrystallization from chloroform yielded colorless crystals, mp 156–176°C; ir (KBr) *inter alia*: 3600–2100, 1695, 1560, 1405, 1310, 1245, 970, and 910 cm^{-1}; uv λ_{max} (EtOH): 281 nm (ε 20 300); λ_{max} (alkaline EtOH): 272 nm (ε 19 200); ^1H and ^{13}C nmr spectra described in text; mass spectrum *m/e*: 190 (M^+), (($M + 2$)$^+$ 34% of M^+), 155 (base peak) ($M - Cl$)$^+$. *Anal.* calcd. for $C_7H_7ClO_4$: C 44.12, H 3.70, Cl 18.60, O 33.58; found: C 44.26, H 3.21, Cl 18.61, O 33.80.

The filtrate from above was concentrated, and on standing further crystals separated and were filtered at the pump. Crystalline **7** (548 mg, 0.63%) was thus obtained. Recrystallized from chloroform, the material sublimed at ca. 192°C and was completely molten at 206°C. Recrystallization from acetone–cyclohexane gave colorless needles which began to sublime around 200°C and melted at 225–235°C (dec.). Spectral characteristics of **7** are as follows: ir (KBr) *inter alia*: 3650–2250, 1805, 1695, 1645, 1420, 1260, 1195, and 975 cm^{-1}; uv λ_{max} (EtOH): 281 nm (ε 19 800); 60 MHz ^1H nmr spectrum described in text; mass spectrum *m/e*: 188 (M^+); (($M + 2$)$^+$ 35% of M^+). *Anal.* calcd. for $C_7H_5ClO_4$: C 44.58, H 2.67, Cl 18.80; found: C 44.42, H 2.83, Cl 18.71.

Evaporation of the filtrate gave an oil (17.6 g), which on redissolving in hot chloroform deposited 2.36 g (2%) of "Hantzsch acid" (**1**, R = CH_3), mp 148–152°C (1). Additional Hantzsch acid could be obtained from the mother liquors.

X-ray Diffraction Study of 7

A preliminary photographic investigation was used to obtain approximate cell dimensions and determine the space group as $P2_1/n$. Final unit cell dimensions were obtained by centering 12 reflections and their Friedel opposites on a Picker FACS-I diffractometer, and fitting the cell parameters and an orientation matrix to the coordinates by a least-squares routine. Graphite monochromated Mo K_α radiation was used, and throughout the investigation the diffractometer was controlled by the NRC FORTRAN control routines of Larson and Gabe (11). The relevant crystallographic data are:

$C_7H_5O_4Cl$ fw = 188.6
Monoclinic, $P2_1/n$, a = 5.0640(7), b = 13.312(3), c = 11.561(2) Å, β = 99.94(1)°, V = 767.7 Å^3, D_c = 1.63 Mg m^{-3}, Z = 4, (20°C, Mo K_α, λ = 0.71069 Å). Crystal size = 0.02 × 0.02 × 0.05 cm, μ = 0.47 mm^{-1}.

Intensities were measured on the diffractometer using an ω–2θ scan at a rate of 2 deg (2θ) min^{-1} over a range of 2° (2θ) corrected for dispersion of the K_α doublet. The background was estimated by an analysis of the profile of each peak measured by the computer during each scan. Three reference reflections, monitored every 50 reflections, showed no significant variation in intensity throughout the data collection. Data were collected for $2\theta \leq 45°$ which resulted in 1006 unique reflections of which 178 (17.6%) were considered unobserved ($I \leq 1.5\sigma(I)$) and were not included in the subsequent refinement.

Structure Determination and Refinement

The structure was solved by multiple solution direct methods using a version of the computer program MULTAN modified for use on the PDP8/E computer. The set of phases with the highest figure of merit was used to phase an *E*-map which revealed the positions of all the nonhydrogen atoms. The oxygen positions were assigned using chemical considerations and later confirmed by the geometry of the structure.

The structure was refined by least-squares methods, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$. The weighting scheme was of the form $w = 1/\sigma^2(F)$, with σ estimated from the measured intensity. After initial refinement of the positions of the nonhydrogen atoms a difference synthesis was calculated which revealed the positions of the hydrogen atoms. The final cycles of least squares included the positional parameters of all atoms, isotropic thermal parameters for the hydrogens, and anisotropic thermal parameters for all other atoms. The final agreement indices were R = 0.071 and R_w = 0.085 (0.085 and 0.090 respectively including the unobserved reflections). Table 3 contains the final atomic positional parameters.[5]

All computations were performed on a Digital Equipment PDP8/A computer, equipped with a floating point processor, using the NRC PDP-8e Crystal Structure System (11) and locally written programs.

A regiospecific synthesis of protoberberine alkaloids

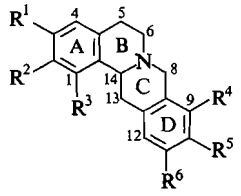
ZINOVIA KIPARISSIDES, ROBERT H. FICHTNER, JANUSZ POPLAWSKI, BALA C. NALLIAH, AND DAVID B. MACLEAN

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 9, 1980

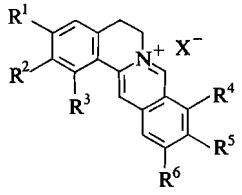
ZINOVIA KIPARISSIDES, ROBERT H. FICHTNER, JANUSZ POPLAWSKI, BALA C. NALLIAH, and DAVID B. MACLEAN. Can. J. Chem. **58**, 2770 (1980).

The protoberberine skeleton has been prepared in two steps from *N*-benzyl-3,4-dihydroisoquinolinium salts. Treatment of the salts with the anion of methyl methylthiomethylsulfoxide yields mixtures of diastereomeric adducts that cyclize on heating with concentrated hydrochloric acid to dihydroprotoberberines. The latter compounds may be reduced to their tetrahydro analogues with sodium borohydride, oxidized to protoberberinium salts with iodine, or converted to 13-methyltetrahydroprotoberberines by treatment with formaldehyde according to an established procedure. The method has been applied successfully to the synthesis of (±)-tetrahydropalmatine, palmatine iodide, (±)-xylopinine, (±)-sinactine, and (±)-corydaline. *N*-Benzylisoquinolinium salts may be used in place of their dihydro analogues as starting materials in this synthesis, thereby extending the range of substitution patterns potentially available.



ZINOVIA KIPARISSIDES, ROBERT H. FICHTNER, JANUSZ POPLAWSKI, BALA C. NALLIAH et DAVID B. MACLEAN. Can. J. Chem. **58**, 2770 (1980).

On a préparé en deux étapes le squelette de la protoberbérine à partir des sels de *N*-benzyldihydro-3,4 isoquinolinium. Les sels traités par l'anion du méthylthiométhylsulfoxyde de méthyle donnent un mélange d'adduits diastéréoisomères qui, par chauffage dans de l'acide chlorohydrique concentré, se cyclisent en donnant les dihydroprotoberbérines. Ces derniers peuvent être soit réduits en leurs analogues tétrahydro par le borohydrure de sodium, soit oxydés par l'iode en sels de protoberbérinium, soit transformés en méthyl-13 tétrahydroprotoberbérines par réaction avec le formol selon une méthode connue. On a utilisé cette méthode avec succès pour la synthèse des composés suivants: la (±)-tétrahydropalmatine, l'iodure de palmatine, la (±)-xylopinine, la (±)-sinactine et la (±)-corydaline. Dans cette synthèse, on peut utiliser comme produit de départ le sels de *N*-benzylisoquinolinium au lieu de leurs analogues dihydro ce qui augmente le nombre potentiel de modèles de substitution disponibles.



[Traduit par le journal]

The protoberberine alkaloids exist in nature as tetrahydroprotoberberines or quaternary protoberberine salts as shown in structures **1** and **2**, respectively. The R groups are present as hydroxy, methoxy, or methylenedioxy. The substitution pattern most commonly encountered is 2, 3, 9, 10 but other substitution patterns are found in the aromatic rings and in some cases methyl groups are also present at C-8 or at C-13 and hydroxy groups at C-5 or at C-13. Many methods have been described for the construction of this ring system and excellent reviews are available not only on the synthesis of the protoberberines but also on other aspects of their chemistry (1–6). However, many of the methods of synthesis are not regiospecific, and many are multistep or require intermediates that are not readily accessible. The new method described here is regiospecific and uses starting materials that are easily prepared. It has been applied to the synthesis of 2,3,9,10- and 2,3,10,11-tetrasubstituted alkaloids, and in principle is adaptable to the preparation of other alkaloids of the series differently substituted in the aromatic rings.

Appropriately substituted *N*-benzyl-3,4-dihydroisoquinolinium salts such as **3** were used initially as starting materials in this work. They were prepared from substituted benzyl halides and substituted 3,4-dihydroisoquinolines, both of which are accessible by standard procedures. The objective of the work was to insert a one-carbon unit between C-1 and C-6′ of **3** (eventually to become C-13 of the protoberberine) and in this way to generate the protoberberine skeleton. Carbon atom 1 of **3** is a reactive centre amenable to attack by one-carbon nucleophiles while C-6′ is an activated site amenable to electrophilic attack. Thus a one-carbon nucleophile that, once introduced, might be converted into an electrophilic centre was required. The reagent of choice proved to be lithio methyl methylthiomethylsulfoxide (7), a reagent already known to add to iminium salts (8). This reagent, generated from methyl methylthiomethylsulfoxide (MMTS), added readily to the

dihydroisoquinolinium salts **3**. The reagent, generated at −35°C in anhydrous tetrahydrofuran (THF), was added by a syringe to a suspension of the dihydroisoquinolinium salt in THF at a temperature of ca. −30°C and the mixture was held at this temperature for 3 h during which time the suspended solids had entered solution. The reaction mixtures were worked up in a conventional manner yielding crude residues that were purified by chromatography or in some cases used directly in the next reaction step. The products were obtained as oils in yields of 90% and their nmr spectra indicated that they were mixtures of isomers (see Scheme 1).

A detailed chromatographic examination was carried out on the adduct **4***a* in an attempt to ascertain its composition. Initially the crude residue was chromatographed over alumina and in this way a product was obtained as an oil in yields in excess of 90%. The ^{1}H nmr spectrum showed a multiplicity of signals in the S—Me region suggesting that the compound was a mixture of diastereomers. Examination of the crude adduct by tlc on silica using ether–ethanol (absolute) 8:1 as eluent showed three components at R_f 0.16, 0.20, and 0.33. By using flash chromatography (9) on silica and the same solvent system used for tlc it was possible to separate the crude reaction product into the three fractions obtained on tlc. ^{1}H nuclear magnetic resonance examination showed that the middle fraction contained two S—Me signals in its spectrum and was apparently pure, while the other two fractions contained four S—Me signals each in their spectra and were mixtures. Two S—Me peaks in the fraction R_f 0.16 were found to be coincident with the corresponding peaks of MMTS. Unused MMTS from the condensation must therefore have been carried through the purification procedure and chromatographic conditions were not found for its separation from this isomer. A more complex solvent system (hexane–ethanol–THF 6:3:1) proved effective in resolving the fraction, R_f 0.33, into two components. Variable temperature nmr studies showed that the two components of this fraction were not rotamers since the four peaks failed to coalesce to two even at 90°C. Mass spectrometric examination of the three fractions obtained by flash chromatography showed only slight differences in their spectra (taking into account the presence of MMTS in the R_f 0.16 fraction). The chromatographic work combined with the nmr and ms studies suggests that the adduct is a mixture of four racemic diastereomers as expected of a compound having three chiral centres.

Further attempts were not made to characterize the diastereomers since it was found that the crude reaction mixture derived from alumina chromatography, or any of the three fractions obtained from silica chromatography, were all suitable starting materials in the next synthetic step. In all cases the same product was obtained on treatment with concentrated hydrochloric acid, for 5–10 min, at steam bath temperatures under a nitrogen atmosphere.

Two methods were used to work up the product of the reaction with concentrated HCl. In the first method the reaction mixture was cooled and carefully basified with sodium hydroxide solution. The products were not the expected 1-carboxaldehydes but instead the dihydroprotoberberines **5**. Only in one case, that of **5***b*, was the product characterized by spectroscopic examination. In other cases the dihydro compounds **5**, because of their sensitivity to aerial oxidation, were treated directly with sodium borohydride in ethanol to give the tetrahydroprotoberberines, **1***a*, **1***b*, and **1***c*. The synthetic sequence is outlined in Scheme 1.

In this way (±)-tetrahydropalmatine **1***a*, (±)-xylopinine **1***b*, and (±)-sinactine **1***c*, were prepared beginning with **3***a*, **3***b*, and **3***c*, respectively, in overall yields of ca. 45% based on the dihydroisoquinolinium salts. In all cases the spectral properties, ir and nmr, of the synthetic alkaloids in solution were identical with those of the naturally occurring bases. Their mass spectra were also identical.

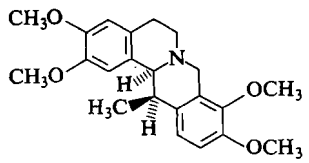
The second method of work-up was based on the observation that fine yellow crystalline needles separated in yields of 70–90% from the reaction mixture of **4***a* and concentrated HCl when the mixture was cooled and allowed to stand. The iminium salt structure **6** has been assigned to this product. Unfortunately good analytical data were not obtained on this compound, presumably because it was highly solvated. Moreover it appeared to suffer decomposition on heating in a drying pistol. However, the ^{1}H nmr spectrum in trifluoroacetic acid (TFA) supported this structure. Besides the methoxyl and the aromatic protons there were signals attributed to 8 aliphatic protons in the spectrum. Two of these hydrogens appeared upfield from the methoxyl signals as a multiplet at 3.40 δ and were assigned to the hydrogen atoms at C-5, and two other hydrogens in the region 4.16–4.35 δ to those at C-6. The latter were partially obscured by the methoxyl resonances. At lower field from the methoxyl resonances there were two broad absorptions each of area 2 at 4.64 δ and 5.30 δ that were assigned to hydrogen atoms at C-13 and C-8, respectively. The infrared spectrum of **6** in $CDCl_3$ showed a peak at 1634 cm^{-1} characteristic of a $C{=}N^+$ function. The mass spectrum had peaks at *m/e* 355 (35), 354 (35), 353 (100), and 352 (45). The dihydro palmatinium ion would be expected at *m/e* 354. It is possible that the ions at *m/e* 355 and *m/e* 353 may arise by disproportionation of the sample at the source temperatures required for volatilization of the sample. Ions at *m/e* 190 (25) and *m/e* 164 (50) present in the spectrum are characteristic of protoberberine systems (10). Compound **6** was readily reduced with sodium borohydride in ethanol to **1***a*, thus lending further support to the assigned structure.

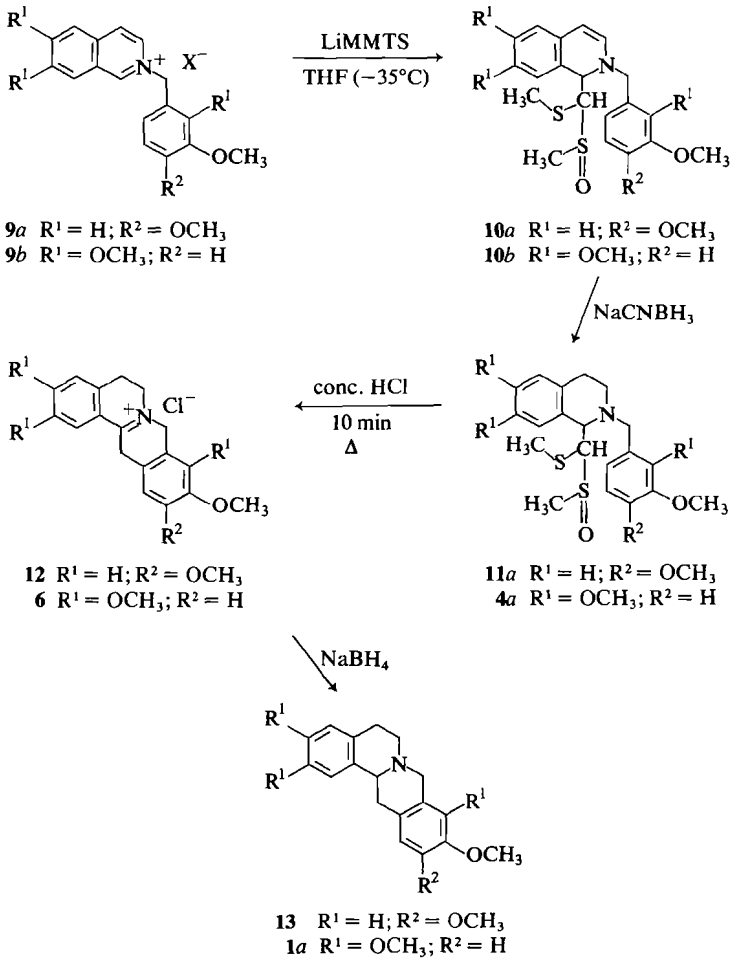
Compound **6** was a convenient starting material for the synthesis of corydaline. Bersch (11) reported that the reaction of formaldehyde with dihydroprotoberberines yielded quaternary protoberberinium salts methylated at C-13. When **6** was heated with formaldehyde in aqueous acetic acid containing sodium acetate, and then with sodium iodide it was converted into dehydrocorydaline iodide **7**. Reaction of **7** with sodium borohydride yielded (±)-corydaline **8** and none of its isomer, in agreement with the work of Kondo (12). This total synthesis of corydaline proceeds in 46% yield from **6** and is shorter by several steps than a recently reported route (13). In principle this method should be applicable to other protoberberines methylated at C-13.



The syntheses reported to this point all involve dihydroisoquinoline intermediates prepared by

6

7



8

Bischler–Napieralski cyclization (14). In order to extend this synthetic approach to substituted protoberberines not available by the Bischler–Napieralski reaction we have investigated the applicability of isoquinolines in place of 3,4-dihydroisoquinolines as starting materials in this synthesis. Through the use of isoquinolines a full range of substituted compounds is available by making use of the other synthetic pathways to this ring system. In preliminary studies we have found that isoquinoline itself and 6,7-dimethoxyisoquinoline are suitable starting materials and we plan in the future to extend the reaction to other isoquinolines.

Treatment of isoquinoline with 3,4-dimethoxybenzyl chloride yielded the salt **9***a* that was treated with the anion of MMTS at −35°C (Scheme 2). Structure **10***a* has been assigned to the product of this reaction. Like the analogues discussed previously this compound was a mixture as shown by tlc and by its nmr spectrum. Unlike the compounds of structure **4**, compound **10***a* was unstable and decomposed on attempted column chromatography.[1] It also failed to give recognizable products on attempted cyclization in concentrated HCl or on treatment with sodium borohydride in ethanol. It did, however, undergo reduction with sodium cyanoborohydride in methanolic acetic acid, a reaction accompanied by spectacular color

[1]Other workers (ref. 15, and references therein) have noted that 2-alkyl-1,2-dihydroisoquinolines are unstable and undergo disproportionation to isoquinolines and tetrahydroisoquinolines. This and other reactions may be occurring here.

changes. The product, to which structure **11a** was assigned, was a mixture of isomers as evidenced by its tlc behaviour and by its nmr spectrum. In its properties **11a** resembled compounds **4**. It was formed in 60% overall yield from **9a**. Without further purification the yellow oil **11a** was heated with concentrated HCl for 10 min on the steam bath. A yellow solid, assigned structure **12**, crystallized from the reaction mixture in 62% yield. The spectroscopic properties of this compound were very similar to those of **6**. In particular, in the ^1H nmr spectrum in TFA, there were four signals attributed to methylene signals as follows. There were two apparent triplets at 3.40 and 4.30 δ assigned to hydrogens at C-5 and C-6, respectively, and two broad singlets at 4.65 and 5.20 δ attributed to hydrogens at C-13 and C-8, respectively. The ir and ms were also in accord with the assigned structure and were similar to those of **6**. Reduction of **12** with sodium borohydride afforded **13**, a compound previously described in the literature (16. 17). The mass spectrum of this compound was typical of the protoberberine group in that it showed a molecular ion at *m/e* 295 (90) and a typical fragment ion at *m/e* 164 (100).

In a second series of experiments to test this new route to the tetrahydroprotoberberines, the quaternary salt **9b** was prepared and converted to the mercaptal **10b**. Like its analogue **10a**, this compound was relatively unstable and decomposed on attempted chromatography. When it was treated with $NaCNBH_3$ under the same conditions that led to the conversion of **10a** to **11a**, it did not give the expected product but instead *N*-(2,3-dimethoxybenzyl)-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline was obtained. Apparently in this medium **10b** must exist in equilibrium with **9b** and MMTS anion and suffers reduction to the observed product. Conversion to **4a** was achieved by changing the solvent system by replacing methanol with

THF. Under these conditions **10***b* was converted into **4***a* again accompanied by spectacular color changes. The overall yield of **4***a* from **9***b* was 43%. The chromatographic behaviour of this reaction sequence was identical with that reported in the derivation of **4***a* from a dihydroisoquinoline. Nevertheless the product **4***a* from this sequence was carried through the sequence **4***a* → **6** → **1***a* to verify its structure.

The conversion of **9***a* and **9***b* to the tetrahydroprotoberberine system demonstrates that isoquinolines may be substituted for dihydroisoquinolines in this synthetic route although the yields are not as high. Nevertheless the fact that isoquinolines may be used as starting materials greatly broadens the range of substitution patterns available using this synthetic approach.

The synthetic strategy used here is similar to that of Bradsher *et al.* (18) in that ring C is formed in the final step of the synthesis by introduction of a one-carbon unit that becomes C-13 of the protoberberine system. This procedure is however more direct than its earlier counterpart.

The manner in which compounds of structure **4** cyclize to compounds of structure **5** has not been investigated in detail. Previous investigators (19) have studied the hydrolysis of mercaptal sulfoxides to aldehydes and it is possible that an aldehyde intermediate may be involved in the cyclization step in this instance, although our attempts to intercept an aldehyde were unsuccessful. It is more likely that the cyclization proceeds through the cation generated in the acidic medium by loss of CH_3SOH from the mercaptal sulfoxide. This cation would be stabilized not only by the adjacent sulfur atom but also by the neighboring nitrogen (20). The cyclized product would then lose CH_3SH to form the dihydroprotoberberines, isolated as compounds **5** or **6**, depending upon the procedure employed.

Trost *et al.* (21) have reported similar cyclizations of mercaptals and mercaptal sulfoxides in which they isolated the cyclized product still containing an S—CH_3 group. They noted that CH_3SH was expelled when the initial cyclization product was heated in a more strongly acidic medium. We have not observed a sulfur-containing cyclization product in these studies but, in view of the results of Trost *et al.*, one would not be expected under the strongly acidic reaction conditions that were used.

Oikawa and Yonemitsu (ref. 22, and references therein) have reported on the cyclization of β-ketosulfoxides in the presence of acids and have used this reaction in the synthesis of a variety of carbocyclic and heterocyclic systems. They too have isolated S—CH_3 compounds as primary products of cyclization and have proposed a similar cyclization process.

Experimental

Apparatus, Materials, and Methods

The continuous wave ^1H nmr spectra were run on a Varian EM 390 or T-60 spectrometer. The Fourier transform spectra were run on either a Bruker WP 80 or WH 90 spectrometer. Unless otherwise specified, the samples were dissolved in chloroform-*d* using tetramethylsilane (TMS) as the internal standard. Chemical shifts, quoted as δ values, were measured in relation to TMS. The symbols s singlet, d doublet, t triplet, q quartet, and m multiplet are used in reporting spectra.

Mass spectra were recorded on either a Consolidated Electrodynamics Corporation Model #21-110B mass spectrometer or a V.G. Micromass 7070 F mass spectrometer, at 70 eV.

Infrared spectra were recorded on a Perkin Elmer 283 spectrometer in chloroform solution. Melting points were determined on a Kofler micro hot stage and are uncorrected. The microanalyses were performed by the Guelph Chemical Laboratories Ltd., Guelph, Ontario or by Microanalysis Laboratories Ltd., Toronto, Ontario.

Column and thin-layer chromatography (tlc) were performed using silica gel 60 as the adsorbent. Gravity columns were run using Baker 60–200 mesh silica, and "flash" columns prepared as described in the literature (9). Lobar columns were run using a prepacked Merck silica gel 60, size B column.

Tetrahydrofuran (THF) was dried by distillation from sodium in a nitrogen atmosphere, just prior to use. The following compounds were prepared by standard methods and gave satisfactory physical and spectral data: 6,7-dimethoxy-3,4-dihydroisoquinoline (23), 2,3-dimethoxybenzyl chloride (24), 2,3-dimethoxybenzyl bromide (25), 3,4-dimethoxybenzyl chloride (26), and 6,7-dimethoxyisoquinoline (27).

*3,4-Dihydro-6,7-dimethoxy-*N*-(2,3-dimethoxybenzyl)isoquinolinium Bromide 3*a

To a solution of 3,4-dihydro-6,7-dimethoxyisoquinoline (5.6 g) in benzene (40 mL), 2,3-dimethoxybenzyl bromide (6.7 g) was added slowly. The mixture was stirred for 24 h at room temperature, and the yellow precipitate was filtered and recrystallized from ethanol (11 g, 89%) yielding pale yellow crystals melting at 202–205°C; ^1H nmr (CD_3OD): 3.0–4.0 (m, 4H, $-CH_2-CH_2-N^+$), 3.83 (6H, s, 2 × OCH_3), 3.86 (3H, s, OCH_3), 3.93 (3H, s, OCH_3), 5.10 (2H, s, N^+-CH_2-Ar), 7.03 (1H, s, aromatic), 7.08 (3H, s, aromatic), 7.43 (1H, s, aromatic), and 9.01 (1H, s, $H-C=N^+$). *Anal.* calcd. for $C_{20}H_{24}O_4NBr$: C 56.91, H 5.68, N 3.31, Br 18.93%; found: C 56.57, H 5.72, N 3.21, Br 18.78%.

*3,4-Dihydro-6,7-dimethoxy-*N*-(2,3-dimethoxybenzyl)isoquinolinium Chloride*

To a stirring solution of the 3,4-dihydro-6,7-dimethoxyisoquinoline (2.0 g, 10.5 mmol) in benzene (50 mL) was added the 2,3-dimethoxybenzyl chloride (2.0 g, 10.7 mmol) dropwise. The solvent was removed under vacuum after 24 h, and the oily residue crystallized from benzene–ethanol 20:1 to yield yellow prisms (3.87 g, 10.2 mmol, 97%), mp 187–189°C; ^1H nmr: 3.16 (2H, t, $-CH_2-CH_2-N^+$, J = 7.5 Hz), 3.8–4.0 (2H, m, $CH_2-CH_2-N^+$), 3.88 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 3.96 (3H, s, OCH_3), 4.00 (3H, s, OCH_3), 5.44 (2H, s, N^+-CH_2-Ar), 6.94–7.34 (4H, m, arom.), 7.74 (1H, s, arom.), 10.46 (1H, s, $-CH=N^+$).

*Condensation of Iminium Salt 3*a *with MMTS Anion*

To a solution of methyl methylthiomethylsulfoxide (MMTS)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

(700 mg) in anhydrous tetrahydrofuran (30 mL), 2.5 mL *n*-BuLi (2.2 *M* in hexane, a stoichiometric quantity) was added under an atmosphere of nitrogen. The temperature was maintained at −35°C during the addition and for 30 min afterwards. This cold solution was added dropwise via a syringe to a stirred suspension of iminium bromide **3***a* (1.5 g) in anhydrous tetrahydrofuran (50 mL). The suspension was cooled in Dry Ice – acetonitrile and the reaction was conducted under nitrogen. The mixture was stirred at −30°C for 3 h and during this period the solution became clear. Finally, 100 mL methylene chloride was added followed by 30 mL of water to hydrolyse excess LiMMTS. The organic phase was separated, dried over Na_2SO_4, and evaporated. The residue showed one major spot and two minor spots on tlc (alumina), (eluent, chloroform – ethyl acetate 4:1). The product (2 g) was separated by column chromatography on alumina (neutral) (80 g of Brockmann activity 1, mixed with 4.8 mL water). The solvents used as eluents were benzene, benzene–chloroform 9:1, 4:1, 1:1, and chloroform in that order. The pale yellow oil **4***a* (1.4 g, 98%) was a mixture (*vide infra*) that was used directly in the next step. ^{1}H nuclear magnetic resonance: 2.05, 2.23 (3H, 2s, SCH_3), 2.63, 2.70 (3H, 2s, $S(O)CH_3$), 3.78 (3H, s, OCH_3), 3.86 (9H, s, 3 × OCH_3), 2.3–4.8 (8H, m, 3 × CH_2 and N—C*H*—C*H*—S), and 6.6–7.3 (5H, m, arom.).

(±)-Tetrahydropalmatine **1***a from Mercaptal* **4***a*

(*a*) A mixture of **4***a* (370 mg) and concentrated HCl (7 mL) was heated on a steam bath for 5 min under nitrogen. The reaction mixture was cooled rapidly to 0°C, diluted with water (20 mL), and extracted three times with ether (50 mL) and the extract discarded. The aqueous phase was made basic by adding NaOH pellets slowly and then extracted three times with ether (50 mL). The combined ethereal extract was dried over K_2CO_3 and the solvent evaporated to dryness giving a yellow solid (216 mg, 66%) which was very air-sensitive. From its spectral properties (nmr and ir) the presence of the cyclized product **5***a* was indicated. The next step was carried out without purification.

(*b*) The cyclized yellow product **5***a* (216 mg) was dissolved in ethanol (25 mL) and an excess of $NaBH_4$ was added. The mixture was stirred at room temperature under nitrogen for one hour or until the color disappeared. After the solvent had been removed on the rotary evaporator, water was added to the reaction mixture and the excess hydride destroyed by careful addition of glacial acetic acid. The aqueous mixture was basified to pH 10 with NaOH pellets and extracted with ether (3 × 50 mL). The organic phase was shaken twice with 10% HCl to take up the basic material into the aqueous phase. Basification of the aqueous phase followed by extraction with ether (3 × 50 mL) and removal of the solvent gave a product, which did not need further purification. The compound was a white solid (167 mg, 76.7%), which melted at 147°C (lit. (28) mp 148°C); ^{1}H nmr: 2.7–4.0 (8H, m, two hydrogens each at C-5, C-6, C-13, and one each at C-8 and C-14), 3.90 (12H, s, 4 × OCH_3), 4.41 (1H, low field proton of AB quartet from hydrogens at C-8, J = 15 Hz), 6.70 (1H, s, arom.), 6.80 (1H, s, arom.), and 6.86 (2H, d, arom.).

The free base, tetrahydropalmatine, is air and light sensitive and the compound was converted to palmatine iodide to confirm the identity of the product.

Palmatine Iodide **2***a*

A solution of iodine (100 mg) in methanol (20 mL) was added dropwise to a refluxing solution of tetrahydropalmatine **1***a* (100 mg) prepared above and potassium acetate (100 mg) in methanol (15 mL) over a period of 4 h. Refluxing was continued for another two hours, and the mixture was cooled. The orange needle-shaped crystals were separated by filtration (128 mg, 95%), mp 237–238°C (authentic sample mp 239°C).

The ir and nmr spectra of the synthetic sample and of an authentic sample were superimposable, ^{1}H nmr (CF_3CO_2H); 3.35 (2H, t, hydrogens at C-5), 3.98 (3H, s, OCH_3), 4.05 (6H, s, 2 × OCH_3), 4.22 (3H, s, OCH_3), 5.00 (2H, t, hydrogens at C-6), 6.92 (1H, s, arom.), 7.52 (1H, s, arom.), 7.90 and 8.08 (2H, AB quartet, H-11 and H-12, J = 9 Hz), 8.65 (1H, s, H-13), 9.76 (1H, s, H-8).

*3,4-Dihydro-6,7-dimethoxy-*N*-(3,4-dimethoxybenzyl)isoquinolinium Chloride* **3***b*

To a solution of 3,4-dihydro-6,7-dimethoxyisoquinoline (3 g) in benzene (30 mL), 3,4-dimethoxybenzylchloride (3 g) was added slowly. The mixture was stirred for 24 h at room temperature, the yellow precipitate was separated by filtration and crystallized from 6:3:1 benzene–acetone–ethanol yielding 5.3 g (89.8%) of yellow hygroscopic prisms, melting at 123–127°C; ^{1}H nmr (CD_3OD): 2.9–3.5 (4H, m, H's at C-5 and C-6), 3.81 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 3.95 (3H, s, OCH_3), 5.06 (2H, s, Ar—CH_2—N^+), 6.8–7.2 (4H, m, arom.), 7.40 (1H, s, arom.), and 9.01 (1H, s, H-1).

Condensation of Iminium Salt **3***b with MMTS Anion*

The solution of the MMTS anion, generated from MMTS (700 mg) and *n*-BuLi 2.2 *M* (2.5 mL) in dry THF, as previously described, was added dropwise via a syringe to a stirred suspension of the iminium chloride **3***b* (1.5 g) in anhydrous THF (50 mL). The system was cooled in Dry Ice – acetonitrile and kept under nitrogen. The mixture was stirred at −35°C for 3 h and during this period the solution became clear. In the work-up methylene chloride was added and then water. The organic phase was separated, dried (Na_2SO_4), and evaporated. The crude residue, a brownish oil (~2 g), was separated by column chromatography using the same stationary phase and eluents as before. The pale yellow oil **4***b* (1.5 g, 94%) was examined by nmr; ^{1}H nmr: 2.00 and 2.20 (3H, 2s, SCH_3), 2.63 and 2.73 (3H, 2, $S(O)CH_3$), 3.85 (12H, s, 4 × OCH_3), 2.9–4.7 (8H, m, other nonarom. H's), 6.6–7.4 (5H, m, arom.).

(±)-Xylopinine **1***b from Mercaptal* **4***b*

(*a*) A mixture of **4***b* (600 mg) and concentrated HCl (7 mL) was heated on a steam bath for 5 min under nitrogen. Following the same work-up as with (±)-tetrahydropalmatine, a bright yellow solid was obtained (350 mg, 66%) which was recrystallized from CH_2Cl_2–ether–methanol 7:2:1 yielding **5***b* as yellow square crystals melting at 173–176°C with decomposition; ^{1}H nmr: 2.7–3.4 (4H, m, H's at C-5 and C-6), 3.83 (9H, s, 3 × OCH_3), 3.90 (3H, s, OCH_3), 4.13 (2H, s, H's at C-8), 5.92 (1H, s, H-13), 6.55 (3H, s, arom.), and 7.15 (1H, s, arom.). The cyclized product **5***b* was air sensitive and the next step followed immediately.

(*b*) The $NaBH_4$ reduction of the cyclized product **5***b* (350 mg) in ethanol was carried out at room temperature under nitrogen until the color disappeared. The reduction product was obtained following the same work-up as before, yielding a white flaky solid (270 mg, 77%) which was recrystallized from ethanol (mp 156–157°C). The nmr spectrum is identical with the published spectrum (10); ^{1}H nmr: 2.56–4.32 (9H, m, H's at C-5, C-6, C-8, C-13, and C-14) 3.82 (9H, s, 3 × OCH_3), 3.83 (3H, s, OCH_3), 6.54–6.71 (4H, m, arom.).

2,3-Methylenedioxybenzyl Chloride

To 2,3-methylenedioxybenzyl alcohol (2 g) (29), thionyl chloride (3 mL) was added dropwise and the mixture was stirred at room temperature for 2 h. The excess thionyl chloride was removed on the rotary evaporator and the dark brown oil distilled under vacuum. The product was a colorless oil (bp 52°C/0.05 Torr) (1.5 g, 68%); ^{1}H nmr: 4.50 (2H, s, CH_2Cl), 5.85 (2H, s, O—CH_2—O), and 6.72 (3H, s, arom.).

*3,4-Dihydro-6,7-dimethoxy-*N*-(2,3-methylenedioxybenzyl)isoquinolinium Chloride* **3***c*

To a solution of 3,4-dihydro-6,7-dimethoxyisoquinoline

TABLE 1. ^{1}H nmr data of fractions from chromatography of mercaptal **4***a*

Component (R_f on silica gel, Et_2O/EtOH = 8:1)	Wt. recovered from column (mg)	^{1}H nmr chemical shifts: —S—CH_3 and —S(=O)—CH_3	^{1}H nmr chemical shifts: —OCH_3	^{1}H nmr chemical shifts: Aromatic
0.33[a]	360	2.16(s), 2.22(s) 2.36(s), 2.62(s)	3.78(3H, s), 3.88(3H, s) 3.89(3H, s), 3.91(3H, s).	6.60–7.16(5H, m)

0.16[b]	280	2.02(s), 2.30(s) 2.68(s), 2.70(s)	3.78(3H, s), 3.85(6H, s), 3.88(3H, s).	6.62–7.24(5H, m)

[a]This fraction was later resolved into two components by tlc using hexane–ethanol–THF 6:3:1.
[b]This fraction contains MMTS.

(1.5 g) in benzene (30 mL), 2,3-methylenedioxybenzyl chloride (1.5 g) was added slowly. The mixture was stirred for 24 h at room temperature. The yellow solid was filtered and recrystallized from methylene chloride – ether 4:6 yielding yellow crystals melting at 164–166°C. Yield: 2.5 g, 80%, ^{1}H nmr: 3.0–3.7 (4H, m, 2 × CH_2), 3.88 (3H, s, OCH_3), 3.95 (3H, s, OCH_3), 5.38 (2H, s, Ar—CH_2—N^+), 5.95 (2H, s, O—CH_2—O), 6.7–7.2 (4H, m, arom.), 7.68 (1H, s, arom.), and 10.05 (1H, s, H-1).

Condensation of Iminium Salt **3***c with MMTS Anion*

The solution of the MMTS anion, generated from MMTS (680 mg) and 2.2 *M* *n*-BuLi (2.4 mL) in anhydrous THF, was added dropwise via a syringe to a stirred suspension of the iminium chloride **3***c* (1.3 g) in anhydrous THF (50 mL). The mixture was cooled in Dry Ice – acetonitrile and kept under N_2 during the addition and was stirred at −35°C for an additional 3 h. Methylene chloride was added and then water. The organic phase was separated, dried (Na_2SO_4), and evaporated. The crude oily residue (~1.7 g) was separated by column chromatography as in the previous cases. The pale yellow oil, **4***c* (1.2 g, 92%), gave an ^{1}H nmr spectrum with the characteristic peaks present. Because of the complexity of the spectrum, probably because of impurities, assignment of the chemical shifts is not given.

(±)-Sinactine **1***c from Mercaptal* **4***c*

(*a*) The cyclization of **4***c* (310 mg) was carried out as before yielding a bright yellow solid, which was the cyclized product **5***c* (200 mg, 73%).

(*b*) The $NaBH_4$ reduction of **5***c* (200 mg) was carried out at room temperature and for 24 h under nitrogen. After work-up the product was obtained as a white solid (160 mg, 79%) melting at 166°C, lit. (30) mp 170°C. The ir spectrum and the nmr spectrum were superimposable on those of an authentic sample of sinactine; ^{1}H nmr: 2.4–4.4 (8H, m, two H's each at C-5, C-6, and C-13 and 1H each at C-8 and C-14), 3.81 (3H, s, OCH_3), 3.83 (3H, s, OCH_3), 4.08 (1H at C-8, lower field portion of an AB quartet, J = 15 Hz), 5.85 (2H, m, O—CH_2—O), and 6.5–6.8 (4H, m, arom.).

Chromatography of Adduct **4***a*

The yellow oily residue **4***a*, obtained by condensation of **3***a* with MMTS anion, showed a mixture of components by tlc on silica. Using ether–ethanol (abs.) 8:1, three components were visible at R_f 0.16, 0.20, and 0.33. Large scale (1.0 g) chromatography of the crude oil by the method of Still *et al.* (9) using the same solvent system used for tlc gave three fractions corresponding in R_f value to the three components found on tlc. Each of these fractions was examined by ^{1}H nmr and the data are summarized in Table 1.

The three fractions were also examined by ms. Apart from differences in intensity of the peaks, the 3 spectra were similar, as expected of diastereomers. Major peaks in the spectrum of the fraction, R_f 0.20, are given expressed as *m/e* values with intensities in brackets: 447(10), 432(20), 401(80), 386(40), 370(40), 354(100), 342(40), 340(15), 338(10), 325(40), 324(100), 323(50), 322(60), 308(15), 250(15).

Cyclization of Mercaptals **4***a to Dihydropalmatine Chloride* **6**

Each of the three fractions (Table 1) isolated from the column was subjected to cyclization by the following procedure. The yellow oil (75 mg) was dissolved in concentrated HCl (3.5 mL) and heated in a flask equipped with a reflux condenser on a steam bath in an atmosphere of N_2. The flask was allowed to cool to room temperature and was then placed in an ice–salt bath. Bright yellow crystals of **6** were obtained in 70 to 90% yield, which were recrystallized from concentrated HCl and washed with cold acetone and ether. The melting points observed for the cyclized materials obtained from the R_f 0.33, 0.20, and 0.16 mercaptals were 152–157°C (dec.), 153–162°C (dec.), and 157–165°C (dec.), respectively. The differences in the melting points of the three products are probably due to varying degrees of solvation of the crystals. The samples were examined spectroscopically as follows. In the ms the three products of cyclization gave similar fragmentation patterns, including a base peak at *m/e* 353, corresponding to the loss of H from the iminium cation. The intensities of the peaks in the three spectra varied, probably because of decomposition of the samples at the probe temperatures necessary to volatilize the chloride salts. The spectrum of the cyclization product of the mercaptal R_f 0.33 is given, where only peaks ≥ 20% of the base peak are recorded: 355(35), 354(35), 353(100), 352(45), 338(35), 190(25), 164(50), 149(35).

The ir spectrum of the samples were also similar and that of the sample obtained from the fraction R_f 0.33 is ir $\nu_{max}(CHCl_3)$: 1634, 1602, and 1564 cm^{-1}.

The ^{1}H nmr spectrum of the sample in TFA is: 3.40 (2H, m, C-5), 4.04 (3H, s, —OCH_3), 4.15 (9H, s, 3 × OCH_3), 4.16–4.35 (2H, m, C-6), 4.64 (2H, s(broad), C-13), 5.30 (2H, s(broad), C-8), 6.94–7.78 (4H, m, arom.).

Reduction of Dihydropalmatine Chloride **6** *to (±)-Tetrahydropalmatine* ***1****a*

Each of the cyclized products was subjected to borohydride reduction by the following method. To a solution of the chloride (14 mg, 0.04 mmol) in absolute EtOH (10 mL) was added sodium borohydride in excess. The mixture was stirred mechanically under N_2 for 45 min, at which time the reaction appeared complete by tlc (ether). Solvent was removed under vacuum, H_2O added (15 mL), and glacial acetic acid added dropwise with cooling to remove unreacted $NaBH_4$. Basification with a saturated solution of NaOH to pH > 10 was followed by extraction with ether (4 × 15 mL). The organic phase was shaken with 10% HCl (3 × 10 mL) after which the aqueous layer was basified to pH > 10 with NaOH (saturated solution). Extraction of the basic solution with ether (3 × 15 mL), followed by drying over Na_2SO_4 and concentration under vacuum, yielded a pale white crystalline product (11.7 mg, 90%) mp 146–148°C (lit (28) mp 148°C), whose spectroscopic properties were identical with those of (±)-tetrahydropalmatine.

All three reduction products were identical.

Dehydrocorydaline Iodide **7**

Dihydropalmatine chloride **6** (288 mg, 0.74 mmol) was treated with 10% acetic acid (10 mL), 30% formaldehyde (1 mL), and sodium acetate (124 mg). The mixture was heated on a steam bath for 15 min under N_2, after which 2.5 mL of a saturated solution of NaI was added. The flask was cooled to room temperature, then placed in the refrigerator. The fine yellow needles which formed (247 mg, 68%) were recrystallized from 47–51% HI to yield bright yellow square prisms, mp 139–143°C (dec.). ^{1}H nmr: 3.00 (3H, s, CH_3), 3.30 (2H, m, CH_2—CH_2—N^+), 3.96 (3H, s, OCH_3), 4.02 (3H, s, OCH_3), 4.08 (3H, s, OCH_3), 4.32 (3H, s, OCH_3), 5.12 (2H, m, CH_2—CH_2—N^+), 7.00 (1H, s, arom.), 7.25 (1H, s, arom.), 8.02 (2H, s, arom.), 10.25 (1H, s, arom.).

(±)-Corydaline ***8***

To a solution of the iodide (65 mg, 0.13 mmol) in 95% EtOH (10 mL) was added $NaBH_4$ (10 mg, 0.26 mmol). The mixture was stirred mechanically under N_2 for 1 h, at which time the reaction mixture was still deep orange in color. A further 10 mg of borohydride were then added along with one drop of glacial acetic acid. The color of the reaction mixture changed immediately to pale yellow, and tlc (ether – petroleum ether 9:1) showed one major component present at R_f 0.4. Solvent was removed under vacuum, H_2O added (15 mL), and excess $NaBH_4$ was destroyed by the careful addition of glacial acetic acid. Basification to pH > 10 with a saturated solution of NaOH was followed by extraction with ether (3 × 20 mL). This extract was shaken with 10% HCl (2 × 25 mL) and the aqueous layer basified to pH > 10 as before. This alkaline solution was extracted with ether (3 × 25 mL), and the organic extract dried over Na_2SO_4 and concentrated under vacuum to yield a yellow solid (29 mg, 60%). Recrystallization from absolute EtOH yielded deep yellow prisms, mp 135–136°C (lit. (20) mp 135°C); ^{1}H nmr (identical with that of natural corydaline): 0.90 (3H, d, CH_3, J = 6 Hz), 2.40–4.45 (8H, m, H's at C-5, C-6, C-8, C-13, and C-14), 3.88 (12H, s, 4 × OCH_3), 6.59 (1H, s, arom.), 6.68 (1H, s, arom.), 6.82 (1H, s, arom.), 6.86 (1H, s, arom.). ms: The mass spectrum showed a parent peak at m/e 369 (intensity 30%) and a base peak at m/e 178 corresponding to $C_{11}H_{14}O_2$ (21).

N-*(3,4-Dimethoxybenzyl)isoquinolinium Chloride* ***9****a*

Isoquinoline (3.22 g, 25 mmol, freshly distilled from zinc dust (224°C/760 Torr)) was dissolved in benzene (30 mL). 3,4-Dimethoxybenzylchloride (4.41 g, 23.6 mmol) was added slowly, and the mixture refluxed gently for 24 h. At this time, the yellow crystals which had formed were filtered off and washed. The solid was dried on filter paper to yield 3.92 g (12.4 mmol, 50%) of product. The mother liquor was heated under reflux for a further 3 h producing 0.30 g of yellow crystals (total yield 54%); ^{1}H nmr (CD_3OD): 3.81 (3H, s, OCH_3), 3.85 (3H, s, OCH_3), 5.95 (2H, s, N—CH_2—Ar), 6.98–7.30 (3H, m, arom.), 7.96–8.30 (4H, m, arom.), 8.48–8.82 (2H, m, —CH=CH—N), 10.20 (1H, s, HC=N). *Anal.* calcd. for $C_{18}H_{18}O_2NCl$: C 68.52, H 5.75, N 4.44, Cl 11.24%; found: C 68.53, H 5.69, N 4.14, Cl 11.15%.

Condensation of MMTS Anion with Quaternary Salt ***9****a*

(a) Anion Generation

To 1.10 g of freshly distilled MMTS was added THF (50 mL), and the solution was stirred mechanically under dry argon and cooled to −35°C. To this solution was added 4.2 mL of *N*-BuLi (2.14 *M* in hexane, 1 equiv.) dropwise via a syringe. The solution was stirred under dry argon for 45 min at −35°C.

(b) Condensation

The cold solution from (*a*) was added dropwise via a syringe needle to a cold (−35°C) stirred suspension of isoquinolinium chloride **9***a* (1.57 g, 5.0 mmol) in THF (75 mL). The suspension was stirred mechanically under argon and its temperature maintained at −35°C for a further 3.5 h, during which time the solution became red in color. At this time, 150 mL of CH_2Cl_2 were added, followed by 40 mL H_2O to hydrolyse unreacted LiMMTS. The organic layer was drained off, and the aqueous fraction washed with CH_2Cl_2 (20 mL). The organic layers were combined, dried over Na_2SO_4, and concentrated under vacuum to yield 2.66 g (6.6 mmol, > 100%) of brown oil (crude **10***a*) which showed four components present by tlc (THF–hexane 6:1). The ^{1}H nmr of the crude material was very complex, showing at least six S—CH_3 peaks. Attempts to chromatograph the mixture on silica gel resulted in rapid decomposition to very polar material.

Reduction of Enamine ***10****a*

A stirred solution of **10***a* (2.62 g), in methanol (20 mL) and glacial acetic acid (50 mL), was treated with $NaCNBH_3$ (419 mg). Within two minutes of the addition of the cyanoborohydride, the deep purple solution turned clear yellow. Since the tlc of the solution (THF–hexane 6:4) was not conclusive, and no further changes were noted in the reaction flask, the solvent was removed under vacuum, 0.1 *N* NaOH added (30 mL), and the solution extracted with ether (3 × 40 mL). During the course of the extraction, 2 *M* NaOH was added to maintain pH > 10. The ethereal layers were combined and shaken with 10% HCl (4 × 20 mL) to take the basic material into the aqueous phase. Basification of the aqueous extract to pH > 10 with saturated NaOH solution was followed by extraction with ether (3 × 50 mL). The extract was dried over Na_2SO_4 and concentrated under vacuum to yield a yellow oil **11***a* (1.23 g, 60% based on quaternary salt **9***a* used in the MMTS condensation). The tlc of the oil (THF–hexane 6:4) showed three components present at R_f 0.12, 0.21, and 0.24, whereas the starting material showed four spots from R_f 0.14 to 0.29; ^{1}H nmr: 1.94 (3H, s, S—CH_3), 2.18 (3H, s, S—CH_3), 2.50 (3H, s, S(O)CH_3), 2.76 (3H, s, S(O)CH_3), 2.62–4.75 (4H, m, N—CH_2—Ar and N—CH—CH—S), 3.56 (2H, t, —CH_2—CH_2—N, J = 4.5 Hz), 3.72 (2H, t, —CH_2—CH_2—N, J = 4.5 Hz), 6.72–7.34 (7H, m, arom.).

Cyclization of **11***a to Iminium Salt* **12**

The reduction product above, **11***a* (1.23 g, 3.04 mmol as pure compound), was dissolved in concentrated HCl (15 mL) and heated in a steam bath in a flask equipped with a reflux condenser under N_2 for 10 min. The flask was placed in the refrigerator overnight, after which the crystals were filtered off, washed, and dried on the vacuum line over P_2O_5. The yield of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12
For personal use only.

yellow crystals was 617 mg (1.87 mmol, 62% in this step, 37% relative to the *N*-benzyl isoquinolinium salt **9***a*); ir $\nu_{max}(CHCl_3)$: 1631, 1610 and 1576 cm^{-1}; ^1H nmr (TFA): 3.40 (2H, t, C-5, J = 7.5 Hz), 4.04 (6H, s, 2 × OCH_3), 4.30 (2H, t, C-6, J = 7.5 Hz), 4.65 (2H, s(broad), C-13), 5.20 (2H, s(broad), C-8), 6.98 (1H, s, arom.), 7.08 (1H, s, arom.), 7.50–8.20 (4H, m, arom.). The mass spectrum showed a peak at *m/e* 295 ($M^+ + 1$) and the expected peaks at *m/e* 132 and 164 (base peak).

10,11-Dimethoxy-5,6,13,13a-tetrahydro-8H-dibenzo[a,g]-quinolizine **13**

To an ice cold solution of the iminium salt **12** (100 mg, 0.30 mmol) in 95% EtOH (10 mL) was added excess $NaBH_4$. The mixture was allowed to warm to room temperature and was stirred under N_2 for 1 h. At this time the reaction appeared complete by tlc (ether) so the solvent was removed under vacuum, H_2O added (10 mL), and unreacted $NaBH_4$ destroyed by adding glacial acetic acid with cooling in ice. Basification to pH > 10 with a saturated solution of NaOH was followed by extraction with ether (4 × 20 mL). The ethereal extract was shaken with HCl (3 × 25 mL) and the aqueous extract basified to pH > 10 as above. Extraction with ether (4 × 25 mL) followed by drying over Na_2SO_4 and concentration under vacuum yielded white crystals (75 mg, 0.25 mmol, 83%) which were recrystallized from EtOH (abs.)/$CHCl_3$, mp 124–125°C; ^1H nmr: 2.62–3.85 (9H, m, H's at C-5, C-6, C-8, C-13, and C-14), 3.85 (6H, s, 2 × OCH_3), 6.55 (1H, s, arom.), 6.60 (1H, s, arom.), 7.10–7.20 (4H, m, arom.). The mass spectrum showed a molecular ion at *m/e* 295(90) corresponding to $C_{19}H_{21}N$ and a base peak at 164 corresponding to $C_{10}H_{12}O_2$. *Anal.* calcd. for $C_{19}H_{21}O_2N$: C 77.29, H 7.12, N 4.74%; found: C 77.60, H 7.55, N 4.73%.

6,7-Dimethoxy-N-(2,3-dimethoxybenzyl)isoquinolinium Chloride **9**b

To a solution of 6,7-dimethoxyisoquinoline (1.5 g, 7.9 mmol) in benzene (30 mL, freshly distilled from $CaCl_2$) was added 2,3-dimethoxybenzyl chloride **41** (1.5 g, 8.0 mmol) dropwise with mechanical stirring. The mixture was gently refluxed under a $CaCl_2$ drying tube for 24 h. At this time the fine white needles which had formed were filtered off, washed with fresh benzene, and dried. Since the yield of crystals was only 1.37 g (3.6 mmol, 46%), the mother liquor was stirred under reflux for a further 48 h. A further 1.22 g of crystals were obtained (3.2 mmol, total yield 86%). The solid was recrystallized from benzene–chloroform producing white rods mp 109–112°C; ^1H nmr: 3.82 (3H, s, OCH_3), 3.94 (3H, s, OCH_3), 4.08 (3H, s, OCH_3), 4.15 (3H, s, OCH_3), 6.10 (2H, s, N^+—CH_2—Ar), 6.92–7.58 (4H, m, arom.), 7.98 (1H, s, arom.), 8.14, 8.48 (2H, AB quartet, N^+—CH=CH, $J_{3,4}$ = 7.5 Hz), 10.72 (1H, s, HC=H^+).

Reaction of **9**b *with the Anion of MMTS*

A solution of MMTS anion generated from MMTS (445 mg) as previously described was added dropwise to a stirring suspension of the chloride **9***b* (735 mg, 1.96 mmol, dried overnight over P_2O_5, 0.01 Torr at 82°C) in 30 mL freshly distilled THF. The suspension was stirred mechanically under argon at −35°C for 3 h.

To the flask was then added 80 mL CH_2Cl_2, followed by 20 mL H_2O to hydrolyse excess LiMMTS. The organic layer was drained off and the aqueous layer washed with 10 mL CH_2Cl_2 which was then combined with the organic extract. This organic solution was dried over Na_2SO_4 and concentrated under vacuum to yield 1.09 g (2.4 mmol, > 100%) of brown oil (crude **10***b*).

Reduction of **10**b

To the enamine **10***b* (1.06 g, 2.3 mmol as pure material) was added THF (15 mL) and glacial acetic acid (25 mL). The deep purple mixture was stirred mechanically under N_2. To this solution was added $NaCNBH_3$ (239 mg, 3.8 mmol) and within 15 min, the color of the solution had changed from deep purple through red and orange, to yellow. At this time, tlc (ether–EtOH 8:1) showed that the reaction was complete. The solvent was removed under vacuum, H_2O (20 mL) added, then 2 *M* NaOH (20 mL) to make the solution strongly alkaline. This solution was extracted with ether and the organic extracts filtered on paper to remove an oily precipitate. The ethereal solution was shaken with 10% HCl (3 × 30 mL) and the ether layer was discarded. The aqueous solution was rendered strongly alkaline with a saturated NaOH solution. Extraction with ether (3 × 30 mL), followed again by filtration of the organic layer on paper, yielded a clear yellow ethereal solution which was dried over Na_2SO_4 and concentrated under vacuum. The product (crude **4***a*) was a yellow-green oil (383 mg, 0.824 mmol, 43% relative to quaternary salt **9***b*).

To remove both the polar and fast-moving contaminants, 200 mg of the crude oil were chromatographed on a flash column (ether–EtOH 8:1) which yielded 140 mg (70% recovery) of clear yellow oil. Thin-layer chromatography in this solvent system showed only the characteristic three components of **4***a* to be present. In order to confirm its identity the product was cyclized to **6** with concentrated HCl and the latter reduced to (±)-tetrahydropalmatine, identical with an authentic sample (28).

3-Diethylphosphonoacrolein diethylthioacetal anion (6*), a reagent for the conversion of aldehydes to α,β-unsaturated ketene dithioacetals and three-carbon homologated α,β-unsaturated aldehydes

GEORGE JUST,[1] PIERRE POTVIN, AND GHOLAM HOSEIN HAKIMELAHI
Department of Chemistry, McGill University, Montreal, P.Q., Canada H3A 2K6

Received July 21, 1980

GEORGE JUST, PIERRE POTVIN, and GHOLAM HOSEIN HAKIMELAHI. Can. J. Chem. **58**, 2780 (1980).

A short synthesis of the title compound is reported. It can be used to transform aldehydes to the corresponding α,β-unsaturated ketene dithioacetals, the sulfoxides of which can be converted to α,β-unsaturated aldehydes.

GEORGE JUST, PIERRE POTVIN et GHOLAM HOSEIN HAKIMELAHI. Can. J. Chem. **58**, 2780 (1980).

On décrit une courte synthèse du composé du titre, qui peut transformer les aldéhydes en dithioacétals de cétenes α,β-insaturés, dont les sulfoxides conduisent aux aldéhydes α,β-insaturées correspondantes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.105 on 09/05/12

No synthesis of the title compound (**6***) has hitherto been described. We felt that its chemistry should be useful and interesting, since the anion is stabilized and could be used as a three-carbon homologating agent for base-sensitive aldehydes (10).[2] We describe here the synthesis of **6***, and some of its applications.

Diethyl 2,3-epoxyprop-1-ylphosphonate **1** (2) was treated with sodium methoxide in methanol, and the resulting allylic alcohol **2** oxidized with pyridinium chlorochromate (4) to give the phosphonoacrolein **4**. Both **2** and **4** were characterized as their *p*-nitrobenzoate **3** and 2,4-dinitrophenylhydrazone **5** respectively. Reaction of phosphonoacrolein **4** with ethanethiol and zinc chloride (6) gave the dithioacetal **6**, which could be oxidized with *m*-chloroperbenzoic acid to give sulfoxide **9** as a mixture of geometric isomers. In the oxidation, the double bond of α,β-unsaturated phosphonate **6** was shifted into conjugation with the sulfoxide, providing a ketene dithioacetal *S*-oxide **9**.

Reaction of **6** with potassium *tert*-butoxide in tetrahydrofuran at −23°C for 15 minutes, followed by addition of either benzaldehyde **7***a*, diisopropylidene-L-arabinose **7***b*, or *tert*-butyl glyoxalate **7***c*, gave in nearly quantitative yield the corresponding α,β-unsaturated ketene dithioacetals **8***a–c*. Their oxidation with *m*-chloroperbenzoic acid gave the corresponding *S*-oxides **10***a–c*. Whereas ketene dithioacetals **8** were quite stable, the corresponding *S*-oxides had to be kept at low T (~−20°C) to ensure survival for a few days. *S*-oxide **10***b* was also obtained by reaction of **7***b* with ketene dithioacetal sulfoxide **9**, albeit in lower yield.

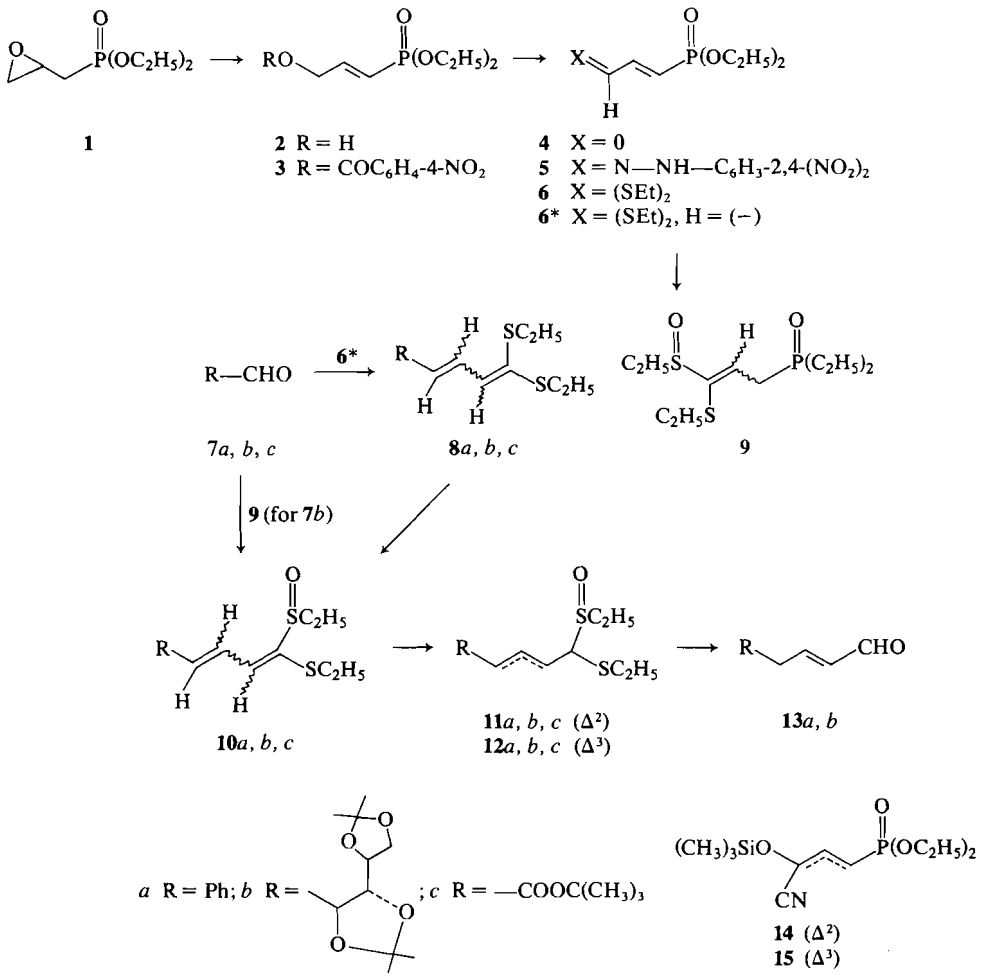
All attempts to hydrolyse either compounds **8***a,b* with mercuric chloride – mercuric oxide or red mercuric oxide – boron trifluoride (8), or **10***a,b* with perchloric acid (9), iodine, or mercuric chloride – mercuric oxide failed, or gave mixtures which were not identified. However, reaction of sulfoxides **10***a–c* with lithium triethylborohydride proceeded smoothly to provide a mixture of olefins **11** and **12**. Reaction of **11***a*/**12***a* with mercuric chloride – mercuric oxide in aqueous acetonitrile gave aldehyde **13***a*, which was extremely unstable. Similarly, **11***b*/**12***b* was converted to **13***b*; **13***c* could not be obtained by this method.

In pursuing the chemistry of aldehyde **4**, we reacted it with trimethylsilyl cyanide (12), and obtained an approx. 1:1 mixture of olefins **14** and **15**,[3] in quantitative yield. This mixture, when treated successively with potassium *tert*-butoxide and benzaldehyde in tetrahydrofuran at room temperature, did not give the Wittig-type product. The sole product obtained still contained the phosphonate grouping as well as a phenyl ring, by nmr analysis. Therefore, **14**/**15** cannot be used as a three-carbon homologating agent.

Experimental

For general procedures, see ref. 13. Although ir spectra were recorded for all compounds, only characteristic, assignable peaks are reported.

3-Diethylphosphonylallyl Alcohol (2) and its p-*Nitrobenzoate 3 (1)*



Diethyl 2,3-epoxyprop-1-ylphosphonate **1** (2) (9.71 g, 50 mmol) was treated with sodium methoxide in methanol (0.1 equiv.) dropwise, slowly, at 0°C, with stirring. After the addition, the

reaction was stirred a further 0.5 h at room temperature. Then 2 g of Dowex 50W-X8 (H^+) resin, previously washed with methanol, was added and the mixture was stirred for 15 min, at which time the resin was filtered off, washed with methanol, and the combined filtrate and washing were evaporated to dryness to give 9.71 g of crude allylic alcohol (100%), suitable for the next step, and characterized as its *p*-nitrobenzoate, prepared by standard means, and purified by flash chromatography (3) using ethyl acetate as eluent.

Compound **2**: ir (neat): 3450 (OH), 1630 (CH=CH) cm^{-1}; nmr ($CDCl_3$) δ: 1.32 (t, 6H, J = 7 Hz, OCH_2CH_3), 4.06 (2q, 4H, J = 7, 8 Hz, OCH_2CH_3), 4.28 (m, 2H, CH_2OH), 4.74 (b, 1H, OH, D_2O exch.), 5.96 (4t, 1H, J = 2, 17.5, 23 Hz, P—CH=CH), 6.84 (4t, 1H, J = 3, 17.5, 22 Hz, P—CH=CH); mass spectrum (70 eV, E.I.) *m/e*: 193 (M^+ − 1), 177 (M^+ − OH), 166, 165 (M^+ − Et), 163 (M^+ − CH_2OH), 149 (M^+ − OEt).

Compound **3**: ir (neat): 1727 (COOAr), 1640, 1608, 1525 (NO_2) cm^{-1}; nmr ($CDCl_3$) δ: 1.27 and 1.37 (2t, 6H, J = 7.5 Hz, OCH_2CH_3), 4.17 (2q, 4H, J = 7.5, 7.5 Hz, OCH_2CH_3), 5.01 (m, 2H, J = 1.5, 4.5 Hz, CH_2OBz), 6.01 (ABq of t, 1H, J = 1.5, 17, 18 Hz, P—CH=CH), 6.96 (ABq of t, 1H, J = 4.5, 18, 22 Hz, P—CH=CH), 8.33 (s, 4H, Ar); mass spectrum (70 eV, E.I.) *m/e*: 344 (M^+ + 1, base peak). *Anal.* calcd. for $C_{14}H_{18}NO_7P$: C 48.98, H 5.29, N 4.08; found: C 48.62, H 5.45, N 4.09.

3-Diethylphosphonoacrolein 4 and its 2,4-DNPH 5[4]

3-Diethylphosphoallyl alcohol **2** (1.94 g, 10 mmol) in 5 mL of dry methylene chloride was added dropwise to a stirred mixture of 2.59 g of pyridinium chlorochromate (4) (12 mmol) and 3 g of Celite in 30 mL of dry methylene chloride. The mixture was stirred for 2 h at room temperature, at which time it was filtered through Celite. The Celite pad was washed several times with methylene chloride, and the combined filtrate and washings were evaporated to dryness. The residue was triturated with ether and the solution was filtered through a Florisil pad, which was then washed several times with ether. The combined ethereal solutions were evaporated to dryness, giving 1.12 g of crude aldehyde containing some inorganic matter. This was distilled in a Kugelrohr apparatus (0.05 Torr, 100°C) to afford 1.00 g of pure aldehyde **4** (52%), bp 85–87°C (0.1 Torr). Its 2,4-dinitrophenylhydrazone **5** was prepared by the method of Parrick and Rasburn (5) and recrystallized from ethanol, mp 155–156°C.[4]

Compound **4**: ir (neat): 1710 (CHO), 1610 (CH=CH) cm^{-1};

[4]The aldehyde prepared here is of *trans*-geometry. The *cis*-isomer has been prepared by another, lengthier route, and it gives a *trans*- 2,4-dinitrophenylhydrazone, mp 160.5–161.5°C (see ref. 7).

nmr ($CDCl_3$) δ: 1.37 (t, 6H, J = 7 Hz, OCH_2CH_3), 4.15 (2q, 4H, J = 7, 8.5 Hz, OCH_2CH_3), 6.77 (m, 2H, CH=CH), 10.93 (t, 1H, J = 3.5 Hz, CHO); mass spectrum (70 eV, E.I.) m/e: 193 ($M^+ + 1$), 191 ($M^+ - 1$), 163 (M^+ − CHO), 147 (M^+ − OEt), 137 (M^+ − CHO—HC≡CH).

Compound **5**: *Anal.* calcd. for $C_{13}H_{17}N_4O_7P$: C 41.94, H 4.60, N 15.05; found: C 41.73, H 4.62, N 14.82.

3-Diethylphosphonoacrolein Diethyldithioacetal 6

Using a modification of the procedure of Barry and Craig (6), dithioacetal **4** was prepared as follows.

In an ice-salt bath, 1.08 g of 3-diethylphosphonoacrolein **4** (5.62 mmol) in 9.8 mL of ethanethiol were treated with 0.5 g of anhydrous zinc chloride, and the mixture was stored in the freezer (−15°C) for 18 h, at which time a further 0.5 g of zinc chloride was added. After a further 6 h in the cold, the ethanethiol was blown away through a copper sulphate solution with a nitrogen stream, and the thick residue was taken up in ethyl acetate (10 mL). The solution was washed with water (2 × 10 mL) and saturated sodium bicarbonate solution (2 × 10 mL). After standing exposed to bicarbonate for a few minutes, some precipitate formed, and was filtered off. The precipitate was washed with ethyl acetate, and the combined filtrate and washings were dried ($MgSO_4$) and evaporated to afford 1.39 g of crude dithioacetal (83%) suitable for further transformations. An analytical sample was obtained by purification through flash chromatography, using 60% ethyl acetate in petroleum ether as eluent. Infrared (neat): 1620 (CH=CH) cm^{-1}; nmr ($CDCl_3$) δ: 1.26 (t, 6H, J = 7.5 Hz, SCH_2CH_3), 1.33 (t, 6H, J = 7.5 Hz, OCH_2CH_3), 2.63 (q, 4H, J = 7.5 Hz, SCH_2CH_3), 4.11 (2q, 4H, J = 7.5, 7.5 Hz, OCH_2CH_3), 4.43 (dd, J = 1, 8 Hz, C*H*—CH=CH), 5.80 (A portion of ABq of dd, 1H, J = 2, 17, 19 Hz, P—C*H*=CH), 6.69 (B portion of ABq of dd, 1H, J = 7.5, 16.5, 20.5 Hz, P—CH=C*H*); mass spectrum (70 eV, E.I.) m/e: 298 (M^+, S_2-cluster), 269 (M^+ − Et, S_2-cluster), 237 (M^+ − SEt, S-cluster). *Anal.* calcd. for $C_{11}H_{23}O_3PS_2$: C 44.27, H 7.77, S 21.49; found: C 44.63, H 7.75, S 21.60.

3-Diethylphosphono-1,1-di(thioethyl)but-1-ene Mono-S-oxide 9

A solution of dithioacetal **6** (1.00 g, 3.35 mmol) in 35 mL of dry methylene chloride cooled to 0°C (ice bath) was treated dropwise with a solution of 0.68 g of *m*-chloroperbenzoic acid (85% pure, 3.95 mmol, 1.18 equiv.) in 35 mL of dry methylene chloride, under an N_2 atmosphere. The mixture was stirred 0.5 h after the addition, and then transferred to a separating funnel, where it was washed with saturated sodium bicarbonate solution (3 × 20 mL) and water (20 mL), dried ($MgSO_4$), and evaporated to dryness. Flash chromatography of the product using ethyl acetate as eluent afforded 0.85 g of pure *S*-oxide **9** (81%). Nuclear magnetic resonance ($CDCl_3$) δ: 1.18 (t, 3H, J = 7 Hz, SCH_2CH_3), 1.27 (t, 3H, J = 7.5 Hz, $S(O)CH_2CH_3$), 1.33 (t, 6H, J = 7 Hz, OCH_2CH_3), 2.61–3.41 (m, 6H, P—CH_2CH=C, SCH_2CH_3, $S(O)CH_2CH_3$), 4.13 (2q, 4H, J = 7, 7 Hz, OCH_2CH_3), 6.84 (dt, 1H, J = 6, 8 Hz, P—CH_2C*H*=C); mass spectrum (70 eV, E.I.) m/e: 315 ($M^+ + 1$), 299 ($M^+ - CH_3$), 269 (M^+ − OEt), 237 (M^+ − S(O)Et, S-cluster), 181 (S-cluster).

Ketene-S,S-acetals 8: General Procedure

A 1 *M* THF solution of 3-diethylphosphonoacrolein diethyldithioacetal **6** was added dropwise to a cooled (dry ice/CCl_4) and stirred suspension of potassium *tert*-butoxide (1.05 equiv.) in dry THF (2 mL/mmol), under an inert atmosphere. Fifteen minutes after the addition, a 1 *M* THF solution of the aldehyde **7** was added dropwise, and the mixture was allowed to stir a further 30 min. Water and ether were then added, and the separated aqueous layer was reextracted with ether. The combined ether layers were washed with water, dried ($MgSO_4$), and evaporated to give crude product, which was purified by flash chromatography. Crude product may be used directly for the next step.

Compound **8***a*: this compound was obtained in 75% yield, and chromatographed using 0.5% ethyl acetate – petroleum ether (30–60°C); nmr ($CDCl_3$) δ: 1.27 (t, 6H, J = 7 Hz, SCH_2CH_3), 2.81 and 2.83 (2q, 4H, J = 7 Hz, SCH_2CH_3), 6.43–7.70 (m, 8H, PhC*H*=C*H*—C*H*); mass spectrum (70 eV, E.I.) m/e: 250 (M^+, S_2-cluster). *Anal.* calcd. for $C_{14}H_{18}S_2$: C 67.15, H 7.25, S 25.61; found: C 66.68, H 7.52, S 25.71.

Compound **8***b*: this compound was obtained in 72% yield, and chromatographed using 5% ethyl acetate – petroleum ether; $[\alpha]_D^{22}$ −1.17° (*c* 4.88, $CHCl_3$); nmr ($CDCl_3$) δ: 1.10–1.40 (m, 18H, CH_3), 2.78 (q, 4H, SCH_2), 3.58–4.93 (m, 5H), 5.28–7.18 (m, 3H, C*H*=C*H*—C*H*); mass spectrum (70 eV, E.I.) m/e: 374 (M^+, S_2-cluster), 345 (M^+ − Et, S_2-cluster), 313 (M^+ − SEt, S-cluster).

Compound **8***c*: the *cis–trans* mixture was obtained in 60% yield, and purified by normal chromatography on silica gel, using CH_2Cl_2 as eluent. The *trans*-isomer was obtained by refluxing the *cis–trans* mixture in benzene for 24 h. Infrared (CH_2Cl_2): 1705 (COOR) cm^{-1}; nmr ($CDCl_3$) δ: 1.10–1.60 (m, 15H, CH_3), 2.61–3.20 (m, 4H, SCH_2), 5.40–5.90 (q, 1H, J = 14, 16 Hz, CH=C(SEt)$_2$), 6.40–8.00 (m, 2H, C*H*=C*H*—CH=C); nmr of *trans*-isomer ($CDCl_3$) δ: 1.10–1.60 (m, 15H, CH_3), 2.61–3.10 (q, 4H, J = 6 Hz, SCH_2), 5.71 (d, 1H, J = 14 Hz, C*H*=C(SEt)$_2$), 6.51 (d, 1H, J = 11 Hz, C*H*—COOC$(CH_3)_3$), 7.58–8.00 (2d, 1H, J = 11, 14 Hz, C*H*—CH=C(SEt)$_2$); mass spectra (70 eV, E.I.) m/e: 274 (M^+, S_2-cluster), 245 (M^+ − Et, S_2-cluster), 173 (M^+ − COOC$(CH_3)_3$, S_2-cluster); (70 eV, C.I.) m/e: 275 ($M^+ + 1$, S_2-cluster), 219 ($M^+ + 1 - CH_2$=C$(CH_3)_2$, S_2-cluster). *Anal.* calcd. for $C_{13}H_{22}O_2S_2$: C 56.93, H 8.03, S 23.35; found: C 56.81, H 8.10, S 23.09.

Ketene-S,S(O)-acetals 10

(a) Compound 10b, from Aldehyde 7b and 9

Using the same procedure as for **8***b*, the oxide **10***b* was obtained directly from **7***b* in 43% yield, after flash chromatography using 60% ethyl acetate in petroleum ether; $[\alpha]_D^{22}$ +5.66° (*c* 2.21, $CHCl_3$); nmr ($CDCl_3$) δ: 1.08–1.44 (m, 18H, CH_3), 2.59–3.17 (m, 4H, CH_2), 3.53–5.01 (m, 5H), 5.65–7.87 (m, 3H, CH=CH—CH=C(SEt)(S(O)Et)); mass spectrum (70 eV, E.I.) m/e: 390 M^+, S_2-cluster), 375 ($M^+ - CH_3$, S_2-cluster), 361 (M^+ − Et, S_2-cluster). *Anal.* calcd. for $C_{18}H_{30}O_5S_2$: C 55.35, H 7.74, S 16.42; found: C 55.44, H 8.00, S 16.53.

(b) From Ketene-S,S-acetals 8

To a stirred and cooled (ice bath) 0.1 *M* CH_2Cl_2 solution of ketene-*S,S*-acetal **8** was added 1.18 equiv. of a 0.16 *M* CH_2Cl_2 solution of technical grade *m*-chloroperbenzoic acid (85% pure), under an atmosphere of N_2. The solution was stirred an additional 30 min, then washed with saturated $NaHCO_3$ solution (2×) and water, dried ($MgSO_4$), and evaporated. All compounds were purified by flash chromatography, using 60% ethyl acetate in petroleum ether.

Compound **10***a*: this compound was obtained in 80% yield using crude **8***a*; nmr ($CDCl_3$) δ: 1.17 and 1.28 (2t, 6H, J = 7 Hz, CH_3), 2.78 and 3.38 (2q, ~3.2H and 0.8H, J = 7 Hz, CH_2), 6.47–8.00 (m, 8H, Ph—CH=CH—CH); mass spectrum (70 eV, E.I.) m/e: 266 (M^+, S_2-cluster), 237 (M^+ − Et, S_2-cluster), 205 (M^+ − SEt, S-cluster), 189 (M^+ − S(O)Et, S-cluster), 128. *Anal.* calcd. for $C_{14}H_{18}OS_2$: C 63.11, H 6.81, S 24.07; found: C 63.18, H 6.77, S 24.05.

Compound **10***b*: obtained by this method in 75% yield from crude **8***b* (60% overall from **7***b*). The product has identical physical data as that prepared previously using **9** on **7***b*.

Compound **10***c*: the *cis–trans* mixture was obtained in 85% yield. The *trans*-isomer was obtained by refluxing for 24 h a benzene solution of the *cis–trans* mixture. Infrared (CH_2Cl_2):

1690 (COOR) cm^{-1}; nmr ($CDCl_3$) δ: 1.10–1.60 (m, 15H, CH_3), 2.70–3.30 (m, 4H, SCH_2—), 5.80–6.38 (2d, 1H, J = 14, 16 Hz, C*H*=C(SEt)(S(O)Et)), 7.00–8.60 (m, 2H, C*H*=C*H*—CH=C); nmr of *trans*-isomer ($CDCl_3$) δ: 1.10–1.60 (m, 15H, CH_3), 2.70–3.10 (m, 4H, SCH_2—), 6.28 (d, 1H, J = 14 Hz, C*H*=C(SEt)(S(O)Et)), 7.11 (d, 1H, J = 10 Hz, C*H*—COOC$(CH_3)_3$), 7.80–8.60 (2d, 1H, J = 10, 14 Hz, CH=C*H*—CH=C); mass spectrum (70 eV, C.I.) *m/e*: 291 ($M^+ + 1$, S_2-cluster), 261 ($M^+ - Et$, S_2-cluster), 229 ($M^+ - SEt$, S-cluster), 152.

Olefins 11 and 12

Oxide **10** is dissolved in dry THF (3 mL/mmol) and 1.5 equiv. of a 1 *M* THF solution of lithium triethylborohydride were added at 0°C. After stirring for 1 h, the solution was evaporated and treated with water. This was then extracted with ether, and the ether solution was dried ($MgSO_4$) and evaporated to give crude product which was chromatographed on silica gel, using first CH_2Cl_2 to remove impurities, then $CHCl_3$ to elute the mixture of olefins.

Mixture **11***a*/**12***a*: this mixture was obtained in 80% yield. Compound **12***a* was fractionated by chromatography in 10% yield. Nuclear magnetic resonance ($CDCl_3$) δ: 1.02–1.60 (m, 6H, CH_3), 2.30–3.40 (m, 6H, CH_2—, SCH_2—), 3.50–4.40 (m, 1H, C*H*(SEt)(S(O)Et)), 5.40–6.80 (m, 2H, CH=CH), 7.3 (2s, 5H, Ph); nmr of **12***a* ($CDCl_3$) δ: 1.31, 1.45 (2t, 6H, CH_3), 2.41–3.21 (m, 6H, CH_2— and SCH_2—), 3.70, 3.81 (2t, 1H, CH(SEt)-(S(O)Et)), 6.00–6.80 (m, 2H, CH=CH), 7.4 (s, 5H, Ph); mass spectra (70 eV, E.I.) *m/e*: 268 (M^+, S_2-cluster); (70 eV, C.I.) *m/e*: 269 ($M^+ + 1$, S_2-cluster), 191 ($M^+ - Ph$). *Anal.* calcd. for $C_{14}H_{20}OS_2$: C 62.68, H 7.46, S 23.88; found: C 62.49, H 7.41, S 24.01.

Mixture **11***b*/**12***b*: the isomeric mixture was obtained in 75% yield; $[\alpha]_D^{22}$ −10.4° (*c* 1.25, $CHCl_3$); nmr ($CDCl_3$) δ: 1.20–1.42 (m, 18H, CH_3), 2.40–3.00 (m, 6H, CH_2— and SCH_2—), 3.80–4.21 (m, 5H), 5.40–6.60 (m, 2H, CH=CH); mass spectra (70 eV, E.I.) *m/e*: 392 (M^+, S_2-cluster); (70 eV, C.I.) *m/e*: 393 ($M^+ + 1$, S_2-cluster), 316 ($M^+ + 1 - S(O)Et$, S-cluster). *Anal.* calcd. for $C_{18}H_{32}O_5S_2$: C 55.10, H 8.16, S 16.32; found: C 55.31, H 8.09, S 16.61.

Mixture **11***c*/**12***c*: this mixture was obtained in 65% yield. Infrared (CH_2Cl_2): 1700 (COOR) cm^{-1}; nmr ($CDCl_3$) δ: 1.10–1.58 (m, 15H, CH_3), 2.30–3.10 (m, 6H, CH_2— and SCH_2—), 4.00–4.30 (m, 1H, CH(SEt)(S(O)Et)), 5.40–7.40 (m, 2H, CH=CH); mass spectrum (70 eV, C.I.) *m/e*: 293 ($M^+ + 1$, S_2-cluster), 236 ($M^+ + 1 - C(CH_3)_3$, S_2-cluster), 232 ($M^+ + 1 -$ SEt, S-cluster), 216 ($M^+ + 1 - S(O)Et$, S-cluster). *Anal.* calcd. for $C_{13}H_{24}O_3S_2$: C 53.42, H 8.21, S 21.91; found: C 53.61, H 7.99, S 22.17.

Aldehydes 13

Olefins **11**/**12** were dissolved in 95% aqueous CH_3CN (3 mL/mmol). Mercuric oxide (2.2 equiv.) and mercuric chloride (2.2 equiv.) were added, and the mixture was gently refluxed for 10 h. The whole was then evaporated, redissolved in CH_2Cl_2, and filtered. The filtrate was washed with water, dried ($MgSO_4$), and evaporated to give crude product, which was chromatographed on silica gel, using CH_2Cl_2 as eluent.

Compound **13***a*: this compound was obtained in 60% yield. Infrared (CH_2Cl_2): 1690 cm^{-1}; nmr ($CDCl_3$) δ: 3.50–3.70 (m, 2H, CH_2), 6.10 (2d, 1H, J = 8 Hz, C*H*CHO), 6.70–7.60 (m, 6H, Ph and C*H*=CHCHO), 11.12 (d, 1H, J = 8 Hz, CHO); mass spectra (70 eV, E.I.) *m/e*: 146 (M^+), 118 ($M^+ - CO$), 91 ($PhCH_2^+$); (70 eV, C.I.) *m/e*: 147 ($M^+ + 1$).

Compound **13***b*: this was obtained in 50% yield; $[\alpha]_D^{22}$ −13.3° (*c* 0.89, $CHCl_3$); ir (CH_2Cl_2): 1690 cm^{-1}; nmr ($CDCl_3$) δ: 1.10–1.30 (m, 12H, CH_3), 2.30–2.80 (m, 2H, CH_2—), 3.60–4.20 (m, 5H), 6.12 (2d, 1H, J = 8 Hz, C*H*CHO), 6.85 (2t, 1H, C*H*=CHCHO), 11.13 (d, 1H, J = 8 Hz, CHO); mass spectra (70 eV, E.I.) *m/e*: 270 (M^+); (70 eV, C.I.) *m/e*: 271 ($M^+ + 1$), 213 ($M^+ + 1 - (CH_3)_2CO$), 155 ($M^+ + 1 - 2(CH_3)_2CO$), 185 ($M^+ + 1 - CO - (CH_3)_2CO$).

The reactions of ethyl-, vinyl-, and ethynyl(trichloromethyl)carbinols with aqueous and methanolic potassium hydroxide, thiourea, and cyanamide[1]

WILKINS REEVE AND THOMAS F. STECKEL

Department of Chemistry, University of Maryland, College Park, MD 20742, U.S.A.

Received May 12, 1980

WILKINS REEVE and THOMAS F. STECKEL. Can. J. Chem. **58**, 2784 (1980).

The reactions of ethyl(trichloromethyl)carbinol, dimethyl(trichloromethyl)carbinol, (trichloromethyl)vinylcarbinol, ethynyl (trichloromethyl)carbinol, and 1,1,1,-trichloro-3-nonyn-2-ol have been studied with the following reagents. *Methanolic potassium hydroxide*: α-methoxy acids are formed in 70 and 79% yields with the ethyl- and vinylcarbinols respectively. Double bond migration to the conjugated position was observed with the vinylcarbinol. *Thiourea*: substituted 2-imino-4-thiazolidinones are formed in 27 to 66% yield with the first three carbinols with double bond migration in the case of the vinylcarbinol. *Cyanamide*: the saturated carbinols were converted to substituted ethyl 2-imino-4-oxo-1-imidazolidinecarboximidates in 30 to 60% yield. *Aqueous potassium hydroxide*: α-chloro acids were formed from the ethyl- and vinylcarbinols in 23 and 24% yields respectively, again with double bond migration in the case of the vinylcarbinol.

The results are discussed in terms of the known parallel reactions with phenyl (trichloromethyl)carbinol, and provide information which illustrates the usefulness and defines the limits of certain known synthetic reactions when applied to the alkyl, alkenyl, and alkynyl trichloromethylcarbinols.

WILKINS REEVE et THOMAS F. STECKEL. Can. J. Chem. **58**, 2784 (1980).

On a étudié les réactions des alcools éthyl(trichlorométhyl)carbinol, diméthyl(trichlorométhyl)carbinol, (trichlorométhyl)vinylcarbinol, éthynyl(trichlorométhyl)carbinol et trichloro-1,1,1 nonyne-3 ol-2 avec divers réactifs. Par réaction avec une solution méthanolique d'hydroxyde de potassium, on obtient les α-méthoxy acides avec des rendements respectifs de 70 et 79% dans le cas des alcools éthylique et vinylique. On a observé une migration de la double liaison vers la position conjuguée avec le carbinol vinylique. Avec la thiourée, il se forme des imino-2 thiazolidinones-4 substituées avec des rendements allant de 27 à 66% pour les trois premiers carbinols et une migration de la double liaison dans le cas du vinylcarbinol. Avec la cyanamide, les carbinols saturés se transforment en imino-2 oxa-4 imidazolidinecarboximidates-1 substitués avec des rendements allant de 30 à 60%. Avec l'hydroxyde de potassium aqueux il y a formation des acides α-chlorés avec des rendements respectifs de 23 et 24% dans les cas des carbinols éthylique et vinylique. On observe également une migration de la double liaison dans le cas du carbinol vinylique.

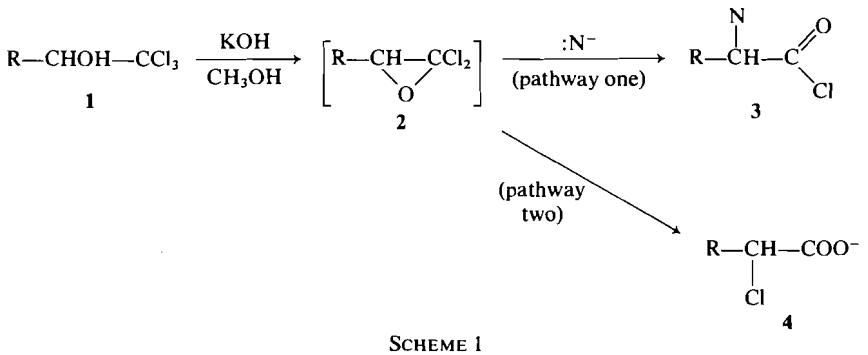
On discute des résultats en fonction des réactions paralèlles connues du phényl(trichlorométhyl)carbinol. Ces résultats fournissent des informations qui illustrent l'utilité et définissent les limites de certaines réactions connues quand on les applique aux alkyl, alkényl et alkynyl trichlorométhylcarbinols.

[Traduit par le journal]

Phenyl(trichloromethyl)carbinol has been shown to be a valuable reagent for the synthesis of α-alkoxy acids (1), α-chloro acids (2, 3), α-amino acids (4), as well as many heterocyclic compounds such as substituted thiadiazinones (5, 7), hydroxythiazoles (5), thiazolones (6, 7), and imidazolidinecarboximidates (8). Almost nothing is known about how well alkyl-, alkenyl-, and alkynyl-(trichloromethyl) carbinols undergo these reactions. Accordingly, we report here on the reactions of these carbinols with methanolic potassium hydroxide, thiourea, cyanamide, and cold aqueous potassium hydroxide solution. We have previously reported on the reactions of the aliphatic-(trichloromethyl)carbinols with phosphorus pentachloride and shown that a wide variety of compounds are formed (9).

Most of the various reactions summarized above can occur by either of two possible mechanisms (10). In both of the mechanisms the (trichloromethyl)carbinol is first converted *in situ* into epoxide **2**. In pathway one, the epoxide ring is opened by attack of a nucleophile to give **3** which is closely related to the final product. In contrast, the conversion of **2** to **4** via pathway two is a slower reaction which involves a chlorine migration at the epoxide stage to give alkyl or aryl substituted α-chloroacetate **4**. These compounds undergo further reaction in the usual way with nucleophiles to give α-substituted alkyl- or arylacetates. This second mechanism accounts for the conversion of secondary (trichloromethyl)carbinols into α-chloro acids (3) and is also a minor pathway in the formation of α-methoxyphenylacetic acid (10).

Reaction with Methanolic Potassium Hydroxide



Phenyl(trichloromethyl)carbinol is known to react with methanolic potassium hydroxide at 50°C by pathway one to form α-methoxyphenylacetic acid in 70 to 80% yield (10); and dimethyl(trichloromethyl)carbinol (chloretone) is known to react with sodium ethoxide in ethanol to form ethyl α-ethoxyisobutyrate in 72% yield (11), and with

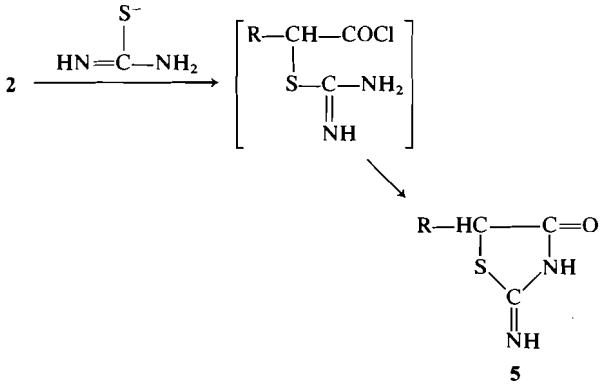
SCHEME 1

potassium hydroxide in methanol to form α-methoxyisobutyric acid in 71% yield (1).

In this work we have studied the reaction of methanolic potassium hydroxide with ethyl(trichloromethyl)carbinol as an example of a saturated alkyl(trichloromethyl)carbinol, and also with the unsaturated carbinols (trichloromethyl)vinylcarbinol, ethynyl(trichloromethyl)carbinol, and 1,1,1-trichloro-3-nonyn-2-ol.

Ethyl(trichloromethyl)carbinol gave α-methoxybutyric acid in 79% yield. (Trichloromethyl)vinylcarbinol gave a 70% yield of α-methoxycrotonic acid. In all reactions of this carbinol under basic conditions, the migration of the terminal double bond to the conjugated position was observed.



No α-methoxy acid could be isolated from reactions with ethynyl (trichloromethyl)carbinol or with 1,1,1-trichloro-3-nonyn-2-ol. The acid fraction from the former was a black tar with no ir absorption bands corresponding to the triple bond or the acetylenic proton. The latter acetylenic carbinol formed an intractable black oil, and part must also have undergone a reverse Claisen reaction to 2-octynal, for a crude acid having the ^{1}H nmr and ir spectra of 2-octynoic acid was isolated.[2]

In conclusion, substituted (trichloromethyl)carbinols react with methanolic potassium hydroxide to form substituted α-methoxyacetic acids in excellent yield if the substituent group in **1** is aryl, alkyl or dialkyl, or vinyl. The reaction fails with ethynylcarbinols. The reaction works equally well if the methanol is replaced by ethanol or other alcohols (1, 13).

Reaction with Thiourea

Phenyl(trichloromethyl)carbinol is known to react with thiourea in methanolic potassium hydroxide solution at 50°C to form 2-imino-5-phenyl-4-thiazolidinone in 55% yield (6). By analogy with the reaction of **1** (R = Ph) with methoxide, the reaction is believed to involve the attack of the thioenolate anion of thiourea on epoxide **2** (R = Ph) followed by ring closure to give **5**.

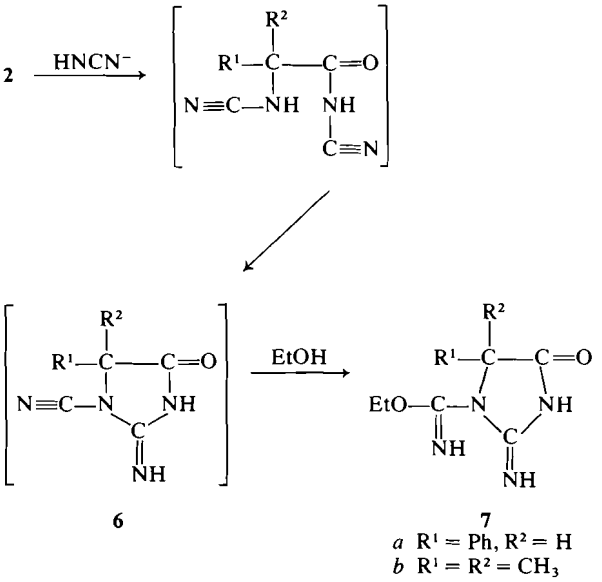
We have studied the reaction of thiourea in methanolic potassium hydroxide with ethyl(trichloromethyl)carbinol, dimethyl(trichloromethyl)carbinol, (trichloromethyl)vinylcarbinol, ethynyl(trichloromethyl)carbinol, and 1,1,1-trichloro-3-nonyn-2-ol. As in the case of the reaction of these carbinols with methanolic potassium hydroxide alone, the reaction works well with the alkyl-, dialkyl-, and vinylcarbinols; it fails with the two acetylenic carbinols. 5-Ethyl-2-imino-4-thiazolidinone[3] was formed in 57% yield from ethyl(trichloromethyl)carbinol. With dimethyl(trichloromethyl)carbinol, the yield of 5,5-dimethyl-2-

imino-4-thiazolidinone was reduced to 27%, but 40% of α-methoxyisobutyric acid was formed. This suggests the smaller methoxide nucleophile is more

[2]Dichloroacetic acid was also detected (ir and ^{1}H nmr spectra); this could be formed from chloral by preliminary epoxide formation followed by cleavage to dichloroacetic acid. Dichloroacetic acid is known to be formed from chloral in the presence of potassium cyanide (12).

[3]The traditional thiazolidinone names are used here. The ^{1}H nmr spectra indicate the 5-ethyl- and 5-ethylidene-2-imino-4-thiazolidinones to be 2-amino-4(5*H*)-thiazolones in the inner-salt form. See ref. 7.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.



effective than the more bulky thioenolate of thiourea in opening the tertiary epoxide ring. 5-Ethylidene-2-imino-4-thiazolidinone was formed in 66% yield from (trichloromethyl)vinyl carbinol; again, migration of the terminal double bond to the conjugated position had occurred. The only products obtained from ethynyl(trichloromethyl)carbinol and 1,1,1-trichloro-3-nonyn-2-ol were high melting, dark-colored polymeric materials. These contained sulfur and nitrogen, showing thiourea had been incorporated into the final product.

Reaction with Cyanamide

Phenyl(trichloromethyl)carbinol has been shown to react with cyanamide in ethanolic potassium hydroxide solution at 2°C to form ethyl 5-phenyl-2-imino-4-oxo-1-imidazolidinecarboximidate (*7a*) in 50% yield (8). The reaction involves the attack of two cyanamide anions on epoxide **2** followed by ring closure and alcoholysis of a nitrile group.

We have found that dimethyl(trichloromethyl)carbinol reacts with cyanamide in ethanolic potassium hydroxide solution in the same manner to give a 60% yield of ethyl 5,5-dimethyl-2-imino-4-oxo-1-imidazolidinecarboximidate (*7b*). On hydrolysis with 20% sulfuric acid, *7b* gave the known ethyl 5,5-dimethyl-2,4-dioxo-1-imidazolidinecarboxylate, thus establishing that the carboximidate group is in the one position, as would be predicted from the earlier work on *7a* (8). Ethyl(trichloromethyl)carbinol appeared to react in the same way, but the product, obtained in approximately 30% yield, was impure and could not be purified by repeated crystallization. Partial hydrolysis with 3 *N* hydrochloric acid substituted a keto group for one of the imino groups, and complete hydrolysis with 20% sulfuric acid gave ethyl 2,4-dioxo-5-ethyl-1-imidazolidinecarboxylate. (Trichloromethyl)vinylcarbinol reacted with cyanamide under the same conditions, but only a 3% yield of 1- or 3-cyano-5-ethylidene-2-imino-4-imidazolidinone could be isolated. The major fraction was an ether-insoluble, brown oil which slowly became a tar. The reactions of ethynyl(trichloromethyl)carbinol and of 1,1,1-trichloro-3-nonyn-2-ol with cyanamide were not studied because of their instability to base (*vide supra*).

Cyanamide is not as good a nucleophile as is methoxide or thiourea, and this probably accounts for the unsatifactory reactions of ethyl(trichloromethyl)carbinol and (trichloromethyl)vinyl carbinol. The successful reaction of dimethyl(trichloromethyl)carbinol with cyanamide demonstrates that two alkyl groups have no adverse effect on the reaction. This reaction must be occurring by

6

7
a $R^1 = Ph, R^2 = H$
b $R^1 = R^2 = CH_3$

pathway one in Scheme 1 since pathway two with tertiary carbinols gives only small yields of α-chloro acids.

Reaction with Aqueous Potassium Hydroxide at 0°C

Phenyl(trichloromethyl)carbinol is converted into α-chlorophenylacetic acid in 60% yield on stirring with 10% aqueous potassium hydroxide solution at 0°C for 30 h (2, 3). This unusual reaction (pathway two in Scheme 1) has been shown to be 83% intramolecular and therefore must involve a migration of chlorine from the terminal to the α position; the mechanism of the rearrangement is uncertain (3).

All available evidence indicates that an α-hydrogen is necessary for the formation of more than traces of the α-chloro acid. Thus, dimethyl(trichloromethyl)carbinol gave at most a 3% yield of crude 2-chloro-2-methylpropanoic acid. In contrast ethyl(trichloromethyl)carbinol gave a 23% yield of α-chlorobutyric acid. More was probably formed, but hydrolysis to the hydroxy acid was a troublesome competing reaction. (Trichloromethyl)vinyl carbinol gave a 24% yield of crude *Z*-2-chloro-2-butenoic acid, the double bond again shifting to the conjugated position. This reaction could be carried out at room temperature since the final chloro acid was stable to base.

Again, the reactions of ethynyl(trichloromethyl)carbinol and of 1,1,1-trichloro-3-nonyn-2-ol were unsatisfactory. Dichloroacetic acid could be detected in both reaction mixtures and 2-octynoic acid was isolated from the latter reaction mixture.

Experimental

Ethynyl(trichloromethyl)carbinol, 1,1,1-trichloro-3-nonyn-2-ol, (trichloromethyl)vinylcarbinol, and ethyl(trichloromethyl)carbinol were synthesized as previously described (9). Dimethyl(trichloromethyl)carbinol is commercially available (as Chloretone). Elemental microanalyses were performed by Dr. Franz J. Kasler.

α-Methoxy-n-butyric Acid

This follows our standard procedure for the conversion of (trichloromethyl)carbinols to α-methoxy acids. To 8.9 g (0.05 mol) of ethyl(trichloromethyl)carbinol in 15 mL of methanol was added over a 1 h period a filtered solution of 16.3 g (0.25 mol) of potassium hydroxide in 60 mL of methanol. The reaction mixture was stirred and maintained at 50°C during the addition and for an additional two hours, and then allowed to stand while cooling to room temperature overnight. The potassium chloride was filtered off (94% of theory), and the filtrate was diluted with an equal volume of water and extracted with ether to remove traces of neutral materials. The aqueous solution was acidified to pH 1.7, and extracted with ether. Evaporation yielded 4.7 g (79% of theory) of α-methoxy-*n*-butyric acid; the ^{1}H nmr spectrum indicated the material to be pure except for a trace of water; bp 114–120°C/26 Torr (lit. (14) bp 94–95°C/15 Torr); ir (film): 3600–2800, 1730, 1450, 1200, 1135, 1110, 1085, and 950 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 9.0 (s, 1.5, COO*H* plus 3.5% H_2O), 3.8 (t, 1, J = 5.7 Hz, CH), 3.46 (s, 3, OCH_3), 2.1 to 1.6 (m, 2, —CH_2—), and 1.0 (t, 3, J = 7.2 Hz, CH_3).

The *p*-phenylphenacyl ester was also prepared and melted at 81°C in agreement with the literature value (14).

α-Methoxycrotonic Acid

This was prepared from 8.8 g of (trichloromethyl)vinylcarbinol by the above procedure. There was obtained 4.1 g of crude product (70% of theory). It distilled at 113–115°C/14 Torr and crystallized in the receiving flask. After recrystallization from cyclohexane it melted at 60–61°C (lit. (14) bp 117°C/16 Torr, lit. (14, 15) mp 58°C and 60–62°C); ir (KBr): 3400–2500, 1695, 1640, 1445, 1410, 1320, 1275, 1195, 1135, 1085, 1020, 955, 895, 840, 800, and 770 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 10.2 (s, 1, COOH), 6.5 (q, 1, J = 7.2 Hz, —CH=), 3.7 (s, 3, OCH_3), and 1.8 (d, 3, J = 7.2 Hz, CH_3).

5-Ethyl-2-imino-4-thiazolidinone (5, R = Et)

This followed the same procedure used with phenyl(trichloromethyl)carbinol (6). From 8.9 g of ethyl(trichloromethyl)carbinol, there was obtained 3.7 of product (57% of theory), mp 190–193°C (dec.). Recrystallization from water gave white crystals, mp 195–197°C (dec.) (lit. (16, 17) mp 195–196°C (dec.) and 198–200°C (dec.)); ir (KBr): 3250, 3050, 1690, 1650, 1500, 1360, 1280, 1130, and 740 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 8.8 (broad s, 2, —NH—), 4.23 (m, 1, —CH_2—C*H*=), 2.15 to 1.1 (m, 2, CH_3—CH_2—), and 0.9 (t, 3, J = 7.2 Hz, CH_3). From the filtrate, 0.9 g (15% of theory) of crude α-methoxy-*n*-butyric acid was isolated and identified by ir.

5,5-Dimethyl-2-imino-4-thiazolidinone

This was prepared as above; from 9.8 g of dimethyl(trichloromethyl)carbinol there was obtained 2.1 g of product (27% of theory), mp 247°C. After recrystallization from water, it melted at 249–251°C (lit, (18, 19) mp 242°C and 245°C); ir (KBr): 3230, 2960–2600, 1670, 1500, 1440, 1390, 1350, 1270, 1185, 1125, 770, and 710 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 8.8 (broad s, 1, NH), 3.44 (broad s, 1, NH), and 1.5 (s, 6, CH_3). From the filtrate, 2.6 g of crude 2-methoxy-2- methylpropanoic acid (40% of theory) was isolated and identified by ir and nmr.

5-Ethylidene-2-imino-4-thiazolidinone

This was prepared as above; from 4.4 g of (trichloromethyl)-vinylcarbinol there was obtained 2.35 g of product (66% of theory). Three recrystallizations from ethanol (decolorizing carbon) raised the mp to 233–235°C (dec.) (lit. (16, 20) mp 240–241°C and 250°C (dec.)); ir (KBr): 3200, 3000–2700, 1675, 1500, 1360, 1270, 1245, and 1145 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 8.2 (broad s, 2, —NH—), 5.85 (q, 1, J = 7.1 Hz, —CH=), and 1.0 (d, 3, J = 7.1 Hz, CH_3).

Hydrolysis of 0.3 g of the above with 9 mL of 20% sulfuric acid for 3 h gave the known 5-ethylidene-2,4-thiazolidinedione, mp 119.5–121.5°C in agreement with literature values (16, 20); ^{1}H nmr ($CDCl_3$) δ; 9.6 (broad s, 1, NH), 7.14 (q, 1, J = 7.3 Hz, —CH=), and 1.95 (d, 3, J = 7.3 Hz, CH_3).

Ethyl 5,5-Dimethyl-2-imino-4-oxo-1-imidazolidinecarboximidate (7b)

This followed Barron's procedure (8) using ethanol as a solvent. From 17.8 g of dimethyl(trichloromethyl)carbinol there was obtained at pH 7.5, after concentrating and chilling the aqueous alcoholic reaction mixture, 10.6 g of product, mp 149–162°C (dec.). Another 1.3 g was obtained from ether extractions making a total of 11.9 g, 60% of theory. Recrystallization from water and from ethanol raised the mp to 165–166°C (dec.); ir (KBr): 3330, 3220, 2980, 1730, 1660, 1470, 1420, 1390, 1355, 1295, 1235, 1150, 1120, 1075, 770, 745, and 675 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 9.64 (broad s, 1, NH), 8.86 (broad s, 1, NH), 7.48 (broad s, 1, NH), 4.15 (q, 2, J = 7 Hz, —CH_2—O—), and 1.35 (s) and 1.30 (t) with combined area of 9, J = 7 Hz, 3 CH_3). *Anal.* calcd. for $C_8H_{14}N_4O_2$: C 48.48, H 7.12, N 28.26; found: C 48.59, H 7.08, N 28.54.

From an ether extraction of the filtrate was obtained 0.5 g of *N*-cyano-*O*-ethylpseudourea ($H_2N(EtO)C$=N—CN), mp 117–117.5°C after crystallization from water. This agrees with the literature value (21); C,H,N analysis, ir, and ^{1}H nmr confirmed the structure.

The above carboximidate was hydrolyzed to the known ethyl 5,5-dimethyl-2,4-dioxo-1-imidazolidinecarboxylate by refluxing 2.5 g for 1.6 h with 25 mL of 20% sulfuric acid to establish the position of the carboximidate group as at the one position. On chilling, 1.5 g white platelets (60% of theory) was obtained which melted at 173.5–174°C after crystallization from water (lit. (22) mp 174–175°C); ir (KBr): 3240, 1830, 1815, 1770, 1700, 1420, 1390, 1360, 1340, 1145, 1130, 1110, 1100, 1020, 945, and 770 cm^{-1}; ^{1}H nmr (DMSO-d_6) δ: 4.25 (q, 2, J = 7.1 Hz, —CH_2O—), 3.4 (broad s, 1, NH), 1.53 (s, 6, CH_3), and 1.26 (t, 3, J = 7.1 Hz, CH_3CH_2—). *Anal.* calcd. for $C_8H_{12}N_2O_4$: C 48.00, H 6.04, N 14.00; found: C 47.93, H 5.98, N 14.20.

Reaction of Ethyl(trichloromethyl)carbinol with Cyanamide

This was carried out as above starting with 8.9 g of ethyl(trichloromethyl)carbinol, but the 5.0 g of product which precipitated at pH 6.1, mp 137–141°C after crystallization from ethanol, could not be further purified. The carbon analysis was 3% low.

One gram of the above product was refluxed for 1 h with 6 mL of 20% sulfuric acid and the reaction mixture extracted with ether. There was obtained 0.35 g of *ethyl 2,4-dioxo-5-ethyl-1-imidazolidinecarboxylate*, mp 73–74°C (dec.) after crystallization from water. The carboxylate group is assigned to the 1-nitrogen by analogy with the reaction of cyanamide with dimethyl(trichloromethyl)carbinol and with phenyl(trichloromethyl)carbinol, and also by the fact that it dissolves easily in cold 5% sodium hydroxide. Infrared (KBr): 3200, 1800, 1730, 1380, 1300, 1180, 1170, 1110, 1045, and 765 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 8.23 (broad s, 1, NH), 4.4 (m, 3, —CH_2O— and —CH=), 2.2 (m, 2, CH_3—C*H*$_2$—CH=), 1.35 (t, 3, J = 7.1 Hz, CH_3), and 0.9 (t, 3, J = 7.5 Hz, CH_3). *Anal.* calcd. for $C_8H_{12}N_2O_4$: C 48.00, H 6.04, N 14.00; found: C 48.27, H 5.86, N 14.70.

1- or 3-Cyano-5-ethylidene-2-imino-4-imidazolidinone

This was prepared starting with 8.8 g of (trichloromethyl)vinylcarbinol. Ether extraction of the acidified aqueous reaction mixture gave 1.8 g of a mixture of oil and solid. The solid (0.26 g) was recrystallized from ethanol. It did not melt below 360°C. Infrared (KBr): 3180, 2940, 2700, 2200, 1740, 1650, 1460, 1380, 1340, 1270, 1130, 980, 830, and 630 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 5.93 (q, 1, J = 7.7 Hz, CH_3—CH=), 4.1 (broad s, 2.5, NH + H_2O), and 1.96 (d, 3, J = 7.7 Hz, CH_3). *Anal.* calcd. for $C_6H_6N_4O$: C 48.00, H 4.03, N 37.32; found: C 48.14, H 4.16, N 37.60.

α-*Chlorobutyric Acid*

This was prepared by stirring 13.3 g (0.075 mol) of ethyl(trichloromethyl)carbinol with 18.8 g (0.284 mol) of potassium hydroxide in 150 mL of water at −5°C for 12 h followed by ether extraction of first the basic and then the acidified reaction mixture. The crude acid (23%) was redistilled to give 1.1 g of α-chlorobutyric acid; bp 99–101°C/16 Torr (lit. (23) bp 98–99°C/15 Torr); ir identical with Sadtler prism spectra number 21372; ^1H nmr ($CDCl_3$) identical with Sadtler nmr spectra number 23254 M.

Z-2-Chloro-2-butenoic Acid

This was prepared by stirring 8.8 g (0.05 mol) of (trichloromethyl)vinylcarbinol with 20 g (0.3 mol) of potassium hydroxide in 200 mL of water at room temperature for 7 h. After extraction with ether as above, 1.45 g (24%) of brown crystalline *Z*-2-chloro-2-butenoic acid was obtained; bp 110–119°C/19 Torr (lit. (24) bp 111–112°C/14 Torr); mp (from cyclohexane) 98–99°C (lit. (24) mp 98–99°C); ir (film): 3100–2400, 1670, 1610, 1420, 1315, 1280, 1110, 950, 895, 840, and 735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 11.6 (s, 1, COOH), 7.35 (q, 1, J = 6.9 Hz, —CH=), and 2.16 (d, 3, J = 6.9 Hz, CH_3).

The adsorption of lower trialkylphosphates at the dodecane–water interface[1,2]

NORMAN H. SAGERT AND WOON LEE

Research Chemistry Branch, Atomic Energy of Canada Research Company, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received June 3, 1980

NORMAN H. SAGERT and WOON LEE. Can. J. Chem. **58**, 2789 (1980).

The adsorption of tripropylphosphate, triethylphosphate, and trimethylphosphate at the dodecane–water interface has been studied at temperatures from 293 to 313 K. Standard free energies of adsorption were obtained from the lowering of interfacial tensions in the low ($< 10^{-4}$) solute mole fraction region. Standard enthalpies and entropies of adsorption were then obtained from the temperature variation of the standard free energies of adsorption.

Standard free energies of adsorption from dodecane showed little variation with solute chain length, with the exception of trimethylphosphate. On the other hand, free energies of adsorption from water decreased by 3.45 kJ/mol for each methylene group added, again with the exception of trimethylphosphate. Enthalpies of adsorption increased linearly with increasing solute chain length for adsorption from either phase. For each methylene group added, the enthalpy of adsorption from dodecane increased by 2.9 kJ/mol, while that from water increased by 2.4 kJ/mol.

Results for tripropylphosphate adsorption and for triethylphosphate adsorption at higher temperatures could be adequately described by the Schofield–Rideal equation of state, but not by simple two-dimensional solution models. Results for trimethylphosphate adsorption and for triethylphosphate adsorption at lower temperatures could not be fitted adequately by either type of equation of state.

NORMAN H. SAGERT et WOON LEE. Can. J. Chem. **58**, 2789 (1980).

On a étudié l'adsorption des phosphates de tripropyle, de triéthyle et de triméthyle à l'interface dodécane–eau, à des températures variant de 293 K à 313 K. On a obtenu les énergies libres d'absorption à partir de l'abaissement des tensions interfaciales dans la région ou la fraction molaire du soluté est faible ($< 10^{-4}$). On a alors obtenu les enthalpies et entropies normales d'absorption à partir de la variation, en fonction de la température, des énergies libres normales d'adsorption.

A l'exception du phosphate de triméthyle, les énergies libres normales d'absorption des autres phosphates à partir du dodécane varient peu avec la longueur de la chaîne de soluté. D'autre part, les énergies libres d'adsorption à partir de l'eau décroissent de 3,45 kJ/mol avec l'addition de chaque groupe méthylénique, la encore le phosphate de triméthyle fait exception. Les enthalpies d'adsorption augmentent linéairement avec la longueur de la chaîne du soluté lors de l'adsorption dans l'une ou l'autre phase. Pour chaque addition de groupes méthylènes, l'enthalpie d'adsorption à partir du dodécane augmente de 2,9 kJ/mol alors que celle provenant de l'eau augmente de 2,4 kJ/mol.

Les résultats de l'adsorption des phosphates tripropyle et de triéthyle à des températures plus élevées peuvent être décrits adéquatement par l'équation d'état de Schofield–Rideal et non pas par de simples modèles de solution en deux dimensions. Les résultats de l'adsorption des phosphates de triméthyle et de triéthyle à des températures plus basses ne s'accordent pas adéquatement à un type quelconque d'équation d'état.

[Traduit par le journal]

Introduction

We have reported previously on our study (1) of the adsorption of tributylphosphate (TBP) at the dodecane–water interface. Our work was done as part of a program to study the interfacial properties of those solvent extraction systems used for separating the components of irradiated nuclear fuel. The work reported here extends the study to three other trialkylphosphate solutes, tripropylphosphate (TPP), triethylphosphate (TEP), and trimethylphosphate (TMP).

Adsorption of nonionic alkylphosphates at alkane–water interfaces has not been studied as thoroughly as adsorption of alcohols at the same surfaces (2–4), although some studies have been done on the adsorption of TBP at benzene–water interfaces (5, 6). Our studies of TBP adsorption from dodecane to the dodecane–water interface (1) concentrated on determining the thermodynamic parameters of the adsorption process. The free energy change was large and negative, since adsorption was strong, and a high negative enthalpy of adsorption was also obtained. Since available thermodynamic data (7–9) were not sufficient to allow an accurate calculation of solute distribution coefficients as a function of temperature and thus calculation of the thermodynamics of adsorption from both phases, distribution coefficients of TBP, TPP, TEP, and TMP were measured in our laboratory (10). Then in a related study, which we are reporting here, the adsorption of the three lower trialkylphosphates at the dodecane–water interface was examined. Both the thermodynamics of adsorption and equations of state for the adsorbed layer could then be compared with those for TPB adsorption.

Experimental

Interfacial tensions were measured using the drop-volume method. The apparatus and general procedures have been described (1). Drops were formed on a stainless steel tip of radius 3.166 mm, and were aged at least 5 min. The cell was a Ramé–Hart thermostatted chamber with temperature control to ±0.002 K. Temperatures were known to ±0.05 K. Interfacial tensions were calculated using the Harkins and Brown correction curve (11), and were reproducible to ±50 μN/m.

The sources and purification of the water and dodecane have been described previously (1). The three lower trialkylphosphates were obtained from Aldrich, and their purification has also been described (10).

For experiments using TPP as solute, a stock solution of TPP in dodecane was prepared and appropriate amounts of the stock solution were added to 50 cm^3 dodecane plus 50 cm^3 water in the cell to make up the required mole fraction of TPP in dodecane. For experiments using TEP and TMP as solutes, the procedure was similar except that stock solutions were made up in water and were freshly prepared for each solute mole fraction. Our measured distribution coefficients (10) were used to calculate solute mole fractions in both phases.

Densities were measured to within ±0.2 mg/cm^3 using a 25 cm^3 pycnometer flask.

Two preliminary experiments were done to test for possible hydrolysis of the trialkylphosphates in water. Stock solutions were allowed to stand for several weeks and during this period there was no detectable change in pH. Furthermore, interfacial tensions remained constant over the period. Thus, it was concluded that hydrolysis of the trialkylphosphates would not seriously affect our results.

Adsorption of each of the three trialkylphosphates at the dodecane–water interface was studied at 293.2, 298.2, 303.2, 308.2, and 313.2 K by measuring interfacial tensions. At these five temperatures, interfacial tensions were measured over an "extended" concentration range which meant that to the system of 50 cm^3 water and 50 cm^3 dodecane, we added up to 150 μmol TEP, or up to 20 μmol TMP. In addition, interfacial tensions were measured in the "dilute" region for four intermediate temperatures of 295.7, 300.7, 305.7, and 310.7 K. For these studies up to 5 μmol solute were added to the system.

Results

Adsorption of Trialkylphosphates

Typical results[3] for TEP at 298.2 K are shown in Fig. 1. For computational purposes, it was convenient to express the interfacial data by eq. [1].

$$[1] \quad \gamma = C_1 + C_2 \ln X + C_3 (\ln X)^2 + C_4 (\ln X)^3$$

In eq. [1], γ is the interfacial tension in N/m and X is the mole fraction of trialkylphosphate in the phase being considered. The values of the constants, C_i, obtained by the third-order least-squares fit to eq. [1] are given in Table 1. For the TEP and TMP, the constants give the interfacial tensions as a function of solute mole fraction in the water phase whereas for TPP they give the interfacial tensions as a function of TPP mole fraction in dodecane. Dodecane was used as the reference phase merely for convenience since the distribution coefficient is such that most of the TPP stays in the dodecane. The fits are reasonably good, as indicated by the standard deviations obtained. At this point, it is necessary to note two incorrect entries in a recently published table of constants for expressing these interfacial tensions with TBP as the solute. In Table 1 of ref. 1, C_3 should be -1.617146×10^{-4} and -1.730985×10^{-4} at 293.15 K and 298.15 K respectively.

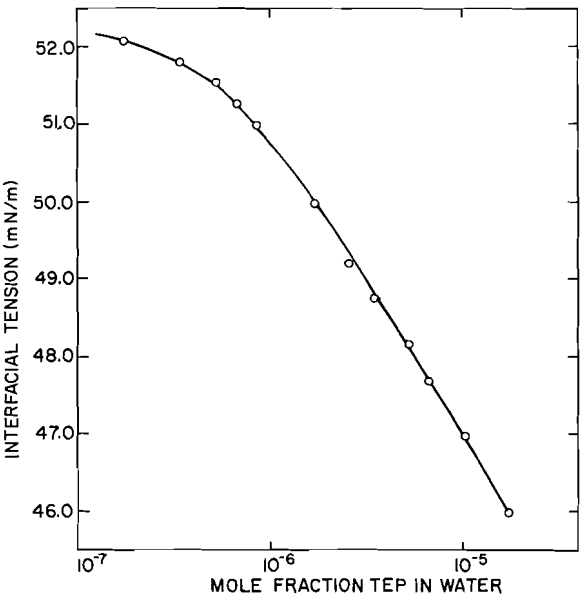

FIG. 1. Interfacial tensions at the dodecane–water interface as a function of TEP mole fraction in the aqueous phase. T = 298.2 K.

Molecular Areas

The simple form of the Gibbs adsorption equation (eq. [2]) was used to calculate the area available to each molecule at the interface, A.

$$[2] \quad A = -kT(\partial\gamma/\partial \ln fX)^{-1}$$

where f is the activity coefficient of the solute in the solvent from which it is being adsorbed. The activity coefficient is chosen as approaching unity when the solution becomes infinitely dilute. In this work, activity coefficients will be taken as unity. Previous work has shown (12, 13) that this is a reasonable assumption for the mole fractions used here. Equations [1] and [2] may be combined to yield eq. [3], giving the area available per molecule in terms of the constants of eq. [1].

$$[3] \quad A = -kT(C_2 + 2C_3 \ln X + 3C_4 (\ln X)^2)^{-1}$$

[3]All the measured data on interfacial tensions are available, at a nominal charge, from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

TMP	313.2	22.44065	3.773422	2.670953	6.238312	0.685

Discussion

Thermodynamics of Adsorption

The standard free energies of adsorption, $\Delta_a\mu^\theta$, were calculated from the initial slopes of the plots of interfacial pressure against solute mole fraction where interfacial pressure is, of course, the difference between the interfacial tension in the absence of solute and that in its presence. Such plots were linear in the low mole fraction region and Fig. 2 shows some typical results with the solute TEP. From the slopes of the lines in Fig. 2, free energies of adsorption were calculated using eq. [4],

$$[4]\quad \Delta_a\mu^\theta = -RT \ln \{(\pi/X)_0(X_s/\pi_s)\}$$

where $(\pi/X)_0$ is the initial slope of the plot of surface pressure against mole fraction of solute. The standard states, denoted X_s and π_s were those used previously by us (1) and by Aveyard and Briscoe (3, 14). The surface standard state is simply a surface pressure of 1 μN/m, and the bulk standard state is that hypothetical standard state where the solute mole fraction is unity, but the solute activity coefficient is also unity.

Standard free energies of adsorption for the three solutes, TMP, TEP, and TPP at all temperatures used are shown in Table 2 for adsorption from both phases. All these standard free energies are large and negative, being considerably larger in the negative sense than the standard free energies of adsorption of alcohols at the same interface (3, 14). Thus strong adsorption of these solutes is noted from both phases. The TMP results at the highest temperatures are not reported since the plots did not go through the origin, although the nonlinearity was just within the claimed reproducibility

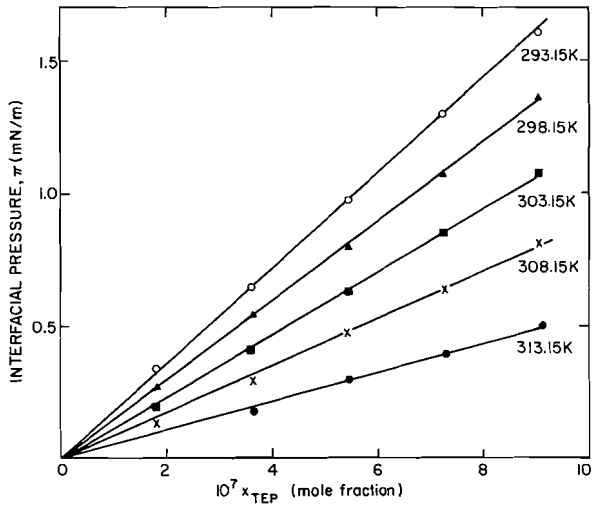

FIG. 2. Interfacial pressures at the dodecane–water interface as functions of TEP mole fraction in the aqueous phases.

of the surface pressures (±100 μN/m). Possibly at higher temperatures there is some reversible sorption of TMP in the seals of the cell.

Figure 3 shows standard free energies of adsorption at 298.2 K from both the aqueous phase and the dodecane phase plotted as a function of the number of carbon atoms in the trialkylphosphate solution. Also shown on the same figure are previously reported standard free energies of transfer of the trialkylphosphates from water to dodecane (10), as well as standard free energies for the adsorption of tributylphosphate (1). These three standard free energies add algebraically to zero.

Apart from the results for TMP adsorption, which may well be atypical since TMP is the first

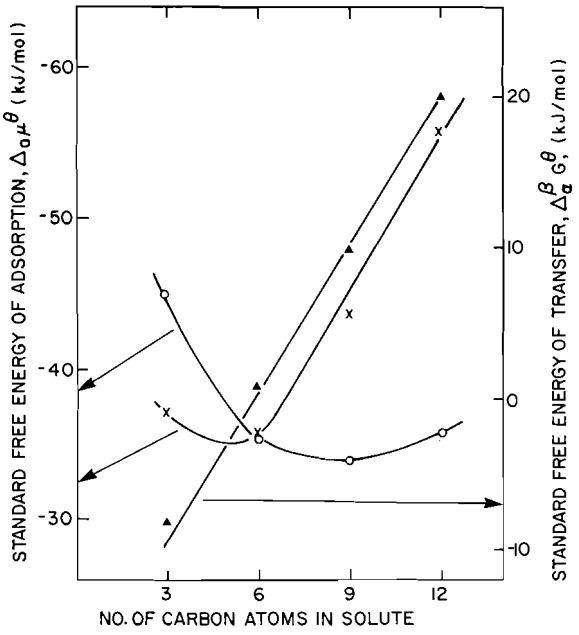

FIG. 3. Comparison of standard free energies of adsorption from water to the interface (×), dodecane to the interface (○), and of transfer from water to dodecane (▲). T = 298.2 K.

member of the series, the standard free energies of adsorption from dodecane do not change greatly with increasing chain length. If the hydrophilic phosphate group is attracted to the water phase, while the alkyl chains remain in the dodecane, then this constant free energy change can be associated with the transfer of the phosphate group into the water from the dodecane.

On the other hand, the standard free energy of adsorption from water to the interface becomes about 3.45 kJ/mol more negative for each CH_2 group added to the chain, again omitting the result for TMP adsorption. This value is very close to the 3.5 kJ/mol decrease in standard free energy change per CH_2 group for complete transfer of the solute from water into the dodecane (10), which in turn is very similar to the value quoted for transfer of CH_2 groups from water to oil for many classes of organic compounds (15, 16). It is therefore tempting to interpret the close correspondence of the changes in the standard free energies of transfer to the changes in the standard free energy of adsorption from water as evidence that the alkyl groups exist entirely in the dodecane when equilibrium is achieved during adsorption. This is certainly a reasonable interpretation. However, Aveyard and Briscoe (3) have pointed out that the free energies of adhesion are such that the possibility that some methylene groups may be in contact with water at the interface cannot be excluded.

The TMP seems to be adsorbed more strongly from both media than would be predicted by extrapolating the standard free energies of adsorption of the trialkylphosphates with longer chain lengths. The reasons for this seem to lie with specific enthalpic and entropic effects which will be discussed later.

Standard enthalpies of adsorption, $\Delta_a h^\theta$, were obtained from the temperature variation of the standard free energies of adsorption using eq. [5].

$$[5] \quad \Delta_a h^\theta = \partial(\Delta_a\mu^\theta/T)/\partial(1/T)$$

Over the temperature range investigated, straight lines were obtained, of comparable precision to those obtained for TBP (1). Having determined the standard enthalpies of adsorption, and knowing the standard free energies of adsorption, the standard entropies of adsorption were calculated directly. These enthalpies and entropies of adsorption calculated at 298.2 K are shown in Table 3 for the three solutes studied.

In Fig. 4, the standard enthalpies of adsorption are plotted as a function of the number of carbon atoms in the solute. These enthalpies decrease linearly as the chain length is increased, the change

TABLE 3. Standard enthalpies, $\Delta_a h^\theta$, and entropies, $\Delta_a S^\theta$, of adsorption at 298.2 K

Solute adsorbed	Phase from which adsorbed	$-\Delta_a h^\theta$ (kJ/mol)	$\Delta_a S^\theta$ (J/mol K)
TMP	Aqueous	40.0	−9.6
TMP	Dodecane	71.6	−87.7
TEP	Aqueous	33.0	7.9
TEP	Dodecane	62.4	−87.5
TPP	Aqueous	23.6	67.3
TPP	Dodecane	52.3	−61.7

being about 2.9 kJ/mol per CH_2 group for adsorption from the dodecane and 2.4 kJ/mol per CH_2 group for adsorption from the water.

Adsorption from the dodecane phase is, to a first approximation, the hydration of the hydrophilic phosphate group while the alkane chain remains in the dodecane, perhaps in contact with the interface. In principle, the phosphoryl oxygen is capable of forming two hydrogen bonds and the bridging internal oxygens one each for a potential total of five. The standard enthalpy of adsorption of TMP from water is −71.6 kJ/mol, which corresponds to the enthalpy of formation of four to five hydrogen bonds (17), close to the maximum possible. The small methyl groups must allow the TMP molecule good access to the water near the interface. As the length of the alkyl chain increases the relative attraction of the solute molecules to the dodecane increases, and the phosphate groups will not penetrate as far into the water. For TBP the enthalpy of adsorption increases to −45.5 kJ/mol, which is equivalent to between only two or three hydrogen bonds. As an alternative to this steric model, it is also possible that the larger alkyl groups decrease the basicity of the oxygen, leading to weaker hydrogen bonds (18). However, Karyakin and Muradova (17) found no spectroscopic evidence for much weaker hydrogen bonds between water and TEP as compared with TBP.

When trialkylphosphates are dissolved in water, from 12 to 25 kJ/mol of heat is evolved (7, 9) and these exothermic heats of solution have been attributed to the hydrophobic effect (9, 15, 19). The hydrophobic effect is characterized by a large increase in the order of the hydrogen-bonded structure close to the hydrophobic solute molecule. The entropy change is large, and while the enthalpy change for dissolution of trialkylphosphates is also large (7, 9), it is very much less than that associated with the formation of five hydrogen bonds. It seems that the cooperative hydration envelope, formed by the hydrophobic interactions and thought by Lindenbaum *et al.* (9) to involve some 30 water molecules, shields at least some of the oxygens of the solute from hydrogen-bonding with water. Of course trialkylphosphates are highly associated in the liquid state (20, 21) so this simple explanation is not sufficient. Since we are dealing with the dodecane–water system, it is perhaps useful to note that the enthalpy of transfer of trialkylphosphates from dodecane to water is −27 to −30 kJ/mol (1), again equivalent to about two hydrogen bonds rather than five. Again, there is association with water molecules in the dodecane phase so again this simple explanation of the shielding of some oxygen atoms by the hydration envelope cannot be entirely sufficient.

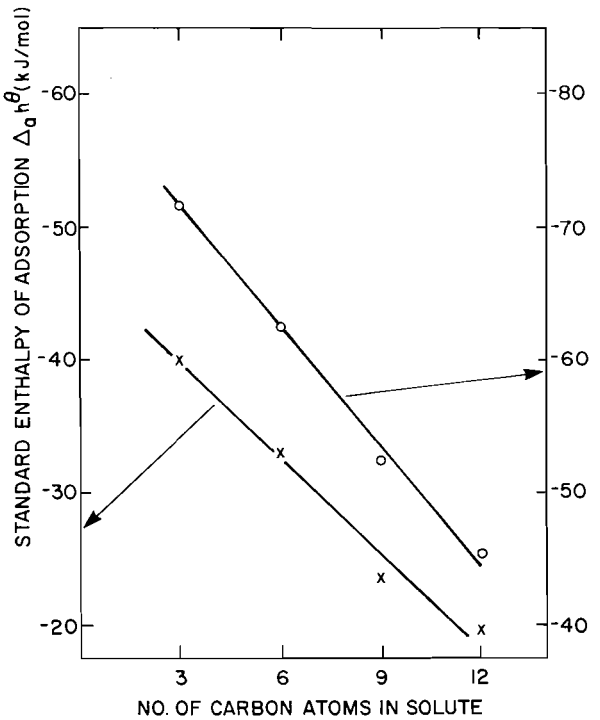

FIG. 4. Standard enthalpies of adsorption from water (×) and from dodecane (○) to the interface.

Adsorption from water to the interface is accompanied by another sizable enthalpy release. This release is expected when we note that the cooperative hydration envelope associated with the alkyl groups in water is destroyed when they are taken up by the dodecane, freeing the hydrophilic phosphate to hydrogen-bond more strongly with the water. On the other hand, the enthalpy change on adsorption from water per CH_2 group is very close to the negative of that for solution in water (9). This suggests, enthalpically at least, some similarity in the changes of environment per CH_2 group for the hy-

drocarbon chain in the adsorbed state and in liquid trialkylphosphate.

Using the standard states described above, entropies of adsorption from water become very large and positive for the longer-chain trialkylphosphates, reflecting increasing loss of water structure during the adsorption process as the chain length is increased (Fig. 5). The TMP results aside, the entropy increase is 19.3 J/mol K for each CH_2 group added to the solute. Similarly, there is also a gain in entropy with increasing chain length for adsorption from the dodecane, but in this case, the increase is only 9.3 J/mol K for each CH_2 group added, again omitting the TMP results.

A comparison of Figs. 4 and 5 shows that the high adsorption of TMP at the dodecane–water interface is the result of high entropies of adsorption, rather than anomalies in the enthalpies of adsorption. While we believe that these entropic effects are real, nevertheless the possibility exists that TMP hydrolysis products (23) play some role in the anomalous behaviour of this system. Our results showed no detectable hydrolysis in the aqueous phase, but increased hydrolysis in the surface phase is possible and the extent of hydrolysis necessary to affect the results is unknown. The hydrolysis of TMP is known to be about five times faster than that of TEP (24).

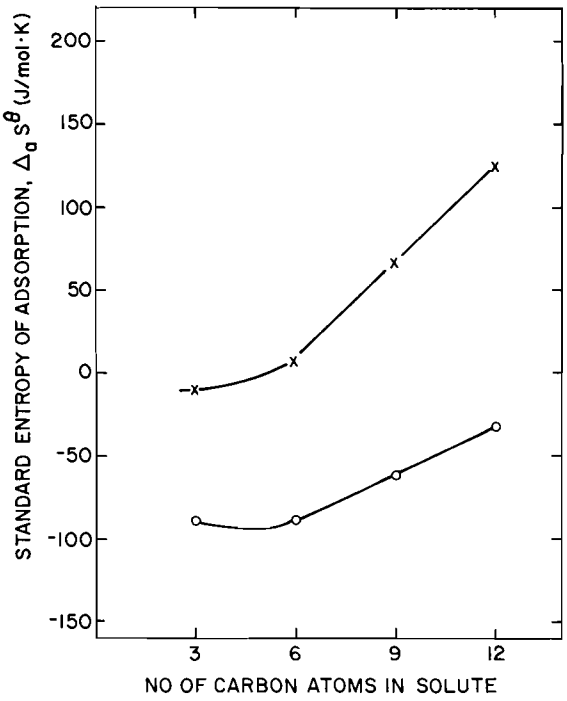

FIG. 5. Standard entropies of adsorption from water (×) and from dodecane (○) to the interface.

Surface Equation of State

Attempts were made to fit the measured values of π and A to a two-dimensional equation of state known as the Schofield–Rideal equation (22), shown here as eq. [6], where i and A_0 are fitting constants.

$$[6] \quad \pi(A - A_0) = ikT$$

To obtain values of i and A_0, eq. [6] was combined with eq. [3], eq. [1], and the constants listed in Table 1. The interfacial tension – solute mole fraction data were then fitted using a non-linear, least-squares fitting routine based on Marquardt's method employing the algorithm of Brown and Dennis (25) (Chalk River Nuclear Laboratories CDC Fortran program MLSQQ). The results obtained are shown in Table 4 and the errors listed are the standard deviation of the fit, as returned by the program. Fits could not be obtained to the TMP data and to the TEP data at the two lower temperatures. In all these cases, an inflection was noted in the curve of interfacial tension against the logarithm of the solute mole fraction. Activity coefficient corrections in the aqueous and organic phases may be large enough that they can no longer be neglected at the higher mole fractions used here.

The values of A_0 obtained for TPP and for TEP at 313.2 K are only about one half those obtained for TBP under the same conditions (1). Although A_0 is, strictly speaking, only a fitting constant, it is generally associated with the static geometric area of the molecule at the interface (3). Thus it is tempting to rationalize the values obtained in terms of geometric areas. From its geometry, the cross-sectional area of the TPP molecule is about 0.6 nm² and that of the TEP molecule is about 0.5 nm². Thus, the A_0's obtained for TPP are only slightly smaller than the static geometric area. The A_0 for TEP is about equal to the geometric area at 313.2 K, but appears to rise enormously as the temperature is lowered. This is most likely apparent, due to changes in activity coefficients in the solvent.

As with TBP (1), the best fit of eq. [6] is not with $i = 1.0$, the Volmer equation, but with i substantially

TABLE 4. Constants of Schofield–Rideal Equation

Solute	T (K)	A_0 (nm²)	i
TPP	293.2	0.50 ± 0.03	1.36 ± 0.07
TPP	298.2	0.43 ± 0.03	1.56 ± 0.07
TPP	303.2	0.34 ± 0.03	1.75 ± 0.06
TPP	308.2	0.33 ± 0.06	1.41 ± 0.06
TPP	313.2	0.39 ± 0.04	1.38 ± 0.08
TEP	303.2	1.50 ± 0.02	0.89 ± 0.03
TEP	308.2	0.86 ± 0.05	1.31 ± 0.06
TEP	313.2	0.56 ± 0.04	1.32 ± 0.04

greater than unity. The deviations from the Volmer equation are in a direction suggesting extra repulsions in the monolayer, rather than the increased cohesion observed at vapor–liquid interfaces (26). Previously, we suggested (1) that some of this repulsion could be accounted for by dipole–diple repulsions in the adsorbed layer, or alternatively, by variations of A_0 with coverage. It should also be noted that relatively small errors in the interfacial tension can give rise to fairly large errors in the area, A. Thus, the Volmer equation, with $A_0 \sim 0.8\ nm^2$, while not the best fit of the data is not an unreasonable one.

Attempts were made to use a two-dimensional solution model for the surface (27, 28), employing the simplifying assumptions that the solute is located entirely in the dodecane (3). However, it was not possible to fit our data in this way using any reasonable values of the surface areas of the trialkylphosphates and dodecane.

Heats of vaporization of esters by the gas chromatography–calorimetry method[1]

RICHARD FUCHS AND L. ALAN PEACOCK
Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.
Received May 27, 1980

RICHARD FUCHS and L. ALAN PEACOCK. Can. J. Chem. **58**, 2796 (1980).

A recently developed gc–calorimetry procedure involving a combination of gas chromatography and heat of solution measurements has been used to measure heats of vaporization of 17 esters, including methyl 2,2-dimethylpropanoate, butyl acetate, glyceryl triacetate, diethyl phthalate, methyl 9-octadecenoate, and 12 methyl esters of C_3- to C_{15}-fatty acids. Comparison with measurements of ΔH_v reported in the literature indicates that the gc–calorimetry method often has smaller uncertainties in measurements (0.25 to 1.00 kJ mol^{-1}) and more consistent methylene increments for the series of fatty acid methyl esters. Two of the experimental ΔH_v measurements which differ appreciably from recent literature values have been verified by vaporization calorimetry.

RICHARD FUCHS et L. ALAN PEACOCK. Can. J. Chem. **58**, 2796 (1980).

Pour mesurer les chaleurs de vaporisation de 17 esters comprenant le diméthyl-2,2 propionate de méthyle, l'acétate de butyle, le triacétate de glycéryle, le phtalate de diéthyle, l'octadécène-9 oate de méthyle et 12 esters méthyliques d'acides gras allant de C_3 à C_{15}, on a utilisé un procédé récemment mis au point (cpg/calorimétrie) qui fait intervenir une combinaison de la chromatographie en phase gazeuse et de mesures des chaleurs de solutions. Une comparaison avec les valeurs de ΔH_v rapportées dans la littérature indique que la méthode cpg/calorimétrie a souvent de plus faibles incertitudes (0,25 à 1,00 kJ/mol^{-1}) et des incréments pour les méthylènes qui sont plus réguliers pour la série d'esters méthyliques des acides gras. On a vérifié par calorimétrie de vaporisation deux des mesures expérimentales de ΔH_v qui diffèrent de façon appréciable de celles de la littérature.

[Traduit par le journal]

The determination of enthalpies of formation in the gaseous state (from enthalpies of combustion or hydrogenation in solution), and comparisons of acidities, basicities, and reactivities in the gaseous state and in solution require a knowledge of the enthalpies of vaporization (ΔH_v) of the involved species (1–3). The available body of good experimental data is far more limited than is generally recognized. Much of the ΔH_v literature (4) consists of estimates based on various schemes and experimental values using methods with large uncertainties.

We have recently developed the gc–calorimetry technique for measuring ΔH_v by a combination of gas chromatography and solution calorimetry (5, 6). Excellent results have been obtained for low boiling compounds ($< \sim 425$ K), but the method is especially useful for high boiling compounds. Partial sample decomposition, which leads to serious problems with other methods, does not affect the gc–calorimetry results.

In view of the biological importance of fatty acids, the common use of the methyl esters in gc analysis of the acids, and the incomplete and inconsistent nature of the ΔH_v data available at the time this work was started, it appeared that the fatty acid methyl esters would constitute an appropriate series of compounds for determination of ΔH_v values by the gc–calorimetry method. In the interim new values for these compounds have been published (7), which furnish useful comparisons and contrasts with the present values. Several additional esters have been examined (Tables 1 and 2), although for only two, butyl acetate and glyceryl triacetate (triacetin), have ΔH_v values with reasonable uncertainties been previously determined.

Values for methyl propanoate and methyl butanoate based on vapor pressure measurements (8) are available, but it was necessary to correct the resulting ΔH_v values to 298.15 K using calculated heat capacities (9, 10). Calorimetric values have recently been determined (11). Enthalpies of vaporization of the remaining esters in Table 1 have been calculated from more recent vapor pressure measurements (4, 12–15) or estimated (4). Two values of ΔH_v originally reported at higher temperatures have been corrected to 298.15 K using calculated values of C_p(l) and C_p(g) (9, 10): glyceryl triacetate (12) ((94.40 ± 0.21) kJ mol^{-1} at 301.1 K) and methyl 9-octadecenoate (13) (methyl oleate) ((84.5 ± 4.2) kJ mol^{-1} at 427 K). Direct vaporization calorimetry has been used to obtain enthalpies of vaporization for several acetates (16).

Recently, enthalpies of vaporization for the methly esters of C_5–C_{15} fatty acids have been measured (7) using the Wadsö calorimeter (16) for the methyl esters of C_5–C_7 fatty acids and the

[g] Gas chromatographic retention times measured on DC-200 capillary column I (ref. 6). Others measured using column II.

Morawetz calorimeter (17) for the others. These values show considerably smaller uncertainties than previous data.

The recently developed gc–calorimetry method for determining enthalpies of vaporization (5, 6) relies upon calorimetric enthalpies of solution at infinite dilution, ΔH_s, and solvation enthalpies, $\Delta H(v \rightarrow S)$, obtained by gas chromatography.

$$[1] \quad \Delta H_v = \Delta H_s - \Delta H(v \rightarrow S)$$

Solvation enthalpies are obtained from the temperature coefficient of the corrected retention times (Δt) (which are linearly related to retention volumes),

$$[2] \quad \Delta H(v \rightarrow S) = R\mathrm{d}(\ln \Delta t)/\mathrm{d}(1/T)$$

and are corrected to 298.15 K using calculated heat capacity values,

$$[3] \quad \Delta H^{0\ 298.15\ K}(v \rightarrow S) = \Delta H^{T}(v \rightarrow S) + \int_{T}^{298.15\ K} [C_p^{0}(l) - C_p^{0}(g)]\,\mathrm{d}T$$

The solvent in which enthalpies of solution are obtained is the same as the gc stationary phase, DC-200 silicone fluid.

Experimental

Ester sample (Fluka, Aldrich, and Fisher Companies) were of 99 mass% or greater purity (by gas chromatography) or brought to this purity by preparative gc. The samples used for vaporization calorimetry were distilled just before use through a Vigreux column, and a center fraction with a boiling point range < 0.1°C was collected in each case.

Gas chromatographic retention times were determined three times at each of six temperatures over a 50°C range using 30 m × 0.5 mm id stainless steel capillary columns, and corrected for the dead volume time which was assumed to be equal to the retention time of methane at each temperature. The stationary phase was DC-200 silicone fluid of 100 cSt viscosity. Heats of solution of the esters in the silicone fluid were determined in a vacuum jacketed isoperibol (isothermal environment) solution calorimeter at 25°C. $\Delta H(v \rightarrow$ DC-200) was calculated (eq. [2]) from the slope of the plot of ln Δt vs. $1/T$. From this quantity at the mean temperature of the Δt measurements $\Delta H(v \rightarrow$ DC-200) at 25°C can be calculated (eq. [3]) by making appropriate ΔC_p corrections. Apparent ΔH_v^{25} values were calculated from the 25°C values of ΔH_s and $\Delta H(v \rightarrow$ DC-200), and corrected by a calibration equation determined from a series of calibration compounds of known ΔH_v. The detailed gas chromatographic and calorimetric procedures, analysis of the data, and calibration method have been previously reported (6).

Calorimetric heats of vaporization were determined by evaporating 100 μL samples inside a coiled copper tube 15 cm in length and 0.3 cm id, imbedded in a copper disc 4 cm in diameter and 2.5 cm high. A thermistor and a metal-film electronic resistor (heater) are mounted in small wells in the copper disc. The entire assembly is contained in a vacuum jacketed solution calorimeter. The copper coil is connected to the outside by Teflon tubing. The block is thermally equilibrated with a nitrogen flow of 4 cm^3/min, with appropriate vacuum drawn on the outlet. A sample of 100 μL is introduced (microliter syringe, 30 cm Teflon needle) through a stopcock, down the Teflon con-

necting tubing, and well into the copper coil. Nitrogen flow is then reestablished, and evaporation of the sample begins. The cooling effect is compensated by short periods of heating from a timed constant current source. When no further evaporation cooling occurs (12–20 min) the block is brought to the original temperature (±1 × 10^{-4} K). Heat capacity corrections are made for the sample and needle which are introduced at 22.0°C. The sample mass is established by weighing several 100 μL samples. The heat of vaporization (J mol^{-1}) is calculated from the equation

$$[4] \quad \Delta H_v = I^2R(\mathrm{MW})t/m$$

where I is the heater current (A), R is the heater resistance (Ω), MW is the molar mass, t is the total heating period (s), and m is the sample mass.

Operation of the vaporization calorimeter was verified by measurements of compounds with well established values of ΔH_v (4): pentane, 26.87 ± 0.38 kJ mol^{-1} (reported, 26.74 ± 0.21); heptane, 36.61 ± 0.12 (36.57 ± 0.04); nonane, 46.42 ± 0.16 (46.44 ± 0.04); 1-butanol, 52.34 ± 0.16 (52.30 ± 0.08); and 2-heptanone 47.53 ± 0.20 (47.45 ± 0.29 (18), 47.24 ± 0.04 (11)). The indicated uncertainties are twice the standard deviations from the mean. Details of the calorimeter design may be obtained from the senior author.

Results and Discussion

Enthalpies of vaporization from the gc–calorimetry method, and literature values (4, 7, 8) are listed in Table 2. For the methyl esters of the C_8–C_{15} fatty acids the gc–calorimetry values and the recent literature values (7) measured with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 210.87.254.40 on 09/05/12
For personal use only.

Morawetz calorimeter (17) have comparable uncertainties, and generally agree within the combined uncertainties. For the esters of the C_5–C_7 acids measured (7) using the Wadsö calorimeter (16), ΔH_v values are lower than by the gc–calorimetry method. However, the gc–calorimetry value for butyl acetate is in excellent agreement with the value measured by Wadsö (16).

Because of the considerable differences (1–1.5 kJ mol^{-1}) between several gc–calorimetry values of ΔH_v and the reported calorimetric values (7), we have remeasured several ester heats of vaporization by vaporization calorimetry. Values for methyl pentanoate, methyl heptanoate, and butyl acetate obtained this way are in excellent agreement with the gc–calorimetry results.

In the methyl ester series of the C_5–C_{15} acids the gc–calorimetry method shows methylene increments of 4.27–5.31 kJ mol^{-1} and a mean (4.73 ± 0.33), compared with literature values (7) varying from 3.60 to 6.49, with a mean value of (5.02 ± 0.79). The gc–calorimetry method therefore appears to be capable of somewhat higher self-consistency within the set of values.

The highly branched ester, methyl 2,2-dimethylpropanoate (methyl pivalate), has an enthalpy of vaporization 4.27 kJ mol^{-1} lower than that of the straight chain isomer, methyl pentanoate. This is consistent with the behavior of hydrocarbons (18) and ketones (19) for which each quaternary carbon atom lowers ΔH_v by 3.8 to 4.8 kJ mol^{-1}. The ΔH_v value for the isomers methyl pentanoate and butyl acetate agree within 0.42 kJ mol^{-1} implying that ΔH_v for linear esters is not highly dependent on the location of the ester linkage.

A comparison of the unsaturated ester methyl *cis*-9-octadecenoate (methyl oleate) and methyl pentadecanoate indicates a difference of 15.27 kJ mol^{-1}. The effect of the double bond mush be taken into consideration. The literature ΔH_v values for *n*-hexane (4) and *cis*-3-hexene (4) are (31.55 ± 0.04) and (31.34 ± 0.21) kJ mol^{-1}, respectively. Assuming this double bond contribution to be representative of higher alkenes, a value of 107.03 kJ mol^{-1} would be calculated for the saturated ester, methyl octadecanoate. The ΔH_v difference between methyl pentadecanoate and methyl octadecanoate would be 15.48 kJ mol^{-1}, corresponding to a methylene increment of 5.16 kJ mol^{-1} CH_2^{-1}. This is consistent with the methylene increments of the higher members of the methyl ester sequence.

ROSS C. BEIER, BRADFORD P. MUNDY, and GARY A. STROBEL. Can. J. Chem. **58**, 2800 (1980).

A ^{13}C nmr analysis method is described for the identification of carbohydrate residues in galactosides and glucosides. This method reveals the capability of ^{13}C nmr to distinguish the difference in structural configuration of these carbohydrate residues. Not only can the anomeric configuration be assigned, the furanyl and pyranyl nature of the ring is concomitantly determined. This method is consistent for all reported ^{13}C nmr spectra of nonaromatic galactosides and glucosides.

ROSS C. BEIER, BRADFORD P. MUNDY et GARY A. STROBEL. Can. J. Chem. **58**, 2800 (1980).

On décrit une méthode d'analyse par rmn du ^{13}C permettant d'identifier les unités d'hydrate de carbone contenues dans des galactosides et dans des glucosides. Cette méthode met en évidence la capacité de la rmn du ^{13}C de distinguer les différences de configuration de ces unités d'hydrates de carbone. On peut déterminer à la fois la configuration du carbone anomère ainsi que la nature furannyle ou pyrannyle du cycle. Cette méthode est en accord avec tous les spectres de rmn du ^{13}C des galactosides et glucosides non aromatiques qui ont déjà été publiée dans la littérature.

[Traduit par le journal]

The structural characteristics of carbohydrates have been a general theme intertwined throughout our investigations of naturally occurring plant toxins. As a consequence of this program, we have been concerned with assignment of anomeric configuration, also the concern of many other research groups. Proton nmr spectroscopy has been used extensively, and this technique has been reviewed by Bundle and Lemieux (1) who suggest that it is not a totally reliable method. Carbon nmr spectroscopy has also been used as a tool for carbohydrate structural analysis (2–4). It has been suggested (1) that, like ^{1}H nmr, the assignment of anomeric configuration by ^{13}C requires more input data than just a single parameter, i.e., the resonance of the anomeric carbon.

Coupling constants have been used for evaluating the anomeric configuration of glycopyranosides. The two-bond $^{13}C—^{1}H$ coupling constant has an opposite sign for the α (+) than for the β (−) anomer (5). This sign difference would seem to be a most definitive way of assigning configuration; however, there are problems associated with the technique, and improvements are needed to afford a generally applicable method. Two- and three-bond $^{13}C—^{1}H$ coupling constants have now been obtained from natural abundance ^{13}C nmr spectra (6); however, the three-bond coupling constant is more difficult to obtain.

In our investigation of naturally occurring disaccharides containing galactose and glucose residues, assignment of the linkage position between these residues by ^{13}C nmr was required (7, 8). Before the linkage assignment could be made, the configuration of the individual residues had to be determined. An approach to this problem is described below, where chemical shift relationships enable the identification of eight isomeric glycosides.

Results and Discussion

We evaluated all the carbon nmr data published for galactosides and glucosides. When all six carbons are considered simultaneously, a useful correlation is observed, which can be likened to a fingerprint for each isomer.

All ^{13}C nmr values for the carbohydrate residues in α- and β-D-galactopyranosides are presented in Table 1; for α- and β-D-glucopyranosides, Table 2; for α- and β-D-galactofuranosides, Table 3; and for α- and β-D-glucofuranosides, Table 4. For each reported compound a value was tabulated for every carbon of the carbohydrate moiety (C-1 through C-6). The mean values and standard deviations, where applicable, are included in these tables. Since large downfield shifts (7–10 ppm) can be expected for carbons with *O*-methylation or *O*-glycosylation (7), the carbons (C-4 through C-6)

involved in these substitutions were not evaluated.

In Fig. 1 are presented the data of Table 1–4. A rectangular box is drawn enclosing the maximum and minimum values for each carbon atom. A vertical line within that box shows the position of the mean values, and a horizontal bar delineates the standard deviation. It is clear from Fig. 1 that each isomer has a definite set of intervals or fingerprint, each one being different from the other. Therefore, by using these intervals one can, in principle, not only determine the anomeric configuration, but also predict the nature of the carbohydrate moiety.

We have synthesized a number of α-D-galactopyranosides, and their ^{13}C nmr spectra are listed in Table 5. A plot of these resonance values is compared to the α- and β-D-galacto- and glucopyranoside intervals, shown in Fig. 2. It is clear that these α-D-galactopyranosides correlate only with

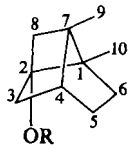
Crystal structure of camphor-1,4-homoenol *p*-bromobenzoate

RICHARD A. PAUPTIT AND JAMES TROTTER

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received July 2, 1980

RICHARD A. PAUPTIT and JAMES TROTTER. Can. J. Chem. **58**, 2805 (1980).



Crystals of the title compound, $C_{17}H_{19}BrO_2$, are orthorhombic, $P2_12_12_1$, $a = 6.875(1)$, $b = 8.522(2)$, $c = 26.658(6)$ Å, $Z = 4$. The structure was determined by Patterson and Fourier methods, and refined to $R = 0.045$ for 697 reflections with $I \geq 3\sigma(I)$; the absolute configuration was established. The four-membered ring is tightly folded, and bond angles in the vicinity of this ring indicate considerable strain.

RICHARD A. PAUPTIT et JAMES TROTTER. Can. J. Chem. **58**, 2805 (1980).

Les cristaux du composé du titre, $C_{17}H_{19}BrO_2$, sont orthorhombiques, $P2_12_12_1$, $a = 6,875(1)$, $b = 8,522(2)$, $c = 26,658(6)$ Å, $Z = 4$. La structure a été determinée par les méthodes de Patterson et de Fourier, et a été affinée jusqu'à $R = 0,045$ pour 697 réflexions avec $I \geq 3\sigma(I)$; la configuration absolue a été établie. Le cycle de quatres membres est bien plié, et les angles de liaison à proximité de ce cycle indiquent une tension considérable.

Introduction

In investigations of homoenolization of bicyclic ketones (1), intermediacy of a highly strained 1,4-homoenol was proposed to account for hydrogen exchange at the C(8) position of camphor. Support for this mechanism was provided by synthesis of material with properties which suggest the 1,4-homoenol structure (**1**, R = H). The present X-ray study was undertaken to verify the structure (**1**, R = $OCOC_6H_4Br$, camphor-1,4-homoenol *p*-bromobenzoate, 7-*p*-bromobenzoyloxy-1,2-dimethyltricyclo[3,3,0,$0^{2,7}$]octane).

1

Experimental

Crystal data are as follows:

$C_{17}H_{19}BrO_2$ fw = 335.2
Orthorhombic, $P2_12_12_1$, $a = 6.875(1)$, $b = 8.522(2)$, $c = 26.658(6)$ Å, $V = 1562$ Å^3, $Z = 4$, $\rho_c = 1.43$ g cm^{-3}, MoKα, $\lambda = 0.71073$ Å, $\mu = 25.5$ cm^{-1}.

Intensity data were measured on an Enraf-Nonius CAD-4 Diffractometer with monochromatic MoKα radiation and an ω–(4/3)θ scan, with an ω scan angle of $(0.80 + 0.35 \tan\theta)°$. The horizontal aperture width was $(2.5 + \tan\theta)$ mm and the vertical aperture width was 4 mm. Three intensity control reflections were measured every 1 h and used to scale the data, although variations were small. Three other reflections were used as orientation controls and were measured every 100 reflections. Reorientation occurred if the difference between the observed and calculated scattering vectors was greater than 0.050°.

700 out of 1645 (42.6%) reflections in the range $0 < \theta \leq 25°$ had $I/\sigma(I) \geq 3.0$ (where $\sigma^2(I) = S + B + (0.04S)^2$ and S and B are the scan and background counts), and were classified as observed. In the refinement the range $0 < \theta \leq 23°$ was used where 697 out of 1300 (53.6%) reflections were observed. Unobserved reflections were not included in the refinement.

The crystal shape was approximated by 11 faces for an absorption correction. In the correction 184 sampling points with an average spacing of 5.0×10^{-3} cm were used for the crystal (volume = 0.0205 mm^3). Transmission factors ranged from 0.450 to 0.633. Lorentz and polarization corrections were also applied.

A Patterson map revealed the position of the Br atom. Three successive difference maps interspersed with least-squares refinement cycles revealed all non-hydrogen atoms. After three more least-squares cycles with all atoms anisotropic R had dropped to 0.062. All the hydrogens could be located on a difference map but best results were obtained when the hydrogens were kept fixed in calculated positions with fixed isotropic temperature factors.

To determine the absolute configuration, the two enantiomers were each refined in three equivalent least-squares cycles, with scattering factors of ref. 2 for non-hydrogen atoms, those of ref. 3 for hydrogen atoms, with anomalous dispersion corrections (4) applied to Br, O, and C, and with a Hughes weighting scheme: $\sqrt{w} = 1.0$ for $|F_o| \leq 23.5$ and $\sqrt{w} = 23.5/|F_o|$ for $|F_o| > 23.5$. For the enantiomer originally chosen, the three cycles refined to $R = 0.056$ and $R_w = 0.070$; for the enantiomer obtained by changing signs of x, y, z, the three cycles refined to $R = 0.046$ and $R_w = 0.056$. The latter is therefore the correct enantiomorph and was refined until convergence, with the weighting scheme modified such that $\sqrt{w} = 1.0$ for $11.5 \leq |F_o| < 17.8$, $\sqrt{w} = |F_o| / 11.5$ for $|F_o| < 11.5$, and $\sqrt{w} = 17.8 / |F_o|$ for $|F_o| > 17.8$. In the final refinement the mean and maximum shifts were 0.001σ and 0.005σ, and R and R_w had dropped to 0.045 and 0.054, respectively (0.123 and 0.054 for all reflections).[1] The atomic positional parameters are given in Table 1.[1]

Discussion

The structure and atomic labelling scheme are shown in Fig. 1. All bond distances (Table 2) agree with accepted values. The *p*-bromobenzoate group is not far from planar (there is an angle of 5° be-

*Estimated standard deviations are given in parentheses and correspond to the least significant digits.

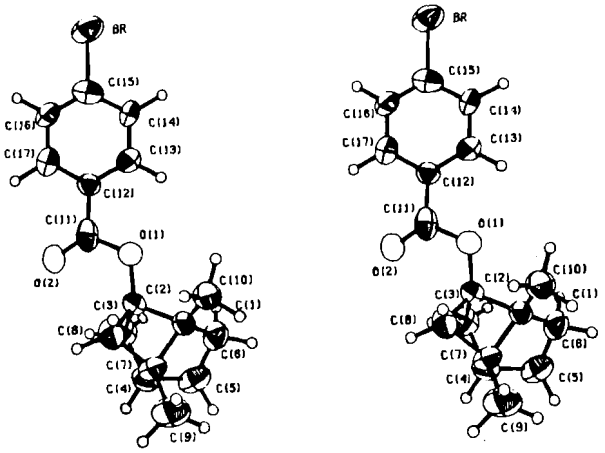

FIG. 1. A stereoview of the molecule.

tween the bromophenyl and carboxyl planes), with normal bond angles (Table 2). The C—C—C angles in the four-membered ring are 80, 88, 81, and 89(1)°, i.e. two opposite angles are significantly smaller than the free cyclobutane C—C—C angle, 89.3° (5). These two angles C(2)—C(1)—C(7) and C(2)—C(8)—C(7) also form envelopes of two five-membered rings whose conformations are adapted to allow for the four-membered ring. The C—C—C angles in the five-membered rings are lower than normal (97, 99, 101, 81, 106 and 97, 99, 104, 95, 80°) and the dihedral angles between the envelopes and the remainder of the rings are 117 and 110° (Fig. 2), i.e. quite small.[2] The envelope of the C(1)C(2)C(3)C(4)C(7) ring has shifted from C(7) in the free camphor to C(1) in the title compound.

The four-membered ring is fairly tightly folded; the dihedral angles are 133 and 129° (Fig. 2) which are significantly smaller than the 162.6° for free cyclobutane (5). Further away from the four-membered ring the deviations from ideal bond angles are less pronounced.

The crystal is held together by van der Waals forces.[1]

[2]Plane C(2)—C(3)—C(4)—C(7) has equation $-0.7953X + 0.0525Y - 0.6039Z = 1.3643$, with atom displacements C(2) 0.05, C(3) −0.08, C(4) 0.09, C(7) −0.06, C(1) 1.12, C(8) −1.04(1) Å.

Absolute rate constants for hydrocarbon autoxidation. 29. Rate constants for abstraction of primary aliphatic hydrogens from 2,2-dimethylbutane by the *tert*-butylperoxy radical[1]

J. A. HOWARD AND J. H. B. CHENIER

Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9

Received April 16, 1980

J. A. HOWARD and J. H. B. CHENIER. Can. J. Chem. **58**, 2808 (1980).

Rate constants for abstraction of primary and secondary hydrogens from 2,2-dimethylbutane by the *tert*-butylperoxy radical at temperatures from 323 to 353 K have been determined from autoxidations and co-autoxidations in the presence of *tert*-butyl hydroperoxide. At 333 K the rate constant for abstraction of a secondary hydrogen is $\sim 1.5 \times 10^{-3}$ M^{-1} s^{-1} and the rate constants for abstraction of a primary hydrogen from the *tert*-butyl and methyl groups of 2,2-dimethylbutane are $\sim 4 \times 10^{-5}$ and $\sim 6 \times 10^{-5}$ M^{-1} s^{-1} respectively.

J. A. HOWARD et J. H. B. CHENIER. Can. J. Chem. **58**, 2808 (1980).

On a déterminé, à partir des autoxydation et co-autoxydations en présence de l'hydroperoxyde de *tert*-butyle, la vitesse d'élimination des hydrogènes primaire et secondaire du diméthyl-2,2 butane par le radical *tert*-butylpéroxy à des températures allant de 323 à 353 K. A 333 K, la constante de vitesse d'élimination d'un hydrogène secondaire est d'environ $1,5 \times 10^{-3}$ M^{-1} s^{-1} et les constantes de vitesse de l'élimination d'un hydrogène primaire des groupes *tert*-butyle et méthyle du diméthyl-2,2 butane sont respectivement d'environ 5×10^{-5} et 6×10^{-5} M^{-1} s^{-1}.

[Traduit par le journal]

Introduction

We have recently reported absolute rate constants for abstraction of secondary and tertiary aliphatic hydrogens by the *tert*-butylperoxy radical in solution at temperatures from 303 to 353 K (1, 2). These rate constants were obtained from the concentrations of propagation products produced by competitive co-oxidations in the presence of *tert*-butyl hydroperoxide under conditions where *t*-$BuO_2^{\bullet}$ was the principal radical involved in rate controlling propagation and termination reactions.

We have since discovered that autoxidation of 2,2-dimethylbutane under these conditions gives significant yields of oxidation products derived from abstraction of the primary hydrogens. Consequently we are able to report here the first reasonably accurate rate constants for abstraction of a primary aliphatic hydrogen by an alkylperoxy radical.

Experimental

Materials

Cyclohexane and 2,2-dimethylbutane (Phillips Research Grade) were used without further purification. *tert*-Butyl hydroperoxide (Aldrich Chemical Co., Inc., 70%) was purified by the method of Hiatt, Clipsham, and Visser (3) and triphenylphosphine (Aldrich) was purified by the method of Hiatt, Smythe, and McColeman (4). 2,2,3,3-Tetraphenylbutane was obtained from L. R. Mahoney (Ford Motor Co., Dearborn, MI). Cyclohexyl hydroperoxide was a gift from V. Malatesta (N.R.C.) and had been prepared by the method of Caglioti, Gasparrini, and Palmieri (5). Di-*tert*-butyl peroxide, 3,3-dimethylbutan-2-one (Matheson, Coleman and Bell), 3,3-dimethylbutan-2-ol (J. T. Baker), 3,3-dimethylbutan-1-ol (Aldrich), 2,2-dimethylbutan-1-ol (Chem. Samples Co.), cyclohexanone (Aldrich), and cyclohexanol (Fischer) were commercially available.

Procedure

Co-autoxidations were carried out in the presence of *tert*-butyl hydroperoxide (1 *M*). Reactions conducted below 323 K were initiated by thermolysis of 2,2,3,3-tetraphenylbutane while at and above 323 K this initiator was not needed because homolysis of *t*-BuOOH provided adequate initiation. Oxidized samples were reduced with enough Ph_3P to convert all hydroperoxides to the corresponding alcohol. They were then pumped into a trap maintained at the temperature of liquid nitrogen and analyzed by gas chromatography (Varian 2800 chromatograph equipped with 12 ft × 1/8 in. columns packed with FFAP or FC-431 stationary phases). It is well known that hydroperoxides are quantitatively reduced to alcohol. Consequently the concentration of an alcohol found by glc was equal to the concentration of the corresponding hydroperoxide formed in propagation.

Oxidized samples were also reduced with lithium aluminum hydride (6) and analyzed by glc.

Results and Discussion

2,2-Dimethylbutane

We can assume from our previous work on autoxidation of hydrocarbons in the presence of *tert*-butyl hydroperoxide (1, 2) that autoxidation of 2,2-dimethylbutane in the presence of *t*-BuOOH can be described by the elementary reactions shown in Scheme 1.

The yields of the major autoxidation products at temperatures from 323 to 353 K (after reduction with Ph_3P) are given in Table 1 and it is apparent that di-*tert*-butyl peroxide (**1**) and 3,3-dimethylbutan-2-one (**2**) were the major products while 3,3-dimethyl-2-hydroperoxybutane (**3**), 2,2-dimethyl-1-hydroperoxybutane (**4**), and 3,3-di-

Initiation

[1] $2t\text{-BuOOH} \longrightarrow t\text{-BuO}_2^{\cdot} + t\text{-BuOH} + H_2O$

Propagation

[2] $t\text{-BuO}_2^{\cdot} + (CH_3)_3CCH_2CH_3 \xrightarrow{k_{2a}} (CH_3)_3CC(CH_3)H^{\cdot} + t\text{-BuOOH}$

$\xrightarrow{k_{2b}} CH_3CH_2C(CH_3)_2CH_2^{\cdot} + t\text{-BuOOH}$

$\xrightarrow{k_{2c}} (CH_3)_3CCH_2CH_2^{\cdot} + t\text{-BuOOH}$

$(CH_3)_3CC(CH_3)H^{\cdot} \xrightarrow{O_2} (CH_3)_3CC(CH_3)HO_2^{\cdot}$

[3] $CH_3CH_2C(CH_3)_2CH_2^{\cdot} \xrightarrow{O_2} CH_3CH_2C(CH_3)_2CH_2O_2^{\cdot}$

$(CH_3)_3CCH_2CH_2^{\cdot} \xrightarrow{O_2} (CH_3)_3CCH_2CH_2O_2^{\cdot}$

Chain transfer

$(CH_3)_3CC(CH_3)HO_2^{\cdot} \xrightarrow{t\text{-BuOOH}} (CH_3)_3CC(CH_3)HOOH + t\text{-BuO}_2^{\cdot}$

3

[4] $CH_3CH_2C(CH_3)_2CH_2O_2^{\cdot} \xrightarrow{t\text{-BuOOH}} CH_3CH_2C(CH_3)_2CH_2OOH + t\text{-BuO}_2^{\cdot}$

4

$(CH_3)_3CCH_2CH_2O_2^{\cdot} \xrightarrow{t\text{-BuOOH}} (CH_3)_3CCH_2CH_2OOH + t\text{-BuO}_2^{\cdot}$

5

[5] $2t\text{-BuO}_2^{\cdot} \longrightarrow 2t\text{-BuO}^{\cdot} + O_2$

[6] $t\text{-BuO}^{\cdot} + t\text{-BuOOH} \longrightarrow t\text{-BuOH} + t\text{-BuO}_2^{\cdot}$

Termination

[7] $2t\text{-BuO}_2^{\cdot} \xrightarrow{2k_t} t\text{-BuOOBu-}t + O_2$

1

SCHEME 1. k_{2a}, k_{2b}, and k_{2c} are overall rate constants for reaction of $t\text{-BuO}_2^{\cdot}$ with 2,2-dimethylbutane and $2k_t$ is the termination rate constant for $t\text{-BuO}_2^{\cdot}$.

methyl-1-hydroperoxybutane (**5**) were formed in significant but lower yields.

Kinetic chain lengths for this autoxidation must have been quite short because concentrations of the termination product **1** were greater than the combined concentrations of the propagation products **3** + **4** + **5**. They were, however, almost certainly greater than 2[**1**]/[**3**] + [**4**] + [**5**] because the substantial yields of 2,2-dimethylbutan-2-one were probably formed by induced decomposition of **3** (reaction [8]) rather than in the cross termination reaction [9]. This is because the termination rate constant was equal, within experimental error, to the rate constant for reaction [7] ($2k_t$ at 303 K = $1.2 \times 10^3\ M^{-1}\ s^{-1}$ (7)).

[8] $t\text{-BuO}_2^{\cdot} + (CH_3)_3CC(CH_3)HOOH \rightarrow t\text{-BuOOH} + (CH_3)_3CC(O)CH_3 + OH^{\cdot}$

[9] $t\text{-BuO}_2^{\cdot} + (CH_3)_3CC(CH_3)HO_2^{\cdot} \rightarrow t\text{-BuOH} + (CH_3)_3CC(O)CH_3 + OH^{\cdot}$

2

We can, therefore, make the reasonable assumption that the total concentration of **3** produced was equal to [**3**] + [**2**].

It has been suggested by a referee that the yields of **4** and **5** may also have been influenced by the following reactions

$t\text{-BuO}_2^{\cdot} + CH_3CH_2C(CH_3)_2CH_2OOH \rightarrow t\text{-BuOOH} + CH_3CH_2C(CH_3)_2CHO + OH^{\cdot}$

$t\text{-BuO}_2^{\cdot} + (CH_3)_3CCH_2CH_2OOH \rightarrow t\text{-BuOOH} + (CH_3)_3CCH_2CHO + OH^{\cdot}$

2,2-Dimethylbutan-1-al, 3,3-dimethylbutan-1-al, and the corresponding acids were, however, not formed in significant yields after reduction with Ph_3P. Furthermore, the ratios of [**2**] + [**3**]/[**4**] and [**2**] + [**3**]/[**5**] after reduction with Ph_3P were equal, within experimental error to the ratios [**3**]/[**4**] and [**3**]/[**5**] after reduction with $LiAlH_4$ — confirming that a significant fraction of **4** and **5** had not been oxidized to aldehyde. Thus the aldehydes would have been reduced by $LiAlH_4$ and the ratios obtained from the two reducing agents would not have been equal.

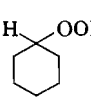
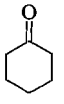
A comparison of [**3**] + [**2**] with [**4**] indicates that a secondary C—H in 2,2-dimethylbutane is about 300 times more reactive than a primary hydrogen of the *tert*-butyl group in this alkane. More interestingly, it would appear, from the relative concentrations of **4** and **5**, that a primary hydrogen of the *tert*-butyl group is somewhat less reactive than a primary hydrogen of the methyl group, i.e. $3k_{2c} > k_{2b}$.

2,2-Dimethylbutane–Cyclohexane





In order to estimate absolute rate constants for abstraction of primary aliphatic hydrogens from 2,2-dimethylbutane we co-autoxidized this substrate with cyclohexane in the presence of *tert*-butyl hydroperoxide because rate constants for reaction of cyclohexane with *t*-$BuO_2^{\cdot}$ from 303 to 353 K are known (2). This co-autoxidation produced cyclohexyl hydroperoxide (**6**) and cyclohexanone (**7**) as well as **1**, **2**, **3**, **4**, and **5** in the yields given in Table 2.

Cyclohexyl hydroperoxide must have been formed by the propagation reaction [10]

[10] *t*-$BuO_2^{\cdot}$ +  $\xrightarrow{k_{10}}$ *t*-BuOOH + 

and total product yields indicated that kinetic chain lengths were of the order of 2–15, i.e. they were substantially longer than chain lengths for autoxidation of 2,2-dimethylbutane in the presence of *t*-BuOOH.

Cyclohexanone was almost certainly produced by autoxidation of cyclohexyl hydroperoxide, reaction [11],

[11] *t*-$BuO_2^{\cdot}$ +  $\longrightarrow$ *t*-BuOOH +  + $HO^{\cdot}$

7

because co-autoxidation of 2,2-dimethylbutane and **6** (using concentrations of **6** similar to those produced by co-autoxidation of 2,2-dimethylbutane and cyclohexane) gave significant yields of **7**. For instance, 2,2-dimethylbutane (6.78 *M*), **6** (0.02 *M*), and *t*-BuOOH (1 *M*) under oxygen at 353 K for 24 h gave [**2**] + [**3**] = 0.014 *M* and [**7**] = 0.004 *M* which suggests that at this temperature the *t*-C—H in cyclohexyl hydroperoxide is about 225 times more reactive than a *s*-C—H in 2,2-dimethylbutane towards *t*-$BuO_2^{\cdot}$.

As was found from autoxidations of neat 2,2-dimethylbutane yields of **4** and **5** were not influenced to any significant extent by autoxidation. We have, therefore, concluded that the reactivities of the secondary and primary hydrogens in 2,2-dimethylbutane relative to cyclohexane, k_{2a}/k_{10}, k_{2b}/k_{10}, and k_{2c}/k_{10} are proportional to ([**2**] + [**3**])/([**6**] + [**7**]), [**4**]/([**6**] + [**7**]), and [**5**]/([**6**] + [**7**]).

TABLE 3. Rate constants per active H (in M^{-1} s^{-1}) for abstraction of primary and secondary H-atoms from 2,2-dimethylbutane and cyclohexane by t-BuO_2·

	Rate constants			
Temperature/K		$(CH_3)_3CCH_2CH_3$	$(CH_3)_3CCH_2CH_3$	$(CH_3)_3CH_2CH_3$
303	0.0002	0.00013	—	—
323	0.0016	0.0007	0.00001	0.00002
333	0.0040	0.0015	0.00004	0.00006
343	0.0095	0.004	0.00005	0.0001
353	0.021	0.009	0.0002	0.0003

Values of these relative rate constants at different ratios of 2,2-dimethylbutane and cyclohexane are given in Table 2 and absolute values of k_{2a}, k_{2b}, and k_{2c} per active H relative to absolute rate constants for cyclohexane are given in Table 3.

A comparison of these rate constants indicates that a secondary hydrogen in 2,2-dimethylbutane is about one half as reactive as a hydrogen in cyclohexane. This difference is due to a difference in both activation parameters since $\log (k_{2a}/k_{10}) = (-2.6 \pm 0.5) + (2.3 \pm 0.8)/\theta$, where $\theta = 2.303RT$ kcal mol^{-1} confirming our previous conclusions regarding the relative reactivities of cyclic and acyclic secondary aliphatic hydrogens towards t-BuO_2· (2). A secondary hydrogen in 2,2-dimethylbutane is also slightly less reactive than a secondary hydrogen in 3-methylpentane (1) which is consistent with our previous conclusions regarding the influence of steric effects on H-atom abstraction from alkanes by t-BuO_2· (2).

It should be pointed out that ratios of **2** to **3** were much lower in the co-autoxidations than they were in autoxidation of 2,2-dimethylbutane, a difference that can probably be attributed to the lower chain lengths in the latter case. Furthermore co-autoxidations always gave [**2**]/[**3**] > [**7**]/[**6**] probably because **3** is more susceptible to induced decomposition than **6**.

The yields of the primary alcohols **4** and **5** relative to [**6**] + [**7**] indicate that at 323 K $k_{2b} = 0.0045k_{10}$ and $k_{2c} = 0.003k_{10}$, i.e. a primary H in the *tert*-butyl and methyl groups of 2,2-dimethylbutane are ~170 and 80 times less reactive than a H atom in cyclohexane.

In addition the relative yields of **4** and **5** support our suggestion that the primary hydrogens of the *tert*-butyl group are slightly less reactive than the primary hydrogens of the methyl group in 2,2-dimethylbutane. This conclusion must, however, be very tentative because of the extremely low yields of **4** and **5**.

Mill, Mayo, Richardson, Irwin, and Allara (8) have previously concluded that the secondary hydrogens in *n*-butane are ~45 times more reactive than the primary hydrogens at 373 K while Van Sickle, Mill, Mayo, and Richardson (9) have reported a relative selectivity of 38 for the primary and secondary hydrogens in pentane towards the *t*-butylperoxy. Our work suggests a similar selectivity bearing in mind, however, that the reactivity of an aliphatic *s*-C—H bond to t-BuO_2· can vary by a factor of about 10 depending on its environment (2).

Our rate constants for reaction of t-BuO_2· with cyclohexane and cyclohexyl hydroperoxide, $k_{10} = 0.25$ M^{-1} s^{-1} and k_{11}/t-C—H = 2 M^{-1} s^{-1} at 353 K are in reasonable agreement with the rate constants reported by Hendry, Gould, Schuetzle, Syz, and Mayo (10), $k_{10} = 0.175$ M^{-1} s^{-1} and k_{11}(overall) = 9.8 M^{-1} s^{-1} at this temperature.

We can conclude from the present work and our previous work on alkane autoxidation (1, 2) that the relative reactivities of 1°, 2°, and 3° hydrogens in acyclic alkanes towards t-BuO_2 at 323 K are 1:35–70:325–3000 which can be compared with relative reactivities towards Br· at 380 K (1:220:19400) and t-BuO· at 323 K (1:12:44) (11). Clearly t-BuO_2· is more selective than t-BuO· which is consistent with the relative strengths of the t-BuO—H and t-BuOO—H bonds (12, 13). It is, however, less selective than Br· which is not entirely consistent with the conclusion that $D_{ROO-H} \sim D_{Br-H}$ (12–14).

Finally Roberts (15) has very recently discovered that the primary hydrogens of the ethyl group in isopentane are about twice as reactive (on a per hydrogen basis) to $(Me_3Si)_2N$· as the primary hydrogens of the isopropyl group in this alkane. This observation makes our finding regarding the relative reactivity of the primary hydrogens of 2,2-dimethylbutane towards t-BuO_2 more credible.

Polymérisation du norbornène par des amorceurs au ruthénium. Etude cinétique de la réaction

CHARLES TANIELIAN, ALAIN KIENNEMANN[1] ET TEMEL ÖSPARPUCU
Laboratoire de Chimie Organique Appliquée, 1, rue Blaise Pascal, 67008 Strasbourg, France
Reçu le 13 mai 1980

CHARLES TANIELIAN, ALAIN KIENNEMANN et TEMEL ÖSPARPUCU. Can. J. Chem. **58**, 2813 (1980).

La détermination des paramètres cinétiques de la réaction de polymérisation du norbornène avec $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$ en catalyse homogène (ordre un par rapport aux deux amorceurs, ordre zéro par rapport au monomère avec $RuCl_3,3H_2O$, ordre variable avec $RuCl_2(P\Phi_3)_3$, E_a de 6,2 kcal/mol pour $RuCl_2(P\Phi_3)_3$ et 22,8 pour $RuCl_3,3H_2O$) nous permet de conclure à une interprétation différente du schéma réactionnel de la polymérisation à partir de ces deux amorceurs tout au moins en ce qui concerne l'étape d'amorçage. Avec $RuCl_2(P\Phi_3)_3$ l'étape lente de la réaction serait la métathèse alors que pour $RuCl_3,3H_2O$, celle-ci serait un échange de ligand au niveau de l'amorceur faisant intervenir le solvant (alcool) suivant un mécanisme dissociatif ou associatif. Cette étape lente est confirmée par une étude en fonction de la concentration en alcool et du vieillissement du amorceur.

CHARLES TANIELIAN, ALAIN KIENNEMANN, and TEMEL ÖSPARPUCU. Can. J. Chem. **58**, 2813 (1980).

The kinetic parameters for the polymerisation reaction of norbornene with $RuCl_3 \cdot 3H_2O$, and $RuCl_2(P\Phi_3)_3$ using homogeneous catalysis have been determined (first-order with respect to two initiators, zero-order with respect to the monomer with $RuCl_3 \cdot 3H_2O$, and variable order with $RuCl_2(P\Phi_3)_3$: E_a 6.2 kcal/mol for $RuCl_2(P\Phi_3)_3$ and 22.8 for $RuCl_3 \cdot 3H_2O$) and leads us to propose different reaction mechanisms for the polymerisation starting from the two initiators, at least for the initiation step. With $RuCl_2(P\Phi_3)_3$ the slow step of the reaction is the metathesis whereas with $RuCl_3 \cdot 3H_2O$ the slow step is a ligand exchange at the initiator involving solvent (alcohol) by a dissociative or associative mechanism. This slow step is confirmed by a study of varying alcohol concentration and initiator aging.

[Journal translation]

Introduction

Depuis les premiers exemples de la réaction de métathèse d'oléfines en catalyse hétérogène ou homogène (1, 2), les travaux sur cette réaction sont exposés périodiquement dans un certain nombre de mises au point (3–10). Les alcènes cycliques présentent un intérêt particulier et l'étude, en catalyse homogène, du mécanisme de la polymérisation est toujours d'actualité (11–15). Nous étudions ici une cycloléfine, le norbornène, pour laquelle les sels ou les complexes de métaux du groupe VIII (Ru, Ir, Os) (11, 16–19) et d'autres éléments de métaux de transition (14, 20), permettent une polymérisation par ouverture de cycle. Avec les amorceurs $RuCl_2(P\Phi_3)_3$ et $RuCl_3,3H_2O$, nous avons pu montrer (21), comme le suggérait Hiraki et coll. (11), une participation du solvant alcool voisine de celle montrée pour l'eau (14). L'effet des alcools (EtOH, *n*BuOH et *t*-BuOH) ne se traduit pas d'une manière identique pour les deux amorceurs ce qui permet de supposer un schéma réactionnel différent tout au moins pour l'étape d'amorçage de la réaction de polymérisation. Ceci nous a conduit dans ce travail, à étudier pour ces deux amorceurs, en milieu alcool, les paramètres cinétiques de la réaction afin de pouvoir d'une part confirmer le rôle de l'alcool et d'autre part traduire les différences de comportement des deux amorceurs au niveau d'un schéma réactionnel.

Partie expérimentale[2]

Toutes les réactions sont effectuées en utilisant l'argon comme gaz protecteur. Les alcools utilisés (puriss Fluka) ont été séchés et distillés selon la méthode au phtalate (22). Le norbornène (purum Fluka) a été distillé puis contrôlé par chromatographie en phase gazeuse et rmn. Les amorceurs $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$ (purum Fluka) ont été utilisés sans autre purification.

Conduite d'une réaction de cinétique: dans un ballon de 100 mL, on dissout l'amorceur $RuCl_3,3H_2O$ ou $RuCl_2(P\Phi_3)_3$ ($3{,}94 \times 10^{-3}$ mol/L) dans EtOH puis on ajoute le monomère (3,94 mol/L) dans EtOH. La consommation de norbornène est mesurée en chromatographie en phase vapeur par la méthode de l'étalon interne: octane (2×10^{-4} mol/L). Des prélèvements du milieu réactionnel (0,1 mL) sont effectués à intervalles réguliers (10 min). Du dicyclopentadiène (0,3 mL) est ajouté de suite pour bloquer la réaction et le mélange est injecté immédiatement en chromatographie en phase gazeuse. Pour chaque essai, la courbe de conversion en fonction du temps présente deux parties distinctes: une partie linéaire donc à vitesse de polymérisation constante, tant que le milieu reste homogène (~ 1 h 30 min), et une partie où la vitesse décroît lentement à partir du moment où le milieu devient hérérogène par précipitation du polymère formé. Le système devient ensuite progressivement inactif.

Différentes raisons peuvent être évoquées pour expliquer ce phénomène: hétérogénéité du milieu, diminution de la quantité d'amorceur par entraînement lors de la précipitation du polymère, ou établissement d'un équilibre entre norbornène, oligomère et polymère comme montré pour le cyclopentène ou le cyclooctène (23–25). Pour notre part, nous n'avons pu montrer

un tel équilibre. Lors de la détermination de tous nos paramètres cinétiques, nous nous limiterons à la partie linéaire de la courbe.

Les conditions chromatographiques sont les suivantes: appareil Varian 202, détecteur catharomètre, gaz vecteur He 30 mL/min, colonne SE 30, 10% sur chromosorb W (80–100 mesh), longueur 2 m, diamètre, 3,2 mm, isotherme 75°C, t injecteur 150°C, t détecteur 150°C.

Le polymère obtenu en fin de réaction est soigneusement lavé au méthanol, séché et pesé ce qui permet en fin de réaction de contrôler les résultats obtenus par chromatographie. Bien que l'action des deux amorceurs conduise à des paramètres cinétiques différents, nous obtenons, avec $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$, un polymère de même type: ouverture de cycle *trans* (21).

Résultats

I. Détermination des paramètres cinétiques

Il est d'usage, lors de l'étude cinétique des réactions de polymérisation de distinguer la cinétique en fonction des concentrations initiales ou des paramètres courants, c'est la première qui sera considérée ici. La vitesse de polymérisation peut s'exprimer par:

$$V = V_a + V_p = -d[M]/dt$$

où V, V_p et V_a sont les vitesses de polymérisation, de propagation et d'amorçage et [M] la concentration en monomère. Si la chaîne cinétique est longue $V = V_p$. Si de plus, nous supposons que toutes les molécules d'amorceur donnent naissance à autant de chaînes actives, la loi de vitesse pourra s'exprimer par $v = k[\text{amorceur}]^{\alpha}[\text{monomère}]^{\beta}$.

(1) Ordre par rapport à l'amorceur

Les figs 1 et 2 représentent les variations du taux de conversion en fonction du temps pour différentes concentrations en $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$. Pour chaque concentration en amorceur, la pente de la partie linéaire (taux de conversion <20–25%) donne directement la valeur de chaque vitesse. Celle-ci, reportée en fonction de [Co], concentration initiale en amorceur, conduit à une droite. L'ordre de la réaction est donc un par rapport à l'amorceur pour $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$.

(2) Ordre par rapport au monomère

(a) Cas de $RuCl_2(P\Phi_3)_3$. Pour des concentrations en monomère allant de 7,6 mol/L à 0,13 mol/L la vitesse de polymérisation reste constante alors que pour des concentrations plus faibles 0,13 mol/L à 0,023 mol/L, la vitesse de polymérisation décroît avec la concentration initiale en monomère (fig. 3). L'ordre par rapport au monomère est variable: proche de zéro pour les concentrations importantes et proche de un pour de faibles concentrations.

(b) Cas de $RuCl_3,3H_2O$. La réaction est d'ordre zéro par rapport au monomère car la vitesse de polymérisation reste constante pour un domaine de

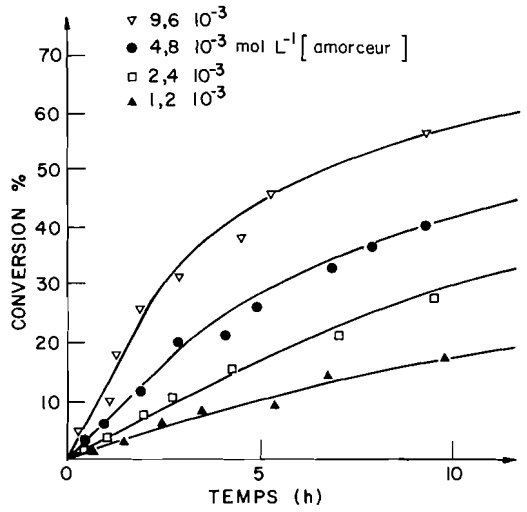

FIG. 1. Influence de la concentration de l'amorceur $RuCl_3,3H_2O$ sur la conversion du norbornène. Solvant EtOH; T = 60°C; [monomère] = 2,5 mol/L.

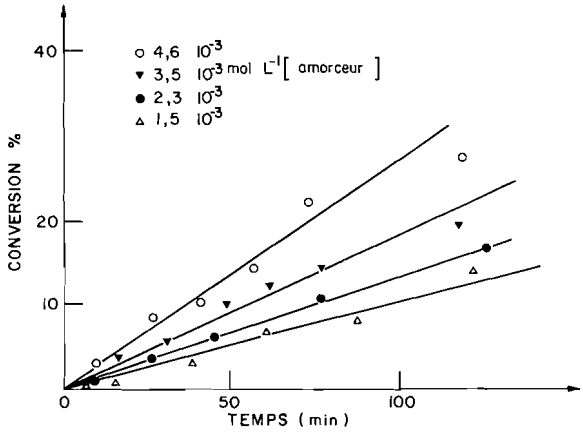

FIG. 2. Influence de la concentration de l'amorceur $RuCl_2(P\Phi_3)_3$ sur la conversion du norbornène. Solvant EtOH; T = 55°C; [monomère] = 2,5 mol/L.

concentration initiale de 0,011 à 5,25 mol/L de norbornène (fig. 4).

Pour $RuCl_3,3H_2O$ et pour $RuCl_2(P\Phi_3)_3$ à partir d'une certaine concentration en monomère, la loi de vitesse peut s'écrire $v = k[\text{Co}]^1[\text{Mo}]^0 = k[\text{Co}]$. Pour la détermination des constantes de vitesse de la réaction et des paramètres thermodynamiques d'activation, la concentration en monomère sera toujours telle que cette loi de vitesse reste vérifiée.

(3) Constante de vitesse et paramètre thermodynamique d'activation

L'étude de la vitesse de réaction en fonction de la température (figs 5 et 6) permet de calculer les constantes de vitesse k (L mol^{-1} s^{-1}): 3,7; 9,7; 21 et 88 × 10^{-6} respectivement à 40, 50, 60 et 68°C avec

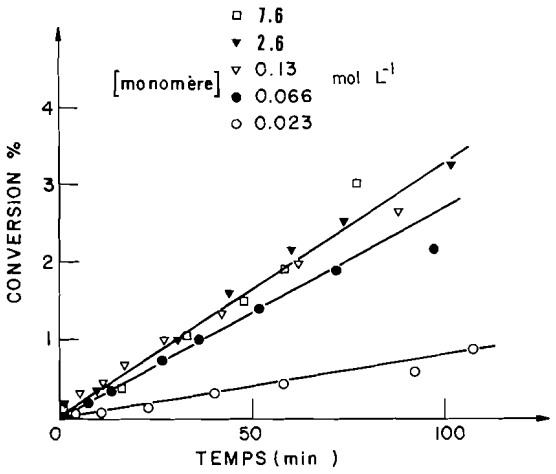

FIG. 3. Influence de la concentration en monomère sur la conversion du norbornène. Solvant EtOH; $T = 60°C$; amorceur: $[RuCl_2(P\Phi_3)_3] = 3{,}95 \times 10^{-3}$ mol/L.

$RuCl_3,3H_2O$. 1,4; 1,75 et 2,1 $\times 10^{-4}$ respectivement à 60, 68 et 76°C pour $RuCl_2(P\Phi_3)_3$. Ces valeurs, à l'aide de la représentation $\log k = f(1/T)$ déterminent les différents paramètres thermodynamiques d'activation (tableau 1).

Discussion

De nombreux essais ont été tentés en catalyse hétérogène afin d'approcher le mécanisme réactionnel par l'étude cinétique (8). Cependant la mauvaise fiabilité des résultats, due, soit à des catalyseurs non reproductibles, soit à une variation du nombre de sites actifs, fait que les énergies d'activation et les chaleurs d'adsorption calculées sont très relatives. Cependant, Clark et Cook (26) pour la métathèse hétérogène du propène et Ramain et Trambouze (27) pour le 2-pentène en homogène concluent que la réaction est du premier ordre par rapport à l'alcène et du premier ordre par rapport à l'amorceur dans le second cas. Davie et coll. (28) pour sa part indique qu'il est impossible de distinguer entre premier et deuxième ordre pour une réaction réversible. Si l'on développe le modèle de Langmuir–Hinshelwood vérifié par Moffat et Clark (29) et Lewis et Wills (30) pour la métathèse hétérogène du propène et par Hughes (31) pour la métathèse homogène du 2-pentène, cette expression laisse prévoir que la réaction doit être du premier ordre par rapport au catalyseur et d'ordre variable par rapport à l'oléfine ce qui est le cas pour $RuCl_2(P\Phi_3)_3$.

(1) Cas de $RuCl_2(P\Phi_3)_3$

Nous pensons que le type de schéma réactionnel pouvant le mieux rendre compte de nos résultats peut se résumer ainsi:

[1] $RuCl_2(P\Phi_3)_3 + M \rightleftharpoons C(M)$

[2] $C(M) \rightleftharpoons CM_D$

[3] $CM_D + M \rightleftharpoons CM_D(M)$

[4] $CM_D(M) \rightleftharpoons CM_{D+1}$

[5] $CM_{D+1} + M \rightleftharpoons CM_{D+1}(M)$

[6] $CM_{D+1}(M) \rightleftharpoons CM_{D+2}$

. . . . . .

. . . . . .

[7] $CM_{Dn} + M \rightleftharpoons CM_{Dn}(M)$

[8] $CM_{Dn}(M) \rightleftharpoons CM_{Dn+1}$

L'étape [1] consiste en la formation d'une espèce C(M) dans laquelle le norbornène M se trouve

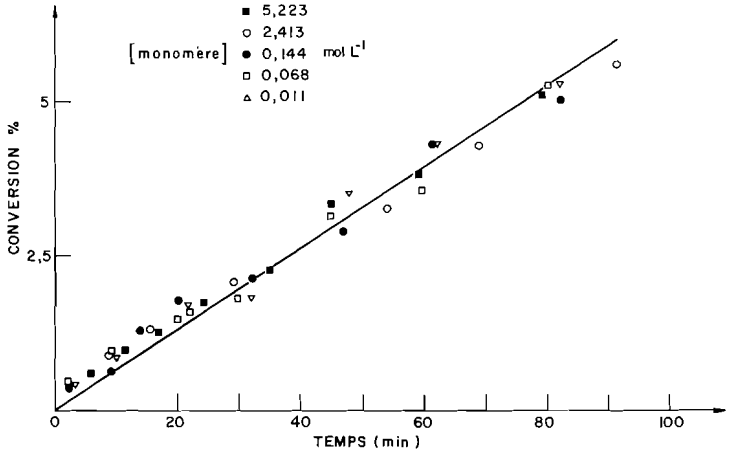

FIG. 4. Influence de la concentration en monomère sur la conversion du norbornène. Solvant EtOH; $T = 60°C$; amorceur: $[RuCl_3,3H_2O] = 3{,}94 \times 10^{-3}$ mol/L.

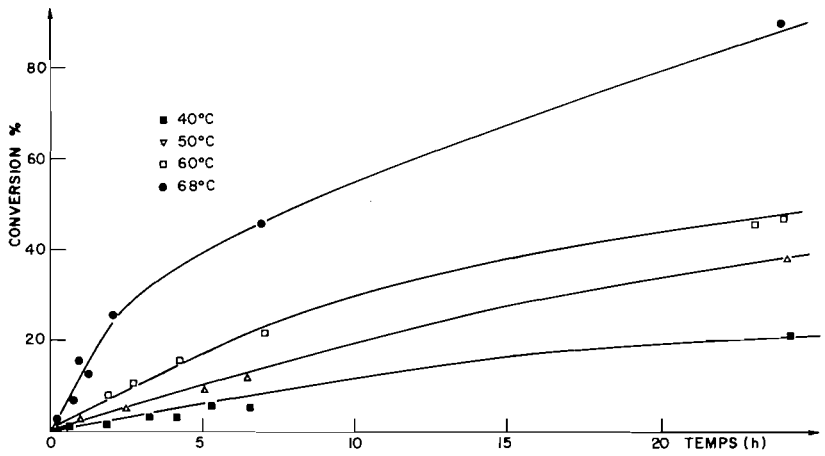

FIG. 5. Influence de la température sur la conversion du norbornène. Solvant EtOH; amorceur: [$RuCl_3,3H_2O$] = 3,94 × 10^{-3} mol/L; [monomère] = 3,95 mol/L.

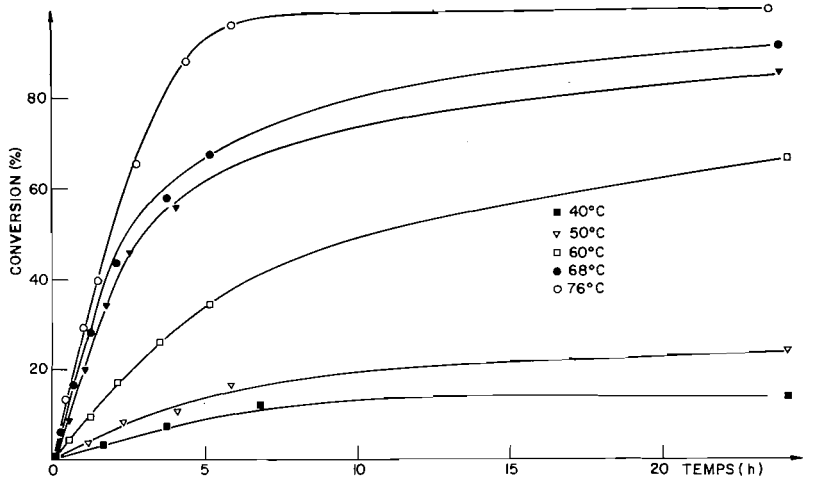

FIG. 6. Influence de la température sur la conversion du norbornène. Solvant EtOH; amorceur: [$RuCl_2(P\Phi_3)_3$] = 3,94 × 10^{-3} mol/L; [monomère] = 3,94 mol/L.

TABLEAU 1. Paramètres thermodynamiques d'activation

	A (L mol s^{-1})	E (kcal/mol)	$\Delta S^{\neq}$ (ue) (60°C)	$\Delta H^{\neq}$ (kcal) (60°C)	$\Delta G^{\neq}$ (kcal) (60°C)
$RuCl_3,3H_2O$	$2,8 \times 10^{10}$	22,8	−10,9	22,1	25,7
$RuCl_2(P\Phi_3)_3$	1,6	6,2	−57,7	5,5	24,7

coordiné au ruthénium par complexe π. L'ensemble de nos résultats étant en accord avec un mécanisme par métathèse faisant intervenir des espèces métallocarbéniques, l'étape [2] représente la formation d'un métallocarbène CM_D à partir de C(M), conformément au schéma réactionnel de Hérisson et Chauvin (32). Le stade [3] correspond à la complexation d'une molécule d'oléfine avec le métallocarbène et la réaction [4] au premier processus de métathèse (constante de vitesse k_p). On a ensuite, de nouveau, la coordination d'une molécule de monomère (étape [5], constante d'équilibre K) suivie d'une métathèse (stade [6], constante k_p) et ainsi de suite [7], [8].

La réaction de métathèse serait l'étape lente de l'ensemble du phénomène et l'expression de la vitesse est alors donnée par:

$$v = -\frac{d[M]}{dt} = k_p \sum_n [CM_{Dn}(M)]$$

or:

$$\sum_n [CM_{Dn}(M)] = K[M] \sum_n [CM_{Dn}]$$

et:

$$[Co] \simeq \sum_n [CM_{Dn}] + \sum_n [CM_{Dn}(M)]$$

où [Co] est la concentration initiale en catalyseur, puisque la chaîne cinétique est longue, d'où:

$$\sum_n [CM_{Dn}(M)] = K[M]\left\{Co - \sum_n [CM_{Dn}(M)]\right\}$$

et:

$$\sum_n [CM_{Dn}(M)] = \frac{K[M][Co]}{1 + K[M]}$$

la vitesse de la polymérisation devient alors:

$$v = k_p \frac{K[M][Co]}{1 + K[M]}$$

Cette expression laisse bien prévoir que la réaction doit être du premier ordre par rapport à l'amorceur, à concentration constante en oléfine, et d'ordre variable par rapport au norbornène, à teneur fixe en amorceur.

Dans le cas de la polymérisation du norbornène par ouverture de cycle les valeurs trouvées des paramètres d'activation sont proches de celles de la littérature. L'énergie d'activation 6,2 kcal/mol est voisine de celles données par Hughes (31) 6,6 et 7,2 kcal/mol pour le 2-pentène et le 4-nonène, par Kranz et Beck (33) 4,17 et 3,23 kcal/mol pour le *trans* et le *cis* polypentenamère, 7,3 (26) et 7,3 kcal/mol (28) pour le propène et même 12,1 kcal/mol (34) pour le 1,4 polybutadiène. L'entropie d'activation 57,7 ue est aussi proche de celle trouvée par Hughes (31). Cette concordance semble bien indiquer la réaction procède bien par un mécanisme de métathèse avec $RuCl_2(P\Phi_3)_3$. La valeur de 6 kcal/mol pour E_a est vraisemblablement inférieure à l'énergie de dissociation des liaisons les plus faibles mises en jeu ce qui indique l'établissement d'un processus concerté faisant intervenir simultanément des ruptures et des formations de liaisons. La valeur très fortement négative de $\Delta S^{\neq}$ est l'indice d'une réduction des degrés de liberté du système et confirme la formation d'un état de transition cyclique.

(2) Cas de $RuCl_3,3H_2O$

Avec $RuCl_3,3H_2O$, les données cinétiques très différentes de celles obtenues pour $RuCl_2(P\Phi_3)_3$ excluent une interprétation analogue venant ainsi confirmer une étude de la réaction en présence de différents alcools (21). Nos résultats s'expliquent si l'étape lente de la réaction n'est plus la réaction de métathèse mais est un échange de ligands au niveau de l'amorceur. Cette étape ne fait pas intervenir le monomère mais le solvant suivant un mécanisme dissociatif ou associatif.

Le mécanisme dissociatif représenté par les deux équations:

$$L_3MX_3 \xrightarrow{\text{lent}} L_2MX_3 + L$$

$$L_2MX_3 + L' \xrightarrow{\text{rapide}} L_2L'MX_3$$

suppose une cinétique d'ordre un par rapport à l'amorceur et zéro par rapport au solvant. Par contre, la deuxième possibilité:

$$L_3MX_3 + ROH \rightarrow L_2(ROH)MX_3 + L$$

suppose un ordre un par rapport à l'alcool. Une étude en fonction de la concentration en alcool en milieu hexane (de $3{,}4 \times 10^{-3}$ à 0,274 mol de EtOH) montre que l'ordre de la réaction est nul par rapport à l'alcool donc nous avons un mécanisme dissociatif. La valeur très élevée de l'énergie d'activation (22,8 kcal/mol) montre aussi que l'étape lente ne se situe pas au niveau de la réaction de métathèse mais lors de la formation de l'espèce active initiale. Ceci est confirmé par une étude du vieillissement de l'amorceur. Si l'on chauffe une solution alcoolique de $RuCl_3,3H_2O$ pendant 4, 24 et 72 h ($T = 60°C$) avant d'additionner le monomère nous constatons une augmentation très nette de la vitesse initiale de polymérisation: 3×10^{-4} pour les essais à 24 et 72 h; (sans vieillissement: $0{,}2 \times 10^{-4}$) suivie d'une vitesse voisine pour les quatres essais après cette période initiale (10 min).

Les vitesses initiales identiques pour les essais à 24 et 72 h indiquent l'établissement d'un équilibre entre espèce initiale et dissociée. Les vitesses initiales ainsi obtenues sont proches de celles avec $RuCl_2(P\Phi_3)_3$ à la même température mais sans vieillissement: (3×10^{-4} mol L^{-1} s^{-1} comparé à $1{,}4 \times 10^{-4}$). Nous pouvons donc conclure que d'après cette étude, l'étape lente de la réaction avec $RuCl_3,3H_2O$ est la formation de l'espèce active obtenue par un mécanisme dissociatif.

(3) Mécanismes relatifs aux systèmes $RuCl_3,3H_2O$ et $RuCl_2(P\Phi_3)_3$

(a) $RuCl_2(P\Phi_3)_3$. Différents mécanismes (11, 16, 17) ont été suggérés pour la polymérisation du norbornène par les amorceurs au ruthénium. Nous avons montré la participation de l'alcool (21) selon un schéma voisin de celui de Laverty et coll. (14, 35). L'étude cinétique confirme la possibilité de ce schéma en mettant en évidence les différences existant entre $RuCl_2(P\Phi_3)_3$ et $RuCl_3,3H_2O$, mais ne permet pas de trancher entre différentes propositions mécanistiques (réfs 10, 36, 37, par exemple).

Cependant nous pensons que pour $RuCl_2(P\Phi_3)_3$, la polymérisation débute par la formation d'un complexe de coordination π ruthénium–norbornène, formation d'un métallocarbène, complexation d'une deuxième molécule d'oléfine suivie de la réaction de métathèse faisant intervenir un état de transition cyclique à quatre centres. La coordination d'une nouvelle molécule de norbornène permet la poursuite de la réaction par métathèses successives.

(b) $RuCl_3,3H_2O$. Il semble logique de supposer que la phase de propagation reste analogue à celle proposée pour $RuCl_2(P\Phi_3)_3$. La différence essentielle se situerait au niveau de l'amorceur comme le montre l'étude en fonction de l'alcool utilisé et du vieillissement. La réaction débuterait par une dissociation du complexe

$$RuX_3L_3 \rightarrow RuX_3L_2 + L$$

suivie d'une fixation de l'alcool pour former un complexe

$$\begin{matrix} & Y_1 & Y_1 = H \\ Ru & \diagup & \\ & \diagdown & \\ & Y_2 & Y_2 = OR, OH \end{matrix}$$

qui en présence de norbornène conduit à la coordination de celui-ci et formation d'un métallocarbène.

Remerciements

Les auteurs remercient très vivement le Docteur Raoul Fonseca pour ses fructueuses discussions et Madame Louise Méchin pour la frappe du manuscrit.

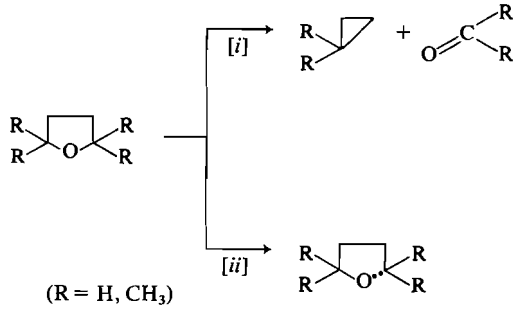
The photolysis of tetrahydrofuran and of some of its methyl derivatives at 185 nm[1]

NURAY KIZILKILIC, HEINZ-PETER SCHUCHMANN, AND CLEMENS VON SONNTAG



Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung, Stiftstr. 34-36, D-4330 Mülheim a.d. Ruhr, West Germany

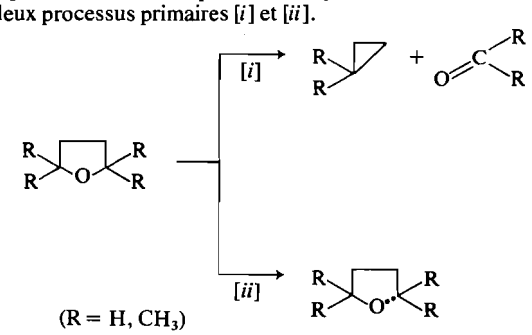
Received March 5, 1980

This paper is dedicated to Prof. K. J. Laidler on the occasion of his 65th birthday

NURAY KIZILKILIC, HEINZ-PETER SCHUCHMANN, and CLEMENS VON SONNTAG. Can. J. Chem. **58**, 2819 (1980).

The uv photolysis of tetrahydrofuran, **1**, 2-methyltetrahydrofuran, **2**, *cis*-2,5-dimethyltetrahydrofuran, **3**, *trans*-2,5-dimethyltetrahydrofuran, **4**, and 2,2,5,5-tetramethyltetrahydrofuran, **5**, has been investigated by product analysis in the liquid phase, and quantum yields have been determined. The photolysis of tetrahydrofuran itself was also studied in the gas phase at pressures ranging from 1 to 120 atm (pressurizing gas N_2); and very little difference was found between the photolytic behaviour of the vapour at 120 atm and that of the liquid. The major products are in all cases the cyclopropanes and the corresponding carbonyl compounds, as well as the olefinic alcohols and the carbonyl compounds that are isomeric with the starting material. These products are considered to be formed by the two major primary processes [*i*] and [*ii*].

The cyclopropanes formed in reaction [*i*] retain some excess energy (apparently more than is needed to realize the trimethylene form), and in the photolysis of tetrahydrofuran vapour the hot cyclopropane rearranges to a considerable extent into propene. The propene to cyclopropane yield ratio falls strongly with increasing pressure, to a value of 0.065 at 120 atm. A similar value is observed in the liquid phase photolysis.



The five-membered oxyl alkyl diradical from reaction [*ii*] is the likely intermediate in the *cis–trans* photoisomerization that is observable with the 2,5-dimethyltetrahydrofurans ($\phi(cis \rightarrow trans) \approx \phi(trans \rightarrow cis) \approx 0.2$). The photolysis of these compounds also demonstrates that steric factors have a strong bearing on the course of the reaction, e.g. the quantum yield of methylcyclopropane from the *cis* compound is 0.22, vs. 0.08 from the *trans* compound.

Molecular hydrogen is produced if the tetrahydrofurans carry hydrogen in α-position. Its production is enhanced if the α-position is shared with a methyl group (**1** gives a hydrogen quantum yield of 0.07, **2** of 0.17, **3** of 0.27, **4** of 0.29, and **5** of zero).

NURAY KIZILKILIC, HEINZ-PETER SCHUCHMANN et CLEMENS VON SONNTAG. Can. J. Chem. **58**, 2819 (1980).

La photolyse à 185 nm du tétrahydrofuranne et de quelques-uns de ses dérivés méthylés à l'état liquide a été étudiée par l'analyse des produits; les rendements quantiques des produits ont été déterminés.

De même, la photolyse du tétrahydrofuranne fut étudiée, à l'état gazeux sous des pressions variant d'une à 120 atm, N_2 servant à soutenir la pression. On trouve que les comportements photolytiques à l'état gazeux à 120 atm, et à l'état liquide, sont presque identiques. Dans tous les cas, les produits majeurs sont les cyclopropanes et les composés carbonylés qui leur sont complémentaires, ainsi que des alcools oléfiniques et d'autres composés carbonylés isomères des tétrahydrofurannes originaux. Ces produits résultent vraisemblablement des deux processus primaires [*i*] et [*ii*].

La génération de la molécule de cyclopropane à la forme chaude, voire triméthylénique, paraît établie par le fait que, dans la photolyse du tétrahydrofuranne gazeux, la proportion de propylène par rapport au cyclopropane décroît fortement quand la pression croît, et atteint la valeur de 0.065 quand la pression s'élève à 120 atm. Une valeur similaire est trouvée lors de la photolyse en phase liquide. Le diradical oxyle alkyle à cinq chaînons est l'intermédiaire fort probable de la réaction de photoisomérisation *cis–trans* que l'on observe chez les tétrahydrofurannes diméthylés en 2,5 ($\phi(cis \rightarrow trans) \approx \phi(trans \rightarrow cis) \approx 0.2$). En plus, la photolyse des ces derniers montre que des facteurs stériques peuvent influer puissamment sur le cours de la réaction photochimique. Le rendement quantique du méthylcyclopropane provenant du composé *cis* égale 0.22 alors que, à partir du composé *trans*, il atteint 0.08 seulement. De l'hydrogène est produit quand le composé original porte des atomes d'hydrogène en position α. Sa production est augmentée quand un atome d'hydrogène partage la position α avec un groupement méthyle.

Introduction

In saturated ethers photolyzed at 185 nm the C—O bond is cleaved with high quantum yields, through homolytic and molecular primary processes (1). In cyclic ethers the first of these paths leads to a diradical. The second kind of pathway is not easily distinguished from the first because in principle reactions of the diradical as well as concerted rearrangements may lead to the same products. In the gas phase, tetrahydrofuran (2–4) as well as oxetane (5) and 1,4-dioxane (6) are known to undergo extensive fragmentation into products of molecular weight below that of the starting material. The same is true of liquid 1,4-dioxane (7, 8), whereas liquid tetrahydropyran (9) and oxepane (10) mainly yield unsaturated alcohols $CH_2{=}CH{-}(CH_2)_n{-}OH$ and aldehydes $CH_3{-}(CH_2)_n{-}CHO$ that are isomeric with the starting material. One does expect a high degree of fragmentation from non-thermalized intermediates in the gas phase compared to in the liquid phase. Even so, ring size appears to emerge as an influencing factor in the photolytic behaviour of the homologous monooxacyclanes.

The present work addresses itself to the question whether the products cyclopropane, propene, formaldehyde, hydrogen, and carbon monoxide that are observed besides other minor products in the tetrahydrofuran gas phase photolysis (2–4) are due to the fragmentation of non-thermalized larger intermediates, or rather formed primarily. The influence that is exercised by non-chromophoric substituents such as methyl groups has also been studied.

Experimental

Tetrahydrofuran (Merck), 2-methyltetrahydrofuran (Aldrich), and 2,2,5,5-tetramethyltetrahydrofuran (11) were fractionated from sodium under argon to a gc purity of better than 99.9% (the former two) and 99.6%. 2,5-Dimethyltetrahydrofuran (Aldrich) was separated by preparative gc into the *cis* and *trans* isomers, assigned as such according to their ^1H nmr spectra (12). After subsequent distillation under argon they showed a gc purity of better than 99.6% (*cis*) and 98.3% (*trans*). The latter still contained some *cis*-2,5-dimethyltetrahydrofuran.

Samples (2 mL) were deaerated by purging with argon for 20 min. Deaeration by this procedure is sufficient since longer purging does not change the product distribution, and oxydation products otherwise present are not formed in measurable amounts. Irradiation was carried out with a low pressure Hg arc at 15°C in a Suprasil QS cell with an exposed area of 2 cm². Only the 185 nm light is photoactive in pure tetrahydrofuran as shown by the fact that on interposition of a Vycor quartz plate, which absorbs at 185 nm but passes 254 nm radiation, the decomposition yield is negligible ($\leq 10^{-3}$) compared to that at 185 nm. For this reason the light could be used unfiltered. Dose rates of 185 nm light were near 5×10^{17} quanta/min. Dosimetry was done by means of the ethanol actinometer (1). In the kinetic runs, doses totalled up to 3×10^{19} quanta, corresponding roughly to a conversion of 0.25%. The products (except formaldehyde) were identified by gc with the help of reference materials and/or gc–ms, and determined by gc using a suitable alkane as an internal standard. Formaldehyde was determined photometrically by the acetylacetone – ammonium acetate method (13). In general, procedures employed were similar to those previously described (14, 15).

The photolysis of tetrahydrofuran vapour was also studied. Relative quantum yields were determined at different pressures. A cell (Beckman Instruments, type RIK F 076) that could be pressurized up to 150 atm was charged by passing through it a stream of argon saturated with tetrahydrofuran at 0°C. Then the sample was brought to the desired pressure with N_2. The optical path length of the cell was 5 cm, its window size 3 cm². There is total absorption of the 185 nm light under these conditions. Conversions were kept below 20%. After photolysis the contents of the cell were expanded through a sampling device where part of the gas mixture was retained for gc analysis. A complicating feature in these vapour phase photolyses was the gradual formation of a polyformaldehyde deposit on the cell window whereby the effective light intensity was diminished somewhat from one run to the next. No attempt was made to determine formaldehyde in these experiments because of its poor gc flame ionization response.

The molar extinction coefficients of the substituted tetrahydrofurans studied were determined in the region from 185 nm to near 200 nm on a Cary model 17 spectrophotometer (Figs. 1 and 2). The procedure was similar to that described previously (16).

Results

Ultraviolet absorption of the methylated tetrahydrofurans sets in near 200 nm, ε(185 nm, gas phase) reaching about $10^3\ M^{-1}\ cm^{-1}$ (Figs. 1 and 2). The molar extinction coefficient of tetrahydrofuran itself at that wavelength is between 600 and $700\ M^{-1}\ cm^{-1}$, cf. ref. 17.

The products of the liquid tetrahydrofuran photolysis, and the quantum yields, are given in Table 1. The results from the photolysis of the substituted tetrahydrofurans in the liquid phase are summarized in the subsequent tables (2-methyltetrahydrofuran, Table 2; *cis*- and *trans*-2,5-dimethyltetrahydrofuran, Table 3; 2,2,5,5-tetra-

methyltetrahydrofuran, Table 4). The quantum yields of the major products from the liquid phase photolysis are considered accurate within ±10%. Product formation was linear with dose in the dose range employed. The combined yield of unidentified products as seen by gc amounted to less than 5% of the starting material consumed. The quantum yields of cyclopropane, ethylene, and propylene appear to slightly decrease with temperature, whereas that of propane increases.

The cyclopropanes and the corresponding carbonyl compounds are major products in all cases. A remarkable feature is the large difference between

methyl substitution. Hydrogen in α-position appears to be a prerequisite for H_2 formation. Otherwise $\phi(H_2)$ rises with the number of methyl substituents in α-position. With the 2,5-dimethyltetrahydrofurans a *cis* ⇄ *trans* isomerization with a quantum yield of ~ 0.2 is observed. In principle the same type of reaction should occur with the other compounds but cannot be detected there.

From the vapour phase photolysis of tetrahydrofuran, only products more volatile than the starting material were measured. Since it was impractical to determine quantum yields from these runs, the product yields are expressed in terms relative to the sum of the cyclopropane and propylene yields at different pressures (Fig. 3 and Table 6). Beside the products shown there, acetaldehyde and ethylene oxide, some methane, but-1-ene, and pent-1-ene as well as traces of butane, *cis*- and *trans*-pent-2-ene, hex-1-ene, and allyl methyl ether were observed at the lower pressures employed. There were also traces of a further few unidentified products. At the highest pressures where a proportionally greater part of the sample cannot be brought to analysis owing to the procedure employed, conversions needed to be higher for easy product measurement. In these cases, the relative yield of butyraldehyde after the longer photolysis times tended to fall below the value reached after a shorter time. Within experimental error, which is estimated at about ±10%, such behaviour was not observed in the other products measured.

Discussion

In the liquid phase, vibrationally excited intermediates formed subsequent to the primary act of photolysis are for the most part thermalized if their lifetime with respect to fragmentation is not very short. In this way, species can be trapped which would undergo fragmentation at low pressures. Vapour phase photolysis at high pressure provides a transition between these extreme regimes. In the case of tetrahydrofuran it appears that the high pressure limits of certain quantities can be taken to be identical with their values obtained from the liquid phase photolysis (Table 1, Fig. 3). The present work indicates that the tetrahydrofurans studied essentially obey, if structurally possible, the same photolysis mechanism represented in Scheme 1 where the case of *cis*-2,5-dimethyltetrahydrofuran is shown as an example.

The Oxyl Alkyl Diradical

In general, the cleavage of a C—O bond is the most important process in the photolysis of ethers (1). In the cyclic ethers such as the tetrahydrofurans such a process would lead to an oxyl alkyl diradical (reaction [3], Scheme 1). The assumption of oxyl alkyl diradical intermediates in the photolysis of cyclic ethers is supported by results from the oxepane system (10). If the lifetime of the oxyl alkyl diradical with respect to reclosure is long

enough, rotation around an adjacent bond can lead to an isomerization which will be detected in the case of suitably substituted compounds such as the *cis*- and *trans*-2,5-dimethyltetrahydrofurans. One might consider that the observed *cis* ⇄ *trans* isomerization of these compounds is due to a process like reaction [10]. With quantum yields of about 0.2 in the forward direction this process appears to be of major importance. The reverse of reaction [3] which must also occur cannot be measured. It is probably of similar importance and constitutes a major path of deactivation applicable to all systems examined.

In principle, a *cis* ⇄ *trans* isomerization would also occur if a C(α)—C(β) bond were broken in the primary step. We consider this process unlikely because C—C bond cleavage has been found to be insignificant in the ethers investigated except when highly branched (1). The following discussion rests upon the assumption that the oxyl alkyl diradical is indeed an intermediate.

In competition with reclosure the oxyl alkyl diradical may disproportionate to give the ring-

SCHEME 1. Primary processes in the photolysis (185 nm) of liquid *cis*-2,5-dimethyltetrahydrofuran.

opened isomers, carbonyl compounds (reaction [11]) and olefinic alcohols (reactions [8] and [9]). However, the same products could be formed via true molecular processes (reactions [2] and [4]). It is difficult to distinguish between such processes and the disproportionation reactions of the oxyl alkyl diradical (a similar difficulty is encountered in open-chain ethers with respect to cage disproportionation reactions (1)). Nevertheless, the approach taken in the following suggests that one of the reaction modes is favoured over the other. To this end we consider the formation of butyraldehyde which could be formed either directly (reaction type [4]) or through the oxyl alkyl diradical (reaction type [3] followed by reaction type [11]).

The rate constant (classical) for the unimolecular decay of a molecule containing an energy $E - E_0$ in excess of its decomposition threshold E_0 is assumed at $k_{dec} = A(1 - E_0/E)^{s-1}$ (where A is the frequency factor; s, the number of oscillators in the molecule, cf. ref. 18*a*). The original energy input at 185 nm is 640 kJ mol^{-1}. The initial hotness (E) of the alkyl oxyl diradical equals the energy input minus the C—O bond dissociation energy, plus release of ring strain (19), i.e. about 280 kJ mol^{-1}. The initial hotness of a directly formed butyraldehyde molecule (reaction type [4]) equals the energy input minus the ground state energy difference between butyraldehyde and tetrahydrofuran, i.e. about 660 kJ mol^{-1} (for heats of formation, see e.g. ref. 20). These estimates give upper limits for the initial hotness E, because energy loss through vibrational thermalization of the electronically excited tetrahydrofurans has been neglected. The critical energy E_0 for bond cleavage of the diradical is estimated at about 60 kJ mol^{-1}; it equals the endothermicity of reaction [13] (28 kJ mol^{-1} as estimated according to (21)) plus the activation energy of the back reaction [−13] which is assumed at ~30 kJ mol^{-1} (for similar reactions cf. ref. 19). This estimate is based on the assumption that in the bond-breaking process [13] the electrons of the trimethylene species neither effectively interact nor that the diradical decomposes concertedly into cyclopropane and formaldehyde, a process which is likely to require a rather strained transition state. For butyraldehyde E_0 is probably near 340 kJ mol^{-1}

[13] $\cdot CH_2—CH_2—CH_2—CH_2—O\cdot$
$\rightarrow \cdot CH_2—CH_2—CH\cdot_2 + CH_2O$

(cf. 341 kJ mol^{-1} for acetaldehyde (22) and 343 kJ mol^{-1} for propionaldehyde (23)). It thus appears that the probability of the thermalization of the hot diradical before decomposition should be considerably smaller (hotness $E = 280$ kJ mol^{-1}, $E_0 = 60$ kJ mol^{-1}) than for the hot butyraldehyde molecule (hotness $E = 660$ kJ mol^{-1}, $E_0 = 340$ kJ mol^{-1}). On the other hand, the rate constant for deactivation, $k_{deact} \approx Z\Delta E/(E - E_0)$, cf. ref. 18*b*, should be roughly the same for both species (Z, collision number; ΔE, energy loss per collision: for N_2 as the medium perhaps 25 kJ mol^{-1}, cf. ref. 24). While the energy quantities appear accessible, it does not seem feasible to assign proper values to the other parameters that appear in k_{dec}, i.e. A and s. The assumption that these parameters do not differ from one species to the other leads to the conclusion that the excited butyraldehyde is much more easily thermalized than the oxyl alkyl diradical. If there were two precursors of butyraldehyde, one of them readily thermalized (hot butyraldehyde), the other more difficult to thermalize (oxyl alkyl diradical), one would expect to distinguish two pressure regions, in the lower of which the hot butyraldehyde is stabilized whereas the oxyl alkyl radical is thermalized only at higher pressures.

Figure 3 shows that there is only one thermalization range, and that at low pressure (1 atm) virtually no butyraldehyde is formed. It may thus be inferred that the butyraldehyde yield curve (Fig. 3) essentially reflects the thermalization of the oxyl alkyl diradical, suggesting that the aldehyde is formed in reaction type [11]. This leaves little room for reaction type [4].

The rearrangement of an α-oxolanyl radical such as might be generated in reaction [7], followed by hydrogen abstraction from the starting material, is not expected to furnish butyraldehyde at room temperature (25).

The Path to the Cyclopropanes

A major reaction in all cases is the formation of the cyclopropane and the conjugate carbonyl compound. It appears likely that this is a molecular process (reaction [1]) rather than the fragmentation of the oxyl alkyl diradical (reaction [13]) and closure of the trimethylene species. As discussed above, in the liquid the oxyl alkyl diradical is largely thermalized before it enters into most of its reactions, and one therefore expects reaction [13] to be unimportant. The remarkable difference between the methylcyclopropane quantum yields (and those of the complementary product acetone) from the isomeric *cis*- and *trans*-2,5-dimethyltetrahydrofurans (ϕ(methylcyclopropane) = 0.22 vs. 0.08, Table 3), both of which would generate the same alkyl oxyl diradical, lends strong support to the occurrence of reaction [1] rather than type [13]. This result again proves the influence of configurational factors on molecular fragmentation processes (cf. also ref. 26). In the present case the two 2,5-dimethyltetrahydrofurans are not only of different symmetry but also of different ring conformation (half-chair (*trans*) vs. envelope (*cis*)). The fragments formed in reaction type [1] will, between themselves, retain an excess energy of almost 600 kJ mol^{-1}. The cyclopropanes and the corresponding carbonyl compounds are therefore hot. Hot cyclopropanes are known to rearrange into the corresponding olefins (cf. refs. 27, 28). In accordance with this there is a considerable yield of propene at low pressures in the gas phase photolysis of tetrahydrofuran (Fig. 3; refs. 2–4). The increase of $\phi(\Delta)/[\phi(\Delta) + \phi(\diagup\!\diagdown)]$ is considered to be due to the thermalization of the hot cyclopropane. The high pressure limit of the above ratio is 0.94, near to the value of 0.96 found for the liquid phase. It is much higher than had earlier been believed (2, 3) and similar to the yield ratio obtained after chemical activation at high pressures (29) and thermolysis of liquid 1-pyrazoline (30).

It has been postulated that the rearrangement of cyclopropane into propene occurs via the trimethylene diradical (reactions [14] and [15], e.g. ref. 21; for reviews see refs. 27, 28). There might be an activation barrier with respect to the closure of this diradical (reaction [−14]), although this point is controversial (cf. refs. 19, 31–34). It is noted that such an activation barrier has also been observed with cyclobutane systems (19, 35).

With the assumption that propene is formed via reactions [14] and [15] with the intermediacy of a thermalized trimethylene, the ratio of the rate constants for reactions [−14] and [15] may be estimated: $k_{-14}/k_{15} = \phi(\diagup\!\diagdown)/\phi(\triangle) = 0.037$ at room temperature, whereas from transition state estimates (19) a value of 0.008 is obtained.

The Path to the Oxirans

A further set of interrelated products are, in the case of tetrahydrofuran, ethylene and acetaldehyde/ethylene oxide. The fragmentation of the thermalized oxyl alkyl diradical according to reaction [16] appears precluded near room temperature on account of its relatively high endothermicity of about 80 kJ mol^{-1}, estimated according to ref. 21.

It has been argued above that, owing to the rapid thermalization of the hot cyclopropanes, rearrangement to the corresponding olefins occurs to only a very small extent in the liquid phase. A similarly rapid thermalization of the hot oxirans is expected if they are formed in similar true molecular processes. However, comparable amounts of the rearranged carbonyl compounds are found. This suggests a somewhat different mechanism, possibly the intermediacy of ·O—CH_2—CH_2· diradicals. A considerable effort has been made (36–40) to produce such species both in the triplet and in the singlet state by reacting olefins with $O(^3P)$ and $O(^1D)$ atoms, respectively. In each of these cases, comparable amounts of oxirans and rearranged carbonyl compounds were observed. Owing to the complex nature of these systems firm conclusions with respect to the details of the mechanism are difficult to draw.

In Scheme 1 the formation of the oxirans and the corresponding carbonyl compounds is therefore only given summarily (reaction [5]) and the question as to the nature of the precursor must remain open. In particular, it cannot be decided yet whether these products result from singlet or triplet excited tetrahydrofurans. The latter might be formed to some extent by intersystem crossing from the primarily generated excited singlet state.

If one admits, as appears plausible on the basis of the present results, that all the tetrahydrofurans investigated here decompose in a like manner, the ethylene molecule can be said to comprise an α and

a β carbon atom from the tetrahydrofuran molecule but not both β, since from the 2,5-dimethyl- and 2,2,5,5-tetramethyltetrahydrofurans no ethylene is produced. In the gas phase photolysis of tetrahydrofuran at 147 nm (4), the ethylene seems to be both of the kind α–β and β–β in the above sense.

The Path to Hydrogen

The degree of hydrogen production varies within wide limits. In tetrahydrofuran itself as well as in the mono- and dimethyl-substituted compounds its quantity is found to exceed what can easily be explained via homolytic processes such as [7] (Scheme 1) since $\phi(H_2)$ outweighs that of the products stemming from radicals, such as the dehydrodimers, unless one accepts rather high ratios of α-oxolanyl radical disproportionation vs. combination. For the 1-ethoxyethyl radical which has structural analogies, $k_d/k_c \sim 0.42$ (cf. ref. 41). From this, and the fact that $\phi(H_2)$ from 2,2,5,5-tetramethyltetrahydrofuran is nil, i.e. 3,4-hydrogen elimination is unimportant, reaction [6] is chosen to explain most of the hydrogen. It should be pointed out that while a hydrogen atom in α position seems to be needed for the formation of H_2, $\phi(H_2)$ strongly increases with methyl substitution at this position (see Table 5).

Minor Products

Products so far not discussed include the saturated alcohols and the products termed "dimers" (see Tables 1–4). All these are formed in comparatively small yields. In the tetrahydropyran (9) and oxepane (10) systems such "dimers", to which the structure of 2-(ω-hydroxyalkyl)oxacycloalkanes can be assigned, are also found, with a particularly high quantum yield in the former case (9). Arguments have been put forward (10) which point to their formation in the excited state without free radicals intervening. As well, saturated alcohols are produced in the photolysis of tetrahydropyran and oxepane. It has been suggested (10) that a disproportionation reaction occurring in the excited state might lead to this kind of product.

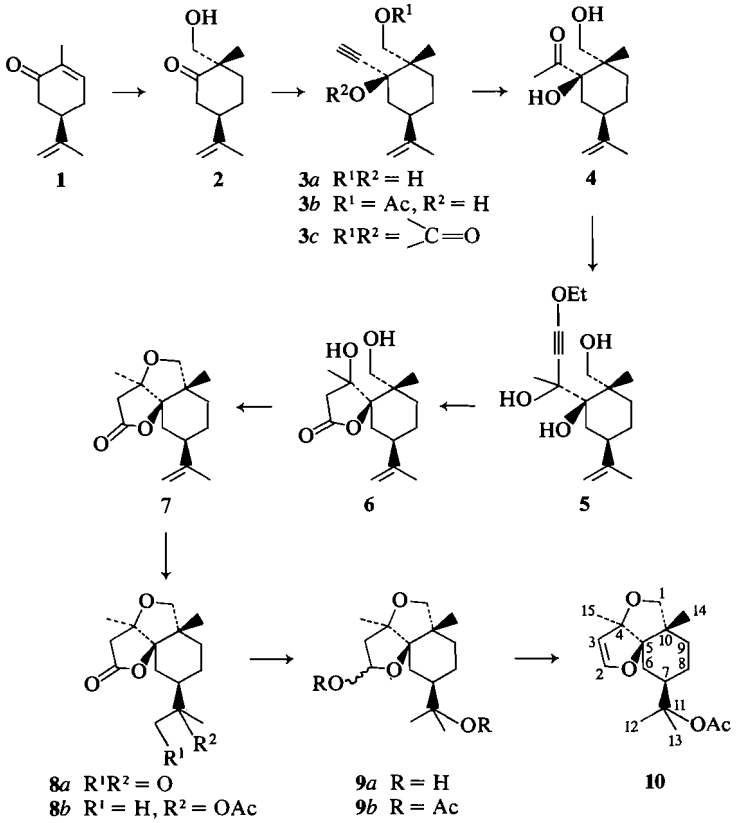
An efficient, total synthesis of the phytoalexin (−)-phytuberin **10** is described starting from (−)-carvone **1**.

JOHN A. FINDLAY, DIXIT N. DESAI, GREG C. LONERGAN et PETER S. WHITE. Can. J. Chem. **58**, 2827 (1980).
Une synthèse totale du (−)-phytuberin **10** est décrite à partir de les (−)-carvone **1**.

[Traduit par le journal]

The structure of phytuberin, a novel sesquiterpenoid phytoalexin originating in potato tubers and tobacco, was established as **10** by the X-ray crystallographic studies of Hughes and Coxon (1). The only synthesis of this stress metabolite reported (2) to date contains a fourteen-step sequence from (+)-α-cyperone which, in turn, is available via a choice of multistage pathways from commercially available (−)-carvone **1**. The overall yield from (−)-carvone is ~1.5% at best. We report here a total synthesis of (−)-phytuberin **10** from (−)-carvone **1** with very substantial economies both in number of steps and overall yield (~10%).



Alkylation of the lithium enolate of (−)-carvone with formaldehyde at −78°C under N_2 afforded a mixture of **2** plus its C10 (phytuberin numbering system) epimer (2:3) in 98% yield, readily separable by short column silica gel G chromatography. The undesired C10 epimer of **2** can be equilibrated to a mixture with **2** (5:4) by pyrolysis at 185°C for 15 min, the equilibration apparently proceeding via a dealdolization/aldolization mechanism currently being investigated. Thus the yield of the desired diastereomer **2** can be augmented substantially.

Ethynylation of the hydroxy ketone **2** with lithium acetylide in THF at −78°C gave, after chromatography, the crystalline diol **3***a* in 64% yield, mp 88–91°C, separated from its C5 epimer (9%). X-ray crystallographic examination[1] of the carbonate **3***c* of **3***a* confirmed the structure and stereochemistry of this series in every detail as portrayed. Acetylation of the acetylenic diol **3***a* through the agency of acetic anhydride/pyridine at room temperature for 6 h furnished, in quantitative yield, the corresponding monoacetate **3***b* which was hydrated to the methyl ketone **4** using $HgSO_4$ catalyst in aqueous methanol at room temperature for 30 h. Treatment of **4** with ethoxyacetylene/*n*-butyllithium in THF at 0°C under N_2 gave a mixture of C4 diastereomers **5**. The latter, obtained in 91% yield, were separated by preparative tlc on silica gel and fully characterized individually. Hydration of either isomer of **5** using dilute methanolic oxalic acid at room temperature for 4 h gave directly the corresponding lactone **6** in quantitative yield, each of which was quantitatively converted into the same furano lactone **7** possessing the appropriate tricyclic skeleton, correctly substituted and with all chiral centres correctly generated for transformation into (−)-phytuberin. The structure of the key intermediate **7** was fully substantiated by spectroscopic data. The ir spectrum ($CHCl_3$) ν_{max}: 1740 cm^{-1} (lactone). The ^1H nmr spectrum ($CDCl_3$) δ_{TMS}: 1.13 (s, 3H, 14 Me), 1.60 (s, 3H, 15 Me), 1.71 (s, 3H, C11 Me), 2.71 (s, 2H, C3 methylene), 3.68 (s, 2H, C1 methylene) ppm. Mass spectrum *m/e* 250 (M^+, $C_{15}H_{22}O_3$). The synthetic product **7** was identical in all respects with the compound obtained quantitatively by pyrolysis (3) of phytuberin lactone (4) **8***b* at 310°C for 0.5 h in an evacuated sealed tube.

Treatment of the key synthetic intermediate **7** with *m*-chloroperbenzoic acid (1 equiv.) in CH_2Cl_2 at room temperature for 4.5 h effected complete conversion to the epoxy lactone **8***a* whose ^1H nmr spectrum displayed a broad singlet at δ 2.68 ppm for the new ethereal hydrogens. Reduction of **8***a* with $LiAlH_4$/ether at room temperature for 1 h gave the epimeric mixture of diols **9***a* (~65% yield after chromatography) whose diacetate (**9***b*)

[1]Details to be disclosed in a forthcoming full paper on phytuberin synthesis by the authors of the present communication.

(Ac_2O/pyridine at 80°C) was pyrolyzed in a sealed tube at 150°C for 0.5 h affording **10** (66% yield from **9***a*), indistinguishable in all spectroscopic properties and chromatographic behaviour from natural (−)-phytuberin (4).
